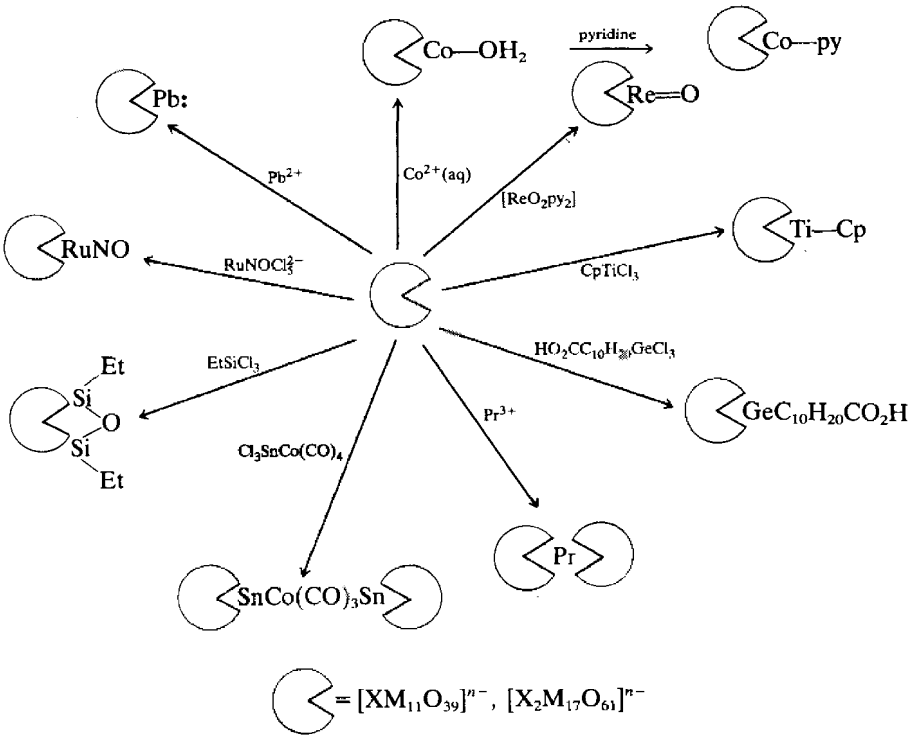
growing area of polyanion chemistry. Among other reasons, such chemistry is perceived as being particularly pertinent to mechanisms of catalysis on metal oxide surfaces, or indeed to the development of new catalysts.

38.4.1 Complete Polyanion Ligands

The first complexes incorporating an intact polyanion were $[X(Nb_6O_{19})_2]^{12-}$ ($X = Mn^{IV}$, Ni^{IV}). In these complexes the Mn and Ni atoms are bound to three bridging oxygens on the surface of the $[Nb_6O_{19}]^{8-}$ anions, which therefore act as tridentate ligands.[87] The salts $Na_5X(en)(Nb_6O_{19})\cdot nH_2O$ ($X = Cr^{3+}$, Co^{3+}) probably contain a similar ligand (*i.e.* $[(H_2O)(en)X(Nb_6O_{19})]^{5-}$). More recently, analogous derivatives of *cis*-$[Nb_2W_4O_{19}]^{4-}$ and $[MW_5O_{19}]^{3-}$ ($M = Nb$, Ta) have been synthesized, *e.g.* $[(OC)_3Re(Nb_2W_4O_{19})]^{3-}$, $[Me_5CpRh(Nb_2W_4O_{19})]^{2-}$ and $[Cp_3X(MW_5O_{19})_2]^{5-}$ ($X = U$, Th).[88] With the 16-electron d^8 species $[(C_7H_8)RhCl]_2$ (C_7H_8 = norbornadiene), a bizarre bridged complex results, $[\{(C_7H_8)Rh\}_5(Nb_2W_4O_{19})_2]^{3-}$.[89]

Similar complexes should be formed by Keggin anions, for each edge-shared triplet of WO_6 octahedra in the Keggin structure is analogous to one half of the M_6O_{19} structure. Two Keggin derivatives have been reported: $[Me_5CpRh(SiW_9Nb_3O_{40})]^{5-}$ and $[(cod)Rh(SiW_9Nb_3O_{40})]^{6-}$ (cod = cyclooctadiene).[90] All of the above organometallic derivatives have been structurally characterized by single crystal X-ray diffraction and/or ^{17}O, ^{183}W NMR spectroscopy.

The anions $[XMo_{12}O_{42}]^{8-}$ (Figure 19), form weak complexes in aqueous solution with divalent Mn, Fe, Co, Ni, Zn, Cu, Cd, trivalent Y, Er, Yb and tetravalent Th.[91] Two crystal structures have been determined and contain the anions $[(UMo_{12}O_{42})\{Er(OH_2)_5\}_2]^{2-}$ and $[(UMo_{12}O_{42})Th(OH_2)_3]_x^{4x-}$.[1,2] In both cases the external metal atoms are attached to opposite sides of the heteropolyanion *via* three terminal oxygen atoms, one from each of three different Mo_2O_7 units.



38.4.2 Lacunary Polyanion Ligands

Heteropolyanion structures in which the local site symmetry of each metal atom is approximately C_{4v} (*i.e.* each metal has one terminal oxygen) frequently undergo partial hydrolysis to lose an MO^{n+} group and generate a so-called lacunary structure, see for example the $[XM_{11}O_{39}]^{n-}$ (Figure 11) and $[X_2M_{17}O_{61}]^{n-}$ anions. The lacunary anions function as tetra- or penta-dentate ligands and react with an astonishing variety of metal ions or organometallic groups to form 1:1 or 2:1 complexes. In some cases such complexes are stable even although the lacunary 'ligand' itself may have no independent existence. The $[XW_{10}O_{36}]^{6-}$ anions described in Section 38.3.3.1 may be viewed in this light as 2:1 complexes of the hypothetical lacunary anion $[W_5O_{18}]^{6-}$. The organometallic derivatives $[CpTiM_5O_{18}]^{3-}$ ($M = Mo$, W) are analogous '1:1' complexes. In the last two examples the $[TiCp]^{3+}$ group plays the same role as WO^{4+} does in $[W_6O_{19}]^{2-}$. Further organometallic groups may be attached to the surface oxygens of the substituted polyanion in the manner described in Section 38.4.1, *e.g.* $[Me_5CpRh(Cp)TiMo_5O_{18}]^{3-}$.[92]

38.4.2.1 Derivatives of $[XM_{11}O_{39}]^{n-}$ and $[X_2M_{17}O_{61}]^{n-}$

The number of complexes of this type is legion. The general formula is $[XM_{11}Z(L)O_{39}]^{n-}$ (or $[X_2M_{17}Z(L)O_{61}]^{n-}$) where Z is a secondary heteroatom and L is a terminal ligand on Z. In some cases L is another lacunary polyanion, an organic or organometallic moiety, or is absent. Scheme 5 illustrates some of the possibilities.

When Z is a simple aquacation, two types of complex are formed depending upon the ionic radius of Z. For alkali, alkaline earth and most transition metal cations the product contains Z^{n+} in quasi-octahedral coordination. Equilibrium constants for reaction (6) have been determined for Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+}.[93] For the transition metals, $\log K$ lies between 3 and 9, and is sensitive both to Z and to the lacunary polyanion involved. Larger cations, Sr^{2+}, Ba^{2+}, and tri- and tetra-valent lanthanides and actinides are also able to bind two lacunary ligands in a manner similar to that illustrated in Figure 18. Although the stepwise formation of 1:1 and 2:1 complexes of the

Scheme 5

lanthanide cations can be demonstrated spectroscopically, only the 2:1 complexes have been isolated. The local symmetry around the cation is approximately square antiprismatic, as confirmed in structures of $Cs_{12}[U(\alpha\text{-}GeW_{11}O_{39})_2]\cdot aq$ and $K_{16}[Ce(\alpha_2\text{-}P_2W_{17}O_{61})_2]\cdot aq$.[94] These anions generally have a high charge, and favor the stabilization of unusual oxidation states, *e.g.* tetravalent Pr, Tb, Am, Cm and Cf and pentavalent U.

$$[XM_{11}O_{39}]^{n-} + Z^{p+}(aq) \rightleftharpoons [XM_{11}Z(OH_2)O_{39}]^{(n-p)-} \quad (6)$$

Although lacunary derivatives of Keggin anions with divalent heteroatoms have never been detected, derivatives of these species are readily prepared by other methods. Examples are $[(H_2)W_{11}Co(OH_2)O_{39}]^{7-}$, $[CoW_{11}Fe(OH_2)O_{39}]^{7-}$ and $[BeW_{11}Mn(OH_2)O_{39}]^{7-}$. The ligand field exerted by the lacunary anion seems to be weaker than that of the corresponding aqua complex, *e.g.* for $[SiW_{11}Ni(OH_2)O_{39}]^{6-}$ $\Delta = 8100\,cm^{-1}$ *vs.* $8600\,cm^{-1}$ for $[Ni(H_2O)_6]^{2+}$. In the Anderson anions $[H_6NiM_6O_{24}]^{4-}$ (Section 38.3.2.1) Δ is significantly larger: $9520\,cm^{-1}$ (Mo), $9800\,cm^{-1}$ (W).

The terminal water molecule may be replaced by other ligands, *e.g.* NH_3, pyridine, Cl^-.[95] With pyrazine or 4,4′-bipyridyl two polyanions can be linked together. In aqueous solution the equilibrium constants for water replacement are not very large, although only a handful have been measured. As an example, $K = 250\,M^{-1}$ for the substitution of NO_2^- for water in $[BW_{11}Co^{III}(OH_2)O_{39}]^{6-}$. Typically, the aqua derivatives are stable at $4 < pH < 8$, although several exceptions are known. It has been possible to remove the coordinated water molecules of such anions in nonpolar solvents.[131] Kinetic inertness of Z^{n+} frequently extends the effective pH range over which the complexes may be studied. For example the free acid of $[SiMo_{11}Cr^{III}(OH_2)O_{39}]^{5-}$ can be isolated, and the anion also can be deprotonated to $[SiMo_{11}Cr(OH)O_{39}]^{6-}$ at pH 9.[96]

Within the last few years there has been considerable activity directed towards the synthesis of organic and organometallic derivatives of heteropolyanions. Reactions of lacunary polyanions with $RMCl_3$, where R is an organic or organometallic radical, provide a simple route to such derivatives.[97] Some examples of these reactions are presented in Scheme 5. For the most part the reactions proceed smoothly and the products are remarkably stable towards hydrolysis. Apart from their structural characterization *via* crystallography and NMR spectroscopy the chemistry of these complexes has not been completely described.

38.4.2.2 Multisubstituted heteropolyanions

Heteropolyanion structures in which more than one W or Mo atom has been replaced range from the mixed metal species such as $[PW_8V_4O_{40}]^{7-}$ to anions like $[P_2W_{18}(SnC_6H_5)_2O_{60}]^{8-}$ and α-$[SiW_9(CoOH_2)_3O_{37}]^{10-}$. In some cases there are systematic methods of synthesis from an isolated lacunary species, *e.g.* α-$[SiW_9O_{34}]^{10-}$; in others, 'brute force' methods lead to complex mixtures of isomeric polyanions. As more work is done in this area, patterns are beginning to emerge. Thus several anions have been shown to contain B-α-XW_9 units (see Figure 11): $[(P^{V}W_9O_{34})_2Co_4(H_2O)_2]^{10-}$,[98] $[(As^{III}W_9O_{33})_2Cu_3(H_2O)_2]^{12-}$,[99] $[(Se^{IV}W_9O_{33})_2Mn_2^{III}WO(H_2O)_n]^{8-}$ [100] and $[(AsW_9O_{33})_2Co(WO)_2(H_2O)_n]^{8-}$. On the other hand the A-type anions $[SiW_9O_{34}]^{10-}$ and $[PW_9O_{34}]^{9-}$ react to give complete Keggin-like structures such as $[SiW_9Fe_3(OH_2)_3O_{37}]^{7-}$ [127] and $[PW_9V_3O_{40}]^{6-}$.[128]

38.4.2.3 Heteropoly cryptands

In Section 38.3.1.1.ii we noted that the large tungstophosphate anions $[P_5W_{30}O_{110}]^{15-}$ and $[P_8W_{48}O_{184}]^{40-}$ act as cryptands towards alkali metal cations. Two other leviathans, $[(NH_4)As_4W_{40}O_{140}(CoOH_2)_2]^{23-}$ (a)[101] and $[NaSb_9W_{21}O_{86}]^{18-}$ (b)[102] are illustrated in Figure 20. Anion (a) is constructed of four B-α-AsW_9 units linked by four WO_6 octahedra; it has a central crypt (optimum size for K^+ and Ba^{2+}) occupied by NH_4^+, and has four 'lacunae', two of which are occupied by Co^{2+}. The anion shows novel allosteric behavior; when it binds two small cations like Co^{2+}, the remaining two coordination sites expand and are incapable of binding further Co^{2+}, although two Ag^+ ions can be complexed.

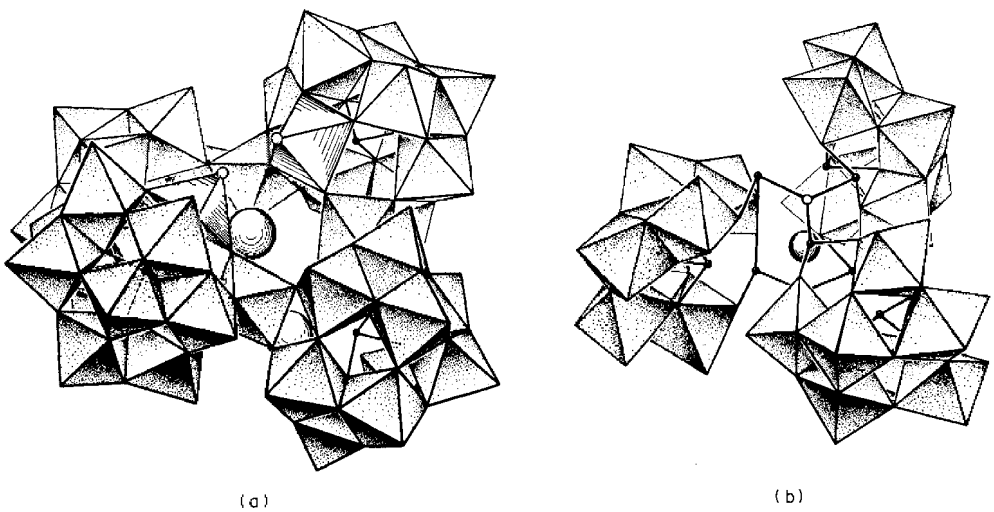


Figure 20 (a) $[(NH_4)As_4W_{40}O_{140}(CoOH_2)_2]^{23-}$ with aquacobalt(II) ions represented in the square pyramids with open circles. The large circle represents the ammonium ion in the central crypt. Two other ammonium ions (one partly visible) are weakly coordinated in positions corresponding to the cobalt(II) sites on the other side of the anion. (b) $[NaSb_9W_{21}O_{86}]^{18-}$. The β-SbW_7 units are shown in polyhedral fashion. The Sb atoms are represented as small dark spheres and the Na^+ ion as the large sphere

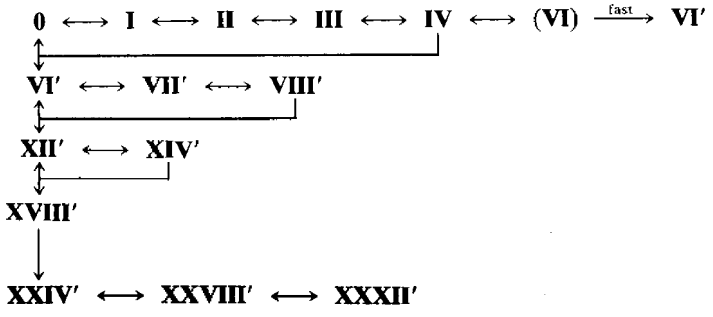
Anion (b) contains three B-β-SbW_7 units linked to an Sb_6O_2 'axis'. The central cavity is optimum size for Na^+. Both (a) and (b) have been found to exhibit antiviral and antitumoral properties at non-cytotoxic doses *in vitro* and *in vivo*, and are potent inhibitors of cellular, bacterial and viral DNA and RNA polymerases. Anion (b) has recently been used to treat patients with Acquired Immune Deficiency Syndrome.[129]

38.5 HETEROPOLY BLUES AND OTHER REDUCED SPECIES



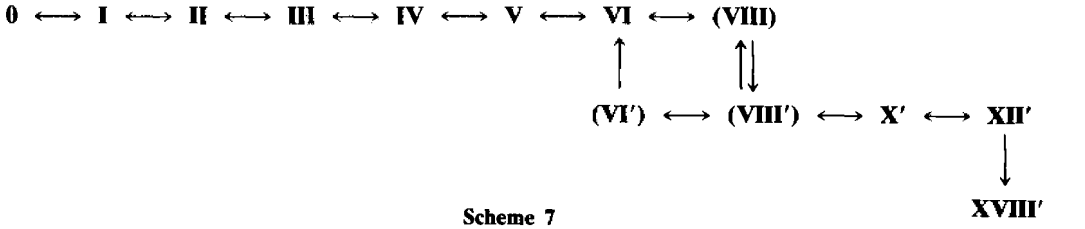
The formation of intensely colored species ('heteropoly blues') upon partial reduction of certain heteropolyanions forms the basis of widely used analytical procedures for the heteroelements in such anions (P, Si, *etc.*), or for the reductant (*e.g.* uric acid). Photochemical

reduction, which can, for example, lead to hydrogen evolution from aqueous solution is of particular current interest.[103] Although a pioneering study of the reduced molybdo- and tungsto-phosphates was made in 1920,[104] most of our present knowledge has developed from more recent electrochemical and spectroscopic studies.[1,105] The reduction of a heteropolyanion to a heteropoly blue involves the reversible addition of one or more electrons. In most cases there are no significant structural changes during the first stages of reduction. The added electrons must therefore enter orbitals that are mainly nonbonding in character. Such orbitals are present only in those anions in which each metal atom has a single terminal oxygen atom (approximate local symmetry, C_{4v}), *e.g.* the Keggin (Figure 10), Dawson (Figure 12) and M_6O_{19} (Figure 5) structures. Such structures are referred to as Type I and contain a nonbonding *d* orbital on each metal atom (in C_{4v} the orbital (d_{xy}) has B_2 symmetry). Other polyanion structures (Type II) have metal atoms with two (*cis*) terminal oxygens. In this symmetry all of the metal's *d* orbitals are involved in σ and π bonding. Consequently Type II polyanions (*e.g.* the Anderson anions, Figure 16) do not undergo reversible reduction to heteropoly blue species.

38.5.1 Electrochemistry

38.5.1.1 Polytungstates

Careful polarographic and voltammetric studies of several Keggin anions have revealed an elaborate redox behavior. The most complete study has been made on the metatungstate anion, α-$[(H_2)W_{12}O_{40}]^{6-}$.[50] In Scheme 6 and the subsequent discussion, the oxidized anion will be designated as **0** and each reduced species by a roman numeral representing the number of added electrons. In the scheme the horizontal double-headed arrows represent polarographically reversible electron transfer processes. Slower disproportionations or reductions are represented by the vertical arrows. The unprimed species are blue, and are mixed valence $W^{V,VI}$ anions, *e.g.* $[(H_2)W_2^{V}W_{10}^{VI}O_{40}]^{8-}$ (**II**). The primed species are red-brown, are less air sensitive and appear to contain W^{IV}, *e.g.*, **VI′** is $[(H_2)W_3^{IV}W_9^{VI}O_4H_6]^{6-}$ with a metal–metal bonded group of three edge-shared WO_6 octahedra. As the anion is reduced further, the remaining W_3 groups become metal–metal bonded. Electrons added to **XXIV′** enter delocalized nonbonding orbitals of which there is one for each set of three W^{IV} atoms. It is remarkable that the Keggin framework does not appear to be destroyed in this process; **XXIV′**, which is amphoteric, an orange cation (pH < 3) or a violet anion (pH > 12), can be reoxidized quantitatively to **0** under acidic conditions. As mentioned in Section 38.2.6.2, **XXIV′** slowly loses one of the central protons to yield the corresponding reduced version of $[(H)W_{12}O_{40}]^{7-}$.



Scheme 6

The other Keggin anions undergo similar redox processes, although there are individual variations. The initial reduction potentials, **0/I**, of $[XW_{12}O_{40}]^{n-}$ vary approximately linearly with *n*, from *ca.* 0 V (*vs.* SCE) for $[PW_{12}O_{40}]^{3-}$ to −0.7 V for $[Cu^{I}W_{12}O_{40}]^{7-}$. The maximum reduction states attainable for $[PW_{12}O_{40}]^{3-}$, $[SiW_{12}O_{40}]^{4-}$ and $[BW_{12}O_{40}]^{5-}$ are **VI**, **XX′** and **XVIII′** respectively. This behavior is attributed to coulombic repulsions between the heteroatoms and the W^{IV} atoms which must move towards the center of the anion in **VI′** and more reduced species. Reduction of other XW_{12} anions, $[X_2W_{18}O_{62}]^{6-}$, $[W_6O_{19}]^{2-}$, $[W_{10}O_{32}]^{4-}$ and lacunary species has not been explored much beyond stages **I** and **II**.

38.5.1.2 Polymolybdates

The electrochemistry of heteropolymolybdates parallels that of the tungstates but with the following differences: the reduction potentials are more positive and the primed species (metal–metal bonded?) are much less stable. Scheme 7 applies for α-$[SiMo_{12}O_{40}]^{4-}$. Species in parentheses are detectable only by rapid scan cyclic voltammetry, and **XVIII'** decomposes rapidly at 0 °C. The reduced anions such as **II** and **IV** are easily obtained by controlled potential electrolysis or by careful chemical reduction, *e.g.* with ascorbate. The use of metal ion reductants generally leads to other reactions, (equation 7). The reduced anions slowly isomerize (equation 8). The isomerization can be followed polarographically (all β potentials are more positive) or by NMR spectroscopy. By this means β isomers of most Keggin and Dawson molybdates have been prepared.

Scheme 7

$$0\,(\alpha\text{-}SiMo_{12}) \xrightarrow{Sn^{II}} \mathbf{IV}\,(SiMo_{10}Sn_2) \qquad (7)$$

$$\mathbf{IV}\,(\alpha \text{ series}) \longrightarrow \mathbf{IV}\,(\beta \text{ series}) \qquad (8)$$

38.5.2 Spectroscopy and Electronic Structures

The electronic spectra of heteropoly blues show broad bands in the visible and near IR regions that are attributable to intervalence charge transfer (*e.g.* $W^V \rightarrow W^{VI}$) and to *d–d* transitions. The intensities of these bands vary considerably with the structure of the polyanion. The reduced species, **I**, which have received the greatest attention so far, are currently assumed to be Class II mixed valence complexes in the Robin–Day classification.[106] This implies that the ground state may be described in terms of an electron that is weakly trapped on one of the W (or Mo) atoms. Partial delocalization of the electron on to the neighboring W^{VI} atom is defined by an electron-transfer integral (electron-tunnelling matrix element), J. Valence interchange between the metal centers can take place by optical excitation or by adiabatic electron transfer ('hopping'). In the high temperature limit, $kT \gg h\nu$ (where ν is the frequency of the vibrational mode(s) coupled to the electron transfer), $E_{th} = E_{op}/4$, where E_{th} is the activation energy for electron hopping and E_{op} is the energy of the intervalence transition. When allowance is made for partial electron delocalization, equation (9) applies. In favorable cases, unambiguous evidence for temperature dependent electron hopping is provided by ESR spectroscopy. The high and low temperature ESR spectra of $[P_2V^{IV}V_2^{V}W_{15}O_{62}]^{10-}$ (Figure 21) show that the electron interacts equally with the three $I = \frac{7}{2}$ ^{51}V nuclei at 350 K and is trapped on a single vanadium atom at 5 K. The high temperature activation energy (E_{th}) for this compound is 29 kJ mol^{-1} and J is 13 kJ mol^{-1}. Values for J and E_{th} for some polymolybdates and polytungstates have been estimated from ESR line broadening and intervalence band parameters, and are given in Table 11.

$$E_{th} = \tfrac{1}{4}E_{op} - J + \frac{J^2}{E_{op}} \qquad (9)$$

The electronic spectra of heteropoly blue anions (see Figure 22 for examples) show other intense broad bands in addition to the intervalence transitions. These are believed to result from intensity-enhanced *d–d* transitions.[108] For a given polyanion structure, the intensity of the spectra increase approximately linearly with the degree of reduction until state **VI** is reached. This behavior implies that successive electrons occupy orbitals of different metal atoms. The intensities of the intervalence bands are structure dependent: $M_6O_{19} < \alpha\text{-}XM_{12}O_{40} < \beta\text{-}XM_{12}O_{40} < \alpha,\beta\text{-}X_2M_{18}O_{62} < W_{10}O_{32}$. The molar extinction coefficient per W^V increases from 280 for $[W_6O_{19}]^{3-}$ to 7500 for $[W_{10}O_{32}]^{5-}$. The variation has been attributed to the change in M^V—O—M^{VI} bond angles (100° to 175° over the series). A greater bond angle leads to more

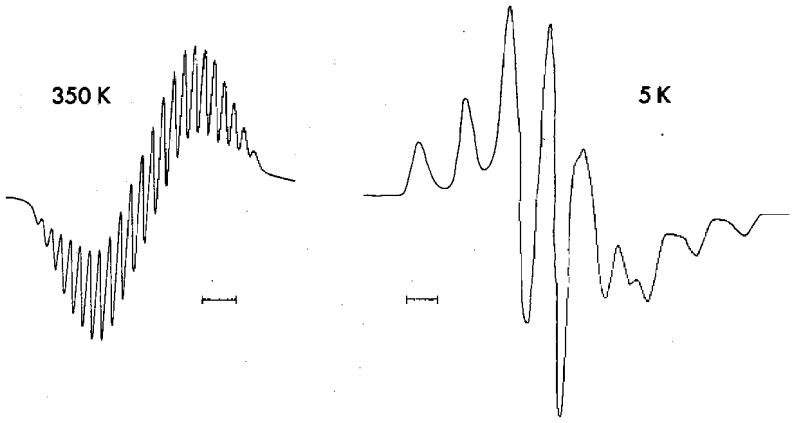


Figure 21 ESR spectra of α-$[P_2W_{15}V^{IV}V^{V}_2O_{62}]^{10-}$ at 350 K and 5 K. Scale bars represent 100 G

Table 11 Intervalence Parameters for some Heteropoly Blues

Anion	*Intervalence band frequency* (cm^{-1})	E_{th} (kJ mol^{-1})	J (kJ mol^{-1})
$[Mo_6O_{19}]^{3-}$	9000	15	14
$[PMo_{12}O_{40}]^{4-}$	6400	3.4	33
$[GeMo_{12}O_{40}]^{5-}$	7300	4.3	24
$[W_6O_{19}]^{3-}$	10 200	5.3	37
$[SiW_{12}O_{40}]^{5-}$	8000	3.4	30
$[(H_2)W_{12}O_{40}]^{7-}$	8400	3.4	32
$[As_2W_{18}O_{62}]^{7-}$	11 000	3.9	43

efficient electron delocalization *via* π bonding, and this is also reflected in the values of J (Table 11).

38.6 ORGANIC DERIVATIVES OF POLYANIONS

The introduction of organic and organometallic moieties into lacunary polyanion structures has been described in Sections 38.4.2.1 and 38.4.2.2. Other organic derivatives of polyanions are discussed in the following sections.

38.6.1 Organophosphonate Complexes

Pentamolybdobis(organophosphonates), $[(RPO_3)_2Mo_5O_{15}]^{4-}$, are readily formed in weakly acidic solution (pH 2–5).[73] The following derivatives have been isolated: R = H, Me, Et, $C_2H_4NH_3^+$, Ph, p-$C_6H_4NH_3^+$ and n-$C_{22}H_{45}$. The last-mentioned complex has been shown to be an effective electron-dense stain for electron microscopy of phospholipid vesicles.[109] X-Ray investigations of the methyl and β-aminoethyl derivatives show the anions to be isostructural with $[P_2Mo_5O_{23}]^{6-}$ (Figure 15) with R groups occupying the unshared vertices of the PO_4 tetrahedra.[110] A 'neutral' zwitterionic analog, prepared from *cis*-$[Co(en)_2(H_2O)OPO_3H)]^+$, has been isolated, as have several derivatives of phosphate monoesters.[74]

The corresponding pentatungsto complexes are less common; only those with R = Ph and $C_2H_4NH_3^+$ have been reported. According to ^{31}P and ^1H NMR the phenyl derivative is partially dissociated in aqueous solution, in contrast to the molybdates. In organic solvents, however, the tungstate appears to be undissociated, but ^{183}W and ^{17}O NMR spectra of these solutions reveal the anion to be fluxional at temperatures above −38 °C. The dynamic process is described as a pseudorotation of the nonplanar ring of five tungsten atoms, coupled to an oscillation of the $PhPO_3$ groups.[111] There is little doubt that the corresponding molybdates behave analogously.

38.6.2 Organoarsonate Complexes

Three polyanion structures incorporating $RAsO_3^{2-}$ groups have been reported. Two of these are analogous to $[As_2Mo_6O_{26}]^{6-}$ and $[H_4As_4Mo_{12}O_{50}]^{4-}$ described in Section 38.3.1.2. The As_2Mo_6 complexes are formed under similar conditions to the P_2Mo_5 species and the structure of $(Me_4N)_2Na_2[(MeAsO_3)_2Mo_6O_{18}]\cdot 6H_2O$ corresponds to that shown in Figure 15 for $[As_2Mo_6O_{26}]^{6-}$.[112] However, a hydrated version of the anion was observed in crystals of $(CN_3H_6)_4[(PhAsO_3)_2Mo_6O_{18}(OH_2)]\cdot 4H_2O$ and is shown in Figure 23. In aqueous solution the hydrated anion is the predominant species (IR and Raman spectra), but the R groups are made NMR equivalent by rapid exchange of the bridging water molecule.[113] The corresponding tungstate is isolated as a deprotonated species, $[(PhAsO_3)_2W_6O_{18}(OH)]^{5-}$, and the NMR spectrum of this complex at pH 3.6 shows two nonequivalent phenyl groups. As the pH of the solution is lowered, the phenyl resonances coalesce. This behavior is attributed to increased protonation of the anion to $[(PhAsO_3)_2W_6O_{18}(OH_2)]^{4-}$ and consequent water exchange as for the molybdate.[114]

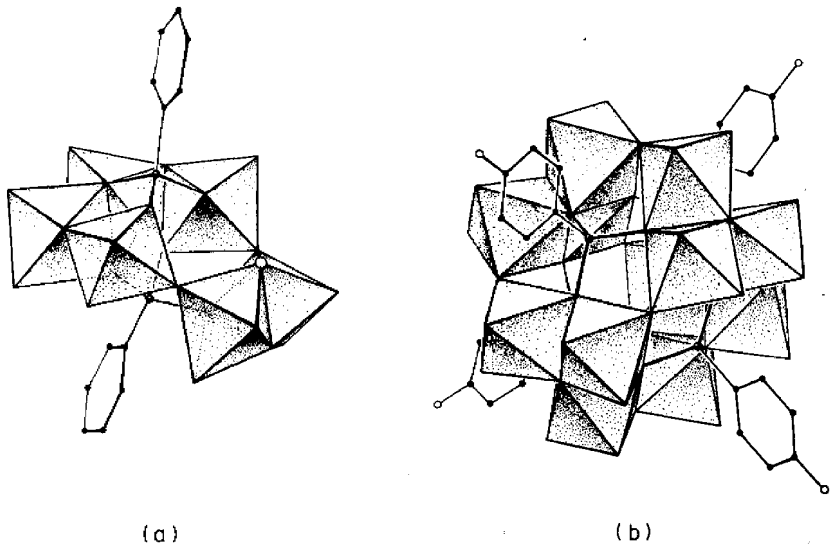

Figure 23 Structures of (a) $[(PhAsO_3)_2Mo_6O_{18}(OH_2)]^{4-}$, showing coordinated water as an open circle, and (b) $[(H_3NC_6H_4AsO_3)_4Mo_{12}O_{34}]$

Several derivatives of $[(RAsO_3)_4Mo_{12}O_{34}]^{4-}$ have been isolated from acidic solutions (pH < 1). The structure of the neutral zwitterionic species with R = p-$C_6H_4NH_3^+$ has been reported[115] (Figure 23) and it corresponds to that found for the 'inorganic' analog (R = OH).

The anion $[(MeAsO_3)Mo_6O_{18}(H_2O)_6]^{2-}$ has been reinvestigated.[116] Its structure contains a ring of $MoO_5(H_2O)$ octahedra and can be viewed as the structure of A-α-$[AsMo_9O_{31}(H_2O)_3]^{3-}$ (Figure 11) with the Mo_3O_{13} 'cap' removed.

38.6.3 Diorganoarsinate and Related Complexes

The anion shown in Figure 24, $[(Me_2AsO_2)Mo_4O_{12}(OH)]^{2-}$, is readily formed in aqueous solution at pH 3–5. Among its unusual features is the presence of a hydroxide group that bridges four molybdenum atoms.[117] Anions of this structure have proved to be remarkably effective inhibitors of certain acid phosphatases.[118] The structure may be considered to have been assembled from $R_2AsO_2^-$, OH^- and cyclic Mo_4O_{12}. Similar complexes based on $R_2C(OH)_2$ (acetal) units have been prepared by reaction of $[Mo_2O_7]^{2-}$ with aldehydes in nonaqueous solution. The structure of $(Bu_4N)_3[(H_2CO_2)Mo_4O_{12}(OH)]$ has been reported.[119] When the glyoxal derivative, $[(OHCCHO_2)Mo_4O_{12}(OH)]^{3-}$, is treated with HX ($X = F^-$, HCO_2^-), the second carbonyl group inserts into an Mo—O bond, and the four-fold bridging OH^- group is replaced by doubly bridging X^- (see Figure 25).[120]

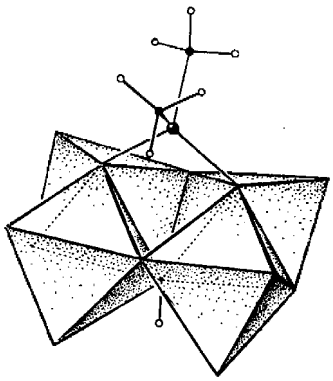

Figure 24 The structure of $[(Me_2AsO_2)Mo_4O_{12}(OH)]^{2-}$ anion

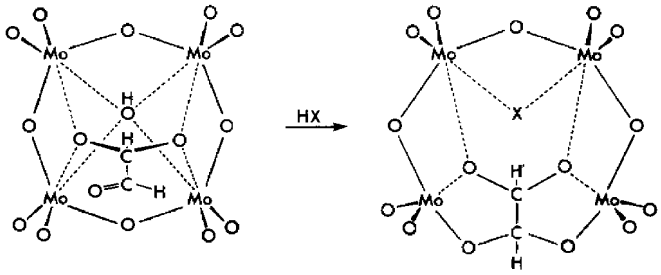

Figure 25 Structural scheme showing the insertion, upon treatment with HX, of the free carbonyl group of $[(OHCCHO_2)Mo_4O_{12}(OH)]^{3-}$ into an Mo—O bond to yield $[HCCHMo_4O_{15}X]^{3-}$. Broken lines denote Mo—O bonds of length 2.00–2.40 Å

38.6.4 Octamolybdate Derivatives

Addition of formic acid to a solution of $(NH_4)_6Mo_7O_{24}$ yields crystals of $(NH_4)_6[(HCO)_2Mo_8O_{26}]\cdot 2H_2O$.[120] When $MoO_3\cdot 2H_2O$ is refluxed with absolute MeOH over a molecular sieve, crystals of $Na_4[Mo_8O_{24}(OMe)_4]\cdot 8MeOH$ are isolated from the mother liquor.[122] The anions of both of these compounds contain the octamolybdate moiety shown in Figure 26. Terminal formyl and methoxy groups are attached to the MoO_6 octahedra with three unshared vertices; two methoxy groups occupy bridging sites. UV irradiation or thermal decomposition of the methoxy derivative yields formaldehyde, and this behavior illustrates some of the potential value of organopolyanion chemistry in modelling heterogeneous catalysis by metal oxides.

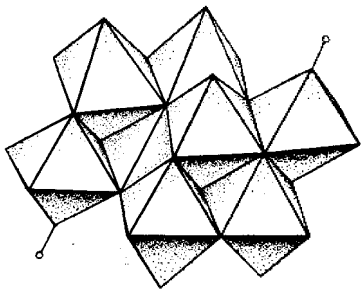

Figure 26 The Mo_8O_{26} unit found in $[(HCO)_2Mo_8O_{26}]^{6-}$ and $[Mo_8O_{24}(OMe)_4]^{4-}$ anions. The small circles indicate points of attachment of the formyl groups

ADDENDUM

Research activity continues to be high with groups in Europe, Japan, Canada and the USA. Considerable interest is focused on catalytic and photocatalytic applications.[130] In this context, transferral of heteropolyanions into nonpolar solvents opens up new possibilities such as oxygen-carrying species.[131] Recent work on organometallic derivatives of polyoxoanions from groups at the Universities of Illinois and Nebraska has been reviewed.[132] High pressure liquid chromatography has been used to separate several heteropolymolybdates, including α- and β-$[SiMo_{12}O_{40}]^{4-}$.[134] The structure of the heteropoly blue species (four-electron-reduced β-$[PMo_{12}O_{40}]^{3-}$) formed in the 'molybdenum blue' determination of phosphorus has been reported[135] and a review of molybdate heteropoly blues has appeared.[136] A 'stability index' of polyanion structures has been discussed.[137] The presence of two PMo_9 anions in aqueous solutions of molybdate and phosphate has been demonstrated by ^{31}P NMR.[138] Solid state NMR (nonspinning and MAS techniques) has been used for characterization of heteropolyanions.[139] Molybdenum-95 NMR spectra of some polymolybdates have been reported.[140]

Acknowledgement: It is a pleasure to acknowledge the contribution of my colleague Dr Howard T. Evans, Jr., US Geological Survey, in the preparation of the structural figures for this chapter.

39.1 SCANDIUM

39.1.1 Introduction

Scandium can truly be described as a little-studied element. In their thorough review[1] 'The Coordination Chemistry of Scandium', Melson and Stotz showed that, at that date, though many of the fundamental topics relating to this element had been to some extent investigated, much careful work needed still to be done to bring our knowledge of scandium chemistry to the level of that of its neighbours such as titanium or vanadium. By the present date, a number of advances have indeed been made but the chemistry of scandium is still backward compared with other elements. Of course, the element is very expensive but it is hard to see this as a major deterrent to study. With essentially only one oxidation state, the chemistry may lack variety to some extent, but still has much of interest to offer to the researcher.

With an ionic radius of 0.81 Å (Pauling), the ion Sc^{3+} lies on the borderline between six-coordination and higher coordination numbers. In those crystal structures which are known, Sc^{3+} is predominantly six-coordinated, but examples of seven-, eight- and nine-coordination do occur, together with a limited number of examples of lower coordination numbers than six where ligands are very bulky.

Regarding ligand preferences, Sc^{3+} is a typical Chatt–Ahrland Class A metal ion. Thus we see ready coordination with ligands based on oxygen, nitrogen or halides, but virtually no complexes with sulfur- or phosphorus-based ligands. While there is a small but interesting organoscandium chemistry in which considerable development has recently taken place, that is not dealt with in these pages.

39.1.2 Nitrogen Donor Ligands

39.1.2.1 Ammonia

There is little doubt that ammines are formed. Thus scandium hydroxide is incompletely precipitated by ammonium hydroxide, perhaps owing to the formation of ammine complexes.[2] Also the oxalato–ammine $\{Sc(NH_3)_6\}_2(C_2O_4)_3$ and its 12-hydrate have been obtained,[3] though some of the ammonia molecules in these species might be hydrogen bonded to the carboxylate anions rather than being coordinated. A further amino–carboxylate $Sc_2ac_6(NH_3)_3$ is also known.[4] A series of ammines of ScX_3 (X = Cl, Br or I) have been prepared by direct interaction of the anhydrous salt and ammonia.[5–7] The initial products are $ScX_3{\cdot}nNH_3$ ($n = 7$–8) but gentle heat (~100–115 °C) gives $ScCl_3(NH_3)_4$ or $ScBr_3(NH_3)_5$. IR studies[8] of deuterated halo–ammines have been interpreted in terms of structures such as $[ScCl(NH_3)_5]Cl_2$, and dissociation pressure measurements[9] gave heats of formation ($ScCl_3(NH_3)_5$, 72 kJ mol^{-1}; $ScCl_3(NH_3)_4$, 76 kJ mol^{-1}). Localized molecular orbitals have been calculated for $Sc(NH_3)_5X^{3+}$ ($X = H^-$, NH_3, F^-, Cl^-, H_2O). *d*-Orbital participation and π bonding were discussed and electron density contours given.[10] A hydrazine adduct $ScF_3{\cdot}N_2H_4$ has been described,[11] but its constitution is uncertain.

39.1.2.2 Amines

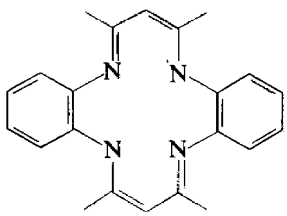
Both bis and tris ethylenediamine complexes have been described;[12] the latter have been formulated $[Sc(en)_3]X_3$ (X = Cl or Br), this being supported by IR data. Heating in vacuum leads to formation of *cis*-$[ScX_2(en)_2]X$. A number of complexes of $ScCl_3$ with primary and secondary amines, mainly aliphatic, have been prepared and their thermochemistry and IR spectroscopy studied.[13–15] The compounds are $ScCl_3{\cdot}n(RR'NH)$, where $n = 1$–4 and R = R′ = Me, Et, Pr, Bu or Pe; or R = H and R^1 = Et, Pr, Bu, Pe, phenyl, benzyl or 2-naphthyl. Further investigation would be necessary to establish the structural nature of these complexes.

Several investigations have explored monodentate and bidentate aromatic amine complexes. Treatment of $ScCl_3$ or $ScBr_3$ with hot neat pyridine gave $ScX_3 \cdot 4py$ (X = Cl or Br) where the IR spectrum suggested the presence of coordinated and uncoordinated pyridine; under vacuum these compounds were converted into $ScX_3 \cdot 3py$.[16] IR studies suggested that $\nu_{Sc-N} = 260$–$280\ cm^{-1}$, $\nu_{Sc-Cl} = 300$–$350\ cm^{-1}$ and $\nu_{Sc-Br} = 266$–$268\ cm^{-1}$. A series of pyridine thiocyanato complexes has also been prepared. The stoichiometries are $Sc(NCS)_3(py)_n(EtOH)_x$, where $n = 1$–4 and $x = 0$ or 1, the most stable complex being $Sc(NCS)_3(py)_3$. The anions of course dissociate in water, in which medium the presence of $[Sc(py)_n(H_2O)_y]^{3+}$ cations was suggested.[17]

The bidentate ligands 1,10-phenanthroline and 2,2'-bipyridyl form complexes with scandium chloride and thiocyanate. From anhydrous THF solutions $ScCl_3(bipy)_2$ and $ScCl_3(phen)_2$ were isolated. They dissociate to some extent as 1:1 electrolytes in acetonitrile or in nitromethane. Far IR evidence is that the structures are *cis*-$[ScCl_2L_2]Cl$ (L = phen or bipy). Somewhat similar thiocyanato complexes were also obtained.[18,19] However, in this case the tris complexes $Sc(NCS)_3L_3$ were both isolated and were assigned the formulation $[ScL_3](NCS)_3$ from IR and conductivity data. In the thiocyanate series, the bis complexes $[Sc(NCS)_2L_2]NCS$ were each obtained in *cis* and *trans* forms, again as determined mainly from IR spectra. Here $\nu(Sc—NCS) = 300$–$325\ cm^{-1}$. It would be interesting to have single crystal X-ray data on these compounds.

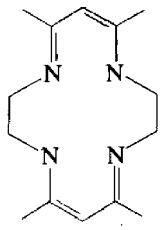
A comparatively large amount of work has been done on polydentate amine complexes, which show considerable stability and force high coordination numbers on the metal ion. Thus $Sc(NO_3)_3 \cdot 6H_2O$ and 2,2':6',2''-terpyridyl (terpy) gave, from acetonitrile, $[Sc(NO_3)_3(terpy)]$ as golden needles. A single crystal X-ray determination showed nine-coordination, the nitrate ions being bidentate, and the organic ligand essentially coplanar, with Sc—N = 2.272–2.322 Å and Sc—O = 2.234–2.322 Å but with one longer Sc—O distance at 2.482 Å. This seems to be a case where one of the nitrate oxygen atoms is almost being expelled from the coordination sphere by what must be a very considerable interligand repulsion. The terpyridyl ligand dissociates in water but the complex retains its integrity in nitromethane. The ligand tripyridyltriazine (tpta), which is similar in coordination geometry to terpyridyl if one of its pyridine groups remains uncoordinated, forms a complex $ScCl_3(tpta)$ where IR evidence suggests the presence of an uncoordinated pyridine, and the formulation as six-coordinated $[ScCl_3(tpta)]$ is suggested. Interconversion of the coordinated and uncoordinated pyridine groups takes place in methanol solution.[20]

A variety of tetradentate amine ligands have been used to form scandium complexes. Thus 1,2-bis(pyridine-α-carbaldimino)ethane (bpce) forms a dimeric complex $[Sc_2(NO_3)_2(\mu\text{-}OH)_2(bpce)_2](NO_3)_2 \cdot 3MeCN$ whose structure has been determined by single crystal X-ray.[20] Each metal ion is eight-coordinated and each bpce ligand is essentially coplanar, while the two hydroxy and two nitrate oxygen atoms which are coordinated to one particular scandium ion form an approximately coplanar system which is perpendicular to the plane of the tetraimine, producing a distorted dodecahedral coordination. The four Sc—N distances are 2.341–2.403 Å, and Sc—O(nitrate) are 2.333 and 2.295 Å. The Sc—OH distances are notably short at 2.053 and 2.089 Å and an sd_{z^2}–sp^2 covalent interaction is suggested. A complex $Sc(NO_3)_3(bpce)(H_2O)_2$ was also obtained and the formulation $[Sc(NO_3)_3(bpce)] \cdot 2H_2O$ was suggested. The bpce ligand, despite being quadridentate, dissociates in water and in DMSO.[20]



The cyclic hexaimine (L) formed by cocondensation of two molecules each of hydrazine and 2,6-diacetylpyridine under template conditions gives a complex formulated as $[ScL(H_2O)_2](ClO_4)_3 \cdot 4H_2O$. Only four nitrogen atoms of the six are geometrically able to coordinate.[21] The best-known tetradentate macrocyclic amine complexes are those of the porphyrins, however, and a good deal of work has been done on these, usually in conjunction with studies of similar complexes of other metal ions. Much of this attention is due to the relevance to photosynthetic chlorophylls, where a dimer similar to a dimer formed by scandium is proposed to participate in the photosynthetic reaction centres. Octaethylporphyrin (H_2OEP) gives complexes $Sc(OEP)(O_2CMe)$[22] and a dimer (OEP)Sc—O—Sc(OEP). The latter was first prepared by the action of H_2OEP on $Sc(acac)_3$ in imidazole, followed by chromatography on Al_2O_3 and was characterized by NMR, IR and mass spectrometry.[23] A preferred method uses H_2OEP and $ScCl_3$ reacting in hot pyridine, followed by treatment with water and extraction into, and recrystallization from, CH_2Cl_2 giving purple plates. The corresponding tetraphenylporphyrin complex was prepared similarly. The dimer readily dissociates to monomers in alcohols. It shows a two band absorption at ~410 nm and ~550 nm and very strong fluorescence with moderate phosphorescence. The phosphorescence lifetime of

$Sc(OEP)O_2CMe$ is 0.4 s, which is the longest for any porphyrin, while the fluorescent yield of 0.2 is very high. The radiative properties are explained in terms of covalent interactions between the metal and the ring as modified by the probable location of the metal ion above the porphyrin plane.[24] Scandium OEP complexes are reduced to the α,γ-dihydro derivatives on reduction with sodium anthracenide and methanol.[25] The redox potentials of Sc(OEP)OH have been determined by cyclic voltammetry to be: ligand oxidation in PrCN, 1.03 and 0.70; ligand reduction in DMSO, −1.54 ($E_{1/2}$ values in V *vs.* SCE); no metal redox wave was observed.[26]



The dimer (OEP)Sc—O—Sc(OEP) has been examined by optically detected magnetic resonance with the conclusion that the rings are approximately coplanar.[27] The NMR spectra of the dimer and the monomer show that the methylene protons are anisochronous, this probably not being caused by hindered rotation but by the inherent asymmetry of the ligands.[28]

Scandium phthalocyanine (H_2pc) complexes have been obtained and quantum mechanical calculations carried out on these systems. Thus Sc(pc)Cl is obtained from reaction of $ScCl_3$ with either phthalonitrile or with $Li_2(pc)$ and gives a molecular ion in the mass spectrum.[29] The molecular orbitals of scandium (and other) phthalocyanines have been calculated and the electron distribution over the ring system studied in relation to the effect of the scandium ion.[30]

The uncharged tetradentate macrocyclic tetramines Me_4Bz_4[14]-tetraene-N_4 (L) and Me_4[14]-tetraene-N_4 (L′) (**1** and **2**) form complexes $Sc(NCS)_3L$ and $Sc(NCS)_3L'\cdot 0.5(THF)$ when the ligands react with ethereal $Sc(NCS)_3$. IR evidence, namely the appearance of non-hydrogen-bonded NH around 3200 cm^{-1} and the lowering of ν(CN) by 10–40 cm^{-1}, tends to indicate coordination of the tetramines. It is suggested that the complex of the more rigid L is five-coordinated square pyramidal, while the more flexible L′ may permit another anion to coordinate giving six-coordination.[31]

(1)

(2)

39.1.2.3 Amido complexes

Scandium (and the lanthanides) forms a very interesting tris-silylamide $[Sc\{N(SiMe_3)_2\}_3]$ where the eighteen methyl groups are effective in reducing the scandium coordination to its lowest known value of three. Surprisingly, the coordination is pyramidal, with N—Sc—N = 115.5°, possibly owing to van der Waals attractive forces between the ligands. The Sc—N distance is 2.049 Å.[32] This configuration contrasts with the trigonal planar configuration of the tris-aryloxide (*vide infra*). The compound is volatile and very air sensitive. It is prepared by the reaction of $LiN(SiMe_3)_2$ with $ScCl_3$.[33]

39.1.3 Oxygen Donor Ligands

39.1.3.1 β-Diketonates

Scandium tris-β-diketonates are monomers, in contrast to the lanthanide analogues which form oxygen-bridged dimers except in the cases of bulky β-diketonates combined with smaller-radius lanthanides. $Sc(acac)_3$ itself is a compound of some antiquity[34] and has been studied by a number of authors.[35–38] Other β-diketonates are also known: $Sc(tfaa)_3\cdot 3H_2O$,[36] $Sc(hfaa)_3$,[36] $Sc(tta)_3$,[39] $Sc(baa)_3$,[35] $Sc(bza)_3$,[40] $Sc(dbm)_3$[39] and $Sc(dpm)_3$[36,41] (Htfaa = 1,1,1-trifluoroacetylacetone, Hhfaa = 1,1,1,5,5,5-hexafluoroacetylacetone, Htta = thienoyltrifluoroacetone, Hbaa = 3-bromoacetylacetone, Hbza = benzoylacetone, Hdbm = dibenzoylmethane and Hdpm = dipivaloylmethane). The heat of sublimation of $Sc(acac)_3$ is 99.6 kJ mol^{-1} which is comparable with those of the iron and vanadium analogues.[42] The first stability constant K_1 for Sc^{3+}–acetylacetonate is two to three orders of magnitude larger than for the lanthanides.[43] The

^{1}H NMR spectrum of $Sc(acac)_3$ has been measured,[35,41] and a ^{13}C NMR study in $CDCl_3$ has also been reported.[44]

Two single crystal structural determinations of tris-β-diketonates have been reported. [$Sc(acac)_3$] shows nearly D_3 symmetry[45] with monomeric six-coordination. The Sc—O interatomic distance is 2.070 Å which would give an ionic radius for Sc^{3+} of 0.67 Å for six-fold coordination to oxygen. The other example[46] is [$Sc(trop)_3$] which shows crystallographic D_3 symmetry with Sc—O = 2.102 Å.

The mass spectrometry of scandium β-diketonates, which are fairly volatile, has been the subject of several studies. In an earlier study, dimeric species were detected in the mass spectra of the vapour.[47] The compounds $M(RCOCHCOCF_3)_3$ where M = Sc or Y and R = Me, Ph, 2-thienyl or 2-furyl showed fluorine migration in their mass spectra, ions containing CF_2 groups being observed.[48] The mass spectra of scandium (and Y and lanthanide) acetylacetonates and dipivaloylmethanates and some adducts with bipyridyl, phenanthroline or Ph_3PO have been examined and detailed fragmentation schemes proposed. Appearance potentials of the mono and bis β-diketonates were measured, but no adducts of the dipivaloylmethanates were detected in the spectra.[49,50] Russian authors have also examined the vapour phase chromatography of $Sc(acac)_3$.[51]

The tris-β-diketonates fairly readily form the tetrakis-diketonate anions. Thus the compounds M[Sc(diket)$_4$], where M = K, Rb, Cs and diket = $CF_3COCHCOMe$, $CF_3COCHCOMe$ or $CF_3COCHCOCF_3$, have been synthesized by the reaction of Sc(diket)$_3$ with M(diket) in equimolar proportions in ethanol or ethanol/CCl_4. X-Ray powder and thermogravimetric studies were made. The hexafluoro compounds M[$Sc(CF_3COCHCOCF_3)_4$] were particularly stable, subliming without decomposition at 0.1 mmHg, though Cs[$Sc(CF_3COCHCOMe)_4$] decomposes into [Sc(diket)$_3$] on attempted sublimation.[52,53] The tetrakis-tropolonate adducts $HSc(trop)_4$ and $NaSc(trop)_4$ have been prepared[54] and the structure of the former has been determined by single crystal X-ray.[55] Scandium is eight-coordinated to four bidentate ligands: three tropolonate anions and one uncharged tropolone molecule. The latter forms a hydrogen bond with a neighbouring molecule giving a dimeric structure, each dimer unit having two hydrogen bonds with O···O = 2.484 Å. The coordination geometry is intermediate between bicapped trigonal prismatic and dodecahedral, with Sc—O in the range 2.161–2.310 Å.

39.1.3.2 Carboxylates and hydrated carboxylates

Scandium complexes readily with carboxylic acid anions, and the resulting solid compounds often have a polymeric structure with a resulting tendency towards insolubility. The formate, prepared from the hydroxide and the acid,[56] is a three-dimensional network where scandium ions are connected by bridging HCO_2^- ions. The coordination around Sc^{3+} is nearly octahedral with the average Sc—O distance equalling 2.03 Å.[57] The hydrated oxalate $Sc_2(C_2O_4)_3(H_2O)_6$ has a polymeric structure in which the Sc^{3+} ion is approximately dodecahedrally coordinated with two water molecules and three bidentate $C_2O_4^{2-}$ anions, the latter bridging to other Sc^{3+} ions by means of their remaining carboxylate oxygen atoms. The Sc—O distances lie in the range 2.18–2.26 Å.[58]

The hydrated basic malonate $Sc(OH)(C_3H_2O_4)H_2O{\cdot}H_2O$ is approximately octahedrally coordinated, each Sc^{3+} being linked to three carboxylate oxygen atoms, two hydroxyl ions and one water molecule, with Sc—O in the range 2.05–2.12 Å. In this structure a linear hydroxo- and malonato-bridged polymer is three-dimensionally cross-linked by hydrogen bonds.[59] The hydrated hydroxyacetate $Sc(HOCH_2CO_2)_3(H_2O)_2$ is found to have the constitution $[Sc(HOCH_2CO_2)_2(H_2O)_4][Sc(HOCH_2CO_2)_4]$ with each type of Sc^{3+} being approximately dodecahedrally coordinated and the hydroxyacetate anions each coordinating by the hydroxo oxygen and one carboxylate oxygen giving a five-membered ring chelate.[60] It will be noticed that in these carboxylate structures, scandium is very much on the borderline between six- and eight-coordination with Sc—O at about 2.05 Å for the former and about 2.20 Å for the latter. The sterically inefficient seven-coordination is not observed.

The complexation constants K_1 for interaction of Sc^{3+} ions with substituted and unsubstituted carboxylates in aqueous solution have been determined potentiometrically at 25 °C and 0.1 M KNO_3 ionic background. They are listed in Table 1, the ΔH values being derived with the aid of additional measurements at 40 °C.[61] These values for scandium are greater than those for the lanthanides by roughly one order of magnitude.[62]

Table 1 Complexation Between Aqueous Carboxylic Acids and Scandium[61]

Acid	*log K*	$-\Delta G$ (kJ mol^{-1})	$-\Delta H$ (kJ mol^{-1})
α-Hydroxyisobutyric	4.84	27.6	115
Isobutyric	4.47	25.5	90.1
Glycolic	4.40	25.5	121
Acetic	3.48	19.6	1.2
Propionic	3.77	21.3	8.8
Mandelic	2.91	16.7	−5.4
D-Gluconic	4.21	23.8	−52.3
Acetylacetone	7.77	44.3	388

39.1.3.3 Hydrates and complexes with oxyanions

There is rather little definitive information on the hydrated Sc^{3+} ion, which is generally agreed to be $[Sc(H_2O)_6]^{3+}$ This ion, together with its interaction with anions in aqueous solution, has been studied by ^{45}Sc NMR. Thus nitrate, perchlorate and chloride were all found to complex with the hydrated Sc^{3+} ion,[63] and in aqueous solution containing HCl at various molarities, the following species were believed to be present: $[ScCl(H_2O)_5]^{2+}$ (4 M), $[ScCl_2(H_2O)_4]^{+}$ (7 M), and $[ScCl_4(H_2O)_2]^{-}$ (saturated).[64] The IR and Raman spectra of the hydrated Sc^{3+} ion have been reported.[65]

A variety of hydroxoscandates are known. On hydrolysis of $Sc^{3+}(aq)$ in 0.1 M KNO_3 at 25 °C, potentiometric studies indicated the formation of $[Sc(OH)(H_2O)_x]^{2+}$, $[Sc_2(OH)_2(H_2O)_x]^{4+}$ and $[Sc_3(OH)_5(H_2O)_x]^{4+}$, and formation constants were evaluated.[66] A number of solid hydroxoscandates have been isolated but their structures are not well established. Most reported species are tetra- or hexa-hydroxoscandates but $K_2Sc(OH)_5(H_2O)_4$ has been obtained from a solution of scandium and potassium hydroxides.[67] The hexahydroxo compound $Na_3Sc(OH)_6(H_2O)_2$ has been isolated from an aqueous solution of scandium and sodium hydroxides[68] and decomposes into the tetrahydroxo compound and NaOH at temperatures above 120 °C.[69] The anhydrous compound $Na_3Sc(OH)_6$ may be obtained from reaction in methanol[70] or by gently heating the hydrate. The Group II analogues $M_3Sc_2(OH)_{12}$ (M = Ca or Ba) and $MSc_2(OH)_8(H_2O)_2$ (M = Ca, or Sr) have been obtained in crystalline form.[71]

A number of well-defined nitrato complexes have been established. As mentioned above, the nitrate ion complexes with Sc^{3+} even in water, and the ion $[Sc(NO_3)_5]^{2-}$ is stable in concentrated aqueous nitric acid. Salts of this anion of the type $M_2[Sc(NO_3)_5]$, where M = K, Rb or Cs, have been obtained.[72] From $ScCl_3$ and N_2O_4 in ethyl acetate was obtained $(NO)_2[Sc(NO_3)_5]$ from which a single crystal X-ray analysis showed scandium with the very high, for this metal, coordination number of nine, four NO_3^- being bidentate and one monodentate, with Sc—O being 2.283 Å and 2.176 Å respectively. The coordination polyhedron is irregular.[73] Some double sulfates $MSc(SO_4)_2$, where M = K, Rb or Cs, have been studied by means of high temperature X-ray powder photography and their phase diagrams determined,[74] but their structures are uncertain.

39.1.3.4 Other uncharged oxygen donor ligands

Scandium coordinates fairly readily with several other types of oxygen donors, especially those with a little negative charge on the oxygen atom, as in $Ph_3P\rightarrow O$. It usually takes a coordination number of six, judging from the stoichiometry of the compounds formed and from structures in the limited number of cases where there are single crystal X-ray data available.

Tetrahydrofuran complexes are among the most studied. The chloride $[ScCl_3(THF)_3]$ has a meridional octahedral structure with Sc—O = 2.18 Å and Sc—Cl = 2.41 Å (mean values).[75] This complex may be simply prepared from a suspension of $ScCl_3{\cdot}6H_2O$ in THF by addition of $SOCl_2$ and reflux.[76] Alternatively, scandium metal may be added to a refluxing solution of $HgCl_2$ in THF; the material obtained thus was characterized by IR spectrum.[77] Other THF complexes include the tetrahydroborate $[Sc(BH_4)_3(THF)_2]{\cdot}2(THF)$. The cation is trigonally

bipyramidally coordinated with the two THF molecules in the axial positions.[78] Tetrahydrofuran often stabilizes organometallic compounds, and the neopentyls $Sc(Me_3MCH_2)_3(THF)_2$, where M = C or Si, can be isolated from reaction of the appropriate lithium reagent with $ScCl_3$ in THF–hexane–ether at 0 °C. NMR data are consistent with a trigonal bipyramidal structure with axially coordinated THF.[79]

A number of compounds of scandium salts with cyclic crown polyethers have been described.[80] They comprise $Sc(NCS)_3$(b-15-c-5)·1.5(THF)·$2H_2O$, $Sc(NCS)_3$(db-18-c-6)$_2$·3(THF), $(ScCl_3)_3$(b-15-c-5)$_2$·H_2O, $ScCl_3$(db-18-c-6)·1.5(THF) and $ScCl_3$(db-18-c-6)·1.5MeCN where (db-18-c-6) is dibenzo-18-crown-6. The characteristic lowering of ν(CO) in the IR spectrum when a crown ether coordinates was minimal in most cases and though evidence for complexation was adduced from the UV spectra, coordination of the crown ligands cannot be regarded as established. In the compound $[Sc(NO_3)_3(H_2O)_2]$·(b-15-c-5), the crown ether is uncoordinated, the Sc^{3+} being eight-coordinated to two H_2O at 2.131 and 2.145 Å and to six O (NO_3) at 2.166–2.256 Å.[81]

There have been a number of studies of urea complexes. Thus the Sc^{3+}–acetate–water–urea (or thiourea) system at 30 °C shows the presence of a phase $Sc(MeCO_2)_3$·(urea)·H_2O but no thiourea complex was observed.[82] The complexes ScX_3 $(urea)_x$ (X = Cl, x = 6 or 4; X = Br, ClO_4 or NO_3, x = 6) have all been isolated[83,84] but structural data other than X-ray powder photographs are lacking, though coordination by the urea is fairly certain as ν(CO) was lowered by some 110 cm^{-1}. However, single crystal data are available for $[Sc(NO_3)_2(urea)_4]NO_3$, where there is coordination to oxygen atoms of four urea molecules and two nitrate groups.[85]

Amine *N*-oxides, phosphine oxides and other phosphoryl compounds and analogous arsenic derivatives, and sulfoxides all give well-defined complexes with scandium. In many cases, authors deal with several of these classes of ligand in the same paper, so it will be most convenient to consider them together here.

Complexes of scandium perchlorates, chlorides and thiocyanates with pyridine oxide, 2-, 3- and 4-picoline oxides, lutidine oxide, bipyridyl dioxide, hexamethylphosphoramide, bis(diphenylphosphino)ethane dioxide $Ph_2P(O)C_2H_4(O)PPh_2$ (dpeo) and the corresponding arsenic compound (daeo), tributylphosphate, trimorpholinophosphine oxide (tmpo) and thioxane oxide (toxo) have been examined. They are mostly obtained from ethanolic solution. The stoichiometry ScX_3L_3 (X = Cl, L = hmpa, tbp or tmpo; X = NCS, L = DMSO, tppo, tpao, pyo, 2-, 3-, 4-pico or luto) was most prevalent for the fairly strongly coordinating chloride or thiocyanate anions, but for the perchlorates, $Sc(ClO_4)_3L_6$ (L = DMSO, pyo, 2-pico, hmpa or toxo) or $Sc(ClO_4)_3L_3$ (L = bipo, dpeo and daeo) were preferred. While no single crystal data are available, it is highly likely that six-coordination is present in most, if not all, of these compounds. The lowering of the S=O or P=O IR frequency on coordination is quite variable, 95 cm^{-1} for $Sc(ClO_4)_3(toxo)_6$, 10 cm^{-1} for $Sc(ClO_4)_3(hmpa)_6$ and almost nil for $Sc(ClO_4)_3(daeo)_3$. IR data indicate the SCN^- ions to be N-coordinated.[86–90]

Structural data are available for $[Sc(NO_3)_3(OPPh_3)_2]$. This complex was obtained by reaction of hydrated scandium nitrate with the phosphine oxide in hot, very dilute, benzene solution. The P—O stretching mode was lowered from 1195 cm^{-1} in the free ligand to 1170, 1140 cm^{-1} in the complex. The scandium ion is eight-coordinated to both phosphine oxides and the three bidentate nitrates in a very irregular dodecahedral arrangement. Leading bond lengths (Å) and angles are Sc—O(P) = 2.036, 2.076; Sc—O(NO_3) = 2.207–2.338; Sc—O—P = 161.2°, 174.8°.[91]

The kinetics of ligand exchange of some phosphoryl-coordinated complexes of scandium are of a convenient rate to be studied by NMR lineshapes. $[Sc\{OP(OMe)_3\}_6]^{3+}$ exchanges with free ligand in CD_3CN, *sym*-$C_2D_4Cl_2$ or CD_3NO_2. In the first two solvents, rate is independent of the concentration of added ligand (CD_3CN: $\Delta H^{\ddagger}$ = 29.8 kJ mol^{-1}; $\Delta S^{\ddagger}$ = −111 J K^{-1} mol^{-1}) but in CD_3NO_2, exchange rates are first order in each reactant.[92] Similar studies have been made on analogous $(MeO)_2P(O)Me$ systems.[93]

39.1.3.5 Alkoxides

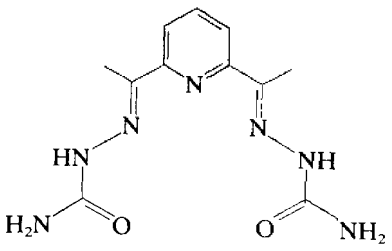
Some well-defined scandium alkoxides have been synthesized and studied (together with lanthanide analogues). The compounds are $[Sc(OR)_3]$, $Sc(OR)_3(THF)$, $Sc(OR)_3(tppo)$ and $(RO)_2Sc(\mu\text{-}OR)_2Na(THF)$, where R = 2,6-di-*t*-butyl-4-methylphenate. $[Sc(OR)_3]$ was prepared by reaction of $Sc\{N(SiMe_3)_2\}_3$ with ROH in hexane at 20 °C followed by reflux, or by reaction of NaOR and $ScCl_3$ in boiling THF, or by sublimation of $Sc(OR)_3(THF)$. The latter and

$Sc(OR)_3(tppo)$ are prepared by direct addition of ligand to $Sc(OR)_3$ in benzene at 20 °C. The bridged compound is obtained together with $Sc(OR)_3(THF)$ by reaction of NaOR·THF on $ScCl_3$ followed by appropriate work-up. These compounds are soluble in hydrocarbons and of course very easily hydrolyzed. Single crystal X-ray data are available for $Sc(OR)_3$; the coordination is trigonal planar (O—Sc—O = 123.3° + 120.1° + 115.1° = 358.5°) with Sc—O = 1.854–1.889 Å. Sc—O—C is not quite linear, averaging 168.4°.[94]

39.1.3.6 Amides

A few complexes of organic amides such as dimethylformamide and dimethylacetamide are known, *e.g.* $Sc(NCS)_3(DMF)_3$, and $Sc(ClO_4)_3L_3$, where L = *N,N,N',N'*-tetramethylmalonamide. In the latter complex, IR, conductimetric (1:3 electrolyte) and X-ray measurements indicate a six-coordinated complex $[ScL_3](ClO_4)_3$.[95] NMR rate measurements on ligand exchange of $[ScL_6]^{3+}$, where L = *N*-mono (or di) alkyl formamides or acetamides, showed that the acetamides exchanged considerably faster than the formamides. It was concluded that steric interactions due to the introduction of the carbonyl-attached alkyl group were of importance, rather than inductive effects.[96]

39.1.4 Ligands Containing Both Nitrogen and Oxygen Donors



Scandium complexes readily with 8-hydroxyquinolinate ion. Many years ago, $Sc(hq)_3$·Hhq, which was obtained from aqueous solution, was described,[97] and this compound does not lose Hhq cleanly on heating but does so in benzene solution.[98] However, it has been stated that the solid deposited at about pH 7 is in fact $Sc(hq)_3$.[99] More recently, stability constant values have been determined for the $Sc^{3+}/hq^-/50\%$ aqueous dioxane system and the corresponding 2-methyl-8-hydroxyquinoline system.[100] Chinese workers, who are showing some interest in spectrophotometric analysis, have detected Sc^{3+} on the microgram scale by fluorometry using 8-hydroxyquinoline-5-sulfonate and cetyltrimethylammonium bromide as an extractant system.[101]

There have been rather few investigations describing complexes of scandium with simple amino acids. There are Russian papers describing the isolation from aqueous solutions of several such complexes but it is not clear whether both the amino and the carboxylate groups are coordinated; in some cases IR criteria were used as evidence for coordination of the carboxylate group. Among compounds isolated were $Sc(glut)(Hglut)\cdot 3H_2O$, $Sc_2(glut)(Hglut)_4\cdot 5H_2O$, and several compounds of the type $Sc_2(SO_4)_3\cdot A_x\cdot (H_2O)_y$ where A is an uncharged amino acid.[102] Various concentrations of $ScCl_3$, acid and potassium salt of acid at pH 2–7 gave $Sc(OH)(anth)_2\cdot H_2O$ and $Sc(anth)_3$ (anth = anthranilate anion) and the corresponding *p*-aminobenzoates.[103]

With amino acids of the polydentate chelating type, there are a number of studies. Thus $Sc_2(ida)_3\cdot H_2O$, $ScCl(ida)\cdot 2H_2O$ and $KSc(ida)_2\cdot 3H_2O$ have been isolated and studied by thermal and IR methods.[104] Association constant values have been obtained for edta ($\log K = 23.1 \pm 0.15$) at 20 °C and $\mu = 0.1$ by polarography,[105] and for diethylenetriaminepentaacetic acid, where $\log K = 26.28 \pm 0.37$.[106] These values are rather greater than corresponding ones for the lanthanides. The rate of exchange of KSc(edta) with added ligand has been determined by NMR and was found to be slower than for the lanthanum analogue.[107] The exchange of $^{46}Sc^{3+}$ with the scandium complex of *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate has been studied, also by NMR. The exchange proceeds by way of dissociation of a protonated complex. Activation parameters were obtained.[108] The interaction has been studied by potentiometry between edta or nitrilotriacetic acid complexes of scandium and a variety of added phenols in anionic form. Mixed ligand complexes were observed and *K* values obtained.[109]

There has been some interest in complexes of a class of ligands formed by aldimine-type condensations, either free or scandium-templated, giving complexes where polydentate ligands, which may be coplanar or non-coplanar, complex the scandium ion. Thus β,β',β''-triaminotriethylamine condenses with three molecules of 3,5-dichlorosalicylaldehyde to yield a potentially heptadentate ligand H_3saltren, $N(CH_2CH_2N{=}C{-}R)_3$, where R = 3,5-dichloro-6-hydroxybenzene, which yields the complex [Sc(saltren)]. However, on steric grounds it is unlikely that the tertiary amine nitrogen coordinates with scandium, though it probably coordinates in the analogous lanthanide complexes. This is because of steric limitations of the ligand, not because

of the incapacity of Sc^{3+} to accept seven-coordination.[110] There is a case, however, where scandium is forced into the inefficient pentagonal bipyramidal seven-coordination by a coplanar quinquedentate ligand. This is formed by condensation of 2,6-diacetylpyridine with two molecules of semicarbazide giving a three-nitrogen, two-oxygen donor, dapsc (**3**). Four of the nitrogen atoms are unable to coordinate for steric reasons. The complex $[Sc(dapsc)(H_2O)_2](OH)(NO_3)_2$ was obtained from aqueous alcohol. The ligand is very nearly coplanar with an average deviation of only 0.023 Å, and the two water molecules are in the axial positions. Internuclear distances are Sc—O = 2.110 (av) and Sc—N = 2.283 (av) Å.[111]

(**3**)

39.1.5 Complex Halides

Association constants between Sc^{3+} and fluoride ion in aqueous solution have been obtained.[112] They are as follows ($\Delta H^{\ominus}_{298}$ values in kJ mol^{-1} in parenthesis): $K_1 = 1.2 \times 10^7$ (1.3), $K_2 = 6.4 \times 10^5$ (−6.3), $K_3 = 3.0 \times 10^4$ (−3.3), $K_4 = 7 \times 10^2$. Although only ScF_4^- has thus been observed in solution, salts of ScF_6^{3-} have been isolated in the solid state. Thus M_3ScF_6 (M = NH_4, Na or K) is obtained by action of aqueous scandium ion.[113] Both $(NH_4)_3ScF_6$ and Na_3ScF_6 exist in high temperature (α) and low temperature (β) forms; the former salt[114] is cubic (α) and tetragonal (β) while the latter[115] has a monoclinic β form. The Raman spectrum of $(NH_4)_3ScF_6$ has been reported in terms of O_h symmetry for the ScF_6^{3-} ion, as A_{1g}, 504; E_g, 370; T_{2g}, 240 cm^{-1}.[116] Other fluoro species have been obtained from aqueous media, namely $NaScF_4 \cdot H_2O$ and $MScF_4$ (M = Na or K).[115,117] The thermal decomposition of $(NH_4)_3ScF_6$ yields NH_4ScF_4 at around 200 °C.[118]

Scandium complexes with chloride ion in aqueous solution, and there is ion-exchange evidence for anionic species, presumably $ScCl_4^-$ aq, in concentrated hydrochloric acid,[119] while values of $K_1 = 90$ and $K_2 = 37$ for the first two association constants have been reported.[120] Solid salts of the anions $ScCl_6^{4-}$, $Sc_2Cl_9^{3-}$ and $ScCl_5^{2-}$ have been isolated with alkali metal cations.[121,122] It seems likely that both the first two species are octahedral and bridged-octahedral respectively, in line with $Cs_2NaScCl_6$ which has an X-ray powder pattern in accord with a face-centred cubic structure.[123]

The first two association constants between Sc^{3+} and Br^- in aqueous solution are $K_1 = 120$ and $K_2 = 10$ respectively.[120] Despite the greater radius of the bromide ion, Sc^{3+} should be amply large for six-coordination by this ligand and the complexes M_3ScBr_6 and $M_3Sc_2Br_9$ (M = Na, K, Rb or Cs) which are formed in the solid state[124,125] are almost certainly six-coordinated like the chloride which they resemble in stoichiometry. The formation of $[ScX_6]^{3-}$ (X = Cl or Br) in aqueous solution is proposed as an intermediate in the preparation of ScX_3 from aqueous media;[126] ScI_3 cannot be obtained in this way and indeed, the formation of any substantial quantity of iodo complex would not be expected in water. As noted above (Section 39.1.3.3) however, ^{45}Sc NMR detected only $[ScCl_4(H_2O)_2]^{2+}$ in aqueous solution,[64] no $ScCl_6^{3-}$ species being recorded. The nature of scandium and lanthanide chloro complexes has been examined by ultrasonic absorption in 0.2 M solutions of aqueous methanol. Scandium behaved differently from the lanthanides but no firm conclusions were possible.[127]

There are a number of solid phases of the types $MScCl_x$ and $ScCl_x$ where the formal oxidation state of scandium is less than three. They are usually made by direct combination at elevated temperatures of MCl, $ScCl_3$ and metallic scandium. Their structures often show evidence of Sc—Sc bonds. Thus $CsScCl_3$ is made by action of Sc on $Cs_3Sc_2Cl_9$ at 700 °C. The shiny blue product has the hexagonal perovskite $CsNiCl_3$ structure. This is similar to the $Cs_3Sc_2Cl_9$ structure but with all Sc positions filled. Non-stoichiometric phases exist between the two end structures.[128] When scandium is heated with $ScCl_3$ at 940–960 °C in a sealed Ta

container for several weeks, Sc_5Cl_8 is obtained. Its structure contains two types of chain which are interlinked by bridging chlorine atoms. Both types consist of linear arrays of octahedra, each linked to the next octahedron at two adjacent vertices. One chain consists of chlorine atoms with Sc at the centre of each octahedron, while the other type consists of scandium atoms, some of which are coordinated to Cl. The bonded Sc—Sc distance is 3.021 Å (Sc—Sc is 3.26 Å in the metal).[129] At 890–900 °C, Sc_7Cl_{12} is obtained. This contains Sc^{3+} ions and $Sc_6Cl_{12}^{3-}$ clusters, in which Sc—Sc distances of 3.204 and 3.234 Å are observed.[130]

39.2 YTTRIUM AND THE LANTHANIDE ELEMENTS

39.2.1 Introduction

The study of coordination compounds of the lanthanides dates in any practical sense from around 1950, the period when ion-exchange methods were successfully applied to the problem of the separation of the individual lanthanides,[131–133] a problem which had existed since 1794 when J. Gadolin prepared mixed rare earths from gadolinite, a lanthanide iron beryllium silicate. Until 1950, separation of the pure lanthanides had depended on tedious and inefficient multiple crystallizations or precipitations, which effectively prevented research on the chemical properties of the individual elements through lack of availability. However, well before 1950, many principal features of lanthanide chemistry were clearly recognized, such as the predominant trivalent state with some examples of divalency and tetravalency, ready formation of hydrated ions and their oxy salts, formation of complex halides,[134] and the line-like nature of lanthanide spectra.[135]

Since 1950 and at an ever-increasing pace during the last 20 years, the picture of lanthanide coordination chemistry has become much broader and clearer. The use of anhydrous conditions and a sophisticated variety of ligands has led to an extensive nitrogen ligand chemistry, a great extension of oxygen ligand chemistry, the discovery of reactive organolanthanide complexes, and the beginnings of phosphorus and sulfur donor chemistry. There have been other important advances also, including syntheses of macrocyclic complexes and cryptates, investigations of electronic spectra in terms of crystal field effects, and the introduction of lanthanide NMR shift reagents. So extensive has lanthanide chemistry now become, that coverage and selection of material for inclusion in this review poses, in some areas of activity, considerable problems, and an apology is offered to those authors whose fine work has through pressure of space, or perhaps even through inadvertence, been omitted.

The most stable state of the lanthanides in their complexes is in all cases the M^{3+} ion, in which all outer electrons reside in the 4*f* shell, in contrast to the uncharged atom M where, in addition to the 4*f* and 6*s* electrons, the 5*d* shell may be partly occupied. The M^{4+} ions also have all outer electrons in the 4*f* shell, but there is partial 5*d* occupation in some M^{2+} ions.

Ionic radii of the M^{3+} ions range from 1.06 to 0.85 Å and a graphical plot shows a shallow cusp shape whose origin has been discussed,[136–138] and which arises only partially in an analogous manner to the corresponding effect in the 3*d* transition metals (being much less pronounced because the ligand field–4*f* electron interaction is much weaker than in the 3*d* series) but is probably mainly due to 4*f*–4*f* interactions. A strictly comparable set of values for ionic radii is difficult to obtain, as structures and coordination numbers usually change along the series.

The large ionic radii, combined with the generally electrostatic nature of the metal–ligand bonding in complexes of these metals, lead to high coordination numbers.[139] Where the ligands are not sterically hindered, but are not chelate or polydentate with some of the ligand–ligand repulsion subsumed within the ligand, coordination numbers of nine to six are usually shown, depending on the relative cation/anion radii. Examples are $[La(H_2O)_9]^{3+}$ and $[LaBr_6]^{3-}$. Where the ligands, such as NO_3^-, themselves contain close pairs of donor atoms, coordination numbers up to 12 may be obtained, as in $[La(NO_3)_6]^{3-}$. Coordination polyhedra are not governed by considerations arising from covalency or strong crystal fields, as in the *d* transition metals, with their emphasis on regular geometries such as square planar or octahedral. Lanthanide coordination geometries are governed purely by minimization of repulsive terms. These terms usually arise from ligated atom–ligated atom repulsions but in the case of bulky ligands non-ligated interactions are important also. The steric requirements of polydentate ligands, in the sense that for example a terpyridyl complex must of course contain a roughly coplanar LnN_3 system, have also to be taken into account.

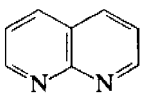
In a useful series of papers,[140–143] Kepert has considered high coordination number stereochemistries, including lanthanide examples, on the basis of a point-charge repulsion model, where the point charges lie on the surface of a sphere and are constrained only by intraligand factors.

For bulky ligands, the cone-angle approach, developed mainly for actinide complexes but equally applicable to lanthanides, is available.[144] A cone of sufficient solid angle to enclose the whole ligand is drawn, using suitable van der Waals radii for the non-ligated atoms. The ligand cone angles are then summed and for stable complexes the sum is found empirically to lie near to $0.80 \times 4\pi$. This enables coordination numbers to be rationalized or predicted. Coordination numbers lower than six are sometimes obtained with bulky ligands, particularly in the organo- and alkylamido-lanthanide area. In the case of all the ligands of a complex having very similar steric requirements, regular or semiregular polyhedra may be obtained, particularly in the cases of six-coordination (octahedron), eight-coordination (dodecahedron) and nine-coordination (face-centred trigonal prism). Other regular or semiregular polyhedra, namely the tetrahedron, trigonal prism, square antiprism and distorted icosahedron (point group *O*) are sometimes observed. Where ligands are unequal in their steric requirements then irregular polyhedra occur. There is a considerable tendency on the part of some authors to rationalize these irregular polyhedra of high coordination number in terms of semiregular polyhedra; thus a nine-coordinated complex might well be described as of distorted capped square antiprismatic shape. These descriptions tend to have little significance and such a complex could probably be described equally well as distorted face-centred trigonal prismatic.

39.2.2 Nitrogen Donor Ligands

39.2.2.1 Bipyridyls, o-phenanthrolines and 1,8-naphthyridines

These ligands are now well represented in complexes with the lanthanides, but were not investigated until 1962, when a study[145] in aqueous solution using a Job's plot method, *e.g.* at 451 nm for Ho^{3+}, showed that a complex $Ho(phen)_2^{3+}$ was formed. Pr, Nd and Er tripositive ions were also studied, but no solid products were characterized. Indeed, stability constants in water are possibly too low for a solid complex to be isolated. A little later, there were several reports[146–151] of the isolation of bipyridyl and 1,10-phenanthroline complexes from ethanolic solution. It is perhaps of interest that at this time, the lanthanides were believed not to form stable amine complexes and the role of higher coordination numbers in lanthanide complexes was not fully appreciated. Complexes isolated included the stoichiometries $M(NO_3)_3(bipy)_2$, where M = La–Lu;[146,148,151] $M(NCS)_3(bipy)_3$, where M = La, Ce, Dy;[151] $M(MeCO_2)_3(bipy)$, where M = Pr, Nd, Yb;[151] $MCl_3(bipy)_2H_2O$, where M = La–Nd;[151] $MCl_3(bipy)_2$, where M = Eu, Gd, Ho–Lu;[151] $M(NO_3)_3(phen)_2$, where M = La–Lu;[147,150] $M(NCS)_3(phen)_3$, where M = La–Lu;[147,149] $M(NCS)_3(phen)_2$, where M = Yb;[147–149] and $La(ClO_4)_3(phen)_4$.[152] The crystal structure of $[La(NO_3)_3(bipy)_2]$ has been determined. The La^{3+} ion is irregularly ten-coordinated, with La—N = 2.59 Å average.[153]



These complexes, which either are salts, or at least contain coordinated anionic ligands in which case a large Ln–ligand bond moment should result from the rather electrostatic nature of the bond, tend to be insoluble in solvents other than polar solvents in which they dissociate. Hence physicochemical studies in solution are limited. However, solid state fluorescence spectra of phenanthroline and bipyridyl complexes of Eu have been obtained[154] and correlated with the molecular site symmetry (for a discussion of this type of fluorescence, see Section 39.2.7.2). Magnetic susceptibility values have been measured[150] for the series of complexes $M(NO_3)_3(phen)_2$ at 293 K and are (BM) as follows: La, 0; Ce, 2.46; Pr, 3.48; Nd, 3.44; Sm, 1.64; Eu, 3.36; Gd, 7.97; Tb, 9.81; Dy, 10.6; Ho, 10.7; Er, 9.46; Tm, 7.51; Yb, 4.47; Lu, 0. These values correspond closely with the calculated values.[155] The complexes $Ln(NO_3)_3$(4,4-di-*n*-butyl-2,2′-bipyridyl)$_2$ and $Ln(NO_3)_3$(5,5′-di-*n*-butyl-2,2′-bipyridyl)$_2$ are soluble in organic solvents and give NMR spectra which show paramagnetic shifts.[156] These were at first believed to be of a covalently induced, or contact, nature but it later[157] became evident that they incorporate a substantial dipolar, or pseudocontact, component also. Electronic spectra of these complexes were also obtained in solution.[158] They showed only a small nephelauxetic effect with $\beta = 0.96$, which indicated very little covalent character in the Ln—N bond.

The solubility in chloroform of the 4,4′-di-*n*-butyl-2,2′-bipyridyl (L) complex $Eu(NO_3)_3L_2$ enabled an NMR study of the kinetics of the ligand exchange shown in equation (1) to be

carried out.[157] Temperature–line width plots showed that the reaction was first order in $Eu(NO_3)_3L_2$ but zero order in L and therefore presumably proceeded by a dissociative mechanism, with $\Delta G^{\ominus}_{273} = 72\ kJ\ mol^{-1}$.

$$Eu(NO_3)_3L_2 + L^* \longrightarrow Eu(NO_3)_3LL^* + L \quad (1)$$

The ligand 1,8-naphthyridine (**4**; naph) is enabled by its very short N—N distance to form complexes with lanthanide ions which have very high coordination numbers. Thus when anhydrous solutions of lanthanide perchlorates in ethyl acetate were treated with this ligand, complexes $[Ln(naph)_6](ClO_4)_3$, where Ln = La–Pr, or $[Ln(naph)_5](ClO_4)_3$, where Ln = Nd–Eu, were formed.[159] These formulations as 12- or 10-coordinated complexes respectively were fairly well established by IR, conductivity, and particularly by their paramagnetic NMR shifts which were independent of dilution, showing that all 1,8-naphthyridines were coordinated in nitromethane solution. An X-ray structure of $[Pr(naph)_6](ClO_4)_3$ showed[160] icosahedral coordination distorted by the difference between intraligand N—N distances (2.257 Å) and interligand distances (2.890–3.195 Å). (Figure 1). Pr–N distances are comparatively great at 2.735–2.768 Å, and this undoubtedly reflects the considerable interligand repulsions. Other complexes of 1,8-naphthyridines have been described,[161] namely $M(NO_3)_3L_2$ (M = Y, La–Yb, L = naph; M = Y, Sm–Yb, L = 2,7-dimethyl-1,8-naphthyridine), where the coordination number is probably 10.

(**4**)

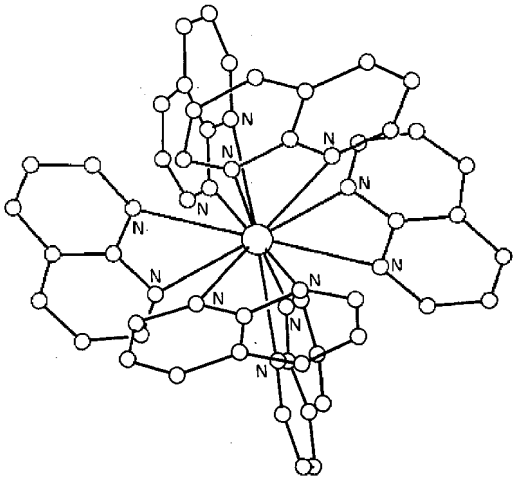


Figure 1 Structure of the $[Pr(naphthyridine)_6]^{3+}$ ion (reproduced with permission from ref. 160. Copyright, American Chemical Society, 1977)

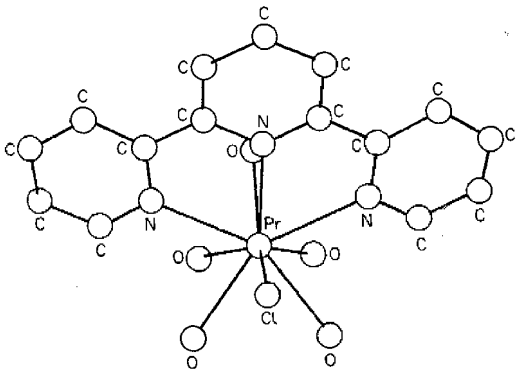
39.2.2.2 2,2':6',2''-Terpyridyl

Despite being tridentate, this ligand is inferior to water in competition for coordination sites on lanthanide ions and non-aqueous solvents are used for preparative reactions. Using the poorly coordinating perchlorate as counterion, a complex $[M(terpy)_3](ClO_4)_3$, where M = La, Eu or Lu, is obtained.[162] The fluorescence spectrum of the Eu complex supported a nine-coordinated D_3 configuration with three terpyridyl ligands each bound by all three nitrogen atoms, a structure confirmed by X-ray.[163] Under different conditions, the 1:1 complex hydrated chlorides $MCl_3(terpy)(H_2O)_n$, where M = Ce–Gd may be obtained.[164] They have variable amounts of water of hydration, and the X-ray structure[165] of $[PrCl(terpy)(H_2O)_5]Cl_2 \cdot 3H_2O$ showed nine-coordination also (Figure 2). In these compounds,

Eu—N distances were 2.57–2.62 Å, while the Pr—N distances were 2.63–2.64 Å, with Pr—Cl at 2.88 Å and Pr—O at 2.48–2.54 Å. The visible spectra of the monoterpyridyl complexes have been used to investigate the nephelauxetic effect arising from the M—N bonds.[148]



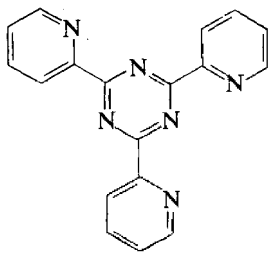


Figure 2 Structure of the cation of $[PrCl(terpyridyl)(H_2O)_5]Cl_2 \cdot 3H_2O$. The structure of this complex would have been impossible to establish by other means than diffraction, and the same is true for many other lanthanide complexes, owing to the lanthanides' great variety of coordination patterns (Reproduced with permission from ref. 165. Copyright, American Chemical Society, 1971)

Complexes of 2,4,6-tri-α-pyridyl-1,3,5-triazine (**5**) have also been prepared.[166] This readily available ligand is rather similar to terpyridyl in its stereochemistry and coordinating properties, and 3:1, 2:1 and 1:1 complexes were obtained. The rates of ligand-exchange reactions of the tris-terpyridyl complexes are quite slow, doubtless because of the considerable negative entropy change associated with dissociation of the tridentate ligand. Reaction (2) was investigated[167] in nitromethane solution.

(**5**)

$$[Eu(terpy)_3]^{3+} + Tb^{3+} \longrightarrow [Eu(terpy)_2]^{3+} + [Tb(terpy)]^{3+} \quad (2)$$

When irradiated at 360 nm, $[Eu(terpy)_3]^{3+}$ fluoresces at 595 nm while $[Tb(terpy)]^{3+}$ fluoresces at 540 nm; the other species do not fluoresce and hence the reaction kinetics could be followed by measurement of fluorescence intensity giving $k = 1.9 \times 10^{-3}\ s^{-1}$. The reaction was first order in $[Eu(terpy)_3]^{3+}$ and zero order in Tb^{3+}, proceeding as shown in equations (3) and (4). The rapid nature of the second step was confirmed directly in separate experiments by similar means. Dye-laser excited emission and excitation spectra of $[Eu(terpy)_3](ClO_4)_3$ in the solid state and in acetonitrile solution have been measured[168] and evidence has been obtained which was interpreted as pointing towards the presence of some mono- or bi-dentate terpyridyl ligands in addition to those which are tridentate as observed in the X-ray structural determination.

$$[Eu(terpy)_3]^{3+} \xrightarrow{\text{rate determining}} [Eu(terpy)_2]^{3+} + terpy \quad (3)$$

$$terpy + Tb^{3+} \xrightarrow{\text{fast}} [Tb(terpy)]^{3+} \quad (4)$$

39.2.2.3 Dialkylamido complexes

These compounds are not numerous but have some important and unique features. The disubstituted amido group, R_2N^-, forms many complexes with *d* transition metals which have

been extensively investigated, and the case $R = SiMe_3$ has been particularly closely examined.[169] In these compounds, interest attaches both to the effect of the very large cone angle of the $N(SiMe_3)_2$ group and to the nature of the bonding, which may involve metal *d*–N*p*–Si*d* interactions. The lanthanides form the tris(amides) $M(NR_2)_3$ and some adducts and derivatives of these, and the considerable bulk of the ligand is effective in producing a coordination number of three, the lowest known for lanthanides, in some of these compounds.

The compounds $[M\{N(SiMe_3)_2\}_3]$ where M = Y, La–Eu, Gd, Ho, Yb and Lu, have been synthesized by reaction of MCl_3 with $LiN(SiMe_3)_2$.[170,171] They are slightly volatile and very soluble in non-polar solvents. The M—N bond is avidly attacked by traces of water. Single crystal X-ray structural determinations of the europium[172] and neodymium[173] compounds of this isostructural series show an unusual situation. The coordination about the metal ion is pyramidal with Eu—N = 2.259 Å and N—Eu—N = 116.6°. If the metal ion is ignored the symmetry of the ligands is D_3, with the europium ion placed randomly above or below the N_3 triangle to give the slightly pyramidal configuration observed; the pyramidal situation of the metal ion does not reduce the D_3 symmetry of the group of three ligands considered alone. The dipole moment of these compounds is close to zero and hence they must have coplanar MN_3 groups in solution. It is possible that attractive van der Waals forces among the ligands are responsible for a 'squeezing' of the metal ion upwards into a pyramidal position in the crystalline state.

Reaction of $OPPh_3$ with the tris(silylamides) gave two different products.[174,175] With about one molecular proportion of Ph_3PO, the expected adducts $[M\{N(SiMe_3)_2\}_3OPPh_3]$ were obtained, and the crystal structure of the lanthanum compound showed a nearly tetrahedral configuration with La—N = 2.38–2.41 Å, O—La—N = 104.8–107.8° and N—La—N = 109.2–116.4°. The P—O—N system was nearly linear at 174.6°. Attempts to prepare bis(phosphine oxide)-substituted compounds using 2–5 molar proportions of $OPPh_3$ surprisingly yielded $[(Ph_3PO)\{N(SiMe_3)_2\}_2M(\mu\text{-}O_2)M\{N(SiMe_3)_2\}_2(OPPh_3)]$. The origin of the peroxy group is obscure; it could not have been introduced by air or traces of peroxides. The same compounds could be obtained by reaction of 0.5 mol $(Ph_3PO)_2{\cdot}H_2O_2$ with the tris(silylamides). An X-ray structural determination of the lanthanum complex showed a five-coordinated structure with each metal ion coordinated to two silylamide N, one phosphine oxide O and the two peroxide O atoms. The La·O_2·La system is coplanar, with La—O = 2.33 and 2.34 Å, and O—O = 1.65 Å. Again, La—O—P is nearly linear at 172.6°, with La—O = 2.42 Å; La—N is similar to the tris(silylamide) and the monophosphine oxide adduct, at 2.37 and 2.49 Å. There was evidence from the UV absorption spectra that the amide ligand was a particularly effective σ donor relative to donors such as H_2O or Cl^-, the nephelauxetic parameter β taking values of 0.993 (Pr) and 0.978 (Nd) for the tris(amides).

Compounds of the less severely hindered di-2-propylamido group have also been reported.[176] These are $Nd\{N(CHMe_2)_2\}_3(THF)$ and $M\{N(CHMe_2)_2\}_3$ where M = Y or Yb. It is significant that the Nd compound was isolated with coordinated THF which was not removed under vacuum, while the compounds of the smaller Y and Yb ions were presumably too sterically crowded to allow adduct formation by this weak ligand. These compounds were less stable than the tris (trimethylsilylamido) analogues, decomposing at 80 °C and 10^{-4} mmHg.

39.2.2.4 Other nitrogen donors

Although ammonia undoubtedly forms complexes with lanthanide ions, these materials are not fully characterized.[177] The aliphatic polyamines, however, form a fairly extensive series of complexes, but must be prepared in completely anhydrous conditions as they are avidly hydrolyzed to hydroxy species which form insoluble precipitates. With ethylenediamine, tetrakis complexes $MX_3(en)_4$ were obtained for M = La–Yb, $X = NO_3$; or for M = La–Lu, X = Cl; or for M = La, Nd, Gd, X = Br. These series showed IR evidence of discontinuities of structure, the nitrates being formulated $[M(en)_4(NO_3)](NO_3)_2$ for M = La–Sm, but $[M(en)_4](NO_3)_3$ for the remainder of the series. The tris complexes $[M(en)_3(NO_3)_2]NO_3$, where M = Gd–Ho, and $MX_3(en)$ where M = Gd, Er and X = Cl; or M = Gd and X = Br, were also obtained, as were tetrakis(perchlorates) $[M(en)_4](ClO_4)_3$ where M = La–Nd.[178,179] Bis complexes of triethylenetetramine[180,181] and tris and bis complexes of diethylenetriamine[182] have also been described. They are exemplified by $[M(dien)_3](NO_3)_3$ where M = La–Gd, and $[M(trien)_2](ClO_4)_3$ where M = La–Ho. The exchange of ligand between $[Nd(trien)_2]^{3+}$ and

trien in acetonitrile has been studied and is believed to proceed by way of an intermediate when trien is not fully coordinated.[183]

Turning now to complex thiocyanates and azides, where the pseudohalide is a nitrogen donor, the series $[NBu^t_4][M(NCS)_6]$, where M = Pr–Yb or Y, has been obtained and the erbium compound has been submitted to X-ray ($R = 12\%$).[184,185] The latter has octahedral coordination by six nitrogen atoms at Er—N = 2.34 Å (average) and Er—N—C = 174°. This compound shows SCN^- IR frequencies of 2090 sh, 2045 and 480 cm^{-1}.

Association between lanthanide ions and azide or thiocyanate ions has been studied in solution by electronic, Raman and NMR spectroscopy.[186,187] The complexation constant in water between Nd^{3+} and N_3^- is approximately 2.5. Longitudinal relaxation time studies for Gd–Dy indicate that the M—N—NN angle is bent (135° approximately).

The solution NMR[188] and structure[189] of the tripyrazolylborohydride $Yb\{(C_3H_3N_2)_3BH\}_3$ have been correlated in terms of a dipolar-shifted spectrum, which corresponds with the X-ray solid structure determination, where bicapped trigonal prismatic eight-coordination was observed from one bidentate and two tridentate anions. Surprisingly, the NMR spectrum indicated slow interconversion of the two types of ligand in solution. The range of NMR shifts was 200 p.p.m.

39.2.3 Phosphorus Donor Ligands

Under most normal circumstances, lanthanide–phosphine complexes are not formed, but phosphines have been shown to be capable of coordinating when the lanthanide ion is in the form of an organolanthanide. Thus $[Yb(C_5Me_5)_2Cl(Me_2PCH_2PMe_2)]$ is obtained from the reaction of $[Yb(C_5Me_5)_2(Me_2PCH_2PMe_2)]$ with $YbCl_3$ in toluene (see also Section 39.2.11.4 for the Yb^{2+}–diphosphine complexes). Here the Yb is bonded to two η^5-C_5Me_5 with Yb—C = 2.612–2.718 Å, one Cl at 2.532 Å and one P at 2.941 Å (the diphosphine having only one phosphorus atom coordinated).[190] It seems clear from the large Yb—P internuclear distance that the bond cannot be a strong one.

39.2.4 Oxygen Donor ligands

39.2.4.1 Hydrated ions and salt hydrates

(i) Thermodynamic parameters of hydrated lanthanide ions

Values of free energies of formation, heats of formation and entropies for the series La–Yb, including Pm, have been given,[191–193] together with standard reduction potentials. The $\Delta H_f^\ominus$ values were obtained from $\Delta H_f^\ominus$ for MCl_3,[194] together with heats of solution for MCl_3.[195] $S^\ominus$ values were obtained from the entropies of the hydrated ions[196] and those of the metals. The $\Delta G_f^\ominus$ and $E^\ominus$ values were obtained by calculation from the foregoing data. These data are shown in Table 2.

Table 2 Thermodynamic Parameters of Hydrated Lanthanide Ions[191,192]

	$-\Delta H_f^\ominus(M^{3+}, aq)$ (kJ mol^{-1})	$-S^\ominus(M^{3+}, aq)$ (J K^{-1} mol^{-1})	$-\Delta G_f^\ominus(M^{3+}, aq)$ (kJ mol^{-1})	$-E^\ominus[M^{3+}/M]$ (V)
La	709.4 ± 1.6	218 ± 13	685 ± 5	2.37 ± 0.02

(ii) Hydrated lanthanide ions—structures and properties

X-Ray structural determinations of fully hydrated lanthanide ions in salts with weakly coordinating anions show the predominating coordination number is likely to be nine water molecules. Thus after some early structural determinations[199–202] of $[M(H_2O)_9]X_3$, where M = Pr, Nd, Sm or Er and X = BrO_3 or $EtOSO_3$, the structures of the hydrated Pr and Yb bromates and ethyl sulfates have been more accurately determined.[203,204] The hydrated bromates and ethylsulfates each form an isostructural series for all lanthanide ions, the bromates $P6_3/mmc$ and the ethylsulfates in space group $P6_3/m$. Tricapped trigonal prisms of water oxygen atoms with symmetry D_{3h} in the bromates and C_{3h} in the ethylsulfates surround the metal ions. M—O distances are (a) for the bromates: Pr—O (prism) = 2.49(1), Pr—O (equatorial) = 2.52(1), Yb—O (prism) = 2.32(1), Yb—O (equatorial) = 2.43(1), and (b) for the ethyl sulfates: Pr—O (prism) = 2.470(2), Pr—O (equatorial) = 2.592(3), Yb—O (prism) = 2.321(3), Yb—O (equatorial) = 2.518 Å. The decrease in the prismatic M—O distances is what is expected from the lanthanide contraction, 0.155 Å, but van der Waals repulsions between prismatic and equatorial oxygen atoms make the decrease in the equatorial M—O bonds about half this value. The anions are hydrogen bonded to the complex ions. Accurate values of unit cell dimensions were obtained for both these series.

In the light of these results, it is very surprising therefore that $M(ClO_4)_3 \cdot 6H_2O$ (M = La, Tb or Er) when studied by X-ray single crystal methods[205] shows the lanthanide ion octahedrally coordinated to six water molecules in the $Fm3m$ crystal, with M—O = 2.48 (La), 2.35 (Tb) and 2.25 Å (Er). The perchlorate anions show rotational disorder and are held by weak M—O—H···O (perchlorate) hydrogen bonding at O(water)—O(perchlorate) distances of 3.23 (La), 3.20 (Tb) and 3.27 Å (Er).

The problem of lanthanide coordination numbers in aqueous solutions of the tripositive lanthanide ions was for long unsolved. Thus Choppin stated in a 1971 review:[206] 'At this time we know little about the coordination numbers of trivalent lanthanide and actinide ions in complexes in aqueous solution.' This remark referred particularly to the role of the water molecules in complexing the cation. Some of the lines of evidence then used to estimate n in $[Ln(H_2O)_n]^{3+}(aq)$ were the following. X-Ray diffraction measurements[207] on concentrated solutions of $ErCl_3$ and ErI_3 seemed to show octahedral cations $[ErCl_2(H_2O)_4]^+$ or $[ErI_2(H_2O)_4]^+$. However, electronic spectra of $Nd(BrO_3)_3 \cdot 9H_2O$ in aqueous solution were very similar to the solid state spectra of the same compound,[208] thus pointing towards $[Nd(H_2O)_9]^{3+}$ in solution. There was considerable evidence from discontinuities in various properties near Gd^{3+} or Tb^{3+} in the lanthanide series that n in $[M(H_2O)_n]^{3+} \cdot aq$ took a different value for the later members of the series as opposed to the earlier. Thus values of ΔG and K, ΔH and ΔS for complexation of tripositive lanthanide ions in aqueous solution with edta, nta and several related ligands showed these discontinuities;[206] but significantly, no discontinuity (apart from a

small discontinuity of about 10 J mol^{-1} at Eu^{3+}, the f^7 member, doubtless related to an ionic radius or crystal field discontinuity) was observed for reaction (5).[209]

$$[M(H_2O)_9]X_3(solid) + 3L^{2-}(aq) \longrightarrow [ML_3]^{3-}(aq) + 3X^-(aq) \quad (5)$$

$$X = BrO_3^- \text{ or } EtOSO_3^-; \quad H_2L = O(CH_2CO_2H)_2 \text{ or } 2,6\text{-}NC_5H_3(CO_2H)_2$$

Other properties of aqueous solutions where discontinuities were observed were molar volumes, heat capacities and viscosities.[210–212] From all these pieces of evidence, the general opinion was that n in $[M(H_2O)_n]^{3+}(aq)$ was nine for the lighter lanthanide ions, but eight for the heavier,[213] though some workers were of the opinion that n did not change along the series.[214] Solution X-ray studies have provided evidence for an average coordination number of 8.9 for $Nd^{3+}(aq)$,[215] while neutron diffraction supports a value of 8.5 for the same ion.[216]

However, considerable weight must attach to the following luminescence lifetime studies, in which it has been established from measurements made in dilute aqueous solution[217,218] that the hydrated europium ion is $[Eu(H_2O)9.6 \pm 0.5]^{3+}$ and the corresponding terbium ion is $[Tb(H_2O)9.0 \pm 0.5]^{3+}$. The error limits should certainly be no larger and are probably smaller than the 0.5 molecule stated. In these experiments, the lanthanide ions are excited by a tunable pulsed dye laser, and there are then two competing deexcitation routes (Figure 3). The first is by direct emission of a quantum of light in the visible region of the spectrum, *e.g.* at around 545 nm for the $^5D_4 \rightarrow {}^7F_5$ deexcitation of Tb^{3+}. The second route is a deexcitation in which the

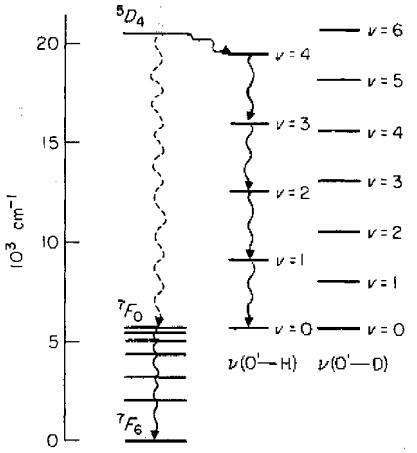

Figure 3 Alternative deactivation pathways for a Tb^{3+} ion coordinated to H_2O or to D_2O (adapted from ref. 218)

energy of the excited ion is transferred to O—H vibrational energy in water molecules in the first coordination sphere by excitation of perhaps the third vibrational overtone at around 19 000 cm^{-1}. The result of the second mechanism is that the observed luminescence lifetime is reduced according to equation (6), where K_{nat} is the natural rate constant for photon emission, K_{nonrad} is the rate constant for the transfer of energy to the O—H vibrations of coordinated water and K_{obs} is the observed exponential decay constant. The contribution of K_{H_2O} can be quantified by a similar experiment using D_2O where this mechanism is virtually unavailable owing to the closer spacing of the O—D vibrational levels, and is found to be proportional to the number of coordinated water molecules in crystalline solids where these numbers are known. The principle can be extended to solutions and then gives the hydration numbers referred to above for the plain hydrated ions. Also, very reasonable values for hydration numbers of complexes in solution have been obtained, such as $[Eu(nta)(H_2O)_{6.0}]$ and $[Tb(nta)(H_2O)_{5.0}]$.

$$K_{obs} = K_{nat} + K_{nonrad} + K_{H_2O} \quad (6)$$

(*iii*) *Salt hydrates*

In this section are discussed hydrates of lanthanide salts where the water molecules form a majority of the coordination sphere and where there is evidence concerning the number or

geometry of the coordinated water molecules. Using laser excitation as described above, it has been shown[219] that the 1:1 association product between Eu^{3+} ions and NO_3^- in aqueous solution is $[Eu(NO_3)(H_2O)_{6.8\pm0.4}]^{2+}$, the nitrate ion presumably being bidentate. However, luminescence lifetime measurements have shown that there is little complexation by Cl^- in water, though SO_4^{2-} and NO_3^- do associate.[220] Enthalpy and free energy changes on crystallization of hydrated chlorides, nitrates and perchlorates have been calculated from literature activity data, and the results were interpreted in terms of anion crowding at higher lanthanide atomic numbers.[221]

X-Ray single crystal data show that in the solid state, coordination numbers of around nine predominate in this type of complex. Thus $La_2(SO_4)_3{\cdot}9H_2O$ contains La^{3+} coordinated to six H_2O in a trigonal prism and three SO_4^{2-} in the equatorial face-capping positions,[222] while $[M(NCS)_3(H_2O)_6]$, where M = Dy or Pr, both contain distorted nine-coordinated polyhedra.[223] However, with the slightly more bulky chloride ion present, $[MCl_2(H_2O)_6]Cl$, where M = Eu[224] or Gd,[225] has distorted square antiprismatic eight-coordination with one Cl^- in each square in *cis* positions. Interatomic distances are Gd—O = 2.39–2.42 and Gd—Cl = 2.768 Å. The complex cations are linked together in two ways, directly by Gd—$OH_2\cdots$Cl—Gd hydrogen bonds and indirectly by the system Gd—$OH_2\cdots Cl\cdots H_2O$—Gd. The O···Cl distances of the first sort are 3.17–3.24 Å, and the second type are 3.16–3.18 Å.

Russian workers have continued to study hydrated salts of lanthanide ions. Some of these studies are of a rather detailed nature and a summary of some of the more recent work will be given here to indicate its general nature. There is considerable emphasis on phase studies, X-ray powder data, thermogravimetric and differential thermal analysis, and IR data.

$RbM(SO_4)_2{\cdot}H_2O$ (M = Gd—Lu) have been obtained from solution and belong to space group $P2_1/c$.[226] The deposition from aqueous solution of $Ce_2Sr_3(SO_4)_6{\cdot}3H_2O$ has been studied, and the product characterized by DTA, TGA, powder pattern and IR.[227] The thermal properties of $M_2SO_4{\cdot}Gd_2(SO_4)_3{\cdot}2H_2O$ (M = Na, K, Rb, Cs, NH_4) have been studied by DTA, TGA and powder pattern.[228,229] $M_2SO_4{\cdot}Gd_2(SO_3)_3{\cdot}8H_2O$ (M = Rb, Cs, NH_4) have been obtained from aqueous solution and characterized by analysis and powder pattern.[230]

Solid phases have been isolated from the systems $M(NO_3)_3$–quinolinium nitrate–H_2O (M = Ce, Sm, Tb, Ho).[231,232] The composition of many solid phases, *e.g.* $Gd(NO_3)_3{\cdot}4H_2O$, has been determined in the system $M(NO_3)_3$–HNO_3–H_2O (M = Y, Gd, Lu).[233] $M_2Nd(NO_3)_5{\cdot}H_2O$ (M = Li, Na, K) has been prepared and characterized by TGS, DTA and IR.[234] The system piperidinium (Hpip) nitrate–$Sm(NO_3)_3$–H_2O yielded $(Hpip)Sm(NO_3)_4{\cdot}4H_2O$ and $(Hpip)_3Sm(NO_3)_6{\cdot}2H_2O$ which were studied by DTA and TGA.[235] The system Me_4NNO_3–$Tb(NO_3)_3$–H_2O yielded $Me_4NTb(NO_3)_4{\cdot}2H_2O$ which was characterized by analysis, IR and powder pattern.[236] A solubility study identified phases in the system $Ca(NO_3)_2$–$M(NO_3)_3$–H_2O (M = Ce, Pr, Nd) at 25 °C.[237] The thermal decomposition of $M(NO_3)_3{\cdot}6H_2O$ (M = Sm–Gd) was studied by DTA, TGA and IR.[238]

The single crystal X-ray structure of hydrated neodymium hypophosphate, $NdHP_2O_6{\cdot}4H_2O$, has been determined.[239] The Nd ion is eight-coordinated to four H_2O and two bidentate hypophosphate anions. The details of interatomic distances and bond angles were compared with other members of this isostructural series, which extends at least from Nd to Er.[240]

A number of hydrated carboxylates have been studied. Isothermal solubility studies of $Y(HCO_2)_3$–$KHCO_2$–H_2O gave the compounds $KY(HCO_2)_4{\cdot}H_2O$ (of which a single-crystal X-ray structure was obtained) and $K_5Y(HCO_2)_8$.[241] The enthalpies of dissolution of $M(Me_3CO_2)_3{\cdot}2H_2O$ (M = La–Lu) were measured and standard heats of formation calculated.[242] $K_4Pr_2(C_2O_4)_5{\cdot}nH_2O$ (n = 7–9) have been characterized by analysis, powder pattern and IR.[243] M_2 (dimethylmalonate)$_3{\cdot}nH_2O$ (n = 5–8, M = La–Lu) have been synthesized and characterized by analysis, IR, powder pattern, DTA and TGA.[244]

The thermal behaviour of $MCl_3{\cdot}xH_2O$ (x = 6 or 7, M = Y, La–Lu) was investigated by DTA, TGA and X-ray powder photography.[245] Equilibrium diagrams for the MCl_3–H_2O systems (M = Y, Gd, Tb, Dy, Er) were obtained by DTA and evidence obtained for the hydrates $MCl_3{\cdot}nH_2O$ (n = 6, 8, 9 and 15).[246]

The system $Nd(IO_3)_3$–MIO_3–H_2O (M = K, Rb) were studied by the isothermal saturation method, and $3Nd(IO_3)_3{\cdot}2KIO_3{\cdot}2H_2O$ was described and studied by TGA and IR.[247]

Perrhenates and pertechnetates $M(M'O_4)_3{\cdot}4H_2O$ (M = Y, Ho–Lu; M' = Tc or Re) are shown to be isostructural by powder pattern[248] with the single crystal X-ray structure which had been obtained for M = Yb, M' = Re.[249] IR studies were also made.[250]

Behaviour in aqueous alkali has been investigated. Thus $M(OH)_3$ (M = Yb or Lu) when heated at 170 °C for 12 h in aqueous NaOH gave $Na_4M(OH)_7{\cdot}2{\cdot}5H_2O$ and a single crystal

X-ray structure showed octahedral YbO_6 groups to be present.[251] Ion exchange, dialysis and spectrophotometry using Arsenazo-III have been used to study the hydrolysis of the hydrated Y^{3+} ion at 10^{-5} to 10^{-2} M and pH 1 to 9. Mono- and poly-nuclear complexes were present, and K_1 for Y(OH)·aq was 2.52×10^6.[252]

39.2.4.2 β-Diketonates and their adducts

Under this section are considered lanthanide complexes of β-diketones and their adducts, but work specifically in the area of lanthanide shift reagents is dealt with in Section 39.2.9. Of course, the majority of lanthanide shift reagents are lanthanide β-diketonates, and when they function as shift reagents they do so by forming adducts in solution. Furthermore, interest in shift reagents has directly stimulated a considerable amount of fundamental research on lanthanide β-diketonates and their adducts. Much of this fundamental work was, therefore, carried out in the early 1970s. All this means that the division between this section and Section 39.2.9 is not entirely clear cut.

The general position regarding lanthanide complexes of the simple parent β-diketone, acetylacetone, is that its anion readily complexes, but that the resulting uncharged compounds $M(acac)_3$ are coordinatively unsaturated, and accordingly form hydrates in hydrous conditions, or polymerize in order to attain a higher coordination number, the process being driven by the consequent gain in bond energy. There have been several investigations[253–8] of anhydrous and hydrated lanthanide acetylacetonates, of which the study by Richardson *et al.* will be discussed here. The initial product prepared from aqueous solution is $M(acac)_3 \cdot 3H_2O$, except for M = La when it is the dihydrate. Complexes may be converted into the anhydrous compound, or into the monohydrate or dihydrate, or remain as the trihydrate, by recrystallization from appropriately hydrous solvents under various conditions, or by vacuum drying at room temperature. These compounds are very easily partially hydrolyzed to $M(acac)_2(OAc) \cdot nH_2O$ or $M(acac)_2(OH) \cdot nH_2O$, hence some early reports may need reinterpretation. The freshly prepared $M(acac)_3$ readily rehydrate, but after storage an insoluble material is obtained which is probably polymeric. None of the compounds is appreciably volatile. Several X-ray structures of the hydrates have appeared, thus $[M(acac)_3(H_2O)_2]$[259,260] (M = La, Nd) are eight-coordinated, as is $[Eu(acac)_3(H_2O)_2] \cdot H_2O$[261] and $[Ho(acac)_3(H_2O)_2] \cdot 2H_2O$,[262] while $[Yb(acac)_3(H_2O)]$[263,264] shows seven-coordination of the smaller Yb^{3+} ion. However, $Gd(acac)_3(H_2O)_4$ is dimeric, with Gd^{3+} coordinated to six oxygen atoms from the diketonate anions, two from water molecules and one oxygen atom from a diketonate anion which is bidentate towards the other Gd^{3+} ion. The relationship between the repulsion energy and coordination polyhedron of this $M(bidentate)_3(monodentate)_3$ coordination was explored.[265]

Solid state studies of adducts where the β-diketone is not very bulky include the monohydrate $[Ho(PhCOCHCOPh)_3H_2O]$, where the X-ray structure[266] shows a capped octahedron, resembling a three-bladed propeller with the H_2O molecule located on the trigonal axis. Here Ho—O(water) = 2.39 Å, with Ho—O(diketone) = 2.28 and 2.31 Å. The corresponding complexes having M = La–Ho are isostructural[267] and the oscillator strength of the $^4I_{9/2} \rightarrow {}^4G_{5/2}$ transition of the Ho compound at 17 000 cm^{-1} has been related to the Judd–Ofelt equation.

Lanthanide complexes of β-diketones $RCOCH_2COR$, where R is not methyl, have steric demands which are greater than those of acetylacetone, either slightly as when $R = CF_3$ or Ph, or considerably as when $R = CMe_3$. Many investigations have been reported into the state of aggregation of the complexes $M(diketonate)_3$ and their capability of forming adducts $[M(diketonate)_3L_x]$, and the relationship of these properties to the lanthanide radius and the nature of the group R.

The dipivaloylmethanates $M(Me_3CCOCHCOCMe_3)_3$ have been well studied. This highly hindered ligand is sufficiently space filling that the monomeric tris complex is reasonably stable in the case of the smaller lanthanides and yttrium, though a mono adduct $M(dpm)_3L$ (dpm = $Me_3CCOCHCOCMe_3$, dipivaloylmethanate) is readily formed, where $L = H_2O$, ROH, R_3PO *etc.* The larger lanthanide ions do not form monomers but bridged dimers $M_2(Me_3CCOCHCOCMe_3)_6$. The complete series $M(dpm)_3$, where M = Y, La–Lu, was first prepared by Eisentraut and Sievers,[268] using a standard method (β-diketone, metal salt and ammonia in aqueous alcohol) but under reduced pressure. These complexes are remarkably volatile and can be separated by gas chromatography.[267] The solids are dimeric in the cases of La–Dy as exemplified by the X-ray crystal structure determination[269] of $[Pr_2(dpm)_6]$, and

monomeric for Y, Tb–Lu, as exemplified by the X-ray structure[270] of [Er(dpm)$_3$]. The terbium and dysprosium complexes can apparently have either structure.[271] Bond lengths are in the region 2.39–2.44 Å, with one bond distance at 2.59 Å, for [Pr$_2$(tmd)$_6$] and 2.156–2.262 Å for [Er(dpm)$_3$]. The coordination polyhedron of the praseodymium complex is irregular, while the erbium complex shows trigonal prismatic coordination, probably a consequence of the comparatively large ionic radius of Er^{3+} compared with the intraligand O—O distance, giving the angle O—Er—O = 74.4°. The complexes are monomeric in non-polar solvents but avidly form hydrated adducts with traces of water.[272] An X-ray crystal structure of the hydrate [Dy(dpm)$_3$H$_2$O] shows seven-coordination with a side-capped trigonal prismatic coordination, with Dy—OH$_2$ = 2.36 and Dy—O(dpm) = 2.25, 2.36 Å. The molecules are arranged in dimeric pairs, but the interconnection is by means of hydrogen bonding, and not by Dy—O—Dy interaction.

The vapour pressures of M(dpm)$_3$, where M = La–Lu, have been determined[273] over a range of temperature within 410–530 °C and the heats of sublimation, and heats of vapourization of the ligands, were calculated. The heats of sublimation of the lighter lanthanides (*e.g.* Pr, 165.4 kJ mol^{-1}) are considerably greater than those of the heavier (*e.g.* Yb, 133.3 kJ mol^{-1}) and doubtless this increase reflects the enthalpy of cleavage of the dimeric [M$_2$(dpm)$_6$].[274]

The complexes M(fod)$_3$, where fod = $CF_3CF_2CF_2COCHCOCMe_3$, have been synthesized[275] and studied because they are probably the most effective lanthanide shift reagents known for general applications. They readily form hydrates, including the interesting [Pr$_2$(fod)$_6$H$_2$O]·H$_2$O where the X-ray determination[276] shows a similar structure to that of [Pr$_2$(dpm)$_6$] but with an additional water molecule bridging the two Pr^{3+} ions and H-bonded to the fluorocarbon chains giving eight-coordination. For one Pr^{3+} ion, the coordination is distorted dodecahedral; the other has irregular coordination. The smaller Lu^{3+} ion gives[227] seven-coordinated [Lu(fod)$_3$H$_2$O] with Lu—O(diketone) = 2.17 and Lu—O(water) = 2.29 Å. In an influential early paper,[275] Sievers and co-workers prepared M(fod)$_3$·H$_2$O, where M = Y, La–Lu, using standard methods (β-diketone, M(NO$_3$)$_3$·aq and NaOH in aqueous methanol). The hydrated complexes were converted into M(fod)$_3$ by P$_4$O$_{10}$/vacuum, but are avidly rehydrated. They are very soluble in benzene and very volatile, volatilizing completely by 260 °C (La) or 180 °C (Lu). They may easily be separated by gas chromatography, a plot of retention times against ionic radii giving a smooth curve. It is of interest that in these two last volatility-dependent properties, Y(fod)$_3$ has properties intermediate between those of the Ho and Er complexes; in broader terms, all types of complexes of Y resemble the corresponding complexes of the Dy, Ho, Er group (except, of course, in those properties which are directly related to electronic configuration, such as electronic spectra).

M(fod)$_3$, where M = Pr or Eu, have been shown[278] to undergo association in carbon tetrachloride solution, doubtless of a similar nature to that observed[269] in the case of [Pr$_2$(dpm)$_6$]. Vapour pressure osmometry on carefully dried solutions showed association into dimers and trimers, with association quotients as follows (mol^{-1}): Pr$_2$(fod)$_6$, 140 ± 8; Pr$_3$(fod)$_9$, 45 ± 5; Eu$_2$(fod)$_6$, 367 ± 22; Eu$_3$(fod)$_9$, 12 ± 2; all at 37 °C. Controlled addition of traces of water was observed to reduce these values; presumably it coordinates and splits the β-diketonate bridge. This association in solution is in contrast to the more highly hindered M(dpm)$_3$ complexes which are monomeric in carbon tetrachloride.[279]

The lanthanide β-diketonates readily form stable, isolable adducts with amines, phosphine oxides and other ligands with a fairly strong affinity for lanthanide ions. They do not generally form stable, isolable complexes with alcohols or ethers, although their interaction in solution with the species is evident from their effectiveness as NMR shift reagents for alcohols and, in some cases, ethers. Studies[280] in carbon tetrachloride of [Ho(dpm)$_3$] and its adducts with triphenylphosphine oxide, borneol, cedrol and camphor by means of Job's plots of the electronic absorption spectra showed that only 1:1 association took place with stability constants (log K_1) as follows: triphenylphosphine oxide, 4.48 ± 0.3; borneol, 2.66 ± 0.1; cedrol 2.66 ± 0.1; campor, 1.75 ± 0.1. The large difference between the coordinating abilities of the phosphoryl group and those of the alcohols and ketone is noteworthy. However, with Eu(fod)$_3$ and methyldimethylcarbamate in carbon tetrachloride, both 1:1 and 1:2 association were found with log K_1 = 3.20 ± 0.14 and log K_2 = 2.03 ± 0.04.[278]

Evidence for a cooperative type of association in forming 1:2 adducts, in which the second association constant K_2 is greater than K_1, was found by emission titration studies.[281] These involve study of the dependence of intensity of the $^5D_o \rightarrow {}^7F_n$ emission of the Eu^{3+} ion upon the nature of the emitting complex. An example of the results is that log K_1 = 2.34 and log K_2 = 5.00 for association between Eu(dpm)$_3$ and *n*-propylamine. However, some evidence

was obtained from circularly polarized luminescence (CPL) and IR studies that Schiff bases are formed by interaction between $Eu(dbm)_3$ or Eu(benzoylacetonate)$_3$ and aminoalcohols such as D-α-phenylglycinol.[282]

The thermodynamic parameters for association between pyridine or dimethyl sulfoxide and lanthanide β-diketonates have been determined by titration calorimetry. In a valuable paper,[283] complexation was investigated between $M(dpm)_3$, where M = Eu or Yb, or $M(fod)_3$, where M = Eu or Pr, and pyridine, 2-, 3- or 4-picoline, 2,4,6-trimethylpyridine, or Me_2SO. Typical results are shown in Table 4. Various points are exemplified here. The more crowded $Yb(dpm)_3$ complex gives only a mono adduct, while the two fod complexes coordinate with two molecules of ligand. The inductive effect of the 4-methyl group is just discernible, but the steric effects of the 2-methyl or 2,6-dimethyl groups are plainly evident. K_2 is, as is normal, not greater than K_1, thus contrasting with the results[281] with *n*-propylamine. Finally, the K values for DMSO are roughly comparable with those of the unhindered pyridines.

Table 4 Interaction Between Lanthanide β-Diketonates and Ligands in Benzene[283]

		$\log K$[a]		$-\Delta H°$ (kJ mol^{-1})		$-\Delta G°$ (kJ mol^{-1})	
$Yb(dpm)_3$	py	3.14		22.7		18.2	
	4-pic	3.27		22.8		18.9	
	2-pic	2.16		18.0		12.5	
		$\log K_1$	$\log K_2$	$-\Delta H_1°$	$-\Delta H_2°$	$-\Delta G_1°$	$-\Delta G_2°$
$Pr(fod)_3$	py	3.3	3.0	24	9	19.1	17.4
	4-pic	4.3	3.0	24	13	24.9	17.4
	2-pic	3.0	2.0	11	20	17.4	11.6
		$\log K_1$	$\log K_2$				
$Eu(fod)_3$	py	4.0	2.7				
	DMSO	3.3	3.3				
	2,4,6-Me_3py	1.0	0.5				

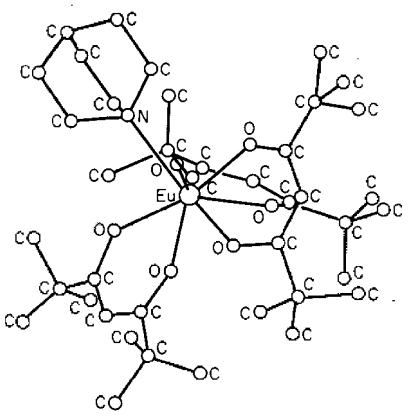
[a] K in dm^3 mol^{-1}.

Ten-coordination has ben claimed for $M(fod)_3(bipy)(H_2O)_2$, where M = Y, La, Pr, Eu or Lu, but the evidence (thermogravimetric analysis) is slender and a coordination number of eight as $[M(fod)_3bipy]\cdot 2H_2O$ seems more likely, in line with the complexes $M(fod)_3$ phen where M = Y, La, Pr, Yb, or Lu, prepared at the same time.[284] The electronic spectra were also studied and related to covalency parameters and the NMR spectra were discussed, but as might be expected, the complexes show no ability to act as shift reagents as they are already too crowded.

As in the case of most classes of lanthanide complexes, an X-ray structure determination is necessary to give convincing proof of structure and configuration, and many lanthanide β-diketonate adducts with amines and other ligands have been subjects of such reports. In general, the method of preparation of the adducts is straightforward, namely an addition reaction in an inert solvent or in excess ligand, followed by removal of solvent and recrystallization. Coordination numbers are usually seven or eight, depending on ionic radius, bulk of β-diketone and bulk of added ligand, but can rise to nine. Thus for $[Eu(acac)_3phen]$ where the β-diketone is unhindered, the lanthanide is reasonably large, and the phenanthroline is fairly undemanding sterically, eight-coordination is achieved,[285] with a rather distorted square antiprismatic configuration having Eu—O at 2.356–2.409 and Eu–N = 2.643 Å (average). The molecule has approximate C_s symmetry, which is consistent with the number of lines observed in the fluorescence spectrum. Eight-coordination can still be achieved even with the bulky dpm ligand. Thus both $[Eu(dpm)_2py_2]$,[286,287] and $[Ho(dpm)_3(4\text{-picoline})_2]$[288] have very similar structures. The former has near C_2 symmetry with a distorted square antiprismatic, nearly dodecahedral, structure with Eu—O = 2.312–2.372 and Eu—N = 2.649 Å (average). With the very bulky ligand, quinuclidine (**6**), only seven-coordination is achieved[289] in $[Eu(dpm)_3(quin)]$. Here the symmetry interestingly is almost C_3 with a capped octahedral configuration in which the three quinuclidine strands bisect the positions of the set of three oxygen atoms closest to the amine. The interatomic distances are Eu—O = 2.33 (average) and Eu—N = 2.60 Å (Figure 4). The molecular configuration is thus similar to that of

[Ho(PhCOCHCOPh)$_3$H$_2$O] mentioned above. In the case of the smallest lanthanides, coordination may be restricted to one ligand even when it is quite small. Thus [Lu(dpm)$_3$(3-picoline)] has a seven-coordinated, distorted, side-face-capped trigonal prismatic configuration.[290] An oxygen is the capping atom. Interatomic distances are Lu—O = 2.24 (average) and Lu—N = 2.49 Å.

(6)



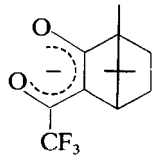


Figure 4 Structure of [Eu(Me$_3$CCOCHCOCMe$_3$)$_3$ (quinuclidine)] (reproduced with permission from ref. 289)

Among oxygen donors, the groups C=O, P=O and S=O are effective. The adduct [Pr$_2$(facam)$_6$(dmf)$_3$] provides an interesting example of nine-coordination.[291] Here facam is 3-trifluoroacetyl-(+)-camphor (**7**) a bulky ligand but one in which the main bulk is located at some distance from the metal ion. The three nitrogen atoms from the dimethylformamide ligands act as symmetrically bridging donors to both Pr^{3+} ions, giving distorted capped square antiprismatic coordination. Interatomic distances are Pr—O(diketone) = 2.46 Å; Pr—O(dmf) = 2.60 Å. The bridging angle Pr—O—Pr is 103.6°.

(7)

The phosphine oxide adduct [Pr(dpm)$_3$(OPPh$_3$)] is of interest as although Pr^{3+} is a large ion, and Ph$_3$PO is not perhaps too sterically demanding except at a distance from the ion, only a seven-coordinated mono adduct is obtained. The X-ray structure[292] shows Pr—O(diketone) = 2.30–2.39 and Pr—O(phosphoryl) = 2.35 Å. The comparatively short Pr–phosphoryl link is to be noted (compare Section 39.2.4.4) and would increase repulsion between the ligating atoms. The seven-coordination is in agreement with the solution studies mentioned above.[283]

The X-ray crystal structure[293] of a sulfoxide adduct, [Eu(dpm)$_3$L], where L is the cyclic sulfoxide (**8**), shows irregular seven-coordination with Eu—O(diketone) = 2.33 (average) and Eu—O(sulfoxide) = 2.40 Å; the sulfoxide group, like the phosphine oxide group just previously mentioned, forms a short, and presumably strong, bond.

(8)

In the case of β-diketones which are not too sterically demanding, the $[M(\beta\text{-diketonate})_4]^-$ anion may be obtained. An example is $NH_4[M(CF_3COCHCOCF_3)_4]$, where M = Y, Nd, Gd or Er. Preparation is by treatment of a benzene solution of $[M(CF_3COCHCOCF_3)_3]$ with $CF_3COCH_2COCF_3$ (1 mol) and gaseous ammonia.[294] The $(\text{rhodamine 6G})^+$ salts of $[EuL_4]^-$, where L is benzoylacetonate or thenoyltrifluoroacetonate, have also been prepared and their fluorescence spectra studied.[295]

Europium, and to a lesser extent terbium, complexes of β-diketones have been studied in solution and in the solid state by means of their fluorescence (luminescence) spectra. As explained further in Section 39.2.10, it is possible to relate the splitting of the $^5D_o \rightarrow {}^7F_n$ transitions of Eu^{3+} to the symmetry of the emitting complex, and studies of circularly polarized luminescence (CPL) spectra can give related information. Thus a study[296] of $EuCl_3$ and complexes of Eu^{3+} with hexafluoroacetylacetone and four other β-diketones in methanol or DMF showed that while $EuCl_3$ itself had axial symmetry in solution, the complexes had orthorhombic symmetry. The emission spectra of solutions of adducts of $Eu(dpm)_3$ with Ph_3PO or borneol have been studied at low temperatures where conformal lability is reduced; the Ph_3PO adduct has uniaxial symmetry but the bulky, less symmetrical borneol molecule confers lower symmetry on its adducts.[297]

Russian workers have been active recently in this field. Thus [Eu(thenoyltrifluoroacetate)$_3$(phen)] has been shown to retain its structure in polystyrene or PVC;[298] the second order crystal field parameters B_2^0 and B_2^2 have been obtained for a series of complexes $[EuL_3(phen)]$ where L was a series of eight β-diketonates,[299] and the temperature broadening has been investigated, for similar adducts and for $EuL_2(NO_3)(Ph_3PO)_2$, of the Stark components of the ^7F_J levels.[300]

39.2.4.3 Amine oxides

These compounds have been known for some time, having been described in 1964 by Melby *et al.*[301] who investigated the fluorescence spectrum of $Eu(tfa)_3$(4-picoline *N*-oxide)$_2$. Pyridine oxides bond firmly to lanthanides, the strength of the interaction being doubtless associated with the partial charge on the oxygen atom, and a considerable number of papers have appeared in which the preparation and general properties of pyridine oxide or substituted pyridine oxide complexes with lanthanide salts, often with poorly coordinating anions such as perchlorate, methylsulfate or hexafluorophosphate, but also with halides or nitrates, have been studied.

Before describing these, it is of interest to survey X-ray crystallographic data on this type of complex. The compounds $M(ClO_4)_3(pyo)_8$, where M = La or Nd and pyo = pyridine *N*-oxide, are both dimorphic, existing in a $P2_1/a$ and a $C2/c$ modification.[302] The first modification consisted of twinned crystals only, but in the case of the Nd compound the crystal structure was obtained despite this. The $C2/c$ version of the lanthanum compound was also submitted to structure determination. Both compounds are formulated $[M(pyo)_8](ClO_4)_3$ with all *N*-oxide atoms coordinated, the leading dimensions being: La—O = 2.493–2.500; Nd—O = 2.356–2.447 Å; La—O—N = 127.7–136.3°; Nd—O—N = 129.0–133.3°. The Nd compound has only C_1 symmetry but very nearly S_8, with the coordination polyhedron very nearly a square antiprism. The La compound had C_2 symmetry, with near D_4 symmetry, the polyhedron being distorted from a square antiprism towards a cube by rotation of the four upper pyridine oxide molecules around the 'D_4' axis some way towards a cube configuration. The La—O—N linkage seems sterically unconstrained and there is little doubt that this is a natural bonding angle of about 132° reflecting localized lanthanide–lone pair interaction.

In the complex $[La(bpyo)_4](ClO_4)_3$, where bpyo = 2,2′-bipyridyl *N*,*N*′-dioxide, the configuration is cubic, with one bidentate ligand spanning each vertical edge. The complex ion has symmetry C_2, but is very near to D_4. The two rings in each ligand are twisted relative to each other at a dihedral angle of 61.4° average. The cube is slightly compressed along the 'D_4' axis, the angle between this axis and the La—O vectors being 56.1° average (compare 54.7° required for the cube). Leading dimensions are La—O = 2.495–2.512 Å; La—O—N = 121.7–124.3°.[303]

The lanthanide trifluoromethylsulfonates $M(CF_3SO_3)_3$ have been prepared and their complexes with pyo and bpyo have been prepared in ethanol or ethanol/triethylformate and examined. Complexes $[M(pyo)_8](CF_3SO_3)_3$ and $[M(bpyo)_4](CF_3SO_3)_3$ (M = La, Nd, Eu or Ho in each case) were obtained and results indicated that the anions were not coordinated.[304,305] A number of complexes of pyo, bpyo and 2,2′,6′,2″-terpyridyl-*N*,*N*′,*N*″-trioxide (tpyo) with

lanthanide trifluoromethylsulfonates, perchlorates, nitrates and thiocyanates have been isolated from ethanolic solution and their constitution and emission spectra studied. The complexes are as follows: $M(NO_3)_3(pyo)_8$ (M = La–Ho); $M(NCS)_3(pyo)_4(H_2O)_2$ (M = La–Tb); $M(NCS)_3(pyo)_3(H_2O)_2$ (M = Ho–Tm); $M(NO_3)_3(bpyo)_2$ (M = La–Tm); $M(NCS)_3(bpyo)_2(H_2O)_n$ (M = La–Eu, $n = 1$; M = Gd–Er, $n = 2$); $M(ClO_4)_3(tpyo)_3(H_2O)_2$ (M = La–Tb); $M(NO_3)_3(tpyo)(H_2O)$ (M = La–Ho); and $M(CF_3SO_3)_3(tpyo)_3(H_2O)_2$ (M = La–Tb). Conductivity studies in MeCN established the constitution of some of these, *e.g.* $[M(pyo)_8](NO_3)_3$, or $[M(NO_3)_3(bpyo)_2]$ (earlier lanthanides) and $[M(NO_3)_2(bpyo)_2](NO_3)$ (later lanthanides), but where water was present its status was uncertain. The bpyo and tpyo ligands remained coordinated in aqueous solution. The intensity of the hypersensitive absorption bands is very considerably increased by these ligands; thus the $^5I_8 \rightarrow {}^5G_6$ Ho^{3+} band is increased four-fold by bpyo in aqueous solution. The magnitude of this effect increases in the series pyo < tpyo < bpyo. The emission spectra of the Tb and Eu complexes were studied and it was concluded that the octa pyo complexes have high symmetry.[306–308]

Other complexes of pyo with chloride or bromide have been studied.[309,310] Products were examined by IR, emission spectra, NMR and conductance. Compounds isolated include $[MCl_3(pyo)_8]$ (M = Y, La, Pr, Nd, Sm or Er); $[MBr_2(pyo)_8]Br$ (M = La, Pr, Nd, Sm, Tb or Er); and $[MBr_2(pyo)_6(H_2O)_2]Br$ (M = Y, La, Pr, Nd, Sm, Gd, Dy or Yb).

Complexes of 2-, 3- and 4-picoline oxides have been made in large numbers. These include $[M(2po)_7](PF_6)_3$ (M = La–Sm) and $[M(2po)_6](PF_6)_3$ (M = Sm–Lu or Y; 2po = 2-picoline oxide).[311] This seems a good example of reduction of coordination number with ionic radius of metal ion. Another series showing this effect is $[M(NCS)_3(2po)_x]$ (M = La–Pr, $x = 5$; M = Nd–Eu, $x = 4$; M = Eu–Lu, Y; $x = 3$). Powder X-ray photographs show three series and all are non-conductors. In the IR, ν(NO) is reduced from 1240 cm^{-1} to 1220–1240 cm^{-1} and δ(NO) increased from 840 cm^{-1} to 845–850 cm^{-1}.[312] Other series are $M(MeSO_3)_3(2po)_x$ (M = Ce–Sm, $x = 2$; M = La–Lu or Y, $x = 4$);[313,314] $[M(NO_3)_3(2po)_3]$ (M = Nd, Sm, Tb, Dy, Yb);[315,316] $[MCl_3(2po)_x]$ (M = La, Pr, $x = 4$; M = Nd, Sm, Tb, Er or Y; $x = 5$;[316] $M(ClO_4)_3(2po)_7(H_2O)_x$ (M = La–Lu, Y; $x = 3$ or 2);[317] and $MCl_3(2po)_3(H_2O)_2$ (M = La–Ho), where IR and conductivity (MeOH) suggested a formulation $[MCl_2(2po)_3(H_2O)_2]Cl$.[318] On the whole, these coordination numbers tend to be lower than for the unsubstituted pyridine *N*-oxide. In the case of the oxides 3-picoline and 4-picoline, steric effects should however be less pronounced. Series isolated with the 3-picoline oxide ligand include $[M(3po)_8](PF_6)_3$ (M = La–Lu, Y);[319] $[M(3po)_8](ClO_4)_3$ (M = La–Yb (some) or Y)[320] and $MI_3(3po)_8 \cdot (H_2O)_x$ (M = La–Yb (some), Y; $x = 0$, 1 or 2). In the last series, NMR results indicated restricted rotation of the pyridine ring in the Yb compound.[321] This has also been observed in $[MI(2po)_5]I_2$.[322] Series with 4-picoline oxide as ligand include $MBr_3(4po)_8$ (M = La–Er (some), Y)[323] and $MI_3(4po)_8$ {M = La–Yb (some)}.[322]

39.2.4.4 Phosphine and arsine oxides and related ligands

Lanthanide ions complex more readily with phosphine or arsine oxides and other ligands containing the P=O or As=O groups than with most other uncharged monodentate ligands. Doubtless much of this affinity can be ascribed to the negative charge on the oxygen atom produced by the canonical form $P^+–O^-$, which confers an electrostatic component on the cation ligand bond energy. The fact that trivalent lanthanide cations formed stable isolable complexes with phosphine or arsine oxides was fairly early recognized. Thus the complex $EuCl_3(OPPh_3)_3$ was reported[324] in 1964 and its fluorescence spectrum examined, while a wide variety of phosphine and arsine oxide complexes were reported shortly afterwards.[325] These were prepared in ethanol or acetone solution and included $M(NO_3)_3L_2(EtOH)$, where M = Y or La–Lu and L = $OPPh_3$ or $OAsPh_3$; $M(NO_3)_3L_3$, where M = Y or La—Lu and L = $OPPh_3$ or where M = Y or La–Yb and L = $OAsPh_3$. Other complete series included $M(NO_3)_3(OPPh_3)_3(Me_2CO)_2$ and $M(NO_3)_3(OAsPh_3)_4$, and other complexes prepared included $M(NO_3)_3(OPPh_3)_4(EtOH)_x$ where $x = 0$ and 1, M = Y and Tb–Lu. The thiocyanates $M(NCS)_3L_4$, where L = $OPPh_3$ or $OAsPh_3$, $M(NCS)_3(OPPh_3)_3$, and the chlorides $MCl_3(OPPh_3)_x$ where M = Nd or Sm and $x = 3$ or 4 have also been prepared and characterized.[326–328] Some of these were soluble and monomeric in organic solvents, *e.g.* $SmCl_3(OPPh_3)_4$ which should thus be seven-coordinate, but others contained ionic nitrate, *e.g.*

$[Eu(NO_3)_2(OAsPh_3)_4]NO_3$, as shown by conductivity and IR data. There is a characteristic lowering of the PO IR stretching frequency on coordination, from 1195 cm^{-1} to about 1160 cm^{-1}, while the AsO frequency is raised on coordination, from 878 cm^{-1} in the free ligand to about 910 cm^{-1}. As coordination is expected to strengthen the PO and AsO σ bonds inductively and weaken the corresponding π bonds inductively, this result is in accord with the expected greater importance of the π bond in PO as compared with AsO.[327] For both ligands the stretching frequency increases along the series La→Lu. Many of the complexes of different stoichiometries could be interconverted by heat or action of solvents or addition of further ligand. Some apparently rather similar complexes have been reported in the Russian literature.[329] These comprised $M(NCS)_3\{OP(i\text{-}C_5H_{11})_3\}_4$, where M = La–Sm; $M(NCS)_3\{OP(i\text{-}C_5H_{11})_3\}_3$, where M = Y, Sm–Yb; and $M(NO_3)_3\{OP(i\text{-}C_5H_{11})_3\}_3$, where M = Y, La, Nd, Sm, Gd, Er, Yb, Lu. Other work on simple complexes of phosphine oxides with lanthanide salts is not extensive but includes the preparation by a solvent extraction method of MX_3L_3, where M = La–Dy and Er, X = NO_3, Cl or NCS, and L = $OP(n\text{-}C_4H_9)_3$ or $OP(n\text{-}C_8H_{17})_3$.[330] Complexes of Y and lanthanide perchlorates of the stoichiometry $M(ClO_4)_3\{OP(n\text{-}C_4H_9)_3\}_4$ have also been reported,[331] as have the complexes $Nd(NO_3)_3(OPR_3)$, where R_3 = Ph_3, Ph_2(benzyl), Ph(benzyl)$_2$, (benzyl)$_3$, Et_3 or Me_3.[332]

Phosphine oxides are effective ligands in forming adducts with preexisting lanthanide complexes, particularly β-diketonates. The crystal structure of the 2:1 adduct $[Nd(ttf)_3(OPPh_3)_2]$, where Httf = thenoyltrifluoroacetone, shows an eight-coordinated dodecahedral monomer. The Nd—O(P) distances are 2.399 and 2.423 Å and the Nd—O(C) distances lie in the range 2.40–2.50 Å. The coordination polyhedron is very closely dodecahedral.[333] In contrast to this 2:1 adduct, $M(dbm)_3$, where Hbdm = dibenzoylmethane, give 1:1 adducts $M(dbm)_3L$, where L = OPR_3 and R = Ph, n-C_8H_{17} or OBu. These were prepared in alcohol and isolated, and there was evidence that the stability of the adducts increased in the sequence R = C_8H_{17} < Ph < OBu.[334] Other papers have also described the preparation of other adducts of phosphine oxides with lanthanide β-diketonates.[335,336]

Phosphine oxides are found to exert a synergic effect on the extraction of lanthanides from aqueous into organic phases by means of β-diketones or other ligands; doubtless the replacement of coordinated water in $M(diket)_3(H_2O)_x$ by a trialkylphosphine oxide would have a favourable effect on solubility in the non-aqueous phase. In an investigation of the effect of $OP(n\text{-}C_8H_{17})_3$ on extraction of Tm^{3+} ions from an aqueous phase using thenoyltrifluoroacetone at a variable temperature, values of ΔH and ΔS for the equilibria involved were obtained and mechanisms were discussed.[337] The synergic effect of $OP(C_8H_{17})_3$ on extraction of lanthanide ions by means of 1-phenyl-3-methyl-4-acyl-5-pyrazolones has been also studied and extraction constants and separation factors determined.[338]

Adducts of triphenylphosphine oxide with complexes of the chelate sulfur-coordinating ligand $S_2P(OEt)_2^-$ have been investigated and X-ray structures obtained. Reaction of Ph_3PO with $[M\{S_2P(OEt)_2\}_4]^-$ gave, for M = La–Pr, $[M\{S_2P(OEt)_2\}_3(OPPh_3)_2]$, and where M = Y or Nd–Lu, $[M\{S_2P(OEt)_2\}_2(OPPh_3)_3]^+$ was produced. The lanthanum complex is eight-coordinated and approximately square antiprismatic, with La—O = 2.456 or 2.422 Å, O—La—O = 152.8°, and La—O—P = 168.2° or 165.7°. The longer La—S interatomic distances lie within the range 2.982–3.092 Å. In the case of the Sm complex, an example of the group of smaller cations where two chelate dithiophosphate ligands are displaced by three monodentate phosphine oxides, a very closely pentagonal bipyramidal configuration is adopted with the Ph_3PO occupying both axial positions and one equatorial. Here Sm—O = 2.28–2.32 Å and Sm—O—P = 171.2–175.5°.[339]

Another class of adducts where there are structural data is formed by adducts of complexes of the bulky amido anion $N(SiMe_3)_2^-$. The action of Ph_3PO (1.5 molar proportions) on $[M\{N(SiMe_3)_2\}_3]$, where M = La, Eu or Lu, gave $[M\{N(SiMe_3)_2\}_3OPPh_3]$. The X-ray structure of the La complex showed an approximately tetrahedral geometry, with N—La—N and O—La—N in the range 104.8° to 116.4°. La—O at 2.40 Å was approximately equal to La—N at 2.38–2.41 Å, while La—O—P was not quite colinear, at 174.6°. Curiously, treatment of $[M\{N(SiMe_3)_2\}_3]$, where M = La, Pr, Sm or Eu, with $OPPh_3$ (2–5 molar proportions) gave peroxo complexes $[M_2\{N(SiMe_3)_2\}_4(O_2)(OPPh_3)_2]$, despite rigorous exclusion of oxygen and preparation of the phosphine oxide from Ph_3PBr_2 rather than treatment of Ph_3P with H_2O_2. In the La complex, two pyramidal $La\{N(SiMe_3)_2\}_2(OPPh_3)$ entities are bridged by a peroxo group, such that O—O is at right angles to La—La, while La_2 and O_2 are coplanar.[174,175] Interatomic distances and angles were given in Section 39.2.2.3.

(i) Other ligands containing the phosphoryl group

Hexamethylphosphoramide $OP(NMe_2)_3$ forms two series of complexes with lanthanide perchlorates. Thus complexes $[M\{OP(NMe_2)_3\}_6](ClO_4)_3$, where M = La, Nd, Gd, Ho or Yb, were obtained from acetonitrile solution, IR spectra showing that the perchlorate anions remained uncoordinated.[340] These complexes had also been studied previously.[341,342] From ethanolic solution, complexes $M(ClO_4)_3\{OP(NMe_2)_3\}_4$, where M = La, Nd, Gd, Ho or Yb, were obtained.[340] The PO IR stretching frequency was reduced by about 17 cm^{-1} compared with the free ligand. The cation in $[Nd\{OP(NMe_2)_3\}_6](ClO_4)_3$ has been shown by X-ray crystallography to be octahedrally coordinated, with Nd—O at 2.37 Å.[343]

The hexamethylphosphoramide perchlorates have been studied in acetonitrile solution by means of ^{139}La NMR spectrometry.[344] This nucleus has an electric quadrupole and therefore the line width of the ^{139}La resonance is much broadened by an unsymmetrical coordination geometry (which produces an electric field gradient at the nucleus). Accordingly, the coordination of added $OP(NMe_2)_3$ can be observed to alter the ^{139}La line-width from a broadened resonance characteristic of unsymmetrical cationic species $[La\{OP(NMe_2)_3\}_x(MeCN)_y]^{3+}$ where $x < 6$, to a narrow resonance characteristic of $x = 6$, $y = 0$. This latter species exchanges ligand only slowly on the NMR time scale with the other species present in solution, which suggests that the La—O bond may be quite strong.

Structures of an interesting pair of hexamethylphosphoramide complexes[345] where the coordinated anion is nitrosodicyanomethanide [X, O—N=C(CN)$_2$] have been obtained. Thus $[NdX_3\{OP(NMe_2)_3\}_4]$ is a seven-coordinated distorted capped octahedron, where X is monodentate *via* oxygen, while $[YbX_2\{OP(NMe_2)_3\}_4]^+$ is nearly *trans* octahedral with Yb—O (hmpa) = 2.197 Å average.

Some complex chlorides $[MCl_3\{OP(NMe_2)_3\}_3]$ have been described[346] and the X-ray crystal structure of the Pr complex has been reported.[347] It is very closely octahedral, with O—P—O, Cl—P—Cl and Cl—P—O in the range 82.6–96.6°. Interatomic distances include Pr—Cl at 2.706–2.733 Å, Pr—O at 2.351–2.356 Å and P—O at 1.483–1.493 Å; the coordination is meridional. Some bromides $MBr_3\{OP(NMe_2)_3\}_4$ have been described,[348] as have a number of nitrates.[349,350] Two series of trifluoromethanesulfonates have been obtained;[351] for La—Eu, the hexakis complexes $[M\{OP(NMe_2)_3\}_6](CF_3SO_3)_3$, and for Y and Nd–Lu, the tetrakis complexes $[M(CF_3SO_3)\{OP(NMe_2)_3\}_4](CF_3SO_3)_2$. The formulations shown here are based on conductivity values in acetonitrile appropriate to 3:1 and 2:1 electrolytes respectively. Fluorescence spectra of europium hexamethylphosphoramide complexes have been discussed in this paper and another[352] and their relationship to the symmetry of the emitting species discussed.

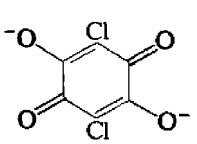
The anion $(EtO)_2PO_2^-$ forms the complex $Nd\{(EtO)_2PO_2\}_3$ on treatment of anhydrous $NdCl_3$ with $OP(OEt)_3$ in non-aqueous solution. X-Ray analysis shows a linear chain of slightly distorted octahedrally coordinated Nd^{3+} ions, with Nd—O = 2.40 Å average. Each pair of adjacent Nd^{3+} ions is bridged by three anions, and each anion bridges thus: Nd—O—P(OEt)$_2$—O—Nd.[353]

Complexes of some bidentate or terdentate phosphoryl ligands have been studied. The tetraphenylimidodiphosphate anion $\{(PhO)_2P(O)\}_2N^-$ (= L) acts as a bidentate ligand towards lanthanide ions, giving complexes ML_3.[354] The Yb complex, studied by X-ray crystallography shows coplanar Yb—O—P—N—P—O chelate rings, the three ligands giving almost octahedral coordination with nearly D_3 symmetry. The coordinated atoms are well separated (interligand O—O = 3.07–3.39 Å, intraligand O—O = 2.883 Å). The angle Yb—O—P, at 135.4–137.7°, is constrained to be smaller than in monodentate complexes, while Yb—O = 2.199–2.219 and P—O = 1.490–1.496 Å.[355] Diisopropyl-*N*,*N*-diethylcarbamylmethylenephosphonate (L) $Pr^i_2P(O)CH_2C(O)NEt_2$, which is an extractant agent for lanthanide ions from aqueous acid into hydrocarbons,[356] gives complexes $M(NO_3)_3L_2$, where M = La–Gd, and $M(NO_3)_3L_2(H_2O)$, where M = Tb–Lu.[357] The structures of these complexes have been investigated by X-ray diffraction, which shows a 10-coordinated monomeric structure $[Sm(NO_3)_3L_2]$ with L being coordinated by the phosphoryl (Sm—O = 2.418 Å) and carbonyl (Sm—O = 2.433 Å) oxygen atoms, and the nitrate groups are bidentate. The other complexes, exemplified by Er, are nine-coordinated $[Er(NO_3)_3L_2(H_2O)]$. Here, L is monodentate only, being coordinated by the phosphoryl oxygen (Er—O = 2.275 Å). The carbonyl oxygen is hydrogen bonded to the coordinated water (Er—OH_2 = 2.302 Å). The coordination geometry is nearly a face-centred trigonal prism.[358] The extraction chemistry of the dihexyl analogue of L has been studied and monodentate tris coordination in the organic phase was suggested.[359]

The bidentate ligand nonamethylimidodiphosphoramide $(Me_2N)_2P(O)N(Me)P(O)(NMe_2)_2$

(= L) forms a series of complexes $[ML_3](ClO_4)_3$, where M = La–Lu, which are X-ray isomorphous and in which the PO stretching frequency is reduced from 1205 cm^{-1} in the free ligand to 1170 cm^{-1}, while the PO bend increases in frequency by 25 cm^{-1}. The IR spectra and the conductivity in nitromethane support the formulation as a six-coordinated tris-chelate cation.[360] Other ligands, rather similar to that just mentioned, whose lanthanide complexes have been investigated are $(Me_2N)_2P(O)OP(O)(NMe_2)_2$, octamethylpyrophosphoramide;[361] $(Pr^iO)_2P(O)CH_2P(O)(Pr^iO)_2$, tetraisopropylmethylenediphosphonate;[362] and $(Pr^iO)_2P(O)$-$C_2H_4P(O)(Pr^iO)$, tetraisopropylethylenediphosphonate.[363]

Complexes of the interesting terdentate ligand $(Me_2N)_2P(O)N(Me)(P(O)(NMe_2)$-$N(Me)P(O)(NMe_2)_2$, bis(methylimido)triphosphoric acid (pentakisdimethylamide) (L) have been prepared, and investigated by NMR. The complexes are $[ML_3](ClO_4)_3$, where M = Y, or La–Lu, this presumably nine-coordinated structure being supported by the IR spectra. The NMR spectra show that there is (on the NMR time scale) no intermolecular ligand exchange, which is hardly surprising since we are dealing with a presumably terdentate ligand bonding *via* its powerful phosphoryl groups. However, there is evidence for intramolecular conformational rearrangements of some complexity. The very small ^1H paramagnetic shifts, up to 0.35 p.p.m., suggest that a very symmetrical coordination polyhedron is adopted; however, the ^{31}P shifts are quite large, up to 111 p.p.m., and it is suggested that a contact mechanism is responsible for these.[364]



Mono and bis complexes of Pr^{3+} and Nd^{3+} in aqueous solutions of iminodiaceticmonomethylenephosphonic acid have been studied over the pH range 1–12 by visible spectroscopy and association constant values determined.[365]

A short review of lanthanide phosphoryl complexes has appeared, which deals particularly with recent Russian work.[366]

39.2.4.5 Other oxygen donors

The lanthanides complex readily with the carboxylate anion and a variety of anhydrous and hydrated carboxylates have been described; most are hydrated. Preparation of the solid hydrated compounds is usually straightforward from aqueous solution, but long chain aliphatic anhydrous carboxylates may be prepared from organic solvents, either directly or by ligand exchange with the acetate.[367] A number of X-ray single crystal determinations are available, and these often show a polymeric structure. Thus the structures of hydrated and anhydrous oxalates show chelation of oxalate ion forming five-membered rings, not four-membered rings, with the lanthanide ions in nine-coordinated polymeric $\{M(ox)_3H_2O\}\cdot 2H_2O$, where M = Nd–Tb,[368] and in $K_8M_2(ox)_7\cdot 14H_2O$, where M = Y, Tb, Dy, Er or Yb.[369] In both these compounds M—(oxalate)—M bridges are present, where one anion forms two five-membered rings with two lanthanide ions. The bridging capability of the carboxylate ligands extends into solutions. Thus citric acid (H_4L) forms heterocationic complexes $GdM(H_2A)_4^{2-}$, $GdM(H_2A)(HA)_2^{2-}$ and $GdM(HA)_3^{3-}$, where M = Tb–Tm. These complexes were established by Job-type plots of relaxation times, which showed $1/T_1$ to maximize at a 1:1 Gd:M ratio.[370]

In the lanthanide tris-glycolates $M(O_2CCH_2OH)_3$, the glycolate anion chelates *via* one carboxylate and one hydroxyl oxygen, and also forms carboxylate bridges to neighbouring cations.[371–373] The diglycolates form anions, as in the salts $Na_3[M(O_2CCH_2OCH_2OCH_2CO_2)_3]$-$2NaClO_4\cdot 6H_2O$, where the cations are nine-coordinated in an approximately D_3 configuration, each diglycolate anion being tridentate.[374] The ether–lanthanide bond distances are slightly longer than those of the carboxylates, thus Nd—O = 2.523 and 2.428 Å. The chloroanilate anion (*ca*, **9**) coordinates to two separate lanthanide ions, each in a bidentate manner leading to a three-dimensional network. In $Pr_2(ca)_3\cdot 8EtOH$ each Pr^{3+} ion is nine-coordinated with three ca and three EtOH (a relatively rare example of an ethanol complex of known structure) with Pr—O(ca) = 2.483 (average) and Pr—O(EtOH) = 2.553 Å (average).[375]

(**9**)

There are many complexes of lanthanides with organic ligands which bond by means of a carbonyl oxygen atom. Representative examples are $M(Me_2NCOMe)_n(ClO_4)_3$, where M = La–Nd, $n = 8$ and M = Sm–Er or Y, $n = 7$ and M = Tm–Lu, $n = 6$ (this is a progression doubtless due to decreasing ionic radius);[376] $M\{CO(NMe_2)_2\}_6(ClO_4)_3$, where M = La–Lu or Y;[377] $M(NO_3)_3\{CO(NMe_2)_2\}_3$, where M = La–Lu or Y;[378] and M(*N*,*N*′-ethyleneurea)$_n(NO_3)_3$, where M = La or Ce, $n = 8$ and M = Ho or Tm, $n = 6$.[379] An extensive solution study has been made[380] of the equilibrium between $[M(DMF)_n](ClO_4)_3$, where $n = 8$ or $n = 9$ in DMF solution. Variable temperature and pressure studies of absorption spectra and NMR showed that $n = 8$ is the major species for Ce–Nd and the only species for Tb—Lu. For Nd, equilibrium parameters are $\Delta H^{\ominus} = -14.9 \pm 1.3$ kJ mol^{-1}; $\Delta S^{\ominus} = -69.1 \pm 4.2$ J K^{-1} mol^{-1}, and $\Delta V^{\ominus} = -9.8 \pm 1.1$ cm^3 mol^{-1}. The kinetic parameters for DMF exchange in $[Tb(DMF)_8]^{3+}$ were $\Delta H^{\ddagger} = 14.1 \pm 0.4$ kJ mol^{-1}, $\Delta S^{\ddagger} = -58 \pm 2$ J mol^{-1} K^{-1} and $\Delta V^{\ddagger} = 5.2 \pm 0.2$ cm^3 mol^{-1}. In solid $[M(DMF)_8](ClO_4)_3$ there is eight-coordination for M = La–Lu and NMR integration showed the species $[Tm(DMF)7.7 \pm 0.2]^{3+}$ in $Tm(ClO_4)_3$ dissolved in DMF/CD_2Cl_2.[381]

The oxyanions OH^-, SO_4^{2-} and NO_3^- coordinate strongly. The two first named have a considerable tendency to give polymeric structures. A rare single crystal X-ray determination is that of $Na_4Yb(OH)_7 \cdot 2.5H_2O$, mentioned in Section 39.2.4.1. It shows octahedral coordination of the Yb^{3+} ion.[251]

Sulfato complexes have been included in a recent review.[382] To exemplify sulfate structures, the hydrated sulfate $Ce_2(SO_4)_3 \cdot 9H_2O$ contains, in addition to nine-coordinated $Ce(H_2O)_6(SO_4)_3$ groups, Ce^{3+} ions twelve-coordinated to sulfate groups.[383] A number of other sulfates have been structurally investigated, and coordination by monodentate and bidentate sulfate groups is observed. Thus $Nd_2(SO_4)_3 \cdot 5H_2O$ shows Nd^{3+} in pairs, coordinated in a very distorted tricapped trigonal prismatic manner to two H_2O, and six or seven SO_4^{2-}. Two SO_4^{2-} are bridging groups, monodentate or bidentate to each Nd^{3+} ion in the pair, and the pairs are further linked in a three-dimensional network.[384]

Nitrate complexes, including hydrated nitrates, have been well studied. This ion is almost always bidentate towards a lanthanide ion, and discrete complexes or complex anions are usually formed, in contrast to the sulfate complexes mentioned above. The complex anions $[M(NO_3)_5]^{2-}$, where M = Ce, Eu, Ho or Er, have had their structures reported and are pseudotrigonal bipyramidal. The M—O distances are Ce—O = 2.553–2.591 Å and Er—O = 2.392–2.493 Å.[385–8] The $(Hpy)NO_3$–$Yb(NO_3)_3$ aqueous system has been studied, and $(Hpy)_2[Yb(NO_3)_5]$ isolated from it and characterized by X-ray powder pattern.[389]

The nine-coordinated uncharged aqua complex $[M(NO_3)_3(H_2O)_3]$ is found in $[Ho(NO_3)_3(H_2O)_3] \cdot 2(4\text{-bipy})$, in which Ho—O(nitrate) = 2.42–2.63 Å and Ho—O(water) = 2.30–2.35 Å,[390] and in $[Gd(NO_3)_3(H_2O)_3]$, in which Gd—O(nitrate) = 2.411–2.533 Å and Gd—O(water) = 2.308–2.459 Å.[391] The slightly larger ion Nd^{3+} will, however, accept either ten-coordination in $[Nd_2(NO_3)_8(H_2O)_4(4\text{-bipy})]^{2-}$ where each Nd^{3+} ion is coordinated to three bidentate and one monodentate NO_3^-, two H_2O and one nitrogen atom of the bipyridyl;[392] or eleven-coordination where all four nitrate ions are bidentate. Another hydrated nitrate is the irregularly ten-coordinated $[Nd(NO_3)_3(H_2O)_4] \cdot 2H_2O$ where Nd—O(nitrate) = 2.547–2.718 Å and Nd—O(water) = 2.429–2.462 Å,[393] while the rare eleven-coordination is observed in $[M(NO_3)_3(H_2O)_5]$ where M = La or Ce.[394,395]

39.2.5 Sulfur Donor Ligands

Sulfur is a comparatively weak donor towards lanthanide ions, but in favourable circumstances coordination does occur. The sulfur should preferably be part of a bidentate or polydentate system, and should preferably carry a negative charge, to judge from the nature of the few compounds of this class which have been isolated.

The bidentate anions $R_2PS_2^-$ give a number of complexes which are fairly stable, soluble in organic solvents, and have been studied by single crystal X-ray and by NMR. Thus treatment of hydrated lanthanide chlorides with salts of $S_2PR_2^-$ (R = Me, C_6H_{11} or OEt) gives complexes $[M(S_2P(C_6H_{11})_2)_3]$ or $M'[M(S_2PR_2)_4]$ (M′ = Na, Ph_4As or Ph_4P; M = La–Lu and Y). The electronic spectra of these complexes show oscillator strengths of three to nine times those of the hydrated ions, and this may be caused by a transfer of intensity from charge-transfer bands.[396,397]

The dithiophosphate complexes react with Ph_3PO to give adducts, whose crystal structures

have been determined, of the types $[M\{S_2P(OEt)_2\}_3(Ph_3PO)_2]$ (M = La–Pr) or $[M\{S_2P(OEt)_2\}_2(Ph_3PO)_3]^+$ (M = Nd–Lu and Y) (see Section 39.2.4.4).

The X-ray crystal structures of $[M(S_2P(C_6H_{11})_2)_3]$, where M = Pr or Sm, have been determined. Interatomic distances are Pr—S = 2.804–2.877 Å, and Sm—S = 2.781–2.796 Å. The Pr complex is isostructural with the Nd analogue and the Sm complex with the Eu–Lu and Y analogues.[398] Both these complexes are trigonal prismatic, slightly distorted by a small rotation of all three ligands about the M—P vector. This geometry, as opposed to trigonally distorted octahedral, is necessitated by the small ratio of ligand bite to metal ionic radius. This last point was explored by crystal structure determinations of the Dy and Lu analogues. The angle of twist of the ligands about the M—P vector increases from 18.5–17.3° (Sm) to 19.1–17.8° (Dy) to 20.0–18.6° (Lu) as the bite:M—S distance ratio increases in the sequence 1.203, 1.219, 1.234. In the Lu complex, coordination geometry is best described as a trigonally distorted octahedron.[399]

The tetrakis-dithiophosphinate complex $[PPh_4][Pr(S_2PMe_2)_4]$, whose crystal structure has also been determined, has a distorted tetragonal antiprismatic geometry with Pr—S = 2.888–3.015°.[400] The complex ions $[M\{S_2P(OEt)_2\}_4]^-$, have been the subject of an NMR paramagnetic shift study (see Section 39.2.9.4).

Early among the lanthanide–sulfur complexes were the dithiocarbamates, of which two types $[M(Et_2NCS_2)_3]$ and $[NEt_4][M(Et_2NCS_2)_4]$ were first reported.[401] Later the series $Na[M(Et_2NCS_2)_4]$, where M = La–Yb, was prepared[402] and the X-ray structure of the La example showed distorted dodecahedral coordination with La—S = 2.97 Å average. Charge-transfer bands obtruded considerably into the visible, the Eu compound being brick-red and the Yb bright yellow. The *f*–*f* bands showed definite red shifts, and the $f \rightarrow d$ transition of the Ce complex was brought into the visible. All these effects are as usually observed with conjugated or polarizable ligands.

Uncharged thioester sulfur atoms are forced to coordinate with lanthanides in a series of thia-18-crown-6 macrocyclic ligands. The ligands are 1,10-dithia-18-crown-6 (L^2), 1,4,10,13-tetrathia-18-crown-6 (L^4) and hexathia-18-crown-6 (L^6). Complexes obtained were $M(ClO_4)_3(L^2)\cdot H_2O$ (M = La–Pr), $Nd(ClO_4)_3(L^2)$, $Eu(ClO_4)_3(L^4)\cdot H_2O$ and $M(ClO_4)_3(L^6)\cdot H_2O$ (M = Sm, Eu or Yb), together with some similar acetonitrile adducts. There is no doubt that all three ligands are coordinated at least with europium merely from the colours: the Eu complexes are respectively yellow (L^2), yellow-orange (L^4) and orange (L^6). This is confirmed by a study of the charge-transfer bands in the near UV, which are due to $n \rightarrow f$ transitions, and of course by the crystal structure of $[La(ClO_4)_2(H_2O)(L^2)]ClO_4$ which shows a slightly folded six-coordinated macrocycle with a bidentate perchlorate on one side of it, and a monodentate perchlorate and a water molecule coordinated on the other side. Interatomic distances are La—S = 3.030, 2.045; La—O(L^2) = 2.591–2.623; La—O(water) = 2.539; La—O(perchlorate) = 2.494 (monodentate) and 2.683, 2.738 Å (bidentate). The definitely bonded La—S distance of over 3 Å is noteworthy.[403]

The Bu^tS^- group acts as a bridging ligand in $[Gd_2(\mu\text{-}SBu)_2\{N(SiMe_3)_2\}_4]$. This was made from the rather similar chloro-bridged complex $[Gd_2(\mu\text{-}Cl)_2\{N(SiMe_3)_2\}_4(THF)_2]$ where each Gd^{3+} ion is five-coordinated. X-Ray structures of both these complexes were obtained. In the sulfide complex, which can also be made by reaction of $[Gd\{N(SiMe_3)_2\}_3]$ with Bu^tSH, Gd—S = 2.760 and 2.823 Å and Gd—N = 2.230 and 2.244 Å, while the coordination is distorted tetrahedral with angles ranging from 135° to 71°.[404]

39.2.6 Ligands Containing Nitrogen and Oxygen Donors

Of the compounds which fall into this category, complexes of edta and its derivatives form an important group and will be treated separately. Among complexes of other ligands, there has been a fair amount of work directed at synthesis or at obtaining stability constants for multifunctional organic ligands where the structure of the resulting complexes must be in substantial doubt in the absence of specific structural data. In this section, emphasis is placed upon those studies where, for one reason or another, the experimental results being discussed can be viewed in terms of an at least reasonably probable structure.

39.2.6.1 Edta and related ligands

Complexation between lanthanide ions and edta or related ligands was invesigated in a number of early studies, and has been the subject of a short review[405] which is still useful

(though there have been changing views on coordination numbers of the hydrated lanthanide ions). There are two main points. First, complexation by these ligands is often entropy driven, values of ΔH being only moderately negative or even slightly positive, while ΔS values are strongly positive. This seems to be in very reasonable agreement with the chemical process involved, namely the displacement of a number of water molecules from a strongly hydrated tripositive ion by a polydentate ligand whose N or O donors are forming bonds with the lanthanide ion, probably of a similar enthalpy to those formed by water.

The second salient feature is the decidedly non-monotonic trend usually observed when ΔH or ΔS values are plotted against atomic number or any simple function of ionic radius. This is usually interpreted in terms of a discontinuity of hydration number at some point in the lanthanide series, both in the hydrated ion $[M(H_2O)]^{3+}$ and in the complex $[M(ligand^{n-})(H_2O)_y]^{(3-n)+}$. Certainly the fact that the value of y in complexes of this type is finely balanced is shown by the two structures adopted by La–edta complexes, depending on ligand charge, in the solid state. These are $K[La(edta)(H_2O)_3]\cdot 5H_2O$ which is nine-coordinated[406] with average interatomic distances of 2.755 (La—N), 2.507 (La—O(edta)) and 2.580 Å (La—O(water)); and $[La(Hedta)(H_2O)_4]$ which is ten-coordinated[407] with corresponding distances of 2.865, 2.555 and 2.592 Å respectively. These two structure determinations, as a point of historical interest, first made high (greater than six) coordination numbers for lanthanide complexes widely accepted, though there had been previous evidence in their favour.[408,409]

The complex anions $[M(edta)(H_2O)_3]^-$ where M = Pr, Sm, Gd,[410] Tb[411] and Dy[412] all have similar coordination to the lanthanum complex, but for Er and Yb, $[M(edta)(H_2O)_2]^-$, which are eight-coordinated, are obtained.[412,413] The change in coordination number occurs at some point in the Ho area. Of course, it is by no means certain that a change, if there is one, occurs at exactly the same position in the series in solution.

In many cases, the inflexions present in the plots of ΔH and ΔS *vs.* atomic number compensate, leading to much smoother curves for corresponding plots of ΔG or K. Examples of this type of behaviour are shown in reference 405, where values of ΔG, ΔH and ΔS for lanthanide complexes with edta and related ligands are plotted. Extensive lists of association constants for edta-type and other carboxylate ligands have been given.[414,415]

NMR has been used to study the mode of complexation of La^{3+} and Lu^{3+} with 2-hydroxyethylenediaminetriacetic acid (H_4L) at 0–95 °C and various pH values. Both six-coordinated and five-coordinated (*i.e.* without the hydroxyl oxygen coordinated) complexes were observed, depending on the conditions.[416]

Edta-related lanthanide complexes are of course coordinatively unsaturated in the absence of other ligands. In water, they are hydrated and the water of hydration may be displaced by other species. The kinetics of such a process, the reaction of europium 1,2-diaminocyclohexanetetraacetate, $[Eu(dcta)aq]^-$ with iminodiacetate ion, ida^{2-}, to give $[Eu(dcta)(ida)]^{3-}$, have been studied by the elegant method of selective tunable laser excitation of the $^7F_0 \rightarrow {}^5D_0$ transition in either species. If the fluorescent lifetimes of the excited states are comparable with the rate of reaction, a study of these in the reacting system will give kinetic parameters. Those obtained in this instance at 23.5 °C were k (forward) $= 1.6 \times 10^7\ M^{-1}\ s^{-1}$; k (reverse) $= 2.6 \times 10^3\ s^{-1}$; and $\log K = 3.80$. The lifetimes of the species were: $[Eu(dcta)aq]^-$, 0.320 ms; $[Eu(dcta)(ida)]^{3-}$, 0.805 ms.[417] A similar system, but using edta instead of dcta, has been investigated by NMR[418] and pH titration methods[419] and gave greater $\log K$ values of 4.28 and 4.23 respectively. It is possible that the greater bulk and rigidity of the dcta ligand is related to this difference, but the ionic strengths were different in the various studies.

In addition to these kinetic studies, there has been a considerable amount of work on the thermodynamic parameters associated with this type of reaction. Thus the interaction of $[M(edta)aq]^-$ with anions of 8-hydroxyquinoline-5-sulfonic acid (oxs^-), ida^{2-} and nitrilotriacetic acid (nta^{3-}) was thoroughly studied for M = Y, La–Lu (except Pm) by calorimetry and pH titration,[419] and ΔG, ΔH, ΔS and K found. Some of these values are given in Table 5. It was, however, concluded from the variation of these parameters with atomic number that all M^{3+} in aqueous solution have the same coordination number (nine) but that the coordination number of the $[M(edta)aq]^-$ species changes between Sm^{3+} and Tb^{3+}.

It will be seen from Table 5 that the variation of parameters with atomic number is by no means always monotonic. The explanation of this must again be connected with variation of coordination number along the series of lanthanides. If the strongly coordinating organic ligands are reasonably assumed to exert their full ligancy, then any variation must be in the extent of inner-sphere hydration of the various species, as it is rather unlikely that there is a

Table 5 Thermodynamic Parameters[419] for the Reaction

ΔG, ΔH in kJ mol^{-1}, ΔS in J mol^{-1} k^{-1}.

dramatic alteration in outer-sphere hydration at some point in the series. The detailed interpretation of these changes is of course not easy.

