There are many old reports of solid vanadyl phosphates.[355] Complex formation in aqueous acidic ($pH \leq 3$) vanadyl phosphate solutions was explained by formation of $[VOHPO_4]$, $[HVO(HPO_4)_2]^-$ and $[VO(HPO_4)_2]^{2-}$.[568] Orthophosphate coordinates as bidentate HPO_4^{2-}. The most important is $[VOHPO_4]$. The formation of 1:3 complexes was considered unlikely. These[568] and spectrophotometric results[569] include a total of five monomeric species and were later discussed on the basis of Scheme 17.[570] $[VO(H_2PO_4)_2]$ is dominant in 1 M $H_2PO_4^-$ solution at pH 2,[570] and the rate of loss of $H_2PO_4^-$ was determined from ^{31}P NMR. Aquation and anation rate constants at 25 °C were estimated to be $2.5 \times 10^4\ s^{-1}$ and $2 \times 10^6\ mol^{-1}\ s^{-1}$, respectively. The anation rate constant indicates that coordinated water in $[VO(H_2PO_4)]^+$ is more labile than the equatorial H_2O molecules in the complex $VO(H_2O)_5^{2+}$.

$$VO^{2+} + H_2PO_4^- \rightleftharpoons VO(H_2PO_4)^+$$
$$VO(H_2PO_4)^+ + H_2PO_4^- \rightleftharpoons VO(H_2PO_4)_2$$
$$VO(H_2PO_4)^+ \rightleftharpoons VO(HPO_4) + H^+$$
$$VO(H_2PO_4)_2 \rightleftharpoons VO(H_2PO_4)(HPO_4)^- + H^+$$
$$VO(H_2PO_4)(HPO_4)^- \rightleftharpoons VO(HPO_4)_2^{2-} + H^+$$

Scheme 17

The 22-line ESR spectra of oxovanadium(IV) pyrophosphate ($5 \leq pH \leq 6$) suggested a pyrophosphate trimer.[572] $Na_6(VO)_3(P_2O_7)_3 \cdot 18H_2O$ had $\mu = 3.6$ BM and its solution ESR also exhibits a 22-line signal. Osmometry supported the trimeric nature.[573] Addition of base to its solution causes a decrease in the intensity of the ESR and at $pH \geq 11$ no signal was detected. The explanation assumed (i) at pH 7–8, disproportionation of trimer to monomeric $[VO(P_2O_7)_2]^{6-}$ and an anionic species $[(VO)_4(OH)_{10}]^{2-}$ and (ii) at pH 9.5–10.5, base hydrolysis of the monomeric complex to $[(VO)_4(OH)_{10}]^{2-}$.[572]

In vanadium phosphorus oxides, the oxidation state and the phosphorus:vanadium ratio can be varied. They act as heterogeneous catalysts in the oxidation of *n*-butane and *n*-butene to maleic anhydride.[574–576] The best catalysts have vanadium in the +4 state and a P:V ratio of ~1. Understanding mechanisms requires crystal structures. That of $[(VO)_2P_2O_7]$ is built of double chains of VO_6 octahedra that share edges across the chain.[577] Pyrophosphates link the double chains into a three-dimensional network by sharing oxygen corners with vanadium. This compound forms at 400 °C from $[(VO)_2H_4P_2O_9]$, was studied by several techniques[575,576] and characterized as $VO(HPO_4) \cdot 0.5H_2O$.[578] Vanadyl hydrogen phosphate layers stacked along the *c* axis are held together by H bonding. The layers contain face-sharing VO_6 octahedra; one face-shared O atom is from an H_2O molecule that bridges the two vanadyl groups. The four remaining O atoms of each octahedron are shared with phosphate tetrahedra. Each

tetrahedron has three oxygens shared with vanadium and one OH group. $(VO)_2P_2O_7$ contains double chains of $V^{(IV)}$ cations, and $VO(HPO_4)\cdot 0.5H_2O$ contains isolated $V^{(IV)}$—$V^{(IV)}$ dimers.[575]

(iii) Perchlorate–oxovanadium(IV) solutions and salts

Solutions of the perchlorate have been prepared by several methods (*e.g.* ref. 357a, p. 250): (i) precipitate VO_2 in the absence of O_2 and dissolve the solid with perchloric acid;[579] (ii) start with $VOSO_4$ and precipitate with $Ba(ClO_4)_2$;[580] (iii) reduce $V^{(V)}$ compounds, *e.g.* reduce NH_4VO_3 with HCl and KI and precipitate halides with $AgClO_4$;[460] (iv) reduce a slurry of V_2O_5 in perchloric acid at a platinum cathode.[581] SO_2 has also been used.[582] Oxovanadium(IV) in stock solutions has been determined mainly by oxidation by $KMnO_4$ but several have used spectrophotometry.[460] Frausto da Silva and co-workers used titrations of 1:1 VO^{2+} and edta,[377,378] Tapscott and Belford titrated 1:2 vanadyl perchlorate–sodium oxalate[583] and others[584,585] used Gran's method.[586]

The blue, very hygroscopic $[VO(H_2O)_5](ClO_4)_2$ has been shown to involve no ClO_4^- coordination in solution or solid[387] and has $\mu = 1.70$ BM[587] (see also ref. 357a, p. 250). It is easier to get solids with ligands other than water, for example $[VO(DMSO)_5]\cdot(ClO_4)_2$.[355]

Benali-Baitich studied spectra of VO^{2+}–perchloric acid ($0 \leq [HClO_4] \leq 13.3$ M).[461] For high acid concentrations, V^{IV} is oxidized; others observed rapid oxidation in solutions containing ~2.2 M $NaClO_4$ for pH ≥ 2.5.[588] From the visible spectra, ClO_4^- coordinates.[461] However, such changes may arise from VOH^+ (see Section 33.5.5.1.i), not ClO_4^- coordination.[460]

(iv) Nitrate–oxovanadium(IV) solutions

Although dilute solutions of nitrate may be prepared, the instability of concentrated solutions and the reaction of HNO_3 with VO^{2+} have been reported.[582,588] Oxidation of $VOSO_4$ in acid at 80 °C by nitrate is rapid, after a long induction which resembles an autocatalytic reaction.[582]

(v) Miscellaneous anions

A few sulfite, arsenate, selenite and selenate compounds were reported[355,357] but should be reinvestigated. VO^{2+} forms a deep purple complex with phosphotungstic acid,[589] in contrast with the yellow complex with V^V. Spectrophotometrically, the formation constant is 1.3×10^5. The kinetics with 12-tungstovanadophosphates were analogous to those with 12-molybdotungstophosphates.[590]

33.5.5.6 Carboxylates

(i) Monocarboxylates

Table 24 summarizes most known $VO(RCO_2)_2$ complexes. The magnetic properties of formate hydrates differ from those of higher carboxylates. $\mu_{eff}^{r.t.}$ values are normally 1.45–1.80 BM and these complexes obey the Curie–Weiss law.[358,595] A magnetically normal hydrated formate, $VO(HCO_2)_2\cdot H_2O$, is known[596] and the compound $K_2[VO(HCO_2)_4]$ consists of infinite zigzag chains in which the V atoms are linked in an axial–equatorial manner by formate bridges (Figure 24).[597] The geometry is pseudo-octahedral, the V atom lying 0.27 Å out of the equatorial plane. $\mu_{eff}^{r.t.} = 1.79$ BM, indicating little or no magnetic interaction between the V atoms. Formation constant studies have been performed.[591–594]

Subnormal magnetic oxovanadium(IV) complexes that include this type of ligand have been reviewed by Syamal (Table 24).[358] ν(V=O) values appear ~100 cm^{-1} lower than commonly found. Vanadyl acetate and halogenoacetates $VO(CH_{3-n}X_nCO_2)_2$, ($n = 1, 2, 3$; X = Cl or Br) are characterized by one ν(V=O) at 895 ± 5 cm^{-1}, by very low $\mu_{eff}^{r.t.}$ (Table 24) and by antiferromagnetic spin–spin interactions. These results have been interpreted on the basis of a polymeric structure (**52**).[358,598] The same characteristics and interactions exist in many complexes of other aliphatic and aromatic carboxylic acids.[358] [VO(salnpn)],[599] polymeric with

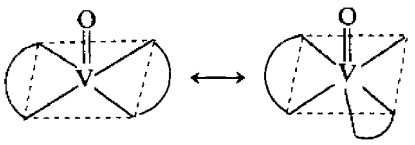
Revision of early work[603] on carbonato complexes formulated the violet NH_4^+ salt obtained at pH ~3.5 as $V_{12}O_{28}H_{14}(CO_3)_8(NH_4)_{10}\cdot 23H_2O$ and the purple K^+ salt obtained at pH ~8.5 as $V_{12}O_{28}H_{14}(CO_3)_8K_{10}\cdot 16H_2O$.[602] ν(V=O) occurs at 950 cm^{-1} in both and ν(V—O—V) at 525 and 515 cm^{-1} for the NH_4^+ and K^+ salts.[602] Deep violet crystals of the NH_4^+ salt made by reacting $VOCl_2$ with NH_4HCO_3 under CO_2 had the formula $(NH_4)_5[(VO)_6(CO_3)_4(OH)_9]\cdot 10H_2O$.[604] The anion (Figure 24b) consists of crown-shaped hexanuclear aggregates consolidated by bridging hydroxo and carbonato groups, the latter functioning in a μ_6 mode as well as in the more common μ_2 mode. The six V atoms, each octahedral, are within 0.07 Å of their mean plane in a pseudo-hexagonal arrangement.



(*ii*) *Polycarboxylates*

Oxovanadium(IV) forms stable complexes with polycarboxylic acids and many formation constants have been determined, including mixed complexes (Section 33.5.10). Potentiometry and NMR led to analysis of the paramagnetic contribution to relaxation as a function of $[VO^{2+}]$, [VO(oxal)] and $[VO(oxal)_2]^{2-}$ for the oxalate system and $[VO^{2+}]$, $[VO(Hmalon)]^+$, [VO(malon)] and $[VO(malon)_2]^{2-}$ for the malonate system.[584] Table 26 summarizes their rate constants. Proton exchange rate constants are higher than those for the free ion ($k = 1.7\times10^5\ s^{-1}$,[584] $6.2\times10^{-4}\ s^{-1}$,[459] $8\times10^4\ s^{-1}$ [605] and $1.8\times10^5\ s^{-1}$ [606]). Similar faster exchange was found in other systems and may be explained assuming that the coordination of the ligand weakens the VO—OH_2 bond, increasing the exchange rate of the water molecule, reflected also in the proton exchange. The surprising proton exchange rate for $[VOL_2]^{2-}$ was explained by an intramolecular rearrangement (**53** ↔ **54**).[584]

Table 26 First-order Rate Constants of the Proton Exchange Between the Bulk Water and the Different Paramagnetic Species (I = 1 M $NaClO_4$ and T = 25 °C)

Species	$k\times10^{-5}$ (s^{-1})
[VO(oxalate)]	1.85
$[VO(oxalate)_2]^{2-}$	2.30
[VO(malonate)]	1.85
$[VO(malonate)_2]^{2-}$	1.55
$[VO(Hmalonate)]^+$	1.43

I. Nagypál and I. Fábyán, *Inorg. Chim. Acta*, 1982, **61**, 109.

(53) (54)

Che and Kustin studied complexation;[438] results for oxalic and malonic acids are in Table 27. From previous relaxation data[607] and their own results, they concluded that the rate constants are more consistent with a 'normal' dissociative pathway if VOL formation from $[VO(OH)]^+$ is assumed.

Table 27 Forward Rate Constants for Vanadyl Complexation ($I = 0.5$ M KNO_3 and $T = 25$ °C)

Many formation constants involve polycarboxylates; Table 28 summarizes the data. Nágypál and Fábián's report on the oxalic and malonic systems seems the most complete as hydrolysis of both metal ion and complexes has been included.[584] A concentration distribution of the complexes in the malonic system is shown in Figure 25. The order of basicities is succinic > citraconic > itaconic > maleic > malonic acid and $\log \beta_{110}$ should follow the same order. However, from Table 28, the order of stabilities is citraconic > malonic > maleic > itaconic > succinic acid.[608]

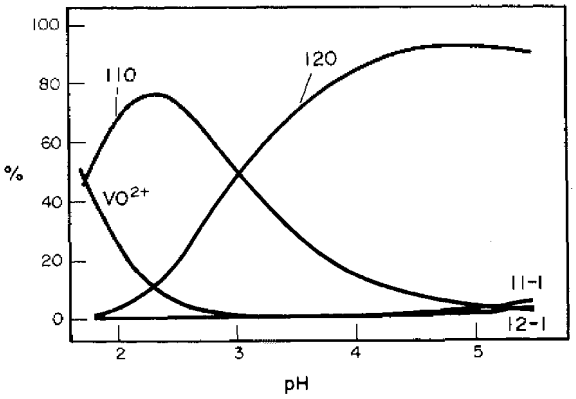

Figure 25 Speciation in oxovanadium(IV) + malonic acid solutions calculated assuming Nágypál *et al.*[584] formation constants ($I = 1.0$ M $NaClO_4$ and 25 °C) for $C_{VO} = 0.02$ M and $C_{mal}/C_{VO} = 2.0$

Many solids have been isolated and Table 29 summarizes most. Solid oxalate complexes have been prepared from vanadium(IV) salts and from V_2O_5. They form readily and are mainly of two types: $(M)_2[VO(oxal)_2]\cdot xH_2O$ and $(M)_2[(VO)_2(oxal)_3]\cdot xH_2O$. VO(malon)·$4H_2O$ and VO(maleate)·$2H_2O$ were prepared from vanadyl hydroxide,[609] and bis malonate and maleate complexes have been synthesized from vanadium(IV) and vanadium(V) salts. Several mixed-ligand complexes containing polycarboxylates as one ligand have also been prepared (see Section 33.5.10).

Complexes with succinate, glutarate and adipate have subnormal magnetic properties that indicate V···V interactions.[358] Oxalato, malonato and maleato 1:1 complexes appear monomeric as indicated by ν(V=O) and $\mu_{eff}^{r.t.}$, and ease of formation, stability constants and decrease in ν(V=O) follow the order: oxalate > malonate > maleate. For the 1:2 complexes

the stability and bond strength (as indicated by ν(V=O)) follow the same order.[610] The ease of dissociation follows the inverse order.

$(NH_4)[VO(oxal)_2(H_2O)]\cdot H_2O$ has been studied by X-ray diffraction and involves the equatorial coordination of one water molecule (see Figure 26a).[611] (Hpy)[VO(oxal)(F)$(H_2O)_2$] is monomeric with a pseudo-octahedral geometry (see Figure 26b).[612] In $(H_2Tmen)[VO(malon)_2(H_2O)]\cdot 2H_2O$, the vanadium is octahedrally coordinated to four malonato oxygens, to vanadyl oxygens and to a water molecule (*trans* to V=O).[613] Comparison with $[VOCl_2(tmn)_2]$ (tmn = *N,N,N',N'*-tetramethylurea) suggests that a weak extended exchange interaction of magnitude comparable to the nuclear hyperfine splitting is responsible for the ESR.[614]

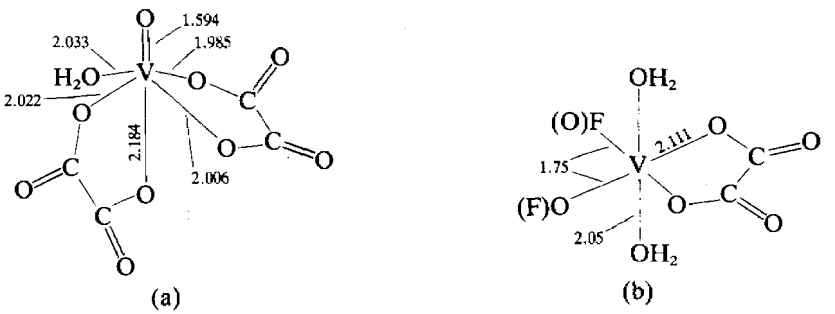

Figure 26 Perspective diagrams of the complex anions (a) $[VO(oxal)_2(H_2O)]^{2-}$ [611] and (b) $[VO(F)(oxal)(H_2O)_2]^-$;[612] interatomic distances are in Å. In (b) the H_2O and F^- are distributed in a 'disordered fashion' and the 1.75 Å distance may be considered an average of the distances expected for a V—F bond (1.9 Å) and a V=O bond (1.6 Å)

According to M (Na^+, K^+, NH_4^+, NMe_4^+, Rb^+, Ba^{2+}, NEt_4^+), $M_n[(VO)_2\{(+)\text{-tart}\}\{(-)\text{-tart}\}]\cdot xH_2O$ or $M_n[(VO)_2\{(+)\text{- or }(-)\text{-tart}\}_2]\cdot xH_2O$ have been obtained.[583,615] Several methyl tartrate derivatives have been used as ligands and compounds isolated. Table 30 summarizes products. The (+, +) [or (−, −)] isomer requires a *trans* configuration about vanadyl and the ± a *cis* configuration. Compounds include $(NH_4)_4[(VO)_2\{(+)\text{-tart}\}_2]\cdot H_2O$,[615] $Na_4[(VO)_2\{(+)\text{-tart}\}\{(-)\text{-tart}\}]\cdot 12H_2O$,[616] $(NEt_4)[(VO)_2\{(+)\text{-tart}\}\{(-)\text{-tart}\}]\cdot 8H_2O$ (V—V distance = 3.895 Å), $Na_4[(VO)_2\{(+)\text{-dmt}\}\{(-)\text{-dmt}\}]\cdot xH_2O$ ($x = 6$,[617] 12[618]) and $Na_4[(VO)_2\{(+)\text{-}threo\text{-mmt}\}\{(-)\text{-}threo\text{-mmt}\}]\cdot 14H_2O$.[619] The geometries of the dimeric anions are those of Figure 27 and only slight changes occur with the counterion.[620]

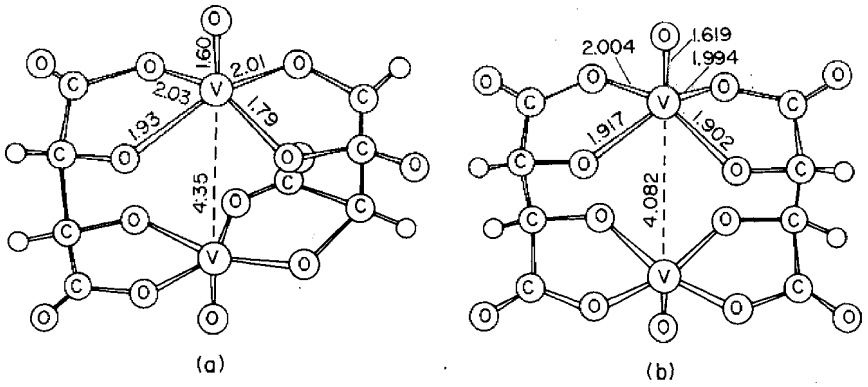

Figure 27 Schematic representation of $[(VO)_2(tart)_2]^{4-}$ units in tartrate complexes. Internuclear distances are given for (a) $(NH_4)_4[(VO)_2\{(+)\text{-tart}\}_2]\cdot H_2O$[615] and (b) $Na_4[(VO)_2\{(+)\text{-tart}\}\{(-)\text{-tart}\}]\cdot 12H_2O$[616]

ESR suggested that the methyl-substituted dimers exhibit a shortened V—V distance.[621] In $Na_4[(VO)_2\{(+)\text{-dmt}\}\{(-)\text{-dmt}\}]\cdot 12H_2O$ the V—V distance is 3.429 Å and the vanadium distance to the basal plane is 0.394 Å, 0.60 and 0.13 Å shorter than for (±)-tartrate^{4-}.[619]

Tartaric acid is dibasic (H_2tart), carboxyl protons being ionized by pH 5. The hydroxyl groups are not ionized ($pK_{a3} \approx 14$ and $pK_{a4} \approx 15.6$).[622] The formation constants of (+)-, (−)-, (±)- and *meso*-tartaric acids with VO^{2+} confirm binuclear complexes of optically active and, to a lesser extent, *meso* acids with VO^{2+}.[623]

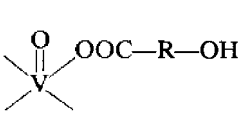
Electronic and CD spectra[624] of the solid and solutions of oxovanadium(IV) (+)-tartrate are identical, as are their IR spectra,[615] good evidence that the dimeric species in solution is the same as that found in the crystals. An unusually well-defined triplet state ESR has been recorded for liquid and frozen solutions.[625,626]

Racemic and optically active solutions behave differently, with large stereoselective

effects.[627] The reaction corresponding to equation (44) has $K = 16$[623] and a reaction enthalpy of $(6.9 \pm 0.4) \times 10^3$ J mol^{-1}.[628,629] The kinetics were also studied.[629]

$$\tfrac{1}{2}[(VO)_2\{(+)\text{-tart}\}_2]^{4-} + \tfrac{1}{2}[(VO)_2\{(-)\text{-tart}\}_2]^{4-} \rightleftharpoons [(VO)_2\{(+)\text{-tart}\}\{(-)\text{-tart}\}]^{4-} \quad (44)$$

(*ii*) *Other hydroxycarboxylate ligands*



Hydroxycarboxylate systems have been extensively studied. Solution spectra of most VO^{2+} complexes contain, at most, three bands in the visible region that may be assigned to *d–d* transitions; however, alkaline solutions of most α-hydroxycarboxylates exhibit four bands[365] ascribed to a reduced symmetry of the ligand field by *trans* coordination of two strongly bound ionized hydroxyl oxygens[478] (perhaps accompanied by distortion towards a trigonal bipyramidal geometry).[630] Table 31 summarizes part of the reported spectra: in several cases, the four bands suggest that α-hydroxycarboxylato complexes have *trans* coordination. In $Na(Et_4N)[VO(benzilato)_2]\cdot 2PrOH$, vanadium is five-coordinate and distorted square pyramidal, and the bidentate ligands are mutually *trans*.[630] The solution, single crystal and polycrystalline optical spectra exhibit four bands similar to those of the *trans*-vanadyl–(+)-tartrate system (Table 31).

Table 31 Spectral Bands Observed in Optical Spectra of Oxovanadium(IV) Hydroxycarboxylates in Aqueous Solution

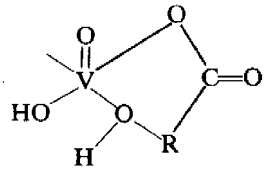
Complexes with (*R*)-lactate have been studied by ESR[631] and CD.[580,632] Lactate is near water in the spectrochemical series and its low pK_a helps reduce error due to hydrolysis and oxidation. Table 32 summarizes the data. The pK_a of the R—OH is quite high (especially for the aliphatic acids). Many have considered coordination in VO^{2+} hydroxycarboxylate to involve the CO_2^- and OH groups and assumed the dissociation of the OH. As structures (**55**) and (**56**) or (**57**) and (**58**) are not pH-metrically distinguishable, if the pK_a^{OH} is not known, other techniques must establish the species present.



(**55**)

(**56**)

(**57**)

(**58**)

From ESR, for (*R*)-lactic acid (H_2lact), five species were required: $[VO(Hlact)]^+$, $[VO(Hlact)_2]_2$, $[VO(lact)]$, $[VO(lact)(Hlact)]^-$ and $[VO(lact)_2]^{2-}$; for glycolic acid (H_2glyc): $[VO(glyc)]$ and $[VO(glyc)_2]^{2-}$.[631] Another ESR study assumed only $[VO(glyc)_2]^{2-}$ formation.[626]

With salicylic acid (H_2SA) and 5-sulfosalicylic acid (H_2SSA), titrations have been interpreted in terms of coordination with CO_2H and OH ionized, although the pK_a values of the OH groups are high ($pK_a^{OH} \approx 11.4$ for $HSSA^-$ and $\gtrsim 13$ for HSA).[633] ESR spectra of solutions containing salicylic acid (H_2SA) at pH ≲ 5 were interpreted in terms of VO^{2+}, $[VO(SA)]$ and $[VO(SA)_2]^{2-}$ species.[634] A different model involves VO^{2+}, $[VO(HSA)^+]$ and

[a] Constants β_{mnp} refer to the reaction $mVO^{2+} + nHOXCO_2^- + pH^+ = [(VO)_m(HOXCOO^-)_n(H^+)_p]$.
[b] Constants β_{mnp} refer to reaction $xVO^{2+} + yOXCO_2^{2-} + zH = [(VO)_x(OXCO_2^-)_y(H^+)_z]$.
[c] Complexes correspond to $[VO(L^{2-})_2]^{2-}$. As K_a^{OH} is not known, $[VO(L^{2-})_2]^{2-}$ and $[VO(HL^-)(OH^-)_2]$ are not pH-metrically distinguishable; the constant corresponds to $\beta_{12\text{-}2}$ in terms of HL^-.
[d] A value defined as $K2 * K_{a2}$ is reported; it is not equal to the defined $\beta_{12\text{-}2}$.
[e] Other species may be present in minor amounts in the pH range studied (2.5–4).

[VO(SA)] (see Table 32).[635] Early reports include $(Ct)_2[VO(SA)_2]\cdot 3H_2O$ ($Ct = K^+$, NH_4^+ and $\frac{1}{2}Ca^{2+}$) and $Tl_2[VO(SA)_2]$.[3,357b]

DMF solutions of chelates of 1-hydroxycyclohexanecarboxylate and mandelate exhibit the half field ESR at ~1500 G due to $\Delta M = 2$ ($g \simeq 4$),[358] as does aqueous VO^{2+} citrate at pH 6–9, indicating V···V interactions.[636] $[(VO)_3(citrato)_2]\cdot 4H_2O$ has $\mu_{eff}^{r.t.} = 1.51$ BM, like VO(trihydroxyglutarato)·$0.5H_2O$ ($\mu_{eff}^{r.t.} = 1.57$ BM).[637] Dimeric 2:2 complexes with citrate and malate explain proton relaxation in the pH range 3–10;[638] comparative dialysis and spectrophotometry at pH 2–7 suggested the existence of 1:3, 1:2, 1:1 and polymeric 1:1 species.[639] Early reports include $(Ct)_4[(VO)_2(citrato)_2]\cdot nH_2O$ ($Ct = Na^+$, K^+, NH_4^+ with $n = 12$, 6 and 0 respectively).[357b]

$(NH_4)_2[VO(benzilato)_2]$, $(NH_4)_2[VO(fsa)(OH)_2H_2O]$ and $(NH_4)_2[VO(fsa)_2]\cdot 2H_2O$ (fsa = 3-formylsalicylato) have $\mu_{eff}^{r.t.}$ 1.67–1.73 BM,[640] as well as $[VO(3,5\text{-dinitro})SA)_2]\cdot 2H_2O$.[641] Some of these have high antimicrobial activity.[640]

The effect of exchange of lactic, mandelic and sulfosalicylic acids on the relaxation of solvent protons gave rate constants (k) of exchange from 1.73 to 0.70 l mol^{-1} s^{-1}.[642] Kinetics of complex formation with mandelic (HMDA) and vanillomandelic acids (HVMDA) gave rate constants (1.09×10^3 and 1.13×10^3 mol^{-1} s^{-1} for MDA^- and $VMDA^-$) consistent with a dissociative (Eigen) mechanism.[438] As in the case of oxalic and malonic acids (Section 33.5.5.5.ii; Table 27), species with coordinated hydroxyl are labilized.

33.5.5.8 Other oxygen ligands

(*i*) *Sulfoxides*

Complexes with DMSO as one of several ligands have been reported frequently and early ones include $[VO(X)_2(DMSO)_3]$ where $X = \frac{1}{2}SO_4^{2-}$, Cl^-, Br^-[387,643] and $[VO(L)_2(DMSO)]$ where L is a bidentate ligand (*e.g.* acac).[355] $[VOBr_2(DPSO)_3]$ (DPSO = diphenyl sulfoxide) and $[VO(DMSO)_5]Br_2$ were prepared by the reaction of $VOBr_3$ with the sulfoxides in cyclohexene.[401] $[VOCl_2(DMSO)_3]$ and $[VOCl_2(DPSO)_3]$ were prepared by the method in equation (16);[409] two V—Cl IR-active bands were observed for both compounds (353, 321 cm^{-1} and 312, 282 cm^{-1}, respectively), suggesting a trigonal bipyramidal (**13**) structure. For adducts of VOX_2 ($X = Cl$, $\frac{1}{2}SO_4^{2-}$) with aromatic and aliphatic sulfoxides, the sulfoxide groups are coordinated through the oxygen.[644] In $[VO(DMSO)_5](ClO_4)_2$, $d(V{=}O) = 1.591$, $d(V{-}O(equatorial)) = 2.034$ (av) and $d(V{-}O(axial)) = 2.18$ Å.[387,645] 'Adducts' of $VOBr_2$ and VOI_2 with DMSO and DMF have been isolated; in $[VO(DMSO)_5]I_2$ the distances are slightly shorter (*ca.* 0.01 Å) than in $[VO(DMSO)_5](ClO_4)_2$.[646]

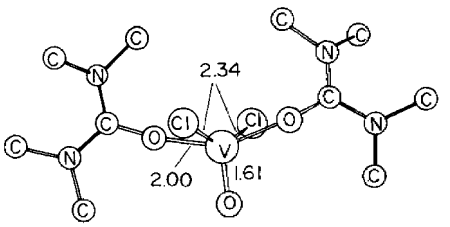
(*ii*) N-*Oxides and related ligands*

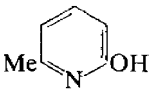
$[VO(C_5H_5NO)_5](ClO_4)_2$, $[VOCl_2(Ph_3PO)_2]$, $[VO(Ph_3PO)_4]$, $[VO(Ph_3AsO)_4](ClO_4)_2$ and $[VOCl_2(DMSO)_2]$ have been prepared by the reaction of $VCl_3\cdot 6H_2O$ with the ligand in ethanol.[643] Perchlorates are obtained if $LiClO_4$ is added. In $[VOCl_2(Ph_3PO)_2]$, vanadium is pentacoordinate with the Ph_3PO ligands *trans*; their O atoms and two Cl atoms comprise the base of a square pyramid completed by an apical multiply bonded O atom.[647] Internuclear distances are as follows: $d(V{=}O) = 1.584$, $d(V{-}O) = 1.986$ and 2.002, and $d(V{-}Cl) = 2.312$ and 2.304 Å. This and $[VOCl_2(hmpa)_2]$ (hmpa = hexamethylphosphoramide) have also been prepared by equation (16) and have only one IR-active V—Cl band each at 384 and 385 cm^{-1}. Seddon's suggestion would imply square pyramidal structures.[409] However, the structure determined by X-ray is based on a distorted trigonal bipyramid.[648] In $[VOCl_2(dimp)_2]$ (dimp = Pr^i_2MePO), ν(V—Cl) is at 431 cm^{-1}.[649]

From the single crystal ESR of $[VOCl_2(Ph_3PO)_2]$, no magnetic exchange interactions exist; the spectrum consists of eight lines from interaction of the electron with the nuclear spin of ^{51}V ($I = \frac{7}{2}$).[650] In poly(dimethylsiloxane) mulls of $[VOCl_2(Ph_3PO)_2]$ and $[VOCl_2(hmpa)_2]$, optical bands were assigned according to a crystal field orbital splitting different from that of Ballhausen and Gray (Section 33.5.1, Figure 16).[364]

(iii) Miscellaneous oxygen ligands

Complexes with *N,N,N',N'*-tetramethylurea (tmu) have been extensively studied. In $[VOCl_2(tmu)_2]$, the vanadium is pentacoordinate and square pyramidal (see Figure 28).[651] The single crystal ESR of $[VOX_2(tmu)_2]$ (X = Br, Cl) gave unusual fine structure at 170–120 K, which was interpreted in terms of an electronic exchange interaction, within a two-dimensional layer.[614] ESR for $[VO(pftc)_2]$ (pftc = perfluoropinacolate) and the deoxygenated $[VCl_2(pftc)_2]$ obtained by its reaction with $SOCl_2$[429] suggests a trigonal prismatic structure for $[VCl_2(pftc)_2]$. The reaction between VCl_3·3THF and three equivalents of 2-hydroxy-6-methylpyridine (Hmhp; **59**) in CH_2Cl_2 in air produces bright blue $[V_2O_2Cl_4(\mu\text{-Hmhp})_3]$ (**60**) characterized by crystallography, ESR ($g = 1.976$) and IR,[652] in the region $1000 \pm 50\,cm^{-1}$. The structure consists of discrete dinuclear units.





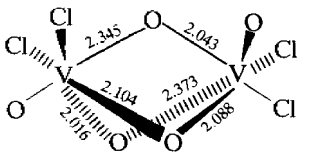


Figure 28 Molecular structure of $[VOCl_2(tetramethylurea)_2]$. Some internuclear distances (in Å) are indicated[651]

(**59**)

(**60**)

Several complexes which contain halogen ligands (with and without the vanadyl bond) with oxygen donors such as diethyl ether, $MeOCH_2CH_2OMe$, benzaldehyde, benzophenone, THF, dioxane and pyridine *N*-oxide derivatives are included in 'Gmelins Handbuch'.[357b] $[VOF_2L_n]$ complexes[428] (equation 22) include $[VOF_2L_2]$ with L = urea and formamide (fmd) and $[VOF_2(H_2O)L]$ with L = DMF and dioxane.

33.5.6 Sulfur Ligands

33.5.6.1 Thiovanadyl complexes

The first complexes of the thiovanadyl ion, VS^{2+}, were made by the reaction of [VO(salen)] or [VO(acen)] (H_2salen = *N,N'*-ethylenebis(salicylideneamine), H_2acen = *N,N'*-ethylenebis(acetylacetonylideneamine)) with the powerful oxophile B_2S_3 in CH_2Cl_2 with rigorous exclusion of oxygen and moisture (equations 45 and 46).[653,654] The magenta [VS(salen)] is relatively stable to oxidation or hydrolysis and shows no colour change in air for months, although it then smells of H_2S and IR shows the presence of V=O. In sharp contrast, on swirling in air a solution in CH_2Cl_2, it quickly changed to green, forming [VO(salen)] quantitatively with the liberation of H_2S.[654] The magenta [VS(acen)] is also relatively stable but — in contrast to [VS(salen)] — solutions in organic solvents are decomposed to [VO(acen)] only after a few hours of exposure to the atmosphere. IR of (**61**) and (**62**) showed no V=O stretch, and new medium-to-strong bands at 543 (**61**) and 556 cm^{-1} (**62**), were assigned to ν(V=S). (**61**) and (**62**) exhibit eight-line isotropic solution ESR; g and A decrease in magnitude on substitution of oxygen by sulfur, consistent with greater covalency in the VS bond.[653] [VS(acen)] has square pyramidal geometry with the sulfur atom at the apex and the coordinated atoms of acen comprising the basal plane.[655] V=S was 2.061 Å, shorter than V—S single bonds (Section 33.5.6.2 and 33.5.6.3). The vanadyl analogue (Figure 32, p. 536) also has

square pyramidal geometry around the V atom; the difference between V=S and V=O is 0.47 Å.

$$VO(salen) + B_2S_3 \xrightarrow[48\,h\ reflux]{CH_2Cl_2} \xrightarrow{hexane} VS(salen) \quad (45)$$

(61)

$$VO(acen) + B_2S_3 \xrightarrow[24\,h\ at\ 25\,°C]{CH_2Cl_2} \xrightarrow{hexane} VS(acen) \quad (46)$$

(62)

By allowing a slurry of $(PPh_4)Na[VO(edt)_2]\cdot 2EtOH$ (edt^{2-} = ethane-1,2-dithiolate) in MeCN to react with $(Me_3Si)_2S$, orange-brown crystals were obtained.[656] They contain $[VS(edt)_2]^{2-}$, whose structure is essentially identical with $[VO(edt)_2]^{2-}$ (see Section 33.5.6.3). The difference between V=O and V=S is 0.462 Å.

In $(NMe_4)Na[VO(edt)_2]\cdot 2EtOH$, ν(V=O) was at 930 cm^{-1} and the V=O distance (1.625 Å) is rather long but is similar to that in $[VO(pdt)_2]^{2-}$ (pdt = propane-1,3-dithiolate) (1.628Å).[656] On O/S substitution, the band at 930 cm^{-1} disappears and a strong, sharp band at 502 cm^{-1} appears, ν(V=S). This change (428 cm^{-1}) is similar to that between VE(acen) and VE(salen) (E = O, S), paralleling changes in V=E bond length.

Electrochemical oxidations of [VS(acen)] and [VO(acen)] are reversible at 0.45 and 0.66 V *vs.* SCE, with one electron involved.[657] In contrast to $[VO(acen)]^+$, which is quite stable, the $[VS(acen)]^+$ product readily reacts with residual water and is converted to $[VO(acen)]^+$ and H_2S. Vanadyl complexes with O/N-based ligands have oxidation potentials in the range 0.6–1.1 V.[516,657] The potential for $[VO(edt)_2]^{2-}$ is more negative by ~1 V.[656] On O/S substitution, the potential becomes even more negative by 0.27 V, behaviour also present in VE(acen) (E = O, S) (~0.26 V). Again the basal ligands govern the absolute magnitude of a property whereas changes in O/S substitution are essentially constant.[656]

By treatment with $(Me_3Si)_2S$ the conversion of $[VO(edt)_2]^{2-}$ to $[VS(edt)_2]^{2-}$ gave an intermediate $[V(OSiMe_3)(edt)_2]^-$ as the PPh_4^+ salt.[658] It contains a discrete, square pyramidal V^{IV} with d(V—O) = 1.761 Å, mean d(V—S) = 2.322 Å and a V—O—Si angle of 140.8°.

Changes in ESR and electronic absorption from $[VO(edt)_2]^{2-}$ to $[VS(edt)_2]^{2-}$ are similar to those in the series [VE(acen)] and [VE(salen)] (E = O, S).[654] The spectroscopic results for the $[VE(edt)_2]^{2-}$ complexes have been interpreted assuming a $d_{x^2-y^2}$ ground state.[658]

33.5.6.2 CS_2-based and related ligands

(*i*) *Dithiocarboxylates*

The interesting reaction of oxovanadium(IV) with dithiocarboxylates RCS_2^- cleaves the vanadyl bond, in water or ethanol, with formation of stable $[V(RCSS)_4]$. When pure, they are not air-sensitive.[661] They are insoluble in polar solvents and generally soluble in nonpolar ones however, the solutions decompose rapidly. Various stereochemistries are possible bu molecular weights, IR, electronic and ESR spectra are consistent with eight-coordinate geometry,[661–664] with $d_{x^2-y^2}$ lowest-lying (D_{2d} symmetry). Several [V(dithiocarboxylato)$_4$ complexes have vanadium coordinated to eight sulfur atoms with a dodecahedral geometry.[663,665,666] The V—S distances are of two kinds and for $[V(MeCS_2)_4]$, nonequivalent atoms have (i) a regular or (ii) a distorted dodecahedral configuration. Some data are in Table 33.

(*ii*) *Dithiocarbamates*

Dithiocarbamato (dtc) complexes are prepared by mixing $VOSO_4$ and the ligand in water–ethanol solutions. Some of the isolated complexes are in Table 34; they are susceptible to air oxidation, especially in solution, and are generally monomeric.

$[VO(Et_2NCS_2)_2]$ has discrete molecules with five-coordinate square pyramids, with the oxygen at the apex with d(V=O) = 1.59 Å.[667] The vanadium atom lies approximately 0.75 Å above the 'plane' of the four sulfur atoms and the average V—S distance is 2.402 Å, shorter than for most vanadium dithiolate complexes;[667] IR, electronic and ESR spectra are consisten

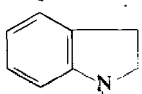
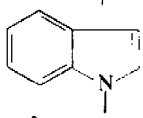
with a square pyramidal structure for other $[VO(dtc)_2]$ complexes. The structures are undoubtedly similar to $[VO(acac)_2]$ (Figure 22) and so it is not surprising that adducts form in solution[668,669] and in the solid state.[670] The tendency of $[VO(dtc)_2]$ to bind a sixth ligand is lower than for $[VO(acac)_2]$ and no correlation between $\nu(V{=}O)$ and the ligands seems to exist.[669] The studies are more difficult than with $[VO(acac)_2]$ owing to the sensitivity to oxygen.

Although some $[V(dtc)_4]$ complexes have been isolated,[671] oxovanadium(IV) compounds are usually obtained by the direct reaction of oxovanadium(IV) salts with dtc bases. Several $[V(dtc)_4]$ complexes have also been prepared by insertion of CS_2 into V—N bonds of vanadium tetraamides (equation 47).[419,672]

$$V(NR_2)_4 + 4CS_2 \xrightarrow[\text{(oxygen-free conditions)}]{\text{cyclohexane}} V(R_2NCS_2)_4 \qquad (47)$$





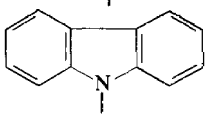


Table 35 shows some of the $[V(dtc)_4]$ complexes prepared. Compounds 2–7 in Table 35 were prepared from $VOSO_4$ and in some cases in the presence of water. This therefore is one more example where the vanadyl bond is broken; others include $SOCl_2$ (and $SOBr_2$), catechols and dithiocarboxylates (these forming eight-coordinate complexes). However, $[V(dtc)_4]$ complexes are not stable towards conversion back to vanadyl. Thus, these ligands seem to be intermediate in behaviour between dithiocarboxylates and other dithiocarbamates; this probably reflects π-bonding capabilities.[671] ESR spectra of compounds 4–7 (Table 35) show well-resolved hyperfine structure and the rather low $A_{\parallel}$ and $A_{\perp}$ values ($\sim$117 and $\sim 37 \times 10^{-4}\,cm^{-1}$) indicate both a significantly covalent system and an eight-coordinate geometry.[671] The ESR spectra of $[VO(dtc)_2]$ complexes with the same ligands show much higher $A_{\parallel}$ and $A_{\perp}$ values ($\sim$151 and $\sim 49 \times 10^{-4}\,cm^{-1}$).[673] In addition to the reaction of $[V(Et_2NCS_2)_4]$ with oxygen producing vanadium(V) (equation 48), two other reactions may occur upon heating (equations 49 and 50).[672]

$$2V(Et_2NCS_2)_4 + O_2 \longrightarrow 2VO(Et_2NCS_2)_3 + (EtNCS_2)_2 \qquad (48)$$

$$V(Et_2NCS_2)_4 \xrightarrow{\Delta} V(Et_2NCS_2)_3 + \tfrac{1}{2}(Et_2NCS_2)_2 \qquad (49)$$

$$VO(Et_2NCS_2)_3 \xrightarrow{\Delta} VO(Et_2NCS_2)_2 + \tfrac{1}{2}(Et_2NCS_2)_2 \qquad (50)$$

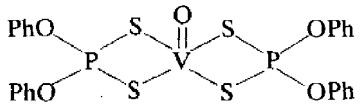
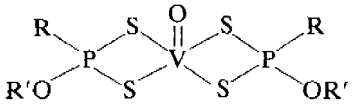
Treatment of tris(tricaprylylmethylammonium)tetrathiovanadate(V) solution with solid tetraisobutylthiuram causes an immediate change from violet to brown. Yellow-brown crystals

were obtained and characterization showed that a dimer (**63**) formed *via* induced internal redox (equation 51).[674]



$$2VS_4^{3-} + 2(Bu_2^iNCS_2)_2 \longrightarrow V_2(\mu\text{-}S_2)_2(Bu_2^iNCS_2)_4 + S_x^{2-} \quad (51)$$

(**63**)



(**63**) consists of discrete dimers where the V atoms are bridged by two symmetry-related μ-η^2-S_2 ligands, forming an $M_2(\mu\text{-}\eta^2\text{-}S_2)_2$ core, the octahedral coordination of vanadium being completed by two bidentate dithiocarbamates.[673] d(V—S) = 2.405 (av) and d(V—V) = 2.851 Å;[674] the V—V distance and the observed diamagnetism are consistent with a V—V bond.

(*iii*) *Dithiophosphate and related ligands*

ESR spectra of complexes of dithiophosphate (dtpo, $P(OR)_2SS^-$), dithiophosphinate (dtpi, PR_2SS^-), $PR'(OR)SS^-$ and dithioarsinate are of particular interest since they exhibit appreciable phosphorus-31 superhyperfine splitting which arises from V—P interactions over distances of about 3 Å or more. For example, in solutions containing (**64**), phosphorus causes the vanadium hyperfine lines to be further split into three components, intensitities 1:2:1. A total of 24 lines are predicted; however, owing to overlap, only 17 were observed.[675,676] With the cyclohexanol (R'O) ethyl (R) derivative, 23 of the expected lines are resolved whereas only 17 are for the corresponding cyclohexanol phenyl complex (**65**).[677] The superhyperfine splittings have been attributed to direct transannular V–P interactions involving mainly the $3d_{x^2-y^2}$ vanadium orbital and 3*s* (and 3*p*) phosphorus orbitals.[676,677] Wasson and co-workers[677] studied $[VO\{S_2PR(OR')\}_2]$ and discussed $[VO(dtpo)_2]$ and $[VO(dtpi)_2]$.[678,679] The general trend of the phosphorus superhyperfine splitting constants is $S_2P(OR)_2 > (S_2PR(OR') > S_2PR_2$. The ESR of $[VO(S_2PCy_2)_2]$,[676] $[VO(dtc)_2]$, $[VO(dtpi)_2]$ and [VO(dtc)(dtpo)] have been reported,[680,681] as has coordination of py, DMF and hexamethylphosphoramide to five-coordinate $[VO(S_2PMe_2)]$, $[VO(S_2PPh_2)]$ and $[VO\{S_2P(OEt)_2\}]$,[682] using hyperfine interactions between ^{51}V and ^{31}P.

(**64**)

(**65**)

Most solid compounds (see Table 36) were prepared with $VOSO_4$ as starting material ($VOCl_3$ for the fluoro complex) and can be kept indefinitely under nitrogen or vacuum. The ethoxy, fluoro and trifluoromethyl complexes are rapidly decomposed by air. $[VO(S_2PMe_2)_2]$ consists of monomeric square pyramidal chelate complexes.[679] However, the clearly different properties of the F- and Me-substituted complexes, with anomalously high $\mu_{eff}^{r.t.}$ (~2.0 BM) and ν(V=O) at 860–870 cm^{-1}, suggest V···V interactions. In solution, the 860–870 cm^{-1} bands disappear and $\mu_{eff}^{r.t.}$ are close to 1.75 BM, indicating absence of magnetic exchange. The inverse dependence of susceptibility on field strength (H), and the slight increase of μ_{eff} with decrease in temperature suggest ferromagnetic interaction.[358] However, molecular weights suggest a monomeric nature and no half-field ESR spectrum was observed.

The compound $[VO(dtas)_2]$,[683] prepared by the reaction of $VOCl_2$ with dimethyldithioarsinate (dtas), has ν(V=O) = 986 cm^{-1} and the electronic spectrum is similar to those for $[VO(dtc)_2]$ and $[VO(dtpi)_2]$ complexes. Its isotropic ESR spectrum shows at least 27 discernible lines, from interaction with at least one ^{75}As atom.

$[VO(dpd)_2]$ (Hdpd = $(EtO)_2P(O)NHCSSH$) has been reported.[684]

(*iv*) *Xanthates*

Xanthato compounds have been prepared by the addition of aqueous $VOSO_4$ to a solution of the ligand at 0–5 °C;[685] green products precipitate and were recrystallized from CH_2Cl_2, $CHCl_3$ or *n*-hexane (or mixtures). Some properties are in Table 37. They were studied by electronic

spectroscopy, thermogravimetry and differential thermogravimetry.[685] $[VO(Pr^iOCSS)_2]$ with pyridine and piperidine produces the last compounds in Table 37, which are diamagnetic and have no visible band. These vanadium(V) compounds result from oxidation during the long reflux times used to prepare them. In fact, in most reactions with long reflux times, oxidation can be avoided only by taking extreme care to avoid O_2 participation, or in the presence of reducing agents.[686,687]

33.5.6.3 Dithiolates

By mixing stoichiometric amounts of $VOSO_4\cdot 5H_2O$ and $NaS_2CCN\cdot 3DMF$ at 20–50 °C for ~1.5 h an olive green maleonitrile dithiolate (mnt) $(Ph_3PMe)_2[VO(mnt)_2]$ was obtained.[688] If heated for 3–5 h at about 80 °C, deoxygenation occurs and $[V(mnt)_3]^{2-}$ forms. The vanadyl complex is monomeric and $\nu(V{=}O) = 963\ cm^{-1}$. In M(1,2-dithiolate)$_3$, the more oxidized species usually have a trigonal prismatic coordination, whereas highly reduced species possess near octahedral structures.[49] A detailed ESR study of magnetically dilute oriented crystals (with diamagnetic hosts, $(Ph_4P)_2[Mo(mnt)_3]$ for $[V(mnt)_3]^{2-}$ and $(MePPh_3)_2[TiO(C_2O_4)_2]$ for $[VO(mnt)_2]^{2-}$) led for the vanadyl complex to a scheme $d_{x^2-y^2} < d_{xz}$, $d_{yz} < d_{xy} < d_{z^2}$ ($d^1_{x^2-y^2}$ ground state).[689] Kwik and Stiefel[49] also studied the ESR spectrum of $[V(mnt)_3]^{2-}$ doped in crystals of $(Ph_4As)_2[Mo(mnt)_3]$. While the experimental results agree, the interpretations differ. A third assignment differs again.[690]

$(Ct)_2[V(mnt)_3]$ ($Ct = Me_4N^+$, Et_4N^+, Bu_4N^+, Ph_4N^+, Ph_3PMe^+, Ph_4As^+) have been prepared from $VOCl_3$,[52,688,691] and in $(Me_4N)_2[V(mnt)_3]$ the six sulfur atoms are around the vanadium at an average distance of 2.36 ± 0.01 Å (Figure 29a), in distorted D_{3h} symmetry.[52]

Reaction of $[VO(acac)_2]$ ethanolic solutions containing an excess of sodium ethane-1,2-dithiolate (Na_2edt) under inert atmosphere yields deep green solutions. NMe_4Cl slowly deposits green prisms of $(NMe_4)Na[VO(edt)_2]\cdot 2EtOH$ (Figure 29b);[656,692] the vanadium is square pyramidal with d(V=O) = 1.625 Å and d(V—S) = 2.378 Å (av). The V atom lies 0.668 Å above the sulfurs. $(NMe_4)Na[VO(edt)_2]$ in DMSO exhibits rather similar $g_{\|}$ and $g_{\perp}$ (1.981 and 1.984) and relatively small values of $A_{\|}$ and $A_{\perp}$ (133 and $42 \times 10^{-4}\ cm^{-1}$) when compared with $[VO(acac)_2]$ for example. This suggests significant π interactions between the sulfur lone pairs and the metal d orbitals.[692] $[VO(pdt)_2]^{2-}$ (pdt = propane-1,3-dithiolate) is similar to $[VO(edt)_2]^{2-}$.[656]

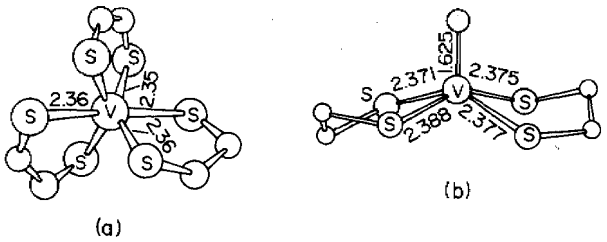

Figure 29 Molecular structure of (a) the $[V(mnt)]_3^{2-}$ anion[52] (the cyano groups are not included) and (b) the $[VO(SCH_2CH_2S)_2^{2-}]$ anion[692]

33.5.6.4 Other S-containing ligands

Early publications include the vapor-phase reaction of VCl_4 with thiophene to yield $VCl_4 \cdot C_4H_4S$.[693] Reduction of $VOCl_3$ by sulfides has long been known and fairly pure $[VOCl_2L_2]$ (L = Me_2S and Et_2S) complexes have been obtained.[399]

$[VOCl_2(tmtu)_2]$ (tmtu = tetramethylthiourea) had $\nu(V{=}O) = 990\ cm^{-1}$.[369] In $[VOF_2(tu)_2]$ (tu = thiourea), prepared by the method in equation (22), the IR indicates a V—S bond[428] in contrast with $[VO(NCS)_2L_2]$ (L = tu or *N*-substituted thioureas), with nitrogen bonding (see also Table 12).

33.5.7 Selenium Ligands

Early reports include 1:1 $[VCl_4]$ adducts with $MeSe(CH_2)_3SeMe$ and Pr^iSeMe, purple-grey decomposing at 114 and 130 °C.[694]

From iterative extended Hückel molecular orbital (EHMO) calculations, $[VX]^{n+}$ (X = S, Se; $n = 0, 1, 2$) ions and their tetrachloro complexes $[VXCl_4]^{m-}$ ($m = 4, 3, 2$) decrease in stability O > S > Se and with increasing charge of the anion.[695] The $[VXCl_4]^{2-}$ and $[VXCl_4]^{4-}$ complexes are expected to be $S = \frac{1}{2}$ systems while $[VXCl_4]^{3-}$ species are expected to be diamagnetic.[695]

33.5.8 Halogen Ligands

Only complexes $[VOX_n]^{2-n}$ and $[VX_m]^{4-m}$ will be included. Gmelins Handbuch discusses work in this area up to 1967.[357a]

33.5.8.1 Oxovanadium(IV) Complexes

Stability of the VO^{2+} complexes will decrease $F^- \gg Cl^- > Br^- > I^-$, with complexes formed by the three heavier halides being weak. Fluoride and chloride have been studied in aqueous solutions.[696–698] For fluoride, the following stability constants have been determined (at 20 °C and $I = 1$ M $NaClO_4$): $\beta_1 = 2.0 \times 10^3$, $\beta_2 = 3.7 \times 10^5$, $\beta_3 = 1.3 \times 10^7$ and $\beta_4 = 6 \times 10^7$,[698] much stronger than chloride ($\beta_1 \approx 1\ M^{-1}$). The fluoride complexes are more stable than those of Cu^{2+}, Zn^{2+} and Ni^{2+} but are weaker than the UO_2^{2+} complexes.[697] VOF_2 is known as well as some hydrated forms $VOF_2 \cdot xH_2O$.[355,428] Fluoro complexes have been mainly studied with alkali and ammonium ions[356] and stoichiometries $[VOF_3]^-$, $[VOF_4]^{2-}$, $[VOF_5]^{3-}$, $[V_2O_2F_7]^{3-}$ and $[V_2O_2F_6(H_2O)_2]$ have been reported.[699,700] The basic structural units are $[VOF_5]^{3-}$ octahedra, found isolated in $(Ct)_3[VOF_5]$[701,702] and $[M(NH_3)_6][VOF_5]$,[699] connected in infinite chains linked by *cis*-bridging F atoms in $K_2[VOF_4]$[703] and $(NH_4)_2[VOF_4]$[704] or to complex chains in $\{Cs[VOF_3]\}_2 \cdot H_2O$,[705] where two VOF_5 octahedra are linked *via* an F—F edge; the V—F distances span the range 1.881–2.205 Å and V=O (1.583 and 1.595 Å) are shorter than in $[VOF_4(H_2O)]^{2-}$ ($d(V{=}O) = 1.602$ and $d(V{-}O(trans)) = 2.268$ Å).[706] In $Cs_3[V_2O_2F_7]$, the anion consists of two octahedra sharing a face.[707] In $(NMe_4)_2[V_2O_2F_6(H_2O)_2]$, dimeric units of $[V_2O_2F_6(H_2O)_2]^{2-}$ are linked in chains by short hydrogen bonds, V—F distances ranging from 1.894 to 2.173 Å.[708] $d(V{-}V) = 3.292$ and $d(V{-}OH_2) = 2.074$ Å. Blue crystalline

$(N_2H_5)[VOF_3]$ has been synthesized from V_2O_5 and an excess of hydrazine hydrate in aqueous HF.[700] The hydrazine hydrate not only acts as a reducing agent but also provides the $N_2H_5^+$ cation. The Ct(Na^+, K^+ and NH_4^+) salts were prepared by metathesis between $(N_2H_5)[VOF_3]$ and CtF. Their $\mu_{eff}^{r.t.}$ are in the range of 1.51–1.53 BM.[700] Spin-Hamiltonian parameters are in Table 38.

Low ν(V=O) values are expected for fluoride complexes. In fact, in $(NMe_4)_2[V_2O_2F_6(H_2O)_2]$ the ν(V—O) was at 968 cm^{-1} (980 cm^{-1} Raman); in $(NH_4)_3[VOF_5]$ it was at 937 and 947 cm^{-1},[388] in $Ni[VOF_4]\cdot 7H_2O$ at 950 cm^{-1},[709] in (Ct)$[VOF_3]$ (Ct = $N_2H_5^+$, NH_4^+, Na^+, K^+) at 970–980 cm^{-1},[700] while in $(M(NH_3)_6)[VOF_5]$ (M = Cr, Co or Rh) ν(V=O) was at 907–913 cm^{-1}.[699] ν(V=O) in hexamminemetal(III) pentafluorooxovanadates(IV) reflected multiple hydrogen bonds.[699]

Simple $(Ct)_2[VOCl_4]$ are green (hydrates may have other colours) and are extremely air and moisture sensitive, due to the ease with which V—Cl bonds are hydrolyzed. In many $(Ct)_2[VOCl_4]$, $[VOCl_4]^{2-}$ probably has a square pyramidal structure as they present only one strong IR-active band (ν(V—Cl) = 340–350 cm^{-1})[409] (Sections 33.5.3.1 and 33.5.3.2) and the ESR spectra of $[VOCl_4]^{2-}$ and $[VOCl_5]^{3-}$ have been interpreted according to this (Table 38). (Ct)$[VOCl_3]$ have also been reported.[712]

Oxobromovanadates(IV) were first characterized in 1973, of the types (Ct)$[VOBr_3]$, $(Ct)_2[VOBr_4]$ and $(Ct)_3[VOBr_5]$ as well as several $[VOBr_2]$ adducts.[400,401] Most $[VOBr_2]$ adducts were included in a special report.[711] Normally, the oxobromovanadates(IV) are prepared by reduction of $VOBr_3$ by bromides in acetonitrile and/or nitromethane. When V^V is reduced by Br^-, free bromine is liberated and unless conditions are carefully regulated, perbromides form, giving preparative difficulties.[400] Generally, ν(V—F) have been assigned in the region 460–520 cm^{-1},[699,700,708] ν(V—Cl) bands in the region 340–400 cm^{-1} [409] and ν(V—Br) in the region 320–360 cm^{-1}.[400,711] The adducts reveal the trend for ν(V=O): anionic > five-coordinate > six-coordinate > bidentate.[711] The far IR of $(NEt_4)_2[VOBr_4]$ shows a complete and reversible transformation within the temperature range −30 to 35 °C, due to a reversible equilibrium (equation 52) between two forms of $[VOBr_4]^{2-}$, a C_{4v} form being stable at room temperature with ν(V—Br) at 296 cm^{-1}, a C_{2v} form being stable at lower temperatures with two ν(V—Br) bands at 274 and 325 cm^{-1}.[400] A similar transformation has been suggested for $[VOF_4]^-$ [713] as well as for $[VOCl_4]^{2-}$ (Section 33.5.3.2).

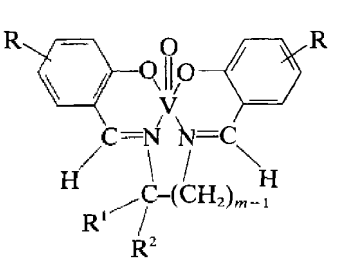
C_{2v} (−30 °C) C_{4v} (35 °C) (52)

Anhydrous VOI_2 has not yet been prepared and most reports of iodides of V^{IV} are not firmly based. I^- can reduce vanadium(IV).

33.5.8.2 Vanadium(IV) complexes

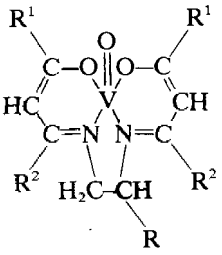
Potassium hexafluorovanadate(IV) can be prepared from $[VF_4]$ and KF in selenium tetrafluoride(III)[416] or by fluorination of K_2VF_5 for example. K^+, Rb^+ and Cs^+ salts obey the Curie–Weiss law with high values of θ. $[VF_4]$ reacts with py and NH_3 forming $[VF_4L]$, probably fluorine-bridged polymers.[416]

Chloro complexes of V^{IV} have been reported ($[VCl_5]^-$, $[VCl_6]^{2-}$, $[VCl_7]^{3-}$ and $[VCl_8]^{4-}$),[714] but the last two at least need to be confirmed. In the reaction of PCl_5 with $VOCl_3$ in hot $POCl_3$ or CH_2Cl_2 and of $[VOCl_2]$ with PCl_5 in $AsCl_3$ or $POCl_3$, $(PCl_4^+)[VCl_5]^-$ may be precipitated.[714] The anion is trigonal bipyramidal and exhibits weak, presumably *d–d* transitions at 6200, 8100 and 16 000 cm^{-1}.[715] By the reaction of $[VCl_4]$ or its ethyl cyanide adduct with alkylammonium chloride, $(Ct)_2[VCl_6]$ ($Ct^+ = Et_3NH^+$ and $Et_2NH_2^+$) may be isolated.[716] Other salts were prepared by the reaction of $SOCl_2$ with $(Ct)_2[VOCl_4]$.[717] $[VCl_4]$ may form adducts with oxygen, sulfur, selenium, nitrogen, phosphorus and arsenic donors.[6,718,720] With unidentate ligands, 1:2 complexes are normal (*e.g.* with $S(CN)_2$ or $Se(CN)_2$).[719] Thermal decomposition often results in V^{III} compounds.[6] With bidentate ligands, 1:1 complexes normally form.[6] Besides additions, another method has been used. $[VO(chelate)_2]$ complexes react with $SOCl_2$, PCl_5 and $SOBr_2$ producing $[VX_2(chelate)_2]$ (X = Cl or Br) hexacoordinate V^{IV} complexes[428,555,721] where the two halide ligands may add either *cis* or *trans* (*cf.* Section 33.5.5.4.ii, where the chelate is acac, or to other sections according to the chelate ligand involved, *e.g.* salen, oxine, *etc.*).



33.5.9 Mixed Donor Atom Ligands

33.5.9.1 Schiff base ligands



No general review has been published since 1967.[357b] Reviews by Syamal[358] and others[722] cover only part of the published work on oxovanadium(IV) Schiff base complexes.

(*i*) *Vanadium(IV) complexes with Schiff bases derived from the reaction of diamines and salicylaldehyde and derivatives*

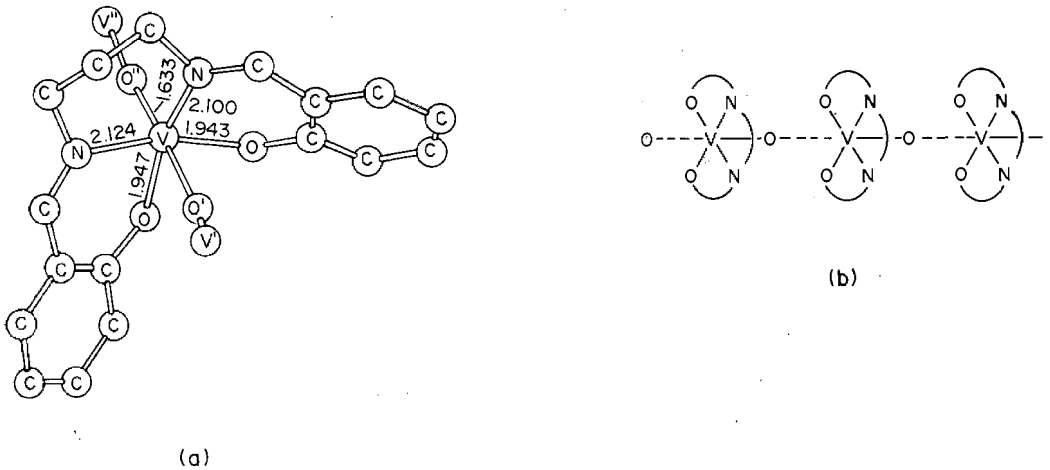
The complexes with Schiff bases (SBs) derived from diamines and salicylaldehydes (**66**) or β-diketones (**67**) normally have a 1:1 stoichiometry.

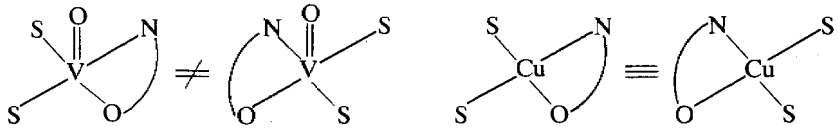
(**66**)

(**67**)

[VO(salnpn)] (**66**; $R^1 = R^2 = R = H$; $n = 3$), prepared simply by mixing vanadyl salts and the SB, even in the presence of DMSO or py, as sparingly soluble yellow-orange needles, consists of molecules packed so that the vanadyl oxygen of one occupies the sixth position of the V in a neighbour.[723] The result is an infinite chain of molecules about a two-fold screw axis (Figure 30). d(V=O) (1.633 Å) is one of the longest reported to date, consistent with ν(V=O) = 854 cm^{-1}, and the bridging character of the vanadyl oxygen.

The magnetic moment was 1.78 BM at 295 K and it obeys the Curie–Weiss law over the range 95–295 K with $\theta = -7$ K.[599b] Other authors conclude that not only do magnetic spin–spin





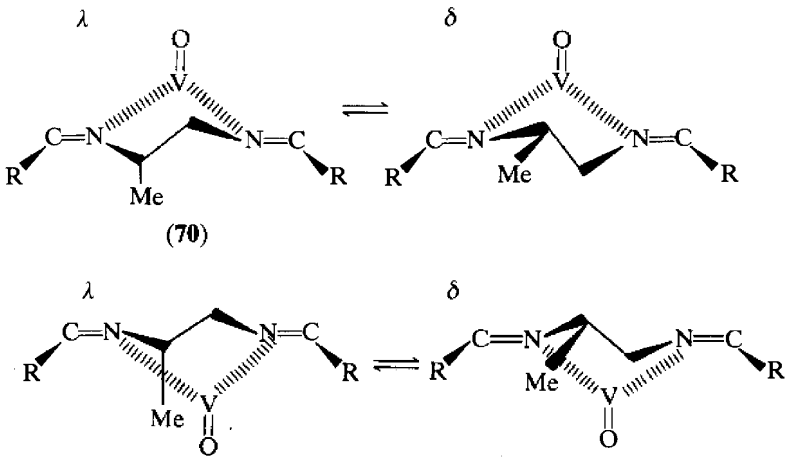


Figure 30 (a) A view of [VO(salnpn)] molecule with some internuclear distances (in Å);[723] (b) schematic representation of the chain structure

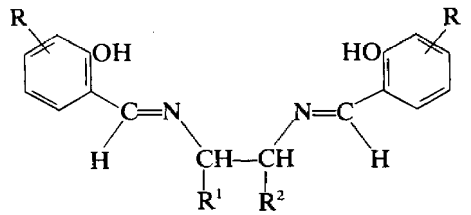
interactions exist in this compound but also that a small ferromagnetic interaction is indeed found.

Because the vanadyl ion is lopsided, its chelates have the possibility of forming a greater number of isomers than monatomic ions. For example, for an N,O-coordinating chelate (*e.g.* glycine), two enantiomers, (**68a**) and (**69a**), may form (S = solvent).

In the case of dissymmetric SB (**66**), VO^{2+} has the possibility of forming twice the number of isomers for each *R* or *S* configuration of the diamine chain (Scheme 18). For example, in the case of [VO(sal(*S*)pn)], where sal(*S*)pn is the SB derived from Hsal and (*S*)-(+)-propane-1,2-diamine, the preferred conformation does not always depend on the absolute configuration of the diamine; structure (**70**) represents the favoured form since it involves the least steric interaction between the vanadyl oxygen and the (*S*)-pn methyl group.[724,725] The actual situation existing in solution is probably an equilibrium of the isomers with a predominance of the λ conformation since the barrier for ring interconversion from λ to δ is small.[724] In some complexes, as in [VO(sal(*SS*)chxn)] ((*SS*)chxn = (S,S)-(+)-cyclohexane-1,2-diamine), the ligand is stereospecifically coordinated so that the chelate ring is locked in a δ conformation.

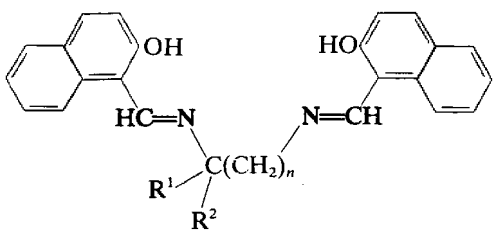
Scheme 18

Dissymmetry may occur if the ligand adopts a preferred flattened tetrahedral geometry about the metal ion. CD spectra of [VO(sal(*S*)pn)] and [VO(sal(*SS*)chxn)] exhibit evidence of Δ (**71**) and Λ (**72**) configurations.[724] From CD spectra, for complexes with tetradentate SBs,[726] the geometry around VO^{2+} has a slight pseudotetrahedral distortion.



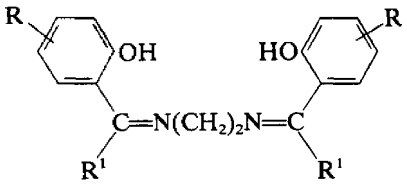
λ, Δ (**71**) δ, Λ (**72**)

Many investigations have involved vanadyl complexes of type (**66**),[599a,723–726] particularly with 1,2-diamines. In the solid state $\mu_{eff}^{r.t.}$ values are normally near the spin-only value.[725,727]

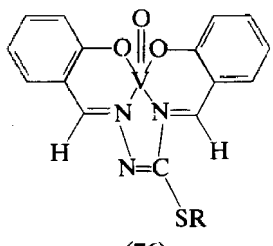


Complexes of SB (**73**) are five-coordinate in solution and normally show no tendency to coordinate a basic ligand to form six-coordinate compounds.[725] The formation of adducts depends on the chelate ring, as in (**70**). With electronegative groups in the aromatic ring, *e.g.* 5-NO_2salen (**73**; $R^1 = R^2 = H$, R = 5-NO_2), electronic and CD spectra show hexacoordinate adducts, and solid adducts were obtained with py and DMSO.[725]

Expansion of the 'central chelate ring' in tetradentate (**66**) from $n = 2$ to $n = 3$ favours six-coordinate species, as [VO(salnpn)] (Figure 30).[726]



Complexes (**66**; R = H and $n = 2$) were five-coordinate square pyramidal monomers; in py, six-coordinate species form.[728] Compound (**66**; $R^1 = R^2 = R = H$), polymeric in the solid state (Figure 30), was considered to break down to five-coordinate monomers in $CHCl_3$ and six-coordinate in py. Changes in the spectrum of (**66**; $R^1 = R^2 = R = H$, $n = 9$) in $CHCl_3$ on dilution indicate that the complexes with $n \geq 4$ are not monomers. Compounds (**66**; R = 3-MeO) were five-coordinate monomers except when $R^1 = R^2$ and $n = 3$.[557] Compounds (**66**; R = 5-Cl) tend to be polymeric solids. Complexes with (**74**) appear monomeric in the solid state except when $n = 3$.[559]



(**73**)

(**74**)

(**75**)

(**76**)

For (**66**; $R^1 = R^2 = H$, R = 3-MeO), the changes in the ordering of *d* orbitals as *n* varies are schematically represented in Figure 31. Complexes with (**75**; R′ = Me or Ph) have been reported.[729,730]

Alkylation of the thiocarbonyl sulfur of thiosemicarbazone derivatives induces not only complexation through the terminal amino group but also enough acidic character for it to

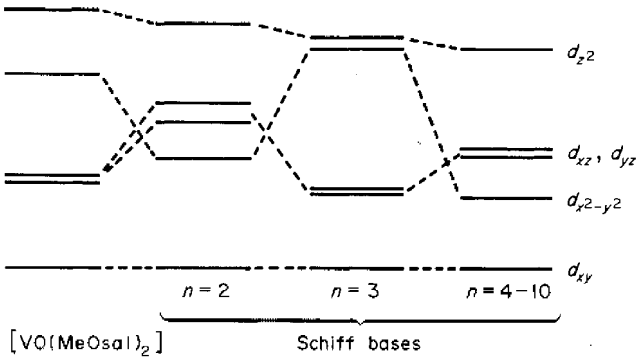


Figure 31 Changes in the ordering of the oxovanadium(IV) *d* orbitals proposed for complexes with Schiff bases (**66**) with $R^1 = R^2 = H$ and R = 5-MeO[557] (not to scale)

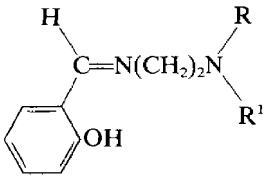
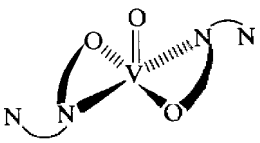
function as a monoacidic ligand.[731] In the presence of VO^{2+} (and Ni^{2+}, Cu^{2+}) salts, these ligands are capable of condensing at the terminal amino nitrogen atom through another aldehyde or ketone producing quadridentate ligands and forming (**76**).[732] In (**76**) and similar Ni^{2+} and Cu^{2+} complexes (R = H, NH_4, Na, K), the set of coordinating atoms and the geometry appear similar to those with (**73**).[733–735] The VO^{2+} compounds react with alkyl iodides producing complexes with R = Me, Et, Pr. Their electronic spectra in pyridine differ from the spectra in $CHCl_3$;[736] a decrease in intensity with parallel decrease of the ESR show that VO^{2+} is oxidized to vanadium(V),[736] surprising compared with examples of V^V complexes being reduced to V^{IV}[385,686,687] and even to V^{III} compounds.[720] Other oxidations in the presence of py are in Table 37.



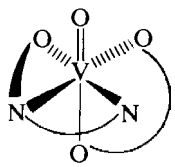
When [VO(salen)], only slightly soluble in THF, acetone and acetonitrile, is added to $NaBPh_4$ in these solvents, a green solution is produced from which the sodium cation complex (**77**) crystallizes as a light green solid, stable in air (equation 53).[737] [VO(saloph)] (saloph = *N,N'*-(*o*-phenylene)bis(salicylidenimine)) gives ([(VO(saloph)]$_2$Na)BPh_4.[737] Compound (**77**) contains Na^+ trapped in a coordination cage provided by six oxygen atoms. In ([VO(salen)]$_2$Na)BPh_4, all the oxygens of [VO(salen)] are involved in coordination to the Na^+ giving a cationic polymeric structure. The geometry around Na^+ is pseudo-octahedral; the six oxygens are provided by four different [VO(salen)] units: two vanadyl O at an average of 2.368 Å and two pairs of O from salen units at an average of 2.405 Å. Vanadium is five-coordinate square pyramidal and is 0.606 Å above the plane of the O_2N_2 atoms of the salen unit. The mean V=O is 1.584 Å.

$$Na^+BPh_4^- + 2VO(salen) \longrightarrow [\{VO(salen)\}_2Na]BPh_4 \quad (53)$$
(**77**)



Treatment of a basic aqueous solution of EHPG (EHPG = ethylenebis(*o*-hydroxyphenylglycine), protonated and deprotonated forms will not be specified) with $VOSO_4$ afforded light blue $(NH_4)[VO(EHPG)]\cdot H_2O\cdot EtOH$;[738] the VO^{2+} is bonded to five atoms of the EHPG^3 ligand with one amine nitrogen, one phenolate oxygen and two carboxylate oxygens coordinated equatorial and an amine nitrogen coordinated *trans* to the vanadyl oxygen. In contrast, $VOSO_4$ and EHPG in aqueous ethanol yield a neutral dark blue product characterized as the V^V complex $[V^VO(EHPG)]$,[738–741] stable as a solid. On allowing warm solution to stand, green [VO(salen)] forms.[338,339] This corresponds to an oxidative decarboxylation in which two molecules of CO_2 are lost. The reaction, rapid in DMF, proceeds slowly in alcohol with $[V^VO(EHGS)]$ (EHGS = *N,N'*-ethylene((*o*-hydroxyphenyl)glycine)) as monodecarboxylated intermediate, isolated as the sodium salt $Na[VO(EHGS)]\cdot 1.5H_2O\cdot MeOH$, which may be prepared by exhaustive electrolysis of the V^V analogue. It is six-coordinate with the two nitrogens and phenolic oxygen binding equatorial and an oxygen of carboxylate *trans* to the vanadyl oxygen.[738,739] The final product of decarboxylation is formed by discrete molecules of [VO(salen)];[738,739] all aspects of the structure agree with those for ([VO(salen)]$_2$Na)BPh_4 (**77**).[737] The electrochemistry of $[V^{IV}O(EHPG)]^-$ and *meso*-$[V^VO(EHPG)]$ has been studied by cyclic voltammetry.[741]

In $[VO(EHPG)]^-$, $[VO(EHGS)]^-$ and [VO(salen)], ν(V=O) correlates well with axial (V=O) and equatorial bond lengths.[738]



Complexes with SBs of general formula (**78**) form by adding a $VOCl_2$ solution to a solution containing the appropriate derivative and substituted ethylenediamine, followed by the addition of $NaMeCO_2$ and heating under reflux for 10–60 min.[742] According to the nature of R and R′, two types may be obtained: (i) complexes $[VO(XsalenN(R)R')_2]$ in which the vanadium is linked to two SBs, and (ii) complexes [VO(Xsal)(XsalenN(R)R′)] in which the vanadium is linked to only one SB and to a salicylaldehyde molecule. When the R and R′ groups have an electron-releasing effect, the β nitrogen becomes a strong donor, the SB acts as a tridentate ligand, and six-coordinate mixed-ligand complexes of type (ii) form. However, while with Ni^{2+}, the bidentate ligand is an SB, with VO^{2+} it is a sal^- ion; this occurs even if the reaction is carried out using stoichiometric amounts of preformed SB (**78**) and the vanadyl salt. Type (i) complexes are green, and monomeric, with structure (**79**); the pyridine readily adds to vanadium in solution.[742] In type (ii) complexes, the vanadium is coordinatively saturated and the electronic spectra in inert solvents and in py are very similar; this and other observations led to a proposed structure (**80**).[742]

(**78**)

(**79**)

(**80**)

(ii) Vanadium(IV) complexes with Schiff bases derived from the reaction of diamines and β-diketones

Several complexes with Schiff bases derived from the reaction of β-diketones and diamines (**67**) have been prepared and many publications on them have appeared.[523,725,743–748] Almost all are monomeric (no V···V interactions) and five-coordinate square pyramidal, as in (**67**). This structure has been confirmed in [VO(acen)] (acen = **67**; $R^1 = R^2 = Me$, R = X = H).

Complexes (**67**) are often prepared by chelate exchange (equation 54), using $[VO(acac)_2]$ as the starting product. In the case of H_2tfen (tfen = **67**; $R^1 = CF_3$, $R^2 = R = X = H$) this yields [VO(acen)], and [VO(tfen)] was obtained starting with $[VO(tfacac)_2]$ instead of $[VO(acac)_2]$.[745] The complexes may be recrystallized from benzene, $CHCl_3$, *etc.*, but, as in the case of (**66**), solvates are often obtained.

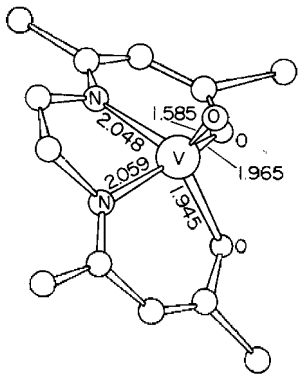
$$VO(acac)_2 + \beta\text{-diketone·diamine} \xrightarrow{\Delta} VO(\beta\text{-diketone·diamine}) + 2acac \qquad (54)$$

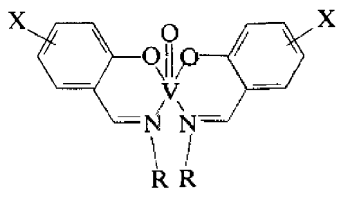
The separation of the four possible isomers of [VO(acpn)] (**67**; $R^1 = R^2 = R = Me$, X = H) *Sλ*, *Sδ*, *Rλ*, *Rδ* (compare with Scheme 18) was claimed.[743,744] The O_2N_2 chromophore is not planar but has a slight tetrahedral distortion and the CD spectra suggest that the corresponding chirality has Δ absolute configuration for diamines of *S* or *S,S* absolute configuration.[725]

In [VO(acen)], the geometry around the vanadium is square pyramidal (see Figure 32),[746,747] but β-ketimine VO^{2+} complexes do not readily add a ligand to form six-coordinate complexes, except if electron-withdrawing groups are attached to the acac portion of the SB. For example, Cotton effects appear in the *d–d* transition of [VO(tfen)] in the presence of (−)-1-phenyl-1-aminoethane in acetonitrile,[725] and, also, though a solid [VO(tfen)]·DMSO adduct forms, the sulfoxide is lost on standing overnight in the air.

In (**67**; $R^1 = R^2 = Me$, R = H) with X = Br green or yellow complexes were obtained, according to the solvent used, with ν(V=O) at *ca.* 980 and 900 cm^{-1}, respectively.[748] When X = Cl, only the green-type complex may be obtained. The authors assume five-coordinate square pyramidal geometry for the green complexes and a chain structure ···V=O···V=O···, similar to [VO(salnpn)], for the yellow complex. Solid adducts were isolated with 1-methylimidazole.

Allowing [VO(acen)] to react with $SOCl_2$, $[VCl_2(acen)]$ was isolated,[749] which is soluble in acetone, DMSO and CH_2Cl_2. This is less stable as a solid than $[VCl_2(salen)]$ but its decomposition product from reaction with air is not [VO(acen)].





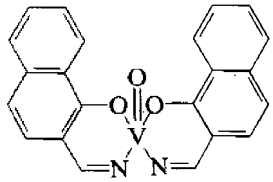


Figure 32 The molecular structure of [VO(acen)].[747] Some internuclear distances are indicated. The 'en' portion of the ligand assumes a configuration approximately halfway between *gauche* and eclipsed. The V atom is 0.58 Å above the plane of the SB coordinating atoms

(*iii*) *Bidentate Schiff bases*

Most of the compounds with SBs expected to have structure of type (**81**) or (**82**) are in Table 39. Compounds 1–6 of this table were included in Gmelins Handbuch.[357] Preparation consists simply in adding an aqueous-alcoholic (EtOH or MeOH) solution of the corresponding amine and $NaMeCO_2$ to an alcoholic solution of $VOCl_2$ (or $VOSO_4$) and the salicylaldehyde derivative. The complexes are often purified by recrystallization from ethanol. Compounds 7–13 are brownish grey-green and complexes 14–21 are green;[750] they are soluble in $CHCl_3$ and CH_2Cl_2 but less soluble in methanol, ethanol and benzene. These complexes show electronic spectra in pyridine which are different from the spectra of the same complexes in the solid state and in $CHCl_3$; this indicates, in pyridine, six-coordinate solvates.[750]

(**81**)

(**82**)

For several SB complexes ranging from yellow to green and maroon (22–30 in Table 39), poor solubility with failure to obtain six-coordinate species initially suggested a polymer.[721] However, they are soluble in hydrocarbons, and cryoscopy in benzene suggests a monomeric nature. For yellow bis(*N*-(4-chlorophenyl)salicylideneiminato)oxovanadium(IV) (22 in Table 39, $\nu(V{=}O) = 885\ cm^{-1}$), the unit cell comprises monomers of C_2 symmetry and the coordination was distorted trigonal bipyramidal (**13**). The three oxygens and vanadium are in the equatorial plane and the two nitrogen donors axial. V=O (1.615 Å) is longer than normal.

Syamal and Kale[751–753] reinvestigated previous reports[727,754,755] where a dimeric structure was proposed for compounds 33–36 in Table 39 and concluded that all exhibit moments in the range 1.73–1.75 BM at 295 K and obey the Curie–Weiss law with $\theta = 0$–4 K, indicating the absence of magnetic ordering in the temperature range 83–296 K. Osmometry indicates a monomeric nature. ESR spectra in $CHCl_3$ give the 'normal' eight-line spectra with $g = 1.98$ and no triplet state spectra ($\Delta M_s = \pm 2$ transition) were detected around 1600 G. On the basis of this evidence, complexes with SBs (**81**) and (**82**) with R = Ph are monomers and have square pyramidal structures. Although the compounds are not strictly the same, this conclusion disagrees in part with the work of Pasquali *et al.*[721] where a distorted trigonal bipyramidal structure was established for compound 22 in Table 39.

Oxovanadium(IV) complexes with SBs derived from Hsal or substituted Hsal and 2-aminoethanethiol (**83**) and 3-aminothiophenol (**84**) were reported by Syamal[756–758] and some properties are summarized in Table 40. The corresponding ligands with oxygen atoms instead of sulfur form tridentate complexes with antiferromagnetic properties (see Section 33.5.9.1.iv).

However, (**83**) and (**84**) behave as bidentate monobasic ligands and form complexes $[VO(SB)_2]$; a square pyramidal structure was suggested with coordination through the oxygen atom and nitrogen of the azomethine group. The $[VO(SB)_2]$ complex with (**83**; R = H) was also studied by IR and cyclic voltammetry.[759] Although the presence of the protonated SH group could not be confirmed, the coordination probably involves N and O donors. Schiff bases (**85**) may behave as tridentate ONS ligands forming $VOL{\cdot}nH_2O$ complexes (Section 33.5.9.1.iv); however, if heated, these SBs are capable of cyclization and may then form $[VO(SB)_2]$ with (**86**) bidentate.[760]

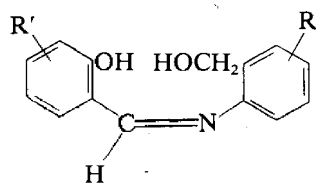
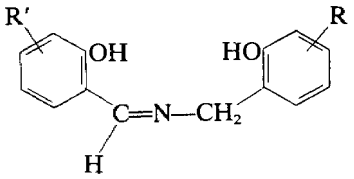
(*iv*) *Tridentate Schiff bases*

With bidentate SBs, monomeric $[VO(SB)_2]$ complexes are normally formed. On the contrary, with tridentate dibasic SBs, dimeric species often form. It appears that the dibasic character of the ligands forces the VO^{2+} ion to dimerize leading to anomalous magnetic properties. Proposed structures have not been verified owing to their non-crystalline nature. Insolubility precluded molecular weight determinations and ESR and electronic spectral studies have been carried out in the solid state only.

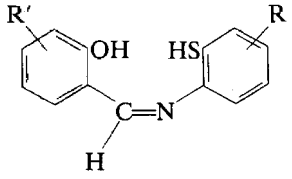


Solutions containing VO^{2+} and dinegative, tridentate ligands of the type $^-O—N—O^-$ are easily oxidized to the corresponding V^V complexes and possibly V^{IV} complexes are stable only if insoluble. Evidence for dimeric structures based on single-temperature subnormal magnetic moments should be treated with caution, as small amounts of a V^{IV} contaminant in a V^V complex may be the cause of the observed magnetic susceptibility.

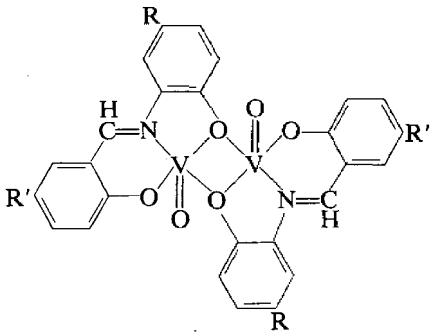
Complexes with the tridentate dibasic SBs (**87**)–(**90**) have subnormal magnetic properties. Part of the published work on these type of complexes was reviewed by Syamal[358] and Casellato *et al.*[722] and many of the reported compounds are included in Table 41. They are normally obtained by mixing alcoholic (MeOH or EtOH) solutions of the appropriate SB, often prepared *in situ*, and an alcoholic solution of a vanadyl salt. Zelentsov first characterized such complexes,[762] prepared from SB (**87**) derived from Hsal or substituted Hsal and *o*-aminophenol. Ginsberg *et al.* prepared these as well as some others and studied the magnetic properties in detail from 1.4 to 300 K.[763] The moments of the complexes (with the exception of R = NO_2, R′ = NO_2) decrease considerably as the temperature is lowered and the temperature dependence of the susceptibility is characteristic of intramolecular antiferromagnetic exchange. The authors suggested a dimeric structure (**91**) and calculated the exchange integral, *J*, according to the Bleaney–Bowers equation,[764] concluding that substituents at R and R′



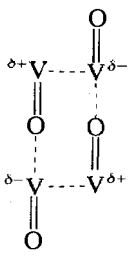
positions influence J in a different manner in oxovanadium(IV) and copper(II) complexes of the same ligands.[764] This was attributed to a difference in the exchange mechanism operating in VO^{2+} complexes resulting from the orbitals containing the unpaired electron not having the same symmetry. A tetrametallic structure (**92**) with V=O···V interaction was proposed for complex 5 in Table 41 to explain its higher J value and IR spectra.



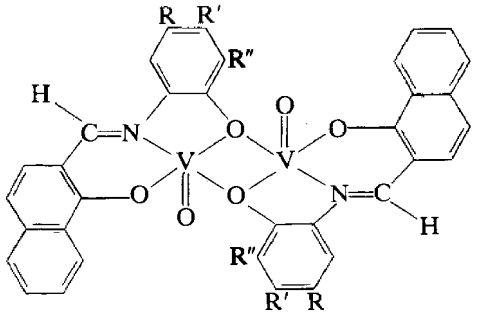
(**87**)



(**88**)



(**89**)



(**90**)

(**91**)

(**92**)

(**93**)

The complex with R = NO_2, R′ = H (7 in Table 41) has only a small TIP (temperature independent paramagnetism) term and does not follow the single–triplet susceptibility curve; the spins are completely coupled and only the diamagnetic single state ($S = 0$) is populated. The IR spectrum provides no evidence for bridging through the vanadyl oxygen and the complex probably has a different structure.[763] The complex with R = R′ = 5-NO_2 (9) obeys the Curie–Weiss law with $\theta = 1.4$ K and $\mu = 1.62$ BM and the authors suggest a five-coordinate monomer in which a molecule of solvent occupies a coordination position.[763]

On treatment of (**91**; R = R′ = H) with a strong chelating agent, such as phen, the dimer is broken, with the formation of a mononuclear mixed-ligand complex [VO(SB)(phen)].[765] The dimeric structure is also broken on treatment of complex (**91**; R = H, R′ = 5-Cl) with pyridine; a monopyridine adduct forms which obeys the Curie–Weiss law with $\theta = 2$ K and $\mu_{eff}^{r.t.} = 1.75$ BM.[763]

Syamal reported the ESR spectrum of complex (**91**; R = R′ = H) in polycrystalline solids; it exhibits a single-line spectrum with $g_{av} = 1.99$ at room temperature and 77 K, with no half-field band or hyperfine splitting.[358]

Subnormal VO^{2+} complexes (**93**) of SBs derived from 2-hydroxynaphthaldehyde and *o*-aminophenol and some substituted derivatives have also been obtained.[765] The ESR spectra of the complexes (**93**; R = R′ = R″ = H; R = Cl, R′ = R″ = H) in polycrystalline solids at room temperature exhibit two parallel lines, two perpendicular lines and a broad line around 1600 G due to the $\Delta M_s = 2$ transition. At 77 K, both high- and low-field spectra exhibit hyperfine splittings. Several complexes of type (**93**) were also studied by Carlisle *et al.* (Table 41, 27–34).[766,767] ν(V=O) values of complexes (**93**) lie in the range 955–1000 cm^{-1} and the compounds exhibit only one *d–d* band in the region 620–700 nm. As in the case of (**91**; R = R′ = H), on treatment of compound (**93**; R = R′ = R″ = H) with phen the dimer is broken and a mixed-ligand complex is obtained.[765]

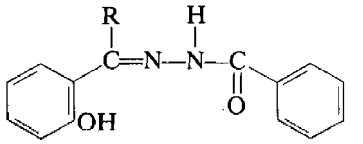
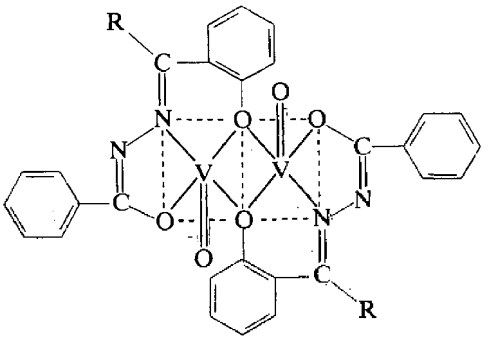
With (**88**) and (**89**), several VO^{2+} complexes were prepared (Table 41).[768–771] High melting or decomposition temperatures (>250 °C) and insolubility in common noncoordinating solvents suggest a dimeric or polymeric nature. ν(V=O) occurs at 910–985 cm^{-1} for complexes of (**88**) and at 900–910 cm^{-1} for those of (**89**); this argues against the presence of a $\cdots V{=}O\cdots V{=}O\cdots$ chain structure. IR suggests a phenolic oxygen bridge in (**89**) complexes[769] and enolic oxygen bridges in (**88**) complexes.[771] $\mu_{eff}^{r.t.}$ values of the complexes are remarkably less than the spin-only value (Table 41) and the magnetic moments decrease significantly as the temperature is lowered, suggesting antiferromagnetic exchange interaction

of neighbouring VO^{2+} ions. The ground state is $S = 0$ (singlet state) and the complexes exhibit no dependence on the magnetic field strength.



The J values of the VO^{2+} complexes with (**89**) are higher than those with (**88**); this suggests that in complexes with (**88**) and (**89**), bridging does not involve the phenolic O atoms of Hsal. If this was the case one should expect similar J values in the two series of complexes[769,771] since the electronic environment in the chelate ring would be the same.

Complexes with (**90**) involving ONS coordination apparently similar to the ONO coordination in (**87**) were reported (Table 41).[760] ν(V=O) lies in the range 900–1005 cm^{-1} and some exhibit splitting of the V=O band. $\mu_{eff}^{r.t.}$ values are in the range 1.27–1.52 BM and the temperature dependence indicates exchange-coupled antiferromagnetism. A dimeric oxygen-bridged structure, similar to (**91**), which provides an appropriate symmetry for the $3d_{xy}$ orbitals to overlap and form a strong σ V—V bond, was suggested.[760]



The synthesis and characterization of VO^{2+} complexes of hydrazones (**94**) and (**95**) derived from benzoylhydrazine and *o*-hydroxy aromatic aldehydes and ketones were also reported[772] and molecular weight determinations, IR, electronic spectra and magnetic properties were explained assuming a dimeric structure (**96**) with each unit having a five-coordinate square pyramidal geometry.

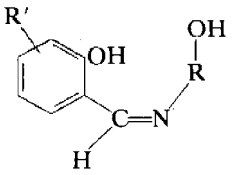
(**94**)

(**95**)

(**96**)

Oxovanadium(IV) complexes with (**97**) and (**98**) derived from alkyl aminoalcohols and Hsal or *o*-hydroxyacetophenone (and substituted derivatives), respectively, have been prepared as well as VO^{2+} complexes with (**99**) derived from 2-hydrazinoethanol and Hsal and substituted Hsal. Most of these and some properties are summarized in Table 42. Generally the complexes were prepared by adding an alcoholic solution of the SB, either previously obtained as a solid or prepared *in situ*, to alcoholic vanadyl acetate. The mixture is normally refluxed for several hours and the precipitates are collected by filtration; as they are not soluble they are not recrystallized.

Compounds obtained with SBs (**97**)–(**99**) have been formulated as $[VOL]_2$ compounds with structure (**100**). This is based on magnetic properties and IR spectra.[773–776] They have subnormal $\mu_{eff}^{r.t.}$ and the dependence of χ_M^{corr} on temperature is characteristic of antiferromagnetic exchange. For at least some (15–23 in Table 42), it was reported[773,774] that the complexes exhibit no dependence of χ_M^{corr} on magnetic field strength, indicating absence of ferromagnetic interaction. ESR studies on polycrystalline samples at room temperature normally give g_{av} ~1.99 and the half-field spectrum corresponding to the $\Delta M_s = 2$ is often observed. At 77 K, the high-field spectra often exhibit hyperfine splittings similar to those observed in VO^{2+} tartrates (Section 33.5.5.7.i).



The spectra of complexes with the tridentate SBs (**97**)–(**99**) generally exhibit three ligand field bands: (i) *ca.* 715–770, (ii) *ca.* 625 and (iii) *ca.* 500–550 nm, assigned to d–d transitions according to the Vanquickenborne and McGlynn MO scheme,[360] which corresponds to an ordering of levels as in the Ballhausen and Gray model (Figure 16a): $d_{xy} < d_{xz}$, $d_{yz} < d_{x^2-y^2} <$

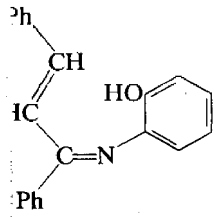
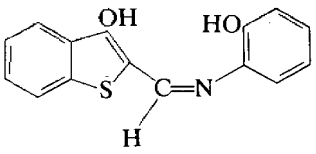
(**97**)

(**98**)

(**99**)

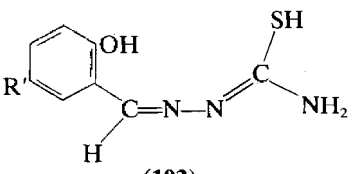


(**100**)

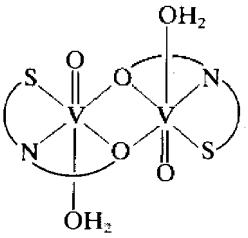


d_{z^2}.[364] Some of these bands are not well developed and this gave rise to ambiguity in their assignment. No band characteristic of VO^{2+}–VO^{2+} interaction has been observed in complexes with these SBs.

In Table 42, in complexes with SBs (**97**)–(**99**), the $|J|$ values of compounds with $n = 2$ (n in $R = (CH_2)_n$) are larger than with $n = 3$. This suggests that the antiferromagnetic exchange interaction is stronger with $n = 2$, and this has been attributed to the difference in the chelate ring (five- or six-membered).[775] For $n = 2$, the J values also depend appreciably on the nature and position of the Hsal substituent; for $n = 3$, they are relatively insensitive to ring substituents.[358]

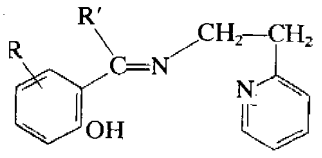


In an early publication, Zelentsov reported the preparation of a complex with subnormal magnetic properties ($\mu_{eff}^{r.t.} = 0.87$ BM) with the SB (**101**).[777] The compound was prepared from dibenzoylmethane and *o*-aminophenol. The VO^{2+} complex with (**102**) has also been shown to be involved in antiferromagnetic exchange with $J = -139\,cm^{-1}$. Revenko and Gerbeleu prepared several VO^{2+} complexes of (**103**) derived from Hsal and thiosemicarbazide which were reported to involve ONS coordination.[778] The measured $\mu_{eff}^{r.t.}$ were 1.27, 1.21 and 1.33 BM for R′ = H, Cl and Br, respectively. The complexes are not anhydrous and a dimeric structure (**104**) was proposed.

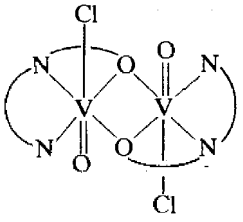


(**101**)

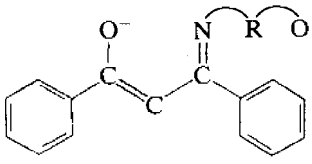
(**102**)



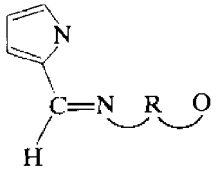
(**103**)



(**104**)



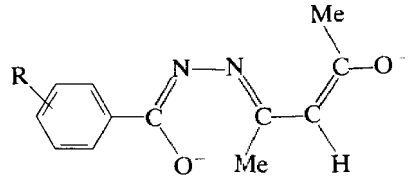
Several complexes were prepared with (**105**; R′ = H or Me). All decompose above 300 °C and are insoluble in common nonpolar solvents. $\mu_{eff}^{r.t.}$ values, in the range 1.32–1.58 BM, suggest exchange-coupled antiferromagnetism. The authors formulated the complexes as $[VO(SB)(Cl)]_2$ and proposed a dimeric structure (**106**) but report no χ_M^{corr} temperature dependence results. In the IR, ν(V=O) and ν(V—Cl) were in the range 975–985 and 360–385 cm^{-1}.[779] Electronic spectra in Nujol mulls had three bands: (i) ~395–412, (ii) 640–670 and (iii) 745–800 nm. Structure (**106**) is probably not correct.



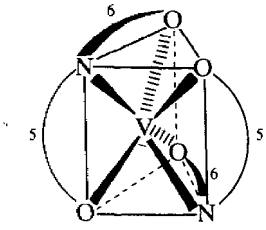
(**105**)

(**106**)

(**107**)



(**108**)



Several VO^{2+} complexes with (**107**) and (**108**) derived from dibenzoylmethane or pyrrole-2-carboxyaldehyde and several amines (taurine, anthranilic acids, β-alanine) were formulated as $[VO(SB)(H_2O)_2]$;[780–783] it was proposed that these SBs behave as tridentate ligands and assume a monomeric structure on the basis of $\mu_{eff}^{r.t.}$ and ebulliometric measurements in dioxane. A pyridine adduct $[VO(PE)(py)_2]$ was also obtained where PE is the SB (**108**; R—O = $CH_2CH_2SO_3^-$).[782]

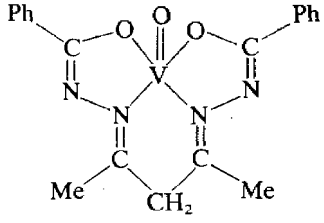
Benzoylhydrazine and $[VO(acac)_2]$ react in methanol under dry N_2 to produce violet $[V(abh)_2]$ where abh is the dianion of acetylacetone benzoylhydrazone (**109**; R = H).[784] In air, a smaller yield of $[V(abh)_2]$ is obtained, with V^V complexes containing abh. The violet complex has $\mu_{eff}^{r.t.} = 1.87$ BM and the ESR shows the 'normal' eight peaks with $g = 1.972$; the structure has trigonal prismatic coordination in which the tridentate abh ligand forms both five- and six-membered chelate rings (**110**). Depending on the relative amounts of the reactants, chelate exchange between $[VO(acac)_2]$ and Schiff bases (**109**) provides (i) complexes with subnormal $\mu_{eff}^{r.t.}$, probably dimeric, if a 1:1 stoichiometry is used, and (ii) vanadium bis complexes, in which abstraction of vanadyl oxygen occurs, if 1:2 $[VO(acac)_2]$:SB stoichiometry is used.[785]

Complexes with SBs from Hsal and α-amino acids (glycine, L- and DL-alanine, L-methionine, L-valine, L-leucine, L- and DL-phenylalanine) were prepared and characterized.[786] The complexes are bluish-grey and there is no appreciable interaction between V atoms. The compounds were $[VO(SB)(H_2O)]$ (**111**), confirmed in an X-ray study of (**111**; R = Me, L-Ala derivative).[787] ν(V=O) was at ~1000 cm^{-1}; the compounds are not soluble in noncoordinating solvents, but when dissolved in py ν(V=O) shifts to ~970 cm^{-1}; several orange py adducts (**112**) were isolated.[686] Complexes (**111**) have electronic spectra that resemble those of

(**109**)

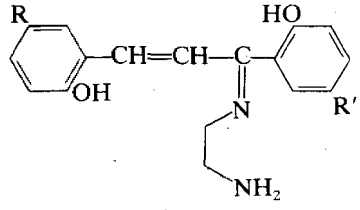
(**110**)

[VO(acac)$_2$] and were considered as having a square pyramidal structure, although a trigonal bipyramidal structure was not precluded.[786] Detailed IR studies of [VO(sal-Gly)(H$_2$O)] were reported.[788,789]



In complexes (**111**), one water molecule occupies a coordination position and 'prevents' the dimerization of the compounds. Dimers were obtained on dissolving the monomer (**111**) in absolute methanol, when equilibrium (ii) in Scheme 19 takes place. The dimeric nature of the isolated complexes[790] is supported by the marked differences from the mononuclear complexes, by the low $\mu_{eff}^{r.t.}$ obtained and by molecular weights; ν(V=O) was around 980 cm^{-1}. From dry methanol the orange products are the vanadium(V) complexes (**114**) (probably dimeric); the oxidizing agent seems to be dissolved O_2.[686] In wet methanol, complexes (**115**) were obtained as red needles. Further evidence for V^V arises from the fact that on treating (**115**) or (**114**) with a reducing agent (*e.g.* NaSH·xH$_2$O), bluish-grey complexes (**111**) are regenerated. Reaction of (**115**) with py gives (**112**), corroborating other reports of the reducing action of pyridine on vanadium(V).[395]

Dimeric oxovanadium(IV) complexes (NBu$_4$)[(VO)(SB)]$_2$·nH$_2$O have also been prepared with the SB from salicylaldehyde and L, D,L-serine and *L*-cysteine.[791] Magnetic moments are 1.1–1.4 BM, higher than for the dimeric SB derived from the L-amino acids: Ala, Val, Leu, Met or Phe (0.5–0.8 BM) which are probably best described as V^V complexes (**114**).[790]



Green complexes [VO(SB)(H$_2$O)], where H$_2$SB = 2-hydroxynaphthylidene amino acids, react with py or phen to form [VO(SB)(py)$_2$] or [VO(SB)(phen)], which exhibit $\mu_{eff}^{r.t.}$ near the spin-only value.[765] In methanol, these gave brown solutions from which the monomeric brown V^V complexes [VO(OMe)(SB)(MeOH)] were isolated. The treatment of these brown complexes with CH$_2$Cl$_2$ followed by *n*-hexane gave green precipitates of [VO(OH)(SB)]$_2$;[765] in CH$_2$Cl$_2$, the complexes are dimers.

(*v*) *Other polydentate Schiff bases*

Several polydentate SBs may act as binucleating ligands; see Section 33.5.12.1. Only a few miscellaneous polydentate SBs will be included here. A complex with the SB obtained in the reaction of two moles of benzoyl hydrazide with acetylacetone had ν(V=O) = 995 cm^{-1}, $\mu_{eff}^{r.t.}$ = 1.7 BM and was monomeric square pyramidal (**117**).[792] A few complexes with the ethylenediamine derivatives of 2,2′-dihydroxychalcones (**118**) were prepared in ethanol.[793] The stoichiometry is 1:1 and the atoms involved in the coordination were two deprotonated oxygens and two nitrogen atoms. ν(V=O) (970–985 cm^{-1}) and $\mu_{eff}^{r.t.}$ (1.73–1.83 BM) suggest a monomer; however, molecular weights in nitrobenzene suggest a dimer.

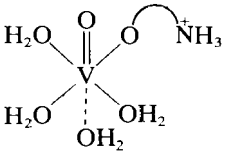
concentration for complex formation. At pH ≥ 4, however, hydrolysis of VO^{2+} takes place and oxidation to V^{V} may also be significant. Hydrolysis of VO^{2+} in the pH range 5–12 is not well understood (see Section 33.5.5.1.ii).



For the glycine system, models I and II in Table 43 have been suggested.[581] But (*cf.* Section 33.5.5.1.ii), for pH ≥ 5 other VO^{2+} hydrolysis products should be included.[585,588] For the L-alanine system (certainly similar to glycine), results were explained according to model III included in Table 43. $[VO(HAlaO)^{2+}]$ (**119**) must be included to explain the CD spectra. The inclusion of (**124**) gives a better fit of the data.

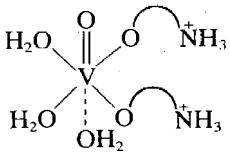
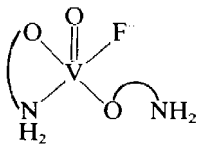
(**120**)



(**121**)



(**122**)

(**123**)

(**124**)

(**125**)

The kinetics of processes involving glycinato–VO^{2+} are summarized in Table 44. Only one species is formed from the addition of F^- ion to a $[VO(GlyO)_2]$ solution (equation 55; calculated $K = 17\ mol^{-1}$), with structure (**125**).[800] From ^{19}F NMR, relaxation is controlled by the exchange reaction (56), which is first order in F^-.

Cysteine reduces vanadium(V);[803] the kinetics have been studied.[804] VO^{2+}–cysteine compounds form in the reduction of vanadium(V) with an excess of cysteine[805] and a Chinese publication reports $K[VO(HCysO)(H_2O)]SO_4$ and *cis*- and *trans*-$K_2[VO(CysO)_2]$ (H_2CysO = cysteine), and ESR as a function of pH.[806] A purple complex from a 5:1 mixture of cysteine

$$VOF(GlyO)GlyO^- + {}^*F \rightleftharpoons VO{}^*F(GlyO)GlyO^- + F^- \quad (56)$$

methyl ester and $VOSO_4$ in borate buffer stirred in air for 5–6 hours showed a typical isotropic eight-line ESR spectrum and a second component in the ESR, IR and Raman.[807] The two species were considered to be the *trans* and *cis* isomers (**126**) and (**127**) but further work is needed. The reduction of A_{iso} for histidine and sulfhydryl side chain residues is large enough to be of diagnostic utility for VO^{2+} protein labelling studies.[798]

(**126**)

(**127**)

Van Willigen and co-workers reported an ENDOR study of frozen solutions containing VO^{2+} and histidine (**20**), carnosine (**21**) and imidazole (**19**) (*cf.* Section 33.5.3.2).[383] The complex formed between VO^{2+} and an excess of histidine in aqueous solutions of pH ~7 showed no axial H_2O lines. Coordination involved the N-3 nitrogen atom of the im ring of histidine, giving a structure in which the cation is shielded from water. According to the ENDOR spectra,[383] the geometry of the VO^{2+}–im moiety in the $[VO(im)_4]^{2+}$ and VO^{2+} carnosine complexes is similar but a distinct structure appears to exist for the VO^{2+} histidine complex.

33.5.9.3 Complexones

pH titrations show that in solutions containing VO^{2+} and ttha (triethylenetetramine-hexaacetic acid) (2:1), only one major complex is formed in the pH range *ca.* 4–10.[809,810] The ESR spectrum was attributed to a binuclear chelate.[809] $Na_2[(VO)_2ttha]\cdot 10H_2O$ is composed of discrete $[(VO)_2ttha]^{2-}$ units and the V atom is octahedrally coordinated to the oxo ligand and three O and two N atoms of the ttha ligand (Figure 33a). The V atom is displaced 0.39 Å towards the oxo ligand. The molecular structure of the solid gives no explanation for the ESR spectrum observed. Reduction of O_2 with dinuclear $[V_2^{III}O(ttha)]^{2-}$ may produce $[V^{III},V^{IV}]$ and/or $[V^{IV},V^{IV}]$ complexes.[942]

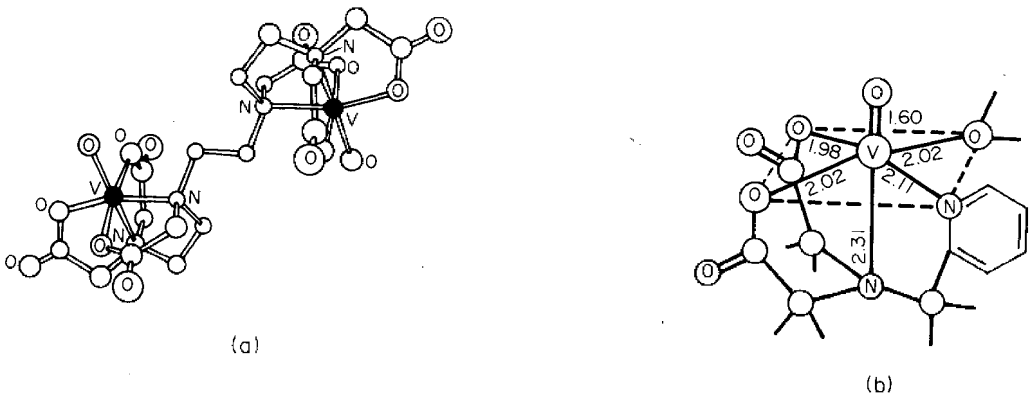

Figure 33 Schematic representation of the molecular structure of (a) $Na_2[(VO)_2ttha]\cdot 10H_2O$[810] and (b) $[VO(pmida)(H_2O)]\cdot 2H_2O$[811]

In $[VO(pmida)(H_2O)]\cdot 2H_2O$ (pmida = *N*-(2-pyridylmethyl)iminodiacetic acid), vanadium deviates by 0.39 Å from the equatorial plane of two *cis* carboxylate oxygens, a water molecule and the pyridine nitrogen (see Figure 33b).[811]

The structures of $[VO(S\text{-peida})(H_2O)]\cdot 2H_2O$ (**128**), $Na[V_2O_3(S\text{-peida})_2]\cdot NaClO_4\cdot H_2O$ (**129**) and $Li[VO_2(S\text{-peida})]\cdot 2MeOH$ (**130**) (*S*-peida = (*S*)-((1-(2-pyridyl)ethyl)imino)diacetic acid) were also determined (Figure 34).[812] In the mixed-valence binuclear ion (**129**), two octahedra share the equatorial oxo ligand. In the $O{=}V_A{-}O_b{-}V_B{=}O$ segment, the $V{-}O_b{-}V$ angle is ~180° and the $V_A{-}O_b$ bond (1.875 Å) differs from the $V_B{-}O_b$ bond (1.763 Å). Furthermore, the volumes of the octahedra around V_A and V_B are close to those of the V^{IV} and V^V complexes, (**128**) and (**129**) respectively. This and other features indicate that V_A and V_B are quadri- and quinque-valent.

Other compounds containing the $V_2O_3^{3+}$ core, $H[V_2O_3(pmida)_2]\cdot 4H_2O$ and $K_7[V_9O_{16}(bdta)_4]\cdot 27H_2O$ (btda = butanediaminetetraacetate), were prepared and their molecular structures were determined.[813] Both also contain $V_2O_3^{3+}$ with both terminal O atoms *cis* to the bridge but *trans* to each other. Contrary to (**129**), no systematic variation in bond lengths around the two V atoms was detected. The $[V_9O_{16}(btda)_4]^{7-}$ anion exhibits a quite unusual structure. It is organized around a central tetrahedral V^VO_4 group from which four mixed-valence binuclear groups spread, each containing the $V_2O_3^+$ core. The mixed-valence groups are linked together by the four bdta ligands.[813] Contrary to $[V_2O_3(pmida)_2]^-$, the two V atoms are in different environments. As in (**129**), V^{IV} is more displaced than V^V with respect to the equatorial plane.

In the spectra of $[V_2O_3(pmida)_2]^-$ and $[V_2O_3(nta)_2]^{3-}$, a new band around 1000 nm was assigned to the intervalence transition.[814] The spectrum of $[V_9O_{16}(btda)_4]^{7-}$ is the same in solution and in the solid.[813] The band at 900 and a shoulder at 1020 nm corresponded to two components of the intervalence band.

Mixed-valence species containing V^{II} and V^{IV} bridged by an oxygen atom were intermediate in electron transfer between $[V(Hedta)]^-$ and $[VO(Hedta)]^-$, and $[V(edta)]^{2-}$ and $[VO(edta)]^{2-}$.[815] Similarly bridged species were assumed in the reaction of $[V(H_2O)_6]^{2+}$ with $[VO(H_2O)_5]^{2+}$. Vanadium(III) dimeric complexes are the reaction products (see Section 33.4.9.3).

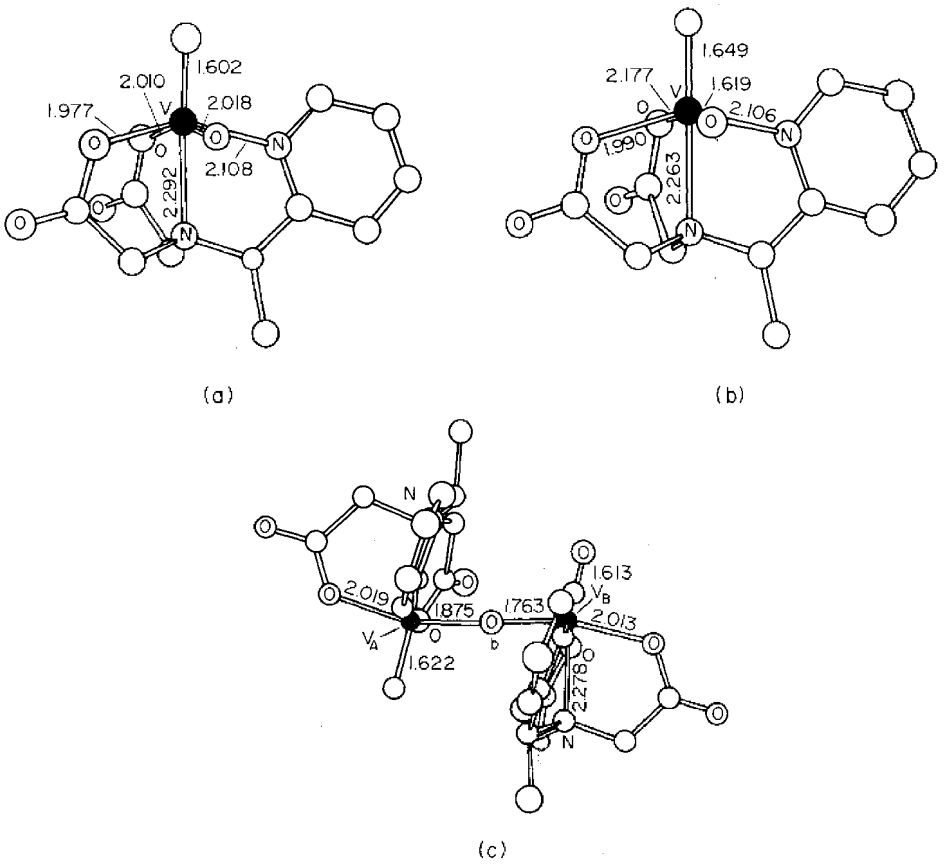
Compounds $[VOL_2]$ (L = ida and idpa; see Table 45) involved addition of $VOSO_4$ to the barium salt of the complexones. IR spectra suggest both coordinated and noncoordinated carboxyl groups and structure (**131**; R = H) was proposed.[816]

Complexes of polyaminocarboxylic acids (**132**)–(**134**) were investigated by Felcman and Fraústo da Silva.[377] Their results and other data are in Table 45. Log K_{VOL} values are almost equal to the values for Ni^{II} and a linear correlation (log K_{VOL} *vs.* log K_{NiL}) exists.

Fraústo da Silva and co-workers proposed structure (**131**; R = OH) for the species predominant in the pH range 4–7, which corresponds to the structure normally assumed for 'amavadin' which occurs in the toadstool *Amanita muscaria*.[377,378]

Edta, egta and dtpa (diethylenetriaminepentaacetic acid) all form 1:1 chelates and give rise to a broadened ESR signal.[809]

When equimolar solutions of $[V^{IV}O(nta)(H_2O)]^-$ and $[V^VO_2(nta)]^{2-}$ are mixed, a deep blue appears and the product was obtained crystalline as the Na^+ and NH_4^+ salts.



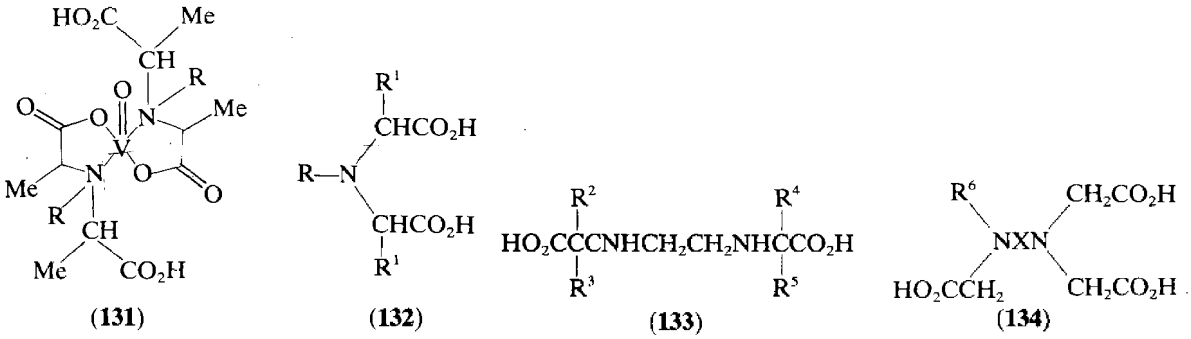


Figure 34 The molecular structure of (a) [VO(*S*-peida)(H_2O)] (**128**), (b) [VO_2(*S*-peida)]$^-$ (**129**) and (c) [V_2O_3(*S*-peida)$_2$]$^-$ (**130**). Internuclear distances are in Å[812]

$(NH_4)_3[V_2O_3(nta)_2]\cdot 3H_2O$ is a binuclear species containing the $V_2O_3^{3+}$ core.[817,818] Near IR and electronic spectra of the solution and of the crystals indicated the establishment of an equilibrium (equation 57) with $K = 20\ mol^{-1}$. The binuclear complex gives very large extinctions in the visible and near IR region, and ESR spectroscopy also indicates an almost equal distribution of unpaired electrons around the two vanadium atoms. The two vanadium ions are equivalent, both in the crystalline state and in solution.

$$V^{IV}O(nta)(H_2O)^- + V^{V}O_2(nta)^{2-} \rightleftharpoons (nta)V(=O)-O-V(=O)(nta) + H_2O \qquad (57)$$

Saito and coworkers prepared the *cis*-aquaoxovanadium(IV) complex

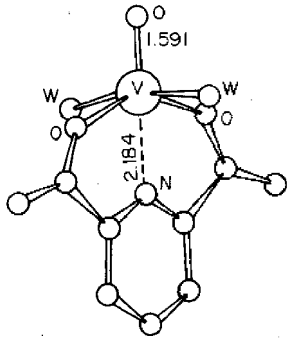
$Na_2[VO(pida)(H_2O)]\cdot 3.5H_2O$ ($pida^{4-}$ = ((phosphonomethyl)imino)diacetate), which undergoes protonation at the phosphonate oxygen with $pK_{a_1} = 3.8$ and deprotonation from the coordinated water with $pK_{a_2} = 8.4$.[819] All kinetic parameters were considered consistent with a hydrogen-bonded aqua ligand in $[VO(pida)(H_2O)]^{2-}$ having an intermediate character between aqua and hydroxo ligands.

33.5.9.4 Other polydentate ligands

(*i*) *Polydentate ligands involving nitrogen and oxygen coordination*

Several complexes with pyridinecarboxylic acid derivatives were isolated. Two forms of VO^{2+} lutidinato tetrahydrate were obtained. One is green and orthorhombic (see Figure 35), the other is blue and triclinic. Both have a square pyramid of O donors around V^{IV} and nitrogen coordination in the sixth position.[820]



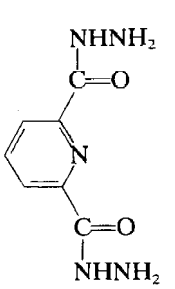


Figure 35 Perspective view of the green (orthorhombic) form of $[VO(lut)(H_2O)]\cdot 2H_2O$ (H_2lut = lutidinic acid). The V atom is six-coordinate in a distorted octahedral site which closely approximates C_{2v} symmetry; the remaining two water molecules (w) link the chelate molecules by hydrogen bonding. Some other internuclear distances are V—O(carboxylate) = 2.017 and V—O(water) = 2.027 Å

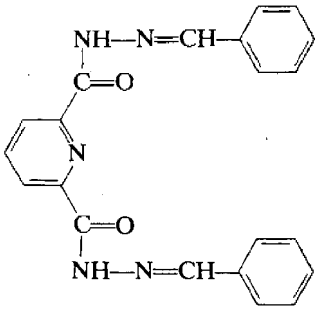
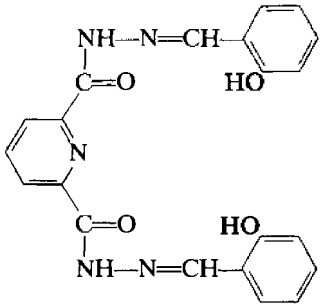


With the hydrazides (**135**)–(**137**) from lutidinic acid, monomeric compounds were obtained[432] by reaction (58). For all complexes, the IR spectra suggest that the ligands (**135**)–(**137**) are pentadentate.

$$\begin{matrix} VOSO_4 \\ \text{or} \\ VOCl_2 \end{matrix} + \text{hydrazides (L)} \xrightarrow[\text{or}\ \text{water–acetone}]{\text{water–ethanol}} \begin{matrix} VOLX_2 \\ \text{or} \\ VOL \end{matrix} \qquad (58)$$



(**135**)–(**137**)

(**135**)

(**136**)

(**137**)

The stability constants[821] for the 8-hydroxyquinoline (oxine) complexes have been questioned owing to the ease with which the V^{IV} complexes undergo oxidation, even by atmospheric O_2.[355,687] However, adducts $[VO(oxine)_2L]$ (L = py or other nitrogen bases) were more stable towards oxidation. The V^{IV} oxine complex gradually turns magenta black when extracted into a nonpolar solvent, indicating formation of the V^{V} oxine complex in air, but in

the presence of a nitrogen base (*e.g.* py), the extract remains yellow. The adducts can be schematically represented as in equation (59).[687]

$$VO(oxine)_2 + base \rightleftharpoons VO(oxine)_2(base) \quad (59)$$

$$\begin{matrix} VO(OMe)(oxine)_2 \\ \text{or} \\ VO(OH)(oxine)_2 \end{matrix} + VO(oxine)_2 + OH^- \longrightarrow [(V^{V}O)(oxine)_2O(V^{IV}O)(oxine)_2]^- + \begin{matrix} MeOH \\ \text{or} \\ H_2O \end{matrix} \quad (60)$$

An equimolar mixture of $[VO(OMe)(oxine)_2]$, $[VO(oxine)_2]$ and base in methanol results in the binuclear complex (equation 60). Likewise, an equimolar mixture of $[VO(OH)(oxine)_2]$, $[VO(oxine)_2]$ and base in methanol yields the same product.[822] This V^{IV}–V^{V} dimer was isolated as the tetra-*n*-butylammonium salt.

Early solid complexes include $[VO(oxine)_2]$, $[VO(oxine)_2py]$ and $[VO(5,7\text{-}X_2oxine)_2]$ (X = Br, I).[357] [VOX(oxine)] (X = Cl, Br, OH) were also prepared with magnetic moments dependent on temperature.[823] On the contrary, for brown $[VO(oxine)_2]$, prepared from $VOSO_4$ in aqueous solution,[387] $\mu_{eff}^{r.t.}$ is near the spin-only value and $\nu(V{=}O) = 979\ cm^{-1}$.[595] These values indicate a monomeric structure and this was confirmed for its 2-methyl derivative by X-ray diffraction (Figure 36).[824]

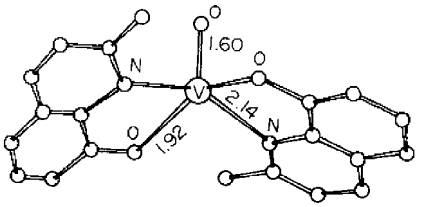


Figure 36 A perspective view of the molecular structure of [VO(2-methyl-8-quinolinolato)$_2$] with some internuclear distances (in Å)[824]

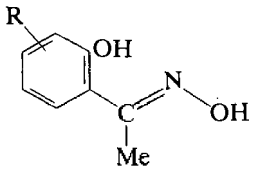
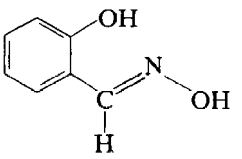
Attempts to prepare adducts directly from $[VO(oxine)_2]$ (**138**) were unsuccessful and a trigonal bipyramidal structure was suggested for this compound as for $[VO(2\text{-Me-oxine})_2]$ (**139**).[825] The $[VO(oxine)_2X]$ compounds were prepared by addition of $VOSO_4$ to an aqueous solution containing 8-hydroxyquinoline and the base X. For the adducts $[VO(oxine)_2X]$, a correlation was found between $\nu(V{=}O)$ and the pK_a of the X ligand, except with bases with substituents where steric hindrance may be operating, and no evidence was obtained for the existence of both *cis* and *trans* isomers, unlike the case of $[VO(acac)_2]$ adducts (Section 33.5.5.4.ii). For the tris complexes $[VO(oxine)_3]^-$, an octahedral structure in which one oxine ligand is unidentate and bonded to V was proposed.[825]

$[VO(oxine)_2]$ (**138**) and $[VO(oxine)_2py]\cdot C_6H_6$ (**140**), prepared by a ligand displacement reaction (equation 61), had $\nu(V{=}O) = 963$ and $945\ cm^{-1}$ and $\mu_{eff} = 1.75$ and 1.64 BM, respectively. When 8-quinolinol is replaced by 2-methyl-8-quinolinol in reaction (61), $[VO(2\text{-Me-oxine})_2]$ is obtained, with $\nu(V{=}O) = 970\ cm^{-1}$. Complexes (**138**) and (**140**) react readily with O_2 and a diamagnetic dinuclear μ-oxo V^{V} species $[(oxine)_2\text{—}OV\text{—}O\text{—}VO(oxine)_2]$ is produced.[826] Nitrobenzene and 2-nitrosobiphenyl also react in a similar manner in THF giving the same complex. With *p*-benzoquinone a dinuclear diamagnetic V^{V} complex $[(oxine)_2OVOC_6H_4OVO(oxine)_2]$ is obtained.



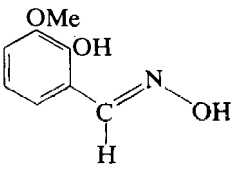
$$VO(acac)_2 + 2Hoxine \underset{C_6H_6}{\rightleftharpoons} VO(oxine)_2 + 2Hacac \quad (61)$$

The preparation of $[VCl_2(oxine)_2]$ by the reaction of $[VO(oxine)_2]$ with $SOCl_2$ in benzene or in 1,4-dioxane with PCl_5 (Section 33.5.5.4.ii) was found to be much easier than from $[VCl_4]$[555] as it proceeds at room temperature in a few minutes.



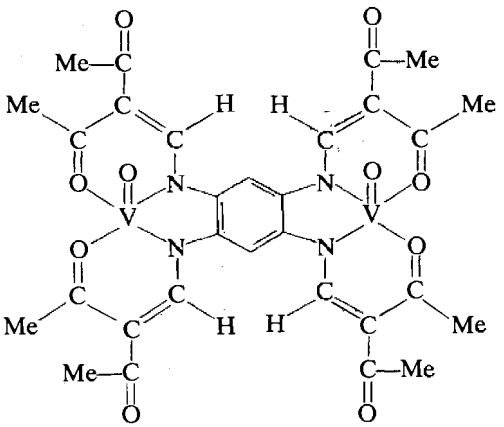
Early publications with N,O donor ligands include oxovanadium(IV) and (V) complexes with a large number of substituted hydroxytriazenes.[828,829] The vanadyl complexes are of the $[VOL_2]$ type with $\mu_{eff}^{r.t.} = 1.6\text{–}2.1$ BM and cryoscopic measurements in freezing benzene suggest a monomeric nature. In basic medium containing pyridine, 2-picoline or aniline, the complexes are oxidized and produce diamagnetic V^{V} complexes formulated as $[VO_2LX]$ compounds.

Several complexes with hydroxyoximes (especially aromatic) have been prepared. Typically, an ethanolic solution of ligand is added to a solution of a vanadyl salt, the pH and temperature

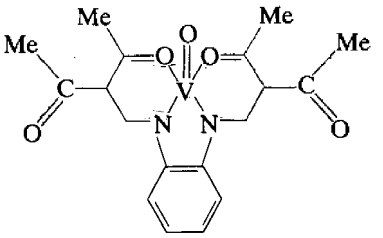


are adjusted and the solid precipitates. Most complexes are of $[VOL_2]$ type and include ligands L with HL = 2-hydroxybenzaldoxime[830,831] and derivatives,[830] several 2-hydroxyalkylphenone oximes and derivatives (**141**),[832–838] salicylaldoxime (**142**),[831,839] 2-hydroxynaphthaldoxime[830,840] and *o*-vanillin oxime (**143**).[839]

(**141**)



(**142**)



(**143**)

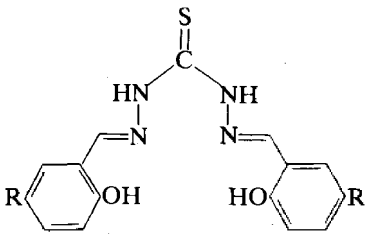
Other complexes with N,O donor ligands include the dimeric compound (**144**) and monomeric (**145**).[841] The ESR spectra of the vanadyl dimer (**144**) in frozen DMSO and DMF exhibited only zero-field splitting and the V—V distance estimated from this was 8.66 Å.

(**144**)

(**145**)

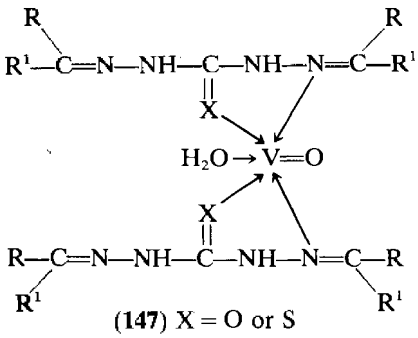
$[VOL_2]$ (HL = salicylaldehyde hydrazone (salhy) and salicylaldehyde phenylhydrazone (salpheny)) are monomeric ($\mu_{eff}^{r.t.}$ = 1.76 and 1.74 BM).[842,843] Reaction of $SOCl_2$ in DMF gave the corresponding deoxygenated $[VCl_2L_2]$.[843] $\mu_{eff}^{r.t.}$ values are 1.78 and 1.79 BM for L = salhy and salpheny, respectively, suggesting a d^1 configuration but $[VCl_2(salhy)_2]$ in DMF at 77 K gives no ESR signal.[843] As in the case of the porphyrinato vanadium(IV) dihalide, the absence of an ESR spectrum was attributed to a degenerate ground state.[843] The reaction of $[VOCl_2(salhy)_2]$ with several nitrogen bases such as aniline, 1,4-diaminobenzene, aminopyridine and adenine proceeds according to equation (62).[843]

$$VCl_2L_2 + 2Hamine \longrightarrow VL_2(amine)_2 + 2HCl \qquad (62)$$



(L = salicylaldehyde hydrazone and salicylaldehyde phenyl hydrazone)

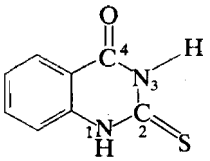
Complexes with thiocarbohydrazones (**146**; R = H, Me, OMe, Cl) have been prepared in an ethanolic medium.[844] They have 1:1 stoichiometry, and $\mu_{eff}^{r.t.}$ are 1.73–1.94 BM; ν(V=O) was at 980 cm^{-1}.



Oxovanadium(IV) complexes have also been prepared with the carbohydrazones and thiocarbohydrazones formed in the condensation of carbohydrazide or thiocarbohydrazide with benzaldehyde, *o*-nitrobenzaldehyde, anisaldehyde, cinnamaldehyde, acetophenone and 2-acetylpyridine.[845] $\mu_{eff}^{r.t.}$ values are 1.68–1.72 BM and ν(V=O) is at 960–980 cm^{-1}. The compounds, $[VO(L)_2(H_2O)]$ (**147**), were suggested to be of structure (**12**) (p. 487).[845]

(ii) Polydentate ligands involving oxygen, sulfur and/or nitrogen coordination

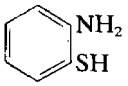
A complex with 8-mercaptoquinoline $[VO(thiooxine)_2]$ is magnetically dilute.[823,358] Complexes with Cl and Br derivatives of 8-mercaptoquinoline have also been reported.[357] In



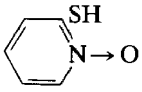
(146)

(147) X = O or S

$[VO(QT)_2]$ (HQT = **148**), with $\mu_{eff}^{r.t.} = 1.85$ BM, coordination involves sulfur (as S^{-2}) and nitrogen.[846]



Hodge *et al.* synthesized complexes containing the N,S and O,S bidentate ligands (**149**)–(**152**).[847] These were of $[VOL_2]$ type with a square pyramidal geometry (except $[VO(pto)_2]$) (pto = **152**); all attempts to prepare *N,N*-dialkyl-2-aminoethanethiol VO^{2+} complexes failed. $[VO(pto)_2py]$ appears more stable than $[VO(abt)_2py]$, and may exist as a mixture of *cis* and *trans* isomers (in relation to the oxo group). The reaction of $[VO(abt)_2py]$ with a variety of 4-substituted pyridine *N*-oxides, where the steric factor is expected to be approximately constant, resulted in a systematic change in the visible spectra, and the changes correlated with the Hammett σ values of the bases.[847]



(148)

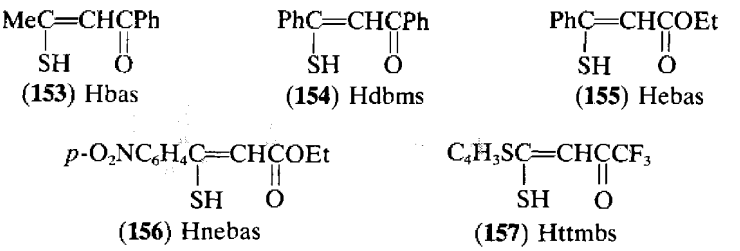
(**152**) Hpto

With 3-hydroxyquinazoline-4(3*H*)-thiones (HQ) (Scheme 20; Z = S, Y = NOH), the ESR spectra were explained assuming equilibria (63).[848] Compounds isolated, $[VOQ_2]$, involved sulfur and oxygen atoms in a square pyramidal geometry.



$$VO^{2+} \overset{HQ}{\rightleftharpoons} VOQ^{+} \overset{HQ}{\rightleftharpoons} VOQ_2 + 2H^{+} \qquad (63)$$

Scheme 20

Bozis and McCormick prepared several green complexes with monothio-β-diketones (**153**)–(**155**), formulated as monomeric square pyramidal $[VOL_2]$.[849] With (**156**) and (**157**), the complexes have a golden yellow colour, diffuse reflectance spectra differ from those with (**153**)–(**155**) and ν(V=O) was at 868 and 876 cm^{-1} for $[VO(ttmbs)_2]$ and $[VO(nebas)_2]$, respectively.[850] The solid complexes probably have a structure that involves —V—O—V— bridging, as found for [VO(salnpn)] (Figure 30).

Early reports on tetrasulfur tetranitride (S_4N_4 = L) suggest the formation of $[VCl_4L]$

adducts.[851] More recently, it was found that S_4N_4 reacts with excess of VCl_4 in CH_2Cl_2 forming a mixture of $VCl_2(S_2N_3)$ and $S_2N_2{\cdot}VCl_4$. Sublimation at 110 °C gives black needles $[VCl_2(S_2N_3)]$, chlorine-bridged dimers linked by additional weak V—N interactions to form polymeric chains (Figure 37).[852] Thus, only nitrogen coordination is involved. The six-membered VNSNSN ring is planar.

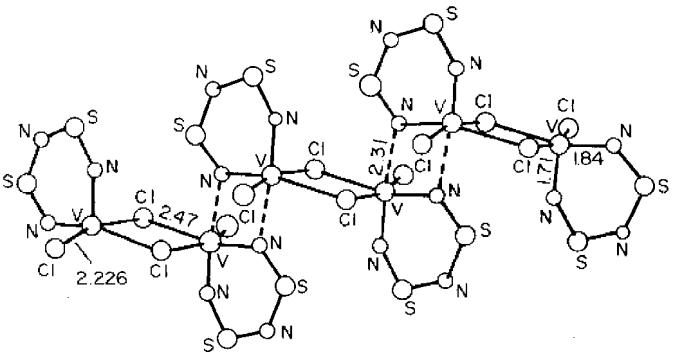


Figure 37 Three-dimer section of the polymeric chain of the compound $[VCl_2(S_2N_3)]$.[852] The longer V—N 'interactions' which link the dimers are indicated

33.5.10 Mixed-ligand Complexes

Strictly speaking, all oxovanadium(IV) complexes should be considered of mixed-ligand type. Of course, such criteria have not been used and this section concerns complexes with at least two different chelating ligands.

The overall reaction for the formation of a 1:1:1 mixed-ligand chelate in aqueous solution may be written as in equation (64) where A^{n-} is considered the 'primary ligand' and L the 'secondary ligand'. Ternary complexes will form only if complex $[VOAL]^{(2-m-n)}$ is more stable than the binary complexes of VO^{2+} with A^{n-} or L^{m-}. Table 46 summarizes most of the data available. For a given primary ligand, the relative stabilities of [VOAL] follow the order of the relative basicities of the secondary ligand, although steric factors might also be operating in some cases; steric interference increases with the increasing size of the ligand and invariably decreases the stability of the chelate.[633,676,853–855]

$$VO^{2+} + A^{n-} + L^{m-} \rightleftharpoons VOAL^{(2-m-n)} \tag{64}$$

$$\beta_{VOAL} = \frac{[VOAL]}{[VO^{2+}][A^{n-}][L^{m-}]} \tag{65}$$

Early mixed-ligand complexes $[VO(A)(L)]$[856–858] with A potentially tridentate (or bidentate) (lutidinic, chelidamic, collidinic, iminodiacetic and oxalic acids) and L a bidentate ligand (phen, bipy, acac, glycine, oxine, salicylaldoxime and others) appear to be monomeric and were prepared from the parents $[VO(A)(X)(H_2O)]$, where X is a monodentate ligand (H_2O, py, 2-picoline, aniline, *etc.*), by displacement. One such, $[VO(ida)(bipy)]{\cdot}2H_2O$, consists of monomeric units with two loosely bound water molecules of crystallization.[859] The geometry around V is octahedral ($d(V{=}O) = 1.596$ Å). Several [VO(A)(L)], A being the anions of oxalic, malonic and maleic acids and L = phen, were prepared from $[VO(A)(H_2O)_2]$.[860] The ease of preparation follows the order: oxalate > malonate > maleate.

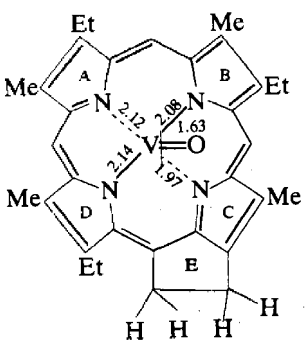
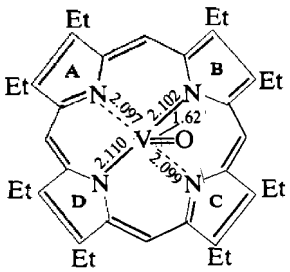
Compounds [VO(acac)(2-aminobenzoato)]·$n$$H_2O$ (n = 0 or 1) were prepared with rather low $\mu_{eff}^{r.t.}$ (1.49 and 1.34 BM for n = 1 and 0).[861] In $CHCl_3$, the ESR spectrum shows splitting of $A_\perp$ into A_x and A_y components ascribed to asymmetry of the ligands.[861] In [VO(oxine)(2-aminobenzoato)]·$n$$H_2O$ (n = 0 or 1), a $\mu_{eff}^{r.t.}$ value of 1.33 BM was reported for n = 1.[862]



33.5.11 Multidentate Macrocyclic Nitrogen Ligands

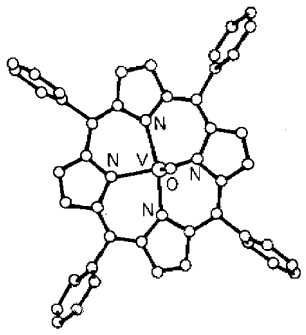
33.5.11.1 Porphyrins



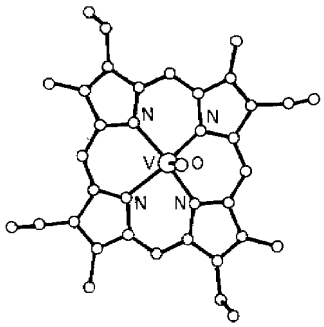
Much interest in environmental vanadium stems from its presence in fossil fuels, largely as porphyrins and related compounds which pose problems in refining and burning of high-vanadium-content fuels. The metal porphyrins in crude oils and oil shales have been extensively studied since their discovery by Treibs, who postulated that the principal compound in geological samples is vanadyl deoxophylloerythroetioporphyrin (DPEP) and developed a detailed scheme to show that this compound was formed from chlorophyll.[863,864] Based on Treibs' observations, metal porphyrins in crude oils show their biological origin. The literature is extensive and will be very briefly covered. Although the geoporphyrin system is more complex than Treibs' original scheme,[865] vanadyl porphyrins found in crude oils and bitumens are believed to be the end product of the diagenesis of chlorophyll. The vanadyl analogue of chlorophyll, [VO(DPEP)] (**158**), provides some insight into some of chlorophyll's properties, including its resistance to oxidation.[866] XANES/EXAFS experiments on pulverized coal gave arguments discounting the presence of vanadyl porphyrins.[867,868] More recently, the identification, including X-ray structure, of a vanadyl porphyrin isolated from a geological sample unlikely to have been chemically altered by the extraction procedure was reported.[869] Further, using asphaltenic fractions, from EXAFS, XANS, ESR and UV-vis spectroscopy vanadium is predominantly porphyrinic.[870] Several chemical and structural studies of vanadium porphyrins emphasize low valent metalloporphyrins and related systems with sulfur and selenium.[128] Two general methods can be used to prepare vanadyl porphyrins: (1) using $VO(acac)_2$ in phenol at reflux temperatures, or (2) using VCl_4 or VCl_3 in various solvents. In boiling quinoline, 100% incorporation is obtained in 2 h for *meso*-tetraphenylporphyrin (TPP) and octaethylporphyrin (OEP).[871,872]

ESR has been used to characterize vanadium compounds in crude oil.[354,873] In ESR spectra of [VO(TTP)], extrahyperfine structure from interactions with N atoms was detected in CS_2 and $CHCl_3$ glasses and the splitting constants $A_\parallel^N$, $A_\perp^N$ were calculated (2.9 ± 0.05 and 2.8 ± 0.05 G).[517]

In [VO(DPEP)] (**158**), the four nitrogens are coplanar and the vanadium lies 0.48 Å out of plane.[874] In [VO(OEP)] (**159**) (OEP = 2,3,7,8,12,13,17,18-octaethylporphyrinato), the four V—N distances average 2.10 Å, the same as for [VO(DPEP)] (excepting V—N(c)).[875] The vanadium is 0.543 Å from the mean plane of the four N atoms, in the range 0.48–0.72 Å predicted by EHMO calculations.[876] For [VO(TTP)] (**160**), [VO(ETP)] (**161**) and [$VO(ETP)_2$](H_2Q) (**162**) (ETP = etioporphyrin and H_2Q = 1,4-dihydroxybenzene) (Figure 38), the vanadium is five-coordinate.[877] One interesting feature in (**162**) is the hydrogen bond between the quinol (H_2Q) and the VO group. The O···O distance is 2.82 Å and the V=O···O and C—O···O angles are 159.3 and 118.9°.



(**158**)



(**159**)

EXAFS with [VO(OEP)] and [VO(DPEP)] gave V=O and V—N bond lengths almost equal

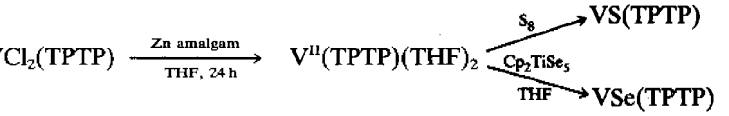
(c)

Figure 38 Schematic representation of the molecular structures of (a) [VO(TPP)], (b) [VO(ETP)] and (c) $[VO(ETP)]_2(H_2Q)$ (side view).[877] The V=O bond distances are 1.625, 1.599 and 1.614 Å, respectively, and the vanadium 'N_4 plane' distances are 0.53, 0.49 and 0.51 Å, respectively. The V—N bond lengths are all in the range 2.04–2.09 Å

to the X-ray results,[878] showing that this is a useful tool for investigating the coordination sphere of metalloporphyrins; it is often difficult to obtain good quality crystals.

In solution, vanadyl porphyrins [VOP] can form adducts [VOPX] in the presence of a large excess of X (X = py or piperidine) but the equilibrium constants are rather small.[879–881]



For vanadyl uroporphyrin[I], spectra in alkaline medium are different from those in organic solvents or crystalline.[882] If a six-coordinate dihydroxide species $[V(OH)_2UroP]$ really forms, it would be the first example of a deoxygenated V^{IV} complex bound to two OH^- groups. However, the arguments presented leave the possibility of $[VO(OH)UroP]^-$ in alkaline solution.[882]

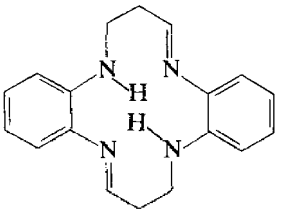
The action of SOX_2 or COX_2 (X = Cl or Br) on several VO^{2+} porphyrins gives the dihalogenovanadium(IV) porphyrins.[883] These are extremely reactive and act as precursors in the synthesis of low-valent porphyrins. $[VBr_2(OEP)]$ was studied by EXAFS and the two Br atoms were coordinated *trans*. In reactions of porphyrins with halides MX_n ($TiCl_4$, $SnCl_4$, $AlCl_3$, $AlBr_3$ and also $SbCl_5$ and $SOCl_2$), deoxygenation of the vanadyl occurs, octahedral $[VX_2P]$ being formed.[884] In the intermediate stage, the authors suggest the formation of a bimetallic complex of vanadium porphyrin with halide. In air, the products are dihalogen complexes of V^{IV} with mono- and di-cation porphyrin ligands. All are entirely converted to the original [VOP] when small amounts of water are added.

Reduction by zinc amalgam of a dry and oxygen-free THF solution containing $[VCl_2(TPTP)]$ (TPTP = *meso*-tetra-*p*-tolylporphyrinato) and addition of elemental sulfur yields [VS(TPTP)].[659] Similar thiovanadyl complexes were prepared with OEP, TPP and TMTP (TMTP = *meso*-tetra-*m*-tolylporphyrinato). Analytical results and mass spectra agree with the formulation [VS(por)], and ν(V=S) was at 550–565 cm^{-1} (see Section 33.5.6.1). FT-EXAFS of [VO(OEP)] and [VS(OEP)] were recorded and the difference FT spectrum yielded

approximate values for the interatomic distances: V=O ≈ 1.6 and V=S ≈ 2.06 ± 0.02 Å, which agrees with 2.061 Å for [VS(acen)].[659]

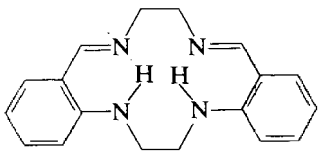
A convenient procedure for the isolation of selenovanadium(IV) porphyrins has been reported and involves the use of Cp_2TiSe_5 (instead of elemental selenium) (Scheme 21).[885,886] The IR spectra exhibit a medium-to-strong band at 434–447 cm^{-1} assigned to ν(V=Se). EXAFS with VSe(OEP) suggests that the V—Se bond is ~2.19 Å and that the V atom is ~0.47 Å above the plane of the four nitrogen ligands.[128]

Scheme 21



33.5.11.2 Phthalocyanines

The VO^{2+} phthalocyanine [VO(pc)] has been the subject of patents as it is useful in photoelectrophoretic and xerographic imaging.[887] It can exist in at least three solid phases[888] and the structure of so-called phase II was determined.[889] It is composed of sheets of parallel and overlapping [VO(pc)] molecules and no discrete dimer pair exists. The vanadium is five-coordinate and square pyramidal, and is 0.575 Å above the 'plane' of the four nitrogens. The V—N distances do not differ significantly with a mean of 2.026 Å; the V=O distance is 1.580 Å.

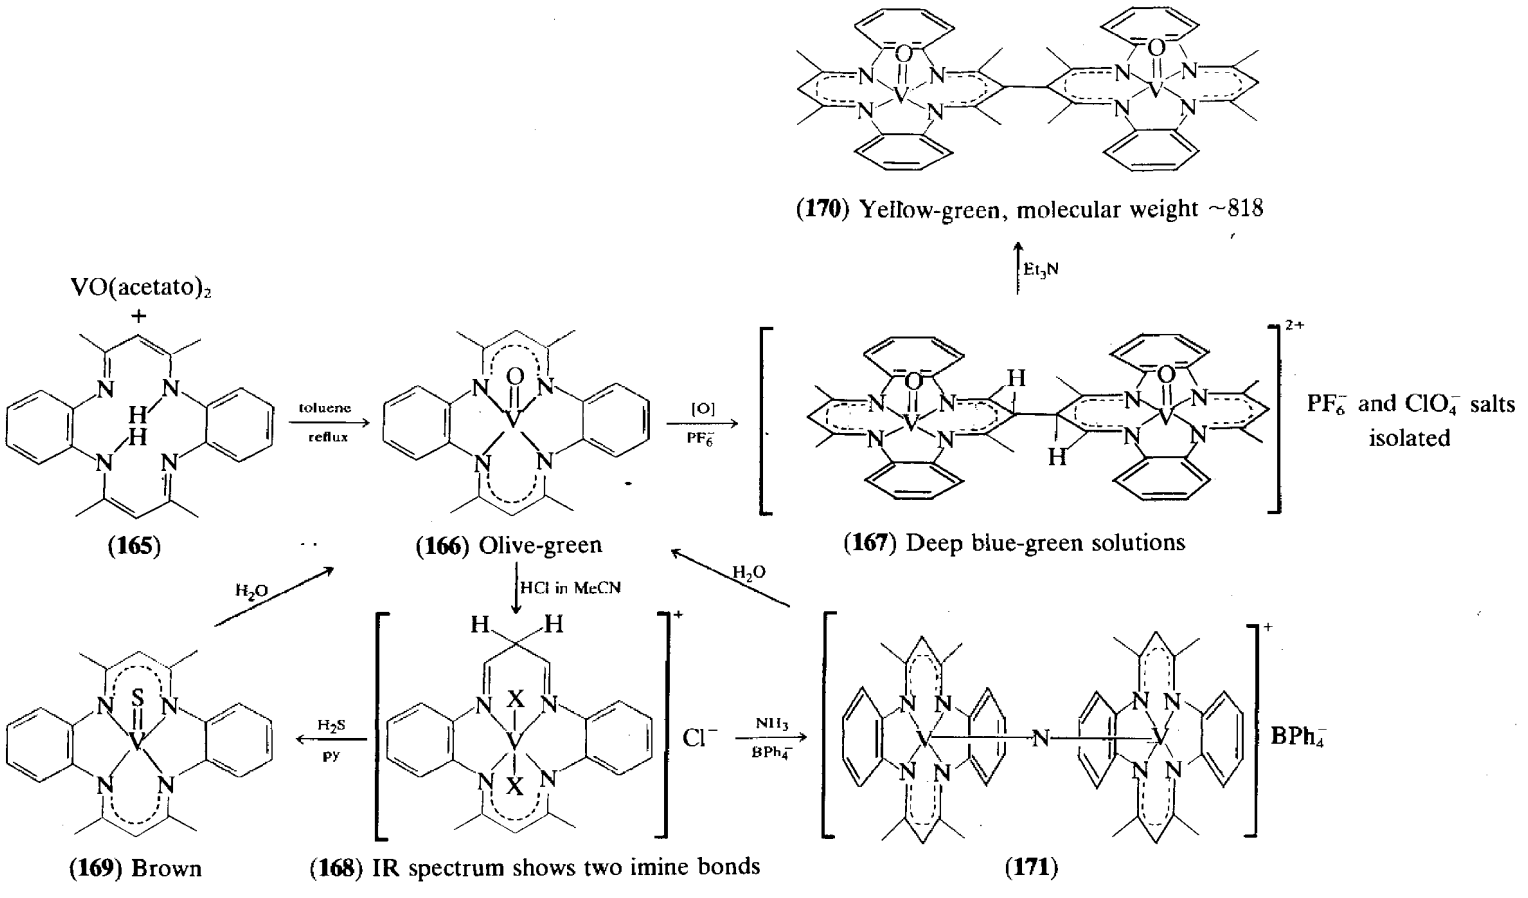


ESR measurements of aqueous solutions of the VO^{2+} complex of 4,4′4″,4‴-tetrasulfophthalocyanine (tspc) show that it is polymeric.[890] In dilute solutions (10^{-5} M), the dimeric form predominates and higher polymers increase with concentration.[891] The formation of adducts prevents polymerization and in solutions containing DMF most of the chelate is dimeric with a V—V distance of ~4.5 Å.

33.5.11.3 Tetraaza[14]annulenes and other macrocycles

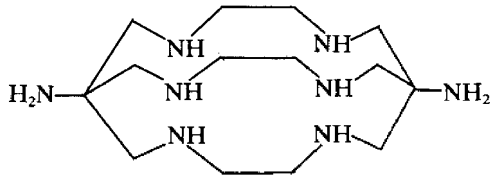
Complexes with the tetradentate tetraaza[14]annulenes (**163**) and (**164**) (= H_2L), studied by spectroscopy,[892] were formulated as [VOL], probably similar to the complexes with porphyrins. ν(V=O) was at 967 and 940 cm^{-1} for (**163**) and (**164**). In the ESCA spectra, the nitrogen donors are equivalent.[892]

(**163**)



(**164**)

The tetramethyltetraaza[14]annulene (**165**) reacts with vanadyl acetate to yield (**166**) similar to complexes of (**163**) and (**164**).[660] It was the starting material for several reactions shown in Scheme 22, and exhibits a reversible one-electron oxidation wave at +0.245 V (*vs.* SCE) but reacts irreversibly with mild oxidants (O_2, Ag^+, Ce^{4+} or I_2) to yield (**167**). With Et_3N, (**167**) yielded a complex with properties similar to (**166**) but which mass spectral data indicate is a dimer. Structure (**170**) was proposed.



Reaction of (**166**) with anhydrous HCl deoxygenates the VO^{2+} compound, forming (**168**).[660] Its ESR parameters are those expected for the substitution by two chloride ligands. (**168**) with H_2S and base yielded the thiovanadyl analogue of (**166**) for which ν(V=S) was at 545 cm^{-1}. Hydrolysis of (**169**) regenerates (**166**).

On allowing $V(acac)_3$ to react with di(am)sar (**172**) for 3 days under N_2, a deep red-brown developed.[893] After separation (by cation exchange chromatography) of the red-brown product, its crystalline chloride was converted into the dithionate [V^{IV}(di(amH)sar-

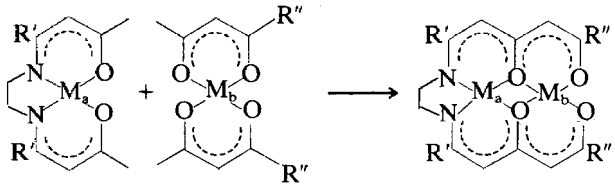
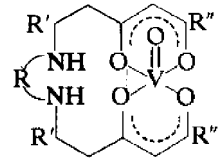
$2H)](S_2O_6)_2 \cdot 2H_2O$ whose geometry is close to trigonal prismatic with V—N in the range 2.06–2.10 Å. It has $\mu_{eff}^{r.t.} = 1.80$ BM and is stable in the pH range 1–10. Spectroscopic techniques have been used to study the V^{IV} di(am)sar complex[943] and other macrocyclic complexes.[944]



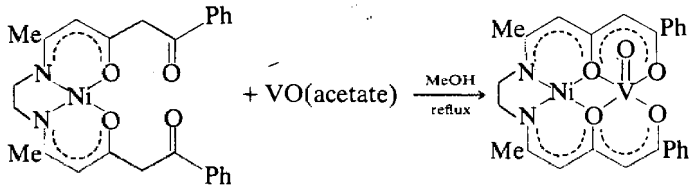
(**172**) di(am)sar

33.5.12 Polynuclear Complexes



33.5.12.1 Binucleating and compartmental ligands

Mononuclear VO^{2+} and heterodinuclear VO^{2+} complexes (with Cu^{2+}, Ni^{2+}, Mn^{2+}, Zn^{2+}, Pd^{2+} as the second metal ion) have been reviewed.[894] In this section, we shall mainly discuss more recent work. Many complexes were with Schiff bases from the reaction of β-triketones or β-ketophenols with ethylenediamine. One important aim has been to compare the magnetic, spectral and chemical properties for the metal ion M_a in $[M_a(diken)]$ and M_b in $[M_b(diketonato)_2]$, with the corresponding properties in the binuclear complexes formed (see equation 66).



$M_a(diken)$ $M_b(diketonato)_2$ (**173**) (66)

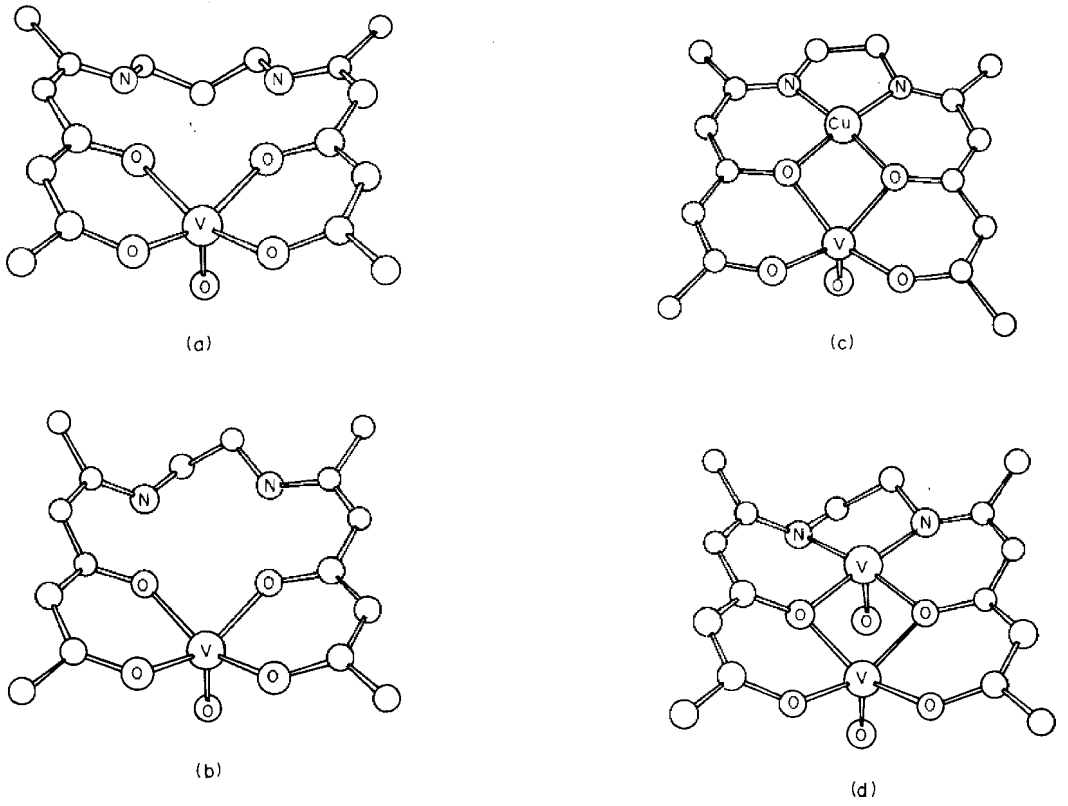
In mononuclear complexes with ligands of type (**173**), VO^{2+} has a strong preference for the O_2O_2 environment as clearly demonstrated by the single crystal molecular structure determinations with $[VO(H_2baaen)]$ (**174**; R = $(CH_2)_2$, R′ = Me, R″ = Ph),[893,895,896] $[VO(H_2daaen)]$ (**174**; R = $(CH_2)_2$, R′ = R″ = Me)[897] and $[VO(H_2daanpn)] \cdot CHCl_3$ (**174**; R = $(CH_2)_3$, R′ = R″ = Me).[897] In the case of ligands (**178**; R = Me, Et), the outside O_2O_2 donor set shows a low tendency to coordinate and VO^{2+} coordinates in the N_2O_2 site as was found for the Ni^{2+} complex.[898]

(**174**)

(**175**) (**176**) (67)

To prepare pure heterobinuclear complexes, it is important to minimize the possibility of producing homobinuclear chelates and to avoid the problem of the metal ions changing positions, *i.e.* positional isomers. $[Ni(H_2baaen)]$ (**175**) was the starting material for binuclear complexes including [NiVO(baeen)] (**176**).[896] As Ni^{2+} in (**175**) has a relatively strong selectivity

to N_2O_2, it can be easily prepared as a pure mononuclear N_2O_2 positional isomer and used for the synthesis of binuclear complexes (equation 67). In (**176**), the Ni^{2+}, coordinated in a square planar geometry, is diamagnetic with the entire paramagnetism arising from VO^{2+};[899] μ_{eff} values at 297 and 77 K are 1.71 and 1.73 BM.[896] The vanadium is 0.616 Å above the O_2O_2 'plane' in a square pyramidal geometry; the Ni—V distance is relatively short (2.991 Å). [CuVO(daaen)]·H_2O (**179**) and [NiVO(daaen)]·H_2O came from the parent Cu and Ni complexes by a reaction similar to equation (67), and [$(VO)_2$(baaen)] from [VO(H_2baaen)]·Me_2CO.[900] The crystal structures of (**179**) and of the mononuclear VO^{2+} complexes [VO(H_2daaen)] and [VO(H_2daanpn)] were determined (Figure 39).[897] Cu—V distance in (**179**) is 2.985 Å and [VO(H_2daaen)] crystallizes in two forms (monoclinic and triclinic), but the corresponding molecular structures are indistinguishable. The molecular structure of [$(VO)_2$(daaen)], only a small proportion of the molecules in the structure of [VO(H_2daaen)], was proposed and is shown in Figure 39(d);[897] one important feature is that both vanadyl bonds point in the same direction and thus the vanadium atoms are probably in good positions for relatively strong V···V interaction.



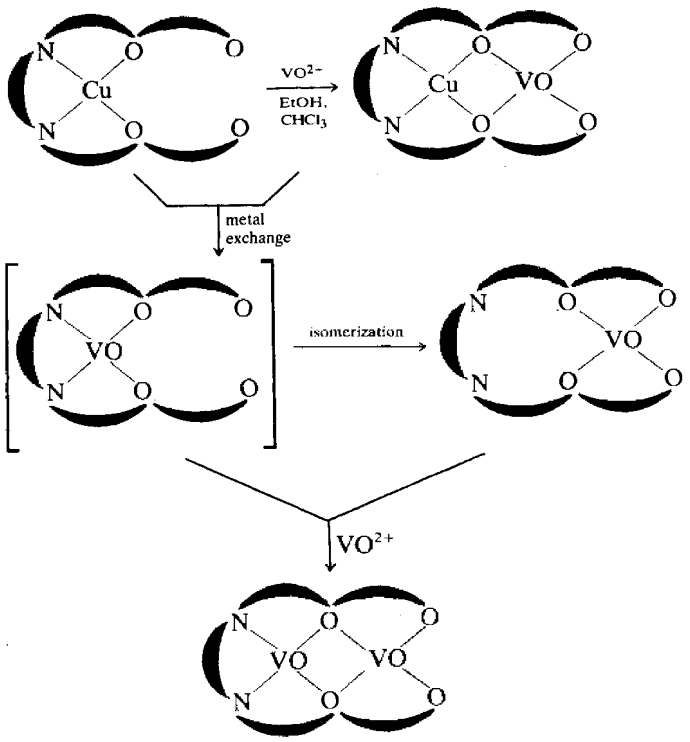


Figure 39 The molecular structure of (a) [VO(H_2daaen)], (b) [VO(H_2daanpn)], (c) [CuVO(daaen)]·H_2O (**179**) and (d) [$(VO)_2$(daaen)]. In all four molecules, the vanadium atom is coordinated in a square pyramidal geometry and is displaced above the O_2O_2 'plane' by *ca.* 0.56 Å (for (d), no data are given)[897]

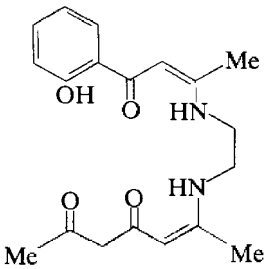
As mentioned above, in the heterobinuclear preparations the presence of both mono- and homobi-nuclear VO^{2+} complexes was detected;[897] two alternative explanations were suggested: (i) any HCl present in the $CHCl_3$ used for recrystallizing could strip the metals from the ligand and allow subsequent incorporation of VO^{2+} into the outer compartment; (ii) during the synthesis, the mechanism depicted in Scheme 23 could take place. These observations suggest that in solutions of the heterobinuclear complexes, several species are probably present and the product isolated is a function of the insolubility of the individual species.

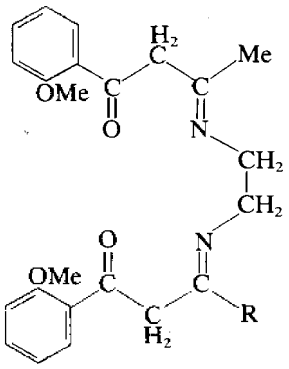
When $VOCl_2$ was reacted with the β,δ-triketones 1,5-bis(p-methoxyphenyl)1,3,5-pentanetrione (H_2dmba), 1,5-diphenyl-1,3,5-pentanetrione (H_2dba), 2,4,6-heptanetrione (H_2daa) or the β-diketophenols 2-acetoacetylphenol (H_2aap) and 2-benzoylacetylphenol (H_2bap) in the presence of 2 moles of LiOH, mononuclear complexes were normally obtained.[901] With cations other than VO^{2+}, *e.g.* Ni^{2+} and Co^{2+}, binuclear complexes were the usual result. With ketophenols, mononuclear chelates can be obtained but are only stable at

Scheme 23



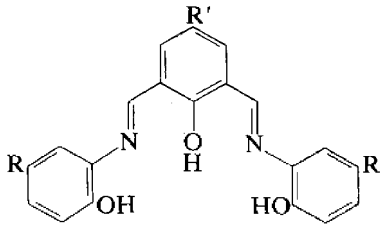
low temperatures. With the exception of [VO(Hbap)$_2$(OH)], which is yellow and diamagnetic (it is a V^V compound), $\mu_{eff}^{r.t.}$ values of the complexes obtained (in the range 1.65–1.73 BM) are those expected for magnetically dilute VO^{2+} complexes.

While attempts to prepare heterobinuclear complexes starting from the mononuclear chelates were unsuccessful, green or red oxovanadium(IV) homobinuclear complexes may be obtained (depending on the reaction conditions) with ligands dba and dmba, while only one type of complex is obtained with all other ligands. The main difference in the IR spectra is that the green compounds show only one ν(V=O) at 985–990 cm^{-1}, while the red ones have an additional strong band at 890–900 cm^{-1} suggesting V=O···V=O interactions.[901] The $\mu_{eff}^{r.t.}$ of the binuclear complexes are lower than the spin-only values except for [(VO)$_2$(bap)$_2$OH]; $\mu_{eff}^{r.t.}$ = 1.98 BM, suggesting the presence of a VO^V and a VO^{IV} in the molecule.[901] The authors also report results of polymerization tests with these VO^{2+} complexes as Ziegler–Natta catalysts. The features of the copolymer obtained are similar to those from widely used industrial catalysts but while the mononuclear complexes showed catalytic activities comparable to those of [V(acac)$_3$] and [VOCl$_3$], dinuclear compounds show much lower activities.

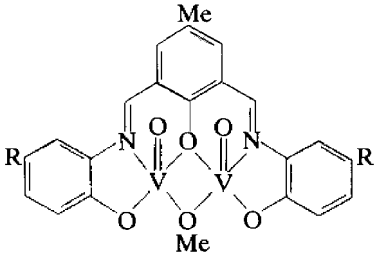


The complex [(VO)$_2$(dana)$_2$] (dana = 1,5-bis(*p*-methoxyphenyl)-1,3,5-pentanetrionato) was prepared and temperature dependent χ_M measurements show antiferromagnetic behaviour with $J = -80$ cm^{-1}.[902] The $|J|$ value is much lower than with [M$_2$(dana)$_2$(py)$_2$] (M = Co, Cu) and this probably results from a different spatial orientation of the exchanging electrons: if the unpaired electron is considered to be initially in a d_{xy} orbital, a direct metal–metal interaction may be possible; as the V—V distance is large (*ca.* 3.0–3.2 Å; V atoms are probably 0.5–0.6 Å out of the plane and possibly one above and one below the ligand plane[902]), one would expect a weak exchange for the direct V—V interaction.

A VO^{2+} complex with the compartmental ligand (**177**) was obtained by the dropwise addition of a $VOSO_4$ solution to an aqueous acetone solution containing LiOH and the ligand.[903] The complex is monomeric and the coordination involves the four O atoms. With Ni^{2+} and Cu^{2+} both mononuclear positional isomers N_2O_2 and O_2O_2 may be prepared according to conditions, but with VO^{2+} only the O_2O_2 positional isomer is obtained.

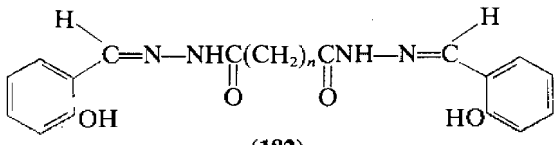


From the reaction between isophthalaldehyde (Hfsal) and substituted derivatives and aminophenol in boiling methanol, the ligand H$_3$fsal(ap)$_2$ (**180**) may be obtained, which in its trianionic form may act as a binucleating agent. Several VO^{2+} complexes with SBs (**180**; R′ = Me and R variable) were studied by Okawa *et al.* and were formulated as



(177)

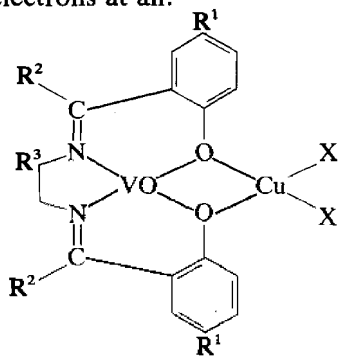
(178)



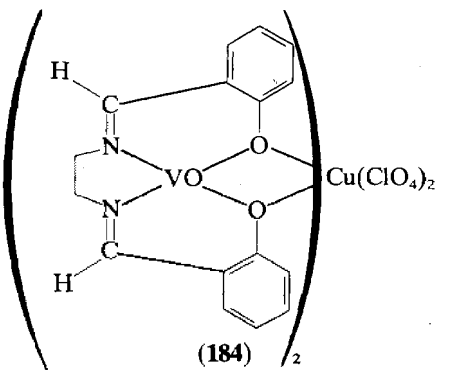
(180)

(181)

$[(VO)_2\{fsal(ap)_2\}(OMe)]$ with a structure (**181**).[904] $\nu(V{=}O)$ of the complexes is at about 990 cm^{-1} except for (**181**; $R = NO_2$) for which $\nu(V{=}O) = 900\ cm^{-1}$. All the ESR spectra are comparable and show bands at about 3200 and 1600 G. From magnetic susceptibility data, the $|J|$ values were obtained and increase with the increasing order of electron-withdrawing abilities of the substituent R. Since direct coupling between d_{xy} orbitals seems to be the determining factor for the spin-exchange interaction in the binuclear VO^{2+} complexes, one may expect that the overlapping of these orbitals will increase in the order $R' = Me > H > Cl$; in fact the $|J|$ values increase in the same order.[722]



Oxovanadium(IV) complexes with SBs (**182**; $n = 1, 2, 4$) were prepared and formulated as $[(VO)_2(SB)(H_2O)_2]$ having coordinating sites at the azomethine nitrogen and enolic and phenolic O atoms.[905] $\mu_{eff}^{r.t.}$ values are in the range 1.62–1.70 BM, close to the spin-only value, but χ_M measurements as a function of temperature were not performed.



(182)

Selbin and Ganguly obtained complex (**183**) with $R^1 = R^2 = R^3 = H$ by reacting [VO(salen)] and a Cu^{II} halide.[906] The $\mu_{eff}^{r.t.}$ of 1.69–1.90 BM per complex molecule was considered as indicating the presence of strong antiferromagnetic interaction between the Cu^{2+} and VO^{2+} ions. However, Okawa and Kida[907] argue that the large g value determined from ESR measurements is not compatible with the low $\mu_{eff}^{r.t.}$ and prepared Selbin's compounds and four other new complexes (R^1, R^2 or R^3 = Me, X = Br or Cl). They obtained much lower $\mu_{eff}^{r.t.}$ than the values reported by Selbin and from χ_M measurements at several temperatures[907] concluded that most of these compounds are diamagnetic, the paramagnetism being attributed to a paramagnetic impurity such as monomeric Cu^{2+} and VO^{2+} complexes. In order to explain the diamagnetism of the present complexes in terms of the antiferromagnetic spin-exchange interaction between VO^{2+} and Cu^{2+}, one would have to consider a strong spin pairing between the two metal ions and this seems unlikely since their ground state configurations, $(d_{xy})^1$ for VO^{2+} and $(d_{x^2-y^2})^1$ for Cu^{2+}, are not appropriate for strong interaction (see also Section 33.5.12.2). A different explanation, suggested by Okawa and Kida for the diamagnetism of

complexes (**183**) is that they are composed of V^{V} and Cu^{I}, and thus the metal ions have no unpaired electrons at all.

(**183**) X = Cl, Br

(**184**)

Selbin and Ganguly also reported the preparation of the heterotrinuclear complex (**184**) with a $\mu_{eff}^{r.t.}$ value of 3.93 BM,[906] and the authors infer the absence of magnetic exchange in the complex although one would expect a value of only 3.0 BM if this were the case. Orbital contribution, especially from the Cu atom, may be a partial explanation, but magnetic exchange is also probably involved.[358]

Polynuclear complexes with more than two metal ions have been prepared with polyketone ligands but no such complexes have been reported with VO^{2+}. With the tetraketone 1,1′-(2,6-pyridyl)-bis-1,3-butanedione (H_2L), several polynuclear complexes have been prepared including $[(VO)_2(L)_2]$ for which $\mu_{eff}^{r.t.} = 1.21$ BM was obtained.[908]

33.5.12.2 Heteropolynuclear complexes

Studies involving heteropolynuclear complexes containing V^{IV} have been discussed throughout this review. Magnetic interactions (VO^{2+}–VO^{2+} and VO^{2+}–Cu^{2+}) have been mentioned. A study comparing the interaction in Cu^{2+}–Cu^{2+}, VO^{2+}–VO^{2+} and Cu^{2+}–VO^{2+} pairs through the same oxalato bridging ligand was reported.[909] Two new bimetallic complexes were synthesized, namely $[(acac)VO(C_2O_4)VO(acac)]\cdot 4H_2O$ and $[(tmen)Cu(C_2O_4)VO(C_2O_4)]\cdot 3H_2O$ (tmen = *N,N,N′,N′*-tetramethylethylenediamine) and the crystal and molecular structure of $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)](ClO_4)_2$ was determined (Figure 40). The energy gaps arising from the intramolecular interaction, determined from magnetic data, are 385.4, 5.75 and $<1\ cm^{-1}$ in the CuCu, VOVO and CuVO compounds, respectively. The authors rationalized the results according to an orbital model in which the 'magnetic orbitals' are defined as the singly occupied molecular orbitals for each monomeric fragment (Φ_{VO} and Φ_{Cu}), made up by the metal centre surrounded by the nearest neighbour ligands. The 'magnetic orbital' Φ_{VO} around VO^{2+} in the VOO_5 chromophore, schematized in Figure 40(c), transforms as *a′* (referring to C_s site symmetry) and is delocalized towards the oxygen atoms of the bridge with π metal–oxygen overlaps. Since the π overlaps are weaker than the σ ones, the delocalization towards the bridge is less pronounced in Φ_{VO} than in Φ_{Cu}. In the VOVO compound the interaction between the two 'magnetic orbitals' is weaker than in the CuCu compound since the delocalization of Φ_{VO} towards the nearest neighbour oxygen atom is less pronounced. In the CuVO compound the two magnetic orbitals are strictly orthogonal but as they do not give any region of strong overlap density this explains why the triplet and singlet states are found to be almost degenerate.

A rather different situation is found in the complex $[CuVO\{(fsa)_2en\}(MeOH)]$ (**185**) where $(fsa)_2en^{4-}$ denotes the binucleating ligand derived from the SB *N,N′*-(2-hydroxy-3-carboxybenzylidene)-1,2-diaminoethane. The crystal structure is made up of heterobinuclear units (Figure 41a) with the MeOH molecule weakly bound to the Cu atom.[910,911] The thermal variation of χ_M shows that upon cooling from 300 K to around 50 K, $\chi_M T$ increases and this clearly demonstrates that the triplet state ($S = 1$) is actually the lowest in energy. Thus, the intramolecular coupling is ferromagnetic and the separation between the triplet and singlet states was found to be $118\ cm^{-1}$. The nature of the intramolecular interaction was explained by the orthogonality of the 'magnetic orbitals' Φ_{Cu} and Φ_{VO}, centred on the Cu^{2+} and VO^{2+} ions (see Figure 41b). The overlap integral of Φ_{Cu} and Φ_{VO} is identically zero and this means that

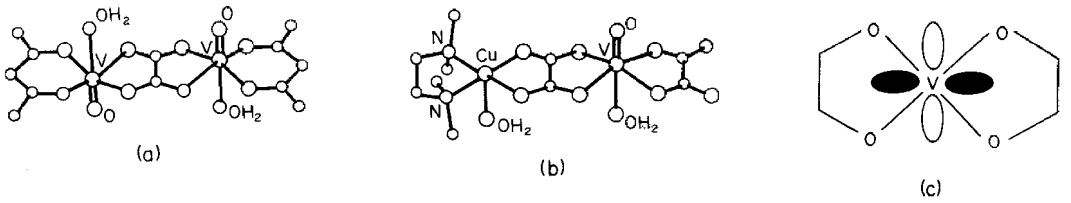


Figure 40 Schematic structures proposed for (a) $[(acac)VO(C_2O_4)VO(acac)]\cdot 4H_2O$ and (b) $[(tmen)(H_2O)Cu(C_2O_4)VO(C_2O_4)]\cdot 3H_2O$[909] (only the structure of $[(tmen)(H_2O)Cu(C_2O_4)Cu(tmen)(H_2O)]^{2+}$ was determined by X-ray diffraction); (c) schematic representation of the 'magnetic orbital Φ_{VO}' in the VOO chromophore[909]

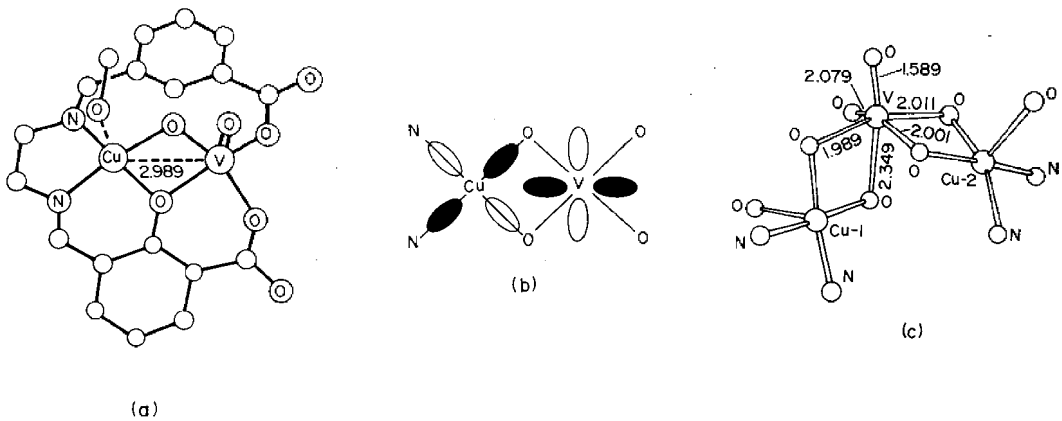
there is no interaction between the orbitals favouring the pairing of electrons on a molecular orbital of low energy. In order to explain why J is so large, the authors emphasize that the entire molecular symmetry is important in deciding the nature of the coupling and not only the local symmetry for each A—O—B linkage.[911] In the Cu^{2+}–VO^{2+} pair, the strict orthogonality which leads to ferromagnetic interaction occurs only if the phases at both bridging oxygen atoms are taken into account.



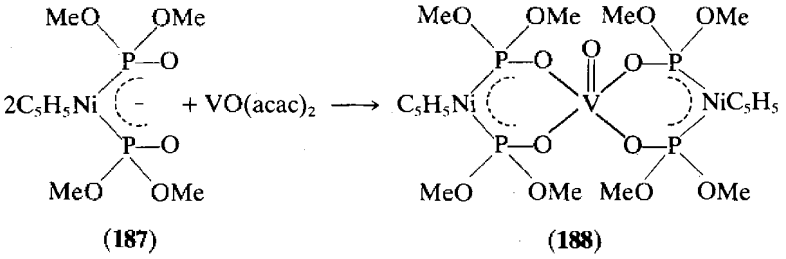


Figure 41 (a) schematic representation of the molecular structure of [CuVO((fsa)$_2$en)(MeOH)] (**185**);[911] (b) relative symmetries of the 'magnetic orbitals';[911] (c) schematic representation of the geometry around VO^{2+} in the trinuclear cation $[VO(CuHAPen)_2]^{2+}$ (**186**)[914]

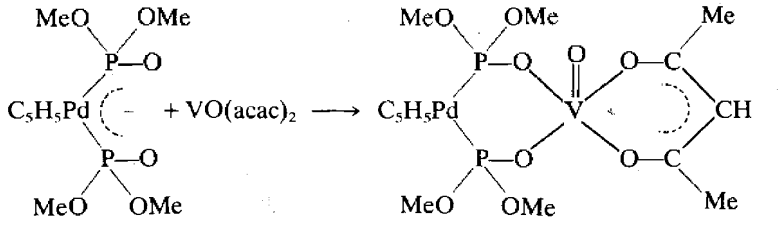
Copper complexes can act as bidentate ligands towards transition metal ions.[912,913] On mixing a solution of CuHAPen in $CHCl_3$ (CuHAPen = *N,N'*-ethylenebis(*o*-hydroxyacetophenone iminato)copper(II)) with an ethanol solution of $VO(ClO_4)$, a precipitate formed. After recrystallization from nitroethane the compound $[VO(CuHAPen)_2](ClO_4)_2\cdot 3H_2O\cdot \frac{1}{2}EtNC$ (**186**) was obtained and its crystal structure determined.[914] The two CuHAPen complex ligands bind to a central hexacoordinate VO^{2+} occupying nonequivalent positions in a distorted octahedron forming a dipositive trinuclear cation (see Figure 41c). The V atom lies 0.38 Å above the 'equatorial plane'. The Cu(1)—V, Cu(2)—V and Cu(1)—Cu(2) distances are 3.132, 3.015 and 4.558 Å, respectively. The temperature dependence of χ_M of (**186**) was studied in the range 4.2–300 K;[914] the ground state of the trinuclear cation is a spin doublet, with the quartet separated by $\sim 3\ cm^{-1}$, and a second doublet at $\sim 85\ cm^{-1}$ ($= J_{12}$). The large ferromagnetic constant J_{12} is associated with the coupling between Cu-2 and V, based (i) on comparisons with other similar copper complexes and with (**185**) and (ii) on the geometry of the Cu—V bridge and the symmetry of the 'magnetic orbitals' of Cu-1, Cu-2 and V.



Oxovanadium(IV) complexes were also prepared by the reaction of the phosphonate anion (**187**) and (**189**) with $[VO(acac)_2]$ (equations 68 and 69), and the products were characterized by elemental analysis and mass spectra.[915] In contrast to the reaction of (**187**) with $[VO(acac)_2]$ which gives (**188**) with $\mu_{eff}^{r.t.} = 2.03$ BM, in the reaction of (**189**) only one acac ligand is displaced by the organometallic chelate.

Allowing $TiCl_3(THF)_3$ and [VO(acen)] to react in THF at room temperature, a reductive deoxygenation of the VO^{2+} occurs and a red solid precipitates, characterized as $[V^{II}$

(68)

(187) (188)

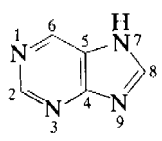
(69)

(189) (190)

(acen)(Cl)(THF)] (**4**) (Section 33.4.8.1).[916] However, if the reaction is carried out at low temperature (*ca.* −70 °C), a red crystalline solid precipitates which was shown to be the bimetallic vanadium(IV)–titanium(IV) μ-oxo complex [(Cl)(acen)VOTi(Cl)$_3$(THF)$_2$]. This is paramagnetic, with one unpaired electron and is probably an intermediate in the reductive deoxygenation of [VO(acen)] to yield (**4**). X-Ray data show that the μ-O atom bridges the [V(Cl)(acen)] and [Ti(Cl)$_3$(THF)$_2$] units with a rather long V—O bridging distance: 1.937 Å (or 1.973 Å?); the Cl^- is coordinated *trans* to the μ-O and the V atom lies approximately in the plane of the N_2O_2 core of the acen ligand, its displacement from it being 0.042 Å towards chlorine.[916]

33.5.13 Naturally Occurring Ligands

This subject covers a wide range of compounds and many of them have been included in previous sections. Most investigations concerning complex formation between VO^{2+} and proteins have been carried out with VO^{2+} acting as a physicochemical marker of the binding sites. In recent years, there has been growing interest in employing VO^{2+} in protein studies because of its chemical and spectroscopic properties. Vanadyl forms hundreds of stable complexes with almost all kinds of ligands; thus, it may coordinate with the functional groups encountered in proteins. Since vanadium(IV) complexes are d^1 systems, the interpretation of optical spectra is relatively simple. Further, oxovanadium(IV) has one position occupied by the vanadyl oxygen and the IR stretching frequency of the VO bond can be used as an additional probe of metal-binding sites in crystalline proteins where the VO^{2+} concentration is sufficiently large.[917]

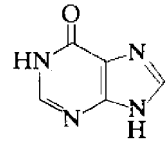


As vanadyl complexes consistently give sharp ESR spectra both in frozen and room temperature solutions and ^{51}V is nearly 100% abundant, ESR is particularly useful and there has been a growing interest in employing VO^{2+} as an ESR spin probe. ENDOR studies have also been performed and future work using this technique and electron spin echo (ESE) will possibly be of great value in giving an insight into VO^{2+} binding site structure. The use of VO^{2+} as an ESR spin probe was reviewed by Chasteen.[354] A few studies have appeared since, *e.g.* ESR studies of the VO^{2+} apoferritin complex[918] and the VO^{2+}–*S*-adenosylmethionine synthetase interaction,[919] a CD, ESR and acid–base study of VO^{2+} binding to bleomycin,[920] and redox kinetics and complexation of V^{IV} and V^{V} with serum proteins.[945] Some equilibria in solution, likely coordination geometries and ligand contributions to the observed hyperfine splitting A_0 were also discussed.[798]

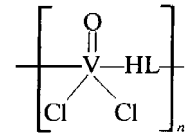
Since the discovery by Cantley *et al.* that vanadate is a powerful and allosteric inhibitor of Na^+,K^+-ATPase,[921] vanadium began to interest biochemists; and Chasteen has reviewed work published up to 1983.[471] Particularly interesting new studies involve vanadium peroxidases[946] and nitrogenases.[947]

Waltermann *et al.* studied the nonenzymatic hydrolysis of ATP by VO^{2+} and VO^{2+} coupled

with H_2O_2 and concluded that oxidation of V^{IV} to V^{V} is an important factor in enhancement of ATP hydrolysis.[922] The authors also observed that ATP protects the VO^{2+} from oxidation by H_2O_2 and from ESR spectra they concluded that binding occurs between VO^{2+} and ATP in aqueous solution. Sakurai *et al.* studied the formation of complexes between ATP and VO^{2+} by potentiometric titrations, optical and ESR spectra and by ^{31}P and ^{13}C NMR spectrometry.[923,924] They concluded that as pH increases three different complexes form and proposed detailed coordination geometries for each of them. At acidic and neutral pH, two different 1:1 species predominate and in alkaline solutions a green 2:1 complex forms. The authors argue that ^{31}P and ^{13}C NMR are very effective for determining coordination sites in compounds containing organic phosphate and that the detailed structures for the ATP–VO^{2+} complexes can thus be determined.[924]



Complexes formulated as $[VOCl_2(HL)]$ [HL = purine (**191**), adenine (**192**) and guanine (**193**)] were prepared by refluxing the ligand and $VOCl_2$ mixtures in ethanol–triethyl orthoformate.[925,926] Characterization was based on elemental analysis and spectral and magnetic studies. In the visible spectra (Nujol mulls) the *d–d* transitions were at ~695, ~500 and ~430 nm, and in the IR, ν(V=O) was assigned at ~1005 cm^{-1}; $\mu_{eff}^{r.t.} \approx 1.7$ BM. These $VOCl_2$ adducts are said to be polymeric with a linear, chain-like structure (**194**) involving single bridges of bidentate ligands between adjacent VO^{2+} ions, the bridging probably being through N-7 and N-9 of imidazole.[925,926] This suggestion is based on IR evidence and by comparison with the molecular structure of $[Cu(HL)(H_2O)_4](SO_4)\cdot 2H_2O$ (HL = **191**).[927]



(**191**)

(**192**)

(**193**)

(**194**)

Several VO^{2+} complexes with nucleotides have been prepared by the addition of aqueous $VOSO_4$ to an aqueous solution of the nucleotide.[928] The compounds were formulated as $[VOL]\cdot nH_2O$ with a suggested polymeric structure. As in the case of the complexes with the purines (**191**)–(**193**), further work is needed to sort out the molecular structure of these compounds.

