Preface

Since the appearance of water on the Earth, aqua complex ions of metals must have existed. The subsequent appearance of life depended on, and may even have resulted from, interaction of metal ions with organic molecules. Attempts to use consciously and to understand the metal-binding properties of what are now recognized as electron-donating molecules or anions (ligands) date from the development of analytical procedures for metals by Berzelius and his contemporaries. Typically, by 1897, Ostwald could point out, in his 'Scientific Foundations of Analytical Chemistry', the high stability of cyanomercurate(II) species and that 'notwithstanding the extremely poisonous character of its constituents, it exerts no appreciable poison effect'. By the late 19th century there were numerous examples of the complexing of metal ions, and the synthesis of the great variety of metal complexes that could be isolated and crystallized was being rapidly developed by chemists such as S. M. Jørgensen in Copenhagen. Attempts to understand the 'residual affinity' of metal ions for other molecules and anions culminated in the theories of Alfred Werner, although it is salutary to remember that his views were by no means universally accepted until the mid-1920s. The progress in studies of metal complex chemistry was rapid, perhaps partly because of the utility and economic importance of metal chemistry, but also because of the intrinsic interest of many of the compounds and the intellectual challenge of the structural problems to be solved.

If we define a coordination compound as the product of association of a Brönsted base with a Lewis acid, then there is an infinite variety of complexing systems. In this treatise we have made an arbitrary distinction between coordination compounds and organometallic compounds that have metal–carbon bonds. This division roughly corresponds to the distinction — which most but not all chemists would acknowledge as a real one — between the cobalt(III) ions $[Co(NH_3)_6]^{3+}$ and $[Co(\eta^5\text{-}C_5H_5)_2]^+$. Any species where the number of metal–carbon bonds is at least half the coordination number of the metal is deemed to be 'organometallic' and is outside the scope of our coverage; such compounds have been treated in detail in the companion work, 'Comprehensive Organometallic Chemistry'. It is a measure of the arbitrariness and overlap between the two areas that several chapters in the present work are by authors who also contributed to the organometallic volumes.

We have attempted to give a contemporary overview of the whole field which we hope will provide not only a convenient source of information but also ideas for further advances on the solid research base that has come from so much dedicated effort in laboratories all over the world.

The first volume describes general aspects of the field from history, through nomenclature, to a discussion of the current position of mechanistic and related studies. The binding of ligands according to donor atoms is then considered (Volume 2) and the coordination chemistry of the elements is treated (Volumes 3, 4 and 5) in the common order based on the Periodic Table. The sequence of treatment of complexes of particular ligands for each metal follows the order given in the discussion of parent ligands. Volume 6 considers the applications and importance of coordination chemistry in several areas (from industrial catalysis to photography, from geochemistry to medicine). Volume 7 contains cumulative indexes which will render the mass of information in these volumes even more accessible to users.

The chapters have been written by industrial and academic research workers from many countries, all actively engaged in the relevant areas, and we are exceedingly grateful for the arduous efforts that have made this treatise possible. They have our most sincere thanks and appreciation.

We wish to pay tribute to the memories of Professor Martin Nelson and Dr Tony Stephenson who died after completion of their manuscripts, and we wish to convey our deepest sympathies to their families. We are grateful to their collaborators for finalizing their contributions for publication.

Because of ill health and other factors beyond the editors' control, the manuscripts for the chapters on Phosphorus Ligands and Technetium were not available in time for publication.

However, it is anticipated that the material for these chapters will appear in the journal *Polyhedron* in due course as Polyhedron Reports.

We should also like to acknowledge the way in which the staff at the publisher, particularly Dr Colin Drayton and his dedicated editorial team, have supported the editors and authors in our endeavour to produce a work which correctly portrays the relevance and achievements of modern coordination chemistry.

We hope that users of these volumes will find them as full of novel information and as great a stimulus to new work as we believe them to be.

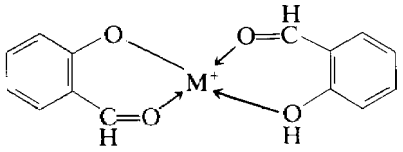
23.1 PREFACE

The chemistry of the alkali and alkaline earth metals has generally been regarded as straightforward and discernible using an ionic model.[1,2] The interaction between metal ions and ligands in coordination complexes can be regarded as ion–dipolar in nature and this leads to the prediction that large cations having low charge (or low ionic potential[3]) will be unlikely to form complexes. As the alkali and alkaline earth metals provide the largest known cations, they were long regarded as being unlikely to form complexes.

In a book review written in 1974,[4] R. J. P. Williams commented that 'the inorganic chemistry of these elements—Na, K, Mg and Ca—is taught no more because there are no spectra to tease the mind' and consequently they remain 'out of sight (spectroscopic), out of mind'. Certainly this bore much truth with regard to coordination chemistry, especially as the watershed established in 1967, when C. J. Pedersen[5] discovered that macrocyclic polyethers can act as efficient ligands for alkali and alkaline earth metals, had barely reached the textbooks.

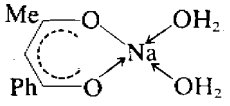


This discovery, followed by the exploitation of macrobicyclic multidentate ligands (crypt-

ands) as complexing agents,[6] and accompanied by an increasing realization of the need to understand the vital role played by Na, K, Mg and Ca in biological systems, has led to a renaissance of interest in the coordination chemistry of these metals.[7–9]

23.1.1 Historical Perspective

Whilst what has been termed the real scientific advancement in this area took place in 1967,[5] complexes of alkali and alkaline earth metal cations (M^{n+}) with simple monodentate ligands can be traced back, through the 'metal-ammonias', to Faraday.[10] It was not until almost a century later, however, that precise determinations of the stoichiometries of the M^{n+}—NH_3 products were realized and the term coordination was introduced to describe the bonding mode of the ligand.[11–13] The alkali metals themselves were first noted to dissolve in liquid ammonia in 1863[14] and since that time it has been found that the metals also dissolve in amines and ethers.[15]



The interaction of potentially chelating ligands with M^{n+} was first noted by Ettling, in 1840, who reported (salicylaldehydato)sodium(salicylaldehyde), hemihydrate.[16] The monohydrated analogue was later reported by Hantzsch who termed it, and similar compounds, 'acid salts'.[17] Compounds having the general formula ML·*n*HL ($n = 1, 2$) were then extensively studied by Sidgwick and his coworkers,[18,19] who considered the ML·HL complexes to consist of a quadridentate cation coordinated independently by both L and HL, as in (**1**). The ML·2HL series were believed to contain a hexacoordinated cation. Later Pfeiffer suggested that although this bonding mode could operate, it was also possible for L to interact with M^{n+} and HL simultaneously, with the HL having no direct link to M^{n+}.[20] The essential correctness of this proposal has been demonstrated more recently[21] and is discussed later.

(**1**)

Several isolated reports of stable, solid complexes of M^{n+} with a range of organic solvents (*e.g.* alcohols, ketones, aldehydes, esters, ethers, acetonitrile and pyridine) were made available during this same period. Some were obtained by crystallization of a salt from the relevant solvent, and others more serendipitously through observations made during solubility studies.

The observations made by Sidgwick and Brewer, in 1925, on the solubility charactersitics of alkali metal-β-diketonates are of seminal importance.[19] (1-Phenyl-1,3-butanedionato)sodium was found to be insoluble in toluene, whereas the dihydrated form was toluene soluble. This was explained by proposing the formation of a complex in which the diketonate acts as a chelating anion and the two waters act as monodentate ligands (**2**). This suggestion was vindicated in the 1960s with the solution of the X-ray crystal structure of the corresponding ethylene glycol complex.[22] In this molecule the glycol acts as a bridging, doubly monodentate ligand linking two sodium cations; each sodium is coordinated by one diketonate and two monodentate glycol oxygen atoms.

(**2**)

The area then developed in a non-systematic way. Representative examples illustrating the coordination of M^{n+} can be seen in the syntheses of well-defined complexes with the bidentate nitrogen-containing ligands, en and phen;[23] the isolation of metal complexes of sugars;[24] and the preparation of complexes with amino acids, di- and tri-peptides and related small molecules of biological interest.[25,26] Just prior to Pedersen's disclosures concerning the formation of metal complexes involving macrocyclic polyethers,[5] interest in solvent extraction and desalination led to the availability of ligands such as *p,p'*-diamino-2,3-diphenylbutane which readily precipitate

NaCl from water.[27] Moore and Pressman's discovery that the antibiotic valinomycin exhibits alkali metal cation selectivity in rat liver mitochondria then provided a starting point for studies in the area of M^{n+} selectivity by biological and model systems.[28]

Since Pedersen's disclosures, and the subsequent extension into the third dimension through Lehn and his macrobicyclic and macrotricyclic cryptands,[29] there have been a plethora of papers concerning many aspects of M^{n+} complexation, the majority being centred on crown ether and related species. Their literature has been extensively reviewed and attention is drawn to articles by Poonia and Bajaj[30] and by Vögtle and Weber[31] which are comprehensive and provide excellent bibliographies of the area.

There is also an extensive organometallic chemistry of the alkali and alkaline earth metals. Many of these compounds, particularly those of Li, Be and Mg, form coordination complexes with appropriate donor ligands. This topic has been recently surveyed in the companion volume 'Comprehensive Organometallic Chemistry' and so only apposite references will be included here.[32]

23.1.2 General Remarks

The alkali and alkaline earth metals are usually regarded as having 'hard', or class 'a', character and so are capable of binding to 'hard' or class 'a' ligands. The ionic size increases down each group (Table 1), and individually with increasing coordination number. The ionic potential (charge–radius ratio) is diminished in the same direction, and this is reflected in the more covalent character found in compounds of Li, Be and Mg relative to their higher congeners. Li^+ and Be^{2+} have the greatest polarizing power in each series and the highest tendency towards solvation.

Table 1[a] Ionic Radii and Hydration Energies

(a)	Li	Na	K	Rb	Cs
Ionic radius (Å)	0.60	0.95	1.33	1.48	1.69
Hydration energy (kJ mol^{-1})	−498	−393	−310	−284	−251
(b)	Be	Mg	Ca	Sr	Ba
Ionic radius (Å)	0.31	0.65	0.99	1.13	1.35
Hydration energy (kJ mol^{-1})	−2455	−1900	−1565	−1415	−1275

[a] Data compiled from F. A. Cotton and G. Wilkinson, 'Advanced Inorganic Chemistry', 4th edn., Wiley, New York, 1980. Pauling ionic radii are quoted.

There is an increase in coordination number going from $Li^+(4)$ through $Na^+(6)$ to K^+, Rb^+ and $Cs^+(8)$, and from $Be^{2+}(4)$ through $Mg^{2+}(6)$ to Ca^{2+}, Sr^{2+} and $Ba^{2+}(8)$. All of the M^{2+} ions are smaller and considerably less polarizable than the isoelectronic M^+ ions. The oxidation state is +1 for the alkali metals and +2 for the alkaline earth metals. In contrast to the transition metals, there is no preferred coordination geometry for this group of cations except that, in the absence of crystallographically imposed symmetry, a roughly spherical distribution of neighbours is sought.

Beryllium is normally divalent in its compounds and, because of its high ionic potential, has a tendency to form covalent bonds. In free BeX_2 molecules, the Be atom is promoted to a state in which the valence electrons occupy two equivalent *sp* hybrid orbitals and so a linear X—Be—X system is found. However, such a system is coordinatively unsaturated and there is a strong tendency for the Be to attain its maximum coordination of four. This may be done through polymerization, as in solid $BeCl_2$, *via* bridging chloride ligands, or by the Be acting as an acceptor for suitable donor molecules. The concept of coordinative saturation can be applied to the other M^{n+} cations, and attempts to achieve it have led to attempts to deliberately synthesize new compounds.

Multidentate ligands, both acyclic and cyclic, are now abundant and herein the nomenclature used will follow that recently proposed by Vögtle and Weber.[33] Coronands are taken to mean macromonocyclic compounds having any heteroatoms present as potential donors, with crown ethers being reserved for compounds of the same type having only oxygen atoms present as

donor species. Cryptands are bi- and poly-cyclic compounds having any heteroatoms present as donors and podands are acyclic coronand and crown ether analogues.

23.2 MONODENTATE LIGANDS

Many salts of the alkali and alkaline earth metals occur as solvated species and are obtained by crystallization of the salt from an appropriate solvent. It is only recently that such compounds have been seriously considered as coordination compounds and factors such as the coordination number of the cation and whether the interaction between Na^+ and H_2O leads to $[Na–H_2O]^+$,[34] a species comparable to the oxonium cation, have been thoroughly investigated. One problem is precise definition, or when does a complex become too complex? Alkali metal compounds range from discrete molecular solvates through various degrees of association to extensive arrays and networks. The Na^+ in NaCl is regarded as six coordinated, having six nearest Cl^- neighbours, but the system is not usually regarded as anything other than an ionic compound. In this review complexes have been generally restricted to discrete molecular entities, and solvated species have been divided into two general categories:[30,35] (i) solvates, or compounds in which the cation is surrounded by the solvent and the anion is separate, and (ii) solvated ion pairs in which both solvent and anion are coordinated to the cation.

23.2.1 Alkali Metal Complexes

A comparison of the commoner alkali metal salts showed that ~76% of the Li salts gave solid hydrates, as did ~74% of the Na salts and ~23% of the K salts; very few hydrates of Rb and Cs are available. The degree of hydration of the cation diminishes down the group, with decreasing ionic potential. The Li salts do not form hydrates with more than four waters present, except for the bromide, iodide and hydroxide at low temperature. The cation is coordinated only to the solvating molecules and so the species is charge separated; the anion, in the case of the protic solvent derivatives, is generally held by the hydrogens of the solvent. An X-ray structure of $Na_2SO_4·10H_2O$ shows the cation to be present in an octahedral environment as $[Na(H_2O)_6]^+$;[36] the K^+ in $CaKAsO_4·8H_2O$ is present as $[K(H_2O)_8]^+$[37] in a square antiprismatic environment.

A related series of complexes is formed with ammonia; some of these complexes have considerable stability such as $LiI·4NH_3$, in which the cation is believed to be tetrahedrally coordinated and charge-separated $[Li(NH_3)_4]^+$. Results of studies on the dissociation properties show that the stability of the ammines falls off in the sequence $Li^+ > Na^+ > K^+$, and with halides of the same metal in the order $I^- > Br^- > Cl^-$.[38] The ammonia may be replaced by primary, secondary and tertiary amines but the products are less stable.

The alkali metals are soluble in liquid ammonia, and certain amines, to give solutions which are blue when dilute. The solutions are paramagnetic and conduct electricity, the carrier being the solvated electron. In dilute solutions the metal is dissociated into metal ions and ammoniated electrons. The metal ions are solvated in the same way that they would be in a solution of a metal salt in ammonia, and so comparison can be made with, for example, $[Na(NH_3)_4]^+I^-$, the IR and Raman spectra of which indicate a tetrahedral coodination sphere for the metal.[39]

Many solid solvates of the alkali metals are known[30] and the monodentate ligands involved include pyridine, MeOH, EtOH and higher alcohols, acetone, dioxane, THF, aryl- and alkyl-phosphine oxides, DMSO, amides (acetamide, NMA, DMA, NMF, DMF, urea, *etc.*) and thiourea. The X-ray structures of several compounds have been solved and representative examples are given in Table 2. Although these fall broadly into the two categories of complex given earlier, one observation is that discrete molecules are not always available. In the complexes $LiI·5tppo$,[40] $Li[Li\{C(SiMe_3)_3\}_2]·4THF$[41] and $LiCl·4NMA$[42] the cation is tetrahedrally coordinated as $[Li(solvent)_4]^+$. In the first molecule there is an additional, non-complexed tppo present, and in the last the NMA also hydrogen bonds to the Cl^-. In contrast, in the sodium complexes $NaI·3Me_2CO$[43] and $NaI·3DMF$,[44] the cation coordination number is six and the geometry is octahedral, and midway between octahedral and trigonal prismatic respectively. The triads of oxygen atoms are shared between pairs of cations giving rise to infinite cationic columns.

All halides of alkali metals, except Li, are practically insoluble in pyridine; this situation is

Table 2 Some Representative Structures of Alkali Metal Solvates

Complex	*Bond lengths* (Å)	*Coordination numbers*	*Comments*	*Ref.*
(i) Solvated species				
LiI·5tppo[a]	Li—O_{av}, 1.97	4	Td, one uncomplexed tppo	1
LiCl·4nma[b]	Not given	4	Td	2
$Li[Li\{C(SiMe_3)_3\}_3]$·4THF	Li—O_{av}, 1.97	4	Td, $Li(THF)_4^+$	3
NaI·3MeOH	Na—O_{av}, 2.47	6	Oh, shared donor triads	4
NaI·3acetone	Na—O_{av}, 2.46	6	Oh, shared donor triads	5
NaI·3DMF	Na—O_{av}, 2.40	6	Trigonal prism Oh, shared donor triads	6
$NaClO_4$·3dioxane	Na—O_{av}, 2.43	6	Elongated Oh, bridging dioxane	7
LiI·2urea	Li—O, 1.88, 1.95	4	Td, each urea binds $2\,Li^+$	8
(ii) Solvated ion pairs				
LiCl·pyridine	Li—Cl, 2.38, 2.39 Li—N, 2.01	4	Td: 3 Cl^-, 1 N	9
LiCl·H_2O·2pyridine	Li—O, 1.94 LiCl, 2.33 Li—N, 2.05, 2.06	4	Td: 1 Cl^-, 1 N, 1 O	10
LiCl·dioxane	Li—O, 1.88, 1.95 Li—Cl, 2.39, 2.42	4	Distorted Td	11
NaBr·2am[c]	Na—O, 2.33, 2.37	6	Distorted Oh, shared Br^- and O	12
$NaClO_4$·2DMA	Na—O_{lig}, 2.35, 2.39 Na—O_{ClO_4}, 2.38	5	Shared DMA and ClO_4^-	13

[a] tppo = triphenylphosphine oxide. [b] NMA = *N*-methylacetamide. [c] am = acetamide.

generally modified by stepwise addition of water, and the observation served as the basis for an early process for the separation of Li from the other alkali metals.[45] The structure of LiCl·H_2O·2py has present a four-coordinate cation bound to the three donor atoms and the Cl^- anion and so serves as an example of a solvated ion pair.[46] In NaBr·2acetamide the Na^+ is six-coordinated and this is achieved by the sharing of one Br^- anion and two oxygen atoms between pairs of Na^+ cations to give electrically neutral columns.[47]

For some solvent systems, it has not yet been possible to obtain structural information in the solid state. The ion-pair loosening ability of DMSO has been thoroughly illustrated in studies of M^+–DMSO interactions in solution using several different techniques: NMR;[48,49] solution IR;[50–52] conductometry[53] and calorimetry.[54] In the case of Na^+, a coordination number of six has been confirmed. IR techniques have also been used to monitor alkali metal complexation with the related sulfoxides, diisopropyl and dibutyl sulfoxide.[50] Solid M^+–DMSO species have

been recovered from salt solutions in DMSO; the IR spectra suggest that the DMSO molecules present in these complexes are not equivalent but no X-ray structural information is presently available.

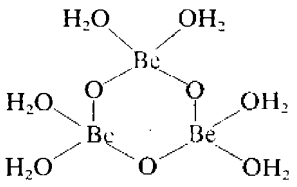
Amides and related compounds have been thoroughly investigated as ligands for alkali metals. Studies in solution have been made using various physicochemical techniques; these, and MO calculations, show that the interaction of amides with M^+ is *via* the carbonyl function.[56,57] This leads to a delocalization of the amide N electron pair and so it is possible to follow the decrease in C—O, and the increase in C—N, bond orders using IR spectroscopy. X-Ray crystal structures of amide complexes have shown both types of complexation interaction to be present (Table 2).

The amides have been employed as primitive models for peptides in studies concerning the denaturing of proteins by alkali metal salts; it has been suggested that as alkali metal cations have strong interactions with amides this could indicate that denaturing occurs *via* interactions with peptide units.[58] It is therefore pertinent to comment, at this point, that the crystal structures of $NaI(glycine)_2 \cdot H_2O$[59] and $LiBr(alanylglycine) \cdot 2H_2O$[60] have been solved and in each the amino acids function as zwitterions. The M^+ is then coordinated to the carboxylic acid functions and water molecules to give six and four coordination respectively. A survey of the earlier work on metal salt interactions with amino acids has been published.[61]

An interesting structural feature arises in the coordination of Li^+ by urea in the complex $LiI \cdot 2urea$;[62] each urea bridges two cations. This may be compared with $LiCl \cdot dioxane$[63] in which a related bridging occurs, and contrasted with $NaCl \cdot urea \cdot H_2O$[64] in which the octahedral metal environment is due to two Cl^- anions, two water oxygen atoms and two urea oxygen atoms.

Thiourea complexes of the type $MX(thiourea)_4$ have been found if the lattice energy of MX is less than 670 kJ mol^{-1}. This leads to complexes of K^+, Rb^+ and Cs^+, especially with Br^- and I^- as anions. The polarizable thiourea separates the anions from the cations and each cation is probably surrounded by eight sulfur atoms at the corner of an approximately regular cube.[65]

The complexation of M^+L^- (M^+ = Li–Rb; L^- = *e.g.* 2,4-dinitrophenolate) by triphenylphosphine oxide (tppo) has been studied conductometrically and shows that M^+L^- association constants decrease down the group.[66] Tri-*n*-octylphosphine oxide (topo) has been used to extract alkali metal cations into organic media; the extractant species are designated as either $[M(topo)_3]^+ClO_4^-$ (M^+ = Li–Cs) or $[M(topo)_4]^+ClO_4^-$ (M^+ = Rb, Cs). The most efficacious transfer occurs for the smaller cations.[67] The study of the synergic effect of various aryl- and alkyl-phosphine oxides on the extraction of alkali metal cations has been reviewed.[68] Using the dibenzoylmethane anion, water-insoluble complexes such as $Li(dbm)(topo)_2$ have been characterized; the use of topo as the extractant in a water–*p*-xylene system gave separation of Li^+ from the other alkali metal cations as this dbm complex.[69]



Solid alkali metal complexes of hexamethylphosphoramide (hmpa) have been isolated and IR studies indicate coordination through the oxygen of the phosphine oxide.[70] Solution studies have also been carried out and show that hmpa coordinates to alkali metal cations in solution.[48] Rather interestingly a solution of sodium metal dissolved in hmpa gives, in the ^{23}Na NMR spectrum, a signal corresponding to Na^-.[71] This provided the first example of the generation of Na^- in a solvent in the absence of an added complexor; here the hmpa can itself coordinate to the Na^+ formed during dissolution.

23.2.2 Alkaline Earth Metal Complexes

The alkaline earth metal cations follow similar trends to the alkali metal cations in their complexation reactions with monodentate ligands. 'Hard', class 'a' donor atoms are preferred, and beryllium and magnesium show a greater tendency to form complexes than do their larger congeners.

The strong hydration of Be^{2+} can be explained by the formation of $[Be(H_2O)_4]^{2+}$ in which coordinate links with water are formed. This contrasts with, for example, Ba^{2+} where the molecular forces would be electrostatic in origin. The presence of the tetrahedral $[Be(H_2O)_4]^{2+}$ unit has been confirmed in the X-ray crystal structures of $BeSO_4 \cdot 4H_2O$[72] and $Be(NO_3)_2 \cdot 4H_2O$.[73] Solid hydrates have been obtained for $BeCl_2$ and $BeBr_2$, but not for the fluoride or iodide.[74] The product of direct hydration of $BeCl_2$ has been identified as a cyclic trimer, $\{[Be(OH)(H_2O)_2]Cl\}_3$, by IR and Raman spectroscopic studies.[75] The cationic unit is shown in (**3**). $BeF_2 \cdot 2H_2O$ has been suggested as the formula for the solution adduct, but attempts to isolate the compound led to HF and basic residues being formed. ^9Be NMR studies

support the existence of the dihydrate in saturated aqueous solutions. The species are prone to hydrolysis and this increases from the fluoride to the iodide; this hydrolysis has been reviewed by Bell[74] in a survey of the chemistry of beryllium halides, and a review of aqua complexes including Li, Be, Mg and Ca has recently appeared.[76] The predominate species in solution are affirmed as polymeric in nature: $[Be_2OH]^{3+}$ and $[Be_3(OH)_3]^{3+}$.[77]

(3)

A recurrent feature in the solid state chemistry of magnesium hydrates is the ready formation of $[Mg(H_2O)_6]^{2+}$. This is evidenced in many X-ray studies, *e.g.* $Mg(NO_3)_2{\cdot}6H_2O$,[78] $MgX{\cdot}6H_2O$ ($X = SO_3^{-}$[79], $S_2O_3^{-}$[80]), $Mg_2CdCl_6{\cdot}12H_2O$,[81] $MgCO_3{\cdot}3H_2O$[82] and $MgSO_4{\cdot}7H_2O$.[83] In this latter compound the seventh water molecule is readily lost at 48.3 °C. The tenacity of Mg^{2+} for its solvated water is illustrated in the formation of complexes such as $MgBr_2{\cdot}6H_2O{\cdot}2$caffeine[84] and $MgCl_2{\cdot}6H_2O{\cdot}12$-crown-4[85] in which the $[Mg(H_2O)_6]^{2+}$ unit is present and the second ligands are not coordinated.

About 150 examples of Ca^{2+}–H_2O interactions in crystalline hydrates of Ca^{2+} have been reviewed; higher coordination numbers are generally achieved in these species.[86] $CaX_2{\cdot}6H_2O$ ($X = Cl$, Br) have present a nine-coordinated cation ligated by both water molecules and halide anions;[87] $CaKAsO_4{\cdot}8H_2O$ has Ca^{2+} eight-coordinated by water molecules.[37] The complexes $CaCr_2O_7{\cdot}7H_2O{\cdot}2$hmt[88] and $CaBr_2{\cdot}10H_2O{\cdot}2$hmt[89] are both solvent-separated systems (hmt = hexamethylenetetramine). The cations have coordination numbers of seven and six respectively and the hmt ligand is too weak a donor to desolvate the cation. $CaCl_2{\cdot}4H_2O$ has present a seven-coordinated cation in which four water molecules and three chloride anions interact with the metal.[90] This involves sharing and the beginnings of the build-up of intricate networks. $BaCl_2{\cdot}2H_2O$ provides an example of such a network, the metal being eight-coordinated by four shared water molecules and four shared chloride anions,[91] as does $Ba(NCS)_2{\cdot}3H_2O$ wherein the cation has tricapped trigonal prismatic coordination sharing water and N-bonded thiocyanate anions to build up continuous chains.[92]

BeF_2 forms the ammine $BeF_2{\cdot}NH_3$ at −78.5 °C but this complex decomposes at higher temperatures; the formation of only a single, unstable ammine is in contrast with the behaviour of the remaining beryllium halides which form a series of ammine complexes increasing in stability with increasing weight of the halogen (Table 3).[1,74,93] The weaker donor power of alkyl- and aryl-amines, together with the introduction of steric constraints on complexation, is seen in the reactions of amines with BeX_2. Only $MeNH_2$ gives a tetramine complex with $BeCl_2$; related primary, secondary and tertiary amines give 1:2 adducts. Benzidine gives a non-chelated, binuclear complex $2BeCl_2{\cdot}3$benzidine. There appears to be no report of characterized amine complexes for $BeBr_2$ and BeI_2.[74]

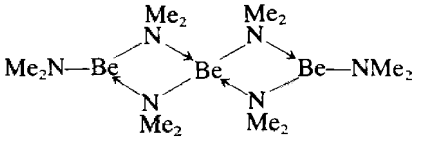


Table 3 Ammonia Complexes of Beryllium Halides

$BeF_2{\cdot}NH_3$			
$BeCl_2{\cdot}2NH_3$	$BeCl_2{\cdot}4NH_3$	$BeCl_2{\cdot}6NH_3$	$BeCl_2{\cdot}12NH_3$
$BeBr_2{\cdot}4NH_3$	$BeBr_2{\cdot}6NH_3$	$BeBr_2{\cdot}10NH_3$	
$BeI_2{\cdot}1.5NH_3$	$BeI_2{\cdot}4NH_3$	$BeI_2{\cdot}6NH_3$	$BeI_2{\cdot}13NH_3$

(The tetraammines are the most stable species; adducts having more than four NH_3 present are stable only at low temperature. The table is compiled from data given in ref. 74.)