Though edta forms very stable 1:1 complexes with lanthanides, its 2:1 complexes are much less stable. In the case of praseodymium, these have been investigated by ^{1}H NMR using shift and broadening data. The 1:1 complex shows resonances which are consistent with the two types of proton present. The 2:1 complex shows, however, two distinguishable molecules of edta, one similar in line widths to the 1:1 complex, and another more broadened. The second molecule exchanges rapidly on the NMR time scale with an excess of edta and it is postulated that the first molecule is fully coordinated while the second is coordinated by only one iminodiacetate residue, there being rapid intra- and inter-molecular rearrangement involving this molecule only. These studies were at pH 5–12, edta:Pr^{3+} ratios of 1–50 and temperatures of 8–98 °C. At the higher temperature, inner-sphere exchange between the two coordinated edta molecules began to take place also.[420]

The kinetics of exchange of cerium with other lanthanide ions in lanthanide edta complexes has been investigated in some detail by isotope exchange and spectrophotometry.[421–423] Exchange takes place by two concurrent routes: by the proton-catalysed dissociation of the complexes, or by direct attack of the exchanging metal on the complex. In the interval $3 < pH < 5$ the dissociative path predominates. By spectrophotometric methods using the Ce^{3+} absorption at 280 nm, the very fast rates of the lanthanide–edta complex formation can be obtained.[424] They are shown in Table 6. It seems probable that the rate-controlling step in the reaction between M^{3+} and $Hedta^-$ is the ring closure, which follows the initial formation of a metal–carboxylate bond.

Table 6 Rate Constants for Formation of Lanthanide–edta Complexes[424]

k ($M^{-1}s^{-1}$)	Nd^{3+}	Gd^{3+}	Er^{3+}	Y^{3+}
10^{-8} k(assoc, Hedta)	2.7	3.0	1.8	0.9
10^{-6} k(assoc, H_2edta)	1.1	1.1	0.54	0.18
k(exch)	0.35	0.28	0.22	0.14

The reactions referred to are as follows:

$$Hedta^{3-} + M^{3+} \xrightarrow{k(\text{assoc, Hedta})} M(edta)^- + H^+$$

$$H_2edta^{2-} + M^{3+} \xrightarrow{k(\text{assoc, } H_2\text{edta})} M(edta)^- + 2H^+$$

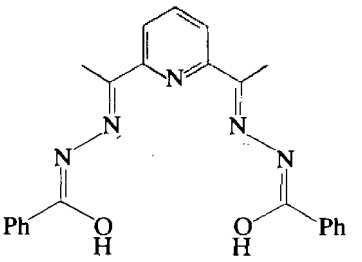
$$Ce(edta)^- + M^{3+} \xrightarrow{k(\text{exch})} M(edta)^- + Ce^{3+}$$

In another investigation,[425] the exchange between $[Ce(edta)aq]^-$ and hydrated Pb^{2+}, Ni^{2+} or Co^{2+} ions again show reaction by dissociation of protonated [Ce(Hedta)aq] as well as by the direct attack of metal ions on $[Ce(edta)aq]^-$ or [Ce(Hedta)aq]. The kinetic parameters for the Ni^{2+} or Co^{2+} ions could be related to the relatively slow ($k = 2.6 \times 10^6$ s^{-1} for Co^{2+} and 3.4×10^4 s^{-1} for Ni^{2+}) water exchange reactions of these ions. The direct attack was interpreted in terms of an intermediate in which one of the carboxylate groups was coordinated to the incoming ion rather than to Ce^{3+}. These reactions were followed by spectrophotometry at 280 nm, where the absorbance of Ce^{3+}aq is much lower than the edta complex.

39.2.6.2 Other nitrogen and oxygen donors

The tris(dipicolinate) complexes of the lanthanides have been submitted to X-ray crystallographic examination. These are rather important compounds, being very stable, water-soluble and having nine-coordinated D_3 symmetry, and several examples have been examined. All these show nearly side-face-centred trigonal prismatic coordination, with the triangular faces slightly rotated relative to one another to accommodate the bite of the tridentate ligands. Complexes examined were $Na_3[Nd(dipic)_3]\cdot 15H_2O$ (Ce–Dy are isostructural) with Nd—O = 2.37–2.61 Å and Nd—N = 2.57–2.59 Å;[426] $Na_3[Yb(dipic)_3]\cdot 13H_2O$ (Ho—Tm are isostructural) with Yb—O = 2.34–2.43 Å and Yb—N = 2.50–2.53 Å;[427] $Na_3[Yb(dipic)_3]\cdot NaClO_4\cdot 10H_2O$ (Ho—Lu isostructural) with Yb—O = 2.38 Å and Yb—N = 2.43 Å;[428] and $Na_3[Yb(dipic)_3]\cdot 14H_2O$ with Yb—O = 2.35 Å and Yb—N = 2.35 Å av.[429] The $[Eu(dipic)_3]^{3-}$ ion has been examined by magnetic field-induced circularly polarized emission spectroscopy at 0–4.2 T using a c.w. Ar ion laser. The $^7F_0 \rightarrow {}^5D_2$ emission indicated that D_3 symmetry is maintained in solution.[430]

There are difficulties associated with the use of ordinary electronic absorption spectra of lanthanide complexes in solution to provide detailed information regarding coordination number and geometry. However, difference spectra *versus* $NdCl_3$ are reported for Nd^{3+}–ligand (L) solutions for the $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^4G_{7/2}$ transitions (L = dipicolinate, oxydiacetate, iminodiacetate, malate, methyliminodiacetate and *N,N'*-ethylenebis{*N*-(*o*-hydroxyphenyl)glycinate}). Hypersensitive behaviour was examined and transition dipole strengths were discussed in terms of the nature of the complex species present.[431]

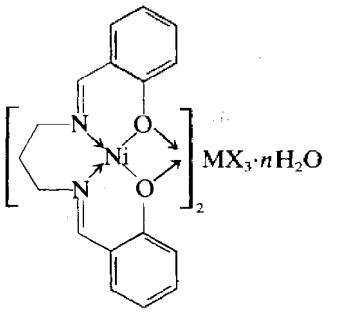


A somewhat similar investigation[432] of aqueous complexes of Er^{3+} with the ligands dipicolinate, oxydiacetate, iminodiacetate, (methylimino)diacetate and *N,N'*-ethylenebis{*N*-(*O*-hydroxyphenyl)glycine} has been carried out over a range of pH. The oscillator strengths of the hypersensitive transitions $^4I_{15/2} \rightarrow {}^2H_{11/2}$, $^4G_{11/2}$ were rationalized in terms of ligand structure and coordination properties, and ligand field geometry. Intensity calculations, based on a theoretical model for $4f \rightarrow 4f$ electric dipole strengths,[433] were carried out for some of the structures believed to be those adopted, and the spectra–structure correlations discussed. There was remarkably good agreement between calculated and observed oscillator strengths, but though encouraging, this should not be taken as either confirmation of the validity of the intensity model or as proof of the solution structures.

Complexes of the ligand acetylhydrazine, $NH_2NHCOMe$ (ah) which coordinates by the italicized atoms, have been prepared and examined by single crystal X-ray. The complexes are $[Er(ah)_4(H_2O)](NO_3)_3$ and an isostructural pair $[M(ah)_3(H_2O)_3]Cl_3$, where M = Ho or Dy. The polyhedron of the erbium complex approximates to a capped square antiprism, with Er—N = 2.54 (average), Er—O(ah) = 2.337 (average) and Er—O(water) = 2.363 Å. The chloride complexes form a face-capped trigonal prism, with Dy—N = 2.571, Dy—O(ah) = 2.360 and Dy—O(water) = 2.425 Å.[434] However, in the related ligand $H_2NNHCONHNH_2$, carbohydrazide (ch) a series of complexes $M(ch)_3Cl_3$, where M = La–Eu or Ho, has been obtained from anhydrous ethanol, where IR spectra indicate that a six-membered chelate ring is formed by coordination of the italicized nitrogen atoms; this needs to be confirmed.[435] Another hydrazine-related ligand, thiosemicarbazidediacetic acid (H_2tsda) $H_2NCSNHN(CH_2COOH)_2$, gives hydrated complexes of the types M(tsda)Cl, M(tsda)(OH) and $NaM(tsda)_2$, where M = Nd, Ho or Er, in which coordination by 3N and 2O as italicized was postulated, and the visible spectra were investigated.[436]

Still another hydrazide ligand, 4-pyridyl-$C(O)NHNH_2$ (L) gives complexes $[ML_3(H_2O)_3](NO_3)_3$, where M = La, Nd, Sm, Gd, Ho and Yb. The X-ray structure of the Sm example shows irregular nine coordination involving bidentate L, using the amide oxygen and the NH_2 nitrogen; the pyridine nitrogen is not coordinated.[437]

Yet another hydrazine-based ligand, 2,6-diacetylpyridine bis(benzoic acid hydrazone) (dpbh; **10**) forms an interesting complex with $La(NO_3)_3$ in which the coplanar penannular pentadentate dpbh coordinates together with three bidentate nitrate ions to give an 11-coordinated complex. One nitrate ion is disposed near the gap in the dpbh chain with the other two above and below the dpbh plane. Interatomic distances are: La—N(ligand) = 2.769–2.790, La—O(ligand) = 2.507 and 2.560, and La—O(nitrate) = 2.563–2.648 Å.[438]

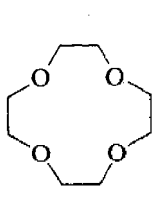


A structurally very interesting complex is formed by the related ligand 2,6-diacetylpyridine bis(semicarbazone) (dapsc; **3**). This ligand and $Ce(ClO_4)_3$ in aqueous alcohol gave $[Ce(dapsc)_2](ClO_4)_3\cdot 3H_2O$ in which the ligands are each pentadentate and are essentially arranged each in one of two mutually perpendicular planes, though each ligand is slightly

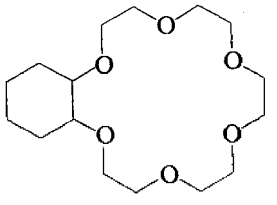
(10)

twisted out of planarity. The IR CO band shifted from 1690 cm^{-1} in the free ligand to 1650 cm^{-1}. Interatomic distances are Ce—N = 2.642–2.724 while Ce—O = 2.483–2.597 Å.[439]

A series of complexes between lanthanide ions and the transition metal complexes *N,N'*-1,3-propylene-bis(salicylideniminato)nickel(II), Ni(psal), or the corresponding copper complex, has been obtained (**11**).[440] In these compounds, the two phenate oxygen atoms of the copper or nickel complex are able to form a chelate group which apparently coordinates with lanthanide ions, giving the stoichiometries $MM'(psal)X_3 \cdot nH_2O$ where M' = Ni, M = La–Sm, X = NO_3, $n = 0$; M' = Ni, M = Eu–Lu, X = NO_3, $n = 2$; M' = Ni or Cu, M = La–Dy, X = NCS, $n = 3$; M' = Ni or Cu, M = Ho–Lu, X = NCS, $n = 4$; M' = Ni or Cu, M = La–Lu, X = ClO_4, $n = 4$; M' = Ni or Cu, M = La–Sm, X = Cl, $n = 4$; and M' = Ni or Cu, M = Eu–Lu, X = Cl, $n = 2$.

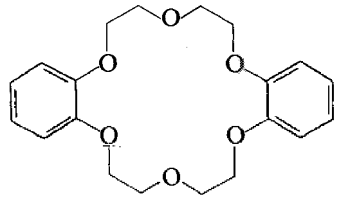


(11)



39.2.7 Complexes with Macrocyclic Ligands

39.2.7.1 Introduction



Since Pedersen's remarkable paper[441] appeared as long ago as 1967, in which he described a wide variety of cyclic polyethers (crown ethers) and their complexes with Group I and Group II metal ions, a considerable interval of about 10 years occurred before the principle was extended to the lanthanide ions. This is surprising, because the ionic radii of the tripositive lanthanides together with the non-directional electrostatic nature of their bonding should indicate that they might form strong complexes with such ligands. The factor that may have prevented early extension of this work into the lanthanide area is the large hydration energy of the tripositive lanthanide ions which in fact leads to dissociation of most lanthanide–crown ether complexes in aqueous solution. However, the use of non-aqueous solvents allows the ready formation of these interesting complexes. Later work, detailed below, has shown that crown thioethers will also complex, though not strongly, while nitrogen analogues of crown ethers will form extremely stable lanthanide complexes. Crown nomenclature is illustrated by 12-crown-4 (**12**), cyclohexyl-18-crown-6 (**13**) and dibenzo-18-crown-6 (**14**).

(12)

(13)

(14)

39.2.7.2 The crown ethers $(CH_2CH_2O)n$ and their derivatives

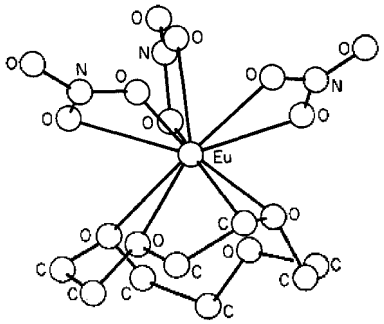
Molecular models indicate that 15-crown-5 and its substituted derivatives should on the basis of ionic radii give stable complexes with lanthanides,[442] and an early report[443] of lanthanide–crown coordination in fact described the formation in acetonitrile solution of complexes $M(NO_3)_3$(benzo-15-crown-5) and $M(NCS)_3$(benzo-15-crown-5)·H_2O, where M = La–Lu. Other contemporary work[444] described a large number of lanthanide complexes of this same ligand, $M(NO_3)_3$(benzo-15-crown-15), where M = La–Sm, and $M(NO_3)_3$(benzo-15-crown-5)·$3H_2O$·Me_2CO, where M = Sm–Lu, together with $M(NO_3)_3$(dibenzo-18-crown-6), where M = La–Nd. Conductance measurements showed that the nitrate ions were coordinated in solution. Coordination of the macrocycle was indicated by UV or IR absorption; thus Pedersen[441] had observed that the absorption band of dibenzo-18-crown-6 at 275 nm was modified by addition of sodium hydroxide, while the C—O stretching frequency of the polyethers at about 1100 cm^{-1} is moved by about 30 cm^{-1} to lower wavenumber by coordination. The latter effect seems to be a reliable indicator of coordination to a lanthanide ion.

A number of X-ray crystal structure determinations, mainly involving six-oxygen crowns and nitrate or perchlorate ions, have made the structural principles of lanthanide–crown complexes clearer. It appears that lanthanides, when coordinating with six-oxygen crowns (in which case only the lighter lanthanides form stable complexes) will form total coordination numbers of twelve, eleven or ten, depending on the nature of the anionic ligands and the size of the lanthanide cation (Table 7). Thus in $[La(NO_3)_3$(18-crown-6)] where the lanthanide radius is the largest possible and the steric demands of the closely bidentate nitrate anion are quite small, twelve-coordination results.[445] However, the smaller Nd^{3+} ion, besides giving an analogous twelve-coordinated complex,[446,447] also gives $[Nd(NO_3)_2$(18-crown-6)$]_3[Nd(NO_3)_6]$ where the complex cations are ten-coordinated only,[448] and with the more bulky chloride anion, nine-coordinated $[GdCl_2(EtOH)$(18-crown-6)]Cl is the resulting complex.[449] In $[Y(NCS)_3$(18-crown-6)][450] where the N-coordinated anions are not sterically demanding, but the Y^{3+} cation is smaller than in the preceding examples, nine-coordination again occurs, and the crown ligand shows some steric strain. Interestingly, in $[Sm(ClO_4)_3$(dibenzo-18-crown-6)],[451] the rather wide bite and poorer donor properties of the perchlorate ligand compared with nitrate lead to ten-coordination only, with one bidentate and two monodentate perchlorate ions.

Table 7 Lanthanide–Ether Distances in Crown Ether Complexes

Complex	*Coordination number*	$M—O_{ether}$(Å)	*Ref.*
$[La(NO_3)_3$(18-crown-6)]	12	2.644–2.680	445
$[La(ClO_4)_2$(dithia-18-crown-6)$(H_2O)]^+$	10	2.59–2.62	461
$[Nd(NO_3)_3$(18-crown-6)]	12	2.580–2.615	446, 447
$[Nd(NO_3)_2$(18-crown-6)$]^+$	10	2.56–2.71	448
$[Eu(NO_3)_3$(15-crown-5)]	11	2.55–2.69	453
$[Eu(NO_3)_3$(12-crown-4)]	10	2.477–2.570	452

X-Ray structure determinations of complexes of smaller crown ligands are much fewer than those of the six-oxygen crowns, but Bünzli and co-workers have reported ten-coordinated $[Eu(NO_3)_3$(12-crown-4)][452] and eleven-coordinated $[Eu(NO_3)_3$(15-crown-5)],[453] both of which show pyramidal coordination of the small crowns (Figure 5).



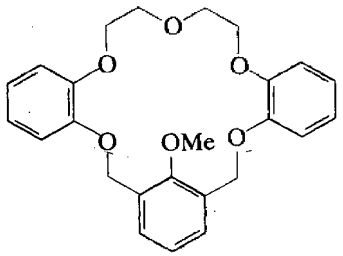


Figure 5 Structure of $[Eu(NO_3)_3$(15-crown-5)] (reproduced with permission from ref. 453)

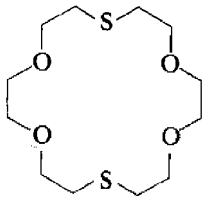
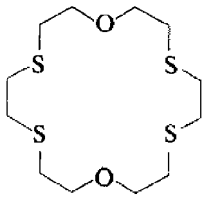
Where the lanthanide ionic radius and the macrocyclic cavity are incompatible, though in hydrous conditions the crown ether is likely to be displaced by water ligands, the crown may still be present in the structure of the crystal as a hydrogen-bonded adduct. This behaviour is seen in $[Gd(NO_3)_3(H_2O)_3]\cdot$(18-crown-6).[445] This type of compound is quite well known in the case of *s* block metals also, *e.g.* $[Mg(H_2O)_6]Cl_2\cdot$(12-crown-4)[454] and, a more subtle case, [Ca(nitrobenzoate)$_2$(benzo-15-crown-5)]$\cdot 3H_2O\cdot$(benzo-15-crown-5)[455] in which an apparent 2:1 complex has only half its crown ligand coordinated to Ca^{2+}.

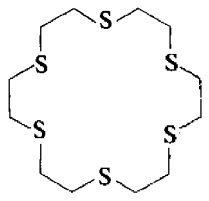


The modified crown ligand (**15**), which is sterically unsuitable for coordination of all six ether oxygen atoms, forms a complex $[Sm(NO_3)_3(H_2O)(L)]$ where L is the 2-methoxy-1,3-xylyl crown (**15**).[456] This is an irregular bicapped square antiprism in which three consecutive oxygen atoms of the crown ligand (the third being the OMe) are coordinated.



(**15**)

Although they are not macrocyclic ligands, polyethyleneglycols behave somewhat similarly to the crown ethers regarding lanthanide complexation, as established by a number of crystal structure determinations. Thus a series of neodymium complexes shows consistent 10-coordination, namely $[Nd(NO_3)_3$(tri-eg)],[458] where tri-eg is triethyleneglycol, $[Nd(NO_3)_2$(penta-eg)]NO_3,[458] and $[Nd(NO_3)_2(NO_3')$(tetra-eg)],[459] where NO_3' is monodentate. The larger La^{3+} ion shows 11-coordination in $[La(NO_3)_3$(tetra-eg)].[460]



Lanthanides form far fewer complexes with sulfur-based ligands than with oxygen-based ligands, and this appears to be a real effect based on chemical properties and not simply on lack of exploration. It is very interesting, therefore, that the relatively favourable entropy change upon complexation of the crown ligands is sufficient to force sulfur into coordination.[461] Thus dithia-18-crown-6 (**16**) forms, from acetonitrile solution, a series of complexes of the type $M(ClO_4)_3$(dithia-18-crown-6)$(H_2O)_x(MeCN)_y$ where M = La–Eu, Ho or Yb; $x = 0$ or 1; $y = 0$, 1.5 or 2. The crystal structure of $[La(ClO_4)_2(H_2O)$(dithia-18-crown-6)]ClO_4 shows ten-coordination with one bidentate and one monodentate perchlorate ion, but with both sulfur atoms coordinated. The related ligands (**17**) and (**18**) also gave 1:1 complexes $M(ClO_4)_3$(ligand)(H_2O) where IR evidence indicated coordination by sulfur, but no X-ray data are available. See also Section 39.2.5.

(**16**)

(**17**)

(**18**)

Although the lanthanide crown ether complexes tend towards insolubility in non-polar solvents and dissociate in water, they may be studied by physicochemical methods in solvents such as acetonitrile. Thus a ^{13}C and ^{1}H study[462] of $[Pr(ClO_4)_3$(*cis*-syn-*cis*-dicyclohexyl-18-crown-6)] in $CD_3CN/CDCl_3$ was carried out and the results of an analysis of paramagnetically shifted spectra indicated that the conformation of the coordinated crown determined[463] by X-ray (for the lanthanum nitrate analogue) was adopted in solution by the $Pr(ClO_4)_3$ complex. The ^{1}H paramagnetic shifts were largely dipolar in origin, but the ^{13}C shifts had a considerable contact contribution. In acetonitrile, ^{1}H NMR and conductivity measurements[445] provided evidence for

an equilibrium with a stability constant $\log K = 2.82$ and an enthalpy of dissociation $\Delta H_{dis} = 0 \pm 2$ kJ mol^{-1} (equation 7).

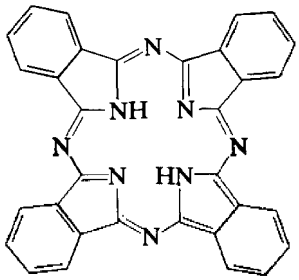
$$Yb(NO_3)_3(CD_3CN)_n + 18\text{-crown-6} \longrightarrow [Yb(NO_3)_2(18\text{-crown-6})]^+ + NO_3^- + nCD_3CN \quad (7)$$

Similar measurements[463] led to the following values of $\log K$ for $M(NO_3)_3$ with 18-crown-6: La, 4.4; Pr, 3.7; Nd, 3.5; Eu, 2.6; Yb. 2.3. The increased stability of the complexes of the larger lanthanides is very noticeable here. The low-temperature spectrum[463] of $[Pr(NO_3)_3(18\text{-crown-6})]$ in CD_3CN shows splitting into two equal peaks, both paramagnetically shifted, whereas only one (in addition to a little dissociated ligand) is seen at room temperature. It must be probable that the X-ray structure, with two nitrate groups on one side of the crown and one on the other side, is being observed at low temperature whereas rapid nitrate exchange occurs at the higher temperatures, while rotation of crown relative to nitrate occurs at all temperatures.

In a potentiometric study in propylene carbonate, using Pb^{II} or Tl^{I} as auxiliary ions, stability constants have been determined for a variety of crown ethers. Some results[464] are shown in Table 8. They show that the 'wrap-around' ligand dibenzo-30-crown-10 is relatively quite effective, while the 2:1 complexes, presumably of the sandwich type, are favoured for larger lanthanides and smaller crowns.

Table 8 Log Association Constant Values for Lanthanide–Crown Ether Complexes in Propylene Carbonate[464]

Crown	*I*		*II*		*III*	*IV*	*V*
	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_1$	$\log K_1$
La	5.0	2.0	6.5	3.7	5.2	3.2	4.3
Yb	5.0	—	5.9	2.0	2.6	2.8	4.8



I = 12-crown-4; II = 15-crown-5; III = *tert*-butylbenzo-15-crown-5; IV = di(*tert*-butylbenzo)18-crown-6; V = dibenzo-30-crown-10.

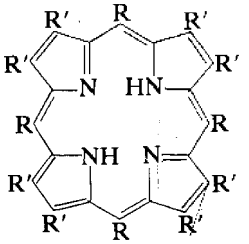
The excitation and fluorescence spectra of some crown ether complexes have been interpreted in terms of the molecular point group symmetry and vibronic coupling.[452,453] This approach tends to be limited to europium(III) complexes.

Non-cyclic long-chain polyethers also form stable complexes with lanthanide ions, as exemplified by $[La(NO_3)_2(pe)]_3([La(NO_3)_6]$, where $pe = MeO(C_2H_4O)_5Me$.[465] Here the cation contains 10-coordinated La^{3+} in a structure similar to that of $[Nd(NO_3)_2(18\text{-crown-6})]^+$.

39.2.7.3 Nitrogen donor macrocycles

As the amines as a class form much stronger complexes with lanthanides than do ethers, so it would be expected that nitrogen-based macrocycles should complex more strongly than do the crown ethers. That this is in fact the case is confirmed by the preparation and properties of a small but representative number of lanthanide complexes of nitrogen donor macrocycles. These may be divided into two groups: complexes of porphyrins and phthalocyanines, which have four nitrogen donors, and complexes of ligands usually with six nitrogen donors which are analogues of crown ethers. Much the earliest compounds to be reported were those of phthalocyanine[466,467] (H_2pc; **19**), and this area has since been extensively developed by Russian workers.

(19)



Lanthanide phthalocyanines may be prepared by heating the metal chlorides[468] or formates[469] with 1,2-cyanobenzamide, 1:1 complexes, for example Er(pc)Cl, being the products. An alternative and better route used phthalonitrile (equation 8).[470,471]

$$C_6H_4(CN)_2 + MCl_3 \xrightarrow{280\,^{\circ}C} M(pc)Cl.nH_2O \quad (8)$$
$$(M = Y,\ n = 4;\ M = Er,\ n = 2)$$

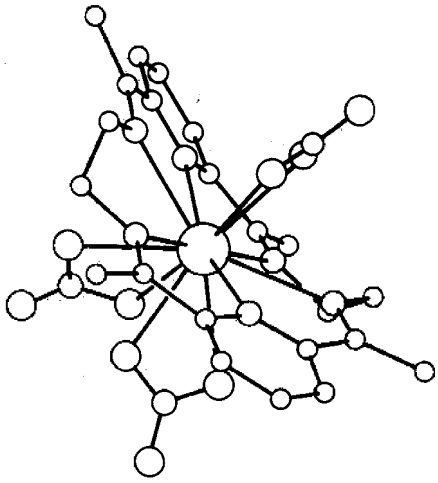
It was later established that with neodymium, 2:1 and 3:2 complexes of constitution Nd(pc)(Hpc) and $Nd_2(pc)_3$, respectively, could be prepared,[472–474] and 2:1 complexes of Y, La, Ce, Nd, Eu, Er and Yb have been reported.[475–477] The lighter lanthanides tend to give 2:1 complexes, while the heavier ones give 1:1 preferentially.[478,9] The X-ray crystal structure of [Nd(pc)Hpc)][480] shows a sandwich structure with one coplanar macrocycle and one concave towards the Nd^{3+} ion. The two ligands are staggered, and Nd—N is in the range 2.39–2.49 Å. The acidic H atom was not located. The 2:1 complexes M(pc)(Hpc) can be anodically oxidized to $M(pc)_2$ (M = Nd, Eu, Ho or Lu).[481] These products $M(pc)_2$ give adducts with molecular iodine with the I_2:complex ratio increasing along the series and reaching 2:1 for Er (Pr, 0.85:1). The addition is reversible on heating, and the resistivity of the brown iodine adducts is less by a factor of ten than the green $M(pc)_2$ complexes.[482]

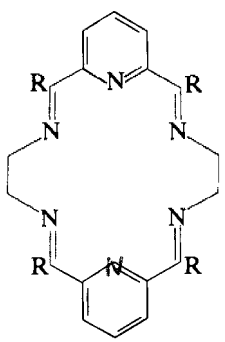
A variety of substituted phthalocyanines has been used to confer solubility in various solvents upon these complexes. Thus water-soluble sulfonated complexes, stable even in strong ammonia, were obtained[483,4] by sulfonation of M(pc)(Hpc) (M = Y, Eu, Gd, Tm, Yb or Lu). The *t*-butyl-substituted complexes M(pc')(Hpc'), where pc' is tetra-4-butylphthalocyanine, are quite soluble in ethanol in contrast to the unsubstituted compounds and their solution absorption spectra, dominated by the ligand, have been studied[485] alone and in the presence of NaOH. These spectral changes, which must correspond with the deprotonation of the Hpc' ligand, are discussed in terms of the magnitude of the splitting of the excited states and the relative orientation of the moments of the electronic transitions of the interacting ligands. The pronounced electrochromism of the lanthanide phthalocyanines has been investigated.[486]

As might be expected in the light of the phthalocyanine complexes described above, the lanthanides also form complexes with porphyrins. Thus the reaction of $Eu(acac)_3$ with *meso*-tetraphenylporphyrin (**20**; R = Ph, R' = H; phporph) gave Eu(acac)(phporph).[487] This reaction was extended[428] to other lanthanides, β-diketonates and porphyrins, giving M(acac)(tolporph) and M(dpm)(tolporph), where M = Pr through to Lu, and tolporph = (**20**; R = *p*-tolyl, R' = H). Soluble in organic solvents, these complexes functioned as upfield ring-current diamagnetic shift reagents. A further extension to *p*-sulfonatophenylporphyrin gave compounds $M(sulporph)(OH)(imidazol)_x$, where M = Gd–Lu, sulporph = (**20**; R = *p*-sulfonatophenyl, R' = H) and $x \leq 2$. These complexes were stable in neutral or highly basic aqueous solution, and induced paramagnetic shifts in cations, anions and neutral species. These shifts received detailed study.[489] An ESCA study[490] of complexes of octaethylporphyrin (**20**; R = H, R^1 = Et, etporph) and phporph of the type M(etporph)(OH), where M = Eu, Gd, Yb or Lu, and M(phporph)(acac), where M = Eu, Gd, Yb or Lu, has been carried out. The results implied the presence of covalent interaction of lanthanide 4*f* and outer 6*s*, 6*p* and 5*d* orbitals, together or as alternatives, with nitrogen valence orbitals.

(20)

There has been recent interest in lanthanide complexes of ligands of the type (**21**). These are in some sense nitrogen analogues of the crown ethers. As Schiff bases, their lanthanide complexes may be synthesized by a template condensation, for example from 2,6-diacetylpyridine, 1,2-diaminoethane and lanthanum nitrate. These components react in alcohols to give $[La(NO_3)_3L]$, where the aza-crown L = (**21**; R = Me). This compound has a structure (Figure 6), quite analogous to that of $[La(NO_3)_3(18\text{-crown-}6)]$, in which La—N





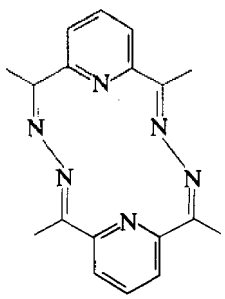


Figure 6 Structure of the aza-crown complex $[La(NO_3)_3(C_{22}H_{26}N_6)]$ ($C_{22}H_{26}N_6$ is **21**; R = Me) (reproduced with permission from ref. 491)

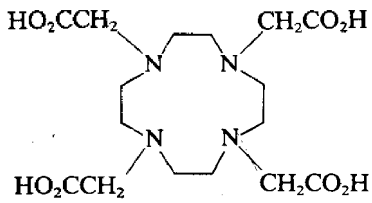


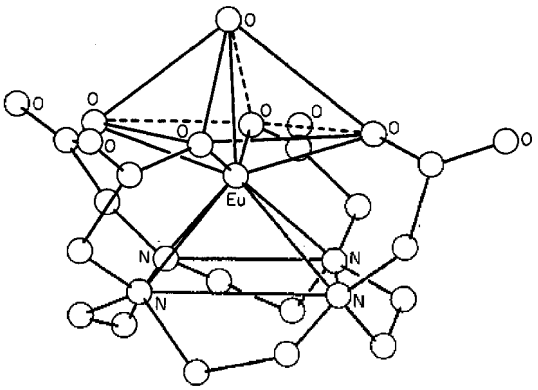
interatomic distances lie in the range 2.672–2.764 Å. Unlike 18-crown-6, however, the aza-crown remains coordinated in aqueous solution and even in an alkaline or fluoride-containing aqueous medium.[491] The use of lanthanum perchlorate in the condensation reaction gives $La(ClO_4)_3L(H_2O)_2$.[492] A number of complexes of the ligand (**21**; R = H) and related ligands formed by condensations using $H_2N(CH_2)_3NH_2$ or $H_2NCH(Me)CH_2NH_2$, rather than $H_2NCH_2CH_2NH_2$, have also been reported.[493,494] In these, the imine double bond has a tendency to hydrate and the original product of the template reaction for the series Nd, Sm, Gd–Lu shows hydration of one of the imine double bonds to give the partial structure —NH—CH(OH)— while the larger ions La—Pr and Eu yield complexes of the unhydrated macrocycle. The Sm complex, which is in the hydrated form, may be converted into a complex of (**21**; R = H; L′) by recrystallization from water, and X-ray analysis of the recrystallized complex shows a ten coordinated Sm^{3+} ion in $[Sm(NO_3)(OH)(H_2O)L']NO_3{\cdot}2MeOH$. The Sm—OH internuclear distance (2.46 Å) is shorter than the Sm—OH_2 distance (2.52 Å).[493] It is also possible to prepare this type of complex by a metal transfer reaction, the complex $[Ba(ClO_4)_2L)]$ reacting in aqueous solution with lanthanide nitrates to give $[M(NO_3)_2L(H_2O)]NO_3{\cdot}H_2O$ (M = La–Pr) or $[M(NO_3)L(H_2O)_2]_2(NO_3)(ClO_4)_3{\cdot}4H_2O$ (M = Nd–Er). The structures of the eleven-coordinated Ce and ten-coordinated Nd compounds were established by X-ray.[495] Lanthanide complexes of the macrocycle (**22**) which, though it contains six nitrogen atoms, is sterically only capable of four-coordination, have been also obtained.[496]

(**21**)

(**22**)

(**23**)

A most interesting functionalized four-nitrogen crown ligand (**23**; H_4dota) has been synthesized.[497] The X-ray structure of the complex Na[Eu(dota)(H_2O)] (Figure 7) shows that the nine-coordinated geometry is approximately capped square antiprismatic with the four N forming a basal square, four carboxylate O forming an upper square, and the H_2O capping the latter.[498] This geometry leads to very large paramagnetic NMR shifts, and the complex acts as an effective shift reagent for H_2O and Cl^-.[499]



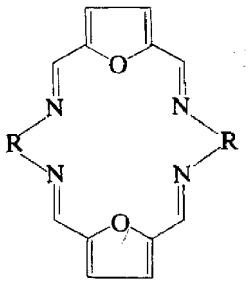


Figure 7 Structure of the anion of Na[Eu(dota)] (H_4dota is **23**) (reproduced with permission from ref. 498. Copyright, American Chemical Society, 1984)

39.2.7.4 Mixed nitrogen and oxygen macrocycles

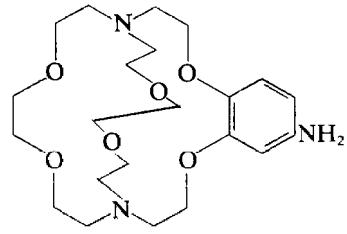
There have been one or two reports of lanthanide complexes of this type of ligand. Thus three furan Schiff bases (**24**; R = $(CH_2)_2$, $(CH_2)_3$ or CH_2CHMe) have been obtained as their complexes with the series La–Nd. These slowly dissociate in water.[500] The functionalized crown ligand 1,10-diaza-4,7,13,16-tetraoxacyclooctadecane-*N,N'*-diacetic acid (dacda) is 18-crown-6 with NCH_2CO_2H units replacing two opposite oxygen atoms. It is characterized by very high association constants for lanthanide ions, determined by potentiometric titration. Thus log *K* values are: La, 12.21; Gd, 11.93; Lu, 10.84. Values for Group I and II ions are much lower.[501]

(**24**)

39.2.7.5 Cryptates

Lanthanides form stable complexes with cryptands typified by $N(CH_2CH_2OCH_2CH_2OCH_2CH_2)_3N$ (this molecule is 2,2,2-cryptate and similar ligands are named analogously). In such complexes the lanthanide ion lies completely inside the cryptate ligand which, in the example given, fills eight positions on the lanthanide coordination sphere. Depending on the relative size of the lanthanide ion and the cryptate ligand, other donors may also coordinate in positions between two —$CH_2CH_2OCH_2CH_2OCH_2CH_2$— strands of the cryptate.

The complexes MCl_3(2,2,1-cryptate), where M = La, Pr, Eu, Gd or Yb, may be prepared from the ligand and MCl_3 in anhydrous organic solvents, and together with $La(NO_3)_3$(2,2,2-cryptate) were the subject of the first report of this type of lanthanide complex.[502] Cyclic voltammetry showed that the redox potentials of the europium and ytterbium complexes of 2,2,1-cryptate and 2,2,2-cryptate were significantly affected in water by complexation. Thus the redox potential decreased from 626 mV for the aqueous Eu^{3+} ion to 205 mV for the Eu^{3+} complex with 2,2,2-cryptate.[502] Using polarography, one-electron reduction kinetics for $[Eu(2,2,1\text{-cryptate})]^{3+}$ and the corresponding 2,2,2 complex with Eu^{2+} or V^{2+} were investigated, together with the oxidation kinetics of $[Eu(2,2,1\text{-cryptate})]^{2+}$ when oxidized by $[Co(NH_3)_6]^{3+}$. The rate constant for electron exchange was estimated to increase over the $Eu^{2+}_{aq}/Eu^{3+}_{aq}$ rate by a factor of 10^7 upon encapsulation by 2,2,1-cryptate. The results indicate



that the low reaction rates observed for the $Eu^{2+}_{aq}/Eu^{3+}_{aq}$ exchange are not due to adiabaticity, but probably due to large Franck–Condon barriers.[503]

These complexes, unlike the crown ether complexes but similar to the aza-crown and phthalocyanine complexes, are fairly stable in water. Their dissociation kinetics have been studied and not surprisingly they showed marked acid catalysis.[504] Association constant values for lanthanide cryptates have been determined.[505,506] A study in dimethyl sulfoxide solution by visible spectroscopy using murexide as a lanthanide indicator showed that there was little lanthanide specificity (but surprisingly the *K* values for Yb are higher than those of the other lanthanides). The values are set out in Table 9.[507]

Table 9 Log Association Constant Values for Lanthanide Cryptates in DMSO[507]

Cryptate	2,2,2	2,2,1	2,1,1
Pr	3.22	3.47	3.86
Nd	3.26	3.01	3.97
Gd	3.45	3.26	3.87
Ho	3.47	3.11	3.80
Yb	4.11	4.00	4.43

Other methods of preparation of lanthanide cryptates have been reported,[508] including the functionalized cryptate (**25**) whose La, Pr and Eu nitrate complexes were obtained. Paramagnetic shifts over a range of about 40 p.p.m. showed complexation with the lanthanide enclosed in the ligand cavity. Preparation was in dry acetonitrile to which triethylorthoformate was added, permitting the use of hydrated lanthanide nitrates.[509] The preparation of an organo derivative $LaCl_2(CPh_3)$(2,2,2-cryptate) has also been reported.[510] The difficulty in straightforward preparation of lanthanide cryptates probably arises from an initial tendency to form insoluble 'external' (*i.e.* not enclosed) complexes and from the formation of hydroxyl ion if any water is present. Cryptates of Eu^{2+} may be prepared in aqueous solution, however, and then converted into the corresponding trivalent complex by electrochemical oxidation.[503]

(**25**)

A number of X-ray crystal determinations have made the principles of lanthanide cryptate structural chemistry fairly clear. In $[La(NO_3)_2$(2,2,2-cryptate)$][La(NO_3)_6]$ (Figure 8), the La^{3+} ion is 12-coordinated with two bidentate nitrate ions coordinating in two of the three spaces between the cryptate chains; the third space is thus too compressed to be occupied also.[508] $[Sm(NO_3)$(2,2,2-cryptate)$][Sm(NO_3)_5(H_2O)]$ shows only one such space occupied[511] and the structure of $[Eu(ClO_4)$2,2,2-cryptate$](ClO_4)_2$·MeCN is similar to the samarium cryptate.[512,513] Internuclear distances in these complexes are shown in Table 10.

Interesting conformation information has been given by a ^1H NMR study of the series of complexes MX_3(2,2,1-cryptate), where X = Cl, NO_3 or ClO_4 and M = La–Yb. A plot of paramagnetic shift against Bleaney's anisotropy constant gives a good straight line, which is evidence that all these lanthanide cryptate species are isostructural in D_2O. Furthermore, a single conformation is either dynamically favoured or stable, because the same AMXY pattern for all four $NCH_2CH_2OCH_2CH_2OCH_2CH_2N$ protons is observed.[514]

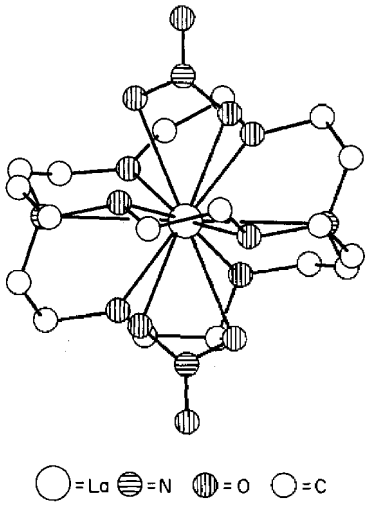


Figure 8 Structure of the cation in $[La(NO_3)_2(2,2,2\text{-cryptate})][La(NO_3)_6]$ (reproduced with permission from ref. 508)

Table 10 Lanthanide–Ligand Distances in Cryptate Complexes

Complex	*Coordination Number*	*M—O$_{ether}$*(Å)	*M—N*	*M—O$_{anion}$*	*Ref.*
$[La(NO_3)_2(2,2,2\text{-cryptate})]^+$	12	2.64–2.74	2.81–2.85	2.63–2.69	508
$[Sm(NO_3)(2,2,2\text{-cryptate})]^{2+}$	10	2.441–2.566	2.748–2.779	2.484, 2.402	511
$[Eu(ClO_4)(2,2,2\text{-cryptate})]^{2+}$	10	2.44–2.52	2.64–2.70	2.67, 2.71	512, 513

39.2.8 Complex Halides

Phase diagrams have been given for the $NaF–MF_3$ systems, where M = La–Lu.[515] In all these systems, hexagonal phases $NaMF_4$ exist below 700 °C. Above this temperature, for M = Pr–Lu, these phases become converted into disordered fluorite-like cubic phases of variable composition. Particularly for the heavier lanthanides, orthohombic phases $Na_5M_9F_{32}$ also exist at lower temperatures, $Na_5Lu_9F_{32}$ being stable from 778 °C to room temperature; other $Na_5M_9F_{32}$ are not stable below 450 °C. The system $NaF–YbF_3$ has also been investigated[516] by DTA and X-ray powder methods; $NaYbF_4$ was again found, together with a fluorite phase $Na_{0.38}Yb_{0.62}F_{2.24}$ and another phase $Na_{0.32}Yb_{0.68}F_{2.36}$ which is somewhat different from the $Na_5M_9F_{32}$ previously reported.[515] The structure of $NaMF_4$ (M = La–Tm or Y) in the lower-temperature hexagonal phase contains two types of M^{3+}, both nine-coordinated to tricapped trigonal prisms, with Nd–F = 2.377–2.503 Å in the Nd^{3+} compound.[517] The high temperature fluorite-like phase of course shows cubic eight-coordination.[518] The 1:1 stoichiometry $M'MF_4$ has also been observed for M′ = Li, M = Eu–Lu or Y and these compounds have the $CaWO_4$ structure.[519]

In the case of the larger alkali metal cations, the 1:1 complexes $M'MF_4$ (where M′ = K, M = La or Ce; M′ = Rb, M = La–Pr) can be obtained, but the predominant stoichiometry is M'_3MF_6, examples of which are K_3YF_6, $RbMF_6$ (M = La–Pr, Sm, Tb, Er or Y), and Cs_3MF_6 (M = La–Pr, Sm, Gd, Dy–Er or Y), the X-ray parameters of which have been reported.[520,521]

The chloride and bromide complexes show four structure types, $M'M_2X_7$, $M'_3M_2X_9$, M'_2MX_5 and M'_3MX_6 (M′ = alkali metal, M = lanthanide or Y).[522] They may be conveniently prepared by evaporation of aqueous acidic solutions of the appropriate metal ratios, followed by heating in a stream of HCl or HBr gas. The most stable phases are generally $M'MX_6$, but are considerably subject to phase transitions at fairly low temperatures so that single crystals for X-ray study are difficult to obtain and structures are dependent on powder data. Thus K_3LuCl_6 crystallizes in the K_3MoCl_6 structure[523] containing individual $LuCl_6^{3-}$ octahedra. The compounds $(NH_4)_3MCl_6$ (M = Sm–Lu or Y) and $(NH_4)_2MCl_5$ (M = La–Tb) have been obtained as two isostructural series.[524,525] The compounds K_3MCl_6 (M = Nd–Lu and Y) and K_2MCl_5 (M = Nd–Tb) have also been characterized by powder diffraction[526] following phase studies.[527]

Synthesis was by heating above 450 °C in evacuated quartz vessels of the stoichiometric components. The isostructural K_2MCl_6 series underwent a phase transition in the range 350–410 °C, and became monohydrated in air. The K_2MCl_5 series was also isostructural.

The complexes M'_3MX_6, where $M' = Ph_3PH$ or C_5H_5NH and X = Cl with M = Pr–Sm or Dy–Tm, or X = Br with M = Pr–Eu, have been prepared from acetonitrile solution and their electronic spectra have been studied. This is of importance because there are limited numbers of lanthanide complexes where the metal ion is octahedrally coordinated to identical ligands in separated octahedra. As expected, in the absence of unsymmetrical components of the crystal field, these complexes show much weaker oscillator strengths than other lanthanide complexes. The hexaiodo complexes $[Ph_3PH][MI_6]$, where M = La–Yb, and the corresponding pyridinium salts, have been prepared, working rapidly on the small scale, by action of liquid HI on the solid $[MCl_6]^{3-}$ compound. These compounds are moisture sensitive and dissociate even in non-aqueous solvents in the presence of excess iodide ion. The series of halo complexes have been used to obtain values of optical electronegativities from the charge-transfer spectra. The values of $d\beta$, the nephelauxetic constant, from the $f \rightarrow f$ transitions, are similar for all three halides.[528,529]

The structure of Cs_2DyCl_5 has been determined from single crystal data.[530] It contains $DyCl_6^{3-}$ octahedra connected by *cis* corners to form chains, the connecting Dy—Cl—Dy angle being 180°. The heavier lanthanides and yttrium are isostructural.

All the compounds of the type $M'_3M_2Cl_9$ which have been obtained (M' = K, M = Ce–Nd; M' = Cs, M = Ho–Lu or Y) contain paired octahedra $M_2Cl_9^{3-}$ joined at one face; they have one or other of the $Cs_3Cr_2Cl_9$ or $Cs_3Tl_2Cl_9$ structures.[531] These structures are also adopted by a number of bromides or iodides, namely $Cs_3Y_2I_9$ and $Cs_3M_2Br_9$ (M = Sm–Lu or Y). Single crystal data are available for $Cs_3Y_2I_9$ which has the dimensions Y—I—Y = 80.8°, Y—I(terminal) = 2.90 Å and Y—I(bridging) = 3.13 Å.[532]

In the case of the stoichiometries $M'M_2X_7$, structures tend not towards more highly condensed MX_6 octahedra but towards seven-coordinated metal ions, as in KM_2Cl_7 (M = Gd–Tm or Y), where monocapped trigonal prisms are interconnected to form layers, and in $M'M_2Cl_7$ (M' = Rb, M = Sm–Yb or Y; M' = Cs, M = La or Pr) where the lanthanide ions are seven- and eight-coordinated.[522]

39.2.9 NMR Spectra of Paramagnetic Lanthanide Complexes

39.2.9.1 Introductory summary

In 1969, Hinckley reported[533] the extraordinary effect produced by $[Eu(dpm)_3(py)_2]$ upon the NMR spectrum of cholesterol in non-polar organic solvents. The spectrum was greatly shifted to low field, and in general the resonances of those protons nearer to the hydroxyl group were shifted more. This meant that firstly, accidental degeneracies in spectra of large organic molecules may often be removed because of differential shifts. Secondly, assignments of peaks may be confirmed, where there might otherwise be doubt, on the basis of their geometric position relative to the lanthanide ion. Thirdly and perhaps most important, structural information concerning the organic molecule may be obtained by means of a knowledge of the relative positions of the protons (or other nuclei) obtained through their differential shifts. It soon became clear that the β-diketonates themselves rather than their pyridine adducts should be used[534] and that the process depended on the formation of an adduct M(β-diketonate)$_3L_x$, where L is the molecule under investigation, usually termed the substrate, which is often an alcohol, amine or ketone. Furthermore, the use of different lanthanides produced shifts in either direction and of various magnitudes.[535] Another variable is of course the nature of the β-diketone. This must be sufficiently bulky to prevent polymerization by intermolecular coordination, but not so very bulky that an adduct with the substrate cannot be formed.

The NMR shift is produced by an interaction between the resonating nucleus and the magnetic field produced by the unpaired f electrons of the lanthanide. This interaction may occur in a through-space dipole-dipole manner, or by delocalization of the f-electron density towards the resonating nucleus through the bonds of the substrate. Usually the dipole–dipole effect predominates. Much of the research on the mode of action of lanthanide shift reagents (LSRs) has been directed towards study of the following: the stoicheometry and geometry of the LSR–substrate adduct; the stability constant(s) relevant to this association; and the quantification of the two shift mechanisms in terms of molecular properties and the

establishment of the relative importance of the two mechanisms. There is of course much literature concerned with the application of LSRs to the solution of individual problems in organic chemistry, but this will not be dealt with here in detail.

There are a number of reviews on the principles and applications of LSRs[536–540] and on the important uses of lanthanides as NMR probes in biological systems.[541–543] It should be noted that adducts of LSRs of the tris(β-diketonate) type constitute only a special case of paramagnetic shifts of NMR resonances of lanthanide complexes. All the nuclei of any lanthanide complex (except La, Gd, Lu) will in principle show a paramagnetic shift unless the complex is cubic, and some of the most interesting work has in fact been carried out on widely differing types of lanthanide complexes, particularly complexes of uncertain structure formed in solution, including aqueous solution, by interaction of lanthanide salts with various ligands.[544]

39.2.9.2 The magnetic interaction between lanthanide ions and coordinated ligands

The most important magnetic interaction between lanthanide ions and nuclei which are components of coordinated molecules is probably the through-space dipole–dipole interaction, usually termed the dipolar, or in earlier work the pseudocontact, interaction. The reason for this statement is that the dipolar shift is related to the geometry of the adduct, obeying equation (9).[545] Here, r, θ and ϕ are the polar coordinates of the particular nucleus under study, relative to the principal magnetic axes of the molecule (whose origin of coordinates is the lanthanide ion). A is a constant which is different for each lanthanide and depends on the lanthanide electronic configuration; and F_n^m are crystal field coefficients which depend on the nature and geometry of the ligands.

$$\Delta H_d/H = \{K_1(3\cos^2\theta - 1) + K_2 \sin^2\theta \cos^2\phi\}/r^3, \quad \text{where} \quad K_1,\ K_2 \text{ are functions of } A\langle F_n^m\rangle \qquad (9)$$

The values of A have been tabulated.[545] In the cases of Eu^{3+} and Sm^{3+}, there are substantial magnetic contributions from excited states. Eu^{3+} with a ground state of $^7F_0$, which is diamagnetic, depends totally upon the $^7F_{1,2,3}$ excited states, which are thermally accessible, for its magnetic properties. From the equation it follows that for one complex of any individual lanthanide, the relative dipolar shifts of all the nuclei are determined by their geometric relationship in terms of θ, ϕ and r. Also for an isostructural series of complexes of different lanthanides, the shifts of analogous nuclei are related only by the values of A, assuming the crystal field parameters are not appreciably different.

Since each nucleus has three parameters, θ, ϕ and r, but yields only one experimental datum, ΔH, it is not of course possible to determine the overall structure of the complex *ab initio*. However, uncertainty between alternative structures of substrates is capable of being resolved, as is uncertainty in alternative assignments of the NMR resonances, or uncertainty in the orientation or position of coordination of substrates of known structure. A computer optimization of agreement between observed shifts and coordination orientation (or whatever other uncertain features are to be investigated) is the normal procedure, as first demonstrated for the [Pr(dpm)$_3$(borneol)] adduct.[546]

The mechanism of this type of paramagnetic shift can be understood in a purely qualitative way by considering a lanthanide complex tumbling in the magnetic field of an NMR spectrometer. This field causes the magnetic dipole of the lanthanide ion on average to provide a component opposed to the field. The magnetic field due to the lanthanide ion, as experienced by a hydrogen nucleus which is part of the complex, will be in opposite directions depending on whether the nucleus, during molecular tumbling, is on the axis of, or at right angles to, the magnetic dipole of the lanthanide ion. For isotropic complexes, it can be shown that tumbling over all orientations averages the resultant shift to zero (except for the Evans shift[547] on all nuclei). However, for anisotropic complexes the magnitudes of the lanthanide magnetic dipole will be different in the two situations mentioned and the resultant time-averaged field is non-zero and will provide a paramagnetic shift.

It has been stated above that for a series of isostructural lanthanide complexes the paramagnetic shifts of analogous nuclei should be proportional to the parameter A, if a purely dipolar mechanism operates. The paramagnetic shift is usually taken as the difference between the chemical shift of the nucleus in the paramagnetic complex under investigation, and the

corresponding shift of the diamagnetic lanthanum complex (or the mean value of the lanthanum and lutetium shifts). In many series of complexes it is found that this simple relationship does not apply, certainly to all nuclei, even if the series is isostructural. Furthermore, it is almost always found that the geometrical relationship of the Bleaney equation is not valid for all nuclei when high levels of accuracy are concerned and in many cases it is not even approximately valid, especially for nuclei other than hydrogen or those connected to the lanthanide ion through a small number of bonds. This situation is caused by the presence of contact shifts arising from the through-bond delocalization of unpaired electron density associated with the lanthanide ion, which then directly influences the nucleus concerned. Equation (10) expresses the contact shift,[548] where a is the hyperfine coupling constant, while S_z is the spin expectation value of the particular lanthanide. Equation (11) then expresses the total paramagnetic shift.

$$\Delta H_c/H = a\langle S_z\rangle \tag{10}$$

$$\Delta H_{total} = \Delta H_d + \Delta H_c \tag{11}$$

It is clearly necessary to estimate the relative contributions of the contact and dipole mechanisms to the overall shift in order to make use of the structural information inherent in the dipolar shifts. This may be done in different ways.[549–551] Firstly, the shift of any gadolinium complex is entirely contact, as the $^8S_{7/2}$ ground state of Gd^{3+} is necessarily isotropic. Hence a, the hyperfine coupling constant, may be found and if it is assumed constant for the series of lanthanides, then the contact component for each lanthanide complex may be found from the appropriate value of S_z. Unfortunately, the very long relaxation time for Gd^{3+} confers considerable broadening on the NMR spectra of its complexes which usually prevents resonances from being observed. An alternative method compares the observed shifts of analogous nuclei in two complexes, in which case a is assumed constant, A and S_z are known for each ion, and hence a can be calculated and ΔH_c and ΔH_d found. If a is constant over a series of several lanthanides, then computer optimization of such a series of complexes would be preferable. If this type of treatment, of which there are a number of variations,[552] gives good quantitative agreement with the observed data for a series of lanthanide complexes, then they may normally be assumed isostructural. Furthermore, the values of θ, ϕ and r from which follow the value of ΔH_d for the various different nuclei can be computer optimized for consistency of the shifts with hypothetical molecular models which are structurally acceptable.

The dipolar paramagnetic shifts depend, as has been stated, on unsymmetrical terms in the crystal field expansion. An unsymmetrical crystal field can be caused by unsymmetrically disposed ligands of similar type, or by the presence in the same complex of ligands which exert dissimilar crystal fields although the coordination polyhedron may be fairly symmetrical. The practical effect of the unsymmetrical crystal field is to confer anisotropy on the magnetic susceptibility tensor by perturbing the f electron shell. The intensity of magnetization of an individual lanthanide ion thus varies with the orientation of the complex, of which it forms part, relative to the prevailing magnetic field. Bleaney[545] has given the relationship between the magnetic anisotropy and the resulting paramagnetic shift. It is as shown in equation (12), where $\chi_{x,y,z}$ are the principal components of the molecular magnetic susceptibility tensor and $\bar{\chi}$ is their mean.

$$\Delta H_d/H = \{(3\cos^2\theta - 1)(\chi_z - \bar{\chi}) + \sin^2\theta\cos 2\phi(\chi_x - \chi_y)\}/2Nr^3 \tag{12}$$

Hence, if the magnetic anisotropy of the crystalline complex is measured experimentally, usually by single crystal measurements using the torsion fibre method, and if its crystal structure is known, then the molecular anisotropy usually can be calculated. Provided that the complex has the same conformation in solution as in the solid state, the solution dipolar shifts can be calculated and compared with the experimental data. This procedure and variations of it may be used to investigate the relative crystal fields of different ligands, and to test experimentally the validity of the theoretical approach employed.[553,554] A direct NMR measurement of anisotropic magnetic susceptibilities can be obtained from the ^2H spectra of lanthanide complexes of known structure. The method depends on quadrupole coupling of the ^2H nuclei, which splits absorption lines at high field owing to partial ordering of the molecules in the field.[555]

The question of the effect of molecular symmetry on dipolar shifts may be briefly discussed next. If a complex has a principal axis of symmetry of order three or more, that is, it is uniaxial, then χ_x is equal to χ_y and a simplified geometric factor $(3\sin^2\theta - 1)r^{-3}$ is valid. Although some lanthanide complexes have such symmetry in the solid state, most do not and are said to be biaxial. However, if an individual ligand undergoes NMR-rapid rotation about a single bond relative to the remainder of the complex, then an averaging effect is naturally observed for the nuclei of that ligand even though the complex instantaneously may have even C_1 symmetry.[556,557] This situation is common in solutions of lanthanide complexes and the simplified geometric factor is often capable of fitting the experimental data.

There is some evidence that while mono adducts of the β-diketonate shift reagents may show time-averaged uniaxial symmetry, bis adducts often do not. Thus the spectra of $[M(dpm)_3L_2]$, where M = Pr, Sm, Dy, Ho, Er or Yb and L = 3-picoline or 3,5-lutidine, have been interpreted in terms of biaxial magnetic anisotropy. One magnetic axis is defined by the molecular C_2 axis present in the X-ray crystal structure and the other two axes lie in similar orientations in all the adducts. A variable-temperature study of this system shows restricted rotation of the aromatic rings with a very solvent-dependent conformational equilibrium resulting from this.[558–560]

39.2.9.3 Nuclear relaxation rates

A further, most important, feature which does not produce a paramagnetic shift but which falls naturally into place for discussion at this point is the lanthanide contribution to the nuclear relaxation. This is a dipole–dipole interaction and hence follows an r^{-6} law. The longitudinal relaxation rate of a nucleus of a diamagnetic atom near a paramagnetic lanthanide ion (except Gd^{3+}) is given by equation (13), where $1/T_1$ = longitudinal relaxation rate of the nucleus, γ_1 = magnetogyric ratio, τ_e = electron spin relaxation time, μ = magnetic moment, β = Bohr magneton and r = ion–nucleus distance.[561]

$$\frac{1}{T_1} = \frac{4}{3}\left(\frac{\mu_0}{4\pi}\right)^2 \gamma_1^2 \mu^2 \beta^2 \tau_e r^{-6} \tag{13}$$

The effect of this equation is that the ratios of the paramagnetic contributions to the relaxation rates of a set of, for example, ^1H nuclei belonging to the same complex are determined by the lanthanide ^1H distance only. Hence a similar type of computer optimization as for the paramagnetic shifts may be used to test compatibility with hypothetical structures which incorporate distance-dependent parameters such as the orientation or conformation of an organic ligand.

A further application of relaxation rate measurements is that similar $1/T_1$ ratios in a series of lanthanide complexes may be taken to indicate an isostructural series. However, this approach has the limitation that if only part of the complex is studied, perhaps an organic ligand, its T_1 ratios would be independent of changes, for example changes in the extent of hydration in the remainder of the complex, provided that the conformation of the ligand relative to the lanthanide ion were preserved. An excellent example of the use of T_1 data in a quite different way is its use to determine hydration numbers of lanthanide dipicolinate complexes.[562]

39.2.9.4 Examples of applications of shift or relaxation measurements

A good example of an investigation into the conformation of coordination of an organic ligand is the work of Singh, Reynolds and Sherry[563] on lanthanide L-proline complexation. The ^1H and ^{13}C paramagnetic shifts and relaxation rates were measured for all H and C atoms of aqueous proline–lanthanide ion solutions at pH 3 for ten lanthanides. It was concluded that while the relaxation data were consistent with an isostructural series, there were inconsistencies in the dipolar shift data, after separation from contact shifts, which could be resolved either by division into two, rather than one, isostructural series, or by invoking biaxial rather than uniaxial symmetry.

Adenosine-2′-monophosphate and adenosine-3′-monophosphate have been investigated

in aqueous solution and were indicated by shift and relaxation data to be in conformational equilibrium when bound to lanthanide ions. The lanthanides bind to bidentate phosphate groups.[564]

Adenosine-5′-monophosphate has also been examined similarly. It was studied in $D_2O/(CD_3)_2SO$ in the presence of lanthanide ions under various conditions of solvent composition and temperature. Shifts and relaxation times for the series Pr–Yb gave results more nearly consistent with axial symmetry for the first half of the lanthanide series than for the second.[565] The extraction of structural information from NMR data has been described for aqueous systems where lanthanide edta and related complexes interact with cytidine-5′-monophosphate, (−)-alanine[566] and *endo-cis*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic acid.[567] The shift reagents [M(fod)$_3$] where M = Pr, Eu, Gd, Ho, Er or Yb have been used to elucidate the solution structure of nicotine *N*-methiodide, ^{13}C and ^1H spectra being studied. The experimental data indicated effective axial symmetry, good agreement with theory being obtained. Calculation of the relative magnitudes of ΔH_d and ΔH_c showed that the dipolar mechanism predominated.[568] Of course, many other examples could be given of studies of adducts of LSRs and organic substrates but these fall within the purview of organic chemistry rather than the present discussion.

There has been some work on interactions between LSRs and transition metal complexes, both NMR shifts and relaxation rates being studied. Presumably the mode of interaction is by means of bridges formed by the donor atoms of one complex which bond in a labile manner to the metal ion of the second complex. Interactions examined include those between [Eu(fod-d_9)$_3$] and azido{*N*,*N*′-ethylenebis(acetylacetoneiminato)}pyridinecobalt(III), where a 1:1 adduct with a lifetime of 8.4×10^{-4} s was formed in $CDCl_3$;[569] [Gd(fod)$_3$] and *N*,*N*′-ethylenebis(acetylacetoniminato)nickel(II)[570,571] or *N*,*N*′-vinylenebis(acetylacetoniminato)nickel(II); [Pr(fod)$_3$] and [Pt(acac)$_2$];[572] and [M(fod)$_3$] and cobalt(III) tris-β-diketonates (M = La–Eu).[573]

Other more specialized interactions of β-diketonate lanthanide shift reagents are those with alkenes, which require the mediation of a silver complex.[574] Thus [M(fod)$_3$], where M = Pr or Yb, together with Ag(fod) will shift the resonances of alkenes, aromatic molecules or phosphines, which are ligands which will not coordinate directly to lanthanide β-diketonates.[575,576] The shifted spectrum resulting from the interaction between a platinum alkene complex and [Eu(hfc)$_3$] has also been studied (Hhfc = 3-heptafluoropropylhydroxymethylene-(+)-camphor). In this case the alkene complex is prochiral and the shift reagent is of course optically active.[577] Optically active shift reagents such as Eu(hfc)$_3$ have often been used to demonstrate quantitatively the presence of chiral isomers of organic substrates; two sets of resonances are obtained.[578,579] Chiral interactions in aqueous solution are also possible,[580] and various types of such interaction, leading to spectral resolution of substrates or to assignment of chirality, have been discussed.[581]

Paramagnetic shifts may be induced in cations which associate with suitable lanthanide complexes. Thus in aqueous solution, [M(hpda)$_3$]$^{6-}$, where M = Dy or Tm and H_3hpda = 4-hydroxypyridine-2,6-dicarboxylic acid, associates with $^{25}Mg^{2+}$, $^{39}K^+$, $^{23}Na^+$, $^{87}Rb^+$ or $^{14}NH_4$ and produces shifts of up to 25 p.p.m. which are most marked above pH 7.[582] A similar effect is shown for cations (and anions and uncharged molecules) by lanthanide tetra-*p*-sulfonatophenylporphyrins in aqueous solutions.[583] This is discussed in Section 39.2.6.3, as are the large shifts produced in aqueous solution by Na[Eu(dota)(H_2O)] (H_4 dota = **23**).[584]

Most examples of the application of paramagnetic lanthanide NMR spectra quoted here have so far been based on transient association in solution between a preexisting lanthanide species and a substrate, often organic. However, the shifted NMR spectra of stable isolable lanthanide complexes have been studied since it was established[585] that in contrast to many paramagnetic complexes of the *d* transition metals, lanthanide complexes in general gave fairly sharp spectra. The kinetics of ligand exchange processes were early studied by these means,[586] and in more recent work, the conformations of stable isolable lanthanide complexes and their interconformational or dissociative equilibria have often been usefully investigated. Thus the paramagnetically shifted spectra of [M(dipic)$_3$]$^{3-}$, [M(dipic)$_2$(H_2O)$_3$]$^-$ and [M(dipic)(H_2O)$_6$]$^+$, where M = Ce–Yb and H_2dipic = pyridine-2,6-dicarboxylic acid, have been shown to be consistent with an approximately tricapped trigonal prismatic configuration of all three types of complex,[587] similar to the X-ray crystal structure of the Yb tris complex.[588] The lanthanide diethyldithiophosphonates [M{$S_2P(OEt)_2$}$_4$]$^-$ which are dodecahedral in the solid state, divide into two series in CD_2Cl_2 solution, the heavier lanthanides having square antiprismatic geometry.[589] Other examples, drawn from the NMR spectra of macrocyclic complexes are given in Section 39.2.7.

39.2.9.5 Studies of complexation with lanthanide shift reagents

Owing to their special utility in structure elucidation of organic molecules in non-hydroxylic solvents, the lanthanide tris(β-diketonate) complexes have undergone much investigation into their complexation with lone pair donors, mainly with the objectives of determination of association constant values and determining whether 1:1 or 2:1 adducts are formed. Many of these papers naturally rely on NMR measurements though other methods have been used. The complexes mainly investigated are $M(RCOCHCOR')_3$ where M = Eu, Pr or Yb. These ions are used because they give fairly large shifts but without too much broadening. The β-diketones are usually $R = R' = CMe_3$ (dpm) or $R = CMe_3$, $R' = n\text{-}C_3H_7$ (fod). This topic is discussed in more detail in Section 39.2.4.2.

39.2.10 Electronic Spectra of Lanthanide Complexes

This area has been the subject of recent extensive reviews,[590–592] which deal particularly with the physical and theoretical aspects. In this section, a more chemical and descriptive approach will be adopted.

The tripositive lanthanide ions have the general outer configuration $4f^n5s^2p^6$ and follow the Russell–Saunders *L,S,J* coupling scheme but with a certain amount of configuration interaction. The 5*s* and 5*p* shells have a radial dispersion which is greater than the 4*f* electrons[593] and hence shield the latter from the effect of coordinated ligands to a very large extent, but not completely. Thus the electronic spectra of tripositive lanthanide compounds can be considered as derived from the spectra of the gaseous ions by a fairly small perturbation. This perturbation may be of two general types. The first is a general nephelauxetic effect owing to a drift of ligand or 5*s*, 5*p* electron density into the lanthanide ion, slightly expanding the 4*f* shell and reducing the 4*f*–4*f* interactions. The second is a crystal field splitting effect, which removes the degeneracy of the free-ion levels, and which can be represented with fair success by a point negative charge model having the appropriate molecular symmetry.

The experimental energy level schemes of the gaseous free tripositive ions are obtainable with some difficulty but are available in some cases, *e.g.* praseodymium[594] or gadolinium.[595] Values for Pr^{3+} (gaseous) *versus* $PrCl_3$ (solid) are shown in Table 11, and differ by about 2–5%, those for $PrCl_3$ being the smaller, as expected. Most of the basic experimental data regarding the energy levels of lanthanides must therefore be derived from the solid state, in

Table 11 Positions (cm^{-1}) of Energy Levels of Pr^{3+} (Gaseous, Obtained from Arc Spectra) Compared with $PrCl_3$ (Crystalline)[594]

	$^3H_4$	$^3H_5$	$^3H_6$	$^3F_2$	$^3F_3$	$^3F_4$	$^1G_4$	$^1D_2$	$^3P_0$	$^3P_1$	$^1I_6$	$^3P_2$
E(crystal)	0	2117.4	4306.3	4846.6	6232.3	6681.7	9697.6	16 639.3	20 383.4	20 984.9	21 324.5	22 139.1

which the ion under study is often present in dilute solid solution in a lanthanum salt matrix. Of course, except for the ground state multiplet, identifiable from Hund's rules, the observed levels cannot be definitely assigned to particular $^{(2S+1)}L_J$ terms unless a theoretically derived set of energy levels is available for comparison. Considerable effort has been devoted to theoretical prediction of the energy levels of f^n configurations. The total energy *H* of a system consisting of a point nucleus surrounded by *N* electrons can be represented by the Hamiltonian in equation (14), where H_0 is the kinetic energy and nuclear interaction term, H_E is the electronic repulsion term, and H_{SO} is the spin–orbit interaction term.

$$H = H_0 + H_E + H_{SO} \tag{14}$$

Model Hartree–Fock calculations which include only the electrostatic interaction in terms of the Slater integrals F_0, F_2, F_4 and F_6, and the spin–orbit interaction ζ, result in differences between calculated and experimentally observed levels[596] which can be more than 500 cm^{-1} even for the f^2 ion Pr^{3+}. However, inclusion of configuration interaction terms, either two-particle or three-particle, considerably improves the correlations.[597,598] In this way, an ion such as Nd^{3+} can be described in terms of 18 parameters (including crystal field

parameters) which reproduced 101 of the energy levels observed for Nd^{3+} in $LaCl_3$ with an rms deviation from experimental values of $8\,cm^{-1}$.[599] Although the parameters can be evaluated theoretically, it is usual to obtain them from a best fit of the observed spectra. The energy levels for all the tripositive lanthanide ions in $LaCl_3$ solid solution have been given.[600]

Using modern computers it is possible to diagonalize a complete free-ion and crystal-field Hamiltonian. However, for the lanthanides, if not for the actinides, the effect of the crystal field can usually be treated as a perturbation on the unsplit $^{2S+1}L_J$ levels. The levels are split into $2J + 1$ components in a crystal field of C_1 symmetry, or into fewer components in higher symmetries, depending on the degeneracy of the J vector representation in the crystal field point group. Typical values of the crystal field parameters $B_q^{(k)}$ are 200–2000 cm^{-1}. Owing to the small effect of the ligands on the $4f$ levels, the $4f \rightarrow 4f$ spectra of lanthanide complexes tend to have narrow bands that are also weak owing to the transitions being Laporte forbidden. The intensities of the transitions have been the subject of much study and are usually quantified by the Judd–Ofelt theory. Judd[601] and Ofelt[602] used the odd parity terms of the ligand field to mix electronic states of opposite parity, including states derived from d configurations, into the f^n configurations, thus obtaining non-zero matrix elements for the electric dipole operator. The Judd–Ofelt theory also accommodates the existence of the hypersensitive transitions. These are transitions that are dramatically increased in intensity in complexes, particularly those of low symmetry and with polarizable ligands, compared with for example the hydrated ions. These transitions correspond to those having large values of Judd's second rank tensor operator $U^{(2)}$, and mostly have $\Delta J = \pm 2$. These selection rules correspond with those for a radiative electric quadrupolar process. It is, however, fairly certain that these hypersensitive transitions are electric dipolar in the main. Their mechanism can be described in two physically related ways, the inhomogeneous dielectric theory and the ligand polarization model.[603,607] The dipolar components of the radiation field induce a set of transient electric dipoles in the ligand environment which can couple with the $4f$ electrons by way of $4f$ electrostatic quadrupolar–ligand dipolar interactions. In a non-centrosymmetric complex, or in a centrosymmetric complex subject to an ungerade vibrational mode, large amplifications of $4f \rightarrow 4f$ transitions may be obtained from these quadrupole–induced dipolar interactions. These transitions are thus often referred to as pseudoquadrupolar. For a short readable discussion of this still controversial area, see Judd.[608]

In a recent paper,[609] the hypersensitive transitions $^4I_{15/2} \rightarrow {}^2H_{11/2}$ or $^4G_{11/2}$ of Er^{3+} have been examined for complexes with five amino- or oxo-carboxylate anions. They showed four- to six-fold increase in oscillator strengths over the hydrated ion Er^{3+} aq. Using likely models for the structures of the complexes and calculating crystal field wave functions and energy levels for the $4f^{11}$ configuration of Er^{3+}, electric and magnetic dipole transition strengths were calculated. The structural models were based on X-ray solid state determinations and charge and polarizability parameters were assigned to the ligand molecules. The calculated magnetic dipole intensitities were at least two orders of magnitude less than the electric dipolar; the latter were very successful in accounting quantitatively for the observed intensitities. In a related paper, the oscillator strengths of Nd, Ho and Er acetates and propionates in aqueous solution have been related to solution structures and hypersensitivity mechanisms discussed.[610]

In practice, the hypersensitive transitions are often used for the determination of stability constants in aqueous solution. Lanthanide absorption bands in solution do not normally change in position on complexation to such an extent that bands due to the complexed and uncomplexed ion can be clearly observed independently, as is often the case for d transition metal ions, but the marked change of intensity of the hypersensitive bands is sufficient to allow determination of K values, for example as demonstrated for various adducts of $[Ho(dpm)_3]$.[611]

There has been a marked increase recently in the interest shown in fluorescence, phosphorescence or emission spectra. There is little useful distinction between these terms when applied to lanthanide ions, and the term emission will be preferred here. The two ions mainly studied are Tb^{3+} and, especially, Eu^{3+}. The energy level schemes for Eu^{3+} and Tb^{3+} are given in Figure 9. In both these ions there is a large energy gap between the ^7F and ^5D levels, which corresponds with emission in the red and the green regions respectively of the visible spectrum. The main emitting state in each case is the lowest component of the excited multiplet, as higher components rapidly descend by a cascade process to $^5D_0$ or $^5D_4$ respectively. In the case of Eu^{3+}, emission corresponding to $^5D_0 \rightarrow {}^7F_{0,1,2,3}$ can be observed with $^5D_0 \rightarrow {}^7F_1$ or $^7F_2$ the strongest.

This emission is useful in two respects. Firstly, for Eu^{3+}, the crystal field splitting of the $^7F_1$ and $^7F_2$ levels can be observed and can be related to the symmetry of the complex if that is

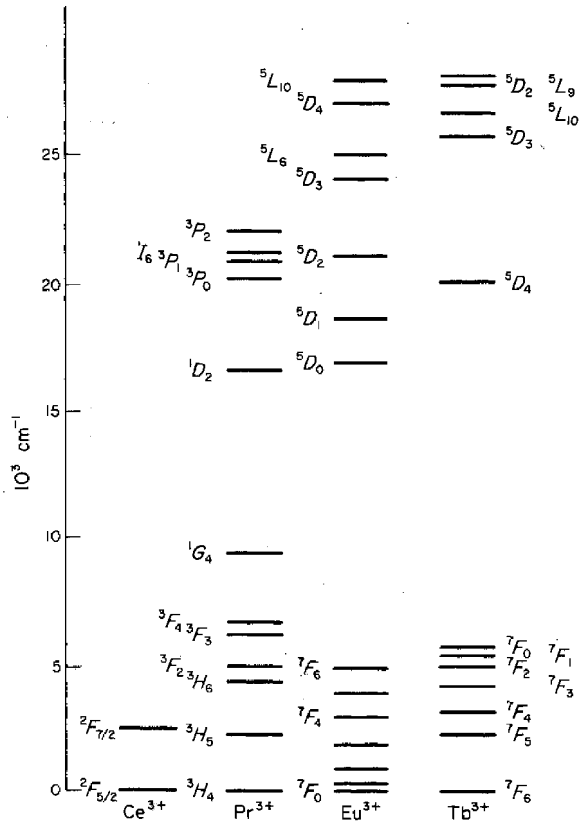

Figure 9 Energy levels of some representative lanthanide tripositive ions. Ce and Pr, full set; Eu and Tb, partial set (energy values taken from S. Hüfner, 'Optical Spectra of Transparent Rare Earth Compounds', Academic Press, 1978)

unknown.[612,613] The J values for both the excited and ground states of Tb^{3+} are too large for this effect to be so useful for that ion, as it is difficult to assign the multiply split transitions. Most of these transitions could in principle be observed in absorption but are too weak to be easily studied.

Secondly, the emission of a particular complex species is characteristic of that species and can be used to identify the species present. Particularly is this so if excited state lifetimes are measured, as these vary dramatically depending on the number of OH groups coordinated to the Eu^{3+} or Tb^{3+} ion. This is because multiple excitation of the OH stretching mode provides an alternative deexcitation route. Measurement of lifetimes thus can be used to determine the number of coordinated water molecules.[218]

Excitation of the Eu^{3+} or Tb^{3+} ions has traditionally been indirect, by broad-band UV excitation of a conjugated organic ligand which is followed by intramolecular energy transfer to the lanthanide ion f system, followed in turn by $f \rightarrow f$ emission.[614] However, more recently, following the advent of tunable dye lasers, direct excitation of an excited f^n level is in many cases preferable. By scanning this frequency, an excitation spectrum can be obtained whose energy values are independent of the resolution of a monochromator and not subject to spectral interferences.

Excitation spectra have been of considerable use recently in studying both hydration numbers (by lifetime measurements) and inner-sphere complexation by anions (by observing appearance of the characteristic frequencies for *e.g.* the Eu^{3+} $^5D_0 \rightarrow {}^7F_0$ transition for the different possible species). Thus using a pulsed dye laser source, it was possible to demonstrate the occurrence of inner sphere complexes of Eu^{3+} with SCN^-, Cl^- or NO_3^- in aqueous solution, the K values being 5.96 ± 2, 0.13 ± 0.01 and 1.41 ± 0.2 respectively. The ClO_4^- ion did not coordinate. Excited state lifetimes suggest the nitrate species is $[Eu(NO_3)(H_2O)_{6.8\pm0.4}]^{2+}$; the technique here is to compare the lifetimes of the H_2O and the corresponding D_2O species, where the vibrational deactivation pathway is virtually inoperative.[219] The reduction in lifetime is proportional to the number of water molecules complexed.[217,218]

A study of hydration of the complex $[EuL_2(H_2O)_x](BF_4)_3$ where $L = \{(C_3H_7)_2N{\cdot}CO{\cdot}CH_2{-}OCH(Me){-}\}_2$ shows by lifetime studies of a similar sort that in aqueous acetone, $x = 0.9 \pm 0.4$ which gives a coordination number of nine. This complex was prepared from $Eu(MeCN)_x(BF_3)_3$, itself prepared from the action of $NOBF_4$ on europium metal in acetonitrile.[615]

The emission spectra of the complexes $R_2[Eu(NO_3)_5]$, where $R = Ph_3EtP^+$ or Ph_4As^+, have been investigated and it was found that the spectrum of the former could be interpreted in terms of D_{3h} pseudosymmetry (each NO_3 ion considered as occupying one ligand position in the coordination sphere) but the position as regards the Ph_4As^+ salt was less clear.[616] In a similar study, using lifetime measurements, the species $Tb(NO_3)_3L_3$, where L = DMSO or H_2O, were identified in MeCN solution. Also, efficiencies were determined of energy transfer from excited Tb^{3+} ions in $Tb(ClO_4)_3$ or $Tb(NO_3)_3$ to Nd^{3+} ions in MeCN and other more polar organic solvents.[617]

The $^4F_{3/2} \rightarrow {}^4F_{5/2}$ emission of Nd^{3+} at 885 nm can also be monitored in a rather similar way, and a study of emission lifetimes together with absorption spectra for the hypersensitive Nd^{3+} transitions, *e.g.* $^4I_{9/2} \rightarrow {}^4G_{5/2}$, has been made in order to investigate the solvation of neodymium nitrate and perchlorate in MeCN, Me_2CO, DMSO or DMF. Excited lifetimes varied from 300 ns in Me_2CO to 2300 ns in CD_3CN. It was found that species $\{Nd(NO_3)_n\}^{(3-n)+}$ were formed, where $n = 1$–5, on addition of NO_3^- ions to perchlorate solutions, but that addition of DMSO to $Nd(ClO_4)_3$ in MeCN gave $[Nd(DMSO)_n]^{3+}$, where $n = 9.7 \pm 0.8$.[618]

A further variation on the theme of emission is circularly polarized emission, where chiral interactions, for example between a lanthanide complex and a chiral ligand in solution, can be studied. Selection rules have been given[619] based on *S*, *L* and *J* values for 4*f* states perturbed by spin–orbit coupling and 4*f* electron–crystal field interactions, and four types of transition were predicted to be highly active chiroptically. These are given in Table 12.

Table 12 Active Chiroptical Transitions in Lanthanide Complexes

Type	$\lvert\Delta S\rvert$	$\lvert\Delta L\rvert^*$	$\lvert\Delta J\rvert$
a	0	0	$0, 1 (J \neq 0 \neq J')$
b	0	0	$1 (J \text{ or } J' = 0)$
c	>0	≥0	$0, 1 (J \neq 0 \neq J')$

* $\Delta L \not> 6$.

The Pfeiffer effect, the outer-sphere interaction of a chiral substrate with a rapidly interconverting racemic solution of a chiral lanthanide complex, can be investigated by measurement of the luminescence dissymmetry factor (the ratio of circularly polarized luminescence to total luminescence) for Eu^{3+} or Tb^{3+} complexes. Thus the racemic D_3 chiral complexes $[M(dpa)_3]^{3+}$, where M = Eu or Tb, interact in an outer-sphere manner with the following optically active species: cationic chiral transition metal complexes,[620] ascorbic acid,[621] aminocarboxylates,[622,623] tartrates,[624] amines[625] and phenols.[626] Association constants can be obtained from limiting values of the dissymmetry factors. In some cases, inner-sphere complexation[626] can be demonstrated, as judged by changes in the general nature of the circularly polarized luminescence spectrum and pH irreversibility of the complexation.

The interaction of aspartic acid and other ligands with complexes of Tb^{3+} with edta and related ligands has also been studied and association constants determined.[627] The complex formation between Tb^{3+} or Eu^{3+} and (R)-(−)-1,2-propanediaminetetraacetic acid or (R,R)-*trans*-1,2-cyclohexanediaminetetraacetic acid has been similarly investigated. The pH dependence of the circularly polarized and total luminescence shows a drastic configurational change of the chelate system at pH 10.5–11, corresponding, it is believed, to formation of hydroxide complexes.[628] The technique of magnetic-field-induced circularly polarized emission has been introduced for lanthanide ions;[629] the mechanisms of lanthanide transition intensities are also discussed in the paper.

A useful short general review[630] of the utility of Eu^{3+} and Tb^{3+} emission spectra in investigations of biological systems gives also an account of the relevant basic spectroscopy of the lanthanide ions. The importance of these techniques for exploring proteins and nucleotides

is that Eu^{3+} is easily bound by such molecules, and that it readily substitutes Ca^{2+} naturally present. The effects of coordinated ligands upon the fluorescence spectrum can then be used for structural exploration. An example is the investigation of complexes of Eu^{3+} or Tb^{3+} with the ionophores lasalocid A and A23187 in MeOH. These are polyfunctional compounds containing keto, ether, carboxylate or amine groups. Mono and bis species were observed, and the high K values showed multidentate complexing. Suggestions as to the nature of this could be made.[631]

The bulk magnetic susceptibilities of lanthanide complexes are accurately predicted by theory, as the crystal field splitting of the ground state has little effect on these. The effective magnetic moment μ(eff) is thus given by equation (15) where g_J is the Landé factor. Values of these parameters together with a typical set of room temperature experimental values, for $[M(NO_3)_3(phen)_2]$,[150] are given in Table 13. In the case of Sm^{3+} and particularly Eu^{3+}, the excited states $^6H_{7/2}$ (Sm) and $^7F_{1,2}$ (Eu) are thermally populated at room temperature and lead to higher observed values of μ(eff) than those calculated from the ground term only.

$$\mu_{\text{eff}} = g_J\sqrt{J(J+1)}, \quad \text{where} \quad g_J = \{S(S+1) - L(L+1) + 3J(J+1)\}/2J(J+1) \tag{15}$$

The crystal field does, however, have a dramatic effect on the magnetic anisotropy of lanthanide complexes. For complexes of less than cubic symmetry the three principal values of the susceptibility tensor are unequal. For uniaxial symmetry, $\chi_x = \chi_y \neq \chi_z$ and for biaxial symmetry $\chi_x \neq \chi_y \neq \chi_z$. Very extensive studies[632–640] have been carried out on the single crystal susceptibilities of the D_{3d} lanthanide hexakis(antipyrene) triiodides over the temperature range 80–300 K, and crystal field parameters were obtained. This crystal field-induced anisotropy is responsible for the effectiveness of lanthanide complexes as NMR shift reagents, and single crystal anisotropies of lanthanide complexes have been determined in this connection also.[553]

39.2.11 Lanthanides in the Dipositive Oxidation State

Although all the lanthanides are stable in the solid state as M^{2+} ions doped into CaF_2 crystals, only in the cases of europium, ytterbium and samarium is there any real coordination chemistry, and that is very limited. There is a small but developing organometallic chemistry of the lower oxidation states,[641] but that is not within the scope of the present review. Much of the chemistry of the dipositive state depends on solvated species[642] and it is convenient to begin with these.

39.2.11.1 Hydrated species

The hydrated ions of europium, ytterbium or samarium can be obtained by electrolytic reduction or by dissolution of MCl_2 in water, and are reasonably stable. Colourless or pale yellow-green Eu^{2+}(aq) is stable for more than ten days in the absence of oxidizing agents or of platinum catalysts.[643] Pale green Yb^{2+}(aq) decays in water with $k = 2.4 \times 10^{-5}\,s^{-1}$, and red Sm^{2+}(aq) has $k = 0.6 \times 10^{-4}\,s^{-1}$, both reactions being first order.[646] These rates of decomposition follow the sequence of standard electrode potentials which are listed together with other parameters of the M^{2+}(aq) ions in Table 14. Of course, as not all the M^{2+}(aq) ions exist, many of these parameters cannot be determined directly. Pulse radiolysis has been used to demonstrate the short-lived existence of red Tm^{2+}(aq), Er^{2+}(aq) and surprisingly Gd^{2+}(aq).[648] Electrochemical reduction has been used to investigate stabilities and reduction potentials of

M^{2+} ions.[649,650] Thus polarography and cyclic voltammetry of 10^{-4}–10^{-3} M Sm^{3+} or Gd^{3+} in 0.001 M H_2SO_4 showed, for the cyclic voltammetry, a two step reduction in each case, which was reversible for samarium with fast scan rates (50 V s^{-1}) but which showed no anodic waves for gadolinium. The reduction for the latter was interpreted as being similar to dysprosium[651] where there is a two-stage reduction of water *via* lanthanide hydroxy species, no M^{2+} species being involved (equations 16 and 17).

$$2M^{3+} + 2H_2O + 2e^- \longrightarrow 2M(OH)^{2+} + H_2 \quad (16)$$

$$M(OH)^{2+} + 2H_2O + 2e^- \longrightarrow M(OH)_3 + H_2 \quad (17)$$

[c] Standard free energy of hydration of the gaseous M^{2+} ions.
[d] Standard electrode potential relative to NHE.

There has been some exploration of the mechanism of reduction of *d* transition metal complexes by $M^{2+}(aq)$ (M = Eu, Yb, Sm). Both inner- and outer-sphere mechanisms are believed to operate. Thus the ready reduction of $[Co(en)_3]^{3+}$ by $Eu^{2+}(aq)$ is necessarily outer-sphere.[652] However, the strong rate dependence on the nature of X when $[Co(NH_3)_5X]^{2+}$ or $[Cr(H_2O)_5X]^{2+}$ (X = F, Cl, Br or I) are reduced by $Eu^{2+}(aq)$ possibly suggests an inner-sphere mechanism.[653] The more vigorous reducing agent Yb^{2+} reacts with $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ by an outer-sphere route but with $[Cr(H_2O)_5X]^{2+}$ (X = halide) by the inner-sphere mechanism.[654] Outer-sphere redox reactions are catalyzed by electron-transfer catalysts such as derivatives of isonicotinic acid, one of the most efficient of which is *N*-phenyl-methylisonicotinate, as the free radical intermediate does not suffer attenuation through disproportionation. Using this catalyst, the outer-sphere reaction between $Eu^{2+}(aq)$ and $[Co(py)(NH_3)_5]^{3+}$ proceeds as in reactions (18) and (19). Values found were $k_1 = 5.8 \times 10^2$ M^{-1} s^{-1} and $k_2/k_1 = 16$.[655]

$$Eu^{2+} + cat \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} cat^- + Eu^{3+} \quad (18)$$

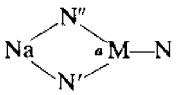
$$cat^- + Co^{3+} \xrightarrow{k_2} cat + Co^{2+} \quad (19)$$

The crown ether 18-crown-6 has been shown by polarography to stabilize aqueous solutions of dipositive europium and samarium relative to the tripositive state.[656]

39.2.11.2 Other solvated species

Solutions of dipositive lanthanide cations have been obtained in liquid ammonia, ethanol, THF, acetonitrile and hexamethylphosphoramide. Ions stabilized, or for which there is evidence for stabilization, include Nd^{2+}, Dy^{2+} and Tm^{2+} as well as Eu^{2+}, Yb^{2+} and Sm^{2+}. The non-hydroxylic solvents are best at stabilizing M^{2+} ions. Thus $NdCl_2(THF)_2$ has been reported from the reduction of $NdCl_3$ in THF by Na(naphthalene),[657] and corresponding reductions of MCl_3 (M = Eu, Yb or Sm) have also been achieved.[658] Solutions of solvated MI_2 (M = Sm or Yb) in THF may easily be made by the quantitative reaction of the metal with 1,2-diiodoethane, producing ethane. The solid THF adducts may be isolated.[659]

In hexamethylphosphoramide, sodium reduction of lanthanide trihalides gives solutions of Eu^{2+} (pale yellow), Yb^{2+} (yellow), Sm^{2+} (red-violet) and Tm^{2+} (red-brown). The latter has a half-life at 4.5 hours. The solution of $SmCl_2$ tends to be more stable (half-life, 60 hours) than those of $SmBr_2$ (30 hours) or SmI_2 (25 hours).[660,661] In liquid ammonia, Eu^{2+} or Yb^{2+} may be



obtained by dissolution of the metal, but sodium reduction of $Sm(ClO_4)_3$ must be used to prepare solutions of Sm^{2+}.[662]

39.2.11.3 Complexes with nitrogen donors

Some interesting examples of this class of complexes have recently emerged. Most of them are based on the bis(trimethylsilyl)amido ligand. Silylamides of two types have been prepared by the action of EuI_2 or YbI_2 on $NaN(SiMe_3)_2$ (NaL) in diethyl ether or glyme (reactions 20 and 21). Using YbI_2, reaction (21) gave $YbL_2(Et_2O)_2$ when the product was recrystallized from ether, but $NaYbL_3$ upon recrystallization from toluene. A single crystal X-ray of $NaML_3$ showed a planar three-coordinated configuration (**26**) with Eu—N = 2.448 Å, Yb—N = 2.38 Å, Eu—N′ = 2.554 Å, Yb—N′ = 2.45 Å, Eu—N″ = 2.539 Å, Yb—N″ = 2.47 Å; $a = 94.3°$ (Eu) or 97.4° (Yb). The metal–carbon distances are rather short at Eu—C = 3.21 Å average and may indicate some interaction.[663]

$$MI_2 + 2NaL \xrightarrow[M=Eu,\,Yb]{MeOCH_2CH_2OMe} ML_2(glyme)_2 + 2NaI \qquad (20)$$

$$EuI_2 + 3NaL \xrightarrow{Et_2O} NaEuL_3 + 2NaI \qquad (21)$$

(**26**)

The X-ray structure of $[EuL_2(glyme)_2]$ has also been determined.[664] The six-coordination polyhedron has only C_2 symmetry, doubtless relating to the presence of two very bulky ligands and two bidentate ones with rather short 'bites', giving N—Eu—N = 134.5°. Bond lengths are: Eu—N = 2.530, Eu—O = 2.638, 2.756 Å. Magnetic susceptibility measurements show the Curie law obeyed, with $\mu = 8.43$ BM. Other compounds isolated[664] were $EuL_2(bipy)_2$ and $EuL_2(THF)_2$. These were yellow or orange and soluble in hydrocarbons; doubtless they are six- and four-coordinated monomers.

Complexes of $EuCl_2$ with 1,10-phenanthroline and 2,2′:6′,2″-terpyridyl have been obtained from acetonitrile. They are purple $EuCl_2(phen)_2$ and dark blue $EuCl_2(terpy)$, both air-sensitive solids. In the NMR spectrum of the latter in Me_2SO solution, ligand peaks were broadened but not shifted, as expected for the f^7 configuration. In Me_2SO solution, only 1:1 association occurred with the phenanthroline complex, giving an association constant value $\log K = 3.9$. Chloride-bridged associated structures are likely for these complexes in the solid state.[665]

39.2.11.4 Complexes with phosphorus donors

The compound $[Yb\{N(SiMe_3)_2\}_2(Me_2PCH_2CH_2PMe_2)]$ is a well-established member of this rare group. It is made by the action of diphosphine on $YbL_2(Et_2O)_2$ and the structure has been determined. It is monomeric and four-coordinated with N—Yb—N = 123.6°, P—Yb—P = 68.4° and N—Yb—P = 101.2°. Bond lengths are Yb—P = 3.012 Å, Yb—N = 2.331 Å, and Yb—C (silylamide) shows a probable weak interaction at 3.04 Å. Also obtained similarly were $ML_2\{PBu^n_3\}_2$ where M = Eu (orange) or Yb (brown-red).[666] Phosphines also complex with divalent lanthanide organo compounds.[667]

39.2.11.5 Complexes with oxygen donors

A number of complexes in which ethers and silylamido ligands shared the coordination sphere were mentioned in the preceding two sections, and there are also several examples of ethers participating in the coordination spheres of dipositive lanthanide organo compounds.[667] There seem to be no examples of well-defined complexes with coordination spheres composed completely of oxygen donors, although M^{2+} in solutions of water or $OP(NMe_2)_3$ must contain these. Also, though not strictly complexes, MCO_3, where M = Sm, Eu or Yb, adopt the

aragonite structure with nine-oxygen coordination.[668] An interesting organo complex with oxygen coordination is $\{(C_5Me_5)_2Yb\}_2Fe_3(CO)_{11}$ where each $(C_5Me_5)_2Yb$ group is also coordinated by the oxygen atoms of two carbonyl groups (the carbon atoms of which bridge two iron atoms). The Yb—O distance is quite short at 2.243 Å, showing a strong interaction. The compound is made by treating $(C_5Me_5)_2Yb(Et_2O)_2$ with $Fe_3(CO)_{12}$.[669]

39.2.11.6 Electronic spectra of dipositive lanthanides

All the lanthanides can be obtained as M^{2+} ions in dilute solid solution in the CaF_2 lattice by means of either γ-irradiation or by reduction by metal vapour. These materials have been instrumental in providing good spectra of the dipositive lanthanide ions[670] in an electrostatic field provided by the cube of fluoride ions which of course surround the M^{2+} ions in this structure. Stabilization of dipositive lanthanides in SrF_2 or BaF_2 matrices is also possible. Perovskite phases such as yellow $CsEuF_3$, bright green $CsYbF_3$ and orange $RbYbF_3$ can also be made by reduction of MF_3 with Cs or Rb;[671] these ternary halides have been reviewed.[672]

The spectra of dipositive lanthanides differ from those of tripositive ions (except Ce^{3+}) in that the excited $4f^{n-1}5d^1$ configuration lies at a level up to about 40 000 cm^{-1} and dominates the spectrum with more intense absorption than is the case for the tripositive ions. The single d electron is subject to crystal field splitting of 10^4 cm^{-1} order of magnitude and will, in a cubic field, give d_ϵ and d_γ levels. This contrasts with the $4f^{n-1}$ configuration where the crystal field parameters are small compared with the spin–orbit coupling. There are therefore two states to be considered separately, the Russell–Saunders coupled $4f^{n-1}$ shell and the crystal field affected d^1 state. These in turn will interact and the details of the interaction will depend on the relative energies of the ^SL_J split levels of the $4f^{n-1}$ configuration. An approximate energy diagram for the Er^{2+} ion in CaF_2 is shown in Figure 10 and the experimental values for the parameters Δ, E_{ff} and E_{fd} are listed in Table 15. The La^{2+} and Gd^{2+} ions have d^1 and f^7d^1 ground states respectively. It will be noticed that the values of Δ decrease towards the centre of each half series La–Gd and Gd–Yb. This is because there is little or no f–d interaction for f^0, f^7 or f^{14} (S states) but in other cases increasing f–d coupling broadens the levels so that Δ as measured is no longer a simple crystal field parameter but also depends on the nature and extent of the f–d interaction.[673]

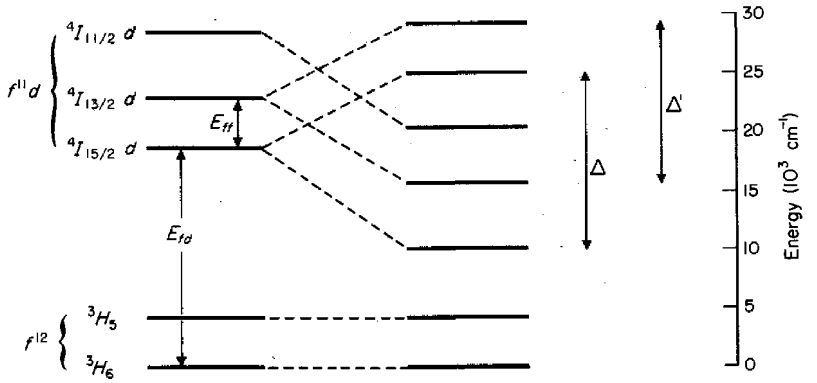


Figure 10 Energy levels of Er^{2+} in CaF_2 (adapted from ref. 673).

Table 15 Energies (10^3 cm^{-1}) Associated with Dipositive Lanthanide Ions in CaF_2

	La	*Ce*	*Pr*	*Nd*	*Pm*	*Sm*	*Eu*	*Gd*	*Tb*	*Dy*	*Ho*	*Er*	*Tm*	*Yb*
E_{fd}[a]	−3.4	25	10.9	13.6		25.6	37.7	−3.3	25.2	17.8	17.6	19.3	26.5	37.3
E_{ff}[a]			4.8	14.2		7.7			8.5	3.8	4.0	5.0	6.5	
Δ[a]	24	15	11.5	9.8		16.1	17	24.3	14.5	11.1	9.3	14.2	15	16.3

[a] As shown in Figure 10.

The spectra of a number of dipositive lanthanide species have been investigated, often in solution. The bands are fairly broad, owing to the effect of varying crystal fields on the 5*d* electron. Spectra have been measured in water, ethanol, acetonitrile, THF or HMPA and values of Δ and E_{fd} derived. In THF, the maximum observed value of Δ was 14 600 cm^{-1} for Tm^{2+}.[661,674] The absorption spectra of [EuCl(phenanthroline)]$^+$ and [EuCl(terpyridyl)]$^+$ in dimethyl sulfoxide have been reported.[665] The absorption spectrum of the Eu^{2+}–2,2,2-cryptate complex has been measured, together with its emission spectrum at 77 K.[675] Eu^{2+}–crown ether complexes when suitably excited give a strong blue emission at ~440 nm.[676] When excited at 365 nm, Sm^{2+} stabilized in ternary fluorides gives a deep red to orange fluorescence believed to be due to a $^5D \rightarrow {}^7F$ transition within the f^6 configuration.[677]

39.2.12 Complexes of Lanthanides in the Tetrapositive Oxidation State

39.2.12.1 Introduction

This is a somewhat restricted area in two respects. Firstly, only cerium has a tetrapositive oxidation state which is sufficiently stable to coexist with organic ligands. Although praseodymium and terbium give one or two binary salts and simple halide complexes, that is the limit of their achievement as tetravalent complex formers, and the remaining elements either form no tetrapositive compounds at all, or are restricted to fluoro complexes only. Secondly, the oxidizing nature of even cerium as Ce^{4+} is normally sufficiently great to limit its complexes to those with ligands which are not too easily oxidized. Some data relevant to the behaviour of tetrapositive lanthanide ions are given in Table 16. The fourth ionization potential (I_4) values are derived spectroscopically, and the standard reduction potential ($E^{\ominus}$) values are also derived spectroscopically, specifically from positions of charge-transfer and $f \rightarrow d$ bands particularly in hexahalo complexes $[MX_6]^{3-}$. It will be noticed that the correlation between these values and the stabilities of various classes of tetrapositive compounds is very good.

Table 16 Data Concerning the 4+ State in Lanthanides

		(1.74)	(3.2)	(5.0)					(3.1)	(5.2)					

A, no compounds known; *B*, complex fluorides only; *C*, complex fluorides, binary salts and alkaline-aqueous ions only; *D*, binary salts and a variety of complexes. I_4 values in eV. E values for $M^{3+}(aq)/M^{4+}(aq)$ are in volts relative to NHE. I_4 and E values[678,679] are derived from spectroscopic data except those in parentheses which are experimental values.

39.2.12.2 Hydrated ions

Although a single value is given in Table 16 for $E^{\ominus}$ ($Ce^{3+}(aq)/Ce^{4+}(aq)$), the oxidation potential of Ce^{3+} ion in aqueous media varies considerably with the nature of the counterion, doubtless due to stabilization of Ce^{4+} to different extents by complexation. Thus in 1 M H_2SO_4, $E^{\ominus} = 1.4435$ V,[680] but in perchloric acid solutions, $E^{\ominus} = 1.6400$–1.7310 V depending on concentation,[681] while a range of 1.6085–1.6104 V was observed in nitric acid solutions.[682] There is some evidence for the formation of polymeric species in aqueous nitric acid solutions, and this may explain some anomalies in electrode potential determinations. Values for association constants of 17 and 2 respectively for Ce^{4+}–Ce^{4+} and Ce^{4+}–Ce^{3+} interactions were obtained.[683]

The value of $E^{\ominus}$ ($Ce^{3+}(aq)/Ce^{4+}(aq)$) is rather greater than that for the oxidation of water, since $E^{\ominus}$ (H_2O/O_2) = 1.23 V, and Ce^{4+} ion is in fact capable of oxidizing water to oxygen in 0.5 M H_2SO_4 in the presence of RuO_2 catalyst. Yields are up to 73% theoretical.[684,685]

Tetrapositive Pr^{4+} and Tb^{4+} are quite stable in strongly alkaline carbonate solutions. Thus electrolytic oxidation for three hours of 2–5.5 mol dm^{-3} aqueous M_2CO_3 (M = K or Cs), 1 mol dm^{-3} in KOH, containing $CeCl_3$, $PrCl_3$ or $TbCl_3$ (0.1–0.01 mol dm^{-3}) gave stable solutions of yellow Pr^{4+} ($\lambda_{max} = 283$ nm), dark reddish-brown Tb^{4+} ($\lambda_{max} = 365$ nm), and of

course Ce^{4+}. The alkaline medium provided considerable stabilization of the tetrapositive ions; $E_0^{\ominus}$ for Ce^{3+}/Ce^{4+} being only +0.05 V.[686] The ion Tb^{4+} is also stabilized in solutions of sodium tripolyphosphate $Na_5P_3O_{10}$. The solutions show λ_{max} at 375 nm ($\varepsilon = 1095$) and oxidize Ce^{3+} or Mn^{2+} at an acid pH, while slowly reducing ascorbic acid in neutral solution.[687] Oxidation of $Tb^{3+}(aq)$ by the conducting glass electrode, which exhibits an unusually high overvoltage towards the oxidation of water, produces Tb^{4+} in a solid form, perhaps a hydroxycarbonate, as the aqueous medium was 2.5 K_2CO_3/0.5 M KOH.[688]

39.2.12.3 Nitrogen donor ligands

These complexes are rare, doubtless owing to the comparatively ready oxidation of amines. However, the template preparation of $Ce(NO_3)_4L{\cdot}3H_2O$ has been described; L is the eighteen-membered macrocycle formed by cocondensation of two molecules of ethylenediamine and two molecules of 2,6-diacetylpyridine. The structure of this compound is unknown and it is uncertain to what extent the macrocycle is bonded to the metal ion.[689]

39.2.12.4 Oxygen donor ligands

These compounds, together with the halo complexes described in the next section (39.2.7.5), form the bulk of the known complexes of tetrapositive lanthanides.

(*i*) *Complexes of inorganic oxy anions*

A number of double sulfates of Ce^{4+}, for example $(NH_4)_4Ce(SO_4)_4{\cdot}2H_2O$, may be obtained by concentration of acidic solutions of ceric sulfate and alkali sulfates. The ceric sulfate may be obtained by heating ceric oxide with fairly concentrated sulfuric acid (it dissolves rather slowly), cooling, filtration and washing with acetic acid. A series of hydrated double sulfates of caesium and cerium(IV) have been prepared and their IR spectra have been interpreted in terms of crystal symmetry and point group symmetry.[690] Cerium(IV) salts are solvolyzed in chlorosulfuric acid and the properties of the resulting solutions have been interpreted in terms of the formation of $Ce(SO_3Cl)_4$ which, however, polymerizes at higher concentrations.[691]

Ceric ammonium nitrate, the well-known volumetric standard oxidant, is formulated $(NH_4)_2[Ce(NO_3)_6]$ with 12-coordinated Ce^{4+} ions (each NO_3 ion being bidentate) in approximately T_d symmetry. The Ce—O distances are in the range 2.488–2.530 Å. The ligand 'bite' is only 50.6–50.9° and the other O—Ce—O angles are 65.0–69.9°.[692] The carbonato complexes $Na_6[Ce(CO_3)_5]{\cdot}12H_2O$ and $[C(NH_2)_3]_6[Ce(CO_3)_5]{\cdot}4H_2O$ each show cerium ten-coordinated to five bidentate carbonate ions with Ce—O = 2.379–2.504 Å in the first complex and 2.388–2.488 Å in the second. The coordination polyhedra are irregular.[693,694]

The preceding three structures show that the ionic radius of Ce^{4+} is about 1.10 Å for 12-coordination and about 1.04 Å for 10-coordination. Thus the ionic radius of Ce^{4+} is surprisingly similar to that of Ce^{3+}, but as noted below (Section 39.2.12.4.iii) can vary according to the nature of the ligand.

(*ii*) *Complexes of organic oxy anions*

Cerium tetrakis(acetylacetonate), a venerable compound,[695] exists as α and β modifications. Both these contain $[Ce(acac)_4]$ monomers of D_2 square antiprismatic coordination but differ in the crystal packing. In the α form,[696] Ce—O = 2.36–2.43 Å with the ring angle O—Ce—O = 72°, while in the β form[697] Ce—O = 2.32 Å and O—Ce—O = 71.3°. The tetrakis(acetylacetonates) of Zr, Hf, Th, U and Pu also show dimorphism. The tetrakis(dibenzoylmethanate) $[Ce(dbm)_4]$ adopts a similar square antiprismatic structure with Ce—O = 2.299–2.363 Å and O—Ce—O = 70.8° or 71.2°.[698] There is some tendency for Ce^{3+} β-diketonates to pass into the Ce^{4+} tetrakis(β-diketonate). A series of tri- and tetra-valent cerium β-diketonates has been examined from the point of view of the effect of additional ligands such as Ph_3PO on this process, and it was found that Ce^{3+} β-diketonates were stabilized by adduct formation, particularly by 1,10-phenanthroline.[699]

A very interesting species is the very stable catechol complex $Na_4[Ce(cat)_4]\cdot 21H_2O$, where H_2 cat = 1,2-$C_6H_4(OH)_2$, which forms deep red crystals, the colour ($\lambda_{max} = 517$ nm) probably being due to a ligand-to-4*f* charge-transfer band. It has D_{2d} chelated dodecahedral symmetry with ring O—Ce—O angles of 68.3° and Ce—O distances of 2.357 and 2.362 Å. Cyclic voltammetry showed a quasireversible one-electron reduction at −692 mV *vs.* SCE. The complex is diamagnetic. It is rather surprising that this complex exists, when the highly reducing nature of the catecholate ligand is considered, but the $[Ce(cat)]^{4-}$ ion is unequivocally established.[700]

(iii) Ligands with uncharged oxygen donors

Tetravalent cerium forms complexes with amine oxides or phosphine oxides fairly readily, as do the trivalent lanthanides. Thus the following complexes have been described: $CeCl_4L_2$, where L = Ph_3PO,[701] bipyridyl dioxide or hexamethylphosphoramide,[702] $CeCl_4(DMSO)_3$[703] and $Ce(NO_3)_4(Ph_3PO)_2$.[704] A single crystal X-ray structure is available of the orange Ph_3PO complex, which was prepared by the action of the ligand on $(NH_4)_2Ce(NO_3)_6$ in acetone. The metal ion is ten-coordinated in a pseudo-*trans*-octahedral manner to two *trans* phosphoryl oxygen atoms and four bidentate nitrate ions, but the CeO_{10} polyhedron is irregular. Leading distances and angles are: Ce—O(P) = 2.21 and 2.23 Å, Ce—O(NO_3) = 2.41–2.54 Å, O(P)—Ce—O(P) = 174° and P—O—Ce = 168°. The fairly short Ce—O(P) distances, compared with the Ce—O(NO_3) distances, are noteworthy. The corresponding thorium complex is isostructural.

A number of complexes of Ce^{4+} may conveniently be prepared as follows. Hydrous ceric oxide is added to $SOCl_2$ in cold diglyme and yields stable $H_2CeCl_6\cdot 3$(diglyme) which is soluble in organic solvents, to which solutions of suitable ligands may be added to form complexes such as $CeCl_4\{OP(NMe_2)_3\}_2$.[705]

39.2.12.5 Complex halides

(i) Complex fluorides

This is arguably the most prolific area of tetravalent lanthanide chemistry, and Ce, Pr, Nd, Tb and Dy are all represented.

A variety of cerium(IV) ammonium fluorides are known. Thus the CeF_4–NH_4F–H_2O system gives $(NH_4)_4CeF_8$ at concentrations of NH_4F greater than 28.9%. At lower concentrations, a monohydrate $(NH_4)_3CeF_7\cdot H_2O$ is obtained, which on dehydration is converted into $(NH_4)_4CeF_8$ and $(NH_4)_2CeF_6$. The structure of $(NH_4)_2CeF_6$ contains chains of distorted square antiprisms with Ce—F = 2.198–2.318 Å, while $(NH_4)_4[CeF_8]$ contains isolated distorted square antiprisms. $(NH_4)_3CeF_7\cdot H_2O$ contains dimeric ions $[Ce_2F_{14}]^{6-}$ in which the metal ions are eight-coordinated in a distorted dodecahedral manner with Ce—F = 2.133–2.375 Å. Other complex ammonium cerium(IV) fluorides reported are $(NH_4)_7Ce_6F_{31}$ and NH_4CeF_5.[706–708]

The alkali metal fluoro complexes M_2CeF_6 (M = Na, K, Rb, Cs) and M_3CeF_7 (M = Na, Rb, Cs) have been obtained as colourless diamagnetic crystals by fluorination of MCl/CeO_2 mixtures. They liberate iodine from aqueous iodide and decompose in water.[709] The analogous terbium compound Cs_3TbF_7, which is colourless and paramagnetic ($\mu = 7.4$ BM), has been obtained similarly by fluorination at 390 °C, and its magnetic moment is much more consistent with the presence of Tb^{4+} (theory, 7.9 BM) than with Tb^{3+} (9.7 BM).[710]

Compounds of tetrapositive praseodymium can be made by the action of fluorine at 400–500 °C on MCl and Pr_6O_{11} mixtures. Thus obtained were M_3PrF_7 and M_2PrF_6 (M = Na, K, Rb or Cs). They are colourless and decompose in water. The Curie–Weiss law is obeyed with observed room-temperature moments of 2.10–2.45 BM (Pr^{4+}, 2.56 BM theory; Pr^{3+}, 3.61 BM).[711] The compounds $Na_7Pr_6F_{31}$ and Na_2PrF_6 have been obtained by fluorination of $PrCl_3$/NaCl at 200–400 °C. These products were characterized by X-ray powder pattern and iodine equivalent.[712,713] More recently, a wide variety of compounds M_3LnF_7 (M = K, Rb or Cs; Ln = Ce, Pr, Nd, Tb or Dy) have been obtained, mainly by fluorination of M_3LnCl_6 at 50–150 bar and 400 °C for 2–3 hours. All the fluorides were isostructural with $(NH_4)_3ZrF_7$; examples are $KRbCsPrF_7$, $RbCs_2NdF_7$ (orange) and KCs_2DyF_7 (orange). Compounds $MPrF_6$

(M = Sr, Ba or 2Li) were also obtained starting from $MPrO_3$ (itself made from the action of O_2 on the mixed lower oxides).[714]

The series of fluoro complexes Cs_3MF_7 (M = Ce, Pr, Nd, Tb or Dy) have also been made by reaction of Cs_3MCl_6 with XeF_2 at temperatures of 100 °C for Ce, Pr or Tb, and 400 °C for Nd or Dy. Corresponding treatment of Cs_3MCl_6 (M = Er or Yb) yielded only Cs_3MF_6.[715]

It should be noted that definitive X-ray single crystal work is really needed on some of these compounds, as structures are often based on powder correlations with type structures of non-lanthanide complex fluorides, some of which are themselves quite early single crystal studies.

Good electronic spectra may be obtained from these fluoro complexes which thus provide a unique source of information about electronic energy levels in tetravalent lanthanides. The electronic spectra of Cs_3NdF_7 have been obtained in absorbance and fluorescence and an excellent correlation is observed with expected behaviour for the Nd^{4+} f^2 ion in intermediate-field coupling. Values of $F_2 = 352$, $F_4 = 52.3$, $F_6 = 5.56$, and spin–orbit coupling constant $\xi = 1109\ cm^{-1}$ explained the spectra, with the first nine excited states up to $^3P_1$ at 25 700 cm^{-1} being observed above the $^3H_4$ ground state.[716] Similar spectra for Cs_3DyF_7 have been obtained and agree with theoretical values calculated using only two parameters, $F_2 = 465.8\ cm^{-1}$ and $\xi = 2270\ cm^{-1}$. Only the ^7F ground state multiplet and the $^5D_3$ excited state at 21 600 cm^{-1} were observed.[717]

(*ii*) *Complex chlorides*

Complex chlorides of Ce^{4+} may be prepared by dissolution of cerium(IV) hydroxide in methanolic hydrochloric acid followed by addition of a base B, giving $(BH)_2[CeCl_6]$. $(NH_4)_2CeCl_6$ can be used as a selective precipitant for Cs^+ ions in presence of other alkali metals, with separation coefficients ranging from 5300 (Na) to 60 (Rb).[718]

The thermal decomposition of $Cs_2[CeCl_6]$ has been studied. In nitrogen at 600 K it decomposes into $CeCl_3$, Cl_2 and CsCl,[719] but in air CeO_2, Cl_2 and CsCl are formed.[720] The enthalpies of decomposition and formation were determined as: $\Delta H^{\ominus}_{f,298} = -1974.09 \pm 8.37\ kJ\ mol^{-1}$ and ΔH (decomp. 600 K) $= 25.5 \pm 3.3\ kJ\ mol^{-1}$. Hexachlorocerates of organic cations vary in their thermal decomposition behaviour. Thus the pyridinium or some tetraalkylammonium compounds give chlorine, but the PPh_4^+ or $AsPh_4^+$ compounds do not.[721]

The IR and Raman spectra of $R_2[CeCl_6]$, where R = Cs or various substituted ammonium, has been studied and assignments to the vibrational modes of the octahedral $[CeCl_6]^{2-}$ ion have been made.[722,723] These are: A_{1g} stretch, 295 cm^{-1}; T_{1u} stretch, 265 cm^{-1}; T_u bend, 116 cm^{-1}, and T_{2g} bend, 123 cm^{-1}. The complexes are made from $(NH_4)_2CeCl_6$ and RCl.[724]

40.1 GENERAL SURVEY

40.1.1 Introduction

Most of this chapter relates to two earlier members of the actinide group, thorium and uranium, both available in large quantities and relatively cheap. The radioactivity arising from the naturally occurring isotopic mixture of these two elements presents no serious handling problems, whereas ^{231}Pa, ^{237}Np, ^{239}Pu, *etc.*, are much more intensely radioactive, requiring very costly handling facilities. These isotopes are also very expensive. Consequently, basic research on these elements is restricted to government-supported research establishments, such as AERE, Harwell in the UK and the Argonne and Oak Ridge National Laboratories in the USA, where much of the effort is of an applied nature. Beyond californium ($Z = 98$), the elements can only be produced in very small quantities and all known isotopes of $Z = 99$ to 103 are short-lived and, consequently, of very high specific radioactivity. This makes it exceedingly difficult to prepare solid, characterizable compounds of any kind, and most of the scanty information that is available is based on tracer level studies.

40.1.2 Oxidation States

In contrast to the lanthanide 4*f* transition series, for which the normal oxidation state is +3 in aqueous solution and in solid compounds, the actinide elements up to, and including, americium exhibit oxidation states from +3 to +7 (Table 1), although the common oxidation state of americium and the following elements is +3, as in the lanthanides, apart from nobelium ($Z = 102$), for which the +2 state appears to be very stable with respect to oxidation in aqueous solution, presumably because of a high ionization potential for the $5f^{14}$ No^{2+} ion. Discussions of the thermodynamic factors responsible for the stability of the tripositive actinide ions with respect to oxidation or reduction are available.[1,2]

Table 1 Known Oxidation States of the Actinide Elements

Th	*Pa*	*U*	*Np*	*Pu*	*Am*	*Cm*	*Bk*	*Cf*	*Es*	*Fm*	*Md*	*No*	*Lw*
					2			2	2	2	2	2

40.1.3 Steric Crowding

Ligand field interactions in 5*f* transition element complexes are very small,[3] so that there is little or no contribution to the kinetic stability of the complexes, all of which can be regarded as kinetically labile. Ligand exchange will therefore occur quite readily for there will be virtually no gain (or loss) of ligand field stabilization energy in an inter- or intra-molecular rearrangement. There will also be a marked degree of flexibility in the coordination geometries adopted by the complexes formed by these elements. Consequently, steric crowding about the central metal atom is the principal factor governing the coordination number and geometry adopted by actinide complexes.

One simple way of quantifying steric effects in actinide complexes [the cone angle factor (caf) approach] uses the sum of the solid angles subtended by the ligands to the centre of the metal

atom in a given complex, divided by 4π (abbreviated to Σ caf) to represent the fraction of the total sphere surface enclosing the metal atom which is occupied by the ligands.[4,5] Obviously the value of Σ caf can never be unity, which would represent complete filling of the sphere surface about the metal atom, because of ligand–ligand repulsions, and for thorium(IV) and uranium(IV) complexes of known structure, values for Σ caf are 0.80 ± 0.04 and 0.80 ± 0.03 respectively. This approach has some predictive value; for example, seven-coordination would be expected for complexes of thorium tetrachloride with medium sized ligands, and both six- and seven-coordination for similar complexes of uranium tetrachloride.

However, prediction of the most likely geometry to be adopted in a given compound is best based on a consideration of the repulsions between the metal–ligand bonds in the complexes, and will depend on whether the ligands are uni-, bi- or poly-dentate. The actual combinations of the different ligands in individual compounds seem to be very important in determining which particular geometry and coordination number are adopted, as shown in the possible geometries for eight-coordination.[6]

40.1.4 Coordination Numbers and Geometries

The radii of the actinide cations at the beginning of the series are, for any given oxidation state, larger than *d* transition metal cations in the same oxidation state, so that high (>6) coordination numbers are common in actinide complexes. Because the ionic radii decrease with increasing atomic number (the actinide contraction), the observed coordination number also decreases along the series for a given oxidation state with the same ligand. Much published work concerned with the coordination chemistry of these elements has compared the behaviour of the early and later members of the series. A useful survey of structural information is available.[7]

Examples of the known coordination numbers and geometries are given in Table 2. Low (<6) coordination numbers are observed only with very bulky ligands, *e.g.* $[N(SiMe_3)_2]^-$, or high oxidation states, *e.g.* $[NpO_4]^-$, and the highest (12 to 14) are found only with relatively small multidentate ligands, such as bidentate NO_3 and bi- and ter-dentate BH_4 groups. Seven-coordination is very common in dioxoactinide(VI) complexes, in which the rigid O=M=O group provides the axis for pentagonal bipyramidal geometry, but several examples of this geometry have been recorded for complex cations (*e.g.* $[UCl_3(EtCONEt_2)_4]^+$),[8] the neutral complex $[U(NCS)_4(Me_2CHCONMe_2)_3]$[9] and the anion $[UF_7]^{3-}$ in $K_3[UF_7]$.[10] The analytical stoichiometry of a complex may well mislead, for $UCl_4 \cdot 3DMSO$ does not involve seven-coordinate uranium(IV), but is actually $[UCl_2(DMSO)_6]^{2+}[UCl_6]^{2-}$.[11]

40.1.5 Literature Sources

Exhaustive accounts of the chemistry of thorium, protactinium, uranium and the trans-uranium elements appear in the most recent supplementary volumes of the Gmelin series.[12] Unless otherwise indicated by the inclusion of references to specific papers, further information on the compounds discussed in this chapter will be found in the Gmelin volumes and in the work cited in reference 2.

40.2 THORIUM, PROTACTINIUM, URANIUM, NEPTUNIUM AND PLUTONIUM

40.2.1 The +3 Oxidation State

Thorium(III) and protactinium(III) complexes are unknown, and relatively few uranium(III), neptunium(III) and plutonium(III) compounds have been described. This is mainly because of the ease of oxidation to the +4 state in all three cases, accentuated for plutonium(III) by the oxidizing nature of the α-radiolysis products formed in solutions.

40.2.1.1 Nitrogen ligands

(*i*) *Ammonia*

The only reported complexes are those with uranium and plutonium trihalides. The products of composition $UCl_3 \cdot (6.8–6.9)NH_3$ and $UCl_3 \cdot (7.0–7.4)NH_3$ lose ammonia at 20 or 45 °C to

form $UCl_3\cdot 3NH_3$, which decomposes to $UCl_3\cdot NH_3$ above 45 °C. $UBr_3\cdot 6NH_3$ is apparently obtained by treating the tribromide with gaseous ammonia, whereas $UBr_3\cdot(3–4)NH_3$ is said to form with liquid ammonia. $PuCl_3$ and PuI_3 yield products of composition $PuCl_3\cdot ca.\ 8NH_3$ and $PuI_3\cdot ca.\ 9NH_3$ with either gaseous or liquid ammonia;[13] these lose ammonia readily to yield the products $PuCl_3\cdot(4.1–4.5)NH_3$ and $PuI_3\cdot(5.5–6)NH_3$ respectively. No structural information is available for any of these products.

(*ii*) *N-Heterocyclic ligands; pyridine*

The existence of the only recorded complex, $[U(py)_6][Cr(NCS)_6]$, is doubtful because uranium(III) reduces the $[Cr(NCS)_6]^{3-}$ ion.[14]

(*iii*) *Amides*

The compound with the bulky silylamide,[15] $U\{N(SiMe_3)_2\}_3$, may be a monomer, in which case the molecular geometry is probably pyramidal.

(*iv*) *Nitriles*

The only recorded compounds are $UCl_3 \cdot MeCN$, which may be polymeric, and $NpCl_3 \cdot 4MeCN$, for which the ^{237}Np Mössbauer spectrum has been reported.[16a] Mössbauer studies indicate[16a] that products of composition $M^I NpCl_4 \cdot x MeCN$ are mixtures of $NpCl_3 \cdot 4MeCN$ and $M^I_2 NpCl_5$.

40.2.1.2 Phosphorus ligands

The bis diphosphine complex, $[U(BH_4)_3(dmpe)_2]$ (dmpe = $Me_2PCH_2CH_2PMe_2$), has been prepared by treating $U(BH_4)_3 \cdot THF$ with an excess of dmpe in THF. The uranium centre is formally 13-coordinate, with the three BH_4 groups tridentate.[16b]

40.2.1.3 Oxygen ligands

(*i*) *Aqua species, hydroxides and oxides*

A selection of the known hydrated compounds is given in Table 3. In many cases they are easily dehydrated and the water is presumably held in the lattice. Water does not appear to be coordinated to the metal atom in the hydrated trifluorides, such as $PuF_3 \cdot (0.4–0.75)H_2O$, whereas it is coordinated in $PuCl_3 \cdot 6H_2O$ and the bromides $MBr_3 \cdot 6H_2O$ (M = U, Np, Pu), which are isostructural with the lanthanide hydrates $LnCl_3 \cdot 6H_2O$ and with $AmCl_3 \cdot 6H_2O$, being of the form $[MX_2(H_2O)_6]^+X^-$. The hydrated plutonium(III) hexacyanoferrate(III), $Pu[Fe(CN)_6] \cdot ca.\ 7H_2O$, is black, indicating a considerable degree of charge transfer.

Table 3 Some Hydrates of Actinide(III) Compounds

$PuF_3 \cdot (0.4 \text{ to } 0.75)H_2O$	
$PuCl_3 \cdot 6H_2O$	
$M^{III}Br_3 \cdot 6H_2O$	M^{III} = U, Np, Pu
$M^IUCl_4 \cdot 5H_2O$	M^I = Rb, NH_4
$M^{III}_2(SO_4)_3 \cdot xH_2O$	M^{III} = U, x = 8; Pu, x = 5 or 7
$NaNp(SO_4)_2 \cdot xH_2O$	
$M^IPu(SO_4)_2 \cdot xH_2O$	x = 1, 2, 4 or 5 variously with M^I = Na, K, Rb, Cs, Tl, NH_4
$(NH_4)_2U_2(SO_4)_4 \cdot 9H_2O$	
$Pu_2(SO_3)_3 \cdot xH_2O$	
$PuPO_4 \cdot 0.5H_2O$	
$HM^{III}[Fe^{II}(CN)_6] \cdot xH_2O$	M^{III} = U, x = 9 to 10; Pu, x uncertain
$Pu[Fe^{III}(CN)_6] \cdot ca.\ 7H_2O$	
$M^{III}_2(C_2O_4)_3 \cdot xH_2O$	M^{III} = Np, x = *ca.* 11; Pu, x = 1, 2, 3, 6, 9 or 10

The only recorded hydroxide, $Pu(OH)_3 \cdot xH_2O$, rapidly oxidizes to a plutonium(IV) species, but two forms of Pu_2O_3 are known, one with the hexagonal La_2O_3 structure and the other cubic; in these the Pu^{3+} is seven- and six-coordinate respectively. Ternary oxides, such as $PuAlO_3$, are also known.

(ii) β-Ketoenolates and ethers

β-Ketoenolates have not been isolated for the tripositive elements; in the attempted preparation of $Pu(MeCOCHCOMe)_3$, oxidation to plutonium(IV) occurred very readily.[17] Complexes with ethers appear to be restricted to THF solvates; apart from $UCl_3 \cdot THF$, a useful starting material for uranium(III) preparative chemistry,[18] the only other examples are solvated organometallic compounds, such as $Cp_3Np \cdot 3THF$ and $Cp_3Pu \cdot THF$.

(iii) Oxoanions as ligands

Hydrated sulfato complexes of the type $M^IM^{III}(SO_4)_2 \cdot xH_2O$ (Table 4) are known for M^{III} = U and Pu, and $(NH_4)_2U_2(SO_4)_4 \cdot 9H_2O$ may be of the same type. $KPu(SO_4)_2 \cdot H_2O$ and the corresponding dihydrate are isostructural with the neodymium(III) analogues and $NH_4Pu(SO_4)_2 \cdot 4H_2O$ is isomorphous with the corresponding cerium(III) compound. Salts of other complex anions, such as $K_5M^{III}(SO_4)_4$ (M^{III} = Np, Pu), are also known.

Table 4 Some Actinide(III) Sulfato complexes

$M^IM^{III}(SO_4)_2 \cdot xH_2O$	$x = 1$, M^I = K, M^{III} = Pu
	$x = 2$, M^I = Na, M^{III} = U and M^I = K, M^{III} = Pu
	$x = 4$, M^I = Rb, M^{III} = U and M^I = Na, NH_4, Rb, Cs or Tl, M^{III} = Pu
$M^I_2U_2(SO_4)_4 \cdot xH_2O$	$x = 9$, $M^I = NH_4$ and $x = 11$, M^I = Cs
$K_3U(SO_4)_3$	
$K_5M^{III}(SO_4)_4$	M^{III} = Np, Pu
$K_8Pu_2(SO_4)_7$	

(iv) Carboxylates and carbonates

Uranium(III) formate, $U(HCO_2)_3$, isostructural with $Np(HCO_2)_3$,[19] $Pu(HCO_2)_3$[20a] and $Nd(HCO_2)_3$, is precipitated when a solution of UCl_4 in 95% formic acid is treated with a large excess of zinc amalgam. The corresponding uranium(III) acetate and propionate could not be obtained by this route. $Np(HCO_2)_3$ has been prepared[19] in the same way as $U(HCO_2)_3$ and $Pu(HCO_2)_3$ by treating $Pu(OH)_3$ with 90% formic acid.[20a]

The hydrated oxalates, $Np_2(C_2O_4)_3 \cdot ca.\ 11H_2O$ and $Pu_2(C_2O_4)_3 \cdot 10H_2O$, are precipitated on addition of oxalic acid to aqueous solutions containing the tripositive elements. The hydrated oxalato complexes, $M^IPu(C_2O_4)_2 \cdot xH_2O$ (M^I = Li, Na, K, Cs and NH_4, $x = 0.3$–3.5) have also been recorded.[20b] Very little else is known about the metal(III) carboxylates. A carbonate, $Pu_2(CO_3)_3$, has also been recorded.

(v) Aromatic hydroxyacids

Neptunium(III) and plutonium(III) are precipitated from aqueous solution by salicyclic acid; the neptunium salicylate, $Np(C_6H_4(OH)CO_2)_3 \cdot 1.5H_2O$, can be dehydrated at 50 to 150 °C.

(vi) N,N-Dimethylformamide and related ligands

The DMF and antipyrine (2,3-dimethyl-1-phenylpyrazol-5-one, ap) complexes $[UL_6][Cr(NCS)_6]$, and the pyrimidone (4-dimethylaminoantipyrine, pym) analogue $[U(pym)_3][Cr(NCS)_6]$, are probably uranium(IV) compounds.[14] However, $[U(ap)_6]Cl_3$ has been obtained by dissolving $RbUCl_4 \cdot 5H_2O$ in ethanol containing the stoichiometric quantity of the ligand, followed by evaporation at low temperature,[14] and the corresponding tetraphenylborates, $[U(ap)_6](BPh_4)_3$ and $[U(pym)_4](BPh_4)_3$, are precipitated when ethanolic $Na(BPh_4)$ is added to a solution of $NH_4UCl_4 \cdot 5H_2O$ and the ligand in the same solvent, a method also used to obtain the dicarboxylic acid amide complexes,[21] $[UL_4]X_3$ where $L = (CH_2)_n(CONR_2)_2$ ($n = 1$–4) and $Me_2C(CH_2CONR_2)_2$ with R = Me or Et, and X = BPh_4 or PF_6.

40.2.1.4 Sulfur ligands

(*i*) *Sulfides*

The sulfides M_2S_3 (M = Np, Pu) exist in three crystal modifications. Th_2S_3 and M_2S_3, however, may be metallic in character like the monosulfides MS (M = Th, U, Np, Pu). Plutonium disulfide, PuS_2, is a plutonium(III) polysulfide and the sulfides of composition M_3S_5 (M = U, Np, Pu) are mixed phases, $M_2S_3 \cdot MS_2$. Other known sulfides include Pu_3S_4 and Th_7S_{12}. Isostructural oxosulfides, Np_2O_2S and Pu_2O_2S, are also known. A detailed discussion of actinide sulfides is available.[22]

(*ii*) N,N-*Diethyldithiocarbamates* (*dtc*)

The complexes $M^{III}(dtc)_3$ (M^{III} = Np, Pu) are obtained by treating the metal tribromide with Na(dtc) in anhydrous ethanol. $Pu(dtc)_3$ is fairly stable to oxidation, but $Np(dtc)_3$ and the even less stable $U(dtc)_3$ are rapidly oxidized to $M(dtc)_4$, so that neither can be isolated. However, the anionic complexes, $(NEt_4)[M^{III}(dtc)_4]$ (M^{III} = Np, Pu), have been prepared and the geometry about the metal atom is a distorted dodecahedron, best regarded as a planar pentagon of five S atoms with one S atom above and two S atoms below the pentagon.[23] These salts of the $[M(dtc)_4]^-$ ion are isostructural with the analogous lanthanide complexes, whereas $Pu(dtc)_3$ is not isostructural with any of the lanthanide $Ln(dtc)_3$.

40.2.1.5 Selenides and tellurides

A variety of selenides and tellurides of composition MX (M = Th, U, Pu; X = Se or Te), M_2X_3 (M = Th, U, Pu, X = Se; M = Th, X = Te), M_3X_4 (M = U, Np, Pu, X = Se; M = U, Np, X = Te), U_3X_5 (X = Se, Te) and Th_7Se_{12} have been recorded. These are probably structurally similar to the corresponding sulfides.

40.2.1.6 Halogens as ligands

The known trifluorides, MF_3 (M = U, Np, Pu), possess the LaF_3-type structure in which the coordination geometry about the metal atom is a fully capped trigonal prism, an interesting example of 11-coordination.[24] The trichlorides, MCl_3 (M = U, Np, Pu), adopt the UCl_3-type structure in which the nine-coordinate metal atom lies at the centre of a tricapped trigonal prism, a structure also found for UBr_3 and α-$NpBr_3$. β-$NpBr_3$ and $PuBr_3$ have the eight-coordinate $PuBr_3$-type structure in which the coordination geometry is a bicapped trigonal prism and this is found also for the triiodides, MI_3 (M = U, Np, Pu). Amido chlorides, $U(NH_2)Cl_2$ and $U(NH_2)_2Cl$, obtained by heating UCl_3 in NH_3 at 450 to 500 °C, are also known; the other trihalides would probably react in a similar manner. Examples of the known halogeno complexes are given in Table 5. $NaPuF_4$ is isostructural with $NaNdF_4$; the geometry about the M^{III} centre is a tricapped trigonal prismatic arrangement of fluorine atoms.[25] The $[M^{III}Cl_6]^{3-}$ anions (M = U, Np, Pu) are octahedral and the geometry about the central metal atom in the complex anions of the salts $M^I_2M^{III}Cl_5$ is a monocapped trigonal prism. Crystallographic data for $M^I_2M^{III}Cl_5$ (M^I = K, Rb, Cs), $CsUCl_4$ and RbU_2Cl_7, obtained in M^ICl/UCl_3 phase studies, have been reported.[26a]

40.2.1.7 Hydrides as ligands

Hydrides of composition MH_2 (M = Th, Np, Pu; all fluorite structure) and MH_3 (M = Pa, U, Np, Pu) have been recorded, as well as phases of intermediate composition, such as $NpH_{2.7}$. The only recorded borohydride, $U(BH_4)_3$, obtained by thermal or photochemical decomposition of $U(BH_4)_4$, probably involves multiple U—H—B bonding.

Table 5 Some Actinide(III) Halogeno Complexes

$M^IM^{III}F_4$	M^{III} = U, Pu with M^I = Na, K

[c] J. Drozdzynski, *Inorg. Chim. Acta*, 1979, **32**, L83.

40.2.1.8 Mixed donor atom ligands

The neutral 2-(diphenylphosphino)pyridine complex, $[U(BH_4)_3(Ph_2Ppy)_2] \cdot 0.5C_6H_6$, has been prepared by treating $U(BH_4)_3 \cdot THF$ with the ligand. If each triply bridging BH_4 group is regarded as occupying one coordination site, the geometry of the formally 13-coordinate uranium atom is close to pentagonal bipyramidal.[26b]

The only other recorded compound for the +3 oxidation state is the 8-hydroxyquinoline complex, $Pu(C_9H_6NO)_3$, precipitated when an aqueous solution containing plutonium(III) is added dropwise, in a stream of nitrogen, to an aqueous solution of the ligand in the presence of reducing agents. It is rapidly oxidized in air.

40.2.1.9 Multidentate macrocyclic ligands

The only examples of complexes with this type of ligand are the crown ether compounds UCl_3L (L = 15-crown-5,[18] benzo-15-crown-5[18] and 18-crown-6[27]), which precipitate when the ligand is added to a solution of $UCl_3 \cdot THF$ in THF, and $U(BH_4)_3 \cdot 18$-crown-6, prepared by treating the UCl_3 complex with $NaBH_4$. It appears that the 15-crown-5 ligands provide a better cavity match than 18-crown-6.

40.2.2 The +4 Oxidation State

40.2.2.1 Group IV ligands

(i) Cyanides

Actinide cyanide systems have scarcely been investigated. A product described as Th[Th(CN)$_8$] [Th(CN)$_4$?] is reported to be formed when a thorium(IV) hydroxide gel is treated with a 10–20% excess of a solution of stabilized HCN in an autoclave.[28] Uncharacterized cyanide-containing products are obtained when $ThCl_4$ or $ThBr_4$ is treated with an alkali metal cyanide in anhydrous liquid ammonia, a reaction which yields $UCl_3(CN) \cdot 4NH_3$ [ν(CN) = 2120 cm^{-1}] in the case of UCl_4.[29] UBr_4 and UI_4 appear to react in the same way as UCl_4. An impure product of approximate composition $(Et_4N)_2UCl_4(CN)_2$ has also been recorded. Alkali metal cyanides do not react with UCl_4 in anhydrous liquid HCN, the only product being a UCl_4–HCN adduct.

(ii) Isocyanides, RNC

A cyclohexyl isocyanide complex, probably $[ThI_4(C_6H_{11}NC)_4]$ [ν(NC) = 2194 cm^{-1}, $\Delta\nu$(NC) = +59 cm^{-1}] has been obtained by treating ThI_4 with $C_6H_{11}NC$ in *n*-hexane. The

analogous uranium(IV) complex [ν(NC) = 2190 cm^{-1}, $\Delta\nu$(NC) = +55 cm^{-1}] was obtained in the same way. Similar complexes appear to be formed with UCl_4 and UBr_4.[30]

40.2.2.2 Nitrogen ligands

(i) Ammonia and amines

(*a*) *Ammonia.* A selection of the known thorium(IV), uranium(IV) and plutonium(IV) ammines is given in Table 6. Most of them were obtained from the parent compound or ($PuCl_4 \cdot xNH_3$) from $Cs_2[PuCl_6]$ by treatment with gaseous or liquid ammonia. $ThBr_4 \cdot 4NH_3$ (reported[31a] as $(NH_4)_2ThBr_4(NH_2)_2$) is obtained when $(Et_4N)_2[ThBr_6]$ is treated with liquid ammonia at low temperature. Its nature is uncertain. Although no structural data are available for any of these compounds, two of them, $UCl_4 \cdot 4NH_3$ and $UBr_4 \cdot 4NH_3$, are reported to be white solids, which suggests a centrosymmetric structure, possibly cubic. $UCl_3(CN) \cdot 4NH_3$, in contrast, is light green. Hydrated products, formulated earlier as $Th(NO_3)_4 \cdot 3NH_3 \cdot H_2O$ and $2Th(NO)_3)_4 \cdot 7NH_3 \cdot 3H_2O$, are doubtful; $Th(NO_3)_4 \cdot 4H_2O$ and $Th(SO_4)_2$ undergo ammonolysis in liquid ammonia, but $Th(C_2O_4)_2$ is soluble, which may indicate the formation of a complex.

Table 6 Some Ammonia Complexes of Actinide(IV) Compounds

$UF_4 \cdot xNH_3$	x = 0.5 (?), 1 or 4.2 to 4.6
$MCl_4 \cdot xNH_3$	M = Th, x = 3 (?), 6; M = U, x = 1, 2, 4, 5, 7.3 to 7.6, 8, 9 to 10 or 12; M = Pu, x = *ca.* 5 or *ca.* 7
$UCl_3(CN) \cdot 4NH_3$	
$MBr_4 \cdot xNH_3$	M = Th, x = 4; M = U, x = 4, 5 to 6 or 10
$MI_4 \cdot xNH_3$	M = Th, x = 7 or 8; M = U, x = 4 to 5 or 10
$ThI_3(NH_2) \cdot 4NH_3$	
$ThI_2(NH_2)_2 \cdot 3NH_3$	
$U(OR)_4 \cdot xNH_3$	x = 1, R = Ph, *o*-ClC_6H_4, *o*-, *p*-MeC_6H_4, α-, β-$C_{10}H_7$ x = 2, R = *m*-, *p*-ClC_6H_4
$U(OR)_4 \cdot 2ROH \cdot NH_3$	R = Ph, *p*-ClC_6H_4, *o*-, *p*-MeC_6H_4
$U(RCO_2)_4 \cdot xNH_3$	R = H, x = 2; R = Me, x = 1
$U(C_2O_4)_2 \cdot 3NH_3 \cdot H_2O$	
$UO(OR)_2 \cdot 4ROH \cdot NH_3$	R = Ph, *p*-ClC_6H_4
$UO(RCO_2)_2 \cdot xNH_3$	R = H, x = 1 or 2; R = Me, x = 1

(*b*) *Aliphatic and aromatic amines.* Amine complexes are known only for thorium(IV) and uranium(IV) species (Table 7), prepared either by treating the parent compound with the amine, removing the excess by vacuum evaporation, or by precipitation from a solution of the parent compound in a non-aqueous solvent by addition of a solution of the amine in the same solvent.

The thorium atom in $[ThCl_4(Me_3N)_3]$ is seven-coordinate in a capped octahedral environment, with one Cl in the cap position; three N atoms occupy the capped face and three Cl atoms occupy the uncapped face.[31b]

The IR spectra of $Th(NO_3)_4 \cdot x\text{amine} \cdot yH_2O$ indicate that no ionic nitrate is present when $x = 1$ and $y = 3$, or $x = y = 2$, whereas with $x = 3$ and $y = 4$ both coordinated and ionic nitrate groups are present. When $x = y = 4$ nearly all the nitrate groups are ionic.[32] No other structural information is available for these compounds.

(*c*) *Hydrazines.* The few known complexes are listed in Table 8. $ThCl_4 \cdot 4PhNHNH_2$ behaves as a 1:4 electrolyte in DMF but this could be due to displacement of all chloride anions and hydrazine molecules by solvent.

(*d*) *Ethylenediamine and other diamines.* Complexes with these ligands (Table 9) are normally prepared from the parent compound and the ligand, either alone or in a non-aqueous solvent. For example, the diaminobenzene complexes, $ThCl_4 \cdot 2C_8H_8N_2$, precipitate when ethereal solutions of the chloride and the ligand are mixed. It is not known whether the water molecules in the hydrated complexes $ThBr_4 \cdot xL \cdot yH_2O$ (Table 9) are bonded to the thorium atom. The *N,N,N',N'*-tetramethylethylenediamine (tmed) complex, $\{(CF_3)_2CHO\}_4U \cdot (tmed)$, is obtained by treating $\{(CF_3)_2CHO\}_4U \cdot 2THF$ with tmed.[33] The majority of the known complexes probably involve eight-coordinate actinide(IV) ions, and it is possible that the 1,2-diaminobenzene complex of composition $2UCl_4 \cdot 5L$ is of the form $[UCl_3L_4]^+[UCl_5L]^-$,

Table 7 Some Amine Complexes of Thorium(IV) and Uranium(IV) Compounds

$ThCl_4 \cdot 4L$	L = RNH_2, with R = Me, Et, Pr^n, $PhCH_2$, *m*-, *p*-MeC_6H_4, *o*-, *p*-$MeOC_6H_4$, *p*-$EtOC_6H_4$, *α*-, *β*-$C_{10}H_7$ (naphthyl) L = RR′NH, with R = Ph and R′ = Me, Et, $PhCH_2$, Ph L = $R_2R'N$, with R = Me or Et and R′ = Ph
$ThBr_4 \cdot 4RNH_2$	R = Et, Ph
$[ThCl_4(Me_3N)_3]$	
$ThCl_4 \cdot 3MeC_6H_4NH_2$	(toluidine)
$ThCl_4 \cdot 2Et_3N$	
$ThCl_4 \cdot \beta\text{-}C_{10}H_7NH_2$	
$Th(acac)_4 \cdot PhNH_2$	
$Th(NO_3)_4 \cdot x Bu^nNH_2 \cdot yH_2O$	$x = 1$, $y = 3$; $x = 2$, $y = 1$; $x = 3$ or 4, $y = 4$
$Th(NO_3)_4 \cdot xMe_2NH \cdot yH_2O$	$x = 1$, $y = 2$ and $x = 4$, $y = 8$
$Th(NO_3)_4 \cdot xEt_3N \cdot H_2O$	$x = 1$ or 2
$Th(C_2O_4)_2 \cdot 4Bu^nNH_2 \cdot 2H_2O$	
$UCl_4 \cdot xRNH_2$	$x = 1$, R = Et,[a] Pr^n;[a] $x = 2$, R = Me,[a] Et,[a] Ph; $x = 3$, R = Bu^t; $x = 4$. R = Pr^n,[a] Bu^n
$UCl_4 \cdot xR_2NH$	$x = 2$, R = Et; $x = 3$, R = Me, Pr^i, Bu^t
$UCl_4 \cdot xR_3N$	$x = 1$, R = Et; $x = 2$, R = Me
$UBr_4 \cdot 2Et_2NH$	
$U(OPh)_4 \cdot 2PhOH \cdot Et_3N$	
$UO(OPh)_2 \cdot 4PhOH \cdot Et_3N$	

[a] Evidence for the formation of these species was obtained from X-ray and thermal desorption studies of the solid phases in the UCl_4–amine systems (I. Kalnins and G. Gibson, *J. Inorg. Nucl. Chem.*, 1958, **7**, 55).

Table 8 Some Complexes with Hydrazine, N_2H_4 and Phenylhydrazine, $PhNHNH_2$

$U\{(CF_3)_2CHO\}_4 \cdot tmed$	
Diaminoalkanes	
$ThBr_4 \cdot xL \cdot yH_2O$	$x = 2$, $y = 5$, L = 1,2-diaminopropane and 1,4-diaminobutane $x = 2$, $y = 2$ and $x = 4$, $y = 6$, L = 1,4-diaminobutane $x = 4$, $y = 2$, *L* = 1,2-diaminopropane
Diaminoarenes	
$ThCl_4 \cdot 2L$	L = 1,2-, 1,3- or 1,4-diaminobenzene, 4,4′-diamino-biphenyl (benzidine), 4,4′-diamino-3,3′-dimethyl-biphenyl (*o*-tolidine) or 4,4′-diamino-3,3′-dimethoxybiphenyl (*o*-dianisidine)
$UCl_4 \cdot 2L$	L = 1,8-diaminonaphthalene
$2UCl_4 \cdot 5L$	L = 1,2-diaminobenzene
$UBr_4 \cdot 4L$	L = 1,2-diaminobenzene
$[Th(NO_3)_2L_2](NO_3)_2$	L = 1,2-diaminobenzene

analogous to the known amide complexes of this stoichiometry. Thorium tetraacetate is soluble in ethylenediamine, but the complex formed has not been identified.

(*ii*) *N-Heterocyclic ligands*

(*a*) *Pyrrolidine, C_4H_9N, and β-pyridyl-α-N-methylpyrrolidine (nicotine), $C_{10}H_{14}N_2$.* The only recorded complexes appear to be $ThCl_4 \cdot C_{10}H_{14}N_2$ and $UCl_4 \cdot 3C_4H_9N$. The latter may be an example of seven-coordinate uranium(IV).

(*b*) *Pyridine, C_5H_5N, py, and derivatives.* Thorium(IV) complexes with pyridines (Table 10) are commonly of the form ThX_4L_4, where X = Cl, Br or NCS and L is pyridine or a variety of substituted pyridines. They are precipitated when a solution of the parent compound in, for example, absolute ethanol, is treated with an excess of the ligand, and are non-electrolytes in nitrobenzene.[34] The thorium atom is evidently eight-coordinate, and the same applies to $ThI_4 \cdot 6L$, which behaves as $[ThI_2(L)_6]I_2$ in nitrobenzene, and complexes of the perchlorate, $[ThL_8](ClO_4)_4$, formed with pyridine and less sterically demanding substituted pyridines; with 2,4- and 2,6-dimethylpyridine, $[ThL_6](ClO_4)_4$ are obtained. The coordination numbers of the metal sites in the bis complexes $Th(NO_3)_4 \cdot 2L$ (L = py or a substituted pyridine) and $Th(Cl_3CCO_2)_4 \cdot 2py$ are uncertain. Thorium(IV) and uranium(IV) complexes of composition $[M(py)_8]_3[Cr(NCS)_6]_4$ have also been recorded, and bis pyridine complexes $UX_4 \cdot 2py$ (X = Cl, Br), which presumably involve six-coordinate uranium(IV), have been reported.

(*c*) *Piperidine, $C_5H_{11}N$.* The piperidine complexes $ThCl_4 \cdot 4C_5H_{11}N$ and $UX_4 \cdot 4C_5H_{11}N$ (X = Cl, Br) are probably examples of the eight-coordinate metals. The nature of the hydrated compound, $Th(NO_3)_4 \cdot C_5H_{11}N \cdot 6H_2O$, is uncertain.

Table 10 Some Complexes of N-Heterocyclic Ligands with Actinide(IV) Compounds

Pyridine, C_5H_5N (py) and substituted pyridines	
$ThCl_4 \cdot 2L$	L = 2-Me- or 2-H_2N-C_5H_4N
$UX_4 \cdot 2py$	X = Cl, Br
$ThX_4 \cdot 4L$	X = Cl, Br, NCS; L = py, 2-Me-, 2,4-Me_2- and 2,6-Me_2-pyridine
$UCl_4 \cdot 4L$	L = (2-H_2N, 3-HO)C_5H_3N
$ThI_4 \cdot 6L$	L = py, 2-Me-, 2,4-Me_2- and 2,6-Me_2-pyridine
$Th(NO_3)_4 \cdot 2L$	L = py, 2-Me-, 2-H_2N-, 2,4-Me_2- and 2,6-Me_2-pyridine
$Th(ClCCO_2)_4 \cdot 2py$	
$[ThL_6](ClO_4)_4$	L = 2-H_2N-, 2,4-Me_2- and 2,6-Me_2-pyridine
$[ThL_8](ClO_4)_4$	L = py, 2-Me-C_5H_4N
$[M(py)_8]_3[Cr(NCS)_6]_4$	M = Th, U
$UCl_2(C_7H_5O_2)_2 \cdot 2py$	$C_7H_6O_2$ = 2-hydroxybenzaldehyde
Quinoline and isoquinoline, C_9H_7N	
$ThX_4 \cdot 4C_9H_7N$	X = Cl, Br, NCS
$Th(NCS)_4 \cdot 4$-iso-C_9H_7N	
$ThI_4 \cdot 6C_9H_7N$	
$Th(NO_3)_4 \cdot 2L$	L = C_9H_7N or *iso*-C_9H_7N
$[ThL_8](ClO_4)_4$	L = C_9H_7N or *iso*-C_9H_7N

(*d*) *Quinoline and isoquinoline, C_9H_7N.* The quinoline complexes $ThX_4 \cdot 4C_9H_7N$ (X = Cl, Br, NCS) (Table 10) are non-electrolytes in nitrobenzene, as is the isoquinoline complex $Th(NCS)_4 \cdot 4isoC_9H_7N$, whereas the complex $ThI_4 \cdot 6C_9H_7N$ behaves as a 1:2 electrolyte, $[ThI_2(C_9H_7N)_6]I_2$. The complexes of the perchlorate with quinoline and isoquinoline behave as 1:4 electrolytes, $[ThL_8](ClO_4)_4$, and in all of these, the thorium(IV) ion is evidently eight-coordinate. The complexes of both ligands with thorium tetranitrate, $Th(NO_3)_4 \cdot 2L$, are non-electrolytes in nitrobenzene and may be examples of 10-coordinate thorium(IV). The only recorded uranium(IV) complex with quinoline, $UCl_4 \cdot C_9H_7N$, is doubtful.

(*e*) *2,2′-Bipyridyl, bipy.* The complexes $ThX_4 \cdot 2bipy$ (Table 11) (X = Cl, Br,[34] NCS[35]) and $Th(NO_3)_4 \cdot bipy$[35] are non-electrolytes in nitrobenzene, whereas $ThI_4 \cdot 3bipy$ behaves as a 1:2 electrolyte,[34] $[ThI_2(bipy)_3]I_2$, and $Th(ClO_4)_4 \cdot 4bipy$ as a 1:4 electrolyte.[35] The metal ion is evidently eight-coordinate in these compounds, and in the uranium(IV) complexes, $UX_4 \cdot 2bipy$ (X = Cl, Br), except for the nitrate in which it is presumably 10-coordinate.

The tetraethylammonium salt of the rather unusual complex anion $[U(NCS)_5(bipy)_2]^-$ is obtained by reaction of $(NEt_4)_4[U(NCS)_8]$ with bipy in MeCN. In the structure of this anion the uranium atom is bonded to nine nitrogen atoms in a highly distorted monocapped square antiprismatic arrangement in which one bipy molecule occupies a position bridging the cap and the near square of the antiprism, while the other bipy molecule spans the opposite edge of the far square of the antiprism (Figure 1). The structure could also be described in terms of a seven-coordinate pentagonal bipyramidal arrangement in which each bipy molecule occupies an axial position.[36a]

The nature of the other recorded bipy complexes, and of those with 4,4′-dimethyl-2,2′-bipyridyl, $ThX_4 \cdot 1.5C_{12}H_{12}N_2$ (X = Cl or NO_3) is unknown.

Table 11 2,2′-Bipyridyl (bipy) Complexes with Actinide(IV) Compounds

$M^{IV}X_4 \cdot 2bipy$	M^{IV} = Th, X = Cl[a], Br[a], NCS[b] and M^{IV} = U, X = Cl, Br
$ThI_4 \cdot 3bipy$[a]	
$Th(NO_3)_4 \cdot bipy$[b]	
$Th(ClO_4)_4 \cdot 4bipy$[b]	
$ThCr_2O_7 \cdot 0.5bipy$

[c] R. O. Wiley, R. B. von Dreele and T. M. Brown, *Inorg. Chem.*, 1980, **19**, 3351.

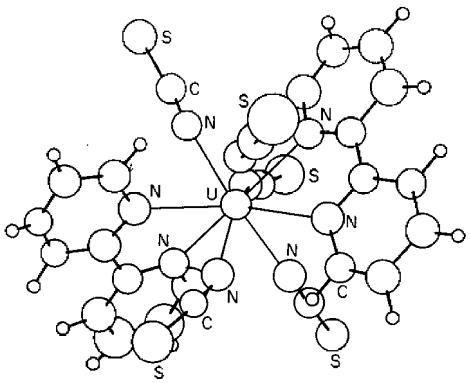

Figure 1 Perspective view of the structure of the $[U(NCS)_5(bipy)_2]^-$ anion[36a] (reproduced with permission from *Inorg. Chem.*, 1980, **19**, 3353, Copyright 1980, American Chemical Society)

(*f*) *Terpyridyl,* $C_{15}H_{11}N_3$. The only recorded complexes are $ThCl_4 \cdot 2C_{15}H_{11}N_3 \cdot 8H_2O$ and $Th(NO_3)_4 \cdot 1.5C_{15}H_{11}N_3$.

(*g*) *Imidazole,* $C_3H_4N_2$. Complexes ThX_4L_2, some solvated (*e.g.* X = Cl), have been recorded for L = imidazole or substituted imidazole. Conductivity data for the 2-(2′-pyridyl)benzimidazole ($C_{12}H_9N_3$) complexes $ThX_4(C_{12}H_9N_3)_2$ indicate that the chloride complex is a non-electrolyte in MeOH, $MeNO_2$ or DMF, whereas the thiocyanate and nitrate are appreciably dissociated in solution. The molar conductivity of $Th(ClO_4)_4 \cdot 4C_{12}H_9N_3$ is lower than that expected for a 1:4 electrolyte.

(*h*) *Dipyridylethanes and dipyridylamine.* Hydrated complexes with 1-(3-pyridyl)-2-(4-pyridyl)- and 1,2-di(4-pyridyl)-ethane, $Th(NO_3)_4 \cdot L \cdot H_2O$, and di(2-pyridyl)amine, $ThCl_4 \cdot 2L \cdot 2H_2O$ and $Th(NO_3)_4 \cdot 2L$, have been reported. Very little is known about them.

(*i*) 1,10-*Phenanthroline, phen.* $[Th(NCS)_4(phen)_2]$ (Table 12) is a non-electrolyte in nitrobenzene, whereas $ThI_4 \cdot 3phen$ behaves as a 1:2 electrolyte, $[ThI_2(phen)_3]I_2$. The perchlorate behaves as a 1:4 electrolyte in methyl cyanide, $[Th(phen)_4](ClO_4)_4$, so that the thorium ion is evidently eight-coordinate in these complexes. $Th(NO_3)_4 \cdot 2phen$, and the 1:1 complexes with the β-diketonates, presumably involve 12- or 10-coordinate thorium(IV). A few complexes with 2,9-dimethyl-1,10-phenanthroline, ThX_4L_2 (X = Cl or NO_3), are also known.

(*j*) *Pyrazine,* $C_4H_4N_2$. The hydrated bis pyrazine complex, $Th(NO_3)_4 \cdot 2C_4H_4N_2 \cdot 6H_2O$, and the anhydrous tris complex, $Th(NO_3)_4 \cdot 3C_4H_4N_2$, have been recorded. The IR spectrum of the latter suggests that the pyrazine is acting as a monodentate ligand and that the nitrate groups are bidentate, indicating 11-coordination. However, the tris complex behaves as a 1:4 electrolyte in DMF and as a 1:2 electrolyte in methyl cyanide or nitromethane. Complexes of UCl_4 with pyrazine or pyrazine-2-carboxamide, $UCl_4 \cdot 2.5L$, and with pyrazine-2,3-dicarboxamide, $UCl_4 \cdot 2L$, have also been reported.[36b]

Table 12 1,10-Phenanthroline (phen) Complexes with Actinide(IV) Compounds

$Th(NCS)_4(C_4H_{12}N_4)_6$·$4H_2O$	

(*iii*) *Dialkyl- and diaryl-amides*

Compounds of the type $M(NR_2)_4$ (M = Th or U) are obtained by reaction of the metal tetrachloride with $LiNR_2$ in non-aqueous solvents. They are all highly reactive towards protonated species and they readily undergo CO_2, COS, CS_2 or CSe_2 insertion into the M—N bond to form carbamates.

When the group R is very bulky, as in $U(NPh_2)_4$,[37] $HU\{N(SiMe_3)_2\}_3$[38] and $ClTh\{N(SiMe_3)_2\}_3$,[39] the compounds are monomeric. The coordination arrangement in the diphenylamide is highly distorted from tetrahedral or other regular geometry,[37] whereas in $U(NEt_2)_4$ the compound is a dimer in the solid state and the geometry about each uranium atom is a distorted trigonal bipyramid.[40]

A partially hydrolyzed derivative of the diphenylamide, $[UO(Ph_2N)_3Li(OEt_2)]_2$, has been isolated as a by-product in the preparation of $U(NPh_2)_4$ and in this compound each five-coordinate uranium atom is bonded to two bridging oxygen atoms and three terminal nitrogen atoms with approximately trigonal bipyramidal geometry; one nitrogen atom and one oxygen atom occupy the axial positions.[37] In the preparation of the uranium(IV) alkylamides derived from *N,N'*-dimethyldiaminoethane, the main product is the trimer, $U_3(MeNCH_2CH_2NMe)_6$; the tetramer, $U_4(MeNCH_2CH_2NMe)_8$, is obtained as a by-product. The central uranium atom in the trimer is octahedrally coordinated to six bridging nitrogen atoms, and the other two uranium atoms are coordinated to three bridging and three terminal nitrogen atoms in a distorted trigonal prismatic array,[41] whereas in the tetramer the bridging leads to a closed unit in which each uranium atom is bonded to six nitrogen atoms in a highly distorted trigonal prismatic geometry.[42]

(iv) Triazenes, thio- and seleno-cyanates

(a) Triazenes and related compounds. A complex of thorium tetranitrate with 2,4,6-tris(dimethylamino)triazene ($C_9H_{18}N_6$, hexamethylmelamine), $Th(NO_3)_4 \cdot C_9H_{18}N_6$, and the probably polymeric derivatives of purine and adenine, $Th(C_5H_3N_4)_2Cl_2$, have been recorded,[43] but little is known about them.

(b) Thiocyanates. Anhydrous $Th(NCS)_4$ has been reported, on the basis of thermogravimetric evidence, to be the product of the thermal decomposition of complexes of the type $Th(NCS)_4L_2$ (*e.g.* L = 2,6-lutidine *N*-oxide); it is said to decompose to $ThO(NCS)_2$ above 490 °C.[44] The hydrate, $[Th(NCS)_4(H_2O)_4]$, is better established; the uranium(IV) analogue is known only as the solvate of composition $[U(NCS)_4(H_2O)_4] \cdot (18\text{-crown-6})_{1.5} \cdot 3H_2O \cdot MeCOBu^i$, in which the structure of the $[U(NCS)_4(H_2O)_4]$ molecule is a distorted square antiprism in which the upper square comprises one $O(H_2O)$ and three N(NCS) atoms and the lower square three $O(H_2O)$ and one N(NCS) atoms.[45]

Anionic complexes of the type $M^I_4[M^{IV}(NCS)_8]$ are well known (Table 14). The tetraethylammonium salts of this anion have been reported for M^{IV} = Th, Pa, U, Np and Pu and all have the same crystal structure. The coordination geometry of the anion in $(Et_4N)_4[U(NCS)_8]$ is a cube, which requires *f*-orbital participation in the bonding, but the $[U(NCS)_8]^{4-}$ anion in the cesium salt is an almost perfect square antiprism. The IR spectra of the dihydrated rubidium and cesium salts of the $[M(NCS)_8]^{4-}$ ion (M = Th, U) suggest that the coordination geometry of the anion is dodecahedral in the solid salts, but square antiprismatic in acetone solution.[46] (Crystalline $Cs_4[Th(NCS)_8] \cdot 2H_2O$ is not isostructural with the uranium(IV) analogue.) The hydrated rubidium and cesium salts dehydrate at 60 to 100 °C. The other thiocyanato complexes listed in Table 14 require further investigation.

Table 14 Actinide(IV) Thiocyanates and Thiocyanato Complexes

$[Th(NCS)_4(H_2O)_4]$	
$[U(NCS)_4(H_2O)_4] \cdot (18\text{-crown-6})_{1.5} \cdot 3H_2O \cdot MeCOBu^i$	
$Rb[Th(NCS)_5(H_2O)_3]$	
$Na_2[Th(NCS)_5(OH)(H_2O)_x]$	$x = 2$ to 3
$(NH_4)_3Th(NCS)_7 \cdot 5H_2O$	
$K_4[U(NCS)_8] \cdot xH_2O$	$x = 0$ or 2
$(NH_4)_4[M(NCS)_8] \cdot xH_2O$	M = Th or U, $x = 0$ and M = Th, $x = 2$
$Rb_4[M(NCS)_8] \cdot xH_2O$	M = Th, $x = 0$, 2 or 3 and M = U, $x = 0$ or 1
$Cs_4[M(NCS)_8] \cdot xH_2O$	M = Th, $x = 0$ or 2 and M = U, $x = 0$, 1 or 2
	M = Pu, $x = 0$
$(NEt_4)_4[M(NCS)_8]$	M = Th, Pa, U, Np and Pu

(c) Selenocyanates. The salts $(Et_4N)_4[M(NCSe)_8]$ (M = Pa, U) are isostructural with the corresponding thiocyanates. Compounds of composition $M^I_2Th(NCSe)_6 \cdot xDMF$ (M^I = Na, $x = 3$ and K, $x = 4.5$) and $K_4Th(NCSe)_8 \cdot 2DMF$ have been recorded, but their nature is uncertain.

(v) Polypyrazol-1-ylborates

The known thorium(IV) and uranium(IV) complexes are listed in Table 15. The attempted preparation of $Th(H_2BPz_2)_4$ (Pz = $C_3H_3N_2$) yields the salt $KTh(H_2BPz_2)_5$. Although the ^1H NMR spectrum of this salt indicates dissociation to $Th(H_2BPz_2)_4$ and $K(H_2BPz_2)$ in $(CD_3)_2CO$, $Th(H_2BPz_2)_4$ could not be isolated.

Table 15 Actinide(IV) Polypyrazol-1-ylborates

$ThCl(HBPz_3)_3$	Pz = $C_3H_3N_2$
$M^{IV}X_2L_2$	M^{IV} = Th, L = $HBPz_3$ with X = Cl or Br; L = BPz_4 with X = Br
	M^{IV} = U, L = $HBPz_3$, $HB(3,5\text{-}Me_2Pz)_3$, Ph_2BPz_2 or BPz_4, with X = Cl
$U(H_2BPz_2)_4$	
$M^{IV}(HBPz_3)_4$	M^{IV} = Th, U
$U[H_2B(3,5\text{-}Me_2Pz)_2]_4$	
$KTh(H_2BPz_2)_5$	

The ^1H NMR spectra of the thorium(IV) complexes $ThX_2(HBPz_3)_2$ (X = Cl, Br) in CD_2Cl_2 or $(CD_3)_2CO$ (X = Cl) indicate that the $HBPz_3$ ligand is tridentate, in contrast to $UCl_2(HBPz_3)_2$ and $UCl_2(HB\{3,5\text{-}Me_2Pz\}_3)_2$, in which the ligand appears to be bidentate, a conclusion in agreement with the solid reflectance spectra of the two compounds which are consistent with six-coordinate uranium(IV). The ^1H NMR spectrum of $ThBr_2(BPz_4)_2$ in CD_2Cl_2 is more complicated and suggests that the proportion of $C_3H_3N_2$ rings that are bonded to thorium to those that are not bonded is 3:2, so that the complex may be of the form[47] $[(Pz_2BPz_2)_2Th(\mu\text{-}Pz_2BPz_2)Th(Pz_2BPz_2)_2]^{3+}$ $[Th(BPz_4)Br_6]^{3-}$. In contrast, the ^1H NMR spectrum of $UCl_2(BPz_4)_2$ is consistent with the presence of one bidentate and one tridentate BPz_4 ligand, suggesting seven-coordination. The ^{13}C NMR spectrum of $U(HBPz_3)_4$ indicates the presence of two bidentate and two tridentate $HPBz_3$ ligands, suggesting 10-coordination. Cyclopentadienylthorium(IV) and -uranium(IV) pyrazol-1-ylborates of the types $(\eta^5\text{-}C_5H_5)MCl_2(H_nBPz_{4-n})$ (M = Th, $n = 0$; M = U, $n = 1$ or 2) are also known.

(*vi*) *Nitriles*

The majority of the known complexes are with the tetrahalides (Table 16) and are obtained directly from the halide and the ligand. In most cases they have the composition $MX_4(RCN)_4$ and the UV–visible spectra of the uranium(IV) compounds are consistent with eight-coordination. However, with the more sterically demanding nitrile, Bu^tCN, tris complexes, $UX_4(Bu^tCN)_3$ (X = Cl, Br), are obtained in which the metal centre is presumably seven-coordinate. In the IR spectra of the nitrile complexes the ν(CN) feature is always shifted to higher frequency by 20 to 30 cm^{-1} on complexation, except for the UF_4 compounds for which the shifts are 44 to 54 cm^{-1}. The shifts in ν(CN) for the cyanogen chloride complexes, $MCl_4 \cdot x$NCCl (Table 16), are +23 to +24 cm^{-1}. $ThCl_4 \cdot 2$MeCN and $ThOCl_2 \cdot$MeCN have been obtained respectively by thermal decomposition and by controlled hydrolysis of $ThCl_4 \cdot 4$MeCN.

Table 16 Nitrile Complexes with Actinide(IV) Compounds

$UF_4 \cdot$MeCN$\cdot y$HF	$y = 0$ or 2
$ThCl_4 \cdot 2$MeCN	
$MCl_4 \cdot 4$MeCN	M = Th, Pa, U, Np
$MBr \cdot 4$MeCN	M = Th, Pa, U, Np, Pu
$MI_4 \cdot 4$MeCN	M = Th, Pa
$ThCl_4 \cdot 4$RCN	R = Ph, $PhCH_2$
$UX_4 \cdot 4$RCN	X = Cl, Br; R = Et, Pr^n, Pr^i, Bu^n, Ph
$UX_4 \cdot 3Bu^tCN$	X = Cl, Br
$ThOCl_2 \cdot$MeCN	
$MCl_4 \cdot x$NCCl	M = Th, U, Np; $x = 1$ or 2

(*vii*) *Oximes and related ligands*

Very few complexes with oximes have been recorded. A pyridine-2-aldoxime $\{(C_5H_4N)CH{=}NOH\}$ complex, possibly $Th(C_6H_5N_2O)_4$, is obtained as a green solid by evaporating an absolute ethanol solution containing $Th(NO_3)_4$ and the ligand. Isatin β-oxime ($C_6H_4C(=NOH)C(OH)=N$) and the isomeric α-oxime ($C_6H_4C(O)C(=NOH)NH$) yield yellow and red precipitates respectively with ammoniacal solutions of thorium(IV) salts, and phenyl pyruvic acid oxime ($PhCH_2C(=NOH)CO_2H$) precipitates thorium from aqueous solutions of the tetranitrate, but the composition of these products is unknown.

A large number of urea and substituted urea complexes with actinide(IV) compounds are known; in these the ligands are bonded to the metal *via* the carbonyl oxygen atom, and these complexes are therefore described in the section dealing with carboxylic acid amide complexes (p. 1164).

40.2.2.3 Phosphorus and arsenic ligands

Most of the early reports of phosphine or arsine complexes are erroneous, the products being phosphine oxide or arsine oxide compounds.

(*i*) *Phosphines*

A complex with trimethylphosphine, $UCl_4(PMe_3)_3$, has been reported, and complexes with $Me_2PCH_2CH_2PMe_2$(dmpe) are now well established. $ThI_4(dmpe)_2$ separates when a solution of ThI_4 in CH_2Cl_2 containing an excess of dmpe is cooled to −20 °C and $ThCl_4(dmpe)_2$ is obtained by heating $ThCl_4$ with dmpe at 80 °C.

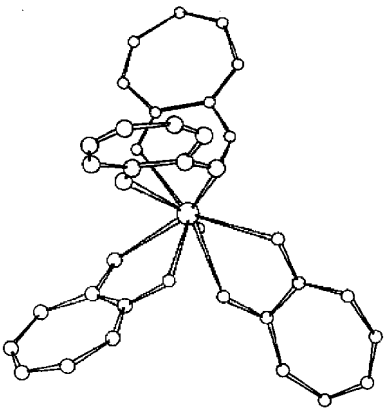
$ThCl_4(dmpe)_2$ reacts with MeLi at 0 °C to form $ThMe_4(dmpe)_2$, and this product reacts readily with hydrogen chloride or phenol in toluene to form $ThCl_4(dmpe)_2$ and $[Th(OPh)_4(dmpe)_2]\cdot C_7H_8$, which is isostructural with $[U(OPh)_4(dmpe)_2]$. This last is obtained either from $UMe_4(dmpe)_2$ and phenol or by direct reaction of UCl_4 with LiOPh in the presence of dmpe. The uranium(IV) complexes $UX_4(dmpe)_2$ (X = Br, Me) have also been reported.

In the structure of $[U(OPh)_4(dmpe)_2]$, four phosphorus and four oxygen atoms occupy the A and B sites respectively of a D_{2d} dodecahedron.[48] Although the attempted preparation of complexes of $Ph_2P(CH_2)_2PPh_2$(dppe) with $ThCl_4$ and $Th(NO_3)_4$ led to the diphosphine dioxide complexes, UCl_4(dppe) has been obtained as a precipitate from a THF solution of the chloride and dppe.

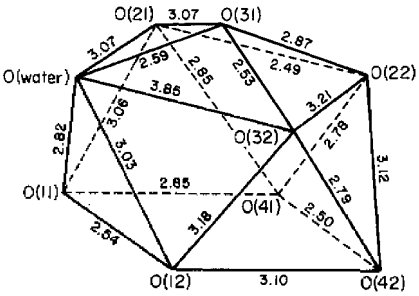
(*ii*) *Arsines*

The complex $PaCl_4$(diars) [diars = *o*-phenylenebis(dimethylarsine)] is reported to be formed by reaction of the ligand with $PaCl_5$ in benzene.[49] Treatment of $UCl_5\cdot C_3Cl_4O$ (C_3Cl_4O = trichloroacryloyl chloride) or UCl_4 with diars yields the analogous UCl_4(diars) as a yellow (? oxidized) or blue-green solid respectively.

40.2.2.4 Oxygen ligands



(*i*) *Aqua species, hydroxides and oxides*



(*a*) *Aqua species.* Some of the reported hydrates of actinide(IV) compounds are listed in Table 17. A very large number of other hydrates have been recorded, but in many cases it is uncertain whether any or all of the water molecules are coordinated to the actinide metal atom. In the absence of a structure determination, the only evidence for bonded water is a high dehydration temperature. For example, the octahydrated sulfates, $M(SO_4)_2\cdot 8H_2O$ (M = Th, U, Pu) lose four molecules of water at about 70 °C and the remaining water can be removed only at temperatures exceeding 400 °C, indicating that four molecules of water are bonded to the metal atom, a conclusion confirmed by the determination of the structure of $U(SO_4)_2(H_2O)_4$. The uranium atoms are surrounded by a square antiprism of oxygen atoms, with each uranium atom bonded to four molecules of water and linked by bridging sulfate groups to other uranium atoms.[53] The coordination geometry is similar to that of $[U(NCS)_4(H_2O)_4]$ (p. 1142). Higher coordination numbers have been reported for hydrates of compounds which involve more compact bidentate ligands. The nine-coordinate arrangement in $[Th(CF_3COCHCOMe)_4(H_2O)]$ consists of a capped square antiprism with the bidentate ligands spanning the edges linking the two square faces[54] and in the hydrated tropolonate, $[Th(trop)_4(H_2O)]$, one trop ligand occupies a slant position on the cap of the square antiprism and the water molecule occupies another vertex of the cap[55] (Fig. 2). The coordination geometry in the hydrated γ-isopropyltropolonate, $[ThL_4(H_2O)]$, is also a singly capped square antiprism.[56a] The same geometry has been reported for the diaqua (oxodiacetato) sulfato thorium(IV) complex, $[Th\{O(CH_2CO_2)_2\}(SO_4)(H_2O)_2]\cdot H_2O$. In the polymeric network, each oxodiacetate group is chelated to one thorium atom *via* the ether oxygen atom and two carboxylate oxygen atoms, and also links two different thorium atoms through the two remaining carboxylate oxygen atoms. The sulfate groups are also bridging and the polyhedron is completed by the two bonded water molecules.[56b]

In the hydrated hydroxyacetate, $[U(HOCH_2CO_2)_4(H_2O)_2]$, the uranium atom is 10-coordinate in a bicapped square antiprismatic arrangement in which the eight carboxylate oxygen atoms occupy the corners of the square antiprism and the oxygen atoms from the two water molecules occupy the cap positions (Figure 3).[57] Bicapped square antiprismatic geometry has also been reported[58a] for the hydrated pyridine-2,6-dicarboxylate, $[Th\{C_5H_3N\text{-}2,6\text{-}(CO_2)_2\}_2(H_2O)_4]$, as has that of the oxodiacetate, $[Th\{O(CH_2CO_2)_2\}_2(H_2O)_4]\cdot 6H_2O$.[58b]

Figure 2 Perspective view of the $[Th(trop)_4(H_2O)]$ (trop = tropolonate) molecule and of the coordination polyhedron[55]

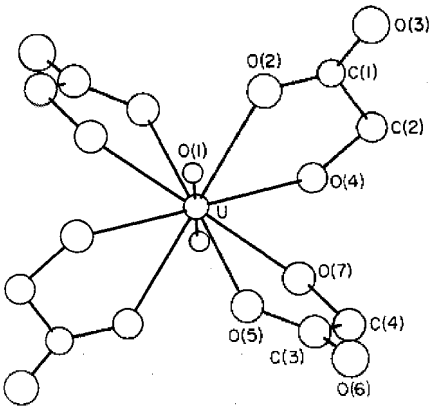

Figure 3 The structure of the uranium(IV) glycolate dihydrate molecule, $[U(HOCH_2CO_2)_4(H_2O)_2]$[57]

The coordination geometry about the 11-coordinate thorium atom in $Th(NO_3)_4 \cdot 5H_2O([Th(NO_3)_4(H_2O)_3] \cdot 2H_2O)$ is basically a monocapped trigonal prism in which four of the prism apices are occupied by bidentate nitrate groups.[59] In the dimeric basic nitrate, $[Th_2(OH)_2(NO_3)_6(H_2O)_6] \cdot 2H_2O$, the thorium atoms are bridged by two OH groups, and each thorium atom is also coordinated to three bidentate nitrate groups and three molecules of water. The geometry can be considered as a rather distorted dodecahedron in which the nitrate groups occupy three apices.[60]

(*b*) *Hydroxides.* The structures of the known hydroxides have not been recorded; a few structures have been reported for basic compounds. The structure of $Th(OH)_2CrO_4 \cdot H_2O$ is built up of infinite chains, $[Th(OH)_2]_n^{2n+}$, containing two almost parallel rows of OH groups so that each thorium atom is in contact with four OH groups; the CrO_4 groups are so packed that each thorium atom is in contact with four oxygen atoms of four different CrO_4 groups, making up a square antiprismatic arrangement of oxygen atoms about each thorium atom.[61] The structure of $Th(OH)_2SO_4$ is the same.[62]

(*c*) *Oxides.* All the dioxides have the cubic fluorite lattice, with the eight-coordinated metal ion at the centre of a cube of oxygen atoms. A considerable number of ternary oxides, such as K_2ThO_3, $BaM^{IV}O_3$ (M^{IV} = Th, Pa, U, Np or Pu), Li_8PuO_6 and BaCe(or Ti)PuO_6, are also known.