Amavadin, a natural compound which occurs in the toadstool *Amanita muscaria* has been said to be a 1:2 VO^{2+} complex of Hidpa (**131**; R = OH).[378,816,929–934,948,949] Fraústo da Silva and co-workers studied the formation of complexes of VO^{2+} with ligands of type (**132**) by pH potentiometric methods and concluded that with a ligand-to-metal ratio of 2, only 1:1 complexes form (see Table 45) except for the *N*-hydroxy derivatives (**132**; R = OH). With these ligands (*e.g.* Hidpa), the pK_a associated with the N group drops ~10 000 times and at pH ~7 the 2:1 complexes predominate. However, the formation constants calculated[378,932] seem low to explain the existence of amavadin in the toadstool and its 'intact' isolation after several extraction and chromatographic procedures, and further studies are needed to establish the detailed structure of amavadin and understand why VO^{2+} binds *N*-hydroxyiminodiacetate ligands so strongly. Different formation constants have recently been estimated.[948]

Several studies have concerned interaction of VO^{2+} with soil humic and fulvic acids. Strongly complexed VO^{2+} occurs naturally in the organic fractions isolated both from lignite and ball clay[935] and from soil.[936,937] Since the ESR spectra of VO^{2+} provide information on the environment of the metal, much can be learned about the interactions between vanadium and fulvic and humic acids using VO^{2+} as a paramagnetic probe, and several studies have appeared with VO^{2+} synthetically introduced to probe the metal-binding sites of these materials.[938–941] The ESR parameters indicate that in most cases the ligands are oxygen donors, probably from carboxylate and phenolate groups. Nitrogen coordination has also been suggested[938] but, as noted by Chasteen,[354] catechol coordination complexes have VO^{2+} ESR parameters which are comparable to those obtained with nitrogen chelates. McBride[941] studied the influence of pH and metal ion content on VO^{2+}-fulvic acid interactions and concluded that very low pH values prevent VO^{2+} from bonding with fulvic acid and that insignificant quantities of free VO^{2+} remain in solution at pH values of 4 or higher. Very high pH caused all the VO^{2+} associated with fulvic acid to be oxidized except for a very small quantity apparently strongly bound to four nitrogen ligands, possibly porphyrin.

VO^{2+} bound to wet humic acids exhibits a rigid limit ESR spectrum indicative of a highly

immobilized probe ion.[939] The ESR parameters suggest that bonding is mainly ionic. Room temperature solution ESR spectra of VO^{2+} complexes with podzol fulvic acid exhibit reduced intensity due to VO^{2+}–VO^{2+} magnetic dipole interactions within the same fulvic acid molecule[940] and VO^{2+} binding facilitates aggregation of fulvic acid to form a soluble polymeric system.

34.1 SURVEY

Niobium (formerly called columbium) and tantalum, when compared with the neighboring early transition metals, are seen to share with titanium and zirconium an affinity for dioxygen

and a reluctance to be reduced, but to differ from them in their much stronger tendency to form metal–metal bonds and in their rich cluster chemistry. With molybdenum and tungsten they share a propensity to yield oxo species and an ability to give multiple bonds with non-metals, as in carbenes, alkylidenes, nitrenes, *etc.*, and to form M_6-based clusters, although these are mainly of the $[M_6X_8]^{q+}$ type for molybdenum and of the $[M_6X_{12}]^{q+}$ type for niobium or tantalum. Carbonyls are generally much less stable for the group V than for the group VI metals. Roughly, it may be said that niobium and tantalum have chemistries more comparable to those of titanium and zirconium in their higher oxidation states, but closer to those of molybdenum and tungsten in their lower ones.

Compared to vanadium, the higher oxidation states are much more frequently and the lower ones much less frequently encountered in niobium and tantalum. Niobium and tantalum are also much more prone to extended metal–metal bonding in their lower oxidation states; V_6-based clusters, for example, remain undiscovered. Little resemblance is found to the group VB elements phosphorus and arsenic.

The chemistry of niobium and tantalum ranges from oxidation state +V to −III, but with no species of oxidation state −II presently known (Table 1). The largest number of molecular compounds, by far, is found for oxidation state V. The very reactive pentahalides provide the most convenient entry to the molecular chemistry of these metals.

Table 1 Oxidation States and Common Stereochemistries of Nb and Ta Compounds

Oxidation state	*Coordination number*	*Idealized geometry*	*Examples*
M^{V}	4	Tetrahedron	$[NbO_4]^{3-}$, $[NbO\{N(SiMe_3)_2\}_3]$
	5	Trigonal bipyramid	$[Ta(NEt_2)_5]$
		Square-based pyramid	$[Nb(NMe_2)_5]$, $[NbOCl_4]^-$, $[NbSCl_3(Ph_3PS)]$
	6	Octahedron	$[M_2X_{10}]$, $[MOX_3]$, $[NbAlCl_8]$, $[Nb(OMe)_5]_2$, $[MCl_3(OR)_2]_2$

		Dodecahedron	$[MCl_4(diars)_2]^+$, $[M(O_2)_4]^{3-}$, $[M(O_2)_3(phen)]^-$, $[M(O_2)_2(C_2O_4)_2]^{3-}$
	9	?	$[\{NbCl_2(Cp)_2\}_2O]$
	10	?	$[MCl_5(OxH)_5]$
M^{IV}	4	D_{2d} tetrahedron	$[Nb(NR_2)_4]$
	5	Trigonal bipyramid	$[MH_2(OSiBu^t_3)_2]_2$
	6	Octahedron	$[MbX_4L_2]$
	7	Pentagonal bipyramid	$[NbF_7]^{3-}$
	8	Dodecahedron	$[Nb\{S_2P(OR)_2\}_4I]$, $[NbCl_4(diars)_2]$
		Square antiprism	$[Nb(dpm)_4]$, $[TaCl_4(dmpe)_2]$, $[Nb_2Cl_4(PhPMe_2)_4(\mu\text{-}Cl)_4]$
	9	?	$[Nb(acac)_4(dioxane)]$
M^{III}	6	Octahedron	$[NbCl_3(py)_3]$, $[Nb_2X_9]^{3-}$, $[M_2Cl_4L_4(\mu\text{-}Cl)_2]$
	7	Pentagonal bipyramid	$[Ta(PMe_3)_3(\eta^2\text{-}CH_2PMe_2)(\eta^2\text{-}CHPMe_2)]$, $[TaH(PPh_2)_2(dmpe)_2]$
	8	Dodecahedron (solid)	$[Nb(CN)_8]^{5-}$
		Square antiprism (solution)	
M^{II}	6	Octahedron	$[MCl_2(PMe_3)_4]$
	8	Dodecahedron	$[TaH_2Cl_2(PMe_3)_4]$
		Square antiprism	$[TaH_2Cl_2(dmpe)_2]$
M^{I}	5	Pentagonal bipyramid	$[TaL_2R(C_2H_4)_2]$
	6	?	$[M(\eta^4\text{-}C_4H_6)_2(\eta^3\text{-Meallyl})]$
	7	Capped octahedron	$[TaH(CO)_2(dmpe)_2]$, $[Ta(CO)_3(PMe_3)_4]^+$
		Capped trigonal prism	$[TaX(CO)_2(dmpe)_2]$, $[MCl(CO)_3(PMe_3)_3]$
		'Four-legged pianostool'	$[Nb(CO)_4(Cp)]$
M^{0}	6	Octahedron	$[M(dmpe)_3]$
		Sandwich	$[M(arene)_2]$
M^{-I}	6	Octahedron	$[M(CO)_6]^-$
M^{-III}	5	?	$[M(CO)_5]^{3-}$
	6	?	$[M(CO)_3(Cp)]^{2-}$

Until recently little attention was paid to oxidation states lower than III, with the exceptior of the octahedral clusters of type $[M_6X_{12}]^{q+}$, which are predominant in aqueous solutions Preparation of molecular compounds in these oxidation states was for a long time more or les accidental unless cyclopentadienyl groups were present. This lack of development is mainly du to the paucity until recently of suitable precursors (halides or carbonyls), as well as to the higl sensitivity to dioxygen and to moisture of products in such intermediate oxidation states a +III. Chemical reduction of pentavalent or tetravalent derivatives under strictly controlle conditions has since proven able to provide convenient starting materials for developing th chemistry of niobium and tantalum in their lower oxidation states. Powerful reductants such a sodium amalgam or naphthalenide are required for access to oxidation states lower than III The least -documented chemistry of the formally positive oxidation states of these metals is tha of oxidation state +II.

Among the most valuable starting materials now available for access to oxidation states IV t II are the tetrahalides and some of their more soluble molecular adducts such a $[NbCl_4(THF)_2]$, $[NbCl_4(MeCN)_2]\cdot MeCN$ and $[MCl_4(dmpe)_2]$, adducts of the trihalides, i particular $[M_2Cl_6(PR_3)_4]$, and their derived hydrides, $[M_2Cl_6L_3]$ ($L = SMe_2$, THT) an $[MCl_2(dmpe)_2]$. Pentavalent alkylidenes also offer attractive entries into the chemistry o oxidation states +III and +I.

Oxidation state −I is mainly represented by $[M(CO)_6]^-$ and $[M(PF_3)_6]^-$. The firs compounds isolated with a metal in the −III oxidation state were $Cs_3[M(CO)_5]$ an $Cs_2[M(CO)_3(Cp)]$ with M = Nb or Ta.

Niobium and tantalum compounds form adducts with virtually all types of neutral an anionic donors. The coordination chemistry of the higher halides is widely developed, and thei activity as Friedel–Crafts catalysts is another manifestation of their Lewis acidity. The stron acceptor capacity of the high valent metal compounds tends to favor the formation of dimers and sometimes of higher condensation products, which competes with coordination with othe donor molecules. Numerous simple anionic or heteropolyanionic species, but little cationi chemistry, and no simple metal salts, are known.

Specific to the lower oxidation states is the tendency to metal bonding found in variou arrangements, including isolated dimers (with single or double metal–metal bonds), polymer with M—M···M—M··· bond alternation, triangular M_3 units, and, the most abundant octahedral M_6-derived clusters. These clusters, with non-integral oxidation states ranging fror +2.67 for $[M_6X_{12}]^{q+}$ to +1.67 for $[Nb_6I_8]^{q+}$ exhibit complex redox chemistry that may be use in photocatalysis.

Being among the largest early transition metals, niobium and tantalum can easil accommodate high coordination numbers. Although coordination number six is the mos frequent, stable compounds with coordination numbers of seven (especially in the lowe oxidation states), eight, nine and even ten are found; in contrast, coordination numbers belo five are extremely rare. The rate relatively large metal radii also account for the less tigh coordination sphere, and hence for the stereodynamic character often encountered in th complexes.

Reactions other than Lewis acid–base associations/dissociations are frequently observed wit donor molecules, leading notably to solvolysis, oxygen or sulfur abstraction, insertion reaction and carbon–carbon coupling reactions. The tendency to form metal–element multiple bonds i remarkable; in this respect the activation of dinitrogen by tantalum or niobium is unique. Th formation and chemistry of constrained reactive metallacycles open another promisin fast-developing area, on the frontier with organometallic chemistry.

Owing to lanthanide contraction, niobium and tantalum have virtually identical atomic rad (1.47 Å) and close ionization energies (Nb 6.67, Ta 7.3 eV), and usually display very simil chemical behavior. Some definite differences can however be noted; these can usually be trace to the lower sensitivity of tantalum to reduction and to its higher affinity for dioxygen. Th tantalum–element multiple bonds are usually stabler, while M_6X_8 arrangements are so f known only for niobium.

The ^{93}Nb nucleus has 100% abundance, $I = 9/2$, and the third highest sensitivity (after ^{1} and ^{19}F and before ^{27}Al) in NMR; the use of this technique is therefore likely to expand. ^{181}T (99.9877%), $I = 7/2$, is less promising in view of its much lower sensitivity and its tenfold larg quadrupolar coupling. The magnetic moment in the Nb^{IV} derivatives usually ranges betwee 1.6 and 1 BM (the spin only value expected for d^1 compounds being 1.73 BM). The magnet moments of Ta^{IV} are usually lower than 1 BM as a result, at least in part, of a larger spin–orb coupling ($\lambda = 750\ cm^{-1}$ for Nb^{4+} and $1400\ cm^{-1}$ for Ta^{4+}). The magnetic susceptibilities usual

exhibit a Curie law dependence upon reciprocal temperature, which strongly supports an orbital singlet ground state well separated from the next excited state. Typical isotropic ESR spectra display 10 lines for niobium and eight lines for tantalum derivatives, the line width being larger for the latter, probably owing to non-resolved quadrupolar coupling. The g values of the niobium compounds are closer to 2 than are those of tantalum, which is no surprise as the latter has a higher spin–orbit coupling constant. Magnetic data on the other oxidation states are still scarce.

This review intends to cover essentially the molecular non-organometallic chemistry of niobium and tantalum. When organometallic compounds are mentioned, it is in principle only in so far as they are involved in some coordination process. The literature has been covered to the end of 1983; thanks to their authors, a few more recent preprints were able to be analyzed. Emphasis is given to the more recent material. Some of the presently most active areas such as those involving multiple bonding, dinitrogen activation and nitrenes are highlighted by subtitles. Earlier reviews on the subject are those of Fairbrother (1967),[1] Kepert (1972),[2] Walton (1972),[3] Gmelin (1973),[4] Brown (1973)[5] and Mehrotra (1976).[6] The first review of the chemistry of the d^1 metal compounds of early transition metals was published by Bereman in 1972.[7] For the organometallic chemistry of these elements see Labinger (1982).[8]

The following abbreviations and conventions will be used throughout this chapter: A: cation; Z: anion, M = Nb, Ta; M′ ≠ Nb, Ta; X: halogen; X and Y′: halogens when mixed; Y = S, Se, Te; E = N, P, As, Sb or Bi; LL = bidentate; ax: axial; eq: equatorial; b: bridging; t: terminal. Ligands: bzac: benzoylacetone; bipyO_2: bipyridyl N,N'-dioxide; cat: catechol; Cp′: η^5-C_5R_5; dbmH: dibenzoylmethane; DEF: diethylformamide; DMA: dimethylacetamide; dpac: 1,2-bis(diphenylarsino)ethane; dmpe: 1,2-bis(dimethylphosphino)ethane; dpmH: dipivaloylmethane; dth: 2,5-dithiahexane; edta: ethylenediaminetetraacetate; oxH: 8-quinolinol (8-hydroxyquinoline); pic: picoline; pyO: pyridine N-oxide; R_2dtc: dialkyldithiocarbamate; SB: Schiff's base; T: tropolone; THP: tetrahydropyran; THT: tetrahydrothiophene; TPO: triphenylphosphine oxide; triars: triarsine; TU: thiourea.

34.2 OXIDATION STATE +V

34.2.1 Pentahalides

The pentahalides of niobium and tantalum are predominantly covalent. Their volatility decreases from the fluorides to the iodides. Nb and Ta belong to the few elements which form stable pentaiodides. Selected physical and thermodynamic properties for the halides are listed in Table 2. All are sensitive to moist air, water or hydroxylic solvents.

Table 2 Selected Thermodynamic Properties for the Pentahalides[a,b]

34.2.1.1 Pentafluorides

The pentafluorides are best prepared by direct fluorination of the metals at 250 °C.[1,2] Alternative methods include reactions of the metals with HF, ClF_3 or BrF_3, or SnF_2. They have

also been prepared from MCl_5 and HF or ZnF_2. The synthesis of high purity NbF_5 by competitive Lewis acid–base reactions between $[SbF_5]$ and $[MF_6]^-$ in HF has also been reported.[9]

The MF_5 molecules crystallize as tetramers in which the metal atoms are approximately octahedrally surrounded by fluorine atoms, and are linked together by linear bridging fluorine atoms (M—F_b: 2.06 Å; M—F_t: 1.77 Å).[10] It was suggested, on the basis of the high viscosity of the melts and the high Trouton constants, that this polymerization state is retained in the liquid.[2] Molecular weight data in the vapor, obtained through mass spectrometry and vapor density measurements, were interpreted to imply the simultaneous presence of monomeric, dimeric and trimeric species.[11–13] However, a different model, which assumes mixtures of monomers and tetramers, has since been reported to fit the vapor density data better.[14] Electron diffraction investigations also showed that the gaseous MF_5 molecules are associated at lower temperatures;[1] thus, at the nozzle temperature of about 45 °C, TaF_5 was found to be mostly trimeric (Ta—F_b: 2.062(2) to 2.076(3) Å; Ta—F_t: 1.81(6) to 1.894(6) Å).[15] The molten pentafluorides possess measurable electrical conductivities that were attributed to slight (<1%) self-ionization.[2]

34.2.1.2 Pentachlorides

The pentachlorides have been prepared by a variety of methods,[2,3] chief of which are the direct chlorination of the metal and the action of chlorinating agents on the pentoxides.

The crystal structure of $NbCl_5$ consists of Nb_2Cl_{10} dimers (Nb—Cl_b: 2.56 Å; Nb—Cl_t: 2.25 and 2.30 Å).[2] $TaCl_5$ was presumed to have the same structure; $TaCl_5$ and $NbCl_5$ form a complete series of mixed crystals. The dimeric structure of M_2Cl_{10} was confirmed by IR and Raman spectroscopy, and normal coordinate analyses were performed.[16] Raman spectroscopy shows a gradual dissociation of Ta_2Cl_{10} to monomeric $TaCl_5$ between 220 and 350 °C.[17] Halogen and metal NQR transitions of M_2X_{10} (M = ^{93}Nb, ^{181}Ta; X = ^{35}Cl, ^{81}Br, ^{127}I) indicate that coordination about M becomes closer to octahedral symmetry as the halogen is varied from Cl to Br and I. Terminal halogen atom resonances were reported to indicate M—X π bonding.[18] MX_5 appears to remain dimeric in non-complexing solvents,[1,3] while monomeric adducts are formed in donor solvents. In the vapor state MCl_5 is monomeric, with a trigonal bipyramidal structure.

Despite the drastic solvent limitations, polarographic data could be obtained for MCl_5 in non-aqueous solvents (Nb^V/Nb^{IV}: $E^\circ = -0.52$ V; Nb^{IV}/Nb^{II}: $E^\circ = -0.88$ V; Ta^V/Ta^{III}: $E^\circ = -0.88$ V in MeCN). Data on molten salts are also available for both metals.[1] The reduction of Nb^V in aqueous concentrated HCl solutions proceeds through Nb^{IV}, which disproportionates to Nb^V and Nb^{III} (assumed to be $[NbCl_6]^{3-}$). The Nb^{IV} species may be stabilized by addition of ethylene glycol. Further reduction to Nb^{II} has been suggested.[4]

34.2.1.3 Pentabromides

The orange-yellow $NbBr_5$ and yellow $TaBr_5$ are prepared in the same way as the pentachlorides.[1,3,19] $NbBr_5$ has also been obtained by halogen exchange between $NbCl_5$ and BBr_3 at room temperature.

α-MBr_5 is isomorphous with $NbCl_5$ and consists of M_2Br_{10} dimers.[1] When $NbBr_5$ was mixed with sulfur in a closed tube, crystals of a new modification, β-$NbBr_5$, which show a one-dimensional disorder, were isolated.[20] β-$NbBr_5$ is isostructural with TaI_5 and consists of layers of Nb_2Br_{10} molecules (Nb—Br_b: 2.462(2) and 2.403(3) Å); the bromine atoms have a hexagonal-close-packed arrangement. Electron diffraction studies showed that the gaseous bromides consist of trigonal bipyramids.[3]

34.2.1.4 Pentaiodides

MI_5 species contrast in their preparation and properties with the other pentahalides, and differ from one another.[1,3] TaI_5 is stable to at least 500–600 °C, and can be sublimed under vacuum, while NbI_5 must be prepared and sublimed in the presence of an excess pressure of

iodine vapor; when heated under vacuum, it loses iodine at temperatures as low as 200 °C, and is the most air sensitive of these halides.

TaI_5 consists of iodine atoms in a hexagonal-close-packed arrangement in which 2/5 of the octahedral holes are randomly occupied by tantalum atoms.[21] The Ta_2I_{10} molecules are arranged in layers (Ta—I_b: 2.932 Å; Ta—I_{ax}: 2.704 Å; Ta—I_{eq}: 2.619 Å). Triclinic NbI_5 is isostructural with β-UCl_5.[22]

34.2.1.5 Mixed pentahalides

MCl_4F was obtained by the action of AsF_3 on the $[MCl_5(PCl_5)]$ adducts in $AsCl_3$.[3,23] The compounds are tetrameric, with bridging fluorines (M—F: 2.10–2.11 Å; M—Cl: 2.26–2.31 Å). A series of mixed $[M_4Cl_xF_{20-x}]$ derivatives was isolated.[24,25] Reactions of mixtures of $AlBr_3$ and AlI_3 with Ta_2O_5 have been reported to yield $[TaBr_4I]$ and $[TaBrI_4]$.[3]

Crystalline $[NbAlCl_8]$ was prepared directly from Al_2Cl_6 and Nb_2Cl_{10}:[26] the crystal structure consists of an $AlCl_4$ tetrahedron sharing an edge with an $NbCl_6$ octahedron (Nb—Cl_{ax}: 2.288(1) Å; Nb—Cl_{eq}: 2.210(1) Å; Nb—Cl_b: 2.643(1) Å). Raman spectra of $SbCl_5$–$NbCl_5$ mixtures were interpreted in terms of formation of the $[NbSbCl_{10}]$ dimer.[27,28] The interaction of MCl_5 with chlorides of other elements has been described; $TaCl_5$ was reported to exhibit no chlorinating ability, and $NbCl_5$ to chlorinate only $SnCl_2$.[29]

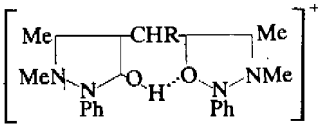
34.2.1.6 Applications of the pentahalides

MF_5 and MCl_5 are strongly electrophilic, and catalyze Friedel–Crafts type reactions, as first shown by Fairbrother.[30] The alkylation of aromatic compounds[31] and of alkenes[32] was reported. Among the group of extremely strong acid catalysts, the HF/TaF_5 system has interesting characteristics. It is very stable to reduction, especially by hydrogen and organic ions, and this has been exploited in the selective acid-catalyzed isomerization and hydrogenolysis of cycloalkanes.[33] It is also a liquid phase hydrogenation catalyst for aromatics,[34,35] alkylaromatics and heteroaromatics.[36] Synthesis of high polymers with simple Nb^V and Ta^V halides as catalysts has been reported;[37–40] disubstituted alkynes which, owing to steric hindrance, cannot be polymerized by Ziegler–Natta type catalysts were polymerized, whereas monosubstituted alkynes selectively gave cyclotrimers.

34.2.2 Halo Adducts

34.2.2.1 Anionic halo complexes

(i) Anionic fluoro complexes



Several species, including $[MF_6]^-$, $[MF_7]^{2-}$, $[MF_8]^{3-}$, $[MF_9]^{4-}$ and $[M_2F_{11}]^-$, have been detected in HF solutions of the metals, using a selective fluoride ion electrode,[41–43] or by ^{19}F NMR studies.[42,44–46] These complexes can be extracted by organic solvents; IR showed that solutions of trioctylamine in To or CCl_4 extract M^V from 1–12 M HF solutions as $[MF_6]^-$.[47]

MF_5 forms double salts with most ionic fluorides (Table 3). These can be obtained by direct mixing of the constituents in the molten state, or more usually by addition of an ionic fluoride to a solution of M_2O_5 in aqueous HF. Oxofluoro species were also formed; as expected, this occurred more readily for Nb than for Ta. Thus the addition of the appropriate metal carbonate to M_2O_5 solutions in HF yielded $[NbOF_5]^{2-}$ and $[TaF_7]^{-2}$ salts.[48]

The structure of $K_2[NbF_7]$ was first determined by X-ray diffraction,[49] then confirmed by neutron diffraction.[50] The niobium atom is at the center of a slightly distorted capped trigonal prism of six fluorine atoms, the seventh capping one of the rectangular faces of the prism (Nb—F: 1.940–1.978 Å); the same structure is found for $K_2[TaF_7]$. The $[TaF_8]^{3-}$ ion consists of a square antiprism.[51] The standard heats of crystallization of $A_2[MF_7]$ were evaluated from the heats of dissolution of the complexes in 3 M H_2SO_4 (2970 kJ mol^{-1} for $(NH_4)_2[TaF_7]$ to −3215 kJ mol^{-1} for $K_2[TaF_7]$).[52] The fused salt baths that are used in electrolytic production of the metals were shown to consist mainly of $[MF_7]^{2-}$ and $[MF_8]^{3-}$.[52,54]

$(NH_4)(HF_2)$[55] reacts exothermically with powdered Nb and Ta with intermediate formation

of metal hydrides to yield $(NH_4)_2[MF_7]$. Fluoride ion transfer reactions to the MF_5 Lewis acids were found to occur quite readily (Table 4).

The $[MF_5(SeF_4)]$ adducts are isostructural; the structure of the niobium compound, solved by X-ray diffraction, led to the ionic formulation $[SeF_3][NbF_6]$.[56] Strong bridging was found to occur between the ions, with four formulae units linked together in such a way that the Se and Nb atoms alternate at the corners of a distorted cube. The atomic arrangement found for $[(NbF_5)_2(SeF_4)]$[57] indicated the ionic structure $[SeF_3][Nb_2F_{11}]$.

The Lewis acidity of BF_3 and SbF_5 towards F^- was found to be higher than that of TaF_5 and NbF_5 (Table 4). $[NbF_5(SbF_5)]$ consists of an endless zigzag chain arrangement with alternating Sb and Nb atoms linked by *cis*-bridging fluorines.[58] Both metal atoms show a distorted octahedral coordination by F atoms consistent with a substantial contribution from the ionic $[NbF_4][SbF_6]$ form; four Nb—F distances were found at 1.81 Å and two at 2.17 Å.

While $K[MoF_6]$ was found to donate fluorine to MF_5, the ^{19}F NMR spectra measured on solutions of $[MF_6]^-$ and MoF_5 indicated the formation of $[M_2F_{11}]^-$ and $[MoMF_{11}]^-$.[59] The $[NbTaF_{11}]^-$ heteroanion was prepared from $[NbF_6]^-$ and TaF_5.[60] The $(O_2)[M_2F_{11}]$ salts[61] were obtained by heating the powdered metals with an F_2/O_2 mixture at 300–500 °C. When an excess of NOF was allowed to react with these salts, $(NO)[MF_6]$ and $(NO)_2[MF_7]$ were formed (equation 1).

$$(O_2)[M_2F_{11}] + 2NOF \longrightarrow 2(NO)[MF_6] + O_2 + 0.5F_2$$
$$(NO)[NbF_6] + NOF \longrightarrow (NO)_2[NbF_7] \qquad (1)$$

MF_5 was reported to combine with brown solutions of iodine in IF_5 to give intense blue paramagnetic solutions, but only in the case of Ta was a stable solid of composition $I[TaF_6]$ isolated.[62] KrF_2, when allowed to react with NF_3 in the presence of NbF_5 in HF solution, gave $(NF_4)[NbF_6]$.[63]

(*ii*) *Anionic complexes of the higher halogens*

MCl_5 and MBr_5 show much less affinity for Cl^- or Br^- than does MF_5 for F^-. MCl_5 when allowed to react with ACl (A = NH_4^+, alkali metal) in closed systems at *ca.* 300 °C gave $A[MCl_6]$.[64–66] The Ta derivatives are thermally more stable than those of Nb.[79] $(NH_4)[TaCl_6]$ was also obtained through the reaction of $ClNH_2$ with MCl_5 in CCl_4.[65] The $[MX_5(RCN)]$ adducts (X = Cl, Br), when allowed to react with $(NEt_4)X$, afforded $(NEt_4)[MX_6]$.[67] The ^{93}Nb spectra measured on MeCN solutions of MX_5 (X = Cl, Br) indicate the presence of $[NbX_6]^-$. Passing HX′ through these solutions gave the $[NbX'_6]^-$ anions (X′ = F or Cl).[68] $[MCl_6]^-$ can be extracted from 10 M HCl solutions in chloroform by amines.[69,70] Reactions of $K[HB(Me_2pz)_3]$ with MCl_5 yielded the interesting new compounds $[MCl_4][HB(Me_2pz)_3]$ and $[HB(Me_2pz)_3BH][NbCl_6]$;[71] the structure of the novel dibora cation was established.

Halogen transfer reactions were observed in the $Bu^tCl + RPCl_2 + MCl_5$ (R = Cl or Me) systems, yielding complexes of type $(Bu^tRPCl)[MCl_6]$.[72] The compounds $(EPh_4)[MX_6]$ (E = P, As) were obtained from the reaction of MX_5 (X = Cl, Br) with $(EPh_4)X$ in CH_2Cl_2 solution.[73,74] The $[MCl_5(PCl_5)]$ adducts are ionic and consist of discrete tetrahedral $(PCl_4)^+$ cations and octahedral $[MCl_6]^-$ anions.[75] A 1:1 mixture of $NbCl_5$ and $GaCl_3$ was reported to react in the melt to give molecular $[NbGaCl_8]$ built of an octahedron and tetrahedron sharing an edge.[76]

The X-ray powder patterns of $A[MX_6]$ (A = Na, K, Rb, Cs, Tl)[65,66,77] showed the low temperature modifications, with the exception of $K[NbCl_6]$, to be isotypic with $Cs[WCl_6]$, and the high temperature forms to crystallize in a cubic-face-centered arrangement. The Raman

spectra were taken to indicate O_h symmetry of the $[MCl_6]^-$ ions (A = Li, Na, K, Rb, Cs, Tl),[64] while other authors interpreted the spectra measured on $K[NbCl_6]$ and $Na[TaCl_6]$ as supporting a formulation such as $K_2[Nb_2Cl_{10}]Cl_2$ with isolated edge-sharing bioctahedra.[65] The electron transfer spectra of $(Et_4N)[MX_6]$ (X = Cl, Br) were investigated.[3,78]

The structures of $A[NbCl_6]$ $(A = (PCl_4)^+,[75]$ $(PPh_4)^+,[73])$, of $(PPh_4)[NbBr_6]$,[74] of $A[TaCl_6]$ $(A = (PCl_4)^+,[75]$ $[HB(Me_2pz)_3BH]^+$ [71]) and of $[TaBr_4(diars)_2][TaBr_6]$[80] have been reported. The metal displays octahedral coordination, with M—Cl distances ranging from 2.29 to 2.37 Å and M—Br distances from 2.48 to 2.51 Å.

(*iii*) *Mixed halo complexes*

MeCN solutions containing MCl_5[81] or MBr_5[82] and HF in a ratio of *ca.* 1:3 were found by ^{19}F NMR to contain the $[MF_6]^-$, $[MF_5X]^-$, *cis*- and *trans*-$[MF_4X_2]^-$, *mer*-$[MF_3X_3]^-$, and *cis*- and *trans*-$[MF_2X_4]^-$ ions. The ^{93}Nb NMR spectra of mixtures of $NbCl_5$ and $NbBr_5$ in MeCN show the presence of all seven possible mixed halides $[NbCl_xBr_{6-x}]^-$ with close to random halogen distributions.[83]

Solutions of mixed anions containing three halides were prepared.[84] Of the 46 possible octahedral $[MF_xCl_yBr_z]^-$ complex anions, the formation in solution of 38 tantalum complexes, of which 22 were bromochlorofluoro species, was recognized. The redistribution of the halides did not occur randomly, and the differences in free energy changes, $\Delta G = \Delta G_{exp} - \Delta G_{random}$, showed that the stability of the fluorochloro complexes decreases in the series: *trans*-$[TaF_4Cl_2]^- >$ *trans*-$[TaF_2Cl_4]^- > [TaF_5Cl]^- >$ *fac*-$[TaF_3Cl_3]^- >$ *cis*-$[TaF_4Cl_2^- >$ *cis*-$[TaF_2Cl_4]^- >$ *mer*-$[TaF_3Cl_3]^-$.[85]

34.2.2.2 Neutral adducts of the pentahalides

Characteristic of the Lewis acid behavior of MX_5 are their reactions with donor molecules. Differences are found, however, between the reactions of MF_5 and those of the other pentahalides. For example, $NbCl_5$ reacts with L = DMSO or HMPA to give $[NbOCl_3L_2]$, and the reaction of $TaCl_5$ with py under appropriate conditions gives $[TaCl_4(py)_2]$, while MF_5 reacts with DMSO and py to give $[MF_5L_n]$ complexes (n = 1, 2). $NbCl_5$ behaves both as a softer and as a weaker Lewis acid than $TaCl_5$ with respect to ethers and sulfides, for example.[86] The acceptor power of $[NbCl_{5-x}Me_x]$ decreases with x.[87,88]

The pentahalides form stable 1:1 adducts with a variety of donors. These are octahedral monomeric non-electrolytes, except for the adduct of TaF_5 with PBu_3,[89] which was shown by NMR to be the ionic $[TaF_4(PBu_3)_2]F$. NMR has been thoroughly used to study their structures in solution, as well as their relative stabilities and dynamic behavior. Relative stability scales for adducts with nitriles,[90] dialkyl chalcogenides[86,91] and phosphine oxides[92,93] have been established. The stability of the nitrile and phosphine oxide adducts was found to be controlled by inductive factors, while it was concluded that steric factors were determinant in the ether and sulfide adducts. The ligand exchange (equation 2) was reported to take place through a dissociative mechanism for L = RCN and OPR_3,[92,95] while an associative mechanism was postulated for $L = Me_2Y$ (Y = S, Se, Te)[96] in non-coordinating solvents. The exchange rates obey the sequences $MCl_5 \ll MBr_5$ for the dissociative mechanism, and $MF_5 > MCl_5 > MBr_5$ for the associative one.[97] NMR studies of $[TaCl_4(dppe)(Cp')]$ showed exchange between the free and monodentate dppe. The rates of intramolecular exchange between equatorial and axial fluorine atoms in $[MF_5L]$[95] have been evaluated by ^{19}NMR for $L = OMe_2$ and $OP(NMe_2)_{3-n}(OMe)_n$, where n = 0–3. NQR spectra have been measured for $[MCl_5L]$, where L = nitriles, ethers and phosphine oxides.[98] The electron transfer spectra of MX_5 adducts of several series of ligands (nitriles, dialkyl chalcogenides, phosphoryl and thiophosphoryl ligands, phosphines)[99] have been reported. Intermolecular charge transfer spectra indicate that MCl_5 interacts with aromatic hydrocarbons;[100] the equilibrium constants showed these interactions, however, to be very weak. The donor capacity of the solvent towards $NbCl_5$ was reported to decrease in the order: $Me_2NCOH > MeCN > RCOOR' > RCOR' > R_2O \approx C_4H_8O_2 > C_6H_6$.[101]

$$[MCl_5L] + L^* \rightleftharpoons [MCl_5L^*] + L \qquad (2)$$

L = RCN, OPR_3, Me_2Y (Y = S, Se, Te)

$[MX_5L_2]$ has also been isolated for many O, S, N, P and As donors. The MF_5 derivatives consist of ionic $[MF_4L_4][MF_6]$ in solution, while molecular structures with seven-coordinate metals appear to be equally likely in the solid state.[102,103] The analogous chlorides and bromides seem to be essentially molecular.

(*i*) *Oxygen donors*

MF_5 reacts with aliphatic ethers to yield volatile adducts of the $[MF_5(OR_2)]$ type; DMSO forms the bis adducts $[MF_5(DMSO)_2]$. MCl_5 and MBr_5 form numerous $[MX_5(ether)]$ adducts. Abstraction of oxygen from the ethers occurs at around 100 °C to produce oxo trihalides and alkyl halides.[1] The ability of crown ethers to coordinate and reduce MCl_5 has been explored;[104] $[(MCl_5)_2L]$ and $[MCl_5L]$ were isolated with L = dibenzo-18-crown-16, 18-crown-6 and 15-crown-5. NMR data indicate that these compounds disproportionate.

MCl_5, MBr_5 and acetophenone or benzophenone yield 1:1 complexes.[105] $TaCl_5$, when allowed to react with ethyl methyl ketone or diethyl ketone in a 1:1 molar ratio, gave 1:1 adducts, whereas oxygen abstraction occurred in the case of $NbCl_5$, resulting in the formation of $[(NbCl_4)_2O(R_2CO)_2]$;[106] with excess ketone, $[MOCl_3(R_2CO)_2]$ was obtained in both cases. Ketone complexes $[NbCl_5L]$ were, however, isolated from benzene solutions.[107] The reactions of $[MCl_{5-x}Me_x]$ ($x = 1, 2$) with bulky ketones yielded $[MCl_{5-x}Me_x(RR'CO)]$ for R = R′ = cyclohexyl; R = Me, R′ = Bu^t; R = Me, R′ = neopentyl, while addition of the methylmetal group to the carbonyl was found to occur with less bulky ketones and with benzaldehyde.[108] Dialkyl esters RCOOR′ were allowed to react with $NbCl_5$[109] to yield 1:1 and 2:1 complexes; the former, partially ionic in solution, were formulated as $[NbCl_4(RCOOR')_2][NbCl_6]$.

In the $[MX_5L_n]$ adducts formed with amides (X = Cl, $n = 1, 3, 4$; X = Br, $n = 1, 3$; L = $RCONH_2$, R = H, Me or Ph), the amide is bonded to the metal through its oxygen only.[110] Urea complexes $[MX_5L]$[111] (X = Cl, Br) have been prepared from MX_5 and tetramethylurea in CH_2Cl_2; coordination was shown by IR to be through oxygen only. On the other hand, oxathiane and oxaselenane gave $[NbCl_5(C_4H_8OY)]$ (Y = S, Se) in which, on the basis of IR and NMR data, they were proposed to be S- or Se-bonded, and not O-bonded, to the metal.

(*ii*) *Adducts of phosphine or arsine oxides, sulfides and selenides*

MF_5 forms $[MF_5L]$ and $[M_2F_{10}L]$ complexes with phosphoryl ligands.[93,112,113] In the dimeric compounds, the ligand is *cis* to the bridging fluorine.[113] With PSX_3 and $PSeX_3$, molecular pseudooctahedral $[MF_5L]$ complexes were obtained in which the ligands are bound to the metal through S or Se.[114] Atmospheric oxygen reacts with $[MF_5(SPX_3)]$ or $[MF_5(SePX_3)]$ to give $[MF_5(OPX_3)]$ along with sulfur or selenium precipitates.[114] Oxygen coordination took place when MF_5 was allowed to react with $R_2P(O)SR$ to give $[MF_5L]$ and $[M_2F_{10}L]$.[113] A thione–thiol rearrangement was observed when thiophosphoric esters $(EtO)_2P(S)OMe$ were added to a solution of TaF_5,[115] resulting in the formation of $[TaF_5\{OP(OEt)_2SMe\}]$; in the presence of traces of oxygen $[TaF_5\{OP(OEt)_2OMe\}]$ was also detected. The same rearrangement occurred in a solution of TaF_5 and $Ph_2P(S)OEt$, but at slower rates, so that both $[TaF_5\{SP(OEt)Ph_2\}]$ and $[TaF_5\{OP(SEt)Ph_2\}]$ complexes could be identified along with (in the presence of air) $[TaF_5\{OP(OEt)Ph_2\}]$. Solutions of TaF_5 and PBu_3 yielded $[TaF_5(OPBu_3)]$ upon aging.[89] ^{19}F NMR showed that equimolar solutions of MF_5 and of R_3AsY (Y = O, S; R = Bu, Ph) contain molecular $[MF_5L]$ together with ionic $[MF_4L_2][MF_6]$ compounds.[116] The following donor capacities towards TaF_5 were derived from ^{19}F NMR chemical shifts: $R_3AsO > R_3PO > R_3AsS \approx R_3PS$.

Phosphine oxide complexes $[MCl_5(R_3PO)]$ (R = Ph, Me, NMe_2)[117–119] and $[MCl_5(R_2R'PO)]$ (R = Ph; R′ = Bz) have been prepared. Nb^V forms an oxochloro adduct in the presence of excess $OPPh_3$.[1,120] When conducted in a non-basic solvent in the absence of MeCN, the action of HMPA on Nb_2Cl_{10} led to oxygen abstraction and formation of $[NbOCl_3(HMPA)_2]$,[117] while the 1:1 adduct $[NbCl_5(HMPA)]$ formed exclusively when a mixture of MeCN and CH_2Cl_2 was used as solvent, indicating the initial formation of a stable monomeric six-coordinate adduct $[NbCl_5(MeCN)]$. The O-coordinated $[MCl_5(OPCl_3)]$ adducts are monomeric in benzene but dissociate in nitromethane.[121] The existence of the niobium adduct in the gas phase has also been established.[122] The enthalpy of formation of the crystalline adduct from its components

was evaluated.[123] $TaCl_5$ and $NbCl_5$ were found to react readily with triphenylphosphole oxide to yield 1:1 adducts.[124]

MX_5L (X = Cl, Br; L = $SPPh_3$ and $SePPh_3$) was obtained; the formation of 2:1 complexes was not observed with these ligands. The pentabromides, but not the pentachlorides, gave 1:1 complexes with $Ph_2P(S)CH_2P(S)Ph_2$.[125]

(*iii*) *Sulfur, selenium and tellurium donors*

$[MX_5L]$ complexes (X = F, L = SMe_2, SEt_2; X = Cl, L = SMe_2, SEt_2, SPr_2, SC_4H_8, SC_4H_{10}, SC_4H_8O, SeC_4H_8O; X = Br, L = SMe_2, SEt_2, SC_4H_8, SC_5H_{10}, SC_4H_8) were easily prepared; they could all be either distilled or sublimed unchanged, except for $[NbBr_5(SEt_2)]$, which decomposed on heating. Alternatively, the ether ligands of $[MCl_5(OEt_2)]$ and $[MCl_5(OPr_2)]$ were readily replaced by their sulfide analog, while $[MCl_5(OMe_2)]$ remained unaffected by SMe_2. IR, Raman and NMR studies of the complexes formed with ambidentate O,S ligands showed bonding to occur *via* sulfur exclusively and the complexes to be mononuclear. With SMe_2 and SC_4H_8 evidence was found for $[NbX_5L_2]$ adducts.[126]

In $[NbCl_5(dth)]$, the dth = $MeSCH_2CH_2SMe$ ligand was shown by IR to be in the *gauche* chelating form. Bidentate ligands having bulky end groups, *e.g.* $Bu^tSCH_2CH_2Bu^t$ and $PhSCH_2CH_2SPh$, adopt a *trans* conformation and bridge the two metal atoms in the $[(MCl_5)_2L]$ adducts isolated.[126] Reactions of MCl_5 with cyclic polysulfides yield dimeric complexes in which the two MCl_5 units are bridged by the ligand; such $[(MCl_5)_2L]$ complexes were isolated with L = 1,4-dithiane[127] and various S_4 and S_6 cyclic polysulfides.[128] A 1:1 complex $[TaCl_5L]$ was, however, obtained with 1,3,5-trithiane.[127] The structure of $[(NbCl_5)_2(C_{10}H_{20}S_4)]$ (Figure 1) shows that the ligand exists with the most unusual 'inside out' conformation.[129,130] MCl_5 yielded S-coordinated 1:1 complexes when allowed to react with tetramethylthiourea.[111] A sulfur abstraction reaction occurred however when the reaction was followed by exposure to an intense light source, leading to $[(Me_2N)_2CCl][NbSCl_4]$.

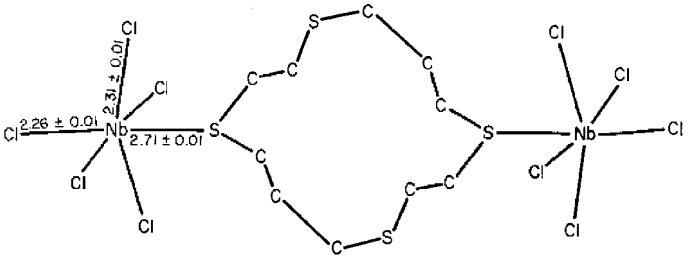

Figure 1 Molecular structure of $[(NbCl_5)_2(C_{10}H_{20}S_4)]$ (reproduced from ref. 128 with permission)

$NbCl_5$ and $TaCl_5$ were found to form 1:1 adducts with MeNCS and MeSCN;[131,132] the presence of both S- and N-bonded isomers was assumed on the basis of IR. Sulfur abstraction reactions occurred when $TaCl_5$ was allowed to react with PhNCS, to yield $[TaSCl_3(PhNCCl_2)]$. Reactions of $[MCl_{5-x}Me_x]$ ($x = 1, 2$) with MeSCN afforded $[MCl_4Me(MeSCN)]$ and $[MCl_3Me_2(MeSCN)]$,[133] which consist of mixtures of N- and S-bonded isomers.

(*iv*) *Nitrogen donors*

Niobium and tantalum halides form adducts with various nitrogen donor ligands including aliphatic and aromatic amines; nitriles, Schiff's bases and imidazoles (Table 5). The reactions of MX_5 with pyridine and related ligands such as bipy or phen depend critically on the reaction conditions. With py at low temperature MX_5 (X = Cl, Br) yielded 1:1 adducts that are rapidly reduced to $[MX_4(py)_2]$ on increasing the temperature, with formation of 1-(4-pyridyl)pyridinium halide. Similarly, bipy and phen reduced the metal in MeCN to oxidation state +IV and formed monoadducts of type $[MX_4(bipy)]$ at room temperature, while at 0 °C the same reactions yielded $[NbCl_5(bipy)(MeCN)]$ and $[TaX_5(bipy)(MeCN)]$ (X = Cl or Br). $NbBr_5$ and TaI_5 formed $[MX_5(bipy)_2]$, which were formulated as the eight-coordinate $[MX_4(bipy)_2]X$.[1] Reduction of the metal can however be prevented, even at room temperature,

when the reaction is conducted in dry benzene;[134] a series of isomorphous heptacoordinate compounds of type $[MX_5(bipy)]$ have thus been obtained.

The structure of $[TaCl_2Me_3(bipy)]$[135] shows tantalum to have distorted capped trigonal prismatic environment, with one chlorine atom in the capping position (Ta—Cl: 2.54(1) Å); the nitrogen atoms (Ta—N: 2.29(2) Å), one chlorine and one methyl group form the capped quadrilateral face, with two methyl groups (Ta—C: 2.24(4) and 2.16(6) Å) occupying the remaining edge.

Reactions of MX_5 (X = Cl, Br) with 2,2′,2″-terpyridyl[136] yielded the poorly soluble and moisture sensitive $[MBr_5(terpy)]$, $[NbCl_5(terpy)]$ and $[Ta_2Cl_{10}(terpy)]$. IR data suggest that all three pyridyl groups are coordinated.

Alkanenitriles readily gave 1:1 and 2:1 adducts with MF_5;[137,103] the 2:1 adducts are ionic and should be formulated as $[MF_4L_4][MF_6]$, while the 1:1 adducts are neutral $[MF_5L]$. The penta-chlorides, -bromides and -iodides afforded the monomolecular $[MX_5(RCN)]$ (Table 5).[13]

In $[NbCl_5(HCN)]$,[139] the niobium atom is octahedrally surrounded by five chlorines and by the nitrogen atom of HCN; the Nb—Cl bond *trans* to nitrogen is the shortest (2.243(1) a

compared to an average 2.313(1) Å for the other Nb—Cl distances); the N≡C distance of 1.090(4) Å is shorter than in free HCN. The reactions of $[MCl_{5-x}Me_x]$ ($x = 1$–3) with nitriles yield simple 1:1 adducts (Table 5), except for the formation of a small quantity of insertion product in the reaction of $[TaCl_4Me]$ with CCl_3CN.[140]

Complexes of MX_5 with dinitriles $CN(CH_2)_nCN$ ($n = 1$–4) have been prepared.[141,142] Both $[MX_5L]$ and $[MX_5L_2]$ have been isolated in the case of malonitrile, succinonitrile and glutaronitrile, whereas only $[(MX_5)_2L]$ formed with adiponitrile. In the case of succinonitrile and glutaronitrile, *trans* conformers have been assigned to the 2:1 adducts, while a *gauche* conformation was assumed in 1:1 complexes; the more stable *gauche–trans–gauche* conformation for adiponitrile was proposed in its 1:2 adducts.

The reactions of 8-quinolinol (oxH) with NbX_5 (X = Cl, Br) produced $[MX_5(oxH)_n]$ ($n = 2$, 4, 5, 6 or 10).[143,144] The interaction of $NbCl_5$ with Schiff's bases led to isolation of crystalline, sparingly soluble compounds having 1:1, 2:1 and 3:1 stoichiometries (Table 5); the ligands act as monodentates through the azomethine nitrogen atom. $NbCl_5$ was reported to form 4:1 adducts with substituted imidazoles,[145–147] which are 1:1 electrolytes in DMF. IR data indicate that coordination takes place through the unsaturated nitrogen of the imidazole ring in an eight-coordinated $[NbCl_4L_4]^+$ cation.

$TaCl_5$ and S_4N_4 were reported to form $[TaCl_5(S_4N_4)]$,[148,149] the S_4N_4 group being bonded to the metal through one of its nitrogen atoms (Figure 2).

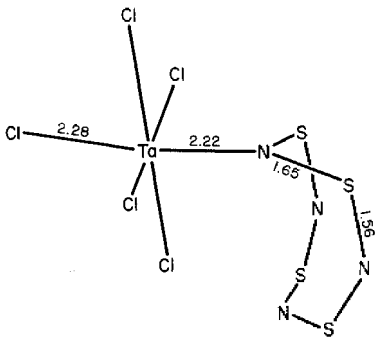

Figure 2 Molecular structure of $[TaCl_5(S_4N_4)]$ (reproduced from ref. 149 with permission)

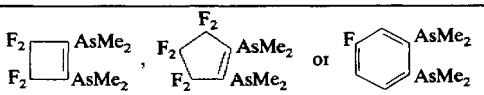
Complexes $[NbCl_4L]Cl$, where L = RNHCSNHpy, were obtained;[150] their IR spectra indicate bidentate behavior of L *via* sulfur and the heterocyclic nitrogen; they exhibit semiconductor properties. Similar behavior and properties were reported for the adducts formed with *N,N'*-diaryl-substituted formamidino-*N''*-aryl-substituted carbamides and thiocarbamides.



(*v*) *Phosphorus and arsenic donors*

The group Vb triphenyls form $[NbCl_5(EPh_3)]$ (E = N, P, As, Sb or Bi) in carbon tetrachloride, *n*-hexane or cyclohexane, while $[(NbCl_5)_2(EPh_3)]$ was obtained in benzene.[1] Table 6 illustrates the tendency toward increasing coordination numbers in the series $PPh_3 < PPh_2Me < P(OPh)_3 < PMe_2Ph \approx$ dppe < dmpe, which follows the decrease in the ligand's cone angle

Addition of diars to MCl_5 immediately precipitated the isomorphous red $[NbCl_5(diars)]$ and yellow $[TaCl_5(diars)]$;[151] being diamagnetic, they were reported to be seven-coordinate. X-Ray structure determinations,[152] however, indicated the presence of $[TaCl_4(diars)_2][TaCl_5(OEt)]$, $[NbCl_4(diars)_2][NbOCl_4]$ and $[NbCl_4(diars)_2][NbCl_3O_2]$, with an eight-coordinate dodecahedral cation. Similarly the compound first formulated as $[TaBr_5(diars)]$[151] was shown to be $[TaBr_4(diars)_2][TaBr_6]$;[80] the cation is a crystallographically imposed dodecahedron, (Ta—Br: 2.583(10); Ta—As: 2.765(1) Å). Fluorinated ditertiary arsines afforded $[MX_5(diarsine)]$[153] (X = Cl, Br), for which the exact formulation could not be established.

34.2.3.1 Alkoxides

(*i*) *Synthesis*

Equation (3) represents the reactions of MCl_5 with alcohols and phenols. They can be driven to completion by using ammonia as proton acceptor in the case of primary and secondary alcohols (Table 7).[154–156] $[Ta(OBu^t)_5]$ was obtained in the presence of pyridine, while under the same conditions $NbCl_5$ yielded $[NbO(OBu^t)_3]$. $[Nb(OBu^t)_5]$ could, however, be prepared from $[Nb(NR_2)_5]$.[157]

$$\begin{aligned} MCl_5 + 3ROH &\longrightarrow [MCl_2(OR)_3] + 3HCl \\ MCl_5 + 5PhOH &\longrightarrow [M(OPh)_5] + 5HCl \end{aligned} \qquad (3)$$

Transesterification reactions have been extensively used for the preparation of further alkoxides.[158–165] Mixed alkoxides $[M(OR)_{5-x}(OR')_x]$ were obtained from the same alcoholysis reactions.[166,167] Exchange reactions between $[Nb(OEt)_5]$ or $[Nb(OPr^i)_5]$ and organic acetates have also been exploited for the preparation of higher alkoxides.

Trialkylsiloxo derivatives were prepared by the reaction of the pentaethoxides with

trialkylsilanols,[158] or trialkylsilyl acetates, or by that of dialkylamides with triethylsilanol.[157] Mixed alkoxo–siloxo derivatives were obtained when $M(OEt)_5$ was allowed to react with Me_3SiOAc in various molar ratios.[168]

Double alkoxides with alkali metals $A[M(OR)_6]$ (Table 8) were formed from the reaction of the pentaalkoxides with alkali metal alkoxides.[6] The double alkoxides of Mg, Ca, Sr and Ba with Nb and Ta have been synthesized in the presence of $MgCl_2$ as a catalyst.[169] Refluxing $M(OPr^i)_5$ and $A(OPr^i)_3$ (A = Al or Ga) in isopropyl alcohol afforded double isopropoxides of the type $[MA(OPr^i)_8]$ and $[MA_2(OPr^i)_{11}]$[170]. $[NbTa(OMe)_{10}]$ appears to be the first mixed transition metal alkoxide isolated.[171] NMR showed it to be in dynamic equilibrium with the symmetrical $M_2(OMe)_{10}$ dimers in solution, with close to random distribution of the three species.

(*ii*) *Structural aspects*

$Nb(OMe)_5$ appears to be the only one of these pentaalkoxides whose structure has been solved.[172] It revealed the presence of two crystallographically different dimers with distinct conformations in the unit cell. Both are centrosymmetric and consist of two approximately octahedral units with a shared edge, but with either a *cis* or a *trans* arrangement of the terminal methoxo groups on each metal atom with respect to the equatorial plane (Figure 3).

The volatility of the alkoxides increases, and their molecular complexity decreases, with increased ramification of the alkyl chains (Tables 7 and 8). Variations observed in the degree of association in different solvents were assigned to the donor capacity of the solvent rather than to differences in dielectric constants.[154,155] The mean dissociation energies of the M—OR bonds

were estimated to be 429 ± 10 and $440 \pm 12\ kJ\ mol^{-1}$ for the Nb and Ta alkoxides respectively.[173]

Proton NMR studies have shown that $M(OR)_5$ species (R = Me, Et, Bu, Pr)[6,174–178] have dimeric bioctahedral structures in solution, and that the bridging and the two distinct types of terminal groups rapidly exchange positions. When R = Me the terminal–terminal alkoxide exchange was found to occur at a significantly faster rate than the terminal–bridging alkoxide exchange; hence these proceed through distinct mechanisms. The activation energy (E_a) for the intramolecular scrambling of terminal and bridging alkoxo groups was found to be fairly constant (42 to 50 kJ mol^{-1}), while the activation free energy $\Delta G^{\ddagger}$ increased by small amounts as the degree of chain-branching in the alkoxo ligand increased.[177] The presence of a monomer–dimer equilibrium was proven in the case of the pentaisopropoxides and the enthalpy of dissociation of the dimer was evaluated.[178] The monomeric *t*-butoxides showed a rapid intramolecular exchange down to −90 °C. Alcohol interchange was slower with dimeric species than with monomeric ones.

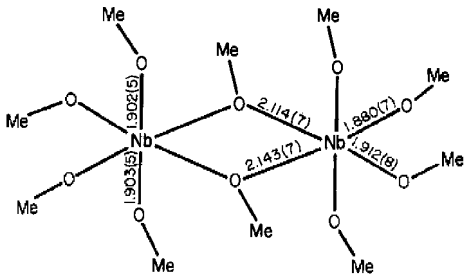

Figure 3 Molecular structure of $[Nb_2(OMe)_{10}]$ (reproduced from ref. 172 with permission)

Low temperature ^1H NMR of $[Nb_2(OMe)_{10}]$ in a variety of solvents has revealed significant variations of the chemical shifts, different for the various non-equivalent methoxo sites, particularly where bulky polar solvents are concerned; these were interpreted in terms of preferential solvation.[176]

(*iii*) *Chemical properties*

$M(OR)_5$ species do not readily form coordination complexes but prefer to autoassociate into dimers, trimers, *etc.* The coordination chemistry of $M(OMe)_5$ has been investigated by low

temperature NMR, and rationalized in terms of frontier orbitals and charge distribution on both the ligand and alkoxide.[176,179–184]

The electro-attractive alkoxo groups render metal alkoxides very sensitive to nucleophilic attack.[6] They are extremely susceptible to hydrolysis, which under controlled conditions yields oxo alkoxides; they require strictly anhydrous conditions of handling.

$M(OR)_5$ reacts with β-diketones, thio-β-diketones, β-keto esters and β-hydroxy esters (Table 9). Only three of the five OR groups could be replaced by these bidentate monoanionic $\overline{O}\ OH$ ligands. Surprisingly, the reaction of tropolone (HT) with $Nb(OEt)_5$ was reported to yield $[Nb(OEt)T_4]$,[185] whose structure remains unknown.

A more versatile behavior was observed with dianionic $H\overline{O}\ \overline{O}H$ ligands (Table 9): diols act as bidentates,[186,187] while α-hydroxycarboxylic acids behave as monodentate monoanionic ligands, *e.g.* in cinnamates,[188] or as bidentate dianionic ligands[189,190] in alkoxycarboxylates. In the case of catechol, ionic species were shown to exist in solution for both metals, but were isolated for tantalum only.[191] The bidentate monoanionic diphenylphosphinate ligand can replace from one to three alkoxo groups in $Ta(OMe)_5$ to yield low molecular weight polymers (Table 9).[192]

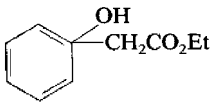
The alkoxo groups on Nb^V and Ta^V are not readily replaced by nitrogen ligands. Thus, with one equivalent of ethanolamine only the hydroxylic group was substituted.[193,194] Substitution by the amino group could however be forced by using a two- or three-fold excess of ethanolamine. Diethanolamine behaved as a tridentate trianionic ligand, while triethanolamine yielded metallatranes. The oximates and oxyaminates of Nb and Ta have been isolated.[185,195–198] The reactions of $M(OR)_5$ with both monofunctional bidentate and bifunctional tridentate Schiff's bases have been studied (Table 10).[199–203]

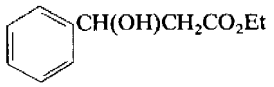
Insertion of unsaturated isocyanates into the M—O bond of $M(OR)_5$ has been reported[6,204,205] to give mono- to penta-substituted products (equation 4). No insertion into the Nb—O bond was observed with phenyl isothiocyanate.

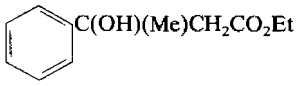
$$[M(OR)_5] + x\,PhNCO \longrightarrow [M(OR)_{5-x}\{N(Ph)COOR\}_x] \quad (4)$$

$M(OMe)_5$ undergoes peroxidation[206] on treatment with H_2O_2. The use of labelled $H_2O_2^*$ indicated the fixation of the labeled oxygen between M and OMe.

$M(OEt)_5$, when allowed to react with MeCOX (X = Cl, Br)[207] in 1:1, 1:2 and 1:3 molar ratios, formed $[MX(OEt)_4]$, $[MX_2OEt)_3]$ and $[MX_3(OEt)_2(MeCOOEt)]$, respectively; molar ratios of 1:4 or higher yielded $[MX_4(OEt)(MeCOOEt)]$, while the reaction with acetyl bromide afforded $[MOBr_3(MeCOOEt)]$. $Nb(OPh)_5$, when refluxed with excess acetyl bromide, gave $[NbBr_5(MeCOOPh)]$.[183] Redistribution reactions were shown to occur between TaI_5 and $[Ta(OPh)_5]$ in MeCN, and $[TaI_4(OPh)(MeCN)]$ crystallized out. Attempts to synthesize mixed $[NbI_{5-x}(OR)_x]$ derivatives from similar reactions have so far failed.[208]



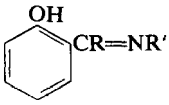


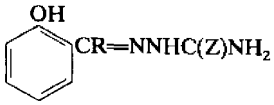


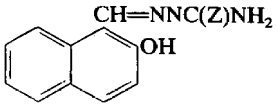
34.2.3.2 Halide alkoxides and related compounds

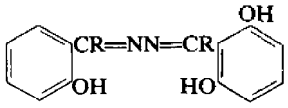
(*i*) *Halide alkoxides*

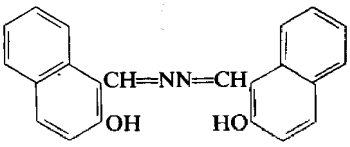
Direct reaction of MCl_5 with ROH yielded the mixed halide alkoxides $[MCl_x(OR)_{5-x}]$ (R = Me or Et, $x = 2$ or 3;[6] R = $MeOCH_2CH_2$, $x = 2$;[209] R = Ph, $x = 1$; R = β-naphthyl, $x = 2$; R = anthranyl, $x = 2$;[210] R = $CHF_2CF_2CH_2$, $x = 3$[6]). Stepwise alcoholysis of MX_5 in CCl_4 afforded $[MX_x(OR)_{5-x}]$ ($x = 0$–4 when X = Cl, R = Ph or naphthyl;[211] $x = 1$ or 2 for X = Br and R = Ph[212]). The reactions of $M(OR)_5$ with acetyl halides afforded easy access to $[MX_x(OEt)_{5-x}]$ (X = Cl, Br; $x = 1$ or 2[207]) and to $[TaI(OPh)_4]$.[208] Substitution of chlorine for a third or a fourth alkoxo group proceeded with coordination of the corresponding ester to the metal, while substitution by a fourth bromine resulted in the formation of oxo derivatives. Treatment of $TaCl_5$ with an excess of LiOAr (OAr = 2,6-di-*t*-butylphenoxide) in benzene led to $[TaCl_3(OAr)_2]$.[213] $TaCl_5$, when allowed to react with the chelating ether $MeOCH_2CH_2OMe$, gave $[TaCl_4(OCH_2CH_2OMe)]$, through cleavage of an alkyl–oxygen bond.[214] Neopentylidene complexes of the type $[TaX_3(CHCMe_3)(PR_3)_2]$ reacted with $[WO(OBu^t)_4]$ to yield $[TaX_3(OBu^t)_2]_2$.[215] Alkoxo fluorides were synthesized from the appropriate chloro methoxide with KF, or by the reaction of $M(OEt)_5$ with MF_5.[6]

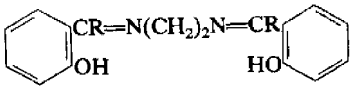


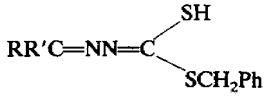


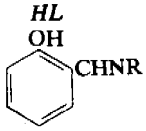


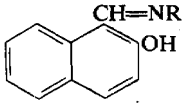












Treatment of the halide alkoxides with $(NEt_4)Cl$ afforded crystalline $(NEt_4)[MCl_x(OR)_{6-x}]$.[216] With 1:2 molar ratios, the oxo derivative $(NEt_4)_2[NbOCl_5]$ was

formed. The reaction between $(NEt_4)[MCl_6]$ and methanol yielded $(NEt_4)[MCl_4(OMe)_2]$, while $(NEt_4)[TaCl_x(OCH_2CH_2OMe)_{6-x}]$ ($x = 4$, 5) was obtained with 2-methoxyethanol.[209] NaOEt and pyHCl, when allowed to react with $[NbCl_4(OEt)]$ and $[NbCl(OEt)_4]$, yielded $Na[NbCl_5(OEt)]$, $Na[NbCl_4(OEt)_2]$, $(pyH)[NbOCl_4]$ and $Na[Nb(OEt)_6]$.[6] The thermal decomposition of $[NbCl_2(OMe)_3]$[217] in an argon or oxygen atmosphere gave Nb_2O_5 and ethylene as the main products.

The ^{19}F and ^{93}Nb NMR spectra of $MF_5/M(OEt)_5$ or $M(OEt)_5/HF$ mixtures established the formation of neutral, anionic and cationic complexes.[218–221]

The structure of $[TaCl_3(OCH_2CH_2OMe)_2]$[222] showed the metal atom to have an octahedral environment, one ligand being bidentate and the other monodentate, with three different Ta—O bond lengths (1.80(3) Å for the monodentate; 1.91(3) and 2.23 Å for the chelating ligand).

(*ii*) *Adducts of the halide alkoxides and related compounds*

The halide alkoxides behave as Lewis acids; they react with O, S, N and P donor ligands to give the adducts listed in Table 11. Haloalkoxo adducts of the type $MX_3(OR)_2L$ were obtained in anhydrous alcohol.[223,224] Unexpectedly, $[NbCl_3(OR)_2(HMPA)]$ was also obtained from the reaction of $[Nb(OR)_3Cl_2]_2$ with HMPA in CH_2Cl_2 or Et_2O.[225] Mixing of $M(OR)_5$ and MX_5 in MeCN gave $[NbCl(OEt)_4(MeCN)]$,[6] $[NbBr_4(OR)(MeCN)]$,[212] where R = Me, Et, Pr, Bu, CH_2Me_3, CMe_3, $[NbI_{5-x}(OR)_x(MeCN)]$, where $x = 0$–4 and R = Me, Et, Pr, Ph, and $[TaI_4(OR)(MeCN)]$, where R = Et, Ph.[208] $[NbCl_3(OEt)_2(MeCOOEt)]$ was isolated by allowing MeCOCl to react with $[NbCl_2(OEt)_3]_2$ and further afforded $[NbCl_3(OEt)_2(py)]$ by addition of pyridine.[207] These adducts are moisture sensitive, monomeric and predominantly non-ionic. The crystal of $[NbCl_3(OPr^i)_2(HMPA)]$ is built up of the meridional isomer.[225] The same isomer was always predominant in fresh solutions, while oxo species were detected in aged solutions.

MCl_5 when allowed to react with *N*-arylsalicylaldimines [(salR)H] in methanol or ethanol[226] afforded $[MCl_2(OR)_3(salR)H]$, in which the neutral Schiff's base behaves as a unidentate ligand bound through the oxygen atom. When chlorophenoxo derivatives were allowed to react with (salR)H, $[MCl_{4-x}(OPh)_x(salR)]$ ($x = 1$–4) was obtained.[227] When MCl_5 was treated in CCl_4 with a slight excess of monoanionic HL or dianionic H_2L' Schiff's bases derived from salicylaldehyde, vanillin, *p*-phenylazoaniline or *p*-aminodiphenylamine, $[NbCl_3L_2]$, $[NbCl_3L']$ and $[NbClL'_2]$[228] were obtained, in which Nb is heptacoordinated. The mass spectra and fragmentation paths of $[MCl(OR)_2L]$ were examined.[229]

Halide–8-quinolinol adducts $[MX_5oxH)_n]$ lose HX upon heating:[143] $[MX_x(ox)_{5-x}]$ complexes ($x = 1$–4) were prepared for all combinations of M, X and x except for $[NbBr_2(ox)_3]$. $[MBr(ox)_4]$ complexes were found to be 1:1 electrolytes, while conductance measurements and IR indicated the others to be non-electrolytes, with metal coordination numbers of nine, eight, seven and six for $x = 1$ to 4. Complexation of $NbCl_5$ by 1,6-dihydroxyphenazine yielded a brown insoluble linear coordination polymer formulated as $[M_2Cl_8(C_{12}H_6N_2O_2)_n]$.[230] With bidentate hydroxy esters (HL), MCl_5 gave $[MCl_{5-x}L_x]$ ($x = 1$, 2).[231]

Complexes of the type $[MX_x(OR)_{4-x}(\beta\text{-diket})]$, where X = Cl or Br, R = Me or Et, β-diket = acac, bzac (Table 11), have been obtained from MX_5 and the β-diketones in the parent alcohol as solvent. Chlorophenoxo niobium and tantalum derivatives react with benzoin (HL) to yield $[MCl(OPh)_3L]$ and $[MCl_2(OPh)_2L]$ in which L acts as a chelating ligand,[232] while MCl_5 were found to form $[MCl_4L]$ and $[MCl_3L_2]$ with benzoin.[233] The preparation of relatively stable Nb^V complexes containing *N*,*N*-dialkyldithiocarbamate ligands (R_2dtc) has been reported; the structure of $[NbCl(OMe)_2(Et_2dtc)_2]$[234] shows the metal's environment to be a pentagonal bipyramid with the halide and four sulfur atoms forming a plane containing the metal; the two OMe groups occupy the apical sites.

(*iii*) *Halide carboxylates and related compounds*

Chlorocarboxylato complexes were obtained from the reaction of $TaCl_5$ with RCOOH;[235] dimeric $[MCl_4(RCOO)]_2$ compounds were isolated for R = H, Me, Et, Pr, Pr^i, Bu^t, CF_3, while $[TaCl_3(Bu^tCOO)_2]$ was the only compound obtained with two carboxylato groups. Both types of compound were proposed to have sevenfold coordination. The reaction of $NbCl_5$ with dicarboxylic acids[236] gave $[NbCl_3\{X(COO)_2\}]$, where $X = (CH_2)_n$ ($n = 0$–4), CH(OH)CH(OH)

and *o*-C_6H_4. ^{19}F NMR data on solutions of $[MF_5]$ and $(CF_3COO)^-$ indicated that $[TaF_5(CF_3COO)]^-$ and $[TaF_4(CF_3COO)_2]^-$ had formed[237] with monodentate trifluoroacetate; a *cis* structure was assigned to the dicarboxylato derivative.

Reactions between MCl_5 and hydrogen phosphonates (HL = $(RO)_2P(O)H$; R = Et, Pr^i, Bu, Ph) afforded $[MCl_{5-x}L_x]$ (x = 1–3), which were reported to be polymeric through —O—P—O bridges.[238] NbX_5 when allowed to react with $Na[S_2P(OR)_2]$ (R = Me, Et, cyclohexyl) gave $[Nb(OMe)_2Cl\{S_2P(OR)_2\}_2]$;[239] recrystallization from the appropropriate alcohol afforded complexes having other alkoxo groups. The reaction of dithiophosphates with TaX_5 did not afford the analogous tantalum derivatives.

34.2.3.3 Thiolato and dithiocarbamato derivatives

Dithioalkoxo- and dithiophenoxo-niobium(V) trichlorides $[MCl_3(SR)_2]$ were obtained from $NbCl_5$ and thiols and benzenethiol respectively.[240] The synthesis of tris(benzenedithiolato) complexes was accomplished by reaction of the appropriate metal amide with a mixture of the dithiol and its sodium salt in THF. The structures of $(AsPh_4)[M(S_2C_6H_4)_3]$[241–243] showed the

metal to be surrounded by six sulfur atoms in a close to trigonal prismatic coordination, with the dithiolene ligands radiating from the metal in the usual 'paddle-wheel' arrangement (Figure 4). The coordination sphere of $[Nb(SCH_2CH_2S)_3]^-$ is midway between trigonal prismatic and octahedral.[243b]

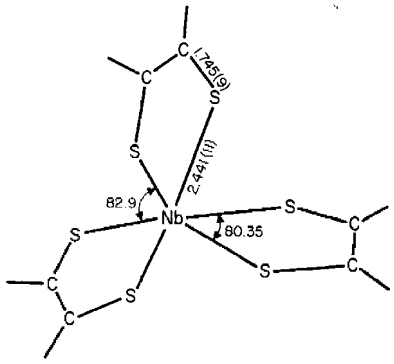

Figure 4 Structure of $[Nb(S_2C_6H_4)_3]^-$ (reproduced from ref. 243 with permission)

The trinuclear $[Ta(Cp)_2(\mu\text{-SMe})_2Pt(\mu\text{-SMe})_2Ta(Cp)_2]^{2-}$ anion was obtained by reaction of $[Ta(SMe)_2(Cp)_2]$ and $[PtCl_2(PhCN)_2]$.[244] The X-ray diffraction analysis[245] showed the arrangement around the Pt atom to be an almost regular tetrahedron, a situation hitherto unknown for Pt^{II}. The compound was therefore assumed to formally contain Ta^V and Pt^O, although the short Pt—Ta contacts of 2.788(7) and 2.809(8) Å are indicative of metal–metal bonds.

$[Ta(R_2dtc)_5]$, where $(R_2dtc) = (S_2CNR_2)^-$, were reported to result from insertion of CS_2 into $Ta(NR_2)_5$; in the case of niobium, the final product was $[Nb(R_2dtc)_4]$.[246] $[Ta(R_2dtc)_5]$[247] and $[MX_x(R_2dtc)_{5-x}]$ ($x = 1$–3) have been obtained in the reaction between MCl_5 and $Na(R_2dtc)$ in oxygen free solvents, while $[MX(OR)_2(R_2dtc)_2]$ was formed in alcohol.[239] $[Nb_2Br_3(R_2dtc)_5]$ was isolated from $NbBr_5$ in benzene.[250] Niobium, in acidic media in the presence of ClO_4^- ions, was found to form $[Nb(R_2dtc)_4](ClO_4)$ with pyrrolidine- and hexamethylene-dithiocarbamates.[251] $[Nb(R_2dtc)Me(Cp)_2](R_2dtc)$ was obtained when $[NbMe_2(Cp)_2]$ was allowed to react with $R_2NC(S)SC(S)NR_2$.[252]

In all these air sensitive complexes the dithiocarbamate ligand is bidentate through the sulfur atoms. The $[MX_x(R_2dtc)_{5-x}]$ adducts were found to be ionic, hence must be formulated as $[M(R_2dtc)_4]X$, $[\{Nb(R_2dtc)_3\}_2Cl_3]Cl$ and $[M(R_2dtc)_4][MX_6]$.[249] The structures of $[Ta(S_2CNMe_2)_4]^+$ in the Cl^- [253] and $[TaCl_6]^-$ [254] salts showed the eight-coordinate $[Ta(R_2dtc)_4]^+$ cation to be at the center of a D_{2d} dodecahedron, the bidentate ligand spanning the AB edges. Surprisingly, this cation is stereochemically rigid on the NMR time scale and appears to be the first eight-coordinate chelate for which this is observed.

34.2.3.4 Amido derivatives

Several reviews have dealt with the chemistry of transition metal–nitrogen derivatives,[255–257] including compounds with metal–nitrogen multiple bonds,[258,259] especially those encountered in high oxidation states.

Solvolysis of MCl_5 by ammonia was studied as early as 1924, but the products were not conclusively characterized.[260,261] Halo monoalkylamides[262] and dialkyl amides were prepared. The monoalkylamides undergo facile α-H abstraction reactions to nitrenes, especially when labile substitutents are present (Section 34.2.3.5); dialkylamides (Table 12) have been extensively studied by Bradley.[263–265]

(*i*) *Synthesis and structure*

Homoleptic Nb^V and Ta^V dialkylamides have been obtained (equation 5).[263,264] Extensive reduction, increasing with the length of the alkyl chain, was observed with niobium, the predominant products then being $[Nb(NR_2)_4]$ (R = Et, Pr^n, Bu^n; Section 34.3.5.4). Oxidation

state +V was retained for tantalum, and either the amides $[Ta(NR_2)_5]$ or the mixed nitrene amides $[Ta(NR)(NR_2)_3]$ (R = Et, Pr^n; Section 34.2.3.5) were isolated.

$$MCl_5 + 5LiNR_2 \longrightarrow [M(NR_2)_5] + 5LiCl \qquad (5)$$
$$R = Me, Et, Pr^n, Bu^n$$

The coordination polyhedron of the dialkylamides is largely determined by the steric requirements of the NR_2 groups and by their ability to form σ and π bonds.[256] Even the NMe_2 group is sterically demanding, and the homoleptic Nb and Ta amides are all monomers. Dimeric halogen-bridged structures were observed for mixed dialkylamido compounds, as, for example, in $[TaCl_2(NMe_2)_3]_2$. For pentacoordinated d^0 compounds, a trigonal bipyramidal geometry is expected to be the most stable.[266] $[Ta(NEt_2)_5]$ indeed exhibits this geometry,[256] but $[Nb(NMe_2)_5]$ (Figure 5) and $[Nb(NC_5H_{10})_5]$ approach a square pyramidal geometry.[267] Although all nitrogen atoms have approximately planar geometry, only the axial Nb—N bond appears to have some π character on the basis of its shorter length (single Nb—N bond lengths are expected to be in the 2.04 to 2.08 Å range); the planarity found for nitrogen has been interpreted to result from the rather tight packing of the ligands around the metal. $[M(NMe_2)_5]$ species were found by photoelectron spectrometry to be isomorphous in the vapor phase, but their exact geometry has not been established.[268]

Mixed halodialkylamido derivatives are accessible by several methods.[262,269] The chlorodimethylamidotantalum(V) derivatives have received special attention from Chisholm and coworkers.[270] Reaction of the pentachloride with an excess of dimethylamine provided $[TaCl_3(NHMe_2)]$ as the major product (85%), accompanied by $[TaCl_2(NMe_2)_3(NHMe_2)]$ (6%) and by a dinuclear oxo derivative $[\{TaCl_2(NMe_2)_2(NHMe_2)\}_2O]$ (2%), whose origin is undetermined. A common feature of these products is their fairly strong Ta—N bond. Metathesis reactions between $[Ta(NMe_2)_5]$ and Me_3SiCl led to close to random distributions of the halodialkylamido complexes, from which $[TaCl_2(NMe_2)_3]_2$ was easily isolated from pentane

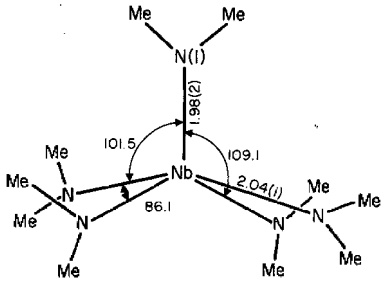

Figure 5 Coordination polyhedron of $[Nb(NMe_2)_5]$ (reproduced from ref. 267 with permission)

and a mixture of $[TaCl_2(NMe_2)_3]_2$ and $[TaCl_3(NMe_2)_2]_2$ from toluene solutions. The dimeric $[TaCl_2(NMe_2)_3]_2$ is readily cleaved by nitrogen donors to form $[TaCl_2(NMe_2)_3L]$ adducts (L = Me_2NH, γ-pic). Attempts to isolate $[TaCl(NMe_2)_4]$ were unsuccessful.

The structures of $[TaCl_3(NMe_2)_2(NHMe_2)]$ and $[TaCl_2(NMe_2)_3]_2$ have been solved.[270] Tantalum adopts a distorted octahedral geometry in all structures. The central $TaCl_3N_3$ core of the trichloro adduct has a meridional arrangement of the chlorine atoms with *cis* dimethylamido ligands. The two Ta—NMe_2 bonds are comparable in length (1.958 Å av.), and much shorter than the Ta—$NHMe_2$ distance (2.370(6) Å). The centrosymmetric dimeric structure of $[TaCl_2(NMe_2)_3]_2$ displays two *fac*-TaN_2Cl_3 arrangements with bridging chlorines (Ta—Cl_b: 2.586(1) and 2.635(2) Å). The amido $TaNC_2$ units are all planar. This, together with the short Ta—N distances and the close to 90° dihedral planes between these units, provides evidence for strong Ta—N d_π–p_π bonding. The Me_2N ligand in each of these molecules was considered as a four-electron donor ($\sigma^2 + \pi^2$), leading to 18- or 16-electron valence shells in $[TaCl_2(NMe_2)_3]_2$ and $[TaCl_3(NMe_2)_2(NHMe_2)]$, respectively. A *fac*-$TaN_3$ arrangement is a common feature of all these structures, as ligands having a strong *trans* influence tend to prefer a mutual *cis* configuration, irrespective of their π acceptor or π donor properties.[271] A *cis* arrangement of the dimethylamido groups was therefore assumed for $[TaCl_3(NMe_2)_2]_2$ and $[TaCl_2(NMe_2)_3(NHMe_2)]$.

Pentavalent silylamido derivatives are limited to Ta, as reduction occurs with Nb.[272,273] The bulkiness of the $[N(SiMe_3)_2]^-$ ligand precluded complete chlorine substitution as well as formation of dimers. $[TaCl_3\{N(SiMe_2)_2\}_2]$ has a trigonal bipyramidal structure with short equatorial Ta—N bonds (1.930 Å av.).

The first hydrazido(−1) compounds, $[M_2Cl_8(HNNRR')_2]$ (R = Ph, R′ = H or Me) and $[TaCl_3(HNNHPh)_2(H_2NNHPh)]$, were obtained from the reaction of the pentachlorides with the hydrazines.[274] Spectroscopic data on $[TaCl_3(HNNHPh)_2(H_2NNHPh)]$ are consistent with an equilibrium between neutral and ionic structures, as also observed for molybdenum hydrazido derivatives.

(*ii*) *Reactivity*

Niobium and tantalum dialkylamides can easily undergo substitution or insertion reactions, as well as C—H activation. Substitution reactions have been used to obtain dialkylamides[262] or dithiolenes.[275] Aminolysis reactions, for instance, were assumed to occur *via* a simple associative mechanism (equation 6).[276]

$$M{-}NR_2 + NHR'_2 \rightleftharpoons \left[\begin{array}{c} R'_2N{-}H \\ \vdots \quad \vdots \\ M{-}NR_2 \end{array}\right] \rightleftharpoons M{-}NR'_2 + HNR_2 \qquad (6)$$

The M—N bond is susceptible to insertion reactions, the Ta—N being even more reactive than the Ta—C bond; thus in $[Ta(NMe_2)_2Me_3]$, insertion of CS_2 was found to occur only in the former bond.[277] Insertion of CO_2, CS_2 and COS in $[M(NR_2)_5]$ has been observed.[276,278] In the case of niobium, the insertion of CS_2 was accompanied by reduction, giving $[NB(S_2CNR_2)_4]$ (Section 34.3.5.3.i).[279] The *N,N*-dialkylcarbamato ligand, O_2CNR_2, is much less prone to oxidation and the pentavalent state was retained for both niobium and tantalum. The synthesis of monothiocarbamates is limited to $[Ta(OSCNMe_2)_5]$.[278]

The mechanism of the CO_2 exchange and insertion reactions has been extensively studied on $[M(NMe_2)_5]$ using kinetic and labeling experiments. The insertion is catalyzed by amines (equations 7 and 8). It is rapid and quantitative, and proceeds through $[M(NMe_2)_{5-x}L_x]$ intermediates, the Ta derivatives being more stable than those of Nb.[272] None of the mixed species is favored. $[M(NMe_2)_2(O_2CNMe_2)_3]$ formed for both metals, but could be isolated only for tantalum. The formation of $[M(NMe_2)_3(O_2CNMe_2)_2]$ was not observed.

$$HNMe_2 + CO_2 \rightleftharpoons HO_2CNMe_2 \quad (7)$$

$$MNMe_2 + LH \rightleftharpoons ML + HNMe_2 \qquad L = O_2CNMe_2 \quad (8)$$

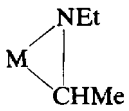
The coordination spheres of $[M(O_2CNMe_2)_5]$ and $[Ta(NMe_2)_2(O_2CNMe_2)_3]$ contain both mono- and bi-dentate dialkylcarbamato ligands. The magnitudes of the $\Delta\nu(^{12}C-^{3}C)$ and $\Delta\nu(^{16}O-^{18}O)$ ($\Delta^{18}O$) shifts in the IR were rationalized by assuming that $\nu(O_2CN)$ is mainly C=N in character for a bidentate ligand ($\Delta^{18}O < 5\ cm^{-1}$), while a significant contribution from the C=O moiety is observed for a monodentate ligand ($\Delta^{18}O$ *ca.* $20\ cm^{-1}$).

X-Ray diffraction data for $[Nb(O_2CNMe_2)_5]$[278] show that niobium is eight coordinated, with three bidentate and two monodentate *cis* $(Me_2NCO_2)^-$ ligands; The NbO_8 moiety does not correspond to any idealized MX_8 polyhedron. The Nb—O bond distances are much shorter for the monodentate (av. Nb—O = 1.91(2) Å) than for the bidentate ligands, the latter being asymmetrically bonded (av. Nb—O = 2.08(4) and 2.19(2) Å). In $[Ta(NMe_2)_2(O_2CNMe_2)_3]$[280] the metal's coordination polyhedron can be described as a distorted pentagonal bipyramid with two bidentate carbamato ligands in the equatorial plane and one monodentate ligand in an axial site. This geometry is particularly propitious to Ta—N π bonding (Ta—N: 1.970 Å av.), to attain a saturated valence shell configuration, which accounts for the kinetic and thermodynamic stability of the compound. It should be noted that the bite of the carbamato ligand (2.15(5) Å) compares with that of NO_3^- in $[Ti(NO_3)_4]$ and is considerably smaller than that of the dithiocarbamato ligand (2.84(3) Å), which may explain why oxidation state +V is maintained for niobium.

In solution these compounds are highly fluxional. Whereas the methyl groups are all stereochemically inequivalent in solid $[Nb(O_2CNMe_2)_5]$, they appear equivalent in solution, even at −80 °C, on the ^{13}C NMR time scale. The mono- and bi-dentate carbamato substituents can, however, be distinguished in solution by IR. A facile exchange between coordinated and uncoordinated oxygens of the monodentate carbamato ligand was also observed in $[Ta(NMe_2)_2(O_2CNMe_2)_3]$. Hindered rotation about the Ta—N linkage was detected at −95 °C by ^{13}C NMR.[280]

Although cyclometallation reactions have seldom been observed with d^0 metal compounds, intramolecular metallation involving early transition metal dialkylamides with formation of azametallacyclopropane, which occurs by β H abstraction, has been reported.[281]

On distillation, $[Ta(NEt_2)_5]$ undergoes substantial decomposition (equation 9) to give ethyliminoethyl(*C,N*)tris(diethylamido)tantalum (**1**) and ethylimidotris(dimethylamido)tantalum (**2**).[282,283] The IR and NMR data of the methine carbon of (**1**) [^{13}C: $\delta = 64$ p.p.m., $J(C-H) = 147$ Hz (d)] indicate a notable C—N double bond character. Compound (**1**) reacts easily with methyl isocyanate, according to equation (10). The metallacycle (**1**) was shown to be an intermediate in the formation, above 100 °C, of the ethylimido complex (**2**) and ethylene. The reaction is first order with respect to the azametallacycle; the activation parameters were evaluated. The formation of ethylimino (*C,N*) groups (**3**) appears to be a general feature in the thermolysis of 'overcrowded' early transition metal diethylamido derivatives. It has also been observed for niobium, together with $[Nb(NEt_2)_4]$ as the major product. A similar three-membered metallacycle could not be isolated in the case of $[Ta(NMe_2)_5]$, but was presumed to form as an intermediate in the facile and reversible incorporation of deuterium from $^2HNMe_2$ into the methyl groups (equation 11). The intermediate azametallacyclopropane (**4**) can apparently be trapped by terminal alkenes, resulting in the catalytic aminomethylation of the alkenes (Scheme 1). $[Ta(NMe_2)_5]$ was recovered unchanged after the reaction, while the niobium analog was reduced to an as yet unidentified active species with evolution of methane.



Hydrogen abstraction reactions from the $(NR_2)^-$ ligand have been observed even at room temperature (equation 12).[284] With diisopropylamidolithium, the reaction is more complex; the only product isolated (≈10%) was the unusual methylene- and hydride-bridged compound (**7**; equation 13). Labeling experiments gave evidence that the hydride originates from the

$$[Ta(NEt_2)_5] \xrightarrow{\Delta} \left[\begin{array}{c} EtN \\ | \\ MeCH \end{array}\!\!>\!Ta(NEt_2)_3\right] + [Ta(NEt)(NEt_2)_3] + Et_2NH \qquad (9)$$

diisopropylamide. It was suggested that the formation of a Ta—N bond is prevented by the steric bulk of the NPr^i group; hydride donation then becomes competitive. These spontaneous or thermally induced reactions may all be viewed as unimolecular β hydrogen abstraction or elimination reactions. With monoalkylamides, α hydrogen transfer processes appear to be more facile than β hydrogen migrations, and open a route to nitrenes (equation 14). The rate of the hydrogen transfer process depends on the nature of the group (OR, NR_2, CR_3) bonded to tantalum; caution should be used in extrapolating the observed rate order, since it is based on compounds with the $TaMe_3(Cp')$ moiety.

34.2.3.5 *Nitrenes*

Coordinated nitrenes RN^{2-} have been thoroughly investigated in recent years[285,286] owing to their formal similarity to carbenes and to their potential importance, *e.g.* as catalysts in the Haber ammonia process. Theoretical studies have suggested that imido ligands may also prove effective in promoting alkene metathesis.[287]

(*i*) *Synthesis and structure*

The first tantalum nitrene was obtained in 1959 by thermolysis of $[Ta(NEt_2)]_5$.[288] This class of compounds is presently accessible by several routes, including hydrogen abstraction from the mono- or di-alkylamides, reaction of metallacarbenes with organic imines, oxidation of low valent species by organic azides, or reductive coupling of nitriles (Table 13). The tantalum derivatives are usually stabler than those of niobium.

As stated above, α H abstraction is favored with respect to β H transfer, and the unstable monoalkylamides are converted to nitrenes. $[Ta(NBu^t)(NMe_2)_3]$ (**8**) has been prepared by two

Scheme 2

The structure of $[TaCl(NBu^t)(NHBu^t)(NH_2Bu^t)(\mu - Cl)]_2$ (**9**) was shown to be dimeric with nearly symmetrical, long chloro bridges (Figure 6). Compound (**9**) is remarkable as imido, amido and amino ligands are present simultaneously on the same metal. Also of interest is the very short Ta—N(amido) bond and the large corresponding TaNC bond angle. The lengthening of the Ta—Cl bond *trans* to it has been considered as a confirmation of significant π contribution to the Ta—N(amido) bond. A close intermolecular approach to the metal (Ta · · · H—N: 2.0 Å), resulting in pseudo seven-coordination, was observed for amido protons; a two-electron three-centered bond has been suggested.

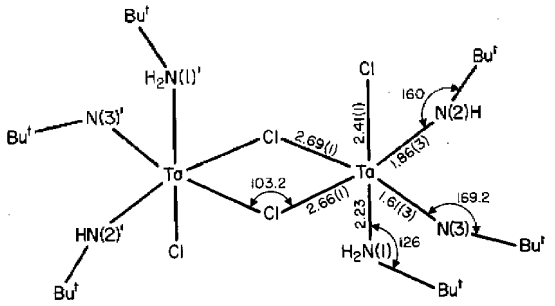

Figure 6 Molecular structure of $[TaCl(NBu^t)(NHBu^t)(NH_2Bu^t)]_2^-$ (**9**) (reproduced from ref. 290 with permission)

More complicated sequences involving successive substitutions of the chlorine on the metal have also been used successfully to obtain nitrenes (equation 17).[291] A comparable approach led to the first Nb hydrazido(−2) compounds: $[Nb(NNR_2)(R'_2dtc)_3]$ ($R_2 = Me_2$; PhMe; R′ = Me or Et) and $[Nb\{NN(CH_2)_5\}(Et_2dtc)_2]$.

$$NbCl_5 + 3RNH_2 + 3Me_3Si(R'_2dtc) \longrightarrow [Nb(NR)(R'_2dtc)_3] + 3Me_3SiCl + 2RNH_3Cl$$
$$R = Me, Pr^n, Bu^i, Bu^t, Ph, p\text{-tolyl}, p\text{-}NC_6H_4OMe, \quad R' = Et; \quad (17)$$
$$R = Bu^t, p\text{-tolyl}, p\text{-}C_6H_4OMe, \quad R' = Me$$

Metatheses between neopentylidene complexes and organic imines are an attractive simple general and selective entry to alkylimido compounds.[292] The experimental results can be rationalized by the formation of an intermediate with an MC_2N ring (equation 18). They also provide a straightforward route to μ-dinitrogen compounds, using PhCH=NN=CHPh (Section 34.2.3.6). Alkenylimides were prepared by nucleophilic attack of nitriles on the α

carbon of alkylidenes (equation 19). A similar reaction with acetonitrile was used to trap the unstable $[TaCl(CHCMe_3)(CH_2CMe_3)_2]$ at −78 °C.[293]

$$M{=}CHCMe_3 \xrightarrow{R'CH{=}NR} \underset{\displaystyle N\atop\displaystyle R}{\overset{CMe_3}{M\!\!<^{R'}}} \xrightarrow{-Me_3CCH{=}CHR'} M{=}NR \qquad (18)$$

$$[M(=CHCMe_3)(CH_2CMe_3)_3] \xrightarrow{RCN} \left[(Me_3CCH_2)_3M{=}N\!-\!\underset{R}{C}{=}CHCMe_3\right] \qquad (19)$$

M = Ta; R = Me, Ph
M = Nb; R = Me

Oxidative addition of organic azides to low valent species, mainly in oxidation state +III, was found to be a general method for obtaining pentavalent mono- or di-nuclear nitrene derivatives.[294] Applied to Nb^{I} compounds, it led to the first dinitrene compound.

Niobium(III) and tantalum(III) adducts with sulfur or nitrile ligands undergo remarkable reactions involving reductive coupling of nitriles and oxidation of the metal to pentavalent nitrenes.[295,296,297] $[Ta_2Cl_6(THT)_3]$ (**10**) (THT = C_4H_8S) can serve as a convenient source of Ta^{III}; its reaction (equation 20) with nitriles is rapid and quantitative. As the reaction was not observed with pivalonitrile or benzonitrile, it appears to be sensitive to steric hindrance. $[Ta_2Cl_6(THF)_2(\mu\text{-}C_6H_4N_2)]$ (**11**; Figure 7)[297] and the $[Nb_2Cl_8(MeCN)_2(\mu\text{-}C_6H_4N_2)]^{2-}$ anions (**12**)[295] are centrosymmetric with octahedral arrangements around the metal atoms. Most remarkable is the new bridging 1,2-dimethyl-1,2-diimodoethylene ligand, which derives from two MeCN molecules by a process formally represented in equation (21). The Ta—N and Nb—N bond distances (1.75(1) Å for both **11** and **12**) imply a close to triple bond character (a distance of 1.70 Å is expected for an M≡N bond). The MNC arrangements are essentially linear, the organic skeleton being planar with a *trans* configuration. The central C—C distances are slightly longer than the standard C=C distance of 1.335 Å. A notable lengthening, of *ca.* 0.20 Å, is seen in (**11**) for the Ta—O distance *trans* to the multiple Ta—N bond.

$$[(THT)Cl_3Ta(\mu\text{-}Cl)_2(\mu\text{-}THT)TaCl_3(THT)] \xrightarrow{RCN} \left[L_2Cl_3Ta{=}N\!-\!\underset{R}{C}{=}\underset{R}{C}\!-\!N{=}TaCl_3L_2\right] \qquad (20)$$

(**10**)

L = RCN; R = Me, Et, Pr^n, Bu^i

$$\begin{matrix}Me & N\\ | & \|\\ C & +\ C\\ \| & |\\ N & Me\end{matrix} \longrightarrow \begin{matrix}Me & & \ddot{N}:\\ & C{=}C & \\ :N & & Me\end{matrix} \qquad (21)$$

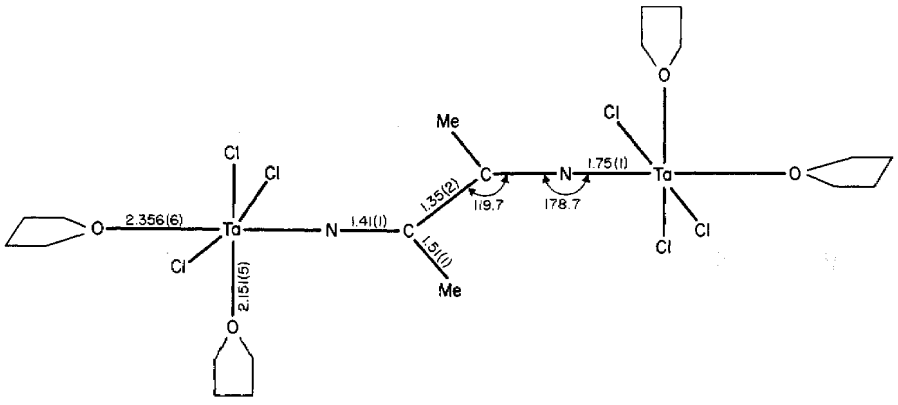

Figure 7 X-Ray structure of $[Ta_2Cl_6(THF)_2(\mu\text{-}C_6H_4N_2)]$ (**11**) (reproduced from ref. 297 with permission)

X-Ray data are also available for monomeric nitrene derivatives such as $[Ta(NBu^t)(NMe_2)_3]$ (**8**),[290] $[Ta(NPh)Cl_3(PEt_3)(THF)]$ (**13**)[298] and $[Nb(p\text{-}NC_6H_4Me)(Et_2dtc)_3]$ (**14**).[291] M—N bonds compare well with those reported above, and the MNC angles are close to 180°, in all but (**14**) in which the metal is heptacoordinated. The metal–nitrene bond was therefore described as an M≡NR triple bond, and the imido ligand as a four-electron donor. The oxo and organoimido ligands are isoelectronic. The Nb≡NR bond in (**14**) is indeed just 0.04 Å longer—the expected difference in radii between N and O—than the oxo bond (1.74(1) Å) in $[NbO(Et_2dtc)_3]$. These observations are consistent with those made for tantalum on $[TaO(NPr^i_2)_3]$[285] and $[Ta(NBu^t)(NMe_2)_3]$.[290]

All these compounds have high thermal stability, and are more soluble than their oxo analogs. They show a vibration around 1350 cm^{-1} in the IR, which shifts to lower frequency upon ^{15}N labeling ($\Delta\nu(^{14}N\text{–}^{15}N) = 22\ cm^{-1}$).[299,292] This fairly high energy absorption, whose frequency is only slightly affected by the ancillary ligands, has been interpreted as a combination of the M—N and N—C stretching modes.[291] ^{15}N NMR data have been reported for both Ta^V and Ta^{III} nitrenes, the latter appearing at higher fields.[292] In the ^1H NMR, the key feature is a downfield shift of *ca.* 1 p.p.m. of the hydrogen on the α carbon of the NR group.[285] The ^{13}C chemical shift difference, $\Delta = \delta C_\alpha - \delta C_\beta$, was used as a probe for evaluating the electron density on nitrogen.[300]

(*ii*) *Reactivity*

Information on the chemical reactivity of these nitrenes is limited; the NR groups are tightly bound to the pentavalent metal and not readily displaced.

The Ta^V nitrenes formed by reductive coupling of acetonitrile appear to be relatively resistant to protic attack.[296] $[M(NR)(R'_2dtc)_3]$ undergoes reversible protonation by strong acids, but the site of attack, as well as the reaction products, could not be determined.[291] It is of interest that hydrogenation of $[Ta(NR)Me_2(Cp')]$ afforded the imido hydrides $[TaH_2(NR)L(Cp')]$ (**15**) and not the amide complexes, even in the presence of an excess of phosphine (equation 22).[284] Compounds (**15**) appear to be, with the Re^V derivatives $[ReH(NR)Cl_2(PPh_3)_2]$ and $[ReH(NR)Cl(OR')(PPh_3)_2]$, the only mononuclear transition metal imide hydride complexes described so far. Their hydrogens are 'hydridic'; they reduce acetone to the isopropoxo group (equation 23). This reaction and the metathesis of imidochloride derivatives by alkaline reagents[292] constitute alternatives for producing imido alkoxides. The action of alcohols removes the imido ligand (equation 24). $Ta(OR)_5$ was obtained in high yields from $[Ta(NPr)(NPr_2)_3]$, although the NR group is more resistant to alcohols than the NR_2 group.[157]

$$[Ta(NR)Me_2(Cp')] + L \xrightarrow{H_2(\sim 4\ atm)} \underset{(\mathbf{15})}{[TaH_2(NR)L(Cp')]} + 2CH_4 \qquad (22)$$

$$R = Bu^t,\ CH_2CMe_3;\quad L = PMe_3,\ PPhMe_2$$

$$\underset{(\mathbf{15})}{[TaH_2(NR)L(Cp')]} + 2O{=}CMe_2 \longrightarrow [Ta(NR)(OCHCMe_2)(Cp')] + L \qquad (23)$$

$$R = Bu^t,\ CH_2CMe_3;\quad L = PMe_3,\ PPhMe_2$$

$$\underset{(\mathbf{15})\ L = PMe_3}{[TaH_2(NR)L(Cp')]} + MeOH \longrightarrow [Ta(OMe)_4(Cp')] + RNH_2 + L \qquad (24)$$

The various Nb and Ta nitrenes were converted to oxo derivatives by an excess of carboxylic compounds.[291,296] This seems characteristic of the nucleophilic reactivity of nitrenes, but water is sometimes required (equation 25).

$$[M(NBu^t)(Me_2dtc)_3] + PhCHO \underset{dry}{\overset{H_2O}{\rightleftharpoons}} [M(O)(Me_2dtc)_3] + Bu^tN{=}CHPh \qquad (25)$$

Apart from the reactivity involving the NR group, the above compounds display the

reactivity of their ancillary ligands. Compound (**8**) undergoes the typical reactions of the NR_2 ligands with electrophiles (ROH, R_2CO, CO_2, CS_2 or RI). The insertion observed with ketones (equation 26) is noteworthy, both for its reversibility and for its sensitivity to steric restrictions.[289] Alkoxo substituents allow the reactions of an alkylidene ligand to give metathesis products with alkenes.[301] An imidoalkylidene analog $[Ta(NSiMe_3)Cl(CHCMe_3)(PMe_3)_2]$ reacted with ethylene to give rearrangement but no metathesis products.[292]

$$[Bu^tN{=}Ta(NMe_2)_3] \xrightarrow[\textbf{(8)}]{Ph_2C{=}O(excess)} Bu^tN{=}Ta(OCPh_2NMe_2)_2(NMe_2) \xrightarrow{CO_2\ excess} [Bu^tN{=}Ta(O_2CNMe_2)_3] \quad (26)$$

34.2.3.6 Dinitrogen activation

The reaction of niobium and tantalum derivatives in low oxidation states with N_2 led to $[\{NbBu(Cp)_2\}_2(N_2)(O_2)]$ (equation 27),[302] $[\{NbCl(dmpe)_2\}_2(\mu\text{-}N_2)]$[303] (equation 28) and $[Nb_2Cl_6(Bu^t_3P)_3(N_2)]$ (equation 29),[304] which were only poorly characterized owing to their low stability. IR investigations of the interaction between the terminal N_2 ligand of *trans*-$[ReCl(N_2)(PhPMe_2)_4]$ and a number of acceptor transition metal halides showed that $NbCl_5$ produces the greatest shift of the N_2 stretching frequency (292 cm^{-1}), but the nature of the polynuclear species formed was not reported.[305] The development of this exciting area is mainly due to Schrock and coworkers, who were able to obtain stable tantalum μ-N_2 compounds in high yields, by reducing neopentylidene complexes in the presence of N_2 at normal pressure (equation 30).[292,306]

$$[NbCl_2(Cp)_2] + BuLi \xrightarrow[0.1\%\ N_2,\ 0.1\%\ O_2]{Ar} [\{NbBu(Cp)_2\}_2(N_2)(O_2)] \quad (27)$$

$$[NbCl_4(dmpe)_2] + Mg\ (excess) \xrightarrow[N_2\ (1\ atm)]{CH_2Cl_2} [\{NbCl(dmpe)_2\}_2(\mu\text{-}N_2)] + 3/2MgCl_2 \quad (28)$$

$$2NbCl_5 + 3PBu^t_3 + Mg\ (excess) \xrightarrow[N_2\ (1\ atm)]{CH_2Cl_2} [Nb_2Cl_6(PBu^t_3)_3(N_2)] + MgCl_2 \quad (29)$$

$$[TaCl_3(CHCMe_3)(PMe_3)_2] \xrightarrow{2Na/Hg} \begin{cases} \xrightarrow{N_2} [\{TaCl(CHCMe_3)(PMe_3)\}_2(\mu\text{-}N_2)] \ \textbf{(16)} \\ \xrightarrow{Ar} [TaCl(CHCMe_3)(PMe_3)_4] \end{cases} \quad (30)$$

The structure of $[\{Ta(CHCMe_3)(CH_2CMe_3)(PMe_3)_2\}_2(\mu\text{-}N_2)]$ (**17**) revealed an unusually high activation of the N_2 ligand, with formation of a close to linear $Ta(\mu\text{-}N_2)Ta$ bridge, formulated as a Ta=N—N=Ta system.[307] This 'diimido' character is confirmed by the fact that similar compounds are accessible in high yields by reaction of tantalum or niobium alkylidenes with a diimine reagent, PhCH=NN=CHPh (equation 31).[292,308] The molecular structure of the centrosymmetric $[\{TaCl_3(PBz_3)(THF)\}_2(\mu\text{-}N_2)]$ (**19**) is depicted in Figure 8. The μ-N_2 ligand is the sole bridge between the two metals, which present distorted octahedral environments with a meridional arrangement of the chlorine atoms.[309] The Ta—N bonds (1.796(5) Å) are much

$$2\ cis,mer\text{-}[MCl_3(CHCMe_3)(THF)_2] \xrightarrow[-2PhCH{=}CHCMe_3]{+PhCH{=}NN{=}CHPh} [\{MCl_3(THF)_2\}_2(\mu\text{-}N_2)] \ \textbf{(18)} \xrightarrow[-2THF,\ 2PBz_3]{} [\{TaCl_3(PBz_3)(THF)\}_2(\mu\text{-}N_2)] \quad (31)$$

shorter than the usual Ta^{V}—N single bond (*ca.* 1.97 Å), and close to the Ta=N distance of 1.765(5) Å found in $[Ta(NPh)Cl_3(PEt_3)(THF)]$ (**13**).[298] It is also notable that in the alkylidene (**17**), the Ta—N bonds (av. 1.839(8) Å) are shorter than the Ta=C bonds (av. 1.935(9) Å). These data support the description of the Ta—N linkages in (**17**) and (**19**) as double bonds. The N—N bond length of 1.282(6) Å in (**19**) is significantly longer than in free dinitrogen (N≡N: 1.0976 Å), suggesting a bond order between one (N—N ≈ 1.45 Å) and two (N=N ≈ 1.24 Å). The production of such μ-dinitrogen compounds with M=N—N=M units could become a common feature in niobium and tantalum chemistry (Table 14).

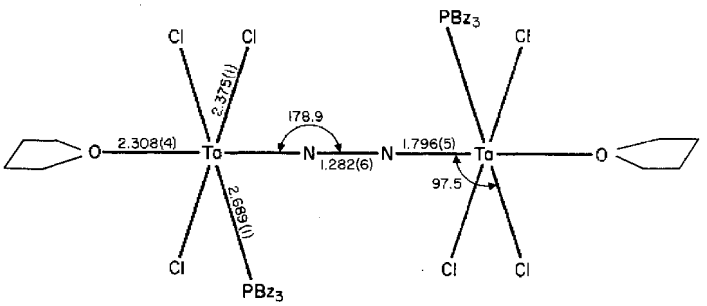

Figure 8 Molecular structure of $[\{TaCl_3(PBz_3)(THF)\}_2(\beta\text{-}N_2)]$ (**19**) (reproduced from ref. 309 with permission)

These μ-N_2 complexes contain the longest most 'activated' N_2 groups reported to date for simple M_2N_2 systems (longer N—N bonds, *ca.* 1.35 Å, are known for complexes such as $[\{(PhLi)_3Ni\}_2(N_2)(Et_2O)_2]_2$ and related species, but in which N_2 interacts with more than two metallic centers [310]). They contrast sharply with the μ-N_2 complexes reported for group IVA metals, where these bridges are almost linear and relatively short (N—N bonds ranging from 1.15 to 1.18 Å for $[\{M'(N_2)(Cp')_2\}_2(\mu\text{-}N_2)]$ (M' = Ti[311a] or Zr[311b]), the corresponding metal–nitrogen bonds being relatively long (2.00 to 2.09 Å).

If one considers the metal to be Ta^{V}, the Ta=N bond then implies a combination of ligand to metal σ and π donation from a formal N_2^{4-} ligand, with unit N—N bond order. The experimental N—N bond lengths suggest bond orders between 1 and 2, consistent with donation of electrons from the π^* 2*p* orbitals of N_2^{4-} into the empty *d* orbitals of Ta^{V}.[320] This description also accounts for the eclipsed conformation of the equatorial ligands in (**19**), although the staggered one should be the more favored sterically.[309]

Compounds (**17**) and (**19**) are formally 14-electron species. By contrast, the μ-dinitrogen complexes $[\{M'(N_2)(Cp')_2\}_2(\eta\text{-}N_2)]$ (M' = Ti, Zr) are respectively 16-electron and 18-electron species, and the low oxidation state of the metal is preserved. The spectroscopic data also illustrate the differences between the tantalum and these Ti^{II} or Zr^{II} μ-dinitrogen compounds. The ^{15}N spectrum of (**16**) shows a singlet at 414 p.p.m.,[306] a chemical shift comparable to that

found in imido compounds such as $[Ta(NPh)Cl_3(THF)_2]$ ($\delta = 350–370$ p.p.m.), but different from the 679 p.p.m. observed for the bridging dinitrogen in $[\{Zr(N_2)(Cp')\}_2(\mu\text{-}N_2)]$.[311b] ^{15}N labeling experiments have established that the Ta=N—N=Ta group is characterized by an absorption around 845 cm^{-1} in the IR. This description of the Ta=N—N=Ta bridge is also supported by the reactivity of these μ-N_2 adducts, which behave as imido complexes. Thus the addition of an excess of acetone produced dimethylketazine, $Me_2C{=}N{-}N{=}CMe_2$. Several μ-N_2 complexes also reacted readily with excess HCl to give hydrazine (as $N_2H_4{\cdot}2HCl$) only; no ammonia was detected.[292,306,308]

34.2.3.7 Azides (Table 15)

Both neutral and ionic niobium and tantalum chloride azides are known. The neutral azides $[MN_3Cl_4]_2$ were obtained from MCl_5 and ClN_3.[312] They both explode spontaneously, although the tantalum derivative is somewhat stabler. The more stable ionic $[MN_3X_5]^-$ (X = Cl, Br) species were synthesized from the hexahalometallates(V) and iodoazide or from the pentahalides and phosphonium or arsonium azides.[73,258]

Table 15 Azido and Phosphineiminato compounds

Compounds	*Comments*	*Ref.*
(*a*) *Azido compounds*		
$[MCl_4N_3]_2$	$MCl_5 + ClN_3$ or NaN_3; explosive; X-ray structure for M = Ta	1
$(PPh_4)[MX_5N_3]$ (X = Cl, Br)	$MX_5 + N_3PPh_3$; non-explosive; X-ray structure for M = Nb and X = Cl (disorder of the azido group)	2, 3
$(AsPh_4)[TaCl_5N_3]$		2
$(Et_4N)[NbCl_5N_3]$	$NbCl_5 + Et_4NN_3$; non-explosive; analysis only	4
$[Ta\{N(SiR_3)_2\}_2(N_3)_3]$	$[TaCl_3\{N(SiMe_3)_2\}_2] + Me_3SiN_3$	5
(*b*) *Phosphaneiminato compounds*		
$[MCl_4(NPPh_3)]_2$	X-Ray structure for both M = Nb and Ta	6, 7
$(PPh_4)[MX_5(NPPh_3)]$ (X = Cl, Br)		3, 2
$(AsPh_4)[NbCl_5(NAsPh_3)]$	Photochemical synthesis	3
$(PPh_4)[TaCl_4(NPPh_3)_2]$	$TaCl_4N_3 + PPh_3$; X-ray structure, *trans* isomer	6
$[(NHPPh_3)TaCl_4(NPPh_3)]$	Proton abstraction from the solvent ($C_2H_4Cl_2$) by $[TaCl_4][TaCl_4(NPPh_3)_2]$	7

The structures of $[TaN_3Cl_4]_2$[312] and $(PPh_4)[NbN_3Cl_5]$[73] have been determined. Two independent dimeric molecules, of C_{2h} and D_{2h} symmetry, were found for the former with azido groups bridging the two metals in a slightly asymmetric manner, in a dimer of C_{2h} symmetry (Figure 9). The (Ta—μ-N)$_2$ rings are planar, and the Ta—N linkages are all longer than expected for single bonds (2.08 Å). The azido compounds are characterized by stretching frequencies around 2100 [$\nu_{as}(N_3)$], 1350 [$\nu_s(N_3)$] and 420 [ν(M—N)] cm^{-1} in the IR.

Both the neutral and the ionic azides undergo reactions analogous to the Staudinger reaction, giving compounds containing the phosphineiminato M=N=P group (equation 32)[313,314] The reaction between $[TaN_3Cl_4]_2$ and PPh_3 provided $[TaCl_4(NPPh_3)]_2$ and $[TaCl_4(NPPh_3)(NHPPh_3)]$.[314] The latter was suggested to result from the reaction of the initially formed $[TaCl_4][TaCl_4(NPPh_3)_2]$ salt with the solvent $C_2H_4Cl_2$. As a result of the higher stability of the tantalum azides, the reactions with $[TaN_3X_5]^-$ must be activated photochemically. Attempts to extend the Staudinger reaction to $AsPh_3$ were successful only with $[NbN_3Cl_5]^-$.[74]

$$[NbN_3Cl_4]_2 + 2PPh_3 \longrightarrow [NbCl_4(NPPh_3)]_2 + 2N_2 \qquad (32)$$

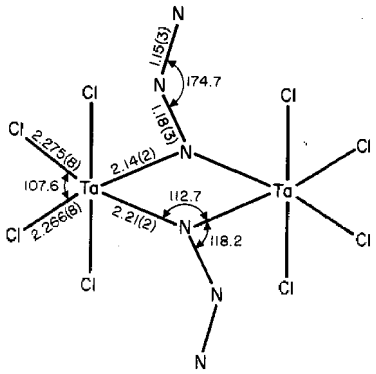

Figure 9 X-Ray structure of the $[TaCl_4N_3]_2$ dimer of C_{2h} symmetry (reproduced from ref. 312 with permission)

Centrosymmetric dimers with terminal phosphineiminato groups were found in the solid for $[MCl_4(NPPh_3)]_2$ (Figure 10).[313,314] The asymmetry of the bridge was interpreted as resulting from the strong *trans* effect (0.34 Å for M = Ta) of the phosphineiminato ligand, which also leads to a very long Ta—Cl bridge. The PNM sequence is linear, and the distances consistent with P=N and M=N double bonds. The Ta—N bond is longer (1.97 Å) in *trans*-$[TaCl_4(NPPh_3)_2]^-$, while the N—P distance is only 1.56 Å and the TaNP arrangement is slightly bent (162°). Thus the Ta—N linkage exhibits almost single bond character, probably as a result of the unfavorable *trans* position of the phosphineiminato groups.[316] Although no X-ray data are presently available for the arsineiminato $[NbCl_5(NAsPh_3)]^-$ compound, the IR data suggest a lower π character of the As=N bond with respect to the P=N bond.

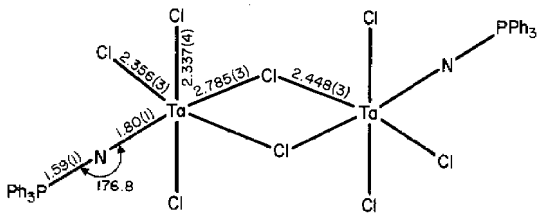

Figure 10 Structure of the phosphineiminato complex $[TaCl_4(NPPh_3)]_2$ (reproduced from ref. 313 with permission)

34.2.3.8 Nitrides (Table 16)

The obtention of nitrides by thermal decomposition of the azides was only successful for the synthesis of $[MNBr_4]^{2-}$ from $[MN_3Br_5]^-$. Thermolysis of MX_5 with ammonium salts afforded a more general access to nitride halides in oxidation state V, or IV if higher temperatures were used.[316,317] Oxo nitrides were obtained if moisture was admitted during the process.[318]

The only well-characterized nitrides are $[Ta_2NBr_{10}]^{3-}$ [316] and the oxo nitrides MON.[318] The structure of the former is similar to that of $[Ta_2OF_{10}]^{2-}$ (Section 34.2.6.1.i), with a symmetrical linear TaNTa arrangement and a Ta—N bond length (1.849(2) Å) consistent with double bond character. The ligands *cis* to the bridge are eclipsed; the lengthening of the axial Ta—Br bond (0.18 Å) reflects a strong *trans* effect. A polymeric ribbon type structure with nitrido and halo bridges has been assumed for all nitride halides $[MNX_2]_n$ (X = F, Cl, Br).[319,320] Their stability decreases from the fluoride to the bromide, as does the bond order of the M=N linkage, as reflected for instance by the diminution of the Nb=N frequency in the IR from 800 for X = F to 720 cm^{-1} for X = Br.

34.2.3.9 Miscellaneous

(*i*) *Porphyrin and related complexes*

Porphyrin derivatives of Nb^V and Ta^V were first reported in 1972 and have since aroused increasing interest. Fluoride complexes MF_3L were obtained from MCl_5 and the octaethylporphyrin in the presence of HF (L = OEP).[321,322] Niobium chloride and bromide

complexes have been prepared by treatment of $[NB_2O_3L_2]$ with dry gaseous HX for L = TPP (*meso*-tetraphenylporphyrinato), TMTP (*meso*-tetra-*m*-tolylporphyrinato) and TPTP (*meso*-tetra-*p*-tolylporphyrinato).[323,324] The kinetics of the solvoprotolytic dissociation of $[NbCl_3(TPP)^-]$ in $MeCOOH/H_2SO_4$ mixtures have been studied.[325]

The reaction of porphyrins with $NbCl_5$ afforded after hydrolysis the $[Nb_2O_3L_2]$ dimers,[326] with L = OEP, TPP, TPTP and OMP (octamethylporphyrinato). An unusual geometry was found for these dimers, as illustrated in Figure 11 in the case of L = TPP.[327,330] The Nb atoms are heptacoordinated with the two Nb—TPP units linked together through three μ-oxo bridges; Nb atoms lie 1.00 Å from the 4N planes of the porphyrinato ligands. The geometry of this d^0–d^0 $[(NbL)_2O_3]$ compound was rationalized in terms of optimal Nb—O π interactions.[331]

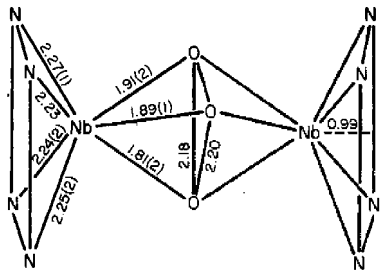

Figure 11 Coordination polyhedron of $[Nb_2(TPP)_2O_3]$ (reproduced from ref. 330 with permission)

Bubbling HF through solutions of the $[Nb_2O_3L_2]$ dimer in anhydrous benzene afforded [NbOFL] (L = OEP, TPP, OMP, TPTP).[321,332] The structure with L = OEP showed a *cis* geometry on the six-coordinate niobium. The metal–macrocycle distance of 0.905 Å is shorter than in seven-coordinated complexes, probably as a result of decreased steric hindrance (Nb=O: 1.7620(6) Å; Nb—F: 1.888 Å). Addition of HI to $[Nb_2O_3(OEP)_2]$ in CH_2Cl_2 solutions yielded $[NbOI_3(OEP)]$, which on heating under vacuum liberated iodine and [NbOI(OEP)].[322] [NbO(TPP)(acac)] was prepared by reaction of $[Nb_2O_3(TPP)_2]$ with excess acacH.[324]

Recrystallization of $[Nb_2O_3L_2]$ from acetic acid gave [NbOL(MeCOO)(MeCOOH)] (L = OEP, TPP, TPTP and OMP).[326] The structure of the L = TPP derivative[332,333] showed the niobium atom to be seven-coordinated by the four nitrogen atoms of the porphyrin and by the three oxygen atoms, which are *cis* to each other; the metal is displaced by 0.99(2) Å from the porphyrinato plane towards the oxygens. A high resolution NMR study of [NbOL(MeCOO)(MeCOOH)] and $[Nb_2O_3(OEP)_2]$ revealed the anisochrony of the methylenic protons of the porphyrin, induced by the out-of-plane position of the metal atom.

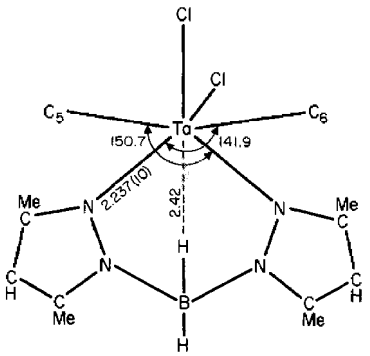
The redox chemistry of [NbO(TPP)(MeCOO)] was investigated by means of cyclic voltammetry and controlled potential electrolysis; the reduction of Nb^V to Nb^{III} was found to occur prior to the reduction of the ligand. The redox potentials were measured for the $[Nb^VO(TPP)(MeCOO)]/[Nb^{IV}O(TPP)]/[Nb^{III}(TPP)]^+/[Nb^{II}(TPP)]$ systems and found to be −0.94, 1.1 and −1.48 V respectively.[334]

Irreversible oxygenation of the low valent $[NbX_2L]$ porphyrins by O_2 yielded $[Nb(O_2)X_2L]$ which, from ESR and IR data, was described as a superoxide.[323]

Phthalonitrile and phthalocyaninedilithium react with MX_5 to yield $[MX_3(PC)]$.[335,336] The reaction between $[TaCl_2Me_3]$ and Nasalen yielded $[Ta(salen)Me_3]$.[277]

(*ii*) *Pyrazolylborate derivatives*

Tantalum pyrazolylborate derivatives $[TaClMe_3\{HB(pz)_3\}]$ (**20**) and $[TaClMe_3\{H_2B(3,5\text{-}Me_2pz)_2\}]$ (**21**) (pz = pyrazolyl) have been reported and characterized by X-ray and NMR studies.[337] Complex (**21**) adopts a capped octahedral structure in the solid with a close contact between tantalum and one hydrogen, which was described as a three-centered B—H—Ta bond, filling the seventh coordination site (Figure 12). The Ta—B distance is short (2.90(1) Å; usual M′ - - - B distances are *ca.* 3.8 Å) probably as a consequence of extreme puckering of the six-membered ring. A methyl group is found to cap the face formed by C(5), C(6) and Cl(4); there are two geometrical isomers (one chiral) in the crystal. The existence of the Ta—H—B interaction was also shown by IR (ν(B–H) = 2013, 2070 cm^{-1}) and by ^{11}B NMR in solution, where it is preserved up to at least 110 °C. Dynamic behavior, which equilibrates the three isomers present in solution, was observed.



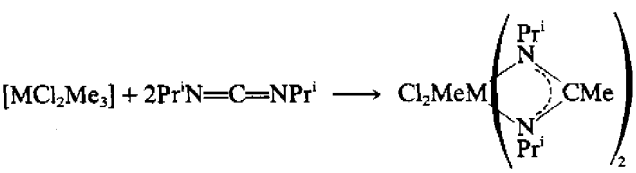


Figure 12 Molecular structure of one isomer of $[TaClMe_3\{H_2B(3,5\text{-}Me_2pz)_2\}]$ (**21**) (reproduced from ref. 337 with permission)

Reactions of $K[HB(Me_2pz)_3]$ with MCl_5 in equimolar proportions yielded $[MCl_4\{HB(Me_2pz)_3\}]$ and $[HB(Me_2pz)_3BH][MCl_6]$.[71] The presence of the novel dibora cation was confirmed by X-ray diffraction in the case ot tantalum. Acid-catalyzed cleavage of B—N(pyrazolyl) bonds also takes place and generates, for instance, $[NbCl\{HB(Me_2pz)_3\}(Me_2pz)_3]$ with pyrazolate ligands. Reactions between $NbCl_5$ and $K[HB(pz)_3]$ and $K[H_2B(pz)_2]$ have led to ready reduction to Nb^{IV} products (Section 34.3.5.4.iii); the Nb^V salts $K[NbCl_5\{HB(pz)_3\}]$ and $K[NbCl_5\{H_2B(pz)_2\}]$ could however be isolated from low temperature reactions.[338]

(*iii*) *Nitrogen-containing insertion products* (Table 17)

Reactions of $[MCl_{5-x}Me_x]$ (x = 1, 2 or 3) with heterocumulenes have led to insertions into the M—C bond.[8] *N,N′*-Dialkylacetamidinato derivatives[339] were obtained (equation 33). *N*-Acetamides or *N*-thioacetamides[340] were formed with isocyanates or isothiocyanates, respectively (equation 34). The rate of insertion varied in the order $[MCl_4Me] > [MCl_3Me_2] > [MCl_2Me_3]$, following the established order of acceptor properties of the methylmetal chlorides, the isocyanates being more reactive than the isothiocyanates. Hexa- or hepta-coordinated species were obtained.

$$[MCl_3Me_2] + 2MeNCX \longrightarrow Cl_3M\left(\begin{array}{c} Me \\ N \\ \diagup \quad \diagdown \\ CMe \quad X \end{array}\right)_2 \qquad (34)$$

X = O or S

The coordination polyhedron of the metal in its *N,N*-dialkylacetamidinato derivatives is generally a distorted pentagonal bipyramid with two chlorines in the apical positions.$[TaCl_2Me\{CyNC(Me)NCy\}_2]$ adopts a different geometry, with one bidentate ligand in equatorial sites, while the other spans axial and equatiorial positions, thus maximizing the intramolecular distances between the cyclohexyl group.[341]

Comparable insertions occurred when methylmetal derivatives were exposed to NO, yielding *N*-alkyl-*N*-nitrosohydroxylaminato compounds (equation 35).[342] Nitric oxide may however also behave as an oxidant, and the reactions are sometimes more complicated (Section 34.2.6.3).[343]

$$[MCl_3Me_2] + NO \longrightarrow Cl_3M\left(\begin{array}{c} O \\ \diagup \\ O \\ \diagdown \\ N \\ \diagup \quad \diagdown \\ N \quad Me \end{array}\right)_2 \qquad (35)$$

34.2.4 Pseudohalo Derivatives

34.2.4.1 Cyanides and isocyanides

$NbCl_5$ and HCN yielded $[NbCl_4(CN)(Et_2O)]$ in Et_2O and $[NbCl_5(HCN)]$ in CCl_4. The addition of NEt_3 to the latter afforded $(HNEt_3)[NbCl_5(CN)]$; the corresponding bromo complex was also obtained.[344]

No isocyanide complex of Nb^V or Ta^V appears to have been reported. The insertion of isocyanides into M—C bonds of $[TaCl_2Me_3]$[340] and into the M—X bonds of MX_5[345–347] has however been described. $[MX_4\{CX(NR)\}(RNC)]$ was isolated (R = Me, Bu^t). In the case of R = Me,[345] further insertion occurred, yielding $[MCl_3\{CCl(NMe)\}]_2 \cdot (MeNC)$.

$[TaBr_2\{Br(NMe)\}_3(MeNC)]$ could even be obtained by the reaction of Ta_2Br_{10} with excess MeNC in CH_2Cl_2; in Et_2O, the same reactants afforded an oxo species, $[TaOBr_2\{CBr(NMe)\}(MeNC)]$.[347]

The monoinserted compounds $[MX_4\{CX(NMe)\}(MeNC)]$ reacted with PPh_3 to form, through a second insertion, $[MX_3\{CX(NMe)\}_2(PPh_3)]$.[345] $[TaBr_3\{Cbr(NMe)\}(dppe)]Br$ was prepared directly from $[TaBr_5(dppe)]$ and MeNC. Attempts to induce further insertion under the action of phosphines when $R = Bu^t$ instead of Me resulted in the displacement of the terminal isocyanide ligand to yield $[MX_4\{CX(NBu^t)\}L]$, where $L = PPh_3$, PMe_2Ph, $PMePh_2$, dppe.[347]

34.2.4.2 Thio- and seleno-cyanates (Table 18)

The synthesis of $M(NCS)_5$ complexes was first effected by allowing KSCN to react with $TaCl_5$ in MeOH.[348] They were isolated from MeCN solutions as $A[M(NCS)_6(MeCN)]$. Complexes of the type $[MCl_x(NCS)_{5-x}L]$ ($x = 0$–4) were obtained on varying the $KSCN/MCl_5$ stiochiometry in MeCN or Et_2O. $[TaX_5L]$ (X = NCS or NCSe) formed with L = bipy or phen. $[Nb_2Cl_{10}\{\mu\text{-}C_2H_4(SCN)_2\}]$ was obtained from Nb_2Cl_{10} and the organic thiocyanate in CCl_4.[349] ^{93}Nb NMR data on MeCN solutions of $NbCl_5$ in the presence of KSCN[350] were taken to indicate the presence of $[Nb(NCS)_xX_{6-x}]^-$ (X = Cl or Br) and $[Nb(NCS)_7]^{2-}$.

12. F. Dahan, R. Kergoat, M.-C. Senechal-Tocquer and J. E. Guerchais, *J. Chem. Soc., Dalton Trans.*, 1976, 2202.

Alkoxoisothiocyanato complexes $[M(NCS)_2(OR)_2(dbm)]$ or $[M(NCS)(OR)_3(dbm)]$ have been synthesized from $NbCl_5$, KSCN and dibenzoylmethane (dbmH) in the appropriate alcohol.[351] The $[M(NCS)_2(OR)_3(bipy)]$ adducts were obtained from $[MCl_2(OR)_3]$.[352]

$[M_2(NCS)_{10}]$ reacts with ammonia and with primary and secondary aliphatic amines to yield $[M(NCS)(NH_2)_2(NH)]_2$, $[M(NCS)_3(NHBu)_2(H_2NBu)]$ or $[M(NCS)_3(NEt_2)_2(HNEt_2)]$.[353] Similar reactions with $[M(NCS)_5(MeCN)]$ afforded, through aminolytic cleavage of the M—NCS bonds, $[M(NCS)\{NC(NH_2)Me\}_4\{MeC(NH)NH_2\}]_n$ and $[M(NCS)_3\{NC(NHBu)Me\}\{MeC(NH)NHBu\}]$ complexes.[353]

The isothiocyanate groups are N bonded, in agreement with the hard and soft acid–base model. The structures of $[Nb(NCS)_2(OEt)_2(dbm)]$[355] and $[Nb(NCS)(OPr^i)_3(dbm)]$[356] showed the niobium atom to be located at the center of a distorted octahedron (Nb—N: 2.088(5), 2.101(5) and 2.176(7) Å respectively).

Bonding of the thiocyanate ligand through its sulfur atom has however been proposed[357] on the basis of ^{93}Nb NMR investigations of acetonitrile solutions containing $[Nb(NCS)_x(SCN)_yCl_{6-(x+y)}]^-$; $[Nb(SCN)_6]^-$, the first example of a homoleptic complex in

which the thiocyanate ion is S bonded to a class a metal ion, was shown to be present in these solutions at concentrations comparable to those of $[Nb(NCS)_6]^-$.

34.2.5 Oxo, Thio and Seleno Halides

34.2.5.1 Oxo halides

The synthetic routes available for the preparation of the known oxyhalides, listed in Table 19, range from the halogenation of the oxides to the carefully controlled reaction of the halides with dioxygen.

Table 19 Anhydrous Oxo Halides of Niobium(V) and Tantalum(V)

$[Nb_{31}O_{77}F]$	—	—	—	—	—	—	—

(i) Oxo fluorides

MOF_3, in contrast to the other oxo trihalides, has not been fully characterized but merely described as an intermediate formed during the hydrolysis of MF_5, or the thermal decomposition at 600 °C or above of MO_2F.[358] The IR on the vapor above NbO_2F at 600–800 °C shows a strong band at 1030 cm^{-1}, which was assigned to the ν(NbO) stretching vibration of $NbOF_3$; on cooling this species was reported to decompose into NbO_2F and NbF_5.[359]

NbO_2F and TaO_2F were obtained by allowing the oxides to react with HF or F_2.[360,361] They show an ReO_3 type structure in which the fluorine and oxygen atoms are randomly distributed in octahedral positions around the metal atoms.[360] The thermal decomposition of TaO_2F was reported to result in the formation of gaseous TaF_5 and $TaOF_3$ and in the release of solid Ta_3O_7F and Ta_2O_5.[358]

Nb_3O_7F and $Nb_5O_{12}F$ were prepared by heating mixtures of Nb_2O_5 and NbO_2F in sealed platinum tubes at 800 °C. Nb_3O_7F crystallized in the orthorhombic system[359] with the U_3O_8 structure type.[362]

(ii) Oxo chlorides, bromides and iodides

Of the known oxo halides (Table 19), $NbOCl_3$ is the most extensively studied, partly because it forms during the preparation of $NbCl_5$ from which, owing to their similar volatilities, it is extremely difficult to separate. $NbOCl_3$ can however be conveniently prepared by the reaction of oxygen on $NbCl_5$ at 300–500 °C, or of anhydrous Nb_2O_5 with an excess of $NbCl_5$ vapor.[3] The activation energy of 93.5 kJ mol^{-1} found for the formation of $NbOCl_3$ from solid Nb_2O_5 and molten $NbCl_5$ is relatively low, and this redistribution has been shown to be mainly diffusion controlled.[363] Partial hydrolysis of $NbCl_5$ by $H_2{}^{18}O$ has been utilized to prepare $Nb^{18}OCl_3$.[364] $NbOCl_3$ was also formed when $NbCl_5$–R_2O adducts were heated, as well as from the reaction of $NbCl_5$ with oxygen-containing ligands such as sulfoxides, phosphine oxides or arsine oxides.[3] Similar reactions were observed with substituted halides.

The structure of $NbOCl_3$ consists of chains of dimeric Nb_2Cl_6 units linked together by bridging oxygen atoms, the coordination around each niobium being approximately octahedral.[3] A strong band at 770 cm^{-1} in the IR was attributed to the Nb—O—Nb stretching vibration. The Raman spectra of gaseous $NbOCl_3$ was shown to be consistent with a monomeric C_{4v} molecule, and the vibration found at 997 cm^{-1} is characteristic of an Nb=O double bond.

$TaOCl_3$ has been much less extensively studied. Unlike $NbOCl_3$ it can apparently not be prepared by partial hydrolysis of $TaCl_5$.[3]

Disporportionation of $MOCl_3$ at 300–400 °C yielded MO_2Cl and MCl_5.[3] Nb_3O_7Cl has been prepared from Nb_2O_5 and $NbOCl_3$ at 600 °C; its structure shows octahedrally coordinated metal atoms. A tantalum analog has been mentioned.

$NbOBr_3$ was obtained by methods analogous to those used for $NbOCl_3$.[365] A broad complex absorption around 740 cm^{-1} in the IR, characteristic of Nb—O—Nb chains, and in the NQR two groups of lines with markedly different frequencies, indicating the presence of both terminal and bridging bromine atoms, attest that the structure of $NbOBr_3$ is analogous to that of $NbOCl_3$. $TaOBr_3$ and TaO_2Br have also been obtained.[3]

$NbOI_3$ was conveniently prepared by the reaction of Nb_2O_5 with NbI_5, or from a mixture of niobium and iodine.[3] It decomposes to $NbOI_2$. MO_2I has been obtained as red needles by heating a 1:2:6 molar ratio of $M:M_2O_5:I_2$ at *ca.* 500 °C.[3] By contrast with the oxo triiodides, they are air stable.

34.2.5.2 Thio and seleno halides and their complexes

The thio and seleno derivatives reported so far for Nb^V and Ta^V appear to be limited to the $[M_6S_{17}]^{4-}$,[366] $[MY_4]^{3-}$ (Y = S or Se),[367] $[NbOS_3]^{3-}$ [368] and $[NbO_2S_2]^{3-}$ [369] anions (Section 34.2.8.2.i), to $[MYX_3]$ species and to some of their adducts and derivatives.

The thio and seleno halides $[MYX_3]$ were prepared by the reaction of Sb_2Y_3 with MCl_5 at room temperature in CS_2.[370] $MSCl_3$ was formed when B_2S_3 was allowed to react with MCl_5.[371] MYX_3, with Y = S, Se, and X = Cl, Br, were obtained through thermal decomposition of MY_2X_2.[372]

$[NbSX_3(THT)_2]$ was formed from $NbSX_3$ and THT in solution; a crystal structure (X = Br)[373] showed the Nb atom to be six-coordinated (Nb=S: 2.09 Å). The reaction between $NbSCl_3$ and Ph_3PS afforded a 1:1 adduct[374,375] whose unit cell contains two identical five-coordinate monomers and a centrosymmetric six-coordinate dimer with halogen bridges, the coexistence of which is rather unusual. The niobium atom is displaced from the plane formed by the three chlorine and the ligand's sulfur atoms toward the sulfido sulfur atom (0.533 Å monomer, 0.397 Å dimer); this displacement is larger than in $NbOCl_3$ adducts. $[TaSCl_3(PhNCCl_2)]$ was obtained, as the result of sulfur abstraction, when Ta_2Cl_{10} was allowed to react with PhNCS.[132] It was reported to react with alkali metal thiocyanates to give $[TaSCl_x(NCS)_{3-x}(PhNCCl_2)]$ ($x = 1$ or 2) and $[TaS(NCS)_4(PhNCCl_2)]^-$.[376] $[MS(Et_2dtc)_3]$[249] was isolated from the reaction of MCl_5 and NaS_2CNEt_2 in non-aqueous solvents. The Ta compound[377] is monomeric with seven sulfur atoms bound to Ta at the corners of a distorted pentagonal bipyramid (Ta=S: 2.181 Å).

34.2.6 Complexes of the Oxo Halides

34.2.6.1 Anionic oxohalo complexes

(*i*) *Oxofluoro anions*

Oxofluoro complexes are formed much more readily for niobium than for tantalum. This difference, indeed, is the basis of the classical method of separation of the two metals. When, for example, a 2–3% HF solution of the oxides is concentrated, K_2TaF_7 precipitates first and $K_2(NbOF_5)\cdot H_2O$ only later.[1]

(*a*) $[MOF_6]^{3-}$. Guanidinium oxohexafluoroniobate was synthesized by adding CN_3H_6F to a solution of Nb_2O_5 in HF.[378] The crystals consist of $[NbOF_6]^{3-}$ and guanidinium ions linked together into chains through NH···F hydrogen bonds. The structure determination for α-$Na_3[NbOF_6]$[379] shows niobium to be located at the center of a slightly distorted pentagonal bipyramid and displaced from the equatorial plane toward the oxygen atom (Nb—F_{eq}: 2.016–2.050(3) Å; Nb—F_{ax}: 2.084(3) Å; Nb=O: (1.738(3) Å).

(*b*) $[MOF_5]^{2-}$. Oxofluoroniobates $A[MOF_5]$ (A = Mn, Co, Ni, Cu, Zn, Cd) were obtained from Nb_2O_5, HF and the carbonates of the bivalent metals; in the same conditions Ta_2O_5 gave fluorotantalates.[48] The strength of the M=O bond depends on the nature of the counterion, as illustrated by the Nb=O bond strength constants shown in Table 20. In the hydrazinium salt the $[NbOF_5]^{2-}$ anion has a distorted octahedral configuration (Nb=O: 1.75 Å).[380]

(*c*) $[M_2OF_{10}]^{2-}$. The formation of $[Ta_2OF_{10}]^{2-}$ from $[TaF_6]^-$ and Et_4NOH was proposed to

Table 20 Calculated Nb=O bond strength in $A[NbOF_5]$[1]

A	*Mn*	*Co*	*Ni*	*Cu*	*Zn*	*Cd*	*Rb*
$k \times 10^8$ (N Å^{-1})	7.24	7.31	6.87	6.78	7.36	7.17	6.50[2]

1. R. L. Davidovich, T. F. Levchishina, T. A. Kaidalova and V. I. Sergienko, *J. Less-Common Met.*, 1972, **27**, 35.
2. L. Surendra, D. N. Sathyanarayana and G. V. Jere, *J. Fluorine Chem.*, 1983, **23**, 115.

proceed through an intermediate hydroxo compound $[TaF_5OH]^-$ followed by a condensation reaction.[381] Its X-ray analysis[382] showed the two tantalum atoms to be bridged by an oxygen atom, the overall symmetry being approximately D_{4h}. The linearity of the M—O—M bridge (M—O = 1.875 Å) may be interpreted as resulting from π-bonding interactions between tantalum and oxygen. This is further supported by the high value of $\nu_{as} = 880\ cm^{-1}$ and low value of $\nu_s = 270\ cm^{-1}$ found for ν(Ta—O—Ta) in the IR and Raman spectra.[381]

(*d*) $[MOF_4]^-$. $[NbOF_4]^-$ was first obtained in 1866 by C. Marignac, by adding NH_4F to an HF solution of Nb_2O_5.[1] It contains Nb—O—Nb bridges.[383]

(*e*) *Miscellaneous.* $(NEt_4)_4[Ta_4O_6F_{12}]$ was obtained by hydrolysis of $(NEt_4)_2[(TaF_5)_2O]$.[384] The anion has an adamantane type Ta_4O_6 skeleton comparable to that of P_4O_6, each metal atom being further coordinated by three fluorine atoms in a *fac* octahedral arrangement (Figure 13). ^{19}F NMR data indicated the presence of the $[Nb_2O_2F_9]^{3-}$, $[NbOF_5]^{2-}$, $[NbOF_6]^{3-}$, $[TaOF_6]^{3-}$ and $[Ta_2O_3F_7]^{3-}$ anions in aqueous solutions.[385–388] The stepwise formation constants of the $[NbOF_x]^{(5-x)}$ complexes with $2 < x < 6$, which exist in solution for a range of concentrations in acid, metal and fluoride ion, were also determined.[41]

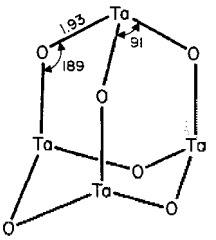

Figure 13 The Ta_4O_6 skeleton of $[Ta_4F_{12}O_6]$ (reproduced from ref. 384 with permission)

(*ii*) *Oxo anions of the higher halides*

(*a*) $[MOX_5]^{2-}$ ($X = Cl, Br$). $NbCl_5$, $NbOCl_3$ and Nb_2O_5 dissolve in concentrated HCl, from which $A_2[MOCl_5]$ salts ($A = NH_4^+$) were obtained by addition of an excess of ACl.[318,389–392] $A_2[NbOCl_5]$ salts also formed as intermediates during the oxygenation of $A[NbCl_6]$ (A = K, Rb, Cs).[393] $A_2[TaOCl_5]$ was prepared by heating the appropriate hexachlorometallate(V) with a stoichiometric amount of Sb_2O_3 in chlorine or under vacuum.[5] Analytical methods for extracting niobium(V) from HCl solutions involve the use of A = amines,[394] salicylhydroxamic acid[395] or benzohydroxamic acid;[396] the substances entering the organic phase were shown to be $(AH)_2[NbOCl_5]$. $(AsPh_4)_2[NbOCl_5]$ was formed in the reaction of $NbOCl_3$ with $(AsPh_4)Cl$.[397] The structure shows an octahedral arrangement for $[NbOCl_5]^{2-}$ with a very long Nb=O distance of 1.97 Å. Nb_2O_5 forms oxobromo complexes $A_2[NbOBr_5]$ (A = Rb, Cs) in concentrated HBr solutions of the alkali metal bromides.[5]

(*b*) $[Ta_2Cl_{10}O]^{2-}$ *and related species.* The compound $(PMe_3Ph)_2[Ta_2Cl_{10}O]$ was obtained 'serendipitously' by passing oxygen through a toluene suspension of $TaCl_5$ in the presence of PMe_2Ph and Na/Hg amalgam.[398] The structure revealed a linear Ta^V—O—Ta^V unit (Ta—O: 1.880(1) Å) comparable to that found in the $[F_5Ta—O—TaF_5]^{2-}$ ion (Section 34.2.6.1.i).[382] $(PPh_4)_2[Ta_2Cl_{10}O]$ was prepared from $NO[TaOCl_4]$ and PPh_4Cl.[399] $[\{TaCl_2(NMe_2)_2(HNMe_2)\}_2O]$, where three chlorine atoms on each tantalum of the parent $[Ta_2Cl_{10}O]^{2-}$ ion are replaced by nitrogen atoms, was obtained as a minor product (2%) from the reaction of $TaCl_5$ and $HNMe_2$.[270] The central Ta—O—Ta bonds are almost equal (Ta—O: 1.928(6) and 1.917(6) Å) and significantly longer than those found in $[Cl_5Ta—O—Cl_5]^{2-}$[398] and

$[F_5Ta—O—TaF_5]^{2-}$ (1.880 and 1.875(1) Å respectively).[382] The Ta—Cl bonds *trans* to the NMe_2 groups are longer than in the decachloro anions, which can be accounted for by the stronger tendency of these groups, as compared to bridging oxygen, to be involved in π bonding to the metal.

(*c*) $[M_2Cl_9O]^-$. $[\{TaCl_2(Cp')\}_2(\mu\text{-}Cl)_3]_2[Ta_2Cl_9O)_2]$[400] was isolated as a by-product in the reaction of $[SnBu_3(C_5Me_5)]$ with $TaCl_5$. $(C_4ClPh_4)_2[Nb_2Cl_9O]_2$ [401] was obtained from $NbCl_5$ and PhC≡CPh in the presence of water. The M—O—M bridges are asymmetrical in both $[M_2Cl_9O]_2^{2-}$ anions, as are the two central chlorine bridges that link the two $[M_2Cl_9O]$ units together (Figure 14).

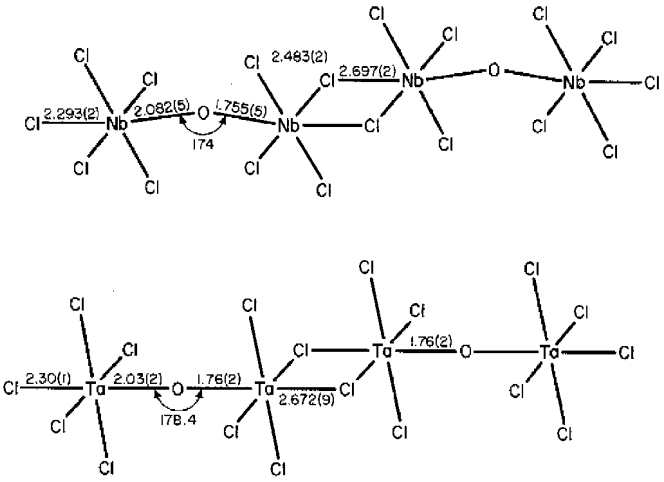

Figure 14 The $[M_2Cl_9O]_2^{2-}$ anions (reproduced from refs. 400 and 401 with permission)

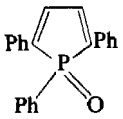
(*d*) $[MOCl_4]^-$ *and* $[MO_2Cl_3]^{2-}$. $A[MOCl_4]$ (A = alkali metal) salts were obtained by heating the appropriate hexachlorometallate(V) with the stoichiometric amount of Sb_2O_3 in chlorine or under vacuum.[420] $(NO)[NbOCl_4]$ was prepared from NOCl and $NbOCl_3$. $[NbOCl_4](pyH)$[403,404] and $(R_3NH)[NbOCl_4]$[405] were precipitated from HCl solutions of $NbCl_5$ or $NbOCl_3$ and the appropriate amine; IR indicated the presence of —NbONbONb— chains.

The addition of diars to $NbCl_5$ in dry CCl_4 caused the precipitation of $NbCl_5$(diars); attempts to recrystallize it yielded $[NbCl_4(diars))_2][NbOCl_4]$ and $[NbCl_4(diars)_2]_2[NbO_2Cl_3]$. $[NbOCl_4]^-$ is basically a square pyramid with the oxygen at the apex (Nb=O: 1.70(2) Å); one of the Nb—Cl bonds is outstandingly long (2.438(4) Å) with the chlorine atom pointing to the sixth potential coordination site of the metal of a neighboring $[NbOCl_4]^-$ anion, with a very short contact of 3.011(6) Å.[152]

(*e*) $[MO_2Cl_2]^-$. Compounds of composition $A[TaO_2Cl_2(H_2O)]$, where A = K, Rb, Cs or NH_4, were isolated by saturating solutions of $TaCl_5$ and of the alkali or ammonium chloride with HCl.[406] The IR absorptions found in the 830–875 cm^{-1} region were assigened to tantanyl groups joined by asymmetrical Ta=O—Ta bridges. Under the same conditions, $NbCl_5$ led to $A_2[NbOCl_5]$ (see above).

34.2.6.2 Neutral adducts of the oxo halides and related compounds

Numerous 1:1 and 1:2 adducts are known for MOX_3, but few for $NbOF_3$, and none yet for $NbOI_3$. The adducts of the oxo trihalides of Nb^V and to a lesser extent of Ta^V were often obtained from the pentahalides through oxygen abstraction from the ligand or the solvent. Others were prepared directly from the oxo trihalides.



(*i*) *Oxygen, sulfur and selenium donors*

Oxygen was abstracted from phosphine oxides, phosphonates,[407] arsine oxides and sulfoxides by MX_5 as well as by $[MX_4Me]$ (X = Cl, Br),[408] and more easily by the Nb than by the Ta derivatives, to yield MOX_3 adducts (equation 36; Table 21). IR indicated the following sequence for the metal's acceptor character: $MCl_5 > MOCl_3 > MOCl_2Me$. NMR showed that in

the presence of an excess of oxo ligand $[NbCl_4Me]_2$ is first and rapidly converted to the 1:1 adduct $[NbCl_4MeL]$; the oxygen *vs.* chlorine exchange then occurs at a slower rate, which depends, in the case of phosphoryl ligands, on the π character of the phosphoryl bond (Table 22).[408]

$$MX_5 + 3O{=}E \longrightarrow [MOX_3(O{=}E)_2] + ECl_2 \qquad (36)$$

Although the P═O bond is weaker in the phosphole oxides (TPPO) than in Ph_3PO, only traces of $[NbOCl_3(TPPO)]$ were obtained from $NbCl_5$ and excess phosphole.[124] Furthermore, oxygen was picked up at phosphorus and not at the metal, to form $[NbX_5(TPPO)]$, when NbX_5 was allowed to react with TPPSe in a non-rigorously-oxygen-free atmosphere.

(*ii*) *Nitrogen donors* (Table 23)

Niobium and tantalum oxo halides react with amines in stoichiometric amounts to form polymeric 1/1 materials containing MOMO chains. Monomolecular $[MOX_3(NR_3)_2]$ derivatives were obtained in the presence of excess amine.[365,408–411]

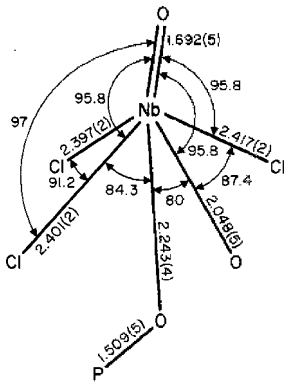
Reactions of bipy with MX_5 and $NbOCl_3$[134,364,412–414] yielded $[MX_5(bipy)]$ and $[NbOCl_3(bipy)]$ in benzene, while mixtures formulated as $[NbOCl_3(bipy)][NbCl_5(bipy)]$ and $[TaOCl_3(bipy)][TaCl_5(bipy)]_3$ were isolated in ether. Solutions of $NbCl_5$ and bipy in alcohols containing a small, controlled amount of water yielded $[NbOCl_2(OR)(bipy)]$.

A series of monomeric, six-coordinate niobium(V) adducts with neutral Schiff's bases was synthesized from $NbOCl_3$[410] or $NbOCl_3(OPPh_3)_2$.[207]

(*iii*) *Structures*

In spite of the large number of oxo trihalide adducts reported, there is still little structural information available on them. X-Ray diffraction studies are limited to those of $[NbOCl_3(MeCN)_2]$,[419] $[NbOCl_3(HMPA)_2]$[416] and $[NbOCl_3(OPCl_3)]_4$.[235] $[NbOCl_3(HMPA)_2]$ is monomeric in the solid (Figure 15) and in solution. In the solid the metal is octahedrally surrounded; the two HMPA ligands are *cis* to each other, one of them being *trans* to the oxo bond; the same isomer always predominates in solution. The Nb=O distance is comparable to that found in $[NbOCl_3(MeCN)_2]$ (1.68(2) Å); the lesser steric requirement of the MeCN ligands allows for a larger distortion of the coordination polyhedron and for shorter Nb—Cl bonds. A considerable *trans* effect was found for the metal–ligand bonds in both the HMPA and the MeCN adducts. In solution $[NbOCl_3(HMPA)_2]$ undergoes drastic changes and gives complex solvent dependent mixtures, as depicted in Scheme 3. All the species in solution are in dynamic equilibrium on the NMR time-scale. By evaporation the initial crystalline *trans* isomer of $[NbOCl_3(HMPA)_2]$ was integrally recovered. Similar solution behavior was observed for $[NbOCl_3(DMSO)_2]$, $[NbOCl_3(OMPA)]$, $[NbOCl_2(OEt)(HMPA)_2]$ and $[NbOCl_2Me(HMPA)_2]$.[408]



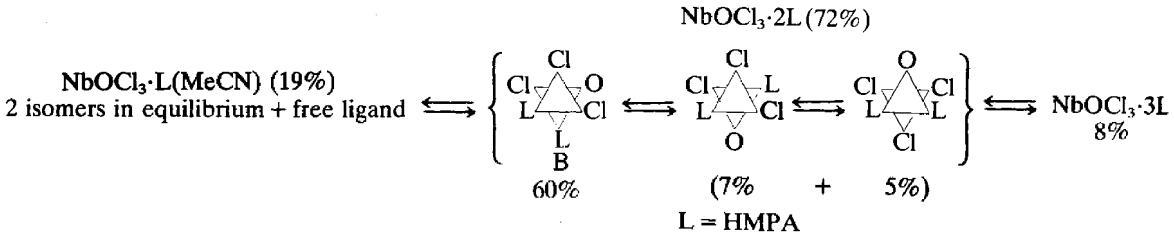


Figure 15 Coordination polyhedron of $[NbOCl_3(HMPA)_2]$ (reproduced from ref. 410 with permission)

Scheme 3

The oxygen-bridged tetrameric Nb_4O_4 unit in $[NbOCl_3(OPCl_3)]_4$ [235] is almost planar with two different values for the Nb—O distances in agreement with a $(—Nb{=}O—)_4$ structure.

34.2.6.3 Miscellaneous oxygen abstraction reaction products

Oxygen abstraction reactions from alcohols, ketones, acyl halides and other oxygen-containing compounds by MCl_5 or related derivatives also afforded a route to relatively simple complexes of the oxo halides (Table 24). Thus Nb_2Cl_{10} was found to abstract oxygen from higher ketones to yield, after hydrolysis, alkanes, chloroalkanes or arylalkanes.[414]

Table 24 Typical Oxygen Abstraction Reactions

O species	*Reactions*	*Compounds*	*Ref.*
RCOX (X = Cl, Br)	$Nb(OR')_5$ + RCOX (excess)	$[NbOX_3(RCOOR')]$	1
Et_2O	$NbCl_5 + NbCl_5(Et_2O)$ + 2bipy	$[Nb_2OCl_8(bipy)_2]$	2
	$3TaCl_5 + TaCl_5(Et_2O)$ + 4bipy	$[Ta_4OCl_{18}(bipy)_4]$	2
Me_2CO	$NbCl_3Me_2 + 2Me_2CO$	$[NbOCl_2(OCMe_3)]$	3
RR'CO(R = R' = Et;	MCl_5 + RR'CO	$[\{MCl_4(RR'CO)\}_2O]$	4
R = Me, R' = Et)	MCl_5 + RR'CO (excess)	$[MOCl_3(RR'CO)_2]$	4

Oxygen abstraction from $SOCl_2·H_2O$ by $[NbCl_2(RCp)(R'Cp)]$ led to a series of new $[NbOCl(Cp)(Cp')]$ compounds.[417] This reaction, which allowed the synthesis of diastereoisomeric pairs of optically active species, could be reversed upon heating (Scheme 4).

The unexpected formation of $[NbOCl(Cp)_2]$ as a by-product in the synthesis of $[NbCl_3(Cp)_2]$[418] can probably be attributed to the presence of traces of oxygen or moisture. When $[NbCl_2(Cp)_2]$ was allowed to react with oxygen, $[NbOCl(Cp)_2]$[302,419,420] or $[\{NbCl_2(Cp)_2\}_2O]$[421] was obtained. The latter compound shows anticancer activity, lower than

$$[Nb^{IV}Cl_2(Cp)_2] \xrightarrow{SOCl_2 \cdot H_2O} [Nb^{V}OCl(Cp)_2]$$
$$\uparrow \qquad\qquad \downarrow$$
$$\xleftarrow{SOCl_2}$$

Scheme 4

that of $[NbCl_2(Cp)_2]$ but paralleled by a significant reduction of the toxic side-effects. The ionic $[\{NbCl(Cp)_2\}_2O][BF_4]$[422] derivative was obtained from $[NbCl_2(Cp)_2]$ by oxygen abstraction from water and addition of HBF_4; its Nb—O—Nb bridge is significantly non-linear (169°) but the Nb—O bonds (1.88(1) Å) are relatively short, indicating a certain degree of π bonding.[423] The reaction between $[NbMe_2(Cp)_2]$ and an excess of NO proceeded *via* a nitrosyl adduct, probably with a bent MNO arrangement (ν(NO): 1670 cm^{-1}) and gave a methyloxo derivative which further inserted NO (equation 37).[343]

$$[NbMe_2(Cp)_2] \xrightarrow[-70\,^{\circ}C]{NO} [NbMe_2(Cp)_2(NO)] \xrightarrow[25\,^{\circ}C]{} \left[\left\{\begin{array}{c} NMe \\ Nb \\ O \end{array}\right\} Me(Cp)_2\right] \longrightarrow [Nb(O)Me(Cp)_2] \xrightarrow{NO} [NbO(ONMeNO)(Cp)_2]_n \quad (37)$$

Catalytic oxidation cycles involving the niobium oxide cations NbO^+ and NbO_2^+ in the gas phase have been reported.[424]

34.2.7 Solvolysis Products of the Oxo Trihalides

34.2.7.1 From Oxygen Compounds

(*i*) *Oxoalkoxo compounds* (Table 25)

Synthetic routes to well-characterized Nb^V and Ta^V oxoalkoxides remain surprisingly scarce. The direct alkoxylation of MOX_3 is far from providing a general route to these compounds. The alternative exchange of oxygen *vs.* chlorine between $[NbCl_2(OR)_3]_2$ and an oxo ligand often results in redistribution products.

The controlled hydrolysis of MCl_5 or $[Ta(OR)_5]_2$ (R = Et, $SiMe_3$) led to polymeric oxo alkoxides. On the other hand the hydrolysis of $[NbCl_2(OR)_3]_2$ in the presence of bipyridyl led to $[NbOCl_2(OR)(bipy)]$ (R = Et, Pr^i) adducts.[134,364,412] An X-ray structure for R = Et showed a distorted coordination octahedron, with the two chlorine atoms *trans* to each other (Nb=O: 1.71(3) Å). The Nb—OR bond is only 0.16 Å longer than the Nb=O oxo bond, and was presumed to have considerable double bond character, which is also consistent with the very open NbOC bond angle of 149°.

MCl_5 when allowed to react with acidic aqueous solutions of tropolone (HT) gave the tetrakis(tropolonate) cations $[MT_4]^+$. Hydrolysis of the niobium derivative afforded $[NbOT_3]$;[425] an oxygen-labeling experiment established that the oxo atom is abstracted from the displaced tropolone molecule.

N-Benzoylphenylhydroxylamine (BPHA) reacts with Nb_2O_5 in bioling acidic aqueous solutions to yield a monomeric seven-coordinated niobium compound $[NbO(BPHA)_3]$.[426] The hydroxylamine ligand could be displaced by tropolone or 8-quinolinol, and the rate-determining step was shown to be associative (equation 38).[427] Oxoniobium and tantalum(V) 8-quinolinolates have also been reported. The optimal conditions for the formation and extraction of the $[NbO(C_6H_4O_2)_3]^{3-}$ ion formed in the niobium(V)–pyrocatechol system, have been investigated.[428]

$$[NbO(BPHA)_3] \underset{L=HT,\,oxH}{\overset{HL}{\rightleftharpoons}} [NbO(BPHA)_3(HL)] \longrightarrow \text{products} \quad (38)$$

(*ii*) *Oxo-β-diketonato derivatives*

The action of acetylacetone on MOX_3 (X = Cl, Br) was reported to yield $[NbOX_2(acac)]$,[413,429] while the analogous Ta^V compounds were not formed. Ionic β-diketonates $[NbOCl_3(RCOCHCOR')]^-$ were obtained from oxotetrachloroaquaniobates.[430]

Table 25 Oxoalkoxo Derivatives

Compounds	*Comments*	*Ref.*
$[NbOCl_2(OR)bipy)]$	R = Et, Pr; monomeric	1, 4

Their solutions consisted of mixtures of the three possible monomeric octahedral isomers; these are rapidly interconverting on the NMR time-scale through an intramolecular mechanism.[431] The crystal structure of the $[NBOCl_3\{C_4H_3SC(O)CHC(O)CF_3\}]^-$ ion established that the isomer present in the solid state has the thenoyl groups *trans* to the Nb=O bond.[432] The niobium atom displays a distorted octahedral arrangement, and is displaced toward the oxo oxygen by 0.295 Å (Nb=O: 1.70(3) Å). Of the two chelate Nb—O distances, 2.044(34) and 2.285(3) Å, the longer is *trans* to the oxo group.

(*ii*) *Oxocarboxylato*

Oxocarboxylato derivatives were shown to form by treatment of NbX_5 or $Nb(OR)_5$ with an excess of carboxylic acids[235,433,434] or anhydrides[435] (equations 39a and 39b).

$$[MCl_5]_2 + 4RCOOH \longrightarrow 2[MOCl_2(RCOO)] + 4HCl + 2RCOCl \quad (39a)$$

M = Ta; R = H, Me, Et, Pr^i, Bu^t

M = Nb; R = Me, Et, Pr^i, Bu^t, CH_2Cl, CH_2F, Ph

$$[M(OEt)_5] + 4RCOOH \longrightarrow [MO(RCOO)_3] + RCOOEt + 4EtOH \quad (39b)$$

M = Nb, Ta; R = Me, Et, Pr

The reaction of niobioporphyrin $[Nb_2O_3(TPP)_2]$ with acetic acid gave [NbO(TPP)(MeCOO)] in which the metal is seven-coordinated and lies within a polyhedron of symmetry close to C_s,

with a square based defined by the four nitrogen atoms of the pyrrole rings and a nearly parallel triangular base formed by the three oxygen atoms (Figure 16).[330]

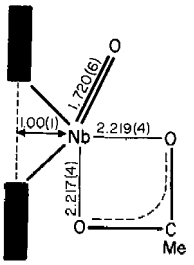

Figure 16 Structure of [NbO(TPP)(MeCOO)] (reproduced from ref. 339 with permission)

Ascorbic acid with niobium(V) in acid solution forms an intensely colored complex $[NbO(OH)_2(C_6H_7O_6)]$, which was used for the spectrophotometric determination of Nb.[436] Malato complexes of niobium(V) were obtained from aqueous racemic malic acid solutions of Nb_2O_5.[437] Niobic and tantalic acids dissolve in solutions of oxalic acid,[1] and mono-, bis- or tris-oxalatooxo niobium(V) compounds were reported to exist in these solutions, depending on pH and concentrations.[438–440] X-Ray diffraction studies on $[NbO(C_2O_4)_3]^{3-}$,[441,442] $[NbO(C_2O_4)_2(OH)(H_2O)]^{2-}$ [443] and $[NbO(C_2O_4)_2(H_2O)_2]^{-}$ [444] have shown niobium to be seven-coordinated. The oxo atom is at one of the apices of a pentagonal bipyramid and the metal is displaced toward the oxo atom by 0.18, 0.21 and 0.245 Å (Nb=O: 1.71, 1.66 and 1.69 Å respectively). The water molecules in $[NbO(C_2O_4)_2(H_2O)_2]^{-}$ exchange with oxygen donors; mixed ligand complexes with sulfoxides,[445] phosphine and arsine oxides[446] have been reported. Mixed complexes with the 4-(2-pyridylazo)resorcinol (PAR) N donor ligand are used in analytical chemistry.[447,448]

Oxohalooxalato niobium anions $[NbO(C_2O_4)_2F_2]^{3-}$ [449] and $[NbO(C_2O_4)_3Br]^{4-}$ [450] have been obtained from the parent tris(oxotrioxalato) anion. Complexation of the oxalato ligand as a bis(bidentate) bridge in $[Nb_2O_2X_6(C_2O_4)]^{2-}$ (X = F, Cl, Br) has been established on the basis of IR.[451]

The solubility of Ta_2O_5 in aqueous oxalic acid solutions is much lower than that of Nb_2O_5 and the resulting solutions are more complex owing to the presence of polymeric species.[452]

34.2.7.2 From sulfur compounds

$[NbO(R_2dtc)_3]$ has been prepared for R = ethyl[453,454], cyclopentyl and cycloheptyl.[455] All are monomers, with sulfur-bonded dithiocarbamates. The structure of the *N*-diethyl derivative[456] showed the niobium atom at the center of a pentagonal bipyramid with the oxygen at one of the apices. Two of the chelating ligands lie approximately in the equatorial plane, while the third spans an axial and an equatorial site. The axial M—S distance (2.753(4) Å) is longer than the equatorial ones (2.47–2.598 Å). The metal atom lies above the best plane passing through the equatorial sulfur atoms on the side of the oxygen (Nb=O: 1.74(1) Å).

34.2.7.3 From nitrogen compounds: oxo amides and oxo isothiocyanates

The aminolysis of $NbOCl_3$ [410] or $NbOBr_3$ [365] by an excess of primary amine was shown to affect only one of the halogen atoms, to give $[NbOX_2(NHR)]$. Excess of secondary amines with short alkyl chains displaces two bromine atoms. With increasing chain length, the tendency of a second halide atom to be substituted decreases and the second molecule of amine rather coordinates to the initial aminolysis product to yield $[NbOX_2(NR_2)(NHR_2)]$. Trialkylamines gave the addition products $[NbOX_3(NR_3)]$. Monomeric $[NbO\{N(SiMe_3)_2\}]$ was obtained from $NbCl_4(THF)_2$.[458]

$[NbO(NCS)]^{2-}$ salts were precipitated from acidic solutions of Nb^V with excess thiocyanate.[459] The structure[457] of its $(Ph_4As)^+$ salt showed the metal to be at the center of a distorted octahedron (Nb=O: 1.70 Å), and to be displaced by 0.21 Å out of the nitrogen's plane toward the oxygen. The Nb—N bond *trans* to the oxo ligand is longer (2.27 Å) than the others (2.03 to 2.16 Å).

Addition of heterocyclic nitrogen bases to acid solutions of Nb and KSCN gave the mixed monomeric complexes listed in Table 26. $[TaOCl_3(MeCN)_2]$ and $[TaSCl_3(PhNCCl_2)]$ react with alkali metal thiocyanates in MeCN to yield $[TaOCl_{3-x}(NCS)_x(MeCN)_2]$, $A[TaO(NCS)_4]$, $[TaSCl_{3-x}(NCS)_x(PhNCCl_2)]$ or $A[TaS(NCS)_4(PhNCCl_2)]$ ($x = 1–3$; $A = NH_4$, K, Na).[376] $[NbO(NCS)_3L]$, where L is $C_6H_{10}O$ or $C_9H_{14}O$, was isolated from $NbCl_5$ and KNCS solutions in acetone.[460]

Table 26 Mixed Oxo–Isothiocyanato complexes[1]

Compounds	*Medium*	$\nu(Nb{=}O)$ (cm^{-1})
$(HA)[NbO(NCS)_3(OH)H_2O)]$[a]	H_2SO_4	914

34.2.8 Oxide- and Sulfide-derived Compounds

34.2.8.1 Oxides and peroxides

The ultimate products of the oxidation of the metals are the pentoxides. Reduction of M_2O_5 by H_2 yields MO_2 and MO. These are beyond the scope of this chapter. Numerous orthometallates $[MO_4]^{3-}$, metametallates $[MO_3]^-$ and polymetallates are known; their chemistry is reviewed in Chapter 38.

(*i*) *Peroxo acids and salts*

Orthoperoxometallates $A_3[M(O_2)_4]$ precepitate from alkaline solutions of niobates or tantalates on additon of H_2O_2.[461–467] The four O_2 groups are linked side-on to the metal in $[M(O_2)_4]^{3-}$, which releases oxygen progressively in mild conditions, and explosively at 80 °C.[468] The $[Nb(O_2)_4]^{3-}$ ion has nearly D_{2d} symmetry; the M—O distances range from 1.99 to 2.07 Å, and the O—O mean distance is 1.50 Å.[466]

On treatment with H_2SO_4, the orthoperoxo salts gave the corresponding acids HMO_4.[461,469–472] The niobium derivative was formulated as $[Nb_2O_2(O_2)_2(OH)_2]\cdot xH_2O$ on the basis of IR data.[461] Metaperoxo salts AMO_5 (A = Na, K, Rb, Cs) have also been obtained.[1,473] Oxidation of the coordinated O_2^{2-} moiety by Ce^{IV} or OH radicals yielded complexes of Nb^V of type $[Nb(O_2)(OH)_2]$ containing the O_2^- radical ion, as evidenced by EPR.[474,475]

(*ii*) *Peroxo complexes*

The di- and tri-peroxo compounds (Table 27), in which the metal is bound to the oxalato,[476,477] phen,[478] or edta ligands, were prepared from alkali metal niobates or tantalates(V) in hydrogen peroxide solutions. $[Nb(O_2)_3phen]^-$ is to date the only example of a triperoxo complex authenticated by X-ray crystallography (Figure 17). The metal, at the center of a distorted dodecahedron, is located 0.34 Å above the mean plane containing two peroxo groups and one nitrogen atom, on the same side as the third peroxo group. In $[Nb(O_2)_2(C_2O_4)_2]^{3-}$,[441] the two peroxo groups are *cis*, which is unusual (O—O mean distance 1.48 Å); the coordination polyhedron is a distorted dodecahedron.

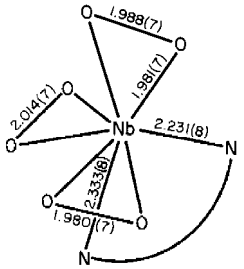

Figure 17 Structure of the $[Nb(O_2)_3(phen)]^-$ anion (reproduced from G. Mathern and R. Weiss, *Acta Crystallogr., Sect. B*, 1971, **27**, 1582 with permission)

(*iii*) *Peroxohalo derivatives* (Table 28)

Peroxofluoro complex anions $[Nb(O_2)F_6]^{3-}$, $[M(O_2)F_5]^{2-}$, $[M(O_2)F_4L]^-$, $[M(O_2)_2F_4]^{3-}$, $[M(O_2)_2F_3]^{2-}$ and $[Ta_3(O_2)_3OF_{13}(H_2O)]^{6-}$ were reported. Their structures often proved difficult to solve, due to disorder in the crystal and to facile decomposition of the peroxo moiety. The structure of the $[M(O_2)F_5]^{2-}$ anion has been repeatedly investigated; pentagonal bipyramidal arrangements have been found with the peroxo group in the equatorial plane (O—O: 1.45–1.47 Å for M = Nb; 1.389–1.443 Å for M = Ta at 170 K).

The $[Ta(O_2)F_4(C_6H_7NO)]^-$ anion also exhibits a seven-coordinate tantalum atom at the center of a pentagonal bipyramid, the two apical positions being occupied by fluorine (O—O: 1.43–1.67 Å). Salts of $[M(O_2)_2F_4]^{3-}$ were isolated and characterized by IR; a disordered structure has been reported for $[Ta(O_2)_2F_4]^{3-}$. $[Ta_3(O_2)_3OF_{13}]^{6-}$ consists of $[Ta(O_2)_2F_5]^{2-}$ and of μ-oxo-bridged $[Ta_2O(O_2)_2F_8]^{4-}$ anions in the same unit cell, with very different O—O distances in the various peroxo groups. The Ta—O—Ta bridge in the dimeric anion is asymmetrical (Figure 18).

A series of $[M(O_2)F_3(diket)]^-$ complexes has been prepared by the reaction of β-diketones with $[M(O_2)F_4(H_2O)]^-$. ^1H and ^{19}F NMR spectra indicate that the products exist as a mixture of geometrical isomers in MeCN. The reaction of oxalic acid with $[Nb(O_2)F_4(H_2O)]^-$ yielded $[Nb_2(O_2)_2F_6(C_2O_4)]^{2-}$. A bridging oxalato group and a coordination number of seven for the metal were proposed. $[M(O_2)F_3(phen)]$, $[M_2O(O_2)F_4(bipy)_2]$ and $[M(O_2)F_3(OAsPh_3)_2]$ were obtained when the neutral ligands were allowed to react with $[M(O_2)F_4(H_2O)]^-$.

A few peroxochloro derivatives of the $[M(O_2)Cl_5]^{2-}$ [391] and $[M(O_2)Cl_4(H_2O)]^-$ [431] anions are known. Addition of β-diketones to solutions of the latter afforded $[Nb(O_2)Cl_3(diket)]^-$; the stereorigidity of these heptacoordinated species in solution was assigned to the bidentate peroxo moiety.[431]

$[NbCl_2(RCp)_2]$ (R = H, Me) complexes react with H_2O_2, affording $[Nb(O_2)Cl(RCp)_2]$. In the complex with R = H the two oxygen atoms (O—O: 1.47(1) Å) and the chlorine atom are in the plane which bisects the $Nb(Cp)_2$ bent sandwich system; the coordination around niobium is thus pseudotetrahedral. In the presence of H_2O_2, $[Nb(O_2)Cl(Cp)_2]$ catalytically converts cyclohexene to its epoxide.

34.2.8.2 Sulfides, selenides and related compounds

$[MY_4]^{3-}$ (Y = S or Se)[367] and $[NbOS_3]^{3-}$ [368] are known only as insoluble salts synthesized from the elements at high temperatures; $[NbO_2S_2]^{3-}$ [369] was obtained from strongly basic solutions of Nb_2O_5 saturated with H_2S. The salts $(NEt_4)_4[M_6S_{17}]$,[366] sensitive to O_2 and H_2O, were prepared from $[M(OEt)_5]$, $(Me_3Si)_2S$ and Et_4NCl (1:6:3) in MeCN. Single crystal X-ray analysis (Figure 19) revealed 10 non-planar M_2S_2 rhombs in convex fusion forming a crown-shaped M_6S_{10} cage. Each metal atom is additionally bonded to a terminal S atom and to the bridging S atom inside the cage, thus achieving pentagonal seven-coordination for top M(1), and tetragonal six-coordination for the other metal atoms.

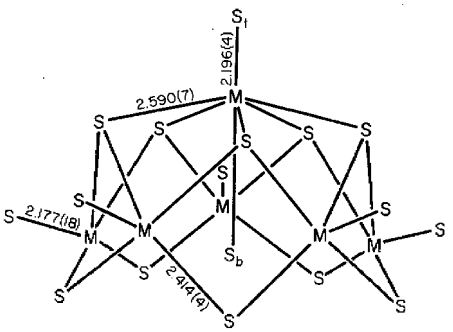

Figure 19 Structures of $[M_6S_{17}]^{4-}$ (reproduced from ref. 366 with permission)

Nb^V and Ta^V complexes with the S_2 and Se_2 ligands, formally similar to O_2, appear to be limited to bis(cyclopentadienyl) complexes. The reaction of $[NbCl_2(OH)(Cp)_2]$ with H_2S in methanol, in the presence of ionic halides or pseudohalides (KCl, KBr, NH_4I, KSCN), afforded the monomeric $[Nb(S_2)X(Cp)_2]$ (X = Cl, Br, I, SCN) complexes.[418] When X = Cl or Br, a second compound of the same formula was obtained and assumed to be polymeric with disulfide bridging groups. Surprisingly, when X = SCN, a cyano complex, $[Nb(S_2)CN(Cp)_2]$, was formed. $[NbMe_2(Cp)_2]$ was reported to be oxidized by S_8 to yield $[Nb(S_2)Me(Cp)_2]$.[479] Similar procedures with $[Nb(\eta^1\text{-Cp})_2(Cp)_2]$, $[NbH(CH_2{=}CHEt)(Cp)_2]$ and $[TaMe_2(Cp)_2]$ gave the $[M(S_2)R(Cp)_2]$ complexes, where R = η^1-Cp, Bu and Me, respectively.[480] The reaction of $[NbMe_2(Cp)_2]$ with red selenium afforded $[Nb(Se_2)Me(Cp)_2]$.[480] $[Nb(S_2)\{SP(S)(OR)_2\}(Cp)_2]$ complexes (R = Me, Et, Pr^i, Bu^t) were obtained from $[NbCl_2(Cp)_2]$ and P_4S_{10}.[481] The R = Et and Pr^i derivatives were reported to form from S_8 and $[Nb\{SP(S)(OR)_2\}_2(Cp)_2]$.[252] The structures of $[Nb(S_2)X(Cp)_2]$ were solved for X = Cl,[482] CN[482] and Me[483] (S—S: 2.03(1) Å). $[Nb(S_2)Me(Cp)_2]$ was shown to transfer sulfur to a phosphine.[480]

34.2.8.3 Other oxygen- or sulfur-substituted metal compounds

(i) Sulfates

The interest in sulfates arises mainly from the development of processes using sulfuric acid in the treatment of mineral concentrates. MCl_5 reacts with SO_3 in SO_2Cl_2 to form the insoluble $[Nb_2O(SO_4)_4]$ and $[Ta_2(SO_4)_5]$, respectively. Whereas $[Nb_2O(SO_4)_4]$, $[Nb_2O_2(SO_4)_3]$, $[Nb_2O_3(SO_4)_2]$ and $[Nb_2O_4(SO_4)]$ could be isolated from the Nb_2O_5–SO_3–H_2O system, only $[Ta_2(SO_4)_5]$ and $[Ta_2O_4(SO_4)(H_2O)]$ were obtained in the case of Ta^V.[1] The hydrated oxo sulfates $[Ta_2O_3(SO_4)_2(H_2O)_n]$ (n = 3, 4 or 5) were also reported. In H_2SO_4, M_2O_5 and $MOCl_3$ form $H[MO(HSO_4)_4]$, while MX_5 gives $H[M(HSO_4)_6]$.[484] The more soluble NH_4,[1] Na,[485] Cs[486,487] and Rb[488] double sulfates have also been described.

(ii) Nitrates, phosphates, arsenates and related compounds

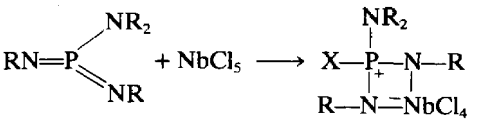
The reaction between MCl_5 and liquid N_2O_5 resulted in the moisture sensitive tris(nitrato)oxo compounds $[MO(NO_3)_3]$.[1] The $(NMe_4)[NbO(NO_3)_4]$ complexes were prepared by addition of liquid N_2O_5 to the appropriate hexachloro complexes with covalently bonded

nitrato groups. Solvated polymeric nitratodioxides, $[MO_2NO_3]$, were obtained from MCl_5 and N_2O_4 in ionizing solvents.

Metaphosphates, $[MOPO_4]$ or $[M_2O_5(P_2O_5)]$, have been reported. Single crystals of $NbOPO_4$ were prepared by heating together H_3PO_4 and Nb_2O_5 in a gold capsule at 600 °C under 1800 bar.[489] A compound of composition $[Nb_9O_{25}P]$ was obtained by a similar procedure at 750 °C under 2000 bar.[490] $[TaOPO_4(H_2O)]$, $[TaOPO_4]$, $[TaOAsO_4]$ and $[Ta_9AsO_{25}]$ are also known.[491] The orthophosphates $[M_3(PO_4)_5]$ were prepared by reaction of excess H_3PO_4 with MX_5 in the molten state.[1]

$NbOPO_4$ has tetragonal symmetry, and its structure is made up of chains of corner-sharing NbO_6 octahedra with non-equivalent Nb—O bonds (1.78 and 2.32 Å), linked together by PO_4 tetrahedra. In the hydrated crystalline niobium phosphates, the individual NbO_6 octahedra are no longer connected to each other, and display a layer structure capable of hosting various molecules such as H_2O[492,493] or H_3PO_4.[494]

$NbCl_5$ and $TaCl_5$ abstract oxygen from diisopropylmethylphosphonate to yield polymeric complexes $[Mo(IMP)_3]_n$ (IMP = isopropoxymethylphosphonate),[407] which contain M=O groups and both chelating and bridging phosphonato groups.



The methylphosphinates $[M_2O(MePO_3)_4]$ precipitate when methylphosphinic acid and the pentachlorides are heated together.[1] $[Ta(OR)_{5-x}(Ph_2PO_2)_x]$ ($x = 1$–3) were prepared from $Ta(OR)_5$ and $Ph_2P(O)OH$ as low molecular weight polymers. The polymeric oxides $[TaO_2(Ph_2PO)]_n$, $[Ta_2O_3(Ph_2PO)_2]_n$ and $[TaO(Ph_2PO)_3]_n$ have been obtained by suspending the methoxide or ethoxide in boiling water.

The sodium salts of dialkyldithiophosphate (ddtp) react with NbX_5 (X = Cl or Br) in methanol to yield $[MX(OMe)_2(ddtp)_2]$; recrystallization from the appropriate alcohol afforded $[MX(OR)_2(ddtp)_2]$.[239] The P—S stretching vibrations in the IR around 600–750 cm^{-1} suggest that the ligands coordinate through both sulfur atoms. The surprising formation of the diamagnetic $[Nb(S_2)\{SP(S)(OR)_2\}(Cp)_2]$ from P_4S_{10} and $[NbCl_2(Cp)_2]$ in ROH illustrates the ease with which Nb^{IV} is oxidized in such complexes;[481] the dialkyldithiophosphate ligand appears to be monodentate; the origin of the S_2 group is as yet not understood.

The reactions of F_2PS_2H with MCl_5 gave the chloro(difluorophosphinato) complexes $[MCl_3(S_2PF_2)_2]$,[495] in which both $S_2PF_2^-$ ligands are bidentate.

34.2.9 Miscellaneous Metal–Element Derivatives

Zwitterionic four-membered PN_2Nb heterocycles were obtained in the reaction of η^5-phosphorus–nitrogen ylides with $NbCl_5$ according to equation (40).[496]

(40)

R = $SiMe_3$

In the course of an investigation of the Ta/P/S system, formation of a compound of overall composition $TaPS_6$ was noted.[497] Its structure showed each tantalum atom to have eight nearest sulfur neighbors arranged in a bicapped triangular prism. Two such prisms, sharing a common face, form Ta_2S_{12} units; these are linked together by PS_4 tetrahedra into endless chains. The compound can be formally considered as containing two cations, Ta^{5+} and P^{5+}, and two anions, $(S_2)^{2-}$ and S^{2-}, and can be formulated as $[Ta(PS_4)S_2]$.

Compounds containing Nb—Zn or Ta—Zn bonds have been obtained by the reaction of $[MH_3(Cp)_2]$ with $[Zn(Cp)_2]$. The structures of $[NbH_2(Cp)_2Zn(Cp)]$ and $[TaH(Cp')_2\{Zn(Cp)\}_2]$ were determined.[499] The reaction of $[NbH_3(Cp)_2]$ with HgX_2 afforded the first complexes with Nb—Hg bonds;[500] $[Nb(Cp)_2(HgS_2CNEt_2)_3]$ has been characterized by X-ray diffraction analysis (Nb—Hg: mean 2.790 Å).

34.3 OXIDATION STATE +IV

34.3.1 Tetrahalides

The niobium and tantalum tetrahalides are all known, except TaF_4, whose non-existence is consistent with the fact that $[TaF_5]_4$ should be the least reducible halide of the group VA

elements.[1,2,4,5] They are dark solids, obtainable by reduction of the pentahalides by H_2, Al, Nb or Ta at high temperatures. The most popular preparation involves the thermal gradient method, with a metal as reductant. NbI_4 is easily obtained on heating NbI_5 to 300 °C.[501] The reduction of TaI_5 is slower, and an easier way to prepare TaI_4 is to allow TaI_5 to react with an excess of pyridine, giving $[TaI_4(py)_2]$ which, upon heating, loses the ligand.[502] NbI_4 and TaI_4 are trimorphic and dimorphic, depending on the synthetic procedure. All tetrahalides except NbF_4 disproportionate thermally. These reactions may be suppressed by maintaining a sufficiently high partial pressure of the pentahalides during the high temperature synthesis.

NbF_4 is a paramagnetic solid in which the Nb atoms lie at the center of octahedra that share four corners in an infinite sheet structure.[2] The other tetrahalides are essentially diamagnetic, and often orthorhombic. $NbCl_4$[503] and NbI_4[504] form one-dimensional polymers consisting of *trans* edge-sharing polyoctahedra, with very weak interchain coupling. These $[Nb_2X_4(\mu\text{-}X)_4]_\infty$ polymers exhibit bond alternation (Figure 20), with metal–metal pairs. Powder data suggest that $NbBr_4$ and TaX_4 (X = Cl, Br, I) are isomorphous with $NbCl_4$ and α-NbI_4. $NbBr_4$ is extremely sensitive to moist air, while $NbCl_4$ is relatively air stable.

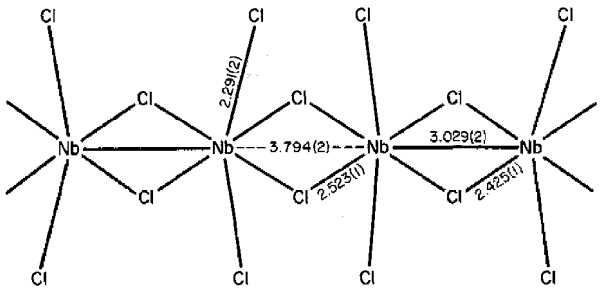


Figure 20 Section of the linear chain of $(Nb_2Cl_8)_n$ showing the bond alternation (reproduced from ref. 503 with permission)

Recent interest in low dimensional conducting materials has led to various experimental and theoretical studies on NbX_4.[505,506] Their structure, with two types of metal-bridging halide bonds on unequal lengths alternating along the chain, is responsible for their semiconducting properties. Their electrical conductivities increase sharply with temperature or pressure, and NbI_4 was shown to exhibit metallic behavior under high pressure.[507] The activation energy for conduction decreases from $NbCl_4$ to NbI_4, despite the increase in metal–metal distance. This trend has been accounted for by a diminution of the valence band and band gap energies (~0.1 and 1.0 eV in $NbCl_4$; ~0.3 and 0.8 eV in NbI_4).

34.3.2 Halo Complexes

34.3.2.1 Halometallates(IV)

The hexahalometallates obtained by electroreduction of NbX_6^- or from MX_4 have been isolated as their alkali or tetraalkylammonium salts $A_2[MX_6]$ (M = Nb, X = Cl, A = K, Rb, Cs, NH_4; X = Br, Et_4N, A = Cs and M = Ta, X = Cl).[7,508] Their thermal stability, higher for tantalum, is in marked contrast with that of the corresponding neutral tetrahalides (ΔH°_{298} in the −1614 to −1719 kJ mol^{-1} range, compared to −694 kJ mol^{-1} for $NbCl_4$).[508] $K_3[NbF_7]$ is isostructural with $K_3[NbOF_6]$ and $(NH_4)_3[ZrF_7]$; it approaches D_{5h} symmetry.[510]

34.3.2.2 Neutral adducts of tetrahalides

(*i*) *Synthesis*

Numerous adducts of MX_4 with nitrogen, phosphorus, arsenic, oxygen and sulfur donors have been obtained, mainly for niobium with X = Cl or Br[7] (Tables 29–33). The absence of MF_4 adducts, except for $[NbF_4(py)_2]$,[511] may be due less to their instability than to a lack of investigations. An ill-defined fluoro trichloride complex, $[NbCl_3F(MeCN)_{2.65}]$, has also been reported.[512]

These adducts were synthesized by extraction of solid $[M_2X_8]_n$ by the ligand, or by reduction of MX_5 (X = Cl, Br, I) with an excess of ligand. Such reductions occur most readily with monodentate, or, even better, with bidentate or heterocyclic nitrogen donors (equation 41),[502,515] although it was also observed with macrocyclic ethers, phosphines[513] and diarsines.[514] Longer reaction times or higher temperatures are required with the tantalum pentahalides. As a result, the adducts of Nb^{IV} and Ta^{IV} with nitrogen donors (nitriles and heterocycles) are predominant (Table 29). Partial solvolysis of NbX_4 was often observed with aliphatic amines (Et_2NH, en, *etc.*) and their adducts are confined to $[NbCl_4(NEt_3)]_n$. Adducts with nitriles are limited to $[NbCl_4(RCN)_2]$ (R = Me, Ph) and acrylonitrile $[MX_4(C_2H_3N)_2]$ (X = Cl, Br) adducts.[516] Adducts with various phosphines have been isolated (Table 30), while the adducts with arsenic donors are limited to those of the bidentate *o*-phenylenebisdimethylarsine (diars) and related ligands (Table 31). A few mixed ligand adducts have also been reported.

$$\begin{aligned} 2NbBr_5 + 7py &\longrightarrow [NbBr_4(py)_2] + pyH^+Br^- + (py)_2^{2+}Br \\ NbI_5 + 3py &\longrightarrow [NbI_4(py)_2] + pyI_2 \end{aligned} \qquad (41)$$

The complexes with group VIB donors are collected in Table 32. No TaX_4 adducts with monodentate oxygen donors have so far been isolated, probably as a consequence of the strong O abstraction properties of Ta^{IV}; the reaction between $TaCl_4$ and dioxane led, for instance, to $[TaOCl_3(diox)_2]$.[517] Such reactions are less favored for Nb^{IV} and require powerful oxo ligands such as DMSO;[512] they are not observed with dry DMF.[519] $[NbCl_4(THF)_2]$ is of interest because of the lability of the THF molecules, which makes it a useful starting material in Nb^{IV} chemistry.[519] So far, only crown ethers have been able to achieve O complexation of $TaCl_4$, providing $[(TaCl_4)_2(18\text{-CRW-6})]$.[513] Sulfide adducts are listed in Table 33.

(*ii*) *Structure*

The solubility of the MX_4 adducts is generally poor, but increases from the chlorides to the iodides. In contrast to the tetrahalides themselves, most of their adducts are monomeric and paramagnetic. Characterization by ESR was sometimes achieved. The absence of notable paramagnetism was usually taken to support the existence of oligomeric or polymeric structures. X-Ray data remain scarce, other than for a number of phosphine adducts.