Amine complexes have been used to facilitate the purification of BeH_2[94] and 1:1 species have been found using Me_3N and $PhCH_2NMe_2$.[95] The reaction of $BeCl_2$, NaH and Me_3N gave the complex $ClBeH{\cdot}Me_3N$ and this and the analogous BrBeH complex are dimeric in benzene solution having bridging hydrogen atoms.[96,97] If there is a reactive hydrogen present on the

amine used, then an elimination reaction is possible, yielding oligomeric products. BeH_2 and Me_2NH give the trimer $\{(Me)_2N)_2Be\}_3$ in which there are alternatively three- and four-coordinate beryllium atoms present (**4**).[98] The chemistry of alkylamidoberyllium compounds has been reviewed.[99,100]

(**4**)

Beryllium acetate has been found to give complexes of the type $Be(OAc)_2 \cdot 2L$ with ammonia and primary amines, and beryllium borohydride forms 1:1 complexes with primary amines.[101] IR studies on the complex $Be(ClO_4)_2 \cdot 2H_2O$ show it to be in the form $[Be(H_2O)_4]^{2+}[Be(ClO_4)_4]^{2-}$; at elevated temperatures $Be_4O(ClO_4)_6$ is formed from the dihydrate.[102]

Nearly all magnesium salts take up NH_3 and some of the resulting ammines are stable to loss of NH_3 on heating, *e.g.* $MgCl_2 \cdot 6NH_3$, and $Mg(ClO_4)_2 \cdot 6NH_3$. Aromatic amines can replace the ammonia in these compounds.[1] The stability of ammine complexes decreases down the group. X-Ray powder studies on $CaCl_2 \cdot 8NH_3$ and $CaCl_2 \cdot 2NH_3$ suggest that in the former the cation is contained in a distorted triangular prism of NH_3 molecules, and in the latter the cation is coordinated by an irregular octahedral array comprising two NH_3 and four, presumably shared, Cl^- anions.[103]

Beryllium halides form 1:2 complexes with monodentate heterocyclic aromatic nitrogen compounds (pyridine, *etc.*) as does $Be(NCS)_2$.[74] The X-ray structure of $MgBr_2 \cdot 6py$ reveals the cation as six-coordinated; there are two non-bonding pyridine molecules present as well as the four which coordinate.[104] Bis-pyridine and bis-imidazole complexes of bis(dinitrophenoxy)magnesium have been proposed as model complexes for the coordination of histamine in Mg-ATPases.[105] The cation is six-coordinated with the two pyridines occupying *cis* octahedral sites. Hydrazine acts as a monodentate ligand in the complex $BeCl_2 \cdot 4N_2H_4$ and the more bulky phenylhydrazine forms a 1:3 complex, together with a very unstable 1:4 species. $BeCl_2$ also forms a 1:4 complex with HCN, but only 1:2 adducts with RCN. With both ligand types, this is believed to be a consequence of increased steric constraint imposed by the substituted ligands.[74] $BeCl_2 \cdot 2L$ (L = MeCN, ClCN) have been synthesized by direct reaction of $BeCl_2$ and the nitrile;[106] the X-ray structure of $BeCl_2 \cdot 2MeCN$ reveals the metals to be in a distorted tetrahedral environment.[107] Ligand exchange occurs with nucleophilic species such as diethyl ether and benzonitrile and the metathetical reaction between $BeCl_2 \cdot 2MeCN$ and KSCN leads to the isolation of $Be(NCS)_2 \cdot 2MeCN$ and of $ClBeNCS \cdot 2MeCN$.[108] A ^9Be NMR study of $BeCl_2$ in MeCN shows the following species to be present in solution: $[BeCl_4]^{2-}$, $[BeCl_3 \cdot H_2O]^-$, $[BeCl_3 \cdot MeCN]^-$, $BeCl_2 \cdot 2MeCN$ and $[Be_2Cl_2 \cdot 4MeCN]^{2+}$.[109] Nitriles also give complexes of the types $MgBr_2 \cdot n MeCN$ ($n = 3, 4$) and $MgI_2 \cdot 6MeCN$. The complex $[Mg(Me(CN)_6]^{2+}[SnCl_4(NO_3)_2]^{2-}$ has been recovered from $Mg(NO_3)_2$–$SnCl_4$–MeCN and its nature established both in solution and in the solid state.[110]

Solid solvates such as $MgX_2 \cdot 6ROH$ ($X = Br^-$, NO_3^-, ClO_4^-; R = Me, Et) and $Ca(NO_3)_2 \cdot EtOH$ are believed to be charge separated in nature as is the more unusual mixed solvate $MgBr_2 \cdot 4THF \cdot 2H_2O$.[111–113] Solvated ion pairs have also been found for Group IIA cations and the structures of $MgBr_2 \cdot 2THF$,[114] $MgBr_2 \cdot 4THF$[115] and $MgBr_2 \cdot 2Et_2O$[116] show coordination numbers of six, six and four respectively for the cation. The sites are composed from anions and donors and so, for example, in $MgBr_2 \cdot 2THF$ the distorted octahedral geometry derives from two Mg—O, two Mg—Br (terminal) and two Mg—Br (bridging) bonds. Solvated organometallic complexes are also known; this aspect has been reviewed but a representative compound is $EtMgBr \cdot 2Et_2O$, which consists of discrete monomers with the bromide anion, ethyl group and two ether oxygen atoms tetrahedrally arranged around the magnesium.[117]

$BeCl_2 \cdot 2Et_2O$ has been extensively studied;[74] it may be prepared by reaction of anhydrous $BeCl_2$ and diethyl ether. A two-phase system is found in which the top layer is a solution of ether in the complex and the bottom layer is composed oppositely. The product is recovered on removal of the solvent. The crystal structure shows it to contain the cation in a distorted tetrahedral environment.[118] $BeBr_2 \cdot 2Et_2O$ is readily available, but although BeI_2 is soluble in ether no solid product has yet been recovered. THF and dioxane complexes of $BeCl_2$ are also known.[74]

It would be inappropriate not to mention the contribution made by the Leiden school to the development of techniques which have made available a wide range of metal complexes containing relatively weak donor molecules.[119] Using strictly anhydrous conditions and by reacting the required anhydrous metal salt with the ligand, species having the general formulae $M^{II}X{\cdot}6L$ and $M^{III}X_2{\cdot}6L$ have been prepared from such diverse ligands as ethanoic acid, ethanol, diphenyl sulfoxide, acetonitrile, nitromethane, methyl formate, 2-pyridone, acetaldehyde, THF, *etc.* For the alkaline earths mostly Mg^{2+} and Ca^{2+} have been used, although in some cases Sr^{2+} and Ba^{2+} have also been employed. An interesting synthetic stratagem in the above work has been to react the required anhydrous metal chloride with a Lewis acid such as iron(III) chloride, indium(III) chloride or antimony(V) chloride (usually as its nitromethane adduct) and with the appropriate ligand to give complexes of the type $MX_2{\cdot}6L$ ($X = FeCl_4^-$, $InCl_4^-$ or $SbCl_6^-$).

Beryllium halides have been found to form complexes with several aldehydes, ketones and esters.[74] Antipyrine, which acts as a monodentate carbonyl ligand, dissolves alkaline earth metal salts to give solid products of the type $MX_2{\cdot}6ap$ ($M^{2+} = Mg$, Ca, Sr; $X = ClO_4^-$; $M^{2+} = Mg$, Ca; $X = BF_4^-$). The X-ray structure of $Mg(ClO_4)_2{\cdot}6ap$ confirms the monodentation and shows the magnesium to be octahedrally coordinated.[120]

Magnesium and calcium complexes derived from triphenylphosphine oxide,[121] phenacyldiphenylphosphine oxide[122] and trishydroxymethylphosphine oxide[123] have been characterized. A study of the interaction of trioctylphosphine oxide with alkaline earth salts has shown that the order of extraction into an organic phase is $Be^{2+} > Ca^{2+} > Sr^{2+} \approx Mg^{2+} \approx Ba^{2+}$.[124] The low placement of Mg^{2+} is believed to be due to the exceptionally strong hydration of this cation. The metals are transferred as MX_2, 4 topo ($M^{2+} = Be$–Ba; $X = ClO_4^-$; $M^{2+} = Sr$, Ba; $X = SCN^-$). The extracted species for $Be(NCS)_2$ contains two or three ligands only. The crystal structures of $Mg(ClO_4)_2{\cdot}5Me_3PO{\cdot}H_2O$ and $Mg(ClO_4)_2{\cdot}5Me_3PO$ show that whereas in the former the cation is octahedrally coordinated by the mixed solvates, in the latter a square pyramidal geometry is found.[125] Exchange studies in d_2-CH_2Cl_2 led to the postulate that such complexes are formed by a dissociation of Me_3PO from a putative $[Mg(Me_3PO)_6]^{2+}$ species.[126]

NMR has been used to study ligand exchange in non-coordinating solvents for a series of $Be(ClO_4)_2{\cdot}4L$ (L = trimethyl phosphate, DMSO, DMA, DMF, NMA, 1,1,3,3-tetramethylurea, dimethyl methylphosphonate and dimethyl phenylphosphonate) complexes. ^1H NMR studies show that the mode of activation for exchange on beryllium varies from dissociative to associative depending upon L and the nature of the non-coordinating solvent.[127,128]

Pyridine *N*-oxide complexes have been prepared for Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, and arsine *N*-oxide complexes for Mg^{2+} and Ca^{2+}.[30] An X-ray structure of $Mg(ClO_4)_2{\cdot}5Me_3AsO$ shows the cation to be in a square pyramidal environment provided by the donor ligands; the charge separation and unusual geometry are believed to be a consequence of the electronic and spatial needs of the ligand.[129]

An interesting method of synthesis has been employed to produce $MgBr_2{\cdot}2HMPA$; the ligand is reacted with EtMgBr in Et_2O to produce unstable crystals of the product.[30] The pathway presumably is by displacement of the Grignard equilibrium. A complex of barium *p*-nitrobenzoate with DMSO has been synthesized and actually separated from DMSO with water present in the system.[130]

Amide complexes of alkaline earth metals have been prepared. The crystal structure of $MgBr_2{\cdot}4urea{\cdot}2H_2O$ shows the cation to be octahedrally coordinated to four urea and two water molecules.[131] In $CaBr_2{\cdot}6urea$ the cation is exclusively within the octahedral environment of urea donors, whereas in $Ca(NO_3)_2{\cdot}4urea$[132] and $Ca(NO_3)_2{\cdot}urea.\ 3H_2O$[133] there is a difference in environment. The cation in the former is linked to four urea molecules and two monodentate nitrates; in the latter bidentate nitrates are present and together with a urea and water molecule complete an eight-coordination around the cation. The last complex is not discrete but through sharing of donors and hydrogen bonding builds up a three-dimensional array. A survey of urea–cation interactions is available.[134] The compound formed from the reaction of $Ba(ClO_4)_2$ with DMA has been shown to be the bimetallic complex, bis-μ-(DMA)-bis(aqua-tris-DMA-barium) tetraperchlorate. Each barium is eight-coordinated by three terminal DMAs, one water molecule, two monodentate perchlorates and two bridging DMA molecules.[135a] Thiourea complexes of the type $CaX_2{\cdot}6TU$ ($X = Cl^-$, I^-) have been reported.[65] The interaction of Ca^{2+} with glycine and glycylglycylglycine parallels that of Na^+ in that the zwitterionic form of the ligand is used. The structure of $CaBr_2{\cdot}3glycine$[135b] shows two independent Ca^{2+} cations each linked to six oxygens from the glycine and a bromide anion. The two coordination polyhedra are then edge-linked to provide a dimer having each Ca^{2+} in a distorted pentagonal bipyramidal geometry. The structure of $CaCl_2(Gly\text{-}Gly\text{-}Gly){\cdot}3H_2O$ has

each cation linked to donors from four different peptides in a much more complicated network structure.[135c]

$BeCl_2$ does not dissolve in H_2S; weak 1:2 adducts of H_2S with $BeBr_2$ and BeI_2 have, in contrast, been obtained at low temperatures.[74] Solutions containing adducts of beryllium halides with thioethers have been prepared and $BeCl_2{\cdot}2Me_2S$ has been isolated. The complexes $BeCl_2{\cdot}3R_2S$ (R = Me, Et, Bu^i) have been obtained as needles at low temperatures. Thioamide and thiourea compounds of $BeCl_2$ have been obtained as 1:2 complexes; steric factors are believed to preclude the formation of 1:2 complexes when symmetrically and asymmetrically substituted thioureas are used as donors.[74] Only a few phosphine complexes are known; $Be(BH_4)_2$ forms 1:1 complexes with Ph_3P, Me_3P, Me_2PH and Et_3P, all of which are monomeric in benzene. $Be(BH_4)_2{\cdot}Me_3P$ will add further phosphine but with accompanying decomposition to give $Me_3P{\cdot}BH_3$.[136]

The possibility of forming complex anions is also open to alkaline earth metals. There is an abundant literature concerning fluoroberyllates and this has been reviewed.[74,93] Much work concerns phase distribution in molten mixtures, although fluoroberyllates can be prepared in, and isolated from, aqueous solution. The fluoroberyllates may be compared with silicates: $[BeF_4]^{2-}$ is analogous to orthosilicate $[SiO_4]^{4-}$; $[Be_2F_5]^-$, which has double networks of BeF_4 tetrahedra infinite in two directions, is rather like the Si–O network in dimetasilicates;[137] and $[Be_2F_7]^{3-}$ with two BeF_4 tetrahedra linked at one corner resembles pyrosilicate.[138]

The sequence of halide complexes is shown to be $F^- \gg Cl^- > Br^- > I^-$ which is as expected if the complex formation is due to electrostatic forces. Consequently, the chloroberyllates are formed only under anhydrous conditions. In the alkali metal tetrachloroberyllates there is a distortion of the $[BeCl_4]^{2-}$ tetrahedron on going from the sodium to the lithium salt.[74] The addition of hydrogen halide to anhydrous $BeCl_2$ produces the liquid complexes $HBeCl_2X{\cdot}2Et_2O$ (X = Cl, Br); pyridine can replace the ether molecules to give a complex formulated as $[py\cdots H\cdots py]^+[BeCl_2X]^-$.[139]

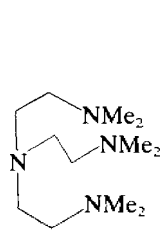
A similarity between BeF_4^{2-} compounds and the corresponding sulfates has been established. In general, the solubilities of the salts are similar, and double salts such as $M_2^IBeF_4{\cdot}6H_2O$ are available.[1] The aqueous chemistry of the haloberyllates has been reviewed.[140]

Other anionic complexes of beryllium that have been detected are $(NH_4)_2Be(NO_3)_4$,[141] $(NH_4)_2Be(NCS)_4{\cdot}MeCN$ and $(NH_4)_2Be(NCS)_3{\cdot}MeCN$.[142] ESCA studies on beryllium and magnesium complexes of the type $[M(NCS)_4]^{2-}$ and $[M(CNS)_3L]^-$ (L = DMF, py, MeCN) are consistent with N-bonding thiocyanate anions being present.[142] The structure of $K[Be(NH_2)_3]$ shows the beryllium to be in a trigonal planar unit.[143]

Although various complex magnesium halides have been identified from Raman spectra of mixed salts melts, $(NEt_4)_2MgCl_4$ is the only reported salt containing a complex halide anion. Vibrational spectroscopic studies have shown the anion to be tetrahedral.[144] Studies on Cs_2MgCl_4, Cs_3MgCl_5 and Rb_3MgCl_5 have also shown the presence of discrete $[MgCl_4]^{2-}$ anions, and in melts of high $MgCl_2$ concentration $[Mg_2Cl_7]^{3-}$ has been found in equilibrium with $[MgCl_4]^{2-}$.[145] The crystal structure of tachyhydrate, $Mg(H_2O)_6CaCl_6$, shows it to consist of discrete $[Mg(H_2O)_6]^{2+}$ cations and octahedral $[CaCl_6]^{2-}$ anions.[146] A brief survey of species available from melts involving strontium has been given.[147]

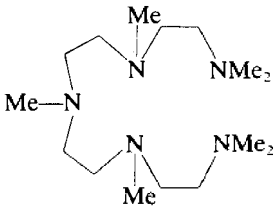
A large number of organometallic derivatives of alkali and alkaline earth cations, particularly those of Li, Be and Mg, form coordination complexes involving monodentate ligands.[32] For Li and Mg, these are primarily oxygen donor ligands such as THF and Et_2O. There is an extensive coordination chemistry of Be compounds of the types BeR_2, BeRR′ and RBeX.[32b] The degree of association has been explored for these complexes and steric effects are of paramount importance in influencing the degree of coordination to the beryllium. For Me_2Be a stability sequence of N > O > P, S > As is found and in general there are few complexes of the last three donors. Be—C bonds are polar and so are susceptible to protolysis; it is preferable to use ligands devoid of acidic hydrogens otherwise, even at low temperature, an elimination of hydrocarbon occurs to give Be donor atom bonds. As an example of Re_2Be complexation, R_2Be form 1:2 complexes with pyridine, but only 1:1 complexes with Me_3N. This is seen as a manifestation of steric problems; furthermore if 2-methyl pyridine is used as a ligand only a 1:1 complex results.[32b]

23.3 NEUTRAL ACYCLIC POLYDENTATE LIGANDS



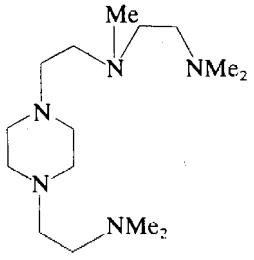
A diverse range of acyclic polydentate ligands has been used to form complexes with alkali and alkaline earth metal cations. For convenience of description these ligands have been subdivided into anionic and neutral species.

23.3.1 Nitrogen Donors



1,2-Diaminoethane (en), which can be regarded as the simplest bidentate ligand of this type, is capable of dissolving various inorganic salts to produce solvates such as LiCl·2en, LiBr·2en, LiI·3en, NaI·3en, $NaClO_4$·3en, $CaCl_2$·6en, $SrCl_2$·6en and $BaCl_2$·6en.[148] $BeCl_2$·en has also been prepared,[149] and in all of these compounds the en may be viewed as paralleling the behaviour of ammonia, or water. The structures of LiCl·2en[150] and LiI·3en[151] reveal the cation to be tetrahedrally and distorted octahedrally coordinated respectively. In the former complex the Li^+ is coordinated by four nitrogens from three en molecules; one en is chelating (*gauche*) and the other two are monodentate (*trans*) and bridging to produce infinite columns. In LiI·3en the ligands are chelating only. This mode of bonding is also seen in $Ba(SbSe)_2$·4en in which the cation is eight-coordinated.[152]

It has been noted that the complexes M(picrate)$_2$·*n*en (M^{2+} = Mg, Ca; $n = 1, 2$) can be prepared in EtOH, and that the IR spectra show bands *ca.* 1900 and 2500 cm^{-1} indicative of $NH_2 \cdots$anion interactions. Such an effect is general and has also been noted in the complexes LiX·*n*en (X = Cl^-, Br^-; $n = 2$; X = I^-; $n = 3$). Conformational studies on these complexes reveal that the ligand is in the *gauche* and *trans* forms in LiX·2en and only in the *gauche* form in LiI·3en; this is as found in the X-ray structures.[30]



Polyethylene polyamines are available as mixtures of isomeric and homologous compounds; by using inorganic salts of alkali and alkaline earth metals individual polyamines have been selectively complexed from several multicomponent samples.[153] Commercial polyamine mixtures containing primary and secondary nitrogens, as well as their *N*-permethylated tertiary amine counterparts can be separated *via* metal complexation, complex isolation and subsequent complex destabilization leading to product recovery. One example of differential selectivity is found with tetramethylcyclohexanediamine where the *trans* isomer complexes with LiBr, but the *cis* isomer prefers $MgCl_2$·$6H_2O$. Other solid complexes found include NaI·L [L = *iso*-HMTT (**5**), *n*-HMTP (**6**)] and LiCl·L [L = *N,N'*-c-PMPP (**7**), *sym*-c-TMTT (**8**)] which are isolated and used in the separation of permethylated tetramine and pentamine mixtures. With mixtures containing primary and secondary amines, complex formation often varied with reaction time. Commercial trien (**9**) generally contains about 75% of the linear (**9**) and about 8% of the branched tetramine tren (**10**). The remainder is composed of other tri- and tetr-amine isomers. With NaBr the complex isolated after five minutes was essentially pure NaBr·tren; after 75 minutes the complex isolated was mainly NaBr·trien. Similar results were obtained using LiBr. In general in these reactions, complexation was favoured for salts of low lattice energy.

(10)

The crystal structure of the complex LiBr·pmdeta [pmdeta = permethylated (**11**)] reveals a dimeric association in the solid state; each Li^+ cation is five-coordinated by the three nitrogen donors and by two bridging bromide anions. The bridging —Li_2Br_2— unit is non-symmetric,

and the cation is in a distorted trigonal bipyramidal geometry in which the three nitrogen donors are coordinated facially, with one axial and one equatorial bromide anion. The complex was formed by salt elimination in the reaction of Bu^nBr and Bu^nLi·pmdeta.[154] Solid complexes of alkaline earth metal cations with (**11**) have been characterized as $[M(\mathbf{11})_3]^{2+}X_2$ (M^{2+} = Ca, Sr, Ba; X = ClO_4^-, Br^-, I^-). The cation is proposed as being nine-coordinated.[155]

(**11**)

Permethylated diamines and triamines have also been used for the complexation of organometallic derivates of groups IA and IIA.[32,156] This is because of the absence of acidic protons. Well-defined complexes have been isolated in a number of instances and several have been characterized by X-ray structural analysis. *N,N,N′,N′*-Tetramethylethylenediamine (TMEDA) has been used to monomerize alkyllithium clusters, and Bu^nLi·TMEDA is used extensively as a reagent for lithiation in non-polar media. The structure and binding of N-chelated alkali metal complexes have been reviewed.[156] Many of the structures are of contact ions pairs in which the metal is coordinated to the di- or tri-amine and to the carbanion. Consequently the structures have been of great value in giving information on the nature of carbanion–metal interactions. The systems studied are diverse and a representative collection are given in Table 4. In these examples all of the donor nitrogen atoms coordinate the metal; in the cyclopentadienyl complex, $[(Me_3Si)_3C_5H_2]$Li·pmdeta the cyclopentadienyl ring is

pentahapto-coordinated to the metal but only one pair of chelating nitrogen donors is involved in binding to the metal, the third nitrogen remaining non-coordinated (Figure 1).[157] A pentahapto cyclopentadienyl ring is also found in the structure of (cyclopentadienyl)-MgBr·teeda (teeda = *N,N,N′,N′*-tetraethylethylenediamine) (Figure 1).[158] The area of organoalkaline earth metal complexes has been comprehensively reviewed.[32b,c]

Early work by Pfeiffer,[23] who isolated crystalline complexes of *o*-phen with the perchlorates of Li^+, Na^+, Ca^{2+}, Sr^{2+} and Ba^{2+}, has been resurrected from obscurity and the results have recently been reconsidered. The range of complexes was extended and the role of the anion and the potential protonation of the anion discussed.[30] *o*-Phenanthroline has also been used to generate M^{2+} complexes and structural studies show the chelating ability of the ligand. Complexes of the type $M(ClO_4)_2$·4phen·$4H_2O$ were characterized and it was suggested that all four phen ligands were associated with the metal. IR and X-ray studies reveal that even for the larger cations the complexes are correctly assigned as $[M(phen)_2(H_2O)_4](ClO_4)_2$·2phen with, in the case of Sr^{2+} and Ba^{2+}, the metal in an eight-coordinated environment and two of the phen molecules non-coordinating.[159] The structures of Na(onp)·2phen and Rb(onp)·2phen (onp = *o*-nitrophenolate) show that in each complex both phen ligands coordinate to the metal. The sodium complex is monomeric, but the rubidium complex dimerizes *via* a nitro group oxygen donor.[160] Bis(2,4-dinitrophenolato)barium·3phen[161] and bis(2,4,6-trinitrophenolato)-barium·2phen·acetone[162] both contain bidentate phen; in the former the Ba^{2+} is nine-coordinated through the three phen molecules, a phenolic oxygen and a nitro oxygen from the anion and a phenolic oxygen from the other; the latter has Ba^{2+} eight-coordinated to the two phen molecules, the acetone oxygen, the phenolic and nitrooxygens from one anion and a phenolic oxygen from the other. The structures of $Ca(NCS)_2$·2bipy·H_2O and *catena*-$Ba(NCS)_2$·2bipy[163] have shown that the Ca^{2+} is seven-coordinated, with N-bonded thiocyanates present, and that the Ba^{2+} is eight-coordinated *via* the six nitrogen donors and two sulfur atoms from adjacent molecules leading to catenation.

In $M(hfacac)_n$ salts, where the coordinating ability of M^{n+} is enhanced by the presence of the fluorinated ligand, addition of further donor atoms leads to coordinative saturation of the central metal. Li(hfacac) forms Li(hfacac)·TMEDA[164] which also exists as the mono- and di-hydrates;[165] Li(hfacac)·phen and Na(hfacac)·phen·H_2O are also available.[165] A comparative study of the role of increasing trifluoromethylation in magnesium β-diketonates shows that whereas $Mg(hfacac)_2$, $Mg(tfacac)_2$ and $Mg(acac)_2$ all form 1:1 complexes with phen and bipy, only the fluorinated compounds yield 1:1 complexes with en, dmen (*sym* and *asym*), TMEDA and dben (dmen = dimethylethenediamine, dben = *N,N′*-dibenzylethylenediamine).[166] $Ca(hfacac)_2$bipy and $Ca(hfacac)_2$phen·H_2O have been isolated[165] and although the complexes have been studied by IR and ^1H NMR, no solid-state structural information is available.

The use of ^7Li, ^{23}Na, ^{39}K and ^{133}Cs NMR allied with ^{13}C NMR has shown that in nitromethane, bipy interacts with M^+ in the sequence $Li^+ > Na^+ > K^+$. Cs^+ does not appear to interact and for Li^+, $[Li(bipy)_2]^+$ was identified.[167]

An interesting area of study was provided by the ligands *rac-p,p'*-diaminodiphenylbutane (DDB)[27] and *p,p'*-methylene-dianiline (MDA).[168] These were the first ligands found to precipitate NaCl from aqueous solution and so were of interest in the potential desalination of brine. IR studies suggested the presence of the then unusual Na–N interaction and this was later confirmed by X-ray studies on the NaCl·3L complexes. The cation was shown to be approximately octahedrally coordinated by six donor nitrogens from separate ligands. The structures therefore consist of columns of cations and anions interspersed with the amino groups to give infinite repetition of the contacts. Each ligand, having two amino functions, can bind to two cations.[169,170]

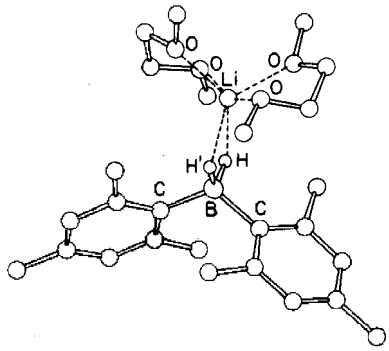
23.3.2 Oxygen Donors

The interaction of oxygen-containing acyclic ligands with alkali and alkaline earth metal cations has provided a burgeoning area of interest. In historic terms, this was preceded by the advent of crown ethers and the accompanying almost retrospective look at their acyclic precedents. This section is sub-divided into five parts: simple chelates, metal complexes as ligands, podands, polypodands and sugars.