(*ii*) *Peroxides*

Because of the ease of oxidation of protactinium(IV) and uranium(IV), peroxides and peroxo complexes are limited to their higher oxidation states. The compounds $MO_4 \cdot xH_2O$ precipitated from dilute acid solutions of neptunium(IV) and plutonium(IV) by hydrogen peroxide appear to be actinide(IV) compounds. Soluble intermediates of the type $[Pu(\mu\text{-}O_2)_2Pu]^{4+}$ are formed at low hydrogen peroxide concentrations.

The hydrated thorium peroxide sulfate, $Th(O_2)SO_4 \cdot 3H_2O$, is very stable to heat, and thorium(IV) peroxo compounds of variable composition, approximating to $Th(O_2)_{1.6}(A^-)_{0.5}O_{0.15}^{2-} \cdot 2.5H_2O$, with A = Cl or NO_3, are obtained from aqueous solutions of hydrogen peroxide and the appropriate thorium compound, and in the case of the nitrate the analytical results of one such product are compatible with a hexameric formulation,[63] $Th_6(O_2)_{10}(NO_3)_4 \cdot 10H_2O$. Peroxocarboxylato and phenoxo compounds are also known;[64] examples are $Th(RCO_2)_2(O_2)$ (R = C_5H_4N-2- and 2-$H_2NC_6H_4$), $Th(2\text{-}H_2NC_6H_4O)_2)_2(O_2)$ and $Th(2,6\text{-}(O_2C)_2C_5H_3N)(O_2) \cdot H_2O$.

(*iii*) *Alcohols, phenols, alkoxides, aryloxides and silyloxides*

(*a*) *Alcohols and phenols.* Alcohol solvates of thorium and uranium tetrachlorides, $MCl_4 \cdot 4ROH$ (Table 18), are obtained by evaporating solutions of the tetrachloride in the alcohol (M = Th, U) or by treating the hydrated chloride with a mixture of the alcohol and benzene, removing the liberated water by azeotropic distillation (M = Th). $ThCl_4 \cdot 4Bu^nOH$ and $ThCl_4 \cdot 4Bu^iOH$ are, however, best prepared by heating $ThCl_4 \cdot 4Pr^iOH$ with a mixture of benzene and the butanol, removing the liberated Pr^iOH as the benzene azeotrope. The attempted preparation of the butanol (R = Bu^n, Bu^{sec} or Bu^t) adducts of UCl_4 led to solvolysis.

Table 18 Alcohol and Phenol Adducts of Actinide(IV) Compounds

$MCl_4 \cdot 4ROH$	M = Th, R = Me, Et, Pr^n, Pr^i, Bu^n, Bu^i M = U, R = Me, Et, Pr^n, Pr^i
$ThCl_4 \cdot C_7H_7OH$	C_7H_7OH = *o*- or *m*-cresol
$Th(C_9H_6NO)_4 \cdot EtOH$	
$Th(C_9H_6NO)_4 \cdot 2ROH$	R = 2,4-$(O_2N)_2C_6H_3$, 2,4,6-$(O_2N)_3C_6H_2$
$Th(C_9H_6NO)(OMe)(Cl_3CCO_2)_2 \cdot MeOH$	
$U(CF_3COCHCOPh)_4 \cdot Bu^nOH$	
$Np(OEt)_4 \cdot EtOH$[a]	
$Pu(OPr^i)_4 \cdot Pr^iOH$	

[a] A. K. Solanki and A. M. Bhandari, *Radiochem. Radioanal. Lett.*, 1980, **43**, 279.

The bis 2,4-dinitro- and 2,4,6-trinitro-phenol adducts of the 8-hydroxyquinolinate, $Th(C_9H_6NO)_4 \cdot 2ROH$, are obtained when $Th(C_9H_6NO)_4 \cdot C_9H_7NO$ is heated with the phenol. The frequencies of the asymmetric and symmetric $\nu(NO)$ features due to the nitrophenols are almost identical in their IR spectra to those of the free phenols, which may therefore be hydrogen bonded to oxygen atoms of the C_9H_6NO groups.

(*b*) *Alkoxides.* The tetraalkoxides, $M(OR)_4$, are best prepared by reaction of the tetrachlorides or their alcohol solvates with the sodium or lithium alkoxide in the corresponding alcohol [$Th(OPr^i)_4$, $M(OR)_4$ with M = U or Np, R = Me or Et] or in dimethyl cellosolve [$U(OR)_4$; R = Pr^n or Pr^i]. $PuCl_4$ does not exist, but $Pu(OPr^i)_4$ has been obtained by treating a suspension of $(pyH)_2[PuCl_6]$ in benzene and Pr^iOH with ammonia; $Th(OPr^i)_4$ has been prepared from $(pyH)_2[ThCl_6]$ in the same way. An alternative, but expensive, preparative route is by reaction of the dialkylamide [*e.g.* $U(NR_2)_4$] with the alcohol in ether. The uranium *t*-butoxide seems only to have been obtained by reaction of UCl_4 and Bu^tOH with a solution of KNH_2 in anhydrous liquid ammonia and by dropwise addition of Bu^tOH in ether to a solution of the allyl, $U(\eta\text{-}C_3H_5)_4$, in the same solvent at −30 °C. Because of the relative ease of preparation of the isopropoxides, $M(OPr^i)_4$ (M = Th, Pu), other alkoxides are commonly prepared from them by reaction with an excess of the appropriate alcohol in boiling benzene. The only recorded fluoroalkoxides are the THF solvates, $U\{OC(CF_3)_3\}_4 \cdot 2THF$ and $U\{(OCH(CF_3)_2\}_4 \cdot 2THF$ (Table 19).

Table 19 Actinide(IV) Alkoxides

$Li_2U(OMe)_6$	
$Np_2O(OEt)_6$[a]	

[a] A. K. Solanki and A. M. Bhandari, *Radiochem. Radioanal. Lett.*, 1980, **43**, 279.

All the known tetraalkoxides are very easily hydrolyzed by water vapour and the uranium(IV) compounds oxidize rapidly in air, so their preparation must be carried out under nitrogen. Molecular weight determinations (M = Th, U) indicate a considerable degree of polymerization, approximately tetrameric in the case of $Th(OR)_4$ with R = Pr^i or MeEtCH, but the molecular complexity decreases to about 3.4 for R = Bu^t, and with R = CEt_3 and $CMeEtPr^i$ the alkoxides are monomers in boiling benzene.[65a] The plutonium compound $Pu(OCMeEt_2)_4$ is volatile at 150 °C/0.05 torr, suggesting a low molecular complexity.

The oxoalkoxides $U_3O(OBu)_{10}$[65b] and $U_3O(OCMe_3)_{10}$[65c] are structurally similar to the molybdenum analogue, $Mo_3O(OCH_2CMe_3)_{10}$, but the U—U bond distances, 3.576(1) Å and 3.574(1) Å, show that metal–metal bonding does not occur.

Anionic alkoxide complexes of the type $M^ITh_2(OPr^i)_9$ (M^I = Li, Na) have been mentioned in a review[66] and $Li_2U(OMe)_6$ precipitates when UCl_4 is added to the stoichiometric quantity of LiOMe in MeOH. Compounds of the type $U[Al(OPr^i)_4]_4$ and $U[Al(OPr^i)_4]_2Cl_2$ are also known. The dialkoxide dichlorides, $U(OR)_2Cl_2$ (R = Me, Bu^n), are obtained by reaction of UCl_4 with the stoichiometric quantity of the sodium alkoxide in ether (R = Me) or THF (R = Bu^n).

(*c*) *Aryloxides.* A few thorium(IV) aryloxides have been recorded (Table 20); the 4,6-dinitro-2-aminophenol derivative, $Th[OC_6H_2(NO_2)_2(NH_2)]_4 \cdot 2H_2O$, is precipitated when aqueous sodium picramate is added to an aqueous solution of thorium tetranitrate. Its IR spectrum suggests that the amino nitrogen atom may be bonded to the thorium atom.[67] Unsolvated uranium(IV) tetraaryloxides are not known; for solvates with ammonia, amines and phenols see Tables 6 (p. 1137), 7 (p. 1138) and 18 (p. 1146) respectively. However, $U(OPh)_2Cl_2$ is obtained in the same way as $U(OMe)_2Cl_2$ (see above).

(*d*) *Silyloxides.* The only actinide(IV) compound of this type appears to be $U(OSiMeEt_2)_2Cl_2$, which is precipitated when UCl_4 is treated with $Li(OSiMeEt_2)$ in a mixture of benzene and dimethyl cellosolve. It oxidizes readily in air.[68]

Table 20 Actinide(IV) Aryloxides

$Th(OR)_4 \cdot 2H_2O$	4,6-Dinitro-2-aminophenoxide, R = $\{4,6\text{-}(NO_2)_2\}(2\text{-}H_2N)C_6H_2$
$MCl_2(OR)_2$	M = Th, R = Ph, *o*- or *p*-$NO_2C_6H_4$, *α*- or *β*-$C_{10}H_7$
	M = U, R = Ph
$MCl_3(OR)$	M = Th, R = *o*- or *m*-MeC_6H_4, *α*- or *β*-$C_{10}H_7$

(*vi*) *β-Ketoenolates, Tropolonates, Catecholates, Quinones, Ethers, Ketones and Esters*

(*a*) *β-Ketoenolates.* The wide range of known β-diketone, ketoaldehyde and ketoester complexes is summarized in Table 21. They are commonly prepared by treating a dichloromethane, ethanol, aqueous or aqueous methanol solution of the actinide(IV) with the ligand (or its sodium or thallium salt) followed, when necessary, by addition of ammonia or aqueous alkali to precipitate the complexes ML_4. Alternative methods include reaction of the metal tetrachloride with the ligand in the presence of sodium (*i.e.* reaction with NaL) or reaction of a carboxylate [*e.g.* $U(EtCO_2)_4$] with the ligand in dibutyl ether or benzene. Solvent extraction is also a useful preparative method; examples are the extraction of $Np(MeCOCHCOMe)_4$ into benzene by shaking an aqueous solution of neptunium(IV), saturated with the ligand, with benzene at pH 4.5 to 5.0, and extraction of $Pu(MeCOCHCOPh)_4$ from an aqueous plutonium(IV) solution (at pH 8) into a chloroform solution of the ligand. The product is recovered from the extract by evaporation to dryness. The complexes are normally purified by recrystallization from benzene, mixtures of hydrocarbons or methanol and many of them can be sublimed under vacuum.

Analogous salicylaldehyde complexes, $M(OC_6H_4CHO)_4$ (M = Th, U) and $Th(OC_6H_4CHO)_3(NO_3)\cdot H_2O$, are also known.

A complex of composition $Pu(MeCOCHCOMe)_3Cl$ has been mentioned in the patent literature.[69] The reaction of $Th(MeCOCHCOMe)_4$ in benzene with carboxylic acids, RCO_2H (R = CF_3, CCl_3, $CHCl_2$, 2-C_5H_4N) leads to partial displacement of the β-diketone, yielding products of the type $Th(MeCOCHCOMe)_3(RCO_2)\cdot xH_2O$ ($x = 4$ for R = CF_3, CCl_3 and $CHCl_2$ and $x = 1$ for R = 2-C_5H_4N). The products of further displacement of the β-diketone appear to contain acetate (*e.g.* $Th(MeCOCHCOMe)(MeCO_2)_2(C_5H_4NCO_2)\cdot 2H_2O$) which presumably results from the decomposition of the acetylacetonate group.

The attempted preparation of lithium or thallium salts of the complex anion $[U(MeCOCHCOMe)_5]^-$ have been unsuccessful.

Structural information is available for several β-diketonates. $Th(MeCOCHCOMe)_4$ exists in two crystal forms, the coordination geometry in the *α* form being principally dodecahedral, with significant distortion to square antiprismatic geometry, while in the *β* form the geometry is principally square antiprismatic. It has also been suggested that the *α* form approximates most closely to a C_{2v} bicapped trigonal prism.[70] In the benzene solvate, $[Th(MeCOCHCOMe)_4]\cdot 0.5C_6H_6$, the geometry is square antiprismatic.[71] Uranium(IV) acetylacetonate also exists in the *α* and *β* forms, isostructural with the thorium analogues, but the protactinium(IV), neptunium(IV) and plutonium(IV) complexes have only been reported as the *β* form. The *α* and *β* forms of $Th(Bu^tCOCHCOBu^t)_4$ are isomorphous with the uranium(IV) analogues.[72]

$Th(PhCOCHCOPh)_4$ has been reported as being isomorphous with the corresponding protactinium(IV), uranium(IV) and cerium(IV) complexes; the coordination geometry in the last is a triangular faced dodecahedron, but a more recent publication[73] reports the coordination geometry of the uranium(IV) compound as square antiprismatic.

The coordination geometry in anhydrous $Th(CF_3COCHCOMe)_4$ is a 1111 (D_4-422) antiprism;[74] the structure of the monohydrate has been discussed earlier (p. 1144). $Th[CF_3COCHCO(2\text{-}C_4H_3S)]_4$ is isostructural with the cerium(IV), uranium(IV) and plutonium(IV) analogues. The coordination polyhedron is a distorted dodecahedron in which the four ligands span the two perpendicular trapezoids of the dodecahedron.[75] In the complexes $M(n\text{-}C_3F_7COCHCOBu^t)_4$, the thorium(IV), uranium(IV) and neptunium(IV) compounds are isomorphous, but the plutonium compound is not.

The coordination geometry about the thorium atom in the salicylaldehyde complex, $Th(OC_6H_4CHO)_4$, is dodecahedral;[76] the compound is isostructural with $U(OC_6H_4CHO)_4$.

(*b*) *Tropolonates.* The compounds $M(trop)_4$ (trop = $C_7H_5O_2$), have been reported for M = Th, Pa, U, Np and Pu. The thorium complex is precipitated when a slight excess of

tropolone in methanol is added to a solution of $Th(NO_3)_4 \cdot 4H_2O$ in 33% aqueous methanol, and by the reaction of $ThCl_4$ with an excess of tropolone in oxygen free dichloromethane. The hydrate, $[Th(trop)_4(H_2O)]$, is obtained from preparations in water or ethanol, and also by recrystallizing $Th(trop)_4$ from a mixture of ethanol, methyl cyanide and water. Its structure is described on p. 1144. $Pa(trop)_4$ is rather easily oxidized, but is obtained by reaction of $PaCl_4$ or $PaBr_4$ with Li(trop) in oxygen-free dichloromethane. The uranium(IV) compound precipitates when a slurry of $U(MeCO_2)_4$ in tropolone and methyl cyanide is heated under reflux. It is also obtained by reaction of UCl_4 with an excess of tropolone in dichloromethane, ethanol or water; $Np(trop)_4$ is prepared in the same way from ethanol solution. $Pu(trop)_4$ precipitates on mixing methanol solutions of tropolone and $Pu(NO_3)_4$; it can be recrystallized from DMF. $U(trop)_4$ is isomorphous with the cerium(IV), neptunium(IV) and plutonium(IV) analogues, but not with $Th(trop)_4$.

The complexes ML_4 (M = Th, U) with HL = α-, β- or γ-isopropyl tropolone are also known. Molecular weight determinations (benzene solution) for the thorium compounds indicate that the α compound is close to a dimer, whereas the β and γ derivatives are approximately trimeric. The corresponding uranium(IV) complexes are all monomers. All three thorium compounds readily form monohydrates and the structure of the hydrated γ-isopropyltropolonate is described on p. 1144.

Uranium(IV) complexes, UL_4, are known also for kojic acid and chlorokojic acid, both of which behave as the enolic forms of α-diketones.

Anionic pentakis tropolonato complexes, $M^I[M^{IV}(trop)_5]$, are known for M^{IV} = Th (M^I = Li, Na or K), M^{IV} = Pa or U (M^I = Li). The thorium compounds are prepared by heating $Th(trop)_4$ with H trop and M^IOH in a mixture (1:1:2 by volume) of ethanol, water and methyl cyanide. $Li[Pa(trop)_5]$ has been obtained from $Pa(trop)_4$ in the presence of Li(trop) in DMF, and $Li[U(trop)_5]$ has been prepared by both of the above methods. Sodium salts, $Na[ThL_5]$, are also known for HL = α- and γ-isopropyltropolone.

(*c*) *Catecholates.* Complexes formed by catechol and the related compounds resorcinol, phloroglucinol, orcinol and pyrogallol are listed in Table 22. Thorium dichloride catecholate, and the corresponding resorcinolate, phloroglucinolate and orcinolate have been obtained by evaporating an ethereal solution of the components to dryness and heating the residue until the evolution of hydrogen chloride ceased;[77] when thorium tetrachloride is added to an excess of molten catechol, the product is $H_2[Th(C_6H_4O_2)_3]$.[78] The anionic catecholato complex salts, $Na_4[M(C_6H_4O_2)_4]\cdot 21H_2O$ (M = Th, U), separate when a solution of catechol in aqueous sodium hydroxide is added to aqueous solutions of the tetrachlorides. The geometry of the anion is a trigonal faced dodecahedron and the oxygen atoms of the water molecules form a hydrogen-bonded network throughout the crystal.[79] The other compounds noted in Table 22 were also obtained from aqueous media. In addition to the listed compounds, thorium(IV) bis derivatives of 2,2′-dihydroxybiphenyl or -dinaphthyl and 1,8-dihydroxynaphthalene, ThL_2, are precipitated from methanolic solutions of the tetrachloride and the diol in the presence of di- or tri-ethylamine as a hydrogen chloride acceptor.[78]

$M^I_2[Th(C_6H_3O_3)_2]\cdot 7H_2O$	M^I = Na, K

(*d*) *Quinones.* A few thorium(IV) complexes with hydroxyquinones have been recorded. The complex with 2,5-dihydroxybenzo-1,4-quinone ($C_6H_4O_4$), $Th(C_6H_2O_4)_2$, precipitates when an excess of aqueous $Th(NO_3)_3$ is added to an aqueous solution of the ammonium salt of the quinone at pH 3, 7 or 11. The corresponding 3,6-dichloroquinone ($C_6H_2Cl_2O_4$) and 3,6-diphenylquinone ($C_{18}H_{12}O_4$, polyporic acid) derivatives, $Th(C_6Cl_2O_4)_2$, $Th(C_6Cl_2O_4)F_2$ and $Th(C_{18}H_{10}O_4)_2$ (?), have also been reported. With 2,3,5,6-tetrahydroxybenzo-1,4-quinone ($C_6H_4O_6$) products formulated as $[Th_2(C_6H_2O_6)](NO_3)_6$ and $[Th_4(C_6O_6)](NO_3)_{12}$ separate when a mixture of $Th(NO_3)_4$ and the ligand is heated.[80a] A complex with 2-hydroxynaphtho-1,4-quinone ($C_{10}H_6O_3$), presumably $Th(C_{10}H_5O_3)_4$, precipitates from aqueous solutions of thorium(IV) on addition of the quinone and, as precipitation is quantitative, this has some value for the gravimetric determination of thorium in a procedure in which the precipitate is ignited and weighed as ThO_2. All of these compounds require further investigation.

(*e*) *Ethers.* In addition to the ether complexes with thorium(IV) and uranium(IV) compounds listed in Table 23, a considerable number of THF solvates of Schiff base complexes with these elements are known [see ref. 12, Thorium (vol. E) and Uranium (vol. E1)]. Diethyl ether solvates of imidazole and related complexes of the type $ThCl_4\cdot 2L\cdot n Et_2O$, where L = imidazole, 1-benzylimidazole and 4,5-diphenylimidazole, with n = 14, 8 and 6 respectively, have been recorded but it is uncertain whether any of the ether molecules are coordinated to the metal atom. Otherwise, the only simple ether complexes which have been reported are those of dimethyl and diethyl ether with the tetrahalides, and the dimethoxyethane, THF and

dioxane complexes. These compounds are usually obtained by treating the parent compounds with the appropriate ether. For example, $UBr_4 \cdot 2THF$ is prepared by adding a 10% solution of THF in carbon disulfide to a solution of uranium tetrabromide in the same solvent. In some cases the ether complexes result from the method of preparation of the parent compound. Thus treatment of a solution of uranium tetrachloride in THF with the stoichiometric quantity of thallium acetylacetonate, followed by addition of *n*-hexane to the supernatant, yields a precipitate of $UCl_2(acac)_2 \cdot 2THF$. In the dimethoxyethane (DME) complex, $[\{(Me_3Si)_2N\}_2UCl_2(DME)]$, obtained by reaction of UCl_4 with $NaN(SiMe_3)_2$ in DME, the uranium atom is coordinated to two nitrogen, two chlorine and two oxygen (from DME) atoms.[80b]

[a] R. A. Andersen, *Inorg. Nucl. Chem. Lett.*, 1979, **15**, 57.

(*f*) *Ketones and aldehydes.* The only complexes with ketones and aldehydes appear to be those with thorium and uranium tetrahalides. The complexes $MCl_4 \cdot x$MeCOMe (M = Th, x = 2 and M = U, x = 3), $ThCl_4 \cdot 4$RCOPh (R = Me or Ph), $2ThBr_4 \cdot 3$MeCOPh, $ThCl_4 \cdot 2$RCHO (R = Me, $C_6H_4(OH)$(salicyl) or PhCH=CH) and $ThBr_4 \cdot 4$PhCHO are obtained from the components. The acetone solvated lactam complex, $ThCl_4 \cdot 4C_7H_{13}NO \cdot$MeCOMe ($C_7H_{13}NO$ = 1-azacyclooctan-2-one), is precipitated when ethyl acetate is added to a heated solution made up from thorium tetrachloride in 1:1 acetone-nitromethane and an excess of the lactam in acetone.

(*g*) *Esters.* Ethyl acetate complexes of composition $UX_4 \cdot y MeCO_2Et$ (y = 3, X = Cl, Br; y = 2, X = Br) are reported to be formed from the components. However, both ethyl and *n*-propyl acetates react with uranium tetrachloride, yielding the complexes $UCl_3(MeCO_2) \cdot L$, where L is the ester. The bis isopropyl acetate complex, $ThCl_4 \cdot 2MeCO_2Pr^i$, is obtained when the alkoxide, $Th(OPr^i)_4$, is heated with the stoichiometric quantity (molar ratio, 1:4) of acetyl chloride in benzene under reflux. With 1:3 and 1:2 molar ratios of the reactants under similar conditions, the products are reported to be $ThCl_3(OPr^i) \cdot MeCO_2Pr^i$ and $ThCl_2(OPr^i)_2 \cdot 0.5MeCO_2Pr^i$ respectively.

The ethyl carbamate complexes, $MCl_4 \cdot xR_2NCO_2Et$ (R_2 = Me_2 or MeH, M = Th, x = 3 and M = U, x = 2) are obtained by treating a solution of the tetrachloride in THF with an excess of the ligand, followed by dropwise addition of *n*-hexane until the solution becomes turbid. $ThCl_4 \cdot 3(MeEt)NCO_2Et$ is obtained by adding an excess of the ligand to a suspension of the tetrachloride in benzene. ^{1}H NMR data are available for these compounds[81] and their IR spectra indicate that the ligands are bonded to the metal *via* the carbonyl oxygen atom.[81]

Hydrated *N*-pentylisonicotinate adducts, $ThX_4 \cdot yL \cdot zH_2O$ (X = Cl, y = 2, z = 8; X = Br, y = 4, z = 9; X = I, y = 2, z = 9) have been obtained by grinding the solid, hydrated tetrahalide with an excess of the ester, but their IR spectra indicate that the ester molecules are not bonded to the metal atom.

(*v*) *Oxoanions as ligands*

(*a*) *Nitrates.* Hydrated nitrates, $M(NO_3)_4 \cdot xH_2O$ (M = Th, Np and Pu), and the structure of $[Th(NO_3)_4(H_2O)_3] \cdot 2H_2O$, are included in Section 40.2.2.4.i.a (pp. 1145, 1146). Anhydrous

$Th(NO_3)_4$ is obtained by heating $(NO_2)_2[Th(NO_3)_6]$ at 150 °C or $(NO)_3[Th(NO_3)_6]$ at 90 °C under vacuum. Hexanitrato complexes (Table 24) are obtained from moderately concentrated (8 M to 14 M) nitric acid, in the presence of sulfamic acid to inhibit oxidation by nitrite in the case of uranium(IV). The nitrate groups in these compounds are bidentate and the structure of the anion in $[Mg(H_2O)_6][Th(NO_3)_6]\cdot 2H_2O$ is an irregular icosahedron.[82] The corresponding zinc, cobalt and nickel salts are isomorphous with the magnesium salt. The high symmetry of the complex anion is apparent in the almost white appearance of the salts $M^I_2[U(NO_3)_6]$. The product of composition $Np(NO_3)_4\cdot 1.2N_2O_5$, obtained by the reaction of $NpCl_4$ with N_2O_5, is presumably a nitrato complex.

Table 24 Hexanitrato Actinide(IV) Complexes

$M^I_2[M^{IV}(NO_3)_6]$	$M^I = NH_4$, M^{IV} = Th, U, Pu[a]
	M^I = K, M^{IV} = Pu

$(bipyH_2)[U(NO_3)_6]$	
$M^{II}[M^{IV}(NO_3)_6]\cdot 8H_2O$	M^{II} = Mg or Zn, M^{IV} = Th, U, Pu
	M^{II} = Co or Ni, M^{IV} = Th, Pu
	M^{II} = Mn, M^{IV} = Th
$M^ITh(NO_3)_5\cdot xH_2O$	M^I = Na, x = 8.5; K, x = 6
$K_3H_3M^{IV}(NO_3)_{10}\cdot xH_2O$	M^{IV} = Th, x = 4; U, x = 3

[a] A dihydrate has also been reported.

In the hydrated compounds (included in Table 24) the water molecules are almost certainly not bonded to the actinide(IV) ion, with the possible exception of the complexes formulated as $M^ITh(NO_3)_5\cdot xH_2O$ (M^I = Na or K) and $K_3H_3Th(NO_3)_{10}\cdot xH_2O$, the nature of which is uncertain.

(*b*) *Phosphates.* Metaphosphates, $M(PO_3)_4$ (M = Th, Pa, U, Pu), the hydrated compounds $Pu(HPO_4)_2\cdot xH_2O$, $Pu_2H(PO_4)_3\cdot xH_2O$ and $Pu_3(PO_4)_4\cdot xH_2O$, and the pyrophosphates $M(P_2O_7)$ (M = Th, Pa, U, Np, Pu) have been recorded. The structure of the triclinic form of $U(PO_3)_4$ consists of eight-coordinate square antiprisms, UO_8, connected by $(P_4O_{12})^{4-}$ rings.[83a]

Alkyl phosphates, $U\{O_2P(OR)_2\}_4$ (R = Me, Et or Bu^n) and $U\{O_2PH(OR)\}_4$ (R = Me, Et, Pr^i or Bu^n), and the phenyl derivative, $U(O_3PPh)_2$, have also been reported.[83b]

(*c*) *Sulfites.* The only simple sulfite appears to be $Th(SO_3)_2\cdot 4H_2O$. Salts of hydrated complexes of the type $M^I_{2n}M^{IV}(SO_3)_{n+2}\cdot xH_2O$ (Table 25) are known for thorium(IV) and uranium(IV), both of which form a series of hydrated salts of what appear to be sulfitooxalato complex anions, $Na_{2n}M^{IV}(SO_3)_n(C_2O_4)_2\cdot xH_2O$, obtained by dissolving $Th(C_2O_4)_2$ in concentrated aqueous sodium sulfite in varying molar proportions, and then pouring the resulting solution into ethanol to yield a syrup which becomes crystalline on treatment with ethanol.[84,85] The product of composition $Na_2U(SO_3)(C_2O_4)_2\cdot 5H_2O$ is formulated as $Na_2[U(SO_3)(C_2O_4)_2(H_2O)_2]\cdot 3.5H_2O$ in the original paper.[84] All these products require further investigation.

(*d*) *Sulfates.* Hydrated sulfates, including the structure of $[U(SO_4)_2(H_2O)_4]$, have been described in Section 40.2.2.4.i.a (pp. 1144, 1145); some anhydrous sulfates are also known. Fluorosulfates $U(SO_3F)_4$, $UO(SO_3F)_2$ and $M^{II}U(SO_3F)_6$ (M^{II} = Mg, Zn) have been obtained by treating $U(MeCO_2)_4$ or $M^{II}U(MeCO_2)_6$ with HSO_3F. The compound $U(SO_3F)_4$ appears to involve two mono- and two bi-dentate SO_3F groups.[86] Salts of sulfato complex anions of the type $M^I_{2n}M^{IV}(SO_4)_{2+n}\cdot xH_2O$ (n = 1 to 4) are listed in Table 26, together with sulfatooxalates and salts of complex anions derived from them.

The structure of the anion in $K_4Th(SO_4)_4\cdot 2H_2O$ consists of chains of thorium atoms linked by pairs of bridging sulfate groups, and the coordination geometry about the thorium atom is a

tricapped trigonal prism.[87] It would be useful to have similar information for the other complex anions.

(*e*) *Selenites and selenates.* Hydrated selenites, $M(SeO_3)_2 \cdot xH_2O$ (M = Th, U, Pu), have been isolated from aqueous solution, and a hydrated thorium selenate, $Th(SeO_4)_2 \cdot 9H_2O$, has been recorded; very little is known about these compounds.

(*f*) *Tellurites and tellurates.* Actinide(IV) tellurites,[88] $M(TeO_3)_2$ (M = Th, U, Np, Pu), and a basic thorium(IV) tellurate, $ThO(TeO_4) \cdot xH_2O$ ($x = 4$ or 8), which may be $ThO(H_4TeO_6) \cdot yH_2O$ ($y = 2$ or 6), have been recorded. There is also evidence for the formation of complexes of composition $M^{II}_5Th(TeO_3)_7$ (M^{II} = Ba or Ca) from phase studies.[89]

(*vi*) *Carboxylates, carbonates and nitroalkanes*

(*a*) *Monocarboxylates.* In addition to the compounds listed in Table 27, which includes basic and mixed carboxylates, a large number of hydroxocarboxylato compounds, such as $[Th_3(HCO_2)_6(OH)_5X] \cdot yH_2O$, where X = NO_3, ClO_3, ClO_4 or NCS, with y in the range 7 to 16, and anionic derivatives formulated as $K_2[Th_3(HCO_2)_6(O)_2(OH)_2(NCS)_2]$, have been recorded, but these require further investigation.

The formates and acetates, $M(RCO_2)_4$, are prepared either by reaction of the tetrachloride with the acid or (M = U) by reduction of a dioxouranium(VI) compound in non-aqueous media. The product obtained by reaction of the tetrachloride with the carboxylic acid depends on the temperature of the reaction, lower temperatures giving only partial replacement of chloride, so that compounds of the type $M(RCO_2)_xCl_{4-x}$ are obtained (see Table 27). Other

[a] V. S. Shmidt and V. G. Andryushin, *Sov. Radiochem.* (*Engl. Transl.*), 1982, **24**, 498.

carboxylates are commonly prepared by heating the tetraacetate with the appropriate carboxylic acid, a method used also to obtain compounds of the type $M(RCO_2)_2(MeCO_2)_2$. In some cases [*e.g.* $UO(2\text{-}MeC_6H_4CO_2)_2$] a basic product precipitates and similar basic compounds are often obtained from aqueous media, although many of the known tetracarboxylates can be obtained anhydrous from aqueous solution. Some authors report the basic species as hydroxocarboxylato compounds, and others report them as hydrated monoxo compounds, and it is uncertain whether such compounds should be regarded as $MO(RCO_2)_2{\cdot}xH_2O$ or $M(OH)_2(RCO_2)_2{\cdot}(x-1)H_2O$.

Anhydrous thorium, protactinium and neptunium tetraformates are isostructural,[90] but $U(HCO_2)_4$ does not possess the same crystal structure and appears to exist in three crystal modifications. Hydrated thorium formate, $Th(HCO_2)_4{\cdot}3H_2O$, has a formato bridged structure in which each thorium atom is surrounded by eight oxygen atoms from eight HCO_2 groups in a bicapped trigonal prismatic array.[91] Thorium tetraacetate is isomorphous with $U(MeCO_2)_4$ in which the structure consists of infinite columns parallel to the c axis with acetate groups bridging the uranium atoms, giving rise to square antiprismatic geometry. There are two additional oxygen atoms in neighbouring polyhedra at 2.80 Å from each uranium atom.[92] Although salts of formato complex anions of composition $[Th(HCO_2)_{4+n}]^{n-}$ (n = 1–4, Table

27) have been recorded, no structural data are available for them. $Zn_2[U(HCO_2)_8]$ is obtained by reduction of UO_2Cl_2 in formic acid by zinc amalgam, but otherwise only basic uranium(IV) formato complexes have been reported. Acetato complexes are always $M^I_2[M^{IV}(MeCO_2)_6]$ or $M^{II}[M^{IV}(MeCO_2)_6]$. The uranates(IV) (M^{II} = Mg, Fe or Zn) are easily obtained by reduction of $UO_2(MeCO_2)_2 \cdot 2H_2O$ with the appropriate metal in a mixture of glacial acetic acid and acetic anhydride, but the zinc salt readily loses $Zn(MeCO_2)_2$ to yield the tetraacetate. A few trichloroacetato complex salts, $M^I[Th(Cl_3CCO_2)_6]$, are also known, and, somewhat surprisingly, a sodium salt formulated as $NaU(CH_2ClCO_2)_5 \cdot H_2O$ has been reported. Otherwise virtually nothing is known about anionic complexes with other carboxylic acids or with other actinides(IV).

(*b*) *Chelating carboxylates.* Pyridine-2- and -3-carboxylic acids appear to form simple carboxylates [*e.g.* $U(NC_5H_4\text{-}2\text{-}CO_2)_4$, Table 28], whereas pyridine-4-carboxylic acid can also act as a neutral ligand,[93] as in the complex $Th(NO_3)_4 \cdot (NC_5H_4\text{-}4\text{-}CO_2H) \cdot H_2O$. Quinoline-2-carboxylates are also known. It is not clear whether the heterocyclic nitrogen atom is bonded to the metal in these carboxylates.

The simple hydrated pyridine-2,6-dicarboxylate (pdc), $[Th(pdc)_2(H_2O)_4]$, is precipitated from methanol solutions of $Th(NO_3)_4 \cdot 5H_2O$ by the acid; the thorium atom is 10-coordinate in a bicapped square antiprismatic arrangement in which the pyridine nitrogen atoms cap the two opposite faces of the antiprism, the corners of which are occupied by two oxygen atoms from each dicarboxylate group and the four oxygen atoms from the water molecules.[94] The tetrahydrate yields the anhydrous polymer, $[Th(pdc)_2]_n$, on heating. The corresponding uranium(IV) compound, $U(pdc)_2$, is prepared by heating $U(MeCO_2)_4$ with a solution of the acid in methanol under reflux, and mixed carboxylates, such as $U(Hpdc)(MeCO_2)_3$, are obtained in a similar manner using methanol or ethanol as the solvent.

The tetraphenylarsonium salts, $(Ph_4As)_3[M(pdc)_3] \cdot 3H_2O$, have been prepared by adding the metal tetrachloride (M = Th, U) or tetranitrate (M = Th) to an excess of the acid and Ph_4AsCl in water. In the structure of the anion of the uranium compound, the uranium atom is nine-coordinated with distorted tricapped trigonal prismatic geometry in which the three nitrogen atoms of the pdc groups cap the rectangular faces of the prism.[95]

The imino-, oxo- and 4,4′-diaminodiphenylmethane-*N*,*N*′-diacetates have been isolated from aqueous solution (Table 28). The central nitrogen or oxygen atoms of these diacetate groups are probably bonded to the metal as found for the pyridine-2,6-dicarboxylates.

(*c*) *Carbonates.* The simple carbonates (Table 29) are not well known, and their preparation usually requires autoclave techniques; for example, $Th(CO_3)_2 \cdot 0.5H_2O$ is obtained[96] from thorium(IV) hydroxide and carbon dioxide at 1800–3000 atm and 100–150 °C. The best

established carbonato complexes are salts of the $[M^{IV}(CO_3)_4]^{4-}$ and $[M^{IV}(CO_3)_5]^{6-}$ anions, but tri-, hexa- and octa-carbonato complexes (Table 29) have also been reported. The two last require confirmation, for the preparation of the hexa- and octa-carbonato plutonates(IV) was by dissolution of $Pu(C_2O_4)_2$ in a solution of the appropriate alkali carbonate, after which the solution was poured into aqueous ethanol, yielding an oil which became crystalline on standing or on treatment with 99% ethanol. The same procedure can also be used to prepare the tetra- and penta-carbonato complexes.[97]

[a] Yu. Ya. Kharitonov and A. I. Moskvin, *Sov. Radiochem.* (*Engl. Transl.*), 1973, **15**, 240.

In the cases of the hydrated salts, some authors include a part of the water in the coordination sphere (*e.g.* $M^I_6[Th(CO_3)_5] \cdot xH_2O$ is sometimes written as $M^I_6[Th(CO_3)_5(H_2O)] \cdot (x-1)H_2O$ and $(NH_4)_2[Th(CO_3)_3] \cdot 6H_2O$ as $(NH_4)_2[Th(CO_3)_3(H_2O)_3] \cdot 3H_2O$), but there does not appear to be sufficient experimental evidence to support this. The same applies to the formulations of the basic carbonato complexes listed in Table 29.

The coordination polyhedron of the anion in $(CN_3H_6)_6[Th(CO_3)_5] \cdot 4H_2O$ is an irregular decahexahedron[98] and the geometry is a bicapped square antiprism. Replacement of CN_3H_6 by Na, in $Na_6[Th(CO_3)_5] \cdot 12H_2O$, leads only to a slight deformation of the polyhedron.[99] The water molecules are not bonded to the thorium atom in either salt. The thorium atom in the carbonatofluorothorate(IV), $(CN_3H_6)_5[Th(CO_3)_3F_3]$, is nine-coordinate, with three bidentate carbonate groups and three terminal fluorine atoms making up a monocapped square antiprism.[100]

(*d*) *Oxalates.* A large number of oxalato (Table 30) and mixed oxalato complexes (Table 31) have been recorded. The hydrated oxalates, $M(C_2O_4)_2 \cdot xH_2O$, are precipitated from aqueous media, the basis of a useful gravimetric method for the elements. The thorium compounds (x = 0, 1, 2 or 6) are isomorphous with their uranium(IV) analogues. The hydrated basic oxalate, $UO(C_2O_4) \cdot 6H_2O$, precipitates on photoreduction of $UO_2(HCO_2)_2$ in the presence of oxalic acid; other hydrates are known and some authors describe them as hydroxo compounds [*e.g.* $U(OH)_2(C_2O_4) \cdot 5H_2O$], but this requires confirmation.

[a] Also reported as $(H_3O)_2[Th_2(C_2O_4)_5] \cdot 5H_2O$.

A few salts of the tris oxalato actinide(IV) anions are known, such as the acid benzylquinolinium compounds (Table 30), but the more usual complexes are the tetraoxalato and pentaoxalato species. The coordination geometry of the 10-coordinate thorium atom in the anion of $K_4[Th(C_2O_4)_4] \cdot 4H_2O$ is a slightly irregular bicapped square antiprism in an oxalate bridged structure cross-linked into a three-dimensional framework by hydrogen bonding (Figure 4).[101] The geometry in both crystal modifications of $K_4[U(C_2O_4)_4] \cdot 4H_2O$ is the same as in the thorium compound; in one phase the three bidentate C_2O_4 groups and a tetradentate bridging C_2O_4 group link the metal atoms in a one dimensional polymeric array and the other phase is isostructural with the thorium compound.[102] It would be useful to have structural information for the $[Th(C_2O_4)_6]^{8-}$, $[U_2(C_2O_4)_6]^{4-}$ and $[Th_2(C_2O_4)_7]^{6-}$ anions, for it is not clear whether these are genuine complexes or mixtures involving other known oxalato anions.

Mixed oxalates and oxalato complexes (Table 31) also require further investigation. The sulfito and sulfato oxalates have been mentioned earlier (p. 1152) and an equally large number of carbonatooxalato species have been recorded,[103,104] some of which may well be mixtures. In addition to the compounds listed in Table 31, products of the rather unlikely compositions $K_7[U(OH)(C_2O_4)_2(CO_3)_3] \cdot 6H_2O$ and $K_{16}[U_2(OH)_2(C_2O_4)_3(CO_3)_8] \cdot 10H_2O$ have been reported.[105]

(*e*) *Other dicarboxylates.* Compounds with dicarboxylic acids other than oxalates or chelating carboxylates have scarcely been investigated (Table 32). In some cases the *bis* compounds, $M^{IV}L_2$, are precipitated from aqueous solution, often as hydrates, a preparative method which also gives rise to a variety of basic compounds reported either as $M^{IV}OL \cdot xH_2O$ or $M^{IV}(OH)_2L \cdot (x-1)H_2O$. These are presumably identical compounds, but no structural information is available. A better preparative route, used for example for the phthalates, is by heating the metal tetraacetate with the dicarboxylic acid in ethanol under reflux, a method which could usefully be applied to the preparation of a much wider range of dicarboxylates. The only recorded dicarboxylato complex anions are the malonato compounds, $M^I[M^{IV}\{CH_2(CO_2)_2\}_3] \cdot xH_2O$ and $Na_2[Th\{O(CH_2CO_2)_3\}_3] \cdot 2NaNO_3$. In the structure of the

anion of the latter, the nine-coordinated thorium atom is at the centre of a tricapped trigonal prism, with three tridentate $O(CH_2CO_2)_2$ groups bonded to the metal.[58b]

(*f*) *Carbamates.* *N,N*-Dialkylcarbamates, $M^{IV}(R_2NCO_2)_4$ (M^{IV} = Th, U) are obtained by reaction of the appropriate dialkylamide, $M(NR_2)_4$, with carbon dioxide. A much simpler route is by reaction of UCl_4 with R_2NH and carbon dioxide in benzene (R = Et) or toluene (R = Me). The carbamates precipitate on addition of *n*-heptane after evaporation to small volume. $U(Et_2NCO_2)_4$ is a monomer in benzene, and the ^1H NMR spectra of the known compounds (Table 27) indicate that the alkyl groups are equivalent.

A by-product of the preparation of $U(Et_2NCO_2)_4$ from the tetrachloride and the amine is a product of composition $U_4O_2(Et_2NCO_2)_{12}$; this is a tetramer in which there are two non-equivalent uranium(IV) sites. In one of them the coordination geometry is a distorted tricapped trigonal prism, and the geometry of the other does not fit any type of regular polyhedron.[106]

(*g*) *Tetracarboxylates.* Thorium pyromellitate, $[Th(1,2,4,5\text{-}C_6H_2(CO_2)_4)]_n$, and the 2,3,6,7-naphthalenetetracarboxylate, $[Th(2,3,6,7\text{-}C_{10}H_4(CO_2)_4)]_n$, are both polymers as expected.

(*h*) *Nitroalkanes.* The only recorded complexes appear to be $UCl_4 \cdot xMeNO_2$; $UCl_4 \cdot MeNO_2$ is formed initially when $MeNO_2$ is condensed onto UCl_4 at low temperature and the mixture is allowed to warm to room temperature, and $UCl_4 \cdot 2.5MeNO_2$ is obtained from the mixture on standing.

(*vii*) *Aliphatic and aromatic hydroxyacids*

(*a*) *Aliphatic hydroxyacids.* The majority of the known hydroxycarboxylates (Table 33) are precipitated from aqueous solutions of the actinide(IV) ion on addition of the appropriate acid; many of these products are hydrated. Uranium(IV) glycollate, $[U(HOCH_2CO_2)_4(H_2O)_2]$, precipitates on photochemical reduction of $UO_2(NO_3)_2$ in aqueous solution in the presence of an excess of the acid[57] and the structure of this compound has been described earlier (p. 1144). The thorium analogue probably has the same molecular structure.

The alkali metal salts, such as those of the malato complex ions, have been isolated by dissolving the actinide carboxylate [*e.g.* $(U_2OCCH_2CH(OH)CO_2)_2 \cdot H_2O$] in a hot, aqueous solution containing the stoichiometric quantity of the alkali carboxylate, and then evaporating the resulting solution. The hydroxocarboxylato salts of the type $M^I_2M^{IV}(OH)_2X_n \cdot yH_2O$, where X_n represents the hydroxycarboxylate anions, have also been reported as $M^I_2M^{IV}OX_n \cdot zH_2O$ (Table 33); these are obviously identical compounds, but it is uncertain which formulation is

correct. The tartrato- and citrato-oxalato compounds are precipitated on dropwise addition of ethanol to a solution of $U(C_2O_4)_2$ in an aqueous mixture of the hydroxy acid and alkali in the stoichiometric proportions.

(*b*) *Aromatic hydroxyacids.* Most of the compounds with aromatic hydroxyacids (Table 34) are precipitated from aqueous solution; the composition of the product depends on the pH; for example, with 2-hydroxy-3-naphthoic acid, $Th(OC_{10}H_6CO_2)_2 \cdot 4H_2O$ is reported to precipitate at at pH 4 to 5, whereas $Th(HOC_{10}H_6CO_2)_4$ is said to precipitate at pH 6 to 7. In both cases the stoichiometric quantities of the reagents were used. It is quite possible that compounds such as $Th(OC_{10}H_6CO_2)_2 \cdot 4H_2O$ are really basic species of the type $ThO(HOC_{10}H_6CO_2)_2 \cdot 3H_2O$. In

addition to the compounds listed in Table 34, 3- and 5-nitro-, 3,5-dinitro- and 5-bromo-salicylates of composition ThL_2 (all) or $ThL(HL)_2$ (3- and 5-nitro) have been recorded. The hydroxynaphthoate acetates, $M^{IV}(HL)_x(MeCO_2)_{4-x}$, have been obtained by heating the metal tetraacetate with the naphthoic acid in ethanol under reflux.

(*viii*) *Amides and related compounds, carboxylic acid hydrazides, ureas, N-oxides, P-oxides, As-oxides and S-oxides*

The majority of the known complexes with neutral oxygen donor ligands have been prepared from the parent compound and the ligand in a non-aqueous solvent of relatively poor donor ability. When the parent compound does not exist (*e.g.* $PuCl_4$) or is difficult to obtain anhydrous (*e.g.* $M^{IV}(NCS)_4$), the alternative route is to react salts such as $Cs_2M^{IV}Cl_6$ with the ligand in a non-aqueous solvent, relying on the low solubility of CsCl in such solvents to shift the following equilibrium to the right:

$$Cs_2MCl_6 + xL \rightleftharpoons MCl_4L_x + 2CsCl(solid)$$

In the thiocyanate case, the complexes of the metal tetrachlorides are simply treated with the stoichiometric quantity of KNCS in suitable solvents. In some instances the preparations can be carried out in one step from the metal tetrachloride, potassium thiocyanate and the ligand, but this procedure can make the purification of the final product quite difficult. A number of complexes of the type $(\eta^5\text{-}C_5H_5)MX_3L_2$ (M = Th, U, Np) have been recorded; these are described elsewhere.[107]

(*a*) *Amides and related compounds.* Complexes with formamide do not appear to have been recorded, but several acetamide complexes are known (Table 35). In the group $MCl_4{\cdot}6L$ (M = U, Np, Pu), the uranium compound is ionic and is probably of the form $[UCl_2(MeCONH_2)_6]^{2+}Cl_2$ rather than $[U(MeCONH_2)_6]^{4+}Cl_4$. The complex with the sulfate, $U(SO_4)_2{\cdot}4MeCONH_2$, has been prepared by heating the sulfate in molten acetamide, and the anionic complex, $(NH_4)_2[U(SO_4)_3(MeCONH_2)]{\cdot}xH_2O$, was obtained from aqueous solution.

Relatively few complexes with *N*-alkylacetamides have been reported. No structural information is available for any of them, but the thorium nitrate complexes,

$Th(NO_3)_4 \cdot 2.5MeCONHR$ (R = Me, Et), and the analogous DMF complex, are probably ionic $[Th(NO_3)_3L_4]^+[Th(NO_3)_5L]^-$ like the diethylpropionamide complex, $UCl_4 \cdot 2.5EtCONEt_2$ (p. 1164). In the case of the uranium(IV) perchlorate complexes with MeCONHMe (Table 35), it appears that the $[U(MeCONHMe)_8]^{4+}$ anion is unstable with respect to loss of ligand, and the corresponding seven-coordinate cation may be formed; this is surprising, for in cone-angle terms (p. 1130), the estimated value of Σ caf is well within the stable region.

A much wider range of complexes has been reported for *N,N*-dimethylformamide (DMF) and for *N,N*-dimethylacetamide (DMA). Structural information is available for four DMF complexes. The mixed oxidation state compound, $[U^{IV}Cl(DMF)_7]_2[U^{VI}O_2Cl_4]_3$, is formed by treating UCl_4 in acetone with DMF, and in this compound the coordination geometry of the cation is dodecahedral, and the anion is *trans* octahedral.[108] In the complex with the 8-hydroxyquinolinate, $[Th(C_9H_6NO)_4(DMF)]$, which separates from a solution of $Th(C_9H_6NO)_4 \cdot C_9H_7NO$ in warm DMF, the coordination polyhedron is a slightly distorted tricapped trigonal prism.[109a] In the complex with the tropolonate, $[Th(trop)_4(DMF)]$, which is precipitated when $Th(trop)_4$ is heated in anhydrous DMF, the structure of the molecule is a monocapped square antiprism in which one tropolone ligand spans a slant edge of the cap, and the DMF molecule is bonded at another vertex of the cap.[110] The structure of the 1-oxo-2-thiopyridinato compound, $[ThL_4(DMF)]$, is very similar.[109b]

The DMF complex with thorium(IV) perchlorate behaves as a 1:4 electrolyte in methanol or nitromethane and its IR spectrum suggests that the perchlorate groups are ionic, indicating that the complex is $[Th(DMF)_8](ClO_4)_4$. The same complex cation is reported for the compounds $[M(DMF)_8]_3[Cr(NCS)_6]_4$ (M = Th, U). *N,N*-Diphenylformamide complexes of composition $UX_4 \cdot 4HCONPh_2$ (X = Cl, Br) have also been recorded.

No structural data are available for any of the DMA complexes (Table 35). However, the UV–visible spectrum of $2UCl_4 \cdot 5DMA$ is virtually identical to that of $2UCl_4 \cdot 5EtCONEt_2$, indicating the presence of both six- and seven-coordinate uranium(IV) centres, and it is therefore probable that the DMA complex, as well as the other complexes of composition $2MX_4 \cdot 5L$ (Table 35), is ionic and of the form $[MX_3L_4]^+[MX_5L]^-$, even though the conductance of $2UCl_4 \cdot 5DMA$ in nitromethane is low.

The thorium atom in $ThCl_4 \cdot 4DMA$ appears, on the basis of the cone-angle approach to steric crowding (p. 1130), to be very overcrowded, and it is probable that this complex should be written as $[ThCl_3(DMA)_4]^+Cl^-$, even though its conductivity in nitromethane is very low. Repeated dissolution of this complex in THF and reprecipitation with a mixture of *n*-pentane and toluene yields the tris complex, $[ThCl_4(DMA)_3]$.[111a]

The conductances of $2Th(NO_3)_4 \cdot 5DMA$ (in nitromethane) and $Th(NO_3)_4 \cdot 3DMA \cdot 3H_2O$ (in

DMA) are, however, consistent with 1:1 electrolyte behaviour and $ThI_4 \cdot 6$DMA behaves as a 1:2 electrolyte in nitromethane, presumably ionizing as $[ThI_2(DMA)_6]^{2+}I_2$. The conductivity of $Th(ClO_4)_4 \cdot 6$DMA in nitromethane is low for a 1:4 electrolyte, and the $[Th(DMA)_6]^{4+}$ ion would be very much undercrowded in cone-angle terms (p. 1130), so that one or more ClO_4 groups may be covalently bound to the thorium atom. The IR spectrum of $Th(ClO_4)_4 \cdot 8$DMA, however, is consistent with presence of ionic perchlorate only, and the $[Th(DMA)_8]^{4+}$ cation

would be well within the stable region insofar as steric crowding is concerned (Σ caf = 0.80, p. 1130).

The ^{1}H NMR spectrum of $ThCl_3(HBPz_3)\cdot DMA\cdot THF$ ($Pz = C_3H_3N_2$) indicates that the $HBPz_3$ ligand is bidentate, but it uncertain whether the THF molecule is bonded to the thorium atom or not.

A selection of a very wide variety of complexes with other *N,N*-dialkylamides is included in Table 35. The UV–visible spectra and magnetic susceptibility results for many of the uranium(IV) complexes of composition UX_4L_2 are consistent with octahedral geometry and all of the bis complexes MX_4L_2 probably adopt this geometry. The complex of composition $2UCl_4\cdot 5EtCONEt_2$ is ionic, $[UCl_3(EtCONEt_2)_4]^+[UCl_5(EtCONEt_2)]^-$, and the cation is pentagonal bipyramidal with the Cl—U—Cl axis normal to the pentagon.[8] The other known complexes of composition $2MX_4\cdot 5L$ are probably of the same structure. Pentagonal bipyramidal geometry has also been found for the neutral complex[9] $[U(NCS)_4(Me_2CHCONMe_2)_3]$ (Figure 5) and for $[ThCl_4(EtCONEt_2)_3]$.[111b] The other known tris complexes may have similar coordination geometries. In the complexes $M(NCS)_4\cdot 4RCONR'_2$ the metal centres are presumably eight-coordinate; the coordination geometry of $[Th(NCS)_4(EtCONMe_2)_4]$ is a distorted square antiprism.[111b]

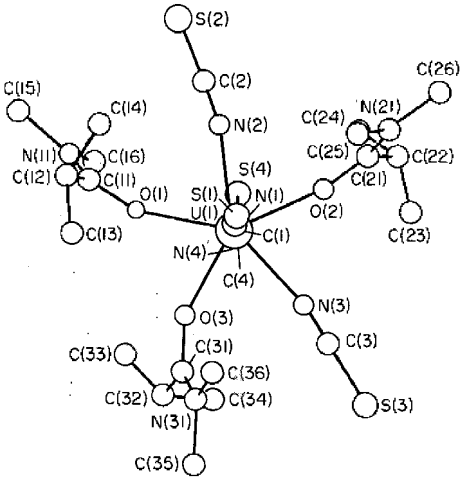

Figure 5 Perspective view of the molecular structure of $[U(NCS)_4(Me_2CHCONMe_2)_3]$ viewed down the SCN—U—NCS axis[9]

A number of complexes with ligands related to amides, lactams and antipyrine (2,3-dimethyl-1-phenylpyrazol-5-one), as well as complexes with dicarboxylic acid amides are also known (Table 36), but little structural information is available for them. The diantipyrylmethane complex, $UI_4\cdot 4L\cdot 2H_2O$, is probably ionic, $[UL_4]I_4\cdot 2H_2O$.

(*b*) *Carboxylic acid hydrazides.* Ligands of this type can be regarded as analogous to amides; the few known complexes are listed in Table 37.

(*c*) *Ureas.* A selection of the known complexes with urea and substituted ureas is given in Table 38. The hydrated compounds have been obtained by fusing together the stoichiometric quantities of the components, or by simply grinding them together and finally drying the product to constant mass in a desiccator; alternatively, some have been prepared from aqueous methanol solutions of the components. The anhydrous complexes have been prepared from solutions of the components in non-aqueous solvents, such as ethyl acetate. The complexes with $UICl_3$, UI_3Cl and $UIBr_3$ were obtained from mixtures of the component tetrahalides ($UI_4 + UCl_4$ or UBr_4) and urea in the same way as the complexes with the tetrahalides. The product of composition $ThBr_4\cdot 11.6$urea is probably a mixture of $ThBr_4\cdot 8$urea and free urea; this product, and the majority of the other urea complexes, require further investigation.

The IR spectra of all the complexes indicate that the ligands are bonded to the metal atom *via* the carbonyl oxygen atom. From the IR spectra of $Th(NO_3)_4\cdot 2$urea$\cdot$(1 or 6)H_2O it is clear that ionic nitrate is absent, but the spectra of most of the other urea complexes of thorium tetranitrate show that both covalent and ionic nitrate are present.

The systems with substituted ureas are less complicated than those with urea, and most of these compounds have been obtained from non-aqueous solutions of the components.

Table 37 Actinide(IV) Complexes with Carboxylic Acid Hydrazides, RCONHN=CHR[1]

$ThCl_4 \cdot 2L$	R = Ph, R^1 = CH=CHPh, (4-MeO)(3-HO)C_6H_3
$Th(NO_3)_4 \cdot 2L$	R = Ph, R^1 = 2-HOC_6H_4
	R = 2-HOC_6H_4, R^1 = 2-HOC_6H_4, (3-MeO)C_6H_4, (4-MeO)(3-HO)C_6H_3

$ThBr_4 \cdot 3\{(Me_2N)_2CO\}$ behaves as a 1:1 electrolyte in methyl cyanide and the coordination geometry of $[Th(NCS)_4\{(Me_2N)_2CO\}_4]$ is a slightly distorted dodecahedron.[112] The bis complexes, $M^{IV}X_4 \cdot 2L$, are probably octahedral, but otherwise structural information is lacking for complexes with these ligands.

(*d*) N-*Oxides*. Most of the known complexes are thorium(IV) compounds (Table 39) because of the oxidizing nature of the ligand. Conductivity data are available for most of these complexes; the complexes with $Th(NCS)_4$ are non-electrolytes in nitrobenzene, as are $ThBr_4 \cdot 2$(2,6-Me_2pyNO) (in methyl cyanide) and the 2,2′-bipyridyl *N,N′*-dioxide complexes $Th(NO_3)_4 \cdot L$ (in nitrobenzene or DMSO) and $ThX_4 \cdot 3L$ (X = Cl, Br; in DMSO). However, $ThI_4 \cdot 4$(2,6-Me_2pyNO) and $ThI_4 \cdot 4$(bipy-*N,N′*-O_2) behave as $[ThI_2L_4]I_2$ in methyl cyanide or nitrobenzene and DMSO or nitrobenzene respectively. $Th(NO_3)_4 \cdot 4$(2,6-Me_2pyNO) behaves as $[Th(NO_3)_2L_4](NO_3)_2$ in methyl cyanide, consistent with its IR spectrum, which indicates the presence of both ionic and covalent nitrate. The conductivities of the complexes with thorium(IV) perchlorate are consistent with 1:4 electrolyte behaviour.

The IR spectrum of $Th(NO_3)_4 \cdot 8$pyNO shows ionic nitrate only, and the complex is presumably $[Th(pyNO)_8](NO_3)_4$, whereas the spectrum of the quinoline *N*-oxide complex, $Th(NO_3)_4 \cdot 3L$, indicates bidentate nitrate only, and thorium is presumably 11-coordinate in this compound. The IR spectra of $Th(NO_3)_4 \cdot 2$(bipy-NO) and $Th(NO_3)_4 \cdot$(bipy-*N,N′*-O_2) also indicate that only bidentate nitrate groups are present, so that in these two complexes thorium is evidently 10-coordinate.

The complex with nitrosyl chloride, $ThCl_4 \cdot 2NOCl$, is a nitrosonium salt, $(NO)_2[ThCl_6]$.

(*e*) P-*Oxides*. Because of the importance of phosphate esters in the separation of uranium from other actinides by solvent extraction, ligands of this type, as well as phosphine oxides and phosphinate esters (Table 40), have attracted a great deal of research interest and the structures of a number of complexes with these ligands have been reported.

In the structure of $[UCl_4\{(Me_2N)_3PO\}_2]$, the coordination is *trans* octahedral,[113] as also found in the structure[114] of $[UBr_4(Ph_3PO)_2]$, whereas in $[UCl_4(Ph_3PO)_2]$ the coordination

$UX_4 \cdot 2L$	X = Cl, Br

geometry is *cis* octahedral as a result of a ring–ring interaction between two Ph rings in the molecule, one from each of the two adjacent Ph_3PO molecules.[115] The thorium, protactinium, neptunium and plutonium complexes, $MCl_4 \cdot 2Ph_3PO$, are isostructural with this form of $[UCl_4(Ph_3PO)_2]$, and the complexes $MBr_4 \cdot 2Ph_3PO$ (M = Th, Pa, Np, Pu) are isostructural with the uranium(IV) bromide complex. A second crystal form of $[UCl_4(Ph_3PO)_2]$, isostructural with the bromide complex, has recently been reported.[114] The complex with trimethylphosphine oxide, $UCl_4 \cdot 6Me_3PO$, is ionic, $[UCl(Me_3PO)_6]^{3+}Cl_3$, and the coordination geometry of the seven-coordinate cation approximates to a singly capped octahedron.[116] The coordination geometry in $[U(NCS)_4(Me_3PO)_4]$,[117] $[U(NCS)_4\{(Me_2N)_3PO\}_4]$[118] and $[U(NCS)_4(O\{Me_2N)_2PO\}_2)_2]$[119] is square antiprismatic, whereas in $[ThCl_4(O\{(Me_2N)_2PO\}_2)_2]$[119] the geometry is dodecahedral.

$[Th(NO_3)_4(Ph_3PO)_2]$ is isostructural with the cerium(IV) analogue, in which the coordination geometry is best described as distorted *trans* octahedral, with the four bidentate nitrate groups each occupying one corner of the equatorial plane.[120] Several apparently non-stoichiometric compounds have been reported for complexes with the actinide(IV) nitrates. The complex of composition $Th(NO_3)_4 \cdot 2.67Me_3PO$ is ionic, $[Th(NO_3)_3(Me_3PO)_4]_2^+$ $[Th(NO_3)_6]^{2-}$, and the 10-coordinate geometry in the cation can be described as a 1:5:4 arrangement with a planar face (Figure 6).[121] The coordination geometry in the cation $[Th(NO_3)_3\{(Me_2N)_3PO\}_4]^+$ of the analogous complex $Th(NO_3)_4 \cdot 2.67(Me_2N)_3PO$ is described as a 1:6:3 arrangement.[122] $Th(NO_3)_4 \cdot 2.67Pr^n_3PO$ is probably similar in structure to the Me_3PO complex. The products of composition $Th(NO_3)_4 \cdot 2.33$ and $3.67Me_3PO$ appear to be mixtures. It has been suggested that $Th(NO_3)_4 \cdot 3Me_3PO$ may be ionic, $[Th(NO_3)_2(Me_3PO)_5]^{2+}[Th(NO_3)_5(Me_3PO)_2]_2^-$, but this requires confirmation. The complexes $Th(NO_3)_4 \cdot 4L$ (L = Me_3PO, Bu^n_3PO) behave as 1:1 electrolytes in nitromethane, and these may be of the form $[Th(NO_3)_3L_4]^+NO_3^-$. Their IR spectra confirm the presence of both ionic and covalent nitrate groups. Similarly,

$Th(NO_3)_4 \cdot 5Me_3PO$ may be $[Th(NO_3)_2(Me_3PO)_5]^{2+}(NO_3)_2$. The geometry of 12-coordinate thorium in the anion of $(Ph_4P)[Th(NO_3)_5(Me_3PO)_2]$ is distorted icosahedral[121] and the same geometry has been reported for the 12-coordinate thorium atom in the diethyl-*N,N'*-(diethylcarbamyl) methylene phosphonate complex, $[Th(NO_3)_4\{(EtO)_2P(O)CH_2C(O)NEt_2\}_2]$, in which two carbonyl, two phosphoryl and eight nitrate oxygen atoms are bonded to the thorium atom.[123]

The geometry of the nine-coordinate thorium atom in the thenoyltrifluoroacetonate complex, $[Th\{CF_3COCHCO\text{-}(2\text{-}C_4H_3S)\}_4\{(n\text{-}C_8H_{17})_3PO\}]$, is a 4,4,4-tricapped trigonal prism (Figure 7).[124]

The complexes $MBr_4 \cdot 2(Me_2N)_3PO$ (M = Th, Pa, U, Np, Pu) are isostructural, and the tris complex, $ThBr_4 \cdot 3(Me_2N)_3PO$, behaves as a 1:1 electrolyte in nitromethane.[125]

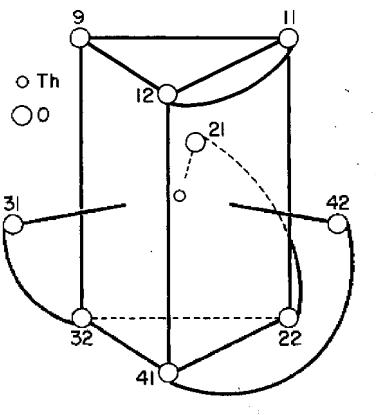

Figure 7 The coordination geometry of $[Th(CF_3COCHCO(2\text{-}C_4H_3S))_4\{(n\text{-}C_8H_{17})_3PO\}]$[124]

The complexes with thorium(IV) perchlorate, $Th(ClO_4)_4 \cdot 4L$ behave as 1:4 electrolytes in nitromethane when $L = [(Me_2N)_2PO]_2O$ or $[(Me_2N)_2PO]_2NMe$, but with $L = Ph_3PO$ the conductance is consistent with 1:3 electrolyte behaviour in nitromethane, perhaps as $[Th(Ph_3PO)_4(O_2ClO_2)]^{3+}(ClO_4)_3$. The IR spectrum of $Th(ClO_4)_4 \cdot 5Bu^n_3PO$ shows that both ionic and coordinated perchlorate groups are present, and this compound may have a similar ionic structure.

(*f*) As-*Oxides*. The few known complexes with arsine oxides (Table 41) appear to be very similar in composition and behaviour to those formed by the analogous phosphine oxides. The only reported structure is that of the complex $[UCl_4(Et_3AsO)_2]$, in which the coordination geometry is *trans* octahedral.[126]

Table 41 Complexes of Actinide(IV) Compounds with Arsine Oxides

$UCl_4 \cdot xL$	$x = 1$, 2 for $n = 2$; $x = 1$ for $n = 4$

(*g*) S-*Oxides*. The complexes with sulfoxides are usually prepared from the parent compound and the ligand in dry, non-aqueous solvents; the Ph_2SO complexes of $NpCl_4$ and $PuCl_4$ can, however, be obtained by treating a hot 6 M HCl solution of Cs_2MCl_6 with the ligand. The complexes with the nitrates have been prepared either by treating the salts $Cs_2M(NO_3)_6$ with the ligand or by treating the corresponding complex of the metal tetrachloride with silver nitrate in methyl cyanide (*e.g.* refs. 127, 128).

In addition to the large number of complexes with these ligands listed in Table 42, products of composition $ThX_4 \cdot yMe_2SO \cdot zH_2O$ (X = Cl, Br, I, with values of y ranging up to 12) have been recorded, prepared by treating the hydrated parent thorium compound either with the stoichiometric amount of Me_2SO or, in some instances, with an excess of the ligand. These products require further investigation.

$ThCl_4 \cdot 3Me_2SO$ is isostructural with $UCl_4 \cdot 3Me_2SO$, which is an ionic compound, $[UCl_2(Me_2SO)_6][UCl_6]$. The coordination geometry of the uranium atom in the cation is a distorted dodecahedron.[129] The complex of composition $ThCl_4 \cdot 5Me_2SO$ may also be ionic, possibly $[ThCl_3(DMSO)_5]Cl$, but this requires verification. The IR spectra of the complexes $M^{IV}Cl_4 \cdot 7Me_2SO$ (M^{IV} = Th, U, Np, Pu) indicate the presence of both bonded and free ligand, but the structures are not known. Three crystal modifications of $Th(NO_3)_4 \cdot 3Me_2SO$ have been reported, one of which (designated the γ form) is isostructural with the analogous complexes of uranium(IV), neptunium(IV) and plutonium(IV).

The coordination geometry in the Me_2SO complex of thorium 8-hydroxyquinolinate, $Th(C_9H_6NO)_4 \cdot 2Me_2SO$, is a monocapped square antiprism in which only one Me_2SO molecule is coordinated to the metal.[130]

In the structure of $[ThCl_4(Ph_2SO)_4]$ the Cl atoms occupy the B sites and the sulfoxide O atoms the A sites in the dodecahedral complex.[131]

(*ix*) *Hydroxamates, cupferron and related ligands*

The known complexes, $M^{IV}L_4$ (Table 43), precipitate from aqueous solutions of actinide(IV) compounds on addition of the ligand. Somewhat surprisingly, one hydroxamic acid, (PhCO)NHOH, behaves as a neutral ligand, and the complex $Th(NO_3)_4 \cdot 2(PhCO)NHOH$ precipitates from aqueous solution at pH 7. Structural information is available for $[Th\{(Bu^tCO)(Pr^i)NO\}_4]$ and $[Th\{(t\text{-}C_5H_{11}CO)(Pr^i)NO\}_4]$; the coordination geometry in the former is a distorted cube, whereas in the latter the geometry is an *mmmm* dodecahedron.[132]

40.2.2.5 Sulfur ligands

(*i*) *Sulfides and thiols*

(*a*) *Sulfides*. Disulfides, MS_2, are known for M = Th, U and Pu, but the plutonium compound is a plutonium(III) polysulfide (p. 1135). The compounds M_2S_5 (M = Th, U, Np) and

MS_3 (M = U, Np) are actinide(IV) polysulfides; the geometry of 10-coordinate thorium in Th_2S_5, which is isomorphous with U_2S_5 and Np_2S_5, is derived from a square-based antiprism surmounted by a capped, approximately pentagonal array of S atoms.[133] Oxide sulfides, such as the compounds $M^{IV}OS$ (M^{IV} = Np, Pu), $Pu_2O_2S_3$ [$(Pu^{4+})_2(O^{2-})_2S^{2-}(S—S)^{2-}$] and $M_4O_4S_3$ (M = Np, Pu; possibly $2MO_2 \cdot M_2S_3$) are also known.

(*b*) *Thiols.* The only recorded compounds appear to be $U(SR)_4$ with R = Et or Bu^n,

prepared by reaction of $U(NEt_2)_4$ with the thiol in ether; both compounds are oxidized very easily and they inflame in air.

(*ii*) *Thioethers*

A complex with 1,2-dimethylthioethane, $UCl_4 \cdot 2(MeSCH_2CH_2SMe)$, has been recorded.

(*iii*) *Monothio- and dithio-carbamates, and thiohydroxamates*

(*a*) *Monothiocarbamates.* The thorium(IV) and uranium(IV) compounds, $M^{IV}(R_2NCOS)_4$ (M^{IV} = Th, R = Me, Et; M^{IV} = U, R = Et) have been obtained by insertion of COS into the M—N bond of the dialkylamides, $M(NR_2)_4$. The ^1H NMR spectrum of $Th(Et_2NCOS)_4$ indicates that rotation about the $(Et_2)N$—C bond is slow on the NMR time scale, and the two ethyl groups are not equivalent.

(*b*) *Dithiocarbamates.* The compounds $M^{IV}(R_2NCS_2)_4$ (R = Me, M^{IV} = Th; R = Et, M^{IV} = Th, U, Np, Pu) have been prepared by reaction of $M^{IV}Cl_4$ or $M^I_2M^{IV}Cl_6$ with the alkali metal dithiocarbamate in non-aqueous solvents, and by CS_2 insertion into the M—N bond of the dialkylamides (M^{IV} = Th, U only). A much simpler route is by reaction of UCl_4 with the dialkylamine and CS_2 in toluene.

$U(Et_2NCS_2)_4$ is a monomer in benzene and is very sensitive to air oxidation in solution. It is isomorphous with $Th(Et_2NCS_2)_4$, in which the coordination geometry is close to an ideal dodecahedron.[134] The ^1H NMR spectra of $Th(R_2NCS_2)_4$ (R = Me, Et) indicate that the two alkyl groups are equivalent.

Mixed complexes with Schiff bases, $M^{IV}(Et_2NCS_2)_2(2\text{-}OC_6H_4CH{=}NCH_2CH_2N{=}CHC_6H_4O\text{-}2)$ (M^{IV} = Th, U), have also been recorded.

(*c*) *Thiohydroxamates.* The acids $R^1C(S)R^2NOH$ (R^1 = Ph or 4-MeC_6H_4, R^2 = Me) yield precipitates of composition $Th(R^1C(S)R^2NO)_4 \cdot H_2O$ when aqueous thorium tetrachloride is added to an aqueous solution of the sodium hydroxamate.[135]

(*iv*) *Dithiolates*

The maleonitriledithiolate complex, $(Ph_4As)_4[U(cis\text{-}S_2C_2(CN)_2)_4]$, precipitates when Ph_4AsCl is added to a solution containing UCl_4 and $Na_2\text{-}(cis\text{-}S_2C_2(CN)_2)$; it oxidizes on exposure to air.

Uranium tetraiodide reacts with toluene-3,4-dithiol in hexane under reflux to yield a product of composition $U_2I_4(C_7H_6S_2) \cdot C_7H_8S_2$, which may be a uranium(III) compound and is possibly a sulfur-bridged dimer. A product of somewhat similar composition, $U_2Cl_4(S_2C_4F_6)$, is obtained when UCl_4 is heated with bis(trifluoromethyl)-1,2-dithiete, whereas the reaction of UI_4 with $S_2C_4F_6$ in ethylcyclohexane yields a product of composition[136] $U_3F_3I(S_2C_4F_6)_2$. These last two products are probably dithiolates, but they require further investigation.

(*v*) *Thiocarboxamides*

The only recorded complex is the product of composition $UF_4 \cdot SC_3N_2H_2$ which results from the reaction of UF_6 with dithiooxamide.[137]

(*vi*) *Thioureas*

A few complexes of composition $ThCl_4 \cdot xL$ ($L = SC(NH_2)_2$, $x = 2, 8$; $L = SC(NH_2)(2\text{-}ClC_6H_4)NH$, $x = 4$ and $L = SCNHCH_2CH_2NH$, $x = 8$) have been reported. They are 1:1 electrolytes in methanol and although there is no detectable shift in $\nu(CS)$ in their IR spectra as compared with the free ligand, the ligands do not appear to be bonded to the metal *via* the thiourea nitrogen atoms.

(*vii*) *Dithiophosphinates*

Thorium compounds of composition $Th(S_2PR_2)_4$ (R = Me, Et, Pr^i, Ph, C_6H_{11}, OEt and OPr^i) have been reported. In the structures of the compounds with R = Me and R = C_6H_{11}, the thorium atoms are dodecahedrally surrounded by eight sulfur atoms.[138]

40.2.2.6 Selenium and tellurium ligands

(*i*) *Selenides and tellurides*

Diselenides, MSe_2, and ditellurides, MTe_2 (M = Th, U, Pu), are known but the oxidation state of the metal in these compounds is uncertain. Other selenides and tellurides [*e.g.* Th_2Se_5, USe_3, MTe_3 (M = Th, U) and UTe_5] are presumably analogous to the actinide(IV) polysulfides (p. 1135). A more detailed description of these systems is available.[139]

(*ii*) *Diselenocarbamates*

The thorium(IV) and uranium(IV) compounds, $M^{IV}(Et_2NCSe_2)_4$, have been prepared by insertion of CSe_2 into the M—N bond of the diethylamides, $M(NEt_2)_4$, and (M = U) by reaction of $Et_2NH_2(Et_2NCSe_2)$ with UCl_4 in methanol under nitrogen. The ^1H NMR spectrum of the thorium(IV) compound indicates that the two ethyl groups of the ligand are equivalent.

(*iii*) *Phosphine selenides*

The complex $ThCl_4 \cdot 2Ph_3PSe$ separates when $ThCl_4$ is heated with the stoichiometric quantity of Ph_3PSe in benzene under reflux. It is a non-electrolyte in DMF.

40.2.2.7 Halogens as ligands

The known halides, and a selection of the halogeno complexes derived from them, are listed in Table 44.

(*i*) *Tetrahalides and oxohalides*

These compounds are halogen bridged polymers in the solid state. All of the tetrafluorides, MF_4 (M = Th–Pu), have the same structure in which the M^{IV} centre is surrounded by eight F atoms in a slightly distorted square antiprismatic array. In the hydrated neptunium compound, $Np_3F_{12} \cdot H_2O$, the water molecule is not bonded to the metal atom, and three kinds of fluorine polyhedra surround the neptunium atoms. These are a tricapped trigonal prism with two vacant apices, a bicapped trigonal prism and a square antiprism.[140] The coordination geometry in solid $ThCl_4$ is dodecahedral[141] and the other tetrachlorides, MCl_4 (M = Pa, U, Np), have the same structure. Two of the tetrabromides, β-$ThBr_4$ and $PaBr_4$, are isostructural with the tetrachlorides, whereas the coordination geometry in ThI_4 is a distorted square antiprism.[142]

Several oxohalides, MOX_2, have been recorded (Table 44); the structure of $PaOCl_2$ consists of an infinite polymer in which the Pa atoms are seven-, eight- and nine-coordinate.[143]

(*ii*) *Halogeno complexes*

A detailed account of the very wide range of fluoro complexes is available.[144] The structures of the main types of fluoro complex are well established. In $LiUF_5$ the U atom is surrounded by nine F atoms in a tricapped trigonal prismatic array, with adjacent prisms sharing edges and corners.[145] The analogous Th, Pa, Np and Pu compounds adopt the same structure. The coordination geometry about the metal(IV) centres in the compounds $KM^{IV}_2F_9$ (M^{IV} = Th–Pu)[146] and in the structure of $NH_4U_3F_{13}$, which is isostructural with other $M^IM^{IV}_3F_{13}$ ($M^I = NH_4$, Rb; M^{IV} = Th, U, Np), is also a tricapped trigonal prism.[147]

[a] H. Abazli, J. Jové and M. Pagès, *C. R. Hebd. Seances Acad. Sci., Ser. C*, 1979, **288**, 157.
[b] J. Jové and A. Cousson, *Radiochim. Acta*, 1977, **24**, 73.
[c] D. Brown, P. Lidster, B. Whittaker and N. Edelstein, *Inorg. Chem.*, 1976, **15**, 511.

The structures of the compounds $Rb_2M^{IV}F_6$ (M^{IV} = U, Np, Pu) consist of chains of $M^{IV}F_8$ units with triangular faced dodecahedral geometry (K_2ZrF_6 type)[148] whereas in δ-Na_2UF_6 the coordination geometry in the UF_9 chains is a tricapped trigonal prism,[149] as in the structure of β_1-K_2UF_6.[150] The compounds $M^{II}M^{IV}F_6$ (M^{II} = Ca, Sr, Ba, Pb, Cd, Eu; Table 44) adopt the LaF_3 structure.[151] In contrast, the nine-coordination geometry about the Np atom in the $[NpF_8(H_2O)]$ chains in $CoNpF_6 \cdot 3H_2O$ consists of singly capped square antiprisms sharing two F atoms, with the water molecule occupying the cap position. The uranium compound is analogous.[152]

In the structures of compounds of the type $M^I_3UF_7$ the seven F atoms are statistically distributed over fluorite lattice sites.[153] The nine-coordinate thorium atom in $(NH_4)_4ThF_8$ is surrounded by a distorted tricapped trigonal prismatic array of fluorine atoms, with the prisms sharing edges to form chains, whereas the uranium(IV) compound contains discrete dodecahedrally coordinated $[UF_8]^{4-}$ ions. The protactinium(IV), neptunium(IV) and plutonium(IV) analogues are isostructural with the uranium compound.[154]

Compounds of the type $M^I_7M^{IV}_6F_{31}$ (Table 44) are isostructural with $Na_7Zr_6F_{31}$, in which the basic coordination geometry about the Zr atom is approximately square antiprismatic, and six antiprisms share corners to form an octahedral cavity which encloses the additional F atom.[155]

The complex anions formed with the other halogens are all of the form $[MX_6]^{2-}$, with

octahedral geometry. For example, $Cs_2[NpBr_6]$ is isomorphous with $Cs_2[UBr_6]$ (face-centred cubic, $K_2[PtCl_6]$ type).[156] The IR and Raman spectra of the salts $M^I_2[M^{IV}Cl_6]$ (M^{IV} = Th, Pa, U, Np, Pu; M^I variously Cs, Et_4N, Bu^n_4N, Ph_4As), $(Me_4N)_2[PaBr_6]$ and $(Et_4N)_2[M^{IV}X_6]$ (M^{IV} = Th, Pa, U; X = Br, I) have been reported.[157] The far IR spectra of the compounds $M^I_2[NpCl_6]$ (M^I = Cs, Me_4N, Et_4N) have also been published.[158]

40.2.2.8 Hydrogen and hydrides as ligands

The only examples of compounds of this type are the borohydrides, $M^{IV}(BH_4)_4$ (M^{IV} = Th–Pu) and $M^{IV}(MeBH_3)_4$ (M^{IV} = Th, U, Np). These compounds are conveniently prepared by reaction, for example, of the metal tetrafluoride with $Al(BH_4)_3$ in a sealed tube, followed by vacuum sublimation of the product.[159] The neptunium and plutonium compounds are liquids at room temperature and are more volatile than the thorium, protactinium or uranium analogues.

In the structures of $Np(BH_4)_4$ and $Pu(BH_4)_4$ the four BH_4 groups are arranged tetrahedrally around the metal atom and three hydrogen atoms from each BH_4 group are bonded to the metal, making it 12-coordinate,[160] whereas in the polymeric uranium(IV) compound the uranium atoms are each surrounded by six BH_4 groups, two of which provide three hydrogen atoms each as above, and the other four provide two hydrogen atoms to each of two uranium atoms, making a 14-coordinate arrangement which could be regarded as a distorted bicapped hexagonal antiprism.[161] In the structures of the methylborohydrides, $M^{IV}(MeBH_3)_4$(M^{IV} = Th, U, Np) the $MeBH_3$ units are tetrahedrally coordinated to the metal *via* triple hydrogen bridges.[162]

40.2.2.9 Mixed donor atom ligands

(*i*) *Schiff base ligands*

There is a wide variety of complexes with neutral Schiff bases derived from benzaldehyde, as well as mono- and di-basic ligands derived from salicylaldehyde. A selection of these is given in Table 45, from which it can be seen that the mono- and di-basic derivatives can also act as neutral ligands. The range of complexes can be further extended by utilizing substituted salicylaldehydes, an example[163] being the compounds $M^{IV}L_2$ (M^{IV} = Th, U) formed with (5-Bu^t)(2-HOC_6H_3)CH=NCH_2CH_2N=CH(C_6H_3OH-2)(5-Bu^t).

The coordination geometry in the complex $[Th(2\text{-}OC_6H_4CH{=}NC_6H_4N{=}CHC_6H_4O\text{-}2)_2]$ is a distorted square antiprism in which the corners of each square face are occupied by the two N and two O atoms of one ligand.[164] In the structure of $[Th\{(3\text{-}MeO)(2\text{-}O)C_6H_3CH{=}N(CH_2)_2N{=}CHC_6H_3(2\text{-}O)(3\text{-}OMe)\}_2]\cdot$py, the pyridine molecule is not bonded to the metal atom, and the coordination geometry is dodecahedral, with the two Schiff base ligands each occupying one of the trapezia which make up the polyhedron; the imine nitrogen atoms occupy the dodecahedral A sites and the phenolic oxygen atoms the B sites.[165]

(*ii*) *Amino acids*

The majority of the aminocarboxylates listed in Table 46 have been prepared by precipitation from aqueous solution, a procedure which frequently yields partially hydrolyzed products. No structural information is available for any of these compounds. The iminodiacetates, derived from $HN(CH_2CO_2H)_2$, are discussed on p. 1155.

(*iii*) *Complexones*

The simple thorium(IV) and uranium(IV) compounds of the type $[M^{IV}L]\cdot xH_2O$ (Table 47) separate from aqueous solutions of the actinide(IV) salts on addition of the acid, or on concentrating the resulting aqueous solution. The salts of the complex anions (*e.g.* $M^I_2H_2[U_2L_3]$) are obtained from concentrated solutions of UL in aqueous $M^I_2H_2L$. The pentaacetic acid compound, $(NH_4)_6[UL_2]\cdot 4H_2O$, is precipitated when ethanol is added to a solution of $U(C_2O_4)_2\cdot 6H_2O$ in the aqueous acid after neutralizing with ammonia and evaporation to small volume.

Table 45 Some Actinide(IV) Schiff Base Complexes

Neutral ligands: $L = C_6H_5CH{=}NR$

$M^{IV}L\cdot xH_2O$	M^{IV} = Th, x = 2, 3, 9; M^{IV} = U, x = 0, 2, 2.5–3.5
$U_2L(OH)_4\cdot xH_2O$	
$M^{I}_2H_2[U_2L_3]\cdot xH_2O$	M^{I} = K, x = 9–18; NH_4, x = 8–16
$M^{II}_2[U_2L_3]\cdot xH_2O$	M^{II} = Ca, x = 8, 12; Sr, Ba, x = 4, 12, 18
$M^{I}[ThL(OH)]\cdot 4H_2O$	M^{I} = Na, NH_4
1,6-Diaminohexane-*N,N,N′,N′*-tetraacetic acid, $H_4L =$ $(HO_2CCH_2)_2N(CH_2)_6N(CH_2CO_2H)_2$	
$M^{IV}L\cdot xH_2O$	M^{IV} = Th, x = 4.5; M^{IV} = U, x = 0
1,2-Diaminocyclohexane-*N,N,N′,N′*-tetraacetic acid, $H_4L =$ $(HO_2CCH_2)_2N(C_6H_{10})N(CH_2CO_2H)_2$	
$ThL\cdot xH_2O$	x = 0, 1
$NH_4[ThL(OH)]\cdot 5H_2O$	
Pentacarboxylic acids	
Diethylenetriaminepentaacetic acid, $H_5L =$ $(HO_2CCH_2)_2N(CH_2)_2N(CH_2CO_2H)(CH_2)_2N(CH_2CO_2H)_2$	
$H[ThL]\cdot H_2O$	
$Na[ThL]\cdot 4H_2O$	
$(NH_4)_6[UL_2]\cdot xH_2O$	x = 0, 4

In addition to the complexes listed in Table 47, the compounds *N,N′*-di(2-hydroxyphenyl)ethylenediamine-*N,N′*-diacetic acid and *N′*-(2-hydroxyethyl)ethylenediamine-*N,N,N′*-triacetic acid behave as tetrabasic ligands, forming $ThL\cdot xH_2O$ (x = 6 and 2 respectively).

(*iv*) *Ligands containing N,O donor sites*

(*a*) *Hexafluoroacetonylpyrazolides.* These ligands, derived from hexafluoroacetone and pyrazole or 3-methylpyrazole, form complexes of the type $M^{IV}[OC(CF_3)_2\overline{NCHCRCH{=}N}]_4$ (R = H, Me; M^{IV} = Th, U, Np, Pu) which are prepared by adding a methanol solution of $(CF_3)_2CO$ to the solid obtained when, for example, solid $(Et_4N)_2UCl_6$ is added to a toluene solution of potassium pyrazolide.

The four compounds with R = H are isostructural, and in the thorium complex the eight-coordinate metal atom lies at the centre of a distorted square antiprismatic array of four N and four O atoms. In benzene solution, however, the molecular weights of the complexes with R = H indicate that they are dimers, whereas those with R = Me are monomers.[166]

(*b*) 8-*Hydroxyquinolines.* 8-Hydroxyquinoline can act as a neutral ligand, forming complexes of the type $ThCl_4\cdot xC_9H_7NO$ (x = 2, 3, 4 or 6), but the majority of the known compounds are of composition $M^{IV}L_4$ (HL = 8-hydroxyquinoline or the 5,7-dibromo ligand, M^{IV} = Th, U, Np, Pu; 5-chloro- and 5-chloro-7-iodo-8-hydroxyquinoline, M^{IV} = Np, Pu; 5,7-dichloro-8-hydroxyquinoline, M^{IV} = Th, Np, Pu; 2-methyl-8-hydroxyquinoline, M^{IV} = Th, Np). Many other substituted 8-hydroxyquinoline complexes of this type are known for M^{IV} = Th; most of them are precipitated on addition of the ligand to aqueous solutions of actinide(IV) compounds. In some cases (for example, HL = 8-hydroxyquinoline, M^{IV} = Th, U and the 5,7-dibromoligand, M^{IV} = Th) the product obtained from aqueous solution has the approximate composition $M^{IV}L_4\cdot HL$, but detailed studies have shown that the composition is variable, an example being $Th(C_9H_6NO)_4\cdot xC_9H_7NO$ with x = 0.5, 0.8 or close to unity. A hydrate, $Th(C_9H_6NO)_4\cdot 2H_2O$, has also been recorded.

Chloro and hydroxo compounds, $ThCl(C_9H_6NO)_3$ and $Th_2(C_9H_6NO)_7(OH)\cdot xH_2O$ (x = 0 or 4) are known, and a variety of mixed 8-hydroxyquinolinate/trichloroacetate species, obtained by heating a suspension of $Th(C_9H_6NO)_4$ with the appropriate quantity of trichloroacetic acid in benzene, have been recorded.

(*c*) 2,6-*Diacetylpyridine bis*(p-*methoxybenzoyl hydrazone*) ($= H_2L$). The coordination geometry in the complex of composition $[UL_2]\cdot 2C_6H_6\cdot 2H_2O$ is a pseudo bicapped square antiprism in which the two N_3O_2 donor ligands are chelated to the uranium atom.[167]

40.2.2.10 Multidentate macrocyclic ligands

(i) Phthalocyanine

The bis phthalocyanine complexes, $M^{IV}Pc_2$ (M^{IV} = Th, Pa, U, Np, Pu), can be prepared by heating a tetrahalide, usually the iodide (M = Th, Pa, U), or a triiodide (M = Np, Pu) with an excess of *o*-phthalodinitrile alone at 240–250 °C or, better, in 1-chloronaphthalene (see, *e.g.* ref. 168). The thorium compound has also been prepared[169] by heating the metal powder with the dinitrile at about 270 °C. An iodine adduct, $UPc_2 \cdot I_2$, is also known.

In the structure of UPc_2, the nitrogen atoms of the pyrrole rings of the two Pc ligands form a distorted prism in which the Pc ring systems are rotated by about 37° from the prismatic configuration.[170] The structure of $ThPc_2$ has also been published.[169] The five complexes (M = Th, Pa, U, Np, Pu) are isostructural. The bonding in UPc_2 has been investigated by X-ray PE spectroscopy.[171]

(ii) Crown ethers and cryptands

The structures of some of the known crown ether compounds (Table 48) have been reported; the dicyclohexyl-18-crown-6 compound of composition $3UCl_4 \cdot 2L$ is ionic, $[UCl_3L]_2[UCl_6]$, with the uranium atom in the cation bonded to all six oxygen atoms of the crown ether and to three chlorine atoms.[172] The 18-crown-6 complex of the same composition is probably of this form, for on recrystallization from nitromethane the mixed oxidation state complex $[UCl_3L]_2[UO_2Cl_3(OH)(H_2O)] \cdot MeNO_2$ is obtained, in which the nine-coordinate uranium atoms in the cations are bonded to six oxygen atoms of the crown ether and to three chlorine atoms in an irregular polyhedron, while the anions adopt the pentagonal bipyramidal geometry commonly found for dioxouranium(VI) species.[173] However, in the uranium(IV) thiocyanate compound with 18-crown-6, the ether (L) is not bonded to the metal atom and the structure of this product, $[U(NCS)_4(H_2O)_4] \cdot 1.5L \cdot 3H_2O \cdot MeCOBu^i$, is described on p. 1142.

Table 48 Some Complexes of Actinide(IV) Compounds with Crown Ethers and Cryptands

L = 12-crown-4 = $C_8H_{16}O_4$

$Th(NO_3)_4 \cdot L \cdot 3H_2O$	
L = dicyclohexyl-24-crown-8 = $C_{24}H_{44}O_8$	
$Th(NO_3)_4 \cdot 2L \cdot HNO_3$	
L = kryptofix ⟨2,2,2⟩, 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane = $C_{18}H_{36}N_2O_6$	
$Th(NO_3)_4 \cdot L \cdot 4H_2O$	
$UX_4 \cdot L$	X = Cl, NCS

^1H NMR spectroscopy of the complexes of UCl_4 with 18-crown-6 and dicyclohexyl-18-crown-6, and of $U(CF_3CO_2)_4$ with these two ligands and with the cryptands [2.1.1], [2.2.1], [2.2.2] and [2.2.2.B] in nitromethane or methyl cyanide indicate that the metal atom is bonded to the oxygen atoms of the ligand.[172]

40.2.3 The +5 Oxidation State

40.2.3.1 Nitrogen ligands

(*i*) *Ammonia and amines*

(*a*) *Ammonia.* The only recorded ammine appears to be the alkoxide compound, $U(OCH_2CF_3)_5 \cdot (6–12)NH_3$, described as a green liquid. It is obtained by the reaction of UCl_5 with CF_3CH_2OH in the presence of an excess of ammonia.

(*b*) *Aliphatic amines.* Complexes of the trifluoroethoxide, $U(OCH_2CF_3)_5 \cdot 2RNH_2$ (R = Pr^n, Pr^i), $U(OCH_2CF_3)_5 \cdot xR_2NH$ ($x = 3$, R = Me and $x = 2$, R = Pr^n) and $U(OCH_2CF_3)_5 \cdot 2Me_3N$ are prepared by treating an ethereal solution of the alkoxide with an excess of the amine in ether, followed by vacuum evaporation of the mixture below 40 °C and, finally, vacuum distillation of the green liquid products. No other actinide(V) complexes with amines appear to have been reported.

(*c*) *Dihydroazirine (ethyleneimine, C_2H_5N).* The complex $U(OCH_2CF_3)_5 \cdot 3C_2H_5N$, a volatile green liquid, is obtained in the same way as the amine complexes (see above).

(*ii*) *N-Heterocyclic ligands*

(*a*) *Pyridine, C_5H_5N, py, and derivatives.* Complexes of uranium pentachloride, $UCl_5 \cdot xL$ ($x = 2$, L = py or 2-HSC_5H_4N and $x = 3$, L = py) and of the *t*-butoxide, $U(OBu^t)_5 \cdot py$, have been recorded. Very little is known about them.

(*b*) *Quinoline and isoquinoline, C_9H_7N.* Quinoline and isoquinoline complexes of uranium pentachloride, $UCl_5 \cdot xL$ ($x = 2$ and 3) have been recorded, but it is not known whether the uranium atoms are seven ($x = 2$) and eight-coordinate ($x = 3$), or whether the compounds are ionic (*e.g.* $[UCl_4L_2]^+Cl^-$).

(*c*) *2,2′-Bipyridyl, bipy.* The only known complex, $UCl_5 \cdot$bipy, behaves as a 1:1 electrolyte in nitromethane[174] and is evidently $[UCl_4(bipy)]^+Cl^-$.

(*d*) *1,10-Phenanthroline, phen.* An anionic complex of composition $(Et_4N)_2UOCl_5(phen)_2$ has been recorded.[175] It is probable that some of the chloride ions are displaced from the coordination sphere.

(*e*) *Pyrazole, substituted pyrazoles and 1,8-naphthyridine.* Complexes of composition $UCl_5 \cdot 1.5L$ (L = pyrazole or 3,5-dimethylpyrazole) and $UCl_5 \cdot 2L$ (L = 1-phenylpyrazole or 1,8-naphthyridine) have been obtained by treating a solution of UCl_5 in $SOCl_2$ with the appropriate ligand.[176]

(*f*) *Pyrazine, $C_4H_4N_2$, phthalazine, $C_8H_6N_2$, and phenazine, $C_{12}H_{18}N_2$.* Complexes of UCl_5 with these ligands ($UCl_5 \cdot 2C_4H_4N_2$, $UCl_5 \cdot 2C_8H_6N_2$ and $UCl_5 \cdot C_{12}H_8N_2$) are precipitated from benzene solutions of the trichloroacryloyl chloride compound, $UCl_5 \cdot C_3Cl_4O$, and the ligand. An anionic product of composition $(Et_4N)_2UOCl_5 \cdot C_{12}H_8N_2$ has also been reported, but the reaction of salts of the $[UOCl_5]^{2-}$ ion with phenazine in nitromethane appears to yield a salt of a free radical cation, $(C_{12}H_8N_2)H_2Cl$.[177]

(*iii*) *Thiocyanates*

A salt of a dioxoneptunium(V) thiocyanato complex, $Cs_4[NpO_2(NCS)_5]$, has been recorded; the coordination geometry of the complex anion is presumably pentagonal bipyramidal.

(*iv*) *Nitriles*

Reaction of UF_5 with Me_3SiCl or UCl_5 in methyl cyanide yields a complex with the mixed halide, $UCl_2F_3 \cdot MeCN$.[178] Complexes with the pentabromides, $M^VBr_5 \cdot xMeCN$ (M^V = Pa, $x = 3$; M^V = U, $x = 2$ to 3) and with an oxonitrate, $Pa_2O(NO_3)_8 \cdot 2MeCN$, are also known.

40.2.3.2 Phosphorus and arsenic ligands

The only recorded compound appears to be the complex with *o*-phenylenebis(dimethylarsine), $PaCl_5 \cdot xC_6H_4(AsMe_2)_2$ ($1 < x < 2$).[49]

40.2.3.3 Oxygen ligands

(*i*) *Aqua species, hydroxides and oxides*

(*a*) *Aqua species.* A selection of the reported hydrates is given in Table 49. The structure of one of them, $K_3NpO_2(CO_3)_2 \cdot xH_2O$ ($x \leqslant 2$), has been reported to consist of layers of $[KNpO_2(CO_3)_2]^{2-}$ ions with K^+ ions in between the layers,[179a] but in a later paper[180] the M^VO_2 group in the compounds $M^I_3M^VO_2(CO_3)_2 \cdot xH_2O$ (M^V = Np or Pu with M^I = Na, K or Rb) is reported to be coordinated to six oxygen atoms from three bidentate carbonate groups to form a distorted hexagonal bipyramid. In most cases it is not known whether any or all of the water molecules are bonded to the actinide(V) metal ion in these compounds. In the hydrated carbonates, $KM^VO_2(CO_3) \cdot xH_2O$ and $K_3M^VO_2(CO_3)_2 \cdot xH_2O$ (M^V = Np, Pu) the water is considered to be zeolite type.[179a]

Table 49 Some Hydrates of Protactinium(V), Uranium(V), Neptunium(V) and Plutonium(V) Compounds

$PaF_5 \cdot xH_2O$	$x = 1, 2$

$[Co(NH_3)_6]NpO_2(SO_4)_2 \cdot M^I_2SO_4 \cdot xH_2O$	M^I = Na, K
$[Co(NH_3)_6](NpO_2)_2(IO_3)_5 \cdot 4H_2O$	
$PaO(ReO_4)_3 \cdot xH_2O$	

[a] V. G. Zubarev and N. N. Krot, *Sov. Radiochem.* (*Engl. Transl.*), 1981, **23**, 690.

The basic structure of the hydrated oxalato complex, $NaNpO_2C_2O_4 \cdot 3H_2O$, is made up of infinite chains of composition $[NpO_2C_2O_4(H_2O)]^{n-}_n$ connected by Na^+ ions and H_2O molecules in a three-dimensional network. The neptunium atom is at the centre of a pentagonal bipyramid, coordinated to four O atoms from two C_2O_4 groups and a fifth from the water molecule in the equatorial plane.[179b]

(*b*) *Hydroxides and oxides.* Protactinium(V), neptunium(V) and plutonium(V) hydroxides precipitate from alkaline aqueous solutions of the actinides(V); the last two appear to be of the form $M^VO_2(OH) \cdot xH_2O$.

Oxides such as Pa_2O_5, Np_2O_5 and U_3O_8 (+5 and +6 oxidation state metal centres) are well established and a number of mixed oxides such as $Li_3M^VO_4$, $Li_7M^VO_6$ (M^V = Pa, U, Np, Pu) and $Ba_2U_2O_7$ have been recorded.

(*ii*) *Alcohols, alkoxides, aryloxides and silyloxides*

(*a*) *Alcohols.* The only known actinide(V) alcohol adducts appear to be the uranium(V) compounds $UOCl_3 \cdot EtOH$, $UO(OR)_3 \cdot ROH$ (R = Et, Bu^t) and $U(OBu^t)_5 \cdot Bu^tOH$. No structural information is available for any of these compounds.

(*b*) *Alkoxides.* A very large number of uranium(V) alkoxides are known (Table 50), for these compounds are more stable with respect to disproportionation than any other uranium(V) compound. However, protactinium(V) and neptunium(V) alkoxides have scarcely been investigated, and no examples of plutonium(V) alkoxides have been recorded.

$M^I[U(OEt)_2X_4]$	X = Cl, M^I = Et_4N, Ph_4As
	X = Br, M^I = Et_4N

$U(OEt)_5$ is easily prepared by oxidation of $U(OEt)_4$ by bromine in ethanol, followed by addition of the calculated quantity of sodium ethoxide, a reaction which yields[181] only $Np(OEt)_4Br$ in the case of $Np(OEt)_4$. $U(OEt)_5$ is commonly used as the starting material for the preparation of other uranium(V) alkoxides by alcohol exchange reactions. A comprehensive review of metal alkoxides includes a useful discussion of the uranium(V) compounds.[182]

Molecular weight determinations indicate that in solution $U(OMe)_5$ is probably a tetramer in equilibrium with a dimer, whereas the other alkoxides are principally dimeric in non-aqueous media unless the alkyl group is bulky as in the compounds $U\{OCEt_3\}_5$ and $U\{OC(MeEtPr^i)\}_5$, which are monomers in solution.

The reaction of $U(OEt)_5$ with bidentate ligands, such as β-diketones, HL, has been reported to yield products of composition $U(OR)_4L$, $U(OR)_3L_2$ and $U(OR)_2L_3$, depending on the quantities of HL used, but the last two products are probably mixtures of $U(OR)_4L$, UL_4 and dioxouranium(VI) compounds.

The alkoxide fluorides, $U(OR)_2F_3$ (R = Me, Et) are obtained by treating UF_5 with the calculated quantities of Me_3SiOMe or $U(OEt)_5$. The other alkoxide halides are commonly prepared by reaction of $U(OR)_5$ with the calculated quantities of hydrogen chloride, acetyl chloride or bromide in ether or benzene.

Anionic compounds of the type $M^I[U(OR)_6]$ are also known (Table 50) and in these compounds the uranium atom is probably octahedrally coordinated.

(*c*) *Aryloxides.* The only known compounds of this type are the phenoxides $U(OPh)_4(OEt)$, $U(OPh)_2Cl_2Br$, $Na[U(OPh)_6]$ and a mixed uranium(V)/uranium(VI) compound of composition $U_4O_6(OPh)_{10}\cdot 4THF$. This last is obtained by atmospheric oxidation of the product of the reaction of $UCl_3\cdot x$THF with NaOPh in THF. The structure of the compound consists of two uranium(V) and two uranium(VI) centres which are connected by four bridging phenoxide groups and two triply bridging oxygen atoms, that is, $\{[U^V(OPh)_3THF]_2[U^{VI}O_2(THF)]_2(\mu\text{-}OPh)_4(\mu_3\text{-}O)_2\}$. The coordination polyhedron about each uranium atom is a distorted pentagonal bipyramid.[183]

(*d*) *Silyloxides.* The few known uranium(V) silyloxides are similar in properties to the corresponding alkoxides; $U(OSiMe_3)_5$ is mainly dimeric in non-aqueous media and the degree of dimerization of the compounds $U(OSiR_3)_5$ in solution decreases sharply in the order $U(OSiMe_3)_5 \gg U(OSiMe_2Et)_5 > U(OSiMeEt_2)_5 > U(OSiEt_3)_5$, the last being a monomer. Anionic species, $Na[U(OSiR_3)_6]$ (R = Me, Et), are also known.

(iii) β-Ketoenolates, tropolonates, ethers, ketones and esters

(a) β-Ketoenolates. Apart from the protactinium(V) compound of composition $PaCl_3(MeCOCHCOMe)_2$, all the reported compounds are uranium(V) products obtained by reaction of $U(OR)_5$ with the stoichiometric quantity of the β-diketone in benzene under reflux. These products are of composition $U(OR)_{5-n}(R^1COCHCOR^2)_n$ (R = Et or Bu^t, $R^1 = R^2 = Me$ and $R^1 = R^2 = Ph$, both with $n = 1$, 2 or 3; R = Et and $n = 1$, 2 or 3, or Bu^t and $n = 1$ or 3, $R^1 = Ph$, $R^2 = Me$). As mentioned earlier (p. 1181) only the products of composition $U(OR)_4(R^1COCHCOR^2)$ are likely to be genuine compounds. The same applies to the majority of the β-ketoester products of composition $U(OR)_{5-n}(R^1COCR^2CO_2R^3)_n$ (R = Et, $R^1 = Me$, $R^2 = H$ and $R^3 = Me$ or Et or $R^1 = R^2 = Me$, $R^3 = Et$; R = Bu^t, $R^1 = R^2 = Me$, $R^3 = Et$, all $n = 1$, 2 or 3), although the products of composition $U(OR)_3(CF_3COCHCO_2R^1)_2$ (R = Me, R^1 = Et and R = Et, R^1 = Me, Et or Bu^n) may be genuine compounds.

(b) Tropolonates. The tropolonates $M^V(trop)_5$ (M^V = Pa, U) and $M^V(trop)_4X$ (M^V = Pa, X = Cl, Br, ClO_4; U, X = Cl) have been recorded. $U(trop)_5$ is precipitated when Htrop is added to a solution of $U(OEt)_5$ in ether and is very unstable with respect to decomposition to $U(trop)_4$. $U(trop)_4Cl$ is isostructural with $Pa(trop)_4Cl$. The ethoxide, $Pa(trop)_4(OEt)$, was subsequently shown to be $Pa(trop)_5$.

(c) Ethers. The only recorded compounds are $UCl_5 \cdot R_2O$ (R = Me, Et, Pr^i, Bu^n, i-C_5H_{11}), $UCl_5 \cdot THF$ and the dioxane complexes, $UCl_5 \cdot xC_4H_8O_2$ ($x = 1$ or 3).

(d) Ketones. 1:1 Complexes, $UCl_5 \cdot L$ [L = anthr-10-one ($C_{14}H_{10}O$), 9-methyleneanthr-10-one ($C_{15}H_{10}O$), 1,9-benzoanthr-10-one ($C_{17}H_{10}O$) and 9-benzylideneanthr-10-one ($C_{21}H_{14}O$)] and the bis complexes, $UCl_5 \cdot 2L$ with L = $C_{14}H_{10}O$ or $C_{17}H_{10}O$ have been reported. Benzil adducts, $UCl_5 \cdot x$PhCOCOPh ($x = 1$ or 2) are also known. These products presumably involve six- and seven-coordinate uranium(V).

(e) Esters. Ester complexes of composition $U(OR)X_4 \cdot MeCO_2R$ (R = Et, X = Cl or Br; R = Pr^i, X = Cl) have been obtained by reaction of $U(OR)_5$ with the acyl halide, MeCOX, in benzene under reflux.

(iv) Oxoanions as ligands

(a) Nitrates. The hydrated nitrates $PaO(NO_3)_3 \cdot xH_2O$ ($1 < x < 4$) and $NpO_2NO_3 \cdot xH_2O$ ($x = 1$, 5), as well as the hydrated nitrato complex, $RbNpO_2(NO_3)_2 \cdot H_2O$, have been mentioned earlier (p. 1180). The hexanitratoprotactinates(V), $M^I[Pa(NO_3)_6]$ (M^I = Cs, Me_4N, Et_4N) have been prepared by treating the chloro complex salts, $M^I[PaCl_6]$ with liquid N_2O_5. The acid, $HPa(NO_3)_6$ is also known. In these compounds the protactinium(V) centre is presumably 12-coordinate.

(b) Phosphates. Some hydrated phosphates and phosphatocomplexes are included in Table 49, p. 1180. Hydrated protactinium(V) phosphate, $PaO(H_2PO_4)_3 \cdot 2H_2O$, dehydrates at 250 °C and decomposes to $PaO(PO_3)_3$ at 700 °C, then to $(PaO)_4(P_2O_7)_3$ at 1000 °C. The structures of these compounds are not known.

(c) Arsenates. A protactinium(V) phenylarsonate, $H_3PaO_2(PhAsO_3)_2$ and a number of hydrated salts of neptunium(V) arsenato complexes have been recorded, but no structural information is available for them.

(d) Sulfates. Protactinium(V) oxosulfate, $H_3PaO(SO_4)_3$, is obtained on evaporating HF/H_2SO_4 solutions of protactinium(V); it decomposes at 375 to 400 °C to $HPaO(SO_4)_2$, which yields $HPaO_2SO_4$ at 525 °C. $(NpO_2)_2SO_4$ has been reported and hydrated hexammine cobalt(III) salts of the $[NpO_2(SO_4)_2]^{3-}$ anion (Table 49, p. 1180) are also known.

(e) Selenates. The protactinium(V) compound, $H_3PaO(SeO_4)_3$, is obtained from HF/H_2SeO_4 solutions of protactinium(V). Unlike the sulfate, it decomposes directly to Pa_2O_5 on heating.

(f) Iodates. Hydrated neptunium(V) iodate and a salt of the complex anion $[(NpO_2)_2(IO_3)_5]^{3-}$ have been recorded (Table 49, p. 1180).

(v) Carboxylates and carbonates

(a) Monocarboxylates. Hydrated neptunium(V) formate, $NpO_2(HCO_2) \cdot 2H_2O$, and the formato complex, $Cs_2NpO_2(HCO_2)_3$, have been reported, the latter precipitated from aqueous

solution. The HCO_2 group appears to be bidentate in both compounds.[184] Salts of acetatodioxoactinates(V),[185] $Cs_2M^VO_2(MeCO_2)_3$ (M^V = Np, Pu) and $Na_4NpO_2(MeCO_2)_5$, have been reported. The two cesium salts are isostructural[186] and presumably have the same hexagonal bipyramidal coordination as the anion of the barium salt, $Ba[NpO_2(MeCO_2)_3]\cdot 2H_2O$, in which the oxygen atoms from the three bidentate acetate groups are in the equatorial plane.[187]

A number of mixed alkoxide/monocarboxylate compounds of the type $U(OR)_{5-n}(R^1CO_2)_n$ (R = Et, R^1 = Me, Et, Pr^n with n = 1, 2, 3 or 4; R = Et or Bu^t, R^1 = Ph with n = 1, 2 or 3) have been obtained by heating the alkoxide $U(OR)_5$ (R = Et) with the stoichiometric quantity of the acid in benzene under reflux or (R = Bu^t) by heating the appropriate ethoxide carboxylate with an excess of *t*-butanol in benzene.

(*b*) *Chelating carboxylates.* The anhydrous pyridine-2-carboxylate, $NpO_2(C_5H_4NCO_2)$, is obtained by heating the dihydrate at 125 °C; its IR spectrum indicates that the pyridine N atom is bonded to the Np atom. Similarly, in the *N*-oxide analogue, $NpO_2(C_5H_4N(O)CO_2)$, the amine oxide O atom is bonded to the metal.

The hydrated furan-2-carboxylate, $NpO_2(C_4H_3OCO_2)\cdot 2H_2O$, and the thiophene-2-carboxylate, $NpO_2(C_4H_3SCO_2)\cdot 2H_2O$, dehydrate at 90 °C and 100 °C respectively; it is possible that the ring O and S atoms in these two carboxylates are also bonded to the metal atom.

(*c*) *Carbonates.* Hydrated neptunium(V) carbonate, $NpO_2CO_3\cdot xH_2O$, and salts of hydrated carbonatocomplexes of the type $KM^VO_2CO_3\cdot xH_2O$ and $K_3M^VO_2(CO_3)_2\cdot xH_2O$ (M^V = Np, Pu) are included in Table 49 (p. 1180); the structure of $K_3NpO_2(CO_3)_2\cdot xH_2O$ is described on p. 1180. The basic structure of the salts $M^INpO_2CO_3\cdot xH_2O$ (M^I = Na, K) consists of $(NpO_2)CO_3$ layers with the M^+ cations distributed in between.[188] Anhydrous salts of carbonato complexes, $KM^VO_2CO_3$ (M^V = Np, Pu),[185] $NH_4PuO_2CO_3$ and $M^I_5NpO_2(CO_3)_3$ (M^I = K, Cs) have also been recorded.

(*d*) *Oxalates.* Hydrated oxalates and oxalato complex salts are included in Table 49, p. 1180. $(NpO_2)_2C_2O_4\cdot H_2O$ dehydrates at 180 °C and the anhydrous salt, $CsNpO_2C_2O_4$, has been recorded.

(*e*) *Polycarboxylates.* Salts of dioxoneptunium(V) mellitate and pyromellitate complex ions, $Na_4(NpO_2)_2(C_6(CO_2)_6)\cdot 8H_2O$ and $\{Na_3NpO_2(C_6H_2(CO_2)_4)\}_2\cdot 11H_2O$, have been reported; in the pyromellitate complex the NpO_2^+ ion is coordinated to four pyromellitate anions, the carboxylate oxygen atoms of which form a pentagon in the pentagonal bipyramidal coordination geometry.[189]

(*vi*) *Aliphatic and aromatic hydroxyacids*

(*a*) *Aliphatic hydroxyacids.* Uranium(V) 3-hydroxypropionates, formulated as $U(OEt)(OCH_2CH_2CO_2)_2$, $U(OEt)_3(OCH_2CH_2CO_2)$, $U(OCH_2CH_2CO_2)_2(HOCH_2CH_2CO_2)$ and $U_2(OCH_2CH_2CO_2)_5$, are obtained in the same way as the ethoxide monocarboxylates. Phenyl hydroxyacetates of composition $U(OR)_3(PhCH(O)CO_2)$, $U(OR)(PhCH(O)CO_2)_2$ (R = Et, Bu^t), $U(PhCH(O)CO_2)_2(PhCH(OH)CO_2)$ and $U_2(PhCH(O)CO_2)_5$ have been prepared in a similar manner.

(*b*) *Aromatic hydroxyacids.* The only recorded compounds appear to be the uranium(V) salicylates, $U(OEt)_3(OC_6H_4CO_2)$, $U(OEt)(OC_6H_4CO_2)_2$, $U_2(OC_6H_4CO_2)_5$, $HU(OC_6H_4CO_2)_3$ and the analogous *t*-butoxide salicylates, $U(OBu^t)_{5-2n}(OC_6H_4CO_2)_n$ (n = 1 or 2), obtained in the same way as the analogous alkoxide monocarboxylates.

(*vii*) *Amides,* P-*Oxides and* S-*Oxides*

(*a*) *Amides.* The only amide complex appears to be $U(OPh)_4Cl\cdot 2DMF$, obtained by reaction of $CsUCl_6$ with Na(OPh) in benzene under reflux, followed by extraction of the residue into DMF and evaporation of the extract to dryness. The reaction of UBr_5 with DMA in a mixture of acetone and dichloromethane results in disproportionation to the mixed oxidation state compound $[U^{VI}O_2(DMA)_5][U^{IV}Br_6]$.

(*b*) *Trichloroacryloyl chloride.* A product of composition $UCl_5\cdot Cl_2C{=}CClCOCl$ is obtained as an intermediate in the reaction of UO_3 with hexachloropropene (C_3Cl_6); its IR spectrum indicates that the acid chloride molecule is bonded to the metal atom *via* the carbonyl oxygen atom.

(*c*) P-*Oxides*. The known phosphine oxide complexes (Table 51) are nearly all derived from the actinide pentahalides. They are obtained from the pentahalide and the ligand in a non-aqueous solvent or by reaction of a chloro complex salt (*e.g.* $Cs[UCl_6]$) with the ligand in dichloromethane. $UBr_5 \cdot (Me_2N)_3PO$ is obtained by bromine oxidation of a 1:1 mixture of UBr_4 and the ligand in MeCN, and the complexes $UF_5 \cdot 2Ph_3PO$ and $UCl_2F_3 \cdot 2Ph_3PO$ have been isolated by addition of Ph_3PO to UF_5 and to UCl_2F_3 respectively. The structure of $[UCl_5(Ph_3PO)]$ is a slightly distorted octahedron.[190]

Table 51 Complexes of Actinide(V) Compounds with *P*-Oxides

$MX_5 \cdot R_3PO$	$R = n\text{-}C_8H_{17}$, M = U, X = Cl $R = Me_2N$, M = U, X = Br R = Ph, M = Pa, U, X = Cl, Br
$PaCl_5 \cdot Ph_2(PhCH_2)PO$	
$MX_5 \cdot 2Ph_3PO$	M = Pa, X = F, Cl, Br; M = U, X = F, Cl
$UCl_2F_3 \cdot 2Ph_3PO$	
$PaBr_5 \cdot (Ph_2PO)_2CH_2$	
$Pa(OEt)_2X_3 \cdot Ph_3PO$	X = Cl, Br
$PaOX_3 \cdot 2Ph_3PO$	X = Cl, Br
$NpO_2NO_3 \cdot 3(n\text{-}C_8H_{17})_3PO$	
$[NpO_2\{(n\text{-}C_8H_{17})_3PO\}_4]ClO_4 \cdot H_2O$	

(*d*) S-*Oxides*. The dimethyl sulfoxide complex, $Pa(trop)_4Cl \cdot DMSO$ appears to be the only known complex with this type of ligand. The thionyl chloride compound, $UCl_5 \cdot SOCl_2$, obtained by heating UO_3 with $SOCl_2$ in a sealed tube for 24 hours at 150–200 °C, is probably ionic, possibly $SOCl^+UCl_6^-$.

40.2.3.4 Sulfur ligands

(*i*) *Thiols*

A compound of composition $[UCl_4(SPh)]_2$, which is presumably a thiophenolate, is precipitated when diphenyl disulfide is added to a benzene solution of the trichloroacryloyl chloride complex, $UCl_5 \cdot Cl_2C{=}CClCOCl$.[174] The thioglycolate ester compounds $U(OEt)_{5-n}L_n$ ($HL = HSCH_2CO_2R$ with R = Me, Et or Bu^n and $n = 1, 2, 3, 4$ or 5) have been obtained by heating $U(OEt)_5$ with the appropriate quantity of the ester in benzene under reflux and the *t*-butoxide analogues $U(OBu^t)_{5-n}L_n$ ($n = 1, 2, 3$ or 4) have been prepared by treating the corresponding ethoxide compounds with Bu^{t}OH in benzene under reflux. An ethoxide-*p*-thiocresolate $U(OEt)(1\text{-}S\text{-}4\text{-}MeC_6H_4)_4$, thiosalicylate and thiolactate compounds of composition $U(OR)_{5-2n}L_n$ and $UL_2(HL)$ ($H_2L = 2\text{-}HSC_6H_4CO_2H$ or $C_2H_4(SH)CO_2H$, R = Et or Bu^t and $n = 1$ or 2) and the thiobenzoate $U_2(2\text{-}SC_6H_4CO_2)_5$ have been obtained in the same way as the ethoxide–thioester compounds. It is not clear whether the thiolactates[191] are α- or β-mercaptopropionates.

(*ii*) *Thiocarboxylates*

Alkoxide-thiobenzoates of composition $U(OR)_{5-n}(PhCOS)_n$ (R = Et or Bu^t and $n = 2$, 3 or 4) have been prepared in the same way as the thioglycollate ester analogues.

(*iii*) *Dithiocarbamates*

The only recorded complexes appear to be the protactinium(V) compounds, $Pa(Et_2NCS_2)_4X$ (X = Cl, Br), prepared by treating a suspension of the pentahalide in dichloromethane with an excess of $Na(Et_2NCS_2)$, followed by vacuum evaporation of the filtrate.

(*iv*) *Thiourea*

A product of composition $UF_5 \cdot 2SC(NH_2)_2$ has been obtained by treating UF_6 in methyl cyanide with thiourea; this may be a mixture of uranium(IV) and uranium(VI) species.

(*v*) *Phosphine sulfides*

The protactinium(V) complexes of composition PaX_5L (X = Cl, Br; R = Ph_3PS, $(Ph_2PS)_2CH_2$) have been recorded.

40.2.3.5 Selenium and tellurium ligands

(*i*) *Diphenyl diselenide and ditelluride*

The complexes $UCl_5 \cdot Ph_2X_2$ (X = Se or Te) are precipitated when a solution of the diselenide or ditelluride in benzene is added to a solution of the trichloroacryloyl chloride complex, $UCl_5 \cdot C_3Cl_4O$, in the same solvent.

(*ii*) *Phosphine selenides*

The protactinium(V) complexes PaX_5L (X = Cl, Br; L = Ph_3PSe, $(Ph_2PSe)_2CH_2$) have been recorded.

40.2.3.6 Halogens as ligands

(*i*) *Pentahalides*

Two modifications of UF_5 are known; in the high temperature form, α-UF_5, the structure consists of an infinite chain of UF_6 octahedra linked by opposite corners. The low temperature form, β-UF_5, with which PaF_5 and NpF_5 are isostructural, was originally thought to consist of an infinite chain of UF_7 pentagonal bipyramids[192], but is now known to be an eight-coordinate arrangement with the geometry intermediate between dodecahedral and square antiprismatic.[193] The structure of $PaCl_5$ is a chain of $PaCl_7$ pentagonal bipyramids[194] whereas UCl_5 is a dimer with UCl_6 octahedra sharing an edge.[195] β-$PaBr_5$ and UBr_5 are also dimers, like UCl_5. The only pentaiodide known is PaI_5.

Intermediate oxidation state fluorides, such as Pa_2F_9 and M_4F_{17} [M = Pa, U and Pu(?)] are also known.

(*ii*) *Oxohalides*

The main types of actinide(V) oxohalide are given in Table 52. The oxohalides can be prepared by heating the parent pentahalide with the appropriate quantity of oxygen; for example, Pa_2OCl_8 is obtained by this method at 400 °C. $NpOF_3$ has been prepared by heating the hydrate in dry HF at 100–150 °C.

Table 52 Actinide(V) Oxohalides

$M^V_2OX_8$	M^V = Pa, X = F, Cl; M^V = U, X = F
$NpOF_3$	
M^VOX_3	M^V = Pa, X = Br, I; M^V = U, X = Cl, Br
M^VO_2X	M^V = Pa, X = F, Cl, Br, I; M^V = U, X = Cl, Br; M^V = Np, X = F
$Pa_2O_3Cl_4$	
Pa_3O_7F	

The structure of $PaOBr_3$ consists of a polymer in which the protactinium atoms are surrounded by a slightly distorted pentagonal bipyramidal arrangement of three oxygen and four bromine atoms; two of the latter occupy the axial positions,[196] and the same geometry has been reported for UO_2Br, again with three oxygen and two bromine atoms in the equatorial plane.[197]

(*iii*) *Halogeno complexes*

Hexahalogeno complexes (Table 53) are well known; the cesium salts, $CsMF_6$, are readily obtained by fluorination of the tetrafluoride in the presence of cesium fluoride (M = Np, Pu) and others have been prepared by reaction of the pentafluoride with the cation fluoride; for example, reaction of CuF_2 with UF_5 in methyl cyanide yields $Cu[UF_6]_2$ which is reduced to $Cu[UF_6]$ by metallic copper.[198] In the compound $[(Ph_3P)_2N][UF_6]$ the anion is octahedral[199] as in the salts $Cs[M^VF_6]$ (M^V = U, Np, Pu), whereas the protactinium atom in $RbPaF_6$ is dodecahedrally coordinated.[200] In the protactinium(V) compounds of the type $M^I_2PaF_7$, the metal atom is surrounded by nine fluorine atoms in a slightly distorted tricapped trigonal prismatic array (K_2PaF_7 type),[201] while the salts $M^I_2UF_7$ and $Rb_2M^VF_7$ (M^V = Np, Pu) have the seven-coordinate (K_2TaF_7 type) structure. In the octafluoro complexes, $Na_3[M^VF_8]$ (M^V = Pa, U, Np), the coordination geometry is cubic.[202] The chloro complexes are obtained from the pentachloride and, in the case of uranium(V), from thionyl chloride solutions of $UCl_5{\cdot}SOCl_2$; examples are Cs_2UCl_7 and K_3UCl_8.[203] The anion in $[Ph_3(PhCH_2)P][UCl_6]$ is octahedral[204] and the structure of $PCl_4^+UCl_6^-$ has also been reported.[205]

Table 53 Actinide(V) Halogeno Complexes

$M^I[M^VF_6]$	M^V = Pa, M^I = Li, Na, K, Rb, Cs, NH_4, Ag
	M^V = U, M^I = Li, Na, K, Rb, Cs, NH_4, Ag, Tl, Cu, $(Ph_3P)_2N$, NO, NO_2
	M^V = Np or Pu, M^I = Cs
$Cu[UF_6]_2$	
$M^I_2M^VF_7$	M^V = Pa or U, M^I = K, Rb, Cs, NH_4

(*iv*) *Oxohalocomplexes*

A few salts of composition $(Et_4N)_2[M^VOX_5]$ (M^V = Pa, X = Cl, Br; M^V = U, X = F) are known; the uranium(V) compound is obtained from the dihydrate under vacuum, and the protactinium(V) chlorocompound is prepared by hydrolysis of the hexachloro complex salt in methyl cyanide containing 0.5% water. Salts of composition $(Et_4N)[Pa(OEt)_2X_4]$ (X = Cl, Br) are also known.

Difluorodioxoactinates(V), $M^IM^VO_2F_2$ (M^V = Np, M^I = K, Rb; M^V = Pu, M^I = Rb, NH_4) and the tetrachlorodioxoactinates(V), $Cs_3[M^VO_2Cl_4]$ (M^V = Np, Pu) are obtained from aqueous acid solutions of the actinide(V). $Cs_3[NpO_2Cl_4]$ and $Cs_3[PuO_2Cl_4]$ are isostructural and the $[M^VO_2Cl_4]^{3-}$ anion has a distorted octahedral geometry.[206]

A mixed oxidation state compound, $Cs_7(Np^VO_2)(Np^{VI}O_2)_2Cl_{12}$ is obtained by treating neptunium(V) hydroxide with ethanolic hydrochloric acid saturated with cesium chloride or from $Cs_3[Np^VO_2Cl_4]$ and hydrochloric acid.[207] The analogous neptunium(V)/uranium(VI) compound, $Cs_7(Np^VO_2)(U^{VI}O_2)_2Cl_{12}$, is isostructural with the Np^V/Np^V complex.[208] Products of the composition $M^I_2Np^VOCl_5$ (M^I = Cs, Ph_4As) obtained in a similar manner appear to be disproportionation mixtures.

40.2.3.7 Mixed donor atom ligands

(*i*) *Complexones*

The only compounds with this type of ligand appear to be the hydrated neptunium(V) complexes with ethylenediaminetetraacetic acid (H_4edta), $(NpO_2)_2H_2$(edta)·$5H_2O$ and $[Co(NH_3)_6]NpO_2$(edta)·$3H_2O$.

(*ii*) *8-Hydroxyquinolines*

Complexes in which 8-hydroxyquinoline acts as a neutral donor ligand, $UCl_5 \cdot xC_9H_7NO$ ($x = 2$ or 4), have been isolated from non-aqueous media. Hydrated dioxoneptunium(V) and dioxoplutonium(V) compounds of composition $Np^VO_2(C_9H_6NO)\cdot 2H_2O$, $M^VO_2L\cdot HL\cdot H_2O$ (M^V = Np, Pu; HL = 2-MeC_9H_6NO), $Pu^VO_2L\cdot 2HL\cdot xH_2O$ (HL = C_9H_7NO, x unspecified; 5-ClC_9H_6NO, $x = 1$; 5,7-$Cl_2C_9H_5NO$, $x = 2$) and $(Ph_4As)NpO_2(C_9H_6NO)_2\cdot H_2O$ have been obtained from aqueous solution.

40.2.4 The +6 Oxidation State

40.2.4.1 Group IV ligands

(*i*) *Cyanides*

The only recorded compound has the composition $K_2UO_2(CN)_2(NO_3)_2$; it was reported to be precipitated when a saturated solution of KCN in a 1:1 mixture of ethanol and ether was added to a solution of $UO_2(NO_3)_2\cdot 6H_2O$;[209] however, this was not confirmed in later work.[210]

(*ii*) *Isocyanides*

A cyclohexyl isocyanide complex with UO_2Cl_2 has been mentioned in the literature.[30]

40.2.4.2 Nitrogen ligands

The available IR data for the complexes with ureas indicate that the ligands are bonded to the metal *via* the carbonyl oxygen atom and these compounds are therefore discussed in the section on oxygen ligands.

(*i*) *Ammonia and amines*

(*a*) *Ammonia.* Although a number of ammonia adducts of dioxouranium(VI) compounds are known (Table 54), analogous neptunium(VI) and plutonium(VI) systems do not appear to have been investigated. The uranium(VI) complexes are obtained by treating the parent compounds with anhydrous liquid ammonia, with gaseous ammonia in a non-aqueous solvent or (the 7-methyl-8-hydroxyquinolate) by precipitation from aqueous solution in the presence of ammonia. The complexes with β-diketonates, originally reported as $UO_2(acac)_2\cdot NH_3$ and $UO_2(ba)_2$ (Hba = 1-phenylbutane-1,3-dione) are now known to be β-ketoimine adducts[211] but the analogous ammines $UO_2L_2\cdot NH_3$ (HL = $PhCOCH_2COPh$ and $CF_3COCH_2COCF_3$) are genuine compounds. In the molecule $[UO_2(CF_3COCHCOCF_3)_2(NH_3)]$ the coordination geometry is pentagonal bipyramidal;[212] this appears to be the only actinide ammine for which a crystallographic structure determination has been recorded. Basic compounds of composition $U_2O_5Cl_2\cdot xNH_3$ ($x = 2$ or 4), $(NH_4)_2UO_3Cl_2\cdot xNH_3$ ($x = 1$ or 2) and $(NH_4)_2U_2O_5Cl_3\cdot xNH_3$ ($x = 1$, 2, 4 or 7) have also been recorded.

(*b*) *Aliphatic and aromatic amines.* The known amine complexes, all with dioxouranium(VI) compounds (Table 55), are obtained in a similar manner to the actinide(IV) complexes (p. 1137).

Table 54 Ammonia Complexes of Dioxouranium(VI) Compounds

$UO_2F_2 \cdot xNH_3$	$x = 2$, 3 or 4
$UO_2Cl_2 \cdot xNH_3$	$x = 0.5$, 1, 2, 3, 4, 5 or 10
$UO_2Y_2 \cdot xNH_3$	Y = Br, I, $x = 2$, 3 or 4
$UO_2Y_2 \cdot xNH_3 \cdot Et_2O$	Y = Cl, Br, I, NO_3 and $x = 2$; Y = Cl, NO_3 and $x = 3$
$UO_2(NO_3)_2 \cdot xNH_3$	$x = 2$ or 4
$UO_2(NO_3)_2 \cdot 3NH_3 \cdot 2H_2O$	
$UO_2(NH) \cdot xNH_3$	$x = 1$ or 2
$UO_2Y_2 \cdot xNH_3$	Y = $MeCO_2$, $0.5SO_4$ and $x = 2$, 3 or 4; Y = HCO_2, $0.5C_2O_4$ and $x = 2$
$UO_2(OH)Y \cdot NH_3$	Y = HCO_2, $0.5C_2O_4$
$UO_2(C_{10}H_8NO)_2 \cdot NH_3$	$C_{10}H_9NO$ = 7-methyl-8-hydroxyquinoline
$UO_2(RCOCHCOR)_2 \cdot NH_3$	R = CF_3, Ph

Table 55 Amine Complexes of Dioxouranium(VI) Compounds

$UO_2Cl_2 \cdot 2RNH_2$	R = $PhNH_2$, $H_2NC_6H_4NO_2$, 2-, 3-, 4-$MeC_6H_4NH_2$, 2-, 3-$MeOC_6H_4NH_2$, 4-$EtOC_6H_4NH_2$, $H_2NC_6H_3$-3, 4-Me_2, 1-, 2-$H_2NC_{10}H_7$
$UO_2Cl_2 \cdot 2$ to $3RNH_2$	R = Me, Et, Pr^n, Bu^n
$UO_2Cl_2 \cdot R_2NH$	R_2 = Ph_2, $(PhCH_2)_2$, (Ph)(Et), (Ph)($PhCH_2$)
$UO_2Cl_2 \cdot 2L$	L = Ph_3N, PhCH=NPh, $Et_2N(C_2H_4OH)$
$UO_2(NO_3)_2 \cdot 2L$	L = $MeNH_2$, $PhNH_2$, 2-$H_2NC_6H_4OH$, Et_2NH, Et_3N
$UO_2(HCO_2)_2 \cdot 2MeNH_2$[a]	
$UO_2(MeCO_2)_2 \cdot 2RNH_2$	R = Me,[a] Ph
$UO_2(EtCO_2)_2 \cdot 2MeNH_2$[a]	
$UO_2SO_4 \cdot 2PhNH_2 \cdot 3H_2O$	
$UO_2C_2O_4 \cdot 2PhNH_2 \cdot 2H_2O$	
$UO_2(C_7H_3NO_4) \cdot 2C_3H_7N$	C_3H_7N = allylamine; $C_7H_5NO_4$ = pyridine-2,6-dicarboxylic acid
$UO_2A_2 \cdot L$	HA = H(acac) with L = Me_3N and Et_3N; $PhCOCH_2COPh$, $C_7H_6O_2$ (tropolone), C_9H_7NO (8-hydroxyquinoline) with L = $PhNH_2$
$[UO_2(S_2CNEt_2)_2(Et_2NH)]$	

[a] IR data are given in G. N. Mazo, N. A. Santalova and K. M. Dunaeva, *Sov. Radiochem. (Engl. Transl.)*, 1981, **23**, 547.

The structure of the complex with the *N,N*-diethyldithiocarbamate $[UO_2(S_2CNEt_2)_2(Et_2NH)]$ is pentagonal bipyramidal, with four sulfur atoms and the amine nitrogen atom in the equatorial plane.[213] No other structural information is available for the remaining amine complexes, but it is probable that the monoamine complexes of the β-diketonates, tropolonate and 8-hydroxyquinolinate, UO_2A_2L, have the same coordination geometry. The bis amine complexes of dioxouranium(VI) nitrate and the monocarboxylates, $UO_2A_2L_2$, may involve eight-coordinate uranium(VI) if the anions A^- are bidentate, in which case hexagonal bipyramidal geometry would be expected. In other *bis* amine complexes of the type $UO_2Cl_2L_2$ the geometry is presumably octahedral.

A number of aminoacid adducts, such as $UO_2(MeCO_2)_2 \cdot xH_2NCH_2CO_2H$ ($x = 1$, 2 or 3) have been recorded and in these the amino nitrogen is probably the only donor atom. Di- and tri-ethylamine adducts of several diolates are also known.

(*c*) *Hydrazines.* The only recorded complexes are those with dioxouranium(VI) compounds (Table 56). Very little is known about them.

Table 56 Complexes of Dioxouranium(VI) Compounds with Hydrazines

$UO_2X_2 \cdot 4L$[a]	X = Cl, Br, I, NO_3, NCS; L = N_2H_4, $PhNHNH_2$, Me_2NNH_2
$(UO_2Cl_2)_2 \cdot N_2H_4 \cdot 6H_2O$	
$UO_2X \cdot yN_2H_4 \cdot zH_2O$	X = SO_4, $y = 2$, $z = 0$; X = C_2O_4, $y = 1$, $z = 0.75$ and $y = 2$, $z = 1$
$UO_2SO_4 \cdot PhNHNH_2$	
$(UO_2)_2(OH)_2X_2 \cdot yN_2H_4 \cdot zH_2O$	X = Cl, $y = 1$, $z = 6$ and $y = 3$, $z = 0$; X_2 = SO_4, $y = 1$, $z = 0$

[a] A. K. Srivastava, R. K. Agarwal, V. Kapur, S. Sharma and P. C. Jain, *Transition. Met. Chem. (Weinheim, Ger.)*, 1982, **7**, 41.

(*d*) *Ethylenediamine and other diamines.* In addition to the complexes listed in Table 57, a considerable number of 1:1 complexes of dioxouranium(VI) Schiff base compounds with en and Me_4en are also known. No structural information is available for these compounds. The phosphate compound, UO_2HPO_4·en, precipitated when en is added to a 95% ethanol solution of $UO_2(NO_3)_2·2H_2O$ containing phosphate ion, is probably an ethylenediammonium salt, $(enH)UO_2PO_4$. The hydrated 2,3-diaminotoluene complex, $UO_2(NO_3)_2·2L·2H_2O$, is reported to be maroon violet,[214] a colour which is unusual for dioxouranium(VI) compounds.

Table 57 Complexes of Ethylenediamine and other Polydentate Nitrogen Ligands with Dioxouranium(VI) Compounds

Ethylenediamine, en	
$UO_2(NO_3)_2·x$en	$x = 1$ or 2
$UO_2(HPO_4)$·en (?)	
L = 1,2-diaminopropane	
$UO_2(NO_3)_2·L$	
L = hexamethylenetetramine, $(CH_2)_6N_4$	
$UO_2X_2·L$	X = NCS, $MeCO_2$
Diaminoarenes	
$UO_2Cl_2·xL$	$x = 1$ or 2, L = 1,2-diaminobenzene
$UO_2Cl_2·2L$	L = 1,3- or 1,4-diaminobenzene
$UO_2(NO_3)_2·2L·H_2O$	L = 1,2-diaminobenzene
$UO_2(NO_3)_2·xL·yH_2O$	$x = 3$, $y = 0$, L = 3,4-diaminotoluene; $x = y = 2$, L = 2,3-diaminotoluene
$UO_2SO_4·L·THF$	L = 4,4′-diaminobiphenyl (benzidine)

(*ii*) *N-Heterocyclic Ligands*

(*a*) *Pyridine, C_5H_5N, and derivatives.* The central metal atom in the complexes $UO_2Cl_2·2L$ (Table 58), where L is pyridine or a monosubstituted pyridine, is probably six-coordinate, whereas in the complexes UO_2X_2L in which X is a β-diketone, *N,N*-dialkyldithiocarbamate or 8-hydroxyquinolinate, and in $[UO_2(py)_5](ClO_4)_2$, the coordination number is almost certainly seven, with pentagonal bipyramidal geometry, as in the diethylamine complex $[UO_2(S_2CNEt_2)_2(NHEt_2)]$ (p. 1188). The metal atom is probably eight-coordinate in the complexes $UO_2Cl_2·4py$ and $UO_2(NO_3)_2·2py$, but this requires confirmation.

Table 58 Some Complexes of N-Heterocyclic Ligands with Dioxouranium(VI) Compounds

Pyridine and substituted pyridines	
$UO_2X_2·yL$	X = Cl, $y = 1$ (+H_2O) or 2, L = py; $y = 2$, L = 2-Me-, 3-Me- and 2-H_2N-C_5H_4N; $y = 4$, L = py
	X = NO_3, $y = 1$ (+H_2O or Et_2O) or 2, L = py
	X = OPh, O(2- or 4-MeC_6H_4), O(4-ClC_6H_4), $y = 1$, L = py
	X = O(2-MeC_6H_4), $y = 3$, L = py
	X = MeCOCHCOMe, MeCOCHCOPh, PhCOCHCOPh, $y = 1$, L = py
	X = MeCOCHCOMe, $y = 1$, L = 3- or 4-H_2N-, 4-HO-, 3- or 4-MeCO-, 3- or 4-NC-, 3-Cl-, or 4-Me-C_5H_4N
	X = S_2CNEt_2, $y = 1$, L = py, 4-Bu^t-, 4-Ph-, 4-$Ph(CH_2)_3$-, or 2-$(CHEt_2)$-C_5H_4N
	X = C_9H_6NO, $y = 1$, L = py; C_9H_7NO = 8-hydroxyquinoline
$UO_2X·ypy$	X = SO_4, $y = 2$ or 3; Cr_2O_7, $y = 2$; dibasic Schiff base anions, $y = 1$
$[UO_2(py)_5](ClO_4)_2$	
Piperidine, $C_5H_{11}CN$	
$UO_2L_2·C_5H_{11}N$	HL = $CF_3COCH_2CO(2\text{-}C_4H_3S)$ or n-$C_3F_7COCH_2COBu^t$
Quinolines	
$UO_2X_2·L$	X = NO_3, L = quinoline (+H_2O) or 2-methylquinoline (+H_2O)
	X = MeCOCHCOMe, L = quinoline
	X = C_9H_6NO (8-hydroxyquinolinate), L = quinoline
$UO_2SO_4·L$	L = 2-methylquinoline
$UO_2Cr_2O_7·2L$	L = isoquinoline

(*b*) *Piperidine,* $C_5H_{11}N$. 1:1 complexes with the β-diketonates $UO_2\{CF_3COCHCO(C_4H_3S)\}_2$ and $UO_2(n\text{-}C_3F_7COCH_2COBu^t)_2$ are known; in both cases the uranium atom is probably seven-coordinate.

(*c*) *Quinoline and isoquinoline,* C_9H_7N. The few known quinoline, isoquinoline and 2-methylquinoline complexes with dioxouranium(VI) compounds are included in Table 58. The uranium atom in the quinoline complexes with the acetylacetonate and 8-hydroxyquinolinate, $UO_2(acac)_2\cdot C_9H_7N$ and $UO_2(C_9H_6NO)_2\cdot C_9H_7N$, the uranium atom is presumably seven-coordinate.

(*d*) *2,2′-Bipyridyl, bipy, and 4,4′-bipyridyl,* $C_{10}H_8N_2$. In addition to the complexes listed in Table 59, a number of compounds with dioxouranium(VI) Schiff base products are also known. The complex with the cyanocyanamide, $UO_2[N(CN)_2]_2\cdot 2bipy$, is obtained by reaction of $UO_2(NO_3)_2$ with $K[N(CN)_2]$ and bipy.[215] The dioxoplutonium(VI) compound formulated as $PuO_2Cl_2(bipy\cdot HCl)_2$ should be regarded as the chloro complex salt, $(bipy\cdot H)_2[PuO_2Cl_4]$. $UO_2(MeCO_2)_2\cdot bipy$ and $UO_2(OH)(MeCO_2)\cdot bipy$ behave as non-electrolytes in water or methanol whereas $UO_2Cl_2\cdot bipy\cdot H_2O$ and $UO_2(NO_3)_2\cdot bipy$ behave as 1:1 electrolytes, $[UO_2Cl(H_2O)(bipy)]Cl$ and $[UO_2(NO_3)(bipy)](NO_3)$.[216]

Table 59 Complexes of 2,2′-Bipyridyl, bipy, and 4,4′-Bipyridyl, $C_{10}H_8N_2$, with Dioxouranium(VI) Compounds

$UO_2X_2\cdot y bipy$	X = Cl, NO_3, $MeCO_2$, 2-, 3- or 4-$H_2NC_6H_4CO_2$, $C_8H_4F_3S$ (tta), $y = 1$ X = NCS, NCSe, NO_3, $N(CN)_2$, $y = 2$
$UO_2X_2\cdot yC_{10}H_8N_2$	X = Cl, $y = 1$; X = NO_3, $y = 1.5$
$UO_2Cl_2\cdot bipy\cdot xH_2O$	$x = 1$ or 2
$UO_2(OH)X\cdot bipy$	X = NO_3, $MeCO_2$
$UO_2X\cdot y bipy$	X = SO_4, $y = 1$; X = Cr_2O_7, $y = 2$
$UO_2SO_4\cdot C_{10}H_8N_2$	
$UO_2X\cdot bipy\cdot yH_2O$	X = SO_4, $y = 4$; X = CrO_4, C_2O_4, $y = 1$

(*e*) *Imidazoles,* $C_3H_4N_2$. The only recorded complexes with this type of ligand appear to be those formed by 2-(2′-pyridyl)benzimidazole ($C_{12}H_9N_3$) with dioxouranium(VI) compounds, for which products of composition $UO_2X_2(C_{12}H_9N_3)$ (X = Cl, I, NO_3 or $0.5SO_4$), $UO_2(NCS)_2(C_{12}H_9N_3)_2$ and $UO_2(ClO_4)_2(C_{12}H_9N_3)_3$ have been reported.

(*f*) *Dipyridylalkanes.* Complexes of dioxouranium(VI) compounds with these ligands are listed in Table 60. Very little is known about them.

Table 60 Complexes of Dipyridylalkanes with Dioxouranium(VI) Compounds

1-(2-Pyridyl)-2-(3-pyridyl)ethane, $C_{12}H_{12}N_2$	
$UO_2(NCS)_2\cdot C_{12}H_{12}N_2\cdot H_2O$	
1-(3-Pyridyl)-2-(4-pyridyl)ethane, $C_{12}H_{12}N_2$	
$UO_2X_2\cdot yC_{12}H_{12}N_2$	X = NO_3, $MeCO_2$, $y = 1$ X = NCS, ClO_4, $y = 2$
1,2-Di(4-pyridyl)ethane, $C_{12}H_{12}N_2$	
$UO_2X_2\cdot 2C_{12}H_{12}N_2$	X = NCS, NO_3, ClO_4, $MeCO_2$
1,3-Di(4-pyridyl)propane, $C_{13}H_{14}N_2$	
$UO_2X_2\cdot C_{13}H_{14}N_2$	X = Cl, NO_3, $0.5SO_4$

(*g*) *Di(2-pyridyl)amine,* $C_{10}H_9N_3$. Dioxouranium(VI) compounds of composition $UO_2X_2\cdot yC_{10}H_9N_3$ (X = Cl, NCS, $y = 1$; X = NO_3, $0.5SO_4$, $y = 2$) have been reported. The imine nitrogen atom is probably not bonded to the uranium atom in these compounds.

(*h*) 1,10-*Phenanthroline, phen.* In addition to the compounds listed in Table 61, a few complexes with dioxouranium(VI) Schiff base compounds are also known. Conductivity measurements indicate that $UO_2Cl_2\cdot 2phen$ is ionic in methanol, $[UO_2(phen)_2]Cl_2$, whereas $UO_2Cl_2\cdot phen$ is a non-electrolyte and $UO_2(NCS)_2\cdot 2phen$ behaves as a 1:1 electrolyte, $[UO_2(NCS)(phen)_2]NCS$, in that solvent. Only one of the water molecules in the complex formulated as $(UO_2)_2(OH)_2SO_4(phen)_2\cdot 2H_2O$ appears to be bonded to the metal atom. A hydroxo-bridged structure has been suggested for the complex with the basic acetate, $UO_2(OH)(MeCO_2)\cdot phen$.

Table 61 Complexes of 1,10-Phenanthroline (phen) with Dioxouranium(VI) Compounds

UO_2X_2·phen	X = F,[a] Cl,[a] NO_3 (also $+0.5H_2O$),[a] $MeCO_2$ (also $+2.5H_2O$), Me_3CCO_2, 2-, 3- or 4-$H_2NC_6H_4CO_2$, $CF_3COCHCO(2\text{-}C_4H_3S)$, n-$C_3F_7COCHCOBu^t$, C_9H_6NO (8-hydroxyquinolinate)
UO_2X_2·2phen	X = Cl, NCS, NCSe, $N(CN)_2$[c]
UO_2X·phen	X = SO_3 ($+H_2O$),[b] SO_4 (also $+5H_2O$), CrO_4, $C_5H_3N(O)$-2,6-$(CO_2)_2$,[d] C_2O_4 ($+H_2O$)
$UO_2Cr_2O_7$·2phen	
$UO_2(OH)X$·phen·yH_2O	$y = 0$, X = $MeCO_2$; $y = 2$, X = Cl, NO_3; $y = 2.5$, X = NO_3
$UO_2(NO_3)X$·phen·yH_2O	$y = 0$, X = 2-$H_2NC_6H_4CO_2$; $y = 2$, X = 4-$H_2NC_6H_4CO_2$
$(UO_2)_2(OH)_2(SO_4)$·2phen·yH_2O	$y = 1$ or 2

[a] The corresponding 2,9-dimethyl-1,10-phenanthroline complexes are also known.
[b] R. N. Shchelokov, G. T. Bolotova and N. A. Golubkova, *Sov. J. Coord. Chem. (Engl. Transl.)*, 1977, **3**, 810.
[c] E. L. Ivanova, V. V. Skopenko and Kh. Keller, *Ukr. Khim. Zh. (Russ. Ed.)*, 1981, **47**, 1024 (*Chem. Abstr.*, 1982, **96**, 45232).
[d] Polymeric; S. Degetto, L. Baracco, M. Faggin and E. Celon, *J. Inorg. Nucl. Chem.*, 1981, **43**, 2413.

(*i*) *5-Methylpyrazole, $C_4H_6N_2$.* One complex only, $UO_2(S_2CNEt_2)_2$·$C_4H_6N_2$, has been recorded.

(*j*) *Pyrazine, C_4H_4N and derivatives.* Hydrated complexes of composition UO_2Cl_2·L·H_2O, where L = pyrazine, 2-methylpyrazine and 2,5- and 2,6-dimethylpyrazine, have been recorded.

(*iii*) *Triazenes, cyanates and thiocyanates*

(*a*) *Triazenes.* A few complexes with substituted 1,3,5-triazenes have been recorded, including those with the 2,4,6-tris(dimethylamino) derivative (hexamethylmelamine), UO_2Cl_2·$C_9H_{18}N_6$, and the hydrated complex with the tris(2-pyrimidyl) derivative, $UO_2(NO_3)_2$·$C_{15}H_9N_9$·$7H_2O$.

(*b*) *Cyanates.* The hydrated complex salt of composition $(Et_4N)_2[UO_2(NCO)_4(H_2O)]$ is precipitated when an acetone solution of $UO_2(NO_3)_2$·$6H_2O$ is added to an ethanol solution of $Et_4N(NCO)$[217] and a basic salt, $K_3[(U_2O_5)(NCO)_5]$·H_2O, has also been reported. There is IR evidence[218] for the formation of the cyanato complex anions $[UO_2(NCO)_4]^{2-}$ and $[UO_2Cl_3(NCO)]^{2-}$ in non-aqueous solutions containing $R_4N[UO_2Cl_3]$ and $R_4N[Ag(NCO)_2]$ (R = $C_{10}H_{21}$).

(*c*) *Thiocyanates.* The anhydrous and a number of hydrated forms of dioxouranium(VI) thiocyanate, $UO_2(NCS)_2$, are known, but no structural information is available for these. The complex thiocyanato anion is usually of the form $[UO_2(NCS)_5]^{3-}$ (Table 62), and in the cesium salt of this anion the coordination geometry is a distorted pentagonal bipyramid.[219] A few salts of tri-, tetra- and hexa-thiocyanato complex anions are also known, but no structural information is available for them. Mixed thiocyanato-acetato and -oxalato complexes have been recorded, as well as salts of complex anions of the type $[UO_2(NCS)_3L_2]^-$, where L is a neutral ligand, but very little is known about them.

Table 62 Dioxouranium(VI) Thiocyanate and Thiocyanato Complexes

$UO_2(NCS)_2$·xH_2O	$x = 0$, 1, 2 or 8
$M^I[UO_2(NCS)_3(H_2O)_x]$	$x = 0$, $M^I = N(C_{10}H_{21})_4$; $x = 2$, M^I = K, Rb and NH_4
$(NH_4)_2[UO_2(NCS)_4(H_2O)_x]$	$x = 0$ or 1
$M^I_3[UO_2(NCS)_5]$·xH_2O	$x = 0$, M^I = K, NH_4, Cs, Et_3NH, $N(C_{10}H_{21})_4$, bipyH
	$x = 1$, M^I = K, NH_4, Et_3NH, pyH, C_9H_7NH and $C_5H_{11}NH$
	$x = 2$ or 6, M^I = K, NH_4
$[Co(en)_3]_2[UO_2(NCS)_6](NO_3)_2$·$5H_2O$	
$\{N(C_{10}H_{21})_4\}_2[(UO_2)_3(NCS)_8]$	

(*iv*) *Nitriles*

Methyl cyanide complexes of composition UO_2X_2·yMeCN (X = Cl, $y = 1$; X = NO_3, $y = 2$; X = ClO_4, $y = 3$), $\{(C_{10}H_{21})_4N\}NpO_2Cl_3$·MeCN and UO_2SB·xMeCN, where SB represents a Schiff base anion, have been recorded. In the IR spectra of the last, the frequency of ν(CN) is

almost identical to that of the free ligand. A cyanogen chloride adduct, $UO_2Cl_2 \cdot NCCl$, is also known.

(v) *Oximes*

A wide variety of dioxouranium(VI) aldoxime and ketoxime complexes of composition UO_2L_2 are known. Examples of the ligands used are 2-hydroxy-naphthaldehydeoxime, $HOC_{10}H_6CH{=}NOH$, salicylaldoxime, $HOC_6H_4CH{=}NOH$, isatin α- and β-oximes and substituted 2-hydroxyacetophenone oximes.[220] In the structure of the 1,2-naphthoquinone-2-oxime complex, $[UO_2L_2(H_2O)_2] \cdot 2CHCl_3$, the coordination geometry is hexagonal bipyramidal.[221]

40.2.4.3 Oxygen ligands

(i) *Aqua Species, hydroxides and oxides*

(a) *Aqua species.* A short selection of the very wide range of aquated actinide(VI) compounds is given in Table 63. Although the hydrated thiocyanato complex salts have been reported as $M^I[UO_2(NCS)_3(H_2O)_2]$ (M^I = K, Rb, NH_4), the number of bonded water molecules is uncertain. The coordination geometry of the anion in $(enH_2)[UO_2F_4(H_2O)]$ is pentagonal bipyramidal[222] and the same coordination geometry has been found for the uranium atom in $UO_2(MeCO_2)_2 \cdot 2H_2O$, in which only one water molecule is bonded to the metal atom. Half of the acetate groups are chelated to individual uranium atoms, and the remainder link adjacent bipyramids to form chains.[223] In the hydrated oxalate, $UO_2C_2O_4 \cdot 3H_2O$, each uranium atom is again seven-coordinate in a pentagonal bipyramidal array with four oxygen atoms from two independent C_2O_4 groups and one from the water molecule in the equatorial plane; the C_2O_4 groups are tetradentate in this structure.[224]

$Na_4NpO_2(O_2)_3 \cdot 9H_2O$	

[a] M. A. Nabar and V. J. Iyer, *Bull. Soc. Fr. Mineral. Crystallogr.*, 1977, **100**, 272.

Four crystal modifications of $[UO_2(acac)_2(H_2O)]$ have been reported; in the β form the molecular geometry is a pentagonal bipyramid with four oxygen atoms from the acac groups and one from the water molecule in the equatorial plane.[225]

The compounds of composition $M^I_2U_2O_5Cl_4{\cdot}2H_2O$ (M^I = Rb, Cs), obtained by the reaction of $UO_2(OH)_2$ with $M^IUO_2Cl_4{\cdot}xH_2O$ (M^I = Rb, $x = 2$ and M^I = Cs, $x = 0$), are actually $M^I_2[(UO_2)_4O_2Cl_8(H_2O)_2]{\cdot}2H_2O$, with the uranium atoms in the equatorial plane of a pentagonal bipyramidal arrangement of triply bridging oxygen and doubly bridging chlorine atoms.[226] In the analogous hydrated basic chloride, $K_2(UO_2)_4O_2(OH)_2Cl_4{\cdot}6H_2O$, the structure consists of discrete tetranuclear $[(UO_2)_4O_2(OH)_2Cl_4(H_2O)_4]^{2-}$ ions, with four almost parallel OUO groups linked through double oxo or mixed oxo-chloro or oxo-hydroxo bridges; there are two coordination sites, both pentagonal bipyramidal, one with three oxygen and two chlorine atoms, and the other with four oxgyen and one chlorine atoms in the equatorial plane.[227]

It has been reported[228] that $UO_2HPO_4{\cdot}3H_2O$ behaves as a solid ionic conductor because of H^+ mobility across the water network in the compound, and it appears that the two-dimensional network of hydrogen bonds serves as the conduction path.[229] In the IR spectra of the perchlorate hydrates, $UO_2(ClO_4)_2{\cdot}xH_2O$, the ClO_4 groups appear to be ionic for $x = 5$ and 7, but covalent and monodentate for $x = 3$. Structural information on other hydrated dioxoactinide(VI) compounds is included in the following sections which deal with the parent compounds.

(*b*) *Hydroxides.* The trioxide monohydrates, $M^{VI}O_3{\cdot}H_2O$ (M^{VI} = U, Np, Pu), can be regarded as hydroxides, $M^{VI}O_2(OH)_2$; however, the IR spectrum of $NpO_2(OH)_2{\cdot}H_2O$ does not appear to exhibit any feature assignable to the O═Np═O group.[230] The neptunium(VI) and plutonium(VI) compounds are obtained by ozone oxidation of aqueous suspensions of neptunium(V) and plutonium(IV) hydrated oxides; they cannot be dehydrated and decompose on heating to lower oxides.

The basic compound of composition $Zn(UO_2)_2SO_4(OH)_4{\cdot}1.5H_2O$ involves tridentate bridging OH groups; the structure consists of chains of pentagonal bipyramidal $UO_2(OH)_3O_2$ groups.[231] Many other hydroxo complexes, such as $TlUO_2(OH)_2(MeCO_2)$ and $M^I_3[UO_2(OH)(C_2O_4)_2]$ (M^I = Na, K, Et_2NH_2, CN_3H_6), have been recorded, but structural information is lacking for them.

(*c*) *Oxides.* UO_3 is the only anhydrous trioxide known, but a number of actinide(VI) ternary oxides have been recorded. The principal types are $M^I_2M^{VI}O_4$ (M^{VI} = U, Np, Pu[232]; M^I = Li, Na, K, Rb, Cs), $M^{II}M^{VI}O_4$ (M^{VI} = U, M^{II} = Mg, Ca, Sr, Ba; M^{VI} = Np, M^{II} = Ca, Sr, Ba; M^{VI} = Pu, M^{II} = Ca, Sr), $Li_4M^{VI}O_5$ (M^{VI} = Np, Pu), $M^{II}_2UO_5$ (M^{II} = Ca, Sr), $M^{II}_3UO_6$ (M^{II} = Ca, Sr, Ba), $Li_2U_3O_{10}$, $Cs_2Np_3O_{10}$,[232] $Li_6M^{VI}O_6$ (M^{VI} = Np, Pu) and[232] $M^I_2Np_2O_7$ (M^I = K, Rb, Cs).

The structure of the anion in $Li_2U_3O_{10}$ ($= Li_2[(UO_2)_3O_4]$) consists of octahedral $(UO_2)O_4$ and pentagonal bipyramidal $(UO_2)O_5$ groups linked by oxygen bridges.[231]

(*d*) *Superoxides and peroxides.* The only simple actinide(VI) peroxide appears to be the hydrated compound, $UO_4{\cdot}2H_2O$, which is probably of the form $[UO_2(O_2)(H_2O)_2]$. Hydrated salts of peroxo complex anions, such as $Na_4M^{VI}O_2(O_2)_3{\cdot}9H_2O$ (M^{VI} = U, Np) have been mentioned earlier, and complexes of composition $[U(O)(O_2)_2L_2]{\cdot}H_2O$, L = Ph_3PO, Ph_3AsO, pyNO) have also been reported.[233]

$UO_4{\cdot}2H_2O$ reacts with hydrated dioxouranium(VI) oxalate, $UO_2(C_2O_4){\cdot}H_2O$ in the presence of aqueous alkali oxalate to form salts of peroxooxalato complex anions, $M^I_6[(UO_2)_2(\mu\text{-}O_2)(C_2O_4)_4]$ (M^I = Na, K, Rb). Salts of the peroxocarbonato complex anion, $[(UO_2)_2(\mu\text{-}O_2)(CO_3)_4]^{6-}$, are obtained in a similar manner.[234] Other reported salts of peroxooxalato and peroxocarbonato complex anions include $M^I_2[UO_2(O_2)(C_2O_4)]$ (M^I = Na, K, NH_4), $M^I_4[(UO_2)_2(O_2)_2(C_2O_4)_2(H_2O)]_4{\cdot}2H_2O$ (M^I = Na, K), $Na_8[(UO_2)_2(O_2)_2(C_2O_4)_4]{\cdot}7H_2O$, $K_2[UO_2(O_2)(CO_3)(H_2O)_2]{\cdot}xH_2O$, $K_4[UO_2(O_2)(CO_3)_2]$ and $K_8[(UO_2)_2(O_2)(CO_3)_5]$.

(*iii*) *Alcohols, alkoxides and aryloxides*

(*a*) *Alcohols.* A considerable number of alcohol adducts of dioxouranium(VI) compounds have been recorded, some of which are listed in Table 64. They are obtained either as the primary product in the preparation of the parent compound using an alcohol as the solvent, or by treating the parent compound with an alcohol. For example, $UO_2Cl_2{\cdot}2EtOH$ is obtained by dissolving the hydrated chloride in a mixture of ethanol and benzene, the displaced water being

	L = $OC_6H_4CH{=}NC_6H_4N{=}CHC_6H_4O$, R = Et
$UO(OR)_4 \cdot ROH$	R = Pr^i, Bu^s, Bu^t
$U_2O_5(OR)_2 \cdot 2ROH$	R = Pr^i, Bu^s, Bu^t

[a] L. Rodehuser, P. R. Rubini, K. Bokolo and J. J. Delpuech, *Inorg. Chem.*, 1982, **21**, 1061.

removed as the H_2O—EtOH—C_6H_6 azeotrope, followed by evaporation of the solution to dryness under reduced pressure.

The coordination geometry about the uranium atom in the ethanol complex of the tropolonate, $[UO_2(trop)_2(EtOH)]$, is a distorted pentagonal bipyramid[235] and the same geometry has been found for the alcohol complexes with the 2,2,6,6-tetramethylheptane-3,5-dionate (thd), $[UO_2(thd)_2(MeOH)]$,[236] and with the Schiff base compounds, $[UO_2(MeC(O){=}CHCOCH{=}C(Me)NHCH_2CH_2NHC(Me){=}CHCOCH{=}C(O)Me)(MeOH)]$,[237] $[UO_2(OC_6H_4CH{=}NCH_2CH_2N{=}CHC_6H_4O)(MeOH)]$[238] and $[UO_2(OC_6H_4CH{=}NC_6H_4N{=}CHC_6H_4O)(EtOH)]$.[239] In the last two compounds two oxygen and two nitrogen atoms from the Schiff base anion and the alcohol oxygen atom take up the equatorial plane positions, whereas in the first three compounds four oxygen atoms are provided by the anion or anions and one by the alcohol molecule.

(*b*) *Alkoxides.* The main types of uranium(VI) alkoxide are summarized in Table 65. The hexaalkoxides, $U(OR)_6$, are monomeric, slightly volatile, but thermally unstable compounds. $U(OEt)_6$ was originally prepared by oxidation of $Na[U(OEt)_6]$ with benzoyl peroxide, and this was then used as the starting material to prepare other hexaalkoxides by reaction with higher alcohols, but the most convenient preparative route to compounds of this type is *via* $U(OMe)_6$, which can be obtained by the reaction of UF_6 with $Si(OMe)_4$ in dichloromethane, followed by alcohol exchange as above. The compound $U(OMe)F_5$ has been prepared by reaction of UF_6 with the stoichiometric quantity of MeOH at 90 °C in $CFCl_3$ and other fluoride alkoxides, $U(OMe)_{6-n}F_n$ ($n = 2$–5), have been obtained by reaction of UF_6 with the appropriate quantities of $U(OMe)_6$ or $Me_3Si(OMe)$. $U(OEt)_5Cl$ has been prepared by reaction of $U(OEt)_6$ with the stoichiometric quantity of dry hydrogen chloride in ether.

Table 65 Uranium(VI) Alkoxides

$U(OR)_6$	R = Me, Et, Pr^n, Pr^i, Bu^n, Bu^s, Bu^t, CH_2CMe_3
$U(OBu^t)_5(OMe)$	
$U(OMe)_{6-n}F_n$	$n = 1$ to 5
$U(OEt)_5Cl$	
$UO(OR)_4 \cdot ROH$	R = Pr^i, Bu^s, Bu^t
$U_2O_5(OR)_2 \cdot 2ROH$	R = Pr^i, Bu^s, Bu^t
$UO_2(OR)_2$	R = Me, Et, Pr^n, *i*-C_5H_{11}, *t*-C_5H_{11}

The monooxoalkoxides, $UO(OR)_4 \cdot ROH$, result from the reaction of $UO_2(OMe)_2 \cdot MeOH$ with the appropriate alcohol, and the isopropoxide of this type has also been obtained by reaction of UO_2Cl_2 in Pr^iOH with ammonia or $NaOPr^i$, apparently as a result of disproportionation:

$$3UO_2(OR)_2 \cdot ROH \xrightarrow{ROH} UO(OR)_4 \cdot ROH + U_2O_5(OR)_2 \cdot 2ROH(\text{solid})$$

The nature of these products is unknown, but they may be mixed oxidation state U^V/U^{VI} species. Dioxouranium(VI) alkoxides, $UO_2(OR)_2$, and some alcohol solvates are also known.

(*c*) *Aryloxides.* The only aryloxides known are the dioxouranium(VI) compounds

$UO_2(OR)_2$ with R = 2-$MeOC_6H_4$ or 1-$NOC_{10}H_6$-2, and the products formed when $UO_2(MeCO_2)_2$ is dissolved in a carbon tetrachloride solution of a phenol in the presence of an amine; these may be salts of the form $M^I_2[UO_2(OR)_4]$ where R = Ph, 2- or 4-MeC_6H_4 with $M^I = Et_2NH_2$ or Et_3NH, and R = 2- or 4-ClC_6H_4 with $M^I = Et_3NH$.

(*d*) *Silyloxides.* The only recorded compounds are $U(OSiR_3)_6$ (R = Me, Et), $U\{OSi(Me_2Et)\}_6$ and $U\{OSi(MeEt_2)\}_6$, prepared by reaction of $U(OEt)_6$ with a slight excess of the trialkylsilanol in benzene under reflux.

(*iv*) *β-Ketoenolates, tropolonates, catecholates, quinones, ethers, ketones, aldehydes and esters*

(*a*) *β-Ketoenolates.* In a few instances the β-ketoenol can act as a neutral ligand, as in $UO_2(NO_3)_2 \cdot 2PhCOCH_2CO(2\text{- or } 4\text{-}C_5H_4N)$, but the common type of complex is of composition UO_2L_2, for which a wide range of compounds is known (Table 66). In the compound $UO_2(PhCOCHCOCO_2H)_2$, the carboxylate group is probably bonded to the metal atom. Several β-ketoamide complexes, such as $UO_2(MeCOCHCONHR)_2 \cdot MeCOCH_2CONHR$ (R = Ph, 2-ClC_6H_4, 2-$MeOC_6H_4$, 2-MeC_6H_4, 3,5-$Me_2C_6H_3$) and $UO_2(MeCOCHCONHR)_2 \cdot 2H_2O$ (R = Ph, 3-$O_2NC_6H_4$), as well as a considerable number of complexes derived from cyclic β-diketones, such as 2-hydroxy-1-naphthaldehyde, 2-hydroxybenzaldehyde, 1-hydroxyanthracene-9,10-dione and pyrimidine-2,4,6-trione (barbituric acid), are also known.

$UO_2(MeCOCHCO\{\eta\text{-}C_6H_5Cr(CO)_3\})_2 \cdot H_2O$

(*b*) *Tropolonates.* Tropolonates of composition $M^{VI}O_2(trop)_2$ (M^{VI} = U, Pu), $M^{VI}O_2(trop)_2 \cdot Htrop$ (M^{VI} = U, Pu) and $UO_2(trop)_2 \cdot H_2O$ have been recorded, as well as complexes of composition UO_2L_2 with ligands related to tropolone, such as 3-hydroxy-2-methyl-4*H*-thiopyran-4-one (thiomaltol) and 3-hydroxy-2-methyl-4*H*-pyran-4-one (maltol; trihydrate), and derivatives of more complex 1,2-diketones.

(*c*) *Catecholates.* Pyrocatecholates of composition $UO_2(1,2\text{-}C_6H_4O_2) \cdot xH_2O$ (x = 1 or 3) and $(pyH)H[UO_2(1,2\text{-}C_6H_4O_2)(OH)] \cdot H_2O$, as well as the resorcinol compound, $UO_2(1,3\text{-}C_6H_4O_2)$, have been reported.

(*d*) *Quinones.* A complex of composition UO_2L_2, where HL = 2-hydroxy-1,4-naphthaquinone, is known.

(*e*) *Ethers.* Several complexes of dioxouranium(VI) compounds with ethers have been reported (Table 67). In the case of $[UO_2(NO_3)_2(THF)_2]$ the eight-coordination geometry is hexagonal bipyramidal, with four oxygen atoms from two bidentate nitrate groups and two oxygen atoms from the THF molecules in the equatorial plane.[240] The coordination geometry in the THF complexes with dioxouranium(VI) *N*-phenylbenzohydroxamate (L) chloride, $[UO_2Cl(L)(THF)_2]$,[241] and the volatile hexafluoroacetylacetonate, $[UO_2(CF_3COCHCOCF_3)_2(THF)]$,[242] are pentagonal bipyramidal. In the former the equatorial plane positions are occupied by two hydroxamate and two THF oxygen atoms, together with the chlorine atom.

(*f*) *Ketones.* A selection of complexes of dioxouranium(VI) compounds with ketones is given in Table 68. In the dibenzylidene acetone complex, $[UO_2Cl_2\{(PhCH{=}CH)_2CO\}_2] \cdot 2MeCO_2H$, the acetic acid molecules, which were introduced when the complex was

recrystallized from that acid, are not bonded to the uranium atom and the octahedral six-coordinate geometry is made up of two *trans* ketone oxygen atoms, two *trans* chlorine atoms and the two *trans* oxygen atoms of the UO_2 group.[243]

(*g*) *Aldehydes.* Very few complexes with aldehydes are known. The formaldehyde complex of dioxouranium(VI) phosphite, $UO_2(HPO_3) \cdot 2HCHO \cdot H_2O$, has been obtained from aqueous solution[244] and the 2-furaldehyde complex $UO_2(NO_3)_2 \cdot OC_4H_3CHO \cdot H_2O$, has also been reported.[245] The anhydrous complex, $UO_2(NO_3)_2 \cdot H_2NCH{=}CHCH{=}CHCHO$, is obtained by irradiation of $UO_2(NO_3)_2 \cdot py \cdot EtOH$ in ethanol at 254 nm; the IR spectrum of the compound indicates that the aldehyde molecule is bonded to the uranium atom *via* the carbonyl oxygen atom only.

(*h*) *Esters.* Complexes of composition $UO_2X_2 \cdot 2RCO_2R'$ (X = Cl, R = Me, R' = Et; X = NO_3, R = R' = Me and R = Me, H_2N, MeNH and Me_2N with R' = Et) are obtained by vacuum evaporation of a solution of anhydrous UO_2Cl_2 in the ester (R = Me, R' = Et), whereas the ethyl carbamate complexes are prepared by heating the parent nitrate with an excess of the molten ester at 70 to 100 °C for one to two hours. The coordination geometry about the uranium atom in $[UO_2(NO_3)_2(H_2NCO_2Et)_2]$ is an irregular hexagonal bipyramid, with the equatorial positions occupied by four oxygen atoms from the two bidentate nitrate groups and two carbonyl oxygen atoms from the ester molecules.[246] An ill-defined methyl formate complex, $UO_2(NO_3)_2 \cdot xHCO_2Me$, has been recorded, and ethyl carbamate complexes of the tropolonate, $UO_2(trop)_2 \cdot H_2NCO_2Et$, and the basic acetate, $[UO_2(MeCO_2)(OH)(H_2NCO_2Et)]_n$, are also known. Polymeric ethyl carbamate complexes, $[UO_2X(L)]_n$, have also been recorded for X = C_2O_4, C_6H_4-1,2-$(CO_2)_2$ and C_5H_3-2,6-$(CO_2)_2$.

(*V*) *Oxoanions as ligands*

(*a*) *Nitrates.* Hydrated dioxoactinide(VI) nitrates, $M^{VI}O_2(NO_3)_2 \cdot 6H_2O$ (M^{VI} = U, Np, Pu), are included in Table 63 (p. 1192). A product of composition $NpO_2(NO_3)_2 \cdot N_2O_5 \cdot H_2O$ is obtained by vacuum evaporation of a solution of $NpO_3 \cdot H_2O$ in N_2O_5; this may be $H_2NpO_2(NO_3)_4$, but the normal nitrato complex anions are $[M^{VI}O_2(NO_3)_3]^-$ (M^{VI} = U, Np,

Pu), for which alkali metal, ammonium and tetraalkylammonium salts are known. The salts $M^I[M^{VI}O_2(NO_3)_3]$ (M^{VI} = U, Np, Pu with M^I = K, Rb, Cs, NH_4) are isostructural.[247] The anion in $Rb[NpO_2(NO_3)_3]$ consists of a hexagonal bipyramidal arrangement of oxygen atoms about the neptunium atom, with six oxygen atoms from the bidentate nitrate groups in the equatorial plane.[248] The IR spectra of $Rb[M^{VI}O_2(NO_3)_3]$ (M^{VI} = U, Np, Pu) have been reported.[249]

(*b*) *Phosphites and phosphates.* A phosphite of composition $UO_2(H_2PO_2)_2$ is precipitated from aqueous solution and the salts $NaUO_2(H_2PO_2)_3 \cdot xH_2O$ ($x = 3.5$ or 5) are also known. Treatment of $UO_2(NO_3)_2$ with KH_2PO_3 or K_2HPO_3 in aqueous solution yields products of composition $K_2(UO_2)_2(HPO_3)_3 \cdot 4H_2O$, and other hydrated salts of this type with Na, Rb, Cs or NH_4 in place of K, as well as $Ba(UO_2)_2(HPO_3)_3 \cdot 6H_2O$, have also been obtained. Other salts of composition $M^IUO_2(HPO_3)(H_2PO_3) \cdot nH_2O$ (M^I = Na, K, Rb, Cs, NH_4), and $BaUO_2(HPO_3)(H_2PO_3)_2 \cdot 5H_2O$, are obtained by treating the corresponding $M^I_2UO_2(HPO_3)_2$ with a three- to five-fold excess of H_3PO_3.[250] Several hydrated phosphates and phosphato complexes are included in Table 63 (p. 1192).

In the structure of the phosphato complex, $K_4UO_2(PO_4)_2$, the coordination geometry about the uranium atom is described as a tetragonal bipyramid with four oxygen atoms from four tetrahedral PO_4^{3-} groups in the equatorial plane, making up a $[UO_2(PO_4)_2]_n^{4n-}$ layer structure.[251] The phosphate of composition $UO_2H(PO_3)_3$ is obtained[252] by heating $UO_2(NO_3)_2 \cdot 6H_2O$ with 85% H_3PO_4 at 340–380 °C and the salt $NaUO_2(PO_3)_3$ crystallizes[253] from 85% H_3PO_4 at 360 °C.