With monodentate ligands, paramagnetic pseudooctahedral diadducts $[MX_4L_2]$ of D_{4h} or C_{2v} symmetry are most frequently formed. X-Ray structure determinations are available on *trans*-$[MCl_4(PEt_3)_2]$, *cis*-$[TaCl_4(PMe_2Ph)_2]$,[520] *cis*-$[NbBr_4(MeCN)_2]$[521] and *cis*-$[NbCl_4(MeCN)_2]\cdot MeCN$.[522] The stereochemistry of most $[MX_4L_2]$ compounds has however been

deduced from IR or ESR data. Distorted d^1 octahedral MX_4L_2 complexes generally exhibit $g_\parallel > g_\perp$ except for $[NbCl_6]^{2-}$, where all ligands have similar electron-donating properties. The hyperfine coupling parameters decrease with increasing ligand basicity (Table 34).

A few monoadducts have been reported for Nb^{IV}. These are favored by bulky ligands; thus tetrahydrothiophene formed diadducts with $NbCl_4$, while the bulkier methyl and ethyl sulfides provided monoadducts and unstable diadducts.[523] Monoadducts were also obtained with HMPA, NEt_3 and PBu^t_3; they are only slightly paramagnetic, and halogen-bridged bioctahedral structures with M—M bonds have therefore been postulated. The monoadducts are stabler for the chlorides than for the iodides, illustrating the importance of M—M bonding.

The systematic study of the phosphine adducts of MCl_4 offered a series of $[MCl_4(PR_3)_n]$ compounds. Of particular interest are the dinuclear $[Nb_2Cl_8(PR_3)_4]$ ($R_3 = Me_3$, Me_2Ph), which display two square antiprismatic $[NbCl_4(PR_3)_2]$ units sharing a square Cl_4 face (Figure 21).[524] Strongly basic phosphines such as PBu^t_3 or PCy_3 also favor metal–metal interactions to give soluble dinuclear $[Nb_2Cl_8(PBu^t_3)_2]$ and $[Nb_2Cl_8(PR_3)_3]$ ($R = Bu^t$, Cy) complexes.[304] The latter stoichiometry is rather unusual, and triply-chloride-bridged structures, comparable to those found in $[Nb_2Cl_9]^{3-}$ [525] or $[Nb_2Cl_3(CO)_8]^-$,[526] have been assumed. Tantalum is apparently less prone to adopt dinuclear structures, and the seven-coordinate $[TaCl_4(PMe_3)_3]$ (a capped octahedron of C_{3v} symmetry) and *cis*-$[TaCl_4(PhPMe_2)_2]$ have been obtained.

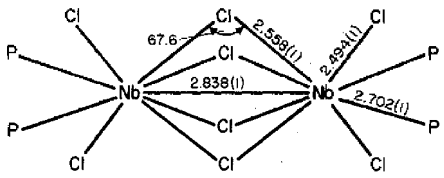

Figure 21 Drawing of the central core of the $[Nb_2Cl_8(PPhMe_2)_4]$ molecule (reproduced from ref. 524 with permission

Multidentate ligands tend to stabilize higher coordination numbers, generally giving monomeric paramagnetic structures, although distorted octahedral complexes were obtained with some bidentate ligands such as bipy and phen. Heptacoordination is seldom encountered with bidentates, but occurs in $[MCl_4(terpy)]$. Octacoordination is more common, as illustrated by the formation of $[MCl_4(dmpe)_2]$,[519] $[NbX_4(dth)_2]$[527] and $[NbX_4(diars)_2]$ (X = Cl, Br, I),[528] in which the coordination polyhedra were assumed to be dodecahedral on the basis of UV or ESR data. It has been found that usually $g_{\parallel} > g_{\perp}$ for an archimedian antiprism, while $g_{\parallel} < g_{\perp}$ for a triangular dodecahedron (Table 34). The latter geometry was established by X-ray diffraction for $[NbCl_4(diars)_2]$,[530] while $[TaCl_4(dmpe)_2]$[529] was found to be a square antiprism. The bidentate *o*-phenylenebisdimethylarsine displays a different behavior, since only the monoadduct $[TaCl_4(diars)]$ was found to be stable, but its structure remains unknown. The $[MCl_4(dmpe)_2]$ (**22**) complexes have been widely used as precursors to lower oxidation states.

The tetrahalide adducts are stable to disproportionation, except for '$TaX_4(MeCN)_2$' (X = Cl, Br), which gives Ta^V and Ta^{III} species, the latter undergoing reductive coupling with MeCN. These observations corroborate the results obtained through polarography in MeCN; $TaCl_5$ is reduced directly to Ta^{III}.[531]

Spontaneous reduction to niobium(III) was observed for the crowded dinuclear PCy_3 and

PBu^t_3 adducts. Reduction to undefined products was also noted for $[NbI_4(py)_2]$[515] and $[NbX_4(LL)]$, where LL = *N,N,N′,N′*-tetramethylethylenediamine.[532]

A poorly characterized borohydride derivative $[Nb(BH_4)_2Cl_2(MeCN)_2]$ has been reported.[533]

34.3.3 Pseudohalo Complexes (Table 35)

A number of stable niobium(IV) isothiocyanates and less stable isoselenocyanates are known. Rigorous exclusion of water is required to avoid the formation of selenium during the synthesis of the latter.[534]

Neutral six- or eight-coordinated adducts were obtained by allowing $[Nb(NCS)_6]^{2-}$ or $[Nb(NCSe)_6]^{2-}$ to react with pyridine or bipyridyl, respectively. An alternative route to the paramagnetic pyridine adducts is the reduction of $[Nb(NCS)_6]^-$ by the ligand. $[Nb(NCS)_4(bipy)_2]$ adopts a nearly perfect D_{4d} square antiprismatic structure, with the bidentate ligand bridging the square faces.[535] N coordination has generally been established for the ambidentate thiocyanate ligand in the solid.

Paramagnetic Nb^{IV} octacyanide anions have been isolated as alkali metal or tetraalkylammonium salts. $K_4[Nb(CN)_8]$ has been obtained in low yield by air- or hydrogen-peroxide-oxidation of $K_5[Nb(CN)_8]$ prepared by electrolytic reduction of $NbCl_5$ in an MeOH–KCN medium.[536] $K_4[Nb(CN)_8]\cdot 2H_2O$ disproportionated photolytically to restore the Nb^{III} derivative. The $[Nb(CN)_8]^{4-}$ anion is dodecahedral in the solid; all Nb—C distances are equal

(2.255 Å).[537] ESR, IR and Raman spectroscopies support a configurational change from D_{2d} symmetry in the solid to D_{4d} (antiprism) in solution.

The known cyanato compounds are summarized in Table 35.

34.3.4 Oxo, Thio and Seleno Halides

34.3.4.1 Oxo halides and oxo compounds

Apart from the fluorides, all six MOX_2 compounds have been reported.[1,2,5] Attempts to prepare $NbOF_2$ yielded a single phase between the stoichiometric limits NbO_2F and $[NbO_{1.25}F_{1.75}]$ (average metal oxidation state of 4.25), with an ReO_3 type structure, and it was concluded that $NbOF_2$ does not exist.

The oxo halides are generally obtained through high temperature reduction of M_2O_5 by the metal in the presence of the halogen. $NbOI_2$ may also be prepared by decomposition of $NbOI_3$. They are diamagnetic, stable in air as well as thermally, and the structure of $NbOCl_2$ is closely related to that of $NbCl_4$.

Some Nb^{IV} oxohalo anions have been identified (Table 36), but only the slightly paramagnetic dioxofluoroniobate salts $A[NbO_2F]$ (A = Li, Na, K) were isolated. $[NbOCl_4(L)]^{2-}$ (L = H_2O or EtOH) and $[NbOCl_5]^{3-}$ were prepared by reduction of MX_5 by Zn in aqueous HCl; they result from the hydrolysis of $[NbCl_6]^{2-}$, and have been characterized *in situ* by ESR. Extraction with acetylacetone yielded $[NbO(acac)_2]$, whose structure is related to that of $[VO(acac)_2]$.[538]

Neutral adducts are limited to the oxo porphyrin derivatives (Section 34.3.5.4.i) and to the uncharacterized $[NbOCl_2(NO)(MeCN)_2]$ obtained by hydrolysis of $[NbCl_4(NO)(MeCN)_2]$.[539] This high stability of the MOX_3 (X = Cl, Br) adducts toward reduction probably hinders easy access to such M^{IV} adducts. The reduction of $NbSX_3$ (X = Cl, Br), on the contrary, allowed the development of sub-thiohalide coordination chemistry.

34.3.4.2 Thio, seleno and telluro halides

The sulfido, seleno and telluro halides of the transition metals have been reviewed recently.[540–542] Numerous Nb^{IV} chalcogenide halides have been reported. For tantalum, only $[Ta(S_2)Cl_2]$ and $[Ta(S_2)_mCl_n]$ (m = 1–3, n = 1–4), of unknown structure, obtained from $TaCl_5$ and S_8, have so far been reported.[543]

$[Nb(Y)_2X_2]$ (Y = S or Se, X = Cl, Br, I) was prepared from the elements at 400–500 °C by chemical transport reactions. The obtention of pure $[Nb(Y)_2I_2]$ required an excess of iodine,

and it must be stored under a pressure of NbI_4 even at room temperature. The chlorine derivatives are also available (equations 42–43). A similar reaction between tantalum and S_2Cl_2 led to impure TaS_3. $[Nb_2(Y)_2Br_6]$ (Y = Se, Te) and $[Nb_2(Te)_2I_6]$ were obtained by heating the elements to 780 °C.

$$3Nb + 10Y + 2NbCl_5 \xrightarrow{500\text{–}480\,^\circ C} 5NbY_2Cl_2 \quad (42)$$

$$Y = S, Se$$

$$Nb + S_2Cl_2 \xrightarrow{500\text{–}480\,^\circ C} NbS_2Cl_2 \quad (43)$$

The isomorphous $[Nb(Y_2)X_2]$ compounds are monoclinic[544,545] at room temperature and triclinic at low temperature. The structure of $[Nb(S_2)Cl_2]_2$ (Figure 22) exhibits the pairwise connection of two niobium atoms by metal–metal bonds specific of most of the Nb^{IV} halides. The molecules contain cage-shaped $Nb_2(Y_2)_2$ units of approximate D_{2h} symmetry consisting of a pair of Nb atoms lying perpendicular to the plane of the two Y_2 groups. The Y—Y distances in $[Nb(Y_2)Cl_2]$ (Y = S, Se) correspond to single bonds, and the structures may be described as $^2_\infty[Nb_2(Y_2)_2X_{8/2}]$. The occurrence of metal pairs explains their diamagnetic and semiconducting properties. The IR and Raman spectra of $[Nb(S_2)X_2]$ (X = Cl, Br, I) have been extensively studied.[546] The vibrations of the S_2 groups, at 588 cm^{-1} for $[Nb(S_2)Cl_2]$, decrease from the chloride to the iodide; they are higher than those of the thioniobyl group.

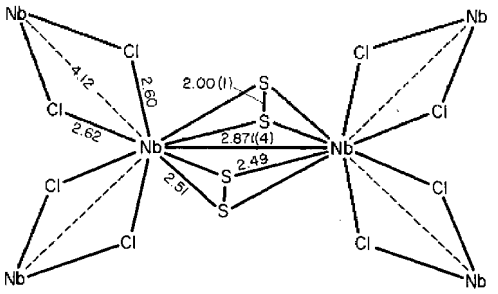

Figure 22 Drawing showing the $^2[Nb_2(S_2)Cl_{8/2}]$ structure of NbS_2Cl_2 (reproduced from ref. 545 with permission)

$[Nb_2(Y_2)X_6]$ is best described as chains of type $^1_\infty[Nb_2(Y_2)X_4X_{4/2}]$ with short Nb—Nb and Y—Y distances. The Nb_2 and Y_2 pairs (Nb—Nb: 2.832(4); Se—Se: 2.305 Å for $[Nb_2(Se_2)Br_6]$) interact to form a quasitetrahedral cluster. The structural and magnetic properties support the formal oxidation states Nb^{4+} and Y^{1-}.[547]

Isotypic compounds of stoichiometry $[Nb_3Se_5X_7]$ (X = Cl, Br) have been obtained from the corresponding $[Nb(Se_2)X_2]$ derivatives and $NbCl_4$ in the case of the chlorine compounds, or in the case of bromine by decomposition of $[Nb(Se_2)Br_2]$ in the presence of $[NbSeBr_3]$.[548] The structure of $[Nb_3Se_5Cl_7]$ (Figure 23) shows two types of niobium atoms; Nb(1) which form pairs, while Nb(2) is isolated. Similarly, the atoms Se(1) and Se(2) form an Se_2 group (2.30 Å) corresponding to a single bond, while Se(3) is coordinated to one metal atom only, at a remarkably short distance, which suggests the existence of a selenoniobyl group. X-Ray and ESCA data established that $[Nb_3Se_5Cl_7]$ is a mixed valence compound that should be formulated as $[Nb_2^{IV}Nb^{V}(Se_2)_2SeCl_7]$, Nb(2) being in oxidation state +V. The overall structure consists of chains of composition $[Nb_2^{IV}(Se_2)_2Cl_5]$ to which side chains $[Nb^{V}SeCl_2]$ are attached. Semiconducting behavior was found for this compound.

34.3.4.3 Adducts of the thio and seleno halides

A synthesis of $[NbSCl_2]$ from a solid state reaction between $NbCl_4$ and Sb_2S_3 at 200 °C has been claimed,[549] but attempts to reproduce it were unsuccessful.[522] By contrast, the reaction between NbX_4 (X = Cl, Br) and Sb_2S_3 in MeCN at 50 °C easily provided adducts of type $[NbSX_2(MeCN)_2]_2$ as highly air sensitive solids. The chlorine adducts were obtained as brown or green materials, depending on the number of MeCN groups. They are the only adducts of $NbSX_2$ that have been obtained directly from tetravalent metal derivatives. The dimers have D_{2h} symmetry; the niobium atoms are bridged by two sulfur atoms (Nb—S: 2.338(8)–

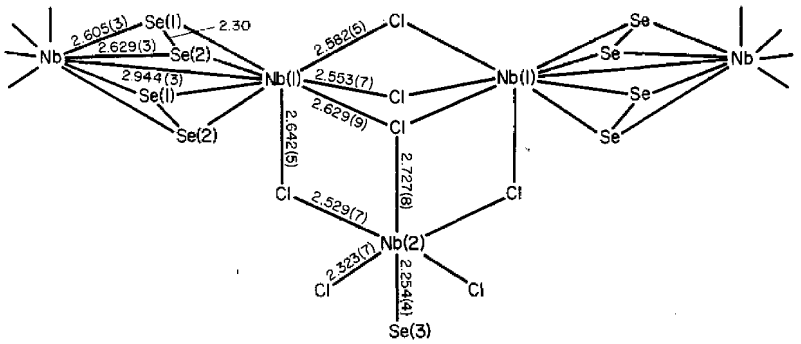

Figure 23 Section of the structure of the mixed valence $[Nb_2^{IV}Nb^{V}(Se)_2SeCl_7]$ (reproduced from ref. 548 with permission)

2.349(7) Å), and bear two chlorine atoms in apical and two acetonitrile ligands in equatorial positions. The octahedral environment of the metal is distorted as a result of niobium–niobium interactions (2.862(2)–2.872(3) Å).

$[Nb_2S_3X_4(THT)_4]$ (X = Cl, Br) results from a complex disproportionation in neat THT (equations 44 and 45), two S^{2-} ions being formally oxidized to $(S_2)^{2-}$. Sulfur abstraction reactions from $[NbSBr_3]$ have also been suggested.[373] Reactions between $[NbSCl_3]$ and THT, and those between $[NbSX_3]$ (X = Cl, Br) and Me_2S follow similar patterns. Analog studies with $[TaSX_3]$ and THT gave no evidence for Ta^{IV} compounds. Crystal structure determination led to the formulation $[Nb_2X_4(THT)_4(\mu\text{-}S)(\mu\text{-}S_2)]$ of approximate C_{2v} symmetry (Figure 24), the most salient feature being the $Nb(\mu\text{-}S)Nb(\mu\text{-}S_2)$ ring. The Nb—Nb distances suggest a single bond; the three sulfur atoms form isosceles triangles (3.78(1), 3.76(1) and 2.01(1) Å). The S—S distances are slightly shorter than in ionic $(S_2)^{2-}$. No significant *trans* effect was observed.

$$[NbSBr_3] + 2THT \longrightarrow [NbSBr_3(THT)_2] \quad (44)$$

$$[NbSBr_3(THT)_2] \longrightarrow [Nb_2S_3Br_4(THT)_4] + [NbBr_5(THT)_n] \quad (45)$$

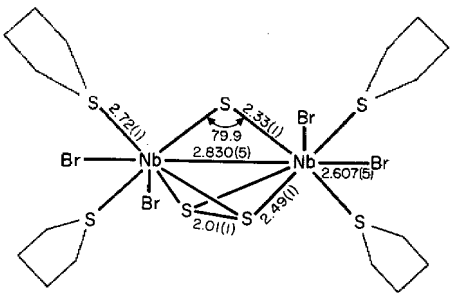

Figure 24 Molecular structure of $[(THT)_2Br_2Nb(\mu\text{-}S)(\mu\text{-}S_2)NbBr_2(THT)_2]$ (reproduced from ref. 373 with permission)

Attempts to synthesize selenium analogs of $[NbSX_2(MeCN)_2]_2$ from $[NbSeBr_2]$ led to reduction of the metal and formation of a tetranuclear cluster (equation 46). Formally two Se^{2-} ions form an $(Se_2)^{2-}$ ion with concomitant release of two electrons, which reduce two Nb^{IV} to Nb^{III} atoms, and formation of the mixed valence tetramer.[550] The latter (Figure 25) is best described as consisting of a central $(MeCN)_2Br_2Nb(\mu\text{-}Se_2)(\mu\text{-}Se)NbBr_2(MeCN)_2$ fragment linked by long bromide bridges to two *fac*-$NbBr_3$ units. Se(3) is bound to all three metal atoms. No metal–metal interaction is found between the two Nb^{III} centers, as also observed for $[NbCl_3(PhC{\equiv}CPh)]_4$ (Section 34.4.2.2.ii). The sample was ESR silent down to −196 °C, and diamagnetic, which was considered to be consistent with the two Nb^{III} atoms' being in an approximately C_{3v} environment and having a low-lying doubly occupied dz^2 orbital, while the two Nb^{IV} atoms exhibit a metal–metal interaction.

$$4[NbBr_4(MeCN)_2] + Sb_2Se_3 \xrightarrow[50\,^{\circ}C,\,7\,d]{MeCN} [Nb_4Br_{10}(Se_2)(Se)(MeCN)_4] + 2SbBr_3 \quad (46)$$

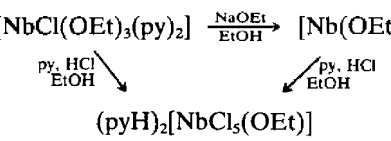
34.3.5 Solvolysis of the Tetrahalides

34.3.5.1 Alkoxides (Table 37)



Several Nb^{IV} alkoxo compounds have been obtained, by miscellaneous methods, but were often only poorly characterized. A series of salts containing the $[NbCl_5(OR)]^{2-}$ anion (R = Me, Et, Pr^i) has been prepared by electrolytic reduction of $NbCl_5$ in saturated HCl–ROH solutions.[7] A different experimental treatment of the initial electrolytic solution led to the diamagnetic $[NbCl(OEt)_3py]_2$, which was further converted to the extremely moisture- and oxidation-sensitive diamagnetic $[Nb(OEt)_4]_n$ (Scheme 5).

Scheme 5

The synthesis of $M(OEt)_4$ shows that, contrary to previous observations, tetravalent alkoxides are stable in the presence of alcohol, at least for a short time. The alcoholysis of $[Nb(NR_2)_4]$ usually led to $[Nb(OR')_5]$,[263] but oxidation state +IV was retained with bulky alcohols, *e.g.* for tetra(1-adamanto)niobium and tetra(1-adamantylmethoxo)niobium, illustrating the close dependence of the metal's oxidation state on steric requirements. $[Nb(1\text{-ado})_4]$ was reported to be monomeric, but the absence of ESR signals down to −150 °C, as well as its reluctance to form complexes (Me_2NH, PMe_3, THT) is puzzling.[551] Dinuclear and tetranuclear diamagnetic niobium chlorocatecholates have also been obtained. The Ta^{IV} alkoxides are limited to some diamagnetic chloro alkoxide adducts.

34.3.5.2 β-Diketonates, carboxylates and related chelates

$NbCl_4$ reacts with a variety of β-ketoenols or oximes in the presence of a base to give moderately soluble eight-coordinate tetrakischelates (Table 38). These have one unpaired electron and are not isostructural with the related Zr and Hf compounds. Dodecahedral structures have generally been proposed on the basis of UV or ESR data.[552] However, the larger bite of the dipivaloylmethane ligand ($b = 1.28$ Å) allows the stabilization of a square antiprism. $[Nb(dpm)_4]$ corresponds to an idealized $D_4(1111)$ isomer, and was the first example of this geometry to be reported.[553] Evidence for nine-coordination was found in $[Nb(acac)_4(dioxane)]$.[557] $TaCl_4$ generally reacts by abstraction of oxygen, and tetrakischelated compounds are limited to $[Ta(dbm)_4]$. Some chloro-β-diketonato compounds, which result from reactions conducted in the absence of base, are also described. $[Ta_2Cl_4(dpm)_4]$ was derived from the tantalum(III) adduct $[Ta_2Cl_6(\gamma\text{-pic})_4]$.[544]

The O dealkylation reactions often observed between carboxylic acids and group VA halides could be controlled by the use of bulky substituted acids. Stepwise substitution and oxidation of $[Nb(BH_4)(Cp)_2]$ *via* $[Nb(O_2CBu^t)(Cp)_2]$ and $[Nb(O_2CBu^t)_2(Cp)_2]$ thus provided $[Nb(O_2CBu^t)_4]$ in good yield.[555] The latter is paramagnetic, the metal being octacoordinated. It is a rare example of a monomeric Nb^{IV} compound soluble in non-polar hydrocarbons, and may therefore constitute an interesting starting material for Nb^{IV} chemistry, but its reactivity does

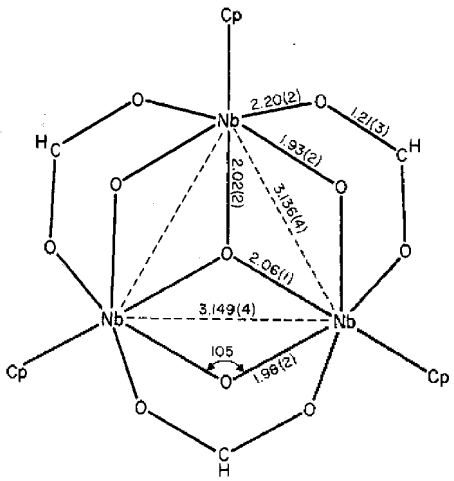

Figure 26 Molecular geometry of $[\{(Cp)Nb(\mu\text{-}O_2CH)\}_3(\mu\text{-}OH)_2(\mu_3\text{-}O)]$. The nature of μ_2 groups is not known with certainty (reproduced from ref. 556 with permission)

not seem to have been investigated. $[Nb(O_2CCR_3)_2(Cp)_2]$ (R = F, Ph) was formed in similar reactions. The only Ta^{IV} carboxylate known is the diamagnetic $[\{Ta_2Cl_4(O_2CBu^t)_4\}2Bu^tCO_2H]$.

A trinuclear compound $[\{Nb(O_2CH)(Cp)\}_3(OH)_2(O)_2]$ was isolated from the reaction between $[Nb(CO)_3PPh_3)(Cp)]$ and HCOOH, which involves decarboxylation of the formate group.[556] It has an almost regular triangular structure (Figure 26) with Nb - - - Nb distances close to the usual single Nb—Nb bond length, but the magnetic properties (one unpaired electron) and the large angles around the bridging oxygen argue against direct metal–metal bonding.

34.3.5.3 Thiolato and related derivatives

The dialkylthiocarbamates (Table 39) were initially made by insertion of CS_2 into the M—N bond of $[M(NR_2)_5]$, which, in the case of niobium, proceeds with reduction to Nb^{IV} and

oxidation of the organic moiety to tetraalkylthiuran disulfides.[279] In the case of tantalum, the pentavalent state is retained, and no Ta^{IV} dithiocarbamates are presently known. IR has been used as a criterion for establishing the coordination mode of the dithiocarbamato ligand, which appears to act as a bidentate in all these compounds. Nb^{IV} dithiocarboxylates have been prepared, and were studied by single crystal ESR. Their geometries are intermediate between a triangular dodecahedron and a square antiprism.[557]

Tris(maleonitriledithiolato)niobate $[Nb(mnt)_3]^{2-}$ ($mnt = S_2C_2H_4^{2-}$) has been obtained in solution by reduction of $NbCl_5$ by Zn in an HCl–MeOH solution followed by *in situ* complexation of the Nb^{4+} species.[558] The ESR data ($\langle g \rangle = 1.988$, $\langle A \rangle = 94.4$ G) are consistent with a nearly trigonal prismatic arrangement. They exclude the formation of an oxo species such as $[Nb(mnt)_2]^{2-}$ whose ESR parameters should compare with those of $[NbO(acac)_2]$ ($\langle g \rangle = 1902$, $\langle A \rangle = 142$ G). Polarographic results indicated that tris(dithiolene) Nb^V and Ta^V undergo one-electron transfers. $[NbCl_2(S_2C_6H_4)]_2$ appears to be the only dithiolene adduct isolated so far. Compounds with thiolato groups are unstable, especially in solution, but may be stabilized as $[M(SR)_2(Cp)_2]$ derivatives (M = Nb; R = Me, Pr, Ph;[8,559] M = Ta, R = Me). Selenium analogs are known for niobium, and have been used as ligands toward Fe(NO)(CO) and $Co(CO)_2$ moieties.[560]

Tetrakis *O,O'*-dialkylthiophosphates have been obtained for niobium starting from oxidation states +V or +IV (Table 40). These chelates display a distorted dodecahedral geometry in the solid (X-ray) as well as in solution (ESR).[561] An unusual cation, $[\{Nb(Cp)_2\}_2(PS_4)]^+$, in which a PS_4^{3-} moiety is doubly bridging the terminal $NbCp_2$ units, has been obtained from $[NbCl_2(Cp)_2]$ and P_4S_{10}. The metal has a distorted tetrahedral environment of approximate D_{2d} symmetry, while symmetry at phosphorus is reduced to C_{2v}.

34.3.5.4 Alkylamides and related compounds

(*i*) *Dialkylamides and dialkylphosphides*

A series of homoleptic Nb^{IV} dialkylamido compounds has been obtained as highly air sensitive liquids by spontaneous reduction of $[Nb(NR_2)_5]$ (R = Et, Pr^n, Bu^n; Table 41). Aminolysis of either Nb^V or Nb^{IV} dialkylamides provided mixed species.[256] The existence of quadrivalent tantalum dialkylamides is still questionable. $[Ta(NEt_2)_4]$ was reported to have been detected during the thermolysis of $[Ta(NEt_2)_5]$,[263] which led predominantly to the Ta^V nitrene (**2**; Section 34.2.3.4.ii), but other workers could not find any evidence for its formation in a similar experiment.[282] $[Ta(NMeBu)_4]$ has been reported to be formed in the decomposition of the corresponding pentavalent dialkylamide.

The monomeric, paramagnetic alkylamides constitute rare examples of magnetically dilute

tetrahedral Nb^{IV} compounds. The ESR data ($g_\perp > g_\parallel$; Table 34) are consistent with the unpaired electron residing in the $d_{x^2-y^2}$ orbital in a field of D_{2d} symmetry, with strong metal–nitrogen covalent character.[279]

The alkylamides should constitute valuable starting materials for the synthesis of other Nb^{IV} derivatives, but studies of their reactivity have so far been limited to some substitution (with ROH, R_2NH, RLi) and CS_2 insertion reactions. Compounds of type $[Nb(NR_2)_{4-x}R'_x]$ ($x = 1, 2$; R = Me, Et; R′ = Bu^t, Np, Bu, Me_3SiCH_2) have proven useful for removing small amounts of oxygen from gases and as components of catalysts for the polymerization of ethylene.[562] Although solvolysis of NbX_4 by primary and secondary aliphatic amines has been shown to occur, no reaction products were identified.[532] A product of puzzling formula, $[NbCl_4(salen)]$, was formed by the reaction of $NbCl_4$ with *N,N′*-bis(salicylidene)ethylenediammine.[563]

The unstable neutral $[Nb(PCy_2)_4]$ has recently been obtained through oxidation of an anionic Nb^{III} precursor $[Nb(PCy_2)_4][Li(DME)_2]$.[565] The spectral data were consistent with a distorted tetrahedral structure similar to that of $[Mo(PCy_2)_4]$. It is the first group Va member of a potentially large class of analogs of the dialkylphosphides. Mixed halodialkylphosphides were also obtained by oxidative addition of phosphines to M^{II} adducts.[564]

(*ii*) *Porphyrin and phthalocyanine adducts*

Zinc amalgam, or electrochemical reduction of porphyrinatoniobium(V) oxide acetates led to $[Nb^{IV}OL]$ (L = OEP, TPP, TPTP).[566] The $[NbOLF]^-$ anions have been obtained by controlled potential electrolysis of (i) the corresponding Nb^V oxo acetate in the presence of PF_6^-, and (ii) the appropriate Nb^V oxo fluoride. Reduction by zinc amalgam of $[NbLX_3]$ (X = Cl, Br) gave $[Nb^{IV}LX_2]$;[327] the ESR spectra of the six-coordinate complexes in frozen THF solution are consistent with *trans* coordination.

Reaction between $NbCl_5$ and phthalonitrile in quinoline at 100 °C led to $[NbCl_2(PC)]$ (PC = phthalocyanine); the metal is displaced by 0.98 Å from the central C_8N_8 core.[567]

(*iii*) *Miscellaneous derivatives with M—N bonds*

A number of dinuclear, diamagnetic, but rather unstable Nb^{IV} poly(1-pyrazolyl)borates have been obtained from either $NbCl_5$ or $NbCl_4$ with $[KH_xB(pz)_{4-x}]$ ($x = 1, 2$).[338] $[HB(pz)_3]$ generally acted as a bidentate ligand. Bridging through the chlorine or the poly(1-pyrazolyl)borate anion was postulated. Formation of dinuclear species even with bulky ligands such as $HB(pz)_3$, $N(SiMe_3)_2$ or Cp[568] illustrates the tendency towards metal–metal bonding.

The stronger reducing character of $PhMeNNH_2$ as compared to $PhNHNH_2$ gave, directly from Nb^V, diamagnetic $[Nb_2Cl_6(HNNMePh)_2(MeCN)_2]$.[274]

Nb^{IV} iminoethyl derivatives have been obtained by insertion of Bu^tNC into the Nb—Cl bond of $[NbCl_4(THF)_2]$ and substitution of the remaining chlorine. The products

$[NbCl_3\{C(Cl)NBu^t\}(CNBu^t)]_2$, $[NbCl_2\{C(Cl)NBu^t\}(ox)]_2$ and $[NbCl\{C(Cl)NBu^t\}(S_2CNEt_2)]_2$ are dinuclear, but only the last two are diamagnetic.[569]

Diamagnetic polymeric nitrides, $[TaNBr]_n$[324] and $[NbNI]_n$,[325] have been obtained by high temperature thermolysis of MX_5 with ammonium salts.

34.3.6 Chalcogenides

The chalcogenides MY_3 and MY_2 (Y = S, Se) can be prepared by various methods, including heating the elements together, thermal decomposition of the $[Nb(Y_2)X_2]$ halides, and action of CS_2 on the oxides at about 900–1300 °C.[1,542]

The structures of $[NbS_3(py)]$ and $NbSe_3$[570] show trigonal prismatic chain arrangements in which the chalcogenide atoms form approximate isosceles triangles. It was suggested that they should formally be considered as $[Nb^{IV}(Y^{2-})\{(Y_2)^{2-}\}]$ (Y = S or Se), an idea which is supported by studies on the electronic structure of $NbSe_3$.[571] The presence of Nb—Nb pairs (3.04 Å) in NbS_3 is responsible for the observed diamagnetism and semiconducting properties; by contrast no Nb—Nb pairs were found in $NbSe_3$, which indeed exhibits metallic properties. The remarkable electrical properties of TaS_3 may also be explained by Ta—Ta pairing.[572]

A number of nearly two-dimensional intercalates of formula $[MY_2(L)_x]$ (Y = S, Se; L = N donors; $x = 0.5$ for L = py, Et_2NH, Et_3N, piperdine, *etc.*) with promising superconducting properties have been described.[573] Niobium disulfide is an intercalation electrode in lithium batteries, whose effectiveness is close to that of titanium disulfide.[574]

34.3.7 Activation of small molecules

The short-lived $[MH_2(Cp)_2]$ and $[TaH_4(dmpe)_2]$ have been obtained from the M^V hydrides using photogenerated *t*-butoxy radicals, and were characterized by low temperature ESR.[575] On the other hand, thermally stable, well-defined dinuclear or mononuclear M^{IV} hydrides have been prepared by oxidative addition of H_2 to dinuclear M^{III} or mononuclear M^{II} halide phosphine adducts, respectively. They constitute attractive entries to lower oxidation state compounds, and will be reviewed in Sections 34.4.3.1.i and 34.6.1.2.i.

$[TaHCl_2(Cp'')]_2$ (**24**) ($Cp'' = \eta^5$-C_5Me_4Et) reacts easily with CO (equation 47) to give $[\{Ta(Cl_2(Cp'')\}_2(\mu\text{-H})(\mu\text{-CHO})]$ (**25**).[576] Crossover experiments have established that the dimer (**24**) is not split by CO. X-Ray diffraction data show that the hydride and formyl ligands are bridging two skewed $TaCl_2(Cp'')$ fragments; the Ta—Ta distance was considered too long for a full single bond, but consistent with some interaction (Figure 27).[577] The C—O distance is unusually long; this activation is in agreement with its being cleft by PMe_3 (equation 48) to give (**26**) for which a Ta—Ta bonding has been proposed (2.992(1) Å).[578] The formyl ligand of (**25**) is apparently stabilized by side-on bonding between the two metals, and (**25**) does not react readily with CO or H_2. It is, however, susceptible to electrophilic or nucleophilic attack; methanol is produced when excess aqueous HCl is added to (**25**) in protic solvents.

$$[TaHCl_2(Cp'')]_2 + CO \xrightarrow{1\text{ atm}, -78\,^\circ C} [\{TaHCl_2(Cp'')\}_2(CO)]$$

(**24**)

$$\xrightarrow{0\,^\circ C} [\{TaCl_2(Cp'')\}_2(\mu\text{-H})(\mu\text{-CHO})] \quad (47)$$

(**25**)

$$[\{TaCl_2(Cp'')\}_2(\mu\text{-H})(\mu\text{-CHO})] + PMe_3 \longrightarrow [\{TaCl_2(Cp'')\}_2(\mu\text{-H})(\mu\text{-O})(\mu\text{-CHPMe}_3)] \quad (48)$$

(**25**) (**26**)

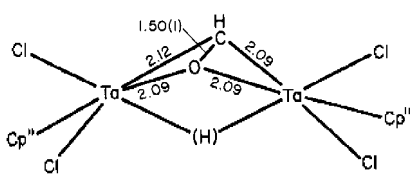

Figure 27 Drawing of the structure of $[\{TaCl_2(Cp'')\}_2(\mu\text{-H})(\mu\text{-CHO})]$ (**25**) (reproduced from ref. 576 with permission)

$[TaHCl_2(Cp'')]_2$ (**24**) reacts rapidly with one and only one equivalent of acetonitrile to give $[\{TaCl_2(Cp'')(\mu\text{-H})(\mu\text{-Cl})(\mu\text{-}\eta^1\text{-}N,\eta^2\text{-}C,N\text{-NCHMe})\}TaCl(Cp'')]$ (**27**),[579] whose molecular structure resembles those of (**25**) and (**26**). The $TaCl_2(Cp'')$ and $TaCl(Cp'')$ fragments are asymmetrically triply bridged by a chloride ligand, a hydride ligand and the NCHMe ligand derived from acetonitrile by hydrogenation. Multiple bond character has been suggested for Ta(1)—N (1.901(8) Å), but not for Ta(2)—N (2.059(8) Å).

The paramagnetic $[\{Nb(Bu^n)(Cp)_2\}_2(N_2)(O_2)]$ (equation 27) is the first example of simultaneous fixation of N_2 and O_2 by a niobium complex ($\nu(N_2) = 1740\ cm^{-1}$).

The reaction between NO and $[NbCl_4(MeCN)_2]\cdot MeCN$ led to $[NbCl_4(NO)(MeCN)_2]$.[539] Ligand exchange reactions provided $[NbCl_4(NO)(MeCN)(LL)]$ (LL = bipy or phen), $[NbCl_4(NO)(MeCN)(DMF)_3]$ and $[NbCl_4(NO)(MeCN)(Ph_2PO)]$, this last resulting from the oxidation of the PPh_3 ligand by NO. The diamagnetism of these products suggests polymeric structures in the solid. The phenanthroline and dimethylformamide adducts behave as electrolytes in solution. For the reaction between $[NbMe_2(Cp)_2]$ and excess NO, see Section 34.2.6.3.

34.4 OXIDATION STATE +III

34.4.1 Survey

The chemistry of niobium and tantalum in their lower oxidation states is expanding rapidly. The first structurally characterized molecular Nb^{III} derivative was reported in 1970,[525] while Nb^{III} and Ta^{III} halide adducts were described in 1973[580] and 1978, respectively.[581]

That this now fertile ground had long remained untilled is essentially attributable to the lack of convenient starting materials (in particular those without cyclopentadienyl ligands). Indeed, the stoichiometric trihalides MX_3 (X = Cl, Br) are only incidental compositions in homogeneous phases.[1,2,5] They can be obtained by reduction of the pentahalides by the metal, or, in the case of tantalum, by disproportionation of the tetrahalides. Reduction to the trichloride can be used as a means of separating tantalum from niobium. Stoichiometric NbI_3 appears as a residue in the thermal decomposition of the higher iodides; it is also the main product of the reaction of the metal with iodine at about 500 °C. NbI_3 is, however, unstable and disproportionates at 513 °C to α-NbI_4 and Nb_3I_8.[501]

The existence of trifluorides has been claimed, but the products isolated invariably contained oxygen, and the existence of pure MF_3 remains doubtful.[5,582]

The 'trihalides' are thermally unstable, dark-colored, polymeric, unreactive solids, and their chemical properties have received little attention.

34.4.2 Halo Adducts

34.4.2.1 Anionic halo complexes

The niobium(III) salts $Cs_3[Nb_2X_9]$ (X = Cl, Br, I) and $Rb_3[Nb_2Br_9]$ have been prepared by disproportionation reactions (equation 49). Other alkali metals gave rise to different reaction products.[525] There is as yet no evidence for the corresponding tantalum anions $[Ta_2X_9]^{3-}$. These salts were reported to be isotypic with $Cs_3[Cr_2X_9]$. The magnetic susceptibility of $Cs_3[Nb_2X_9]$ corresponds to two unpaired electrons ($\mu = 2.68$ BM, $\theta = -210$ °C, for X = Br), which was considered to be in agreement with a formal Nb=Nb double bond and a D_{3h} symmetry.

$$3Nb_3X_8 + 12AX \xrightarrow{600\text{–}690\ ^\circ C} 4A_3[Nb_2X_9] + Nb \qquad (49)$$

$$A = Cs, Rb \quad X = Cl, Br, I$$

The reaction between $[Nb_2Cl_6(THT)_3]$ and Et_4NCl in various stoichiometries provided the ionic $(Et_4N)_2[Nb_2Cl_8(THT)]$ and $(Et_4N)_3[Nb_2Cl_9]$.[580]

34.4.2.2 *Neutral adducts of the trihalides*

(i) Synthesis

Activity in this area has stemmed from the discovery that reduction of MX_5 or their complexes to yield molecular M^{III} trihalide adducts can be achieved rather easily by using reductants such as sodium amalgam, sodium–potassium alloy and magnesium in the presence of ligands.

The first report on this approach was on the synthesis of $[Nb_2X_6(THT)_3]$ (X = Cl, Br, I) by McCarley and Maas, using a one-electron procedure (equation 50).[525] The soluble Nb^{III} adducts formed were easily separated from the sodium derivative and isolated in high yields (60–70%). The tantalum analogues $[Ta_2X_6(THT)_3]$ (**10**; X = Cl, Br) were similarly prepared, but from TaX_5.[581]

$$2[NbX_4(THT)_2] + 2Na/Hg \xrightarrow{C_6H_6} [Nb_2X_6(THT)_3] + 2NaX + THT \quad (50)$$
$$X = Cl, Br, I$$

Similar reducing procedures—the commonest using Na/Hg in toluene, or Mg in methylene chloride—were applied to the pentahalides in the presence of a large variety of monodentate ligands (Table 42). Dinuclear diamagnetic compounds of different stoichiometries, such as $[M_2Cl_6(SMe_2)_3]$ (**28**),[583–585] $[M_2X_6(PhPMe_2)_4]$ (**29**; M = Nb, X = Cl; M = Ta, X = Cl),[586] $[M_2Cl_6(PMe_3)_4]$[587,588] and $[Ta_2Cl_6(\gamma\text{-pic})_4]$ (**30**)[554] were thus obtained in variable yields. $[NbCl_6(diox)_2]$ was obtained by reduction of $NbCl_5$ with Mg in the presence of dioxane.[584] Side-reactions were often observed when oxygen donors were used. Reduction of $NbCl_5$ by Mg also occurred in the presence of THF, but no pure Nb^{III} trihalide adduct could be isolated, as a result of THF degradation reactions.[589]

The nature of the adducts formed with phosphines depends on the experimental procedure. The diamagnetic $[Ta_2Cl_6(PMe_3)_4]$ (**31**) was obtained through reduction of $TaCl_5$ by sodium amalgam in toluene,[587] while the paramagnetic $[TaCl_3(PMe_3)_3]$ was isolated when the reduction was achieved in diethyl ether in the presence of an excess of ligand, or by an exchange reaction from $[Ta_2Cl_6(THT)_3]$ at 60 °C.[306] Alkylidene derivatives may also be converted to trivalent phosphine adducts (equations 51 and 52).[590] $[TaCl_3(PMe_3)_3]$ converts readily in solution to the dimer (**31**). Puzzling results were obtained when $TaBr_5$ was reduced by Mg in the presence of $PhPMe_2$.[586] A very clean one-step reduction of $NbCl_5$ was observed with diphenylacetylene, which acts both as the reductant and as the ligand (equation 53).[592]

$$2[NbCl_3(CHCMe_3)(PMe_3)_2] \xrightarrow[Et_2O]{C_2H_4\ (3\text{–}4\ atm)} [Nb_2Cl_6(PMe_3)_4] \quad (51)$$

$$[TaI_3(CHCMe_3)(PMe_3)_2] \xrightarrow[To]{C_2H_4\ (2\ atm)} [TaI_3(C_2H_4)(PMe_3)_2] \quad (52)$$
$$\uparrow C_2H_4\ (2\ atm),\ To \quad \downarrow PMe_3,\ To$$
$$mer\text{-}[TaI_3(PMe_3)_3]$$

$$4NbCl_5 + 8PhC{\equiv}CPh \xrightarrow{CH_2Cl_2} [NbCl_3(PhC{\equiv}CPh)]_4 + 4t\text{-}PhClC{=}CClPh \quad (53)$$
$$75\%$$

Although some adducts with monodentate ligands, including $[NbCl_3L_3]$ (L = py, γ-pic 3,5-Me_2py)[593] and $[TaCl_3(PMe_3)_3]$ have been obtained from $[M_2Cl_6L_3]$ (L = SMe_2 or THT through ligand exchange reactions, this procedure was mainly employed to prepare adducts with bidentate donors, yielding $[M_2Cl_6(LL)_2]$ [LL = dppe,[594] bipy, dto (dto = dithiaoctane)] $[Nb_2Cl_6(LL)_2]$ [LL = diars, triars (triars = 1,1,1-tris(dimethylarsinomethyl)ethane)] and $[Ta_2Cl_6(dmpe)_2]$.[595] The latter compound could not be prepared directly from $TaCl_5$ with Mg since the reduction stopped at $[TaCl_4(dmpe)_2]$,[557] while the use of Na/Hg offered $[TaCl_2(dmpe)_2]$,[596] without evidence for a Ta^{III} intermediate. Mixed ligand adducts such as $[Ta_2Cl_6(SMe_2)\{P(NMe_2)_3\}_2]$,[597] $[Nb_4Cl_{12}(SMe_2)_4(dppm)]$[598] and $[Nb_4Cl_{12}(PhPMe_2)_6\{MeN(PF_2)_2\}]$[599] were also obtained by the ligand exchange procedure.

Table 42 Neutral Adducts of the Niobium and Tantalum Trihalides with Monodentate Donors

Compounds	*Comments*	*Ref.*
$[M_2X_6(THT)_3]$ ($M = Nb$, $X = Cl$, Br, I; $M = Ta$, $X = Cl$, Br)	X-Ray structure for $M = Nb$, $X = Br$ and $M = Ta$, $X = Cl$, Br; NQR	1, 2, 3
$[M_2Cl_6(SMe_2)_3]$	X-Ray structure for $M = Ta$ (Ta—Ta = 2.691(1) Å)	4, 5, 6, 7
$[Ta_2Cl_6(SMe_2)\{P(NMe_2)_3\}_2]$	X-Ray structure (Ta—Ta = 2.704(1) Å)	8
$[NbCl_3L_3]$ (L = py, γ-pic; 3,5-Me_2py)	ESR at room temperature: $\langle g \rangle = 2.04$, $\langle A \rangle = 179.1$ G for L = γ-pic	9
$[Ta_2Cl_6L_4]$ (L = py, γ-pic)	Diamagnetic, dissociation in solution for L = γ-pic	9, 10
$[TaX_3(PMe_3)_3]$ (X = Cl, Br, I)	ESR active in frozen solution only: $\langle g \rangle = 1.92$, $\langle A \rangle = 240$ G; unstable towards dimerization, oxidative addition of H_2	11, 12
$[M_2Cl_6(PR_3)_4]$ ($R_3 = Me_3$, $PhMe_2$)	X-Ray structure for $M = Ta$; oxidative addition of H_2	13, 14, 15
$[NbBr_3(PhPMe_2)_3]$	X-Ray structure	16
$[M_2Cl_6(PR_3)_x]$ ($M = Nb$, $R = Bu^t$, $x = 2$; $R = Cy$, $x = 3$, 4; $M = Ta$, $R = Cy$, Bu^t, $x = 3$)	Activation of N_2(1 atm) during the reductive synthesis with Mg; $[M_2Cl_6(PCy_3)_4]$ in solution by addition of PCy_3	17
$[TaCl_3L_2(C_2H_4)]$ ($L = PMe_3$, THF)		11, 18
$[TaCl_3LL'(C_2H_4)]$	$L = L' = PhPMe_2$; $L = PMe_3$, $L' = PhPMe_2$ not isolated, identified by ^{31}P NMR	18

(*ii*) *Structure and characterization*

The isolated monomeric trivalent adducts are limited to $[NbCl_3L_3]$ (L = py, γ-pic), $[TaX_3(PMe_3)_3]$ (X = Cl, Br, I) and $[NbBr_3(PhPMe_2)_3]$. The existence of magnetically dilute d^2 compounds was confirmed by magnetic susceptibility ($\mu = 2.03$ BM for $[NbCl_3(\gamma\text{-pic})_3]$ at 20 °C), and ESR data.[593] The ESR signal of $[TaCl_3(PMe_3)_3]$ could be detected only in frozen solutions, and ^1H NMR indicates a meridional arrangement of the PMe_3 ligands.[306] $[NbBr_3(PhPMe_2)_3]$ is the only monomeric structurally characterized adduct.[591]

The formation of diamagnetic compounds involving metal–metal bonding is more frequent. Four different geometries—for dinuclear and tetranuclear compounds—have so far been found by X-ray crystal studies. The metal center is generally heptacoordinated. The adducts with monodentate ligands were characterized by ^1H or ^{31}P NMR techniques. Usually no ligand dissociation reactions were observed. The adducts formed with bidentate ligands are often of poor solubility.

^1H NMR data on the diamagnetic $[M_2X_6L_3]$ ($L = SMe_2$ or THT[583,580]) show one bridging neutral ligand for two terminal ones. Their crystal structures display confacial bioctahedra of C_{2v} symmetry with one bridging sulfur atom *trans* to both terminal ones (Figure 28). The short

M—M distances (Nb—Nb: 2.728(5); Ta—Ta: 2.710(2) Å) found for [{MBr_2(THT)}(μ-Br)$_2$(μ-THT){MBr_2(THT)}] were considered to reflect strong M—M bonding,[600] and to be in agreement with a formal double bond. The M—S_b bonds are markedly shorter than the M—S_t bonds; the S_t atoms appear to be hindered from closer approach to the metal by the repulsion exerted by the four *cis* halogens in the plane (short S_t—Br contact of 3.51 Å in [Ta_2Br_6(THT)$_3$]). An unusually close approach (3.30 Å) of the two bridging bromines has been observed, and was explained, on the basis of MO considerations, by the stereochemical activity of the metal–metal π-bonding electrons. The low C_{2v} symmetry of these [$M_2X_6L_3$] adducts was considered to be responsible for their diamagnetic behavior, compared to the paramagnetic behavior of $[Nb_2X_9]^{3-}$.

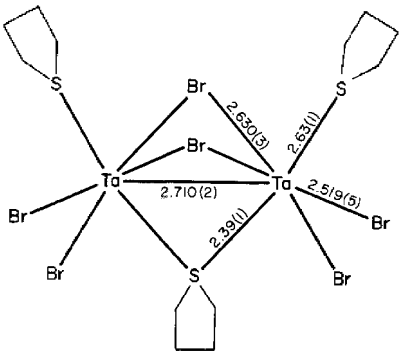

Figure 28 Molecular structure of [(THT)$TaBr_2$(μ-Br)$_2$(μ-THT)$TaBr_2$(THT)] (**10**) (reproduced from ref. 580 with permission)

A thorough NQR study (^{93}Nb, ^{35}Cl, ^{81}Br, ^{127}I) reflects the environmental difference between bridging and terminal halides. The latter resonate at lower frequencies, which was considered to mean that the relative amount of π bonding from halide to metal is much larger for X_t than for X_b.

A single crystal X-ray study of [Ta_2Cl_4{P(NMe_2)$_3$}$_2$(μ-Cl)$_2$(μ-SMe_2)], the only one available on a mixed ligand adduct in oxidation state +III, showed the structure to be related to that of [Ta_2Cl_4(SMe_2)$_2$(μ-Cl)$_2$(μ-SMe_2)].[597]

The isolation of [M_2Cl_6(PR_3)$_3$] (Table 42) shows that adducts of that stoichiometry can also be stabilized by crowded phosphines;[304] their structure is probably related to that of $[Nb_2Cl_9]^{3-}$ with triple chlorine bridges.

The [$M_2Cl_6L_4$] stoichiometry is the most commonly encountered with phosphines, although it has also been observed for M = Ta and L = py, γ-pic. X-Ray data are limited to (**31**), which consists of two somewhat distorted octahedra sharing a common edge (Figure 29). The short Ta—Ta distance and acute Ta—Cl_b—Ta angle indicate strong metal–metal bonding. Considerable distortions involving the axial substituents and non-bonded H · · · Cl interactions are observed. The structure with axial and equatorial phosphines was reported to be favored for electronic reasons.[587] According to the MO calculations of Hoffmann *et al.* for bridged M_2L_{10} complexes,[601] the ordering of the low-lying *d*-orbitals is $\sigma(a_g) < \pi(b_{1u}) < \sigma^*(a_u) < \delta(b_{3g}) < \pi^*(b_{2g}) < \sigma^*(b_{3u})$. This means a formal bond order of 2 for the d^2–d^2 system. The ^{31}P NMR of (**31**) offered a rare example of P–P coupling across a metal–metal bonded dimer ($J(P–P') = \pm 2.46$ Hz).

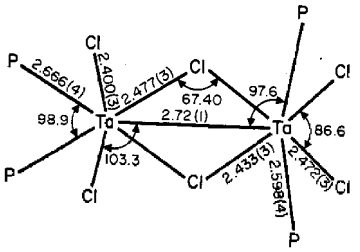

Figure 29 Coordination polyhedron of: [Ta_2Cl_4(PMe_3)$_4$(μ-Cl)$_2$] (**31**) (reproduced from ref. 587 with permission)

The adducts involving bidentate ligands are all of type $[M_2Cl_6(LL)_2]$. The structures of those with bidentate phosphines (M = Nb, LL = dppe;[602] M = Ta, LL = dmpe[595]) are related to that of (**31**), but with the chelate rings spanning two equatorial positions. The metal–metal distances are consistent with either a double or a single bond (Nb—Nb: 2.712(2) Å; Ta—Ta: 2.710(1) Å).

In contrast to the diamagnetism—with small temperature independent paramagnetic contributions—of the adducts formed with monodentate ligands, those with bidentate ligands exhibit temperature dependent paramagnetism and produce easily observable ESR spectra even at room temperature.[594] Although the magnetic moments (0.54 to 0.87 BM at room temperature for the niobium adducts) are lower than those generally observed for the tetravalent adducts, it has been suggested that the metals are only singly bonded, the magnetism being presumed to be lowered by spin–orbit coupling and/or antiferromagnetic interactions. A complex hyperfine structure was observed for the bipyridyl adducts. The IR data suggest that the bipy ligand is negatively charged with electron delocalization into the ligand ring system.

^{1}H NMR data on the niobium(III) adducts with triphos and triars established that these ligands behave as bidentates only.[583,603]

$[NbCl_3(PhC{\equiv}CPh)]_4$, the only structurally characterized tetranuclear compound (Figure 30),[592] can be regarded as a centrosymmetric distorted double hexahedron with two missing corners. The Nb atoms are heptacoordinated, linked by two triply bridging chlorines, but do not exhibit metal–metal bonding. The alkyne C—C distances and C—C—C angle are consistent with its formulation as a metallacyclopropene (Section 34.4.3.2.i).

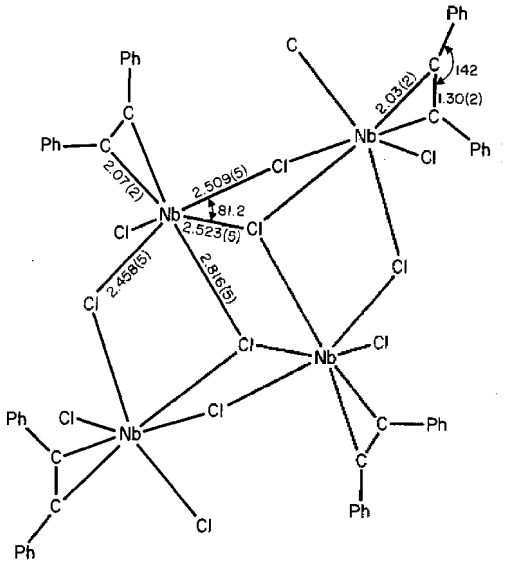

Figure 30 Molecular structure of $[NbCl_3(PhC{\equiv}CPh)]_4$ (reproduced from ref. 592 with permission)

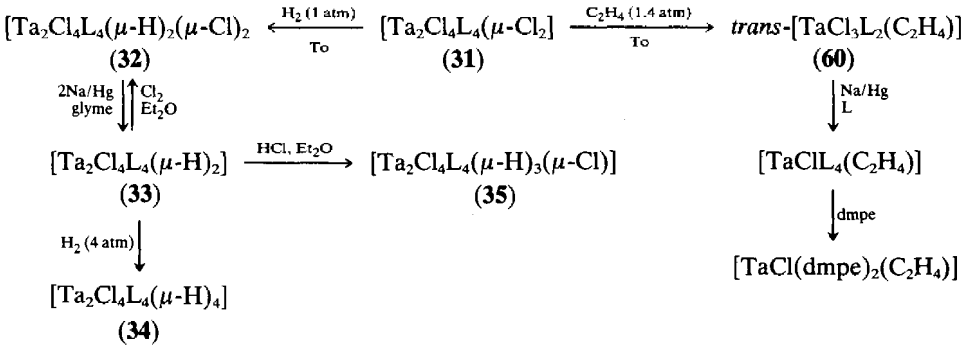
The trivalent adducts display a wide range of colors, but electronic absorption spectra have been reported only for $[M_2X_6(THT)_3]$ (X = Cl, Br), $[Nb_2I_6(THT)_3]$, $(Et_4N)_2[Nb_2Cl_8(THT)]$ and $(Et_4N)_3[Nb_2Cl_9]$;[580,599] the magnitude of the extinction coefficients supports strong metal–metal interactions. The similarity between the spectra of $[Nb_2Cl_6(THT)_3]$ and $(Et_4N)_2[Nb_2Cl_8(THT)]$ incidates that the bridging THT ligand is retained.

(*iii*) *Reactivity*

Investigations on the reactivity of the M^{III} trihalide derivatives have so far mainly been limited to that of $[Ta_2Cl_6(PMe_3)_4]$, $[M_2Cl_6(PhPMe_2)_4]$, $[Ta_2Cl_6(\gamma\text{-pic})_4]$ and $[M_2Cl_6L_3]$ (L = SMe_2 or THT). Oxidative additions occur easily, and these compounds are therefore suitable precursors of M^V and dinuclear M^{IV} derivatives. Metathesis reactions may lead to other trivalent derivatives. The dinuclear unit is generally retained, although condensation to tetranuclear species is sometimes observed. The only monomeric substitution products

reported so far, $[Nb(NCS)_3(py)_3]$ and $[Nb(Et_2dtc)_3]$, derive from $[NbCl_3(py)_3]$. Chemical reduction of the chloro adducts appears difficult, and seems favored for monomeric M^{III} adducts (Section 34.6). Electrochemical reduction offers possible alternatives.[604]

34.4.3 Activation Reactions Involving Niobium(III) and Tantalum(III) Adducts



34.4.3.1 Activation of small molecules

(i) Dihydrogen and related molecules

The reactivity of the red $[Ta_2Cl_4(PMe_3)_4(\mu\text{-}Cl)_2]$ (**31**) is of interest, because it leads to Ta^{IV} and Ta^{I} compounds (Scheme 6). Complex (**31**) reacts cleanly with H_2 under mild conditions to produce the air stable emerald green diamagnetic $[Ta_2Cl_4(PMe_3)_4(\mu\text{-}H)_2(\mu\text{-}Cl)_2]$ (**32**), one of the very few compounds with a metal–metal bond bridged by four ligands (Ta—Ta: 2.621(1) Å). It is also the first example of direct interaction of H_2 with a metal–metal multiple bond.[605–607]

The terminal and bridging groups are in a mutually staggered arrangement, and the coordination polyhedron about each tantalum is roughly a square antiprism. The equatorial phosphines, but not the axial ones, are chemically equivalent. The presence and location of the hydrides were established by spectroscopic techniques ($\delta_H = 8.5$(m) p.p.m.; ν(Ta—H—Ta) ≈ 1280 cm^{-1}). The Ta—Ta separation (2.621(1) Å) is shorter than the Ta=Ta bond in the original Ta^{III} adduct.

Compound (**32**) is the precursor of the air sensitive $[Ta_2Cl_4(PMe_3)_4(\mu\text{-}H)_2]$ (**33**), characterized by X-ray diffraction at −160 °C. The $Ta_2Cl_4(PMe_3)_4$ substructure resembles that of the quadruply bonded dimers $[M'_2Cl_4(PMe_3)_4]$ (M′ = Mo or W) with the ligands in eclipsed conformation and retention of the Ta=Ta bond (2.545(1) Å). Rapid rotation of the end groups and/or bridging hydrides is required to account for the apparent magnetic equivalences in ^1H and ^{31}P NMR. Complex (**33**) offers a convenient entry into dinuclear Ta^{IV} chemistry. Its ether solutions react readily with H_2, HCl or Cl_2 to give the quadruply bridged Ta^{IV} compounds (**34**), (**35**) or (**32**) (Scheme 6). Alternative syntheses of $[Ta_2Cl_4L_4(\mu\text{-}H)_4]$ (**34**) are the hydrogenation of the $[TaHCl_2(CHCMe_3)L_3]$ alkylidene or the thermolysis of $[TaH_2Cl_2(PMe_3)_4$ (Section 34.6.1.2.i, Scheme 9).

Scheme 6 (L = PMe_3)

Compound (**34**) has an imposed D_{2d} symmetry and a very short Ta—Ta length (2.511(2) Å)—the shortest reported to date; the bridging hydrogens were located in the solid (Ta—H: 1.81(2) Å). Unlike its tantalum(III) precursor (**33**), it is static on the NMR time-scale. According to the predictions of Hoffmann,[601] all the metal μ type orbitals are engaged in the Ta—H—Ta bonding, and a substantial rotational barrier arises from the overlap of orbitals of π symmetry.

The oxidative addition of H_2, HCl and Cl_2 to the multiply bonded metal–metal complex (**31**) occurs without gross structural rearrangements, and has no equivalent in binuclear chemistry. Oxidative addition of H_2 under mild conditions with formation of diamagnetic M^{IV} hydrides appears to be a general feature for the dinuclear M^{III} adducts with monodentate phosphines. Bridging or terminal hydrides are found.[557] $[Ta_2Cl_6(dmpe)_2]$ and $[Nb_2Cl_6(dppe)_2]$, however, are inert toward H_2 even under severe conditions.[595] Monomeric diamagnetic $[TaH_2Cl(PMe_3)_4]$

(**36**), was obtained by reduction of Ta^{IV} monomeric hydride, resulting from the oxidative addition of Ta^{II} derivatives (Section 34.6.1.2.i).

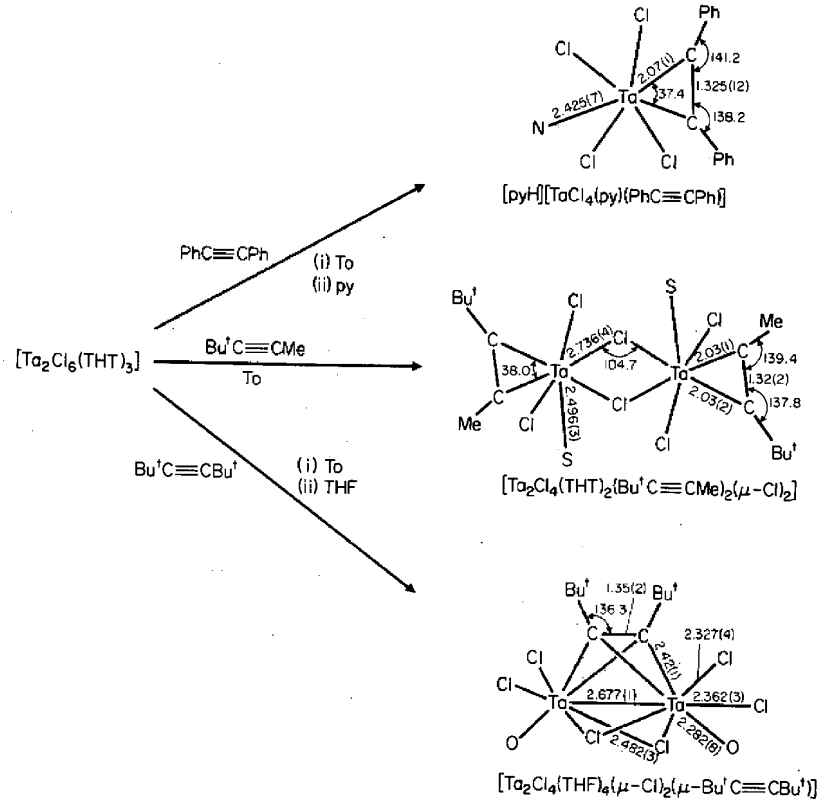
(ii) Dioxygen and dinitrogen

Admission of oxygen into a solution obtained by reduction of $TaCl_5$ by two equivalents of Na/Hg in the presence of PMe_2Ph led to the linear oxo derivative $(PMe_3Ph)_2[Cl_5TaOTaCl_5]$ (Section 34.2.6.1.ii).

Although $[\{TaCl_3(PMe_3)_2\}_2(\mu\text{-}N_2)]$ could be obtained *via* the 'azine route' (Section 34.2.3.6), this product did not form when $[TaCl_3(PMe_3)_3]$ was exposed to dinitrogen, even under 68 atm. The dimer (**31**) probably forms too rapidly from $[TaCl_3(PMe_3)_3]$, and does not react readily with dinitrogen.[306]

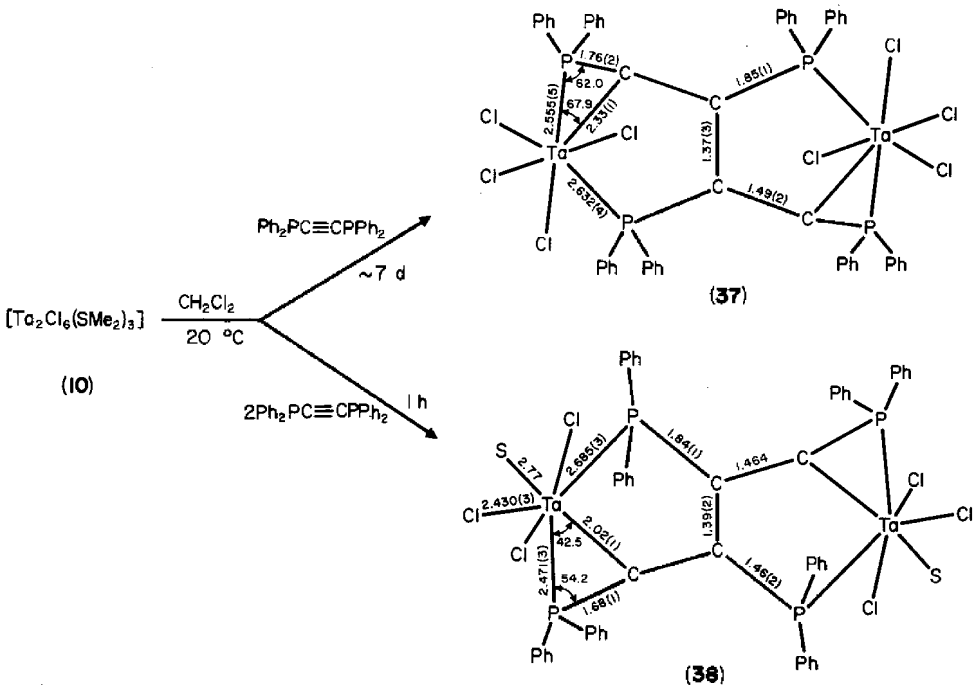
Activation of N_2 under mild conditions (25 °C, 1 atm) was observed during the reduction of the MCl_5 by magnesium (equation 29).[304] Unfortunately, the products were unstable and only a compound of empirical formula $[Nb_2Cl_6(PBu^i_3)_3N_2]$ could be isolated. IR data ($\nu(N_2) \approx 1720\ cm^{-1}$) suggest a mode of bonding different from those found in Schrock's compounds.

34.4.3.2 Reactions with unsaturated substrates



(i) Alkynes—three-membered metallacycles

The tetrahydrothiophene adducts $[M_2Cl_6(THT)_3]$ (**10**) react with a variety or alkynes RC≡CR′, but the result depends considerably on R and R′ (Scheme 7). With diphenylacetylene the initial product, presumed to be $[TaCl_3(THT)_2(PhC{\equiv}CPh)]$, converted to $(pyH)[TaCl_4(py)(PhC{\equiv}CPh)]$ by recrystallization in the presence of pyridine.[608] The most remarkable feature of this seven-coordinate anion is the very strong symmetrical binding of tolan to Ta^V. The Ta—C and C—C distances were interpreted to mean that the alkyne acts as a four-electron donor, or as a two-electron donor in a simple bent bond mode.[609] A comparable metallacyclopropane–Ta^V moiety was obtained when *t*-butylmethylacetylene was used, giving $[Ta_2Cl_4(THT)_2(Bu^tC{\equiv}CMe)_2(\mu\text{-}Cl_2)]$.[610] Evidence for strong interaction with the alkyne is given by the substantial asymmetry of the chlorine bridges, the Ta—Cl(1) bond *trans* to the alkyne being the longest. The Ta—Ta distance of 4.144(1) Å is too long to support any bonding interaction. Di-*t*-butylacetylene afforded $[Ta_2Cl_4(THT)_2(\mu\text{-}Cl)_2(\mu\text{-}Bu^tC{\equiv}CBu^t)]$,[611] whose structure derives from that of (**10**) with THF molecules in place of the terminal THT ligands and a bridging alkyne substituted for the THT bridge. The short metal–metal distance indicates the retention of the double bond.



Adducts (**10**) catalyze the polymerization of substituted alkynes: into cyclic trimers for the primary alkynes RC≡CH (R = Ph, Et, Pr^i), into high polymers for the internal alkynes RC≡CR′ (R = Ph, R′ = Pr; R = Me, R′ = Bu^t).[612] Metallacyclopropene complexes might be the first step in cyclotrimerization. Quite different results were obtained by allowing the unusual alkyne $Ph_2PC{\equiv}CPPh_2$ to react with $[Ta_2Cl_6(SMe_2)_3]$.[613] Two products were obtained: $[Cl_4Ta{-}CH(PPh_2)C(PPh_2){=}C(PPh_2)CH(PPh_2){-}TaCl_4]$ (**37**) and $[(Me_2S)Cl_3Ta{=}C(PPh_2)C(PPh_2){=}C(PPh_2)Cl(PPh_2){=}TaCl_3(SMe_2)]$ (**38**; Scheme 8). In these two centrosymmetric compounds, the starting alkyne has dimerized to form a four-carbon chain, which acts as a bridging ligand (equation 54), while the tantalum atom's oxidation state has increased to +V. Each metal atom belongs to an unusual three-membered metallacycle, Ta—C—P for (**37**) and Ta=C—P for (**38**). In (**37**), one Cl^- ligand is replaced by Me_2S in a heptacoordinated environment. Complex (**37**) appears to contain the first example of an M—C—P ring reported for an early transition metal, while the ring with the Ta=C double bond of (**38**) is entirely unprecendented.

$$2Ph_2PC{\equiv}CPPh_2 \longrightarrow \begin{matrix} Ph_2PC & & PPh_2 \\ & C{=}C & \\ Ph_2P & & CPPh_2 \end{matrix} \qquad (54)$$

Comparable three-membered metallacycles were also obtained by oxidative addition of C—H bonds. Reduction of $TaCl_5$ by sodium sand in PMe_3 as a solvent afforded $[Ta(PMe_3)_3(\eta^2\text{-}CH_2PMe_2)(\eta^2\text{-}CHPMe_2)]$ (**39**; 7% yield), whose structure (Figure 31) shows that C(1) is bonded

Scheme 7

Scheme 8

to only one hydrogen atom, which is coplanar with the Ta—C—P triangle, the whole group affording the first example of an M(η-CHPMe$_2$) moiety. Complex (**39**) is an example of a seven-coordinate, pentagonal bipyramidal, 18-electron Ta^{III} compound.[614]

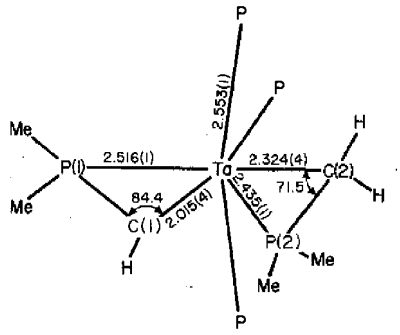


Figure 31 Crystal structure of [Ta(PMe$_3$)$_3$(η^2-CH$_2$PMe$_2$)(η^2-CHPMe$_2$)] (**39**) (reproduced from ref. 614 with permission)

(*ii*) *Reactions with other unsaturated substrates*

Reductive coupling reactions with C—C bond formation of unsaturated ligands such as nitriles (Section 34.2.3.5.i), alkynes and isocyanides were often observed for the [M$_2$Cl$_6$L$_3$] (L = THT, SMe$_2$) adducts. Thus the reaction between (**28**) and an excess of *t*-butyl isocyanide led to binuclear and trinuclear products (Section 34.5.2.2; equation 55).[615] In the dinuclear species (**40**), the bridging ligand arises from the *cis* coupling of two isocyanides (Figure 32). The average C—N distance (1.35(2) Å), the C—C distances and the planarity at the nitrogen atoms suggest a delocalized π system with C—C and C—N bond orders higher than one. The molecule is fluxional. Oxidation state +IV for each niobium, or +III for one and +V for the other, may account for the observed diamagnetism.

$$[Nb_2Cl_6(SMe_2)_3] \xrightarrow{Bu^tNC} [Nb_2Cl_6(Bu^tNC)_4(\mu\text{-}Bu^tNCCNBu^t)] + [Nb_3Cl_8(Bu^tNC)_5] \quad (55)$$

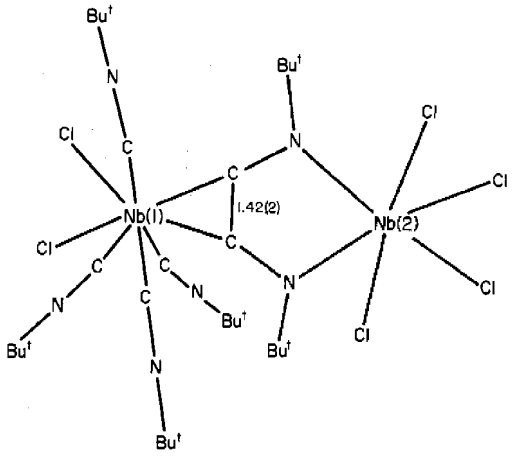

Figure 32 [Nb$_2$Cl$_6$(Bu^{t}NC)$_4$(μ-Bu^{t}NCCNBu^t)] (**40**) (reproduced from ref. 615 with permission)

34.4.4 Solvolysis Products of the Trihalides

Products that formally derive from the trihalides by solvolysis have been obtained (i) by metathesis of M^{III} trichloride adducts; (ii) from reactions of [TaCl$_2$(dmpe)$_2$] (**23**); and (iii) by

reductive synthesis starting from M^V compounds. The second and third procedures usually give mononuclear species, while di- or poly-nuclear compounds are generally obtained by solvolysis of M^{III} adducts.

34.4.4.1 Alkoxides and related compounds

Diamagnetic $[Ta_2Cl_2(OR)_4]$, $[Ta_2Cl_2(OR)_4(\gamma\text{-pic})_2]$ (**42**; R = Pr^i, Bu^t) and $[Ta_2Cl_2(OBu^t)_4]_2$ have been obtained from $[Ta_2Cl_6(\gamma\text{-pic})_4]$ (**30**) and the lithium alkoxides.[554,616] Complex (**42**) may coordinate an additional molecule of γ-picoline to give the paramagnetic $[TaCl(OR)_2(\gamma\text{-pic})_3]$. Reaction of (**42**) with excess acetone generated various pinacolates by reductive coupling of acetone. Carbon–carbon coupling was also observed with $MeCO_2C{\equiv}CCO_2Me$. $[Nb_2Cl_5(OPr^i)(Pr^iOH)]$ has been characterized by X-ray diffraction.[616b] Monomeric chloro butoxides $[TaCl_2(OBu^t)(PMe_3)_2(C_2H_4)]$ and $[MCl(OBu^t)_2(PMe_3)_2(C_2H_4)]$ were also shown to form by reduction of alkylidenes in ethylene metathesis experiments (equation 56).[301]

$$[TaCl_2(OBu^t)(CHCMe_3)(PMe_3)_2] + C_2H_4 \longrightarrow [TaCl_2(OBu^t)(PMe_3)_2(C_2H_4)] + Me_3CCH{=}CHMe + Me_3CCH_2CH{=}CH_2 \quad (56)$$

24% 65%

The reaction between (**28**) and $o\text{-}C_6H_4(OSiMe_3)_2$ offered tetranuclear chloro catecholates $[Nb_4Cl_8(cat)_2(SMe_2)_2]$ or $[Nb_4Cl_4(cat)_4(SMe_2)_2]$ depending on the atmosphere—Ar or NO—used. A diamagnetic complex $[Nb(SQ)_3]$ (SQ = semiquinone of 3,5-di-*t*-butyl-1,2-benzoquinone) of unknown structure has been synthesized from $NbCl_5$.[617] Displacement of the alcoholic ligands from impure '$NbCl_3(C_4H_8O)_3$' by salicylaldehyde provided $[Nb_2Cl_4(OC_6H_4CHO)_2(THF)_4]$.[584]

$[Ta_2Cl_4(dmpe)_2(\mu\text{-}O)(\mu\text{-}SMe_2)]$, whose formula was established by X-ray diffraction, was isolated as a minor product in the preparation of $[Ta_2Cl_6(dmpe)_2]$. By contrast with $[Ta_2Cl_4(dmpe)_2(\mu\text{-}Cl)_2]$, the chelating ligand spans axial and equatorial positions. The Ta—Ta distance (2.726(1) Å) has been taken to support the assignment of oxidation state +III to the metal.[618]

34.4.4.2 β-Diketonates and carboxylates

M^{III} trihalide adducts display different types of behavior towards β-diketones. With nobium, a careful control of the reaction conditions allowed the isolation of the diamagnetic, dinuclear, soluble Nb^{III} chlorodiketonato complexes $[Nb_2Cl_3(dpm)_3]$, $[Nb_2Cl_5(dpm)(PhPMe_2)_2]$ and $[Nb_2Cl_4(acac)_2(acacH)_2(PhPMe_2)_2]$.[619] No Ta^{III} chloro diketonates have so far been stabilized, even with the bulky dpmH ligand; oxidation to $[Ta_2Cl_4(dpm)_4]$ was observed with (**30**), while oxygen abstraction reactions, with formation of $[TaOCl_2(dpm)]_2$ are favored for (**29**). A paramagnetic (μ = 1.39 BM) compound formulated as $[Ta(dbm)_3]$ has been obtained by addition of Et_3N and dbmH to the solution which results from refluxing $TaCl_4$ in MeCN.[620] Its formulation is however questionable, because in these conditions $[Ta_2Cl_6(MeCN)_2(\mu\text{-}C_4H_6N_2)]$ would be expected to form instead of $[TaCl_3(MeCN)_3]$.

Adducts $[Nb_3O_2(O_2CR)_6(THF)_3]^+$ (R = Ph, Bu^t) have been prepared by allowing (**28**) to react with sodium carboxylates (Section 34.5.2.3). $[Nb_2Cl_2(OAc)_5(THF)]$ was obtained with NMe_4OAc.[621] The reaction between (**30**) and excess pivalic acid afforded $[Ta_2Cl_4(Bu^tCO_2)_4]\cdot 2Bu^tCO_2H$ as a diamagnetic soluble species. The reaction between $Ta_2Cl_6(SMe_2)_3$ and lithium pivolate gave $Ta_2Cl_5(O_2CBu^t)(SMe_2)(THF)_2$.[621] A niobium trilactate has been isolated by adding lactic acid to the Nb^{III} species generated electrochemically from $NbCl_5$ in DMF–HCl.[622] $[Nb(O_2CBu^t)(Cp)_2]$ with an anomalously high $\nu(CO_2)$ coordination shift (347 cm^{-1}) has also been described, but chelating behavior was found by X-ray diffraction.[623]

34.4.4.3 Thiolates and dithiocarbamates

The arenethiolates $[M(SR)_3]$ (R = phenyl or naphthyl) were easily obtained as monomeric soluble products by reductive elimination of organic disulfides from the pentathiolates

$[M(SR)_5]$.[624] The selenophenolates were formed by a similar procedure. Monomeric $[Nb(Et_2dtc)_3]$ has been prepared (equation 57); dimerization was observed in non-polar solvents in the presence of dithiocarbamates.[593] Poorly characterized pyrrolidinedithiocarbamate, $[Nb(S_2NC_5H_8)_3]$, has also been reported.[625]

$$[NbCl_3(py)_3] + 3NaEt_2dtc \xrightarrow{MeCN} [Nb(Et_2dtc)_3] + 3NaCl + 3py \quad (57)$$

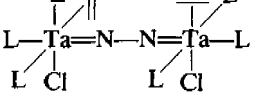
34.4.4.4 Dialkylphosphides

Attempts to obtain M^{III} amido derivatives have apparently so far been restricted to the reactions between $[Nb_2Cl_6(SMe_2)_3]$ or $Nb_2Cl_6(PhPMe_2)_4$ and $LiN(SiMe_3)_2$, but these reactions are of poor selectivity. Related M^{III} dialkylphosphides are better known. A diamagnetic phosphido compound, $[TaH(PPh_2)_2(dmpe)_2]$, was formed from $[TaCl_2(dmpe)_2]$, apparently by hydrogen abstraction from the solvent (equation 58). It was the first structurally characterized example of a terminal phosphide, and consists of a pentagonal bipyramid, with apical PPh_2 moieties.[626] Salient features are the monodentate diphenylphosphido ligands and the tilting of two of their phenyl rings toward the hydride ion. The geometry about the diphenylphosphido centers is nearly trigonal planar, as often observed in the structurally related dialkylamides. The metal achieves a closed shell electronic configuration if the Ta—$P(PPh_2)$ bond orders are assumed to be 1.5.

An ionic homoleptic Nb^{III} dialkylphosphide, $[Li(DME)_2][Nb(PCy_2)_4]$, has been obtained directly from $NbCl_5$.[565] Terminal phosphido groups, stabilized by interaction of two of the phosphorus atoms with lithium, have been postulated.

$$[TaCl_2(dmpe)_2] + 2KPPh_2(dioxane)_2 \xrightarrow[0\,°C]{THF} [TaH(PPh_2)_2(dmpe)_2] + 2KCl + 2\,dioxane \quad (58)$$

56%



34.4.4.5 Nitrenes

Ta^{III} nitrenes have been prepared by reduction of Ta^{V} nitrenes under argon (equation 59). The lability of the PMe_3 ligands allowed the production of $[Ta(NPh)ClL_3(alkene)]$ (alkene = ethylene or styrene).

$$[Ta(NR)Cl_3(THF)_2] \xrightarrow[4L,\ Ar,\ THF]{2Na/Hg} \textit{trans}\text{-}[Ta(NR)ClL_4] \quad (59)$$

$R = Me, Bu^t, Ph \quad L = PMe_3, 0.5\,dmpe$

A diimido Ta^{III} complex (**43**) analogous to the Ta^{V} derivatives (Section 34.2.3.6) was formed by reduction of $[TaCl_3(PMe_3)_2(C_2H_4)]$ (equation 60). Dissociation of the PMe_3 ligand *trans* to the μ-N_2 unit was observed by NMR.

trans-$[TaCl_3(PMe_3)_2(C_2H_4)]$ $\xrightarrow[N_2\,(1\ atm)]{2Na/Hg,\ Et_2O,\ THF}$  (60)

(**43**)

34.4.4.6 Organometallics

A few salient results that have appeared since the publication of 'Comprehensive Organometallic Chemistry' have been collected here.

Low-valent tantalum–bromide–$PhPMe_2$ adducts undergo facile P—Me bond cleavage reactions spontaneously or in the presence of strong bases, giving tantalum σ-methyl and tantalum methylphosphido derivatives.[627]

Smooth substitution of chlorine in $[M_2Cl_6(PhPMe_2)_4]$ using Me_3SnCp easily yielded $[Ta_2Cl_4(PhPMe_2)_2(Cp)_2]$, while the poorly soluble $[Nb_2Cl_5(PhPMe_2)_3(Cp)]$, is favored for niobium, although the disubstituted compound may be obtained after long reaction times. The reaction of $[TaCl_2(dmpe)_2]$ with [NaCp(DME)] apparently proceeds through disproportionation, giving $[Ta(dmpe)(Cp)_2]Cl$ and $[TaCl(dmpe)_2(Cp)]Cl$.[528]

$[MX_2(CO)_3(Cp)]$ has been obtained by several routes.[8] Carbonylative reduction at atmospheric pressure of $[MCl_4(Cp)]$ was achieved (equation 61).[629] The tantalum derivative was obtained only as an impure material in poor yield (<10%). The niobium compound is a chlorine-bridged dimer (**44**).[564] $[NbI_2(CO)_3(Cp)]$ (**45**) was prepared by oxidative addition of iodine to $[Nb(CO)_4(Cp)]$.[630] Its carbonyl groups can be removed under vacuum, resulting in a carbonyl free material that reversibly absorbs CO to give a compound suggested to be a dimer comparable to (**44**). Complex (**45**) could be converted quantitatively to $[NbI_2(CO)(dmpe)(Cp)]$.

$$3[MCl_4(Cp)] + 9CO + 2Al \xrightarrow[THF]{HgCl_2} 3[MCl_2(CO)_3(Cp)] + 2AlCl_3 \quad (61)$$

(**44**)

A thermally robust dihapto CO_2 complex was easily obtained according to equation (62).[631] Complex (**46**) is the first authentic (X-ray diffraction) CO_2 complex of a hard oxophilic early transition element. The CO_2 (C—O bond lengths: 1.283(8) and 1.216(8) Å) lies close to the alkyl group, but its orientation is such that its insertion into the metal–alkyl bond would produce the unfavored metallacarboxylate ester instead of a carboxylato complex.

$$[NbCl(CH_2SiMe_3)(CpR)_2] \xrightarrow[\substack{CO_2\,(1\,atm)\\30\,mn}]{Na/Hg,\ THF} [Nb(CH_2SiMe_3)(\eta^2\text{-}CO_2)(CpR)_2] + [Nb(CH_2SiMe_3)(CO)(CpR)_2] + [Nb(CH_2SiMe_3)(CO_3)(CpR)_2] \quad (62)$$

(**46**) 34%

R = Me

$[NbX(Cp)_2L]$ (L = PMe_2Ph, $P(OMe)_3$, PhC≡CPh, PhC≡CH for X = Cl or Br; L = HC≡CH, CNCy, CNPh for X = Cl; L = CO for X = Br) has been obtained by reduction of $[NbX_2(Cp)_2]$ with Na/Hg in the presence of the ligands;[632,633] the remarkable stability of the alkyne adducts contrasts with that of the derivatives with phosphorus donors. Formation of strong metal–alkyne bonds seems to be a common feature of the mono- and dicyclopentadienyl derivatives. $[NbX(Cp)_2]$ were obtained for both X = Cl and X = Br,[8] but they display different behavior toward π-acid ligands. A dinuclear structure has been suggested for $[NbBr(Cp)_2]$ on the basis of its inertness toward CO or $PhPMe_2$.

34.4.5 Pseudohalo Derivatives

The monomeric $[NbCl_3(py)_3]$ has been used for the preparation of $[Nb(NCS)_3(py)_3]$.[593] $K_5[Nb(CN)_8]$, obtained by electrosynthesis,[536] is the only X-ray-characterized monomeric homoleptic Nb^{III} compound. A dodecahedral D_{2d} geometry with two sets of Nb—C distances was found in the solid.[635] IR data suggest a change to a D_{4d} geometry in solution. ^{13}C NMR data are compatible with either a D_{4d} or a fluxional D_{2d} polyhedron.

34.4.6 Miscellaneous

34.4.6.1 Chemistry in aqueous solution: sulfato, oxalato and related compounds

Reduction in aqueous solutions under argon of M^V sulfato complexes by Zn in the presence of sulfuric acid for Nb, by zinc amalgam or electrolytically in the presence of an oxalate for Ta, provided $K[Nb(SO_4)_2]\cdot 4H_2O$[636] or $K_5[Ta(C_2O_4)_4]$ and $[(PhCH_2)_3NH]_5[Ta(C_2O_4)_4]\cdot 4H_2O$[637] as diamagnetic, oxygen sensitive solids. A distorted dodecahedral geometry was assumed for the highly labile Ta^{III} oxalate.

The redox potential of the Nb^V–Nb^{III} couple has been determined in 3 N H_2SO_4 ($E'^\circ \approx -0.275$ V).[638] Its reducing power is comparable to that of Ti^{III}. Solutions of $K[Nb(SO_4)_2]\cdot 4H_2O$ are stable under CO_2, and were used for the titration of Cu^{II}, Fe^{III}, Tl^{III}, Mo^{VI}, V^V and U^{VI}.[639] Strongly reducing behavior of the Nb^{III} solutions towards NO, giving ammonia, was also observed. The reducing power of the Ta^V–Ta^{III} couple is close to that of the $Cr^{3+}(aq)/Cr^{2+}(aq)$ couple.

The potassium disulfatoniobate(III) tetrahydrate was used as starting material for the

synthesis of $[Nb(oxin)_3]$ (oxin = oxinate) and of $[Nb_2O(PO_4)_2]\cdot 6H_2O$. The two products are weakly paramagnetic ($\mu = 0.76$ and 0.68 BM, respectively). $[Nb(oxin)_3]$ is quantitatively oxidized to $[NbO(oxin)_3]$ in air. Potentiometric titration of the phosphato derivative showed that it should be regarded as a niobyl phosphoniobate(III) of formula $[Nb^{V}ONb^{III}(PO_4)_2]\cdot 6H_2O$.[640]

34.4.6.2 Other products

Chalcogeno halides NbYX (Y = S, Se; X = Br, I) were formed according to equation (63). Their structure contains $Nb_2(Y_2)_2$ fragments and is best described as $[Nb_2(Y_2)_2X_{8/2}]$.[641] Reduction of $NbCl_5$ with excess $LiAlH_4$ in Et_2O at room temperature led to a product presumed to be $[LiNb_2(AlH_4)_7]$.[642]

$$Nb_3X_8 + 5Nb + 8Y \xrightarrow{700\text{–}800\,^{\circ}C} 8NbYX \qquad (63)$$
$$X = Br, I; \quad Y = S, Se$$

34.5 NON-INTEGRAL OXIDATION STATES

34.5.1 Survey

The lower halides of niobium and tantalum consist of tightly bound clusters of metal atoms, with metal–metal distances close to those found in the metal. They contain ions with average oxidation numbers between +III and +I (Table 43). Their size depends on the valence electron concentrations (VEC) that are available on the metal atoms for M—M bonding, and on the halide-metal ratio.[644] Several reviews have been devoted to the clusters of early transition metals.[3,643]

Table 43 Various Niobium and Tantalum Clusters with Non-integral Oxidation States

Average oxidation number of the metal	*Close-packed structures*	*Cluster strucures*
3.00	$[Cs_3Nb_2X_9]$(X = Cl, Br, I)	—
2.67	$[Nb_3X_8]$(X = Cl, Br, I)	$(M_6X_{12})^{4+}$
2.50	$[CsNb_4X_{11}]$(X = Cl, Br)	$(M_6X_{12})^{3+}$ X = Cl, Br
2.33	—	$(M_6X_{12})^{2+}$
1.83	—	$(Nb_6I_8)^{3+}$
1.67	—	$(Nb_6I_8)^{2+}$

34.5.2 Triangular Clusters

The triangular clusters, the simplest ones, have been obtained under a variety of conditions, including ligand exchange and metathesis reactions of molecular Nb^{III} derivatives. The three basic structural types[645]—without, with one, and with two μ_3-ligands—are known, and compounds with seven or eight valence electrons on the M_3 core have been described.

34.5.2.1 Binary halides

Trimeric clusters of formula M_3X_8 (X = Cl, Br, I) are known for Nb but not for Ta.[1,5,643] They were usually prepared by thermal decomposition of higher halides or by reduction of the pentahalides by niobium. The light green Nb_3Cl_8 and black Nb_3Br_8 are the Nb rich limits of the homogeneous phases that extend over the composition ranges $NbCl_{2.67}$ to $NbCl_{3.13}$ and $NbBr_{2.67}$ to $NbBr_{3.03}$.

Both the α and β forms contain Nb_3 triangles, with metal–metal distances ranging from 2.81 (for Nb_3Cl_8) to 3.00 Å (in β-Nb_3I_8). In β-Nb_3Br_8, for instance, the niobium atoms are bridged by three bromine atoms located below the plane of the triangle, while a fourth is located above

the plane and bridges all three metal atoms.[5] The remaining halogen atoms are involved in intercluster bridging, and the structure is described as $^{2}_{\infty}[(Nb_3X_4^i)\,|\,X^{o-o}_{6/2}X^{o-o}_{3/3}]$, where i and o stand for the halogen inside and outside the core, respectively.[646] The metallic centers are crystallographically and chemically equivalent in all the Nb_3X_8 compounds. The α and β forms differ mainly in the arrangement of the successive layers of the X—Nb—X atoms. Only the β form of Nb_3I_8, which is stable in air for several days, is stoichiometric.[501] Nb_3Cl_8, β-Nb_3Br_8 and β-Nb_3I_8 are paramagnetic. The low magnetic moment (1.95 BM at 573 K falling to 0.5 BM at 90 K for Nb_3Cl_8) indicates that there is some magnetic exchange between distinct Nb_3 clusters.

The Nb_3 binary halides with seven electrons available for metal–metal bonding within the triangle are 'electron poor' clusters. A simplified MO scheme suggests that the HOMO and LUMO possess metal *d* character.[645] One unpaired electron is expected to be present. The existence of a low-lying metal cluster orbital is also indicated by the electronic spectra.

34.5.2.2 Adducts of the neutral halides

The reactivity of the Nb_3X_8 clusters has received little attention as yet. The metal–metal bonds were however found to be susceptible to disruption, leading to dinuclear,[525] tetranuclear[647] and hexanuclear species.[648]

Several complexes of the M_3X_8 clusters have been obtained, generally during reduction procedures promoted by the ligands; thus, the reaction between $[Nb_2Cl_6(SMe_2)_3]$ and Bu^{t}NC (equation 55) yielded $[Nb_3Cl_8(Bu^tNC)_5]$ (**41**). The molecule has an approximate symmetry plane.[615] The Nb atoms define an isosceles triangle, with a bridging chlorine atom located below each edge and an unprecedented type of multiply bridging isocyanide ligands above the triangle (Figure 33). The short Nb(1)—Nb(2) distance suggests a two-electron bond, while the interpretation of the two larger Nb—Nb distances is more problematical. It is difficult to assign oxidation numbers unambiguously; ESR data at room temperature ($\langle g \rangle \approx 1.95$ and $\langle A \rangle =$ 130 G) are consistent with the unpaired electron localized on Nb(3). Two pairs of π electrons of the bridging Bu^{t}NC ligand are probably involved in bonding with Nb(1) and Nb(2), while C(1) forms a strong donor bond to Nb(3). A formally similar situation is found for one of the CO ligands in $[Nb_3(CO)_7(Cp)_3]$ (**47**).[649]

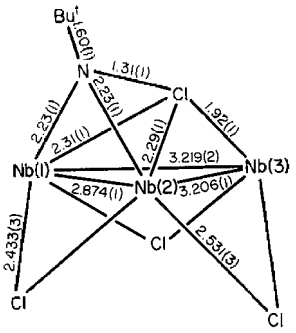


Figure 33 Central core of the $[Nb_3Cl_8(Bu^tNC)_5]$ (**41**) molecule. Each Nb is surrounded by two Cl and one Bu^{t}NC ligand (reproduced from ref. 615 with permission)

A compound of formula $[Nb_3Cl_8(SMe_2)_2(OEt_2)]$, but of unknown structure, has been observed to form during the synthesis of $[Nb_2Cl_6(SMe_2)_3]$.[584] Another, formulated as $[Ta_3Br_8(SMe_2)_2]$, resulted from a low yield reduction of $TaBr_4$.[650]

34.5.2.3 Solvolysis products

Compounds of formula $[M_3X_2B_6L_3]$, where B is a bridging anionic donor and L a neutral one, may be considered as formally derived from M_3X_8 adducts by solvolysis. The reduction of Nb^V in acid solutions has been used for its qualitative and quantitative determination, but the exact nature of the reduced species remains unknown. The red-brown salt obtained as early as 1912 by reduction of Nb^V in aqueous H_2SO_4 has been formulated as $[K_4(H_5O_2)][Nb_3O_2(SO_4)_6(H_2O)_3]\cdot 5H_2O$ (**48**) on the basis of a recent X-ray structure

determination.[651] Complex (**48**) has nearly D_{3h} symmetry and is the first example of a cluster having bridging sulfate ligands (Figure 34). Its overall geometry, with two μ_3-ligands, is reminiscent of the structural and coordination type $[M'_3X_2(O_2CR)_6L_3]$, mainly found for Mo and W. The $[H_5O_2]^+$ ion exhibits an O · · · H · · · O distance of 2.42(1) Å, comparable to those found in other compounds containing the diaquahydrogen ion. The 5− charge of the cluster leads to a non-integral oxidation number of +3.66 for the metal atoms, and suggests that four electrons are involved in Nb—Nb bonding. According to MO calculations, the bond order should be 2/3, in agreement with the experimental M—M distance.

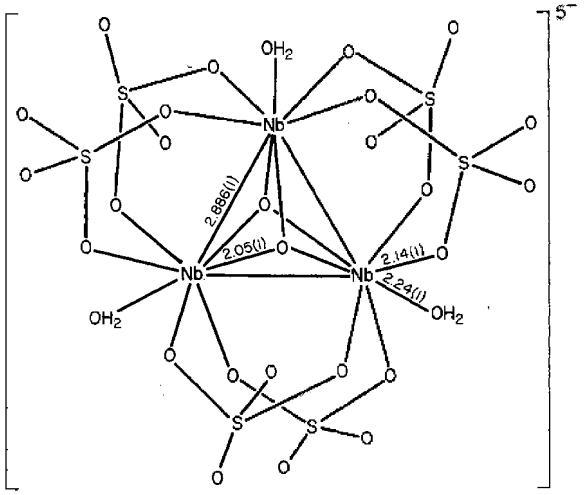

Figure 34 Structure of the $[Nb_3O_2(H_2O)_3(\mu\text{-}SO_4)_6]^{5-}$ (**48**) anion. The distances reported correspond to average values (reproduced from ref. 651 with permission)

The structurally related niobium complexes $[Nb_3O_2(O_2CR)_6(THF)_3]^+$ ($Z = [NbOCl_4(THF)]^-$ for R = Ph; $Z = BPh_4^-$ for R = Bu^t) have been prepared from $[Nb_2Cl_6(SMe_2)_3]$ and sodium carboxylates.[621] The triangular array of Nb atoms (Nb—Nb: 2.824(3) Å for R = Bu^t) is capped by two oxygen atoms, bridged by six carboxylato ligands, and coordinated in the axial position by the THF molecules. Unlike (**48**), they are diamagnetic. $[Nb_3(\mu_3\text{-}S)(\mu_2\text{-}O)(NCS)_9]^{6-}$ further illustrates the tendency of Nb to form oxo trinuclear species, and has been considered to derive from the green $[Nb_3O_4(H_2O)_9]^{n+}$ cation.[651b]

34.5.2.4 Clusters with the hexamethylbenzene ligand

Trimetallic cations $[M_3(\mu\text{-}X)_6(C_6Me_6)_3]^+$ (M = Nb, X = Cl, Br; M = Ta, X = Cl) have been obtained from hexamethylbenzene, aluminum powder, $AlCl_3$ and MX_5 in the molten state.[8,652] The same approach, applied to $TaBr_5$, led to $[TaBr_2(C_6Me_6)]_n$, where the metal is in the formal oxidation state +II. The diamagnetic $[Nb_2(\mu\text{-}Cl)_6(C_6Me_6)]Cl$ has C_{3h} symmetry. Each metal is coordinated in an approximately square planar fashion and bears an η^6-C_6Me_6 ligand parallel to this plane. The Nb—Nb distances (3.334(6) Å) are consistent with the three metals' sharing two electrons.[653]

The $[M_3(\mu\text{-}X)_6(C_6Me_6)_3]^+$ derivatives show an unusual, reversible redox behavior.[654] Their oxidation by ammonium hexanitratocerate(IV) yields a species of stoichiometry $[Nb_3Cl_6(C_6Me_6)_3]^{2+}$, whose diamagnetic behavior implies dimerization to $[Nb_6Cl_{12}(C_6Me_6)_6]^{4+}$. This cluster is related to those of type $[(M_6X_{12})X_6]^{(q-6)}$ from which they derive by substitution of the six terminal halides by the C_6Me_6 ligand acting formally as a two-electron donor. The oxidation reaction (equation 64), analogous to that of $[(M_6Cl_{12})Cl_6]^{4-}$ to $[(M_6Cl_{12})Cl_6]^{2-}$ (Section 34.5.4.1.iii), has been accomplished by Ce^{IV}, NBS, iodine and even air in acidic solutions. The water soluble hexanitratocerate(IV) salt was converted to the insoluble $[Nb_6Cl_{12}(C_6Me_6)_6]Z_4$ ($Z = PF_6^-$, BPh_4^-, SCN^-). The related tantalum chloride and niobium bromide clusters display comparable behavior, but their derivatives are generally less stable.

$$2[Nb_3Cl_6(C_6Me_6)_3]^+ \xrightarrow{-2e^-} [Nb_6Cl_{12}(C_6Me_6)_6]^{4+} \quad (64)$$

The paramagnetic purple trimer $[Nb_3(\mu\text{-}Cl)_6(C_6Me_6)_3]^{2+}$ could be stabilized when using the dimeric $(TCNQ)_2^{2-}$ as counterion.[655] It has *m* symmetry with two Nb—Nb distances of 3.327(2)

and 3.344(3) Å. The overall structural arrangement is novel, and displays strongly bonded TCNQ dimers interacting with the C_6Me_6 ligands in a zigzag chain. The nearly isotropic ESR spectra at room temperature ($g = 1.996$) are consistent with the unpaired electron residing on the niobium cluster. The polycrystalline conductivity data indicate a semiconductor behavior.

All the hexamethylbenzene metal halide cluster cations exhibit characteristic electronic spectra which can be used for their identification in their green or brown solutions. Various attempts to obtain derivatives of $[Nb_3(\mu\text{-}Cl)_6(C_6Me_6)_3]$ under the action of donors or organometallic reagents failed.

34.5.3 Tetranuclear Clusters

The formation of $[CsNb_4X_{11}]$ (X = Cl, Br) and $[RbNb_4Cl_{11}]$ (equation 65) instead of A_2MX_6, $A_2M_2X_9$ or $A_6M_6X_8$ illustrates the importance of the alkali metal cation in stabilizing a given cluster.[647] These brown-black compounds are soluble only with decomposition. Their X-ray structures show the presence of planar Nb_4 clusters (Figure 35), and they can be described as $(Nb_4X_6^i)$ units linked together into chains by four and six X^{o-o} bridges. The holes between the chains are occupied by the alkali metal cations in a $Cs_\infty^2[(Nb_4X_6^i)X_{4/2}^{o-o}X_{6/2}^{o-o}]$ configuration. The structure is closely related to that of Nb_3X_8.

$$5Nb_3X_8 + Nb + 4AX \longrightarrow 4ANbX_{11} \qquad (65)$$
$$A = Cs, Rb; \quad X = Cl, Br, I$$

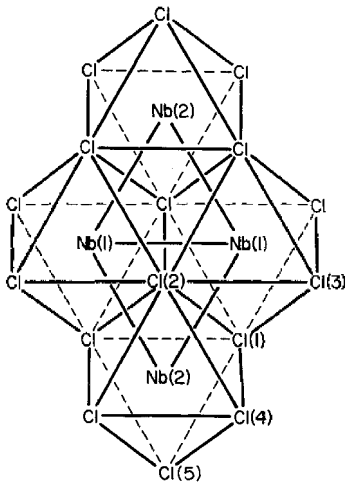

Figure 35 Drawing of the structure of CsM_4Cl_{11} showing the five different chlorine environments (Nb(1)—Nb(1): 2.84, Nb(1)—Nb(2): 2.95 Å; (reproduced from ref. 647 with permission)

In these clusters the metal has a formal oxidation state of 2.5, with 10 electrons available for M—M bonding in the Nb_4 group; the compounds are diamagnetic with a slight temperature independent paramagnetism. It is noticeable that Nb(1) and Nb(2) have different arrangements, which led to the proposal of different formal oxidation states: +II for Nb(1) and +III for Nb(2).

34.5.4 Octahedral Clusters

The lowest halides, obtained under strongly reducing conditions or thermal disproportionation of the higher halides, are Nb_6F_{15} and Ta_6X_{15} (X = Cl, Br, I), Nb_6X_{14} (X = Cl, Br), Ta_6X_{14} (X = Br, I) and Nb_6I_{11}.[1,5,643] Their oxidation numbers follow the expected trends: Ta > Nb and F > Cl > Br > I, and Nb_6I_{11} is the lowest niobium subhalide reported so far. All are based on octahedral $(M_6X_{12})^{q+}$ (X = Cl, Br; $q = 2, 3, 4$) or $(M_6X_8)^{q+}$ ($q = 2, 3$) units (Figure 36) as for Nb_6I_{11} (Section 34.5.4.2). Although their chemistry has long been investigated—mainly in aqueous solutions—their formulation and structure, and those of their derivatives, have been

established only recently, or, in many cases, remain uncertain. The first evidence for the existence of the $[M_6X_{12}]^{2+}$ group is due to Vaughan *et al.*, who in 1950 studied ethanolic solutions of some of these complexes by X-ray scattering.[656]

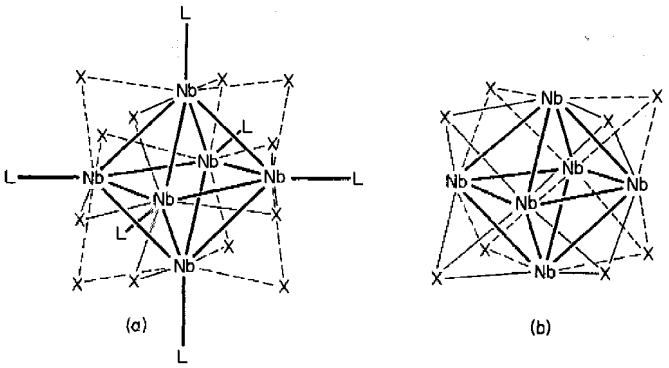

Figure 36 Octahedral clusters: (a) the $(M_6X_{12})^{q+}$ core with additional centrifugal ligands L; (b) the $(M_6X_8)^{q+}$ core

Conflicting data, due to studies performed on mixtures of compounds in which different oxidation states were present (oxido–reduction processes occur easily, especially in the presence of air[657–659]) are reported.

The metals of the octahedral clusters can readily add a variety of ligands in 'centrifugal' positions, resulting in compounds of type $[(M_6X_{12})Y_nL_{6-n}]^{(q-n)}$ (X = Cl, Br; Y = F, Cl, Br, I, OH; L = neutral donor; n = oxidations state). In the description of such species, the central core containing the metal atoms will be represented in parentheses.

34.5.4.1 Clusters based on the $(M_6X_{12})^{q+}$ core

(*i*) *Neutral binary halides*

The first metal-cluster fluoride known, $[(Nb_6F_{12})F_3]$, was prepared by disproportionation of NbF_4 or by reduction of NbF_5 by Nb. The compounds of composition M_6X_{14} have been obtained by reduction of the higher halides by various metals, and Nb_6Cl_{14} also by heating Nb_3Cl_8. Phase diagram studies established that the only tantalum cluster iodide formed was Ta_6I_{14}, whereas in the case of bromine both Ta_6Br_{14} and Ta_6Br_{15} formed. The compounds are dark, air stable solids; Ta_6Cl_{14} and Nb_6Br_{14} dissolve in water and ethanol, and Nb_6F_{15} and Ta_6Cl_{15} are unaffected by dilute mineral acids.

Regular octahedra of metal atoms were found with rather short metal–metal distances (Table 44) for Nb_6F_{15} and Ta_6Cl_{15}. Nb_6Cl_{14} and Ta_6I_{14} are isotypic and contain flattened octahedra, hence two types of centrifugal ligands. The strong equatorial Ta—Ta bonds of Ta_6I_{14} are accompanied by a greater distortion of the Ta_6 octahedron as compared to that of Nb_6 in Nb_6Cl_{14}. The regular O_h symmetry usually given for isolated clusters is obviously an oversimplified view here. For the M_6X_{14} class of compounds, the three-dimensional network can be described as $^3_\infty[(Nb_6Cl_{10}Cl^{i-o}_2)Cl^{o-i}_{2/2}Cl^{o-i}_{4/2}]$.[646] For Nb_6F_{15} and Ta_6Cl_{15} additional intercluster bridging halogen atoms are bonded to each type of metal atom.

(*ii*) *Ionic halides $[(M_6X_{12})X_6]^{4-}$ and hydrates with an $(M_6X_{12})^{2+}$ core*

(*a*) *Synthesis and structure.* The hydrates $M_6X_{14}\cdot 8H_2O$ (X = Cl, Br), being more soluble than the anhydrous lower halides, are useful starting materials for preparing subsequent derivatives.[658]

The preparation of $[M_6X_{14}]\cdot 8H_2O$ generally involves high temperature reactions, the $(M_6X_{12})^{2+}$ cation-containing products being extracted with boiling water and crystallized from aqueous HX. When the extraction was achieved with warm water, $[M_6Cl_{14}]\cdot 9H_2O$ was obtained.[660] The first of these hydrates, $[Ta_6Cl_{14}]\cdot 8H_2O$, was prepared as early as 1907, but at that time it was formulated as $[TaCl_2]\cdot 2H_2O$.

Harned's method, which has long been used to obtain the ternary halides required for the

preparation of the hydrates, involves the reduction of the pentahalide by cadmium and formation of $[Cd_2(M_6X_{12})X_6]$ (<20%).[661] The high temperature disproportionation of Nb_3X_8 with an alkali halide (equation 66) or its reduction to $A_4[(Nb_6X_{12})X_6]$ in the presence of niobium have also been proposed. A disadvantage of these methods is that they require Nb_3X_8 as a precursor. More efficient is the fast and quantitative comproportionation of niobium or tantalum whith their pentahalides in the presence of an alkali halide (equation 67).[648] This synthesis is facilitated by the stabilization of the cluster through complexation into an $[M_6X_{18}]^{4-}$ anion, and is particularly valuable for $[Nb_6Br_{14}]\cdot 8H_2O$. The selection of the appropriate alkali metal halide is essential for obtaining the $[M_6X_{18}]^{4-}$ cluster, since the relative stabilities of $[A_2MX_6]$, $[A_3M_2X_9]$ (Section 34.4.2.1) and $[AM_4X_{11}]$ (Section 34.5.3), which are competing with it, depend on the cation. For all compounds competing with $[A_4Nb_6Cl_{18}]$, the sodium derivatives have markedly lower stabilities than those of the heavier alkali metals; NaCl was therefore generally selected as complexing agent when the $NbCl_{18}$ derivatives were sought. For the less stable bromine derivatives, Na^+ was replaced by K^+.

$$5Nb_3X_8 + 14AX \longrightarrow 2A_4[(Nb_6X_{12})X_6] + 3[A_2NbX_6] \quad (66)$$

$$A = Na, K; \quad X = Cl, Br$$

$$14MX_5 + 16M + 20AX \xrightarrow[1\,d]{700\,^\circ C} 5A_4[(M_6X_{12})X_6] \quad (67)$$

$$A = Na, K; \quad X = Cl, Br$$

An undistorted octahedral symmetry has been established for the $(Nb_6Cl_{12})^{2+}$ core in $[K_4Nb_6Cl_{18}]$. The structure of $[Ta_6Cl_{14}]\cdot 7H_2O$ shows that the compounds should be written as $[(Ta_6Cl_{12})Cl_2(H_2O)_4]\cdot 3H_2O$.[662] The short centrifugal Ta—Cl distance of 2.35 Å (2.50 for the Ta—Cl bridges) is accompanied by an elongation of the Ta_6 octahedron along this axis (Ta—Ta: 3.15 and 2.78 Å).

(*b*) *Reactivity of the hydrates* (*Table* 45). .The preparation of pure $(M_6X_{12})^{2+}$ (X = Cl, Br) complexes from aqueous solutions is not easy, as oxidation to $(M_6X_{12})^{3+}$ readily occurs. The latter may be detected by the emergence of a band near 8000 cm^{-1}. Addition of reductants such as $SnCl_2$ or Cd to oxidized solutions caused a return of the familiar green color of $(M_6X_{12})^{2+}$. The bromides are soluble in water and methanol, while the chlorides dissolve well only in methanol. Titration with NaOH precipitates $[(M_6X_{12})(OH)_2]\cdot 8H_2O$, which redissolves as $[(M_6X_{12})(OH)_4]^{2-}$ by further addition of NaOH.[659]

The $(M_6X_{12})^{2+}$ clusters act as Lewis acids and a number of $[(M_6Cl_{12})Cl_2L_4]$ complexes have been obtained, mainly with oxygen donors, including DMSO, DMF, $OAsPh_3$, $OPPh_3$ and pyO. The more recently obtained phosphine complexes are the only examples of Nb or Ta hexameric clusters with neutral ligands without oxygen donors. Whereas bidentate ligands have been widely used to form derivatives of the molybdenum and tungsten $(M'_6X_8)^{q+}$ clusters, only $[(Nb_6Cl_{12})Cl_2(bipyO_2)_2]$ has been reported.[663] Models showed that $bipyO_2$ is able to occupy two *cis* centrifugal positions, and the electronic spectrum of the complex was comparable to that of the adducts formed with monodentate ligands.

The inner halogens of the $(M_6X_{12})^{q+}$ core are relatively inert; no exchange was detected (within a ±20% margin of error) between $(Ta_6Cl_{12})^{2+}$ and $^*Cl^-$ over 13 hours at room temperature.[2] No solvolysis reactions have been reported. The higher lability of the outer halogen atoms allowed the production of mixed halide clusters, for instance $[(Nb_6Cl_{12})X'_2(H_2O)_4]\cdot 4H_2O$ (X' = Br, F).

(*iii*) *Oxidized clusters*

(*a*) *Synthesis.* In the solid state, $[Ta_6Cl_{14}]\cdot 8H_2O$ was found to undergo reversible oxidation by topotactic electron/proton transfer (equation 68).[664]

$$[(Ta_6Cl_{12})Cl_2(H_2O)_4]\cdot 4H_2O \rightleftharpoons [(Ta_6Cl_{12})(OH)_x(H_2O)_{4-x}]\cdot 4H_2O + xe^- + xH^+ \quad (68)$$

$$0 \leqslant x \leqslant 1.5$$

In aqueous solution the green diamagnetic $(M_6X_{12})^{2+}$ is oxidized by air, I_2, or Hg^{II} to the paramagnetic yellow $(M_6X_{12})^{3+}$, and by two or more moles of strong oxidizing agents such as BrO^{3-}, H_2O_2, Cl_2, Fe^{III}, Ce^{IV} or VO_2^+ ions to the red-brown diamagnetic $(M_6X_{12})^{4+}$ (X = Cl, Br).[665-668] Oxidation is always faster for the chlorine than for the bromine derivatives. No redox chemistry is known so far for $(Nb_2F_{12})^{3+}$ or $(Ta_6I_{12})^{2+}$, the latter being unstable in aqueous solution. Standard potentials have been measured (Table 46).[657,659] The instability of the niobium bromine clusters with respect to hydrolysis hindered the obtaining of $E°$ values. Only the $(Ta_6Cl_{12})^{3+}/(Ta_6Cl_{12})^{2+}$ couple has found analytical applications.

[a] $(M_6X_{12})^{3+}/(M_6X_{12})^{2+}$ [b] $(M_6X_{12})^{4+}/(M_6X_{12})^{3+}$

Oxidation of $(M_6X_{12})^{2+}$ by dioxygen is slow in neutral solutions, but occurs rapidly in acidic or basic media (equations 69 and 70). Cyclic voltammetry data are available on the $(Ta_6Br_{12})^{q+}$ system in aqueous solutions.[669] Controlled oxidation of $[M_6X_{14}]\cdot 7H_2O$ led to the hydrates $[M_6X_{15}]\cdot 7H_2O$ or $[M_6H_{16}]\cdot 7H_2O$. Spontaneous reduction was observed for all the $(M_6X_{12})^{4+}$ clusters except $(Ta_6Br_{12})^{4+}$ upon redissolution. The $(M_6X_{12})^{q+}$ ($q = 3, 4$) ions are also reduced to $(M_6X_{12})^{2+}$ species by Cr^{II} or V^{II}.[668] Examples of reduction by ligands seem to be limited to that of $[Nb_6Cl_5]\cdot 7H_2O$ by phosphines to give $[(Nb_6Cl_{12})Cl_2(PR_3)_4]$ (R = Et, Pr^n).[670]

$$2(M_6X_{12})^{2+} + 0.5O_2 + 2H^+ \longrightarrow 2(M_6X_{12})^{3+} + H_2O \quad (69)$$

$$2(M_6X_{12})^{2+} + 0.5O_2 + 10OH^- \longrightarrow 2[(M_6X_{12})(OH)_6]^{3-} \quad (70)$$

X = Cl, Br

Reversible redox processes were also observed in non-aqueous solutions. The behavior of $[(M_6Cl_{12})Cl_2(PR_3)_4]$ (R = Et, Pr^n) in CH_2Cl_2 or MeCN was investigated by cyclic voltammetry, revealing several one-electron processes (equation 71). Chemical oxidation by $NOPF_6$ yielded $[(M_6Cl_{12})Cl_2(PPr^n_3)_4](PF_6)_n$ ($n = 1, 2$). The electron transfer is proposed to occur *via* M—Cl · · · + NO bridges. The monoanions $[(M_6Cl_{12})Cl_2(PR_3)_4]^-$ are formally derived from the previously unknown $(M_6Cl_{12})^+$ core. The stabilizing influence of the phosphine led to a redox chemistry which is more extentive than that in aqueous solutions. Attempts to obtain the monoanions by electrochemical or chemical reductions (Li, Mg, Na/Hg) failed. The average oxidation state of the metal in the monoanions remains higher than for $(Nb_6I_8)^{2+}$.

$$[(M_6Cl_{12})Cl_2(PR_3)_4]^- \overset{-e^-}{\rightleftharpoons} [(M_6Cl_{12})Cl_2(PR_3)_4] \overset{-e^-}{\rightleftharpoons} [(M_6Cl_{12})Cl_2(PR_3)_4]^+ \overset{-e^-}{\rightleftharpoons} [(M_6Cl_{12})Cl_2(PR_3)_4]^{2+} \quad (71)$$

Within the $(M_6X_{12})^{q+}$ (X = Cl, Br; q = 2-4) cluster halides, the only series that cover all three oxidation states are the tantalum halide hydrates and the haloanions $[(M_6X_{12})X_6]^{(q-6)}$. The isolation of $[(Ta_6Cl_{12})Cl_2(PR_3)_4](PF_6)_n$ ($n = 1, 2$) led to the first complete series of group VA cluster stabilized by an organic ligand.

Polarographic measurements have also been performed on $[(Nb_6Cl_{12})Cl_6]^{(q-6)}$ ($q = 2, 3$) in DMSO. While in aqueous solutions iodine causes a two-electron oxidation, only a one-electron oxidation was observed in DMSO.

(*b*) *Reactivity.* The oxidation of the hydrates $[M_6X_{14}]\cdot 8H_2O$ in ethanolic or aqueous HX, in the presence of a suitable counterion, was used to prepare anions of type $[(M_6X_{12})X'_6]^{(q-6)}$ ($q = 2, 3$; equation 72).[658,672] The species that have been isolated include $(pyH)_2[(M_6Cl_{12})Cl_6]$

and $(A)_n[(M_6X_{12})X_6]$ (X = Cl, Br; A = R_4N, Ph_4As, *etc.*; Table 47). To obtain pure compounds containing the $(Ta_6X_{12})^{3+}$ unit, air must be rigorously excluded.

$$(Ta_6Br_{12})^{2+} + X'_2 + 2Et_4NX' \longrightarrow (Et_4N_2)[(Ta_6Br_{12})X'_6] \quad (72)$$
$$X' = Cl, Br$$

The stability of the $(M_6X_{12})^{q+}$ compounds towards hydrolysis decreases in the order Ta > Nb, Cl > Br, and with increasing oxidation states. Evidence has been reported for partial replacement of the chlorines by hydroxo groups in $[Nb_6Cl_{15}]\cdot 7H_2O$.[672]

Irradiation of $(Ta_6Br_{12})^{2+}$ in deaerated HCl solution led to $(Ta_6Br_{12})^{3+}$ and evolution of H_2. It was assumed that the key step involves a two-electron transfer from $(Ta_6Br_{12})^{2+}$ to a water molecule in the solvent cage, yielding $(Ta_6Br_{12})^{4+}$ and H^-, which is scavenged by H^+, generating H_2.[673]

The mixed metal octahedral clusters $(Ta_5MoCl_{12})^{3+}$ and $(Ta_4Mo_2Cl_{12})^{4+}$ were obtained by reduction of $TaCl_5$–$MoCl_5$ mixtures with aluminum in $NaAlCl_4$–$AlCl_3$ melts.[674] Further reduction of $(Ta_5MoCl_{12})^{3+}$ by zinc offered the +2 cluster. Spectroscopic and magnetic data indicate that $[(Ta_5MoCl_{12})Cl_6]^{3+}$ and $[(Ta_4Mo_2Cl_{12})Cl_6]^{2-}$ are analogous to $[(Ta_6Cl_{12})Cl_6]^{4-}$ (16 M—M bonding electrons), and $[(Ta_5MoCl_{12})Cl_6]^{2-}$ to $[(Ta_6Cl_{12})Cl_6]^{3-}$ (15 bonding electrons).

(*c*) *Structure.* The influence of the oxidation state on the structure of $(M_6X_{12})^{q+}$ or $(M_6X_{18})^{(q-6)}$ can be evaluated from the comparison of X-ray data available on $K_4[(Nb_6Cl_{12})Cl_6]$, $(Me_4N)_3[(Nb_6Cl_{12})Cl_6]$ and $(pyH)_2[(Nb_6Cl_{12})Cl_6]$[675], and, in the case of

tantalum, on $H_2[(Ta_6Cl_{12})Cl_6]\cdot 6H_2O$[676] and $H_4[(Ta_6Cl_{12})(CN)_6]\cdot 12H_2O$.[677] In an M_6Cl_{18} unit each metal is surrounded by an approximately square planar set of four bridging chlorine atoms Cl_b. The metal is located slightly below this plane. One- and two-electron oxidations of, for instance, $[Nb_6Cl_{18}]^{4-}$ result in an increase of the Nb—Nb distances in two equal steps, from 2.92 to 2.97 and to 3.02 Å with retention of the octahedral symmetry (Table 44), which has been interpreted as meaning that the electrons are removed from bonding orbitals centered mainly on the M_6 cluster. Since $(Nb_6Cl_{12})^{3+}$ and $(Nb_6Cl_{12})^{4+}$ are diamagnetic, and since $(Nb_6Cl_{12})^{3+}$ shows a paramagnetism corresponding to one electron, these electrons appear to be removed from the same orbital.

As anticipated, a significant shortening of the Nb—Cl bond occurs after oxidation. However, the terminal Nb—Cl_t distances remain longer than that of Nb—Cl_b or the covalent bond (2.35–2.40 Å); even the strongest Nb—Cl_t bonds therefore appear relatively weak, which was attributed to the geometry of the Nb_6Cl_{18} unit: upon oxidation, the niobium atom moves up below the plane of its four Cl_b atoms, and becomes more accessible to Cl_t. Apparently only the Nb—Cl_t bonds benefit from the lowering in Nb—Nb bonding strength upon oxidation.

$[(Ta_6Cl_{12})(CN)_4]^{4-}$ consists of a regular Ta_6 octahedron with terminal cyanide ligands. The Ta—C and C—N distances are comparable to those found in normal cyanide complexes. Each nitrogen atom is hydrogen-bonded to two oxygen atoms.

(*d*) *Other characterizations.* The $(M_6X_{12})^{q+}$ clusters have been the subject of far-IR studies and normal coordinate analysis.[671,678–680] A uniform high shift (*ca.* 10 cm^{-1}) per unit increase in the charge of the cluster has been observed for the strong bands assigned to the M—X stretching modes. The M—M stretching vibration has been located around 140 cm^{-1} or in the 59 to 109 cm^{-1} range, *i.e.* at much lower frequencies than for $(Mo_6Cl_8)^{q+}$ (230 cm^{-1}). The force constant for the M—M bonds in the niobium or tantalum cluster halides was estimated to be less than 3×10^{-9} J $Å^{-1}$.

ESCA spectra have been recorded on several ionic or neutral niobium and tantalum clusters.[681] The C12$p_{1/2,3/2}$ spectra generally exhibit three doublets, which were assigned to intracluster and intercluster bridging Cl_b and to terminally bonded Cl_t halogens. The binding energy order was found to be $Cl_b > Cl_t$ with $\Delta E(Cl_b - Cl_t)$ between 1.4 and 2.1 eV, the lower values being characteristic of the hydrates. No discernible variations in the metal core electron-bonding energies of $[(M_6X_{12})X_6]^{(q-6)}$ clusters were observed upon oxidation. By contrast, an increase in the oxidation state in $[(M_6Cl_{12})Cl_2(PPr^n_3)_4](PF_6)_n$ ($n = 0$–2) is paralleled by an increase in the metal core electron-bonding energies Nb3$d_{5/2}$ or Ta4$f_{1/2}$ These results in conjunction with the ESR spectra and the fact that the cyclic voltammetry data are quite unaffected by changes of the phosphines[671] point to the HOMO of $(M_6Cl_{12})^{q+}$ ions' being almost exclusively metal-based in character.

NQR studies on $(Me_4N)_2[(Nb_6Cl_{12})Cl_6]$ revealed only the Cl_b resonance. It was suggested that the Cl_t resonance may have occurred outside the observed range (3 to 33 MHz) as a result of a high ionic character of the Nb—Cl_t bonds.

(*iv*) *Bonding, electronic spectra and magnetism*

A bonding scheme for the $(M_6X_{12})^{q+}$ clusters should account for the magnetic properties and observed electronic transitions. Several semiempirical MO calculations, for instance those of Cotton and Haas[682] based on the M_6 group, or those of Robin and Kuebler[683] on the $(M_6X_{12})^{2+}$ group, are available. A valence bond description has also been proposed.[2]

The effects of both X and L on the bonding have also been considered;[684] the energy level scheme closely resembles that of Cotton *et al.* Another model including both metal–metal and metal–ligand interactions, with spin–orbit coupling introduced as a final perturbation, is available.[685]

The observation that both the $(M_6X_{12})^{2+}$ (16 electrons) and $(M_6X_{12})^{4+}$ (14 electrons) clusters are diamagnetic, and the magnetic moments found for the $(M_6X_{12})^{3+}$ (15 electrons) cluster (1.62 BM), show that the fifteenth and sixteenth electrons occupy a non-degenerate MO. The ESR spectra obtained on $(Nb_6Cl_{12})^{3+}$ ($g = 1.95$) display a complex splitting, with 49 detectable components. The isotropic hyperfine structure accounts for a single electron uniformly delocalized over six equivalent Nb atoms (55 components expected) and suggests that the HOMO is an M–M orbital, of type A symmetry.

The absorption spectra of the $(M_6X_{12})^{q+}$ (X = Cl, Br; $q = 2$–4) clusters, as well as those of $(Nb_6F_{12})^{3+}$ and $(Ta_6I_{12})^{2+}$, have been measured over the range 4–50 kK;[663,678,683] they are fairly

complex. The correspondence between the spectra of the niobium and tantalum complexes ($\varepsilon(Nb)/\varepsilon(Ta) = 0.5–0.8$) supports the absence of notable spin–orbit coupling influence. A compilation of detailed visible spectra on the solid state or in solution is available.[686] Several tentative assignments have been presented.[674,684]

Magnetic circular dichroism spectra[685] and magnetic susceptibilities[687,688] have been measured. The $(M_6X_{12})^{3+}$ ions are paramagnetic, and $[(M_6X_{12})X_6]^{3-}$ anions generally display simple Curie law behavior. The magnetic moments at room temperature are significantly larger than expected for one unpaired electron. Deviations from Curie law behavior were observed for M_6X_{15} (M = Nb, X = F; M = Ta, X = Cl, Br) and for $[(Ta_6Cl_{12})Cl_3(H_2O)_3]\cdot 3H_2O$. The existence for the anhydrous halides of bridging halogens between cluster units could cause Curie–Weiss behavior *via* superexchange interactions. The origin of the same behavior for the hydrate remains unexplained. Large temperature independent paramagnetic susceptibilities were found for the diamagnetic clusters. The higher values for niobium than for the analogous tantalum compounds indicate a decrease in energy separation between the excited and the ground states for niobium.

34.5.5 Clusters Based on the $(M_6X_8)^{q+}$ ($q = 2, 3$) Core

The group VA clusters containing the $(M_6X_8)^{q+}$ unit are limited to the niobium subiodides. Nb_6I_{11} is formed by thermal decomposition of Nb_3I_8 or by its reduction with niobium.[1,643] Nb_3Br_8 is not reduced under similar conditions. In contrast to the $(M'_6X_8)^{q+}$ (M' = Mo, W) clusters, which possess a formal oxidation state of 2 and a closed shell electronic configuration, $(Nb_6I_8)^{3+}$ has a non-integral oxidation state and an open shell electronic configuration.

A salient feature of the structure of Nb_6I_{11}[689,690] is the pronounced orthorhombic distortion of the Nb_6 core with Nb—Nb distances ranging from 2.72 to 2.94 Å, comparable in average to those found in the metal (2.86 Å). In contrast to the $(Nb_6X_{12})^{q+}$ clusters, there are eight bridging halogen atoms, one above each face of the distorted octahedron (Figure 36b). The $(Nb_6I_8)^{3+}$ clusters are joined together by sharing centrifugal iodine atoms, forming $[(Nb_6I_8)I_{6/2}]$.

Nineteen valence electrons are available for the Nb_6 framework. The magnetic susceptibility of Nb_6I_{11}, studied over the 5–863 K temperature range, suggests the presence of one and three unpaired electrons per cluster at low and high temperatures, respectively.

Heating Nb_6I_{11} with H_2 at 300 °C under normal pressure yielded the remarkable hydride $[Nb_6HI_{11}]$. Neutron diffraction investigations on $[Nb_6HI_{11}]$ and $[Nb_6DI_{11}]$ permitted the location of the hydrogen atom at the center of the cluster. The compound is diamagnetic below 200 K, but approaches the magnetic susceptibility of Nb_6I_{11} between 400 and 800 K. A vibration was found at 1120 cm^{-1} for the hydride in the cluster.

A more reduced, moderately air stable cluster, $[CsNb_6I_{11}]$, containing the $(Nb_6I_8)^{2+}$ unit, was obtained by reaction of Nb_6I_{11} or of its precursor Nb_3I_8 with CsI in the presence of the metal (equations 73 and 74).[691] It has D_{3d} symmetry and Nb—Nb distances of 2.835 Å, comparable to those in Nb_6I_{11}. The distortions of the $(Nb_6I_8)^{q+}$ ($q = 2, 3$) octahedra were attributed to different modes of packing and to strains at the bridging iodine atoms. Hydrogenation of $[CsNb_6I_{11}]$ at 400 °C (1 atm) gave the isostructural hydride $[CsNb_6HI_{11}]$. No hydrogenation was observed in comparable conditions for the $(M_6X_{12})^{q+}$ clusters.

$$10Nb_6I_{11} + 6Nb + 11CsI \longrightarrow 11CsNb_6I_{11} \quad (73)$$

$$5Nb_3I_8 + 9Nb + 4CsI \longrightarrow 4CsNb_6I_{11} \quad (74)$$

34.6 OXIDATION STATE +II

Molecular compounds in which niobium or tantalum has a d^3 configuration are still very rare, and are mainly limited to adducts of monomeric dihalides with phosphorus donors $[MCl_2(dmpe)_2]$ and $[MCl_2(PMe_3)_4]$. Niobium aryloxo analogs have recently been described.[731a]

34.6.1 Dihalide Adducts

34.6.1.1 Synthesis and structure

The first member of this series, $[TaCl_2(dmpe)_2]$,[596] was reported in 1977; all the other compounds have been reported, since 1983, by Sattelberger.[692,588] $TaCl_5$ is reduced smoothly

by sodium amalgam in ether in the presence of PMe_3 to give the brown, air sensitive $[TaCl_2(PMe_3)_4]$ (**49**) in a typical yield of 60% (equation 75). Excess phosphine is necessary to counter the tendency towards dimerization of the intermediate *mer*-$[TaCl_3(PMe_3)_3]$. Once (**31**) is formed, it is no longer reduced. The reduction of $NbCl_5$ $[NbCl_4(PMe_3)_2]$ in similar conditions gave poor, but reproducible, yields of $[NbCl_2(PMe_3)_4]$, the Nb^{III} dimer $[Nb_2Cl_4(PMe_3)_4(\mu\text{-}Cl)_2]$ being the major product.

$$TaCl_5 + 3Na/Hg + PMe_3\ (\text{excess}) \xrightarrow[1\,h]{Et_2O} [TaCl_2(PMe_3)_4] + 3NaCl \qquad (75)$$

(**49**)

The dmpe adducts have been obtained in high yields as brown sublimable thermally stable solids, soluble in hexane and other non-polar solvents (equation 76). Reduction of $TaCl_5$ by one equivalent of sodium amalgam in the presence of dmpe in THF and benzene solvent gave $[TaCl_4(dmpe)_2]$, together with $[TaCl_2(dmpe)_2]$ when the THF:C_6H_6 ratio was higher than 15%.[596] The Ta^{II} and Nb^{II} dmpe complexes were also obtained quantitatively from $[MCl_2(PMe_3)_4]$; there was no evidence for dinuclear products. $[TaBr_2(dmpe)_2]$ was identified by mass spectrometry as the major product of the reaction between $[TaCl_4(dmpe)_2]$ and an excess of LiMe containing LiBr.

$$[MCl_4(dmpe)_2] + 2Na/Hg \xrightarrow{THF} [MCl_2(dmpe)_2] + 2NaCl \qquad (76)$$

(**22**) (**50**)

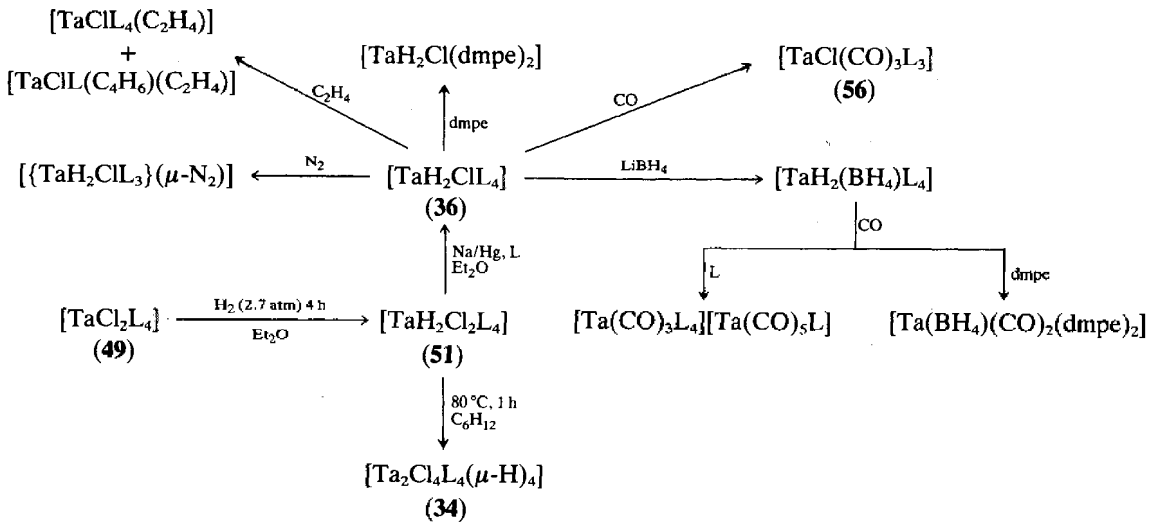
The products are paramagnetic ($\mu = 1.45$ BM, for instance, for **49**). Solutions of (**49**) in toluene are ESR silent at room temperature, and ^1H NMR data suggest a *trans* octahedral geometry. This was confirmed by X-ray crystallography (D_{2d} symmetry; Ta—Cl: 2.464(3) Å, Ta—P: 2.543(2) Å).[692]

Poorly characterized hexamethylbenzene adducts $[Nb_2Cl_4(C_6Me_6)_2]$ and $[TaBr_2(C_6Me_6)]_n$ formed in 9% and 51% yields, respectively, on application of the reducing Friedel–Crafts procedure to the pentahalides.[654] Short-lived M^{II} species have also been generated by electrochemical reduction of $[Nb_2Cl_6(PhPMe_2)_4]$[604] or electrochemical oxidation of seven-coordinated M^I complexes of types $[MX(CO)_2(dmpe)_2]$ (M = Ta, X = Cl, Br, I, Me, H; M = Nb, X = Cl) or $[TaCl(\eta^4\text{-}C_4H_8)(dmpe)_2]$.[693]

34.6.1.2 Reactivity of the dihalo adducts

The paramagnetic 15-electron M^{II} species react readily with H_2 or D_2 (equations 77 and 78) to give paramagnetic, thermally stable M^{IV} 17-electron hydrides, except for $[NbCl_2(PMe_3)_4]$.[588,692] These inorganic radicals are the first isolated M^{IV} monomeric hydrides, as $[TaH_4(dmpe)_2]$ and $[NbH_2Cp_2]$ were characterized only by low temperature ESR.[575] Ether solutions of $[NbCl_2(PMe_3)_4]$ react with H_2, but $[Nb_2Cl_4(PMe_3)_4(\mu\text{-}H)_4]$ was the only product isolated, even in the presence of excess ligand, and may arise from the rapid decomposition of transient $[NbH_2Cl_2(PMe_3)_4]$. Preliminary results show the potential of (**51**) as a starting material for preparing tantalum compounds in low oxidation states (Scheme 9), especially $[TaHCl_2(PMe_3)_4]$.

$$[MCl_2(dmpe)_2] + X_2 \xrightarrow[2.7\ \text{atm},\ 25\,^\circ C,\ 2\,h]{\text{hexane}} [MX_2Cl_2(dmpe)_2] \qquad (77)$$



(**50**) 90%

$$[TaCl_2(PMe_3)_4] + X_2 \xrightarrow[2.7\ \text{atm},\ 25\,^\circ C,\ 4\,h]{OEt_2} [TaX_2Cl_2(PMe_3)_4] \qquad (78)$$

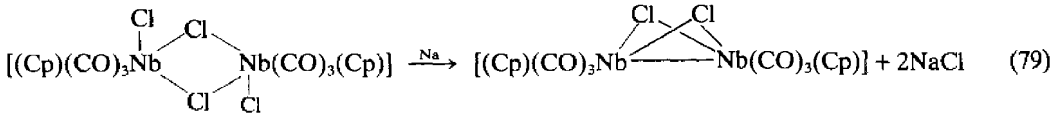
(**49**) (**51**) 75%

$X_2 = H_2, D_2$; X = H

Strong terminal M—H stretching modes are found in these adducts. The magnetic moments are indicative of d^1 complexes with orbitally non-degenerate ground states. ESR spectra are observed at room temperature ($[NbH_2Cl_2(dmpe)_2]$: $\langle g \rangle = 1.96$, $\langle A \rangle_{Nb} = 109$ G, $\langle a \rangle_P = 25.5$ G, $\langle a \rangle_H = 11.1$ G).

Scheme 9 (L = PMe_3)

The tantalum(IV) hydrides $[TaH_2Cl_2(PMe_3)_4]$ (**51**) and $[TaH_2Cl_2(dmpe)_2]$ (**50**) were characterized by low temperature X-ray crystallography.[588,692] Complex (**51**) adopts a distorted dodecahedral geometry in the solid state, while (**50**) is better described as a distorted square antiprismatic complex. The hydrogen atoms have been located.



Reductive carbonylation of $[NbCl_2(PMe_3)_4]$ or reduction of $[TaCl_2(dmpe)_2]$ (**50**) by vitride offered $[NbCl(CO)_3(PMe_3)_3]$ and a Ta^I aluminohydride adduct, respectively (Section 34.7).

No divalent product derived from solvolysis of the dihalide adducts is yet known. The reactions of (**50**) with Cp^- and PPh_2^- show that replacement of chloride by ligands having stronger fields leads to species resembling organic radicals in reactivity, which rapidly disproportionate or abstract hydrogen atoms from the solvent. The Ta^{III} derivatives $[Ta(dmpe)(Cp)_2]Cl$, $[Ta(dmpe)_2Cl(Cp)]Cl$ and $[TaH(PPh_2)_2(dmpe)_2]$ (Section 34.4.4) were obtained. No evidence for the $[Ta(PPh_2)_2(dmpe)_2]$ intermediate was found by ESR.

34.6.2 Miscellaneous

Air stable materials of formula MPc (Pc = phthalocyanine) have been obtained from MCl_5, phthalonitrile and quinoline at 220 °C.[694] Nb^{II} alanates $[LiNb_2(AlH_4)_5]$ and $[LiNb(AlH_4)_3]$ were obtained from the low temperature reaction of $NbCl_5$ with excess $LiAlH_4$.[642]

Reduction of (**44**) yielded a singly bonded Nb—Nb dimer (equation 79).[568]

(44) (79)

34.7 OXIDATION STATE +I

The number of authenticated niobium and tantalum coordination compounds in oxidation state +I is very limited. They were generally obtained through reduction of $[MCl_4(dmpe)_2]$, $[TaCl_2(dmpe)_2]$ or $Nb(OC_6H_3Me_2\text{-}3,5)_2(dmpe)_2$.[731a]

34.7.1 Phosphine Adducts

Treatment of $[TaCl_2(dmpe)_2]$ with two equivalents of vitride offered $[TaCl(CO)_2(dmpe)_2]$ (**53**) under CO, while a coordinatively unsaturated complex, $[Ta\{H_2Al(OC_2H_4OMe)_2\}(dmpe)_2]$

(**54**), was obtained under an argon or ethylene atmosphere. It is the only structurally characterized non-carbonyl M^I compound.[695]

Its molecular structure (Figure 37) consists of a centrosymmetric dimer with a bridging $H_2Al(OR)(\mu\text{-}OR)_2Al(OR)H_2$ entity. The Ta atoms are approximately square pyramidal, with the four phosphorus atoms forming the basal plane (Ta lies 0.64 Å out of it). The relatively short Ta—Al distances are comparable to those found in other transition metal aluminum complexes (Ta—Al: 2.79–3.13 Å). The hydrogen atoms have not been located, but were evidenced by chemical and spectroscopic techniques (IR: 1605, 1540 cm^{-1}; δ^1H NMR: 16.30 p.p.m.). The Ta—$(\mu\text{-}H_2)$Al unit is relatively stable, and (**54**) is inert to carbon monoxide or trimethylamine. It is a poor catalyst in the isomerization of 1-pentene. Formation of complexes analogous to (**54**) may explain the low yields often obtained from alkoxoaluminohydrides and metal halides.

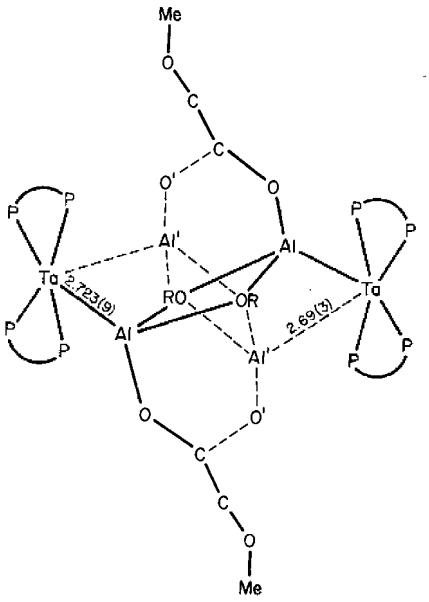


Figure 37 Molecular structure of $[Ta\{H_2Al(OC_2H_4OMe)_2\}(dmpe)_2]$ (**54**) (the dotted lines indicate the less abundant (20%) structural form resulting from a different orientation of the Al_2O_2 bridge) (reproduced from ref. 695 with permission)

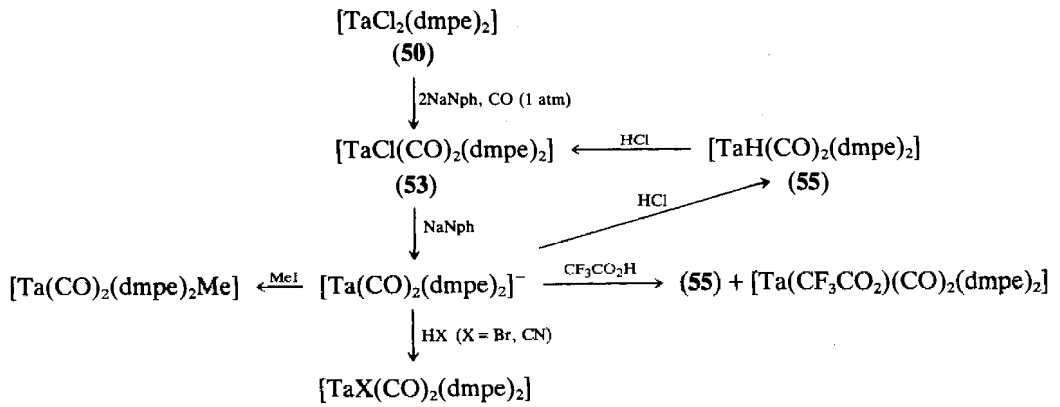

$[\{NbCl(dmpe)_2\}(\mu\text{-}N_2)]$ was formed through reduction of $[NbCl_4(dmpe)_2]$ (equation 28). Electrochemical reduction of $[Nb_2Cl_6(PhPMe_2)_4]$ yielded a dimeric Nb^I derivative. Compounds of empirical formula $[Ta(py)](ClO_4)$ and $[Ta(Et_2NH)](ClO_4)$, generated by anodic dissolution, were also reported.[696]

34.7.2 Carbonyl Derivatives

34.7.2.1 Non-cyclopentadienyl carbonyls

The monomeric carbonyl complexes of d^4 M^I isolated so far are mainly the seven-coordinated $[MX(CO)_2(dmpe)_2]$ compounds (M = Nb, X = Cl, Br, N_3;[697] M = Ta, X = H, Cl, Br, CN, Me, Et, Pr^i); (**53**) has been obtained by reduction of $[TaCl_2(dmpe)_2]$ with one equivalent of sodium naphthalenide under CO; the other tantalum derivatives were generally prepared by oxidative additions to $[Ta(CO)_2(dmpe)_2]^-$ formed *in situ* by reduction of (**53**; Scheme 10). The niobium analogs were formed by reductive carbonylation of $[NbCl_4(dmpe)_2]$.[698]

The hydride (**55**), also obtained through carbonylation of $[TaH_5(dmpe)_2]$, has a distorted capped octahedral structure (A) established by X-ray diffraction (Figure 38).[699] Spectroscopic data show that bulkier ligands (X ≠ H) all favor a capped trigonal prismatic geometry (B). Stable seven-coordinated monomeric carbonyls $[MCl(CO)_3(PMe_3)_3]$ (**56**) could also be synthesized.[700] The smooth reaction of (**36**) with CO offered $[TaCl(CO)_3(PMe_3)_3]$ (equation 80). The niobium analogue of (**36**) is still unknown and $[NbCl(CO)_3(PMe_3)_3]$ was obtained by

Scheme 10 (all reactions in THF, Nph = $C_{10}H_8$)

reductive carbonylation of $[NbCl_2(PMe_3)_4]$ (equation 81). Attempts to prepare (**56**) directly from $NbCl_5/PMe_3$ mixtures by reductive carbonylation have been unsuccessful. These new carbonyls (sharp CO stretching modes at 1962, 1862 and 1845 cm^{-1} for M = Ta) are diamagnetic, 18-electron monomers. They are stereochemically rigid in solution, as are also the $[MX(CO)_2(dmpe)_2]$ adducts. Complex (**56**) (M = Ta) has an overall C_1 symmetry and is best described as a capped trigonal prism with the chlorine atom in the apical position, three phosphines and one carbonyl ligand constituting the capped quadrilateral face.

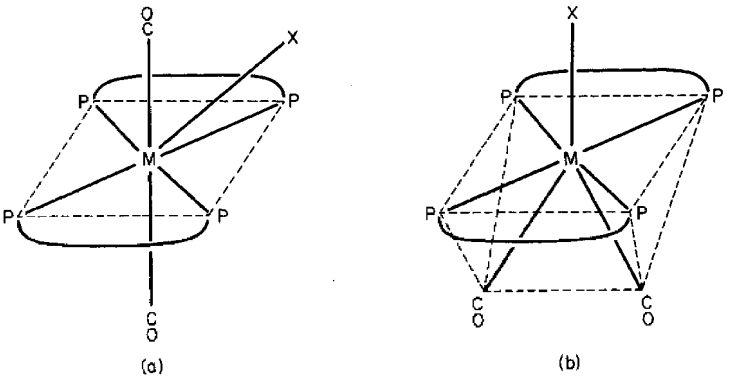

Figure 38 Coordination polyhedron found for the heptacoordinated species of type $[MX(CO)_2(dmpe)_2]$: X = H (structure a); X ≠ H (structure b)

$$[TaH_2Cl(PMe_3)_4] + 3CO \xrightarrow[2.7\ atm,\ 25\ °C]{Et_2O} [TaCl(CO)_3(PMe_3)_3] + PMe_3 + H_2 \quad (80)$$

(**36**) (**56**) 80%

$$[NbCl_2(PMe_3)_4] + 3CO + Na/Hg \xrightarrow[2.7\ atm,\ 25\ °C]{THF} [NbCl(CO)_3(PMe_3)_3] + PMe_3 + NaCl \quad (81)$$

(**56**) 40%

The reaction of $[TaH_2(BH_4)(PMe_3)_4]$ in the presence of CO and PMe_3 led quantitatively to a salt $[Ta(CO)_3(PMe_3)_4][Ta(CO)_5(PMe_3)]$. The cation has a capped octahedral geometry, one PMe_3 capping a trigonal $Ta(CO)_3$ face.[698]

Dinuclear carbonyl anions $[M_2(CO)_8X_3]^-$ were obtained through a two-electron transfer to protons by treatment of $[M(CO)_6]^-$ with HX (X = Cl, OAc, OMe) (equation 82).[526] The anion has C_{2v} symmetry. The niobium atoms are heptacoordinated with four terminal carbonyl groups each and three bridging chlorides located at the vertices of an approximately equatorial triangle perpendicular to the metal–metal axis (non-bonded Nb - - - Nb distance: 3.63 Å). The carbonyl stretching vibrations are in agreement with the local C_{4v} symmetry of the $M(CO)_4$ moiety.

$$2[M(CO)_6]^- + 4HCl \xrightarrow{To} [M_2Cl_3(CO)_8]^- + 2H_2 + 2Cl^- + 4CO \quad (82)$$

The $[M_2(CO)_8Cl_3]^-$ anions are the first halocarbonyl complexes (without other ligands in the coordination sphere) of group VA metals to be reported. They probably originate from the unstable $HM(CO)_6$ carbonyls.

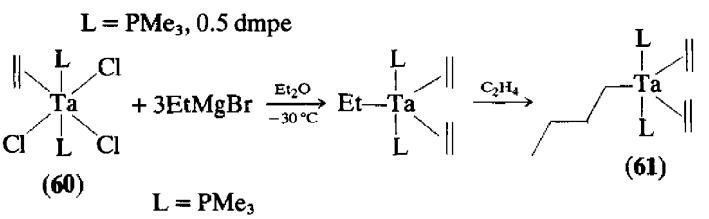
34.7.2.2 Cyclopentadienyl carbonyls

The recent development of the synthesis of $[Nb(CO)_4(Cp)]$ by reductive carbonylation of $[NbCl_4(Cp)]$ (**57**) (i) by Zn in THF under CO (200 atm)[630] with 27% yield; or (ii) by Na sand, in the presence of a Cu/Al alloy as a halogen acceptor, in benzene under CO (135 °C, 330 atm, 90% yield)[701] has spawned a renaissance in its chemistry. Extension of the latter procedure to $[TaCl_4(Cp)]$ gave $[Ta(CO)_4(Cp)]$ in 7% yield, the main products being chlorocarbonyl derivatives, isolated as η^4-oxabutadiene Ta^{IV} compounds (equation 83).

$$[TaCl_4(Cp)] \xrightarrow[CO]{Na} [TaCl_2(CO)_y(Cp)] \xrightarrow{Me_2C{=}CHCOMe} (Cp)Cl_2Ta\text{—}\langle\!\rangle\!\!=\!\!\rangle O \qquad (83)$$

Photolysis of (**57**) in the presence of phosphines yielded $[Nb(CO)_2(LL)(Cp)]$ with LL = $2PEt_3$, $Ph_2P(CH_2)_nPPh_2$ ($n = 1$–5), $Ph_2PCH{=}CHPPh_2$, $Ph_2AsCH_2CH_2PPh_2$ (arphos), and $C_6H_4(AsPh_2)_2PPh_2$.[702] The air sensitive tetrahaptocycloheptatriene and cyclooctatetraene complexes $[(Cp)Nb(CO)_2(\eta^4\text{-}C_7H_8)]$ and $[(Cp)Nb(CO)_2(\eta^4\text{-}C_8H_8)]$ have also been obtained. The C_8H_8 ring is fluxional.

Photolysis of (**57**) in the absence of additional ligands provided an unusual cluster, $[Nb_3(CO)_7(Cp)_3]$, the sole carbonyl cluster of niobium reported to date (equation 84).[649] Its quantitative declusterification to the parent carbonyl is also uncommon. X-Ray diffraction techniques revealed that one of the CO ligands acts as an $\eta^2(\mu_3\text{-}C,\mu_2\text{-}O)$ bridge symmetrically spanning a nearly equilateral triangle, and was proposed to act as a six-electron donor towards the three metal atoms. Its length (1.303(14) Å) as compared to that of the terminal carbonyls (1.08–1.17 Å) is also reflected by a long-wave shift of its ν(CO) absorption in the IR (1330 cm^{-1}). This $\eta^2\text{-}(\mu_3\text{-}C,\mu_2\text{-}O)$ ligand is mobile; a migratory process as well as its conversion from a six-electron to a four- or two-electron donor bridging Nb=Nb double bonds were observed.[703]



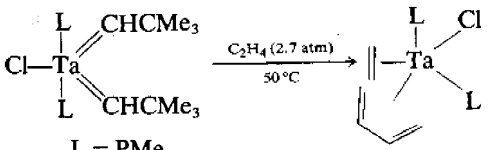
$$\underset{(\mathbf{57})}{[Nb(CO)_4(Cp)]} \underset{CO\ (20\ atm),\ THF}{\overset{h\nu,\ hexane\ (-5CO)}{\rightleftharpoons}} \underset{(\mathbf{47})}{[Nb_3(CO)_7(Cp)_3]} \qquad (84)$$

Photolysis of (**57**) in the presence of H_2S or MeSH produced $[\{Nb(CO)_2(Cp)\}_2(\mu\text{-}S)_2]$ (**58**), $[\{Nb(CO)_2(Cp)\}_2(\mu\text{-}S)_3]$ and $[\{Nb(CO)_2(Cp)\}_2(\mu\text{-}SMe_2)_2]$ (**59**). Complexes (**58**) and (**59**) are isostructural with comparable Nb—Nb bond lengths (3.143(1) and 3.164(9) Å) and NbSNb angles (≈75°), but the introduction of a third sulfur atom leads to the opening of the bridge angle (up to 85°) and loss of the metal–metal bonding (3.555(1) Å).[704] Complex (**57**) afforded $[Nb(CO)_3I_2(Cp)]$ by oxidative addition of iodine. It may therefore provide a useful entry to Nb^{III} chemistry.[630] The reaction between (**57**) and $[\{Cr(SBu^t)(Cp)\}_2S]$ provided the tetranuclear heterometallic cluster $[NbCr_3(\mu\text{-}S)_4(Cp)_4]$.[705].

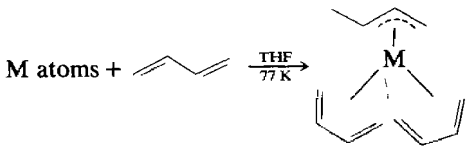
34.7.3 Alkene and Diene Adducts

Ta^I adducts with ethylene have been obtained as highly air sensitive solids by reduction of the corresponding Ta^{III} compounds under argon (equation 85),[292] or by reductive elimination of H_2 from $[TaH_2ClL_4]$ (Scheme 9). A similar procedure, but under dinitrogen, gave Ta^V nitrenes (Section 34.2.3.6). The same Ta^{III} precursor (**60**) provided σ alkyl derivatives (equation 86). Complex (**63**) catalyzes the selective dimerization of ethylene to 1-butene.

$$trans,mer\text{-}[TaCl_3L_2(C_2H_4)] + 2Na/Hg \xrightarrow[THF]{L} [TaClL_4(C_2H_4)] + 2NaCl \qquad (85)$$



(86)



Butadiene d^4 complexes were obtained (i) from $[NbCl_4(dmpe)_2]$ and magnesium butadiene (equation 87);[706] (ii) by dimerization of ethylene using alkylidenes (equation 88);[707] or (iii) by metal vapor techniques (equation 89), which yielded sublimable methylallyl derivatives.[708] Compound (**62**) could not be prepared by Na/Hg reduction of (**22**) in the presence of butadiene. Compound (**63**) is also accessible from $[TaH_2ClL_4]$ (Scheme 9).

$$[NbCl_4(dmpe)_2] + [Mg(THF)_2(C_4H_6)] \xrightarrow{THF} [NbCl(dmpe)_2(C_4H_6)] + MgCl_2 \quad (87)$$

(**22**) (**62**) 24%

$L = PMe_3$ (**63**) (88)

(89)

Treatment of $[TaCl_4(dmpe)_2]$ with sodium naphthalenide afforded $[TaCl(dmpe)_2(\eta^4\text{-}C_{10}H_8)]$ (**64**), which was reduced by further addition of sodium naphthalenide to unisolated $Na[Ta(dmpe)_2(\eta^4\text{-}C_{10}H_8)]$. Protonation or methylation of this anion afforded the Ta^I adduct $[TaX(dmpe)_2(\eta^4\text{-}C_{10}H_8)]$ (X = H, Me). Related procedures gave the analogous 1,3-cyclohexadiene adduct $[TaCl(dmpe)_2(\eta^4\text{-}C_6H_8)]$ in poor yields.[709]

The molecular structure of (**64**) may be considered as a pentagonal bipyramid with the naphthalene, the chlorine and two phosphorus atoms in the pentagonal plane. It is structurally related to (**53**) by a 45° rotation of the naphthalene unit about the Ta—Cl vector. The temperature dependent ^1H and ^{31}P NMR spectra indicate that such a process is operative in solution. The structural parameters suggest that the π-accepting interaction is substantial; this is consistent with the inertness of the Ta–naphthalene unit toward substitution.

An allyltetrakistrifluorophosphine Ta^I compound, unstable at room temperature, has also been obtained (equation 90). Attempts to substitute all the allyl groups under higher pressure led to metallic tantalum and propane.[710]

$$2[Ta(\eta^3\text{-allyl})_4] + 10PF_3 \xrightarrow{200\ atm} 2[Ta(PF_3)_5(\eta^3\text{-allyl})] + 3C_6H_{10} \quad (90)$$

34.8 OXIDATION STATE 0

Examples of derivatives of zerovalent niobium and tantalum are very rare. Cocondensation of vapors of the metals, generated by an electron gun furnace at 3000 °C, operating at a positive potential with dmpe, gave excellent yields (> 60%) of stable crystalline $[M(dmpe)_3]$, which displays a distorted octahedral geometry.[711] Attempts to obtain the corresponding niobium compound by reduction of $NbCl_5$ with sodium naphthalenide at room temperature in the presence of an excess of dmpe failed and led to metal deposition.[712] By contrast, reduction of MX_5 by sodium amalgam in the presence of bipy or *o*-phen (LL) afforded the paramagnetic $M(LL)_3$ adducts in *ca.* 80% yield.[713]

Bis(arene) $[M(\eta^6\text{-}C_6H_3R_3)_2]$ niobium (R = H_3, H_2Me or 1,3,5-Me_3), and less stable tantalum derivatives (R = H_3) were prepared in a similar way.[714] They are extremely sensitive to oxygen, but relatively stable to water. The photoelectron spectra of the volatile bis(η^6-arene) niobium display low values for the first ionization potentials (5.18–5.57 eV), indicating that the compounds are electron rich. The IR spectra of $[Nb(C_6H_3R_3)_2]$ (R = H, Me) in an argon matrix at 80 K are in agreement with a symmetrical sandwich structure.

The ESR spectra of all zerovalent derivatives are consistent with the paramagnetism expected for 17-electron d^5 compounds with one unpaired electron ($[Nb(\eta^6\text{-}C_6H_5Me)_2]$: $\langle g \rangle = 1.992$, $\langle A \rangle = 45.9$ G). Cocondensation of Nb atoms with N_2 in an Ar matrix gave

unusually numerous absorptions, some of which were assigned to $Nb(N_2)$ and to an $Nb(N_2)_4$ complex of D_{4h} symmetry. $[Nb(CO)_x(N_2)_y]$ species were similarly produced.[715]

34.9 OXIDATION STATES LOWER THAN 0

Compounds containing niobium or tantalum in negative formal oxidation states −I and −III are mainly metal carbonyl anions. Although these are organometallic derivatives, the report of efficient procedures for the synthesis of $[M(CO)_6]^-$ since the review of Labinger[8] merits mention, as it can be anticipated that these highly reduced and reactive species will be important precursors of a large variety of new coordination compounds and metal clusters.

34.9.1 Oxidation State −I

34.9.1.1 $[M(CO)_6]^-$

Until recently, the synthesis of the yellow $[M(CO)_6]^-$ required the reduction of Nb_2Cl_{10} by Na or Na–K alloy in diglyme as solvent under a high pressure of CO (>360 atm), and only poor and non-reproducible yields (<14%) of the anions were obtained.[716] Several mild and efficient carbonylation procedures have now become available. The reductive carbonylation of MCl_5 using the Mg/Zn couple as reductant and pyridine as reactive solvent occurs at room temperature under one atmosphere of CO (yields ≈ 48% and 35% for M = Nb and Ta respectively). The reduction is largely due to magnesium.[717]

Treatment of MX_5 with alkali metal naphthalenide in DME at −60 °C provides thermally unstable brown intermediates, assumed to be $[M(C_{10}H_8)_2]^-$ or $[M(1\text{-}MeC_{10}H_7)_2]$, which react with CO (1 atm) to give $[M(CO)_6]^-$ in 30–54% yields.[718] Carbonylation, using sodium in the presence of cyclooctatetraene in THF under CO (1 atm, 40 °C), has also been reported, although its efficiency is low in the case of Ta (12%).[719] Cyclooctatetraene complexes are thought to form as intermediates, but the mild carbonylation conditions compared to those of $[Nb(COT)_3]^-$ (50 atm, 100 °C) suggest that a compound of different stoichiometry may be involved.[720]

The $[M(CO)_6]^-$ anions were isolated with solvated sodium or organic cations as counterions. $[Ni(phen)_3][Nb(CO)_6]_2$ has also been obtained.[721] The unsolvated $Na[Ta(CO)_6]$ is pyrophoric, and the Nb analog is light- and air-sensitive.

The crystal structures of both $(PPN)[M(CO)_6]$ derivatives have been determined.[717] The coordination polyhedron is octahedral (Nb—C: 2.098(5) Å; CNbC: 89.2(2)°). The PPN moiety is constrained to be centrosymmetric, and thus linear. These compounds correspond to the lowest oxidation state of niobium and tantalum for which structural data are available. A single $\nu(CO)$ is found in the IR (1854 and 1852 cm^{-1} for Nb and Ta respectively). Comparable spectra are observed for $Na[M(CO)_6]$ in pyridine, but in solvents of lower dielectric constants such as tetrahydrofuran, additional bands attributed to distortion of the anion by the countercation are observed. $[Nb(CO)_6]^-$ appears to be the most labile carbonyl of the group VA analogs.

34.9.1.2 Other derivatives

$[Nb(PF_3)_6]^-$ has been prepared by photolysis of $[Nb(CO)_6]^-$ under PF_3 and studied by multinuclear NMR. The ^{93}Nb chemical shifts suggest weaker Nb–PF_3 than Nb–CO interactions.[722]

A diamagnetic compound whose analysis corresponds to $Li[Nb(bipy)_3]\cdot 3.5THF$ was reported to form by reduction of $NbCl_5$ with Li_2bipy. As bipy can behave as $bipy^{\cdot-}$, and in the absence of any spectroscopic data, the metal's oxidation state may still be questioned.[723,724] $Na[Ta(dmpe)_2(CO)_2]$ was characterized by its derivatives only (Scheme 10).

34.9.2 Oxidation State −III

34.9.2.1 $[M(CO)_5]^{3-}$ and $[HM(CO)_5]^{2-}$

The pentacarbonylmetallate trianions of Nb and Ta are the first compounds to contain these elements in a formal oxidation state of −III; they appear to be the first transition metal

trianions isolated as analytically pure substances (equation 91).[725] The unsolvated $Na_3[M(CO)_5]$ are thermally unstable, but isolation was achieved as $Cs_3[M(CO)_5]$ in 40–50% yields. These salts are shock sensitive, and their reactivity was mainly explored in solution. Addition of Ph_3SnCl and NH_4Cl provided $[M(CO)_5(Ph_3Sn)]^{2-}$ and $[M(CO)_5(NH_3)]^-$, which were isolated as their Et_4N and Ph_4As salts, respectively. The amine complexes are very labile and react readily with a variety of π acceptor ligands L, such as PR_3, $P(OR)_3$ and RNC, to provide $[M(CO)_5L]^-$ in 50–80% yields. Addition of Et_4NBH_4 to $M(CO)_5^{3-}$ provided $(Et_4N)_2[HM(CO)_5]$.[525b]

$$Na[M(CO)_6] + 3Na \xrightarrow[-78\,^\circ C]{NH_3\,liq} Na_3[M(CO)_5] + 0.5Na_2C_2O_2 \qquad (91)$$

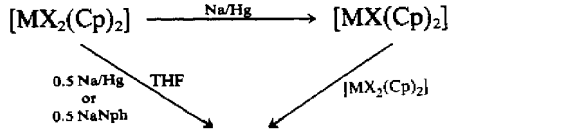
34.9.2.2 $[M(CO)_3(Cp)]^{2-}$

Treatment of $[M(CO)_4(Cp)]$ with sodium in liquid ammonia at −78 °C generates the corresponding pyrophoric $Na_2[M(CO)_3(Cp)]$ salts.[726] Exchange reactions offered the thermally very stable $Cs_2[M(CO)_3(Cp)]$ (dec. >250 °C). These dianions are the only established examples of transition metal complexes of formula $[M(CO)_x(Cp)]^{2-}$. Reactions of $[M(CO)_3(Cp)]^{2-}$ with weak Brönsted acids such as MeCN, Et_4N^+ gave $[MH(CO)_3(Cp)]^-$, for which ^{93}Nb NMR data are available.[727] The $[M(CO)_3(Cp)]^{2-}$ dianions were also characterized by their triphenylstannyl derivatives $(Et_4N)[M(CO)_3(SnPh_3)(Cp)]$.

34.10 MIXED VALENCE COMPOUNDS

The only well-established, structurally characterized mixed valence compounds are the niobium selenide derivatives $Nb_3Se_5Cl_7^{V/IV}$ and $[(MeCN)_2Br_2Nb(\mu\text{-}Se)_2(\mu\text{-}Se)NbBr_2(MeCN)_2]^{IV/III}$ (Section 34.3.4).

The niobyl phosphoniobate $[Nb^{V}ONb^{III}(PO_4)_2]\cdot 6H_2O$ has been described in aqueous solution (Section 34.4.6.1).



The reaction between $NbCl_5$ and $LiAlH_4$ in ether offered highly reactive, generally pyrophoric, lower valent niobium alanates $[Nb(AlH_4)_n]$ ($n < 5$).[642] The mean oxidation state n decreases with increasing temperatures (equation 92). In the presence of an excess of $LiAlH_4$, ionic derivatives were isolated: $[LiNb_2(AlH_4)_7]$ at −70 °C, $[LiNb_2(AlH_4)_5]$ at +25 °C and $[LiNb(AlH_4)_3]$ at +25 °C. No structural data are however available on these compounds, of formal oxidation states 3.5 or 2.5, and their re-examination might prove rewarding. Unstable mixed valence M^{II}–M^{III} compounds have also been formed by pulsed radiolysis of dinuclear M^{III} adducts.[728]

$$NbCl_5 + 5LiAlH_4 \xrightarrow{Et_2O} [Nb(AlH_4)_n] + (5-n)AlH_3 + \left(\frac{5-n}{2}\right)H_2 + 5LiCl \qquad (92)$$

Dicyclopentadienyl derivatives in a formal oxidation state of 3.5 appear to be relatively common. A purple, paramagnetic compound with one unpaired electron (1.32 BM) for two Ta atoms was isolated and formulated as a dimer (**65**; equation 93).[729] A similar reaction did not yield the niobium analog, but violet or red-brown compounds were observed as intermediates in the reduction of $[MX_2(Cp)_2]$ to $[MX(Cp)_2]$ (X = Cl, Br). They could be isolated in good yields (~60%, Scheme 11).[730]

$$TaCl_5 + NaCp + LiPPh_2 \xrightarrow{THF} \underset{\textbf{(65)}\ \ 20\%}{[Ta_2Cl_3(Cp)_4]} + P_2Ph_4 + \cdots \qquad (93)$$

Structural studies are as yet limited by the lack of stability of these M^{IV}–M^{III} compounds, especially in polar solvents. Their formation was considered a consequence of the acidic character of the $MX(Cp)_2$ entity, which achieves 18 electrons, and an alternative structure with

$[M_2X_3(Cp)_4]$ (**65**) M = Nb; X = Cl, Br; M = Ta; X = Cl

Scheme 11

only one bridging chlorine has been proposed. Reaction with $AgClO_4$ led to cationic complexes.

Note: Since the chapter was completed, relevant papers concerning the chemistry of niobium and tantalum in various oxidation states with bulky anionic oxygen donors [2,6-dialkylaryloxo[731] or silox (Bu^t_3SiO)[732]] have appeared. Reviews concerning the analysis and classification of X-ray data of niobium[733] and tantalum[734] are also now available.

35.1 INTRODUCTION TO CHROMIUM COMPLEXES 701

35.2 CHROMIUM(0) AND CHROMIUM(I) 702

35.2.1 Group IV Ligands 703
35.2.1.1 Cyanides 703
35.2.1.2 Aryl and alkyl isocyanides 704
35.2.1.3 Si-, Ge-, Sn- and Pb-containing ligands 709

35.2.2 Nitrogen Ligands 709
35.2.2.1 Complexes of bi- or tri-dentate N heterocyclic ligands 709
35.2.2.2 Nitrosyls and dinitrogen complexes 713
35.2.3 Phosphorus Ligands 713
35.2.3.1 Mixed complexes of dinitrogen and tertiary phosphines 713
35.2.3.2 Fluorophosphine complexes 714
35.2.4 Miscellaneous Chromium(0) Complexes 716

35.3 CHROMIUM(II) 716

35.3.1 General Synthetic Methods 716
35.3.1.1 Chromium(II) solutions 716
35.3.1.2 Chromium(II) salts 717
35.3.2 Group IV Ligands 718
35.3.3 Nitrogen Ligands 718
35.3.3.1 Ammines 718
35.3.3.2 Bidentate saturated amines, ethylenediamine, propylenediamine, etc. 720
35.3.3.3 Polydentate amines, diethylenetriamine, triethylenetetramine and facultative ligands 721
35.3.3.4 N heterocyclic ligands 722
35.3.3.5 Nitrosyls and hydrazine 729
35.3.3.6 Dialkylamides and disilylamides 729
35.3.3.7 Thiocyanates 729
35.3.3.8 Polypyrazolylborates and carboranes 731
35.3.3.9 Nitriles 732

35.3.4 Phosphorus and Arsenic Ligands 732
35.3.4.1 Mono- and bi-dentate P donor ligands 732
35.3.4.2 o-Phenylenebis(dimethyldiarsine) 734
35.3.4.3 Tetradentate 'tripod' ligands 734

35.3.5 Oxygen Ligands 735
35.3.5.1 Aqua complexes 735
35.3.5.2 Alcohols, alkoxides and aryloxides 737
35.3.5.3 β-Ketoenolates, tetrahydrofuran, ureas and biuret 738
35.3.5.4 Oxo anions 740
35.3.5.5 Carboxylato and other complexes containing Cr—Cr quadruple bonds 740
35.3.5.6 Aliphatic and aromatic hydroxy acids 753
35.3.5.7 Dimethyl sulfoxide, phosphine oxides and arsine oxides 753

35.3.6 Sulfur Ligands 754
35.3.6.1 Dithiocarbamates 754
35.3.6.2 Ethane-1,2-dithiol 755
35.3.6.3 Thioureas 755
35.3.7 Halogens as Ligands 755
35.3.7.1 Anhydrous halides 755
35.3.7.2 Complex fluorides 756
35.3.7.3 Complex chlorides, bromides and iodides 758

35.3.8 Hydrogen and Hydrides as Ligands 766

35.3.9 Mixed Donor Atom Ligands 766
35.3.9.1 Complexes of β-ketoamines and Schiff's bases 766

35.3.9.2 *Amino acids* 768
35.3.9.3 *Complexones* 768
35.3.9.4 *Bidentate mixed donor atom ligands* 769
35.3.10 *Multidentate Macrocyclic Ligands* 770
35.3.10.1 *Planar (closed) macrocycles; porphyrins, corrins and phthalocyanines* 770
35.3.10.2 *Other polyazamacrocycles* 770
35.3.11 *Stereochemistry of Bivalent Chromium* 772

35.4 CHROMIUM(III) 772
35.4.1 *Group IV Ligands* 773
35.4.1.1 *Cyanides* 773
35.4.1.2 *Isocyanides* 779
35.4.1.3 *Alkyls and aryls* 779
35.4.2 *Nitrogen Ligands* 779
35.4.2.1 *Ammonia* 780
35.4.2.2 *Monodentate amines* 787
35.4.2.3 *Ethylenediamine and related bidentate amines* 789
35.4.2.4 *Open-chain polyamines* 806
35.4.2.5 *N heterocyclic ligands* 815
35.4.2.6 *Nitrosyl, thionitrosyl, azo, hydrazine, hydroxylamine and related ligands* 823
35.4.2.7 *Amido ligands* 835
35.4.2.8 *N-Thiocyanato, N-cyanato, N-selenocyanato, azido and related ligands* 837
35.4.2.9 *Polypyrazolylborates* 845
35.4.2.10 *Nitriles* 846
35.4.2.11 *Oximes, biguanides, guanidines, N-coordinated ureas and amides* 849
35.4.3 *Phosphorus, Arsenic and Antimony Ligands* 852
35.4.4 *Oxygen Ligands* 856
35.4.4.1 *Aqua complexes* 856
35.4.4.2 *Polymeric hydroxy complexes* 857
35.4.4.3 *Oxides and oxide hydroxides* 859
35.4.4.4 *Other oxide systems* 859
35.4.4.5 *Peroxides* 859
35.4.4.6 *Alcohol and alkoxide complexes* 860
35.4.4.7 *β-Ketoenolates and related ligands* 861
35.4.4.8 *Catecholates, quinones, tetrahydrofuran and O-bonded urea* 865
35.4.4.9 *Non-C oxo anions* 867
35.4.4.10 *Carbon-containing oxo anions* 869
35.4.4.11 *Hydroxy acids* 873
35.4.4.12 *Sulfoxides, N-oxides and P-oxides* 874
35.4.5 *Sulfur Ligands* 876
35.4.5.1 *Thiolate, disulfido and thioether ligands* 876
35.4.5.2 *Bidentate S donor ligands: dithiocarbamates, dithiophosphates, 1,1- and 1,2-dithiolates,* etc. 883
35.4.5.3 *Thiourea* 888
35.4.6 *Selenium and Tellurium Ligands* 889
35.4.7 *Halogens as Ligands* 889
35.4.7.1 *Simple halides CrX_3* 889
35.4.7.2 *$[CrX_4]^-$ and related anions* 889

35.1 INTRODUCTION TO CHROMIUM COMPLEXES

Chromium, molybdenum and tungsten are the transition metal members of group VI of the periodic table. Chromium has the outer electronic configuration $3d^5 4s^1$ and forms compounds in oxidation states −II to +VI (Table 1). It differs in its chemistry from molybdenum and tungsten, which are alike because of their similar atomic and ionic radii. Most resemblances are in the 0 and I oxidation states, which are stabilized by π-acceptor C,N heterocyclic and P donor ligands. The extensive organometallic chemistry of Cr, Mo and W is described in the companion series 'Comprehensive Organometallic Chemistry'.[1]

Chromium(II) has extensive coordination chemistry provided the strongly reducing complexes are protected against aerial oxidation. Coordination numbers from three to seven are exhibited by chromium(II), although it is commonly six-coordinate, forming complexes which are high-spin ($t_{2g}^3 e_g^1$ configuration) or, with strong-field ligands, low-spin (t_{2g}^4 configuration). Marked Jahn–Teller distortion of the octahedron (4 + 2 coordination), arising from the uneven filling of the *d*-orbitals, has been found for the d^9 (Cr^{2+}) and high-spin d^4 (Cr^{2+}) ions, and complexes of these ions are often isomorphous. The distortion leads to weak ferromagnetism in the halide-bridged structures of $[NRH_3]_2[CrX_4]$. Examples of planar chromium(II) complexes (the limit of 4 + 2 coordination) are becoming more common, but none containing tetrahedral chromium(II) has been firmly established except the atypical complex $[Cr(NO)\{N(SiMe_3)_2\}_3]$. There are similarities to molybdenum(II) in dinuclear complexes like the carboxylates, but the ionic nature of CrX_2 is very different from the covalent clusters of MoX_2.

Complexes of chromium(III), the most stable and important oxidation state, continue to be discovered as the complexing ability of new ligands with the first transition series is investigated. There are now a few examples of coordination number greater than six. The coordination chemistry of chromium(III) far surpasses that of molybdenum(III) and tungsten(III). Octahedral chromium(III) complexes are kinetically inert and this, combined with ease of synthesis, is why so many have been isolated. Their magnetic moments are close to the spin-only value (t_{2g}^3 configuration, 3.87 BM), except in the numerous hydroxo-bridged and other polynuclear species where antiferromagnetism produces lower, temperature-variable values. Chromium(III) complexes have well-characterized electronic spectra and extensive photochemistry.

Chromium(IV) and chromium(V), previously encountered as the oxides and halides and as unstable intermediates in solution, are now represented by complexes of ligands stabilized by heavy substitution against oxidation by the metal ion, and oxo and nitrido derivatives. These remain unimportant oxidation states compared with molybdenum and tungsten.

Chromium(VI) is powerfully oxidizing and is found in comparatively few but important

Table 1 Oxidation States and Stereochemistry of Chromium[a]

Oxidation state	*Coordination number*	*Stereochemistry*	*Examples*
Cr^0, d^6	6	Octahedral	$Cr(bipy)_3$, $Cr(PF_3)_6$, $Cr(CNBu^t)_6$
Cr^I, d^5	6	Octahedral	$[Cr(CNPh)_6]^+$, $[Cr(bipy)_3]^+$
Cr^{II}, d^4	3	Distorted 'T'	$Cr(OCBu^t_3)_2{\cdot}LiCl(THF)_2$
	4	Planar	$Cr\{N(SiMe_3)_2\}_2(THF)_2$, Cr(acacen), $[NEt_4]_2[Cr(S_2C_2H_4)_2]$
		Distorted tetrahedral	$Cr(NO)\{N(SiMe_3)_2\}_3$, $CrCl_2(MeCN)_2$?
	5	Trigonal bipyramidal	$[CrBr\{N(CH_2CH_2NMe_2)_3\}]^+$, $Cr_2(S_2CNEt_2)_4$?
		Square pyramidal	$[Cr(NH_3)_4H_2O]^{2+}$
	6	High-spin (distorted octahedral)	$[Cr(en)_3]^{2+}$, $[CrCl_4]_n^{2n-}$
		Low-spin (octahedral)	$[Cr(phen)_3]^{2+}$, $[Cr(CN)_6]^{4-}$
		$(Cr{\equiv}Cr)^{4+}$ units	$[Cr_2(O_2CMe)_4(H_2O)_2]$, $[Cr_2(2\text{-}(O), 6\text{-Mepy})_4]$
	7	Tetragonal base: trigonal cap (4:3)	$[Cr(CNBu^t)_7]^{2+}$
		Pentagonal bipyramidal	$CrH_2\{P(OMe)_3\}_5$
Cr^{III}, d^3	3	Trigonal planar	$Cr(NPr_2)_3$
	4	Tetrahedral	$[CrCl_4]^-$?
	5	Trigonal bipyramidal	$CrCl_3(NMe_3)_2$
	6	Octahedral	$[Cr(NH_3)_6]^{3+}$, $Cr(acac)_3$, $[Cr(CNPh)_6]^{3+}$
	7	Pentagonal bipyramidal	$[CrC_5H_3N(CMeNNHCONH_2)_2(H_2O)_2]^{3+}$
Cr^{IV}, d^2	4	Tetrahedral	$Cr(OBu^t)_4$, CrO_4^{4-}, $CrCl_4$
	5	Square pyramidal	CrO(TPP)
	6	Octahedral	$[CrF_6]^{2-}$
	7	Pentagonal bipyramidal	$Cr(NH_3)_3(O_2)_2$
	8	Dodecahedral	$CrH_4(PMe_2CH_2CH_2PMe_2)_2$
Cr^V, d^1	4	Tetrahedral	CrO_4^{3-}
	5	Square pyramidal	$[CrOCl_4]^-$, CrN(salen), $[CrO(O_2COCMeEt)_2]^-$
		Trigonal bipyramidal	CrF_5
	6	Octahedral	$[CrOCl_5]^{2-}$
	8	Dodecahedral	$[Cr(O_2)_4]^{3-}$

[a] There are many examples of organometallic compounds of chromium in oxidation states −II to III.[1]

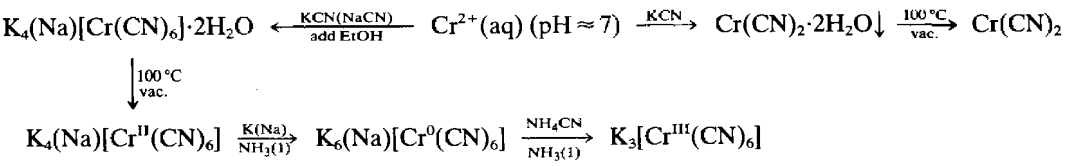
compounds. These are usually oxo or oxo halide species. Besides chromates and dichromates, tri- and tetra-chromates are known, but compounds analogous to the isopoly- and heteropoly-molybdates and -tungstates, and the molybdenum and tungsten bronzes, are not formed by chromium. There are weak similarities to sulfur(VI).

The industrial and biochemical importance of coordination compounds of chromium is described in Volume 6, and aspects of theoretical, mechanistic and solution chemistry are discussed in Volume 1 of this series.

Earlier work on the coordination and general chemistry of chromium is described in several treatises:[2–4] there are reviews for the years 1979–1983,[5,6] and a list of crystal structures to mid-1976 is available.[7] Summaries of chromium chemistry have been provided in two recent textbooks.[8,9]

35.2 CHROMIUM(0) AND CHROMIUM(I)

The extensive organometallic chemistry of chromium, *i.e.* the hexacarbonyl and its derivatives, organochromium compounds without carbonyl ligands, cyanide and isocyanide complexes, alkene, allyl, diene, cyclopentadiene and arene derivatives, and complexes of σ-donor carbon ligands, has been recorded in Chapters 26.1 and 26.2 of Volume 3 of 'Comprehensive Organometallic Chemistry'.[1] In the present section, chromium complexes



mostly in oxidation states 0 and I are considered, although where the ligands are such that redox reactions lead to easy interconversion between oxidation states, complexes of other oxidation states have been included.

35.2.1 Group IV Ligands

35.2.1.1 Cyanides

Homoleptic cyanochromium complexes are known in oxidation states 0 to III, examples being $K_6[Cr(CN)_6]$, $K_3[Cr(CN)_4]$, $K_4[Cr(CN)_6]$ and $K_3[Cr(CN)_6]$. In addition, there are the cyanonitrosyls $K_4[Cr(CN)_5NO]$ and $K_3[Cr(CN)_5NO]$, the chromium(IV) peroxo derivative $K_3[Cr(O_2)_2(CN)_3]$ and mixed cyanoamine derivatives such as *cis*-$[Cr(CN)_2(en)_2]I$. All except the last, for which see Section 35.4.2.3, have been discussed in the companion series (Volume 3, Section 26.1.3.2).[1] More recent research on chromium(III) cyano and cyanonitrosyl complexes is covered in Sections 35.4.1.1 and 35.4.2.6 and the present section is restricted to some recent work on chromium(II) and chromium(0) complexes.

Attempts to isolate pure cyanochromium(II) complexes from the deep red solutions containing $[Cr(CN)_6]^{4-}$ ions formed when chromium(II) acetate is added to aqueous potassium cyanide in excess, and in other ways, have not been very successful. Now, through careful control of concentration and of pH, the known but poorly characterized green crystalline hexacyanochromates(II) $M_4[Cr(CN)_6]\cdot 2H_2O$ (where M = Na or K), the new dark green simple cyanide $Cr(CN)_2\cdot 2H_2O$, and their anhydrous forms have been prepared pure (Scheme 1 and Table 2).[10]

The low-spin t_{2g}^4 configuration of these complexes gives rise to a $^3T_{1g}$ ground term. Spin-allowed transitions to the ^3E_g, $^3T_{2g}$, $^3A_{1g}$ and $^3A_{2g}$ terms are possible, but no assignments have been made because of the breadth of the reflectance bands. The CN stretching frequencies of $Cr(CN)_2$ and $Cr(CN)_2\cdot 2H_2O$ suggest that the former contains bridging and the latter bridging and terminal cyano groups. The decahydrate $Na_4[Cr(CN)_6]\cdot 10H_2O$ has been prepared by reduction of $Na_3[Cr(CN)_6]$ with amalgamated aluminum sheet and its crystal

structure determined.[11] Apparently, the decahydrate crystallizes but the dihydrate is the stable phase.

In liquid ammonia, hexacyanochromates(II) can be reduced to the diamagnetic chromium(0) complexes $M_6[Cr(CN)_6]$ by the appropriate alkali metal. The K salt was earlier obtained by reduction of $K_3[Cr(CN)_6]$. Greater metal–ligand π bonding is presumably responsible for the lower CN stretching frequencies of $M_6[Cr(CN)_6]$. The potassium salt is oxidized to $K_3[Cr(CN)_6]$ by ammonium cyanide in liquid ammonia (equation 1).[12]

$$2K_6[Cr(CN)_6] + 6NH_4CN \longrightarrow 2K_3[Cr(CN)_6] + 6KCN + 6NH_3 + 3H_2 \quad (1)$$

35.2.1.2 Aryl and alkyl isocyanides

Only more recent investigations of organic isocyanide complexes of chromium are in this section, because general synthetic methods for metal isocyanide complexes, including mixed carbonyl isocyanides, and the nature of the metal–isocyanide bond are discussed in Sections 27.1.3.2.2 and 26.1.2.5.2.ii of Volume 3 of 'Comprehensive Organometallic Chemistry'.[1] Organic isocyanides are π-bonding ligands like CO but are stronger σ donors and weaker π acceptors. Chromium(0) complexes such as $Cr(CNPh)_6$ are formally isoelectronic with $Cr(CO)_6$, but differ markedly in being sequentially oxidizable to Cr^{I}, Cr^{II} and Cr^{III} derivatives. These oxidation states were first observed in electrochemical studies (equations 2 to 4)[13,14] but solids of all four oxidation states are known, so, unlike carbon monoxide, isocyanides, owing to their greater σ-donor ability, form homoleptic complexes in normal as well as low oxidation states (Table 3 and Schemes 2–4). The earlier assignment of the $E_{1/2}$ value of equation (2) (*ca.* −0.3 V) to the half reaction $Cr(CNPh)_6^0/Cr(CNPh)_6^-$ has been revised[15] since attempts to reduce $Cr(CNPh)_6$ were unsuccessful, and $Cr(CNR)_6^-$ would be one electron in excess of the 18-electron configuration.

$$Cr(CNAr)_6 \rightleftharpoons Cr(CNAr)_6^+ + e^-, E_{1/2} \sim -0.3\ V\ (versus\ SCE) \quad (2)$$

$$Cr(CNAr)_6^+ \rightleftharpoons Cr(CNAr)_6^{2+} + e^-, E_{1/2} \sim 0.2\ V \quad (3)$$

$$Cr(CNAr)_6^{2+} \rightleftharpoons Cr(CNAr)_6^{3+} + e^-, E_{1/2} \sim 1\ V \quad (4)$$

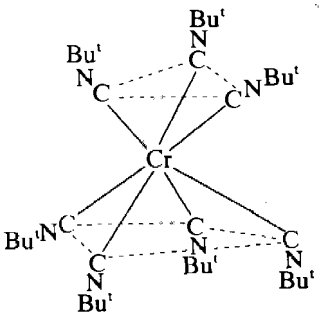
Scheme 4

Some recent advances are the isolation of aryl isocyanide complexes of chromium(III) $[Cr(CNAr)_6]X_3$, and six- and seven-coordinate alkyl isocyanide complexes of chromium(II) $[Cr(CNR)_{6,7}]X_2$. All but the chromium(0) and the seven-coordinate chromium(II) complexes have less than 18 electrons in the valency shell.