23.3.2.1 Simple chelates

The simplest chelates of this type, ethyleneglycol (eg) and 1,2-dimethoxyethane (glyme-2), give complexes with alkali and alkaline earth metal cations. The complexes $MX_2 \cdot 2eg$ (M^{2+} = Mg, Ca; X = NO_3^-), $MX_2 \cdot 3eg$ (M_2^+ = Mg, Ca; X = Cl^-, Br^-), $CaX_2 \cdot 4eg$ (X = Cl^-, Br^-) and $SrBr_2 \cdot 2eg$ have been isolated and IR studies suggest that the majority are likely to contain monodentate eg.[171,172] The Sr^{2+} complex is, however, believed to have bidentate eg present. $Mg(hfacac)_2$, $Mg(tfacac)_2$ and $Mg(acac)_2$ all form 1:1 complexes with eg; the IR shows the latter to be different and it was suggested that a bridging bis-monodentate eg might be present giving a species related to Na(bzacac)·eg.[166] The X-ray structure of this sodium complex shows the eg to be bridging two sodium cations.[22]

1,2-Dimethoxyethane (glyme-2) also forms complexes and several have been found as a consequence of the use of glyme-2 ('monoglyme') as a solvent medium in many diverse reactions involving M^{n+}.[30] In this context, problems were found in the potential use of glyme-2 with Grignard reagents as precipitation of MgX_2·glyme-2 occurs readily, disturbing the Grignard equilibrium and rendering the system unsuitable.[173] Glymes are weak coordinators and generally require stringent conditions for synthesis. $M(SbCl_6)_2$·glyme-2 (M^{2+} = Mg, Ca) complexes have been prepared under anhydrous conditions and using the glyme as a solvent; the complexes are derived from anhydrous MCl_2 and $SbCl_5$ is added to act as a Lewis acid so generating a bulky anion.[174] Glyme-2 complexes with organometallic species have been proposed and discussed[32] and the chelating potential of the ligand is revealed in the structure of Li(dimesitylborohydride)2glyme-2 wherein the chelated cation also interacts with the hydrogen atoms of the anion (Figure 2).[175] Lithium alkoxide has been found to be dimeric in glyme-2 and is believed to have the formulation (**12**).[176] Beryllium halides have also been shown to give 1:1 complexes with glyme-2, and with the thioether analogue.[74]



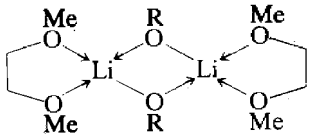


Figure 2 The molecular structure of Li(dimesitylborohydride)·2(glyme-2) (reproduced with permission from reference 175)

(12)

Phosphine oxides, phosphoramides, diacetamide and related species form alkali and alkaline earth metal complexes.[30] The chelation of alkali metal halides with $Ph_2POCH_2POPh_2$, and of NaI with $R_2POCH_2POR_2$ (R = Bu, BuO and *p*-$MeOC_6H_4$) and $Ph_2POCH_2PO(OEt)CH_2POPh_2$ has been followed conductometrically.[177] The structure of $NaBr{\cdot}3(Ph_2POCH_2POPh_2)$ shows it to be a charge-separated species with the six-coordinated cation in a chair-shaped trigonal prismatic geometry. Phenacyldiphenylphosphine gives 1:1 complexes with LiBr and LiCl but here the bonding is believed to be monodentate only.[122]

Octamethylpyrophosphoramide (ompa) has been shown to loosen ion pairs in solution[178] and a 1:3 complex has been isolated with $Mg(ClO_4)_2$. The crystal structure shows that the ligand is bidentate and chelates to the cation through the phosphine oxide oxygens.[179]

Diacetamide has been widely used as a ligand and a number of alkali and alkaline earth metal complexes have been characterized.[30] Neither $KI{\cdot}2DA$[180] nor $NaBr{\cdot}2DA$[181] is charge-separated, the metal interacting with the cation and two chelating DA molecules. DA complexes can be prepared in solution, or by solid reaction; this event suggests caution in using KBr discs for running IR spectra of putative ligands. The salts forming complexes with DA were those with less than 64% ionic character, or differing by two units in electronegativity.[180] With M^{2+} salts, there is a range of stoichiometries in complexes with DA and the coordination number increases from Mg^{2+} to Ba^{2+} (Table 5).

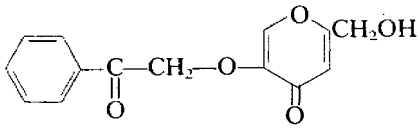

Table 5 Alkaline Earth Cation–Diacetamide Complexes

Complex	*Coordination Number*	*Donor Species*	*Ref.*
$Mg(ClO_4)_2{\cdot}4DA{\cdot}2H_2O$	6 (octahedral)	2 DA, 2 H_2O (axial)	a
$Ca(ClO_3)_2{\cdot}4DA{\cdot}H_2O$	8 (square antiprism)	4 DA	b
$CaBr_2{\cdot}4DA$	8 (square antiprism)	4 DA	c
$Ca(ClO_4)_2{\cdot}5DA$	8 (square antiprism)	4 DA	d
$Sr(ClO_4)_2{\cdot}4DA{\cdot}H_2O$	9 (monocapped square antiprism)	4 DA, H_2O	e
$Ba(ClO_4)_2{\cdot}5DA$	10 (symmetrical bicapped square antiprism)	5 DA	f

These complexes are all charge-separated, in contrast to the alkali metal complexes which are ion-paired.

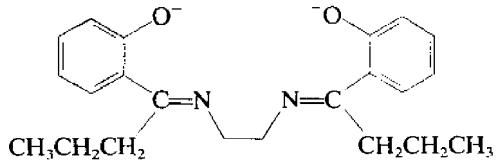
Phenacyl kojate (**13**) was found to form crystalline NaX complexes during its preparation in MeOH.[182] These complexing properties were investigated more fully[183] and the ligand was found to give the complexes MX·PK with CsBr, CsI, RbI, NaNCS, KNCS, RbNCS and CsNCS, and the complexes MX·2PK with NaCl, KCl, RbCl, CsCl, NaBr, KBr, RbBr, NaI and KI. Factors influencing the stoichiometries were discussed and later generalizations suggest that MX·2PK should be charge separated.[21] The structures of $KI{\cdot}2PK$,[184] $CsSCN{\cdot}PK$[185] and $NaI{\cdot}2PK{\cdot}2H_2O$[186] have been solved. The K^+ is eight-coordinated through three tridentate PK molecules and two oxygen atoms from the CH_2OH of adjacent molecules; the Cs^+ is also eight-coordinated due to extensive bridging between the cation, ligand and anion in adjacent molecules; and the Na^+ is six-coordinated through one tridentate and one monodentate PK as well as two water molecules.

(13)

Dimethyl phthallate acts as a neutral bidentate ligand towards Ca^{2+} and Mg^{2+};[187] the cations are linked to three ligands using both carbonyl groups to give regular octahedral geometry. A large counteranion such as $[InCl_4]^-$ is required. A 1:2 complex is formed between *o,o'*-catecholdiacetic acid and KCl.[188] This has a complicated layer structure in which the cations are enclosed by 10 oxygen atoms, sandwich fashion, in an irregular pentagonal antiprismatic geometry.



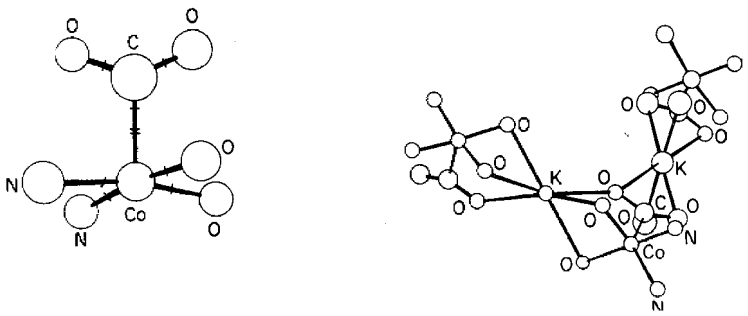
23.3.2.2 Metal complexes as ligands

Metal complexes have been found to be capable of acting as ligands for alkali and alkaline earth metal cations. In particular, metal complexes of tetradentate Schiff bases (TMSB) such as H_2salen can use the residual lone pairs on the oxygen atoms as donors.[189] Complexes of the type $[(TMSB)_2M^+ \cdot x(solvent)]X^-$ and $[(TMSB)_2MX \cdot solvent]$ have been isolated from mixtures of the components. The first group have $[B(C_6H_5)_4]^-$ as the counterion and are charge-separated; X-ray structures of $\{[Co(salen)]_2Na \cdot 2THF\} \cdot BPh_4$,[190] $\{[Ni(salen)_2]Na \cdot 2MeCN\} \cdot BPh_4$[191] and $\{[VO(salen)]_2Na\} \cdot BPh_4$[192] furnish this evidence with the Na^+ being six-coordinated to the TMSB and solvent in the first two instances, and six-coordinated in a cationic polymeric structure in the latter. The second group have ClO_4^- as the counterion and are ion-paired. X-Ray structures again provide the evidence; $\{[Cu(salen)]_2NaClO_4 \cdot p\text{-xylene}]$[193] and $\{[Ni(acen)]_2NaClO_4\}$[194] have present Na^+ in a distorted octahedral site generated by the TMSB and a bidentate perchlorate anion. The complex $\{[Co(salen)]_2NaCo(CO)_4 \cdot THF\}$ has been synthesized by reaction of NaCo(salen) with CO and shown by X-ray studies to be a complexed ion pair in which the Na^+ is octahedrally coordinated to two TMSB ligands, the THF and to one carbonyl of the $[Co(CO)_4]^-$ anion.[195] In the alkaline earth metal complex $\{[Cu(salen)] \cdot Mg(hfacac)_2\}$ the Mg^{2+} is octahedrally coordinated to the TMSB and the two hfacac anions.[196]

Reduction of Co(salen) with Li or Na in THF leads to the isolation of the bimetallic complexes Co(salen)Na·THF or Co(salen)Li·1.5THF, which are active in CO_2 carriage.[197] The structure of the former consists of infinite chains of the monomer unit $\{[Co(salen)]_2Na_2 \cdot 2THF\}$ with distorted octahedra around the Na^+ cations sharing opposite faces and with both THF and Co(salen) acting as bridging ligands. The lithium species has present two different complexes, $\{[Co(salen)]Li \cdot 2THF\}$ and $\{[Co(salen)]Li \cdot 2THF\}$ and $\{[Co(salen)]_2Li_2 \cdot 2THF\}$ in 2:1 ratio. In the first the Li^+ is in a distorted tetrahedral environment and in the second one of the THF molecules is replaced by a Co(salen) oxygen atom which then acts in a bridging capacity. This class of complex is active in the bifunctional activation of CO_2, and provides reversible CO_2 carriers. The structure of $\{[Co(pr\text{-}salen)]K \cdot CO_2 \cdot THF\}$ has been solved and shows the K^+ coordinated by the TMSB, THF and CO_2 in a dimeric repeat unit (Figure 3). One K^+ is six-coordinated to two CO_2 and two THF molecules and the second K^+ is bound to two bidentate pr-salen units and to two oxygen atoms of two CO_2 molecules. Each CO_2 molecule shares one oxygen between two K^+ ions.[198] The structure of the corresponding Na^+ complex is also available and the general principles of the reaction have been elucidated and discussed.[199] The alkali metal acts as a Lewis acid centre, helping to hold the CO_2 in close proximity to the basic cobalt centre.

$$Co(L)K + CO_2 \overset{THF}{\rightleftharpoons} [Co(L)KCO_2THF]$$

L =



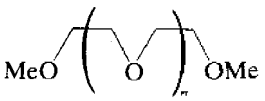


Figure 3 The repetitive unit of polymeric (Co(pr-salen)K·CO_2·THF) and the coordination sphere around the cobalt (reproduced with permission from reference 198)

Alkaline earth metal salts, such as the perchlorates, are also complexed by TMSB,[189] and isolated species such as bis(2-amino-2-hydroxymethyl-1,3-propanediolato(1 −)O,N)-copper(II)·sodium perchlorate·H_2O[200] have also been found.[30]

23.3.2.3 Podands

In a historic context, podands should be preceded by crown ethers and coronands (*vide post*) and much of the work carried out on podands was stimulated by studies on the macrocyclic analogues. Podands have the advantage of relatively facile syntheses, using neither dilution nor template procedures, to provide inexpensive materials of versatile ligand structure. In contrast to macrocycles though, they form complexes of relatively low stability; the hexadentate pentaethyleneglycol dimethyl ether ('pentaglyme'; glyme-6) is found to have a 10^4-fold drop in stability from the cyclic 18-crown-6 in its reaction with K^+, and of 10^3 in its reaction with Na^+.[33] This effect has been termed the 'macrocyclic' effect and was explained originally in terms of entropy factors and later in terms of enthalpy changes coupled with solvation effects.[201] A 'macrobicyclic' effect also operates on going from mono- to bi-cyclic macrocycles.[202]

In keeping with the low stability constants, isolable alkali and alkaline earth metal complexes of acyclic oligoethylene glycols and their ethers, the 'glymes', were unknown until recently although solution studies had given information on probable stoichiometries. Studies on the complexation of difluorenylbarium with glymes[203] of varying chain lengths revealed that glyme-7 (**14**; $n = 5$) and glyme-9 (**14**; $n = 7$) gave 1:1 complexes which were mixed tight and loose ion pairs of the type fluorenyl$^-$ Ba^+/glyme/fluorenyl$^-$. Glyme-5 (**14**; $n = 3$) was further able to form a 1:2 complex, hinting that glyme-10 (**14**; $n = 8$) should give a 1:1 separated ion pair complex. Complexation is generally enhanced on increase of chain length.

(**14**)

Glyme complexes of M^+ with bulky anions present have been known for some time and tended to arise as a consequence of work in, and recrystallization from, a particular glyme solvent, *e.g.* $[M(diglyme)_2][Ta(CO)_6]$, $[M(diglyme)_2][Mo(CO)_5I]$[204] and $[K(diglyme)][Ce(cot)_2]$.[205] The structure of the latter shows the K^+ coordinated by the diglyme (glyme-3) molecule and by one of the cot rings (Figure 4). The complexes $[M(glyme\text{-}4)_2][SbCl_6]_2$ (M^{2+} = Ca, Sr) have been isolated, and IR studies indicate octacoordination of the metal by the glymes.[206] In $[Mg(glyme\text{-}4)_2][SbCl_6]_2\cdot 2H_2O$, however, the ligand is proposed to act as a tridentate donor, particularly because of the limited space around the Mg^{2+} cation.

The parent glycols have also been studied, particularly in solution and in connection with their possible role in the template synthesis of crown ethers.[33] Crystalline complexes have been isolated in certain instances and the structures of Ca(picrate)$_2$·glycol-5·H_2O,[207] $Sr(NCS)_2$·glycol-8[208] and $Sr(NCS)_2$·glycol-7[209] have been solved. (Glycol-5 is $HO(CH_2CH_2O)_nH$, $n = 4$, *etc.*) The Sr^{2+} complexes show the metal to be coordinated by the

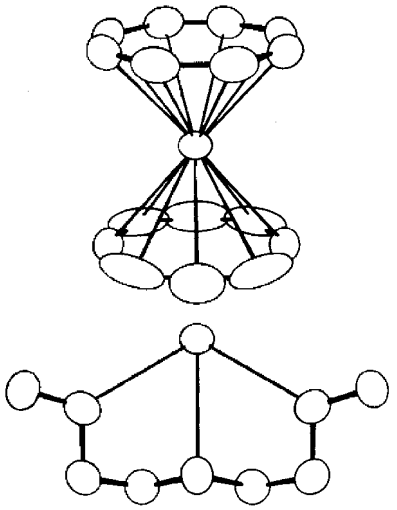

Figure 4 The molecular structure of [K(diglyme)][Ce(cot)$_2$] (reproduced with permission from reference 205)

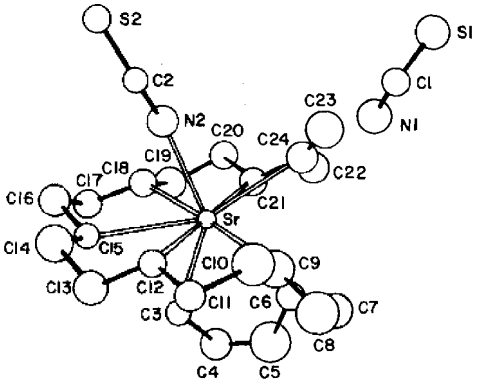
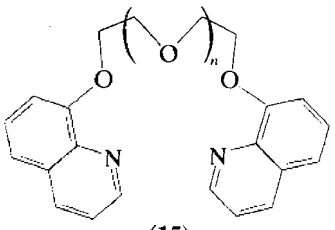
eight donors of glyme-8, and one NCS^-, and by the seven donors of glyme-7, and two NCS^- respectively to give nine-coordination in each case with the ligand wrapping around the metal in a helical fashion (Figure 5). In the Ca^{2+} complex, the five glycol donor atoms, one phenoxide oxygen, one nitro oxygen and a water molecule give a distorted square antiprismatic cation environment.





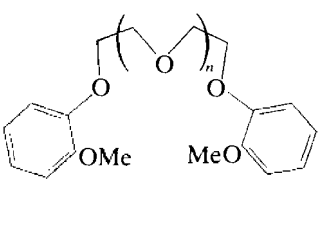


Figure 5 The molecular structure Sr(NCS)$_2$·glycol-7 (reproduced with permission from reference 209)

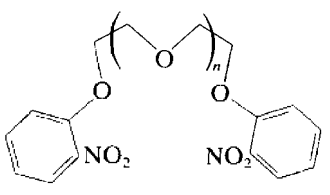


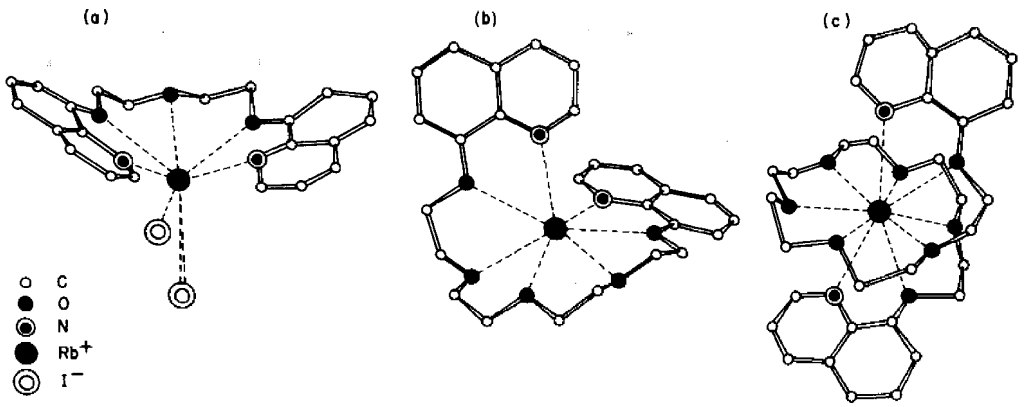
The attachment of rigid terminal groups such as substituted aromatic rings to the oligo-ethylene glycol units affords neutral ligands which now readily form stable complexes with alkali and alkaline earth metal cations.[33] Many terminal groups have been used, such as 8-quinolyloxy (**15**), methoxyphenoxy (**16**) and *o*-nitrophenoxy groups (**17**). These groups function as anchorage points with locally fixed donor centres on which the cation can take hold. If a polymethylene chain is used, then only a limited ability to form complexes is demonstrated. Symmetrical and non-symmetrical podands of the above type may be synthesized extending the range and versatility of the ligands.

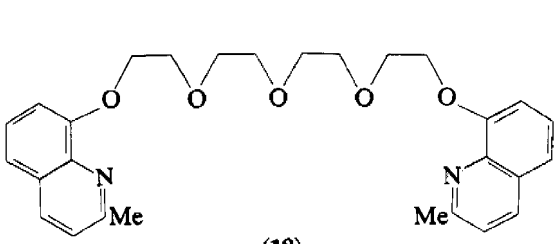
(**15**)
(**a–g**; $n = 0$–6)

(**16**)
(**a–d**; $n = 0$–3)

(**17**)
(**a–d**; $n = 0$–3)

The stoichiometries of the complexes formed from podands are usually precise. For example (**15d**) always gives a 1:1 complex with KNCS regardless of the mole ratio of ligand to salt.[210] X-Ray structures are now available for several of these complexes of open-chain ligands. One useful series has been that concerning complexes based on (**15**). Models of the ligand (**15d**) suggested that participation of all seven heteroatom donors in coordination to a central cation would lead to a screw-shaped arrangement of the ligand and this would allow the ligand to wrap around an ion of appropriate radius in a helical fashion, thus providing a plausible model for acyclic ionophores (*vide infra*).[210] The complexation of Rb^+ by the podands (**15b**),[211a] (**15d**)[212] and (**15g**)[213] is illustrated in Figure 6.





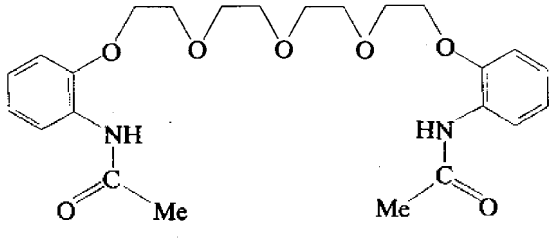


Figure 6 The complexation of Rb^+ by podands; the molecular structures of complexes derived from: (a) (**15b**), (b) (**15d**) and (c) (**15g**) (reproduced with permission from reference 33)

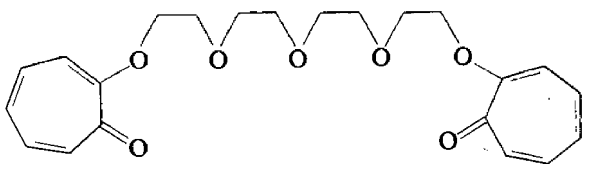
The structure of the complex involving (**15d**) confirms the expected geometry, affording a helical arrangement of the donors around the cation; the complex is also charge-separated. The M—O bond lengths are not all equivalent and the variations are ascribed to the differing donor strengths of aliphatic and aromatic oxygen donors (~2.88–2.99 Å and ~3.07–3.09 Å respectively). The chain is too long to enclose the Rb^+ in a planar donor array, but the major part of the donor array is fixed close to a plane. This helical arrangement is replaced in the shorter (**15b**) ligand by an approximately planar array of donor atoms. These are 'butterfly-folded' and reminiscent of the shape found in the dibenzo-18-crown-6·RbNCS complex (*vide infra*). The ligand is pentadentate and two iodides per cation participate alternately in the complexation. With the decadentate ligand (**15g**), a spherical wrapping of the Rb^+ occurs with the heteroatoms on the surface of a sphere of ~3.0 Å radius. The iodide ions lie in cavities between the 'spheres' and the eight oxygen atoms of the ligand are coiled around the cation in the equatorial plane with the quinolyl moieties coordinating from above and below this plane.



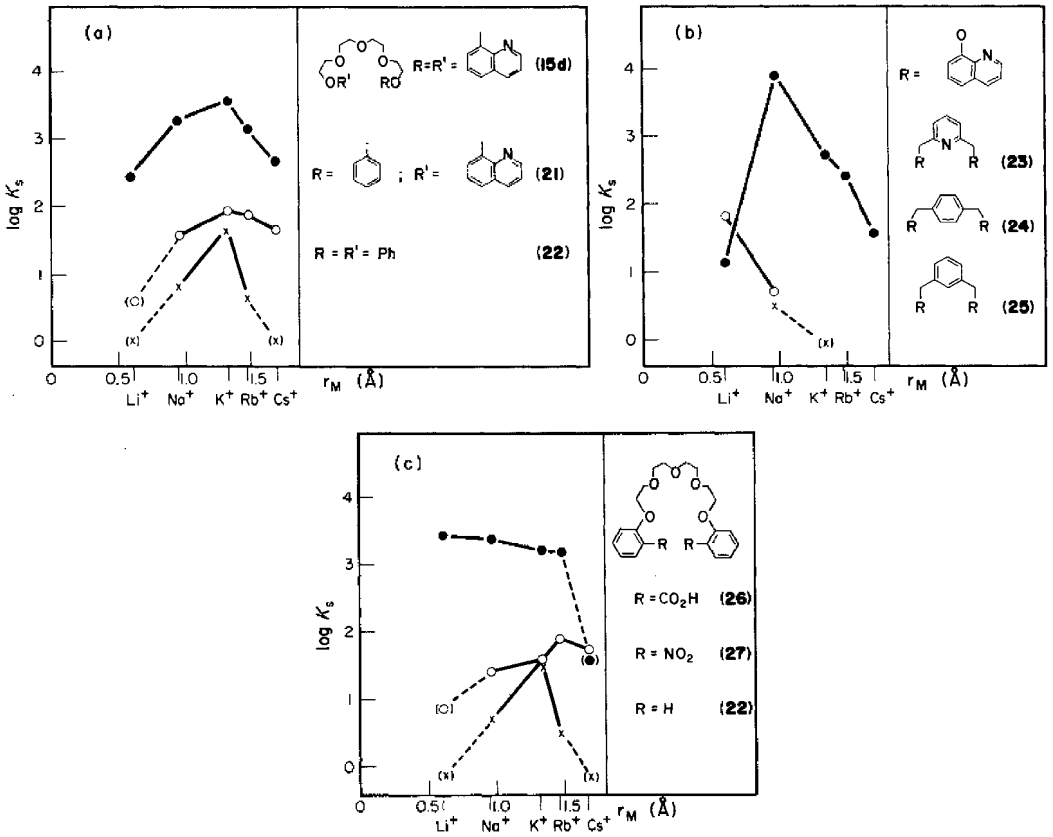
The structure of the related complex (**18**) RbI[211b] shows a significant difference in ligand conformation compared to that in (**15d**) RbI. The heptadentate ligand is arranged as a continuous helix, due presumably to steric hindrance to planar inclusion of the cation by the methyl groups. A continuous helix is also found in the structure of (**16c**) NaSCN,[214] in which the Na^+ is coordinated to all six donors of the ligand and to the thiocyanate anion which lies above the helix. Similar wrap-around structures are found for (**17d**)KSCN,[215] {(**19**)KSCN}$_2$·H_2O[216] and (**20**)RbI.[217]

(**18**)

(**19**)

(20)

NMR studies have proved useful in the identification of complexation in solution in these systems.[33] In the ^1H NMR of complexes of podands with rigid terminal groups pronounced changes are seen in the splitting patterns of the aromatic region on complexation. The structure of **(15d)**RbI is in full accord with the upfield shift found for the heterocyclic terminal units. This area of study shows much promise for the future with the availability of multinuclear NMR techniques. Studies have also been made on the selectivity between metals, and on the stability of the complexes. Examples of the effects of loss of terminal group, the introduction of rigid ligand spines and the variation of the terminal group are shown in Figure 7.