The pyrophosphates $M^I_2UO_2P_2O_7$ (M^I = Na, K, Rb, Cs) have been prepared by heating $UO_2(NO_3)_2 \cdot 6H_2O$ with $(NH_4)_2HPO_4$ in the presence of the alkali metal pyrophosphate or nitrate.[254] The rubidium and cesium compounds are isostructural and in the latter, layers of $UO_2P_2O_7^{2-}$ groups are held together by cesium ions. The UO_2^{2+} ion is coordinated by four oxgyen atoms from four P_2O_7 groups in the equatorial positions of a tetragonal bipyramid.[255]

(*c*) *Arsenates.* A number of hydrated arsenates are included in Table 63 (p. 1192). Products of composition $UO_2HAsO_4 \cdot 4H_2O$, $UO_2(H_2AsO_4)_2 \cdot H_2O$, $(UO_2)_3(AsO_4)_2$, $(UO_2)_2As_2O_7$ and $UO_2(AsO_3)_2$ have also been reported.[256]

(*d*) *Sulfites.* Hydrated dioxouranium(VI) sulfite is precipitated when aqueous $UO_2(NO_3)_2$ is treated with sodium thiosulfate;[257] it is completely dehydrated at 130–150 °C. The sulfito complex, $[Co(NH_3)_6]_4[UO_2(SO_3)_3]_3 \cdot 22H_2O$, is precipitated from aqueous solution,[258] and a basic compound of composition $bipyH[(UO_2SO_3)_2(OH)(H_2O)_2]$ has also been reported.[259]

(*e*) *Sulfates.* Dioxouranium(VI) sulfate hydrates, $UO_2SO_4 \cdot xH_2O$ (x = 1, 2, 2.5, 3 or 4), and the fluorosulfate, $UO_2(SO_3F)_2$, have been recorded; the last is obtained[86] by treating $UO_2(MeCO_2)_2$ with HSO_3F. Salts of sulfato complex anions, such $M^I_2UO_2(SO_4)_2 \cdot 2H_2O$ (M^I = K, NH_4), $(NH_4)_4UO_2(SO_4)_3 \cdot 4H_2O$ and $(NH_4)_2(M^{VI}O_2)_2(SO_4)_3 \cdot 5H_2O$ (M^{VI} = U, Pu), have been recorded. Other known salts include $M^{II}UO_2(SO_4)_2 \cdot xH_2O$ (M^{II} = Ni, Zn, $x = 4$; M^{II} = Cu, $x = 3$), $M^{II}(UO_2)_3(SO_4)_5 \cdot xH_2O$ (M^{II} = Mn, $x = 5$; M = Cd, $x = 2$; M = Hg, $x = 3$), $Co_3UO_2(SO_4)_4 \cdot H_2O$, $Ce(UO_2)_2(SO_4)_4 \cdot 3H_2O$[261] and the two isomorphous hexammine cobalt(III) salts,[262] $\{[Co(NH_3)_6]HSO_4\}_2[M^{VI}O_2(SO_4)_3] \cdot xH_2O$ (M^{VI} = U, Np), all of which are obtained from aqueous solution.

The coordination geometry about the uranium atom in $(NH_4)_2UO_2(SO_4)_2 \cdot 2H_2O$ is pentagonal bipyramidal, with sulfate groups joining the polyhedra to make up a layered structure.[263] The structure of $K_4UO_2(SO_4)_3$ involves the anion $[(SO_4)_2UO_2(SO_4)_2UO_2(SO_4)_2]^{8-}$, in which each UO_2 group is bonded to five oxygen atoms from four non-equivalent sulfate groups in the equatorial plane of a pentagonal bipyramid.[264] The structure of $MgUO_2(SO_4)_2 \cdot 11H_2O$ consists of infinite layers of composition $[UO_2(SO_4)_2(H_2O)]_n^{2n-}$ in which the coordination geometry about the uranium atoms is also pentagonal bipyramidal,[265a] and the same coordination geometry has been found for the metal atom in $NH_4UO_2SO_4F$, in which the equatorial plane is made up from three O atoms from three tridentate sulfate groups together with two bridging fluorine atoms.[265b] Crystallographic data for the hydrated salts $M^{II}UO_2(SO_4) \cdot 5H_2O$ (M^{II} = Mg, Fe, Co, Ni, Cu, Zn, Mn, Cd) are also available.[266]

(*f*) *Selenates.* Hydrated dioxouranium(VI) selenate, $UO_2SeO_4 \cdot 4H_2O$, is not isostructural with $UO_2SO_4 \cdot 4H_2O$; its structure consists of an infinite strip, $[UO_2SeO_4(H_2O)_2]_\infty$, with the equatorial positions of the pentagonal bipyramidal arrangement of oxygen atoms surounding each uranium atom occupied by the oxygen atoms from three monodentate SeO_4 groups and two water molecules.[267] Hydrated salts of the selenato complex anion, $M^{II}UO_2(SeO_4)_2 \cdot 6H_2O$ (M^{II} = Mg, Co, Zn), are also known.[268]

(*g*) *Tellurites.* Compounds of composition $UTeO_5(UO_3 \cdot TeO_2)$ and $UTe_3O_9(UO_3 \cdot 3TeO_2)$ are obtained by heating UO_3 with the appropriate quantity of TeO_2. The structure of $UTeO_5$

consists of infinite chains, $[UO_5]_n^{4n-5}$, in which pentagonal bipyramidal UO_7 groups share edges,[269] whereas UTe_3O_9 involves eight-coordinate uranium in which the UO_2^{2+} group is surrounded by six oxygen atoms in a flattened octahedral array.[270] The structure of the lead compound, $Pb_2UO_2(TeO_3)_3$, prepared by hydrothermal treatment of a stoichiometric mixture of PbO, $UO_2(MeCO_2)_2{\cdot}2H_2O$ and TeO_2 at 230 °C, consists of UO_7 pentagonal bipyramids in sheets, $[UO_2(TeO_3)_3]_n^{4n-}$, connected by Pb atoms.[271]

(*vi*) *Carboxylates, carbonates and nitroalkanes*

(*a*) *Monocarboxylates.* Most of the available information concerns dioxouranium(VI) compounds and very few neptunium(VI) or plutonium(VI) analogues have been reported (Table 69). The hydrated formate, $UO_2(HCO_2)_2{\cdot}H_2O$, precipitates when solid $UO_2(NO_3)_2{\cdot}xH_2O$ is added to anhydrous formic acid and when aqueous $UO_2(NO_3)_2$ is heated with an excess of the acid. The structure of the compound consists of an infinite chain of seven-coordinate (pentagonal bipyramidal) uranium units linked by bridging HCO_2 groups and by hydrogen bonds involving the water molecules.[272] The monohydrated neptunium(VI) and plutonium(VI) formates are isostructural with the uranium(VI) compound.[273] The anhydrous formate is obtained by washing the hydrate with dry methanol or by heating it at 105–170 °C. The basic formate, $UO_2(OH)(HCO_2){\cdot}H_2O$, is obtained by hydrolysis of $UO_2(HCO_2)_2{\cdot}H_2O$; the structure again consists of a pentagonal bipyramidal arrangement of oxygen atoms about the uranium atom with the uranium atoms doubly bridged by OH groups and linked to the two second nearest neighbouring uranium atoms *via* HCO_2 groups. The pentagonal plane is completed by the water oxygen atom.[274]

In the structure of $Na[UO_2(HCO_2)_3]{\cdot}H_2O$ the coordination arrangement is also pentagonal bipyramidal, with the bipyramids connected through two types of bridging bidentate HCO_2 groups and linked with the Na^+, H_2O layers by a third type of bridging bidentate HCO_2 group.[275] The tetraformato complex salt, $(NH_4)_2UO_2(HCO_2)_4$, is obtained when a solution of $UO_2(HCO_2)_2$ in aqueous HCO_2H and HCO_2NH_4 is evaporated and then cooled; the pentagonal bipyramidal coordination geometry is made up of two oxygen atoms from one bidentate HCO_2 group, and the remaining three HCO_2 groups bridge U and N atoms, making a layer structure.[276] The strontium salt, $SrUO_2(HCO_2)_4.1{\cdot}38H_2O$, obtained when a hot solution of $Sr(HCO_2)_2{\cdot}2H_2O$ and $UO_2(HCO_2)_2{\cdot}H_2O$ in aqueous formic acid is cooled slowly from 80 °C, shows a similar arrangement in which the HCO_2 groups bridge either two U atoms or one Sr and one U atom.[277]

The structure of the 2,6-dihydroxybenzoate, $[UO_2\{(HO)_2C_6H_3CO_2\}_2(H_2O)_2]{\cdot}8H_2O$ consists of an irregular hexagonal bipyramidal arrangement with two bidentate carboxylate groups and two H_2O molecules in *trans* positions in the equatorial plane.[278b]

Five crystal modifications of anhydrous $UO_2(MeCO_2)_2$ have been reported. The structure of the dihydrate consists of chains of pentagonal bipyramidal coordination polyhedra in which half of the $MeCO_2$ groups link adjacent bipyramids and the remainder are chelated to individual uranium atoms; one water molecule is bonded to each uranium atom.[278a]

The coordination polyhedron of the anion in $Na[UO_2(MeCO_2)_3]$ is a hexagonal bipyramid with three bidentate $MeCO_2$ groups in the equatorial plane[279] and this has also been found for the anion in $Na[NpO_2(MeCO_2)_3]$.[248] Hexagonal bipyramidal geometry has also been reported for the anthracene-9-(or 10)-carboxylate, $[UO_2(C_{14}H_9CO_2)_2(H_2O)_2]{\cdot}3C_4H_8O_2$; the dioxane molecules are not bonded to the uranium atom, and the six equatorial positions of the bipyramid are occupied by four oxygen atoms from two bidentate carboxylate groups and two oxygen atoms from the water molecules.[280] The IR spectra of $Na[M^{VI}O_2(MeCO_2)_3]$ (M^{VI} = U, Np or Pu) have also been reported.[249] The coordination geometry in the crotonate, $[UO_2(C_4H_5O_2)_2(H_2O_2)]$, is similar to that of the anthracene carboxylate, with the oxygen atoms of two bidentate carboxylate groups and two water molecules coordinated to the UO_2^{2+} ion.[281]

The precipitation of salts $M^IM^{II}[UO_2(RCO_2)_3]_3$ (Table 69) has been used for the gravimetric determination of alkali metals (particularly M^I = Li and Na). For this purpose an anhydrous product is desirable, but in many cases hydrates of varying composition are obtained.

Salts of basic species, such as $TlUO_2(MeCO_2)(OH)_2$, and of mixed thiocyanato/carboxylato anions, such as $Cs_3(UO_2)_3(MeCO_2)_7(NCS)_2$, have been reported, but require further investigation. A variety of halo- and mercapto-propionates, $UO_2(RCO_2)_2$, are also known.

(*b*) *Chelating carboxylates.* Furan-2- and thiophene-2-carboxylates are included in Table 70 because the heterocyclic oxygen or sulfur atoms may be bonded to the metal atom. The

[a] Hydrated.

pyridine-2-carboxylates, $M^{VI}O_2(NC_5H_4CO_2\text{-}2)_2$ (M^{VI} = U, Np, Pu), precipitate from aqueous solutions of the actinide(VI) in the presence of the acid, but at lower pH and higher $NC_5H_4CO_2H$-2 concentrations the acid salts $HM^{VI}O_2(NC_5H_4CO_2\text{-}2)_3$ are obtained. In the case of the *N*-oxopyridine-2-carboxylates, $M^{VI}O_2(ONC_5H_4CO_2\text{-}2)_2$, the primary products are hydrated, but are easily dehydrated at 120 °C. Similarly, the hydrated pyridine-3-carboxylates lose water at 160 °C (U) or 130 °C (Pu). In addition to the compounds listed in Table 70, 6-methylpyridine-2-carboxylates of composition UO_2L_2, HUO_2L_3 and $UO_2L(OH) \cdot 3H_2O$ (dehydrated at 95 °C) are known (L = 6-$MeC_5H_3CO_2$-2).

The pyridine-2,6-dicarboxylate groups in the polymeric compound $[UO_2(C_7H_3NO_4)(H_2O)]_n$ are terdentate to each uranium atom and each of the $UO_2(C_7H_3NO_4)$ units is linked to an adjacent unit through one of the carboxylate group oxygen atoms; the slightly distorted pentagonal bipyramidal coordination of the uranium atom is completed by the oxygen atom of the coordinated water molecule.[282] The coordination geometry of the anion in $(AsPh_4)_2[UO_2(C_7H_3NO_4)_2] \cdot 6H_2O$ is an irregular hexagonal bipyramid with four oxygen and

two nitrogen atoms of the two terdentate pyridine-2,6-dicarboxylate groups in the equatorial plane.[283]

In the structure of the dimeric *N*-oxopyridine-2,6-dicarboxylate, $[UO_2(ONC_5H_3(CO_2)_2)(H_2O)_2]_2 \cdot 2H_2O$, the two units of the dimer are bridged by carboxylate group oxygen atoms and the coordination geometry is pentagonal bipyramidal, with one oxygen atom each from a monodentate carboxylate group, a bridging group and the *N*-oxide, and two from the water molecules, all in the equatorial plane.[284]

Both carboxylate groups in the iminodiacetate, $UO_2\{HN(CH_2CO_2)_2H\}_2$, are ionized, with the extra proton linked to the imino nitrogen atom. The iminodiacetate groups bridge UO_2^{2+} ions in infinite chains, with one CO_2 group of each ligand monodentate and one bidentate to two adjacent uranium atoms, making up an irregular hexagonal bipyramid about each uranium atom.[285] In the polymeric iminodiacetate, $[UO_2\{HN(CH_2CO_2)_2\}]_n$, each UO_2^{2+} ion is bonded to two carboxylate oxygen atoms, the imino nitrogen atom of one $HN(CH_2CO_2)_2$ group and oxygen atoms from two other dicarboxylate ligands to form an irregular pentagonal bipyramid.[286] The polymeric oxydiacetate, $[UO_2\{O(CH_2CO_2)_2\}]_n$, has the same coordination geometry, with the ether oxygen atom in place of the imino nitrogen atom.[287] In the anion of the oxydiacetato complex, $Na_2[UO_2\{O(CH_2CO_2)_2\}_2] \cdot 2H_2O$, each $O(CH_2CO_2)_2$ group is terdentate, making up an irregular hexagonal bipyramid about the uranium atom.[288]

(*c*) *Carbonates.* The main types of carbonato complex are listed in Table 71; in addition, peroxocarbonato and fluorocarbonato complexes, such as $K_4[UO_2(O_2)(CO_3)_2]$ and $K_3[UO_2F_3(CO_3)]$, are also known. The coordination geometry about the uranium atom in UO_2CO_3 is approximately hexagonal bipyramidal, with two bidentate and two monodentate carbonate groups in the equatorial plane.[289] The tricarbonato complex anion in $(NH_4)_4[UO_2(CO_3)_3]$ is a distorted hexagonal bipyramid with three bidentate carbonate groups in the equatorial plane[290] and the same geometry has been reported for the anion in $K_4[UO_2(CO_3)_3]$.[291]

[a] The assignment of water molecules within the coordination sphere requires confirmation.
[b] Yu. Ya. Kharitonov and A. I. Moskvin, *Sov. Radiochem.* (*Engl. Transl.*), 1973, **15**, 240.
[c] J. D. Navratil, US report RFP-1760, 1971 (*Chem. Abstr.*, 1972, **77**, 66876).

(*d*) *Oxalates.* Only one water molecule is bonded to the metal in $UO_2C_2O_4 \cdot 3H_2O$; the pentagonal bipyramidal coordination geometry is made up of four oxygen atoms from two independent C_2O_4 groups and one from the water molecule in the equatorial plane. Each C_2O_4 group is tetradentate, bridging two UO_2^{2+} ions.[292]

In addition to the salts of the type $M^I[UO_2(C_2O_4)_2]$ listed in Table 72, a wide range of hydrates are also known; some have been reported in the form $M^I_2[UO_2(C_2O_4)_2(H_2O)_x] \cdot yH_2O$ without adequate justification. The coordination geometry in the polymeric anion $[UO_2(C_2O_4)_2]^{2n-}_n$ of the ammonium salt is approximately pentagonal bipyramidal, with one bidentate C_2O_4 group and one C_2O_4 group which is bidentate to one uranium atom and monodentate to a second uranium atom.[293] The oxalate groups in the anion of $(NH_4)_4[UO_2(C_2O_4)_3]$ are all bidentate, giving rise to distorted hexagonal bipyramidal coordination geometry,[294] whereas in the polymeric anion of $(NH_4)_2[(UO_2)_2(C_2O_4)_3]$ the coordination geometry is pentagonal bipyramidal, with one quadridentate C_2O_4 group coordinated to two uranium atoms and the other bidentate to one and unidentate to a second uranium atom, forming infinite double chains,[295] $[(C_2O_4)UO_2(C_2O_4)UO_2(C_2O_4)]^{2n-}_n$. In $K_6[(UO_2)_2(C_2O_4)_5] \cdot 10H_2O$, the coordination geometry is again pentagonal bipyramidal, with two oxygen atoms each from two bidentate C_2O_4 groups and one from the bridging C_2O_4 group in the equatorial plane.[296]

A number of basic oxalates, such as $(UO_2)_2C_2O_4(OH)_2 \cdot 2H_2O$, and salts of basic oxalato complex ions of the types $M^I_3UO_2(C_2O_4)_2(OH)$ and $M^I_5(UO_2)_2(C_2O_4)_4(OH)$ have also been reported, as well as salts of a wide range of peroxo-, halogeno-, sulfito-, sulfato-, selenito-, selenato-, thiocyanato- and carbonato-oxalato complex anions: all need further investigation.

(*e*) *Other dicarboxylates.* A number of peroxomalonato compounds, such as $K_4[(UO_2)_2\{CH_2(CO_2)_2\}_3(O_2)(H_2O)_4]$, have been recorded in addition to the compounds listed in Table 73. The anion in $(NH_4)_2[UO_2\{CH_2(CO_2)_2\}_2] \cdot H_2O$ is polymeric, with one malonate group bidentate to one uranium atom and the second terdentate, with two oxygen atoms bonded to one uranium atom and one to an adjacent uranium atom, producing infinite chains in which the coordination geometry about the uranium atom is approximately pentagonal bipyramidal.[297] The coordination geometry in the polymeric anions of the salts

Table 72 Dioxoactinide(VI) Oxalates

$M^{VI}O_2C_2O_4{\cdot}3H_2O$	M^{VI} = U, Np,[b] Pu[b]
$UO_2C_2O_4{\cdot}xH_2O$	x = 0 or 1
$M^I_2[UO_2(C_2O_4)_2]$[a]	M^I = Li, Na, K, Rb, Cs, NH_4, Tl, CN_3H_6

$K_6[(NpO_2)_2(C_2O_4)_5]{\cdot}2–4H_2O$[b]	

[a] Hydrates are also known.

[b] M. P. Mefod'eva, M. S. Grigor'ev, T. V. Afonos'eva and E. B. Kryukov, *Sov. Radiochem.* (*Engl. Transl.*), 1981, **23**, 565. The neptunium(VI) and plutonium(VI) compounds are isostructural with their uranium(VI) analogues.

$M^{II}[UO_2\{CH_2(CO_2)_2\}_2]{\cdot}3H_2O$ (M^{II} = Sr, Ba) is similar, except that the terdentate malonate group in these salts has a boat conformation whereas a chair conformation is adopted in the ammonium salt.[298] The coordination geometry in the succinate, $[UO_2\{C_2H_4(CO_2)_2\}(H_2O)]_n$ is an irregular pentagonal bipyramid, with four carboxylate oxygen atoms from four different succinate groups and one from the water molecule in the equatorial plane.[299]

Table 73 Dioxouranium(VI) Dicarboxylates

Malonates	$UO_2\{CH_2(CO_2)_2\}$
	$M^I_2[UO_2\{CH_2(CO_2)_2\}_2]$, M^I = Li, Na, K, Rb, Cs, NH_4
	$M^{II}[UO_2\{CH_2(CO_2)_2\}_2]{\cdot}3H_2O$, M^{II} = Sr, Ba
Succinates	$UO_2\{C_2H_4(CO_2)_2\}{\cdot}xH_2O$, x = 1, 2 or 3
	$Ca[UO_2\{C_2H_4(CO_2)_2\}_2]$
Fumarate and maleate	$UO_2\{cis$- or *trans*-$CH{=}CH(CO_2)_2\}$
	$(NH_4)_2[UO_2\{cis\text{-}CH{=}CH(CO_2)_2\}_2]$
Glutarate	$UO_2\{(CH_2)_3(CO_2)_2\}$
	$M^I[(UO_2)_2\{(CH_2)_3(CO_2)_2\}_3]$, M^I = Li, Na, K
	$UO_2\{(CH_2)_3(CO_2)_2\}{\cdot}LiH\{(CH_2)_3(CO_2)_2\}{\cdot}4H_2O$
Benzenedicarboxylates	$UO_2\{C_6H_4(CO_2)_2\}$ 1,2-, 1,3- and 1,4-dicarboxylates; hydrates are also known

In the glutarate of composition $UO_2(C_5H_6O_4){\cdot}Li(C_5H_7O_4){\cdot}4H_2O$, one glutarate group bridges the UO_2^{2+} ions in infinite chains and the other bridges UO_2^{2+} and Li^+ ions, the coordination geometry about the uranium atom being hexagonal bipyramidal;[300] the same coordination geometry has been reported for the hydrated fumarate, $UO_2(C_4H_2O_4)(H_2O)_2$, in which fumarate groups bridge the UO_2^{2+} ion in chains, and the water molecules are *trans* in the hexagonal ring.[301]

(*f*) *Carbamates.* The only recorded compound of this type appears to be $UO_2(Et_2NCO_2)_2$, which is precipitated when the uranium(IV) carbamate, $U(Et_2NCO_2)_4$, is oxidized in heptane.

(*g*) *Hexacarboxylates.* A mellitate (benzene-1,2,3,4,5,6-hexacarboxylate), $(UO_2)_3\{C_6(CO_2)_6\}{\cdot}12H_2O$, has been recorded.

(*h*) *Nitroalkanes and nitroarenes.* The nitromethane solvate, $UO_2(ClO_4)_2{\cdot}2MeNO_2$, is obtained by treating the anhydrous perchlorate with nitromethane, either alone or in solution in carbon tetrachloride, followed by evaporation of the resulting solution in the latter case. The ClO_4 groups may be covalent and bidentate in this product. Complexes of the corresponding nitrate, $UO_2(NO_3)_2{\cdot}2RNO_2$ (R = Me, Ph) crystallize from saturated solutions of $UO_2(NO_3)_2$ in RNO_2. The complex $UO_2(NO_3)_2{\cdot}MeNO_2$ has also been reported, and in this the $MeNO_2$ molecule may be bidentate.

(*vii*) *Aliphatic and aromatic hydroxyacids*

(*a*) *Aliphatic hydroxyacids.* A considerable number of dioxouranium(VI) compounds with aliphatic hydroxyacids are known (Table 74); alkali metal and barium salts of tartrato complexes, such as $Na_2[UO_2(C_4H_4O_6)_2]{\cdot}2H_2O$, have also been recorded. The glycolate,

$UO_2(HOCH_2CO_2)_2$, is obtained on cooling a warm aqueous solution of the acid which has been saturated with UO_3. The polymeric structure consists of infinite chains of pentagonal bipyramidal $UO_2(O)_5$ units with two sets of glycolate groups, one tridentate, which is bonded to one uranium atom and bridges two other uranium atoms, and the other bidentate, which bridges two uranium atoms.[302] Salts of the type $M^I[UO_2(HOCH_2CO_2)_3]$ are not known and very little information is available for the other compounds listed in Table 74.

Table 74 Some Dioxoactinide(VI) Compounds with Aliphatic Hydroxyacids

$UO_2(RCO_2)_2$	R = $HOCH_2$, PhCHOH (also $+2H_2O$), $Ph_2C(OH)(+2H_2O)$, MeCHOH (also +2 or $5H_2O$), MeC(OH)Ph ($+2H_2O$), $HOCH_2CHPh$, 2-$HOC_6H_4CH_2CH_2$
$PuO_2(C_6H_{13}CHOHCO_2)_2$	1-Hydroxycaprylate

$UO_2(PhCH(O)CO_2)\cdot 2H_2O$	
$M^I_2[UO_2\{PhCH(O)CO_2\}_2]$	M^I = Na, K, NH_4, pyH
$M^I[(UO_2)_2(O)(HOCH_2CO_2)_2(OH)(H_2O)]$	M^I = Na, Cs
$Na_2[UO_2\{Ph_2C(O)CO_2\}_2]$	
$UO_2\{C(OH)_2(CO_2)_2\}$	Mesoxalate
$UO_2\{HOCHCH_2(CO_2)_2\}\cdot xH_2O$	Malate; x = 0, 1 or 3
$K[UO_2\{OCHCH_2(CO_2)_2\}\cdot H_2O]$	Malate
$[Co(NH_3)_6]_2[UO_2\{HOCHCH_2(CO_2)_2\}_2]_3\cdot xH_2O$	Malate; x = 0 or 2
$UO_2\{(CHOH)_2(CO_2)_2\}\cdot xH_2O$	Tartrate; x = 1 or 4
$K_2[UO_2\{(CHOH)_2(CO_2)_2\}_2]\cdot 2H_2O$	Tartrate
$[(UO_2)_2\{cis\text{-}O_2CC(O)=C(O)CO_2\}(H_2O)_2]_2$	Dihydroxymaleate
$UO_2\{(CHOH)_3(CO_2)_2\}\cdot xH_2O$	Trihydroxyglutarate; x = 1 or 1.5
$UO_2(C_6H_6O_7)\cdot 4H_2O$	$C_6H_8O_7$ = citric acid, $HOC(CH_2CO_2H)_2CO_2H$
$(UO_2)_3(C_6H_5O_7)_2\cdot 2H_2O$	Citrate
$[Co(NH_3)_6]_2[UO_2(C_6H_6O_7)_2]_3\cdot 4H_2O$	Citrate

(*b*) *Aromatic hydroxyacids*. In addition to the hydroxybenzoates listed in Table 75, a number of compounds derived from substituted hydroxybenzoic acids have been recorded; a 2,3,4-trihydroxybenzoate (pyrogallate) and salts of complex anions derived from 3,4,5-trihydroxybenzoic acid (gallic acid) are also known.

Table 75 Some Dioxouranium(VI) Compounds with Aromatic Hydroxyacids

$UO_2(2\text{-}HOC_6H_4CO_2)_2\cdot xH_2O$	x = 0, 2, 3, 5 or 9
$[UO_2\{(2\text{-}HOC_6H_4CO_2)(NO_3)\}\{4\text{-}Me_2NC_5H_4N\}_2]_2$	
$M^I[UO_2(2\text{-}HOC_6H_4CO_2)_3]$	M^I = K, NH_4 ($+4H_2O$)
$M^I_2[UO_2(2\text{-}OC_6H_4CO_2)_2]\cdot xH_2O$	M^I = Na, x = 9; K, x = 2 or 10; NH_4, x = 13
$UO_2(3\text{-}HOC_6H_4CO_2)_2\cdot 6H_2O$	
$pyH[UO_2(3\text{-}HOC_6H_4CO_2)_3]\cdot 7H_2O$	
$UO_2(4\text{-}HOC_6H_4CO_2)_2\cdot 4H_2O$	
$pyH[UO_2(4\text{-}HOC_6H_4CO_2)_3]\cdot 4H_2O$	
$UO_2(2,4\text{-}(HO)_2C_6H_3CO_2)_2\cdot 10H_2O$	β-Resorcylate
$UO_2(2,5\text{-}(HO)_2C_6H_3CO_2)_2\cdot 3H_2O$	Gentisate
$UO_2(3,4\text{-}(HO)_2C_6H_3CO_2)_2\cdot 8.5H_2O$	Protocatechuate

The salicylato nitrato complex, $[\{UO_2(2\text{-}HOC_6H_4CO_2)(NO_3)\}\{(4\text{-}Me_2N)C_5H_4N\}_2]_2$, is obtained when the aminopyridine is added to a mixture of $UO_2(NO_3)_2\cdot 6H_2O$ and 2-$HOC_6H_4CO_2H$ in methanol. In this compound the pyridine molecules are not coordinated to the uranium atoms, but are hydrogen bonded to the phenolic oxygen atom of the salicylate group. The hexagonal bipyramidal arrangement of oxygen atoms about each uranium atom in the dimer is made up of one carboxylate oxygen from each of the two salicylate groups which bridge the two uranium atoms, and the second carboxylate oxygen atom of one salicylate group and the phenolic oxygen atom of the other, together with two oxygen atoms from the bidentate nitrate group.[303] In the structure of the *p*-aminosalicylato complex anion in $Na[UO_2(2\text{-}HO\text{-}4\text{-}H_2NC_6H_3CO_2)_3]\cdot 6H_2O$, the coordination geometry is again hexagonal bipyramidal, with the six carboxylate oxygen atoms from three nearly planar aminosalicylate groups in the equatorial plane.[304]

(viii) Amides, carboxylic acid hydrazides, ureas, N*-oxides,* P*-oxides,* As*-oxides and* S*-oxides*

(a) Amides and related compounds. The normal preparative route for complexes with these ligands (Table 76) is from the parent compound, usually hydrated, and an excess of the ligand in a non-aqueous solvent; in most cases the complex crystallizes on addition of a small amount of ether or a hydrocarbon to the solution. In some instances the complexes have been obtained from aqueous solution. The complexes with the peroxide chloride, formulated as $ClL_2UO_2(\mu_2\text{-}O_2)UO_2L_2Cl$ (L = DMF or DMA), in which the bridging O_2^{2-} group appears to act as a tetradentate ligand, are obtained by treating the complexes $UO_2Cl_2L_2$ with H_2O_2 in aqueous ethanol.[305]

In the polymeric acetamide complex of the chromate, $[UO_2CrO_4(MeCONH_2)_2]_n$, the structure consists of chains of $(UO_2)O_5$ pentagonal bipyramidal coordination polyhedra in which the equatorial plane is made up from three oxygen atoms from $[CrO_4]^{2-}$ tetrahedra and two from the acetamide molecules.[306] Similarly, in the dimeric DMA complex with the acetate, $[UO_2(MeCO_2)_2(DMA)]_2$, the structure consists of two pentagonal bipyramidal polyhedra

bridged by two bidentate acetate groups, the other two acetate groups each chelating a uranium atom.[307]

Several complexes with ligands related to amides, such as lactams, lactones and antipyrine (atp) have also been recorded (Table 77); apart from preparative and IR spectroscopic information, little is known about them. The precipitation of $UO_2(NCS)_2 \cdot 3atp$ from aqueous acid in the presence of thiocyanate has been used as a method for the determination of uranium in minerals.

Table 77 Some Complexes of Lactams, Lactones and Antipyrine (atp) with Dioxouranium(VI) Compounds

(*b*) *Carboxylic acid hydrazides.* The IR spectra of many of the known complexes with this type of ligand (Table 78) suggest that the hydrazides are bidentate, with bonding to the metal atom *via* a carbonyl oxygen and a hydrazine nitrogen atom in the case of the ligands $RCONHNH_2$.

Table 78 Some Complexes of Carboxylic Acid Hydrazides with Dioxouranium(VI) Compounds

(*c*) *Ureas.* A very large number of urea complexes with dioxouranium(VI) compounds are known, a selection of which is given in Table 79. In all of them the urea, or substituted urea, molecules are bonded to the metal atom through the carbonyl oxygen atom. The complex $UO_2F_2 \cdot 3urea$ is obtained by treating $UO_2F_2 \cdot 2H_2O$ with urea in aqueous solution, and the dimeric complex, $[UO_2F_2(urea)_2]_2$, in which two pentagonal bipyramidal $[UO_2F_3(urea)_2]$ groups share a common F(1)—F(1′) edge, is obtained in the same way by slow crystallization from dilute aqueous solutions.[308] The coordination geometry in the complex $[UO_2(urea)_4(H_2O)](NO_3)_2$ is again pentagonal bipyramidal, with four urea and one water molecule oxygen atoms in the equatorial plane[309] and the structure of the dimeric basic iodide, $[UO_2(OH)(urea)_3]_2I_4$, is made up of two pentagonal bipyramidal UO_7 units bridged along one edge by two hydroxyl groups.[310] The same coordination geometry has been reported for the complex with the phosphite,[311] $[UO_2(HPO_3)(NH_2CONMe_2)(H_2O)]$ and for the cation in the complex $[UO_2(MeCO_2)(urea)_3]^+$ $[UO_2(MeCO_2)_3]^-$ (= $UO_2(MeCO_2)_2 \cdot 1.5urea$), in which two oxygen atoms from the chelating acetate group and three from the urea molecules lie in the equatorial plane.[307]

The structures of three urea complexes of dioxouranium(VI) sulfate have also been reported. In the bis complex, $UO_2SO_4 \cdot 2urea$, the structure consists of infinite ribbons of OUO groups

[c] V. I. Spitsyn, V. V. Kolesnik, V. E. Mistryukov, Yu. N. Mikhailov and K. M. Dunaeva, *Dokl. Chem.*, 1983, **268/273**, 362.

coordinated to two urea oxygen atoms and to three oxygen atoms from tridentate sulfate groups, making an approximately pentagonal bipyramidal arrangement about each uranium atom,[312] and in $UO_2SO_4 \cdot 3$urea the polymeric structure is similar, with three urea oxygen atoms and one oxygen each from two bridging bidentate sulfate groups.[313] The same coordination geometry has been found for $[UO_2SO_4(urea)_4]$ in which the four oxygen atoms from the urea molecules and one from a monodentate sulfate group lie in the equatorial plane.[314]

(*d*) N-*Oxides*. A selection of the known Me_3NO and pyNO complexes with dioxouranium(VI) compounds is included in Table 80; in addition, a large number of pyridine *N*-oxide complexes with β-diketonates, $UO_2L_2 \cdot pyNO$, and many complexes with substituted pyridine *N*-oxides, quinoline and isoquinoline *N*-oxides, 2,2′-bipyridyl *N*-oxide and 2,2′-bipyridyl *N,N′*-dioxide have also been recorded. Several complexes with *p*-nitroso *N,N*-dimethyl and -diethylaniline are also known; they are precipitated when an ethanol solution of UO_2X_2 (X = Cl, Br, NO_3 or $MeCO_2$) or UO_2X (X = SO_4 or C_2O_4) is treated with the ligand in the same solvent; their IR spectra indicate that the ligand is bonded to the uranium atom *via* the nitroso oxygen atom only.

The uranium atom in $[UO_2(Et_2NCS_2)_2(Me_3NO)]$ is seven-coordinate, with four sulfur and one oxygen atom from the amine oxide in the equatorial plane of a pentagonal bipyramid[315]

	X = $O(CH_2CO_2)_2$, $y = 1$ (polymer) or 2
	L = 2-MeC_5H_4NO; X = ONC_5H_3-2,6-$(CO_2)_2$, $y = 2$[a]

[a] S. Degetto, L. Baracco, M. Faggin and E. Celon, *J. Inorg. Nucl. Chem.*, 1981, **43**, 2413.

and the coordination geometry in $[UO\{O(CH_2CO_2)_2\}(pyNO)_2]$ is probably the same, with three oxygen atoms from the $O(CH_2CO_2)_2$ group, including the ether oxygen atom, and the two *N*-oxide oxygen atoms bonded to the UO_2 group.[288]

(*e*) P-*Oxides*. In addition to the complexes listed in Table 81, several 1:1 complexes of $UO_2(NO_3)_2$ with bis(dialkylphosphinyl)alkanes, $R_2P(O)(CH_2)_nP(O)R_2$, and many complexes of phosphine oxides, phosphate and phosphonate esters, $(RO)_3PO$ and $(RO)_2R'PO$, with dioxouranium(VI) β-diketonates and Schiff base compounds have been recorded.

In the complexes $[M^{VI}O_2Cl_2L_2]$, *trans* octahedral geometry has been reported for $M^{VI} = U$ with $L = (Me_2N)_3PO$[316] or Ph_3PO[317] and for $M^{VI} = Np$ with Ph_3PO;[318] in the complexes $[M^{VI}O_2(NO_3)_2(Ph_3PO)_2]$ ($M^{VI} = U$ or Np), the coordination geometry is hexagonal bipyramidal, with the bidentate nitrate groups *trans*,[318] as found also for the structure of $[UO_2(NO_3)_2\{(EtO)_3PO\}_2]$.[319] The cation $[UO_2\{Me_2N)_3PO\}_4]^{2+}$ in the perchlorate[320] and in the polyiodide, $[UO_2L_4](I_3)_2$, obtained by atmospheric oxidation of a mixture of UI_4 and $(Me_2N)_3PO$,[321] exhibits *trans* octahedral geometry.

In the dimeric compound $[UO_2(MeCO_2)_2(Ph_3PO)]_2$, which crystallizes when a cold acetone solution of $UO_2(MeCO_2)_2 \cdot 2H_2O$ containing the stoichiometric quantity of Ph_3PO is stirred for 20–30 minutes, the coordination geometry about the uranium atom is pentagonal bipyramidal with two bridging and two chelating $MeCO_2$ groups.[322] The same coordination geometry has been reported for monomeric $[UO_2(MeCSS)_2(Ph_3PO)]$, which is precipitated from methanol solutions of the dithioacetate and Ph_3PO,[323a] for the dithiophosphinate complex, $[UO_2(S_2PR_2)_2(Me_3PO)]$[323b], for the complex $[UO_2\{CF_3COCHCO(2\text{-}C_4H_3S)_2\}\{(n\text{-}C_8H_{17})_3PO\}]$[324] and for the α and β forms of the complex $[UO_2\{CF_3COCHCOCF_3)_2\{(MeO)_3PO\}]$, which differ in that the β-diketonate groups in the α form are tilted by 22.5° to the plane of the pentagon in a boat conformation[325] whereas the pentagon is nearly planar in the β form.[326]

(*f*) As-*Oxides*. Complexes with these ligands (Table 82) are usually obtained by treating the parent compound with the ligand in a non-aqueous solvent. The complexes $[UO_2(MeCO_2)_2(Ph_3AsO)]_2$ and $[UO_2(MeCO_2)_2(Ph_3AsO)_2]$ are isomorphous with their Ph_3PO analogues. The coordination geometry in the dithio- and diseleno-carbamate compounds, $[UO_2(Et_2NCX_2)(Ph_3AsO)]$ is pentagonal bipyramidal, with four sulfur[327] or four selenium[328] and one oxygen atom in the equatorial plane. As expected, the coordination geometry in $[UO_2(NO_3)_2(Ph_3AsO)_2]$ is hexagonal bipyramidal, as in the phosphine oxide analogue; the U—O(As) bond length is shorter than the U—O(P) bond length in the latter.[329]

(*g*) S-*Oxides*. In addition to the compounds listed in Table 83, a large number of R_2SO (R = Me, Bu^n, $i\text{-}C_5H_{11}$, $n\text{-}C_6H_{13}$, $PhCH_2$ and Ph) complexes with dioxouranium(VI) β-diketonates and Me_2SO complexes with analogous Schiff base compounds are known and a few complexes of dioxouranium(VI) compounds with thioxane *S*-oxide, thianthrene 5-oxide, substituted sulfoxidothiophenes (RC_4H_3SO) and thiourea dioxide ($(H_2N)_2CSO_2$) have also been reported.

The structure of the polymeric complex $[UO_2F_2(Me_2SO)]_n$ consists of zigzag chains of uranium atoms linked by di-μ-fluoro bridges; the coordination geometry about each uranium

atom is pentagonal bipyramidal, with four fluorine and one oxygen atom in the equatorial plane.[330] The same coordination geometry has been reported[331] for $[UO_2(Me_2SO)_5](ClO_4)_2$ and for the complex with the phosphite,[311] $[UO_2(HPO_3)(Me_2SO)(H_2O)]$.

(*ix*) *Hydroxamates, cupferron and related ligands*

A selection of the known dioxouranium(VI) complexes with this type of ligand is given in Table 84. These compounds are precipitated from aqueous solution, usually after the addition of alkali. The coordination geometry of the anion in the ammonium salt of the cupferron complex, $NH_4[UO_2\{(ON)N(Ph)O\}_3]$, is close to hexagonal bipyramidal.[332]

40.2.4.4 Sulfur ligands

(*i*) *Monothiocarbamates, dithiocarbamates and xanthates*

(*a*) *Monothiocarbamates.* The diethylammonium salt, $(Et_2NH_2)[UO_2(OEt)(Et_2NCOS)_2]$, precipitates when a saturated solution of $UO_2Cl_2 \cdot 3H_2O$ in ethanol is added to the solution obtained by passing COS through ethanolic diethylamine at 0 °C. The coordination geometry in the anion is pentagonal bipyramidal, with two sulfur and three oxygen atoms in the rather irregular pentagonal plane.[333] The anion structure is the same in the di-*n*-propylammonium salt of the $[UO_2(OEt)(Pr^n_2NCOS)_2]^-$ ion, prepared in a similar manner.[334] In the structure of an analogous compound, $(Pr^n_2NH_2)_2[UO_2(Pr^n_2NCOS)_2(S_2)]$, the uranium atom is at the centre of an irregular hexagonal bipyramid, with the equatorial plane positions occupied by the $(S—S)^{2-}$ group bonded sideways on, together with two oxygen and two sulfur atoms from the monothiocarbamate groups.[335]

(*b*) *Dithiocarbamates.* The existence of the compounds reported as $UO_2(R_2NCS_2)_2$ (R = Et, Pr^n, Bu^t) and $UO_2(RHNCS_2)_2$ (R = Et, Bu^i) is dubious and these are more likely to be salts of the anion $[UO_2(R_2NCS_2)_3]^-$. A number of salts of composition $M^I[UO_2(Et_2NCS_2)_3] \cdot xH_2O$ [M^I = Na ($x = 2, 3$ or 6), K ($x = 1$), Rb, Cs, NH_4 and NMe_4 (all $x = 0$)] and $(R'R''NH_2)[UO_2(R'R''NCS_2)_3]$, with R' = Me and R'' = Me, Pr^i, CH_2CHMe_2, $CH(CHMe_2)_2$, $CH_2CH_2CHMe_2$, CH(Me)CMe_3 and $CHMeCH_2CMe_2OH$, or R' = R'' = CH_2CHMe_2, Bu^n or CH_2CH_2OH, have been reported. The coordination geometry in the anion of $(NMe_4)[UO_2(Et_2NCS_2)_3]$ is approximately hexagonal bipyramidal, with six sulfur atoms in the non-planar hexagon.[336]

(*c*) *Xanthates.* The salts $K[UO_2(ROCS_2)_3]$ (R = Et, Pr^i) are precipitated when an excess of the potassium alkyl xanthate is added to an aqueous solution of UO_2SO_4. Early reports of the formation of xanthates of the type $UO_2(ROCS_2)_2$ from aqueous solution appear to be doubtful.

(*ii*) *Dithiolates*

The *cis* maleonitriledithiolate salts $(NR_4)_2[UO_2(cis\text{-}C_4N_2S_2)_2]$ (R = Et, Pr^n) and the corresponding isomaleonitrile compounds $(NR_4)_2[UO_2\{(CN)_2C{=}CS_2\}_2]$ (R = Et, Pr^n) have been recorded.

(*iii*) *Thioureas*

A number of complexes of dioxouranium(VI) compounds with thioureas have been reported (Table 85) but little is known about them. In addition to those listed in the table, a number of complexes with dioxouranium(VI) nitrate formulated as $[UO_2L_x(NO_3)](NO_3)$, with $x = 4$ and L = *o*-chlorophenyl thiourea, $x = 3$ and L = *o*- or *p*-hydroxyphenyl thiourea, and $x = 2$ and L = *o*-methoxyphenylthiourea, as well as $[UO_2L(NO_3)_2]$ with L = benzylthiourea, have also been recorded.[337]

Table 85 Some Complexes of Thioureas with Dioxouranium(VI) Compounds

$L = SC(NH_2)_2$	
$UO_2X_2{\cdot}yL$	X = Cl, $y = 2$; X = NO_3, $y = 2$ or 4;[a] X = $MeCO_2$, $y = 1$, 2 or 4
$UO_2SO_4{\cdot}yL$	$y = 1$ or 2
$L = SC(NHMe)_2$	
$UO_2(NCS)_2{\cdot}3L$	
$L = SC(NH_2)(NHPh)$	
$UO_2(MeCO_2)_2{\cdot}2L$	
$L = SC(NMe_2)_2$	
$UO_2X_2{\cdot}yL$	X = Cl,[b] NO_3,[b] $y = 2$; X = NCS, $y = 3$
$UO_2(NCS)(NO_3){\cdot}2L$

(*iv*) *Dithiophosphinates*

Dithiophosphinates, $UO_2(R_2PS_2)_2$, have been obtained by ether[50] (R = Me) or benzene[51] (R = Ph) extraction of a mixture of concentrated aqueous solutions of $UO_2(NO_3)_2$ and $Na_2(R_2PS_2)$, followed by concentration of the extract, or (R = *p*-tolyl, *p*-ClC_6H_4) by heating a methanol solution of the ligand under reflux with the calculated quantity of[52] $UO_2(MeCO_2)_2$. These last, and the phenyl analogue, are monomers in benzene.[52] Alcohol adducts of the type $UO_2(S_2PR_2)_2{\cdot}R^1OH$ are obtained when UO_2Cl_2 in R^1OH (R^1 = Me, Et, Pr^i) is treated with a salt of the dithiophosphinic acid, R_2PS_2H (R = Me, Et, Pr^i, OMe, OEt, OPr^i, Ph or cyclo-C_6H_{11}). In the presence of an excess of chloride ion, the adducted R^1OH is displaced and salts of the type $Et_4N[UO_2(S_2PR_2)_2Cl]$ are formed. The coordination geometry about the uranium atom in $UO_2(S_2PR_2)_2{\cdot}R^1OH$ (R = Ph, cyclo-C_6H_{11}; R^1 = Et) and in the anion $[UO_2(S_2PR_2)_2Cl]^-$ (R = Me, Ph) is pentagonal bipyramidal with four S atoms from two bidentate S_2PR_2 ligands in the plane together with either one O atom from coordinated EtOH or one Cl atom, as in the structure of $[UO_2S_2PMe_2(Me_3PO)]$ (p. 1207).[323b]

40.2.4.5 Halogens as ligands

(*i*) *Hexahalides*

Octahedral hexafluorides, MF_6 (M = U, Np and Pu), are usually prepared by fluorination of lower fluorides, MF_4, at relatively high temperatures (*e.g.* M = Np, at *ca.* 500 °C). They are low

melting, volatile solids. The only known hexachloride is UCl_6, prepared by chlorination of UCl_4, for example in $SbCl_5$. This is also octahedral.[338]

(*ii*) *Oxohalides*

The oxotetrafluorides, $M^{VI}OF_4$, are prepared by hydrolysis of the hexafluoride in HF with the stoichiometric quantity of water or, more elegantly, by using the calculated quantity of silica wool to provide the water by reaction with the solvent ($M^{VI} = U$,[339] Np[340] and Pu[341]). The coordination geometry about the metal atom in α-UOF_4 is close to pentagonal bipyramidal, with an oxygen and a fluorine atom in the axial positions.[339] $NpOF_4$[340] and $PuOF_4$[341] are isostructural with α-UOF_4. The coordination geometry in β-UOF_4 is also pentagonal bipyramidal, but with the two non-bridging axial fluorine atoms and a non-bridging equatorial oxygen atom together with four equatorial bridging fluorine atoms.[342] Complexes of the composition $UOF_4 \cdot xSbF_5$ ($x = 1$, 2 or 3) are also known. In these the structure consists of a fluorine-bridged network of UOF_4 and SbF_5 molecules in which each uranium atom is surrounded by a pentagonal bipyramidal array of one oxygen and six fluorine atoms.[343] The dioxodihalides, $M^{VI}O_2X_2$, are known for X = F ($M^{VI} = U$, Np, Pu), X = Cl [$M^{VI} = U$, Pu ($+6H_2O$)] and X = Br ($M^{VI} = U$, hydrated).

(*iii*) *Halo complexes*

Heptafluorouranates(VI), M^IUF_7 (M^I = Na, K, Rb, Cs or NF_4), have been prepared by reaction of M^IF with UF_6 in C_7F_{16}; the NF_4^+ compound is obtained from UF_6 and $NF_4 \cdot HF_2$ in HF.[344] Octafluorouranates(VI), $M^I_2[UF_8]$ are obtained by heating M^IUF_7 (M^I = Na, K, Rb or Cs) at 100 °C (M^I = Na) to 210 °C (M^I = Cs).[345] The U—F bond lengths in $Na_2[UF_8]$ are all equal.[346a] Oxidation of $(NH_4)_4U^{IV}F_8$ with XeF_2 at 55 °C yields a product of composition $(NH_4)_4UF_{10}$ which appears[346b] to be an example of uranium(VI) with coordination number greater than eight. The compounds $M^I_3UF_9$ (M^I = K or Rb) are prepared by fluorination of $M^I_3UF_7$ at 400 (K) to 500 °C (Rb).[347]

(*iv*) *Oxohalogeno complexes*

A few salts of complex anions derived from monoxoactinide(VI) halides are known; $(Ph_4P)[UOCl_5]$ is obtained when a solution of $(Ph_4P)_2[UO_2Cl_4]$ in thionyl chloride is heated under reflux for a few minutes and then cooled. The U—Cl bond length *trans* to the oxygen atom is shorter than the equatorial U—Cl bond lengths. The chloro complex reacts with HF at low temperature and with HBr in dichloromethane to form $(Ph_4P)[UOF_5]$ and $(Ph_4P)[UOClBr_4]$ respectively.[348]

The more common complexes are derived from dioxoactinide(VI) dihalides. The structure of the aquated anion in $(enH_2)[UO_2F_4(H_2O)]$ has been described earlier (p. 1192) and a number of hydrated salts of the type $M^IM^{VI}O_2F_3 \cdot xH_2O$ ($M^{VI} = U$, M^I = an organic base and $x = 0$–6; $M^{VI} = Pu$, M^I = Na, K, Rb, Cs, NH_4, C_9H_7NH (quinolinium), $x = 1$), $M^I_2PuO_2F_4$ (M^I = Na, K, Rb, NH_4), $M^{II}UO_2F_4 \cdot 4H_2O$ (M^{II} = Zn, Cd, Cu, Mn, Co, Ni), $M^I(M^{VI}O_2)_2F_5 \cdot xH_2O$ ($M^{VI} = U$, M^I = an organic base, $x = 0$–6; $M^{VI} = Pu$, $M^I = Cs$, $x = 3$) and $M^I(UO_2)_3F_7 \cdot xH_2O$ (M^I = an organic base) have been reported. The more usual fluoro complex anion is $[M^{VI}O_2F_5]^{3-}$ ($M^{VI} = U$, Np, Pu), for which several alkali metal salts are known. The potassium salts for the three elements are isostructural; in $K_3[UO_2F_5]$[349a] and $K_3[NpO_2F_5]$[349b] the coordination geometry of the anion is pentagonal bipyramidal. The IR spectra of $K_3[M^{VI}O_2F_5]$ ($M^{VI} = U$, Np, Pu) have also been reported.[249]

The compounds $Cs_2NH_4(UO_2)_2F_7$,[350] $Na_3(UO_2)_2F_7 \cdot 6H_2O$[351] and $Ni_3\{(UO_2)_2F_7\}_2 \cdot 18H_2O$[352] each involve infinite chains, $[(UO_2)_2F_7]^{3n-}_n$, formed by UO_2F_5 pentagonal bipyramids joined by a common edge and a common apex, with three bridging and two terminal fluorine atoms in the equatorial plane.

Chloro complexes are normally of composition $M^I_2[M^{VI}O_2Cl_4]$($M^{VI} = U$, Np, Pu, with M^I = Cs, NEt_4; $M^{VI} = U$, with M^I = Li or Na ($+6H_2O$), K ($+2H_2O$), NH_4, 1,10-phenH, PPh_4, PBu^n_4; $M^{VI} = Pu$, $M^I = NMe_4$, NPr^n_4, Et_3NH), $M^{II}[UO_2Cl_4] \cdot xH_2O$ (M^{II} = Be, $x = 4$; Mg, Ca, Ba or VO, $x = 2$; Sr, $x = 1$). The coordination geometry of the anion in $(1,10\text{-phenH})_2[UO_2Cl_4]$ is

a flattened square bipyramid.[353] The IR spectra of $Cs_2[M^{VI}O_2Cl_4]$ (M^{VI} = U, Np and Pu) have also been reported.[249] Products of composition $M^{III}[UO_2Cl_5]\cdot xH_2O$ (M^{III} = Y, $x = 3$ or La, $x = 2$), $M^{IV}[UO_2Cl_6]\cdot xH_2O$ (M^{IV} = Ce, $x = 5$ or Th, $x = 4$), $Mn_3[UO_2Cl_8]\cdot 6H_2O$, $Al_2[UO_2Cl_8]\cdot 6H_2O$ and a number of salts which appear to contain the anion $[(UO_2)_2Cl_7]^{3-}$ have been reported,[354] but these could be salts of the UO_2^{2+} ion. For example, $Ce[UO_2Cl_6]\cdot 5H_2O$ is more likely to be $[UO_2(H_2O)_5][CeCl_6]$.

Relatively few salts of bromo and iodo complex anions, $M_2^I[UO_2X_4]$, have been reported (X = Br, $M^I = PPh_3Bu^n$, $PPh_3(CH_2Ph)$, $HPPh_3$, $HPEt_3$, $HPPr^n_3$,[355] NBu^n_4; X = I, $M^I = PPh_3Bu^n$). The coordination geometry of the anion in $(NBu^n_4)_2[UO_2Br_4]$ is again a flattened square bipyramid.[356]

40.2.4.6 Mixed donor atom ligands

(i) Schiff bases

A very large number of dioxouranium(VI) compounds with this type of ligand have been recorded (see ref. 12, Uranium, vol. E2), examples of which are given in Table 86; these include some instances in which the mono- and di-basic ligands behave as neutral donors. Structure determinations indicate that the usual coordination geometry is approximately pentagonal bipyramidal; examples are $[UO_2(2\text{-}OC_6H_4CH{=}N(CH_2)_2NH(CH_2)_2NMe_2)(NO_3)]$, in which four equatorial positions are occupied by one oxygen and three nitrogen atoms of the tetradentate Schiff base and the fifth by an oxygen atom of the monodentate nitrate group;[357] $[UO_2(2\text{-}OC_6H_4CH{=}N(CH_2)_2NMe_2)_2]$, in which the equatorial sites are occupied by two oxygen and three nitrogen atoms from the two potentially tridentate ligands;[358] $[UO_2(2\text{-}OC_6H_4CH{=}N(CH_2)_2NH(CH_2)_2N{=}CHC_6H_4O\text{-}2)]$, with two oxygen and three nitrogen atoms of the ligand in the puckered equatorial plane;[359] and $[UO_2(2\text{-}OC_6H_4N{=}CHCH{=}NC_6H_4O\text{-}2)(H_2O)]$ with two oxygen and two nitrogen atoms from the ligand and one oxygen atom from the water molecule in the near planar pentagon.[360a]

Table 86 Some Dioxouranium(VI) Schiff Base Complexes

$UO_2(MeCO_2)_2\cdot LH$	LH^a = 2-$HOC_6H_4CH{=}NR$ and 2-$HOC_{10}H_6CH{=}NR$ with R = Et, Pr^n, Bu^n and Ph
$UO_2(MeCO_2)_2\cdot LH_2$	$LH_2{}^a$ = 2-$HOC_6H_4CH{=}N(A)OH$ and 2-$HOC_{10}H_6CH{=}N(A)OH$ with A = CH_2CHMe or $(CH_2)_3$
$UO_2X_2\cdot 2LH$	LH = 2-$HOC_6H_4CH{=}NR$ with X = Cl or NO_3 and R = Et, Pr^n, Bu^n, $(CH_2)_2NHPh$
UO_2XL	LH = 2-$HOC_6H_4CH{=}NR$ with R = $(CH_2)_2NH(CH_2)_2NMe_2$ and X = F, Cl, Br, NCS, NO_3, $MeCO_2$ or trop (tropolonate)
UO_2L_2	LH = 3-Me, 2-$HOC_6H_3CH{=}NHCOPh$ and 2-$HOC_6H_4CH{=}N(CH_2)_2NMe_2$
UO_2L	LH_2 = 2-$HOC_6H_4CH{=}N(CH_2)_2NH(CH_2)_2N{=}CHC_6H_4$-2-OH
$[UO_2L(H_2O)]$	LH_2 = 2-$HOC_6H_4N{=}CHCH{=}NC_6H_4$-2-OH

[a] R. G. Vijay and J. P. Tandon, *Monatsh. Chem.*, 1979, **110**, 889.

(ii) Amino acids

Dioxouranium(VI) compounds with aminoacetic acid (glycine), $UO_2(H_2NCH_2CO_2)_2$ and $UO_2(H_2NCH_2CO_2)(OH)\cdot 2H_2O$, and similar derivatives of α and β-aminopropionic acid (α- and β-alanine), $UO_2(MeCHNH_2CO_2)_2\cdot 4H_2O$, $UO_2(MeCHNH_2CO_2)(ClO_4)\cdot 2H_2O$ and $UO_2(H_2NCH_2CH_2CO_2)_2\cdot xH_2O$ ($x = 0$ or 4), have been recorded. In the glycine compound $[UO_2(O_2CCH_2NH_3)_4](NO_3)_2$ all of the glycine ligands are in the zwitterionic form and act as oxygen donor ligands; two are bidentate and two unidentate, making up the equatorial plane of a hexagonal bipyramidal arrangement of oxygen atoms around the uranium atom.[360b] L-Arginine $[H_2NC(=NH)NH(CH_2)_3CHNH_2CO_2H$ (= HX)] compounds of the type $UO_2XY\cdot zH_2O$ (Y = NO_3, $z = 2$; Y = ClO_4 or $MeCO_2$, $z = 3$) are also known.[361] 2-, 3- and 4-$H_2NC_6H_4CO_2H$ form compounds of composition UO_2L_2; an acid salt of the 2-amino acid (= HL), $UO_2L_2\cdot HL\cdot 2H_2O$, and a mixed oxalato salt, $Na_2[UO_2(C_2O_4)(L)_2]\cdot 2H_2O$, have been recorded.

(iii) Complexones

Nitrilotriacetic acid, $N(CH_2CO_2H)_3$(= H_3L), forms the complexes $UO_2(HL)\cdot xH_2O$ ($x = 0$, 2 or 5) and $(UO_2)_3(L)_2\cdot xH_2O$ ($x = 3$ or 10), and the analogous phosphorus tripropionic acid, $P(CH_2CH_2CO_2H)_3$(= H_3L), forms the salt of the complex anion, $Na[UO_2L]\cdot H_2O$. The hydrates are precipitated from aqueous solution. Similarly, ethylenediamine-*N,N,N',N'*-tetraacetic acid, $(HO_2CCH_2)_2NCH_2CH_2N(CH_2CO_2H)_2$ (= H_4edta), yields compounds of composition $UO_2(H_2edta)\cdot xH_2O$ ($x = 0$, 1 or 2), $(UO_2)_2(edta)\cdot xH_2O$ ($x = 0$, 2, 3 or 4) and salts of the complex anion, such as $M^I_2[UO_2(edta)]\cdot xH_2O$ (M^I = K, x unspecified; $M^I = NH_4$, $x = 0$, 2 or 3), $[Co(NH_3)_6]_2[UO_2(edta)]_3\cdot 22H_2O$ and $Na_2[UO_2(H_3edta)_4]$. Mixed peroxo-edta compounds of composition $[(UO_2)_2(H_2edta)(O_2)]\cdot 4H_2O$, $[(UO_2)_2(H_4edta)(O_2)_2]\cdot 9H_2O$, $[(UO_2)_2(H_4edta)_2(O_2)_2]\cdot 10H_2O$ and $Na_2[(UO_2)_2(edta)(O_2)]\cdot 7H_2O$ have also been recorded.

Hydrated compounds of the type $UO_2(H_2L)\cdot xH_2O$ have been reported for 1,2-diaminopropane-*N,N,N',N'*-tetraacetic acid (x unspecified), *trans* diaminocyclohexane-*N,N,N',N'*-tetraacetic acid ($x = 0$ or 3; $(UO_2)_2L\cdot xH_2O$, with $x = 0$ or 6 also known), 2,2'-diaminodiethyl ether-*N,N,N',N'*-tetraacetic acid ($x = 3$), and 2,2'-diaminodiethyl sulfide-*N,N,N',N'*-tetraacetic acid ($x = 0$ or 4); the hydrates are precipitated from aqueous media, but in the last instance a mixture of ethanol and acetone was added to induce precipitation. The analogous di(2-aminoethoxy)ethane-*N,N,N',N'*-tetraacetic acid (H_4L) forms the compounds $[(UO_2)_2L(H_2O)_2]$ and $Na[UO_2(HL)(H_2O)]$.

(iv) Ligands containing N,O and S,O donor sites

(a) 8-Hydroxyquinolines. Neptunium(VI) and plutonium(VI) are reduced to lower oxidation states by 8-hydroxyquinoline or its derivatives[362] and only dioxouranium(VI) compounds are known; these are of composition UO_2L_2, $UO_2L_2\cdot HL$ and $M^I[UO_2L_3]$ (Table 87). In addition, 1:1 adducts with the pyridine-2-carboxylate, $UO_2(NC_5H_4\text{-}2\text{-}CO_2)_2\cdot HL$, are formed by 8-hydroxyquinoline and the 2-methyl derivative. Further work on the wide range of substituted 8-hydroxyquinolates is desirable, for the existence of some of the reported solvates, $UO_2L_2\cdot HL$, is uncertain.

Table 87 Dioxouranium(VI) Complexes with 8-Hydroxyquinoline and Substituted 8-Hydroxyquinolines

UO_2L_2	HL = 8-hydroxyquinoline,[a] 2-, 5- or 7-methyl,[b] 5-acetyl, 5-chloro, 5-nitro-, 5-phenyl, 7-*t*-butyl-, 2,7-dimethyl-,[b] 5-chloro-7-iodo, 5,7-dibromo-[b] and 5,7-dichloro-8-hydroxyquinoline[b]
$UO_2L_2\cdot HL$	HL = 8-hydroxyquinoline,[c] 2- or 5-methyl-, 5-nitro-, 5-phenyl-, 5-acetyl-, 5-chloro-, 5-iodo-, 7-fluoro-, 7-phenyl-, 7-(α-anilinobenzyl)-, 7-[α](*m*- or *p*-nitroanilinobenzyl]-, 7-(*p*-carboxyphenylaminobenzyl)-, 5,7-dichloro-, 5,7-dibromo- and 5,7-diiodo-8-hydroxyquinoline
$M^U[UO_2L_3]$	HL = 8-hydroxyquinoline

[a] Mono-, tri- and tetra-hydrate also known.
[b] Monohydrate also known.
[c] Mono- and di-hydrate also known.

In the complex $[UO_2L_2(HL)]\cdot CHCl_3$ (HL = 8-hydroxyquinoline), the additional molecule of HL is coordinated to the uranium atom through the phenolic oxygen atom; the coordination geometry is approximately pentagonal bipyramidal.[363]

(b) Ligands with S,O donor sites. The complex with S(cyclo-$C_6H_{10}OH)_2$, $[UO_2Cl_2L]$, is obtained by adding an excess of the ligand in ethyl acetate to a solution of $UO_2Cl_2\cdot 3H_2O$ in the same solvent. The ligand is terdentate in this compound, with the two oxygen atoms from the hydroxyl groups and the sulfur atom, together with the two chlorine atoms, in the equatorial positions of a distorted pentagonal bipyramid.[364] Thiovanol ($HSCH_2CH(OH)CH_2OH = C_3H_8SO_2$) complexes, $[UO_2(C_3H_7SO_2)_2(H_2O)_2]$ and $[UO_2(C_3H_7SO_2)Cl(H_2O)_3]\cdot H_2O$, have been recorded,[365] and these may involve bonding to sulfur as well as oxygen, but the assignment of the water molecules to the coordination sphere requires confirmation. An 8-mercaptoquinolinate, $UO_2(C_9H_6NS)_2$, the sulfur analogue of the 8-hydroxyquinolinate, has been prepared by reaction of $UO_2(NO_3)_2\cdot 6H_2O$ with $Ca(C_9H_6NS)_2$ in benzene.[366]

40.2.4.7 Multidentate macrocyclic ligands

(i) Phthalocyanine and superphthalocyanine

The dioxouranium(VI) phthalocyanine complex, $UO_2(C_{32}H_{16}N_8)\cdot C_6H_4(CN)_2$ ($C_{32}H_{18}N_8$ = phthalocyanine), has been reported to be formed by reaction of UO_2Cl_2 with *o*-phthalodinitrile, $C_6H_4(CN)_2$, but this reaction in DMF has been shown to yield the cyclopentakis(2-iminoisoindoline) ($C_{40}H_{22}N_{10}$) derivative, $[UO_2(C_{40}H_{20}N_{10})]$, in which the coordination geometry about the uranium atom can be described as a compressed pentagonal bipyramid, with five nitrogen atoms of the $C_{40}H_{20}N_{10}$ ligand in the irregularly distorted pentagonal girdle.[367] This compound reacts with di- and tri-valent metal halides with contraction of the ring and formation of the corresponding metal phthalocyanine complex.[368]

Complexes with 2,3,9,10,16,17,23,24,30,31-decaalkyl superphthalocyanines, $(4,5\text{-}R_2)_5PcUO_2$ (R = Me, Bu^n), and the analogous pentamethylphthalocyanine complex, $(4\text{-}Me)_5PcUO_2$, have been reported. In these the uranium atom is bonded to five nitrogen atoms of the superphthalocyaninate group.[369]

(ii) Crown ethers and kryptands

A number of crown ether and kryptand solvates of dioxouranium(VI) compounds have been recorded (Table 88). The IR and ^1H NMR spectra of many of these products suggest that the crown ether is not bonded to the metal atom, and an X-ray study has shown that the 18-crown-6 solvate, $UO_2(NO_3)_2\cdot L\cdot 4H_2O$, consists of layers of hexagonal bipyramidal $[UO_2(NO_3)_2(H_2O)_2]$ units with the crown ether lying between the uranium atoms.[370] However, IR evidence suggests that the ether in the hydrated and anhydrous 15-crown-5, 18-crown-6 and dicyclo-hexyl-18-crown-6 solvates of UO_2Cl_2 may be bonded to the metal.[371] The constitution of the salt $Na_2UO_2Cl_4\cdot$2-benzo-15-crown-5 has been shown to be [Na(benzo-15-crown-5)]$_2$[UO_2Cl_4], with the anion octahedral.[372]

Table 88 Crown Ether and Kryptand Solvates of Dioxouranium(VI) Compounds

40.2.5 The +7 Oxidation State

Salts of oxoderivatives of the types $[MO_4]^-$, $[MO_5]^{3-}$ and $[MO_6]^{5-}$ have been reported for neptunium(VII) and plutonium(VII). Compounds of composition $M^I_3M^{VII}O_5$ (M^{VII} = Np, M^I = K, Rb or Cs; M^{VII} = Pu, M^I = Rb or Cs) have been prepared by heating the alkali metal peroxides with the actinide dioxide at 320 to 355 °C (Np) or 250 °C (Pu). Hydrated compounds, $M^{II}_3(NpO_5)_2\cdot xH_2O$ [M^{II} = Ca, Sr, Ba ($x = 3$)] have been prepared from aqueous alkaline

solutions of neptunium(VII), as have the hydrated salts $M^{III}NpO_5 \cdot xH_2O$ [$M^{III} = [Co(NH_3)_6]$, $[Co(en)_3]$ ($x = 5$) and $[Pt(NH_3)_5Cl]$ ($x = 1$)]. The IR spectra of $Ba_3(M^{VII}O_5)_2 \cdot xH_2O$ (M^{VII} = Np, $x = 3$; Pu, $x = 3$), $[Co(NH_3)_6]M^{VII}O_5 \cdot xH_2O$ (M^{VII} = Np, $x = 5$; Pu, $x = 3$),[373] $[Pt(NH_3)_5Cl]M^{VII}O_5 \cdot xH_2O$ (M^{VII} = Np, $x = 1$; Pu[373], $x = 3$) suggest that the oxoanion structure consists of infinite chains of $[NpO_6]_n^{5n-1}$ units.[374] Structural investigations of compounds of the general composition $M^INpO_5 \cdot xH_2O$ indicate that they are really $M^I_3[NpO_4(OH)_2] \cdot (x-1)H_2O$; the coordination geometry of the neptunium(VII) centre in the anion is described as tetragonal bipyramidal, with the two OH groups in the axial positions (M^I = Na,[375] $x = 5$; K,[376] $x = 3$). The anion preserves the same coordination geometry in $Na_3[NpO_4(OH)_2] \cdot xH_2O$ ($x = 0$,[377a] 2[377b] and 4[377c]); both hydrates lose all their water at 373 K. $Ba_3(NpO_5)_2$ has also been prepared by heating $NpO_3 \cdot H_2O$ with barium peroxide in oxygen at 500 °C.

Compounds of composition M^INpO_4 (M^I = K, Rb, Cs) are prepared in the same way as the hydrated salts $M^I_3(NpO_5)_2 \cdot xH_2O$ but with concentrated alkaline solutions of neptunium(VII).[378] The ammonium salt, $NH_4NpO_4 \cdot nH_2O$ ($n = 1.5$ to 3) has been prepared by anodic oxidation of neptunium(VI) in $(NH_4)_2CO_3$ solution; it is isostructural with $M^INpO_4 \cdot 2.5H_2O$ (M^I = Li or Na).[379]

The compounds $Li_5M^{VII}O_6$ (M^{VII} = Np, Pu) have been obtained by heating the actinide dioxide with lithium oxide in oxygen at *ca.* 400 °C(Np), and the analogous $Ba_2M^INpO_6$ (M^I = Li or Na) by heating $NpO_3 \cdot H_2O$ with the alkali metal peroxide in oxygen above 400 °C. The $[NpO_6]^{5-}$ anion appears to be octahedral.

The IR spectrum of $Li_3NpO_2(OH)_6$ has been reported; it was prepared by dissolving $NpO_2(OH)_3 \cdot 3H_2O$ in aqueous lithium hydroxide and then evaporating the solution.[380] In the structure of the compound $Li[Co(NH_3)_6][Np_2O_8(OH)_2] \cdot 2H_2O$, precipitated from a lithium hydroxide solution of neptunium(VII) by allowing aqueous $[Co(NH_3)_6]Cl_3$ to diffuse into it, there are two independent neptunium centres, each coordinated by an octahedron of oxygen atoms; the octahedra share corners to form a chain.[381]

40.3 THE TRANSPLUTONIUM ELEMENTS

40.3.1 The +2 Oxidation State

The americium halides AmX_2 (X = Cl, Br[382] and I[383]) have been obtained by heating americium metal with the appropriate mercury(II) halide; they are isostructural with the corresponding europium dihalides. The californium(II) compounds CfX_2 [X = Cl,[384] Br[385] and I (dimorphic[386])], as well as the einsteinium analogues EsX_2 (X = Cl, Br, I),[387] have been prepared by hydrogen reduction of the trihalides at high temperatures. $CfBr_2$ has also been obtained[385] by heating Cf_2O_3 in HBr at 500–625 °C, and there is also tracer level evidence[388] for the formation of $FmCl_2$. The known monoxides and monosulfides, such as AmO and AmS, are probably semimetallic in character.

40.3.2 The +3 Oxidation State

Complexes involving group IV or group V ligands do not appear to have been recorded.

40.3.2.1 Oxygen ligands

(*i*) *Aqua species, hydroxides and oxides*

(*a*) *Aqua species.* A selection of the known hydrates is given in Table 89. The hydrated xenate(VIII), $Am_4(XeO_6)_3 \cdot 40H_2O$, has also been reported.[389] The hydrated trichlorides, $MCl_3 \cdot 6H_2O$ (M = Am or Bk), and tribromides, $MBr_3 \cdot 6H_2O$ (M = Am or Cf), are isostructural with the hydrated lanthanide chlorides, $LnCl_3 \cdot 6H_2O$, and involve aqua ions, such as[390] $[AmCl_2(OH_2)_6]^+Cl$. In the hydrated salicylate, $Am(C_7H_5O_3)_3 \cdot H_2O$, each metal atom is linked to six different salicylate groups and is surrounded by nine oxygen atoms, eight from the salicylate groups and one from the water molecule; two salicylate groups are bidentate, one *via* its carboxylate group and the other *via* its carboxylate and phenolic groups, and the other four are monodentate *via* the carboxylate group.[391]

Table 89 Some Hydrates of Transplutonium Actinide(III) Compounds

$M^{III}X_3 \cdot 6H_2O$	X = Cl, M^{III} = Am, Bk; X = Br, M^{III} = Am, Cf
$M^{III}_2(SO_4)_3 \cdot xH_2O$	M^{III} = Am, $x = 5$; M^{III} = Cf, $x = 12$
$M^{I}Am(SO_4)_2 \cdot xH_2O$	M^{I} = Na, $x = 1$; K, $x = 2$; Rb, Cs, Tl, $x = 4$
$K_3Am(SO_4)_3 \cdot H_2O$	
$Am_2(CO_3)_3 \cdot xH_2O$	$x = 4$ or 5
$NaAm(CO_3)_2 \cdot 4H_2O$	
$Na_3Am(CO_3)_3 \cdot 3H_2O$	
$M^{III}_2(C_2O_4)_3 \cdot xH_2O$	M^{III} = Am, $x = 0.5$, 1, 3, 4, 7, 9 or 11
	M^{III} = Cm, $x = 1$, 2, 3, 4, 5, 6, 7, 8, 9 or 10
$M^{III}PO_4 \cdot 0.5H_2O$	M^{III} = Am, Cm
$[Am(C_7H_5O_3)_3(H_2O)]$	$C_7H_6O_3$ = salicyclic acid

(*b*) *Hydroxides.* The hydroxides $M(OH)_3$ are known for M = Am, Cm, Bk and Cf; $Am(OH)_3$ is isostructural with $Nd(OH)_3$.[392]

(*c*) *Oxides.* Three crystal modifications have been reported for both Am_2O_3 and Cm_2O_3, two of which (the A and C types) have been found for Bk_2O_3 and the A and B types have been reported for Cf_2O_3. Ternary oxides, such as $LiAmO_2$, obtained by heating AmO_2 with Li_2O in hydrogen at 600 °C, $M^{II}(AmO_2)_2$ (M^{II} = Sr or Ba) and $M^{III}AlO_3$ (M^{III} = Am or Cm) have been reported.

(*ii*) *β-Ketoenolates*

The hydrated americium compounds, $AmL_3 \cdot xH_2O$ (HL = $MeCOCH_2COMe$, $x = 1$; CF_3COCH_2COPh and $CF_3COCH_2CO(2\text{-}C_4H_3S)$, $x = 3$), are precipitated from aqueous media[393] and $Am(Bu^tCOCHCOBu^t)_3$ is precipitated from an aqueous ethanol solution of the components. It is isomorphous with the praseodymium and neodymium chelates, in which (Pr) the metal atoms are seven-coordinate.[394] The berkelium compounds, $Bk(CF_3COCHCOR)_3$ (R = CF_3, Bu^t and 2-C_4H_3S), have been obtained by a solvent extraction method[395] and the sublimation behaviour of $M(Bu^tCOCHCOBu^t)_3$ (M = Am,[396,397] Cm[397] and Cf[396,397]) has also been reported. Compounds of composition $CsM(CF_3COCHCOCF_3)_4 \cdot xH_2O$ have been isolated for M = Am ($x = 0$ or 1) and Cm ($x = 1$), and there is evidence for the formation of analogous compounds with M = Bk, Cf or Es. In the structure of the anhydrous americium compound, the metal atom is surrounded by a dodecahedral arrangement of oxygen atoms.[398]

(*iii*) *Oxoanions as ligands*

(*a*) *Phosphates.* Hydrated phosphates, $MPO_4 \cdot 0.5H_2O$ (M = Am, Cm), are obtained from aqueous solution and can be dehydrated at about 200 °C.

(*b*) *Sulfates.* Hydrated sulfates and sulfato complexes are included in Table 89. Anhydrous $Am_2(SO_4)_3$ is obtained by heating the pentahydrate at 500 °C; anhydrous sulfato complexes of composition $KAm(SO_4)_2$ and $M^{I}_8Am_2(SO_4)_7$ (M^{I} = K, Cs or Tl) are also known. The oxosulfates, $M^{III}_2O_2SO_4$ (M^{III} = Cm or Cf), have been reported; the curium compound is obtained by calcining the Cm^{3+} form of Dowex 50W-X8 resin in air at 900 °C. $Cm_2(SO_4)_3$ may be formed at 760 to 870 °C in this process[399] and the californium compound is obtained by heating $Cf_2(SO_4)_3 \cdot 12H_2O$ in air at 700 to 800 °C.[400]

(*iv*) *Carboxylates and carbonates*

(*a*) *Monocarboxylates.* The only recorded compound appears to be the formate, $Am(HCO_2)_3$, prepared by evaporating a solution of $Am(OH)_3$ in concentrated formic acid at 50 °C.

(*b*) *Carbonates.* Hydrated americium carbonate, $Am_2(CO_3)_3 \cdot 4H_2O$, is precipitated from aqueous solutions containing americium(III) by $NaHCO_3$. It decomposes to $Am_2O(CO_3)_2$, and then to $Am_2O_2(CO_3)$ on heating. The anhydrous carbonates, $M^{III}_2(CO_3)_3$ (M^{III} = Am or Cm) are formed in the radiolytic decomposition of the oxalate (Am) or by heating the anhydrous

oxalate at 360 °C (Cm); $Cm_2O(CO_3)_2$ and $Cm_2O_2(CO_3)$ are obtained at 420 and 510 °C respectively.

(*c*) *Oxalates.* The hydrated oxalate, $Am_2(C_2O_4)_3 \cdot xH_2O$ ($x = 7$, 9, 10 or 11), is precipitated from aqueous solutions containing americium(III) by oxalic acid and the anhydrous oxalate is obtained by heating the hydrate above 240 °C. The corresponding berkelium and californium compounds are precipitated from aqueous nitric acid solutions of Bk^{III} or Cf^{III} by oxalic acid.[401a] The oxalato complexes, $MAm(C_2O_4)_2 \cdot xH_2O$ ($M = NH_4$, $x = 5$, $M = Na$, Cs), have been prepared from $Am_2(C_2O_4)_3 \cdot 10H_2O$ and $M_2C_2O_4$ in neutral solution.[401b] The potassium salts ($x = 2.5$, 3.5 and 5) have been obtained in the same way.[401c]

(*v*) *Aliphatic and aromatic hydroxyacids*

The only recorded compounds appear to be the citrates, $Am(C_6H_5O_7) \cdot xH_2O$ and $[Co(NH_3)_6][Am(C_6H_5O_7)_2] \cdot xH_2O$,[402] and the hydrated salicylate, $Am(C_7H_5O_3)_3 \cdot H_2O$, the structure of which is described on p. 1215.

(*vi*) P-*Oxides*

The only complexes known (Table 90) are those of β-ketoenolates with $(n\text{-}C_8H_{17})_3PO$ and $(Bu^nO)_3PO$, prepared by solvent extraction from aqueous solutions of the actinides(III) with a mixture of the β-ketoenol and the *P*-oxide. There is also solution chemistry evidence for the formation[403] of $Am[CF_3COCHCO(2\text{-}C_4H_3S)]_3 \cdot 2(Bu^nO)_3PO$. $Am[CF_3COCHCOCF_3)_3 \cdot 2(Bu^nO)_3PO$ is volatile at 175 °C[404] and a gas chromatography study of this complex and the curium analogue has been reported.[405]

Table 90 Complexes of Transplutonium Actinide(III) β-Ketoenolates with *P*-Oxides

$M^{III}L_3 \cdot x(n\text{-}C_8H_{17})_3PO$	$HL = CF_3COCH_2COR$, with R = Me, CF_3 or Bu^t, M^{III} = Am or Cm, *x* unspecified[a]
$M^{III}L_3 \cdot x(Bu^nO)_3PO$	$HL = CF_3COCH_2COR$, with R = Me or Bu^t, M^{III} = Am or Cm, *x* unspecified[a]
	$HL = CF_3COCH_2COCF_3$, M^{III} = Am, $x = 2$;[a,b] Cm, *x* unspecified;[a] Bk, $x = 1$[c]

40.3.2.2 Sulfur ligands

Compounds with sulfur containing ligands do not appear to have been reported, but the sulfides $M^{III}_2S_3$ (M^{III} = Am, Cm, Bk or Cf) and $AmS_{1.9}$ [probably an americium(III) polysulfide] are known. Am_2S_3 is polymorphic, the α form having the α-Ce_2S_3 structure, and the γ form the Th_3P_4 structure which is also adopted by the other sesquisulfides. Oxysulfides, $M^{III}_2O_2S$ (M^{III} = Am, Cm or Cf), are also known; Cf_2O_2S is obtained by heating $Cf_2(SO_4)_3 \cdot xH_2O$ ($x = 0$ or 12) in hydrogen or in a vacuum at 800 °C.

40.3.2.3 Selenium and tellurium ligands

The only recorded compounds appear to be americium selenide and telluride, Am_3X_4.

40.3.2.4 Halogens as ligands

(i) Trihalides

The trifluorides, $M^{III}F_3$ (Table 91), possess the 11-coordinate LaF_3 structure (M^{III} = Am, Cm and one form of BkF_3), and a second modification of BkF_3 has the eight-coordinate high temperature LaF_3-type structure, found also for CfF_3 and EsF_3.[406] The trichlorides, $M^{III}Cl_3$, have the nine-coordinate UCl_3-type structure (M^{III} = Am, Cm, Bk and one form of $CfCl_3$), and the second modification of $CfCl_3$ has the eight-coordinate $PuBr_3$ structure. $EsCl_3$ has the UCl_3-type structure at 425 °C. The structures of the tribromides, $M^{III}Br_3$ (M^{III} = Am, Cm and Bk), are $PuBr_3$-type, and α-AmI_3 has this structure also. However, β-AmI_3 and the other triiodides $M^{III}I_3$ (M^{III} = Cm, Bk and Cf) have the six-coordinate BiI_3 structure. The structure of the hydrated trichlorides and tribromides, $MX_3 \cdot 6H_2O$, has been discussed earlier (p. 1215).

Table 91 Transplutonium Actinide(III) Halides and Halogeno Complexes

$M^{III}X_3$	X = F, Cl, Br or I, M^{III} = Am, Cm, Bk, Cf and Es[a]
$M^{III}OX$	X = F, M^{III} = Cf; X = Cl, M^{III} = Am, Cm, Bk, Cf and Es; X = Br, M^{III} = Cm, Bk and Cf; X = I, M^{III} = Am,[b] Bk and Cf
$M^{I}AmX_4$	X = F, M^{I} = Na, K,[c] Rb;[c] X = Cl, M^{I} = Cs (also $+4H_2O$)
K_2AmF_5[c]	
K_3AmF_6[c]	
KAm_2F_7	
$Cs_2NaM^{III}Cl_6$	M^{III} = Am,[d,e] Cm[e] and Bk[d,e]
$(Et_4N)_2LiAmCl_6$	
$M^{I}_3AmX_6$	X = Cl, M^{I} = Cs, Et_4N and Ph_3PH; X = Br, M^{I} = Ph_3PH

[a] For EsF_3, see D. D. Ensor, J. R. Peterson, R. G. Haire and J. P. Young, *J. Inorg. Nucl. Chem.*, 1981, **43**, 2425.

[e] M. E. Hendricks, E. R. Jones, Jr., J. A. Stone and D. G. Karracker, *J. Chem. Phys.*, 1974, **60**, 2095.

(ii) Halogeno complexes

The fluoro complexes $M^{I}AmF_4$ (M^{I} = K or Rb) are isostructural with the analogous plutonium compounds[407] and the anion in the salts $Cs_2Na[M^{III}Cl_6]$ is octahedral (*e.g.* M^{III} = Bk).[408]

40.3.2.5 Hydrides as ligands

The only recorded compounds are the hydrides AmH_3 and MH_{2+x} (M = Am, Cm or Bk, $x < 1$).

40.3.2.6 Mixed donor atom ligands

Compounds of composition AmL_3, where HL is 8-hydroxyquinoline, 5-chloro- or 5,7-dichloro-8-hydroxyquinoline, are precipitated when an aqueous solution containing americium(III) is added to an aqueous, or aqueous dioxane, solution of the ligand in the pH range 5.1–6.5.[409] There is solvent extraction evidence for the californium(III) 5,7-dichloro-8-hydroxyquinoline complex.[410]

40.3.2.7 Multidentate macrocyclic ligands

The bis phthalocyanine (Pc) complex, $AmPc_2$, has been obtained by heating AmI_3 with *o*-phthalodinitrile in 1-chloronaphthalene[411] or from americium(III) acetate and *o*-phthalodinitrile; it is probably a sandwich compound similar to those obtained with the tripositive lanthanides.[412]

40.3.3 The +4 Oxidation State

40.3.3.1 Oxygen ligands

(*i*) *Oxides*

All the reported dioxides, $M^{IV}O_2$ (M^{IV} = Am, Cm, Bk and Cf), possess the fluorite structure. Ternary oxides of the types $M^I_2Am^{IV}O_3$ (M^I = Li or Na), $M^{II}Am^{IV}O_3$ (M^{II} = Sr or Ba) and $Li_8M^{IV}O_6$ (M^{IV} = Am or Cm) have been recorded; they are obtained by heating the dioxides with the alkali or alkaline earth metal oxide at high temperatures under vacuum or in nitrogen.

(*ii*) *β-Ketoenolates*

The berkelium(IV) complexes BkL_4 [HL = $CF_3COCH_2COBu^t$[395] and $CF_3COCH_2CO(2\text{-}C_4H_3S)$[395,413]] are formed by solvent extraction of aqueous Bk^{IV} solutions with the β-ketoenol.

40.3.3.2 Halogens as ligands

(*i*) *Tetrahalides*

The tetrafluorides $M^{IV}F_4$ (M^{IV} = Am, Cm, Bk and Cf) are obtained by fluorination of lower oxidation state compounds; for example, CfF_4 has been prepared[414] by heating CfF_3, Cf_2O_3 or $CfCl_3{\cdot}xH_2O$ in fluorine at 400–450 °C under pressure (3 atm). All have the eight-coordinate UF_4 structure (p. 1173); for crystallographic data see refs. 415 and 416.

(*ii*) *Halogeno complexes*

The fluoro complexes $LiM^{IV}F_5$ (M^{IV} = Am or Cm) and $Rb_2M^{IV}F_6$ (M^{IV} = Am or Cm) have the $LiUF_5$ and Rb_2UF_6 structures (p. 1173) respectively. Compounds of composition $M^I_7M^{IV}_6F_{31}$ (M^I = Na, M^{IV} = Am, Cm, Bk or Cf and M^I = K, M^{IV} = Am, Cm or Bk) are also known (see p. 1174).

Cs_2BkCl_6 is not isomorphous with Cs_2PuCl_6 or Cs_2CeCl_6;[408] this compound would provide a useful starting material for the preparation of oxygen donor complexes of $BkCl_4$, which are at present unknown, by the methods used to prepare $PuCl_4$ complexes of this type (p. 1161).

40.3.4 The +5 Oxidation State

There is tracer scale evidence[455] for the formation of the CfO_2^+ ion during ozonization of ^{249}Bk and subsequent β decay to ^{249}Cf. However, the only compounds isolated in this oxidation state are all americium(V) species.

40.3.4.1 Oxygen ligands

(*i*) *Aqua species, hydroxides and oxides*

(*a*) *Aqua species.* Hydrated americium(V) carbonato and oxalato complexes are discussed below in the sections on carbonates and oxalates. The hydrated hydroxide, $AmO_2(OH){\cdot}ca.2.3H_2O$, is precipitated from aqueous solution by alkali. It decomposes to AmO_2 on heating.[418]

(*b*) *Oxides.* Pentoxides, $M^V_2O_5$, are unknown, but ternary oxides, such as $Li_3Am^VO_4$, Li_7AmO_6 and Na_3AmO_4, are obtained by heating AmO_2 with the alkali metal oxide (*e.g.* Li_7AmO_6 in N_2/O_2 at 900 °C; this decomposes to Li_3AmO_4 at 1000 °C). Crystallographic data have been reported for these compounds.[419]

(*ii*) *Carboxylates and carbonates*

(*a*) *Monocarboxylates.* The acetato complex salt, $Cs_2AmO_2(MeCO_2)_3$, is isostructural with the analogous neptunium(V) and plutonium(V) compounds (p. 1183)[186] and its vibrational spectrum has also been reported.[185]

(*b*) *Carbonates.* The hydrated carbonato complexes $KAmO_2CO_3 \cdot xH_2O$ and $K_3AmO_2(CO_3)_2 \cdot xH_2O$ have been obtained by electrochemical reduction of americium(VI) solutions in the presence of carbonate. The carbonato complex salts $M^I_3AmO_2(CO_3)_2 \cdot xH_2O$ are isostructural with the analogous neptunium(V) compounds[180] (p. 1180). The vibrational spectrum of $CsAmO_2CO_3$ has also been reported.[185]

(*c*) *Oxalates.* The hydrated oxalato complex salts $M^IAmO_2(C_2O_4) \cdot xH_2O$ (M^I = K or Cs) are precipitated from aqueous solution.[418]

40.3.4.2 Halogens as ligands

The chlorocomplex salt, $Cs_3[AmO_2Cl_4]$, is isostructural with the analogous neptunium(V) and plutonium(V) compounds.[206] Its vibrational spectrum has also been reported.[185]

40.3.5 The +6 Oxidation State

40.3.5.1 Oxygen ligands

(*i*) *Aqua species and oxides*

(*a*) *Aqua species.* Hydrated phosphato and arsenato complex salts, $M^IAmO_2XO_4 \cdot yH_2O$ (M^I = K, Rb, Cs or NH_4 and X = P or As, with *y* in the range 0 to 3) are precipitated from americium(VI) solutions[421] at pH 3.5. $NH_4AmO_2PO_4 \cdot 3H_2O$ is isomorphous with the analogous dioxouranium(VI) and neptunium(VI) compounds[422] (Table 63, p. 1192). The hydrated sulfatocomplex salt, $([Co(NH_3)_6]HSO_4)_2AmO_2(SO_4)_3 \cdot xH_2O$, is isostructural[262] with the corresponding dioxouranium(VI) and neptunium(VI) compounds (p. 1197).

(*b*) *Oxides.* AmO_3 is unknown, but ternary oxides of the type $M^I_2AmO_4$ (M^I = K, Rb or Cs), $M^I_4AmO_5$ (M^I = Li or Na), $M^I_6AmO_6$ (M^I = Li or Na) and Ba_3AmO_6 have been recorded, prepared by heating AmO_2 with the metal hydroxide or oxide in oxygen (*e.g.* $M^I_2AmO_4$).[423]

(*ii*) *Oxoanions as ligands*

The nitratocomplexes $M^IAmO_2(NO_3)_3$ (M^I = Rb or Cs[424]) are precipitated from nitric acid solutions of americium(VI). The IR spectrum of $RbAmO_2(NO_3)_3$ has been reported.[249] Hydrated phosphato, arsenato and sulfato complex salts are included under 'Aqua species' in the preceding section.

(*iii*) *Carboxylates and carbonates*

(*a*) *Monocarboxylates.* The IR spectrum of $NaAmO_2(MeCO_2)_3$ has been reported.[249]

(*b*) *Chelating carboxylates.* The pyridine- and *N*-oxopyridine-2-carboxylates, AmO_2L_2 and $HAmO_2L_3$, have been obtained from aqueous solutions of americium(VI) and the acid HL; the *N*-oxide 2-carboxylate is formed as the dihydrate which is dehydrated at 100 °C.[425]

(*c*) *Carbonates.* The carbonato complex salts, $M^I_4AmO_2(CO_3)_3$ (M^I = Cs or NH_4), are obtained on addition of $M^I_2CO_3$ to a bicarbonate solution containing americium(VI).[424]

40.3.5.2 Halogens as ligands

AmO_2F_2 has been prepared by the reaction of $NaAmO_2(MeCO_2)_3$ with anhydrous HF and fluorine at −196 °C. It is isostructural with UO_2F_2, NpO_2F_2 and PuO_2F_2.[426] The IR spectrum of $Cs_2AmO_2Cl_4$ has been reporetd[249] and the corresponding rubidium salt has been mentioned in a report.[427] The cubic phase of $Cs_2AmO_2Cl_4$[428] is probably a mixed oxidation state compound, $Cs_7(Am^VO_2)(Am^{VI}O_2)_2Cl_{12}$.[207]

36.1.1 THE ELEMENT

Molybdenum occurs chiefly as molybdenite, MoS_2, but also as molybdates $PbMoO_4$ and $MgMoO_4$. The largest known deposits are in Colorado (USA), but it is also found in Canada and Chile. The natural abundance in the earth's crust (~1.2 p.p.m.) is about the same as that of tungsten, but is much less than of chromium (122 p.p.m.). The name in fact originates from the Greek *molybdos* meaning lead.

The Swedish chemist Scheele (1778) produced the oxide of a new element from (black) MoS_2, thereby distinguishing the element from graphite with which it had been confused. The metal was isolated by Hjelm in Sweden three to four years later by heating the oxide with charcoal. In the procedure now used to isolate the metal, the MoS_2 component in ores is concentrated by flotation methods. The concentrate is then converted by roasting into MoO_3, which, after purification, is reduced with hydrogen. Reduction with carbon is avoided since carbides rather than the metal are obtained.

The chief use of molybdenum is in steels. The oxides and sulfides have some applications as catalysts. Molybdenum is the only element in the second and third transition series which appears to have a major role as a trace metal in enzymes. Several aspects of molybdenum chemistry have been widely studied in order to gain a better understanding of the biological relevance. Molybdenum is one of the few elements which currently has its own series of international conferences.[1]

Molybdenum and tungsten are similar chemically, although there are differences which it is difficult to explain. There is much less similarity in comparisons with chromium. In addition to the variety of oxidation states there is a wide range of stereochemistries, and the chemistry is amongst the most complex of the transition elements.

36.1.2 AQUEOUS SOLUTION CHEMISTRY

36.1.2.1 General Introduction

Molybdenum has an extensive aqueous solution chemistry for oxidation states II through VI. It is unique in having aqua or aqua/oxo ions for all five states in acidic solution ($pH < 2$). These are well defined in all but the Mo^{VI} case, the study of which is complicated by the existence of rapid equilibria involving protonated/deprotonated monomer/dimer (and higher) forms. The VI state is without question the most stable and in contrast to Cr^{VI} is only the mildest of oxidants. Compounds which have contributed to the development of the aqueous solution chemistry, including the aqua ions themselves, are considered under Section 36.1.2. It is only since 1971 that the aqua forms of oxidation state II–V ions have been identified, and

preparative as well as structural features defined.[2] The chemistry of aqua ions generally has a somewhat elevated position, since they are often regarded as a point of reference or prototype for the behaviour of a particular oxidation state. Since they are difficult to crystallize, structures of derivative complexes are relevant. The simple aqua ions of oxidation states II–V are indicated in Table 1. The quite different structures of adjacent oxidation states are to be noted, which gives rise to an interesting and varied redox chemistry. All but $[Mo(H_2O)_6]^{3+}$ are diamagnetic and metal–metal bonding is a significant contributing feature.

Table 1 Summary of Aqua Ions of Molybdenum at pH < 2

Description	*Formula*	*Mo—Mo bonding*	*Colour*
Mo_2^{II}	$[Mo_2(H_2O)_8]^{4+}$	Quadruple	Red
Mo^{III}	$[Mo(H_2O)_6]^{3+}$	None	Pale yellow
Mo_2^{III}	$[Mo_2(OH)_2(H_2O)_8]^{4+}$	Triple	Green
Mo_3^{IV}	$[Mo_3O_4(H_2O)_9]^{4+}$	Single	Red
Mo_2^{V}	$[Mo_2O_4(H_2O)_6]^{2+}$	Single	Yellow
Mo_x^{VI}	Different forms $x = 1$ and 2	None	Colourless

The three most often used 'lead in' compounds for the chemistry described are sodium molybdate, $Na_2[MoO_4]\cdot 2H_2O$, molybdenum hexacarbonyl, $[Mo(CO)_6]$, and potassium hexachloromolybdate, $K_3[MoCl_6]$. Synthesis of II and III state complexes generally requires rigorous O_2-free techniques, using a range of methods from those involving Schlenk apparatus, to the use of N_2 or Ar gas, syringes, Teflon tubing and/or stainless steel needles, and rubber seals. In some cases solutions of IV and V state complexes must also be stored O_2 free. Perchlorate cannot be used with II and III aqua ions, and also appears to oxidize some trimeric Mo^{IV} ions on leaving overnight. Instead weakly coordinating, redox inactive and strongly acidic trifluoromethanesulfonic acid, CF_3SO_3H (abbreviated HTFMS or triflate), or *p*-toluenesulfonic acid, $C_6H_4(Me)SO_3H$ (abbreviated HPTS), finds wide usage. Methanesulfonic acid, $MeSO_3H$, has also been used.

36.1.2.2 Oxidation State II

The aqueous chemistry of the II state is dominated by dimeric complexes. The latter constitute the largest group of compounds of any element containing quadrupule bonds, a subject extensively covered in the Cotton and Walton text.[3] Soon after the recognition of the quadruple bond in $[Re_2Cl_8]^{2-}$ in 1964 the structure of $[Mo_2(O_2CMe)_4]$, Figure 1, was published (Mo—Mo distance 2.09 Å).[4] The $[Mo_2Cl_8]^{4-}$ complex, Figure 2, is obtained by treating $[Mo_2(O_2CMe)_4]$ in aqueous KCl solution with 12 M HCl at 0 °C when crystals of $K_4[Mo_2Cl_8]\cdot 2H_2O$ are obtained. Similarly the bromo analogue $(NH_4)_4[Mo_2Br_8]$ has been isolated. There are no bridging ligands and in both cases the Mo—Mo distance remains short (2.14 Å), consistent with retention of a quadruple metal–metal bond.[5] For comparison, typical M—M distances for quadruply bonded dimeric d^4 complexes are 2.21 Å (for $[W_2(O_2CCF_3)_4]$),[6] 2.19 Å (for $[Tc_2(O_2CCMe_3)_4Cl_2]$)[7] and 2.2 Å (for $K_2[Re_2Cl_8]\cdot 2H_2O$).[3,4b] The d^4–d^4 technetium complex is the only Tc_2^{III} example for which there is structural information, and the ease with which $[Tc_2Cl_8]^{3-}$ rather than $[Tc_2Cl_8]^{2-}$ is obtained is at present puzzling. The range of metal–metal distances in Mo_2^{II} complexes (2.04–2.18 Å) is much smaller than that observed for Cr_2^{II} (1.83–2.54 Å).[3]

Examples of monomeric Mo^{II} complexes are much less common. It has been demonstrated that the $[Mo(CN)_7]^{5-}$ ion has a pentagonal bipyramidal structure. Other examples are nitrile (*i.e.* isocyanide) complexes $[Mo(CNR)_7]^{2+}$, which has a capped trigonal prismatic structure, and the diarsine complex $[Mo(diars)_2X_2]$.

The acetate complex $[Mo_2(O_2CMe)_4]$ is obtained by heating $[Mo(CO)_6]$ with glacial acetic acid or a mixture of the acid and its anhydride.[8] Yields are low (15–20%), but can be improved (~80%) when diglyme is used as solvent.[9] The low yields are the result of the formation of trinuclear Mo^{IV} complexes of the type $[Mo_3X_2(O_2CMe)_6(H_2O)_3]^{4+}$, where the Mo_3X_2 unit is a trigonal bipyramid with capping groups X either O or CMe (alkylidene).

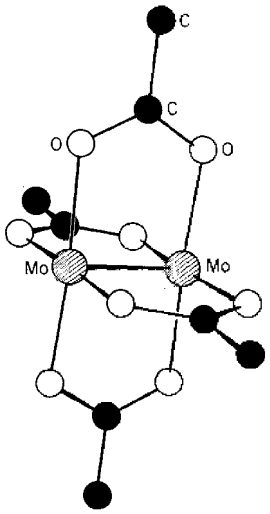

Figure 1 The structure of the Mo_2^{II} complex $[Mo_2(O_2CMe)_4]$[4a]

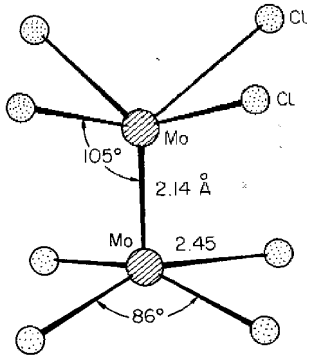

Figure 2 The structure of the Mo_2^{II} complex $[Mo_2Cl_8]^{4-}$ [5]

A listing of structural data of compounds containing Mo—Mo quadruple bonds with no bridging ligands (16 examples), with carboxylato bridges (23 examples), and a number of other compounds (25) up to 1981 has appeared.[2] A further listing of 67 structures from 1981 to 1984 has been reported.[10] The chemistry of this type of compound is therefore well established. As far as the bonding between two d^4 metals is concerned,[2] the eight electrons fill four bonding orbitals in a configuration $\sigma^2\pi^4\delta^2$. The order of energies of the molecular orbitals beginning with the most stable is $\sigma < \pi \ll \delta < \delta^* \ll \pi^* < \sigma^*$. Since there are eight bonding electrons and no non-bonding electrons the bond order is four. Features of the structures are the shortness of the M—M bond, and the tendency with no bridging ligands to get an eclipsed configuration. Whereas the σ and π bonds are cylindrically symmetrical the δ component is markedly angle sensitive. A rotation away from the eclipsed to the staggered conformation is expected to result in complete loss of the δ bond component. The δ bond is only weakly bonding, and consequently the δ^* orbital is only weakly antibonding. In the case of the $[Mo_2Cl_8]^{4-}$ complex there is mutual repulsion of the chloro ligands in one plane with those in another, with Mo—Mo—Cl angles 105° as indicated in Figure 2.

If more electrons are added the M—M bond order is reduced without loss of overall structure. Thus Rh^{II} dimers such as $[Rh_2(O_2CMe)_4(H_2O)_2]$ with an electron configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ contain a single bond, and oxidation to $Rh^{II,III}$ gives a product of bond order 1.5. This has been shown to bring about a decrease in Rh—Rh bond length from 2.39 to 2.32 Å.[11] Similarly a large number of $Ru^{II,III}$ dimers $[Ru_2(O_2CR)_4]X$ are known which have an electron configuration $\sigma^2\pi^4\delta^2\delta^{*2}\pi^*$ (or $\sigma^2\pi^4\delta^2\pi^{*2}\delta^*$) and the bond order is 2.5.[12]

The mixed-metal dimer $[CrMo(O_2CMe)_4]$ has been prepared in ~30% yield by addition of $[Mo(CO)_6]$ in acetic acid, acetic anhydride and CH_2Cl_2, to a refluxing solution of $[Cr_2(O_2CMe)_4(H_2O)_2]$ in acetic acid and acetic anhydride.[13] The yellow product is volatile and gives the expected parent ion peak in the mass spectrum. It has a Raman active ν(Cr—Mo) mode at 394 cm^{-1} consistent with quadruple bonding. The crystal structure gives a metal–metal

distance of 2.05 Å, which is shorter than in $[Mo_2(O_2CMe)_4]$ (2.09 Å) and $[Cr_2(O_2CMe)_4(H_2O)_2]$ (2.36 Å). A molybdenum–tungsten mixed-metal pivalato complex $[MoW(O_2CCMe_3)_4]$ has also been prepared.[14] The procedure involves refluxing a 1:3 mixture of $[Mo(CO)_6]$ and $[W(CO)_6]$ with pivalic acid in 1,2-dichlorobenzene. The purified product gives the $[MoW(O_2CCMe_3)_4]^+$ parent peak in the mass spectrum. A structure determination gives an Mo—W distance of 2.08 Å,[14] compared to 2.09 Å in $[Mo_2(O_2CCMe_3)_4]$. Attempts to prepare a mixed-metal octachloro complex from $[CrMo(O_2CMe)_4]$ were unsuccessful,[13] and the chemistry of these mixed-metal complexes is not at present extensive.

The carboxylate complexes $[Mo_2(O_2CR)_4]$ (R = Et, CMe_3 or Ph) are readily oxidized with iodine to give $[Mo_2(O_2CR)_4]I_3$ in 1,2-dichloroethane.[15] The complexes are paramagnetic, $\mu = 1.66$ BM for $R = CMe_3$, and give narrow ESR signals ($g = 1.93$) with hyperfine pattern consistent with two equivalent Mo(+2.5) nuclei. Oxidation of $[MoW(O_2CCMe_3)_4]$ with iodine to the 1+ ion was used in the separation from $[Mo_2(O_2CCMe_3)_4]$. The only example in which reduction of an Mo_2^{II} has been observed is in a pulse radiolysis study on $[Mo_2(O_2CCF_3)_4]$ in methanol.[16] The transient product believed to be the 1− ion with a peak at 780 nm undergoes rapid decay.

Studies on solutions containing 0.01 M $K_4[Mo_2Cl_8]$ in 0.10 M CF_3SO_3H have provided evidence for rapid loss of three Cl^- ions per $[Mo_2Cl_8]^{4-}$.[17] A number of compounds have been characterized in which limited replacement of halide ions of $[Mo_2X_8]^{4-}$ by H_2O has been achieved.[18] Preparative procedures include reacting the Mo_2^{III} compound $(NH_4)_3[Mo_2Cl_9]\cdot H_2O$ in hydrobromic acid with pyridinium bromide to give $(pyH)_3Mo_2Br_7\cdot 2H_2O$,[19] which has been shown to be the double salt $(pyH)_3[Mo_2Br_6(H_2O)_2]Br$. Other crystal structures of the 4-methylpyridinium salt $(pyH)_2[Mo_2X_6(H_2O)_2]$, and of $(picH)_2[Mo_2X_6(H_2O)_2]$ ($X^- = Br^-$ and I^-) have been reported.[20] All have the eclipsed configuration with one H_2O on each molybdenum. The Mo—Mo distance is ~0.02 Å shorter than in $[Mo_2X_8]^{4-}$ forms, possibly reflecting the decrease in anion charge.

The reaction of $K_4[Mo_2Cl_8]$ with acetic acid (up to 0.5 M) in solutions of HCl and HPTS of varying ratios, $[H^+] = 0.05$–1.95 M, has been studied.[21] The reaction proceeds in two kinetic stages which have been assigned to the entry of the first and third acetate ligands. Since there is the possible involvement of aqua intermediates, such studies are complicated. Further information on the manner of substitution on dimeric Mo^{II} will be considered below.

The kinetics of the reaction of $[Mo_2Cl_8]^{4-}$ and protons to produce the triply bridged Mo^{III} dimer $[Cl_3Mo(\mu\text{-}Cl)_2(\mu\text{-}H)MoCl_3]^{3-}$ have been studied at 25 °C in 6–12 M HCl.[22] The reaction is first order in $[Mo_2Cl_8]^{4-}$ and obeys a linear dependence with respect to the acidity function H_o. Decomposition of the hydrido-bridged product in HCl solutions (<3 M) to yield hydrogen and the green di-μ-hydroxo Mo^{III} dimer $Mo_2(OH)_2Cl_x^{(x-4)-}$ is observed, and the kinetics have again been determined.

The reverse of the $[Mo_2Cl_8]^{4-}$ to $[Mo_2Cl_8H]^{3-}$ conversion although not quite as facile has been accomplished.[23] Solutions of both the Mo_2^{III} complexes $[Mo_2Cl_8H]^{3-}$ and $[Mo_2Cl_9]^{3-}$ can be reduced with amalgamated zinc to yield red Mo_2^{II} solutions.

Electrochemical experiments on $[Mo_2Cl_8]^{4-}$ in 6 M HCl have also been reported.[24] In cyclic voltammetry studies a single oxidation peak is present at +0.5 V (*vs.* SCE), but except at high sweep rates (500 mV s^{-1}), the corresponding reduction peak is not observed. It is likely that $[Mo_2Cl_8H]^{3-}$ is formed in an irreversible step.

Replacement of chloro ligands on $K_4[Mo_2Cl_8]$ occurs on treating with H_2SO_4, and the structure $K_4[Mo_2(SO_4)_4]\cdot 2H_2O$ has been determined,[25] confirming an eclipsed structure with four bridging sulfates. An interesting feature is that the axial positions are occupied by O atoms of neighbouring sulfate groups. Air oxidation of a saturated solution of the red $K_4[Mo_2(SO_4)_4]\cdot 2H_2O$ in 2 M H_2SO_4 gives the blue Mo(+2.5) complex $K_3Mo_2(SO_4)_4\cdot 3.5H_2O$. The structure of the latter closely resembles that of $K_4[Mo_2(SO_4)_4]\cdot 2H_2O$ except that H_2O molecules are bound in each axial position.[26] The Mo—Mo distance is longer for the 3− ion (2.17 Å) as compared to the 4− ion (2.11 Å). No further oxidation is observed. In the corresponding reaction of $K_4[Mo_2Cl_8]$ with 2 M H_3PO_4 in air for 24 h in the presence of large cations, the purple crystalline μ-HPO_4 bridged dimeric Mo^{III} product is obtained,[27] which has triply bonded Mo's (2.23 Å). Analogous Mo_2^{II} and $Mo^{II,III}$ phosphato-bridged complexes do not appear to be formed.

Displacement of bridging acetate ligands of $[Mo_2(O_2CMe)_4]$ by treatment at 100 °C with methyl sulfonate (in diglycine) and trifluoromethanesulfonate gives the bridged dimers $[Mo_2(O_3SMe)_4]$ and $[Mo_2(O_3SCF_3)_4]$.[28] These complexes find use in the synthesis of other Mo_2^{II} complexes, since the ligands are good leaving groups.

On heating $K_4[Mo_2Cl_8]$ with ethylenediamine, and then adding hydrochloric acid to an aqueous solution of the crude product, orange crystals of $[Mo_2(en)_4]Cl_4$ are obtained.[17] These give an absorbance ($\delta \rightarrow \delta^*$) band at 475 nm. It is unlikely that the ethylenediamine ligand is bridging. Cyclic voltammetry measurements have shown that the complex exhibits an irreversible oxidation at +0.78 V (SCE).

The red dimeric Mo^{II} aqua ion is obtained under rigorous O_2-free conditions by adding Ba^{2+} to the sulfate complex $[Mo_2(SO_4)_4]^{4-}$.[17] Starting from $[Mo(CO)_6]$ the preparative route can be summarized as in Scheme 1. Following centrifugation to remove $BaSO_4$ the aqua Mo_2^{II} solution in 0.1 M CF_3SO_3H can be kept unchanged for up to 3 h (under N_2). As with $[MoCl_8]^{4-}$ and $[Mo_2(SO_4)_4]^{4-}$, solutions are red in colour and a comparison of UV–visible spectra, Figure 3, leaves little doubt that the aqua ion is also quadruply bonded. The absorbance peak at 510 nm (ε 370 M^{-1} cm^{-1} per dimer) has been assigned to a $\delta \rightarrow \delta^*$ transition.[29] Although the aqua ion does not display a peak at ~370 nm, the absorbance is sufficiently intense in this region for the peak to have become concealed.[30] Although the aqua ion is generally formulated as $[Mo_2(H_2O)_8]^{4+}$, in solution weak additional coordination in the axial positions may be present in which case a more precise formulation is $[Mo_2(H_2O)_8(H_2O)_2]^{4+}$.

$$[Mo(CO)_6] \xrightarrow{MeCO_2H} [Mo_2(O_2CMe)_4] \xrightarrow{KCl} [Mo_2Cl_8]^{4+} \xrightarrow{K_2SO_4}$$

$$[Mo_2(SO_4)_4]^{4-} \xrightarrow{Ba^{2+}} [Mo_2(H_2O)_8]^{4+}$$

Scheme 1

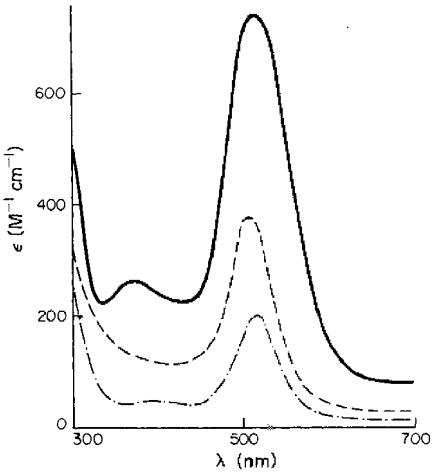

Figure 3 UV–visible spectra of $[Mo_2(H_2O)_8]^{4+}$ in 0.1 M CF_3SO_3H (– – –), $[Mo_2Cl_8]^{4-}$ in 2 M HCl (——) and $[Mo_2(SO_4)_4]^{4-}$ in 2 M H_2SO_4 (–·–)[30]

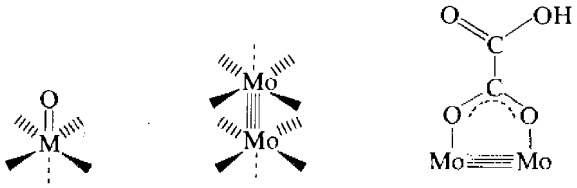

The kinetics of the 1:1 substitution of aqua Mo_2^{II} with NCS^- and $HC_2O_4^-$ have been studied in trifluoromethanesulfonic acid solutions, $I = 0.10$ M (CF_3SO_3Na), with the Mo_2^{II} reactant in greater than ten-fold excess (to avoid higher complex formation).[30] First-order equilibration rate constants, k_{eq}, determined by the stopped-flow method can be expressed as in equation (1). At 25 °C k_1 for the formation is 590 M^{-1} s^{-1}, and k_{-1} for the reverse reaction is 0.21 s^{-1}. With oxalate the rate law is equation (2), where K is the acid dissociation constant for $H_2C_2O_4$ to $HC_2O_4^-$, which is believed to be the reactant. In this case, at 25 °C, k_2 for formation is 43 M^{-1} s^{-1} and k_{-2} is 4.7×10^{-3} s^{-1}.

$$k_{eq} = k_1[Mo_2^{4+}] + k_{-1} \quad (1)$$

$$k_{eq} = \frac{k_2 K[Mo_2^{4+}]}{(K + [H^+])} + k_{-2} \quad (2)$$

The mechanism of substitution is believed to be similar to that of oxo ions such as VO^{2+} and TiO^{2+}.[31,32] Thus rapid (possibly approaching diffusion controlled) equilibration of NCS^- in the labile axial position (K) is followed by a subsequent slower step k leading to occupancy of an

in-plane position on the complex (**1**). The observed rate constant is therefore the product of the two terms kK. Clearly a similar mechanism is possible for Mo_2^{II} (**2**). Hydrated $(NH_4)_4[Mo_2(NCS)_8]$ has N-bonded (monodentate) thiocyanate, and formation of the N-bonded product is likely in the kinetic study. In the case of $HC_2O_4^-$, bridging to give the μ-carboxylato product (**3**) can be presumed to occur in a rapid subsequent step.

(**1**) (**2**) (**3**)

Values of rate constants and activation parameters for the VO^{2+}, TiO^{2+} and Mo_2^{4+} reactions with NCS^- are quite similar. The same mechanism has been proposed for the exchange of $CF_3CO_2^-$ with $[Mo_2(O_2CCF_3)_4]$ in acetonitrile from studies using ^{19}N NMR spectroscopy.[33]

Oxidation of aqua Mo_2^{II} in 1 M CF_3SO_3H to green aqua Mo_2^{III} with evolution of hydrogen is observed on irradiating at 254 nm.[34] More generally oxidation of Mo^{II} to Mo^{III} is difficult to bring about in a controlled manner. Studies on the oxidation of Mo_2^{II} in 1 M HCl have reported a new Mo^{III} dimer (λ_{max} 430 nm) possibly having a triple metal–metal bond and no bridging ligands.[35] The same product is not observed however on addition of Cl^- to the well-characterized green di-μ-hydroxo Mo^{III} aqua dimer.[36] The possible separate existence of dimeric Mo^{III} ions with and without bridging is of interest.

36.1.2.3 Oxidation State III

Hexachloromolybdate(III), prepared by electrolytic reduction of molybdate(VI) in 11 M HCl followed by addition of KCl,[38] provides a relatively easy route into Mo^{III} chemistry. The pink salt $K_3[MoCl_6]$ is stable indefinitely in dry air. In solution it aquates and is O_2 sensitive. The preparation of $[MoCl_5(H_2O)]^{2-}$ has also been described, and can be isolated as the ammonium salt, $(NH_4)_2[MoCl_5(H_2O)]$. Air-free aquation (two days) of $[MoCl_6]^{3-}$ followed by Dowex cation-exchange resin gives the pale yellow monomeric aqua ion.[17,39] In the earlier work, traces of O_2 resulted in contamination with the yellow Mo^V dimer, $Mo_2O_4^{2+}$, which because of its strong absorbance obscures the Mo^{III} spectrum.[40] The most recent spectrum in 2 M CF_3SO_3H gives peak positions λ/nm (ε/M^{-1} cm^{-1}) at 320 (19) and 386 (13.3) assigned as $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow a^4T_{1g}$ d–d ligand-field transitions.[41] The spectrum in CF_3SO_3H, which has only small background absorbance in the 250–300 nm range, contrasts with that of other inert electrolytes such as HPTS and HBF_4 which gives a peak at 310 nm (ε 23.2 M^{-1} cm^{-1}), Figure 4. A comparison of the spectrum with that of $[MoCl_6]^{3-}$ is consistent with the hexaaqua structure, Figure 4. This point has now been confirmed crystallographically following the isolation of the bright-yellow cesium molybdenum alum $Cs[Mo(H_2O)_6](SO_4)_2 \cdot 6H_2O$. The structure, belonging to the β class of alums,[42] gives an Mo—O distance of 2.09 Å. When exposed to air the crystals become brown within a few hours.

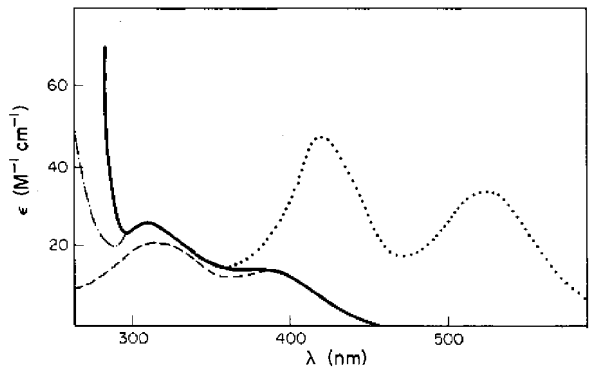

Figure 4 UV–visible spectra of $[Mo(H_2O)_6]^{3+}$ in 1.0 M CF_3SO_3H (– – –), p-$C_6H_5MeSO_3H$ (——) and HBF_4 (–·–·) compared with $[MoCl_6]^{3-}$ in 12 M HCl (· · · ·)[40,41]

An important advance in the above work was the isolation of a new compound, sodium hexakis(formato)molybdate(III), $Na_3[Mo(HCO_2)_6]$,[41] which can be aquated in strong acid to give concentrated solutions (~0.5 M) of $[Mo(H_2O)_6]^{3+}$ within a few minutes. To prepare the formato complex $(NH_4)_2[MoCl_5(H_2O)]$ (10 g) is dissolved in saturated sodium formate (~9 M) in 0.1 M formic acid. After one day the light green formato complex is filtered off. It gives in ~10 M saturated sodium formate a UV-vis spectrum with λ_{max}/nm (ε/M^{-1} cm^{-1}) at 385 (115) and an absorption minimum at 357 (97). The second ligand-field transition is obscured by this intense absorption.

From the energies of the two absorption bands for $[Mo(H_2O)_6]^{3+}$ in 2 M CF_3SO_3H, Figure 4, the values of the spectrochemical parameter separating the t_{2g} and e_g levels is 25 900 cm^{-1}, and the interelectronic repulsion parameter B is 476 cm^{-1}.[41] The shift of bands into the UV as compared to those for $[Cr(H_2O)_6]^{3+}$ at 408 and 587 nm is noted. An additional very weak band ($\varepsilon < 0.5$ M^{-1} cm^{-1}) has been observed for $[Mo(H_2O)_6]^{3+}$ between 560 and 600 nm, which may be the spin-forbidden $^4A_{2g} \rightarrow {}^2T_{2g}$ transition. At present $[Mo(H_2O)_6]^{3+}$ is the only monomeric and paramagnetic (3.69 BM) aqua ion of Mo. The acid dissociation constant of $[Mo(H_2O)_6]^{3+}$ has not yet been determined.

Conversion of $[MoCl_6]^{3-}$ (10 g) into $[Mo(NCS)_6]^{3-}$ can be achieved by dissolving in 50 ml of KNCS (7 M), and heating on a steam bath at 60 °C for 2 h.[43] A red to orange colour change is observed, and $K_3[Mo(NCS)_6]\cdot 4H_2O$ can be isolated. An X-ray crystal structure of the adduct $K_3[Mo(NCS)_6]\cdot MeCO_2\cdot H_2O$ has provided conclusive evidence for octahedral coordination, as well as for N-bonded thiocyanate.[44] Studies on the rate of exchange of NCS^- on $[Mo(NCS)_6]^{3-}$ have indicated an inert Mo^{III} centre. The potassium and pyridinium salts of the Mo^{IV} complex formulated as $[Mo(NCS)_6]^{2-}$ (and purple/red-brown in colour) have been obtained.[45] On further oxidation to the Mo^V state there are three possible products: $[MoO(NCS)_5]^{2-}$, $[Mo_2O_3(NCS)_8]^{4-}$ (μ-oxo) and $[Mo_2O_4(NCS)_6]^{4-}$ (di-μ-oxo). Oxidation of the Mo^{III} complex through Mo^{IV} to the Mo^V state therefore requires inclusion of at least one oxo ligand per Mo. In the oxidation of $[Mo(NCS)_6]^{3-}$ by $[IrCl_6]^{2-}$ formation of the Mo^{IV} ion is rapid.[46] The subsequent first-order stage monitored by stopped flow gives an inverse $[H^+]$ dependence which requires the presence of coordinated H_2O. It is suggested that the rate-determining step corresponds to loss of NCS^- from the hydroxo form of this complex, followed by (rapid) oxidation or disproportionation through to the Mo^V product. In studies relating to the one- and two-electron photooxidation of $[Mo(NCS)_6]^{3-}$ in which $[Mo(NCS)_6]^{2-}$ is first generated,[47] it has been demonstrated that the $[Mo(NCS)_6]^{2-}$ undergoes deproportionation in a mixed $MeCN/H_2O/CCl_4$ solvent (62:31:7 w/w) to give, in 0.2 M KNCS, $[Mo_2O_3(NCS)_6]^{4-}$ as the final Mo^V product.

The Mo^{III} cyano complex $K_4[Mo(CN)_7]\cdot 2H_2O$ has been isolated.[48] At room temperature it has a magnetic moment of 1.75 BM. The presence of only one unpaired electron has been attributed to d-orbital splitting in the low symmetry $[Mo(CN)_7]^{4-}$ or $[Mo(CN)_7(H_2O)]^{4-}$ ion. The complex is readily oxidized to $[Mo(CN)_8]^{4-}$.

The kinetics of the 1:1 substitution reactions of $[Mo(H_2O)_6]^{3+}$ with Cl^- and NCS^- have been investigated in HPTS, $I = 1.0$ M (LiPTS), and found to be independent of $[H^+]$ in the range 0.17–1.0 M.[49] At 25 °C formation rate constants are 4.6×10^{-3} M^{-1} s^{-1} for Cl^- ($\Delta H^{\neq}$ = 98.3 kJ mol^{-1}; $\Delta S^{\neq} = 40.2$ J K^{-1} mol^{-1}), and 0.28 M^{-1} s^{-1} for NCS^- ($\Delta H^{\neq} = 68.2$ J mol^{-1}; $\Delta S^{\neq} = -26.8$ J K^{-1} mol^{-1}) (1 cal = 4.2 J). The ratio of the two rate constants of 59 suggests an associative interchange (I_a) mechanism. This is also supported by the volume of activation ($\Delta V^{\neq}$) of −11.4 cm^3 mol^{-1} at 11.9 °C for the reaction of NCS^- with $[Mo(H_2O)_6]^{3+}$.[50] On replacing PTS^- by $TFMS^-$ the rate constant for the NCS^- reaction increases to 0.36 M^{-1} s^{-1}, and a similar small effect is observed for the Cl^- reaction. It is interesting that $[Mo(H_2O)_6]^{3+}$ is more labile than $[Cr(H_2O)_6]^{3+}$ by ~10^5 for both NCS^- and Cl^-, a trend which is in contrast to that observed with Co^{3+}, Rh^{3+} and Ir^{3+}. This is explained by the increased associative character of the reaction of $[Mo(H_2O)_6]^{3+}$, stemming from the low (d^3) electron population, and the size of 4d as opposed to 3d orbitals. While there is evidence for associative character in the reactions of Cr^{III} complexes, $\Delta V^{\neq} = -9.6$ cm^3 mol^{-1} for H_2O exchange on $[Cr(H_2O)_6]^{3+}$, this is less than observed for the d^1 ion $[Ti(H_2O)_6]^{3+}$ (−12.1 cm^3 mol^{-1}), and in some cases, *e.g.* with $[Cr(NH_3)_5H_2O]^{3+}$, Cr^{III} is best regarded as displaying borderline I_a/I_d properties.[5] Pathways involving the conjugate-base form, here $[Mo(H_2O)_5OH]^{2+}$, which often represent a more facile route for substitution involving an I_d mechanism, make little or no contribution alongside the dominant associative pathway involving $[Mo(H_2O)_6]^{3+}$. Alternatively, since Mo^{III} can adopt a higher coordination as in $[Mo(CN)_7]^{4-}$, an associative A-type mechanism is possible in the substitution of $[Mo(H_2O)_6]^{3+}$.

Other rate constants for 1:1 substitution into $[Mo(H_2O)_6]^{3+}$ include the value for $HC_2O_4^-$,[52] Table 2. Also the observation that the $[Co(C_2O_4)_3]^{3-}$ oxidation of $[Mo(H_2O)_6]^{3+}$ is independent of $[H^+]$, whereas that of $[IrCl_6]^{2-}$ displays an $[H^+]^{-1}$ dependence, suggests a substitution-controlled process.[53] The similarity of the rate constant to that for $HC_2O_4^-$ is noted. From kinetic studies on the O_2 oxidation of $[Mo(H_2O)_6]^{3+}$ two further rate constants, which may well be substitution-controlled processes, are obtained (see below). These are surprisingly large however, as are similar rate constants for the corresponding reactions of $[V(H_2O)_6]^{2+}$ (also d^3) with O_2 ($2000\ M^{-1}\ s^{-1}$), and with $[V(H_2O)_5O_2]^{2+}$ ($3700\ M^{-1}\ s^{-1}$). The latter are to be compared with values for NCS^- substitution ($24\ M^{-1}\ s^{-1}$), and H_2O exchange ($87\ s^{-1}$) on $[V(H_2O)_6]^{2+}$.[54]

Table 2 Rate Constants for 1:1 Substitution Reactions of $[Mo_2(H_2O)_6]^{3+}$ in HPTS at 25 °C, $I = 1.0$ M (LiPTS) Except as Indicated

Reactant	$k\ (M^{-1}\ s^{-1})$	*Ref.*
Cl^-	0.0046	49
NCS^-	0.27	49
$HC_2O_4^-$	0.49	52
$[Co(C_2O_4)_3]^{3-}$	0.34[a]	53
O_2	180	57
MoO_2	42	57

[a] $I = 2.0$ M (LiPTS).

Kinetic studies have been reported with three strongly coloured one-equivalent oxidants $[IrCl_6]^{2-}$, $[Co(C_2O_4)_3]^{3-}$ and $[VO(H_2O)_5]^{2+}$,[53] which oxidize $[Mo(H_2O)_6]^{3+}$, *e.g.* $2Mo^{III} + 4Ir^{IV} \rightarrow Mo_2^V + 4Ir^{III}$, to give the Mo_2^V product $[Mo_2O_4(H_2O)_6]^{2+}$. Reactions were studied with $[Mo(H_2O)_6]^{3+}$ present in large excess. Rate laws are consistent with a rate-determining first stage as in equation (3), in which Mo^{IV} is formed. No monomeric aqua Mo^{IV} species has yet been identified, and no build-up of Mo^{IV} is apparent in this study. With $[IrCl_6]^{2-}$ (0.89 V; all reduction potentials are quoted against NHE) first-order rate constants from the stopped-flow decay of $[IrCl_6]^{2-}$ at 489 nm gave a dependence (4), where at 25 °C, $I = 0.2$ M (LiPTS), $k_a = 3.4 \times 10^4\ M^{-1}\ s^{-1}$ and $k_b = 2.9 \times 10^4\ s^{-1}$. On replacing *p*-toluenesulfonate (PTS^-) by trifluoromethanesulfonate ($TFMS^-$) k_{obs} shows little variation (~12% greater). The oxidant decay was also monitored in the $[Co(C_2O_4)_3]^{3-}$ (0.58 V) and $[VO(H_2O)_5]^{2+}$ (0.36 V) studies ($t_{1/2} > 1$ min). Here more complicated dependences are observed in the presence of PTS^-. At 25 °C, $I = 2.0$ M (LiPTS), the method of initial rates (R) gives dependence (5) for the $[Co(C_2O_4)_3]^{3-}$ reaction, with $k_c = 0.34\ M^{-1}\ s^{-1}$. Similarly for the $[VO(H_2O)_5]^{2+}$ reaction (6) was obtained, with $k_f = 3.3 \times 10^{-3}\ M^{-1}\ s^{-1}$. On replacing PTS^- by $TFMS^-$ the oxidant dependent terms k_d ($1.87 \times 10^{-3}\ M^{-1}\ s^{-1}$) and k_e ($4.9 \times 10^{-5}\ s^{-1}$), which are common to both reactions, make no contribution. It seems likely therefore that k_d and k_e are spurious terms stemming from rate-determining processes involving PTS^-, which are not observed for the much faster $[IrCl_6]^{2-}$ reactions (or with $TFMS^-$ present). The rate constants for the $[IrCl_6]^{2-}$ reaction are much faster than those obtained for substitution into the $[Mo(H_2O)_6]^{3+}$ coordination sphere, and an outer-sphere mechanism is implied. With $[Co(C_2O_4)_3]^{3-}$ on the other hand, as already indicated, the oxidation is independent of $[H^+]$ and consistent with an inner-sphere substitution-controlled process, Table 3.

$$Mo^{III} + Ir^{IV} \longrightarrow Mo^{IV} + Ir^{III} \quad (3)$$

$$k_{obs}/2[Mo^{III}] = k_a + k_b[H^+]^{-1} \quad (4)$$

$$R = 2k_c[Mo^{III}][Co^{III}] + 4k_d[Mo^{III}]^2 + 2k_e[Mo^{III}] \quad (5)$$

$$R = 2k_f[Mo^{III}][V^{IV}] + 4k_d[Mo^{III}]^2 + 2k_e[Mo^{III}] \quad (6)$$

In a further study with $[Fe(H_2O)_6]^{3+}$ as oxidant, the concentration of $[Mo(H_2O)_6]^{3+}$ (initially 1.2×10^{-3} M) was monitored at 450 nm (millisec timescale) with the Fe^{3+} reactant (0.045 M) in large excess.[55] The rate constant (25 °C) of $1.3 \times 10^3\ M^{-1}\ s^{-1}$, in $I = 1.0$ M (HPTS), is too fast for substitution into either coordination sphere to occur. The formation of Mo_2^V and its subsequent decay to Mo^{VI} can also be monitored (half-lives of order of seconds), Figure 5. What is particularly interesting is that the rate of formation of Mo_2^V does not match the decay

Table 3 Rate Constants (25 °C) for the First Stage in the Oxidation of $[Mo(H_2O)_6]^{3+}$

	k ($M^{-1}s^{-1}$)	*Conditions*	*Ref.*
$[IrCl_6]^{2-}$	3.4×10^4 [a]	$I = 0.2$ M (LiPTS)	53
$[Fe(H_2O)_6]^{3+}$	1.3×10^3	$I = 1.0$ M (HPTS)	55
O_2	180[b]	$I = 2.0$ M (HPTS)	57
$[Co(C_2O_4)_3]^{3-}$	0.34[c]	$I = 2.0$ M (LiPTS)	53
$[VO(H_2O)]^{2+}$	3.3×10^{-3}	$I = 2.0$ M (HPTS)	53

[a] Corresponds to k_a in a rate law dependence $k_a + k_b[H^+]^{-1}$.
[b] May be a substitution-controlled process.
[c] Assigned as a substitution-controlled process (no $[H^+]^{-1}$ dependence).

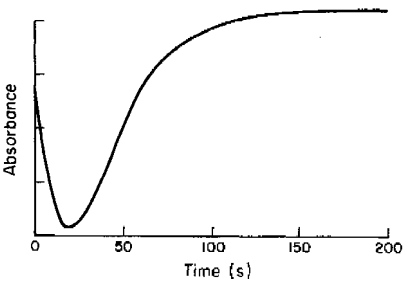

Figure 5 Oxidation of $[Mo(H_2O)_6]^{3+}$ (1.2×10^{-3} M) with $[Fe(H_2O)_6]^{3+}$ (0.045 M) monitored at λ 450 nm, 25 °C, $I = 1.0$ M (HPTS)[55]

of Mo^{III}, thus providing clearcut evidence for formation of an intermediate, Mo^{IV} and/or monomeric Mo^{V}. Further studies on this system would be of interest.

Perchlorate also oxidizes $[Mo(H_2O)_6]^{3+}$, but the features displayed are quite unusual and different to all previous reactions involving ClO_4^- and metal ions.[56] The formation of Mo_2^{V} with time is indicated in Figure 6, the reaction being characterized by induction, propagation and termination stages. Remarkably in such studies at 25 °C, $I = 1.0$ M (LiPTS), solutions of Mo^{3+}, $(2.2–8.6) \times 10^{-3}$ M, give little or no detectable reaction with ClO_4^- (0.2–0.7 M) over a period of at least 0.5 h and as long as 3 h, after which complete reaction can be observed in as little as 1 h. Overall the reactions are faster at higher $[ClO_4^-]$, higher $[Mo(H_2O)_6^{3+}]$ and higher $[H^+]$. Details of the precise mechanism remain uncertain. Since perchlorate reactions are believed to involve O-atom transfer by either (7) or (8), substitution of ClO_4^- into the $[Mo(H_2O)_6]^{3+}$ coordination sphere is required. In an I_a substitution process a poor donor such as ClO_4^- is not expected to react very rapidly, and this no doubt contributes to the slowness of the reaction. The higher $[H^+]$ is known to assist O-atom transfer. The instability and transient nature of monomeric Mo^{IV} and/or Mo^{V} with a correspondingly high activation barrier for formation is also expected to contribute to the slowness of the reaction. Once under way the $ClO_4^- \rightarrow Cl^-$ eight-equivalent change, and presumably the ability of monomeric Mo^{IV} or Mo^{V} to reduce ClO_4^-, will account for the rapid propagation of the reaction. The reaction of the green aqua dimer of Mo_2^{III} with ClO_4^- exhibits similar behaviour.

$$ClO_4^- - e^- \longrightarrow ClO_3 + O^{2-} \quad (7)$$

$$ClO_4^- - 2e^- \longrightarrow ClO_3^- + O^{2-} \quad (8)$$

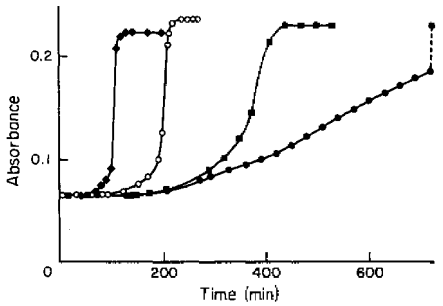

Figure 6 Absorbance changes at 385 nm for the reaction (25 °C) of $[Mo(H_2O)_6]^{3+}$ (4.3×10^{-3} M) with ClO_4^- at $[H^+] = 0.30$ M, $I = 1.0$ M (LiPTS). Concentrations of perchlorate introduced as $LiClO_4$ were 0.20 (●), 0.30 (■), 0.50 (○) and 0.70 (◆)[56]

The reaction of $[Mo(H_2O)_6]^{3+}$ with O_2 in *p*-toluenesulfonic acid solutions, $I = 2.0$ M (LiPTS), gives $[Mo_2O_4(H_2O)_6]^{2+}$ as product: $2Mo^{3+} + O_2 + 2H_2O \rightarrow Mo_2O_4^{2+} + 4H^+$.[57] Three stages are observed (Figure 7). Use of isotopically labelled O_2 followed by IR spectroscopy on the isolated $Mo_2O_4^{2+}$ product has demonstrated that ^{18}O is taken up in the μ-oxo positions. With Mo^{3+} in large excess an intense yellow intermediate MoO_2Mo^{6+} (or a related form) with a peak at 395 nm ($\varepsilon = 2300\ M^{-1}\ cm^{-1}$) is observed. At 25 °C stopped-flow studies on the decay of this intermediate give rate constants $k_{3(obs)}$ which can be expressed as in equation (9). Various constants were obtained as defined in equations (10)–(12), where values indicated are for 2.0 M HPTS.

$$k_{3(obs)} = \frac{K_1K_2k_3[Mo^{3+}]^2}{1 + K_1[Mo^{3+}] + K_1K_2[Mo^{3+}]^2} \quad (9)$$

$$Mo^{3+} + O_2 \rightleftharpoons MoO_2^{3+} \qquad (K_1\ 360\ M^{-1}) \quad (10)$$

$$MoO_2^{3+} + Mo^{3+} \rightleftharpoons MoO_2Mo^{6+} \qquad (K_2\ 535\ M^{-1}) \quad (11)$$

$$MoO_2Mo^{6+} + 2H_2O \longrightarrow Mo_2O_4^{2+} + 4H^+ \qquad (k_3\ 0.23\ s^{-1}) \quad (12)$$

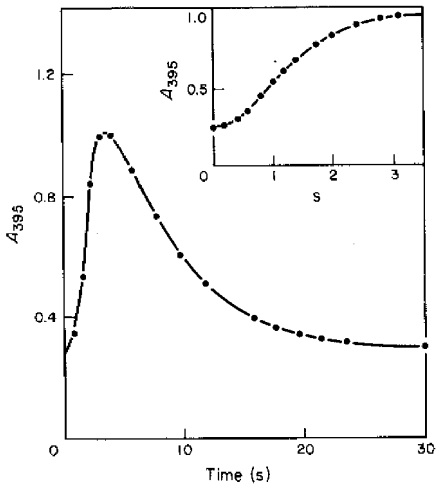

Figure 7 Identification of three stages in the reaction of $[Mo(H_2O)_6]^{3+}$ (10.6×10^{-3} M) with O_2 (5.3×10^{-4} M) monitored at 395 nm (1.67 cm pathlength), at 25 °C in 2.0 M HPTS[57]

Estimates of rate constants for reactions (10) and (11) were obtained from studies on the formation of MoO_2Mo^{6+}. All parameters were further refined by a fitting procedure using the program KINSIM for multistep reactions. The values of k_1 ($180\ M^{-1}\ s^{-1}$) and k_2 ($42\ M^{-1}\ s^{-1}$) are in excess of previous substitution rate constants for $[Mo(H_2O)_6]^{3+}$ as already mentioned. An alternative mechanism is that Mo^{IV} and O_2^- are generated in an outer-sphere pathway and that substitution then occurs. A similar process might also be relevant for $[V(H_2O)_6]^{2+}$ with O_2, where the substitution properties of $[V(H_2O)_6]^{3+}$ are already established and consistent with the results obtained. With O_2 in excess of Mo^{3+} (0.72×10^{-4} M) there was no evidence for MoO_2Mo^{6+}, and an alternative route for conversion of MoO_2^{3+} to $Mo_2O_4^{2+}$, which is first order in MoO_2^{3+} ($k_4 = 0.037\ s^{-1}$), was identified. In the refinement this step was included alongside equations (10)–(12). The reactions of MoO_2Mo^{6+} (k_3) and MoO_2^{3+} (k_4) exhibit $[H^+]^{-1}$ dependences consistent with an increase in hydrolysis of the metal on oxidation to a higher state.

A green Mo^{III} dimeric product is obtained on reduction of Mo^{VI} as $[MoO_4]^{2-}$, or Mo^V as $[Mo_2O_4(H_2O)_6]^{2+}$ in acidic solutions (not $HClO_4$), generally at $[H^+]$ in the range 0.5–2.0 M.[58] The reduction can be achieved using a Zn/Hg Jones reductor column, or by electrolytic reduction at a Hg-pool electrode at −0.5 V (*vs.* NHE). The product can be purified on a Dowex cation-exchange column. The charge per Mo has been determined as 2+ and the elution behaviour is consistent with a total charge of 4+.[58] By comparison of the UV–visible spectrum (Figure 8) with that of the Mo_2^{III}–edta complex,[36] the structure of which is known,[59] a di-μ-hydroxo structure is likely. This has been confirmed by EXAFS studies which indicate an Mo—Mo distance of 2.54 Å.[60] Two different Mo—O components in the fit correspond to bridging Mo—OH (2.06 Å), and terminal Mo—OH_2 (2.2 Å), bond distances.

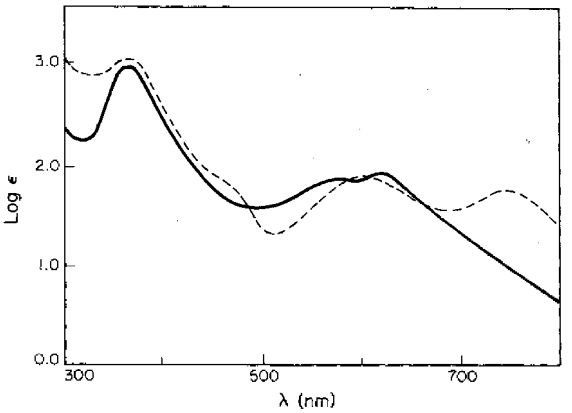

Figure 8 UV–visible spectra (ε values per dimer) for the Mo^{III} aqua dimer (——), $[H^+] = 1.0$ M (HPTS), and the Mo_2^{III}–edta complex $[Mo_2(OH)_2(O_2CMe)(edta)]^-$ (– – –) at pH 6[36]

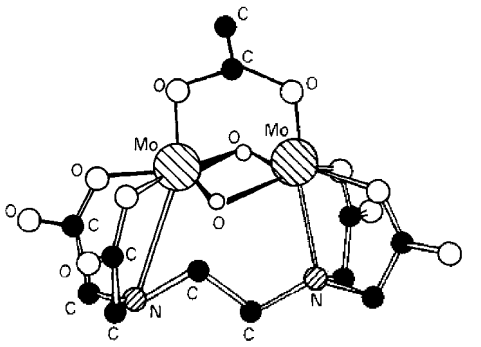
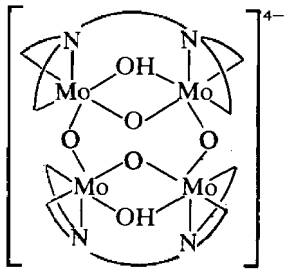
From studies in aqueous HPTS there is some uncertainty concerning the applicability of Beer's law at $[Mo_2^{III}] < 4 \times 10^{-4}$ M, and comparative studies in $TFMS^-$ are called for. Kinetic studies on substitution reactions of Mo_2^{III} would also be of interest. Oxidation of Mo_2^{III} to Mo_2^{V} is observed with $[Co(C_2O_4)_3]^{3-}$ (stopped-flow range) and $[IrCl_6]^{2-}$ (fast). Again no build-up of other Mo states is evident even when there is a deficiency of oxidant. The faster rates for Mo_2^{III} as compared to the $[Mo(H_2O)_6]^{3+}$ implicate a more facile oxidation of the dimer, which is reasonable in view of the similar dimeric structures of the Mo_2^{III} and Mo_2^{V} ions. On oxidation of monomer $2Mo^{III} \rightarrow Mo_2^{V}$ the interplay of electron uptake ($4e^-$) and proton release ($8H^+$) is noted. In the corresponding $Mo_2^{III} \rightarrow Mo_2^{V}$ change $4e^-$ and $6H^+$ are involved. In the first stage a dimeric $Mo^{III,IV}$ transient is presumably formed. From preliminary studies at least two stages are observed in the reaction of Mo_2^{III} with O_2.

The preparation of the binuclear Mo_2^{III} complex $K[Mo_2(OH)_2(O_2CMe)(edta)]$ (edta = ethylenediaminetetraacetate) has been reported.[61] The procedure involves Zn—Hg reduction of the Mo_2^{V} complex $[Mo_2O_4(edta)]^{2-}$ in acetate buffer at pH 5. Incorporation of the bridging acetate was not anticipated. In the pH 3–4 range, with and without acetate, a water insoluble product $[Mo_2(OH)_2(H_2O)_2(edta)]$ with no charge is obtained.[61] The structure of the μ-acetato complex has been determined, Figure 9.[59] There are four bridging ligands in this complex with the edta coordinated to the binuclear unit in a 'basket' like conformation. The short Mo—Mo distance of 2.43 Å is possibly due to the presence of the μ-acetato ligand as well as the bridging edta. A bis(thiocyanato) complex $[Mo_2(OH)_2(NCS)_2(edta)]^{3-}$ has been isolated following treatment of the μ-acetato complex with thiocyanate. All three complexes are diamagnetic consistent with a triple metal–metal bond. A derivative with formate in place of acetate has been prepared. The μ-acetato complex is stable in air for only limited periods (a few hours), and in water it reacts rapidly with O_2 to give the Mo_2^{V} complex $[Mo_2O_4(edta)]^{2-}$.





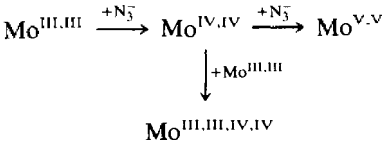


Figure 9 The structure of the Mo_2^{III} complex $[Mo_2(OH)_2(O_2CMe)(edta)]^-$ [59]

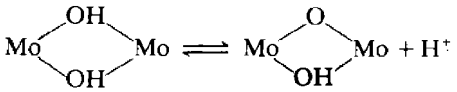
With the mild two-equivalent oxidizing agent azide as N_3^- (and with hydrazine) at pH > 6, the μ-acetato Mo_2^{III}–edta complex gives a maroon-red $Mo^{III,IV}$–edta complex.[62] The crystal structure has indicated a tetramer, $K_4[Mo_4O_4(OH)_2(edta)_2]\cdot 16H_2O$ (**4**), in which the four Mo atoms are in the same plane.[63] The number of oxidizing equivalents per Mo has been determined by titration, and indicates an average oxidation state of 3.5. The complex is diamagnetic and all bridging groups are symmetrically disposed (equal bond lengths) to adjacent Mo atoms. The short Mo—Mo distance of 2.41 Å bridged by the μ-oxo-μ-hydroxo ligands is consistent with metal–metal bonding. These two bridges can be distinguished from each other, the μ-oxo Mo—O bonds (1.93 Å) being shorter that the μ-hydroxo Mo—O bonds (2.08 Å). The single μ-oxo bridges have Mo—O bond lengths of 1.90 Å and an MoOMo angle of 164°. It is possible to comment on the mechanism of formation. The products of the reaction of azide are both the $Mo^{III,III,IV,IV}$ tetramer and Mo_2^V dimer. Quantitative formation of N_2 and NH_3 is observed, consistent with equations (13) and (14). A maximum yield (37%) of $Mo^{III,III,IV,IV}$ is observed for a 1:1 ratio of reactants. Competition between Mo_2^{III} and N_3^- for an intermediate is implied. Since azide is capable of a two-equivalent change we tentatively suggest that this intermediate is an Mo_2^{IV} dimer. Reaction Scheme 2 is proposed. No reaction is observed at pH 4.7 (the pK_a for HN_3 is 4.68) in the presence of free acetate, but reaction does occur slowly when no acetate is present. Displacement of acetate would therefore seem to favour reaction. As the pH is increased to 8 (even in the presence of acetate) the rate increases markedly. This corresponds to acid dissociation of one of the μ-hydroxo ligands determined spectrophotometrically as pK_a 7.73 at 0 °C (equation 15). Furthermore no reaction of the bis(thiocyanato) Mo_2^{III} complex is observed with N_3^- at pH 8. It is concluded that coordination of N_3^- precedes reaction.



(**4**)

Scheme 2

$$2Mo_2^{III} + N_3^- \xrightarrow{H^+} Mo^{III,III,IV,IV} + N_2 + NH_3 \quad (13)$$

$$Mo_2^{III} + 2N_3^- \xrightarrow{H^+} Mo_2^V + 2N_2 + 2NH_3 \quad (14)$$

(15)

Controlled O_2 oxidation of the $Mo^{III,III,IV,IV}$ tetramer yields a product which titrates for Mo^{IV} and from an incomplete X-ray crystal study appears to be basically the same tetrameric structure, except that all the bridging ligands are now μ-oxo. This Mo^{IV} tetramer is also an intense red colour, Figure 10. The reduction potential for the couple involving the two tetramers is +0.07 V. Rapid reactions of both tetramers with O_2 are of interest in that there is no site for binding unless the coordination number increases. Mild oxidants such as $[Co(NH_3)_5Cl]^{2+}$ react rapidly ($t_{1/2} < 1$ min) with both tetramers to give the Mo_2^V dimer.

As already mentioned under Mo^{II} the reaction of $K_4[Mo_2Cl_8]$ with 2 M H_3PO_4 in air for 24 h yields a dimeric Mo^{III} product. The structures of $Cs_2[Mo_2(HPO_4)_4(H_2O)_2]$, which has axial H_2O molecules, and $(pyH)_3[Mo_2(HPO_4)_4Cl]$, in which there are infinite chains with shared axial

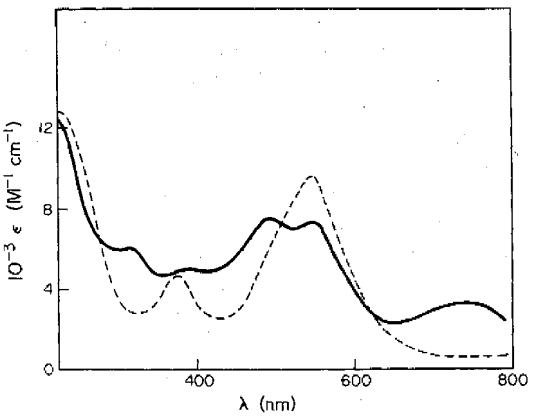


Figure 10 UV–visible spectra (ε values per tetramer) for the $Mo^{III,III,IV,IV}$ complex $[Mo_4O_4(OH)_2(edta)_2]^{4-}$ (——), and the related Mo_4^{IV} complex, $[Mo_4O_6(edta)_2]^{4-}$ (– – –) in H_2O[62]

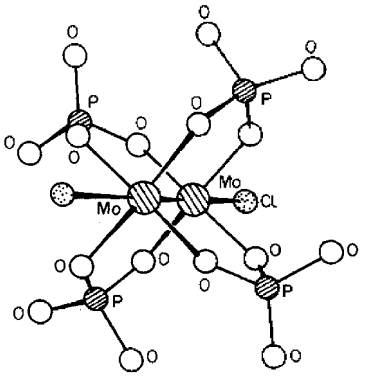
chloride ligands, have been reported (Figure 11).[27] The Mo—Mo distance of 2.23 Å is consistent with a triple bond ($\sigma^2\pi^4$). Interestingly the positions of the protons can be identified as attached to outer O atoms of the μ-HPO_4 ligands, outer P—O distances being 1.48 Å as compared to 1.54 Å for P—OH.



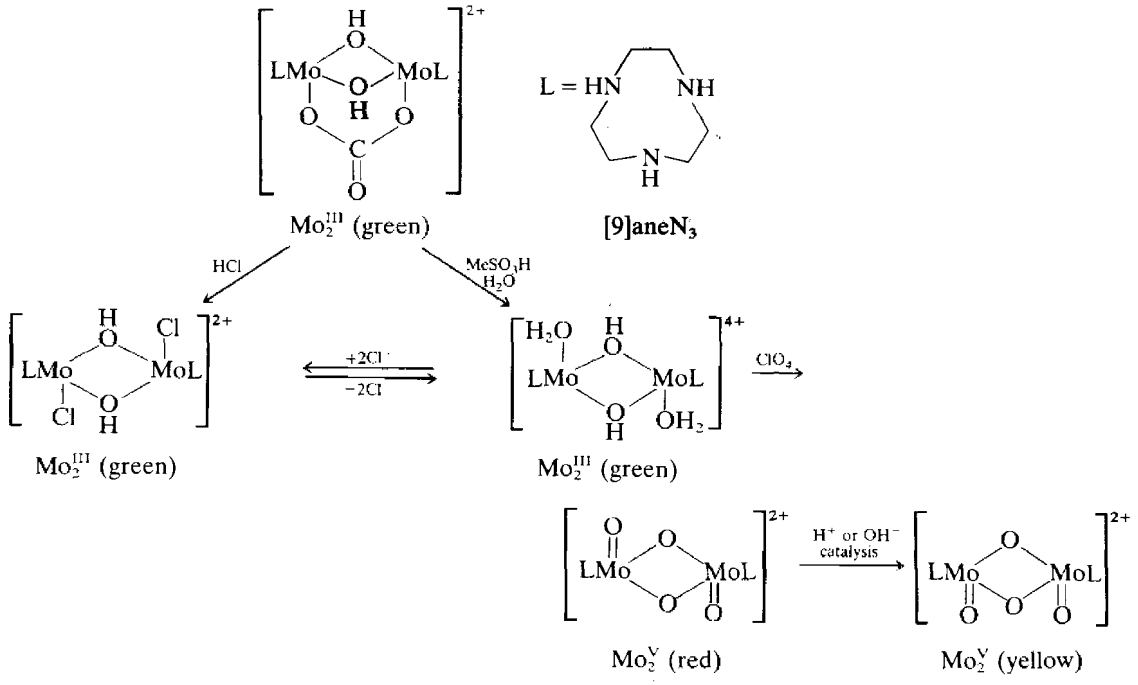


Figure 11 The structure of the Mo_2^{III} complex $[Mo_2(HPO_4)_4(Cl)]^{3-}$, where the chlorides are bridging[27]

Binuclear complexes of Mo^{III} have been prepared from paramagnetic mononuclear halogeno complexes of the type $LMoX_3$, where L = 1,4,7-triazacyclononane, sometimes referred to as 9-aneN_3.[64] Hydrolysis of $LMoCl_3$ in aqueous solution containing acetate or HCO_3^- yields $[LMo(OH)_2(O_2CMe)MoL]I_3{\cdot}H_2O$ and $[LMo(OH)_2(CO_3)MoL]I_2{\cdot}H_2O$. The acetato-bridged complex has been shown to have an Mo—Mo distance of 2.41 Å, which compares with 2.43 Å for $[Mo_2(OH)_2(O_2CMe)(edta)]$.[59] On treating the μ-carbonato complex with acids, products as indicated in Scheme 3 are obtained. A feature of the structure of the dichloro complex (Figure 12) is the *anti* (sometimes referred to as *trans*) dichloro arrangement. The $Mo_2(OH)_2$ ring is planar and the Mo—Mo distance 2.50 Å. On oxidation, *e.g.* with ClO_4^-, the corresponding red-purple Mo_2^V complex with *anti* terminal oxo ligands (and planar Mo_2O_2 ring) has been observed for the first time, and the structure verified.[65] Cleavage of a bridge in triply bridged complexes to give *anti* rather than *syn* structures has been observed previously with $[(NH_3)_3Co(OH)_3Co(NH_3)_3]^{3+}$.[66] A comparison of different metal–metal bond distances is made in Figure 13, indicating the influence of M—M bonding.[64] All di-μ-hydroxo Mo_2^{III} complexes are diamagnetic.

Kinetic studies on the reaction of $[L(H_2O)Mo(OH)_2Mo(H_2O)L]^{4+}$ with Cl^- (0.11 $M^{-1}\,s^{-1}$ at 25 °C) and ClO_4^- (a redox process) ($2.0 \times 10^{-3}\ M^{-1}\,s^{-1}$ at 21 °C) give rate constants independent of $[H^+]$ in the range 0.05–1.0 M. It is proposed that the ClO_4^- reaction is substitution controlled. This reaction proceeds $Mo_2^{III} \rightarrow$ *anti*-Mo_2^V (red-purple) $\rightarrow$ *syn*-Mo_2^V (yellow). No intermediates were identified. The reaction with NO_3^- has also been studied (again strictly air-free), when quantitative formation of the red-purple *anti*-$[L_2Mo_2O_4]^{2+}$ complex and nitrite is observed (equation 16).[67]

$$Mo_2^{III} + 2NO_3^- \longrightarrow Mo_2^V + 2NO_2^- \qquad (16)$$

Scheme 3

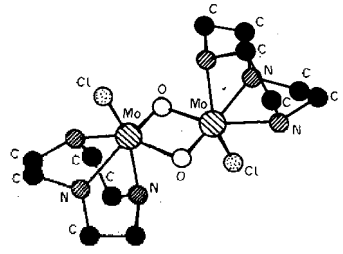

Figure 12 The structure of the Mo_2^{III} complex $[Mo_2L_2Cl_2(OH)_2]^{2+}$, where L is the [9]aneN$_3$ ligand 1,4,7-triazacyclononane[64a]

The formation of NO_2^- was demonstrated by carrying out the reaction in acid solution in the presence of sulfanilic acid and α-naphthylamine, neither of which reacts with the Mo complexes. The formation of the known red azo dye is diagnostic of NO_2^- formation. The stoichiometry was confirmed by determining the N_2 evolved (equation 17).

$$H_2NSO_3H + NO_2^- \xrightarrow{\text{fast}} HSO_4^- + N_2 + H_2O \tag{17}$$

At 25°C the kinetics give a rate law (equation 18), with $k = 0.10\,M^{-1}\,s^{-1}$, and activation parameters $\Delta H^{\neq} = 69\,kJ\,mol^{-1}$ and $\Delta S^{\neq} = -33\,J\,mol^{-1}\,K^{-1}$, $I = 0.50\,M$ (CF_3SO_3Na). By using 90% ^{18}O-enriched NO_3^- it was demonstrated by IR that the terminal oxo ligands of the *anti*-$Mo_2O_4^{2+}$ product were labelled and that reaction is therefore by O atom transfer. The increase in k with $[H^+]$ is possibly related to the need to transfer an O atom as in ClO_4^- reactions.

$$-d[Mo_2^{III}]/dt = d[Mo_2^V]/dt = k[Mo_2^{III}][NO_3^-] \tag{18}$$

A less extensive study of the reaction of $[Mo(H_2O)_6]^{3+}$ with NO_3^- has also been reported.[68] As in the above study rate constants are consistent with a substitution-controlled process.

By adjusting conditions, aqueous HCl solutions of $Na_2[MoO_4]$ can be reduced electrolytically to give $[Mo_2Cl_9]^{3-}$ rather than $[MoCl_6]^{3-}$.[69] An alternative procedure[70] yielding a purer product is by electrolytic oxidation of $[Mo_2Cl_8]^{4-}$. The W^{III} complex $[W_2Cl_9]^{3-}$ is known, but $[WCl_6]^{3-}$ is more difficult to prepare. The $[M_2X_9]^{3-}$ ($X^- = Cl^-, Br^-$) complexes have three bridging halide ions in a cofacial bioctahedral arrangement, which is also present in $[Cr_2Cl_9]^{3-}$.

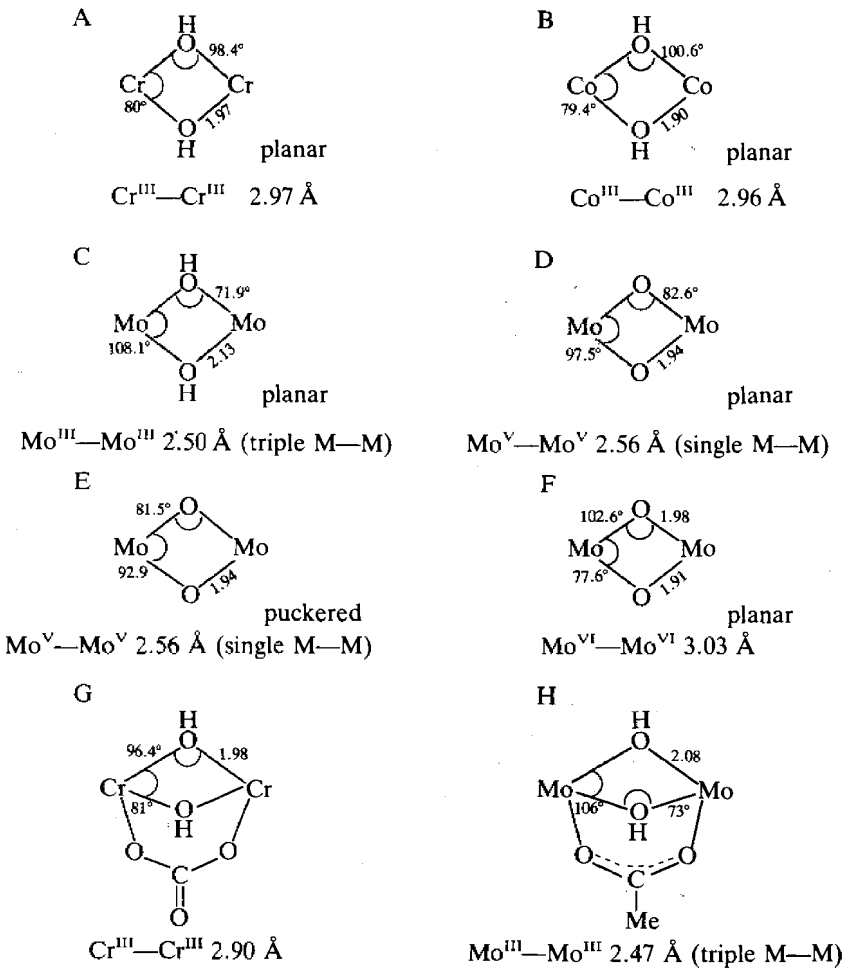

Figure 13 A comparison of M—M distances and bond angles in bridged binuclear complexes[64a]

However, the strength of interaction between two d^3 ions increases markedly in the series, Cr, Mo, W. There is no M—M bond in the case of Cr, and the Cr atoms actually repel each other. The magnetic and spectroscopic properties are essentially those of two unperturbed d^3 ions. In the case of $W_2Cl_9^{3-}$ the M—M interaction is very strong (2.45 Å),[71] with no unpaired electrons. The M—M distances in the case of $[Mo_2Cl_9]^{3-}$ (2.67 Å) and $[Mo_2Br_9]^{3-}$ (2.78 Å) indicate intermediate behaviour.[71] In the latter a temperature dependent magnetism has been observed suggesting that the Mo—Mo interaction is weak enough to allow some unpairing of electrons.

The reaction of $[Mo_2(O_2CMe)_4]$ and RbCl or CsCl in deoxygenated 12 M HCl at ~60 °C gives green-yellow products,[70] initially assigned formulae $Rb_3[Mo_2Cl_8]$ or $Cs_3[Mo_2Cl_8]$. Until they were demonstrated to be diamagnetic they were thought to be mixed-valent II,III complexes. Tritium labelling experiments have demonstrated the presence of an H atom, and the complexes are therefore reformulated as $[Mo_2X_8H]^{3-}$ ($X = Cl^-$ and Br^-) molybdenum(III) species. Consistent with Mo—H—Mo hydrido bridging, IR spectroscopy gives ν(Mo—H—Mo) at 1260 cm^{-1}.[72] The structure has been verified crystallographically for the pyridinium salt, Figure 14.[73]

36.1.2.4 Oxidation State IV

Souchay and colleagues were the first to report a red Mo^{IV} aqua ion.[74] Since that time preparative procedures have changed very little and generally involve heating Mo^{VI} as $Na_2[MoO_4]\cdot 2H_2O$, or Mo^V as the aqua dimer $Mo_2O_4^{2+}$, with $K_3[MoCl_6]$ in 2 M HPTS for 1–2 h at 80–90 °C.[2] The product can be stored in this form and purified by Dowex cation-exchange chromatography as required. Elution can be carried out with 2 M acid, but in perchloric acid

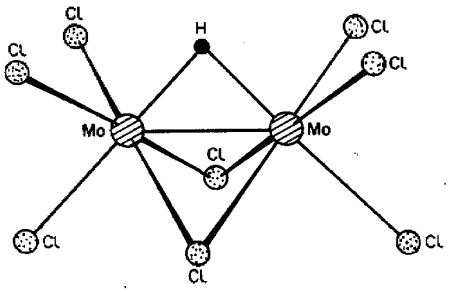

Figure 14 The structure of the Mo_2^{III} complex $[Mo_2Cl_6(Cl_2)(H)]^{3-}$ [73]

solutions accelerated conversion to yellow Mo_2^V occurs overnight. This process has not been studied and may have features similar to the reaction of $[Mo(H_2O)_6]^{3+}$ with ClO_4^-. X-Ray crystal structures of the oxalate, $Cs_2[Mo_3O_4(C_2O_4)_3(H_2O)_3]\cdot H_2O$[75] (Figure 15), the thiocyanate, $[Me_4N]_4[Mo_3O_4(NCS)_8(H_2O)]$,[76] and the *N*-methyliminatodiacetate complex, $Na_2[Mo_3O_4((O_2CCH_2)_2NMe)_3]\cdot 7H_2O$,[77] have indicated trinuclear structures. The Mo_3O_4 core has an incomplete cube structure with one corner unoccupied. In the case of the edta complex $Na_4[Mo_3O_4)_2(edta)_3]\cdot 4H_2O$, there are two trimeric Mo_3O_4 units per molecule, and the three edta ligands coordinate *via* two carboxylates and the imine group to an Mo of each $Mo_3O_4^{4+}$ cluster, giving three bridging edta ligands. This results in a prolate spheroid shape.[78] In much earlier work[79] the Mo^{IV} complex $K_2Mo_3O_4(C_2O_4)_3\cdot 5H_2O$ was reported, but full structural implications were not realized at the time.

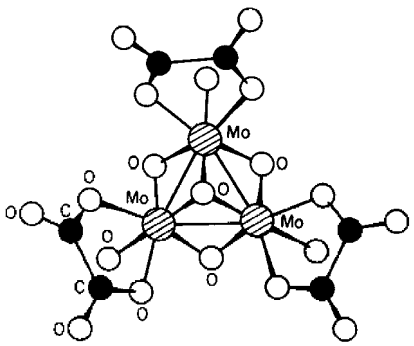

Figure 15 The structure of the Mo_3^{IV} complex $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$ [75]

The spectrum of the aqua $Mo_3O_4^{4+}$, peak at 505 nm ($\varepsilon = 63\ M^{-1}\,cm^{-1}$ per Mo), is shown in Figure 16. Substituents often have little effect, and equilibration with 4 M HCl followed by ion-exchange chromatography provides evidence for at least two chloro products, with visible spectra difficult to distinguish from that of the aqua ion. The colour originates therefore from the central $Mo_3O_4^{4+}$ core. With thiocyanate, on the other hand, changes in absorbance at 340 nm are observed, and substitution processes can be monitored. There is no evidence in the aqueous solution chemistry for the existence of stable monomer and dimer forms, which are transients only in redox processes. Thus $[Mo(H_2O)_6]^{3+}$ is oxidized to the Mo_2^V aqua dimer, and with a deficiency of oxidant unreacted $[Mo(H_2O)_6]^{3+}$ and Mo_2^V are the only identifiable Mo species present. Reports from a number of groups in the period 1973–1980 referring to the red aqua Mo^{IV} ion as dimeric or monomeric are now known to be incorrect.

The $Mo_3O_4^{4+}$ core has a coordination number of nine. Evidence for retention of the $Mo_3O_4^{4+}$ unit in the aqueous solution has come from ^{18}O studies, also directed at measuring the rate of oxygen-atom exchange.[80–82] The precipitating agent used was tetramethylammonium thiocyanate which gives $[Me_4N]_5[Mo_3O_4(NCS)_9]$ within 2 min at 0 °C. With ^{18}O enrichment of the solvent the amount of label transferred to the solid after minimal contact times was <5%. Furthermore it was possible to convert the aqua $Mo_3O_4^{4+}$ ion through the changes solid $[Mo_3O_4(NCS)_9]^{5-} \rightarrow$ aqua $Mo_3O_4^{4+} \rightarrow$ solid $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-} \rightarrow$ aqua $Mo_3O_4^{4+} \rightarrow$ solid $[Mo_3O_4(NCS)_9]^{5-}$ with <4% core O-atom exchange with solvent. Since the crystal structures of the oxalate and thiocyanate complexes have demonstrated that the $Mo_3O_4^{4+}$ core is present, all four core O atoms must exchange slowly in solution. Accordingly the aqua ion can be designated the $Mo_3O_4^{4+}$ structure, with nine water ligands attached (Figure 17). There

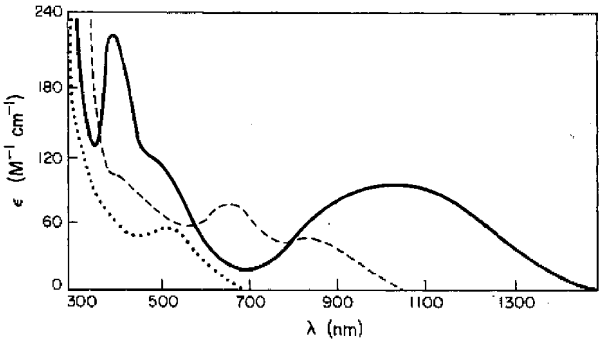

Figure 16 UV–visible–NIR spectra (ε values per Mo) for the Mo^{IV} aqua ion $[Mo_3O_4(H_2O)_9]^{4+}$ (· · ·), the Mo^{III} aqua trimer (– – –) and the mixed valence trimer $Mo^{III,III,IV}$ (——) in HPTS[84]

are four different types of O atom coordinated to each Mo. Present information suggests that the O atoms of type A exchange significantly faster than those of type B.[80–82] At 30 °C the half-life is about four days in 1.0 M $MeSO_3H$, and the number of O atoms exchanging at this rate was determined as 1.1. The rate was not significantly affected by small changes in $[H^+]$ (0.8–1.2 M) or $[Mo_3O_4^{4+}]$ (0.08–0.14 M). This result is difficult to explain because, in the process of exchange, a μ_3-oxo ligand (type A) should become a μ_2-oxo ligand (type B). At 25 °C the type B O atoms exchange very slowly and only a fraction of exchange occurs in 534 days in 1.1 M $MeSO_3H$. The half-life is estimated as 5 ± 2 years. To determine the exchange characteristics at type C positions the loss in enrichment of $[Mo_3O_4(H_2O^*)_6(H_2O^*)_3]^{4+}$ on conversion to $[Mo_3O_4(C_2O_4)_6(H_2O^*)_3]^{4+}$ was determined, where the latter can be precipitated with $[Pt(en)_2]^{2+}$. The crystal structure of the product was confirmed.[82] These experiments indicated three type C waters, with a half-life for exchange of ~1 h at 25 °C in 1.0 M $MeSO_3H$. Using $[Mo(CN)_8]^{4-}$ as a precipitating agent the half-life for type D waters was determined as 25 min at 0 °C in 1.2 M $MeSO_3H$. This is slower than might have been expected on the basis of NCS^- for H_2O substitution studies.

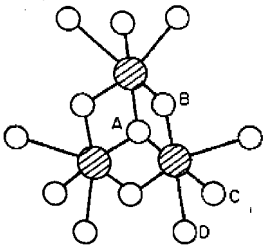

Figure 17 Structure of the Mo_3^{IV} aqua ion $[Mo_3O_4(H_2O)_9]^{4+}$ and designation of four different O atoms, A–D

Other relevant ^{18}O exchange studies have demonstrated that through the sequence of changes aqua $Mo_3O_4^{4+} \rightarrow Mo^{IV}$ (hydroxide precipitate) $\rightarrow$ aqua $Mo_3O_4^{4+}$, there is at least 96% core O-atom retention. Apparently the core is retained in the precipitate and no dramatic base-catalyzed core O-atom exchange is observed.

From crystal structure information Mo—O bond lengths for the different O atoms are 2.02 Å (A), 2.92 Å (B), 2.16 Å (C) and 2.26 Å (D). EXAFS data for aqua Mo^{IV} in 4 M $MeSO_3H$ are consistent with the accepted $Mo_3O_4^{4+}$ structure,[60] with an Mo—Mo distance of 2.49 Å compared to 2.51 Å from X-ray crystallography.[78]

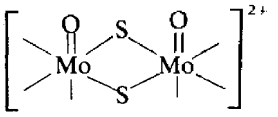
The existence of equivalent and non-equivalent H_2O ligand sites on $Mo_3O_4^{4+}$ results in unusual kinetic situations when the complexing with NCS^- is studied.[83] For the conditions in which $[NCS^-]$ is in large (>10-fold) excess, a statistically corrected rate constant is obtained assuming three equivalent sites on the $Mo_3O_4^{4+}$ ion, and equilibration rate constants k_{eq} can be expressed as in equation (19). With $[Mo_3O_4(H_2O)_9]^{4+}$ in excess the reaction is constrained by the low $[NCS^-]$ to form only $Mo_3O_4(NCS)^{3+}$, and the rate law in equation (20) applies.

$$k_{eq} = (k_1/3)[NCS^-] + k_{-1} \quad (19)$$

$$k_{eq} = k_1[Mo_3O_4^{4+}] + k_{-1} \quad (20)$$

A comparison was made using the different anions, *p*-toluenesulfonate, trifluoromethanesulfonate and perchlorate ($I = 2.0$ M). At 25 °C forward and backward rate constants at $[H^+] = 2.0$ M are $k_1 = 0.78$, 1.02, 2.13 $M^{-1} s^{-1}$ and $10^3 k_{-1} = 1.57$, 1.94, 2.18 s^{-1}, for these three anions respectively. Rate constants k_1 and k_{-1} have $[H^+]$ dependences of the kind $a + b[H^+]^{-1}$, with b dominant for $[H^+] = 0.8$–2.0 M. In common with other conjugate-base pathways, b can be assigned an I_d mechanism. The large contribution from such a path for a low electron population metal (here d^2) is believed to be in some part due to the steric crowding around each Mo^{IV} resulting from Mo—Mo bonding. Thus with the inclusion of Mo—Mo bonding each Mo is eight-coordinate. Solutions containing higher complexes obtained by equilibrating $Mo_3O_4^{4+}$ (1.3×10^{-3} M) with NCS^- (5×10^{-3} M) give, on ion exchange, bands that in order of elution analyze (Mo and NCS^-) for $Mo_3O_4(NCS)_2^{2+}$, $Mo_3O_4(NCS)^{3+}$ and $Mo_3O_4^{4+}$. A fraction not held on the column at $[H^+] = 0.3$ M is believed to contain $Mo_3O_4(NCS)_3^+$ as well as free NCS^-. Two kinetic stages are observed in the aquation of $Mo_3O_4(NCS)_2^{2+}$ in 2 M HPTS, which are assigned to k_{-1} (here 1.7×10^{-3} s^{-1}), and k_{-2} (0.24×10^{-3} s^{-1}).

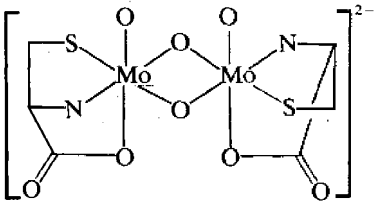
The red aqua $Mo_3O_4^{4+}$ ion is reduced by amalgamated Zn under air-free conditions to a green Mo_3^{III} aqua ion.[84] The spectrum, Figure 16, is different from that of the green Mo_2^{III} aqua ion previously discussed. It is held more strongly on a Dowex column than $Mo_3O_4^{4+}$, which suggests that it may have a fully protonated core $Mo_3(OH)_4^{5+}$. This is an interesting point which requires confirmation. The oxalato complex $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$ can be similarly reduced.[85] Both nine-electron Mo_3^{III} complexes exhibit EPR spectra. On labelling the core with ^{18}O atoms the complete redox cycle can be accomplished with as high as 97% retention of the labelling.[82] In one experiment the Mo_3^{III} ion was allowed to exchange with solvent for two months at room temperature, and no (±3%) exchange was detected.[81]



Rapid (<1 min) equilibration of Mo_3^{III} with Mo_3^{IV} (2:1 amounts) gives quantitative formation of an orange pink $Mo^{III,III,IV}$ trimer (Figure 16) in 4.0 M HPTS (*p*-toluenesulfonic acid), 80% in 2.0 M HPTS, and 30% in 0.5 M HPTS.[84] At $[H^+] > 2.0$ M electrolytic reduction of Mo_3^{IV} at a potential of −0.25 V (*vs.* NHE) confirmed these results with spectrophotometric evidence for the formation of the same $Mo^{III,III,IV}$ ion. There is no evidence for the other mixed-valence state, $Mo^{III,IV,IV}$, which presumably rapidly disproportionates. Detailed electrochemical studies have suggested two forms of Mo_3^{III},[85] but have failed to identify the nature of these. From studies on the dependence of the Mo_3^{III}/Mo_3^{IV} equilibration on $[H^+]$ it is concluded that the $Mo^{III,III,IV}$ trimer is also protonated, and at least 4+ in charge.[84] A feature of the spectrum of the $Mo^{III,III,IV}$ form is the broad absorbance band at 1050 nm (ε 100 $M^{-1} cm^{-1}$ per Mo). Both the Mo_3^{IV} and $Mo^{III,III,IV}$ ions are diamagnetic.[83,85] Exposure of the Mo_3^{III} ion to O_2 results in oxidation to $Mo^{III,III,IV}$ and then Mo_3^{IV}.[84]

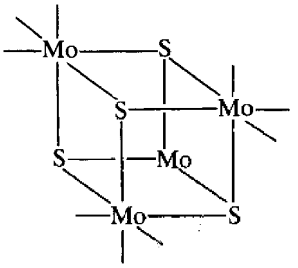
Whereas an oxidant such as $[Co(C_2O_4)_3]^{3-}$ readily converts $[Mo(H_2O)_6]^{3+}$ and aqua Mo_2^{III} through to the aqua Mo_2^V state, it is not able to oxidize Mo_3^{IV}.[86] The implication is that monomeric and dimeric Mo^{IV} containing forms generated as intermediates are readily oxidized, whereas Mo_3^{IV} is not. This is also borne out by electrochemical studies, in which it has been reported that it is difficult to electrooxidize Mo_3^{IV} to Mo_2^V. The trimeric form is oxidized by strong oxidants such as $[IrCl_6]^{2-}$ (0.89 V) and $[Fe(phen)_3]^{3+}$ (1.06 V), and conventional range kinetic studies have been reported.[86] Reactions proceed exclusively by an $[H^+]^{-1}$ dependent rate-law term, reflecting the greater degree of hydrolysis of the Mo^V product. In the $[IrCl_6]^{2-}$ case oxidation to Mo_2^V is faster than the subsequent $Mo_2^V \rightarrow Mo^{VI}$ oxidation. The converse holds in the case of $[Fe(phen)_3]^{3+}$. Because of these differences it is likely that the mechanisms are different and that the $[IrCl_6]^{2-}$ reaction is of the inner-sphere type. The nature of the phenanthroline ligands of $[Fe(phen)_3]^{3+}$ precludes an inner-sphere mechanism.