(*i*) *Syntheses: oxidation state 0*

Hexakis(aryl isocyanide)chromium(0) complexes have been known since 1952 when they were described by Malatesta and co-workers.[16] Alkyl isocyanide chromium(0) complexes were thought to be less stable than their aryl analogues, but this appears to be due mainly to a lack of suitable preparative methods because the complexes $Cr(CNR)_6$ (R = Bu, Bu^t or C_6H_{11}) have now been obtained by the action of RNC in excess on $Cr(C_{10}H_8)_2$, $Cr_2(C_8H_8)_3$,[17] the chromium(IV) compound $CrPr^i_4$[18] or, more conveniently, anhydrous chromium(II) acetate in THF in the presence of Na/Hg.[19] The cleavage of the quadruple metal–metal bond in $[Cr_2(O_2CMe)_4]$ or the dihydrate by an excess of aryl isocyanide has long been standard[13] for the synthesis of the aryl derivatives $Cr(CNAr)_6$. This reaction (equation 5) involves disproportionation, although no Cr^{3+} complexes have been isolated from the reaction mixture. It may be that the use of Na/Hg as for the alkyl isocyanide complexes would improve the overall yield by reducing the Cr^{3+} species. The same reducing agent produces *trans*-$[Cr(CNBu^t)_2(dmpe)_2]$ from $[CrCl_2(dmpe)_2]$ (Scheme 8). Many zerovalent aryl isocyanide complexes are now known (Table 3).

$$3[Cr^{II}_2(O_2CMe)_4(H_2O)_2] + 12CNAr \longrightarrow 2Cr^0(CNAr)_6 + 4Cr^{3+} + 12MeCO_2^- + 6H_2O \qquad (5)$$



(*ii*) *Syntheses: oxidation states I, II and III*

Air oxidation of chromium(0) aryl isocyanides will produce chromium(I) cations $[Cr(CNAr)_6]^+$, but oxidation by stoichiometric amounts of $AgPF_6$ to give first the chromium(I) complexes $[Cr(CNAr)_6]PF_6$ and then the chromium(II) complexes $[Cr(CNAr)_6](PF_6)_2$ (Scheme 2 and Table 3) is far more efficient.[13,20] Chromium(I) alkyl isocyanide complexes have not been reported except for a comment[17] that $Cr(CNBu^t)_6$ oxidizes in air, presumably to $[Cr(CNBu^t)_6]^+$. In addition to the series $[Cr(CNAr)_6]PF_6$, $[Cr(CNPh)_6]BPh_4$ has been isolated[20] so that the species thought to be $[Cr(CNPh)_5]BPh_4$ was probably mischaracterized. Solid complexes in oxidation states I and II are often stable, although decomposition occurs in solution. Irradiation of $Cr(CNAr)_6$ in well-degassed $CHCl_3$ at 436 nm causes oxidation to $[Cr(CNAr)_6]^+$ (Ar = 2,6-$Pr^i_2C_6H_3$), whereas on irradiation in pyridine with Ar = Ph photosubstitution produces $Cr(CNPh)_5py$.[21]

Alkyl isocyanide chromium(II) complexes could not be prepared from $[Cr_2(O_2CMe)_4(H_2O)_2]$ or $[Cr_2(mhp)_4]$ (mhpH = 2-hydroxy-6-methylpyridine), but by the addition of alkyl isocyanides and KPF_6 to Cr^{2+} solutions from the reduction of $CrCl_3{\cdot}6H_2O$ in ethanol with Zn/Hg, the homoleptic complexes $[Cr(CNR)_6](PF_6)_2$ (R = Bu^t or C_6H_{11}) are obtained (Scheme 4).[22] However, with phenyl isocyanide, the mixed-ligand complex $[CrCl(CNPh)_5]PF_6$ forms, apparently through its kinetic stability in the Cl^--containing medium since it decomposes to $[Cr(CNPh)_6](PF_6)_2$ in CH_2Cl_2. All are paramagnetic, low-spin complexes (t^4_{2g} configuration). It seems that the reaction product is substituent- and medium-dependent because the same procedure with the more reducing 4-methylphenyl isocyanide yields the chromium(I) salt $[Cr(CNC_6H_4Me\text{-}4)_6]PF_6$, and in the presence of Bu^{t}NH$_2$ phenyl isocyanide produces the chromium(0) complex $Cr(CNPh)_6$.[23] Also, the use of CrX_2 (X = Cl, Br) instead of the acetate in equation (5) produces crystalline orange-red $[CrCl_2(CNPh)_4]$ or olive brown $[CrBr_2(CNPh)_4]$. These low-spin chromium(II) complexes are stable in air but structures have not been determined.[24]

Partial replacement of isocyanide in $[Cr(CNR)_6](PF_6)_2$ or $[CrCl(CNPh)_5]PF_6$ by phosphines PR_3, bis(diphenylphosphino)ethane (dppe) or bis(diphenylphosphino)methane (dppm) provides two series of mixed-ligand complexes (Scheme 4).[22,23] The complexes $[Cr(CNR)_4(dppe)](PF_6)_2$, which must be *cis*, have more complicated spectra in the ν(CN) region than the complexes $[Cr(CNR)_4(PR'_3)_2](PF_6)_2$, which are therefore *trans* (Table 3). Nitric oxide reacts with $[Cr(CNR)_6](PF_6)_2$ to give $[Cr(NO)(CNR)_5](PF_6)_2$ from which many mixed nitrosyl isocyanide complexes of Cr^I and Cr^0 can be derived (Section 35.4.2.6).

The low-spin, diamagnetic complexes $[Cr(CNR)_7](PF_6)_2$, which contain seven-coordinate cations (**1**; see also Table 95), result when neat RNC is added to $[Cr(CNR)_6](PF_6)_2$. The reducing ability of the ligands and perhaps steric effects prevent the formation of seven-coordinate cations from aryl isocyanides.

(1)

Chromium(III) complexes, of aryl isocyanides only, *e.g.* $[Cr(CNPh)_6](SbCl_6)_3$, have recently been prepared in good yield by oxidation of Cr^0 or Cr^I isocyanides with an excess of $SbCl_5$ or $NOBF_4$ (Schemes 2 and 3). Strong oxidizing agents are necessary because of the highly positive formal reduction potentials (equation 4 and Table 3). The Cr^{III} complexes are stable in the absence of water. On exposure to the atmosphere solid $[Cr(CNC_6H_3Me_2\text{-}2,6)_6](BF_4)_3$ is slowly reduced, presumably by water vapour, to an orange Cr^{II} complex (Table 3). Unlike typical Cr^{III} complexes, the isocyanide ligands are labile in polar non-aqueous solvents.[25]

(*iii*) *Spectroscopic and crystallographic results*

The general increase in the values of ν(CN) as the metal's oxidation state increases from 0 to III (Table 3) reflects the decrease in number of *d* electrons and the diminution in π donation to the ligand; the chromium(III) complexes have higher CN stretching frequencies even than the unbonded isocyanides (*ca.* 2130 cm^{-1}), suggesting a balance of σ-donor and π-acceptor behaviour by the ligands. There is also crystallographic evidence[26–28] for d_π–p_π back-bonding, in that the Cr—C bonds shorten with decreasing oxidation state in the series $[Cr(CNPh)_6]^{n+}$ ($n = 0$, 1, 2, 3) and in $Cr(CNPh)_6^0$, compared with $[Cr^{II}(CNBu^t)_7](PF_6)_2$, where the difference in formal charge alone should have the opposite effect. There are parallel increases in C≡N bond lengths (Table 4).

Table 4 Bond Length Variation with Oxidation State in Hexaorganoisocyanide and Hexacyano Complexes

2. J. C. Dewan, W. S. Mialki, R. A. Walton and S. J. Lippard, *J. Am. Chem. Soc.*, 1982, **104**, 133.

The Cr $2p_{3/2}$ binding energies (XPES) increase from $Cr(CNPh)_6$ to $[Cr(CNPh)_6]^+$ to $[Cr(CNR)_6]^{2+}$, the values being 574.5, 575.3 and 576.7 eV respectively.[22,29] The shake-up satellite structure associated with the N 1*s* and C 1*s* binding energies in these spectra most probably arises from M $(d) \rightarrow \pi^*$ {CNAr(R)} excitations accompanying the primary photoemission.

(*iv*) *Electrochemistry*

Electrochemical studies have established the three reversible one-electron transfers in equations (2) to (4).[13-15,23] The electrochemical behaviour of a series of complexes $[Cr(CNAr)_6](PF_6)$, in which Ar is Ph, 4-$Me_2NC_6H_4$, 4-$MeOC_6H_4$, 4-MeC_6H_4, 4-ClC_6H_4, 2-MeC_6H_4, 2,6-$Me_2C_6H_3$ or 2,6-$Pr^i_2C_6H_3$, has been studied by cyclic voltammetry in CH_2Cl_2 and MeCN.[14] With *para* substituents, and some *meta* substituents,[13] there is a linear relation between the formal potentials of equations (2) to (4) and the Hammett σ_p parameter, as expected from the usual operation of electronic effects. With *ortho* substituents this was true for the $0 \leftrightarrow 1+$ couple (equation 2) and the σ_o parameter, but not for the $1+ \leftrightarrow 2+$ and $2+ \leftrightarrow 3+$ couples (equations 3 and 4), particularly the latter. There were significant anodic potential shifts in the formal potentials beyond those expected from the σ_o values indicating destabilization of the higher oxidation state of a couple, particularly Cr^{3+} in the $2+ \leftrightarrow 3+$ couple. The anodic shifts also increased with the number of *ortho* substituents. These effects are attributed to weakening of the Cr^{III}—C bonds due to interligand repulsion among the substituents in the *ortho*-substituted complexes, a weakening also manifested through the appearance of new waves in certain media arising from substitution of *ortho*-substituted ligands by MeCN or ClO_4^-.[14] The photochemical behaviour of the *ortho*- and *para*-substituted complexes also differs markedly.[21]

Comparison between the half-wave potentials (equations 2 to 4) of $[Cr(CNR)_6](PF_6)_2$, *e.g.* for R = Bu^t, −1.04, −0.28 and 0.84 V (*versus* SCE),[22] with those for $[Cr(CNPh)_6](PF_6)_2$, *i.e.* −0.35, 0.25 and 1.00 V,[20] shows that alkyl and aryl isocyanides favour respectively the higher and the lower oxidation states as expected from the greater σ-donor and weaker π-acceptor capabilities of the alkyl over the aryl isocyanides. Similarly, the phosphines in the mixed ligand complexes (Table 3),[22,23] relative to isocyanide ligands, stabilize the Cr^{III} oxidation state. The great difference in the relative stabilities of Cr—C bonds in the cyano and phenyl isocyanide complexes is indicated by the magnitude of the shift (*ca.* 2.0 V) between the $Cr(CN)_6^{3-}/Cr(CN)_6^{4-}$ (−1.130 V) and the $Cr(CNPh)_6^{3+}/Cr(CNPh)_6^{2+}$ reduction potentials.[28]

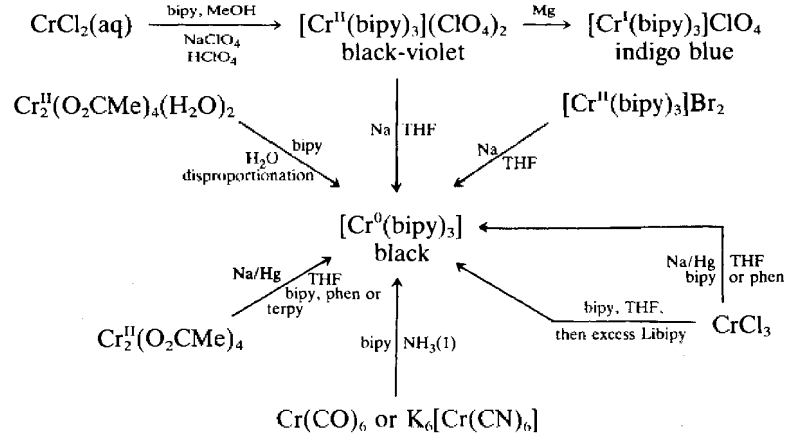
(*v*) *Tricyanomethide*

The pale blue tricyanomethide complex $Cr[C(CN)_3]_2$ has a magnetic moment of *ca.* 4.7 BM and is thought to be polymeric.[30]

35.2.1.3 Si-, Ge-, Sn- and Pb-containing ligands

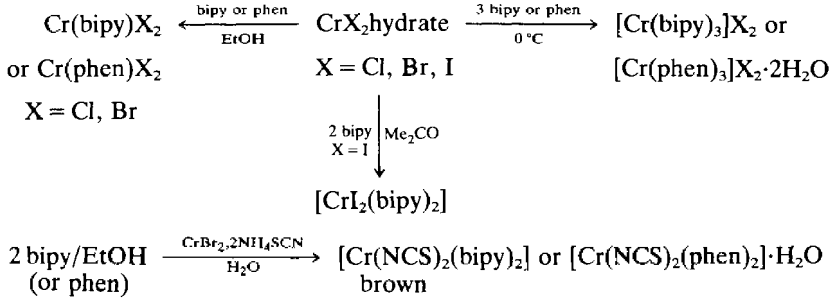
The yellow complex $[NPr_4]_6[Cr(GeCl_3)_6]$ is formed in poor yield if $Cr(C_6H_6)_2$ is refluxed in acetone with $[NPr_4][GeCl_3]$.[31]

35.2.2 Nitrogen Ligands



35.2.2.1 Complexes of bi- or tri-dentate N heterocyclic ligands

Since complexes of 2,2′-bipyridyl and 1,10-phenanthroline with chromium in oxidation states I and 0 can be obtained by reduction (Scheme 64) of the chromium(II) complexes, these oxidation states will be considered together. Oxidation, as shown in Schemes 65 and 68 of Section 35.4.2.5, gives chromium(III) complexes, which are often best prepared in this way. Earlier work has been extensively reviewed, and few complexes of 2,2′:6′,2″-terpyridyl are known.[32] A chromium(I) phthalocyanine derivative is mentioned in Section 35.4.9.3.



(*i*) *Syntheses*

Various methods to prepare tris(α-diimine) complexes of many metals in low oxidation states have been devised, mainly by Herzog and co-workers.[32] Those used for chromium complexes are illustrated in Schemes 5 and 6. Chromium(II) salts, anhydrous or hydrated, are the commonest starting materials. To these are added stoichiometric amounts of the diimine,

and the Cr^{II} complex is then reduced. When bipy is added to the acetate suspended in water, disproportionation into $[Cr(bipy)_3]^0$ and $[Cr(bipy)_3]^{3+}$ occurs. The use of the anhydrous acetate in THF with bipy or phen and Na/Hg seems to provide a more efficient route to the zerovalent complexes.[33] The complexes $LiCr(bipy)_3 \cdot 4THF$, $Na_2Cr(bipy)_3 \cdot 7THF$, $Na_3Cr(bipy)_3 \cdot 7THF$ and $Ca_3Cr(bipy)_3 \cdot 7NH_3$, which are prepared from $Cr(bipy)_3$ and as appropriate Li_2bipy, Li or Na metal in THF, or Ca in liquid ammonia,[34] are not included in Schemes 5 and 6.

Scheme 5

Scheme 6

(*ii*) *Magnetic properties*

The mono(amine)chromium(II) complexes, $CrCl_2(bipy)$ *etc.*, are high-spin ($t_{2g}^3 e_g^1$), but show antiferromagnetic interaction presumably through halide-bridged structures.[35] The bis- and the tris-(amine) chromium(II) complexes are low-spin (t_{2g}^4), as are all the terpy complexes and those of chromium in oxidation states below II (Table 5).[35,36] That spin pairing takes place in chromium(II) on the coordination of a second bipy molecule is in agreement with the observation that the second stepwise stability constant is greater than the first: $\log K_1 \approx 4$, $\log K_2 \approx 6.4$, $\log K_3 \approx 3.5$ (H_2O, ionic strength 0.3 M) (Table 39).[37]

The ground term of low-spin Cr^{II} is $^3T_{1g}$ and incomplete quenching of the orbital contribution is expected to produce magnetic moments in excess of the spin-only value (2.83 BM) which are temperature-dependent. This is not generally found with the low-spin bipy, phen or terpy complexes (Table 5), and attempts to account for the small or zero temperature dependence theoretically in terms of spin–orbit coupling, distortion from octahedral symmetry, and electron delocalization have not been very successful especially at low temperatures (~50 K) where the experimental values do not drop as the theory predicts. This may be because there is greater deviation from cubic symmetry than the theory can accommodate.[36] From further magnetochemical studies[38] and NMR measurements[39] it has been concluded that there is an appreciable trigonal component in the ligand field and relatively little delocalization of the unpaired electrons. The low-spin complexes $[CrX_2(diars)_2]$ also have essentially temperature-independent moments.[40]

Table 5 Complexes of bipy, phen and terpy with Chromium(0), (I) and (II) (see Section 35.4.2.5 for Chromium(III) Complexes)

Complex	*Comments*	*Ref.*
Chromium(0) complexes[a]

(*iii*) *Proton NMR studies of tris(bipy) and tris(phen) chelates*

Proton NMR spectroscopy has been used to investigate paramagnetic complexes of low-valent transition metal ions because the contact shifts provide information on the degree of covalency of the metal–ligand bond. The low-spin complexes $[Cr(phen)_3]Cl_2$ and $[Cr(bipy)_3]Cl_2$, and their methyl-substituted derivatives (Table 5), have been extensively investigated.[39,41,42] Narrow, well-resolved ^1H NMR spectra have been obtained from $[Cr(R_2phen)_3]^{2+}$ (R = H; R_2 = 4,7- and 5,6-dimethyl) and $[Cr(R_2bipy)_3]^{2+}$ (R = H; R_2 = 4,4′-dimethyl) and the shifts result from both L → M σ and M → L π charge transfer. The π bonding is not obvious in the tris chelates with symmetric ligands owing to near cancellation of two contributions of opposite sign.[41] The relative π-acceptor abilities of the differently substituted

ligands, and the orbital ground states of the complexes were elucidated only after some mixed-ligand chelates (obtained in solution only) had been investigated. The M→L delocalized π spin density is centred predominantly at the 4,7 positions of phen or 4,4′ positions in bipy. This facilitates the reducing ability of these chelates and is believed[42] to be consistent with the stereoselective outer-sphere reduction of $[Co(phen)_3]^{3+}$ by $[Cr(phen)_3]^{2+}$: it is found that (+)-$[Co(phen)_3]^{3+}$ yields (−)-$[Cr(phen)_3]^{3+}$ as the main product on reduction with racemic $[Cr(phen)_3]^{2+}$.[43] Anomalously broadened methyl resonances are ascribed to solvent (water) complex interactions at the 4,7 positions which involve hydrogen bonding to pockets of electron density on the ligand assisted by the π bonding. From spectral changes it was suggested[35] that bipy separated from $[Cr(bipy)_3]X_2$ (X = Cl, Br, I) in ethanol, but there are no NMR signals of the free ligand from solutions of these salts in d_4-MeOH unless some is added.

(*iv*) *Electronic, ESR and IR spectra*

The electronic spectrum of $Cr(bipy)_3$ resembles that of $bipy^-$ in the lower wavenumber region, but formulation of the complex in terms of integral oxidation states is unrealistic.[44,45] According to an X-ray study, the molecule is trigonally distorted, the N—Cr—N angle being 74.7 ± 1.5°. The Cr—N distance is 2.08 Å.[46]

The ion $[Cr(bipy)_3]^+$ in solution exhibits an ESR spectrum from which $g = 1.9971$ and the hyperfine splitting constant of ^{53}Cr, A^{Cr}, is 20.4×10^{-4} cm^{-1}. There is further splitting of the ^{53}Cr hyperfine lines due to the ^{14}N nuclei of the ligands, which indicates strong σ bonding.[47] Its electronic spectrum consists of charge-transfer and intraligand bands.[45]

Ligand-field theory gives a reasonable account of the energies but not the intensities of the bands between 12 000 and 32 000 cm^{-1} in the spectrum of $[Cr(bipy)_3]^{2+}$, which are due to spin-allowed transitions of the low-spin d^4 configuration. There are also many charge-transfer or internal-ligand bands which are weakly perturbed by methyl substitution in bipy.[48] The assignment of formal oxidation states (II and III respectively) to the metal in $[Cr(bipy)_3]^{2+}$ and $[Cr(bipy)_3]^{3+}$ (Section 35.4.2.5) is valid but not in complexes of lower overall charge.[45] From spectral changes in aqueous solution the mixed complex $[Cr(bipy)_2(4,4'\text{-bipyH})(H_2O)]^{3+}$ has been identified in rapid equilibrium with $[Cr(bipy)_3]^{2+}$ and the free ligands.[49]

In the series $[Cr(bipy)_3]X_3$, $[Cr(bipy)_3]X_2$, $[Cr(bipy)_3]X$, $[Cr(bipy)_3]$ the Cr—N stretching frequency varies little with oxidation state from III to 0. Since this implies small changes in bond strength with decreasing oxidation state and greater occupation of the t_{2g} orbitals, it appears that increasing M→L π donation is offset by lower L→M σ donation as the oxidation state is lowered. Some complexes were labelled with ^{50}Cr or ^{53}Cr to aid in the assignment of the two Cr—N stretching bands (Table 6).[50] There are discrepancies with assignments for unlabelled complexes.[51] The splitting of the ν(CN) band in the IR spectra of the complexes $[Cr(NCS)_2(bipy)_2]$ and $[Cr(NCS)_2(phen)_2]$ indicates *cis* configurations but this has not been confirmed crystallographically.[35]

Table 6 Far IR Spectra of the $[Cr(bipy)_3](ClO_4)_n$ Series (cm^{-1})

$[Cr(bipy)_3]^{3+}$	$[Cr(bipy)_3]^{2+}$	$[Cr(bipy)_3]^{+}$	$[Cr(bipy)_3]^{0}$	*Assignment*
385m	351s	371m	382m	ν(Cr—N)
(Hidden)	359m	352m	357vw	Ligand
349m	343m	343m	308s	ν(Cr—N)
226w	225m	228w	227w	Ligand
193vw	205w			
	189w	195w	203s	Ligand
177w	175vw	179w	178w	Ligand

The absorption spectrum and first formation constant of $[Cr(bipy)]^{2+}$ have been determined spectrophotometrically in hexamethylphosphoramide (HMPA) (see also Table 39). Since $\log K_1$ (4.61) is slightly larger in HMPA than in water, it is said that $[Cr(bipy)(HMPA)_2]^{2+}$ is tetrahedral, although from the general chemistry of chromium(II) the ion would be expected to be in planar or distorted octahedral coordination.[52]

(*v*) *Electrochemistry*

Voltammetric investigations of chromium complexes of bipy, phen and terpy in MeCN and other solvents, as well as magnetic and other data above, show that the metal forms series of tris-(bipy) and -(phen) and bis(terpy) complexes related by reversible one-electron transfers in which the metal has formal oxidation states III, II, I, 0, −I (see also Section 35.4.2.5). Some half-wave potentials are given in Table 7.[53] In aqueous solution complications occur because $[Cr(bipy)_3]^{3+}$ undergoes catalyzed ligand exchange at the dropping mercury electrode to form $[Cr(bipy)_2(H_2O)_2]^{3+}$, which reduces more cathodically than the tris complex, to give $[Cr(bipy)_2(H_2O)_2]^{2+}$. The phen complexes and $[CrCl_2(bipy)_2]^+$ behave similarly [54,55]

Table 7 Half-wave Potentials

Complex couple	*DC polarography* (V)[a]	*AC polarography* (V)[a]

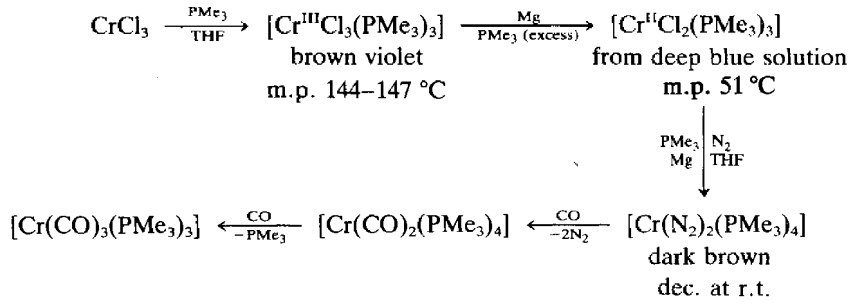
35.2.2.2 Nitrosyls and dinitrogen complexes

Nitrosyls are included in Section 35.4.2.6 and dinitrogen complexes with the phosphorus donors immediately below.

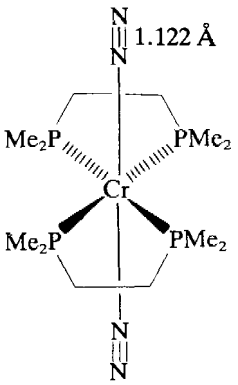
35.2.3 Phosphorus Ligands



35.2.3.1 Mixed complexes of dinitrogen and tertiary phosphines

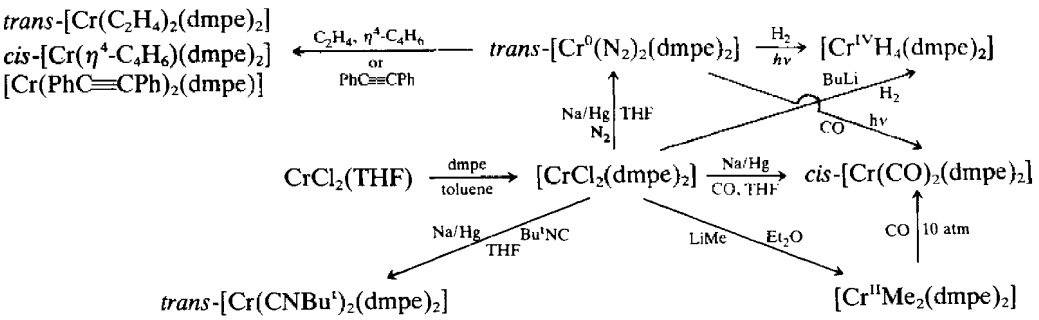
There are few examples of complexes of chromium with molecular nitrogen, although molybdenum and tungsten form many such complexes.[1] Unstable species containing Cr—N_2 bonds produced by matrix isolation techniques have not been included.[56]

The chromium(0) complex $[Cr(N_2)_2(PMe_3)_4]$ is not well established because it decomposes at room temperature with liberation of PMe_3 and N_2. Since there are two IR absorption bands at 1990 and 1918 cm^{-1} [ν(N≡N)] it has been assigned a *cis* octahedral structure. The dark brown complex can be prepared from anhydrous $CrCl_3$ by Scheme 7 or directly from the reactants. There is no spectroscopic or structural information on the intermediates $[Cr^{III}Cl_3(PMe_3)_3]$ and $[Cr^{II}Cl_2(PMe_3)_3]$.[57]



The systems $CrCl_2$–Mg–THF and $CrCl_2$–Mg–dppe–THF absorb nitrogen and some NH_3 and N_2H_4 are produced on hydrolysis. The paramagnetic solids $Cr_2N_2Mg_4Cl_4(THF)_5$ (black) and $[Cr(dppe)_2]_2N_2$ (brown), which are difficult to obtain reproducibly, have been isolated.[58]

The chromium(0) complex *trans*-$[Cr(N_2)_2(dmpe)_2]$ (**2**) has been prepared together with some incompletely characterized *cis* isomer from $[CrCl_2(dmpe)_2]$ according to Scheme 8, which also shows that its reactions all involve displacement of dinitrogen. The *trans* dinitrogen ligands are linear, and the N—N bond distance (1.122 Å) is normal. The IR spectrum of the *trans* isomer



Scheme 7

has one band (N≡N stretch) at 1932 cm^{-1} and the *cis* isomer bands at 1920 and 1895 cm^{-1}. Since the Cr—P distance (2.296 Å) is shorter than in $[CrMe_2(dmpe)_2]$ (2.345 Å, Section 35.3.4.1) there is significant metal–ligand π back-bonding.[59]

(2)

Scheme 8

The cocondensation of chromium vapour and the phosphorus ligand is used to prepare $[Cr(dmpe)_3]$ and the trimethyl phosphite complex $[Cr\{P(OMe)_3\}_6]$ (Table 8). The former has a distorted octahedral structure, and the latter forms a seven-coordinate hydride $CrH_2\{P(OMe)_3\}_5$ which, with other chromium(II) complexes of P donor ligands, is considered in Section 35.3.4.

35.2.3.2 Fluorophosphine complexes

The reaction of tris(π-allyl)chromium with the π-acceptor ligand PF_3 produces stable crystals of $[Cr(PF_3)_6]$ *via* $[(C_3H_5)_3Cr(PF_3)]$ (Scheme 9). At high pressure, only $[Cr(PF_3)_6]$ is isolated;[60] it can also be obtained by metal vapour synthesis,[61] and its He(I) PE spectrum has been assigned.[62]

Complexes of chelating aminodifluorophosphines $Cr\{(PF_2)_2NR\}_3$ (R = Ph (m.p. 233 °C)[63] or Me (m.p. 182 °C)[64]) can be prepared by UV irradiation of $Cr(CO)_6$ with an excess of the ligand

Table 8 Tertiary Phosphine and Arsine Complexes of Chromium(0) Including Mixed Complexes with Dinitrogen

dark green — colourless, m.p. 193 °C

Scheme 9

in diethyl ether. Cocondensation of chromium vapour and $MeN(PF_2)_2$ also affords $[Cr\{(PF_2)_2NMe\}_3]$.[65,66] Although the ligands have a small bite and must form four-membered chelate rings, the colourless complexes (**3**) are volatile and stable. In accordance with the formulation as zerovalent tris(bidentate) chelates, the ^1H and ^{13}C NMR spectra each exhibit a single resonance from the three equivalent methyl groups, and there are intense molecular ions in the mass spectra. The strong P—F stretching absorptions are at 831 cm^{-1} (R = Me) and 865 cm^{-1} (R = Ph).

(**3**)

The cocondensation of chromium vapour with a 4:1 mixture of Me_2NPF_2 and $MeN(PF_2)_2$ forms the homoleptic chromium(0) derivative $[Cr(PF_2NMe_2)_6]$ and the mixed ligand derivative $[Cr(PF_2NMe_2)_4\{(PF_2)_2NMe\}]$. The former slowly decomposes when left in air, especially if in solution. This instability, compared with $[Cr(CO)_6]$ or $[Cr(PF_3)_6]$, is due to the steric hindrance of the six bulky monodentate ligands. The latter, with only four monodentate ligands and one bidentate ligand, can be sublimed and is considerably more stable. When prepared, it was contaminated with a little $[Cr(PF_2NMe_2)_2\{(PF_2)_2NMe\}_2]$. An X-ray determination of the

structure of $[Cr(PF_2NMe_2)_4\{(PF_2)_2NMe\}]$ shows the expected octahedral configuration distorted by the small bite of bidentate $(PF_2)_2NMe$ (P—Cr—P = 66°), which relieves steric strain compared with $Cr(PF_2NMe_2)_6$; no bond distances were supplied.[65]

The stable zerovalent complexes $[Cr(PF_2OPr)_6]$ and $[Cr\{(PF(OMe)_2\}_6]$ can be obtained by UV irradiation of $[Cr(CO)_6]$ in pentane in the presence of a slight excess of the ligand.[67]

35.2.4 Miscellaneous Chromium(0) Complexes

Several chromium nitrosyls, and complexes of quinones which are members of redox series, can be considered to contain chromium(0) or chromium(I) (see Sections 35.4.2.6 and 35.4.4.8).

35.3 CHROMIUM(II)

Chromium(II) complexes, especially in solution, are very rapidly oxidized by air, and this restricted synthetic and other investigations until comparatively recently when efficient inert atmosphere boxes had been developed, and the use of Schlenk and similar techniques had become general.[68,69] Solids show varying behaviour towards aerial oxidation; some are pyrophoric but a few are stable for days or longer. The need to use oxygen-free conditions should be assumed throughout the Cr^{II} section. Few chromium(II) compounds, possibly the acetate and some anhydrous halides, are commercially available. Consequently, those wishing to investigate the coordination chemistry of chromium(II) must first prepare their starting materials.

Chromium(II) has been extensively used in investigations of inner-sphere electron transfer because inert chromium(III) captures the ligands attacked by chromium(II).[70]

35.3.1 General Synthetic Methods

Methods for the preparation of chromium(II) solutions and the isolation of solids for synthetic work are set out below.

35.3.1.1 Chromium(II) solutions

(i) Dissolution of chromium in acids

The impure metal dissolves easily in mineral acids and in fluoroboric, sulfamic and trifluoromethylsulfonic acids to give Cr^{2+} solutions, but oxidation of Cr^{2+} by hydrogen ion (equation 6), $E°(Cr^{3+}, Cr^{2+}) = -0.41$ V) even in an inert atmosphere is catalyzed by the impurities and various ions.[71] Indefinitely stable chromium(II) solutions can be obtained from the pure (electrolytic) metal (99.5% or better), although the reaction with acid may need to be initiated by heat and the inclusion of some metal previously attacked by acid. The use of an excess of metal, which can be filtered off, ensures that little acid remains. In near neutral solution the hydrogen potential is lowered and the Cr^{2+} ion is stable. In alkaline condition brown $Cr(OH)_2$, which slowly reduces water, precipitates.[72,73]

$$Cr^{2+} + H^+ \longrightarrow Cr^{3+} + \tfrac{1}{2}H_2 \qquad (6$$

(ii) Reduction of chromium(III) solutions

The reduction of aqueous chromium(III) solutions can be carried out electrolytically or chemically with zinc amalgam, zinc and acid or a Jones reductor.[2,24] Electrolytic procedures can be cumbersome, and with chemical reductants contamination with other products can occur. Chromium metal and acid can be used to reduce chromium(III) salts, and this requires less of the metal than in the method described in Section 35.3.1.1.i.

(iii) Non-aqueous solutions

The hydrated chloride, bromide and iodide (Table 9) are soluble in ethanol, butanol and other organic solvents, but in many systems traces of water cause oxidation, hydrolysis or failure to complex with weak donor ligands. Water can be avoided by dissolving the metal in THF, ethanol or diethyl ether through which hydrogen chloride is bubbled.[24,74,75] It is also possible to dissolve or suspend in organic solvents the anhydrous acetate or the halides CrX_2 (Table 9), and dehydration of the hydrated halides with 2,3-dimethoxypropane in ethanol, followed by vacuum removal of the liquid, produces mixed alcoholates suitable for use in water-free conditions.[76] Triethyl orthoformate may be used similarly.

Table 9 Preparations of Some Chromium(II) Compounds Used as Starting Materials

Compound	*Preparation*	*Ref.*
$[Cr_2(O_2CMe)_4(H_2O)_2]$ Dark red	$Cr^{2+}(aq) + NaO_2CMe$; brown $[Cr_2(O_2CMe)_4]$ on pumping at 100 °C	1, 2
$Cr_2(O_2CMe)_4 \cdot 2MeCO_2H$	Cr powder, anhydrous $MeCO_2H$ with some MeCOCl	3
$CrCl_2 \cdot 4H_2O$ Blue	Cr + HCl, conc. solution, add Me_2CO; [a] $CrCl_2$ by thermal dehydration at 140 °C	4–6
$CrBr_2 \cdot 6H_2O$ Blue	Cr + HBr, conc. solution, add Me_2CO; [a] $CrBr_2$ by thermal dehydration at 120 °C	4–7
$CrI_2 \cdot 6H_2O$ Blue	Cr + HI, conc. solution; soluble org. solvents, 'CrI_2' on pumping at r.t.[a]	4–6
$Cr(ClO_4)_2 \cdot 6H_2O$ Blue	Cr + $HClO_4$, conc. solution; soluble org. solvents, solid decomposes under N_2, internal oxidation/reduction	4–6
	$[Cr(bipy)_3](ClO_4)_2$ known but probably dangerous to prepare ClO_4 salts of Cr^{II} cations generally	2, 6
$CrSO_4 \cdot 5H_2O$ Blue	Cr + H_2SO_4, add acetone; forms $CrSO_4 \cdot H_2O$ and then $CrSO_4$ on heating, stable in air when dry	2, 4–6
$[Cr(acac)_2]$ Light yellow	$Cr_2(O_2CMe)_4(H_2O)_2$ + acacH, H_2O, reacts slowly with H_2O	1
$[CrCl_2(MeCN)_2]$ Pale blue	Anhydrous[a] $CrCl_2$ (above) in EtOH + MeCN	6
$[CrCl_2(THF)_2]$ Pale green	$CrCl_2$ extracted with THF	8
$[CrCl_2(THF)]$ White	Cr + HCl(g) in THF	9
$[CrBr_2(THF)_2]$ Pale blue-green	Crystallized from $CrBr_2$ in THF	10

[a] The anhydrous halides are also prepared by the methods in Section 35.3.7.

A method which gives a chromium(II)-substituted alkoxide ($[Cr(OCBu^t_3)_2 \cdot LiCl(THF)_2]$, Section 35.3.5.2) directly from $CrCl_3$ is to add a solution of the alcohol previously treated with BuLi to a slurry of the halide in THF.[77] How the reduction to chromium(II) takes place has not been clarified.

35.3.1.2 Chromium(II) salts

The poorly soluble acetate $[Cr_2(O_2CMe)_4(H_2O)_2]$ can be crystallized from aqueous Cr^{2+} solutions by the addition of sodium acetate. When dry it reacts slowly with oxygen and can be handled briefly in air, but the anhydrous acetate chars on exposure.

The hydrates $CrSO_4 \cdot 5H_2O$, $CrCl_2 \cdot 4H_2O$, $CrBr_2 \cdot 6H_2O$ and $CrI_2 \cdot 6H_2O$, and the anhydrous halides, all most easily isolated as in Table 9, are useful starting materials. Thermal

dehydration of halides can lead to hydrolysis, but this is not significant for preparative use o the anhydrous chromium(II) compounds. The iodide and perchlorate are difficult to obtai hydrated to a definite degree. On pumping $CrI_2 \cdot 6H_2O$ loses its blue colour as water is removed but the solid remains a chromium(II) species. The perchlorate should be used with extrem caution, if at all, because the juxtaposition of Cr^{2+} as part of a complex cation containing a organic ligand and ClO_4^- is intrinsically dangerous and not only impact but the accidenta admission of air to the solid could cause an explosion. The use of BPh_4, BF_4, NH_2SO_3, PF_6 an CF_3SO_3 salts has not yet been much exploited.

Aqueous chromium(II) solutions have long been available as standard reducing agents i volumetric analysis.[78] More recently, the use of chromium(II) salts as reducing agents i organic chemistry has been reviewed. Chromium(II) chloride, sulfate and perchlorate hav been classified as powerful reducing agents whereas the acetate, a relatively insoluble salt, act as a mild reducing agent in near neutral conditions. Chromium(II) ethylenediamine complexe have been used in dimethylformamide,[79] and transition metal chelates have been reduced b chromium(II) acetylacetonate in toluene and THF.[80] Chromium(II) compounds also readil reduce various iron oxides.[81] These uses of chromium(II) compounds are likely to increase.

Metals can be used as sacrificial anodes in the electrochemical synthesis of anhydrous salt and complexes. This method frequently produces chromium(III) complexes, but electrochemi cal oxidation of chromium in a mixture of concentrated aqueous HBF_4 and acetonitrile yield $[Cr(MeCN)_6](BF_4)_2$.[82]

35.3.2 Group IV Ligands

Cyanide and organic isocyanide complexes of chromium(II) have been included with th lower oxidation states in Sections 35.2.1.1 and 35.2.1.2.

35.3.3 Nitrogen Ligands

35.3.3.1 Ammines

(i) Syntheses

A deep blue colour appears when concentrated solutions of ammonia and aqueou chromium(II) are mixed, but brown chromium(II) hydroxide separates before any ammine ca be isolated.[83] Gaseous ammonia and solid $CrCl_2$ form $CrCl_2 \cdot nNH_3$ ($n = 2$, 3, 5 and 6) an when ammonia is bubbled through ethanolic solutions of the hydrated halides pale blue, viol and then greyish precipitates successively appear corresponding to the formation of diammine pentaammines and hexaammines (Table 10).[84] The hexaammines lose ammonia so readily (an reversibly) to form pentaammines that they must be sealed in ammonia gas. The easy loss c ammonia appears to be a 'chemical' effect of the Jahn–Teller distortion (see later). Th tetraammine $[Cr(NH_3)_4(H_2O)]SO_4$ is obtained by bubbling ammonia through an ethanol suspension of $CrSO_4 \cdot 5H_2O$[85] and the diammines by heating the tetraammine or th pentaammines.

(ii) Magnetic and spectroscopic properties and structures

Chromium(II) complexes may be high- or low-spin (Figure 1), and the hexaammines an pentaammines are typical, high-spin Cr^{2+} compounds with effective magnetic moments close t the spin-only value ($t_{2g}^3 e_g^1$ configuration, $\mu_{so} = 4.90$ BM). With these magnetically dilut complexes the experimental moments are temperature-independent (Table 10) so the Curie la is obeyed ($\theta = 0$ °C). The diammines show weak antiferromagnetic interaction since th moments decrease as the temperature is lowered and the Curie–Weiss law is followe ($\theta \approx 35$ °C).

The σ antibonding effect, arising from the uneven occupancy of the d orbitals in high-spi chromium(II) complexes, has a marked effect (Jahn–Teller distortion) on the electronic spect and structures. Chromium(II) has a ^5D free ion ground term and this is split in an octahedr (O_h) ligand field as shown in Figure 2 to give a ^5E_g ground term. The Jahn–Teller theore

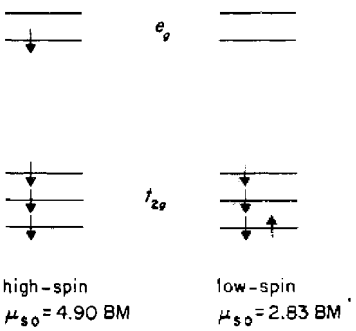

Figure 1 Occupancy of *d* orbitals in octahedral chromium(II) complexes

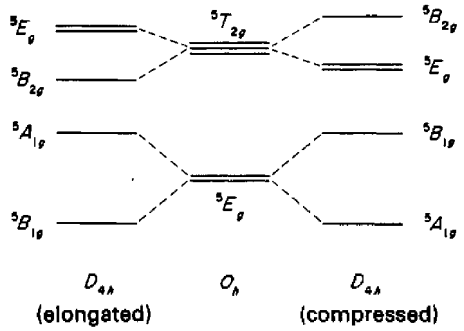
requires that in an orbitally degenerate, non-linear system, distortion will occur to remove the degeneracy, and this can take place in high-spin d^4 (and d^9) systems by elongation or compression along an octahedral four-fold axis (Figure 2, tetragonal distortion, D_{4h}). In solids, the Jahn–Teller distortion may be local to the coordination spheres of the individual Cr^{2+} ions or there may be interactions between neighbouring ions affecting the whole lattice, and this cooperative Jahn–Teller effect has been reviewed (Section 35.3.7).[86]



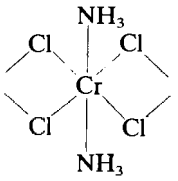


Figure 2 Energy levels of high-spin chromium(II) in ligand fields of O_h and D_{4h} symmetry

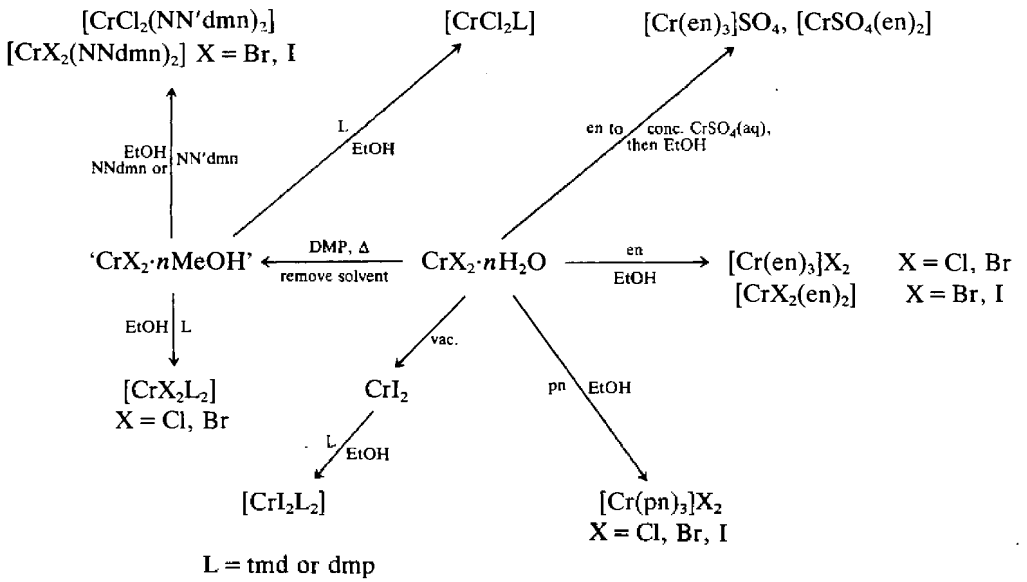
From Figure 2, one spin-allowed d–d transition is expected for a regular octahedral complex, and three such transitions for a tetragonally distorted complex. Experimentally, most high-spin chromium(II) complexes exhibit one absorption band (ν_2, the main band) with a weaker band or shoulder (ν_1, the distortion band) to lower wavenumber; ν_1 is usually assigned to the $^5B_{1g} \rightarrow {}^5A_{1g}$ transition and ν_2 to superimposed $^5B_{1g} \rightarrow {}^5B_{2g}$, ^5E_g transitions. There are also examples where there is one very broad band due to the overlap of all three transitions and others where they are resolved. There are few single crystal spectroscopic studies of chromium(II) complexes.



The spectra of the ammines follow the general patterns outlined above. From the magnetic and spectroscopic data, and X-ray powder comparisons with copper(II) complexes, the hexaammines and pentaammines have been assigned tetragonal octahedral and square pyramidal structures respectively, and the diammines anion-bridged six-coordinate structures (**4**). The tetraammine sulfate is square pyramidal, with coordinated water; other five-coordinate chromium(II) complexes are listed in Table 42. The acetates $[Cr_2(O_2CMe)_4(NH_3)_2]$ and $Cr(NH_3)_4(O_2CMe)_2$ are discussed in Section 35.3.5.5.

(**4**)

35.3.3.2 Bidentate saturated amines, ethylenediamine, propylenediamine, etc.

Although earlier attempts to isolate chromium(II) complexes of various bidentate amines from aqueous solutions produced chromium(III) complexes and hydrogen, the predominantly non-aqueous methods outlined in Scheme 10 provide complexes of ethylenediamine (en), 1,2-diaminopropane (pn), 1,3-diaminopropane (tmd), 1,2-diamino-2-methylpropane (dmp), *N*,*N*-dimethylethylenediamine (NNdmn) and *N*,*N*′-dimethylethylenediamine (NN′dmn) (Table 11). In general, ethanol is a suitable solvent but with some amines it is necessary to dehydrate the halide with 2,2-dimethoxypropane (DMP) and dry the ethanol carefully to prevent hydrolysis and oxidation.

Scheme 10

$[CrI_2(NNdmn)_2]$	Purple	4.93	4.77	8	16 500s	

The $[Cr(en)_3]^{2+}$ and $[Cr(pn)_3]^{2+}$ salts have reflectance spectra (Table 11) resembling those of the hexaammines, and the six N donor atoms are assumed to complete tetragonally distorted octahedra around the metal. Stability constant measurements (Table 39) have shown that the ions $[Cr(en)(aq)]^{2+}$ ($\bar{\nu}_{max} = 18\,300\ cm^{-1}$, $\varepsilon = 25\ dm^3\ mol^{-1}\ cm^{-1}$) and $[Cr(en)_2(aq)]^{2+}$ ($\bar{\nu}_{max} = 17\,500\ cm^{-1}$, $\varepsilon = 17\ dm^3\ mol^{-1}\ cm^{-1}$) exist in aqueous solution, but that, as in the copper(II) system, the third ethylenediamine molecule is only weakly bound, and care is needed to prevent loss of en from tris(amine) complexes in the preparations. Several bis(amine) complexes, *e.g.* $[CrBr_2(en)_2]$, have been isolated, and these are assigned *trans* structures because of IR spectral resemblances to the corresponding copper(II) complexes. Since the spectrum of $[Cr(SO_4)(en)_2]$ also shows the presence of bidentate sulfate, this is assigned a *trans* octahedral structure with bridging anions.

The pale blue tris(amine) complexes $[Cr(pn)_3]X_3$ separate readily from solutions containing an excess of the amine. Violet solutions form when 2:1 ratios of pn and metal halide are used, but pure bis(amine) complexes have not been obtained. On the other hand, the other bidentate amines give only the bis(amine) complexes $[CrX_2(tmd)_2]$, $[CrX_2(dmp)_2]$, $[CrX_2(NNdmn)_2]$ and $[CrCl_2(NN'dmn)_2]$ (Table 11), even from solutions containing an excess of amine. These are also given *trans* structures. The antiferromagnetic monoamine complexes $[CrCl_2(tmd)]$ and $[CrCl_2(dmp)]$ are believed to be chloride-bridged polymers. No crystallographic evidence is available.

The bands ν_2 and ν_1, particularly the latter, move to higher wavenumber with weaker field axial ligands: $I > Br > SO_4 > NH_2$. This behaviour is characteristic of distorted systems.[87,88]

35.3.3.3 *Polydentate amines, diethylenetriamine, triethylenetetramine and facultative ligands*

(*i*) *Diethylenetriamine*

The ions $[Cr(dien)_2]^{2+}$ and $[Cr(dien)]^{2+}$ have been identified in aqueous solution by stability constant (Table 39) and other measurements: $\mu_{eff}^{293\ K} \approx 4.9$ BM, $\bar{\nu}_{max} = 17\,000\ cm^{-1}$, $\varepsilon = 39\ dm^3\ mol^{-1}\ cm^{-1}$ $[Cr(dien)_2]^{2+}$; $\bar{\nu}_{max} = 16\,300\ cm^{-1}$, $\varepsilon = 32\ dm^3\ mol^{-1}\ cm^{-1}$ $[Cr(dien)(aq)]^{2+}$, but the solutions decompose on standing, and the solids $[Cr(dien)_2]X_2$ and $[CrX_2(dien)]$ have been crystallized from alcoholic media. The bis(dien) complexes have similar magnetic moments and electronic spectra to the tris(en) complexes and so contain tetragonally distorted six-coordinate Cr^{2+}. Unlike $[Cr(en)_3]^2$ ions, which lose en, the $[Cr(dien)_2]^{2+}$ ions maintain their integrity in solution in organic solvents. Halide-bridged binuclear structures have been suggested for the antiferromagnetic mono(dien) complexes (Table 12).

Table 12 Diethylenetriamine Complexes

Complex[a]	μ_{eff} (BM) 300 K	90 K	θ (°)	Reflectance spectra (cm^{-1}) ν_2	ν_1
$[Cr(dien)_2]Cl_2 \cdot H_2O$	4.82	4.80	0	16 100	[b]

[d] *J ca.* 10 cm^{-1}, $g = 2$.
[e] *J ca.* 4 cm^{-1}, $g = 2$.

(*ii*) *Triethylenetetramine*

From stability constant measurements (Table 39) the $[Cr(trien)]^{2+}$ ion ($\mu_{eff} \approx 4.9$ BM, $\bar{\nu}_{max} = 16\,900\ cm^{-1}$, $\varepsilon = 46\ dm^3\ mol^{-1}\ cm^{-1}$) exists in aqueous solution, but only incompletely characterized solids have been isolated.[89]

(*iii*) *Facultative ligands*

Chromium(II) forms the trigonal bipyramidal complex $[CrBr(Me_6tren)]Br$ with the 'tripod' ligand tris(2-dimethylaminoethyl)amine (Me_6tren) (Section 35.3.4.3), and pyrazolyl-substituted ligands also form five-coordinate complex cations (Section 35.3.3.4.v; see also Table 42).

35.3.3.4 N heterocyclic ligands

(*i*) *Pyridine and substituted pyridines*

Like other bivalent metals of the first transition series, chromium(II) forms many complexes with pyridine and substituted pyridines. These are mostly of the types $[CrX_2L_4]$, in which X = Cl, Br and I, and $[CrX_2L_2]$, where X = Cl, Br and occasionally I, but a few of the general formulae $[CrX_2(H_2O)_2L_2]$ and $[Cr(py)_6]X_2$ are known (Table 13). The complexes $[CrX_2L_2]$ invariably obey the Curie–Weiss law, with large θ values, and this antiferromagnetic interaction is evidence for the halide-bridged structure (**5**), which is confirmed by the isomorphism of $[CrX_2(py)_2]$ and $[CuX_2(py)_2]$ (X = Cl, Br).

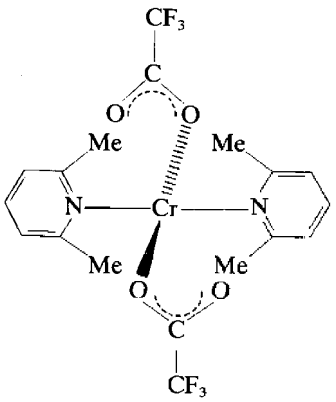
(5)

The complexes $[CrX_2L_4]$ and $[CrX_2(H_2O)_2L_2]$ are high-spin and magnetically dilute. The former are believed to have *trans* octahedral structures and there is some evidence that the latter have too.[85,90–93]

Some pyridine complexes, *e.g.* $[CrCl_2(py)_2]$, have been prepared from the hydrated chromium(II) halide in aqueous solution, but it is more common to use solvents such as acetone, which is particularly useful for iodo complexes, and ethanol. In some cases it is necessary to recrystallize from dimethylformamide to remove water arising from the use of the hydrated halide. It is also sometimes necessary to control the amount of pyridine fairly closely, use cold solutions and wash with solvents containing small amounts of pyridine if the desired complex is to be obtained. Some complexes, *e.g.* $[Cr(py)_6]Br_2$ and $[Cr(py)_6]I_2$, have been prepared by dissolving the bis- or tetrakis-amine complex in an excess of pyridine. These two complexes, which are isomorphous[91] with $[Cu(py)_6]Br_2$, are the only known hexakispyridine complexes of chromium(II), although more could probably be obtained with $[BPh_4]^-$ and similar anions. The iodo complex $[CrI_2(3,5\text{-}Clpy)_2]$ was prepared by warming the tetrakis(amine) in acetone so that it lost two chloropyridine molecules, and $[CrI_2(3\text{-}Brpy)_2]$ was obtained by the use of 2,2-dimethoxypropane in acetone.

Attempts to isolate complex halides containing 2-methylpyridine produced blue substances, which could not be characterized.[93] Bridging iodide is less common than bridging chloride or bromide and the few chromium(II) iodo complexes, $[CrI_2(3\text{-}Brpy)_2]$, $[CrI_2(3\text{-}Ipy)_2]$ and $[CrI_2(3,5\text{-}Clpy)_2]$, might be expected to be tetrahedral. However, because of their antiferromagnetic behaviour, they are apparently linear polymers; tetrahedral monomers would be expected to have magnetic moments greater than 4.90 BM. The reflectance spectra of the iodo complexes are also similar to those of the corresponding bromides and chlorides and the molar absorbances are low ($\varepsilon \approx 30$ dm^3 mol^{-1} cm^{-1} in ethanol).[92]

Bands in the far IR spectrum of $[CrCl_2(py)_2]$ at 328 and 303 cm^{-1} were assigned[94] to ν(Cr—Cl), and a band at 219 cm^{-1} to ν(Cr—N), but in a reinvestigation[93] rather different frequencies (322vs, 281s and 215s cm^{-1}) were found. The band at 322 cm^{-1} has been assigned to ν(Cr—Cl) since it was absent from the spectrum of $[CrBr_2(py)_2]$. Instead, the bromide has an intense, broad and asymmetric band at 272 cm^{-1}, and strong absorption rising to a maximum at 200 cm^{-1}. It has therefore been suggested that ν(Cr—N) is at 281 cm^{-1} in the chloride, the band at 272 cm^{-1} for the bromide contains superimposed ν(Cr—N) and ν(Cr—Br) absorptions, and the band near 200 cm^{-1} corresponds to δ(N—Cr—N). These spectra were recorded only to 200 cm^{-1}, but the assignments are confirmed by investigations of $[CrX_2(Mepy)_2]$ (X = Cl, Br) and $[CrX_2(halo\text{-}py)_2]$ (X = Cl, Br, I), which show that ν(Cr—Cl) is near 320 cm^{-1}; ν(Cr—Br) and ν(Cr—N) sometimes overlap in the range 250–300 cm^{-1}, and, from a few examples, ν(Cr—I) is near 240 cm^{-1}. The ν(Cr—N) vibrations are generally at lower frequencies in the halopyridine complexes because of the greater mass of the amines (Table 13).[92,93]



The far IR spectra of $[CrX_2(Mepy)_4]$ (X = Cl, Br, I) do not differ significantly over the range 400–70 cm^{-1} except that the chlorides have two bands in the region of 136 cm^{-1} which may be due to 'long-bonded' ν(Cr—Cl) vibrations, *i.e.* in these complexes the halide ions lie along the elongated tetragonal axis.

The reflectance spectra show the usual two band pattern of distorted six-coordinate, high-spin chromium(II).

The complexes $[CrCl_2(py)_2]$ and $[Cr(CF_3SO_3)_2(py)_4]$ have been used in the preparation of macrocyclic complexes of Cr^{II} and Cr(NO) (Section 35.3.10.2 and Table 64).

The chromium(II) ion is in an uncommon *trans* planar environment (**6**) in bis(2,6-dimethylpyridine)bis(trifluoroacetato)chromium(II), which is prepared by the reaction sequence in

Scheme 11. Each ligand is monodentate and the methyl groups of the 2,6-Mepy molecules above and below the CrO_2N_2 plane block further coordination.[95]

(6)

$$CrCl_3 \xrightarrow{NaBH_4} [(THF)Cr(BH_4)_2] \xrightarrow{CF_3CO_2H} [(THF)Cr(O_2CCF_3)_2]_2 \xrightarrow{2,6\text{-Mepy}} [Cr(O_2CCF_3)_2(2,6\text{-Mepy})_2]$$

Scheme 11

Thermal decomposition of $[CrBr_2(H_2O)_2py_2]$ takes place[96] according to reactions (7) to (9).

$$[CrBr_2(H_2O)_2(py)_2]\,(cryst.) \longrightarrow [CrBr_2(py)_2]\,(cryst.) + 2H_2O\,(g) \quad (7)$$

$$[CrBr_2(py)_2]\,(cryst.) \longrightarrow [CrBr_2(py)]\,(cryst.) + py\,(g) \quad (8)$$

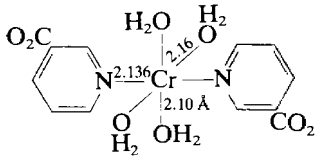
$$[CrBr_2(py)]\,(cryst.) \longrightarrow CrBr_2\,(cryst.) + py\,(g) \quad (9)$$

$[CrI_2(py)_4]$ was found to lose two pyridine molecules to give $[CrI_2(py)_2]$, with the loss of further pyridine not beginning until 237 °C, but it was not possible to distinguish the stepwise loss of the remaining two ligands.

The heat of reaction for the removal of $2H_2O$ from $[CrBr_2(H_2O)_2(py)_2]$ ($\Delta H = 117.5$ kJ mol^{-1}) is close to that for the removal of 2py from $[CrI_2(py)_4]$, suggesting H_2O and pyridine form bonds of similar strength.

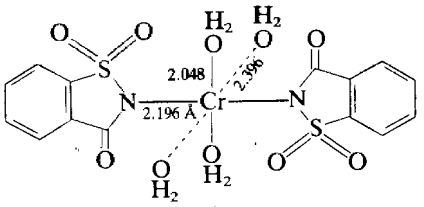
Values of ΔH for the loss of two pyridine molecules from $[CrX_2(py)_2]$ are 148.4, 132.1 and 103.7 kJ mol^{-1}, for X = Cl, Br and I respectively. The value for $[CrCl_2(py)_2]$ is greater than those for $[MCl_2(py)_2]$ where M = Mn through Cu. The chloride decomposes according to equations (8), (10) and (11).

$$[CrCl_2(py)]\,(cryst.) \longrightarrow [CrCl_2(py)_{2/3}]\,(cryst.) + \tfrac{1}{3}py\,(g) \quad (10)$$



$$[CrCl_2(py)_{2/3}]\,(cryst.) \longrightarrow CrCl_2\,(cryst.) + \tfrac{2}{3}py\,(g) \quad (11)$$

(*ii*) *Nicotinic acid and saccharine*

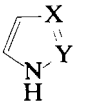


Nicotinic acid (nic) forms a series of complexes $[M^{II}(nic)_2(H_2O)_4]$ in which it is N-bonded. The yellow, crystalline chromium(II) complex is prepared by running an aqueous Cr^{2+} solution into a nicotinic acid solution under hydrogen. It is air-stable and the analyses were consistent with $[Cr^{III}(nic)_2(H_2O)_3OH]$ or $[Cr^{II}(nic)_2(H_2O)_4]$, but the molecular structure (**7**) agrees with the chromium(II) formulation. The complex has a magnetic moment (3.1 BM) corresponding to low-spin chromium(II), which is unexpected since the complexes $[CrX_2(py)_4]$ are high-spin (Section 35.3.3.4.i above), and two bipy or phen molecules are necessary to cause spin pairing (Section 35.2.2.1).* This complex was prepared in an investigation of chromium(III) nicotinic acid complexes related to the glucose tolerance factor (Section 35.4.8.3). The X-ray powder patterns and IR spectra of the complexes $[M^{II}(nic)_2(H_2O)_4]$ in general are closely similar to those of the Cr^{II} complex.[97]

Saccharine forms a similar series of complexes $[M^{II}(C_7H_4NO_3S)_2(H_2O)_4]\cdot 2H_2O$. The chromium(II) complex is yellow and has a *trans* structure (**8**) analogous to that of

* Found later to be contaminated with isomorphous Zn^{II} complex; Cr—N = 2.128, Cr—O, two at 2.039, two at 2.471 Å (W. E. Broderick, M. R. Pressprich, U. Geiser, R. D. Willet and J. I. Legg, *Inorg. Chem.*, 1986, **25**, 3372).

(7)



(8)

$[Cr(nic)_2(H_2O)_4]$ (**7**), but with the effect of Jahn–Teller distortion apparent in the Cr—O distances (Table 34).[98]

(*iii*) *Pyrazoles and imidazoles*

Complexes of imidazole (iz),[99,100] *N*-methylimidazole (Nmiz), pyrazole (pz), 3,5-dimethylpyrazole (dmpz),[99] 3(5)-methylpyrazole (5Mepz), 1-methylpyrazole (NMepz), 2-methylimidazole (2Meiz) and 1-ethylimidazole (NEtiz)[101] (**9**) have been prepared from ethanol or butanol by methods resembling those in Scheme 10. As with the analogous pyridine complexes, those of the general formula $[CrX_2L_4]$ are high-spin, tetragonally distorted, six-coordinate complexes, and those of the formula $[CrX_2L_2]$ are also six-coordinate, but are antiferromagnetic halide-bridged polymers; 2-methylimidazole, however, forms cations which are probably square pyramidal: $[CrX(2Meiz)_4]X$ (X = Cl, Br), $[Cr(2Meiz)_5](BPh_4)_2$ and $[Cr(NCS)_2(2Meiz)_2]$ (Table 14). In the last complex five-coordination (Table 42) is believed to be achieved through NCS bridges.The reduction of chromium(III)–imidazole complexes at the dropping mercury electrode has been studied (Section 35.4.2.5.iii).

(**9**) X = N, Y = CH, imidazole
X = CH, Y = N, pyrazole

A pale blue-green complex $[CrCl_2(PMT)_2]$ ($\mu_{eff}^{297\,K} = 4.55$ BM) of pentamethylenetetrazole (PMT) has been obtained by the addition of solid PMT in excess to a solution of hydrated chromium(II) chloride in a 50% DMP/MeOH mixture.[102] Pyrazines and Cr^{2+} give intensely coloured 'pyrazine green' products (Section 35.4.2.5.iv).

(*iv*) *Bidentate ligands: bipyridyls, phenanthrolines, 2-aminomethylpyridine, 8-aminoquinoline and adenine*

Chromium(II) complexes of bipyridyls, terpyridyl and the phenanthrolines have been discussed in Section 35.2.2.1. Complexes of the ligands 2-aminomethylpyridine (pic, 2-picolylamine) and 8-aminoquinoline (amq), which have one heterocyclic and one amino nitrogen donor atom, have been prepared by methods similar to those in Scheme 10. The bis(amine) complexes are typical high-spin, distorted octahedral complexes, and the mono(amine) complexes, from their antiferromagnetic behaviour and reflectance spectra, are six-coordinate, halide-bridged polymers (Table 15).[103] No tris(amine) complexes could be prepared so the attempt to find spin isomeric systems in octahedral chromium(II) systems was unsuccessful ($[Cr(en)_3]X_2$ are high-spin and $[Cr(bipy)_3]X_3$ and $[CrX_2(bipy)_2]$ low-spin).

Complexes of adenine (**10**; Ade) have been isolated by mixing the ligand in 2-methoxyethanol with chromium(II) halides in butanol. The low magnetic moments (Table 16)[104] indicate dinuclear species $[Cr_2X_2(Ade)_4^{2+}]$ (Section 35.3.5.5), or polynuclear structures with bidentate adenine.

(*v*) *Bi-, tri- and tetra-dentate pyrazolyl-substituted ligands*

Chromium(II) complexes of the ligands 1,1′-methylenedipyrazole (**11**; H_2Cpz_2), 1,1′-methylenebis(3,5-dimethylpyrazole) (**12**; H_2Cdmpz_2), tris(1-pyrazolyl)methane (**13**; $HCpz_3$),[105] tris(1-pyrazolylethyl)amine (**14**; R = H, TPyEA)[106,107] and tris(3,5-dimethyl-1-pyrazolylethyl)amine

(**14**; R = Me, MeTPyEA) have been isolated from non-aqueous solvents (Table 17).[105–108] From their electronic spectra, simple paramagnetic behaviour and stoichiometry $[CrCl(H_2Cdmpz_2)_2]BF_4$, $[CrX(H_2Cdmpz_2)_2]BPh_4$ and $[CrX(H_2Cdmpz_2)_2]X$ (X = Br, I) are thought to be five-coordinate. The spectra differ from those of distorted six-coordinate or square pyramidal chromium(II) complexes and, except for intensity differences, resemble those of other trigonal bipyramidal chromium(II) complexes. Conductance and solution spectra suggest that the trigonal bipyramidal cations are present in solution too. From similar evidence $[CrX(MeTPyEA)]BPh_4$ (X = Br, NCS) contain square pyramidal cations.[108] The blue complex $[CrNCS(TPyEA)]BPh_4$, dissolved in acetone or acetonitrile, is oxidized very rapidly by air to give a green solution from which the μ-oxo chromium(III) complex $[\{Cr(NCS)(TPyEA)\}_2O](BPh_4)_2$ crystallizes (Section 35.4.2.5.iv).[107] The remaining complexes are mostly high-spin six-coordinate complexes with temperature-independent magnetic moments, but in a few, *e.g.* $[CrCl_2(H_2Cpz_2)]$ and $[CrBr(TPyEA)]BPh_4$, the halide bridges needed to produce six-coordination lead to weak antiferromagnetism.

Table 17 Complexes of Pyrazolyl-substituted Ligands

Complex		μ_{eff} (BM)		*Reflectance spectra* (cm^{-1})

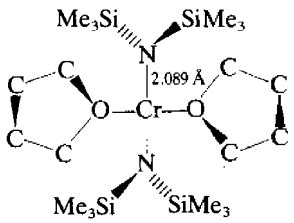
35.3.3.5 Nitrosyls and hydrazine

Nitrosyls are discussed in Section 35.4.2.6, and hydrazine is the only ligand of its type from which chromium(II) complexes have been prepared.

(*i*) *Hydrazine*

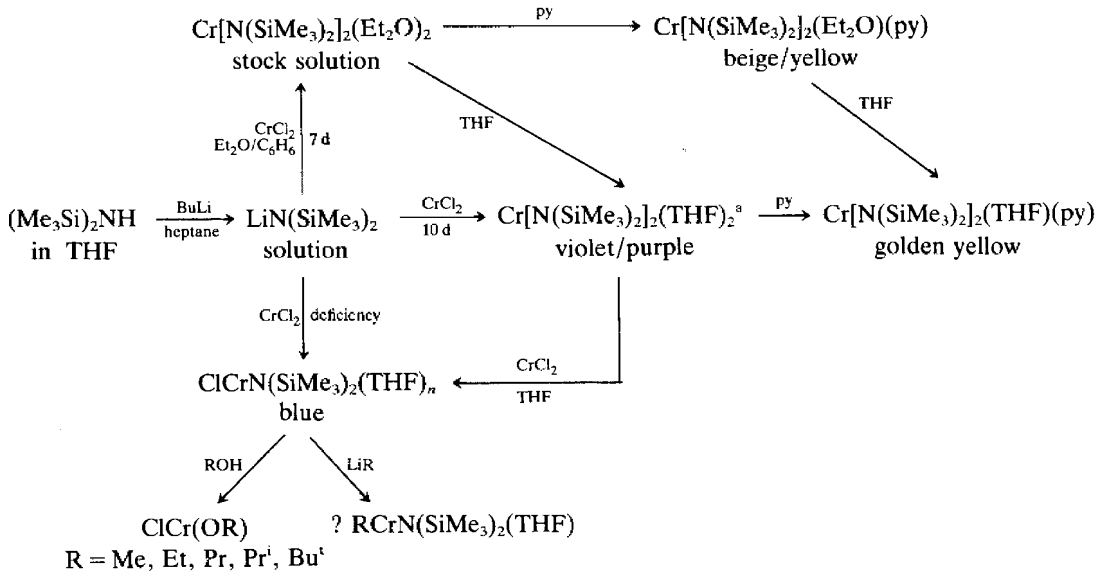


The pale blue complexes $[CrX_2(N_2H_4)_2]$ (X = Cl, Br or I), which are reasonably stable to dry air, separate rapidly when an excess of hydrazine is added to an aqueous solution of the appropriate halide.[109] The chloride has also been prepared by the addition of hydrazine to a solution of $[CrCl_2(H_2O)_4]Cl$ reduced with Na/Hg.[110] The complexes have been assigned the polymeric structure (**15**) because the IR spectra are almost identical to those of analogous complexes with crystallographically determined structures. The reflectance spectra (absorption bands at *ca.* 17 500s and 11 000m cm^{-1}) are independent of the halide ion suggesting that these lie along the distortion axis, and the magnetic moments show little temperature variation, consistent with weak antiferromagnetic interaction arising from hydrazine rather than halide bridges. The reaction of CrF_2 with N_2H_4 gives unstable and impure $[CrF_2(N_2H_4)_2]$.[111]

(**15**)

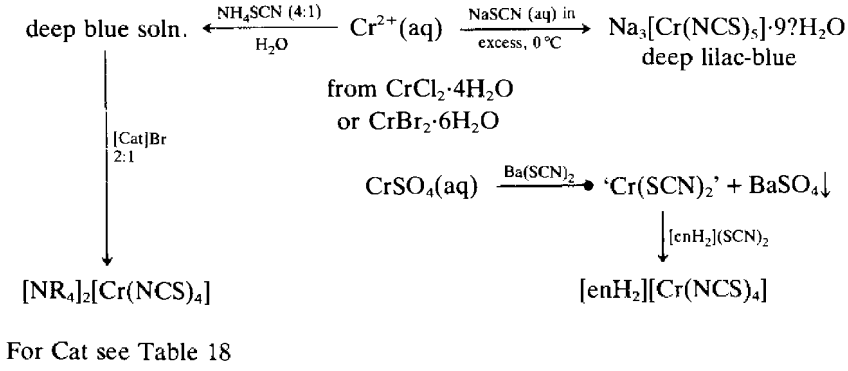
35.3.3.6 Dialkylamides and disilylamides

The disproportionation of chromium(III) dialkylamides, *e.g.* $[Cr(NEt_2)_3]$ into $[Cr^{IV}(NEt_2)_4]$ and $[Cr^{II}(NEt_2)_2]$, has been used to prepare several chromium(IV) dialkylamides (Section 35.5.4.3) but pure chromium(II) dialkylamides have not been obtained by this procedure. In fact, detailed work is restricted to silylamide derivatives. The first, $[Cr\{N(SiMe_3)_2\}_2(THF)_2]$, is *trans* planar (**16**), an uncommon stereochemistry (Table 41) for chromium(II); and it has a magnetic moment of 4.93 BM at 298 K.[112] Other presumably planar complexes in which one or more THF molecules are replaced by other bases are exemplified in Scheme 12. Some solids, *e.g.* $[Cr\{N(SiMe_3)_2\}_2(Et_2O)_2]$, decompose even in an inert atmosphere, but solutions in organic solvents are stable for several weeks so dietherate solutions especially were used in other reactions. The compounds were characterized by analyses and reflectance spectra, and it was necessary to use carefully prepared anhydrous $CrCl_2$ in the preparations. The reflectance spectra were not assigned and no magnetic measurements were reported.[113]



(**16**)

The nitrosyl $[Cr(NO)\{N(SiMe_3)_2\}_3]$ is diamagnetic and has a pseudotetrahedral structure (**135**). It can be formally considered to contain Cr^{II} and NO^+ ($\nu(NO) = 1698\ cm^{-1}$) and is the only example of a crystallographically confirmed tetrahedral Cr^{II} compound (Section 35.4.2.6).[112]



35.3.3.7 Thiocyanates

The deep blue solutions produced on the addition of thiocyanates to aqueous Cr^{2+} decompose on standing or concentration. Nevertheless, thiocyanato complexes can be

[a] Also $Cr[N(SiMe_3)_2]_2L_2$, L = Bu^{t}CN, 1,3-dimethoxyethane, *etc.*

Scheme 12

For Cat see Table 18

Scheme 13

crystallized if the cations are Na^+ (but not NH_4^+, K^+, Cs^+ or Ba^{2+}) or various substituted ammonium ions (Scheme 13).

The pentathiocyanato complex $Na_3[Cr(NCS)_5]\cdot 9\text{–}11H_2O$ is thought from its magnetically dilute behaviour and IR and electronic spectra to contain N-bonded NCS groups in a square pyramid around the metal ion with a water molecule possibly in the sixth position. With organic cations, tetrathiocyanatochromium(II) salts crystallize, and several were isolated in two forms dependent upon the experimental procedure: NBu_4^+, brown or blue; and with or without ethanol $hexH^+$, NEt_4^+ and NPr_4^+. One of each pair of complexes, and all the complexes which were obtained in one form only, are antiferromagnetic since their magnetic moments are below the spin-only value and are temperature-dependent. Thiocyanato-bridged structures have been proposed and this is compatible with the complexity of the ν(CN) absorptions and reflectance spectra. Dissolved in acetone, both NBu_4^+ salts and the NMe_4^+ salt give high-spin magnetic moments showing that the low moments of the solids arise from intermolecular antiferromagnetism. Tetrahedral anions are excluded by the low extinction coefficients. Those which are magnetically dilute *i.e.* $[hexH]_2[Cr(NCS)_4]$, $[NEt_4]_2[Cr(NCS)_4]\cdot EtOH$, $[NPr_4]_2[Cr(NCS)_4]\cdot EtOH$ and brown $[NBu_4]_2[Cr(NCS)_4]$, probably have planar $[Cr(NCS)_4]^{2-}$ anions with bridging prevented by the cations or coordinated EtOH molecules (Table 18).[114]

The tetragonally distorted ion $[Cr(NCS)_6]^{4-}$ has been identified in molten KSCN,[114] and a few mixed ligand complexes containing thiocyanate are known (Sections 35.2.2.1, 35.3.3.4 and 35.3.10.2). Thiocyanate will displace H_2O from $[Cr_2(O_2CMe)_4(H_2O)_2]$ (p. 746).

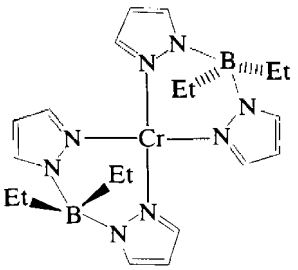
35.3.3.8 Polypyrazolylborates and carboranes

On the addition of anhydrous $CrBr_2$ dissolved in warm ethanol to a warm solution of the $[NEt_4]^+$ salt of the appropriate polypyrazolylborate (**17**) in the same solvent, crystals of the complexes $[Cr\{H_nB(pz)_{4-n}\}_2]$ ($n = 0$, 1 or 2 appear) (Table 19).[115] These are moderately air-stable, and the ethyl derivative $[Cr\{Et_2B(pz)_2\}_2]_2$, which was obtained from $[Cr_2(O_2CMe_2)_4]$ and $Na\{Et_2B(pz)_2\}$ in THF on which hexane was layered to induce crystallization, is stable to air.[116] An indazole (a 4,5-substituted pyrazole) derivative $[Cr(H_2B\{4,5\text{-}(5\text{-}NO_2benzo)pz\}_2)_2]$ is also known (Table 19). The isolation of $[Cr\{HB(pz)_3\}_2]$ and $[Cr\{B(pz)_4\}_2]$ from aqueous solution[117] could not be repeated.[115]

(**17**) $B(pz)_4^-$ ($n = 0$), $HB(pz)_3^-$ ($n = 1$), $H_2B(pz)_2^-$ ($n = 2$)



The complexes $[Cr\{HB(pz)_3\}_2]$ and $[Cr\{B(pz)_4\}_2]$ are high-spin, with similar reflectance and solution spectra indicative of distorted octahedral structures, which implies that $B(pz)_4^-$ is acting as a tridentate ligand. Both $[Cr\{H_2B(pz)_2\}_2]$[115] and $[Cr\{Et_2B(pz)_2\}_2]$ (**18**)[116] are planar, the latter with the Et groups positioned protectively over the Cr^{II} atoms. This stereochemistry is unusual for Cr^{II} (Table 41), and the extreme distortion is manifest in the reflectance spectrum of $[Cr\{H_2B(pz)_2\}_2]$, which has a band at 20 500 cm^{-1}, much further to high wavenumber than its less distorted six-coordinate analogues, and an ill-defined absorption at 11 000 cm^{-1}.

(18)

Magnetic data for the low-spin, air-stable chromium(II) metallocarborane sandwich[118] compound $[NEt_4]_2[Cr(C_2B_{10}H_{12})_2]$ have been compared with those for chromocene.

35.3.3.9 Nitriles

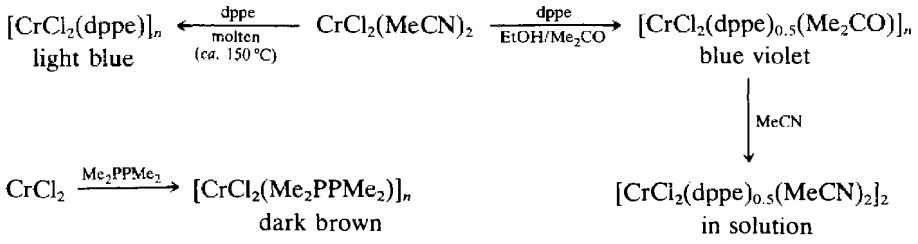
The acetonitrile complexes $[CrX_2(MeCN)_2]$ (X = Cl, Br or I) may be planar or tetrahedral monomers or halide-bridged polymers, and there is no clear evidence. The chloride and bromide are high-spin at room temperature, but variable temperature studies have not been carried out; the reflectance spectra are very similar, and typical of Cr^{II} in six-coordination presumably achieved through bridging halide. The much higher wavenumber of the main band in the spectrum of $[CrI_2(MeCN)_2]$ must be due to greater distortion suggestive of a planar structure (Table 20).[119] The addition of tetraalkylammonium halides to solutions of the chloride and bromide in acetonitrile and ethanol causes shoulders at *ca.* 10 000 cm^{-1} to be replaced by moderately intense bands ($\varepsilon \approx 45$ $dm^3\,mol^{-1}\,cm^{-1}$), which were thought to be due to the formation of distorted tetrahedral anions $[CrX_4]^{2-}$. In view of the results in Section 35.3.7.3 it is likely that the changes are due to the formation of *trans*-$[CrX_4(solvent)_2]^{2-}$ species.

The complexes $[Cr(MeCN)_4](BF_4)_2$ and $[Cr(MeCN)_6](BF_4)_2$ have been prepared electrolytically (Table 20).[82]

35.3.4 Phosphorus and Arsenic Ligands

35.3.4.1 Mono- and bi-dentate P donor ligands

Strongly basic aliphatic tertiary phosphines form blue solutions with CrX_2 (X = Cl or Br) in benzene or xylene and it is believed that the equlibrium (12) is set up.



$$\underset{\text{blue}}{[CrCl_2(PR_3)_2]} \rightleftharpoons \underset{\text{white}}{[CrCl_2(PR_3)]} + PR_3\ (R = Et, Pr, Bu) \qquad (12)$$

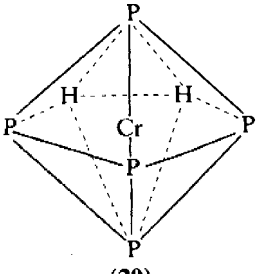
[a] ε ($dm^3\ mol^{-1}\ cm^{-1}$).

The only solid isolated was white $[CrCl_2(PEt_3)]_n$, and the system is difficult to handle.[120] A related complex $[CrCl_2(PMe_3)_3]$ has been suggested as an intermediate (Section 35.2.3.1). Greater success has been achieved with PMe_2Ph in hexane since the complexes $[CrX_2(PMe_2Ph)_2]$ have been prepared with good analyses and magnetic susceptibilities approximating to high-spin chromium(II).[121] Polymers containing dppe and tetramethyldiphosphine have been prepared from $[CrCl_2(MeCN)_2]$ or $CrCl_2$ (Scheme 14); these phosphines also combine with coordinatively unsaturated Cr^{II} in a silica surface.[122] Chromium(II) surface compounds have catalytic activity and can be used for gas purification *etc.*[123] The complex $[CrCl_2\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ has been formed electrochemically in MeCN but not isolated, and the Cr^{3+}/Cr^{2+} potential determined.[124]



Scheme 14

The reactions of $[CrCl_2(dmpe)_2]$, from which $[Cr(N_2)_2(dmpe)_2]$ is prepared, are given in Scheme 8, Section 35.2.3.1. Included in Scheme 8 are the dimethyl compound, *trans*-$[CrMe_2(dmpe)_2]$ (**19**), which is an unusual Cr^{II} alkyl (others are the diamagnetic, quadruply bonded species in Section 35.3.5.5), and the hydride $[CrH_4(dmpe)_2]$, which is the first example of eight-coordinate Cr^{IV} (Section 35.5). The tetrahydride is diamagnetic, and the coordinated hydrogen appears as a binomial quintet in the ^1H NMR spectrum, in agreement with a dodecahedral structure.[59]

(**19**)

(**20**)

The chromium(II) hydride $[CrH_2\{P(OMe)_3\}_5]$ is fluxional and the seven-coordinate structure (**20**) is likely from an analysis of the ^{31}P and ^1H NMR spectra (Table 21).[125]

Some mixed ligand complexes with organic isocyanides are given in Table 3.

35.3.4.2 o-Phenylenebis(dimethylarsine)

Diarsine forms the low-spin, *trans* octahedral chromium(II) complexes $[CrX_2(diars)_2]$ (X = Cl, Br, I); the magnetic moments are in the range 2.85 to 2.99 BM and independent of temperature (84–298 K). Reflectance spectra have been recorded, but no assignments made.[40]

35.3.4.3 Tetradentate 'tripod' ligands

A few five-coordinate complex cations, apparently of trigonal bipyramidal stereochemistry, are known. These contain coordinated halide and a tripod-like quadridentate ligand, which can be a P, mixed P,N or N donor: $[CrX\{P(CH_2CH_2PPh_2)_3\}]^+$, $[CrX\{P(2\text{-}C_6H_4PPh_2)_3\}]^+$, $[CrX(N\{CH_2CH_2P(C_6H_{11})_2\}_3)]^+$, $[CrX\{N(CH_2CH_2PPh_2)_3\}]^+$, $[CrBr\{N(CH_2CH_2PPh_2)(CH_2CH_2NEt_2)_2\}]^+$ and $[CrBr\{N(CH_2CH_2NMe_2)_3\}]^+$.[40,126–128] To prepare the complexes, the anhydrous chromium(II) halide in butanol or ethanol is added to the ligand in the same solvent or in 1,2-dichloromethane, and the cations isolated as BPh_4 or PF_6 salts (Table 22). Attempts to prepare complexes of $N(CH_2CH_2AsPh_2)_3$[127] and the linear quadridentate ligand $(—CH_2PPhCH_2CH_2PPh_2)_2$[40] have not succeeded.

The complexes are high-spin. As $[CrBr\{N(CH_2CH_2NMe_2)_3\}]Br$ is isomorphous with its trigonal bipyramidal cobalt(II) analogue, this stereochemistry is suggested for the chromium(II) complex too.[128] In the cobalt(II) complex the bromide lies along the three-fold axis and the symmetry is C_{3v} rather than D_{3h}.[129] All complexes are 1:1 electrolytes, and there are close resemblances between the solution (1,2-$C_6H_4Cl_2$) and reflectance spectra, which consist of a broad intense band with a shoulder or less intense band to higher frequency; thus the five-coordinate structures are retained in solution. The electronic bands are assigned to the $^5A_1' \rightarrow {}^5E'$ and $^5A_1' \rightarrow {}^5E''$ transitions. The bands are to higher wavenumber in the spectra of the phosphine complexes, which also exhibit extinction coefficients many times greater than those

of $[CrBr\{N(CH_2CH_2NMe_2)_3\}]Br$, presumably because of the greater covalent character of the Cr—P bonds. The electronic spectrum of this last compound is quite different from those containing CrN_6 or CrX_2N_4 chromophores (Section 35.3.3.2), and square pyramidal structures would be expected to produce electronic spectra resembling those of the CrX_2N_4 chromophore; thus the trigonal bipyramidal structures are well established, although not yet confirmed in detail crystallographically. Other five-coordinate species are given in Table 42.

35.3.5 Oxygen Ligands

35.3.5.1 Aqua complexes

(i) Hydrated chromium(II) salts

Hydrated chromium(II) salts can be prepared by the methods in Section 35.3.1.2. They are high-spin and magnetically dilute except for the monohydrogen phosphate, which is weakly antiferromagnetic (Table 23).[130,131] The fluoride $CrF_2{\cdot}2H_2O$ has been little studied.[85] The reflectance spectra are typical of Cr^{II} in distorted six-coordination. Only one crystal structure determination has been reported, that of $CrCl_2{\cdot}4H_2O$; there are four normal length Cr—O bonds to water molecules in a square plane, and two long *trans* Cr—Cl bonds (Table 34).[132] Chromium(II) sulfate pentahydrate is isomorphous with $CuSO_4{\cdot}5H_2O$, and the parameters $D = 2.24\,cm^{-1}$, $E = 0.10\,cm^{-1}$, $g_x = g_y = 2.00$, $g_z = 1.96$ gave the best fit to its ESR spectrum.[133]

Aqueous Cr^{2+} solutions have a broad asymmetric absorption at $14\,000\,cm^{-1}$ and a weak shoulder at $9500\,cm^{-1}$ due to tetragonally distorted $[Cr(H_2O)_6]^{2+}$ ions.[131]

(*ii*) *Hydrated double sulfates*

Chromium(II) double sulfates can be crystallized by the addition of ethanol to concentrated aqueous solutions containing equimolar quantities of the components. The hexahydrates $A_2SO_4 \cdot CrSO_4 \cdot 6H_2O$ (A = NH_4, Rb or Cs) are high-spin and have reflectance spectra compatible with the presence of tetragonally distorted $[Cr(H_2O)_6]^{2+}$ ions (Table 24).[134] The potassium and sodium salts crystallize as pale blue dihydrates with similar properties, and from the splittings of the SO_4^{2-} absorption bands in their IR spectra it seems that coordinated sulfate anions are present.

Table 24 Double Sulfates

$(N_2H_5)_2SO_4 \cdot CrSO_4 \cdot H_2O$	Blue	4.89		5		

The cesium salt is unusual; it loses water readily at room temperature in vacuum or over P_4O_{10} to give a violet dihydrate. This dihydrate has a very low magnetic moment and its IR spectrum contains bands exactly as expected for bidentate sulfato groups. Consequently, it is proposed that the violet dihydrate has a sulfato-bridged dinuclear structure analogous to that of $[Cr_2(O_2CMe)_4(H_2O)_2]$ (Section 35.3.5.5). Complete dehydration affords dark blue $Cs_2SO_4 \cdot CrSO_4$.

Hydrated and anhydrous chromium(II) hydrazinium sulfates $(N_2H_5)_2Cr(SO_4)_2$ are known. They are air-stable, and in the latter (from isomorphism with the Zn^{II} complex) each metal ion is coordinated to the nitrogen atoms of two hydrazinium ions and four O atoms of bridging sulfato anions.[135]

35.3.5.2 Alcohols, alkoxides and aryloxides

(i) Alcohols

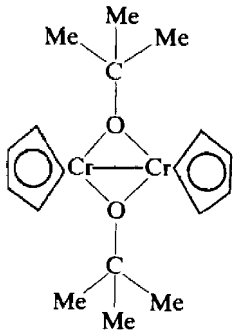
Anhydrous and hydrated chromium(II) halides are soluble in alcohols, and these are useful reaction media. The hydrated halides can be dehydrated by heating with 2,2-dimethoxypropane or triethyl orthoformate and alcoholates remain on removal of the solvent, but none have been characterized. The spectra of $CrCl_2$ in EtOH and MeOH have been recorded.[136]

(ii) Alkoxides and aryloxides

Many alkoxides have been prepared by alcoholysis of $[Cr\{N(SiMe_3)_2\}_2(THF)_2]$ and similar compounds (Section 35.3.3.6). The general reaction is represented by equation (13), in which L and L′ are Et_2O, THF, py or Bu^tCN or various combinations of them, and ROH is an alcohol or a phenol [R = Me, Et, Pr, Pr^i, Bu^n, Bu^s, Bu^t, C_5H_{11}, CHMePr, $CHEt_2$, 1-adamantyl, CEt_3, CPh_3, Ph, 2,6-Ph$(Bu^t)_2$, 2,4,6-Ph$(Bu^t)_3$ and 2,4,6-Ph(Ph_3)]. The solvent can be a hydrocarbon, Et_2O, THF or a mixture of these. Some complexes of the type $[Cr(OR)_2(ROH)]$ were obtained from the phenols and the alcohols with bulky aliphatic groups. It is necessary to dry the alkoxides carefully to obtain materials free from solvent. Alkoxides containing branched alkyl chains and aromatic groups show reasonable solubility in organic solvents, but the alkoxides of primary alcohols are insoluble.[137]

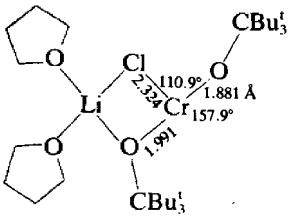
$$Cr\{N(SiMe_3)_2\}_2(L)(L') + 2ROH \xrightarrow[\text{solvent}]{25\,^\circ C} Cr(OR)_2 + 2HN(SiMe_3)_2 + L + L' \qquad (13)$$

Many alkoxides have been prepared from chromocene in THF or hydrocarbons (equation 14). Only partial replacement of cyclopentadienyl by R occurs with Me_3COH and silanols (equation (15)).



$$[Cr(C_5H_5)_2] + 2ROH \longrightarrow [Cr(OR)_2]_x + 2C_5H_6 \qquad (14)$$

R = Me, Et, Pr, Pr^i, Bu^n, Bu^i;[138] R = Me, Et, Pr^i, Me_3CCH_2 [139]

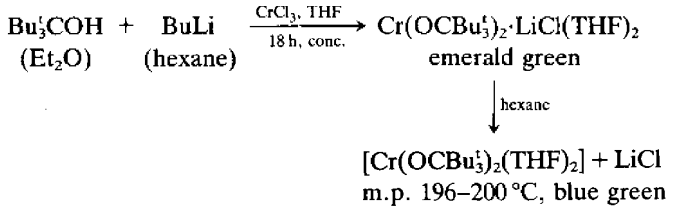


$$[Cr(C_5H_5)_2] + ROH \longrightarrow \tfrac{1}{2}[Cr(C_5H_5)(OR)]_2 + C_5H_6 \qquad (15)$$

$R = Bu^t$, Me_3Si, Ph_3Si[139]

The product from Bu^tOH is an antiferromagnetic, butoxy-bridged dimer (**21**) with a non-planar central $(Cr—\mu\text{-}O)_2$ moiety and a Cr—Cr separation of 2.65 Å. The magnetic properties (μ_{eff} = 1.88 BM at 333.5 K) suggest that there is one unpaired electron per metal atom. It is thought that the compound may contain a Cr—Cr single bond. The dimer structure is preserved by reaction with CO, NO and $CF_3C{\equiv}CCF_3$ but with CO_2 in THF, $[Cr(C_5H_5)_2]$ and $[Cr_2(O_2CBu^t)_4(THF)_2]$ (Cr≡Cr-bonded, Section 35.3.5.5) are formed. Antiferromagnetic interaction has been found in $Cr(OMe)_2$ (prepared from $CrCl_2$ and LiOMe in MeOH as well as from chromocene) and other alkoxides, and polymeric O-bridged structures have been proposed.[140]

(21)



(22)

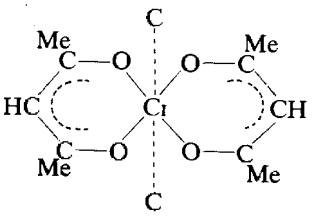
When the more sterically hindered alkoxides dissolve in donor solvents such as THF, adducts $[Cr(OR)_2(THF)_2]$ form and these are probably *trans* planar like $[Cr\{N(SiMe_3)_2\}_2(THF)_2]$. There are considerable colour variations among the alkoxides and their adducts, so there must

be considerable structural differences imposed by the different R groups. The magnetic and spectroscopic properties have not been investigated in any detail.[137]

The complex $[Cr(OCBu^t_3)_2 \cdot LiCl(THF)_2]$, which was obtained according to Scheme 15,[77] has a unique structure. The metal ion is three-coordinate, and the donor atoms outline a distorted T (**22**). It is not obvious how the reduction occurs because the BuLi is added in stoichiometric quantity to the alcohol and this solution then added to the $CrCl_3$ suspension. Since LiCl is eliminated on the addition of hexane to give $[Cr(OCBu^t_3)_2(THF)_2]$, Scheme 15 may provide a simpler route to chromium(II) alkoxides than that from the very air- and moisture-sensitive complex $[Cr\{N(SiMe_3)_2\}_2(THF)_2]$.

Scheme 15

On addition to halogenated solvents the alkoxides give intensely coloured solutions, stable to oxygen and believed to contain Cr^{III}—C species.[137]



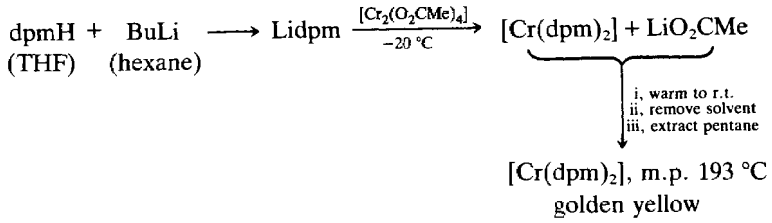
The μ-oxoalkoxide $[Cr\{OAl(OPr^i)_2\}_2]$ dissolves in benzene and cyclohexane to give blue solutions in which it is associated.[141]

35.3.5.3 β-Ketoenolates, tetrahydrofuran, ureas and biuret

(i) β-Ketoenolates

Complexes of acetylacetone (acacH), benzoylacetone (bzacH) and dipivaloylmethane (dpmH) have been reported. The acetylacetonate $[Cr(acac)_2]$ has been prepared from chromium(II) acetate and acetylacetone.[142,143] It can also be obtained by the addition of aqueous sodium acetylacetonate to an aqueous solution of chromium(II) chloride, but in any preparation the yellow solid must be filtered off and dried as rapidly as possible, otherwise the chromium(III) compound is obtained. Its magnetic moment is 4.99 BM at room temperature consistent with a high-spin d^4 configuration.[142] The powerful reducing ability of $[Cr(acac)_2]$ has been used to prepare iron(II) and chromium(II) complexes[80] of porphyrins and related ligands.

On slow sublimation[144] of $[Cr(acac)_2]$ a mixture of separate purple and light brown crystals was obtained. The cell constants of the former showed them to be $[Cr(acac)_3]$, and the latter were $[Cr(acac)_2]$. In the chromium(II) complex the metal atom lies on an inversion centre and has rigorously planar coordination to four oxygen atoms at a mean Cr—O distance of 1.98 Å (Table 41). Methine carbon atoms of adjacent molecules lie at 3.05 Å above and below the CrO_4 plane so that there is severely tetragonally distorted octahedral coordination of the chromium atom (**23**). At this distance there cannot be much Cr—C σ-bonding. Chromium(II), copper(II) and palladium(II) acetylacetonates are isomorphous. It is presumably the weak axial interactions that lead to the poor solubility of the essentially planar $[Cr(acac)_2]$, but the structure is very different from that found in other metal(II) acetylacetonates, which are trimers (Ni, Zn) or tetramers (Co) with bridging anions coordinated by oxygen atoms.



(**23**)

The benzoylacetonato complex is known only as the black bis(pyridine) adduct $[Cr(bzac)_2(py)_2]$, which crystallizes when a mixture of the ligands in acetone is added to

aqueous chromium(II) acetate.[145] It is a low-spin $3d^4$ compound: $\mu_{eff} \approx 3.2$ BM independent of temperature over the range 295 to 90 K. The IR spectra of the Cr^{II}, Ni^{II} and Zn^{II} complexes are almost identical and they are considered to have *trans* octahedral structures.

$[Cr(dpm)_2]$ is prepared from anhydrous chromium(II) acetate in strictly air- and water-free conditions according to Scheme 16.[146] Attempts to prepare the monothio analogue were unsuccessful. There is no absorption band below 23 000 cm^{-1} in the mull spectrum of $[Cr(dpm)_2]$, although the spectrum of a toluene solution has a weak shoulder at 16 500 cm^{-1} ($\varepsilon \approx 12$ dm^3 mol^{-1} cm^{-1}) as well as a band at 23 000 cm^{-1} superimposed on a more intense band in the UV region. It is high-spin ($\mu_{eff}^{292\,K} = 4.84$ BM in toluene), but the spectrum is quite different from high-spin complexes such as $[CrX_2(en)_2]$ (Section 35.3.3.2) in which there is moderate tetragonal distortion. This is because $[Cr(dpm)_2]$ is planar, it is isomorphous with planar $[Ni(dpm)_2]$, and the extreme distortion has caused the *d–d* transitions to move to high frequency where metal-to-ligand charge transfer transitions occur. There appears to be no theoretical study of the spectra to be expected for high-spin, planar chromium(II).

Scheme 16

(*ii*) *Tetrahydrofuran*

Adducts of chromium(II) halides with tetrahydrofuran $[CrX_2(THF)_2]$ can be prepared by extraction of $CrCl_2$ with the hot solvent,[147] and by crystallization from solutions of $CrBr_2$ in THF[148] (Table 25). The latter method did not give solvates of reproducible composition with CrI_2 or $CrCl_2$. When dry hydrogen chloride is bubbled through THF over an excess of chromium, the metal dissolves with evolution of hydrogen to give a mauve solution (Cr^{III} spectrum). When the passage of HCl is stopped and the mixture heated to 65–70 °C, evolution of hydrogen from residual metal and dissolved HCl continues and the solution becomes bright blue (Cr^{II} spectrum). The light blue crystals which separate after filtration and the addition of more THF could not be characterized because on drying in vacuum white $[CrCl_2(THF)]$, suitable as a source of Cr^{II} for non-aqueous preparations, is formed.[59,74]

Table 25 Tetrahydrofuran and Substituted Ureas

Complex		μ_{eff} (BM) *295 K*	*90 K*	θ (°)	*Reflectance spectra* (cm^{-1}) ν_2		ν_1

$[CrBr_2(mur)_4]$	Pale blue	4.87	4.90	−2		13 500	
$[CrCl_2(bi)_2]$	Pale blue	4.85	4.86	0	15 000		11 000sh

(*iii*) *Ureas and biuret*

The complexes of urea (ur) and biuret (bi) in Table 25 crystallized when a solution of the ligand in ethanol was added to a solution of the hydrated chromium(II) halide in the same solvent (an ethanol/2,2-dimethoxypropane mixture in the case of $[CrCl_2(ur)_4]$). Complexes of methylurea would not crystallize from ethanol; they were obtained from the halide dissolved in a mixture of acetone and 2,2-dimethoxypropane, and methylurea in acetone. The reflectance spectra indicate *trans* octahedral complexes, achieved through chloride bridges in $[CrCl_2(ur)_2]$, which is antiferromagnetic. The positions of the reflectance bands indicate O coordination as do the IR spectra. X-Ray powder data show that $[CrCl_2(bi)_2]$ is isomorphous with $[CuCl_2(bi)_2]$,

which is known to have a *trans* structure with 'long' Cu—Cl bonds and O donor biuret. Copper(II) forms complexes in which anionic biuret is coordinated *via* nitrogen, but when biuret in alkaline solution was added to aqueous chromium(II) chloride, immediate oxidation occurred.[76]

35.3.5.4 Oxo anions

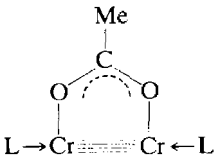
(*i*) *Sulfato complexes*

Sulfato complexes of chromium(II) are known, and the insolubility of the monohydrogen phosphate $Cr(HPO_4)\cdot 4H_2O$ suggests anion coordination (Section 35.3.5.1).

The high-spin phosphites $CrHPO_3\cdot H_2O$ ($\mu_{eff}^{298\,K} = 4.82$ BM, $\theta = 10°$) and $CrH_4P_2O_6\cdot H_2O$ ($\mu_{eff}^{298\,K} = 4.91$ BM) have reflectance bands at *ca.* 13 500 cm^{-1} typical of hexacoordinate Cr^{II}, and their Raman and IR spectra have been assigned. The loss of water on heating under nitrogen is followed by internal oxidation/reduction.[149]

The chlorosulfate $Cr(SO_3Cl)_2$ has been prepared from the acid and $[Cr_2(O_2CMe)_4]$. It forms adducts $Cr(SO_3Cl)_2L_4$ (L = MeCN, py, pyNO, acridine, L_2 = bipy).[150]

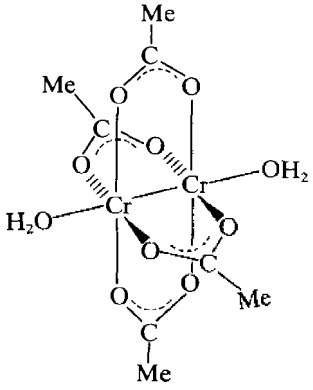
The formation of chromium(II) complexes of many oxo anions, *e.g.* NO_3^-, is precluded by the reducing ability of the metal ion.



(*ii*) *Phosphinato complexes*

A few chromium(II) phosphinates $[Cr(OPR_2O)_2]$ (R = Me, Ph, C_8H_{17}; R_2 = Me, Ph) have been prepared from chromium(II) acetate[151] or aqueous $CrCl_2$[152,153] and the potassium phosphinate. They have been little investigated because their preparation was incidental to that of the green, phosphinato-bridged and linear chromium(III) polymers to which they are easily oxidized by air. The *n*-octyl derivative $[Cr\{OP(C_8H_{17})_2O\}_2]$ is blue and anhydrous. Since there is a typical Cr^{II} band at 15 400 cm^{-1} and the symmetric and antisymmetric PO_2 stretching bands at 1055 and 1133 cm^{-1} are broad, it is believed that the Cr^{II} is six coordinate through different types of phosphinate bridge. When heated above 185 °C, there is a colour change from blue to pink, which is reversed on cooling. The diphenyl derivative is pink and a monohydrate, and insoluble in common solvents.[153] The colour suggests a chromium(II) acetate type structure, but the magnetic moment has not been reported.

35.3.5.5 Carboxylato and other complexes containing Cr—Cr quadruple bonds



Chromium(II) acetate monohydrate, discovered by Peligot in 1844, is the best known chromium(II) compound because it can be precipitated readily from aqueous Cr^{II} solutions by sodium acetate, is stable in air for short periods, and is used as a reducing agent and a source of other chromium(II) compounds (Table 9). Nonetheless, in its deep red colour, feeble paramagnetism and acetate-bridged, binuclear structure (**24**) (determined in 1953 and refined in 1971),[154,155] which are still not completely understood, it differs sharply from other chromium(II) salts (Section 35.3.5.1).

Extensive investigations by Cotton and his co-workers have shown that structure (**24**) is a prototype for a great variety of complexes of chromium(II) (and Mo^{II} and W^{II}) in which there are quadruple metal–metal bonds.[156] Besides carboxylates (**24**) to (**35**), the anionic bridging ligands in these complexes are zwitterionic glycinate (**36**), diethylcarbamate (**37**), carbonate (**38**), various 2-oxopyridines (**39**) to (**41**), 2,4-dimethyl-6-oxopyrimidine (**42**) and 2-methyl-6-iminopyridine (**43**), substituted acetanilido groups (**44**) to (**51**), carbanilido (**52**), 1,3-diphenyltriazinate (**53**) and *N,N'*-dimethylbenzamidinate (**54**). In addition, there are organochromium dimers containing 2-substituted phenyl (**55**) to (**58**), $Me_2P(CH_2)_2$ (**59**) and Me_3SiCH_2 (**60**) bridges, the methyl (**61**) and allyl (**62**) complexes which are binuclear but do not contain bridging ligands, and the solvated lithium dimers (**63**) and (**64**). There are also a few examples with mixed bridging ligands (**65**) and (**66**), complexes containing Cr_2^{4+} and Cr^{2+} units in the same lattice (**32**), and the mixed metal complex (**67**). In general only one bridge is illustrated in the structural formulae, and as indicated by the Cr–Cr and Cr–axial ligand distances, these structures have been determined by single crystal methods. Furthermore, there are the tetramers (**68**) and (**69**) which contain Cr_2^{4+} units.

(*i*) *Syntheses*

The method used by Peligot can be extended to carboxylates generally (equation 16). Since the complexes with $n > 1$ were dried in vacuum at 100 °C before analysis, their degree of hydration has not been established. All have low magnetic moments ($\mu_{eff} \approx 0.7$ BM) so it is likely that they have the acetate structure.[157]

$$2Cr^{2+} + 4RCO_2^- + 2H_2O \longrightarrow [Cr_2(O_2CR)_4(H_2O)_2]\downarrow \qquad (16)$$
$$R = C_nH_{2n+1},\ n = 1\text{–}7,\ 11,\ 17$$

Water can be replaced by ligands L through recrystallization from L if a liquid, or from an

organic or aqueous solvent containing L (L = $MeCO_2H$, piperidine,[158] pyridine, pyrazine[160]). Adducts $[Cr_2(O_2CR)_4L_2]$ (R = CMe_3, L = pyridine, 2- and 4-methylpyridine, quinoline and 2-methylquinoline, R = Ph, C_4H_3S, L = THF; R = C_4H_3O, L = THF, pyridine, 2-methylpyridine, 2-methylquinoline) have been prepared[159] directly in THF by Scheme 11 in which RCO_2H and L replace CF_3CO_2H and $Me_2C_5H_3N$.[95]

When ammonia gas is bubbled through a suspension of the acetate in ethanol, ammonia molecules replace the water, but in liquid ammonia the dinuclear structure is destroyed to give the tetraammine (Scheme 17). Unless kept in an atmosphere of ammonia the tetraammine reverts to the dinuclear ammine adduct.[161]

$$[Cr_2(O_2CMe)_4(NH_3)_2] \xleftarrow[EtOH]{NH_3(g)} [Cr_2(O_2CMe)_4(H_2O)_2] \xrightarrow{NH_3(l)} Cr(O_2CMe)_2(NH_3)_4$$

red-purple — violet

Scheme 17

The water molecules can be displaced by thiocyanate to give $[NR'_4]_2[Cr_2(O_2CR)_4(NCS)_2]$ (R' = Me, Et; R = Me, Et[162]) and a complicated reaction between $[Cr(NEt_2)_4]$ and CO_2 leads to a diethylcarbamato-bridged complex $[Cr_2(O_2CNEt_2)_4(NEt_2H)_2]$ (Section 35.5.4.3, Scheme 119).[163]

Formate gives a complicated series of hydrates according to conditions (Scheme 18),[157,164,165] and adducts of $Cr(O_2CH)_2$ with urea, THF *etc.* are known, but their structures have not been determined.[157]

$$CrCl_3 \cdot 6H_2O \xrightarrow[\text{reductor}]{\text{Jones}} Cr^{2+}(aq) \xrightarrow{NaO_2CH/HCO_2H} [Cr_2(O_2CH)_4(H_2O)_2]_3 \cdot 10H_2O$$

red

$$Cr^{2+}(aq) \xrightarrow{NH_4O_2CH} \text{purple gel} \xrightarrow{\Delta} [Cr_3(O_2CH)_6(H_2O)_2] \xrightarrow{py} [Cr_2(O_2CH)_4(py)_2]$$

red

Scheme 18

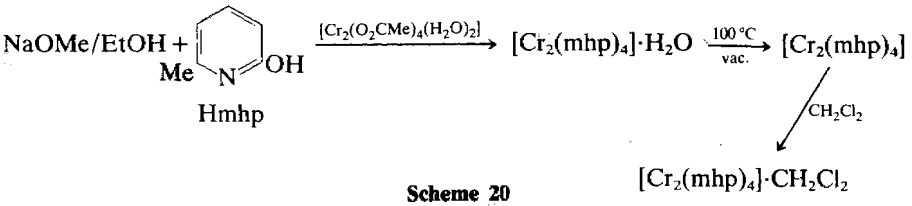
Dimeric carbonato-bridged complexes $A_4[Cr_2(CO_3)_4(H_2O)_2]$ (A = NH_4, Li, Na, K, Rb, Cs; A_2 = Mg) can be precipitated[166] from aqueous suspensions of the acetate, and the ammonium salt (or $CrCO_3$)[157] suspended in ether will react with the stronger acids CF_3CO_2H[164] and CF_2HCO_2H[167] to give dinuclear carboxylates (equation 17).

$$[Cr_2(CO_3)_4(H_2O)_2]^{4-} + 4CF_3CO_2H \overset{Et_2O}{\underset{\Delta}{\rightleftharpoons}} [Cr_2(O_2CCF_3)_4(Et_2O)_2] + 4CO_2 + 4H_2O \quad (17)$$

Pyridine and 4-cyanopyridine react with $[Cr_2(O_2CCF_2H)_4(Et_2O)_2]$ to give the mixed oxidation state, oxo-centred complexes $[Cr^{II}Cr^{III}_2O(O_2CCF_2H)_6(py)_3(Et_2O)]$ and $[Cr^{II}Cr^{III}_2O(O_2CCF_2H)_6(4\text{-}CNpy)_3] \cdot PhMe$ (see also p. 869).[167]

Dichromium(II) complexes with zwitterionic glycine bridges can be crystallized[168] from aqueous solutions (equation 18).

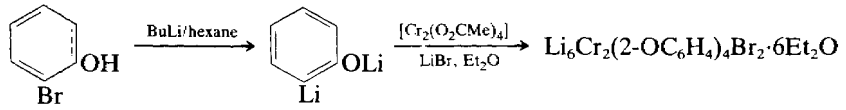
$$2CrX_2 + 4H_3\overset{+}{N}CH_2CO_2^- \xrightarrow{H_2O} [Cr_2(O_2CCH_2NH_3)_4X_4] \quad (18)$$



purple (X = Cl, Br)

Crystals of the anhydrous acetate[169] and $[Cr_2(O_2CBu^t)_4]$[164] for X-ray investigation were grown by vacuum sublimation. The anhydrous acetate (Table 9) is the source of Cr_2^{4+} for the preparation of many water-sensitive dinuclear complexes. In general, the lithium salt (not usually isolated) of the anionic ligand which is to replace the acetato bridges is first prepared from BuLi and the acid. The solid anhydrous acetate is then added to the lithium salt solution, the solution filtered after reaction to remove the lithium acetate, and the $[Cr_2Y_4]$ crystallized from the filtrate, or, if poorly soluble, extracted from the LiO_2CMe (Scheme 19).

$$\text{BuLi/hexane} + \text{YH/THF or } Et_2O \xrightarrow{0\,^\circ C} \text{LiY} \xrightarrow{[Cr_2(O_2CMe)_4]} [Cr_2Y_4] + LiO_2CMe$$

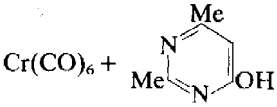


Scheme 19

These reactions were used to prepare complexes of 2-oxopyridines (**39**) to (**41**), 2-substituted phenyl derivatives (**55–57**) and others. One of the first oxopyridine complexes was prepared slightly differently (Scheme 20).[170]

Scheme 20

In another variation the dilithium salt was obtained from 2-bromophenol and 'contamination' with LiBr followed by Soxhlet extraction to solubilize the binuclear anionic salt and obtain crystals of $Li_6Cr_2(2\text{-}OC_6H_4)_4Br_2{\cdot}6Et_2O$ (Scheme 21).[171]



Scheme 21

The 2-methoxyphenyl complex, $[Cr_2(2\text{-}MeOC_6H_4)_4]$, has been prepared from $CrBr_2(THF)_2$ (equation 19).[172] The yellow, poorly soluble and pyrophoric product is diamagnetic and is likely to be a Cr_2^{4+} dimer (equation 19).

$$[CrBr_2(THF)_2] + 2\text{-}MeOC_6H_4MgBr \xrightarrow{THF} [Cr_2(2\text{-}MeOC_6H_4)_4] \quad (19)$$

Oxidation of the metal carbonyl is used in the preparations illustrated by equations (20) to (22),[173–175] in the third of which a heteronuclear dimer is formed. No reaction occurred between $Cr(CO)_6$ and 2-amino-6-methylpyridine.[176] The binuclear nature of red $[Cr\{PhC(NPh)_2\}_2]$ has not been established, and an impure sample of $[CrMo(mhp)_4]$ has been prepared from $[CrMo(O_2CMe)_4]$.[177]

dimethylhydroxypyrimidine (dmhpH) (20)

$$Cr(CO)_6 + PhC(NPh)(NHPh) \xrightarrow[\text{reflux}]{\text{pet. ether}} [Cr\{PhC(NPh)_2\}_2] \quad (21)$$

N,N'-diphenylbenzamidine red

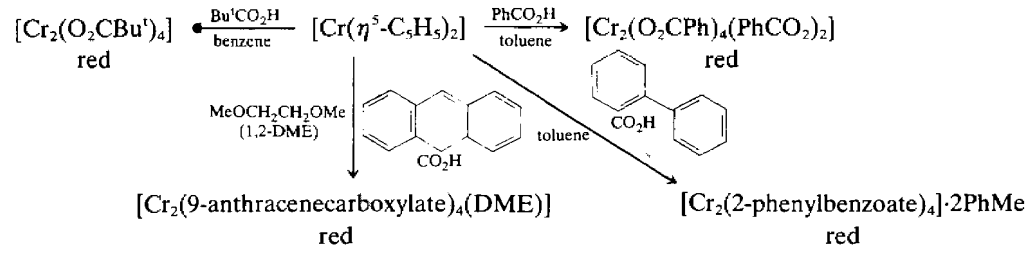
$$Mo(CO)_6 + [Cr_2(O_2CMe)_4] \xrightarrow[CH_2Cl_2,\ MeCO_2H]{(MeCO)_2O} [CrMo(O_2CMe)_4] \quad (22)$$

in excess pale yellow

In the preparation[178] of the 1,3-diphenyltriazinato-bridged complex an organochromium dimer was the source of Cr_2^{4+} (equation 23).

$$[Li(THF)]_4[Cr_2Me_8] + 4PhNHNNPh \xrightarrow{THF} [Cr_2(PhN_3Ph)_4] + 4CH_4 + 4LiMe \quad (23)$$

Chromocene can also be used as a starting material (Scheme 22).[164]



Tetranuclear complexes, composed of two Cr_2^{4+} subunits are made by[116,179] reactions (24) and (25) in which the acetate bridges were not all displaced.

$$[Cr_2(O_2CMe)_4] + NaOCH_2CH_2NMe_2 \xrightarrow{THF} [Cr_4(O_2CMe)_4(OCH_2CH_2NMe_2)_4] \quad (24)$$

red

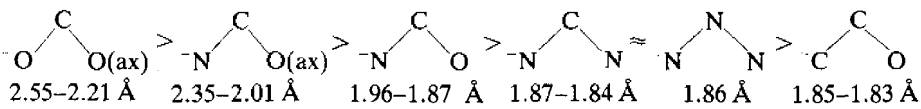
$$[Cr_2(O_2CMe)_4] + 2Li(2\text{-}NMe_2CH_2C_6H_4) \xrightarrow{THF} [Cr_4(2\text{-}NMe_2CH_2C_6H_4)_4(O_2CMe)_2O] \quad (25)$$

orange

Scheme 22

Several organochromium(II) dimers containing short Cr≡Cr bonds (**55–64**) have been included for completeness. For their preparations the companion series[1] should be consulted. Complexes (**65**) and (**66**)[180] contain mixed carboxylato and organo bridges.

(*ii*) *Structures*



Crystallographic investigations demonstrate that the length of the Cr—Cr quadruple bond is primarily dependent upon whether axial ligands are present and, if so, upon their nature and number. This is apparent from a comparison of the Cr—Cr separations found for complexes (**25**) to (**38**), (**41**), (**46**) to (**52**) and (**67**), and, without axial ligands, (**39**), (**40**), (**42**) to (**45**) and (**53**) to (**66**). Those without axial ligands and r(Cr—Cr) < 1.9 Å are considered[156] to contain 'supershort' bonds compared with those in the carboxylates (2.28–2.55 Å). The Cr—Cr separations in the tetramers (**68**) and (**69**) are equal to the greatest found in the dinuclear carboxylates.

There is considerable variation of r(Cr—Cr) within the tetracarboxylate series mainly dependent upon the donor ability of the axial ligands. In $[Cr_2(O_2CR)_4(R'py)_2]$ (R = Bu^t, Me, H, $CClH_2$ or CHF_2; R′ = H, 4-NH_2, 4-CN *etc.*) the Cr—Cr and Cr—N distances are inversely related,[167b] and axial coordination of oxindole in $[Cr_2(oxindolate)_4(oxindole)_2]$ produces a long Cr≡Cr bond (2.495 Å).[167c] No carboxylates without axial ligands are known: in anhydrous compounds oxygen atoms of neighbouring dimers bond axially (**26**) to give polymers; and substitution in the bridge is too distant to be effective (**30**) or is nullified by the final configuration (**33**). In (**33**) the four 2-phenyl groups are directed towards the same end of a Cr≡Cr unit and block association [though not coordination of THF (**34**)], but dimers of dimers are formed through association at the other end. Carboxylates producing steric hindrance at both ends of the Cr_2 units have not been devised.

Careful choice of bridging ligand is necessary to prevent axial donation or association and produce very short Cr—Cr bonds. In the acetanilido complex (**44**) this is achieved: the unlike ligand atoms on each chromium atom are *trans* and with a small torsion angle ω about the NPh bond the axial positions are blocked. Dichromium compounds (**46**) to (**50**), in which ω has been increased to approximately 90° to open up the axial positions, have been obtained by introducing 2,6-dimethyl groups. Steric effects then force the rings to be perpendicular to the O—Cr_2—N plane. Electron donation by a 4-NMe_2 substituent acts similarly. Access by axial ligands then lengthens the Cr—Cr bond in the series of complexes (**48**) to (**51**) compared with (**44**) without change in bridging ligand or overall geometry. Complexes (**44**) and (**45**) have no axial ligands and the smallest Cr—Cr separations, and the axial CH_2X_2 molecules in (**46**) and (**47**) interact at the most very weakly with the metal. Axial donation modifies the Cr—Cr distance as in the carboxylates, but in the acetanilido compounds the bond separation without axial ligands is known. Metal–metal separations in dimolybdenum complexes are not sensitive to axial donation.

There are no axial ligands in the 2-oxopyridine, 2-iminopyridine and 2-phenyl derivatives which have the shortest Cr—Cr bonds. The bromide ions in (**58**) are off-axis and beyond bonding distance.

The nature of the bridging ligand is also important; the quadruple bonds (the ranges are given) shorten with type of bridging bidentate ligand in the order:[183]

The presence of axial ligands is signified by (ax), and the formally negatively charged atom is shown, but with N—C—O bridges the formal charge is on N or O according to whether the anion is from an amide or an hydroxypyridine. In addition to the 2-phenyl derivatives (**55**) to (**58**) with CCO bridges, there are organodichromium species (**59**) to (**64**) with Cr—Cr separations in the range 2.1 to 1.89 Å, two of which do not contain bridging ligands. In the mixed ligand complexes (**65**) and (**66**) (CCCN bridge) the Cr—Cr distances are very short presumably because the C donor dominates. The general trend is that the Cr—Cr bonds shorten as the donor strength (basicity) of the anions increases: $O^- < N^- < C^-$.

In keeping with the so far perceived trends, the longest bond (2.541 Å) is in $[Cr_2(O_2CCF_3)_4(OEt_2)_2]$ (**27**) where there is axial ligation and the bridging ligand the least basic, and the shortest (1.828 Å) in $[Cr_2(2\text{-}MeO\text{-}5\text{-}MeC_6H_3)_4]$ (**57**). The ranges of metal–metal distances in the O—C—O(ax) and N—C—O(ax) series overlap so that dichromium compounds no longer fall into two distinct classes, *i.e.* carboxylates and others with much shorter Cr—Cr bonds.

In order to compare Cr—Cr bond lengths with other bond lengths a formal shortness ratio (FSR) for a bond A—B has been defined:

$$\text{FSR} = \frac{D_{A-B}}{R_A + R_B} = \frac{r(\text{Cr—Cr})}{2 \times 1.186(R_{Cr})}$$

The FSR values for complexes (**57**) and (**27**) are 0.771 and 1.07, compared with 0.786 for N≡N.[156]

Chromium resembles molybdenum and tungsten in its quadruply bonded compounds but differs in not forming dimetal compounds of lower bond order. Although salts of the stable binuclear anions $[Mo_2Cl_8]^{4-}$ and $[Mo_2(SO_4)_4]^{4-}$ are well known, chromium(II) forms very different chloro complexes (Section 35.3.7.3), and the violet, nearly diamagnetic sulfato-bridged dichromium complex $Cs_4[Cr_2(SO_4)_4(H_2O)_2]\cdot 2H_2O$, obtained only by heating $Cs_2SO_4\cdot Cr_2SO_4\cdot 6H_2O$, re-forms $[Cr(H_2O)_6]^{2+}$ with water.[162]

(*iii*) *Theoretical description of Cr≡Cr bonds*

The Cr—Cr bond lengths vary from supershort bonds of about 1.85 Å to long bonds approaching 2.6 Å. This is a wide range for what is formally considered a quadruple bond. Molecular orbital calculations of electron density in the formate $[Cr_2(O_2CH)_4]$ as a long-bonded example and in '$Cr_2\{H_2P(CH_2)_2\}_4$' as a model for the supershort Cr—Cr complexes $[Cr_2\{(CH_2)_2P(CH_3)_2\}_4]$ and $[Cr_2(mhp)_4]$ show agreement with the experimental electron densities obtained by high resolution low temperature single crystal X-ray investigations on $[Cr_2(O_2CMe)_4(H_2O)_2]$[185] and $[Cr_2(mhp)_4]$.[187] The contraction of the Cr—Cr bond in (**25**; L = H_2O) by 0.009 Å on cooling to 90 K agrees with a shallow Cr—Cr potential and the sensitivity of the bond to axial donors. From the X-ray experiment, there is an electron-deficient area along the Cr—Cr bond, and a broad region of excess electron density off it, but the computed map for $[Cr_2(O_2CH)_4]$ has a broad maximum around the centre of symmetry. The difference is tentatively related to weakening of the σ bond by interaction of the axial water molecules present in the acetate.

In the supershort cases, the electron density is at a maximum at the bond midpoint.[187] The pure quadruple bond configuration $\sigma^2\pi^2\delta^2$ (Figure 3) makes only a small contribution as a leading term in the calculations for the carboxylates, but is much more important in short Cr—Cr species (as for Mo_2^{4+});[185,187–190] in each case excited configurations must be included in the calculations. From comparisons of the results of calculations on the formate and the hypothetical tetrakis(formamidato) species $[Cr_2(NH(O)CH)_4]$, and the formate and '$[Cr_2\{H_2P(CH_2)_2\}_4]$', it has been suggested[188–190] that greater charge on the ligand donor atoms leads to better overlap of the *d* orbitals and a shorter quadruple bond. The importance of the inductive effects of the bridging ligands does not seem to have been clearly established experimentally: on the other hand the importance of the axial ligands on Cr—Cr bond lengths is clear from X-ray work, but not quantitatively explained theoretically.

Other calculations of the Cr—Cr interaction are based on a model in which there is weak antiferromagnetic interaction between high-spin Cr^{2+} atoms.[191] This is not believed to be realistic, at least for the supershort bonds.[187] A computational method which supposes multiple bonds to be single bonds intensified by screening of the internuclear repulsion is said not to support the antiferromagnetic interaction mode.[192]

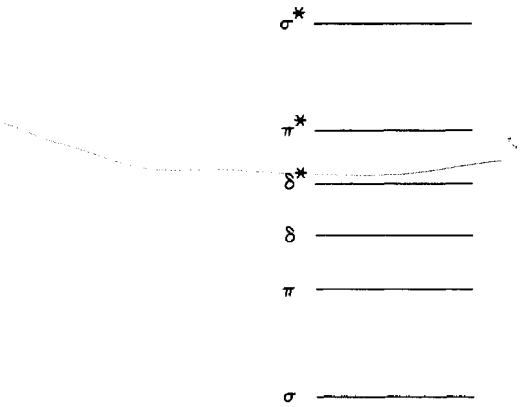


Figure 3 Qualitative order of energies of orbitals formed by metal $d - d$ overlaps

The standard enthalpies of formation of crystalline (**25**; L = H_2O), (**26**), (**67**), (**39**), (**55**), $[Mo_2(O_2CMe)_4]$ and $[Mo_2(O_2CMe)_2(acac)_2]$ have been derived from calorimetric measurements of oxidative hydrolysis in solution. It has not been possible to distinguish between various theoretical treatments from the thermochemical data.[193,194]

(*iv*) *Photoelectron spectroscopy*

Assignments by different workers of the photoelectron spectra of $[Cr_2(mhp)_4]$ agree that the lowest energy peak A (6.7–6.8 eV) is due to ionization from the δ metal–metal bonding level. The next feature is complex with an intense peak B at 7.75 eV and a shoulder C at 8.15 eV. It was considered that B and C are the π and σ ionizations, but it seems that B is due to ionization from π levels of the ligand and C is the π metal–metal ionization.[177,190,195] The σ ionization has been assigned to the second of three components at 9.8, 10.2 and 11.1 eV of a complex peak, and the other two components to ligand π ionizations.[177] (When metal–ligand interactions are included, the molecular orbital diagram is of course more complicated than Figure 3.)

Ionizations from the δ and π levels of dimolybdenum tetracarboxylates have been resolved, but as shown in Table 26,[190] not those from $[Cr_2(O_2CMe)_4]$. The location of the ionization from the σ metal–metal bonding levels remains uncertain.[190,196] Table 26 also contains core electron ionization energies.

[a] Gas-phase X-ray PES.
[b] He^I and He^{II} PES.
[c] Formate data also in ref. 190.

The oxygen core IE values of $[M_2(O_2CMe)_4]$ (M = Cr, Mo) are the same within experimental error, as are the oxygen and nitrogen IE values for $[M_2(mhp)_4]$. Also, the decrease in the binding energy of the Cr 2*p* levels from $[Cr_2(O_2CMe)_4]$ to $[Cr_2(mhp)_4]$ matches that of the Mo 3*d* levels. Thus, the charge distribution is the same within $[Cr_2(O_2CMe)_4]$ and $[Mo_2(O_2CMe)_4]$, and within $[Cr_2(mhp)_4]$ and $[Mo_2(mhp)_4]$. Consequently, the significant lengthening (0.40 Å) in going from $[Cr_2(mhp)_4]$ to $[Cr_2(O_2CMe)_4]$ as compared with the Mo pair (0.03 Å) is not due to differences in the bonding of the ligands, but to the different nature of the metal–metal interactions, notably the shallower Cr—Cr potential well, which makes the Cr—Cr separation more sensitive to changes in the electron density distribution.

(*v*) *Electronic spectra*

The absorption spectra of $[M_2(mhp)_4]$ (M = Cr, Mo, W) in THF are similar. The lowest frequency band (22 500 cm^{-1}, M = Cr, Table 27) has been assigned to the metal-localized $\delta \rightarrow \delta^*$ transition ($^1A_1 \rightarrow {}^1B_2$, D_{2d} symmetry). The vibronic structure on this band in the low temperature spectra of the solids, with progressions of 320 (M = Cr), 400 (M = Mo) and 320 cm^{-1} (M = W), is consistent with the assignment.

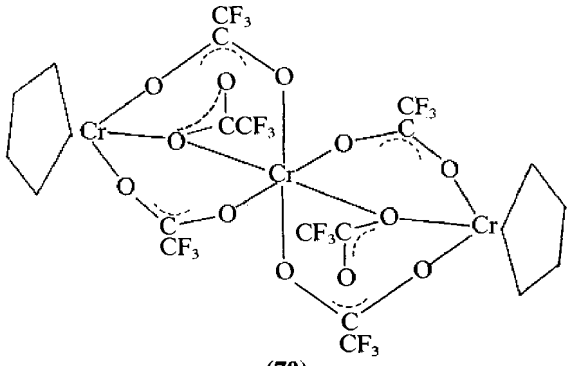
Two Raman lines, either of which may be the Cr—Cr mode, have been observed at 340 and 400 cm^{-1} for $[Cr_2(mhp)_4]$. The former is preferred[197] since the vibronic progression is 320 cm^{-1}, and this is lower than earlier proposed.[169] Others believe that this is a Cr—O or Cr—N totally symmetric stretch.[198] The 22 500 cm^{-1} band and the shoulder at 29 600 cm^{-1} are metal-dependent since they are intensified, and move together and to lower frequency from Cr to Mo to W. The shoulder at 29 600 cm^{-1} is assigned to the $\delta \rightarrow \pi^*$ ($^1A_1 \rightarrow {}^1E$) transition.[197]

The low temperature single crystal spectrum of the acetate contains two polarization dependent bands near 21 000 cm^{-1} and 30 000 cm^{-1} (I and II, Table 27). Different assignments (I, $\delta \rightarrow \pi^*$; and II, $n p\pi(O) \rightarrow \pi^*$) to the above have been made,[199] and further work seems necessary. Bands I and II move to lower wavenumber with increasing Cr—Cr separation, and powder reflectance spectra of several dinuclear Cr_2^{4+} species show the same general features as the detailed acetate spectrum.[162] The ground state Cr—Cr stretching frequency is estimated at 150 to 200 cm^{-1}. The Cr—Mo stretch of (**67**) is reported as 394 cm^{-1}. An accurate spectrum of $[Cr_2\{(CH_2)_2P(CH)_3)_2\}_4]$ could not be obtained because of decomposition.[200]

(vi) Magnetic properties

The red chromium(II) carboxylates $[Cr(O_2CR)_4L_2]$ are weakly paramagnetic ($\mu_{eff} = 0.4$–0.9 BM at room temperature)[157,161] and it is generally believed that this is due to paramagnetic impurities (chromium(III) species, from ESR measurements)[156] arising from inadvertent aerial oxidation. However, the temperature variation of susceptibility of several carefully isolated samples of carboxylates (including **35**) can be explained by assuming strong antiferromagnetic interactions in the dinuclear structures ($2J \approx 700\ cm^{-1}$), and the presence of *ca.* 1% or less chromium(III) impurity.[161] It seems that at least in the carboxylates with the longest Cr—Cr separations the paramagnetism is genuine. Carboxylates can crystallize with a proportion of mononuclear chromium(II), *e.g.* in (**32**),[164] or form blue paramagnetic species on dehydration.[201] The carbonato complexes also have low magnetic moments.[202]



The yellow colour and temperature-dependent moment of the oxalate $CrC_2O_4 \cdot H_2O$ ($\mu_{eff}^{340\ K} = 4.5$, $\mu_{eff}^{100\ K} = 4.0$ BM) suggest that it is polymeric.[201,203] The malonato complexes $Cr(C_3H_2CO_2)_2 \cdot 2H_2O$ (red) and $Na_2Cr(C_3H_2O_4)_2 \cdot 4H_2O$ (blue) have normal magnetic moments at room temperature ($\mu_{eff} \approx 4.8$ BM),[204] which is inconsistent with the colour of the former.

Red or blue, variously hydrated chromium(II) complexes of thiocarboxylic acids, *e.g.* $S[(CH_2)_2SCH_2CO_2H]_2$, have been isolated, and the red complexes are antiferromagnetic.[205] Some antiferromagnetic complexes of adenine may have binuclear structures (Table 16).

(vii) Miscellaneous investigations of carboxylates and related complexes

The molecular ions have been identified in the mass spectra of $[(Cr_2(O_2CR)_4]$ (R = Me, Et, Pr^i, CMe_3 and $C_{11}H_{23}$)[206] and two reversible one-electron oxidations have been found for $[Cr_2(map)_2]$ (**43**) (−0.53 and −0.09 V *vs.* $Ag/AgNO_3$).[207]

In the molecule $[Cr_3(\eta^5\text{-}C_5H_5)_2(O_2CCF_3)_6]$ the central metal atom is in oxidation state II and forms four short (2.01 Å) and two long (2.58 Å) Cr—O bonds (**70**).[208]

(**70**)

The pentaacetatodiborate $Cr[B_2O(OCOMe)_5]_2$ has been prepared ($\mu_{eff}^{293\ K} = 4.80$ BM).[209]

Chromium(II) acetate is predominantly dimeric in water in which it is not very soluble. The equilibria are shown below.

$$Cr_2(O_2CMe)_4 \overset{K_{DO}}{\rightleftharpoons} 2Cr(O_2CMe)_2 \qquad \log K_{DO} = -4.4\ (25\ ^\circ C,\ I = 3.0\ M)$$

$$Cr(O_2CMe)_2 \overset{K_2^{-1}}{\rightleftharpoons} Cr(O_2CMe)^+ + MeCO_2^- \qquad \log K_2 = 0.9$$

$$Cr(O_2CMe)^+ \overset{K_1^{-1}}{\rightleftharpoons} Cr^{2+} + MeCO_2^- \qquad \log K_1 = 0.8$$

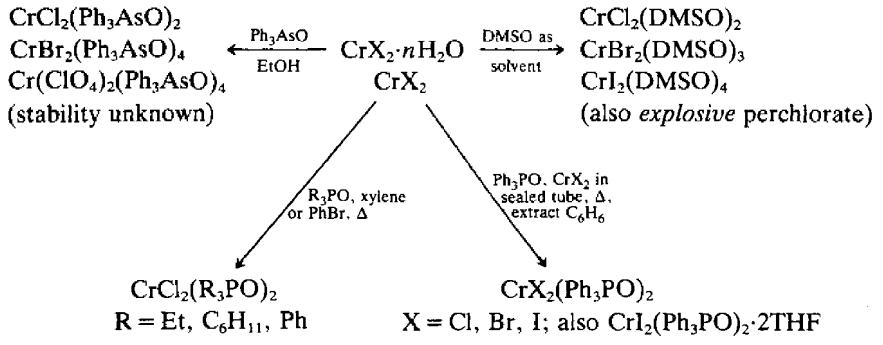
Reaction of edta with the aqueous dimer causes rapid decomposition to the monomer which appears to be the effective reductant in redox reactions of the acetate. The difference between the Cr≡Cr and Cu—Cu bond energies has been estimated from the dissociation data for the acetates to be only about 45 kJ mol^{-1} even though the Cu—Cu bond is formally a single bond.[210] Oxidation of the dimer by I_2 has been investigated kinetically.

From a spectrophotometric study of the equilibria between various chelating agents and $[Cr_2(O_2CMe)_4]$ some stability constants of mononuclear Cr^{II} complexes have been determined

(malonate, $\log \beta_2 = 6.0 \pm 0.2$; *N*-methyliminodiacetate, $\log \beta_2 = 12.3 \pm 0.5$; ethylenediamine-*N*,*N*′diacetate, $\log K_1 = 9.1 \pm 0.2$; at $T = 25\,°C$, $I = 1.0\,M$ $NaClO_4$) and the values agree with prediction.[211]

The binuclear formate is incompletely formed over the intermediate formate concentration range. At the highest formate concentrations the binuclear complex dissociates to mononuclear complexes with $HCO_2^-/Cr > 3$.[212]

$$2Cr(O_2CH)^+ + HCO_2^- \overset{K}{\rightleftharpoons} Cr_2(O_2CH)_3^+ \quad K = 2.1 \pm 0.2$$



Stability constants have also been determined for oxalate and malonate (Table 39). The succinate $[Cr(C_4H_4O_4)H_2O]_2 \cdot 2H_2O$ is isostructural with the copper(II) compound.[213a]

35.3.5.6 Aliphatic and aromatic hydroxy acids

The glycolate $Cr(C_2H_3O_3)_2 \cdot H_2O$,[213] salicylate $Cr(C_6H_4(O)CO_2) \cdot 3H_2O$ and tartrate $Cr(CO_2CHOHCHOHCO_2)^3$ have been prepared. Stability constants have been determined for complexation of Cr^{II} with salicylate and 5-sulfosalicylate (Table 39).

35.3.5.7 Dimethyl sulfoxide, phosphine oxides and arsine oxides

Complexes of dimethyl sulfoxide[214] and some phosphine and arsine oxides[148,215,216] have been prepared by the methods in Scheme 23. The phosphine oxide complexes are decomposed by polar solvents, and were obtained by heating the reactants in sealed tubes, or in xylene or bromobenzene. The use of halogenated solvents can lead to Cr^{III}—C bonds but apparently not in this case. No structures have been clearly established. The complexes are all high-spin, and have reflectance spectra suggestive of distorted six-coordinate chromium(II). Thus those of the formula $[CrX_2L_4]$ have monomeric *trans* configurations and those with the formula $[CrX_2L_2]$, which are known to be weakly antiferromagnetic ($\theta \approx 0°$), have polymeric structures. However, the chloro complexes $[CrCl_2(R_3PO)_2]$ are non-electrolytes, and a dipole moment of 4.9 Debye for $[CrCl_2(Et_3PO)_2]$ in C_6H_6 excludes a *trans* planar structure. The complex $[CrBr_2(Ph_3PO)_2]$ has been obtained as a green polymer and as a yellow form which, like $[CrI_2(Ph_3PO)_2]$, is thought to have a flattened tetrahedral structure. Different reflectance spectra provide the main structural evidence, the yellow form having a broad band at lower wavenumber (Table 28, 10 000 cm^{-1}). However, complexes such as $[NEtH_3]_2[CrBr_4]$, in which the Cr^{II} is six-coordinate through bromide bridges between planar $[CrBr_4]^{2-}$ units, absorb at approximately 10 500 cm^{-1} (Section 35.3.7.3); thus tetrahedral structures are unlikely. Possibly different ligands lie along the distortion axis in the two forms.

Scheme 23

The IR spectra of the DMSO complexes show that the ligand is O-bonded; and the lack of splitting of the perchlorate stretching absorptions of $[Cr(ClO_4)_2(Ph_3AsO)_4]$ shows that ClO_4^- interacts only weakly with the metal in the probably planar $Cr(Ph_3AsO)_4$ unit.

35.3.6 Sulfur Ligands

35.3.6.1 Dithiocarbamates

A few very air-sensitive dialkyldithiocarbamato complexes $[Cr(S_2CNR_2)_2]$ (R = Me, Et or $R_2 = C_4H_8$) have been prepared from aqueous or aqueous ethanolic solutions of $CrCl_2$ and the sodium dithiocarbamate (Table 29).[217,218] The diethyl-substituted derivative $[Cr(S_2CNEt_2)_2]$ is isomorphous with other metal(II) diethyldithiocarbamates[217] known to be S-bridged dimers with distorted trigonal bipyramidal arrangements of S atoms around the metal, *e.g.* $[Fe(S_2CNEt_2)_2]$.[219] The reflectance spectrum resembles the spectra of other square pyramidal rather than trigonal bipyramidal chromium(II) complexes (Table 42). The complexes are antiferromagnetic. (For R = Et, $J = 26\ cm^{-1}$, $g = 2.19$; binuclear expression.)

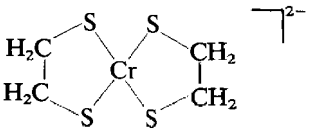

Table 29 Complexes of Dialkyldithiocarbamates and Thiourea

[a] Néel point at *ca.* 100 K.

35.3.6.2 *Ethane-1,2-dithiol*

Chromium(II) is in planar coordination (**71**) in $[NEt_4]_2[Cr(S_2C_2H_4)_2]$ ($\mu_{eff}^{297\,K} = 4.95$ BM in MeCN), which separates as a violet solid when ether is added, after stirring for several days, to a mixture of $CrCl_2$, sodium ethane-1,2-dithiolate and $[NMe_4]Cl$.[220]

(71)

35.3.6.3 *Thioureas*

Complexes of chromium(II) halides with thiourea (tu), *N,N'*-ethylenethiourea (etu) and *N,N'*-dicyclohexylthiourea (dctu) have been isolated from solutions of the halides which had been dehydrated with an excess of 2,2-dimethoxypropane. Attempts to isolate complexes from more polar solvents such as water, DMF and the lower alcohols were unsuccessful. The bromides and iodides $CrBr_2 \cdot 4tu$, $CrI_2 \cdot 6tu$, $CrBr_2 \cdot 5etu$, $CrI_2 \cdot 4etu$, $CrBr_2 \cdot 5dctu$ and $CrI_2 \cdot 6dctu$ are high-spin, with temperature-invariant moments in the range 4.74–4.97 BM. There is a band in the range 11 000 to 14 000 cm^{-1} (ν_2) and a weaker band or shoulder to lower wavenumbers (ν_1) in the reflectance spectra. This is the usual pattern for distorted six-coordinate high-spin chromium(II) complexes. Since ν_2 is well below the values found for comparable complexes containing N donor ligands, *e.g.* for $[CrX_2(mepy)_4]$, $\nu_2 \approx 17\,000\ cm^{-1}$, the thioureas are acting as S donors. Square pyramidal structures were not excluded for the cations in $CrBr_2 \cdot 5etu$ (or 5 dctu). The chloride $CrCl_2 \cdot 2tu$, its acetone adduct, $CrCl_2 \cdot 2etu$ and $CrCl_2 \cdot dctu$ are antiferromagnetic and chloride- or perhaps thiourea-bridged polymers (Table 29).[221] No X-ray data are available.

35.3.7 Halogens as Ligands

35.3.7.1 *Anhydrous halides*

Only more recent work on the anhydrous halides CrX_2 (X = F, Cl, Br or I) will be considered as their preparations, properties and structures have already been ably summarized.[222] Generally, they are prepared by a variety of solid state reactions at high temperature, *e.g.* from the metal and the hydrogen halide or by reduction of a higher halide with hydrogen or the metal. Thermal dehydration of the hydrated chloride, bromide and iodide provides adequately pure anhydrous halides for preparative use (Table 9). It has been found that in the preparation of $CrCl_2$ by reduction of $CrCl_3$ with Al, Cr or H_2 in a temperature gradient of 450 to 350 °C, the $CrCl_2$ is transported as gaseous $CrAl_2Cl_8$ from the 450 °C zone, where reduction occurs, to the 350 °C zone.[223] Besides the solid state procedures,[222] CrF_2 can be obtained by thermal dehydration of $CrF_2 \cdot 2H_2O$[85] and by volatilization of NH_4F from NH_4CrF_3.[224] In oxygen at 300 °C, CrF_2 forms CrO_2F_2, and with sulfur Cr_2S_3 is formed. It liberates hydrogen from water, and NO at 600 °C produces CrF_3, Cr_2F_5 and Cr_2O_3.[225] It is also not inert to N_2 at high temperatures because at 650 °C over 100 h a dark product of unknown structure Cr_2NF_3 is obtained.[226] With an excess of XeF_6 at 120 °C, CrF_2 forms $XeF_6 \cdot Cr^{IV}F_6$.[227]

In the halides bridging anions lead to distorted CrX_6 octahedra sharing corners in which there are four short approximately equal Cr—X bonds and two long *trans* Cr—X bonds. There is also angular distortion of the octahedra. The fluoride has the tetragonal (distorted) rutile structure and the other halides chain-type structures. The mixed crystal (Mn, Cr)I_2 is isotypic with monoclinic CrI_2 (Table 34).

The anhydrous difluoride is antiferromagnetic; the magnetic moment is 4.3 BM at room temperature and the Néel temperature 53 K (neutron diffraction). The magnetic axis is parallel to the direction of the long Cr—F bonds. The chloride also is antiferromagnetic ($T_N = 20$ K).[222]

In the single crystal absorption spectra of CrF_2 and $CrCl_2$ the pattern of spin-allowed (quintet–quintet) bands for the ammines and hydrates is repeated. Gaussian analysis of the higher wavenumber bands has allowed assignments of all three transitions and calculation of

the ligand field parameters. There is some controversy over the ordering and extent of splitting of the D_{4h} levels but those in Table 30 and Figure 2 seem generally accepted. The many observed spin-forbidden transitions (mainly quintet–triplet transitions) in the single crystal spectra have also been assigned, and there is good agreement between observed and calculated energies. The decrease in intensity of these bands which takes place between 70 and 6 K is believed to be due to the onset of magnetic ordering; neutron diffraction studies show that below the Néel temperature the spins in $CrCl_2$ align parallel within the ferromagnetic (011) planes, but adjacent planes have opposite spins.[228]

Table 30 Spin-allowed Transitions and Ligand Field Parameters for CrF_2 and $CrCl_2$

Assignment	*Theoretical formula*	*Experimental (6 K)* CrF_2	$CrCl_2$
$^5B_{1g} \rightarrow {}^5A_{1g}$	$4Ds + 5Dt$	10 495	9100
$^5B_{1g} \rightarrow {}^5B_{2g}$	$10Dq$	11 623	11 050[a]
$^5B_{1g} \rightarrow {}^5E_g$	$10Dq + 3Ds - 5Dt$	14 669	12 250[a]
Dq (cm^{-1})		1162	1100
Ds (cm^{-1})		1934	1470
Dt (cm^{-1})		551	640

[a] Maxima of Gaussian components of band at 11 750 cm^{-1}.

The gaseous dihalides are believed to be linear monomers, and the PE spectrum of $CrCl_2$ has been assigned on this basis with the assumption of a high spin molecule.[229] Anomalies in the heat capacity data of CrF_2 (10–300 K) have been associated with the magnetic ordering.[230] From the temperature dependence of the ^{129}I Mössbauer spectra of CrI_2 a Néel temperature of 45 ± 5 K has been deduced.[231]

The treatment of Cr metal with anhydrous HF acidified with the Lewis acids BF_3, AsF_5 and SbF_5 gives solutions believed to contain the ions $[Cr(FH)_6]^{2+}$ because there is a single broad absorption band (9900 cm^{-1}),[232] as is observed in aqueous solution (14 100 cm^{-1}), and in molten $AlCl_3$ (8400 cm^{-1}) and fluoride melts (14 000 cm^{-1}),[233]

The green adduct $CrF_2 \cdot AsF_5$ ($\mu_{eff} = 4.68$ BM) has been prepared by the reaction of CrF_2 with AsF_5 in anhydrous HF.[234]

35.3.7.2 Complex fluorides

Much information on the correlation between magnetic and other properties and structure has come from investigations of the complex fluorides of the transition metals,[235] and chromium(II) provides several examples (Table 31) of such complexes.

(*i*) *Preparations*

Trifluorochromates, $ACrF_3$ (A = NH_4, K or Rb), can be prepared in aqueous conditions from chromium(II) chloride and AF or chromium(II) acetate and AHF_2.[224,236] The potassium salt has also been prepared by fusing CrF_2 with KF under argon.[237]

Sodium tetrafluorochromate has been prepared in aqueous conditions as above, and from solutions of chromium(II) sulfamate.[238] Some workers[236,238] have isolated Na_2CrF_4 only in spite of varying the reaction conditions, but others have obtained $NaCrF_3$[239,240] although Li and Cs salts could not be obtained from aqueous or dry conditions. The salt Na_2CrF_4 is the only one of its stoichiometry among the chromium(II) complex fluorides. Attempts to prepare tetrafluorochromates in the solid state from $MCrF_3$ (M = K or Rb) and MF lead[224] to disproportionation:

$$3M\mathrm{Cr^{II}F_3} + MF = 2M_3\mathrm{Cr^{III}F_6} + \mathrm{Cr^0} \qquad (26)$$

The complexes $MCrF_4$ (M = Ca, Sr or Ba), Ba_2CrF_6, $CrZr(Hf)F_6$ and $CrMF_5$ (M = Al, Ti, V), and the mixed oxidation state species Cr_2F_5, Rb_xCrF_3 and $Cs_4Cr_5F_{18}$[24] have been obtained by solid state reactions (see Table 31). Cr_2F_5 is an example of a general class of chromium(III) fluoro complex $M^{II}Cr^{III}F_5$.[235]

Table 31 Complex Fluorides

(*ii*) *Properties*

Down to liquid nitrogen temperatures, $KCrF_3$ and Na_2CrF_4 have essentially temperature-independent magnetic moments, but NH_4CrF_3 is antiferromagnetic.[236] Other measurements have shown that antiferromagnetism develops in $KCrF_3$ at lower temperatures ($T_N = 40$ K, $\theta = 5°$). Neutron diffraction experiments at 4.2 K have established that ferromagnetic (001) sheets are coupled antiferromagnetically along the (001) direction. The exchange constants in and between the layers are of similar magnitude, $J = 1.4°$ and $-2.2°$ respectively.[237]

Solid state electronic spectra show the expected pattern for high-spin chromium(II) complexes, and for $KCrF_3$,[236,241] $SrCrF_4$[242] and $CrZrF_6$[243] all three spin-allowed d–d transitions have been resolved. A theoretical analysis of the sharp spin-forbidden (quintet–triplet) electronic transitions in the solid state spectra of $KCrF_3$ has been made.[240]

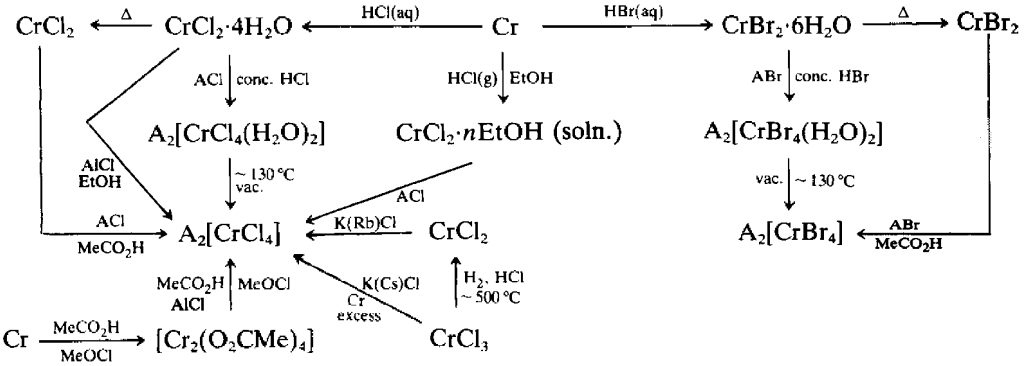
The salts $KCrF_3$ and $RbCrF_3$ have distorted perovskite structures, and from analysis of powder data the former contains tetragonally compressed CrF_6 octahedra in which two Cr—F bond distances are 2.00 Å and four 2.14 Å.[244] The ionic radius of Cr^{2+} in fluoride perovskites has been estimated at 0.73 Å as a weighted average from lattice constants.[245]

The complex fluoride $CrZrF_6$ (Table 31) is an example of a class of compound $A^{II}M^{IV}F_6$ which undergoes phase transitions as the temperature changes. In the chromium(II) and copper(II) compounds additional modifications occur because of local and cooperative Jahn–Teller distortions. From the three spin-allowed d–d transitions for high-spin Cr^{2+} in strongly distorted CrF_6 octahedra (Table 31) an octahedral Δ value of 7600 cm^{-1} is calculated. Transitions between the monoclinic II′, pseudotetragonal I′ and cubic I phases have been

$$CrZrF_6\text{: II}' \xrightarrow{\approx 150\,K} \text{I}' \xrightarrow{\approx 400\,K} \text{I}$$

established by X-ray and neutron diffraction methods. Additionally, ^{57}Fe doped into $CrZrF_6$ has a Mössbauer spectrum with an isomer shift typical of high-spin iron(II), and a large quadrupole splitting below 400 K ($\Delta E \approx 1.4$ mm s^{-1}), which decreases almost to zero over a few degrees as the temperature rises above 400 K. The large ΔE arises from the presence of Fe^{2+} in lattices (II′ and I′) where there are statically distorted CrF_6 octahedra, but above *ca.* 400 K, *i.e.* in the cubic phase I, a dynamic Jahn–Teller effect takes over; the time for interchange of the tetragonal axis among the three four-fold axes of the FeF_6 octahedron being short on the Mössbauer timescale. The Mössbauer data also show that the FeF_6 octahedra in II′ and I′ are elongated,[243] and the phase transitions have been monitored by neutron powder diffraction studies.[246]

35.3.7.3 *Complex chlorides, bromides and iodides*



(i) *Solvated tetrachloro- and tetrabromo-chromates(II)*

The dihydrates $A_2[CrX_4(H_2O)_2]$ (X = Cl or Br) have been crystallized from solutions of the constituents in the appropriate halogen acid except for the pyridinium salts which were isolated from ethanol (Table 32 and Scheme 24). All are magnetically dilute, high-spin compounds with reflectance spectra as expected for tetragonally-distorted octahedral anions $[CrX_4(H_2O)_2]^{2-}$. The NH_4, Rb and Cs salts are isomorphous with the corresponding copper(II) complex halides, which contain *trans* anions $[CuBr_4(H_2O)_2]^{2-}$ with two short and two long CuX bonds. Similar structures are therefore likely for the chromium(II) anions.[247–249]

For cations A see Table 33

Scheme 24

From the diffuse reflectance and IR spectra and the absence of magnetic interaction, it was deduced that there are analogous *trans* anions containing coordinated acetic acid molecules in the guanidinium salt $[C(NH_2)_3][CrBr_4(MeCO_2H)_2]$; and this has been confirmed by a single crystal investigation which also shows that there are two distinctly different Cr—Br bond distances (Table 34 and **72**).[250] However, in $[pyH]_2[CrBr_4(H_2O)_2]$ there are discrete *trans* planar $CrBr_2(H_2O)_2$ units and bromide ions instead of the expected *trans* octahedral anions (Table 41). This is an example of Cr^{2+} in an uncommon planar environment.[251] The chloride $[pyH]_2[CrCl_4(H_2O)_2]$ may have the same structure since it is green unlike $[NH_4]_2[CrCl_4(H_2O)_2]$ which is blue.

(72)

(*ii*) *Tetrachlorochromates(II): syntheses*

Complex salts of the general formula $A_2[CrCl_4]$, where A represents NH_4, K, Rb, Cs or an organic cation (usually unipositive), have been intensively investigated during the last decade particularly because many of them are weakly ferromagnetic. Ferromagnetism is well known for certain metals and alloys, but not for magnetically concentrated transition metal complexes, the great majority of which are antiferromagnets. Many tetrabromochromates(II) behave similarly and with the tetrachlorochromates(II) provide the most numerous class of ionic ferromagnets.[252]

The alkali metal tetrachlorochromates(II) can be crystallized from the melt (A = K, Rb, Cs)[253,254] or glacial acetic acid containing acetyl chloride (A = Rb, Cs, NH_4),[255] or obtained by thermal dehydration *in vacuo* of the dihydrates (A = NH_4, K, Rb, Cs)[256] (Scheme 24 and Table 33). Many salts of organic cations have been crystallized from concentrated hydrochloric acid or various non-aqueous solvents.[257–260] The complexes $[dienH_3][CrCl_4]Cl$ and $[trienH_4][CrCl_4]Cl_2$ are also tetrachlorochromates because, as indicated, the additional chlorides are ionic.[257] There is obviously scope for the preparation of salts of many more cations, and whereas the monoalkylammonium salts (and the few known monoarylammonium salts) are ferromagnetic, the more heavily substituted cations, *e.g.* NMe_2H_2 and pyH, produce different structures (see below) and antiferromagnetic tetrachlorochromates.

Large crystals of $Rb_2[CrCl_4]$ and $[N(CH_2Ph)H_3]_2[CrCl_4]$ have been grown; the former from the melt by the Bridgman and Czochralski methods, and the latter by careful temperature control from solutions in sealed tubes.[252,261]

(*iii*) *Ferromagnetic tetrachlorochromates(II): magnetic behaviour, structure and optical properties*

The ferromagnetic behaviour of these complexes was detected by magnetic moments which are considerably higher at room temperature ($\mu_{eff} \approx 5.7$ BM) than the spin-only value, and increase rapidly to *ca.* 9 BM at 90 K as the temperature is lowered.[262] At high temperatures, the reciprocal magnetic susceptibility follows the Curie–Weiss law with large positive intercepts on the absolute temperature axis, and it is apparent from the measurements that the Curie temperatures T_C lie a little below liquid nitrogen temperature. The susceptibility data become field dependent below the T_C values, which have been estimated for several complexes from plots of reduced magnetization against temperature. The persistence of short range order above T_C reduces the accuracy, and more accurate values have been obtained from neutron diffraction and optical spectroscopy (see below), which are zero field methods dependent on spontaneous magnetization.

The high temperature susceptibility data have been fitted to a series expansion formula suitable for a layer ferromagnetic (see below for structures) with $S = 2$, to give estimates of the nearest neighbour exchange integrals J, and some representative results for J and examples of T_C are in Table 33.

Values of J of 7 to 9 cm^{-1} with g *ca.* 1.98 give reasonable fits for the chlorides. For the bromides J is generally larger (Table 35), indicating greater coupling through bridging bromide. J, however, varies little with increasing interlayer separation; thus there is strong magnetic coupling *via* the bridging halide between the cations in the layers and little interaction between the cations in adjacent layers so it is reasonable to assume that the magnetic properties are essentially two-dimensional.[259] Similarly, the Curie temperatures, where known, are not very sensitive to the interplanar spacing. The T_C values themselves are dependent on the method used to measure them. For example, T_C for $[NMeH_3]_2[CrCl_4]$ has been reported as 41 K from very low field magnetization experiments,[263] whereas higher field magnetization experiments and optical studies have given values of 58 K. There is no sign of a phase transition from heat capacity measurements[264] from 10 to 302 K although by comparison with data from the analogous Mn^{II} complex the corrected curve has a maximum at approximately 45 K, where the three-dimensional order breaks down as the temperature rises.

The alkali metal salts have the distorted K_2NiF_4 structure (*cf.* K_2CuF_4) in which there are sheets of chloride-bridged $(CrCl_4)^{2-}$ units separated by double layers of ACl from which chloride ions complete tetragonally elongated ($CrCl_6$) octahedra. The principal axes of the octahedra lie in the sheets and are directed alternately at right angles. Related structures have been described from single crystal studies for $[NMeH_3]_2[CrCl_4]$, $[dienH_3][CrCl_4]Cl$ and $[tmdH_2][CrCl_4]$, in which the sheets $[CrCl_4]_n$ are separated by the organic cations (**73**) (and chloride also in the $dienH_3$ salt) (Table 34). In addition, the salts $A_2[CrCl_4]$ (A = $NMeH_3$,

$NEtH_3$ and $NPhH_3$) are isomorphous with the corresponding copper(II) complexes, which are known to have chloride-bridged sheets intercalated with the organic cations.

(73)

The ferromagnetic chloro complexes have unusual electronic spectra. Besides the usual broad, spin-allowed *d–d* transitions of Jahn–Teller distorted chromium(II), $^5B_{1g} \rightarrow {}^5A_{1g}(\nu_1)$(*ca.* 8000 cm^{-1}) and $^5B_{1g} \rightarrow {}^5B_{2g}$, $^5E_g(\nu_2)$ (*ca.* 11 250 cm^{-1}), the solid state spectra contain relatively intense spin-forbidden bands near 18 700 and 15 900 cm^{-1}. These bands all but vanish on cooling to 4.2 K. Owing to the density of triplet levels (see Tanabe–Sugano diagram) precise assignments are difficult, but the bands have been assigned to transitions to the $^3E_g(^3H)$ and $^3A_{1g}(^3G)$ levels. Transitions to these levels should be independent of ligand field strength, and in confirmation, ferromagnetic bromides (Table 35) have bands at 18 400 and 15 600 cm^{-1}. The greater nephelauxetic effect of bromide would account for the small decrease in wavenumber. The unusual intensity arises from the 'hot band' mechanism (exciton–magnon combination) by which, coincidently with the $\Delta S = -1$ change accompanying the optical excitation of one chromium(II) ion, there occurs a $\Delta S = +1$ change at an adjacent magnetically coupled ion, which drops from a thermally populated magnetic energy level to a lower one. Effectively, $\Delta S = 0$ and the spin-forbidden absorptions gain considerable intensity. At low enough temperatures, when all the metal ions are in the ferromagnetic ground state (all spins parallel), the intensity of the optical transition is zero because no compensating $\Delta S = +1$ changes can occur. Almost up to T_C, which has been estimated from the data, the intensity follows a T^2 law, and this has been explained theoretically.[252,263]

The transparency of the tetrachlorochromates(II) in the visible region could be of technological importance because other ferromagnets are opaque, but their relatively low Curie temperatures and air-sensitivity are severe limitations.

There are many pathways for magnetic interaction in 180° high-spin d^4 systems, some leading to ferromagnetic and others to antiferromagnetic coupling. The pathways have been described for the situation where two planar $[CrX_4]^{2-}$ units share a corner, and it has been calculated that the net result is likely to be antiferromagnetic coupling.[265] No complex with this structure has been isolated.

Parameters such as metal–metal separation, *d*-electron configuration, size and polarizability of bridging atom, bridging angle and planarity of the bridging system are important in determining whether the magnetic interaction will be ferromagnetic or antiferromagnetic. The local environments are very similar in the few ferromagnetic chromium(II) complexes for which structural data are available (Table 34). They all have layer structures, the bridges are approximately linear, the direct Cr—Cr separations are in the range 5.05–5.25 Å and the elongated distortion axes alternate at 90° in the plane of the metal ions. This cooperative Jahn–Teller distortion permits superexchange *via* bridging chloride anions between a half-filled d_{z^2} orbital on one metal ion and the empty $d_{x^2-y^2}$ orbital of a neighbour throughout the lattice. Departure of the bridging angles from 180° will affect the degree of interaction but too few structures have been determined for any pattern to emerge.

(*iv*) *Antiferromagnetic tetrachlorochromates(II)*

Several complexes: $A_2[CrCl_4]$ (A = pyH, NMe_2H_2 or NEt_3H) and $[N_2H_6]_2[CrCl_6]$ are antiferromagnets. This behaviour and the reflectance spectra of the complexes suggest that they contain distorted six-coordinate Cr^{II}. One structure has been determined; that of

$[NMe_2H_2]_2[CrCl_4]$.[266] It does not have a layer structure, but contains isolated trimeric units $[Cr_3Cl_{12}]^{6-}$ in which the metal ions are linearly arranged and antiferromagnetically coupled (**74**). The central chromium atom can be considered to be surrounded by a tetragonally flattened octahedron of chlorine atoms, which bridge to the terminal metal atoms. These form four short and two long Cr—Cl bonds. There is considerable distortion of the angles at the metal atoms from 90°. Now that the structure is known, it is apparent that the successful fitting

Table 35 Bromochromates(II)

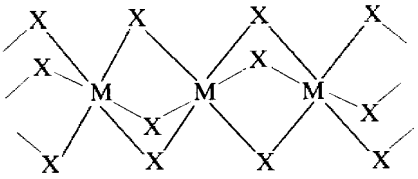
of the magnetic data to the equation for a sheet antiferromagnet was fortuitous[257] and illustrates the difficulty often experienced in distinguishing between possible structures magnetochemically.

(**74**) $[Cr_3Cl_{12}]^{6-}$

There is evidence for the formation of a trimeric anion $[Cr_3Cl_{10}]^{4-}$ ($\mu_{eff} = 4.78$ BM) in solutions of $CrCl_2$ and $[NBu_4]Cl$ in CH_2Cl_2.[267] The antiferromagnetism of $[N_2H_6]_2[CrCl_6]$ suggests that its lattice does not contain $[CrCl_6]^{4-}$ units, since this would lead to magnetically dilute behaviour, but contains ionic chloride and halide-bridged complex anions. The powder photograph of $[NEt_3H]_2[CrCl_4]$ bears no resemblance to that of $[NEt_3H]_2[CuCl_4]$.[260] The latter contains discrete distorted tetrahedral $[CuCl_4]^{2-}$ anions for which no Cr^{II} analogues are known.

(*v*) *Tetrabromochromates(II)*



Like the chlorides, some salts A_2CrBr_4 are ferromagnetic and others antiferromagnetic. They can be prepared by thermal dehydration, but non-aqueous procedures are preferable (Scheme 24). Salts of enH_2^{2+}, $dienH_3^{3+}$ and p-$MeC_6H_4NH_3^+$ could not be obtained. Compared with the chlorides, few investigations have been carried out. The ferromagnetic complexes generally have slightly higher moments and larger J values than the chlorides suggesting that the magnetic interaction is greater. The Curie temperatures are known approximately for $[NRH_3]_2[CrBr_4]$ (R = Me, Pr or n-$C_{12}H_{25}$) and are similar to those of the chlorides[268,269] (Table 35). No structural data have been reported but there seems little doubt that the ferromagnetic complexes will be found to have sheet structures. Since J and T_C do not vary significantly with R, the interplanar coupling between the metal ions is much weaker than the intraplanar coupling as in the chlorides.

Many of the tetrabromochromates(II), *i.e.* the Rb, NH_4, $NPhH_3$, pyH, NEt_4 and NMe_2H_2 salts, are antiferromagnets. Since the chloro analogues of the first three are ferromagnets, structural comparisons would be informative.

Whether ferromagnetic or antiferromagnetic, the salts A_2CrBr_4 have a very broad band near 10 500 cm^{-1}, asymmetric or with a shoulder to lower wavenumber, in their reflectance spectra. These typical spectra of six-coordinate Cr^{II}, with the absorptions at lower wavenumber than in the chlorides (*ca.* 11 000 cm^{-1}), confirm that the $[CrBr_4]^{2-}$ units are polymerized. There are many spin-forbidden bands to higher wavenumber, including two bands near 18 400 and 15 600 cm^{-1}, which are unusually intense in the spectra of the ferromagnetic complexes. Their intensity presumably arises from the same mechanism as for the chlorides.

(vi) Trihalochromates(II): syntheses and structures

Complexes of the general formula AMX_3, where A is a unipositive cation, M a bivalent metal ion and X a halide ion (Cl^-, Br^- or I^-) crystallize in several different lattice types, but have structures comprising infinite parallel chains $(MX_3)_n^{n-}$ of face-sharing octahedra separated by the cations A (**75**). Since the metal–metal separation in the chains is 3.1 to 3.5 Å, increasing from Cl to Br to I, and the distance between chains is much greater at approximately 8 Å, there is strong intrachain interaction, but weak interchain interaction when M is a paramagnetic transition metal ion.[270] In addition, the M—Cl—M bridge angles are approximately 90° so that the structures of the trihalochromates(II) contrast sharply with those of the layer tetrahalochromates(II).

(**75**) $(MX_3)_n^{n-}$

The alkali metal trihalochromates, $ACrX_3$ (X = Cl, Br) can be crystallized from a melt of the constituent anhydrous halides[271–273] or from non-aqueous solvents, especially acetic acid. The latter method is particularly useful in the preparation of salts of non-metallic cations $ACrCl_3$ ($A = NH_4$, NMe_4, pyH and NMe_2H_2).[255] Thermal dehydration in vacuum has also been used to produce $pyHCrCl_3$ and $CsCrCl_3$[256] from $[pyH]_2[CrCl_4(H_2O)_2]$ and $CsCrCl_3(H_2O)_2$. The triiodides $ACrI_3$ (A = Rb, Cs[274]) and the hexaiodides (Tl or $In)_4CrI_6$[275] have been crystallized from the melt. There is no report of attempts to crystallize iodides from non-aqueous solvents.

There is agreement over the gross structural features of these linear chain chromium(II) complexes (and the isomorphous copper(II) analogues), but different models have been used for structural refinement. Phase transitions associated with the Jahn–Teller distortion (α to β to γ as the temperature is lowered) complicate the structural studies.

In the first full structural investigation, that of $CsCrCl_3$ (295 K, hexagonal, α phase), it was concluded that the space group was $P6_3mc$ and the $[CrCl_6]$ octahedra were of C_{3v} symmetry with three short and three long bonds (Table 36), *i.e.* there is no evidence of a static Jahn–Teller distortion, unlike in $CsCuX_3$ (X = Cl, Br).[271] Single crystal X-ray data for $CsCrBr_3$ were analyzed on the same model.[272] If the site symmetry of the Cr^{2+} ion is C_{3v}, the degeneracy of the E_g ground level is not removed and this modifies the assignments of the electronic spectra (see below). However, the space group of the α phases of $ACrX_3$ cannot be uniquely determined from the data,[271,273] and the choice of a disordered $P6_3/mmc$ space group rather than $P6_3mc$ is more logical in relation to the expected operation of the Jahn–Teller effect. With the assumption of pseudo D_{4h} symmetry at each Cr^{2+}, and a random distribution of elongated octahedra, better refinement results for α-$CsCrCl_3$ and α-$CsCrI_3$. The large anisotropic thermal motion of anions parallel to the *c* axis is now attributed to the disorder. The same disordered Jahn–Teller distorted structure is expected for α-$CsCrBr_3$ and α-$RbCrX_3$ (X = Cl, Br or I).[273]

In β-$RbCrCl_3$ the deformation around Cr-1 is elongation along a particular axis, but elongations along other axes average to an apparent compression about Cr-2.[276,277] In γ-$RbCrCl_3$ the elongated axes alternate along different directions.[276]

Whereas the Mössbauer spectra at 77 K of $CsM^{129}I_3$ (M = V, Mn) can be fitted assuming quadrupole splitting at a single metal site, two sites ($a/b = 2/1$), with coupling constants of opposite sign, must be assumed when M = Cr. In the *a* and *b* sites the ^{129}I atoms are in asymmetric and symmetric bridging positions respectively, consistent with axially distorted octahedra. The α to β phase transition (Table 36) is confirmed from X-ray powder diffraction, but at 165 ± 5 K.[278]

(vii) Trihalochromates(II): electronic spectra and magnetic behaviour

The single crystal electronic absorption spectra of $CsCrX_3$ (X = Cl or Br) have been examined in some detail. There are intense broad bands at 22 000 and 11 500 cm^{-1} with a

weaker broad band at 6500 cm^{-1}. The last two bands have been assigned[273] to the usual $^5B_{1g} \rightarrow {}^5B_{2g}$, ^5E_g and $^5B_{1g} \rightarrow {}^5A_{1g}$ transitions (Figure 2, D_{4h} symmetry), but because the E_g and T_{2g} levels of O_h symmetry remain unsplit in C_{3v} symmetry, an alternative assignment of the bands at 11 500 and 6500 cm^{-1} is to the $^5E \rightarrow {}^5T_2$ transition and the spin-forbidden $^5E \rightarrow {}^3T_1$ transition respectively.[279] The alternative seems less likely in view of the recent crystallographic work, which indicates pseudo D_{4h} symmetry for the $[CrCl_6]$ units in all phases.

The band at 22 000 cm^{-1} (anomalous because other Cr^{II} complexes of Cl^- and Br^- do not absorb strongly here) has been assigned to simultaneous excitation of a pair of antiferromagnetically coupled Cr^{II} ions so that the absorption is at *ca.* $2 \times 11\,500\ cm^{-1}$.

A number of weak sharp bands in the region 15 000 to 25 000 cm^{-1} have been assigned to spin-forbidden transitions and charge transfer is found beyond 25 000 cm^{-1}.[279] The iodide $CsCrI_3$ absorbs strongly throughout the visible–near IR region; a shoulder at 10 000 cm^{-1} may be a *d–d* transition.[270]

The trihalochromates(II) behave antiferromagnetically and the temperature-dependence of susceptibility has been analyzed in terms of linear chains of interacting spins (high spin Cr^{II}, $S = 2$, Table 36). Direct exchange should increase as the Cr—Cr separation decreases (I → Br → Cl), while superexchange *via* the bridging anions should increase with increasing covalency (Cr → Br → I). The second effect predominates in $CsNiX_3$,[270] but there have not been enough investigations for correlations to appear in the Cr^{II} case.

The only known hydrated trichlorochromate is $Cs[CrCl_3(H_2O)_2]$ (Table 32), the antiferromagnetic behaviour of which can be reproduced by substitution of $J = -3.0\ cm^{-1}$ and $g = 1.93$ in the expression for a binuclear compound with $S = 2$. This suggests[256] that it has the

structure found in copper(II) compounds of the same stoichiometry in which binuclear $Cu_2Cl_6(H_2O)_2$ units, formed by symmetrical chloride bridges, are weakly linked in chains by further chloride bridges.

(viii) Pentahalochromates(II)

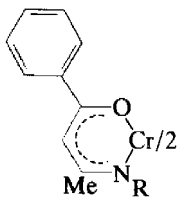
When sodium chloride is fused with anhydrous chromium(II) chloride the product is $NaCrCl_5$ regardless of the proportions of chlorides used.[222] Other cations give tetra- or tri-chlorochromates(II) as in Sections 35.3.7.3.ii and 35.3.7.3.vi above. The solvate $[pyH]_3[CrBr_5]\cdot 2MeCO_2H$ has been isolated from the metal acetate and pyridine in a mixture of acetyl bromide and acetic acid, and there is considerable splitting of the spin-allowed *d–d* band in the reflectance spectrum of this complex,[255] but no detailed investigations of pentahalochromates have been reported.

(ix) Hexaiodochromates(II)

The complexes A_2CrI_6 (A = Tl or In) contain isolated $[CrI_6]^{4-}$ units; in the α phase there is a random distribution of Jahn–Teller distorted octahedra, which are elongated perpendicular to the *c* axis, and below 77 K the β-phase forms in which the directions of elongation are ordered (Table 36). Refinement leading to axially compressed octahedra in the $[CrI_6]^{4-}$ units [Cr—I, 3.046 Å (4 ×), 2.738 Å (2 ×)][280] is said[275] to be due to an inadequate model.

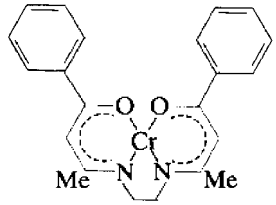
35.3.8 Hydrogen and Hydrides as Ligands

The borohydride $Cr(BH_4)_2\cdot 2THF$ has been prepared from $[Cr(OBu^t)_4]$ and B_2H_6 (Section 35.3.4.2) and from $CrCl_3$ (p. 725). CrH_2 has a cubic close packed structure and in hexagonal close-packed CrH the CrH distance is 1.91 Å.[281] The hydride $[CrH_2\{P(OMe)_3\}_5]$ is discussed in Section 35.3.4.1.



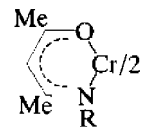
35.3.9 Mixed Donor Atom Ligands

Several types of mixed donor ligand (N—O, C—O) bridge the $(Cr—Cr)^{4+}$ unit in dinuclear species (Section 35.3.5.5).

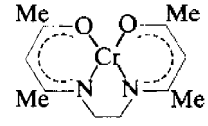


35.3.9.1 Complexes of β-ketoamines and Schiff's bases

(i) β-Ketoamines



Chromium(II) complexes (**76**) to (**79**) have been made[282,283] by the procedure outlined in Scheme 16 for the preparation of $[Cr(dpm)_2]$. Complexes (**76**; R = Me, Pr^i) are thought to be planar because they are high-spin (Table 37), with solution and solid state spectra[282] like those of planar high-spin $[Cr(dpm)_2]$. One member (R = Bu^n) of the related series (**78**) and [Cracacen] (**79**), have been shown to be planar by single crystal X-ray studies; resemblances between the electronic spectra suggest that series (**78**) are all planar. Unlike the nickel(II) series analogous to (**78**), bulky R groups do not induce the formation of tetrahedral chromium(II) presumably because Cr^{2+} is larger than Ni^{2+}



(**76**) R = Me, Pr^i

(**77**) Cr(bzacen)

(**78**) R = Me, Et, Pr^n, Pr^i, Bu^n

(**79**) Cr(acacen)

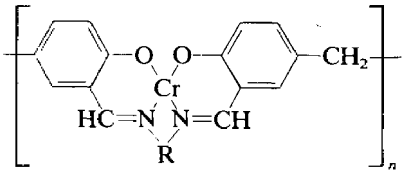
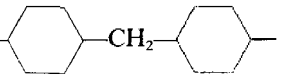
Series **(78)** and [Cracacen] have magnetic moments at room temperature which are below the value of 4.90 BM expected for high-spin chromium(II) and decrease still further at lower temperatures. Such magnetic behaviour is usually associated with antiferromagnetic interaction, but the crystal structures do not indicate any obvious pathways for the interaction. It is possible that the magnetic data can be accounted for by the progressive formation of low-spin forms ($S = 1$ and/or 0) as the temperature is lowered.[283] The magnetic moment of 2.22 BM found[282] for **(77)** [CrBzacen] at room temperature may imply strong antiferromagnetic interaction, or that the molecule is predominantly in a low-spin state. Further structural and magnetic work is needed. Complexes **(76)** react with chlorinated solvents to form chromium(III) species which have not been characterized (Table 37).

(*ii*) *Schiff's base complexes*



Chromium(II) chelates of 3-(*N*-2-furfuralideneimino)propionic acid (HFP), *o*-(*N*-α-furfuralidene)benzoic acid (HFB), and *o*-(*N*-α-furfuralideneimino)ethanesulfonic acid (HFE)[284–286] have been found to have magnetic moments of approximately 4.8 BM at room temperature. A band near 14 500 cm^{-1} ($CHCl_3$ solution) has been assigned to the $^5E_g \rightarrow {}^5T_{2g}$ transition and formation constants have been measured. However, there is no indication of difficulties arising from the air sensitivity of chromium(II) solutions.

A low-spin chromium(II) complex of pyruvic acid thiosemicarbazide has been reported (Table 96).[287]



(*iii*) *Complexes of polymeric Schiff's bases*

Chromium(II) complexes of the polymeric Schiff's bases **(80)** are said[288,289] to be produced when chromium(II) acetate dissolved in DMF is added under nitrogen to a hot solution of the ligand in which sodium acetate is suspended. The yellow-green complexes are insoluble in all common solvents, are surprisingly stable to air, and oxidation to the Cr^{3+} complex with hydrogen peroxide occurs only on heating. The magnetic moments are approximately 3.0 BM at room temperature, indicating a low-spin d^4 configuration. In view of the difficulties in the preparation of complexes of β-ketoamines, it would seem possible that the polymeric complexes are of chromium(III), and cross-linked oxo or hydroxo structures could, through antiferromagnetic interaction, lead to moments below the 3.87 BM expected for chromium(III) complexes. It is true that direct preparation of the chromium(III) complex of **(80;** R = —$(CH_2)_3NMe(CH_2)_3$—) gives a product with an essentially normal moment of 3.6 BM but in

this case coordinated chloride is present. Irrespective of their precise nature, the chromium Schiff's base complexes have molecular sieve properties, and as gas chromatographic stationary phases can be used[290] for the separation of noble gases and oxygen at room temperature.

(I) R = —$(CH_2)_3N(CH_3)(CH_2)_3$—

(II) R = 

(80)

35.3.9.2 Amino acids

The glycinato complex $[Cr(gly\text{-}o)_2]\cdot H_2O$ has been prepared by mixing aqueous solutions of sodium glycinate and chromium(II) sulfate[85] or aqueous lithium glycinate with ethanolic $CrCl_2\cdot 4H_2O$. The second method reduces the chance of hydrolysis to brown $Cr(OH)_2$ and has been used with minor modifications in the preparations of the methionato, *S*-methyl-L-cysteinato and histidinato complexes: $[Cr(met\text{-}o)_2]$, $[Cr(mcys\text{-}o)_2]$ and $[CrCl(his\text{-}o)]\cdot H_2O$.[100] The general similarity in the spectra (Table 38) of the bis(amino acidato) complexes suggests that the metal environment is the same in each, *i.e.* NH_2 and CO_2^- coordination. The weak antiferromagnetic interaction apparent from the small variation of magnetic moment is likely to be due to extended structures arising through carboxylate bridges. The histidinato complex $[CrCl(his\text{-}o)]\cdot H_2O$ shows stronger interaction and may be chloro bridged.

Table 38 Amino Acid Complexes

Complex	μ_{eff} (BM) *295 K*	*90 K*	θ (°)	*Reflectance spectra* (cm^{-1}) ν_2	ν_1
$[Cr(gly\text{-}o)_2]\cdot H_2O$ Pale violet	4.61	4.52	6	16 300	12 000sh
$[Cr(met\text{-}o)_2]$ Pale violet	4.76	4.61	11	17 000	12 100sh
$[Cr(mcys\text{-}o)_2]$ Pale violet	4.67	4.54	8	16 800	13 100sh
$[CrCl(his\text{-}o)]\cdot H_2O$ Blue-violet	3.70	3.38	24	18 000	12 700sh

A green, air-stable homocystine complex, $[Cr\{(—SCH_2CH_2CHNH_2CO_2)_2\}_2]$ (μ_{eff} = 4.83 BM, $\bar{\nu}_{max}$ = 40 800, 39 200 and 14 300 cm^{-1}), has been prepared from aqueous $CrCl_2$ and homocystine (pH 8, $NaHCO_3$).[291]

Table 39 contains some stability constant data for chromium(II) and amino acids in aqueous solution.

35.3.9.3 Complexones

The chromium(II)–edta system is powerfully reducing (the half-wave potential is −1.48 V at pH 12 *vs.* SCE) and has been used in the reduction of iron–sulfur clusters.[292] No solid complex has been isolated because of its instability to oxidation, but Cr^{II}–edta is high-spin in aqueous solution (μ_{eff} = 5.12 BM) and its stability constant has been determined. The edta is believed to be pentadentate with H_2O in the sixth position.[293]

Stability constants, usually determined pH-metrically, for complexation between Cr^{2+}(aq) and

various ligands including edta and other complexones are given in Table 39. There are discrepancies between recent and earlier work, but there is agreement with 'preparative' observations. No complex formation could be detected in the Cr^{2+}–ammonia system even in 2 mol dm^{-3} NH_4Cl before hydrolytic precipitation of Cr^{2+}, and it was necessary to take various measures, *e.g.* use a large excess of ligand, to avoid hydrolytic precipitation in other systems. The greater ionic radius of Cr^{2+} (0.82 Å) compared with Cu^{2+} (0.69 Å) modifies the $\log K_1/K_2$ ratios as well as leading to smaller overall constants.[294] The rates of formation and dissociation of $[Cr(gly\text{-}o)]^{2+}$ and $[Cr(gly\text{-}o)_2]^{2+}$ have been measured.[295]

35.3.9.4 Bidentate mixed donor atom ligands

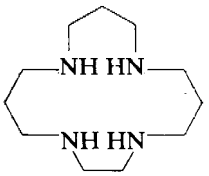
(i) N—O ligands

Unidentified orange–yellow precipitates have been obtained from aqueous Cr^{2+} solutions and 8-hydroxyquinoline or an alkali metal 2-aminobenzoate.[83]

(ii) N—S ligands: 2-aminobenzenethiol

When aqueous ethanolic solutions of 2-aminobenzenethiol (abt) and chromium(II) chloride are mixed, the green suspension first formed turns light blue within one hour. The blue product

$[Cr(abt)_2]$ is high-spin ($\mu_{eff}^{322\,K} = 4.71$ BM, $\theta = 1°$), with a broad reflectance band at 16 900 cm^{-1}. Axial donation from adjacent $[Cr(abt)_2]$ units seems necessary to produce six-coordinate Cr^{II} so it is surprising that the magnetic moment is not temperature-dependent. Possibly the molecule is essentially planar.[296]



35.3.10 Multidentate Macrocyclic Ligands

35.3.10.1 Planar (closed) macrocycles; porphyrins, corrins and phthalocyanines

Chromium(II) porphyrins and phthalocyanines are dealt with in Sections 35.4.9.1 and 35.4.9.3 respectively.

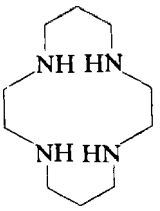
35.3.10.2 Other polyazamacrocycles

The chromium(II) complex of 1,4,8,12-tetraazacyclopentadecane ([**15**]aneN$_4$; **81**) has been prepared in aqueous solution and used as an intermediate in the production of chromium(III) complexes (Scheme 25), including some which contain Cr—C σ bonds.[297] Its powerful reducing ability and the chemical inertness of the Cr^{III} products (it is preferable to Cr^{2+}aq) have been exploited[298] in kinetic studies of the reduction of ferredoxins.

(**81**) [15]aneN$_4$

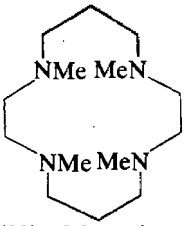
$$CrCl_2{\cdot}4H_2O \xrightarrow[H_2O]{[15]aneN_4} \underset{\text{royal purple}}{[Cr^{II}([15]aneN_4)(H_2O)_2]^{2+}} \xrightarrow{air} \underset{\text{orange}}{[Cr^{III}([15]aneN_4(H_2O)_2]^{3+}}$$

$$(E^0 = -0.58\ V)$$



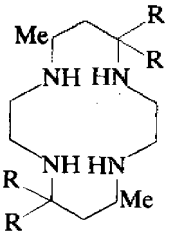
$$\downarrow RX$$

$$[RCr^{III}([15]aneN_4)(H_2O)]^{2+} + [XCr^{III}([15]aneN_4)(H_2O)]^{2+}$$



R = Me, Et, Pr, Pr^i, Bu^n, n-C_5H_{11}, Cy, 1-adamantyl, benzyl

Scheme 25



The reaction of chromium(II) with cyclam, 1,4,8,11-tetraazacyclotetradecane ([**14**]aneN$_4$; **82**) results in oxidation to Cr^{III} derivatives, but several complexes of 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (Me$_4$cyclam; **83**);[299] *meso*-5,12-dimethyl-1,4,8,11-tetraazacyclotetradecane (Me$_2$[**14**]aneN$_4$; **84**, R = H) and *meso*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (Me$_6$[**14**]aneN$_4$; **84**, R = Me)[300] have been prepared according to Scheme 26. The use of CH_2Cl_2 as solvent and even as the source of chloride in the formation of $[CrCl(Me_4cyclam)]BPh_4{\cdot}0.5CH_2Cl_2$ would seem inadvisable in view of the formation of Cr^{III}—C species from organic halides referred to above. However, this complex and the others have magnetic moments consistent with high-spin chromium(II). The complexes $[CrX_2(Me_4cyclam)]$(X = Br, I) are non-electrolytes in CH_2Cl_2 and have closely similar solution and reflectance spectra. Since the reflectance spectra are not typical of *trans*-CrX_2N_4 species the complexes appear to be *cis* with Me$_4$cyclam in a folded configuration. In DMF five-coordinate cations $[CrBr(Me_4cyclam)]^+$ and $[Cr(DMF)(Me_4cyclam)]^{2+}$ form because the spectra resemble those of the BPh_4 salts of these cations (Table 40) and the conductance behaviour agrees. The cations in $[CrX(Me_4cyclam)]BPh_4$ and $[Cr(solv)(Me_4cyclam)](BPh_4)_2$ have respectively been assigned distorted trigonal bipyramidal and square pyramidal structures. There is no crystallographic evidence.

2. F. Mani, *Inorg. Chim. Acta*, 1982, **60**, 181.

The complexes $[CrX_2(Me_2[14]aneN_4)]$ and the purple forms of $[CrX_2(Me_6[14]aneN_4)]$ are high-spin with electronic spectra of the usual pattern for *trans* octahedral chromium(II). The blue complexes $[CrX_2(Me_6[14]aneN_4)]$ are also high-spin but have a different spectral pattern. It is not clear whether they contain the folded macrocyclic ligand in *cis* octahedral or distorted trigonal bipyramidal cations. The brown complex $[Cr(Me_6[14]4,11\text{-dieneN}_4)(py)](PF_6)_2$ reacts with sodium nitrite to give $[Cr(Me_6[14]\text{-}4,11\text{-dieneN}_4)(NO_2)(NO)]PF_6$ (Section 35.4.2.6).

35.3.11 Stereochemistry of Bivalent Chromium

Excluding the dinuclear and related complexes (Section 35.3.5.5), the structures of comparatively few chromium(II) complexes have been determined by single crystal X-ray or other diffraction methods. From the structures reported it is apparent that high-spin chromium(II) has as rich a stereochemistry as copper(II). In most complexes (Table 34) Cr^{2+} forms four coplanar bonds with two longer bonds completing a distorted octahedron (4 + 2 coordination), but the number of planar complexes (the limit of 4 + 2 coordination) is increasing rapidly (Table 41), and there are many for which trigonal bipyramidal or square pyramidal structures (Table 42) have been inferred from the general properties of the complexes. Seven-coordinate chromium(II) complexes are also known (Table 95).

Table 41 Planar Chromium(II) Complexes

35.4 CHROMIUM(III)

The coordination chemistry of chromium(III) was first seriously investigated by Pfeiffer at the turn of the century; in many ways his studies parallel the work of Werner on cobalt(III). The complexes of chromium(III) are almost exclusively six-coordinate with an octahedral disposition of the ligands. Many are monomeric ($\mu_{eff} \approx 3.6$ BM), although hydroxy-bridged and other polynuclear complexes are known in which spins on neighbouring chromiums are coupled.

The electronic[301] and magnetic properties of mononuclear chromium(III) complexes are quite well understood; however there is a distinct tendency for octahedral symmetry to be invoked in cases where the true symmetry is much lower. Chromium(III) is a hard Lewis acid and many stable complexes are formed with oxygen donors. In particular hydroxide complexes are readily formed in aqueous solution, and this may be a problem in synthesis. Substitution at chromium(III) centres is slow[302,303] and may well have some associative character in many cases. The kinetic inertness of chromium(III) has led to the resolution of many optically active complexes; this work has been extensively reviewed.[304]

Table 42 Five-coordinate Chromium(II)

Complex[a]	*Comments*	*Ref.*
$[Cr(NH_3)_5]X_2$ X = Cl, Br, I	Square pyramidal from electronic spectra, magnetic and powder data	1

The organometallic chemistry of chromium(III) has been the subject of two recent reviews.[1,305]

35.4.1 Group IV Ligands

The reported complexes of chromium(III) with group IV ligands are limited mainly to those containing CN^- and to a lesser extent those containing other C donor ligands.

35.4.1.1 Cyanides

(i) Hexacyanochromate(III) and its aquation products

By far the most widely studied cyanochromium(III) complex is the pale yellow, water-soluble $K_3[Cr(CN)_6]$.[306,307] The most convenient synthesis reported for this complex involves the addition of $Cr(OAc)_3$, prepared by H_2O_2 reduction of CrO_3 in acetic acid, to a solution of KCN.[308] Results of a number of structure determinations carried out on salts containing $[Cr(CN)_6]^{3-}$ are summarized in Table 43.

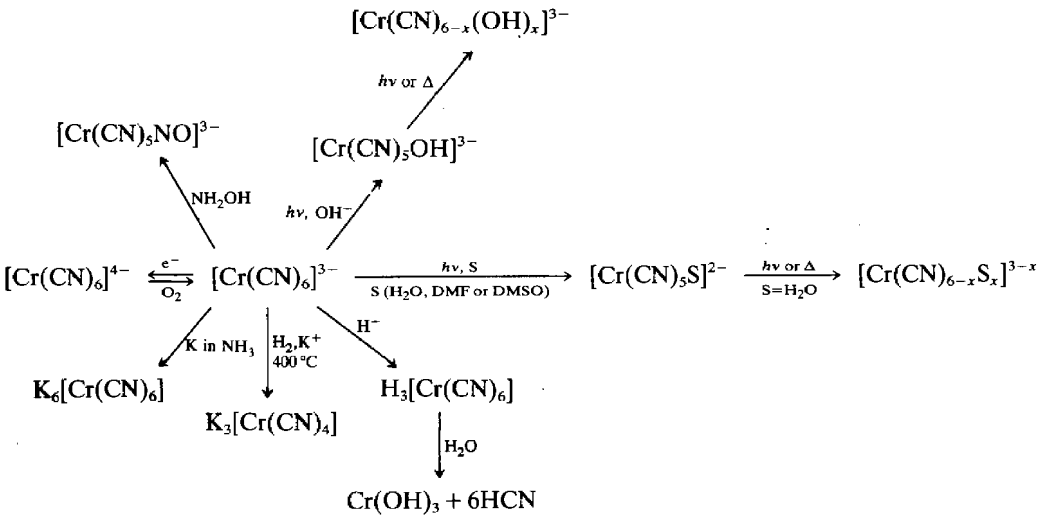

Table 43 Bond Distances in $[Cr(CN)_6]^{3-}$ Salts

Complex	*Cr—C* (pm)	*Cr—N* (pm)	*Comments*	*Ref.*
$Cs_2K[Cr(CN)_6]$	206.8–207.5	113.7–113.8	295 K	1
$K_3[Cr(CN)_6]$	203.8–209.0	113.6–119.8	4.2 K, neutron	2
$Cs_2Li[Cr(CN)_6]$	205.8	114	381 K	3
$Cs_2Li[Cr(CN)_6]$	199–222	110–116	295 K, neutron	4

The Raman spectrum of $K_3[Cr(CN)_6]$ has recently been assigned and earlier work on its vibrational spectrum has been summarized.[309] Raman spectra of single crystals show ν(CN) at 2131, 2132 and 2135 cm^{-1} while ν(CN) for aqueous solutions occurs at 2132 cm^{-1}. The electronic spectrum of $[Cr(CN)_6]^{3-}$ in aqueous solution has *d–d* bands at 377 (ε = 90 $dm^3\,mol^{-1}\,cm^{-1}$) and 309 nm (ε = 65 $dm^3\,mol^{-1}\,cm^{-1}$) and a charge transfer band at 263 nm (ε = 6240 $dm^3\,mol^{-1}\,cm^{-1}$).[310] Detailed *ab initio* SCF calculations have recently been carried out on the ligand field bands of this anion.[311] The X-ray photoelectron spectrum of $K_3[Cr(CN)_6]$ in the regions 24 and 9 eV is similar to that of KCN, indicating that the 3σ and 4σ molecular orbitals of CN^- are invariant to complex formation.[312] However, the broad lines due to photoemission from the 5σ and 1π orbitals in KCN are completely smeared in the spectrum of the complex suggesting that these ligand orbitals participate strongly with the metal in bonding. Discrete variational X_α-methods have been applied to the calculation of orbital energies and results are in good agreement with the experimentally determined XPS values.[313] The difference between the phosphorescent spectra of $Ag_3[Cr(CN)_6]$ and $K_3[Cr(CN)_6]$ has been attributed to an interaction between the nitrogen end of the cyano ligand and the Ag^+ ion in the former complex.[307]

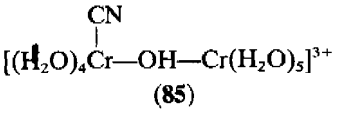
Some representative reactions of $[Cr(CN)_6]^{3-}$ are depicted in Scheme 27.[306,308,314–318] The properties of $[Cr(CN)_5NO]^{3-}$ are discussed in Section 35.4.2.6.