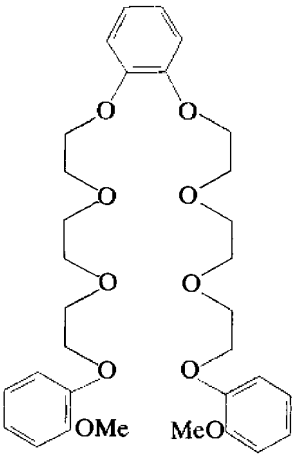


Figure 7 Stability constants (log K_s) of various podand alkali metal complexes as a function of ionic radius: (a) stepwise loss of terminal groups; (b) ligands with stiffened chains; (c) variation of terminal group (reproduced with permission from reference 33)

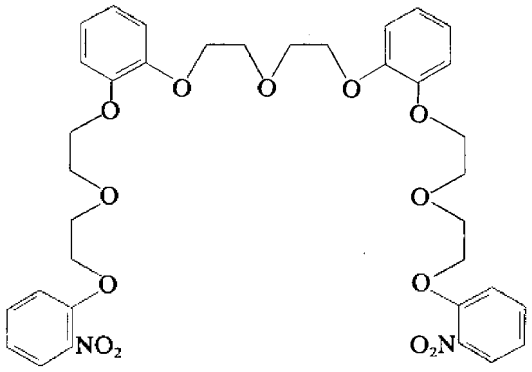
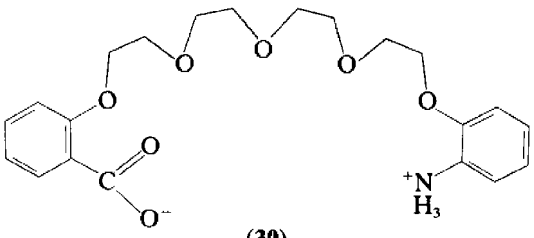


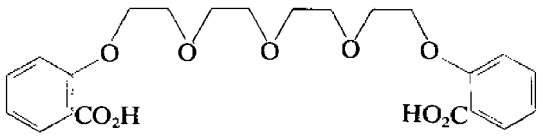
In the first instance, a relatively small K^+/Na^+ discrimination is maintained (Figure 7a) but stiffening the spine leads to a movement towards the selectivity of individual cations (Figure 7b). Changing the terminal group (Figure 7c) can also introduce a more individual selectivity and also a plateau selectivity.[33] When the quinolyl terminal group is present, then Mg^{2+} complexes are more stable than are the other alkaline earth complexes. This is anticipated from the known propensity of 8-hydroxyquinoline for magnesium.

The process of complexation is believed to occur through the stepwise incorporation of the ligand, *i.e.* stepwise replacement of the existing solvation, or hydration, sheath. The process is likely to be entropy controlled and entropy increases have been noted in thermodynamic studies on these systems.[33]

When the chain length is dramatically increased, as in (**28**), podands are available which could imitate the helical ion channels believed to be available in membranes and so give information on the selective transfer of cations across such barriers. This type of ligand shows pronounced transfer of inorganic salt into organic phases and NMR studies indicate a likely helical coordination of the cation.[33,218] Complexes have been isolated and the structure of (**29**)2KNCS has been solved.[219] In this molecule, the podand wraps, in an S-shaped manner, within the dinuclear complex, and contains a KNCS unit within each loop of the S shape.



(**28**)



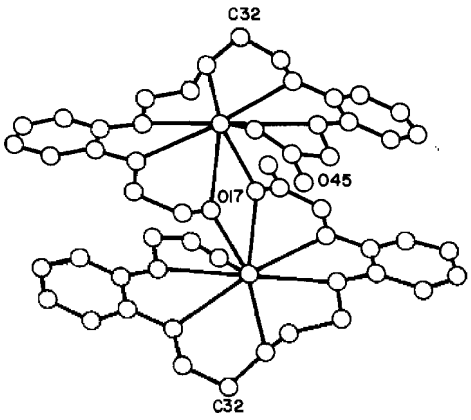
(**29**)

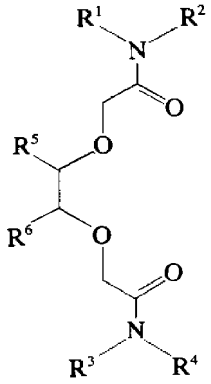
Interactions between terminal groups are of interest, as in the natural ionophores terminal linkage through hydrogen bonding readily occurs to produce a pseudo-macrocyclic structure (*vide infra*). Although the existence of such a link is not yet found in podands, amino-to-carboxy bonding has been found in the $NaClO_4$ complex of (**30**).[220] This ligand is zwitterionic in solution, and in the structure of the complex one of the NH_3^+ hydrogen atoms forms an internal hydrogen bond to a carboxylate oxygen atom. The dicarboxylic acid (**31**) forms a series of crystalline complexes with alkali metal salts in which the ligand acts as a neutral species.[221] However, contrary to expectation the crystal structure of the K(picrate) complex revealed a dimeric unit with no internal, or 'head-to-tail', hydrogen bonding present. Each unit of the dimer is arranged spirally and contains its K^+ in an irregular eight-fold coordination. One carboxyl oxygen from the monomer serves as a bridging unit and binds to the second K^+ (Figure 8).[222]

(**30**)

(**31**)

A family of podands containing as terminal groups variously substituted amides, and having a wide range of linking chains have been developed as sensors for particular alkali and alkaline earth cations.[223] Particular emphasis has been directed towards Ca^{2+} and Li^+; for example, a selectivity for Li^+ over other alkali, and alkaline earth cations, in membranes, of the order of 100 and 1000 respectively is induced by *cis-N,N,N',N'*-tetraisobutylcyclohexane-1,2-carboxamide.[224] The cation selectivity is dependent mainly upon the nature and number of coordinating sites, the nature of the chain termini and the choice of solvent. In general, divalent cations are preferred over monovalent cations with increasing polarity of both the ligand skeleton and the dielectric constant of the solvent phase.[33,224] Comparative studies have





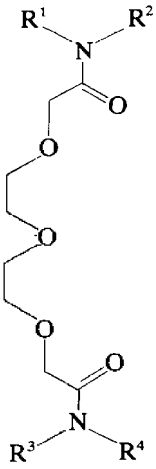


Figure 8 The molecular structure of potassium picrate (**31**) dimer (reproduced with permission from reference 222)

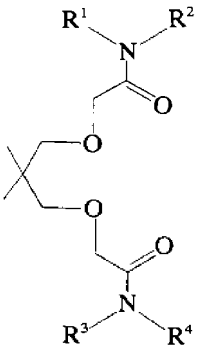
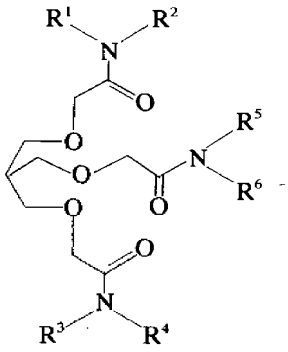


shown (**32a**) to be an Na^+-selective ionophore,[225] (**32b**) a Ca^{2+}-selective ionophore[226] and (**33**) a Ba^{2+}-selective ionophore.[227] The Na^+ ionophore (**35**), in which the tripodal arm helps adaptation of the ligand to the cation size, discriminates against K^+ cations sufficiently strongly to allow its use in intracellular studies under physiological conditions.[228]



(**32**) **a**; $R^1 = R^2 = R^3 = R^4 = CH_2Ph$, $R^5 = R^6 = H$

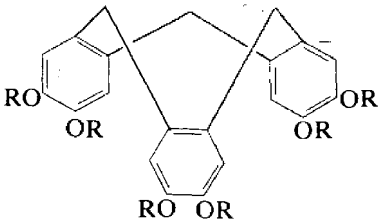
(**35**) $R^1 = R^3 = R^5 = Me$, $R^2 = R^4 = R^6 =$ heptyl

These comparatively lipophilic ligands have been conceived as ion carriers for systems such as ion-selective electrodes,[229] therefore they do not have high stability constant values, but require fast complexation kinetics in order to achieve rapid equilibration. Nevertheless, it has been possible to recover crystalline species which often have present additional water molecules to help stabilize the crystal lattice. Coordinative participation of the carbonyl oxygen

atoms, which was indicated by ^{13}C NMR studies,[230] was confirmed in the solid state by IR studies and by crystal structure analysis of (**32e**)$_2$CaCl$_2$.[231] The Ca^{2+} is coordinated to four ether oxygen atoms and four carbonyl oxygen atoms from the pair of symmetrically equivalent ligands and is in a trigonal dodecahedral environment.



23.3.2.4 Polypodands

Polypodands are many-armed neutral ligands. The first described were a series of compounds bearing several donor-containing 'tentacles' attached to a benzene ring *via* sulfur atoms, and reminiscent of octopuses, (**36**).[232] The compounds show phase transfer properties towards cations and (**33a**) transfers alkali and alkaline earth picrates efficiently from aqueous solution into dichloromethane. This phase transfer is inhibited by reducing the number of available donor sites by shortening the tentacles (**36b**) or by reducing the number of tentacles present on the aromatic nucleus.[33] Similar properties are exhibited for hexapodands derived from cyclotriveratrylene (**37**),[233] but if a more rigid central unit is introduced then loss of activity occurs (**38**).[233] Similarly loss of activity is found if the oxygen-free hexasubstituted benzenes are examined.[232]

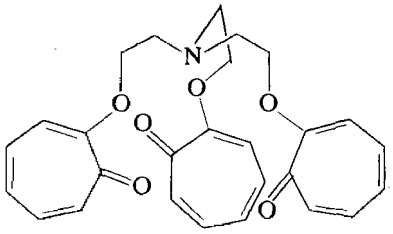
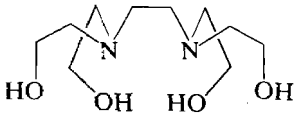
Strict stoichiometries have been found for alkali and alkaline earth metal complexes of triethanolamine (te), and 2,2′,2″-trimethoxytriethylamine (tmt). The crystal structure of NaI·tmt consists of discrete molecules in which the Na^+ is pentacoordinated by the heteroatoms of one ligand and by the iodide anion.[234] In the structure of NaI·te each sodium cation is seven-coordinated by the four heteroatoms of one ligand, the iodide anion and two oxygen atoms of a neighbouring ligand.[235] Two OH groups of each molecule bridge two sodium cations and so the structure is catenated. The structure of Sr(NO$_3$)$_2$·2te has present an eight-coordinated cation, the cubic environment arising from the eight heteroatoms of the ligands,[236] and in Ba(MeCO$_2$)$_2$·2te[237] the cation is bonded to the eight heteroatoms of the two ligands and an acetate oxygen donor. A predominate 1:1 complexation has also been noted in alkali and alkaline earth metal complexes of the related tetra- and penta-podands (**42**, **43**); even addition of excess BaI$_2$ to (**43**) gave only the 1:1 complex. This type of compound has been viewed as an example of fundamental facile recognition and selectivity processes on a molecular level.[238]

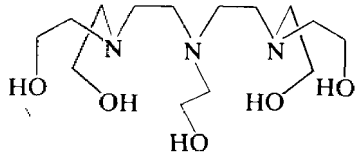
Many polypodands having terminal donor groups are also available, *e.g.* (**39**)–(**41**).[33] These also exhibit cation complexation and phase transfer properties. KMnO$_4$ and aqueous alkali metal picrates are much more readily taken into organic phases in the presence of these podands than with dibenzo-18-crown-6.[239] The KSCN complex of (**39**) exhibits a novel coordination geometry as all 10 donor atoms participate in coordination of the metal cation, and in order to do this the three arms wrap around the cation in a propeller-like fashion.[240]



In terms of selectivity (**40**) selects Na^+ over K^+ and Li^+, but also has a high selectivity for the divalent cations Sr^{2+} and Ba^{2+}. The ligand (**41**) has an even higher complexing capability for the alkaline earth metal cations and a BaI$_2$ complex is isolable whereas a KNCS complex is not. The ligating differences presumably arise from the inability of the pseudocavity produced on complexation to allow suitable contact with the metal cation by the donor atoms. Ligand–ligand interactions also induce steric constraint to complexing small cations.[239]

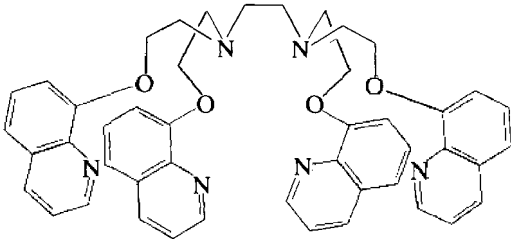


(39) R = H, OMe, NO_2

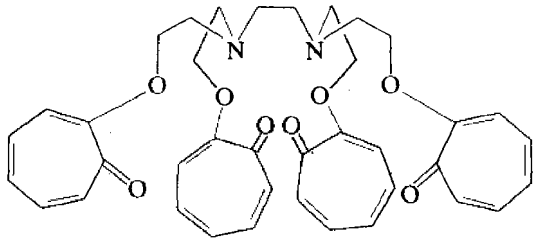


(40)

(41)



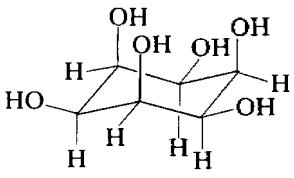
(42)



(43)

The stability constants of the corresponding tetrapodands (**44**, **45**) are generally lower than those for the tripodands, presumably because of more severe steric hindrance to complexation.[241]

(44)



(45)

23.3.2.5 Carbohydrates

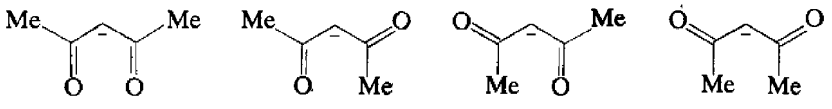
The complexation of M^{n+} by carbohydrates is now well known.[242] The conditions that influence such complexation have been discussed at length, as have complexation processes in solution with particular reference to NMR studies.[243] Structural aspects of calcium–carbohydrate interactions have also been reviewed.[244]

This area of study has been stimulated by information that sugars and related species can help in the transfer of M^{n+} across membranes.[245] The studies made have generally been concerned with conformational aspects of ligand behaviour under the influence of the cation rather than the nature of the coordination of the metal.[30].

The essential bonding mode of sugars is *via* the hydroxyl groups, and complexation in solution is due basically to the presence of three sequential hydroxyl groups in a *cis–cis* state for a five-membered ring, and an *ax–eq–ax* state for a six-membered ring. These sequences give, for solution complexation, a required equilateral triangle of donor atoms for the cation and favourable entropy factors. In the solid state where lattice packing factors become important, just the pairs of adjacent hydroxyl groups are involved with the cation.[30] If these criteria are not met, as in D-glucose, the sugar is non-complexing. *cis*-Inositol (**46**) with three *ax–eq–ax*, which can act jointly with three axial hydroxyl groups, serves as an example of an alkaline earth metal complexor.

(46)

The first sugar complex structure to be solved was NaBr·sucrose·$2H_2O$, in which the Na^+ is six-coordinated through the water molecules and hydroxyl groups from three different sugar molecules, and is paired with the bromide anion.[246] This extensive sharing is a feature of the solid state chemistry and the X-ray structures of Ca^{2+} carbohydrate complexes reveals the cation to be seven- or eight-coordinated, as in the hydration of Ca^{2+} in the solid state.[244] Representative structures are those of $CaBr_2$·(D-lactose)·$2H_2O$,[247] $CaBr_2$·(α-D-galactose)·$3H_2O$[248] and $CaBr_2$·(myoinositol)·$5H_2O$,[249] in all of which the cation is eight-coordinated in a square antiprismatic geometry. This environment is produced by the water molecules and hyroxyl groups from different sugars. $CaBr_2$·(α-D-fructose)·$3H_2O$ has a reduced coordination number of seven, but a similar environmental build-up.[250]



Two unusual Ca^{2+} complexes are $CaCl_2$·(β-D-fructose)$_2$·$3H_2O$, in which a 1:2 complex is found,[251] and $CaCl_2$·(β-D-mannofuranose)·$4H_2O$, in which the sugar is triply chelating through sequential hydroxyl groups.[252] Unequivocal coordination of Sr^{2+} in sugar systems is known through structural analysis of $SrCl_2$·(epiinositol)·$5H_2O$; the cation is nine-coordinated by four water molecules, one bidentate and one tridentate ligand.[253] For Mg^{2+}, $MgCl_2$·(myoinositol)·$4H_2O$ has been investigated crystallographically and has the cation coordinated to the water molecules and two *cis* hydroxyl groups of the inositol in an octahedral arrangement. In this latter complex the cation is part of an essentially discrete molecule;[254] however, there is an extensive hydrogen bonding network present which leads to an effective extended array.

23.4 ANIONIC ACYCLIC POLYDENTATE LIGANDS

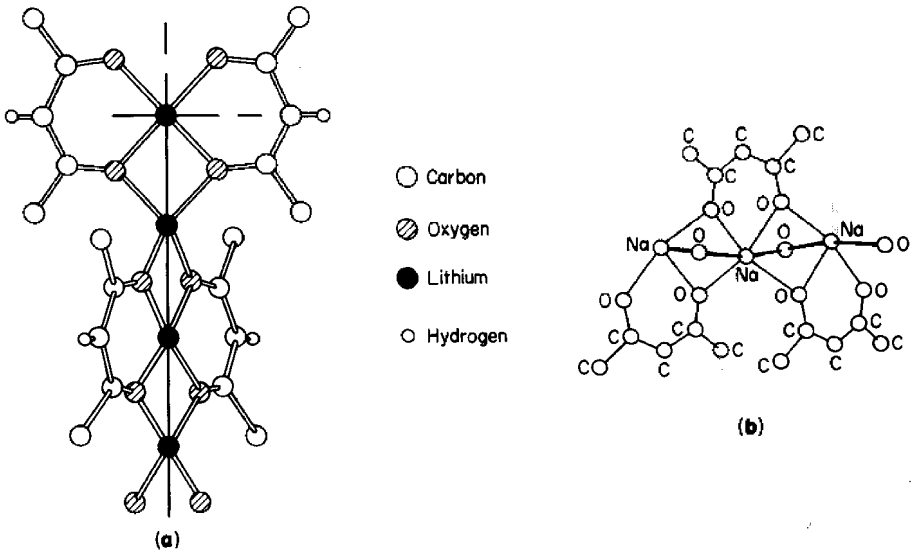
23.4.1 β-Diketonates

The coordination of β-diketonates and related species to alkali and alkaline earth cations has long been recognized. Combes first prepared $Be(acac)_2$ in 1887,[255] and the contribution of Sidgwick and Brewer concerning the nature of dihydrated alkali metal β-diketonates plays a seminal role in the development of this area of coordination chemistry.[19] A review concerning the structure and reactivity of alkali metal enolates has been written,[256] and sections on alkali and alkaline earth β-diketonates can be found within more generalized accounts of β-diketone complexes.[257,258]

2,4-Pentanedione (acetylacetone, acacH) forms strong complexes with alkali metal cations, even in polar media. The stability constants fall in the sequence Li > Na > K > Rb > Cs and this is in keeping with the decreasing ionic potential of the cation.[259] ^1H NMR studies have given similar evidence for the strength of the M^+—$acac^-$ ion pair. Li^+ tends to be completely chelated and Na/Li exchange can be detected when $LiClO_4$ is added to Na(acac). At low concentrations of Li^+ with respect to acacH an anionic species $[Li(acac)_2]^-$ exists in solution; in the presence of excess cation the species $[Li_2(acac)]^+$ is found.[30,98] The $acac^-$ ion can exist in four conformations (**47**); small cations which enforce chelation arrest the anion in the *Z,Z* form whereas larger cations which form weak ion pairs allow *E,Z*, *Z,E* and *E,E* formation. For example, the $acac^-$ in Na(acac) can be converted, in DMF[260] or pyridine,[261] to the *E,E* isomer by addition of 18-crown-6 which complexes the Na^+ and removes the 'ion-pairing' potential of the cation by generating a 'large' cation.

(47)

X-Ray crystal structures have been carried out on Li(acac), Na(acac)·H_2O, K(acac)·0.5H_2O and Na(bzac)·eg and show contrasting features. The lithium derivative is composed of chains of $[Li(acac)_2]^-$ anions linked to Li^+ cations; the anions are square planar and the cations tetrahedral in that coordination environments and the cations are bonded to pairs of oxygen atoms from neighbouring anionic units (Figure 9a).[262] The Na(acac)·H_2O structure consists of zigzag chains of Na^+ cations bridged by two water molecules and acac units; the Na—O bonds to the water molecules are slightly longer (2.42 Å) than those to the anionic oxygen atoms (2.31 Å chelated and 2.38 Å bridging) (Figure 9b).[263] The movement towards polymeric lattices is further evidenced in the structure of K(acac)·0.5H_2O, where the cation is surrounded by seven oxygen donors, six from four different $acac^-$ units and one from the water molecule.[264] Although the structure of a dihydrate is not yet available, that of the somewhat analogous Na(bzac)·eg has been determined. The structure is again polymeric with the glycol acting as a bidentate, non-chelating ligand. The cation is five coordinated in a square pyramidal environment consisting of the β-diketonate, two oxygens from bridging glycols and a shared oxygen from a neighbouring chelating anion.[22]



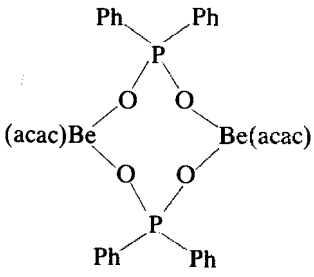


Figure 9 The molecular structures of (a) Li(acac) and (b) Na(acac)·H_2O (reproduced with permission from references 262 and 263)

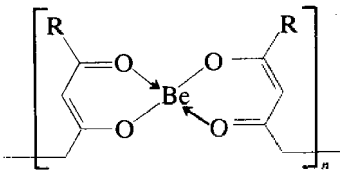
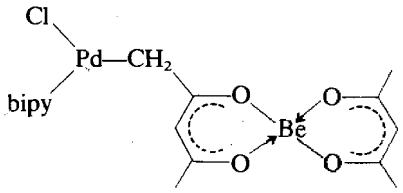


The alkaline earth metal β-diketonates follow similar stability trends to those of the alkali metals: Be > Mg > Ca > Sr > Ba, with beryllium β-diketonates having extensive covalent character.[259] The crystal structure of $Be(acac)_2$ shows a discrete molecule bearing a tetrahedral beryllium atom,[265] and an electron diffraction study shows retention of this shape in the gas phase.[266] The tetrahedral arrangement of the bonds was first demonstrated in the 1920s.[267] Beryllium complexes such as $Be(bzac)_2$ should exist in optically active forms and resolution into the optical antipodes has been achieved on active quartz, or by coprecipitation.[268,269] Oxy-bridged polymers containing beryllium β-diketonates can be found (**48**), as can coordination polymers derived from bis(1,3-dicarbonyl) compounds (**49**).[93,257] The reaction of N_2O_4 in benzene, or 'acetyl nitrate' generated *in situ*, with $Be(acac)_2$ leads to the introduction of the nitro group in the 3-position and bromination at the same position is obtained using *N*-bromo–succinimide.[270]

Heterobinuclear complexes have been formed between PdCl(acac-C_1), bipy and $Be(acac)_2$.[271] The palladium compound retains an acid character and so replacement of an $acac^-$ from the $Be(acac)_2$ gives a product which can be formulated as (**50**) from MW and ^1H NMR studies.



For the heavier alkaline earth β-diketonates, X-ray studies are available for $Mg(acac)_2·2H_2O$, $Mg(dpp)_2·2DMF$, $Ca(acac)_2·3H_2O$, $Ca(dpp)_2·0.5EtOH$ and $Sr(dpp)_2·0.5$acetone (dpp = 1,3-diphenyl-1,3-propanedione). $Mg(acac)_2·2H_2O$ is *trans* octahedral with the water molecules occupying axial positions; the bond lengths to the axial and equatorial oxygen atoms are different (2.15 and 2.03 Å).[272] In contrast $Mg(dpp)_2·2DMF$ is *cis* octahedral with a similar difference in bond lengths between the $acac^-$ and DMF oxygen to sodium bonds (2.06 and 2.10 Å).[273] $Ca(acac)_2·3H_2O$ is a discrete molecule having *cis* octahedral geometry with the

third water molecule non-coordinating; here the bond lengths become comparable: Ca—O (acac) = 2.32 Å, and Ca—O(H_2O) = 2.36 Å.[274] Ca(dpp)$_2$·0.5EtOH is a tetrameric polymer in which there are two calcium environments, one six- and one seven-coordinate. The former site is built up of dpp oxygen donors and the latter also has present the EtOH. Each Ca^{2+} shares two oxygens with each of two neighbouring Ca^{2+} atoms of the other kind such that four are linked around a centre of symmetry (Figure 10.).[275] Sr(dpp)$_2$·0.5acetone is also a tetrameric polymer having six- and seven-coordinate strontium present.[276] Unusually, perhaps, the acetone is preferred to ethanol which was the bulk medium of recrystallization.

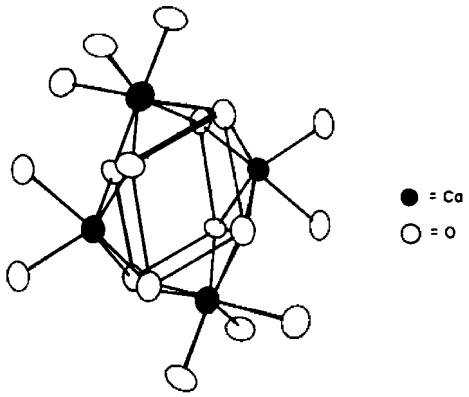

Figure 10 The calcium environment in Ca(ddp)$_2$O·5EtOH (reproduced with permission from reference 275)

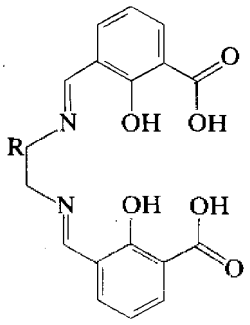
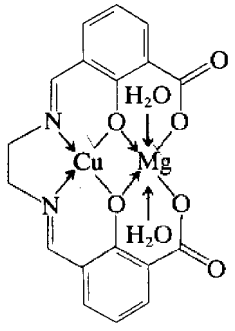
^{1}H NMR studies have been carried out on BeL_2, MgL_2, CaL_2, and BaL_2 (L = acac, bzac), and on Mg(dpm)$_2$.[277] These show Mg(acac)$_2$, Ca(acac)$_2$ and Ba(acac)$_2$ to be polymeric in solution, but the others are monomeric and tetrahedral. The polymeric nature of M(acac)$_2$ has also been detected in the gas phase by mass spectrometry.[278]

The reaction of neutral donor ligands with metal β-diketonates to effect coordinative saturation has been commented on in Section 23.3.1. If an enolate ion is added to a neutral metal β-diketonate, then an anionic complex results.[165,279,280] Two types of complex have been reported: (i) $(M^+)_m[M^+(hfac)_n^-]$ ($m = 1$ or 2; $n = 2$ or 3) and $M^+[M^{2+}(\beta\text{-diketonate})_3]^-$, and (ii) $TMNDH^+(M^{n+}(hfac)_m^-)$ ($m = 2$, 3 or 4). In the mixed metal complexes, the metal having highest charge density attracts the enolate anion. This is evidenced in the crystal structure of $Rb_2[Na(hfac)_3]$, which is isomorphous with $Cs_2[Na(hfac)_3]$.[280] The lattice contains $[Na(hfac)_3]^-$ anions in which the Na^+ is six-coordinated to the enolate anions. The Rb^+ cations interact with both O and F atoms on the top of the trigonal prism, giving a rare example of an alkali cation coordinated by a halogen. Exchange reactions between alkali metal β-diketonates within the ion source of a mass spectrometer also gave species such as $M^1M^2L_2^+$ and $M_2L_2^+$.[281]



For the second group of complexes, the structure of $TMNDH^+[Mg(hfac)_3]^-$ ($TMNDH^+$ = monoprotonated 1,8-bis(dimethylamino)naphthalene) is determined and shows the Mg^{2+} octahedrally coordinated by the anions.[282] It is likely that the structure of $NaMg(acac)_3$ is also of this type.[283]

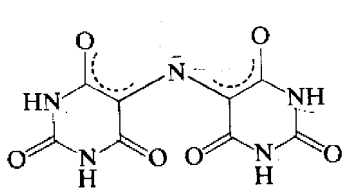
Neutral diketone complexes are not generally available and so it is of interest to find $Mg(ClO_4)_2$·2acacH·2H_2O. The keto form of the ligand has been shown to predominate in the complex in solution, by use of ^{1}H NMR, and although exchange between free and complexed ligand is fast, the keto–enol tautomerization is slow.[284]



Complexes of related species such as keto acids, keto esters, and acetoacetanilides are known, particularly for beryllium.[93,270,285,286,287] Bromination and nitration studies have been carried out on a wide range of *N*-substituted *N*-acetoacetamides of beryllium and show introduction of bromo and nitro groups at the 3-position.[285,286]

Heterobinuclear complexes containing alkali or alkaline earth metal cations have been derived from mononuclear transition metal complexes of compartmental ligands (**51**).[288] The molar conductivities of the (**51**)–$CuLi_2$ series suggest that the complexes are uniunivalent electrolytes in water and so are present in solution as $Li[(\mathbf{51b})CuLi]\cdot nH_2O$; the corresponding di-sodium, -potassium or -cesium complexes are unibivalent electrolytes and so likely to be present in solution as $M_2[(\mathbf{51})Cu]\cdot nH_2O$.