The synthesis of oxo–sulfido Mo_3^{IV} complexes in the series $Mo_3O_xS_{4-x}$ as aqua ions has been reported. Synthesis of the grey-coloured $Mo_3O_2S_2^{4+}$ μ_3-sulfido containing ion has been achieved by essentially the same route as for $Mo_3O_4^{4+}$, by reacting $[MoCl_6]^{3-}$ with the aqua di-μ-sulfido Mo_2^V complex $[Mo_2O_2S_2(H_2O)_6]^{2+}$ (**5**).[87] The reaction can be expressed as in equation (21), where the transient Mo^{IV} (or some related form) presumably also gives an Mo_3^{IV} product. The ~70% conversion of Mo_2^V to $Mo_3O_2S_2^{4+}$ after column chromatography is consistent with retention of the dimer unit and attachment of Mo^{III} to the dimer. The product has been characterized crystallographically as $(pyH)_5[Mo_3O_2S_2(NCS)_9]\cdot 2H_2O$.[87]



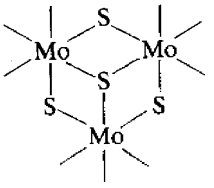
$$2Mo^{III} + Mo_2^V \longrightarrow Mo_3^{IV} + Mo^{IV} \qquad (21)$$

Using different approaches the dark green $Mo_3OS_3^{4+}$ ion has been obtained along with the



(5)

green cubic cluster complex $Mo_4S_4^{5+}$. Two procedures have been described involving either $NaBH_4$ or electrochemical reduction of the di-μ-sulfido Mo_2^V cysteinato complex, $[Mo_2O_2S_2(cys)_2]^{2-}$ (**6**), in HCl, under N_2 (or Ar), and followed by air oxidation.[88,89] The green cubic complex $Mo_4S_4^{5+}$ (**7**) yields $Mo_3S_4^{4+}$ (**8**) on heating solutions in 1 M HCl to ~90 °C for 3–4 h. Another preparative route yielding both (**7**) and (**8**) has been described in which $[Mo(CO)_6]$ is refluxed in acetic anhydride containing dry Na_2S under N_2. Water is added to hydrolyze the cooled reaction mixture.[90,91]



(6)

$[Mo_4S_4(H_2O)_{12}]^{5+}$

(7)

$[Mo_3S_4(H_2O)_9]^{4+}$

(8)

The existence of the $Mo_3S_4^{4+}$ core has been confirmed by X-ray structure analysis of the iminodiacetate and oxalate complexes, $Ca[Mo_3S_4(ida)_3]\cdot 11.5H_2O$ and $Cs_2[Mo_3S_4(C_2O_4)_3(H_2O)_3]\cdot 3H_2O$.[88,90] Selected mean bond distances from the first of these are Mo—Mo (2.7 Å), Mo—μ_3(S) (2.35 Å), and Mo—μ_2(S) (2.30 Å). Corresponding values for the $[Mo_3O_4(mida)_3]^{2-}$ complex are Mo—Mo (2.50 Å), Mo—μ_3(O) (2.04 Å) and Mo—μ_2(O) (1.92 Å).[77] The aqua ion of the $Mo_4S_4^{5+}$ cluster has formal oxidation states III, III, III and IV. X-Ray crystal structure determinations of both $Na_3[Mo_4S_4(edta)_2]$,[92] and the NCS^- complex $(NH_4)_6[Mo_4S_4(NCS)_{12}]\cdot 10H_2O$,[91] which appears to be a derivative of $Mo_4S_4^{6+}$, have been reported.

In the above preparations from di-μ-sulfido Mo_2^V, the cubic $Mo_4S_4^{5+}$ product is obtained in up to *ca.* 20% yield.[93] This suggests a mechanism involving dimerization of a reduced form of Mo_2^V at some stage to give the cubic Mo_4 product. Some subsequent (partial) decomposition to the trimer then occurs, although details of the reaction and the oxidation states involved have not been fully established.[93] If alternatively a mechanism involving addition of mononuclear Mo to the dimer occurred it is difficult to see how retention of all four bridging S^{2-} ligands could be achieved.

The μ-oxo-μ-sulfido, $[Mo_2O_3S(cys)_2]^{2-}$, and di-μ-oxo, $[Mo_2O_4(cys)_2]^{2-}$, complexes have also been used singly or in mixes in the above preparations, and other members of the $Mo_3O_xS_{4-x}^{4+}$ series have been identified.[93] Structures of $Mo_3OS_3^{4+}$ and $Mo_3O_3S^{4+}$, both with μ_3(S) ligands, have been determined.[94,95] Because, in the wider application of the preparative procedures using $[Mo_2O_4(cys)_2]^{2-}$, it has been found that there is a tendency for cysteine to remain attached to the Mo, there are advantages in using the corresponding Mo_2^V aqua ions, and mixtures of these.[93] Although $Mo_3O_4^{4+}$ can be prepared by this route, the formation of $Mo_4O_4^{5+}$ has to be confirmed. Complexes in the $Mo_3O_xS_{4-x}$ series with a μ_3-oxo ligand have not been prepared.

Studies on the 1:1 complexing of NCS^- for H_2O on aqua $Mo_3S_4^{4+}$ indicate an ~10^2 labilizing effect as compared to $Mo_3O_4^{4+}$.[96] A cyclic voltammogram of $[Mo_3S_4(ida)_3]^{2-}$ at a glassy carbon electrode shows two reversible one-electron waves indicating the existence of $Mo^{III,IV,IV}$ and $Mo^{III,III,IV}$ oxidation states.[88] This is the first time the $Mo^{III,IV,IV}$ state has been identified. Although evidence has been obtained in cyclic voltammetry for reduction of aqua $Mo_3S_4^{4+}$ the products have not as yet been prepared quantitatively. In 2 M HPTS the 4+ aqua ion at greater than 10^{-3} M is extremely stable. It reacts (*e.g.* 25 ml of 0.05 M) with metallic Fe (5 g) over a

few hours to give the cubic mixed-metal complex $Mo_3FeS_4^{4+}$. From the crystal structure of $[Mo_3FeS_4(NH_3)_9(H_2O)]Cl_4$ (Figure 18), the Fe is seen to be four-coordinate whereas the three Mo atoms remain six-coordinate.[97]

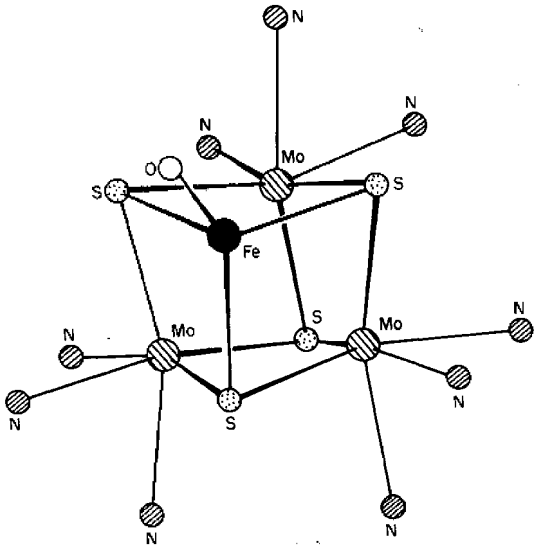


Figure 18 The structure of $[Mo_3FeS_4(NH_3)_9(H_2O)]Cl_4$[97]

The aqua ion of $Mo_4S_4^{5+}$ in acid (2 M HPTS) solutions is also stable,[89] but less so than with $Mo_3S_4^{4+}$, and at 50 °C (in air) gives $Mo_3S_4^{4+}$ with a half-life of approximately four days. The reaction is slower under N_2. It can be reduced to the orange 4+ ion, which is stable, whereas on oxidation the 6+ complex is unstable. UV–visible spectra of the 4+ and 5+ complexes are compared in Figure 19. With two edta ligands coordinated to $Mo_4S_4^{5+}$ the corresponding orange 4+ and red 6+ states are both stable, Figure 20.[98] Complexes having mixed oxo–sulfido cubic $Mo_4O_xS_{4-x}^{5+}$ clusters have not been isolated.

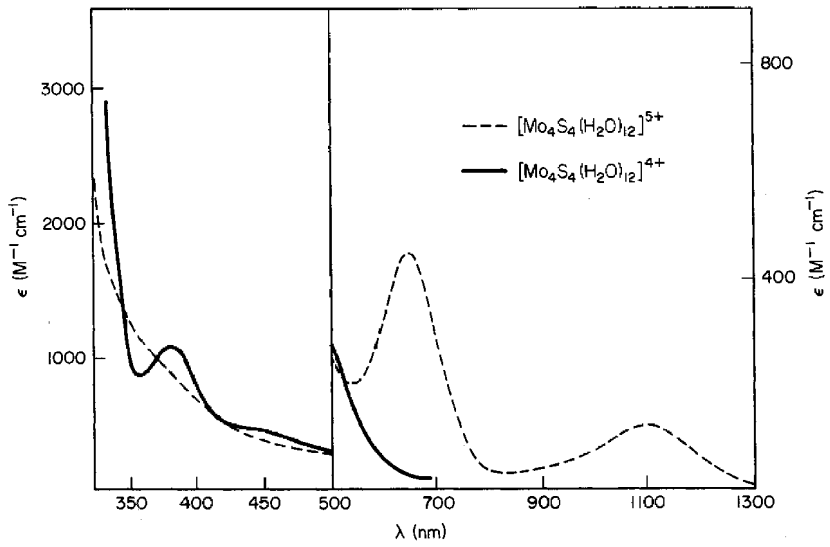

Figure 19 UV–visible–NIR spectra of $[Mo_4S_4(H_2O)_{12}]^{4+}$ (——) and $[Mo_4S_4(H_2O)_{12}]^{5+}$ (– – –) in 1 M HPTS

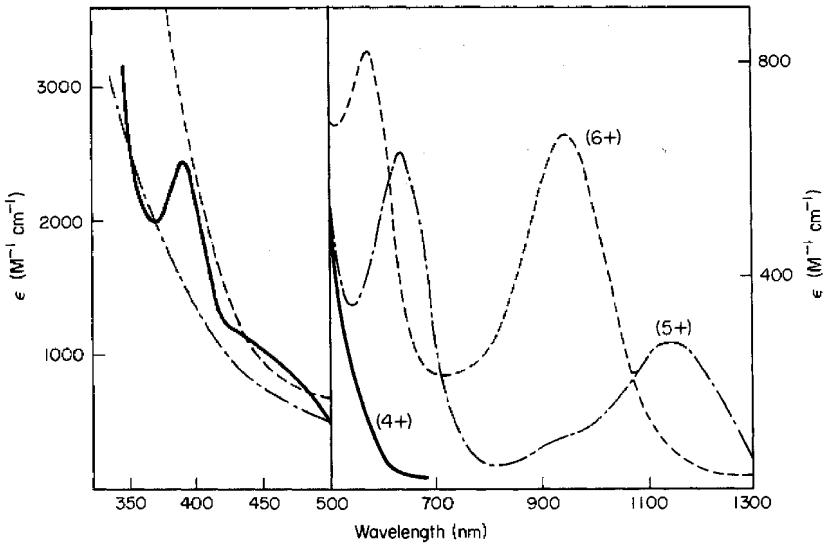
Cyano complexes $[Mo_3O_4(CN)_9]^{5-}$ and $[Mo_4S_4(CN)_{12}]^{8-}$, with $Mo_3S_4^{4+}$ and $Mo_4S_4^{4+}$ core structures, have been prepared by the reaction of amorphous MoS_3 with CN^- and characterized crystallographically.[99] It should also be mentioned that $[Mo_3S_4(\eta^5\text{-}C_5H_5)_3]^{+,0}$ and $[Mo_4S_4(\eta^5\text{-}C_5H_4Pr^i)_4]$ have also been obtained.[100–102]

In addition to the extensive trinuclear chemistry of Mo^{IV} there are a few examples of mononuclear complexes. These include $[Mo(CN)_8]^{4-}$ and *trans*-$[MoO(H_2O)(CN)_4]^{2-}$. The



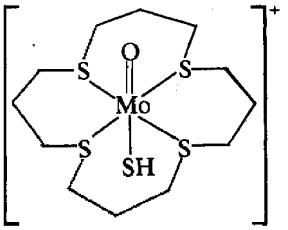


Figure 20 UV–visible–NIR spectra of $[Mo_4S_4(edta)_2]^{4+}$ complexes ($n = 4$, 5, 6) in H_2O[98]

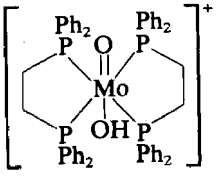
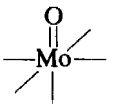


variation of Mo—O bond lengths for the series of complexes $[Mo(O)_2(CN)_4]^{4-}$, $[MoO(OH)(CN)_4]^{3-}$ and $[MoO(OH_2)(CN)_4]^{2-}$ has been noted.[103] Increased protonation of one of the oxo groups results in an increase in Mo—O from 1.83 through 2.08 to 2.27 Å. Concomitantly the terminal Mo—O bond decreases from 1.83 through 1.70 to 1.67 Å. In the case of $[MoO(H_2O)(CN)_4]^{2-}$ blue salts with $[Ph_4As]^+$ and green salts with $[Ph_4P]^+$ provide an example of distortional isomerism.[104] The major structural difference is the Mo=O distance which is reported to be 1.72 Å in the blue and 1.60 Å in the green form.

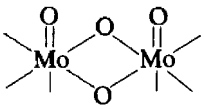
A number of Mo^{IV} complexes of the type $[MoOCl_2(PR_3)_3]$ have also been isolated in both blue and green forms.[105] X-Ray structure determinations have shown that both forms possess the meridional stereochemical arrangement, with the oxo and the Cl^- ligand *trans* to each other.[106,107] The green form has a shorter Mo=O distance (1.68 Å) compared to the blue (1.80 Å) which is unusually long. No satisfactory explanation for the existence of distortion isomers in the crystalline state has been forthcoming.

Octahedrally coordinated mononuclear complexes with S- and P-donor atoms (**9**) and (**10**) have also been reported.[108,109]

(**9**)

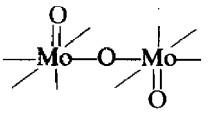


(**10**)



36.1.2.5 Oxidation State V

The Mo^V state is readily obtained as the binuclear orange-yellow $Mo_2O_4^{2+}$ ion by reduction of Mo^{VI} as $Na_2[MoO_4]\cdot 2H_2O$ in acidic solutions. Procedures used include reduction with hydrazine, shaking with mercury, or controlled potential reduction at a Hg-pool electrode. On addition of NCS^- three products $[MoO(NCS)_5]^{2-}$, $[Mo_2O_4(NCS)_6]^{4-}$ and $[Mo_2O_3(NCS)_8]^{4-}$ (*anti* form) are obtained, depending on the concentrations of NCS^- and Mo as well as the pH. These forms are representative of the three different Mo^V structures (**11**)–(**13**).



Probably the best known monomeric Mo^V form is the green chloro complex, which can be isolated as the solid $(NH_4)_2[MoOCl_5]$, and is retained in solution at >7 M HCl. The closely related $[MoOCl_4]^-$ and $[MoOCl_4H_2O]^-$ ions are also known, and chloro and iodo analogues

(11)

(12)

(13)

have been obtained.[110] Other preparative routes in addition to the reduction of $[MoO_4]^{2-}$ include the oxidation of $[Mo_2(O_2CMe)_4]$ in aqueous HX ($X^- =$ halide), or by dissolving $MoCl_5$ in an appropriate acid. In aqueous solution, at lower HX concentrations, orange-yellow $Mo_2O_4^{2+}$ is obtained. Elution of $Mo_2O_4^{2+}$ from Dowex cation-exchange columns with 0.5–2.0 M $HClO_4$ gives the orange-yellow aqua ion $[Mo_2O_4(H_2O)_6]^{2+}$.

Monomeric oxo–Mo^V complexes have a characteristic EPR spectrum with a strong central band, and EPR provides the most direct and definitive means of distinguishing this form.[111] The $4d^1$ electron is believed to be located in an orbital in the plane perpendicular to the Mo=O bond. The bond *trans* to the terminal oxo ligand is relatively weak and five- as well as six-coordinate complexes are known. The structure of $K_2[MoOCl_5]$ gives four Mo—Cl bonds at 2.40 Å (mean) and one *trans* to the oxo at 2.95 Å.[112] The difference is similar to that for the VO^{2+} aqua ion (0.18 Å) in hydrated vanadyl sulfate. A bigger *trans* effect is expected in the case of the nitrido complex $[MoN(Cl)_5]^{3-}$.[113] The length of the Mo=O bond is shorter in five-coordinate complexes, and is 1.61 Å in $(AsPh_4)[MoOCl_4]$.[114] On addition of a sixth ligand as in $K_2[MoOCl_5]$ the Mo=O bond is ~1.67 Å. The presence of the terminal oxo results in doming as in $(AsPh_4)[MoOCl_4(H_2O)]$ (Figure 21),[115] and this is also a feature of Mo_2O_4 type structures with an O_tMoO_b angle between terminal and bridging oxo ligands of ~105°. The stabilization of $[MoO(SR)_4]^-$ type complexes using small peptides containing cysteine residues, and with bulky aromatic thiolate ligands has been reported.[116]

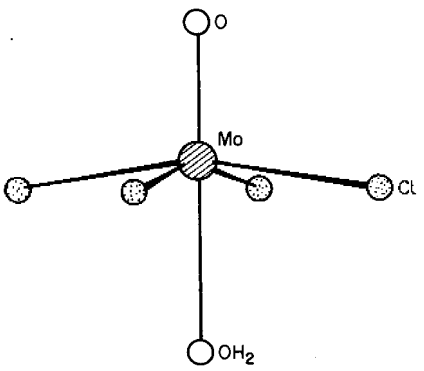


Figure 21 The structure of the Mo^V complex $[MoOCl_4(H_2O)]^-$[115]

Typical UV-visible spectra of $Mo_2O_4^{2+}$ complexes are shown in Figure 22. Crystal structures have been reported for the compounds $(pyH)_2[Mo_2O_4Cl_4(H_2O)_2]\cdot H_2O$, $(pyH)_3[Mo_2O_4(HCO_2)(NCS)_4]\cdot 2H_2O$ and the μ-acetato analogue (Figures 23 and 24).[112] The complexes are diamagnetic and Mo—Mo distances are short (2.56–2.58 Å), consistent with metal–metal bonding.[117] Structure data for $[Mo_2O_4(NCS)_6]^{4-}$ have indicated a difference in the *cis* and *trans* Mo—N bonds of 0.15 Å.[118] However, for the oxalate complex $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$, it has been demonstrated that the waters are coordinated *cis* to each terminal oxo, with the oxalate *cis* and *trans* to the same oxo. No difference in the oxalate Mo—O distances is detected in this and the corresponding di-μ-sulfido complex $[Mo_2O_2S_2(C_2O_4)_2(H_2O)_2]^{2-}$ (**14**).[119] In a similar bipyridyl complex (**15**) the Mo—N bond length *trans* to the terminal oxo is 2.32 Å, while that in the *cis* position is 2.25 Å,[120] giving an intermediate elongation effect. The absence of a *trans* influence in the case of oxalate suggests it has a low *trans* susceptibility as compared with bipyridyl and other ligands. A more extensive list of compounds would be of interest to explain this effect. It has been noted that the ^{13}C NMR spectrum of $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ in water at pH 4 gives only one sharp peak at 168 p.p.m. at 34 °C, which suggests that in solution there is some rapid exchange process taking place.[32,118]

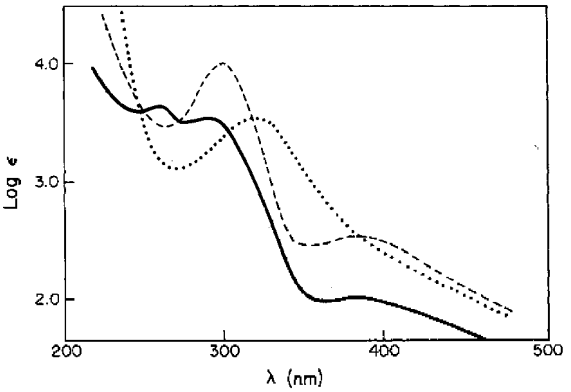

Figure 22 UV–visible spectra (ε values per dimer) of the Mo^{V} aqua dimer $[Mo_2O_4(H_2O)_6]^{2+}$ in 0.5 M $HClO_4$ (——), and of $[Mo_2O_4(edta)]^{2-}$ (– – –) at pH 5 (acetate buffer), and (ε per Mo) for the polymeric Mo^{V} ion (· · ·)[138b,136]

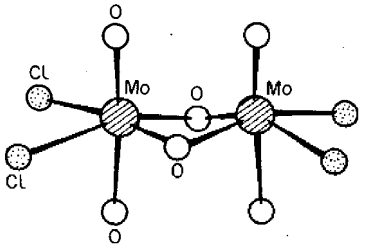

Figure 23 The structure of the Mo_2^{V} complex $[Mo_2O_4Cl_4(H_2O)_2]^{2-}$[112]

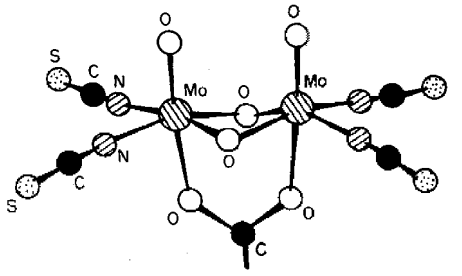

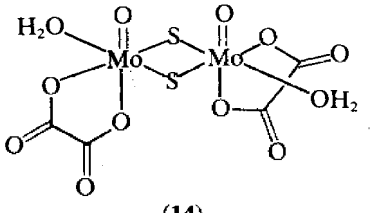

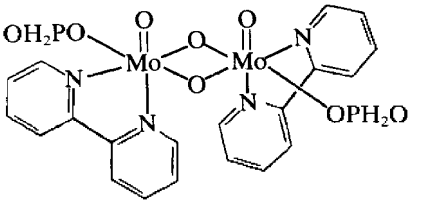

Figure 24 The structure of the Mo_2^{V} complex $[Mo_2O_4(HCO_2)(NCS)_4]^{3-}$[112]

(14)

(15)

As in the case of the Mo_2^{III}–edta complex the edta ligand in $[Mo_2O_4(edta)]^{2-}$ is coordinated to the binuclear core in a 'basket' like conformation. Studies on complexes of $Mo_2O_4^{2+}$ having optically active amine-carboxylate ligands such as propylenediaminetetraacetate have been reported.[121]

Oxidation of the Mo_2^{III} complex $[L(H_2O)Mo(OH)_2Mo(H_2O)(L)]^{4+}$, where L is the cyclic triamine 1,4,7-triazacyclononane ligand, with (for example) ClO_4^- gives the red-purple coloured *anti*-$[Mo_2O_4L_2]$ complex (λ_{max} 525 nm), which undergoes irreversible acid-catalyzed isomerization to the yellow *syn*-$[Mo_2O_4L_2]$ complex (Figure 25).[64] If the 1,5,9-triazacyclododecane ligand L′ is used the *anti*-$[Mo_2O_4L'_2]$ form is likewise obtained, and in contrast to the behaviour observed with L, is stable for at least two days in 1 M $HClO_4$ at 25 °C.[65] Base-catalyzed isomerization is observed in both cases. Structures of the *anti* forms have been determined. For

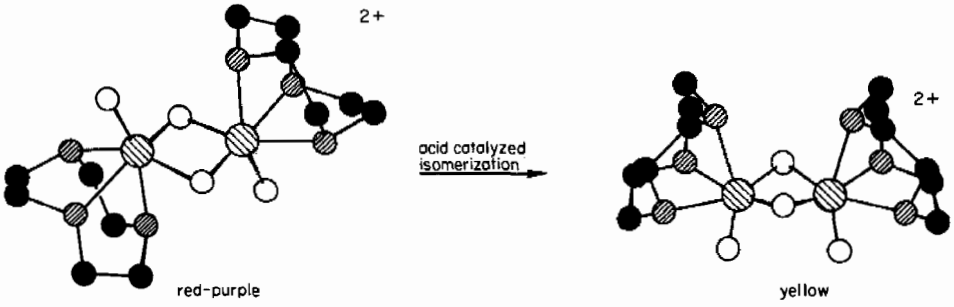
the L complex the short Mo—Mo distance (2.55 Å) is essentially the same as that for the yellow isomer (2.56 Å).[122] The diamagnetism in both cases is consistent with metal–metal bonding. The four-membered Mo_2O_2 ring in the *anti* form is planar whereas for the *syn* isomer it is puckered with an O_tMoO_b angle of 109°. Kinetic studies on the acid-catalyzed isomerization of the L complex (red-purple → yellow) give a dependence (equation 22), which is consistent with H^+-induced reaction (equations 23–25).

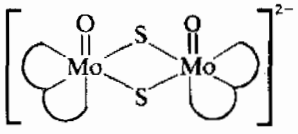
$$k_{obs} = \frac{k[H^+]}{[H^+] + K_a} \tag{22}$$

$$anti\text{-}[L_2Mo_2O_4]^{2+} + H^+ \overset{K_a^{-1}}{\rightleftharpoons} anti\text{-}[L_2Mo_2O_4H]^{3+} \tag{23}$$

$$anti\text{-}[L_2Mo_2O_4H]^{3+} \xrightarrow{k} syn\text{-}[L_2Mo_2O_4H] \tag{24}$$

$$syn\text{-}[L_2Mo_2O_4H]^{3+} \xrightarrow{fast} syn\text{-}[L_2Mo_2O_4] + H^+ \tag{25}$$





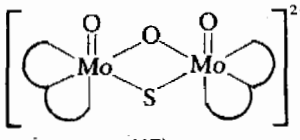


Figure 25 The structures and isomerization of *anti*- to *syn*-$[Mo_2O_4L_2]^{2+}$, L = 1,4,7-triazacyclononane[64a]

A mechanism involving protonation at a terminal oxo ligand followed by addition of a *trans* H_2O has been proposed.[64b] At 21 °C $K_a = 2.3$ M and $k = 2.4 \times 10^{-4}$ M^{-1} s^{-1}. Theoretical calculations on *syn*- and *anti*-$[Mo_2S_4(S_2C_2H_4)_2]^{2-}$ indicate that the Mo—Mo bond is stronger in the *syn* isomer.[123] At present these are the only examples of the *anti* form.

The preparations of di-μ-sulfido and μ-oxo-μ-sulfido complexes of Mo^V with edta, cysteine and cysteine-ester ligands have been described.[124] Formulae with cysteine coordinated are shown in (**16**) and (**17**). To prepare (**16**) hydrogen sulfide is bubbled slowly through a solution of $Na_2MoO_4 \cdot 2H_2O$ in H_2O for ~2 h and after removal of excess H_2S and adjustment of the pH, the appropriate ligand is added. To prepare (**17**) H_2S is bubbled slowly through a solution of $MoCl_5$ in 3 M HCl for 2 h. Both types of complex are an orange-yellow colour. The ligands can be removed by addition of acid, *e.g.* 1–2 M HCl, followed by gel filtration chromatography to give the aqua ion analogues of $[Mo_2O_4(H_2O)_6]^{2+}$. Absorption bands in the UV–visible for $Mo_2O_2S_2^{2+}$ (277, 311, 340 and 463 nm) are at lower wavelengths than the corresponding bands for $Mo_2O_4^{2+}$ (280, 324, 365 and 493 nm). The edta and cysteine complexes undergo electrochemical reduction in a single four-electron step to Mo^{III} dimers in aqueous (buffered) solutions. Although the ease of reduction and electrochemical reversibility of the Mo_2^V/Mo_2^{III} couples increase with insertion of S^{2-} into the bridging positions, the Mo^{III} dimers become increasingly unstable for the S^{2-}-bridged complexes. With 1,1-dithiolate ligands such as *N,N*-diethyldithiocarbamate and diisopropyldithiophosphinate bridging and terminal oxo positions of the $Mo_2O_4^{2+}$ structure have been replaced to yield all the products from $Mo_2O_4(dtc)_2$ to $Mo_2S_4(dtc)_2$.[125] Using IR spectroscopy and ^{18}O for ^{16}O replacement, it has been demonstrated that substitution of O^{2-} by S^{2-} at the bridging positions is fairly facile. Much more extreme conditions using P_4S_{10} for example are required to effect terminal oxo substitution.

(**16**)

(**17**)

The second main category of dimeric Mo^{V} complexes having a single μ-oxo bridge can also give *syn* and *anti* (rotamer) forms. Structures of *anti*-$[Mo_2O_3(NCS)_4(C_2O_4)_2]^{4-}$ and *anti*-$[Mo_2O_3(NCS)_6(HCO_2)_2]^{4-}$ have been determined (Figures 26 and 27), and indicate a linear Mo—O—Mo bridge with Mo—O_b distances 1.85 and 1.86 Å, and Mo—O_t of 1.68 and 1.67 Å respectively.[112] Other examples of this type are with bidentate thiophosphate in $[Mo_2O_3\{(S_2POEt)_2\}_4]$ and $[Mo_2O_3(LL)_4]$, where LL represents *O*-thiopyridine.[126] Examples of the *syn* structure (**18**) are with bidentate sulfur-donor ligands in $[Mo_2O_3(S_2COEt)_4]$ and $[Mo_2O_3(S_2CNPr)_4]$. In the first of these (*O*-ethyldithiocarbonate) the Mo—Mo bond is 3.72 Å, and the Mo—O_t bond is 1.65 Å.[127] All known μ-oxo-bridged dimers are diamagnetic or exhibit only a small practically temperature independent paramagnetism.

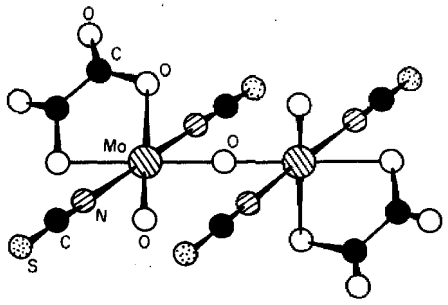

Figure 26 The structure of the Mo_2^{V} complex $[Mo_2O_3(NCS)_4(C_2O_4)_2]^{4-}$ [112]

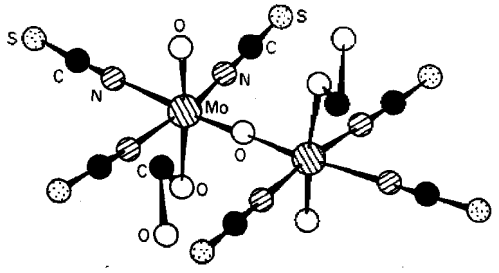

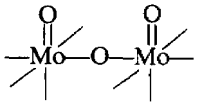

Figure 27 The structure of the Mo_2^{V} complex $[Mo_2O_3(NCS)_6(HCO_2)_2]^{4-}$ [112]

(**18**)

It is possible to use IR spectroscopy as a means of distinguishing between $Mo_2O_3^{4+}$ and $Mo_2O_4^{2+}$ complexes.[125] No interconversion of these two forms has been studied, and no aqua ion having the $Mo_2O_3^{4+}$ structure has yet been identified.

The staggered conformation of terminal oxo ligands observed for Mo^{VI} in $Mo_2O_3^{6+}$ is not observed for Mo^{V}.[128] However, in the tetraphenylporphyrin complex $[Mo_2O_3(TPP)_2]$ the linear Mo—O—Mo structure is retained, and the terminal oxo ligands lie *trans* to the μ-oxo group giving the opposed O_t—Mo—O_b—Mo—O_t structure.[129]

In a recent comprehensive study of the coordination of polypyrazolylborate, $HB(pz)_3^-$, to Mo^{V} a number of complexes have been prepared.[130] First by reacting $HB(pz)_3MoCl_3$ with O_2 the mononuclear complex $[HB(pz)_3MoOCl_2]$ is obtained (Figure 28). A pair of geometric isomers, $[Mo_2O_3Cl_2(H(Bpz)_3)_2]$ and $[Mo_2O_4(HB(pz)_3)_2]$, can be isolated from the reaction of $MoCl_5$ with $HB(pz)_3^-$ in dilute HCl. By further reaction of the latter with MeOH the zigzag tetramer $[Mo_4O_4(OMe)_2(HOMe)_2(HBpz_3)]_2$ is obtained (Figure 29). Crystal structures of all but the $Mo_2O_4^{2+}$ complex have been determined. The Mo_2O_3 geometric forms provide an example of distortional isomerism with terminal Mo=O distances of 1.67 and 1.78 Å respectively. Both are however yellow-brown in colour, unusual for $Mo_2O_3^{4+}$, which is generally purple with an intense band at ~525 nm. The latter was thought to be independent of the ligands present, a belief which it seems has now to be modified.

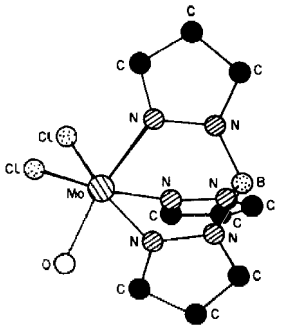

Figure 28 The structure of the hydrotripyrazolylborate, $HBpz_3^-$, Mo^V complex, $[MoOCl_2(HBpz_3)]$[130]

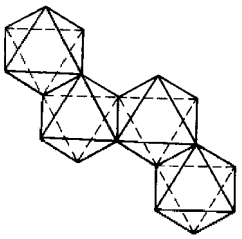

Figure 29 Representation of the tetrameric zigzag chain structure as found in $[Mo_4(HBpz_3)_2(O)_4(\mu\text{-}OMe)_2(HOMe)_2]$[130]

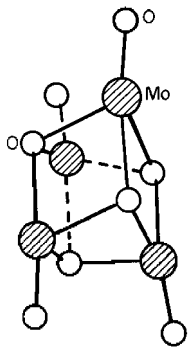
Complexes reported as mixed-valence tetramers $Mo^{V,V,VI,VI}$, with formulae $[Mo_4O_6Cl_4(O\text{-}Pr^n)_6]$ and $[Mo_4O_8Cl_4(OEt)_4]^{2-}$,[131,132] have been reformulated as $[Mo_4O_6Cl_4(OPr^n)_4(HOPr)_2]$ and $[Mo_4O_8Cl_4(OEt)_2(HOEt)_2]^{2-}$,[130] indicating the importance in this chemistry of distinguishing between a coordinated alkoxide and coordinated alcohol. Both are accordingly tetrameric Mo^V, with close structure analogies to the above zigzag complex. The latter occurs also as a central unit in the $[Mo_6O_{10}(OPr^i)_{12}]$ complex.[133] A cyclic Mo^V octamer has been reported.[134] One example of a distorted cubane $(MoO)_4$ complex of Mo^V, $[Mo_4O_8(Me_2POS)_4]$, having four terminal oxo ligands has been reported (Figure 30).[135]



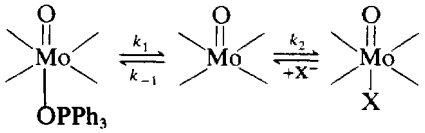


Figure 30 The structure of the Mo^V tetramer core in $[Mo_4O_8(Me_2POS)_4]$ showing the Mo_4O_4 cubic arangement with terminal oxo ligands attached to each Mo^V[135]

The structure of an amorphous orange-brown polymeric Mo^V form obtained from aqueous solutions has not been determined.[136] It has a distinctive peak at 318 nm (ε 3300 $M^{-1}\,cm^{-1}$ per Mo) and is stable in H_2O at pH ~6. On adjustment of $[H^+]$ to 0.17–0.50, I = 0.50 M ($H^+/LiClO_4$), aquation to $Mo_2O_4^{2+}$ proceeds by rapid protonation followed by a single rate-determining step. At 25 °C the protonation gives an acid dissociation constant K_a = 0.13 M, and $k = 5.5 \times 10^{-3}\,M^{-1}\,s^{-1}$ for the kinetic step.

The rate of ^{18}O exchange of O^{2-} in $[MoOCl_5]^{2-}$ has been studied under conditions of high Cl^- (~12 M), and found to be slow, with a half-life of 1–2 h.[81] One of the reaction paths is believed to involve formation of $[MoOCl_4(H_2O)]^-$ as an intermediate. In dichloromethane the substitution of Cl^-, Br^-, NO_2^- and NO_3^- for $OPPh_3$ (which is *trans* to the oxo group) in

$[MoOCl_3(OPPh_3)_2]$ is consistent with a dissociative (D) mechanism (equation 26). Rate constants obtained are $k_1 = 42.0$, 41.6, 51.8 and 40.3 s^{-1} and $k_2/k_{-1} = 27$, 8, 47 and 31 respectively.[137] Thus in a non-coordinating solvent k_1 is seen to be relatively small.

(26)

Measurement of H_2O solvent ^{18}O exchange into aqua $Mo_2O_4^{2+}$ has been possible, using a procedure in which complexing with edta was followed by precipitation of the $[Pt(en)_2]^{2+}$ salt.[81] The two types of oxo ligand were shown to have quite different exchange rates. Using vibrational spectroscopy it was demonstrated that the fast exchanging O atoms are those in the terminal positions. At 0 °C in 0.50 M H^+, these two O atoms exchange with a half-life of ~4 min. The other two O atoms have a half-life of ~70 h at 40 °C in 0.5 M H^+ and ~3 years at 0 °C in 1 M H^+. The rate law for the latter exchange has an $[H^+]^2$ dependence consistent with a mechanism involving Mo_2O_2 ring opening. An involvement of other ligand positions in the exchange of terminal oxo ligands is strongly implicated by the observation that $[Mo_2O_4(edta)]^{2-}$ gives <1% exchange of terminal ligands after 4.25 days. With $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$, four O atoms (the terminal oxo and H_2O ligands) exchange at indistinguishable rates followed by the $>10^3$ times slower exchange of bridging O atoms.[81]

Kinetic studies on the 1:1 complexing of NCS^- for H_2O on $[Mo_2O_4(H_2O)_6]^{2+}$,[138] $[Mo_2O_4(C_2O_4)(H_2O)_2]^{2-}$ [118] and di-μ-sulfido $[Mo_2O_2S_2(C_2O_4)_2(H_2O)_2]^{2-}$ [139] (the latter two at pH values of 3.0–4.5) have been reported. Formation rate constants ($10^{-4}k$) are respectively 2.9, 0.50 and 21 $M^{-1}s^{-1}$ at 25 °C, with I at either 2.0 (first study) or 1.0 M in perchlorate. With pyridine as the incoming ligand the rate constant of 0.50 decreases to 0.30 $M^{-1}s^{-1}$. The mechanistic interpretation has to take into account the observation that the oxalate of $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ may be undergoing rapid rearrangement.[32] Therefore substitution is not necessarily confined to a basal plane site, and as in the case of $[VO(H_2O)_5]^{2+}$, rapid substitution at an axial position (equilibration process K) is believed to be followed by the slower exchange to a position in the plane of the complex. The not too dissimilar rate constants for $[Mo_2O_4(H_2O)_6]^{2+}$ and $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ are noted. With the di-μ-sulfido complex a faster rate is observed and the μ-sulfido ligands produce a labilizing effect. The kinetics of the multistage equilibration reaction of $[Mo_2O_4(H_2O)_6]^{2+}$ with edta to give $[Mo_2O_4(edta)]^{2-}$ have been studied, $[H^+] = 0.5$–2.0 M, and are observed to be much slower ($t_{1/2} < 1$ min).

From kinetic studies the oxidation of aqua $Mo_2O_4^{2+}$ with $[IrCl_6]^{2-}$, $[Fe(phen)_3]^{3+}$ and $[(NH_3)_5Co(O_2)Co(NH_3)_5]^{5+}$ proceed by competing pathways.[140,141] The first is oxidant independent, and is the result of the dimer undergoing rate-determining change to a singly bridged form, or to monomeric Mo^V, which then reacts rapidly with the oxidant. Interestingly, this path has an $[H^+]^{-1}$ dependence suggesting involvement of a conjugate-base form of $Mo_2O_4^{2+}$, and gives $k = 3 \times 10^{-6}$ M s^{-1}. This contrasts with the $[HCl]^2$ dependence (not at constant ionic strength) indicated for the ^{18}O exchange of bridging oxo ligands.[142] A second rate law term, first order in oxidant as well as $[Mo_2O_4^{2+}]$, and representing direct attack of the oxidant on the dimer, is observed. This has a dependence on $[H^+]^{-1}$ of the form $a + b[H^+]^{-1}$, where the contribution from b is presumably favoured because of the increase in extent of hydrolysis accompanying the $Mo^V \rightarrow Mo^{VI}$ change. The reactions with I_3^-, NO_3^- and $[PtCl_6]^{2-}$ as oxidants are very much slower.

In contrast to the above study the $[IrCl_6]^{2-}$ oxidation of $[Mo_2O_4(edta)]^{2-}$ gives evidence for an $Mo^{V,VI}$ intermediate.[143] In the presence of edta the $Mo^{V,VI}$ is presumably held together for a sufficiently long time for it to become kinetically significant. Thus on addition of the product $[IrCl_6]^{3-}$ the reverse reaction is seen to be effective, and there is a decrease in the rate of reaction, which can be quantified in terms of the mechanism shown in equations (27)–(29).

$$Mo_2^V + Ir^{IV} \rightleftharpoons Mo^{V,VI} + Ir^{III} \quad (27)$$

$$Mo^{V,VI} \longrightarrow Mo^V + Mo^{VI} \quad (28)$$

$$Mo^V + Ir^{IV} \longrightarrow Mo^{VI} + Ir^{III} \quad (29)$$

The reaction of $Mo_2O_4^{2+}$ with NO_3^- in tartrate buffer (which is capable of coordinating to the Mo_2^V) at pH 2.2–3.5 has also been studied.[144] The kinetics give a half-order dependence on

$[Mo_2O_4^{2+}]$ consistent with a mechanism shown in equations (30) and (31). From EPR measurements it has been confirmed that mononuclear Mo^V is present.

$$Mo_2^V \rightleftharpoons 2Mo^V \quad (30)$$

$$Mo^V + NO_3^- \longrightarrow \text{products} \quad (31)$$

Pulse radiolysis studies on $[Mo_2O_4(edta)]^{2-}$, $[Mo_2O_2S_2(edta)]^{2-}$, $[Mo_2O_4(cys)_2]^{2-}$ and $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ at pH ~6, in which the Mo_2^V is reduced with e_{aq}^- and Zn^+ to the $Mo^{IV,V}$ mixed-valence form have been reported.[145] The latter absorbs in the visible range (ε 300–500 $M^{-1}\,cm^{-1}$ per dimer). In the absence of O_2 the decay is relatively slow ($t_{1/2}$ ~5–10 s), and does not result in Mo^{III} production. With O_2 present there is rapid (~$10^8\,M^{-1}\,s^{-1}$) oxidation back to Mo_2^V.

Inner-sphere paths are observed in the Cr^{2+} reduction of 10^{-4}–10^{-3} M solutions of Mo_2^V, $[Mo_2O_4(H_2O)_6]^{2+}$, and of Mo_3^{IV}, $[Mo_3O_4(H_2O)_9]^{4+}$, at 25 °C, $I = 2.0$ M (NaPTS).[146] In 1.9 M HPTS and with $[Cr^{2+}]$ in a greater than ten-fold excess of Mo_2^V, the reaction proceeds *via* a grey-green Cr-containing intermediate (~1 min), to give a product with the Mo_2^{III} spectrum (~24 h). The rate law for formation of the intermediate is of the form $k_1[Cr^{2+}]^2[Mo_2^V][H^+]$, with $k_1 = 9.1 \times 10^3\,M^{-3}\,s^{-1}$. Decay of the intermediate is independent of Cr^{2+} and can be expressed as k_2[intermediate][H^+]. The rate constant $k_2 = 2.0 \times 10^{-5}\,M^{-1}\,s^{-1}$ is believed to correspond to a process involving loss of Cr^{III}. With a Cr^{2+}:Mo_2^V ratio of reactants of 2:1 evidence for two intermediates is obtained (~1 min), one (green in colour) giving a Cr:Mo ratio of 1:1, and the other the same as that generated in the reaction of excess Cr^{2+} with Mo_2^V giving a Cr:Mo ratio of 2:1. Some 30% of the Mo remains as Mo_2^V. Over longer periods (~22 h) 60–70% overall conversion to Mo_3^{IV} is observed, and 24–30% of the Mo is present as Mo_2^V. In separate experiments, with Cr^{2+} in a greater than ten-fold excess, Mo_3^{IV} is reduced to $Mo^{III,III,IV}$ in a two-stage process, complete within 1 min, and then through to Mo_3^{III} (~40 min). Reduction of Mo_2^V to either Mo_2^{III} or Mo_3^{III} is observed therefore, depending on whether a single addition of excess Cr^{2+} or successive additions of Cr^{2+} are made.

36.1.2.6 Oxidation State VI

The solution chemistry of the Mo^{VI} state has been an area of intense research activity for several decades. It is dominated by the isopolymolybdate and heteropolymolybdate forms,[147] brief mention of which is included here. Such studies remain an active area of research with applications in the area of industrial catalysis.[1] More than 65 elements from all groups of the Periodic Table (except the rare gases) are implicated as heteroatoms in such structures.[147] In addition to the text by Pope,[147] a review of isopolyanions has appeared.[148] An overview on the hydrolysis of cations is also relevant.[149] At pH > 7 Mo^{VI} exists as the monomeric tetrahedral $[MoO_4]^{2-}$ ions. Polymers are generated by conversion of tetrahedral Mo^{VI} to octahedral forms in which there is edge, corner and (occasionally) face sharing of coordinated O^{2-} ions between adjacent Mo atoms. In the absence of heteropolyanions protonation to give $[HMoO_4]^-$, more precisely $[MoO_3(OH)]^-$ (pK_a 3.47 in 1 M HCl), is followed by a second protonation to give $[H_2MoO_4]$ (pK_a 3.7 in 1 M NaCl). The latter at least (possibly both) is believed to be octahedral and is sometimes referred to as $[Mo(OH)_6]$ although other formulations have been suggested.[150] The incidence of protonation at pH ~ 7 triggers polymerization. Polymeric forms play a dominant role in the chemistry of Mo^{VI} from pH 7 down to 2.[151] At pH 2 to 1 (depending on the concentration) break down of polymers to give dimeric and monomeric octahedral forms occurs, where the latter are often referred to as $[Mo(OH)_6]$. The first protonation constant for $[Mo(OH)_6]$ has been determined.[151b] Singly and doubly charged cationic species are present in such solutions,[151b,152] and formulae which have been suggested include *cis*-$[MoO_2(H_2O)_4]^{2+}$ and $[Mo(OH)_4(H_2O)_2]^{2+}$. The *cis*-dioxo structure is found in a number of mononuclear coordination complexes, including *cis*-$[MoO_2(Et_2dtc)_2]$ (Et_2dtc = *N*,*N*-diethyldithiocarbamate),[153] *cis*-$[MoO_2(tox)_2]$ (tox = thiooxine or 8-mercaptoquinolate),[154] Λ-*cis*-$[MoO_2\{(2R)\text{-cysOMe}\}_2]$ (cysOMe = 1-cysteine methyl ester)[155] and Λ-*cis*-$[Mo_2(S)\text{-penOMe})_2]$ (penOMe = penicillamine methyl ester).[156] Two *cis* oxos are also present in the oxalato μ-oxo complex $[(H_2O)(C_2O_4)O_2MoOMoO_2(C_2O_4)(H_2O)]^{2-}$ (Figure 31).[157] Facial trioxo coordination is on the other hand present in $[MoO_3dien]$ (dien = diethylenetriamine)[158] and the ethylenediaminetetraacetate complex $[O_3Mo(edta)MoO_3]^{4-}$ [159] (Figure 32). Features of both structures are the MoO_3 bond angles (~106°) which are approaching those of a regular tetrahedron,

and the Mo—O(oxo) bond lengths of ~1.74 Å which indicate a bond order of two. The bond angles N—Mo—N (75°) for the dien complex, and N—Mo—O (73°) and O—Mo—O (75°) for the edta complex also suggest that the structures should be regarded as pseudotetrahedral. From Raman studies[160] it has been concluded that $[MoO_3dien]$ is largely dissociated in water (equation 32), and reforms rapidly and quantitatively as a solid on addition of alcohol at pH ~7. Thus although it is necessary to replace an oxo ligand on $[MoO_4]^{2-}$ the reaction occurs rapidly.

$$[MoO_3dien] + H_2O \rightleftharpoons [MoO_4]^{2-} + dienH_2^{2+} \quad (32)$$

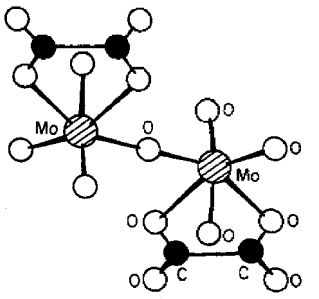

Figure 31 The structure of the Mo^{VI} complex $[Mo_2O_5(C_2O_4)_2(H_2O)_2]^{2-}$ [157]

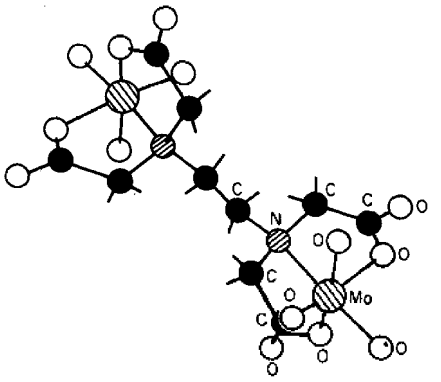

Figure 32 The structure of the Mo^{VI} complex $[O_3Mo(edta)MoO_3]^{4-}$ [159]

The polymeric forms obtained on decreasing the pH from 7 have been extensively investigated. For solutions with Mo^{VI} concentrations greater than 10^{-3} M, and pH in the range 3.0 to 5.5, the predominant form present is the heptamolybdate(VI) ion, $[Mo_7O_{24}]^{6-}$, sometimes referred to as paramolybdate (equation 33). Commercially available ammonium molybdate, $(NH_4)_6[Mo_7O_{24}]\cdot 4H_2O$, is obtained by crystallization of a solution of MoO_3 in aqueous NH_3. In spite of numerous attempts, no intermediate has been unambiguously characterized in the aqueous conversion of $[MoO_4]^{2-}$ to $[Mo_7O_{24}]^{6-}$. At pH < 4 the β-$[Mo_8O_{26}]^{4-}$ octamolybdate form is obtained (equation 34). Representations of $[Mo_7O_{24}]^{6-}$ and $[Mo_8O_{26}]^{4-}$ are shown in Figure 33. The existence of significant amounts of the $[Mo_8O_{26}]^{4-}$ ion has been controversial, but recent Raman and X-ray scattering[161] studies would seem to provide confirmation of its existence. Previously the interpretation of EMF data (pH 2–3) has been uncertain, because equally acceptable fits are given by a series of protonated $[Mo_7O_{24}]^{6-}$ forms, as by a mixture of protonated $[Mo_7O_{24}]^{6-}$ and $[Mo_8O_{26}]^{4-}$. From one set of stability constant determinations, Figure 34 has been obtained, indicating the distribution of different species. The ditetrahedral $[Mo_2O_7]^{2-}$ ion has recently been identified in $Mg[Mo_2O_7]$ and in the double salt $K_2[Mo_2O_7]$,KCl.[162,163] These structures are to be contrasted with the crystalline product $(NH_4)_2[Mo_2O_7]$, obtained from hot aqueous ammonium molybdate solution after some hours, which consists of infinite chains of tetrahedral MoO_4 and octahedral MoO_6 units.[164]

$$7[MoO_4]^{2-} + 8H^+ \rightleftharpoons [Mo_7O_{24}]^{6-} + 4H_2O \quad (33)$$

$$8[MoCl]^{2-} + 12H^+ \rightleftharpoons [Mo_8O_{26}]^{4-} + 6H_2O \quad (34)$$

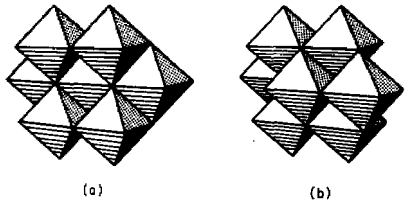

Figure 33 The structures of (a) heptamolybdate, $[Mo_2O_{24}]^{6-}$, and (b) octamolybdate, $[Mo_8O_{26}]^{4-}$ (one MoO_6 octahedron hidden)

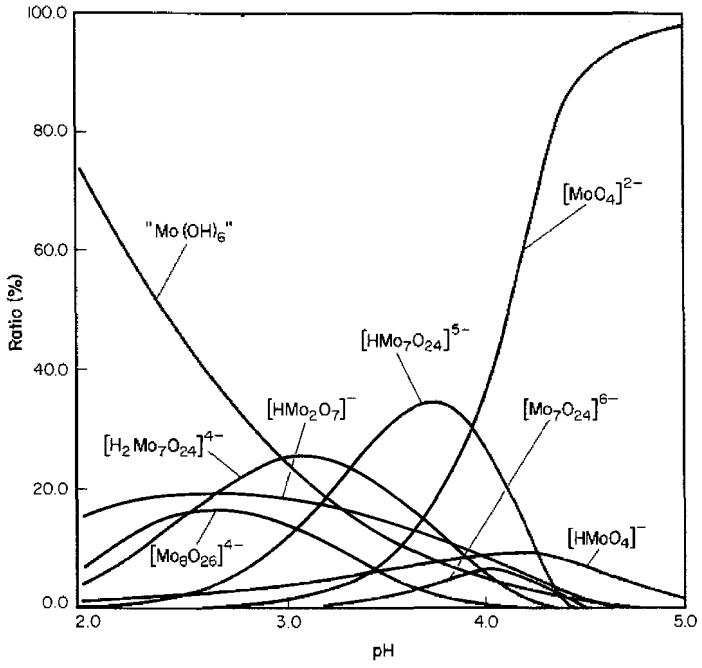

Figure 34 Distribution of Mo^{VI} forms with pH for a solution of 5×10^{-4} M molybdate at 25 °C, $I = 1.0$ M (NaCl), as calculated by A. Nagasawa and R. Iwata (unpublished work) from data in ref. 151

Solutions of Mo^{VI} acidified to $H^+/[MoO_4]^{2-} \sim 1.8$ contain one or more very large polymolybdate structures. Earlier measurements based on ultracentrifugation and EMF studies,[165] through to a recent structure report,[166] are consistent with a formula $[Mo_{36}O_{112}(H_2O)_{18}]^{8-}$. The reaction can be summarized as in equation (35). There are two seven-coordinate Mo^{VI} atoms in this structure. In all isopoly and heteropoly structures the metal ion does not lie at the centre of its polyhedron, but is displaced towards the exterior of the structure and towards a vortex or edge of its own polyhedron. Structures appear to be governed by electrostatic and radius-ratio principles as observed for extended ionic lattices. The Mo^{VI} tetrahedral radius is 0.55 Å (0.56 Å for W), the octahedral radius 0.73 Å (0.74 Å for W), and the radius of O^{2-} is 1.40 Å.[167]

$$36[MoO_4]^{2-} + 64H^+ \rightleftharpoons Mo_{36}O_{112}^{8-} + 32H_2O \qquad (35)$$

Important differences are observed in comparing the behaviour of Mo^{VI} and W^{VI}. Equilibria involving $[MoO_4]^{2-}$ and polymolybdates in aqueous solution are established rapidly and are complete in a matter of minutes, whereas those for W^{VI} can take several weeks. The polyanions of tungsten are made up of WO_6 octahedra, but in other respects the behaviour of W^{VI} solutions is quite different, and structurally the polyanions in one series do not have precise counterparts in the other. Known structures of isopolytungstates from aqueous solution include $[W_4O_{16}]^{8-}$, $[W_4O_{19}]^{2-}$, $[W_{10}O_{32}]^{4-}$, $[H_2W_{12}O_{42}]^{10-}$ and $[H_2W_{12}O_{40}]^{6-}$.[147]

A number of other isopolymolybdate anions including $[Mo_6O_{19}]^2$, α-$[Mo_8O_{26}]^{4-}$ and $[Mo_5O_{17}H]^{3-}$ can be stabilized in non-aqueous or mixed solvents.[168] The $[Mo_2O_7]^{2-}$ ion is also obtained from acetonitrile solution. Tetrahedral coordination is retained in the latter.[169] There

are two distorted tetrahedra in α-$[Mo_8O_{26}]^{4-}$ above and below a crown of six octahedra formed by edge sharing. A tetrahedron spanning a ring of four edge- and face-shared octahedra is also believed to be present in $[Mo_5O_{17}H]^{3-}$.[170] The α and β structures can coexist in solution, and a cation dependent isomerization of α into β has been observed.[171]

Isopolymolybdates are generally colourless, and heteropoly forms can be coloured if another transition metal ion is present. Some other heteropolyanions can be coloured, for example that obtained by addition of ammonium molybdate to phosphoric acid to give ammonium 12-molybdophosphate, $[NH_4]_3[PMo_{12}O_{40}]$, which is yellow. The $[Mo_6O_{19}]^{2-}$ anion is unique for an isopolyanion in being yellow (λ_{max} 325 nm) and having a structure with a monocoordinated terminal oxo group rather than MoO_2 units. This ion is electrochemically reduced to the mixed valence $[Mo_6O_{19}]^{3-}$ and $[Mo_6O_{19}]^{4-}$ forms in DMF. Incorporation of the Mo^V state in blue-red and yellow mixed-valence species formulated as $[Mo^V_2Mo^{VI}_4O_{18}]^{2-}$, $[Mo^V_3Mo^{VI}_3O_{18}]^{2-}$ and $[Mo^V_2Mo^{VI}_4O_{17}H]^{2-}$ respectively has also been reported. The reduction of addenda atoms in heteropolyanions results in the formation of heteropoly blues, and gives rise to a vast chemistry. The added electrons are delocalized according to varying timescales over certain atoms and/or regions of the structure.

Because the surfaces of polyanions have some similarities to those of metal oxides, it is thought they may have some relevance in the area of heterogeneous catalysis. As a result a whole new area concerned with the synthesis and study of organic and organometallic derivatives of polyanions is being investigated.[173]

A kinetic investigation of the ^{18}O exchange between water and molybdate $[MoO_4]^{2-}$ at pH > 11, $[OH^-] = 3 \times 10^{-3}$–0.15 M, $I = 1.00$ M ($NaClO_4$), has been carried out.[174] The rate law (equation 36) indicates paths involving reaction with H_2O and OH^- ($k_1 = 0.33\ s^{-1}$, $k_{OH} = 2.22\ M^{-1}\ s^{-1}$ at 25 °C). The corresponding k_1 values for $[CrO_4]^{2-}$ ($3.2 \times 10^{-7}\ s^{-1}$) and $[WO_4]^{2-}$ ($0.44\ s^{-1}$) provide one of the few kinetic comparisons for Cr, Mo and W. The difference in rate constants is attributable to the larger enthalpy of activation in the case of chromate, reflecting tighter Cr^{VI}—O bonds. It has to be borne in mind that there are other contributing paths for chromate, the full rate law having been determined as equation (37). The molybdate exchange cannot readily be studied by ^{18}O labelling at pH 11, because protonation is effective and much faster rates are observed.[174]

$$\text{Rate} = k_1[MoO_4^{2-}] + k_{OH}[MoO_4^{2-}][OH^-] \tag{36}$$

$$\text{Rate} = k_1[CrO_4^{2-}] + k_2[HCrO_4^-] + k_3[H^+][HCrO_4^-] + k_4[HCrO_4^-] + k_5[HCrO_4^-]^2 \tag{37}$$

Fast monomer–dimer equilibria involving Mo^{VI} in 0.2–0.3 M $HClO_4$, $I = 3.0$ M ($LiClO_4$), have been studied by the temperature-jump method.[176] A major pathway involves rapid dimerization of a monomer form, referred to as $[HMoO_3]^+$, which might alternatively be written $[MoO_2(OH)(H_2O)_3]^+$ or a related form. At 25 °C, $I = 3.0$ M $[LiClO_4]$, rate constants are $k_f = 1.71 \times 10^5\ M^{-1}\ s^{-1}$, and $k_b = 3.2 \times 10^3\ s^{-1}$. Information has been obtained by the stopped-flow method for the interconversion of tetrahedral chromate and dichromate ions.[177] At pH 2–4 hydrogen chromate, $[HCrO_4]^-$, is specified as the reactant. From this and other similar studies on the substitution reactions of $[HCrO_4]^-$ there is evidence for a dissociative process.[178] Further information concerning precise formulae of Mo^{VI} in acidic solutions is required to enable more extensive comparisons.

Temperature-jump studies of Mo^{VI} solutions at pH 5.50–6.75 have been reported for the monomer–heptamer and heptamer–octamer interconversions which are complete within a few milliseconds.[179] Molybdate as $[HMoO_4]^-$ (here assumed to be tetrahedral) reacts with bidentate 8-hydroxyquinoline[180] and catechol,[181] to give octahedral products in net 4→6 conversions.[180] Table 4 summarizes the kinetic data, where different degrees of protonation of the ligating groups are indicated. For the reaction with edta a path assigned to the reaction of $[H_2edta]^{2-}$ with $[HMoO_4]^-$ gives a rate constant of $2.3 \times 10^5\ M^{-1}\ s^{-1}$.[182] A reaction in which the tetrahedral geometry of $[MoO_4]^{2-}$ is retained is the rapid stopped-flow equilibration of molybdate with $[Co(NH_3)_5(H_2O)]^{3+}$ (pK_a 6.3) at pH 7–8 (equation 38).[183]

$$[Co(NH_3)_5(H_2O)]^{3+} + [MoO_4]^{2-} \rightleftharpoons [Co(NH_3)_5(OMoO_3)]^+ + H_2O \tag{38}$$

Substitution is at the Mo^{VI} centre with retention of the Co—O bond. The first-order $[H^+]$-dependent term is consistent with $[HMoO_4]^-$ as a reactant, and the $[H^+]$-independent term is assigned to the reaction of $[HMoO_4]^-$ with $[Co(NH_3)_5OH]^{2+}$. An interesting situation arises in the reaction of $[MoO_4]^{2-}$ with $[Cr(edta)(H_2O)]^-$ at pH 7.3–8.7.[184] As in the case of

Table 4 Second-order Rate Constants for Reactions of $[HMoO_4]^-$ at 25 °C

Ligand	*Ionic strength*	*Coordination change at Mo^{VI}*	k ($M^{-1}s^{-1}$)
H-oxine	0.20	4→6	4.5×10^6
H-oxine-SO_3^-	0.20	4→6	3.9×10^6
oxine$^-$	0.20	4→6	1.5×10^8
oxine-SO_3^{2-}	0.20	4→6	4.0×10^7
H-catechol$^-$	0.10	4→6	1.9×10^8
H_2-edta	0.10	4→6	2.3×10^5
$[Co(NH_3)_5H_2O]^{3+}$	1.0	4→4	3.2×10^5
$[Co(NH_3)_5OH]^{2+}$	1.0	4→4	6.6×10^4
$[Cr(edta)H_2O]^-$	1.0	4→4	3.1×10^4
HS^-	0.50	4→4	1.3×10^6

H-oxine = 8-hydroxyquinoline.
H-oxine-SO_3^- = 8-hydroxyquinoline-5-sulfonic acid.
H-catechol$^-$ = product of first acid dissociation of catechol.

$[Co(NH_3)_5(H_2O)]^{3+}$, there are two terms for complex formation in the rate law, one of which can be assigned to the reaction of $[Cr(edta)(H_2O)]^-$ with $[MoO_4]^{2-}$ (rate constant 21 $M^{-1}s^{-1}$). The second, which is first order in $[H^+]$, corresponds to replacement of the H_2O of $[Cr(edta)H_2O]^-$ by $[HMoO_4]^-$ (3.1×10^4 $M^{-1}s^{-1}$). Whereas the first is believed to correspond to replacement of the H_2O (labilized by the presence of the carboxylate) at the Cr^{III}, the latter as in other cases corresponds to substitution at the Mo^{VI} centre. There are proton ambiguities however because the first reaction could also be assigned to the reaction of $[Cr(edta)OH]^{2-}$ (pK_a 7.4) with $[HMoO_4]^-$. In all these examples the interpretation requires that there are pathways in which there is protonation of $[MoO_4]^{2-}$ prior to complexation. Protonation labilizes at least one oxo ligand and may itself induce a 4→6 change in coordination to give a more labile species. Consistent with this, rates are much more rapid than for $H_2{}^{18}O$ exchange with $[MoO_4]^{2-}$.

Tetrahedral sulfido or thiolate complexes are known for a number of d^0 transition metal ions including Mo^{VI}.[185] Preparative procedures involve the reaction of solutions of oxyanions with H_2S. In addition to $[MoS_4]^{2-}$ the mixed oxo/sulfido complexes $[MoOS_3]^{2-}$, $[MoO_2S_2]^{2-}$ and $[MoO_3S]^{2-}$ are well characterized. Although the latter is difficult to obtain in a pure crystalline state, X-ray crystal structure information on $(NH_4)_2[MoS_4]$ (Mo—S = 2.17 Å),[186] and $Cs_2[MoOS_3]$ (Mo—S = 2.18 Å; Mo—O = 1.79 Å)[187] have been reported, and the Mo—O distance is slightly longer than in Mo^{VI} complexes $K_2[MoO_4]$ (1.76 Å), $[MoO_3(dien)]$ (1.74 Å) and $[Mo_2O_5(C_2O_4)_2(H_2O)_2]^{2-}$ (Mo—O_t 1.69 Å). Bridged Mo^{VI} μ-sulfido complexes do not appear to be formed and there are no counterparts in the polymeric (and heteropoly) species found from $[MoO_4]^{2-}$. Kinetic studies on the interconversion of $[MoO_xS_{4-x}]^{2-}$ forms have been carried out.[188] The 1:1 equilibration of H_2S with $[MoO_4]^{2-}$ can be expressed as in equation (39).

$$[MoO_4]^{2-} + H^+ + HS^- \underset{k_{10}}{\overset{k_{01}}{\rightleftharpoons}} [MoO_3S]^{2-} + H_2O \qquad (39)$$

There are few quantitative studies with H_2S as a reactant, and some difficulties were experienced in choosing conditions appropriate to the study. At pH 9.2–10.2 (0.25 M NH_3/NH_4^+ buffer), I = 0.50 M (NaCl), plots of equilibration rate constants k_{eq} against $[MoO_4^{2-}]$ are in accord with equation (40).

$$k_{eq} = k_f[MoO_4^{2-}] + k_b \qquad (40)$$

The formation constant k_f is dependent on $[H^+]$ giving $k = 4.0 \times 10^9$ $M^{-2}s^{-1}$, and k_b for the reverse reaction is 6.5×10^{-3} s^{-1}. Interpretation of k in terms of a reaction between $[HMoO_4]^-$ and HS^- is preferred rather than the alternative of $[MoO_4]^{2-}$ with H_2S, and on this basis a second-order rate constant of 1.3×10^6 $M^{-1}s^{-1}$ is obtained, of similar magnitude to those listed in Table 4. Other formation rate constants for the different $[MoO_xS_{4-x}]^{2-}$ ions have to be left in the form of the experimental third-order rate constants since the relevant protonation constants are not known. For the rate law $k[MoO_xS_{4-x}^{2-}][HS^-][H^+]$, k values range from 4.0×10^9 $M^{-2}s^{-1}$ for the reaction of $[MoO_4]^{2-}$ to less than 1.6×10^6 $M^{-2}s^{-1}$ for $[MoOS_3]^{2-}$. Rate constants for aquation of $[MoO_3S]^{2-}$ (6.5×10^{-3} s^{-1}), $[MoOS_3]^{2-}$ ($\sim 5 \times 10^{-5}$ s^{-1}) and

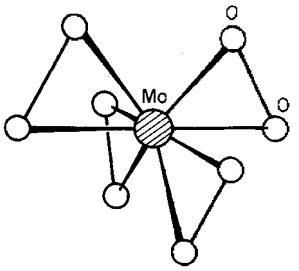

Figure 35 The structure of the Mo^{VI} peroxo complex, $[Mo(O_2)_4]^{2-}$ [190]

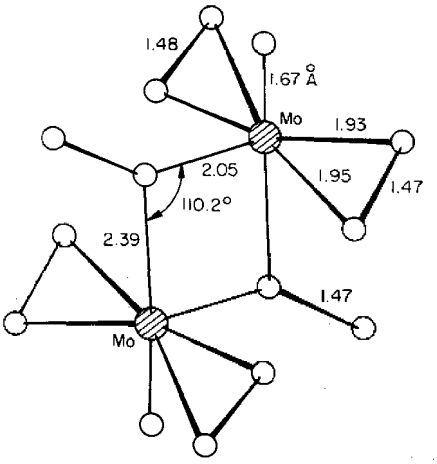

Figure 36 The structure of the Mo^{VI} peroxo/hydroperoxo complex $[(O_2)_2OMo(OOH)_2MoO(O_2)_2]^{2-}$ [196]

$[MoS_4]^{2-}$ ($1.6 \times 10^{-6}\ s^{-1}$) indicate a trend to smaller values as more sulfide ligands are introduced. The presence of sulfide does not appear to give a labilizing effect.

Different crystalline phases can be separated from aqueous solutions of potassium molybdate(VI) following reaction with varying amounts of hydrogen peroxide, pH 4–8.[189] Crystal structure determinations of $[Zn(NH_3)_4][Mo(O_2)_4]$,[190] $K_2[O\{MoO(O_2)_2(H_2O)\}_2]\cdot 2H_2O$,[190] $K_4[Mo_4O_{12}(O_2)_2]$[192] and $K_6[Mo_7O_{22}(O_2)_2]\cdot 8H_2O$[193] have for example been reported. In all cases the O_2^{2-} is bound sideways to the metal, with O—O distances varying from 1.38 to 1.55 Å, but generally around 1.48 Å, which is the expected value for peroxide. The peroxo ligands in the dark red $[Mo(O_2)_4]^{2-}$ compound (O—O distance 1.55 Å) are positioned tetrahedrally about the Mo^{VI} (Figure 35). A Cr^{V} analogue $[Cr(O_2)_4]^{3-}$, having a similar configuration (O—O distance 1.48 Å), is known. An interesting variation is the occurrence of hydroperoxide as a bridging ligand in $(pyH)_2[(O_2)_2OMo(OOH)_2MoO(O_2)_2]$,[194] where the bridge has a pendant —O(OH)— arrangement (Figure 36). Only one other example of this structure is known in the Co_2^{III} complex $[(en)_2Co(NH_2, O_2H)Co(en)_2]^{4+}$.[195] The complex $K_2[MoO(O_2)_2(C_2O_4)]$ is monomeric,[196] and to be regarded as five- or seven-coordinate depending whether the O_2^{2-} is assigned one or two coordination positions.

36.2.5 REFERENCES 1296

36.2.1 INTRODUCTION

This survey of the lower oxidation states of molybdenum concentrates on those compounds which have a minimum of metal–carbon bonds. This is because there is an extensive literature of low-valent carbonyls, arene, alkene, alkyne and other organometallic complexes of molybdenum which has been thoroughly reviewed in 'Comprehensive Organometallic Chemistry'. We therefore exclude compounds of alkenes, alkynes and higher organic entities. Nevertheless, reference is made to significant compounds which contain molybdenum–carbon bonds where it is judged appropriate. Coverage of complexes containing molybdenum–molybdenum bonds is also kept to a minimum because these compounds are reviewed in Chapter 36.3.

In certain cases the nature of the ligands involved makes definition of the metal oxidation state difficult, *e.g.* NO, N_2R, dithiolenes, *etc.* For simplification, therefore, arbitrary assignment of ligand charge and therefore metal oxidation state has been made in the text, *e.g.* NO is

defined as being NO^+ in its compounds and N_2R is arbitrarily regarded as N_2R^-. Hydride is regarded as H^-. Complexes of formal oxidation state below zero, *e.g.* the anion $[Mo(CO)_5]^{2-}$, are not reviewed here because of the high number of Mo—C bonds, as explained above.

36.2.2 MOLYBDENUM(0)

36.2.2.1 Carbon Ligands

36.2.2.1.1 Carbon monoxide

There is an extensive chemistry of Mo^0 formally based upon substitution of $[Mo(CO)_6]$ by various ligands, without oxidation of the metal. These include hydride; nitrogen donors such as bipy, phen, NR_3, RCN, NCS^-; oxygen donors such as OH^-, THF, RCO_2^-; sulfur donors such as R_2S, Me_2PhPS; selenium and tellurium donors such as R_2Se and R_2Te; and halogens. In general compounds of the type $[Mo(CO)_5L]$, $[Mo(CO)_4L_2]$, $[Mo(CO)_3L_3]$ and $[Mo(CO)_2L_4]$ result from direct substitution reactions using $[Mo(CO)_6]$, which are summarized in 'Comprehensive Organometallic Chemistry' (COMC).[1a]

A recent significant development has been the application of ^{95}Mo NMR to the study of these carbonyl compounds. Ranges of chemical shifts (p.p.m. relative to $[MoO_4]^{2-}$) which have been determined are: $[Mo(CO)_6]$ −1858; $[Mo(CO)_5L]$ (L = N, P, As or Sb donor) −1350 to −1870; $[Mo(CO)_4L_2]$ −1100 to −1600; $[Mo(CO)_3L_3]$ (here L may also be an arene or related ligand) −1100 to −1750; $[Mo(CO)_2L_4]$ −1400 to −1800.[2]

Alternative routes to carbonyl compounds are also known, *e.g.* by direct reduction of a higher oxidation state compound in presence of CO or by displacement of a more labile ligand by CO. Reaction (1) illustrates these routes.[1a] Mixed substituted complexes can also be obtained, *e.g.* $[Mo(CO)_2(PR_3)_2(CNMe)_2]$.[1a]

$$\begin{array}{ccc} [MoCl_2(dppe)_2] + Mg & \xrightarrow[CO]{THF} & \textit{cis}\text{-}[Mo(CO)_2(dppe)_2] \\ {\scriptstyle Mg}\downarrow{\scriptstyle N_2} & & \uparrow{\scriptstyle \Delta} \\ \textit{trans}\text{-}[Mo(N_2)_2(dppe)_2] & \xrightarrow{CO} & \textit{trans}\text{-}[Mo(CO)_2(dppe)_2] + 2N_2 \end{array} \quad (1)$$

A series of monocarbonyl complexes is known of which the five-coordinate complex $[Mo(CO)(dppe)_2]$ may be regarded as the parent. It has an almost square pyramidal structure and adds ligands L to give the series $[Mo(CO)(L)(dppe)_2]$ (L = N_2, DMF, C_2H_4, 4-ClC_6H_4CN, PhCN, C_5H_5N, Me_2NCHO, CN^-, SCN^- or N_3^-).[3a] Further analogues of this series, *fac*-$[Mo(CO)\{PhP(CH_2CH_2PPh_2)_2\}(PMe_2Ph)_2]$ and $[Mo(CO)(PF_3)_4(dppe)]$, have also been prepared.[3] These compounds are notable for their low values of ν(CO) for mononuclear compounds, in the range 1690–1820 cm^{-1}.

36.2.2.1.2 Isocyanide ligands

Molybdenum carbonyl–isocyanide complexes may be obtained as in Section 36.2.2.1.1. In most respects isocyanides behave in a very similar way to carbon monoxide, with which they are isoelectronic. As for the carbonyls, the isocyanide complexes may be regarded as derivatives of $[Mo(CNR)_6]$ and have been reviewed comprehensively.[1a,b]

Isocyanides are rather more reactive than CO at low-valent molybdenum centres and may react with nucleophiles, *e.g.* $R'NH_2$, to give carbene complexes,[1a] *e.g.* equation (2), or with electrophiles to give carbyne complexes,[1,4] *e.g.* (3).

$$[Mo(CNR)_5(NO)]^+ + R'NH_2 = [Mo\{C(NHR)(NHR')\}(NO)(CNR)_4]^+ \quad (2)$$

$$\textit{trans}\text{-}[Mo(CNMe)_2(dppe)_2] \xrightarrow{R^+} \textit{trans}\text{-}[Mo\{CN(R)Me\}(CNMe)(dppe)_2]^+ \quad (3)$$

$$R^+ = H^+ \text{ or } Me^+$$

Simple oxidation/reduction has also been studied for a wide range of isocyanide complexes. Again those complexes containing mainly molybdenum–carbon bonds have been reviewed in

COMC and here we merely give as an example the series *trans*-$[Mo(CNR)_2(dppe)_2]$ (R = alkyl or aryl). They are not reducible under normal conditions, but they can be reversibly oxidized electrochemically[4,5] by one electron to give the series $[Mo(CNR)_2(dppe)_2]^+$ (see Section 36.2.3).[4,5] Complexes with aryl substituents are less easily oxidized than those with alkyl substituents, as might be expected and these compounds are notable for their low ν(NC) values, 1850–1920 cm^{-1}. The X-ray structure of *trans*-$[Mo(CNR)_2(dppe)_2]$ confirms the *trans* geometry of the series.[5]

36.2.2.2 Dinitrogen Complexes

These complexes are reviewed in a variety of articles[6,7] and are collected in Table 1.

In general they are prepared by the following methods.

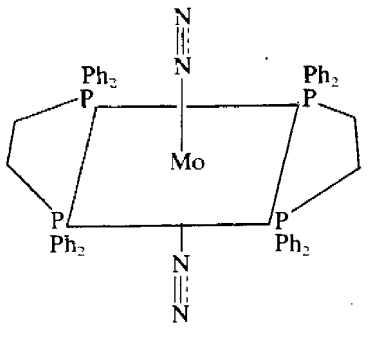
(A) Reduction of a high-valent molybdenum species in presence of dinitrogen, *e.g.* reaction (4).

$$[MoCl_3(THF)_3] \xrightarrow[4PMe_2Ph]{Mg/THF/N_2} cis\text{-}[Mo(N_2)_2(PMe_2Ph)_4] \quad (4)$$

(B) Displacement of a ligand from a preformed complex by dinitrogen, free or coordinated, *e.g.* reactions (5) and (6).[6,8]

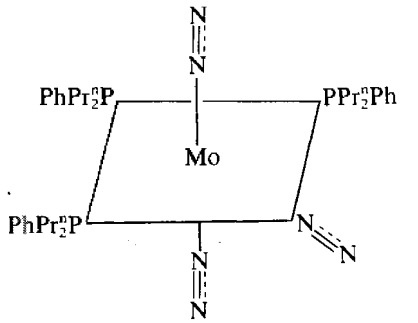
$$trans\text{-}[Mo(N_2)_2(PPr^n_2Ph)_4] + N_2 \longrightarrow mer\text{-}[Mo(N_2)_3(PPr^n_2Ph)_3] + PPr^n_2Ph \quad (5)$$

$$[MoH_4(Ph_2PCH_2CH_2PPh_2)_2 + N_2 \longrightarrow trans\text{-}[Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2] + 2H_2 \quad (6)$$



(C) Displacement of dinitrogen by a ligand, *e.g.*, reaction (7).[9]

$$trans\text{-}[Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2] + RCN \longrightarrow trans\text{-}[Mo(N_2)(RCN)(Ph_2PCH_2CH_2PPh_2)_2] \quad (7)$$



(D) Displacement of a coligand by a second coligand, *e.g.* reaction (8).[10]

$$trans\text{-}[Mo(N_2)_2(PPh_2Me)_4] + C_5H_5N \longrightarrow [Mo(N_2)_2(PPh_2Me)_3(C_5H_5N)] + PPh_2Me \quad (8)$$

The binding of dinitrogen to the metal centres in these mononuclear complexes is end-on to the molybdenum as shown, for example, by the X-ray structures of *trans*-$[Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2]$ (**1**)[11] and *mer*-$[Mo(N_2)_3(PPr^n_2Ph)_3]$ (**2**). (Data for other structurally characterized complexes are in Table 1).[8] Characteristic of this bonding mode for dinitrogen are slight elongation of the N≡N bond on binding (by about 0.01–0.02 Å from that of 1.0976 Å in free N_2) and a $\nu(N_2)$ value some 300–400 cm^{-1} less than the 2331 cm^{-1} value of free N_2 in its Raman spectrum.

(1)

(2)

The majority of complexes contain tertiary phosphines or arsines as coligands but there is also a class which has π-arene coligands which is included in Table 1 for completion.

Despite the obvious relevance of dinitrogen complexes to the chemistry of the molybdenum–sulfur site of nitrogenase,[6] dinitrogen complexes of molybdenum with sulfur ligation have proved to be very elusive. They are confined to the compounds

$[Mo(N_2)_2(PhSCH_2CH_2SPh)(PMe_2Ph)_2]$[12] (said to decompose at 20 °C) and $[Mo(N_2)_2(Ph_2PCH_2CH_2SMe)(PPh_2Me)_2]$.[13]

^{15}N NMR data can be used to characterize these compounds and to follow their reactions in solution. Characteristic resonances are shown in Table 1. Dinitrogen occupies a low position in a spectroscopic series of ligands based on ^{95}Mo NMR spectroscopy.[13,14]

Many dinitrogen complexes show a reversible one-electron oxidation in solution but are not reducible under normal conditions. The complexes $[Mo(N_2)(RCN)(Ph_2PCH_2CH_2PPh_2)_2]$ are exceptional in that they show two successive one-electron polarographic oxidation waves.[15] $E_{1/2}$ values ($0 \rightarrow 1$), shown in Table 1, can be used to deduce that dinitrogen is a relatively good electron-accepting ligand to molybdenum(0).[15] Dinitrogen complexes of molybdenum(I) are generally poorly stable (see Section 36.2.3).

Because of the electron-accepting properties of dinitrogen when bound to molybdenum in the phosphine complexes, it is susceptible to attack by acids (HX) to give ammonia *via* complexes of the type $[MoX(N_2H)(PR_3)_4]$ (X = anionic ligand, PR_3 = tertiary phosphine) and $[MoX(NNH_2)(PR_3)_4]X$. Hydrazine can also be formed, depending upon the solvent and acid used. Attack by organic reagents RX can also occur to give analogous compounds $[MoX(N_2R)(PR_3)_4]$ and $[MoX(NNR_2)(PR_3)_4]X$. The first step in this process can involve a radical mechanism for certain RX. The chemistry involved in these reactions has been reviewed in depth[16] and the diazenido complex products are described in Section 36.2.4.3.

Attack at terminal nitrogen by other electrophilic reagents can also be used to give binuclear complexes with bridging dinitrogen. Thus treatment of *trans*-$[Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2]$ with $AlMe_3 \cdot Et_2O$ gives *trans*-$[Mo(N_2AlMe_3)(N_2)(Ph_2PCH_2CH_2PPh_2)_2]$ and $[(\eta^6\text{-}C_6H_5Me)(PPh_3)_2Mo(N_2)Fe(\eta^5\text{-}C_5H_5)(Me_2PCH_2CH_2PMe_2)]BF_4$ is obtained by displacement of acetone from $[Fe(\eta^5\text{-}C_5H_5)(Me_2PCH_2CH_2PMe_2)(Me_2CO)]BF_4$ by the dinitrogen of $[Mo(\eta_6\text{-}C_6H_5Me)(N_2)(PPh_3)_2]$.[17]

Although displacement of one dinitrogen in *trans*-$[Mo(N_2)_2(dppe)_2]$ and its analogues can give rise to a new series of dinitrogen complexes *trans*-$[Mo(N_2)(RCN)(dppe)_2]$, more generally dinitrogen is completely displaced by such ligands as CO, H_2, RNC, CO_2 and alkenes to give new series of complexes, *e.g.* *trans*-$[Mo(RNC)_2(dppe)_2]$,[4] *trans*-$[Mo(C_2H_4)_2(PMe_3)_4]$,[7] $[Mo(CO_2)_2(PMe_3)_4]$[7] and *cis*-$[Mo(CO)_2(dppe)_2]$.[5] (See above and Section 36.2.2.6.)

36.2.2.3 Nitrogen Monoxide Complexes

With our definition of NO in its complexes as NO^+, a range of compounds is then formally of Mo^0. Often they have analogues containing the isoelectronic ligand N_2R, which we formally regard as N_2R^-. This consequently means that the N_2R analogues of NO complexes will appear in a section concerning the higher oxidation states and we cross refer to, or list, analogous complexes where this occurs. Nitrosyl complexes have been extensively reviewed.[18,19,20]

36.2.2.3.1 Complexes of the type $MoX_2(NO)_2$

These complexes may be regarded as the precursors of a wide range of derivatives, $[MoX_2(NO)_2L_2]$, *etc.* discussed in subsequent sections.

$[\{MoX_2(NO)_2\}_n]$ (X = Cl, Br or I) are generally prepared by the reaction of [NO]X with a carbonyl derivative, sometimes followed by metathesis (method A). Thus $[\{MoX_2(NO)_2\}_n]$ (X = Cl or Br) are obtained by treatment of $[Mo(CO)_6]$ with NOX, whereas $[\{MoI_2(NO)_2\}_n]$ is obtained from $[\{MoBr_2(NO)_2\}_n]$ and KI in acetone.[18,19,20] $[MoX_2(CO)_4]$ when treated with NO also gives these complexes (method B). Alternatively (C) the reduction of $MoCl_5$ or $MoOCl_3$ with NO in CH_2Cl_2, C_6H_5Cl, $CHCl_3$ or CCl_4 gives $[\{MoCl_2(NO)_2\}_n]$.[21] The structure of these compounds appears to be halide-bridged polymers, with a linked structure caused by a *cis* disposition of NO ligands [X = Cl, ν(NO), 1805 and 1609 cm^{-1}).[19,20]

Compounds of the type $[MoXCp(NO)_2]$ ($Cp = \eta^5 - C_5H_5$ or $\eta^5\text{-}C_5Me_5$) and $[MoX(Rpzb)(NO)_2]$ are also known ($Rpzb^- =$ anion tris(2-pyrazolyl)(R)borate)[18,22] and are monomeric in solution, the Cp derivatives having the 'three-legged piano stool' structure (see **5**).[1a,19]

The ^{95}Mo chemical shifts of this class of compounds are in the range −800 to −985 p.p.m. (rel. $[MoO_4]^{2-}$).[22]

36.2.2.3.2 Complexes of the type $[MoX_2(NO)_2L_2]$ (L = monodentate or 1/2-bidentate neutral ligand)[15]

This is the largest class of nitrosyl complex and the members are shown in Table 2, together with notable physical properties. They are prepared by the following routes.

(A) By treatment of $[\{MoX_2(NO)_2\}_n]$ with neutral ligands. For example, treatment of $[\{MoX_2(NO)_2\}_n]$ with ligands L gives the series $[MoX_2(NO)_2L_2]$ (L = $MeC_6H_4NH_2$, $C_6H_{11}NH_2$, PPh_3, $AsPh_3$, py).[23]

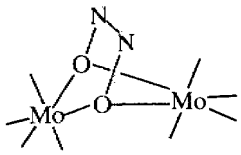
(B) By treatment of a molybdenum(II) compound such as $[MoX_2(CO)_3L_2]$ with NO. Typically $[MoX_2(CO)_3(PPh_3)_2]$ (X = Cl or Br) gives, on treatment with NO, $[MoX_2(NO)_2(PPh_3)_2]$.[24]

(C) By 'reductive nitrosylation', *i.e.* reaction of a high-valent molybdenum compound with NO in presence of a reductant and another ligand, *e.g.* $[MoCl_4(PPh_3)_2] + NO + PPh_3 + AlCl_2Et$ in hexane gives $[MoCl_2(NO)_2(OPPh_3)_2]$.



For completion, we list compounds of the class $[MoX(\eta^5\text{-}C_5H_5)(NO)_2L_2]$ in Table 2. Their analogues, $[MoCl\{Rpzb\}(NO)_2L_2]$ are also included.

As can be seen from the data of Table 2, these compounds have in general a *cis* arrangement of nitrosyl groups (two ν(NO) values) and the X-ray structure of $[MoCl_2(NO)_2(PPh_3)_2]$ confirms this[18,19] as shown in (**3**). The average Mo—N distance (1.19 Å) is consistent with the NO^- formalism and the Mo—N—O angle is significantly less than linear (162° average). Bending in nitrosyl complexes commonly occurs as a result of removal of the degeneracy of the π^*(NO) levels and has been discussed in detail elsewhere.[18] The *cis* NO structure has also been confirmed by X-rays for $[MoCl_2(NO)_2(bipy)]$,[18] and for $[MoBr_2(NO)_2(OSMe_2)_2]$.[18]

The reaction of $[\{MoCl_2(NO)_2\}_n]$ with diars and en gives $[MoCl_2(NO)_2(diars)]$ and $[MoCl_2(NO)_2(en)]$ but if these compounds are left in solution their colour changes from green to yellow and the formation of a hyponitrite-bridged complex, product (**4**), has been suggested.[25]

(**3**)

(**4**)

36.2.2.3.3 Other dinitrosyl complexes

Treatment of $[\{MoX_2(NO)_2\}_n]$ with sodium dialkyl dithiocarbamates (Nadtc) affords the dinitrosyl complexes *cis*-$[Mo(NO)_2(S_2CNR_2)_2]$ (R = Me or Et). These compounds may also be prepared by treatment of $[Mo(NO)_2(MeCN)_4][PF_6]_2$ with Nadtc and the complex $[Mo(NO)_2(acac)_2]$ is obtained using Na[acac].[26,27]

The cationic precursor complex $[Mo(NO)_2(MeCN)_4]^{2+}$ is itself prepared from $[Mo(CO)_3(MeCN)_3]$ and $[NO]PF_6$ in MeCN.[26] The exchange reactions of the MeCN in this dication have been studied by NMR, two MeCN ligands being relatively easily dissociated. It is assumed that these are *trans* to the *cis* NO groups. The cationic complexes $[Mo(acac)(NO)_2(MeCN)_2]^+$ and $[MoCl(NO)_2(MeCN)_3]^+$ have also been prepared, the former in which the MeCN groups are mutually *trans* does not dissociate MeCN, whereas the latter exchanges the one MeCN which is *trans* to NO.[28]

Two series of cationic complexes, $[Mo(NO)_2L_4]^{2+}$ (L = RCN, py, *etc.*) and $[MoCl(NO)_2L_3]^+$ have been prepared by halide abstraction from $[MoCl_2(NO)_2L_2]$ using silver salts in DME (method D). Some members of the series catalyze the polymerization of norbornadiene, whereas the uncharged parent compounds do not.[29] The series $[Mo(NO)_2L_4]^{2+}$ (L is a displaceable solvent such as THF) may also be obtained by treatment of $[Mo(CO)_6]$ with $NO[PF_6]$ followed by addition of further ligands such as bipy.[29] This latter reaction also gives $[\{Mo(NO)_2(PF_6)_2\}_n]$ which is assumed to be a polymer with weak PF_6 bridges.[29]

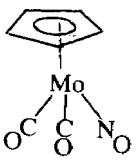
The reduction of $[Mo(ttp)Cl_2]$ (ttp = tetra-4-tolylporphinate) with zinc amalgam in benzene under NO followed by chromatography gave the dinitrosyl complex $[Mo(ttp)(NO)_2]\cdot C_6H_6$ which has the *cis* NO geometry established by X-rays. The NO groups are bent towards each other [NMoN = 78.4(5)° and OMoO = 60.0(3)°], a mutual NO attraction which is observed in other dinitrosyl compounds. In order to accommodate the *cis* geometry, the Mo is displaced 0.99 Å from the porphinato skeleton towards the nitrosyls.[30a]

A further class of dinitrosyl complex is that containing dithiolene and related ligands. Because of electronic delocalization, there are problems of assignment of oxidation state in

these complexes,[27] *e.g.* in $[Mo(NO)_2(MNT)_2]^{2-}$ and $[Mo(NO)_2(S_2C_6Cl_4)_2]^{2-}$, but they are included in this section (see Table 2) for convenience. A further series of anionic complexes in this class are the green compounds $[MoX_4(NO)_2]^{2-}$ (X = Cl, Br or I), prepared from $[\{MoX_2(NO)_2\}_n]$ and *e.g.* $[NEt_4]X$, and $[MoClBr(NO)_2]^{2-}$, prepared from $[\{MoCl_2(NO)_2\}_n]$ and $[Ph_4P]Br$.[23] A binuclear, bromide-bridged dinitrosyl $[Mo_2Br_2(NO)_4]^{2-}$ has been structurally characterized by X-rays.[30b]

An important use of dinitrosyl complexes of molybdenum has been as catalyst precursors in the alkene disproportionation reaction. Thus $[MoCl_2(NO)_2L_2]$ (L = PPh_3 or py) together with $AlCl_2Et$ forms an active homogeneous catalyst for alkene disproportionation. The catalysis appears to require loss of NO from the metal and the field has been reviewed.[19,31]

36.2.2.3.4 Mononitrosyl complexes



These complexes are generally prepared by methods similar to those employed for the dinitrosyl compounds, treatment of a low-valent molybdenum compound with NO or a nitrosyl derivative being the principal method. Compounds and major physical properties are collected in Table 3.

Treatment with nitrosylating reagents of molybdenum–carbonyl precursors leads to a variety of carbonyl–nitrosyl complexes. Examples of these are included in Table 3, but they are not reviewed in depth for the reasons cited earlier. They have been reviewed in COMC (vol. 3, pp. 1112–1115), *e.g.* $[Mo(CO)_4(diars)]$ with $NO[PF_6]$ gives[32] $[Mo(diars)(CO)_3(NO)]^+$, and $[Mo(CO)_4(bipy)]$ gives $[MoX(CO)_2(NO)(bipy)]$, (X = Cl, Br or I)[32] (method A). This method has also given the series *trans*-$[MoX(NO)(dppe)_2]$ (X = F, Cl, Br, I, OH, SCN, CN, NCO, N_3, SPh or PPh_2), by treatment of *trans*-$[MoX(N_2H)(dppe)_2]$ with NO or *trans*-$[Mo(N_2)_2(dppe)_2]$ with $MeN(NO)C(O)NH_2$ (X = CNO) or Et_2NNO (X = OH).[33]

The *trans* structure of this latter series has been established by X-rays for X = OH, disorder preventing accurate determination of the NO distance.[33] The carbonyl analogues $[MoCl(NO)(CO)_2(diphos)_2]$ (diphos = dppe or dppm) have been obtained from $[Mo(CO)_3(MeCN)_3]$, diphos and NOCl.[32] Use of PPh_3 gives $[MoCl(NO)(CO)(MeCN)(PPh_3)_2]$. The compound $[MoCl(NO)(PPh_2H)_4]$ results from treatment of $[MoCl_5(NO)]^{2-}$ with PPh_2H and Mg.[31]

The monocationic complexes $[Mo(CO)(NO)(dppe)_2]^+$ (method A, $[Mo(CO)_4(dppe)] + NO[PF_6]$) on treatment with NaS_2CNR_2 (R = Me or Et) give[34] $[Mo(CO)(NO)(S_2CNR_2)(dppe)]$; the analogues $[Mo(S_2CNR_2)(CO)(NO)(diars)]$ were similarly prepared[35] (Table 3). The anionic complex $[Mo(NO)(MNT)_2]^{2-}$ obtained[36] from $[\{MoCl_2(NO)_2\}_n]$ and Na_2MNT is also included in this section.

The compounds $[Mo(\eta^5\text{-Cp})(NO)(CO)_2]$ (Cp = C_5H_5 or C_5Me_5) are also included in this section for completion (Table 3) (see COMC vol. 3 for details). Their analogues with pyrazolylborate ligands $[Mo(CO)_2L(NO)]$ [L = $HB(3,5\text{-}Me_2HC_3N_2)_3$, $HB(C_3H_3N_2)_3$ or $B(C_3H_3N_2)_4^-$] have been prepared by treatment of $[Mo(CO)_6]$ with the appropriate pyrazolylborate salt followed by NO or an NO source.[36] The complexes $[Mo(\eta^5\text{-Cp})(NO)(CO)_2]$ have been shown to have the 'three-legged piano stool' structure (**5**) by X-ray spectroscopy[37] and presumably the pyrazolylborates have a similar structure. Treatment of the compound $[Mo(Bpz_4)(NO)(CO)_2]$ (pz = pyrazolyl) with RNC (R = C_6H_5MeCH, $PhCH_2$, Et) gives the adducts $[Mo(Bpz_4)(NO)(CO)(RNC)]$ which are enantiomeric and diastereoisomeric because of the asymmetry at molybdenum and in the isocyanide chain (Table 3).[35] Phosphine analogues $[Mo\{3,5\text{-}X_2pzb\}(NO)(CO)(PPh_2R')]$ (Table 3) are also diastereoisomeric.[35]

(5)

The complexes *trans*-$[MoX(NO)(dppe)_2]$ show a well-defined reversible one-electron oxidation in solution and the monocations can be isolated. They are described in Section 36.2.3.3. Treatment of *trans*-$[Mo(OH)(NO)(dppe)_2]$ with $Ag[BF_4]$ in MeCN gives $[Mo(NO)(NCMe)(dppe)_2][BF_4]$ as well as its dicationic, oxidized analogue.[32]

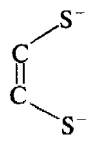
36.2.2.4 Nitrogen Donor Ligands

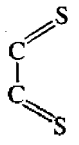
The complexes [Mo(bipy)$_3$] can be prepared by reduction of $[Mo(bipy)_3]^{3+}$ with Li_2bipy[37] or of [$MoCl_4$(MeCN)$_2$] with sodium in presence of bipy.[38] Formally, the oxidation state is zero, but there must be considerable distribution of electronic charge in orbitals which are ligand-based.

There are a considerable number of molybdenum carbonyl derivatives with nitrogen bases, *e.g.* of the types $[Mo(CO)_nL_{6-n}]$ (L = RCN, py, DMF, amines, various diamines, *etc.*, $n = 1–4$) which are not reviewed here but have received extensive coverage in COMC (vol. 3, p. 1087). We include $[Mo(PF_3)_2(bipy)_2]$ in this section.[38b] It is obtained by substitution of CO by PF_3 in $[Mo(CO)_2(bipy)_2]$.



36.2.2.5 Phosphorus Donor Ligands

These compounds, of the general formulation $[MoP_6]$ (P = PMe_3, PH_2Ph or $P(OMe)_3$, or P_2 = dmpe or dppm), may be synthesized by displacement of CO from $[Mo(CO)_6]$ under forcing conditions (for dmpe);[34] by reaction of molybdenum vapour with the ligand (for PMe_3 and dmpe);[40] by reduction of a molybdenum complex, in presence of the ligand, with $AlEt_3$ (for dppm) or Mg (for PMe_3, PH_2Ph or $P(OMe)_3$];[19] or by displacement of N_2 from *trans*-$[Mo(N_2)_2(dppe)_2]$. These compounds are red or brown, octahedral and react readily with dioxygen in solution. The X-ray structures of $[Mo(PMe_3)_6]$ and $[Mo(dmpe)_3]$ confirm the essentially octahedral structures (there is disorder in the case of $[Mo(PMe_3)_6]$) with d(Mo–P) 2.467(2) Å (for PMe_3) and 2.421(3) Å (P_2 = dmpe).[40] $[Mo(PMe_3)_6]$ is particularly reactive; thus PMe_3 is displaced by N_2, CO and C_2H_4 to give $[Mo(N_2)(PMe_3)_5]$,[21] $[Mo(PMe_3)_3(CO)_3]$ and $[Mo(C_2H_4)_2(PMe_3)_4]$ respectively; H_2 adds to give $[MoH_4(PMe_3)_4]$ in which a PMe_3 group will oxidatively add a C—H bond to the metal and a variety of organometallic and oxidized compounds may be obtained.[40] In contrast to this high reactivity, $[Mo(dppe)_3]$ is very inert to substitution and $[Mo\{P(OMe)_3\}_6]$ is only substituted when photolyzed.[40] This difference is reflected in the relatively long Mo—P bond in $[Mo(PMe_3)_6]$ (see above) compared to that of $[Mo(dmpe)_3]$, presumably because of greater steric pressure in the former complex. The complex [Mo(triphos)(η^2-dppFe)(η^1-dppFe)] (dppFe = $Ph_2PC_5H_4FeC_5H_4PPh_2$) has also been prepared.[42]

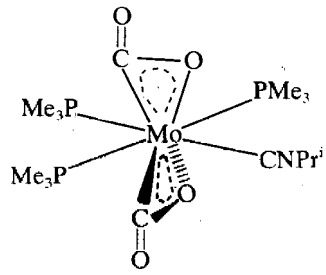


36.2.2.6 Miscellaneous Compounds

36.2.2.6.1 Complexes with dithiolene ligands

Compounds of the type $[Mo\{S_2C_2(CF_3)_2\}_3]^{n-}$ ($n = 0–2$) present a problem of assignment of oxidation state because ligands of this type may be regarded as having two limiting structures (**6**) and (**7**) in their complexes. Thus the oxidation state of complexes if the limiting form is (**7**) would be low, *i.e.* (0), (I) and (II) in the above series. However, a range of spectroscopic and other investigations indicate that these compounds have oxidation states at the higher range [*e.g.* the above series could be viewed as (VI), (V) and (IV)] and therefore they are not included in this survey; they have been reviewed elsewhere.[19]

(6)



(7)

36.2.2.6.2 Complexes of CO_2, COS and SO_2

Complexes of these ligands are included in this section, again because of an ambiguity of oxidation state. This is exemplified by the X-ray structure of $[Mo(CO_2)_2(PMe_3)_3(CNPr^i)]$ (**8**) where the CO_2 ligands are C—O bonded to the metal. For the purposes of this review, CO_2 is regarded as a neutral ligand, and its bonding in the above complex resembles that of C_2H_4 in the analogue $[Mo(C_2H_4)_2(PMe_3)_4]$.[43] Compound (**8**) was obtained by treatment with RNC (R = Me, Pr^i or Bu^t) of $[Mo(CO_2)_2(PMe_3)_4]$, which in turn is obtained by displacement of N_2 from $[Mo(N_2)_2(PMe_3)_4]$ by CO_2.[43] The analogue $[Mo(CO_2)_2(dppe)_2]$ is similarly prepared from *trans*-$[Mo(N_2)_2(dppe)_2]$, but treatment of this complex with MeNC evolves CO_2 to give *trans*-$[Mo(CNMe)_2(dppe)_2]$.[44] Reaction of COS with $[Mo(N_2)_2(PMe_3)_4]$ gives the complex

$[Mo(S_2CO)(CO)_2(PMe_3)_2]$. The disproportionation of CO_2 and COS to give carbonato species commonly occurs at Mo^0 centres.[43]

(8)

Several SO_2 complexes of molybdenum have been prepared which are assigned both the η^2-(S—O)— and η^1(S-bound)-bonding modes. Generally the metal coordination site has a mainly carbon environment and we give here only the examples *fac*-$[Mo(CO)_3(dmpe)(\eta^2\text{-}SO_2)]$; *mer*-$[Mo(CO)_3(dmpe)(\eta^1\text{-}SO_2)]$, *mer,trans*-$[Mo(CO)_3(PR_3)(\eta^1\text{-}SO_2)]$ and *trans*-$[Mo(CO)_2(dppe)(PR_3)(\eta^1\text{-}SO_2)]$ ($PR_3 = PMe_3$, PPh_2Me or PPr^i_3) and *fac*-$[Mo(CO)_3(MeCN)_2(\eta^2\text{-}SO_2)]$. They are generally prepared by displacement of a labile ligand, such as MeCN, from a precursor complex, *e.g.* $[Mo(CO)_3(MeCN)_3]$ by SO_2.[45]

36.2.3 MOLYBDENUM(I)

36.2.3.1 Carbon Ligands

36.2.3.1.1 Carbon monoxide

In this section we mention the paramagnetic monocationic complexes $[Mo(CO)_2(dppe)_2]^+$ and $[Mo(CO)_2(bipy)_2]^+$, both of which are produced by oxidation of the parent Mo^0 complexes. In the former case, the oxidants used include $[MeC_6H_4N_2][BF_4]$,[46] $NO[PF_6]$, I_2 and Ag^I [1a,47] and a variety of analogues $[Mo(CO)_2L_2]^+$ has been obtained (L_2 = dppm, dmpe, diars, *etc.*).[1a,47] Electrochemical oxidation has also been used, with other measurements, to show that a rapid *cis* → *trans* isomerization follows oxidation and an explanation for this phenomenon has been proposed on the basis of extended Hückel molecular orbital calculations, the stereochemical change being dependent on the number of valence electrons and the nature of the coligand π-donor or π-acceptor capacity. Similar studies have been made upon the compounds $[Mo(CO)_2L_2]^+$ (L = bipy or phen).[47]

36.2.3.1.2 Isocyanide ligands

The isocyanide analogues of the above carbonyls, *trans*-$[Mo(CNR)_2(dppe)_2]$ (R = alkyl or aryl) undergo a reversible one-electron oxidation in solution[4,5] and oxidation with I_2 or Ag^I salts allows isolation of the paramagnetic cation $[Mo(CNC_6H_4Me)_2(dppe)_2]^+$ ($\mu_{eff} = 2.01$ BM). With other isocyanides, substitution at the metal centre occurs on further oxidation.[48]

36.2.3.2 Dinitrogen Complexes

Oxidation of *trans*-$[Mo(N_2)_2(dppe)_2]$ with I_2 in methanol allows isolation of the unstable cationic complex *trans*-$[Mo(N_2)_2(dppe)_2]I_3$.[6] This cation has also been prepared electrochemically and the rate of its decomposition by loss of N_2 studied.[6] A range of dinitrogen complexes shows reversible one-electron oxidation in solution, but in general the monocations are too unstable to be isolated for molybdenum.[6]

Species of the type $[MoX(N_2)(dppe)_2]$ (X = Cl, Br or I) are thought to be intermediates in the alkylation reactions of coordinated dinitrogen in *trans*-$[Mo(N_2)_2(dppe)_2]$ and their isolation for X = Cl or Br has been claimed. The analogue $[MoCl(N_2)(PMe_3)_4]$ was also thought to exist but subsequent studies have indicated that the properties attributed to $[MoX(N_2)L_4]$ ($L = PMe_3$ or L_2 = dppe) can be reproduced by an equimolar mixture of $[MoX_2L_4]$ and $[Mo(N_2)_2L_4]$ and at

best it appears that $[MoX(N_2)L_4]$ very rapidly disproportionates in solution.[49] However, the analogue $[Mo(SCN)(N_2)(dppe)_2]$ is stable at room temperature.[50]

36.2.3.3 Nitrogen Monoxide Complexes

These complexes are collected in Table 4.

The pale green paramagnetic complexes $[MoCl_2(NO)L_2]$ (Table 4) result from reaction[31] of alkyl phosphines with the red solution obtained from $MoCl_5$ and NO in CH_2Cl_2. Treatment of $[MoCl_2(NO)(PMePh_2)_2(PMePh_2O)]$ with $[NEt_4]Cl$ gives[31] the green paramagnetic salt $[NEt_4][MoCl_3(NO)(PMePh_2)_2]$. Other complexes in this series are generally obtained by oxidation of the formally Mo^0 nitrosyl (Section 36.2.2.3) or reduction of the formally Mo^{II} nitrosyl (Section 36.2.4.2).

The compound $[Mo(NO)(NH_2O)(NCS)_2(phen)]$ on heating under reflux in acetophenone or on photolysis at 80 °C gives the five-coordinate, paramagnetic isomeric pair $[Mo(NCS)_2(NO)(phen)]$ (Table 4); a square pyramidal analogue $[Mo(NCS)_2(NO)(bipy)]$ was also obtained. In all compounds the NCS is N-bonded.[51]

The reaction of HNO_3 with $[Mo(Hacn)(CO)_3]$ (Hacn = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) gives the air- and water-stable complex cation $[Mo(CO)_2(NO)(Hacn)]^+$ which on bromination and reduction gives the paramagnetic complex $[MoBr_2(NO)(Hacn)]$

(Table 4). The complexes $[MoX_2(NO)(Hacn)]^+$ can be reduced electrochemically by one electron to give the formally Mo^I species in solution.[52] The complexes $[Mo(S_2CNR_2)_2(NO)(OPPh_3)]$ (R = Me or Et), obtained by treatment of $[Mo(S_2CNR_2)_2(CO)_2]$ with NO, are formulated solely on the basis of analysis and IR spectroscopy.[53] The compound $[Mo(ttp)(NO)(MeOH)]\cdot 2C_6H_6$ is obtained upon reduction of $[Mo(ttp)Cl_2]$ by zinc followed by chromatography on Al_2O_3 with CH_2Cl_2 containing traces of MeOH (ttp = *meso*-tetra-*p*-tolylporphinate). Its X-ray structure confirms octahedral coordination with NO *trans* to MeOH.[29]

Electrochemical reduction of $[Mo\{Me_2pzb\}NOI_2]$ (Me_2pzb = tris(3,5-dimethylpyrazolyl)-borate) gives the green, paramagnetic monoanion, which dissociates I^- to give the uncharged, green, paramagnetic $[Mo\{Me_2pzb\}NO]$.[54] A range of pyrazolylborate–Mo^{II} complexes can also be reduced electrochemically to give the Mo^I species in solution, *e.g.* the compounds $[Mo\{Me_2pzb\}XY(NO)]$ (X, Y = anions) and the bimetallic series $\{Mo\}NHRNH\{Mo\}$ ($\{Mo\} = Mo(Me_2pzb)I(NO)$; $R = C_6H_4R'C_6H_4$; $R' = CH_2$, C_2H_4, SO_2, O) and $\{Mo\}NHC_6H_4Y$ ($Y = NH_2$ or OH).[54]

The magenta, paramagnetic complex $[Mo\{Me_2pzb\}(NO)I_2Li(OEt)_2]$ was also isolated by reduction of $[Mo\{Me_2pzb\}I_2(NO)]$ in ether with LiPh.[54]

An alternative procedure for the production of Mo^I nitrosyl species is to oxidize Mo^0 complexes. Thus oxidation[33] (electrochemical, Ag^I, Fe^{III} or Cu^{II}) of the series *trans*-$[MoX(NO)(dppe)_2]$ (X = F, Cl, Br, I, OH, SPh, CN, H, NCO, NCS or N_3) gives the violet or brown, monocationic series $[MoX(NO)(dppe)_2]^+$.

The green-brown, monocation $[Mo\{Me_2pzb\}(NO)(MeCN)_2]^+$ is obtained by oxidation of the uncharged parent compound with Ag^I in MeCN[54] and the dications $[Mo(NO)(RCN)(dppe)_2]^{2+}$ are similarly obtained from the monocationic precursors[33] (Table 4). Treatment of $[Mo(CO)_6]$ with an excess of $NO[PF_6]$ in MeCN gives[55] $[Mo(NO)(MeCN)_5]^{2+}$.

The complex anions $[Mo(CN)_5(NO)]^{3-}$ and $[MoCl_4(NO)(OH_2)]^{2-}$ have been prepared by oxidation of $[Mo(CN)_5(NO)]^{4-}$ with air (in conc. HCl in the latter case) and have been structurally characterized as the expected octahedral complexes, with NO *trans* to H_2O in the dianion.[56] A compound formulated as $[Mo(NCS)_4(NO)]^{2-}$ has also been prepared[56] by treatment of $[MoO_4]^{2-}$ with NH_2OH in presence of SCN^-.

36.2.3.4 Nitrogen Donor Ligands

The one member of this class is the cation $[Mo(bipy)_3]^+$ obtained by reduction of $MoCl_5$ with Mg in THF in presence of bipy, or by oxidation of $[Mo(bipy)_3]$.[38]

36.2.3.5 Phosphorus Donor Ligands

The green, paramagnetic cation $[Mo(dmpe)_3]^+$ is obtained by oxidation of $[Mo(dmpe)_3]$ with iodine or methyl iodide in toluene.[57]

36.2.4 MOLYBDENUM(II)

36.2.4.1 Carbon Ligands

36.2.4.1.1 Carbon monoxide

Here in general we exclude compounds with more than two Mo—C bonds as discussed earlier.

(*i*) *Complexes of the type* $[MoX_2(CO)_2L_2]$ *and* $[MoX(CO)_2L_4]^+$

These complexes (in which X = anionic, L = uncharged ligand) form the largest class of Mo^{II} carbonyls and examples are shown in Table 5 with pertinent physical properties. We have excluded complexes of the type $[\{MoX_2(CO)_4\}_2]$, $[MoX(CO)_4L_2]^+$ and related compounds for the reasons cited earlier and for the same reasons $[MoX_3(CO)_4]^-$, $[MoX(CO)_3L_2]^-$ and related anions are excluded. They are reviewed in COMC.[1a] Complexes of the type $[MoX_2(CO)_2L_2]$

where L is not a carbon ligand are prepared generally by two main routes: oxidation and substitution of a zero-valent carbonyl derivative with halogen (method A), *e.g.* reaction (9);[1a,19] and reduction of a high-valent molybdenum compound in presence of CO and another ligand if necessary (method B), *e.g.* reaction (10).[1a,19] Simple displacement of CO by another ligand may also be used (method C), *e.g.* reaction (11).

$$[Mo(CO)_4(diars)] + I_2 \longrightarrow [MoI_2(CO)_2(diars)] + 2CO \quad (9)$$

$$[MoCl_4(PPh_3)_2] + AlEtCl_2 + CO + PPh_3 \longrightarrow [MoCl_2(CO)_3(PPh_3)_2] \quad (10)$$

$$[\{MoBr_2(CO)_4\}_2] + 2dpam \longrightarrow [MoBr_2(CO)_2(dpam)_2] + 2CO \quad (11)$$

The coordination number for these complexes may be six or seven and extensive X-ray structural studies have been carried out, particularly on the seven-coordinate complexes. The geometry and some other details of a representative selection of these compounds are shown in Table 5. In some cases, *e.g.* $[Mo(CO)_2Cl_2(dpam)_2]$, one potentially chelating ligand is

monodentate to maintain seven-coordination.[58] Sulfur coordination may also be introduced at the metal centre by use of displacement metathesis by *e.g.* the dithiocarbamato ligand, see reaction (12) (method D).[59]

$$\tfrac{1}{2}[\{MoCl_2(CO)_4\}_2] + 2Na[Me_2NCS_2] \longrightarrow [Mo(CO)_3(Me_2NCS_2)_2] \rightleftharpoons [Mo(CO)_2(Me_2NCS_2)_2] + CO \quad (12)$$

The reversible loss of CO from $[Mo(CO)_3(Me_2NCS_2)_2]$ is a property shown by other Mo^{II} carbonyls. For example, the complexes $[MoX_2(CO)_3(PR_3)_2]$ (X = Cl or Br) also lose one mole of CO reversibly to give blue, diamagnetic $[MoX_2(CO)_2(PR_3)_2]$, which (for X = Br) has been structurally characterized as a 'badly distorted octahedron'.[59,60] A common geometry for the seven-coordinate complexes is the capped octahedron, with a CO ligand in the capping position, although there are variations (Table 5), in particular $[MoCl(CO)_2(diars)_2]^+$ is a capped trigonal prism.[60]

A further series of dithiocarbamato complexes has been obtained from $[MoCl_2(CO)_2(PMe_3)_3]$ (obtained from $[MoCl_2(PMe_3)_4]$ and CO directly)[61] by treatment with $Na[S_2CNR_2]$. These are the dicarbonyls $[Mo(S_2CNR_2)_2(CO)_2(PMe_3)]$ and the monocarbonyls $[Mo(S_2CNR_2)_2(CO)(PMe_3)_2]$, the latter being obtained when a slight excess of PMe_3 is used in the reaction of $[MoCl_2(CO)_2(PMe_3)_3]$ with $Na[S_2CNR_2]$.[61] The analogues $[Mo(S_2CNEt_2)_2(CO)L_2]$ (L = PMe_2Ph or $PMePh_2$; L_2 = dppe) have also been synthesized.[62] These monocarbonyl compounds are notable for their very low value of ν(CO) (1760–1735 cm^{-1}) implying a very electron-rich metal centre in these complexes.[62] They transform readily into the dicarbonyl complexes with CO.

The structures of the $[Mo(SCNR_2)_2(CO)_2(PR_3)]$ series appear to be analogous to that determined for $[W(S_2CNEt_2)_2(CO)_2(PPh_3)]$, namely a tetragonal base (4:3 'piano stool') geometry.[61] As is often observed for dithiocarbamate complexes, the alkyl groups of the S_2CNR_2 ligands show ^1H NMR equivalence at room temperature. The fluxional process required for this does not appear to involve phosphine dissociation.[61] The series $[Mo(S_2CNEt_2)_2(CO)_2L]$ derived from $[Mo(S_2CNEt_2)(CO)_2]$ has been investigated by ^{95}Mo NMR spectroscopy. The resonance region (310 to −430 p.p.m. relative to $[MoO_4]^{2-}$) has shown that all the resonances are shielded relative to $[Mo(S_2CNEt_2)_2(CO)_2]$ (390 p.p.m.) and the dependence of nuclear shielding upon L is $NH_2NHSO_2C_6H_4Me < Cl^- < OPPh_3 < \mu$-pyrazine < py < $NH_2NHCOPh < NH_2NMe_2 < \mu$-$NH_2NHMe < \mu$-$NH_2NH_2 < \mu$-$NH_2CH_2CH_2NH_2 < NH_3 < N_3^- < F^- < AsPh_3 < PPh_3 < SbPh_3 < PPh_2Et < PPh_2Me < PMe_3 < P(OPh)_3 < P(OEt)_3 < P(OMe)_3 < CO$.[63] The $OPPh_3$, halide and nitrogen donor ligand adducts participate in a dynamic equilibrium with $[Mo(S_2CNEt_2)_2(CO)_2]$ on the NMR timescale. The chelating oxygen donor series $[Mo(B–B)Y(CO)_2L_2]$ (B–B = acac, hexafluoroacetylacetonate, tropolonate or carboxylate, L = PEt_3 or PPh_3, Y = halide or carboxylate) has also been prepared from $[MoY_2(CO)_2L_2]$ by metathesis.[64] The structure of one member of the series $[Mo(O_2CH)_2(CO)_2(PEt_3)_2]$ shows the formate ligand to engage in monodentate (η^1) and bidentate (η^2) bonding modes in the solid state. These bonding modes exchange very rapidly in solution.[64] The series $[\{Mo(S_2CNEt_2)_2(CO)_2\}(\mu - L)]$ (L = pyrazine, NH_2NHMe, NH_2NH_2 or $NH_2CH_2CH_2NH_2$) noted above were obtained by treatment of $[Mo(S_2CNR_2)_2(CO)_3]$ with the appropriate difunctional ligand.

The hydride complexes $[MoH(CO)_2(chel)_2]^+$ (chel = variety of chelating diphosphines and arsines) are prepared by protonation of the parent Mo^0 dicarbonyls and appear to have a monocapped octahedral structure in solution, with the fluxional hydride moving around the possible capping positions. This process has been extensively studied by NMR.[65] A number of other cationic seven-coordinate analogues $[MoX(CO)_2(chel)_2]^+$ (X = halide or pseudohalide; chel = chelating ligand usually phosphine or arsine) are also known (Table 5).[1a]

The complexes $[Mo(CO)_2(py)_2(OR)_2]$ (R = Pr^i or Bu^t) have been prepared by treatment of $[Mo_2(OR)_8]$ with CO in presence of pyridine and their octahedral structure established by X-ray diffraction;[66] they have low ν(CO) values (1906, 1768 cm^{-1}). The (μ-OR) dimers $[Mo_2(OR)_8(CO)_2]$ also have low ν(CO) values.[66] Because of steric pressure in the potentially seven-coordinate complexes, a chelating ligand may also act as a bridge, to form dinuclear complexes, *e.g.* $[Mo_2(CO)_4(dppm)_3Br_4]$.[67]

The anions $[Mo(S_2CNR_2)X(CO)_2]^-$ (R = Me or Et; X = F or N_3) are obtained by treatment of $[Mo(S_2CNR_2)(CO)_2]$ with X^-; the crystal structure of $[NEt_4][Mo(S_2CNR_2)F(CO)_2]$ shows the geometry at molybdenum to be a fluoride-capped trigonal prism, very similar to that seen

for $[MoF(CO)_2(dppe)_2][PF_6]$. Oxidation of $[Mo(CO)_2(chel)_2]$ (chel = bipy or phen) with Ag^+ in solution gives the dications $[Mo(CO)_2(chel)_2]^{2+}$ (Table 5).[68]

The zwitterion Et_3PCS_2 reacts with $[Mo(CO)_6]$ or $[Mo(C_7H_8)(CO)_3]$ to give $[\{Mo(CO)_2(PEt_3)(\mu\text{-}S_2CPEt_3)\}_2]$. X-Ray structural determination has shown that both zwitterions coordinate one metal through an η^3-S_2C linkage and the second metal through a single sulfur atom.[69]

The monocarbonyl complexes $[MoX(\eta^2\text{–}COR)(CO)(PMe_3)_3]$ (X = Cl, Br, I or NCO; R = Me, CH_2SiMe_3, CH_2CMe_3, CH_2CMe_2Ph) have been prepared by the action of the appropriate Grignard or lithium reagent with $[MoCl_2(CO)_2(PMe_3)_3]$ followed by metathesis. The ν(CO) values are low (in the region of 1800 cm^{-1}), and the η^2-aryl coordination has been confirmed by X-ray crystallography for $[MoCl(\eta^2\text{-}COCH_2SiMe_3)(CO)(PMe_3)_3]$. The analogue $[Mo(COMe)(S_2CNMe_2)(CO)(PMe_3)_2]$ attains an 18-electron configuration for molybdenum by a β-C—H interaction of the acetyl group (X-ray structure).[70]

36.2.4.1.2 Isocyanide ligands

The majority of complexes in this category have a high number of Mo—C bonds and they have been reviewed elsewhere.[1a,68] Typical examples are $[Mo(CNR)_6X]^+$ (X = Cl, Br, I, $SnCl_3$, or O_2CCF_3; R = aryl, Me, Bu^t or C_6H_{11}); $[Mo(CNR)_6(PR_3)]^{2+}$; $[Mo(CNR)_5X_2]$; $[Mo(CNR)_7]^{2+}$; $[Mo(CNR)_5(chel)]^{2+}$ (chel = dppm, dppe, bipy, *etc.*); $[MoCl(CNBu^t)_4(bipy)]^+$; $[Mo(CNC_6H_{11})_5(bipy)]^{2+}$; $[Mo(CNR)_3(bipy)_2]^{2+}$. They are generally prepared by displacement of CO, bipy, OAc, NO or other ligands from a suitable precursor by RNC and have capped octahedral or capped trigonal prismatic structures.[1a,70]

Protonation of the series $[Mo(CNR)_2(dppe)_2]$ (Section 36.2.2.1.2) gives the seven-coordinate hydrides $[MoH(CNR)_2(dppe)_2]^+$ which, like their carbonyl analogues (Section 36.2.4.1.1), are fluxional in solution with the hydride moving between face-capping sites in an octahedral structure.[71]

Oxidation of *trans*-$[Mo(CNR)_2(dppe)_2]$ with Ag^+ or halogen gives the cations $[Mo(CNR)_2(dppe)]^{2+}$ (R = Me or C_6H_4Me-4) and $[MoX(CNR)_2(dppe)_2]^+$ (X = Cl or Br).[72]

The alkyne complex $[MoI\{C(NHBu^t)\}_2(CNBu^t)_4]^+$ results from 'reductive coupling' upon reduction of $[MoI(CNBu^t)_6]^+$.[1a] The thiolate–isocyanide complex $[Mo(SBu^t)_2(CNBu^t)_4]$, prepared from $[Mo(SBu^t)_4]$ and $CNBu^t$, forms the adduct $[Mo(CNBu^t)_4(\mu\text{-}SBu^t)_2CuBr]$. All these compounds have been structurally characterized.[73]

Isocyanide acts as a reducing agent in the preparation of $[MoCl_2(CNMe)_2(N\text{—}N)]$ [N—N = $Me_2NCH_2CH_2NMe_2$, RN=CHCH=NR or R=NCMeCMe=NR (R = C_6H_4OMe-4)] from $[MoCl_3(THF)_3]$, MeCN and N–N.[74]

36.2.4.1.3 Cyanide ligands

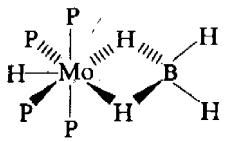
Cyanide complexes of molybdenum(II) generally appear elsewhere under other classifications, where CN^- is an ancilliary ligand. The homoleptic anions $[Mo(CN)_6]^{4-}$ and $[Mo(CN)_7]^{5-}$ (pentagonal bipyramid) have been reviewed elsewhere.[1a]

36.2.4.2 Complexes of Group 15 and Group 16 Ligands

36.2.2.4.1 Complexes of the type $[MoX_2L_4]$ (X = anionic ligand, L = monodentate uncharged ligand, L_2 = bidentate chelate ligand, L_3 = tridentate chelate ligand)

The largest group of this class are those of general formula $[MoX_2P_4]$ (where X = H, Cl, Br, I, SR, O_2R and P = PR_3, P_2 = chelating diphosphine, P_3 = chelating triphosphine). The main route to their preparation (method A) is by reduction of a higher-valent molybdenum compound under argon or dinitrogen in presence of the ligand. Thus the complexes *trans*-$[MoCl_2(PR_3)_4]$ (PR_3 = PMe_3 or PMe_2Ph) are obtained by reduction of $[MoCl_3(PR_3)_3]$ in presence of PR_3 with zinc or sodium amalgam (PMe_3), or LiR (PMe_2Ph, R = Bu or Ph).[61,75] Both compounds have their *trans* octahedral structures confirmed by X-rays and have similar structural parameters [d(Mo—Cl) = 2.420, d(Mo—P) = 2.496 Å].[75,49] The compounds are paramagnetic, with μ_{eff} values in the region of 2.8 BM. The analogue $[MoI_2(PMe_3)_4]$ has also been prepared by interaction of molybdenum vapour with PMe_3 and MeI.[40]

The analogues *trans*-$[MoX_2(dppe)_2]$ (X = Cl, Br or I) have been obtained by method (A) and their electrochemical reduction studied.[75] In the presence of ligands L (L = CO, N_2, RNC, H_2) the $[MoX_2(dppe)_2]$ compounds are reduced to give $[MoL_2(dppe)_2]$; detailed mechanistic studies are reported.[76] The structure of *trans*-$[MoCl_2(dppe)_2]$ has been confirmed as *trans* octahedral by X-rays and *cis*-$[MoCl_2(dppe)_2]$ was also structurally characterized as a very distorted octahedron.[77] The preparation of the latter compound was by oxidation of *trans*-$[Mo(N_2)_2(dppe)_2]$ using $SnCl_2Ph_2$ over a long period and the apparent distortion could be due to the presence of hydride ligands; HCl (from *e.g.* hydrolysis of $SnCl_2Ph_2$) is known[5] to produce $[MoH_2Cl_2(dppe)_2]$ from *trans*-$[Mo(N_2)_2(dppe)_2]$.[3] The compound $[MoCl_2(triphos)(PPh_3)]$ has been obtained by route (A) and reacts with HCl to produce $[MoCl_4(Ph_2PCH_2CH_2PPhCH_2CH_2PHPh_2)][HCl_2]$.[78]

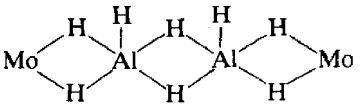


The arsine analogues of this series, $[MoX_2(diars)_2]$ (X = Cl, Br, I) have been obtained by the anaerobic reaction of acid molybdenum(III) halide solutions with diars in water and/or alcohol. They are paramagnetic (μ_{eff} 2.8–2.9 BM), with a possible d–d UV band at 11 000 cm^{-1} in $[MoCl_2(diars)_2]$.[74]

A number of molybdenum(II) compounds have been obtained by oxidation of *trans*-$[Mo(N_2)_2(chel)_2]$ (chel = chelating diphosphine). Thus treatment of *trans*-$[Mo(N_2)_2\{(S,S)$-chiraphos$\}_2]$ [(*S*,*S*)-chiraphos = (−)-(2*S*,3*S*)-bis(diphenylphosphino)butane, $Ph_2PCH(Me)CH(Me)PPh_2$] with bromooctane gives *inter alia*, a small amount of $[MoBr_2\{(S,S)$-chiraphos$\}_2]$.[80] Treatment of *trans*-$[Mo(N_2)_2(diphos)_2]$ (diphos = dppe or dmtpe) with RSH gives the diamagnetic compounds *trans*-$[Mo(SR)_2(diphos)_2]$ [R = Me, Et, Pr^n, Bu^n or C_6H_4X-4 (X = Me, H, NH_2, OMe, F or Cl)], the *trans* octahedral structure being confirmed by X-rays for R = Bu^n.[81] If bulky thiols R′SH (R′ = Pr^i, Bu^t, 2,4,6-$Me_3C_6H_2$, 2,4,6-$Pr^i_3C_6H_2$ or 4-Br-$C_6H_2Pr^i_2$-2,6) are used in this reaction, the green diamagnetic hydride complexes $[MoH(SR')(dppe)_2]$ are obtained. Hydride complexes of this type appear to be intermediates in the formation of *trans*-$[Mo(SR)_2(dppe)_2]$ described above. They have Mo—^{1}H chemical shifts in the range −4 to −5 p.p.m. (rel. $SiMe_4$).[82]

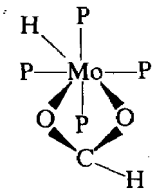
The diamagnetic dithiolate complexes *trans*-$[Mo(SR)_2(diphos)_2]$ are reversibly oxidized to the Mo^{III} species and the $E^{ox}_{1/2}$ values for R = C_6H_4X-4 (X = Me, H, NH_2, OMe, F, Cl) show a linear dependence upon the Hammett σ function for X, as do the ^{31}P chemical shifts of these compounds.[81]

The hydride compound *trans*-$[MoH_2(dppe)_2]$ was claimed from reaction of *trans*-$[Mo(N_2)_2(dppe)_2]$ with H_2, but some doubt exists about its formulation because its low solubility prevents accurate ^{1}H NMR integration.[83] Preparation of a more soluble analogue with $(2\text{-}MeC_6H_4)_2PCH_2CH_2P(C_6H_4Me\text{-}2)_2$ allowed accurate integration and demonstrated the presence of four hydrides per Mo. By analogy, the above dihydride is probably $[MoH_4(dppe)_2]$, although one could not exclude the existence of it and of $[\{$*trans*-$MoH_2(dppe)_2\}_2(\mu$-dppe)] which also appeared to be formed by reaction of *trans*-$[Mo(N_2)_2(dppe)_2]$ with H_2.[83]



A number of other hydride complexes have been prepared; the purple, diamagnetic hydride $[MoH(BH_4)(PMe_3)_4]$ has been obtained by reaction of $NaBH_4$ with $[MoCl_3(PMe_3)_3]$. The essentially *trans* octahedral structure of this molecule has been determined by X-rays as shown in (**9**); the hydride, the molybdenum and the boron atom of the bidentate BH_4 group lie precisely on the intersection of two mirror planes in the molecule.[86]

(**9**) P = PMe_3



In a related reaction, treatment of $[MoCl_2(PMe_3)_4]$ with $LiAlH_4$ gives the bridged hydride aluminohydride complex $[(Me_3P)_4HMo(\mu\text{-}H)_2AlH(\mu\text{-}H)_2AlH(\mu\text{-}H)_2MoH(PMe_3)_4]$, which has been shown by NMR to be non-rigid in solution. The central core of the structure is shown in (**10**).[85]

The carboxylato hydrides $[MoH(O_2CR)(PMe_3)_4]$ (R = H, Et or CF_3) are obtained by treatment of $[MoH_2(PMe_3)_5]$ (see Section 36.2.4.2.2) with CO_2 (R = H) or RCO_2H (R = Me or CF_3)[86] or by reaction of $[Mo(C_2H_4)_2(PMe_3)_4]$ with CO_2 followed by H_2 (R = Et).[87] The X-ray structure of $[MoH(O_2CH)(PMe_3)_4]$ is essentially pentagonal bipyramidal, with a chelating

(10)

formate *trans* to hydride (**11**). The interaction of $[MoH_2(PMe_3)_5]$ with PhNCO gives a moderate yield of the analogous, red complex $[MoH\{PhNC(H)O\}(PMe_3)_4]$, formally by the insertion of the isocyanate into the Mo—H bond.[86]

(**11**) P = PMe_3

The phosphite analogue, $[MoH(O_2CCF_3)\{P(OMe_3\}_4]$, is obtained by treatment of $[Mo\{P(OMe)_3\}_6]$ (see Section 36.2.2.5) with CF_3CO_2H; it has δ(MoH) at −4.6 p.p.m. (rel. $SiMe_4$). It has a similar solid-state structure to $[MoH(O_2CH)(PMe_3)_4]$, but is fluxional in solution with non-pairwise exchange of phosphorus-donor atoms being the dominant process.[88]

36.2.4.2.2 Complexes of the type $[MoH_2P_5]$ (P = tertiary phosphine or phosphite)

The reduction of $[MoCl_4(THF)_2]$ by magnesium in presence of PMe_3 in THF under dihydrogen gives a high yield of the yellow, air-sensitive hydride $[MoH_2(PMe_3)_5]$. Its crystal structure contains two crystallographically independent molecules which have essentially pentagonal bipyramidal goemetry, equal within the limits of experimental error. The Mo—P bond lengths vary in the structure. The axial Mo—P distances are very similar (2.424–2.428 Å) but one unique Mo—P(equatorial) bond in each molecule, which lies between two hydrogens, is some 0.6–0.7 Å shorter than the other two Mo—P(equatorial) bonds, probably because the long bond is almost *trans* to hydride.[89] The hydride resonance is a sextet at −5.23 p.p.m. (rel. $SiMe_4$) indicative of fluxionality at ambient temperature. $[MoH_2(PMe_3)_5]$ reacts with CO_2 and RCO_2H (R = Me or CF_3) to give the monohydrides $[MoH(CO_2CR)(PMe_3)_4]$ as described in Section 36.2.4.1.[86]

Photolysis of $[Mo\{P(OMe)_3\}_6]$ (Section 36.2.2.5) in presence of dihydrogen gives the off-white hydride $[MoH_2\{P(OMe)_3\}_5]$. The hydride resonance is indicative of fluxionality in solution [sextet at −5.8 p.p.m. (rel. $SiMe_4$)] down to −90 °C, and its structure is most likely a pentagonal bipyramid, analogous to that of $[MoH_2(PMe_3)_5]$ above. The analogous cation $[MoH\{P(OMe)_3\}_6]^+$, is obtained in low yield by treatment of $[Mo\{P(OMe)_3\}_6]$ with acids; the cation $[Mo\{P(OMe)_2\}\{P(OMe)_3\}_5]^+$ was also obtained by the same route. These products are not interconvertible and the isolation of the one or the other depends upon as yet undefined kinetic factors.[88]

36.2.4.2.3 Nitrosyl complexes

The largest group of molybdenum(II) complexes is constituted by the nitrosyls (oxidation states being assigned on the somewhat arbitrary assumption that nitrogen monoxide, as a ligand, is NO^+). Tables 6 and 7 give a selection of the compounds discussed.

The most important molybdenum nitrosyl, used in many studies as a starting material or as a catalyst, particularly for alkene metathesis, is $\{MoCl_3(NO)\}_n$.[89–91] It is produced[92] in a reasonably pure state by reaction of NOCl with $[Mo(CO)_4Cl_2]$, the chief contaminant probably being $\{MoCl_2(NO)_2\}_n$ or $K_4[Mo_2Cl_8]$.[93] The greenish-black hygroscopic, air-sensitive solid has ν(NO) at 1590 cm^{-1}. It reacts with acid species to eliminate chloride, for example with 1,2-$MeSC_6H_4SLi$ it generates $[Mo(NO)(SC_6H_4SMe)_3]$,[94] and forms adducts with neutral

Table 6 Nitrosyl Complexes of Molybdenum(II) (Excluding Pyrazolylborates)

Complex	$\nu(NO)$ (cm^{-1})
$\{Mo(NO)Cl_3\}_n$	1590 (Nujol);[1] 1739, 1851 (KBr)[2]
$[Mo(NO)(SC_6H_4SMe)_3]$	1655 (KBr)[3]
$[Mo(NO)Cl_3(OPPh_3)_2]$	1710 (Nujol),[1] 1705 (CH_2Cl_2),[2] 1710 (Nujol)[4]
$[Mo(NO)Cl_3(bipy)]$	1705 (Nujol),[1] 1706 (CH_2Cl_2)[2]
$[Mo(NO)Cl_3(MeCN)_2]$	1740 (KBr),[2] 1740 (Nujol)[4]
$[Mo(NO)Cl_3(py)_2]$	1707 (CH_2Cl_2)[2]
$[Mo(NO)Cl_3(HCONMe_2)_2]$	1713 (CH_2Cl_2)[2], 1712 (CH_2Cl_2)[4]
$[Mo(NO)Cl_3(OSMe_2)_2]$	1700 (CH_2Cl_2)[2], 1692 (CH_2Cl_2)[4]
$[Mo(NO)Cl_3\{OP(NMe_2)_3\}_2]$	1692 (CH_2Cl_2)[2]
$[Mo(NO)Cl_3(OPCl_3)_2]$	1725 (Nujol)[5]
$[Mo(NO)Cl_3(PPh_3)_2]$	1700 (CH_2Cl_2)[4]
$[Mo(NO)Cl_3(AsPh_3)_2]$	1720 (CH_2Cl_2)[4]
$[Mo(NO)Cl_3(OPMePh_2)_2]$	1695 (Nujol)[6]

donors, sometimes with oxidation. Thus Ph_3P and also $OPPh_3$ react to give $[MoCl_3(NO)(OPPh_3)_2]$,[92] and bipy reacts to generate $[MoCl_3(NO)(bipy)]$.[92] The former complex is also attainable from $[Mo(CO)_4(PPh_3)_2]$, or $[Mo(CO)_3(PPh_3)_3]$ with NOCl.[89]

An alternative synthesis of $\{MoCl_3(NO)\}_n$ (described as brown-black) is from $MoCl_5$ and NO. The temperature and reaction time need to be controlled to avoid further reductive nitrosylation to the green Mo^0 species $\{MoCl_2(NO)_2\}_n$. Addition of pyridine to such a reaction mixture yields $[MoCl_3(NO)py_2]$, and similarly $OPPh_3$ yields $[MoCl_3(NO)(OPPh_3)_2]$.[89] It is puzzling that the two sources for $\{MoCl_3(NO)\}_n$ quoted give different products with different IR spectra, yet the $OPPh_3$ complexes appear the same from either source, whereas the bipy complexes are different.

It is also pertinent that $MoCl_5$ and NO react in benzene rather than in dichloromethane to give a red solid. This is not $\{MoCl_3(NO)\}_n$, and may even be $[MoCl_5(NO)]$, and has ν(NO) at 2000 cm^{-1}.[31] However, it is a good source of nitrosyl complexes such as $[MoCl_5(NO)]^{2-}$.

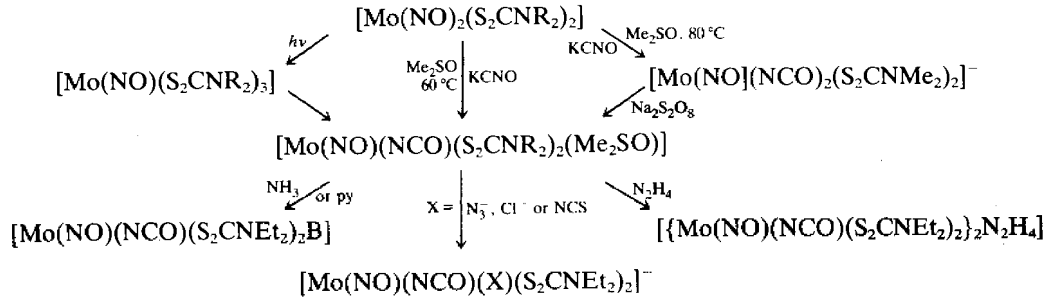
The complex $[Mo(NO)(SC_6H_4SMe)_3]$[94] is probably seven-coordinate, although its NMR spectrum in CD_2Cl_2 is more complex at 0 °C than one might expect. It reacts with nucleophiles, such as N_2H_4, PMe_3 and OH^-.[94]

The adducts of the general formula $[MoCl_3(NO)L_2]$ (see Table 6) are all probably obtainable by reaction of $\{MoCl_3(NO)\}_n$ with the neutral ligand, L.[89] However, reductive nitrosylation can be used directly. Thus, reaction of NOCl with $[Mo_2(O_2CMe)_4]$ followed by treatment with $OPPh_3$ gives $[MoCl_3(NO)(OPPh_3)_2]$ directly.[93] Alternative preparations have been reported.[95] Molybdenum(II) chloride and NOCl react in $POCl_3$ to yield $[MoCl_3(NO)(POCl_3)_2]$, which loses one $POCl_3$ in solution in CH_2Cl_2 to generate $[\{MoCl_3(NO)(POCl_3)\}_2]$.[96] The dinuclear species has chloro bridges, with chlorides in the axial positions and the $POCl_3$ molecules, NO ligands and remaining chlorides bound to give similar octahedral coordination about the molybdenum atoms, but all *trans* with respect to the pair of metal atoms. The MoNO system is approximately linear (178°), with Mo—N = 1.81 and N—O = 1.08 Å.[96] The mononuclear complex reacts with chloride to generate $[MoCl_4(NO)]^-$ and $[MoCl_5(NO)]^{2-}$.

All the complexes $[MoCl_3(NO)L_2]$ are presumably six-coordinate and octahedral. Clearly, this is not a limiting coordination number, since seven-coordination is allowed by electron-counting rules for molybdenum(II), and is observed among nitrosyls (*cf.* $[Mo(NO)(SC_6H_4SMe)_3]$). Specific examples based on this chloro system include $[MoCl_3(NO)(PMe_2Ph)_3]$ and $[\{MoCl_3(NO)\}_2(Ph_2PCH_2CH_2PPh_2)_3]$, prepared by variation of the routes discussed above.[31a]

Complete replacement of chloride to give complexes based upon $\{Mo(NO)X_3\}_n$ (X = CN,[97,98] N_3,[99] SR[100] or S_2CNR_2) has also been observed. For example, the compound $[Mo(CO)_3L]$ (L = 1,4,7-triazacyclononane) reacts with nitric acid to yield $[Mo(CO)_2(NO)L]^+$ which contains Mo^0, but inclusion of KCN in the reaction mixture causes formation of $[Mo(CN)_3(NO)L]$.[97] Probably all the nitrogens of the cyclononane are coordinated, making this complex seven-coordinate. Reaction of molybdate $[MoO_4]^{2-}$ at pH 8 in the presence of KCN and L (L = bipy or phen) with hydroxylamine can give rise to $[Mo(CN)_3(NO)L]\cdot H_2O$, though the precise products are a function of reaction conditions.[99] In an unusual reaction $[Mo(CO)_3(terpy)]$ and $MeSiN_3$ in nitromethane produce yellow $[Mo(NO)(N_3)_3(terpy)]$. This has a pentagonal bipyramidal structure with NO and a bent azide in axial positions. Mo—N is 1.777(4) and N—O 1.196(5) Å, and ∠MoNO is practically linear [176.2(4)°].[97]

The reaction of SR^- with $\{MoCl_3(NO)\}_n$ does not normally stop with $[Mo(NO)(SR)_3]$. Exceptions to this are $[Mo(NO)(SC_6H_4SMe)_3]$ cited above[94] and $[Mo(NO)(NH)(SC_6H_2Pr^i_3)_3]$, which has a thiolate ligand with exceptional steric requirements.[100] This is produced by reaction of $Pr^i_3C_6H_2S^-$ with 'Mo(NO)(NH_2O)'.[101] This is a genuinely five-coordinate, trigonal bipyramid with a thiolate in the trigonal plane and NO *trans* to NH_3. Again ∠MoNO is close to 180° [176.1(3)°] with Mo—N = 1.78(3) Å and N—O not reported. In contrast $Me_3C_6H_2S^-$ gives rise to $[Mo(NO)(SC_6H_2Me_3)_4]^-$,[100] Bu^tS^- produces $[MoCl(NO)(SBu^t)_3]^-$, and PhS^- yields $[Mo(NO)(SPh)_4]^-$.[102] The last complex has a trigonal bipyramidal structure (note that $[MoCl_4(NO)]^-$ is essentially square pyramidal), a linear NO occupying an axial position, Mo—N = 1.766(6), N—O = 1.188(8) Å and ∠MoNO = 178.5(5)°.[102] The steric influences at work are obvious, though not the precise way in which they operate.



We now discuss some compounds which may be formally considered to be based on $\{MoCl_3(NO)\}_n$, though they include a collection of miscellaneous species not easy to categorize. A complex described as $[Mo(NO)(acac)_2(hia)]$ [acac = 1,3-pentadionate, hia = hydroximinoacetylacetone (*sic*)] with ν(NO) at 1635 cm^{-1} (CH_2Cl_2) has been mentioned.[103] The complex $[LMo(CO)_3]$ (L = *N,N',N''*-trimethyltriazacyclononane) reacts with nitric acid to give $[LMo(CO)_2(NO)]^+$, and this with HBr gives rise to $[LMoBr_2(NO)]^+$, isolated as the hexafluorophosphate. The dichloride and diiodide were obtained similarly. The former reacts with ethanol to produce $[LMoCl(NO)(OEt)]^+$.[52,98] The electrochemistry of the species has been reported, and the structures and NMR spectra rationalized. Several of these complexes are present in two isomeric forms. A comparison is made between L and tris(pyrazolyl)borate as a ligand.[52] Finally, $\{MoCl_3(NO)\}_n$ reacts with the Schiff base H_2salen to give [Mo(NO)Cl(salen)], which has not been characterized in detail.[89,104] The reaction is probably general for Schiff bases. A range of complexes can be synthesized from [Mo(CO)$_4$(Schiff base)] and NO in benzene. They analyze for [Mo(NO)$_2$(NO$_2$)$_2$(Schiff base)] and may contain Mo^{II}. The values of ν(NO), two bands in the ranges 1770–1785 and 1650–1670 cm^{-1}, would be consistent with this.

The seven-coordinate complexes $[Mo(NO)(S_2CNR_2)_3]$ (R = Me, Et, Pr^n or Bu^n) were originally prepared from $\{MoCl_3(NO)\}_n$ and the appropriate $Na(S_2CNR_2)$,[105–107] although

irradiation of $[Mo(NO)_2(S_2CNR_2)_2]$ also leads to $[Mo(S_2CNR_2)_3]$.[107] They are volatile, and have NMR spectra consistent with the structures established by X-ray analysis.[108–110] The compound with R = Bu^n is pentagonal bipyramidal, with NO in the axial position, ∠MoNO = 173.2(07)°, Mo—N = 1.731(8) and N—O = 1.154(9) Å. A detailed discussion of the structure has been provided,[109] and the ^{95}Mo NMR spectra have been reported for the complexes with R = Me, and R = Et.[111] The structure of $[Mo(NO)(C_2O_4)_3]$ has been reported. It is similar.[112]

Compounds formally related to these are $[Mo(NO)(NCO)(S_2CNEt_2)_2X]^-$ (X = Cl, N_3, NCS or NCO), $[Mo(NO)(NCO)(S_2CNEt_2)_2B]$ (B = NH_3, Me_2SO or py) and $[\{Mo(NO)(NCO)(S_2CNEt_2)_2\}_2N_2H_4]$.[113,114] These are also all reckoned to be seven-coordinate species, with one of two possible structures admitted as likely on the basis of NMR and IR data. The general relationships are indicated in Scheme 1. These compounds are of interest in the context of nitrogen fixation, and the observation that the azido ligand in $[Mo(NO)(N_3)(S_2CNEt_2)_2(Me_2SO)]$ reacts with acid to give ammonia (*via* a nitrido complex) and N_2 is particularly interesting in view of the reduction of azide by nitrogenase. A reasonably comprehensive list of compounds is given in Table 6.

The dithiocarbamato complex $[Mo(NO)(S_2CNR_2)_3]$ has a homologue based upon NS rather than NO. The preparation (for R = Me) is not related to that of the nitrosyl, but is by reaction of propylene sulfide or S on $[MoN(S_2CNMe_2)_3]$.[115,116] However, its structure is very similar, pentagonal bipyramidal with NS in an axial position, and ∠MoNS = 172.0(7)°, Mo—N = 1.738(11) and N—S = 1.592(11) Å. These complexes are part of a series of approximately isostructural compounds $[MoX(S_2CNR_2)_3]$ (X = N, O, NS or NO).[117] Thionitrosyl compounds with $R_2 = Et_2$ or $(CH_2)_4$ have also been prepared. A band assignable to ν(NS) could not be identified in the IR spectra, though it is characteristically found in other complexes at *ca.* 1160 cm^{-1}.[116]

Scheme 1

The ^{95}Mo NMR spectra of $[Mo(NS)(S_2CNR_2)_3]$ (R = Me or Et) have been reported.[111]

The complex $\{MoCl_3(NO)\}_n$ is capable, formally, of adding chloride ions to form $[MoCl_4(NO)]^-$ and $[MoCl_5(NO)]^{2-}$. The six-coordinate species seems to crystallize as the cesium salt, and the five-coordinate as the tetraphenylphosphonium salt, from similar reaction mixtures which use $K_4[Mo(CN)_5(NO)]\cdot 2H_2O$ as the starting material.[118] There is an alternative route to the tetraphenylarsonium salts starting from $[MoCl_3(NO)(POCl_3)_2]$.[96] (The bromo analogues have also been reported.[118]) An alternative preparation from $MoCl_5$ + NO seems rather more easy to use.[31a] The complex $[Et_4N][MoCl_4(NO)]$ reacts with tertiary phosphine and phosphine oxides (L) to give adducts $[Et_4N][MoCl_4(NO)L]$ (see Table 6). The other adduct of $[MoCl_4(NO)]^-$ which has been described is $[MoCl_4(NO)(O_2PCl_2)]^{2-}$, obtained by reaction of $[AsPh_4](O_2PCl_2)$ with $[MoCl_4(NO)]^-$. This mildly air-sensitive complex has a roughly octahedral structure, with the O_2PCl_2 binding through one oxygen only, ∠MoNO being 176.8(10)°, Mo—N = 1.701(13) and N—O = 1.182(11) Å.[119] A hint that $[Mo(CN)_4(NO)]^-$ can be synthesized[118] has not been amplified.

The complex $[MoCl_5(NO)]^{2-}$ has had its structure determined as the tetraphenylarsonium salt. It has an octahedral structure, with ∠MoNO = 173.9(25)°, Mo—N = 1.751(32) and N—O = 112.0(38) Å.[96] It is apparently a rather inert complex, said not to be of much value for synthetic work.[31a] It can be prepared from $K_4[Mo(CN)_5(NO)]\cdot 2H_2O$,[118] $MoCl_5$ and NO,[31a] $\{MoCl_3(NO)\}_n$[89] or $[NEt_4][Mo_2Cl_9]$ and nitrosyl chloride.[93] Finally, the ion $[Mo(NO)(CN)_5]^{2-}$ has been prepared by the action of cyanide on the complex material obtained from the reaction of sodium molybdate with hydroxylammonium chloride.[99,101] Some interesting nitrosyls, formally of molybdenum(II), have been obtained using this complex. These contain protonated

nitrosyl as well as NO. Thus HCl reacts to give $[MoCl_4(NO)(H_2NO)]^{2-}$, and sodium azide produces $[Mo(NO)(H_2NO)(N_3)_4]^{2-}$.[101] The latter, as the tetraphenylphosphonium salt, has been shown to contain seven-coordinate molybdenum, with pentagonal bipyramidal coordination. The hydroxylamido(1 −) ligand is side-on, and the axial NO has ∠MoNO = 172.4(5)°, Mo—N = 1.761(8) and N—O = 1.21(1) Å.[101] The structure is very similar to that of $[Mo(NO)(H_2NO)(NCS)_4]^{2-}$,[120] and can be compared with $[Mo(NO)(H_2NO)_2(bipy)]^+$, which has two side-bonded hydroxylamido groups, $[Mo(NO)(H_2NO)(phen)_2]^{2+}$, which has one,[121] and $[Mo(NO)(H_2NO)(H_2O)(terpy)]^{2+}$, which also has one.[122] All these structures contain seven-coordinate pentagonal bipyramidal molybdenum, with linear, axial NO. The nitrosyl complexes containing hydroxylamine derivatives include $[Mo(NO)(H_2NO)(dipic)(L)]^{n-}$ (dipic = pyridine-2,6-dicarboxylate, $n = 0$ or 1, L = H_2O, CN, N_3 or SCN),[121] $[Mo(NO)(NH_2OH)(H_2NO)(terpy)]$,[121] $[Mo(NO)(H_2NO)(phen)_2]^{2+}$, $[Mo(NO)(H_2NO)_2(terpy)]^+$[121] and $[Mo(NO)(H_2NO)(pic_2]$ (pic = pyridine-2-carboxylate).[121]

The molybdate/hydroxylamine reaction which gives rise to the species which is the source of these materials is clearly complex, and its constitution depends upon the pH of its preparation. For example, reaction in water at pH 4–4.5 can give rise to $[Mo(NO)(H_2NO)(NCS)_4]^{2-}$, $[Mo(NO)(H_2NO)(NCS)_2L]$ (L = bipy or phen) and $[Mo(NO)(H_2NO)(S_2CNEt_2)_2]$.[123] At higher pH the products are similar, but formally Mo^I or Mo^0. Possibly hydroxylamine derivatives could also be used, to give, for example, $[Mo(NO)(Et_2CNO)(NCS)_4]^{2-}$[120] and $[Mo(NO)(Me_2CNO)(NCS)_4]^{2-}$[124] which have actually been synthesized from the H_2NO precursor and a ketone. The structure of the latter has been shown to contain side-on hydroxylaminate.[112,120] They again fit the usual pattern, with axial NO. However, MeHNOH and molybdate do not give rise to a homologue, but to $[MoO_2(MeHNO)_2]$,[121] so that the reactivity pattern seems to depend upon the particular hydroxylamine used.

The H_2NO^- ligand can be deprotonated to give HNO^{2-} complexes. Thus, $[Mo(NO)(H_2NO)(terpy)(H_2O)]^{2+}$ and CN^- yield a complex [Mo(NO)(HNO)(CN)-(terpy)].[122] The deprotonation is reversible and the proposed structure has been confirmed by X-ray analysis. In this case, too, the basic seven-coordinate pentagonal bipyramidal structure is observed, with NHO side-on, and NO axial, ∠MoNO = 178.0(7)°, Mo—N = 1.802(7) and N—O = 1.209(9) Å.[122]

Tris(pyrazolyl)borate has a formal resemblance to cyclopentadienide, in that it can behave as a six-electron donor and occupy three sites in a coordination sphere. Consequently, one might expect a similarity between complexes containing the Mo(pzb)(NO) group and those containing the Mo(Cp)(NO) group [pzb = tris(pyrazolyl)borate(1 −), cp = cyclopentadienide(1 −)]. This is indeed the case, and an extensive chemistry has developed for complexes of the types $[Mo(NO)(pzb)X_2]$ and [Mo(NO)(pzb)XY] (X and Y = anionic ligands). Much of this chemistry developed from an attempt to synthesize $[\{Mo(NO)(pzb)X_2\}_2]$, analogous to $[\{Mo(NO)(cp)X_2\}_2]$.[54] In this work, the differences between tris(pyrazolyl)borate and tris(3,5-dimethylpyrazolyl)borate (Me_2pzb) also became evident.

The compounds $[Mo(NO)(Me_2pzb)X_2]$ (listed in Table 7) are obtained by the general reaction of $[Mo(CO)_2(NO)(Me_2pzb)]$ with X_2. This is not always a straightforward reaction, and is sometimes accompanied by halogenation of the tris(pyrazolyl)borate. The Me_2pzb derivatives tend to be monomeric, whereas those based on pzb itself are dimeric.[125,126]

The dihalides react with alcohols leading to the formation of an enormous range of alkoxides and even aryloxides [Mo(NO)(Me_2pzb)X(OR)] as detailed in Table 7. The crystal structure of $[Mo(NO)(Me_2pzb)Cl(OPr^i)]$ has been determined,[125] and the molybdenum shows normal octahedral six-coordination, albeit with a very short Mo–O bond.

Reaction of [Mo(NO)(Me_2pzb)I(OR)] with silver acetate in the presence of the alcohol ROH leads to the bis(alkoxides) $[Mo(NO)(Me_2pzb)(OR)_2]$. The mixed alkoxides were similarly prepared.[126] The structures of several dialkoxides (Et, Pr^i; Pr^i, Pr^i; Et, Et) have been investigated in detail in view of the rather bulky character of the ligands at molybdenum.

The reaction of the dihalides with alcohols is paralleled by their reactions with other organic species containing acid hydrogens, such as phenols, amines and thiols. The resulting compounds are all detailed in Table 7. Representative structures include $[Mo(NO)(Me_2pzb)I(NHC_6H_4OMe)]$ and $[Mo(NO)(Me_2pzb)I(NHC_6H_4Me)]$[127] which are octahedral and very similar, with linear ∠MoNO systems [Mo—N = 1.754(11) and 1.78(2), N—O = 1.211(14) and 1.16(3) Å, respectively].[127] The thiolato complex $[Mo(NO)(Me_2pzb)I(SC_6H_{11})]$ is also distorted octahedral with a rather short Mo—S (2.31 Å); ∠MoNO = 176(3)°, Mo—N = 1.74(4) and N—O = 1.18(5) Å.[128]

The compounds with $NHNH_2$ are unusual and rare examples of hydrazide(1 −) as a ligand, and have end-on, rather than side-on, hydrazide coordination. The structures are otherwise as expected with ∠MoNO = 174(3) and 174.8(9)°, Mo—N = 1.70(3) and 1.80(2), and N—O = 1.24(4) and 1.17(3) Å for X, Y = I, NHNMePh and X, Y = I, $NHNMe_2$ in [Mo(NO)(Me_2pzb)XY], respectively.[129] So far, the rich hydrazine/hydrazide chemistry of the cyclopentadienide homologues[130] has not been reproduced.

The NO stretching frequencies quoted in Table 7 fall into classes as shown [Mo(NO)(Me_2pzb)XY]: X, Y = I, SR (mean 1679 ± 5) > SR, SR (1675) > I, NHR (1667) > SR, OR (1656) > OR, OR (1646) > SR, NHR (1635) > OR, NHR (1632) (all cm^{-1}), generally consistent with the donor capacities of X, Y.[128] For a discussion of the reactions of the cyclopentadienyl analogues of some of these pyrazolyborate complexes, see the references cited.[54,131]

Whereas these reactions of dihalides with proton-active compounds seem reasonably simple, [Mo(NO)(Me_2pzb)I_2] reacts with Me_2CO, MeEtCO or diacetone alcohol in complex fashion, affording some [Mo(NO)(Me_2pzb)I(OEt)] but also some [{Mo(NO)(Me_2pzb)I}$_2$O],[132,133] presumably *via* a reduced species such as the paramagnetic Mo(NO)(Me_2pzb)I.[133] The possible reaction course has been discussed, and it has been established that the dinuclear species has a slightly bent MoOMo system [171.0(15)°], with linear ∠MoNO (176(3)°, mean), Mo—N = 1.74(3) and N—O = 1.21(4) Å (mean values). The two molybdenum coordination shells are eclipsed with respect to each other.[133]

Less usual reactions of [Mo(NO)(Me_2pzb)I_2] are with 1,2-C_6H_4(XH)(YH) where X and Y bind replaceable (acid) protons. In general, only one group loses its proton, giving [Mo(NO)(Me_2pzb)(XC_6H_4YH)I] for X = N, Y = N; X = N, Y = O; X = N, Y = S and X = S, Y = S. Why this should be isn't clear. Even more, for X = O, Y = O, the product is [Mo(NO)(3,5-$Me_2C_5N_2H_3$)$_3$(OC_6H_4O)]I_3 in which the catechol is still monodentate though dianionic, and from which a proton has been lost. The mechanism is again unclear, though the structure is unequivocal.[134] The molybdenum is still six-coordinate, with ∠MoNO = 173.3(12)°, Mo—N = 1.771(13) and N—O = 1.188(18) Å.[134]

The Mo^{II} diiodide reacts with heterocyclic compounds to give [Mo(NO)(Me_2pzb)Z_2]$^+$ (Z = pyridine, *etc.*), and with sodium amides to give diamido species, as detailed in Table 7. The product containing pyrollidides has the usual octahedral structure with ∠MoNO approaching linear, and N—O = 1.163 Å.[135]

Although 1,2-C_6H_4(XH)(YH) (see above) do not form chelate or bridging (dinuclear) species, dinuclear species are formed if the groups XH and YH are far enough apart to enable the two centres to react with different metal ions quite independently. Thus 4-$H_2NC_6H_4CH_2C_6H_4NH_2$-4 forms [Mo(NO)I(Me_2pzb)($NHC_6H_4CH_2C_6H_4NH_2$)] and thence [{Mo(NO)(Me_2pzb)I}$_2$$NHC_6H_4CH_2C_6H_4NH$]. The species so formed, together with their reduction potentials, are reported in Table 8.[136] The two metal ions may be the same or different. Apart from those species listed in Table 8, [Mo(NO)(Me_2pzb)I-{$NHC_6H_4Pd(PPh_3)_2$I}] and [Mo(NO)(Me_2pzb)I{$NH(CH_2)_3PPh_2$}$_2$$HgI_2$] have also been mentioned.[136]

The electrochemical properties of these species have been studied, and it is apparent that there is no electrochemical influence of one metal atom upon the other if there are CH_2 groups in the bridge, However, if the bridge contains S, SO_2 or O, which allow transmission of electronic effects, two overlapping reduction waves are observed, suggesting some interaction. Finally, where the bridge is C_6H_4, the interaction is very strong. There is a linear correlation between $E_{1/2}$ and the Hammett σ *para* constants for compounds containing appropriate *para*-substituted groups.[136]

This study is part of a wider discussion of the electrochemistry of these Mo^{II} species.[137] In particular, [Mo(NO)(Me_2pzb)I_2] is reduced reversibly in a range of solvents, S, to generate [Mo(NO)(Me_2pzb)I(S)], in a one-electron process. The product is itself redox active. The $E_{1/2}$ value is +0.22 V (THF) whereas the corresponding dichloride is reversibly reduced at −0.09 V, under similar conditions. The reduction product is substantially more stable than [Mo(NO)(Me_2pzb)I_2]$^-$, and shows little sign of the production of free chloride. The only product isolated from the reduction of the diiodide is [Mo(NO)(Me_2pzb)I_2){$Li(OEt_2)_2$}].[137]

36.2.4.2.4 Diazenido complexes

The principal interest of diazenido complexes of molybdenum(II) is that they are formed by the alkylation or protonation of coordinated dinitrogen. They thus represent a unique group of

Table 8 Reduction Properties of Some Bimetallic and Monometallic Mo^{II} Species

[a] For one-electron process unless otherwise stated, *Mo* = Mo(NO)(Me_2pzb)I, *W* = W(NO)(Me_2pzb)I. See G. Denti, C. J. Jones, J. A. McCleverty, B. D. Neaves and S. J. Reynolds, *J. Chem. Soc., Chem. Commun.*, 1983, 474; and T. N. Briggs, C. J. Jones, J. A. McCleverty, B. D. Neaves, N. El Murr and H. M. Colquhoun, *J. Chem. Soc., Dalton Trans.*, 1985, 1249 for a complete discussion.

compounds, since well-defined species from the reactions of coordinated dinitrogen which contain dinitrogen hydride residues are uncommon. The general formula of the majority is $[Mo(N_2R)X(diphosphine)_2]$ (R = H or alkyl, X = halide, diphosphine usually dppe). They are listed in Table 9.

The base members of the series $[Mo(N_2H)X(dppe)_2]$ (X = F or Br) were obtained initially by treatment of $[Mo(N_2H_2)X(dppe)_2]^+$ (themselves obtained from reaction of $[Mo(N_2)_2(dppe)_2]$ with HX) with exactly one mole of NEt_3.[138] If an excess of base is used, reaction under N_2 regenerates the parent $[Mo(N_2)_2(dppe)_2]$. They react with acid, primarily to regenerate the hydrazide(2 −) complexes, and kinetic studies suggest that they are also formed as intermediates during the conversions of coordinated dinitrogen to hydrazide(2 −).[139]

$$Mo{-}N_2 \rightleftharpoons Mo{-}N_2H \rightleftharpoons Mo{-}N_2H_2 \qquad (13)$$

Their proton base strengths are less than that of the dinitrogen complex, but greater than that of the hydrazido(2 −) complexes.[139] Their structures are likely to be similar to those of the alkyldiazenido complexes discussed below, that is *trans* octahedral with a linear MoNN system and NNH ≈ 120°, but definite evidence is lacking.

The alkyldiazenido complexes $[MoX(N_2R)(dppe)_2]$ are generally synthesized by reaction of alkyl halides with $[Mo(N_2)_2(dppe)_2]$. The reaction mechanism has been elucidated in some detail,[140] and is believed to involve a step in common with substitution reactions of the bis(dinitrogen) species, namely rate-controlling reversible thermal loss of N_2 (equation 14). The full reaction sequence is set out in equation (15).

$$[Mo(N_2)_2(dppe)_2] \rightleftharpoons [Mo(N_2)(dppe)_2] + N_2 \qquad (14)$$

$$[Mo(N_2)_2(dppe)_2] \rightleftharpoons [Mo(N_2)(dppe)_2] \xrightarrow{RX} [Mo(N_2)(XR)(dppe)_2]$$

$$\longrightarrow [Mo(N_2)X(dppe)_2] + R\cdot \qquad (15)$$

The radical R· may then attack the solvent, as it does with THF, affording RH and a solvent radical. If R· is unreactive, it may eventually dimerize, yielding R_2 (*e.g.* for $R = PhCH_2$) and the principal complex product is $[MoX_2(dppe)_2)_2]$. If R· is unstable, then it can decay (*e.g.* $BrCH_2CH_2$· yields C_2H_4 and $[MoBr_2(dppe)_2]$). Finally, and in the most significant case, R· (or the solvent radical produced by it) can attack the remaining coordinated N_2 to produce $[Mo(N_2R)X(dppe)_2]$. The compounds obtained by this route are all listed in Table 9. In general, reactivity of alkyl halides falls in the sequence RI > RBr > RCl, but certain activated

chlorides form diazenido complexes although most simply give $[MoCl_2(dppe)_2]$.[140] This mechanism has received support from studies involving chiral phosphines.[80,141] The rarer acylation reactions are believed to follow the same pattern.[140] An alternative reaction route for electron-rich dinitrogen complexes, such as $[Mo(N_2)(SCN)(dppe)_2]^-$ giving $[Mo(N_2Bu^n)(SCN)(dppe)_2]$, has been described,[50] as has a rather restricted reaction sequence for $[Mo(N_2)_2(dppe)_2]$ and $(CF_3CO)_2O$ yielding $[Mo(N_2COCF_3)(O_2CCF_3)(dppe)_2]$. This is believed to involve non-radical nucleophilic reaction of the coordinated N_2.[143]

The general reactions of the compounds are much as expected. They react with strong reducing agents to give ammonia and amines, with complete destruction of the complexes.[143–147] The halides are labile and can be substituted.[144] The compounds react with acids to form alkylhydrazido complexes,[148] and with alkyl halides to form dialkylhydrazido(2 –) complexes, in reactions which are typical S_N2 reactions,[149] though electrophilic attack (*viz.* by Me^+) is also a possibility.[150]

The structures of some of these complexes have been determined. They all have a *trans* configuration, with octahedral coordination around the molybdenum, with a linear MoNN system, and ∠NNC *ca.* 120°. For $[MoI(N_2C_6H_{11})(dppe)_2]$, ∠MoNN = 176(1)°, ∠NNC = 142(2)°, Mo—N = 1.95(1) and N—N = 0.91(1) Å.[151] This last value is almost certainly an artefact of the poor quality of the crystals used, and a value of *ca.* 1.15 Å might be expected. In $[MoCl(N_2CO_2Et)(dppe)_2]$, ∠MoNN = 178.9(5)°, ∠NNC = 117.0(6)°, Mo—N = 1.732(5) and N—N = 1.382(10) Å.[152] The acyldiazenido complex $[MoCl(N_2COPh)(dppe)_2]$ has ∠MoNN = 172.1(6)°, ∠NNC = 116.7(7)°, Mo—N = 1.813(7) and N—N = 1.255(10) Å.[9,153]

XPS data on $[MoI(N_2Me)(dppe)_2]$ and $[MoI(N_2C_6H_{11})(dppe)_2]$ have been reported, and in the latter case suggest the presence of two types of nitrogen, as expected, but for the former the two nitrogens give rise to only one signal.[154,155] ^{15}N NMR spectroscopy has been carried out on $[MoBr(N_2Et)(dppe)_2]$.[156]

The other diazenido complexes of Mo^{II} are generally carbonyl species and almost all are phenyldiazenido complexes. None is obtained *via* coordinated dinitrogen.

The complex $[Mo(CO)_3(N_2C_6H_4F)(bipy)]BF_4$ was prepared by reaction of $(p\text{-}FC_6H_4N_2)(BF_4)$ with $[Mo(CO)_4(bipy)]$.[157] This is the only compound of the class characterized, although the preparative route is suggested to be quite general for aryldiazonium salts. The complex shows two IR bands assigned to ν(CO), which were used as a basis for ascribing a *fac* conformation to the carbonyls.[157] The presence of two IR bands associated with ν(N=N) was explained by mixing of N=N and phenyl-ring vibrations, which finds support from ^{15}N-labelling studies.[157]

Dicarbonyl complexes $[Mo(CO)_2(N_2Ar)(L\text{–}L)(PPh_3)]^+$ (L–L = phen or bipy, Ar = aryl) can be prepared by reaction of the tricarbonyls with PPh_3, but the preferred route appears to involve the reaction of $[Mo(CO)_3(L\text{–}L)(PPh_3)]$ with the appropriate diazonium salt at −78 °C. The compounds so prepared are listed in Table 9. No discussion of structure is provided. These dicarbonyls react with triphenylphosphineiminium salts to lose phosphine and generate another series of dicarbonyls. $[Mo(CO)_2(N_2Ar)X(L\text{–}L)]$ (X = Cl, Br or I). Again, no structural discussion is provided. Finally $[Mo(CO)_2(N_2Ar)(L\text{–}L)(PPh_3)]^+$ react with PPh_3 in acetone at reflux to yield $[Mo(CO)(N_2AR)(L\text{–}L)(PPh_3)_2]^+$. Preparations and characterizations of all these compounds are fully described.[157] The structures (not fully discussed) are presumably the same as those of their nitrosyl analogues (classified under Mo^0).

The last considerable group of diazenido complexes contain tris(pyrazolyl)borate as a ligand. The complexes $[Mo(CO)_2(N_2Ar)(pzb)]$ and $[Mo(CO)_2(N_2Ar)(pzpzb)]$ (pzpzb = $B(pz)_4$, where pz = pyrazolyl) were first obtained by the reaction of the appropriate tricarbonyl(pyrazolylborato)molybdenum(1 –) with a diazonium salt.[158] The values of ν(CO) follow the trends expected from the electronic properties of the pyrazolylborate and arenediazenide groups. Where appropriate, the ^{19}F NMR spectra were discussed, but no specific values of ν(N=N) were reported. These compounds are remarkably stable, and $[Mo(CO)_2(N_2Ph)(pzb)]$ is unaffected by hot 70% sulfuric acid.[158] However, halogens produce very stable $\{Mo(N_2Ph)(pzb)X\}_n$ (X = Cl, Br or I).[159] Later Raman studies, involving labelling with ^2H and/or ^{15}N enabled assignments of ν(N=N) to be made with more precision. The band assigned to ν(N=N), or predominantly to (N=N), occurs in the region of 1550 cm^{-1} and is strongly Raman active.[160]

The crystal structure of $[Mo(CO)_2(N_2Ph)(pzb)]$ shows the expected octahedral coordination around molybdenum, with a 'singly bent' ∠NNPh and Mo—N = 1.83 Å.[161]

The pyrazolylborate dicarbonyls react with PPh_3 in refluxing xylene to generate monocarbonyls $[Mo(CO)(N_2Ar)(pzb)(PPh_3)]$, and with $(4\text{-}MeC_6H_4S)_2$ to produce $[Mo(N_2Ar)(pzb)(SC_6HMe)_2]$.[162] They also undergo oxidative additions with NOCl in CH_2Cl_2,

to produce [Mo(Cl)(N_2Ph)(pzb)(NO)], for example.[163] The chloride seems inert to Grignard reagents and to halide abstractions.

36.2.4.3 Miscellaneous

The five compounds in this group are unrelated, and even open to question to some degree. Thus, reaction between $[MoO_4]^{2-}$ and H_2S in the presence of cyanide yields $[Mo_2S_2(CN)_8]^{6-}$ which has a double sulfide bridge[164] and hence is formally Mo^{III}. However, if there is significant S—S interaction, this could be formulated as Mo^{II}. In the presence of O_2, this plus $[Mo(CN)_7]^{5-}$ yields $[Mo_2S(CN)_{12}]^{6-}$, which has a single Mo—S—Mo bridging system, the first of its kind reported, with short Mo—S [2.172(5) Å] and a linear MoSMo[169.5(3)°].[164]

The reaction of $[MoCl_4(bipy)]$ with Me_3SiN_3 results in a mixture of $[MoN(N_3)(bipy)]$ (isolated and characterized by X-ray structural analysis) and an insoluble material which analyzes for $MoCl_2(N_2)(bipy)$, and possesses no IR bands assignable to ν(Mo≡N), $\nu(N_3)$ or $\delta(N_3)$ [nor, apparently, to $\nu(N_2)$]. It has $\mu_{eff} = 2.2$ BM. If confirmed, it would be the first stable Mo^{II} dinitrogen complex.[165]

Carbon dioxide reacts with $[Mo(N_2)_2(PMe_2Ph)_4]$ to produce not a carbon dioxide complex, but a carbonato–carbonyl, whose formation involves reductive disproportionation of CO_2 (equation 16). The structure of the Mo^{II} product $[\{Mo(CO)(PMe_2Ph)_3\}_2(\mu\text{-}CO_3)_2]$ has been determined by X-ray structure analysis.[166]

$$4CO_2 + 4e^- \longrightarrow 2CO_3^{2-} + 2CO \qquad (16)$$

Nitrobenzene reacts with $[Mo(CO)_2(S_2CNEt_2)_2]$ to yield $[Mo(ONPh)O(S_2CNEt_2)_2]$ which is reduced by PPh_3 giving $[Mo(ONPh)(S_2CNEt_2)_2]$ and $OPPh_3$. This is regarded as a η^2-nitrosodurene complex on the basis of NMR evidence. If PhNO is regarded as a neutral ligand, this material contains Mo^{II}. It does not isomerize to $[MoO(NPh)(S_2CNEt_2)_2]$, a known compound, either thermally or photolytically.[167]

The complex $[Mo(CO)_2(S_2CNEt_2)_2]$ also reacts with acetylenes, losing one CO, to be replaced by acetylene, and with diazenes, yielding $[Mo(RN_2R')(S_2CNEt_2)_2]$ and $[Mo(RN_2R')_2(S_2CNEt_2)_2]$ (R = R′ = CO_2Et). Both complexes hydrolyze to give $EtO_2CNHNHCO_2Et$.[169] There is, of course, an extensive organometallic chemistry, some of it of Mo^{II}, based on the $Mo(S_2CNEt_2)_2$ moiety. Only the little discussed above is appropriate to this chapter.