Scheme 27

The slow addition of $K_3[Cr(CN)_6]$ to a solution of $FeSO_4{\cdot}7H_2O$ at 0 °C gives a polymer of approximate composition $Fe_3[Cr(CN)_6]_2$, which on the basis of IR (ν_{CN} at 2170 cm^{-1} and therefore indicative of a bridged chromicyanide, ν_{MC} = 488 cm^{-1}) and Mössbauer (all the iron present as high-spin Fe^{2+}) spectroscopy seems to contain Cr^{3+}—C≡N—Fe^{2+} linkages.[307,319] On heating at 50 °C in an inert atmosphere half the Cr^{3+} ions are displaced by Fe^{2+} ions from their carbon 'sites'. In the presence of air further rearrangement and partial oxidation occurs to give a compound which on reduction with hydrazine affords an isomer of the starting material containing Cr^{3+}—N≡C—Fe^{2+} linkages (ν_{CN} = 2100 cm^{-1}, ν_{MC} = 525 cm^{-1}).

In aqueous acid solution $[Cr(CN)_6]^{3-}$ aquates *via* a series of stepwise stereospecific reactions to give $[Cr(H_2O)_6]^{3+}$ as the final product.[320] Some of the intermediate cyanoaqua complexes in this sequence have been isolated and details of their electronic spectra are presented in Table 44. These complexes aquate by both acid-independent and acid-dependent pathways, the latter involving protonation of the cyano ligands followed by aquation of the singly protonated species. Some of these reactions are found to be catalyzed by Cr^{2+} and kinetic data for the aquation of $[CrCN(H_2O)_5]^{2+}$ are consistent with the transition state structure (**85**).[307] In the presence of Hg^{2+} and Ag^+ cyanoaquachromium(III) complexes undergo strong association followed by 'flipping' of one or more of the cyano ligands, depending on the heavy metal to complex concentration ratio and the time elapsed since mixing the reactants (Scheme 28).[321] Addition of Cr^{2+} to solutions of cyanocobalt(III) complexes produces the metastable intermediate $[CrNC(H_2O)_5]^{2+}$ (at $[H^+]$ = 0.9 M, λ_{max} = 535 nm, ε = 19.6 $dm^3\,mol^{-1}\,cm^{-1}$; λ_{max} = 396 nm, ε = 23 $dm^3\,mol^{-1}\,cm^{-1}$).[322] This isomerizes to $[CrCN(H_2O)_5]^{2+}$ (λ_{max} = 525 nm, ε =

25.2 $dm^3\ mol^{-1}\ cm^{-1}$; $\lambda_{max} = 393$ nm, $\varepsilon = 20.0\ dm^3\ mol^{-1}\ cm^{-1}$) in a Cr^{2+}-catalyzed reaction which occurs by a ligand-bridge electron-exchange mechanism. In aqueous solution containing CN^- and OH^-, $[Cr(CN)_6]^{3-}$ exists in equilibrium with $[Cr(CN)_5OH]^{3-}$ when $[CN^-]$ and $[OH^-]$ are both greater than 0.1 M and when $[OH^-]/[CN^-] < 2$.[323] The Cr^{2+}-catalyzed aquation of $[Cr(CN)_6]^{3-}$ under these conditions seems to proceed by an outer-sphere redox mechanism represented by equation (27) although the formation of a short-lived bridged intermediate is not excluded by the kinetic data. The complex $K_3[Cr(CN)_5OH]\cdot H_2O$ may be obtained as orange-yellow crystals by reaction of $[CrCl(NH_3)_5]Cl_2$ and KCN in boiling water, followed by purification on a Sephadex column.[324]



$$[Cr(CN)_6]^{3-} + [Cr(CN)_5OH]^{4-} \rightleftharpoons [Cr(CN)_6]^{4-} + [Cr(CN)_5OH]^{3-} \quad (27)$$

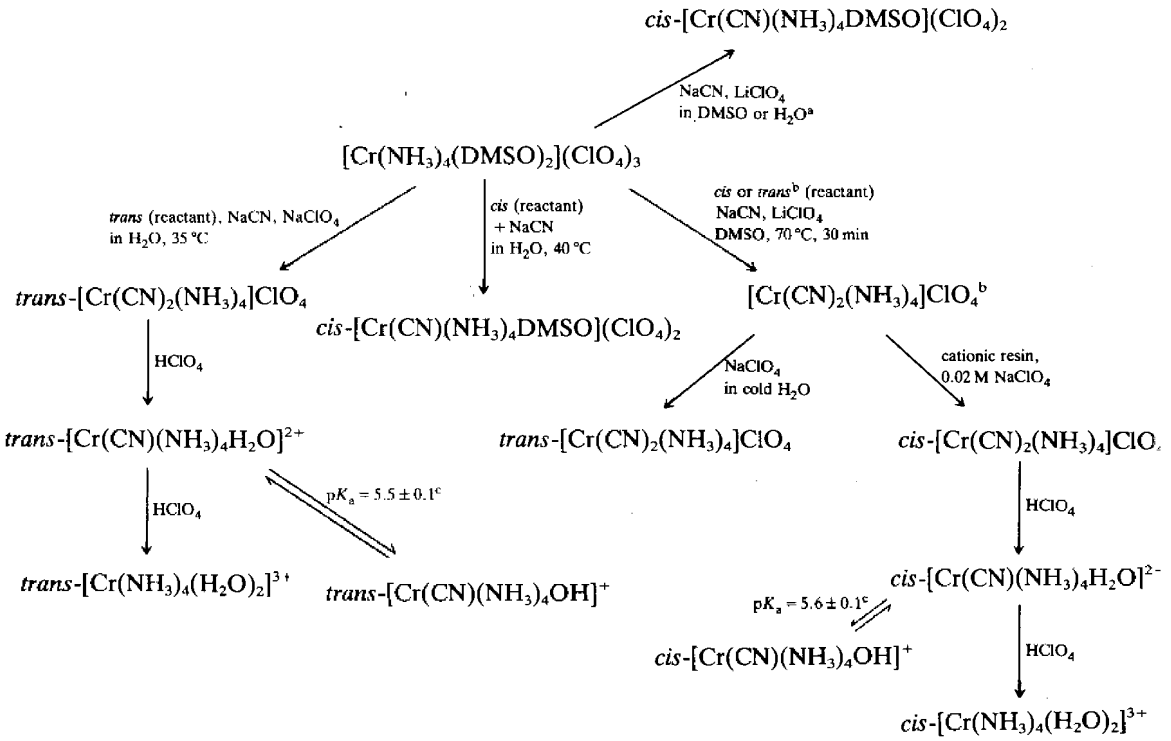
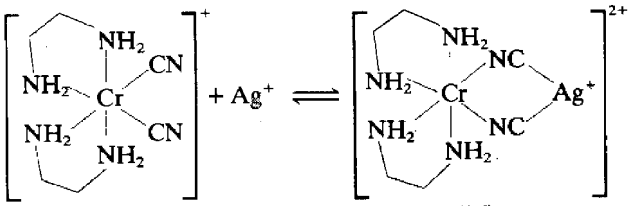


Scheme 28

(*ii*) *Cyanoammine- and cyanoamine-chromium(III) complexes*

Although the range of reported acidoammine/amine chromium(III) complexes is quite extensive, only a few such cyano species have so far been prepared, due mainly to the difficulties associated with the CN^- anation of the appropriate aqua complexes. These difficulties stem largely from the ionization of coordinated water in the presence of CN^-. This not only generates a leaving group of greater nucleophilicity but also makes complex

decomposition competitive with anation.[325] Anation reactions of non-aqueous solvates circumvent these problems.[325] Hence the reaction between $[Cr(NH_3)_5DMSO](ClO_4)_3$ and excess NaCN in DMSO at 70 °C affords the monocyano complex $[Cr(CN)(NH_3)_5]^{2+}$, which was isolated as a perchlorate in 40% yield.[326] Details of the electronic and IR spectra of the complex are presented in Table 44. This complex phosphoresces in aqueous solution and its photoreactivity on LF band irradiation consists exclusively of NH_3 aquation. Thermal aquation of the complex on the other hand involves loss of CN^- and follows both acid-independent and acid-dependent pathways, the latter involving N protonation of the CN^- ligand.



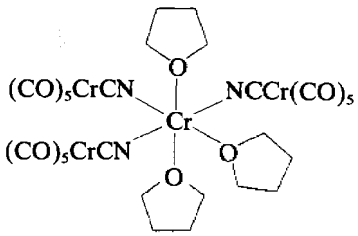
The isomers *cis*- and *trans*-$[Cr(CN)_2(NH_3)_4]^+$ as well as *cis*-$[Cr(CN)(NH_3)_4DMSO](ClO_4)_2$ have also been synthesized by the anation reactions shown in Scheme 29.[325] While anation in DMSO is accompanied by stereochemical change, the reaction in H_2O is stereoretentive. The dicyano complexes undergo H^+-assisted thermal aquation, involving the successive loss of the CN^- ligands. The *trans* complex is about ten-fold more reactive in the first step than the *cis*, an observation attributed to the *trans* labilizing effect of CN^-.

[a] This reaction proceeds as shown with either reactant isomer in DMSO (15 min, 70 °C) but only with the *cis* isomer in H_2O (2 h, 40 °C). [b] Both isomers give a mixture containing 50% *cis* and 50% *trans* product but the *cis* isomer is the recommended starting material because of its ease of preparation. [c] These are concentration pK_a values at 298 K, $I = 0.1$ mol dm^{-3}.

Scheme 29

The synthesis of the isomers of $[Cr(CN)_2(en)_2]^+$ is discussed in Section 35.4.2.3. Like the previously mentioned cyanoammine complexes, *cis*-$[Cr(CN)_2(en)_2]^+$ is quite labile in acid solution.[327,328] This behaviour contrasts markedly with that of *cis*-$[Co(CN)_2(en)_2]$,$^+$ which undergoes no apparent decomposition over a period of five days at 80 °C in aqueous acid.[327] The addition of Ag^+ to an aqueous solution of *cis*-$[Cr(CN)_2(en)_2]^+$ results in ligand isomerization, equation (28), and formation of adduct (**86**) which has an electronic spectrum

(28)



(**86**)

characteristic of a CrN_6 chromophore.[328] The IR spectrum of the adduct, which has been isolated as its perchlorate salt, has a CN stretching band (2128 cm^{-1}) in a similar position to that of the parent complex (2130 cm^{-1}) but of much greater intensity, consistent with extensive chromium cyanide π bonding. Addition of NaI to a solution of the adduct causes the precipitation of AgI and the regeneration of the original complex, a reaction which emphasizes the critical role played by Ag^+ in stabilizing the isocyano isomer. The preparation of *trans*-$[Cr(CN)_2(cyclam)]ClO_4$ is described in Section 35.4.9.2.

The photochemical behaviour of cyanoammine/amine chromium(III) complexes differs from that of other acido chromium(III) species. The higher ligand field strength of CN^- relative to ammine/amine ligands causes the $^4B_{2g}$ component of the first spin-allowed quartet excited state to lie at lower energy than the ^4E_g component for D_{4h} complexes.[329] Since this state is associated with selective population of the $d_{x^2-y^2}$ orbital, LF band irradiation causes photolabilization of the in-plane amine ligands. Hence the complexes *trans*-$[Cr(CN)_2(NH_3)_4]^+$ and *trans*-$[Cr(CN)_2(en)_2]^+$ behave 'antithermally' on photolysis, the former losing an ammine ligand (on 440 nm excitation, $\phi_{NH_3} = 0.24$, $\phi_{CN^-} = 0.005$)[329] and the latter undergoing a reaction involving release and protonation of one end of an en ligand.[330] In the case of *trans*-$[Cr(CN)_2(cyclam)]^+$, however, the presence of the macrocyclic ligand militates against cleavage of a chromium–amine bond and this complex shows no discernible photochemical reactivity.[331] The complex $Na_3[Cr(CN)_2edta(H_2O)]\cdot 4H_2O$ which contains tridentate (2N,O) edta, is referred to in Table 44.

(*iii*) *Bi- and multi-nuclear cyanochromium(III) complexes*

A number of binuclear complexes containing Cr^{III}—NC—M bridges have been reported. The methods of preparation and spectroscopic properties of these complexes are presented in Table 45. The IR spectrum of each complex displays two CN stretching bands, the higher wavenumber one attributed to bridging CN and the other due to terminal CN ligands.[332] Magnetic susceptibilities down to liquid helium temperatures have been determined for *cis*-$K[(N—N)_2FCr—NC—Cr(CN)_5]$ (N—N = en, tn) and *cis*-$K[(en)_2FCr—NC—CrNO(CN)_4]$.[333] Whereas the first two complexes show weak antiferromagnetic interaction between the chromium ions, the nitrosyl complex behaves as a Curie paramagnet. The absence of antiferromagnetic superexchange in this complex has been suggested to indicate that the NO ligand is *trans* to the cyano bridge. Reaction of $Na_2Cr(CO)_5$ with $Br_2CNNCBr_2$ in THF affords the tetranuclear complex $(THF)_3Cr^{III}[NCCr(CO)_5]_3$ (**87**).[334] A pair of binuclear linkage isomers involving the CN^- ligand has been prepared in solution according to Scheme 30.[335]

The thermal decomposition of a number of double complexes containing the $[Cr(CN)_6]^{3-}$ anion has been investigated and the results obtained under quasi-isothermal and -isobaric conditions are summarized in Scheme 31.[336] The 'CN-flipping' reactions involved in the scheme resemble similar reactions of Prussian blue analogues such as $Co_3[Cr(CN)_6]_2$[337] and $Fe_3[Cr(CN)_6]_2$.[338] The unusually low magnetic moment of $Cr(CN)_6Cr$ indicates considerable metal–metal interaction *via* the CN bridges.

35.4.1.2 Isocyanides

Some aryl isocyanide complexes of the type $[Cr(CNR)_6]X_3$ ($X = SbCl_6^-$, BF_4^-) have recently been reported. Details of the preparations and properties of these complexes are given in Table 3.

35.4.1.3 Alkyls and aryls

The chemistry of alkyl and aryl chromium(III) complexes is covered in the companion series[306] and has recently been the subject of a thorough review.[305] Some of these complexes are also referred to in Sections 35.4.2.5 and 35.4.8.1.iv.

35.4.2 Nitrogen Ligands

Complexes of chromium(III) with ammonia and amines were among the first to be recognized by the early coordination chemists. Consequently, there is a vast literature, and this section is restricted to work since the comprehensive review by Garner and House[302] in which

new solids have been characterized. In many cases the compounds are tabulated without comment.

35.4.2.1 Ammonia

Some cyanoammines are discussed in Section 35.4.1.1; other ammines which are new or have been prepared by improved methods are listed in Table 46 or mentioned below.

Table 46 Ammines

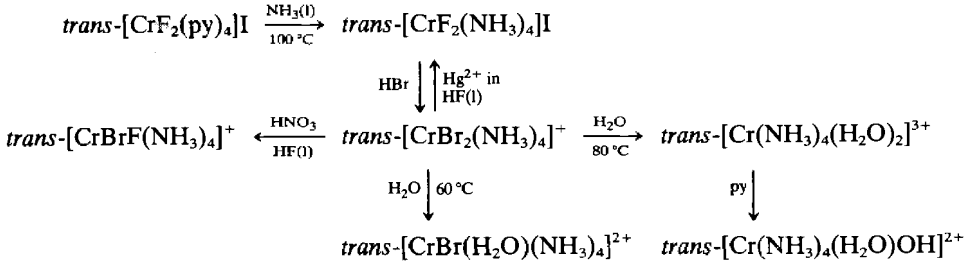
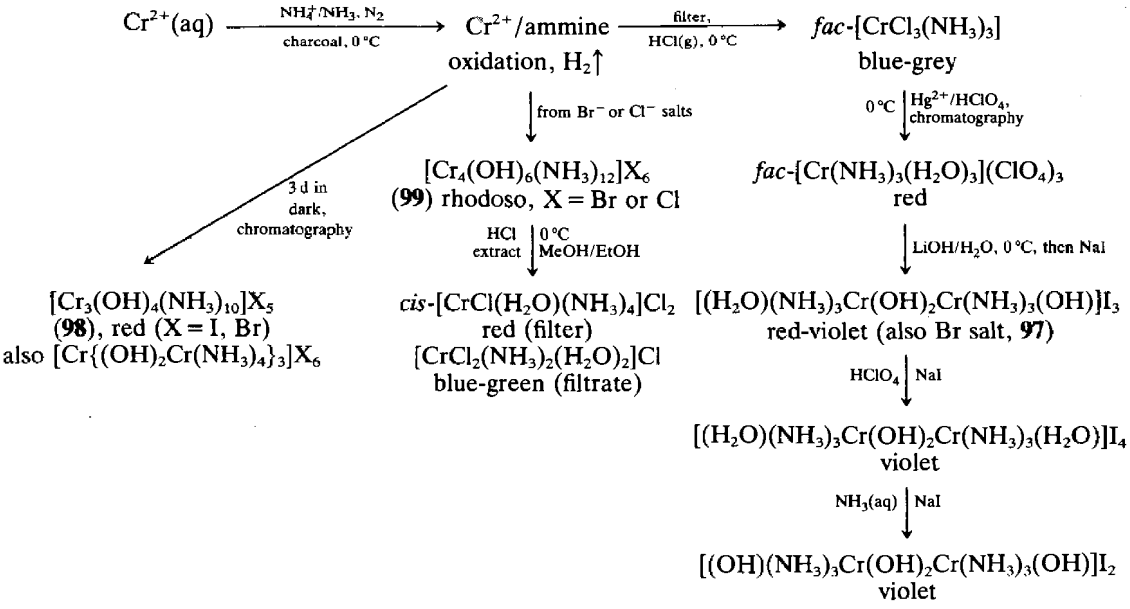
(*i*) *Diammines and triammines*



Of the five possible isomers of the diammine $[CrCl_2(NH_3)_2(H_2O)_2]Cl$ the one with all-*trans* ligand pairs,[339] and that which is *cis* with respect to NH_3 and *trans* with respect to Cl[340] have been isolated; $[CrBr_2(NH_3)_2(H_2O)_2]Br$ is also known.[341] The triammines *mer*-$[CrX_3(NH_3)_3]$ (X = Cl, Br), *mer*-$[CrBrCl_2(NH_3)_3]$ and *mer*-$[CrBr_2Cl(NH_3)_3]$ have been obtained by thermal decomposition of the hexaammines *etc.* in a quasi-closed system which produces much purer intermediate compounds than the more usual open dynamic conditions;[342] *fac*-$[CrCl_3(NH_3)_3]$ and *fac*-$[Cr(NH_3)_3(H_2O)_3](ClO_4)_3$ have been isolated as in Scheme 34.[343]

(*ii*) *Tetraammines*



Schemes 32 and 33 illustrate the preparations of various members of the numerous *trans*-tetraammine Cr^{III} series[344] starting from *trans*-$[CrF_2(py)_4]I$. Analogous *cis* complexes

Scheme 32

Scheme 33

Scheme 34

have long been known. The electronic[344,345] and ESR spectra[346] of various *trans* ammines and $[CrXY(py)_4]^{n+}$ have been determined and ligand field parameters derived.

Cyanide anation in DMSO has proved useful in the preparation of cyano complexes (Scheme 29).[325] Cyanide displaces coordinated DMSO cleanly but deprotonates rather than displaces coordinated water. The preparation of *trans*- and *cis*-$[Cr(CN)_2(NH_3)_4]ClO_4$ starts from $[Cr(DMSO)_2(NH_3)_4]^{3+}$ or $[CrCl(DMSO)(NH_3)_4]^{2+}$. The insolubility of *trans*-$[Cr(CN)_2(NH_3)_4]ClO_4$ permitted its isolation from solution, but it was necessary to separate the *cis* isomer by ion exchange. Rapid *trans* to *cis* isomerization of *trans*-$[Cr(DMSO)_2(NH_3)_4]^{3+}$ occurs on the addition of CN^- before anation produces the dicyano complexes stepwise, both apparently *via* *cis*-$[CrCN(DMSO)(NH_3)_4]^{2+}$, which in an uncommon rearrangement gives a mixture of *trans*- and *cis*-dicyano complexes. Substitution of DMSO by CN^- in water is stereoretentive.

(iii) *Pentaammines*

Many new pentaammines have been isolated, mainly for photochemical and kinetic investigations. The absorption and luminescence spectra of single crystals and powders of $[Cr(OH)(NH_3)_5](ClO_4)_2$ have been investigated[347] from 7 K to room temperature. The OH^- group produces a large tetragonal component, which causes a large splitting of the second but not the first spin-allowed band. From the fine structure in the luminescence spectrum the totally symmetric Cr—O stretch is at 570 cm^{-1}. The far-IR, Raman and vibronic spectra of $[Cr(NCO)(NH_3)_5](NO_3)_2$ have also been studied.[348] There is some dispute over the ability of crystal field calculations to account for the detailed splittings. The ESR spectra of $[CrX(NH_3)_5]^{n+}$ and other tetragonal Cr^{III} complexes have been analyzed.[349] Little magnetic ordering occurs at very low temperatures in complexes such as $[Cr(H_2O)(NH_3)_5][Cr(CN)_6]$, $\theta = 0.34$ K.[350]

(iv) *Hexaammines*

As might be expected with the well-known hexaammines, there has been little additional work. Scheme 31 describes the thermal decomposition of some hexaammines and pentaammines; the borohydride $[Cr(NH_3)_6][BH_4]_3$ has been prepared by a modified method and its thermal stability studied,[351,352] and $[Cr(NH_3)_6][Co(N_3)_6]$ has been isolated.[353] The skeletal vibrational frequencies of $[Cr(NH_3)_6](NO_3)_3$ have been assigned,[354] and from low temperature single crystal investigations of $[Cr(NH_3)_6](ClO_4)_2Cl{\cdot}KCl$ it has been deduced[355] that the Cr—NH_3 bonds are lengthened by 0.12 Å along two axes and shortened by 0.02 Å along a third in the excited $^4T_{2g}$ state compared with the $^4A_{2g}$ ground state. The zero field splitting in $[Cr(NH_3)_6](ClO_4)_2Br{\cdot}CsBr$ has been determined[356] by single crystal magnetic susceptibility studies from 0.040 to 4.2 K, and the value is in agreement with ESR results. Even allowing for zero field splitting in $[Cr(NH_3)_6][CdCl_5]$ it appears that there is weak antiferromagnetic interaction between the cations ($\theta = 1.4$ K) although the Cr—Cr separation is 7.9 Å.[357]

The study of equilibria between Cr^{III} and ligands in aqueous solution is complicated by the robustness of Cr^{III} complexes. Equilibria can be established quickly in Co^{III} systems if charcoal is added because this reduces a little Co^{III} to Co^{II}, but in Cr^{III} systems Cr^{II} must be added as well as charcoal. Oxidation by the medium could remove all the Cr^{II} before equilibrium is reached among the Cr^{III} species, but it has been found[358] that a constant concentration of Cr^{II} can be maintained by electrolytic reduction until equilibrium is reached. Then the remaining Cr^{II} can be allowed to oxidize and the equilibrium concentrations of the different Cr^{III} species determined. In this way $\log \beta_6$ for complexation with ammonia has been found to be 13 (24 °C, 4.5 M NH_4Cl) and $\log \beta_3$ (en) = 19.5 (24 °C, 1 M NaCl). The method works also with pn and edta, but fails with glycine and non-amine ligands like ox and SCN^- where a steady state concentration of Cr^{II} cannot be built up.

The photoinduced reactions of the cations $[Cr(NH_3)_{6-n}(H_2O)_n]^{3+}$ have been investigated,[359] and their visible spectra recorded during a study[360] of the formation of $[Cr(NH_3)_6]^{3+}$ by the acid-catalyzed hydrolysis of $[Cr(NCO)(NH_3)_5]^{2+}$.

(v) *Polynuclear complexes*

Table 47 lists the polynuclear ammines which have been extensively investigated since the review by Garner and House.[302]

The interconversions between monobridged dinuclear Cr^{III} ammines with their traditional names are illustrated in Scheme 35.[302,361] Inter-relations exist between the mono-μ-hydroxo and di-μ-hydroxo species in acid solution, and these are outlined in Scheme 36. Acid hydrolysis of the mono-bridged dinuclear cations to mononuclear species is slow and salts of (**94**) and (**95**) as well as of the long-established μ-diols are known. In ammonia buffer $[(OH)(NH_3)_4Cr(OH)Cr(NH_3)_4(OH)]^{3+}$ forms.[362]

The basic rhodo complexes $[(NH_3)_5CrOCr(NH_3)_5]X_4$ (**88**) cannot be obtained free from the basic *erythro* salts $[(NH_3)_5Cr(OH)Cr(NH_3)_4OH]X_4$ (**90**) unless cold solutions protected from light and containing concentrated ammonia are used.[361] The pure samples exhibit reproducible antiferromagnetic behaviour; it seems that the linear Cr—O—Cr bridge with its short Cr—O distances (≈1.80 Å)[363,364] permits the transmission of strong exchange interactions in which π

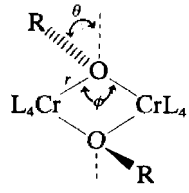
Scheme 35

bonding is important. An almost linear bridge is also present in $[\{Cr(NCS)(TPyEA)\}_2O](BPh_4)_2$.[107]



The normal (acid) rhodo complex $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5 \cdot H_2O$ (**89**) has a bent bridge (Cr—O—Cr angle = 165.6°) and shows much weaker antiferromagnetic interaction (Table 47).[365] The Cr—N bonds *trans* to the bridge are a little longer (0.07 Å) than the other Cr—N bonds. This may relate to the formation of the basic *erythro* salts by the substitution of a terminal NH_3 by OH. However, no bond lengthening is apparent in the structure of the dihydrate $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5 \cdot 2H_2O$, the polarized electronic spectrum of which has been investigated in order to gain information on the exchange-induced intensity-gaining mechanisms for spin-forbidden transitions.[366]

Scheme 36

Structural, spectroscopic and magnetic investigations have been carried out on the basic *erythro* complex *cis*-$[(NH_3)_5Cr(OH)Cr(NH_3)_4(OH)](S_2O_6)_2{\cdot}3H_2O$[367] (**90**), the acid *erythro* complex *trans*-$[(NH_3)_5Cr(OH)Cr(NH_3)_4(H_2O)]Cl_5{\cdot}3H_2O$[368] (**91**), for which the bridging angles are respectively 142.8° and 155.1°, and the di-μ-hydroxo complexes $[(NH_3)_4Cr(OH)_2Cr(NH_3)_4]X_4{\cdot}4H_2O$ (X = Cl, Br or $0.5S_2O_6$).[369–373]

The dibridged ammines are examples of the general dinuclear complex (**96**), with L = NH_3 and R = H. Much research has been aimed at relating antiferromagnetic behaviour and spectroscopic properties to structure. There does not seem to be a simple correlation between the magnitude of the exchange parameter J (singlet–triplet splitting) and bridge geometry, *i.e.* the Cr—O—Cr angle ϕ, the Cr—O bond length r, or the Cr—Cr separation. Evidence is accumulating that there is a correlation between the magnitude of J and the angular displacement of the R (or H) atom out of the Cr_2O_2 plane (dihedral angle θ). The implications are that superexchange through a $p\pi$ orbital on O is dominant and this is at a maximum only if the H atom lies in the plane. Recently, a model has been proposed which relates the magnitude of the magnetic interaction to all three parameters r, ϕ and θ.[372,374]

(**96**)

The synthetic work has been extended to di-μ-hydroxo-*fac*-triammine derivatives (**97**) (Table 47 and Scheme 34). The crystals of (**97**) contain two different centrosymmetric cations, the *trans* diaqua and *trans* dihydroxo species, linked alternately in infinite chains by short (2.45 Å) hydrogen bonds. The bond distances of the diaqua cation differ slightly from those of the dihydroxo cation.[375]

The preparations of the trinuclear complex $[Cr_3(OH)_4(NH_3)_{10}]Br_5$ (**98**) and the tetranuclear complexes $[Cr\{(OH)_2Cr(NH_3)_4\}_3]Br_6$ and $[Cr_4(OH)_6(NH_3)_{12}]Cl_6$ (**99**) (Table 47 and Scheme 34) start with aqueous Cr^{II}—NH_4^+/NH_3 buffer solutions and charcoal.[376] The antiferromagnetic behaviour of (**98**) has been analyzed in terms of its triangular structure [J_{12} (7.90 or 18.7 cm^{-1}), $J_{13} = J_{23}$ (18.7 or 4.3 cm^{-1})], which resembles that of (**99**) (Table 47). The complex $[Cr\{(OH)_2Cr(NH_3)_4\}_3]Br_6$ also behaves antiferromagnetically, and is structurally an analogue of Werner's brown salt $[Co\{(OH)_2Co(NH_3)_4\}_3]Cl_6$.

The tetranuclear 'rhodoso' complex $[Cr_4(OH)_6(NH_3)_{12}]Cl_6{\cdot}4H_2O$ has the structure (**99**).[376,377] Its antiferromagnetic behaviour can be reproduced in terms of dominant exchange parameters along the side and shorter diagonal of the planar rhombus formed by the four chromium atoms. Some differences in parameters may be due to the use of slightly different crystal modifications.[377,378] Neutron inelastic scattering has been used to observe the exchange

splittings of the ground electronic state and provide refined and additional exchange parameters. There is a sharp drop in magnetic moment below 10 K which requires that the lowest level of the ground state be a spin singlet with a low-lying triplet. The triplet from the temperature dependence of the neutron inelastic scattering spectra lies less than 4 cm^{-1} above the singlet. The exchange splittings of the ground state have also been observed through the temperature dependent intensities (<11 K) of the transitions to the ^2E and $^2T_1$ levels.[378]

35.4.2.2 *Monodentate amines*

A number of chromium(III) complexes containing monodentate amine ligands are known and details of their electronic spectra are given in Table 48.

Table 48 Electronic Spectra of Monodentate Amine Chromium(III) Complexes

(*i*) *Aliphatic hexamines*

The reaction between $CrBr_3$ and liquid alkylamines RNH_2 (R = Me, Et) at reflux temperatures affords the yellow-coloured hexamines $[Cr(RNH_2)_6]^{3+}$, which have been isolated as nitrate (R = Me),[379,380] bromide (R = Me)[380] and perchlorate (R = Me,[380] Et[381]) salts. Hydrolysis of $[Cr(MeNH_2)_6]^{3+}$ in $HClO_4$ solution gives $[Cr(MeNH_2)_5H_2O]^{3+}$ but in solutions of other inorganic acids (HX) gives the acidopentamine complexes $[CrX(MeNH_2)_5]^{2+}$.[380,382] Reaction between $[Cr(MeNH_2)_6]Br_3$ and $(NH_4)_2[B_{10}H_{10}]$ in aqueous solution leads to crystalline $[Cr(MeNH_2)_6]Br(B_{10}H_{10})\cdot 2H_2O$ which undergoes thermal decomposition to a monodentate decaborane complex (Scheme 37).[383] The isomers *cis*- and *trans*-$[Cr(MeNH_2)_2(en)_2]Br(B_{10}H_{10})$ are stable up to 250 °C but above this temperature both lose $MeNH_2$ and give the common product *trans*-$[Cr(B_{10}H_{10})Br(en)_2]$.[383]

$$[Cr(MeNH_2)_6]Br(B_{10}H_{10})\cdot 2H_2O \xrightarrow{70\text{–}80\ ^\circ C} [Cr(MeNH_2)_6]Br(B_{10}H_{10})$$

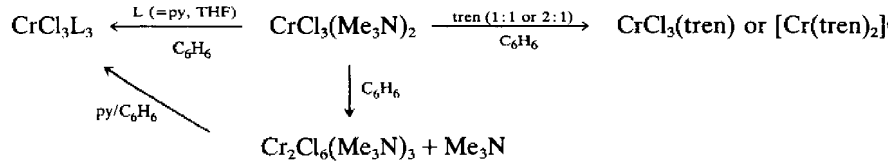
$$\downarrow 100\ ^\circ C$$

$$Cr(B_{10}H_{10})Br(MeNH_2)_4 \xleftarrow{120\text{–}150\ ^\circ C} [CrBr(MeNH_2)_5]B_{10}H_{10}$$

Scheme 37

(*ii*) *Aliphatic pentamines*

In contrast to $CrBr_3$ the reaction of $CrCl_3$ with neat alkylamines stops at the pentamine stage and gives the products $[CrCl(RNH_2)_5]Cl_2$ (R = Me, Et, Pr^n, Bu^n, Bu^i, C_3H_5).[384,385] The



light-red-coloured complexes $[CrBr(RNH_2)_5]Br_2$ (R = Me, Et) may however be obtained by controlled addition of liquid amine to $CrBr_3$.[381,386] These complexes readily react with liquid NH_3 to give $[Cr(NH_3)(RNH_2)_5]Br_3$.[381] Owing to the general lability of the triflate ligand, the complex $[Cr(OSO_2CF_3)(MeNH_2)_5](CF_3SO_3)_2$, obtained from a solution of $[CrCl(MeNH_2)_5]Cl_2$ in CF_3SO_3H, is a potential starting material for the synthesis of $[CrX(MeNH_2)_5]^{n+}$ complexes.[387]

An X-ray crystal structure determination of $[CrCl(MeNH_2)_5]Cl_2$ shows that the cation is severely distorted having Cr—N—C and N—Cr—N bond angles which deviate by up to 15 and 6.6° from normal tetrahedral and octahedral angles respectively.[388] In accordance with the sterically crowded nature of its ground state, this complex undergoes base hydrolysis 225 times faster than $[CrCl(NH_3)_5]^{2+}$ at 298 K which is in the expected direction for a D_{cb} mechanism.[388] Aquation of $[CrCl(MeNH_2)_5]^{2+}$, however, is 38 times slower than that of the ammine complex at 298 K, an order which is reversed in the analogous cobalt(III) complexes.[388–390] This reversal in reactivity is attributed to a change in mechanism from I_d in cobalt(III) to I_a in chromium(III).[390] The orange-coloured complex $[Cr(MeNH_2)_5H_2O](NO_3)_3$ may be prepared by passing a solution of $[CrBr(MeNH_2)_5]^{2+}$ through an ion exchange resin in the OH^- form followed by acidification of the effluent with concentrated HNO_3.[391]

(*iii*) *Aliphatic tetramines, triamines and diamines*

Reaction of *trans*-$[CrF_2(py)_4]^+$ with amines (RNH_2) at 100 °C provides a convenient route to *trans*-$[CrF_2(RNH_2)_4]^+$ complexes, a number of which have been isolated and characterized (R = Me, Et, Pr^n, C_3H_5).[392] Thermal decomposition of $[CrCl(EtNH_2)_5]Cl_2$ in the solid state at 250 °C gives the green-coloured complex $CrCl_3(EtNH_2)_3$, while its reaction with KSCN in aqueous solution leads to the isomers 1,2,6- (red) and 1,2,3-$Cr(NCS)_3(EtNH_2)_3$ (lilac).[302]

The reaction between $CrCl_3$ and Me_3N in the presence of zinc dust catalyst gives the five-coordinate purple-blue solid $CrCl_3(Me_3N)_2$.[393] This complex has a distorted *trans* trigonal bipyramidal structure and a magnetic moment of 3.88 BM (298 K), which is virtually independent of temperature.[394] In benzene solution this complex undergoes either ligand substitution or decomposition as outlined in Scheme 38.[395,396] The hexacoordinated chromium(III) dimer $Cr_2Cl_6(Me_3N)_3$ has magnetic (μ_{eff} at 297 K = 3.68 BM; obeys the Curie–Weiss law over the temperature range 103–297 K) and spectroscopic ($^4A_{2g} \rightarrow {}^4T_{2g}$ at 13 300 cm^{-1}; $^4A_{2g} \rightarrow {}^4T_{1g}$ at 18 520 cm^{-1}) properties like those of $[Cr_2Cl_9]^{3-}$, suggesting a similar confacial bioctahedral structure with no significant metal–metal interaction. A mechanism involving halogen bridging with synchronous Me_3N expulsion and ligand reorientation is suggested for dimer formation. No reaction was observed between $CrCl_3(Me_3N)_2$ and the potential ligands CO_2, CS_2 and $(Pr^i)_2O$. In the reaction products, $CrCl_3(tren)$ and $[Cr(tren)_2]Cl_3$, tren behaves as a tridentate ligand, bonded to the metal through its primary amino groups in both cases.

Scheme 38

(*iv*) *Anilines*

A number of chromium(III) complexes containing aniline $PhNH_2$ and substituted aniline ligands are known. These include $[CrCl_2(PhNH_2)_4]^+$ [302] and $CrCl_3(PhNH_2)_3$ [397] although the configuration is not stated in either case. The latter complex was prepared by refluxing a solution of $CrCl_3$ in aniline (the pyridine complex $CrCl_3(py)_3$, prepared analogously, was shown to have a *mer* configuration). Reaction of $CrCl_3(PhNH_2)_3$ and Br_2 in glacial acetic acid proceeds at a similar rate and with identical substitution orientation (*i.e.* 2,4,6-Br_3PhNH_2 product) as that of uncoordinated $PhNH_2$.[397] Coordination to chromium(III) therefore has a

contrasting effect to protonation, which greatly deactivates aniline with respect to electrophilic substitution and causes it to occur at the *meta* position.

Some Reinecke-type salts containing aniline ligands have been prepared.[302] The complexes $Bi[Cr(NCS)_4L_2]_3$ (L = $PhNH_2$, morpholine, *p*-$MePhNH_2$, *p*-anisidine, 0.5bipy), $BiX_4[Cr(NCS)_4L_2]_3$ (X = thiourea, L = $PhNH_2$, morpholine), $CdX_2[Cr(NCS)_4(PhNH_2)_2]_2$ (X = en, piperazine) and $Cd[Cr(NCS)_4(PhNH_2)_2]_2$ may be used in the analysis of Bi and Cd by titrimetric, spectrophotometric or gravimetric methods.[398–400] A number of double complex salts of the type $A[Cr(NCS)_4(PhNH_2)_2]_n$ (A represents a range of cobalt(III) and silver(I) complexes) have been prepared and in the case of the Ag salts magnetic moments and positions of IR bands have been reported.[401] Reaction of *trans*-$[Cr(C_2O_4)_2(H_2O)_2]^-$ and aniline gives $[Cr(C_2O_4)_2(PhNH_2)_2]^-$, which can exist in a rose-coloured or in an unstable green-coloured modification.[302]

35.4.2.3 Ethylenediamine and related bidentate amines

The chemistry of amine complexes of chromium(III) up to 1969 has been extensively reviewed by Garner and House;[302] consequently earlier work will not be covered here. Fluorodiamine complexes of chromium(III) have also been carefully reviewed by Vaughn.[402,403]

(*i*) *General preparative methods*

The easy formation of hydroxo- or oxo-bridged Cr^{III} polymers in basic aqueous solution, the comparative lability of the Cr—N bond, and the precautions needed to obtain chromium(II) complexes compared with cobalt(II) complexes have meant that the preparative chemistry of chromium(III) is more difficult than that of cobalt(III). A greater variety of non-aqueous solvents is now in use, and there is greater knowledge of chromium(II) chemistry to be exploited in the preparation of chromium(III) complexes generally, but few new methods of preparation of amine complexes have been devised since the early work.

The general synthetic methods are: (a) reaction of anhydrous $CrCl_3$, $CrBr_3$ or the sulfate with anhydrous amines alone or in an organic solvent, sometimes with the addition of zinc powder to provide a catalytic pathway *via* chromium(II) complexes—the anhydrous halides can be prepared from the hydrated salts by reaction with 2,2-dimethoxypropane, triethylorthoformate or thionyl chloride, or by distillation of water from solutions of the hydrates in DMF or DMSO; (b) reaction of hydrated chromium(III) salts such as $CrCl_3·6H_2O$, $[Cr(H_2O)_4Br_2]Br$ and $Cr(NO_3)_3·6H_2O$ in solutions buffered with an amine/amine-salt mixture to prevent the formation of oxo and hydroxo polymers followed by acidification—carbon, added as a catalyst, can change the course of the reaction; (c) reaction of $[CrCl_3X_3]$ (X = py, THF, DMF, DMSO) with amines—the preliminary preparation of these compounds, even if only *in situ*, gives essentially anhydrous starting materials soluble in organic solvents, although aqueous solutions can be used in some cases; (d) reaction of salts such as $K_3[Cr(NCS)_6]$, $K_3[Cr(ox)_3]$ and $[Cr(urea)_6]Cl_3$ with amines; (e) reaction of diperoxochromium(IV) amines with acids and the reduction of chromium(VI) compounds—these methods have not been applied recently; (f) oxidation of chromium(II) complexes; and (g) substitution of aqua or acido ligands in amine complexes by ammonia (from liquid ammonia) or other amines to produce mixed ligand complexes.

Complexes containing ethylenediamine and related bidentate N donor ligands which are new since 1969, or have been prepared by new methods, are listed in Tables 49 and 50. Water of hydration has not been specified. In general, the complexes have been prepared for kinetic and photochemical investigations. The list is restricted to solids which have been characterized at least by analyses. Cations obtained only in solution have not been included. Most complexes have also been characterized by conductance measurements, and IR, UV and visible spectroscopy. Spectroscopic methods have been used to distinguish between *cis* and *trans* isomers, and where *cis* isomers have been resolved this is indicated in the tables.

(*a*) *Recent syntheses.* The most numerous complexes are those with the donor set X_2N_4 (X is anionic or neutral), especially with $N_4 = (en)_2$. The nitrosation of Cr—OH_2 groups has been used to synthesize many *trans* compounds containing Cr—ONO groups (NO^+ addition reactions), *e.g.* *trans*-$[CrBr(ONO)(en)_2]ClO_4$, but *cis* compounds could not be obtained because the ONO group labilizes *cis* ligands.[404] Destruction of Cr—ONO groups with acids

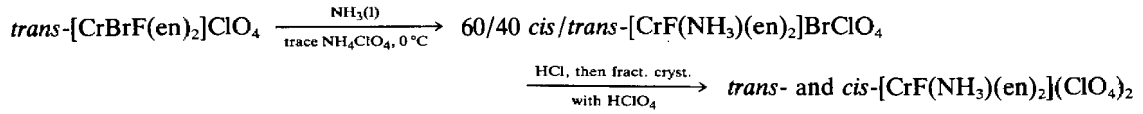
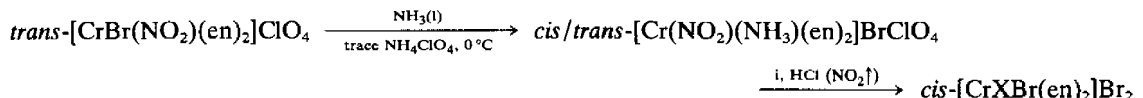
provides aqua derivatives, *e.g.* $trans\text{-}[CrBr(H_2O)(en)_2]Br_2$, with rentention of configuration since the Cr—O bond does not break. Anation in dipolar aprotic solvents such as DMF, DMSO and DMA, and solvolysis induced by the addition of $AgClO_4$, HgF_2 or $Hg(MeCO_2)_2$ are also useful preparative procedures.[404,405] The inversion in relative solubility of perchlorates and halides in passing from water to these solvents has facilitated the isolation of certain water-soluble complexes.

Examples of the preparations of $cis\text{-}[Cr(CN)_2(en)_2]^{2+}$ salts, mono- and di-ammine- and fluoro-bis(ethylenediamine) salts are given in Schemes 39 to 46.

(*b*) *Cyano series.* The preparation of a series of *cis*-dicyanobis(ethylenediamine)-chromium(III) salts (Scheme 39) starts with the reaction of green $trans\text{-}[CrCl_2(H_2O)_4]Cl\cdot 2H_2O$ and liquid hydrogen cyanide, but no *trans*-dicyano complex was obtained, presumably because of the lability of systems with CN *trans* to CN.[327] The purity of $cis\text{-}[Cr(CN)_2(en)_2]^+$ was established by ion exchange chromatography, and its reactions and visible and IR spectra, and particularly the resolution of the iodide, support the *cis* assignment. The $\nu(C{\equiv}N)$ absorption of 2139 cm^{-1} was unexpectedly unsplit, but there were four $\nu(Cr—N, en)$ bands at



550, 536, 491 and 425 cm^{-1} and *trans* complexes show fewer bands in this region. Unusually, spin-forbidden bands were observed in the solution spectrum. From the CD spectra the $(+)_{589}$ isomer was assigned the Δ configuration (see also Section 35.4.1.1.ii).



Scheme 39

A safer procedure, starting from aqueous $[Cr(en)_3]Cl_3$ and NaCN in the presence of charcoal, has been reported[406] to yield both *trans*- and *cis*-$[Cr(CN)_2(en)_2]Cl$, but others[330] have not been successful with this method.

(*c*) *Reactions with liquid ammonia.* Ammonolysis of $[CrXY(en)_2]^{n+}$ salts sealed in Carius tubes with liquid ammonia has afforded many mono- or di-ammine derivatives (Table 49 and Schemes 40–45).[407–409] The preparation of the *cis* isomers is straightforward, but thermal substitution with *trans* → *cis* rearrangement is common. Thus, *cis*-$[CrCl_2(en)_2]^+$ reacts smoothly to yield *cis*-$[Cr(NH_3)_2(en)_2]^{3+}$ with a few per cent of the *trans* compound, whereas *trans*-$[CrCl_2(\text{or } Br_2)(en)_2]^+$ gives 95% *cis*-$[Cr(NH_3)_2(en)_2]^{3+}$; *trans*-$[Cr(NH_3)_2(en)_2]^{3+}$ has been isolated[408] in 30% yield from the less accessible complex *trans*-$[CrCl(NH_3)(en)_2](ClO_4)_2$ [407] (Scheme 44) by ammonolysis followed by fractional crystallization. For a particular pair of *cis* and *trans* isomers the geometrical assignment was based on IR spectral data and on the overall molar absorptivities, the *cis* having the more intense bands, because the electronic spectra are otherwise very similar. An easier route to *cis*-$[CrF(NH_3)(en)_2]^{2+}$ salts has been devised (Scheme 45), and the isolation of one chiral form has confirmed the *cis* geometry (Δ configuration).[409] HPLC was useful in determining the *cis*/*trans* ratio (4:1) in the crude ammonolysis product.

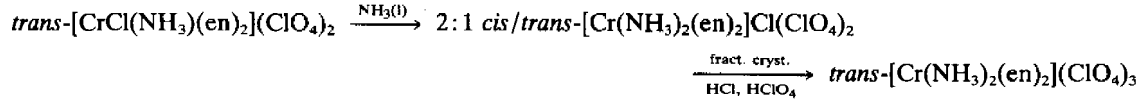
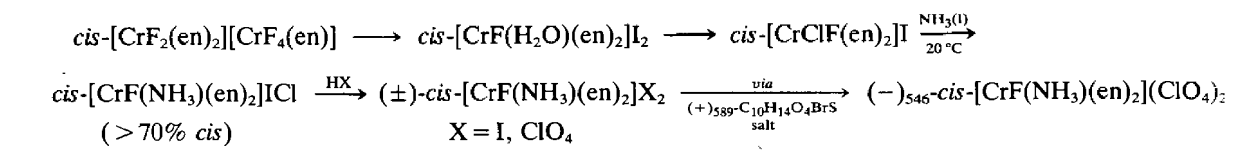


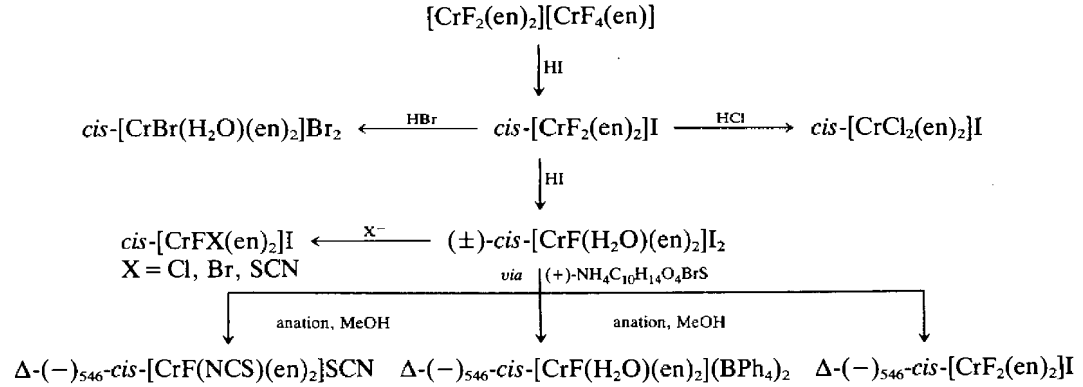
Scheme 41



Scheme 42

Scheme 43

Scheme 44



Scheme 45

(*d*) *Fluoro complexes.* The fluoro complex $[Cr(en)_2F_2][Cr(en)F_4]$ (Schemes 45 and 46) is easily prepared by reaction of anhydrous ethylenediamine with $CrF_3{\cdot}3.5H_2O$. Thus equation (29) is a general reaction of bidentate amines AA and many fluoro-containing complexes have been derived from the anion or the cation. The small, highly basic fluoride ion is strongly bound to Cr^{III} so it can be carried through various syntheses and removed when necessary in acid. Some procedures are in Schemes 45 and 46.[402,409] The fluoride $CrF_3{\cdot}3.5H_2O$, $CrCl_3{\cdot}6H_2O$ in dilute HF, *trans*-$[CrF_2(py)_4]^+$ in boiling 2-methoxyethanol and CrF_2 suspended in dry ethereal HF can be used to form fluoro-containing complexes in reactions with various amines. Other methods include anation of *cis*- or *trans*-$[CrF(H_2O)(AA)_2]^{2+}$ in methanol, thermal dehydration of *trans*-$[CrF(H_2O)(AA)_2]X_2$, chloride abstraction from *cis*-$[CrCl_2(AA)_2]^+$ with HgF_2 in liquid HF and thermal deamination of $[Cr(AA)_3]X_3$ in an NH_4F matrix.

$$3AA + 2CrF_3{\cdot}3.5H_2O \longrightarrow [CrF_2(AA)_2][CrF_4(AA)] + 7H_2O \qquad (29)$$

AA = en, pn, tmd or dach

cis-$[CrF(H_2O)(en)_2]^{2+}$ has been resolved and the absolute configuration of its chiral forms established by ORD spectral studies.[410] The cation in $(-)_{546}$-*cis*-$[CrF(H_2O)(en)_2](BPh_4)_2$ has the Δ configuration. Anation of the optical isomers with SCN^- or F^- in MeOH takes place with retention of configuration[410] and this provides an expeditious route to *cis*-$[CrFX(en)_2]X$ complexes.[411]

Scheme 46

(*e*) *Thiolato complexes.* During kinetic investigations of the efficiency of thiolato sulfur as an electron transfer bridge a number of thiolatobis(ethylenediamine)chromium(III) salts have been prepared by reduction of the appropriate disulfide with chromium(II) ethylenediamine perchlorate[412] (Table 49). The structure of the mercaptoacetato derivative $[Cr(en)_2(SCH_2CO_2)]ClO_4$ has been determined[413] and it contains enantiomeric forms ($\Delta\lambda\delta$ and $\Lambda\delta\lambda$) of the pseudooctahedral cation; the mercaptoacetato ligand is bidentate, and there is some lengthening of the Cr—N bond (2.112 Å) *trans* to the S atom. The mean Cr—N (*cis*) distance is 2.090 Å, and the Cr—O and Cr—S distances are 1.966 and 2.337 Å respectively.

(*f*) *General investigations.* The electronic spectra of amine complexes are routinely recorded to aid in the assignment of structure. For details the original literature and reviews[301,302,402,414,415] should be consulted. Measurements of the single crystal polarized electronic spectra accompanied by appropriate calculations provide considerable information concerning ligand parameters, site symmetry, the ordering of energy levels and selection rules.

Many tris(diamine)- and *cis*-diacidobis(diamine)chromium(III) complexes have been resolved into their enantiomers, thus providing proof of structure. Absolute configurations are frequently inferred from ORD and CD measurements, which have become of great importance because they provide quick structural information. The spectra–structure correlations are

empirical, but when X-ray single crystal investigations have been carried out, they have confirmed the assignments.[304]

The four possible isomers of $[Cr(cis\text{-}1,2\text{-chxn})_3]^{3+}$ (*mer*-Λ, *mer*-Δ, *fac*-Λ and *fac*-Δ) have been separated by cation exchange using disodium hydrogen phosphate and disodium tartrate, and isolated as the perchlorates. They were identified from their electronic, CD and ESR behaviour and comparisons with the Co^{III} analogues. The ligand has two dissymmetric centres of opposite chirality (*R*,*S*) and *fac* and *mer* refer to the spatial arrangement of the dissymmetric centres.[416] Some correlations of X-ray powder photographs and absolute configurations of $[Cr(trans\text{-}1,2\text{-chxn})_3]Cl_3$ have been made.[417]

Developments in instrumentation have allowed measurements of the single-crystal CD spectra of $[(+)_D\text{-}Cr(en)_3]^{3+}$ doped in $[Ir(en)_3]Cl_3$ between 7 and 293 K. Transitions to the excited states $^4T_2$, $^4T_1$, ^2E, $^2T_1$ and $^2T_2$ were observed.[418] The discussion refers to much earlier work. The polarized electronic spectra of single crystals of several *trans*-$Cr[XY(en)_2]$ complexes have been assigned and ligand field parameters evaluated.[419] CD, absorption and circularly polarized emission spectra have been reported for $[Cr(en)_3]^{3+}$ in the region of the $^4A_{2g} \rightleftarrows {}^2E_g\,{}^2T_{1g}$ transitions.[420]

Thermal deamination of tris(ethylenediamine)chromium(III) complexes is a standard preparative method for *cis*- and *trans*-diacidobis(ethylenediamine) complexes[421,422] and the thermal behaviour of the starting materials has been related to their crystal structures.[423] The cyano complex *cis*-$[Cr(CN)_2(en)_2]ClO_4$ in DMSO undergoes stepwise reduction III → II → I at the DME.[424] The standard redox potential for the Cr^{III}/Cr^{II} couple is −1.586 V (*versus* SCE).

From Raman investigations the strong metal sensitive band at 450–600 cm^{-1} shown by $[Cr(en)_3]^{3+}$ compounds has been assigned to the totally symmetric M—N stretching vibration and the band at 280–320 cm^{-1} to a totally symmetric N—M—N bending mode. Studies of electronic spectra suggest that the vibration responsible for the latter band has at least as much M—N stretching character as the former.[425] It appears that mixed ring conformations can be identified from the IR spectra of tris(ethylenediamine) complexes.[426]

The XPES of a number of ethylenediamine and cyano complexes, including $[Cr(en)_3]Cl_3$ and $K_3Cr(CN)_6$, have been measured in order to obtain the difference between the N1*s* and C1*s* binding energies. For the en complexes the ΔE values are related to σ donation, and for the cyano complexes are mainly controlled by the nitrogen charge, which depends on the π back-donation.[427]

(*ii*) *Bidentate diamines excluding ethylenediamine*

Synthetic methods with bidentate amines generally follow those developed for complexes of ethylenediamine, but there can be differences in detail, *e.g.* thermal dehydration of *trans*-$[CrF(H_2O)(en)_2]X_2$ (X = Cl, Br, I, SCN) produces *cis*-FX isomers, whereas the major products from *trans*-$[CrF(H_2O)(tmd)_2]X_2$ are the *trans*-FX isomers (Table 50). Similarly, the reaction of liquid ammonia with *trans*-$[CrFBr(en)_2]ClO_4$ provides *cis*- and *trans*-$[CrF(NH_3)(en)_2]^{2+}$ in 60:40 ratio; with *trans*-$[CrFBr(tmd)_2]ClO_4$ the only product is *trans*-$[CrF(NH_3)(tmd)_2]^{2+}$; tmd complexes appear more resistant to stereochemical change than en complexes. Reactions of diamines with $CrCl_3 \cdot 6H_2O$ in aqueous HF, or *trans*-$[CrF_2(py)_4]ClO_4$ in 2-methoxyethanol under reflux are general synthetic methods for *trans*-$[CrF_2(AA)_2]^+$ complexes. However, the less accessible isomers, *cis*-$[CrF_2(AA)_2]^+$ (AA = en and pn) have now been isolated from the mother liquors left by the less soluble *trans* complexes or by using longer reaction times to allow *trans* → *cis* isomerization to occur.[402,428]

The structure of *trans*-$[CrF(NH_3)(tmd)_2](ClO_4)_2$ has been confirmed crystallographically.[429] In the absence of crystallographic data, assignments of geometry in $[CrX_2(diamine)_2]$ complexes can be aided by IR spectroscopy. Commonly, *trans* isomers show essentially three bands in the 390 to 550 cm^{-1} region, while *cis* isomers show four or more (Table 51),[430] although these criteria did not work well with a series of *cis* and *trans* complexes $[CrX_2(tmd)_2]^{n+}$ (X = NCS, ONO, N_3, H_2O; X_2 = OH, H_2O).[431] Complexes containing Cr—F groups give strong bands in the 350–370 cm^{-1} range due to Cr—F stretching vibrations coupled with other metal–ligand modes. The bands are low by comparison with other chromium(III) fluoride complexes (Table 51) and other chromium–halogen modes, *i.e.* Cr—Cl, 320–360 cm^{-1}, Cr—Br, 250–280 cm^{-1}.[430]

(*iii*) *Mixed bidentate amines including ethylenediamine*

At the time of the Garner and House review[302] there were only five known complexes of Cr^{III} with two different amines; this is no longer the situation (Table 50) and there seem to be no particular difficulties in obtaining mixed amine complexes.[432–434]

Thermal deamination in the solid state of the diamine and mixed diamine complexes $[Cr(AA)_3]X_3$, $[Cr(AA)_2(BB)]X_3$ and $[Cr(AA)(BB)(CC)]X_3$ (AA, BB and CC represent the amines en, pn and tmd and X = Cl or SCN) takes place with the loss of one diamine molecule (the lowest boiling amine with the mixed complexes). The thiocyanates give *trans*-bis(diamine)bis(isothiocyanato) complexes but the chlorides form *cis* complexes although isomerization to *trans* complexes occurs on further heating, especially when *cis*-$[CrCl_2(tmd)_2]Cl$ is the initial product.[432] The *cis* ↔ *trans* thermal isomerization has also been investigated in *cis*- and *trans*-$[CrX_2(AA)_2]X$[435] (AA = bn, chxn or ptn; X = Cl, Br). The presence of two six-membered chelate rings or large cations seems to encourage the formation of *trans* products.[432,435] Since intermediates such as *mer*-$[CrCl_3(bn)_2]\cdot H_2O$ have been isolated, isomerization goes through bond rupture.

A number of complexes with two identical chiral diamines or two mixed diamines of the types *trans*-$[CrF_2(N_4)]^+$ and *trans*-$[Cr(ONO)_2(N_4)]^+$ have been prepared. The diamines are en, tmd, (*R*)- and (*S*)-propylenediamine, (1*R*, 2*R*)-1,2-cyclohexanediamine (chxn) and (2*R*,4*S*)-2,4-pentanediamine (ptn) (Table 50). The *trans* configurations follow from the spectral resemblances to *trans*-$[CrX_2(en)_2]^{2+}$ complexes. Contributions to the CD of complexes with chiral diamines can come from the conformation of the puckered rings and the vicinal effect of asymmetric atoms on the ligands. With *trans*-$[CrF_2(N_4)]^+$ complexes the CD contributions are separable and additive, except for bis(*R*-pn), bis(*R*,*R*-chxn) complexes and mono(*R*-pn) complexes with en and tmd. The overall CD arises mainly from the effect of the λ ring conformations.[436] By studying the CD spectra of the complexes *trans*-$[Cr(ONO)_2(N_4)]^+$ with the same amines in the region of intraligand $n \rightarrow \pi^*$ nitrito absorption bands, the existence of chiral rotational isomers of the nitrito ligands has been deduced. Marked solvent variations of the intraligand CD spectra are attributed to the effects of solvent bulk and donor number on rotamer equilibria.[436]

From the crystal structure of *cis*-$[Cr(NCS)_2(tmd)_2][Sb_2(tart)_2]_2\cdot 2H_2O$, the cation has the Λ configuration and this agrees with the assignment from the CD spectra.[431,437]

The Pfeiffer effect (the shift in a chiral equilibrium on the addition of an optical isomer of a different compound) of racemic $[Cr(ox)_3]^{3-}$ has been examined using for the first time optically stable metal complexes *cis*-$[MXY(AA)_2]^{n+}$ (where M = Cr^{3+} or Co^{3+}, AA = en or tmd and X and Y = anionic monodentate ligand). It was found that the chiral equilibrium of $[Cr(ox)_3]^{3-}$ was always displaced in favour of its Δ enantiomer in the presence of Λ enantiomers of the *cis* complexes, and it is proposed that the absolute configurations of *cis* complexes could be inferred from the equilibrium shift induced in $[Cr(ox)_3]^{3-}$.[438] Laser irradiation of an aqueous solution of racemic $[Cr(ox)_2(phen)]^-$ or $[Cr(ox)(phen)_2]^+$ in the presence of (+)- or (−)-cinchonine hydrochloride rapidly shifts the chiral equilibrium in a direction opposite to that induced by the usual Pfeiffer effect in the dark.[439]

(*iv*) *Ethylenediamine and related diamines — polynuclear complexes*

Many analogues of the dinuclear ammines (Table 47) are known in which ammonia molecules may be considered replaced by ethylenediamine and other bidentate ligands (Table 52). The inter-relations among the complexes are similar to those in Schemes 35 and 36. There are additional examples in the review by Garner and House[302] and other bridged complexes are covered in Sections 35.4.1.1, 35.4.2.3.vi, 35.4.2.4, 35.4.2.5, 35.4.4.2, 35.4.4.10, 35.4.7.4 and 35.4.8.3. Cyano-bridged complexes are listed in Table 45.

In a recent investigation[440] the racemic binuclear cations Δ,Δ-Λ,Λ-$[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ and Δ,Δ-Λ,Λ-$[(H_2O)(en)_2Cr(OH)Cr(en)_2(OH)]^{4+}$ have been isolated from the *meso* isomer Δ,Λ-$[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ as various salts (Table 52). The equilibria between the cations have been studied. The binuclear cations could not be separated into their enantiomers Δ,Δ and Λ,Λ because they react with classical resolving agents to form μ-carboxylato compounds which have been isolated,[441] *e.g.* Δ,Λ-$[(en)_2Cr(OH)(MeCO_2)Cr(en)_2](ClO_4)_4$. They contain symmetrical carboxylate bridges and deprotonate in strong base to give μ-carboxylato-μ-oxo complexes. Deprotonation of $[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ to $[(en)_2Cr(O)(OH)Cr(en)_2]^{3+}$ takes place similarly[442] and sulfato-bridged systems are also known.[443]

As with the dinuclear ammines, most research has been aimed at relating the antiferromagnetic behaviour and spectroscopic properties of the dinuclear complexes to their structures. Great variations in *J* have been observed for the same cation $[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ (R = H in (**96**))[370] in different environments[371] and between these cations and $[(NH_3)_4Cr(OH)_2Cr(NH_3)_4]^{4+}$ (table in ref. 374). Thus external factors such as hydrogen bonding must have an appreciable effect on the exchange in these complexes, probably through altering θ.

It has been possible to derive *J* for several salts of $[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ from low-temperature single-crystal absorption and powder luminescence spectra in the region of the $^4A_2{}^4A_2 \rightarrow {}^4A_2{}^2E$ transition of the paired system.[444] The difference of up to 10% from the values derived from powder magnetic susceptibility data indicates a slight temperature dependence of *J*.

The complex $[(en)_2Cr(OH)_2Co(en)_2](S_2O_6)_2$ has been prepared by heating the cocrystallized optically active dithionates (equation 30).[445] It is an internal active racemate because the chiral centres are different, and it contains Cr^{III} in a dinuclear system not subject to magnetic interaction so that the ESR spectrum is simple.

$$\Lambda\text{-}cis\text{-}[Cr(OH)(H_2O(en)_2]S_2O_6 + \Delta\text{-}cis\text{-}[Co(OH)(H_2O)(en)_2]S_2O_6 \longrightarrow (-)_{589}\text{-}\Lambda,\Delta\text{-}[(en)_2Cr(OH)_2Co(en)_2](S_2O_6)_2 \quad (30)$$

A crystal structure determination has confirmed that Δ,Λ-$[HO(en)_2CrOHCr(en)_2OH](ClO_4)_3 \cdot H_2O$ formed in the reversible ring opening of Δ,Λ-$[(en)_2Cr(OH)_2Cr(en)_2]^{4+}$ has the structure inferred from its chemical properties.[446] Analogous complexes are apparently formed by tmd.[447]

The linear trinuclear cation (**100**) and the tetranuclear cations (**101**) to (**103**)[448–450] (Table 52) exist with mononuclear complexes in aqueous ethylenediamine buffer solutions in which equilibrium has been established by the catalytic effect of Cr^{2+} and charcoal under well-specified conditions.[358] The cations were separated by ion exchange chromatography and fractional crystallization, and isolated as various salts (Table 52). The tetranuclear (rhodoso) compound (**104**)[451] has been reprepared[448] by a modification of Pfeiffer's method.

The antiferromagnetic behaviour of (**101**) and (**104**) has been correlated with their structures. For (**101**) all models indicate that $J_{12} = J_{34} > J_{23}$ and that a spin singlet lies lowest with a triplet

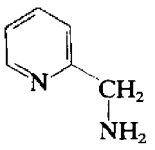
and a quintet at about 10 cm^{-1} and 32 cm^{-1} respectively.[449] In (**102**) the dominant exchange is between the central and each of the three peripheral chromium ions. An $S = 3$ level lies lowest and there is a complicated temperature variation of μ_{eff}.[450]



(v) *Bidentate ligands with primary amine and N heterocyclic donor groups: (2-pyridyl)methylamine and 1-(2-pyridyl)ethylamine*

The geometrical and optical isomerism exhibited by tris(amine) complexes of the bidentate ligands (**105**) and (**106**) has been investigated. The *fac* and *mer* isomers of $[Cr(pic)_3]^{3+}$ (**107**) and (**108**) have been prepared by utilizing slightly different starting materials and solvents (Table 53). The *fac* complexes are yellow and less soluble than the orange *mer* complexes. The latter have more intense, less symmetrical electronic absorption bands to lower energy. The assignments are confirmed by the isomorphism with corresponding cobalt(III) complexes for which the ^1H NMR spectra of the methylene groups clearly indicate the isomeric types.[452]

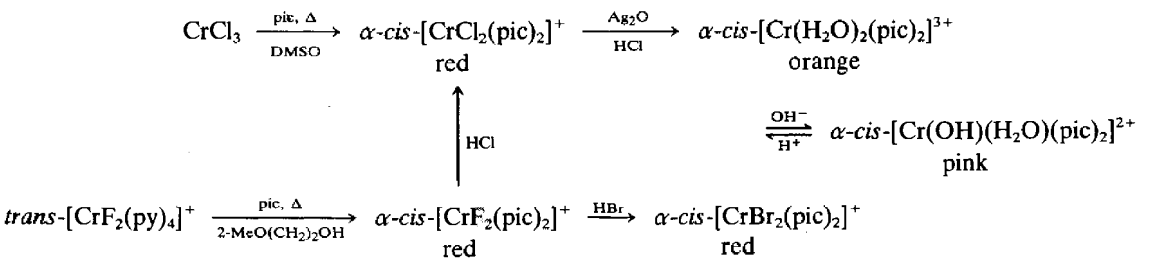
(**106**) 1-(2-Pyridyl)ethylamine (mepic)

facial

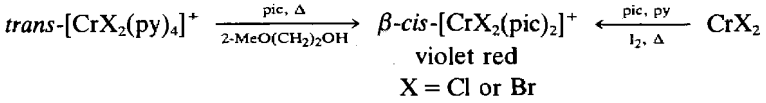
meridional



P = pyridine N, M = methylamine N

(**107**) (**108**)

The possible geometrical isomers of diacidobis(diamine) complexes containing two unsymmetrical amines such as pic are shown in (**109**) to (**113**). The α series are differentiated from the β series by an approximate C_2 axis, and from each other by the relative positions of the pyridine P and methylamine M nitrogen atoms. The preparative routes for *cis*-α and *cis*-β series are outlined in Schemes 47 and 48. Although *trans*-$[CrX_2(py)_4]^+$ salts, where X = F, Cl or Br, were used as starting materials, only *cis* products were produced. In many cases lithium salts LiX (X = Cl, Br or I) were added to aid crystallization. The β series were prepared from



the chromium(II) halide by oxidation with I_2 in pyridine in the presence of pic, or from the *trans*-$[CrX_2(py)_4]^+$ salts in hot 2-methoxyethanol. The *α-cis* and *β-cis* assignments were made from isomorphous relationships between *α-cis*-$[CrCl_2(pic)_2]Cl{\cdot}H_2O$ and *β-cis*-$[CrCl_2(pic)_2]_2S_2O_6$, and the corresponding cobalt(III) complexes (^1H NMR). A decision between the *cis trans cis* or *cis cis trans* arrangements could not be made[453] but from the formation of members of the *α* series on acid treatment of related diols of crystallographically determined structures (see Section 35.4.2.3.vi below) the *cis trans cis* arrangement was proposed and confirmed by a structure determination on $[Cr(H_2O)(OH)(pic)_2]S_2O_6$, which showed that the cation belongs to the *α-cis* series with the pyridine nitrogen atoms *trans*.[454] The Cr—OH bond is considerably shorter than the Cr—OH_2 bond (Table 53).

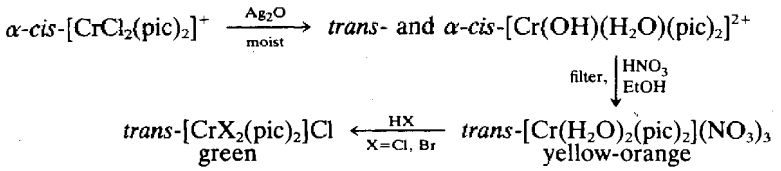
(111) *cis trans cis*

(112) *cis cis trans*

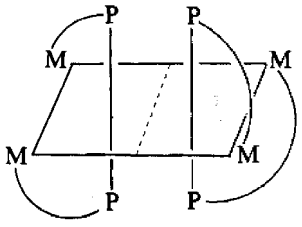
α series



β series **(113)** *cis cis cis*

In the *trans* series (Scheme 49) only one geometrical isomer was obtained, presumably the *trans trans trans* because steric hindrance would prevent the formation of the *trans cis cis* isomer. The assignment was based on comparisons of colours and spectra with those of the bis(en) analogues.[455]

Complexes of the related amine 2-(2-pyridyl)ethylamine (or 2-(2-aminoethyl)pyridine, AEP) $[CrX_2(AEP)_2]Y$ (where X = Y = Cl or Br) have been prepared by methods similar to those in Scheme 48, but *cis* or *trans* assignments were not made.[456]



trans series

Scheme 49

(*vi*) *Di-μ-hydroxo complexes containing (2-pyridyl)methylamine and 1-(2-pyridyl)ethylamine*

In the preparation of *β-cis*-$[CrBr_2(pic)_2]I$ a by-product assumed to contain the diol cation $[(pic)_2Cr(OH)_2Cr(pic)_2]^{4+}$ was obtained.[453] Improved preparative procedures gave the optically active cations $(-)_D$- and $(+)_D$-di-μ-hydroxobis{bis(pic)chromium(III)} (Table 54).[457] Comparisons of CD spectral data suggest that the absolute configurations are ΔΔ and ΛΛ respectively. The binuclear cation can in principle exist in several geometrical and configurational isomeric forms, but from models all except (**114**) and its antipode are grossly sterically hindered and this explains why only one pair of isomers is obtained. Acid treatment of the diols gives $(-)_D$- and $(+)_D$-*α-cis*-$[CrCl_2(pic)_2]^+$, identified by their absorption spectra; consequently they also have Δ and Λ configurations, assuming that cleavage occurs with retention of configuration. It is also believed from these results that the *α-cis* series have the *cis trans cis* configuration.

(**114**) ΛΛ isomer

The diols prepared from racemic mepic (Table 54), purified by column chromatography and resolved with sodium antimonyl $(+)_D$-tartrate, turned out to be identical with the pair prepared directly from $(R)(+)_D$-mepic and $(S)(-)_D$-mepic.[458] There are more potential geometrical isomers than in the pic series because of the introduction of the methyl group, but again almost all are ruled out because of steric hindrance. From models it appeared that the most stable diol would have the pyridine nitrogen atoms *trans*, and from the absorption and CD spectra it was concluded that the diol resulting from the preparation with $(S)(-)_D$-mepic has the ΛΛ absolute configuration. This last assignment was based on empirical rules for mononuclear complexes since all previously reported structures of chromium(III) diols have been either *meso* forms or racemates. An X-ray analysis of $(+)_D$-$[\{(S)(-)_D$-mepic$\}_2Cr(OH)]_2(S_2O_6)_2\cdot 2H_2O$ supports the assignment (Table 54).[459] The cation has almost C_2 symmetry with the pyridine N atoms *trans*. The interplanar angle between the pyridine rings is 50° indicating considerable strain within the binuclear complex because in the related mononuclear complex *cis*-aquahydroxobis(pic)chromium(III) dithionate the pyridine planes are almost perpendicular. The hydrogen atoms of the bridge lie in the coordination plane.

The action of sodium hydroxide on the diol gives the μ-oxo-μ-hydroxo- and di-μ-oxo complexes $[L_2Cr(O)(OH)CrL_2]^{3+}$ and $[L_2Cr(O)_2CrL_2]^{2+}$ (L = mepic; Table 54).[460] The visible and CD spectral parameters have been obtained in media of appropriate pH. The structure of $[(mepic)_2CrO(OH)Cr(mepic)_2]Br_3\cdot 5H_2O$ has been determined by X-ray methods. Equal numbers of enantiomorphic cations (ΔΔ and ΛΛ) are present and, as was the case with the diol, only the isomer with the pyridine nitrogen atoms *trans* has been obtained. The Cr—Cr separation of 2.883 Å is substantially less than in any dihydroxo bridged dimer so far reported (2.95–3.06 Å). The Cr—N distances are in the range 2.057 to 2.130 Å, and the oxo ligand may exert a *trans* effect since it is *trans* to the long Cr—N bond. The Cr_2O_2 bridging unit is significantly non-planar. The dinuclear complexes generally are antiferromagnetic and values of

the singlet–triplet separations are given in Table 54. The chemistry of the diols in Table 54 which contain open chain tetramines is discussed in Section 35.4.2.4.v.

35.4.2.4 Open-chain polyamines

(i) Diethylenetriamine (dien) and related ligands

The complex $[Cr(dien)_2]Cl_3$ may be prepared by a number of methods. These include heating $CrCl_3$ and dien directly,[461] or heating a solution of $CrCl_3$ and dien in DMSO,[462] or heating a solution of $CrCl_3{\cdot}6H_2O$ and dien in absolute alcohol.[463] The perchlorate $[Cr(dien)_2](ClO_4)_3$ has been obtained in crystalline form from a solution of the chloride in dilute $HClO_4$.[463] Although three geometric isomers, two of which should be optically active, are possible for this complex, no resolutions or structural assignments have so far been made. The kinetics of aquation[463] and the phosphorescence behaviour[464] have been reported.

A number of complexes of the type $[CrCl(AA)dien]^{2+}$ (AA = en, pn or tn) have been

prepared by the reaction in equation (31).[465] Only the *a*(Cl)-*b,c*(AA)-*d,f,e*(dien) isomer was isolated in each case. These complexes undergo spontaneous, Hg^{2+}- and base-catalyzed hydrolysis at similar rates and all seemingly by an associative interchange mechanism.[466] Details of the solution electronic spectra of the complexes and their hydrolysis products are in Table 55.

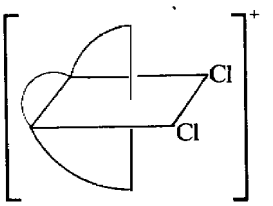
[a] In 0.1 M H^+ solution.
[1] D. A. House, *Inorg. Nucl. Chem. Lett.*, 1976, **12**, 259.

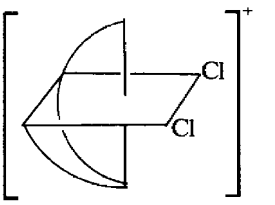
Dissolution of the chromium(IV) diperoxo compound, $[Cr(O_2)_2dien]{\cdot}H_2O$, in concentrated HCl affords the mauve crystalline product *mer*-$[CrCl_3(dien)]$.[467] The *fac* isomer may be obtained as green crystals by the addition of concentrated HCl to the oily residue obtained after evaporating a solution containing $[Cr(urea)_6]Cl_3$ and dien in EtOH.[468] The configurations of the complexes were initially assigned on the basis of spectral[469] and kinetic data[470] and later confirmed by X-ray crystallography, which showed the green material to be the *fac* isomer.[471] The bond lengths (pm) in this complex are shown in (**115**). Hydrolysis of these complexes proceeds as shown in Scheme 50.[468,470] The fact that the partly unwrapped dien complex $[Cr(H_2O)_4dienH]^{4+}$ may be obtained by hydrolysis of either 1,2,3- or 1,2,6-$[Cr(dien)(H_2O)_3]^{3+}$ implies that protonation occurs on a primary amino group. Protonation of the secondary amino group followed by isomerization is an unlikely alternative since such reactions are generally very slow.[468]

[a] This is thought to be the 5,6-dichloro isomer.

Scheme 50

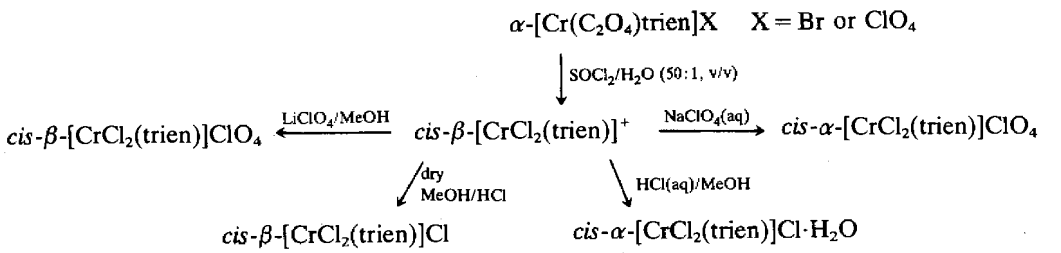


(115)



The mononuclear complex $[CrCl_2(tame)DMSO]I\cdot H_2O$ and the binuclear complexes $[Cr(\mu\text{-}OH)OH(tame)]_2I_2\cdot 2H_2O$ and $[H_2O(tame)Cr(\mu\text{-}OH)_2CrOH(tame)]I_3\cdot H_2O$ containing the tridentate ligand tris(aminomethyl)ethane (tame) have been reported.[472]

(*ii*) *Triethylenetetramine* (*trien*)



The isomers *cis*-α-$[CrCl_2(trien)]Cl$ (**116**) and *cis*-β-$[CrCl_2(trien)]Cl$ (**117**) are prepared in 70–80% yields according to Scheme 51.[473] The use of $SOCl_2$ as solvent in the preparation of *cis*-β-$[CrCl_2(trien)]Cl$ offers the following advantages: (a) it dissolves the starting complex but not the product, (b) its reaction with H_2O provides a homogeneous source of HCl and (c) it provides an anhydrous medium and thus prevents the formation of chloroaquachromium(III) products. Although the isomers of *cis*-$[CrCl_2(trien)]^+$ are stereorigid under anhydrous conditions, the presence of water causes rapid conversion of the *cis*-β to the *cis*-α form, probably *via* the stereomobile aquation product $[CrCl(trien)H_2O]^{2+}$ (Scheme 52). Indeed the first step in this reaction, the aquation of *cis*-β-$[CrCl_2(trien)]^+$, occurs 10^3-fold more rapidly than that of the α isomer[473] and is one of the most rapid aquations reported for chromium(III) complexes. Additional support for this mechanism is provided by the fact that isomerizations of analogous cobalt(III) complexes proceed much more readily after aquation. The lability of *cis*-β-$[CrCl_2(trien)]^+$ relative to its α isomer is consistent with an I_a mechanism in which H_2O attacks the metal ion at a position *trans* to the leaving group. In the *cis*-α isomer this site is blocked and rendered hydrophobic by methylene groups in the trien chain. In the *cis*-β isomer, however, this site is open and is also hydrophilic because of the proximity of amino groups.[473]

(116) *cis*-α

(117) *cis*-β

Scheme 51

The *cis*-α- and -β-$[CrCl_2(trien)]^+$ isomers may be distinguished by spectroscopic methods. The electronic spectrum of the *cis*-α isomer has a long wavelength shoulder on the first ligand field band similar to that observed in the spectra of other *cis*-α-$[MCl_2(trien)]^+$ (M = Co, Rh) complexes. No such shoulder is observed in the spectra of the *cis*-β isomers. The differences in

$$cis\text{-}\beta\text{-}[CrCl_2(trien)]^+ \xrightarrow{H_2O} cis\text{-}\beta\text{-}[CrCl(trien)H_2O]^{2+} + Cl^-$$
$$\Updownarrow$$

Scheme 52

the IR spectra of the complexes, shown in Figure 4, provide support for the assignment of configurations.[473] Details of the electronic solution spectra of these and other chromium(III)–trien complexes are given in Table 56. While the $[Cr(C_2O_4)trien]^+$ starting material used in the above reactions was, on the basis of IR spectroscopy, originally thought to have the *cis*-α configuration, recent evidence based on chiral interconversions indicates that it is in fact the *cis*-β isomer.[474] The primary step in the aquation of this complex involves Cr—N bond rupture and leads to the formation of $[Cr(C_2O_4)(H_2O)trienH]^{2+}$.[475]

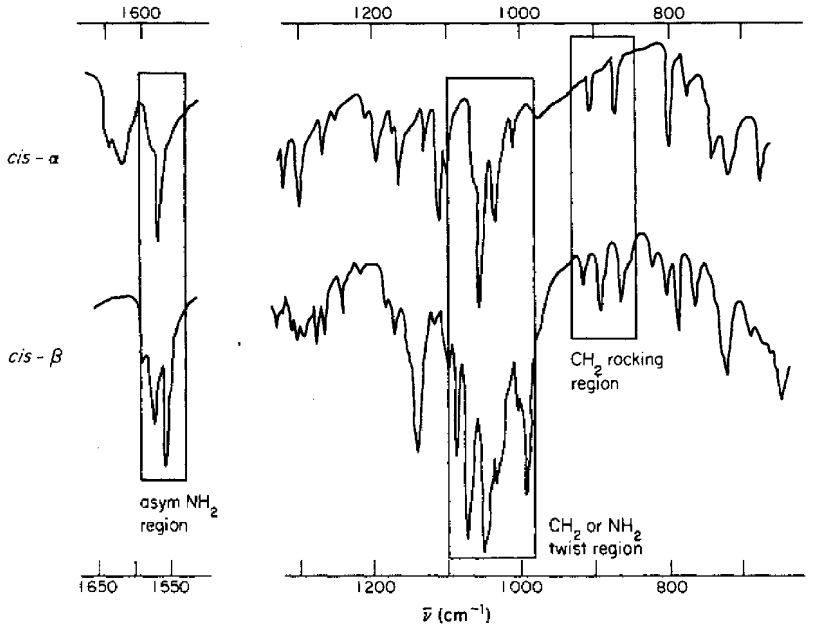

Figure 4 Differences in IR spectra (Nujol mulls) between *cis*-α- and *cis*-β-$[Cr(trien)Cl_2]Cl$ (adapted from *Inorg. Chem.*, 1977, **16**, 1154)

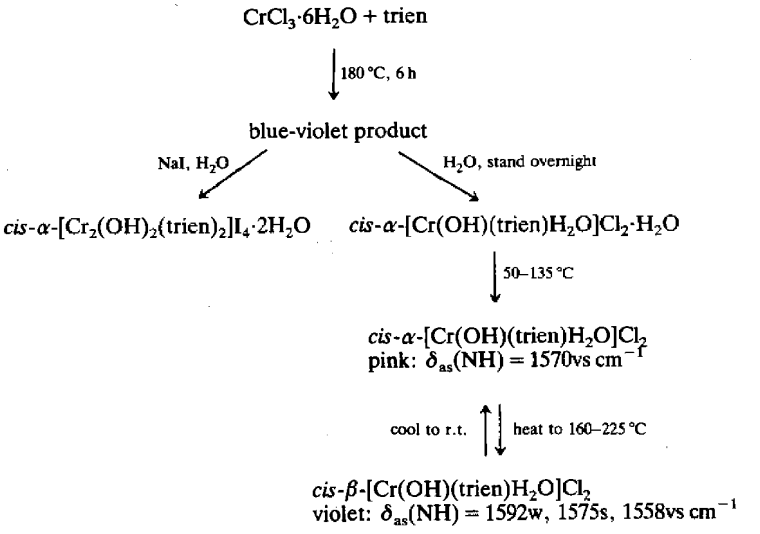
Reaction of $CrCl_3 \cdot 6H_2O$ with trien gives a blue-violet mixture from which some chromium(III)–trien complexes (electronic spectra given in Table 56) may be isolated as indicated in Scheme 53.[476] While the conversion of *cis*-α-$[Cr(OH)(trien)H_2O]Cl_2$ to the *cis*-β isomer in the temperature range 160–225 °C is reversed on cooling, the process is irreversible if the reaction is carried out above 225 °C.

A number of chromium(III) complexes containing 'partially unwrapped' trien ligands have been characterized. The complexes $[Cr(trienH_x)(H_2O)_{x+2}]^{x+3}$ are intermediates in the stepwise aquation of *cis*-α-$[CrCl_2(trien)]^+$ (Scheme 54) and can be isolated by cation exchange chromatography.[477] The aquation of *cis*-α-$[Cr(N_3)_2trien]^+$ similarly affords a series of $[Cr(N_3)(trienH_x)(H_2O)_{x+1}]^{x+2}$ ions as outlined in Scheme 55.[478] The colours and electronic spectra of these trien complexes are also included in Table 56.



Empirical[479] and theoretical[480] models have been developed to predict the photochemical behaviour of chromium(III) complexes. These rules predict that photolysis of *cis*-$[CrN_4Cl_2]^+$ complexes should proceed with aquation of the amino ligands *trans* to the weak field Cl^-. While the photoreactivity of *cis*-$[CrCl_2(en)_2]^+$ is, as expected, dominated by loss of amine, the behaviour of *cis*-α-$[CrCl_2(trien)]^+$ offers a crucial test to these models since photolabilization of the secondary amino groups should occur but because of the geometry of the complex these are constrained from leaving the primary coordination sphere of the metal ion. Indeed photolysis

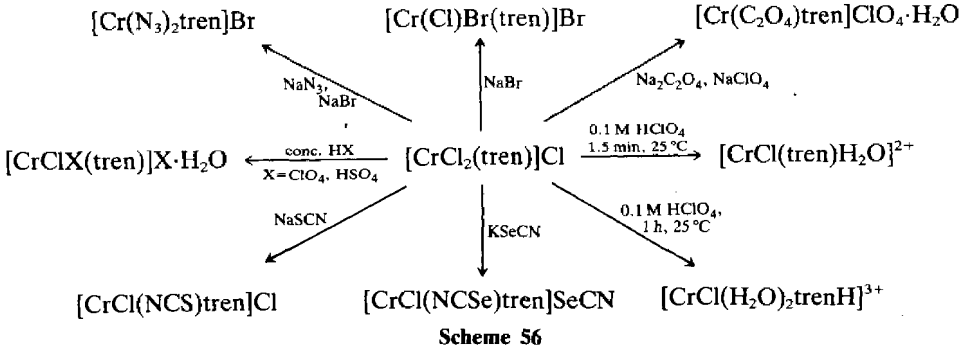
Scheme 54



Scheme 55

of *cis*-α-$[CrCl_2(trien)]^+$ was observed to involve negligible amine loss, with Cl^- aquation being the dominant process. Since the axial coordination sites in this complex contain primary amino groups which are as unconstrained as the photolabile amines in *cis*-$[CrCl_2(en)_2]^+$, the fact that amine loss is not observed confirms that ligand labilization is confined to the *xy* plane. The photolysis proceeds with retention of configuration.

(*iii*) 2,2′,2″-*Triaminotriethylamine* (*tren*)

A number of chromium(III) complexes of tren, a tripodal isomer of trien, have been prepared from $[CrCl_2(tren)]Cl$ according to Scheme 56.[481] This complex is conveniently prepared by the addition of tren to a solution of $[CrCl_2(H_2O)_4]Cl{\cdot}H_2O$ in DMSO which had previously been heated to boiling. In acid solution $[CrCl_2(tren)]^+$ undergoes a two-step aquation, the first involving loss of Cl^- and the second involving Cr—N bond rupture to give the partly unwrapped tren complex $[CrCl(H_2O)trenH]^{3+}$. Solvolysis of $[Cr(Cl)_2tren]^+$ in formamide, *N*-methylformamide, DMF and DMSO appears to occur *via* dissociative mechanisms. A number of these solvolysis products have been isolated and characterized.[482] Reaction of *trans*-$[CrF_2(py)_4]ClO_4$ with tren in 2-methoxyethanol gives *cis*-$[CrF_2(tren)]ClO_4$ as product.[392] From this the tren complexes $[CrF(X)tren](ClO_4)_x$ ($X = H_2O$, NCS, Br, N_3, $MeCO_2$; $x = 0$, 1 or 2) have been prepared.[487] In acid solution *cis*-$[CrF_2(tren)]ClO_4$ is converted to *cis*-α-$[CrF(tren)H_2O]^{2+}$ (H_2O *trans* to the tertiary N) both by acid-catalyzed thermal aquation and by ligand field photolysis.[483] A second but pH-independent thermal aquation process involving rupture of a Cr—N bond has also been observed. The electronic solution spectra of chromium(III)–tren complexes display *d*–*d* bands of greater intensity than those of analogous $Cr—N_4$ complexes having higher symmetry.[481] Dissolution of $[Cr(C_2O_4)tren]^+$ in dilute $HClO_4$ at 15 °C leads to the rapid formation of $[Cr(C_2O_4)H_2O(trenH)]^{2+}$.[484] Heating the product solution to 60 °C causes stepwise red-shifts in the *d*–*d* spectral maxima until the formation of $[Cr(C_2O_4)(H_2O)_4]^+$ is complete. In concentrated HCl solution, however, $[Cr(C_2O_4)tren]^+$ reacts to give $[Cr(Cl)_2tren]^+$ in a two-step process.

Scheme 56

Reaction of $CrCl_3(Me_3N)_2$ with tren in benzene (Scheme 57) leads to products in which tren behaves as a tridentate ligand coordinated to the metal through the primary amino groups[485] (Section 35.4.2.2).

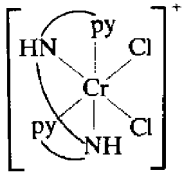
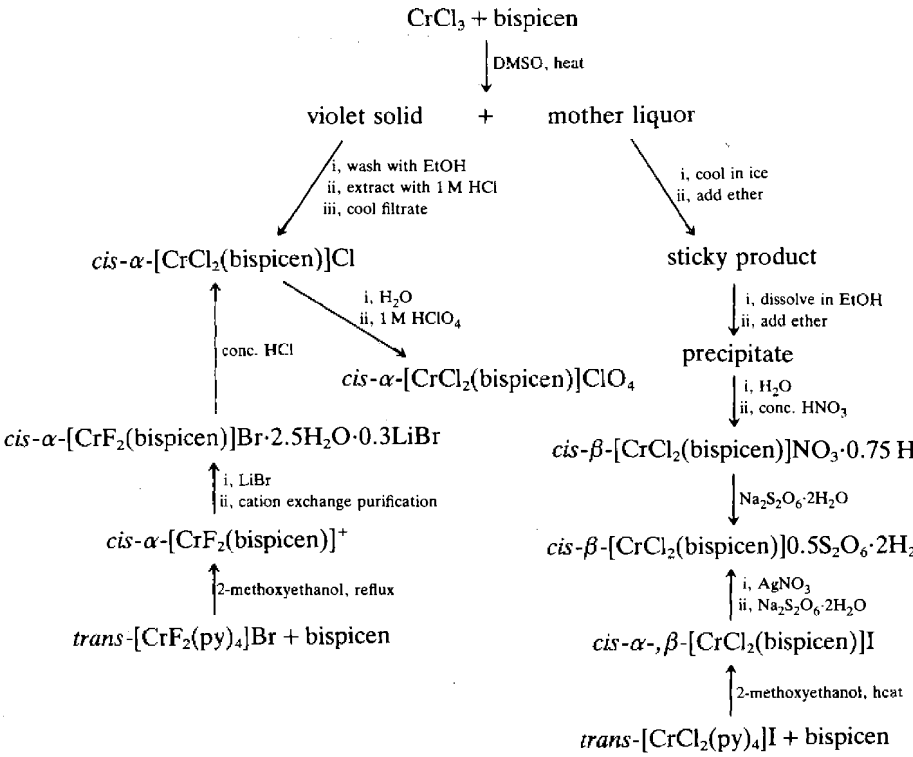
(*iv*) *Linear tetramines other than trien*



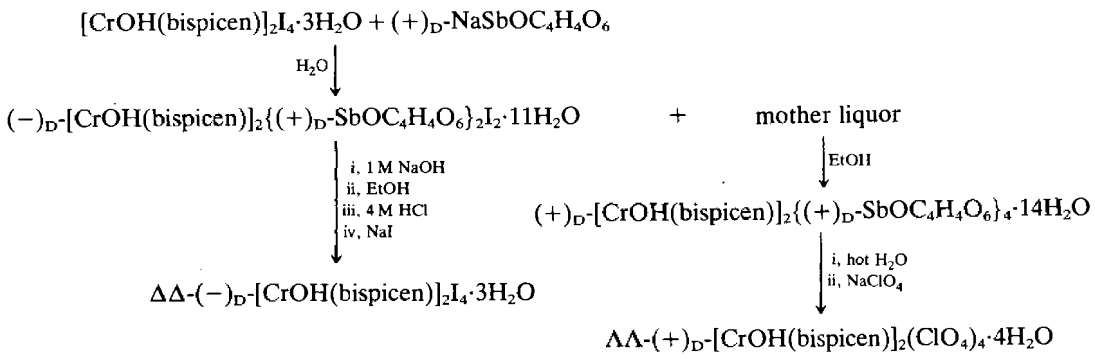
The linear tetramine ligand, 1,9-diamino-3,7-diazanonane (2,3,2-tet), a homologue of trien, forms octahedral complexes which can adopt several isomeric configurations.[486] The complex *cis*-*β*-*RR,SS*-$[Cr(C_2O_4)2,3,2\text{-tet}]^+$ has been synthesized and resolved and then used to prepare racemic and chiral *cis*-*α*-$[Cr(X)(Y)(2,3,2\text{-tet})]^{n+}$ (X = Y = Cl, NCS, CF_3CO_2, H_2O; X = Cl, Y = H_2O) complexes.[486] The *meso* complexes *trans*-$[CrX_2(2,3,2\text{-tet})]^+$ (X = Cl, F, NCS) have also been prepared and the secondary NH isomeric configurations for two of these (X = F, NCS) have been confirmed by X-ray crystallography.[486–489] The complexes *cis*-*β*-*RR,SS*-$[CrX_2(3,2,3\text{-tet})]^+$ ($X_2 = C_2O_4^{2-}$ or $2Cl^-$) and *trans*-*RR,SS*-$[CrY_2(3,2,3\text{-tet})]^+$ (Y = Cl, NCS^-) which contain the ligand 1,10-diamino-4,7-diazadecane (3,2,3-tet) have been synthesized and resolved.[490] Details of the visible absorption spectra of the above complexes have been reported as well as CD spectra and aquation kinetic parameters in some cases.[486,490–493] The complex *trans*-$[CrF_2(3,3,3\text{-tet})]ClO_4$ (3,3,3-tet = 1,11-diamino-4,8-diazaundecane) has been prepared and its electronic spectrum compared with those of other $Cr^{III}X_4Z_2$ complexes (X = a tetramine or two diamines; Z = F, Cl, Br, I, DMF or CO_2^-) using crystal field and angular overlap models[494] (note that the tetramine ligands are incorrectly named in this reference). A spectrochemical series in *Cp*, the second-order crystal-field parameter, shows trends in chromium–ligand interactions which are not apparent from the conventional series in *Dq*.

(*v*) 1,6-*Bis*(2′-*pyridyl*)-2,5-*diazahexane* (*bispicen*) *and related ligands*

Mononuclear and binuclear chromium(III) complexes containing bispicen and related tetradentate ligands have been prepared. The isomers *cis*-*α*- (**118**) and -*β*- (**119**) $[CrCl_2(bispicen)]^+$ are obtained by the methods outlined in Scheme 58[495,496] but complexes with the *trans* geometry are unknown.

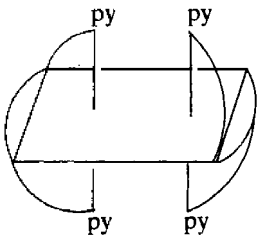


(**118**) *cis*-*α*

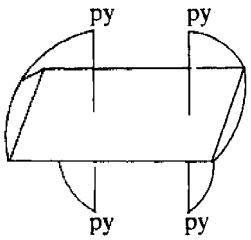


(**119**) *cis*-*β*

Addition of bispicen to a solution of $[CrBr_2(H_2O)_4]Br{\cdot}2H_2O$ in 2-methoxyethanol and in the presence of zinc powder gives the binuclear di-μ-hydroxo complex $[CrOH(bispicen)]_2^{4+}$ (see Table 54 for details of the structure).[495] In principle, 13 possible isomers of this complex exist but the use of molecular models shows that 11 of these are grossly sterically hindered. The remaining two isomers, (**120**) and (**121**), were isolated by the methods outlined in Scheme 59. Treatment of ΛΛ-$(+)_D$-$[CrOH(bispicen)]_2(ClO_4)_4{\cdot}4H_2O$ with concentrated HCl affords $(+)_D$-*cis*-*α*-$[CrCl_2(bispicen)]ClO_4$, which has therefore been assigned the Λ configuration.[495] The stereochemistries of the bispicen complexes were established using electronic and CD spectroscopy and by comparison of their X-ray powder photographs with those of analogous cobalt(III) complexes with structures known from ^1H NMR spectroscopy.



A number of complexes of the type *cis*-*α*-$[CrX_2(S\text{-bispicpn})]Y$ (X = Y = Cl, Δ and Λ;



Scheme 58

Scheme 59

(120) ΛΛ

(121) ΔΔ

X = Cl, Y = I, Δ; X = Br, Y = I, Δ; X = Cl, Y = ClO_4, Δ; X = F, Y = Br, Λ; X = Y = Br, Λ; X = Y = NCS, Λ) containing the unsymmetrically substituted and optically active ligand 1,6-bis(2′-pyridyl)-3-methyl-2,5-diazahexane (bispicpn) have been prepared by methods similar to those in Scheme 58 and characterized by electronic and CD spectra.[497] An X-ray crystal structure determination of Δ-*cis*-α-[$CrCl_2$(*S*-bispicpn)]Cl confirmed the assignment of a Δ configuration, initially based on CD spectroscopy.[498] A number of analogous *cis*-α-[$CrCl_2$(*R*-bispicpn)]$^+$ complexes and also *cis*-β-[$CrCl_2$(*R*-bispicpn)]I have been prepared and

characterized.[499] The complexes $[CrCl_2(S,S\text{-bispicbn})]ClO_4$ (bispicbn = 1,6-bis(2′-pyridyl)-3,4-dimethyl-2,5-diazahexane) and $[CrCl_2(R,R\text{-bispicchxn})]ClO_4$ (bispicchxn = *N*,*N*′-bis(2-pyridylmethyl)-1,2-cyclohexanediamine) have been assigned Λ-*cis*-α structures on the basis of CD spectral comparisons.[500] Details of the electronic spectra of a number of bispicdiaminechromium(III) complexes are presented in Table 57.

5. K. Michelsen and E. Pedersen, *Acta Chem. Scand., Ser. A*, 1983, **37**, 141.

The di-μ-hydroxo complexes $[CrOH(bispicpn)]_2(ClO_4)_4$,[500,501] $[Cr(OH)(S,S\text{-bispicbn})]_2(ClO_4)_4$, $[Cr(OH)(S,S\text{-bispicchxn})]_2(ClO_4)_4$[500] and $[CrOH(bispictmd)]_2(ClO_4)_4$ (bispictmd is 1,7-bis(2′-pyridyl)-2,6-diazaheptane)[502,508] have been prepared by methods similar to those in Scheme 59. Once again, steric repulsion appears to be responsible for the limited number of the potential isomers isolated. From X-ray crystallography (Table 54) the violet form of $[CrOH(bispictmd)]_2(ClO_4)_4$ is shown to be a racemic mixture of ΔΔ and ΛΛ isomers, and the singlet–triplet separation in this antiferromagnetic species is 33 cm^{-1}.[502] For various salts of $[Cr(OH)(bispicpn)]_2^{4+}$ the values are in the range 44–50 cm^{-1}.[501]

(*vi*) *Tetraethylenepentamine* (*tetren*)

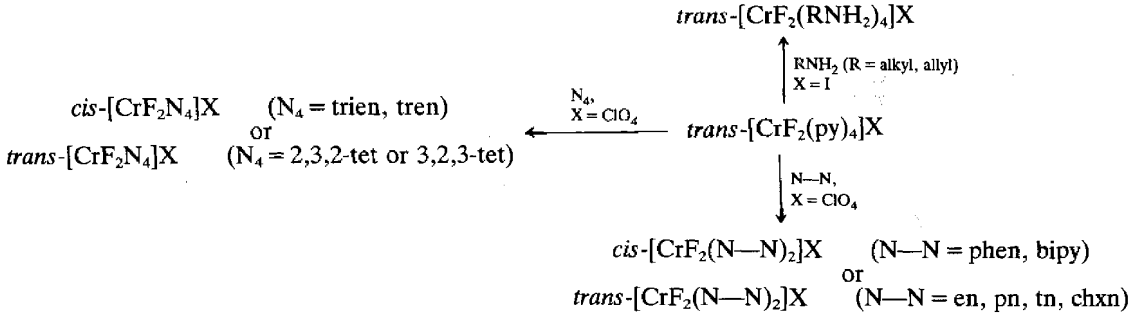
The complex $[Cr(tetren)(H_2O)]^{3+}$, prepared by hydrolysis of α,β,*R*-$[CrCl(tetren)]Cl_2$, undergoes aquation with successive rupture of Cr—N bonds in acid solution (Scheme 60).[503,504] The *N*-thiocyanato complex $[CrNCS(tetren)](SCN)_2$ may be obtained by heating the chloro complex with KSCN in aqueous solution.[505]

$$[Cr(tetren)H_2O]^{3+} \xrightarrow[k=5.5\times10^{-3}\,s^{-1}]{4\ M\ HClO_4,\ 60\,^\circ C} [Cr(tetrenH)(H_2O)_2]^{4+}$$

$$\xrightarrow[k=2.1\times10^{-2}\,s^{-1}\,a]{4\ M\ HClO_4,\ 60\,^\circ C} 1,2,3\text{-}[Cr(tetrenH_2)(H_2O)_3]^{5+} \xrightarrow[k=2.4\times10^{-4}\,s^{-1}]{4\ M\ HClO_4,\ 60\,^\circ C}$$

$$[Cr(tetrenH_3)(H_2O)_4]^{6+} \xrightarrow[k=1\times10^{-5}\,s^{-1}]{4\ M\ HClO_4,\ 60\,^\circ C} [Cr(tetrenH_4)(H_2O)_5]^{7+} \xrightarrow[k=1.7\times10^{-6}\,s^{-1}]{4\ M\ HClO_4,\ 60\,^\circ C} [Cr(H_2O)_6]^{3+} + tetrenH_5^{5+}$$

[a] Rate constant extrapolated from 10–35 °C values.



Scheme 60

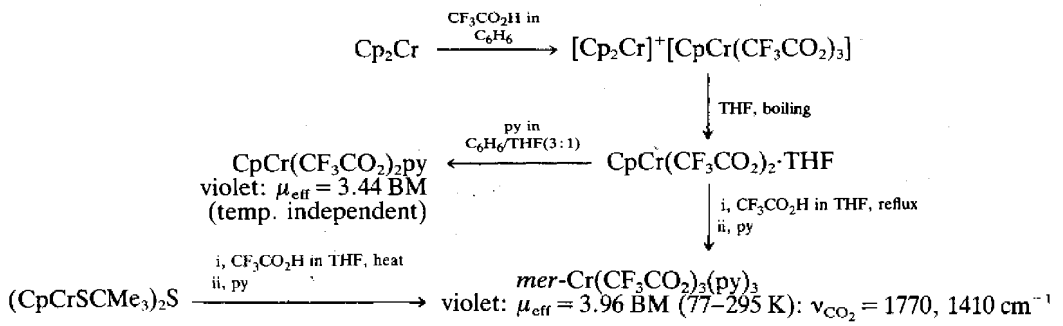
35.4.2.5 *N heterocyclic ligands*

(*i*) *Pyridines*

A large number of chromium(III) complexes containing pyridine (py) ligands are known.

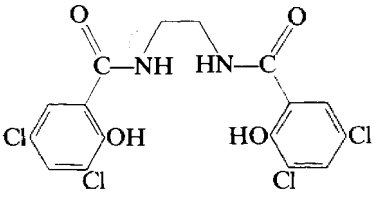
The addition of py to a solution containing high concentrations of Cr^{3+} and F^- gives *trans*-$[CrF_2(py)_4]^+$, which, owing to the high stability of the Cr^{III}—F bond in the absence of acid, is a convenient starting material for a variety of $[CrF_2N_4]^+$ complexes (Schemes 32, 33, 47, 58 and 61).[392,496] These reactions are usually carried out in boiling 2-methoxyethanol. Under acid conditions, the F^- ligands can be substituted to give complexes of the type $[Cr(X)(Y)N_4]^+$. A detailed analysis of the electronic spectra of the complexes *trans*-$[Cr(X)(Y)(py)_4]^+$ (X, Y = F, Cl, Br) using an angular overlap model to describe the Cr—py bond has led to the conclusion that py in these cases acts as a π acceptor.[506] However assumptions leading to this conclusion have been disputed,[507,508] since it has been pointed out that such behaviour is inconsistent with that of py in other complexes, *e.g.* $M(X)(Y)(py)_4$ (M = Fe, Co, Ni), where it acts as a π donor.[507] Frozen solution X-band ESR spectra have been recorded for a series of complexes of the type *trans*-$[Cr(X)(Y)(py)_4]^{n+}$ (X = Y = F, Cl, Br, I, H_2O, OH; X = F, Y = Cl, Br, H_2O, OH; X = Cl, Y = H_2O, OH; X = Br, Y = H_2O).[509] The dihalogeno complexes show tetragonal symmetry with $1.97 \leq g \leq 1.99$ and zero field splittings $0.30 \leq 2D \leq 3.5\ cm^{-1}$. The aqua and hydroxy complexes have rhombic symmetry.

Scheme 61



Reaction of $CrCl_3$ and pyridine at reflux temperatures and under anhydrous conditions affords the green-coloured product $CrCl_3(py)_3$.[397,510] The far-IR spectrum of this complex shows three well-separated ν(Cr—Cl) bands indicative of a *mer* configuration.[511] Subsequent X-ray studies established that both this and $CrBr_3py_3$ are isostructural with the known *mer*-$MoCl_3(py)_3$.[512] The complexes $CrX_3(4\text{-Mepy})_3$ (X = Cl, Br) obtained from CrX_3 and 4-Mepy were also shown to have *mer* configurations.[513] Reaction of $CrCl_3 \cdot 6H_2O$ with a ten-fold excess of each of the cyanopyridine isomers (CNpy) in either 1- or 2-butanol at 80 °C affords the complexes $CrCl_3(CNpy)_3$, although configurations have not been assigned.[514] Thermal decomposition of the complexes *mer*-$[CrCl_3(R\text{-py})_3]$ (R = H, 3-Me, 4-Me) and $pyH[CrCl_4(py)_2]$ gives the dimers $Cr_2Cl_6(R\text{-py})_4$.[515]

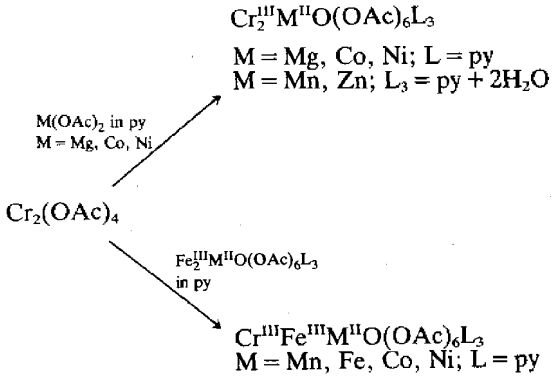
The complexes *mer*-$Cr(CF_3CO_2)_3py_3$ and $CpCr(CF_3CO_2)_2py$ have been prepared by the methods outlined in Scheme 62.[516] An X-ray analysis of the former complex showed it to have a slightly distorted octahedral structure with almost identical Cr—O (mean 195 pm) and Cr—N (mean 210 pm) bond lengths. Reaction of $Cr(MeSO_3)_3$, a CrO_6 complex containing bridging $MeSO_3$ ligands, with py and the appropiate amount of bipy gives the green complexes $Cr(MeSO_3)_3py_3$, $Cr(MeSO_3)_3bipy$ and $Cr(MeSO_3)_3(bipy)_2$ all of which appear to contain octahedrally-coordinated chromium(III).[517]



Reduction of $RpyCr(O)(O_2)_2$ (R = 3-Me, 3-Cl and 3-CN) with Fe^{2+} under acid conditions gives the species $[Cr(Rpy)(H_2O)_5]^{3+}$ in solution.[518] For the aquation of these and the unsubstituted py complex (equation 32) a linear relationship exists between $-\log k$ and the pK_a values of the py ligands.

$$[Cr(Rpy)(H_2O)_5]^{3+} + H_2O \xrightarrow{k} [Cr(H_2O)_6]^{3+} + Rpy \qquad (32)$$

Some multinuclear chromium(III) complexes which contain pyridine ligands have been described. The amide (**122** = H_4L) reacts with $CrCl_3 \cdot 6H_2O$ in pyridine solution containing Na_2CO_3 to give the dimer $[Cr_2(HL)_2(py)_4] \cdot 2py$, the structure of which is described in Section 35.4.2.11.[519]



Scheme 62

(122)

Reaction of chromium(II) acetate with various other divalent metal acetates in py gives a series of oxo-centred trinuclear complexes which contain bridging acetate ligands (Scheme 63).[520] The reaction between various poly-4-vinylpyridines and *cis*-$[CrCl_2(en)_2]Cl$ in water at 70 °C gives complexed polymers which, despite having degrees of coordination between 0.36 and 0.71, show no magnetic interactions between the chromium(III) ions along the polymer chains.[521] Addition of py, 3-Mepy or py-O to benzene solutions of the chromium(III) alkoxides $Cr(Cl)_2OR(ROH)_2$ (R = Et, Pr^i, Bu^n) gives green or brown solids $Cr(Cl)_2OR(py)_2$, $Cr(Cl)_2OR(3\text{-Mepy})_2$ and $Cr(Cl)_2OR(py\text{-}O)_2$, all of which appear to be dimeric with alkoxide bridging ligands.[522]

Scheme 63

Other reported chromium(III) complexes containing py and related ligands are listed in Table 58. Complexes of 2-pyridylmethylamine are dealt with in Section 35.4.2.3 and of pyridine carboxylic acids in Section 35.4.8.

(*ii*) *Bipyridyls, phenanthrolines and terpyridyls*

A number of chromium(III) complexes with bipy, phen, terpy and related ligands have been prepared and their photochemical and photophysical properties investigated, mainly because of their potential applicability as photosensitizers for solar energy conversion and storage. Much of this work has recently been thoroughly and critically reviewed[523,524] and a later article

describing a pulsed laser photochemical study of $[Cr(bipy)_3]^{3+}$ includes some additional references.[525] The ability of these heterocyclic ligands to stabilize a wide range of oxidation states of coordinated metals also renders their complexes suitable for participation in series of one-electron reversible charge transfers. Such electron transfer chains containing four reversible redox couples have been observed for chromium complexes containing bipy (Scheme 64), phen, terpy and related ligands in acetonitrile solution.[53,526] The first three couples for each complex involve redox orbitals which are primarily metal-centred while the last couple in each case involves a molecular orbital with mainly ligand character.[53] All five members of the bipy series, as well as the further reduced complexes $[Cr(bipy)_3]^{2-}$ and $[Cr(bipy)_3]^{3-}$, have been isolated and their magnetic moments and electronic spectra (the latter with the exception of the anionic complexes) reported.[45]

$$[Cr(bipy)_3]^{3+} \rightleftharpoons [Cr(bipy)_3]^{2+} \rightleftharpoons [Cr(bipy)_3]^{+} \rightleftharpoons Cr(bipy)_3 \rightleftharpoons [Cr(bipy)_3]^{-}$$

Scheme 64

A convenient synthesis of $[Cr(bipy)_3]^{3+}$ and its aquation behaviour under various conditions are outlined in Scheme 65.[527–529] The complex $[Cr(phen)_3](ClO_4)_3$ can be prepared in a similar manner[527] and its thermal- and photo-aquation reactions parallel those of the bipy complex under similar conditions.[530] Both complexes have been successfully resolved using $(+)_D$-tris{(−)-cysteinesulfinato}cobaltate(III) as the anionic resolving agent.[527] Similar tris chelates containing the ligands 5-Clphen, 4,7-Me_2phen, 4,7-Ph_2phen, 3,4,7,8-Me_4phen, 4,4′-Me_2bipy and 4,4′-Ph_2bipy as well as the bis complex $[Cr(terpy)_2](ClO_4)_3$, which was shown by X-ray crystallography to have a distorted *mer* configuration,[531] were obtained by chlorine oxidation of the corresponding chromium(II) complexes.[532] The influence of various factors, *e.g.* nature of

oxidant and its rate of addition, on the oxidation of $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ have been summarized in a recent article.[533] Details of the visible absorption spectra of these complexes are presented in Table 59.

Despite a few earlier reports to the contrary it now appears that complexes of the typ $[Cr(N—N)_2(X)(Y)]^{n+}$, (N—N = bipy or phen; X, Y = monodentate ligands) invariably have *ci* configurations.[534,535] The dichloro complexes (X = Y = Cl^-) are conveniently prepared b heating $CrCl_3$ and the amine in boiling ethanol in the presence of zinc dust catalyst.[534] Th preparation, resolution, reactions and properties of a number of such complexes have bee thoroughly investigated and some of the reported chemical interconversions are outlined i Scheme 66.[535] Visible spectral data for these species and for other heterochelates containin bipy or phen ligands are presented in Table 60 and pK_a values of the aqua complexes are liste in Table 61. Details of the crystal and molecular structure of *cis*-$[CrCl(bipy)_2H_2O](ClO_4)_2$ hav been reported.[533] The binuclear di-μ-hydroxo complexes $[CrOH(N—N)_2]_2^{4+}$, some reactions o which are included in Scheme 66 and the pK_a values of which are given in Table 61, can b obtained by the gradual neutralization of a refluxing solution containing $Cr(NO_3)_3\cdot 9H_2O$ and two-fold excess of the amine in 1 M $HClO_4$.[536] Because of the acidic properties (pK_a values i Table 61) and robustness of these complexes the corresponding μ-oxo-μ-hydroxo (**124**) an di-μ-oxo species (**125**) can easily be isolated after the addition of base to (**123**; Scheme 67).[53] Magnetic susceptibilities of salts containing these complex ions over the temperature rang 5–300 K are indicative of antiferromagnetic exchange interactions, which lead to singlet–triple separations of between 40 cm^{-1} in (**123**) and 110 cm^{-1} in (**125**).[537] The complexe $[CrOH(bipy)_2]_2Cl_4\cdot 9H_2O$ and $[CrOH(phen)_2]_2(NO_3)_4\cdot 7H_2O$ have both been resolved.[538] Th crystal and molecular structures of $[CrOH(phen)_2]_2I_4\cdot 4H_2O$ and $[CrOH(phen)_2]_2Cl_4\cdot 6H_2O$ hav been reported.[539] Addition of phen·HNO_3 to an aqueous solution of $CrCl_3$(bipy)DMF give

after the addition of base, the complexes $[CrOH(bipy)phen]_2(NO_3)_4 \cdot 6H_2O$, which has been resolved, and $[CrOH(bipy)(phen)H_2O](NO_3)_2 \cdot 1.5H_2O$.[538] The addition of one equivalent of base and then KI to an aqueous solution of *cis*-$[Cr(bipy)_2(H_2O)_2]^{3+}$ gives a crystalline product which was shown by X-ray analysis to be the $H_3O_2^-$-bridged dimer $[Cr(H_3O_2)_2(bipy)_2]_2$-$I_4 \cdot 2H_2O$.[540] The existence of this dimer in concentrated aqueous solutions has been demonstrated by three-phase vapour tensiometry.[541] The tartrate-bridged complexes $Cr_2(tart_{-H})_2$-$(N—N)_2$ and $Na[Cr_2(tart_{-2H})(tart_{-H})(N—N)_2]$ (tart = tartate = $C_4H_4O_6^{2-}$; $tart_{-H} = C_4H_3O_6^{3-}$; $tart_{-2H} = C_4H_2O_6^{4-}$) containing either two optically active or two *meso* bridging ligands have been prepared and characterized.[542]

The complexes $[Cr(C_2O_4)(N—N)_2]Cl$, $K[Cr(C_2O_4)_2N—N]$ (N—N = bipy or phen) and $[Cr(C_2O_4)(bipy)phen]Cl$ have been resolved.[538,543–545] The kinetics of racemization of a number of chelates described in this section have been studied and evidence for both intermolecular

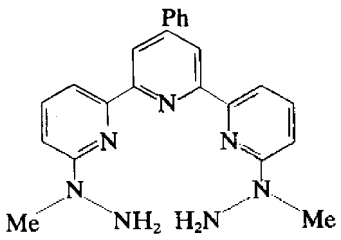
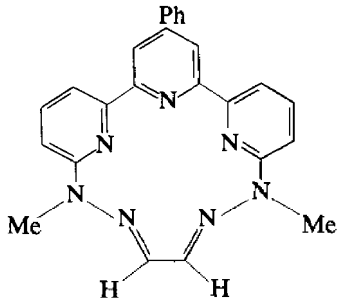
Scheme 66



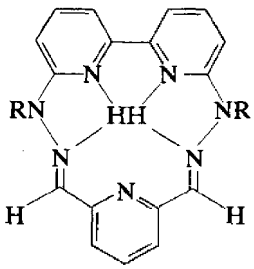
(123) **(124)** **(125)**

Scheme 67



(involving loss of one chelating ligand) and intramolecular (involving either one-ended dissociation of a bidentate ligand from the metal ion or a twist without bond rupture) mechanisms have been obtained for such reactions. Some of the most significant work in this area has been summarized in a recent article.[543]

The reaction between $CrCl_3$ and phen in DMF solution containing a little zinc dust catalyst results in precipitation of a dark green complex $[CrCl_3(phen)(DMF)]$ which according to X-ray crystallographic evidence contains the Cl^- ligands disposed in a *mer* configuration about the metal ion and the DMF coordinated through its O atom ($\nu_{CO} = 1635\ cm^{-1}$).[546,547] Heating a suspension of this complex in DMF causes it to isomerize to a pale green, DMF-soluble species, which presumably is the *fac* isomer. Both complexes lose DMF at 240–250 °C to give



$CrCl_3$(phen), a complex which on the basis of IR and mass spectroscopic evidence appears to contain five-coordinate chromium(III). The preparation of the related complex $CrCl_3$(terpy) is also reported.[547] A chromium(III) complex with the potentially pentadentate planar ligand 6,6″-bis(methylhydrazino)-4′-phenyl, 2,2′:6′2″-terpyridine (**126**) and formulated as [Cr(**126**)]-Cl_3·HCl was obtained by heating the ligand and $CrCl_3·6H_2O$ in refluxing methanol.[548] However this report is preliminary, dealing mainly with ligand synthesis and does not include information pertaining to the structure of the complex. Ligand (**126**) reacts with glyoxal in the presence of $CrCl_3·6H_2O$ to give the macrocyclic ligand (**127**), which after the addition of HCl and NH_4PF_6, can be isolated as $[H_2(\mathbf{127})](PF_6)_2$.[549] Appropriately substituted bis(hydrazines) of bipy and phen similarly react with 2,6-pyridinedicarbaldehyde in the presence of $CrCl_3·6H_2O$ to give metal-free macrocyclic ligands such as (**128**).[550] In these reactions the true template is thought to be the proton and not the metal.

(**126**)

(**127**)

R = CH_2CH_2OH

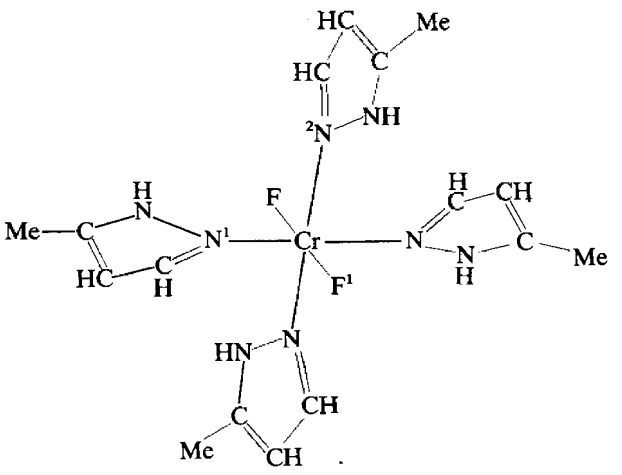
(**128**)

Some air- and water-stable σ-bonded organochromium(III) complexes have been prepared according to Scheme 68 and the structures of three of these (R = Ph, 2-MeOPh and Me_3SiCH_2) have been determined by X-ray methods.[551–553] All three compounds have *cis* octahedral configurations with almost identical Cr—C_R (2.087–2.107 Å); Cr—$N_{trans\ C}$ (2.147–2.156 Å) and Cr—$N_{trans\ N}$ (2.071–2.103 Å) bond distances. The Cr—C bond distances are appreciably longer than that found in the unstable complex *p*-MePhCr(Cl)$_2$(THF)$_3$.[554] These facts suggest that the Cr—C_R bond distance is virtually insensitive to the nature of R (*e.g.* whether it is alkyl or aryl, or the type of substituents in the aryl ring) in a given chromium environment but is influenced strongly by changes in this environment.

$$2RMgBr + CrBr_2 + bipy \xrightarrow{THF} \underset{\text{deep blue solid}}{R_2Cr(bipy)_2} \xrightarrow[ii,\ KI]{i,\ air} cis\text{-}[R_2Cr(bipy)_2]I$$

R = Ph, 2-, 3-, or 4-MeOPh, 4-MePh, Me_3SiCH_2

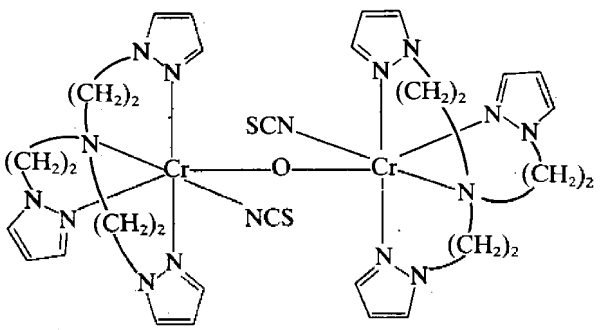
Scheme 68



(*iii*) *Imidazoles and related ligands*

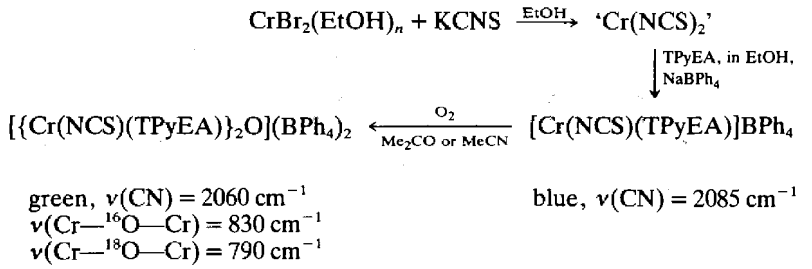
A number of chromium(III) complexes with imidazole (Him) and related ligands have been synthesized. Hence the reaction between $CrCl_3$ and imidazole, 1-methylimidazole (1-Meim) or 2-methylimidazole (2-Meim) in absolute MeOH and in the presence of zinc dust catalyst affords the complexes $[Cr(Cl)_{6-n}(Him)_n]Cl_{n-3}$ ($n = 4$–6), $[Cr(Cl)_{6-n}(1\text{-}Meim)_n]Cl_{n-3}$ ($n = 4$, 5) and $[Cr(Cl)_2(2\text{-}Meim)_4]Cl$, the product obtained with the first two ligands being determined largely by the ligand to metal mole ratio used in the reaction mixture. These complexes have been investigated by IR and ESR spectroscopy and their reduction to the corresponding chromium(II) complexes at the dropping mercury electrode in various electrolyte solutions has also been studied.[555,556] The mixed ligand complexes $Cr(NCS)_3(1\text{-}Rim)_3$, $Cr(NCS)(OH)_2(1\text{-}Rim)_3$, $Cr(NCS)_2(2\text{-}R'im)_3$ and $Cr(NCS)_3(2\text{-}R'im)_2(H_2O)$ (R = H, Me, Et, vinyl; R′ = Me, Et, Pr^i) have been prepared from $K_3[Cr(NCS)_6]$ and the appropriate imidazole in refluxing ethanol.[557] By comparing the positions of the $^4A_{2g} \rightarrow {}^4T_{2g}$ bands in the electronic spectra of the $Cr(NCS)_3(1\text{-}Rim)_3$ and $Cr(NCS)_3(2\text{-}R'im)_3$ complexes the spectrochemical order of imidazole ligands (all of which lie between NH_3 and NCS in the spectrochemical series) was found to be:

Him > 2-Meim > 1-Meim > 2-Etim ~ 1-Vinylim > 2-Pr^{i}im ~ 1-Etim. The complexes have magnetic moments characteristic of octahedral chromium(III) complexes and the thiocyanate groups are N-bonded. While benzimidazole (bzim) and 2-methylbenzimidazole react with $[Cr(NCS)_6]^{3-}$ to give Reinecke-type anions such as $[Cr(NCS)_4(bzim)_2]^-$, [558] bidentate ligands such as 2-guanidino-benzimidazole and 2-(2′-pyridyl)imidazole can under appropriate conditions cause substitution of 2-, 4- or 6-*N*-thiocyanato ligands.[559,560] Treatment of $(2\text{-MeOPh})_2Cr$ with a solution of 2-(2′-pyridyl)imidazole in THF followed by air oxidation gives the orange-red solid tris[2-(2′-pyridyl)imidazolato]chromium(III) dihydrate.[553] A number of 5-substituted tetrazolate (5-Rtet$^-$, R = *p*-$ClC_6H_4CH_2$, *o*-ClC_6H_4, *p*-ClC_6H_4, C_6H_5) complexes $[Cr(5\text{-Rtet})_2OH]\cdot xH_2O$ have been prepared and shown on the basis of spectroscopic and magnetic moment data to contain chromium(III) in octahedral ligand environments.[561]



(*iv*) *Pyrazines and pyrazoles*

The reaction between Cr^{2+} and pyrazines (pyz) in oxygen-free solutions produces intensely coloured 'pyrazine green' products. Data obtained from kinetic, thermodynamic and spectroscopic investigations indicate that formation of the green complex involves Cr^{2+} and H^+ coordination at the ligand N atoms and that the product $[Cr(pyzH)(H_2O)_5]^{3+}$ is best formulated as a chromium(III)–pyrazine radical anion complex.[562] The electrochemical behaviour of a number of these pyrazine greens has been investigated.[563] While the reaction between chromium(II) halides CrX_2 and a 4:1 excess of various pyrazoles (R-pyrH) in deoxygenated alcohol solutions generally leads to the expected $CrX_2(R\text{-pyrH})_4$ products, the addition of 5-methylpyrazole (**9**; 5-MepyrH) to a deoxygenated solution of $Cr(BF_4)_2$ in ethanol results instead in oxidation of the metal, F^- abstraction from the anion and formation of the crystalline complex *trans*-$[CrF_2(5\text{-MepyrH})_4]BF_4$ (**129**).[101] Step-wise and overall formation constants of various $[Cr(R\text{-pyrH})_6]^{3+}$ complexes increase with changing ligand in the order; pyrH < 5-MepyrH < 3,5-Me_2pyrH < 3,4,5-Me_3pyrH.[564] The dimeric chromium(III) complex $[\{Cr(NCS)(TPyEA)\}_2O](BPh_4)_2$ (**130**) containing the tetradentate tris(2-pyrazole-1-ylethyl) amine is prepared according to Scheme 69.[107] The values of μ_{eff} as a function of temperature (1.63 BM at 300 K; 0.98 BM at 86 K) indicate strong antiferromagnetic coupling through the oxygen bridge.



Cr—F^1 = 1.960 Å
Cr—N^1 = 2.027 Å
Cr—N^2 = 2.048 Å
N^1—Cr—N^2 = 86.9°
F^1—Cr—N^1 = 91.4°
F^1—Cr—N^2 = 92.4°

(**130**)

Scheme 69

35.4.2.6 Nitrosyl, thionitrosyl, azo, hydrazine, hydroxylamine and related ligands

(i) Nitrosyls

Although the rough correlation between core electron binding energies, as determined by X-ray photoelectron spectroscopy, and atomic charges has in some instances permitted the assignment of oxidation states to metals in complexes,[565] for the majority of metal nitrosyls such assignments still remain ambiguous. Hence complexes containing the $CrNO^{2+}$ group, for example, are in some cases best formulated as Cr^{I}—(NO^{+}) and in others as Cr^{III}—(NO^{-}). Therefore for convenience this section deals with nitrosyl complexes of chromium in a number of different oxidation states.

(*a*) $[CrNO(CN)_5]^{3-}$. Reduction of CrO_3 by NH_2OH in basic solution containing CN^- affords the bright green solid $K_3[CrNO(CN)_5]\cdot H_2O$,[566] some properties of which are listed in Table 62. A crystal structure determination of $[Co(en)_3][CrNO(CN)_5]\cdot 2H_2O$ by X-ray diffraction showed that the Cr—NO group is almost linear.[567] The value of the chromium 3*p* electron-binding energy in this anion is almost identical to the values for known chromium(III) complexes and on this basis it may be formulated as $[Cr^{III}(NO^-)(CN)_5]^{3-}$ [565] contrary to previous work, which regards the chromium oxidation state as +1 and the ligand as NO^+.

In aqueous solution, $[Cr(NO(CN)_5]^{3-}$ undergoes hydrolysis as outlined in Scheme 70. Electronic absorption spectra and voltammetric properties of this and its hydrolysis products have been reported.[568] The formation, isomerization (Scheme 71) and reactions of bi- ($n = 1$) and tri- ($n = 2$) nuclear cyano-bridged adducts between $[CrNO(CN)(H_2O)_4]^+$ and Ag^+ and Hg^{2+} have been investigated.[569] That the isomerization step in Scheme 71 ($n = 1$) is some 2000 times faster than that of $[CrNO(CN)(H_2O)_4]^+$ alone seems rather surprising in view of the fact that a similar isomerization in $[Cr(CN)(H_2O)_5]^{2+}$ is enhanced only 100-fold on adduct formation with Hg^{2+}. The origin of this effect, caused by the presence of NO, remains unresolved. The binuclear complexes *cis*-$M[(N—N)_2FCr—NC—CrNO(CN)_4]$ (M = Na, K or NH_4; N—N = en or tn) have been obtained by heating the double complex salts *trans*-$M[CrF(N—N)_2H_2O][CrNO(CN)_5]$ at temperatures of 90–120 °C for one to three hours (Table 45). Reaction of $K_3[CrNO(CN)_5]\cdot H_2O$ with various nitrogen donors in aqueous acetic acid solutions gives the complexes $CrNO(CN)_2L—L$ (L—L = $(py)_2$, $(quin)_2$, bipy or phen), for which tetrameric cyano-bridged structures are proposed.[570] Polarographic reduction of $[CrNO(CN)_5]^{3-}$, or $[Cr(CN)_6]^{3-}$, the latter in the presence of nitrite, leads to the same reduced complex $[CrNO(CN)_5]^{4-}$.[571,572]

(*b*) *Other cyano chromium nitrosyls, N-thiocyanato- and azido-chromium nitrosyls.* It has recently been shown that the reductive nitrosylation of tetraoxometallates using NH_2OH as the source of NO requires the presence of another reducing anion (*e.g.* CN^-, SCN^-) in the reaction medium and generally proceeds much more efficiently when a vast excess of nitrosylating agent over tetraoxometallate is used.[573] Hence very high yields of nitrosyl complexes (Table 62) may be obtained under the reaction conditions outlined in Scheme 72.[573–576]

(*c*) *Pyridine-, pyridinecarboxylate- and hydroxylamine-chromium nitrosyls.* The mononitrosylchromium complex $[CrNO(ONO)_2(py)_3]$ (**131**) was obtained by the addition of pyridine to a solution of $Cr(CO)_6$ in THF which had been purged with NO and then UV irradiated.[577] The source of the NO_2 ligands in the green coloured product is thought to be NO_2 impurity in the NO gas. The complex contains a linear CrNO group ($\nu_{NO} = 1708\ cm^{-1}$).

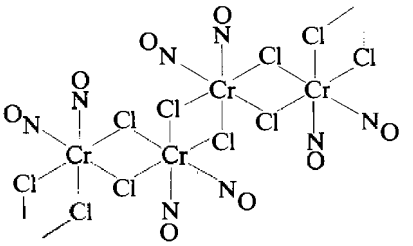
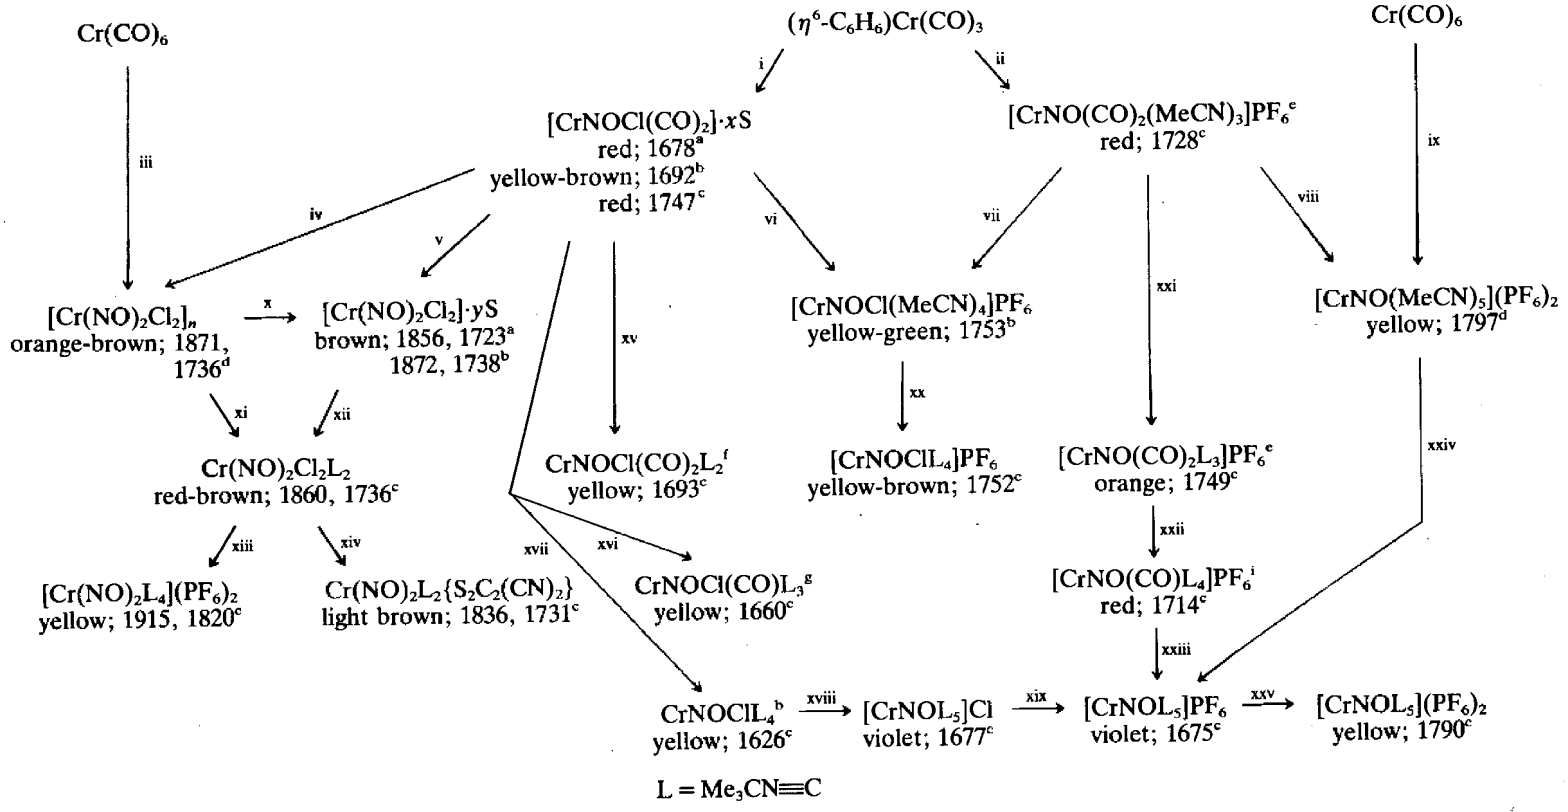


Scheme 72

(131)

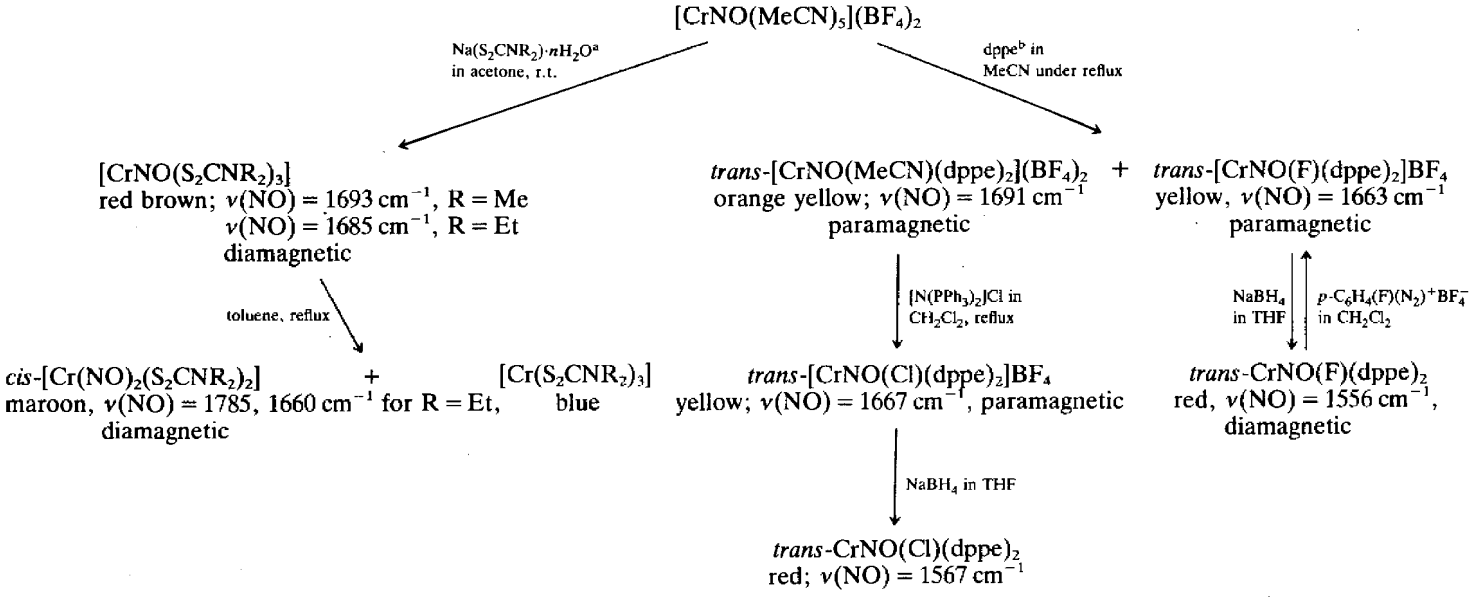
Addition of excess $(NH_3OH)Cl$ to an aqueous solution containing CrO_4^{2-} and pyridine-2,6-dicarboxylic acid (H_2dipic) leads to three products: the nitrosyls $CrNO(dipic)(H_2O)_2$ and $CrNO(dipic)(NH_2OH)_2$ (Table 62), as well as the complex $Cr(NH_2O)(dipic)(NH_2OH)_2$.[578] A crystal structure determination of the first of these shows that NO is bonded to the metal *trans* to the pyridine nitrogen of the tridentate dipic ligand. The Cr^{2+}-reduction of NO in the complex $[CrNO(H_2O)_5]^{2+}$ leads initially to coordinated hydroxylamine, but the product complex readily decomposes to the dimer $[Cr(OH)(H_2O)_4]_2^{4+}$, $[Cr(H_2O)_6]^{3+}$ and NH_3OH^+.[579] Reaction of the pentaammine instead of the pentaaqua complex follows a similar stoichiometry and rate law but produces two additional polymeric materials suggested to be $[(NH_3)_5Cr—X—Cr(H_2O)_4Y]^{n+}$ ($X = OH^-$ or NH_2OH, $Y = H_2O$ or NH_2OH).



(*d*) *Isocyanide-, nitrile-, chalcogeno-, phosphine- and arsine-chromium nitrosyls.* The oxidative nitrosylation of $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ by NOX ($X = Cl^-$, PF_6^-) leads to the solvent (S) stabilized species $[CrNO(Cl)(CO)_2]\cdot xS$ or the complex $[Cr(NO)(CO)_2S_3]PF_6$, both of which are useful precursors for the synthesis of a wide variety of $Cr(NO)^{2+}$ and $Cr(NO)_2^{2+}$-containing complexes.[580] Two of these complexes, the polymeric chloro-bridged species, $[Cr(NO)_2(Cl)_2]$ (**132**) and $[Cr(NO)S_5](PF_6)_2$ can also be prepared from $Cr(CO)_6$ by photonitrosylation and reaction with $NOPF_6$ respectively.[581] The above reactions as well as the colours and positions of NO stretching bands (cm^{-1}) in the intermediates and products are shown in Scheme 73.

(132)

The octahedral dinitrosyl complexes *cis*-$Cr(NO)_2(S—S)_2$, *cis*-$Cr(NO)_2(S—O)$ and *cis*-$Cr(NO)_2(Se—O)_2$ have been prepared by the reaction of $[Cr(NO)_2(Cl)_2]\cdot yS$ (Scheme 73) with the dithio (S—S), thiooxo (S—O) and selenooxo (Se—O) four-membered chelating anions $Me_2AsS_2^-$, $Me_2PS_2^-$, $(MeO)_2PS_2^-$, $Me_2NCS_2^-$, $MeCS_2^-$, $MeSCS_2^-$, $MeOCS_2^-$, Me_2NCOS^-, $MeCOS^-$ and Me_2NCOSe^-.[581] The IR spectra of all the complexes show two NO stretching bands, which with the exception of the dithiocarbamate complex *cis*-$Cr(NO)_2(S_2CNMe_2)_2$ ($\nu_{NO} = 1805, 1684\ cm^{-1}$) lie in the regions 1820–1840 and 1697–1718 cm^{-1}. The nitrile ligands in $[CrNO(MeCN)_5]^{2+}$ are readily displaced by neutral and anionic ligands as outlined in Schemes 73 (reaction xxiv) and 74.[582] An X-ray crystallographic investigation of $[CrNO(S_2CNEt_2)_3]$ (**133**) showed it to be one of the few known examples of seven-coordinate chromium complexes. The geometry of the complex is distorted pentagonal bipyramidal, the NO ligand and an S atom occupying the axial positions, with the remaining five S atoms forming the equatorial girdle. The complex in solution, as shown by its reaction in toluene under reflux, is thermally less stable than its Mo and W analogues, both of which are stable up to at least 130 °C. The F^- ligand in *trans*-$[CrNO(F)(dppe)_2]BF_4$ (Scheme 47) is provided by abstraction from the BF_4^- anion in the reactant. A number of nitrosylchromium complexes of the type represented in (**134**) have been formed in solution by reaction of $[CrNO(S—S)(H_2O)_3]$ ($S—S = EtOCS_2^-$, $Et_2NS_2^-$) with a number of arsine, phosphine and amine Lewis bases (L), and have been studied by ESR spectroscopy.[583]



The purple, diamagnetic isocyanide complexes $[CrNO(RNC)_5]PF_6$ ($R = Me$, Bu^t, $p\text{-}ClC_6H_4$) may be oxidized chemically (Ag^+ in CH_2Cl_2[584] or NO^+ in MeCN[580]) or voltammetrically[584] to the yellow paramagnetic species $[CrNO(RNC)_5]^{2+}$. The reaction of NO with the hexakis(isocyanide) complexes $[Cr(RNC)_6](PF_6)_2$ also gives $[CrNO(RNC)_5](PF_6)_2$ ($R = Bu^t$, Pr^i

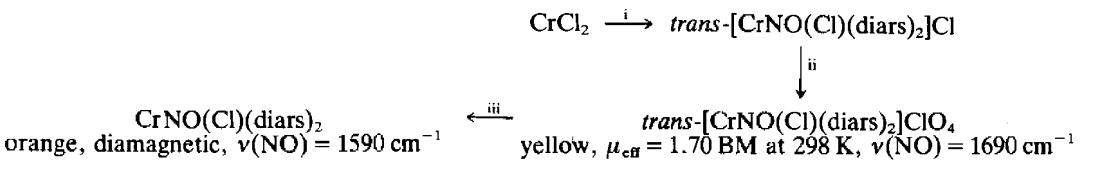
Scheme 75



The products of oxidative nitrosylation of the complexes $Cr(CO)_4P$—P (P—P = dcpe, dmpe) by $NOPF_6$ in MeCN depend on the ratio of nitrosylating agent to complex used in the reaction mixture as illustrated in Scheme 76.[587] The observed decrease in NO stretching frequency on converting *fac*-$[CrNO(CO)_3P$—$P]^+$ to *fac*-$[CrNO(MeCN)_3P$—$P]^{2+}$ shows that the effect of replacing three strong π-acid ligands by weaker ones, a substitution which normally results in a lowering of ν_{NO}, outweighs the effect of increased metal oxidation state which normally affects ν_{NO} in the opposite direction. The above reactions of the dcpe and dmpe complexes contrast with that of $Cr(CO)_4$dppe. In MeOH/toluene, reaction of this complex with $NOPF_6$ affords *cis*-$[Cr(CO)_4$dppe$]PF_6$ but in MeCN the product, although initially thought to be *trans*-$[Cr(NO)_2(MeCN)_4](PF_6)_2$,[588,589] is in fact $[CrNO(MeCN)_5](PF_6)_2$.[582]

Scheme 76

A nitrosylchromium complex stabilized with *o*-phenylenebis(dimethylarsine) (diars) ligands has been prepared and reduced according to reaction Scheme 77.[590] The product $[CrNO(Cl)(diars)_2]ClO_4$ has an X-ray powder pattern similar to that of *trans*-$[MNO(Cl)(diars)_2]ClO_4$ (M = Fe, Co) and therefore must have a six-coordinate *trans* configuration. Its ESR spectrum in CH_2Cl_2 consists of thirteen lines due to interaction of the unpaired electron with four ^{75}As ($I = 3/2$) nuclei. Each line is further split into a triplet due to interaction with the N ($I = 1$) nucleus.

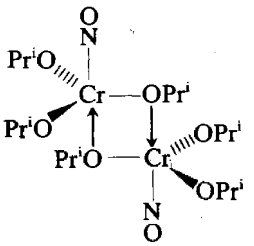
Scheme 77



(*e*) *Amido- and alkoxido-chromium nitrosyls.* Contrasting with the seven-coordinate $Cr(NO)^{3+}$-containing complex (**133**) are a number of complexes also containing this group and bulky ligands which constrain chromium to a coordination number of four. Hence reaction of the three-coordinate complexes CrL_3 (L = NPr^i_2, $N(SiMe_3)_2$ or 2,6-dimethylpiperidide) with NO in pentane solution gave the diamagnetic, chemically stable mononitrosyls $CrNOL_3$.[591,592] The crystal structure of the bis(trimethylsilylamide) complex (**135**) shows that the molecule has space-group-imposed C_3 symmetry with a linear Cr—N—O group. The chemical stability of this group is demonstrated by the reactions of $CrNO(NPr^i_2)_3$ with bulky alcohols (Scheme 78), which occur without loss of the NO ligand.[592,593] The dimer $Cr_2(NO)_2(OPr^i)_6$, represented schematically in (**136**) has virtual C_{2h} symmetry with the two chromium atoms, the two nitrosyl ligands and the bridging alkoxy oxygen atoms in the σ_h plane.[593] Above 80 °C in toluene solution, exchange of bridging and terminal isopropoxy ligands, for which an intramolecular mechanism is implicated, occurs rapidly on the NMR time-scale. The addition of $Mo_2(NO)_2(OPr^i)_6$ or ligands L (L = NH_3, pyridine or 2,4-lutidine) to $Cr_2(NO)_2(OPr^i)_6$ in toluene leads to the equilibria represented by equations (33) and (34). The existence of the heteronuclear dimer $CrMo(NO)_2(OPr^i)_6$ was confirmed by ^1H NMR, IR and mass spectroscopy. The NO stretching frequencies in the IR spectra of $Cr(NO)L_3$ complexes (Table 63) are remarkably sensitive to the nature of the ligand in the trigonal plane.

$$Cr_2(NO)_2(OPr^i)_6 + Mo_2(NO)_2(OPr^i)_6 \rightleftharpoons CrMo(NO)_2(OPr^i)_6 \quad (33)$$

$$Cr_2(NO)_2(OPr^i)_6 + 2L \rightleftharpoons 2Cr(NO)(OPr^i)_3L \quad (34)$$

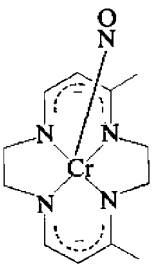
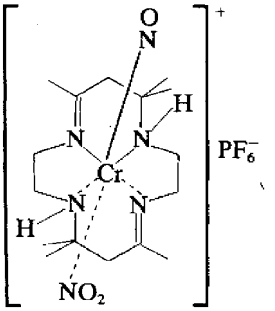
Scheme 78

The electrochemical reductions of $CrNO[N(SiMe_3)_2]_3$, $CrNO(NPr^i_2)_3$ and $CrNO(OBu^t)_2(NPr^i_2)$ in acetonitrile have been studied and the results interpreted in terms of quasi-reversible or irreversible one-electron reductions with the possibility of side reactions.[594]



(*f*) *Macrocyclic chromium nitrosyls.* A number of NO adducts with chromium macrocyclic complexes have been synthesized. The addition of NO to a solution of Cr(TPP) (TPP = tetraphenylporphyrin) in toluene leads to the red-coloured CrNO(TPP) ($\nu_{NO} = 1700\,cm^{-1}$, the visible spectrum in toluene solution has λ_{max} at 600, 555, 520sh and 435 nm).[595] This complex is also obtained by reductive nitrosylation of Cr(TPP)(OMe) in chloroform–methanol solution, a reaction which probably proceeds by a mechanism involving nucleophilic attack by MeOH on coordinated NO (Scheme 79). The complex has an $S = \frac{1}{2}$ ground state and its ESR spectrum, which in toluene solution shows hyperfine splitting from both porphyrin and nitric oxide ^{14}N, is diagnostic of a configuration which is predominantly metal $(d_{xz}d_{yz})^4\ d^1_{xy}$ in character. Its formulation as a $Cr^I(NO^+)$(TPP) complex contrasts with that of $[CrNO(CN)_5]^{3-}$, shown by X-ray photoelectron spectroscopy to be $[Cr^{III}(NO^-)(CN)_5]^{3-}$,[565] despite striking similarities in their ESR spectra. Recent work on ligand addition and electron transfer reactions of CrNO(TPP) is referred to in Section 35.4.9.1. The β-polymorph (but not the α) of phthalocyaninatochromium(II), β-PcCr, absorbs NO at room temperature to give the adduct CrNO(Pc) ($\nu_{NO} = 1690\,cm^{-1}$).[596,597] Treatment of this complex with anhydrous, degassed pyridine affords the stable product CrNO(Pc)py ($\nu_{NO} = 1680\,cm^{-1}$).

The nitrosylchromium complexes (**137**) and (**138**) are produced in the reactions of $[Cr(Me_2[14]tetraenatoN_4)(py)_2]PF_6$ ($Me_2[14]tetraenatoN_4$ = dianion of *trans*-5,14-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene) and $[Cr(Me_6[14]\text{-}4,11\text{-}dieneN_4)py](PF_6)_2$



$$Cr(TPP)(OMe) + NO \longrightarrow CrNO(TPP)(OMe)$$
$$CrNO(TPP)(OMe) + MeOH \longrightarrow Cr(TPP) + MeONO + MeOH$$
$$Cr(TPP) + NO \longrightarrow CrNO(TPP)$$

Scheme 79

(Me_6[14]-4,11-dieneN_4 = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene) respectively with alcoholic $NaNO_2$.[598] The crystal and molecular structure of (**138**) shows that the MNO group is linear and that the NO and NO_2^- ligands are mutually *trans*. A combination of IR, ESR and magnetic data has been interpreted to imply the presence in the complexes of a $Cr^I(NO^+)$ group having, as in the case of CrNO(TPP), a $(d_{xz}, d_{yz})^4\ d_{xy}^1$ configuration. Some properties of these complexes are presented in Table 64. The electronic spectra of complexes (**137**) and (**138**) are similar in band positions despite differences in their macrocyclic ligands and coordination numbers. This tends to suggest that the NO ligand dominates the electronic configurations of such complexes.

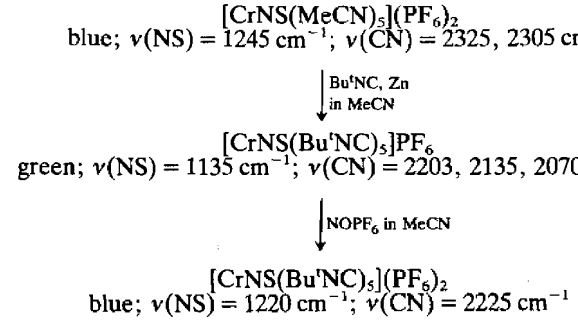
(*g*) *$Cr(NO)_4$*. The binary nitrosyl $Cr(NO)_4$, a dark red volatile solid which is both isoelectronic and isostructural with $Ni(CO)_4$, may be obtained by photolyzing a solution of $Cr(CO)_6$ in pentane while purging with NO.[599] The evidence from IR and Raman spectroscopy suggests that the molecule has T_d symmetry both in solution and in the solid state. Photolysis of $Cr(CO)_6$ and NO in frozen argon and methane matrices also leads to $Cr(NO)_4$ *via* the intermediate $Cr(CO)_3(NO)_2$.[600]



The chemistry of a number of carbonyl and cyclopentadienylchromium–nitrosyl complexes has been discussed in the companion series.[1]

(*ii*) *Thionitrosyls*

The relative scarcity of transition metal complexes containing NS ligands compared to the number containing NO has been attributed to the lower stability of NS and to the lack of reagents for introducing it into complexes.[601] The preparation and reactions of the first reported organometallic thionitrosyl complex, $CpCr(CO)_2NS$, are shown in Scheme 80.[601] Gas-phase core-electron binding energies of this compound have been determined.[602] Addition of a nitromethane solution of $NS^+PF_6^-$, obtained *in situ* from $N_3S_3Cl_3$ and $AgPF_6$, to $C_6H_6Cr(CO)_3$ in ethanenitrile gives the thionitrosyl complex $[CrNS(MeCN)_5](PF_6)_2$.[603] Reactions of this complex and some properties of it and its reaction products are outlined in Scheme 81. The ν(NS) band in the IR spectrum of $[CrNS(Bu^tNC)_5]PF_6$ occurs at lower wavenumbers than the corresponding band in the spectrum of its oxidation product consistent with greater electron density on the metal and increased back-bonding into a π^* orbital on NS.

Scheme 81

(*iii*) *Azo ligands*

Complexes of chromium(III) with multidentate ligands containing azo linkages as well as other donor groups are of interest because of their applications in spectrophotometric analysis and because of their uses as commercial dyestuffs.[604] Some ligands used in the analysis of chromium(III) are listed in Table 65.

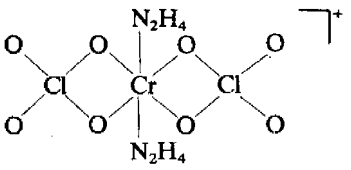
The structures of a number of chromium(III)–azo complexes have been determined by X-ray diffraction methods. The ligands 2,2′-dihydroxyazobenzene and 5-nitro-2-(2-hydroxynaphthylazo)phenol form 2:1 complex anions with chromium(III) which have *mer* configurations.[605] In the 2:1 complex anion formed between 3-methyl-2-[3-methyl-1-(*p*-bromophenyl)-5-oxo-2-pyrazolin-4-ylazo]benzoic acid and chromium(III) (**139**) the azo, carboxylate and enolate groups of one ligand are arranged *trans* to the corresponding groups in the other ligand.[606]

A number of isomeric 2:1 chromium(III) complexes containing ligands derived from

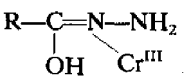
(139)



(140) $n = 2$, 3 or 6

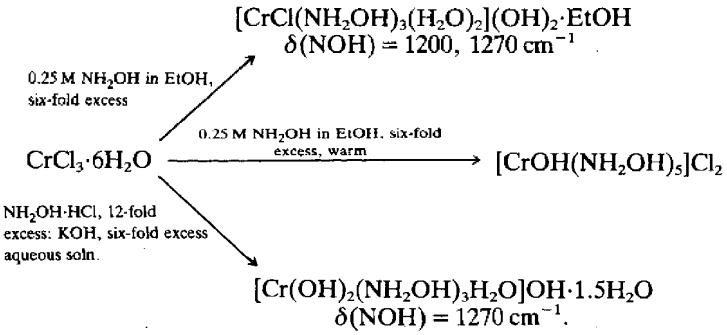
2,2′-dihydroxyazobenzene, *o*-(2-hydroxyl-1-naphthylazo)phenol, 2,2′-dihydroxyazonaphthalene and *o*-(2-hydroxy-1-naphthylazo)pyridine have been prepared.[607] Chromium(III) complexes containing the tridentate ligands 4-methylsulfonyl-2-(4,5-diphenylimidazol-2-ylazo)phenol and 4-chloro-2-(4,5-diphenylimidazol-2-ylazo)benzoic acid have also been prepared.[608] The effects of central ring size on the electronic spectra and stabilities of the pentacyclic chromium(III) complexes (**140**) have been investigated.[609] The preparation and properties of a number of 1:1 chromium(III) complexes containing substituted naphtholazopyrazolone ligands (L) have been reported.[604] These complexes appear to be of the type *fac*-$[CrL(H_2O)_3]^+$ and *fac*-$CrL(Cl)(H_2O)_2$ and react with various bidentate ligands such as acac, salicylaldehyde, amino- and hydroxy-acids (Y) to give the ternary complexes, $Cr(L)(Y)H_2O$. The effects of substituents on the spectra of the dyes and their complexes are discussed.

(*iv*) *Hydrazine, hydroxylamine and related ligands*



Addition of alcoholic $N_2H_4 \cdot H_2O$ to an aqueous solution of $Cr(ClO_4)_3$ affords a violet crystalline compound of composition $Cr(N_2H_4)_2(ClO_4)_3$.[610] The IR spectrum of the product shows split absorption bands at 1100 and 630 cm^{-1} characteristic of chelating ClO_4^- and a band at 950 cm^{-1} characteristic of a monodentate hydrazine ligand. On this basis structure (**141**) is proposed for this complex.

(141)



Addition of $Cr_2(C_2O_4)_3 \cdot 6H_2O$ to a cold alcoholic solution of N_2H_4 gives a violet powder of composition $Cr_2(C_2O_4)_3 \cdot 4N_2H_4 \cdot 4H_2O$.[611] This product is also obtained when the starting complex is stored in a desiccator over a 60% alcoholic solution of N_2H_4. Exposure to a higher partial pressure of N_2H_4 leads instead to the product $Cr_2(C_2O_4)_3 \cdot 7N_2H_4 \cdot H_2O$. Evidence based on spectroscopic[611,612] and magnetic[613] studies indicates that the former product is polymeric containing an infinite —N_2H_4—Cr—N_2H_4— chain in the equatorial plane, while the latter complex contains $C_2O_4^{2-}$ as well as N_2H_4 bridging ligands.

Acetylhydrazide ($AcNHNH_2$) and benzoylhydrazide ($BzNHNH_2$) form complexes with $CrCl_3 \cdot 6H_2O$ having compositions $CrCl_3(AcNHNH_2)_3 \cdot 3H_2O$ and $CrCl_3(BzNHNH_2)_3$ respectively.[614] IR and electronic spectral data suggest that each ligand is coordinated to the metal through the unsaturated nitrogen atom of its imidol form (**142**).

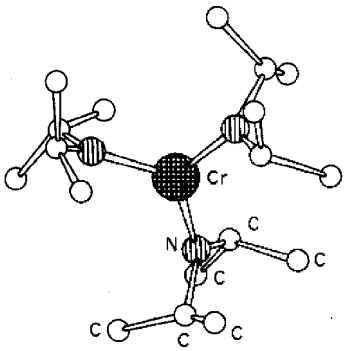
(142)

Chromium(III) forms a number of complexes with NH_2OH depending on the reaction conditions as outlined in Scheme 82.[615] Reaction of $KCr(SO_4)_2 \cdot 12H_2O$ with $NH_2OH \cdot HCl$ (12-fold excess) and KOH (6-fold excess) in aqueous solution affords the lilac-violet complex $[CrCl(SO_4)(NH_2OH)_4] \cdot 2H_2O$ (for which $\delta(NOH) = 1275\,cm^{-1}$). All of these complexes contain N-coordinated hydroxylamine as shown by the characteristic shift to higher wavenumbers in the $\delta(NOH)$ band relative to that in $NH_2OH \cdot HCl$. The electronic spectrum of $[CrOH(NH_2OH)_5]Cl_2$, the only one of these complexes to dissolve in water, shows maxima at 552 and 407 nm; the position of the first implies that the NH_2OH ligand lies between NH_3 and H_2O in the spectrochemical series. Reductive nitrosylation of CrO_4^{2-} by NH_2OH at pH 4–5 in the presence of pyridine-2,6-dicarboxylic acid (H_2dipic) gives the products $CrNO(dipic)(H_2O)_2$ (red, $\mu_{eff} = 1.70$ BM at 298 K), $[CrNO(dipic)(NH_2OH)_2] \cdot 3H_2O$ (yellow-green, $\mu_{eff} = 1.71$ BM at 298 K) and $Crdipic(NH_2O)(NH_2OH)_2$ (dark green, $\mu_{eff} = 3.6$ BM at 298 K, Table 62).[578] The modes of coordination of hydroxylamine and the hydroxylamine anion in these complexes have not been established.

Scheme 82

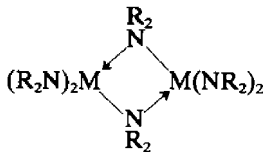
Hydroxylaminechromium(III) complexes have been observed amongst the products of reduction of $[CrNO(NH_3)_5]^{2+}$ by chromium(II) in acid solution.[579] Ion exchange experiments show that at least 50% of the NH_2OH produced (by the two-electron reduction of NO^-) in this reaction is initially coordinated in highly charged complexes such as $[(NH_3)_5CrXCr(H_2O)_4Y]^{n+}$ ($X = OH^-$ or NH_2OH; $Y = H_2O$ or NH_2OH).

In the complex tris(*N*-benzoyl-*N*-phenylhydroxylamine)chromium(III) the ligand acts as a bidentate two O donor.[616]



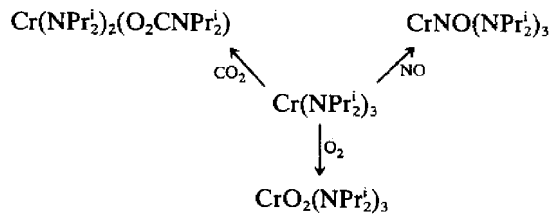
35.4.2.7 Amido ligands

This section is dominated by dialkyl- and disilyl-amide ligands, which, because of steric factors, constrain chromium(III) to the unusual coordination numbers of three or four.



The reaction between $LiNPr^i_2$ and $CrCl_3$ in THF solution leads to the air- and water-sensitive red-brown solid $Cr(NPr^i_2)_3$.[592] The complex is monomeric in solution and in the solid state ($\mu_{eff} = 3.80$ BM at 298–123 K). An X-ray crystal structure analysis shows that the molecule contains a planar CrN_3 and three planar $CrNC_2$ units with 68–70° dihedral angles between the former and each of the latter planes (**143**).[617] The planarity of the nitrogen atoms suggests involvement of their lone pairs in π bonding to the metal, an idea which is further supported by the relatively short Cr—N bond lengths. A number of other chromium(III) dialkylamide complexes, all of which are highly sensitive to air and water, have been prepared and their coordination properties clearly depend on the steric requirements of the specific ligand. Hence in solution both $Cr(NMe_2)_3$ and $Cr(NEt_2)_3$ appear to exist as dialkylamido-bridged dimers in which each chromium is surrounded by a tetrahedral ligand field (**144**).[592] Under vacuum and at mild temperatures the dimers disproportionate according to equation (35). This reaction has been used to synthesize a number of $Cr(NR_2)_4$ compounds ($R = NEt_2$, NPr^n_2, NBu^n_2, piperidide)

(Section 35.5.4.3).[618] The inability of chromium(III) to achieve its preferred hexacoordination because of steric hindrance accounts in part for this unusual disproportionation. In the tetrahedral chromium(IV) compounds the d^2 electrons occupy low energy orbitals. In the dimeric chromium(III) complexes, however, one of the d electrons on each chromium must occupy a high energy orbital. Transfer of an electron from one chromium to another results in formation of the volatile $Cr(NR_2)_4$ and the polymeric residue $[Cr(NR_2)_2]_n$.[618] The monomeric complex $Cr(NPr^i_2)_3$ is stable thermodynamically with respect to disproportionation.[592] While many metal–dialkylamide complexes react with CS_2 to give dithiocarbamate complexes, this insertion reaction is not successful with $Cr(NPr^i_2)_3$. It does, however, react with CO_2, NO (see Section 35.4.2.6) and O_2 (Scheme 83). The species $Cr(O_2)(NPr^i_2)_3$ may be a peroxo chromium(V) compound. At low temperatures the reaction with O_2 produces an explosive compound of composition $CrO_3(NPr^i_2)_3$.[592]



$$[Cr_2(NR_2)_6] \longrightarrow Cr(NR_2)_4 + [Cr(NR_2)_2]_n \qquad (35)$$

(143)

(144) R = Me or Et

Scheme 83

The reaction of $LiN(SiMe_3)_2$ with $CrCl_3$ in THF affords the bright green complex $Cr[N(SiMe_3)_2]_3$.[592] A single crystal X-ray analysis showed that the complex is similar structurally to $Cr(Pr^i_2)_3$ with a trigonal planar CrN_2 and planar $CrNSi_2$ units. Like the dialkylamide complexes, $Cr[N(SiMe_3)_2]_3$ is rapidly hydrolyzed although it is less susceptible to insertion reactions as shown by its inability to react with either CS_2 or CO_2.

Since $Cr(NPr^i_2)_3$ and $Cr[N(SiMe_3)_2]_3$ are both volatile and can be sublimed without decomposition, they are amenable to study by photoelectron spectroscopy. The gas phase He-I photoelectron spectra of these species show Cr—N σ bond ionization energies in similar regions (9.9 and 10 eV respectively).[619] However the nitrogen lone pair ionization and the d (^3A, ^3E) bands occur at significantly lower energies in the spectrum of the dialkylamido complex. This confirms that the nitrogen lone pair is stabilized by delocalization on to the silicon atoms in $N(SiMe_3)_2$, thus making the ligand unable to act as a π donor to the metal. No such delocalization is possible in the dialkylamido ligand, and so in the complex $Cr(NPr^i_2)_3$ π donation from ligand to metal can occur, with a consequent lowering of metal d electron ionization energies.

A study of the electrochemical reductions of $Cr(NPr^i_2)_3$ and $Cr[N(SiMe_3)_2]_3$ in acetonitrile solution shows that the reductions are either quasi-reversible or irreversible and that the dialkylamido complex has a slightly lower reduction potential.[594]

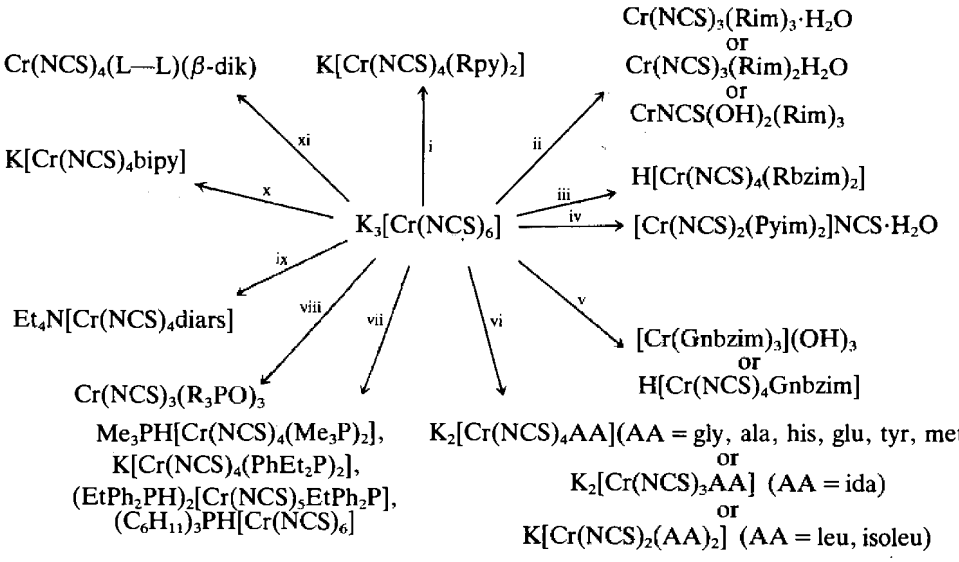
Magnetic susceptibility measurements confirm that $Cr(NPr^i_2)_3$ and $Cr[N(SiMe_3)_2]_3$ behave as magnetically dilute species with μ_{eff} values of 3.80 and 3.73 BM respectively over the

temperature range 123–298 K.[620] Neither complex gives an ESR signal in solution at room temperature. However, frozen solutions of the former in toluene at 130 K and polycrystalline samples of the latter show g anisotropy with principal values $g_{\|} = 2.0$, $g_{\perp} = 4.0$ corresponding to an axially symmetric system with a large zero-field splitting of the chromium ion.[620]

35.4.2.8 N-Thiocyanato, N-cyanato, N-selenocyanato, azido and related ligands

The vast majority of known chromium(III) complexes with the ambidentate chalcogenocyanate ligands NCO^-, NCS^-, $NCTe^-$ are those containing *N*-bonded thiocyanate.

(*i*) N-*Thiocyanates*



(*a*) $[Cr(NCS)_6]^{3-}$. A variety of salts containing the $[Cr(NCS)_6]^{3-}$ anion have been prepared.[621,622] Prior to its structure determination by X-ray diffraction methods, criteria based mainly on IR spectroscopy were used to establish N coordination of the ligand to Cr^{III} in this anion. Hence the IR spectrum of $K_3[Cr(NCS)_6]$ (Table 66) has NCS bending and CS stretching vibrations at 483 and 820 cm^{-1} respectively, positions which are characteristic of N-bonded thiocyanate complexes.[621] In addition a band at 364 cm^{-1} in the IR spectrum of $(Et_4N)_3[Cr(NCS)_6]$ has been assigned to the triply degenerate (T_{1u}) Cr—N stretch of the $Cr(NCS)_6$ group. Some properties of $[Cr(NCS)_6]^{3-}$ are listed in Table 66.

(*b*) *Mixed ligand* N-*thiocyanates*. A large number of mixed ligand *N*-thiocyanatochromium(III) complexes, many of which are of the type $[Cr(NCS)_4L_2]^{n+}$ and similar to the original Reinecke's salt (L = NH_3), are known.[621,623] Generally they are prepared by refluxing a solution of $[Cr(NCS)_6]^{3-}$ and the appropriate ligand L in alcohol and give *trans* isomers except when L = py, $PhEt_2P$ or of course when L_2 is a bidentate ligand. Some representative reactions of $[Cr(NCS)_6]^{3-}$ are shown in Scheme 84.[558–560,623–630] The electronic spectra of the products have been used in many cases to deduce the positions of ligands L in the spectrochemical (the first spin-allowed ligand-field band $^4A_{2g} \rightarrow {}^4T_{2g}$ is a direct measure of $10Dq$) and nephelauxetic series. The reaction of $[Cr(NCS)_6]^{3-}$ with secondary and tertiary phosphines ($R_2R'P$) gives, after acidification, one of the products $R_2R'PH[Cr(NCS)_4(R_2R'P)_2]$ (A), $(R_2R'PH)_2[Cr(NCS)_5R_2R'P]$ (B) or $(R_2R'PH)_3[Cr(NCS)_6]$ (C) depending on the steric requirements of R and R'.[628] Hence straight chain alkylphosphines give products of type A, $EtPh_2P$ gives B, while branching in the alkyl group increases the likelihood of obtaining product C. Neither PPh_3 nor $PHPh_2$ undergoes any of these reactions. The replacement of ligands in $[Cr(NCS)_6]^{3-}$ by imidazole and its derivatives in 95% EtOH has also been investigated.[558,626] While benzimidazole (bzim) and 2-methylbenzimidazole (2-Mebzim) give Reinecke type salts such as $[Cr(NCS)_4(bzim)_2]^-$, imidazole (Him) and its 1- and 2-substituted derivatives give instead complexes of the type $[Cr(NCS)_3(Him)_3]\cdot H_2O$ or $[Cr(NCS)_3(2\text{-}Etim)_2(H_2O)]$. Details of the IR and electronic spectra of some mixed ligand *N*-thiocyanatochromium(III) complexes are presented in Table 67.

i, R = H; heat with py at 110 °C: R = 3-NH_2, 4-NH_2; reflux in EtOH; ii, Rim = imidazole or substituted imidazole (R = H, 1-Me, 1-Et, 1-Vi, 2-Me, 2-Et, 2-Pr^i); reflux in 95% EtOH; iii, Rbzim = benzimidazole or substituted benzimidazole (R = H, 2-Me); reflux in 95% EtOH; iv, Pyim = 2,2′-pyridylimidazole; reflux in EtOH; v, Gnbzim = 2-guanidinobenzimidazole; reflux in EtOH or Pr^nOH; vi, AA = amino acid; 1:1 or 2:1 mole ratio as appropriate, in H_2O; vii, phosphine in Pr^iOH, reflux, H^+; viii, R_3PO (R = Et, Bu^n, C_6H_{11}) in Pr^iOH, reflux; ix, diars in EtOH, reflux, Et_4NCl; x, bipy in EtOH, reflux; xi, β-dik = β-diketone (benzoylacetone, dibenzoylmethane); L—L = bipy, phen, $(4\text{-}NH_2py)_2$; reflux in EtOH.

Scheme 84

A successful separation of the species $[Cr(NCS)_n(H_2O)_{6-n}]^{(3-n)+}$ ($n = 0$–6) including the *cis*, *trans* isomers of $[Cr(NCS)_2(H_2O)_4]^+$ and the *mer*, *fac* isomers of $Cr(NCS)_3(H_2O)_3$ has been accomplished by adsorption chromatography on Sephadex gel.[631] The complete series of anions $[Cr(CN)_{6-n}(NCS)_n]^{3-}$ ($n = 0$–6) has been prepared and separated by gel electrophoresis and by chromatography on alumina.[632] Ligand substitution in $[Cr(NCS)_6]^{3-}$ by CN^- in acetonitrile affords the *trans* ($n = 2$) and *mer* ($n = 3$) mixed ligand intermediates, while substitution in $[Cr(CN)_6]^{3-}$ by NCS^- in the same solvent leads to the *cis* and *fac* isomers (Scheme 85).[633] The position of the low energy $^4A_{2g}(F) \rightarrow {}^4T_{2g}(F)$ band undergoes a step-wise blue shift of about 30 nm on decreasing n (Figure 5) and log ε for the charge transfer band at ~310 nm increases almost linearly with n, the number of thiocyanate ligands. These observations suggest that no change in the mode of NCS^- coordination occurs throughout this series. The reaction of $[Cr(CN)(NCS)_5]^{3-}$ with en in acetonitrile affords the complexes *mer*-$[Cr(CN)(NCS)_3en]^-$ and *cis*-$[Cr(CN)(NCS)(en)_2]^+$.[634]

The solid state deamination of $[Cr(en)_3](SCN)_3$ on its own and in the presence of trace NH_4SCN catalyst, which functions by protonating and breaking loose one end of the coordinated amine in the rate-determining step, gives in a two-step process *trans*-$[Cr(NCS)_2(en)_2]SCN$.[635] At high catalyst levels the *cis* product is obtained. Other *N*-thiocyanatochromium(III) complexes prepared by solid state deaminations include *cis*-$[Cr(NCS)_2(tn)_2]SCN$ and *cis*-$[Cr(NCS)_2(pn)_2]SCN$,[636] while the *trans* isomer of the former was obtained by deamination of a suspension of $[Cr(tn)_3](SCN)_3$ in acetonitrile.[637] A number of *N*-thiocyanatoammine and amine chromium(III) complexes are referred to in Tables 46, 49 and 50. The complex $[\{Cr(NCS)(TPyEA)\}_2O](BPh_4)_2$ contains N-bonded thiocyanate (**130**).

(*c*) *Bridged NCS⁻ complexes.* Complexes containing both bridging and non-bridging NCS^- ligands have been prepared as outlined in Scheme 86.[638] Evidence for formation of bridged complexes is based mainly on the IR spectra which show CN stretching bands at ~2135 cm^{-1} and at ~2100 cm^{-1} corresponding to bridging and terminal *N*-thiocyanate ligands respectively. The homonuclear dimer is both photochemically and thermally the more stable of the two complexes. Evidence from IR and electronic spectroscopy points to the existence of bridging thiocyanate ligands in the salts $M_3[Cr(NCS)_6]$ ($M_3 = Cu_3$, Ag_3, $Cd_{3/2}$, $Hg_{3/2}$, Tl_3, $Pb_{3/2}$) and also in adducts formed between Reinecke's anion and a number of M^{2+} ions of the first row *d*-block

elements.[621] The measured formation constant of $[(NH_3)_5Cr—NCS—Ag]^{3+}$ ($\log K = 5.11$, $I = 0.03$ M, $T = 298$ K) is comparable to the formation constant of AgSCN ($\log K = 4.8$) under the same conditions.[621]

(*d*) *NCS^- linkage isomers.* Although the thiocyanate ion is a potentially ambidentate ligand, examples of linkage isomerism in thiocyanatochromium(III) complexes are rare. This can be attributed to the class *a* nature of the metal ion and its almost exclusive preference for N over S donor atoms. One of the few known *S*-thiocyanatochromium(III) complexes, $[Cr(SCN)(H_2O)_5]^{2+}$, is obtained by the inner-sphere reductions of *trans*-$[CoX(NCS)(en)_2]^{n+}$ ($X = H_2O$, NH_3, Cl^-, SCN^-), $[Fe(NCS)(H_2O)_5]^{2+}$ (remote attack) or $[Co(SCN)(NH_3)_5]^{2+}$ (adjacent attack) by aqueous Cr^{2+}.[639,640] In aqueous solution $[Cr(SCN)(H_2O)_5]^{2+}$ undergoes (as well as aquation) spontaneous and metal-ion-catalyzed isomerization. Catalysis by Cr^{2+} occurs by a redox mechanism involving initial metal ion attack at the N atom of the S-coordinated ligand while catalysis by Hg^{2+} occurs by the non-redox pathway shown in Scheme 87.[639]

Scheme 86

Scheme 87

The products of reduction of $Fe(NCS)^{2+}$ by Cr^{2+} in aqueous solution containing thiocyanate ions (equation 36), include the isomers of $[Cr(NCS)(SCN)(H_2O)_4]^+$, which contains both N- and S-bonded thiocyanate ligands.[641] These isomers undergo spontaneous decomposition by parallel aquation (loss of the *S*-thiocyanato ligand) and isomerization (Cr—SCN→Cr—NCS) reactions. Details of the solution visible spectra of these isomers as well as those of similar chromium(III) complexes for comparison are listed in Table 68. From the compiled data it is apparent that the S-bonded thiocyanate ligand lies very close to Br^- in the spectrochemical series while the N-bonded form lies between N_3^- and NO.

$$Fe(NCS)^{2+} + Cr^{2+} \xrightarrow{H^+} Cr^{3+} + Cr(NCS)^{2+} + Cr(SCN)^{2+} + \textit{cis, trans}\text{-}Cr(NCS)_2^+ + \textit{cis,trans}\text{-}[Cr(NCS)SCN]^+ + Fe^{2+} \quad (36)$$

(*ii*) N-*cyanates and* N-*selenocyanates*

Compared with *N*-thiocyanatochromium(III) complexes, those containing *N*-cyanato and *N*-selenocyanato ligands are relatively few in number. Some crystalline salts $M_3[Cr(NCSe)_6]\cdot nS$ (M = Na, K) have been prepared by heating acetone or dioxane (S) solution mixtures

containing MSeCN and $CrCl_3$, followed by slow evaporation of solvent.[642] The purple-coloured complex $(Me_4N)_3[Cr(NCSe)_6]$ was obtained by addition of Me_4NCl to a cooled solution containing $CrCl_3$ and a ten-fold excess of KSeCN which had been refluxed for four hours.[642] The green-coloured complex $(Ph_4As)_3[Cr(NCO)_6]$ was obtained by the addition of AgCNO to a solution of $CrCl_3$ and Ph_4AsCl in acetone containing a trace of zinc dust.[643] Details of the IR and electronic spectra of these complexes together with those of $[Cr(NCS)_6]^{3-}$ for comparative purposes are listed in Table 69. The suggested presence of *N*-selenocyanato ligands in the anion $[Cr(NCSe)_6]^{3-}$ is based on these data. Hence the appearance of ν(C—Se) in the region 600–700 cm^{-1} indicates N-coordination of this ligand to the metal. In selenium-bonded selenocyanato complexes the ν(CN) and ν(C—Se) bands are generally observed above 2080 cm^{-1} and in the region 500–600 cm^{-1} respectively. The almost identical values to 10 *Dq* for $[Cr(NCS)_6]^{3-}$ (18 080 cm^{-1}), which is known to contain N-bonded ligands, and $[Cr(NCSe)_6]^{3-}$ (17 920 cm^{-1}) further suggest N-bonding by the ligand in the latter species. The situation regarding $[Cr(NCO)_6]^{3-}$ however is less clear. While the ν(CO) band at 1336 cm^{-1} in the IR spectrum of the complex is in the range expected for *N*-cyanato ligands[644] and the strong band at 345 cm^{-1} has been assigned to a Cr—N stretching vibration, the very low value of 10 *Dq* (16 390 cm^{-1}) is more typical of a $Cr^{III}O_6$ rather than a $Cr^{III}N_6$ chromophore. Spectroscopic evidence for the existence of *N*-cyanato ligands in the complex *mer*-$Cr(NCO)_3(py)_3$ is somewhat more convincing.[645] While the ν(CO) and ν(CrN) bands in the IR spectrum of this complex occur at positions close to those reported for $[Cr(NCO)_6]^{3-}$, its visible spectrum is quite similar to that of *mer*-$[Cr(NCS)_3(py)_3]$, from which it is prepared by oxidation with BrO_3^- (equation 37).

$$mer\text{-}[Cr(NCS)_3(py)_3] + 4BrO_3^- \xrightarrow{py} mer\text{-}[Cr(NCO)_3(py)_3] + 4Br^- + 3SO_3 \quad (37)$$

The reaction of $K_3[Cr(NCX)_6]$ or $(Bu^n_4N)_3[Cr(NCX)_6]$ (X = O, Se) with chelating diamine ligands in acetonitrile solution followed by column chromatography on alumina gives salts of the complexes $[Cr(NCX)_4AA]^-$ and *cis,trans*-$[Cr(NCX)_2(AA)_2]^+$ (AA = en, pn, chxn) all of which have been characterized by electronic and IR spectroscopy.[646] Details of the preparations and spectra of $[Cr(NCX)(NH_3)_5]^{2+}$ (X = O, S, Se) complexes are presented in Table 70.

(*iii*) *Azides*

The reaction of $[Cr(NH_3)_5H_2O](ClO_4)_3$ and NaN_3 in dilute acetic acid solution at 60 °C affords the monoazido complex $[CrN_3(NH_3)_5](ClO_4)_2$.[647] The addition of less than one equivalent of KN_3 to a solution of chromium(III) in molten KCNS at 185 °C produces a bathochromic shift in the visible spectrum consistent with the formation of the thermally stable complex $[Cr(NCS)_5N_3]^{3-}$.[648] The neutral triazido complexes $Cr(N_3)_3(NH_3)_3$ and $Cr(N_3)_3(py)_3$

have been prepared, the first by refluxing an aqueous solution containing $[Cr(NH_3)_6](ClO_4)_3$ and NaN_3 and the second by the addition of pyridine to a hot ethanolic solution containing $Cr(NO_3)_3 \cdot xH_2O$ and NaN_3.[302] The green crystals of the latter complex are only slightly water soluble and should be treated with caution because of their potential explosive nature. When an aqueous solution mixture of $[Cr(en)_3]Cl_3$ and NaN_3 is heated the colour changes to rose-red and the salts *cis*-$[Cr(N_3)_2(en)_2]Cl$ and *cis*-$[Cr(N_3)_2(en)_2]N_3$ are coprecipitated from solution on cooling.[302] The brick-red complex *cis*-*α*-$[Cr(N_3)_2(trien)]Br$ has been prepared by heating an aqueous solution of *cis*-*α*-$[Cr(Cl)_2(trien)]Cl \cdot H_2O$ in the presence of excess NaN_3 and then adding KBr.[649] The configuration of the complex was established on the basis of its IR spectrum. Hence in the asymmetric NH_2 bending region (1560–1660 cm^{-1}) it shows a split absorption, whereas in the CH_2 rocking region (860–940 cm^{-1}) it shows two bands of medium intensity, features which distinguish the *cis*-*α* from the *cis*-*β* and *trans* configurations.[649]

The violet complex $(Bu^n_4N)_3[Cr(N_3)]_6$ (μ_{eff} at 295 K = 3.76 BM[650]), in which a large counterion is employed to stabilize the $[Cr(N_3)_6]^{3-}$ anion, was obtained by the addition of Bu^n_4NCl to the filtrate from a reaction suspension containing $CrCl_3 \cdot 6H_2O$ and NaN_3 which had been heated at 50–60 °C for one hour.[651] Evidence from IR spectroscopy points to the fact that $[Cr(N_3)_6]^{3-}$ contains bent M—N—N groups. Comparison of band positions in the electronic spectrum of the complex with those for other hexacoordinated chromium(III) complexes indicates that the azide ligand occupies a position slightly lower than F^- but higher than $(Et_2O)PS_2^-$ in the spectrochemical series and roughly the same position as I^- in the nephelauxetic series.[651]

Electronic spectral data corresponding to the $^4A_{2g} \rightarrow {}^4T_{2g}(F)$ and $^4A_{2g} \rightarrow {}^4T_{1g}(F)$ electronic transitions in a number of azido–chromium(III) complexes are compiled in Table 71.

The photochemical conversion of azidochromium(III) to nitridochromium(V) complexes has in recent years attracted considerable interest.[652] The complexes $[CrN_3(edta)]^{2-}$, $[CrN_3(nta)(H_2O)]^-$, $[Cr(N_3)_2(nta)]^{2-}$, $[CrN_3(VDA)(H_2O)]^-$ and $[Cr(N_3)_2(VDA)]^{2-}$ (VDA = *N,N'*-valinediacetate) when exposed to UV radiation liberated N_2 and gave products having ESR spectra (narrow line, no fine structure) characteristic of species with one unpaired electron and visible spectra similar to those of oxochromium(V) complexes.[652] It was therefore concluded that the products were nitridochromium(V) species. UV irradiation of $CrN_3(salen)(H_2O)$[653] and $Cr(TPP)N_3 \cdot nH_2O$[654] (Scheme 88) also give the corresponding nitridochromium(V) complexes. The evidence for formation of an intermediate nitrene complex $[CrN(NH_3)_5]^{2+}$ in the 313 nm photolysis of $[CrN_3(NH_3)_5]^{2+}$ has been disputed and the results reinterpreted to indicate formation of $[Cr^V(N^{3-})(NH_3)_5]^{2+}$, which undergoes rapid aquation to the nitridopentaaquachromium(V) cation.[653]

$$Cr(TPP)OH \cdot nH_2O \xrightarrow{HN_3} Cr(TPP)N_3 \cdot nH_2O \xrightarrow{h\nu} [Cr^V(TPP)(N^{3-})]$$

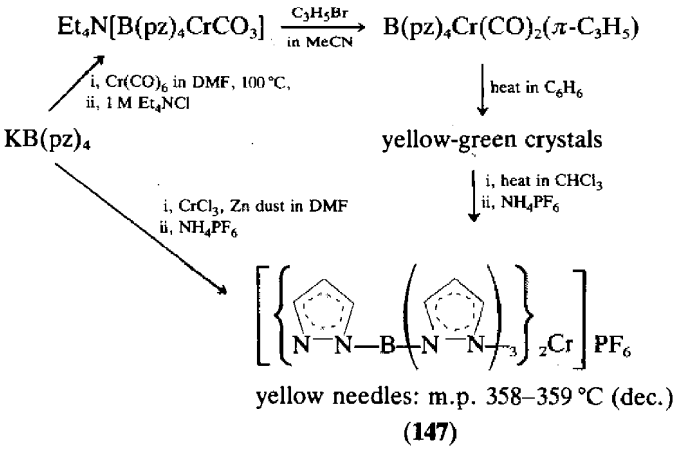
Scheme 88

The kinetics of aquation of a number of azidochromium(III) complexes have been investigated.[303,655] Compared with other acidochromium(III) complexes, the chromium–azide bonds in these species seem remarkably stable to thermal substitution. Hence in the base hydrolysis of $[CrN_3(NH_3)_5]^{2+}$ a pathway involving initial loss of NH_3 concurs with the usual base hydrolysis pathway involving loss of N_3^-. The aquation of azidochromium(III) complexes is H^+-assisted with protonation of the azido ligand accounting for the enhanced reactivity.