For the alkaline earth metals, only the Mg^{2+} complexes were soluble enough to allow a conductivity determination in methanol. A non-electrolyte was indicated and suggested that the species was dinuclear with Mg^{2+} in the outer cavity (**52**). This is confirmed by the X-ray structure[289] which shows two *trans* water molecules helping to achieve coordinative saturation.

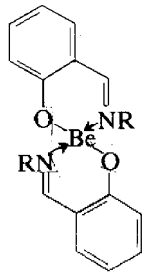


(**51**) **a**; R = H
b; R = Me

(**52**)

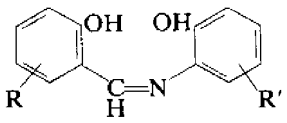
There is a considerable colour change on adding M^+ or M^{2+} to the copper precursors; CuLi and CuMg complexes are red, and as the size of the added metal ion increases, there is a steady reversion to the violet colour of the mononuclear copper(II) complex. This can also be traced by electronic spectroscopy and is viewed as a steady movement away from occupancy of the outer compartment by the second metal.[288]

The purpurate anion (**53**) has a mononegative charge delocalized over more than one donor atom.[30] The kinetics of its complexation with alkali metal cations have been reviewed.[290] The structures of several purpurates have been solved and the ligand consistently acts as a tridentate ligand. However, a variety of bonding modes are exhibited with the cation and polymeric structures resulting.[30]



(**53**)

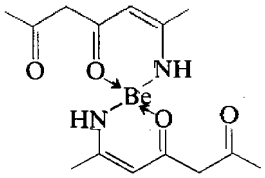
23.4.1.1 Schiff base complexes



In contrast to the extensive coverage of transition metal Schiff base complexes, there is a somewhat desultory presentation of alkali and alkaline earth metal complexes of these ligands.

Bis(*N*-alkylsalicylaldiminato)beryllium complexes (**54**) have been prepared and their physicochemical properties studied. Dipole moment[291,292] and ^1H NMR studies[393] are interpreted in terms of a tetrahedral environment for the beryllium. ^1H NMR studies on the magnesium and calcium analogues are similarly interpreted. The free energy of enantiomerization has been determined for (**54**; R = isopropyl) using NMR techniques and without needing resolution of the optical antipodes;[294] the inversion has been proposed as proceeding *via* a dimerization step.[295] The fluorescent properties of a range of beryllium chelates have been monitored with a

view to developing reagents for the determination of beryllium.[296] The complexes are formulated as having 1:1 stoichiometry and the ligands are of the general type (**55**).

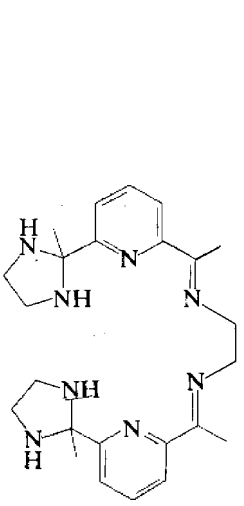


(**54**)

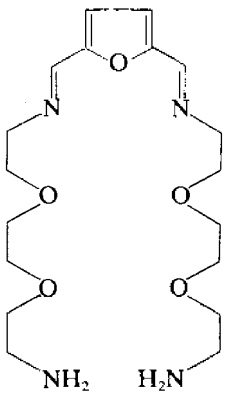
(**55**)

The structure of bis(salicylaldoxime)beryllium has been proposed as being *trans* octahedral by comparison of the space group and unit cell volume with those of related transition metal complexes; it is presumably a dihydrate if it is indeed octahedral in geometry.[297] Stability constants have been reported for a range of beryllium β-ketoamines derived from both salicylaldehyde and acetylacetone precursors. They show strong complexes which are stable to hydrolysis under the conditions used.[298,299]

Salen complexes of beryllium have been reported. The reaction of $BeSO_4$ and H_2salen in alcohol, followed by addition of aqueous alkali to effect precipitation, gave $Be(salen)_2 \cdot H_2O$ in which it was proposed, from IR studies, that each salen was monoanionic and bidentate.[300] $Be(salen) \cdot 2H_2O$ was isolated by addition of salen to an ammoniacal solution of beryllium containing sodium potassium tartrate,[301] and polymeric Be(salen) has been prepared from the reaction of salen and beryllium sulfate (or nitrate) at pH 7.[302] This latter compound has been characterized by IR, ^1H NMR and mass spectrometry. A related complex derived from (±)-2,2′-bis(salicylideneamino)-6,6′-dimethyldiphenyl contains beryllium in a tetrahedral environment.[303] Schiff base complexes of Be and Mg, the former four coordinated and the latter six coordinated, have been prepared by the reaction of the metal acetylacetonate with biguanide, and with *N*′-amidinoisourea.[304] The reaction of diacetylacetone with beryllium salts in the presence of ammonia gave the unexpected beryllium complex (**56**) instead of the anticipated diacetylacetonate.[305]

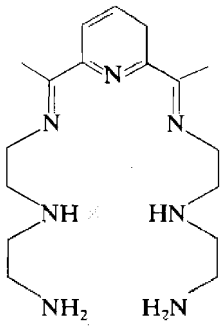


(**56**)

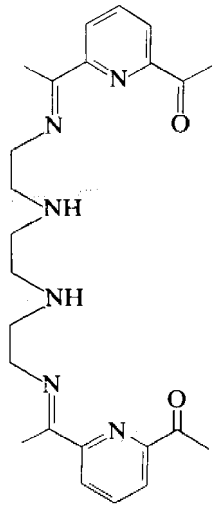


Mg(salen), first reported by Pfeiffer[306] who synthesized it using the classic Schiff procedure of reaction of the metal salicylate with ethylenediamine, has been investigated as a possible reagent for the detection of trace amounts of magnesium. Both fluorimetric and spectrophotometric techniques have been used;[307,308] no structural information is yet available.

Generally, Schiff bases, such as H_2salen, containing phenolic groups can form complexes either by removal of the two phenolic protons to give a neutral metal complex, or by direct ligation as a mono- or non-deprotonated ligand. The latter modes are generally found for A-class metals. In the above discussion fully, and singly, deprotonated H_2salen have been introduced; in the reaction of calcium salts with H_2salen, the non-deprotonated ligand is in evidence. Two types of compound are found: $Ca(H_2L)X_2 \cdot nEt_2O$ ($X = NO_3$, Cl; $n = 0, 2$) and $Ca(H_2L)_2X_2 \cdot nS$ ($X = NO_3$, Cl; $n = 0$, 1; $S = H_2O$, EtOH).[309] The ligands used are H_2salen, H_2salpd, H_2salpn and H_2salhxn (pd = 1,3-propanediamine, pn = 1,2-propanediamine and hxn = 1,6-hexanediamine). The X-ray structure of $Ca(H_2salpd)(NO_3)_2$ has been solved and shows the ligand to be binding to two Ca^{2+} ions *via* two negatively charged oxygen atoms. The azomethine nitrogens are protonated by the proton from the phenolic group and are intramolecularly hydrogen bonded to the oxygen atoms. A bidentate nitrate anion, and a pair of bridging, equivalent nitrate anions complete the eight coordination around the cation.



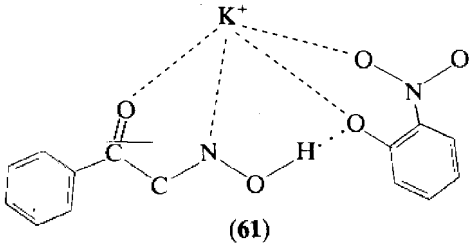
Several alkaline earth metal complexes of polydentate, acyclic Schiff bases have been prepared and characterized during studies on the generation of tetraimine Schiff base macrocycles. $Ba(ClO_4)_2$ complexes of the ligands (**57**),[310] (**58**),[311] (**59**)[312] and (**60**)[313] have been isolated together with $Sr(ClO_4)_2$ complexes of (**58**), (**59**) and (**60**) and $Mg(ClO_4)_2$ and $Ca(ClO_4)_2$ complexes of (**59**).



(**57**)

(**58**)

(**59**)



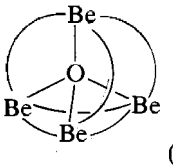
(**60**)

Such complexes have been postulated as possible intermediates in macrocycle formation and whilst (**58**) and (**59**) can be ring-closed, (**60**) cannot. The crystal structure of (**60**)$Ba(ClO_4)_2$ has been solved and shows the barium to be 10-coordinated by all of the ring donor atoms and two perchlorate anions. The conformation of the ligand is such that two planar keto-pyridinylimine segments are inclined at 80.2° to each other forming a cleft. The failure of the ring to close on further diamine addition is likely to be due to a steric barrier to the entry of the nucleophile into the cleft.[313]

23.4.2 Acid Anions and Acid Salts

In discussing the interaction of chelating anions with alkali metal cations, Truter argues that one possible criterion for designating a compound 'complex', namely that the ligand is held exclusively by one metal, is too restrictive because it excludes simple μ-complexes.[35] The proposal is also made that it is reasonable to state that if all anions contact more than three cations, then the solid does not contain complexed cations, as it begins to move towards an extended lattice.[35] The crystal structure of the mixed ligand species K(*o*-nitrophenolate)(iso-nitrosoacetophenone) is used as an illustration. In this compound the anion is present as the acid anion $[LHL']^-$ and the potassium is coordinated by four donor atoms from this anion (**61**).[314] This does not provide coordinative saturation at the metal and so in the solid state polymerization brings the coordination number up to seven (if M—O < 3.0 Å) or eight (if M—O include 3.1 Å interactions). Each anion becomes involved in interactions with four cations, some donor atoms being shared.

(**61**)



Compounds similar to (**61**) and containing *o*-nitrophenol, acetylacetone, salicylaldehyde, *etc.* as neutral ligands were described by early workers in the area and considered as complexes of

ML·HL and ML·HL′, where HL and HL′ acted as chelated ligands.[17,18,19] They were referred to as 'acid salts' and their solubility in organic media was taken as a criterion of complexation. In historic terms they play an important role in the development of the area. Generally, these compounds concerned organic anions, and $KIO_3 \cdot HIO_3$ is a unique example of an inorganic 'acid salt'.[315] With the later generation of interest in alkali metal complexation stimulated by a desire to understand membrane transport phenomena and to establish desalinating agents, a large range of 'acid salts' were investigated and the principles of formation have been discussed by Poonia.[21,30] Speakman has reviewed the structures of 'acid salts' of carboxylic acids[316] and uses a delightful quotation from Flecker, 'we have ... broideries of intricate design', as a preface. This is indeed appropriate as the structures are often infinite, and intricate, networks moving away from discrete molecules, and, although the metal is often chelated, it is considered here that the multiple cation sharing by the anions leads to a complex compound rather than a coordination complex. This is a further extension of the progression seen earlier in β-diketonate chemistry where more intricate polymeric lattices were found on moving to the heavier alkali and alkaline earth metal cations.

23.4.2.1 Basic beryllium carboxylates

An unusual series of beryllium complexes is the basic carboxylates, $Be_4O(RCO_2)_6$, the best known member of which is the acetate, first prepared by Urbain and Lacombe.[317] The principal synthetic route is by reaction of the organic acid or acid anhydride with beryllium oxide or hydroxide;[318] this method does not work for the basic formate. Instead reaction of the organic acid with the basic carbonate will give this compound,[319] as will heating the normal formate to 250–260 °C.[320] The interaction of an organic acid or acid chloride with another basic carboxylate yields mixed carboxylato species;[93] for example, the range of complexes $Be_4O(OAc)_x(OPr)_{6-x}$ can be so prepared.[321]

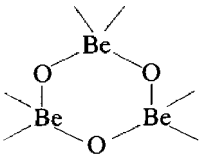
The white crystalline solids are readily soluble in organic solvents (even alkanes) but are insoluble in water and the lower alcohols. They are inert to water but are hydrolyzed by dilute acid. In solution they are monomeric and non-ionized. An X-ray crystallographic study of $Be_4O(OAc)_6$ shows the O to be centrally coordinated to four Be atoms in a tetrahedral geometry; each of the Be atoms is tetrahedrally surrounded by four O donors from bridging acetates and the central oxygen (**62**).[322]

⌒ = acetate

(**62**)

Ammonia and amines form compounds with basic beryllium carboxylates;[323,324] liquid NH_3 gives $Be_4O(OAc)_6 \cdot 12NH_3$ at −33 °C, which then loses ammonia to give $Be_4O(OAc)_6 \cdot nNH_3$ ($n = 3$ or 4). These species lose NH_3 and give the basic acetate at 180 °C. Similar compounds are formed with amines and a study of this reaction suggests that it follows the pathway:[325]

$$Be_4O(OAc)_6 + RNH_2 \rightarrow Be_3O(OAc)_4 \cdot nRNH_2 + Be(OAc)_2RNH_2$$



Thermal decomposition of the tripropylamine or $BuNH_2$ complex at 100 °C gave $Be_3O(OAc)_4$ which was then recrystallized from petroleum ether to give two crystalline forms of a dimeric structure.[325] SO_2 and N_2O_4 have been found to give loose addition products with $Be_4O(OAc)_6$.[326]

The reaction of alcohols with $Be_4O(OAc)_6$ gives a range of novel, but not enirely characterized, products, *e.g.* Be(OR)(OAc), Be(OH)(OAc) and oligomers based on these structures.[93] Be(OEt)(OAc) sublimes at 200 °C to give a reversal of the reaction and formation of $Be_4O(OAc)_5(OEt)$.[328] The related compound $Be_4O(OAc)_5(OH)$ has been prepared from the reaction of $Be_5O_2(OAc)_6$ with water.[327]

NMR studies of the mixed carboxylates containing acetates and trichloroacetates have indicated that ligand scrambling reactions occur in solution; although all of the species were isolated, and isomerization possibilities occur, no discrete isomers were identified.[329] Gas

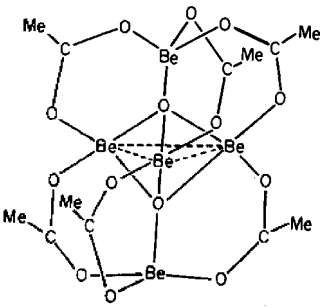
chromatographic studies have shown that the complete series of mixed basic carboxylates generated through ligand distribution in a mixture of the basic acetate and basic propionate can be found and separated clearly.[330] Extraction studies using capric acid have shown that beryllium can be efficiently extracted solely as the basic carboxylate.[331]

An inorganic analogue of these compounds exists in basic beryllium nitrate. This was prepared by heating $Be(NO_3)_2$ to *ca.* 125 °C where a sudden decomposition occurs to give $Be_4O(NO_3)_6$.[332] The structure of this compound is similar to that of the basic acetate;[333] and electron impact studies have confirmed the structural similarity of the two types of basic compound.[334] More complex basic acetates have also been reported. Pyridine-2-carboxylic acid provides a trimeric ring system, the strucure of which has been confirmed by X-ray crystallography (**63**).[335]

(**63**)

Rings containing beryllium, and derived from alkoxides and amides have been reviewed.[100,336] $Be_6O_2(OAc)_8$ has been shown to be comprised of dimeric $Be_3O(OAc)_4$ units.[325] The X-ray structure shows a polymeric network in which BeO_4 tetrahedra share common edges.[337] This compound forms adducts in liquid NH_3 of the type $Be_6O_2(OAc)_8 \cdot 6NH_3$.[338] Thermolysis of $Be_6O_2(OAc)_8$ yields $Be_4O(OAc)_6$ and $Be_5O_2(OAc)_6$, the X-ray structure of which is illustrated in Figure 11.[339]

Oligomeric beryllium oxycarboxylates containing up to Be_7, Be_9 and Be_{11} fragments have also been obtained by the controlled thermolysis of the products of the reaction of $Be_4O(OAc)_6$ and EtOH.[340]



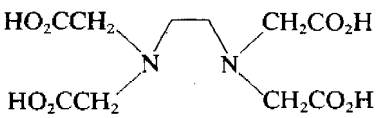


Figure 11 Representation of the molecular structure of $Be_5O_2(OAc)_6$

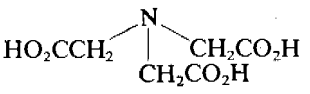
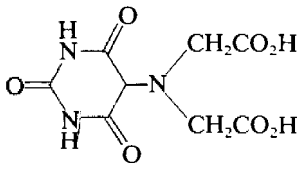


23.4.3 Polycarboxylic and Phosphonic Acids

An extensive range of functionally substituted polycarboxylic acids have been studied as metal-binding reagents (*e.g.* **64**–**66**).[341,342,343] Many such organic sequestering agents have been claimed as potential phosphate substitutes in detergent formulations, for ecological reasons; nta, because of its strong capability to sequester Ca^{2+} has seen application in this area.[344] These ligands have also seen application as analytical reagents, and the ability of edta to form water-soluble complexes with alkaline earth metal cations is the basis of the determination of hardness in water caused by these two cations. This was one of the first applications of edta to be described.[345] 1,2-Diaminocyclohexanetetraacetic acid also forms complexes with calcium and although these are stronger than the corresponding edta complexes, they are formed at a lower rate and so are not as useful for analytical purposes.



edta

(**64**)

nta

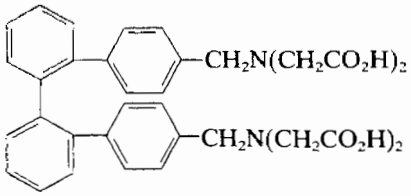
(**65**)

uda

(**66**)

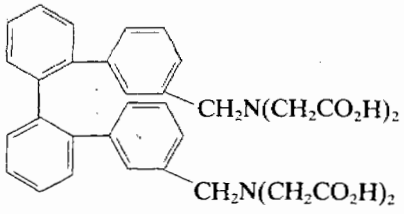
The aminopolycarboxylic acids in particular have been extensively studied in solution;[341,342,346] tabulations of stability constants concerning the interaction with M^+ and M^{2+},[259,341,342] and reviews concerning solid state structures[347,348] and the relationships between solution and solid state structures[349] are available. The stability constant data show that in general $Ca^{2+} > Mg^{2+} \approx Sr^{2+} > Ba^{2+}$ and that group II^A > group I^A. For edta the Mg^{2+} complex is lower in stability than the Ca^{2+} complex owing to the more endothermic nature of the former reaction. A strainless octahedral complex is approached for the Ca^{2+} complex in solution but the presence of a smaller cation results in a strained system being set up. Such strains would be expected to be greater for Be^{2+} and the log K value of 3.8, relative to 8.69 for Mg^{2+} and 10.96 for Ca^{2+}, validates this. In group IA the order of stability is generally $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$, and so follows the ionic potential decrease.

Beryllium is often left out of stability sequence studies; however, in a comparison of the complexing properties of edta, nta and uda, it was found that the Be^{2+} and Mg^{2+} complexes of uda were more stable than those formed with the higher alkaline earth cations.[350] This is in contrast to the edta and nta sequences. In the analysis of the thermodynamic information, it was found that for uda the enthalpy changes were high and negative, and for alkali metals these increased with increasing ionic radius. The entropy terms were negative for the alkali cations but positive for the alkaline earth cations, decreasing with increasing ionic radius for each series. The enthalpy changes for alkaline earth cations, in edta complexation, were small but the entropy changes were positive, decreasing with increasing ionic radius. The enthalpy terms for Mg^{2+} and Be^{2+} were positive and so were unfavourable. The Be^{2+} was predicted to be tetrahedral in these complexes.[350]



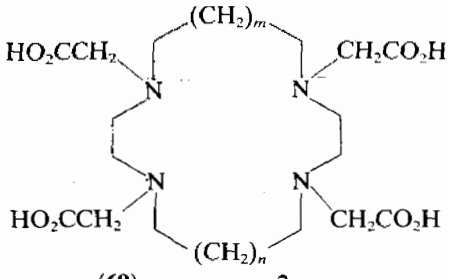
In solution, the potential for binding is six-coordinate for edta and four-coordinate for nta. The total coordination, however, is not well known and water molecules are also involved. $[Ca(edta)]^{2-}$ is often represented as an octahedral complex but it would be anticipated that Ca^{2+} could have a coordination number in excess of six. The denticity of edta has been found to vary from one to six, and the coordination number about the metal from four to nine.[349] A review of the crystal structures of Ca^{2+} complexes of amino acids, peptides and related model systems surveys the coordination patterns found for Ca^{2+}–carboxyl and Ca^{2+}–carbonyl interactions.[351]

In the solid state, the story is quite complicated. The structures of several alkali and alkaline earth metal complexes of acids are known and include those of 2,6-pyridinedicarboxylic acid (H_2dpa), 4*H*-pyran-2,6-dicarboxylate (H_2dpc), oxydiacetic acid (H_2oda), thiodiacetic acid (H_2tda), iminodiacetic acid (H_2ida), ethylenedioxydiacetic acid (H_2edoda), malonic acid, maleic acid, fumaric acid, succinic acid and citric acid, as well as those of edta and nta. These have been reviewed and show a wide variety of structures.[30] These range from $[Mg(H_2O)_6]^{2+}[H_2edta]^{2-}$, which may be crystallized from acid solution,[352] through $Ca(oda)\cdot 6H_2O$, which consists of discrete $Ca(oda)\cdot 5H_2O$ units in which the Ca^{2+} is coordinated by the tridentate ligand and five water molecules and in which there is linking caused by hydrogen bonding involving the sixth non-coordinated water molecule,[353] and $K_2[Be(oxalate)_2]$ and $K_2[Be(malonate)_2]$ which are discrete dianionic beryllium complexes of tetrahedral geometry,[354,355] to the $\{Ca(edoda)\cdot 3H_2O\}_2$ dimer,[356] in which the species are linked together by hydrogen bonding involving the water molecules and eventually to the intricate networks of $Ca_2(edta)\cdot 7H_2O$ and $NaCa(nta)$[357] in which no discrete monomers are detected.



In studies on $Ca(edoda)\cdot 3H_2O$ it was noted that the ethereal oxygen was involved in binding and that there was no effective increase of Ca^{2+} sequestration on going from oda to edoda.[356] The suggestion that the ether oxygen could be involved in complexation was implied from the stability sequence Ca(oda) (log K, 3.4) > Ca(nda) (log K, 2.7) > Ca(glutamate) (log K, 1.1).

In accord with remarks made earlier concerning the nature of complex species containing acid anions (Section 23.4.2) discussion of complexes containing polycarboxylic species has been limited to the general outline above. Recent developments in the area include the derivation of ligands such as (**67**)–(**69**) and their application to complexation. The sequence $Ca^{2+} > Mg^{2+} > Ba^{2+} > Sr^{2+}$ is found for (**67**) and (**68**) with the complexation to (**67**) being stronger, and showing lower complexing powers than edta and nta.[358] For the macrocyclic polycarboxylic acids (**69a**) exhibits the strongest known complexing ability for Ca^{2+}, and the larger (**69b**) shows a noticeable preference for Sr^{2+}.[359]



Polyamino polyalkyl phosphonic acids have been investigated as potential complexors for alkaline earth metal complexes. Ligands investigated include nitrilotrimethylphosphonates (**70**),[360] phosphoryl derivatives of polyamines (**71**)[361] and monoalkylphosphonic acids.[362] They show complexing capability towards Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, but are not as efficient

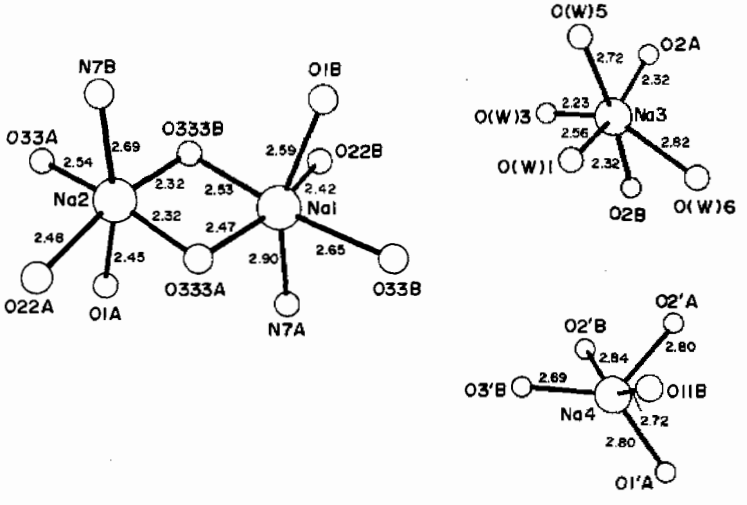
as the corresponding carboxylic acids. Suggestions have been made concerning the likely nature of species by use of IR techniques but no precise structural statement is available.