36.3.1 INTRODUCTION

Molybdenum displays a remarkable propensity to form metal–metal bonds, in all of its oxidation states—even Mo^{VI} if one allows the close (*ca.* 2.7 Å) approach of metal atoms in complexes of $[MoS_4]^{2-}$ (see Section 36.6.1) to be considered as a direct metal–metal interaction. As with other second row transition metals, this tendency to form metal–metal bonds can be rationalized in terms of the effective covalent overlap that can be achieved using the 4*d* orbitals, especially for the metal in its lower oxidation states. As a clear indication of this, the heat of formation[1] of atomic Mo(g) is 658 kJ mol^{-1}, the bond dissociation energy of Mo_2(g) is[2] 404 ± 20 kJ mol^{-1} and the Mo—Mo separation 1.93 Å.[3] The electronic structure of this molecule has been discussed in some detail and potential energy curves calculated.[4] Simple MO considerations lead to the conclusion that the maximum Mo—Mo bond order will occur in Mo_2, which could be considered to possess the configuration $\sigma_g(s)^2\sigma_g(d)^2\pi_u(d)^4\delta_g(d)^4$, corresponding to a sextuple bond; however, correlation effects mean that such a simple description is inappropriate. These effects are also important in molybdenum compounds which involve a close approach of two metal atoms and, hence, there has been vigorous discussion concerning the nature, strength and the interpretation of spectroscopic properties of complexes involving multiple Mo—Mo bonds.

The formal bond order for Mo—Mo interactions in compounds ranges from 4 to <1, with fractional bond orders being well established. The distance between a pair of Mo atoms, in compounds where a definitive and direct interaction between two Mo atoms seems plausible, ranges from 2.037(3) Å in $[Mo(pyNC(O)Me)_4]$[5] to 3.267(6) Å in the guaiazulene (G) complex $[GMo_2(CO)_6]$.[6] Although the former is considered to involve a quadruple bond and the latter a single bond (perhaps lengthened by steric effects), the length of an Mo—Mo bond gives a general, rather than a precise, indication of the bond order. Discrete systems involving Mo—Mo bonds range from Mo_2 dimers, through Mo_3 and Mo_4 to Mo_6 clusters and

molybdenum also displays considerable versatility in forming metal–metal bonds with other *d* transition metal atoms.

The preparation and properties of compounds containing metal–metal bonds, in which molybdenum features prominently or exclusively, have been the subject of several recent and authoritative reviews.[7–10] The following sections will, therefore, concentrate on the salient aspects of the coordination chemistry of these systems and the reader is referred to these reviews for further information.

36.3.2 DIMETALLIC COMPLEXES

36.3.2.1 Complexes Containing a Quadruple Metal–Metal Bond

36.3.2.1.1 Synthesis and structure

Aspects of this topic are included in Section 36.1.2. Complexes based on the Mo_2^{4+} centre presently constitute the largest group of compounds known to contain a quadruple bond (see Table 1). The ligation sites of this centre are illustrated by the structure of $[Mo_2(O_2CMe)_2(MeCN)_6][BF_4]_2$[11] (Figure 1). Each metal atom binds one axial and four equatorial ligands. There is a strong preference for an eclipsed arrangement of the two sets of equatorial ligands, even when there are no bridging ligands, *e.g.* $[Mo_2Cl_8]^{4-}$.[12] The length of the Mo—N_{eq} and Mo—N_{ax} bonds (2.148(4) and 2.759(19) Å, respectively) of $[Mo_2(O_2CMe)_2(MeCN)_6]^{2+}$ provide clear evidence of the static *trans* effect of an Mo—Mo quadruple bond and many Mo_2^{4+} complexes do not involve axial ligands.

$Mo_2(O_2CR)_4$ compounds are the most important systems containing an Mo—Mo quadruple bond because, traditionally, they have been the starting point for the synthesis of other Mo_2^{4+} derivatives. The popular preparative procedure is that developed by Wilkinson *et al.*;[13] $[Mo(CO)_6]$ is heated with the carboxylic acid and (if available) the anhydride, either without an additional solvent or dissolved in diglyme. Generally, the derivatives of mono-[13–15] and di-carboxylic[16] acids can be obtained by carboxylate exchange from $[Mo_2(O_2CMe)_4]$, excepting $[Mo_2(O_2CH)_4]$ which is obtained by reacting $[Mo(\eta^6\text{-PhMe})(\eta^3\text{-}C_3H_5)Cl]_2$ with anhydrous NaO_2CH in EtOH, followed by treatment with HCO_2H,[17] or by reacting $K_4[Mo_2Cl_8]\cdot 2H_2O$ with 90% formic acid and recrystallization of the resultant $K[Mo_2(O_2CH)_4Cl]$ from 90% formic acid.[18] Substitution of $K_4[Mo_2Cl_8]$ by glycine[19] or by DL-amino acids in aqueous solution has been used to prepare Mo_2^{4+} dimers in which four chiral ligands are arranged around the dimetallic centre in the cyclic order of DDLL.[20] The reaction of an aqueous solution of Mo_2^{4+} with D-mandelic acid, to form $[Mo_4(\text{D-mandelate})_4]$,[21] provides a further example of the synthetic routes to $[Mo_2(O_2CR)_4]$ compounds.

Many $[Mo_2(O_2CR)_4]$ compounds have been characterized by X-ray crystallography.[18–28] Although in $[Mo_2(O_2Cbiph)_4]$ (HO_2Cbiph = 2-phenylbenzoic acid) the bulky ligands prevent axial ligation, the general observation is that $[Mo_2(O_2CR)_4]$ compounds crystallize with the molecules linked in infinite chains formed by axial coordination of each molecule by the oxygen atoms of its neighbours. In the case of $[Mo_2(O_2CH)_4]$, three different intermolecular arrangements have been identified.[18] Alternatively, axial ligation may be provided by functional groups on the ligands, as established for $[Mo_2(O_2CC_6H_4OH)_4]$ (Figure 2),[28] or by a wide variety of ligands including halides, H_2O, DMSO, THF, diglyme, phosphine oxides, py, bipy, phosphines or arsines.[18–43] In all of these systems, the basic stereochemistry of the Mo_2^{4+} centre remains essentially as shown in Figure 1 and the length of the Mo—Mo quadruple bond (*ca.* 2.1 Å; Table 1) is insensitive to the nature of the carboxylate. There is, at most, a slight (*ca.* 0.01 Å) lengthening of this bond upon axial coordination and the absence of any significant effect is clearly demonstrated by comparison of the dimensions of $[Mo_2(O_2CCF_3)_4]$ in the gas phase[44] and solid state,[23] for which the Mo—Mo separations are 2.105(9) and 2.090(4) Å, respectively. In the case of $[Mo_2(O_2CMe)_4]$, the corresponding values are 2.079(3)[45] and 2.093(1) Å.[22]

Several reactions have been reported which involve the partial displacement of the carboxylate ligands of an $[Mo_2(O_2CR)_4]$ compound and a wide range of products have been characterized. Simple reactions include halide substitution; thus, $[Mo_2(O_2CMe)_4]$ reacts with dilute HCl to form $[Mo_2(O_2CCMe)_2Cl_4]^{2-}$ [46] and $[Mo_2(O_2CCF_3)_4]$ reacts with $[NBu_4]Br$ to form $[Mo_2(O_2CCF_3)_2Br_4]^{2-}$ [30] and both of these anions have a *trans* arrangement of the carboxylate groups. In contrast, $[Mo_2(O_2CMe)_2(acac)_2]$[46] and $[Mo_2(O_2CH(NH_3)R)_2(NCS)_4]\cdot nH_2O$ (R = H,

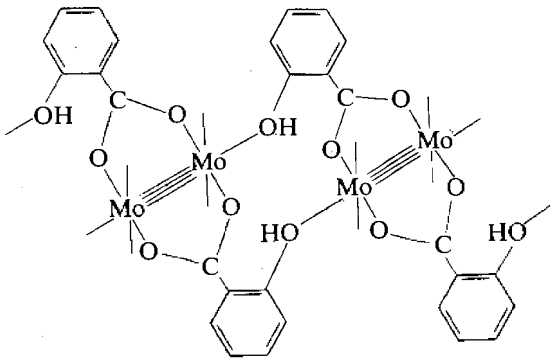

Figure 2 Molecular arrangement in $[Mo_2(O_2CC_6H_4OH)_4]\cdot C_6H_4Cl_2$-1,2[36]

$n = 1$; R = CH(Me)Et, $n = 4.5$)[47] involve a *cis* arrangement of the bridging carboxylato groups. Apart from the steric constraints imposed by the chelating ligands in the above and other[11,48–56] di-μ-carboxylato complexes, the factors which determine a *cis* or *trans* arrangement of the carboxylato ligands remain obscure. Further subtleties in the detailed coordination geometry of Mo_2^{4+} centres are revealed in the products of the reaction between $[Mo_2(O_2CR)_4]$ (R = Me or CMe_3) and lithium silylamides [$LiN(SiMe_3)_2$, $LiN(SiMe_2H)_2$ or $LiN(SiMe_3)(Me)$] in the presence of tertiary phosphines (PMe_3, PMe_2Ph or PEt_3). Complexes of the type $[Mo_2(O_2CMe)_2(NR'_2)_2(PR''_3)_2]$ are formed and their stereochemistry has been probed by NMR and IR spectroscopy. The stereochemistry of these complexes is independent of the carboxylate or phosphine but dependent upon the nature of the silylamide. For $R' = SiMe_2H$ the phosphines and silylamide groups are oriented *trans*, relative to the metal–metal bond. In contrast, for $R' = SiMe_3$ or $R'_2 = (SiMe_3)(Me)$, the phosphine and silylamide groups are *trans* to each other on the same metal atom.[57]

Loss of carboxylate ligands from $[Mo_2(O_2CR)_4]$ compounds can be assisted by protic or Lewis acids. Thus, $[Mo_2(O_2CCF_3)_4]$ and bipy react in the presence of $[Et_3O][BF_4]$ to produce $[Mo_2(O_2CCF_3)_2(bipy)_2][BF_4]_2\cdot Et_2O$.[58] Also, replacement of two of the acetato groups of $[Mo_2(O_2CMe)_4]$ is readily achieved by reaction with strong acids;[11,59,60] thus, with $[Me_3O][BF_4]$ (*ca.* 1:4 mol ratio) in MeCN, $[Mo_2(O_2CMe)_2(MeCN)_6][BF_4]_2$ (Figure 1) is produced.[11] $[Mo_2(O_2CMe)_4]$ reacts with the zwitterion S_2CPEt_3 in the presence of $H[BF_4]$ to yield $[Mo_2(S_2CPEt_3)(O_2CMe)_3(OPEt_3)][BF_4]$.[61] As an example of an alternative means of removing carboxylate groups from an Mo_2^{4+} centre, treatment of $[Mo_2(O_2CCF_3)_4]$ in toluene with Me_3SiCl and EtCN at low temperature affords $[Mo_2(O_2CCF_3)_2(EtCN)_2Cl_2]\cdot[Mo_2(O_2CCF_3)_3(EtCN)Cl]$.[55]

The above examples of the partial substitution of an $[Mo_2(O_2CR)_4]$ molecule serve to demonstrate the considerable scope and variation that exists for the substituted derivatives of Mo_2^{4+}. This versatility is greatly increased by two other major factors; firstly, the large number of bidentate ligands capable[7] of bridging the metal atoms of the Mo_2^{4+} cation (Figure 3) and, secondly, the facile substitution reactions of $[Mo_2X_8]^{4-}$ (X = Cl, Br, NCS),[7] $[Mo_2(O_3SR)_4]$ (R = Me, CF_3),[62] $[Mo_2(MeCN)_8]^{4+}$ [63] or $Mo_{2(aq)}^{4+}$[64] (see Section 36.1.2).

Mo_2^{4+} complexes can also be prepared by the reduction of molybdenum complexes in a higher oxidation state. Reduction of Mo^{VI} in HCl to form $[MoCl_6]^{3-}$, condensation of this anion to produce $[Mo_2Cl_9]^{3-}$, and quantitative reduction of the latter by a Jones reductor provides a convenient, if little exploited, route to Mo_2^{4+} complexes.[65] Furthermore, in principle, an Mo—Mo quadruple bond can be formed by reductive elimination from a compound containing an Mo—Mo triple bond. This potential has been realized for $[Mo_2R_2(NMe_2)_4]$ (R = an alkyl containing a β-hydrogen atom) upon reaction with CO_2 or 1,3-diaryltriazines, according to equations (1) and (2), respectively.[66]

$$[Mo_2R_2(NMe_2)_4] + CO_2 \longrightarrow [Mo_2(O_2CNMe_2)_4] + \text{alkene} + \text{alkane} \quad (1)$$

$$[Mo_2R_2(NMe_2)_4] + 4ArNNNHAr \longrightarrow [Mo_2(ArNNNAr)_4] + 4HNMe_2 + \text{alkene} + \text{alkane} \quad (2)$$

Table 1 illustrates the range of compounds known to contain an Mo—Mo quadruple bond and more comprehensive compilations have been provided.[7,9] This wide range of compounds manifests a variation in the length of the Mo—Mo quadruple bond (from 2.037(3)[5] to 2.302(2) Å[80]) and provides a specific reinforcement of the point that there is not a direct correlation between the length and (formal) bond order of a metal–metal bond.

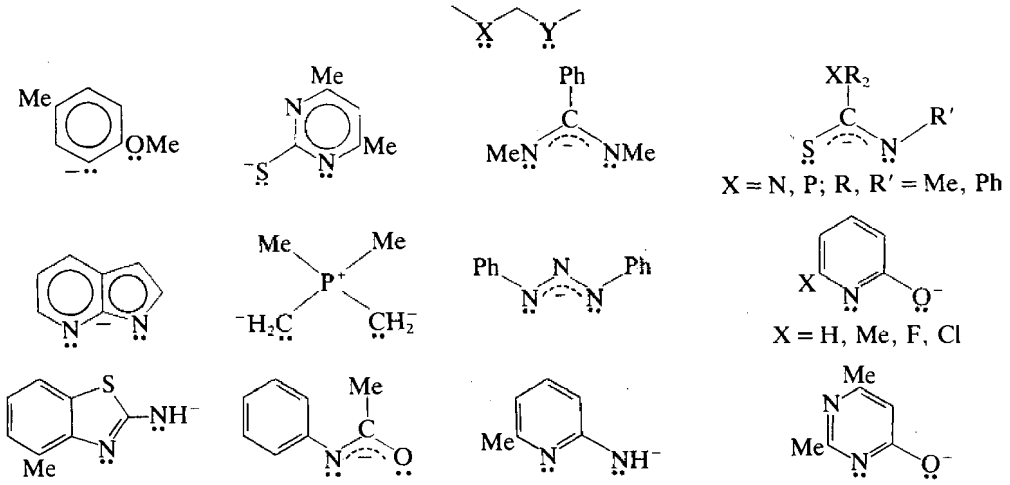

Figure 3 Examples of ligands capable of bridging the metal atoms of a Mo_2^{4+} centre[7]

As represented by the material covered so far in this review, much of the early investigations of Mo_2^{4+} systems involved μ-carboxylato ligands. However, there are a large number of other ligands capable of bridging a dimetal centre (Figure 3) and this is encouraged if: (i) the ligand is bidentate; (ii) the preferred, or only, conformation is such that the donor orbitals of X and Y are parallel; (iii) the distance between X and Y is in the range 2.0–2.5 Å.[7] These criteria are met by a large number of oxyanions, of which sulfate,[77] arsenate,[78] methylsulfonate, trifluoromethylsulfonate,[62] carbamate[66] and, of course, carboxylates have been established as binding to Mo_2^{4+}. Relatives of the carboxylates, with S or RN in place of one or both oxygen atoms, also form Mo_2^{4+} complexes[7,75,76] but perhaps the most important innovation in this area was the introduction of aromatic ligands capable of bridging across a dimetal centre *via* the carbon or nitrogen of the aromatic ring and another donor atom (usually oxygen or nitrogen) of a substituent in the 2-position. The most important sub-group of this latter class of ligands are the anions of the 2-hydroxypyridines, 2-HOC_6H_4-6-X (X = H, Hhp; X = Me, mhp; X = Cl, chp; X = F, fhp). It was with mhp that the first complete series of stable Group VI M_2^{4+} complexes was obtained.[69] Also, ligands of this type have permitted the properties of heteronuclear CrMo and MoW quadruple bonds to be determined.[92,93] These ligands, and their relatives (Figure 3), have a profound effect on the extent of axial ligation because of the location of the X groups (see Figure 4). This figure also shows the normal pattern of these unsymmetrical bridging ligands, *i.e.* the arrangement of the eight donor atoms of the square antiprismatic $\{Mo_2X_4Y_4\}$ central skeleton has D_{2d} symmetry. However, systems have been recognized in which a less symmetrical pattern of ligation occurs and one such example is $[Mo_2(fhp)_4]\cdot THF$, in which the four fhp ligands are all oriented in the same direction. Thus, one metal atom is coordinated entirely by nitrogen atoms and the other entirely by oxygen atoms; a THF molecule is axially coordinated to the latter, sterically unhindered, molybdenum atom.[94]

Reactions between Mo_2^{4+} centres and thiocarboxylates ($RCOS^-$),[95,96] dithiocarboxylates (RCS_2^-),[75,95,97] xanthates ($ROCS_2^-$),[96-98] thioxanthates ($RSCS_2^-$),[97] dithiophosphinates ($R_2PS_2^-$)[76,96,97] and dithiocarbamates ($R_2CNS_2^-$)[99,100] generally lead to products in which the S donor ligands are bridged across the dimetal centre. However, unusual behaviour has been observed and a notable example of this is the isolation of the green dimers '$Mo_2(S_2CNR_2)_2$' (R = Et, Pr^i), which are constituted as $[Mo_2S_2(\mu\text{-}S_2CNR_2)_2(SCNR_2)_2]$ with the bidentate thiocarboxamide ($SCNR_2$) ligands being formed by sulfur abstraction from dithiocarbamate groups.[99] Stoichiometric reactions of $K_4[Mo_2Cl_8]$ with $M(S_2PR_2)$ (M = K, Na; R = Et, Ph) in aqueous MeOH yield the corresponding green dimer $[Mo_2(S_2PR_2)_4]$. The structure of the complex with R = Et has been determined and shown to contain two bridging and two chelating ligands. Recrystallization of the compound from THF leads to a novel isomerization and a crystal structure has shown that $[Mo_2(S_2PEt_2)_4]\cdot 2THF$ possesses the usual quadruply bridged D_{4h} structure with a single axial THF ligand.[76] One of the products of reaction of $[Mo_2(O_2CMe)_4]$ with $[(pz)_2BEt_2]^-$, $[Mo_2\{(pz)_2BEt_2\}_4]$, is unusual in containing four chelating ligands coordinated to the Mo_2^{4+} core.[101] Similarly, unbridged Mo_2^{4+} centres in which each metal is coordinated to a porphyrin have been characterized.[102] Reaction of $Li(PBu_2^t)$ with $[Mo_2(O_2CMe)_4]$ (1:4) in

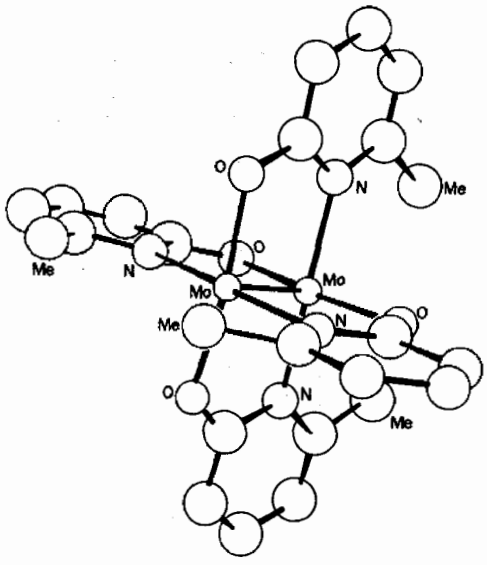

Figure 4 Structure of the $[Mo_2(mhp)_4]$ (Hmhp = 2-hydroxy-6-methylpyridine) molecule[69]

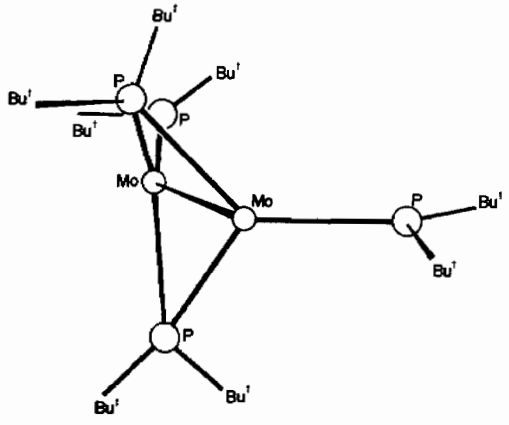

Figure 5 Structure of $[Mo_2(PBu^t_2)_2]$[74]

Et_2O at −78 °C gives $[Mo_2(PBu^t_2)_4]$. The molecule (Figure 5) possesses a central Mo_2P_2 butterfly and a terminal phosphide on each molybdenum completes a planar MoP_3 arrangement about each metal centre.[74]

$[Mo_2(C_3H_5)_4]$ ($C_3H_5 = \eta^3$-allyl) exists in solution as a mixture of two isomers. Each isomer has two inequivalent allyl groups which are mutually *trans* and bridge the Mo—Mo quadruple bond; the other allyl groups are each bonded to one metal. In the major (90%) isomer, these latter two allyls are *cis*, and in the minor isomer they are *trans*. At >80 °C, ^{1}H NMR studies showed that interconversion takes place *via* exchange of the *anti* protons of the non-bridging allyl group of the major isomer with the *anti* protons of the non-bridging allyl group of the minor isomer.[103] The crystal structure of $[Mo_2(C_3H_5)_4]$[79] is in agreement with the structural predictions made for the major isomer. This compound, and more especially $[Mo_2(C_8H_8)_3]$ (C_8H_8 = cyclooctatetraene),[80] involve longer Mo—Mo separations than normal (2.183(2) and 2.302(2) Å, respectively) but the reasons for this have not been established.

The conversion of $[Mo_2(O_2CMe)_4]$ to $K_4[Mo_2Cl_8]\cdot 2H_2O$[12] stimulated the synthesis of related anions,[7] including the centrosymmetric species $[Mo_2Br_8]^{4-}$ [82] and $[Mo_2X_6(H_2O)_2]^{2-}$ (X = Cl,[83] Br, I[104]). Two routes have been developed for the synthesis of $[Mo_2(NCS)_8]^{4-}$; the reaction of $[NH_4][NCS]$ with $[Mo_2(O_2CMe)_4]$[105] or with $K_4[Mo_2Cl_8]$.[88] The latter produces a mixture of the tetra- and hexa-hydrates of $[NH_4]_4[Mo_2(NCS)_8]$, both of which possess an anion with the expected eclipsed D_{4h} symmetry and approximately linear MoNCS groups.

Partially substituted derivatives of $[MoX_8]^{4-}$ (X = Cl, Br, NCS) abound[7] and, of these, the most interesting group are the neutral $[Mo_2X_4(PP)_2]$ (X = Cl, Br; PP = bidentate phosphine).[106]

These systems adopt two types of structure; one, designated α, has two chelating diphosphines and the other, designated β, has two bridging phosphines (Figure 6).[107] When the bidentate ligand possesses one carbon atom linking the phosphorus atoms, *e.g.* $Ph_2PCH_2PPh_2$, only the β isomer is formed with an eclipsed conformation about the Mo—Mo bond. With other, less rigid, bis(phosphines) both α and β isomers are obtained[108] and, for $R_2P(CH_2)_2PR_2$ systems, the former spontaneously isomerizes to the latter with first-order kinetics.[109] The α isomers have an essentially eclipsed conformation, but the β isomers display a variety of angles of internal rotation. The strength of the δ component of a quadruple metal–metal bond depends inversely on the angle of rotation (θ) away from the eclipsed conformation according to $\cos 2\theta$, *i.e.* the maximum overlap is achieved for $\theta = 0$ and zero overlap for $\theta = 45°$. A correlation between the Mo—Mo bond length and $\cos 2\theta$ has been defined and complete loss of the δ bond is associated with an increase of 0.097 Å in the bond length.[110]

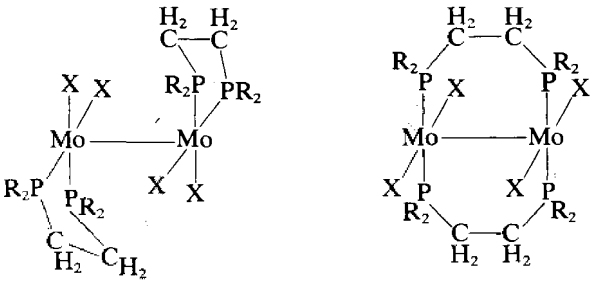

Figure 6 Arrangement of ligands in isomers of $[Mo_2X_4(PP)_2]$ (X = Cl, Br; (PP) = bidentate phosphine)

The alkoxides $[Mo_2(OR)_4L_4]$ (R = Pr^i, Bu^tCH_2; L = py, PMe_3, Pr^iOH, $HNMe_2$) have been prepared and subjected to structural scrutiny. The systems for L = py, PMe_3 involve a long (*ca.* 2.2 Å) Mo—Mo quadruple bond but the introduction of hydrogen bonds to the RO ligands (L = Pr^iOH, $HNMe_2$) causes a shortening of the Mo—Mo distance and a lengthening of the Mo—OR distance. These variations are considered to reflect the influence of the RO π donors on the Mo_2^{4+} centre. Thus, filled oxygen π orbitals interact with vacant Mo—Mo π^* and δ^* MOs, thereby weakening the bond and hydrogen bonding to the RO ligands reduces their π donating ability.[87]

Alkyl and aryl derivatives of Mo_2^{4+} centres are well known. The neatest example, $[Mo_2Me_8]^{4-}$, has been isolated as $Li_4[Mo_2Me_8]\cdot 4THF$ following the reaction of LiMe in Et_2O with $[Mo_2(O_2CMe)_4]$[89] or $[MoCl_3(THF)_3]$.[111] This anion adopts the usual eclipsed Mo_2L_8 structure and is a very reactive species and reaction with $[PMe_4]Cl$ provides a useful route to $[Mo_2\{(CH_2)_2PMe_2\}_4]$.[81,112] Several compounds involving alkyl groups and other ligands bonded to an Mo_2^{4+} centre are known, including: $[Mo_2R_4(PMe_3)_4]$ (R = Me,[90] CH_2CMe_3[113]), $[Mo_2(O_2CMe)_2(CH_2SiMe_3)_2(PMe_3)_2]$ and $[Mo_2(CH_2SiMe_3)_2\{(CH_2)_2SiMe_2\}(PMe_3)_3]$.[52,114] Also, $[Mo_2(O_2CMe)R_3(PMe_3)_3]$ (R = Ph, 4-FC_6H_4) have been prepared by the reaction of $[Mo_2(O_2CMe)_4]$ and MgR_2 in Et_2O containing an excess of PMe_3.[115]

The hydrido-bridged dimer, $[(Me_3P)_3HMo(\mu\text{-}H)_2MoH(PMe_3)_3]$, has been synthesized by reacting $[Mo_2(O_2CMe)_4]$ with Na/Hg in THF containing an excess of PMe_3 under H_2 (3 atm). This compound is pyrophoric and reacts rapidly with a variety of small molecules.[91]

The chemistry of the heteronuclear quadruple bonded species $CrMo^{4+}$ and MoW^{4+} is severely restricted, as compared to that of Mo_2^{4+}. $[CrMo(O_2CMe)_4]$ may be obtained by the slow addition of $[Mo(CO)_6]$ in $MeCO_2H/(MeCO)_2O/CH_2Cl_2$ to $[Cr_2(O_2CMe)_4(H_2O)_2]$ in refluxing $MeCO_2H/(MeCO)_2O$.[116] Synthesis of $[MoW(O_2CCMe_3)_4]$ can be achieved by refluxing $[Mo(CO)_6]$ and $[W(CO)_6]$ with pivalic acid in 1,2-dichlorobenzene. Recrystallization, followed by selective oxidation of the heteronuclear dimer by I_2 produces the insoluble $[MoW(O_2CCMe_3)_4]I$ and reduction of this precipitate by stirring with Zn in MeCN yields pure $[MoW(O_2CMe_3)_4]$.[117] These heteronuclear derivatives adopt the expected structure but the Cr—Mo and Mo—W distances (2.050(1) Å and 2.080(1) Å, respectively) are each shorter than the Mo—Mo quadruple bond in the corresponding $[Mo_2(O_2CR)_4]$ compound. $[MoW(mhp)_4]$ (Hmhp = 2-hydroxy-6-methylpyridine) has been prepared by refluxing a mixture of $[Mo(CO)_6]$ and $[W(CO)_6]$ with Hmhp in diglyme/heptane and small amounts of impure $[CrMo(mhp)_4]$ can be obtained in an analogous manner.[92] The Mo—W distance in $[MoW(mhp)_4]$ (2.091(1) Å) is intermediate between the corresponding Mo—Mo and W—W separations. The first examples of an unbridged heteronuclear quadruple metal–metal bond, $[MoWCl_4L_4]$ (L_4 = $(PMePh_2)_4$,

$(PMe_3)_2(PMePh_2)_2)$, were prepared by reacting $[Mo(\eta^6\text{-}PhPMePh)(PMePh_2)_3]$ in benzene with $[WCl_4(PPh_3)_2]$ suspended in benzene under N_2. This produces the former derivative which may be converted to the latter by reaction with PMe_3.[118]

36.3.2.1.2 Properties of Mo—Mo quadruple bonds

The high metal–metal bond order and short intermetallic distances in Mo_2^{4+} complexes, and the general observation that a wide range of ligand substitution reactions proceed without affecting this entity, imply the existence of a strong Mo—Mo bond. Various estimates of the bond strength have been advanced, including 480–550 kJ mol^{-1} for $[Mo_2X_8]^{4-}$ (X = Cl, Br) on the basis of a Birge–Sponer extrapolation of the frequencies observed in the ν(Mo—Mo) vibrational progressions.[119] However, thermochemical measurements for $[Mo_2(O_2CMe)_4]$ and $[Mo_2(O_2CMe)_2(acac)_2]$, together with assumptions about the transferability of bond enthalpy contributions, have led to the suggestion that D(Mo—Mo) = 334 kJ mol^{-1} in these molecules.[120] This value seems reasonable, especially with reference to D(Mo—Mo) for Mo_2(g) of 404 ± 20 kJ mol^{-1}.[2] Variable temperature ^{1}H NMR studies of *meso*-substituted porphyrin derivatives of Mo_2^{4+} have shown that the activation energy for rotation about the Mo—Mo bond is 42 ± 2 kJ mol^{-1}.[102]

The electronic structure of the Mo—Mo quadruple bond has been the subject of several investigations, especially by relating the theoretical interpretation[121–123] to the results of PES studies on $[Mo_2(O_2CR)_4]$,[17,124] $[Mo_2(mhp)_4]$,[92,93,125] $[Mo_2Cl_4(PMe_3)_4]$[126] and related molecules. There is general agreement about the essential nature of the ground state of the quadruple bond, $\sigma^2\pi^4\delta^2$, and that the first ionization occurs from the δ orbital and the second ionization, some 1.3 to 2.2 eV to higher energy, involves the π electrons. The position of the σ ionization has been controversial[7,92,93,124–126] but, especially due to the clarification provided by the PE spectrum of $[W_2(O_2CCF_3)_4]$,[127] there is now agreement[123,128] that the σ and π ionizations of Mo_2^{4+} compounds occur within the same[125] band envelope of the PE spectrum. The gas-phase core-electron ionization energies of $[Mo_2L_4]$ (L = O_2CH, O_2CMe, mhp) have been reported[129] and the carbon 1*s* spectrum shows an intense satellite peak close to the main 1*s* line which is assigned to a $\delta \rightarrow C2p_\pi$ transition of the core hole ion.

The ν(Mo—Mo) stretching frequency of Mo_2^{4+} complexes has been an important aspect of their spectroscopic characterization.[7] This vibration occurs in the range 336–425 cm^{-1}, with the unbridged species generally exhibiting a lower frequency than tetrabridged complexes (*e.g.* $K_4[Mo_2Cl_8]$[130] = 345 cm^{-1} and $[Mo_2(O_2CMe)_4]$[38] = 406 cm^{-1}); given the symmetry of these compounds, this mode is invariably IR inactive and Raman active. In the case of $[Mo_2(O_2CMe)_4]$, isotopic labelling has shown that this mode primarily involves the isolated ν(Mo—Mo) vibration.[131] Resonance Raman spectroscopy has been used to good effect for a selection of these compounds; in the case of $[Mo_2Cl_8]^{4-}$, 514.5 nm excitation produces a beautiful vibrational progression of ν_1(Mo—Mo), up to and including $11\nu_1$.[130] Such spectra allow an estimate of the dissociation limit of the Mo—Mo bond[119] and provide a useful confirmation of the assignment of the lowest energy absorption in the electronic absorption spectrum.

The lowest energy electronic absorption arises due to the $\delta \rightarrow \delta^*$ transition.[7] Polarized single crystal data, recorded for $K_4[Mo_2(SO_4)_4]\cdot 2H_2O$, are consistent with the $\delta \rightarrow \delta^*$ ($^1A_{1g} \rightarrow {}^1A_{2u}$) assignment; thus, the lowest energy transition (centred at *ca.* 525 nm) is *z* polarized and has an intensity which is temperature independent.[132] However, this particular $\delta \rightarrow \delta^*$ transition is unusual in showing no vibrational structure. The corresponding feature of the electronic spectrum of $K_4[Mo_2Cl_8]\cdot 2H_2O$ (also centred at *ca.* 525 cm^{-1}) displays vibronic coupling with ν(Mo—Mo) at low temperature and, as expected, the ν(Mo—Mo) vibration in the first electronic excited state is lower (by some 30 cm^{-1}) than in the ground state.[133] The assignment of the electronic absorption spectra of $[Mo_2(O_2CR)_4]$ compounds has been controversial. However, definitive studies[18,134] have established that the first observed electronic transition, with highly resolved vibrational structure, is due to a weak but electric dipole allowed $^1A_{1g} \rightarrow {}^1A_{2u}$ promotion. The relationship between the energy of the $\delta \rightarrow \delta^*$ promotion and the torsional twist about the Mo—Mo bond has been discussed for β-$[Mo_2X_4(PP)_2]$ (X = Cl, Br; PP = bidentate phosphine) complexes;[135] the CD spectra of these systems have been reported[136] and the principles established have led to the prediction[137] of a bridged structure for $[Mo_2(en)_4]^{4+}$. The emission spectra of $[Mo_2Cl_4(PMe_3)_4]$, β-$[Mo_2Cl_4(Me_2PCH_2CH_2PMe_2)_2]$, and

several other Mo_2^{4+} complexes have been reported and the energy of the triplet $\delta\delta^*$ state determined.[138]

^1H and, especially for phosphine complexes, ^{31}P NMR spectroscopy have proved a useful means of characterizing Mo_2^{4+} complexes and assigning their stereochemistry. The diamagnetic anisotropy induced by Mo—Mo quadruple bonds has been discussed with special reference to the ^{31}P NMR spectra of $[Mo_2Cl_4(PR_3)_4]$ complexes.[139]

Several Mo_2^{4+} complexes have been investigated by ^{95}Mo NMR spectroscopy.[140] The resonances are broad ($\nu_{\frac{1}{2}} = 320$–1440 Hz) and the chemical shifts (2900 to 4200 p.p.m. relative to $[MoO_4]^{2-}$ at 0 p.p.m.) correspond to the lowest observed shielding of the ^{95}Mo nucleus; this is consistent with the extent of ^{95}Mo shielding decreasing steadily with an increase in Mo—Mo bond order.

36.3.2.1.3 Reactions of compounds containing an Mo—Mo quadruple bond

Several aspects of this topic are covered in Section 36.1.2 and this should be consulted for further information.

Ligand substitution reactions of Mo_2^{4+} centres have been investigated in some detail (Section 36.1.2) and evidence for a *trans* effect is seen in the phosphine exchange of $[Mo_2(O_2CBu^t)_2R_2(PMe_2Et)_2]$ (R = *e.g.* CH_2CMe_3, CH_2SiMe_3, $OSiMe_3$) complexes.[141] $[Mo_2Cl_8]^{4-}$ has been shown to act as a template for the self-condensation of 2-aminobenzaldehyde[142] and $[Mo_2O_2CCF_3)_4]$ observed to catalyze the anti-Markovnikov addition of CF_3CO_2H to propylene in benzene at 50 °C with a selectivity of >90%.[143]

Redox reactions of Mo_2^{4+} complexes are of interest, not least because the simple processes can involve changes in the population of the Mo—Mo orbitals and, therefore, a change in bond order.[7,144] $[Mo_2(O_2CR)_4]$ complexes are capable of undergoing one-electron reduction[145] or oxidation[146] and this latter aspect has been employed to good effect in the preparation of $[Mo_2(O_2CR)_4]I_3$ (R = Et, Bu^t, Ph), by I_2 oxidation. These paramagnetic complexes (μ = 1.66 BM for R = Bu^t) all display a sharp ESR signal and possess Mo—Mo bonds of order 3.5 with a $\sigma^2\pi^4\delta^1$ ground state. This description of the electronic structure of the Mo—Mo interaction is also appropriate to $[Mo_2(OC_6H_3\text{-}3,5\text{-}Me_2)_2(PMe_3)_4]^+$, prepared by one-electron electrochemical oxidation of its neutral parent; the ESR spectrum of this cation shows that the unpaired electron is delocalized and coupled to all four phosphorus nuclei.[147] $[Mo_2(SO_4)_4]^{3-}$ also involves a $\sigma^2\pi^4\delta^1$ ground state; this anion may be prepared by aerial oxidation of $K_4[Mo_2(SO_4)_4]$ in 2 M H_2SO_4,[148] UV irradiation of $K_4[Mo_2(SO_4)_4]$ in 5 M H_2SO_4,[149] or by H_2O_2 oxidation of $K_4[Mo_2Cl_8]$ in 2 M H_2SO_4 containing KCl.[150] Electrochemical studies of $K_4[Mo_2Cl_8]$[151] and $[Mo_2X_4L_4]$ (X = Cl, Br, NCS; L = PMe_3, PEt_3, PPr^n_3, $\frac{1}{2}$dppe, $\frac{1}{2}$dppm) have identified a one-electron oxidation process for all complexes, but reduction appears to be confined to $[Mo_2Cl_4(PMe_3)_4]$[147] and the phosphine–isothiocyanate complexes.[152]

$[Mo_4Cl_4L_4]$ (L = PEt_3, PPr^n_3, $\frac{1}{2}$dppe) undergo oxidation in refluxing CH_2Cl_2/CCl_4 to produce a phosphonium salt of $[Mo_2Cl_9]^{3-}$[153] and, for monodentate phosphines, photochemical oxidation also appears to produce a compound with an Mo—Mo triple bond.[154] The most definitive studies of the conversion of an Mo—Mo quadruple bond to a triple bond are reactions of $[Mo_2(O_2CMe)_4]$ with HX (X = Cl, Br). This may be considered to occur in two stages; the initial process produces $[Mo_2X_8]^{4-}$ with retention of the quadruple bond but, at 60 °C, oxidative addition[155] of HX across the Mo—Mo bond occurs. The final product, $[Mo_2X_8H]^{3-}$, has a confacial (μ-H,X,X) bioctahedral structure[156] analogous to that of $[Mo_2Cl_9]^{3-}$ (Section 36.3.2.2). The corresponding iodo complex has been prepared by reacting $[Mo_2(O_2CMe)_4]$ and $[NEt_4]I$ in aqueous HI.[157] $[Mo_2Cl_4(RSCH_2CH_2SR)_2]$ (R = Et, Bu^n) reacts slowly in CH_2Cl_2 to form the corresponding $[Mo_2Cl_6(RSCH_2CH_2SR)_2]$ compound with an Mo—Mo triple bond;[158] this type of bond is also present in $[Mo_2Et(OPr^i)_5]$, formed when $[Mo_2(OPr^i)_4(Pr^iOH)_4]$ reacts with $HNMe_2$ in the presence of ethylene[87] and in $[Mo_2(HYO_4)_4]^{2-}$ (Y = P,[159] As[160]) obtained by O_2 oxidation of $[Mo_2Cl_8]^{4-}$ in H_3PO_4 or $[Mo_2(O_2CMe)_4]$ in H_3AsO_4, respectively. A reduction in metal–metal bond order can occur upon dimerization of compounds containing Mo—Mo quadruple bonds to form tetramers in which alternating triple and single Mo—Mo bonds occur (Section 36.3.2.3.2).

Reactions in which an Mo—Mo quadruple bond has been converted into a single bond include the following oxidations: $[Mo_2(S_2COEt)_4]$ by X_2 (X = Br, I) (forming $[Mo_2X_2(S_2COEt)_4]$);[161] $[Mo_2Cl_8]^{4-}$ by EtSSEt in the presence of $EtSCH_2CH_2SEt$ (dto) (forming $[Mo_2Cl_4(\mu\text{-}SEt)_2(dto)_2]$), and β-$[Mo_2Cl_4(dmpe)_2]$ (dmpe = bis(dimethylphosphino)ethane) by

EtSSEt (forming $[Mo_2Cl_4(\mu\text{-}SEt)_2(dmpe)_2]$).[162] Cleavage of Mo—Mo quadruple bonds has provided a useful synthetic route to several mononuclear compounds[7] and, of special significance, are the reactions of alkyl and aryl isocyanides with Mo_2^{4+} compounds.[163]

36.3.2.2 Complexes Containing a Triple Metal–Metal Bond

36.3.2.2.1 Synthesis and structure of $[Mo_2L_6]$ ($L = CH_2SiMe_3$, NMe_2, OR) molecules

These compounds are the parents of the most important class of complexes containing an Mo—Mo triple bond; not only do they exhibit a rich coordination chemistry, but also a versatile reactivity.[7,8,10,164] Many of the compounds of this class have been characterized by X-ray crystallography and a selection of these is presented in Table 2, together with their Mo—Mo separation. The chemistry of these systems has been developed in parallel to that of their tungsten analogues and the latter has helped illuminate the former.

Table 2 Examples of Complexes Containing an Mo—Mo Triple Bond

Complex	*Mo—Mo bond length* (Å)	*Ref.*
$[Mo_2(CH_2SiMe_3)_6]$	2.167	165
$[Mo_2(NMe_2)_6]$	2.214(2)	169
$[Mo_2(O_2CH_2CMe_3)_6]$	2.222(2)	171
$[Mo_2(SC_6H_2Me_3)_6]$	2.228(1)	199
$[Mo_2(MeN(CH_2)_2NMe)_3]$	2.190(1)	183
$1,2\text{-}[Mo_2(OC_6H_3\text{-}2,6\text{-}Me_2)_2(CH_2SiMe_3)_4]$	2.218(2)	174
$1,2\text{-}[Mo_2(OBu^t)_2(CH_2SiMe_3)_6]$	2.209(2)	175
$1,2\text{-}[Mo_2Cl_2(NMe_2)_4]$	2.201(2)	176
$1,2\text{-}[Mo_2Me_2(NMe_2)_4]$	2.201(1)	177
$1,2\text{-}[Mo_2(OSiMe_3)_6(NHMe_2)_2]$	2.242(1)	188
$[Mo_2(OBu^t)_4(O_2COBu^t)_2]$	2.241(1)	189
$[Mo_2(OBu^t)_4(O_2CPh)_2]$	2.236(2)	190
$[Mo_2(OPr^i)_4(N(Ph)C(O)OPr^i)_2]$	2.221(5)	191
$[Mo_2(OCH_2CMe_3)_4(acac)_2]$	2.237(1)	193
$[\{Mo_2F_2(OBu^t)_4\}_2]$	2.263(2)	195
$1,2\text{-}[Mo_2(SBu^t)_2(NMe_2)_4]$	2.217(1)	198
$1,2\text{-}[Mo_2(OPr^i)_2(SC_6H_2Me_3)_4]$	2.230(1)	200
$1,2\text{-}[Mo_2\{Sn(SnMe_3)\}_2(NMe_2)_4]$	2.201(2)	202

The first example of Mo_2L_6 compounds, $[Mo_2(CH_2SiMe_3)_6]$, and its neopentyl and benzyl analogues, were obtained by reacting $MoCl_5$ with Grignard reagents. $MoCl_5$ reacts with $LiCH_2SiMe_3$, or Me_3SiCH_2MgCl, to produce $[Mo_2(CH_2SiMe_3)_6]$, the molecules of which have a staggered, ethane-like, D_{3d}, Mo_2C_6 skeleton and a ^1H NMR spectrum which indicates that all the Me_3SiCH_2 groups are equivalent.[165] There is general agreement that the Mo—Mo triple bond in these Mo_2L_6 derivatives has the $\sigma^2\pi^4$ configuration.[7,164,166] Therefore, the metal–metal interaction has cylindrical symmetry and it is considered that the ligand–ligand repulsions are responsible for the adoption of a staggered conformation (see Figure 7).

$[Mo_2(NMe_2)_6]$ is conveniently prepared by adding $MoCl_3$ to a solution of $LiNMe_2$ in THF at 0 °C with subsequent warming; purification by sublimation provides the compound as a yellow crystalline solid in good yield.[167–169] $[Mo_2(NEt_2)_6]$ and $[Mo_2(NMeEt)_6]$ may be prepared in an analogous manner using the corresponding lithium amide. In the solid state[169] $[Mo_2(NMe_2)_6]$ molecules (Figure 7) adopt the staggered conformation with Mo—Mo = 2.214(2) Å; the NMe_2 groups are essentially planar, these planes contain the Mo—Mo axis, and Mo—N π-bonding interactions are important.[170] The orientations of the planar NC_2 moieties and the restricted rotation about the Mo—N bonds leads to the presence of two types of Me groups, classed as proximal or distal according to their locations with respect to the Mo—Mo bond. Variable temperature ^1H NMR studies have shown that the two types give rise to distinct signals at −71 °C, but at higher temperatures interconversion occurs and the signals coalesce at −30 °C. The large (*ca.* 2 p.p.m.) chemical shift separation between the resonances of the proximal and distal methyl protons arises due to the significant diamagnetic anisotropy of the Mo—Mo triple bond.[169]

Several $[Mo_2(OR)_6]$ compounds have been isolated and characterized and, in order to obtain

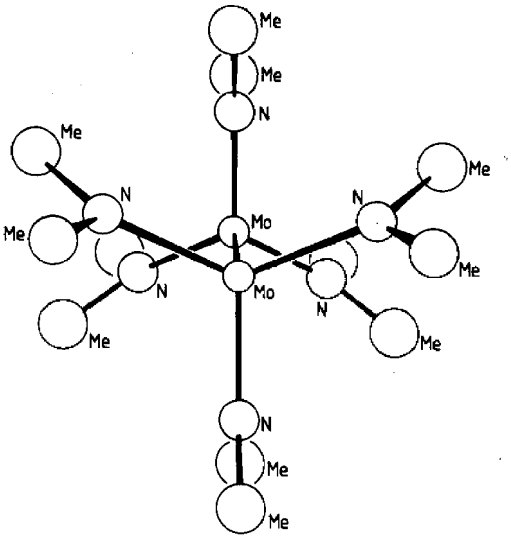

Figure 7 Structure of $[Mo_2(NMe_2)_6]$ viewed nearly along the Mo—Mo axis[169]

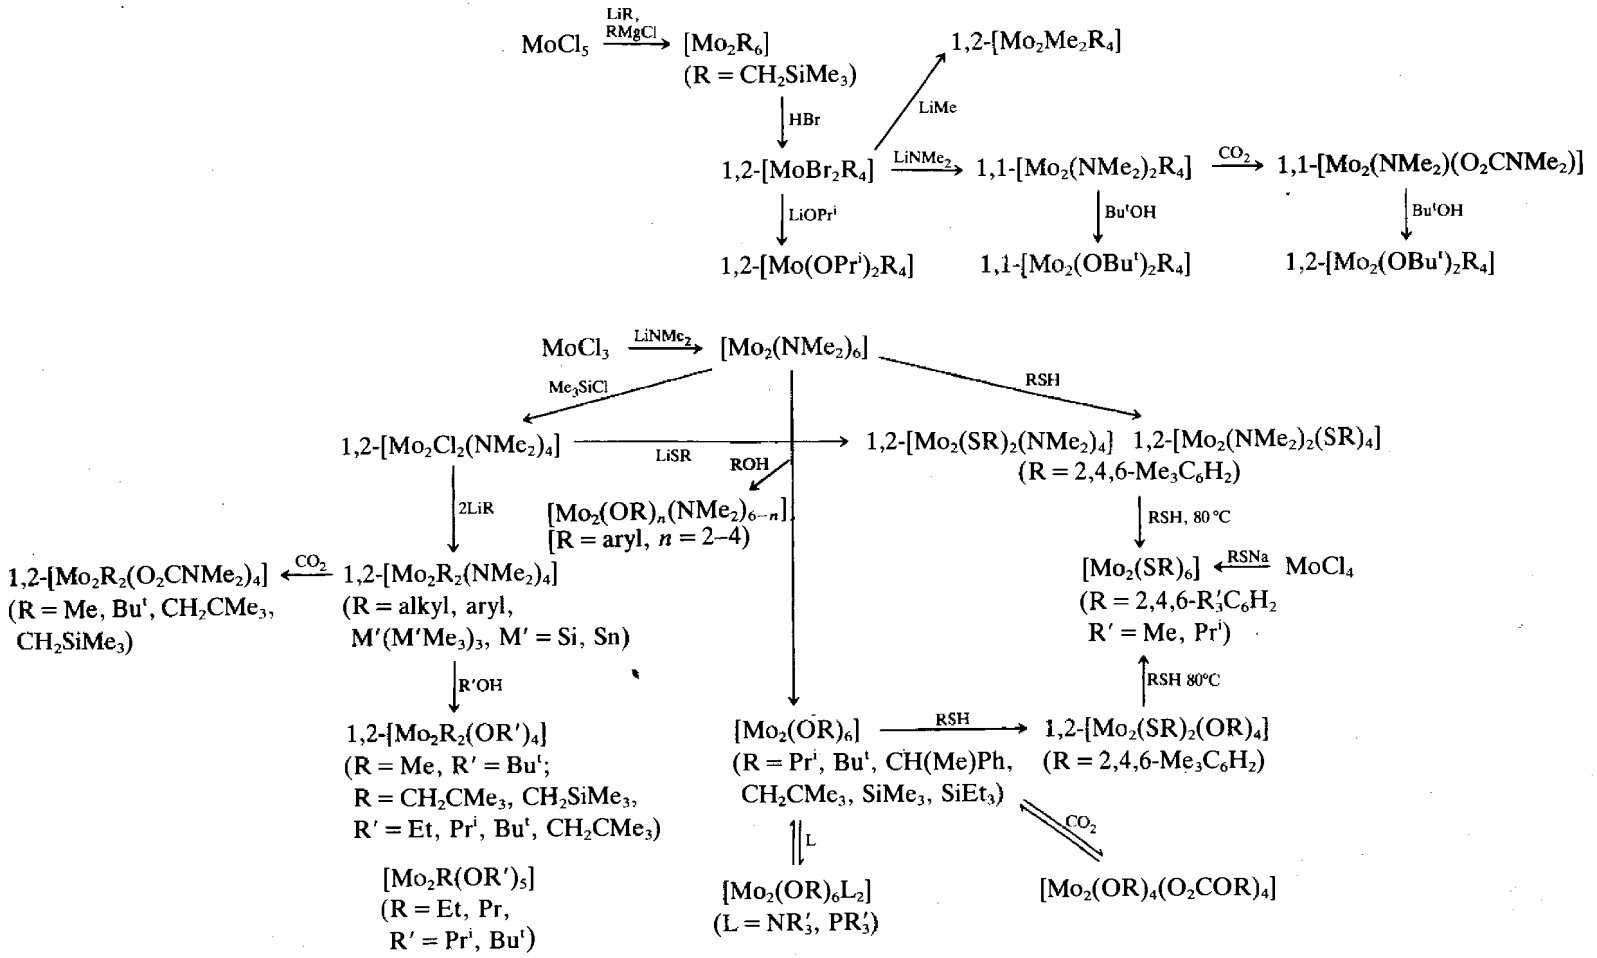

discrete molecular species, R is required to be a bulky group (*e.g.* R = Pr^i, Bu^t, CH(Me)Ph, CH_2CMe_3, Si_3Me_3, $SiEt_3$).[7,10] The molecules have been obtained by reaction of $[Mo_2(NMe_2)_6]$ with the alcohol or trialkylsilanol[168,171,172] and a crystal structure determination of $[Mo_2(OCH_2CMe_3)_6]$ has identified a staggered conformation and an Mo—Mo bond of length 2.222(2) Å.[171]

36.3.2.2.2 Substitution and adduct formation of $[Mo_2L_6]$ molecules

$[Mo_2(CH_2SiMe_3)_6]$ is very reactive and provides an excellent entry into chemistry of compounds with an Mo—Mo triple bond (Scheme 1). Compounds of the general formula $[Mo_2X_2R_4]$ (R = CH_2SiMe_3; X = Br, Me, OPr^i, OBu^t, 2,6-dimethylphenoxide, NMe_2)[173–75] have been reported; the pattern of substitution may be 1,1-$[X_2RMo{\equiv}MoR_3]$ or 1,2-$[XR_2Mo{\equiv}MoR_2X]$, depending upon the nature of X and the preparative route. These 1,1- and 1,2-$[Mo_2X_2R_4]$ compounds do not isomerize, but alkyl group transfer may occur during substitution reactions, *e.g.* 1,2-$[Mo_2Br_2R_4]$ and $LiNMe_2$ (1:2) yield 1,1-$[Mo_2(NMe_2)_2R_4]$. Variable temperature ^1H NMR spectra for 1,1- and 1,2-$[Mo_2X_2R_4]$ (X = NMe_2, OBu^t) are consistent with rotation about the Mo≡Mo bond; this occurs rapidly for the alkoxide (rotational barrier $<33\ kJ\ mol^{-1}$) and significantly slower for the dialkylamide. These results are compatible with the rotational barrier arising due to steric and not electronic effects.[175]

$[Mo_2(NMe_2)_6]$ and $[Mo_2(OR)_6]$ molecules are versatile reagents (Scheme 1). The conversion of $[Mo_2(NMe_2)_6]$ to 1,2-$[Mo_2Cl_2(NMe_2)_4]$[176] and thence to 1,2-$[Mo_2R_2(NMe_2)_4]$[177] opens up a considerable field of chemistry. In each case, the ^1H NMR spectrum of 1,2-$[Mo_2R_2(NMe_2)_4]$ (R = Me, Et, Pr^i, Bu^n, Bu^t, CH_2CMe_3, CH_2SiMe_3) in toluene at −60 °C indicates the presence of a mixture of two rotamers, *anti* and *gauche*; the latter is always predominant and the preference is greater for bulky R groups. 1,2-$[Mo_2R_2(NMe_2)_4]$ compounds are thermally stable, implying that β-hydrogen elimination is unfavorable and the stabilizing influence has been attributed to $Me_2N{\rightarrow}Mo$ π bonding. This view is supported by studies accomplished on 1,2-$[Mo_2Ar_2(NMe_2)_4]$ (Ar = CH_2Ph, 2- or 4-tolyl); in these compounds the $MoNC_2$ units are planar with the NC_2 blades aligned along the Mo—Mo axis, and solution ^1H NMR studies have identified relatively high (*ca.* $59\ kJ\ mol^{-1}$) energy barriers for rotation about the Mo—N bonds.[178] 1,2-$[Mo_2R_2(NMe_2)_4]$ (R = alkyl) compounds react with CO_2 by selective insertion into the Mo—N bonds. Compounds containing alkyl groups lacking the β-hydrogen produce 1,2-$[Mo_2R_2(O_2CNMe_2)_4]$, in which the Mo—Mo triple bond is retained, but the other compounds react according to equation (1) to produce the quadruply bonded species $[Mo_2(O_2CNMe_2)_4]$.[66]

Addition of alcohols (R'OH) to 1,2-$[Mo_2R_2(NMe_2)_4]$ compounds yields either 1,2-$[Mo_2R_2(OR')_4]$ or $[Mo_2R(OR')_5]$ (Scheme 1). The latter reaction involves the elimination of the alkane RH and production of the quadruply bonded dimer which then undergoes oxidative

Scheme 1 Selected syntheses of compounds containing an Mo—Mo triple bond

addition with R'OH, to form (Mo≡Mo)(H)(OR'), and metal hydride alkene insertion. 1,2-$[Mo_2Me_2(OBu^t)_4]$ is coordinatively unsaturated and reacts with Lewis bases to form adducts, *e.g.* $[Mo_2Me_2(OBu^t)_4(py)_2]$.[179]

The reaction of $[Mo_2(NMe_2)_6]$ and 1,2-$[Mo_2Me_2(NMe_2)_4]$ with the precursors of several bridging ligands, *viz.* 6-methyl-2-hydroxypyridine (Hmhp), lithium 2,6-dimethylpyridine (Lidmp) and ditolyltriazine (Hdtz), have been described and the compounds isolated include: $[Mo_2(mhp)_2(NMe_2)_4]$, which contains two mutually *cis* bridging mhp ligands,[180] $[Mo_2(dmp)_2(NMe_2)_4]$, which exists as the non-bridged *gauche* isomer,[181] $[Mo_2(NMe_2)_4(dtz)_2]$ and $[Mo_2Me_2(NMe_2)_2(dtz)_2]$, which involve chelating and bridging dtz ligands, respectively.[182] 1,2-$[Mo_2Cl_2(NMe_2)_4]$ reacts with $Li(MeNH(CH_2)_2NMe)$ to produce $[Mo_2(MeNH(CH_2)_2NMe)_3]$, in which the three bridging *N,N'*-dimethylethylenediamido ligands give rise to an Mo_2N_6 skeleton with a near *eclipsed* conformation.[183] The Mo—Mo bond length (2.190(1) Å) is within the range (Table 2) found for the normal, staggered $[Mo_2L_6]$ compounds.

Phenols (ArOH = 2-*t*-butyl-6-methylphenol, 2,6-diphenylphenol, 2,6-dimethylphenol) react with $[Mo_2(NMe_2)_6]$ to produce $[Mo_2(OAr)_n(NMe_2)_{6-n}]$ ($n = 2$–4) depending on the nature of Ar; the molecular structure and dynamic behaviour of these molecules have been determined.[184] In contrast, the addition of 4-methylphenol (Ar'OH) to $[Mo_2(NMe_2)_6]$ produces $[Me_2NH_2][Mo_2(OAr')_7(NHMe_2)_2]$, which possesses a biconfacial octahedral structure with three μ-OAr' groups and overall C_2 symmetry. The Mo—Mo separation (2.601(2) Å) is similar to that in $[Mo_2Cl_9]^{3-}$ (see Section 36.3.2.2.3) and, like this anion, the complex exhibits a slight paramagnetism at room temperature.[147,185] In a more conventional reaction, $[Mo_2(OPr^i)_2(OAr)_4]$ (ArOH = 2,6-dimethylphenol) has been prepared by the addition of an excess of ArOH to $[Mo_2(OPr^i)_6]$ and the structural characterization of this molecule has allowed a direct comparison of the bonding of alkoxide and aryloxide ligands to an Mo_2^{6+} centre.[186]

Tertiary phosphines react with 1,2-$[Mo_2Cl_2(NMe_2)_4]$ to give a variety of products depending on the phosphine. Monodentate phosphines (L = PMe_3, PMe_2Ph) induce ligand redistribution reactions, producing $[Mo_2(NMe_2)_6]$, $[Mo_2Cl_3(NMe_2)_3L_2]$ and $[Mo_2Cl_4(NMe_2)_2L_2]$; these last compounds undergo β-elimination from an NMe_2 ligand in the presence of added phosphine to give the quadruply bonded $[Mo_2Cl_4L_4]$ compound. Bidentate phosphines (LL = $Me_2P(CH_2)_nPMe_2$, $n = 1$, 2) produce stable 1:1 adducts, $[Mo_2Cl_2(NMe_2)_4(LL)]$, the ^1H and ^{31}P NMR spectra of which are consistent with a bridging phosphine and two MoN_2ClP planes with an eclipsed conformation.[187]

$[Mo_2(OR)_6]$ (R = CH_2CMe_3, $SiMe_3$) react rapidly with N and P donor ligands to give the adduct 1,2-$[Mo(OR)_6L_2]$.[171] The conformation about the Mo—Mo axis of 1,2-$[Mo(OSiMe_3)_6(NHMe_2)_2]$ is intermediate between staggered and eclipsed, but closer to the former.[188] This adduct formation is an equilibrium which has been monitored closely by NMR spectroscopy and the mono adducts, $[Mo_2(OR)_6L]$, shown to be unstable with respect to disproportionation to $[Mo_2(OR)_6]$ and $[Mo_2(OR)_6L_2]$.[10]

$[Mo_2(OR)_6]$ compounds react readily and reversibly, both in the solid state and solution, with CO_2 to produce $[Mo_2(OR)_4(O_2COR)_2]$ (Scheme 1). This insertion is considered to proceed by the direct attack of CO_2 on the Mo—OR bond. In $[Mo_2(OBu^t)_4(O_2COBu^t)_2]$, the bridging carbonato groups are mutually *cis* and the rotational conformation about the Mo—Mo bond is essentially eclipsed.[189] The related compound $[Mo_2(OBu^t)_4(O_2CPh)_2]$ has been prepared by the reaction of $[Mo_2(OBu^t)_6]$ with benzoyl peroxide and shown to have the same conformation.[190] Organic isocyanates will also insert into the Mo—O bond of $[Mo_2(OR)_6]$ compounds; thus, $[Mo_2(OPr^i)_6]$ reacts with PhNCO to produce $[Mo_2(OPr^i)_4(N(Ph)C(O)OPr^i)_2]$, which contains two *cis* bridging bidentate ligands.[191]

$[Mo_2(OR)_6]$ compounds react with bidentate ligands (HLL = 1,3-diaryltriazine, 2-hydroxypyridine) to produce $[Mo_2(OR)_4(LL)_2]$, in which the bidentate ligand spans the Mo—Mo triple bond.[192] However, reactions between $[Mo_2(OR)_6]$ and a β-diketonate produce $[Mo_2(OR)_4(R'COCHCOR'')_2]$ in which each β-diketonate is chelated to one molybdenum atom; in solution there is rapid rotation about the unbridged Mo—Mo triple bond.[193] $[Mo_2(OR)_4(acac)_2]$ (R = CH_2CMe_3) reacts with isocyanides to produce edge-shared (μ-OR)$_2$ octahedral complexes $[Mo_2(OR)_4(acac)_2(R'NC)_2]$. This is a novel conversion, thus: (i) an L_4MoMoL_4 compound is converted to an $L_4Mo(\mu\text{-}L)_2L_4$ derivative; (ii) the multiple bond is *not* cleaved by isocyanide ligands; (iii) the unbridged $\sigma^2\pi^4$ triple bond is converted to an edge-bridged d^3–d^3 dimer with a formal $\sigma^2\pi^2\delta^2$ configuration. This change in electronic structure is accompanied by a significant increase in the Mo—Mo distance, from 2.237(1) to 2.508(2) Å (R' = Bu^t).[194]

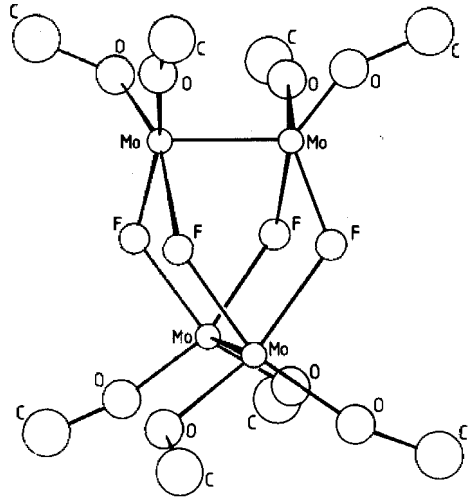

Figure 8 Structure of $[Mo_4F_4(OBu^t)_4]$[195]

$[Mo_2(OBu^t)_6]$ reacts with PF_3 to produce $[Mo_4F_4(OBu^t)_8]$ (Figure 8). This molecule consists of two Mo_2^{6+} centres linked by four bridging fluorides[195] which may be cleaved by PMe_3 to yield $[Mo_2F_2(OBu^t)_4(PMe_3)_2]$.[196]

Thiolato derivatives of Mo_2^{6+} were initially elusive,[197] but the use of 2,4,6-alkyl-substituted aryl thiolates has permitted the isolation of several such compounds. 1,2-$[Mo_2Cl_2(NMe_2)_4]$ reacts with LiSR (R = Me, Bu^t) to produce 1,2-$[Mo(SR)_2(NMe_2)_4]$[198] and this compound reacts with RSH (R = 2,4,6-$Me_3C_6H_2$) to produce $[Mo_2(SR)_6]$.[199] $[Mo_2L_6]$ (L = NMe_2, OPr^i, OBu^t, CH_2CMe_3) react with this thiol at room temperature to form the corresponding $[Mo_2L_2(SR)_4]$ derivatives, but at 80 °C complete substitution is achieved.[200] An alternative route to $[Mo_2(SR)_6]$ derivatives has been developed which involves the reaction of $MoCl_4$ with RSNa (R = 2,4,6-$Me_3C_6H_2$, 2,4,6-$Pr^i_3C_6H_2$) in 1,2-dimethoxyethane.[201]

Metathesis between 1,2-$[Mo_2Cl_2(NMe_2)_4]$ and $[(THF)_3Li][M'(M'Me_3)_3]$ (M' = Si, Sn) yields 1,2-$[Mo_2\{M'(M'Me_3)_3\}_2(NMe_2)_4]$, compounds which involve a branched chain of 10 ($M'_4Mo{\equiv}MoM'_4$) metal atoms. The compounds possess high barriers to rotation about the Mo—N bonds (67–80 kJ mol^{-1}) as a consequence of the severe steric crowding about the Mo_2^{6+} centre.[202]

36.3.2.2.3 Properties of Mo—Mo triple bonds

Thermochemical measurements have been made in an attempt to establish D(Mo≡Mo). The interpretation of the data is dependent upon assumptions of the relevant metal–ligand bond energies and, in view of these uncertainties, ranges of values have been quoted; 592 ± 196 kJ mol^{-1} for $[Mo_2(NMe_2)_6]$ and 310–395 kJ mol^{-1} for $[Mo_2(OPr^i)_6]$.[203] MO calculations have indicated that the strength of the Mo—Mo triple bond is affected significantly by the nature of the attached ligands and π donors, such as NH_2, stabilize this bond.[164]

The $\sigma^2\pi^4$ description[7,164,166] of the electronic structure of the Mo—Mo triple bond in $[Mo_2L_6]$ molecules and their relatives has been reinforced by PES studies[170,204] for molecules with L = CH_2SiMe_3, NMe_2 and OR (R = Pr^i, Bu^t, CH_2CMe_3). The observed spectra have been interpreted successfully by calculations on simpler analogues. The electronic absorption spectra of these molecules have been described and the lowest energy absorption assigned to promotion of an Mo≡Mo π electron into an orbital of e symmetry, which is an admixture of the Mo≡Mo δ^* and π^* orbitals.[10]

Unlike their Mo_2^{4+} counterparts, the ν(Mo—Mo) stretching mode of Mo_2^{6+} complexes is not a distinctive feature of their Raman spectra. Rather, as shown by a study of $[Mo_2(NMe_2)_6]$ and $[Mo_2\{N(CD_3)_2\}_6]$,[169] this mode is strongly coupled with other internal vibrations.

Considerable attention has been paid to the dynamic behaviour of Mo_2^{6+} complexes in solution and ^1H NMR spectroscopy has been an essential probe. These properties have been reviewed[7,10] and emphasis given to the point that the barrier to rotation about the triple bond is determined only by steric factors associated with ligand–ligand interactions.[205] ^{95}Mo NMR

spectroscopic studies of $[Mo_2L_6]$ ($L = NMe_2$, OPr^i, OBu^t, OCH_2CMe_3, CH_2SiMe_3) have been accomplished. The resonances all occur in a very deshielded portion of the known chemical shift range; for $[Mo_2(CH_2SiMe_3)_6]$ resonance occurs at 3624 p.p.m. and for the other molecules between 2430 and 2645 p.p.m.[206]

36.3.2.2.4 Reactions of Mo—Mo triple bonds

Compounds containing an Mo—Mo triple bond have been shown to exhibit novel reactivity[7,8,10,164] with a versatility which goes well beyond the Lewis base association, ligand substitution and CO_2 insertion reactions described in Section 36.3.2.2.2. These compounds undergo reductive elimination and oxidative addition reactions which result in a change in the order of the Mo—Mo bond; the conversion of $\{Mo{\equiv}Mo\}^{6+} \rightarrow \{Mo{=}Mo\}^{8+}$ has been mentioned in Section 36.3.2.1.1 and further information concerning the products of the transformations $\{Mo{\equiv}Mo\}^{6+} \rightarrow \{Mo{=}Mo\}^{8+}$ or $\{Mo{-}Mo\}^{10+}$ is provided in Sections 36.3.2.3 and 36.3.2.4, respectively. These reactions, and the interesting β hydrogen effects observed in the reactions of alcohols with 1,2-$[Mo_2R_2(NMe_2)_4]$ compounds,[179] have no precedence in the chemistry of mono-metal centres.

Oxidative additions to compounds containing an Mo—Mo triple bond can (equation 3) give products containing an Mo—Mo double bond.[175,190,207] Also, $[Mo_2(OCH_2Bu^t)_6]$ reacts with $PhCHBr_2$ in hexane/pyridine to form $[Mo_2(OCH_2Bu^t)_6Br_2(py)]$ which contains an Mo—Mo double bond.[208] The direct addition of halogens ($X_2 = Cl_2$, Br_2, I_2) to $[Mo_2(OPr^i)_6]$ gives $[Mo_2(OPr^i)_6X_4]$ which contains a pair of octahedrally coordinated molybdenum atoms linked by two μ-OPr^i groups and a single Mo—Mo bond[207] and $[Mo_2(OR)_6]$ compounds react with tetrachloroquinone to produce $[Mo_2(OR)_6(O_2C_6Cl_4)_2]$ which contains an Mo_2^V centre.[10]

$$[Mo_2(OPr^i)_6] + X_2 \longrightarrow [Mo_2(OPr^i)_6X_2] \quad (X = Pr^iO, PhCO_2) \qquad (3)$$

Compounds containing an Mo—Mo triple bond have been shown to produce a variety of interesting products in reactions with molecules containing a C—O, C—N or C—C triple bond.[10,194] These may be considered to be oxidative addition reactions, in which electron density is removed from the Mo—Mo triple bond to form metal–ligand bonds. A solution of $[Mo_2(OBu^t)_6]$ in a hydrocarbon solvent reacts with CO; in the first instance, reversible addition to $[Mo_2(OBu^t)_6(CO)]$ occurs and, eventually, $[Mo(CO)_6]$ and $[Mo(OBu^t)_4]$ are formed.[209] Carbonylation of $[Mo_2(OPr^i)_6]$ proceeds in a similar manner and, in the presence of pyridine, $[Mo_2(OPr^i)_6(py)_2(CO)]$ is formed.[210] $[Mo_2(OR)_6]$ compounds form simple adducts with dimethyl- and diethyl-cyanamide (R'_2NCN), the process being reversible for R = Bu and R′ = Me and Et, in which an electronic redistribution occurs forming $\{R'_2NCN\}^{2-}$ and an Mo_2^{8+} centre.[10,211] Aryl-substituted diazomethanes react with $[Mo_2(OR)_6]$ compounds and are reduced to $\{Ar_2CN_2\}^{2-}$ moieties in compounds such as $[Mo_2(OPr^i)_6(N_2CPh_2)_2(py)]$.[212] Alkynes react with $[Mo_2(OR)_6]$, or their adducts $[Mo_2(OR)_6L_2]$, in hydrocarbon solvents at 25 °C to give a wide variety of products. Careful control of the conditions is required to isolate compounds such as $[Mo_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)]$ since the alkyne adducts are labile towards C—C coupling. This coupling can lead to alkyne polymerization, but the interesting derivative $[Mo_2(OCH_2Bu^t)_6(\mu\text{-}C_4H_4)(py)]$ has been isolated and structurally characterized.[213]

Mo—Mo triple bonds may be cleaved by reactions with molecules containing multiple bonds and several interesting products have been isolated and characterized. $[Mo_2(OPr^i)_6]$ reacts with NO (1:2) to form 1,2-$[Mo_2(OPr^i)_6(NO)_2]$, in which the Mo—Mo distance of 3.335(2) Å is spanned by two μ-alkoxy groups. Therefore, the formation of the two Mo—NO triple bonds results in the loss of the Mo—Mo triple bond.[214] Reactions of 1,2-$[Mo_2(OPr^i)_6(NO)_2]$[215] and the formation of the mixed-metal dimer $[CrMo(OPr^i)_6(NO)_2]$[216] have been described. Hydrocarbon solutions of $[Mo_2(OBu^t)_6]$ react with aryl azides and molecular oxygen at room temperature according to equations (4) and (5), respectively.[217] $[Mo_2(OBu^t)_4(NC_7H_8)_4]$ has a structure which resembles that of $[Mo_2(OPr^i)_6(NO)_2]$, with an Mo—Mo separation of 3.247(1) Å bridged by two NC_7H_8 ligands. Although (equation 5) O_2 will cleave Mo—Mo triple bonds, interesting oligomers have been isolated in other reactions. Thus, $[Mo_2(OR)_6]$ ($R = Pr^i$, CH_2CMe_3) react with O_2 to form $[Mo_3O(OR)_{10}]$ initially, subsequently $[Mo_6O_{10}(OPr^i)_{12}]$, and finally $[MoO_2(OPr^i)_2]$.[218] $[Mo_2(OBu^t)_6]$ reacts with Ph_2CN_2 with cleavage of the Mo—Mo triple bond

and formation of $[Mo(OBu^t)_4(N_2CPh_2)]$[212] and, in a similar manner, $[Mo_2(OPr^i)_6]$ reacts with bipy to produce $[Mo(OPr^i)_2(bipy)_2]$.[219]

$$[Mo_2(OBu^t)_6] + 4ArN_3 \longrightarrow [Mo_2(OBu^t)_4(NAr)_4] + 4N_2 + 2Bu^tOH \quad (4)$$

$$[Mo_2(OBu^t)_6] + 2O_2 \longrightarrow 2[MoO_2(OBu^t)_2] + 2Bu^tOH \quad (5)$$

36.3.2.2.5 Dicyclopentadienyltetracarbonyldimolybdenum

$[Cp_2Mo_2(CO)_4]$ is an important member of a group of cyclopentadienyl compounds and, like its chromium and tungsten analogues, this species is considered to involve a metal–metal triple bond.[7,220] These and related compounds manifest a rich and novel chemistry,[221] but this falls outside the field of this review.

36.3.2.2.6 Halide and related complexes[7]

$[Mo_2X_9]^{3-}$ (X = Cl, Br) anions are readily prepared by a variety of methods, including: electrolytic reduction of a solution of MoO_3 in aqueous HX,[222] thermally induced reactions of molybdenum(III) halides with alkali metal halides,[223] conproportion reactions of carbonyl halide anions of molybdenum with molybdenum halides,[224] and (Section 36.3.2.1.3) the oxidation of complexes containing an Mo—Mo quadruple bond in the presence of X^-. These $[Mo_2X_9]^{3-}$ anions consist of two MoX_6 octahedra sharing a face and, in their Cs^+ salt, the Mo—Mo separation is 2.655(11) and 2.816(9) Å for X = Cl and Br, respectively.[225] Although the potential for formation of an Mo—Mo triple bond exists in these anions, this is not realized; thus, as compared to their tungsten counterparts, the molybdenum atoms are shifted but little from the centre of the halide octahedron towards each other and the anions display effective magnetic moments at room temperature of 0.6 ($Cs_3[Mo_2Cl_9]$) and 0.8 BM ($Cs_3[Mo_2Br_9]$).[226] The substitution of μ-H for μ-X in these anions has a significant effect upon the Mo—Mo interaction. The $[Mo_2X_8H]^{3-}$ anions are diamagnetic and involve Mo—Mo separations which are some 0.3 (X = Cl) or 0.4 Å (X = Br)[227,228] shorter and, in contrast to $[Mo_2X_9]^{3-}$ (X = Cl, Br), the Mo—Mo distance in $[Mo_2X_8H]^{3-}$ (X = Cl, Br, I) anions is little affected by a change in X.[229] Initially, these anions were incorrectly formulated as $[Mo_2X_8]^{3-}$ species, but the presence of the μ-hydrido ligand was demonstrated by isotopic labelling, vibrational spectroscopy, and its location determined by X-ray crystallography and neutron diffraction; the Mo—H bonds in $[NMe_4]_3[Mo_2Cl_8H]$ are 1.73(1) and 1.823(7) Å.[230] The heteronuclear anion $[MoWCl_8H]^{3-}$, prepared by the reaction of $[MoW(O_2CMe)_4]$ with HCl, has the $[Mo_2Cl_8H]^{3-}$ structure and involves an Mo—W distance of 2.445(3) Å.[231]

$[NBu_4][Mo_2Br_6]$ has been obtained from the reaction of $[Mo_2(O_2CMe)_4]$ with HBr in MeOH in the presence of $[NBu_4]^+$ and this anion considered to possess a strong Mo—Mo interaction.[232] The synthesis, redox properties and reactivity towards phosphines of $[NBu_4]_2[Mo_2Br_6]$ have been investigated.[233]

The formation of $[Mo_2(HYO_4)_4]^{2-}$ (Y = P, As) anions has been described in Section 36.3.2.1.3; these anions contain an $\{Mo_2\}^{6+}$ centre spanned by four (μ-O_2YO_2H) ligands in an eclipsed conformation and involve Mo—Mo separations of 2.228(5)[159] and 2.265(1) Å,[160] respectively, consistent with the existence of a triple bond (Table 2).

36.3.2.3 Complexes Containing a Double Metal–Metal Bond

MoO_2 adopts a distorted rutile structure in which the metal atoms are drawn together in pairs some 2.511 Å apart,[234] a distance (*vide supra*) which is consistent with the presence of an Mo—Mo double bond.

$[Mo(NMe_2)_4]$ reacts readily with alcohols (ROH) to form the corresponding $[Mo(OR)_4]_n$ compound and, for $R = CHMe_2$ and Pr^i, it has been established that the diamagnetic, $[Mo_2(OR)_8]$, dimer is formed.[235] $[(Pr^iO)_3Mo(\mu\text{-}OPr^i)_2Mo(OPr^i)_3]$ is centrosymmetric, with an Mo—Mo separation of 2.523(1) Å spanned by two bridging isopropoxide ligands which form Mo—O bonds of length 1.958(3) and 2.111(3) Å.[236] Thermochemical measurements for $[Mo_2(OPr^i)_6]$ and $[Mo_2(OPr^i)_8]$ have led to a value in the range 837–962 kJ mol^{-1} being suggested for the Mo=Mo bond strength in the latter compound.[203]

Reactions of $[Mo_2L_6]$ compounds containing an Mo—Mo triple bond can lead to the formation of compounds with an Mo—Mo double bond (Section 36.3.2.2.4).[7,8,10,164,174,175,190,197,198,207–209,213] Thus, as an alternative to the above procedure, $[Mo_2(OPr^i)_8]$ may be prepared by the oxidative addition of Pr^iOOPr^i to $[Mo_2(OPr^i)_6]$,[207] and $[Mo_2(OR)_6]$ ($R = Pr^i, Bu^t$) reacts with $PhCO_2—O_2CPh$ to form $[Mo_2(OR)_6(O_2CPh)_2]$.[190] $[Mo_2(OBu^t)_6(CO)]$ separates as dark purple crystals when $[Mo_2(OBu^t)_6]$ is reacted with CO and the reaction mixture is cooled to −15 °C. Molecules of this compound possess a structure involving an Mo—Mo separation of 2.489(1) Å spanned by one μ-CO and two μ-OBu^t groups.[209] Carbonylation of $[Mo_2(OPr^i)_6]$ proceeds to give $[Mo(CO)_6]$, but in the presence of pyridine the adduct $[(Pr^iO)_2(py)Mo(\mu\text{-}OPr^i)_2(\mu\text{-}CO)Mo(py)(OPr^i)_2]$ can be isolated; this molecule involves an Mo—Mo separation of 2.486(2) Å consistent with the presence of a double bond.[210] This bond order is also considered to occur in the related compound $[Mo_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)]$, in which the Mo—Mo separation is 2.554(1) Å.[213] $[Mo_2(OR)_6]$ compounds form 1:1 adducts with dialkylcyanamides, R'_2NCN, and a crystal structure determination for $R = Bu^t$ and $R' = Me$ has shown that the Me_2NCN ligand spans the Mo≡Mo bond of distance 2.449(1) Å.[10,211] $[Mo_2(OCH_2Bu^t)_6(py)_2]$ and $PhCHBr_2$ react to form $[Mo_2(OCH_2Bu^t)_6Br_2(py)]$ which has a distorted confacial (μ-Br, (μ-OR)$_2$) bioctahedral structure with an Mo=Mo bond of length 2.534(1) Å.[208] $[Mo_2(NMe_2)_6]$ and $[Mo_2(SBu^t)_2(NMe_2)_4]$ react with Bu^tSH to form $[(HNMe_2)(Bu^tS)_2Mo(\mu\text{-}S)_2Mo(SBu^t)_2(HNMe_2)]$ which involves an Mo—Mo separation of 2.730(1) Å.[197,198] $[Mo_2(OAr)_2(CH_2SiMe_3)_4]$ (OAr = 2,6-dimethylphenoxide) undergoes smooth loss of one equivalent of Me_4Si in the presence of pyridine to form $[Mo_2(\mu\text{-}H)(\mu\text{-}CSiMe_3)(CH_2SiMe_3)_2(OAr)_2(py)_2]$ which is considered to involve an $\{Mo_2\}^{8+}$ core and an Mo=Mo bond of length 2.380(2) Å.[174]

The variation in the length of Mo=Mo bonds is a demonstration of the general observation that there is no strict correlation between the bond order and the length of Mo—Mo bonds;[7] the molybdenum atoms in these compounds will have different electronic structures leading to different types of double bond (*e.g.* $\sigma^2\pi^2$ [174] or $\pi^2\delta^2$ [236]), a difference augmented by the particular stereochemical demands of the bridging ligands. With this perspective, it may be possible to view the formally Mo^{IV} dimers $[Mo_2S_2(\mu\text{-}S_2CNR_2)_2(SCNR_2)_2]$[99] as involving an Mo—Mo double bond, even though the metal–metal separation of 2.705 Å is longer than usual.

36.3.2.4 Complexes Containing a Single Metal–Metal Bond

The vast majority of these compounds are to be found in Section 36.4.3.5 which describes the chemistry of systems containing an $\{Mo_2\}^{10+}$ core. Several other complexes containing an Mo—Mo single bond have been prepared by the reaction of dimeric complexes possessing a quadruple (Section 36.3.2.1.3)[7,161,162] or triple (Section 36.3.2.2.4)[7,8,10,164] Mo—Mo bond. Also $[Mo_2(OPr^i)_6]$ reacts with X_2 (X = Cl, Br, I) to produce $[Mo_2(OPr^i)_6X_4]$; an X-ray crystallographic study of the chloro and bromo derivatives has shown that both compounds have central $Mo_2O_6X_4$ moieties with virtual D_{2h} symmetry and Mo—Mo separations of 2.731(1) and 2.739(1) Å, respectively.[207] $[Mo_2(OPr^i)_6(N_2CPh_2)_2(py)]$, formed by addition of diphenyldiazomethane to $[Mo_2(OPr^i)_6]$ in the presence of pyridine, involves an Mo—Mo single bond of length 2.662(1) Å spanned by three (μ-OPr^i) ligands.[212] The Mo—Mo separation in $[Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4)]$ of 2.69(1) Å approaches that of an Mo—Mo single bond, but there are alternatives to this description of the Mo—Mo interaction.[213] A similar situation pertains in $[(Me_2NCS_2)_2Mo(\mu\text{-}S)(\mu\text{-}EtC{\equiv}CEt)Mo(S_2CNMe_2)(SCNMe_2)]$, in which the Mo—Mo separation is 2.647(1) Å.[237] $[Cp_2Mo_2(CO)_6]$[238] and $[GMo_2(CO)_6]$[6] (G = guaiazulene) involve Mo—Mo bonds of length 3.235(1) and 3.267(6) Å, respectively, and are generally considered to involve an Mo—Mo single bond.

36.3.3 METAL CLUSTERS

36.3.3.1 Trimeric Clusters

Despite the proposal[239] in 1929 that molybdenum(IV) complexes such as $Mo_3O_4(C_2O_4)_3^{2+}$ contains an $\{Mo_3O_4\}^{4+}$ core, it was some 50 years later that the significance of trimeric molybdenum clusters was clearly appreciated.[9] Three types of Mo_3 cluster have been

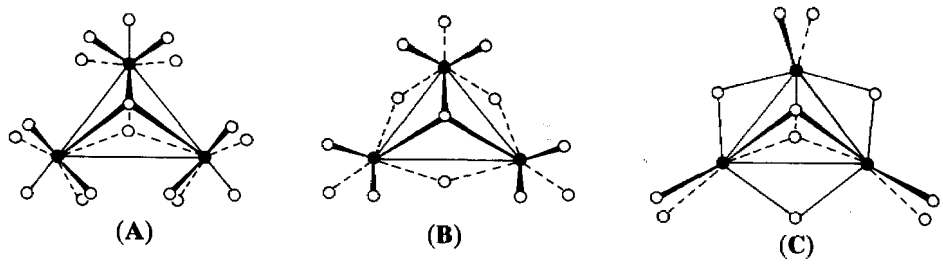

Figure 9 Structural arrangements recognized for Mo_3 clusters (● = Mo, ○ = ligand donor atom)[9]

recognized (Figure 9), involving differing patterns of ligation to an equilateral triangular array of molybdenum atoms. The common types are **A** and **B** and a fundamental understanding of the metal–metal bonding in these species has been achieved.[240]

The bicapped Mo_3X_{17} clusters (**A**) involve two orbitals per metal being used for metal–metal bonding and, therefore, a maximum of six electrons can be accommodated in the Mo—Mo bonding orbitals, thereby forming a metal–metal single bond over each edge of the triangle. Such a centre may be designated as $\{Mo_3\}^{12+}$. Several compounds exist with an oxidized version of this centre, *viz.* $\{Mo_3\}^{13+}$ or $\{Mo_3\}^{14+}$, which have Mo—Mo bond orders of $\frac{5}{6}$ or $\frac{2}{3}$, respectively, and the relative length of the Mo—Mo bonds (typically between 2.75 and 2.80 Å) are consistent with this MO picture. An important reaction in the context of these clusters is the formation of the $[Mo_2O_n(CMe)_{2-n}(O_2CMe)_6(H_2O)_3]^{m+}$ ($n = 0, 2, m = 2; n = 1, m = 1$) ions in the reaction of $MeCO_2H/(MeCO)_2O$ mixtures with $[Mo(CO)_6]$.[241–243] Although the initial report[241] was incorrect in some details, the successful isolation and characterization of these species was important as it stimulated further investigations which led to the synthesis of several $[Mo_3(\mu_3\text{-}X)_2(O_2CR)_6L_3]$ derivatives, in which X is an oxygen atom or an alkylidene group.[242–249] The presence of one μ_3-alkylidene ligand maintains the electron count of six electrons in the Mo—Mo bonding orbitals, as in $[Mo_3O(CMe)(O_2CMe)_6(H_2O_3]^+$, but the presence of two such ligands stabilizes the $\{Mo_3\}^{14+}$ core, as in $[Mo_3(CMe)_2(O_2CMe)_6(H_2O)_3]^{2+}$.

The monocapped Mo_3X_{13} clusters (**B**) have an electronic structure which can accommodate six Mo—Mo bonding electrons,[240] but one or two more electrons can be accommodated in an orbital that has little if any M—M antibonding character. Therefore, in addition to the $\{Mo_3\}^{12+}$ clusters, other type **B** systems based on $\{Mo_3\}^{11+}$ and $\{Mo_3\}^{10+}$ cores exist. Type **B** clusters are known for a wide variety of ligands and those containing $\{Mo_3O_4\}^{4+}$ and the corresponding partial or completely substituted sulfur cores have special importance; details of the synthesis, substitution and redox chemistry of many of these systems are described in Section 36.1.4 with particular attention being given to the trimeric species involved in the aqueous chemistry of Mo^{IV}.[250] The ^{95}Mo NMR chemical shift of the Mo^{IV} aqua ion in acidic media and those of the Mo^{IV} complexes containing oxalate,[239,251] 1,2-diaminoethanetetra-acetate[252] and *N*-methyliminatodiacetate, whose solid state structures are based on an $\{Mo_3O_4\}^{4+}$ core, fall in the relatively narrow range 990–1162 p.p.m. and this observation serves as a useful spectroscopic probe for the presence of this core in solutions of molybdenum complexes.[253] Thiocyanate ligands bind readily to the $\{Mo_3O_4\}^{4+}$ core and kinetic studies have indicated that there are three equivalent sites on this cation to which these ligands have access.[254] The synthesis and characterization of complexes involving $\{Mo_3O_nS_{4-n}\}^{4+}$ ($n = 3$–0) cores have been described[255–257] and, as the number of sulfur atoms in the core increases, so does the Mo—Mo separation, from *ca.* 2.5 Å in $\{Mo_3O_4\}^{4+}$ centres to *ca.* 2.75 Å in $\{Mo_3S_4\}^{4+}$ centres. $[Mo_3S_4(CN)_9]^{5-}$ has been structurally characterized[258,259] and electrochemical studies have identified the quasi-reversible one-electron oxidation of this anion. $[Mo_3(\mu_3\text{-}S)(S_2)_6]^{2-}$ (Figure 10, Section 36.6.1) is also based on an $\{Mo_3\}^{12+}$ core, but involves a $(\mu\text{-}S_2)$ ligand spanning each edge of the triangle and possesses one terminal disulfide ligand on each molybdenum.[260] $\{Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3\}^{4+}$ cores have been shown to bind chloride[261,262] and dialkyldioxo[263] and dialkyldithiophosphinate ligands;[264] in respect to the last ligation, the reaction of $[Mo(CO)_6]$ with $R_2P(S)—S_2—P(S)R_2$ (R = Et, Pr) affords $[Mo_3S_7(R_2PS_2)_3][R_2PS_2]$ and reaction of this cation with PPh_3 leads to sulfur abstraction and formation of the $[Mo_3S_4(R_2PS_2)_4]$ compound.[265]

As indicated above, type **B** clusters can accommodate one or two additional electrons, beyond the six needed to form the three Mo—Mo bonds of the triangular array. This redox versatility is clearly manifest in mixed-metal oxide phases of molybdenum. Examples include

$M_2Mo_3O_8$ (M = Mg, Mn, Fe, Co, Ni, Zn, Cd),[266] $LiZn_2M_3O_8$ and $Zn_3Mo_3O_8$[267] which, respectively, involve Mo_3O_{13} units with six ($\{Mo_3\}^{12+}$), seven ($\{Mo_3\}^{11+}$) and eight ($\{Mo_3\}^{10+}$) electrons in the metal-based orbitals; $La_3Mo_4SiO_{14}$[268] appears to involve six electrons in these orbitals. $[Mo_3(\mu_3\text{-}O)(\mu\text{-}Cl)_3(\mu\text{-}O_2CMe)_3(H_2O)_3]^{2+}$,[269] $[Mo_3(\mu_3\text{-}O)(\mu_2\text{-}Cl)_3(\mu\text{-}O_2CMe)_2Cl_5]^{2-}$,[261,270] $[Mo_3(\mu_3\text{-}O)(\mu_2\text{-}X)_3(\mu\text{-}O_2CR)_3Cl_3]^-$, (X = Cl, R = Me;[261] X = Br, R = H[271]) and $[Mo_3(\mu_3\text{-}CMe)_3(\mu_2\text{-}Br)_3(\mu\text{-}O_2CMe)_3(H_2O)_3]^+$[272] are all based on an $\{Mo_3\}^{10+}$ core.

Type **C** (Mo_3X_{11}) clusters occur for $[Mo_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6]$ (R = Pr^i, CH_2CMe_3).[218,273,274] These species may be considered to involve an $\{Mo_3\}^{12+}$ centre and involve Mo—Mo separations of *ca.* 2.53 Å; their electronic structure has been described and related to their electronic spectra.[275] These species are obtained in the simple conproportionation reactions between the $[Mo_2(OR)_6]$ and $[MoO(OR)_4]$ derivatives and this route has permitted the synthesis of the *triangulo*-Mo_2W cluster.[274] The related systems $[Mo_3(\mu_3\text{-}S)_2(\mu\text{-}Cl)_3Cl_6]^{3-}$ and $[Mo_3(\mu_3\text{-}S)_2(\mu\text{-}Cl)_3\{S_2P(OEt)_2\}_3]$ involve an $\{Mo_3\}^{10+}$ centre and Mo—Mo bonds of *ca.* 2.6 Å[276] and a compound containing an $\{Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3\}$ core appended by diethoxythiophosphinate ligands has been shown to involve a triangular arrangement with two Mo—Mo separations of 2.808(1) and 2.839(1) Å and one longer distance of 3.337(1) Å.[276] The complex $[Mo_3S_8(N_2Me_2)_2]^{2-}$ has been synthesized by the reaction of $[Mo_2S_4(N_2Me_2)_2PPh_3]$ with LiSPh in MeCN. X-Ray structure analysis of the $[PPh_4]^+$ salt has revealed the anion to be a linear molybdenum trimer with two distinct coordination sites. The central metal atom enjoys pseudooctahedral geometry, through coordination of the N atoms of two end-on, linearly bound hydrazido(2−) groups and to four bridging sulfido groups and crystallographic symmetry which gives a rigorously planar Mo_2S_4 unit, with *trans* hydrazido-groups. The terminal molybdenum atoms are tetrahedrally coordinated to two bridging and two terminal sulfido groups. The unusual Mo—N and N—N bond lengths of 2.13(1) Å and 1.16(2) Å, respectively, suggest that the —$NNMe_2$ ligands are best described as isodiazene groups.[277]

Infinite chains of Mo_3 triangles occur in a variety of solid phases of molybdenum chalcogenides, including MMo_3S_3 (M = K, Rb, Cs) and $Tl_2Mo_2Se_6$; the electronic structure of the latter and related systems has been investigated.[278]

36.3.3.2 Tetrameric Clusters

Complexes involving four molybdenum atoms are known for several types of systems including pairs of $\{Mo_2O_4\}^{2+}$, $\{Mo_2(NR)_2S_2\}^{2+}$ and related systems (Section 36.4.3.5.4) and $[Mo_4S_4(NO)_4(CN)_8]^{8-}$ (Section 36.6.4). This section will describe moieties in which a framework of metal–metal bonds links all the molybdenum atoms.

$[Mo_4I_{11}]^{2-}$ has been synthesized by the attack of HI on $[Mo_2(O_2CMe)_4]$[279] and by the I_2 oxidation of $[Mo(CO)_4I_3]^-$;[280] the structure of this entity involves a distorted Mo_4 tetrahedron and may be viewed as containing an $\{Mo_4I_7\}^{2+}$ fragment of an $[Mo_4I_8]^{4+}$ cluster (Section 36.3.3.3) with an iodide bound as a terminal ligand to each molybdenum. $[Mo_4I_{11}]^{2-}$ reacts with diphos to produce $[Mo_4I_6(diphos)_2]$.[279] $[Mo_2Cl_4(PPh_3)_2(MeOH)_2]$, a typical quadruply bonded Mo^{II} dimer (Section 36.3.2.1), undergoes an interesting condensation reaction upon dissolution in benzene; thus, it loses MeOH to form $\{MoCl_2(PPh_3)\}_n$ which reacts with PR'_3 (R′ = Et, Bu^n) to form the corresponding, diamagnetic, tetramer $[Mo_4Cl_8(PR'_3)_4]$ (Figure 10). The Mo—Mo distances for the unbridged and bridged edges of the Mo_4 rectangle are 2.211(3) and 2.901(2) Å respectively, consistent with their formulation as Mo—Mo single and triple bonds respectively. Thus, these systems are molybdenum analogues of the cyclobutadiynes.[281] Alternative procedures may be used to prepare these and analogous tetramers; treatment of $K_4[Mo_2Cl_8]$ with the stoichiometric amount of PR'_3 in refluxing MeOH, or reaction of $[Mo_2(O_2CMe)_4]$ with $AlCl_3$ and PR'_3 (2:4:4) in THF, produces these systems and other derivatives corresponding to the general formula $[Mo_4X_8L_4]$ (X = Cl, Br, I; L = neutral donor ligand, *e.g.* PR'_3, PPh_3 MeOH, THF, RCN) have been isolated.[282] Also, $[Mo_4Cl_8\{P(OMe)_3\}_4]$ is formed when $[Mo_2Cl_4\{P(OMe)_3\}_4]$ is dissolved in CH_2Cl_2, or when $K_4[Mo_2Cl_8]$ reacts with $P(OMe)_3$ in MeOH.[283] The relationship of these tetrameric structures to β-$MoCl_2$ has been considered and the reaction of $[Mo_4Cl_8(PR'_3)_4]$ with $[Mo(CO)_4Cl_2]$ or $[Mo(CO)_6]$ in refluxing chlorobenzene shown to lead to phosphine extraction and the formation of the condensation products $[Mo_4Cl_8(PR_3)_2]_x$, for which the formulation $x = 2$ is favoured.[284] $[Mo_4X_3(OPr^i)_9]^-$ (X = Cl, Br), which have a structure similar to that of $[Mo_4F_4(OBu^t)_4]$ (Figure 8), react with MeCOX to form $[MoX_4(OPr^i)_8]$; an alternative preparative procedure is the reaction of $[Mo_2(OPr^i)_6]$ and MeCOX (1:2). The chloride derivative has a structure based on a square of

molybdenum atoms, some 2.37 Å apart, with eight μ-OPr^i groups and four terminal chloride ligands. This system may be viewed as a molybdenum analogue of cyclobutadiene. However, the bromide involves a butterfly arrangement of molybdenum atoms with five Mo—Mo distances of *ca.* 2.5 Å and one of 3.1 Å; the bromide ligands are all terminal and two of the OPr^i groups are terminal, two μ- and three μ_3-bridging.[285]

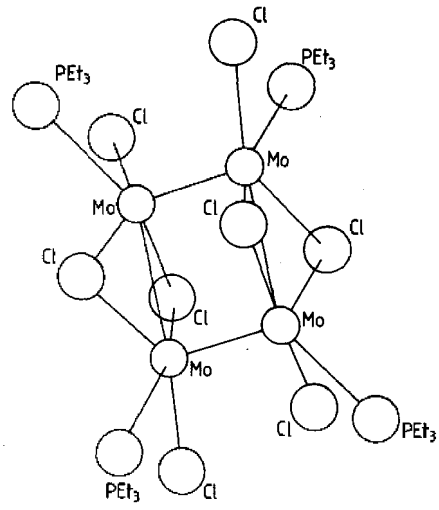

Figure 10 Structure of $[Mo_4Cl_8(PEt_3)_4]$[281]

$Ba_{1.13}Mo_8O_{16}$ contains two types of Mo_4O_{16} subunits which differ most significantly in their Mo—Mo distances and this difference can be correlated with the number of electrons involved in cluster bonding.[286,287] $[MoN(OBu^t)_3]$ reacts with $[Mo_2(OPr^i)_6]$ in hexane/Pr^{i}OH to form $[Mo_4(\mu_3\text{-}N)_2(\mu\text{-}OPr^i)_2(OPr^i)_{10}]$, the structure of which is shown in Figure 11 and involves contiguous Mo—Mo separations of 2.918(1), 2.552(1) and 2.918(1) Å.[288] The aquated $\{Mo_4O_4\}^{5+}$ ion has been claimed[256] and considered to possess a cubane-like structure, as identified in its sulfur analogue (*vide supra*).

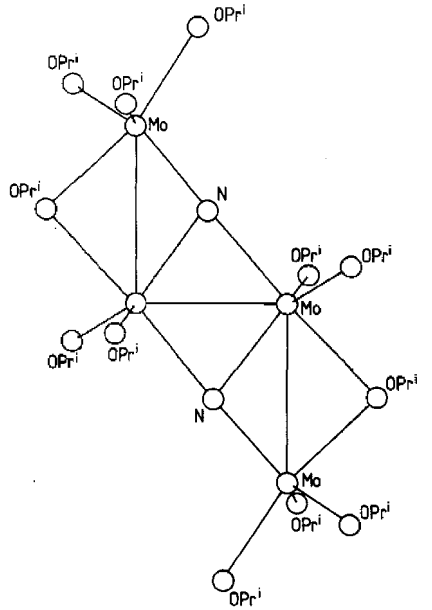

Figure 11 Structure of $[Mo_4(N)_2(OPr^i)_{12}]$[288]

Mo_4 clusters have been identified in many solid phases of molybdenum chalcogenides including $PbMo_6S_8$,[278] MoSX (X = Cl, Br, I)[289] and $GaMo_4(YY')$ (Y, Y' = S, Se, Te);[290] the physical properties of these systems are of particular significance. Tetrahedral arrays of

molybdenum atoms occur in $\{Mo_4S_4\}^{n+}$ cubane-like clusters which have been identified with a variety of ligands appended to the cluster. The number of electrons involved in the metal–metal bonding framework of these systems is variable and the most extensive, homologous, series is $[(Pr^iC_5H_4)_4Mo_4S_4]^{n+}$ ($n = 0, 1, 2$). These complexes are related by reversible, one-electron, redox reactions and oxidation causes only a slight decrease in the volume of the Mo_4 tetrahedra (Mo—Mo = 2.9–2.8 Å). The electronic structure of these systems has been discussed with reference to the MO scheme originally presented for $[Cp_4Fe_4S_4]$ and the PES data recorded for the neutral compound. The 12 electrons available for metal–metal bonding in $[(Pr^iC_5H_4)_4Mo_4S_4]$ are assigned to a_1, e and t_2 Mo—Mo bonding orbitals of the T_d cluster, with the a_1 and e orbitals being strongly bonding, but the t_2 orbital is less stable as manifest by its relatively low ionization potential.[291] $[Mo_4S_4(CN)_{12}]^{8-}$ also possesses a regular Mo_4 tetrahedron with 12 electrons in the Mo—Mo bonding orbitals and involves Mo—Mo separations of 2.855(1) Å.[259,292] An $\{Mo_4S_4\}^{5+}$ cluster has been prepared as the aquated ion and the complexes $[Mo_4S_4(NCS)_{12}]^{7-}$[256] and $[Mo_4S_4(edta)_2]^{3-}$[293] have been isolated; the latter complex approximates to S_4 symmetry with Mo—Mo distances which average 2.808 Å, possesses one unpaired electron, and is capable of undergoing a quasi-reversible one-electron oxidation or reduction. $\{Mo_4S_4\}^{6+}$ has been prepared as the aquated species and crystallized as its $[Mo_4S_4(NCS)_{12}]^{6-}$ salt; the central cluster possesses 10 electrons for metal–metal bonding and the observed change in structure from T_d to C_{3v} symmetry is consistent with a Jahn–Teller type distortion removing the degeneracy of the t_2 orbital to give a filled e and an empty a_2 orbital. The Mo_4 unit is a triangular pyramid with slant edges of length 2.791(1) Å and basal edges of 2.869(1) Å.[294] $[Mo_4S_4(S_2CNEt_2)_6]$ also involves an $\{Mo_4S_4\}^{6+}$ cubane-like cluster in which two of the dithiocarbamate ligands each form a bridge between the two molybdenum atoms on the opposite sides of the cube, the remaining four each coordinate to one molybdenum atom in a bidentate mode; the Mo—Mo distances range from 2.732(5) Å for two Mo atoms bridged *via* the same dithiocarbamate, to an average value of 2.861(6) Å for the other four Mo—Mo distances.[295] The cubane-like $\{Mo_4S_4\}^{6+}$ aquated ion is converted by aerial oxidation to the triangular $\{Mo_3S_4\}^{4+}$ aquated species (Section 36.3.3.1).[294]

36.3.3.3 Hexameric Clusters and Related Extended Arrays

The halides of molybdenum(II) were first described in 1848[296] and the structural characterization of the cluster species accomplished a century later for $[Mo_6Cl_8(OH)_4]\cdot 14H_2O$ and $[NH_4]_2[Mo_6Cl_{14}]\cdot H_2O$.[297] In idealized cubic symmetry, the $[Mo_6Cl_{14}]^{2-}$ ion consists of an octahedron of metal atoms (Mo—Mo is *ca.* 2.6 Å), ligated by eight μ_3 and six terminal chlorine atoms. This $\{Mo_6X_8\}^{4+}$ (X = Cl, Br, I) moiety has been demonstrated as a constituent of a large number of compounds,[298] including the dihalides Mo_6X_{12} which are isomorphous and possess a central Mo_6X_8 unit ligated by four μ and two terminal halides.[299] The reduction of higher molybdenum halides by aluminum in the appropriate $NaAlX_4$ (X = Cl, Br) melt provides a convenient and safe synthesis of the corresponding molybdenum(II) chloride or bromide in good yield.[300] The coordination chemistry of these $\{Mo_6X_8\}^{4+}$ species is well developed and includes the ligation of other halides, carboxylates, thiocyanates, alkoxide ions and a wide variety of neutral donor molecules at the terminal positions.[298,301] The bonding in these clusters has been defined and spectroscopic studies have shown that the $[Mo_6X_{14}]^{2-}$ (X = Cl, Br) ions are luminescent; these clusters undergo a one-electron oxidation and reduction and[303] electrogenerated $[Mo_6Cl_{14}]^{n-}$ ($n = 1$ or 3) ions react with electroactive donors or acceptors, respectively, to produce the luminescent state of $[Mo_6Cl_{14}]^{2-}$.[304]

The ions $[Mo_4I_{11}]^{2-}$[279,280] and $[Mo_5Cl_{13}]^{2-}$[305] may be considered as fragments of the $\{Mo_6X_8\}^{4+}$ cluster; the former involves a distorted tetrahedron, and the latter a square-based pyramid, of metal atoms. The mixed-metal halide cluster cations $\{Ta_5MoCl_{12}\}^{3+}$ and $\{Ta_4Mo_2Cl_{12}\}^{4+}$ have been obtained by reduction of $TaCl_5$–$MoCl_5$ mixtures with aluminum in fused $NaAlCl_4$–$AlCl_3$ at 325 °C and these cations are considered to be molybdenum-substituted derivatives of $\{Ta_6Cl_{12}\}^{n+}$ clusters.[306]

Substitution of sulfide and selenide into $\{Mo_6X_8\}^{4+}$ (X = Cl, Br, I) centres has been achieved in a host of solid phases and cores such as $\{Mo_6Cl_7S\}^{3+}$, $\{Mo_6Br_8S_2\}$, $\{Mo_6I_8Y_2\}$ (Y = S, Se), $\{Mo_6Br_6S_3\}$, $\{Mo_6Cl_2S_6\}$[290,307] and $MMo_6(S_{1-x}Se_x)_8$ (M = La, Yb, Sm, Ca, Sr, Ba, Eu, Sn, Pb)[308] have been characterized. Chevrel phases, *i.e.* ternary molybdenum chalcogenides, $M_xMo_6X_8$ (typically M = Pb, Sn or a rare earth element; X = S or Se) are of particular interest because of their physical properties—high superconducting critical temperatures, high critical

fields and coexistence of magnetic order and superconductivity. Considerable flexibility in composition exists for these phases since, in addition to the variations indicated above, the ratio of Mo:X can be increased from the ideal 6:8 value. The fundamental structural unit in the Chevrel phases is an Mo_6 cluster and these units are coupled together to give linear arrays of the general composition $Mo_{3n}X_{3n+2}$ ($n = 2, 3, 4 \ldots \infty$; X = S, Se, Te).[309] A combined MO and crystal orbital analysis[310] has been presented for these systems and for $NaMo_4O_6$, which is also a metallic, infinite-chain polymer, derived from the condensation of Mo_6 octahedra.[311] Oxygen-donor ligands will also support discrete Mo_6 clusters; thus, Mo_6Cl_{12} when refluxed with NaOMe in MeOH forms $Na_2[\{Mo_6Cl_8\}(OMe)_6]$ and eventually $Na_2[\{Mo_6(OMe)_8\}\{OMe\}_6]$.[312]

36.4.1 MOLYBDENUM(III)

36.4.1.1 Introduction

Molybdenum(III) is a relatively rare oxidation state and is easily oxidized to more stable states by air and other mild oxidants. However, recent work has shown the existence of many Mo^{III}

compounds in both aqueous and nonaqueous systems. Also, Mo^{III} may be involved in catalytic and biological reactions of molybdenum, such as dinitrogen reduction, but there is no firm evidence for this.

This section omits the aqueous chemistry of Mo^{III} (see Section 36.1.2), Mo—Mo triple bonds, including $[Mo_2X_9]^{3-}$ (see Chapter 36.3), $[CpMo(SR)_2]$ and related compounds, and Mo—S clusters (see Section 36.6.5).

Molybdenum trihalides may be prepared either by reduction of higher halides or by direct combination of the elements.[1] They all adopt extended lattice structures: MoF_3 has a rhombohedral structure similar to VF_3 and CrF_3;[2] $MoCl_3$ exists in two polymorphic forms in which Mo atoms occupy octahedral holes in cubic (α) or hexagonal (β) close-packed arrays of chlorines;[3] $MoBr_3$ and MoI_3 have structures containing polymeric strings made up of face-sharing MoX_6 octahedra.[4] The magnetic moments of the trihalides given in Table 1[5] show an increase from Cl to I, indicative of antiferromagnetic coupling between adjacent Mo atoms which decreases with the increase in the metal–metal distance.

Table 1 Magnetic Moments of Molybdenum(III) Complexes

Compound	μ_{eff} (BM)	T (K)	*Ref.*
$MoCl_3$	0.7	a	1
$MoBr_3$	1.2	a	1
MoI_3	1.4	a	1
$Mo(SPh)_3$	0.77	293	6
$Mo(SC_5H_{11})_3$	1.17	293	6
$K_3[MoCl_6]$	3.79	300	37
$K_3[Mo(NCS)_6]\cdot 4H_2O$	3.79	300	37
$[Mo(en)_3](NCS)_3$	3.65	300	34
$MoI_2(phen)_2]\cdot I$	3.69	293	15
$[Mo(acac)_3]$	3.82	302	23
$[Mo(S_2PF_2)_3]$	3.53	b	28
$K_4[Mo(CN)_7]\cdot 2H_2O$	1.73	298	35

[a] Room temperature. [b] Temperature not specified.

Compounds of the stoichiometry $Mo(SR)_3$ can be prepared by oxidation of Mo^0 complexes using thiols or disulfides.[6] Their spectroscopic properties and low magnetic moments, ranging from 0.77 to 1.17 BM (Table 1), indicate a polymeric structure with considerable metal–metal interaction.

36.4.1.2 Monomeric Complexes

36.4.1.2.1 Halide complexes

$K_3[MoF_6]$ can be prepared by reacting $K_3[MoCl_6]$ or MoO_3 with KF or KHF_2; the anion contains Mo octahedrally coordinated with Mo—F bond lengths of 2.00(2) Å.[7] $M^I_3[MoCl_6]$ and $M^I_3[MoBr_6]$ ($M^I = Li^+$, K^+, NH_4^+) have been obtained by electrolytic reduction of MoO_3 in HCl or HBr solution respectively, followed by addition of the appropriate alkali metal halide. Other products isolated from these reactions include salts of the $[MoCl_5(H_2O)]^{2-}$ and $[MoBr_5(H_2O)]^{2-}$ anions.[8] Crystal structure determinations of salts containing these ions all show that the Mo^{III} possesses simple octahedral coordination with typical average bond lengths of, for example, 2.452(3) Å for Mo—Cl in $[Ph_2HP(CH_2)_2PHPh_2]_3[MoCl_6]_2\cdot 12H_2O$,[9] 2.591(1) Å for Mo—Br in $[LH]_2[H_5O_2][MoBr_6]$ (L = 2-amino-4,6-dihydroxypyrimidine),[10] and 2.155(3) Å or 2.185(3) Å for Mo—O in the hydrolysis products $[NH_4]_2[MoCl_5(H_2O)]$ and $[NH_4]_2[MoBr_5(H_2O)]$, respectively.[11] Other monosubstituted halide anions, such as the nitrile complexes $[MoCl_5(NCR)]^{2-}$,[12] can be prepared by ligand substitution from $[MoX_6]^{3-}$ species. $[NEt_3H][MoCl_4(THF)_2]$, obtained from the reduction of $[MoCl_4(THF)_2]$ in the presence of NEt_3, involves octahedral stereochemistry around the Mo, with the THF molecules adopting a *trans* geometry. This complex can be used as a starting material in the synthesis of other disubstituted anions.[13] A *trans* geometry has also been established for the anion of $[SMe_3][MoBr_4(SMe_2)_2]$, formed in the reaction of $MoBr_4$ with Me_2S.[14]

A large number of neutral complexes of the form $[MoX_3L_3]$ (X = halide; L = neutral ligand) are known. These are easily prepared by direct combination of MoX_3 and L, or by substitution

reactions of $[MoX_6]^{3-}$. They can also be formed by a disproportionation reaction of the corresponding Mo^{II} complex $[Mo(CO)_4X_2]$, with L acting as the solvent,[15] or by reduction of the appropriate Mo^{IV} complex $[MoX_4L_2]$. This last reaction has been used to prepare, in high yield, $[MoCl_3(THF)_3]$, which is a useful starting material for the synthesis of other Mo^{III} compounds.[16] Generally, these complexes adopt a *meridional* configuration, even for the tridentate macrocyclic polythiaether 1,4,7,10,13,16-hexathiacyclooctadecane, which forms polymeric chains.[17] However, the *facial* isomer is formed with the tridentate ligand 1,4,7-trimethyl-1,4,7-triazacyclononane.[18] Crystal structure determinations have confirmed the *meridional* geometry of $[MoCl_3(py)_3]$ and $[MoX_3(pic)_3]\cdot 0.5pic$ (X = Cl, Br; pic = 4-methylpyridine).[19]

Mo^{III} halide complexes formed with chelating diazadienes or diamines (N—N) include $[MoCl_3(CNMe)(N—N)]$ species; with aromatic chelates such as 1,10-phenanthroline or 2,2′-bipyridine, salts containing the cation *cis*-$[MoCl_2(N—N)_2]^+$ have been isolated.[20] Compounds of stoichiometry $[MoX_3L_4]$ are known for X = Cl, Br; L = RCN and X = Br; L_2 = 2,6-lutidine,[15] but it is not clear whether these involve seven-coordinate Mo^{III}.

The reaction of potassium hydrotris(3,5-dimethyl-1-pyrazolyl)borate, $K[HB(3,5\text{-}Me_2pz)_3]$, with $[MoCl_3(THF)_3]$ gives the yellow crystalline compound $[K(THF)_3][HB(3,5\text{-}Me_2pz)_3MoCl_3]$. Its magnetic susceptibility (3.69 BM), electronic spectrum and ESR spectrum are consistent with a d^3, $S = \frac{3}{2}$ ground state. An X-ray diffraction study of $[NEt_4][HB(3,5\text{-}Me_2pz)_3MoCl_3]\cdot MeCN$ has revealed a monomeric anion with near octahedral *facial* coordination about the metal. This compound undergoes two one-electron oxidations: Mo^{III}/Mo^{IV} at +0.49 V and Mo^{IV}/Mo^{V} at +1.55 V (*vs.* SCE). As anticipated from the value of the former couple, $[HB(3,5\text{-}Me_2pz)_3MoCl_3]$ is readily reduced to the Mo^{III} anion by mild reductants such as sulfide and alcohols. The stabilization of the Mo^{III} by the polypyrazolylborate has been attributed to the interaction of the Mo d_π orbitals with the ligand π^* orbitals. This view receives support from the preparation of $[(HBpz_3)MoCl_2(pyrazole)]$ by reacting $MoCl_5$ with potassium hydrotris(1-pyrazolyl)borate, $K[HBpz_3]$, in aqueous HCl without the addition of a reducing agent. The structure of this Mo^{III} derivative has been determined and shown to be similar to that of $[HB(3,5\text{-}Me_2pz)_3MoCl_3]$, with replacement of a chloride by a pyrazole group.[21] $[NBu_4][MoBr_4(dppe)]$ has been obtained as a minor product of the reaction of $[NBu_4]_2[Mo_2Br_6]$ with dppe in Me_2CO and its crystal structure has been determined; the Mo atom displays a distorted octahedral coordination geometry.[22]

36.4.1.2.2 Complexes with oxygen and sulfur donor ligands

$[Mo(acac)_3]$ is conveniently prepared from $[MoCl_6]^{3-}$ and Na(acac) or by oxidation of $[Mo(CO)_6]$ with Hacac;[23] the molecule has an octahedral geometry of approximately D_3 symmetry, with Mo—O bonds of average length 2.04(1) Å.[24] Several other tris(β-diketonates) of Mo^{III} are known and, with an unsymmetrical ligand, *facial* and *meridional* isomers have been isolated.[25] Oxidative decarbonylation of $[Mo(CO)_6]$ has also been used to prepare the O,S-bound analogue tris(monothiadibenzoylmethanato)molybdenum(III).[26] A complex of the stoichiometry [Mo(HL)L] is formed in the reaction between the tridentate O,S,N ligand salicylidenethiosemicarbazone (H_2L), and $[Mo(NCS)_6]^{3-}$.[27]

Dithiophosphate[16,28] and dithiocarbamate[29] ligands, $(S—S)^-$, form pseudooctahedral complexes $[Mo(S—S)_3]$ with Mo^{III}; in $[Mo\{S_2P(OMe)_2\}_3]$, the Mo—S average distance is 2.507(2) Å.[16] The Mo^{IV} complex $[MoCl(S_2CNEt_2)_3]$ can be reduced by SO_2 to give $[Mo(S_2CNEt_2)_3(\eta^2\text{-}SO_2)]$, which has an eight-coordinate structure, with the SO_2 bonded through the sulfur and one oxygen atom.[30] Mixed thiolate diphosphine complexes *trans*-$[Mo(SR)_2(diphos)_2]^+$ can be oxidized by $FeCl_3$ or $CuCl_2$ to give $[Mo(SR)_2(diphos)_2]^+$, which has been isolated as the $[FeCl_4]^-$ or $[BPh_4]^-$ salt.[31]

36.4.1.2.3 Complexes with nitrogen donor ligands

A variety of salts containing the $[Mo(NCS)_6]^{3-}$ ion are known, in which the ligand is bonded through nitrogen with almost linear Mo—N—C arrangement. In $K_3[Mo(NCS)_6]\cdot H_2O\cdot MeCO_2H$ the average Mo—N distance is 2.09 Å.[32] A selenocyanate complex, $[NEt_4]_3[Mo(NCSe)_6]$, has also been isolated.[33] Substitution reactions between $[Mo(NCS)_6]^{3-}$ and bidentate nitrogen

ligands, such as 1,2-diaminoethane, give various products containing one, two or three chelates per molybdenum.[34]

36.4.1.2.4 Cyanide complexes

The cyanide ligand, when present in excess, replaces chloride in $[MoCl_6]^{3-}$ to give the seven-coordinate complex $[Mo(CN)_7]^{4-}$. In aqueous solution a pentagonal bipyramidal geometry is adopted, but in the solid state spectroscopic studies indicate a lower symmetry for $K_4[Mo(CN)_7]\cdot 2H_2O$.[35] The crystal structure of $NaK_3[Mo(CN)_7]\cdot 2H_2O$ shows a relatively undistorted pentagonal bipyramidal coordination sphere, with average Mo—C distances of 2.160(3) Å.[36]

36.4.1.2.5 Magnetic and electronic properties

All the monomeric molybdenum(III) complexes are paramagnetic, and in Table 1[5] the magnetic moments of some typical examples are given. For six-coordinate compounds the values lie between 3.53 and 3.86 BM, with most in the region 3.7 to 3.8 BM as predicted for octahedral d^3 complexes.[37] The value of 1.73 BM in $K_4[Mo(CN)_7]\cdot 2H_2O$ is consistent with a spin-doublet ground state d^3 system.[35]

ESR spectroscopy has been used to examine molybdenum(III) complexes with Cl, O, S and N donor ligands.[38] At temperatures between 5 and 80 K, these compounds show broad axial or rhombic signals centred at $g = 2$ and 4. For $[Mo(acac)_3]$ the estimated A values are 10 ± 1 (x, y) and 12.2 ± 0.5 (z) mK. Complexes with sulfur atoms which are part of an extended π system have typical ESR spectra, with all g values near 2.

Electronic absorption spectra of Mo^{III} species can be interpreted using a ligand field approach for a d^3 ion with octahedral symmetry.[39] Three spin-allowed transitions should be seen, corresponding to excitation from the ground state $^4A_{2g}$ to $^4T_{2g}$, $^4T_{1g}(F)$ and $^4T_{1g}(P)$ states. Bands due to spin-forbidden transitions to ^2E_g, $^2T_{1g}$ and $^2T_{2g}$ states can also be detected because of spin–orbit coupling. Table 2 lists the absorption bands observed in some typical complexes.[5] For compounds of the form $[MoX_3L_3]$, the lower symmetry leads to a loss of degeneracy within the T states and this has been observed in some systems, and used to demonstrate the formation of *meridional* rather than *facial* isomers.[15]

Table 2 Electronic Absorption Spectra of Molybdenum(III) Complexes (transitions in cm^{-1}, molar extinction coefficients in parentheses)

Complex	$^4A_{2g} \rightarrow {}^2E_g, {}^2T_{1g}$	$^4A_{2g} \rightarrow {}^2T_{2g}$	$^4A_{2g} \rightarrow {}^4T_{2g}$	$^4A_{2g} \rightarrow {}^4T_{1g}$ (F)	*Ref.*
$[MoCl_6]^{3-}$	9500 (1.4)	14 800 (2.0)	19 400 (23)	24 200 (38)	39
$[MoCl_5(H_2O)]^{2-}$	8500 (4.0)	15 300 (3.1)	19 700 (29)	25 500 (51)	39
$[MoCl_3(py)_3]$	8800 (7.0)	14 500 (7.0)			39
$[Mo(S_2PF_2)_3]$			20 020 (205)	24 310 (99)	28

Phosphorescence has only been observed in $[MoX_3L_3]$ complexes with L = urea or thiourea. The emission lies between 9000 and 10 000 cm^{-1}, and has been assigned to the $^2E_g \rightarrow {}^4A_{2g}$ transition.[40]

36.4.1.3 Dimeric and Polymeric Complexes

The best characterized Mo^{III} dimers are those with a Mo—Mo triple bond alone between the metal atoms or bridged by halides, as in $[Mo_2X_9]^{3-}$, complexes which are discussed in Section 36.3.2.2.6. Substitution of three halides by neutral ligands gives complexes of the type $[Mo_2X_6L_3]$, which probably retain the halide bridges. One example is $[Mo_2Cl_6(THF)_3]$, which is formed from the monomeric $[MoCl_3(THF)_3]$ in solution.[41]

The reactions between $K_3[MoCl_6]$ and various thiols yield dimeric or polymeric complexes of uncertain stoichiometry, thought to be $[Mo_2Cl_4(SR)_2(H_2O)_3]$ or $[Mo_4Cl_7(SR)_5(H_2O)_7]$, with magnetic moments which indicate considerable metal–metal interaction.[42] Crystal structures

have been determined for the chloride-bridged compounds $[PPh_4][(Me_2S)Cl_2Mo(\mu\text{-}Cl)_3MoCl_2(SMe_2)]$ and $[(Me_2S)Cl_2Mo(\mu\text{-}SMe_2)(\mu\text{-}Cl)_2MoCl_2(SMe_2)]$,[43] and of the bromide-bridged compound $[LBrMo(\mu\text{-}Br)(\mu\text{-}OH)MoBrL]Br_2\cdot 4H_2O$ (L = 1,4,7-triazacyclononane).[44] In the chloride complexes, the structure around the Mo atoms is confacial bioctahedral, with three bridging atoms. For the bromide, each molybdenum is octahedrally coordinated and the two centres share a common edge. The short Mo—Mo distances in these compounds indicate strong metal–metal bonding.

Oxo-bridged dimers such as $[Mo_2O_3(H_2O)_5(DMF)]$ and $[Mo_2O_3(DMSO)_3]$ can be obtained by heating $[Mo(CO)_6]$ in wet DMF or DMSO.[45] Other dimeric species have been characterized with a variety of O and N donor ligands, including $[Mo_2O_2Cl_2(H_2O)_xL_y]$ (L = bipy, 4,4′-bipy, pyrrole, pyridazine, py),[46] $[Mo_2O(C_2O_4)L_2(H_2O)_4]$ (HL = phenylalanine),[47] and $[Mo_2O_2(HL)_4]^{2-}$ (H_2L = cysteine).[48] Low magnetic moments of these and analogous complexes, of between 0.4 and 0.6 BM, provide clear evidence for spin pairing between the metal centres.

Molybdenum(III) complexes of 1,4,7-triazacyclononane (L) dimerized by hydroxide bridges can be prepared by hydrolysis of the corresponding $[LMoCl_3]$ complexes.[49,50] Crystal structure determinations on $[LClMo(\mu\text{-}OH)_2MoClL]I_2$ and $[LMo(\mu\text{-}OH)_2(\mu\text{-}O_2CMe)MoL]I_3\cdot H_2O$ have revealed a distorted octahedral geometry around the Mo atoms in both cases, with short Mo—Mo distances thought to indicate a formal bond order of three.[49] In the complex $K[Mo_2(\mu\text{-}OH)_2(\mu\text{-}O_2CMe)(edta)]$, the hexadentate ethylenediaminetetraacetate also bridges the Mo—Mo bond *via* the two N atoms (see **9**, Section 36.1.2).[51] Edta is thought to bridge in a similar manner in the oxo-bridged complexes $MH[Mo_2(\mu\text{-}O)_2(edta)]\cdot nH_2O$ (M = Li, Na, K, NH_4).[52] A mixed oxidation state tetrameric molybdenum(III,IV) complex $Na_4[Mo_4O_4(OH)_2(edta)]\cdot 12H_2O$ has been structurally characterized, and shows essentially two dimeric species connected *via* oxo bridges (see **4**, Section 36.1.2). With the optically active ligand (*R*)-propylenediaminetetraacetate [(*R*)-pdta], strong peaks are observed in the CD spectrum of $[Mo_2(\mu\text{-}OH)_2(\mu\text{-}O_2CMe)\{(R)\text{-pdta}\}]^-$, indicating that the four coordinated carboxylate oxygens arrange asymmetrically.[53]

Dithiocarbamate compounds of Mo^{III} can be prepared by oxidative decarbonylation of $[Mo(CO)_6]$, giving complexes of the form $[Mo_2(R_2dtc)_6]$.[54] Spectroscopic evidence is consistent with the presence of two bridging R_2dtc ligands. The crystal structure of $[(Et_2NCS_2)_2Mo(\mu\text{-}CSC(S)S)(\mu\text{-}S_3C_2NEt_2)Mo(S_2CNEt_2)]$, a product of the reaction between CS_2 and $[Mo(CO)_2(S_2CNEt_2)_2]$, has been determined; the bridging ligands appear to be formed by the insertion of CS into CS_2 and $Et_2NCS_2^-$.[55] Mixed oxidation state molybdenum(III,VI) complexes $[PPh_4]_2[S_2Mo(\mu\text{-}S)_2MoBr_3(SMe_2)]$ and $[PPh_4][S_2Mo(\mu\text{-}S)_2MoBr_2(NO)_2]$, in which the Mo atoms are linked by sulfido bridges, have been prepared by the reaction between $[PPh_4]_2[MoS_4]$ and $MoBr_4$ or $[MoBr_2(NO)_2]$.[56] A disulfide bridge and a sulfur dioxide bridge are found in the $[Mo_2(\mu_4\text{-}S_2)(\mu_2\text{-}SO_2)(CN)_8]^{4-}$ anion, the structure of which has been determined as its $[PPh_4]^+$ and K^+ salts; in the former the Mo—Mo separation is 2.730(4) Å, whereas the latter involves two different anions with Mo—Mo distances of 2.691(1) and 2.974(1) Å, respectively.[57] The salts $K_6[Mo_2(CN)_{12}S]\cdot 4H_2O$[58,59] and $K_{6.68}[MoO_4]_{0.34}[Mo_2(CN)_{12}S]\cdot 5.32H_2O$[58] have been isolated. The crystal structure of the latter has shown that the anion involves the two metal atoms, each in a pentagonal bipyramidal environment, bridged by an axial sulfur atom (Mo—S—Mo *ca.* 170°). The diamagnetic nature of the compounds and their electronic spectra are consistent with $S(p_\pi) \rightarrow Mo(d_\pi)$ bonding over the Mo—S bonds of length *ca.* 2.17 Å.

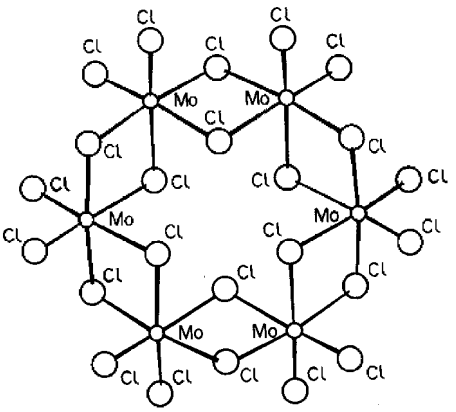
36.4.2 MOLYBDENUM(IV)

36.4.2.1 Introduction

The coordination chemistry of Mo^{IV} is diverse and involves an extensive range of monomeric and trimeric systems; the latter are described in Chapter 36.3 together with the few dimeric systems which involve a Mo—Mo double bond. Although there are many examples of monomeric oxo complexes, unlike the higher oxidation states, Mo^{IV} forms a comparable range of non-oxo complexes and exhibits a greater versatility in coordination number, with examples of four to eight, inclusive, being well established.

The most important binary systems which (formally) involve Mo^{IV} are the chalcogenides MoS_2 and $MoSe_2$; some comments on these systems are included in Section 36.6.3. The synthesis and properties of molybdenum(IV) halides have been thoroughly investigated.[1,60]

Fluorination of $[Mo(CO)_6]$ at −75 °C forms the olive green material Mo_2F_9, which decomposes on heating to the volatile MoF_5 and the light green, involatile MoF_4; reduction of MoF_5 with elemental silicon (4:1) provides an alternative route to MoF_4. The Raman spectrum of MoF_4 suggests that the material possesses a structure similar to that of NbF_4.[61] $MoCl_4$ exists in three forms. α-$MoCl_4$, conveniently prepared[62] by the prolonged refluxing of $MoCl_5$ and C_2Cl_4 in CCl_4, is isomorphous with $NbCl_4$ and comprises infinite chains of $MoCl_6$ octahedra sharing opposite edges over alternating long and short Mo—Mo distances, with magnetic exchange occurring down these chains leading to a room temperature effective magnetic moment of 0.85 BM. β-$MoCl_4$ is obtained by reduction of $MoCl_5$ by molybdenum metal under carefully controlled conditions;[3] the structure consists of cyclic $(MoCl_4)_6$ aggregates in which each molybdenum is octahedrally coordinated by two terminal and four bridging chlorines (Figure 1).[63] The closest approach between the Mo atoms (3.67 Å) does not lead to any significant spin-pairing (μ_{eff} *ca.* 2.4 BM). A third form of $MoCl_4$ has been obtained by treatment of MoO_2 in a stream of CCl_4 vapour.[64] $MoBr_4$ may be synthesized by the reaction between $MoBr_3$ and warm (60 °C) liquid bromine.[65] The tetrahalides are reactive, for example to air and water, and may be used as starting materials for the synthesis of Mo^{IV} complexes.



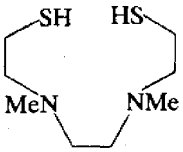


Figure 1 The structure of the $(MoCl_4)_6$ molecule in β-$MoCl_4$[63]

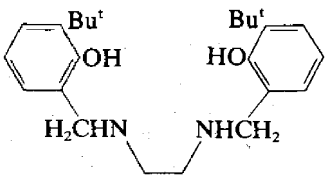

$MoOCl_2$ has been prepared by various chemical transport reactions[1] and $MoSCl_2$ and $MoSeCl_2$ have been described.[66] MoO_2 may be prepared by reduction of MoO_3 by H_2, the compound adopts a distorted rutile structure with Mo---Mo separations of 2.5106(5) and 3.1118(5) Å,[67] the former leading to spin pairing and the absence of a permanent magnetic moment on the metal centres.[68]

Mononuclear Mo^{IV} oxo complexes have special relevance to the molybdenum centres in the molybdenum-containing enzymes. $[MoO(S_2CNR_2)_2]$ complexes undergo addition reactions with a wide variety of unsaturated molecules.[69–79] These were once held to be of relevance to the activation of the substrates of nitrogenase prior to reduction; however, the nature of the molybdenum centre in these $[MoO(S_2CNR_2)_2]$ molecules has not been demonstrated to have any significant similarity to the catalytic site within the Fe—Mo—S cluster of the nitrogenases (see Section 36.6.2) and, therefore, detailed comparisons are unwarranted. $[MoO(S_2CNR_2)_2]$ and a selection of other Mo^{IV} complexes are special in respect of participating in reversible oxygen atom transfer, $MoO^{2+} + XO \rightarrow MoO_2^{2+} + X$, which have particular relevance to the catalyses effected at the molybdenum centres of oxomolybdoenzymes such as xanthine oxidase, sulfite oxidase or nitrate reductase.[80] The forward reaction was first observed in 1972 for $[MoO(S_2CNR_2)_2]$ complexes[81] and X = Ph_3P and this reaction has been developed and used for the preparation of MoO^{2+} complexes[82–84] and the mechanism defined.[85,86] A complicating feature of this reaction is the dimerization (equation 1) which is prevented in the oxomolybdoenzymes by structural constraints within the macromolecular assembly. Macrocyclic ligands have been employed in chemical studies to prevent such dimerization and, thereby, have allowed the development of more realistic chemical analogues of the oxomolybdoenzymes. These ligands include the anions of the molecules (Figure 2)[84,87–91] and these studies represent elegant developments in the coordination chemistry of molybdenum.

36.4.2.2 Monomeric Complexes with Oxo Groups

36.4.2.2.1 General comments

Oxo complexes dominate the chemistry of molybdenum in its higher oxidation states,[5,80,92,93] and play a major role in the catalytic activity of molybdenum in biological systems (see Section 36.6.7). Mo^{IV} complexes have been characterized containing the monooxo $\{MoO\}^{2+}$ and the *trans*-dioxomolybdenum(IV) $\{MoO_2\}$ cores, but no compound has been isolated analogous to the *cis*-dioxomolybdenum(VI) species described in Section 36.5. Crystal structure determinations have been accomplished for a number of Mo^{IV} complexes, and some typical examples are listed in Table 3.[80]

Table 3 Molybdenum–Oxygen Bond Lengths of some Oxomolybdenum(IV) Complexes[80]

Compound	*Mo—O$_t$ (Å)*	*Ref.*
$[MoO(S_2CNPr^n_2)_2]$	1.665	100
trans-$[MoO(hd)(SH)][CF_3SO_3]$[a]	1.667	103
cis,mer-$[MoOCl_2(PEt_2Ph)_3]$[b]	1.803	107
cis,mer-$[MoOCl_2(PMe_2Ph)_3]$[c]	1.676	108
$\{MoOCl(dppe)_2\}[ZnCl_3(OCMe_2)]$	1.69	111
$NaK_3[MoO_2(CN)_4]$	1.834	120
$[Cr(en)_3][MoO(OH)(CN)_4]$	1.698	121
$[Pt(en)_2][MoO(OH_2)(CN)_4]$	1.668	121
$[MoOCl(CNMe)_4](I_3)$	1.636	126

[a] hd = 1,5,9,13-tetrathiacyclohexadecane. [b] Green isomer. [c] Blue isomer.

The nature of the bonding of oxo groups to molybdenum has been discussed in several reviews.[80,92,93] There are three components to molybdenum–oxygen terminal bonds (Mo—O$_t$), comprising a σ interaction along the bond axis (z axis) and two mutually perpendicular π components, each formed by the overlap of an oxgyen p_π orbital (p_x or p_y) with the appropriate molybdenum d_π orbital (d_{xz} or d_{yz}). Normally, each component is considered to

involve donation of an electron pair from O^{2-} to a vacant orbital of the metal, and the formal bond order varies according to the degree of π interaction. Correlations have been observed between the bond order of a Mo—O_t bond and its length and force constant, with a high bond order corresponding to shorter and stronger bonds.[94-96] Generally, the Mo—O_t bond lengths in monooxomolybdenum(IV) compounds are ~1.67 Å (Table 3), consistent with a triple bond: for the *trans*-dioxo species a longer bond length of ~1.83 Å (Table 3) is found, indicative of a bond order between one and two.

In monooxomolybdenum(IV) centres the Mo—O_t bonding dominates the ligand field at the molybdenum, so that the two valence electrons of the metal are spin-paired in an orbital which is in the plane (xy) perpendicular to the Mo—O_t bond, and the complex has the $(d_{xy})^2$ configuration. The dioxo anion *trans*-$[MoO_2(CN)_4]^{4-}$ also possesses this configuration;[97] the two d electrons are in an orbital which is nonbonding with respect to the oxo groups and the σ orbitals of the cyano groups and, hence, at a lower energy than the other d orbitals. This situation may be further stabilized by back-bonding from $(d_{xy})^2$ into the π^* orbitals of the CN^- ligands. Similarly, ligand field stabilization may explain the formation of *trans*-$[MoO_2(CO)_4]$ in the photooxidation of $[Mo(CO)_6]$.[98]

The coordination sphere of molybdenum in the oxomolybdenum enzymes is believed to contain oxo and sulfur ligands,[80] and, therefore, interest has focussed on oxo complexes of Mo^{IV} with S-donor ligands as possible models for the reduced state of these systems. A number of oxomolybdenum(IV) complexes contain a five-coordinate $MoOS_4$ coordination sphere, including the dithiocarbamate species $[MoO(S_2CNR_2)_2]$. These can be prepared by reduction of the Mo^V dimers $[Mo_2O_3(S_2CNR_2)_4]$ using zinc dust or thiophenol, or by reduction of aqueous solutions of $Na_2[MoO_4]$ and $Na(S_2CNR_2)$ with dithionite.[99] An alternative route is by the reaction of PPh_3 with the corresponding Mo^{VI} complex, $[MoO_2(S_2CNR_2)_2]$,[81] in which one atom of oxygen is transferred from the molybdenum to the phosphorus in a reaction which may be analogous to the role played by the molybdenum in xanthine oxidase and other related enzymes.[80] The reverse reaction, involving abstraction of an oxygen atom from a substrate molecule by the monooxo Mo^{IV} complex to give the *cis*-dioxo Mo^{VI} complex, has been observed with dioxygen or pyridine *N*-oxide;[73] the claim that this also occurs with Ph_3PO appears to be erroneous. A kinetic study of the forward and reverse oxygen atom transfer reactions with $[MoO(S_2CNEt_2)_2]$ has shown that the dominant factor in determining reaction rate is the breaking of the bond to oxygen in the substrate.[85] The act of oxygen atom transfer has been suggested to involve a transition state comprising one molecule of each reactant, and the donation of the lone pair of electrons on phosphorus into the Mo=O π^* orbital, thus weakening the Mo—O bond and forming the P—O bond to produce the molybdenum(IV) complex $[MoO(Et_2dtc)_2(Ph_3PO)]$. Isomerization followed by the loss of Ph_3PO would produce the reaction products.[86] The Mo^{IV} complexes can also react with one of the oxo groups of $[MoO_2(S_2CNR_2)_2]$ to give the oxo-bridged Mo^V dimer $[Mo_2O_3(S_2CNR_2)_4]$ (equation 1).

The crystal structure of $[MoO(S_2CNPr^n_2)_2]$ has shown that the molecules possess a square pyramidal geometry, with the molybdenum displaced out of the plane of the four sulfur atoms in the direction of the axial oxo ligand;[100] the Mo—O_t distance is 1.695 Å. Complexes of this type are coordinatively unsaturated and react with ligands, such as pyridine, phosphines, alkynes and alkenes, to form 1:1 adducts. Spectroscopic evidence has indicated that the unsaturated molecules add to produce a seven-coordinate complex,[74] and this has been confirmed by a crystal structure determination of the tetracyanoethylene (TCNE) adduct of $[MoO(S_2CNPr^n_2)_2]$,[72] which shows distorted pentagonal bipyramidal coordination around the molybdenum. The equatorial plane contains the two ethene carbons of TCNE and three of the sulfur atoms; the fourth sulfur occupies an axial position *trans* to the oxo ligand, and the Mo—O_t bond length is 1.682(4) Å. Although the oxidation state of the molybdenum is difficult to define in these compounds, IR spectra of some ethyne adducts suggests that they are complexes of Mo^{VI}, formed by oxidative addition,[76] the d^2 electrons of the molybdenum being donated into the π^* orbital of the multiple bond. Kinetic studies of these addition reactions indicate that they proceed *via* a monocapped trigonal prismatic intermediate, followed by intramolecular rearrangement.[77,78]

$[MoO(S_2CNR_2)_2]$ forms 1:1 adducts with molecules containing nitrogen–nitrogen double bonds in which the —N=N— moiety is thought to be sideways bonded to the molybdenum *via* both nitrogen atoms. In contrast, an end-on nitrogen–molybdenum σ bond is formed in the reaction between molecules of the type $[MoO_2(S_2CNR_2)_2]$ and R'NNH, to produce the adducts $[(R'NN)Mo(S_2CNR_2)_3]$.[71] These complexes may be of interest as models for the intermediates formed during reduction of N_2 by the nitrogenases;[5] the adduct $[MoO(S_2CNEt_2)_2(R'NNR')]$

($R' = CO_2Et$) can be hydrolyzed in moist $CHCl_3$ to produce R'NHNHR' and $[MoO_2(S_2CNEt_2)]$, showing that the N=N bond is activated by adduct formation.[69] The crystal structure of the adduct $[MoO(PhCONNCOPh)(S_2CNMe_2)_2]\cdot C_2H_4Cl$ has been determined.[79] The stereochemistry about the molybdenum is that of a distorted pentagonal bipyramid; the sulfur atoms of the dithiocarbamate ligands and a nitrogen atom of the benzoyldiazene ligand occupy the equatorial positions and the axial sites are occupied by the terminal oxo group and an oxygen atom of the diazene, which thus forms a five-membered chelate ring.

Studies of Mo^{IV}/Mo^{VI} redox reactions involving $[MoO(SCNR_2)_2]$ complexes are complicated by the formation of the Mo^V dimer, $[Mo_2O_3(S_2CNR_2)_4]$ (equation 1). In biological systems this type of dimerization is prevented by structutal constraints exercised by the enzyme, and attempts have been made to emulate this by preparing model compounds with chelates, some of which introduce steric constraints at the metal. Complexes with polydentate ligands of the form [MoOLL'] (L = salicylaldehyde-2-hydroxyanil, salicylaldehyde-2-mercaptoanil; L' = bipy, phen) and [MoOL] (L = *N,N'*-bis(2-mercapto-2-methylpropyl)-1,2-diaminoethane) have been investigated.[84] They undergo electrochemical one-electron oxidation or reduction reactions, but can not be easily oxidized to Mo^{VI} species. $[MoO(PPh_2Et)(dttd)]$ (H_2dttd = *S,S'*-bis-2'-mercaptophenyl-1,2-dimercaptoethane, Figure 2), prepared by reduction of the Mo^{VI} complex $[MoO_2(dttd)]$ with PPh_2Et, loses the phosphine in DMF/$[Et_4N]Cl$ solution to form $[MoOCl(dttd)]^-$. This anion undergoes a reversible one-electron oxidation to produce $[MoOCl(dttd)]$ but is not oxidized further to a Mo^{VI} species.[90]

The ligand 2,6-bis(2,2-diphenyl-2-mercaptoethanyl)pyridine (Figure 2) ($LN(SH)_2$) has been used to prepare the Mo^{IV} complex $[MoO(LNS_2)(DMF)]$ and the complementary dioxo Mo^{VI} complex $[MoO_2(LNS_2)]$; in both cases, the ligand acts as a tridentate N,S,S donor. The Mo^{IV} complex can be oxidized electrochemically to a Mo^V species but not to Mo^{VI}. However, $[MoO(LNS_2)(DMF)]$ reacts with DMSO to abstract an oxygen atom, forming $[MoO_2(LNS_2)]$: the reverse reaction can be accomplished using Ph_3P, generating Ph_3PO and $[MoO(LNS_2)(DMF)]$.[91] These reactions produce a catalytic system for the oxidation of Ph_3P by DMSO, and provide an interesting model for the reactions catalyzed by the oxo-molybdoenzymes.

36.4.2.2.2 Complexes of oxygen and sulfur donor ligands

Reduction of $[NH_4]_2[MoOCl_5]$ with hydrazine, followed by extraction of the product with glacial acetic or malonic acid, gives the Mo^{IV} complexes $[MoO(O_2CMe)_2(H_2O)]$ or $[MoO(O_2CCH_2CO_2)(H_2O)_3]$, respectively.[101] Spectroscopic evidence has indicated that the molybdenum in these species is coordinated to six oxygen atoms. Other oxomolybdenum(IV) complexes with oxygen donor ligands include $[MoO(CN)_4(OH)]^{3-}$ and $[MoO(CN)_4(OH_2)]^{2-}$ (see Section 36.4.2.2.4), $[MoO(dppe)_4(OH)]^+$ and the aqua ions $MoO^{2+}(aq)$ and $MoO(OH)^+(aq)$ (see Section 36.1.4). $[MoO(dppe)_2(OH)]^+$ contains a linear O=Mo—OH group, with the two bidentate dppe ligands completing the octahedral coordination sphere.[102]

An analogous sulfur-bound complex has been isolated, using the macrocyclic tetrathioether 1,5,9,13-tetrathiocyclohexadecane (hd) to form $[MoO(hd)(SH)]^+$.[103] This cation contains a linear O=Mo—SH group, with a Mo—S distance of 2.486(1) Å and an Mo—O_t distance of 1.667(3) Å. The thioether acts as a tetradentate ligand to form a square planar arrangement around the molybdenum. Difluorodithiophosphate forms the five-coordinate complex, $[MoO(S_2PF_2)_2]$, from which the $(S_2PF_2)^-$ ligands are easily displaced by pyridine to give $[MoO(py)_4](S_2PF_2)_2$.[28] The bidentate S,O ligands, $(SCH_2CO_2)^{2-}$, $(SCH(Me_3)CO_2)^{2-}$ and $(SCH(CH_2CO_2H)CO_2)^{2-}$ (S—O), also form five-coordinate complexes of composition $[MoO(S—O)(H_2O)_2]$, which have been isolated as solids. A cysteine complex of MoO^{2+} has been identified in solution, but not characterized as a solid.[104] With the S,P-donor ligand $(SCH_2CH_2PPh_2)^-$, the coordination geometry around the molybdenum in $[MoO(SCH_2CH_2PPh_2)_2]$ has been shown to be intermediate between trigonal bipyramidal and square pyramidal.[105]

36.4.2.2.3 Complexes of phosphine ligands

In ethanol solution, tertiary phosphines react with $[MoCl_4(NCEt)_2]$ to yield *mer*-$[MoOCl_2(PR_3)_3]$, which can undergo exchange reactions to give *mer*-$[MoOX_2(PR_3)_3]$ (X = Br,

I, NCS, NCO).[106] Some of these complexes are green, with ν(Mo=O) stretching frequencies below 946 cm^{-1}, and others blue-green, with ν(Mo=O) above 946 cm^{-1}. In the case of $[MoOCl_2(PMe_2Ph)_3]$, both a blue isomer and a less stable green isomer have been isolated. Crystal structure determinations of green *cis,mer*-$[MoOCl_2(PEt_2Ph)_3]$[107] and blue *cis,mer*-$[MoOCl_2(PMe_2Ph)_3]$[108] have shown that both complexes have an octahedral geometry with notable differences in particular bond lengths and angles. Therefore, it is considered that a balance exists between metal–ligand attraction and ligand–ligand repulsion which, in this case, is very sensitive to the nature of the ligands and results in two possible distortional isomers of the same structural unit. Alternative routes to $[MoOCl_2(PR_3)_3]$ complexes have been developed and these include the reaction of the phosphine with $Na_2[MoO_4]$ in EtOH in the presence of HCl and Zn–Hg reduction of $[MoOCl_3(PR_3)_2]$ in THF.[109]

The reaction of an excess of a diphosphine (PP), such as dppe, with $[MoOCl_2(PR_3)_3]$ yields $[MoOCl(PP)_2]Cl$; the cation has been isolated as $[BF_4]^-$, $[BPh_4]^-$, $[NCS]^-$ and $[NCSe]^-$ salts.[109,110] When a stoichiometric (1:1) amount of (PP) is present, the intermediate, mixed phosphine complex $[MoOCl_2(PP)(PR_3)]$ can be prepared.[109] A crystal structure determination of $[MoOCl(dppe)_2][ZnCl_3(OCMe_2)]$ has shown that the cation contains octahedral Mo^{IV}.[111]

MoO^{2+} complexes with other bidentate ligands have also been prepared, and these include $[MoOCl_2L(PMePh_2)]$ (L = bipy, phen) and $[MoOL'(PMePh_2)]$ (H_2L' = 8-hydroxy- or 8-mercaptoquinoline). All, except the mercaptoquinoline system, undergo an essentially reversible one-electron oxidation.[112]

36.4.2.2.4 Complexes of nitrogen donor ligands

Complexes of Mo^{IV} with tetraphenylporphyrin (TPP) or tetratolylporphyrin (TTP) ligands are generally obtained by reduction of the corresponding Mo^V species. Zn–Hg reduction of $[MoOCl(TPP)]\cdot HCl$ yields [MoO(TPP)], the structure of which has been determined.[113] The Mo^{IV} atom is in a square pyramidal geometry, slightly displaced from the plane formed by the four N ligands, in the direction of the apical oxo group. The Mo—O and Mo—N bond lengths are 1.656(6) and 2.110(6) Å, respectively.

ESR and electronic spectral data suggest that, in the reduction of $[Mo^VOBr(TPP)]$ by O_2^- to give $[Mo^{IV}O(TPP)]$, an intermediate dioxygen complex $[Mo^{IV}O(TPP)(O_2)]^-$ is formed, which is stable in solution at −72 °C.[114] The photochemical reduction of $[Mo^VOX(TPP)]$ (X = NCS, F, Cl, Br) to $[Mo^{IV}OX(TPP)]^-$ at 77 K has also been investigated. On warming the solution, X^- is released to give the $[Mo^{IV}O(TPP)]$ complex.[115]

The reaction of [MoO(P)] (P = TPP, TTP) with HCl in benzene yields the corresponding dichloro complex, $[MoCl_2(P)]$, and these are the only Mo^{IV} complexes with porphyrin ligands which do not contain an oxo group.[113]

[MoO(Pc)] (Pc = phthalocyanate dianion) can be prepared from the reaction between phthalodinitrile and $[Mo(CO)_6]$[116] or $[NH_4]_2[Mo_7O_{24}]\cdot 4H_2O$.[117] A crystal structure determination has shown that this complex possesses the same structure as [MoO(TPP)], with a Mo—O bond length of 1.668(4) Å.

The reaction between MoX_3 (X = Cl, Br), aniline and 2,6-diacetylpyridine in butanol yields $[MoO\{py(anil)_2\}X_2]$, where $py(anil)_2$ is a tridentate Schiff base ligand formed *in situ*.[118] These complexes are isomorphous with $[VO\{py(anil)_2\}X_2]$ and, therefore, are considered to have octahedral coordination of the molybdenum.

36.4.2.2.5 Cyanide and isocyanide complexes

The photolysis of aqueous solutions of $K_4[Mo(CN)_8]$ gives compounds containing the *trans*-$[MoO_2(CN)_4]^{4-}$ ion.[119] These are easily protonated to given *trans*-$[MoO(OH)(CN)_4]^{3-}$ and *trans*-$[MoO(OH_2)(CN)_4]^{2-}$, and crystal structure determinations have been accomplished for compounds of each of these anions. In $NaK_3[MoO_2(CN)_4]$, the Mo—O_t bond length is 1.834(9) Å,[120] which is significantly longer than found in MoO^{2+} complexes (Table 3). In proceeding from $[Cr(en)_3][MoO(OH)(CN)_4]$ to $[Pt(en)_2][MoO(OH_2)(CN)_4]$, the Mo—$O_t$ bond length decreases from 1.698(7) to 1.668(5) Å, whilst the Mo—O distance for the protonated oxygen increases from 2.077(7) to 2.271(4) Å.[121] In the *trans*-$[MoO(OH_2)(CN)_4]^{2-}$ anion, a significant degree of distortional isomerism can occur, and compounds of this anion have been isolated from the reduction of aqueous solutions of $Na_2[MoO_4]$ in the presence of CN^-, in

which the Mo—O_t distance varies between 1.60(2) Å, for the $[AsPh_4]^+$ salt, and 1.72(2) Å, for the $[PPh_4]^+$ salt.[122]

The only ligands, apart from cyanide, which are known to stabilize a dioxomolybdenum(IV) group are carbonyls, in the complex *trans*-$[MoO_2(CO)_4]$, which is formed in the photooxidation of $[Mo(CO)_6]$.[98] The strong π-acceptor capacity of both CN^- and CO removes electron density from the filled d_{xy} orbitals of the molybdenum, thereby increasing the (formal) positive charge on the metal and increasing the σ and π donation from the two terminal oxo groups. Protonation of an oxo group reduces this donation, resulting in the relative bond lengths Mo—O < Mo—OH < Mo—OH_2 with the concomitant decrease in the length of the bond to the *trans*-oxo ligand.

Monooxo complexes containing the $[MoO(CN)_5]^{3-}$ anion have also been isolated from reactions involving the reduction of $[MoO_4]^{2-}$ [122] or the photolysis of $[Mo(CN)_8]^{4-}$.[123] The crystal structure of $[PPh_4]_3[MoO(CN)_5]\cdot 7H_2O$ shows octahedral coordination around the Mo, with the Mo—O_t bond length being 1.705(4) Å.[122]

The reaction between $[MoO_2(CN)_4]^{4-}$ and 1,10-phenanthroline yields $[MoO(CN)_3(phen)]^-$. A crystal structure determination of $Na[MoO(CN)_3(phen)]\cdot 2phen\cdot MeOH\cdot H_2O$ has shown that one nitrogen of the phen ligand is *trans* to the oxo group, with the other nitrogen and the three CN^- ligands completing the octahedral coordination sphere of the Mo.[124] The Mo—N distance *trans* to Mo—O_t is 2.363(7) Å, as compared to a distance of 2.173(8) Å for the bond *trans* to a CN^- ligand, showing the large structural *trans* influence of the oxo group.

Mo^{IV} isocyanide complexes of the form $[MoOX(CNR)_4]Y$ (R = alkyl; X = Cl, Br; Y = Cl, Br, BrI_2, I_3, PF_6) have been prepared by several synthetic routes.[125] These complexes contain a *trans* O—Mo—X arrangement, and in $[MoOCl(CNMe)_4](I_3)$ the Mo—O_t distance is 1.64(4),[126] a length typical of the multiple terminal oxomolybdenum(IV) bond (Table 3).

36.4.2.2.6 Spectroscopic studies

Oxomolybdenum(IV) complexes have been studied by a wide variety of spectroscopic techniques, including NMR, vibrational, electronic and electrochemical measurements. Each of these provides information about different aspects of the compounds, and can be used in conjunction to illustrate various aspects of the bonding.

A survey of 38 complexes of MoO^{2+} has been made using ^{95}Mo NMR spectroscopy and some typical chemical shifts and line widths are given in Table 4.[127] The compounds display a large chemical shift range and highly variable line widths: the most deshielded resonance occurs for $[MoOCl_2(bipy)(PPh_2Me)]$, with δ 3160 p.p.m. (referenced to $[MoO_4^{2-}]$ of 0 p.p.m.), and the most shielded resonance is that of $[MoOCl(CNMe)_4]^+$, which is 1035 p.p.m. ^{17}O NMR spectra have been recorded for $[MoO(S_2CNEt_2)_2]$ and $[MoO(S_2PEt_2)_2]$, and compared with spectra of oxomolybdenum(V) and (VI) compounds. The ^{17}O chemical shifts vary with the strength and multiplicity of the Mo—O_t bond, but changing the oxidation state of molybdenum produces a bigger change, so comparisons between Mo—O bonds using ^{17}O NMR data can only be made within a particular oxidation state.[128]

Table 4 ^{95}Mo NMR data[127]

Compound	*Chemical shift* (p.p.m.)	*Line width* (Hz)
$[MoO(S_2CNEt_2)_2]$	2400	2700
$[MoOCl_2(PEt_2Ph)_3]$[a]	2200	1200
$[MoOCl_2(bipy)(PPh_2Me)]$	3160	800
$[MoOCl(dppe)_2][BPh_4]$	1260	1780
$K_4[MoO_2(CN)_4]\cdot 6H_2O$	1220	240
$K_3[MoO(OH)(CN)_4]$	1444	240
$[MoOCl(CNMe)_4][BPh_4]$	1035	330

[a] Green isomer.

Anomalies in the ^1H and ^{31}P NMR spectra of complexes *mer*-$[MoOX_2(PMe_2Ph)_3]$ (X = Cl, Br) have been interpreted as being due to second order effects caused by the small difference in chemical shifts between the two *trans* phosphines and the unique phosphine *trans* to Cl.[129]

The vibrational spectra of oxomolybdenum(IV) complexes all show a band due to Mo—O_t

stretching at *ca.* 900–1000 cm^{-1}. ^{18}O isotopic substitution has been used to make definitive assignment of this vibration for a series of complexes,[130] and some values are given in Table 5.[5] The frequency of the vibration is a sensitive indicator of the strength and formal order of the bond, and can distinguish between distortional isomers such as the green and blue forms of $[MoOCl_2(PMe_2Ph)_3]$.[106]

Table 5 Molybdenum–Oxygen Stretching Frequencies[5]

Compound	$\nu(Mo—O_t)$ (cm^{-1})	*Ref.*
$[MoO(S_2NCPr^n_2)_2]$	975	100
$[MoOCl_2(PEt_2Ph)_3]$[a]	940	107
$[MoOCl_2(PMe_2Ph)_3]$[b]	954	108
$[MoOCl(dppe)][ZnCl_3(OCMe_2)]$	948	111
$K_4[MoO_2(CN)_4]\cdot 6H_2O$	850[c]	121
$[Cr(en)_3][MoO(OH)(CN)_4]$	900	121
$[PPh_4]Cs[MoO(OH_2)(CN)_4]\cdot 2H_2O$	980	122
$[MoOCl(NCMe)_4](I_3)$	946	125

[a] Green isomer. [b] Blue isomer. [c] Asymmetric stretch.

Electronic absorption spectra have been recorded for a large number of oxomolybdenum(IV) species but, in addition to *d–d* transitions, there is the possibility of two-electron excitations, charge transfer bands and splitting of degenerate energy levels due to low symmetry. These factors make it difficult to interpret or even to compare spectra.[5]

Electrochemistry has been used to investigate the redox properties of Mo^{IV} oxo complexes, particularly those used to model some aspects of molybdenum enzyme chemistry, such as complexes with a $\{MoOS_4\}$ core.[131] $[MoO(S_2NCR_2)_2]$ complexes undergo a reversible one-electron oxidation to the Mo^V species but cannot be further oxidized to Mo^{VI}. Complexes of the type [MoOLL'] (L = salicylaldehyde-2-hydroxyanil, salicylaldehyde-2-mercaptoanil; L' = bipy, phen) can also be reversibly oxidized to the Mo^V species, and reduced to the Mo^{III} complex.[84] Other complexes which undergo reversible one-electron oxidation include $[MoOCl_2(bipy)(PMePh_2)]$, $[MoOCl_2(phen)(PMePh_2)]$ and $[MoOL(PMePh_2)]$ (H_2L = 8-hydroxyquinoline).[112]

36.4.2.3 Complexes Involving Multiple Molybdenum–Nitrogen Bonds

The chemistry of molybdenum with nitrogen ligands has been extensively studied, with particular attention being paid to those species which may serve as models of the nitrogen fixation process catalyzed by the nitrogenases. Complexes of Mo^{IV} which contain multiple Mo—N bonds are known with diazenide $(NNR)^-$, hydrazide $(NNRR')^{2-}$ or $(NHNRR')^-$, nitride $(N)^{3-}$, imide $(NR)^{2-}$ and azide $(N_3)^-$ ligands, and interest has focussed on reactions involving changes in the oxidation state of the molybdenum and the related reaction of the coordinated ligand.

Arenediazenide ligands, such as $(NNPh)^-$, are electronically analogous to NO and, therefore, can act as one- or three-electron donors. Thus, in mononuclear complexes they can coordinate to form linear Mo—N≡N groups, in which the ligand can be regarded as $(NNAr)^+$ with the ligand acting as a three-electron donor, or to form bent Mo—N=N groups, with $(NNAr)^-$ acting as a one-electron donor.[132] The degree of multiple bonding in the Mo—N bond is reflected in the Mo—N—N interbond angle and the closer the angle is to 180° the higher is the bond order.

Diazenide complexes can be obtained by reacting a diazonium salt with a metal complex containing suitable leaving groups, such as carbonyls.[132] $[Mo(SC_6H_2Pr^i_3\text{-}2,4,6)_3(CO)_2]^-$ reacts with $[NNPh][BF_4]$ in MeCN to give $[Mo(NNPh)(SC_6H_2Pr^i_3\text{-}2,4,6)_3(NCMe)]$, in which the NNPh and MeCN ligands occupy the axial sites of a trigonal bipyramid with the sterically hindered thiolates equatorial.[133] The Mo—NNPh bond length is 1.78(1) Å, with a bond angle of 171(1)°, suggesting a considerable amount of Mo—N multiple bonding. This was the first reported example of a molybdenum–thiolate–diazenide complex and its existence supports the suggestion that bulky *ortho*-substituted arenethiolate ligands stabilize the binding of π-acceptor molecules to the molybdenum and, thereby, may provide interesting models for metal–sulfur

sites that will interact with dinitrogen. Diazenide complexes can also be formed by reduction of hydrazide compounds. The Mo^{VI} complex $[Mo(NNHPh)_2L_2]\cdot H_2NNHPh$ (H_2L = 2,3-butanedithiol) reacts with PhSH in MeOH, in the presence of NEt_3, to give $[NHEt_3][Mo_2(NNPh)_4(SPh)_5]$.[134] In this dimer each Mo^{IV} atom is octahedrally coordinated to two terminal diazenides, one terminal thiolate and three bridging thiolates. The Mo—Mo distance is 3.527(1) Å, which is one of the largest separations identified in any simple molybdenum dimer.

For molybdenum dithiocarbamates, several compounds are known with both diazenide and hydrazide ligands attached. In $[Mo(NNCO_2Me)(NHNHCO_2Me)(S_2CNMe_2)_2]$ the overall geometry corresponds to that of a distorted pentagonal bipyramid, with the $NNCO_2Me$ group in one axial site and one sulfur atom from a S_2CNMe_2 group in the other. Two of the equatorial sites are occupied by the nitrogen atoms of the side-on hydrazide ligand, and the remaining three by sulfur atoms of the dithiocarbamates. The Mo—N distances of the hydrazide are 2.13(1) and 2.11(1) Å, whilst the Mo—N distance of the diazenide is 1.71(1) Å, this last value indicating considerable multiple bonding.[135] The reaction of alkyldithiocarbazates, $NH_2NHC(S)SR'$, with $[MoO_2(S_2CNR_2)_2]$ (R, R' = Me, Et) yields mixed diazenidohydrazido complexes of composition $[Mo\{NNC(S)SR'\}\{NH_2NC(S)SR'\}\{S_2CNR_2\}_2]$. A structure determination of the complex R = Me, R' = Et has identified pentagonal bipyramidal coordination at the molybdenum with the axial positions occupied by the diazenide ligand and one sulfur atom of a dithiocarbamate group. The hydrazide ligand is bound as a N,S chelate, *via* the NH_2 nitrogen and the unsubstituted sulfur atom, giving a five-membered ring. The other three equatorial positions are occupied by dithiocarbamate sulfur atoms. The Mo—N distance to the diazenide ligand is 1.77(1) Å, and to the hydrazide ligand is 2.250(8) Å.[136] Treatment of this complex with HCl in MeOH leads to the formation of the dimer $[(Me_2NCS_2)(O)Mo(\mu\text{-}NNC(S)SEt)_2Mo(S_2CNMe_2)]$, in which the bridging ligands are coordinated to both molybdenum atoms, *via* the terminal nitrogen, and are also bonded *via* the unsubstituted sulfur atoms to the non-oxo bound molybdenum.[137] The N—N distances in the bridging ligands are longer than found for bridging diazenido(1−) ligands in other compounds[138] and, hence, can be regarded as hydrazido(3−) groups with the formal oxidation state of each molybdenum being V.

The hydrazido(2−) complexes $[MoBr(NNRR')(dppe)_2]^+$ (R, R' = H, alkyl) can be prepared in a two-stage process by the reaction of RBr with $[Mo(N_2)_2(dppe)_2]$ to give $[MoBr(NNR)(dppe)_2]$, which reacts with R'Br to give $[MoBr(NNRR')(dppe)_2]Br$.[139] Two-electron reduction of these complexes, followed by reaction with HBr, yields the imido-molybdenum(IV) species $[MoBr(NH)dppe)_2]Br$, which can be converted by treatment with base to the nitrido complex $[MoBr(N)(dppe)_2]$.[140] This series of reactions converts a terminally bonded dinitrogen ligand into a nitrido group, thereby breaking the N—N bond and forming an amine; the sequence provides a model of a possible mechanism for the fixation of dinitrogen. A crystal structure determination of $[MoBr(NH)(dppe)_2]Br\cdot MeOH$ has shown that the cation possesses octahedral geometry, with the bromide *trans* to the imido ligand. The Mo—N distance is 1.73(2) Å, typical of a multiple Mo—N bond.[141] The reaction of $Me_3Si(N_3)$ with $[Mo(N_2)_2(dppe)_2]$ yields the nitrido azido complex $[Mo(N)(N_3)(dppe)_2]$. The crystal structure of this compound shows a *trans* N—Mo—N_3 arrangement, with an unusually long Mo–nitrido distance of 1.79(2) Å and a Mo–azide distance of 2.20(2) Å. The Mo—N—N azide angle is 167.1(11)°, suggesting some π interaction in the metal–nitrogen bond.[141]

Complexes of molybdenum(IV) with 4-tolylimido ligands, $(Ntol)^{2-}$, have been prepared by reduction of Mo^{VI} and Mo^{V} species. Thus, $[MoO(Ntol)(S_2CNEt_2)_2]$ reacts with PPh_3 to form $[Mo(Ntol)(S_2CNEt)_2]$, which is easily oxidized by O_2 or DMSO to reform the starting material.[142,143] These oxygen transfer reactions are analogous to those of the *cis*-$[MoO_2(S_2CNR_2)_2]/[MoO(S_2CNR_2)_2]$ systems (see Section 36.4.2.2.1) and form a catalytic cycle for the oxidation of tertiary phosphines by O_2 or DMSO. Reduction of $[Mo(Ntol)Cl_3(PMe_3)_2]$ by Na—Hg in the presence of PMe_3 yields $[Mo(Ntol)Cl_2(PMe_3)_3]$.[143] The geometry of this complex is pseudooctahedral, with the phosphines in a *meridional* configuration and the chlorine atoms in mutually *cis* positions. The Mo—N distance is 1.739(2) Å, with an almost linear Mo—N—C arrangement.

^{15}N NMR spectroscopy has been used to characterize hydrazido, imido, and nitrido complexes of Mo^{IV}, and to monitor the reaction of $[MoI_2(^{15}N^{15}NH_2)(PMe_2Ph)_2]$ with HI in THF to give $^{15}NH_3$.[144] In the imido complexes, coupling between the ^1H and ^{15}N in the $(NH)^{2-}$ ligand was observed, confirming that the proton remains on the nitrogen, a fact which was not clear from other techniques.

36.4.2.4 Other Monomeric Complexes

36.4.2.4.1 Halide complexes

The simplest monomeric molybdenum(IV) halide complexes are the $[MoX_6]^{2-}$ anions. $Na_2[MoF_6]$ was first prepared by reacting MoF_6 with NaI in liquid SO_2, and was obtained as a water sensitive powder.[145] A crystal structure determination has been carried out on $Li_2[MoF_6]$, showing octahedral coordination with Mo—F distances between 1.927(2) and 1.945(2) Å.[146] Potassium salts of $[MoCl_6]^{2-}$ can be prepared by fusing $MoCl_6$ with KCl at 200 °C, or by reacting $[MoCl_5]$ with ICl and KCl at 150 °C.[147] $MoCl_5$ or $[NEt_4][MoCl_6]$ dissolved in either of the room temperature ionic liquids $AlCl_3$/*N*-*n*-butylpyridinium chloride or $AlCl_3$/1-methyl-3-ethylimidazolium chloride gives $[MoCl_6]^{2-}$ in solution as a stable entity.[148] No full crystallographic determination has been reported for an $[MoCl_6]^{2-}$ salt, but interpretation of the powder diffraction pattern of $K_2[MoCl_6]$ has given an Mo—Cl distance of 2.31(5) Å.[147] Hexabromomolybdates, $M_2[MoBr_6]$ (M = Rb, Cs), have been prepared by reacting $MoBr_3$, MBr and IBr in a sealed tube at 200 °C.[147]

Molybdenum(IV) tetrahalides react easily with a variety of ligands to form complexes of stoichiometry $[MoX_4L_2]$ (X = F, Cl, Br; L_2 = two neutral monodentate ligands or a neutral bidentate ligand). Examples of these complexes are known with N donor,[149–151] P donor,[106,150,152,153] As donor[150] and O donor ligands.[150] Complexes of this type can also be prepared by reduction of $MoCl_5$ with an excess of the ligand,[151] reaction between PR_3 and $[Mo_2(NCMe)_3Cl_6]$,[152] or by oxidation of $[Mo(CO)_4(PR_3)_2]$ with X_2 (R = Me, Et, Ph; X = Cl, Br).[153] An alternative and convenient synthesis is *via* $[MoCl_4(OEt_2)_2]$, which can be prepared from $MoCl_5$ and Et_2O in the presence of alkenes which act as Cl acceptors;[164] the Et_2O ligands of this complex are easily exchanged to give $[MoCl_4L_2]$. Vibrational studies have shown that the $[MoX_4(PR_3)_2]$ complexes adopt a *trans* octahedral configuration but, as expected in view of the span of the bidentate ligand, $[MoCl_4(dppe)]$ is obtained as the *cis* isomer.[106] Spectroscopic studies have indicated that $[MoCl_4L_2]$ (L = pyrazine, quinoxaline, 4,4′-bipyridyl or L_2 = 4,4′-bipyridyl) complexes contain a *cis*-$[MoCl_4N_2]$ chromophore.[151] In contrast, for $[NR_4]_2[MoCl_4(SnX_3)_2]$, prepared from $[MoCl_4]$ and $[NR_4][SnX_3]$ (R = H, Me, Et; X = Cl, Br), vibrational spectroscopic evidence favours a *trans* structure.[155]

Oxidation of $[Mo(CO)_3(PMe_2Ph)_3]$ with X_2 (X = Cl, Br) gives the seven-coordinate complexes $[MoX_4(PMe_2Ph)_3]$.[153] The structure of these is monocapped octahedral, the capped face consisting of three phosphorus atoms, while the cap and remaining three vertices are occupied by the halogen. A five-coordinate complex $[MoF_4(NEt_2Ph)]$ has been isolated, but not structurally characterized.[156]

The reaction of $[NR_4][LMo(CO)_3]$ with $SOCl_2$ yields $[LMoCl_3]$ (L = $\{HB(pyrazolyl)_2\}^-$, $\{HB(3,5\text{-}Me_2pyrazolyl)_3\}^-$), in which the tris(pyrazolyl)borate anion acts as a tridentate N donor ligand. An analogous compound is obtained from the oxidation of $[Mo(nane)(CO)_3]$ (nane = 1,4,7-trimethyl-1,4,7-triazacyclononane) by Br_2, which yields the cationic complex $[MoBr_3(nane)]^+$. This has been isolated as the $[PF_6]^-$ salt and a crystal structure determination accomplished; the geometry around the molybdenum is octahedral, with a *facial* configuration of the ligands and an average Mo—Br distance of 2.427(4) Å.[18]

Anionic ligands can replace chloride in $MoCl_4$, giving complexes of the form $[MoCl_2L_2]$, where L is a uninegative bidentate ligand. Thus, heating $MoCl_4$ or $MoCl_5$ with a β-diketone, HL, yields the corresponding monomeric $[MoCl_2L_2]$ complex.[157] Analogous complexes with the anions of 8-hydroxyquinoline and *N*-substituted salicylidenimines can be prepared by the direct substitution of chloride in $[MoCl_4(NCMe)_2]$, or of $(acac)^-$ in $[MoCl_2(acac)_2]$.[158,159] Although two bands are observed in the Mo—Cl stretching region of the IR spectra of these complexes, implying a *cis* geometry,[157–159] the crystal structure of $[MoCl_2(N\text{-}methylsalicylaldimate)_2]$ shows this complex to be the all *trans* isomer, with Mo—Cl, Mo—O and Mo—N bond lengths of 2.388(2), 1.953(6), and 2.137(8) Å, respectively.[160]

Complexes with tetradentate ligands L (L = $(salen)^{2-}$, $(acacen)^{2-}$), of the form $[MoCl_2L]$, have been prepared by reaction of $[MoCl_4(NCMe)_2]$ or $[MoCl_3(py)_3]$ with H_2L.[159] The reaction of HCl with [MoO(TPP)] (TPP = dianion of 5,10,15,20-tetra-4-tolylporphyrin) forms $[MoCl_2(TPP)]$; the structure of the latter involves a planar porphyrin ring with the *trans* chlorides at distances from the molybdenum of 2.347(4) and 2.276(4) Å, although they appear to be chemically equivalent.[113]

Seven-coordinate compounds $[MoClL_3]$ (L = anion of picolinic acid or a derivative of 8-quinolinol) have been prepared by prolonged reaction between $[MoO_2Cl_2]$ and HL; these

complexes have been characterized by spectroscopic and magnetic measurements but no structural conclusions were possible.[161]

36.4.2.4.2 Dithiocarbamate and dithiocarboxylate ligands

Eight-coordinate dithiocarbamate complexes, $[Mo(S_2CNRR')_4]$, have been prepared by several different methods including: substitution reactions between $MoCl_4$ and $(S_2CNRR')^-$ salts;[162] oxidative decarbonylation of $[Mo(CO)_6]$ with $K(S_2CNRR')$,[163] and of $[Mo(CO)_6]$[164] or $[Mo(\eta^6\text{-}C_7H_8)(CO)_3]$[29] with $(RR'NCS_2)_2$. The crystal structure of $[Mo(S_2CNEt_2)_4]$ has shown that the molecule possesses a distorted square antiprismatic (or triangular dodecahedral) geometry around the central molybdenum atom.[165] The reaction between $MoCl_5$ and potassium pyrrole-*N*-carbodithioate in aqueous solution yields $[Mo\{S_2C(NC_4H_4)\}_4]$, which also has dodecahedral coordination about the metal, with the two different sulfur sites at average bond lengths of 2.541(6) and 2.507(6) Å.[166]

Dithiocarbamate ligands are also known to form seven-coordinate mixed-ligand complexes with Mo^{IV}. The complex $[Mo(SH)(S_2CNEt_2)_3]\cdot THF$ has been isolated as a product of the reaction between $[Mo(CO)_2(S_2CNEt_2)_2]$ and $[Fe_4(Cp)_4S_6]$.[167] The coordination around the molybdenum is pentagonal bipyramidal, with the axial sites occupied by the $(SH)^-$ ligand and one sulfur of a dithiocarbamate ligand. Complexes $[MoX(S_2CNR_2)_2L_2]Y$ and $[MoX_2(S_2CNR_2)_2L]$ ($R_2 = Me_2$, Et_2, $(CH_2)_5$; X = Cl, Br; Y = Cl, PF_6, BF_4, BPh_4; L = ½(dppe), PPh_2Me, PMe_2Ph, PEt_2Ph) have been prepared by the reduction of the corresponding $[MoOX_2(S_2CNR_2)_2]$ complex with the phosphine. The crystal structures of $[MoCl(S_2CNEt_2)_2(PMePh_2)_2][BF_4]$ and $[MoCl(S_2CNEt_2)_2(dppe)][PF_6]$ both show pentagonal bipyramidal coordination around the molybdenum but, in the former, both axial positions are occupied by phosphorus atoms and, in the latter, the chlorine atom and one phosphorus of the dppe are in the axial positions.[168]

The reaction between $[MoCl_4(NCPr)_2]$ and dithiocarboxylic acids is a general route to the preparation of eight-coordinate $[Mo(S_2CR)_4]$ complexes.[169] The crystal structure of $[Mo(S_2CPh)_4]$ reveals these compounds to be isostructural with the dithiocarbamates, with a dodecahedral coordination around the molybdenum and average Mo—S distances of 2.475(1) and 2.543(1) Å to the two different sulfur sites.[170] Cyclic voltammetry has shown that in $[Mo(acda)_4]$ (Hacda = 2-aminocyclopent-1-ene-1-dithiocarboxylic acid) the Mo^{IV} can be reversibly oxidized and reversibly reduced in one-electron processes.[171]

The cyclopentadienedithiocarboxylate dianion, $(C_5H_4CS_2)^{2-}$, reacts with $[MoCl_4]$ to give the six-coordinate complex $[Mo(S_2CC_5H_4)_3]^{2-}$, which has been isolated as its $[NEt_4]^+$ salt. This has been characterized by spectroscopic measurements but the structure has not been determined.[172]

36.4.2.4.3 Eight-coordinate complexes with other bidentate ligands

In addition to dithiocarbamate and dithiocarboxylate compounds, Mo^{IV} forms eight-coordinate complexes with several other chelating ligands. For example, $[Mo(CO)_6]$ reacts with $\{PhCOCHC(Ph)S\}_2$ to form $[Mo\{OC(Ph)CHC(Ph)S\}_4]$, in which the monothio-β-diketonate ligands are bound to the metal *via* oxygen and sulfur atoms to form six-membered rings.[173] Compounds have also been prepared and studied with ligands containing both a heterocyclic nitrogen and anionic oxygen donor, such as 8-quinolinolate or picolate derivatives.[174,175] These are prepared by stepwise substitution of chlorides in $MoCl_4$ and, by isolating intermediate partially substituted species, it is possible to prepare mixed-ligand $[MoL_nL'_{4-n}]$ complexes, where L and L′ are anionic bidentate N,O-donor ligands.[175]

36.4.2.4.4 Alkoxy and thiolate ligands

Alkoxy complexes of stoichiometry $[Mo(OR)_4]$ can be prepared from the reaction of $[Mo(NMe_2)_4]$ with alcohols. With bulky groups ($R = Bu^t$, CH_2Bu^t) the complexes are

monomeric, but for R = Pr^i, Et or Me polymeric species are formed.[176] The reaction of $[Mo(NMe_2)_4]$ with 1-adamantol (Hado) yields $[Mo(ado)_4(NHMe_2)]$, The structure of this compound is trigonal bipyramidal, with the amine ligand and one alkoxy group occupying the axial sites.[177] Phenoxy complexes can also be prepared by reacting $[Mo(NMe_2)_4]$ with phenols: the stoichiometry of the products obtained with a series of alkylated phenols was found to be dependent on the size of the substituent. $[Mo(NMe_2)_4]$ reacts with 4-methylphenol (Hmp) to yield $[Mo(mp)_4(NHMe_2)_2]$ but 2,6-diisopropylphenol (Hdpp) only substitutes three amido ligands to give $[Mo(dpp)_3(NMe_2)(NHMe_2)_2]$.[178] Trialkylsilanols also react with $[Mo(NMe_2)_4]$ to give the six-coordinate species $[Mo(OSiR_3)_4(NHMe_2)_2]$, (R = Me, Et). The crystal structure of $[Mo(OSiMe_3)_4(NHMe_2)_2]$ shows a *trans* octahedral geometry, with an average Mo—O bond length of 1.951(4) Å.[176]

$[Mo(SBu^t)_4]$ was the first monomeric four-coordinate thiolate complex of Mo^{IV} to be reported. The compound was prepared by treating $MoCl_4$ with $Li(SBu^t)$ and characterized by X-ray crystallography; the arrangement of the four sulfur atoms around the molybdenum has approximately D_{2d} symmetry, with the Mo—S distance 2.235(3) Å.[179] This complex is very labile and readily undergoes ligand exchange reactions with Bu^{t}NC, CO and PMe_2Ph to yield *cis*-$[Mo(SBu^t)_2(CNBu^t)_4]$, $[Mo_2(\mu\text{-}SBu^t)_2(CO)_8]$, and $[Mo_2(\mu\text{-}S)_2(SBu^t)_4(PMe_2Ph)_2]$, respectively.[180] The reaction between $[Mo(SBu^t)_4]$ and the peptide ligands Ac-Cys-OH, Z-Ala-Cys-OMe and Z-Cys-Ala-Ala-Cys-OMe (Z = carbobenzoxy) (in which the free amino groups at the N terminus is blocked to enforce coordination *via* the cysteine sulfur atoms) give $[Mo(Ac\text{-}Cys\text{-}OH)_4]$, $[Mo(SBu^t)_2(Z\text{-}Ala\text{-}Cys\text{-}OMe)_2]$ and $[Mo(Z\text{-}Cys\text{-}Ala\text{-}Ala\text{-}Cys\text{-}OMe)_2]$, respectively. Reaction of $[Mo(SBu^t)_4]$ with $[Fe_4S_4(SPr^i)_4]^{2-}$ has been followed by CD spectroscopy, and the formation of a Mo—Fe cluster observed.[181]

The bulky thiolate ligand 2,4,6-triisopropylbenzenethiolate (tipt) forms the stable complex $[Mo(tipt)_4]$, which gives monoadducts with alkynes, nitriles, CO and other small ligands and, unlike $[Mo(SBu^t)_4]$, the molybdenum does not appear to be reduced in these reactions.[182]

The reaction of $MoCl_5$ with $(HSCH_2CH_2)_2S_2$ (H_2mes) yields $[Mo(mes)_2]$, in which the $(mes)^{2-}$ dianions act as tridentate S donor ligands. The molecule possesses trigonal prismatic geometry with average Mo—S bond distances of 2.427(8) and 2.361(9) Å for the thioether and mercapto sulfurs, respectively. The complex undergoes a reversible one-electron oxidation and a reversible one-electron reduction;[183] an attempt to oxidize the complex with $Ag[PF_6]$ yielded the adduct $[\{Mo(mes)_2\}_2Ag][PF_6]\cdot\frac{1}{2}DMF$. In this latter compound the molybdenum atoms retain a distorted trigonal prismatic coordination, and one of the mercapto sulfur atoms of each $(mes)^{2-}$ ligand is also coordinated to Ag, forming a severely distorted tetrahedron.[184] The reaction between $[MoCl_4(PPh_3)_2]$ and $(HSCH_2CH_2)_2PPh$ gives $[Mo\{(SCH_2CH_2)_2P\}_2]$. The structure of this compound is analogous to that of $[Mo(mes)_2]$, with the ligands acting as tridentate P,S,S donors in a *trans* octahedral configuration; the average Mo—S distance is 2.348(9) Å.[155]

Addition of CS_2 to $[PPh_4]_2[(S_4)_2MoS]$ leads to insertion of the CS_2 into the Mo—S bonds and formation of perthiocarbonate ligands, $(CS_4)^{2-}$. The crystal structure of $[PPh_4]_2[(CS_4)_2MoS]$ shows that the anion possesses a square pyramidal geometry, with an apical sulfido ligand at a Mo—S distance 2.126(3) Å and two nearly planar CS_4^{2-} ligands in a *trans* arrangement with average Mo—S distances of 2.327(3) and 2.383(3) Å for the persulfido and sulfide S atoms, respectively.[186]

Molybdenum(IV) complexes with dithiolenes, of general formula $[Mo(S_2C_2R_2)_3]^{2-}$, adopt trigonal prismatic coordination. These compounds are discussed in Section 36.6.6.