While the action of oxidants on coordinated azide is generally quite complicated, the peroxymonosulfate ion HSO_5^- reacts cleanly with $[CrN_3(NH_3)_5]^{2+}$ in aqueous solution according to equation (38).[656] Tracer experiments using HSO_5^- enriched with ^{18}O at either the terminal peroxide position or at all other positions indicate that the oxygen transferred from oxidant to reductant in reaction (38) is the terminal peroxide of HSO_5^-. Peroxymonosulfate also reacts cleanly with uncoordinated HN_3 and N_3^- (to give N_2O and N_2) and the observed reactivity follows the order $HN_3 \ll [CrN_3(NH_3)_5]^{2+} < N_3^-$. That HSO_5^- is a more effective oxidant than SO_5^{2-} is consistent with a reaction mechanism which involves nucleophilic attack on the peroxide oxygen.

$$[CrN_3(NH_3)_5]^{2+} + HSO_5^- \longrightarrow [CrNO(NH_3)_5]^{2+} + HSO_4^- + N_2 \qquad (38)$$

(*iv*) *Triazenides*



The distorted octahedral complex $Cr(PhN_3Ph)_3$ (**146**) which contains bidentate triazenido ligands is a major product of the reaction between $[Li(THF)]_4[Cr_2Me_8]$ and diphenyltriazine in THF under argon, equation (39).[178] The formation of this product under the stated reaction conditions seems surprising in view of the expected weak oxidizing capability of the triazene ligand and the severe angle strain in the four-membered chelate rings of the product. In contrast the minor product (**145**) which contains bridging triazenido ligands is virtually strain free.

$$[Li(THF)]_4[Cr_2Me_8] \xrightarrow[THF]{PhN_3HPh} Cr_2(PhN_3Ph)_4 + \underset{\textbf{(146)}}{\text{Cr(PhN}_3\text{Ph)}_3} \qquad (39)$$

(145)

35.4.2.9 Polypyrazolylborates

Despite the vast interest shown by coordination chemists in polypyrazolylborate ligands (**17**) since their discovery in 1966 few complexes of chromium(III) with these ligands have been mentioned in the literature. The complex $[\{B(pz)_4\}_2Cr]PF_6$ (**147**) may be prepared by either of the routes outlined in Scheme 89.[657]

yellow needles: m.p. 358–359 °C (dec.)

(147)

Scheme 89

Although some polypyrazolylborate complexes of chromium(II) have been reported to undergo oxidation on exposure to air,[115] the resulting chromium(III) complexes have not been investigated.

35.4.2.10 Nitriles

Chromium metal may be oxidized by Cl_2, Br_2 or I_2 in ethanenitrile solution to give the octahedral complexes $[CrCl_3(MeCN)_3]\cdot MeCN$, $CrBr_3(MeCN)_3$ and $[CrI_2(MeCN)_4]I$ although the nitrile content of the bromo complex is somewhat variable.[658] The chloro complex loses the uncoordinated nitrile when heated at 80 °C under vacuum. Some properties of these complexes are listed in Table 72. Reaction of $CrCl_3$ with propanenitrile and acrylonitrile affords the dark purple complexes $CrCl_3(nitrile)_3$.[659]

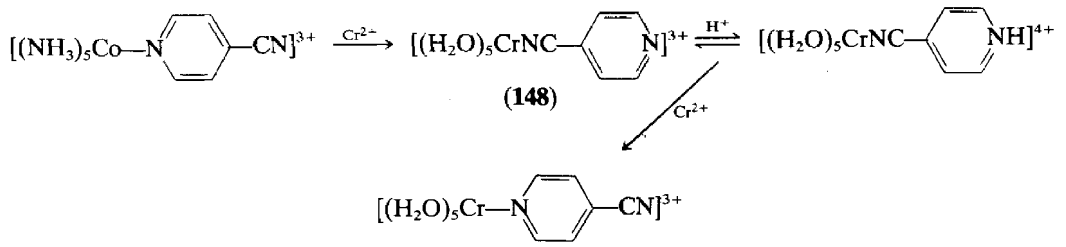
1. B. J. Hathaway and D. G. Holah, *J. Chem. Soc.*, 1965, 537.

The complex $[Cr(MeCN)(H_2O)_5]^{3+}$ may be prepared in solution either by the reaction of iodoethanenitrile and chromium(II) in aqueous acid (equation 40) or by the reduction of $[Co(NH_3)_4(H_2O)_2]^{3+}$ with chromium(II) in 50% aqueous ethanenitrile.[660] The product, which is purified by cation exchange chromatography, undergoes aquation with loss of the nitrile ligand at a rate which is independent of $[H^+]$ and which is some 2×10^3 faster than aquation of the corresponding cobalt(III) complex. Details of the electronic spectrum of $[Cr(MeCN)(H_2O)_5]^{3+}$ are given in Table 73. The reduction of $[Co(NH_3)_5(4\text{-}CNpy)]^{3+}$ by chromium(II) in acid solution occurs by an inner-sphere mechanism, giving the chromium(III) complex (**148**), which undergoes Cr^{2+}-catalyzed linkage isomerization to (**149**; Scheme 90).[661]



$$2[Cr(H_2O)_6]^{2+} + ICH_2CN \longrightarrow \underset{100\%}{[CrI(H_2O)_5]^{2+}} + \underset{25\%}{[CrCH_2CN(H_2O)_5]^{2+}} + \underset{75\%}{[Cr(MeCN)(H_2O)_5]^{3+}} \quad (40)$$

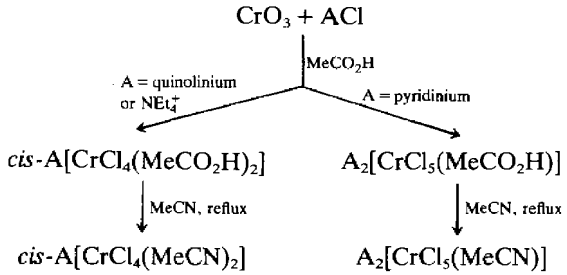
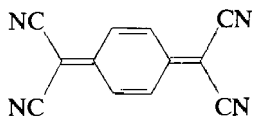
(149)



Scheme 90

The ability of various organic solvents and reagents to reduce tetrachlorooxochromate(V) salts is well known. Hence when a solution of $(bipyH_2)[CrOCl_5]$ (Table 109) in ethanenitrile is refluxed, the colour changes from red-brown to green and crystalline $CrCl_3(bipy)MeCN$ ($\mu_{eff} = 3.83$ BM at 293 K) can be isolated.[662] Some reactions of this complex, the stereochemistry of which could not be established with the available spectroscopic data, are outlined in Scheme 91.



Scheme 91

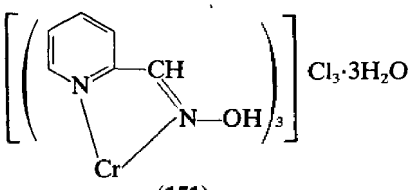
The complexes *cis*-$A[CrCl_4(MeCN)_2]$ and $A_2[CrCl_5(MeCN)]$ (A = quinolinium, NEt_4^+ or pyridinium) have been prepared by heating the corresponding ethanoic acid complexes (rare examples of coordinated $MeCO_2H$) in ethanenitrile (Scheme 92).[663]

Scheme 92

Reaction of tricarbonyltoluenechromium with tetracyanoquinodimethane (TCNQ; **150**) in ethanenitrile gives the dark purple complex $Cr(TCNQ)_2(MeCN)_2$, which contains chromium(III), the radical anion $TCNQ^{\cdot-}$ and $TCNQ^{2-}$.[664] The effective magnetic moment of 4.08 BM at 298 K is close to the predicted value of 4.24 BM for a molecule which contains two magnetic centres, one having three unpaired electrons (metal ion) and the other having one unpaired electron (radical anion).[665] The magnetic moment decreases on lowering the temperature, indicative of antiferromagnetic coupling.

(150)

The complexes $[CrNO(MeCN)_5]X_2$ (X = PF_6, BF_4) and $[CrNS(MeCN)_5](PF_6)_2$, formed by



oxidative nitrosylation of $Cr(CO)_6$ and thionitrosylation of $C_6H_6Cr(CO)_3$ respectively in ethanenitrile solution are, because of the lability of the nitrile ligands, useful starting materials in the synthesis of other $CrNO^{n+}$-containing complexes.[582,603] Reactions of these complexes are dealt with in Section 35.4.2.6.

The colours and spectroscopic properties of a number of ethanenitrilechromium(III) complexes dealt with in this section are listed in Table 73.

35.4.2.11 Oximes, biguanides, guanidines, N-coordinated ureas and amides

(*i*) *Oximes*

Pyridine-2-aldoxime (Hpox) forms complexes $[Cr(Hpox)_3]Cl_3{\cdot}3H_2O$ (**151**), $[Cr(Hpox)_2X_2]ClO_4$ (X = F, Cl, Br) and $[Cr(Hpox)_2(H_2O)_2]Br_3{\cdot}H_2O$ with chromium(III) in which it acts as a bidentate 2-N donor ligand.[666] The first of these may be obtained by simply heating a solution of $[Cr(urea)_6]Cl_3{\cdot}3H_2O$ with an excess of Hpox in ethanol, while the others are conveniently prepared as in Scheme 93. The dihalogeno and diaqua complexes have X-ray powder patterns almost identical to *trans*-$Fe(py)_4(NCS)_2$ and by analogy may be assigned *trans* octahedral configurations. Chromium(III) complexes of 6-methylpyridine-2-aldoxime have also been prepared as in Scheme 93.[667] The positions of bands in the reflectance spectra of some of these aldoxime complexes are given in Table 74. While the spectrum of $[Cr(Hpox)_3]Cl_3{\cdot}3H_2O$ shows bands at 22 300 and 28 820 cm^{-1} corresponding to the $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}(F)$ transitions respectively, in the dihalogeno and diaqua complexes each of these bands is resolved into two components because of splitting of the $^4T_{2g}$ and $^4T_{1g}$ terms in the fields of lower symmetry. The IR spectra of the complexes show bands at *ca.* 3250, 1660 and 1074 cm^{-1} which are assigned to ν_{OH}, ν_{CN}(acyclic) and ν_{NO}, respectively. The effective magnetic moments of the complexes agree well with the theoretical spin-only value of 3.87 BM and are temperature invariant.

The addition of β-furfuraldoxime (Hfox) to a solution of $CrCl_3 \cdot 6H_2O$ in absolute ethanol affords, after refluxing and removal of solvent, a green crystalline product $Cr(Hfox)_3Cl_3$ (μ_{eff} at 297 K = 3.94 BM) which contains monodentate *O*(furan)-bonded Hfox ligands.[668] Stability constants as a function of ionic strength and temperature have been determined for the 1:1, 2:1 and 3:1 complexes between β-furfuraldoxime and chromium(III) in a dioxane–water (75:25) solvent system.[669] The ligand 4-benzoyloxime-3-methyl-1-phenyl-2-pyrazolin-5-one, HL, forms a complex CrL_3 in which it appears, on the basis of evidence from IR spectroscopy, to be coordinated to the chromium through the oxime nitrogen and the oxygen of its enolate tautomer (**152**).[670] Phenanthroquinone monoxime (Hpqox) reacts with $CrCl_3 \cdot 6H_2O$ in aqueous ethanol to give a red-brown complex of composition $Cr(pqox)_2(OH)H_2O$.[671]

(**152**)

(ii) Biguanide and tetramethylguanidine

Biguanide $NH_2C(=NH)NHC(=NH)NH_2$ (bgH) and its derivatives (R—bgH) form two types of complexes with chromium(III): those which contain deprotonated ligands and are uncharged, *e.g.* $Cr(bg)_3$, $Cr(R—bg)_3$ and those which contain the parent ligands and give charged species such as $[Cr(bgH)_3]^{3+}$ and $[Cr(bgH)(H_2O)(OH)]^{2+}$. The complex $Cr(bg)_3 \cdot H_2O$ (**153**) prepared from $KCr(SO_4)_2 \cdot 12H_2O$ and biguanide under alkaline conditions, contains an octahedral arrangement of bidentate biguanidato ligands around the metal.[672] Each of the deprotonated ligands contains a delocalized π electron system and the rings are planar. The structure of $(-)_D$-$[Cr(bgH)_3]^{3+}$ as its (+)-10-camphorsulfonate salt has also been determined by X-ray analysis and although the molecular geometry has not been reported it appears that the complex conforms closely to D_3 symmetry and that the chelate rings are planar.[673]

(**153**)

Other reported biguanide complexes of chromium(III) include $[Cr(RbgH)_3]X_3$ ($R = N'$-$C_6H_{13}^n$, $X = OH$; $R = N'$-Ph, $X = OH$, Cl, Br, I, NO_3, $0.5SO_4$, $0.5CrO_4$; $R = N'$-$PhCH_2$, $X = Cl$, $0.5SO_4$) and $Cr(R'bg)_3$ ($R' = N'$-Ph; N'-$PhCH_2$).[674] Generally the neutral complexes are red whereas the salts are orange or yellow. The kinetics of hydrolysis of $[Cr(bgH)_3](ClO_4)_3$, $[Cr(bgH)_2(H_2O)_2](ClO_4)_3$ and the corresponding substituted biguanide (RbgH) complexes have been investigated.[675] Under acid conditions a first-order dependence of rate on $[H^+]$ was observed and rationalized in terms of rapid preequilibrium formation of a conjugate acid of the reacting complex, with the central nitrogen atom acting as the basic site, followed by its dissociation in the rate-determining step. Consistent with this mechanism is the observation that the reactivity order towards acid hydrolysis correlates with the order of ligand basicity, *i.e.* bgH > N'-$C_6H_{13}^n$bgH > N'-PhbgH. Replacement of the aqua ligands in *cis*-$[Cr(bgH)_2(H_2O)_2]^{3+}$ by phen, bipy[676] and $C_2O_4^{2-}$ [677] in aqueous solution proceeds by a pathway which is first order in ligand concentration but with values of $\Delta H^{\neq}$ which are similar for all three incoming groups. A mechanism involving outer-sphere association of reactants followed by transformation of outer-sphere complexes into products by a dissociative pathway has been proposed for these reactions. The products have been isolated as the perchlorate salts $[Cr(bgH)_2L](ClO_4)_n$ (L = phen, bipy, $n = 3$; $L = C_2O_4$, $n = 1$) and characterized. Some chromium(III) complexes with dibiguanide ligands which contain ethylene, hexamethylene or phenylene bridges linking two biguanide residues have also been reported.[674]

When an aqueous paste containing $Cr(bg)_3 \cdot H_2O$ and NH_4SCN is heated at 80 °C until evolution of ammonia ceases, the red crystalline complex $[Cr(bgH)_2(NCS)_2]NCS$ is obtained.[678] While evidence from IR spectroscopy ($\nu_{CN} = 2095\ cm^{-1}$, $\nu_{CS} = 770\ cm^{-1}$, $\delta_{NCS} = 490\ cm^{-1}$) supports the presence of *N*-thiocyanato ligands, no information regarding the geometrical configuration of the complex can be deduced from its IR and electronic spectra. By comparing the positions of the $^4A_{2g} \rightarrow {}^4T_{2g}$ bands in the electronic spectra of appropriate complexes (Table 75) it may be inferred that biguanide is slightly higher in the spectrochemical series than either the *N*-thiocyanato or biguanidato ligands.

Table 75 Electronic Spectra and Magnetic Moments of Chromium(III) Biguanide Complexes

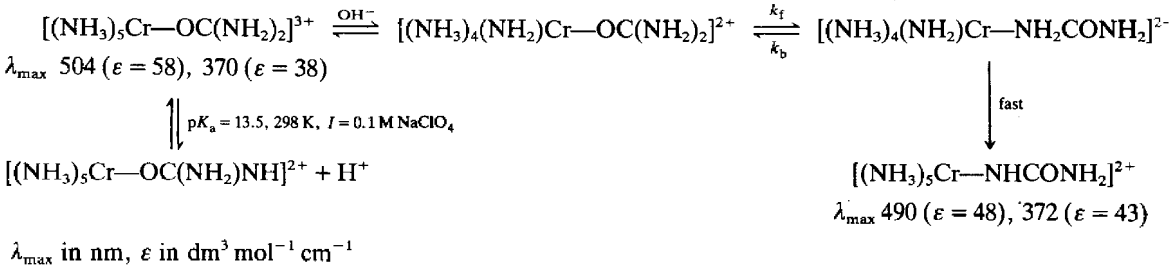
Complexes of chromium(III) with tetramethylguanidine, $HN = C(NMe_2)_2$, have been prepared according to Scheme 94 and although they have not been fully characterized because of the presence of free ligand impurities, the appearance of C=N stretching bands at lower wavenumbers in the IR spectra of the complexes suggest that the ligand is coordinated to the metal through the imine nitrogen.[679]

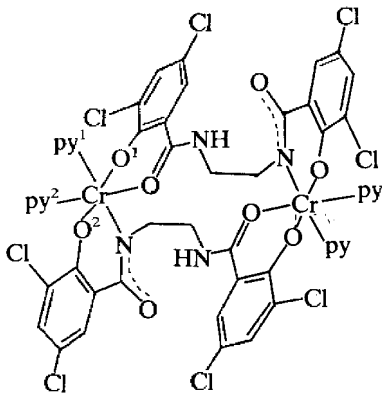


$$CrCl_3 + HN{=}C(NMe_2)_2 \xrightarrow[\text{acetone}]{\text{Zn dust}} CrCl_3 \cdot 4HN{=}C(NMe_2)_2 \xrightarrow[120\,^\circ C]{\text{excess } HN{=}C(NMe_2)_2} CrCl_3 \cdot 6HN{=}C(NMe_2)_2$$

$\nu(C{=}N) = 1609\ cm^{-1}$ — green, $\nu(C{=}N) = 1563\ cm^{-1}$ — grey-green, $\nu(C{=}N) = 1562\ cm^{-1}$

Scheme 94

(iii) N-coordinated ureas and amides



In most of the known urea complexes of chromium(III) the ligand is O-bonded to the metal ion.[679] However the complexes $[Cr(NH_3)_5\{OC(NH_2)_2\}]^{3+}$ and $[Cr(NH_3)_5\{OC(NHMe)_2\}]^{3+}$, both of which can be prepared in high yield by appropriate substitution of the labile triflate ligand in $[Cr(NH_3)_5(OSO_2CF_3)]^{2+}$, undergo isomerization without competitive hydrolysis in basic solution to give deprotonated N-bonded urea complexes (Scheme 95).[680] Reacidification of the product solutions regenerates the O-bonded isomers rapidly and quantitatively. The IR spectrum of the O-bonded urea complex possesses characteristic absorptions at 1570 and 1640 cm^{-1} both of which are absent from the spectrum of the deprotonated N-bonded form. A similar change from O-bonded to deprotonated N-bonded formamide occurs when a solution of $[Cr(NH_3)_5(OCHNH_2)]^{3+}$ is made basic.

λ_{max} in nm, ε in $dm^3\,mol^{-1}\,cm^{-1}$

Scheme 95

Addition of amide (**122**, H_4L) and Na_2CO_3 to a boiling solution of $CrCl_3{\cdot}6H_2O$ in pyridine results in formation of the complex $[Cr(HL)py_2]_2{\cdot}2py$ (**154**), which contains chromium(III) coordinated to the amide oxygen and deprotonated amide nitrogen of different molecules.[519] This is the first reported example of chromium(III) coordinated to a nitrogen of a deprotonated amide. The structure consists of discrete dimers and disordered solvent molecules of pyridine.

(**154**)

Cr—N_{py^1} = 2.145 Å
Cr—N_{py^2} = 2.097 Å
Cr—O^1 = 1.931 Å
Cr—O^2 = 1.915 Å
Cr—O_{amide} = 1.976 Å
Cr—N_{amide} = 2.030 Å

35.4.3 Phosphorus, Arsenic and Antimony Ligands

Complexes of hard Cr^{III} with ligands containing soft P and As donor atoms have not been easy to prepare. It has usually been necessary to use weak donor solvents in the absence of oxygen and moisture, although some hydrates have been obtained by admitting traces of moisture. Structures have generally been inferred from conductance and molecular weight measurements, and IR and electronic spectra. The Cr^{III} is invariably six-coordinate with magnetic moments close to 3.9 BM.

Complexes of a few monodentate tertiary phosphines are known. There are dimers $[CrX_3(PR_3)_2]_2$ (X = Cl, R = Et, Bu^n; X = Br, R = Et),[681,682] polymers $[CrCl_3(PR_3)]_n$ (R = Et, Bu^n, Ph) and anionic complexes $[PPh_4][CrCl_4(PR_3)_2]$[682] (Table 76). The tris(phosphine) complexes $CrCl_3(PHEt_2)_3$ and $CrCl_3(PH_2Ph)_3$ have also been reported,[683] but a number of

organophosphines would not react with chromium(III) halides.[681–683] From $K_3[Cr(SCN)_6]$, several salts $[R_3PH][Cr(SCN)_4(PR_3)_2]$ have been obtained (see also Section 35.4.2.8.i.b).[684] Monodentate phosphines with $[Cr(THF)_6]^{3+}$ solutions (see below) produce green oils.[685]

Earlier work with ditertiary arsines and phosphines produced the compounds: $CrX_3[o\text{-}C_6H_4(AsMe_2)_2]_{1.5}$, $[CrX_2\{o\text{-}C_6H_4(AsMe_2)_2\}_2]ClO_4$ (X = Cl, Br, I), $[CrX_3(H_2O)\{o\text{-}C_6H_4(AsMe_2)_2\}]$ (X = Cl, Br),[686] $[CrX_3\{o\text{-}C_6H_4(AsMe_2)_2\}]_2$ (X = Br, I), $[CrI_2\{o\text{-}C_6H_4(AsMe_2)_2\}_2]I_3$,[687] $CrX_3(Ph_2PCH_2CH_2PPh_2)_{1.5}\cdot nH_2O$ (X = Cl, Br, $n = 2$; X = I, $n = 4$; X = NCS, $n = 0$) and $[CrX_2\{o\text{-}C_6H_4)(PMe_2)_2\}_2]ClO_4$ (X = Cl, Br).[689] Complexes of multidentate tertiary phosphines and arsines were also obtained: $[CrX_3\{P(o\text{-}C_6H_4PPh_2)_3\}]$ (X = Cl, Br), $[CrI_2\{P(o\text{-}C_6H_4PPh_2)_3\}]I_3$,[690] $CrX_3\{PPh(o\text{-}C_6H_4PPh_2)_2\}$ (X = Cl, Br, NCS),[691] $CrX_3\{AsMe(o\text{-}C_6H_4AsMe_2)_2\}$ (X = Cl, Br, I)[692,693] and $CrCl_3\{CMe(CH_2AsMe_2)_3\}$.[693]

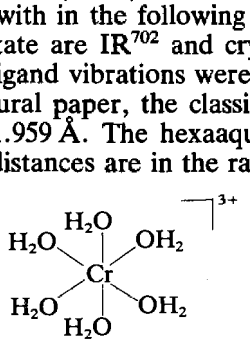
The above complexes were generally prepared from poorly soluble chromium(III) chloride, or $[CrCl_3(THF)_3]$ *in situ* in THF, although a few were obtained by oxidation of phosphine– or arsine–chromium carbonyls[687,690,692] with halogens. By using $[CrX_3(THF)_3]$ (X = Cl, Br or I) in dry CH_2Cl_2 [694] instead of THF, competition for the hard Cr^{III} by an O donor solvent has been avoided, and extensive series[685,695,696] of complexes of multidentate P, As and S (see p. 886) donor ligands have been obtained (Table 76). The pseudooctahedral structure of $[CrCl_4(cis\text{-}Ph_2PCHCHPPh_2)]^-$ has been confirmed crystallographically.[695] The diphosphine does not exert any *trans* influence, consistent with weak bonding to the hard Cr^{III} ion, which is also evident from the electronic spectral parameters of the complexes generally. It has been confirmed that the complexes typified by $CrCl_3[o\text{-}C_6H_4(AsMe_2)_2]_{1.5}$ have the *trans*-$[CrX_2(L^2)_2]$*cis*-$[CrX_4(L^2)]$ structure favoured earlier,[686] but for $CrX_3(Me_2As(CH_2)_3AsMe_2)_{1.5}$ a ligand-bridged structure $[X_3(L^2)Cr(L^2)Cr(L^2)X_3]$ has been put forward because the *ν*(Cr—Cl) absorptions are different from those in $[NPr^n_4][CrCl_4\{Me_2As(CH_2)_3AsMe_2\}]$ (Table 76). Repeat preparations of $CrX_3(Ph_2P(CH_2)_2PPh_2)_{1.5}\cdot nH_2O$, for which similar diphosphine-bridged structures were proposed,[688] failed. The weaker donors $Ph_2PCH_2CH_2PPh_2$, *cis*-$Ph_2PCHCHPPh_2$ or $Ph_2AsCH_2CH_2AsPh_2$ produce complexes $[CrX_3(L^2)_2]$, which are believed to be meridional, containing one uni- and one bi-dentate diphosphine and diarsine, and give $[CrX_3(H_2O)(L^2)]$ in the presence of moisture.

It remains necessary to generate *in situ* solutions[685] presumed to contain $[CrF_3(THF)_3]$ and $[Cr(THF)_6][BF_4]_3$ for the preparation[696] of the fluoro complexes CrF_3L (Table 76), and

the salts $[Cr(L^2)_3][BF_4]_3$[695] ($L^2 = Ph_2PCH_2CH_2PPh_2$, $Me_2PCH_2CH_2PMe_2$, o-$C_6H_4(PMe_2)_2$, o-$C_6H_4(AsMe_2)_2$ or cis-$Ph_2AsCH{=}CHAsPh_2$) and $[Cr(L^3)_2][BF_4]_3$ ($L^3 = PhP(CH_2CH_2PPh_2)_2$, $MeAs(CH_2CH_2CH_2AsMe_2)_2$, $MeC(CH_2PPh_2)_3$ or $MeC(CH_2AsMe_2)_3$) because attempts to isolate solid starting materials caused decomposition. Of these octahedral complexes,[695] only $[Cr(Me_2PCH_2CH_2PMe_2)_3][BF_4]_3$ undergoes reversible electrochemical one-electron reduction in DMSO (as does $[CrX_2\{o\text{-}C_6H_4(PMe_2)_2\}_2]ClO_4$ in MeCN[689]) and reactions with LiX lead to partial displacement of the neutral ligands to give, for example $[CrCl_3\{PhP(CH_2CH_2PPh_2)_2\}_2]$. An attempt[686] to prepare $[Cr\{o\text{-}C_6H_4(AsMe_2)_2\}_3][ClO_4]_3$ from $[Cr(H_2O)_6][ClO_4]_3$ failed.

In the neutral complexes $CrX_3(L^3$ or $L^4)$ (X = Cl or Br) those P or As ligands which are potentially quadridentate act as tridentates.[696] An X-ray study has established that $[CrCl_3\{P(CH_2CH_2PPh_2)_3\}]$ has a *mer* arrangement of the P_3Cl_3 donor set with one PPh_2 group not bonded. This phosphine is usually quadridentate in complexes of other metal ions. Structures have been assigned to the other complexes from the number of ν(Cr—Cl) vibrations. Tripodal tridentates, *e.g.* $CMe(CH_2PPh_2)_3$, constrain monomeric complexes to form *fac* isomers and this provides a further check on the IR data. No 2:1, L^3 or L^4 to Cr complexes were obtained when X = Cl or Br.

The reaction of $[CrI_3(THF)_3]$ with multidentate ligands in a 1:1 ratio gave[696] the complexes CrI_3L [L = $PPh(CH_2CH_2PPh_2)_2$, $P(CH_2CH_2PPh_2)_3$, $CMe(CH_2AsMe_2)_3$, $AsMe(CH_2CH_2CH_2AsMe_2)_2$ or $As(CH_2CH_2CH_2AsMe_2)_3$]. Few physical data are available, but CrI_3L are considered analogous to the corresponding chlorides and bromides. Reaction of $[CrI_3(THF)_3]$ in a 1:2 molar ratio gave two complexes of the type CrI_2L_3; with L = $PPh(CH_2CH_2PPh_2)_2$ the complex is formulated as $[Cr\{PPh(CH_2CH_2PPh_2)_3\}]I_3$ and with L = $CMe(CH_2AsMe_2)_3$ as $[CrI_2\{CMe(CH_2AsMe_2)_3\}_2]I$, the arsine being bidentate.



Treatment of the corresponding halide in CH_2Cl_2 with $AgBF_4$ gave the complexes $[CrX_2L][BF_4]$ (Table 76). The two ν(Cr—X) stretches are consistent with *cis* cations and tetradentate L.

The Cr—P bonds in $[NPr^n_4][CrCl_4(cis\text{-}Ph_2PCHCHPPh_2)]$ and *mer*-$[CrCl_3\{P(CH_2CH_2PPh_2)_3\}]$[696] are long (Table 76) and this is attributed to steric repulsions and the weak binding of the neutral phosphine ligands to the hard Cr^{III} ion. The Cr—Cl bonds are normal.[695] Analysis of the electronic spectra[682,685,688,689,693,695–697] is consistent with octahedral Cr^{III}, and the derived Racah parameters are always much lowered from the free ion value; this also is attributed to weak binding of the soft ligands. An alternative assignment[697] has been proposed[695] for $[CrX_2\{o\text{-}C_6H_4(AsMe_2)_2\}_2]^+$ which places the diarsine lower in the spectrochemical series.

35.4.4 Oxygen Ligands

35.4.4.1 Aqua complexes

The hexaaquachromium(III) ion (**155**) is a regular octahedron and is found in aqueous solution and in many hydrated salts.[698,699,700,701] Typical examples are the violet hydrate $[Cr(H_2O)_6]Cl_3$ and the chrome alums, $MCr(SO_4)_2{\cdot}12H_2O$. The acidity of the aqua complex is marked; the first hydrolysis has $pK_a \approx 4.0$ (25 °C). Further hydrolytic equilibria are complicated by polymerization and are dealt with in the following section. The most recent detailed reports on $[Cr(H_2O)_6]^{3+}$ in the solid state are IR[702] and crystallographic studies[699] of cesium alum. In the vibrational study, metal–ligand vibrations were assigned at 555 cm^{-1} (ν_{as} stretch) and 329 cm^{-1} (ν_{as} bend). In the structural paper, the classification of alums is discussed; the Cr—O bond length was found to be 1.959 Å. The hexaaqua ion is also found in crystals of $Cr_4H_2(SO_4)_7{\cdot}24H_2O$; the Cr—O bond distances are in the range 1.915–1.991 Å.[703]

(155)

The rate of exchange of H_2O at $[Cr(H_2O)_6]^{3+}$ is given as rate = $k[Cr(H_2O)_6]^{3+}$; this reaction has been extensively studied.[704] The most reliable results are summarized in Table 77. The

substantial and negative value of $\Delta V^{\ddagger}$ together with $\Delta S^{\ddagger}$ near to zero suggests an I_a mechanism for exchange.

Table 77 Kinetic Data for Water Exchange at Chromium(III)

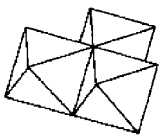
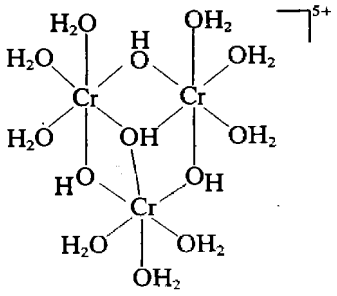
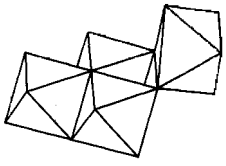
35.4.4.2 Polymeric hydroxy complexes



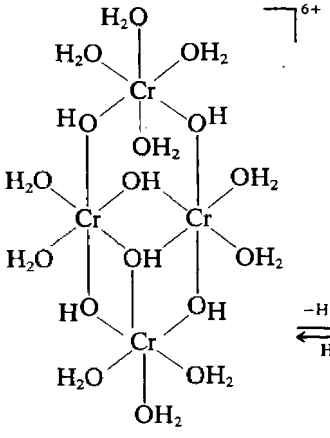
The existence of such complexes was first postulated by Bjerrum in 1908.[705] There have been a number of studies in recent years. Several early members of the series of hydrolytic polymers formed on the addition of base to aqueous chromium(III) solutions have been isolated;[706] purification was achieved by ion-exchange chromatography on Sephadex-SP C25 resin. The structures suggested for these complexes are illustrated (**156–162**). The structural unit (**162**) was held to be singularly important, both as a constituent of higher polymers and in the mechanism of dimerization. Equilibrium data for these complexes are summarized in Table 78.



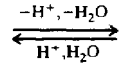
(**156**)



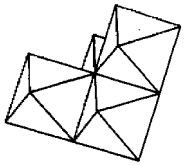
(**156**)



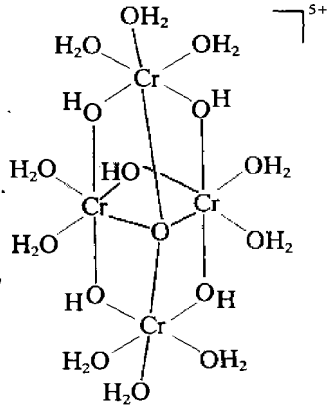
(**157**)



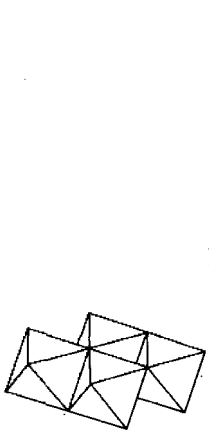
(**157**)



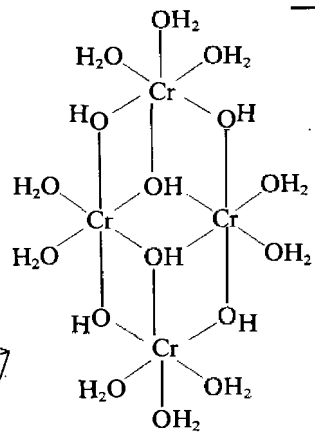
(**158**)



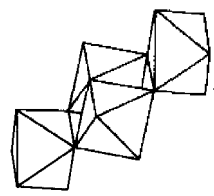
(**158**)



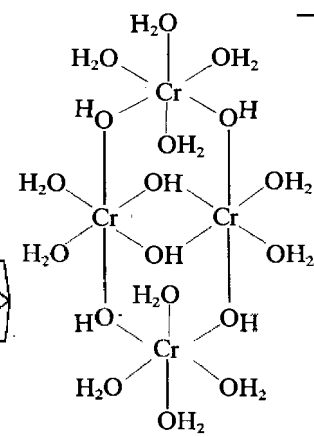
(**159**)



(**159**)



Among the polymeric hydroxy complexes, the dimer has been the most extensively studied species. There is no totally unambiguous crystal structure but the complex is almost certainly as illustrated (**156**). In addition to this doubly bridged dimer a singly bridged $[(H_2O)_5CrOHCr(H_2O)_5]^{5+}$ (**163**) species has been reported.[707] The magnetic properties of both (**156**) and (**163**) have been studied. Coupling in the doubly bridged dimer (**156**) was



(160)

pK_a values	4.29 6.10	3.68 6.04	4.35 5.63 6.01	2.55 5.08

[a] After Marty (ref. 706); charges on complexes omitted, $I = 1.0$ M $NaClO_4$, 25 °C, structures are given in (**155**)–(**159**).

characterized by $-J/k = 7.5°$ and $g = 1.96$, and for the singly bridged species (**163**) by $-J/k = 16°$ and $g = 1.96$. A more favourable bond angle was suggested to explain the stronger coupling in the latter case; direct Cr/Cr interactions were not believed to be important. The dimer (**156**) has also been the subject of an extensive NMR study, in solution, by the inert probe method.[708] Changes in structure at high proton activities were investigated; *p*-dioxane was used as the additive. Magnetic moments were measured, in solution, by the Evans method; values of 3.94 BM and 3.89 BM were obtained for the monomer and dimer respectively. There is obviously no strong spin interaction at ambient temperatures. At high concentrations of perchlorate (>8 M), the complex turns from blue/green to green ($t_{0.5}$ 15 min). Leffler suggested[708] that perchlorate complexation (**164**) causes this change (equation 41) based on the fact that monobridged dimer (**163**) and dimer (**156**) should be distinguishable in NMR line broadening experiments.

(163)

(156) (164)

(41)

A trimeric complex has also been the subject of a detailed study.[709] The mole ratio [Cr]:[OH] was found to be 4:3; the degree of polymerization was assessed, by freezing point depression, to be three. A triangular structure, as shown in (**157**), was suggested on the basis of magnetic studies.

The closely related oxo-bridged complex $[(H_2O)_5CrOCr(H_2O)_5]^{4+}$ is obtained in low yields on the reduction of 1,4-benzoquinone by aqueous solutions of chromium(II).[710] The sole product of the hydrolysis of this dimer[711] ($HClO_4/LiClO_4$ $I = 1.0$) is hexaaquachromium(III).

35.4.4.3 Oxides and oxide hydroxides

The oxide systems deriving from chromium(III) are numerous. Chromium(III) oxide, Cr_2O_3, is the final product of the calcination of many chromium(III) complexes. Chromium(III) oxide has the Al_2O_3 structure (D_5) with hexagonal lattice parameters $a = 4.95$, $c = 13.66$ Å and $c/a = 2.761$.[712]

The oxide is also the product of the spectacular ignition of $(NH_4)_2Cr_2O_7$. The hydrated form of the oxide $Cr_2O_3 \cdot 2H_2O$ is an important pigment,[713] Guignet's green. Chromites formally contain the $Cr_2O_4^{3-}$ ion and are generally prepared by fusing Cr_2O_3 with a binary oxide.[714] They are typical spinels; chromium(III) occupies octahedral sites. The parent spinel, chromite—$FeCr_2O_4$—is the only commercially important chromium mineral. Calcium chromite is not a spinel and exists in two modifications: the β form, which is isomorphous with calcium ferrite, space group P_{nam},[715] and the α form, which is a high-temperature stable modification,[716] prepared by fusing $CaCO_3$ and Cr_2O_3 (1350 °C, 24 h). The spinels formed by chromium are all of the normal type; lattice energy calculations for a large number of such species have recently been reported.[717]

Another important class of oxide-containing solids are the compounds of general formulation CrO_2H, referred to as oxide hydroxides or, occasionally, as chromous acids. The system is polymorphic; a rhombohedral form is obtained by the decomposition of an aqueous solution of Cr_2O_3 (Mallinkrodt analytical reagent) in a high pressure vessel at 300 °C.[718] The material is red/brown and has a layer structure; oxygen atoms are coordinated to chromium(III) in a distorted octahedron. Each octahedron shares six edges with six surrounding coplanar octahedra to form a continuous sheet of close-packed oxygen atoms. The sheets are superimposed, oxygen atoms in one sheet falling directly above those of the sheet below. The structure as a whole is not close-packed; the layers are held together by short H bonds.[719] A second form of CrO_2H has been prepared by the hydrothermal treatment of CrO_2 (derived from CrO_3, 72 h, 450 °C, 40 000 psi); this form is olive green. The compound is orthorhombic and isomorphous with InO_2H, *i.e.* a deformed rutile structure.[720,721] The coprecipitation of γ-$(Al, Cr)O_2H$ and $H(Cr, Al)O_2$ has been investigated.[722]

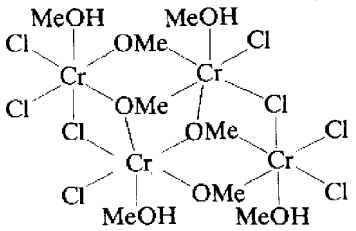
35.4.4.4 Other oxide systems

The novel material $Cr_2Te_4O_{11}$ contains the binuclear ion $[Cr_2O_{10}]^{14-}$, as isolated units, formed by two CrO_6 octahedra sharing an edge.[723] The exchange interaction between the chromium centres has been modelled by the Heisenberg–Dirac–Van Vleck phenomenological model, with the exchange parameter $J_{SASB} = -6$ (± 0.5) cm^{-1}. The substitution into the $M^{III}TeO_6$ system of VO^{2+} has been investigated for a number of metals including chromium(III).[724] The transition between monoclinic and rutile forms can be modelled on the basis of the size of the M^{III} ion. The substitution of chromium(III) into yttrium, iron and gallium garnets has been investigated.[725] In the system $[Y_3][Cr_xFe_{2-x}][Fe_3]O_2$ single-phase specimens were obtained with values of $x = 0.5$. For the gallium system, $x < 0.75$ gave a single phase. Perovskites $A^{III}B^{III}O_3$ involving indium or thallium and chromium(III) have been synthesized.[726] The coupling of the chromium(III) centres in the trirutile compound MCr_2O_6 (M = Te or W) has been investigated.[727] The coupling is dependent on the second metal ion and has been correlated with slight structural variations.

35.4.4.5 Peroxides

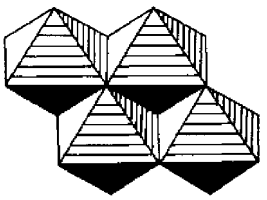
Two green peroxychromium(III) species have been reported.[728] The products of the reaction of H_2O_2 and Cr^{VI} in 2–6 M perchloric acid were purified by ion-exchange chromatography

(Dowex 50W-X2). The compounds were tentatively identified as CrO_2Cr^{4+} and $CrO_2CrO_2Cr^{5+}$ species; their decompositions were not simple processes. Attempts to synthesize these or similar species by the oxidation of chromium(II) with oxygen were unsuccessful. The compound $[(H_2O)_5CrO_2Cr(H_2O)_5]^{4+}$ was also reported earlier.[729]



35.4.4.6 Alcohol and alkoxide complexes

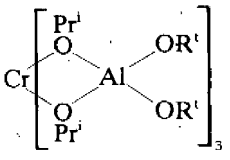
(*i*) *Alcohol complexes*



Alcoholate complexes of the general formula $CrCl_3 \cdot n$ROH (R = Me, Et, Pr^i, Bu^n and *n*-hexyl) have been reported.[730] These purple insoluble complexes were prepared by refluxing $CrCl_3 \cdot 3$THF in the anhydrous alcohol and are typical chromium(III) species. The structure of the related complex *trans*-$[Cr(MeOH)_4Cl_2]Cl$ has been determined.[731] It is similar to that of the related aqua complex and is of approximately C_{4v} symmetry. A detailed study of the complexes formed by ethylene glycol and chromium(III) has been reported;[732] both monodentate and bidentate coordination of chromium by the glycol was postulated.

(*ii*) *Alkoxide complexes*

Alkoxide complexes including those of chromium(III) have been extensively and excellently reviewed.[733,734] Methoxy complexes, $[Cr(OMe)Cl_2]_n \cdot 2n$MeOH and $[Cr(OMe)Cl_2]_n \cdot n$MeOH, have been thoroughly studied.[735] The former is prepared by the reaction of anhydrous $CrCl_3$ with methanol, the latter by heating the former at 100 °C for several hours. Adducts of the dimethanoates can be prepared with acetone, acrylonitrile and dioxane. These compounds are unusual among alkoxides in showing marked solubility: the acetone adduct appears to be a dimer in both solution and the solid state. A tetrameric structure was suggested for the monomethanoate (**165**).

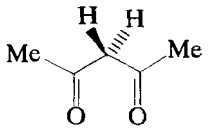


(**165**)

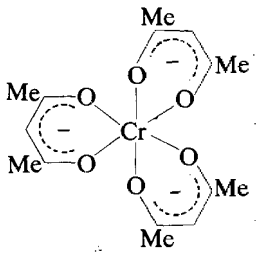
(**165**)

The physical properties of samples of $Cr(OMe)_3$ prepared by a variety of methods have been investigated.[736] Good crystals could not be obtained but limited crystallography suggested a layered lattice with chromium occupying octahedral sites. A useful summary of earlier preparations and attempted preparations of chromium methoxides can be found in this paper.

The insertion of various isocyanates into chromium(III) alkoxide M—O bonds has been reported.[737] The complexes are prepared by refluxing the isocyanates with a suspension of the alkoxide in benzene. No structural data were given for the products. Unusual bimetallic alkoxides have recently been prepared[738] by the reaction of $Cr[Al(OPr^i)_4]_3$ with alcohols and acetylacetone (**166**). A wide range of spectroscopic methods were used to study them. In general, the results were in accord with a monomeric formulation similar to (**166**) below; $Cr[Al(OMe)_4]_3$ was grossly insoluble; the small size of the methyl groups may permit extensive polymerization.

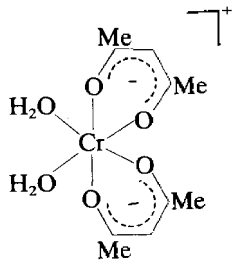


(**166**)



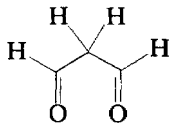
35.4.4.7 β-Ketoenolates and related ligands

(i) Synthesis



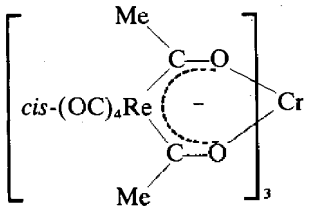
The tris and bis complexes of acetylacetone (2,4-pentanedione) (**167**) with chromium(III) have been known for many years (**168**, **169**).[739] The tris compound is generally prepared by the reaction of an aqueous suspension of anhydrous chromium(III) chloride with acetylacetone, in the presence of urea.[740] Recently a novel, efficient synthesis of tris(acetylacetonato)chromium-(III) from CrO_3 in acetylacetone has been reported.[741] The crystal structure of the tris complex has been determined.[742] A large anisotropic motion was observed for one of the chelate rings, attributed to thermal motion, rather than a slight disorder in the molecular packing.

(**167**)



(**168**)

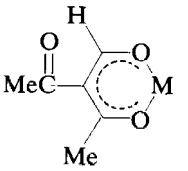
(**169**)



Derivatives of, or ligands closely related to, acetylacetonate have been extensively studied. Compounds of analogous structure are, in general, obtained. Ligands studied include 1-phenylbutane-1,3-dione, 1,1,1-trifluoropentane-2,4-dione, 1,1,1,5,5,5-hexafluoropentane-2,4-dione, 2,2,6,6-tetramethylheptane-3,5-dione and 1-phenyl-5,5-dimethylhexane-2,4-dione.[743] Preparations include the original one detailed above[740] and methods from chromium(III) acetate and metallic chromium.[744] The earlier work and advantages of the various methods are summarized by Dilli and Robards,[743] who noted, particularly with derivatives of acetylacetone, that in the classic method,[740] reaction of the free ligand with urea may markedly reduce the yield.

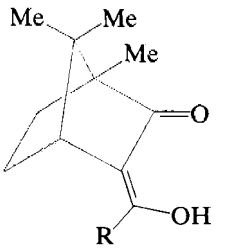
The closely related tris complex of malonaldehyde (**170**) has been synthesized by the reaction of 1,1,3,3-tetramethoxypropane with anhydrous $CrCl_3$ in an ether slurry.[745] The complex was purified by sublimation and contains the simplest structural unit capable of enolizing to form a β-ketoenolate chelate.

(**170**)



Several unusual complexes containing neutral acetylacetonate have been reported.[746] The complex $[CrBr_2(acac)(acacH)]$ was obtained from the reaction of HBr with $[Cr(acac)_3]$; $[CrCl_2(acac)(acacH)]$ was obtained from the reaction of $CrCl_3(THF)_3$ with acetylacetonate. Other unusual β-diketonates include the tris(rhenaacetonates) (**171**).[747,748] Two different forms of the tris complex of 2-nitroacetophenone with chromium(III) have been reported;[749] these are probably geometric isomers.

(**171**)



Complexes containing two different ligands of the β-diketonate type have also been

prepared[750] including the series $[Cr(CF_3COCHCOMe)_n(MeCOCHCOMe)_{3-n}]$ ($n = 1$ or 2); *cis* and *trans* isomers were isolated. The linkage isomerization and disproportionation of the unsymmetrically substituted acetylacetonate complex (**172**) have been studied[751] and were said to be intermolecular.

(**172**)

Camphorate complexes of chromium(III) have been studied. The four possible isomers of the tris complex of (+)-3-acetylcamphorate (**173**) were isolated,[752,753] and absolute configurations were tentatively assigned. The photoisomerization of these complexes has been investigated;[754] quantum yields of the order of 10^{-3} were obtained with visible or ultraviolet radiation at temperatures around 100 °C. Bond-breaking processes were held to be important in the reactivity of *cis* isomers.

(**173**) R = H or Me

Dimeric complexes of bis(acetylacetonates) have also been reported: di-μ-diphenylphosphinatoacetylacetonatochromium(III) prepared by the reaction of diphenylphosphinic acid with an excess of $[Cr(acac)_3]$ has been investigated.[755] It crystallizes in the triclinic space group $P\bar{1}$, the bridge $(CrOPOCr)_2$ forming a puckered eight-membered ring. The crystal structure of the alkoxy-bridged complex bis(μ-methoxy)bis[bis(2,4-pentanedionato)chromium(III)] has been determined; it crystallizes in a racemic rather than *meso* form.[756] Other alkoxy-bridged complexes have also been synthesized.[757]

(*ii*) *Physical studies*

Acetylacetonates have occupied a central position in the study of complexes by physical methods. Some of this work is summarized in Table 79.

Table 79 Some Physical Properties of $[Cr(acac)_3]$

(*a*) *Vapour phase chemistry.* A remarkable feature of the chemistry of the complexes of the tris(acetylacetonate) type is their extreme stability in the vapour phase: there are hence many mass spectral and gas chromatographic studies of them. Much of this emanates from the group of Sievers. The complexes of hexafluoroacetylacetonate are considerably more volatile than those of the parent acetylacetonate. The partial resolution of tris(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)chromium(III) by gas chromatography on pulverised d-quartz has been reported.[758,759] The *cis* and *trans* isomers of the tris(trifluoroacetylacetonate) complexes of chromium(III) can be separated efficiently by gas chromatography (5% silicone grease on Chromasorb-W, 115 °C).[759] To provide better understanding of such studies, vapour pressure measurements have been made on a number of metal β-diketonates.[760] Earlier related measurements are reviewed in this paper. In typical gas chromatographic phases (Apiezon-L, QF1) the results of the above study indicated that the solution behaviour of these tris octahedral complexes is determined solely by non-specific van der Waals type forces; there was no evidence for a direct interaction such as H bonding.

A rate and equilibrium study of the *cis*/*trans* isomerization of tris(1,1,1-trifluoro-2,4-pentanedionato)chromium(III) in the vapour phase has been reported.[761] The equilibrium constant 3.56 was independent of temperature in the range 118–144.8 °C, the same value being measured by both static and kinetic methods. The activation energies for isomerization were both less than 115 kJ mol^{-1}; the Cr—O bond energy is 210 kJ mol^{-1}. On these grounds, a bond-rupture mechanism was rejected. A similar mechanism may operate for the isomerization in solution.

The mass spectra of various β-diketonates have been extensively studied.[762,763] The availability of ionization energies, measured by mass spectra, has led to a fairly detailed debate as to the nature of the orbital from which the first electron ionizes.[764] Gas phase rearrangements,[765] often involving fluorine migration to the metal, have been observed. The SIMS spectrum of [Cr(acac)$_3$] is particularly simple,[766] yielding the base peak [Cr(acac)$_2$]$^+$.

The structure of tris(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)chromium(III) has been determined by gas-phase electron diffraction.[767] A most interesting feature of this study was that the normalized ligand bite angle [(O—O/M—O) 30.1°] was very close to the value found in the solid state by X-ray diffraction (30.8°) but quite different to the value predicted by Kepert's model.[768] The results of this and related work on vapour phase structures are summarized in Table 80.

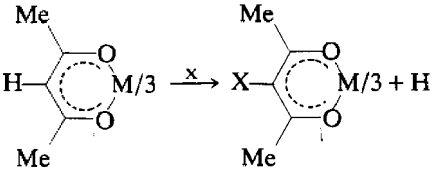
(*b*) *Optical activity.* As tris β-diketonates are neutral D_3 complexes, resolution by the more-popular, less-soluble diastereoisomer and ion-exchange methods is not possible. Various methods have been reported. Potentially most useful are: a stereospecific synthesis from an unisolated (+)-tartrate complex of chromium(III),[769] chiral chromatography using (2*R*,3*R*)-(−)-dibenzoyltartaric acid[770] and chromatography on an L-nickel(II)tris(1,10-phenanthroline)/montmorillonite column.[771] Other methods of resolving [Cr(acac)$_3$] are extensively reviewed in these papers.

The crystal structure and absolute configuration of L-(−)-[Cr(acac)$_3$] has been reported.[772] The circular dichroism of D-[Cr(acac)$_3$] has been studied in the solid state and in solution.[773] The rotational strengths of the *d*–*d* transitions are extensively discussed; competing rather than reinforcing effects lead to the smaller rotational strengths observed for tris(acetylacetonates) as compared to tris-(ethylenediamine) or -oxalate complexes.



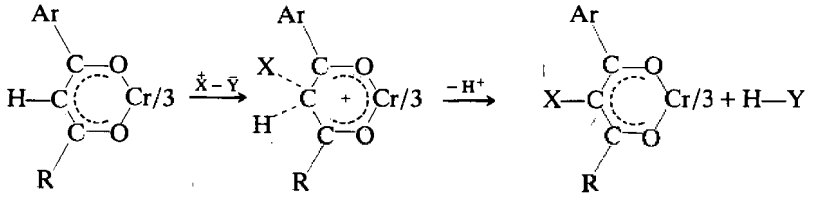
The Cotton effects in mixed amino acidate/acetylacetonate complexes $[Cr(acac)_2L]$ (L = L-alanine, L-valine or L-phenylalanine) have been studied:[774] absolute configurations were assigned by reference to the parent tris(acetylacetonate) complexes. Synthesis was achieved by the photolysis of mixtures of the amino acid and $[Cr(acac)_3]$. The partial photoresolution of both *cis*- and *trans*-(1,1,1-trifluoro-2,4-pentanedionato)chromium has been accomplished by irradiation with circularly polarized light (5461 Å) in chlorobenzene solution.[775] The results indicated that both bond rupture and twist mechanisms were important. A number of other β-diketonates have also been investigated.[776]

(*c*) *NMR.* The complex $[Cr(acac)_3]$ has found use as a spin relaxant in ^{13}C FTNMR spectroscopy.[777] The solution dynamics of $[Cr(acac)_3]$ in methanol, acetonitrile, benzene and DMSO have been studied in some detail.[778] Different models were proposed for solvation by the various solvents. In methanol, the hydroxyl proton is apparently closer to the chromium than the methyl group. An outer-sphere dipolar mechanism of exchange was suggested in DMSO, the oxygen atom of DMSO pointing toward the octahedral face of the $[Cr(acac)_3]$. In benzene a random orientation of the flat and cleft positions, with respect to the solvent, best fits the data. In acetonitrile the results, surprisingly, suggest that the methyl group points toward the complex; weak H bonding may account for this observation. A summary of other spin relaxation studies can be found in this paper.[778]

A detailed understanding of the many factors involved when $[Cr(acac)_3]$ is used as a spin relaxant is required. It has been shown that line widths are affected by the reagent.[779] If temperature dependent features are to be studied, it was concluded that the ratio of relaxant to substrate must be kept as low as possible. Caution in the use of $[Cr(acac)_3]$ as a spin relaxant was also emphasized in a study of cholesterol chloride.[780] Despite the problems with the use of this complex as a spin relaxant, it remains widely used.[779,780]

(*iii*) *Chemical reactivity*

The bromination of tris(acetylacetonato)chromium(III) was first reported by Reihlen.[781] There have been many studies of electrophilic substitution at complexes of both acetylacetonate and its derivatives; this work has been extensively reviewed.[782,783] Some typical reactions are outlined below (equation 42). In this section, we shall briefly mention some more recent work; the interested reader is recommended to study the extensive, although somewhat dated, review by Collman,[782] and Mehrotra's book.[783]



(42)

(174) **(175)**

X = I, Br, Cl, SCN, SAr, SCl, NO_2, CH_2Cl, CH_2NMe, COR, CHO

The electrophilic substitutions of acetylacetonate complexes have been taken as suggesting 'aromatic character' in the chelate ring. Results with seventeen different 1,3-diketonatochromium(III) complexes were recently held to support this suggestion (**176–178**; equation 43).[784] The bromination of tris(1,1,1-trifluoro-2,4-pentanedionato)chromium(III), previously claimed to be unreactive,[785] has been reported.[786]

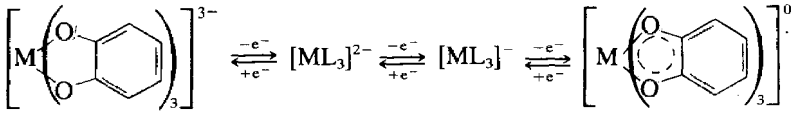
An isolated study of the tris tropolonate complex (**179**) of chromium(III) has appeared;[787] mass spectra were recorded and fragmentation patterns discussed.



(**179**)

35.4.4.8 Catecholates, quinones, tetrahydrofuran and O-bonded urea

The chemistry of the transition metals including chromium(III) with these ligands has been the subject of a recent and extensive review,[788] with references to the early literature. The close relationship between the catechol (**180**), semiquinone (**181**) and quinone (**182**) complexes may be appreciated by considering the redox equation below (equation 44).[789] The formal reduction potentials for the chromium(III) complexes (**183–186**; equation 45) are +0.03, −0.47 and −0.89 V (*vs.* SCE in acetonitrile) respectively.

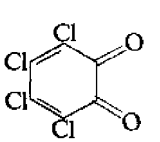
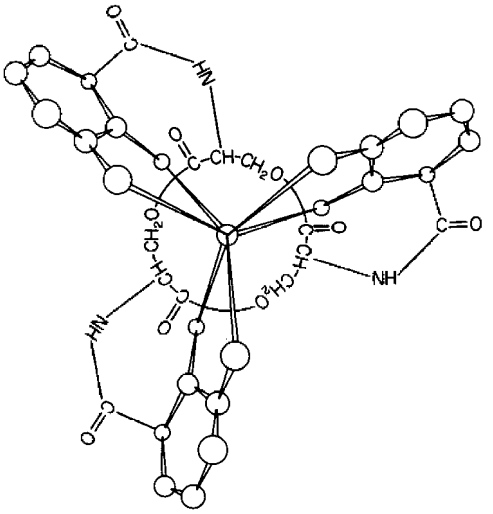
(**183**) (**184**) (**185**) (**186**) (45)



(*i*) o-*Semiquinones*

The preparation of tris(*o*-semiquinone) complexes of chromium(III) has been reported;[790] complexes of formulae $Cr(o\text{-}Cl_4SQ)_3 \cdot 4Ph$ and $Cr(phenSQ)_3$·anisole were prepared (o-Cl_4SQ = tetrachloro-1,2-benzoquinone; **189**). The complexes exhibit temperature-dependent magnetic properties, μ_{eff} 1.1 BM at 286 K dropping to 0.35 BM at 4.2 K. This is the result of intramolecular spin-coupling between chromium(III) and the semiquinone. The complexes were prepared by the reaction of chromium hexacarbonyl with the quinone (equation 46) but are correctly formulated,[790] by comparison with authentic samples, as semiquinones of chromium(III). The above reaction has proved difficult to repeat in the absence of photolysis,[791] and it was hence suggested to be a photochemical, oxidative substitution. In related work, the reaction of Crbipy$(CO)_4$ with a number of quinones was studied.[792] The resulting redox series: $[Cr(SQ)_2(bipy)]^+/[Cr(SQ)(Cat)(bipy)]/[Cr(Cat)_2(bipy)]^-$ was studied; the oxidation state of the chromium remains at three during these reactions.

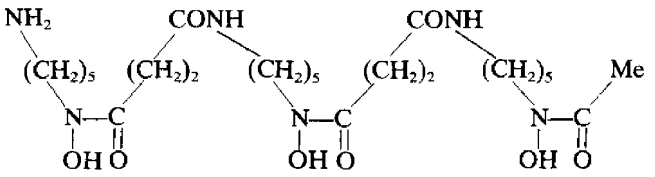
(**187**) (**188**) (46)



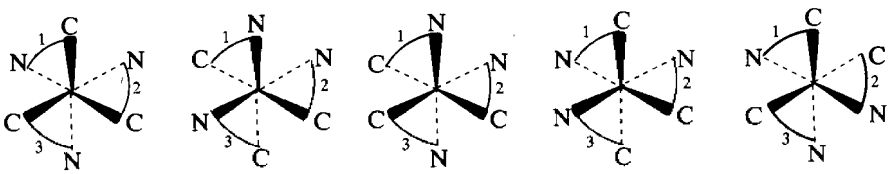
e.g. quinone =

(**189**)

(*ii*) *Catecholates*



The resolution of tris(catecholato)chromate(III) has been achieved by crystallization with L-$[Co(en)_3]^{3+}$; the diastereomeric salt isolated contained the L-$[Cr(cat)_3]^{3-}$ ion.[793] Comparison of the properties of this anion with the chromium(III) enterobactin complex suggested that the natural product stereospecifically forms the L-*cis* complex with chromium(III) (**190**). The tris(catecholate) complex $K_3[Cr(Cat)_3]\cdot 5H_2O$ crystallizes in space group $C2/c$ with $a = 20.796$, $b = 15.847$ and $c = 12.273$ Å and $\beta = 91.84°$; the chelate rings are planar.[794] Electrochemical and spectroscopic studies of this complex have also been undertaken.[795] Recent molecular orbital calculations[796] on quinone complexes are consistent with the ligand-centred redox chemistry generally proposed for these systems.[788]



(**190**) A diagram of the Δ-*cis* chromium(III) enterobactin trianion

(*iii*) *Hydroxamates*

Chromium(III) complexes of a number of polyhydroxamic acids, microbial iron sequestering and transport agents (siderochromes) have been reported.[797,798] The kinetic inertness of the chromium(III) complexes allows the facile separation of isomers; for the model complex tris(*N*-methyl-(−)-methoxyacetylhydroxamato)chromium(III), D-*cis*, L-*cis* and the L/D-*trans* isomers have been separated.[798] The chromium complexes of desferrioxamine B (**191**) have been investigated; the possible isomers are illustrated below (**192–196**). The *cis* isomer was isolated in relatively pure form.[799] Thiohydroxamate[800] and dihydroxamate (rhodotorulic acid) complexes have also been studied.[801]

(**191**)

The five enantiomeric geometrical isomers of ferrioxamine B. The oxygen donor atoms of each hydroxamate group have been omitted for clarity. The Λ optical isomer is shown in each case.

(*iv*) *THF*

The complex $[Cr(THF)_3Cl_3]$ was first prepared in 1958.[802] However pure bromide, iodide and thiocyanate complexes were reported only in 1983.[803] The preparation of $[Cr(THF)_6]^{3+}$ by the reaction of $[Cr(THF)_3Cl_3]$ with $AgBF_4$ in THF was attempted; only an impure brown/pink oil was obtained. The tris complexes are useful starting materials in both organometallic and coordination chemistry.

(*v*) *Urea* (*O-bonded*)

Chromium is unusual in that it forms a stable hexakis O-bonded urea complex. The complex was first prepared as the chloride salt by Pfeiffer[804] and a crystal structure of the complex salt $[Cr\{OC(NH_2)_2\}_6][Cr(CN)_6]\cdot 2DMSO\cdot 2EtOH$ has recently been reported.[805] Coordination at chromium(III) is octahedral; r(Cr—O) is in the range 1.96–1.98 Å. The reduction of the perchlorate salt of this complex to a chromium(II) species has been studied polarographically.[806] Detailed studies of the luminescence spectra of several salts of the chromium urea complex have been reported.[807,808]

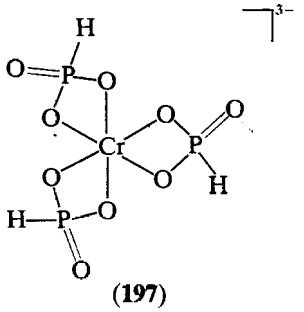
35.4.4.9 Non-C oxo anions

(*i*) *Nitrogen-containing*

Anhydrous chromium(III) nitrate may be prepared by the reaction of dinitrogen pentoxide with chromium carbonyl in dry carbon tetrachloride.[809] The product has rather low thermal stability, is involatile and decomposition begins at 60 °C.

The complex 1,2,3-trinitrotriamminechromium(III) has been prepared and is a nitrito isomer.[810] The nitrito complexes of *cis*- and *trans*-bis(ethylenediamine)chromium(III) have been prepared,[811] *cis*-$[Cr(en)_2(ONO)_2]ClO_4$ and *trans*-$[Cr(en)_2(ONO)_2]X$ ($X = ClO_4^-$ or NO_3^-). The nitrito complexes *cis*- and *trans*-$[Cr(en)_2(ONO)(X)]^+$ ($X = ONO^-$, OH^-, F^-, Cl^-, Br^-) have also been studied.[812]

(*ii*) *Sulfur-containing*



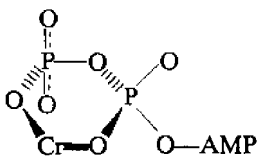
There are old reports of tris sulfate complexes[813,814] and a number of chromium(III) sulfate hydrates are known. In recent years monosulfatopentaaquachromium(III) complexes have been prepared[815] and characterized by IR spectroscopy;[816] sulfate probably behaves as a monodentate ligand. The basic chromium(III) sulfate $Cr(OH)SO_4\cdot H_2O$ crystallizes in the non-centrosymmetric, monoclinic, space group *Cc*.[817] Each chromium atom is coordinated octahedrally by two hydroxo groups, three sulfate O atoms and a water molecule. The metal atoms are joined by single hydroxo bridges forming an infinite chain.

In acidic aqueous solutions the reaction between hexaaquachromium(III) and sulfate has been studied in detail; ion-pairing can be detected in this system.[818] Polymeric species involving μ-hydroxy and μ-sulfato groups have been isolated.[819,820]

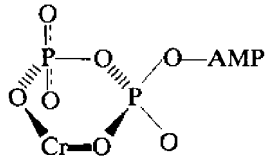
Trifluoromethylsulfate forms weak complexes with chromium(III);[821] this anion may provide a viable alternative to perchlorate as a 'non-coordinating anion' (for $Cr(O_3SCF_3)_3$ see Section 35.7.2). Tris(*O,O'*-sulfinate) complexes of chromium(III) have been prepared (RSO_2^{2-}, R = Me, C_6H_5, p-$CH_3C_6H_4$); typical monomeric complexes are obtained.[822]

(*iii*) *Phosphorus-containing*

(*a*) *Complexes of* H_3PO_3 *and* HPO_2. Ebert prepared a complex which he formulated as $H_3[Cr(HPO_3)_3]^{3-}$ (trisphosphitochromic acid) by refluxing chromium(III) hydroxide with H_3PO_3.[823] The complex was said to be tris-chelated (**197**) and a resolution as the strychninium salt reported.[823,824] It may provide one of the very few examples of molecular optical activity in a non-carbon-containing molecule. Its IR spectrum has been studied in detail.[825] Good analyses, particularly for phosphorus, have not been obtained;[824,825] until such data become available there must be some doubt as to the exact composition of these species. A number of other complexes involving this ligand, including a series of bisphosphites, have been reported.[826,827]

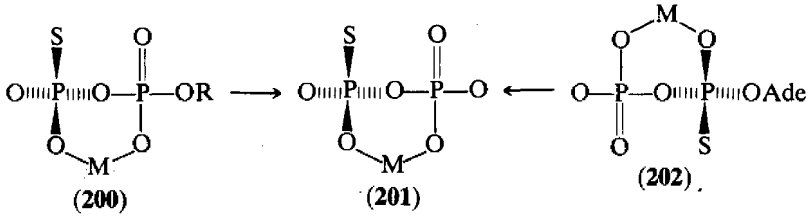


(**197**)



A monophosphite complex has been prepared by the reaction of either chromium(III) perchlorate[828] or chromate[829] with the ligand. The related monohypophosphite complex $[Cr(H_2O)_4H_2PO_2]^{2+}$ has also been reported.[830]

(*b*) *Phosphates.* Although chromium phosphates have been known for years,[831] there are few that are well characterized. A crystalline hexahydrate is the best-characterized species and exists in at least three forms.[832] Simple complexes of phosphate and chromium(III) may be important in the absorption of chromium(III) by biological systems.[833,834] Phosphate derivatives have been studied and simple complexes have been prepared from chromium(III) in combination with: tri-*p*-tolylphosphate,[835] alkoxyalkylphosphate,[836] isopropylphosphate,[837] triethylphosphate[838] and dimethylmethylphosphonate (for $Cr(O_2PF_2)_3$ see Section 35.7.2).[839]



Chromium(III) forms stable complexes with adenosine-5′-triphosphate.[840,841,842] These are kinetically inert analogues of magnesium ATP complexes and may be used to study enzyme systems. The complexes prepared are chiral and may be distinguished in terms of chirality at the metal centre (**198**, **199**).[843] The related complex of chromium(III) with adenosine-5′-(1-thiodiphosphate) has been prepared; the diastereoisomers were separated.[844] The stereospecific synthesis of chromium(III) complexes of thiophosphates has been reported[845] by the method outlined in equation (47), enabling the configuration of the thiophosphoryl centre to be determined. The availability of optically pure substrates will enable the stereospecificity of various enzyme systems to be investigated.[845]

(**199**) Λ-$Cr(H_2O)_4$ATP

(47)

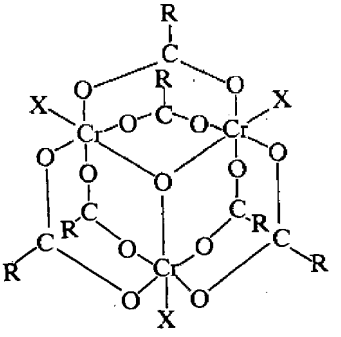
(**200**) (**201**) (**202**)

(*c*) *Phosphinates.* Typical chromium(III) phosphinates are polymeric materials soluble in non-polar solvents (**203**). Poly{di-μ-(diphenylphosphinato)}aquahydroxychromium(III) may be prepared by the aerial oxidation of the chromium(II) precursor.[846] This method leads to a molecular weight of 6000 (number average). Polymers of identical composition may also be prepared from chromium(III) in 1:1 water/THF mixtures.[847,848] Polymers of the general formula $[Cr(H_2O)OH(OPRR'O)_2]n$ (R = R′ = C_6H_5, R = Me, R′ = Ph and R = R′ = C_8H_{17}) were also prepared; on heating to constant weight *in vacuo* these materials are converted to the corresponding hydroxooxo polymers.

(**203**)

Many polymeric chromium(III) complexes in this general class exist. For the general formula $[Cr(L)(OPRR'O)_2]_n$, compounds have been prepared involving hydroxide, perfluorocarboxylate, alkoxide, aryloxide and carboxylates.[849,850]

(*d*) *Miscellaneous.* A perchlorate complex of chromium(III) has been reported; IR evidence was used to suggest bidentate coordination of the anion.[851] Chromium(III) borates have been prepared by solid-state methods;[852] Cr_2O_3 was reacted with molten B_2O_3 at 1100 °C. The solid isolated had the calcite structure. A monomeric complex $[Cr(O_2SeMe)_3]$ has been prepared; the seleninate was a stronger ligand than DMSO but weaker than urea.[853]



35.4.4.10 Carbon-containing oxo anions

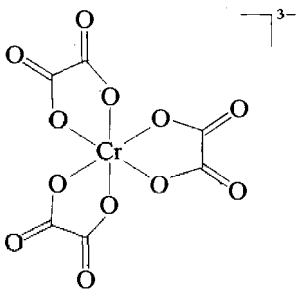
(*i*) *Carboxylates*

Simple carboxylates of chromium(III) find industrial application as catalysts for the polymerization of ω-alkenes[854,855] and in the preparation of chrome-tanning solutions.[856,857] There seems to be no simple carbonate of chromium(III). Compounds formed on the surface of Cr_2O_3, sometimes formulated $Cr_2(CO_3)_3 \cdot nH_2O$, are best viewed as carbon dioxide adsorbed on the oxide.[858] Carboxylate complexes of chromium(III) will now be considered in terms of the various ligand types.

(*ii*) *Acetates and simple carboxylates*

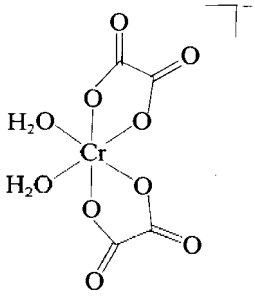
Early investigations[859] showed the product of the reaction between acetic anhydride and chromium(III) chloride to have the composition $[Cr_3(MeCO_2)_6(OH)_2(H_2O)]^+$. Orgel[860] suggested a structure of the kind illustrated below (**204**) for the trimer and crystallography[861] has confirmed this. The three carboxylate-bridged chromium(III) atoms form an equilateral triangle around a shared oxygen atom. The vertex of each chromium(III) octahedron *trans* to the central oxygen atoms is occupied (in the trihydrate) by a water molecule. This is the only ligand in this complex which will readily undergo substitution.

(**204**)



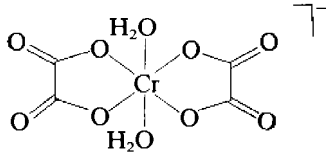
The physical properties of a large number of trimeric acetates of this type have now been investigated. Magnetic coupling between the chromium centres within the trimer occurs, *e.g.* in $[Cr_3O(MeCO_2)_6(H_2O)_3]Cl \cdot H_2O$, $J_0 = 10.5\ cm^{-1}$ and $J_1 = 2.5\ cm^{-1}$.[862] How such results are best interpreted is controversial. Brown and co-workers suggested that inter-trimer coupling is important.[863,864] In contrast, Tsukerblat *et al.* find the majority of results[865] to be interpretable in terms of models which do not invoke inter-trimer interactions. The gross features of the electronic spectrum of trinuclear chromium(III) acetates may be explained[866] in terms of tetragonally distorted chromium(III) centres; fine structure in the 650–750 nm region is the result of exchange coupling. The electronic spectra of a series of acetates $[Cr_3O(MeCO_2)_6R_3]^+$ ($R = H_2O$, NH_3, py, DMSO) have also been successfully explained in terms of ligand field theory.[867] Related complexes of chloroacetic acids have been studied.[868,869]. Mixed valence[870] and mixed metal[871,520] acetates of this type are also known (see also Sections 35.4.2.5.i and 35.7.2). Other simple derivatives of acetate (RCO_2H; R = Me, Et, Pr, CH_2Cl, $CHCl_2$, CCl_3) give trimeric complexes of similar structure.[872]

Simple monomeric acetate complexes have been reported to form in solution from the



reaction of aqua[873] and ammine[874] complexes of chromium(III) with acetate. Chloro carboxylates $CrCl_2(O_2CR)\cdot THF$ and $CrCl(O_2CR)_2$ ($R = C_{17}H_{15}$–$C_{21}H_{43}$) have been prepared in THF. These are dimeric and trimeric respectively, in benzene.[875] Basic trimeric formate complexes of chromium(III) are formed when anhydrous chromium(III) chloride is reacted with HCO_2H.[876]

(*iii*) *Oxalates*



Oxalate complexes of chromium(III) were first characterized at the turn of the century by Rosenheim and Cohen.[877] The most extensively studied are the tris species and the *cis*- and *trans*-bisoxalates (**205–207**): these formulations were first suggested by Werner.[878] All may be made by the reduction of chromate with oxalate. Reliable preparations have been reported for tris by Kauffman and Faoro[879] and for *cis*- and *trans*-diaquabisoxalatochromate(III) by Bailar.[880]

(**205**)

(**206**)

(**207**)

In aqueous solution, the equilibrium between the *cis*- and *trans*-diaqua complexes lies almost completely toward the *cis* isomer[881] ($K \approx 0.17$, pH 3–4). The sparingly soluble potassium salt of the *trans* isomer may, however, be prepared by the slow evaporation of a saturated solution at room temperature,[878,880] and the *cis* isomer by cooling a hot solution or by allowing potassium dichromate and oxalic acid to react in the presence of a minimal quantity of water.[878,879,882] The tris complex was resolved by Werner in 1912,[883] providing the first example of an anionic optically active coordination complex.

(*iv*) *Tris(oxalato)chromate(III)*

Structural and other studies of the salts of this ion are numerous. The crystal structure of potassium tris(oxalato)chromate(III) has recently been reinvestigated.[884] EPR studies of $[Cr(ox)_3]^{3-}$ doped in $K_3[Al(ox)_3]\cdot 3H_2O$ had revealed four magnetically distinguishable sites for substitution,[885] a result in conflict with the reported crystal structure[886] of $K_3[Cr(ox)_3]\cdot 3H_2O$ with which $K_3[Al(ox)_3]\cdot 3H_2O$ is isomorphous. The earlier crystal structure[886] was found to be unsatisfactory. Crystals of $K_3[Cr(ox)_3]\cdot 3H_2O$ are monoclinic ($a = 7.714$, $b = 19.687$, $c = 10.316$ Å and $\beta = 108.06°$). The structure consists of discrete $[M(ox)_3]^{3-}$ ions, K^+ ions and water molecules. One potassium and one water are cooperatively disordered over two possible pair sites (termed α and β) with an occupancy ratio of 3:1. The result is in excellent agreement with the EPR study.[885] The structure of $(NH_4)_3[Cr(ox)_3]\cdot 2H_2O$ has also been reported.[887]

The electronic spectrum of $[Cr(ox)_3]^{3-}$ has been studied extensively both in solution and in the solid state.[888,889] The assignment of the spin-allowed transitions from solution electronic spectroscopy is a popular undergraduate exercise.[890] The low energy spin-forbidden $^4A_2 \rightarrow {}^2E$ transition is readily observed for this complex.[889,890] Table 81 summarizes the most significant features of the electronic spectrum.

Werner resolved the tris oxalate using strychninium ion in 1912.[891] Other effective resolving agents for the tris complex include: (+)-tris(1,10-phenanthroline)nickel(II),[892] (+)- or (−)-tris(ethylenediamine)cobalt(III)[893] and (−)-tris(ethylenediamine)rhodium(III).[896] The (−)-$[Co(ox)_3]^{3-}$ ion has been studied by single-crystal methods[894] and has the D configuration. It has been related to (+)-$[Cr(ox)_3]^{3-}$ by X-ray powder photography,[895] so its absolute configuration is also established as D by the more exact form of the rule of least-soluble diastereoisomers.[897]

Table 81 The Electronic Spectrum of Potassium Tris(oxalato)chromate(III) (after ref. 889)

The 'Pfeiffer effect' is a term used to describe changes in the optical activity of solutions containing a chiral compound (the 'environmental substance') on the addition of a racemic dissymmetric complex. The effect is generally attributed to a shift in the position of the equilibrium between D and L isomers for the racemic complex. The exact mechanism involved in mediating the chiral interaction is unknown. Perhaps surprisingly, both 'environmental substance' and complex may simultaneously be cations. Studies of the 'Pfeiffer effect' usually involve a moderately labile racemic complex; $[Cr(ox)_3]^{3-}$ is a popular choice for such studies, summarized in Table 82. Other studies of the optical activity of tris oxalates include work on photoinduced optical activity,[898] photoracemization[899] and the solid-state racemization of $K_3[Cr(ox)_3]$.[900,901]

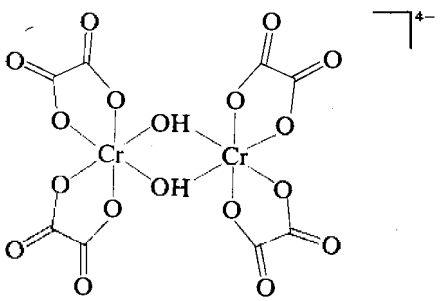
The thermal decomposition of $K_3[Cr(ox)_3]\cdot 3H_2O$ proceeds, after dehydration, *via* the loss of CO and CO_2 to Cr_2O_3.[902] When $[Cr(H_2O)_6][Cr(ox)_3]$ was heated at 303 K in the solid state, along with decomposition, some exchange of the chromium(III) centres could be detected by ^{51}Cr labelling.[903]

(*v*) *Bis oxalate complexes*

Crystallographic studies of the bis oxalates of chromium(III) are not abundant. However, the structure of both *trans*[904] and *cis*[905] isomers has been confirmed crystallographically. Potassium *trans*-bis(oxalato)diaquachromate(III) is monoclinic (space group $P2/c$); the oxalates are strictly coplanar. The crystal structure of the complex salt $[Cr(en)_2(ox)][Cr(en)(ox)_2]$ has been determined:[905] this red salt is obtained as an intermediate in the preparation of salts of mixed ethylenediamine/oxalate chromium(III) complexes. The structure consists of discrete complex ions linked by H bonding to water molecules and neighbouring ions.

The bis oxalato complexes are readily assigned to the *cis* or *trans* geometry on the basis of their electronic spectrum.[906,907] The EPR spectra of a large series of *trans* isomers have been studied (axial ligands studied included H_2O, OH, py and NH_3).[908] The spectra are quite



insensitive to the nature of the axial ligand, but ESR spectra are useful in distinguishing *cis* and *trans* isomers. Potassium *cis*-bis(oxalato)diaquachromate(III) has been resolved using strychnine.[909] The rate of *cis*/*trans* isomerization paralleled that of racemization, suggesting a single mechanism. Many reports concern the kinetics of isomerization and/or aquation of bis oxalato complexes. A number of the more recent and/or significant papers are collated in Table 83.

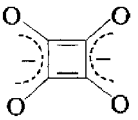
Bridged hydroxy complexes (**208**) of the bisoxalate type have been known for many years.[910,911] Both a trihydrate[910,911,912] and an anhydrous[913] form are known. The trihydrate is isomorphous[912] with the corresponding cobalt(III) complex (Durrant's salt) and the hydrous complex[913] is slowly converted to the hydrate on exposure to moisture.[912] Only a preliminary crystallographic characterization has appeared;[914] it crystallizes as a *meso* rather than racemic complex. IR[915] and magnetic studies[912] are in accord with the hydroxy-bridged structure. Despite the crystallographic *meso* structure, the resolution of the complexes has been reported either photochemically[915] or with *cis*-(−)bis(ethylenediamine)dinitrocobalt(III)[916] and leads to optically active complexes with spectra similar to those of the corresponding tris oxalate.

(**208**)

(*vi*) *Malonates*

Malonic acid $CH_2(CO_2H)_2$ (H_2mal) (**209**) has a coordination chemistry with chromium(III) closely resembling that of oxalate. Malonic acid is a slightly weaker acid than oxalic acid and slightly more labile complexes are formed. The tris complex is the most extensively studied, prepared by the reduction of chromate solutions or the reaction of chromium(III) hydroxide with malonate.[917,918,919] The *cis* and *trans* diaqua complexes may be prepared by the reduction of chromate with malonate; the isomers are separated by fractional crystallization. The electronic spectrum of the tris complex is similar to that of the tris oxalate and a detailed analysis of these spectra has appeared.[889]



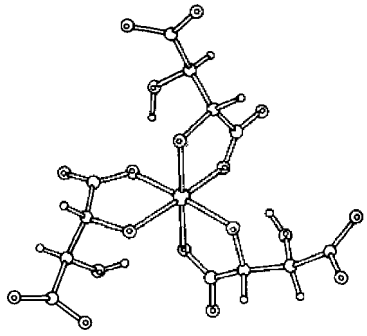
(209)

The resolution of $[Cr(mal)_3]^{3-}$ was achieved with L-$[Co\{(-)$-1,2-diaminopropane$\}_3]Br_3$;[920] the only diastereoisomer to precipitate contained D-$[Cr(mal)_3]^{3-}$. A crystal structure of the diastereoisomer was reported, permitting the correction of earlier work which had suggested the $(+)_{589}$-$[Cr(mal)_3]^{3-}$ ion to have the L-configuration.[921,922] Polarized crystal spectra of $[Cr(mal)_3]^{3-}$ doped into $[NH_4]_3[Fe(mal)_3]$ are extremely similar to those of $[Cr(ox)_3]^{3-}$ under similar conditions.[923]

Solution studies of malonate complexes include the unusual observation that $[(H_2O)_5Cr(Hmal)]^{2+}$ has considerable kinetic stability.[924] The mechanism of ring closure has been the subject of detailed study.[925] The methylenic protons of $[Cr(mal)_3]^{3-}$ undergo bromination when a suspension of the potassium salt is treated with bromine in ether (2 h).[926] Legg and co-workers[927] have recently used a number of malonate complexes to demonstrate that the ^{2}H NMR spectra are both readily observed and useful for solving structural problems. The resolution that may be obtained by this method may be appreciated by the fact that in the complex $[Cr(mal\text{-}d^2)_2(bipy)]^{2-}$ the geminal protons of the malonate are clearly resolved.

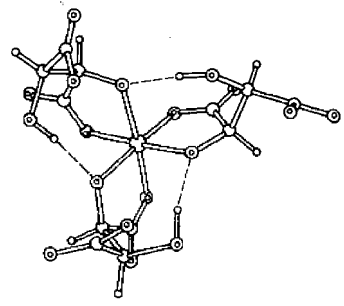
(*vii*) *Squarates*

Complexes of chromium(III) with the squarate ligand (**210**) have been prepared.[928] Subsequently the complex $Cr(C_4O_4)(OH)\cdot 3H_2O$ was investigated crystallographically and shown to contain pairs of chromium atoms joined by two μ-hydroxy bridges and two bridging $C_4O_4^{2-}$ ions.[929] In the same study, a compound of formulation $Cr(C_4O_4)_{3/2}\cdot 7H_2O$ was isolated, a salt of the hexaaquachromium(III) ion.



(210)

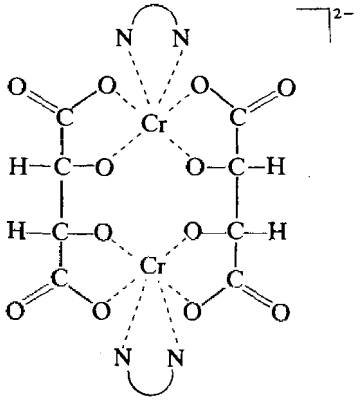
35.4.4.11 Hydroxy acids



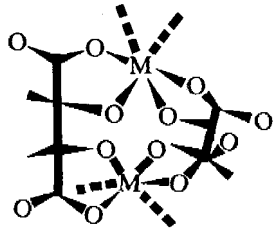
(*i*) *Tartrates and aliphatic hydroxy acids*

While undertaking a study of alkaline solutions of chromium(III) and (+)-tartrate in 1896, Cotton[930] first observed the anomalous rotatory dispersion of light in the region of an absorption band—'The Cotton Effect'. The solutions used probably contained a tris tartrato species. Mason concluded that complexation in such solutions was stereospecific;[931] the complex formed in the presence of an excess of doubly deprotonated tartrate is probably *fac*-D-$[Cr(R,R\text{-tart})_3]^{3-}$.[932] This diastereoisomer may be markedly stabilized by hydrogen bonding when the ligand is doubly deprotonated, a suggestion supported by the fact that the addition of a single proton to the complex greatly decreases the intensity of the CD spectrum (**211**, **212**). Alkaline solutions of chromium(III) in the presence of racemic tartrate become

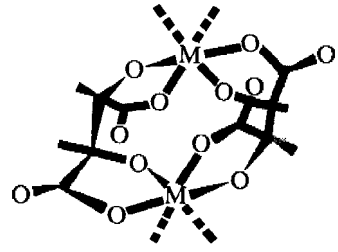
optically active when irradiated with circularly polarized light.[933] Photo inversions at the chromium(III) centre are postulated to account for this observation. In the dark, the optical activity slowly decreases to zero.



(**211**) Δ-*fac*



(**212**) Λ-*fac*



Mixed dinuclear complexes of tartrates and 2,2′-bipyridyl or 1,10-phenanthroline and chromium(III) have been prepared;[934,935] the typical structure is illustrated below (**213**). Stereochemical correlations have been carried out by oxidatively cleaving the tartrate bridge (**214, 215**).[936] The crystal structure of sodium hydrogen bis(μ-*meso*-tartrato)bis(2,2′-bipyridyl)dichromate(III) heptahydrate has been reported.[937]

(**213**)

(**214**) ΔΔ(*dd*)

(**215**) β-ΔΔ(*meso-meso*)

An isolated report of the synthesis and characterization of a number of citrate complexes of chromium(III) has appeared.[938]

(*ii*) *Aromatic hydroxy acids*

Complexes of salicylate with chromium(III) have not been reported but the tris complexes of salicylaldehyde and chromium(III) may be prepared by refluxing $[Cr(THF)_3Cl_3]$ with salicylaldehyde and sodium acetate in ethanol.[939] The acid hydrolysis of this complex was studied in detail, but the isomerism obviously possible for this complex was not apparently considered. Khan and Tyagi[940] studied the formation of phthalate complexes of chromium(III).

35.4.4.12 Sulfoxides, N*-oxides and* P*-oxides*

(*i*) *DMSO*

The complex $[Cr(DMSO)_6][ClO_4]_3$ was first prepared by Cotton in 1959[941] as green needles by reacting concentrated $Cr(ClO_4)_3$ solutions with DMSO. Subsequently Drago established the spectrochemical series for chromium(III) to be $H_2O > DMSO > TMSO > C_6H_5NO$.[942] A

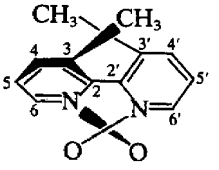
detailed IR study of the hexakis DMSO ion as its perchlorate, and the corresponding d_6-DMSO complex, suggested that the point group of the cation was D_{3d} or S_6.[943] The preparation of $[Cr(DMSO)_6]^{3+}$ from anhydrous $CrBr_3$ has been reported.[944]

The solvolysis of hexaaquachromium(III) in DMSO proceeds *via* the series of complexes $[Cr(DMSO)_n(H_2O)_{6-n}]^{3+}$ ($n = 1$ to 6).[945,946] The anation and solvolysis of several chromium(III) complexes in DMSO have been studied;[947,948] in general the reactions proceed by I_d mechanisms. A direct electrochemical synthesis of $[Cr(DMSO)_6][BF_4]_3$ has been reported.[949] A comprehensive review of metal ion complexation by DMSO contains an extensive section on chromium(III).[950]

(*ii*) *DMF*

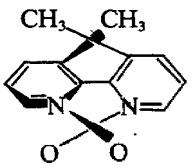
The complex $[Cr(DMF)_6][ClO_4]_3$ has been prepared from the reaction of chromium(III) perchlorate with DMF (90 °C, 10 h).[951] Solvent exchange and substitution proceed by I_a mechanisms.[947,952] The complex $[Cr(DMF)_6]Br_3 \cdot DMF$ was prepared by the reaction of chromium metal with bromine in DMF;[953] the electronic spectrum of this complex was very similar to that of the perchlorate salt.

(*iii*) N-*Oxides*



An extensive, if somewhat dated, review of the coordination chemistry of aromatic *N*-oxides is available.[954] Most studies of the *N*-oxide complexes of chromium(III) involve the preparation and characterization (usually by magnetic and spectroscopic methods) of monomeric or hydroxy-bridged complexes and are summarized in Table 84.

Table 84 N-Oxide Complexes



Ligand	*Complex*	*Ref.*

Interesting complexes have been prepared from the chiral ligands derived from 3,3′-dimethyl-2,2′-bipyridyl *N,N′*-dioxide (**216**, **217**).[955,956] A number of diastereomeric tris complexes were isolated. These could be interconverted photochemically.

(**216**) *R* (λ)

(**217**) *S* (δ)

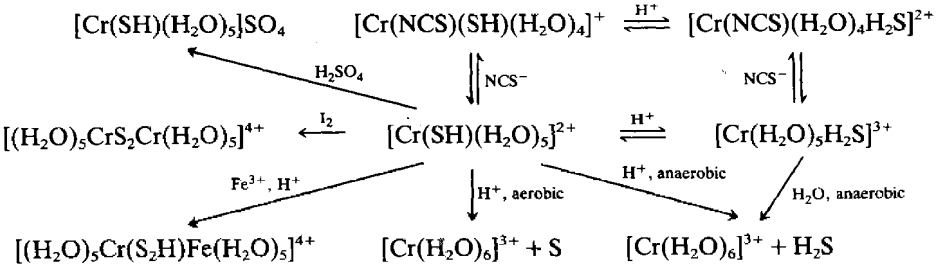
(*iv*) P-*Oxides*

The complex of tri-*n*-butylphosphine oxide (tbo), $[Cr(tbo)_4(ClO_4)_2]ClO_4$, has been prepared.[957] Crystalline samples were obtained, and, on the basis of IR and electronic spectra, monodentate coordination of the perchlorate was suggested. The geometric isomerism possible for this complex was not considered. The hexakis complex of tris(hydroxymethyl)phosphine oxide and chromium(III), $[Cr(L)_6][ClO_4]_3$ has been prepared;[958] it was concluded that bonding in these complexes was weaker than in the corresponding complexes of trimethylphosphine oxide.[959] Tris(dimethylamino)phosphine oxide forms complexes CrL_3Cl_3, for which a facial arrangement of the ligands has been suggested.[960] The reaction of $Cr(CO)_6$ with diisopropylmethylphosphonate results in a series of polymeric complexes.[961] A complex of triphenylphosphine oxide has been said to contain a trigonally bipyramidal chromium(III) ion.[962]

35.4.5 Sulfur Ligands

35.4.5.1 Thiolate, disulfido and thioether ligands

The chemistry of chromium(III) complexes containing sulfur donor ligands, although until recently unexplored, is now an area of considerable research activity. Mechanisms for reactions of these complexes are described in a recent review.[70]



(*i*) $[Cr(SH)(H_2O)_5]^{2+}$

The tendency of chromium to capture whatever ligands are in its first coordination sphere on being oxidized from the +II to the +III state[963] has been exploited in the preparation of $[Cr(SH)(H_2O)_5]^{2+}$ in aqueous solution (equation 48).[964,965] Hence oxidation of $[Cr(H_2O)_6]^{2+}$ by PbS, Ag_2S or $S_2O_3^{2-}$ under N_2 gives the desired product, although in low yield. However the use of polysulfide as oxidant increases the yield of green-coloured product to 10–20%. The scope of this reaction can be extended to include the synthesis of a range of alkyl-, aryl- and chelating-thiolatochromium(III) complexes by choice of an appropriate disulfide oxidant. However, complexes containing simple alkylthiolato ligands cannot be synthesized by this method due to the inability of chromium(II) to reduce the corresponding disulfides.[966]

$$[Cr(H_2O)_6]^{2+} + \text{various S-containing oxidants} \longrightarrow [Cr(SH)(H_2O)_5]^{2+} \quad (48)$$

Some reactions of $[Cr(SH)(H_2O)_5]^{2+}$ are outlined in Scheme 96.[964–968] The ion exchange behaviour of this complex is characteristic of a 2+ species, thus confirming the presence of HS^- rather than H_2S as the sulfur ligand. No spectroscopic evidence for protonation of this ligand was observed even at pH = 0. This, however, is not too surprising, since by analogy with $[Cr(H_2O)_6]^{3+}$, which is more acidic by a factor of 5×10^{11} than free H_2O, the pK_a of H_2S in the complex $[Cr(H_2O)_5H_2S]^{3+}$ should be considerably less than 0. However, kinetic evidence has been obtained for the existence of this species. While the complex $[Cr(SH)(H_2O)_5]^{2+}$ is remarkably stable under anaerobic conditions in aqueous solution at room temperature,[964] it undergoes aquation by both acid-independent and acid-dependent pathways, the latter attributed to a rapid protonation equilibrium preceding the rate-determining step.[965] Aquation

rate constants of $3.1 \times 10^{-5}\ s^{-1}$ and $\gg 3.8 \times 10^{-5}\ s^{-1}$ have been estimated for $[Cr(SH)(H_2O)_5]^{2+}$ and its conjugate acid respectively, both at 313 K, $I = 1.0$.

Scheme 96

The UV–visible spectrum of $[Cr(SH)(H_2O)_5]^{2+}$ in aqueous solution (Table 85) is typical of thiolatochromium(III) complexes. The bands at 575 and 435 nm are identified with the $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}$ transitions respectively, while the very intense band at 258 nm is due to an S ligand to metal charge transfer transition.[966] The aquation of $[Cr(SH)(H_2O)_5]^{2+}$ is characterized by the disappearance of the charge transfer band from the spectrum. Addition of H_2SO_4 to a concentrated solution of $[Cr(SH)(H_2O)_5]^{2+}$ leads to the isolation of the brown-green solid $[Cr(SH)(H_2O)_5]SO_4$.[965] The IR spectrum of this complex has bands at 2560 (ν_{SH}) and 340 cm^{-1} (ν_{MS}), while the Raman spectra of aqueous solutions show a band at 337 cm^{-1} (ν_{MS}).

(*ii*) $[Cr(SAr)(H_2O)_5]^{3+}$ (*Ar = anilinium*)

The aromatic thiolatochromium(III) complexes $[Cr(SAr)(H_2O)_5]^{3+}$ (Ar = 4-$PhNH_3^+$, 4-$PhNMe_3^+$) have been prepared in solution under N_2 (equation 49) and purified by cation exchange chromatography.[969] Initial elution with 1 M $LiClO_4$ solution separated species of charge +3 from more highly charged polymeric products, while subsequent elution with 2 M $LiClO_4$ separated the green thiolato complexes from the blue and slightly faster moving $[Cr(H_2O)_6]^{3+}$. Despite repeated chromatography, however, the complex $[Cr(4\text{-}SPhNH_3^+)(H_2O)_5]^{3+}$ could not be obtained free from the hexaaqua species, in any greater than about 95% purity. The solution spectrum of this complex (Table 85) shows an internal ligand band at 230 nm, a very intense charge-transfer band at 295 nm which masks the $^4A_{2g} \rightarrow {}^4T_{1g}$ *d–d* band and an unsymmetrical band at 595 nm with a shoulder at 640 nm. The shape of this band is due to splitting of the $^4T_{2g}$ excited state and the absorptions at 595 and 640 nm may be attributed to the $^4B_1(^4A_{2g}) \rightarrow {}^4B_2$, $^4E_a(^4T_{2g})$ transitions respectively.

$$[Cr(H_2O)_6]^{2+} + ArSSAr \xrightarrow{HClO_4,\ N_2} [Cr(SAr)(H_2O)_5]^{3+} \qquad (49)$$

As in the case of $[Cr(SH)(H_2O)_5]^{2+}$, the complexes $[Cr(SAr)(H_2O)_5]^{3+}$ undergo anaerobic aquation with loss of the S ligands by both acid-independent and acid-dependent pathways, the kinetically active species in the latter resulting from protonation on the S atom. Aerobic aquation of the thiolatoanilinium complex gives $[Cr(H_2O)_6]^{3+}$ and *p*-aminophenyl disulfide as products. This reaction is autocatalytic (*p*-aminothiophenol acting as catalyst) and is also catalyzed by H_2O_2 and Fe^{3+}, all seemingly by a mechanism which involves oxidation of the thiolate ligand to a labile coordinated free radical.

(*iii*) $[Cr(SR)(H_2O)_5]^{2+}$ (*R = aliphatic*)

Because of the thermodynamic inability of chromium(II) to reduce simple alkyl disulfides, the synthetic method used for the previous complexes is unsuccessful for chromium(III) complexes containing simple alkylthiolato ligands. Hence, whereas complexes containing chelating thiolate and 4-$^-SPhNH_3^+$ ligands are obtained rapidly by chromium(II) reduction of the corresponding disulfides, the complex containing $^-SCH_2NMe_3^+$ is produced only slowly and those containing the ligands MeS^-, EtS^- and $^-S(CH_2)_2NH_3^+$ are unobtainable by this

method.[966] However some of these complexes, *e.g.* $[Cr(SCH_2CH_2NH_3)(H_2O)_5]^{3+}$, can be prepared by chromium(II) reduction of the alkylthiolatocobalt(III) complexes, a reaction which occurs by an inner sphere mechanism and which results in ligand transfer (Scheme 97).[966] The product in solution can be partly purified by cation exchange chromatography but cannot be obtained free from $[Cr(H_2O)_6]^{3+}$, which is present to an extent of 5% in the final effluent. The solution electronic spectrum of this complex (Table 85) contrasts with that of the thiolatoanilinium complex in that the charge transfer band is at a shorter wavelength (274 nm) and does not obscure the $^4A_{2g} \rightarrow {}^4T_{1g}$ band, which is clearly observed at 438 nm. Using this and a series of related complexes $[CrX(H_2O)_5]^{2+}$ (X = F, N_3, OAc, CN) evidence is presented that in the case of ligands derived from weak acids (HX) the acid-independent term in the aquation rate law, like the acid-dependent one, depends on the ability of the coordinated ligand to be protonated and corresponds to the removal of HX from $[Cr(OH)HX(H_2O)_4]^{2+}$ rather than the removal of X from $[CrX(H_2O)_5]^{2+}$.[70,966] Potential ligands have been found to enhance the rate of Cr—S bond cleavage in $[Cr(SR)(H_2O)_5]^{2+}$ and $[Cr(SAr)(H_2O)_5]^{2+}$ complexes and to be incorporated into the coordination sphere of the metal at greatly enhanced rates, indicative of a high *trans* effect associated with thiolate ligands (equation 50).[970]

$$[Cr(SR)(H_2O)_5]^{2+} + L^{n-} + H^+ \longrightarrow [CrL(H_2O)_5]^{(3-n)+} + HSR \qquad (50)$$

Scheme 97

(iv) Complexes containing S, N and S, O chelating ligands

Complexes containing these ligands are also dealt with in Sections 35.4.2.3 and 35.4.8.

The thiolatoamine complexes $[Cr(SCH_2CO_2)(en)_2]ClO_4$ and $[Cr(SCH_2CH_2NH_2)(en)_2](ClO_4)_2$ have been prepared by chromium(II) reduction of the disulfides in the presence of en (Scheme 98).[971] In the preparation of the aminoethanethiol complex a second product, $[Cr(SCH_2CH_2NH_2)_2en]ClO_4$, was also produced. These complexes could be separated by either fractional crystallization of the perchlorate salts from dilute $NaClO_4$ solution or by cation exchange chromatography. The proportion of unipositively charged species in the product mixture was found to increase by using excess disulfide in the preparation. The electronic solution spectra of these complexes are presented in Table 85. The aquation reactions of the complexes in dilute $HClO_4$ solutions proceed predominantly through H^+-catalyzed Cr—S bond fission, although acid-independent processes involving Cr—S and Cr—N bond breaking are also competitive.[971] The aquation of $[Cr(SCH_2CO_2)(en)_2]^+$ in $HClO_4$ proceeds *via* several steps the first of which gives *cis*-$[Cr(O_2CCH_2SH)(en)_2H_2O]^{2+}$. Subsequent aquation steps involving Cr—N and at a later stage Cr—carboxylate bond fission (analogous with aquation reactions of oxalatopolyammine[475,972] and acetatopentaamminechromium(III)[973] complexes) result in $[Cr(en)(H_2O)_4]^{3+}$, the predominant product following extensive hydrolysis.[971] The aquation of $[Cr(SCH_2CH_2NH_2)(en)_2]^{2+}$ in 4 M $HClO_4$ gives $[Cr(en)_2(NH_2CH_2CH_2SH)H_2O]^{3+}$ as the primary aquation product and is much slower than aquation of $[Cr(SCH_2CO_2)(en)_2]^+$. Both complexes however are some 10^4-fold more reactive than their cobalt(III) analogues. Since X-ray crystallographic evidence[413] indicates that (after allowance is made for the different ionic radii of the metal ions) the Cr—S bond is actually stronger than the Co—S bond in the $[M(SCH_2CO_2)(en)_2]^+$ complexes,[970] and since the larger crystal field activation energy of cobalt(III) would account for only a 10^1–10^2 decrease in rate constant,[974] it appears that the greater lability of the Cr—S bond may be due to the greater basicity and ease of protonation of sulfur bound to Cr. The metal–ligand bond distances in the $[M(SCH_2CO_2)(en)_2]^+$ (M = Co, Cr) cations are compared in Table 86.

Oxidation of some of the afore-mentioned complexes as well as $[Cr\{S(CH_2)_2CO_2\}(en)_2]ClO_4$ and $[Cr\{SC(Me_2)CO_2\}(en)_2]ClO_4$ (electronic spectra of these complexes are included in Table

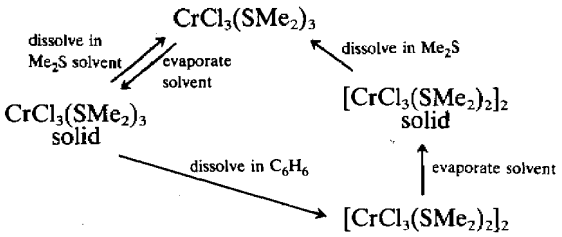
85) by H_2O_2 has been investigated.[412] Reaction of $[Cr(SCH_2CO_2)(en)_2]^+$ produces a complex product mixture, the composition of which has proved difficult to elucidate. However, the thiolate ligand is oxidized and it appears that the oxidation state of sulfur changes from −II to +II (RSO_2^-, sulfinate) and possibly +IV (RSO_3^-, sulfonate), with the likelihood of a transient 0 (RSO^-, sulfenate) state. The mechanism of oxidation by H_2O_2 involves nucleophilic attack by coordinated sulfur on the O—O bond. The reactions follow second-order kinetics and while reactivity is relatively insensitive to the nature of the thiolato complex, steric crowding at the sulfur atom causes decreased reactivity for the complexes $[Cr(SCMe_2CO_2)(en)_2]^+$ and $[Cr(4\text{-}SPhNH_3)(en)_2]^{3+}$.

The nucleophilicity of coordinated sulfur in the complex $[Cr(SCH_2CH_2NH_2)(en)_2]^{2+}$ towards MeI (equation 51) has been measured in DMF/H_2O and compared with sulfur nucleophilicities in thiolatocobalt(III) systems.[975] As in the case of the H_2O_2 oxidations, the nucleophilicity of thiolate coordinated to chromium(III) is only slightly less than when it is coordinated to cobalt(III), implying that nucleophilic attack by coordinated sulfur does not involve any appreciable distortion in the first coordination sphere of the metal.

$$[Cr(SCH_2CH_2NH_2)(en)_2]^{2+} + MeI \longrightarrow [Cr\{S(Me)CH_2CH_2NH_2\}(en)_2]^{3+} + I^- \quad (51)$$

(*v*) *$Cr(SR)_3$, $CrX_3(SR_2)_3$, $CrCl_3(THT)_3$ ($X = Cl$, Br; $R = Me$, Et; THT = tetrahydrothiophene)*



The preparation and properties of a number of these thiolato and thioether complexes are presented in Table 87. X-Ray powder photographs of $Cr(SMe)_3$ show that the compound has a layer-type lattice with chromium(III) occupying octahedral $Cr(SMe)_6$ sites.[976,977] The chemical behaviour of the mixed halogenothioetherchromium(III) complexes is illustrated using $CrCl_3(SMe_2)_3$ as an example in Scheme 99.[978] It was not possible to isolate solid samples of the dimer $[CrCl_3(SEt_2)_2]_2$ or the monomers $CrBr_3(SR_2)_3$ (R = Me, Et). The complexes $CrCl_3(SR_2)_3$ (R = Me, Et) have been assigned *mer* geometric configurations on the basis of their far IR spectra. Hence in the Cr—Cl stretching region these complexes show three absorption bands, which for the *mer* isomer (C_{2v} symmetry) is expected, since the three Cr—Cl stretching modes ($2a_1 + b_1$) are IR active. For the *fac* isomer, however, only two Cr—Cl stretching modes ($a_1 + e$ of C_{3v}) are active.[978] These criteria have also been applied to distinguish between the isomers of $CrCl_3(THT)_3$ (THT = tetrahydrothiophene).[979]

Table 87 Preparation and Properties of Thiolato- and Thioether-chromium(III) Complexes

Scheme 99

(*vi*) *Complexes containing S_2^{2-} and HS_2^- ligands*

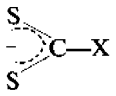
The oxidation of $[Cr(SH)(H_2O)_5]^{2+}$ by I_2 or Fe^{3+} under aerobic conditions in acid solutions gives the disulfido-bridged complexes $[(H_2O)_5CrS_2Cr(H_2O)_5]^{4+}$ and $[(H_2O)_5Cr(S_2H)Fe(H_2O)_5]^{4+}$ respectively (Scheme 100).[967,968] The latter complex can also be obtained by substitution of chromium(III) in the former complex by iron(II) under acid conditions. The product distribution in the iron(III) oxidation of $[Cr(SH)(H_2O)_5]^{2+}$ is pH dependent and at 298 K, pH = 1 the heteronuclear dimer $[(H_2O)_5Cr(S_2H)Fe(H_2O)_5]^{4+}$ constitutes over 80% of the product mixture. The rate of this reaction shows a $[H^+]^{-1}$ dependence, an observation consistent with $[CrS(H_2O)_5]^+$ being the kinetically active species.

[a] λ_{max} in nm (ε in $dm^3\,mol^{-1}\,cm^{-1}$). [b] This reaction also gives $[(H_2O)_5CrS_2Cr(H_2O)_5]^{4+}$ as a minor (pH-dependent) product.

Scheme 100

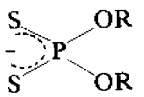
(*vii*) *Binary and ternary sulfides*

A number of binary compounds in the chromium–sulfur system have been identified and their structures established. These include CrS, Cr_2S_3, Cr_3S_4, Cr_5S_6 and Cr_5S_8.[980,981] The origin of ferromagnetism in Cr_2S_3 and Cr_5S_6 lies in the ordered arrangement of cation vacancies with resulting uncompensated spins.[982] Since the magnetic and electrical properties of Cr_5S_8 indicate that the *d* electrons of chromium are localized, the formula $Cr_4^{III}Cr^{IV}S_8$ has been suggested for this compound with chromium(III) occupying the filled cation layers and chromium(IV) occupying the partly filled layers.[981]



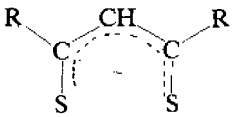
The ternary sulfide $NaCrS_2$, which can be prepared by fusion of either Na_2CrO_4, Na_2CO_3 and sulfur[983] or K_2CrO_4, $NaKCO_3$ and sulfur,[984] contains octahedral $Cr^{III}S_6$ groups in which the Cr—S distances are 244 pm.[985] On lowering the temperature from 300 to 20 K a shoulder at 13 350 cm^{-1} on the $^4A_{2g} \rightarrow {}^4T_{2g}$ band (14 600 cm^{-1}) in the reflectance spectrum becomes prominent.[985] Although this shoulder was originally attributed to splitting of the $^4T_{2g}$ state in a trigonally distorted octahedral field it now appears that it is instead due to a spin-forbidden transition to the ^2E_g state.[986] The sulfides $CuCrS_2$ and $AgCrS_2$ have been prepared by heating the mixed binary chalcogenides.[987] The crystal structures of these compounds show that the sulfur atoms are arranged in a deformed cubic close pack with chromium occupying octahedral sites and copper or silver in tetrahedral sites. Like $NaCrS_2$, these sulfides are antiferromagnetic and Néel temperatures for the three compounds fall in the range 19–40 K.[987] Ferromagnetic interactions occur in the chromium layers of $NaCrS_2$. The structure of $LiCrS_2$ is of the NiAs

type with lithium and chromium atoms occupying octahedral sites.[988] In $CrUS_3$ the chromium atoms have distorted octahedral coordination, while each uranium is located at the centre of a bicapped trigonal prism of sulfur atoms.[989,990]

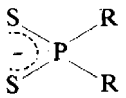


The semiconducting thiospinels MCr_2S_4 (M = Mn, Fe, Co and Zn), which can be prepared by the high temperature combination of the metals and sulfur, contain $M^{II}S_4$ and $Cr^{III}S_6$ groups.[991] However, $CuCr_2S_4$ is metallic and appears from crystallographic and magnetic evidence to contain copper(I) and not copper(II). The chromium atoms occupy octahedral $Cr^{III}S_6$ sites. The metallic properties of this compound have been attributed to a conduction band arising from the absence of a fraction of the valence electrons of sulfur.[986] The structure of $CrPS_4$, determined by X-ray crystallography, consists of puckered hexagonally close-packed sulfur layers stacked parallel to (100) with chromium in octahedral and phosphorus in tetrahedral interstices.[992] This is the first reported metal thiophosphate having the metal ion in octahedral sulfur coordination.

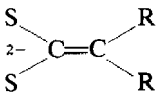
35.4.5.2 Bidentate S donor ligands: dithiocarbamates, dithiophosphates, 1,1- and 1,2-dithiolates, etc.



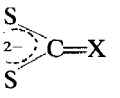
The chemistry of the complexes formed by the dithio ligands (**218**) to (**225**) with transition metals including chromium(III) has been well described in several reviews.[583,986,993–996]



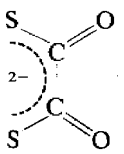
(**218**) X = NR_2, dithiocarbamate
X = OR, xanthate
X = SR, thioxanthate
X = R, dithiocarboxylate



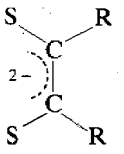
(**219**) Dithiophosphate



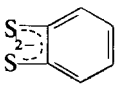
(**220**) 1,3-Dithiodiketone



(**221**) Dithiophosphinate

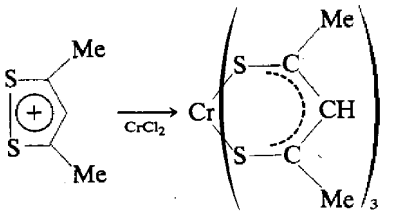


(**222**) 1,1-Dithiolate



(**223**) X = O, dithiocarbonate
X = S, trithiocarbonate
X = NCN, *N*-cyanodithiocarbimate

(**224**) Dithiooxalate



(**225**) 1,2-Dithiolates (dithiolenes)

In general, the complexes are prepared by mixing aqueous or alcoholic solutions of the sodium, ammonium or potassium salt of the ligand and $CrCl_3 \cdot 6H_2O$, sometimes with Zn dust present.[997,998] However, in some cases anhydrous conditions are necessary to prevent the formation of polymeric hydrolysis products,[986] and dithiophosphate is much more resistant to temperature and extremes of pH than dithiocarbamate or xanthate. In the preparation of CrL_3, where L is 4-aminophenazonedithiocarbamate, aqueous $Cr(NO_3)_3$ was added to the reaction mixture from the preparation of the ligand.[999]

Another general method is illustrated by the preparation of $[Cr(S_2CNR_2)_3]$ (where R = Me, Et, Pr, Bu^n, Bu^i, CH_2Bu; $R_2 = (CH_2)_4O$, $(CH_2)_4$, $(CH_2)_5$, MePh or EtPh; equation 52). In this a chromium(II) salt is added to the ligand and the mixture allowed to oxidize.[1000] An alternative is to reduce a precursor, *e.g.* the 3,5-dimethyl-1,2-dithiolium cation, with a chromium(II) salt to the ligand which then coordinates to the Cr^{III} produced (equation 53).[1001]

$$[Cr(O_2CMe)_2H_2O] + NaS_2CNR_2 \xrightarrow[HCl(aq)]{air} [Cr(S_2CNR_2)_3] \qquad (52)$$

(53)

Chromium(III) complexes of some strong acids, *e.g.* HS_2PF_2, have been obtained directly from the metal and the acid.[1002,1003] The complex $[Cr(S_2PF_2)_3]$ can also be made by reduction of CrO_2Cl_2 by the acid.[1004] A specific method is the insertion of CS_2 into the Cr—N bond accompanied by reduction of Cr^{IV} to Cr^{III} (equation 54).[618] An account of the redox behaviour of many complexes containing the CrS_6 core also provides many references to the preparation of the ligands and their chromium(III) complexes.[1005]

$$[Cr(NEt_2)_4] + 4CS_2 \longrightarrow [Cr(S_2CNEt_2)_3] + \tfrac{1}{2}(S_2CNEt_2)_2 \qquad (54)$$

A new method[1006] is the oxidative decarbonylation of $Cr(CO)_6$ with $[Hg(S_2CNEt_2)_2]$ in 2:3 molar ratio to give the chromium(II) complex followed by aerial oxidation of the reaction mixture (Scheme 101). Although the unoxidized intermediate solution has the electronic spectrum of the chromium(II) complex (Section 35.3.6.1) the reaction pathway is not completely clear.

$$Cr(CO)_6 \xrightarrow[N_2,\ \text{toluene}]{[Hg(S_2CNEt_2)_2]} \underset{\text{green solution}}{[Cr(S_2CNEt_2)_2] + Hg + CO} \xrightarrow{\text{air}} \underset{\text{dark blue}}{[Cr(S_2CNEt_2)_3]}$$

Scheme 101

The oxidation of $Na(NH_4)S_2CNR_2$ ($R = Me$, Et; $R_2 = (CH_2)_5$) with $K_2Cr_2O_7$ produces a mixture of $[Cr(S_2CNR_2)_3]$ and the dithioperoxycarbamato complex $[Cr(S_2CNR_2)_2(OS_2CNR_2)]$, which has been separated chromatographically. The new dithioperoxy derivatives are in the second fraction and have additional bands in their IR spectra at 1009 and 488 cm^{-1}, assigned to the ν(S—O) and ν(Cr—O) vibrations respectively.[1007–1009] A redetermination of the crystal structure of $[Cr(S_2CNEt_2)_2(OS_2CNEt_2)]$ taking into account the disorder of the *O,S*-chelate has confirmed the gross structure, improved the refinement and provided distances comparable with those expected from other chromium(III) complexes.[1010] The X-ray results make unlikely the assignment of a dinuclear structure $[Cr_2O(S_2CNR_2)_2(R_2NCSS_2CSNR_2)]$ to the second fraction.[1011] The tris(dithiocarbamates) with $R_2 = (CH_2)_4S$ and $(CH_2)_4NMe$ have also been prepared by the oxidative method.[1012]

Some data from X-ray investigations are given in Table 88. The CrS_6 octahedra show small trigonal distortions but these are less than in related MS_6 complexes, and the Cr—S bond distances fall within a small range.

Perfluoroalkyl derivatives $[R_FCr(S_2CNR_2)_2py]$ ($R = Et$, $R_F = C_2F_5$, C_3F_7, C_4F_9; $R = Me$, Pr^i, Bz, $R_F = C_3F_7$) and $[C_3F_7Cr(S_2CNEt_2)_2(cyclohexylamine)]$ have been prepared in the same way as $[C_2F_5Cr(salen)py]$ (Section 35.4.8.1).[1013] The complexes are light sensitive and produce the cations $[R_FCr(H_2O)_5]^{2+}$ in water, but are otherwise stable σ-bonded chromium(III) species; no stable alkylchromium(III) complexes were obtained. The doublet found for the methylene protons in the ^1H NMR spectrum of $[C_3F_7Cr(S_2CNEt_2)_2py]$ suggested that enantiomers with a high barrier to interconversion were present in solution. A *cis* configuration was found in $[C_3F_7Cr(S_2CNMe_2)_2py]$ and the bond *trans* to the C_3F_7 group is considerably longer than the other Cr—S linkages.

The crystal structure of $[Cr(S_2COEt)_3]$ is composed of enantiomorphous molecules with trigonal symmetry. The short S_2C—O bond distance (1.297 Å) is taken to mean that the resonance structure S_2^{2-}—C=$\overset{+}{O}$—R contributes considerably.[1014]

The magnetic moments of the complexes are usually near 3.8 BM at room temperature. The moment of $[Cr(S_2CNEt_2)_3]$ is essentially independent of temperature down to *ca.* 40 K. Then it falls slowly to approximately 3.6 BM at 4 K and more rapidly to 3.5 BM at 2.5 K.[1015] It was not

9. H. V. F. Schousboe-Jensen and R. G. Hazell, *Acta Chem. Scand.*, 1972, **26**, 1375.

possible to decide whether the low moments at low temperature are due to small zero-field splittings or very weak exchange interactions, or both.[1015] The complex $[Cr(SacSac)_3]$ (**220**; R = Me) has a moment which decreases steadily as the temperature is lowered.[1001] The polymers $[Cr_2(S_2CNHC_2H_4CNHCS_2)_3]$ and $[Cr_2(S_2CNHC_6H_{12}NHCS_2)_3]$ show weak antiferromagnetic interaction, with θ values (negative intercepts on T axis) of 32° and 8° respectively. They are amorphous, and insoluble in water and common solvents.[1016]

The temperature dependence of the ^{1}H NMR spectra of many $[Cr(S_2CNR_2)_3]$ complexes has been investigated.[1000,1017] There were broad double resonances from the N—CH_2 protons indicating that inversion between the Δ and Λ isomers is slow on the ^{1}H NMR time-scale. No exchange broadening was observed up to 84 °C when $[Cr(S_2CNEt_2)_3]$ decomposed. Dithiocarbamato complexes of other tervalent metal ions do not exhibit this stereochemical rigidity.

Assignments of spin-forbidden bands in the spectra of $[Cr(S_2CNR_2)_3]$ and $[Cr(S_2COR)_3]$ (R = Me or Et) have been made and the emission spectra studied.[1018]

MCD spectroscopy has been useful in the location of the spin-forbidden transitions.[1019] That the Cr—S bond is comparatively strong has been adduced from the presence of relatively intense molecular ion peaks in the mass spectra of several Cr^{III} dialkyldithiocarbamates.[1020]

The complexes $[Cr(S_2CNMe_2)_3]$, $[Cr\{S_2P(OEt)_2\}_3]$ and $[Cr(S_2COEt)_3]$ have Pfeiffer CD activity but this develops only when there is a large ratio of optically active environment compound to the racemate.[1021] A normal coordinate analysis of the IR spectra of $[Cr(S_2CNR_2)_3]$ (where R = Me, Et, Pr or Bu^n) has shown that the alkyl substituent affects the thioureide band at *ca.* 1550 cm^{-1} through kinematic as well as electronic effects.[1022]

Complexes $[Cr(L)_2Cl_2]Cl$ in which L is a tetraalkylthiuram sulfide or disulfide have been characterized.[1023]

Other typical chromium(III) complexes of bidentate S donor ligands are the xanthates $[Cr(S_2COR)_3]$ (R = Me, Et, Bz, Ph), thioxanthates $[Cr(S_2CSR)_3]$ (R = Me, Et, Pr, Bu^t, Bz), dithiocarboxylates $[Cr(S_2CR)_3]$ (R = Ph, C_6H_4Me, C_6H_4OMe, $C_6H_4NMe_2$, $C_6H_4NEt_2$, C_4H_3O, $C_5H_3NH_2$, Bz),[1005,1024–1029] dithiooxalate $[Cr(C_2S_2O_2)_3]^{3-}$, trithiocarbonate $[Ph_4P]_3$ or $[Ph_4As]_3[Cr(CS_3)_3]$,[1030–1031] dialkyldithiophosphates $[Cr\{S_2P(OR)_2\}_3]$ (R = Me, Et, Pr^n, Pr^i, Bu^s, Bu^i),[1005,1032,1033] dithiophosphinates $[Cr(S_2PR_2)_3]$ (R = F, CF_3, Me, Ph, OEt)[1002,1005] and, for example, $[Cr\{S_2PMe(C{\equiv}CMe)\}_3]$,[1034] dithio-β-diketonates $[Cr(SCRCHCR'S)_3]$ (R = R' = Me, Ph; R = Me, R' = OMe, OEt)[1001,1005] and dithiocarbazates such as $[Cr(S_2CNHNH_2)_3]$ and $[Cr(S_2CNHNPh_2)_3]$.[1035]

Complexes of Se donor ligands, $[Cr(Se_2CNR_2)_3]$ (R = Et; $R_2 = (CH_2)_5$, $(CH_2)_4O$ or $(CH_2)_4S$) and $[Cr\{Se_2P(OEt)_2\}_3]$ are similar to the corresponding S donor complexes, but their electronic spectra exhibit a pronounced nephelauxetic effect.[986,1036]

A number of chromium(III) complexes of 1,1-dithiolato dianions (**222**) are known: $[Cr(S_2C{=}X)_3]^{3-}$ (where $X = C(CN)_2$, $C(CO_2Me)_2$, NCN, $C(CN)CO_2Et$, $C(CO_2Et)_2$, $C(CN)CO_2Me$ and $C(CN)CONH_2$)[583,993,1005] and the thioselenyl analogues $[Cr\{SSeC{=}C(CN)_2\}_3]^{3-}$ and $[Cr\{SSeCO(CH_2)_2OMe\}_3]$ have been obtained.[1037]

The complex $[Cr(S_2PF_2)_3]$ is volatile and monomeric in the gas phase.[1002] Its He^I photoelectron spectrum has been reported.[1038] The absence of interfering ionization bands of substituent groups outside the coordination sphere permitted detailed assignments. The UVPES spectrum of $[Cr\{S_2P(OEt)_2\}_3]$ has been obtained,[1039] and the symmetric ν(Cr—S) vibration at 282 cm^{-1} has been identified in the RR spectrum of $[Cr(S_2PPh_2)_3]$.[1040]

Complexes of 1,2-dithiolate dianions (**225**) are of interest, although because they undergo successive one-electron transfer processes which involve orbitals of ligand character so unlike those of the dithiocarbamate type of ligand, it is unprofitable to attempt to assign oxidation states.[995,1005] The chromium complexes are shown in Table 89.

The general electrochemical behaviour of the tris(chelate) complexes of Cr^{III} with the ligands (**218**) to (**225**) has been extensively investigated.[996,1008,1027,1041] New data have been correlated with early work.[1005] In general, the Cr^{III} complexes are resistant to oxidation and reduction consistent with the stable t_{2g}^3 subshell. Comparisons have been made between complexes of different ligand types and substituent effects analyzed for a particular ligand type in terms of the Hammett σ^+ constant. The dithiocarbamate ligand stabilizes high and low oxidation states and the redox processes are modified compared with the tris(dithiocarbamates) when one ligand is OS_2CNR_2 and by the presence of bipy in solution, which forms mixed ligand complexes in the lower oxidation states. Substituent effects are prominent in the 1,1-ethylenedithiolate series. With these ligand systems the redox processes are metal based whereas in complexes of the 1,2-dithiolates (dithiolenes) the redox processes are primarily ligand based.

Published data on the volatility of complexes of the transition metals including chromium with bidentate sulfur and sulfur–oxygen donor ligands have been summarized.[1042]

The octahedral complexes $[Cr(cis\text{-}MeSCH{=}CHSMe)_3](BF_4)_3$, $[Cr\{S(CH_2CH_2CH_2SMe)_2\}_2]\cdot(BF_4)_3$,[685] *mer*-$[Cr\{S(CH_2CH_2CH_2SMe)_2\}X_3]$, (X = Cl, Br or I), *fac*-$[Cr\{CMe(CH_2SMe)_3\}X_3]$ (X = Cl or Br) and *fac*-$[Cr(CH_2SCH_2CH_2SMe)_2Cl_3]$[696] have been prepared and characterized by methods used for similar P and As donor ligands.

35.4.5.3 Thiourea

Complexes of thiourea (tu) with chromium(III) have not been studied in detail and the lack of structural investigations in particular has led to uncertainties regarding the ligand donor sites and geometrical configurations of some of the reported species.

The complex $CrCl_3(tu)_3$ is conveniently prepared by evaporating a methanolic solution containing $CrCl_3 \cdot 6H_2O$ and tu (1:4) to dryness, and then washing the residue with hot acetone.[1043] Evidence based on the IR spectrum of this complex (Table 90) indicates that the ligand is bonded through sulfur to the metal ion. Hence the ν(NH) bands in the spectrum of the complex occur at higher wavenumbers than in the spectrum of free tu, indicating a reduction in H bonding and therefore S coordination of the ligand to the metal. Similarly the ν(CS) band at 733 cm^{-1} in the free ligand spectrum is shifted to a lower wavenumber in the spectrum of the complex consistent with a reduction in carbon–sulfur bond order and coordination through the sulfur atom.[1043,1044] Furthermore, the expected increase in the carbon–nitrogen bond order due to S coordination is confirmed by the shift to higher wavenumber of the B_1 NCN band in the complex (1490 cm^{-1}) relative to free tu (1476 cm^{-1}). A strong band at 282 cm^{-1} assigned to ν(MS) lends additional support to the presence of *S*-thiourea ligands. The reflectance spectra of $CrCl_3(N,N'\text{-}Et_2tu)_3$ and $CrCl_3(N,N'\text{-}Bu^ntu)_3$ are strikingly similar to that of $CrCl_3(tu)_3$ (λ_{max} = ~680, 510 nm) implying similar ligand fields in all three cases.[1045] No mention is made of the geometrical disposition of the ligands in any of these complexes.

$CrCl_3(tu)_3$ reacts with various Lewis bases in hot methanol solution as outlined in Scheme 102.[1043] Salient features of the IR spectra of a selection of these complexes are presented in Table 90. Application of the afore-mentioned criteria to the IR spectra of these products leads to the conclusion that in some cases the complexing site of tu changes from sulfur to nitrogen when heterocyclic amines or phenylarsonate ligands are introduced into the complex. In other cases, however, *e.g.* $[CrCl_2(py)_2(tu)_2]Cl$, for which both ν_{asym}(NCN) and ν(CS) occur at higher wavenumbers than the corresponding IR bands for free tu, no definite conclusions can be reached on the basis of IR spectra regarding the mode of ligand coordination. Clearly the IR data on their own are insufficient to establish structures with certainty and X-ray crystallographic studies are needed to clarify both the ligand donor sites and the geometrical configurations of these complexes. The preparation and spectra of complexes of general formula $M[Cr(NCS)_4(tu)_2]$ (M = K or various Ni^{II}–amine complexes) have been reported.[1046,1047]

[a] Rpy = pyridine; 2-, 3- and 4-methylpyridine; 2,4- and 2,6-dimethylpyridine. [b] Rquin = quinoline, isoquinoline and acridine. [c] L—L = phen or bipy.

Scheme 102

A number of substituted tu complexes of chromium(III) have been prepared and characterized. These include $[Cr(N\text{-}Metu)_6](ClO_4)_3$, $[Cr(N,N'\text{-}Me_2tu)_6](ClO_4)_3$, $CrCl_3(N\text{-}Metu)_3$, $CrX_3(N,N'\text{-}Me_2tu)_3$ (X = Cl, Br),[1048] and the *N*-phenylthiourea complexes $CrCl_3(N\text{-}Phtu)_3$ and $CrCl_3(N\text{-}RPhtu)_3$ (R = 2- or 3-Me; 2-MeO; 2-, 3- or 4-Cl; 3-Br; 4-I; 2-OH).[1049] Evidence from IR (Table 90) and electronic spectroscopy strongly suggests that in all these complexes the substituted tu ligands are coordinated through sulfur to the metal ion. Details of the electronic spectra of some of these complexes are given in Table 91. The ligand 3-(4-pyridyl)triazoline-5-thione (L) reacts with $CrCl_3 \cdot 6H_2O$ in refluxing EtOH to give the product *trans*-$[Cr(H_2O)_4L_2]Cl_3$ in which it is S-bonded to the metal ion.[1050] The mixed ligand chromium(III) complexes $[Cr(H_2O)_5Etu](OAc)_3$ and $[Cr(OAc)OH(T\text{-}5\text{-}T)] \cdot 2H_2O$, containing ethylenethiourea (Etu, an S donor) and 1-substituted tetrazoline-5-thiones (T-5-T; N,S donors) have been prepared and characterized.[1051]

Dissolution of thioureachromium(III) complexes in coordinating solvents such as MeOH, DMF, DMSO, MeCN generally results in solvolysis with replacement of the tu ligands.

35.4.6 Selenium and Tellurium Ligands

A number of binary and ternary compounds in the chromium–selenium and the chromium–tellurium systems have been investigated. These include CrSe, Cr_2Se_3, Cr_3Se_4, Cr_7Se_8, Cr_5Se_8, CrTe, Cr_2Te_3, Cr_3Te_4, Cr_5Te_6, Cr_5Te_8, Cr_7Te_8, $Cr_5S_{4.8}Se_{3.2}$,[981] $NaCrSe_2$, $CuCrSe_2$ and $AgCrSe_2$.[986] Some Se donor ligands are included in Section 35.4.5.2.

35.4.7 Halogens as Ligands

35.4.7.1 Simple halides CrX_3

These have been known for many years.[1052–1054] Chromium(III) is approximately octahedral ($\mu_{eff} = 3.69–4.1$ BM); the compounds have a layer structure. In the chloride, r(Cr—Cl) is 5.76 Å between layers and 3.46 Å within layers. The iodide is isomorphous with the chloride and the bromide has a similar but distinct structure. All may be prepared by the direct halogenation of the metal. Other methods are available, *e.g.* $CrCl_3$ may be prepared by heating $Cr_2O_3 \cdot xH_2O$ in CCl_4 vapour at 650 °C.[1055] The anhydrous halides are insoluble in water, however reducing agents such as zinc catalyze dissolution. The trichloride reacts with liquid ammonia to form ammine complexes.

35.4.7.2 $[CrX_4]^-$ and related ions

There has been some controversy[1056,1057] concerning the correct formulation of $[CrCl_4]^-$ ions in salts such as $[PCl_4][CrCl_4]$. In general the evidence supports polymeric six-coordinate anions.[1057] This is supported by a crystal structure of $K[CrF_4]$,[1058] which contains columnar $[CrF_4]^-$ ions. Related compounds such as $NaCrF_4$ [1059] and NH_4CrF_4 [1060] also involve six-coordinate chromium(III); these compounds are weak antiferromagnets. A related antiferromagnetic species is $MnCrF_5$, where a neutron diffraction study shows chromium(III) to be octahedral with a single bridging fluoride;[1061] this is an example of a general class of chromium(III) fluoro complexes $M^{II}Cr^{III}F_5$.[235] The anions $[CrCl_4(MeCO_2H)_2]^-$ and $[CrCl_5(MeCO_2H)]^{2-}$ are known (Scheme 92).

35.4.7.3 $[CrX_6]^{3-}$ anions

Complexes containing anions of the above formulation have attracted a large number of studies because of their alleged simplicity. This is illustrated by the central position such complexes have played in the evolution of crystal field, ligand field and molecular orbital models of bonding in transition metal complexes.

In a study of the heats of formation of first row transition metal fluorides, ΔH_f for K_3CrF_6 was found to be 2977 kJ mol^{-1}.[1062] The usual double-humped distribution of ΔH_f *vs.* d^n was

observed. Semi-empirical[1063] and self-consistent-field molecular-orbital calculations[1064] give similar results for the $[CrF_6]^{3-}$ ion and are in accord with the observed electronic spectrum.[1065] These studies are summarized in Table 92.

7. Ref. 1063.

Luminescence spectrocopy is potentially a powerful technique for studying chromium(III) complexes and a series of fluoro and aqua complexes have been studied.[1066] The luminescence correlates well with ligand field strength and, at liquid air temperatures, the lifetime of the doublet state from which phosphorescence originates is 2×10^{-7} s^{-1}.

A detailed study of the spin density and bonding of the $[CrF_6]^{3-}$ ion in $K_3[CrF_6]$ has appeared.[1067] The results of polarized neutron diffraction experiments[1068] were reinterpreted. A chemically based model of the $[CrF_6]^{3-}$ ion has been fitted to the 92 observed magnetic structure factors by a least squares procedure. The spin density in the chromium(III) orbitals has t_{2g} symmetry ($t_{2g}^{2.66(5)}$, $e_g^{-0.06(5)}$). There is also a region of spin density centred on the chromium atom, radially more diffuse than the theoretical 3*d* orbital and containing 0.4(1) spins parallel to the spin density of t_{2g} symmetry. There are small parallel spin densities in $2p_\pi$ of fluoride and antiparallel spin populations in fluoride $2p_\sigma$ and along the Cr—F vector. There is no significant spin population in fluoride 2*s*. The results of this modelling are in agreement with X_α,[1069] semi-empirical[1070] and *ab initio* molecular orbital calculations.[1071] The magnetic circular dichroism of chromium(III) in dicesium yttrium hexachloride has been studied[1072] down to 6 K. Transitions to all three quartet terms, $^4T_{2g}$ and $^4T_{1g}$ (I and II), were observed. The parameters $D = 1280\ cm^{-1}$ and $a = 78.2\ cm^{-1}$ were determined. At 6 K rich vibronic fine structure was observed, which could satisfactorily be explained only in terms of O_h geometry.

35.4.7.4 *Dimeric structures*

Many complexes contain the $[Cr_2X_9]^{3-}$ ion.[1073–1076] This unit consists of two distorted octahedra which share a face; there are three bridging and three terminal halides (**226**). The distortion of the octahedron is such that the two metal ions are displaced from each other. The magnetic properties of these complexes have been the subject of extensive study summarized in Table 93.

(**226**) Typical structure of a $[Cr_2X_9]^{3-}$ ion

The complexes undergo weak antiferromagnetic interactions with exchange proceeding *via* the halide bridges. The counterion may have a marked effect on the structure; for $[Cr_2Cl_9]^{3-}$, change of the counterion from potassium to tetraethylammonium is accompanied by a decrease

in J from 16 to 5 cm^{-1}. An extreme example of similar behaviour is $[Et_4N]_3[Cr_2Br_9]$ which obeys the Curie–Weiss law.

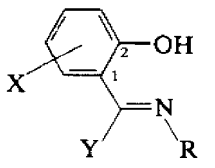
The vibrational spectra of $[Cr_2X_9]^{3-}$ have been variously studied.[1077,1078] The agreement between observed and calculated spectra was excellent for D_{3h} symmetry; no evidence was found for any Cr—Cr interaction.[1077] In related work, the doping of chromium(III) ions into $CsMgCl_3$ and related materials has been investigated.[1079,1080] ESR spectroscopy has shown that there is a distinct tendency for chromium ions to cluster in pairs [for single crystals with 1 part in 1000 chromium(III)]. $CsMgCl_3$ adopts the $CsNiCl_3$ structure (**227**); the structure proposed for the impurity centre is illustrated. The forces controlling the distribution of ions were held to be electrostatic; other trivalent metal ions should behave in a similar way to chromium(III).

(**227**)

A perspective view of an $[MX_3^-]_n$ chain showing the proposed structure of the Cr^{III}—Cr^{III} pair. The corners of the octahedra are occupied by halide ions.[1080]

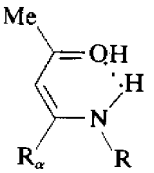
35.4.7.5 Solution chemistry

Werner's early work on coordination chemistry involved the preparation of many of the isomers in the $CrX_3 \cdot nH_2O$ system.[1081,1082] Crystal structures are available for several of these



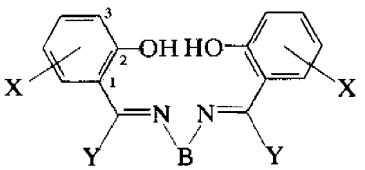
complexes. The green complex *trans*-$[Cr(H_2O)_4Cl_2]Cl{\cdot}2H_2O$, the normal compound supplied as chromium(III) chloride, has been studied on a number of occasions.[1083,1084] Recently a low-temperature structure of the complex dicesium *trans*-dichlorotetraaquachromium(III) trichloride[1085] was determined; the electronic spectrum was also studied. The mechanism of the geometric isomerization of the dichloro complex has been investigated.[1086] The pure *cis* complex may be prepared by the aquation of trichloro complexes followed by purification by ion-exchange chromatography.[1086]

The formations of chloro,[1087,1088] bromo[1089] and iodo[1090] complexes have been studied. Recently, electrochemical methods have been used to measure equilibrium constants for the formation of chloro (0.086), bromo (1.1×10^{-3}) and iodo (1.1×10^{-5}) complexes of chromium(III).[1091]



35.4.8 Mixed Donor Atom Ligands

35.4.8.1 Schiff's bases, β-ketoamines and related ligands



Compared with other transition elements,[1092] few complexes of Schiff's bases or β-keto amines with chromium(III) are known. Most work has been done with ligands (**228**) to (**231**) and their complexes and the interrelations between the more important of them are set out in Table 94 and Schemes 103 and 104.

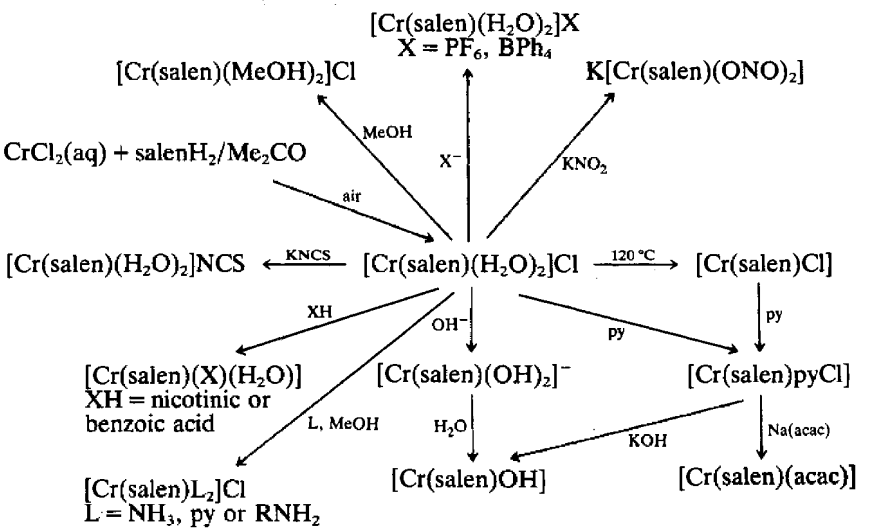
X = 3-CO_2H, Y = H, B = $(CH_2)_2$: 3-CO_2salenH$_2$

(**231**) acacenH$_2$

(i) Syntheses

Many preparative methods have been used, with variable success: oxidative decarbonylation of $Cr(CO)_6$ by the ligand,[1093,1094] reaction of the appropriate amine with $[Cr(sal)_3]$ (salH is salicylaldehyde), reaction of the ligand, either produced in the reaction mixture or preformed,[1095] with hydrated or anhydrous $CrCl_3$, hydrated Cr^{III} acetate,[1096] or $[CrCl_3(THF)_3]$,[1097–1099] and aerial oxidation of the chromium(II) complex produced *in situ*.[1099–1101] No well-established chromium(II) complexes, except of a few β-keto amines (Section 35.3.9.1), have been isolated.

The source of Cr^{2+} can be $[Cr_2(MeCO_2)_4(H_2O)_2]$,[1100] aqueous Cr^{2+} produced by the reduction of Cr^{3+} electrolytically[1101] or by Zn/Hg in hydrochloric acid,[1099] or anhydrous or hydrated $CrCl_3$ reduced by zinc dust in suspension in the reaction mixture.[1100,1102] Presumably the ligands can displace solvent molecules more readily from the labile Cr^{2+} species.



Several hours reflux in organic solvents is usually required for preparations directly from chromium(III) starting materials. No method is of general applicability; for example, $[Cr(salen)(H_2O)_2]Cl$ (Scheme 103) is readily prepared from $[Cr_2(MeCO_2)_4(H_2O)_2]$ but this method affords $[Cr(acac)_3]$ with acacenH$_2$.[1100]

Scheme 103

DMP is 2,2-dimethoxypropane

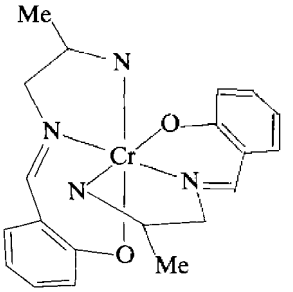
Scheme 104

Since oxidation of [Fe^{II} salen] gives $\{Fe(salen)\}_2O$, the formation of $[Cr(salen)(H_2O)_2]Cl$ from Cr^{II} solutions is unexpected, but it is consistent with the observation[1103] that aerial oxidation of aqueous chromium(II) leads to the formation of hydroxo or aqua species. The elusive $\{Cr(salen)\}_2O$ was eventually prepared by oxidative decarbonylation[1094] of $Cr(CO)_6$ by [Hg(salen)], a method which could have more general application. The reaction of $salenH_2$ with $Cr(CO)_6$ gives a product similar to $[Cr(salen)(OH)]\cdot 0.5H_2O$.[1099] Dichromium and mixed metal μ-oxo complexes such as (TPP)CrOFe(TPP) are now known (Section 35.4.9.1).

Complexes obtained by methods similar to those in Scheme 103 include $[Cr(salen)(H_2O)_2]ClO_4$,[1101] $[Cr(salen)(X)(H_2O)]$ (XH = nicotinic acid or benzoic acid),[1104] $[Cr(salen)X(H_2O)]$ ($X = NCS^-$ or N_3^-),[1105] $[Cr(salphen)(H_2O)_2]X$ ($X = Cl^-$ or OAc^-),[1106] $[Cr(salen)(AA)]BPh_4$, $[Cr(salphen)(AA)]ClO_4$ (AA = bipy, phen or en).[1107] Complexes related to those in Scheme 104 are $[Cr(acacen)A_2]BPh_4$, [Cr(acacen)ClA], [Cr(acacen)(NCS)A], $[Cr(acacen)A_2]ClO_4$, $[Cr(acacen)(H_2O)_2]SCN$ (A = py or 4-methylpyridine)[1108] and $[CrL(H_2O)_2]Cl$, in which L is formed from acac and benzidine.[1109] The salts $[Cr(L)(NH_3)_2]SCN$ (L = salen, salphen or Mesalen) have been prepared[1100] from $NH_4[Cr(NCS)_4(NH_3)_2]$.

(*ii*) *Properties*

Photolysis of the azido complex $CrN_3(salen)\cdot 2H_2O$ produces[1110] the nitrido chromium(V) complex $CrN(salen)\cdot H_2O$ and the reaction[1111] of $[Cr(salen)(H_2O)_2]^+$ with iodosylbenzene gives the oxo chromium(V) derivative $[CrO(salen)]^{2+}$; chromium(III) porphyrin complexes behave similarly (Section 35.4.9.1).

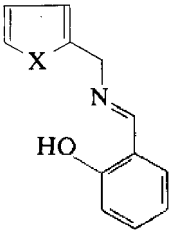


As expected for chromium(III), the complexes generally possess magnetic moments near 3.8 BM at room temperature. A few, ($H[Cr\{C_6H_4(CHNR)O\}_2]$ ($R = o\text{-}C_6H_4OH$ or CH_2CH_2OH)[1100] and $[Cr(salen)(OH)]\cdot 0.5H_2O$) have low moments (≈3.5 BM) ascribed to antiferromagnetic interactions. The magnetic susceptibility of $[Cr(salen)(OH)]\cdot 0.5H_2O$ deviates markedly from the Curie law, but as the results were sample-dependent, no detailed interpretation was attempted.[1099] The room temperature magnetic moment of $\{Cr(salen)\}_2O$ is 2.2 BM, consistent with an oxo-bridged structure. The ESR spectrum confirms that the chromium is trivalent,[1094] so further magnetic and structural investigations are desirable.

The complexes have yellow to red colours and the electronic spectra are dominated by intense ligand absorptions. A weak band ususally found in the range 18 000 to 21 000 cm^{-1} has been assigned to the $^4A_{2g} \rightarrow {}^4T_{2g}$ transition and provides an approximate value for Δ.

The *trans* structure of the cation in $[Cr(salen)(H_2O)_2]Cl$[1099] and the *mer* arrangement of the tridentate ligands in $[Cr(en\text{-}sal)_2]I$ [en-sal is *N*-(2-aminoethyl)salicylaldimine)] have been confirmed by single-crystal X-ray investigations ($Cr—O_{(av)} = 1.93$, $Cr—N_{(av)} = 2.08$ Å).[1112] In $[Cr(salen)(H_2O)_2]Cl$, the Cr—N bond lengths are 1.977 and 2.005 Å, but the Cr—O distances vary considerably (1.916 and 1.951 Å (salen); 1.923 and 2.085 Å to H_2O) and the angles at the chromium atom are distorted from right angles. The ground-state distortion has been related to the lability of the axial ligands.[1113] There must be considerable distortion of salen and acacen from their usual essentially planar geometry in complexes such as [Cr(acacen)(acac)].

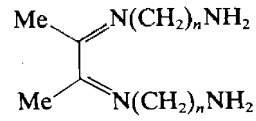
The complexes $[Cr(en\text{-}sal)_2]X$ were prepared (Table 94) in conditions which could have given [Cr(salen)X], but, as indicated by other data and confirmed by the crystal structure of the



iodide, en and salH condensed to give the tridentate ligand en-sal. The solubility of the nitrate has been exploited[1114] in the resolution of $[Cr(en\text{-}sal)_2]^+$ as the hydrogen (*R,R*)-*O,O'*-dibenzoyltartrate. The diastereoisomers were converted into the iodides which formed twinned crystals unsuitable for X-ray investigation. When (*R*)-1,2-diaminopropane (*R*-pn) is used instead of ethylenediamine in the reaction with $Cr(sal)_3$, the salicylaldehyde may condense with either NH_2 group. The product was (**232**), with the ligands meridional, as expected, and the $—CH_2NH_2$ groups condensed.[1115]

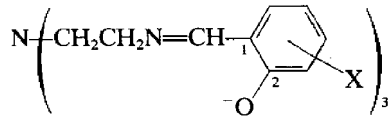
(**232**)

Tris[*N*-(*R* or *S*)-α-benzylethyl-5-nitrosalicylaldiminato]- and tris[*N*-(*R* or *S*)-α-phenylethyl-5-nitrosalicylaldiminato]-chromium(III) have been prepared[1116,1117] from the (*R*)- or (*S*)-amine as appropriate. For ligands of a given chirality, four diastereoisomers are possible (*fac,* Δ and Λ; *mer,* Δ and Λ). Chromatographic separation of the complex with R = (*S*)-α-CH(Bz)Me gave two products A and B (the more rapidly eluted), and with R = (*R*)-α-CH(Bz)Me, A′ and B′ were obtained. A and A′ have identical absorption spectra but from their CD spectra have opposite configurations about the metal. Since they differ in ligand chirality also, they are enantiomers. Steric effects would favour the *mer*(*trans*) configuration, and the corresponding cobalt(III) complexes, which chromatographically separate similarly, have been assigned *mer* configurations from their ^1H NMR spectra. Analogous relationships were found among the pair of diastereoisomers obtained with R = (*R*)- or (*S*)-α-CH(Ph)Me. The more rapidly eluted isomers are thought to have the Λ-*mer* configuration from analogy with the cobalt(III) case, and because studies with the chiral β-diketonate (+)-3-acetylcamphor have shown that diastereoisomers with the same absolute configuration have the same relative rates of elution. The isomers did not interconvert under reflux in the presence or absence of charcoal.



The complexes CrL_3, where LH is formed by condensation of salicylaldehyde with 2-furfurylamine or 2-thenylamine, contain the ligand in isomeric form (**233**).[1118]

(**233**) X = O or S



The addition of en or 1,3-diaminopropane to a mixture of chromium(III) acetate hexahydrate and diacetyl under reflux, followed by addition of $NaClO_4$, has given the complexes $[Cr(diacen)(H_2O)_2]ClO_4$ and $[Cr(diacpn)(H_2O)_2]ClO_4$, which contain the tetradentate Schiff bases (**234**).[1119] The thiocyanates $[CrL(H_2O)(NCS)](NCS)_2$ were also isolated. From their IR spectra, and because the coordinated Schiff base would not react with another molecule of diacetyl to form a macrocycle, they have been assigned *cis* configurations.

In the chromium(III) complex of the potentially heptadentate ligand (**235**, X = 5-Cl) the apical nitrogen atom is not bonded, the Cr—N distance being 3.229 Å. The Cr—O (1.979 Å) and Cr—N (2.137 Å) bonds are longer than in $[Cr(salen)(H_2O)_2]Cl$ and $[Cr(en\text{-}sal)_2]I$ (see above) and the ligand seems to fix a minimum sized 'hole' into which the metal ion fits.[1120] The

(**234**) diacen, $n = 2$
diapn, $n = 3$

Mn^{III} and Fe^{III} complexes are isomorphous with the Cr^{III} complex. The chromium(III) complexes with X = H, 3-OMe, 5-Cl, 5-Br, 5-Me[1121] or 3,5-Cl_2 [1122] have been prepared by methods similar to those for the salen derivatives.

(**235**)

Chromium(III) does become seven-coordinate in two complexes in which the organic ligands are formed by condensation respectively of 2,6-diacetylpyridine and semicarbazide,[1123] and 2,6-pyridinedialdehyde and 6,6′-bis(α-2-hydroxyethylhydrazino)-2,2′-bipyridyl.[550] Seven-coordinate complexes are formed by chromium in several oxidation states (Table 95).

Table 95 Seven-coordinate Chromium[a]

Chromium(III) is also in an unusual situation in the heterobinuclear complex (**236**) synthesized by the addition of $CrCl_3 \cdot 6H_2O$ to Cu(3CO_2-salenH_2).[1124] There is ferromagnetic interaction between the Cu^{II} and Cr^{III} ions because of the orthogonality of the magnetic orbitals (quintet–triplet separation = 120 cm^{-1}).

Chromium(III) complexes of Schiff bases derived from pyridoxal and glycylglycine have been prepared in solution in attempts to find complexes that show good intestinal absorption[1125] (see also Section 35.4.8.3).

(*iii*) *Miscellaneous Schiff's base and related complexes*

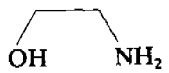
Often, in studies of complexation between metal ions and the great variety of Schiff's base and related ligands, chromium(III) complexes are included amongst many from the first

(236) $[CuCr(3\text{-}CO_2salen)(H_2O)_2]Cl{\cdot}3H_2O$

transition series generally. These Cr^{III} complexes are typical of the oxidation state with no unusual properties. Consequently, only examples are collected in Table 96.

(iv) Organometallic derivatives

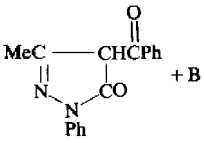
Although tetradentate Schiff's bases stabilize Co^{III}–alkyl σ bonds this behaviour is less common with Cr^{III}. Several perfluoroalkyl derivatives have been obtained by Scheme 105 and the same method yields complexes of bidentate ligands too: $R_FCr(sal\text{-}NR)_2py$, $R_F = C_2F_5$, C_3F_7, $R = 4\text{-}MeC_6H_4$; $R_F = C_3F_7$, $R = Bu^n$; and $C_3F_7CrL_2py$ where LH = salH, acacH or bzacH. The intermediates '$R_FCrCl_2(MeCN)_3$' have not been isolated, but pyridine, bipy, phen and terpy analogues have (Scheme 105). An incompletely characterized mixed chloro–iodo–chromium pyridinate separates first in the reaction with pyridine and is removed before crystallization of $[C_3F_7CrCl_2(py)_3]$. The perfluoroalkyl–chromium(III) derivatives are stable, their electronic and ESR spectra resemble those of other Cr^{III}–salen complexes but the magnetic moments are higher than usual.[1126,1127]

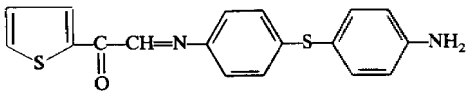


Alkyl halides would not react with $[CrCl_2(MeCN)_2]$, but the alkyl derivatives $[RCr(salen)(H_2O)]$ and $[RCr(salphen)(H_2O)]$ (R = Me, Ph) are said to form on reaction of the organic hydrazines with the Cr^{III}–Schiff's base complexes in MeCN under nitrogen followed by oxidation with oxygen and hydrolysis.[1128]

35.4.8.2 Miscellaneous mixed donor atom ligands

(i) Complexes of N—O chelating ligands





The majority of papers concerned with such complexes are synthetic studies of six-coordinate species with octahedral ligation. In general, such complexes have magnetic moments in the range of 4.0 BM and electronic spectra which have usually been assigned under pseudo-octahedral symmetry. Such studies are summarized in Table 97. A number of ligands have received considerably more attention; these are now considered individually.

There have been a number of studies of ethanolamine (**237**) complexes of chromium(III). A tris complex with deprotonated alcohol groups $[Cr_2(Eta)_3]{\cdot}3H_2O$ and a more complicated complex $[Cr_2(Eta)_3(HEta)_3][ClO_4]_3$ have been prepared.[1129] The tris complex was prepared by reacting anhydrous $CrCl_3$ with 2-aminoethanol for 24 h, followed by recrystallization. The complex $[Cr_2(Eta)_3(HEta)_3][ClO_4]_3$ was prepared by hydrolysis of the tris complex in aqueous ammonium perchlorate. Electronic spectra of $[Cr(Eta)_3]$ were consistent with chelated amino alcohol ligands, though isomerism was not considered. The solid complex $[Cr_2(Eta)_3(EtaH)_3](ClO_4)_3$ was nearly isomorphous with the corresponding cobalt(III) complex. The similarities would suggest a structure involving a hydrogen-bonded dimer with three protons holding two facial $[Cr(Eta)_3]$ molecules together. Other studies of chromium(III) 2-aminoethanol complexes have led to the isolation of tris complexes and dinuclear complexes of various compositions.[1130,1131,1132,1134,1135]

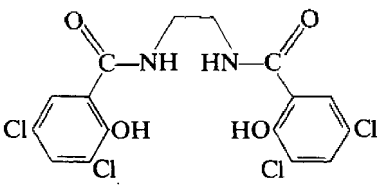
Picolinic acid (pyridine-2-carboxylic acid) complexes of chromium(III) have been the subject of a number of studies. Complexation by picolinic acid in water/ethanol (30% v/v) follows an ion-pairing, Eigen–Wilkins type mechanism.[1136] Activation parameters suggest an associative character for the reaction of the aqua complex. Chelated complexes of chromium(III) and picolinic acid are the products of the rapid, inner-sphere reduction of $[Co^{III}(pico)(NH_3)_5]^{2+}$ with chromium(II).[1137] The reaction of the related 4-carboxylic acid complex of cobalt(III) with chromium(II) is also rapid; in contrast, pyridine-3-carboxylic acid (nicotinic acid) complexes undergo slower reactions. A μ-hydroxy-bridged dimeric complex $[Cr_2(pico)_4(OH)_2]$ has also been prepared. A study of magnetic properties in the temperature range 16–300 K leads to $J = -6\,cm^{-1}$ and $g = 2$, typical for such complexes.[1138]

Complexes of 8-hydroxyquinoline and chromium(III) have been known for many years.[1139] Complexes have been mercurated and the deuterated quinoline isolated.[1139] The bromination of chelated 8-hydroxyquinoline proceeds about thirty-five times faster than that of the free ligand.[1140] Tris(8-hydroxyquinolinato)chromium(III) absorbs large amounts of hydrochloric, hydrobromic and hydrofluoric acids. Chemical reaction with the complex was considered a more likely explanation than solid solution or clathrate formation, even though more than one mole of acid was absorbed per mole of complex.[1141]



The complex diaqua[2,6-diacetylpyridinebis(semicarbazone)]chromium(III) hydroxide dinitrate hydrate (**238**) has a most unusual structure.[1123] Chromium(III) is coordinated in an approximate pentagonal bipyramid (PBP), with the ligand forming the pentagonal plane and

two water molecules in the axial positions. The solution magnetic moment is 4.05 BM. An interesting feature of such a complex is that a regular PBP would lead to a single unpaired electron in the degenerate $d_{x^2-y^2}$ or d_{xy} orbitals. The distortion of the ligand plane removes this degeneracy and provides the first examples of the Jahn–Teller effect in a pentagonal bipyramidal complex (Table 95).

(238)

The coordination of chromium(III) is also unusual in the dimeric complex [Cr{H(chba-Et)}(py)$_2$]$_2$·2py (**239**)[519] (H$_4$(chba-Et) = 1,2-bis(3,5-dichloro-2-hydroxybenzamido)ethane). The structure of this complex is described in Section 35.4.2.11.

(239)

(ii) Chelating ligands containing sulfur and related donor atoms

There are a number of papers reporting the synthesis and characterization of monomeric complexes of this type; the more significant and/or recent are summarized in Table 98.

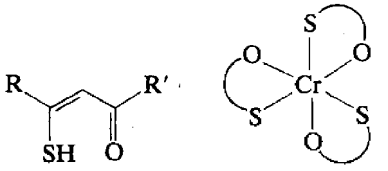
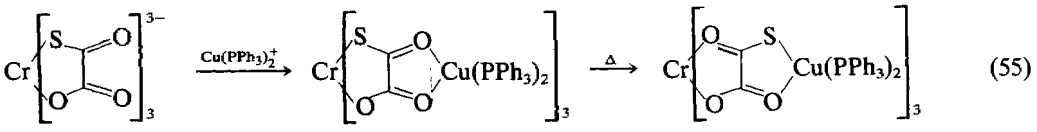
The complex bis(2-mercaptoethylamine)ethylenediaminechromium(III) perchlorate has been prepared by the reaction of cystamine with aqueous solutions of chromium(II) in the presence

of ethylenediamine.[1142] The complex crystallizes from aqueous solution to form opaque violet rectangular bipyramids, the crystal structure of which has been determined. The reaction was said to go *via* an intermediate (**240**) to the chromium(III) complex (**241**) which underwent rapid ring closure. The stereochemistry of (**241**) is dictated by the strong Jahn–Teller effect in the chromium(II) precursor (**240**). A series of thiolato complexes, *e.g.* $[Cr(H_2O)_4SCH_2CO_2]^+$, has been oxidized with H_2O_2.[976] The chromium(III) complexes thus formed, in contrast to the cobalt(III) analogues, decompose, presumably *via* an unstable sulfanato–chromium(III) intermediate.



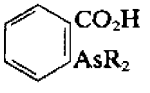
(**240**)



(**241**)

The complexes of the monothio-β-diketonate RC(SH)=CHCOR′ (R = R′ = phenyl; R = phenyl, 2-thienyl, β-naphthyl; R′ = CF_3), which are acetylacetonate analogues have been synthesized (**242**).[1143] Dipole moment measurements are consistent with facial structures (**243**). Mass spectra indicate no metal-containing peaks for the complex $[Cr(PhC(S)=CHCOPh)_3]$: however, for the fluorinated monothio-β-diketonates, various metal-containing peaks, *e.g.* M—2L=F, *were* observed. Such ions involve fluoride migration. Monothiooxalate complexes of chromium(III) have been prepared; fairly unusual complexes, exemplified by $[Cr\{(C_2SO_3)Cu(Ph_3)_2\}_3]$, were reported. On refluxing under chloroform (7 h) reactions of the kind illustrated were alleged to occur (equation 55).[1144]

(**242**)

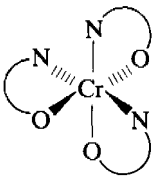


(**243**)

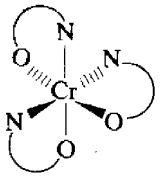
(**244**) (**245**) (**246**) (55)

The complexes formed between thioglycolic acid (mercaptoacetic acid) and chromium(III) have been investigated.[1145] In alkaline solutions above 60 °C, a blue green complex $[Cr(SCH_2CO_2)_3]^{3-}$ is formed. In acidic solutions, two red complexes $[Cr(H_2O)_4(SCH_2CO_2H)]^{2+}$ and $[Cr(H_2O)_2(SCH_2CO_2H)_2]^+$ are predominant with a species $[Cr(H_2O)_2(SCH_2CO_2)_2]^-$ detectable at neutral values of pH. The rates of ring opening and closure for the chromium(III) mercaptoacetate complex $[Cr(H_2O)_4SCH_2CO_2]^+$ have been measured.[1146]

A large number of complexes with arsenic-containing ligands have been reported (**247**). Three types of complex of formula $CrO(o\text{-}R_2AsC_6H_4CO_2)\cdot nH_2O$, $Cr(Ph_2AsC_6H_4CO_2)_2(OH)\cdot 2.5H_2O$ and $Cr(o\text{-}R_2AsC_6H_4CO_2)(OH)_2\cdot nH_2O$ were prepared. The authors concluded that arsenic was probably not coordinated to the chromium in any of these complexes.[1147]

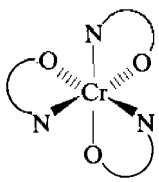


(**247**)

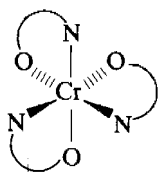


35.4.8.3 Amino acids

(i) Potentially bidentate amino acids



Complexes of simple amino acids with chromium(III) were first prepared by Ley.[1148] The isomers possible for tris chelated complexes of this type are illustrated below (**248–251**). The consequences of such isomerism were first seriously considered by Gillard.[1149] Red complexes of the formulae $[Cr(gly)_3]$ and $[Cr(L\text{-}ala)_3]$ were prepared by neutralizing refluxed solutions of hexaaquachromium(III) and the amino acid in ratios between 1:5 and 1:10. These complexes were shown to be isomorphous with β-$[Co(gly)_3]$ and D-β-$[Co(L\text{-}ala)_3]$ respectively. The crystal structure of red β-$[Cr(gly)_3]$ has also been reported.[1150]



(**248**) Δ-α

(**249**) Λ-α

(**250**) Δ-β

(**251**) Λ-β

There is some controversy concerning the existence of the α isomers of these tris complexes. Israily[1151] reported a purple complex to be α-$[Cr(gly)_3]$; however, subsequent workers have shown that this substance most probably was the dihydroxy dimer $[Cr_2(gly)_4(OH)_2]$.[1149,1152,1153] Careful chromatography, on potato starch, of solutions from chromium(III)/glycine reactions yielded red and purple fractions,[1153] the electronic spectra of which were consistent with β and α isomers respectively. Solutions of the 'α complex' were unstable even in the dark and cold. Hoggard has recently claimed[1154] the preparation of the α isomer of the glycine complex by a fractional crystallization. The complex was anhydrous, unlike its cobalt(III) analogue. X-Ray powder methods could hence not be used to confirm the identity of the complex; the luminescence spectra were held to be consistent with meridional coordination. There have been a number of studies of the physical properties of β-$[Cr(gly)_3]$, summarized in Table 99.

Table 99 Physical Properties of Tris Amino Acidates

Many other amino acids form complexes which are red β isomers with 'glycine-like' coordination at chromium(III). The complexes are most frequently prepared by refluxing the amino acid with chromium(III), followed by neutralization. The problem with this kind of method is that significant quantities of the corresponding bridged hydroxy complex are formed; indeed the solid tris complexes are converted to such complexes on standing under water. Repetition of the literature preparations of these complexes is often difficult and the ease of hydrolysis/kinetic inertness of chromium(III) probably leads to some of the discrepancies in the literature. An approach which potentially avoids the problems of hydrolysis is solid-state synthesis. Amino acid complexes have been prepared by heating (135 °C) solid hexaamminechromium(III) nitrate with the amino acid followed by recrystallization. Complexes of glycine, (±)-alanine, (±)-isoleucine, (±)-leucine, (±)-aminobutyric acid,

(±)-norvaline and (±)-valine[1155] have been prepared by this method as have the corresponding L-amino-acid complexes.[1156] In general, *β-fac* isomers were obtained. In related work, complexes of various basic amino acids were prepared.[1157] The tris complex of (±)-methionine has been prepared by conventional methods.[1158] A number of simple mixed complexes of amino acids with chromium(III) and aminoethanol or 2,2′-iminodiethanol have been reported.[1159]

(*ii*) *Hydroxy-bridged complexes*

These are extremely common and can be a problem when the synthesis of the related tris complexes is being attempted, particularly as they are of rather limited solubility. They have been known for many years.[1148,1160,1161] The isomers possible for these species are profuse.[1149] For the general formula $[(aa)_2Cr\text{-}(\mu\text{-}OH)_2Cr(aa)_2]$ there are three possible geometric configurations about each metal ion: *trans* N *cis* O, *cis* N *trans* O and *cis* N *cis* O. In addition, each metal ion is a dissymmetric centre bringing the total number of geometric and optical isomers to 21.

A crystal structure of the all-*trans* isomer of $[Cr_2(gly)_4(OH)_2]$ has been reported.[1162] Its low temperature magnetic susceptibility has been fitted to both the Van Vleck and modified Van Vleck models. The uncorrected model leads to $\mu_{eff} = 3.80$ BM with $2J = 8.4\ cm^{-1}$;[1162,1163,1164] with the inclusion of quadratic exchange $2J = 7.4\ cm^{-1}$.[1162] Related studies of alanine,[1153,1165] valine, phenylalanine, leucine,[1163,1149] proline[1166,1167] and histidine[1168] complexes have appeared. The proline complex is unusual in that it is soluble in methanol and DMSO. Circular dichroism spectra have been measured; the X-ray structure shows the complex to be the L-*trans*(N), L-*trans*(O) isomer.[1166] More complicated dimers of unusual stoichiometry have been reported.[1169]

(*iii*) *Solution studies*

Stability constant determinations are few;[1170] they are summarized in Table 100. Complexation by acidic amino acids is obviously of relevance to the tanning of leather; the stability constants for L-glutamic and aspartic acid[1171] complexes are much greater than those for glycine or L-alanine.[1172,1173,1174] This is probably because the acidic amino acids form tridentate complexes. In contrast, cysteine[1173] appears to form glycine-like complexes in moderately acidic solution; however, in the solid state L-cysteine is known to be tridentate (*vide infra*).

Table 100 Typical Equilibrium Constants of Amino Acid Complexes[a]

Ligand	K_1	K_2	*Conditions*	*Ref.*

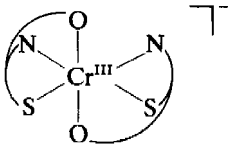
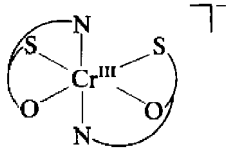
4. A. A. Khan and W. U. Malik, *J. Indian Chem. Soc.*, 1963, **40**, 565.
5. Ref. 1173.
6. Ref. 1174.

Kinetic studies have concentrated on the glycine system.[1174,1175,1176] In the pH range 3.0–3.8 (40 °C), the reaction proceeds by acid-dependent and -independent paths; reaction *via* the hydroxy complex is probably I_d, whereas the aqua complex appears to undergo I_a substitution.



In more acidic solutions, monodentate O-bonded complexes are formed.[1177,1175,1178] Ring closure is rapid if the pH is raised; γ, δ and ε amino acid complexes do not undergo ring closure.[1179]

(*iv*) *Potentially tridentate amino acids*

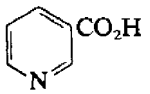


For tridentate amino acids with three non-equivalent donor atoms such as L-aspartic acid or L-cysteine, the isomers possible are illustrated below (**252–254**). There have been a number of reports of the preparation of L-aspartic acid complexes.[1180,1181,1182]. In the earlier work the isomers were not identified, however in the later study, the complexes were tentatively identified by comparison of their spectroscopic properties with those of the corresponding cobalt(III) complexes.[1183] The order of elution of the complexes on HPLC was also similar to that observed for the corresponding cobalt(III) complexes. Mixed complexes containing L- or D-aspartate and L-histidine were also prepared.[1182] A crystal structure of one salt obtained from this kind of system, bis(L-histidinato-*O*,*N*,*N*')chromium(III) nitrate, has been determined.[1184]

(252)

(253)

(254)



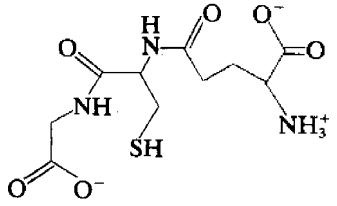
Sodium bis(L-cysteinato)chromate(III) dihydrate has been prepared by refluxing L-cysteine with chromium(III) nitrate and neutralizing the solution.[1185]. The product is a dark blue solid in which cysteine is coordinated with the sulfur atoms *trans* (see **252–254**). A number of chloro and other complexes of cysteine and related amino acids have been studied.[1186] A related complex L-histidinato-D-penicillaminatochromium(III) has been prepared[1187] and its crystal structure reported.

The reaction of chromium(III) with D-pencillamine has been investigated.[1188] Chromium(III) complexes are also rapidly obtained as the products of the reaction of chromium(VI) with D-penicillamine. Several complexes were prepared including a monomeric (S,N,O chelate); equilibrium constants were measured. These studies may be relevant to the treatment of chromium(VI) toxicity with D-penicillamine (see biological chromium(VI) chemistry p. 947). Unusual S-bonded complexes of chromium(III) have been prepared by reacting aqueous solutions of chromium(II) with $[Co(en)_2(L\text{-}cys)]^{2+}$ or the corresponding methionine complex.[1189] Under the fairly acidic conditions used, S,O [excess of chromium(II)] or S,N [limiting chromium(II)] complexes were obtained; these both eventually rearranged to give O,N species.

(*v*) *Chromium(III) and glucose tolerance*

Chromium was recognized as an essential trace element in 1955.[1190] Rats fed a chromium-deficient diet developed an impaired tolerance for intravenous glucose, which could be reversed by an insulin-potentiating factor present in brewer's yeast, meat and various other foods. The insulin-potentiating factor was found to be a complex of chromium(III)[1191] and such substances have been termed Glucose Tolerance Factor(s) (GTFs). Chromium was demonstrated to be essential for humans in 1975.[1192] There are several reviews of the chemistry of chromium(III) and its relationship to glucose tolerance.[1193–1196]

A detailed procedure for the extraction of GTF from *Saccharomyces carlsbergenis* has been reported,[1197] involving ethanolic extraction, hydrolysis and ion exchange chromatography. Nicotinic acid (**255**) was detected in the complex by its characteristic UV and mass spectra. Glycine, glutamic acid and cysteine together with trace amounts of other amino acids were found in the purified sample of GTF. This is probably the most refined GTF yet isolated. Although IR spectra were recorded, no detailed spectroscopic studies were undertaken, which is unfortunate as studies of the ligand field spectra might help to suggest likely structures.

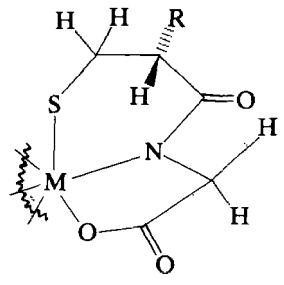


(255)

Nicotinic acid is present in the more active GTF preparations isolated from yeasts. The coordination chemistry of this ligand is particularly relevant to glucose tolerance and the presence of this substance is apparently essential for the maximal activity of complexes in tests *in vitro*. The instability of highly purified GTF fractions has frequently been noted; this may arise because the substance *in vivo* is stabilized by a protein.

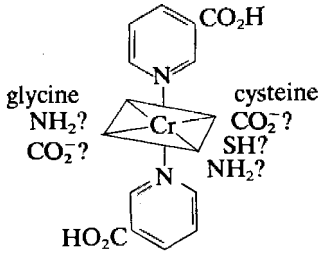
The synthesis and characterization of materials showing biological activity similar to that of GTF isolated from yeast is a logical objective. As already mentioned, Mertz found aqua and similar complexes of chromium to be more active than chelates with strong ligands. An exception to this was an unspecified cysteine complex,[1193] prepared by C. L. Rollinson, which showed marked, but erratic, behaviour in GTF tests. Further investigation of this observation would be interesting, particularly as the crystal structure of a cysteine complex is now known.[1185]

A complex with considerable activity in tests *in vitro* has been synthesized[1197] by reacting chromium(III) acetate in 80% alcohol with two equivalents of nicotinic acid followed by the addition of one equivalent, in turn, of glycine, glutamic acid and cysteine. A complex containing nicotinic acid was isolated from the reaction mixture by ion exchange chromatography. The physical properties and biological activity of this complex were very similar to those of GTF isolated from yeast.[1197] Although this material is probably a mixture, it should be further investigated as it is one of the most potent synthetic materials yet obtained.



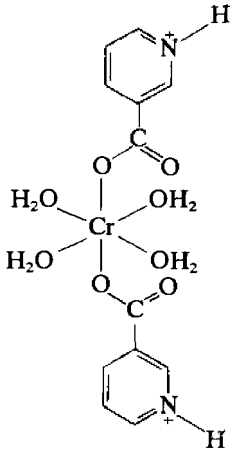
The amino acids believed to be involved in GTF are the constituents of the naturally occurring tripeptide glutathione (**256**). Anderson *et al.* have reported a complex of glutathione/nicotinic acid and chromium(III) to be particularly active in their *in vitro* assay.[1198] The complex was described as being purified by HPLC, but the details of the preparation are not available.

(**256**) Glutathione (GSH)
(shown as $[H_4L]^-$)



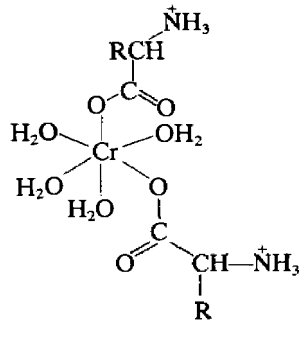
Recently, three different kinds of compounds containing chromium(III) and glutathione have been synthesized:[1199] a bisglutathione complex $K_2[Cr(H_3L)(H_2L)]$, mixed complexes with the amino acids L-cysteine, L-glutamic acid and L-aspartic acid $K_2[Cr(H_2L)(A)]$ (A is the dianion of the amino acid), and a mixed complex with glycine $K_2[Cr(H_2L)(gly\text{-}O)(OH)]$. All exhibit an intense UV charge transfer band characteristic of a Cr—S bond. The sulfhydryl to chromium linkage undergoes an acid-catalyzed hydrolysis. The complexes have been characterized by elemental and thermogravimetric analysis, electronic and IR spectroscopy and circular dichroism. Comparison of these properties with those of known chromium(III) complexes leads to the conclusion that glutathione is bound to chromium(III) by the O-terminal glycine group {N,O} and the deprotonated sulfur of cysteine. The glutamic acid residue does not apparently interact with the chromium centre; the suggested mode of coordination of glutathione is illustrated in (**257**).

The lack of structural information means that any suggested structure for GTF must be highly speculative. Mertz has suggested[1200] that two *trans* nicotinic acids are coordinated to chromium as illustrated in (**258**). The first coordination sphere is completed by the various amino acids involved. There is little evidence to support this and it seems unlikely that the hard chromium(III) centre would bind preferentially to the nitrogen group of nicotinic acid; the idea of N coordination has attracted support and influenced other workers. One product of the reaction of nicotinic acid and chromium(III) (mole ratio 3:1, pH 3.2) has been said to be

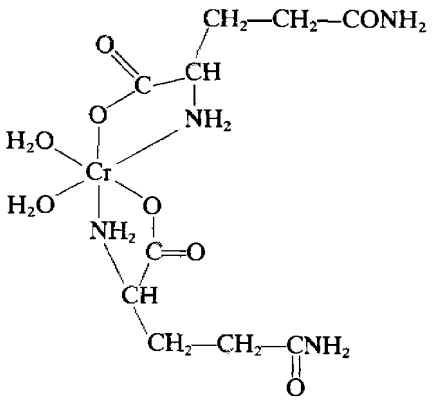


(257) Suggested coordination mode of glutathione
R = $NHCOCH_2CH_2CHNH_2CO_2H$

tetraaqua-*trans*-bis(nicotinate).[1200] It showed some biological activity but no spectral or other characterization was reported. It would be surprising if chloro ligands were not coordinated in this complex and nicotinic acid is most likely to be O-bonded. Indeed, Legg has recently shown,[1201] using deuterium NMR, that carboxyl-bonded nicotinic acid complexes are readily formed in aqueous solution. A crystal structure of a pentaammine nicotinic acid chromium(III) complex shows O-bonded nicotinate,[1202] which again supports the dominance of O-bonded nicotinic acid in chromium(III) chemistry.



(258)



The view that N-bonded *trans* nicotinic acids are involved in GTF has also been challenged[1203,1204] from a more biological viewpoint; an O-bonded nicotinic acid complex has been shown to have some biological activity. The biological significance of chromium(III) was suggested to relate to the ability of the relatively hard chromium(III) centre to form stable complexes with the carboxylate group of nicotinic acid. The crucial grouping recognized by the biological system would hence involve the nitrogen of the O-coordinated nicotinic acid (**259–262**). The surface topology of the complex may be the most important factor and the effect of 1,4-diguanidinobutane (**262**) on yeast metabolism, which is similar to that of chromium(III) complexes, may be explained on this basis.[1204]

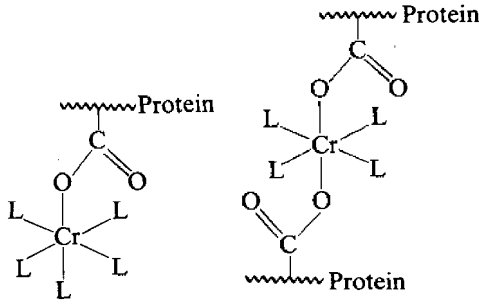
Suggested structures for biological activity

(*vi*) *Chromium and tanning*

Knapp discovered in 1858 that chromium chloride converted raw skins into leather, but he failed to realize the commercial significance of his discovery. Others developed his ideas. A two-bath process due to Schultz (1894) and an adaptation of Knapp's original one-bath process by Dennis (1893), meant that by the early twentieth century chromium tannage was commercially important. At present it accounts for the vast majority of leather production.

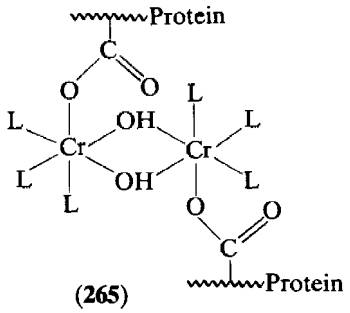
In the tanning process hides are first washed or soaked, hair and keratinous debris are removed, bated (enzymes are used to break down non-collagenous components, which are washed out) and the hide is acid-pickled to prepare for the addition of the chromium salt. Contemporary processes are exclusively based on one-bath procedures and utilize chromium(III). The older two-bath process is now obsolete, mainly because it involved the *in situ* reduction of chromate, a major environmental and toxicological hazard (*cf.* chromate toxicity p. 947) to chromium(III) on the hide. A useful review of the history of chromium tannage processes is available.[1205]



The most popular tanning solution in current use is termed 33% basic chromium(III) sulfate and corresponds to the empirical formula $CrOHSO_4$. In older procedures, chromate was often reduced at the plant using glucose/sulfuric acid mixtures. At present, 33% basic chromium sulfate is provided as either a solution (chrome liquor) or as a commercially available powder,[1206] of constant, but at present slightly uncertain, chemical composition.

The composition of such tanning liquors has been investigated.[1207] As many as 12 components have been identified, including monomeric di- and oligo-nuclear complexes involving hydroxide and/or sulfate bridges. Chrome tanning involves the careful control of the hydrolysis of chromium(III) (*cf.* O donors p. 857). The tanning mixture is introduced to the pelt at fairly acidic values of pH (2.5–3.0). The pH is then increased and the chromium reacts with and is fixed to the collagen. The low pH of introduction minimizes the processes of olation and oxolation (see O donors), which could easily lead to oligomeric and even insoluble material unable to penetrate the hide. At low pH the collagen is protonated and this also favours the penetration of the chromium complex into the hide. The hydroxy complexes, formed on raising the pH, are more reactive than aqua species[1199] due to the *trans* effect, a point not generally mentioned in the literature of tanning. The unfavourable effects of hydroxide are thus balanced against the requirement for a reasonably rapid reaction. Olation may further be limited by the use of a complexing ('masking') agent. However, the reaction of chromium with collagen will be less favourable if the metal is strongly complexed.[1208,1209] Carboxylates of various kinds have been used as masking agents in tanning,[1208] but the present trend seems to be to use 'simple basic sulfate solutions' or relatively low concentrations of carboxylates such as formate under carefully controlled conditions.

An exception to this is the preparation of special leathers, where a suitable chromium-conplexing agent, *e.g.* a hydrophobic ligand, may be used to impart a required property, *e.g.* shower resistance or lubrication, to the finished hide[1208] and similarly the use of fluorocarboxylates to produce soil-resistant leathers.



Gustavson first recognized[1210] that chrome tanning was due to the reaction of chromium with the carboxylic acid groups of collagen. Collagen, the principal component of hide, is an unusual protein consisting of a thin rod *ca.* 3000 Å long and 14 Å thick, composed of three peptide chains of equal length each containing about 1000 amino acid residues. Glycine accounts for about 30% of the amino acid residues and there are large quantities of proline and hydroxyproline. Metal ion binding to collagen has recently been reviewed.[1211]

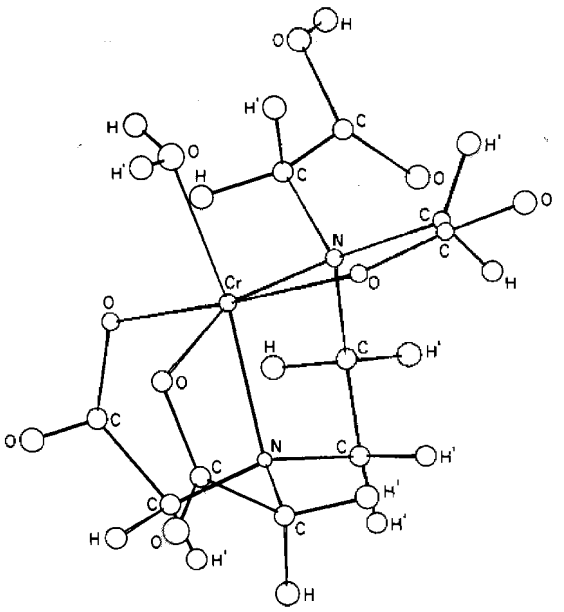
Collagen fibrils tanned with 33% basic sulfate show a distinct cross striation (electron microscopy, 50 000:1), presumably owing to an increased ordering of the collagen monomers.[1212,1213] The exact way in which chromium is incorporated into collagen is not yet fully understood. In the tanning process, chromium may be envisaged as reacting with the free carboxylates of the protein to give three distinct kinds of coordinate linkage: (1) with a single carboxylate (**263**), (2) with cross-linking between strands *via* a single chromium (**264**), or (3) with cross-linking between strands by a di- or oligo-nuclear chromium species polymerized either *via* ol, oxo or sulfato bridges, or a combination of them (**265**). The relative importance of the different kinds of interaction has not been fully established. Bridging by di- and oligo-nuclear complexes, as illustrated in (**265**), is believed to be the most important interaction for the tanning of leather, although as much as 90% of the bound chromium may be bound only to a single collagen strand as in (**263**).

(263) (264)

Schematic representations of possible collagen interactions. L may be a masking ligand, water or hydroxide

(265)

In (**265**) the bridging ligands, shown as ol, could be oxo or sulfato. There are obvious possibilities for isomerism in this interaction



The chemistry of tanning is very complicated. Although reliable procedures have been developed and the general principles of the chromium–collagen interaction are well understood, there is the possibility for much new work in this area.

35.4.8.4 Complexones: edta, pdta, nta and related ligands

(*i*) *Ethylediaminetetraacetic acid* (*edta*)

A violet complex $[Cr(Hedta)H_2O]$ was first prepared in 1943 by Brintzinger, Thiele and Muller.[1214] It was transformed on the addition of base to a blue complex, then formulated as $[Cr(Hedta)OH]^-$. Thus, even from the earliest studies, edta in its chromium(III) complex was thought to be pentadentate; this has now been confirmed crystallographically (**266**).[1215] Coordination at chromium(III) is a distorted octahedron; the average deviation from 90° is 5.1°. The currently accepted protonation schemes for chromium(III)–edta complexes are illustrated in equations (56)–(61).[1216] Deuterium NMR spectroscopy has been used to confirm these solution equilibria.[1217] As well as the quinquedentate ones,[1214,1215] complexes in which edta is of lower denticity have been prepared.[1218] $[Cr(Hedta)H_2O]$ reacted with hydrochloric and hydrobromic acids to give complexes of formulae $[Cr(H_3edta)X_2(H_2O)]\cdot 3H_2O$. The most likely structure was considered to have one of the nitrogens and two of the carboxylates of an edta ligand uncoordinated.

The equilibrium constant ($\log K$) for the formation of the quinquedentate complex is 23.40.[1219] Perhaps the most remarkable feature of chromium(III)–edta chemistry is the kinetic

lability of the coordinated water of $[Cr(Hedta)H_2O]$. The exchange of this water occurs on the stopped-flow time-scale, and has hence attracted a large number of kinetic studies, summarized in Table 101.

Chromium(III)–edta complexes are typically prepared[1220] by refluxing the ligand with a suitable chromium(III) salt for about half an hour followed by recrystallization. The formation of $[Cr^{III}(Hedta)H_2O]$ from acetato, formamato and trifluoroacetato chromium(III) complexes

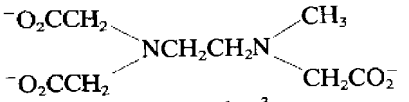
has been studied;[1221] the acetato complex reacted 103 times faster than hexaaqua chromium(III).[1220] The thermal decomposition of $[Cr(NH_3)_6]Naedta{\cdot}3H_2O$ provides[1222] an interesting method of synthesizing $[Cr(Hedta)H_2O]$.

(ii) Other complexones derived from ethylenediamine



Ligand exchanges with a variety of ligands closely related to edta (**267**, **268** and **269**) are rapid.[1223,1224] Typical results are summarized in Table 101. Chromium(III) ethylenediamine-*N*,*N*′-diacetato complexes $[Cr(edda)(H_2O)_2]^+$ have been synthesized.[1225] $CrCl_3{\cdot}6H_2O$ was reacted with H_2edda and neutralized; separation of the isomers (**270**, **271** and **272**) by ion-exchange chromatography was attempted. On the basis of electronic spectra and comparison with the cobalt(III) system, the first complex to elute was assigned as *α-cis* (94%), the second band as *β-cis* (6%). The equilibrium constant for this system is $\log K = 12.42$ (room temperature),[1226] presumably an overall value for both isomers.

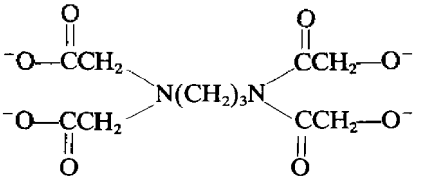
(**269**) medtra^{3-}

(**270**) *trans*



(**271**) *α-cis*

(**272**) *β-cis*

(iii) Other complexones derived from polyamines

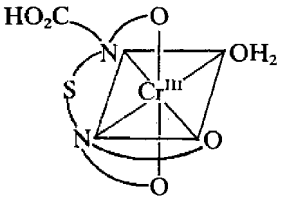
In contrast to edta, the complexes of 1,3-propylenediaminetetraacetic acid are sexidentate.[1227] This may well be because ring strain is reduced (**273**) by the additional —CH_2 group in each chelate ring. The complex (2*S*,4*S*)-2,4-pentanediaminetetraacetatochromate(III) monohydrate has been prepared[1228] and forms stereospecifically. By comparison with Co^{III} analogues, absolute configurations have been assigned. Complexes with ethylenediamine-*N*′,*N*′-diacetic-*N*,*N*′-dipropionic acid (H_4edda) and *S*,*S*-2,2″-(ethylenediimino)disuccinic acid (H_4*S*,*S*-edds) were also made.[1228] An extensive study of triethylenetetraaminehexaacetic acid complexes of chromium demonstrated both mononuclear, dinuclear and heteronuclear chelates with copper(II).[1229]

(**273**) pdta

(iv) Imino acetic acids

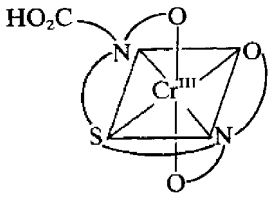
Several complexes with iminodiacetic acid (H_2ida) and methyliminodiacetic acid (H_2mida) have been prepared.[1225] The bis mida complex exists only as the *trans* isomer, ida forms bis *cis* N complexes; this is also the arrangement adopted in the mixed mida/ida complex.

Spectroscopic measurements were used to support these assignments. Related studies of *trans*-bis(*N*-isopropyliminodiacetato)chromium(III) dihydrate[1230,1231] support the earlier suggestions[1225] of specificity in the coordination of mida.