(70)

(71)

Alkali and alkaline earth metal complexes of sugar phosphates and related moieties belonging to nucleosides and nucleotides have been studied, and accounts of the nature of the metal–ligand interaction[363,364] and of the stability of the complexes are available.[365,366] Bidentate and tridentate interactions with the cations occur and generally the structures are networks having multiple cation–anion interactions. The structure of $Na_2ATP{\cdot}3H_2O$ (ATP = adenosine triphosphate) is taken as an example.[367] The structure has two formula units in the asymmetric unit and can be viewed as being dimeric in origin. There are two distinct types of



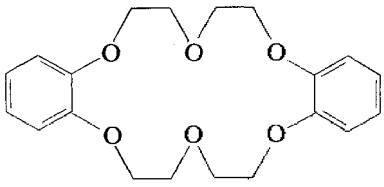


Figure 12 The coordination of the sodium atoms in $Na_2ATP{\cdot}3H_2O$ (reproduced with permission from reference 367)

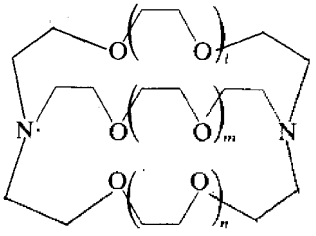
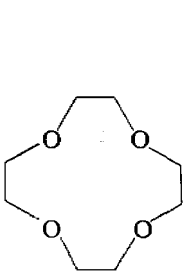
sodium coordination; in the first two independent sodium cations Na1 and Na2 are octahedrally coordinated. This is achieved by interaction with two ATP molecules, one of type A and one of type B. For Na1 the coordinating atoms are three phosphate oxygens (O_1, O_{22} and O_{333}) from a molecule B, a phosphate oxygen (O_{33}) from a second molecule of B, the N7 atom and a phosphate oxygen (O_{333}) of molecule A. Na2 is coordinated with the corresponding O_1, O_{22} and O_{333} atoms from molecule A, the O_{33} from a second molecule of A, and the N7 and O_{333} of molecule B. One of the terminal atoms O_{333} in each molecule is coordinated to both sodium cations, and this, together with the N7 coordination, leads to the formation of dimers, which then repeat through the structure. The second type of sodium coordination involving Na3 and Na4 plays a less significant role in the structure of ATP; its main function is to link the dimers and maintain them in the extended lattice. These sodium atoms are six- and five-coordinated respectively; the first to four waters and two O2 from types A and B, the second to a selection of phosphate O donors (Figure 12). The role of the alkali metal cation can be viewed as that of a network assembler.



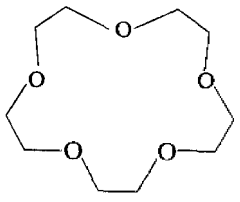
23.5 MACROCYCLIC LIGANDS

Pedersen's discovery[5] that dibenzo-18-crown-6 (**72**) and a related family of cyclic polyethers could readily complex alkali metal cations provided the stimulus required for a renaissance of interest in alkali metal coordination chemistry. Since that discovery, much effort has been directed towards modifying all possible structural parameters within the ligand system in order to make new, and hopefully improved, ligands. Variable parameters include the number and type of heteroatoms available for coordination, the nature and length of bridging units within the polyether and the general nature of any substituent groups present. This general class of ligands was first termed crown ethers,[5]* and more recently the term coronand has been introduced.[33]

(**72**)

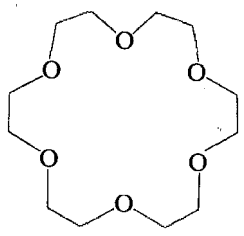


A second important advance was made with the availability of cryptands (**73**), a family of bicyclic polyoxadiamines which have available a three-dimensional cavity for complexation.[6] Again many structural modifications are possible and lead to numerous macropolycyclic ethers.



(**73**)

Selected examples of crown ethers and coronands are given in Figure 13. This area of chemistry has been remarkable for its growth, and many excellent reviews covering a wide range of topics are available; that by Vögtle and Weber[31] carries a full bibliography of work carried out until 1979. Subsequent reviews, of interest here, have been concerned with synthesis and general properties,[368,369,370] complexes,[30] structural aspects,[30,371,372] stability and reactivity,[373,374] cryptands,[375] polymeric polyethers,[376,377] NMR studies[140] and applications to analytical chemistry.[378,379,380]



* The IUPAC nomenclature for crown ethers is cumbersome and so was trivialized for common use. Dibenzo-18-crown-6 is named as follows: dibenzo describes the non-ethyleneoxy content; 18, the total number of heteroatoms in the crown ring; and 6, the number of heteroatoms in the ring.

Figure 13 Some crown ethers and coronands

23.5.1 Crown Ethers and Coronands

Crystalline macrocyclic polyether complexes may be prepared by several routes,[5,381] depending upon the solubilities of the precursors and the products. The polyester and the salt may be dissolved in a small amount of solvent and warmed together; the complex can crystallize either on cooling or after evaporation of some of the solvent. It is also possible to warm a suspension of the ligand and the salt to effect solubilization and subsequent crystallization. The reaction can also be carried out by mixing the components in the solid state and heating to melting.

Complex formation is favoured with salts having low lattice energies,[382] and so, although alkali metal fluorides, nitrates and carbonates give complexes with polyethers in alcoholic solution, it is often difficult to isolate species as crystalline solids because the high lattice energies of the alkali salts lead to a reassembling of themselves. Well-defined crystalline crown ether complexes have been found with alkali and alkaline earth metal thiocyanates,[5,383] chlorides,[384] bromides,[5,385] iodides,[5,386,387] polyiodides,[5,387] perchlorates,[388] benzoates,[383a] nitrophenolates,[383a] tosylates,[386b] picrates,[383a,389] tetraphenylborates,[390] nitrites,[5,386a] tetrafluoroborates[301] and molybdates,[392] and representative references have been given. The X-ray crystal structures of many of these complexes have been solved. Schematic representations of several types of crown ether complexes are given in Figure 14.

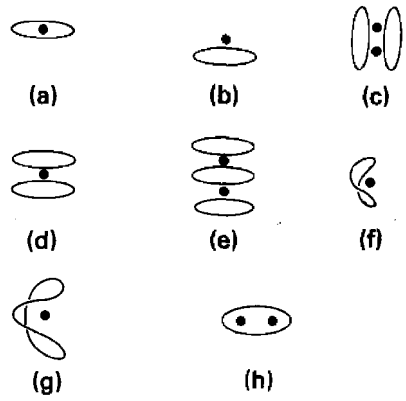

Figure 14 Schematic representations of some bonding modes found in crown ether complexes

For a 1:1 metal–ligand complex, the ideal environment for the cation is at the centre of a torus of donor atoms provided by the cyclic ligand (Figure 14a); this is because the cations, having rare-gas-like electronic structures, have no overriding directional influences on geometry, but, as in the VSEPR approach to covalent interactions, accept the donor atoms at the optimum points of distribution on the surface of a sphere subject to any imposition of steric constraint or uneven distribution of charge from accompanying ligands and anions. This latter effect can cause a shift from the central position (Figure 14b) as can a cation size–cavity size disparity. This occurs when the metal is too large for the cavity and can lead to dimerization (Figure 14c). A further consequence of the cation being too large for the cavity is the formation of 1:2 metal–ligand 'sandwich' complexes (Figure 14d), or 2:3 metal–ligand 'club sandwich' complexes (Figure 14e). If, in contrast, the cation is too small for the cavity then encapsulation of the cation may be effected either in part (Figure 14f) or in full (Figure 14g). Entrapment of two cations within the ligand torus is also possible (Figure 14h). A comparison of structures of free and complexed crown ethers shows that conformational changes occur on complexation.[30,371,372]

By studying a series of complexes, it is possible to observe the differences in structural type that occur with change of cation radius. Table 6 shows the ionic radii for the alkali and alkaline earth metal cations, together with the average ligand cavity radii for simple polyethers.[33] From this information it can be seen that the predicted optimal fit situation for 1:1 complexes would arise for Li^+ and 12-crown-4 (**74**); for Na^+ and 15-crown-5 (**75**); and for K^+ and Ba^{2+} and 18-crown-6 (**76**). For 24-crown-8 (**77**) all of the cations have smaller radii than that of the ligating cavity.

A survey of the structures of complexes derived from 18-crown-6 (**76**) reveals the presence of several of the structural types depicted in Figure 14. The Na^+ cation in $NaSCN(\mathbf{76})\cdot H_2O$ is coordinated by all six oxygen atoms of the ligand; five oxygen atoms lie in a plane containing

Table 6 Correlation of Cation and Cavity Radii (Å) of Alkali and Alkaline Earth Metal Ions and some Crown Ethers

Li^+	0.60		
Mg^{2+}	0.65	12-crown-4 (**74**)	0.72
Na^+	0.95	15-crown-5 (**75**)	0.92
Ca^{2+}	0.99		
Sr^{2+}	1.13		
K^+	1.33		
Ba^{2+}	1.35	18-crown-6 (**76**)	1.45
Rb^+	1.48		
Cs^+	1.69	24-crown-8 (**77**)	1.90

the cation, whilst the sixth is folded out of the plane and partially envelops the cation. The coordination environment of the metal is completed by a water molecule, and this type of complexation is a typical example of Figure 14(f) where the cation is smaller than the polyether cavity.[393]

The prediction from Table 6 is that K^+ showed the best 1:1 fit, and this is borne out in the structure of KSCN(**76**) in which the donor oxygen atoms lie in an almost hexagonal plane, coordinating the K^+ at the centre.[394] When the cation is too large for the cavity, as in RbSCN(**76**), or CsSCN(**76**), then the metal lies out of the plane of the ring donor oxygen atoms and a dimeric entity ensues through N-bonded-NCS bridging;[395,396] this process also ensures 'saturation' of each cation from the other 'naked' side of the coordination sphere (Figure 15).

Further, but monomeric, examples of Figure 14(b) have been found in RbNCS(**72**) and K(acetoacetate)(**76**). In the former a 2:3 metal–ligand ratio is indicated by microanalysis[5] and so a 'club sandwich' structure was envisaged. The X-ray structure showed that only a 1:1 complex was present, together with molecules of free crown ether.[397] The Rb^+ is displaced out of the ligand and the seventh coordination site is taken up by the nitrogen-bonded thiocyanate anion, which is approximately perpendicular to the oxygen-atom ring. A similar geometry is found in K(acetoacetate)(**76**) where the anion is O-chelating.[398]

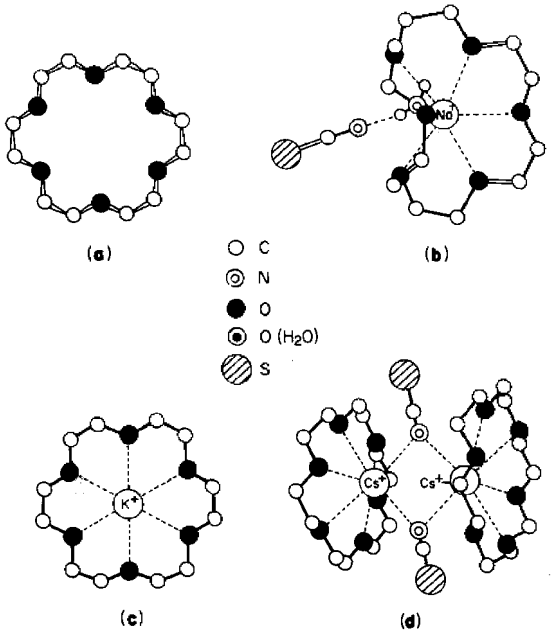

Figure 15 Structures of 18-crown-6 and some 18-crown-6 complexes with different alkali metal salts (reproduced with permission from reference 31)

A dimeric structure has been determined for the Cs(NCS) complex of the *meso* form of tetramethyldibenzo-18-crown-6 (**78**), N-bonded bridging NCS anions being present, and a 1:2 'sandwich' structure with the racemic form.[399] In the dimeric species, the Cs^+ is only

octacoordinated. An unusual Cs^+-bearing compound has been isolated with a transition metal cluster as the anion: $[(\mathbf{76})_{14}Cs_9]^{9+}[Rh_{22}(CO)_{33}H_x]^{5-}[Rh_{22}(CO)_{35}H_{x+1}]^{4-}$.[400] In this complex, the cationic moiety has been shown to be comprised of three distinct Cs^+–crown ether units: $Cs^+(\mathbf{76})$, $Cs^+(\mathbf{76})_2$ and $(Cs^+)_2(\mathbf{76})_3$. Of these, the latter two are of interest as they provide a 'sandwich' structure (Figure 14d) and the first genuine example of a 'club sandwich' structure (Figure 14e) respectively. The former is also a new species in that the cation is pulled out of the ligand plane and interacts with two oxygen atoms from C=O units. An interesting sandwich complex of (**76**) has been found in the reaction of a benzene solution containing excess of (**76**) with potassium phthalocyanine.[401] A discrete trimacrocyclic structure, [(**76**)K—pc—K(**76**)], is found in which the cations are each sandwiched between a terminal crown ether and the central phthalocyanine anion. The benzo-15-crown-5 ligand (**79**) can also be used to illustrate trends in structural type (Figure 16). Na^+ and Ca^{2+} form the 1:1 complexes $NaI(\mathbf{79})\cdot H_2O$ and $Ca(NCS)_2(\mathbf{79})\cdot ROH$ (R = Me, Et); the cations have similar ionic radii. In the Na^+ complex, the cation is coordinated by the five crown oxygen donors and lies out of the plane of the ring in the direction not of the I^- but of the water molecule.[402] In the Ca^{2+} complexes, the Ca^{2+} is displaced further but of the plane of the crown ring and an octacoordination is completed by the two thiocyanates (N-bonded) and the alcohol of solvation.[403] The smaller Mg^{2+} can be found at the centre of the crown ring in $Mg(NCS)_2(\mathbf{79})$, a pentagonal bipyramidal geometry being completed by the two N-bonded thiocyanates occupying the apical positions.[403b]

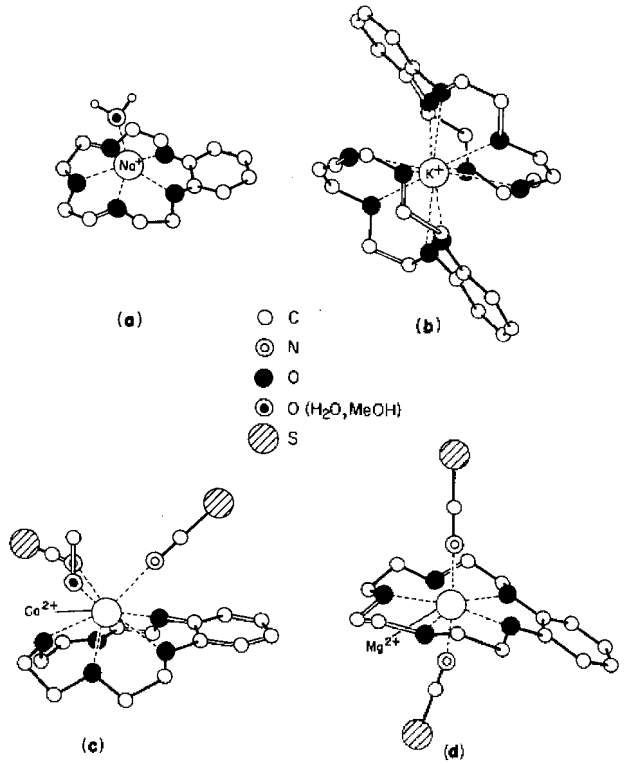

Figure 16 Different types of benzo-15-crown-5 alkali and alkaline earth metal complexes (reproduced with permission from reference 31)

The larger K^+ is found to give a 1:2 metal–ligand complex as in $KI(\mathbf{79})_2$. A sandwich structure is found in which the ligand units are arranged approximately centrosymmetrically relative to one another and the 10 oxygen atoms are at the corners of an irregular pentagonal antiprism.[404] Such a 'sandwich' structure is also found with $BaBr_2(\mathbf{75})_2\cdot 2H_2O$[405] and, rather interestingly, sodium has been found to give 1:2 complexes. The structures of $NaClO_4(\mathbf{79})_2$ and $Na(BPh_4)(\mathbf{79})_2$ both show sandwich arrangements;[406] they differ slightly, and the precise coordination of the metal is uncertain as a range of metal–oxygen distances is found. The preparation of these species depends upon the reaction conditions, requiring concentrated solutions to obtain the 1:2 ratio. If the correct stoichiometric ratio is used, 1:1 solvated complexes are also recovered. A 1:2 complex of Ca^{2+}, Ca(dinitrobenzoate)$_2(\mathbf{79})_2\cdot 3H_2O$, has been found, but in this one of the ethers is not coordinated, rather like the proposed 'club

sandwich' of Rb^+—(**72**) mentioned earlier.[407] Sandwich complexes of $Ca(ClO_4)_2$ have been identified; these have varying degrees of solvation and their precise nature is not established.[383b]

The larger crown ethers dibenzo-24-crown-8 (**80**) and dibenzo-30-crown-10 (**81**) provide examples of the encapsulated and bimetallated structural modes (Figure 14g, h). Dibenzo-24-crown-8 takes up two potassium cations in the complex $[KNCS]_2$(**80**); the eight oxygen donor atoms are shared between the cations, and the anions also participate in the bonding as monodentate N-bonded species (Figure 17a). Each K^+ is heptacoordinated and it is proposed that there is a participation of neighbouring benzene rings in the bonding.[408] The disodium *o*-nitrophenolate complex of this crown ether differs in that two ethers of the octadentate ligand are not involved in the bonding; the *o*-nitrophenolate ions serve to bridge the Na^+ cations and complete a coordination of six at each cation.[409] The bis sodium thiocyanate complex of (**81**) also contains two metals within the ligand framework.[410] Alkaline earth metals, in contrast, form, to date, only 1:1 complexes with (**80**) and this may be a reflection of the difficulty of juxtaposing the two higher-charged cations within the polyether framework. $Ba(picrate)_2$(**80**)$\cdot 2H_2O$ has the ligand using five of the eight donor oxygen atoms from the ring to coordinate to the cation, together with two water molecules, one of which is simultaneously bound within the polyether torus, two phenolate oxygen atoms and one nitro group oxygen atom giving an overall coordination number of 10.[411] The ligand almost encircles the cation in $Ba(ClO_4)_2$(**80**) using all of the available ring donors to coordinate; the perchlorate anions are also bonded to the cation.[412]

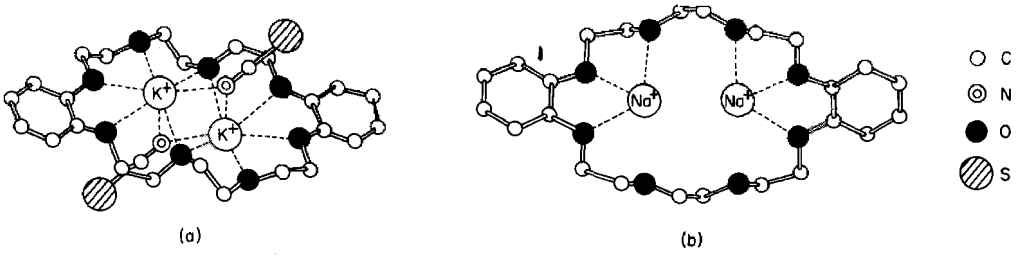

Figure 17 Structures of the Na^+ and K^+ complexes of dibenzo-24-crown-8 (reproduced with permission from reference 31)

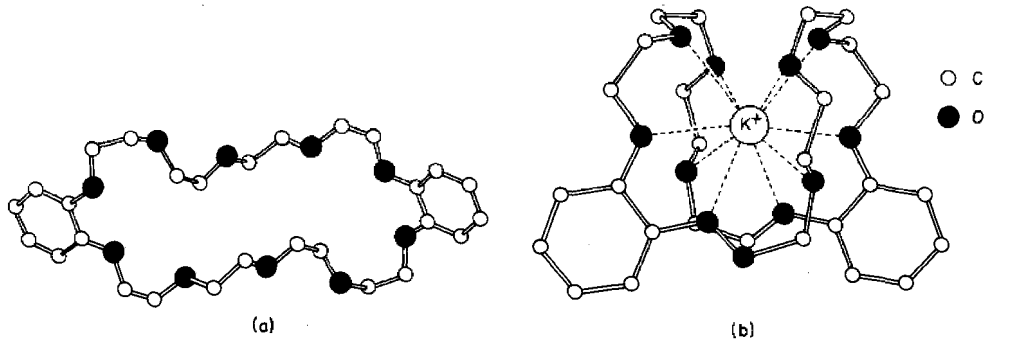
Complete encapsulation has been found in the complexes KNCS(**81**)[413] (Figure 18) and RbNCS(**81**).[414] The free ligand[413] shows an open loop and wraps completely around the central metal cation, perhaps not surprisingly as (**81**) is effectively a dimer of (**79**). The central metal atom is wrapped by the ligand in a 'tennis ball seam' configuration and all 10 donor atoms are involved in the coordination sphere (Figure 18). The first example of a metal complex completely encapsulated by a dibenzo-24-crown-8 ligand is the 1:1 $NaClO_4$ complex of the non-symmetric ligand (**82**).



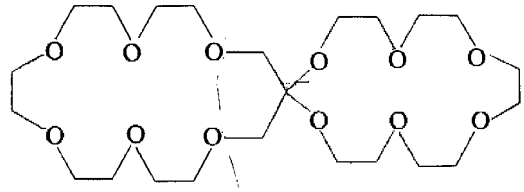


Figure 18 The molecular structures of dibenzo-30-crown-10 and its potassium complex (reproduced with permission from reference 31)

The structures of several Li^+ complexes with crown-4 ethers have been solved. The complexes LiNCS(**83**),[416] LiNCS(**74**),[417] LiNCS(**84**)[418] and LiNCS(**85**)[419] all show Li^+ to be square pyramidally coordinated by the four ring oxygen donors and the nitrogen from the

anion. It has been remarked that this geometrical arrangement could be a common feature of Li^+ coordination in crown systems.[418] A dilithium complex of the spiro crown ether (**86**) has been determined. $(LiI)_2$(**86**)·$4H_2O$ has each lithium in a distorted trigonal bipyramidal environment;[420] one water molecule is incorporated in the crown ring, *cf.* that in the barium picrate complex of (**80**), and the cation interacts with three ring oxygens and two water molecules.

(**86**)

It can be seen from the above discussion that the varying structural modes present in Figure 14 are readily available. For the partially encapsulated complexes there is not only a dependence upon the cation cavity best fit but also on the relative strengths of the competing counter donors, both anions and/or solvent molecules. This is shown in the structures of (**79**)NaI·H_2O, where the water is held by the metal rather than the I^-,[402] and (**72**)NaBr·H_2O, where the sodium is either symmetrically coordinated with two H_2O in axial positions, or non-symmetrically coordinated and lying out of the ligand plane towards the Br^- not the H_2O (Figure 19).[421]

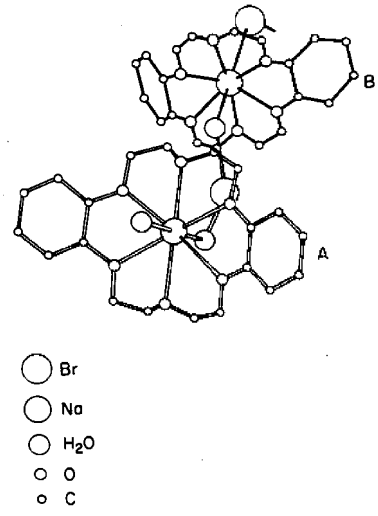

Figure 19 The asymmetric unit in NaBr(**72**)$2H_2O$ showing A, a complex cation Na(**72**)$2H_2O$ and B, a complex ion pair NaBr·(**72**)·H_2O. The fourth water molecule forms a hydrogen-bonded bridge between a coordinated water molecule and the coordinated bromide ion (reproduced with permission from reference 35)

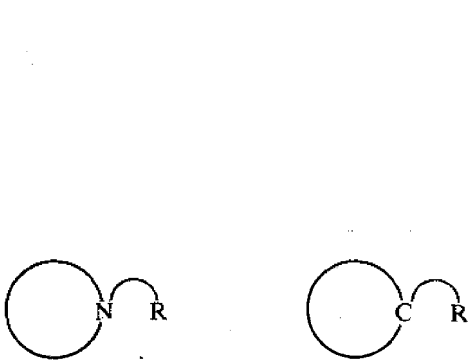
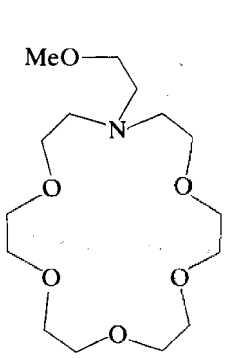


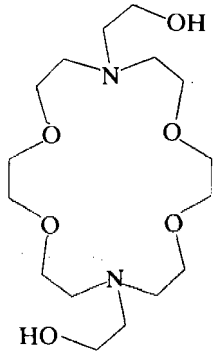
The structures of several related crown ether complexes have also been solved. Ligand (**87**) forms a 1:1 complex with KNCS. In this complex the cation is coordinated to all of the donor atoms of the ligand, with a further weak interaction with the NCS^- anion.[422]

A study of the interaction of ligand (**88**) with alkali metal complexes has been reported.[423] The NaNCS complex contains the ligand bound to the Na^+ by five oxygen donors but the sulfur does not interact at all; the six coordination of the cation is completed by the NCS^- anion.[424] The KNCS complex has the metal at the centre of a hexagon of donors, all of which interact with the metal,[425] and in the RbNCS complex the Rb^+ sits out of the plane towards an N-bonded NCS^- anion and is also coordinated by a sulfur from an adjacent ring to give a dimeric structure.[426]



There has been considerable interest shown in the design and synthesis of functionalized crown ethers, and in whether the appended functional group can then further complex the cation. Examples include the so-called 'lariat' ethers, which may be functionalized on either N or C bridgeheads in the ligand frameworks (**89**).[427]

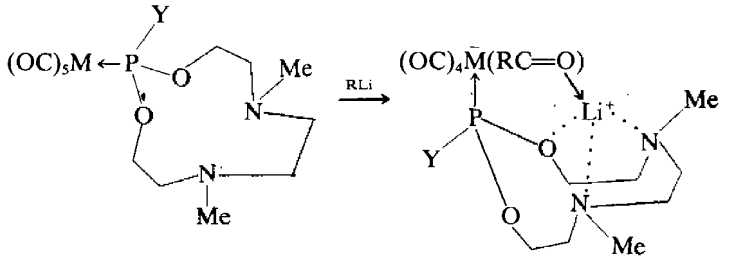
The interaction of the functional group has been established within the structures of the KI



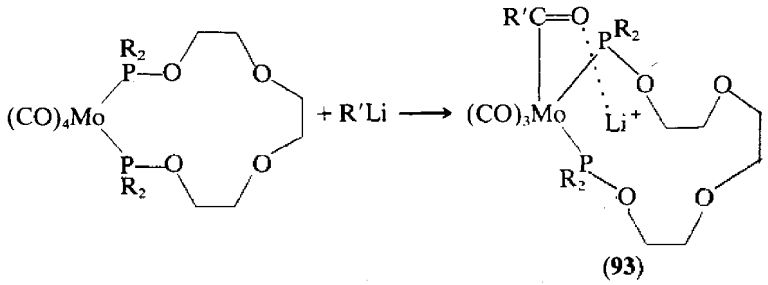
complex of (**90**) and the Na^+ complex of (**91**). In both structures, the metal is held in the ring and the pendant O donor atoms further coordinate to the metal.[428]

(**89**)

(**90**)



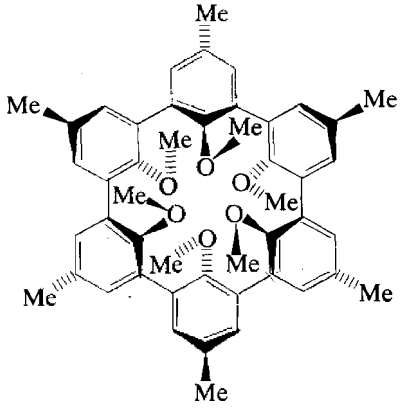
(**91**)



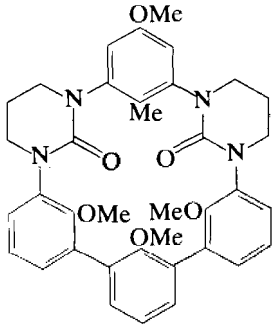
In contrast, in the structures of the RbI complex of *N,N'*-bis(cyanomethyl)-1,10-diaza-4,7,13,16-tetraoxacyclooctadecane, the Rb^+ is complexed by the ring, a water molecule and a further two *inter*molecular interactions with cyanomethyl groups.[429] The structures of bis{4'-OH(**79**)}KNCS[430] and (4'-acetobenzo-18-crown-6)$Sr(ClO_4)_2$[388b] show no interaction of the side chain with the central metal either inter- or intra-molecularly.