36.4.2.4.5 Dialkylamide and other nitrogen donor ligands

The tetrakis(dialkylamido) complexes $[Mo(NR_2)_4]$ (R = Me, Et) have been synthesized by the reaction of $MoCl_5$ with $Li(NR_2)$ and spectroscopic evidence suggests a monomeric distorted tetrahedral geometry for the MoN_4 core. These compounds are highly reactive and the methyl derivative is readily converted into $[Mo(S_2CNMe_2)_4]$ by insertion of CS_2 into the Mo—N bonds,[187] and reactions with alcohols, phenols and silanols yield alkoxy, phenoxy or silanoxy complexes[176–178] (see Section 36.4.2.4.4).

The reaction of $[MoCl_4(NCMe)_2]$ with K(SCN) in MeCN solution yields $[Mo(NCS)_6]^{2-}$ and this anion has been isolated as its $[NBu_4]^+$ and $[AsPh_4]^+$ salts.[188] Vibrational spectroscopy has indicated N-bonded rather than S-bonded thiocyanate ligands. The adduct $[Mo(NCS)_4(bipy)]$ has also been obtained.[189]

36.4.2.4.6 Cyanide and isocyanide complexes

The octacyanomolybdate(IV) anion $[Mo(CN)_8]^{4-}$ has long been known and characterized and many aspects of its chemistry have been reviewed.[190,191] This complex is readily obtained from the addition of cyanide ions to aqueous solutions of Mo^{III} or Mo^{V} compounds. A simple preparation is by the reaction between molybdate(VI), $K[BH_4]$ and CN^- in the presence of acetic acid, followed by precipitation with ethanol.[192] The crystal structure of several complexes containing the $[Mo(CN)_8]^{4-}$ anion have been reported. In $K_4[Mo(CN)_8]\cdot 2H_2O$,[193] $[C_6H_6NO_2]_4[Mo(CN)_8]$[194] and $Rb_4[Mo(CN)_8]\cdot 3H_2O$[195] dodecahedral coordination has been found, but all the Mo—C bond lengths are equal, at 2.163(7) Å.[193] However, the molybdenum atoms in $[NH_4]_4[Mo(CN)_8]\cdot 0.5H_2O$ exist in two different coordination geometries, dodecahedral and square antiprismatic.[195] The structure of $H_4[Mo(CN)_8]\cdot 4HCl\cdot 12H_2O$ has not been completely determined, but the compound is isomorphous with the tungsten analogue, which is known to have a square antiprismatic geometry about the metal.[196] $[NHEt_3]_2[H_3O]_2[Mo(CN)_8]$ contains anions with a coordination polyhedron which is half-way between a dodecahedron and a bicapped trigonal prism.[197] Energy differences between the various topologies of $[Mo(CN)_8]^{4-}$ are small (see ref. 8, pp. 11–22), and rapid interconversion between them may be expected in solution, with crystal packing forces determining the more stable arrangement in the solid state.

Vibrational spectroscopy has been used to investigate the structure of aqueous solutions of $[Mo(CN)_8]^{4-}$. Raman spectra of $K_4[Mo(CN)_8]\cdot 2H_2O$ in the region 500–200 cm^{-1} are identical for solid and solution species and the number of totally symmetric modes is consistent with dodecahedral rather than square antiprismatic geometry.[198] ^{13}C NMR spectroscopy detects only one sharp carbon resonance even at temperatures of −160 °C, which may be due to the formation of square prismatic species, dodecahedral species with negligible differences in chemical shift between the two carbon sites, or rapid interconversion between the two.[199] Polarized UV absorption spectra of $[Mo(CN)_8]^{4-}$ in the temperature range 4.2–300 K have been recorded and show dodecahedral geometry, with appreciably less distortion from idealized geometry at low temperatures than at room temperature.[200]

Salts of stoichiometry $MFe[Mo(CN)_8]$ (M = Cs, Rb, K, NH_4) can be prepared by treating $Li_4[Mo(CN)_8]$ with $FeCl_3$ and MCl, and the corresponding $M_2Fe[Mo(CN)_6]$ complexes are obtained using $FeCl_2$. There is weak interaction between the $[Mo(CN)_8]^{4-}$ and the Fe^{III} or Fe^{II} atoms, and IR spectroscopy has indicated the presence of Mo—CN—Fe bridges.[201,202] Evidence for the formation of $Co_2[Mo(CN)_8]$, on mixing $CoCl_2$ and $K_4[Mo(CN)_8]$ solutions, has been obtained from radiometric titrations[203] and, in a series of complexes $M_2[Mo(CN)_8]\cdot xH_2O$ (M = Mn–Zn), magnetic studies have demonstrated weak electronic interactions between the Mo^{IV} and M^{II} centres.[204]

Photolysis of aqueous solutions of $[Mo(CN)_8]^{4-}$ produces $[MoO_2(CN)_4]^{4-}$, $[MoO(OH)(CN)_4]^{3-}$ or $[MoO(OH_2)(CN)_4]^{2-}$ species, depending upon the pH.[119] In liquid NH_3, photolysis of $[NH_4]_4[Mo(CN)_8]$ yields the six-coordinate $[Mo(CN)_4(NH_3)_2]$ complex.[205] The eight-coordinate complexes $K_2[Mo(CN)_6L]$ (L = bipy, phen) can be prepared *via* substitution reactions of $[Mo(CN)_8]^{4-}$.[206]

A number of isocyanide complexes, $[Mo(CN)_4(CNR)_4]$ (R = Me, Pr, Bu^t, allyl, $NCPh_2$), have been made by the action of RI on $Ag_4[Mo(CN)_8]$. The crystal structure of $[Mo(CN)_4(CNMe)_4]$ shows a dodecahedral geometry, with the CN^- ligands at 2.177(8) Å and the MeNC ligands at 2.148(8) Å from the molybdenum.[207] Both ^{13}C NMR and vibrational spectroscopy indicate that only one isomer is present in solution.

Treatment of an aqueous solution of $K_5[Mo(CN)_7]$ with acetic, hydrochloric or ascorbic acid, or with hydrogen sulfide gives the hydride complex $K_4[MoH(CN)_7]\cdot 2H_2O$.[208] This has been characterized by ^1H and ^{13}C NMR and by vibrational spectroscopy.

36.4.2.4.7 Magnetic and electronic properties

The magnetic moments of some non-oxo molybdenum(IV) compounds are listed in Table 6.[5] The six-coordinate complexes are all paramagnetic, with moments ranging between 1.9 and 2.8 BM. The temperature dependence of the magnetic susceptibility of these complexes is consistent with a configuration derived from a $^3T_{1g}$ ground state split by spin-orbit coupling and/or a ligand field of low symmetry. Electronic absorption spectra have been recorded for many six-coordinate species but assignments have generally been tentative.[159] Seven-coordinate

Table 6 Magnetic Moments of some Non-oxo Molybdenum(IV) Complexes[5]

Compound	μ_{eff} (BM)	*T* (K)	*Ref.*
$K_2[MoCl_6]$	2.28	300	147
$[MoCl_4(NCMe)_2]$	2.48	a	149
$[MoCl_4(PEt_2Ph)_2]$	2.61	300	106
$[MoCl_2(acac)_2]$	2.63	297	159
$[MoCl_2(salen)]$	2.61	292	159
$[MoCl(pic)_3]$	2.70	294	161
$[Mo(S_2CNEt_2)_4]$	0.68	a	164
$[Mo\{SC(Ph)CHC(Ph)O\}_4]$	Diamagnetic		173
$[Mo(SBu^t)_4]$	Diamagnetic		179
$[Mo(NMe_2)_4]$	Diamagnetic		187
$K_2[Mo(NCS)_6]$	3.02	a	188
$[Mo(CN)_4(CNMe)_4]$	Diamagnetic		207

[a] Temperature not reported.

species, such as $[MoCl(pic)_3]$, are also paramagnetic with magnetic moments slightly below the spin-only value for a d^2 system because of spin-orbit coupling.[161]

Most of the eight-coordinate complexes are diamagnetic; although some compounds have been reported to possess a magnetic moment, this may be due to impurities.[5] The dodecahedral geometry results in a *d* orbital splitting pattern that leaves the d_{xy} level lowest and this is thought to contain the two electrons in $[Mo(CN)_8]^{4-}$ and $[Mo(L–L)_4]$ complexes.[187] This interpretation is in agreement with X-ray PES studies and CNDO/INDO MO calculations.[209]

The four-coordinate complexes $[Mo(SBu^t)_4]$ and $[Mo(NR_2)_4]$ are also diamagnetic. The UV–PE spectrum of $[Mo(SBu^t)_4]$ exhibits a low ionization potential at 6.8 eV which has been assigned to the ionization of electrons with predominant molybdenum $4d_{z^2}$ character, on the basis of discrete variational-X_α MO calculations on the model compounds $[Mo(SH)_4]$ and $[Mo(SMe)_4]$.[210] For $[Mo(NR_2)_4]$ (R = Me, Et), the UV–PE spectrum contains a low energy ionization at 5.3 eV which has been attributed to ionization from the molybdenum $4d_{x^2-y^2}$ orbital. This assignment was based on Fenske–Hall calculations on $[Mo(NMe_2)_4]$.[211]

36.4.2.5 Cyclopentadienyl Complexes

Complexes of the general formulae $[Cp_2MoLL']^{2+}$, $[Cp_2MoLX]^+$ and $[Cp_2MoXY]$ (L, L' = neutral ligand; X, Y = uninegative ligand) are known for a wide variety of ligands (ref. 212 and refs. therein). The structure of $[Cp_2MoCl_2]$ is a typical example of these complexes. The cyclopentadiene rings are staggered with respect to each other and lie on either side of the $MoCl_2$ plane; the angle between normals of the two Cp planes is *ca.* 135° and the overall geometry about the metal is that of a distorted tetrahedron.[213] Other compounds are known in which a second metal atom is coordinated to the Cp_2Mo centre *via* bridges formed by the other ligands, such as the hydrides in $[Cp_2MoH_2]$[214] or the thiols in $[Cp_2Mo(SR)_2]$[215] complexes, but there appears to be little direct metal–metal interaction in these systems. Generally, in the course of chemical reactions the two Cp ligands remain coordinated and unchanged while the other two sites are reactive.

36.4.2.6 Dimeric and Polymeric Complexes

Molybdenum(IV) forms a variety of dimeric and polymeric complexes with oxido, hydroxido and carboxylato bridges in aqueous solution, which are discussed in Section 36.1.4. Oxide bridges have also been found in non-aqueous systems. The reaction between $[MoCl_2(TTP)]$ (TPP = dianion of tetra-*p*-tolylporphyrin) and *N*-phenylhydroxylamine yields $[\{MoCl(TPP)\}_2O]$, in which each Mo is octahedrally coodinated and is displaced 0.08 Å from the N_4 plane towards the bridging oxygen. The complex is paramagnetic (μ = 2.82 BM per Mo) with no magnetic interaction between the metal centres.[216] A similar structure has been found in ethoxooxidobis(1,5,9,13-tetrathiacyclohexadecane)-μ-oxidodimolybdenum(IV) trifluoromethylsulfonate hydrate: the cation contains a linear OMoOMo=O unit, with each macrocycle

forming a planar coordination around a molybdenum atom and staggered 43° relative to each other.[217]

The oxo-bridged mixed oxidation state Mo^{IV}, Mo^{V} compound $[\{Mo(S_2CNEt_2)_3\}_2O][BF_4]$ has been prepared by the reaction of $[MoO(S_2CNEt_2)_3][BF_4]$ and PPh_3. The cation contains two pentagonal bipyramidal units linked by an almost linear Mo—O—Mo bridge, with the oxygen occupying an axial site in each coordination sphere. The complex is paramagnetic ($\mu = 2.17$ BM per Mo) and is the first example of a dimolybdenum oxo-bridged species with no terminal oxo or sulfido ligands.[218] The dimeric complexes $[Mo_2O_3(S_2CNR_2)_2]$ (R = alkyl) have been identified spectroscopically and isolated as intermediates in the oxidation of $[Mo_2(S_2CNR_2)_6]$ to Mo^{V} and Mo^{VI} compounds. They have low magnetic moments (1.29 BM per Mo), suggesting the presence of a significant metal–metal interaction.[54]

Molybdenum sulfides react with CN^- in aqueous solution to form a wide variety of oligomeric cyanothiomolybdate anions, which contain Mo_2S, Mo_2S_2, Mo_3S_4 and Mo_4S_4 cores[59] (see Section 36.1.4). These types of complexes are formed under conditions thought to occur in prebiotic times on this planet and, thus, they could be important in the evolution of molybdenum enzymes. Sulfur bridges are also important in other non-oxido dimolybdenum(IV) species. In $[\{(HS)Mo(hd)\}_2][CF_3SO_3]_2$ (hd = 1,5,9,13-hetrathiacyclohexadecane) there is an MoSMoS ring, in which each sulfur atom belongs to an intact macrocycle coordinated in the endo form.[219] An Mo_2S_2 ring is also found in the sulfido-bridged complex $[(Pr_2NCS_2)(Pr_2NCS)Mo(\mu\text{-}S)_2Mo(SCNPr_2)(S_2CNPr_2)]$, which also contains bidentate dithiocarbamates and thiocarboxamido ligands bound to the molybdenums in a side-on manner, and in $[Mo_2(\mu\text{-}S)_2(SBu^t)_4(HNMe_2)_2]$. These compounds involve Mo—Mo distances of 2.707(2) and 2.730(1) Å, respectively, consistent with the formation of a metal–metal bond.[220] A triply-bridging sulfur atom is found in $[Mo_3S_4(Cp)_3]^+$, in which there is a triangular cluster of Mo atoms triply-bridged by one sulfur atom above the centre of the triangle, with three doubly-bridging sulfur atoms below.[221]

$[NEt_4]_2[Cl_3Mo(\mu\text{-}S_2)(\mu\text{-}Cl)_2MoCl_3]$ contains a dimolybdenum(IV) centre bridged by one disulfide and two chloride ligands; the Mo—Mo distance is 2.763(2) Å and the low magnetic moment (1.40 BM per Mo) indicates formation of a metal–metal bond, leaving one unpaired electron per Mo.[222] Disulfide bridges are also found in $[AsPh_4]_2[Mo_2Br_6(S_2)_2(SMe_2)_2]$, which has been obtained from $[MoBr_4(SMe_2)_2]$ and $[AsPh_4]_2(S_7)$.[56]

Chlorides act as bridging ligands in $[\{MoCl_4(PhC_2Ph)\}_2]$ and $[PPh_4]_2[Mo_2Cl_{10}]$. The $[Mo_2Cl_{10}]^{2-}$ anion contains two bridging Cl groups, with a Mo—Mo distance of 3.80 Å and, therefore, there is no direct metal–metal interaction.[223] The bromide-bridged anion $[(NO)_2Br_2Mo(\mu\text{-}Br)_2MoBr_2(NO)_2]^{2-}$ also contains a long Mo—Mo distance (3.978 Å).[56]

36.4.3 MOLYBDENUM(V)

36.4.3.1 Introduction

Molybdenum(V) chemistry is dominated by oxo complexes: many of these exist as dimers, but monomeric species can be isolated from strongly acidic solutions or under nonaqueous conditions. Non-oxo compounds are also known, both as monomers and as dimers or polymers with halide or sulfur bridges. ESR spectroscopy has been used extensively to investigate the properties of monomeric Mo^{V} systems, and has shown the participation of this oxidation state in the reactions of the oxomolybdoenzymes (see Section 36.6.7).

Of the binary halide compounds of Mo^{V}, only fluoride and chloride species have been isolated and characterized. $[\{MoF_5\}_4]$ can be prepared by the reduction of MoF_6 with Si powder in the presence of dry HF; it is also a product of the reactions between $[MoF_6]$ and $[Mo(CO)_6]$ or Mo, and of the direct combination of Mo with F_2. The crystal structure shows formation of a tetramer, in which the four molybdenum atoms form a square plane bridged by four fluorines. Each molybdenum is octahedrally coordinated to four terminal fluorines with an average Mo—F bond length of 1.78(8) Å, and to two bridging fluorines at a distance of 2.06(4) Å.[224] Monomeric $[MoF_5]$ can be prepared by condensation of $[MoF_5]$ vapour in an argon matrix at liquid hydrogen temperature, or by UV photolysis of $[MoF_6]$ in an argon matrix. Vibrational spectra of $[MoF_5]$ formed by the condensation route are consistent with a D_{3h} trigonal bipyramidal structure, but the IR spectrum of the photolysis product has been interpreted assuming a C_{4v} square pyramidal geometry.[225] In the liquid and vapour states $[MoF_5]$ exists as a monomer: the electronic spectrum of liquid $[MoF_5]$ suggests a trigonal bipyramidal shape but ^{19}F NMR data are consistent with a square pyramidal structure.[226]

In the solid state $MoCl_5$ forms dimers of edge-sharing $MoCl_6$ octahedra, with the two bridging chlorides involving significantly longer Mo—Cl bonds (2.53(1) Å) than the terminal chlorides (2.24(1) Å).[227] The long Mo—Mo distance of 3.84(2) Å and magnetic moment of 1.64 BM per Mo are consistent with the absence of significant metal–metal interaction. In the gas phase monomeric $[MoCl_5]$ is formed, which has been shown by electron diffraction and Raman studies to have a trigonal bipyramidal structure.[228]

The reaction of MoF_3 with Cl_2 at 120 °C yields MoF_3Cl_2. Magnetic measurements indicate antiferromagnetic exchange between Mo^V centres in a polymeric structure and mass spectroscopic data show the presence of $[MoFCl_4]$, $[MoCl_5]$, $[Mo_2F_{10-n}Cl_n]$ ($n = 0$–6) and $[Mo_3F_{15-m}Cl_m]$ ($m = 0$–7) in the vapour above solid MoF_3Cl_2.[229]

$MoOCl_3$(s) exists in two structural forms; the monoclinic form contains a terminal oxo group and the tetragonal form involves bridging Mo—O—Mo units. The former is obtained by the reduction of $MoOCl_4$ with Al at 130 °C, the thermal decomposition of $MoOCl_4$, or by reacting SO_2(liq) or SbO_3 with $MoCl_5$.[230–232] The structure is based on an infinite zigzag chain of molybdenum atoms, each possessing two pairs of μ_2-Cl atoms and *cis* terminal oxygen and chlorine atoms in a distorted octahedral environment; the length of the Mo—Cl bond (2.81 Å) *trans* to the oxo group is significantly longer than those *cis* to this group.[232] The room temperature magnetic moment of this material is *ca.* 1.65 BM. The latter form of $MoOCl_3$ is obtained by reduction of $MoOCl_4$ with HI in SO_2(liq) at −23 °C; the compound is isomorphous with $NbOCl_3$;[230] $MoOBr_3$ also adopts this structure.[233] $MoCl_5$ reacts with Sb_2Y_3 (Y = S, Se) at an elevated temperature, or with Sb_2S_3 in CS_2 solution at room temperature, to produce $MoYCl_3$.[66]

36.4.3.2 Monomeric Complexes with an Oxo Group

36.4.3.2.1 General comments

Molybdenum(V) forms many mononuclear complexes containing one oxo group but no analogues have been reported of the *cis*-dioxomolybdenum(VI) or *trans*-dioxomolybdenum(IV) species. The O_t group possesses a multiple bond (see Section 36.4.2.2.1) and dominates the ligand field at the molybdenum, so that the $4d^1$ electron is located in an orbital which is in the plane (xy) perpendicular to the oxo group (z).[80,92,93] Most monomeric Mo^V oxo complexes adopt a square pyramidal or octahedral geometry, and their electronic configuration is $(d_{xy})^1$.

36.4.3.2.2 Halide complexes

A large number of compounds are known containing the anions $[MoOX_5]^{2-}$ (X = F, Cl, Br). These complexes are stable in acidic solution, but magnetic measurements show that as the pH is increased towards neutrality the magnetic moment decreases, indicative of dimer formation, which allows an antiferromagnetic metal–metal interaction.[234] Various other equilibria exist in solution (see Section 36.1.5) and these produce, *inter alia,* the monomeric species $[MoOX_4]^-$ and $[MoOX_4(H_2O)]^-$ (X = Cl, Br), which have been characterized by ESR spectroscopy.[235]

Crystal structures have been obtained for several salts containing the six-coordinate $[MoOX_5]^{2-}$ and the five-coordinate $[MoOX_4]^-$ anions. In $K_2[MoOF_5]\cdot H_2O$ the molybdenum is octahedrally coordinated; the Mo—O_t distance is 1.66(2) Å. The length of the four *cis* Mo—F bonds (1.88(3) Å) is significantly shorter than that of the *trans* Mo—F (2.02(1) Å)[236] and the molybdenum is displaced out of the equatorial plane in the direction of the oxo ligand so that it is located close to the centre of the donor atom array; these are common features of all oxomolybdenum complexes. In $K_2[MoOCl_5]$, the Mo—O_t distance is 1.67 Å and the bond lengths to the *cis* and *trans* chlorides are 2.40 and 2.63 Å, respectively,[237] and $[AsPh_4][MoOCl_4(H_2O)]$ involves the following bond lengths: Mo—O = 1.672(15), Mo—OH_2 = 2.393(15) and Mo—Cl = 2.359(3) Å.[238] A shorter Mo—O_t bond is found in $[AsPh_4][MoOCl_4]$, which has a square pyramidal geometry with the oxo group axial; the Mo—O_t distance is 1.610(10) Å and the Mo—Cl distances are 2.333(3) Å.[239] Crystal structure determinations for related complexes include: $[MoOX_4(H_2O)]^-$ (X = Cl, Br, I),[240] $[MoOBr_4]^-$[241] and $[MoOBr_5]^{2-}$.[242]

Complexes containing $[MoOX_4]^-$ anions (X = Cl, Br) are coordinatively unsaturated and

react readily with neural or anionic ligands to give octahedral species. The mixed halide complex $[NEt_4]_2[MoOCl_4Br]$ can be obtained by treating $[NEt_4][MoOCl_4]$ with $[NEt_4]Br$; spectroscopic data indicate that the *trans* isomer is formed.[243]

Complexes of the form $[LH_2][MoOX_5]$ (L = bidentate N donor ligand; X = Cl, Br) can be isolated from the reaction between MoO_3 in hot HX and HI, followed by addition of L. These compounds lose HCl when dissolved in dry solvents, yielding $[MoOX_3L]$, which form as the *mer* or *fac* isomers depending on the conditions. With the ligand 2,2′-biquinolyl (biquin) an intermediate complex, [biquinH][$MoOCl_4$], has also been isolated. Monodentate ligands L′ form the compounds $[L'H]_2[MoOCl_5]$, which can lose HCl to yield $[MoOCl_3L'_2]$.[244] For the ligand 8-hydroxyquinoline and its derivatives, IR spectra indicate that there is hydrogen bonding between $[LH]^+$ and $[MoOCl_5]^{2-}$ in $[LH]_2[MoOCl_5]$.[245]

Molybdenum halides and oxyhalides, including $[Mo_2Cl_{10}]$, $[Mo_2O_2Cl_6]$ and $[NH_4]_2[MoOCl_5]$, are useful starting materials for the preparation of monomeric MO^V oxo compounds. A large number of these compounds are of the form $[MoOCl_3L_n]$ ($n = 1, 2$) and commonly involve O or S donor ligands.[246,247] $[Mo_2O_2Cl_6]$ reacts with THF to give $[MoOCl_3(THF)_2]$,[248,249] from which the loosely bound THF molecules are easily displaced by a wide variety of ligands, L, yielding $[MoOCl_3L_2]$. Many neutral ligands react directly with $[Mo_2O_2Cl_6]$ to give $[MoOCl_3L_2]$ or $[MoOCl_3L]$ species; $[Mo_2Cl_{10}]$ can also form oxo complexes by abstracting oxygen from the ligand or solvent. Equilibria exist in solution between the five- and six-coordinate products; for the oxygen-donor ligands Ph_3PO, $(Me_2N)_3PO$ or THF, the only product formed is the corresponding $[MoOCl_3L_2]$ compound, but for sulfur-donor ligands Ph_3PS, $(MeN)_2CS$ or Me_2S, the five-coordinate complex $[MoOCl_3L]$ predominates.[235] $[MoOCl_3L_2]$ (L = Ph_3PO; $P(NMe_2)_3O$) possess an octahedral coordination around the molybdenum, with the chloride ligands adopting a *mer* configuration and the phosphine oxides mutually *cis*. In the Ph_3PO adduct the Mo—O_t bond length is 1.662(13) Å, and the Mo—O distances to the phosphine oxide ligands *trans* to the oxo group and *trans* to chloride are 2.136(11) and 2.065(10) Å, respectively.[250] This compound reacts with halide ions and the rate-determining step is the loss of the Ph_3PO ligand *trans* to the oxo group; subsequent to halide substitution, exchange of the substituted halide with the other Ph_3PO molecule occurs.[251] $[MoOCl_3(SPPh_3)]$ adopts a geometry intermediate between square pyramidal, with an axial oxo group, and trigonal bipyramidal, with sulfur and chloride ligands axial. The Mo—O_t bond length is 1.647(3) Å.[252]

Molybdenum(V) forms a wide range of complexes with bidentate and polydentate ligands. The reaction of $[pyH]_2[MoOX_5]$ (X = Cl, Br) with acetylacetone yields $[pyH][MoOX_3(acac)]$ which, on heating, is converted to $[MoOX_2(acac)(py)]$; $[Mo_2Cl_{10}]$ reacts with Hacac and other β-diketones, HL, to give the disubstituted complex $[MoOClL_2]$.[253] In all of these compounds, spectroscopic evidence suggests that the diketonate acts as a bidentate ligand to form an octahedral mononuclear complex. Dithiocarbamates, R_2dtc, form mononuclear $[MoOX(R_2dtc)_2]$ (X = F, Cl, Br, I) products in reactions involving the reduction of MoO_3 by $N_2H_4 \cdot HX$.[254] An analogous complex, [MoOCl(dttd)] (H_2dtdd = S,S′-bis(2′-mercaptophenyl)-1,2-mercaptoethane, Figure 2; Section 36.4.2.2.1), is formed in the reaction between $[NH_4]_2[MoOCl_5]$ and H_2dttd. This complex undergoes a reversible one-electron reduction to $[MoOCl(dttd)]^-$ but is not easily oxidized to an Mo^{VI} species.[90]

Interest in the nature of the molybdenum coordination sphere in the oxo–molybdenum enzymes has led to investigation of complexes formed by Mo^V with Schiff bases and related ligands. $[MoOCl_3(THF)_2]$ has been shown to react with a variety of Schiff bases (H_2L), including $salenH_2$ and its substituted derivatives, in the presence of base, with Li_2L or $L(SiMe_3)_2$ to give the corresponding [MoOLCl] complex, the configuration of which was assigned from ESR and IR data.[255] The anionic complex $[MoOCl_2L]^-$ (H_2L = *N*-2-hydroxysalicylidenimine) has been prepared from $[pyH]_2[MoOCl_5]$ and H_2L, and the crystal structure of its $[AsPh_4]^+$ salt has been determined. The molybdenum atom in the anion is in a distorted octahedral environment in which the planar tridentate Schiff base occupies *meridional* positions, with the nitrogen atom *trans* to the terminal oxo group; the Mo—O_t bond length is 1.673(3) Å.[256] ESR spectroscopy has been used to investigate equilibria in a solution of [MoOCl(salpn)] ($salpnH_2$ = *N*,*N*′-bis(salicylaldehydo)-1,3-diaminopropane); the results showed that considerable dimer formation occurred, with the dominant monomeric species being [MoOCl(salpn)].[257]

The reactions of $[MoOCl_3(THF)_2]$ with substituted quinolines yield a number of different types of complexes containing one or more quinoline ligands. The crystal structure of $[H_2ox][MoOCl_3(ox)]$ (Hox = 8-hydroxyquinoline) has been determined; the hydroxyquinolate acts as a bidentate O,N ligand, with the oxygen bound *trans* to the oxo group in an octahedral

geometry.[258] $[Mo_2O_2Cl_6]$ reacts with 8-mercaptoquinoline, H(tox), to give $[MoOCl_2(tox)Q]$ (Q = solvent) in which tox is bidentate, $[MoOCl(tox)_2Q]$ in which one tox is bidentate and the other monodentate, and $[MoO(tox)_3]$ in which two tox ligands are bidentate and the third is monodentate. $[MoOCl(tox)_2]$ has been prepared by the reaction of $[MoCl_3(DMF)_3]$ and 8,8′-diquinolyl disulfide and its crystal structure determined. The molybdenum atom is in a distorted octahedral environment, with two bidentate tox ligands; the oxo and chloride ligands occupy *cis* positions, and the sulfur atoms of the tox ligands are *trans* to each other; the Mo—O_t bond length is 1.716(4) Å.[259]

The reduction of nitrate and nitrite by a number of monomeric oxomolybdenum(V) complexes, including $[MoOCl_3(OPPh_3)_2]$, $[MoOCl_3L]$ (L = bipy, phen), and $[MoOClL'_2]$ (L′ = ox, tox), has been studied.[80,260–262] These reactions have relevance to the reduction of nitrate and the competitive inhibition by nitrite which occurs at the molybdenum centre of the nitrate reductases. The molybdenum centres of the MoO^{3+} complexes reduce nitrate in a one-electron step with concomitant transfer of an oxygen atom, producing NO_2 and the corresponding *cis*-MoO_2^{2+} complex. The initial substitution of nitrate occurs at the labile position *trans* to the oxo group, but the redox reaction proceeds only after ligand rearrangement so that the nitrate is coordinated by an oxygen atom *cis* to the oxo ligand.[260] Nitrate is also reduced to NO_2 by tripeptide (Gly-Gly-Met or Gly-Gly-His) molybdenum(V) complexes formed in the reaction of $[NH_4]_2[MoOCl_5]$ with the tripeptides immobilized *via* the terminal glycine to a polystyrene matrix. Analysis shows a molybdenum to tripeptide ratio of 1:1, but it is unclear how these potentially tridentate ligands bind to the molybdenum and which other ligands are present in the coordination sphere.[263] Molybdenum(V) chloro complexes of a cysteinyl-containing peptide have been prepared by reaction of $[MoOCl_3(THF)_2]$ with the peptide alone and in the presence of Et_3N. Although the compound produced under the former conditions is capable of reducing nitrate, this is not the case for the latter compound, perhaps because the chelation of the Mo^V prevents nitrate from ligating at a site *cis* to the oxo group.[264]

The properties of [MoOCl(TPP)] (H_2TPP = *meso*-tetraphenylporphyrin) and related complexes are covered in Section 36.4.3.2.4.

36.4.3.2.3 Complexes with sulfur and selenium donor ligands

Complexes of the type $[MoO(SR)_4]^-$ are important, both in their own right as interesting chemical species and as systems which provide information of relevance to the molybdenum centres of the oxomolybdoenzymes.[249,265–8] $[MoO(SAr)_4]^-$ (Ar = Ph, 4-MeC_6H_4, C_6Cl_5) and $[MoO(SePh)_4]^-$ have been prepared by the reaction of the corresponding thiol, or selenol, with $[MoOCl_3(THF)_2]$, $[pyH]_2[MoOCl_5]$ or [pyH][$MoOBr_4$] in MeCN containing Et_3N and isolated as their quaternary ammonium salt. Their alkanethiolato analogues, $[MoO(SR)_4]^-$ (R = Et, CH_2Ph) have been prepared in solution at −60 °C. $[MoO(SPh)_4]^-$ has a square pyramidal structure with Mo—O_t = 1.669(9) Å and Mo—S = 2.403(5) Å. The spectroscopic and magnetic properties of these species have been investigated in considerable detail[265] and chemically reversible one-electron reduction has been observed; oxidation leads to the formation of the dimer $[Mo_2O_2(XR)_6Q]$ (X = S, Se; Q = solvent) and RXXR.[266] An alternative synthesis to $[MoO(SPh)_4]^-$, which has also been used to prepare $[MoO\{S(CH_2)_nS\}_2]^-$ (n = 2, 3), involves the reaction of the Mo^{VI} butanediolato complex, $[MoO_2\{MeCH(O)CH(OH)Me\}_2]\cdot 2[MeCH(OH)CH(OH)Me]$ with the appropriate thiolato anion in MeOH. The crystal structure of $[PPh_4][MoO\{S(CH_2)_3S\}_2]$ has been determined and the anion (Figure 3) has a square pyramidal geometry with Mo—O = 1.667(8) Å and Mo—S = 2.389(4) Å. Although $[MoO(SPh)_4]^-$ reacts with R_2NNH_2 (R_2 = Me_2 or $(CH_2)_5$) in refluxing MeOH to produce $[MoO(NNR_2)(SPh)_3]^-$, it is inert to HN_3; however, $[MoO\{S(CH_2)_3S\}_2]^-$ reacts with HN_3 in MeOH to produce $[Mo_2O_2(\mu\text{-}N_3)\{S(CH_2)_3S\}_3]^-$.[267] $[MoOCl_4]^-$ in MeCN containing Et_3N reacts with the sterically hindered thiol, 2,4,6-$Pr^i_3C_6H_2S^-$ (Htipt) to produce $[MoO(tipt)_4]^-$.[268]

Oxomolybdenum(V) centres can form five- and seven-coordinate complexes with bidentate carbodithioate ligands. The reaction between $Na_2(C_5H_4CS_2)\cdot THF$ and $[Mo_2O_2Cl_6]$ in the presence of $[NEt_4]Br$ gives $[NEt_4][MoO(S_2CC_5H_4)_2]$. ESR spectra of this complex in solution and frozen solution indicate a d^1 monomer with square pyramidal C_{4v} symmetry.[172] Reductions of $[MoO_2L_2]$ with HL′ (HL′ = 2-aminocyclopent-1-ene-1-carbodithoic acid and its *N*-alkylated derivatives) yield the mixed ligand compounds $[MoOL_2L']$. The magnetic moment values (*ca.* 1.60 BM) and ESR spectra are consistent with the $(d_{xy})^1$ ground state.[269] [MoO(NCS)(R_2dtc)$_2$]

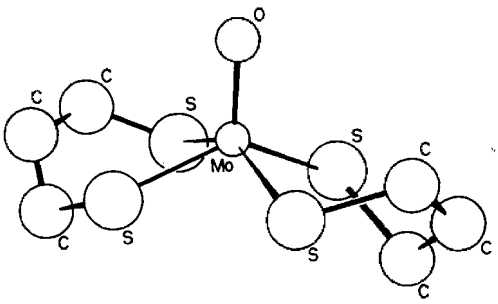

Figure 3 Structure of $[MoO(SCH_2CH_2CH_2S)_2]^-$ in its $[PPh_4]^+$ salt[266]

(R_2dtc = substituted dithiocarbamate) have been prepared and IR spectra show the thiocyanates to be N-bonded. ESR, electronic spectra and magnetic moment values (1.69 BM) confirm the monomeric nature of the complex. Cyclic voltammetry has been used to demonstrate reversible one-electron reduction to the corresponding Mo^{IV} species.[270]

Interesting redox behaviour is exhibited by the complexes $[MoOL]^-$ where L is a tetradentate *S,S',N,N'* aromatic aminothiol group (*N,N'*-bis-2'-mercaptophenyl-1,2-diaminoethane (Figure 2) and its 1,2-diamino-1,2-dimethylethane analogue). In these complexes the amino groups are deprotonated, giving the ligand dithiolene characteristics. The compounds undergo both one-electron oxidation and reduction at a platinum electrode in DMF and show no tendency to form dimeric species due to the geometrical restraint of the ligand L.[271] The electrochemistry of a series of MoO^{3+} complexes, including $MoOClL_2$ (L = 8-mercaptoquinoline) and MoOClL (L = *N,N'*-dimethyl-*N,N'*-bis-2'-mercaptoethyl-1,2-diaminoethane (Figure 2) and *N,N'*-bis-2-mercapto-2-methylpropyl-1,2-diaminoethane), has been reported; the complexes undergo a facile reduction to an Mo^{IV} species but oxidation was not observed.[87]

36.4.3.2.4 Complexes with nitrogen donor ligands

Solutions containing $[MoOCl_5]^{2-}$ react with thiocyanic or selenocyanic acid to produce $[MoO(NCS)_5]^{2-}$ and $[MoO(NCSe)_5]^{2-}$, respectively.[272] Magnetic, vibrational and electronic spectra indicate that in both anions the ligands are N-bonded, forming monomeric complexes with close similarities to the corresponding halide $[MoOX_5]^{2-}$ species.

In HCl solution, in the presence of $SnCl_2$, Mo^V forms complexes $[MoO(Hd)_2]^+$ with the dioximes (H_2d) of cyclohexane-1,2-dione and cyclopentane-1,2-dione.[273] Several compounds of tetradentate Schiff bases[255,274] with oxomolybdenum(V) have been prepared and the crystal structure of *trans*-[MoO(salen)(MeOH)]Br has been determined.[274] The Mo—O_t distance is 1.666(10) Å, and there is close interaction in the crystal between each cation and an attendant bromide anion.

Tetraphenylporphyrin, H_2TPP, reacts with $[Mo(CO)_6]$ in refluxing decalin to give [MoO(TPP)(OH)]. Derivatives of the type [MoO(TPP)X] are known with a wide variety of uninegative ligands X, including Cl, O_2H, F, Br, BF_4, NCO, N_3 and NCS.[275] Vibrational, electronic and ESR spectroscopy confirm the presence of one unpaired electron and a central Mo—O_t group with a *trans* octahedral geometry of C_{4v} symmetry. The cyclic voltammograms of [MoO(TPP)X] (X = MeO, AcO, Cl) show a reversible one-electron reduction to a Mo^{IV} species, whereas that for the related corrolate complex, [MoO(mec)] (mec = trianion of 2,3,17,18-tetramethyl-7,8,12,13-tetraethylcorrole) shows both one-electron reduction and oxidation processes. In addition to one-electron reduction, [MoO(TPP)(OMe)] exhibits other redox couples, involving dissociation of $(OMe)^-$ and formation of Mo^{III} and Mo^{II} complexes.[276]

[MoO(TPP)Br] can be chemically reduced by superoxide to give [MoO(TPP)], *via* Mo^V and Mo^{IV} superoxide complexes, which are stable at low temperatures.[114] In the presence of superoxide, the substitution reaction of [MoO(TPP)Br] with MeOH to give [MoO(TPP)(OMe)] proceeds *via* an Mo^{IV} species rather than *via* $[MoO(TPP)(MeOH)]^+$, which is the pathway in the absence of superoxide.[277] Photochemical reduction of [MoO(TPP)(OMe)] yields [MoO(TPP)], which reacts with O_2 in MeOH to re-form [MoO(TPP)(OMe)] and produce H_2O_2, thus giving a catalytic route for the photoassisted reduction of molecular oxygen to hydrogen peroxide.[278]

36.4.3.2.5 Spectroscopic studies

A comprehensive tabulation of such data is available in ref. 5 and selected details will be presented here. Monomeric oxomolybdenum(V) complexes are paramagnetic, with magnetic moments in the range 1.65–1.73 BM (Table 7) due to the single unpaired electron. This makes Mo^V complexes accessible to investigation by ESR spectroscopy, and many studies have been reported, both with well-defined coordination compounds and with biological systems.[131,238,250,252,255,265,280–284] A monomeric Mo^V complex in solution which possesses sufficient thermal motion to average the molecular anisotropy on the ESR timescale has a characteristic ESR spectrum. This consists of a strong central line, due to resonance of molecules with even molybdenum isotopes ($I = 0$), flanked by six hyperfine lines due to interaction between the unpaired electron and the ^{95}Mo and ^{97}Mo nuclei ($I = \frac{5}{2}$). When molecular tumbling does not occur, for example in solids and frozen solutions, or is slow on the ESR timescale, the spectrum becomes more complex, displaying major features due to the principal g values. Monomeric Mo^V centres with axial symmetry should manifest two principal resonances, $g_{\parallel}$ (g_{zz}) and $g_{\perp}$ (g_{xx}, g_{yy}), whereas in systems of lower symmetry three principal resonances should be observed, each associated with six hyperfine lines.[80] A low-symmetry ligand field allows extensive d orbital mixing, which generally results in the principal molecular g values being displaced from the metal–ligand axes. ESR can provide a fingerprint of a Mo^V centre in a coordination complex or an enzyme, and Table 8 lists the ESR parameters recorded for some typical complexes. ESR spectra of Mo^V complexes can be grouped into two types according to the degree of g anisotropy.[283] One group is typical of octahedral and the other of square pyramidal complexes and, using this criterion, the Mo^V centres of the oxomolybdoenzymes would appear to be square pyramidal; this correlation is based on circumstantial evidence and, so far, no definitive structural prediction has been derived from ESR data alone.

Table 7 Magnetic Moments of some Oxomolybdenum(V) Complexes[5]

Compound	μ_{eff} (BM)	*T* (K)	*Ref.*
$[bipyH_2][MoOCl_5]$	1.73	303	243
$[NEt_4]_2[MoO(NCS)_5]$	1.67	294	272
$[MoOCl_3(THF)_2]$	1.73	a	248
$[MoO(R_2dtc)Cl]$[b]	1.65	293	254
[MoO(TPP)OH][c]	1.70	79	275

The use of ESR spectroscopy to probe Mo^V centres in biological systems has stimulated attempts to reproduce the ESR spectra of molybdoenzymes using well-defined chemical systems. The similarity between ESR parameters of species formed by reacting $Na_2[MoO_4]$ with S-donor ligands and those of xanthine oxidase imply that in the enzyme (cysteinyl)S ligation of molybdenum may occur.[284] However, no well-characterized Mo^V complex has an ESR spectrum which reproduces all the aspects of one observed for the Mo^V centre of an oxomolybdenum enzyme. A particular problem is the absence of superhyperfine coupling constants for well-defined Mo^V systems; a notable exception is the observation of ^{17}O

superhyperfine coupling in ^{17}O-enriched $[^{98}MoO(SPh)_4]^-$, a complex which exhibits exceptionally narrow ESR linewidths.[265]

According to molecular orbital calculations, for a ligand field of C_{4v} symmetry which is dominated by a strong molybdenum–oxygen interaction along the z axis, the d orbitals transform according to a_1 (d_{z^2}), b_1 ($d_{x^2-y^2}$), e (d_{xz}, d_{yz}) and b_2 (d_{xy}) representations, in order of decreasing energy.[285] The ground state configuration of a Mo^V complex is $^2B_2$ $(d_{xy})^1$, and three d–d transitions are predicted: $^2B_2 \rightarrow {}^2E$, $^2B_2 \rightarrow {}^2B_1$ and $^2B_2 \rightarrow {}^2A_1$. Several interpretations of the electronic spectra of MoO^{3+} complexes have been proposed.[238,285–288] The lowest energy band, which appears in the near IR region of the spectrum between 600 and 850 nm and (at low temperature) often manifests vibronic coupling with ν(Mo—O_t) of *ca.* 900 cm^{-1}, is due to the $^2B_2 \rightarrow {}^2E$ promotion. The other two d–d bands are often obscured by intense ligand to metal charge transfer bands,[265,288] but the $^2B_2 \rightarrow {}^2B_1$ transition is generally responsible for the second absorption band which is usually observed between 400 and 450 nm. In the case of $[AsPh_4][MoOCl_4]$, the $^2B_2 \rightarrow {}^2A_1$ promotion has been observed as a shoulder at *ca.* 380 nm on a intense Cl→Mo charge transfer band.[288]

The vibrational spectra of oxomolybdenum(V) complexes display an intense band in the range 940 to 1020 cm^{-1} due to ν(Mo—O_t);[5,80] the higher frequencies, corresponding to the shorter molybdenum–oxygen bonds, are found in square pyramidal complexes, in which there is no ligand *trans* to the oxo group.

36.4.3.3 Complexes Involving Multiple Molybdenum–Nitrogen Bonds

Monomeric non-oxo molybdenum(V) complexes have been isolated with nitride (N^{3-}), imide (NR^{2-}) and amide (NRR'^-) ligands, which may act as models for intermediates in the degradation of dinitrogen in nitrogenase. However, no molybdenum(V) compounds are yet known which correspond to the diazenide or hydrazide analogues of the molybdenum(IV) complexes described in Section 36.4.2.3.

$[PPh_3Me]_2[MoNCl_4]$ can be prepared by reduction of $[PPh_3Me][MoNCl_4]$ or $MoNCl_3$ with $[PPh_3Me]I$. A crystal structure determination has shown the presence of a square pyramidal coordination around the molybdenum in the anion, with an axial nitride ligand at a bond length of 1.634(6) Å.[289] $[MoNCl_2(PPh_3)_2]$ may be obtained by treating $[MoCl_4(THF)_2]$ or $[MoCl_3(THF)_3]$ with Me_3SiN_3, followed by addition of PPh_3.[290] The ESR spectrum of this latter compound at 20 °C shows superhyperfine coupling to two phosphorus nuclei which are equivalent on the ESR timescale. The analogous complexes $[MoNCl_2(bipy)]$[290] and $[MoNBr_2(bipy)]$[291] have also been prepared and characterized. The IR spectrum of all of these nitrido complexes shows a strong absorption in the range 950–1050 cm^{-1}, which is assigned to the stretching of a molybdenum–nitrogen triple bond.

Imido ligands bind to molybdenum in a manner equivalent to the binding of oxo groups, and several compounds have been synthesized which are analogues of known oxo species. 4-Tolylimido ($Ntol^{2-}$) complexes of molybdenum(V) can be prepared from the reduction of molybdenum(VI) compounds; for example, reaction of $[Mo(Ntol)Cl_4(THF)]$ with tertiary phosphines, L, yields $[Mo(Ntol)Cl_3L_2]$. These complexes display magnetic moments close to the spin-only value for one unpaired electron and show strong ESR signals at room temperature. The structure of $[Mo(Ntol)Cl_3(PEtPh_2)_2]$ displays a *meridional* arrangement of chlorine atoms and *trans* phosphines in octahedral geometry; the molybdenum–nitrogen bond length is 1.725(6) Å.[292] The reaction of $[Mo(CO)_4Cl_2]$ with $[NH_4][S_2P(OEt)_2]$ and RN_3 (R = Ph, 4-tolyl) gives $[Mo(NR)\{S_2P(OEt)_2\}_3]$ and $[Mo(NR)Cl\{S_2P(OEt)_2\}_2]$. The ESR spectra of these compounds show that the unpaired electron is coupled to ^{14}N, ^{31}P and $^{35,37}Cl$ nuclei and an unambiguous determination of the superhyperfine coupling constants was achieved using ^{15}N labelling.[293] ESR and IR spectroscopy have been used to monitor the reactions of $[Mo_2Cl_{10}]$ and $[MoOCl_4(DMF)]^-$ with $PhNH_2$. The reactions proceed to give $[Mo(NPh)(NHPh)_5]^{2-}$ *via* $[Mo(NPh)Cl_{4-n}(NHPh)_n(DMF)]$ (n = 0–3) intermediates.[294]

36.4.3.4 Other Monomeric Complexes

36.4.3.4.1 Halide complexes

The hexahalide ions $[MoF_6]^-$ and $[MoCl_6]^-$ form well-characterized compounds which are unstable towards hydrolysis. MoF_6 readily accepts electrons to form $[MoF_6]^-$ ions and will

oxidize Ag metal or I_2 in MeCN at ambient temperatures, yielding the molybdenum(V) salts $[Ag(NCMe)_4][MoF_6]_2$ or $[I(NCMe)_2][MoF_6]$, respectively.[295] Simple salts of $[MoCl_6]^-$ are readily prepared, for example reaction of $[Mo_2Cl_{10}]$ with $[NEt_4]Cl$ gives $[NEt_4][MoCl_6]$.[296] $[MoCl_6]^-$ is also obtained in a KCl—$MoCl_5$ melt.[297]

The reactions of various ligands with $[Mo_2Cl_{10}]$ in dry solvents provide a general route for the preparation of non-oxo chloromolybdenum(V) complexes. $[Mo_2Cl_{10}]$ reacts with ICN, to produce $[MoCl_5(NCI)]$ in which the added molecule is N-bonded,[298] and with $Y(CN)_2$ (Y = S, Se) in CS_2 to give $[MoCl_5\{Y(CN)_2\}_2]$, in which the new ligand is coordinated through its Y atom.[299] The reactions of $[Mo_2Cl_{10}]$ or $[MoOCl_4(DMF)]^-$ with thiols, RSH, in py have been monitored by ESR and IR spectroscopy; $[MoSCl_{4-n}(SR)_n(py)]^-$ ($n = 0$–3) and $[MoS(SR)_5]^{2-}$ were suggested as possible products, in a reaction exactly analogous to that using $PhNH_2$ instead of RSH (see Section 36.4.3.3).[294] The dimer $[Mo_2S_2Cl_6]$ dissolves in MeCN to form $[MoSCl_3(NCMe)_2]$, which reacts with pyridine and HCl to give $[pyH][MoSCl_4(py)]$. Direct reaction of $[Mo_2S_2Cl_6]$ with pyridine gives the seven-coordinate compound $[MoSCl_3(py)_3]$.[300]

The chloro alkoxide complexes $[MoCl_4(OR)_2]^-$ (R = Me, Et) have been prepared by low-temperature reaction of $[Mo_2Cl_{10}]$ with ROH, and have been isolated as their $[NMe_4]^+$, $[pyH]^+$ and $[quinH]^+$ salts.[279] The vibrational, electronic and ESR spectra of these materials are consistent with a *trans* octahedral structure for these anions. $[MoCl_4(NPPrPh_2)(OPPrPh_2)]$ has been obtained by oxidation of $[MoCl_4(PPrPh_2)_2]$ with tolyl-4-sulfonyl azide.[301] An eight-coordinate complex $[MoCl_4(diars)_2]I_3$ has been prepared, and the crystal structure determined; the ligands adopt a dodecahedral geometry around the molybdenum, with arsenic atoms on the *A* sites, and chlorine atoms on the *B* sites.[302]

36.4.3.4.2 Complexes of sulfur donor ligands

Compounds containing the $[Mo(S_2CNEt_2)_4]^+$ cation can be prepared by the reaction of $[Mo_2O_2Cl_6]$ with $[Et_2NH][S_2CNEt_2]$,[303] or by oxidation of the corresponding Mo^{IV} or Mo^{III} complexes.[304,305] Crystal structures have been determined for salts with various anions, all of which display the same geometry for the cation. Crystals of $[Mo(S_2CNEt_2)_4]I_3$ are monoclinic, with dodecahedral coordination of sulfur atoms around the molybdenum; the mean Mo—S distances to the two sites are 2.545(2) and 2.500(2) Å.[305] The electrochemistry of several eight-coordinate complexes, including the dithiocarbamate, $[Mo(S_2CNEt_2)_4]^+$, dithiolenes, $[Mo(S_2C_2R_2)_4]^{3-}$, and the thioxanthate, $[Mo(S_2CSBu^t)_4]^+$, has been investigated.[306] All the systems exhibit a reversible one-electron reduction and, with the exception of the thioxanthate complex, a reversible one-electron oxidation.

Reaction of $[Mo_2O_4(S_2CNR_2)_2]$ (R = Et, Pr^i) with thiol-containing ligands 2-$NHR'C_6H_4SH$ or 1,2-$(HS)_2C_6H_4$ yields the monomeric complexes $[Mo(S_2CNR_2)(NRC_6H_4S)_2]$ or $[Mo(S_2CNR_2)(SC_6H_4S)_2]$, respectively.[307] A determination of the crystal structure of $[Mo(S_2CNEt_2)(NHC_6H_4S)_2]$ has shown a coordination geometry at the molybdenum midway between that of a trigonal prism and an octahedron, in which the two nitrogen atoms are mutually *trans*.[308]

$[NEt_4][MoO(S\text{-}4\text{-}tolyl)_4]$ reacts with *N*-(2-hydroxybenzyl)-2-mercaptoaniline (H_3hbma) to yield $[NEt_4][Mo(hbma)_2]$, the anions of which possess a highly distorted, all-*trans*, octahedral geometry. Cyclic voltammetry has been used to demonstrate reversible one-electron oxidation and reduction processes for this complex.[309]

36.4.3.4.3 Cyanide complexes

The octacyanide ion $[Mo(CN)_8]^{3-}$ can be prepared by oxidation of $[Mo(CN)_8]^{4-}$. Like the Mo^{IV} anion (Section 36.4.2.4.6) $[Mo(CN)_8]^{3-}$ has been structurally characterized in more than one geometry. In $[NBu_4]_3[Mo(CN)_8]$ the anion possesses a near-regular, D_{2d} triangular-dodecahedral structure, with an average Mo—C distance of 2.12(2) Å.[310] However, the eight cyano groups in $Cs_3[Mo(CN)_8]\cdot 2H_2O$ are arranged in a 4,4′-bicapped trigonal prism around the molybdenum, with an average Mo—C distance of 2.17(2) Å.[311] Furthermore, $K_3[Mo(CN)_8]\cdot H_2O$ is isomorphous with $K_3[W(CN)_8]\cdot H_2O$, which has square antiprismatic geometry, although a full structure was not determined for the molybdenum analogue as it decomposed under X-ray irradiation.[312] The ESR spectrum of $K_3[Mo(CN)_8]$ in glycerine solution indicates that all the cyanides are equivalent, consistent with a square antiprismatic structure, or with stereochemical non-rigidity on the ESR timescale.[313]

4.3.4.4 *Spectroscopic studies*

The magnetic moments of monomeric non-oxo molybdenum(V) complexes typically lie between 1.55 and 1.73 BM,[5] corresponding to the spin-only value for one unpaired electron. The ESR spectra of these complexes usually show one strong line with six hyperfine lines due to ^{95,97}Mo coupling; a typical example is $[Mo(S_2CNEt_2)_4]I_3$ with isotropic g and A values of 9794(1) and 37.1(1) $\times 10^{-4}$ cm^{-1}, respectively.[304] $[Mo(S_2CNEt_2)(NHC_6H_4S)_2]$ displays superhyperfine splitting for two equivalent nitrogen and two equivalent hydrogen atoms, with A values deduced from spectral simulation of 2.4×10^{-4} cm^{-1} and 7.4×10^{-4} cm^{-1}, respectively.[307] These couplings are the same order of magnitude as those observed for superhyperfine splittings in the spectra of the molybdenum oxidases, demonstrating the possibility that these may be caused by coordinated N—H groups.

$[NEt_4][Mo(hbma)_2]$ (H_3hbme = *N*-(2-hydroxybenzyl)-2-mercaptoaniline) exhibits an axial ESR spectrum, with $g_\perp > g_\parallel$ and $A_\parallel > A_\perp$. Superhyperfine coupling to the two nitrogens was not detected over a temperature range from room temperature to 77 K.[309] The single crystal X-band ESR spectrum of the D_{2d} anion of $[NBu_4]_3[Mo(CN)_8]$ has been determined at room temperature. The sense of the anisotropy in g values ($g_\parallel > g_\perp$) contradicts predictions based on simple crystal field theory, and possible explanations have been proposed.[314]

The electronic absorption spectrum of the $[MoCl_6]^-$ ion in solidified KCl—$MoCl_5$ melt shows a absorption band at 24 100 cm^{-1}, assigned to the $(t_{2g})^1 \rightarrow (e_g)^1$ transition of an octahedral complex.[297] In $[NEt_4][MoCl_6]$ this band is split by symmetry lowering (as suggested from ESR data obtained for this salt)[315] and/or spin–orbit coupling.[296] Other, more intense, bands at higher energies in $[MoCl_6]^-$ complexes are due to ligand-to-metal charge transfer transitions. Low energy absorption bands in $[MoCl_4(OR)_2]$ (R = Me, Et) complexes can be interpreted assuming a *trans* octahedral structure.[279] The UV–vis spectrum has been reported for $[Mo(S_2CNEt)_4]I_3$, but no assignments have been proposed.[305]

36.4.3.5 Dimeric and Polymeric Complexes

36.4.3.5.1 *General comments*

Dimeric species play a major role in the chemistry of molybdenum(V), and of particular importance are compounds containing one or more oxygen bridges. Examples are also known of complexes bridged by sulfur, selenium or nitrogen, and halide bridges are found in $[\{MoF_5\}_4]$[225] and $[\{MoCl_5\}_2]$.[230] Many dimeric compounds are diamagnetic due to interaction between the two molybdenum(V) atoms, either directly and/or *via* the bridging atoms, which lead to spin-pairing of the two unpaired electrons. However, in some $(Mo^V)_2$ systems spin-pairing does not occur or is incomplete and ESR signals are observed characteristic of monomeric species, with one electron associated with each molybdenum.

36.4.3.5.2 *Dimeric complexes with one bridging ligand*

Almost all of these compounds are based upon an $\{Mo_2O_3\}^{4+}$ core and a representative selection of these compounds is given in Table 9. In these compounds, each molybdenum is coordinated to a terminal oxo ligand with a linear, or near-linear, Mo—O—Mo bridge. The terminal oxo groups are usually *cis* to the oxo bridge, directed either *cis* (*syn*) or *trans* (*anti*) to each other across the bridge, and no complexes are known in which the two terminal oxo ligands are *cis* to the Mo—O—Mo bridge in a skew arrangement, forming a dihedral angle of 90°. Bonding considerations for these $\{Mo_2O_3\}^{4+}$ complexes show that the molybdenum d_{xy} orbitals, which are nonbonding in mononuclear oxo complexes, are in proper alignment with the p_x orbital on the oxygen bridging atom to form three-centre delocalized molecular orbitals, producing a bonding, a nonbonding and an antibonding level.[5] This interaction is maximized at dihedral angles between the terminal oxo ligands of 0° (*syn*) and 180° (*anti*), but cannot occur at 90° (skew). Two electrons from the oxygen and one from each molybdenum fill the bonding and nonbonding orbitals, to give diamagnetic compounds. In the skew arrangement each molybdenum d_{xy} orbital would interact with a different oxygen p orbital, giving, for each Mo—μ-O π bond, one bonding and one antibonding level occupied by one molybdenum and two oxygen electrons; therefore, the electronic structure of the centre would involve the two

degenerate antibonding orbitals each containing one unpaired electron, to give a paramagnetic complex with an $S = 1$ ground state. Although no crystal structures are known with the skew geometry, it is possible that in solution rotation about the Mo—O—Mo bonds may occur, giving rise to paramagnetic species. Bending of the Mo—O—Mo bridge would also reduce the Mo—O—Mo π interaction and lead to paramagnetism.

Table 9 A Representative Selection of Dimeric Molybdenum(V) Complexes Containing a $\{Mo_2O_3\}^{4+}$ Core

Complex	*Ref.*

$[Mo_2O_3(8\text{-hydroxyquinolinate})_4]$	340–343
$[Mo_2O_3(NCS)_2(8\text{-hydroxyquinolinate})]$	337

[a] Hfacac = 1,1,1,5,5,5-hexafluoropentane-2,4-dione.
[b] H(ONN) = $RC_6H_4C(O)NHNC(Me)C(Me)NOH$, $2\text{-}H_2NNHC(O)C_6H_4NC(Me)C(Me)NOH$.

Rarely, a linear O=Mo—O—Mo=O arrangement is adopted, in which the molybdenum d_{xy} orbitals are orthogonal to the oxygen p_π orbitals and, therefore, the system is paramagnetic.

A typical example of a complex with a normal $\{Mo_2O_3\}^{4+}$ core in the *anti* arrangment is $[Mo_2O_3Cl_4(DME)_2]$, prepared by refluxing $[Mo_2Cl_{10}]$ with DME. Each molybdenum is octahedrally coordinated to a bridging oxo group, a terminal oxo group, two chloride ligands and the two oxygen atoms of a bidentate dimethoxyethane ligand; one oxygen of the DME is *trans* to the oxo bridge.[316] The crystal structure of $[Mo_2O_3(acac)_2(facac)_2]$ (Hfacac = 1,1,1,5,5,5-hexafluoropentane-2,4-dione) displays a similar geometry, with the terminal oxo groups *cis* to a linear Mo—O—Mo bridge in an *anti* conformation, and the diketonates completing the octahedral coordination spheres of the molybdenum.[317] Magnetic susceptibility measurements of $[Mo_2O_3(acac)_4]$ between 77 and 292 K show this material to be paramagnetic, with a temperature dependent magnetic moment suggesting some direct or indirect interaction between the molybdenums. The paramagnetism may be due to the presence of a bent Mo—O—Mo bridge, which would be consistent with the IR spectrum of this compound.[318]

There are a large number of well-characterized complexes with 1,1-dithiolate ligands which contain an $\{Mo_2O_3\}^{4+}$ core; these include compounds of dithiocarbamate $(S_2CNR_2)^-$, trithiocarbonate $(S_2CSR)^-$, dithiocarboxylate $(S_2CR)^-$ and dithiophosphate $(S_2P(OR)_2)^-$ ligands[320–328] (see Table 9). All of these complexes are diamagnetic, or have very low magnetic moments, and crystal structure determinations have shown examples of *syn* and *anti* conformations of the $\{Mo_2O_3\}^{4+}$ core; the oxo groups in $[Mo_2O_3\{S_2P(OEt)_2\}_4]$ adopt the *anti* configuration,[328] but in both $[Mo_2O_3(S_2COEt)_4]$[325] and $[Mo_2O_3(S_2CNEt_2)_4]$[100] the *syn* configuration is preferred. The length of the Mo—O_t bonds is significantly shorter than that of Mo—O_b bonds (*e.g.* in $[Mo_2O_3(S_2COEt)_4]$ the distances are 1.65(2) and 1.86(2) Å, respectively) and the longest Mo—S bonds are those *trans* to the terminal oxo ligands. The xanthate complexes, $[Mo_2O_3(S_2COR)_4]$ (R = alkyl), react with dialkylamines, alcohols or hydrogen

sulfide to lose xanthate and produce $[Mo_2O_2S_2(S_2COR)_2]$, which contains two sulfido bridges.[324] The dithiocarbamates $[Mo_2O_3(S_2CNR_2)_4]$ disproportionate in solution to generate an equilibrium with Mo^{IV} and Mo^{VI} species (equation 1, Section 36.4.2.2.1), and can easily be prepared by reacting $[MoO_2(S_2CNR_2)_2]$ with $[MoO(S_2CNEt_2)_2]$.[70] The mixed Mo^V—Mo^{VI} dimer $[Mo_2O_3(S_2CNEt_2)_4]^-$ has been prepared and structurally characterized in a material also containing $[Mo_2O_3(S_2CNEt_2)_4]$ and (probably) $[H_5O_2]^+$.[322] The anion is paramagnetic, and ESR spectroscopy has shown the unpaired electron to be localized on one molybdenum, rather than over the whole molecule.

Complexes with an $\{Mo_2O_3\}^{4+}$ core which contain five-coordinate molybdenum atoms have been isolated with tridentate sulfur donor ligands. These complexes have the form $[Mo_2O_3L_2]$ ($L = S(C_2H_4S)_2^{2-}$, $O(C_2H_4S)_2^{2-}$, $MeN(C_2H_4S)_2^{2-}$), and crystallize with the terminal oxo groups in the *anti* configuration.[330,331] The coordination geometry around each molybdenum is that of a distorted trigonal bipyramid, with the axial positions occupied by the bridging oxygen and the central sulfur, oxygen[330] or nitrogen[331] atom of the tridentate ligand. With the tetradentate ligands $\{SCH_2CH_2N(Me)CH_2CHRN(Me)CH_2CH_2S\}^{2-}$, L, (R = H, Me) the molecules $[Mo_2O_3L_2]$ possess an *anti* configuration and the molybdenum atoms are octahedrally coordinated.[332]

Structure determinations of the isothiocyanate complexes $K_4[Mo_2O_3(NCS)_8]\cdot 4H_2O$[335] and $[pyH]_4[Mo_2O_3(NCS)_4(C_2O_4)_2]$[336] have shown that they adopt the *anti* configuration, with N-bound isothiocyanates. A report has suggested that $[Mo_2O_3(oxine)_4]$ (Hoxine = 8-hydroxyquinoline) can be isolated in four isomeric forms, one of which is strongly paramagnetic ($\mu = 1.83$ BM).[340] However, a later ^1H NMR study of this compound in DMSO showed no evidence of such isomer formation, and indicated that all the N atoms of the oxine ligands are coordinated *trans* to an oxo group.[341] The electrochemistry of $[Mo_2O_3(oxine)_4]$ in DMSO has shown that this molecule can be reduced in two reversible one-electron steps, but oxidation to an Mo^{VI}—Mo^V dimer causes decomposition.[342] An electrochemical study comparing Mo^V dimers with one, two or three bridging ligands has shown that the monooxo-bridged species are reduced by successive one-electron processes, rather than by a two-electron process which is observed for dioxo-bridged complexes.[345]

Assignments have been made of both terminal and bridging ν(Mo—O) stretching modes in the IR spectra of complexes containing the $\{Mo_2O_3\}^{4+}$ core.[130,346] In the Mo—O_t region (900–1000 cm^{-1}) one band should be observed for the *anti* and two for the *syn* conformer; however, only one band has been found in all cases, which may be due in the *syn* complexes to overlap of the two bands or to a low intensity of the antisymmetric mode. A distinctive feature of the electronic absorption spectra of $\{Mo_2O_3\}^{4+}$ complexes is an intense band at *ca.* 19 000 cm^{-1}, which is not appreciably ligand dependent and appears to be characteristic of a linear Mo—O—Mo bridge, as it is not present in the monomers or dimers with two bridging ligands.[5] The ^{17}O NMR chemical shifts of the oxo ligands of molybdenum(V) and (IV) complexes have been used to compare relative Mo—O π-bond strengths.[128]

A complex closely related to those possessing an $\{Mo_2O_3\}^{4+}$ core is $[Mo_2O(Ntol)_2(S_2CNEt_2)_4]$ (tol = 4-tolyl), prepared by reducing $[MoO(Ntol)(S_2CNEt_2)_2]$.[142] IR and ^{17}O NMR studies have indicated an oxo-bridged structure for the dimer; there is an intense absorption at 18 760 cm^{-1} in the electronic spectrum, which does not obey the Lambert–Beer law due to a disproportionation reaction which sets up an equilibrium with Mo^{IV} and Mo^{VI} species.

The only complexes which are known to contain an $\{Mo_2O_3\}^{4+}$ core in which the two terminal oxo groups are *trans* to the Mo—O—Mo bridge are $[Mo_2O_3(TPP)_2]$ and $[Mo_2O_3(OEP)_2]$ with tetradentate porphyrin ligands (TPP = tetraphenylporphyrin, OEP = octaethylporphyrin).[347,348] In $[Mo_2O_3(TPP)_2]$ the Mo—O_t and Mo—O_b bond lengths of 1.707(3) and 1.936(3) Å, respectively, are slightly longer than the corresponding distances observed in the other $\{Mo_2O_3\}^{4+}$ systems,[100,325,328] presumably because of the mutual *trans* effect of the oxo ligands.

A complex containing a mixed Mo^V—Mo^{VI} oxidation state $\{Mo_2O_5\}^+$ core can be obtained by reduction of $[Mo_2O_5(nane)_2][Br_3]_2$ (nane = *N,N',N''*-trimethyl-1,4,7-triazacyclononane). In the Mo^{VI} dimer there is a linear Mo—O—Mo bridge, and each molybdenum is also coordinated to two oxo ligands *cis* to the oxo bridge in an *anti* conformation, but the structure of the Mo^V—Mo^{VI} species is not known. An Mo^V—Mo^V dimer of this system can be produced electrochemically, but not by chemical reduction.[349] The reduction of $[MoO(S_2CNEt_2)_3][BF_4]$ results in the formation of $[Mo_2O(S_2CNEt_2)_6][BF_4]$, an Mo^V—Mo^{IV} dimer which contains a linear Mo—O—Mo bridge. Each molybdenum is seven-coordinate, and the equal Mo—O bond

lengths and equivalent environments suggest that the unpaired electron is likely to be delocalized.[218]

Two types of complex are known with only one bridging ligand which is not an oxo group. In $[Mo_2O_2X_4(C_2O_4)]$ (X = F, Cl, Br) the oxalate is bidentate to each molybdenum; the coordination geometry around the molybdenum is square pyramidal, with axial oxo ligands, and the room temperature magnetic moments of 1.67 BM per molybdenum indicate that the interaction between the two molybdenum atoms is weak.[350] The reaction of $[MoCl_3(THF)_3]$ with $4\text{-}C_6H_4(NO_2)(N_3)$ and $[Et_2NH_2][S_2P(OEt)_2]$ yields $[Mo_2(NC_6H_4N)\{S_2P(OEt)_2\}_6]$, which is bridged by the diimide, $(4\text{-}NC_6H_4N)^{4-}$, ligand. Each molybdenum atom is in a distorted octahedral environment, comprising an imido nitrogen and five sulfur atoms from one monodentate and two bidentate dithiophosphate ligands.[351]

36.4.3.5.3 Dimeric complexes with two bridging ligands

The majority of these complexes contain an $\{Mo_2Y_nY'_{4-n}\}^{2+}$ (Y = O; Y' = S, Se; n = 4–0) core, and such systems constitute an important class of molybdenum compounds;[5,80,93] Table 10 provides a reasonably comprehensive summary of the known complexes and shows the extensive range possible, given the versatility in the nature of both the core and the appended ligands. These cores consist of two molybdenum atoms, each coordinated to one terminal and two bridging O, S or Se atoms and involve a relatively close approach (2.5–2.9 Å) of the two metals. Related dimeric systems with one (or two) terminal imido (RN^{2-}) ligands in place of the Y_t atom(s) are known. Also, Mo^V dimers, in which two $Mo=Y_t$ groups are linked by two bridging ligands of another type, notably Cl^-, $[S_2]^{2-}$, $[SO_4]^{2-}$, have been characterized and are included in this section, as are complexes containing an $\{Mo_2Y_4\}^{2+}$ (Y = O, S) core, the bridging of which is supplemented by an additional *polydentate* ligand. Compounds involving oligomeric aggregates formed by the association of $\{Mo_2Y_4\}^{2+}$ (Y = O, S) cores are described in Section 36.4.3.5.4.

The first structural characterization of a compound containing a $\{Mo_2O_4\}^{2+}$ core was achieved[352] for $Ba[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 5H_2O$, the anion of which (Figure 4) consists of two distorted octahedra sharing an O—O edge. The anion possesses a C_2 axis, with the two terminal ligands *cis* to the oxo bridges to give the *syn* conformation, and each molybdenum centre has structural features identified earlier for MoO^{3+} and $\{Mo_2O_3\}^{4+}$ moieties. The shortest Mo—O bond is that involving the terminal oxo group (1.70(3) Å) and the bonds to the bridging oxygen atoms (1.88(3) and 1.93(3) Å) are shorter than those to the oxalato and aqua oxygens *cis* to the $Mo{=}O_t$ groups (2.14(4) and 2.22(4) Å, respectively), but there is no structural *trans* effect (Mo—O(oxalate) *trans* to $Mo{=}O_t$ = 2.11(3) Å). Each molybdenum lies out of the equatorial plane defined by the four donor atoms *cis* to $Mo{=}O_t$ and this results in a rough equality in the O---O distances at *ca.* 2.78 Å, close to the van der Waals separation for these atoms.[353] The atoms of the Mo_2O_2 bridge are not coplanar and there is a dihedral angle of 152° between the two MoO_2 planes. The terminal oxo groups of the $\{Mo_2O_4\}^{2+}$ core point away from each other; if they were not so aligned, their separation would be the same as the Mo—Mo separation (2.541 Å) and much closer than the van der Waals separation. This short Mo—Mo approach, and the essentially diamagnetic nature of the compound imply a direct Mo—Mo bonding interaction, and the bent bridge permits a closer approach of the Mo atoms without unduly enlarging the O_b—Mo—O_b, and/or contracting the Mo—O_b—Mo, angles. The qualitative description of the Mo—Mo bonding follows from the electronic structure of MoO^{3+} centres. Each molybdenum centre can be considered to possess a $(d_{xy})^1$ configuration and the geometry of the bridge allows a direct overlap of the two d_{xy} orbitals with the resultant bonding level accommodating the two electrons.[5,354]

$[Mo_2O_4(dane)_2][ClO_4]_2$ (dane = 1,5,9-triazacyclododecane) has been obtained both as a purple and a yellow material. The purple form contains[50] an $\{Mo_2O_4\}^{2+}$ core with the *anti* conformation in which the four-membered Mo_2O_2 ring is planar with an Mo—Mo separation of 2.586(1) Å. This separation, and the diamagnetic nature of the compound, are consistent with the formation of an Mo—Mo bond, as in a *syn* structure, by overlap of the molybdenum d_{xy} orbitals. The cation of the yellow form of this compound is considered to possess an $\{Mo_2O_4\}^{2+}$ core with the *syn* conformation by analogy with $[Mo_2O_4(nane)_2]^{2+}$ (nane = 1,4,7-triazacyclononane), which has been shown[355] to exist in both *syn* (*cis*) and *anti* (*trans*) conformers, with the immediate environment at molybdenum almost identical in the two forms and the Mo—Mo separation being 2.555(1) Å and 2.561(1) Å, respectively. *trans*-$[Mo_2O_4(nane)_4]^{2+}$ is

[a] Hdmmpd = *N,N'*-dimethyl-*N,N'*-bis(2-mercaptoethyl)propylenediamine.
[b] Hmpr = 2-mercaptopyrimidine. [c] nane = 1,4,7-triazacyclononane.
[d] dane = 1,5,9-triazacyclododecane. [e] Hoxine = 8-hydroxyquinoline and substituted derivatives.

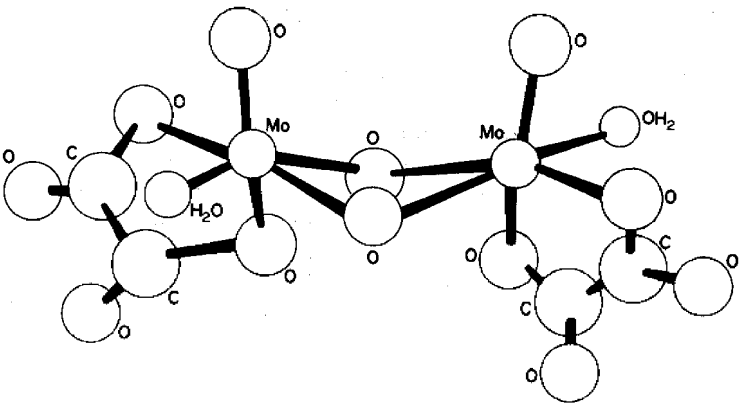

Figure 4 Structure of the anion of $Ba[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 5H_2O$[352]

irreversibly converted into *cis*-$[Mo_2O_4(nane)_4]^{2+}$ *via* acid–base catalysis and reasons for the relative thermodynamic stabilities have been attributed to the increased, local, $O_t\cdots O_b$ nonbonding distances in the latter as compared to the former.[356] Other factors may be important in determining the most stable conformation of $\{Mo_2O_4\}^{2+}$ and related complexes and the effects of Mo—Mo bonding[357] and steric interactions among coordinated ligands[358,359] have been considered.

The series of dithiocarbamato complexes $[Mo_2O_nS_{4-n}(S_2CNR_2)_2]$ ($n = 4$–0; R = alkyl)[360–371] demonstrate two important properties of these systems. Firstly, it is the μ-oxo groups which are substituted initially and, secondly, this substitution leads to an increase in the Mo—Mo separation, from 2.580(1) Å in $[Mo_2O_2(\mu\text{-}O)_2(S_2CNEt_2)_2]$,[360] through 2.673(3) Å in $[Mo_2O_2(\mu\text{-}O)(\mu\text{-}S)(S_2CNPr_2)_2]$,[364] to 2.820(1), 2.826(3) and 2.814(1) Å in $[Mo_2O_2(\mu\text{-}S)_2(S_2CNH_2)_2]$,[366] $[Mo_2OS(\mu\text{-}S)_2(S_2CNEt_2)_2]$[367] and $[Mo_2S_2(\mu\text{-}S)_2(S_2CNEt_2)_2]$,[369] respectively.

Molybdenum(V) dimers with $\{Mo_2Y_nY'_{4-n}\}^{2+}$ (Y = O, S; $n = 4$–0) may involve both molybdenum atoms with five-coordination or six-coordination (not including the Mo—Mo interaction). Examples of five-coordinate complexes include $[AsPh_4]_2[Mo_2O_4Cl_4]$,[372] $[Mo_2O_nS_{4-n}(S_2CNR_2)_2]$ ($n = 4$–0, R = H, alkyl),[360–371] $[Mo_2S_4\{S_2P(OEt)_2\}_2]$,[373] $[Mo_2O_2S_2(S_2)(S_3O_2)]^{2-}$,[374] and $[Mo_2O_nS_{4-n}(S_2)_{2-x}(S_4)_x]^{2-}$ ($n = 2$, $x = 0$, 1; $n = 1$, $x = 1$; $n = 0$, $x = 0$, 1, 2).[375–381] In these compounds the coordination around each molybdenum atom is square pyramidal, with the Mo—X_t (X = O, S) groups axial, *cis* to the two bridging ligands and in the *syn* conformation. The Mo_2X_2 bridging unit is not planar, but involves a dihedral angle between the two MoX_2 planes of 150–160°. The 1,2-dithiolate complex $[NEt_4]_2[Mo_2S_4(SC_2H_4S)_2]$ has been isolated and structurally characterized in both *syn* and *anti* conformations.[382] The *syn* form has a geometry similar to that of the corresponding dithiocarbamate complexes, with an Mo—Mo distance of 2.863(2) Å; in the *anti* conformation the Mo_2S_2 bridge is planar, and the Mo—Mo distance is 2.878(2) Å.

In the five-coordinate species with an $\{Mo_2Y_4\}^{2+}$ (Y = O, S) core there is a vacant coordination site *trans* to each terminal oxo or sulfido ligand. These can be filled to give species in which each molybdenum is six-coordinate; for example, recrystallizing $[Mo_2O_4(OSCPh)_2]$ from pyridine yields $[Mo_2O_4(OSCPh)_2(py)_2]$.[383] The crystal structures of $[Mo_2O_2X_2Cl_4(H_2O)_2]^{2-}$ (X = O, S) show octahedrally coordinated molybdenum atoms, with two bridging oxides or sulfides and *syn* terminal oxo ligands; the water molecules are *trans* to the oxo groups.[336,384] Other complexes with similar geometries include $[Mo_2O_4Cl_2(bipy)_2]$,[385] $[Mo_2O_4(O_2PH_2)_2(bipy)_2]$[386] and $[Mo_2O_4(NCS)_6]^{4-}$.[387] Also, $[Mo_2O_3S\{S_2P(OPr^i)_2\}_2]$ reacts with various ligands to form 1:1 adducts, in which the addended molecule is located in the 'molecular crevice' formed by the phosphorodithioato ligands[388] and forms a third bridging group.

Complexes of molybdenum(V) with biologically relevant ligands, such as L-cysteine, have been investigated as possible models for the molybdenum sites in enzymes. In $[Mo_2O_4(L\text{-cysteinate})_2]^{2-}$, the $\{Mo_2O_4\}^{2+}$ core possesses the *syn* conformation and each $(cysteinate)^{2-}$ acts as a tridentate O,S,N donor ligand giving octahedral coordination at each molybdenum with a carboxylato oxygen atom *trans* to the terminal oxo group.[389] A similar geometry is found

in $[Mo_2O_2S_2(L\text{-cysteinate})_2]^{2-}$, which contains two bridging sulfide atoms.[390] In the corresponding derivatives of the methyl and ethyl cysteinate esters, $(Me\text{-}Cys)^-$ and $(Et\text{-}Cys)^-$, a carboxylate oxygen does not bind to molybdenum and $[Mo_2O_4(Et\text{-}Cys)_2]$ and $[Mo_2O_2S_2(Me\text{-}Cys)_2]$ involve five-coordinate metal atoms;[391,392] in both cases the *syn* conformation is adopted and the geometry around each molybdenum is perhaps best described as distorted trigonal bipyramidal, with one bridging oxygen and the nitrogen of the ester in the axial positions. $[Mo_2O_4(L\text{-histidinate})_2]$ and $[Mo_2O_2S_2(L\text{-histidinate})_2]$ have structures closely resembling those of the corresponding $(L\text{-cysteinate})^{2-}$ complexes, with the amino acids acting as tridentate O,N,N donors and with the carboxylate oxygen *trans* to the terminal oxo ligands.[393,394]

IR and Raman studies of molybdenum(V) dimers with $\{Mo_2O_4\}^{2+}$, $\{Mo_2O_3S\}^{2+}$ and $\{Mo_2O_2S_2\}^{2+}$ cores have established that in complexes with *syn* geometry two bands are observed in the region 900–1000 cm^{-1} which can be assigned to molybdenum–terminal oxygen stretching.[130,395] Vibrations associated with the bridging framework give rise to weaker bands at lower frequencies, which are often obscured by vibrations of other ligands.

^{95}Mo NMR spectra have been measured for a number of oxo and sulfido-bridged spin-paired dimers; the majority of complexes examined to date involve the *syn*-$\{Mo_2O_2Y_2\}^{2+}$ (Y = O, S) core and possess a chemical shift in the range 320–982 p.p.m.[396,397] The chemical shifts are sensitive to the electronic environment of the molybdenum; for example the yellow *syn*-$[Mo_2O_4(nane)_2]$ and the purple *anti*-$[Mo_2O_4(nane)_2]$ (nane = 1,4,7-triazacyclononane) are readily distinguished by ^{95}Mo NMR spectroscopy, having chemical shifts of 586 and 342 p.p.m., respectively. Furthermore, their interconversion and its catalysis by acid are readily monitored by this technique.[50]

CD spectra have been recorded for complexes containing $\{MoO_2XY\}^{2+}$ cores (X, Y = O, S) liganded by optically active chelates, such as (*S*)-cysteinate and (*S*)-histidinate. These spectra manifest two distinctive peaks with opposite signs at *ca.* 26 000 and 33 000 cm^{-1}, which can be related to the nature of the asymmetric distortion around the Mo—Mo axis.[398] Unlike the $\{Mo_2O_3\}^{4+}$ dimers, those containing an $\{Mo_2O_4\}^{2+}$ core do not exhibit any characteristic absorption in their electronic spectra, although the compounds are generally yellow/orange in colour.

The electrochemistry of selected systems containing an $\{Mo_2Y_4\}^{2+}$ (Y = O, S) core has been extensively investigated. For the series of dithiocarbamato complexes $[Mo_2O_{4-n}S_n(S_2CNR_2)_2]$ (n = 0–4; R = alkyl) the μ-dioxo species are reduced by a two-electron process, whereas all other species are reduced by two successive one-electron processes. The substitution of oxygen by sulfur enhances the ease of reduction of the binuclear centre.[346,361,362,366,371] $[Mo_2O_2S_2(S_2CNH_2)_2]$ is reduced irreversibly in a two-electron process, with dissociation of the dithiocarbamates.[366] Both *syn* and *anti* isomers of $[NEt_4]_2[Mo_2S_4(SC_2H_4S)_2]$ undergo a reversible one-electron reduction in DMSO; they also exhibit two irreversible oxidation processes, each of which appear to involve two electrons per dimer.[382] Cyclic voltammetric studies of $[NEt_4]_2[Mo_2S_4(SC_6H_5)_4]$, $[NEt_4]_2[Mo_2S_4(2\text{-}SC_6H_4NH)_2]$ and $[Mo_2S_4\{SC(Me)_2CH_2NHMe\}_2]$ have shown that reversible one-electron reductions occur with complexes of the bidentate ligands, but that the thiophenolate complex is irreversibly reduced and decomposes.[399] The cysteinato complexes $[Mo_2O_{4-n}S_n(L\text{-cysteinate})_2]^{2-}$ (n = 0–2) undergo electrochemical reduction in a single four-electron step to Mo^{III} dimers in aqueous buffers. The ease of reduction and electrochemical reversibility of the Mo_2^V/Mo_2^{III} couple increase with insertion of sulfur into the bridge system. However, the corresponding ethyl cysteinate complexes $[Mo_2O_{4-n}S_n(Et\text{-}Cys)_2]$ (n = 0–2) are reduced by two successive one-electron transfers to Mo_2^{IV} species.[400] $[Mo_2O_4(glycinate)_2(H_2O)_2]$ is reduced in a two-electron transfer to give monomeric Mo^{IV} species, which can be electrochemically oxidized to M^V monomers that dimerize to re-form the initial complex. Proton-assisted oxidation of an aqueous solution of $[Mo_2O_4(glycinate)_2(H_2O)_2]$ yields the Mo^V/Mo^{VI} dimer $[Mo_2O_4(glycinate)_2(OH)(H_2O)_2]$, which can be electrochemically reduced in a one-electron step to a Mo_2^V dimer, which is further reduced in a two-electron step to monomeric Mo^{IV} species.[401]

The references in Table 10 should be consulted for other studies on $\{Mo_2Y_4\}^{2+}$ (Y = O, S, Se) systems. Dimeric complexes, analogous to those containing an $\{Mo_2Y_4\}^{2+}$ (Y = O, S) core, but with one or two terminal NR^{2-} ligands have been reported. $(Me_3CN)_2S$ reacts with $[\{CpMo(CO)_3\}_2]$ to form $[\{CpMo(NCMe_3)_2\}_2S_2]$, in which the central Mo_2S_2 moiety is planar with an Mo—Mo separation of 2.920(1) Å.[412] $[Mo_2S_2(Ntol)_4\{S_2P(OEt)_2\}_4]$ reacts with $(S_2CNBu_2)^-$ to produce $[Mo_2(Ntol)_2S_2(S_2CNBu_2)_2]$, which has a structure very similar to that of $[Mo_2O_2S_2(S_2CNBu_2)_2]$; the imido ligands are *cis* to the two sulfide bridges, in the *syn* conformation, and each molybdenum is five-coordinate with an approximately square

pyramidal geometry. The Mo—Mo distance is 2.807(2) Å.[413] The acid-assisted hydrolysis of $[Mo_4S_4(Ntol)_4\{S_2P(OEt)_2\}_4]$ to give $[Mo_2O_2S_2\{S_2P(OEt)_2\}_2]$, proceeds *via* the binuclear intermediate $[Mo_2O(Ntol)S_2\{S_2P(OEt)_2\}_2]$, which contains one terminal oxo group and one terminal 4-tolylimido group, on different molybdenum atoms, and adopts a *syn* conformation, with an Mo—Mo distance of 2.812(1) Å.[414]

A crystal structure determination of $[pyH]_4[Mo_2O_3(SO_4)(NCS)_6]$ has shown the two molybdenum atoms to be bridged by one oxo and the sulfato ligand. The terminal oxygens are *syn* and each molybdenum has a distorted octahedral geometry.[415] Persulfide bridges have been identified in several dimeric Mo^V complexes. In $[NH_4]_2[Mo_2(S_2)_6]$ each molybdenum is coordinated by four S_2^{2-} ligands in a distorted dodecahedron, with two bridging and two terminal groups. The complex is diamagnetic, and has an Mo—Mo distance of 2.827(2) Å.[416] A similar geometry is found in $[PPh_3Me]_2[Mo_2(S_2)_2Cl_8]$, in which each molybdenum is coordinated to two bridging persulfides and four terminal chlorides; the Mo—Mo distance is 2.857(1) Å.[417]

$[Mo_2O_2Cl_6(OPCl_3)_2]$ contains two chloride bridges; each molybdenum is also coordinated to two terminal chlorides, a terminal oxo ligand and a phosphate oxide in an octahedral geometry. The oxo groups are *cis* to the chloride bridges, in an *anti* conformation, and are *trans* to the $OPCl_3$ ligands.[418] $[Mo_2Cl_2L_8]Cl_8$ ($L = H_2N(CH_2)_nNH_2$, $n = 2$–6, 8) can be prepared by reacting $[Mo_2Cl_{10}]$ with the appropriate diamine under an inert atmosphere. These complexes are diamagnetic, and IR data suggest that they possess a dimeric structure with two bridging chlorides and monodentate diamines. In $[Mo_2Cl_2L_4]Cl_8$ ($L = H_2N(CH_2)_nNH_2$, $n = 9$, 10) the diamines appear to be bidentate.[419]

Asymmetric dinuclear molybdenum(V) complexes with two nitrogen bridges are formed on reaction of $[MoO_2(S_2CNEt_2)_2]$ with the hydrazines $PhC(Y)NHNH_2$ (Y = O, S) in methanol. A structure determination of $[(Et_2NCS_2)Mo\{OC(Ph)NN\}_2MoO(S_2CNEt_2)]$ has shown that one molybdenum is six-coordinate, bound in a trigonal prismatic geometry to two sulfur atoms, two oxygen atoms, and two bridging nitrogen atoms of the $\{OC(Ph)NN\}^{3-}$; the other molybdenum is five-coordinate, bound to the two bridging nitrogens, two sulfurs and an oxo ligand which occupies the axial position of a square pyramid.[420] These dimers undergo a reversible one-electron reduction. $[Mo_2Cl_{10}]$ reacts with thioureas to give $[Mo_2Cl_4\{RNHC(S)NHR'\}_4]Cl_6$ (R = pyridyl, 5-nitropyridyl, 4-methylpyridyl, 6-methylpyridyl; R' = Ph, $2\text{-}MeC_6H_4$, $4\text{-}MeC_6H_4$). Two thioureas are believed to be bridging, coordinated to one molybdenum *via* the sulfur atom and to the other *via* the pyridyl nitrogen atom; the other two thioureas are bidentate N,S donor ligands, and two chlorides on each molybdenum complete an octahedral coordination sphere.[421]

Complexes based on an $\{Mo_2Y_4\}^{2+}$ (Y = O, S) core may involve an additional ligand bridging the two Mo^V atoms. (Section 36.4.3.5.5). However, many of these complexes share characteristics with the dimeric complexes having only two bridging ligands, especially if the two sites *trans* to the terminal ligands are occupied by different atoms of a polydentate ligand. $[Mo_2O_3S\{S_2P(OPr^i)_2\}_2]$ reacts with pyridine or pyridazine (pydz) to give a 1:1 adduct. The structure of these two adducts are similar, in that the basic core of the parent compound is maintained, but there are major differences in the manner of the bonding of the py and pydz molecules; the py molecule is weakly bonded to both molybdenums through nitrogen with Mo—N distances of 2.97(2) and 2.93(1) Å, whereas each nitrogen atom of the pydz molecule coordinates to a different molybdenum atom with Mo—N distances of 2.59(2) and 2.58(1) Å.[388] Bidentate heterocyclic ligands bipy, phen, $5\text{-}NO_2$phen and $2,9\text{-}Me_2$phen (L_2) react with $[Mo_2O_4(ab)_2(py)_2]$ (Hab = picolinic acid, 8-hydroxyquinoline) to give the corresponding $[Mo_2O_4(L_2)(ab)_2]$ derivative, in which the bidentate ligand bridges the $\{Mo_2O_4\}^{2+}$ core. The products are diamagnetic, indicating retention of the metal–metal interaction.[422]

Crystal structure determinations of $[pyH]_3[Mo_2O_4(O_2CR)(NCS)_4]$ (R = H, Me) have revealed N-bonded thiocyanates, with the molybdenum atoms bridged by two oxo groups and a bidentate carboxylate, coordinated to each molybdenum through a different oxygen atom, *trans* to the terminal oxo groups. The Mo—Mo distances are 2.566(1) and 2.560(1) Å for the formate and acetate complexes, respectively.[336,423] A similar structure has been found for the $[Mo_2O_3(OEt)(O_2CC_6H_4OH)Cl_4]^{2-}$ anion, in which the bridging ligands are one oxo group, the ethoxide group and the salicylate; the Mo—Mo bond length is 2.646 Å.[424]

The potentially six-coordinate ligands $(edta)^{4-}$ and $(pdta)^{4-}$ ($H_4edta = N,N,N',N'$-tetrakis(2-ethanoic acid)-1,2-diaminoethane, $H_4pdta = N,N,N',N'$-tetrakis(2-ethanoic acid)-1,2-diaminopropane) add to dimeric molybdenum(V) centres to form complexes such as $[Mo_2O_2Y_2(edta)]^{2-}$ and $[MoO_2Y_2(pdta)]^{2-}$ (Y = O, S).[425–429] The structure of

$Cs_2[Mo_2O_2S_2(edta)]$ shows a *syn* $\{MoO_2S_2\}^{2+}$ core with sulfide bridges; the nitrogen atoms of the $(edta)^{4-}$ are coordinated *trans* to the terminal oxo groups, and the octahedral coordination spheres of the molybdenums are completed by oxygen atoms of the carboxylate groups.[426] The structures of $Na_2[Mo_2O_{4-n}S_n(R\text{-pdta})]$ ($n = 0$–2) are exactly analogous to this.[427] The low magnetic moments (*ca.* 0.5 BM) of $[Mo_2O_4(edta)]^{2-}$ and $[Mo_2O_2S_2(edta)]^{2-}$ indicate a strong interaction between the molybdenum atoms.[428] The kinetics of formation of $[Mo_2O_4(edta)]^{2-}$ in aqueous solution have been investigated, and a detailed mechanism for dissociation proposed.[429] Cyclic voltammetry has been used to study the electrochemistry of $[Mo_2O_2X_2(edta)]^{2-}$ (X = O, S) in aqueous buffers; the complexes undergo reduction in a single four-electron step to molybdenum(III) dimeric species, but no oxidation process was observed.[400]

The reaction of $[PPh_4]_2[MoS_4]$ with the mineral realgar, As_4S_4, yields $[PPh_4]_2[Mo_2O_2S_2(As_4S_{12})]$. The structure of the anion consists of a sulfido-bridged *syn*-$\{Mo_2O_2S_2\}^{2+}$ core and a tetradentate S-bonded $(As_4S_{12})^{4-}$ chelate. Each molybdenum is in a square pyramidal geometry with the terminal oxo groups in the axial positions. The $(As_4S_{12})^{4-}$ ligand contains a 1,5-(As_2S_8) eight-membered ring, which is broken in the reaction between $[PPh_4]_2[Mo_2O_2S_2(As_4S_{12})]$ and $[PPh_4]_2[MoO_2S_2]$, yielding $[PPh_4]_4[(Mo_2O_2S_2)_2(As_2S_5)_2]$. In this complex two $\{Mo_2O_2S_2\}^{2+}$ units are linked by two $(S_2AsSAsS_2)^{4-}$ ligands to give a symmetrical 16-membered macrocycle.[430]

36.4.3.5.4 Oligomeric complexes based on an $\{Mo_2O_4\}^{2+}$ and related cores

Oligomers may be formed by ligands linking two or more $\{Mo_2O_4\}^{2+}$ units together; alternatively ligands may join other molybdenum centres to an $\{Mo_2O_4\}^{2+}$ core.

The anions of $Cs_6[\{Mo_2O_3S(C_2O_4)_2\}_2(C_2O_4)]\cdot H_2O$ and $K_6[\{Mo_2O_3S(C_2O_4)_2\}_2(C_2O_4)]\cdot 10H_2O$ consist of two $\{Mo_2O_3S(C_2O_4)_2\}^{2-}$ dimers bridged by a quadridentate oxalate ligand, in which each carboxylate group bridges one dimeric unit. The Mo—O bond lengths to the quadridentate oxalates (av. 2.303(4) Å) are longer than those to the bidentate, terminal oxalates (av. 2.106(4) Å), due to the *trans* influence of the terminal oxo ligands.[431] A similar structure is adopted by the anion of $K_6[\{Mo_2O_4(O_2CCH_2CO_2)_2\}_2(O_2CCH_2CO_2)]\cdot 4H_2O$ in which one malonate dianion forms a bridge between two dimolybdenum species.[432]

Methoxide bridges between $\{Mo_2O_4\}^{2+}$ dimeric units are found in $[\{Mo_2O_4(PMe_3)\}_4(OMe)_8]$, in which four dimers are joined in an eight-membered Mo ring by four pairs of bridging $(OMe)^-$ ligands. In each dimer one molybdenum is square-pyramidally bound to a terminal oxo group, two bridging oxo groups, and two methoxides; the other molybdenum has an additional phosphine ligand, and is in an octahedral coordination geometry (Figure 5).[433] $[\{Mo_2O_4(HBpz_3)(MeOH)\}_2(OMe)_2]$ (pz = pyrazolyl) contains a zigzag arrangement of four molybdenum atoms composed of two dimeric units, joined by two methoxide bridges. Each dimer consists of one molybdenum octahedrally bonded to a tridentate tris(pyrazolyl)borate ligand, a terminal oxygen, and two bridging oxygens; the other molybdenum is also octahedrally coordinated to two bridging oxygens, one terminal methanol *trans* to a terminal oxo group, and to the two bridging methoxides.[434] In $[Mo_4O_6Cl_4(OPr)_6]$, propoxide bridges are present in two $\{Mo_2O_3(OPr)\}^{3+}$ cores (with Mo—Mo separations of 2.669(2) Å); these two cores are linked by two propoxide bridges and by two bridging oxygens of the $\{Mo_2O_3(OPr)\}^{3+}$ units (Figure 6). This complex formally possesses two Mo^V and two Mo^{VI} centres.[435] $[Mo_4O_8Cl_4(OEt)_4]^{2-}$ adopts a similar structure, but involves a shorter Mo—Mo separation (2.587(3) Å).[436] $[Mo_2(OPr^i)_6]$ in pyridine is oxidized by O_2 to yield, as a minor product, $[Mo_4O_8(OPr^i)_4(py)_4]$, which has been characterized by X-ray crystallography. The complex contains four terminal, two μ_3- and two μ-oxo groups, two terminal and two μ-bridging OPr^i ligands, plus two localized Mo—Mo single bonds.[437] $[Mo_4O_8(Me_2POS)_4]$ also involves the pairing of two $\{Mo_2O_4\}^{2+}$ cores and partial substitution of the Me_2POS ligands by Me_2PO_2 has been achieved.[438]

$[Mo_2O_4(CO_3)(OH)_4\{Mo(CO)(PMe_3)_3\}_2]$ involves a central $\{Mo_2O_4\}^{2+}$ unit in which each molybdenum is also bound to an $\{Mo^{II}(CO)(PMe_3)_2\}^{2+}$ group *via* two bridging hydroxides, with the carbonate ligand bridging all four metal atoms. The two outer Mo^{II} atoms are seven-coordinate and the Mo^V atoms are six-coordinate, with an Mo—Mo distance of 2.5522(9) Å.[439] Another tetranuclear arrangement occurs in $[Mo_2O_4(O_2CMe)_6\{MoOCl\}_2]$, with each of two $\{MoOCl\}^{2+}$ units coordinated to one molybdenum of the $\{Mo_2O_4\}^{2+}$ core through two acetates, to the other through one acetate, and directly bonded to one of the oxygen bridges (Figure 7). The Mo—Mo distance in the central core is 2.609(3) Å.[440] $Mo_6O_{10}(OPr^i)_{12}$, an intermediate in the reaction between $[Mo_2(OPr^i)_6]$ and O_2 consists of a serpentine chain of

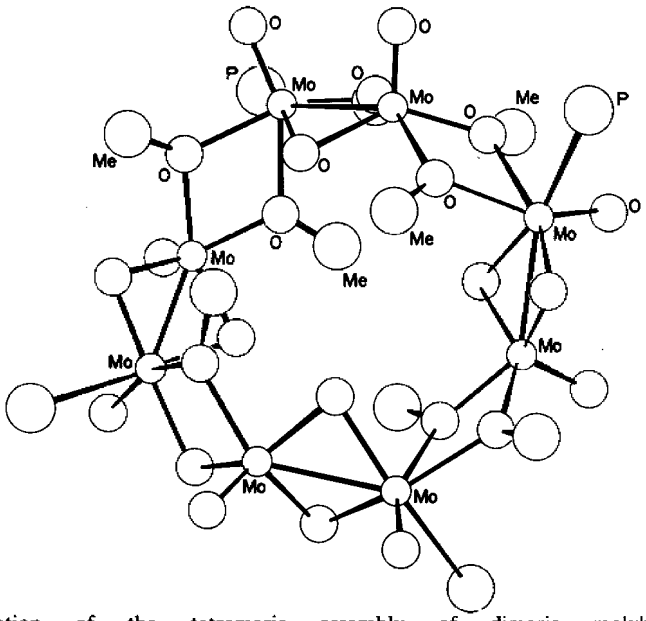

Figure 5 Representation of the tetrameric assembly of dimeric molybdenum(V) centres in $[\{Mo_2O_4(PMe_3)\}_4(OMe)_8]$[433]

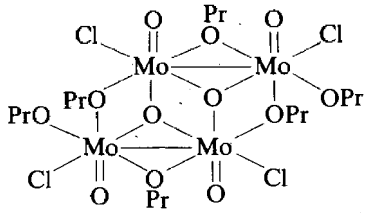

Figure 6 Structure of $[Mo_4O_6Cl_4(OPr)_6]$[435]

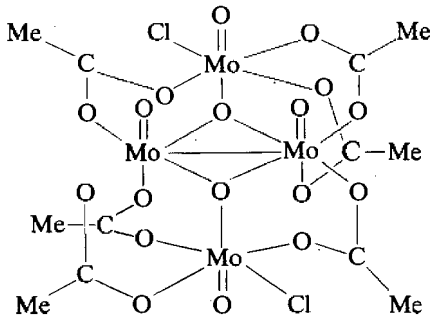

Figure 7 Representation of the structure of $[Mo_2O_4(O_2CMe)_6\{MoOCl\}_2]$[440]

molybdenum atoms, supported by μ-oxo and μ-OPr^i ligands, in which two Mo^V—Mo^V interactions (2.585(1) Å) occur.[441]

The tetranuclear complexes $[\{Mo_2Y(NR)S_2[S_2P(OEt)_2]_2\}_2]$ (Y = O, NR; R = Ph, 4-tolyl) contain two $\{MoY(NR)S_2\}^{2+}$ units linked by weak coordination of the bridging sulfides of one unit to the molybdenums of the other unit, in positions *trans* to the terminal oxo or imido ligands.[413,414] Addition of CF_3CO_2H to solutions of $[\{Mo_2(Ntol)_2S_2[S_2P(OEt)_2]_2\}_2]$ leads to formation of $[Mo_2(Ntol)_2S(SH)\{S_2P(OEt)_2\}_2(O_2CCF_3)]$, in which one of the bridging sulfides is protonated, and the trifluoroacetate bridges the dimolybdenum unit in the positions *trans* to the imido ligands. In solution two conformers have been detected by ^1H NMR spectroscopy, thought to be due to different orientations of the S—H bond.[438] Treatment of $[Mo_2(Ntol)_2S(SH)\{S_2P(OEt)_2\}_2(O_2CCF_3)]$ with triethylamine, followed by addition of MeBr, yields the methylated complex $[Mo_2(Ntol)_2S(SMe)\}S_2P(OEt)_2\}_2(O_2CCF_3)]$, which has an identical structure to the $(SH)^-$-bridged compound.[442]

36.4.3.5.5 Dimeric complexes with three bridging ligands

One of the products of the reaction between thiophenol and $[Mo_2O_4(S_2CNEt_2)_2]$ is $[Mo_2O_3(SPh)_2(S_2CNEt_2)_2]$. A crystal structure determination has shown that this dimer is

bridged by two thiols and an oxo group, and that each molybdenum has distorted octahedral coordination (Figure 8). One of the bridging thiols is *trans* to the two *syn* terminal oxo groups, and the average Mo—S bond lengths to this thiol is *ca.* 0.2 Å longer than that to the *cis* ligand. The Mo—Mo distance is 2.678(9) Å. Prolonged exposure of $[Mo_2O_3(SPh)_2(S_2CNEt_2)_2]$ to $CHCl_3$ gives $[Mo_2O_2Cl(SPh)_2(S_2CNEt_2)_2]^+$, in which the three bridging ligands are a chloride and two thiophenolate anions. The chloride is *trans* to the terminal oxo groups, the two thiophenolate ligands are equivalent and the Mo—Mo distance is 2.822(2) Å.[443] The reaction of $[NBu_4][MoO(SPh)_4]$ with HCl yields $[NBu_4][Mo_2O_2Cl_5(SPh)_2]$, which has been characterized by X-ray crystallography. The structure of the anion is analogous to that of $[Mo_2O_2Cl(SPh)_2(S_2CNEt_2)_2]^+$, with one chloride and two thiolate bridges, the chloride being *trans* to each terminal oxo ligand. However, the Mo—Mo distance of $[Mo_2O_2Cl_5(SPh)_2]^-$ is 2.915(1), which is significantly longer than that of the related cation. The reduction of $[MoO_2(S_2CNMe_2)_2]$ by thiophenol yields $[Mo_2O_3(SPh)_2(S_2CNMe_2)_2]$, which is isostructural with its diethyldithiocarbamate analogue, and involves an Mo—Mo distance of 2.649(1) Å.[444]

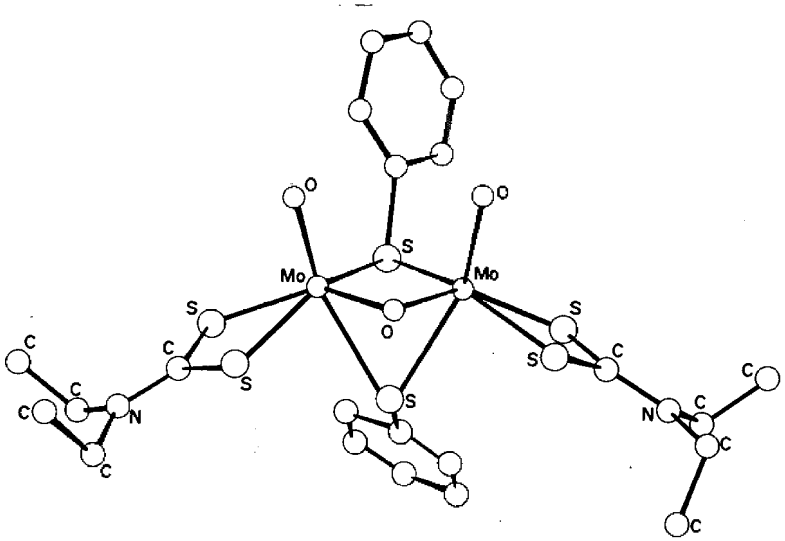

Figure 8 Structure of $[Mo_2O_3(SPh)_2(S_2CNEt_2)_2]$[443]

The reaction between $[MoOCl_3(THF)_2]$ and alkanethiols in the presence of base yields $[Mo_2O_2(SR)_7]^-$ anions, which have been isolated as their tetraalkylammonium salts. Physical data indicate that these binuclear monoanions contain three bridging thiolates. The arylthiolato anions $[MoO(SAr)_4]^-$ (Ar = Ph, 4-tolyl) react in the presence of an alkoxy or amido ligand, Z, to form $[Mo_2O_2(SAr)_6Z]$, in which the Z group and two thiolates act as bridging ligands.[445,446] A rich electrochemistry of $[Mo_2O_2(YR)_6Z]^-$ (Y = S, Se) has been demonstrated and stepwise reduction of these Mo_2^V centres to $Mo^{IV,V}$ and Mo_2^{IV} species has been observed.[266] The reaction between $[MoOCl_3(THF)_2]$ and Na(S-4-tolyl) in methanol, followed by addition of $[NEt_4]Br$, yields $[NEt_4][Mo_2O_2(S\text{-}4\text{-}tolyl)_6(OMe)]$, which has been structurally characterized. The anions involve an Mo—Mo separation of 2.919(5) Å, with two *syn* terminal oxo groups, four terminal and two bridging thiolate ligands, and a bridging methoxide ligand *trans* to each of the terminal oxygens.[444] Interconversion of $[MoO(SR)_4]^-$ (R = aryl, alkyl) and $[Mo_2O_2(SR)_6Z]^-$ (Z = OMe, OEt, SCH_2Ph) anions has been shown to occur *via* redox processes involving both the molybdenum and the thiolate redox centres.[266,448]

Several examples are known of triply bridged dimers in which one ligand provides two of the bridging atoms. The reaction of $[Mo_2O_4(py)_2(oxine)_2]$ (Hoxine = 8-hydroxyquinoline) with 2-hydroxyethanethiol gives $[Mo_2O_3(SCH_2CH_2O)(oxine)_2]$, the X-ray structure of which shows an Mo_2^V unit bridged by one oxo group and by the sulfur and oxygen atoms of the $(SCH_2CH_2O)^{2-}$ ligand. The two *syn* terminal oxo groups are *trans* to the oxygen atom of the mercaptoethanolate, with the nitrogen atoms of the oxines *trans* to the bridging sulfur.[449] A similar structure is found in $[Mo_2O_2S(SCH_2CH_2O)(S_2CNEt_2)_2]$, in which the three bridging atoms are the sulfide ligand and the oxygen and sulfur atoms of the $(SCH_2CH_2O)^-$ ligand; the bridging oxygen is *trans* to each of the terminal oxo groups.[450]

Reactions of 2-hydroxyethanethiol and various bases with $[MoOCl_4(H_2O)]^-$ or

$[MoOCl_3(THF)_2]$ yield many products, including the triply bridged dimers $[Mo_2O_2(SCH_2CH_2O)_2X_2Y]^-$ ($X = Y = Cl$; $X_2 = SCH_2CH_2O$, $Y = Cl$, SCH_2CH_2OH). These complexes involve bridging atoms which are the oxygen and sulfur of one $(SCH_2CH_2O)^{2-}$ ligand and the oxygen atom of another, the sulfur atom of which is coordinated to one of the molybdenum atoms in a terminal position. The terminal oxo groups are *trans* to the oxygen atom of the doubly bridging ligand. In each case the Mo—Mo distance is 2.734(6) Å.[445,446] The reaction of $[Mo_2O_2(SCH_2CH_2O)_2Cl_3]^-$ with excess 2-hydroxyethanethiol and base, B, yields $[BH]_2[Mo_2O_3(SCH_2CH_2O)_3]$ (B = piperidine, morpholine, pyrrolidine). The bridging atoms of the anion are one oxo group and the oxygen and sulfur of a $(SCH_2CH_2O)^{2-}$ ligand; each molybdenum atom is also coordinated to a terminal oxo group and a bidentate $(SCH_2CH_2O)^{2-}$ ligand. The Mo—Mo separation is 2.676(1) Å.[446]

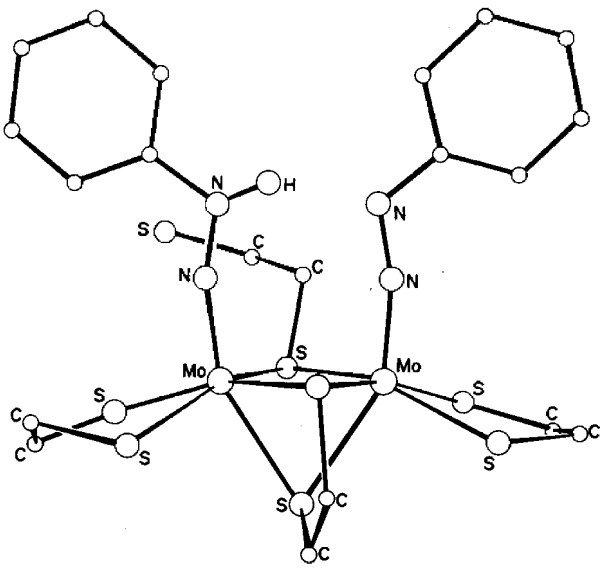

Figure 9 Structure of $[Mo_2(NNHPh)(NNPh)(SCH_2CH_2S)_3(SCH_2CH_2SH)]^{2-}$ [451]

Treating $[Mo(NNHPh)_2(butane\text{-}2,3\text{-}dithiolate)_2]$ with dimercaptoethane and trimethylamine in methanol gives $[NEt_3H]_2[Mo_2(NNPh)(NNHPh)(SCH_2CH_2S)_3(SCH_2CH_2SH)]$, which contains terminal and bridging bidentate thiolate ligands and a bridging monodentate thiolate ligand (Figure 9). The Mo—Mo distance is 2.837(2) Å, which is longer than in triply bridged molybdenum(V) dimers involving one or more bridging oxygens.[451] The anion $[MoO(SCH_2CH_2CH_2S)_2]^-$ reacts with HN_3 in methanol to give $[Mo_2O_2(N_3)(SCH_2CH_2CH_2S)_3]^-$. The crystal structure of this dimeric anion shows that the three bridging atoms are provided by a nitrogen atom of the azide, and by sulfur atoms of two different dithiolates, which are both chelated to the same molybdenum; the third dithiolate ligand is chelated to the other molybdenum. Two terminal oxo groups *trans* to the bridging azide complete octahedral coordination spheres for each molybdenum, and the Mo—Mo distance is 2.893(3) Å.[452]

36.5.1 INTRODUCTION

The chemistry of hexavalent molybdenum is dominated by the oxo ligand and its analogs. This highest of Mo oxidation states requires for its stabilization the presence of ligands that are not only good σ donors but also good π donors. Thereby, sufficient charge density can be placed on the Mo to avoid violating the Pauling Electroneutrality Principle.[1] This requires ligands with filled p orbitals that are not otherwise engaged in bonding with other atoms. Formally, this engenders a situation in which a multiple bond is formed between the Mo and its donor ligand. About 10 years ago[2] the oxo ligand was virtually alone in stabilizing large numbers of formally Mo^{VI} complexes. This situation has changed dramatically in recent years. It is now clearly recognized that the sulfido ligand, S^{2-}, can, in a significant number of cases, isomorphously substitute for the oxo ligand, O^{2-}. Moreover, in certain cases selenido (Se^{2-}), peroxido (O_2^{2-}), persulfido (S_2^{2-}), imido (NR^{2-}), nitrido (N^{3-}), alkylcarbido (RC^{3-}, equivalent to alkylidyne), hydrazido(2−) (R_2NN^{2-}) and hydroxylamido (R_2NO^-) ions can form complexes with strict analogs in oxo chemistry. The oxo chemistry stands as a guidepost from which one can extrapolate to make predictions of the structural chemistry of its analog ligands.

Mononuclear examples are dominant in the simple coordination chemistry of molybdenum(VI). This is due in part to the absence of d electrons in Mo^{VI} complexes, which precludes the formation of Mo^{VI}—Mo^{VI} metal–metal bonds. However, note must be taken of the very large class of homo- and hetero-polymolybdates which contain polynuclear Mo. These

are discussed elsewhere in this treatise. A substantial number of dinuclear complexes of Mo^{VI} are also known and these are discussed in this chapter.

In presenting the chemistry of Mo^{VI} we first discuss complexes in which oxo groups provide the sole π-donating ligands. We then discuss complexes in which sulfido, selenido, imido, nitrido, alkylcarbido, peroxido, disulfido, hydrazido and hydroxylamido can substitute in a direct way for oxo. Within the mononuclear class we make distinctions between complexes with four, three, two and one oxo ligands. Within the dinuclear class we distinguish between singly, doubly and triply bridged species. Finally, we discuss examples of non-oxo Mo^{VI} complexes. Aspects of Mo^{VI} chemistry have been considered in recent reviews.[2–5]

36.5.2 MOLYBDATE AND RELATED SPECIES

The tetrahedral molybdate ion is the key antecedent for much Mo^{VI} chemistry. This ion serves as the starting point for many of the preparative schemes in the chemistry of Mo^{VI} and, directly or indirectly, often for low oxidation state chemistry as well. The molybdate ion is found naturally in alkaline solutions such as sea water (pH = 8.0–8.5). It is the form in which Mo is often added to culture media used for the growth of microorganisms. In solutions of moderate concentrations the mononuclear ion is only present above pH = 7. Below pH = 7, the equilibria in equations (1) and (2) have considerable effect and the heptamolybdate ion predominates at moderate concentrations in aqueous solution. Detailed treatment of equilibria in aqueous Mo^{VI} solutions has been presented.[6] Although the chemistry of polyoxoanions of Mo is discussed elsewhere in this volume, it is worth pointing out that the six-coordinated octahedral MoO_2^{2+} and MoO^{4+} units can be viewed as the mononuclear building blocks of these polynuclear anions.[7] For example, $PMo_{12}O_{40}^{3-}$ has a central phosphate surrounded by an $Mo_{12}O_{36}$ unit in which each Mo^{VI} has a single terminal oxo in its coordination sphere. Similarly, $Mo_4O_{12}CH_2O_2OH^{3-}$ can be pictured as an Mo_4O_{12} ring containing dioxo Mo^{VI} with each Mo additionally bridged to all others by the OH^- and $CH_2O_2^{2-}$ anions.[7]

$$7MoO_4^{2-} + 8H^+ \rightleftharpoons Mo_7O_{24}^{6-} + 4H_2O \quad (1)$$

$$Mo_7O_{24}^{6-} + MoO_4^{2-} + 4H^+ \rightleftharpoons Mo_8O_{26}^{4-} + 2H_2O \quad (2)$$

At low concentrations hexavalent molybdenum in dilute acidic solutions is likely mononuclear.[8] At higher acidity the ion $MoO_2(H_2O)_4^{2+}$ is probably present.[8] In special situations the dimolybdate ion, $Mo_2O_7^{2-}$, is formed whose structure is analogous to that of the better known dichromate ion, $Cr_2O_7^{2-}$. (Dinuclear Mo^{VI} ions are discussed separately below.)

36.5.2.1 Structure of MoO_4^{2-}-containing Compounds

Molybdate, MoO_4^{2-}, is isolated in the form of salts of monovalent, divalent and trivalent cations. The salts of the simple monovalent cations are usually water soluble while salts with larger cations, *e.g. N*-propylammonium, *N*-ethylpyridinium and tetra-*n*-butyl ammonium may also have solubility in non-aqueous solvents.[9] The salts of di- and tri-valent cations are generally insoluble and form three-dimensional structures in the solid state. As discussed below, although many of these maintain the MoO_4^{2-} structural unit, some salts which stoichiometrically contain MoO_4^{2-} have octahedral six-coordinate Mo^{VI}.

In K_2MoO_4,[10] discrete MoO_4^{2-} ions have an Mo—O distance of 1.76 Å and the O—Mo—O bond angles of a regular tetrahedron. This distance is among the longest for *terminal oxo* molybdenum linkages, henceforth designated Mo—O_t. The $(NH_4)_2MoO_4$ salt is isomorphous to K_2MoO_4.[10]

The MoO_4^{2-} ion can act as a ligand to many metal ions. In some cases, as with higher valent metal ions containing labile coordination spheres, all or most of the original ligands around the second metal can be replaced by the O-donor MoO_4^{2-} leading to three-dimensional solid state structures. Recently studied examples, among many,[11,12] include $Fe_2(MoO_4)_3$,[13,14] $NiMoO_4$,[15] $MgMoO_4 \cdot H_2O$,[16] $KDy(MoO_4)_2$,[17] $Tb_2(MoO_4)_2$,[18] Me_2SnMoO_4,[19] $MnMoO_4 \cdot H_2O$[20] and $CdTh(MoO_4)_3$.[21] In the last six compounds the MoO_4^{2-} ion maintains an approximately tetrahedral four-coordination and performs a bridging role. However, in other cases these polymeric structures have six coordinate Mo^{VI}, *e.g.* $NiMoO_4$.[15]

In cases in which the full coordination sphere of the second metal is not accessible to substitution, MoO_4^{2-} can serve as a mono- or bi-dentate ligand. Examples of monodentate MoO_4^{2-} include $Co(NH_3)_5MoO_4^{+}$ [22] and $Cr(edta)MoO_4^{3-}$.[19] An example of bidentate MoO_4^{2-} is $Co(NH_3)_4MoO_4^{+}$. A rare example of bridging MoO_4^{2-} in a non-polymeric structure involves the D_{2d} symmetry $K(MoO_4)K$ unit which is isolated in a matrix of frozen N_2.[23] X-Ray structural studies are notably lacking for compounds containing MoO_4^{2-} as a ligand. One exception is the homopolymolybdate ion $Mo_8O_{26}(MoO_4)_2^{8-}$ which contains two monodentate MoO_4^{2-} units.[24] The tetranuclear complex anion $Mo_4O_8(OMe)_2(NNPh)_4^{2-}$ also contains bridging bidentate MoO_4^{2-} ligands.[25] The structure, shown in Figure 1, is roughly centrosymmetric in its inner coordination sphere. In this complex two $Mo(NNPh)_2^{2+}$ units are bridged by two *trans*-methoxy groups and by two MoO_4^{2-} groups *trans* to each other.[26] The non-molybdate Mo—Mo distance of 3.46 Å indicates the absence of metal–metal bonding. The terminal Mo—O_t distance of 1.72 compares with 1.80 Å for the bridging Mo—O_b. The near-tetrahedral angles show that two MoO_4^{2-}-like ions are present.[25] This brief discussion of MoO_4^{2-} as a ligand contrasts with the extensive structural chemistry of MoS_4^{2-} as a ligand discussed elsewhere in this volume.

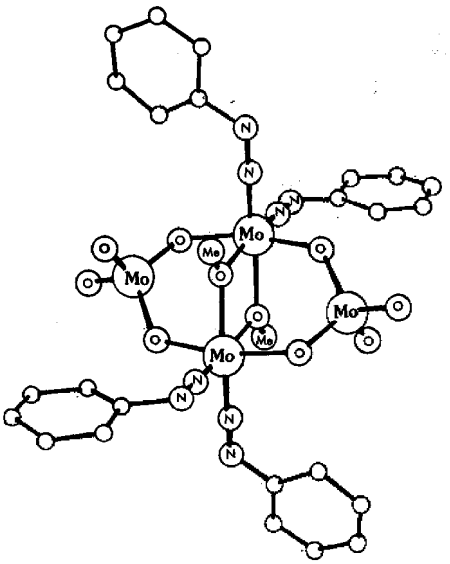

Figure 1 The structure of $Mo_4O_8(OMe)_2(NNPh)_4^{2-}$ in its $HNEt_4^{2-}$ salt (unlabelled atoms are carbon)[25]

36.5.2.2 Thio and Seleno Derivatives of MoO_4^{2-}

There are a significant number of strict analogs of MoO_4^{2-} that contain oxo-analog ligands in place of O while maintaining a tetrahedral or pseudotetrahedral structure about Mo^{VI}. For example, the treatment of basic solutions of molybdate with sulfide leads successively to thio substituted anions according to Scheme 1.

$$MoO_4^{2-} \longrightarrow MoO_3S^{2-} \longrightarrow MoO_2S_2^{2-} \longrightarrow MoO_3S^{2-} \longrightarrow MoS_4^{2-}$$

Scheme 1

Although the chemistry of these conversions had been known for many years, recent thermodynamic and kinetic work[27] has provided quantitative information. Similarly, treatment with Se^{2-} leads to $MoSe_4^{2-}$ [28–30] while treatment with H_2O_2 gives the $Mo(O_2)_2^{2-}$ ion discussed below. The compound MoO_2Cl_2 is also well known and, although containing six-coordinate Mo in the solid state, has a four-coordinate approximate tetrahedral structure in solution or in the gas phase.

Tetrathiomolybdate has been prepared with a number of organic cations including NEt_4^{+},[31] $NC_4H_9^{+}$ (pyrrolidinium),[32,34] $N_2C_4H_{11}^{+}$ (piperazinium), $NC_5H_{12}^{+}$ (piperidinium)[34,32] and $N_4C_6H_{13}$ (monoprotonated hexamethylene imine).[33,32] These salts are useful for structural

and preparative studies. The structure of the MoS_4^{2-} ion was determined in its tetraethylammonium salt.[35] The average Mo—S distance of 2.177(6) and S—Mo—S angle of 107.5(9)° are found in a near perfect tetrahedral arrangement of sulfur atoms about the molybdenum.

The ion $MoOS_3^{2-}$ in Cs_2MoOS_3 [36] has Mo—O = 1.78 and Mo—S = 2.18 Å, values that are indistinguishable from the Mo—O and Mo—S distances found in MoO_4^{2-} and MoS_4^{2-}, respectively. Further, the angles in $MoOS_3^{2-}$ are all within 1° of the 109.5° tetrahedral angle. This identity indicates that Mo—O and Mo—S bonds are similar in their electronic and steric effects on the Mo^{VI} center (barring, of course, fortuitous cancellation of steric and electronic factors).

Reaction of $Mo_2O_7^{2-}$ with $(Me_3Si)_2S$ leads to the series $MoO_{3-x}S_x(OSiMe_3)^-$ ($x = 0$–3) with the $x = 3$ member of the series cleanly isolated. The anions are tetrahedral, derived from MoO_4^{2-}. $MoO_3(OSiMe_3)^-$ has Mo—O = 1.881(7), O—Si = 1.631(8) and Si—O—Mo = 146.6(4)° and Mo—S averaging 2.154.[37] Clearly $OSi(Me)_3^-$ can substitute for oxo in an isostructural series.[37]

36.5.2.3 Spectra and Bonding in the MoO_4^{2-} and Related Ions

In the UV region MoO_4^{2-} displays two band systems, one in the range 42000–46000 cm^{-1} and a second, more intense system, in the range 46000–53000 cm^{-1}. In single crystal studies (*e.g.* MoO_4^{2-} in Cs_2SO_4) both bands show vibrational structure.[38] The progression observed with $\nu_1 = 780\ cm^{-1}$ corresponds to ν(Mo—O_t) for the excited state compared to $\nu_1 = 897\ cm^{-1}$ for the ground state.

The bonding in the $4d^0$ tetrahedral molybdate and related systems has been treated by molecular orbital approaches.[39,40,41] An approximate energy level diagram in T_d symmetry is shown in Figure 2. The oxo (or thio or seleno) ligands are involved in both σ and π bonding with Mo. The difference between the $3t_2^*$ and $2e^*$ levels represents the Δ_t value for the system. Since there are no d electrons, this splitting is not discernible from d–d spectral transitions. It can, however, be estimated from the difference in energy of charge-transfer bands or X-ray absorptions, provided they can be properly assigned.

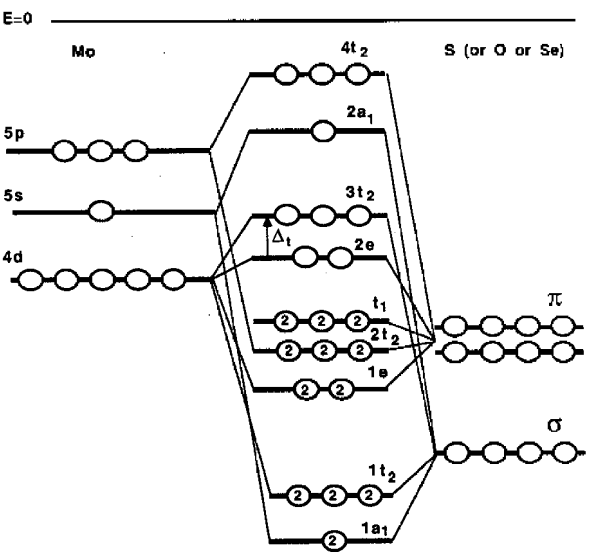

Figure 2 Qualitative energy level diagram for T_d ions such as MoO_4^{2-} and MoS_4^{2-}

The assignment of charge-transfer spectra in tetrahedral oxoanions and their tetrathio derivatives has been a controversial area. Electronic spectra have been studied in some detail.[42,43] The assignments of 'charge-transfer' bands for MoS_4^{2-} are likely to be $t_1 \rightarrow 2e^*(\nu_1)$, $2t_2 \rightarrow 2e^*(\nu_2)$, $t_1 \rightarrow 3t_2^*(\nu_3)$ and $2t_2 \rightarrow 4t_2^*(\nu_3)$.[41] The difference between ν_2 and ν_1 is the Δ_t value. Assignments differ somewhat for other ions. The assignments are supported by detailed electronic spectral studies,[44] valence photoelectron spectroscopy[45] and MCD data.[46]

Interestingly, for MoO_4^{2-} the theoretical studies[47] show that little O → Mo charge transfer occurs in going from the ground to excited states. It is nevertheless clear that the configuration

changes from $4d^0$ to $4d^1$ due to excitation of an electron from mostly ligand-based into predominantly metal-based levels. However, electronic rearrangement in the remaining levels makes the net *charge* transfer negligible. It is therefore more appropriate to call these electron-transfer transitions as a guide to the configurational nature of the transition, since they do not necessarily reflect large net redistribution of charge.

The IR and Raman spectra of the tetrahedral molybdates, tetrathiomolybdates and tetraselenomolybdates have also received study.[28,48–53] For the T_d, tetrahedral dianion MoO_4^{2-}, the two stretching modes (A_1 and F_2) are Raman active and one (F_2) is IR active as well. Bending modes are of E and F_2 symmetry, and while both are Raman active, only F_2 is IR active. Bands at 897 and 837 cm^{-1} have been assigned as stretches, whereas those at 325 and 317 cm^{-1} are assigned to bends. Detailed vibrational analyses of MoO_4^{2-} have included $^{92}Mo/^{100}Mo$ isotopic substitution effects[17,53] and polarized IR measurements.[17] Studies on MoO_3S^{2-} and $MoO_2S_2^{2-}$ reveal the ν(Mo—O) bands expected for C_{3v} and C_{2v} structures, respectively.[42]

When MoO_4^{2-} coordinates to a metal ion, as in $[Co(NH_3)_5MoO_4]Cl$ or $[Co(NH_3)_4MoO_4]NO_3$, the IR and Raman spectra of the MoO_4^{2-} grouping are perturbed.[22] An instructive example considers the coordination isomers $[Co(NH_3)_5Cl]MoO_4$ and $[Co(NH_3)_5MoO_4]Cl$.[22]

36.5.2.4 Reactions of MoO_4^{2-}

In alkaline solutions the exchange reaction of equation (3) occurs in hydroxide-independent and hydroxide-dependent paths.[54] Rate constants, activation parameters and isotope effects have been reported.[54] Although proton transfer is implicated in the rate-determining step of the OH^--independent path and an association involving MoO_4^{2-} and OH^- is likely for the OH^--dependent pathway, no firm mechanistic conclusions can be drawn.

$$MoO_4^{2-} + {}^{18}OH_2 \longrightarrow Mo^{18}OO_3^{2-} + {}^{16}OH_2 \quad (3)$$

The kinetics of reactions of MoO_4^{2-} leading to the binuclear complexes $Co(NH_3)_5OMoO_3^+$ and $Cr(edta)OMoO_3^{3-}$ have been studied around pH = 7.[55] Interestingly, the reaction mechanisms for the formation of these two species differ. The Co complex is formed by equation (4) where Mo—O bond breakage occurs. The Cr complex is formed as in equation (5) where the uncoordinated carboxylate of the $edta^{4-}$ ligand apparently plays a key role in labilizing the H_2O ligand on the otherwise normally inert Cr^{III} linkage.

$$Co(NH_3)_5OH_2^{3+} + MoO_4^{*2-} \longrightarrow Co(NH_3)_5OMoO_3^+ + H_2O^* \quad (4)$$

$$Cr(edta)H_2O^{*-} + MoO_4^{2-} \longrightarrow Cr(edta)MoO_4^{3-} + H_2O^* \quad (5)$$

These species are of interest as they represent examples of Mo bridged to a first transition row element. This is a suspected occurrence in nitrogenase where Mo bridged to Fe (through O or S) is implicated.[5]

36.5.3 COMPLEXES CONTAINING THE MoO_3 CORE

The MoO_3 structural unit is found in a few monomeric oxo Mo^{VI} complexes. The complex MoO_3(dien) has a six-coordinate octahedral structure[56,57] with the *cis*-trioxo arrangement, an Mo—O distance averaging 1.74 Å, O—Mo—O angles averaging 106° and Mo—N averaging 2.32 Å. MoO_3(dien) shows little stability in solution.[57,58] A similar six-coordinate monomeric structure with Mo—O_t = 1.74 Å is found in the $MoO_3(nta)^{3-}$ ion in $K_3[MoO_3(nta)]\cdot H_2O$.[59] Here, as shown in Figure 3, one of the nta^{3-} carboxylate arms is uncoordinated. Interestingly, the NMR spectrum shows that the coordinated and free carboxylate arms of nta^{3-} exchange rapidly.[60]

A related nominally dinuclear complex is the long studied edta complex found in $Na_4(MoO_3)_2edta\cdot 8H_2O$.[61] Here the two MoO_3 groups are connected only by a —NCH_2CH_2N— bridge. A six-coordinate structure with Mo—O = 1.74 Å makes the MoO_3 coordination similar to that in the nta^{3-} complex. Several amino acid complexes appear by spectroscopic criteria to have MoO_3 core structures.[62]

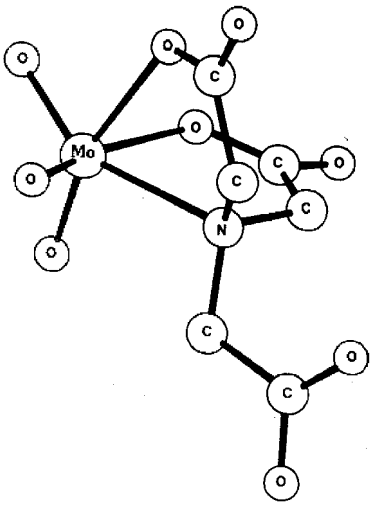

Figure 3 The structure of $MoO_3(nta)^{3-}$ in $K_3[MoO_3(nta)]\cdot H_2O$[59]

The MoO_3 unit is characterized by vibrational bands at ~890 and 840 cm^{-1}.[57,63,64] ^{17}O and ^{95}Mo NMR spectra may also be used to identify the MoO_3 core. In fact, ^{17}O NMR is sensitive to the nature of the group *trans* to oxo[66] as is also the case in MoO_2^{2+} complexes.[65]

In addition to the above structurally characterized complexes there are other cases where the presence of the MoO_3 unit seems possible on stoichiometric grounds. Reaction of K_2MoO_4 with $O{=}C(CF_2)_3C{=}O$ (perfluoroglutaric anhydride) leads to $Na_2\{MoO_3[O_2C(CF_2)_3CO_2]\}$ which is likely to be polynuclear.[67] A band at 945 cm^{-1} due to Mo—O_t and bands at lower energy possibly attributable to Mo—O_b make the presence of the MoO_3 unit in this complex unlikely. Likewise, the stoichiometry $MoO_3(Hars)^{2-}$,[68] where Hars is alizarin red-S (9,10-dihydro-3,4-dihydroxy-9,10-dioxo-2-anthracene sulfonic acid), does not necessarily implicate a *cis*-MoO_3 core.

Interestingly the Mo enzyme formate dehydrogenase shows an EXAFS pattern that has been interpreted in terms of approximately three Mo—O = 1.74 Å distances indicating the likely presence of an MoO_3 unit bound to non-sulfur ligands.[69]

Of late there are also reports of molybdate-like monoanions, namely $ClMoO_3^-$, $R_3SiOMoO_3^-$ and $MeMoO_3^-$, which contain an MoO_3 grouping and a single monodentate monoanonic ligand. $ClMoO_3^-$ is prepared[70] as the Ph_4As^+ or Ph_4P^+ salts by reacting MoO_3 with $[Ph_4As]Cl$ or $[Ph_4P]Cl$, respectively. The Mo—O stretching vibrations occur at 930 and 894 cm^{-1}.[70] $R_3SiOMoO_3^-$ (with R = Ph or *t*-C_4H_9) is prepared[71] by the reaction of equation (6). The crystal structure of the NBu_4^{n+} salt of $Ph_3SiOMoO_3^-$ shows the expected tetrahedral (C_{3v}) structure and ν(Mo—O) stretching frequencies are identified at 906 and 884 cm^{-1}.[71] The complex anion $MeMoO_3^-$ prepared from $MoO_2MeBr(bipy)$ by base hydrolysis has only been characterized in solution.[72] It shows a single ^1H NMR peak at 0.611 p.p.m, downfield from TMS.[72] All of the $XMoO_3^-$ ions are colorless.

$$2R_3SiOH + Mo_2O_7^{2-} \longrightarrow 2R_3SiOMoO_3^- + 2H_2O \qquad (6)$$

36.5.4 COMPLEXES WITH THE MoO_2^{2+} CORE STRUCTURE

Complexes containing the MoO_2^{2+} core are by far the most common in Mo^{VI} chemistry. These complexes are usually six-coordinate although some four-coordinate compounds are known. The latter are tetrahedral or pseudotetrahedral and related to MoO_4^{2-}. Examples include $MoO_2S_2^{2-}$, $MoO_2Se_2^{2-}$, MoO_2Br_2 and $MoO_2(R_2NO)_2$. An example of a five-coordinate complex now exists.[73]

The vast majority of MoO_2^{2+} core complexes are six-coordinate and mostly of distorted octahedral structure. Some non-octahedral complexes are known. In the octahedral structure the two Mo—O_t bonds are invariably *cis* to each other. The strong σ- and π-donor nature of the oxo ligands makes it favorable for them to avoid competing for the same *p* and *d* orbitals. If the oxo groups were *trans* they would be forced to share two *d* orbitals and one *p* orbital. By residing on adjacent coordination sites they are forced to share only a single *d* orbital.

Repulsion between the short Mo—O_t bonds and between these and other bonds determines remaining details of geometry. Several articles have addressed structural trends in oxomolybdenum(VI) complexes.[2,74–78]

An MoO_2^{2+} unit is likely to be present in the oxidized form of sulfite oxidase and in the desulfo form of xanthine dehydrogenase.[20] The reactivity of the MoO_2^{2+} unit has been thoroughly studied, especially with regard to oxygen atom transfer reactions.

36.5.4.1 Structures Containing cis MoO_2^{2+} Cores

The MoO_2^{2+} unit has by far received the most attention in the structural chemistry of Mo^{VI}. There have been over 50 X-ray crystallographic structure determinations of six-coordinate complexes containing this structural unit. All but five of these determinations have revealed a near-octahedral structure with *cis* dioxo groups. The structural results in Table 1 clearly show the narrow range within which both the Mo—O_t distances and the O_t—Mo—O_t angles lie. The five exceptions shown at the bottom of the table are complexes in which a sterically demanding substituted amine thiolate ligand or a porphyrin ligand forbids the molybdenum from having the otherwise highly favored *cis*-octahedral structure. In addition to the mononuclear structures listed in Table 1, there are several dinuclear complexes discussed below and many polymeric structures (see *e.g.* ref. 79) which also have MoO_2^{2+} cores with dimensions similar to those found in the mononuclear complexes.

Table 1 Structural Studies on MoO_2^{2+} Complexes[a]

[a] The ligand is 2-*o*-hydroxyphenylbenzimidazole.

Representative structures are shown in Figures 4–9. In addition to the characteristic Mo—O distance and O—Mo—O angle, there are several other features that the octahedral complexes in Table 1 have in common. The bond *trans* to the Mo—O linkage experiences a structural *trans* influence and is significantly longer than corresponding bonds to the same donor type that are *cis* to the oxo. For example in the complex $MoO_2(Et_2dtc)_2$[80] shown in Figure 4, which has two-fold symmetry, the Mo—S distance *trans* to Mo—O is 2.639 Å, whereas that *cis* to oxo is 2.450 Å. This effect is clearly attributable to the competition for the σ and π orbitals along the shared axis between the oxo group and the sulfur atom *trans* to it.

The complex MoO_2L with $L = {}^-SC_6H_4SCH_2CH_2SC_6H_4S^-$ has the typical distorted octahedral structure[81] with the two thioether donors of the tetradentate ligand lying *trans* to Mo—O_t at Mo—S = 2.69 and the two thiolate donors *trans* to each other with Mo—S = 2.41 Å. The longest known thioether Mo—S distance is 2.79 Å found[23] in the complex of the tripodal ligand $N(CH_2CH_2S)_2(CH_2CH_2SMe)^{2-}$ shown in Figure 5. The dimensions of this complex closely parallel those found by EXAFS for sulfite oxidase.[82]

In complexes where there is a choice, the general rule is that the weaker π-bonding donor atoms are found *trans* to Mo—O_t since they do not compete for the empty *p* and *d* orbitals along the same axis.[74,80,83,84,85] For example in $MoO_2Cl_2[OPPh_3]_2$ the π-donating chloride ligands are found *trans* to each other and *cis* to the Mo—O_t bonds. Likewise, in $MoO_2[(SCH_2CH_2)_2NCH_2CH_2NMe_2]$ the thiolate sulfur atoms are found *trans* to each other and *cis* to the terminal oxo groups.[41] After this preference has been exercised the trends in bond angles can be rationalized qualitatively in terms of interligand repulsions in the Mo coordination sphere.[80,83,84,85]

There are several complexes now known to possess a *cis* dioxo structure and to be non-octahedral in nature. In a number of these the coordination number about Mo is lower.

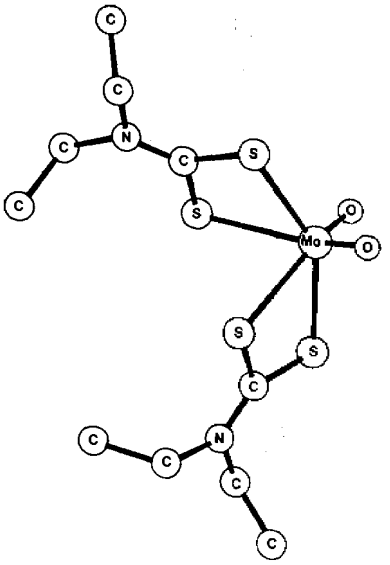

Figure 4 The structure of $MoO_2(Et_2dtc)_2$[80]

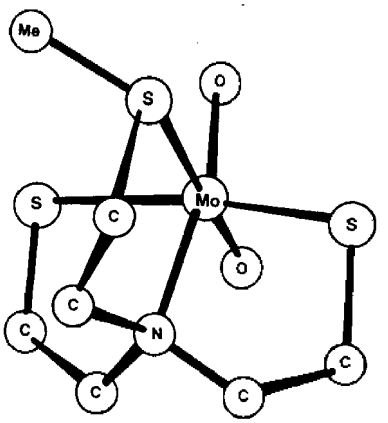

Figure 5 The structure of $MoO_2[N(CH_2CH_2S)_2CH_2CH_2SMe]$[23]

For example, four-coordinate $MoO_2S_2^{2-}$ and MoO_2Cl_2 have tetrahedral structures related to MoO_4^{2-}.

In some cases there may be *formal* six-coordination as in the complexes of deprotonated hydroxylamine ligands.[86–90] These complexes have, in addition to two oxo ligands, two deprotonated hydroxylamine ligands (R_2NO^-) in the Mo coordination sphere. The hydroxylamine(−H) ligands can be considered as bidentate N,O donors, in which case the complexes are formally six-coordinate. Alternatively, the complexes may be considered as four-coordinate with the hydroxylamine(−H) ligands occupying two of the tetrahedral sites about the Mo atom. If the center of the N—O bond is taken as representing the donor site for the ligand, a geometry very near to tetrahedral is indeed obtained.

The monodentate diatomic ligand formulation seems a structurally more consistent way of thinking about the deprotonated hydroxylamine ligands. As illustrated in Figure 6, if the structure of $MoO_2[Et_2NO]_2$ is considered to be six-coordinate then it is distinctly non-octahedral. The O—Mo—O angle of 113.7° is significantly larger than the angles found in the octahedral complexes in Table 1. The N and O atoms of the ligands and the Mo atom lie in a plane with the two oxo ligands roughly equidistant above and below that plane. The structure superficially resembles the skew trapezoidal bipyramid structure that is described more fully below. However, in the present case the trapezoid defined by the N_2O_2 ligand set does not contain the Mo atom within its boundary. The structure is therefore distinctly different from the skew trapezoidal structure discussed below and is really best represented as being tetrahedral with hydroxylamine(−H) ligands occupying two tetrahedral binding sites. Additional complexes containing hydroxylamine(−H) ligands are discussed separately below.

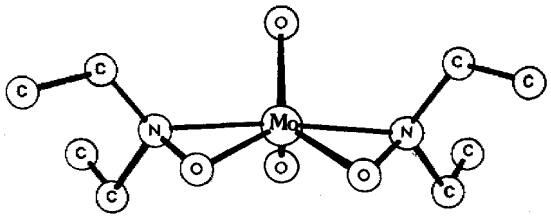

Figure 6 The structure of $MoO_2[Et_2NO]_2$[90]

There is one example[73] of a five-coordinated Mo^{VI} complex wherein the atypical coordination number is enforced by sterically bulky ligands. This structure[73] shown in Figure 7 is describable as a trigonal bipyramid in which two S-donor atoms of the tridentate ligand occupy the apical sites. The oxo groups and pyridine nitrogen of the tridentate ligand define the trigonal plane. Interestingly, the oxygen analog[79,73] of this sulfur donor ligand forms a conventional near-octahedral complex with MeOH or DMSO as the sixth ligand donor. Apparently, the difference in steric bulk and/or donor ability of two sulfur donors compared to two oxygen donors in the tridentate ligand is sufficient to cause the observed change in coordination tendency.

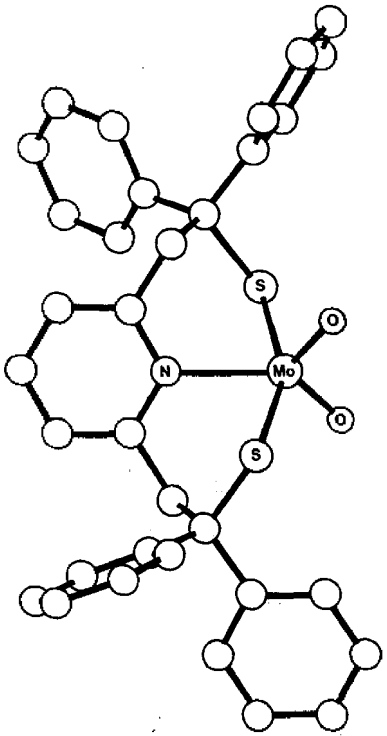

Figure 7 The structure of $MoO_2[NC_5H_3(CPh_2S)_2]$ (unlabelled atoms are carbon)[73]

There are two types of non-octahedral unequivocally six-coordinate formally Mo^{VI} complexes. The first type involves a complex of the ligand tetra(*p*-tolyl)porphyrin.[91] Here the structure shown in Figure 8 reveals the molybdenum atom to possess a distorted trigonal prismatic coordination in which the two oxo groups are found on the same side of a highly deformed porphyrin 'plane'. The O—Mo—O angle of 95.1° is the smallest known for any high resolution crystallographic determination of a *cis*-MoO_2^{2+} core. The simple alternative of having the oxo groups on opposite sides of the porphyrin ring is apparently not viable as this geometry is only known and expected for the $4d^2$ configuration of Mo^{IV}. The Mo atom in MoO_2(ttp) is fully 1.095 Å above the mean plane of the saddle-shaped porphyrin ligand. That the structure is stable, despite the fact that the small O_t—Mo—O_t angle must entail a significant oxo–oxo repulsion, is a testimony to the proclivity of Mo^{VI} to adopt the *cis* dioxo configuration.

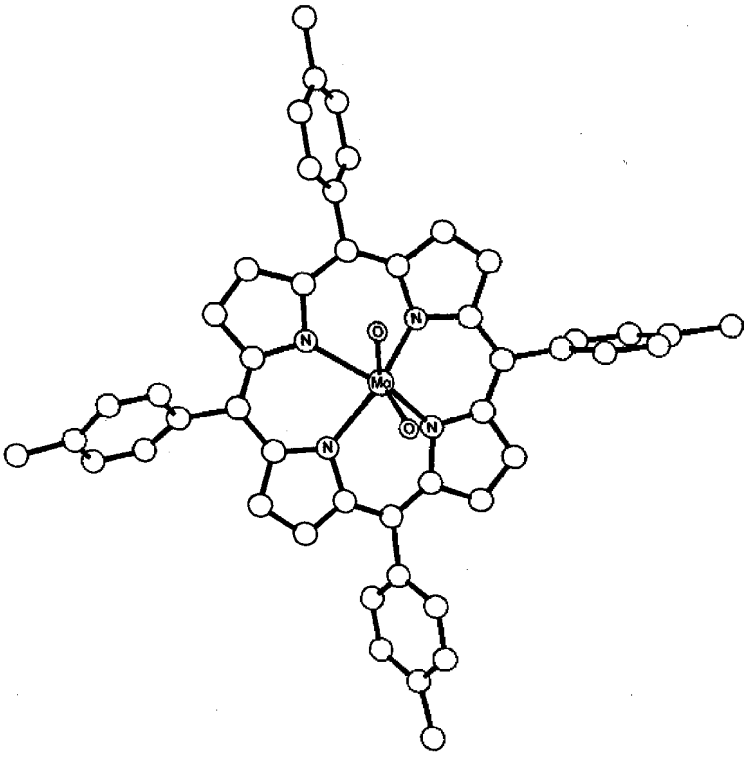

Figure 8 The structure of MoO_2(ttp) (unlabelled atoms are carbon)[91]

The second type of six-coordinate complex in which a distinctly non-octahedral structure is adopted involves *N*-substituted cysteamine ligands. When N is not substituted, a complex such as $MoO_2[NH_2CMe_2CH_2S]_2$ forms and adopts the expected octahedral structure[85] shown in Figure 9. In contrast, as illustrated in Figure 10, a skew trapezoidal bipyramidal structure[92] is found to be present[84,93,94] for $MoO_2[Me_2NCH_2CMe_2S]_2$. The two N- and two S-donor atoms form an approximate plane in which the Mo atom also lies. The oxo donors lie equidistant above and below this plane. The non-octahedral nature of the complex is seen by looking for the atom that is expected to be *trans* to oxo in the octahedral structure. Indeed, the largest angle about the oxo ligand is 122° and this is the O—Mo—O angle. This is the largest O_t—Mo—O_t angle which has been found in oxo Mo^{VI} complexes and it raises the interesting question as to whether these complexes are best formulated as containing Mo^{VI}. Indeed, it has been suggested that the observed short S--S contact of ~2.74 Å may represent the partial formation of a sulfur–sulfur (*i.e.* disulfide) bond. If a full disulfide bond had been formed, the complex would be formulated as one of Mo^{IV} with oxidized ligands. Such a complex would be

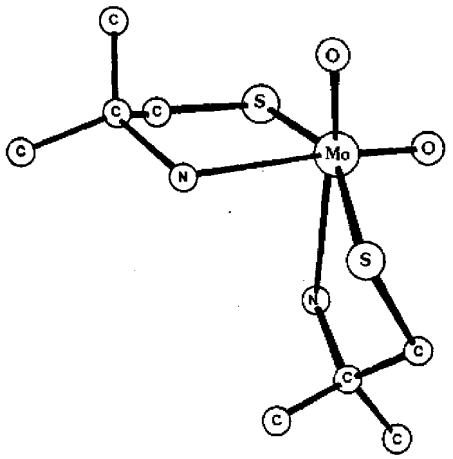

Figure 9 The structure of $MoO_2[NH_2CMe_2CH_2S]_2$[85]

expected to have a *trans* dioxo structure with O_t—Mo—$O_t = 180°$. However, the observed 'bond' length may indicate partial reduction of Mo. This would be consistent with the observed angle being increased from the roughly 105° expected to the larger value actually observed.

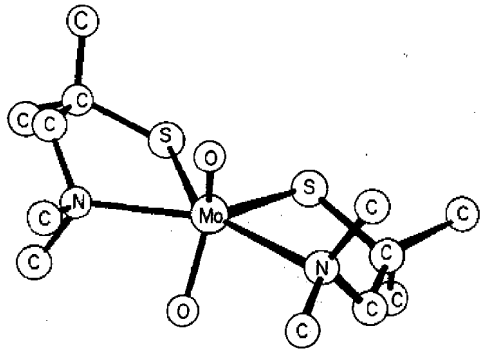

Figure 10 The structure of $MoO_2[Me_2NCH_2CMe_2S]_2$[84]

Clearly there is a universal tendency for dioxo Mo^{VI} complexes to adopt a *cis* configuration and there is a strong disposition toward octahedral structures. The distortions within these structures are clearly attributable to interligand repulsions. However, recent work reveals that appropriately rigid or sterically demanding ligands can enforce lower coordination numbers or non-octahedral coordination geometry on the Mo sphere.[73] In molybdoenzymes there is strong evidence for the presence of an MoO_2^{2+} grouping.[5,82] While octahedral coordination must be considered as a candidate structure for these enzymes, non-octahedral structures and lower coordination numbers cannot be eliminated. Indeed, proteins are capable of acting as extraordinarily sterically demanding ligands.

36.5.4.2 Spectra and Characterization of Complexes with MoO_2^{2+} Cores

The MoO_2^{2+} group manifests itself in the infrared and/or Raman spectrum in the form of an intense two-band pattern corresponding to the symmetric and asymmetric Mo—O stretching vibrations. Values for representative complexes are shown in Table 2 which also displays the lowest visible absorption bands for those complexes where these are available. The infrared (or Raman) absorptions are by far the most characteristic feature by which to identify the presence of the MoO_2^{2+} unit.

Several studies[95–98] of IR and Raman spectroscopy have concentrated on systematics of the MoO_2^{2+} core vibrations. Substitution of ^{18}O for ^{16}O is useful in confirming assignments and calculating forces constants.[96,98] The frequency shifts between complexes are dependent upon the donor ability of the remaining ligands, the geometry of the complex and the participation of the Mo—O_t linkage in H-bonding.[98] Often the IR spectrum along with elemental analysis data is sufficient to identify the MoO_2^{2+} core. Proton and carbon NMR data (see, for example, refs. 99–102) are often useful in a complementary way in establishing the disposition of the remaining non-oxo ligands. NMR can also be useful to establish the liability or fluxionality of the coordinated ligands.[100,102]

^{17}O NMR spectroscopy of oxomolybdenum complexes can give valuable structural information.[103–105] Since the sensitivity of the quadrupolar $I = \frac{5}{2}$ ^{17}O nucleus is inherently low, enrichment with ^{17}O is required to obtain signals in acceptable time periods. Apparently, ^{17}O can be incorporated by exchange into already formed MoO_2^{2+} core complexes.[65] The rates of exchange, although not quantitatively measured, appear to be qualitatively different for Mo—O_t groups in somewhat different ligand environments, *i.e.* with different *trans* groups.[65] In certain skew-trapezoidal bipyramidal structures[106] ^{17}O NMR was used to support the maintenance in solution of the structure found by single crystal X-ray diffraction in the solid.[84] The Mo—O_t resonance occurs at 850–1000 p.p.m. downfield from H_2O making it readily distinguishable from bridging (~400) and ligand oxygen atoms.[65,107]

^{95}Mo NMR has been applied to MoO_2^{2+} core complexes. The chemical shifts range over 900 p.p.m. and display potentially useful ligand dependence.[108–116] A comprehensive review of ^{95}Mo NMR summarizes key trends.[117]

Detailed electronic spectral studies for MoO_2Cl_2 and MoO_2Br_2 have been performed (ref.

118 and refs. therein) and interpreted by SCF-Xα-SW calculations.[119] However, the electronic spectra of the six-coordinate species, which are the major group discussed in this section, have not received much attention.

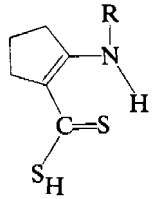
EXAFS studies[120] have shown that the MoO_2^{2+} core is readily identifiable in a variety of known compounds. These have been used[120] to calibrate the EXAFS technique which was subsequently used to identify this core in sulfite oxidase and in desulfo xanthine oxidase.[82]

36.5.4.3 Preparation and Scope of MoO_2^{2+} Core Complexes

The method of choice for the preparation of many dioxo Mo^{VI} complexes involves the use of $MoO_2(acac)_2$ which is easily prepared from MoO_4^{2-} and acacH by adjusting the pH.[121,122] Thermodynamic data for the formation of $MoO_2(acac)_2$ have been presented.[123]

The reaction of equation (7)[124] is typical and proceeds readily in THF. Alcohols, especially MeOH, are also much used in related syntheses with base (often a tertiary amine) sometimes used to help ionize the incoming ligand. In the absence of base, the free acacH (b.p. = 139 °C) formed can be readily distilled under partial vacuum from the reaction solution along with the solvent.

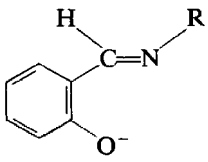
(7)



Alternative preparative approaches, while not systematically directed toward MoO_2^{2+} complexes can nevertheless be useful. For example, oxidation of $Mo(CO)_4$(bipy) with Br_2 in C_2H_5OH—CH_2Cl_2 yields MoO_2Br_2(bipy).[26] The corresponding dichloride can be prepared by ligand exchange in boiling acetone.[125] The complexes MoO_2X(9-ane) (X = Cl, Br; 9-ane = 1,4,7-trimethyl-1,4,7-triazanonane) are also prepared by oxidation of the low valent complex $Mo(CO)_3$(9-ane) with the appropriate halogen and subsequent hydrolysis.[192]

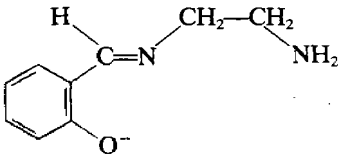
$MoO_2(R_2dtc)_2$ complexes can be prepared from the Mo^{IV} complexes, $MoO(R_2dtc)_2$. As the latter are often formed from the former, the route is not synthetically useful. However, since the oxygen atom donor can be DMSO (forming dimethyl sulfide)[126,127] the route is reminiscent of the enzymic reduction of biotin sulfoxide.[5] Other oxidants capable of effecting the conversion include *N*-oxides such as pyridine *N*-oxide or *N*-hexylmorpholine *N*-oxide[127] and oxygen[128,129] but not N_2O[130] as originally claimed.[127]

Certain classes of ligand deserve special mention as their MoO_2^{2+} complexes have received particular attention. The 1,1-dithiolate ligands, especially *N*,*N*-disubstituted dithiocarbamates, have been very thoroughly studied.[131–133] Evidence for the existence of the dithiophosphate complex $MoO_2[S_2P(OEt)_2]_2$ in solution has been obtained.[95] This and a number of other dithiolate complexes may be unstable toward internal redox in which the S ligand serves as the reductant to produce a lower valent Mo—S complex.

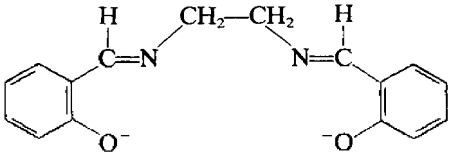


A related ligand is the ferrocenecarbodithioate ligand which behaves similarly to dithiocarbamates in forming an isolable series of Mo^{IV}, Mo^{V} and Mo^{VI} complexes.[134,135] The $MoO_2(S_2CC_5H_4FeC_5H_5)_2$ complex shows ν(Mo=O) at 920 and 889 cm^{-1} and gives a quasireversible reduction wave with $E_{1/2}$ of −0.89 V *vs.* SCE attributable to Mo reduction and a quasireversible oxidation wave at +0.95 V *vs.* SCE attributable to ligand (ferrocene) oxidation.[134,135]

The interesting ligand (**1**)[136] has two potential chelating modes upon ionization. Depending on its tautomeric state, either N,S or S,S coordination allows it to act as a bidentate chelating ligand. Apparently, it acts as a 2-aminocyclopent-1-ene-1-carbodithioate, *i.e.* as a 1,1-dithiolate, to form MoO_2L_2 complexes.[136]



(**1**)



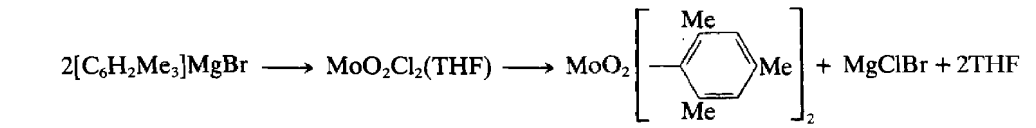
Complexes containing Schiff base chelating ligands have been extensively studied.[137–144] Here the ligands include bidentate, tridentate and tetradentate representatives where O or S donors supplement the imine nitrogen. Examples are listed in Tables 2 and 3. Sample ligands include (**2**), (**3**) and (**4**).

(**2**) L

(**3**) L′

(**4**) Salen

The bidentate ligands (L) form MoO_2L_2 complexes while the tetradentate ligands form complexes such as MoO_2(Salen). The tridentate ligands (L′) form complexes $MoO_2L'(Y)$ where Y can be a variety of O-, N- or S-donor ligands, often the solvent from which the complex is isolated. Extensive studies have probed the effect of substitution on the aromatic ring, substitution for the hydrogen of the Schiff base carbon, and the length of the group pendent (or bridging) on N, the Schiff base nitrogen.[66,145–147] Mixed Fe, Mo complexes with Schiff base ligands have been reported[148] but not structurally characterized.



The complex anion, $MoO_2(cat)_2^{2-}$ (where cat = catecholate = benzene-1,2-diolate) has been extensively studied as the starting point for a series of complexes in the Mo^{III}, Mo^{IV} and Mo^{VI} oxidation states.[149,151,150] $MoO_2(cat)_2^{2-}$ in slightly acidic aqueous solutions undergoes sequential electrochemical one-electron and two-electron reductions leading to penta- and tri-valent Mo.[149] In slightly alkaline solution four oxidation states are electrochemically accessible.[151] Upon reduction the number of oxo groups per Mo decreases leading to reactivity and lability which may be related to the function of oxomolybdenum centers in enzymes.[150] Complexes containing 3,5-di-*tert*-butylcatecholate behave in a somewhat different fashion[152] involving an isolated dinuclear Mo^{VI} species.

The biologically active compounds glycine,[62] hydroxamate,[153] phenacetin[154] and acetanilid[154] each form MoO_2L_2 complexes. While these complexes help define the ways in which these organic molecules may serve as ligands, they have, at present, no obvious biological relevance. Several heterocyclic *N*-oxides also form MoO_2^{2+} complexes.[155]

Neutral complexes are known of the form MoO_2X_2 where X = F,[156] Cl,[118] Br,[118] I,[157] $OSiBu^t_3$,[158] R_2NO[86–89] and mesityl.[159] These complexes contain the MoO_2^{2+} core and two monodentate ligands. The halo complexes[2,118,119,156] are mononuclear in the gas phase and di- or poly-nuclear as solids or in solution. The $—OSiBu^t_3$[158] and $—C_6H_2Me_3$[159] complexes are apparently mononuclear. The siloxy compound[158] is made by the direct reaction of tris(*t*-butylsilanol) with MoO_3, presumably according to equation (8).

$$2Bu^t_3SiOH + MoO_3 \longrightarrow MoO_2[OSiBu^t_3]_2 + H_2O \qquad (8)$$

The mesityl complex[159] is prepared by the reaction of the Grignard reagent and $MoO_2Cl_2(THF)_2$ in THF presumably according to Scheme 2.

Scheme 2

These complexes likely have approximate tetrahedral structures and resemble MoO_4^{2-} rather than the largely octahedral MoO_2^{2+} complexes discussed in this section.

The series of complexes MoO_2X_2 (X = F, Cl, Br) can be used to prepare $MoO_2X_2L_2$ complexes where L_2 is py_2, bipy, $(DMSO)_2$ or other ligands. Examples of these complexes, which are formally adducts of MoO_2X_2, are given in Table 1. The structurally characterized complexes have the π-donor halides *trans* to each other and *cis* to the Mo—O_t bonds.

36.5.4.4 Reactivity of Complexes with the MoO_2^{2+} Core

The dioxo core is susceptible to redox reactions which lead to reduction of the Mo center in conjunction with oxo removal,[131,160,161,162,163,164] Schematically, the core reaction in equation (9) gives the Mo^{VI} complex. The reactant and product of this reaction, however, can combine with comproportionation as in equation (10) to give the dinuclear Mo^{V} core.

$$\overset{VI}{MoO_2^{2+}} \underset{-[O]}{\overset{[O]}{\rightleftharpoons}} \overset{IV}{MoO^{2+}} \tag{9}$$

$$\overset{IV}{MoO^{2+}} + \overset{VI}{MoO_2^{2+}} \longrightarrow \overset{V}{Mo_2O_3^{4+}} \tag{10}$$

A general treatment has been published of oxygen atom transfer kinetics for complexes wherein the dimerization/comproportionation reaction is a complicating feature.[165] This treatment critically summarizes all pertinent earlier information. The assumption that dimerization is very fast with respect to oxygen atom transfer is born out by the agreement of the observed and calculated kinetic parameters.

The oxo removal reaction can be effected by a variety of trialkyl and triaryl group V reactants. For example, the reactivity of $MoO_2(Et_2dtc)_2$ with regard to oxo removal is reported[166] to qualitatively follow the order $Ph_3P \gg Et_3N \approx Ph_3As > Ph_3Sb > Ph_3Bi > Ph_3N$. For phosphines, the rates of reaction follow the expected order of nucleophilicity[165] $PEt_3 > PEt_2Ph > PEtPh_2 > PPh_3$.

As far as the ligand is concerned, toward oxidation of either PPh_3 or PhNHNHPh, the order of reactivity is[163] $S_2CNEt_2 >$ thiooxinate > Cys-OMe. The oxidizing ability of MoO_2^{2+} complexes is enhanced by the presence of S-donor ligands.[163]

The reaction of $MoO_2(R_2dtc)_2$ (R = Et, Pr^n and Bu^i) with PPh_3 and other phosphines has been thoroughly studied.[167] The reaction is first order in both complex and phosphine which, along with the large negative entropy of activation, fits a simple bimolecular mechanism.[167] Similar studies have been performed on $MoO_2(Cys\text{-}OEt)_2$ with similar results. The general equation (11), (with the previously mentioned comproportionation as a complication) is clearly well established.[167,128] It has potential analytical applications for the determination of PPh_3 by monitoring the intensely colored $Mo_2O_3(Et_2dtc)_4$ formed in the comproportionation of equation (12).

$$Mo^{VI}O_2L + PR_3 \longrightarrow OPR_3 + Mo^{IV}OL_2 \tag{11}$$

$$MoO_2[Et_2dtc]_2 + MoO[Et_2dtc]_2 \longrightarrow Mo_2O_3[Et_2dtc]_2 \tag{12}$$

Kinetics of the reaction of certain MoO_2L complexes (L = S-containing salicylaldehyde Schiff base) with $PEtPh_2$ also show the reactions to be first order in complex and in phosphine,[145–147,168] The rate constants depend upon the substituent on the aromatic (salicylaldehyde derived) ring and correlate with reduction potentials of the complexes.[145]

The kinetics of the equilibrium reaction (13) was studied by concentration-jump relaxation techniques[168,169] for $L = S_2CNEt_2$, $SSeCNEt_2$, Se_2CNEt_2, $S_2P(OEt)_2$ and S_2PPh_2. The diethyl diselenocarbamate complex is found to be the most highly dissociated and the rate constant for its dissociation is the highest. The diphenyldithiophosphinate complex is the most stable and slowest to dissociate.[169,168]

$$Mo_2^{V}O_3L_4 \rightleftharpoons Mo^{IV}OL_2 + Mo^{VI}O_2L_2 \tag{13}$$

The porphyrin complex $MoO_2(tpp)$ also reacts with phosphines to form phosphine oxides[170] or with secondary alcohols to produce ketones.[171] The latter reaction appears to occur by one-electron (radical) steps showing the versatile reactivity of the Mo–oxo–porphyrin grouping.[171] A one-electron oxidation of $MoO_2(tpp)$ forms the radical cation which readily undergoes oxygen atom transfer to yield the Mo^{V} complex $MoO(tpp)^+$.[172] The reaction has some features in common with those of cytochrome P450.[172]

Reaction of $MoO_2(MeHNO)_2$ with heterocumulenes such as alkyl or aryl isocyanate

yields[26] by equation (14) an adduct with a five-membered chelating ring. Related 'heterocumulenes' such as SCN^- and CS_2 yield similar structures (see below).

$$MoO_2[MeHNO]_2 + RNCO \longrightarrow MoO_2\left[\begin{array}{l} O{=}C(NHR)-O \\ \quad\quad\quad\

enzymic activity. Photolysis of $MoO_2(Et_2dtc)_2$[180] or MoO_2(dibenzoylmethanato)$_2$[182] leads to yet uncharacterized but interesting reduced Mo-containing products. $MoO_2(Et_2dtc)_2$ is reported to catalyze the reduction of NO_2^- to N_2O by HCO_2H in DMF.[183] This reaction involves the reduction of $MoO_2(Et_2dtc)_2$ by HCO_2H, giving $MoO(Et_2dtc)_2$,[183] a reaction that may be similar to the one catalyzed by formate dehydrogenase.

$MoO_2(Cys\text{-}OMe)_2$, $MoO_2(S_2CNEt_2)$ and other complexes are reported[99] to catalyze the air oxidation of benzoin to benzil. The complex $MoO_2(Cys\text{-}OR)_2$ (R = Me, Et, Pr^i and CH_2Ph) catalyzes the O_2 oxidation[128,184] of PPh_3 in DMF by a mechanistically involved process in which excess H_2O prevents the catalytic redox cycle.[184,185]

The electrochemistry of MoO_2^{2+} core complexes has been extensively studied.[65,73,106,136,126,151,153,149,174,186–193] Virtually all compounds studied show irreversible electrochemistry. However, one complex, $MoO_2(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)$, displays a reversible, one-electron reduction wave.[174,106] The one-electron reduction product[194] has been characterized by EPR spectroscopy as $Mo^VO_2H(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)^-$. This Mo^V complex displays proton super-hyperfine splitting reminiscent of that found in xanthine oxidase.[194]

The formation of MoO_2^{2+} complexes and their substitution, ligand exchange and rearrangement (fluxionality) reactions have been reviewed.[195]

36.5.5 COMPLEXES WITH MoO^{4+} CORES

The MoO^{4+} core structure is found in Mo^{VI} chemistry in a relatively small number of authenticated structures and in a few suggested examples shown in Table 3. The simplest set of complexes which potentially contains the MoO^{4+} core is $MoOX_4$(X = F, Cl, Br). While a square pyramidal structure seems probable for the chloro and bromo complexes,[232] the fluoro complex is polymeric in the solid state and in solution as well.[233–235]

Table 3 Complexes Containing MoO^{4+} Cores

Complex	$n(MO\text{—}O_t)$ (cm^{-1})	*Mo—O$_t$* (Å)	*Ref.*

[a] Polymeric solid.