The oxygen-18 exchange of *trans*-(*fac*)-bis(*N*-methyliminodiacetato)chromate(III) has been studied in detail.[1232]. Acid-dependent and -independent paths are involved; one-ended ligand dissociation was held to be important. The equilibrium constants for complexation of ida are ($I = 0$, 25 °C) $\log K_1 = 9.30$ and $\log K_2 = 7.14$.[1233] The chromium complex of 2-hydroxyethyliminodiacetic acid (H_2OH-A), $K[Cr(HO\text{-}A)_2]$,[1234] has been made. It is approximately octahedral and the hydroxy groups are not deprotonated.

(*v*) *Nitrilotriacetic acid*



Complexation of chromium(III) by nitrilotriacetic acid (H_2nta) has been investigated. Values of equilibrium constants ($I = 0$, 25 °C) are $\log K_1 = 10.66$ and $\log K_2 = 8.73$.[1234] A large number of mixed complexes with nta/chromium(III) have been prepared, including mixed aminoacidates,[1235] acetylacetonates, catecholates, oxalates and complexes with 1,10-phenanthroline and 2,2′-bipyridyl.[1236–1238]

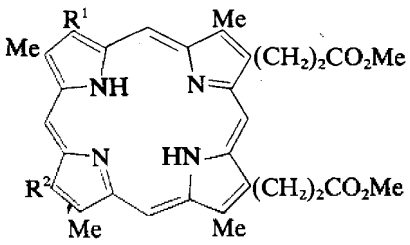
(*vi*) *Sulfur-containing ligands*

Two different isomers (**274** and **275**) have been obtained from the reaction of thiobis(ethylenenitrilo)tetraacetic acid (tedta) with $Cr(ClO_4)_3$, depending on the pH of the reaction. The *cis* isomer has pentadentate (*cf.* edta) ligation, the *trans* isomer is sexadentate; the equilibrium is pH-dependent.[1239] The related complexes of thiobis(ethylenenitrilo)-tetraacetic acid have also been investigated.[1240] The above studies were directed to finding ligands which would bind to the surface of electrodes by spontaneous absorption. Although the chemistry of these systems is complicated, this objective was achieved in both studies.

(**274**)

(**275**)

35.4.9 Multidentate Macrocyclic Ligands

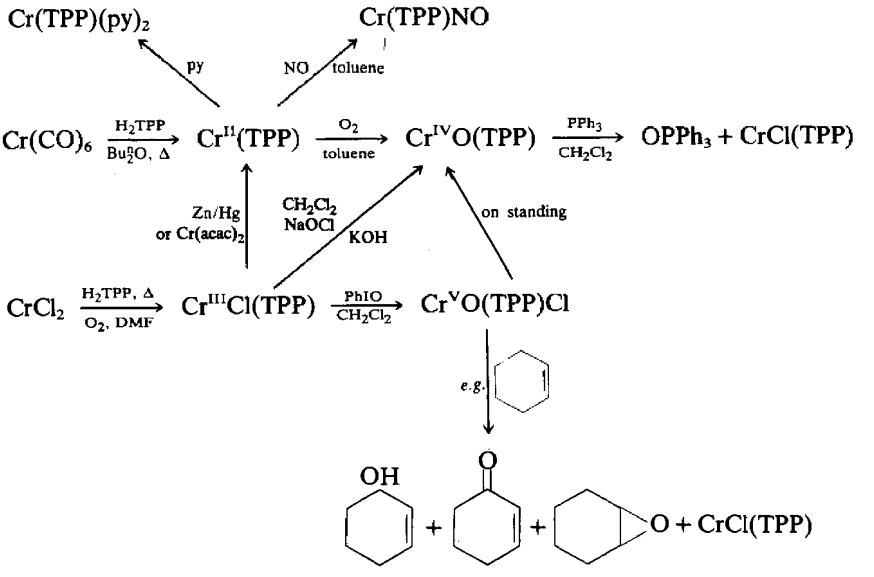


35.4.9.1 Porphyrins and corrins: oxidation states II to V

Chromium porphyrins constitute a comparatively new and important class of compound. In order to avoid an artificial separation, complexes of various oxidation states starting with chromium(II) are dealt with in this section and some chromium(V) salen derivatives are included. Electronic, ESR and IR spectra are routinely recorded to characterize chromium porphyrin complexes and chromatography is extensively used in their purification; for details the original references should be consulted. The chemistry of the porphyrins is covered in a recent series.[1241]

(*i*) *Chromium(II) porphyrin complexes*

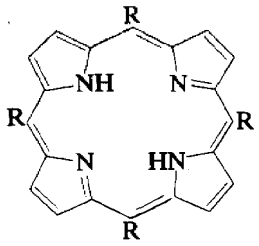
The chromium(II) complex of mesoporphyrin IX dimethyl ester (**276**) can be prepared by metal insertion with an excess of chromium hexacarbonyl under nitrogen.[1242] After removal of solvent and extraction with toluene, Cr^{II}(MPDME) is crystallized by the addition of *n*-pentane. Presumably the weakly acidic NH protons of the porphyrin oxidize Cr^0 to Cr^{II} and form H_2.



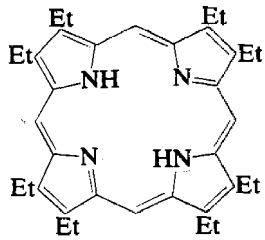
The oxidation of Cr(MPDME) in solution by O_2 or H_2O_2 can be reversed by sodium dithionite. Since $\mu_{eff} = 2.84$ BM in the solid and 5.19 BM in $CHCl_3$, there are axial interactions in the solid state which are removed on dissolution.

(**276**) $R^1 = R^2 = Et$, mesoporphyrin dimethyl ester, H_2MPDME
$R^1 = R^2 = H$, deuteroporphyrin dimethyl ester, H_2DPDME
$R^1 = R^2 = CH{=}CH_2$, protoporphyrin IX dimethyl ester, H_2PPDME
$R^1 = R^2 = CH(OH)Me$, hematoporphyrin dimethyl ester, H_2HPDME

The *meso*-tetraphenylporphyrinate, Cr(TPP), first reported as a tetrahydrate[1243] with $\mu_{eff} = 4.90$ BM, was prepared by metal insertion into H_2TPP (**277**) with $Cr(CO)_6$ in *n*-butyl ether (Scheme 106). The reaction was carried out under nitrogen containing small quantities of air, the need for which was not explained, and the formulation is in doubt because products from other procedures[80] have different visible spectra. It can be prepared by reduction of CrCl(TPP) with $NaBH_4$ in $EtOH/CHCl_3$,[595] activated zinc in $THF/py/H_2O$,[80] or $[Cr(acac)_2]$ in toluene or THF. The last method is of general application to $M^{III}Cl$(porphyrin) complexes (equation 62) because $[Cr(acac)_2]$ is a powerful one-electron reducing agent, soluble in toluene, which is oxidized to a soluble Cr^{III} species, presumably $[CrCl(acac)_2]$, which firmly binds the Cl^-. The solvate Cr(TPP)·2PhMe is obtained and Cr(OEP) (**278**) can be prepared similarly. A disadvantage is that $Cr(acac)_2$ is very air-sensitive and an excess is required because it does not react stoichiometrically.



$$M^{III}Cl(\text{porphyrin}) + Cr(acac)_2 \longrightarrow M^{II}(\text{porphyrin}) + CrCl(acac)_2 \qquad (62)$$



Scheme 106

From its magnetic moment (4.9 BM), Cr(TPP)·2PhMe is high spin. A crystal structure determination[1244] shows that the molecule is centrosymmetric and the Cr atom essentially four-coordinate; each toluene interacts very weakly with the metal and a pyrrole ring.

Planar Cr(TPP) will add two molecules of bases such as pyridine axially to form intermediate

spin complexes (Table 102). The spin-pairing has little effect on the average Cr—N (porphyrin) distances since they are 2.033 Å in Cr(TPP)·2PhMe ($S = 2$)[1244] and 2.027 Å in Cr(TPP)$(py)_2$ ($S = 1$).[1245] However, the Cr—N distances to the axial pyridine molecules (*ca.* 2.13 Å) are considerably less than in isoelectronic high-spin manganese(III) complexes (*ca.* 2.4 Å). This is attributed to the depopulation of the $3d_{z^2}$ orbital on spin-pairing in the Cr^{II} complex. The alternative formulation of the Cr^{II} porphyrin complexes as Cr^{III} porphyrin radical anion complexes is excluded by their visible spectra and oxidation–reduction behaviour.[80,1246]

The rate of oxidation of Cr(TPP) in solution can be lowered by cooling and by having high axial ligand concentrations, but no evidence has been found for reversible oxygenation. Powdered Cr(TPP)$(py)_2$ (the five-coordinate structure earlier proposed[1246] was in error[1244]) irreversibly forms an O_2 adduct which was thought from its magnetic moment (2.7 BM) and IR spectrum to be a Cr^{III} superoxide complex Cr(O_2)(TPP)(py).[1246] In view of recent results (see below) which show that $Cr^{IV}O$(TPP) and $(Cr^{III}TPP)_2O$ exist, it is possible that the adduct is a mixture. Carbon monoxide does not react with Cr(TPP),[1246] but Cr(TPP)NO can be obtained.[595,1247]

(*ii*) *Chromium(III) porphyrin complexes*

Evidence is growing that chromium is an essential trace element (Section 35.4.8.3). If mammalian diets are supplemented with simple ^{51}Cr-labelled salts it is found that less than 1% of the dose is absorbed because at intestinal pHs (>6) insoluble Cr^{III} hydrolysis products are produced. Complexes which remain intact in the acid conditions of the stomach as well as in more alkaline conditions are required. As Cr^{III} porphyrin complexes are stable in these respects, methods for synthesis of the complexes and incorporation of ^{51}Cr have been surveyed.[1248]

Chromium(III) porphyrin complexes have been synthesized *via* aerial oxidation of the chromium(II) complex prepared from $Cr(CO)_6$,[1242] from $CrCl_2$ and the porphyrin in refluxing DMF,[1249] and directly from $CrCl_3$ or [Cr(acac)$_3$] in DMF[1250] and other high boiling solvents such as benzonitrile.[1251] Since the ^{51}Cr radiolabel is supplied as $CrCl_3$ in 0.1 M HCl, the carbonyl method and methods needing an excess of metal[1251] are unsuitable. To incorporate the label the $^{51}Cr^{3+}$ was reduced essentially completely by a 20-fold excess of $CrCl_2 \cdot 4H_2O$ in a 1:1 EtOH/H_2O mixture according to the rapidly established equilibrium (63) for which the equilibrium constant is 1. The dilution of the ^{51}Cr was acceptable. DMF and the porphyrin were then added in an adaptation[1252] of the earlier method.[1249] The labelled complexes, shown in Table 102, were purified chromatographically. The method does not work well for porphyrins with free carboxylate side chains.

$$*Cr^{III}Cl^{2+} + Cr^{II} \rightleftharpoons *Cr^{II} + Cr^{III}Cl^{2+} \qquad (63)$$

Kinetic studies have shown that axial ligands in the complexes $Na_3[Cr(TPPS)(H_2O)_2]$, CrCl(TPP)L (L = monodentate base) and [Cr(Schiff's base)$(H_2O)_2]^+$ are unusually labile,[1113,1253,1254] and equilibrium constants for proton dissociation from coordinated water in the first complex[1252] have been determined.

The chloro complex CrCl(TPP) is a non-electrolyte in DMSO and neutral N, O and S donor ligands will bind to give six-coordinate species.[1255] There is little difference in the stability

Cr(OEP) Purple	[$Cr(acac)_2$] reduction of CrCl(OEP), μ_{eff} = 4.8 BM	2
Cr(TPP)·2PhMe Purple	[$Cr(acac)_2$] reduction of CrCl(TPP), μ_{eff} = 4.9 BM Cr—N (av), 2.033 Å; planar CrN_4	2 3
Cr(TPP)(py)$_2$·PhMe Green-purple	Cr(TPP)·2PhMe and py in toluene or CrCl(TPP), Zn, THF/py/H_2O, μ_{eff} = 2.93 BM indep. of *T*; Cr—N(TPP) (av), 2.033, Cr—N(py) (av), 2.13 Å	2 4
Cr(TPP)(L)$_2$·PhMe Green-purple	Cr(TPP)·2PhMe and L in toluene, L = 3-pic, 4-pic, 1-MeIm; μ_{eff} = 2.9 BM	2
Oxidation state III		
CrCl(MPDME)	$CrCl_2·4H_2O$, H_2MPDME, reflux DMF, expose to air as for CrCl(TPP) below, ^{51}Cr incorporated	5
CrCl(DPDME)	As above	5
CrCl(PPDME)	As above	5
CrCl(HPDME)	As above	5
CrCl(TPP) Deep blue	$CrCl_2$ or $CrCl_2·4H_2O$, H_2TPP, reflux DMF, expose to air. ^{51}Cr incorporated (see text)	6, 7, 5
CrBr(TPP)	From CrCl(TPP), excess [NBu_4]Br in $CHCl_3$	7
Na_3[Cr(TPPS)]	$CrCl_2·4H_2O$, Na_4[TPPS], reflux DMF, expose to air; also from $Cr(CO)_6$; sometimes as $(H_2O)_2$, μ_{eff} = 3.87 BM	5, 8, 9
Cr(OMe)(TPP)·2MeOH	$Cr(CO)_6$, H_2TPP, reflux decalin, expose to air, crystallized from MeOH, μ_{eff} = 3.63 (294 K), 3.60 BM (79 K)	10
Cr(OEt)(TPP)·2EtOH	As above, crystallized from EtOH, μ_{eff} = 3.60 (294 K), 3.59 BM (79 K)	10
Cr(OH)(TPP)·2H_2O	As above, reaction mixture left one month, no alcohols in work-up	10
Cr(ClO_4)(TPP) Dark green	CrCl(TPP) and $AgClO_4$ in THF; monodentate ClO_4	11
Cr(O_2CMe)(TPP)	Cr(O_2CMe)$_3$, H_2TPP, reflux PhCN	12
Cr(TPP)NO Red	ν(NO) = 1700 cm^{-1}, $S = \frac{1}{2}$ (ESR)	11, 13
[Cr(TPP)]$_2$O Purple	Monohydrate, CrCl(TPP) in CH_2Cl_2, NaOH; CrO(TPP) + Cr(TPP); $\mu_{eff}^{300\,K}$ = 1.61 BM	14, 15, 16
(TPP)CrOFe(TPP) Purple	Per dimer, μ = 3.12 (300 K), 1.9 BM (4.2 K), $J = -153$ cm^{-1}, g = 2.04; intermolecular; $J = -1.45$ cm^{-1}, g = 2.14; Cr—O—Fe, 842 cm^{-1}. Also mixed porphyrins and (TPP)CrOFe(PC); Cr—O—Fe linear	7, 18
CrCl(TTP) Green	$CrCl_2$, H_2TTP, reflux DMF, NaCl aq, HCl, Poor analyses, occludes CH_2Cl_2	14
CrCl(TMP) Green	As above, poor analyses, decomp. to ?CrOH(TMP)	14
CrOH(TTP)H_2O·H_2O Violet	$CrCl_3$, H_2TTP, PhCN, reflux in stream of N_2 to remove HCl, chromat., add NaOH	19
CrN_3(TTP) Violet	—	20
CrOH(OEP)·0.5H_2O Violet	$CrCl_3$, H_2OEP, PhCN, reflux stream of N_2 to remove HCl, chromat., add NaOH	19
CrBr(OEP)py Dark brown	[$Cr(acac)_3$], H_2OEP, reflux diethylene glycol	21
Cr(OPh)(OEP)PhOH Violet	[$Cr(acac)_3$], H_2OEP, PhOH, 250 °C, μ_{eff} = 3.2 BM	22
CrCl(OEP)	Prepared as CrCl(TPP)	7
Oxidation state(IV)		
CrO(OEP) Red	CrOH(OEP)·0.5H_2O, NaOCl and NaOH, ν(Cr=O), 1015 cm^{-1}, diam.	23
CrO(TPP) Red	Cr^{II}(TPP), O_2 in toluene, ν(Cr=O), 1020 cm^{-1}, diam., Cr—O, 1.62, Cr—N, 2.036, Cr *ca.* 0.5 Å above N_4 plane; also CrO(TFP), CrO(TXP)	15, 16
	CrCl(TPP), PhIO in CH_2Cl_2, KOH; similarly from NaOCl, Bu^tO_2H, or *m*-chloroperoxybenzoic acid, ν(Cr=O), 1025 cm^{-1}, ν(Cr=^{18}O), 981 cm^{-1}, diam.	14
CrO(TMP) Purple	CrCl(TMP), PhIO in CH_2Cl_2, similarly from Bu^tO_2H and KOH, ν(Cr=O), 1023 cm^{-1}, diam.	14

constants for binding of *s*-$BuNH_2$ ($\log K = 4.28$) and π-acceptor ligands such as pyridine ($\log K = 4.28$) to CrCl(TPP) in acetone (equation 64).[1256] It therefore seems that metal to ligand π bonding is unimportant. However, 1-methylimidazole is anomalously strongly bound ($\log K = 6.71$), consistent with some ligand to chromium π bonding. N donors will displace O donors and S donors but not the coordinated chloride.

$$CrCl(TPP)(acetone) + L \overset{K}{\rightleftharpoons} CrCl(TPP)L + acetone \qquad (64)$$

Cyclic voltammetry shows that the electrochemical reduction of CrCl(TPP) in non-aqueous media is a function of the solvent.[1257] In non-coordinating solvents, *e.g.* CH_2Cl_2, the Cr^{III}/Cr^{II} reduction (equation 65) is irreversible and the Cr^{II}/Cr^{II}-anion radical reduction (equation 66) is reversible. In weakly coordinating solvents, *e.g.* Me_2CO, the solvent L modifies process (65) through weak coordination to give CrCl(TPP)L, and in coordinating media such as DMF is

involved in both reductions and renders equation (65) reversible. The effect of N donors was studied, and in $C_2H_4Cl_2$ and DMF the Cr^{II} and Cr^{II}-anion radical species axially coordinate two substituted pyridine molecules. From the reduction potentials, this stabilized the Cr^{III} oxidation state over the Cr^{II} state, and the Cr^{II} state over the Cr^{II}-anion-radical state. There was no indication that coordinating ligands would displace Cl^- from CrCl(TPP)L. In $Cr(ClO_4)$(TPP) the axial interactions between the metal centre and the counterion are much less than in CrCl(TPP).[1247] Consequently it is easier to reduce and less easy to oxidize and species $Cr(TPP)(L)_2^+$ (where L = DMF, DMSO and py) form in solution.

$$Cr^{III}Cl(TPP) \longrightarrow Cr^{II}(TPP) + Cl^- \quad (65)$$

$$Cr^{II}(TPP) \longrightarrow [Cr(TPP)]^- \quad (66)$$

The reaction of NO with Cr^{II}(TPP) affords Cr(TPP)NO which is a red solid with $\nu(NO) = 1700\,cm^{-1}$ and an ESR spectrum typical of an $S = \frac{1}{2}$ species.[595] When solutions of Cr(OMe)(TPP) in $CHCl_3$/MeOH are exposed to NO, spectroscopic changes indicative of the formation of an NO complex occur. On degassing, the original spectrum reappears. Since the electronic and ESR spectra of the NO complex are similar to those of Cr(TPP)NO, it is believed that reductive nitrosylation has taken place according to equations (67) to (69). It is not stated whether Cr(TPP)NO as the solid or redissolved loses NO. More recent work[1247] shows that DMF, DMSO and py coordinate axially to Cr(TPP)NO in CH_2Cl_2 and formation constants have been determined; at high concentrations some displacement of NO occurs.

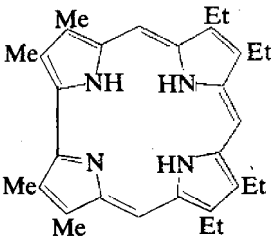
$$Cr(OMe)(TPP) + NO \rightleftharpoons Cr(OMe)(TPP)NO \quad (67)$$

$$Cr(OMe)(TPP)NO + MeOH \longrightarrow Cr^{II}(TPP) + MeONO + MeOH \quad (68)$$

$$Cr^{II}(TPP) + NO \longrightarrow Cr(TPP)NO \quad (69)$$

(iii) Chromium(IV) and (V) porphyrin complexes

Chlorotetraphenylporphyrinatochromium(III) dissolved in CH_2Cl_2 is oxidized by iodosylbenzene or *m*-chloroperbenzoic acid to $Cr^{V}O$(TPP)Cl, which is stable in solution for several hours (Scheme 106).[1258] The addition of alkenes rapidly regenerates CrCl(TPP) and gives alcohols and epoxides; similarly cyclohexanol gives cyclohexanone. The same products are obtained with catalytic amounts of CrCl(TPP), and FeCl(TPP) behaves in a like manner.[1259] The red complex CrO(TPP)Cl has been well characterized in solution by IR, magnetic (Table 102) and ESR investigations. As it forms in CH_2Cl_2, the typical ESR spectrum of CrCl(TPP) is replaced by a sharp signal near $g = 2$ with the expected hyperfine splittings for Cr^{V}.[1260] Details of the ESR spectra show that the unpaired electron is primarily on the metal so that CrO(TPP)Cl is an oxochromium(V) species and not a chromium(IV) porphyrin π cation radical. Coupling effects in the ESR spectra consequent upon the formation of $Cr^{17}O$(TPP)Cl (from $PhI^{17}O$) and substitution of Cl by $BuNH_2$, OH^- or F^- confirm the formulation. On standing at room temperature CrO(TPP)Cl decomposes in CH_2Cl_2 to give a bright red solution containing a diamagnetic oxochromium(IV) complex. This happens so readily that the spectrum of $Cr^{V}O$(TPP)Cl first published[1258] is, in fact, that of red $Cr^{IV}O$(TPP);[1261] CrO(TPP)Cl is also red but the spectrum is different.[1250,1260] $Cr^{IV}O$(TPP) can be directly obtained by oxidation of CrCl(TPP) by iodosylbenzene, Bu^tO_2H, NaOCl or *m*-chloroperbenzoic acid, followed by treatment with base (Scheme 106); CrO(TMP), CrO(TTP) and CrO(OEP)[1250,1261] and others have been prepared similarly (Table 102).



In the crystalline state, the oxochromium(IV) complexes are stable for months. Unlike oxochromium(V) species they do not oxidize hydrocarbons, even in the presence of PhIO, although CrO(TPP) will oxidize $PhCH_2OH$ to PhCHO.[1261] Another route to CrO(TPP) is from Cr^{II}(TPP) by reaction with oxygen.[1262] The structures of CrO(TPP)[1262] and CrO(TTP)[1250] are similar to those of other five-coordinate oxometalloporphyrins. In both complexes the metal atom is ~0.5 Å out of the porphyrin plane towards the oxygen atom, and the Cr—O distances are similar: 1.572 Å [CrO(TTP)] and 1.62 Å [CrO(TPP)]. The average Cr—N distances are almost identical at *ca.* 2.03 Å. The Cr^{II}(TPP) was prepared by zinc amalgam or $Cr(acac)_2$ reduction of CrCl(TPP) and its oxidation to CrO(TPP) was monitored spectrophotometrically. The reaction (equation 70) takes place in two distinct stages believed to involve a μ-oxo intermediate,[1262] although others consider that autoxidation of the solvent toluene is

involved.[1250] $Cr^{IV}O(TPP)$ oxidizes $Fe^{II}(TPP)(pip)_2$ (pip = piperidine) to the mixed-metal μ-oxo complex $(TPP)Cr^{III}OFe^{III}(TPP)$ which contains a strongly antiferromagnetically coupled ($S = \frac{3}{2}$, $S = \frac{5}{2}$) pair (Table 102). Similar complexes can be obtained with two different tetraphenylporphyrins, and $Cr^{IV}O(TPP)$ can also be prepared by stirring CrCl(TPP), $CHCl_3$ and aqueous HCl in air.[1263]

$$4Cr^{II}(TPP) \xrightarrow{O_2} 2\{Cr^{III}(TPP)\}_2O \xrightarrow{O_2} 4Cr^{IV}O(TPP) \quad (70)$$

Oxidation of CrCl(TPP) in CH_2Cl_2 by the radical cation from phenoxathiin hexachloroantimonate produces a species with $\mu_{eff} = 2.8$ BM. The electronic spectrum is consistent with $Cr^{III}(TPP^{\cdot})$ or $Cr^{IV}(TPP)$ and the former is favoured.[1264] An IR band in the 1270 cm^{-1} region is indicative of a ring-oxidized metalloporphyrin, and there is a strong band at 1285 cm^{-1} in the spectrum of $[CrCl(TPP)][SbCl_6]$.[1265]

One oxochromium(V) complex, CrO(TETMC), containing the trinegative anion of a corrole (**279**), has been characterized as the solid.[1266] It is prepared (Table 102) simply by exposure to air of a solution presumably containing a Cr^{II} complex. Aerial oxidation of $Cr^{II}(TPP)$ produces the oxochromium(IV) complex CrO(TPP) so the corrole ligand apparently facilitates autoxidation. The redox behaviour of CrO(TETMC) has been examined by cyclic voltametry.[1267]

(**279**) 7,8,12,13-Tetraethyl-2,3,17,18-tetramethylcorrole, H_3TETMC

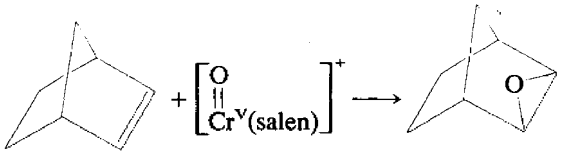
Nitridochromium(V) porphyrins, stable to air, moisture and mild reducing agents unlike oxochromium-(IV) and -(V), have been prepared by two methods (equations 71[1268] and 72).[654,1269] The Cr^{III} porphyrins probably take up NH_3 as one axial ligand and oxidative dehydrogenation produces the nitride (equation 73).

$$CrOH(TTP) + NaOCl + NH_3 \longrightarrow CrN(TTP) + NaCl + 2H_2O \quad (71)$$

$$CrN_3(TTP) \xrightarrow[h\nu]{CH_2Cl_2 \text{ or } C_6H_6} CrN(TTP) + N_2 \quad (72)$$

$$HO{-}{:}Cr^{\cdot}{-}NH_3 \xrightarrow[-H_2O]{-2H} {\cdot}Cr{\equiv}N{:} \quad (73)$$

Cr^{III}, d^3 $\qquad$ Cr^{V}, d^1



The nitrido complexes have been thoroughly characterized. The oxidation state has been confirmed by ESR and ENDOR spectroscopy. The $Cr{\equiv}N^{2+}$ group can be considered weakly electron donating; only the d_{xy} orbital is not involved in σ or π bonding, and it accommodates the single d electron. The stability to reduction compared with $Cr{=}O^{2+}$ species is ascribed to the high energy and low electron affinity of the empty d orbitals.[1268] The expected square pyramidal structure has been confirmed by X-ray methods for $CrN(TTP)\cdot C_6H_6$.[1269] It is isostructural with CrO(TPP). Coordination shell bond distances are given in Table 102, and the Cr≡N distance is short, consistent with a triple bond.

(*iv*) *Chromium(V)–salen derivatives*

Chromium(III) salen will form chromium(V) derivatives in much the same way as porphyrin complexes do. By reaction of iodosylbenzene with chromium(III)salen oxochromium(V) complexes are obtained (equation 74) which will effect oxygen atom transfer to phosphines and alkenes such as norbornene (equation 75) in stoichiometric and catalytic systems.[1270] The

halides [CrO(salen)]X (X = F, Cl, Br) can be prepared from [CrO(salen)]PF_6 by metathesis with $[NR_4]X$.

$$[Cr^{III}(salen)(H_2O)_2]PF_6 + PhIO \xrightarrow[MeCN]{-H_2O} [Cr^{V}O(salen)]PF_6 + PhI \quad (74)$$

(75)

There is disorder in the crystal structure of [CrO(salen)]PF_6, but the average out-of-plane displacement (which takes place on oxygen transfer to the metal) of the Cr atom is 0.52 Å, and the average Cr=O distance 1.56 Å.

The nitrido complex CrN(salen) can be obtained from $[CrN_3(salen)]\cdot 2H_2O$ by photolysis (equation 72).[653] The ν(Cr≡N) frequency is 1012 cm^{-1}.

35.4.9.2 *Polyazamacrocycles: cyclam, tet* a, *tet* b *and related ligands*

In comparison with some other metal ions, limited synthetic work has been carried out on chromium(III) complexes with macrocyclic ligands. The vast majority of reported complexes involve tetraazamacrocycles.

(*i*) *Cyclam*

A number of complexes of the type $[Cr(cyclam)X_2]^+$ (cyclam = 1,4,8,11-tetraazacyclotetradecane, **82**) have been prepared as outlined in Scheme 107.[1271–1273] The difficulty in synthesizing *trans*-$[CrX_2(cyclam)]^+$ complexes directly from the free cyclic ligand is in marked contrast to the behaviour of other ions of the first transition series, *e.g.* cobalt(III), which forms stable *trans* complexes. The colours and spectroscopic properties of these cyclamchromium(III) complexes are presented in Table 103. The use of IR spectroscopy to differentiate between *cis* and *trans* cyclam complexes has been widely explored and the region 790–910 cm^{-1} was found to provide confirmatory evidence of structure, independent of metal or counteranions present.[1272] Hence *trans* complexes generally show two groups of bands in this region, a doublet near 890 cm^{-1} associated with the secondary amine vibration and a singlet near 810 cm^{-1} due to the methylene vibration. The spectra of *cis* isomers on the other hand are more complex with at least three bands between 840 and 890 cm^{-1} and two between 790 and 810 cm^{-1} (Table 104).

Table 103 Colours and Electronic Spectra of Cyclamchromium(III) Complexes

Complex	*Colour*	λ_{max} [a] (ε)[b]	λ_{min} [a] (λ)[b]	*Ref.*

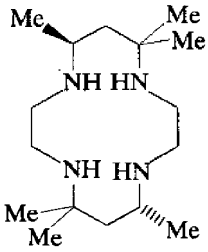
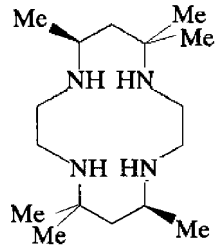
Scheme 107



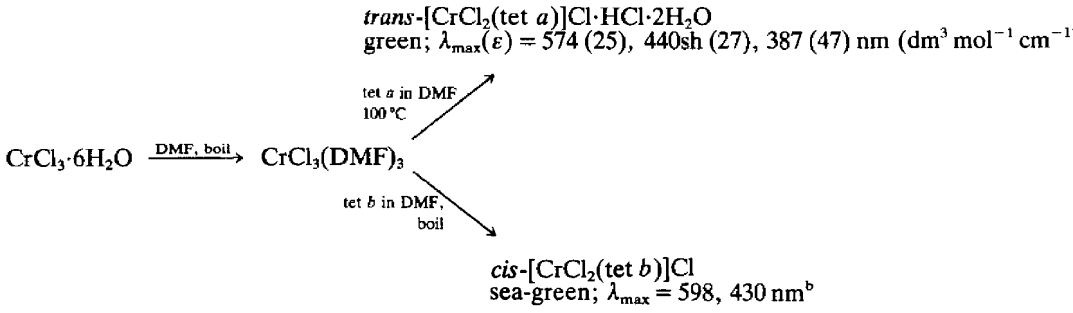
In the attempted preparation of *trans*-$[Cr(cyclam)(NH_3)_2]^{3+}$ from the dichloro complex in liquid NH_3 only a crude product contaminated by an orange material could be isolated.[1274] This impurity was shown to contain the *O*-carbamato complex *trans*-$[Cr(OCONH_2)_2(cyclam)]^+$. Suitable crystals of *trans*-$[Cr(OCONH_2)_2(cyclam)]ClO_4 \cdot 1.5H_2O$ were grown and the structure determined by X-ray diffraction methods. The structure contains two independent centrosymmetrical complex ions, which are almost identical except for the orientation of the carbamate ligands. The macrocyclic ligand has a conformation in which the five-membered ring has a *gauche* and the six-membered ring a chair conformation. The average C—C (151.3 pm), C—N (148.0 pm) and I—N (205.9 pm) distances in the complex are similar to those in the doubly protonated ligand (150.9, 148.2, 204.5 pm respectively). The average Cr—N bond length (205.9 pm) is close to the ideal value (207 pm) calculated for *trans*-cyclam complexes[1275] and also similar to those in chromium(III) complexes with other amines.[1274] The relative substitution inertness of *trans*-cyclamchromium(III) complexes in solution[1276] may be due to steric hindrance by the two axial C—H groups of the six-membered rings towards the entering group in an associative interchange mechanism.[1274]

The photochemistry of *cis*- and *trans*-$[CrCl_2(cyclam)]^+$ on irradiation of the *d–d* bands in dilute acid solution involves monosubstitution by solvent to give the corresponding isomeric $[CrCl(cyclam)(H_2O)]^{2+}$ products.[1277] However, the photobehaviour of $[Cr(CN)_2(cyclam)]^+$ in solution at room temperature is in marked contrast to that normally displayed by chromium(III) complexes.[1273,1278] For this complex, like *trans*-$[Cr(CN)_2(NH_3)_4]^+$,[329] the $^4B_{2g}$ component of the first spin-allowed quartet excited state lies at lower energy than the ^4E_g component, an ordering which in the tetraammine complex restricts photolabilization to the in-plane NH_3 positions. However, in the cyclam complex the nature of the in-plane ligand prevents the occurrence of such a reaction with the result that even after extensive ligand field photolysis no substitution photochemistry is detected. Furthermore the complex exhibits an



intense long-lived $^2E_g \rightarrow {}^4B_{1g}$ phosphorescence which shows equal enhancements in intensity and lifetime on deuteration of the NH groups. These properties of its ^2E_g state make *trans*-$[Cr(CN)_2(cyclam)]^+$ an attractive compound to study in terms of energy- and electron-transfer with various substrate molecules.

(*ii*) *Tet* a *and tet* b



A number of chromium(III) complexes of the diastereoisomeric C-*meso*- and C-*racemo*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (tet *a* and tet *b* respectively; **280** and **281**) have been prepared.[1279,1280] While the tet *b* isomer like cyclam can readily fold to give *cis*-$[CrX_2(\text{tet } b)]^+$ complexes, tet *a* only folds with difficulty because of unfavourable interactions between the methyl substituents and axially coordinated ligands. Hence these isomers react with $CrCl_3(DMF)_3$, prepared *in situ* by dehydration of $CrCl_3 \cdot 6H_2O$ in DMF, according to Scheme 108. Replacement of Cl^- by other anions provides a convenient route to a range of *trans*-$[CrX_2(\text{tet } a)]X$ and *cis*-$[CrX_2(\text{tet } b)]X$ complexes. Details of the electronic spectra of these products are presented in Table 105.

Scheme 108

The first step in the base hydrolysis of *trans*-$[CrCl_2(\text{tet } a)]^+$ (Scheme 109; $k_1 = 145\ dm^3\ mol^{-1}\ s^{-1}$ at 298 K, ionic strength 0.1 M; $\Delta H^{\ddagger} = 114\ kJ\ mol^{-1}$, $\Delta S^{\ddagger} = 179\ J\ K^{-1}\ mol^{-1}$)[1281] proceeds some 112-fold faster than the corresponding reaction of *trans*-$[CrCl_2(cyclam)]^+$ ($k_1 = 1.3\ dm^3\ mol^{-1}\ s^{-1}$ at 298 K).[1276] On the basis of the steric acceleration due to C-methyl substitution, the first-order dependence of rate on $[OH^-]$ and the large positive entropy of activation an S_N1CB mechanism is suggested for this reaction.[1279] Acid hydrolysis of the tet *a* complex is also considerably faster than its cyclam analogue.[1279] The crystal structure of one of the possible isomers of *trans*-$[CrCl(\text{tet } a)H_2O](NO_3)_2$ has been reported.[1282] Addition of base to an aqueous solution of *cis*-$[Cr(mal)(\text{tet } b)]^+$ (mal = malonate) gives rise to a bathochromic shift in the longer wavelength band of its visible spectrum.[1280] This spectral change has been attributed to ionization of the CH_2 group in the malonate ligand (equation 76), although such an explanation must be treated with at least some scepticism since it implies an abnormally large increase in the acidity of this group due to coordination of the neighbouring CO_2^- groups.

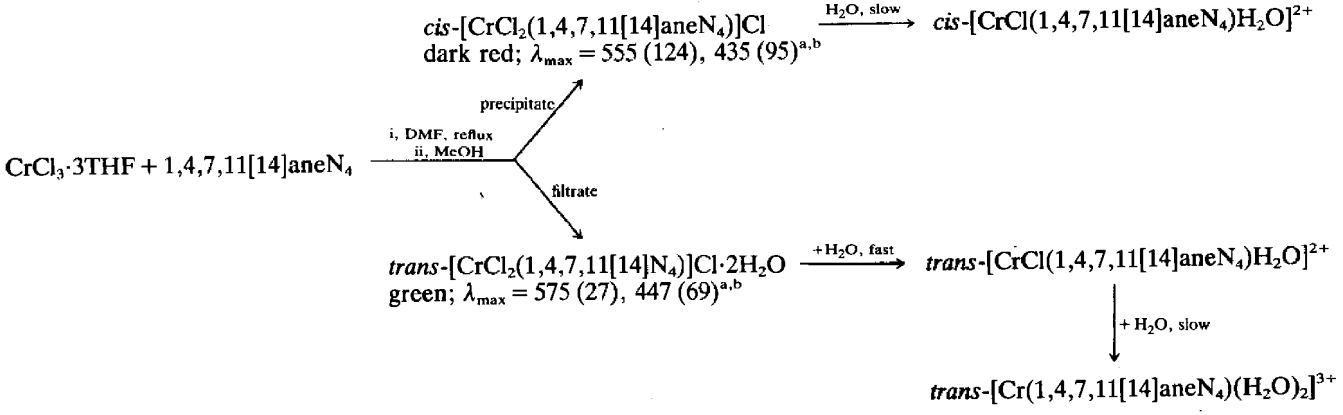
(*iii*) [12]*aneN*$_4$, *unsymmetrical* [14]*aneN*$_4$, [15]*aneN*$_4$



The preparation and properties of some chromium(III) complexes of 1,4,7,10-tetraazacyclododecane ([12]aneN$_4$) are outlined in Scheme 110.[1283] The reaction between $CrCl_3 \cdot 3THF$ and the unsymmetrical 14-membered macrocycle 1,4,7,11-tetraazacyclotetradecane (1,4,7,11[14]aneN$_4$) in DMF leads to equal amounts of *cis*- and *trans*-$[CrCl_2(1,4,7,11[14]aneN_4)]Cl$ and these can be separated on the basis of the insolubility of the former and the solubility of the latter in methanol (Scheme 111). The reaction between $CrCl_3 \cdot 3THF$ and the 15-membered macrocycle [15]aneN$_4$ (**81**) in DMF produces only the *trans* isomer of $[CrCl_2([15]aneN_4)]Cl \cdot 2H_2O$ (green; $\lambda_{max} = 586$ nm, $\varepsilon = 24\ dm^3\,mol^{-1}\,cm^{-1}$; 476 nm, $\varepsilon = 48\ dm^3\,mol^{-1}\,cm^{-1}$; 410 nm, $\varepsilon = 63\ dm^3\,mol^{-1}\,cm^{-1}$), which undergoes a slow one-stage hydrolysis in aqueous solution.[1283]

The reaction between the strongly reducing complex $[Cr([15]aneN_4)(H_2O)_2]^{2+}$ and organic halides (RX) produces the monoalkylchromium(III) complexes *trans*-$[RCr([15]aneN_4)H_2O]^{2+}$, equation (77).[305,1284] The reaction follows second-order kinetics and the reactivity of alkyl halides follows the pattern tertiary > secondary > primary and RI > RBr > RCl (Table 106). This and other information suggests a mechanism which involves rate-limiting halogen atom

abstraction from RX by the chromium(II) complex to generate a carbon-centred free radical which rapidly couples with a second chromium(II) complex (Scheme 112). In the presence of electrophiles such as Hg^{2+} or $MeHg^{+}$, the alkylchromium(III) complexes undergo electrophilic dealkylation as in Scheme 113.[297] These reactions also follow a second-order rate law and the rate constants fall sharply with increasing bulk of R and by two to three orders of magnitude as the electrophile is changed from Hg^{2+} to $MeHg^{+}$ (Table 106). On the basis of such observations a bimolecular electrophilic substitution mechanism, S_E2 is proposed for these reactions. Furthermore these complexes are somewhat less reactive towards Hg^{2+} than the corresponding $[RCr(H_2O)_5]^{2+}$ species[1285] owing to the considerable steric bulk added to the site of reactivity by the macrocyclic ligand. Details of the electronic spectra of *trans*-$[RCr([15]aneN_4)H_2O]^{2+}$ and related complexes are listed in Table 107.

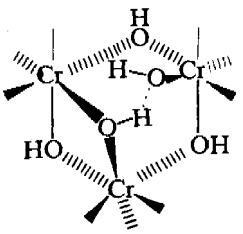
Scheme 113

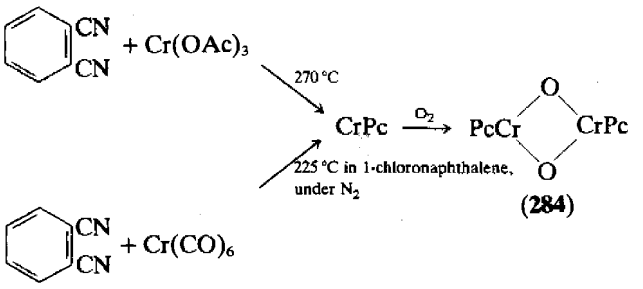


(iv) Other macrocycles

A green chromium(III) complex (**282**) containing the dianionic unsaturated macrocyclic ligand 5,14-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraenate, Me_2[14]tetraenateN_4, has been prepared by the method in Scheme 114.[598] This complex reacts with $NaNO_2$ in refluxing alcohol to give the mononitrosyl Cr(Me_2[14]tetraenatoN_4)NO (**137**), which on the basis of experimental evidence appears to contain chromium(I) and the cationic NO^+ ligand, Section 35.4.2.6. Some chromium(III) complexes with macrocyclic ligands derived from N heterocycles are mentioned in Section 35.4.2.5. A number of chromium(III) complexes of the ligand 1,4,7-triazacyclononane, [9]aneN_3, and its *N,N,N*-trimethylated derivative, Me_3[9]aneN_3, have been investigated.[472,1286] From [Cr([9]aneN_3)$(H_2O)_3$]$^{3+}$ the binuclear complex [Cr(μ-OH)([9]aneN_3)H_2O]$_2^{4+}$ and the trinuclear complex [Cr_3(μ-OH)$_4$OH([9]aneN_3)$_3$]$^{4+}$ have been obtained and the crystal structure of the latter as the iodide salt (+5H_2O) has been determined by X-ray diffraction methods. This cation (**283**) contains two different pairs of μ-OH bridges with Cr—O—Cr bond angles of 98° and 126° and a very short H bond which links the terminal and one of the bridging OH ligands. The crystal structures of the binuclear complexes [Cr_2(μ-OH)$_2$(μ-CO_3)([9]aneN_3)$_2$]I_2·H_2O and [Cr_2(μ-OH)$_3$(Me_3[9]aneN_3)$_2$]I_3·3H_2O, the latter representing the first genuine tris(μ-hydroxo) complex of chromium, have also been reported.

(282)

Scheme 114



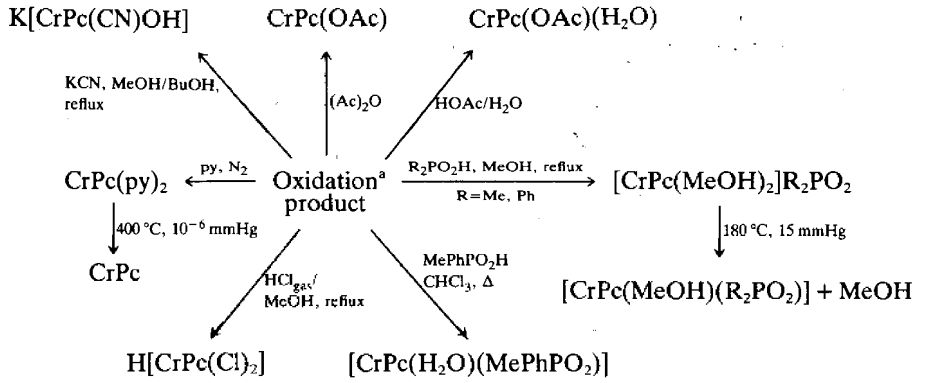
(283)

35.4.9.3 Phthalocyanines

Relatively few chromium complexes with phthalocyanine ligands have been reported and, in view of the chemical relationship between the few known compounds, all of them, irrespective of the metal oxidation state, are dealt with in this section. In the following discussion Pc represents the dianionic phthalocyanine ligand.

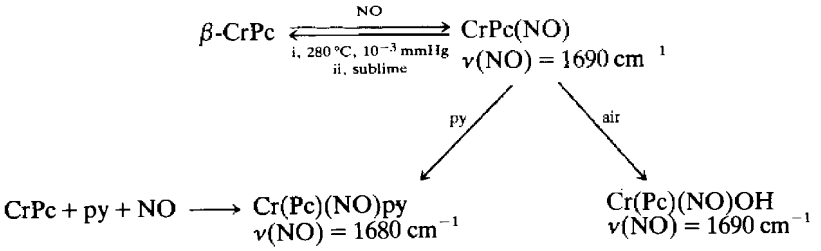
(*i*) *CrPc and* [*CrPc*(*μ-O*)]$_2$

The chromium(II) complex CrPc can be prepared by either of the routes in Scheme 115.[1287–1290] While the $Cr(CO)_6$ method conveniently gives the β polymorph of CrPc (40% yield) and this on sublimation at 300–350 °C can be converted to α-CrPc,[1288] the chromium(III) acetate method gives, after washing the product mixture with organic solvents, both CrPc and an oxidized species which was long thought to be the chromium(III) complex CrPc(OH).[1287,1290] Repeated sublimation of this mixture at 400 °C/10^{-6} mmHg was reported to give the pure hydroxide. In contrast to α-CrPc, which is air stable, the β-polymorph is air sensitive and under anhydrous conditions picks up O_2 (0.5 O_2 per chromium) to give a deep blue product, which on the basis of available experimental evidence seems to be the di-μ-oxochromium(IV) dimer (**284**) rather than CrPc(OH).[1288] Hence the product: (i) lacks characteristic OH vibrations in its IR spectrum, (ii) shows no evidence for $CrPc(OH)^+$ or the characteristic fragments of this ion in its mass spectrum, and (iii) is formed in the absence of water. Furthermore ^{18}O isotopic substitution effects on the IR spectra support a structure containing a Cr=O group and eliminate possible structures such as those with peroxo bridges or those with polymeric —Cr—O—Cr—O— groups. The electronic spectra of the oxidation product and CrPc are quite similar in band positions and shapes, thus eliminating the phthalocyanine ring as the possible site of oxidation.



Scheme 115

The magnetic moment of the oxidation product is 1.9 BM at room temperature ($\mu_{\text{spin only}}$ for a d^2 ion = 2.9 BM) and is temperature-dependent, pointing to the existence of antiferromagnetic coupling between the chromium ions.[1288] The reflectance spectrum of the product has bands at 755sh, 720, 660sh, 490 and 380 nm. Its Raman spectrum has a band at 1041 cm^{-1}, which shifts by 45 cm^{-1} on ^{18}O isotopic substitution and which seems to be due to a Cr=O stretching vibration. The fragmentation pattern in the mass spectrum is similar to that of PcCr except for a group of peaks between 578 and 582 thought to originate from $CrPcO^+$. When ^{18}O is used as oxidant these peaks are observed in the range 580–594. Some of the many reported reactions of the oxidation product are illustrated in Scheme 116.[1287,1291] The magnetic moment of the high-spin CrPC (3.49 BM at 298 K) falls sharply with decreasing temperature (θ = 306 K) to below the spin-only value for a low spin complex.[1290] This behaviour has been attributed to antiferromagnetic interactions ($J = -38.2°$, $g = 2.0$) in stacks of planar molecules. By contrast the relatively air-stable bis(pyridine) adduct, $CrPc(py)_2$, is low spin (μ_{eff} at 298 K = 3.16 BM) and shows a much lower temperature dependence (θ = 35 K).



(*ii*) *CrPc*(*NO*)

Solid β-CrPc reacts reversibly with gaseous NO at ambient temperature to give a 1:1 adduct, which reacts with both py and O_2 (Scheme 117).[596] No structural information is available on the oxidation product of the nitrosyl complex. In contrast to the β form, solid α-CrPc is unreactive towards either O_2 or NO, a difference ascribed to the solid-state structures of the two polymorphs.[597] Although the distance between the phthalocyanine planes is similar (340 pm), in both cases the metal–metal distance increases from 340 to 480 pm on going from the α to the β form. These distances are sufficient to permit access of O_2 or NO in the β form, while excluding them from the α form. The addition of py to CrPc(NO) causes the NO stretching band in the IR spectrum to intensify and to sharpen considerably. The diffuse nature of this band in CrPc(NO) indicates the presence of a perturbed NO ligand but the introduction of py causes lattice expansion and eliminates the perturbation.

[a] In the references to this work the oxidation product was described as CrPc(OH) but was later described as the dimer $[CrPc(\mu\text{-}O)]_2$.

Scheme 116

Scheme 117

(*iii*) *Oxidation and reduction of CrPc*

Reduction of CrPc with Na gives different products in THF and HMPA.[1292,1293] In THF the product obtained is $[Cr^{I}Pc]^{-}$, which has an ESR spectrum consistent with the low-spin chromium(I) configuration $e_g^4 b_{2g}^1$. The product in HMPA on the other hand has an ESR spectrum consistent with the low-spin configuration $b_{2g}^2 e_g^3$. The inversion of orbital energies is due to axial binding of a π donor solvent molecule in HMPA but not in THF. Two-electron reduction of CrPc or $CrCl(Pc)H_2O$ by dilithium benzophenone in THF gives the green crystalline solid $Li_2[CrPc]\cdot 6THF$.[1293,1294] The magnetic moment of the complex indicates that it has two unpaired electrons and this points to the formulation $[Cr^{I}(Pc^{\bullet-})]^{2-}$, which has the electronic configuration $e_g^4 b_{2g}^1\ e_g(\pi^*)^1$ (as Pc represents the doubly negatively charged phthalocyanine ligand, $Pc^{\bullet-}$ represents the radical anion obtained by one-electron addition to Pc). Oxidation of CrPc by $SOCl_2$ affords the complex $CrCl_2Pc$, which is two oxidation equivalents above the starting complex.[665] The magnetic moment of the complex (4.40 BM at 298 K) is consistent with the formulation $Cr^{III}Cl_2(Pc^{\bullet})$, which contains two magnetic centres, one (Cr^{III}) having three unpaired electrons and the other ($Pc^{\bullet}$) one unpaired electron. It also eliminates the alternative formulation $Cr^{IV}Cl_2Pc$ for the oxidation product. Furthermore, the Cr—Cl stretching bands in the far IR spectrum of the product occur at positions close to those in the spectra of known $Cr^{III}Cl$-containing complexes. Since the reactivity of thionyl chloride towards MPc complexes parallels that of NO, it appears that an initial stage of the oxidation involves coordination of thionyl chloride to the metal.

(*iv*) *Other complexes*

The binuclear complexes $H_2O(Pc)CrOCr(Pc)H_2O$ and $NH_3(Pc)CrOHCr(Pc)OH$ form when $[Cr_2O(NH_3)_{10}]Cl_4\cdot H_2O$ and $[Cr_2(OH)(NH_3)_{10}]Cl_5$, respectively, are allowed to react with phthalonitrile at 543 °C.[1295] The 4′,4″,4‴,4⁗-tetrasulfonated phthalocyanine (TSPc) complex, $OH(TSPc)CrOHCr(TSPc)H_2O$ was obtained by fusing $[Cr_2OH(NH_3)_{10}]Cl_5$ with ammonium-4-sulfophthalate and urea.[1295]

The complex $Na_3[Cr(TSPc)]\cdot 9H_2O$ has been prepared from cobalt(II) acetate, sodium 4-sulfophthalic acid, ammonium chloride and ammonium molybdate in nitrobenzene.[1296] Electrochemical reduction of this complex at a platinum electrode at −0.7 V *vs.* SCE gave the highly air-sensitive $[Cr(TSPc)]^{4-}$ in DMF solution. The action of $SOCl_2$ on $Na_3[Cr(TSPc)]$ affords the corresponding tetrasulfonyl chloride which on refluxing with octylamine gives the tetraoctylsulfonamide (TOPc) derivative Cr(TOPc)OH.[1297] The ability of this and related complexes to act as photosensitizers in the reduction of methyl viologen in THF/H_2O (15:85) solutions containing triethanolamine has been investigated. Irradiation of the system containing the chromium(III) complex did not result in formation of reduced methyl viologen. However the corresponding chromium(II) complex, prepared *in situ* by irradiation of the chromium(III) complex in the presence of cysteine, was found to be a more effective photocatalyst than any of the other metallophthalocyanines studied, but the quantum yield even in this case was low ($\phi = 2.6 \times 10^{-3}$).

35.5 CHROMIUM(IV)

Chromium(IV) does not have any aqueous solution chemistry except for the formation of intermediates in the reduction of Cr^{VI} to Cr^{III}. Chromium(IV) compounds tend to disproportionate into Cr^{III} and Cr^{VI} species (equation 78) and the metal ion in this oxidation state is powerfully oxidizing towards organic compounds. An eight-coordinate complex $[CrH_4(dmpe)_4]$ is known (Section 35.3.4.1).

$$3Cr^{IV} \longrightarrow 2Cr^{III} + Cr^{VI} \tag{78}$$

35.5.1 Anhydrous Halides and Complex Fluorides

Chromium tetrafluoride can be prepared by fluorination of the metal, CrF_3 or $CrCl_3$ at high temperature.[1364] It is an amorphous green solid and turns brown with traces of moisture, but is unexpectedly inert towards some reagents at room temperature. It is of intermediate volatility and is antiferromagnetic ($\mu = 3.02$ BM, $\theta = 78°$); it is therefore likely to consist of CrF_6 units sharing edges. The preparations of several CrF_4 adducts such as $XeF_6\cdot CrF_4$ are shown in Scheme 120 (Section 35.6.1). $CrOF_2$ ($\mu_{eff} = 1.1$ BM) is produced on thermal decomposition of CrO_2F_2, and a complex $(NO_2)_2CrO_2F_2$ is known (Section 35.7.1).

At high temperature in the gas phase the chloride and bromide exist in equilibrium with the halogen and solid CrX_3[222] (equation 79) and from their Raman spectra $CrCl_4$ and $CrBr_4$ are tetrahedral.[1298]

$$2CrX_3(s) + X_2(g) \overset{800\text{–}1300\ K}{\rightleftharpoons} 2CrX_4(g) \tag{79}$$

The hexafluorochromates(IV), $M_2[CrF_6]$ (M = Li, K, Rb, Cs) and $M[CrF_6]$ (M = Ba, Sr, Ca, Mg, Zn, Cd, Hg, Ni) are prepared by fluorinating appropriate mixtures of MCl and $CrCl_3$.[1299] The nitrosonium salt $(NO)_2[CrF_6]$ has been obtained[1300] from CrF_5 and NOF and characterized by its Raman spectrum. The symmetric stretch of the $[CrF_6]^{2-}$ unit was found at 610 cm^{-1}. A band at 20 200 cm^{-1} in the reflectance spectra of $A_2[CrF_6]$ (A = K, Rb, Cs) has been assigned to the first spin-allowed *d–d* transition $^3T_{1g} \rightarrow {}^3T_{2g}$. The second transition ($^3T_{1g} \rightarrow {}^3T_{1g}$) may be superimposed on a charge transfer band at ≈30 000 cm^{-1}.[1301] Pentafluorochromates(IV) $M[CrF_5]$ (M = K, Rb, Cs[222]), considered to contain condensed CrF_6 units, and the pink heptafluorochromates(IV) Rb_3CrF_7 and Cs_3CrF_7, which have the $(NH_4)_3SiF_7$ structure,[1302] are also known.

35.5.2 Chloro and Cyano Complexes

Alcoholic reduction of $K[CrO_3X]$ in the presence of pyridine, the pyridinium halide and a little water is reported[1303] to give the stable dimeric complexes $[Cr(OH)_2X_2py]_2$ (X = Cl, Br, I) ($\mu_{eff}^{297\ K} = 2.8$ BM); and hygroscopic $K_2[CrO(CN)_4py]$ ($\mu_{eff} = 3.0$ BM) is obtained on addition of KCN to $[pyH][CrO_3Cl]$ in pyridine to which ethanol has been added.[1304]

35.5.3 Chromates(IV) and CrO_2

There are several types of mixed oxide or chromate(IV). These are $MCrO_3$, M_2CrO_4, M_3CrO_5 and M_4CrO_6 (where M = Sr, Ba) and Na_4CrO_4;[1305] equations 80–82 illustrate typical preparations.[2,24,1306] The reaction of CrO_3 with liquid sodium does not yield Na_2CrO_3 as previously thought.[1307] The compounds M_2CrO_4 are air-stable, coloured substances, which contain tetrahedral CrO_4^{4-} groups and have magnetic moments of 2.8 BM at room temperature.

$$Cr_2O_3 + SrCrO_4 + 5Sr(OH)_2 \xrightarrow[Ar]{900\,^\circ C} 3Sr_2CrO_4 + 5H_2O \quad (80)$$

$$NaCrO_2 + 2Na_2O \xrightarrow[vac.]{410\,^\circ C} Na_4CrO_4 + Na\uparrow \quad (81)$$

$$Ba_2CrO_4 + CrO_2 \xrightarrow[60\text{–}65\ kbar]{1000\,^\circ C} 2BaCrO_3 \quad (82)$$

High pressure and temperature are required to produce the compounds $MCrO_3$, *e.g.* $BaCrO_3$, which exists as several polytypes.[1308–1310] The Cr^{IV} is octahedrally coordinated in these compounds,[1306] the structure consisting of pairs of face-sharing octahedra linked to other pairs by sharing corners. The Cr—Cr distances are *ca.* 2.6 Å.

Chromium(IV) oxide can be prepared in various ways, for example by thermal decomposition of CrO_3 and CrO_2Cl_2.[2,1306] Two recent methods are the thermal decomposition of $Cr(NO_3)_3 \cdot 9H_2O$ and the oxidation of Cr_2O_3 with NH_4ClO_4 under pressure in a heated sealed gold tube.[1311–1313] Its ferromagnetic behaviour ($T_C \approx 120\,^\circ C$) makes it suitable for magnetic tapes. The formula $Cr_4^{III}Cr^{IV}S_8$ has been suggested for Cr_5S_8 (Section 35.4.5.1.vii). For peroxo complexes see Section 35.7.7.

35.5.4 Alkyls, Alkoxides and Amides

35.5.4.1 Alkyls

The chromium(IV) tetraalkyls CrR_4 are air and light sensitive and thermally unstable to different degrees dependent upon R, but if kinetic paths are blocked through the absence of β-hydrogen atoms, or the presence of bulky organic groups, many can be isolated. The chemistry of these tetrahedral monomers has been covered in the companion series.[1] A new tetraalkyl is Cr(1-adamantylmethyl)$_4$[1314] and there is fuller information on the alkenyl compound $Cr(CPh{=}CMe_2)_4$.[1315]

35.5.4.2 Alkoxides

The stability problems with the tetraalkyls also apply to the tetraalkoxides; in addition, the high oxidative power of Cr^{IV} means that alcoholysis with primary alcohols and most secondary alcohols leads to oxidation to the aldehyde or ketone and the formation of a chromium(III) alkoxide. Relatively stable chromium(IV) alkoxides are obtained only from tertiary alcohols and some heavily substituted secondary alcohols.

(i) Syntheses and properties

The tertiary butoxide $Cr(OBu^t)_4$ can be prepared by the following methods: (1) the action of di-*t*-butyl peroxide on $Cr(C_6H_6)_2$, (2) alcoholysis of the alkylamide, *e.g.* $Cr(NEt_2)_4$, (3) oxidation of $Cr(OBu^t)_3$ (prepared *in situ* from $Cr(NEt_2)_3$ and Bu^tOH in excess) by various reagents, *e.g.* $CrO_2(OBu^t)_2$, Br_2, $Bu^t_2O_2$, $Pb(OAc)_4$ or O_2, (4) oxidation of a mixture of $NaOBu^t$ and $[CrCl_3(THF)_3]$ with CuCl and (5) the addition of CuCl to a suspension of $Li[Cr(OBu^t)_4]$ in refluxing THF.

These methods, particularly (2), have been used in the preparation[1316] of other chromium(IV) tertiary alkoxides (Table 108). These are blue liquids or low melting solids which can be distilled in vacuum and are monomeric in cyclohexane. Their magnetic moments are close to 2.8 BM and that of $Cr(OBu^t)_4$ is almost independent of temperature as expected for tetrahedral Cr^{IV} (d^2, $\mu_{so} = 2.83$ BM). The electronic absorption spectrum of blue $Cr(OBu^t)_4$

contains bands centred at 9100, 15 200 and 25 000 cm^{-1} assigned to the $^3A_2(F) \rightarrow {}^3T_2(F)$, $^3T_1(F)$ and $^3T_1(P)$ transitions in T_d symmetry and a band at 41 000 cm^{-1} assigned to charge transfer. No ESR signal was detected for $Cr(OBu^t)_4$ in toluene solution down to 98 K due to fast relaxation in the zero-field split levels of the $^3A_2$ ground term; a small zero-field splitting was confirmed by the detection of ESR signals from frozen toluene samples at much lower temperature (10 K). From thermochemical measurements, $Cr(OBu^t)_4$ has considerable thermodynamic stability ($\Delta H_f^\circ = -1275$ kJ mol^{-1}).

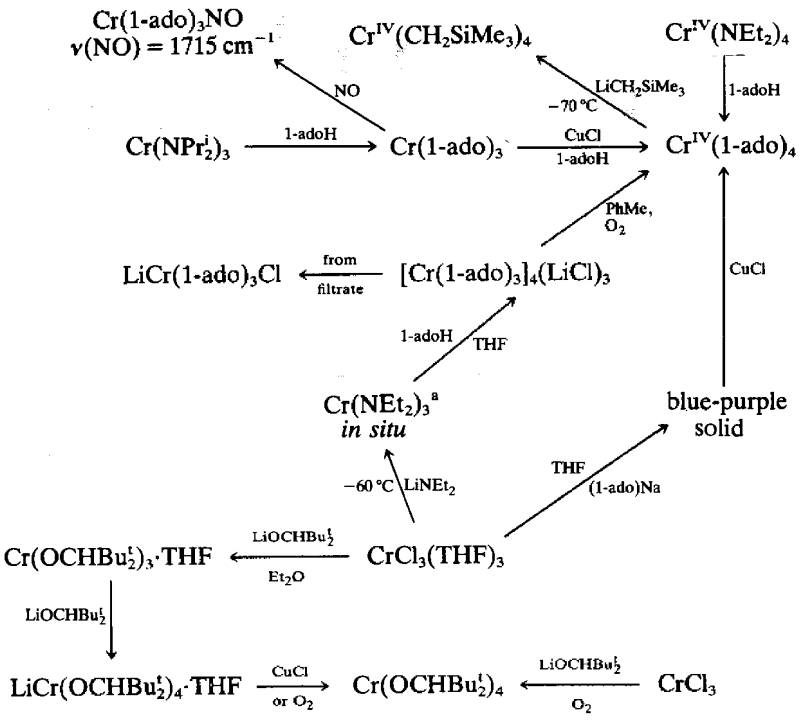
Chromium(II) borohydride is formed[1317] by reduction of $Cr(OBu^t)_4$ with B_2H_6 (equation 83).

$$Cr(OBu^t)_4 \xrightarrow[THF]{B_2H_6} Cr(BH_4)_2 \cdot 2THF \qquad (83)$$

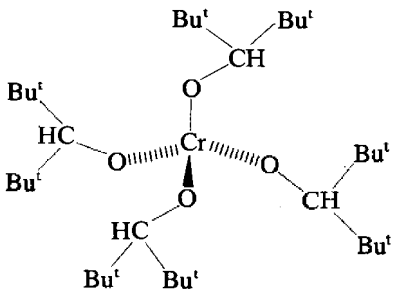
Although the alcoholysis of $Cr(OBu^t)_4$ with several primary and secondary alcohols leads to oxidation by Cr^{IV} to the aldehyde or ketone,[1316] alcoholysis by the secondary alcohol 3,3-dimethyl-2-butanol affords a Cr^{IV} alkoxide (equation 84)[1318] which is sensitive to oxygen and moisture, but otherwise stable. Presumably the bulky *t*-butyl groups prevent the molecule from achieving the conformation required for hydrogen transfer in the oxidation step.



$$Cr(OBu^t)_4 + 4HOCHMeCMe_3 \xrightarrow[36\ h]{70\ °C} Cr(OCHMeCMe_3)_4 + 4Bu^tOH \qquad (84)$$

The methods for the preparation of chromium(IV) alkoxides are well illustrated by Scheme 118, which shows the preparations of adamantoxo (1-adamantanol = adoH, **285**) and bis(*t*-butylmethoxo) complexes of Cr^{III} and Cr^{IV}.[1319,1320] The blue chromium(IV) complex Cr(1-ado)$_4$ is air-stable, presumably because the small covalent radius of Cr^{IV} allows close packing of the bulky adamantyl groups which protect against encroaching ligands. Owing to its stability and easy preparation from $Cr(NEt_2)_4$, and because it does not undergo redox or disproportionation reactions, Cr(1-ado)$_4$ is preferable to $Cr(OBu^t)_4$ as a precursor for organic derivatives of chromium(IV), *e.g.* $Cr(CH_2SiMe_3)_4$ (Scheme 118). The room temperature magnetic moment of 2.68 BM is consistent with the Cr^{IV} formulation; the IR spectrum is consistent with a monomer, and a molecular ion has been observed in the mass spectrum. As with $Cr(OBu^t)_4$,[1316] no ESR signal has been detected down to 98 K.

(285)



The sterically demanding secondary alcohol bis(*t*-butyl)methanol (2,2,4,4-tetramethylpentan-3-ol) does not react with $Cr\{N(SiMe_3)_2\}_3$ or $Cr(NEt_2)_4$, but the chromium(III) complexes $Cr(OCHBu^t_2)_3 \cdot THF$ and $LiCr(OCHBu^t_2)_4$, and the chromium(IV) complex $Cr(OCHBu^t_2)_4$ have

[a] Low yield of $Cr(1\text{-ado})_4$ by this route.

Scheme 118

been prepared as in the lower part of Scheme 118.[1320] All are soluble in non-polar solvents and $Cr(OCHBu^t_2)_3$ is a monomer in benzene, but the solid has a low moment ($\mu_{eff} = 3.2$ BM at 296 K) and the broad IR band, ν(Cr—O), at 555 cm^{-1} also suggests that it is a dimer. The absence of strong bands between 450 and 750 cm^{-1} suggests that $Cr(OCHBu^t_2)_4$ is a monomer, and this has been confirmed by an X-ray investigation. The O—Cr—O angles are close to tetrahedral and the crowding in the molecule prevents coordination oligomerization (**286**). The short Cr—O bond lengths (1.773 Å) indicate O→Cr $p\pi$–$d\pi$ bonding, which may account for the rather large Cr—O—C bond angles (140.5, 141.1°).

(286)

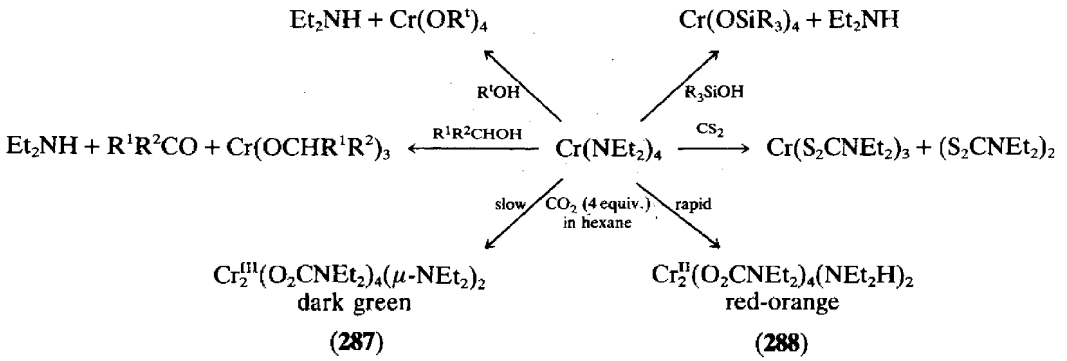
35.5.4.3 Amides

Equations (85) and (86) express the general method[592,618] for the preparation of chromium(IV) dialkylamides. The chromium(III) dialkylamide (Section 35.4.2.7) is extracted into pentane from the residue after removal of the solvent; careful evaporation of the pentane gives $Cr(NR_2)_3$ which disproportionates on further heating in vacuum because of the volatility of $Cr^{IV}(NR_2)_4$. The method has been successful with R = Et, Pr and R_2 = MeBu, C_5H_{10}, but failed with higher homologues because of the low volatility of the Cr^{IV} species, and with

R = Me because the initial reaction is then more complicated than expressed by equation (85). In dimeric $Cr_2(NR_2)_6$, steric hindrance prevents chromium(III) from obtaining its preferred octahedral coordination; this, the ligand field stabilization in $Cr(NR_2)_4$ (tetrahedral, d^2), the covalency of the Cr^{IV}—NR_2 bond, and the polymeric structure of involatile $Cr^{II}(NEt_2)_2$ all contribute to the driving force for reaction (86). The structural changes are represented for R = Et in equation (87).

$$CrCl_3 + 3LiNR_2 \xrightarrow[0\,^\circ C]{THF} Cr^{III}(NR_2)_3 + 3LiCl \quad (85)$$

anhydrous



$$2Cr^{III}(NR_2)_3 \xrightarrow[10^{-3}\ mm\ Hg]{40\text{–}100\,^\circ C} Cr^{IV}(NR_2)_4\uparrow + Cr^{II}(NR_2)_2 \quad (86)$$

$$(Et_2N)_2Cr^{III}\begin{smallmatrix}\diagup NEt_2\\ \diagdown NEt_2\end{smallmatrix}Cr^{III}(NEt_2)_2 \xrightarrow[transfer]{e^-} (Et_2N)_2Cr^{IV}\begin{smallmatrix}\diagup NEt_2\\ \diagdown NEt_2\end{smallmatrix} + [Cr^{II}(NEt_2)_2]_n \quad (87)$$

The magnetic moments (*ca.* 2.8 BM, Table 108) vary little with temperature as expected for tetrahedral Cr^{IV}, and molecular ions were found in the mass spectra. Like $Cr(OBu^t)_4$, no ESR signal was detected over the temperature range 98–298 K. A band in the electronic absorption spectra (for R = Et, $\tilde{\nu} = 13\,700\ cm^{-1}$, $\varepsilon = 1200$) could not be assigned with confidence to simple *d*–*d* transitions because of the covalent nature of the Cr—N bonds in which there is likely to be N→Cr σ and p_π–d_π donor character. The He^I UVPES of $Cr(NEt_2)_4$ has been interpreted; it remains unclear why $Cr(NEt_2)_4$ is paramagnetic and $Mo(NEt_2)_4$ diamagnetic.[1321]

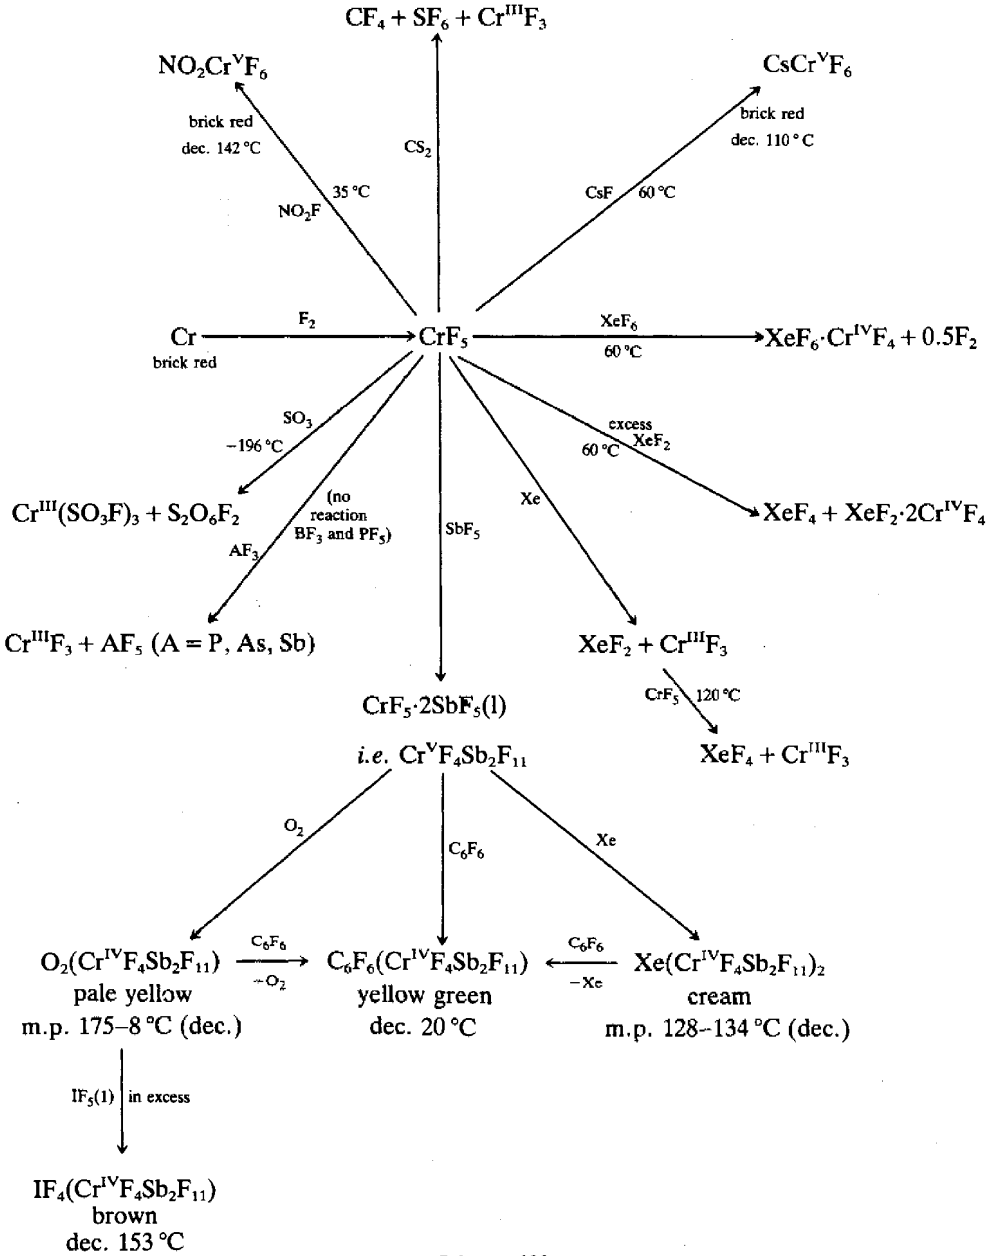
An unstable blue complex, which may be $Cr(O_2)(NPr^i_2)_3$ or the chromium(IV) nitroxide complex $CrO(NPr^i_2)_2(ONPr^i_2)$, is formed in a rapid reaction between oxygen and $Cr(NPr^i_2)_3$ in pentane.[592,1322]

Reactions of $Cr(NEt_2)_4$, some examples of which have been discussed elsewhere, are presented in Scheme 119. The unusual reactions with CO_2, which produce the chromium(III) and chromium(II) carbamato complexes (**287**) and (**288**), are believed[163] to proceed by CO_2 insertion into a Cr—N bond, which promotes β-hydrogen elimination from a coordinated diethylamido ligand, and then reductive elimination of Et_2NH produces a reactive chromium(II) species $Cr^{II}(O_2CNEt_2)(NEt_2)$. The subsequent reaction is dependent upon the relative concentration of CO_2.

Scheme 119

35.5.5 Porphyrins

Chromyl(IV) porphyrins are included in Section 35.4.9.1.

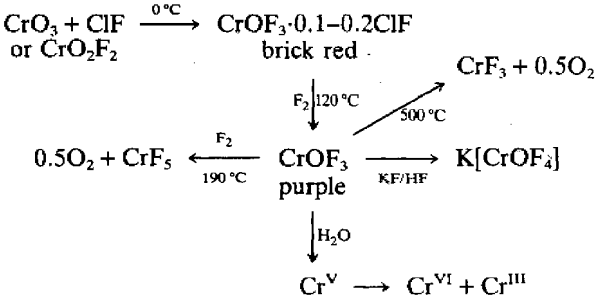


35.6 CHROMIUM(V)

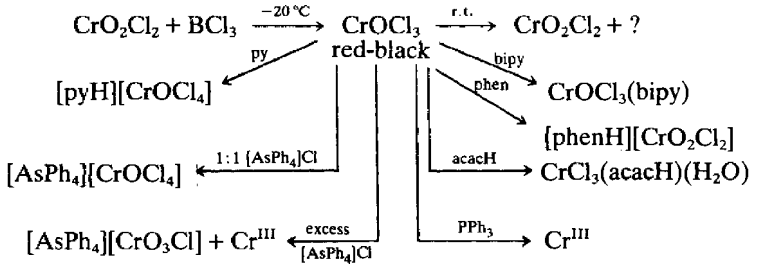
Chromium(V) chemistry is not extensive. Species of this oxidation state are frequently postulated as reactive intermediates during the reduction of chromium(VI). However, compounds of this oxidation state with reasonable stability are being discovered; there are

several classes of well-defined complex: the pentafluoride, oxyhalides and various oxohalochromates; oxo and peroxo complexes; water-soluble chromyl(V) derivatives of α-hydroxy carboxylates; and chromyl(V) complexes of porphyrins and other multidentate ligands (Section 35.4.9.1). There is a recent review.[1323]

35.6.1 Halogen Compounds



Earlier work on CrF_5, $CrOF_3$, $CrOCl_3$ and the oxohalochromates(V), *e.g.* $K[CrOF_4]$ and $K_2[CrOCl_5]$, is described in refs. 222 and 1306. More recent information is outlined in Schemes 120–122 and Table 109.



Scheme 120

35.6.1.1 Chromium(V) fluoride

The pentafluoride is a red solid (m.p. 30 °C) which can be prepared[1324,1325] by the action of fluorine on chromium powder and probably has a distorted trigonal bipyramidal structure in

Scheme 121

Scheme 122

the vapour phase.[1325] The solid and the liquid are fluorine-bridged polymers.[1364] CrF_5 is much more reactive than MoF_5 and WF_5; it is readily hydrolyzed and attacks glass, and is a powerful oxidant and fluorinating agent: for example, it will oxidize Xe to XeF_2 and XeF_4;[1326] and in an unusual reaction with XeF_6, fluorine is evolved and the brick red solid $XeF_6{\cdot}Cr^{IV}F_4$, which decomposes rapidly in air, obtained. Curie law behaviour and a magnetic moment of 2.76 BM support the Cr^{IV} formulation. The action of XeF_6 in excess on CrF_2 also gives $XeF_6{\cdot}CrF_4$.[227] Reaction of SO_3 and CrF_5 produces peroxydisulfuryl difluoride and $Cr(SO_3F)_3$.[1327] The viscous deep brown liquid $CrF_4Sb_2F_{11}$, which can be obtained from SbF_5 and CrF_5 and distils unchanged in vacuum, is another vigorous oxidizing and fluorinating agent comparable to PtF_6 in its ability to oxidize dioxygen and xenon (Scheme 120). It does not react with krypton or molecular nitrogen. There is one strong absorption band at 453 nm in its visible spectrum consistent with a d^1 system. The IR and Raman spectra support the presence of $Sb_2F_{11}^-$ but not CrF_4^+; thus the preferred structure is $CrF_4Sb_2F_{11}$ with fluoride bridges and partial charge separation.

A strong absorption at 1860 cm^{-1} in the Raman spectrum of $O_2(CrF_4Sb_2F_{11})$ is assignable to the dioxygenyl cation, and various bands at lower frequency in the IR and Raman spectra of this and related complexes (Scheme 120) to the $(CrF_4Sb_2F_{11})^-$ group. The magnetic moment of 3.08 BM at 295 K is low for three unpaired electrons (3.87 BM), suggesting that there is some interaction between the unpaired electrons of O_2^+ and $(Cr^{IV}F_4Sb_2F_{11})^-$. Bands characteristic of the cations are found in the IR and Raman spectra of $C_6F_6(CrF_4Sb_2F_{11})$ and $IF_4(CrF_4Sb_2F_{11})$.

The two T_{1u} modes of the octahedral CrF_6^- ion are found at 600 cm^{-1} and near 280 cm^{-1} in the spectra of NO_2CrF_6 and $CsCrF_6$, and the bands of the former at 2315 and 1360 cm^{-1} are assigned to the symmetric and asymmetric stretches of the $[O{=}N{=}O]^+$ group.[1328]

35.6.1.2 Chromyl(V) halides

It is difficult to obtain pure $CrOF_3$ by the reaction between CrO_3 or CrO_2F_2 and ClF because to remove the residual ClF from $CrOF_3{\cdot}0.1$–$0.2ClF$ requires repeated treatments with F_2 (Scheme 121). The purple $CrOF_3$ is slightly hygroscopic; it attacks certain organic solvents and glass above 230 °C.[1329] An apparently purer red-purple product, which hydrolyzes readily but is unreactive towards organic solvents, has been prepared by treatment of the adduct $CrOF_3{\cdot}0.3BrF_3$ with fluorine under mild conditions in which reaction to form CrF_5 (Scheme 121) does not occur.[1330]

Chromyl(V) chloride (Scheme 122) slowly decomposes at room temperature and in organic solvents.[1331,1332] From its IR spectrum $CrOCl_3$ in an argon matrix is a molecular species of C_{3v} symmetry (Cl—Cr—Cl angle ≈105°), but an additional ν(Cr—Cl) band, and the shift of other

bands to lower frequency, in the spectrum of the poorly volatile solid suggest polymerization.[1332] The IR spectrum of $CrOF_3$ also indicates halide bridging (Table 109).

35.6.1.3 Oxohalochromates(V) and other derivatives of chromyl(V) halides

$CrOCl_3(bipy)$ exists in two forms because the product from direct reaction (Scheme 122) exhibits a Cr—O stretching frequency at 964 cm^{-1}, but the product from thermal decomposition of $[bipyH_2][CrOCl_5]$ has a broad band at 898 cm^{-1} suggestive of polymerization through Cr=O···Cr interactions. The protons needed to form $[phenH][CrO_2Cl_2]$ and $[pyH][CrOCl_4]$ (Scheme 122) are presumed to have come from oxidation of the amine. The magnetic moments, ESR and electronic spectra of the oxochlorochromate derivatives are characteristic of Cr^V complexes, and they all disproportionate in water.[1331] The ionization energy (10 eV) of the *d* electron in $CrOCl_3$ has been derived from He^I and He^{II} PES.[1333]

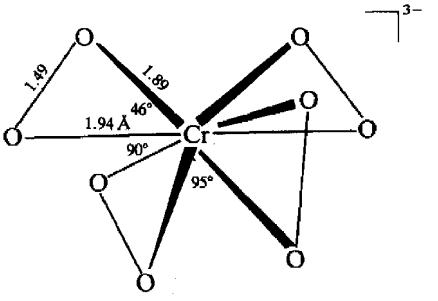
In a typical preparation of a tetrachlorooxochromate(V) salt, the chloride ACl in glacial acetic acid is added to CrO_3 in the same solvent saturated with hydrogen chloride (reaction 88). With some cations pentachlorooxochromates(V) can be obtained but the relation between cation size and coordination number is unclear.[1334,1335] A pentafluorooxochromate(V), $[NEt_4]_2[CrOF_5]$ was prepared by the reaction of AgF/HF with $[NEt_4][CrOCl_4]$ in dichloromethane,[1335] but its composition is in doubt.[1330] Care is needed to prevent contamination by Cr^{VI} or Cr^{III} impurities,[1334,1335] *e.g.* $K_2[CrOCl_5]$ is usually contaminated with $K_2[CrCl_5(H_2O)]$, although pure samples have been obtained,[1336] and attempts to prepare bromooxochromates(V) from CrO_3 produced perbromide (Br_3^-), although the preparation of $[bipyH_2][CrOBr_5]$ has been claimed.[1337] The ν(Cr=O) and ν(Cr—Cl) vibrations (Table 109) of $[CrOCl_4]^-$ and $[CrOCl_5]^-$ are in the ranges expected for isolated anions, and decrease with increase in coordination number from five to six as commonly found in other systems. An X-ray study of $[AsPh_4][CrOCl_4]$ has confirmed the presence of square pyramidal anions (Cr—O = 1.519, Cr—Cl = 2.240 Å).[1338] The short Cr—O distance indicates considerable $p_\pi \rightarrow d_\pi$ bonding. From a single crystal study[1339] the electronic absorption bands of $[CrOCl_4]^-$ at *ca.* 13 000 cm^{-1} and 18 000 cm^{-1} have been assigned to $d_{xy} \rightarrow d_{xz,yz}$ and Cr—O(π)→Cr—O(σ^*) transitions, and bands at higher frequency to charge transfer, but other calculations[1340] assign the band at 18 000 cm^{-1} to halogen-to-metal charge transfer. The ESR spectra have been interpreted. The fact that the addition of $[NEt_4]Cl$ to a solution of $[AsPh_4][CrOCl_4]$ changed $\bar{g}$ from 1.988 to 1.970 indicates that compounds earlier thought to contain $[CrOCl_5]^{2-}$ contained $[CrOCl_4]^-$.[1341]

$$CrO_3 + ACl \xrightarrow[HCl(g)]{MeCO_2H} [A][CrOCl_4] \qquad (88)$$

The product of reaction between CrO_2Cl_2 and PCl_5 (equation 89) at high temperature or in the presence of a reducing agent has been identified as $[PCl_4][CrCl_4]$ (Section 35.4.7.2). The product at room temperature has been shown to be the reactive chromyl(V) salt $[PCl_4][CrOCl_4]$ (Table 109) and not the chromium(VI) adduct $CrO_2Cl_2 \cdot PCl_5$.[1342] The pyridine adducts, $CrO_2Cl_2(py)_2$ and $CrO_2Cl_2(py)$, are believed to be mixtures of chromyl(V) species, and from reaction in acetic acid $[pyH][CrOCl_4]$, $[pyH][CrO_2Cl_2]$ and $[Cr_3O(MeCO_2)_6(py)_2(MeCO_2H)]Cl$ have been isolated; similarly $[bipyH][CrO_2Cl_2]$ has been obtained rather than $CrO_2Cl_2(bipy)$,

and Ph_4AsCl and CsCl with CrO_2Cl_2 in acetic acid yield mixtures of $[AsPh_4][CrO_3Cl]$ and $[AsPh_4][CrOCl_4]$, and $Cs[CrO_3Cl]$ and $Cs_2[CrOCl_5]$, respectively.[1343]

$$CrO_2Cl_2 + 2PCl_5 \xrightarrow{20\,^{\circ}C} [PCl_4][CrOCl_4] + POCl_3 + 0.5Cl_2 \quad (89)$$



Solutions containing $[CrOCl_4]^-$ and $[CrOCl_5]^{2-}$ anions slowly generate Cr^{III}. This has been exploited in the preparation[1334] of the Cr^{III} anions $[CrCl_4(MeCO_2H)_2]^-$ and $[CrCl_5MeCO_2H]^{2-}$, and various bipy complexes, *e.g.* $[CrCl_3(bipy)(NCMe)]$, from $[bipyH_2][CrOCl_5]$.[1344]

Oxidation of *cis*-$[Cr(H_2O)_2(phen)_2](NO_3)_3$ with sodium periodate at pH ≈ 4 produces the periodato complex $[Cr(IO_6)(phen)_2]$ (Table 109).

35.6.2 Complexes of Oxide and Peroxide

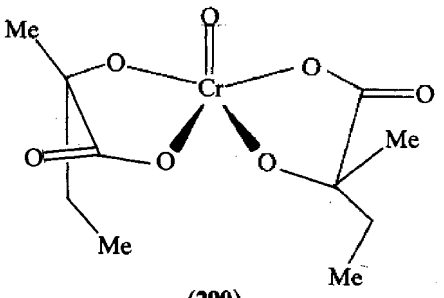
There are some well-defined chromium(V) complexes[1306] in which oxide is the ligand: $M^I_3CrO_4$ (M = Li, Na,[1305] K, Rb, Cs),[1345] $M^{II}_3[(CrO_4)_2]$ (M = Ca, Sr, Ba),[1306] $M^{II}_5(CrO_4)_3OH$ (M = Ca, Sr, Ba) and $M_5(CrO_4)_3X$ (M = Ca, Sr, Ba, X = F or Cl). In these the Cr occupies a tetrahedral site. There are also the peroxides[1346] $M^I_3[Cr(O_2)_4]$ (M = NH_4, Na, K), which are obtained by the action of 30% H_2O_2 on alkaline chromate solutions. They are red-brown, paramagnetic salts (μ_{eff} = 2.94 BM) of some stability, and in $K_3[CrO_8]$ the anion has a distorted dodecahedral arrangement (**289**) with the oxygen coordination occurring in pairs, and the O—O distance close to that for peroxo bonds (O_2^{2-} = 1.49 Å).[1306,1346,1347] Not much coordination chemistry of these complexes has been published since the reviews by Rosenblum and Holt[1306] and Connor and Ebsworth.[1346] Some investigations of the ESR[1348] and electronic spectra[1349] of CrO_4^{3-} doped in chloroapatites [$(PO_4)_3Cl^-$ salts] have been reported. The belief that $Sr_5(PO_4)_3Cl$ is isotypic with apatite has been disproved by a single crystal study.[1350] The three equilibrium phases in the ternary system $CaO—Cr^{VI}O_3—Cr^{III}_2O_3$ (the ternary compound, thought to have a chromate chromite formulation such as $Ca_9(Cr^{VI}_4Cr^{III}_2)O_{24}$, calcium chromate $CaCr^{VI}O_4$ and monocalcium chromite $CaCr^{III}_2O_4$) have been further studied. Comparisons of the solid state IR, diffuse reflectance and ESR spectra of the three phases suggest that Cr^{III} is not present in the ternary phase, but $Cr^VO_4^{3-}$ anions are. Hence, the solid ternary phase is best described as $Ca_3(Cr^VO_4)_2$ rather than $Ca_9(Cr^{VI}_4Cr^{III}_2)O_{24}$. The latter represents what happens when the ternary phase is dissolved in acid, where Cr^V disproportionates into Cr^{VI} and Cr^{III}.[1351] Disproportionation of Li_3CrO_4 (equation 90) takes place in a KCl/LiCl melt.[1352] The thermal decomposition of some rare earth chromates(V) has been related to their structures,[1353] and magnetic measurements on $KSrCrO_4$ and $KBaCrO_4$ confirm the V oxidation state.[1354]

$$3Li_3Cr^VO_4 \longrightarrow 2Li_2Cr^{VI}O_4 + LiCr^{III}O_2 + 2Li_2O \quad (90)$$

(**289**)

35.6.3 Complexes of Tertiary α-Hydroxy Carboxylates

The formation and decomposition of Cr^V in aqueous and non-aqueous media during the oxidation of organic substrates such as oxalic acid and ethylene glycol by potassium dichromate has been recognized for some time. No study resulted in the isolation of a stable, well-characterized chromium(V) complex until 1978 when potassium bis(2-hydroxy-2-methylbutyrato)oxochromate(V) monohydrate was prepared from chromium trioxide and the tertiary α-hydroxy acid in dilute perchloric acid according to equation (91). The Cr^V, which is



produced in equimolar quantity with Cr^{III}, undergoes further reduction, first slowly and then very rapidly. Good yields of the potassium salt are obtained after neutralization with $KHCO_3$, provided the separation procedures are carried out expeditiously, at low temperature as far as possible, and with careful control of pH.[1355] A simpler, generally applicable route with good yields to this type of complex is the reaction of anhydrous $Na_2Cr_2O_7$ with the tertiary α-hydroxy acids $RR'C(OH)CO_2H$ ($R = R' = Me$, Et, Bu; $R = Me$, $R' = Et$, Ph, R,R' = $(CH_2)_n$, $n = 4$, 5) in acetone (equation 92).[1356] The complexes are insoluble in non-polar solvents, soluble in water and acetone and heat stable. Whilst higher alkyl groups stabilize the complex, phenyl groups have a destabilizing effect. Many other hydroxy acids form unstable Cr^V complexes in solution.

$$2HCrO_4^- + 4EtMeC(OH)CO_2H \xrightarrow[2\text{–}3\ d]{4H^+,\ -16\,^\circ C} [OCr(O_2COCMeEt)_2]^- + Cr^{3+} + 2MeCOEt + 2CO_2 + 5H_2O \quad (91)$$

$$Na_2Cr_2O_7 + 5RR'C(OH)CO_2H \longrightarrow 2Na[OCr(O_2COCRR')_2] + RR'CO + CO_2 + 5H_2O \quad (92)$$

The salt $Na[OCr(O_2COCEt_2)_2]$ has been used in recent mechanistic studies of the oxidation of NH_3OH^+ and $N_2H_5^+$ by Cr^V; the former yields Cr—NO derivatives (see also Section 35.4.2.6) and the latter N_2 and Cr^{III}.[1357]

The structure of $K[OCr(O_2COCMeEt)_2]$ (**290**), obtained with difficulty from a poor crystal, contains pentacoordinate Cr^V and *trans* bidentate ligands of the same chirality, although enantiomers of the complete anions are present in the crystal. The short apical Cr—O bond distance (Table 110) is compatible with a Cr^V=O group. The other Cr—O distances are greater and differ from each other, and all O—Cr—O bond angles depart considerably from 90° or 180° so that the coordination polyhedron is much distorted from a square pyramid. In the solid the ethyl groups close off the position *trans* to the chromyl oxygen. The oxidation state of (**290**), and of the sodium salts,[1356] has been established by analytical methods, including a new iodometric method which determines Cr^V separately from its ability to oxidize iodide rapidly at much lower acidities than Cr^{VI} does. The electronic spectrum, magnetic moment and ESR data (Table 110) confirm the Cr^V assignment, and the Cr=O stretching frequency is consistent with a terminal Cr—O multiple bond. The stability of these Cr^V complexes to oxidative decomposition has not yet been explained.

(**290**)

Other chromium(V) complexes stable to reduction and hydrolysis can be prepared[1358,1359] by reaction of chromate with perfluoropinacol $(CF_3)_2C(OH)C(OH)(CF_3)_2$ (H_2pfp) (equation 93). Hydroxy acids slowly displace two chloride ligands of $Cs_2[CrOCl_5]$ in hot MeCN to give $CrO(AB)Cl_3$ in which AB is tartrate, hydroxymalonate or malate. ESR data indicate that these are Cr^V complexes but the magnetic moments are high.[1335] IR bands near 940 cm^{-1} and 340 cm^{-1} have been assigned to the ν(CrO) and ν(CrCl) vibrations respectively. A dibenzoato complex $Cr(O_2CC_6H_5)_2Cl_3$ has also been described.[1360]

$$K_2CrO_4 + H_2pfp \xrightarrow[H_2SO_4,\ \text{boil}]{EtOH/H_2O} K[OCr(pfp)_2] \quad (93)$$

35.6.4 Porphyrins and Schiff's Bases

Chromium(V) complexes of these ligands are included in Section 35.4.9.1.

35.7 CHROMIUM(VI)

Although there are several very important chromium(VI) compounds, the powerful oxidizing ability of this oxidation state leads to the oxidation of many potential ligands, and its coordination chemistry is limited. However, the oxidizing ability is exploited in many organic syntheses,[2] and a new oxidizing system is $CrO_3/HBF_4/MeCN$.[1361] A safer method of preparing the reagent *t*-butyl chromate has been reported.[1362] Aqueous solutions of CrO_4^{2-} react with excess NH_2OH in the presence of various coligands to generate complexes containing the $[Cr(NO)]^{2+}$ moiety (Section 35.4.2.6).

References to the many extensive accounts of the preparation, properties and reactions of chromium(VI) compounds, and their industrial and analytical importance have been collected.[2,1363]

35.7.1 Hexafluoride and Chromyl(VI) Halides

Chromium hexafluoride (Table 111), the only hexafluoride of the first transition series, was first prepared in small yields together with CrF_5 from the metal powder and fluorine at 400 °C and 350 atm. It decomposes rapidly to CrF_5 and F_2. Recently, it has been prepared from CrO_3 and F_2 under less extreme conditions, *i.e.* 170 °C and 25 atm. The lemon yellow CrF_6 sublimes at room temperature from the CrF_5 which is also formed. IR spectra (N_2 matrix) showed Cr—F stretching vibrations centred at 759 cm^{-1}. Weaker bands due to some CrO_2F_2, $CrOF_4$, CrF_5 and CrF_4 were also identified in the spectra.[1364] It has been suggested that the fluorination of CrO_3 by F_2 at 4 atm is stepwise, because as the reaction temperature increases the main products are CrO_2F_2 (150 °C), $CrOF_4$ (220 °C) and a mixture of CrF_5 and CrF_4 (250 °C) believed to come from the decomposition of CrF_6.[1365] This is confirmed by the new preparation of CrF_6.

The oxotetrafluoride $CrOF_4$ is an easily hydrolyzed solid obtained as a by-product when fluorine is passed over chromium,[1365] but it is better prepared from CrO_3 as just outlined. It is a powerful fluorinating and oxidizing agent, is fluoride bridged in the solid state, molecular (C_{4v}) in a low temperature matrix, and forms the salt $Cs[CrOF_5]$ (Table 111).[1366]

The dioxofluoride CrO_2F_2 can be obtained in many ways. The methods starting from CrO_3 outlined in equations (94) to (97) are generally more convenient[1367] than earlier ones which involve F_2[1365], HF, SF_4, SeF_4, CoF_3 or IF_5. In reactions (96) and (97) purification is simplified because CrO_2F_2 is volatile and WOF_4 and $MoOF_4$ are not. Treatment of CrO_2Cl_2 with F_2 or ClF also produces CrO_2F_2. The reaction between CrO_2F_2 and CrO_2Cl_2 gives CrO_2ClF, which from its IR and mass spectra is a true compound.[1368] Decomposition of CrO_2F_2 to $CrOF_2$ occurs at high temperature (500–525 °C).[1369] It is a powerful oxidizing agent and reacts vigorously with NO, NO_2 and SO_2 as equations (98) to (100) show.

$$CrO_3 + \text{excess ClF} \xrightarrow{0\,^\circ C} CrO_2F_2 + Cl_2 + O_2 + ClO_2F \quad (94)$$

$$CrO_3 + COF_2 \xrightarrow{185\,^\circ C} CrO_2F_2 + CO_2 \quad (95)$$

Table 111 Chromium(VI) Fluoride, the Chromyl(VI) Halides and $Cs[CrOF_5]$

Compound	*Comments*	*Ref.*
CrF_6 Yellow	Unstable above −100 °C, dec. to CrF_5 and F_2, ν(Cr—F), 759 cm^{-1}	1
$CrOF_4$ Dark red	M.p. 55 °C, separated by fractional sublimation, readily hydrolyzed, reacts with Pyrex, ν(Cr=O), 1020, Cr—F, 760–690, Cr—F—Cr, ~500 cm^{-1}	2 3
CrO_2F_2 Dark violet-red	M.p. 31.6 °C, reactive, attacks glass, sublimes 29.6 °C, stable in dark; ν(Cr—O), 1006, 1016 cm^{-1}, ν(Cr—F), 727, 789 cm^{-1}	2,4 5

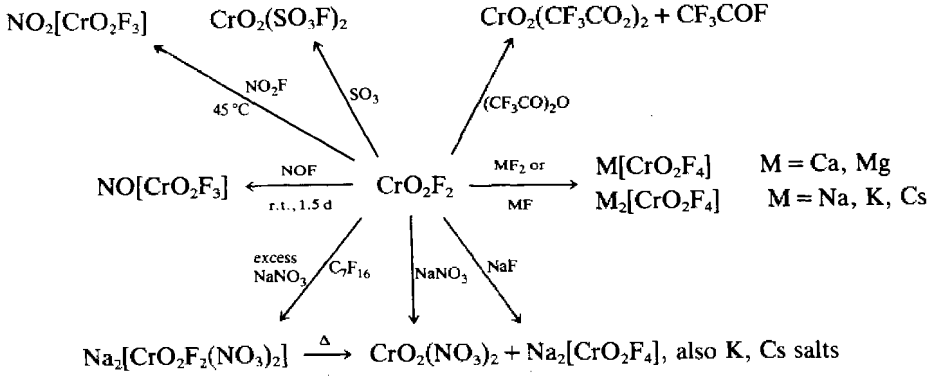
$$CrO_3 + WF_6 \xrightarrow{125\,^\circ C} CrO_2F_2 + WOF_4 \quad (96)$$



$$CrO_3 + MoF_6 \xrightarrow{125\,^\circ C} CrO_2F_2 + MoOF_4 \quad (97)$$

$$NO + CrO_2F_2 = NO{\cdot}CrO_2F_2 \quad (98)$$

$$SO_2 + 2CrO_2F_2 = SO_2{\cdot}2CrO_2F_2 \quad (99)$$

$$2NO_2 + CrO_2F_2 = (NO_2)_2CrO_2F_2 \quad (100)$$

Magnetic moment measurements suggest that the solids produced in equations (98) and (99) contain Cr^V and that produced in equation (100) contains Cr^{IV}.[1370] Other reactions of CrO_2F_2 are shown in Scheme 123.

Scheme 123

Chromyl chloride CrO_2Cl_2 can be prepared by distillation from a mixture of an alkali metal chloride and concentrated sulfuric acid with an alkali metal dichromate or CrO_3. It can also be prepared from dichromate and HCl, CrO_3 and an acid chloride such as PCl_5 or HSO_3Cl,[222] or CrO_3 and $AlCl_3$ in molten LiCl/NaCl/KCl.[1371]

Chromyl bromide CrO_2Br_2 is thermally unstable and little is known of its properties.[222] It can be prepared from CrO_2Cl_2 and HBr in excess at low temperature, and by reaction of CrO_3 with CF_3COBr and HBr in the presence of P_4O_{10}. The existence of the iodide has been claimed but as mentioned in a review[1372] of chromyl(VI) compounds this is unlikely.

Since the metal in the chromyl(VI) halides CrO_2F_2 and CrO_2Cl_2 is formally in the d^0 oxidation state, the structures of these molecules would be expected to follow the valence shell electron pair repulsion theory, *i.e.* $O{=}\widehat{Cr}{=}O > X{-}\widehat{Cr}{-}X$ (X = F or Cl). From the gas phase Raman and matrix IR spectra[1373] of CrO_2F_2 the angles are $O\widehat{CrO}$ 102.5° and $F\widehat{CrF}$ 124°, in agreement with the earlier values from electron diffraction,[1374] but not with those from microwave spectroscopy. Later electron diffraction values[1375] are $O\widehat{CrO}$ 107.8° and $F\widehat{CrF}$ 111.9°. Irrespective of the discrepancies, it is clear that molecular CrO_2F_2, in common with many d^0 complexes of the transition metals, does not follow the VESPR theory. The angles in CrO_2Cl_2 follow[1376] the same pattern: $O\widehat{CrO} = 108.5°$, $Cl\widehat{CrCl} = 113.3°$ (electron diffraction). The IR spectrum of CrO_2Cl_2 in an argon matrix has been reported.[1377]

The Raman spectrum of liquid CrO_2F_2 can be assigned in C_{2v} symmetry, and a band at 708 cm^{-1} arising from the symmetric Cr—F stretch is replaced in the solid-state spectrum by one at 540 cm^{-1}.[1378] The lowered frequency suggests polymerization through fluoride bridges in the solid, and this is consistent with the similar unit cell parameters of CrO_2F_2[1379] and VOF_3, which is known to be polymeric.

35.7.2 Other Chromyl(VI) Compounds

Chromyl derivatives CrO_2X_2 (X = nitrate, sulfate, perchlorate, fluorosulfate, borate, acetate, trichloroacetate, azide and benzoate) have long been known.[2] The perchlorate $CrO_2(ClO_4)_2$ has been obtained as a minor product in the reaction of Cl_2O_6 with $CrCl_3$. From its IR spectrum $CrO_2(ClO_4)_2$ contains monodentate perchlorate groups so the chromium has a tetrahedral environment like CrO_2Cl_2.[851]

Chromyl nitrate is a red, easily hydrolyzed liquid that can be prepared from N_2O_5 and CrO_3, CrO_2Cl_2 or $KCrO_3Cl$. A method which avoids the use of N_2O_5 is the reaction of CrO_2F_2 with sodium nitrate (Scheme 123).[1380] Besides the chromyl derivatives in Scheme 123, CrO_2F_2 forms the adduct $CrO_2F_2{\cdot}TaF_5$, $CrO_2F_2{\cdot}SbF_5$ and $CrO_2F_2{\cdot}2SbF_5$ which may be $[CrO_2F]^+$ salts.[1381]

The fluoro- and chloro-sulfates can be isolated as green solids, stable if dry, by reactions (101) and (102). Brown crystals can be sublimed from green $CrO_2(SO_3F)_2$,[1382] and if the reaction mixture in equation (101) is heated, dark brown crystals separate.[1383] In each case the brown form and the green form have substantially the same analyses, IR spectra and powder photographs $\{CrO_2(SO_3F)_2\}$ and are diamagnetic; the different colours may be due to different degrees of polymerization. Besides CrO_2Cl_2, CrO_3, K_2CrO_4 and $K_2Cr_2O_7$ are solvolyzed to $CrO_2(SO_3Cl)_2$ by HSO_3Cl.[1383,1384] In disulfuric acid $CrO_2(HSO_4)_2$ forms, identified by conductance and freezing point data and electronic spectroscopy.[1384,1385]

$$CrO_2Cl_2 + S_2O_6F_2 \longrightarrow CrO_2(SO_3F)_2 + Cl_2 \quad (101)$$

$$CrO_2Cl_2 + 2HSO_3Cl \longrightarrow CrO_2(SO_3Cl)_2 + 2HCl \quad (102)$$

The reactions (103) to (110) afford further chromyl derivatives: $CrO_2(O_2CR)_2$ (R = CF_3, $CClF_2$ or C_3F_7),[1386] $CrO_2(O_3SCF_3)_2$, $CrO_2(NO_3)(O_2CCF_3)$,[1387] $CrO_2(O_2PF_2)_2$,[1388] $CrO_2(OTeF_5)_2$,[1389] $CrO_2(OSeF_5)_2$,[1390] CrO_2ClN_3,[1391] $CrO_2Cl_2(ICN)_2$[1392] and $[CrO_2Cl(NCS)_3]_2$. The reaction of CrO_2Cl_2 in CS_2 or CCl_4 with various donor molecules (acetone, DMSO, THF, Ph_3P, *etc.*) does not produce stable adducts of higher coordination number but oxidation of the base and ill-defined Cr^{IV} products.[1393]

$$CrO_3 + (RCO)_2O \longrightarrow CrO_2(O_2CR)_2 \quad (103)$$

$$CrO_2(O_2CCF_3)_2 + CF_3SO_3H \longrightarrow CrO_2(O_3SCF_3)_2 + CF_3CO_2H \quad (104)$$

$$CrO_2(O_2CCF_3)_2 + HNO_3 \longrightarrow CrO_2(NO_3)(O_2CCF_3) + CrO_2(NO_3)_2 + CF_3CO_2H \quad (105)$$

$$CrO_3 + P_2O_3F_4 \longrightarrow CrO_2(O_2PF_2)_2 \quad (106)$$

$$CrF_5 + B(OTeF_5)_3 \longrightarrow CrO_2(OTeF_5)_2 + BF_3, TeF_6, CrF_4? \quad (107)$$

$$CrO_2Cl_2 + Hg(OSeF_5)_2 \longrightarrow CrO_2(OSeF_5)_2 \quad (108)$$

$$CrO_2Cl_2 + ICN \longrightarrow CrO_2Cl_2(ICN)_2 \quad (109)$$

$$CrO_2Cl_2 + (SCN)_2 \longrightarrow [CrO_2Cl_2(NCS)_3]_2 \quad (110)$$

The chromyl derivatives generally hydrolyze readily to chromate and the acid corresponding to the coordinated anion. Thermal decomposition of yellow $CrO_2(O_3SCF_3)_2$ and $CrO_2(O_2CCF_3)_2$ produces oxygen and the green anhydrous chromium(III) salts $Cr(O_3SCF_3)_3$[1387] and $Cr(O_2CCF_3)_3$:[1386] $CrO_2(O_2PF_2)_2$ is much less stable and readily yields $Cr(O_2PF_2)_3$; its solutions in CCl_4 are moderately stable, like those of $CrO_2(SCN)_2$ and $CrO_2(NCO)_2$, and have electronic spectra similar to those of other chromyl complexes.[1388] Chromyl chloride reacts with monocarboxylic acids to form trinuclear cations $[Cr_3O(O_2CR)_6(RCO_2H)_3]^+$ (R = H, Me); the low moments of the formate and chloride salts and of derivatives such as $[Cr_3O(O_2CMe)_6L_3]Cl$ (L = py, NH_3) suggest similar structures to other trinuclear complexes[1394] (Section 35.4.4.10). The anionic difluorophosphato complex $K_2[CrO_2(O_2PF_2)_4]$ is prepared by reaction of K_2CrO_4 with $P_2O_3F_4$.[1388] From their IR and Raman spectra, it is concluded that the adduct $CrO_2Cl_2(ICN)_2$ has a *cis* structure with N-bonded ICN and $[CrO_2Cl_2(NCS)_3]_2$ has an —NCS—SCN-bridged structure.[1392]

35.7.3 Chromium(VI) Oxy Compounds

35.7.3.1 Chromium(VI) oxide

Most chromium(VI) compounds may be considered to be derived from the orange-red trioxide CrO_3, the anhydride of chromic acid, which can be crystallized from aqueous solutions of chromates and dichromates by the addition of sulfuric acid. When heated above its melting point, CrO_3 loses oxygen to form Cr_3O_8, Cr_2O_5, CrO_2 and finally Cr_2O_3. It consists of infinite chains of distorted CrO_4 tetrahedra sharing two corners; the bridging Cr—O distances are 1.748 Å and the terminal Cr—O distances 1.599 Å. The angle at the bridging oxygen is 143°.[1306] Electron diffraction data for gaseous CrO_3 can be best interpreted by assuming that it consists of trimers and tetramers.[1395] Depolymerization occurs on dissolution in water (to form H_2CrO_4) and in the few organic solvents in which it is soluble. It is a powerful oxidizing agent. Adducts, CrO_3py and CrO_3py_2, used as organic oxidants in CH_2Cl_2, are formed by pyridine bases, and with alcohols chromate esters are obtained.[2,1396]

35.7.3.2 Chromates, dichromates and polychromates

When CrO_3 is dissolved in water the equilibria (111) to (115) are set up. Above pH 8 the main species is yellow chromate CrO_4^{2-}; in the pH range 2–6 $HCrO_4^-$ and orange-red dichromate $Cr_2O_7^{2-}$ are in equilibrium; and below pH 1 H_2CrO_4 predominates. Chromates and dichromates of ammonium and the common metal ions are known: the ammonium, magnesium and alkali metal chromates are soluble in water, but those of silver, lead and the alkaline earth metals are only slightly soluble. Whether chromates or dichromates crystallize depends on the pH and the cation present. At high Cr^{VI} concentrations trichromates and tetrachromates form and some have been isolated as solids, *e.g.* $K_2Cr_3O_{10}$ and $K_2Cr_4O_{13}$, but, unlike molybdenum and tungsten, chromium does not exhibit an extensive iso- or hetero-polyanion chemistry. Many double chromates and basic chromates are also known.[2]

$$H_2CrO_4 \rightleftharpoons HCrO_4^- + H^+ \quad (111)$$

$$HCrO_4^- \rightleftharpoons CrO_4^{2-} + H^+ \quad (112)$$

$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2HCrO_4^- \quad (113)$$

$$Cr_2O_7^{2-} + OH^- \rightleftharpoons HCrO_4^- + CrO_4^{2-} \quad (114)$$

$$HCrO_4^- + OH^- \rightleftharpoons CrO_4^{2-} + H_2O \quad (115)$$

Chromates and polychromates of organic cations can be prepared by careful hydrolysis of the appropriate ester with the organic base in organic solvents. Examples are $(NBu^nH_3)_2CrO_4$, $(pyH)_2Cr_3O_{10}$ and $(NBu^n_4)_2Cr_4O_{13}$.[1397]

Whereas the ester bis(trimethylsilyl) chromate is explosive and readily hydrolyzed,[1398] the crystal structure[1399] of the triphenyl derivative has been obtained (Table 112). The germanium, tin and lead analogues have been prepared by reactions (116) to (118). These compounds are

better regarded as chromate esters than chromyl(VI) compounds.[1400] Electrochemical reduction of $(Ph_3XO)_2CrO_2$ (X = Si, Ge, Sn or Pb) is generally irreversible and of little use in the characterization of chromium(VI) complexes.[1401] Chromates of the type Me_3SbCrO_4 and $[Me_3Sn]_2[CrO_4]$ are also known.[1402]

$$2Ph_3GeBr + Ag_2CrO_4 \longrightarrow (Ph_3GeO)_2CrO_2 + 2AgBr \quad (116)$$

$$2Ph_3SnCl + Ag_2CrO_4 \longrightarrow (Ph_3SnO)_2CrO_2 + 2AgCl \quad (117)$$

$$2Ph_3PbCl + Na_2CrO_4 \longrightarrow (Ph_3PbO)_2CrO_2 + 2NaCl \quad (118)$$

Table 112 Bond Distances in CrO_3 and Representative Chromates and Polychromates

Compound	*Bond distances* (Å)	*Ref.*
CrO_3	Cr—O (av), 1.599, Cr—O (br), 1.748 Å, Cr—O—Cr, 143°	1

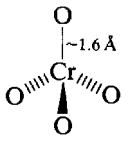
In recent investigations (see also Section 35.6.2) the double chromates $KLn(CrO_4)_2$ (Ln = La–Sm), $RbLn(CrO_4)_2$ (Ln = La–Nd) and $CsLa(CrO_4)_2$ have been found to be isostructural with crocoite ($PbCrO_4$),[1403] the chromates $A_4Pb_4(CrO_4)_6$ (A = K, NH_4) have been obtained,[1404] and the reactions of chromate, dichromate or CrO_3 in alkali carbonate[1405] and bisulfate[1406] eutectics and fused sodium nitrite[1407] have been investigated. Interaction between Ag^+ and CrO_4^- in (K, Na)NO_3 melts leads to the formation of the weak complexes $[AgCrO_4]^-$, $[Ag_2CrO_4]$ and $[Ag(CrO_4)_2]^{3-}$.[1408]

(*i*) *Spectroscopic investigations*

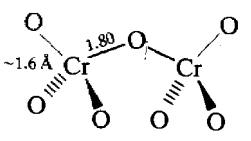
There have been a number of investigations of the electronic and IR spectra of chromates, and attempts to account for the electronic spectrum by molecular orbital theory.[1306,1409]

From the splittings of the IR absorption bands of CrO_4^{2-} it can be determined whether the anion is mono- or bi-dentate, *e.g.* it is monodentate in $[Cr(CrO_4)(NH_3)_5]I$ and bidentate in $[Cr(CrO_4)(NH_3)_4]I$.[1410] Complete vibrational assignments have been made for K_2CrO_4;[1411] and molecular K_2CrO_4 has been isolated in an argon matrix; the IR spectrum shows that its structure is D_{2d} and the O—Cr—O bond angles are $96 \pm 5°$.[1412] RR spectroscopy has been used to investigate the unusual red colour of Ag_2CrO_4.[1413] Crystallographic and IR studies on the hydroxychromates $M^I M^{III}_3(OH)_6(CrO_4)_2$ (M^I = Na, K, NH_4; M^{III} = Fe, Al) have confirmed that they are isomorphous.[1414]



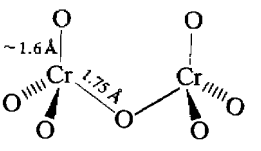
The NMR shifts of the ^{17}O spectra of CrO_4^{2-}, $Cr_2O_7^{2-}$ and CrO_2Cl_2 have been related to the π character of the Cr—O linkages, and from them it has been deduced that the Cr—O—Cr linkage in dichromate is angular rather than linear in solution as well as in the solid.[1415]

(*ii*) *Structures of chromates and polychromates*

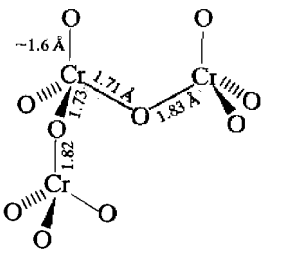


The tetrahedral structure of the anion in simple chromates such as K_2CrO_4 has been confirmed by many single crystal X-ray studies. Within the CrO_4 groups (**291**) the O—Cr—O angles are close to the tetrahedral value and the Cr—O bond distances are essentially equal and close to 1.6 Å unless there is interaction of some oxygen atoms with other cations, *e.g.* Ce^{4+} in $Ce(CrO_4)_2 \cdot 2H_2O$ (Table 112). Chromates are often isomorphous with corresponding sulfates.

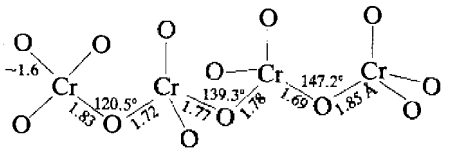
The dichromates consist of two distorted CrO_4 tetrahedra with a corner in common. Rubidium dichromate, for example, exists in several crystal forms which contain anions shaped like (**292**); the bridging Cr—O bonds are considerably longer (~1.8 Å) than the terminal Cr—O bonds, which are similar to those in CrO_4^{2-}, and the Cr—O—Cr angles are 123°. In $SrCr_2O_7$ there are distinct $Cr_2O_7^{2-}$ units of types (**292**) and (**293**) with Cr—O—Cr angles of 133° and 140° respectively.[1306] A more accurate determination of the structure of $(NH_4)_2Cr_2O_7$ has shown that Cr—O_{br} is 1.78 Å (not 1.98 Å as earlier reported).



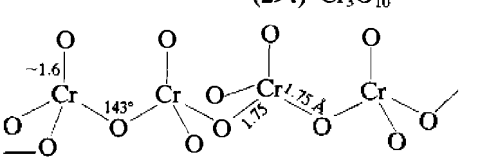
The structures of the tri- and tetra-chromates, *e.g.* $Rb_2Cr_3O_{10}$ (**294**) and $Rb_2Cr_4O_{13}$ (**295**), and of polymeric CrO_3 (**296**) follow the same general pattern, although the detailed structure can vary with the cation.



(**291**) CrO_4^{2-}



(**292**) $Cr_2O_7^{2-}$



(**293**) $Cr_2O_7^{2-}$

(**294**) $Cr_3O_{10}^{2-}$

(**295**) $Cr_4O_{13}^{2-}$

(**296**) CrO_3

The Cr—O—Cr angle varies between 115 and 148° and the Cr—O_{br} distance between 1.7 and 1.9 Å in the condensed chromates. Brief structural details for examples of the different chromates are in Table 112. There are earlier results in Ref. 1306.

Chromates(VI) of the divalent metals (V, Ni, Co, Cu, Zn and Cd) are isomorphous, and each Cr atom is surrounded by six oxygen atoms in distorted, edge-sharing octahedra.[1306]

35.7.4 Anionic Oxo Halides and Other Substituted Chromates

The equilibria (111) to (115) exist only in HNO_3 and $HClO_4$ and are modified when other anions are present because of the formation of substituted chromates, *e.g.* chlorochromate and sulfatochromate, as in equations (119) and (120). Dichromate is slow to oxidize, otherwise no halochromates could be isolated.[2,222]

$$HCr_2O_7^- + HCl \rightleftharpoons CrO_3Cl^- + H_2O \quad (119)$$

$$HCr_2O_7^- + HSO_4^- \rightleftharpoons [CrO_3SO_4]^{2-} + H_2O \quad (120)$$

Salts of the trioxohalochromates(VI) $[CrO_3X]^-$ (X = F, Cl, Table 113) can be crystallized from solutions of the appropriate dichromate and HX and have uses as oxidants of organic compounds. The fluorochromates can also be obtained from CrO_3, HF and the alkali metal carbonate, and the chlorochromates from CrO_3, MCl and HCl. Potassium trioxochlorochromate may also be prepared from K_2CrO_4 and CrO_2Cl_2. Salts of $[CrO_3Br]^-$ and $[CrO_3I]^-$ have been reported but they decompose through oxidation of the halide.

Table 113 Fluoro- and Chloro-chromates(VI)

Compound	*Comments*	*Ref.*
$M[CrO_3F]$ Red	M = K, Rb, Cs, NH_4, easily hydrolyzed; Cr—O, 1.60 and 1.62, Cr—F, 1.68 Å (NH_4) 2 Cr—O, 1.60, 2 Cr—(O, F), 1.67 Å, disorder (Rb)	1, 2

There are three major processes in the thermal decomposition of the alkali metal chlorochromates $M[CrO_3Cl]$ (M = Li, K, Rb or Cs); these are the formation of CrO_2Cl_2, MCr_3O_8 and Cr_2O_3; in each case there is simultaneous formation of $M_2Cr_2O_7$ and MCl.[1416] The rubidium salt is isostructural with the potassium and ammonium salts, but not the cesium salt. The anions are approximately tetrahedral. The average values for the Cr—O bond distances in $Cs(Rb)[CrO_3Cl]$ are rather longer than determined earlier for $K(NH_4)[CrO_3Cl]$ (Table 113).[1417] Some disorder was found in the tetrahedral $[CrO_3F]^-$ anions of $KCrO_3F$ and the average Cr—(O, F) distance is 1.65 Å.[1418]

Salts $M[CrO_3X]$ (where X = iodate, sulfate, NH_2, *etc.*) have earlier been described.[2] Adducts of $KCrO_3X$ (X = F, Cl, Br, IO_3) with primary and secondary aliphatic amines have been characterized in solution by their UV and IR spectra.[1419]

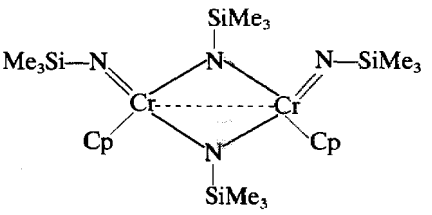
The fluorinated anhydride $(CF_3CO)_2O$ removes chloride from $K[CrO_3Cl]$ and adds across one Cr=O bond according to equation (121).[1420] The same anionic complex is obtained from $K_2Cr_2O_7$ and the anhydride; but $K_2[CrO_2(O_2CCF_3)_4]$ is formed from K_2CrO_4. Other chromates and dichromates, and other fluorinated anhydrides, react similarly. The complexes are red-brown solids, easily hydrolyzed and unstable to heat and light.

$$K[CrO_3Cl] + 2(CF_3CO)_2O \longrightarrow K[CrO_2(O_2CCF_3)_3] + CF_3COCl \quad (121)$$

Boron trifluoride adducts approximating to $K_2[CrO_4(BF_3)_2]$ and $K_2[CrO_4(BF_3)_3]$ have been reported.[1421]

The salts $A[CrO_2F_3]$, ($A = NO^+$ or NO_2^+, Scheme 123) and the other dioxo compounds below are believed to contain *cis*-dioxo groups and fluorine bridges because there are IR bands in the 900–1000 cm^{-1} region, which are assignable to the $\nu_s(CrO_2)$ and $\nu_{as}(CrO_2)$ vibrations, and bands in the regions of 550–750 cm^{-1} and 350 cm^{-1} assignable to terminal and bridging fluoride respectively.[1422] Salts of the anions $[CrO_4F]^{3-}$ and $[CrO_2F_4]^{2-}$ have been described;[2] and $M_2[CrO_2F_4]$ (M = Na, K, Cs), $M[CrO_2F_4]$ (M = Ca, Mg)[1370] and $Na_2[CrO_2F_2(NO_3)_2]$ can be derived from CrO_2F_2 (Scheme 123).[1380]

35.7.5 Organoimidochromium(VI) Complexes



Among the *t*-alkylimido complexes of the d^0 transition metals of groups V to VII is deep red $(Me_3SiO)_2Cr(NBu^t)_2$, which can be prepared from CrO_3 or CrO_2Cl_2 and *t*-butyl(trimethylsilyl)amine and is monomeric from preliminary X-ray data. After removal of the hexane (equation 122), the residue is dissolved in hexamethyldisiloxane and the imide separates at −40 °C.[1423] The preparation from CrO_2Cl_2 (equation 123) has some advantages.[1424] The diimide forms the oxo derivative $(Me_3SiO)_2CrO(NBu^t)$ on reaction with benzaldehyde.

$$CrO_3 + NHBu^t(SiMe_3) \xrightarrow[\text{reflux}]{\text{hexane}} (Me_3SiO)_2Cr(NBu^t)_2 \quad (122)$$

$$CrO_2Cl_2 + NHBu^t(SiMe_3) \xrightarrow[\text{reflux}]{\text{hexane}} (Me_3SiO)_2Cr(NBu^t)_2 + 2[NH_2Bu^t(SiMe_3)]Cl \quad (123)$$

in excess

The reaction of bis(trimethylsilyl)diazene with chromocene or $CpCrCl_2$ affords the dark violet crystalline imide with structure (**297**). The imide shows distinct trimethylsilyl signals in the NMR spectrum, and in methanol forms $[CpCr(NH)(NSiMe_3)]_2$.[1425]

(**297**)

35.7.6 Mixed Oxidation State (III and VI) Oxo Compounds

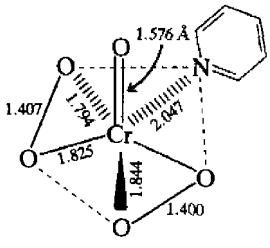
The compounds MCr_3O_8 have long been known. In their structures $Cr^{III}O_6$ octahedra and $Cr^{VI}O_4$ tetrahedra are linked together in the ratio 1:2 by sharing corners and edges.[1306] Several new methods of preparation have been described (equations 124 to 127). Trichromates ($M_2Cr_3O_{10}$, M = K, Cs) give the same products as tetrachromates (equation 127).[1426]

$$KCrO_3Cl \xrightarrow[12\text{ h}]{275\text{ °C}} K_2Cr_2O_7 + KCr_3O_8 + 2KCl + 1.5Cl_2 \quad (124)$$

$$KCrO_3Cl + 2CrO_3 \xrightarrow{350\text{–}400\text{ °C}} KCr_3O_8 + 0.5Cl_2 + 0.5O_2 \quad (125)$$

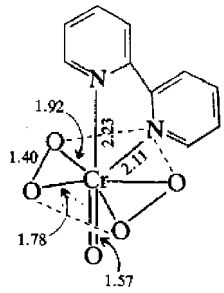
$$3MX + 5CrO_3 \xrightarrow{250\text{ °C}} M_2Cr_2O_7 + MCr_3O_8 + 1.5X_2 \quad (126)$$

$$2K_2Cr_4O_{13} \xrightarrow{\Delta} K_2Cr_2O_7 + 2KCr_3O_8 + 1.5O_2 \quad (127)$$



From the XPES, Cr_2O_5 can be described as a mixed valence compound containing Cr^{3+} and Cr^{6+} in the ratio 1:2 as in KCr_3O_8.[1427] The oxide Cr_5O_{12} is formulated $Cr_2(CrO_4)_3$.[1306]

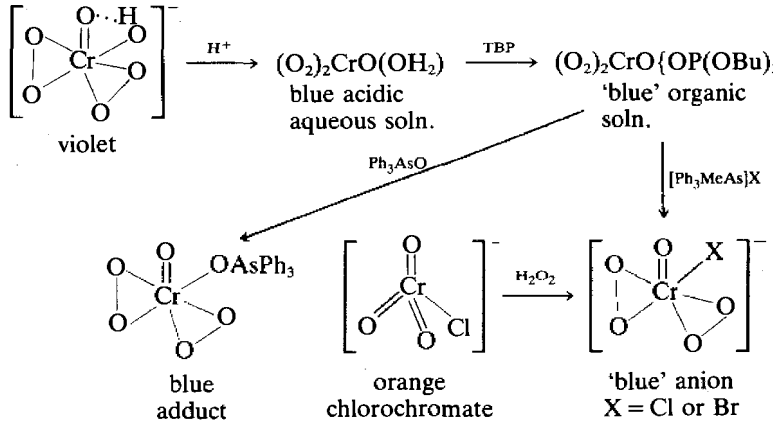
35.7.7 Peroxo Complexes of Chromium(IV), (V) and (VI)



The action of H_2O_2 on acidic dichromate solutions gives an unstable blue species which can be extracted into ether (equation 128).[2,518,1428] On the addition of pyridine the blue compound $Cr^{VI}O(O_2)_2py$ crystallizes. The molecules are distorted pentagonal pyramids with sideways-bonded peroxo groups (**298**);[1429] some workers with less refined data have reported rather different bond distances.[1430] In water the blue species is considered to be $CrO(O_2)_2(OH_2)$, in ether it is $CrO(O_2)_2OEt_2$, and amines such as aniline, bipy and phen can replace the pyridine. With bidentate bipy the coordination sphere becomes essentially a pentagonal bipyramid (**299**),

and the phen compound is similar; it also has one Cr—N bond (2.23 Å) much longer than the other (2.11 Å).[1431] By extraction into tri-*n*-butylphosphate (TBP) containing Ph_3AsO, the adduct $CrO(O_2)_2OAsPh_3$ can be obtained.[1432]

$$HCrO_4^- + 2H_2O_2 + H^+ \longrightarrow \underset{\text{blue}}{CrO_5 \cdot H_2O} + 2H_2O \qquad (128)$$



(298)

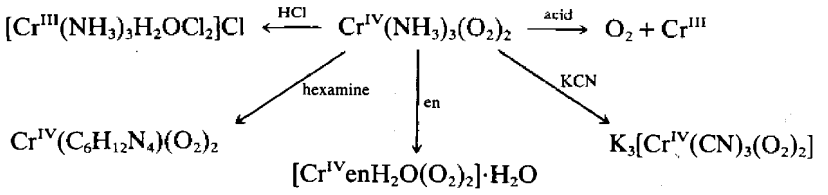
(299)

In neutral or weakly acidic solutions of dichromates and H_2O_2 the violet species $CrO_5(OH)^-$ forms (equation 129) and explosive violet salts $M[Cr^{VI}O(O_2)_2OH]$ ($M = NH_4$, K, Tl) can be isolated.[1433] The salt $[Ph_3MeAs][CrO(O_2)_2OH]$ is more stable, and from the lack of an OH band in the IR spectrum it is believed that the anion contains a strong hydrogen bond; related blue peroxohalochromates $[Ph_3MeAs][CrO(O_2)_2X]$ (where X is Cl or Br) are also known (Scheme 124).[1432] Kinetic studies show that the blue and the violet anions are formed by similar mechanisms.[1434]

$$HCrO_4^- + 2H_2O_2 \longrightarrow CrO_5(OH)^- + 2H_2O \qquad (129)$$

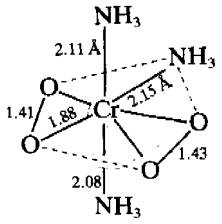
Scheme 124

The unstable, violet black compound $(NH_4)_2[Cr_2^{VI}O_2(O_2)_5]\cdot 2H_2O$ is produced[1435] by reaction of H_2O_2 with CrO_3 in the presence of NH_4Cl and HCl, and $Cr(O_2)(NPr^i_2)_3$ may be a peroxo chromium(V) compound (p. 138).



From the RR spectrum of $CrO(O_2)_2\cdot H_2O$, its instability has been related to the relatively low (952 cm^{-1}) Cr—O stretching vibration and the relatively high (1012 cm^{-1}) O—O stretching vibration.[1436] The peroxidic stretch was earlier assigned to a band in the 865 cm^{-1} region.[1433]

The chromium(V) complexes $M^I_3[Cr(O_2)_4]$, obtained from alkaline solutions, contain dodecahedral anions (see Section 35.6.2).



Brown crystals of paramagnetic, reasonably stable $Cr^{IV}(NH_3)_3(O_2)_2$ can be prepared[1437] according to equation (130). Some reactions of $Cr(NH_3)_3(O_2)_2$ are given in Scheme 125, and its structure (**300**) has been determined.[1438] The anion in $K_3[Cr(CN)_3(O_2)_2]$ is structurally similar,[1439] and the O—O bond distance is 1.45 Å. In $[Cr(en)H_2O(O_2)_2]\cdot H_2O$ this distance is 1.46 Å.[1440]

$$CrO_3 + 3NH_3 + 3H_2O_2 \xrightarrow{<-6\,^\circ C} Cr(NH_3)_3(O_2)_2 + 3H_2O + O_2 \qquad (130)$$

The action of H_2O_2 on aqueous solutions of CrO_3 containing amines gives the chromium(IV) complexes $[CrNH_3en(O_2)_2]\cdot H_2O$, $[Crdien(O_2)_2]\cdot H_2O$, $[CrenH_2O(O_2)_2]\cdot H_2O$, $[CrpnH_2O(O_2)_2]\cdot 2H_2O$ and $[CribnH_2O(O_2)_2]\cdot H_2O$. These and $Cr(NH_3)_3(O_2)_2$ are useful sources of Cr^{III}–

Scheme 125

(300)

amine complexes,[302] but their explosive nature is a disadvantage and rather few amines form this type of complex so the synthetic use is limited.

Further information on peroxo chromium complexes is given in Pascal.[3]

35.7.8 Biological Effects of Chromate(VI)

The biological effects of chromate are apparent in three main areas: mutagenicity and carcinogenicity, an adverse immune response and the use of chromate in clinical chemistry to tag erythrocytes. The clinical use of chromate has recently been reviewed[1441] and although reviews of the immune response to chromate are available[1442] little is known of the chemistry involved; this is surprising as chromate present in cement is a major cause of dermatitis.

The carcinogenicity and mutagenicity of chromium(VI) are well established.[1443] The toxicity is usually considered in terms of the uptake/reduction model[1443] since chromium(VI) readily passes into the cell, *via* anion channels, and once within the cell it is eventually reduced by cellular components to chromium(III) species. Figure 6 illustrates the likely fate of chromate within a mammalian cell. As can be appreciated from Figure 6 it is complexes trapped within the cell that are the agents responsible for the toxic effects of chromate. The systems which reduce the chromium(VI) are as yet unknown, as are the final products of the reaction. However, microsomes[1444] are capable of reducing chromium(VI) as are various nucleotides[1445] and even fulvic acids.[1446] In these cases chromium(V) species of considerable stability have been observed using EPR spectroscopy. Within the cell reduction by a sulfide is the most probable reaction.

Glutathione is an intracellular peptide important in the maintenance of redox status;[1446,1447] it is found at millimolar concentrations in typical mammalian cells and is implicated, in general,

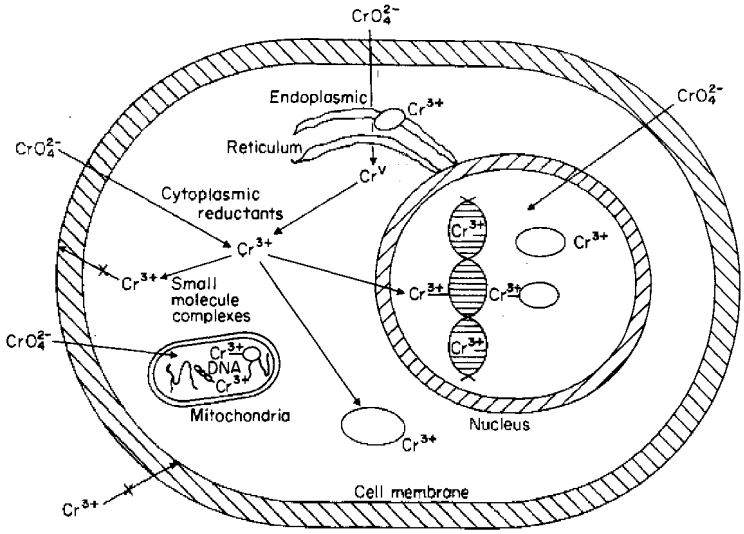


Figure 6 The uptake reduction model for chromate carcinogenicity (after Wetterhahn). Possible sites for reduction of chromate include the cytoplasm, endoplasmic reticulum, mitochondria or the nucleus[1443]

in the defence of cells challenged with oxidizing agents. However, in the case of chromate toxicity, cells with elevated levels of GSH have been shown to have an increased susceptibility to damage,[1449,1450] which perhaps indicates that a chromium complex of glutathione is an active intracellular toxin. It is most unusual for a toxic metabolite to be generated by a reaction with GSH.

The reaction of GSH with chromium(VI) has been studied in acidic solutions[1451,1452] under which the complete reduction of chromate to chromium(III) is rapid. Mechanisms involving thiolate esters of chromium(VI), which react with either protons or GSH, were suggested to be important. A detailed study of the reduction of chromate by various biological reducing agents (in neutral, buffered solutions, at low GSH concentrations) indicates that chromium(V) species are not generated[1453] and also suggests the importance of thiolate esters.

However at neutral pH, solutions of chromium(VI) containing an excess of glutathione (1:10) rapidly develop a green colour,[1454] which slowly decays to a purple colour typical of chromium(III) complexes. Concurrent with the green colour the typical EPR spectrum of a chromium(V) species is observed. Chromium(V) has also been observed in the EPR spectrum of frozen glasses obtained from reaction mixtures of chromium(VI) and glutathione.[1455]

A related reaction, that of L-cysteine with Cr^{VI} at neutral pH, has been studied in detail;[1456] the product was suggested to be the bis-*trans*-*S* complex of cysteine characterized crystallographically by DeMeester *et al.*,[1187] but no evidence for Cr^{V} species could be obtained, and the rate-determining step was suggested to involve two-electron transfer. It has been reported[1457] that initial one-electron reduction of chromium(VI) leads to chromium(III) complexes in which the oxidized form of the substrate is coordinated. The presence of chromium(V) in GSH/chromate reaction mixtures suggests that GSSG may be captured in the reaction of GSH with chromium(VI). This is in marked contrast to the results of Pennington[1456] with L-cysteine, but Wetterhahn[1443] has some evidence for Cr^{III}/GSSG complexes from such reactions.

The way in which the dominant reduction mechanism for chromate changes with the reaction conditions and how this is related to the toxicity of chromate is not as yet clear. As outlined above, the products of the reaction may depend on the mechanism of reduction and these, as yet, unidentified chromium complexes are probably the agents responsible for the mutagenicity of chromate. The substantial stability of the chromium(V) complexes and thiolate esters generated in the reaction of GSH with chromate suggests that if similar complexes were formed *in vivo* they would have time to reach many intracellular compartments and could hence be the crucial active intermediates in the toxicity of chromate.

The complexes responsible for the toxicity have not yet been identified. The possibilities include: the thiolate ester, a relatively stable chromium(V) species, or a chromium(III) complex. More work is needed in this area.

37.1 INTRODUCTION

The chemistry of tungsten is varied and complex not only because it covers nine oxidation states (−2 to +6), but also because of its ability to form complexes with different coordination numbers and geometries, and because of its tendency to form clusters and polynuclear complexes with a variety of metal atoms.

The chemistry of this element has been studied since the characterization of tungstic acid in

1781,[1] and the oxychlorides, the hexachloride and the hexabromide in 1857. Until the 1930s most of the development centered around the higher oxidation states of the element. The development of the lower oxidation states had to await the discovery of $W(CO)_6$. The successful synthesis of cyclopentadienyl compounds has led to the development of its organometallic chemistry. This was followed in the late 1960s and the 1970s by the synthesis and development of the chemistry of complexes containing metal–metal bonds.[2]

This chapter, which is based on the literature that had appeared through the end of 1983, surveys the coordination chemistry of the element with special emphasis on structure, bonding, synthesis and chemical behavior. The discussion is limited to well-characterized complexes and well-understood systems.

37.2 THE ELEMENT

Tungsten was discovered in 1781 in a mineral now known as scheelite,[1] whose principal constituent is $CaWO_4$. Tungsten steel was invented in 1855[3] and the first alloys containing tungsten were manufactured in 1868. These 'high speed steels' have been used ever since as cutting tools because of their hardness even at high temperatures. Because of its high melting point, it has been used as a filament for incandescent lamps[4] since 1904, and for a long time this was its principal application. More recently, there has been increased interest in alloys containing tungsten, as materials for high temperature applications. Tungsten carbide, when cemented, is almost as hard as diamond and is therefore very useful for dies, tools and other applications requiring extreme hardness and wear resistance.

The element is obtained primarily from the two commercially important ores, scheelite ($CaWO_4$) and wolframite [$(Fe,Mn)WO_4$]. WO_3 is produced from these ores and then reduced to the metal with hydrogen.[5]

37.3 THE CHEMISTRY OF W^{VI}

In addition to complexes containing the WO, WO_2 and WO_3 structural units, the element shows quite a varied chemistry in this oxidation state, undoubtedly because the hexahalides are reasonably stable and give rise to a variety of substitution products of the type $[WX_{6-n}L_n]$ ($n = 1$–6). In addition, coordination numbers higher than six can also be obtained. W^{VI} also shows considerable tendency to form bonds of order higher than one with good π donor atoms such as S, Se, N, NR, CHR and CR.

37.3.1 W^{VI} Halides and Derivatives

The three hexahalides WF_6, WCl_6 and WBr_6 are known and synthetic routes to their preparation are summarized in Table 1. WF_6 is a colorless gas while WCl_6 and WBr_6 are blue-black moisture sensitive solids. Under well-defined conditions, the octahedral hexahalides undergo substitution to give products ot the type $[WX_{6-n}L_n]$ ($n = 1$–6). Mixed fluoro–chloro compounds have been reported to result from reaction of WCl_6 with F_2 or from WF_6 with Me_3SiCl.[6]

Table 1 Synthetic Routes to W^{VI} Halides

Compound	*Preparation*	*Ref.*
WF_6	W with F_2	124
	W with ClF, ClF_3 or BrF_3	125
	WO_3 with HF, BrF_3 or SF_4	75
WCl_6	W with Cl_2 or S_2Cl_2	126
	WO_3 with Cl_2, S_2Cl_2, HCl, CCl_4, PCl_5	75
	WO_3 with hexachloropropene	127
WBr_6	W or $W(CO)_6$ with Br_2	75

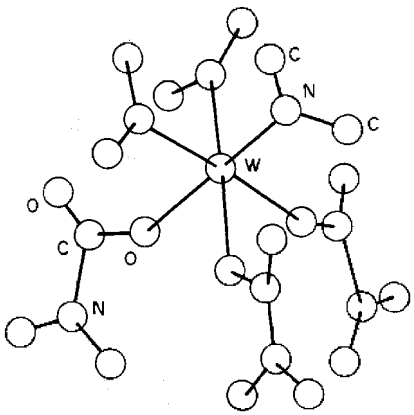

Figure 1 The structure of $[W(NMe_2)_3(O_2CNMe_2)_3]$[14]

^1H and ^{19}F NMR data have established the existence of *cis*- and *trans*-WCl_2F_4, *cis*- and *trans*-WF_4Cl_2, *mer*-WCl_3F_3 and *fac*-WCl_3F_3. WF_6 also reacts with $B(OTeF_5)_3$ at 120 °C to give $[WF_n(OTeF_5)_{6-n}]$. $[WF_5(OTeF_5)]$ and *cis*-$[WF_4(OTeF_5)_2]$ have been isolated and characterized.[7]

Halide substitution by ligands containing nitrogen, oxygen and sulfur donor atoms is also known. The reaction of WCl_6 with NCS^- leads to $[W(NCS)_6]$.[8] WF_6 reacts with Me_3SiNEt_2 to give $[WF_5NEt_3]$ and *cis*-$[WF_4(NEt_2)_2]$.[9] With Me_3SiN_3 one obtains $[WF_5N_3]$.[10]

An interesting six-coordinate complex results from the reaction of WCl_6 with $LiNMe_2$.[11] Crystal structure analysis[12] of $[W(NMe_2)_6]$ shows that the complex is octahedral with an average W—N distance of 2.025 Å. It reacts with ROH (R = Me, Et, Pr^n, Pr^i)[13] to give the known $W(OR)_6$ compounds. With MeOH, under certain conditions, *fac*-$[W(NMe_2)_3(OMe)_3]$ is obtained.[13] $[W(NMe_2)_6]$ reacts with CO_2 to give *fac*-$[W(NMe_2)_3(O_2CNMe_2)_3]$ whose structure is shown in Figure 1.[14] The W—N distance of 1.922 Å is significantly shorter than the one observed in $[W(NMe_2)_6]$ indicating significant N→W π donation. This is believed to be an important factor in limiting the insertion to only three CO_2 molecules. It is not surprising that with CS_2 insertion is coupled with reduction to the known W^{IV} compound $[W(S_2CNMe_2)_4]$.[13]

Both WCl_6 and WF_6 react with Me_3SiOR (R = Me, Ph, C_6F_5) to give $[WX_{6-n}(OR)_n]$ ($n = 1$–4).[9] For $n = 2$ and 4 both *cis* and *trans* isomers are known[15,16] and for $n = 3$ both *mer* and *fac* isomers have been reported. Further substitution to give $[WX(OMe)_5]$, $[W(OMe)_6]$ and $[W(OPh)_6]$ is also known. Crystal structure determination of *trans*-$[WCl_2(OPh)_4]$[17] and *cis*-$[WCl_2(OMe)_4]$[18] has revealed relatively short W—O distances of 1.82 and 1.84 Å respectively. These distances are just 0.1–0.15 Å longer than the ones found for W—O_t indicating considerable O→W π donation. Another example of a short W—O distance (1.908 Å) is furnished by the structure of $[W(O_2C_2H_4)_3]$.[19] With Me_3SiMe, WCl_6 reacts to give $[WCl_5SMe]$.[20]

Methyl derivatives of W^{VI} have also been prepared. Dimethyl mercury reacts with WCl_6 to give $[WMeCl_5]$,[21] while with $AlMe_3$, $[W(Me)_6]$ is obtained.[27] This red air-sensitive material reacts with several reagents[23] to give known compounds such as $[W(OMe)_6]$,[24] $[W(NMe_2)_6]$,[11] $[W(OPh)_6]$[25] and $[W(tdt)_3]$.[26] With NO, the compound $[WMe_4(O_2N_2Me)_2]$ is obtained. Crystal structure analysis has shown that the W atom is eight-coordinate with a geometry between square antiprismatic and dodecahedral (Figure 2).[27] In solution, this complex is stereochemically non-rigid down to −50 °C.

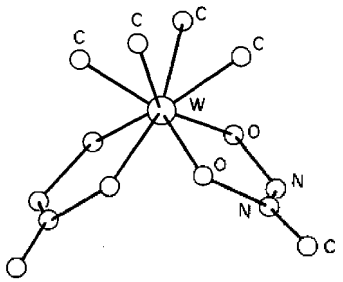

Figure 2 The structure of $[WMe_4(O_2N_2Me)_2]$[27]

The stability of complexes of the type $[W(OR)_6]$ is quite remarkable. It has been shown[28] that short exposure of $[W_2(OPr^i)_6py_2]$ to approximately two molar equivalents of CO gives two products, one of which is (**1**). This structure can best be viewed as a substituted tungsten carbonyl in which two *cis* CO groups have been replaced by donor atoms of the bidentate neutral ligand $[W(OPr^i)_6]$. This complex is unusual in that it contains two atoms of the same element in oxidation states that differ by six units.

$$[W(OPr^i)_4(\mu\text{-}OPr^i)_2W(CO)_4]$$
(1)

Several other W^{VI} complexes with coordination number greater than six have been reported. $[W(Me)_6]$ reacts with tertiary phosphines to give the seven-coordinate adducts $[W(Me)_6L]$ ($L = PMePh_2$, PMe_2PH, $PEtPh_2$, PMe_3).[29,23] The best characterized of these is the PMe_3 adduct, which was shown by ^1H and ^{13}C NMR to be fluxional at room temperature, although a rigid structure such as a capped biprism exists at low temperature. With excess MeLi, $[W(Me)_6]$ gives the bright yellow eight-coordinate compound $Li_2[W(Me)_8]$ which is reasonably stable as the dioxane solvate.[27] $[WMeCl_5]$ was reported to react with octamethylphosphoramide and diphos to give the adducts $[WMeCl_5{\cdot}L]$ which are believed to be eight-coordinate.[21] WF_6 is known to react with TlF and CuF_2 to yield[30] WF_7^{-1} which has physical properties similar to those reported for $(NO)[WF_7]$.[31] WF_7^- can also be prepared from LiN_3 and two equivalents of WF_6.[32] The existence of WF_8^{2-} has also been claimed.[31,33] WCl_6 reacts with Me_2S, 2,5-dithiahexane (dth) and tetrahydrothiophene (tht) to give the seven- and eight-coordinate adducts $[WCl_6L]$ and $[WCl_6L_2]$.[34] $[WF_6N_3]^-$ has been prepared from WF_6 and NH_4N_3.[32]

37.3.2 Complexes Containing the Oxo Ligand

The oxo ligand forms a strong bond with W^{VI} by utilizing both σ and π donation resulting in a short W—O bond length. Complexes containing the WO, *cis*-WO_2 and *cis*-WO_3 structural units are known.

37.3.2.1 Complexes with one oxo ligand

Synthetic routes to the oxohalo complexes of W^{VI} are summarized in Table 2. The oxohalo complexes with one terminal oxygen atom are of the general type $[WOX_4]$ (X = F, Cl, Br). The structures of $[WOCl_4]$ and $[WOBr_4]$ consist of chains of slightly distorted octahedra connected by oxygen bridges with W—O distances of 1.8 and 2.1 Å.[35] In contrast, WOF_4 is tetrameric in the solid state with fluoro bridges[36,37] as depicted in Figure 3. Chloride substitution by NCS^- to give $[WO(NCS)_4]$ has been reported.[8]

The coordinatively unsaturated $[WOX_4]$ complexes react with ligands such as alkyl cyanides, THF or py to give the six-coordinate $[WOX_4L]$ complexes.[38,39] $[WOX_5]^-$ ($X = F^-$, Cl^-, Br^-) are also known.[40,41] Interesting adducts result from the reaction of WOF_4 with XeF_2 in HF. White stable crystalline materials of composition $[WOF_4{\cdot}XeF_2]$ and $[(WOF_4)_2{\cdot}XeF_2]$ have been

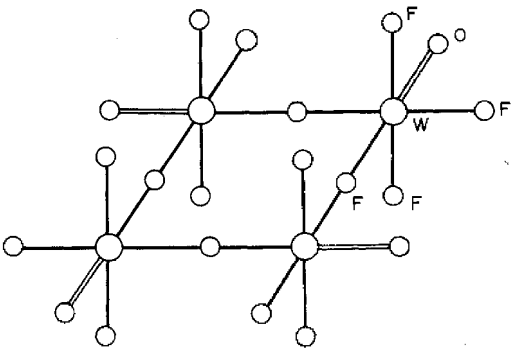

Figure 3 Proposed structure for $[WOF_4]_4$[37]

obtained.[42,43] On the basis of Raman measurements and ^{19}F NMR spectra it has been suggested that the XeF_2 molecule is bonded to the sixth coordination position of the W atom through the fluoro atom, forming a bent W—F—Xe bond. Adduct formation between $[WOF_4]$ and SbF_5 is also known.[44]

$WOCl_4$ reacts with bidentate Schiff bases to give complexes of the type [$WOCl_3$(Schiff base)].[45] These compounds show one ν(W—O_t) at around 970 cm^{-1}. With tridentate Schiff bases, [$WOCl_2$(Schiff base)] is obtained. Complexes of the type $[WOF_3L]^-$ (L = bidentate hydroxy acids) have also been reported.[46]

The structure of the azoxybenzene adduct of $WOCl_4$ has been reported.[47] The azoxybenzene ligand is coordinated through the oxygen atom *trans* to the oxo ligand with a bond length of 2.276 Å. The W—O_t distance is 1.669 Å. The structure reported for the diars adduct of $WOCl_4$[48] appears to be in error. In this structure, the W—Cl bond *trans* to the oxo ligand is shorter than the *cis* W—Cl bond being 2.26 and 2.40 Å respectively. This result is of course contrary to our knowledge of the *trans* influence of the oxo ligand.[49]

With hydrogen peroxide, W^{VI}, like molybdenum, forms peroxy compounds in which the ratio of peroxy groups to metal is 4:1, 3:1, 2:1, and 1:1, but most are not well characterized.[50] A 2:1 peroxy complex, obtained from acidic solution containing alkali metal tungstate and a high concentration of H_2O_2 was shown by X-ray crystallography to be an oxygen-bridged dimer[51] with formula $[(O_2)_2W(O)OW(O)(O_2)_2(H_2O)_2]^{2-}$. The coordination geometry is best viewed as a pentagonal bipyramid with two pentagonal planes rotated by 90°, one with respect to the other. The structure of the 1:1 complex ion $[WO(O_2)F_4]^{2-}$ has been determined[52] and is best described as a distorted octahedron in which the center of the O—O bond occupies a corner. A 2:1 and a 1:1 peroxy complex can also be obtained in the presence of the ligands pyridine carboxylate and pyridine 2,6-dicarboxylate respectively.[53] Phosphine and arsine oxides have been shown to stabilize peroxo complexes of W^{VI}.[59] Thus, complexes of the type $[W(O)(O_2)_2L_2]$ (L = OPR_3; R = Pr^n, Bu^n, Ph; $OAsR_3$, R = Pr^n, Bu^n, Ph) have been prepared and characterized. These compounds show the expected ν(W—O_t) around 950 cm^{-1}, and ν(O—O) around 850 cm^{-1}.

37.3.2.2 Complexes with two oxo ligands

The oxohalo complexes containing two terminally bonded oxygen atoms are of the type WO_2X_2 (X = F, Cl, Br, I). WO_2Cl_2 was shown to be polymeric in the solid state[55] with oxygen bridges and W—O bond lengths ranging from 1.63 to 2.34 Å. WO_2F_2, WO_2Br_2 and WO_2I_2 are believed to be polymeric as well.[56] WS_2Cl_2 is also known.[57]

In spite of its polymeric structure and insolubility in common solvents, it has been shown[58] that complexes of the type $WO_2Cl_2L_2$ and WO_2Cl_2(L–L) can be prepared with mono- and bi-dentate ligands respectively. $WO_2Cl_2L_2$ can also be prepared with Schiff bases.[45]

$[WO_2(S_2CNR_2)_2]$ (R = Me, Et, Pr^n) have been prepared[59] by an oxo transfer utilizing a dinuclear Mo^V complex as depicted in equation (1). Because of their moisture sensitivity, these

$$[W(CO)_2(PPh_3)(S_2CNR_2)] + 2[Mo_2O_3(S_2P(OEt)_2)_4] \longrightarrow [WO_2(S_2CNR_2)_2] + 4[MoO\{S_2P(OEt)_2\}_2] + 2CO + PPh_3 \quad (1)$$

[a] OX = 8-hydroxyquinoline. [b] tox = 8-mercaptoquinoline

complexes cannot be prepared from WO_4^{2-} in a manner analogous to the preparation of $[MoO_2(S_2CNR_2)_2]$.[60]

All complexes containing the WO_2 structural unit have *cis* configuration and exhibit two strong IR absorption bands around 950 and 900 cm^{-1}. The structure of dichloro-dioxo-pentane-2,4-dionato W^{VI} has been determined and it contains the expected *cis* arrangement of the oxygen atoms with a W—O_t distance of 1.730 Å.[61] Table 3 lists well-characterized compounds containing the WO_2 structural unit.

37.3.2.3 Complexes with three oxo ligands

Complexes containing the WO_3 structural unit are the least studied. Of the oxyhalides, $WO_3F_3^{3-}$, $WO_3F_2^{2-}$, WO_3F^- and WO_3Cl^- have been prepared. The isolation of $[WO_3(dien)]$[62] has been reported. The complex is unstable in solution and hydrolyzes to WO_4^{2-} and protonated dien. Formation constants for WO_4^{2-} with aspartic acid and glutamic acid have also been measured,[63] but because of the competitive formation of isopolytungstate in acidic solution and the stability of WO_4^{2-} in basic solution, the pH range over which formation constants of such complexes can be measured is very small. The reaction of WO_3 with oxalate has been reported[64] to give $[WO_3(ox)]^{2-}$ and $[W_2O_5(ox)_3]^{4-}$.

Slow air oxidation of an acidic W^V solution results in the formation of the mixed valence W^{VI}–W^V complex[65] $[W_4O_8Cl_8(H_2O)_4]^{2-}$. It is believed that this ion is obtained by an equilibrated reaction between $[WO_2Cl_4]^{2-}$ and $[WOCl_5]^{2-}$. Its structure consists of four $WO_3Cl_2(H_2O)$ octahedra sharing corners as depicted in Figure 4. The four W atom form a

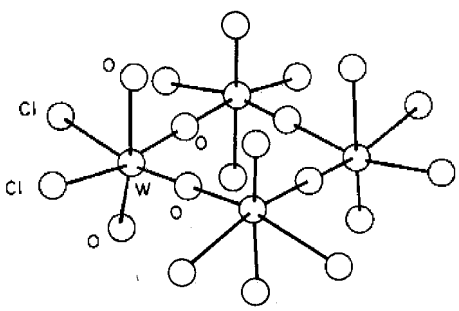

Figure 4 The structure of $[W_4O_8Cl(H_2O)_4]^{2-}$ [65]

nearly planar square and are joined through linear oxygen bridges. The W—O_b distance of 1.86 Å, although short, is significantly longer than the W—O_t bond length of 1.711 Å, as expected.

Substitutions without disruption of the $W_4O_8^{6+}$ core led to the isolation[66] of (**2**), (**3**) and (**4**).

$[W_4O_8Cl_6(DMF)_6]$ (**2**) $[W_4O_8(NCS)_{12}]^{6-}$ (**3**) $[W_4O_8(NCS)_4(C_2O_4)_4]^{6-}$ (**4**)

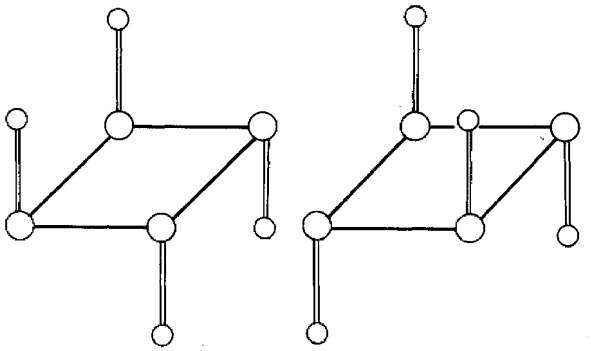

Figure 5 The dispositions of O_t around the W_4O_8 square[66]

The structure of (**3**) is quite similar to that of $[W_4O_8Cl_8(H_2O)_4]^{2-}$ with the exception of the spatial disposition of the terminally bonded oxygen atoms as depicted in Figure 5. As expected from the *trans* effect of the O_t ligand, the W—N bond lengths *trans* to O_t are on the average 0.2 Å longer than the W—N bond lengths *cis* to O_t. Both structures reveal no significant differences between the four tungsten atoms, which, together with theoretical consideration,[67] suggest that these mixed valence complexes are best described as delocalized systems.

37.3.3 Complexes Containing Multiple Bonds to Sulfur, Selenium, Nitrogen and Carbon Atoms

Several good π donor ligands, in addition to the oxo ligand, have been shown to form multiple bonds with W^{VI}. This tendency undoubtedly results from the d^0 electronic configuration of W^{VI} and its high formal positive charge. Thus, the reaction of WX_6 (X = Cl, Br) with Sb_2S_3 and Sb_2Se_3 leads to complexes of the type WSX_4 and $WSeX_4$.[68,69] These compounds are moisture sensitive and evolve H_2S and H_2Se on exposure to moist air. Structure analysis of WSX_4[70] shows that they are dimeric in the solid state with two WSX_4 square pyramidal units linked through unsymmetrical halogen bridges as depicted in Figure 6. The short W—S_t distance of 2.090 Å clearly indicates a W—S bond order higher than one. The IR bands at 569 and 555 cm^{-1} for $[WSCl_4]$ and $[WSBr_4]$ respectively have been assigned to ν(W—S_t). It is believed that $[WSeX_4]$ has similar structures and an IR band at 396 cm^{-1} has been assigned to ν(W—Se_t).[69] The slight paramagnetism of these compounds (~0.4 BM at 25 °C) is believed to arise from W^V impurities, or, at least in part, from TIP.[38]

WF_6 also reacts with Sb_2S_3 to give WSF_4.[71] The reaction of $[WSCl_4]$ with XeF_2 leads to the mixed fluoro–chloro complexes. These have not been isolated, but ^{19}F NMR has established[71] the presence in solution of $[WSF_2Cl_2]$, $[WSFCl_3]$ and $[WSF_3Cl]$ in addition to the ions $[WSF_5]^-$, $[WSF_4Cl]^-$, $[WSFCl_4]^-$ and $[WSF_3Cl_2]^-$. The reaction of $[WYCl_4]$ (Y = O, S, Se) with Sb_2Y_3 in CS_2 leads to complexes of the type WS_2Cl_2, $WSSeCl_2$ and $WOSCl_2$.[72]

Compounds of the type $[WYX_4]$ are coordinatively unsaturated and thus react with a variety of ligands or with donor solvents to give simple six-coordinate adducts.[73a] An example of such

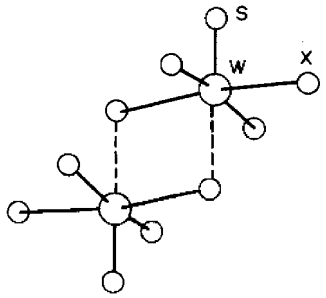

Figure 6 The structure of $[WSCl_4]$[70]

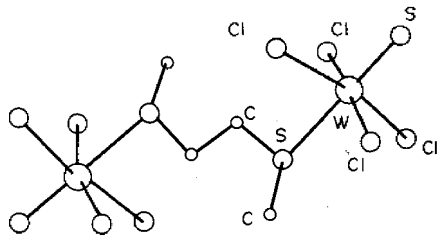

Figure 7 The structure of $[WSCl_4(\mu\text{-dth})WSCl_4]$[73b]

an adduct is shown in Figure 7. Important structural parameters of this and other structurally characterized complexes of W^{VI} are given in Table 4.

[a] Terminally bonded atom. [b] Atom *trans* or *cis* to X.

In some cases, the interaction of $[WYX_4]$ with donor solvents leads to oxygen abstraction or cleavage of an ether linkage. Thus, $[WSCl_4]$ abstracts an oxygen atom from 1,2-dimethoxyethane (DME) to form a complex that was shown by X-ray crystallography[74] to consist of the $[WOSCl_2DME]$ moiety bonded to $[WSCl_4]$ through an oxygen bridge. This oxygen abstraction is characteristic of the high oxidation state halides of the early transition metals,[75] and in some cases can be used as a simple route to oxyhalide complexes. For example, $[WOF_4\cdot Et_2O]$ can be prepared from WF_6 and diethylether.[76] The reaction of $[WSeCl_4]$ with the same solvent leads to cleavage of the ether linkage and the formation of a W–alkoxide bond as shown in Figure 8. A similar reaction was reported for $[WOCl_4]$.

Several nitrido complexes of W^{VI} are known. WCl_6 reacts with ClN_3[77] to give $[WNCl_3]$ whose structure is believed to be tetrameric similar to that of its molybdenum analogue.[78] $[WNCl_3]$ can also be prepared from WCl_6 and IN_3.[79] Impure $[WNBr_3]$ has been prepared from WBr_6 and IN_3.[79] The preparation of $[WNCl_4]^-$ has been reported and $[W_2NCl_{10}]^{2-}$ was isolated from this

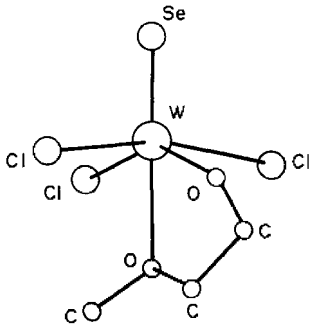

Figure 8 The structure of $[WSeCl_3(2\text{-methoxyethoxide})]$[76b]

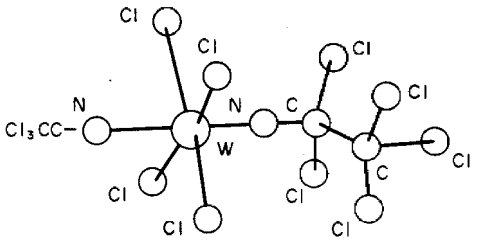

Figure 9 The structure of $[WCl_4(NC_2Cl_5)]\cdot CCl_3CN$[86a]

preparation.[80] The structure of this dinuclear complex consists of W^{VI} and W^{V} linked by a linear asymmetric nitride bridge.[80]

With py, the adduct $[WNCl_3\cdot 3py]$, of unknown structure, is obtained.[81] Other characterized complexes derived from $[WNCl_3]$ are $[WNCl_3\cdot PPh_3]$, $[WNCl_5]^-$ and $[WNCl_3(bipy)]$.[82] The reaction of $[WNCl_3]$ with $POCl_3$ gives the tetranuclear compound $[WNCl_3(OPCl_3)]_4$. This structure contains a planar square W_4N_4 eight-membered ring with alternating W—N bond lengths. The oxygen atom of the $POCl_3$ ligand is coordinated *trans* to the shorter W—N bond.[83] The presence of the nitride ligand is easily detected in these complexes by a strong IR absorption band around 1050 cm^{-1} assigned to $\nu(W{-}N_t)$.[84]

Complexes containing the WNR group are also known. The reaction of WCl_6 with aliphatic and aromatic nitriles[85] leads to the formation of imido W^{VI} complexes. Strong IR absorption around 1280 cm^{-1} is characteristic of the WNR group. These complexes are thought to be intermediates in the alkylcyanide reduction of WCl_6.

The structures of several of these complexes have been determined crystallographically. The structure[86a] of $[WCl_4(NC_2Cl_5)]\cdot NCCCl_3$, which is depicted in Figure 9, reveals a short W—N bond length of 1.70 Å, as expected for a bond order of two or higher. When CCl_3CN reacts with WCl_5, a dichloro-bridged W^{VI} imido complex is obtained (Figure 10). Complexes of the type $[W(NPh)(OCMe_3)_4]$ and $[W(NPh)Cl_5]^-$ have also been prepared.[87] In all known structures containing WNR groups, the *trans* influence of the imido group is clearly seen (Table 4).

The coordinatively unsaturated complex $[WCl_4(NC_2Cl_5)]$ reacts with monodentate ligands to form six-coordinate adducts[88,89] with structures similar to the one depicted in Figure 9. When WCl_6 is reacted with cyanogen in $POCl_3$, a dinuclear complex in which NC_2Cl_4N bridges two $[WCl_4(OPCl_3)]$ moieties is obtained.[90] With bidentate ligands it is suggested that seven-coordinate complexes are formed.[88]

Oxygen abstractions are also observed for the imido W^{VI} complexes. Thus, in addition to the 1:1 adduct of $OPPh_3$ with $[WCl_4(NC_2Cl_5)]$ the complex $[WCl_2O_2(OPPh_3)_2]$ is formed.[91] Also, $W(NMe_2)_6$ reacts with Bu^tOH to give $[WO(OBu^t)_4]$.[13]

It has been shown recently that alkylidene and alkylidyne complexes of W^{VI} also exist, and that some of these are important catalysts for the metathesis of terminal and internal alkenes.[87,92] Crystal structure analysis of the alkylidene complex $[W(O)(CHCMe_3)Cl_2PEt_3]$ shows that the geometry around the metal atom is distorted trigonal bipyramidal with the W—O_t and W=CHCMe$_3$ units in the equatorial plane. The short W—C distance of 1.882 Å is in accord with a W=C double bond.[92] $[W(NPh)(CHCMe_3)Cl_2L_2]$ has also been prepared. Here the tungsten atom is six-coordinate with the W=NPh and W=CHCMe$_3$ units in *cis* position, as expected, similar to complexes containing the WO_2 structural unit.[87,93,94]

The alkylidyne complexes are best prepared by cleavage of a W≡W triple bond[92] as depicted

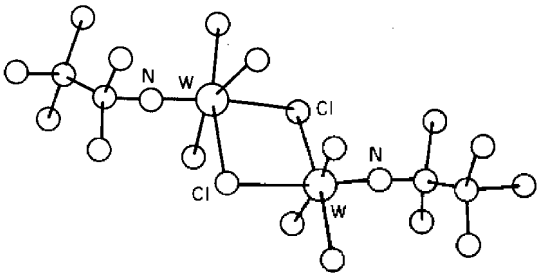

Figure 10 The structure of $[W_2Cl_6(\mu\text{-}Cl)_2(NC_2Cl_5)_2]$[86b]

schematically in equation (2). (These reactions will be discussed in more detail in Section 37.6.2.2.) Thus, the reaction of $[W_2(OBu^t)_6$ with RC≡N and RC≡CR leads to cleavage of the

$$W{\equiv}W + R{-}C{\equiv}N \longrightarrow W{\equiv}N + W{\equiv}CR$$
$$W{\equiv}W + R{-}C{\equiv}C{-}R \longrightarrow 2W{\equiv}CR \qquad (2)$$

W≡W triple bond and formation of both nitrido and alkylidyne complexes of W^{VI}. Crystal structure determination[94] of $[(OBu^t)_3W{\equiv}N]_n$ and $[(OBu^t)_3W{\equiv}CMe]_2$ has shown that the nitrido complex is polymeric with unsymmetrical W—N—W bridges. The alkylidyne complex is dimeric with a short W—C bond length of 1.76 Å. As expected, this distance is significantly shorter than the one observed for the W—C double bond.

37.3.4 WS_4^{2-}, WOS_3^{2-} and $WO_2S_2^{2-}$ as Ligands

The thiotungstate ion WS_4^{2-} has been known since 1826[95] and its exact chemical composition was determined in 1886.[96] Its structure[97] showed the expected tetrahedral geometry with a relatively short W—S distance of 2.165 Å. The mixed oxothio anions are also known.[98] WS_4^{2-} and to a lesser extent WOS_3^{2-} and $WO_2S_2^{2-}$ have been shown in recent years to act as ligands for several metal ions. Complexes of the type $[M(WS_4)_2]^{2-}$ ($M = Ni^{2+}$, Co^{2+}, Zn^{2+}, Pd^{2+}, Pt^{2+}), where the thiotungstate ion acts as a bidentate ligand, have been prepared.[99,100,101,102] Similar compounds with WOS_3^{2-} and $WO_2S_2^{2-}$ are also known,[103,104,104] and in all cases the coordination is through sulfur. It is interesting to note that with trivalent ions such as Cr^{3+}, Eu^{3+} and Dy^{3+}, complexes such as $[M(WO_2S_2)_3]^{3-}$ are not obtained, but rather $WO_2S_2^{2-}$ hydrolyzes to the tungstate ion.[106]

Of particular interest are those complexes which serve as model compounds for biological systems such as the active center of the MoFe protein in nitrogenase.[107] These complexes will be discussed in detail in the relevant chapters. It should be noted here, however, that WS_4^{2-} is a non-innocent ligand, and thus complexes such as $[Co(WS_4)_2]^{n-}$ ($n = 2, 3$)[108,109] and $[Fe(WS_4)_2]^{n-}$ ($n = 2, 3$) can easily be prepared.[110,111,112] In addition, some unusual complexes have been synthesized with WS_4^{2-} as ligands. One such example is $[Fe_3W_3S_{12}]^{4-}$ which contains the $Fe_3(\mu_3\text{-}S)_2$ center as depicted in Figure 11.

Complexes of the type $[Au_2(WS_4)_2]^{2-}$ and $[(Ph_2MeP)_2Au]_2[WS_4]$ have also been prepared and structurally analyzed.[113,114] In the first case, two WS_4^{2-} ions are bridged by gold atoms as shown in Figure 12 (identical structure is obtained with WOS_3^{2-}) and in the second, WS_4^{2-} acts as a bridging group for two $[(Ph_2MeP)_2Au]$ moieties. WS_4^{2-} and WOS_3^{2-} have also been shown to act as tridentate ligands.[115,116,117] One such complex is shown in Figure 13.[117]

Crystal structure analysis of complexes containing the WS_4^{2-}, WOS_3^{2-} and $WO_2S_2^{2-}$ ligands have shown that these ions are tetrahedral with the W—S_b bond length slightly but significantly longer than the W—S_t bond length. Finally it should be mentioned that both WSe_4^{2-} and $WO_2Se_2^{2-}$ are known[118] and $[Zn(WSe_4)]^{2-}$ has been prepared.[119]

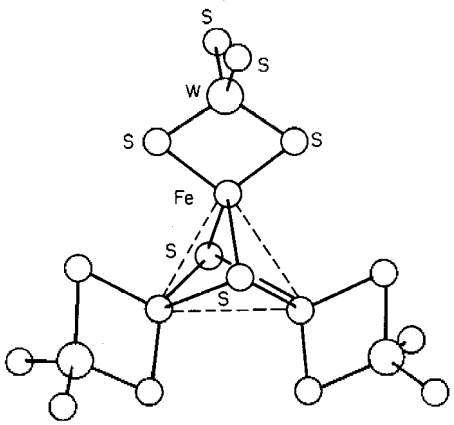

Figure 11 The structure of $[Fe_3W_3S_{12}]^{4-}$ [112]

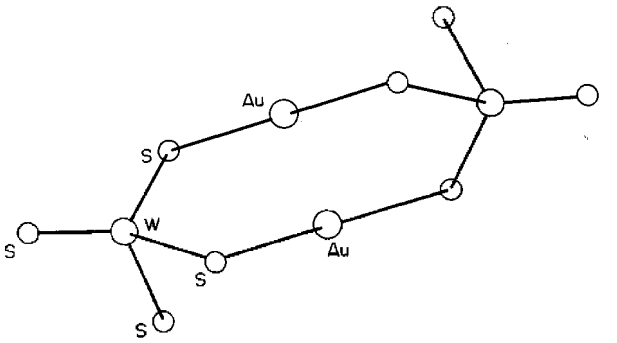

Figure 12 The structure of $[Au_2(WS_4)_2]^{2-}$ [113]

37.3.5 Dithiolene Complexes

Dithiolene complexes attracted considerable interest during the 1960s and early 1970s because of their unusual electronic and structural properties.

Tungsten complexes of the type $W(L–L)_3$ are known for L–L = sdt, bdt, tdt, $S_2C_2Me_2$, $S_2C_2H_2$, $S_2C_2(CF_3)_2$ and $Se_2C_2(CF_3)_2$. These highly colored complexes undergo two reversible one-electron reductions leading to mono- and di-anionic complexes.[26,120] Structurally, the neutral complexes represent examples of a trigonal prismatic coordination in six-coordinate complexes similar to the analogous Re and Mo complexes.[121] The interesting problems associated with this class of compounds, such as their electronic structure and the relation between this and geometry, have been thoroughly reviewed.[121,120]

Of the reduced complexes several have been isolated. Hydrazine reduction of $[W(sdt)_3]$ gives the dianion which reacts with two equivalents of MeI. It is interesting that the methylation reaction occurs only on one of the three ligands. The methylated product reacts with diphos to give $[W(sdt)_2(diphos)]$. The mixed ligand complex $[W(sdt)_2(S_2CNEt_2)]^-$ was also reported. Crystal structure analysis[122] of $(Ph_4As)_2[W(mnt)_3]$ shows that the symmetry of the WS_6 framework is close to D_3 and that the geometry is midway between octahedral and trigonal prism.

The complex $[W\{Se_2C_2(CF_3)_2\}_3]$ has also been prepared[123] and like its sulfur analogue, it undergoes two reversible one-electron reductions. The dianionic complex was isolated as the tetrabutylammonium salt.

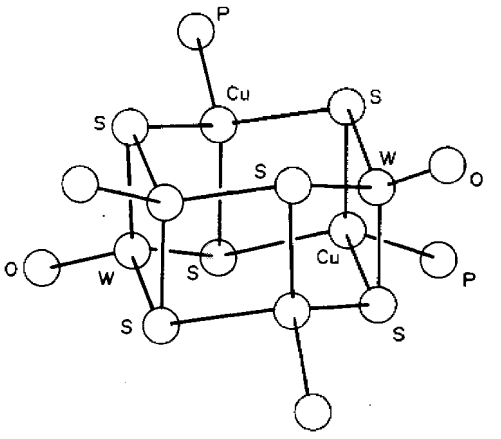

Figure 13 The structure of $[Cu_4(WOS_3)_2(PPh_3)_4]$; phenyl rings are omitted[117]

37.4 THE CHEMISTRY OF W^V

W^V, unlike Mo^V, is not dominated by dinuclear species. Most well-characterized complexes of W^V are monomeric and there are only a few reported examples of dinuclear compounds. These, with the exception of $[W_2Cl_{10}]$, all contain an M—M bond of order one.

37.4.1 W^V Halides and Their Derivatives

The three halides WF_5, WCl_5 and WBr_5 are known. WF_5 can be prepared from WF_6[135] and it was shown to be isostructural with MoF_5, NbF_5 and TaF_5,[136] so therefore probably has the same tetrameric structure with fluoride bridges. The dark green WCl_5 can be prepared by reduction of WCl_6[137] or by disproportionation[138] of WCl_4. It can also be prepared by reduction of WCl_6 with tetrachloroethylene in the presence of strong light.[139] The black-green WBr_5 is prepared by reduction of WCl_6 in HBr, or by thermal decomposition of WBr_6.[140] WCl_5 is dimeric in the solid state[141] and contains bridging Cl atoms. The long W—W distance of 3.814 Å, and the magnetic moment of ~1.0 BM per W[142] at room temperature, are consistent with the absence of a W—W bond.

The octahedral WX_6^- anions (X = F, Cl, Br) are best prepared by reaction of the higher halides in a suitable solvent.[41,143,144] In some cases they can be prepared by the reaction of the pentahalides with halide ions.[142,145,146] Crystal structure determination of $Cs[WCl_6]$ and $(Et_4N)[WCl_6]$[147] has shown that all the W—Cl bond lengths are practically the same, with an average value of 2.33 Å. When dry, they are quite stable, but easily hydrolyzed. The WX_6^- ions have low magnetic moments compared with the spin-only value for a d^1 electronic configuration. This is believed to result from large spin–orbit coupling. The reaction of $W(CO)_6$ with IF_5 in the presence of KI[148] gives the WF_8^{3-} ion which is believed to be eight-coordinate W^V.

Several adducts of WX_5 (X = Cl, Br) have been reported.[149,150] The best characterized is $[WCl_5(diars)]$[149] which is obtained by reduction of WCl_6 with excess diars. This paramagnetic complex (1.19 BM) is isomorphous with the seven-coordinate $[NbCl_5(diars)]$ and $[TaCl_5(diars)]$.[151]

It is well known that nitrogen-containing ligands can reduce W^{VI} and W^V halides to complexes of W^{IV}.[152,153,154] However, several substitution products of WX_5 (X = Cl, Br) have been prepared, and they are best formulated as *cis*-$[WX_4L_2]^+$ (L = Me_3py, py, PhCN, bipy, diphos).[138,155] These adducts are all paramagnetic with magnetic moments in the range of 0.63–1.45 BM. Although magnetic moments below the spin-only value are expected for W^V complexes, some of the reported moments seem to be unreasonably low, perhaps as a result of diamagnetic W^{IV} impurities, or magnetic interactions of adjacent d^1 centers.

Monomeric alkoxo complexes of W^V are also known. The dinuclear alkoxo complexes will be discussed in Section 37.4.4. The blue paramagnetic complex $[WCl_3(OR)_2]$ (R = Me, Et) were first isolated from the reaction of WCl_6 with the corresponding alcohols.[156,157] When ethanol is used, the reaction liberates chlorine which oxidizes the ethanol to acetaldehyde[157] as depicted in equations (3) and (4). Chloroalkoxo complexes of W^V can also be prepared directly from WCl_5 and alcohols at −70 °C. Thus, $M[WCl_4(OR)_2]$ and $M[WCl_5(OR)]$ (M = tetraalkylammonium; R = Me, Et, Pr^n) as well as the seven-coordinate $M[WCl_6(OEt)]$ have been isolated[158,159] and characterized. Similarly, $[WBr_4(OMe)_2]^-$ has been prepared from WBr_5 in methanol. The monomeric chloroalkoxo complexes are paramagnetic and exhibit electronic absorption spectra similar to the W^V oxyhalides.

$$WCl_6 + 2EtOH \longrightarrow \tfrac{1}{2}Cl_2 + [WCl_3(OEt)_2] + 2HCl \quad (3)$$

$$Cl_2 + EtOH \longrightarrow MeCHO + 2HCl \quad (4)$$

It has been suggested previously (Section 37.3.1) that the relatively short W^{VI}—OR bond length is indicative of bond order greater than one. If this holds true for the W^V—OR bonds, then for complexes of the type $[WX_4(OR)_2]^-$ the π donor ligands OR^- will prefer *trans* stereochemistry since the *d* electron can be accommodated in the d_{xy} atomic orbital which is orthogonal to the orbitals involved in the bonding of the π donor atom. Indeed, ESR spectra of the dialkoxo complexes are consistent with axial symmetry.[160] This idea has also been put forth to explain the preference of the dioxo complexes with the d^2 electronic configuration for the *trans* stereochemistry.

An interesting solid state reaction has been reported for $(R_4N)[WCl_5(OR)]$[157] as depicted in

equation (5). For a given R_4N^+ cation, the rate of alkyl chloride elimination follows the order Me > EtCl > PrCl. The rate of evolution of ethyl chloride decreased with increase in the size of the cation.

$$(R_4N)[WCl_5(OR)] \xrightarrow{-RCl} (R_4N)[WOCl_4] + \text{unknown products} \quad (5)$$

37.4.2 The Oxyhalides and Their Derivatives

Of the oxyhalides of W^V, both $[WOCl_3]$ and $[WOBr_3]$ are known. These can be prepared by reduction of $[WOX_4]$[161] or by the reaction of WX_5 with Sb_2O_3[162] as depicted in equation (6).

$$3WX_5 + Sb_2O_3 \longrightarrow 3WOX_3 + 2SbX_3 \quad (X = Cl, Br) \quad (6)$$

The structures of WOX_3 are believed to be similar to that of $[NbOCl_3]$[163] which reveals the presence of infinite chains of Nb—O—Nb bonds. The absence of a strong $\nu(W—O_t)$ around 950 cm^{-1} and the low magnetic moment of ~0.5 BM are in agreement with this structure. In addition, WOX_3 are antiferromagnetic, which is suggested to occur by superexchange mechanism through the W—O—W bridges.[161]

The monomeric $[WOX_5]^{2-}$ (X = Cl, Br) anions have been isolated with a variety of +1 cations. They are easily prepared from WCl_5 or $K_3[WO_2(C_2O_4)_2]$ in concentrated solutions of HCl or HBr in the presence of the desired cation.[164] $[WOX_4]^-$ are also known.[164] These are all paramagnetic with magnetic moments close to the spin-only value, presumably because tetragonal distortion destroys the spin–orbit coupling.[143] Their electronic spectra have been interpreted.[164,165]

Complexes of the type $[WOX_3L_2]$ and $[WOX_3(L–L)]$ are known for a variety of mono- and bi-dentate ligands.[166,167,168] They are best prepared by reacting $[WOX_3(THF)_2]$ or $[WOX_3(MeCN)_2]$ with the desired ligand.[166,167] With some nitrogen containing ligands, complexes of this type can be prepared by reduction of WOX_4. Thus, the reaction of WOX_4 with py or bipy, gives $[WOCl_3py_2]$ and $[WOCl_3(bipy)]$ respectively.[38] All the oxytrihalide adducts are paramagnetic and exhibit the characteristic $\nu(W—O_t)$ around 950 cm^{-1} (Table 5).

Three different isomers are possible, in principle, for the $[WYX_3L_2]$ complexes (Y = O, S, Se, NR) (Figure 14). ESR spectra of $[WOCl_3L_2]$ (L = Ph_3P, Me_2PhP) was reported to be consistent with the *cis-mer* isomer[166] in agreement with the solid state structure of $[WOCl_3(OPPh_3)_2]$. However, the complexes $[WOCl_3(PEt_3)_2]$ and $[W(NPh)Cl_3L_2]$ (L = $OPMe_3$, PMe_3, PMe_2Ph) have been shown to have *trans–mer* stereochemistry in the solid state.[169,170,171]

With bidentate ligands, (Figure 14) it has been suggested that the *fac* isomer is preferred.[167] However, structure determination of $[WSCl_3(mte)]$ (mte = 1,2-bis(methylthio)ethane) has shown that it has the *mer* stereochemistry in the solid state.[172] Whether this is indeed the preferred stereochemistry for complexes of the type $[WYX_3(L–L)]$ will have to await further studies.

The electronic spectra in the visible region of the $[WOX_3L_2]$ and $[WOX_3(L–L)]$ complexes are similar to those reported for WOX_5^- and similar assignments can be made.[166]

Several porphyrin complexes containing the WO unit are known.[173,174] The paramagnetic

Table 5 Properties of Some W^V Oxo Complexes

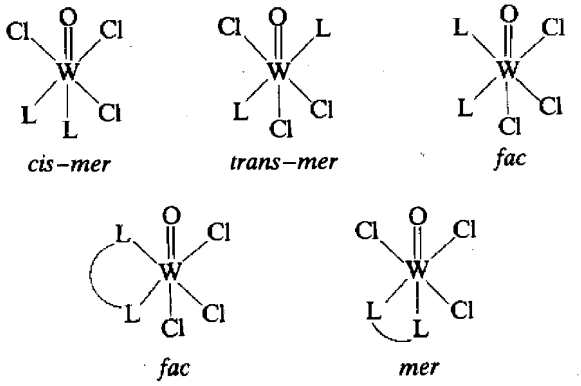

Figure 14 The possible isomers of $[WOCl_3L_2]$ and $[WOCl_3(L\text{–}L)]$

complexes [WO(OAP)L] (OAP = octaethylporphyrin; L = OPh, OMe) are obtained by reduction of H_2WO_4 in the presence of PhOH or by oxidation of $K_3W_2Cl_9$ in methanol. For L = OPh, $\mu_{eff} = 1.4$ BM and $\nu(W—O_t) = 946\ cm^{-1}$ and for L = OMe, $\mu_{eff} = 1.7$ BM and $\nu(W—O_t) = 910\ cm^{-1}$. The reaction of WF_5 with $OAPH_2$ leads to the oxo-bridged dimer $[WO(OAP)]_2O$. [WO(TPP)OMe] and $[WO(TPPS)H_2O]$ are also known. Base treatment of these leads to the oxo-bridged dimers.[175] The TPP complex undergoes electrochemical reduction to the W^{IV} compound (−0.85 V *vs.* SCE independent of solvent).[176]

37.4.3 Complexes with Terminal Sulfur and Selenium Atoms

The pentahalides WX_5 (X = Cl, Br) react with Sb_2S_3 and Sb_2Se_3[177] to give $WSCl_3$, $WSeCl_3$ and $WSeBr_3$. These complexes are insoluble polymeric materials and much less reactive than the corresponding WSX_4 and $WSeX_4$ complexes (Section 37.3.3). They show no IR bands which are expected for $\nu(W—S_t)$ and $\nu(W—Se_t)$. Whether their structures are similar to those of WOX_3 is not known. The only adducts that have been isolated and characterized are $[WSCl_3(mte)]$ and $[WSCl_3(bipy)]$. Both are paramagnetic and exhibit the expected IR absorption for $\nu(W—S_t)$: for $[WSCl_3(mte)]$, $\mu_{eff} = 1.52$ BM and $\nu(W—S_t) = 535\ cm^{-1}$; for $[WSCl_3(bipy)]$, $\mu_{eff} = 1.45$ BM and $\nu(W—S_t) = 531\ cm^{-1}$. On heating, both $WSCl_3$ and $WSeBr_3$ disproportionate to give the W^{IV} compounds $WSCl_2$ and $WSeBr_2$.[177] Attempts to prepare $WSBr_3$ were unsuccessful since the reaction of WBr_5 with Sb_2S_3 leads to the W^{IV} compound $WSBr_2$.[177]

Several complexes containing the W_2S_3 and W_2O_3 structural units have been prepared with thioxanthates and dithiocarbamates.[178,179,180] Whether these have structures similar to the analogous molybdenum complexes is yet to be determined.

37.4.4 Complexes with Metal–Metal Bonds

A dominant structural feature of complexes of Mo^V is the $Mo(\mu\text{-}X)_2Mo$ bridge which can be either planar or bent. It is believed that in these complexes there exists a Mo—Mo bond of order one which arises from the overlap of the d_{xy} atomic orbitals (Figure 15) (each with one electron) leading to a bonding orbital that accommodates the two electrons, in agreement with their diamagnetism. The same type of structures have only recently been shown to exist for W^V. Structural determination of the barium salt[181,182] of $[W_2O_4(edta)]^{2-}$ shows the presence of a bent $W(\mu\text{-}O)_2W$ bridge. The W—W separation is 2.542 Å, the dihedral angle between the

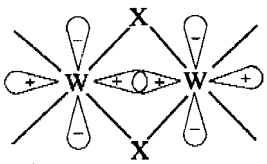

Figure 15 Overlap of W d_{xy} orbitals across the $[W(\mu\text{-}X)_2W]$ bridge; *z* axis is perpendicular to the plane of the paper

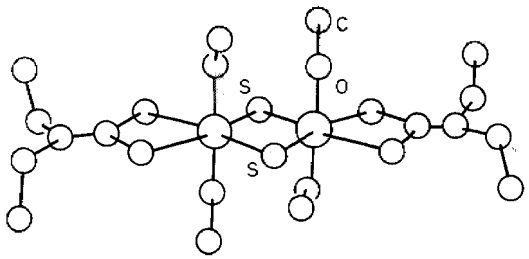

Figure 16 The structure of $[W_2(\mu\text{-}S)_2(S_2CNEt_4)_2(OMe)_4]$[186]

two WO_2 planes is 147°, the W atoms are displaced by 0.34 Å from the plane defined by the six oxygen atoms towards O_t, and the W—W—O_t angles are obtuse. These structural parameters are consistent with the presence of a W—W bond.

Electrochemical or tin reduction of WO_4^{2-} in the presence of oxalic acid and potassium oxalate leads to the isolation of $K_3[W_2O_4(C_2O_4)_{2.5}]\cdot 5H_2O$[183] which contains the $W_2O_4^{2+}$ moiety. This oxalate complex reacts with KF in HF to give $K_3H[W_2O_4F_6]$.[184] In this complex, the $W_2O_4^{2-}$ unit is almost planar with a W—W separation of 2.62 Å. It has been suggested[185] that electrolytic reduction of WO_4^{2-} leads to the formation of compound (**5**) which decomposes to compound (**6**).

W^V complexes containing the $W(\mu\text{-}S)_2W$ bridge are also known. Compound (**7**), prepared by

$[W_4O_8(C_2O_4)_5(H_2O)_4]^{6-}$ (**5**) $\quad$ $[W_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ (**6**) $\quad$ $[W_2S_2(S_2CNEt_2)_2(OMe)_4]$ (**7**)

reacting $[W(CO)_3(MeCN)_3]$ with tetraethyldithiuramdisulfide in methanol,[186] contains a planar $W(\mu\text{-}S)_2W$ bridge (Figure 16). The W—W distance of 2.791 Å, coupled with the other structural parameters, is indicative of a W—W bond. This conclusion is particularly clear when this structure is compared with that reported for $[W_2Cl_{10}]$[141] which has no W—W bond. In $[W_2Cl_{10}]$, the W—W bond length is 3.814 Å, the angles at Cl_b are obtuse and the angles Cl_b—W—Cl_b are acute. These features are expected for a non-bonded structure, since in the absence of an attractive force, there must be a net repulsion that causes the bridge to stretch along the M · · · M direction.