In the structure of a 2:1 complex between LiNCS and 1,4,7,10-tetra(2-hydroxyethyl)-1,4,7,10-tetraazacyclodecane the Li^+ is coordinated by four nitrogens from the tetraaza macrocyclic ring and one oxygen from a side arm to give another example of square pyramidal Li^+.[431] The second Li^+ is coordinated by three different side arm oxygens from different ligands and one water molecule. Similar side arm participation is found in the corresponding NaNCS and KNCS complexes, where in the former three side arm oxygens are involved with the Na^+, and in the latter all of the side arm oxygens complex the K^+; in both cases the cation is held by the ring nitrogen donors.[432]

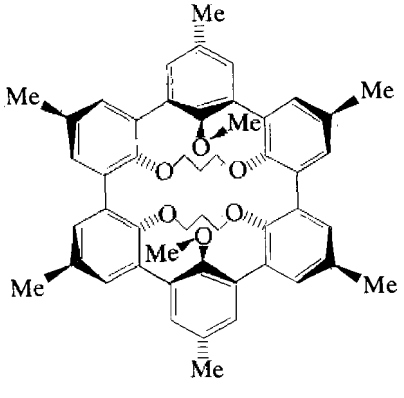
Two interesting examples of alkali metal complexation arise from studies on organometallic systems in which metal acyl binding to the complexed alkali cation is also demonstrated. This type of product has been seen as of value in studies on the kinetics of alkyl migration reactions. A derivative of 1,10-dioxa-4,7-diaza-11-phosphacycloundecane has been shown to give an $Mo(CO)_5L$ complex and this then reacts with PhLi such that the Li^+ is coordinated to two nitrogen atoms and one oxygen atom of the ring and to the PhC=O unit (**92**). The overall structure is dimeric through the acyl binding.[433] The related reaction in which the precursor macrocyclic ring includes an $Mo(CO)_4$ unit gives a product (**93**) wherein the Li^+ is coordinated to the four ring oxygens and to the acyl group oxygen.[434]



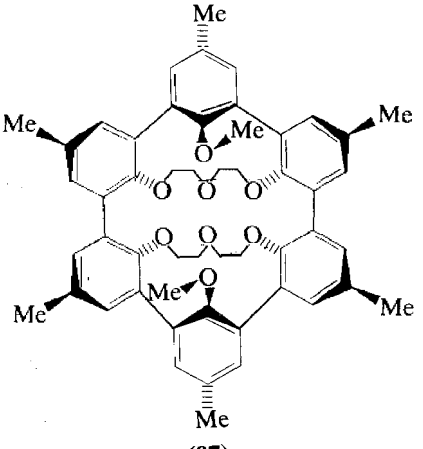
(**92**)



(**93**)

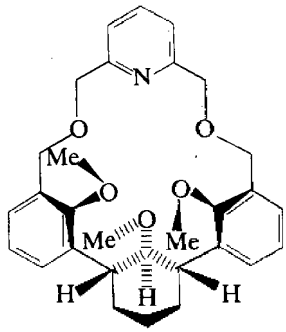


In the derivatives described above, the ligand undergoes conformational change on metal incorporation. Spherands have been described as the first ligand systems fully organized during synthesis rather than during coordination as, unlike the previous examples, the free ligands possess the same conformational organization as do the complexes. The full burden of binding site collection and organization is then transferred from the complexation process to the synthesis of the ligand.[435] This is illustrated in the structures of (**94**), (**94**)LiCl and (**94**)$NaCH_2SO_4$. The Li^+ fills the octahedral cavity of the ligand and causes a reduction in hole diameter from 1.62 to 1.48 Å; the Na^+ sits similarly in its cavity but causes a slight expansion of cavity from 1.62 to 1.75 Å.

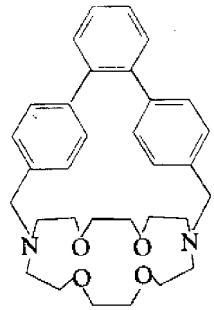


(**94**)

(**95**)



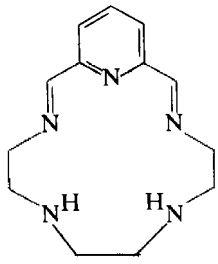
(**96**)



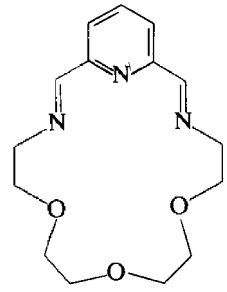
(**97**)

In the NaBr and $CsClO_4$ complexes of the related spherand (**95**) in which *N,N'*-disubstituted cyclic urea moieties have been introduced, the Na^+ forms a nesting complex with five oxygen atoms of the spherand lining a nest capped by a water molecule of solvation. The Cs^+ is too large for the nest and so perches on four *syn* oxygen atoms and is further ligated by a solvent water molecule and the carbonyl from an adjacent spherand to give a dimeric structure, as with cyclic polyethers.[436] The structures of the Li^+ complexes of the augmented spherands (**96**) and (**97**) have been determined.[437] The effect of the bridges is to squeeze one of the methoxy groups of the ligating range (2.48 Å and 3.48 Å respectively). The Li^+ in (**96**)$LiFeCl_4$ is coordinated by the five remaining oxygen atoms to give an Li^+ diameter of 1.27 Å, while in (**97**)LiCl the residual seven oxygen atoms lead to an Li^+ diameter of 1.71 Å and provide a very unusual seven-coordination of the metal. These diameters compare with the value of 1.48 Å given earlier.[436]

Hemispherands have a partial preorganization of the ligand. The X-ray structure of (**98**)$Na(BPh_4)\cdot H_2O$ shows the metal coordinated by the hemispherand donors and by a water molecule.[438] The related complex (**99**)NaNCS·MeOH shows the metal to be coordinated by all six donors of the crown, which is in a boat configuration and the terphenyl is folded away. The metal geometry is a biapical square pyramid.[439]

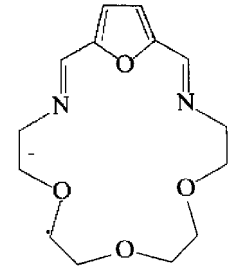


(98)



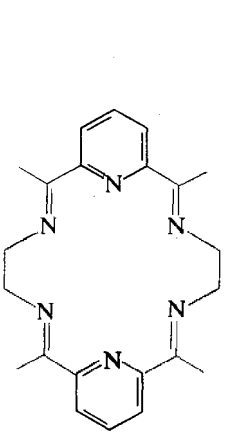
(99)

The crystal structures of alkaline earth metal complexes of several (1 + 1) and (2 + 2) Schiff base macrocycles have been reported. These macrocycles are formed by the metal template-controlled condensation of the required heterocyclic dicarbonyl derivative and α,ω functional diamine in alcoholic solution. (1 + 1) complexes arise from the condensation reaction of one dicarbonyl with one diamine and (2 + 2) complexes from the condensation of two dicarbonyls with two diamines.

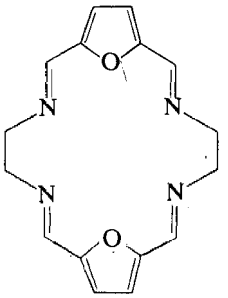


The X-ray structures of $[Mg(H_2O)_2(\mathbf{100})]Cl_2$,[440] $Ca(\mathbf{101})(NCS)_2$,[441] $[Sr(\mathbf{101})H_2O](NCS)_2$[441] and $[Sr(\mathbf{102})H_2O](NCS)_2$[442] have been determined. The magnesium is found to lie in the plane of the donor atoms, pentagonally bipyramidal through interaction with two axial water molecules.[440] The calcium is similarly centrally coordinated with N-bonded thiocyanates axially disposed to give a hexagonal bipyramid.[441] The strontium complexes have the metal interacting with all of the ring donors but displaced out of plane towards two N-bonded anions. A water molecule on the opposite side of the ring completes the nine-coordination of the metal.[441,442]

(100)

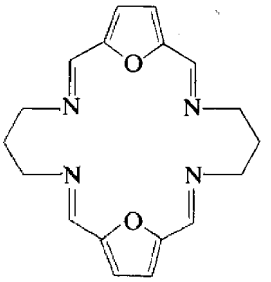


(101)

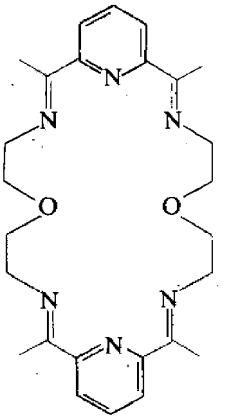


(102)

With (2 + 2) macrocycles several features arise and both 1:1 and 1:2 complexes have been found. The complex $(\mathbf{103})SrCl_2$ has the metal coordinated in a hexagonal bipyramidal geometry comprised of the six ring donor atoms and two apical anions.[443] The barium complexes of (**104**) and (**105**) are, in contrast, sandwich structures: $(\mathbf{104})_2Ba(BPh_4)_2$[444] and $[(\mathbf{105})_2Ba(H_2O)_2][Co(NCS)_4]$.[445] The former has the barium 12-coordinated to the six donors of each ring, whereas in the latter all six donors from one ring are bound and only three from the second ring. The ligand is folded and the complex has fluxional behaviour as determined by NMR studies. The Ba^{2+} is only 11-coordinated, two water molecules occupying the last two sites. Alkaline earth metal complexes of (**106**) have also been reported.[446] One useful role these complexes play is that of precursors for transmetallation reactions leading to dicopper(II) complexes of the macrocycles. These latter complexes serve as speculative models for probing the nature of the bimetallobiosites in copper-containing enzymes and proteins, such as type III oxidases and oxyhaemocyanin.[446]

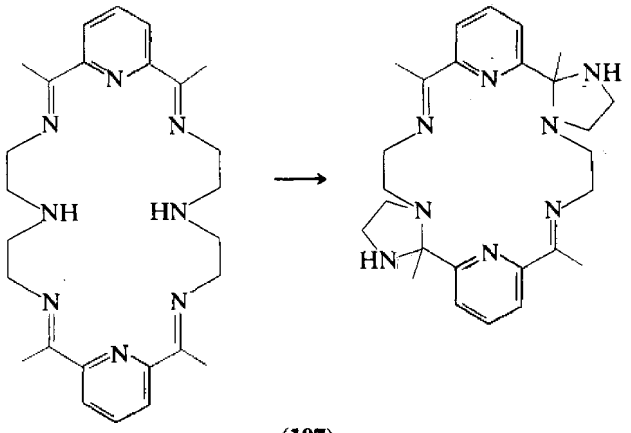


The barium complex of (**107**) is unusual in that a ring contraction reaction occurs on its formation and the imidazolidine ring presence means that a contraction from a 24-membered macrocycle to an 18-membered macrocycle occurs.[312] The cation in $(\mathbf{107})Ba(ClO_4)_2$ is 10-coordinated to the six in-planar nitrogen donor atoms and to two bidentate perchlorate anions.[312] In the complex $(\mathbf{108})Ba(ClO_4)_2{\cdot}2H_2O$, the metal is almost fully encapsulated by the ligand with the hydroxyl groups participating in the bonding.[447] The cation is 10-coordinated by the eight ring donor atoms and two water molecules with the perchlorate anions solvent

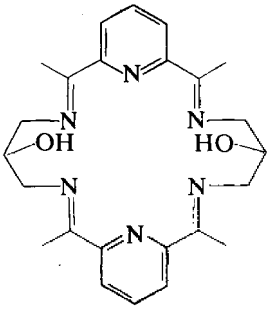


(103)

(104)



(105)



(106)

separated. In the analogous complex having furanyl moieties as head units, instead of pyridinyl units, a similar ligand arrangement is found but the perchlorates are now bound to the cation; this serves as an example of the fine balance that exists between ligand donors, solvent donors and anions in such complexes.

(107)

(108)

Coronands containing pyridinyl, thiophenyl and furanyl head units have been prepared,[33] and their complexation studied. The coronand (**109**; Figure 13) gives a 1:1 complex with KNCS in which the metal is coordinated centrally by the six ring donor atoms; the keto groups are not involved in the coordination.[448]

23.5.2 Cryptands

Macropolycyclic ligands containing intramolecular cavities of a three-dimensional nature are referred to as cryptands. The bicyclic cryptands (**73**) exist in three conformations with respect to the terminal nitrogen atoms, *exo-exo, endo-exo* and *endo-endo*;[6] these forms can rapidly interconvert *via* nitrogen inversion but only the *endo-endo* form has been found in the crystal structures of a variety of complexes[372] and for the free ligand ([2.2.2], **73**, $m = n = l = 1$).[449] In their complexes with alkali and alkaline earth cations, the cryptands exhibit an enhanced stability over the crown ethers and coronands due to the macrobicyclic, or cryptate, effect.[33,202]

The configurations of the free ligand, [2.2.2]cryptand, and its RbNCS complex are shown in Figure 20. The rubidium is complexed by four oxygen and two nitrogen donors and is completely trapped in the three-dimensional cavity.[450]

The ligand shape has changed and it has 'inflated' on encapsulating the cation. The structures of a large number of [2.2.2]cryptand alkali and alkaline earth metal complexes have been studied by X-ray crystallography.[372] Using the criterion that the optimum complexation occurs when the cation and cavity radii are similar, it can be predicted that for this ligand potassium is

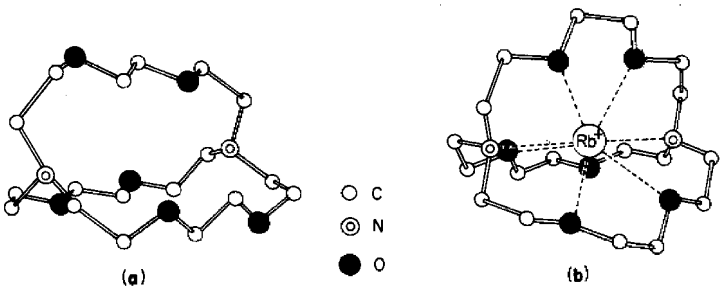


Figure 20 Molecular structures of [2.2.2]cryptand (**73**) and of the rubidium cryptate (reproduced with permission from reference 31)

the best cation (cavity diameter ≈ 2.80 Å, ionic diameter ≈ 2.66 Å). However, the ligand is flexible enough to incorporate the smaller sodium cation by undergoing significant twisting of the ligand.[372] This flexibility is also evidenced with increasing ionic size and coordination number of the embedded cation, as a progressive opening up of the cavity is detected. When this occurs, addition of an anion, or a solvent molecule, is observed. This is a common feature in the alkaline earth metal complexes such as $[Ba(NCS)\cdot H_2O\cdot[2.2.2]]NCS$[451] and $[Ca\cdot H_2O\cdot[2.2.2]]Br_2\cdot 2H_2O$.[452] In the [2.2.2] complex with cesium it was concluded from ^{133}Cs NMR data that in solution the [2.2.2] forms an exclusion complex with the cation. The cation does not occupy the central cavity but is only partly encapsulated by the cryptand.[453]

An exclusion complex of this type has been identified by X-ray crystallography for the KNCS complex of the smaller [2.2.1]cryptand,[454] ([2.2.1]cryptand = **73**, $n = 1$, $m = 1$, $l = 0$). The cation occupies a site in the 18-membered ring provided by the ligand rather than in the central cavity and so resembles the coordination of potassium by 18-crown-6 (Figure 21a). In contrast, the smaller Na^+ cation is of optimal size for the [2.2.1]cryptand and so an inclusion complex occurs with the cation inside the cage (Figure 21b).[454] Binuclear inclusion complexes have not yet been isolated for bicyclic cryptands.

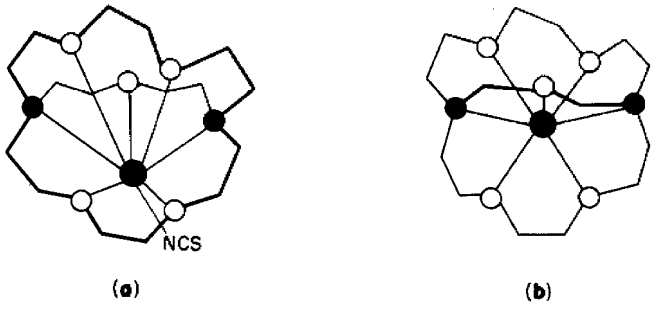

Figure 21 Representatives of the molecular structures of the complexes formed between [2.2.1]cryptand and (a) KSCN and (b) NaSCN

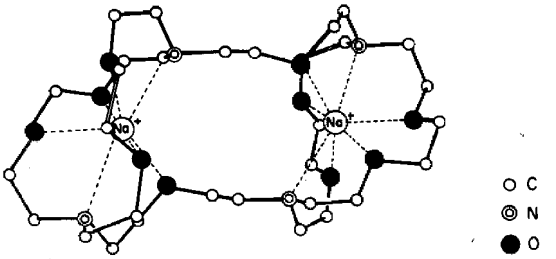
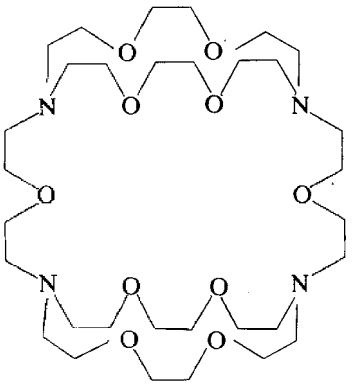
An interesting feature of cryptand complexes has been their use in the stabilization and identification of unusual anions. Structures of interest include those for an alkalide anion, $[2.2.2]Na^+Na^-$,[455] and for polyatomic anions of post-transition metals, $\{[2.2.2]Na^+\}_3Sb_7^{3-}$,[456] $\{[2.2.2]Na^+\}_2Pb_5^{2-}$,[457] $\{[2.2.2]Na^+\}_4Sn_9^{4-}$,[457] $\{[2.2.2]K^+\}_2Sn_4^{2-}\cdot en$,[458] $\{[2.2.2]K^+\}_2Ge_4^{2-}$[458] and $\{[2.2.2]Ba^+\}Se_4^{2-}\cdot en$.[459] The organometallic complex $\{[2.2.2]\}Na^+FeCO_4^{2-}$ was also studied in order to define the stereochemistry of the anion whilst concealing the cation from it.[460] Complexes containing two enclosed cations can be established using macrotricyclic ligands. The structure of (**110**)$(NaI)_2$ shows each sodium to be bound to two nitrogen atoms and five oxygen atoms of each terminal cycle in the ligand, and separated by a distance of ≈6.4 Å (Figure 22).[461]

In the 1:1 $NaBF_4$ complex of (**111**) the cation is completely encapsulated by the tricyclic ligand and bound to all eight donor atoms.[391b] In the structure of the dipotassium complex of





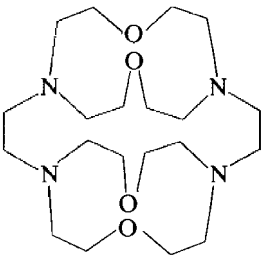


Figure 22 The molecular structure of the binuclear sodium complex of the tricyclic cryptand (**110**) (reproduced with permission from reference 31)

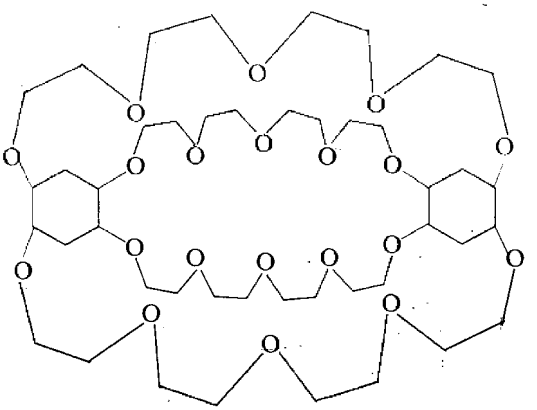
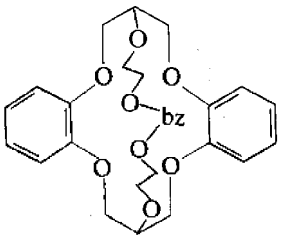
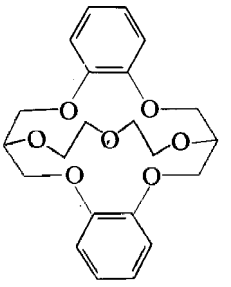


the ligand (**112**),[462] the potassium cations are located in the two '30-crown-10' fragments at a distance of 7.38 Å apart.

(**110**)



(**111**)



(**112**)

As well as N-terminal, or bridgehead, cryptands, C-bridgehead ligands have also been developed. The X-ray structure of (**113**)$KCl \cdot H_2O$[463] shows the potassium coordinated only to the encapsulating ligand. The structure of (**114**)$Mg(ClO_4)_2$ shows the metal to be octacoordinated by the seven donor atoms of the ligand and by a water molecule.[464]

(**113**)

UNIVERSITY OF BRISTOL LIBRARY

23.5.3 Cation Selectivity

One of the driving forces in the study of alkali metal and alkaline earth metal complexes of polyethers and related species has been the retrieval of information on complex stability and selectivity with its possible bearing on the problems associated with the understanding of biological transfer, with selectivity, of those metals. The above information, derived in the main from studies on the solid state, has helped establish the nature of the complexes and, in parallel with these studies, an abundant literature has appeared on studies in the solution state. Several reviews have discussed the methodology of study, and the techniques used to determine the stability constant, K_s, for the complexes including calorimetry, NMR, pH metric methods, conductimetry, ion selective electrodes, temperature jump techniques, osmometry and solvent extraction.[20,33,465,466,467] Extensive compilation of the retrieved data has followed on Frensdorff's original studies using Pedersen's polyethers,[468] and is available through the review articles. It should be mentioned that the constants obtained are determined using different methods, in different media and so are often difficult to compare with each other. Consequently, the discussion here will centre on factors which influence stabilities and selectivity and numerical data will be given where appropriate.

The enhanced K_s values for the crown ethers relative to their open-chain analogues have been attributed to the so-called 'macrocyclic effect' (Figure 23). The complexation reactions are believed to be almost entirely entropy driven. The entropy of formation depends mostly on the change of the number of degrees of freedom of particles during complex formation and the biggest item represents the translational entropy of the released water molecules. Highly charged cations which are strongly hydrated should give larger values of $\Delta S°$ and this is experimentally confirmed on going from K^+ to Ba^{2+} complexes of dicyclohexyl-18-crown-6. The $\Delta S°$ value for Ba^{2+} ($-0.8368\,J\,deg^{-1}\,mol^{-1}$) is more favourable than that for K^+ ($15.899\,J\,deg^{-1}\,mol^{-1}$). There is also a macrobicyclic, or cryptate, effect detected on moving to the analogous cryptand (Figure 23). This effect is caused by a favourable enthalpic effect attributable to the strong interaction of the cation with the poorly solvated ligand.[29,465]

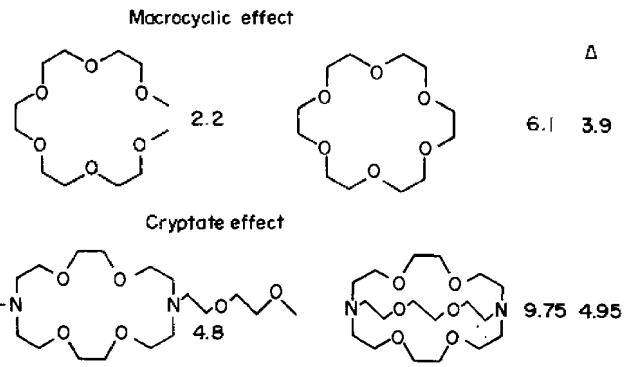

Figure 23 The macrocyclic and macrobicyclic effects (Δ) on complex stability; the values given are the stability constants $\log K_s$ of the K^+ complex in methanol (top) and methanol/water (95.5) (bottom) (reproduced with permission from reference 29)

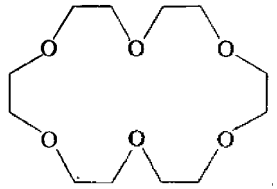
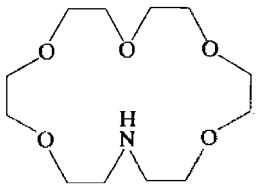
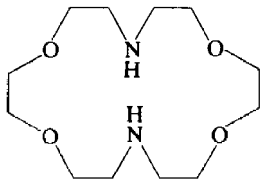
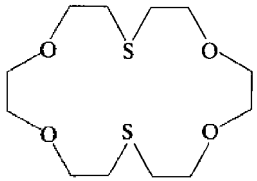
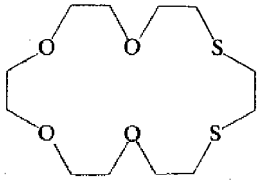




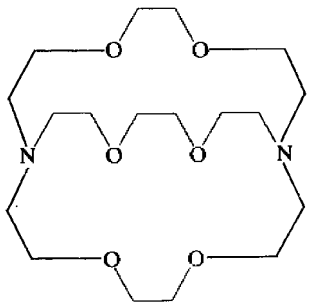


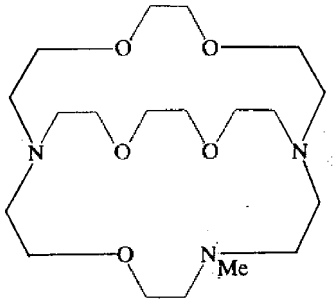


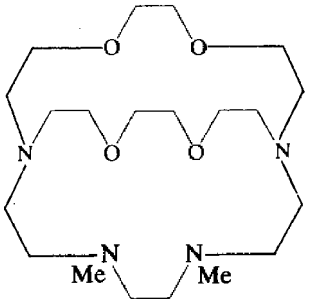


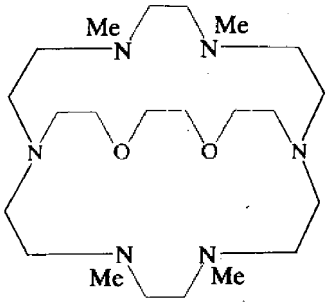
23.5.3.1 Factors influencing selectivity and stability

(i) The nature of the donor atom







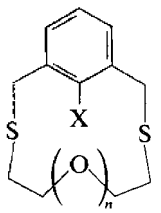


Alkali and alkaline earth metal cations are A-type, 'hard' acceptors and so would be expected to combine most readily with A-type, 'hard' donor atoms. Consequently complexes derived from crown ethers containing solely oxygen donor atoms give high K_s values. The introduction of B-type, 'soft' donors, such as nitrogen, sulfur and phosphorus, gives a destabilizing influence to the complexation process. For example, the K_s values for a series of thia crown analogues having 9-crown-3, 12-crown-4, 15-crown-5, 18-crown-6 and 24-crown-8 skeletons show much reduced K_s values for alkali and alkaline earth cations relative to their oxa crown precursors, but enhanced K_s values for transition metal complexation.[469,470] Substitution of oxygen by an amino (NH) unit in benzo crown ethers has also been seen to lead to a reduction in their complexing ability towards alkali metal picrates and so to affect extraction into an organic phase.[471]

Table 7

(i) A Comparison of log K_s Values for the Complexation of (**73**) and its Aza and Thia Analogues with K^+ and Ag^+

Cation					
K^+ (in MeOH)	6.10	3.90	2.04	1.15	—
Ag^+ (in H_2O)	1.60	3.30	7.80	4.34	3.0



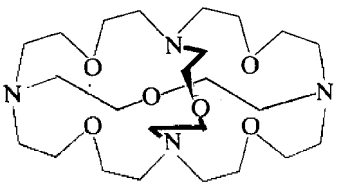
(ii) A Comparison of log K_s Values for the Complexation of [2.2.2]Cryptand and its Aza Analogues with Alkali and Alkaline Earth Cations and with Ag^+

Cation (in H_2O)				
Li^+	<2	1.5	2.4	—
Na^+	3.9	3.0	2.5	—
K^+	5.4	4.2	2.7	1.7
Rb^+	4.3	3.0	2.3	—
Cs^+	<2	<2	<2	—
Mg^{2+}	2	1.9	2.6	—
Ca^{2+}	4.4	4.6	4.3	1.5
Sr^{2+}	8.0	7.4	6.1	1.5
Ba^{2+}	9.5	9.0	6.7	3.7
Ag^+	9.6	10.8	11.5	13.0

Data taken from compilations in ref. 33.