The reaction of $MoO_2(R_2dtc)_2$ (R = Me, Et, Pr^n) with HF, HCl or HBr[246] eliminates H_2O and gives $MoOF_2(R_2dtc)_2$, $MoOCl_2(R_2dtc)_2$ and $MoOBr_2(R_2dtc)_2$, respectively. The structure of $MoOCl_2(Pr^n_2dtc)_2$, shown in Figure 11, reveals a seven-coordinate complex. An approximate pentagonal bipyramid is formed with an apical oxo and a *trans* chloro ligand. The four sulfur donors of the R_2dtc^- ligands and the second chloride ligand form the equatorial plane. An alternative route to $MoOCl_2(R_2dtc)_2$ involves oxidative addition of Cl_2 to $MoO(R_2dtc)_2$.[236] The ligand $C_5H_6NH_2CS_2^- = acda^-$[237] displays similar chemistry.[136]

The cation $MoO(R_2dtc)_3^+$ has been isolated in a number of salts[238,239] with BF_4^-, PF_6^-, ClO_4^-, $Mo_2O_4F_6^{2-}$ and $Mo_6O_{19}^{2-}$ as counterions. The structure of the $Mo_2O_4F_6^{2-}$ salt shows that the cation has a seven-coordinate pentagonal bipyramidal structure[238] with terminal oxo in an apical position. Proton NMR indicates this structure to be present in solution[239] although variable temperature work indicates significant fluxionality. The complex cation can be

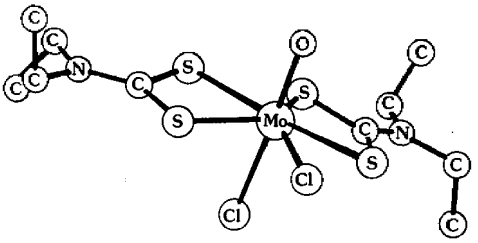

Figure 11 The structure of $MoOCl_2(Pr^n_2dtc)_2$[240]

prepared from $MoO_2(R_2dtc)_2$ and a hydrohalic acid. These reactions, although obviously complex, can give >50% yield of product with the remainder of the Mo presumably ending up as $Mo_6O_{19}^{2-}$. The characteristic Mo—O stretching band appears at ~935 cm^{-1} in the IR spectrum for $MoO(Et_2dtc)_3^+$.

The blue complexes $MoOS_2(R_2dtc)_2$ have been prepared by several routes.[240–242] The structure shown in Figure 12 again reveals a pentagonal bipyramid with S_2^{2-} in the equatorial plane, one R_2dtc^- ligand in the equatorial plane and the second R_2dtc^- ligand spanning axial and equatorial positions.

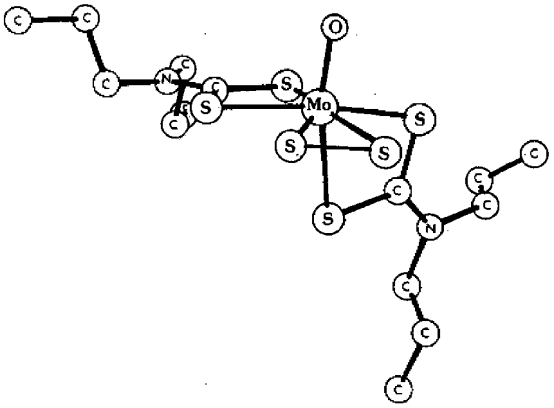

Figure 12 The structure of $MoOS_2(Pr^n_2dtc)_2$[240]

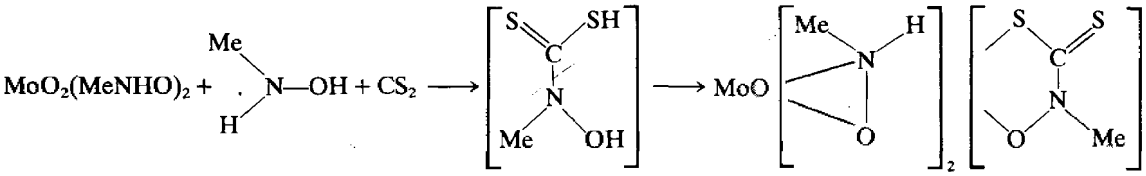
Among the reactions which lead to the $MoOS_2(R_2dtc)_2$ complex are those of equations (18) to (21).

$$MoO(R_2dtc)_2 + S_8 \longrightarrow MoOS_2(R_2dtc)_2 \quad (18)^{50}$$

$$MoO_2(R_2dtc)_2 + H_2S \longrightarrow MoOS_2(R_2dtc)_2 \quad (19)^{240,241}$$

$$MoO_2S_2^{2-} + R_2NC(=S)-S-S-C(=S)NR_2 \longrightarrow MoOS_2(R_2dtc)_2 \quad (20)^{242}$$

$$Mo_2O_3(R_2dtc)_4 + Na_2S_4 \longrightarrow MoOS_2(R_2dtc)_3 \quad (21)^{241}$$



The Mo^{IV} complex $MoO(R_2dtc)_2$ is a potential source of new MoO^{4+} complexes. Thus, reaction with S_8 gives $MoOS_2(R_2dtc)_2$[240] while reaction with Cl_2 gives $MoOCl_2(R_2dtc)_2$.[236] Reaction with $MeO_2CC{\equiv}CCO_2Me$ yields the acetylene adduct $MoO(R_2dtc)_2(MeO_2CCCCO_2Me)$ which, upon protonation with CF_3CO_2H, gives the complex $MoO(R_2dtc)_2(MeCO_2C{=}CHCO_2Me)(O_2CCF_3)$ with coordinated trifluoroacetate[243] according to equation (22).

$$MoO(R_2dtc)_2(MeO_2CCCCO_2Me)_2 + CF_3CO_2H \longrightarrow MoO(R_2dtc)_2(MeO_2CC{=}CHCO_2Me)(O_2CCF_3) \quad (22)$$

Complexes containing a single oxo and hydrazido(2−) ligand are discussed separately below.

The reaction of $MoO_2(MeNHO)_2$ in the presence of the hydroxylamine ligand and CS_2 proceeds according to Scheme 4.[244] The resultant formally seven-coordinate complex has a distorted pentagonal bipyramidal structure with the lone oxo group in the apical position. The five equatorial positions are occupied by two formally bidentate O,N hydroxylamido ligands of

the starting material and the sulfur atom of the *N*-methyl-*N*-oxodithiocarbamate ligand. The oxygen of this ligand binds *trans* to Mo—O_t in the apical position with the O_t—Mo—O angle of 162.1°. As discussed below other heterocumulenes such as RCN, SCN^- and OCS are also reactive toward hydroxylamine to form related ligands and complexes.[244]

Scheme 4

^{95}Mo NMR spectra of a representative sampling of MoO^{4+} complexes containing R_2dtc^- ligands reveal a relatively narrow distribution (55 to 183 p.p.m.) of chemical shifts. The complexes $MoO(R_2dtc)_3^+$ fall in the range 55–80 p.p.m. A combination of IR, ^{95}Mo and ^{17}O NMR spectra should prove powerful in characterizing MoO^{4+}-containing complexes in the future.

There is one reported example in Mo^{VI} chemistry of a MoS^{4+} and $MoSe^{4+}$ core. These are presumably found in $MoSF_4$[245] and $MoSeF_4$.[245] The band at 564 cm^{-1} in the former compound is assigned to the Mo—S stretch.[245]

36.5.6 NITRIDO COMPLEXES

The nitrido ligand N^{3-} is isoelectronic with the oxo ligand O^{2-}. Known nitrido complexes contain a single nitrido ligand and are often structurally related to analogous oxo complexes. However, unlike the situation for oxo complexes, there are as yet no examples of dinitrido or trinitrido complexes. The majority of known nitrido complexes are mononuclear and can be five-, six- or seven-coordinate. Such complexes possess square pyramidal, distorted octahedral or pentagonal bipyramidal structures, respectively. Structural results are given in Table 4 where the Mo—N distance can be seen to be extremely short, even shorter than Mo—O distances. This is due to stronger multiple bonding between Mo and N compared to O. For similar reasons ν(Mo—N) is usually above 1000 cm^{-1}, whereas ν(Mo—O_t) is usually found below 1000 cm^{-1}. The ability of the N^{3-} ligand to σ- and π-bond and hence donate very strongly to Mo may be the reason for the absence of multinitrido or oxo-nitrido complexes of Mo^{VI}.

Table 4 Nitrido Mo^{VI} Complexes

Complex	*Mo—N* (Å)	ν(*Mo—N*) (cm^{-1})	*Ref.*
$MoNCl_3(OPPh_3)_2$		1030	253

$[MoNCl_3]_4$	1.638(11)		268
$[MoNCl_3{\cdot}OPCl_3]_4$	1.659(5)	1042	269
	[2.150(5)]		
$[MoNBr_3]_4$		1025	257
$\{[MoN(Et_2dtc)_3]_2Mo(Et_2dtc)_3\}(PF_6)_3$	1.65(1)		259
	1.66(1)		
	2.12(2)		
	2.14(2)		

Structurally, the Mo nitride bond exerts a significant *trans* influence. In the extreme this leads to empty sites *trans* to Mo—N_t such as in $MoNCl_4^-$ or $MoN(N_3)_3(py)$.[249] In the octahedral complex, $MoN(N_3)_3(bipy)$ the nitrogen of the bipy ligand *trans* to Mo—N_t is 2.42 Å while the N of the same ligand *cis* to Mo—N_t is 2.24 Å.[251] In the seven-coordinate pentagonal bipyramidal complex $MoN(Me_2dtc)_3$ the S *trans* to Mo—O_t has Mo—*S* = 2.85 Å while S in the same ligand *cis* to Mo—N (in the equatorial plane) has Mo—S = 2.51 Å. Clearly, Mo—N_t has a structural *trans* effect comparable to or greater than that of oxo in analogous complexes.

The most common preparative route for Mo^{VI} nitrido complexes involves the reaction of azides such as ClN_3 or Me_3SiN_3 with lower valent Mo complexes.[252] The resultant azido complexes are often unstable and eliminate N_2 to form the nitrido complex as shown in equations (23) and (24) or equation (25).

$$MoCl_5 + ClN_3 \longrightarrow MoCl_5N_3 + \tfrac{1}{2}Cl_2 \quad (23)$$

$$MoCl_5N_3 \longrightarrow MoNCl_3 + N_2 + Cl_2 \quad (24)$$

$$MoCl_4(MeCN)_2 + Me_3SiN_3 + bipy \longrightarrow MoNCl_3(bipy) + N_2 + 2MeCN + Me_3SiCl \quad (25)$$

Once the nitrido complexes are formed they are reactive toward ligand substitution as in equations (26) and (27). Many complexes have been prepared exploiting this substitutional reactivity,[251–257]

$$MoNCl_4^- + bipy \longrightarrow MoNCl_3(bipy) + Cl^- \quad (26)$$

$$MoNBr_3 + H_2tpp \longrightarrow [MoN(tpp)^+]Br_3^- + H_2 \quad (27)$$

The nitrido nitrogen is reactive nucleophilically leading in some cases to di- or tetra-nuclear complexes in which nitrido binds to a second molybdenum as a weak ligand. For example, the structure of $[MoNCl_3(OPCl_3)]_4$ is illustrated in Figure 13. The complex $MoN(R_2dtc)_3$ reacts with S_8 or propylene sulfide to give the thionitrosyl complex $MoNS(R_2dtc)_3$.[258]

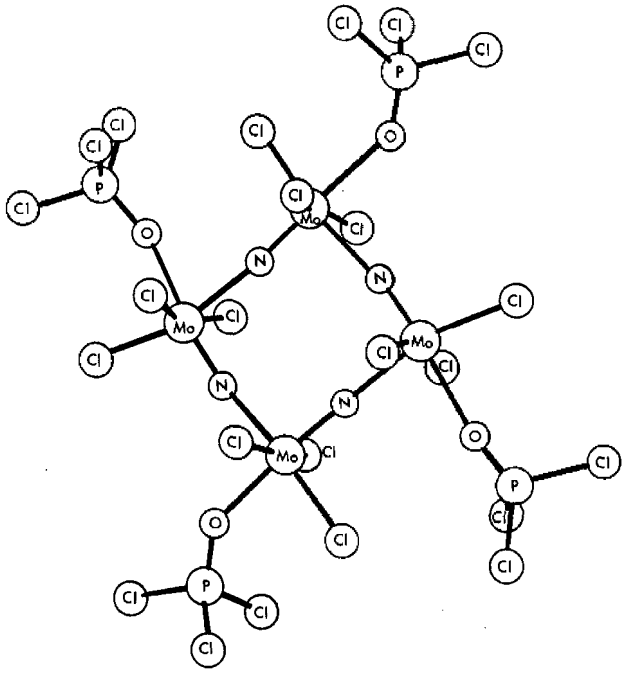

Figure 13 The structure of $[MoNCl_3(OPCl_3)]_4$[269]

Reaction of $MoN(Et_2dtc)_3$ with NH_2OSO_3H (in an attempt to make a hydrazido complex) yields an unusual trinuclear species.[259] The diamagnetic tricationic brown complex $[MoN(Et_2dtc)_3]_2Mo(Et_2dtc)_3$ formed[259] has been shown by X-ray studies to have two bridging nitrido ligands such that the central Mo is eight-coordinate (dodecahedral) while the terminal Mo atoms have pentagonal bipyramidal seven-coordinate structures. The Mo—N distances to terminal Mo atoms are comparable to those in $MoN(Me_2dtc)_3$ at 1.65(1) and 1.66(1) but the

distances to the central Mo are significantly longer at 2.12 and 2.14 Å. The bridging is reminiscent of that found in $[MoNCl_3]_4$ and $[MoNCl_3(OPCl_3)]_4$.

36.5.7 IMIDO AND ARYL- AND ALKYL-IMIDO COMPLEXES

Imido (NH^{2-}) and arylimido (NR^{2-}) complexes have been prepared for Mo^{VI} as well as for lower oxidation states of Mo. The alternative formulation for the ligand is that of a nitrene wherein the ligand is neutral. This, of course, makes the formal oxidation state of the metal two units lower for each ligand compared to the corresponding arylimido formulation. We prefer the arylimido formulation as the resultant complexes all have analogs in the chemistry of oxo Mo^{VI} species and do not have analogs in lower oxidation state Mo chemistry.

The lone structurally characterized imido complex is $MoO(NH)Cl_2(OPEtPh_2)_2$.[270] Here the oxo and imido ligands are *cis* to each other with Mo—O = 1.66 and Mo—N = 1.70 Å, respectively. The N—H hydrogen has been located and the Mo—N—H angle is 157°. The orange-yellow complex was prepared by the reaction of $MoOCl_3$ with Me_3SiN_3 followed by the addition of the tertiary phosphine oxide.[270]

The arylimido complexes are prepared by the reaction of an arylazide with an appropriate Mo starting material. For example, the reaction of $Mo(CO)_2(R_2dtc)_2$ with phenyl azide[271] yields the complex $Mo(NPh)_2(R_2dtc)_2$ whose structure is shown in Figure 14. The structure is clearly analogous to that of $MoO_2(R_2dtc)_2$ with *cis* phenylimido ligands in place of the *cis* oxo ligands. The two phenylimido ligands differ significantly in their Mo—N—C angles and Mo—N bond lengths. These correspond to 139.4° and 1.789 Å, respectively, for one ligand and 169.4° and 1.754 Å, respectively, for the other. Interestingly, the phenylimido ligand does not appear to exert a significant *trans* influence in this or other complexes. The reaction of $MoO(R_2dtc)_2$ with phenyl azide gives the mixed oxo–phenylimido complex $MoO(NPh)(R_2dtc)_2$.[272] These complexes contain two oxo-equivalent ligands (i.e. one oxo and one arylimido) and approximate octahedral coordination geometries. In contrast to these complexes is the *p*-tolylimido complex $Mo(N\text{-}p\text{-}C_6H_4Me)Cl_4(THF)$[273] which has a single oxo-analog ligand and an octahedral six-coordination.

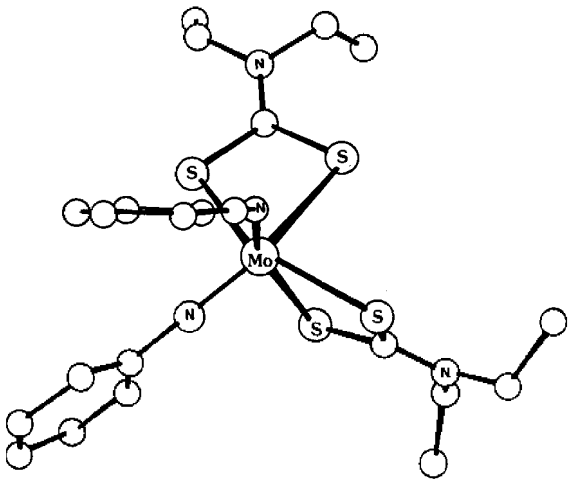

Figure 14 The structure of $Mo(NPh)_2(R_2dtc)_2$ (unlabelled atoms are carbon)[271]

Other aryl imido complexes seem to resemble more closely the seven-coordinate pentagonal bipyramidal complexes with a single oxo-equivalent ligand (in this case an arylimido or alkylimido ligand). The complex cation $Mo(NMe)(R_2dtc)_3^+$[274] is closely related both to the nitrido complex $MoN(R_2dtc)_3$ and to the oxo complex $MoO(R_2dtc)_3^+$. As anticipated, the Mo—N bond distance is, at 1.73 Å, significantly longer in the arylimido compared to either the corresponding nitrido or oxo complex. The complex $Mo(NPh)Cl_2(R_2dtc)_2$[275,272] has the pentagonal bipyramidal structure found for its oxo analog $MoOCl_2(R_2dtc)_2$.[246]

36.5.8 HYDRAZIDO(2−) COMPLEXES

Hydrazine is one of the suggested intermediates on the pathway of the reduction of dinitrogen.[276] Hydrazine can serve as a conventional ligand using the lone pairs on each N atom as donors to a transition metal. However, hydrazine can also be deprotonated by one or two steps to produce monoanionic and dianionic ligands, respectively. The double deprotonation of N_2H_4 leads to the hydrazido(2−) ion which, in its disubstituted manifestation $R_2N_2^{2-}$, is a ligand to a significant number of Mo^{VI} complexes. A majority of these have exact analogs in the chemistry of simple oxo complexes and so hydrazido(2−) joins the ranks of ligands that are oxo-like in character. In a significant number of cases a hydrazido(2−) complex can be prepared directly from the corresponding oxo complex by simply refluxing the oxo complex and the corresponding hydrazine in an appropriate solvent.

For example, reaction of $MoO_2(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)$ with NH_2NPh_2 yields the hydrazido(2−) complex $MoO(N_2Ph_2)(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)$ whose structure[277,278] is shown in Figure 15. Note the placement of the hydrazido(2−) ligand *cis* to oxo, the relatively short Mo—N distance of 1.778(3), and the O—Mo—N angle of 105.9(1)°. These features are reminiscent of the starting *cis* dioxo complex. The near linear Mo—N—N angle of 172.9(2)° and the N—N distance of 1.309 reveals some multiple binding between the N atoms of the hydrazide(2−) ligand.[277] The Mo—N distance at 2.464(3) *trans* to oxo and 2.359(3) *trans* to hydrazido(2−) reveal that the oxo group has a stronger *trans* bond lengthening influence than does the hydrazido(2−) ligand.[277] In most cases the Mo—N—N angle is near linear. A compilation of key distances in hydrazido(2−) complexes is given in Table 5.

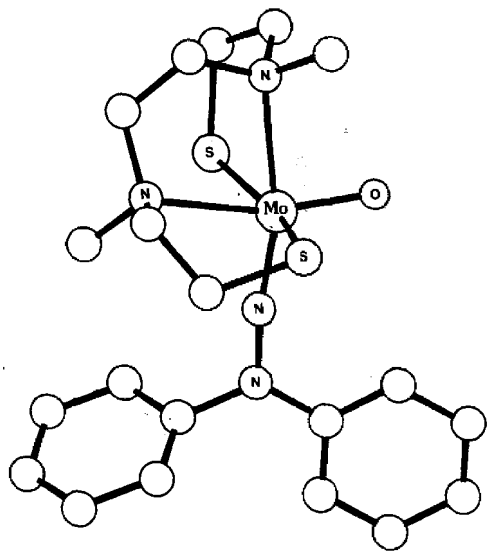

Figure 15 The structure of $MoO(N_2Ph_2)(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)$ (unlabelled atoms are carbon)[277]

Table 5 Hydrazido(2−) Complexes of Mo^{VI}

Complex	*Mo—N* (Å)	*N—N* (Å)	*Mo—O* (Å)	*Ref.*
$\{Mo(NNPhEt)[(CH_2)_5dtc]_3\}BPh_4$	1.715(16)	1.37(2)	—	280

$[MoCl(NNMe_2)_2(PPh_3)_2]Cl$	1.763(2)	1.291(7)	—	282
	1.752(5)	1.276(8)	—	
$[Mo(NNMe_2)_2(bipy)_2](BPh_4)$	1.80(1)	1.27(3)	—	282
	1.79(1)	1.28(2)	—	
$MoO(NNMe_2)(Me_2dtc)_2$	1.85(2)	1.24(2)	—	283
$MoO(NNMe_2)(oxine)_2$	1.800(9)	1.28(1)	1.671(9)	284
$MoO(NNPh_2)(SCH_2CH_2NMeCH_2CH_2NMeCH_2CH_2S)_2$	1.778(3)	1.309(4)	1.696(2)	277
$[PPh_4][MoO(NNMe_2)(SPh)_3]\cdot Et_2O$	1.821(9)	1.292(14)	1.705(8)	285

Reaction of the Mo^{V} complex $MoO(SPh)_4^-$ with H_2NNMe_2 leads to $MoO(N_2Me_2)(SPh)_3$.[285] This complex anion has a distorted square pyramidal structure in the $[PPh_4][MoO(N_2Me_2)(SPh)_3]\cdot Et_2O$ salt with the oxo ligand in the apical position.[285] The complex has an unusually small Mo—N—N angle of 152.5(10)° in contrast to the near linear linkage Mo—N—N = 169°–180° found in all other complexes in Table 5.

The oxo hydrazido complex $MoO(N_2Me_2)(oxine)_2$ reacts with HX (X = Cl, Br, SPh, ½cat, ½tdt) to give $MoO(N_2Me_2)X_2(oxine)_2$.[284] This reactivity is analogous to that of the dioxo complexes reacting with HX to give the corresponding seven-coordinate oxo dihalogeno complexes.[246]

The bis[hydrazido(2−)] complex $Mo(NNMePh)_2(Me_2dtc)_2$ reacts with one equivalent of HCl to produce the cationic complex $Mo(NNMePh)(NHNMePh)(Me_2dtc)_2^+$ which contains one near-linear hydrazido(2−) and one hydrazido(1−) ligand bound to Mo through both N atoms.[279] The side-on bound hydrazido(1−) ligand has Mo—N = 2.069(8) and 2.185(9) and N—N = 1.388(12) Å. Other side-on bound hydrazido complexes are known.[262]

36.5.9 PEROXO COMPLEXES

Early work on peroxo compounds of molybdenum has been reviewed.[286] The stoichiometrically simplest Mo peroxo complex is the red-brown $Mo(O_2)_4^{2-}$ ion formed by the reaction of MoO_4^{2-} with H_2O_2. Although the complex is not stable in solution and decomposes slowly with the evolution of O_2, the anion can be crystallized as the $Zn(NH_3)_4^{2+}$ salt whose structure has been determined. In a sense, $Mo(O_2)_4^{2-}$ is an intermediate in the thermodynamically favored decomposition of hydrogen peroxide to water and oxygen.

As discussed above, the peroxido ligand, O_2^{2-}, is capable of substituting for the oxo ligand, O^{2-}, such that there is no gross change in geometry of the resultant complex. There is no more striking example of this than $Mo(O_2)_4^{2-}$. The structure of the anion in $[Zn(NH_3)_4][Mo(O_2)_4]$ is shown in Figure 16. It consists of a D_{2d} dodecahedron of eight oxygen atoms about Mo.[287] However, if the centroid of each O—O bond is taken, the four points describe a geometric figure close to the tetrahedron, which is, of course, the geometry of MoO_4^{2-}.

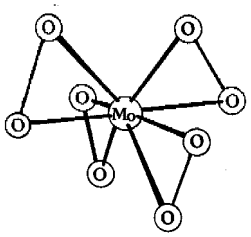

Figure 16 The structure of $Mo(O_2)_4^{2-}$ in $[Zn(NH_3)_4][Mo(O_2)_4]$[287]

A substantial number of Mo^{VI} peroxo complexes has been structurally characterized. These complexes all have nearly symmetrically side-on-bound peroxide. Among them are mononuclear, dinuclear, tetranuclear and heptanuclear compounds. The tetranuclear and heptanuclear complexes are related to the isopolymolybdates. Structural studies have identified $K_6[Mo_7O_{22}(O_2)_2]\cdot 8H_2O$ (O—O = 1.38 Å),[288] $K_5[HMo_7O_{22}(O_2)_2(H_2O)_6]$ (O—O = 1.38 Å)[288,289] and $K_4[Mo_4O_{12}(O_2)_2]$(O—O = 1.48 Å).[289]

The designation of coordination number in peroxo complexes is equivocal since a side-on-bound peroxide can be considered to occupy either one or two coordination sites. For the purpose of the following discussion we initially consider that O_2^{2-} occupies two coordination sites when bound side-on.

36.5.9.1 Mononuclear Peroxo Complexes

Mononuclear peroxo compounds of known crystal structure are listed in Table 6. Except for $Mo(O_2)_4^{2-}$ and $Mo(O_2)_2$(ttp), all structurally characterized mononuclear peroxo complexes have one Mo—O_t in addition to one or two peroxo ligands. The Mo—O_t bond lengths fall in the range 1.63 to 1.73 Å. The Mo—O (peroxo) distances span from 1.83 to 1.96 Å. The peroxo ligand is always found *cis* to the oxo group and two peroxo ligands are always found *cis* to each

other. In mixed oxo-peroxo complexes, the plane determined by the Mo—O—O ring is nearly perpendicular to the Mo—O_t direction. The overall coordination geometry is often describable as a pentagonal bipyramid with the oxo ligand in an apical position and peroxo groups in the equatorial plane.

Table 6 Structural Details for Mononuclear Peroxo Complexes

Complex	*O—O* (Å)	*Mo—O(peroxo)* (Å)	*Mo—O(oxo)* (Å)	*Ref.*
$[Zn(NH_3)_4][Mo(O_2)_4]$	1.55(5)	2.00(2) 1.93(3)		287
$(NH_4)_3[MoO(O_2)F_4]F$	1.36(3)			301
$K_2[MoO(O_2)F_4]\cdot H_2O$	1.44(3)	1.93(2) 1.94(2)	1.64(3)	332
$[MoO(O_2)_2(H_2O)_2]\cdot C_{12}H_{24}O_6\cdot H_2O$	1.445(6)	1.900(5) 1.920(5)	1.647(5)	290
$K_2[MoO(O_2)_2C_2O_4]$	1.47(2) 1.44(2)	1.95(2) 1.93(2)	1.68(1)	333, 292

$Mo(O_2)_2[ttp]$	1.399(6)	1.958(4)		294

[a] The ligand is citrate bound through a single carboxylate oxygen and alcohol. [b] The chiral ligand is (*S*)-*N*,*N*-dimethyllactamide.

The simplest diperoxo structure is that of $MoO(O_2)_2(H_2O)_2$ which cocrystallizes with 18-crown-6 and H_2O.[290] In this pentagonal bipyramidal structure shown in Figure 17 the H_2O ligands occupy equatorial and axial sites at Mo—O_w = 2.325 and 2.084 Å, respectively. Interestingly, this product was formed from the reaction of MoO_3, THF and oxygen. The source of the reducing equivalents necessary to form the peroxo complex was not specified but is likely to be the THF molecule.[291] MoO_3 appears to serve as a free radical initiator causing THF and O_2 to form α-hydroperoxytetrahydrofuran, which leads in acid to H_2O_2.[291]

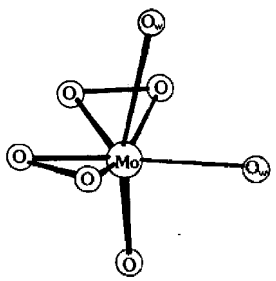

Figure 17 The structure of $MoO(O_2)_2(H_2O)_2$ (O_w is an oxygen atom from a water ligand)[290]

The structure of $MoO(O_2)_2(phen)$ is formally related to that of $MoO(O_2)_2(H_2O)_2$ by substitution of two water ligands by phen. Again the oxo ligand occupies one of the apical positions of the pentagonal bipyramid and the peroxo ligands occupy four of the five positions in the equatorial plane. The phen ligand spans the axial–equatorial edge. The structure of the yellow $MoO(O_2)_2(C_2O_4)^{2-}$ complex was recently redetermined[292] and is shown in Figure 18. It is representative in having a distorted pentagonal bipyramid around Mo with an oxo ligand in the apical position and the peroxo ligands and one O donor of the bidentate oxalate bound in the equatorial plane. The Mo—O stretch is identified at 970 cm^{-1} and ~865 cm^{-1} approximates the O—O stretching vibrational frequency.

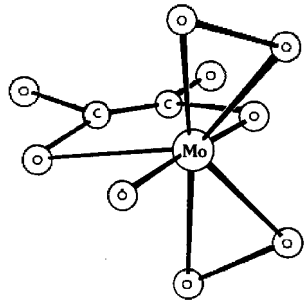

Figure 18 The structure of $MoO(O_2)_2(C_2O_4)^{2-}$ in its K^+ salt[292]

Interestingly, $MoO(O_2)_2(C_2O_4)^{2-}$ can be prepared from an aqueous solution of MoO_3 and H_2O_2 in which the only carbon source is malonate, $^-O_2CCH_2CO_2^-$ or malate, $^-O_2CCHOHCH_2CO_2^-$, but not succinate $^-O_2CCH_2CH_2CO_2^-$. The formation of the degraded two-carbon oxalate complex is proposed[292] to require a five- or six-membered ring chelated intermediate for the oxidation of the organic ligand to oxalate to occur. However, the isolation and structure determination of the apparently stable $MoO(O_2)_2(citrate)^{2-}$ complex[293] which has a five-membered chelate ring must be noted.

The structures of $MoO(O_2)_2(Pro)(H_2O)$[238] and $MoO(O_2)_2(Gly)(H_2O)$[238] also show the pentagonal bipyramidal geometry familiar to this class. The glycine is bound as a monodentate ligand through its carboxylate group in an equatorial position. The water ligand is found *trans* to the terminal oxo group. Although this is the first known amino acid peroxy molybdenum complex, its biological relevance is uncertain as Mo peroxy complexes are not known to play a biological role. The Mo—O_t stretch is found at 970–978 while the O—O stretch appears in the 870–880 cm^{-1} region in the IR spectrum for these complexes.

Despite the utility of the bidentate formulation of O_2^{2-} for descriptive purposes, structural systematics of peroxo complexes are nicely understood by considering the O_2^{2-} ligand as an isomorphous replacement for an oxo ligand. As discussed previously, if the four oxo groups in MoO_4^{2-} are replaced by properly oriented peroxo ligands, the $Mo(O_2)_4^{2-}$ structure quite nearly obtains. In the monooxo, monoperoxo complexes the *cis* arrangement of the oxo and peroxo ligands is reminiscent of the *cis* dioxo structure. Moreover, the orientation of the O—O bond allows it to be a π donor analogously to an oxo ligand. The analogy weakens somewhat for the oxo–diperoxo complexes. Although the oxo and peroxo groups are mutually *cis* as in MoO_3 complexes, there are only two additional coordination sites filled, making the structures analogous to five-coordinate trigonal bipyramidal rather than the more common six-coordinate octahedral MoO_3 core compounds.

The unusual complex $Mo(O_2)_2(ttp)$ (ttp = tetra-*p*-tolylporphyrin) has been synthesized and structurally characterized.[294] As shown in Figure 19, the peroxo ligands are bound side-on on opposite sides of the planar heme group. The two O—O vectors eclipse a perpendicular pair of *trans* N—Mo—N linkages. The O—O distance of 1.40 Å is marginally shorter than that found in the other peroxo complexes. This is perhaps not surprising insofar as the porphyrin may participate significantly in delocalizing the charge placed on Mo by donation from O_2^{2-} π levels. This delocalization allows further $O_2^{2-} \rightarrow$ Mo donation and concomitant slight lengthening of the O—O bonds. The diperoxo porphyrin complex is photochemically active,[295] ejecting an O_2 ligand upon irradiation with a tungsten lamp to produce the *cis* dioxo complex $MoO_2(ttp)$. Interestingly, $Mo(O_2)_2(ttp)$ is thermally stable and reacts neither with cyclohexene or triphenylphosphine.[295] This complex is, however, electrochemically reactive displaying one quasireversible one-electron oxidation and two quasireversible one-electron reduction waves.[296]

The oxidation may involve extensive porphyrin contribution as a dramatic optical spectroscopic change is observed, reminiscent of porphyrin cation radical formation. Further, the EPR spectrum of the oxidized complex, presumably $Mo(O_2)_2(ttp)^+$, generated *in situ*, is devoid of observable $^{95,97}Mo$ hyperfine splitting. In contrast, the first one-electron reduction leads to an EPR active species with $g = 1.980$ and $^{95,97}Mo$ splitting characteristic of Mo^V.[296] Interestingly, neither redox process involves the peroxo ligands, a point to be pondered in attempting to understand the lack of reactivity of the ligands in this complex compared to other peroxo Mo^{VI} complexes. The complex $MoO(O_2)ttp$ reveals once again the oxo/peroxo interchangeability in the Mo coordination sphere.[171]

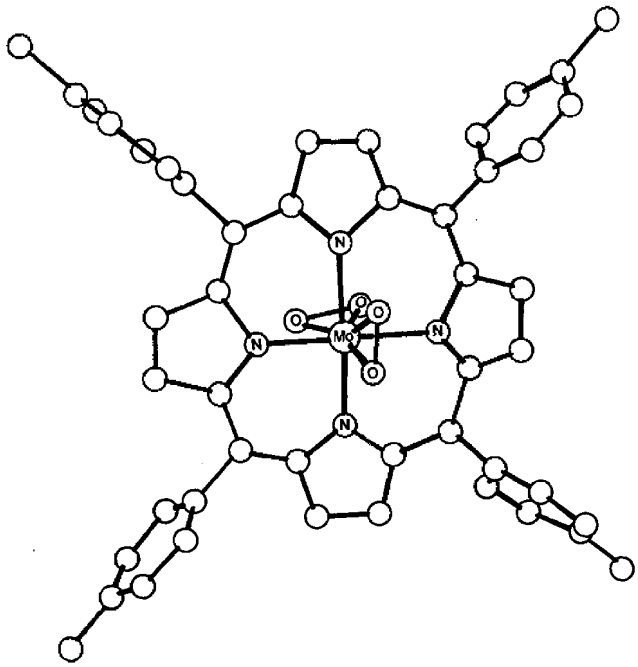

Figure 19 The structure of $Mo(O_2)_2(ttp)$ (unlabelled atoms are carbon)[294]

Structurally yet uncharacterized peroxo complexes include $MoO(O_2)(dtbc)_2$[297] ($dtbc^- = 3,5$-di-*tert*-butylcatecholato) prepared by reaction of $Mo_2O_2(dtbc)_2$ with $[NMe_4^+][O_2^-]$ and isolated as the $(Me_4N)_2[MoO(O_2)(dtbc)_2]\cdot 3DMSO$ salt. The reaction presumably involves disproportionation of O_2^- according to equation (28). The first step may involve O_2^- acting as a nucleophile followed by electron transfer from free O_2^- to bound O_2. $Mo_2O_2(dtbc)_2$ is known to be reactive to donor organic solvents.[297] The ν(Mo—O) at ~950 cm^{-1} is clearly distinguished from a band at ~870 cm^{-1} assigned to the ν(O—O) characteristic of side-on bound O_2^{2-}.

$$Mo_2O_2(dtbc)_2 + 4O_2^- \longrightarrow 2MoO(O_2)(dtbc)_2^{2-} + 2O_2 \qquad (28)$$

Many complexes written as $MoO_5\cdot L_2$ or MoO_5L' (L' = bidentate ligand) undoubtedly contain the $MoO(O_2)_2$ unit. For example, L may be Me_3NO, Bu^n_3PO, Pr^n_3AsO, Ph_3AsO, C_5H_5NO, *etc.*[298] The analytical data and the observation of ν(Mo—O) at 950–970 and ν(O—O) at ~850 cm^{-1} leave little doubt about the formulation of these complexes.[298] The complexes stoichiometrically epoxidize alkenes or catalyze alkene epoxidation by *t*-butylhydroperoxide.[298]

$MoO(O_2)(oxinate)_2$ can be formed[299] from $MoO_2(oxinate)_2$ by treatment with H_2O_2. The *cis* dioxo and *cis* oxo peroxo complexes are electrochemically distinct with the latter converting to the former irreversibly upon electrochemical reduction.[299]

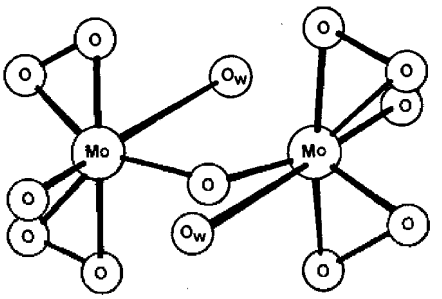
When O_2^{n-} is bound to a transition metal its formal oxidation state and that of the metal are ambiguous. In the compounds discussed above the Mo^{VI}–peroxide formulation is used. However, in the absence of structural data an Mo^{IV}–dioxygen or Mo^V–superoxide formulation is possible. The hypothetical reaction of Mo^{IV} and O_2 can be considered an oxidative addition, wherein the extent of charge transfer determines the proper formulation. In the complexes discussed here the O—O distance lies in the range 1.44 to 1.55 Å. Comparison of these

distances with 1.44 Å in H_2O_2 and 1.21 Å in O_2 indicates that the Mo^{VI} peroxide formulation is quite appropriate for these compounds. Only $MoO(O_2)[PhN(O)C(O)Ph]_2$ with O—O distance 1.212(5) Å seems to be an exception.[300] The intermediate 1.36(3) Å distance reported[301] for $(NH_4)_3[MoO(O_2)F_4]$ may be inaccurate.

The electronic structure of $Mo(O_2)_4^{2-}$ has been studied using SCF-MS-Xα molecular orbital calculations.[302] The Mo^{VI}–peroxide formulation is appropriate as a configurational starting point for discussion of the bonding. However, there is significant lengthening (weakening) of the O—O bond in the complex compared to that in free O_2^{2-}, a feature that may be responsible for the reactivity of peroxo–molybdenum complexes in epoxidation reactions. Moreover, the significant electrophilic character of the bound O_2^{2-} (in the form of low-lying virtual σ-antibonding orbitals) accords well with the proclivity of the peroxo–Mo^{VI} complex to attack and epoxidize electron-rich alkenes.

36.5.9.2 Dinuclear Peroxo Complexes

Dinuclear complexes have been structurally characterized with a single bridging oxo or fluoride ligand or with a set of two bridging hydroperoxo ligands. The dinuclear ion $(H_2O)(O_2)_2OMoOMoO(O_2)_2(H_2O)^{2-}$ in its pyH^+ [303,304] and K^+ salts[305] has a non-linear monooxo bridge (136 and 148°, respectively). The bridging oxo is found to be *cis* to the Mo—O_t group on each Mo. The peroxo ligands on each Mo are *cis* to the Mo—O_t bonds as in the mononuclear compounds. The structure as illustrated in Figure 20 has two-fold symmetry and contains two pentagonal bipyramids bridged through an oxygen atom shared by their equatorial planes. It is clearly related to the $MoO(O_2)_2(H_2O)_2$ structure shown in Figure 17.



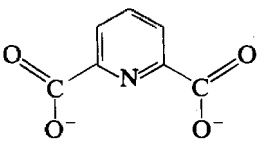


Figure 20 The structure of $(H_2O)(O_2)_2OMoOMoO(O_2)_2(H_2O)^{2-}$ in its K^+ salt (O_w is an oxygen atom from a water ligand)[305]

The unusual complex μ-F-$[MoO(O_2)(pydca)]_2^-$ (see **5**) is formed as the NEt_4^+ salt upon treatment of $Mo(O_2)(pydca)(OH_2)$ with F^- [418] in the presence of NEt_4^+. The complex, shown in Figure 21, is a centrosymmetric dinuclear ion with each Mo atom possessing pentagonal bipyramidal seven-coordination.[307] The linear $O_tMo^{VI}FMo^{VI}O_t$ unit is to date unique to this complex. The Mo—O_t distance is 1.659(3) Å and the Mo—F *trans* to it has the very long distance of 2.135(1) Å. The O—O distance of 1.43 Å is similar to that found in mononuclear peroxo compounds of Mo^{VI}.

(**5**) pydca

The structure of $(pyH)_2[(O_2)_2MoO(O_2H)_2MoO(O_2)_2]$ [304,308] shown in Figure 22 has two bridging hydroperoxo ligands. Each Mo coordination sphere is a heptacoordinate pentagonal bipyramid. Sharing of an axial–equatorial edge gives a centrosymmetric structure. The peroxo ligands occupy the remaining equatorial sites while the remaining axial position on each Mo contains a terminal oxo ligand. The Mo—O_b distance is 2.05 Å. The bridging and non-bridging peroxo groups both have distances near 1.47 Å consistent with their peroxide formulation.

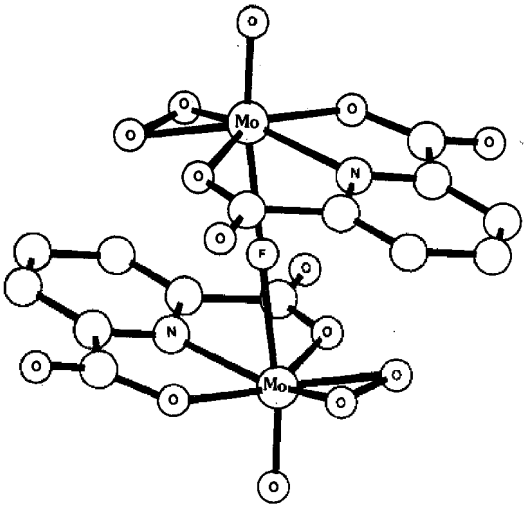

Figure 21 The structure of μ-F[MoO(O_2)(pydca)]$_2^-$ in its NEt_4^+ salt (unlabelled atoms are carbon)[418]

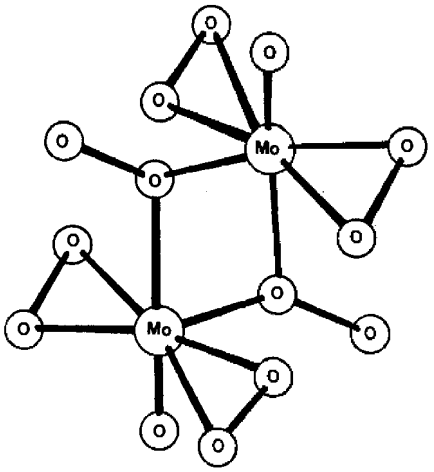

Figure 22 The structure of $(O_2)_2MoO(O_2H)_2MoO(O_2)^{2-}$ in its pyH^+ salt (terminal H atoms on bridging hydroperoxide are not shown)[304,308]

36.5.9.3 Spectral Indicators

Spectroscopically, in the IR region the O—O stretch can be identified between 845 and 895 cm^{-1}. ^{17}O NMR has proven useful insofar as the oxo and peroxo ligands are clearly distinguishable.[309] For example, in $MoO(O_2)(CN)_4^{2-}$ the peroxo signal (although broad) appears at 487 p.p.m., while the oxo signal appears at 705 p.p.m. downfield from H_2O. The latter value is well within the range found for oxo-molybdenum species.[105,310] The peroxo ^{17}O chemical shift in $MoO(O_2)_2$(HMPA) at ~450 p.p.m. with oxo at 850 p.p.m.[311] again illustrates that oxo and peroxo are readily distinguished. Further, in this latter example oxo and peroxo are shown not to exchange their ^{17}O labels. Thus, ^{17}O NMR could prove a powerful tool in elucidation of reaction pathways in oxo–peroxo complexes. Although oxo–peroxo exchange is indeed slow on the NMR time scale, it can occur at a significant rate.[312] Indeed, Mo^{VI} compounds are reported to catalyze the exchange of ^{18}O between H_2O and H_2O_2.[312]

36.5.9.4 Reactivity Toward Organic Molecules

Peroxomolybdenum complexes have been used stoichiometrically to effect a variety of organic conversions and catalytically, usually with *t*-butylhydroperoxide or H_2O_2, to effect

similar reactions.[313] The Mo^{VI} complexes have been anchored on polymers[137] and used under phase-transfer conditions.[314,315] Selective and asymmetric reactions have been reported.[272,316] We cannot even partially review this area which is part of a general thrust in reaction chemistry of early transition metal facilitated or catalyzed peroxidation/epoxidation/oxidation chemistry.[313,316,317] Reactions catalyzed or carried out include alkenes to epoxides,[156,215,318–322] sulfides to sulfoxides,[323] secondary alcohols to ketones,[316,324] aldehydes to carboxylic acids,[316] azo benzenes to azoxy benzenes,[325] N-heterocyclics to *N*-oxides,[326] amides to hydroxamates[154] and more complex reactions.[55,327–330] Theoretical studies offer potential mechanistic insights into reactivity of the Mo—O_2 group.[331]

There is no evidence that dioxygen or peroxides interact with Mo in enzymes in physiologically relevant processes. The evidence is strong that in Mo oxidases the dioxygen reagent interacts with the Fe—S, heme or flavin parts of the protein and not with the Mo site.[2,154] The reduced Mo states of enzymes, however, are susceptible to oxidation by O_2 *in vitro*.

36.5.10 HYDROXYLAMIDO(1−) AND HYDROXYLAMIDO(2−) COMPLEXES

Deprotonated substituted hydroxylamines have provided potent ligands to Mo^{VI}. The *N,N*-dialkyl hydroxylamine, R_2NOH, in its singly deprotonated form, R_2NO^-, *N,N*-dialkylhydroxamido(1−), serves as an N—O bound ligand with some similarity to peroxide. *N*-Alkylhydroxylamine, RNHOH, in its doubly deprotonated form, [RNO^{2-}, *N*-alkylhydroxamido(2−)] forms complexes quite analogous to those formed by peroxo or disulfido ligands. For example, the complex $MoO(R_2dtc)_2(ONR)$[338] is analogous to $MoO(R_2dtc)_2S_2$. The complex Mo(O)(pydca)(ONR)(HMPA)[338,339] whose structure is shown in Figure 23 has an exact analog in peroxo chemistry, $Mo(O)O_2$(pydca)(HMPA). The hydroxylamido complexes can be thought of as metallooxaziridines.[338,339] A systematic study of the one-electron reduction of $MoO(Et_2dtc)_2(ONR)$ complexes as a function of R and in comparison to $MoO_2(Et_2dtc)_2$ leads to the conclusion that the oxaziridine group is a better donor than the oxo group.[340]

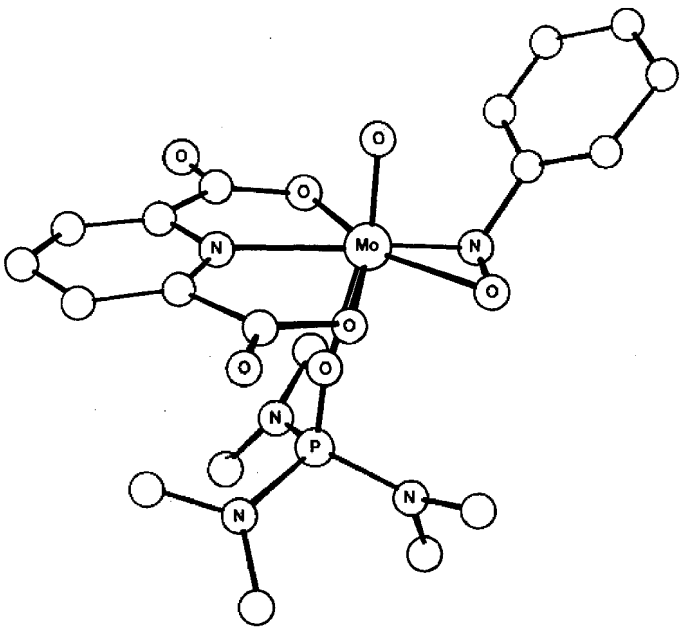

Figure 23 The structure of MoO(pydca)(ONR)(HMPA) (unlabelled atoms are carbon)[338]

The dioxo complexes containing two O,N-coordinated *N,N*-dialkylhydroxylamido(1−) ligands have been extensively studied.[86,87,89,90,191,244,341] They are prepared by the reactions of MoO_4^{2-} and *N,N*-dialkylhydroxylamine, usually in aqueous solution.

$MoO_2(C_5H_{10}NO)_2$ reacts in toluene with H_2S to give $MoOS(C_5H_{10}NO)_2$ and $MoS_2(C_5H_{10}NO)_2$.[342] With H_2Se only $MoOSe(C_5H_{10}NO)_2$ is formed. The structure of the dioxo, disulfido and oxo–sulfido complexes are known.[86,90,342,343] As discussed above, they can

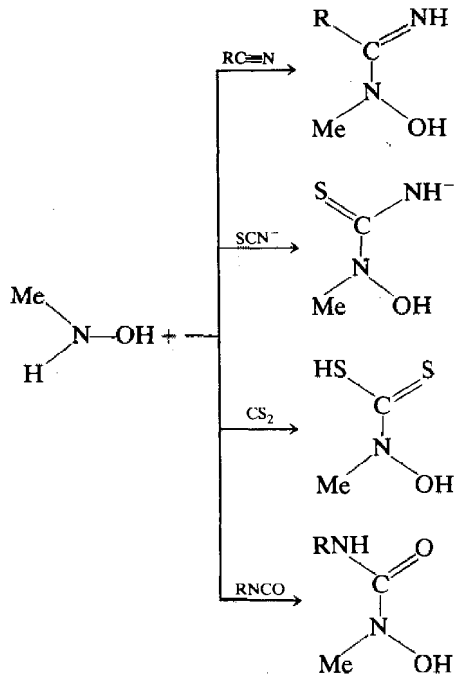
be viewed as distorted tetrahedral structures with each 'bidentate' hydroxylamido(1−) ligand occupying a single coordination site. The hydroxylamido(1−) complexes can therefore be considered as derived from MoO_4^{2-}. Alternatively, the structure shown in Figure 6 is describable in terms of non-octahedral six-coordination in which the N and O of the hydroxylamido(−1) ligand lie in a plane with O_t atoms equidisposed above and below the plane. It is related to the skew-trapezoidal six-coordination found in $MoO_2(SCMe_2CH_2NMe_2)_2$.[94,84] NMR studies of $MoO_2(R_2NO)_2$ and $MoS_2(R_2NO)_2$ reveal configurational lability attributed to rapid dissociation and reformation of the Mo—N bond.[341]

Spectroscopic characterization of the *cis*-$MoOS^{2+}$ unit in $MoOS(R_2NO)_2$ was used to discuss the occurrence of an $MoOS^{2+}$ center in oxidized xanthine oxidase.[343,191] Comparison of the voltammetric behavior of $MoXY(C_5H_{10}NO)_2$ (X = Y = S, O; X = S, Y = O) leads to the finding that the presence of the S atoms lowers the redox potential of the complex.[191] The great difference observed between the $MoOS(C_5H_{10}NO)_2$ and $MoO_2(C_5H_{10}NO)_2$ complexes (voltammetry differing in potential by 0.6 V)[191] contrasts with the tiny difference found between the proposed (inactive) MoO_2^{2+} and (active) $MoOS^{2+}$ forms of xanthine oxidase. This unusual behavior in the pseudotetrahedral complexes may be due to their significantly different electronic structure compared to that of the MoO_2^{2+} and $MoOS^{2+}$ cores found in xanthine oxidase.

The reaction of $MoO_2(R_2NO)_2$ with catechol derivatives yields complexes containing one oxo, two dialkylhydroxylamido(1−) and one catecholate ligand. The structure of $MoO(C_5H_5NO)_2(C_6H_4O_2)$[247] is reminiscent of that of the analogous peroxo complex. Here the hydroxylamido (piperidinolato) ligand binds side-on to the Mo in the equatorial plane of a seven-coordinate Mo structure. The catecholate ligand bridges axial and equatorial positions with Mo—O_t at 1.69 Å typical of monooxo MoO^{4+} core complexes. The N—O distance of 1.38–1.39 Å is shorter than that in $MoO_2(C_5H_5NO)_2$ (1.43–1.47 Å), perhaps indicating a greater π donation by the 1-piperidinolato(1−) group in this complex where it competes with only one oxo ligand. One remarkable feature of this structure is the virtual identity of Mo—O distances *cis* and *trans* to oxo in the same cathecholate ligand Mo—O(*cis*) = 2.016(5) and Mo—O(*trans*) = 2.012(5) Å. This complex also had its structure determined by 2D NMR techniques (^1H–^{13}C chemical shift correlations and ^1H–^1H scalar coupling correlations).[247]

Reaction of *N*-methylhydroxylamine and various unsaturated triatomic reactants yield chelating ligands that form yellow MoO_2L_2 complexes.[212] $MoO_2(MeHNO)_2$ reacts with the appropriate unsaturated molecule to yield complexes with five-membered chelate rings. For example, in equation (29) the resulting complex has the *cis* dioxo distorted octahedral structure.

$$MoO_2[MeHNO] + [Bu^t]NCO \longrightarrow MoO_2\left[\begin{array}{c} O \\ \diagdown \\ \quad N\!-\!Me \\ \diagup \\ \quad C \\ \diagdown \\ O \quad N \\ \quad\quad | \\ \quad\quad Bu^t \end{array}\right]_2 \qquad (29)$$



Scheme 5 shows the relationship of the starting hydroxylamido ligand to the final ligand.[341]

Complexes that contain remaining hydroxylamido as well as these bidentate chelates are also formed (Table 3). For example, $MoO(MeNHO)_2[HNC(S)N(Me)O]$ forms by reaction of MoO_4^{2-}, MeNHOH and SCN^- at 60 °C. Its structure, illustrating the two ligand types, is shown in Figure 24.[87]

36.4.11 COMPOUNDS WITH Mo—C BONDS

Molybdenum(VI) compounds containing Mo—C bonds are a recent addition to the literature. These compounds include both oxo and non-oxo species. The latter have an alkylidyne (alternatively formulated as an alkylcarbido) group which is a bonding equivalent to the oxo group.

Several unexpectedly stable series of Mo—C bonded compounds[344,72,345,346] have been reported. The compounds are of the form $MoO_2RBr(bipy)$ (purple), $MoO_2R_2(bipy)$ (yellow) and MoO_2R^- (in solution, colorless). R can be Me, CH_2Me_3 or CH_2Ph, which, by lacking β-hydrogen atoms, are unable to undergo β elimination. The compounds are prepared by reacting $MoO_2Br_2(bipy)$ with a Grignard reagent according to Scheme 6.

Scheme 5

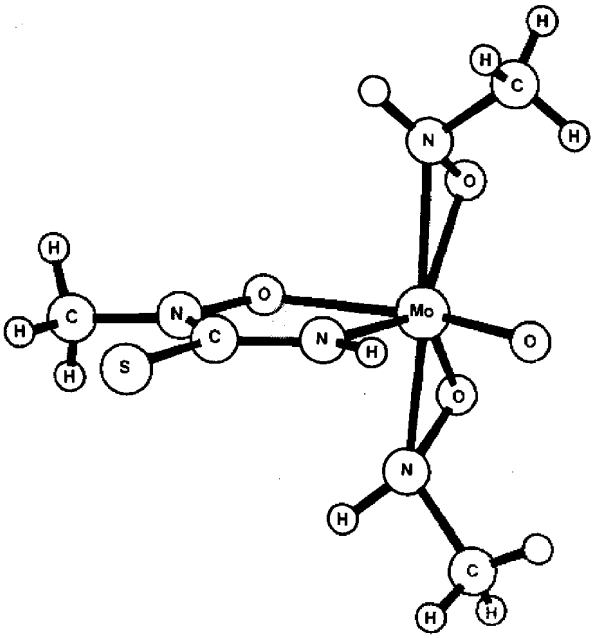


Figure 24 The structure of $MoO(MeNHO)_2[HNC(S)NMeO]$[87]

$$MoO_2Br_2(bipy) \longrightarrow RMoO_2Br(bipy) \longrightarrow MoO_2R_2(bipy) \xrightarrow{OH^-} RMoO_3^-$$

Scheme 6

The last complex, which has yet to be isolated as a salt, decomposes, albeit slowly ($t_{1/2}$ is 26.5 h at pH 11) in basic aqueous solutions at room temperature according to equation (30).

$$Me{-}MoO_3^- + OH^- \longrightarrow MoO_4^{2-} + CH_4 \qquad (30)$$

The dimethyl complex, $MoO_2(Me)_2(bipy)$, shows the expected *cis* dioxo structure[345] with the methyl groups *trans* to each other and bent back from the oxo groups (C—Mo—C = 149°). The Mo—C distance is 2.19 Å in the R = Me complex and 2.20 Å in the $R = CH_2Me_3$ complex.

MoO_2Me_2(bipy) shows ν(Mo—O_t) at 934 and 905 cm^{-1} in the IR and has UV bands at 303 nm (24 900); 293 nm (17 000); and 245 nm (19 600). The near UV band may be responsible for the complexes' photosensitivity.[346] In the NMR the Mo—Me protons resonate at 0.58 p.p.m. downfield from TMS.[345] The neopentyl analog $MoO_2(CH_2CMe_3)_2$(bipy),[346] whose structure is shown in Figure 25, has high thermal stability (to 182 °C in air) attributed to the absence of β-hydrogen atoms. Structurally, it is very similar to the Me derivative with deviations attributed to repulsions due to the bulky neopentyl groups. Thermolysis of the complex in the presence of abstractable hydrogen atoms from silicone oil leads to formation of neopentane, presumably from neopentyl radicals. Reaction with alkaline $Na^+BH_4^-$, Zn in HCl or 1-thioglycerol yields neopentane, quantitatively, through reductive cleavage of the Mo—C bond. In H_2SO_4 a mixture of dineopentyl and neopentane is formed.

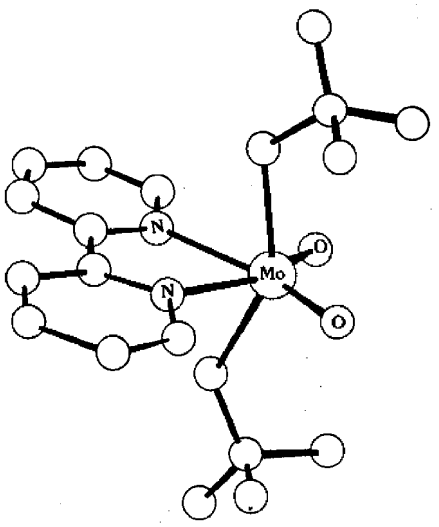

Figure 25 The structure of $MoO_2(CH_2CMe_3)_2$(bipy) (unlabelled atoms are carbon)[346]

Use has been made of Grignard reagents and organolithium reagents to prepare other alkyl Mo^{VI} complexes. For example, reaction of $MoO_2Cl_2 \cdot 2THF$ with (mesityl)MgBr (mesityl = 2,4,6-trimethylphenyl) gives the four-coordinate complex MoO_2(mesityl)$_2$.[159] This complex reacts with the ylide $Bu^n_3PCH_2$ to give Bu^n_3PO and (mesityl)MoO_2[C(mesityl)PBu^n_3] wherein a P-substituted carbene is bound to Mo.[347]

Reaction of $LiCH_2CMe_3$ with $MoCl_5$ gives the remarkable alkylidyne complex $(Me_3CCH_2)_3Mo(CCMe_3)$.[348] This complex can also be prepared from MoO_2Cl_2 and $(Me_3CCH_2)MgCl$ in ether.[353] Reaction of $Mo(CCMe_3)(CH_2CMe_3)_3$ with HX in DME (1,2-dimethoxyethane) gives $Mo(CCMe_3)X_3$DME (X = Cl, Br).[353] These complexes are all formally Mo^{VI} if the alkylidyne ligand is considered as RC^{3-}.

The Mo^{III} complex $Mo_2(OCMe_3)_6$ reacts with phenylacetylene in pentane to give the alkylidyne complex $Mo(CC_6H_5)(OCMe_3)_3$ in 60% yield.[354] In the presence of quinuclidine (quin) both $Mo(CC_6H_5)(OCMe_3)_3$(quin) and $Mo(CH)(OCMe_3)_3$(quin) have been identified. These reactions are remarkable as equation (31) formally involves the breaking of metal–metal and carbon–carbon triple bonds and the formation of a metal–organic triple bond.[354]

$$(Me_3CO)_3Mo{\equiv}Mo(OCMe_3) + C_6H_5CCH \longrightarrow (Me_3CO)_3MoCC_6H_5 \qquad (31)$$

The complex $Mo(CCMe_3)(OR)_3$ is formally Mo^{VI} having a substituted molybdate structure. Here the alkylidyne ligand, formally R_3CC^{3-}, obviously displays the powerful σ- and π-donor ability required to stabilize Mo^{VI}. The complexes $MoOCl(CH_2CMe_3)_3$ and $MoO(CH_2CMe_3)_4$ have been isolated[355] by reaction of $MoOCl_4$ with bis(neopentyl)magnesium dioxane along with the non-oxo $Mo(CCMe_3)(CH_2CMe_3)_3$ complex prepared previously.[130]

The organic reactivity of the alkylidyne complexes has been extensively studied especially with regard to alkene and alkyne metathesis reactions.[353,356]

36.5.12 DINUCLEAR COMPLEXES OF Mo^{VI}

In addition to the multitude of mononuclear and heteropolynuclear complexes that contain Mo^{VI} there are a significant number of dinuclear complexes. These include complexes in which the Mo atoms only coincidentally find themselves in the same ion such as $(MoO_3)_2edta^{4-}$ [61] (where the two Mo atoms are more than 4 Å apart) to ions such as $Mo_2O_5(C_2O_4)_2(H_2O)_2^{2-}$ (where the two Mo atoms are bridged by a single oxygen atom). In no case are Mo—Mo bonds present in the $4d^0$, Mo^{VI}, dinuclear complexes.

The dinuclear complexes are diverse in structure. They can have a single, double or triple bridge. The single bridge is almost always a lone oxo group. The double bridge contains either a single oxo plus a non-oxo ligand or, more commonly, two non-oxo ligands. Besides this variety in the nature of the bridge, the remaining three, four or five ligands on Mo can also be a diverse mixture of oxo and non-oxo groups. As many as three oxo groups in $Mo_2O_7^{2-}$ [197] to one oxo group as in $Mo_2O_2(3,5\text{-dtbcat})_4$[349] may be present in non-bridging positions. There are even examples of dinuclear, formally Mo^{VI} complexes, containing no oxo groups such as $Mo_2(O_2C_6Cl_4)_6$[357] (see below under non-oxo complexes).

The simplest dinuclear ion is the dimolybdate ion. Discrete $Mo_2O_7^{2-}$ ions exist in $K_2Mo_2O_7{\cdot}KBr$,[350] in molten $K_2Mo_2O_7$ above 520 °C[233] and in $MgMo_2O_7$,[351,358] the latter having a dichromate-like structure with an Mo—O—Mo bridging angle of 160.7(3)°. However, the $Mo_2O_7^{2-}$ stoichiometry does not guarantee the presence of discrete $Mo_2O_7^{2-}$ ions as, for example, crystalline $K_2Mo_2O_7$ and $(NH_4)_2Mo_2O_7$ consist of infinite chains of edge-shared octahedra.[359]

The discrete $Mo_2O_7^{2-}$ anion has been structurally characterized as its NBu_4^+ [361,352] and $[(C_5H_4Me)Mo(CO)_2(\mu\text{-dppm})Pt(dppm)]^+$ [360] salts. In the latter salt, $Mo_2O_7^{2-}$ shows Mo—O_t distances from 1.68–1.79 and Mo—O_b distances of 1.82 and 1.95 Å with the Mo—O—Mo angle equal to 160°. In the $(NBu_4)_2Mo_2O_7$ complex, the Mo—O—Mo angle is 153.6°. This complex is soluble and stable in organic solvents and serves as a starting material in various preparations. Its stability in non-aqueous media compared to higher polynuclear species is attributed to counterion effects. ^{17}O NMR studies show peaks at 741 and 248 p.p.m, down field from H_2O in the expected 6:1 ratio assigned to the terminal and bridging O atoms, respectively.[361,352]

Other dinuclear complexes having a single oxo group as the sole bridge contain $Mo_2O_3^{6+}$ or $Mo_2O_5^{2+}$ cores. Of these, the latter is by far the most common. Complexes of known structure containing the $Mo_2O_5^{2+}$ core with a single bridging oxo ligand are listed in Table 7. The Mo—O—Mo angle varies from 136 to 180°. For example, the structure of $Mo_2O_5L_2$ (where L = hydrotris(3,5-dimethyl-1-pyrazolylborate) contains an $Mo_2O_5^{2+}$ core with a singly bridging O atom and an Mo—O—Mo angle of 167.1°. The MoO_2^{2+} unit of each Mo atom in the dimer is, as shown in Table 7, quite similar to the same unit found in mononuclear complexes displayed in Table 1.

Table 7 Structural Data on Oxo-bridged $Mo_2O_5^{2+}$ Complexes

[a] The ligand is *N′,N″,N‴*-trimethyl-1,4,7-triazacyclononane.

In the salt $K_2[Mo_2O_5(C_2O_4)_2(H_2O)_2]$, the complex anion is crystallographically centrosymmetric.[384] As shown in Figure 26, the two terminal oxo ligands on each Mo are mutually *cis* and *cis* to the bridging oxo. One oxalate and one water ligand complete the six-coordination sphere of each Mo atom. The Mo—O_t distance of 1.69 Å is similar to those found in mononuclear *cis* dioxo complexes. The Mo—O_b distance is 1.88 Å. The long Mo—OH_2 distance (*trans* to Mo—O_t) of 2.33 Å illustrates the large structural *trans* effect of the O_t ligand. The two Mo—O distances to the oxalate ligand of 2.09 Å (*trans* to O_b) and 2.19 Å (*trans* to O_t) indicate that O_t has a larger *trans* bond-weakening effect than O_b. The largest O—Mo—O bond angles correspond to the shortest Mo—O bond distances in agreement with the idea that interligand or interbond repulsions determine the details of such coordination spheres. A centrosymmetric structure such as that in $Mo_2O_5(C_2O_4)_2(H_2O)_2^{2-}$ with an $Mo_2O_5^{2+}$ core is found in a number of complexes. In other cases, a structure closer to C_2 symmetry is found with the dioxo moieties on the two Mo atoms adopting a quasieclipsed conformation. In the complex $Mo_2O_5(phen)_2(NCS)_2$, the phenanthroline ligands are eclipsed,[211] i.e. stacked in almost parallel planes as shown in Figure 27.

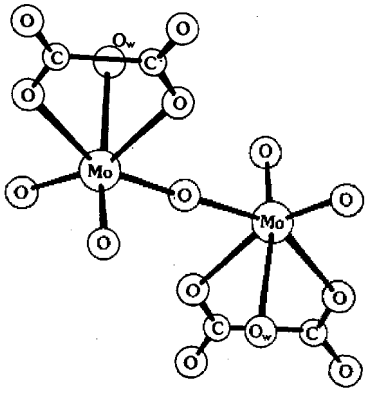

Figure 26 The structure of $Mo_2O_5(C_2O_4)_2(H_2O)_2^{2-}$ in its K^+ salt (O_w is an oxygen atom from a water ligand)[384]

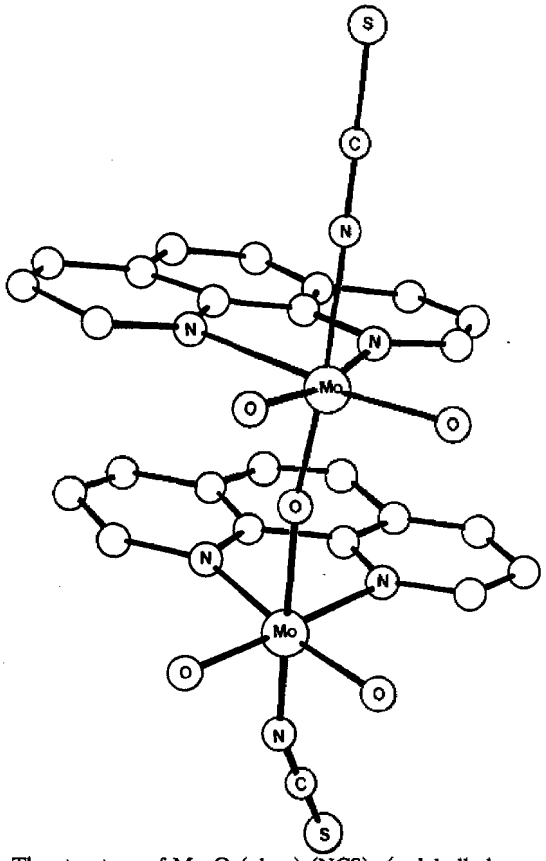

Figure 27 The structure of $Mo_2O_5(phen)_2(NCS)_2$ (unlabelled atoms are carbon)[211]

Complexes containing a triple bridge and an $Mo_2O_5^{2+}$ core are listed in Table 8. The prototypical complex $(NH_4)_2[Mo_2O_5(O_2C_6H_4)_2]\cdot 2H_2O$, shown in Figure 28,[362] has a triple bridge consisting of non-linear oxo and two oxygen atoms of different catecholate ligands. The structure can be considered as two shared distorted octahedra with the three bridging oxygen atoms at average distances of 1.92, 2.16 and 2.37 Å from each Mo. The catechol oxygen atoms do not bridge symmetrically as each catechol is chelated to a single Mo and bridges by one O atom to the second Mo. The two six-coordination spheres are completed by two terminal oxo groups and one non-bridging catechol oxygen on each Mo. The Mo—Mo distance is 3.13 Å as expected for this $4d^0$ system where no Mo—Mo bonding is possible. A similar triple bridge has been found in the complex $Mo_2O_5(PhenSQ)_2$ (where PhenSQ is the 9,10-phenanthrenequinone radical anion)[363] and in complexes containing mannitol,[364] dithiothreitol,[365] 2-mercatophenolato[366] and 4-xanthopterin.[274] The latter complex[274] shown in Figure 29 is the first example of Mo bound to a pterin ligand (as proposed for the molybdenum cofactor Moco). Interestingly, the pterin binds in a mode reminiscent of 8-hydroxyquinolinate ligands. However, the relevance of this binding mode to Moco is uncertain in view of the dinuclear nature of the complex, the proposed reduced nature of the pterin in Moco and the suggested sulfur binding by the Moco pterin.[5,274]

$[Na(DMSO)_2]_2[Mo_2O_5(xanthop)_2]$	1.691(7), 1.707(5)	146.2(3)	274

[a] The organic ligand is the ionized sugar, mannitolate. [b] *n*-pobb = 1-*n*-2α-hydroxybenzimidazole (deprotonated).

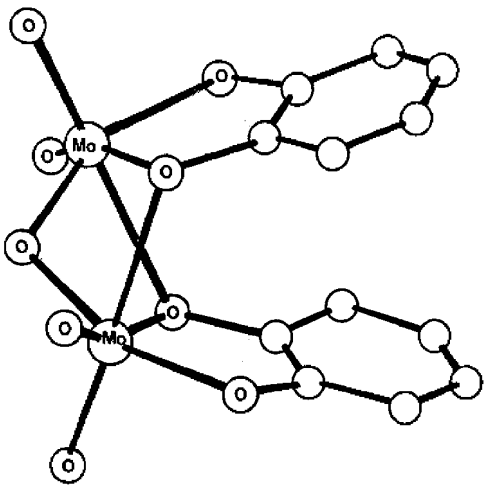

Figure 28 The structure of $Mo_2O_5(O_2C_6H_4)_2^{2-}$ in its NH_4^+ salt (unlabelled atoms are carbon)[362]

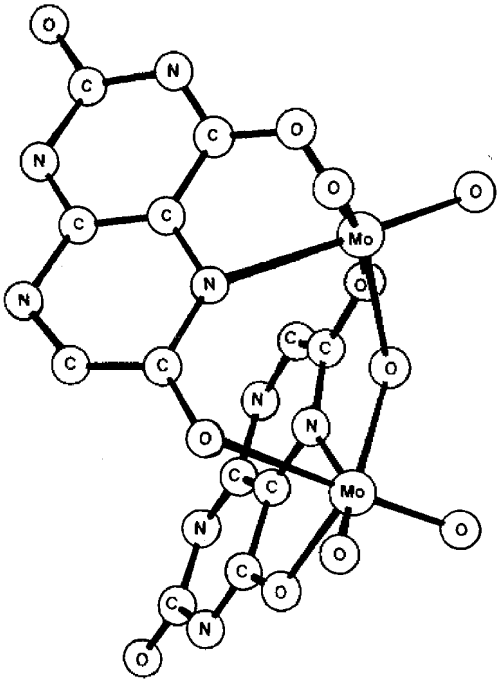

Figure 29 The structure of $Mo_2O_5(xanthopterinate)_2^{2-}$ as found in the salt $[Na(DMSO)_2]_2[Mo_2O_5(xanthopterinate)_2]$[274]

In certain $Mo_2O_5^{2+}$ complexes, the bridging ligand would appear to have a choice between an O and S bridge. In the case of the ligand $C_6H_4OS^{2-}$ (monothiocatecholate) the oxygen atoms of the ligand are the (non-oxo) bridging atoms.[367] Similarly, in $Mo_2O_5(dtt)^{2-}$ [365] again O rather than S bridging is found. In both cases this allows the S ligand to occupy a position *trans* to the bridging oxo rather than *trans* to the terminal oxo. This is the more favorable position for the strong π-donor S atom. This preference for not being *trans* to oxo may be the dominant factor in the adoption of the observed structure.

One interesting complex has a deprotonated 1-*n*-2α-hydroxybenzylbenzimidazole ligand whose O atom forms an additional bridge to an oxo.[368] The complex is unusual in having a double (rather than more common single or triple) bridge. Further, one of the Mo^{VI} atoms is five-coordinate while the other has the more conventional six-coordinate near-octahedral structure.[368]

A related tetranuclear complex having $Mo_2O_5^{2+}$-like units is formed between Mo^{VI} and malate, and has the formula $(NH_4)_2[(MoO_2)_4O_3(C_4H_3O_5)_2]\cdot H_2O$.[234]

Yellow complexes with the $Mo_2O_3^{4+}$ core are formed with substituted glycol ligands such as pinacol (pinH).[369] For example, the structure of $Mo_2O_3(pin)_2(Hpin)$ has a 162.2(9)° Mo—O—Mo bridging angle with intramolecular H bonding presumably helping to stabilize the complex.

There are a few examples in which only non-oxo bridges occur. In these cases alcoholate or phenolate type oxygen atoms form a double bridge. Some of the complexes have MoO_2^{2+} cores bridged doubly by alcoholate ligands. For example, as shown in Figure 30, $\{MoO_2[OCMe_2CMe_2OH]\}_2(-\mu\text{-}OMe)_2$ has a double methoxide bridge,[370] while $[Mo_2O_4(\mu\text{-}OCH_2CMe_2CH_2O)(H_2O)_2]$ has bridging oxygen from a chelating 2,2-dimethylpropanediolato ligand.[371] A related compound is $Mo_2I_2O_{16}^{6-}$, which can be thought of as containing MoO_2^{2+} groups bridged by IO_6^{5-} octahedra as represented in Figure 31.[372]

We have not dealt explicitly with preparative procedures for dinuclear complexes. These preparations have, in most cases, been fortuitous and no general protocol exists. Most preparations leading to dinuclear complexes did not seek them, whereas some efforts actually sought to avoid them!

One class of complexes, that of substituted catecholate ligands, has yielded a variety of mono- and di-nuclear Mo^{VI} complexes. $Mo(CO)_6$ reacts with the oxidized form of the 3,5-di-*tert*-butylcatechol (*i.e.* 3,5-di-*tert*-butyl-1,2-benzoquinone) to yield $Mo(dbcat)_3$ which reacts with O_2 to give the dinuclear complex $[MoO(dbcat)_2]_2$.[373] In contrast, reaction of $Mo(CO)_6$ with 3,4,5,6-tetrachloro-1,2-benzoquinone yields the dinuclear non-oxo complex $Mo_2(O_2C_6Cl)_6$.[357] The complex $Mo_2O_5(phenSQ)$ has already been discussed.[363] This complex

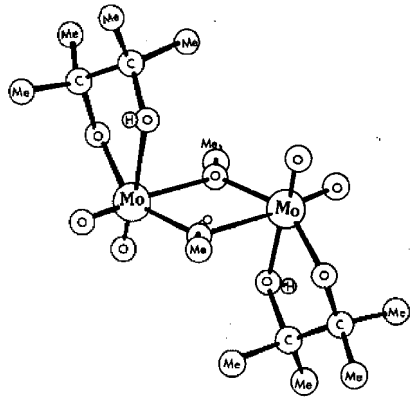

Figure 30 The structure of $\{MoO_2[OCMe_2CMe_2OH]\}(\mu\text{-}OMe)_2$[370]

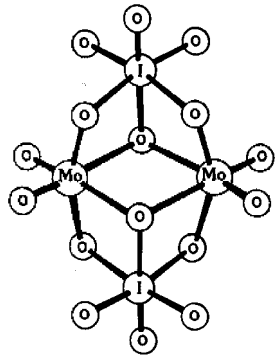

Figure 31 The structure of $Mo_2I_2O_{16}^{6-}$ as found in its K^+ salt[372]

differs by two electrons, *i.e.* is formally oxidized (neglecting the ligand difference) with regard to $Mo_2O_5(cat)^{2-}$ or $Mo_2O_5(dbcat)_2^{2-}$, each prepared from MoO_4^{2-} and the respective catechol. $Mo_2O_5(phenSQ)_2$ reacts by ligand substitution with 3,5-dbcatH_2 to give $Mo(dbcat)_3$. At least in this class of catecholate complexes, there seem to be some reactions that systematically interconnect the mononuclear and various dinuclear complexes.

Infrared and/or Raman spectroscopy are useful in identifying the core structures involved in dinuclear complexes. The Mo—O_t vibrations stand out as they do for mononuclear complexes and the Mo—O_b—Mo stretch can often be detected between 650 and 770 cm^{-1}. For example, in $Mo_2O_5[SCMe_2CCH_2NHCH_2CH_2NMe_2]_2$, ν(Mo—O_t) is found at 860 and 900 cm^{-1} while ν(Mo—O_b—Mo) occurs at 665 cm^{-1}. ^{17}O NMR spectroscopy on enriched samples is particularly informative. For example, in $Mo_2O_5[SCMe_2CCH_2NHCH_2CH_2NMe_2]_2$,[374] the ^{17}O resonance for Mo—O_t ligands occur at 873 and 857 while the bridging Mo—O_b—Mo resonance occurs at 366 p.p.m. downfield from H_2O. ^{95}Mo NMR spectra of dinuclear complexes are also observable[375] and, as more data become available, could also become a structurally useful technique.

In a number of studies spectroscopic techniques have led to the postulation of a dinuclear Mo^{VI} structure for complexes wherein crystallographic information is not yet available. For example, a fluoro-bridged structure has been assigned to $Mo_2O_2F_9^-$ by IR[377] and ^{19}F NMR[53] techniques. IR spectroscopy has been used to assign an $Mo_2O_5^{2+}$ structure with a single oxo bridge to $Cp_2Mo_2O_5$[367] (ν(Mo—O_t) = 920, 898 ν(Mo—O—Mo) = 770 cm^{-1}). Certain oxalate, citrate[378–380] and α-amino acid[381] complexes studied in solution (or isolated) are also indicated to be dinuclear.

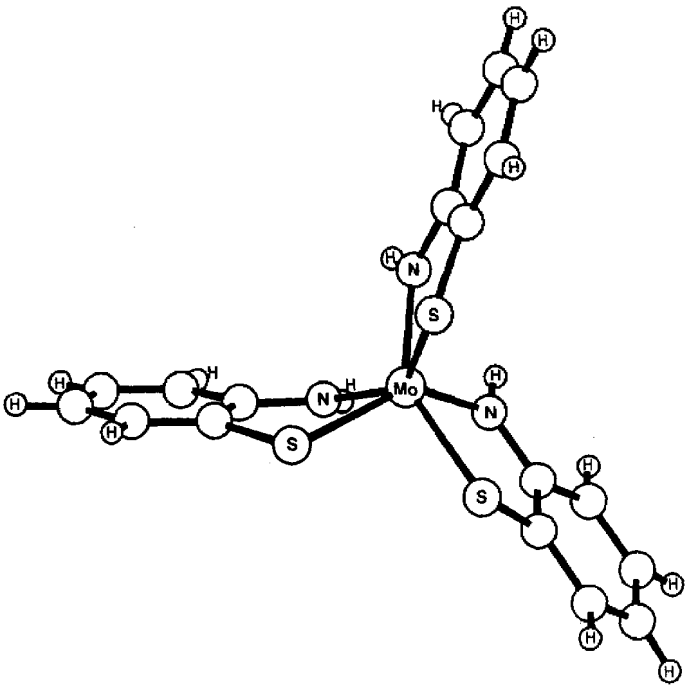
36.5.13 COMPLEXES LACKING OXO-TYPE LIGANDS

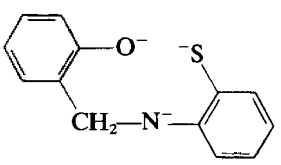
Although the oxo group and its analogs dominate the chemistry of Mo^{VI}, there are several examples of compounds that lack the oxo ligand or any of its analogs. Perhaps the best known of these is molybdenum hexafluoride. MoF_6, prepared by reaction of Mo metal and F_2, has a

regular octahedral structure. The volatile liquid (m.p. = 17.5, b.p. = 35 °C) is reactive toward addition, substitution and reduction. Lewis bases including F^-,[392] Cl^- [393] and Me_2O[392] form adducts with MoF_6[392] whose structures have not yet been determined. For example, K_2MoF_8 has been isolated[393] but not crystallographically characterized. Fluoride in MoF_6 can be substituted by F_5TeO^- or $CF_3CH_2O^-$ to form the series of complexes $MoF_n(OTeF_5)_{6-n}$[395] and $MoF_n(OCH_2CF_3)_{6-n}$ ($n = 1$–6),[394] respectively. As an oxidant, MoF_6 has a potential of +0.93 V *vs.* Cu/CuF_2(1.0 M NaF/HF) in HF[396] and +1.60 V *vs.* Ag^+/Ag^0 in MeCN[397] for the MoF_6/MoF_6^- couple as determined by cyclic voltammetry. MoF_6 is thus a strong oxidant and reacts with metals,[398] I_2,[397] NO[399] and many other molecules. For example, the explosively reactive amber $MoSF_4$ and $MoSeF_4$ molecules have been reported to be prepared from MoF_6 according to equation (32).[245] The vibrational spectrum of MoF_6 has been extensively studied[400] and exploited in laser isotope separation.[401] Although $MoCl_6$ has been briefly reported[402] its existence has not been confirmed and seems unlikely. $Mo(OMe)_6$ has been reported as a low-melting solid (m.p. = 67.6 °C).[403] The unusual complex $MoCl_4(NSNSN)$[404] can formally be considered to contain an Mo^{VI} core, which is consistent with a qualitative bonding scheme for the dithiatriazene ligand.[404]

$$3MoF_6 + Sb_2X_3 \longrightarrow 3MoXF_4 + 2SbF_3 \ (X = S, Se) \tag{32}$$

The remaining non-oxo complexes contain O-, N- or S-donor polydentate ligands. The tris(dithiolene) complexes are the oldest known members of this class. For example $Mo(tdt)_3$,[53,419] $Mo(bdt)_3$[405,419] and $Mo(S_2C_2H_2)_3$[406] are six-coordinate trigonal prismatic complexes whose structural, spectroscopic and redox properties have been thoroughly investigated and reviewed,[2,407–409] The amidothiolate ligand $C_6H_4SNH^{2-}$ = abt^{2-} forms an analogous nearly trigonal prismatic complex $Mo(abt)_3$ with the *cis* arrangement of the ligands illustrated in Figure 32.[121,410] $MoO_2(acac)_2$ reacts with thioaroylhydrazines, e.g. $NH_2NHC(S)Ph$, to give $Mo(HNNHCSPh)_3$ which has a somewhat distorted trigonal prismatic coordination[411] related to that of $Mo(abt)_3$.[410,412] A related complex containing three chemically distinct N,S chelates has been reported.[291] Interestingly, these S,S and N,S donor ligands react with oxo molybdenum starting materials to give non-oxo products. Significantly, the N donors are always found in a deprotonated state such that they can serve as π as well as σ donors to the Mo^{VI} ion.[411,412] The amidothiolate complexes are more difficult to reduce than are the corresponding dithiolene complexes. Complexes of catecholate ligands such as $Mo_2(O_2C_6Cl_4)_6$[357] and $Mo(phenQ)_3$[413] have dinuclear and distorted trigonal prismatic coordination, respectively. These complexes are prepared from $Mo(CO)_6$ and the oxidized (*o*-quinone) form of the catecholate ligand.[413–415]





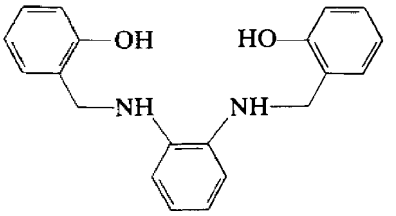


Figure 32 The structure of $Mo(abt)_3 = Mo(NHSC_6H_4)_3$ (unlabelled atoms are carbon)[410]

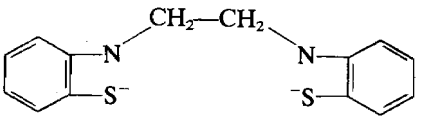

In addition to these complexes of bidentate ligands, several related tri- and tetra-dentate ligands are capable of removing all oxo groups from an Mo^{VI} coordination sphere. The tridentate ligand $hbma^{3-}$ forms $Mo(hbma)_2$ (**6**), a six-coordinate complex with a structure halfway between meridianal octahedral and trigonal prismatic geometries.[189] The related potentially tetradentate ligand H_2bpmp^{2-} (**7**) forms the yellow $MoO_2(H_2bpmp)$ complex[420] on reaction of the ligand with $MoO_2(acac)_2$. However, the brown complex $Mo(Hbpmp)_2 \cdot MeOH$ formed by a less reliable procedure[420] has an octahedral structure with a meridianal arrangement of two of the ligands acting in a tridentate fashion. Each ligand has one uncoordinated phenolic OH group.[420] Complexes of $en(abt)_2^-$ of the form $Mo_2[en(abt)_2]_3$ [see (**8**)] have also been reported.[412]

(**6**) $hbma^{3-}$

(**7**) H_4 bpmp

(**8**) $en(abt)_2$

The non-oxo Mo^{VI} complexes have in common the presence of good σ- and π- donor ligands. These serve the same purpose as the oxo group, namely the neutralization of high formal charge on Mo by strong donation.

Acknowledgement

I thank Professors Sharon J. N. Burgmayer, Karl Dehnicke, John H. Enemark, C. David Garner, Jean-Marie Manoli, Philip C. H. Mitchell, Achim Müller, Jon A. McCleverty, John W. McDonald, William E. Newton, Narayanan Kutty Pariyadath, Franklin A. Schultz, Dieter Sellman, Jack T. Spence, A. Geoffrey Sykes, Joseph L. Templeton, Richard A. Walton, Anthony G. Wedd, Karl Wieghardt and Jon Zubieta for providing me with results prior to publication. I thank Mary Reilly and Pat Deuel for outstanding word processing and Jeannette Stiefel for excellent proofreading of the manuscript.

36.6.1 MOLYBDENUM–SULFUR SPECIES AS LIGANDS

36.6.1.1 Introduction

The thiomolybdate(VI) anions $[MoO_nS_{4-n}]^{2-}$ ($n = 0$–3) have been prepared by a number of methods[1–3] and, with the exception of $[MoO_3S]^{2-}$, act as versatile ligands to a wide variety of metal ions[4] (see Table 1). In each of the compounds listed in this table, the $[MoO_nS_{4-n}]^{2-}$ ion acts as a bidentate ligand to the metal and the resultant structural versatility has been clearly demonstrated for copper(I) (Table 2). In addition, thiomolybdate(VI) anions are of interest since they have special relevance to aspects of bioinorganic chemistry. Thus, $[MoS_4]^{2-}$ has been widely used in the synthesis of Fe—Mo—S clusters, examples of which serve as spectroscopic analogues for the iron–molybdenum cofactor of the nitrogenases (see Section 36.6.2), and Cu—Mo—S aggregates, which are relevant to the copper deficiency induced by molybdenum in ruminant animals.

36.6.1.2 Synthesis and Properties of $[MoO_nS_{4-n}]^{2-}$ ($n = 0$–2) Complexes

A variety of divalent *d* transition metal cations (M = Fe,[5] Co,[21–23] Ni,[23,24,48] Pd and Pt,[25,26] or Zn[23,24,45]) react with thiomolybdate(VI) anions to form the corresponding bis{thiomolybdate(VI)} complex, which has usually been isolated as its quaternary ammonium or tetraphenylphosphonium salt. Copper(II) reacts with $[NH_4]_2[MoS_4]$ to form a polymeric copper(I) derivative $[NH_4]_n[CuMoS_4]_n$, the anion of which is composed of chains of edge-sharing CuS_4 and MoS_4 tetrahedra.[27] Such polymerization of Cu^I and $Mo^{VI}S_4$ is inhibited by a variety of ligands which bind to the copper. Discrete aggregates with up to four Cu^I atoms bound to a thiomolybdate(VI) anion have been characterized (Table 2). $[(PhSCu)MoS_4]^{2-}$ (type I) and $[(PhSCu)_2MoS_4]^{2-}$ (type II) have been prepared[28] by the action of KSPh on the corresponding cyanide complexes and X-ray crystallography has shown that coordination to the copper causes relatively little perturbation of the MoS_4 unit. Reaction of CuCl and $[MoS_4]^{2-}$ (3:1) in MeCN produces $[(ClCu)_3MoS_4]^{2-}$ (type III), which has a T-shaped structure.[36] $[MoS_4]^{2-}$ reacts with an excess (>4 moles) of CuX (X = Cl, Br) in acetone to form $[(XCu)_4MoS_4]^{2-}$ (type IV). The bromo complex is a one-dimensional polymer, in which four edges of the MoS_4 tetrahedron are bridged by copper atoms; two *trans* copper atoms have trigonal planar stereochemistry with a terminal bromine atom, while the other two coppers are

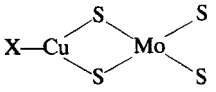
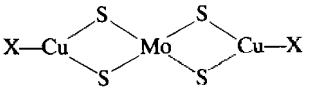
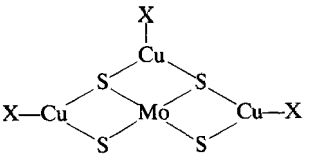
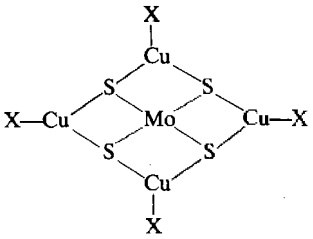
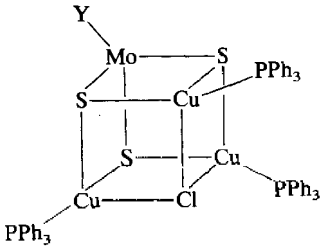
each tetrahedrally coordinated and are bonded to two bromines which are attached to the copper of an adjacent Cu_4MoS_4 unit.[40]

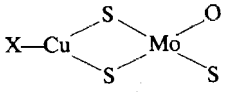


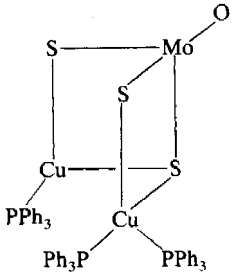


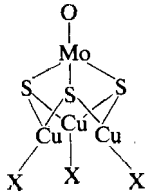


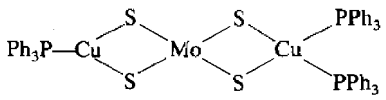












Compounds of the type $[\{Cu_3MoS_3Cl\}(PPh_3)_3Y]$ (type V) (Y = O, S), which contain a distorted Cu—S—Mo—Cl cubane-like cluster, have been prepared from the reaction between $[MoYS_3]^{2-}$, $CuCl_2$ and PPh_3 in CH_2Cl_2.[32,38,39] $[(ClCu)_3MoOS_3]^{2-}$ (type VIII) involves three copper atoms each bound across an S—S edge of the tetrahedral anion; the MoS_3Cu_3 core corresponds to a cubane-like framework with one position vacant.[34,37] Extraction of this complex with a solution of CuCN and PPh_3 in CH_2Cl_2 gives $[(Ph_3P)_3Cu_2MoOS_3]$ (type VII),[34] which can be considered to have a cubane-like framework with two vacancies. The analogous complex of $[MoS_4]^{2-}$, $[\{(Ph_3P)_2Cu\}(Ph_3PCu)MoS_4]$ (type IX),[32,33] and its silver analogue[41] possess a structure similar to $[(PhSCu)_2MoS_4]^{2-}$ (type II) but with one coinage metal in a trigonal planar and one in a tetrahedral environment, rather than two with a trigonal planar coordination geometry. $[\{(Ph_3P)_2Ag\}(Ph_3PAg)MoS_4]$ was obtained by reacting $[MoS_4]^{2-}$ with PPh_3 and $AgNO_3$ in CH_2Cl_2;[43] by adjusting the stoichiometry of the reaction $[\{Mo_2S_8Ag_4\}(PPh_3)_4]$ may be formed.[42,43] The central unit of this latter compound is a novel cage, arising from the fusion of two MoS_3Ag_2 rings. Gold(I) thiomolybdate(VI) derivatives have been prepared; $[(R_3PAu)_2MoYS_3]$ (Y = S, R = Et;[44] Y = O, S, R = Ph[41]) have been obtained by reacting $[MoYS_3]^{2-}$ and R_3PAuCl (1:2). $[(R_3PAu)_2MoOS_3]$ in CH_2Cl_2 reacts with $Cs_2[MoOS_3]$ to form $[\{(Ph_3P)_2Au\}(Ph_3PAu)MoOS_3]$,[41] which has a structure related to type VII of Table 1.

$[(Bipy)_2RuMoS_4]$ has been prepared by reacting $[MoS_4]^{2-}$ with $[(bipy)_2RuCl_2]$ (1:1) and this compound will bind a further ruthenium centre to form $[\{(bipy)_2Ru\}_2MoS_4]^{2+}$. Both complexes have been investigated as catalysts for C_2H_2 reduction and, in the presence of MeOH or other proton source, the electrochemically reduced species react to give C_2H_4 and C_2H_6.[20]

Thiomolybdate(VI) complexes of d^8 metal centres $[M'(MoYS_3)_2]^{2-}$ (M = Ni, Pd, Pt) have been prepared by the reaction of MCl_2 with $[MoYS_3]^{2-}$ (Y = O, S) (1:2) in H_2O/MeCN solution.[22–24,26,48] The 'mixed ligand' complexes $[(Et_2NCS_2)M'(MoS_4)]^{-}$ (M' = Ni, Pd) have been prepared by the reaction of $[MoS_4]^{2-}$ and $[M'(S_2CNEt_2)_2]$ (1:1) in acetone.[25] These systems involve a square planar geometry at the d^8 metal. $[Co(MoS_4)_2]^{3-}$, formally a Co^{I} complex, has been prepared by reacting $CoCl_2$, $[Et_3NH][SPh]$ and $[MoS_4]^{2-}$ in MeCN[21] and the magnetic properties of the complex are consistent with a tetrahedral environment about the cobalt.

Heating $[NH_4]_2[MoS_4]$ in DMF, alone or in the presence of benzenethiol, leads to the formation of $[Mo_3S_9]^{2-}$.[46] $[PPh_4]_2[MoO(MoS_4)_2]$ has been prepared by heating $[NH_4]_2[MoS_4]$ in

MeCN–EtOH in the presence of $Na[BH_4]$.[22] These anions involve a central $Mo^{IV}Y$ (Y = O, S) moiety coordinated by two bidentate $Mo^{VI}S_4$ groups and the central Mo^{IV} atom has a square pyramidal geometry. In the case of $[Mo_3S_9]^{2-}$ the central molybdenum is located 0.62 Å above the plane of the four thiomolybdate(VI) sulfurs; the shortest Mo—S bond (2.086(4) Å) is that of the Mo^{IV}—S group; within the $Mo^{VI}S_4$ groups, the terminal Mo—S bonds (Mo—S_t = 2.231(3)–2.251(3) Å) are significantly shorter than the bridging bonds (Mo—S_b = 2.369(3)–2.429(3) Å; S_b—Mo—S_b (104.1(1) and 103.0(1)°) are reduced from the value in $[MoS_4]^{2-}$; and the Mo · · · Mo separations are *ca.* 2.95 Å.[46] Several of these features, *viz.* the lengthening of the Mo—S_b bonds, the reduction in S_b—Mo—S_b below the tetrahedral value, and the close approach of the metal atoms, are general to the complexes formed by $[MoS_4]^{2-}$ and related anions. For the 3*d* transition metals (M = Fe, Co, Ni and Cu) the Mo · · · M separations are in the range 2.63–2.80 Å. Thus, the Mo · · · M separations in the thiomolybdate(VI) complexes are sufficiently close to be consistent with the formation of an Mo—M bond; this could arise by donation of a pair of electrons from a filled orbital on M into an empty orbital on Mo.

$[MoO_nS_{4-n}]^{2-}$ (n = 0–2) and their complexes have been extensively investigated by IR and Raman spectroscopy, especially in respect of their ν(Mo—O) and ν(Mo—S) stretching vibrations, which occur in the ranges 800–1000 and 400–500 cm^{-1}, respectively. The Mo—S stretching modes of $[MoS_4]^{2-}$ have been assigned;[4] the totally symmetric (a_1) stretching mode occurs at 458 cm^{-1} and the triply degenerate, asymmetric (t_2) stretching mode at 472 cm^{-1}. The symmetry of the MoS_4 group is lowered upon complex formation and, in general, the number of IR and Raman active vibrations observed is consistent with the symmetry of the aggregate.[24–26,50] Resonance Raman spectra have been recorded for thiomolybdate(VI) complexes,[50,51] with excitation using laser lines of energy within the contour of the lowest energy sulfur-to-metal charge-transfer transition. The totally symmetric ν(Mo—S) stretches are easily identified as giving rise to the most intense bands and, especially for $[MoS_4]^{2-}$ complexes of Cu^I, the pattern (*i.e.* the number of bands, their frequencies and relative intensities) observed in the ν(Mo—S) region is distinctive for the number of Cu^I atoms coordinated to $[MoS_4]^{2-}$.[50]

The UV/visible absorption spectra of $[MoO_nS_{4-n}]^{2-}$ (n = 0–2) complexes are dominated by the sulfur-to-metal charge transfer transitions of the anion and these bands often serve to characterize the particular system, even though these absorptions may be correlated with those of the parent anion.[4] The reduction in symmetry due to complex formation often leads to a broadening or splitting of the bands and, in the majority of the *d* transition metal complexes, the lowest energy band is red-shifted by an amount which is dependent both upon the nature of the transition metal and the number of such metals bound per $Mo^{VI}O_nS_{4-n}$ group.

^{95}Mo NMR spectra have been reported for Cu^I, Ag^I and Au^I complexes of the $[MoO_nS_{4-n}]^{2-}$ (n = 0–2) ions.[28,29,32,41,49] The resonance position is characteristic of the complex and, as is seen clearly for the Cu^I systems, the chemical shift (from $[MoO_4]^{2-}$) decreases regularly (by *ca.* 500 p.p.m.) for each CuX unit bound to the thiomolybdate(VI) core.

Cyclic voltammetric investigation[4,26,52,53] of $[M(MoO_nS_{4-n})_2]^{2-}$ (M = Ni, n = 0–2; M = Pd, Pt, n = 0) complexes has shown that each can be reduced reversibly in a one-electron process and a further one-electron reduction is possible for some of the complexes. The first reduction is primarily centred on the d^8 metal but the second reduction is not so easily described, since the nature of it shows a sensitivity to both the nature of M and the thiomolybdate(VI) anion.[26] The electrochemical behaviour of $[Co(MoS_4)_2]^{3-}$ has also been investigated and two reversible processes, assigned to the 2−/3− and 3−/4− couples, have been observed.[21]

36.6.1.3 Other Mo—S Species as Ligands

The molecular fragment *cis*-$Mo(SBu^t)_2$ is capable of acting as a bidentate ligand; reaction of $[Mo(SBu^t)_4]$ or *cis*-$[Mo(SBu^t)_2(CNBu^t)_4]$ with $[CuBr(CNBu^t)_3]$ in acetone under dinitrogen produces $[(Bu^tNC)_4Mo(\mu\text{-}SBu^t)_2CuBr]$. Two isomers, differing in the relative arrangements of the *t*-butyl substituents on the thiolato bridges, have been crystallized and structurally characterized and their interconversion in solution demonstrated by ^{1}H NMR spectroscopy.[54] Similarly, $[Mo(SBu^t)_4]$ reacts with $[Fe_2(CO)_9]$ in toluene to give $[MoFe_2(SBu^t)_4(CO)_8]$ as the main product. Two carbonyls have been transferred to the molybdenum in the reaction and the resultant coordination about this metal corresponds to that of a distorted trigonal prism. The ^{1}H NMR spectrum shows two Bu^tS signals at room temperature which coalesce upon warming.[55] *cis*-$[Mo(SBu^t)_2(CNR)_4]$ (R = cyclohexyl, *t*-butyl) reacts with FeX_2 (X = Cl, Br) to

give $[(RNC)_4Mo(\mu\text{-}SBu^t)_2FeX_2]$, and the related system $[Cp_2Mo(\mu\text{-}SBu^t)_2FeCl_2]$ involves an Mo · · · Fe separation of 3.660(3) Å.[56]

cis-$[MoS_2(pipNO)_2]$ (pipNO = piperidine-*N*-oxide) reacts with CuCl to form the chloride-bridged dimer $[\{(pipNO)_2MoS_2CuCl\}_2]$ (Figure 1). Coordination to the copper atom lengthens the Mo—S from 2.145(2) Å, in the parent Mo^{VI} complex, to 2.179(4) Å; concomitantly the S—Mo—S interbond angle is reduced from 115.0(1) to 110.3(1)°. The Cu · · · Mo separations are 2.639(1) Å.[57] All of these structural features are typical of the coordination of $[MoS_4]^{2-}$ molybdenum-sulfur centres as bidentate ligands to Cu^I and other metals.

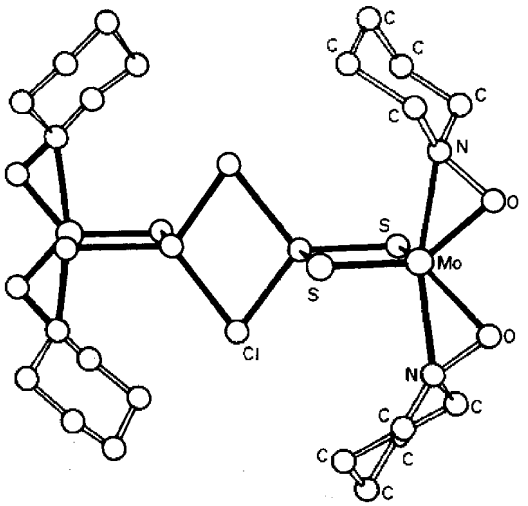

Figure 1 Structure of $[\{\text{piperidine } N\text{-oxide}(1-)\}_2MoS_2CuCl\}_2]$[57]

36.6.2 IRON–MOLYBDENUM–SULFUR CLUSTERS

Interest in the chemistry of Fe—Mo—S clusters has been stimulated by the discovery that the iron–molybdenum cofactor (FeMoco) of the nitrogenase enzymes is an aggregate of these elements, organized in a manner yet unidentified. The nitrogenases catalyze the reduction of dinitrogen to ammonia in nitrogen-fixing organisms. The enzyme complex consists of two types of protein, the Fe protein and the FeMo protein, and activity requires both proteins, ATP, a divalent cation (preferably Mg^{2+}) and a reductant. The Fe protein, which involves an Fe_4S_4-cubane-like cluster, acts as an electron transfer agent to the more complex FeMo protein which contains the catalytic site for substrate reduction.[58] There are two molybdenum atoms per FeMo protein molecule and each is involved with one FeMoco; these entities may be extracted from the protein,[59,60] have been shown to be common to molybdenum-containing nitrogenases of various organisms, and can activate extracts of the FeMo protein component of inactive mutant strains of different microorganisms.[61] In the organism *Klebsiella pneumoniae*, a cluster of 17 genes in seven transcriptional units has been associated with nitrogen fixation. One class of mutants, the *nif* V^- mutants, has altered substrate specificity and the enzyme from these mutants is relatively ineffective at dinitrogen reduction. This altered substrate specificity has been shown to be associated with FeMoco,[62] directly implicating this entity as part of the catalytically active site of the nitrogenases. The elemental composition of FeMoco has been estimated by a variety of analytical and spectroscopic procedures, leading to ranges of values for iron and sulfur per molybdenum of $MoFe_{6-8}S_{4-9}$.[59,60,63] There is no evidence for the presence of any organic entity associated with FeMoco, other than solvents[64] such as *N*-methylformamide (NMF) used in its abstraction.[59]

FeMoco, both as a constituent of the FeMo protein and an isolated entity, has been the subject of detailed spectroscopic examination.[65] ^{57}Fe Mössbauer and EPR studies of the cofactor have been interpreted in terms of an $S = \frac{3}{2}$ centre that contains one molybdenum and *ca.* six irons in a spin-coupled structure. The EPR signal serves as a valuable fingerprint of FeMoco; furthermore, release of FeMoco from the FeMo protein produces an EPR spectrum with broader features, but the same profile, thereby indicating that the core of this cluster is little changed by the extraction procedure. Treatment of FeMoco with *ca.* one equivalent of

benzenethiol sharpens the EPR spectrum so that it more closely resembles that of the MoFe protein.[66,67] In the FeMo protein, FeMoco is capable of existing in at least three distinct levels of oxidation. The $S = \frac{3}{2}$ level is oxidized by the removal of one electron per molybdenum to an EPR-silent species and, during steady-state turnover, the cofactor is converted into an EPR-silent, super-reduced state.[60] The oxidized state can be reproduced by oxidation of FeMoco in NMF solution by methylene blue.[67]

The most definitive structural information concerning the molybdenum site in FeMoco and the FeMo protein has been provided by X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy.[68–70] The profile of the molybdenum *K*-absorption-edge indicates the absence of terminal oxo groups and the position of this edge suggests an oxidation state of *ca.* +IV. Interpretation of the EXAFS has shown that, in the MoFe protein, the molybdenum possesses a first coordination sphere of three to four sulfur atoms 2.36 Å away, with a shell of two to three iron atoms at a distance of 2.68 Å; these structural features remain essentially unchanged for FeMoco in NMF, but there is evidence for an additional shell of two to three oxygen (or nitrogen) atoms at 2.10 Å. These latter atoms could originate from the solvent and IR spectroscopic studies of solutions of FeMoco in NMF have identified an intense band at 1600 cm^{-1}, which has been assigned to the C=O stretching of N-bonded, deprotonated solvent.[64]

The lack of precision in the structural definition of FeMoco has allowed much scope for the synthesis of possible chemical analogues and, thereby, stimulated the preparation and structural and spectroscopic characterization of Fe—Mo—S clusters.[71,72] The majority of these synthetic approaches employ $[MoS_4]^{2-}$ as a reagent and they can be classified in two main categories: (a) ligand exchange reactions between $Fe(L)_n$ complexes and $[MoS_4]^{2-}$ to give complexes containing tetrathiomolybdate(VI) anions acting as ligands[71] and (b) 'spontaneous self-assembly' reactions between $[MoS_4]^{2-}$ and $FeCl_3$, in the presence of a thiol, which yield Fe_3MoS_4 cubane-like clusters in dimeric species which, by subsequent manipulations, have been converted into monomeric species.[72]

Examples of complexes formed between iron and tetrathiomolybdate(VI) anions are given in Table 1,[5–19] and aspects of the vibrational and electronic spectra associated with their molybdenum centres are discussed in Section 36.6.1.2. Magnetic moments and ^{57}Fe Mössbauer spectra of $[S_2MoS_2FeS_2MoS_2]^{3-}$,[73] $[X_2FeS_2MoS_2]^{2-}$ (X = Ph, Cl, SPh, OPh; $X_2 = S_5$)[7,8,11,14] and $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$ [16,17,74] have been recorded and interpreted in terms of Fe^{II} centres which are spin coupled to the $\{MoS_4\}^{2-}$ groups, with some transfer of electron density from the former to the latter. $[NEt_4]_2[(PhS)_2FeS_2FeS_2MoS_2]$ has a ^{57}Fe Mössbauer spectrum consistent with an Fe^{III} ($S = \frac{3}{2}$) centre antiferromagnetically coupled to a formally $\{Fe^{II}S_2Mo^{VI}S_2\}$ ($S = 2$) unit to give an $S = \frac{1}{2}$ ground state.[19] The ^{57}Fe isomer shift in $[S_2MoS_2FeS_2MoS_2]^{3-}$ is smaller than that expected for an oxidation state of I or II for the iron, suggesting extensive Fe→Mo charge transfer; the EPR spectrum indicates an $S = \frac{3}{2}$ ground state, similar to that of FeMoco.[5,73] Electrochemical studies on $[X_2FeS_2MoS_2]^{2-}$ complexes (X = SPh,[7] OPh[14]) show an irreversible reduction at −1.34 V or −1.51 V *vs.* SCE for the thiophenolate and phenolate complexes, respectively. The $[(PhS)_2FeS_2FeS_2MoS_2]^{3-}$ ion displays an irreversible oxidation at 0.05 V and an irreversible reduction at −1.1 V *vs.* SCE.[19] The irreversible electrochemical reduction of $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$ occurs at −0.56 V *vs.* SCE, with loss of a chloride to form $[MoS_4Fe_2Cl_3]^{2-}$, which may exist as a dimer in solution.[16] Mo *K*-edge EXAFS spectra have been recorded for the binuclear complexes $[X_2FeS_2MoS_2]^{2-}$ (X = Cl, SPh, OPh) and the trinuclear complexes $[(4\text{-}Me_3C_6H_4S)_2FeS_2FeS_2MoS_2]^{3-}$, $[S_2MoS_2FeS_2MoS_2]^{3-}$ and $[Cl_2FeS_2MoS_2Cl_2]^{2-}$.[75,76] The Mo—S and Mo—Fe distances determined agree with the X-ray crystallographic data to better than 0.5%. Comparisons of the Fourier transforms of the EXAFS spectra with that of the MoFe protein of nitrogenase show them to be significantly different, and suggest a first coordination sphere around molybdenum in the enzyme that is not simply tetrahedral.

Despite the undoubted chemical interest of the complexes involving $[MoS_4]^{2-}$ ligated to iron, the second category of Fe—Mo—S clusters, involving Fe_3MoS_4 cubane-like cores, appear to have more relevance to FeMoco. Reactions between $FeCl_3$, $[MoS_4]^{2-}$ and an excess of a thiolate anion in methanol solution yield several products based on cubane-like clusters containing one molybdenum and three iron atoms in a tetrahedral arrangement, with each face bridged by a μ_3-sulfide ligand.[72] By varying the stoichiometry, reaction times and cations present in solution, three different types of product have been isolated from this system: $[Fe_6Mo_2S_8(SR)_9]^{3-}$, $[Fe_6Mo_2S_8(SR)_6(OMe)_3]^{3-}$ and $[Fe_7Mo_2S_8(SR)_{12}]^{3-}$ (Figure 2). Each of these anions contains two $\{(RSFe)_3(\mu_3\text{-}S)_4Mo\}$ clusters with each molybdenum atom bonded to

three atoms of a bridging system. The anions $[Fe_6Mo_2S_8(SR)_9]^{3-}$ (R = Et, Ph, 4-ClC_6H_4, 4-MeC_6H_4) and $[Fe_6Mo_2S_8(SPh)_6(OMe)_3]^{3-}$ contain three bridging $(SR)^-$ or $(OMe)^-$ ligands, which have been shown by ^1H NMR spectroscopy not to interchange with the terminal ligands in solution.[77,78] $[Me_3NCH_2Ph]_3[Fe_7Mo_2S_8(SEt)_{12}]$,[79] and the related (reduced) anion of $[NBu^n_4]_4[Fe_7Mo_2S_8(SCH_2Ph)_{12}]$,[78] involve a $(\mu\text{-S})_3Fe(\mu\text{-S})_3$ bridging arrangement containing a central Fe^{III}, or Fe^{II}, atom, respectively.

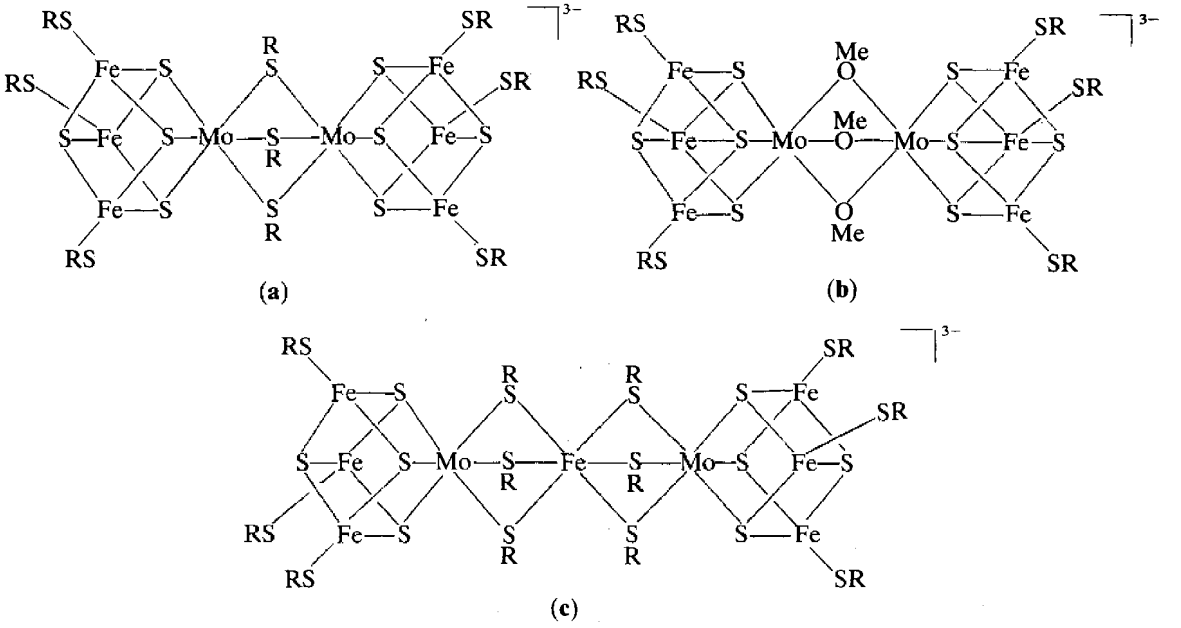

Figure 2 Structure of some dimeric assemblies of Fe_3MoS_4 cubane-like clusters;[72] (a) $[Fe_6Mo_2S_8(SR)_9]^{3-}$; (b) $[Fe_6Mo_2S_8(SR)_6(OMe)_3]^{3-}$; (c) $[Fe_7Mo_2S_8(SR)_{12}]^{3-}$

The bridging system in $[Fe_7Mo_2S_8(SEt)_{12}]^{3-}$ can be broken by reaction with catechol, $catH_2$, which yields $[Fe_4MoS_4(SEt)_3(cat)_3]^{3-}$ (Figure 3). The crystal structure of its $[NEt_4]^+$ salt shows this anion to consist of a single $\{(EtSFe)_3MoS_4\}$ cluster, with the molybdenum coordinated *via* three Mo—O—Fe bridges to an $Fe(cat)_3$ group acting as a tridentate ligand.[80] The reaction between $[NEt_4]_3[Fe_7Mo_2S_8(SEt)_{12}]$ and 3,6-dipropylcatechol, Pr_2catH_2, yields $[NEt_4]_4[Fe_6Mo_2S_8(SEt)_6(Pr_2cat)_2]$. This anion contains two $\{Fe_3MoS_4\}$ cubane-like clusters with each molybdenum chelated by a $(Pr_2cat)^{2-}$ ligand; two of the iron atoms in each cube are coordinated to one terminal ethanethiolate, and the third iron atom is bridged to the molybdenum atom of the other cube by a bridging ethanethiolate group. Similar products have been obtained with 3,6-diallylcatecholate, $(al_2cat)^{2-}$ (Figure 4) and tetrachlorocatecholate, $(Cl_4cat)^{2-}$, ligands.[81,82]

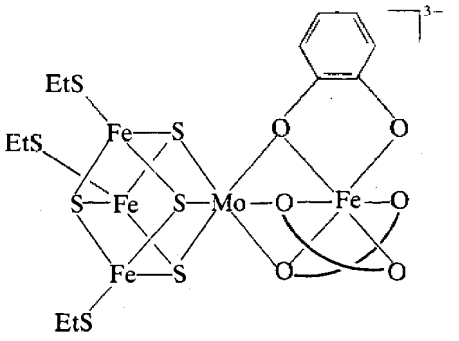

Figure 3 Structure of $[Fe_4MoS_4(SEt)_3(cat)_3]^{3-}$ [80]

Ligand exchange reactions between $[Fe_6Mo_2S_8(SEt)_9]^{3-}$ or $[Fe_7Mo_2S_8(SEt)_{12}]^{3-}$ anions and thiols, acetyl chloride, benzoyl chloride, benzoyl bromide or phenol have shown that the

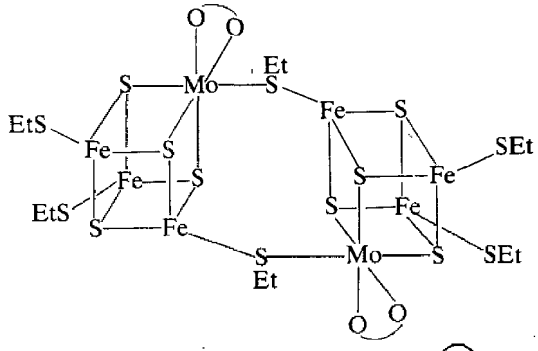

Figure 4 Structure of $[Fe_6Mo_2S_8(SEt)_6(3,6\text{-diallylcatecholate})_2]$ (O O = 3,6-diallylcatecholate)[81]

terminal thiolate ligands are labile and easily replaced by other thiolate groups, halides, or phenolates; the bridging ligands are inert to substitution.[83–85] However, the reaction between arenethiols (RSH) and $[Fe_6Mo_2S_8(SEt)_6(R'_2cat)_2]^{4-}$ (see Figure 4) yields $[Fe_6Mo_2S_8(SR)_6(R'_2cat)_2]^{4-}$ (R = Ph, 4-MeC_6H_4, 4-ClC_6H_4; R' = Pr, allyl) in which both bridging thiolates have been substituted as well as the terminal ligands. In coordinating solvents, including DMSO, DMF, THF and MeCN, $[Fe_6Mo_2S_8(SR)_6(R'_2cat)_2]^{4-}$ double cubane aggregates are cleaved to give the single Fe_3MoS_4 cubane-like cluster solvates $[Fe_3MoS_4(SR)_3(R'_2cat)(solvent)]^{2-}$ (see Figure 5). These systems possess specific reactivities at both the molybdenum and the iron sites.[81,82,86,87] Thus, the solvent molecule is readily replaced by a variety of ligands (RS^- (Figure 5), N_3^-, CN^-, RO^- and PR_3) and catecholate exchange can be effected at the molybdenum site. Normal thiolate exchange at the iron sites occurs and using acetyl chloride results in chloride for thiolate substitution. Reaction of the product $[Fe_3MoS_4Cl_3(cat)(solvent)]^{2-}$ with CN^- produces $[Fe_3MoS_4(CN)_4(cat)]^{3-}$, in which this substrate of nitrogenase is bound at each iron and molybdenum atom.

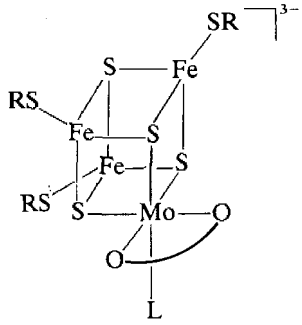

Figure 5 Structure of $[Fe_3MoS_4(SC_6H_4Cl\text{-}4)_4(3,6\text{-diallylcatecholate})]^{3-}$ (R = 4-ClC_6H_4; L = 4-ClC_6H_4S; (O O = 3,6-diallylcatecholate)[86]

A novel double Fe_3MoS_4 cubane-like complex bridged by two persulfide groups has been prepared *via* an intermediate carbonyl cluster. Displacement of the chlorides from $[Cl_2FeS_2MoS_2]^{2-}$ by $[(CO)_6Fe_2S_2]^{2-}$ yields $[(CO)_6Fe_2S_2FeS_2MoS_2]^{2-}$; this reacts with (4-$ClC_6H_4S)_2$ to give $[Fe_6Mo_2S_8(S_2)_2(SC_6H_4Cl\text{-}4)_6]^{2-}$, in which the two persulfides form a bridge between the molybdenum atoms of two $\{Fe_3MoS_4\}$ units. This type of cluster can also be prepared in a self-assembly reaction from $[MoS_4]^{2-}$, $FeCl_3$, a thiolate and Na_2S_2 in methanol.[88]

The electronic structure of compounds containing the single and double Fe_3MoS_4 cubane-like clusters has been investigated by ^{57}Fe Mössbauer, EPR and NMR spectroscopy, and by magnetic moment measurements.[72,89–92] These results have shown that each $\{Fe_3MoS_4\}^{3+}$ framework is electronically delocalized and the coupling of electron spins produces an $S = \frac{3}{2}$ ground state. The EPR spectra of these single cubane systems show little dependence on the nature of the ligands bound to molybdenum and, of particular significance, closely resemble the EPR spectrum characteristic of FeMoco with the same magnetic ground state. Furthermore, none of these spectra manifest molybdenum hyperfine coupling. In the triply bridged double cubanes $[Fe_6Mo_2S_8(SR)_9]^{3-}$, the two $\{Fe_3MoS_4\}^{3+}$ sub-clusters are only weakly coupled, but in the doubly bridged anions $[Fe_6Mo_2S_8(SR)_6(R'_2cat)_2]^{4-}$ there is strong spin coupling between the cubanes to give an $S = 0$ ground state. The ^{57}Fe Mössbauer isomer shifts of compounds

possessing one or two $\{Fe_3MoS_4\}^{3+}$ clusters compare closely with those for the $S = \frac{3}{2}$ state of FeMoco.

Electrochemical studies have shown that each $\{Fe_3MoS_4\}^{3+}$ cubane-like cluster exhibits a reversible one-electron reduction and oxidation process, giving rise, for example, in the dimeric species $[Fe_6Mo_2S_8(SR)_9]^{3-}$ to 1−/2−, 2−/3−, 3−/4− and 4−/5− couples.[72,85,86,89,91,93,94] ^{57}Fe Mössbauer isomer shifts indicate that the redox changes occur primarily at the iron centres.[91] Chemical reduction using sodium acenaphthylenide generates the reduced complexes in solution, and the doubly reduced complex $[Fe_6Mo_2S_8(SPh)_9]^{5-}$ has been crystallized as its $[NEt_4]^+$ salt. This anion retains the double cubane structure of its parent, but with an increased Mo—Mo separation.[94] The reduced clusters react with PhSH to produce dihydrogen, and can catalyze electrochemical reduction reactions, including the conversion of ethyne to ethene and reduction of dinitrogen to ammonia.[95–101]

Crystal structure determinations of the single and double cubane complexes have shown that the internal dimensions of the $\{Fe_3MoS_4\}$ clusters are independent of the nature of the other ligands present and, with Mo—Fe distances of 2.72 ± 0.01 Å and Mo—S bond lengths of 2.35 ± 0.01 Å, closely resemble the environment suggested for molybdenum in FeMoco on the basis of molybdenum *K*-edge EXAFS measurements. The molybdenum *K*-edge EXAFS of $[NBu_4]_3[Fe_6Mo_2S_8(SEt)_9]$, $[NEt_4]_3[Fe_6Mo_2S_9(SEt)_8]$ and $[NEt_3(CH_2Ph)]_3[Fe_6Mo_2S_8(SEt)_3(OPh)_6]$ agree well with crystallographic results, showing back-scattering from both a shell of sulfur atoms and a further shell of iron atoms. The molybdenum XANES of nitrogenases are similar to those of Fe_3MoS_4 cubane-like clusters possessing an MoS_3O_3 coordination.[70] However, unlike FeMoco, the iron *K*-edge EXAFS spectra of Fe_3MoS_4 clusters show no net back-scattering from the molybdenum and iron atoms due to destructive interference of the Fe–Fe and Fe–Mo waves.[102] Therefore, the Fe_3MoS_4 cubane-like clusters are deficient in this respect as models of FeMoco. A more fundamental objection is that their composition is not encompassed by the range of Fe:Mo:S values suggested for FeMoco.

Other approaches to the synthesis of Fe—Mo—S clusters have been made, especially using metal carbonyls as starting materials. The reaction between $[RMo(CO)_2]_2$ (R = Cp, MeCp) and $[FeS(CO)_3]_2$ yields two isomeric iron–molybdenum–sulfur clusters with different $\{Fe_2Mo_2S_2\}$ skeletons, but both products can be formulated as $[R_2Mo_2Fe_2(\mu_3\text{-}S)_2(\mu\text{-}CO)_2(CO)_6]$.[103,104] The major isomer (80%) has the expected butterfly arrangement, with the two molybdenum atoms in the hinge positions and a butterfly angle of 104°; each sulfide bridges an $\{Mo_2Fe\}$ face and two carbonyls bridge different Mo—Fe bonds; the Mo—Mo distance in the Cp product is 2.846(5) Å, and the average Mo—Fe distance is 2.817(56) Å.[103] The minor isomer (20%) is a centrosymmetric cluster (Figure 6) with a planar $\{Fe_2Mo_2\}$ skeleton, with the two (μ_3-S) groups bridging different $\{Mo_2Fe\}$ triangles above and below the plane; in the MeCp complex the Mo—Mo distance is 2.282(1) Å, indicating considerable metal–metal interaction; the average Mo—Fe distance is 2.791(11) Å.[104] $[R_2Mo_2S_2(SH)_2]$ reacts with $[Fe(CO)_5]$ in the presence of Me_3NO, or with $[Fe_2(CO)_9]$ to yield $[R_2Mo_2Fe_2(\mu_3\text{-}S)_2(\mu\text{-}S)_2(CO)_6]$, the structure of which (Figure 7) is related to that in Figure 6, by replacing the two μ-CO groups by μ-S^{2-} ligands.[105]

$[MoOCl_3(THF)_2]$ reacts with $[Fe_2(CO)_6S_2]^{2-}$ to give $[MoOFe_5S_6(CO)_{12}]^{2-}$, in which the central $\{MoO\}$ unit is bonded to two $\{Fe(CO)_3\}$ groups by two μ_3-sulfides, forming an $\{MoFe_2\}$ triangle, and to a tetrahedral $\{FeS_4\}$ group *via* two μ_2-sulfides; the other sulfides of the $\{FeS_4\}$ form μ_3-bridges to two $\{Fe(CO)_3\}$ groups.[106]

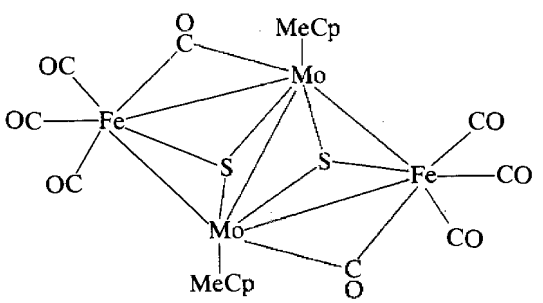

Figure 6 Structure of $[(MeCp)_2Mo_2Fe_2(\mu_3\text{-}S)_2(\mu\text{-}CO)_2(CO)_6]$[104]

The interaction of $[(Cp')_2Mo_2S_4]$ ($Cp' = C_5Me_5$) with $[Fe(NO)(CO)_3]^+$ yields $[(Cp')_2Mo_2Fe_2S_4(NO)_2]$ which, on the basis of spectroscopic evidence, is considered to have a

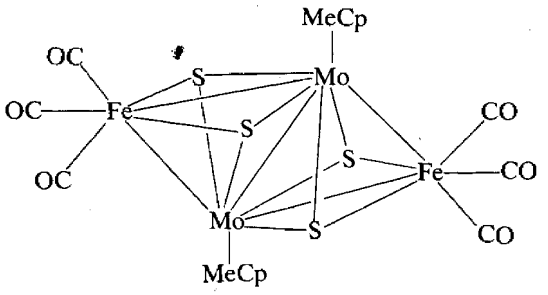

Figure 7 Structure of $[(MeCp)_2Mo_2Fe_2(\mu_3\text{-}S)_2(\mu\text{-}S)_2(CO)_6]$[105]

cubane-like $\{Mo_2Fe_2S_4\}$ core. This reaction demonstrates how attack of a metal–metal bond by an electrophilic metal species can be used to build up larger clusters.[107] $[(Cp')_2Mo_2S_4]$ reacts with $[Fe_2(CO)_9]$ in THF to form $[(Cp')_2MoS_4Fe(CO)_2]$, $[(Cp')_2Mo_2S_2(S_2CO)Fe(CO)_2]$ and $[(Cp')_2Mo_2S_4\{Fe(CO)_2\}_2]$, the structures of which have been confirmed by X-ray crystallography, the last compound having an $Mo_2Fe_2S_4$ cubane-like core. $[(MeC_5H_4)_2Mo_2Fe_2(CO)_6S_4]$ has also been reported.[108]

The addition of $\{Mo(CO)_3\}$ fragments to iron carbonyl anions has also been used to synthesize iron–molybdenum–sulfur compounds. Thus, the reaction between $[Mo(CO)_3(MeCN)_3]$ and $[Fe_6S_6X_6]^{3-}$ (X = Cl, 4-OC_6H_4Me) yields $[Fe_6S_6X_6\{Mo(CO)_3\}_2]^{n-}$ ($n = 3, 4$). A crystal structure determination accomplished for $[NEt_4]_4[Fe_6S_6Cl_6\{Mo(CO)_3\}_2]$ (Figure 8) has shown that the molybdenum atoms cap the top and bottom of the $\{Fe_6S_6Cl_6\}$ 'prismane' cluster. Derivatives containing such $\{Fe_6MoS_6\}$ and $\{Fe_7MoS_6\}$ units have been suggested as models for the Fe—Mo—S centre in nitrogenase but have not yet been synthesized.[109]

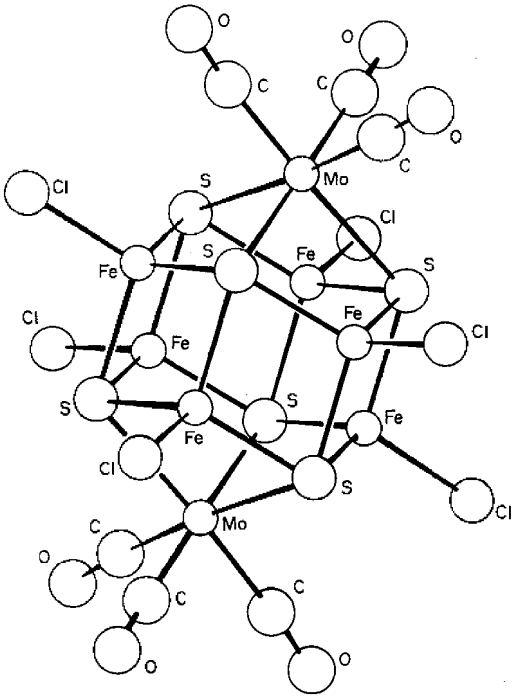

Figure 8 Structure of $[Fe_6S_6Cl_6\{Mo(CO)_3\}_2]^{4-}$ [108]

Several complexes have been prepared containing tetrahedral iron atoms coordinated to two molybdenums through two pairs of μ_2-sulfido ligands. $[NH_4]_2[MoS_4]$ reacts with $Na_2(SCH_2CH_2S)$ and $FeCl_3$; this mixture, on addition of $[NMe_4]Br$, yields $[NMe_4]_3[FeS_4\{MoS(SCH_2CH_2S)\}_2]$, the anions of which involve molybdenum atoms with a distorted square pyramidal geometry, and axial Mo—S ligands.[110] The catalytic activity of this and related complexes in the hydrogenation reaction of ethyne has been investigated.[111]

36.6.3 MOLYBDENUM CHALCOGENIDES

The principal ore of molybdenum is molybdenite, MoS_2, which occurs as fine crystals embedded in quartz. Molybdenum deposits exist in many parts of the world, but few are sufficiently rich to warrant the extensive processing required for commercial exploitation. The two most important molybdenum mines are at Climax and Henderson in Colorado, USA and the alternative source of molybdenum is as a by-product of copper mining. MoS_2 exists as an S—Mo—S · · · S—Mo—S layer lattice, in which each molybdenum atom is surrounded by a trigonal prism of six sulfur atoms. MoS_2 is of considerable commercial importance as a lubricant, catalyst precursor and support, precursor of intercalation superconductors, and as an electrode for photoelectrolysis. Therefore, the physical properties of MoS_2 and its derivatives have been extensively examined.[113] $MoSe_2$ and the low temperature form of $MoTe_2$ adopt the same structure as MoS_2, but in the high temperature form of $MoTe_2$ each molybdenum atom is located in an octahedral arrangement of tellurium atoms and is involved in two close Mo—Mo approaches.[114] The amorphous trichalcogenides, MoS_3 and $MoSe_3$, have interesting electrochemical and other physical properties;[115] molybdenum and selenium EXAFS studies have led to the proposal that an important structural unit of these systems is a binuclear metal site (Mo—Mo *ca.* 2.75 Å) with a triple bridge consisting of one Y^{2-} and one Y_2^{2-} (Y = S, Se) ion.[116]

Mo—Mo and Y—Y bonding and their interrelationships are a dominant feature of the chemistry of discrete molybdenum chalcogenide entities.[117–119] The clearest demonstration of this interrelationship is the *oxidation* of $[MoS_4]^{2-}$ by organic disulfides to form $[Mo_2S_8]^{2-}$, thereby achieving *reduction* of molybdenum (from Mo^{VI} to Mo^{V}), production of persulfide ions and the formation of an Mo—Mo bond.[120] Many other examples of oligomeric molybdenum systems bound to persulfide ligands exist;[118,119] two important examples are $[Mo_2(S_2)_6]^{2-}$ (Figure 9)[121] and $[Mo_3S(S_2)_6]^{2-}$ (Figure 10),[122] both as interesting systems in their own right and as synthetic precursors. Another important aspect of Mo—S chemistry is the demonstration that $[NEt_4]_2[MoS_4]$ reacts with either elemental sulfur or organic trisulfides (RSSSR) in MeCN to produce $[NEt_4]_2[MoS_9]$. This anion involves an $\{MoS\}^{2+}$ (Mo—S = 2.128(1) Å) core coordinated by two tetrasulfide ligands (Mo—S = 2.36(3) Å) to give a square pyramidal geometry at the metal. Heating an MeCN solution of $[MoS_9]^{2-}$ in air produces the $[MoO(S_4)_2]^{2-}$ analogue.[123] Oxomolybdenum centres ligated by groups containing one or more S—S bonds have been identified in many other systems, including: $[MoOS_2(S_2CNPr_2)_2]$,[124] $[Mo_2(S_2O)_2(S_2CNEt_2)_4]$,[125] $[Mo_2S_4(S_2)(S_3O)]^{2-}$ [126] and $[Mo_2O_nS_{4-n}(S_2)_{2-x}(S_4)_x]^{2-}$ ($n = 2$, $x = 0, 1$; $n = 1$, $x = 1$).[127] Anions of this last type, with $n = 0$ and $x = 0, 1, 2$ have been shown to participate in a complicated series of equilibria which arise in reactions of $[MoS_4]^{2-}$ with elemental sulfur, organic trisulfides or $[NH_4]_2S_x$, and thiols; these equilibria involve monomeric and dimeric molybdenum sulfide complexes and the equilibrium position depends upon several factors, including the nature of the solvent and the counterions.[128,129] One product of these reactions $[(S_4)Mo(S)(\mu\text{-}S)_2Mo(S)(S_4)]^{2-}$ (Figure 11) is an isomer of $[Mo_2(S_2)_6]^{2-}$ (Figure 9) with a remarkably different arrangement of sulfur atoms. Complexes involving S_3^{2-} and S_5^{2-} ions ligated to molybdenum have also been characterized.[118]

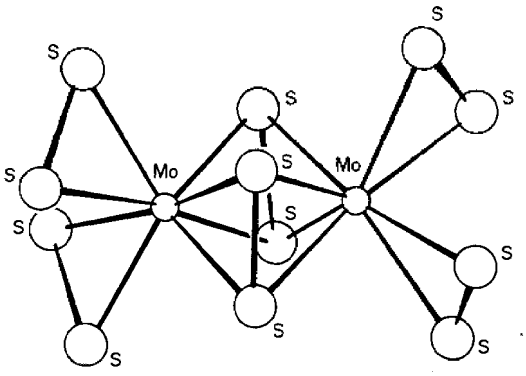

Figure 9 Structure of $[Mo_2(S_2)_6]^{2-}$ [121]

Molybdenum complexes of polysulfide ligands are reactive and, for example, readily make and break sulfur–carbon bonds, a property undoubtedly relevant to the involvement of Mo—S

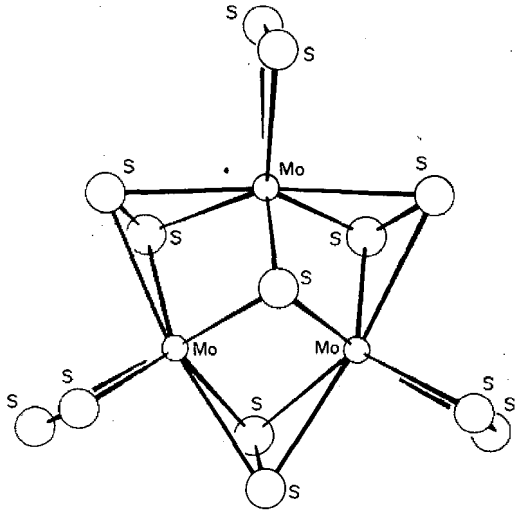

Figure 10 Structure of $[Mo_3S(S_2)_6]^{2-}$ [122]

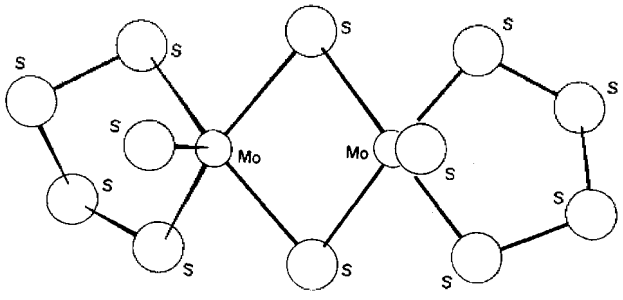

Figure 11 Structure of $[(S_4)Mo(S)(\mu\text{-}S)_2Mo(S)(S_4)]^{2-}$ [129]

centres in hydrodesulfurization catalysis. Addition of CS_2 to $[PPh_4]_2[MoS_9]$ and $[PPh_4]_2[(S_4)Mo(S)(\mu\text{-}S)_2Mo(S)(S_2)]$ produces $[PPh_4]_2[(CS_4)_2MoS]$ and $[PPh_4]_2[(CS_4)Mo(S)(\mu\text{-}S)_2Mo(S)(CS_4)]$, respectively, both products containing the perthiocarbonate ligand bound as an S,S chelate. The former anion contains an $\{MoS\}^{2+}$ core coordinated by two nearly planar $\{CS_4\}^{2-}$ ligands in a *trans* configuration; the latter anion consists of a *syn*-$\{Mo_2S_4\}^{2+}$ core with two $\{CS_4\}^{2-}$ ligands coordinated to the molybdenum atoms in a *cis* configuration.[130] 2-Butyne dimethanoate, $MeO_2CC{\equiv}CCO_2Me$, reacts with $[MoS_9]^{2-}$ to form, as one of the products, $[Mo\{S_2C_2(CO_2Me)_2\}_3]^{2-}$, a trigonal prismatic complex with three dithiolene ligands.[131] Similarly, $MeO_2CC{\equiv}CCO_2Me$ reacts with $[(S)_4Mo(S)(\mu\text{-}S)_2Mo(S)(S_4)]^{2-}$ or $[(CS_4)Mo(S)(\mu\text{-}S)_2Mo(S)(CS_4)]^{2-}$ to form $[Mo_2S_4\{S_2C_2(CO_2Me)_2\}_2]^{2-}$ and with $[MoO(S_4)_2]^{2-}$ to form $[MoO\{S_2C_2(CO_2Me)_2\}_2]^{2-}$. Reaction of $[(S_4)Mo(O)(\mu\text{-}S)_2Mo(O)(S_2)]^{2-}$ with $MeO_2C{\equiv}CCO_2Me$ results in the formation of the dithiolene complex $[Mo_2O_2S_2\{S_2C_2(CO_2Me)_2\}_2]^{2-}$, which is an isomer, in respect of the C—S framework, of the vinyl disulfide complex (Figure 12) obtained by reacting $[(S_2)Mo(O)(\mu\text{-}S)_2MoO(S_2)]^{2-}$ with

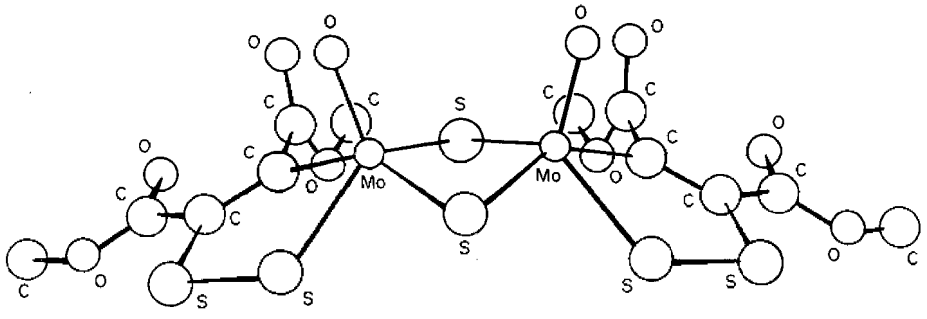

Figure 12 Structure of the bis(vinyl disulfide) complex $[Mo_2O_2S_2\{S_2C_2(CO_2Me)_2\}_2]^{2-}$ [133]

$MeO_2CC{\equiv}CCO_2Me$. Further important reactivities of Mo—S—C systems have been demonstrated by Rakowski DuBois *et al.*, for dimeric Mo—S complexes involving each metal ligated by a cyclopentadienyl ligand (Section 36.6.5).

36.6.4 NITROSYL AND CYANIDE MOLYBDENUM–SULFUR COMPLEXES

The structural chemistry of these systems is interesting and a considerable versatility exists, especially in respect of the nature of the Mo—S framework to which nitrosyl or cyanide ligands are attached.[118,134,135]

$[Mo_4(NO)_4(S_2)_6O]^{2-}$ can be obtained by the reaction of $[MoO_4]^{2-}$ with $NH_2OH{\cdot}HCl$ with H_2S in H_2O. This anion (Figure 13) consists of a central oxygen atom bound to four molybdenum atoms, arranged as a tetragonal bisphenoid over whose edges two handle-shaped and four roof-shaped S_2^{2-} ligands are located; each molybdenum is bound to a terminal nitrosyl ligand.[136] The related anion $[Mo_4(NO)_4S_{13}]^{4-}$ (Figure 14) involves a central sulfur bound to four $\{MoNO\}^{3+}$ moieties, five S_2^{2-} and two S^{2-} ligands (rather than the six S_2^{2-} ligands in Figure 13). $[Mo_4(NO)_4S_{13}]^{4-}$ is one product of the reaction of molybdate with ammonium polysulfide in aqueous solution in the presence of hydroxylamine.[134,137] $[Mo_2(NO)_2(S_2)_3(S_5)(OH)]^{3-}$ (Figure 15) has been obtained and involves an unusual $(\mu\text{-}S_5)^{2-}$ ligand.[138] Other studies of these and related anions have been reported.[139]

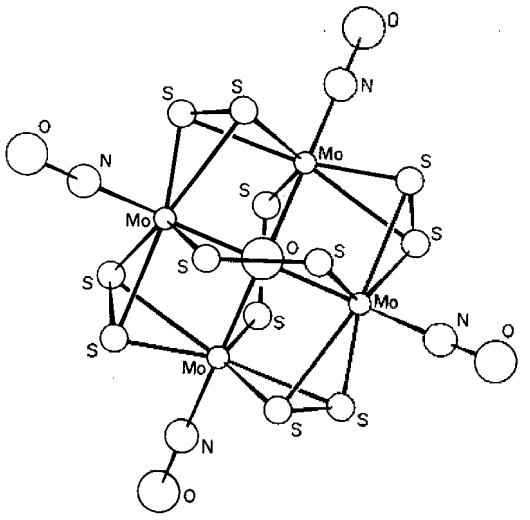

Figure 13 Structure of $[Mo_4(NO)_4(S_2)_6O]^{2-}$ [136]

Nitrosyl and cyanide ligands can coexist bound to a molybdenum–sulfur core, as in $[Mo_2S_2(NO)_2(CN)_6]^{6-}$ [135] and $[Mo_4S_4(NO)_4(CN)_8]^{8-}$.[140] The latter anion has been obtained by reacting $[Mo_4(NO)_4(S_2)_6O]^{2-}$ with KCN and it possesses a distorted cubane-like Mo_4S_4 framework, composed of two Mo_2S_2 quadrilaterals (Mo—Mo = 2.99(3) Å) linked with long (3.67(4) Å) Mo · · · Mo separations; each molybdenum is bound to one nitrosyl and two cyanide ligands external to the Mo_4S_4 cluster.[140] $[Mo_4S_4(CN)_{12}]^{8-}$ also contains an Mo_4S_4 cubane-like cluster, but the molybdenum and sulfur atoms are arranged as two, almost regular, interpenetrating tetrahedra with all the Mo—Mo separations essentially the same (2.85 Å); each molybdenum is octahedrally surrounded by three CN^- and three S^{2-} ligands.[141] $K_5[Mo_3S_4(CN)_9]{\cdot}3KCN{\cdot}4H_2O$ has been structurally characterized and shown to involve cyanide ligation of a normal $\{Mo_3S_4\}^{4+}$ core.[135] Cyanide ligation to $\{Mo_2S\}^{6+}$ (see Section 36.4.1.3), $\{Mo_2S_2\}^{2+}$ and $\{Mo_2S_2\}^{4+}$ cores has also been demonstrated; $[Mo_2S_2(CN)_8]^{4-}$ involves a significantly longer (2.758(7) *vs.* 2.644(5) Å) Mo—Mo bond than in $[Mo_2S_2(CN)_8]^{6-}$.[135,142]

The redox chemistries of di-, tri and tetra-nuclear Mo—S cyanide complexes have been discussed in relation to their electronic structures.[135] Passage of oxygen into an aqueous solution of $[Mo_2S_2(CN)_8]^{6-}$ leads to the formation of a dark violet mixed-crystal compound of the composition $K_{4+x}[Mo_2(SO_2)(S_2)(CN)_8]_x[Mo_2(SO_2)(S_2)(CN)_8]_{1-x}{\cdot}4H_2O$ ($x = 0.3$). In the crystal the two anions, whilst structurally similar, are located at crystallographically independent positions; each involves both molybdenum atoms surrounded by an approximately

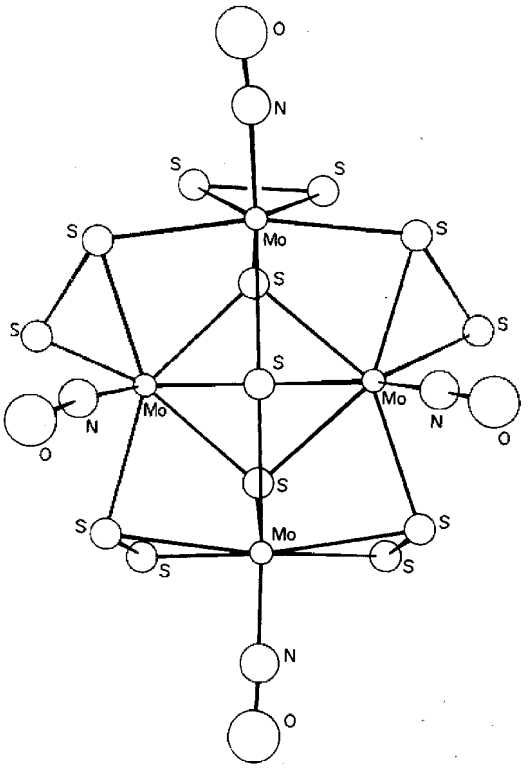

Figure 14 Structure of $[Mo_4(NO)_4S_{13}]^{2-}$ [137]

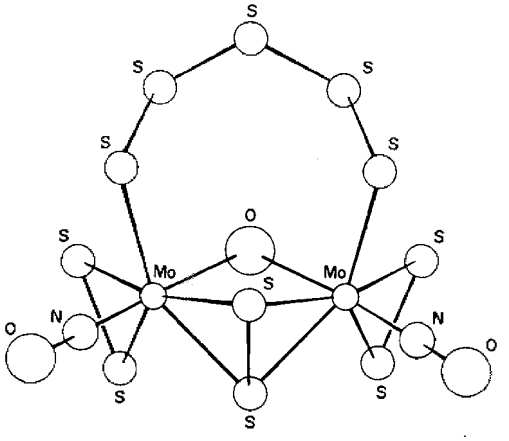

Figure 15 Structure of $[Mo_2(NO)_2(S_2)_3(S_5)(OH)]^{3-}$

pentagonal bipyramidal array of four terminal CN^- and three sulfur atoms of the bridging SO_2^{2-} and S_2^{2-} ligands. However, these anions involve the significantly different Mo—Mo separations of 2.790 and 2.684 Å, respectively, and the results of spectroscopic studies have led to the suggestion that the former is a mixed $Mo^{III}Mo^{IV}$ dimer whilst the latter involves two Mo^{IV} atoms.[143]

36.6.5 CYCLOPENTADIENYL MOLYBDENUM–SULFUR SYSTEMS

Cyclopentadienyl molybdenum–sulfur compounds are useful synthons for the preparation of Mo—M—S (*e.g.* M = Fe (see Section 36.6.2), Co, Ni) clusters[103–108,144] in reactions with metal carbonyls. However, the principal interest in molecules of this class has arisen because of the reactivity of the Mo—S system, primarily in respect of the making and breaking of S—H

and/or S—C bonds, leading to novel chemistry and an illumination of processes relevant to hydrodesulfurization catalysis.

$[Cp_2Mo_2(CO)_6]$ reacts with elemental sulfur to form insoluble products,[145] but the introduction of methyl substituents on the cyclopentadienyl ring permits the isolation of the soluble products $[(Me_5C_5)_2Mo_2S_4]$, $[(MeC_5H_4)_2Mo_2S_4]$ and $[(Me_5C_5)_2Mo_2(S_2)_5]$. The first two products possess an *anti*-$\{Mo_2S_4\}^{2+}$ core (Section 36.4.3.5.3) and the last one involves two η^2-S_2 ligands bound to each metal with each bonded to a single sulfur atom of a μ_2-S_2 ligand.[146] Molecules of the composition $[R'_2Mo_2S_4]$ ($R' = Me_nC_5H_{5-n}$, $n = 0, 1, 5$) may exist in one of three isomeric forms (Figure 16) and photochemical isomerization between them has been demonstrated.[146–149] Dimers related to form I with oxo or imido ligands have been characterized,[150] the electronic structure of these molecules has been investigated,[151] and their intramolecular steric effects have been modelled.[152]

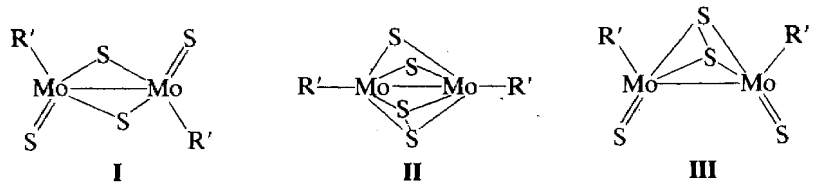

Figure 16 Isomers of molecules with the composition $[R'_2Mo_2S_4]$ ($R' = Me_nC_5H_{5-n}$, $n = 0, 1, 5$)[146–149]

The molecules $[R'_2Mo_2S_4]$ and their relatives manifest interesting reactivity towards H_2, alkenes, alkynes and other compounds with unsaturated linkages.[146,153–156] $[R'_2MoS_4]$ compounds react with H_2 under mild conditions to form a quadruply bridged structure with two hydrosulfido–ligands, $[R'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$. These systems catalyze H—D exchange between H_2 and D_2, as well as between H_2 and D_2O, and catalyze the reduction of elemental sulfur and SO_2.[153,154] Both alkene and arenethiols (RSH) react with $[R'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$ to release H_2S and form the corresponding $[R'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SR)_2]$ derivative; the structure of the $n = 1$, R = Me derivative has been determined and the molecules shown to be centrosymmetric with an Mo—Mo separation of 2.582(1) Å. $[R'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$ reacts with various unsaturated molecules, for example ethylene or benzyl isocyanide, releasing H_2 and forming dimers with two bridging ethane-1,2-dithiolate or dithiocarbonimidate groups, respectively.[153] The kinetics of the reactions of benzyl isocyanide with $[(MeCp)_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$ and $[(MeCp)_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SCH_2CH_2S)]$, to form the same dithiocarbonimidate complex, $[(MeCp)_2Mo_2(\mu\text{-}S_2CNCH_2Ph)_2]$, have been determined and the results suggested that the former reaction proceeds by an associative mechanism whilst the latter proceeds by a dissociative pathway.[155] Deprotonation of $[R'_2Mo_2(\mu\text{-}S)_2(\mu\text{-}SH)_2]$ with NaOMe (1:2) in the presence of excess CH_2Br_2 results in the formation of the dimer $[R'_2Mo_2S_2(S_2CH_2)]$ with a bridging methanedithiolate ligand;[156] this compound will catalyze the homogeneous hydrogenolysis of CS_2.[157]

Addition of C_2H_4 or C_2H_2 to $[R'_2Mo_2S_4]$ yields a quadruply bridged dimer with, respectively, two μ-ethane-1,2-dithiolate or μ-ethylene-1,2-dithiolate ligands.[146] Complexes related to the former, *viz.* $[(Cp)_2Mo(\mu\text{-}SC_nH_{2n}S)_2]$ ($n = 2$ and 3), have been prepared by the reaction of ethylene sulfide and propylene sulfide, respectively, with $[CpMoH(CO)_3]$ or $[(Cp)_2Mo_2(CO)_6]$ and their redox properties have been studied. These neutral dimeric complexes undergo a unique reaction with alkenes and alkynes, in which the hydrocarbon portion of the bridging dithiolate ligand is exchanged.[158] A series of these complexes, in which the molybdenum atoms are bridged by two inequivalent dithiolate ligands, have been synthesized and the relative tendencies of the ethanedithiolate ligands to eliminate ethylene investigated. Alkenes and cumulenes react with these complexes, displacing ethylene to form derivatives with dithiolene bridges.[156]

$[Cp_2Mo_2(CO)_6]$ reacts with $[Zn(S_3CPh)_2]$ to form $[CpMo(CO)_2(S_2CPh)]$ and $[Cp_2Mo_2(\mu\text{-}S)_2(S_2CPh)_2]$, and with 3,4-dimercaptotoluene to yield a purple dimer which, on irradiation, decomposes to produce the green compound $[(Cp)_2Mo_2(\mu\text{-}S_2C_6H_3Me_2)_2]$, which has a structure in which the core is similar to that of $[(Cp)_2Mo_2(\mu\text{-}SCHCHS)_2]$.[159] $[Cp_2Mo_2(\mu\text{-}SMe)_4]$ may be obtained by reacting $[Cp_2Mo_2(CO)_6]$ with MeSSMe and oxidation by $Ag[PF_6]$ yields the monocation; the neutral and cationic species possess the same geometry and oxidation leads to no essential change in dimensions.[160]

A wide variety of other cyclopentadienyl molybdenum–sulfur compounds are known including: monomeric $[Cp_2Mo(SR)_2]$,[161,162] $[Cp_2MoS_2]$ and $[Cp_2MoS_4]$,[163] dimeric

$[(BuCp)_2Mo_2(\mu\text{-}S_2)Cl_4]$ and $[CpMoCl_2(\mu\text{-}X)(\mu\text{-}SMe)_2ClMoCp]$ (X = OH, SMe),[164] trimeric $[Cp_3Mo_3(\mu\text{-}S)_3(\mu_3\text{-}S)]^{n+}$ ($n = 0$,[147] 1[165]) and $[Cp_3Mo_3(\mu_3\text{-}S)(CO)_6]^+$,[166] and the tetrameric $[(Pr^iCp)_4Mo_4(\mu_3\text{-}S)_4]^{n+}$ ($n = 0, 1, 2$)[167] and related systems (see Section 36.3.3.2).[168]

36.6.6 DITHIOLENE AND RELATED COMPLEXES

Transition metal complexes of unsaturated 1,2-dithiolates (metal dithiolenes) have attracted much attention because of their interesting structural and redox properties.[169] Molybdenum dithiolene complexes have featured prominently[170] in these studies and have special significance following the suggestion[171,172] that the molybdenum-containing cofactor of the oxomolybdoenzymes (Section 36.6.7) incorporates a molybdenum complex of an unsymmetrically substituted alkene-1,2-dithiolate.

The best characterized complexes are the tris(dithiolenes) which are known for several ligands, including: $\{S_2C_2(CN)_2\}^{2-}$ (mnt),[173–175] $\{S_2C_2R_2\}^{2-}$ (R = H, Me, CF_3, CO_2Me, Ph, 4-MeC_6H_4),[131,176–183] $\{S_2C_6H_4\}^{2-}$, $\{S_2C_6H_3\text{-}4\text{-}Me\}^{2-}$ (tdt), $\{S_2C_6H_2\text{-}4,5\text{-}Me_2\}^{2-}$, $\{S_2C_6F_4\}^{2-}$ [188] and quinoxaline-2,3-dithiolate.[189] These complexes are intensely coloured, due to S→Mo charge-transfer transitions and they have been synthesized by a variety of procedures, this versatility being required by the instability of some of the free ene-1,2-dithiols. *cis*-1,2-Dicyanoethane-1,2-dithiolate (maleonitriledithiolate, mnt), however, is a stable species and $MoCl_5$ reacts with Na_2mnt in THF to produce $[Mo(mnt)_3]^{2-}$.[173,174] Also, H_2tdt reacts with molybdate in acidic solution,[184] or with $MoCl_5$ in CCl_4,[182] to form $[Mo(tdt)_3]$; H_2tdt reacts with $[MoOCl_2(MePPh_2)_3]$ in MeCN in the presence of Et_3N to form $[Mo(tdt)_3]^{2-}$.[185] Bis(trifluoromethyl)dithieten, $CF_3C(S)(S)CCF_3$ is a convenient reagent and reacts with $[Mo(CO)_6]$ to form $[Mo\{S_2C_2(CF_3)_2\}_3]$;[176] reduction of this compound by hydrazine in ethanol affords the corresponding dianion.[177] Procedures for the *in situ* synthesis of dithiolene ligands have extended the range of metal–dithiolene chemistry. Thus, cyclic thiophosphate esters, prepared from benzoins or acyloins and P_4S_{10}, have yielded ene-1,2-dithiolate complexes when treated with transition metal salts under acidic conditions.[178] Also, hydrolysis of 2-(*N*,*N*-dialkylamino)-1,3-dithiolium salts affords a general method for the synthesis of ene-1,2-dithiolates and allows different substituents to be bound to the alkenic carbons.[190]

Molybdenum tris(dithiolene) complexes undergo electrochemically reversible, one-electron, redox processes. $[Mo(mnt)_3]^{n-}$ displays redox changes corresponding to the 0/1−, 1−/2−, 2−/3− and 3−/4− couples;[174] $[Mo(S_2C_2R_2)_3]^{n-}$ (R = H, Me, Ph, CF_3)[177,182,191] and $[Mo(tdt)_3]^{n-}$ [182] manifest 0/1−, 1−/2− and 2−/3− couples. These observations have encouraged chemical oxidations or reductions of these species, and stimulated a lively debate as to whether the processes are primarily metal- or ligand-based. The ligands are 'non-innocent' and this renders the precise definition of oxidation state difficult in these systems, but it is often assumed that each coordinated dithiolene contributes +II to the count of the metal's oxidation state. Discussions of the electronic structure of these systems have generally incorporated the information available from EPR studies of the paramagnetic species and X-ray crystallographic data.[131,175,181,183,189]

Metal trisdithiolenes were the first non-octahedral, six-coordinate transition metal complexes to be structurally characterized. Much of the interest shown in these complexes has concentrated on attempts to explain the observed trigonal prismatic geometry[192] and it is generally considered that the unusual structures of these complexes are due to electronic, rather than steric, effects. Two MO schemes have been proposed[179,182] which differ slightly in the ordering of the valence orbitals and that due to Gray *et al.*[182] gives better agreement with spectroscopic data. In this scheme, the stability of the trigonal prismatic geometry is attributed to two π-bonding interactions. Firstly, the π_h interaction which results from overlap of the metal d_{z^2} orbital with the sulfur sp^2 lone pair orbitals at 120° to the M—S and S—C bonds and, secondly, the π_v bonding which arises from overlap of the metal d_{xy} and $d_{x^2-y^2}$ orbitals with the butadienoid π orbitals of the ligand S_2C_2 groups. The optimal electron configuration for trigonal prismatic geometry is that of the neutral trisdithiolene complexes of the Group VI transition metals, *i.e.* the bonding π_h and π_v orbitals are filled and their antibonding counterparts unoccupied. The LUMO in these complexes is an antibonding π_h orbital; therefore, the occupation of this orbital in monoanionic and dianionic trisdithiolene complexes of the Group VI transition metals should destabilize the trigonal prismatic structure and allow distortion towards octahedral geometry. In support of this argument, the structure of $[Mo(mnt)_3]^{2-}$ is severely distorted from trigonal prismatic geometry.[175]

$[MoH(C_6H_4S_2\text{-}1,2)_3]^{3-}$ has been synthesized[193] and the selenium analogue of a trisdithiolene complex $[Mo\{Se_2C_2(CF_3)_2\}_6]$ shown to involve the six selenium atoms arranged in a trigonal prismatic manner about the molybdenum.[194]

A wide variety of other molybdenum dithiolene complexes have been prepared and characterized. Mononuclear complexes involving other ligands in the primary coordination sphere include: $[NBu_4][Mo(mnt)_2(S_2CNEt_2)]$, which possesses an essentially trigonal prismatic MoS_6 arrangement,[195] $[CpMo(mnt)_2]^-$, $[Cp_2Mo(mnt)]$ and $[Cp_2Mo(tdt)]$.[161,196] Several dimeric molybdenum complexes with dithiolene ligands are known and, of these, $[Mo_2(tdt)_5]$[197] is the only system based on dithiolene ligands alone. One of the products from the reaction of $[NH_4]_2[Mo_2O_7]$ with benzoin and P_4S_{10} is the binuclear dithiolene complex $[Mo_2(S_2)(S_2C_2Ph_2)_4]$. An X-ray analysis of the structure has revealed that each molybdenum atom is coordinated by seven sulfur atoms, in an approximately monocapped trigonal prismatic arrangement; the two metal atoms are bridged by four sulfur atoms of a shared face of the trigonal prisms, two of the bridging sulfur atoms are supplied by a bridging S_2 ligand and the other two are supplied by two bridging dithiolene ligands.[198] The structure of $[Mo_2O_2S_2\{S_2C_2(CN)_2\}_2]^{2-}$ has been determined; each molybdenum atom possesses distorted square pyramidal coordination geometry with the sulfur atoms forming the basal plane and an oxygen atom in the axial position.[199] Other dimeric molybdenum complexes with dithiolene ligands have been considered earlier in Sections 36.6.3 and 36.6.5.

36.6.7 OXOMOLYBDOENZYMES

The existence of a biological role for molybdenum was first recognized in 1930.[200] Since that time, an increasing volume of evidence has accumulated to show that molybdenum is essential for a significant number of biological processes. For example, molybdenum is required both for nitrogen fixation (Section 36.6.2) and nitrate reduction, and its participation in some animal hydroxylase enzymes and several fungal and bacterial enzymes is now firmly established.[201] The molybdoenzymes are all reasonably large proteins, the functions of which involve the molybdenum centres undergoing redox reactions in concert with other redox active constituents. An important aspect of the composition of the molybdoenzymes has been the demonstration of the existence of a low molecular weight prosthetic group (or cofactor) containing molybdenum necessary for catalytic activity and which may be dissociated reversibly from the main body of the protein. The original concept was of a cofactor common to all the molybdoenzymes.[202] Subsequently, studies demonstrated[59,203] that there are at least two such cofactors; nitrogenases yield FeMoco (Section 36.6.2) which is distinct from the molybdenum-containing cofactor, or Moco, of enzymes such as xanthine oxidase and dehydrogenase, sulfite oxidase and nitrate reductase.

Molybdoenzymes other than the nitrogenases are usually termed *oxo*molybdoenzymes. This prefix relates to the nature of the catalysis effected, *i.e.* the net effect of the conversion (xanthine to uric acid, sulfite to sulfate, nitrate to nitrite, or aldehyde to carboxylate) corresponds to the transfer of one oxygen atom to or from the substrate. Furthermore, molybdenum *K*-edge EXAFS studies have established that this metal is coordinated to one or more terminal oxo groups in each enzyme studied by this technique.[204]

EPR spectroscopy has been extensively applied to the oxomolybdoenzymes.[205] These studies have established that all of these enzymes have similar molybdenum centres, at which the substrate undergoes the catalytic conversion. The redox states of molybdenum, involved in the normal catalytic cycle of these enzymes, are Mo^{VI}, Mo^{V} and Mo^{IV} and the EPR characteristics of the Mo^{V} centres, and hence the Mo^{VI} and Mo^{IV} states, are mononuclear in molybdenum and coordinated to sulfur.[206] EPR spectroscopic studies have established that, at least in the EPR-detectable form of each of the oxomolybdoenzymes at low pH, there is a minimum of one proton magnetically coupled to the unpaired electron of the Mo^{V} centre which is chemically exchangeable with the protons of the external aqueous medium. Furthermore, for xanthine oxidase, EPR spectroscopy has provided direct evidence[207] in support of the hypothesis[208] that the mechanisms of all the molybdoenzymes involve coupled proton–electron transfer at the molybdenum centre. EPR spectra using ^{17}O-enriched H_2O have established that oxygen atoms are bound to the Mo^{V} centres[209] and studies with ^{33}S suggest that the difference between active and desulfo xanthine oxidase involves the replacement of an Mo=S_t group in the former by the Mo=O_t group in the latter.[210] The results of molybdenum *K*-edge EXAFS studies[204] are complementary to those of EPR spectroscopy, not only since it is easier to probe the EPR

silent states by the former technique, but also because the results provide additional information, in respect of the nature, number and distance of the ligand donor atoms attached to molybdenum. For example, in oxidized sulfite oxidase molybdenum is bound to two oxygen atoms at 1.68 A and two to three sulfur atoms at 2.41 Å; reduction to the Mo^{IV} state results in the loss of one of the oxo groups. The molybdenum centre of *Chlorella vulgaris* nitrate reductase resembles that in sulfite oxidase, but some important differences occur for molybdenum in *Escherichia coli* nitrate reductase.[211] Also, molybdenum *K*-edge EXAFS studies have strengthened the view that an Mo=S_t group is present in active, but not desulfo, xanthine oxidase and dehydrogenase[212] and identified a close approach (*ca.* 3.0 Å) of Mo and As atoms in arsenite-inhibited xanthine oxidase.[213]

A major development in the definition of the constitution of Moco was the recognition[214] that an oxidized, inactive, form of this cofactor has the fluorescence properties characteristic of a pterin. Further studies indicated that the fluorescent material was derived from a novel, sulfur-containing reduced pterin substituted at the C-6 position.[171] Subsequently, a metabolic relationship was established between Moco and urothione, since persons genetically deficient in Moco are unique in having no detectable urothione in their urine. This metabolic relationship, and the chemical reactions of the cofactor, formed the basis from which Johnson and Rajagopalan proposed a structure (Figure 17) for Moco.[172]

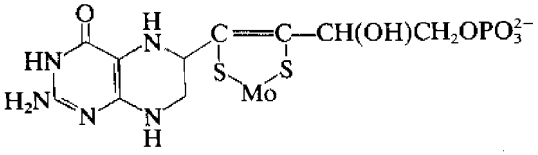

Figure 17 Proposed structure for the molybdenum cofactor of the oxomolybdoenzymes[172]

The biological importance of molybdenum, and the challenge to reproduce the spectroscopic properties and the reactions of the molybdenum centres of the oxomolybdoenzymes, have been considerable stimuli for the development of the coordination chemistry of this element (see Chapters 36.4 and 36.5).

36.6.8 HYDRIDE AND DIHYDROGEN COMPLEXES

The most extensive group of molybdenum hydride complexes are those which contain phosphine ligands, and mononuclear systems with one to six hydride ligands have been identified.

The reaction of $[Mo(acac)_3]$ and diphos in toluene with $AlEt_3$ under Ar affords $[Mo(C_2H_4)(diphos)_2]$ and $[MoH(acac)(diphos)_2]$. The former complex reacts with Hacac to produce the latter and this hydrido complex initiates the polymerization of acrylonitrile.[215] $[MoCl_3(THF)_3]$ reacts with PMe_3 in Et_2O or THF to form $[MoCl_3(PMe_3)_3]$ which reacts with $Na[BH_4]$ to yield $[MoH(BH_4)(PMe_3)_4]$, whose structure has been determined by X-ray crystallography; the molecular unit involves a distorted octahedral environment at the molybdenum, with the bidentate $[BH_4]^-$ group considered to occupy one vertex, and Mo—H = 1.63 Å.[216] The carbonyl hydrides of molybdenum include $[\mu\text{-}H\{Mo(CO)_4PMePh_2\}_2]^-$, which has been obtained by reacting $[\mu\text{-}H\{Mo(CO)_5\}_2]^-$ with a 10-fold excess of $PMePh_2$; its structure has been determined for the $[NEt_4]^+$ salt, the Mo · · · Mo separation in the three-centre, two-electron hydride bridge is 3.443(1) Å, significantly shorter than that of 3.7436(1) Å in $[\mu\text{-}H\{Mo_2(CO)_9PPh_3\}]^-$ and only 0.02 Å longer than in $[\mu\text{-}H\{Mo(CO)_5\}_2]^-$.[217] A combined structural and spectroscopic study has been performed to examine the stereochemical consequences resulting from the deprotonation of the bent Mo—H—Mo bond in $[(\mu\text{-}H)(\mu\text{-}PMe_2)\{CpMo(CO)_2\}_2]$; the most significant structural change is the reduction of the Mo—Mo separation from 3.262(2) A in the hydride to 3.157(2) Å in $[(\mu\text{-}PMe_2)\{CpMo(CO)_2\}_2]^-$.[218]

Reduction of $[MoCl_4(THF)_2]$ by Mg under H_2 in the presence of PMe_3 gives $[MoH_2(PMe_3)_5]$ which possesses a distorted pentagonal bipyramidal stereochemistry with Mo—H bonds of length 1.67 Å. Both the ^1H and $^{31}P\{^1H\}$ NMR spectra of this compound are consistent with a fluxional structure; the former manifests a binomial sextet at $\delta = -5.23$ p.p.m.[219] $[MoH_4(PMe_2Ph)_4]$ reacts with $Ag[BF_4]$ (1:2) in MeCN to give

$[MoH_2(PMe_2Ph)_4(NCMe)_2][BF_4]_2$, the cation of which has been shown by spectroscopy and X-ray crystallography to possess a fluxional dodecahedral structure. The same salt is obtained by treating the tetrahydride with $H[BF_4]\cdot Et_2O$ in MeCN, but $[MoH_4(PMePh_2)_4]$ reacts with $Ag[BF_4]$ or $H[BF_4]\cdot Et_2O$ in MeCN to produce $[MoH_2(PMePh_2)_3(NCMe)_3]^{2+}$.[220] As a further variation on this theme, $[MoH_4(PMePh_2)_4]$ reacts with $H[BF_4]$ in THF to produce $[\{MoH_2(PMePh_2)_3\}_2(\mu\text{-}F)_3][BF_4]$, the structure of which has been determined by X-ray crystallography. Only one hydride per metal was revealed directly by the crystallographic analysis, but the presence of the second hydride was confirmed by IR and NMR studies; the ligands adopt a dodecahedral arrangement about each metal centre.[221] $[MoH_4(dppe)_2]$ reacts with Ph_3CCl in CH_2Cl_2 to form $[MoH_2Cl_2(dppe)_2]\cdot CH_2Cl_2$[222] and $[MoH_2(diphos)_2]$ has been prepared by reacting $[Mo(acac)_3]$ with $AlBu^i_3$ in benzene in the presence of diphos under an atmosphere of H_2,[223] and by reacting $[Mo(N_2)_2(diphos)_2]$ with $[FeH_4(PEtPh_2)_3]$.[224]

$[MoH_4L_4]$ (L = tertiary phosphine; L_2 = diphosphine) complexes are conveniently prepared by borohydride reduction of $[MoCl_4L_2]$ in the presence of the phosphine,[225] or by treatment of $[Mo(N_2)_2L_4]$ with H_2.[226] ^1H NMR spectroscopy has shown that $[MoH_4L_4]$ molecules are non-rigid; the nature of this non-rigidity has been discussed with reference to the molecular structure of $[MoH_4(PMePh_2)_4]$, which has been shown by X-ray analysis to contain a trigonal dodecahedral MoH_4P_4 framework, with the hydrogen atoms at the vertices of the elongated tetrahedron and the phosphorus ones at those of the flattened tetrahedron.[227] The dinuclear complex $[(PMe_3)_3HMo(\mu\text{-}H)_2MoH(PMe_3)_3]$ has been mentioned in Section 36.3.2.1.1.

$[MoH_6L_3]$ (L = PPr^i_3, $PPhPr^i_2$, PCy_3, PCy_2Ph; Cy = cyclohexyl) have been prepared by reacting $[MoCl_4(THF)_2]$, L and $Na[AlH_2(OCH_2CH_2OMe)_2]$ and characterized by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy; the hydridic resonance occurs at *ca.* −4 p.p.m. These complexes have been claimed as the first examples of nine-coordinate mononuclear molybdenum, but attempts to prepare $[MoH_9]^{3-}$ were unsuccessful.[228]

An exciting recent development has been the isolation of transition metal complexes containing a coordinated dihydrogen molecule, bound as an η^2 ligand. Toluene solutions of the 16-electron compound $[Mo(CO)_3(PCy_3)_2]$ react readily and cleanly with H_2 (1 atm) to form *mer-trans*-$[Mo(CO)_3(PCy_3)_2(H_2)]$. The H_2 is extremely labile and, for the corresponding PPr^i_3 complex, the addition is reversible in solution. Neutron and X-ray diffraction performed for $[W(CO)_3(PPr^i_3)_2(H_2)]$ confirmed the η^2 bonding of the H_2 molecule and this is consistent with vibrational spectra obtained for the H_2, D_2 and HD forms.[229] These complexes are important, not only because of their relevance to the participation of metal centres in catalytic hydrogenation, but also since they pose an interesting theoretical challenge. In respect of this latter point, at present it is not clear why $[Mo(CO)_3(PR_3)_2(H_2)]$ complexes involve an η^2-H_2 molecule whereas, for example $[MoH_2(PR_3)_5]$ involve two hydride ligands.

Dimeric molybdenum halide complexes involving a μ-hydride ligand are described in Section 36.5.2.2.6. The novel dithiolene hydride complex $[MoH(C_6H_4S_2\text{-}1,2)_3]^{3-}$ has been characterized;[193] $K_4[MoH(CN)_7]\cdot 2H_2O$ has been prepared by acidification of $K_5[Mo(CN)_7]$ and its reactivity investigated.[230] Hydrido-cyclopentadienyl,[231] -η^6-benzene[232] and -carbonyl[233] molybdenum complexes have a rich chemistry which is outside the scope of this review. $[Mo_2(OAr)_2(CH_2SiMe_3)_4]$ (OAr = 2,6-dimethylphenoxide) in the presence of pyridine undergoes the loss of Me_4Si to form $[Mo_2(\mu\text{-}H)(\mu\text{-}CSiMe_3)_2(OAr)_2(py)_2]$.[234]