The synthesis of the mixed valence W^V, W^{VI} complex $[W_4S_{12}]^{2-}$ has been reported. Its structure analysis[187] reveals the presence of the $W_2S_4^{2+}$ structural unit with a planar $W(\mu\text{-}S)_2W$ bridge, and a W—W distance of 2.950 Å. The coordination sphere around each W atom is completed by a terminal sulfur atom (W—S_t = 2.10 Å; ν(W—S_t) = 495 cm^{-1}) and the bidentate ligand WS_4^{2-}. The W—W distance of 2.950 Å is somewhat longer than expected for a W—W bond of order one which is believed to result from the interaction of the W^V and W^{VI} centers. The structure of $[Cl_2W(O)(\mu\text{-}S)_2W(O)Cl_2]^{2-}$ has also been reported.[188] This complex contains a bent $W(\mu\text{-}S)_2W$ bridge (dihedral angle of 149°) with a W—W separation of 2.844 Å.

An interesting dinuclear complex of W^V has been obtained from the reaction of $[WSeCl_3]$ with Ph_4AsCl in a 1:1 mole ratio. The diamagnetic $[W_2Cl_8Se_3]^{2-}$ contains both an Se^{2-} and Se_2^{2-} bridging units with a W—W distance of 2.862 Å. The presence of a W—W bond in this compound is further supported by the acute angle of 73.3° subtended at the bridging selenium atom.[190b]

Complexes containing the bridge $W(\mu\text{-}SR)_2(\mu\text{-}X)W$ (X = Cl, OMe)[189,190] have also been prepared. The structure of compound (**8**) which is depicted in Figure 17[190] reveals the presence of a W—W bond of order one with a W—W separation of 2.854 Å. Complexes of this type have been shown to have interesting electrochemistry.[189]

$[W_2O_2(\mu\text{-}SBu^i)_2(\mu\text{-}Cl)Cl_4]^-$
(**8**)

Reaction of WCl_6 with ethanol gives the blue paramagnetic $[WCl_3(OEt)_2]$ compound (see Section 37.4.1). Treatment of this with ethanol affords the red diamagnetic dimer of composition $[W_2Cl_4(OEt)_6]$.[157] Crystal structure analysis shows[191] that the compound contains a planar $W(\mu\text{-}OEt)_2W$ bridge (Figure 18) with a W—W bond of order one (W—W separation of 2.715 Å). It is now known that the best method of preparing the ditungsten species $[W_2Cl_4(OR)_6]$ is by $AgNO_3$ oxidation of the W^{IV} complexes (**10**)[192] (see Section 37.5.4.1).

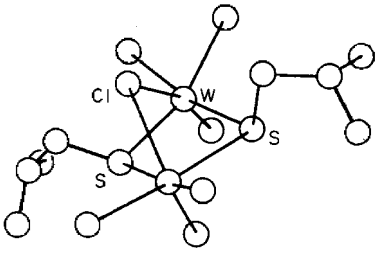

Figure 17 The structure of $[W_2O_2(\mu\text{-}SBu^i)_2(\mu\text{-}Cl)Cl_4]^-$ [190a]

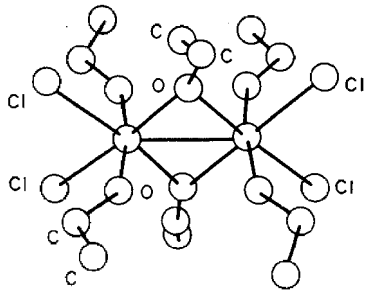

Figure 18 The structure of $[W_2Cl_4(OEt)_6]$ [191]

37.4.5 Thiocyanato Complexes

Reduction of WO_4^{2-} with thiocyanic acid leads to colored species which have been used for tungsten analysis.[193] The color of these species are pH dependent and the structures of some of them are still uncertain. The following sequence of equilibria have been suggested on the basis of several isolated amine salts (equations 7–11).[88,194] Of these species, it is believed that the

$$[WO(OH)_2(NCS)_2]^- + NCS^- \rightleftharpoons [WO_2(NCS)_3]^{2-} + H_2O \quad (7)$$

$$[WO_2(NCS)_3]^{2-} + H^+ + NCS^- \rightleftharpoons [WO(OH)(NCS)_4]^{2-} \quad (8)$$

$$[WO(OH)NCS)_4]^{2-} + H^+ \rightleftharpoons [WO(NCS)_4]^{2-} + H_2O \quad (9)$$

$$2[WO(OH)(NCS)_4]^{2-} \rightleftharpoons [W_2O_3(NCS)_8]^{4-} + H_2O \quad (10)$$

$$[W_2O_3(NCS)_8]^{4-} + 2H^+ + 2NCS^- \rightleftharpoons 2[WO(NCS)_5]^{2-} \quad (11)$$

orange diamagnetic $[W_2O_3(NCS)_8]^{4-}$ and the green paramagnetic $[WO(NCS)_5]^{2-}$ have structures which are similar to the analogous molybdenum complexes. The complex $[W(NCS)_6]^-$ can be prepared[195] by direct reaction of WCl_5 and NCS^-.

37.5 THE CHEMISTRY OF W^{IV}

Monomeric complexes of W^{IV} such as the halides, the oxyhalides and their derivatives have been known for quite some time. In most cases these are six-coordinate, but higher coordination numbers are also known. During the last two decades, new structural types have been reported. Of these, the most interesting are the dinuclear complexes containing W=W double bonds and the trinuclear clusters containing W—W single bonds.

37.5.1 W^{IV} Halides and Their Derivatives

All four tetrahalides, WF_4, WCl_4, WBr_4 and WI_4, are known. WF_4 can be prepared by the reaction of WF_6 with benzene in a bomb at 110 °C.[196] Its structure is not known, but is is certainly polymeric with W—F—W bridges. WCl_4 and WBr_4 are best prepared as black needles

by aluminum reduction of the higher halides in a controlled temperature gradient.[154] These are diamagnetic and isomorphous with their Nb and Ta analogues which consist of infinite linear chains of octahedra sharing a common edge. The alternating short and long metal distances imply the existence of direct metal–metal bonds,[197] in agreement with the diamagnetism of these compounds.

WI_4 is prepared by the reaction of WO_2 with AlI_3 or by the reduction of WCl_6 with HI. The tetraiodide is unstable and decomposes even at room temperature to WI_2 and I_2.

The hexahalide complexes WX_6^{2-} (X = Cl, Br) are easily prepared[144,198] by reduction of the higher halides with alkali iodide. These octahedral complexes have low magnetic moments and high θ values, suggesting antiferromagnetism. WCl_6^{2-} has been reported to react with vicinal diols[199] to give alkenes and species containing the WO_2^{2+} unit. The hexaisothiocyanate complex $[W(NCS)_6]^{2-}$ is also known.[195]

The six-coordinate adducts WX_4L_2 (X = Cl, Br) can be prepared by reduction of the higher halides, by direct addition to WX_4, or by oxidation of lower valent complexes. Certain nitrogen ligands have long been known to reduce WX_6 and WX_5 to complexes of the type WX_4L_2 (L = py, MeCN, EtCN, PrCN).[164] The acetonitrile complex, which is a useful starting material for the preparation of other adducts, can also be prepared by the reaction of WCl_5 with $W(CO)_6$ or by the oxidation of $W(CO)_6$ with Br_2 in acetonitrile[200] as depicted in equations (12) and (13).

$$4WCl_5 + W(CO)_6 \xrightarrow{MeCN} 5[WCl_4(MeCN)_2] + 6CO \quad (12)$$

$$W(CO)_6 + Br_2 \xrightarrow{MeCN} [WBr_4(MeCN)_2] + 6CO \quad (13)$$

Phosphine and arsine adducts of WCl_4 are conveniently prepared by reduction of WCl_6 with amalgamated zinc in the presence of the desired ligand.[201] Some of these complexes can also be prepared by Br_2 or Cl_2 oxidation of *cis*-$[W(CO)_4L_2]$ (L = tertiary phosphine).[202]

The stereochemistry of the WX_4L_2 complexes depends on the nature of L. Crystal structure analysis of $[WX_4(py)_2]$,[203] $[WCl_4(PMe_2Ph)_2]$[204] and $[WCl_4(PPh_3)_2]$[205] (prepared by reduction of $WYCl_4$ (Y = O, S, Se) with excess phosphine) have established *trans* stereochemistry. Far IR measurements suggest the same stereochemistry[200] for L = PrCN and C_4H_2S. However, with L = MeCN, EtCN and Et_2S, *cis*-$[WX_4L_2]$ is formed. The six-coordinate $[WX_4L_2]$ complexes, with the d^2 electronic configuration, are paramagnetic with magnetic moments in the range of 1.7–2.1 BM (Table 6).

The orange complex *trans*-$[WCl_4(PMe_2Ph)_2]$ reacts reversibly with PMe_2Ph to give the red paramagnetic (μ_{eff} = 2.68 BM) seven-coordinate complex $[WCl_4(PMe_2Ph)_3]$.[201,202] Other seven-coordinate W^{IV} complexes have been reported.[144,201,206] With an excess of PMe_3, $[WCl_4(PMe_3)_3]$ is obtained directly from WCl_6.[207] No structural information is available for the seven-coordinate W^{IV} complexes, but it appears that this coordination number is accessible for tungsten in this oxidation state, and that in this respect, the six-coordinate W^{IV} complexes need not be considered coordinatively saturated.

Several β-diketonate complexes of the type $[W(L–L)X_2]$ (X = Cl, Br; L = acac, 6-methyl-2,4-heptanedione, dibenzoylmethane) have been prepared from reaction of the β-diketone ligands with WX_5. The suggested *cis* stereochemistry, based on IR measurements, must be considered tentative.

Table 6 Properties of Some W^{IV} Complexes

Compound	*Color*	μ_{eff} (BM)	$\nu(W—O)$ (cm^{-1})	*Ref.*
$[WCl_4(PMe_2Ph)_2]$	Orange	2.05	—	202
$[WCl_4(PMe_2Ph)_3]$	Red	2.68	—	202
$[WCl_4(AsMe_2Ph)_2]$	Orange	1.88	—	201
$[WO(NCO)_2(PMe_2Ph)_3]$	Blue	Diamagnetic	945	201
$[WO(NCS)_2(PMe_2Ph)_3]$	Blue	Diamagnetic	952	201
$[WCl_4(dth)\cdot MeCN]$	Brown	1.67	—	206
$[WOCl(diphos)_2]BPh_4$	Pink	Diamagnetic	955	167
$[WCl_4(Me_3N)_3]$	Green-brown	1.43	—	149
$[WOCl_2(PMe_2Ph)_3]$	Purple	Diamagnetic	960	201

37.5.2 The Oxyhalides and Their Derivatives

The oxyhalides WOF_2, $WOCl_2$ and $WOBr_2$ are known. WOF_2 is an inert black non-volatile powder. It is prepared by the reaction of WO_2 with HF at 500 °C. $WOCl_2$ was reported to result from the thermal decomposition of $WOCl_3$[162] as a black-purple solid. Golden-brown crystals of $WOCl_2$ have been obtained by $SnCl_2$ reduction of $WOCl_4$ followed by sublimation,[209] and by the reaction of a mixture of W, WO_3 and WCl_6 followed by chemical transport.[210] It is likely that $WOCl_2$ exhibits polymorphism, and that the different preparative routes simply lead to different polymorphs. Nonetheless, its structure, and that of $WOBr_2$, is polymeric, probably involving both oxygen and halogen bridges.

The oxohalo derivatives of W^{IV} can be prepared by reduction of the oxo complexes of W^V and W^{VI},[167,201] by reduction of WCl_6 in wet ethanol, or by the reaction of WCl_6^{2-} with the appropriate ligand in wet solvents.[167] Thus the complexes $[WOX_2L_3]$ (L = PMe_2Ph, PEt_2Ph and $PMePh_2$) are prepared by reacting $(Et_4N)[WCl_6]$, $WOCl_4$ or WCl_6 with the desired ligand in wet ethanol. These complexes exhibit the expected strong IR band around 950 cm^{-1} which is associated with $\nu(W{=}O_t)$. The $[WOX_2L_3]$ complexes can undergo halide substitution and complexes such as $[WOX_2(PMe_2Ph)_3]$ (X = NCO, NCS) result from the reaction of the halide derivatives with NaNCO and KNCS.[167,207]

It has been shown[207] that the seven-coordinate complex $[WCl_4(PMe_3)_3]$ can abstract oxygen to give $[WOCl_2(PMe_3)_3]$. By this method, $[WOCl_2L_3]$ (L = PMe_2Ph, $PMePh_2$, $P(OMe)_3$) have been prepared.

The $[WOX_2L_3]$ complexes are diamagnetic. Their proton and phosphorus NMR and far IR spectra suggest the *cis–mer* stereochemistry (see Section 37.4.2). This suggestion is strongly supported by the crystal structures of blue $[MoOCl_2(PMe_2Ph)_3]$ and green $[MoOCl_2(PEt_2Ph)_3]$ which show that the halide ions are indeed *cis* to one another.[211]

With certain bidentate ligands, it has been shown[167] that W^V complexes of the type $[WOCl_3(L{-}L)]$ (L–L = diphos, *cis*-$Ph_2PCH{=}CHPPh_2$, 1,2-bis(diphenylphosphino)benzene) can be reduced with excess ligand to $[WOCl(L{-}L)_2]^+$. These diamagnetic pink complexes, isolated as the tetraphenylborate salts, are 1:1 electrolytes in nitromethane and exhibit the expected $\nu(W{=}O_t)$ around 950 cm^{-1}. ^{31}P NMR data clearly favor the structure in which the two bidentate ligands occupy the equatorial plane and the Cl^- ligand is *trans* to O_t.

37.5.3 The $W_2OCl_{10}^{4-}$ Ion

The incomplete reduction by tin of K_2WO_4 in concentrated HCl leads to a very deep purple solution which was suggested to result from a compound of apparent composition $K_2[W(OH)Cl_5]$.[212] The high intensity of the electronic absorption band of $[W(OH)Cl_5]^{2-}$ at 19 100 cm^{-1} (ε = 10 000) is inconsistent with a mononuclear formulation (especially with ligands such as OH^- and Cl^-), and indeed, the suggestion has been made[213] that this ion should be formulated as $[W_2OCl_{10}]^{4-}$, an oxo-bridged W^{III}–W^V mixed valence dimer.

The dinuclear structure of $[W_2OCl_{10}]^{4-}$ was established by crystallography.[214] The W—O—W bridge is linear and the W—O separation is quite short (1.871 Å) indicating a bond order higher than one. However, the mixed valence formulation has been questioned. Careful spectral and magnetic measurements suggest that the two tungsten atoms have equivalent d^2 electronic configurations and that they are antiferromagnetically coupled with an exchange energy of ~75 K.[215] The intense absorption at 19 100 cm^{-1} is believed to be associated with the W—O—W chromophore.[215]

37.5.4 Complexes with Metal–Metal Bonds

As mentioned previously, one of the more interesting developments in the chemistry of W^{IV} has been the synthesis and the characterization of dinuclear complexes containing W—W double bonds and trinuclear clusters containing W—W single bonds.

In discussing complexes containing two interacting metal atoms, which are considered to have a metal–metal double bond, and those that contain three interacting metal atoms and have metal–metal single bonds, it should be pointed out that the assignment of bond orders is problematic since these complexes, almost invariably, also contain bridging ligands. For W^V (d^1 electronic configuration), the W—W bond order cannot exceed unity, but for W^{IV} with a d^2

electronic configuration, a metal–metal double bond may be at least postulated. However, arguments for deciding between a double bond on the one hand, and a single bond together with indirect pairing of the spins of the remaining two electrons through the bridging atoms on the other hand, are rarely, if ever, conclusive, because the only data on which to base them are structural. For an isolated case, these structural data can be used to show that there is a metal–metal bond, but they do not generally allow one to conclude that the bond order must be two rather than one. However, there are today a few reported cases in which a W—W double bond can be assigned almost unambiguously on the basis of comparison of structural parameters of two related complexes, which differ from one another only by two electrons, *i.e.* dinuclear complexes of W^{IV} and W^{V}.

37.5.4.1 Complexes with metal–metal double bonds

The synthesis and structural characterization of a W^{IV} complex containing a planar $W(\mu\text{-}S)_2W$ bridge[186] has provided a rare opportunity to develop an unambiguous argument for the existence of a double bond between two W atoms when bridging atoms are also present. Compound (**9**) (Figure 19) was prepared by allowing $[W(CO)_3(MeCN)_3]$ to react with tetraethyldithiuramdisulfide in acetone. The $W(\mu\text{-}S)_2W$ bridge is strictly planar (there is a crystallographic inversion center between the two metal atoms), with a W—W separation of 2.530 Å, indicating a direct metal–metal bond. The presence of such a bond is further supported by the very small W—S_b—W angle of 65.5° and the obtuse S_b—W—S_b angle of 114.5°. The chemical environment and geometry of the metal atoms in this complex are almost identical to those found for the W^{V} compound (**7**) (see Section 37.4.4) where the W—W separation was found to be 2.791 Å. The shortening of the W—W separation by 0.26 Å clearly indicates that a considerably stronger force exists between the metal atoms. This conclusion is further supported by the contraction of the W—S_b—W angle and expansion of the S_b—W—S_b angle (for the W^{V} compound, these angles are 73.2° and 106.8° respectively), whereas the W—S_b distances in both are practically the same. Thus it seems clear that in this case we are dealing with a double bond between the two tungsten atoms.

Other examples which strongly support the existence of a metal–metal double bond are furnished by the dinuclear alkoxo-bridged dimers (**10**).[216] Several synthetic procedures have been reported for the preparation of these compounds. They include the oxidation of quadruply bonded tungsten compounds[217] in alcoholic HCl solutions, the oxidation of $[W_2Cl_9]^{3-}$ in alcohols,[218] the electrolytic reduction of alcoholic solutions of WCl_6[219] and the alcoholysis of WCl_4.[220] Other alkoxy derivatives can be prepared by a simple alcohol exchange reaction.[221]

$[W_2(\mu\text{-}S)_2(\mu\text{-}S_2CNEt_2)_2(S_2CNEt_2)_2]$ (**9**)

$[W_2Cl_4(\mu\text{-}OR)_2(OR)_2(ROH)_2]$ (R = Me, Et) (**10**)

Crystal structures of (**10**)[216] consist of two edge-sharing distorted octahedra. The metal–metal vector bisects the edge formed by the bridging oxygen atoms and the complete $Cl_2W(\mu\text{-}O)_2WCl_2$ unit is planar (Figure 20). Above and below this plane, there is one OR on one W atom and HOR on the other, with a strong hydrogen bond between the two oxygen atoms (O · · · O = 2.48 Å), and therefore the W—O bonds are perpendicular to the plane

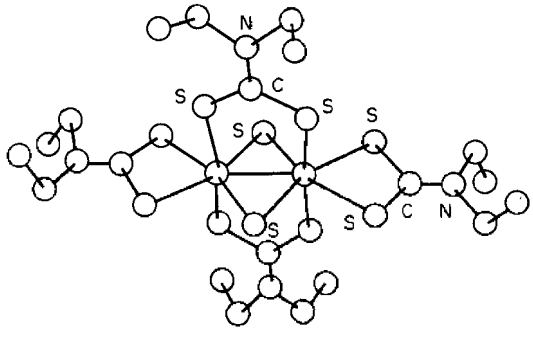

Figure 19 The structure of $[W_2(\mu\text{-}S)_2(S_2CNEt_2)_4]$[186]

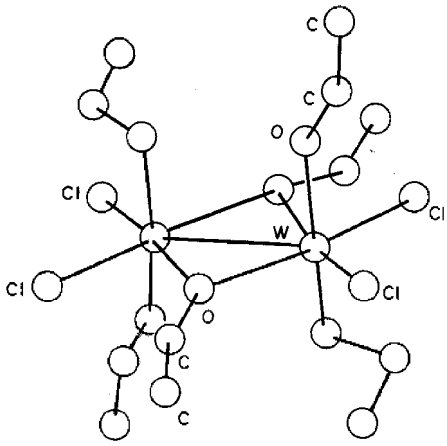

Figure 20 The structure of $[W_2Cl_4(OEt)_4(EtOH)_2]$[216]

instead of bending away from each other because of O · · · O repulsion as is observed in the W^V structure (O · · · O distance is 3.04 Å and the W—W—OR angle is 95.7°) (see Section 37.4.4).

The structures of the alkoxo-bridged dimers of W^{IV} and W^V provide an excellent opportunity to make a detailed analysis of M—M single and double bonding. The number of compositional and structural changes on going from the W^{IV} to the W^V compound are minimal. In composition, only two hydrogen atoms are removed, and structurally, other than the bending away of the two OR groups, all changes are those caused by the increase in the M—M distance from 2.482 Å in the W^{IV} complex to 2.715 Å in the W^V complex. These changes are associated with the W—O_b—W and O_b—W—O_b angles. Thus by going from the d^1–d^1 to d^2–d^2 electronic configuration the bond order increases from one to two. Moreover, qualitative considerations suggest that the double bond consists of the σ component responsible for the d^1–d^1 single bond and a π bond. Fenske–Hall calculations support this interpretation.[216]

As mentioned above, a variety of complexes of type (**10**) can easily be prepared by alcohol exchange and, in this way, compounds with R = Pr^n, Bu^n, Pen^n, Oct^n have been isolated and characterized.[221] However, when secondary alcohols have been used for exchange with (**10**), mixed alkoxy species were obtained. ^1H NMR showed that the bridging ethoxide ligands had not been replaced, a result that was confirmed by the crystal structure determination of the mixed ethoxide–isopropoxide and ethoxide–*sec*-pentoxide derivatives.

The reductive coupling of acetone by (**10**) to give a W^V compound in which the ditungsten center (W—W = 2.701 Å) is bridged by the resulting organic molecule (Figure 21) is another manifestation of the relative ease by which compounds (**10**) can be converted to dinuclear alkoxo-bridged W^V compounds.[222]

In addition to compounds of type (**10**) there is another class of W^{IV} alkoxides with a different structure. The oxidation of $[W_2(NMe_2)_6]$ by methanol and ethanol in hydrocarbon solvent leads to the tetrameric $[W_4(OR)_{16}]$ compounds.[223] These molecules do not possess the localized W—W double bonding as found in (**10**) but, rather, have a structure similar to that of

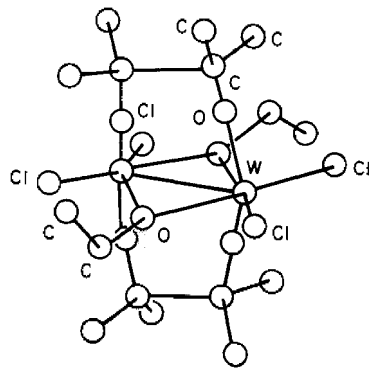

Figure 21 The structure of $[W_2Cl_4(\mu\text{-}OEt)_2(\mu\text{-}L)_2]$ (L = $Me_2COCOMe_2$)[222]

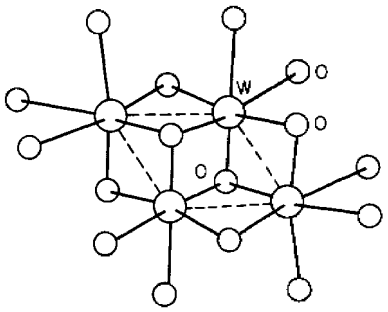

Figure 22 The structure of $[W_4(OR)_{16}]$; carbon atoms are omitted[223]

$[Ti_4(OEt)_{16}]$[224] with distortions due to M—M bonding. Crystal structure analysis of $[W_4(OEt)_{16}]$ (Figure 22) reveals the presence of two short W—W bonds (2.645 and 2.76 Å) and two long bonds of 2.93 Å. In this structure, there is a total of five possible W—W interactions, and thus, to form five bonds of order one, ten electrons are required. Only eight metal electrons are available for metal–metal bonding, which leads to the observed distortions. It has been suggested that this distortion results from a novel second order Jahn–Teller effect.[225]

The reaction of $[W_2(NMe_2)_6]$ with excess Pr^iOH leads to yet another type of tetranuclear W^{IV} alkoxy compound $[W_4(\mu\text{-}H)_2(OPr^i)_{14}]$ as depicted in Figure 23.[226] The molecule is centrosymmetric with alternating short (2.446 Å) and long (3.407 Å) W—W distances, consistent with the presence of a W—W double bond and a non-bonding distance, respectively.

Finally, WO_2, which has a modified rutile structure,[227] exhibits alternate W—W distances of 2.475 and 3.096 Å across shared edges of WO_6 octahedra. Thus, the short distance of 2.475 Å which indicates a W—W double bond makes a recognizable dinuclear unit in the infinitely extended array of the metal oxide.

Dinuclear complexes with a W—W double bond containing three bridging groups are also known. The reaction of $[WCl_4L_2]$ (L = THF, Me_2S) with Me_3SiSR (R = Me, Et, Bu^i, CH_2Ph, Ph) has been shown to give compounds of type (**11**).[228,229,230,231] Crystal structure analysis of

$$[LCl_2W(\mu\text{-}S)(\mu\text{-}SR)_2WCl_2L] \quad (L = THF, Me_2S, Cl;\ R = Me, Et, Bu^i, CH_2Ph)$$
(11)

several of these have revealed a distorted confacial bi-octahedral structure with W—W separation of close to 2.5 Å. The acute bond angles subtended at the bridging atoms agree with a strong metal–metal interaction.

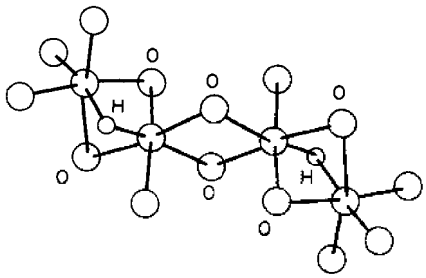

Figure 23 The structure of $[W_4(\mu\text{-}H)_2(OPr^i)_{14}]$; carbon atoms are not shown[226]

37.5.4.2 Trinuclear clusters

During the past several years it has been shown that both molybdenum and tungsten in oxidation states of +4 or thereabouts, have marked predilection to form trinuclear cluster species. For the tungsten cluster species, there are three different structural types with respect to the ligand arrangements (Figure 24 a, b, c) which are based on an equilateral triangle of M—M bonded atoms. Structure (a) contains the $[W_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]$ nucleus, where X = O, Cl,

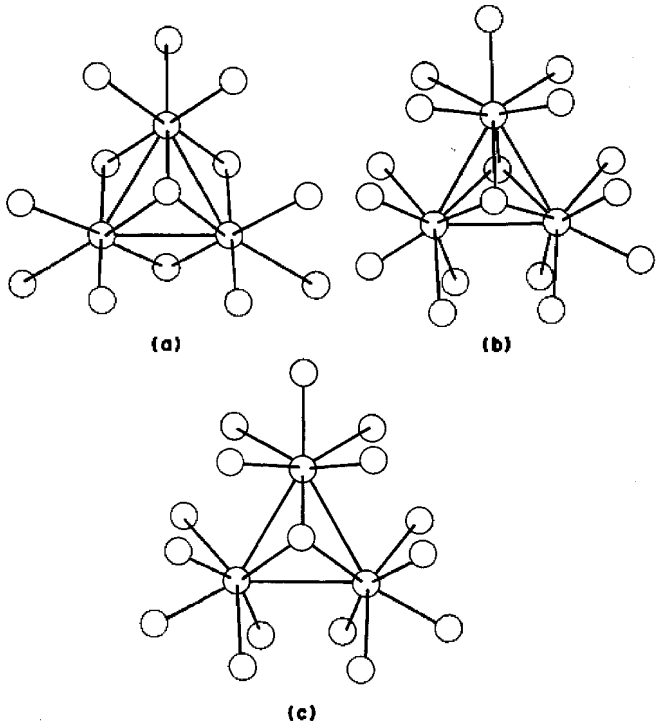

Figure 24 Structural types of trinuclear tungsten clusters

OR and Y = O. This structure is basically the same as the one observed several decades ago for the mixed metal oxide system $Zn_2Mo_3O_8$,[232] and is exemplified by the complexes (**12**), (**13**) and (**14**).

$[W_3O_4F_9]^{5-}$ (**12**) $[W_3O_3Cl_5(O_2CMe)(PBu^n_3)_3]$ (**13**) $[W_3OCH_2CMe_3O_3Cr_3(O_2CCMe_3)_{12}]$ (**14**)

Complex (**12**) has been prepared by treatment of $[W_2O_4(C_2O_4)_{2.5}]^{3-}$ with 40% HF at 70 °C. Crystal structure analysis has established the presence of the $W_3(\mu_3\text{-}X)(\mu\text{-}Y)_3$ nucleus (X = Y = O) with an average W—W distance of 2.515 Å. Without counting the M—M bonds, the coordination number of each metal atom is six and the geometry is distorted octahedral.[233]

Treatment of $[W_2Cl_4(PBu^n_3)_4]$ with acetic acid in diglyme at 160 °C leads to the isolation of (**13**) (Figure 25).[234] In this structure X = Cl, Y = O, and the average W—W distance is 2.609 Å. In both these complexes the metal is in the +4 oxidation state, and therefore each metal atom

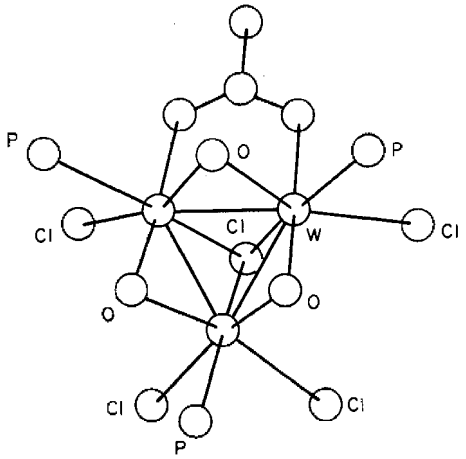

Figure 25 The structure of $[W_3O_3Cl_5(O_2CMe)(PBu^n_3)_3]$; the butyl groups are omitted[234]

has only two *d* electrons to use for M—M bonds. Thus, the two bonds formed by each metal atom cannot exceed a single bond.

Compound (**14**) has been prepared by refluxing 1:1:2 mole ratio of $W(CO)_6$, $Cr(CO)_6$ and pivalic acid in *o*-dichlorobenzene.[235] In this structure $X = OCH_2C(Me)_3$ and $Y = O$, and the average W—W separation is 2.610 Å. The average oxidation state of the tungsten atoms is $+3\frac{1}{3}$ or formally W^{III}, W^{III}, W^{IV}. In this eight electron system, the extra pair of electrons occupies a non-bonding or slightly antibonding molecular orbital. It is therefore reasonable to suggest that two electron oxidation to a six electron configuration may be possible without disrupting the cluster nucleus.

A comparison between the three W—W distances shows that with (μ_3-Cl), the W—W distance is approximately 0.1 Å longer than that with (μ_3-O), as expected when a larger capping atom is placed above the metal triangle. It is tempting to suggest that the longer bond length observed in the eight electron cluster is due to the additional pair of electrons. However, it is important to realize that the W—W bond length is also affected by the nature of the bridging atoms.

Trinuclear clusters of type (b) contain two capping groups, one above and one below the triangular plane. In addition, each pair of tungsten atoms is bridged by two carboxylates, and the coordination sphere is completed by a radial ligand which is bonded to each metal atom. With capping oxygen atoms, the $[W_3O_2(O_2CR)_6]$ unit can be the basis for a varied family of compounds. First, the R group of the carboxylate is variable. Among the four compounds isolated to date are those having R = Me, Et and Bu^t. Second, the radial coordination site may be occupied by neutral ligands, anionic ligands or a mixture of both, to give cationic clusters such as (**15**), neutral ones such as (**16**) and anionic ones such as (**17**).[236]

$[W_3O_2(O_2CR)_6(H_2O)_3]^{2+}$ (**15**) $[W_3O_2(O_2CCMe_3)_6(O_2CCMe_3)_2(H_2O)]$ (**16**) $[W_3O_2(O_2CMe)_6(O_2CMe)_3]^-$ (**17**)

These clusters are prepared by refluxing $W(CO)_6$ in the appropriate acid with or without its anhydride. Cationic clusters are best purified by ion exchange chromatography. The structure of (**15**) is depicted in Figure 26. Structure analysis has shown that the W_3O_2 nucleus is essentially invariant to the carboxylate ligands and that the W—W distance which averages 2.75 Å is only slightly affected by the radial ligands. In these clusters, the oxidation state of the metals is +4 (d^2 electronic configuration) and, therefore, the W—W bond order cannot exceed unity.

The stereochemistry of the tungsten atoms in these species is of particular interest. Each tungsten atom has a coordination number of nine, counting the neighboring metal atoms as well as the coordinated oxygen atoms. The geometry can be regarded as either distorted capped square antiprism or a distorted tricapped trigonal prism. The metal atoms are coordinatively saturated which accounts for the fact that the radical ligands are substitutionally inert.

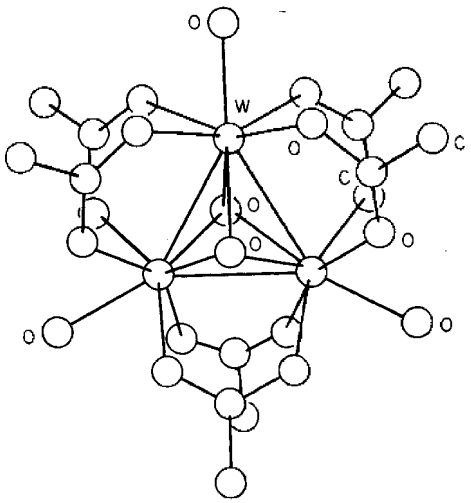

Figure 26 The structure of $[W_3O_2(O_2CMe)_6(H_2O)_3]^{2+}$ [236]

Recently, clusters (**18**) with one capping oxygen atom and one capping ethylidyne moiety have also been prepared.[237] The +1 cluster is prepared by refluxing $W(CO)_6$ with a mixture of acetic acid and its anhydride in MeCN. A one electron oxidation of the +1 ion leads to the +2 ion, whose crystal structure analysis reveals a W—W distance of 2.81 Å. This distance is significantly longer than the one observed for (**15**), in agreement with the fact that the +2 ion is a five electron system and therefore the W—W bond order is less than unity.

$[W_3O(CMe)(O_2CMe)_6(H_2O)_3]^{n+}$ $(n = 1, 2)$ (**18**)

$[W_3O(O_2CR)_6(H_2O)_3]^{2+}$ (R = Me, Et) (**19**)

Clusters of type (c) (**19**) have been prepared by refluxing $W(CO)_6$ in a 1:1 mixture of the acid and its anhydride in the presence of small amounts of triethylamine.[238] These clusters might be considered a variant of (b) in which one capping group is absent. The structure of (**19**) (Figure 27) is virtually identical with the previously reported structures of tritungsten clusters with two capping oxygen atoms except for the absence of one capping oxygen. Of the quantitative differences between the hemicapped and the bicapped structures, the largest and most unambiguous by far is in the W—W distances. In the four bicapped structures,[236] the W—W distance averages 2.75(1) Å, while in the present coumpound, the average distance is 2.710 Å. This is clearly a significant difference in both the statistical and chemical senses.

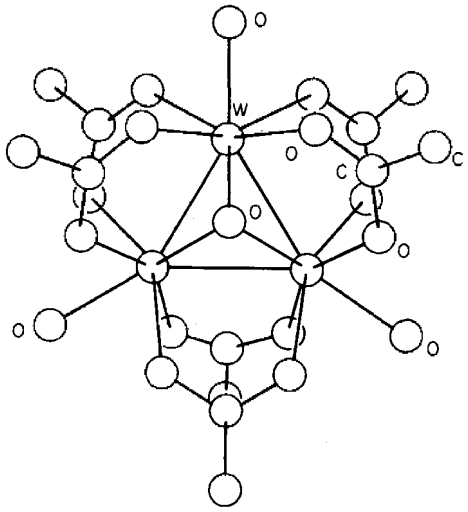

Figure 27 The structure of $[W_3O(O_2CMe)_6(H_2O)_2]^{2+}$ [238]

The hemicapped cluster is an eight electron system and a Fenske–Hall type molecular orbital calculation[238] shows that in addition to the six M—M bonding electrons comparable to those in the bicapped species, an additional electron pair occupies an orbital which is weakly M—M bonding, in agreement with the observed shortening of the W—W bond length.

Finally, although the difference in the W—W distances between structures (a) and (b) are approximately 0.2 Å, they both represent W—W single bonds. On the basis of molecular orbital calculations it has been suggested that this is due in part to the difference in the distribution of charge density in these molecules.[239] However, there is no doubt that changing the bridging ligands will have a considerable effect on the M—M distance, especially when dealing with metal–metal bonds of low order.

37.5.5 Eight-coordinate Complexes

Eight-coordinate dodecahedral complexes of the general type $W(L–L)_4$ are known for several bidentate ligands such as dithiocarbamate, 8-quinolinol, substituted quinolinols, picoline and substituted picolines.

The reaction of $[W(CO)_3(MeCN)_3]$ with tetraethyldithiuram disulfide in refluxing chloroform gives $[W(S_2CNEt_2)_4]$ which can also be prepared from $[WCl_4(MeCN)_2]$ and the dithiocarbamate ligand.[240] It was also reported that the addition of CS_2 to $[W(NMe_2)_6]$ leads to

$[W(S_2CNMe_2)_4]$.[241] $[W(S_2CNEt_2)_4]$ can be oxidized with Br_2 to the eight-coordinate W^V complex $[W(S_2CNEt_2)_4]^+$. Crystal structure analysis of this compound reveals the expected dodecahedral geometry[242] with W—S(A) distance of 2.529 Å and W—S(B) distance of 2.494 Å (A and B refer to the Hoard–Silverton notation).[243] Recently, $[W(S_2CSR)_4]$ (R = Et, Pr^i, Bu^t) have also been prepared and I_2 oxidation leads to the corresponding W^V complexes $[W(S_2CSR)_4]I_5$.[178]

With 8-quinolinol or its derivatives, $W(L–L)_4$ complexes have been prepared by a sealed-tube melt reaction with either $K_3[W_2Cl_9]$ or $W(CO)_6$.[244] Crystal structure analysis of $W(L–L)_4$ (L–L = 5-bromoquinolinol) has established the dodecahedral geometry for this and related compounds.[245] The four quinolinol ligands span the Hoard–Silverton *m* edges, with the oxygen atoms occupying A positions and the nitrogen atoms the B positions.

Another series of eight-coordinate complexes has been prepared with picolinates. All eight-coordinate complexes of the type $W(L–L)_4$ to date are diamagnetic, with the two electrons of the d^2 configuration paired in the low-lying $d_{x^2-y^2}$ level of the D_{2d} dodecahedron.[245] The IR electronic spectra consist of intense low energy bands ($\varepsilon > 10^4$), attributed to $d \rightarrow \pi^*$ charge transfer transitions.

[W(picolinate)$_4$] and several quinolinate derivatives can be oxidized to the corresponding W^V complexes.[246] These are paramagnetic with moments of about 1.7 BM, close to the spin-only value. The two low-intensity near IR transitions are reasonably assigned to d–d transitions from the $d_{x^2-y^2}$ level. Liquid nitrogen ESR measurements suggest lower symmetry for these W^V complexes.[246] They are reasonably stable in the solid, but disproportionate rapidly in solution to the W^{IV} compounds and tungstate.[247]

37.5.6 Complexes with Multiple Bonds to Sulfur, Nitrogen and Carbon

The tendency of W^{IV} to form multiple bonds to good π donor atoms is much less pronounced than for W^V and W^{VI}; however, several such complexes are known.

The reaction of aqueous WS_4^{2-} with dilute HCl gives the $[W_3OS_8]^{2-}$ ion.[248] Its structure consists of the WO unit bonded to two WS_4^{2-} ligands with a short W—O_t distance of 1.68(2) Å. $[W_3S_9]^{2-}$ has also been prepared.[248,249] Its structure is very similar to that of $[W_3OS_8]^{2-}$ with a W—S_t bond length of 2.07(1) Å. In this complex, the geometry around the central W^{IV} ion is that of a distorted square pyramid.

The multiple bond between W^{IV} and a carbon atom is exemplified by $[W(CR)L_4Cl]$ (R = H, CMe_3; L = PMe_3)[250] and by $[W(CPh)(CO)_2(py)_2Br]$.[251] Crystal structure analysis of this last compound revealed the expected short W—C bond length of 1.84 Å.

Complexes containing multiple bonded nitrogen ligands are usually obtained from dinitrogen complexes. The complexes $[W(NH)X(diphos)]^+$ (X = F, Cl, Br) are known[252] and in basic methanol yield ammonia *via trans*-$[W(NH)(OMe)(diphos)_2]$.[253] The nitrido group is readily attacked by electrophiles to give imido, dialkylimido or thionitrosyl complexes. Thus, $[W(N)(N_3)(diphos)_2]$ reacts with EtI to give $[W(NEt)(N_3)(diphos)_2]I$.

Na/Hg reduction of $[W(NR)Cl_4]$ in the presence of the desired ligands leads to the complexes $[W(NR)Cl_2L_3]$ (R = Ph, Et; L = PMe_3, PMe_2Ph, $CNBu^t$).[171] Crystal structure analysis of $[W(NPh)Cl_2(PMe_3)_3]$ has revealed a short W—N distance of 1.755 Å in agreement with ν(W—NR) around 1080 cm^{-1}. The phosphine ligands occupy *mer* positions *cis* to the W(NR) unit. This stereochemistry is similar to that suggested for the analogous complex $[WOCl_2(PMe_2Ph)_3]$.[201]

37.5.7 Cyanide Complexes

The octacyanotungstate ion $[W(CN)_8]^{4-}$ has been known since 1914.[254] It is easily obtained by reacting a variety of starting materials containing W^{III}, W^{IV} and W^V with aqueous cyanide.[255] The trivalent metal is usually oxidized by either air or solvent, while the pentavalent starting materials disproportionate to $[W(CN)_8]^{4-}$ and WO_4^{2-}. The $[W(CN)_8]^{4-}$ ion can be easily oxidized to $[W(CN)_8]^{3-}$, but it does not appear possible to obtain it directly from W^V compounds. $[W(CN)_8]^{4-}$ is diamagnetic while $[W(CN)_8]^{3-}$ is paramagnetic with μ_{eff} = 1.76 BM.[255]

Both $[W(CN)_8]^{4-}$ and $[W(CN)_8]^{3-}$ are stable in solution in the absence of light and no exchange of $^{14}CN^-$ is detected. This exchange is strongly catalyzed by light and the rate is

dependent on the light intensity. Exposing the yellow solution of $[W(CN)_8]^{4-}$ to light leads to a rapid change to red-brown, and then to purple. On the basis of crystallographic studies[256] the red-brown color is due to *trans*-$[WO_2(CN)_4]^{4-}$ and the purple color to *trans*-$[W(O)(OH)(CN)_4]^{3-}$. Recently, the $[W(O)(OH_2)(CN)_4]^{2-}$ ion has been isolated and characterized as its cadmium salt,[257] and protonation of $[WO_2(CN)_4]^{4-}$ was reported to lead[258] to $[W_2O_3(CN)_8]^{5-}$.

The photolysis of $[W(CN)_8]^{3-}$ has been investigated[259] in the pH range 1–13. The photolysis consists of a two-step sequence involving a primary intermolecular redox process and a consecutive thermal process both leading to $[W(CN)_8]^{4-}$. The rate of the oxidation of $[W(CN)_8]^{4-}$ with several oxidizing agents has been studied. With IO_4^- for example,[260] the reaction is first order with respect to both reagents and is catalyzed by H^+. Inorganic cations have an accelerating effect on the oxidation in the order, $Mg \gg Cs > Rb > K > Na > Li$.

The reaction of $[W(CN)_8]^{4-}$ with H_2 at 400 °C was reported to give a green-black product of composition $K_4[W(CN)_6]$.[255] Recently the same reaction has been shown to give $[W(CN)_7H]^{4-}$, and in the presence of base the following equilibrium is established,[261] as depicted in equation (14). $[W(CN)_7]^{5-}$ can also be prepared directly from $[W_2Cl_9]^{3-}$ with an excess of cyanide. The sharpness of the ^{13}C NMR lines suggests that on the NMR time scale there is no exchange of coordinated cyanide and that both structures are fluxional in solution.

$$[W(CN)_7H]^{4-} + OH^- \rightleftharpoons [W(CN)_7]^{5-} + H_2O \quad (14)$$

Salts of $[W(CN)_8]^{4-}$ are dodecahedral both in solution and in the solid state with the exception of the cadmium salt which is believed to have the square antiprismatic structure in both phases.[255] ESR and vibrational spectra suggest that the W^V ion $[W(CN)_8]^{3-}$ has D_{4d} symmetry in solution.[262] However, evidence for both the dodecahedral and square antiprismatic ground state for this ion has also been reported.[263]

Mixed cyanoisonitrile complexes have been reported to result from the reaction of $Ag_4[W(CN)_8]$ with RNC (R = Me, Et, Pr^n, Pr^i, Bu^t and CPh_3).[264] The resulting $[W(CN)_4(CNR)_4]$ complexes are dodecahedral, with the more strongly π accepting isonitrile ligands occupying the B position. These complexes can also be obtained by the reaction of the silver salt with alkyl iodide.[255]

37.6 THE CHEMISTRY OF W^{III}

With a few exceptions, the chemistry of W^{III} is almost entirely that of dinuclear species containing a metal–metal bond of order three. There are only a few well-characterized examples of mononuclear complexes. This undoubtedly results from the tendency of W^{III} to form metal–metal bonds and the susceptibility of mononuclear complexes to oxidation. Of the halides of W^{III}, only WBr_3 and WI_3 are known.[269] The thermally unstable WBr_3 is prepared by the reaction of WBr_2 with excess Br_2 in a sealed tube. It is inert to H_2O and concentrated HCl. WI_3 is prepared from $W(CO)_6$ and I_2 at 120 °C.

37.6.1 Mononuclear Complexes of W^{III}

Complexes of the type WX_3py_3 (X = Cl, Br) have been prepared[265] by treatment of $[W(CO)_4X_2]$ with py at 140 °C. These are paramagnetic with $\mu_{eff} = 3.39$ and 3.40 BM for the chloro and bromo derivatives respectively. $[WX_4L_2]^-$ (X = Cl, Br; L = Py, 4-Mepy) have also been prepared by pyridine reduction at 350 K of the W^{IV} compounds $[WX_4L_2]$. Crystal structure analysis of $[WCl_4py_2]^-$ and $[WBr_4(Mepy)_2]^-$ shows that both have the *trans* stereochemistry.[266,267] Recently, it has been shown that $[LW(CO)_3]^-$ (L = polypyrazolylborate) react with thionyl chloride to give $[LWCl_3]$ which can be reduced[268] to the W^{III} complex $[LWCl_3]^-$.

37.6.2 Dinuclear Complexes of W^{III}

The dinuclear complexes of W^{III} can be divided into two groups. In one, the metal–metal bond is supported by bridging ligands as exemplified by the $[W_3Cl_9]^{3-}$ ion, while in the second,

the dimeric species are of the W_2X_6 type, recognized by the $\sigma^2\pi^4$ electronic configuration, where the two metal atoms are held together by metal–metal bonds only. Structurally, what set these two groups of complexes apart are the M—M bond length, the coordination number and the geometry around the metal atom, and chemically, there is very little that the two groups have in common.

37.6.2.1 The $[W_2X_9]^{3-}$ ion and related compounds

The $[W_2X_9]^{3-}$ (X = Cl, Br) ions were first prepared years ago by electrochemical or chemical reduction of tungstates in concentrated HCl or HBr solutions.[269] More recently, it has been shown that $[W_2X_9]^{3-}$ is readily prepared by passage of HX gas through a solution containing CsX and $[W_2(mhp)_4]$ (mhp = anion of 2-hydroxy-6-methylpridine). It is interesting that when CsX is excluded, compound (**10**) is formed.[270] The bromide derivative can also be prepared by halogen exchange (equation 15). Reaction (15) reaches equilibrium after approximately three hours and $[W_2ClBr_8]^{3-}$ is the major tungsten-containing species.[276] A continuous flow of HBr throughout the course of the reaction leads to complete exchange within 24 hours. Of the several possible mechanisms for this halogen exchange, the most likely seems to involve an intermediate with a $W(\mu\text{-}Cl)_2W$ bridge, and four terminal chlorides bonded to each metal atom. This is a viable intermediate in view of the structure of $[W_2Cl_6py_4]$ (Figure 28).

$$[W_2Cl_9]^{3-} + 9Br^- \rightleftharpoons [W_2Br_9]^{3-} + 9Cl^- \tag{15}$$

$[W_2Cl_9]^{3-}$ has the confacial bioctahedral structure with a W—W bond length of 2.418 Å. (This structure was first solved in 1958[272] and then re-refined in 1983).[273] This experimental result coupled with the electronic configuration of the metals is consistent with a W—W bond order of three.

$[W_2Cl_9]^{3-}$ can be oxidized with oxidants such as Cl_2, Br_2 and I_2.[274] The violet mixed valence complex $[W_2Cl_9]^{2-}$ is paramagnetic with $\mu_{eff} = 1.87$ BM per formula unit. The dianion can also be prepared in low yield by the reaction of $[W(CO)_5Cl]^-$ with WCl_6 in methylene chloride,[275] or in 40–50% yield by the reduction of WCl_4 with Na/Hg in THF[273] in the presence of $[(Ph_3PNPPh_3)Cl]$. Structurally $[W_2Cl_9]^{2-}$ is very similar to $[W_2Cl_9]^{3-}$ with a W—W bond length of 2.540 Å in agreement with a bond order of 2.5. The increase of 0.122 Å in the W—W distance in going from $[W_2Cl_9]^{3-}$ to $[W_2Cl_9]^{2-}$ is believed to result not only from the decrease in the bond order, but also because of the increase in the effective charge of the metal atoms.[273] The electronic absorption spectra of $[W_2X_9]^{n-}$ (X = Cl, Br; $n = 2$, 3) have been interpreted recently.[276] $[W_2Br_9]^{2-}$ is also known, and is obtained in reasonable yield according to equation (16). Its structure is similar to that of $[W_2Cl_9]^{2-}$ with a W—W bond length of 2.601 Å and a magnetic moment of 1.72 BM per formula unit.[277]

$$4[W(CO)_5Br]^- + 7C_2H_4Br_2 \longrightarrow 2[W_2Br_9]^{2-} + 7C_2H_4 + 2CO_2 \tag{16}$$

The reaction of $[Mo_2(O_2CMe)_4]$ with a warm concentrated solution of HCl or HBr affords the $[Mo_2X_8H]^{3-}$ anions. These anions contain the $Mo(\mu\text{-}H)(\mu\text{-}Cl)_2Mo$ bridging unit,[278] and possess structures similar to that of $[W_2Cl_9]^{3-}$. This type of oxidative addition is also possible with the quadruply bonded dimer $[MoW(O_2CCMe_3)_4]$. This molecule when treated in the same way[279] affords $[MoWCl_8H]^{3-}$ with a Mo—W distance of 2.495 Å.

$[W_2Cl_9]^{3-}$ reacts with heterocyclic organic bases[280] to give the diamagnetic compounds

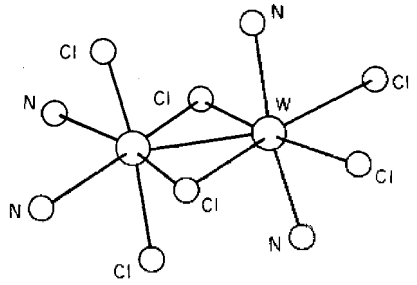

Figure 28 The structure of $[W_2Cl_6py_4]$; pyridine rings are not shown[281]

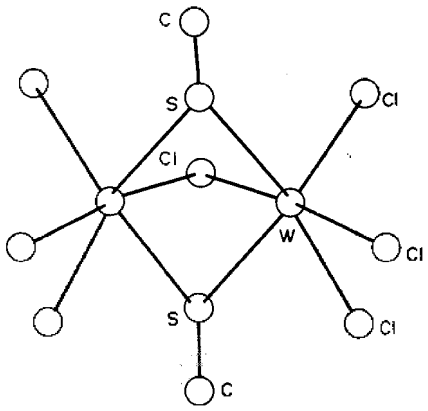

Figure 29 The structure of $[Cl_3(\mu\text{-}Cl)(\mu\text{-}SPh)_2WCl_3]^{2-}$; phenyl carbon atoms are omitted[231]

$[W_2Cl_6L_4]$ (L = py, pic and 4-isopropylpyridine). Structure analysis of $[W_2Cl_6py_4]$ has established[281] the presence of a planar $W(\mu\text{-}Cl)_2W$ bridge with a W—W distance of 2.737 Å (Figure 28). This distance is considerably larger than that expected for a W^{III}–W^{III} (d^3–d^3) dimer of this type with a triple bond. In fact, this distance is consistent with a W—W single bond. It can be argued that the situation here is similar to the one described for the d^4–d^4 $[Re_2Cl_{10}]^{4-}$ ion.[282] The complexes $[W_2Cl_6(PMe_3)_4]$ and $[W_2Cl_6(THF)_4]$ which are prepared by Na/Hg reduction of WCl_4 in THF with or without PMe_3,[283] may possess structures which are related to that of $[W_2Cl_6py_4]$.

Isoelectronic with $[W_2Cl_9]^{3-}$ are the paramagnetic thiolato-bridged dimers (**20**)[284] and (**21**).[231] They possess the confacial bioctahedral structure (Figure 29) with W—W distances of 2.505 and 2.519 Å respectively. These distances are not significantly different than those found for compounds (**11**) (see Section 37.5.4.1) which contain a W—W bond order of two. This result lent strong support to the suggestion that the difference in bond length of 0.122 Å observed in going from $[W_2Cl_9]^{3-}$ to $[W_2Cl_9]^{2-}$ is not caused only by the decrease in the bond order.[273]

The reaction of $[WCl_4(MeS)_2]$ with Et_2SiH gives compound (**22**) from which the anion (**23**) can be prepared.[285] The structure of (**23**) possesses the $W(\mu\text{-}H)(\mu\text{-}SMe_2)_2W$ bridge with a W—W distance of 2.410 Å, consistent with a W—W bond of order three.

37.6.2.2 Complexes of the type W_2X_6

The metal–metal triple bond is formed by overlap of the metals' d_{z^2} orbitals to give a σ bond, and the d_{xz} and d_{yz} orbitals to give the π bonds. In a d^3–d^3 situation, the six metal electrons are accommodated in the three bonding molecular orbitals resulting in the $\sigma^2\pi^4$ electronic configuration. In the absence of the δ component, the triple bond allows free rotation about the M—M axis, and thus the adopted staggered configuration is determined by the steric requirement of the ligands.

The first W^{III} complex of the W_2X_6 type[286] was prepared by the reaction of WCl_6 with $LiCH_2SiMe_3$. The orange-brown organometallic compound $[W_2(CH_2SiMe_3)_6]$ can be sublimed in vacuum at 120 °C. It is stable in air for short periods, but oxidizes very rapidly in solution. The proton NMR spectra indicate that the six Me_3SiCH_2 groups are equivalent. $[W_2(CH_2SiMe_3)_6]$ crystallizes with two independent but virtually identical molecules in the asymmetric unit[287] with a mean W—W bond length of 2.255 Å. The stereochemistry in the solid is staggered as expected (Figure 30).

The compound $[W_2(NMe_2)_6]$ was first obtained as a minor product from the reaction of WCl_6 with $LiNMe_2$.[88] Attempts to prepare this material by reacting $LiNMe_2$ with lower valent starting materials such as $K_3[W_2Cl_9]$ or W_6Cl_{12} were not successful.[289] It is now known that the best preparative route to the compounds $[W_2X_6]$ (X = NMe_2, NMeEt, NEt_2) is by reacting X with a form of WCl_4 which is prepared by the reaction of $W(CO)_6$ with two equivalents of

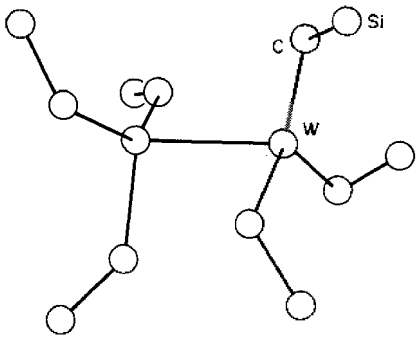

Figure 30 The structure of $[W_2(CH_2SiMe_3)_6]$; methyl groups are omitted[287]

WCl_6 in refluxing chlorobenzene.[284] As can be seen from Figure 31, $[W_2(NMe_2)_6]$ has the expected staggered, ethane-like stereochemistry with a W—W bond length of 2.294 Å. In addition, the methyl groups are not equivalent. One set of methyl groups lie approximately over the W—W bond (for example C-1; these are called the proximal methyl groups), while the other set, called the distal methyl groups (for example C-2), lie away from the W—W bond.

Compounds of the type $[W_2(OR)_6]$ are also known,[290] but they are much less stable than their molybdenum analogues. For example, $[Mo_2(OBu^t)_6]$ can easily be purified by vacuum sublimation at 100 °C, while the corresponding tungsten compound is thermally unstable and is very sensitive to both oxygen and moisture. In addition to $[W_2(OBu^t)_6]$, $[W_2(OSiMe_3)_6(NHMe_2)_2]$ and $[W_2(OPr^i)_6py_2]$[290] have been prepared by the reaction of $[W_2(NMe_2)_6]$ with Me_3SiOH in hydrocarbon or with Pr^iOH in pyridine. These compounds are also thermally unstable. The reaction of $[W_2(NMe_2)_6]$ with MeOH or EtOH gives the tetranuclear cluster compound $[W_4(OR)_{16}]$[223] while the reaction with Pr^iOH in the absence of pyridine gives $[W_4(\mu\text{-}H)_2(OPr^i)_{14}]$[226] (see Section 37.5.4.1).

Compounds of the type $[W_2Cl_2(NR_2)_4]$ (R = Me, Et) are known, and are best prepared by the reaction depicted in equation (17).[291] The lability of the W—Cl bond has led to the preparation of $[WX_2(NEt_2)_4]$ (X = Br, I),[292] and a series of dialkyl derivatives $[W_2R_2(NR'_2)_4]$ (R = Me, Et, Bu^n, Pr^i, CH_2CMe_3, CMe_3, CH_2SiMe_3; R′ = Me, Et).[293] The dialkyl derivatives are red-orange, thermally stable, and in most cases can be sublimed in vacuum around 100 °C. The structures of these molecules are very similar; they have the *anti* rotational conformation with bond length close to 2.3 Å (Table 7).

$$[W_2(NR_2)_6] + 2Me_3SiCl \longrightarrow [W_2Cl_2(NR_2)_4] + 2Me_3SiNR_2 \qquad (17)$$

The reaction of *anti*-$[W_2Cl_2(NEt_2)_4]$ with two equivalents of $LiCH_2SiMe_3$ is stereospecific[294] giving exclusively *anti*-$[W_2(CH_2SiMe_3)_2(NEt_2)_4]$ which then slowly isomerizes to an equilibrium mixture of *anti* and *gauche* rotamers. The stereospecificity clearly requires that the W≡W bond remains intact during the reaction, and that the Me_3SiCH_2 ligand replaces Cl with retention of configuration at the metal atom. NMR studies of this reaction suggest that there is a *trans* labilizing effect which is transmitted through the triple bond. $[W_2Me_2(NEt_2)_4]$[295] was also

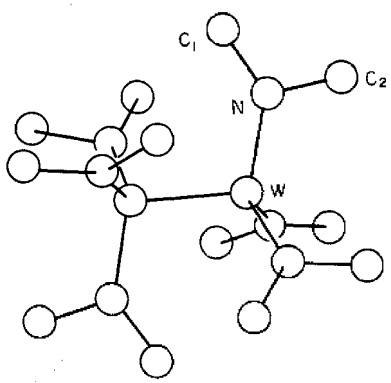

Figure 31 The structure of $[W_2(NMe_2)_6]$[12]

Table 7 Triple Bond Distances Between W Atoms

Compound	*W—W* (Å)	*Ref.*	*Compound*	*W—W* (Å)	*Ref.*
$[W_2(CH_2SiMe_3)_6]$	2.255(2)	289	$[W_2I_2(NEt_2)_4]$	2.300(4)	292
$[W_2(NMe_2)_6]$	2.294(2)	12	$[W_2Me_2(O_2CNEt_2)_4]$	2.272(1)	297
$[W_2Cl_2(NMe_2)_4]$	2.285(2)	291	$[W_2(O_2CNMe_2)_6]$	2.279(1)	297
$[W_2Cl_2(NEt_2)_4]$	2.301(1)	289	$[W_2Me_2(NEt_2)_4]$	2.291(1)	295
$[W_2Br_2(NEt_2)_4]$	2.301(2)	292	$[W_2(OPr)_6py_2]$	2.332(1)	290
$[W_2(OEt)_6(Me(H)NC_2H_4N(H)Me)]$	2.296(2)	299			

shown to exist in solution in an approximately 3:2 equilibrium mixture of *anti* and *gauche* rotamers. The *gauche* rotamer predominates as the bulk of the R group increases.[293] It is interesting that alcoholysis of the $[W_2R_2(NR_2)_4]$ compounds with bulky alcohols leads to $[W_2R_2(OR)_4]$ with retention of the W—R bonds.[296]

Insertion of CO_2 into M—NR_2 and M—OR bonds occurs quite readily in certain cases, leading to dialkylcarbamato and alkylcarbonato groups respectively. Thus, $[W_2(NMe_2)_6]$ reacts completely with excess CO_2 to give $[W_2(O_2CNMe_2)_6]$, while the reaction of $[W_2Me_2(NEt_2)_4]$ with CO_2 leads to $[W_2Me_2(O_2CNEt_2)_4]$. The structures of these molecules (Figures 32 and 33)[297] are quite similar in that both have two bridging and two chelating carbamato ligands similarly disposed around the metal atoms, and in the one case, the methyl groups are *trans* to the chelating ligand while in the other, an oxygen of a unidentate carbamato group is *trans* to the chelating ligand. In both, the W—W triple bond is retained (Table 7). These compounds are fluxional in solution and below −60 °C, the NMR spectrum of $[W_2(O_2CNEt_2)_6]$ is consistent with the solid state structure. The NMR spectra of $[W_2Me_2(O_2CNEt_2)_4]$ has not been completely interpreted.[289]

Until recently, the only two examples of complexes of the type $X_4W{\equiv}WX_4$ were $[W_2(OPr^i)_6py_2]$[290] and $[W_2(NMe_2)_4(PhNNNPh)_2]$.[298] In these complexes, the coordination number of each metal atom is four, and the W—W bond lengths are only slightly longer than those found for the W_2X_6 compounds. It is now known that when $[W_2(NMe_2)_2]$ is allowed to react with EtOH in the presence of $Me(H)NCH_2CH_2N(H)Me$, the adduct (**24**) is formed. In this structure (Figure 34) the W—W triple bond is retained (2.296 Å), and the two ends of the molecule are almost perfectly staggered. $[W_2(NMe_2)_6]$ was also shown to react with alcohols in the presence of PMe_3 to give the phosphine adducts $[W_2(OR)_6(PMe_3)_2]$ (R = Pr^i, CH_2Bu^t and Et). The structure of $[W_2(OCH_2Bu^t)_6(PMe_3)_2]$ reveals two square planar WO_3P units joined by a W—W triple bond of distance 2.362 Å.

$[W_2(OEt)_6(Me(H)NC_2H_4N(H)Me)]$
(24)

1,2-$[W_2\{Si(SiMe_3)_3\}_2(NMe_2)_4]$
(25)

1,2-$[W_2\{CpFe(CO)_2\}_2(NMe_2)_4]$
(26)

As mentioned previously, $[WCl_2(NR_2)_4]$ reacts with LiR to give the 1,2-dialkyl-substituted derivatives. Recently, this reaction has been extended to other anionic ligands.[300] Thus, the reaction of $[W_2Cl_2(NMe_2)_4]$ with two equivalents of $[(Me_3Si)Si]^-$ or $[CpFe(CO)_2]^-$ results in the

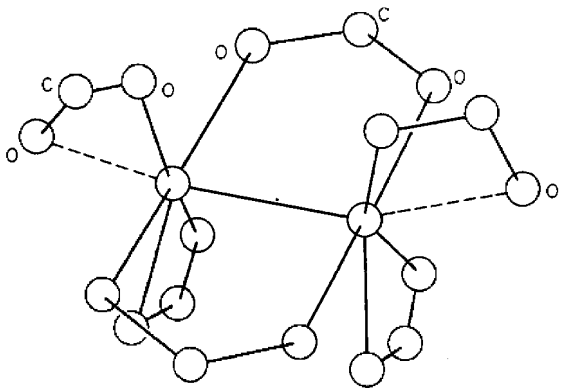

Figure 32 The structure of $[W_2(O_2CNMe_2)_6]$[297]

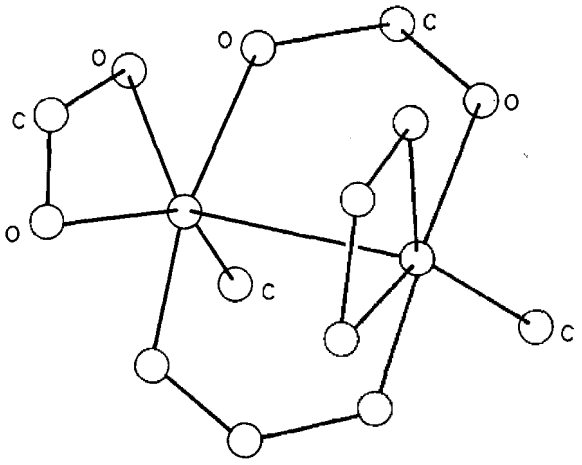

Figure 33 The structure of $[W_2Me_2(O_2CNEt_2)_4]$[297]

formation of compounds (**25**) and (**26**) respectively. These are the first examples of a W—W triple bond supporting a metal–metal single bond between two different metal atoms.

Of considerable interest are reactions in which the metal–metal bond order changes. So far, there are no known examples in which a W—W triple bond is converted to a W—W quadruple bond, a reaction which is known for molybdenum.[289] However, several reactions in which the W—W triple bond is oxidized are known. The preparation of alkoxo clusters of W^{IV} have been mentioned (Section 37.5.4.1) and the reaction in which W≡W reacts with RC≡CR or RC≡N to give mononuclear complexes containing the W≡CR and W≡N units have been discussed (Section 37.3.3).

Recently, several new and important reactions, in which the dinuclear unit remains intact, have been reported. The reaction $[W_2(OBu^t)_6]$ in the presence of pyridine or $[W_2(OPr^i)_6py_2]$ with ethyne gives (**27**).[301] The structure of the isopropoxide derivative contains the $W(\mu\text{-}OPr^i)_2(\mu\text{-}C_2H_2)W$ bridge with a W—W distance of 2.567 Å. In solution, this compound is fluxional showing rapid terminal bridge OR exchange. At low temperature, the NMR spectra is consistent with the solid state structure. The addition of C_2Me_2 to $[W_2(OCH_2Bu^t)_6py_2]$ in hexane yields the blue compound (**28**). In this structure there is only one bridging alkoxy group

$[W_2(O_2CH_2Bu^t)_6py_2(\mu\text{-}C_2H_2)]$ (**27**)

$[W_2(O_2CH_2Bu^t)_6py(\mu\text{-}C_2Me_2)]$ (**28**)

$[W_2(OPr^i)_6(\mu\text{-}C_4Me_4)(C_2Me_2)]$ (**29**)

$[W_2(O_2CH_2Bu^t)_6py\{\mu\text{-}N(CMe_4)N\}]$ (**30**)

(W—W = 2.602 Å), and the C_2Me_2 unit is closer to one of the W atoms (Figure 35). It has also been shown that changing the alkoxy groups and/or the alkyl substituents greatly influences the course of this reaction. Thus, reacting $[W_2(OPr^i)_6py_2]$ with an excess of C_2Me_2 leads to compound (**29**) in which two alkynes are coupled and a third is present as a terminal ligand. In

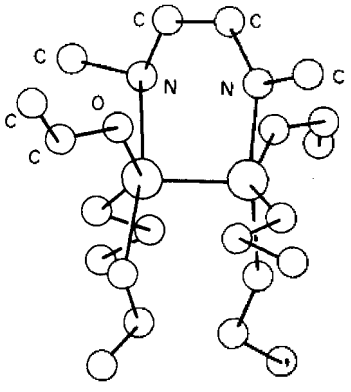

Figure 34 The structure of $[W_2(OEt)_6(Me(H)NC_2H_4N(H)Me)]$[299]

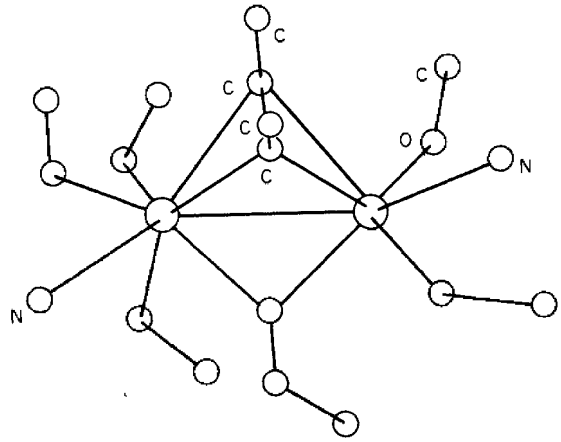

Figure 35 The structure of $[W_2(O_2CH_2Bu^t)_6py(\mu\text{-}C_2Me_2)]$; the tertiary butyl groups and py ring are omitted[301]

this molecule (W—W distance = 2.85 Å), as with the others, W—W interaction is retained. When compound (**28**) is reacted with MeCN, compound (**30**) is obtained.[302a] Its structure (Figure 36) reveals the presence of the deprotonated bridging ligand (μ-N(CMe)$_4$N) which results from coupling of the (μ-C_2Me_2) moiety with two equivalents of MeCN. The W—W bond length of 2.617 Å is consistent with a bond of order one. It has also been shown that $[W_2(OR)_6]$ reacts with α-diketones to give compounds in which the reduced organic moiety is bonded to a dinuclear complex with a W—W bond of order one.[302b]

The reaction of $[W_2(OBu^t)_6]$ with NO in pyridine leads to cleavage of the W—W triple bond,[303] and the formation of $[W(OBu^t)_3(NO)py]$. In this structure, the geometry around the metal atom is trigonal bipyramidal, with the py ligand *trans* to NO.

The reaction of $[W_2(OR)_6]$ (R = Pr^i, CH_2CMe_3) with CO in the presence of excess pyridine leads to $[W_2(OR)_6py_2(\mu\text{-}CO)]$.[304] The structure of the isopropoxide derivative is that of a confacial bioctahedron, with the CO ligand and a pair of OPr^i groups making up the bridging face. The W—W distance of 2.499 Å is consistent with a bond of order two. However, when $[W_2(OPr^i)_6py_2]$ is reacted with CO without additional pyridine,[305] two different products are obtained depending on the amount of CO added. With four equivalents of CO compound (**1**) is formed (Section 37.3.1), while with two equivalents of CO the tetranuclear compound $[W_2(OPr^i)_6py(CO)]_2$ is obtained. The structure of this molecule consists of two $[W_2(OPr^i)_6py(CO)]$ units which are bridged through the oxygen atoms of the CO group (Figure 37), an unprecedented bonding arrangement for the CO ligand. The W—W bond length of 2.654 Å is significantly longer than that found for $[W_2(OPr^i)_6py_2(CO)]$ and falls within the range typical of single rather than double W—W bonds.

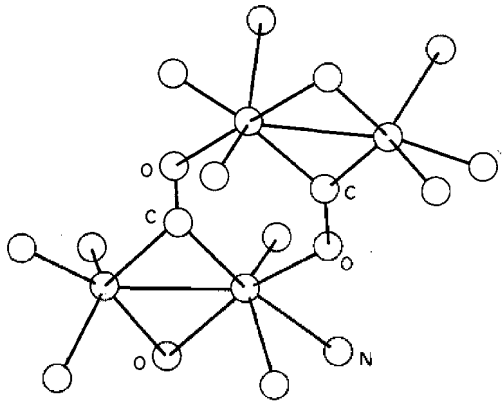

Figure 37 The structure of $[W_2(OPr^i)_6py(CO)]_2$; propyl groups are omitted[305]

37.7 THE CHEMISTRY OF W^{II}

Until several years ago, most of the known compounds of W^{II} were monomeric complexes, which exhibit mainly coordination number seven, and cluster compounds containing the octahedral W_6 nucleus with W—W single bonds. The most important advance in the chemistry of W^{II} has undoubtedly been the preparation and characterization of dinuclear compounds containing W—W quadruple bonds.

37.7.1 Monomeric Complexes

There are two general procedures for the preparation of monomeric W^{II} complexes.[269] In one, substituted tungsten carbonyls are oxidized by halogens under controlled conditions as exemplified by equations (18) and (19). In the second, $W(CO)_6$ is first oxidized by Cl_2 or Br_2 at low temperature, followed by reaction of the oxidized product with the appropriate ligands. This preparative procedure is exemplified by equation (20).

$$[W(CO)_4(bipy)] + Br_2 \longrightarrow [W(CO)_3(bipy)Br_2] + CO \quad (18)$$

$$[W(CO)_2(diars)_2] + Br_2 \longrightarrow [W(CO)_2(diars)_2Br]Br \quad (19)$$

$$[W(CO)_4Cl_2] + 2PPh_3 \longrightarrow [W(CO)_3(PPh_3)_2Cl_2] + CO \quad (20)$$

There are numerous examples of this type of complex. The majority are seven-coordinate; some representatives are given in Table 8. With bidentate and tridentate ligands, when the

stoichiometry suggests a coordination number higher than seven, it is invariably found that not all the donor atoms are coordinated to the metal.

The halocarbonyl anions $[W(CO)_4X_3]^-$ (X = Cl, Br, I) are prepared by the addition of the desired halide to $[W(CO)_4X_2]$ or by oxidation of $[W(CO)_5X]^-$. Mixed halogen derivatives are prepared similarly.[306] For example, oxidation of $[W(CO)_5I]^-$ with Br_2 leads to $[W(CO)_4IBr_2]^-$.

Oxidation of *cis*-$[W(CO)_2(diphos)_2]$ with I_2 leads to the unexpected one electron oxidation product $[W(CO)_2(diphos)_2]^+$. This paramagnetic complex exhibits only one carbonyl stretching frequency, indicating a *trans* stereochemistry.[307] Reaction of $[W(CO)_4diars]$ with excess bromine also results in the seven-coordinate complex $[W(CO)_3(diars)Br_2]^+$, which appears to be a W^{III} derivative.[308] It is unusual that three carbonyls are retained by the metal in this oxidation state.

Refluxing of $[W(CO)_3(PPh_3)_2X_2]$ (X = Cl, Br) in CH_2Cl_2 gives the deep blue crystalline derivatives $[W(CO)_2(PPh_3)_2X_2]$.[309] The structure of this six-coordinate complex is probably similar to that of $[Mo(CO)_2(PPh_3)_2Br_2]$ described as having an unusual nonoctahedral six-coordinate geometry.[310] The complex reacts reversibly with CO as depicted in equation (21).

$$[W(CO)_2(PPh_3)_2X_2] + CO \rightleftharpoons [W(CO)_3(PPh_3)_2X_2] \quad (21)$$

A series of seven-coordinate complexes of the type $[W(CO)_2(PPh_3)(L\text{–}L)_2]$ (L–L = S_2CNR_2, S_2COMe, $S_2P(OEt)_2$) have been prepared by the reaction of $[W(CO)(PPh_3)_3Cl_2]$ with excess ligand.[60] With excess $HS_2P(Pr^i)_2$ or with an equimolar amount of $HS_2P(OEt)_2$, only one Cl is displaced and $[W(CO)_2(PPh_3)(L\text{–}L)Cl]$ is obtained. The visible absorption spectra of these complexes are solvent dependent. This, together with conductance measurements, strongly suggests the presence of the cationic species $[W(CO)_2(PPh_3)(L\text{–}L)]^+$ in polar solvents such as methanol. $[W(CO)_3(PPh_3)(S_2CNEt_2)]$ has been shown to react with acetylene to afford $[W(CO)(C_2H_2)(S_2CNEt_2)_2]$.[311] Crystal structure analysis reveals a distorted pentagonal bipyramidal geometry around the metal with sulfur atoms S-2 and S-3 (Figure 38) occupying the apices of the pyramid. The CO and C—C bonds are nearly coplanar, enabling the acetylene ligand to act as a four-electron donor. More recently it has been shown that $[W(CO)_3(S_2CNR_2)_2]$ also reacts with alkynes to give $[W(CO)(R^1C{\equiv}CR^2)(S_2CNR_2)_2]$ where $R^1 = R^2 = H$, Me, Et, Ph and $R^1 = H$, $R^2 = Ph$.[312]

The seven-coordinate complexes $[W(CO)_3(YPPh_3)X_2]$ (Y = P, As, Sb; X = Cl, Br) can undergo a two-electron reduction in CO atmosphere as depicted in equation (22). No intermediates are observed in this reaction.[313]

$$[W(CO)_3(YPh_3)_2X_2] + 2CO + 2e^- \longrightarrow [W(CO)_5X]^- + 2YPh_3 + X^- \quad (22)$$

Several examples of W^{II} complexes with no carbonyl ligands are also known. The reaction of WI_3 with excess diars at 160 °C gives the paramagnetic complex $[W(diars)_2I_2]$ with $\mu_{eff} = 2.70$ BM.[314] A related complex $[WCl_2(PMe_2Ph)_4]$ can be prepared by Na/Hg reduction of $[WCl_4(PMe_2Ph)_2]$ under argon.[315] This paramagnetic complex ($\mu_{eff} = 2.30$ BM) exhibits only one ν(W—Cl) band at 280 cm^{-1} suggesting the *trans* configuration.

A general procedure has been outlined for the preparation of isocyanide complexes of W^{II} (equations 23, 24).[316] $[W(CNR)_7]^{2+}$ (R = CMe_3, C_6H_{11}) can also be prepared by reaction of the

$$[W(CNR)_6X]X \xrightarrow[PF_6^-]{RNC} [W(CNR)_7](PF_6)_2 \tag{24}$$

The structures of several of the seven-coordinate complexes of W^{II} have been determined and these are listed in Table 9. There are three recognized geometries for coordination number seven,[319,320] the pentagonal bipyramid (PBP), capped octahedron (CO) and capped trigonal prism (CTP). The 4:3 piano stool arrangement, which consists of a plane of four donor atoms parallel to a plane of three donor atoms, is also recognized.[321] Two extreme cases for this geometry, both with C_s symmetry, are considered, and these are related to one another by a rotation of the triangular face. It has been suggested however, that the 4:3 geometry is not sufficiently different from the CO and CTP to warrant its inclusion as a separate geometry. This point was recently questioned, and it is argued that when the dihedral angle between the two planes defining the 4:3 arrangement is close to 0°, the 4:3 geometry is a better representation of the molecular geometry.[322] A case in point is the structure of $[W(CO)_2(CNBu^t)_3I_2]$ (Figures 39 and 40). The 4:3 geometry is also considered as the best description for the structure of $[W(CO)_3(S_2CNMe_2)_2]$.[323] This molecule was also shown to be fluxional, and dynamic ^{13}C NMR measurements suggest two distinct intramolecular rearrangement processes.

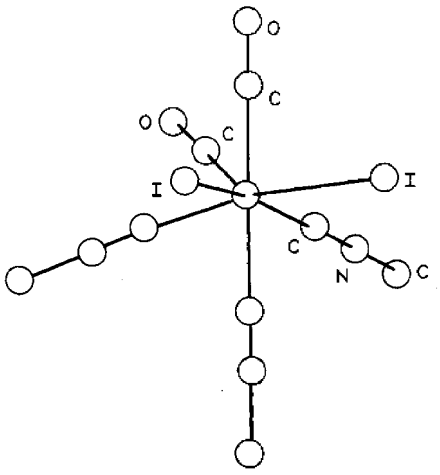

Figure 39 The structure of $[W(CO)_2(CNBu^t)_3I_2]$; the tertiary butyl groups are omitted[322]

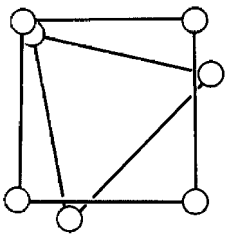

Figure 40 The two planes which define the 4:3 geometry in $[W(CO)_2(CNBu^t)_3I_2]$[322]

The structures of $[W(CO)_3Cl(dcq)(PPh_3)]$ and $[W(CO)_2(dcq)_2(PPh_3)]$ (dcq = 5,7-dichloro-8-quinolinato) have recently been determined.[324] These are best described as having the CTP geometry. The positions of all the donor atoms in the coordination sphere of these complexes are in agreement with electronic arguments.[325]

The first example of a PBP geometry in which a bidentate ligand spans one of the pentagonal edges is furnished by the structure of $[W(CO)_3I_2(Ph_2PCH_2PPh_2)]$.[326]

37.7.2 Complexes with Quadruple Bonds

The existence of quadruple bonds was first recognized in 1964[289] and since then a great many compounds of rhenium, technetium, chromium and molybdenum have been shown to contain them. Both bridged and unbridged compounds are known with a large variety of ligands. The bonding has been described in detail.[289]

The first W—W quadruply bonded complexes characterized were $[W_2Me_nCl_{8-n}]^{4-}$ prepared by treatment of WCl_4 with methyllithium. Crystal structure analysis has established the short W—W distances of 2.264 and 2.263 Å for the methyl and the mixed chloromethyl derivatives respectively. In addition, these compounds have the expected eclipsed stereochemistry.[327,328]

The reaction of WCl_4 with $K_2C_8H_8$ in THF gives a reasonably air-stable material that was shown to be $[W_2(C_8H_8)_3]$. The W—W bond length of 2.375 Å, although long, is consistent with the presence of a quadruple bond.[329] However, it is recognized that this compound (and the related chromium and molybdenum) is electronically different from other quadruply bonded species.

Treatment of $Mo(CO)_6$ with 6-methylpyridone (Hmhp) and 2-amino-6-methylpyridine (Hmap) in refluxing diglyme has led to the isolation of $[Mo_2(map)_4]$ and $[Mo_2(mhp)_4]$ which contain very short Mo—Mo distances.[289] $[W_2(mhp)_4]$ was also prepared by the same way. It reacts with Li(map) in THF to give $[W_2(map)_4]$.[330,331] Both compounds have been structurally characterized and have been shown to contain short W—W distances of 2.164 and 2.161 Å for the map and mhp compounds, respectively. These are the shortest known internuclear distances between any two atoms in the third transition series. $[W_2(mhp)_4]$ was the first and remains the only quadruply bonded tungsten complex to be obtained by oxidation of $W(CO)_6$. The structure of $[W_2(map)_4]$ is shown in Figure 41. The arrangement of the ligands around the W_2 unit is such that the idealized symmetry of the complex is D_{2d}.

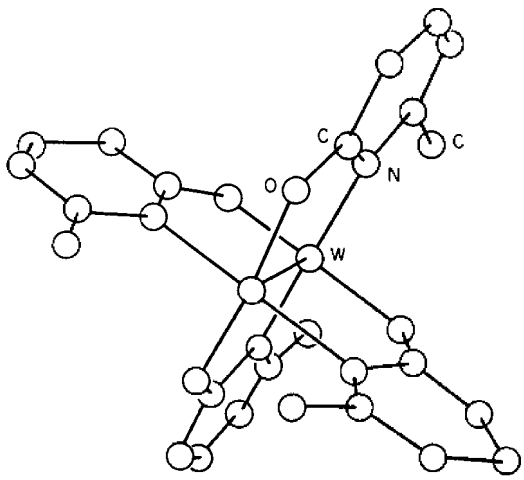

Figure 41 The structure of $[W_2(map)_4]$[331]

A special case in this family of complexes is represented by the tetracarboxylates of the form $[M_2(O_2CR)_4]$. Following the successful preparation of $[Mo_2(O_2CMe)_4]$ from $Mo(CO)_6$ in refluxing acetic acid–acetic anhydride mixture,[289] several attempts to prepare the analogous tungsten derivative by the same procedure have failed. This reaction leads invariably to the trinuclear clusters of type (**15**) (see Section 37.5.4.2). However, the continuous efforts to prepare complexes of the type $[W_2(O_2CR)_4]$ have recently been rewarded by the synthesis of $[W_2(TFA)_4]$. This was achieved by Na/Hg reduction of $[W_2Cl_6(THF)_4]$ in THF followed by addition of NaTFA, or by Na/Hg reduction of $[WCl_4]_x$ in the presence of NaTFA at 0 °C.[332,333]

$[W_2(TFA)]_4$ easily adds two ligands along the W—W bond and the structure of both $[W_2(TFA)_4 \cdot \frac{2}{3}digly]$ and $[W_2(TFA)_4 \cdot 2PPh_3]$ have been determined. The compounds have the expected geometry with short W—W bond lengths of 2.209 and 2.242 Å respectively. The increase of about 0.03 Å in the W—W bond length most likely indicates a stronger M—L σ bonding and a weaker M—M bonding in the phosphine adduct. On the basis of the Raman spectra of $[W_2(TFA)_4]$, $[W_2(TFA)_4 \cdot 2PPh_3]$ and $[Mo_2(TFA)_4 \cdot 2py]$ it is predicted that the W—W bond length in pure $[W_2(TFA)_4]$ should be in the range of 2.20–2.21 Å,[333] some 0.1 Å longer than that found in $[Mo_2(TFA)_4]$, indicating a weaker M—M bonding in the tungsten dimers. This is in agreement with the chemical behavior of these two compounds.

In contrast to the unsuccessful early attempts to produce $[W_2(O_2CR)_4]$, the heteronuclear compound $[MoW(O_2CCMe_3)_4]$ was obtained by reacting a 3:1 mixture of $W(CO)_6$ and $Mo(CO)_6$ in refluxing dichlorobenzene.[334] The heteronuclear complex was freed from $[Mo_2(O_2CCMe_3)_4]$ by careful oxidation with I_2. Structure analysis of $[MoW(O_2CCMe_3)_4]I \cdot MeCN$ shows the expected idealized D_{4h} symmetry with a short W—Mo separation of 2.194 Å. The iodide ion is coordinated to the W atom and the MeCN molecule is coordinated to the molybdenum atom.

$[MoW(O_2CCMe_3)_4]^+$ is reduced with zinc dust to $[MoW(O_2W(O_2CCMe_3)_4]$ whose structure reveals a W—Mo distance of 2.080 Å.[335] The longer distance observed for the iodo derivative is consistent with the fact that in $[MoW(O_2CCMe_3)_4]^+$, the bond order is formally 3.5.

$[MoW(mhp)_4]$ is also known. It is prepared by the reaction of a 1.5:1 mole ratio of $W(CO)_6$ and $Mo(CO)_6$ with Hmhp in refluxing diglyme. $[MoW(mhp)_4]$ is purified from the other products by I_2 oxidation followed by reduction with zinc amalgam.[336] The potentials (*vs.* SCE) of the one electron reversible oxidation of $[Mo_2(mhp)_4]$, $[MoW(mhp)_4]$ and $[W_2(mhp)_4]$ of 0.2, −0.16 and −0.35 V respectively, indicates that in a mixture of these, the heteronuclear compound can be selectively oxidized and thus purified.

The Mo—W distance of 2.091 Å[336] is shorter than the average M—M bond lengths of 2.065 and 2.161 Å found in $[Mo_2(mhp)_4]$ and $[W_2(mhp)_4]$ respectively,[330] suggesting a stronger metal–metal bonding in the heteronuclear species. Raman spectra and force constant calculations are in agreement with the crystallographic results. Also in agreement with this conclusion are the results of photoelectron spectra, which have been measured for a series of M—M quadruply bonded complexes.[337]

Attempts to prepare the octahalo anion $[W_2Cl_8]^{2-}$ were not successful until 1980, when a general procedure for the preparation of mixed halo–phosphine dimers was reported.[338] In this procedure WCl_4 is reduced with Na/Hg in the presence of a phosphine ligand, as depicted in equation (25). With PMe_3, if only one equivalent of reductant is used, the red crystalline $[W_2Cl_6(PMe_3)_4]$ is obtained. Treatment of this compound with an additional equivalent of reducing agent leads to $[W_2Cl_4(PMe_3)_4]$.[339] With the bidentate phosphines, dmpe and diphos, reaction (25) fails to give the desired products $[W_2Cl_4(dmpe)_2]$ and $[W_2Cl_4(diphos)_2]$. However, these can be obtained by treating $[W_2Cl_4(PBu^n)_4]$ with the bidentate ligands in toluene at 80 °C. With diphos, a green α isomer and a brown β isomer are formed in an analogous way to molybdenum. $[W_2Cl_4(dmpe)_2]$ and the green isomer $[W_2Cl_4(diphos)_2]$ possess a centrosymmetric eclipsed structure as depicted in Figure 42. The β isomer is structurally similar to $[Mo_2Cl_4(diphos)_2]$[289] and contains intramolecular diphos bridges. The tungsten compounds adopt a staggered conformation and thus can be considered to have a bond order of three.[340] In contrast, the molybdenum analog has a torsional angle of 30°. This difference undoubtedly reflects a weaker δ component in the W—W quadruple bond and therefore steric requirements are able to enforce a fully staggered conformation.

$$WCl_4 + 2Na/Hg + 2L \xrightarrow{THF} \tfrac{1}{2}[W_2Cl_4L_4] \quad L = PMe_3,\ PMe_2Ph,\ PMePh_2,\ PBu^n_3 \tag{25}$$

When the reduction of $[W_2Cl_6(THF)_4]$ is carried out at low temperature without the phosphine ligand, $[W_2Cl_8]^{4-}$ is formed.[339] Its structure reveals the expected eclipsed stereochemistry with a W—W bond length of 2.259 Å.[341]

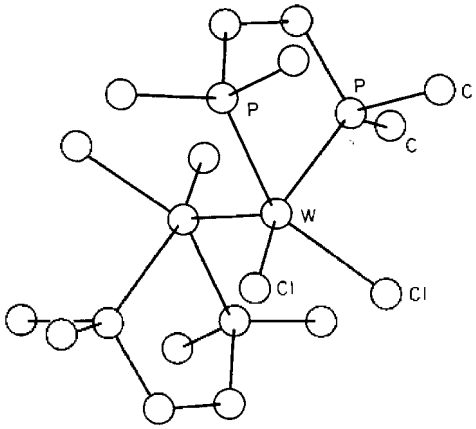

Figure 42 The structure of $[W_2Cl_4(dmpe)_2]$[340]

The complexes $[W_2Cl_4L_4]$ undergo a reversible one-electron oxidation. A comparison of the oxidation potential of analogous molybdenum and tungsten compounds clearly shows that the tungsten compounds are considerably easier to oxidize. This ease of oxidation is believed to be responsible for the fact that it is difficult, if not impossible, to obtain quadruply bonded tungsten compounds by synthetic procedures which are known for molybdenum.[339]

Chemical oxidation was also noted for $[W_2Cl_4(PBu^n_3)_4]$. Treatment of $[W_2Cl_2(PBu^n_3)_4]$ with $[Ag(MeCN)_4]^+$ leads to the paramagnetic $[W_2Cl_4(PBu^n_3)_4]^+$. Reaction of the butyl phosphine derivatives with acetic acid at 160 °C in diglyme affords the trinuclear cluster (**13**) (see Section 37.5.4.2), and with benzoic acid to give compound (**31**) having a W—W triple bond with a W—W distance of 2.423 Å.[342]

$[W_2(\mu\text{-H})(\mu\text{-Cl})(PBu_3)_2Cl_2(O_2CPh)_2]$
(**31**)

The ease of oxidation of the quadruply bonded tungsten dimers is also exemplified by the reaction of $[W_2(mhp)_4]$[343] or $[W_2(TFA)_4]$[333] with HCl to give $[W_2Cl_9]^{3-}$, which is also readily obtained from $[W_2Cl_8]^{4-}$ even at −78 °C. It is believed that these reactions proceed *via* the hydride intermediate $[W_2Cl_8H]^{4-}$.

Recently, it has been shown that the tetranuclear compound $[W_4Cl_8(PBu^n_3)_4]$[344] can be prepared by Na/Hg reduction of $[W_2Cl_6(THF)_2(PBu^n_3)_2]$. The structure of this molecule is similar to that of $[Mo_4Cl_8(PEt_3)_4]$[345] with W—W distances of 2.309 and 2.840 Å along the edges of the rectangular cluster.

The structures of several of the quadruply bonded tungsten dimers have been determined (Table 10) and in all cases the W—W bond length is significantly longer than those found in analogous molybdenum compounds. The crystallographic results coupled with theoretical,[346] spectroscopic[346,347] and electrochemical[339] studies clearly indicate that the W—W quadruple bond is indeed weaker than the Mo—Mo quadruple bond as was intuitively suggested originally by consideration of the core size of these two elements.

37.7.3 The Hexanuclear Clusters $[W_6X_8]^{4+}$

The dihalides of W^{II}, WCl_2, WBr_2 and WI_2 are in reality the hexanuclear compounds W_2X_{12} which contain the $[W_6X_8]^{4+}$ cluster (Figure 43). The metal atoms occupy the corners of an octahedron with a bridging halogen atom above each triangular face. The entire unit has full O_h symmetry and it is connected to other units by halogen atoms (four per unit). There are two non-bridging halogen atoms per cluster.

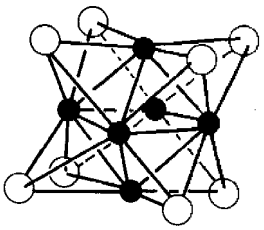

Figure 43 The $[W_6X_8]^{4+}$ core

W_6Cl_{12} and W_6Br_{12} are best prepared by disproportionation of the tetrachloride at about 500 °C or by reduction of WCl_5 and WBr_5 with aluminum in a temperature gradient.[154] W_6I_{12} is obtained by fusion of W_6Cl_{12} with a large excess of a KI–LiI mixture at 550 °C. As might be expected from the structures, the external halogens are readily replaceable by other halogens. Thus, $[W_6Cl_8]Br_4$, $[W_6Cl_8]I_4$, $[W_6Br_8]Cl_4$ and $[W_6Br_8]F_4$ have been prepared.[348,349] The $[W_6X_8]^{4+}$ clusters also readily form complex anions of the type $[W_6X_{14}]^{2-}$ (X = Cl, Br, I) and $[W_6X_8]Y_6^{2-}$ (X = Y = Cl, Br, I).[349]

These clusters are fairly good reducing agents in aqueous solutions and are oxidized even by water.[350] They can also be oxidized by halogens at elevated temperatures. With W_6Br_{12} the products are W_6Br_{14}, W_6Br_{16} and W_6Br_{18}.[351,352] In all these products, the W_6Br_8 unit is oxidized by two electrons. Thus, W_6Br_{14} is best formulated as $[W_6Br_8]Br_6$ while the others contain bridging Br_4^{2-} ions. The reaction of Cl_2 with W_6Cl_{12} at 100 °C leads to a product of stoichiometry WCl_3 which has been shown to contain the $[W_6Cl_{12}]^{6+}$ unit[353] isostructural with the Nb and Ta clusters.

The $[W_6X_8]^{4+}$ clusters are diamagnetic and with the 24 available metal electrons there is a metal–metal bond of order one between each pair of tungsten atoms, in agreement with theoretical treatment of the electronic structure of these clusters.[354,355]

Recently, it has been shown that $[W_6Cl_{14}]^{2-}$ is luminescent and that it undergoes a facile electrochemical oxidation at 1.14 V *vs.* SCE. The resulting monoanion is a powerful oxidizing agent.[356]

37.8 COMPLEXES OF DINITROGEN

Dinitrogen complexes of tungsten have been studied in great detail in relation to the function of nitrogenase. They show considerable versatility both with respect to reduction of the coordinated N_2 and in reactions leading to carbon–nitrogen bond formation.

Dinitrogen complexes of tungsten were first reported in 1970.[358] Na/Hg reduction of $[WCl_2(PMe_2Ph)_4]$ and $[WCl_2(diphos)_2]$ in the presence of excess phosphine under dinitrogen led to the isolation of *trans*-$[W(N_2)_2(diphos)_2]$ and *cis*-$[W(N_2)_2(PMe_2Ph)_4]$. The IR spectra of the *trans* compound show one band at 1953 cm^{-1} assigned to $\nu(N_2)$. The *cis* complex exhibits two such bands at 1931 and 1998 cm^{-1}. Magnesium reduction of *trans*-$[WCl_4(PMePh_2)_2]$ under N_2 in the presence of excess ligand leads to *trans*-$[W(N_2)_2(PMePh_2)_4]$.[359] The complex reacts with nitrogen donor ligands to give $[W(N_2)_2(PMePh_2)_3L]$ (L = py, 3-Mepy, 4-Mepy and 4-(CO_2H)py). It can also be oxidized to the monocation with $FeCl_3$. Reaction of *trans*-$[W(N_2)_2(PMePh_2)_4]$ with diphos gives the mixed phosphine complex $[W(N_2)_2(PMePh_2)_2(diphos)]$. The py-substituted complex exhibits only one $\nu(N_2)$ band in the IR indicating a *trans* configuration and a *mer* arrangement of the phosphine ligands. The reduction of $[WCl_4(PMe_3)_3]$ with dispersed sodium leads to *cis*-$[W(N_2)_2(PMe_3)_4]$ which reacts with excess PMe_3 to give $[W(N_2)(PMe_3)_5]$.[360] When the reduction is performed under ethylene, *trans*-$[W(C_2H_4)_2(PMe_3)_4]$ is obtained. The compound *trans*-$[WCl(N_2)(PMe_3)_4]$ is also known.[361]

Anionic dinitrogen complexes *trans*-$[WX(N_2)(diphos)_2]^-$ were prepared for X = NCS, CN

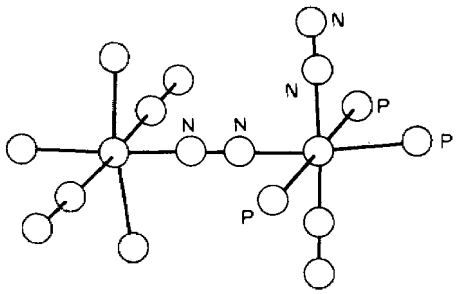

Figure 44 The structure of $[\{W(N_2)_2(PEt_2Ph)_3\}_2(\mu\text{-}N_2)]$; ethyl groups are omitted[363]

and N_3. The effect of ligands L (uncharged) or X^- on the redox properties of *trans*-[W(L or X^-)N_2(diphos)] as well as the correlation of the redox properties with $\nu(N_2)$ have been determined. These properties were also correlated with the susceptibility of the complexes towards attack by electrophilic reagents.[362]

Recently it has been shown that magnesium reduction of *trans*-$[WCl_4(PEt_2Ph)_2]$ under N_2 in THF in the presence of excess ligand leads in low yield to complex (**32**) which contains both terminal and bridging dinitrogen ligands.[363] Its structure is depicted in Figure 44. It has also been shown that *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ reacts with $AlCl_3$ in py to give (**33**) in which two units of $[WClpy(PMe_2Ph)_3N_2]$ are bridged by two $AlCl_2$ moieties through the end nitrogen atoms.[364]

$$[\{W(N_2)_2(PEt_2Ph)_3\}_2(\mu\text{-}N_2)]$$
(32)

$$[WXpy(PMe_2Ph)_3(\mu_3\text{-}N_2)]_2(AlCl_2)_2 \quad (X = Cl, Br)$$
(33)

There are two types of interesting and important reactions involving the coordinated dinitrogen, its reduction to hydrazine and ammonia, and the reactions leading to carbon–nitrogen bond formation.

37.8.1 Reduction of Coordinated Dinitrogen

The protonation of coordinated dinitrogen in a tungsten complex was first observed in the reaction of *trans*-$[W(N_2)_2(diphos)_2]$ with HCl as depicted in equation (26).[365] In the resulting complex, one chloride ligand is labile, and in the presence of BPh_4^- $[WCl(diphos)_2N_2H_2]BPh_4$ is obtained. The N_2H_2 group can coordinate to the metal as a diazene (W—NH=NH) or as a hydrazido(2−) (W=N—NH_2) group. Spectroscopic data suggest that in the parent complex the N_2H_2 ligand is coordinated as a diazene, whereas in the cationic complex it coordinates as a hydrazido(2−) group. The stabilization of diazene by coordination to a tungsten carbonyl complex has been noted.[366,367]

$$[W(N_2)_2(diphos)] \xrightarrow{HCl} [WCl_2(diphos)(N_2H_2)] + N_2 \qquad (26)$$

Crystal structure analysis of $[WCl(diphos)_2(N_2H_2)]BPh_4$[368] clearly shows that the N_2H_2 ligand is indeed coordinated as a hydrazido(2−) group. The W—N—N linkage is linear with W—N and N—N distances of 1.73 and 1.37 Å respectively. The short W—N distance clearly suggests a considerable multiple bond character to the W—N bond.

Treatment of $[W(N_2)_2(diphos)_2]$ with two equivalents of HCl gives the hydrido complex $[WH(N_2)_2(diphos)_2](HCl_2)$, which in refluxing methanol yields the dihydride of W^{IV} $[WH_2Cl_2(diphos)_2]$.[369] Treatment of $[WX_2(diphos)_2(N_2H_2)]$ (X = Cl, Br) with $NaBH_4$ in ethanol, or irradiation of the dinitrogen complex under H_2 atmosphere leads to the tetrahydrido complex $[WH_4(diphos)_2]$.[370]

Deprotonation of $[WX_2(diphos)_2(N_2H_2)]$ and $[WF(diphos)_2(N_2H_2)]^+$ with Et_3N or aqueous K_2CO_3 under N_2 yields $[WX(diphos)_2(N_2H)]$.[371] The resulting diazenido complexes (W=N=N—H) are characterized by a strong IR band at 1890 cm^{-1} assigned to ν(N—N). This reaction can be reversed by an acid. The diazenido group is formally analogous to NO and thus the complex reacts smoothly with NO to give $[WX(NO)(diphos)_2]$ (X = F, Cl, Br).[371]

Ammonia is produced in good yield from dinitrogen complexes containing monodentate

phosphine ligands.[372] Thus, treatment of *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ or *trans*-$[W(N_2)_2(PMePh_2)_4]$ with H_2SO_4 in methanol gives approximately 1.9 moles of NH_3 per gram-atom of tungsten. The fact that hydrazine is a minor product in these reactions indicates that ammonia is formed by splitting of the N—N bond.[372] The amount of hydrazine can be increased if, prior to the addition of H_2SO_4, *trans*-$[W(N_2)_2(PMePh_2)_4]$ is treated with anhydrous HCl to produce the hydrazido(1−) complex $[WCl_3(PMePh_2)_2(NHNH_2)]$. Thus it appears that hydrazine production depends on the formation of the W—$NHNH_2$ moiety.[373]

The reaction of $[WBr_2(PMe_2Ph)_3(NNH_2)]$ with one equivalent of HCl gas in DME affords $[WClBr_2(PMe_2Ph)_3(N_2H_3)]$, which on acid treatment produces hydrazine in preference to ammonia. The complex has one labile halide, and its correct formulation as $[WClBr(PMe_2Ph)_3(N_2H_3)]Br$ has been established by crystal structure analysis. The linear W—N—N linkage indicates that the N_2H_3 group is bonded to the metal as W—N—NH_3 rather than as W—NH—NH_2.[374] It has also been shown that *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ reacts with excess HCl to give hydrazine in moderate yield.[375] $[WBr_2(PMe_2Ph)_3(NNH_2)]$ reacts with one equivalent of HCl to give the hydrido, hydrazido(2−) complex (**34**). It reacts with $NaBPh_4$ to give a novel diazenido complex (**35**) with an N—B bond.[375]

$[WHClBr(PMe_2Ph)_3(NNH_2)]Br$ (**34**)

$[WHClBr(PMe_2Ph)_3(NN(H)BPh_3)]$ (**35**)

37.8.2 Reactions Leading to Carbon–Nitrogen Bond Formation

The reactions of *trans*-$[W(N_2)_2(diphos)_2]$ with acid chloride in the presence of HCl were the first reported in which a stable dinitrogen complex was converted to an organonitrogen compound.[376] The products, $[WCl_2(diphos)_2(N_2HCOR)]$ (R = Me, Et, Ph, *p*-$MeOC_6H_4$), are pink diamagnetic complexes that have no $\nu(N_2)$ stretching bands in their IR spectra. In the presence of a base such as Et_3N these compounds lose HCl to give the diamagnetic complexes $[WCl(diphos)_2(N_2COR)]$ in which the azo ligand is also coordinated through the carbonyl oxygen. The reaction can be reversed by addition of HCl. $[WCl_2(diphos)_2(N_2H_2)]$[369] and $[WX(diphos)_2(N_2H)]$ react in an analogous way with MeCOCX to give $[WX_2(diphos)_2(N_2HCOMe)]$ (X = Cl, Br).[371]

Visible light irradiation of a benzene solution containing alkyl bromides and *trans*-$[W(N_2)_2(diphos)]$ produces the alkylated complexes $[WBr(diphos)_2(N_2R)]$ (R = Me, Et, Bu^t).[377,378] These can be protonated to give complexes containing the (W=N—NHR) unit. $[WBr(diphos)_2(N_2HMe)]$ can also be obtained from the reaction of $[WBr(diphos)_2(N_2H)]$ with MeBr.[377] When the irradiation is carried out in THF rather than in benzene[379] the ω-diazobutanol compound (**36**) is obtained. Crystal structure analysis is consistent with this hydrazido(2−) formulation. The W—N—N linkage is linear and the W—N and N—N distances are 1.778 and 1.306 Å respectively. In the PF_6^- salt these distances are 1.772 and 1.32 Å.[380] Several structures of complexes containing the W=N—NHR or W=N—N=CR_2 groups have been determined. They are all similar in that the W—N—N linkage is linear with a short W—N distance suggesting a considerable multiple bond character to the W—N bond. It should be noted that although there are small differences in the W—N and N—N bond lengths in these structures, the trend expected is usually that observed, namely, the lengthening of the W—N bond is accompanied by the shortening of the N—N bond.[269,380]

$[WBr(diphos)_2(N{-}N{=}CH(CH_2)_3OH)]Br$ (**36**)

The reactions of $[W(N_2)_2(diphos)_2]$ with RBr are clearly catalyzed by visible light. The homolytic fission of the R—Br bond that takes place at the metal center[381] is preceded by the loss of one N_2 molecule. The resulting C—N bond is formed by an alkyl radical attack on the remaining coordinated dinitrogen. Product distribution in these photocatalyzed reactions depends on the solvent and the stability of the free radical.[381,382] This mechanism is strongly supported by flash photolysis experiments.[370] When *gem*-dibromides are used in the photocatalyzed reaction, diazoalkanes are produced. With CH_2Br_2 for example, the diazomethane complex $[WBr(diphos)_2(N_2CH_2)]Br$ is obtained.[383] More recently it has been shown that some of the diazoalkanes do not react with protonic acids, but that the unique carbon atom is attacked by nucleophiles such as MeLi to yield diazenido complexes.[384]

The reaction of $[WBr(diphos)_2(N_2H_2)]^+$ and $(Ph_2I)Cl$ in the two phase system $CHCl_3$–aqueous K_2CO_3 leads to $[WBr(diphos)_2(NN{=}CCl_2)]^+$, which reacts with a variety of

nucleophiles to give novel organonitrogen ligands. It reacts with $MeNH_2$, for example, to give $[WBr(diphos)_2\{N{-}N{=}C(NHMe)\}_2]^+$ and with F^- to give $[WBr(diphos)_2(N{=}N{-}CF_3)]$.[385] $[WBr(diphos)_2(N_2H_2)]^+$ also reacts with cyanoalkenes to give vinyldiazenido complexes or, after loss of the hydrazido(2−) ligand, to form nitrile-derived methylene amino complexes.[386]

Hydrazido(2−) and hydrazido(1−) complexes have also been shown to condense with aldehydes and ketones to give diazoalkane complexes containing the $W{=}N{-}N{=}CR_1R_2$ unit.[387,388] Treatment of these complexes with $LiAlH_4$ gives secondary amines and ammonia, whereas treatment with acid produces hydrazine, keto azines and N_2-free tungsten compounds. Amines can also be produced from organohydrazido(2−) complexes.[389,390]

37.9 NITROSYL COMPLEXES

Nitrosyl complexes of tungsten were first prepared in 1964 by reaction of $W(CO)_6$ with nitrosyl chloride in an inert atmosphere. $[W(NO)_2Cl_2]_n$ is a dark green hygroscopic, air-sensitive material, soluble only in coordinating solvents.[391] The analogous $[W(NO)_2Br_2]_n$ can be prepared by using NOBr[392] or by the reaction of NOBr with $[W_2(CO)_8Cl_4]$.[393]

$[W(NO)_2Cl_2]_n$ reacts with a variety of ligands to form octahedral complexes of the type $[W(NO)_2Cl_2L_2]$ ($L = PPh_3$, $AsPh_3$, py, $MeC_6H_4NH_2$, $C_6H_{11}NH_2$, Ph_3PO).[391,393] The IR spectra of these derivatives consist of two ν(NO) bands around 1750 and 1650 cm^{-1}, indicating a *cis* dinitrosyl arrangement. The positions of these bands suggests the NO^+ formulation and thus formally can be considered as octahedral complexes of W^0. With the bidentate dimethyldithiocarbamate ligand, $[W(NO)_2Br_2]_n$ gives *cis*-$[W(NO)_2(S_2CNMe_2)_2]$.[394]

Several nitrosyl complexes have been prepared by the reaction of nitrosyl chloride with anionic carbonyls. Thus, $[W(CO)_5Cl]^-$ reacts with NOCl[395] to give $[W(CO)_4(NO)Cl]$ while $[W(NO)Cl_2L]$ and $[W(NO)_2ClL]$ ($L = RB(P_z)_3$) were prepared from $[LW(CO)_3]^-$ with variable amounts of NOCl.[396] $[W_2(CO)_8Cl_4]$ also reacts with NOCl to give in addition to $[W(NO)_2Cl_2]_n$ the mononitrosyl $[W(NO)Cl_3]$[393] which exhibits only one ν(NO) bond at 1590 cm^{-1}.

WCl_6 or WCl_5 reacts with NO in benzene to give red air-sensitive material which reacts with phosphine ligands to give $[WCl_3(NO)(OPR_3)_2]$ ($PR_3 = PPh_3$, $PMePh_2$, $PEtPh_2$).[397] $[WCl_3(NO)(OPPh_3)_2]$ can also be obtained from $[W(CO)_4(PPh_3)_2]$ and NOCl.[393] Careful choice of reaction conditions also gives the $[WCl_3(NO)L_2]$ compounds with $L = PMePh_2$, $PEtPh_2$ and py.[397] The mononitrosyl complexes $[WX(NO)(diphos)_2]$ (X = Cl, Br) are also known.[371]

Cationic nitrosyl complexes have also been prepared. The reaction of $[W(CO)_3(MeCN)_3]$ with $NOPF_6$ in acetonitrile affords *cis*-$[W(NO)_2(CO)(MeCN)_3]$ $(PF_6)_2$ which exhibit two ν(NO) IR bands at 1867 and 1775 cm^{-1}. The proton NMR spectra consists of two bands of relative intensities of 2:1 consistent with both *mer* and *fac* arrangement of the MeCN ligands.[24] *cis*-$[W(NO)_2(CO)(MeCN)_3]^{2+}$ reacts with NaS_2CNEt_2 to give the known *cis*-$[W(NO)_2(S_2CNEt_2)_2]$ and with acac in the presence of base to give *cis*-$[W(NO)_2(acac)_2]$.[394]

The reaction of $[W(CO)_4(diphos)]$ with $NOPF_6$ gives $[W(CO)_3(NO)(diphos)]PF_6$.[398] It reacts with halides and dithiocarbamates to yield $[W(CO)_2(NO)(diphos)X]$ (X = Cl, Br, I) and $[W(CO)(NO)(diphos)(S_2CNR_2]$ (R = Me, Et). Spectroscopic data suggest that in the last compound the CO and NO ligands are *cis* to one another. Similar complexes can also be obtained with other bidentate ligands.[398]

Treatment of $[W(NO)_2Cl_2]_n$ with $AgBF_4$ in MeCN leads to *cis*-$[W(NO)_2(MeCN)_4](BF_4)_2$. NMR measurements have shown that this complex undergoes stereospecific exchange of coordinated MeCN *via* a dissociative pathway. The two labile MeCN groups are those *trans* to the nitrosyl ligands.[399]

Anionic nitrosyl complexes were prepared by the reaction of $[W(NO)_2Cl_2]_n$ with Ph_4AsCl,[391] and Ph_4PBr. $[W(NO)_2Cl_4]^{2-}$ and $[W(NO)_2Cl_2Br_2]^{2-}$ are green materials with *cis* dinitrosyl arrangement. They react with dithiolene type ligands to give *cis*-$[W(NO)_2(L{-}L)_2]^{2-}$ (L–L = mnt, i-mnt, tbd).[400] The two IR bands associated with ν(NO) decrease in the order dtc > mnt > i-mnt > tbd. This trend has been rationalized in terms of the effects of charge and π acceptor ability of the various dithiolene ligands.

37.10 HYDRIDO COMPLEXES

Transition metal hydrides are clearly an important class of metal complexes, and a number of books and review articles have appeared during the last 15 years. Hydrido complexes of tungsten contain in addition to the hydride such ligands as C_5H_5, phosphine, NO and CO.

With phosphine ligands, complexes with a different number of hydrides are known. $[WH_4L_4]$ ($L = PMe_2Ph$, $PMePh_2$) were first prepared by the reaction of $[WCl_4L_4]$ with $NaBH_4$ in alcoholic solutions in the presence of excess phosphine.[401] The crystal structures of $[WH_4(PEtPh_2)_4]$ and $[WH_4\{P(OPr^i)_3\}_4]$[402] have been determined. These are all yellow air-stable materials, and exhibit a complex IR spectrum in the 1700–1850 cm^{-1} region associated with ν(WH). The proton NMR spectrum of $[WH_4(PMePh_2)_4]$ at room temperature is consistent with a rigid structure. A fluxional behavior develops above 50 °C. $[WH_4(PMePh)_4]$ behaves similarly.[401] With other phosphines the same fluxional behavior is observed in solution.[403] An intramolecular rearrangement pathway has been suggested to explain this behavior. With the diphos ligand, $[WH_4(diphos)_2]$ is obtained by the reaction of $[WX_2(diphos)_2(N_2H_2)]$ (X = Cl, Br) with $NaBH_4$.[368]

Complexes containing the WH_5 and WH_6 moieties are also known.[404] *trans*-$[WX_4(PMe_2Ph)_2]$ (X = Cl, Br) complexes react with $NaBH_4$ in ethanol to give $[WH_6(PMe_2Ph)_3]$. NMR measurements show that the six hydrides are coupled equally to all three phosphorus nuclei. A reasonable structure for this complex is a trigonal prism of hydrogen atoms with phosphorus donor atoms capping the square faces of the prism.[403]

Hydrogenolysis of $[WMe_6]$ in the presence of phosphine ligands leads to different hydrido complexes depending on the size of the phosphine ligands. Thus, while PMe_2Ph gives primarily $[WH_4L_4]$, with the more bulky PPr^i_2Ph and PPr^i_3 ligands $[WH_6L_3]$ is obtained. $[WH_6(PPr^i_2Ph)_3]$ has been shown by ^{31}P NMR and X-ray diffraction to have approximately C_{2v} symmetry in the solid and in solution.[405]

The pentahydrido complex $[WH_5(PMePh_2)_4]^+$ is obtained[406] from the reaction of $[WH_4(PMePh_2)_4]$ with acids such as HBF_4, HPF_6 and TFA. The isolated salt with TFA, loses hydrogen on melting to give the dihydride $[WH_2(TFA)_2(PMePh_2)_3]$. The dihydride $[WH_2Cl_2(diphos)_2]$ is also known.[369]

The photolysis of a hexane solution of $[WL_6]$ ($L = P(OMe)_3$) in an atmosphere of H_2 yields a mixture of $[WH_2L_5]$ and $[WH_4L_4]$.[407]

Several monohydrido complexes have also been prepared. Treatment of *cis*-$[W(CO)_2(dpm)_2]$ with $O_2/HClO_4$ yields *trans*-$[WH(CO)_2dpm)_2]^+$ which is believed to be seven-coordinate with the capped octahedral geometry.[408] Similar complexes with other bidentate phosphine ligands are also known.[409,410] The preparation of $[WH(N_2)_2(diphos)_2]^+$ and $[WH(CNR)_2(diphos)_2]^+$ have been reported.[369,411] Although $[WH(N_2)_2(diphos)_2]^+$ has a pentagonal bipyramid geometry in the solid state, with the hydride ligand in the pentagonal plane, NMR data are compatible with both the pentagonal bipyramid and capped octahedron structures in solution.[411]

Recently it has been shown that Na/Hg reduction of $[WCl_4(PMe_3)_3]$ under H_2 gives the dihydride $[WH_2Cl_2(PMe_3)_4]$ and that the reaction of $[WCl_2(PMe_3)_4]$ with methanol in THF leads to the same product.[412]

Finally, it should be mentioned that several μ-hydrido-bridged tungsten carbonyl and mixed carbonyl nitrosyl complexes are known. When only one bridging hydride is present the W—H—W bond is always bent.[413] Bridging hydrides are also found together with other bridging groups in several tungsten complexes. For example, the reduction of $[W_2Cl_4(PMe_3)_4]$ in THF with Na/Hg leads to a species which is best formulated as $[W_2H_4(\mu\text{-}H)(\mu\text{-}PMe_2)(PMe_3)_5]$. This complex is described as a W^{II}–W^{IV} dimer (W—W distance = 2.588 Å) with four terminal hydrido ligands and one bridging hydride.[414]

38.1 INTRODUCTION

Hexavalent molybdenum and tungsten, pentavalent vanadium and, to a more limited extent, niobium and tantalum form a very large number of polyoxoanions ('heteropolyanions' such as $[PW_{12}O_{40}]^{3-}$ and 'isopolyanions' such as $[Mo_7O_{24}]^{6-}$).[1–3] Unlike the polyoxoanions of the post transition elements the heteropolyanions for the most part are discrete, compact species of high

symmetry and low basicity. Salts and free acids of heteropolyanions are usually highly soluble in water and other solvents. Their extensive acid–base and oxidation–reduction chemistry, and their structures, which resemble fragments of close-packed metal oxide lattices, make heteropolyanions attractive as potential (and actual) catalysts.[4] Other demonstrated applications of heteropolyanions include their use as analytical reagents, electron microscope stains, and antiviral and antitumoral agents.

Why should the early transition metals form so many polyoxoanions? The answer lies in the size of the $M^{5/6+}$ cations and their π-acceptor properties.[1,5] The effective ionic radii of V^{5+} (0.68 Å), Mo^{6+} (0.77 Å) and W^{6+} (0.74 Å) are consistent with the observation that these cations adopt four-, five- and six-fold coordination by oxide ion. With very few exceptions V, Mo and W atoms in heteropolyanions are six-coordinate. On the other hand Cr^{6+} (0.58 Å) has a maximum coordination number of four in oxides and oxoanions. Few isopoly- and heteropoly-chromates are known and they are all based on groups of corner-shared CrO_4 tetrahedra: $[Cr_2O_7]^{2-}$, $[Cr_3O_{10}]^{2-}$, $[Cr_4O_{13}]^{2-}$, $[O_3SOCrO_3]^{2-}$, $[O_2IOCrO_3]^{-}$, $[HOAs(OCrO_3)_3]^{2-}$, *etc.* These species bear little similarity to the other heteropolyanions of Groups 5a and 6a, and, with the exception of the dichromate anion, have a limited or nonexistent solution chemistry. Several post transition elements have ionic radii similar to those of Mo^{6+} and W^{6+}: Ge^{4+} (0.67 Å), Sb^{5+} (0.74 Å), Te^{6+} (0.70 Å) and I^{7+} (0.67 Å). The polyoxoanions of these elements are quite unlike the molybdates and tungstates and are often polymeric chains and networks of XO_6 octahedra. The typical bond lengths found in oxoanions of Mo^{6+} and I^{7+}, shown in Figure 1, reveal the essential difference between transition and post transition cations. Note that Mo^{6+}, by virtue of its accessible vacant *d* orbitals, forms stronger (shorter) bonds with terminal oxygen atoms than does I^{7+}. The greater bond order of the Mo—O bonds reduces the basicity of the oxygen atoms that lie on the exterior of the heteropolyanion. The consequent low charge density on the polyanion surface minimizes protonation, cation binding (insolubility) and further polymerization. Some years ago Lipscomb[6] speculated that the structures of heteropolyanions might be limited to those in which each MO_6 octahedron has no more than two unshared vertices. At present, no structure has been found that contradicts Lipscomb's proposal, and it is a simple matter to rationalize this. In view of the large *trans* influence of the M—O(terminal) bonds, see Figure 1, an MO_6 octahedron with three terminal oxygens would be attached to the remainder of the polyanion structure by three long, and therefore weak, bonds. It seems probable that such a polyanion would be readily susceptible to the loss of the MO_6 octahedron either directly as a neutral MO_3 group or hydrolytically as $HOMO_3^-$.

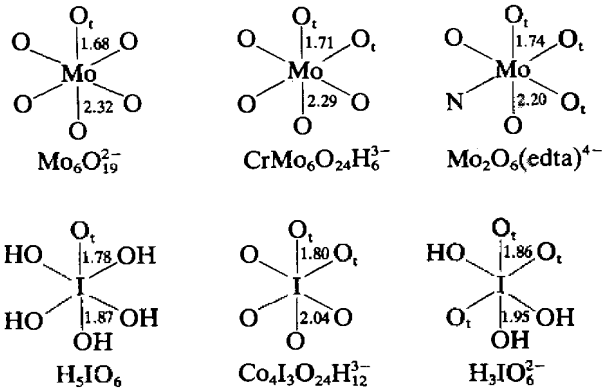

Figure 1 Comparison of the *trans* influence of terminal oxide ligands in octahedral complexes of Mo^{6+} and I^{7+}

Much synthetic and descriptive chemistry of heteropolyanions dates from 1860–1920 when the terms 'isopoly acid' and 'heteropoly acid' were introduced. Reviews of the early work are available[7] and they provide much valuable, if descriptive, information. In the following sections we shall discuss the chemistry of isopolyanions (general formula: $[M_mO_y]^{p-}$) as well as that of heteropolyanions ($[X_xM_mO_y]^{q-}$; $x \leq m$). Excluded from consideration here are substances with similar formula that are the result of high temperature solid state or melt reactions and which are polymeric mixed oxides with no defined solution chemistry.

38.2 ISOPOLYANIONS

38.2.1 General

The chemistry of isopolyanions has to a large extent developed from the study of hydrolytic equilibria in aqueous solution (equation 1).[8] The stoichiometry and equilibrium constants for such reactions are generally evaluated from precise EMF measurements (*i.e.* of the hydrogen ion concentration as a function of metal ion concentration and added acid or base). Measurements of this kind, pioneered by Sillén and his school,[9] have to be made with extraordinary precision, to permit distinction between the large number of species that are often present in polyanion solutions. Even when all experimental difficulties (attainment of equilibrium, liquid junction potentials, *etc.*) appear to have been overcome or allowed for, the EMF method has other limitations. An equilibrium such as equation (1) is defined only by the values of p and q; the number of oxygen atoms in the isopolyanion cannot be determined. For example, the species $[H_2V_3O_{10}]^{3-}$ and $[V_3O_9]^{3-}$ cannot be distinguished. Furthermore, it is becoming clear that factors such as the nature of the counterions and the ionic strength can have significant effects upon polyanion equilibria. In general, investigations have been made at one ionic strength, and the possibilities of specific counterion binding (as observed in some heteropolyanion systems) have not always been excluded.

$$pH^+ + q[MO_4]^{r-} \rightleftharpoons [H_xM_qO_y]^{n-} + (4q - y)H_2O \quad (1)$$

Virtually every experimental chemical technique that can be applied to solutions has at one time or another been used for the investigation of isopolyanions. The often conflicting results that pervade the literature are caused by the investigators' failure (a) to appreciate the complexity of the equilibria and kinetics involved and (b) realistically to assess the experimental limitations of the technique used. Clearly, there is no *one* experimental method that can reveal the complete story, and the literature must therefore be read extremely critically.

Although aqueous hydrolytic equilibria such as equation (1) provide an overall framework for the discussion of isopolyanions, several species have been synthesized in nonaqueous media, and are unstable in water. Other isopolyanions that are crystallized from aqueous solution, may be incongruently soluble and have polymeric structures. It will, however, prove to be convenient to treat all isopolyanions as though they were derived by equation (1), and characterize each by its 'acidity', Z $(=p/q)$. Note that Z for a specific anion is not necessarily equal to the value of p/q for the solution from which the anion was crystallized.[10]

38.2.2 Isopolyvanadates

38.2.2.1 Aqueous solutions

Vanadium(V) oxide is amphoteric, dissolving in alkali to give salts of tetrahedral VO_4^{3-} anion, and in acid to give VO_2^+. The latter cation is almost certainly *cis*-$[VO_2(H_2O)_4]^+$, as in $[VO_2(ox)_2]^{3-}$ and $[VO_2(edta)]^{3-}$ (ox = oxalate dianion; edta = ethylenediamine tetraacetate tetraanion). All dioxo complexes of d^0 metals have *cis* configurations, an arrangement that maximizes $d\pi$–$p\pi$ interactions.

Salts of the orthovanadate anion are frequently isomorphous with the analogous phosphates and arsenates, *e.g.* $Na_3XO_4{\cdot}12H_2O$. In dilute solutions, *ca.* 10^{-5} M, the protonation equilibria parallel those of PO_4^{3-} but with pK values that are greater by 1–2 units (see Table 1). In solutions more concentrated than 10^{-4} M, a multitude of isopolyvanadates is formed. These may roughly be divided into colorless species that predominate above pH 6–7, and orange species in the range pH 2–6. Interconversion between colorless and orange polyanions is kinetically controlled, and equilibrium EMF measurements become unreliable in the region where both types of polyanion exist. The distribution of isopolyvanadate species according to the 'best' fit of potentiometric data for pH 6–14 is shown in Figure 2 for $[V]_{total} = 1.0$ and 10^{-3} M.[11] These conclusions are supported by high field ^{51}V and ^{17}O NMR spectroscopy. The predominant polyanions are listed in Table 2. The di- and noncyclic tri-vanadates are presumed to be analogous to the corresponding phosphates, and their protonation constants (Table 1) are consistent with this. NMR spectroscopy indicates the presence of traces of linear tetramer also. The divanadate anion has been structurally characterized in several salts, *e.g.* $Ca_2V_2O_7{\cdot}2H_2O$

with V—O(terminal) 1.69 Å, V—O(bridging) 1.80 Å and ⟨VOV, 139°. No structures containing $[V_3O_{10}]^{5-}$ have yet been reported.

The cyclic tetramer and pentamer are the major constituents of so-called 'metavanadate' solutions (pH 6.5–8) but the only salts that have so far been crystallized from such solutions contain polymeric anions. Typical structures of metavanadates are (a) infinite chains of corner-shared VO_4 tetrahedra (KVO_3, α-$NaVO_3$, NH_4VO_3, $CsVO_3$), and (b) chains of edge-shared distorted VO_5 trigonal bipyramids ($KVO_3{\cdot}H_2O$, $NaVO_3{\cdot}1.89H_2O$, $Ca(VO_3)_2{\cdot}2H_2O$, $Sr(VO_3)_2{\cdot}4H_2O$).[1] The cyclic tetrameric anion has been structurally characterized in $(Bu^n_4N)_3HV_4O_{12}$, which was prepared by dissolving V_2O_5 in alcoholic Bu^n_4NOH.[13] The Raman spectrum of this salt is similar to that of an aqueous metavanadate solution. Earlier UV and potentiometric measurements had suggested the presence of a trimer in metavanadate solutions, either cyclic $[V_3O_9]^{3-}$ or linear $[H_2V_3O_{10}]^{3-}$. There is no compelling evidence for significant quantities of such a species according to later measurements. The ^{51}V NMR data indicate that traces of a cyclic hexamer may be present and that this could be a precursor to the orange decavanadates.

The decavanadates (Table 2) were first convincingly identified from potentiometric investigations of alkalinized VO_2^+ solutions, since the metavanadate–decavanadate equilibria are established very slowly and involve NMR-detectable intermediates. The structure of the decavanadate anion has been established by several X-ray investigations and is shown in Figure 3.[14] The anion consists of an arrangement of 10 edge-shared VO_6 octahedra with D_{2h} symmetry. The octahedra are distorted in order to maintain approximate valence balance at terminal and bridging oxygens and bond lengths range from 1.60 Å for V—O(terminal) to 2.32 Å for V—O(central). The ^{51}V NMR spectrum of the anion in solution has three lines in the ratio 1:2:2 and is consistent with the solid state structure. Both ^{51}V and ^{17}O NMR have been used to determine the protonation sites of $[V_{10}O_{28}]^{6-}$, with different conclusions. The crystal structure of tetrakis(4-ethylpyridinium)dihydrogen decavanadate reveals protonation at yet a third type of oxygen atom.[15] The kinetics of decomposition of decavanadate by acid and alkali have been investigated,[16] and ^{18}O exchange between water and the polyanion occurs with a half-life of *ca.* 15 h at 25 °C and pH 4–6.3.[17] A mechanism to account for the exchange and for the alkaline degradation has been proposed.

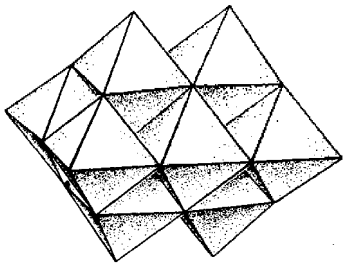

Figure 3 The structure of $[V_{10}O_{28}]^{6-}$ anion shown as an arrangement of VO_6 octahedra

38.2.2.2 Other isopolyvanadates

(*i*) *Polymeric anions*

The polymeric metavanadate anions have been described above. Upon warming or ageing solutions that contain the decavanadate ion, it is possible to precipitate salts of the dark red 'trivanadate' anion, MV_3O_8 (M = NH_4, K, Rb, Cs). The formula is sometimes written as $M_2V_6O_{16}$, and the salts called 'hexavanadates' in the literature. Potassium and cesium trivanadate contain infinite buckled layers of distorted VO_5 and VO_6 polyhedra.[18] Another layer structure is found in yellow $K_3V_5O_{14}$ which also is deposited from aqueous solution. The $[V_5O_{14}]^{3x-}_x$ anion is composed of layers of corner-shared VO_4 tetrahedra and VO_5 square pyramids.[19]

(ii) Polyvanadates containing vanadium(IV)

Vanadium(IV) oxide, like V_2O_5, is amphoteric and dissolves in alkali to yield brown, easily oxidizable solutions. Salts obtained from these solutions were originally formulated as $M_2V_4O_9 \cdot nH_2O$ but were later shown to have the empirical formula, $M_2V_3O_7 \cdot nH_2O$. The structure of the potassium salt reveals the anion $[V_{18}O_{42}]^{12-}$ consisting of an almost spherical arrangement of edge- and corner-shared VO_5 square pyramids with axial V—O bonds directed outwards (see Figure 4).[20] The anion is stable in solution between pH 9 and 13, and is paramagnetic with about eight free spins at 22 °C. Dilute solutions of VO_2 in alkali appear to contain $[VO(OH)_3]^-$ according to ESR spectroscopy. In strongly basic solution (greater than 1 M OH^-) vanadate(IV) disproportionates into vanadium(III) and vanadium(V).

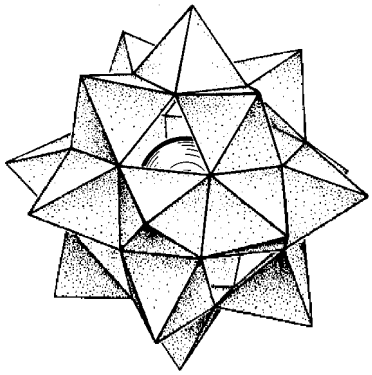

Figure 4 The structure of $[V_{18}O_{42}]^{12-}$ anion. The central cavity has a radius of 4.5 Å and is fractionally occupied by K^+ or H_2O in the crystal

Several mixed-valence polyvanadates(IV, V) are reported in the literature. Almost without exception the anions have been formulated as decavanadates, often with no real justification. Thus Ostrowetsky[21] reported the existence of six anions in the pH range 4–6.5. The anions were given formulas such as $[V_3^{IV}V_7^{V}O_{26}H]^{4-}$ and contained $V^{IV}:V^{V}$ ratios ranging from 2:8 to 7:3. More recently Johnson isolated, from similar solutions, salts of a blue-violet anion $[V_6^{IV}V_{13}^{V}O_{40}H]^{8-}$ and determined its structure.[20] The anion has a structure of virtual C_3 symmetry composed of 18 VO_n polyhedra (tetrahedra, octahedra and square pyramids) surrounding a central VO_4 tetrahedron. The valence stoichiometry of the anion varies from one preparation to another ($V^{IV}:V^{V} = 5:14–7:12$), and given that Johnson's formula is approximately twice those reported by Ostrowetsky, it seems likely that some of Ostrowetsky's complexes are similarly constituted.

Salts of the deep violet anion $[V_2^{IV}V_8^{V}O_{26}]^{4-}$ have been obtained adventitiously from nonaqueous media. The crystal structure of the tetramethylammonium salt shows an anion of virtual S_8 symmetry composed of a ring of eight corner-shared $V^{V}O_4$ tetrahedra capped on either side by $V^{IV}O_5$ square pyramids.[22] The polymeric anion in $K_2V_3O_8$, which is obtained from aqueous solution, has a structure comprising $V^{IV}O_5$ square pyramids linked to ditetrahedral V_2O_7 units. The salt $(NH_4)_2V_3O_8 \cdot O.5H_2O$, prepared by homogeneous acidification of thiovanadate solutions,[23] probably has the same anion.

38.2.3 Isopolyniobates

Aqueous niobate solutions contain the hexaniobate anion, $[H_xNb_6O_{19}]^{(8-x)-}$, throughout most of the accessible pH range (above *ca.* pH 7). Normal and acid salts of $[Nb_6O_{19}]^{8-}$ may be crystallized from aqueous solutions that are generally prepared by dissolution of freshly precipitated Nb_2O_5 in alkali. The structure of the anion, in crystals of $Na_7HNb_6O_{19} \cdot 15H_2O$, is shown in Figure 5. As in the decavanadate structure, the metal atoms are displaced towards the unshared oxygen atoms. The Nb—O bond lengths are 1.75–1.78 Å (terminal), 1.970–2.056 Å (bridging) and 2.371–2.386 Å (central).[24] That the same structure persists in aqueous solutions of sodium and potassium salts is strongly supported by ultracentrifugation, light scattering, Raman spectroscopy and ^{17}O NMR. Vibrational spectra of the crystalline potassium salt have

been subjected to normal coordinate analysis. The successive protonation constants (log K) for $[Nb_8O_{19}]^{8-}$ in 1 M KCl are 12.3(1), 10.94(5) and 9.71(2).[25]

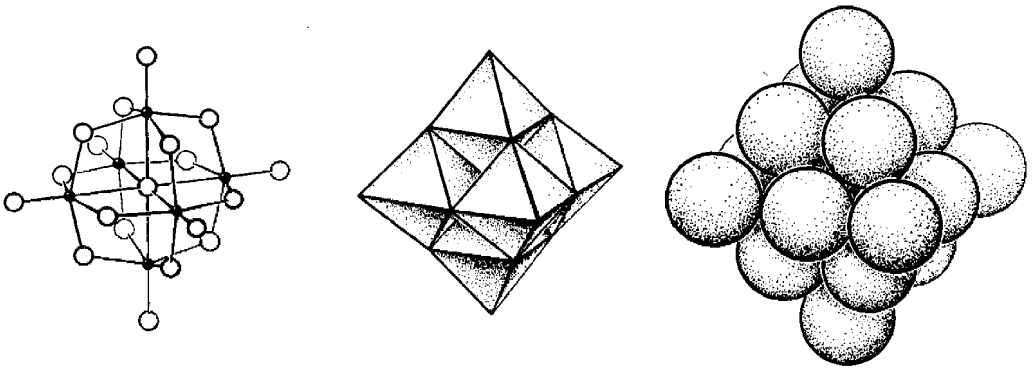

Figure 5 The structure of $[Nb_6O_{19}]^{8-}$ in bond, polyhedral and space-filling representations

On the basis of Raman and UV spectroscopy it has been suggested that $[Nb_6O_{19}]^{8-}$ is degraded into tetrameric and monomeric species in 1–12 M KOH.[26] Acidification of niobate solutions in the presence of NMe_4^+ or NEt_4^+ ion is said to lead to an Nb_9 species. The latter may well be a decaniobate since hydrolysis of a methanolic solution of $Nb(OEt)_5$ with aqueous NMe_4OH and NaOH yields $(NMe_4)_6Nb_{10}O_{28}\cdot 6H_2O$ and $(NMe_4)_4Na_2Nb_{10}O_{28}\cdot 8H_2O\cdot 0.5MeOH$. The structures of both salts have been determined.[27] The $[Nb_{10}O_{28}]^{6-}$ anion is exactly analogous to $[V_{10}O_{28}]^{6-}$ (Figure 3).

38.2.4 Isopolytantalates

The only well-established isopolytantalate is $[Ta_6O_{19}]^{8-}$, isostructural with the corresponding niobate. The bond lengths in $K_4Na_2H_2Ta_6O_{19}\cdot 2H_2O$ are Ta—O(terminal), 1.786–1.817; Ta—O(bridging), 1.976–2.012; Ta—O(central), 2.356–2.426 Å.[28] Hexatantalate solutions have been examined by ultracentrifugation, light scattering, Raman spectroscopy and ^{17}O NMR. Normal coordinate analysis of vibrational spectra reveal that the force constant for the Ta—O stretch is about 8% larger than for Nb—O. Oxygen exchange between water and $[Ta_6O_{19}]^{8-}$ is much slower than that for $[Nb_6O_{19}]^{8-}$ and occurs more rapidly at the terminal oxygen atoms, according to ^{17}O NMR.[29] Protonation constants (log K) of 12.68, 10.81 and 9.28 in 1.0 M KCl have been reported and are similar to those of $[Nb_6O_{19}]^{8-}$.

Solvolysis of $Ta(OEt)_5$ with 85% H_2O_2 in the presence of Bu^tNH_2 leads to a product formulated as a dodecatantalate derivative, $(BuNH_3)_5H_5Ta_{12}O_{17}(O_2)_{20}\cdot 21H_2O$.[30] Ultracentrifugation of an aqueous solution of this material shows two molecular weight fractions, one corresponding approximately to a Ta_{12} species and the other to $[Ta_6O_{19}]^{8-}$. As the solution ages, the proportion of the heavier solute species decreases.

38.2.5 Isopolymolybdates

Salts of about a dozen isopolymolybdate anions have been isolated from aqueous or nonaqueous solutions. The formulas of these anions are listed in Table 3 and their structures (see below) are based predominantly on six-coordinate molybdenum in contrast to those of vanadates and chromates.

38.2.5.1 Aqueous solutions

In dilute solutions ($\sim 10^{-5}$ M) the equilibria (2) are governed by log K values of 3.87 and 3.70 respectively (3 M $NaClO_4$, 25 °C). While the MoO_4^{2-} anion is certainly tetrahedral, the anomalously small value of log K_1 has been taken to indicate an expansion of coordination number upon protonation. In view of the prevalence of octahedral *cis* MoO_2 units in molybdenum(VI) chemistry, formulas such as $[MoO_2(H_2O)(OH)_3]^-$ and $[MoO_2(H_2O)_2(OH)_2]$

Table 3 Isopolymolybdate Anions

Formula	*Acidity, Z*[a]	*Ref. for structure*
MoO_4^{2-}	0	b
$[Mo_2O_7]^{2-}$	1.00	c
$[Mo_2O_7]_x^{2x-}$	1.00	d
$[Mo_7O_{24}]^{6-}$	1.14	e
$[Mo_{10}O_{34}]^{8-}$	1.20	f
$[Mo_8O_{26}(OH)_2]^{6-}$	1.25	g
$[Mo_8O_{27}]_x^{6x-}$	1.25	h
$[Mo_3O_{10}]_x^{2x-}$	1.33	i
$[Mo_5O_{17}H]^{3-}$	1.40	—
α-$[Mo_8O_{26}]^{4-}$	1.50	j
β-$[Mo_8O_{26}]^{4-}$	1.50	k
$[Mo_6O_{19}]^{2-}$	1.67	l
$[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$	1.78	m
$[Mo_5O_{16}H(H_2O)]_x^{x-}$	1.80	n

have been proposed. Molybdenum(VI) is amphoteric and in 0.2–3.0 M H^+ yields cationic species with empirical formulas $[HMoO_3]^+$, $[MoO_2]^{2+}$, $[Mo_2O_5]^{2+}$ and $[HMo_2O_5]^+$, but which also undoubtedly are based on six-coordinate Mo.

$$MoO_4^{2-} \overset{K_1}{\rightleftharpoons} HMoO_4^- \overset{K_2}{\rightleftharpoons} H_2MoO_4 \qquad (2)$$

Acidification of aqueous solutions of Na_2MoO_4 at concentrations greater than about 10^{-3} M leads successively to solutions containing the polyanions $[Mo_7O_{24}]^{6-}$ ('paramolybdate'), β-$[Mo_8O_{26}]^{4-}$ and $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$. The evidence for these species is based on potentiometric and spectroscopic investigations of solutions, and on X-ray structural determinations of salts isolated from these solutions. A reevaluation of the potentiometric data[31] has suggested the presence of additional species, $[H_2Mo_{12}O_{42}]^{10-}$ (analogue of 'paratungstate B', see Section 38.2.6.1) and $[Mo_{18}O_{54}(OH)_4(H_2O)_8]^{4-}$, but confirmatory evidence for these is lacking at present. No stable intermediates seem to exist between $[MoO_4]^{2-}$ and $[Mo_7O_{24}]^{6-}$ in aqueous solution, but $(NH_4)_2Mo_2O_7$ crystallizes from hot solutions after some hours. The anion in this salt is polymeric however with infinite chains of MoO_6 octahedra and MoO_4 tetrahedra.[32] A discrete ditetrahedral $[Mo_2O_7]^{2-}$ anion has been synthesized in acetonitrile solution and isolated as a tetrabutylammonium salt.[33] Although $[Mo_2O_7]^{2-}$ is unchanged in aqueous–acetonitrile solutions, addition of alkali metal counterions caused immediate precipitation of salts of $[Mo_7O_{24}]^{6-}$.

The heptamolybdate anion and its protonated forms, $[H_nMo_7O_{24}]^{(6-n)-}$, $n = 1$–3, predominate in solutions of pH 3–*ca.* 5.5. The structure of the anion, Figure 6, has been determined in sodium, potassium, ammonium and isopropylammonium salts, and has been confirmed in solution by low angle X-ray scattering.[34] The anion structure can be viewed as $\frac{7}{10}$

of the decavanadate structure and involves an arrangement of octahedra with *cis*-MoO_2 stereochemistry for each metal atom. IR, Raman and ^{17}O NMR spectra have been reported. Crystals of the isopropylammonium salt are photoreducible.[35]

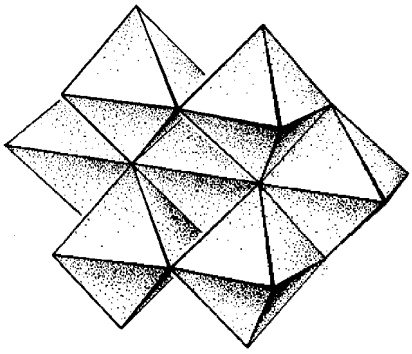

Figure 6 The structure of $[Mo_7O_{24}]^{6-}$ anion

Salts of β-$[Mo_8O_{26}]^{4-}$ may be crystallized from more acidic solutions, pH 2–3. The structure of the anion (Figure 7) is also formally derivable from that of $[V_{10}O_{28}]^{6-}$. The existence of significant concentrations of β-$[Mo_8O_{26}]^{4-}$ in aqueous solutions has been controversial, but Raman and X-ray scattering studies provide more positive evidence.[34]

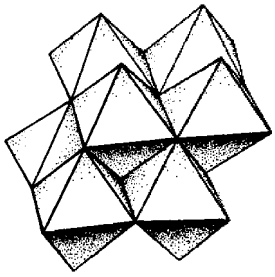

Figure 7 The structure of β-$[Mo_8O_{26}]^{4-}$ anion

The presence of a very large anion in solutions acidified to H^+/MoO_4^{2-} ~1.8 has been inferred from EMF and ultracentrifugation studies. Sodium, potassium, ammonium and barium salts of this anion were isolated from such solutions and the structure of $K_8[Mo_{36}O_{112}(H_2O)_{16}]\cdot 38\text{–}40H_2O$ has been reported. The anion, Figure 8, consists of two Mo_{18} units related by inversion symmetry. Each unit contains an Mo_7O_{24} moiety surrounded by edge- and corner-linked MoO_6 octahedra containing terminal and bridging water molecules as shown. Two of the Mo atoms in the Mo_7 units become seven-coordinate (quasi pentagonal bipyramidal) and an identical feature is seen in the peroxo polymolybdate $[Mo_7O_{22}(O_2)_2]^{6-}$.[37]

38.2.5.2 Nonaqueous solutions

Four isopolymolybdates have been synthesized or stabilized in nonaqueous or mixed solvents: $[Mo_2O_7]^{2-}$, $[Mo_6O_{19}]^{2-}$, α-$[Mo_8O_{26}]^{4-}$ and $[Mo_5O_{17}H]^{3-}$. The first of these has already been discussed. Several salts of $[Mo_6O_{19}]^{2-}$ have been prepared by both rational and serendipitous routes, and five X-ray structural determinations reported.[38] The anion is isostructural with $[Nb_6O_{19}]^{8-}$ and has no significant distortions from O_h symmetry, except in one case, which is attributed to crystal packing. The structure has a rare feature for an oxomolybdate(VI), namely a C_{4v} monooxo site symmetry for the metal atoms. As a consequence (see Section 38.5) the anion can be electrolytically reduced to mixed valence $[Mo_6O_{19}]^{3-}$ and $[Mo_6O_{19}]^{4-}$ species. The oxidized anion is yellow ($\lambda_{max} = 325$ nm) whereas all other isopolymolybdates are colorless. The IR, Raman and ^{17}O and ^{95}Mo NMR spectra have been reported.

The α-$[Mo_8O_{26}]^{4-}$ anion is precipitated by Bu_4N^+ from an aqueous molybdate solution, and has a structure isotypic with $[(MeAsO_3)_2Mo_6O_{18}]^{4-}$ (see Section 38.6.2) and thus contains two

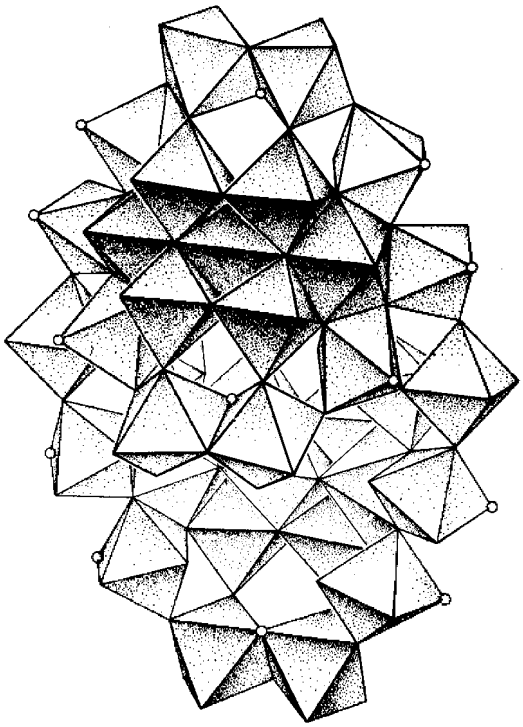

Figure 8 The structure of $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$ anion. A heptamolybdate unit in one of the two Mo_{18} moieties is emphasized. Coordinated water molecules are indicated by open circles

MoO_4 tetrahedra capping a planar ring of six edge-shared octahedra.[39] According to ^{17}O NMR the MoO_4 tetrahedra undergo intermolecular or intramolecular reorientation in acetonitrile solution. Addition of a small counterion such as K^+ to such solutions induces isomerization to β-$[Mo_8O_{26}]^{4-}$. A unimolecular mechanism for the isomerization has been proposed.[40]

A structure for the unstable $[Mo_5O_{17}H]^{3-}$ anion, isotypic with $[Me_2AsMo_4O_{15}H]^{2-}$ (Section 38.6.3), has been proposed from IR and ^1H NMR spectroscopy. The anion is isolated as an amorphous Bu_4N salt from equilibrium (3) in acetonitrile.[42]

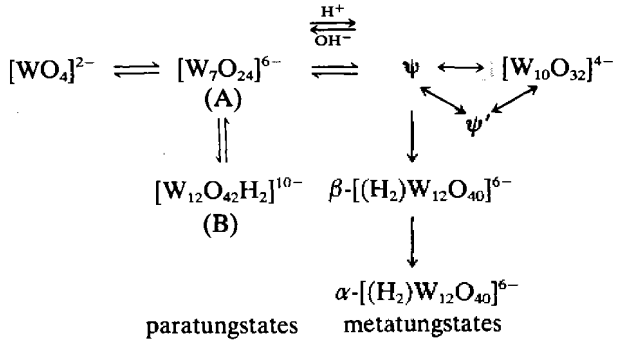
$$7Mo_2O_7^{2-} + H_2O \rightleftharpoons 2[Mo_5O_{17}H]^{3-} + 4MoO_4^{2-} \quad (3)$$

38.2.5.3 Other isopolymolybdates

Several isopolymolybdates which have been isolated from solution are polymeric or appear to have structures that do not persist in solution. These include the trimolybdates $M_2Mo_3O_{10}\cdot xH_2O$, obtained as fibrous crystals from appropriately acidified solutions. The structures of $Rb_2Mo_3O_{10}\cdot H_2O$ and $RbNaMo_3O_{10}$ contain infinite double chains of edge-shared MoO_6 octahedra.[42] From more acidic solution polymeric pentamolybdates $[MMo_5O_{16}H(H_2O)]$ slowly crystallize. The structure of the potassium salt reveals a complex three-dimensional network of MoO_6 octahedra.[43]

Finally, the salts $(NH_4)_6[Mo_8O_{27}]\cdot 4H_2O$, $(NH_4)_8[Mo_{10}O_{34}]$ and $(Pr^iNH_3)_6[Mo_8O_{26}(OH)_2]$ all contain a common Mo_8O_{28} unit of edge-shared MoO_6 octahedra[1] (see Section 38.6.4).

38.2.6 Isopolytungstates



Isopolytungstate anions isolated from solution in the form of crystalline salts are listed in Table 4. Several other species undoubtedly remain to be characterized, but analysis of aqueous polytungstate equilibria is complicated by the extreme range of rates involved. Many apparently stable isopolytungstates may be kinetic intermediates. For this reason, no equilibrium distribution diagrams will be given, nor would such diagrams provide a useful

introduction to aqueous polytungstate chemistry. Scheme 1 is believed to represent the sequence of reactions in aqueous solution at moderate to high ionic strength.

Table 4 Isopolytungstate Anions

Formula	*Acidity, Z*[a]	*Ref. for structure*
WO_4^{2-}	0	b
$[W_4O_{16}]^{8-}$	0	c
$[W_7O_{24}]^{6-}$	1.14	d
$[W_{12}O_{42}H_2]^{10-}$	1.17	e
α-$[(H)W_{12}O_{40}]^{7-}$	1.48	—
α-$[(H_2)W_{12}O_{40}]^{6-}$	1.50	f
β-$[(H_2)W_{12}O_{40}]^{6-}$	1.50	—
$[W_{10}O_{32}]^{4-}$	1.60	g
$[W_6O_{19}]^{2-}$	1.67	h

Scheme 1

38.2.6.1 Paratungstates

As for the molybdates, the protonation constants for WO_4^{2-} ($\log K_1 = 3.5$; $\log K_2 = 4.6$; 0.1 M NaCl, 20 °C) indicate an expansion of coordination number, *e.g.* to $[WO_2(H_2O)(OH)]^-$, *etc.* Potentiometric titration of sodium tungstate solutions ($> \sim 10^{-5}$ M) leads to pH inflections at H^+/WO_4^{2-} values of ~1.1–1.2 and ~1.5. The first corresponds to the formation of 'paratungstates' and the second to the formation of 'metatungstates'.

At least two paratungstate species are known. 'Paratungstate A' is formed rapidly upon acidification, and, after decades of formulation as '$[HW_6O_{21}]^{5-}$', now appears to be a heptatungstate, $[W_7O_{24}]^{6-}$, with a structure identical to that of the corresponding molybdate (Figure 6),[44] although the simultaneous presence of hexatungstate species in these solutions cannot be convincingly ruled out by potentiometric data. Crystals of $Na_6W_7O_{24}{\cdot}21H_2O$ are isolated from paratungstate solutions after prolonged boiling and are more soluble than those of 'paratungstate B', $Na_{10}[W_{12}O_{42}H_2]{\cdot}27H_2O$, the usual product of such solutions. Freshly prepared solutions of paratungstate B hydrolyze slowly to an 'equilibrium' mixture of A and B (equation 4). In dilute solutions (<0.02 M) the paratungstates appear to yield $[WO_4]^{2-}$ and α-$[(H_2)W_{12}O_{40}]^{6-}$ (see below).

$$12[W_7O_{24}]^{6-} + 2H^+ + 6H_2O \rightleftharpoons 7[W_{12}O_{42}H_2]^{10-} \quad (4)$$

The structure of the paratungstate B anion has been established by X-ray and neutron diffraction. The somewhat open structure (Figure 9) contains two internal protons that probably help its stabilization. The neutron diffraction study confirms the conclusion from broadline NMR that the interproton separation is 2.24 Å.[45]

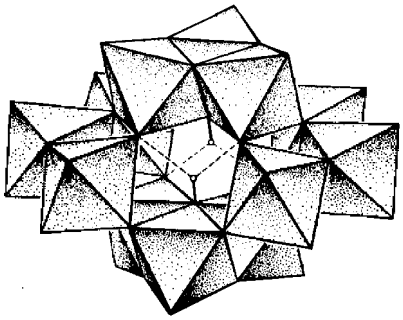

Figure 9 The structure of paratungstate-B anion, $[H_2W_{12}O_{42}]^{10-}$, showing location of two 'internal' protons

Although no intermediates between $[WO_4]^{2-}$ ($Z = 0$) and $[W_7O_{24}]^{6-}$ ($Z = 1.14$) have been detected in solution, $[W_4O_{16}]^{8-}$ ($Z = 0$) is found in crystals of $7Li_2WO_4{\cdot}4H_2O$ (or $Li_{14}(WO_4)_3(W_4O_{16}){\cdot}4H_2O$) which is isolated from alkaline lithium tungstate solutions. The anion structure consists of a tetrahedral arrangement of four edge-shared WO_6 octahedra.[46] The incongruently soluble ditungstate, $Na_2W_2O_7{\cdot}5H_2O$, is probably polymeric.[47]

38.2.6.2 Metatungstates

The initially formed product in tungstate solutions acidified to $H^+/WO_4^{2-} = 1.5$ is so-called pseudometatungstate anion (ψ) which has to date been isolated in noncrystalline form only, but which has a characteristic polarogram. Solutions of ψ are slowly converted successively to β and α isomers of the metatungstate anion $[(H_2)W_{12}O_{40}]^{6-}$. At 80 °C and pH 3 the half-lives of both processes are ~70 min.[48]

The ultimate product, α-$[(H_2)W_{12}O_{40}]^{6-}$, is a particularly stable anion with a structure and chemistry that parallel those of the heteropolyanions $[XW_{12}O_{40}]^{n-}$ (X = P, Si, *etc*). The structure ('Keggin'), deduced from early observations of isomorphism, and from analyses of $[Bu_3NH]^+$ and $[Me_4N]^+$ salts, is described in more detail in Section 38.3.1.1. Two protons occupy the central tetrahedral site, normally occupied by the heteroatom, X. The protons are not susceptible to rapid exchange with solvent water and are detectable by NMR of aqueous solutions.[49] As discussed in Section 38.5, Keggin anions have a rich redox chemistry. Highly reduced metatungstate anions spontaneously lose one of the internal protons and may be reoxidized to metastable $[(H)W_{12}O_{40}]^{7-}$ which has been isolated and characterized by NMR and polarography.[50] Fluoro derivatives of metatungstates have been prepared by indirect methods.[51]

The β isomer of $[(H_2)W_{12}O_{40}]^{6-}$ ('tungstate X') is difficult to isolate in pure form, but can be obtained indirectly from reduced ψ. There seems little doubt, based on comparisons with heteropolyanions, and from ^1H and ^{183}W NMR, that the anion structure corresponds to that of β-$[SiW_{12}O_{40}]^{4-}$.[52] The composition and structure of ψ are still unknown. Although W_6 and W_{24} formulas have been suggested, recent ultracentrifugation measurements indicate a dodecamer. Reduction of ψ by two equivalents/12W causes transformation to a new species ψ', which, upon reoxidation, slowly is converted to ψ. A potassium salt of oxidized ψ' has been isolated.

38.2.6.3 Decatungstate and hexatungstate

Strongly acidified solutions of sodium tungstate ($H^+/WO_4^{2-} > 1.5$) contain a pale yellow species ($\lambda_{max} = 320$ nm) that may be isolated as a metastable potassium salt, $K_4W_{10}O_{32}$(aq). Solutions of this species yield ψ, β-$[(H_2)W_{12}O_{40}]^{6-}$ or $[W_7O_{24}]^{6-}$ depending upon pH and ionic strength. The anion is more conveniently studied as a tetraalkylammonium salt in nonaqueous solutions. The structure of $[W_{10}O_{32}]^{4-}$ in the tri-*n*-butylammonium salt may be viewed as a

dimer of D_{4h} symmetry derived from two W_6O_{19} units, each of which has lost a WO_6 octahedron.[53] The anion is electrochemically and photochemically[123] reducible (see Section 38.5).

The hexatungstate anion, $[W_6O_{19}]^{2-}$, first obtained, like $[Mo_6O_{19}]^{2-}$, from controlled hydrolysis of tungstate esters, is formed by acidification of methanolic solutions of sodium tungstate.[54] Addition of water to a solution of $[W_6O_{19}]^{2-}$ in methanol causes its conversion to $[W_{10}O_{32}]^{4-}$. In methanol solution, $[W_{10}O_{32}]^{4-}$ is slowly (days) converted to $[W_6O_{19}]^{2-}$.

38.3 HETEROPOLYANIONS

At present count, some 68 elements (other than Mo and W) have been observed as heteroatoms in polyanions (see Table 5). Since each element may form more than one heteropolyanion (*e.g.* at least 18 tungstophosphates) and there are polyanions with combinations of several heteroatoms, the total number of known heteropolyanions is extremely large. It is therefore out of the question to attempt a complete accounting of every type of heteropolyanion on the following pages. We shall restrict discussion to the main structural types. More complete reviews are available.[1–3]

Table 5 Confirmed Heteroatoms in Heteropolyanions

H																
Li	Be											B	C			
Na	Mg											Al	Si	P	S	
K	Ca		Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn	Ga	Ge	As	Se	
Rb	Sr	Y	Zr	Nb	Mo		Ru	Rh		Ag		In	Sn	Sb	Te	I
Cs	Ba	La	Hf	Ta	W	Re	Os		Pt		Hg	Tl	Pb	Bi		
			Ce	Pr	Nd		Sm	Eu	Gd	Tb		Ho	Er		Yb	
			Th		U	Np	Pu	Am	Cm		Cf					

The heteroatoms may be divided into (i) those ('primary') that are essential for the maintenance of the polyanion structure and are therefore not susceptible to chemical exchange, *e.g.* Co^{2+} in $[CoW_{12}O_{40}]^{6-}$, and (ii) those ('secondary') that in principle and usually in practice may be removed from the polyanion structure without destroying it. Heteropolyanions containing secondary heteroatoms may be viewed as coordination complexes with polyanion ligands, *cf.* $[(H_3N)_5Cr(OH_2)]^{2+}$ with $[(SiW_{11}O_{39})Cr(OH_2)]^{5-}$. Although there will be occasions in which a clear distinction between primary and secondary heteroatoms may not be possible, in most cases the classification is unambiguous. Heteropolyanions containing secondary heteroatoms will be discussed in Section 38.4.

38.3.1 Four-coordinate Primary Heteroatoms

38.3.1.1 The Keggin structure and derivatives

The structure of $[PW_{12}O_{40}]^{3-}$ in the hexahydrate of the free acid was first reported by Keggin in 1933 on the basis of powder data, and has been confirmed by more recent single crystal X-ray and neutron measurements. The same structure has been found in several other heteropolytungstates and molybdates and is shown in Figure 10. Table 6 lists the currently known Keggin anions. The structure has idealized T_d point symmetry and comprises four trigonal groups of edge-shared MO_6 octahedra, each group sharing corners with its neighbors and with the enclosed central tetrahedron. When examined in noncubic space groups, the heteropolymolybdates are found to have lower (T) symmetry as a result of alternating bond lengths for the Mo—O—Mo bridges. In every case (Mo or W) the metal atoms are displaced outwards from the center of the anion toward the unshared oxygen atoms, the displacement conferring approximate C_{4v} local symmetry on each metal. Although the polyhedral representation may suggest otherwise, the Keggin structure, like that of most polyanions, is a close-packed arrangement of oxygen atoms.

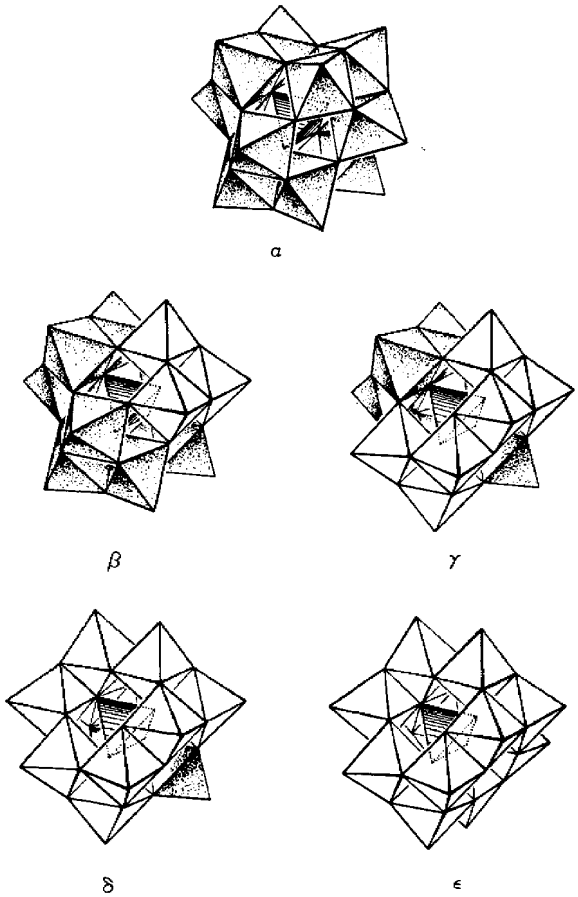

Figure 10 The structures of $[PW_{12}O_{40}]^{3-}$ ('Keggin', α) and four possible skeletal isomers (β, γ, δ, ε) formed by $\pi/3$ rotation of one, two, three and four W_3O_{13} groups, respectively. The rotated groups are shown unshaded

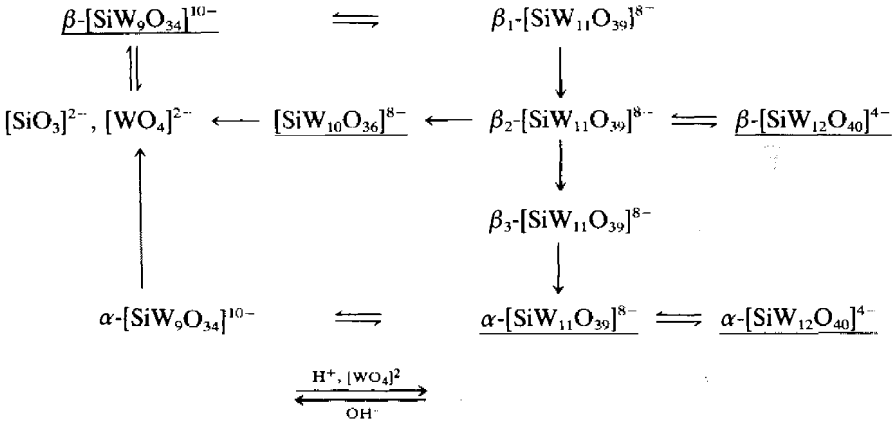
Also shown in Figure 10 are *skeletal* isomers of the Keggin structure in which one or more of the edge-shared groups of octahedra have been rotated by $\pi/3$. The β-isomer structure has been confirmed in $[SiW_{12}O_{40}]^{4-}$ and $[SiMoW_{11}O_{40}]^{4-}$ salts and is slowly converted to the α (Keggin) form in solution, see Section 38.3.1.1.i. The γ, δ and ε structures are expected to be less stable on two accounts, an increased number of coulombically unfavorable edge-shared contacts between MO_6 octahedra (M · · · M, 3.4 *vs.* 3.7 Å for corner sharing) and a decreased number of quasi-linear M—O—M bridges resulting in decreased $d\pi$–$p\pi$ interactions.[55] It is of interest that Al^{3+} which cannot form a $d\pi$–$p\pi$ bond and which has a smaller charge than W^{6+} adopts the ε structure for $[Al_{13}O_4(OH)_{24}(OH_2)_{12}]^{7+}$.

A second form of isomerism occurs with mixed metal polyanions, such as $[PW_8V_4O_{40}]^{7-}$, in which the relative positions of the W and V atoms may vary.[56] That such *positional* isomers do exist has been amply demonstrated by NMR and ESR spectroscopy.[57] The numbers of possible isomers increase with the lowering of skeletal symmetry, *e.g.* five for α-$[PW_{10}V_2O_{40}]^{5-}$, fourteen for β-$[SiMo_2W_{10}O_{40}]^{4-}$.

Several deficit or lacunary derivatives of the Keggin structure exist as individual species or as fragments of other heteropolyanion structures. Removal of one MO_6 octahedron (stoichiometric loss of MO^{n+}) from α- or β-Keggin anions leads to isomers of $[XM_{11}O_{39}]^{n-}$. Removal of three adjacent octahedra leads to A- and B-type XM_9O_{34} anions. The structures of these are shown in Figure 11.

(*i*) *Silicon and germanium heteroatoms*



Both α- and β-$[SiW_{12}O_{40}]^{4-}$ were first described over a century ago and the conversion of $\beta \rightarrow \alpha$ was observed in 1909. The free acids are stable crystalline materials and may be obtained by ion exchange or by extraction as 'etherates' from acidified aqueous solution. The

Table 6 Keggin Structure Heteropolyanions

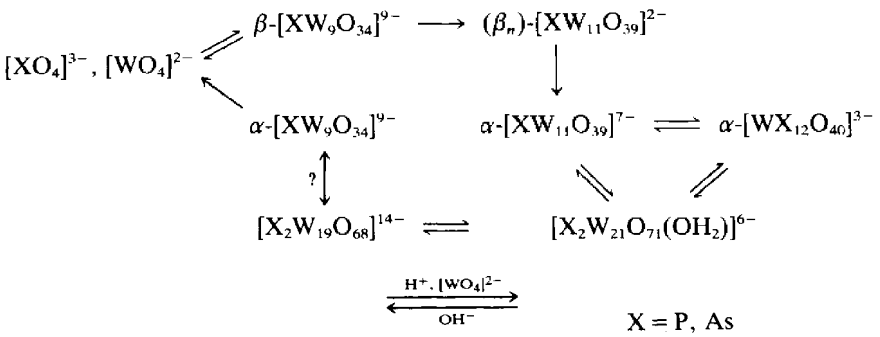
| *Reported heteroatoms, X*[a] | | |

latter behavior is common to all Keggin anions and certain other heteropolyanions.[58] In view of its ease of synthesis and its stability there have been innumerable investigations of α-$[SiW_{12}O_{40}]^{4-}$. In solution, the anion behaves hydrodynamically as an (unsolvated) sphere of radius *ca.* 5.5 Å, according to viscosity and diffusion data. The many spectroscopic methods applied[1] include IR and Raman (solution and solid state), electronic, ^{17}O and ^{183}W NMR, X-ray photoelectron spectroscopy and ^{182}W Mössbauer spectroscopy.[59]

When solutions of $[XW_{12}O_{40}]^{4-}$ (X = Si, Ge) are treated with alkali (pH > 5) a complex series of hydrolyses ensues. Based on polarographic studies the series of equilibria and reactions in aqueous solutions of tungstate and silicate (germanate) are summarized in Scheme 2. All species listed have been isolated as salts, although many are metastable in solution, and the underlined species have been structurally characterized by X-ray diffraction. The structure of β-$[SiW_9O_{34})]^{10-}$ is type A (Figure 11).[60] The anion $[SiW_{10}O_{36}]^{8-}$ has a C_{2v} structure based on the γ-Keggin isomer (Figure 10) with two edge-shared octahedra missing. The three β isomers of $[SiW_{11}O_{39}]^{8-}$ are distinguishable polarographically and the structure of $K_4[SiMoW_{11}O_{40}]\cdot 9H_2O$ prepared from the β_2 isomer shows the Mo atom in the ring of six octahedra adjacent to the rotated W_3O_{13} group (Figure 10). It is concluded that the β_1 and β_3 isomers have vacant sites as shown in Figure 11. All the lacunary tungstosilicate structures conform to the principle enunciated by Lipscomb that no MO_6 octahedron in a polyanion has more than two unshared vertices (see Section 38.1).

Scheme 2

The molybdo-silicates and -germanates seem to parallel the tungsto species, but are considerably more labile, and fewer structures have been determined. Like the corresponding tungstate, α-$[SiMo_{12}O_{40}]^{4-}$ has been intensively studied. The β isomer has recently been shown[124] to have the same structure as β-$[SiW_{12}O_{40}]^{4-}$. Isomerization of $\beta \rightarrow \alpha$ is rapid in aqueous solution, but may be arrested in nonaqueous solvents. The reverse isomerization ($\alpha \rightarrow \beta$) occurs when the polyanion is reduced to a heteropoly blue form (see Section 38.5.1.2). The lacunary anions $[XMo_{11}O_{39}]^{8-}$ and (?β)-$[XMo_9O_{34}]^{10-}$ (X = Si, Ge) are quite unstable and difficult to isolate. They react with divalent transition metal cations to yield $[XMo_{11}MO_{40}]^{n-}$ and other uncharacterized products.[61]



(*ii*) *Phosphorus and arsenic heteroatoms*

There are probably more heteropolyanions of phosphorus than of any other heteroatom (Table 7), and most of these polyanions have structures derived from the Keggin anion $[PW_{12}O_{40}]^{3-}$. Scheme 3 outlines some of the major known species. The pattern of reactions is similar to that of the tungstosilicates except that the β isomers, with the exception of β-$[XW_9O_{34}]^{10-}$, are much less stable and have never been unambiguously identified. The Keggin anion $[PW_{13}O_{40}]^{3-}$ has been the subject of innumerable papers and has been thoroughly characterized by X-ray and neutron diffraction, vibrational, electronic and NMR (^{31}P, ^{183}W and ^{17}O) spectroscopy. The free acid is very soluble in water (*ca.* 85% by weight) and in numerous polar solvents. The acid is levelled in water and crystals of $H_3PW_{12}O_{40}\cdot 6H_2O$ contain $[PW_{12}O_{40}]^{3-}$ and $[H_5O_2]^+$ ions only.[62] The trimethyl ester has recently been

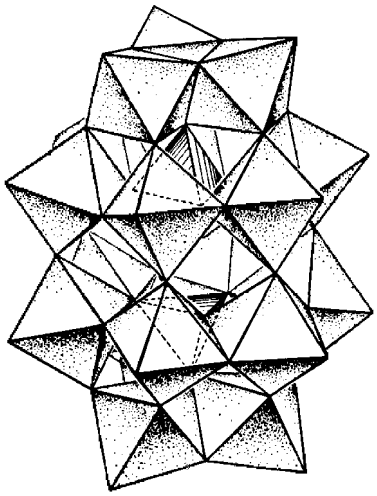
Scheme 3

reported.[125] Solutions of the 12-acid are rapidly converted to $[PW_{11}O_{39}]^{7-}$ at pH > *ca.* 1.5; the latter anion appears to be stable between pH 2 and 6. The corresponding AsW_{12} and AsW_{11} anions are much less stable and must be synthesized and studied in aqueous organic solvents.

The $[X_2W_{19}O_{68}]^{14-}$ and $[X_2W_{21}O_{71}(H_2O)_2]^{6-}$ species have no tungstosilicate analogues. Salts of the 2:21 anion were first described in 1892, but its structure has only recently been determined.

The anion has almost D_{3h} symmetry with two A-α-PW_9O_{34} units (see Figure 11) that sandwich two $WO_5(H_2O)$ octahedra and a WO_5 square pyramid, *i.e.* the equatorial plane contains two radial H_2O—W=O groups and one W=O group. The structure of $[P_2W_{19}O_{68}]^{14-}$ is currently unknown, but it appears to be a lacunary derivative of P_2W_{21} for it reacts with several divalent metal ions to give $P_2W_{19}M_2$ species (see Section 38.4.2.2).

When solutions of sodium tungstate are boiled with a large excess of phosphoric acid (P : W ~ 4 : 1) other tungstophosphates are produced. The main species present in such solutions appear to be α and β isomers of $[P_2W_{18}O_{62}]^{6-}$ and the cryptate $[NaP_5W_{30}O_{110}]^{14-}$ (originally formulated as a P_3W_{18} species). The structure of α-$[P_2W_{18}O_{62}]^{6-}$ (the 'Dawson' anion) is shown in Figure 12 and is seen to be a fused dimer of A-α-PW_9O_{34} moieties. Rotation of one edge-shared W_3O_{13} 'cap' of this structure by $\pi/3$ leads to the β structure.[64] Other possible isomers, not yet known for the phosphates, but identified *via* ^{183}W NMR for $[As_2W_{18}O_{62}]^{6-}$, are γ (both caps rotated) and δ (D_{3d}-symmetrized fusion of PW_9 moieties). The γ and β isomers spontaneously isomerize to the α form in aqueous solution.



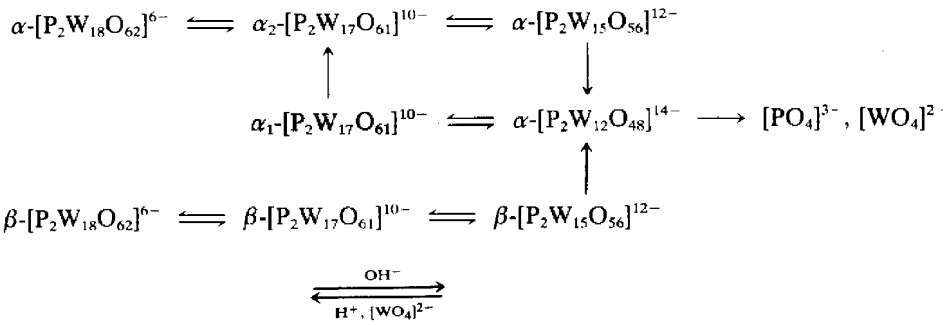


Figure 12 The structure of α-$[P_2W_{18}O_{62}]^{6-}$ ('Dawson') anion

Several lacunary derivatives of the Dawson structure can be synthesized by controlled alkalinization of aqueous solutions, as shown in Scheme 4.

Scheme 4

The α_1- and α_2-$[P_2W_{17}O_{61}]^{10-}$ isomers have been shown by ^{183}W NMR and IR spectroscopy to contain tungsten vacancies in the equatorial ring and terminal cap sites respectively. Numerous metal-ion-substituted derivatives of these species are known (Section 38.4.2). The structures of the P_2W_{15} and P_2W_{12} anions are not known with certainty, although from NMR the two phosphorus atoms are equivalent in P_2W_{12}. A likely structure for the latter corresponds to loss of six WO_6 octahedra from one long side of the Dawson anion (a 'peeled banana'); the

anion $[P_8W_{48}O_{184}]^{40-}$ which can be isolated from solutions of P_2W_{12} consists of a cyclic tetramer of just such units.[65] The P_8W_{48} anion is one of an increasing number of polyanions shown to act as cryptands for alkali and alkaline earth cations (Section 38.4.2.3).

Although formally a cryptate, the sodium ion in $[NaP_5W_{30}O_{110}]^{14-}$ is very tightly bound and is not removed when the free acid $H_{14}[NaP_5W_{30}O_{110}]$ is prepared by ion exchange. The heteropolyanion is one of those rare molecules with full five-fold symmetry, and may be viewed as an assembly of 10 corner-shared W_3O_{13} units forming the faces of a pentagonal bipyramid (*cf.* the same units in the Keggin and Dawson structures that form tetrahedral and octahedral assemblies respectively). The presence of the sodium ion in a cavity on the C_5 axis of the polyanion reduces the overall symmetry from D_{5h} to C_{5v}. The anion has been characterized by vibrational, electronic and NMR spectroscopy, and is stable in solution to pH 11 (*cf.* pH 1.5 for α-PW_{12} and pH *ca.* 6 for α-P_2W_{18}).[66]

Although molybdophosphates and molybdoarsenates corresponding to $[PW_{12}O_{40}]^{3-}$ and $[P_2W_{18}O_{62}]^{6-}$ are well known ($[PMo_{12}O_{40}]^{3-}$ was probably prepared by Berzelius in 1826) these are usually not the most predominant species in aqueous solutions (see Section 38.3.1.2). The Keggin anions $[XMo_{12}O_{40}]^{3-}$ are best studied in aqueous organic solvents to retard hydrolytic degradation. Both α and β isomers are known, the latter being stabilized in the reduced state (Section 38.5.1.2). The Dawson anions are more stable in aqueous solution and are formed *via* XMo_9 species (equation 5). Salts of $[PMo_9O_{31}(OH_2)_3]^{3-}$ and the corresponding arsenate have been isolated. The anion structure is a distorted form of A-α-XW_9O_{34} (Figure 11) in which three of the six (nominally equivalent) terminal oxygen atoms have been converted into weakly bound water molecules (Mo—OH_2, 2.23 Å). The locations of the water molecules and the resulting Mo—O—Mo bond alternation confers a pronounced chirality upon the overall structure, and the chirality is retained in the resulting $[X_2Mo_{18}O_{62}]^{6-}$ anions (D_3 *vs.* D_{3h} for P_2W_{18}).[67] Numerous examples of 'mixed metal' heteropolyanions (Mo + W, V + W, V + Mo) exist with apparent Keggin or Dawson structures, although crystallographic investigation has been limited to salts containing α-$[V_5W_8O_{40}]^{7-}$, α-$[V_3Mo_{10}O_{40}]^{6-}$ and β_1-$[SiW_{11}MoO_{40}]^{4-}$. In each case the high symmetry of the α or β Keggin framework results in crystallographic disorder. Further complications arise with the vanadium-containing anions which are mixtures of isomers (Section 38.3.1.1).

$$2[XMo_9O_{31}(OH_2)_3]^{3-} \longrightarrow [X_2Mo_{18}O_{62}]^{6-} + 6H_2O \qquad (5)$$

A modification of the Keggin structure is seen in the heteropolyvanadates, $[XV_{14}O_{42}]^{9-}$ (X = P, As). In these anions two extra VO^{3+} groups are attached to opposite sides of the Keggin core forming a cluster of reduced charge (see Figure 13).[68]

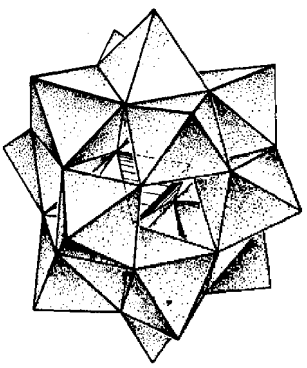

Figure 13 The structure of $[PV_{14}O_{42}]^{9-}$ anion

(*iii*) *Other Keggin species*

Several other heteropolytungstates are known or presumed to have the Keggin structure (Table 6). Two 12-tungstoborates have been known for over a century, but these prove not to be simple α or β isomers. The anion α-$[BW_{12}O_{40}]^{5-}$ seems to be an undoubted Keggin species based on isomorphism, vibrational spectrum and its behavior upon reduction. The second isomer ('h'), crystallizing as the acid in hexagonal crystals, clearly is not a β isomer for its

polarographic and spectroscopic properties[69] are quite unlike those of all other β-XW_{12} species. A crystal structure determination shows h to be $H_{21}B_3W_{39}O_{132}$.[126] No molybdoborates are known.

Of the remaining anions listed in Table 6 the transition-metal-centered species are noteworthy. The cobalt(III) anion was the first example of a tetrahedral (high spin) d^6 complex.[70] Its reduction to $[Co^{II}W_{12}O_{40}]^{6-}$ ($E = +1.00$ V *vs.* nhe) renders it an attractive outer sphere oxidant.[71] The corresponding Fe^{III} anion does not undergo reduction to an Fe^{II} species but directly to a heteropoly blue ($Fe^{III}W^{V,VI}$, see Section 38.5), but $[CuW_{12}O_{40}]^{6-}$ is reducible to the brown Cu^{I} analogue ($E = +0.09$ V). The Mn- and Cr-centered anions have been little studied and are difficult to prepare.

The 12-tungstates of Se^{IV}, Te^{IV}, Sb^{III} and Bi^{III} are unlikely to have an undistorted Keggin structure in view of the unshared pair of electrons on the heteroatoms. No detailed structural studies have been made. There are however several characterized heteropolytungstates of As^{III} and Sb^{III} in which the lone pair is stereochemically active. These are summarized in Table 8. Most of these contain B-α-XW_9O_{33} units (see Figure 11), linked by extra WO_6 or WO_5 polyhedra. See Figure 14 for an example.

38.3.1.2 Non-Keggin metallophosphates and metalloarsenates

Potentiometric and ^{31}P NMR investigations show that in aqueous solutions of molybdate and phosphate the major polyanion solute species are pale yellow PMo_9 species and colorless $[H_nP_2Mo_5O_{23}]^{(6-n)-}$ anions.[71] The structure of the latter anion (Figure 15) has been determined in several crystalline salts and in solution and has a C_2 structure that leaves a vertex of each PO_4 tetrahedron unshared.[72] The anion is quite labile and possibly fluxional (see Section 38.6.1). Protonation (pK values 5.10, 3.65 in 3.0 M $NaClO_4$, 25 °C) occurs on the terminal oxygens of the phosphate groups. Analogous anions are formed by phosphonates (RPO_3^{2-}),[73] phosphate monoesters,[74] sulfites[75] and selenites. The corresponding tungstophosphate $[P_2W_5O_{23}]^{6-}$ has been reported but it appears not to be a major solute species in aqueous solution.

Aqueous solutions of molybdate and arsenate, pH 3–5, contain $[AsMo_9O_{31}(H_2O)_3]^{3-}$ and an As_2Mo_6 anion.[71] The exact structure of the latter ion in solution is in some doubt, although the tetramethylammonium sodium salt contains the anion shown in Figure 15. Low angle X-ray scattering measurements of aqueous molybdoarsenate solutions are *not* compatible with this structure and the anion may be hydrated in a fashion similar to that observed for the analogous

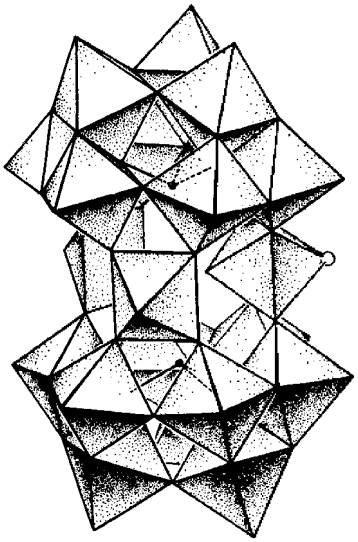

Figure 14 The structure of $[As_2W_{21}O_{69}(H_2O)]^{6-}$ anion. The water molecule is indicated by the open circle

molybdoarsonates (see Section 38.6.2). The D_{3h} structure for $[As_2Mo_6O_{26}]^{6-}$ shown in Figure 15 is also found for α-$[Mo_8O_{26}]^{4-}$ (see Section 38.2.5.2), $[(MeAs)_2Mo_6O_{24}]^{4-}$ (Section 38.6.2) and $[V_2Mo_6O_{26}]^{6-}$. Several other molybdoarsenates are formed in acidic solutions. One long-known species is $[H_4As_4Mo_{12}O_{50}]^{4-}$ which has an arrangement of MoO_6 octahedra like an inverted Keggin anion, a central cavity and external $HOAsO_3$ tripod groups.[76] Analogous organoarsonate derivatives are described in Section 38.6.2.

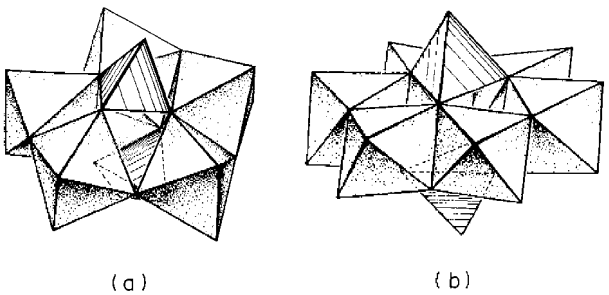

Figure 15 The structures of (a) $[P_2Mo_5O_{23}]^{6-}$ and (b) $[As_2Mo_6O_{26}]^{6-}$ anions

38.3.2 Six-coordinate Primary Heteroatoms

38.3.2.1 The Anderson and related structures

In 1936 Anderson proposed that several 1:6 heteropolyanions and the isopolyanion $[Mo_7O_{24}]^{6-}$ had the planar (D_{3d}) structure shown in Figure 16. The structure was verified for $[TeMo_6O_{24}]^{6-}$ in 1948, but heptamolybdate was shown to have the isomeric (C_{2v}) form shown in Figure 6. Both D_{3d} and C_{2v} structures confer local C_{2v} symmetry on the molybdenum or tungsten atoms; each MO_6 octahedron has two (*cis*) terminal oxygens. The currently known anions are listed in Table 9 and include a periodato complex in which the ring of external octahedra comprises alternate IO_6 and $CoO_4(OH_2)_2$ units. Protonation of the anions (see Cr^{III}, Ni^{II} and Pt^{IV} complexes in Table 9) is believed to take place on the oxygen atoms directly attached to the heteroatom. In most cases, attempts to neutralize the protons result in hydrolytic decomposition of the heteropolyanion. Isomerism has been observed for crystalline protonated $Pt^{IV}Mo_6$ anions (see Table 9).

Some of the anions have been shown to be labile by isotope exchange. Thus Mo exchange between $[Mo_7O_{24}]^{6-}$ and $[H_6XMo_6O_{24}]^{3-}$ at pH 2.5 and 0 °C has $t_{\frac{1}{2}} = 35$ min for $X = Cr^{III}$ and $t_{\frac{1}{2}} \ll 1$ min for $X = Fe^{III}$. Chromium exchange between the polyanion and $[Cr(H_2O)_6]^{3+}$ is fast

(4–45 min at 29.5 °C) and involves transfer of Mo as MoO_4^{2-} or $HMoO_4^-$ rather than breaking of Cr—O bonds.[77]

When solutions of $[H_6CoMo_5O_{24}]^{3-}$ are treated with H_2O_2 in the presence of activated charcoal the anion is converted quantitatively into $[H_4Co_2M_{10}O_{38}]^{4-}$, an olive green species that may be resolved into stable enantiomers.[78] The new polyanion has a structure of D_2 symmetry that may be 'constructed' as follows. Removal of an MoO_6 octahedron from the Anderson anion leaves a chiral $CoMo_5$ fragment of C_2 symmetry. Two (+)- (or two (−)-) $CoMo_5$ groups are slotted together so that the two CoO_6 octahedra share an edge and produce

(+ +)-(− −)-$[H_4Co_2Mo_{10}O_{38}]^{4-}$.[79] Crystals of the ammonium salt are pleochroic and transmit red, blue-green and yellow light along the three molecular axes.

38.3.2.2 Other structures incorporating octahedral heteroatoms

The Anderson structure discussed above can be viewed as a 'close-packed' layer of edge-sharing MO_6 octahedra. Addition of three octahedra above and three octahedra below this layer produces a cluster, $XM_{12}O_{38}$, of octahedral symmetry in which the central XO_6 octahedron shares each of its edges with an MO_6 octahedron.[80] The mineral sherwoodite contains the only naturally occurring heteropolyanion, $[AlV_2^{IV}V_{12}^{V}O_{40}]^{9-}$, and has a structure consisting of the $XM_{12}O_{38}$ cluster with two additional VO_6 octahedra placed in *trans* positions on a four-fold axis (Figure 17).[81] The synthetic heteropolyvanadates, $[XV_{13}O_{38}]^{7-}$ ($X = Mn^{IV}$, Ni^{IV}) have the sherwoodite structure less one of the equatorial VO_6 octahedra.[82] The heteropolymolybdates $[XMo_9O_{32}]^{6-}$ ($X = Mn^{IV}$, Ni^{IV}) also have a structure that can be derived from the $XM_{12}O_{38}$ cluster by removal of three alternate MO_6 octahedra from the original Anderson fragment.[83] The resulting structure has D_3 symmetry. Attempts to resolve the 1:9 complexes have been unsuccessful, although the circular dichroism spectrum of the Mn species has been recorded on crystals of the ammonium salt. The ESR spectrum of the Mn complex has been analyzed and the ^{61}Ni Mössbauer spectrum has been reported for $[NiMo_9O_{32}]^{6-}$.

38.3.3 Eight- and Twelve-coordinate Primary Heteroatoms

38.3.3.1 Decatungstometalates, $[XW_{10}O_{36}]^{n-}$

The heteroatoms listed in Table 10 form complexes of stoichiometry $[XW_{10}O_{36}]^{8-}$. The structure, based on determinations of the Ce^{IV} and U^{IV} anions, can be regarded as the attachment of two quadridentate ligands, derived from W_6O_{19} through the loss of one WO_6 octahedron, to the heteroatom (Figure 18). The site symmetry of the latter is approximately D_{4d}. The XW_{10} anions are of only moderate stability in aqueous solution (pH 5.5–8.5). Electronic, vibrational and ^{17}O NMR spectra have been recorded. The emission spectra and luminescence properties of several of the lanthanide anions have been discussed.[84]

38.3.3.2 Dodecamolybdometalates, $[XMo_{12}O_{42}]^{n-}$

The structure shown in Figure 19 was first described for the $[CeMo_{12}O_{42}]^{8-}$ anion.[85] It contained two unprecedented features, an icosahedrally coordinated heteroatom, and face-shared pairs of MoO_6 octahedra. Other examples of octahedral face-sharing have since been observed, but this feature remains uncommon owing to the high coulombic repulsion between

Table 10 Decatungstometalate Heteropolyanions, $[XW_{10}O_{26}]^{8,9-}$

Heteroatom	*Ref.*

the metal atoms (Pauling's rules). An alternative description of the structure is as a Ce^{4+} cation surrounded by six bidentate ditetrahedral $[Mo_2O_7]^{2-}$ ligands. The overall point symmetry is T_h.

The structure has been confirmed for Ce^{IV} and U^{IV} heteroatoms, and analogous complexes exist with Th^{IV}, Np^{IV} and perhaps Sn^{IV}. All are molybdates. The Ce^{IV} and U^{IV} anions undergo reversible reduction and oxidation respectively to Ce^{III} (unstable) and U^{V} analogues.[86]

38.4 HETEROPOLYANIONS AS LIGANDS: SECONDARY HETEROATOMS

The complexes formed by the attachment of metal ions or organometallic moieties to the surface oxygen atoms of complete or lacunary (deficit) heteropolyanions comprise a rapidly