Similar effects are noted with polycyclic systems; the introduction of NR units into cryptands led to reduced K_s values,[472,473] an effect noted particularly for K^+ complexes of methylaza compounds based on [2.2.2]cryptand. Table 7 lists results showing (i) how K_s values for K^+ and Ag^+ complexation vary on introduction of NH and S units into (**76**), and (ii) the variation of K_s on introduction of NMe into [2.2.2]cryptand.

Donors present in appended groups may also cause gradations in stability and selectivity, for example in systems based on (**115**),[386a,474] there is an enhanced Na^+ stability shown, and this is also seen when pyridinyl, furanyl and thiophenyl units are introduced.[475–477] Careful manipulation of the donors, in conjunction with the properties discussed below, can lead to reasonably discrete metal cation specificities.



X = H, Cl, Br, OH, SH, NH_2, OMe, CN, CO_2H, CO_2Me

(**115**)

(ii) The number of, and spatial arrangement of, donor atoms

The number of donor atoms can be influential in complex formation. Ideally, as the incoming ligand is comparable to an inner solvation sphere, the number of donor atoms should match the preferred coordination number of the cation. An example of this factor comes from a comparison of two similarly sized ligands, [2.2.2]cryptand and [2.2.C_8]cryptand, the latter having one dioxoether chain replaced by a C_8 unit.[478] A reversal of the Ba^{2+}/K^+ selectivity of the order of 10^6 is found, the ratio being 10^4 for [2.2.2]cryptand and $<10^{-2}$ for [2.2.C_8]cryptand; the preferred coordination numbers are six for potassium and eight for barium.

The spatial arrangement for the donor atoms is significant in complexation as every deformation of the donor environment which is not compatible with the required geometry at the metal leads to a reduction in the bonding potential of the ligand and the consequent stability of the complex. For spherical metal cations an optimum donor array should also have a spherical form. The 'soccer ball' molecule (**116**)[479] and the more 'rugby ball'-like cryptands approach this end; the crown ethers, in which the oxygen dipoles are not ideally located in the ring centre, and which have vacant acceptor sites, give somewhat lower K_s values unless they are sufficiently flexible to encapsulate the metal.

(**116**)

Modification of the torus of crown ethers by replacement of $—C_2H_4—$ units with $—C_3H_6—$ or longer hydrocarbon bridges, or by insertion of aromatic units such as *o*-, *m*- or *p*-xylene, naphthalene and biphenylene,[465–467,480,481] also leads to unfavourable complexation as the chelating ability of the donor atom pairs within the crown ether framework is modified. The ethyleneoxy group plays a crucial role in polyethers and this is believed to be related to the enhanced stability of five-membered chelate rings comprised of the binding sites, one ethylene bridge and the recipient metal over four- and six-membered chelate rings.[202]

(iii) Cavity shape and size

As has been indicated in the discussion of solid state systems, the relationship between the cation size and the ligand donor cavity size (the 'best fit' criterion) is rather important, and many correlations have been made between this factor and K_s values.[465]

Figure 24 illustrates the relationship between K_s and the cation radius for dicyclohexyl-18-

crown-6 (isomers A and B) and for benzo-5-crown-5.[465] Figure 25 shows the change in K_s for the reaction of Na^+, K^+ and Cs^+ with several polyethers. It can be seen that for the 18-crown-6 systems, K^+ is preferred, followed by Rb^+, Na^+, Cs^+ and Li^+, and for the 15-crown-5 systems the sequence becomes $Na^+ > K^+ > Rb^+ > Cs^+$. This is a reflection of the diminished ring size and cation compatability. One problem, however, in the latter case, is the necessity to distinguish between the formation of 1:1 and 1:2 complexes in solution.

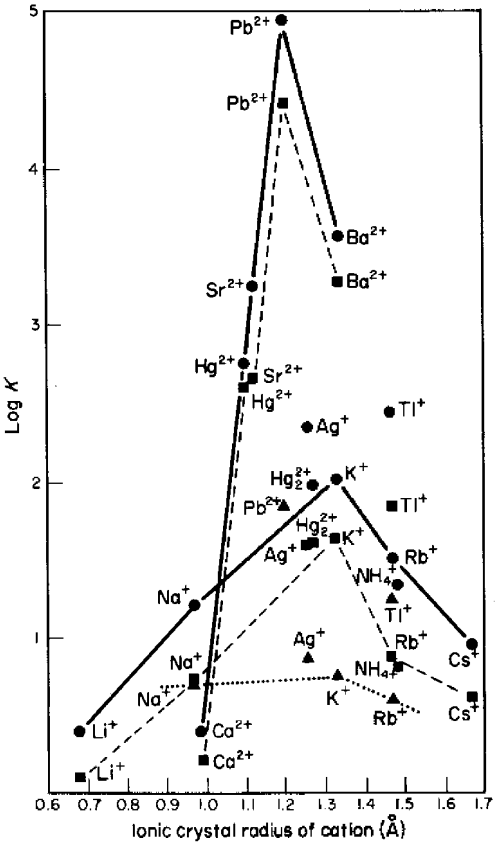


Figure 24 Plot of $\log K$ *vs.* cation radius for the reaction in aqueous solution, $M^{n+} + L = ML^{n+}$ where L = dicyclohexyl-18-crown-6, isomer A (●), dicyclohexyl-18-crown-6, isomer B (■), or 15-crown-5 (▲). $T = 25\,°C$ (reproduced with permission from reference 465)

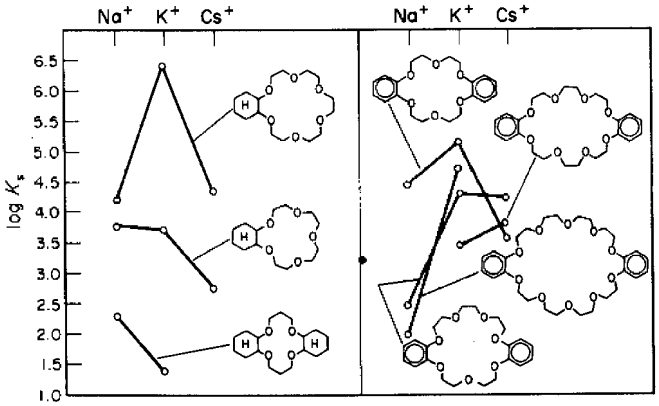

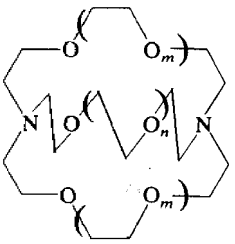

Figure 25 Plots of $\log K_s$ (in MeOH at 25 °C) for complex formation between alkali metal cations and several cyclohexano- and dibenzo-crown ethers (reproduced with permission from reference 31)

More recent studies show some variations to the above generalities. ^{13}C and ^{23}Na NMR studies indicate that for Na^+ the complexation sequence is 18-crown-6 > 15-crown-5 > benzo-15-crown-5,[482] hinting at the need for ligand flexibility; conduction data reveal that for 18-crown-6 the stability sequence is $K^+ > Rb^+ > Cs^+ > Na^+$;[483] extraction studies using metal picrates show that for benzo-15-crown-5, $Na^+ > K^+ > Rb^+ > Li^+ > Cs^+$ for 1:1 complexes and that for the corresponding 1:2 complexes $K^+ > Rb^+ > Cs^+$;[484] further extraction work indicated

that $K^+ > Rb^+ > Cs^+ > Na^+$ if dicyclohexyl-18-crown-6 was the ligand.[485] In general terms such results follow the sequences predicted from comparison of cation and cavity radii; the larger crown ethers, however, have been found to show discrimination against the smaller cations, but do not show much specific preference between the larger cations.

A more precise cavity control is found with the three-dimensional cryptands and Figure 26 shows the variation of K_s with alkali and alkaline earth metal cations for a range of cryptands.[29] Two types of selectivity are displayed. Peak selectivity occurs when there is an excellent correlation between cavity and cation radius (Table 8) and so a sharp discrimination can occur (Figure 26). Plateau selectivity occurs when there is little discrimination between cations of higher radius but discrimination against cations of small radius which are not well accommodated (Figure 26).

Table 8 Log Stability Constants of Some Cryptate Complexes in Water, Log K_1

[a] Recorded in methanol.

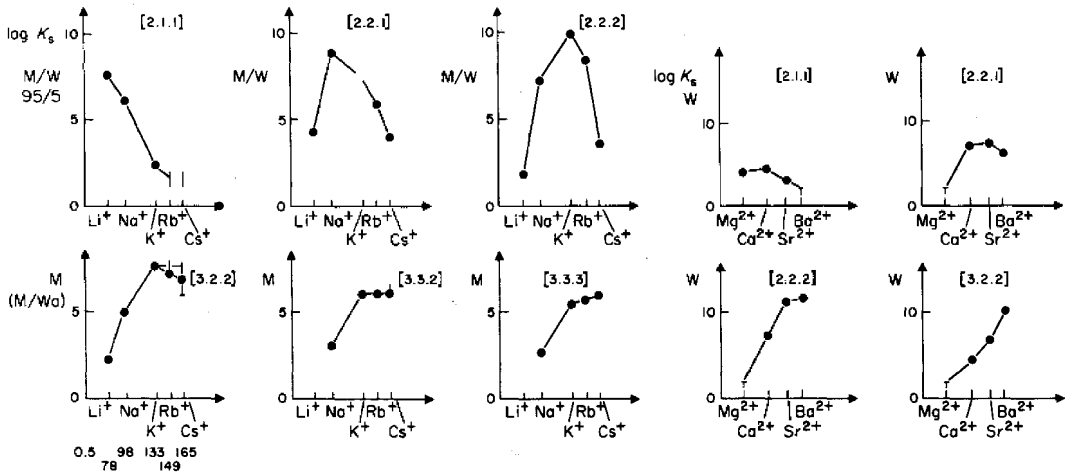

Figure 26 Stability constants ($\log K_s$) of the alkali cryptates (left, in 95:5 methanol/water, M/W, or in pure methanol, M, at 25 °C) and of the alkaline earth cryptates (right, in water at 25 °C) (reproduced with permission from reference 29)

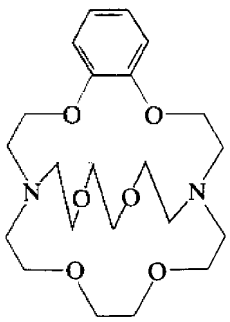
As discussed earlier, the optimum selector for an alkali cation is one in which a spherical cavity is offered for interaction. Ligand (**116**) has a rigid cavity of diameter *ca.* 3.6 Å and so

would be predicted as ideal for complexing Cs^+ (ionic radius 1.65 Å). Up to now this ligand is actually the best one for selective complexation of cesium cations.[479]

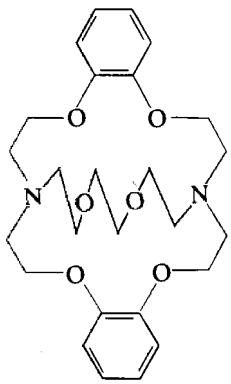
The barium cation (ionic radius 1.43 Å) has a good compatibility with [2.2.2]cryptands (cavity diameter *ca.* 2.8 Å). This cryptand will solubilize even $BaSO_4$ in aqueous solution,[486] and this phenomenon has been investigated with a view to removal of $BaSO_4$ scale deposited by the use of sea water as an injection fluid in oil-producing formations. The scale deposition can lead to blockage of wells.[487]

(*iv*) *Conformational rigidity and flexibility of the ligand*



These factors are very much linked with cavity size. Ligands with small cavities are often rigid in nature simply because of cavity delineation. Larger ligands become more flexible and capable of undergoing often pronounced conformational changes. This leads to a potential availability of a wide range of cavities of variable dimensions. Rigid skeletons should display higher selectivities for individual cations, *i.e.* peak selectivities, and the more flexible ligands exhibit plateau selectivity. The improved selectivity of cryptands over coronands may be related to their more rigid nature.[33]

The unexpectedly large K_s for dibenzo-30-crown-10 and K^+ is consistent with the crystal structure and due to the wrapping round the metal of the ligand such that all donor sites are involved in complexation.[488]



The addition of rings into the skeleton of the polyether can also lead to a stiffening of the skeleton and produce selectivity shifts.[33]

(*v*) *Lipophilicity*

The lipophilic character of a ligand may be controlled by the nature of the hydrocarbon residues present. Ligands with thick lipophilic shells shield the cations from solvent media and decrease the stability of the complex. This effect is four times more strongly felt by the doubly charged M^{2+} cations and so ligand lipophilicity can influence the selectivity between mono- and di-valent cations; the thicker the organic shell, the smaller the selectivity ratio for M^{2+}/M^+ cations.[478] Ba^{2+} and K^+ are of similar size and so if an appropriate cryptand is used, comparisons can be made. The introduction of benzo rings into [2.2.2]cryptand enhances its lipophilicity (**117**, **118**); complexation using (**117**) does not lead to any significant change in Ba^{2+}/K^+ selectivity as the ligand still has an 'open side' to the solvent, but addition of the second benzo ring (**118**) leads to the stabilities becoming similar and a loss of selectivity.[489]

(**117**)

(**118**)

Competition between mono- and di-valent cations has an important role in biological processes. Furthermore, the lipophilicity of a ligand and its complex plays an important role in deciding whether a species is soluble in organic media of low polarity. This has important consequences in areas such as phase-transfer catalysis, the use of crown ethers as anion activators, and in cation transport through lipid membranes. Many crown ethers have now been synthesized with incorporation of long alkyl side chains and enhanced lipophilicity and used successfully in the above areas.

(*vi*) *Electronic influences*

The introduction of substituent groups into the benzo rings on dibenzo-18-crown-6 ethers leads to marked effects on their selectivity. A reversal of the usual selectivity sequences occurs when strong, electron-withdrawing substituents are present.[490] Similar effects are found for benzo-15-crown-5, and a good correlation is found with the Hammett functions of the substituents.[491] In contrast for substituted benzo-18-crown-6 systems, no such correlation was found, indicating that caution must be exercised on extrapolating from one crown ether system to another.

23.5.3.2 Comments on cation transfer

The discriminative uptake of alkali metal cations by biological systems, through their membranes, has been an area of much interest. In the membrane, the cations must pass through a lipid bilayer of low dielectric constant and this has led to the proposition that the cation could be selectively transferred *via* a 'carrier' molecule, or through a suitably donor-lined pore.[7–9] As a consequence of their selective properties, the polyethers and cryptands have been investigated as speculative models for the above process and selectivity sequences have been established.

Much of the preceding discussion has concerned the behaviour of alkali metal complexes in the solid state, and in an equilibrium state. Kinetic studies, to understand the dynamic stability of the complexes, have also been made. Such investigations for monocyclic crown ethers are hindered by several factors: the complexes are relatively weak and so must be studied at high cation concentrations; the rate constants are generally very high; and the complexes often do not exhibit properties commensurate with spectroscopic determinations of reaction rate constants.[33,290,492–495] The rates for the complexes studied are practically diffusion-controlled, therefore the complexes require appreciable conformational flexibility. During the complexation of dibenzo-30-crown-10 the cation is simultaneously desolvated and complexed; it has also been proposed that the loss of solvent is a dominant factor and that it could be a stepwise process in which an indeterminate number of water molecules are removed from the hydration sheath of the metal by the sinuous ligand. The energy barrier to decomplexation is believed to be the energy required to produce a conformational rearrangement of the ligand.[488,496]

The more rigid cryptands exchange cations more slowly and a modified stepwise mechanism of incorporation is agreed.[494] The pronounced selectivity of the cryptands for alkali metal cations is reflected in the dissociation steps; the formation rates increase only slightly with increasing cation size (Table 9). For a given metal the formation rates increase with increasing cryptand cavity size and for the [2.2.2]cryptands they are similar to the rates of solvent exchange in the inner sphere of the cations. This suggests that for the larger cations interaction between the cryptand and incoming cation can compensate effectively for the loss of solvation of the cation on complexation. Conformational change can occur during the process of

Table 9 Overall Rates for Complex Formation Between Cryptands and Alkali Metal Cations (MeOH, 25 °C)

Ligand	*Cation*	$\vec{K}$ ($l\,mol^{-1}\,s^{-1}$)	$\vec{K}$ ($l\,s^{-1}$)

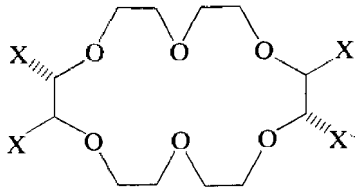
Data compiled from B. G. Cox, H. Schneider and J. Stroka, *J. Am. Chem. Soc.*, 1978, **100**, 4746.

complexation. In general, the most stable cryptates act as cation receptor complexes which release the metal only slowly, whereas the less stable ones can exchange more rapidly and so act as cation carriers.

Selectivity sequences in solvents such as water, methanol and ethanol do not guarantee a similar behaviour in the lipid membrane. Experiments have been carried out in attempts to investigate the selective transfer of cations across model membranes, and these are exemplified here by reference to an investigation concerning the cryptands [2.2.2], [3.2.2], [3.3.3] and [2.2.C_8]. Two aqueous phases (IN and OUT) were bridged by a chloroform layer into which the carrier can be dissolved. Alkali metal picrate was dissolved in two aqueous layers such that the IN layer was 1000 times more concentrated than the OUT layer. All layers were stirred and the transport monitored *via* increase in picrate in the OUT layer (UV) and increase in potassium in the OUT layer (atomic absorption). The membrane phase was also analyzed at the end of the experiment.[497]

The results (Table 10) show that the cryptands could act to produce carrier-mediated facilitated diffusion and there was no transport in the absence of the carrier. The rate of transport depended upon the cation and carrier, and the transport selectivity differed widely. The rates were not proportional to complex stability. There was an optimal stability of the cryptate complex for efficient transport, $\log K_s \approx 5$, and this value is similar to that for valinomycin (4.9 in methanol). [3.2.2] and [3.3.3] showed the same complexation selectivity for Na^+ and K^+ but opposing transport selectivities. The structural modification from [2.2.2] to [2.2.C_8] led to an enhanced carriage of both Na^+ and K^+ but K^+ was selected over Na^+. The modification changes an ion receptor into an ion carrier, and indicates that median range stability constants are required for transport. Similar, but less decisive, results have been found in experiments using open-chain ligands and crown ethers.[498]

Table 10 Rates and Selectivities of Alkali Metal Cation Transport *via* Cryptate Complexes



Carrier	*Cation*	*log K_s (in MeOH)*	*Cation conc. in membrane* (μ mol l^{-1})	*Carrier saturation* (%)	*Initial transport rate* (μ mol h^{-1})	*Transport selectivity, K^+:Na^+*
[2.2.2]	Na^+	7.2[a]	1400	95	0.6	1:20
	K^+	9.7[a]	>1400	>95	0.03	
[3.2.2]	Na^+	5.0	750	60	2.4	1:3.5
	K^+	7.0[a]	1100	75	0.7	
[3.3.3]	Na^+	2.7	110	10	1.5	1:0.55
	K^+	5.4	950	65	2.7	
[2.2.C_8]	Na^+	3.5	140	15	1.6	1:0.45
	K^+	5.2	850	80	3.6	

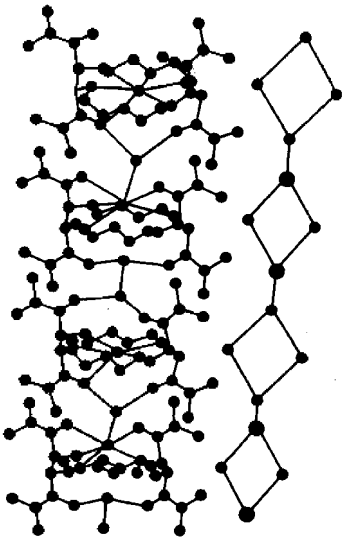
[a] These values are for methanol containing 5% water; higher values are expected for pure methanol.

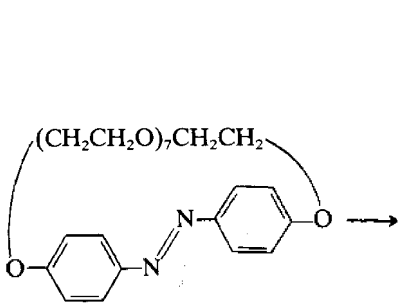
Data compiled from M. Kirch and J. M. Lehn, *Angew. Chem., Int. Ed. Engl.*, 1975, **14**, 555.

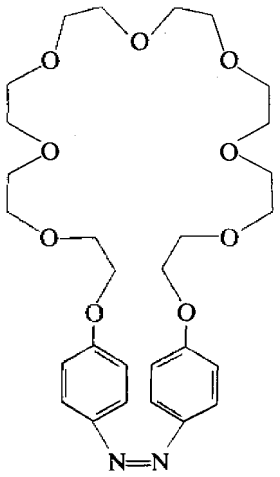
Molecular channels are also thought to play important roles in ion exchange processes across membranes, and data from physiological and biophysical sources point to the existence of Na^+- and K^+-specific pores. The molecular nature of the ion flow through such channels remains obscure in contrast to the carrier-facilitated processes. The crystal structure of the potassium complex (**119**)1.5KBr·3.5H_2O of the chiral macrocyclic tetracarboxamide (**119**) has recently been solved and shows a solid-state model for a molecular channel in which the macrocyclic units are organized in a polymolecular stack. The K^+ cations are located alternatively inside and on top of successive macrocycles, as in a frozen picture of potassium ion carriage through the channel (Figure 27). The water molecules solvate the cation and amide groups and provide hydrogen-bonded links between the component molecules. The stepwise connection of macrocyclic units through their side chains should allow for the construction of an artificial molecular channel with selective properties dependent upon the choice of basic unit.[499]

Other recent developments include crown ethers which contain potential switch mechanisms for complexation and transport. When photoresponsive chromophores are linked to crown ethers, ion binding can change on photoirradiation. The crown (**120**) is formed as its *trans* isomer with no alkali metal affinity, but photoirradiation gives a *cis* isomer capable of alkali metal complexation;[500] this is an example of a reversible all or none ion-binding capability. A

(**119**)







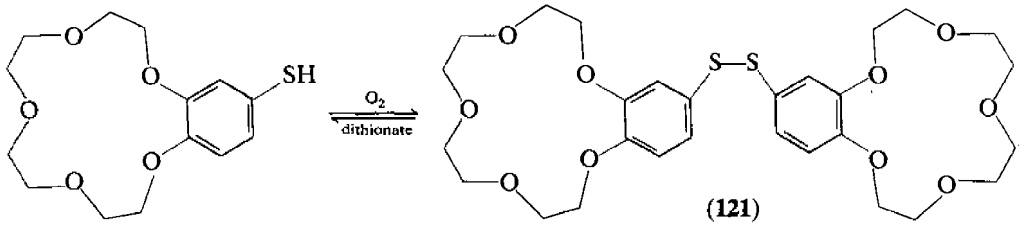


Figure 27 Molecular stacking in the KBr complex of (**119**) (reproduced with permission from reference 499)

redox switch can also be introduced into polyethers (**121**),[501] and solvent extraction studies show the ion affinity of the thiol crown to be significantly higher than the disulfide bis crown. The compounds (**122**) and (**123**) are found to be pre-ionophores, which on oxidation by Fe^{3+} are converted into disulfide-bridged monomacrocycles having M^+ transport capability. These systems have been proposed as models for biological 'ion gates'.[502]

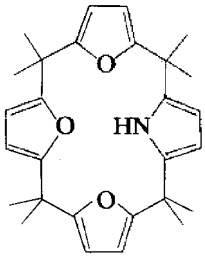
23.5.4 Quaterenes and Calixarenes



The reaction of furan with acetone leads to the isolation of (**124**); similarly (**125**) can be prepared from pyrrole with acetone, and the mixed species (**126**)–(**128**) are also available.[503] There is a donor cavity of 1.2–1.7 Å radius depending upon the construction and so it was thought that these would be suitable ligating systems for the alkali metals.[504] The fully reduced form of (**124**), (**129**), has been found to form 1:1 complexes with $LiClO_4$ and LiSCN,[505] and lithium and magnesium salts have been found to give enhanced yields of (**124**) leading to an invocation of the metal-template effect in the mechanism of synthesis.[506] There is also an anion effect and a pH control at the same time.[507] Conflicting information was presented on the solution complexation of M^+ by quaterenes. Monitoring of the NMR spectra, of absorption bands in the electronic spectra, and picrate extraction into organic phases indicated that (**124**)–(**129**) did not form any complexes.[504] However, work carried out using higher concentrations of reagents shows that (**129**) was indeed capable of complexing Li^+ and preferred this cation to Na^+ and K^+.[508] The larger quaterenes (**130**) and (**131**) were also investigated and showed K^+ preference in the case of (**130**) and no complexation at all using (**128**).[508]

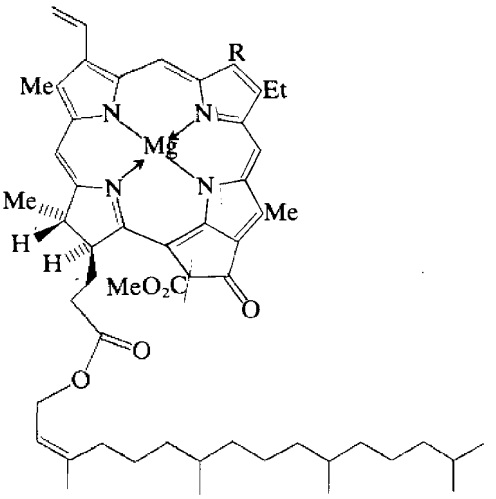
(131)

Macrocyclic phenol–formaldehyde condensation products have been termed calixarenes[509] and are capable of providing a cavity for complexation (**132**). Rb^+ was shown to be a good templating device during synthesis and this hinted at complex formation. Transport experiments have shown calixarenes-[4], -[6] and -[8] to be selective for Cs^+; using MNO_3 no transport was detected but with MOH it occurred. 18-Crown-6 behaved in a contrary fashion;

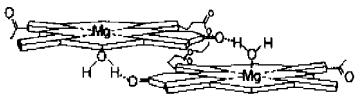


the transport was from an aqueous phase through a chlorocarbon membrane into an aqueous phase. The ligand sequence was found to be calixarene-[4] > calixarene-[6] > calixarene-[8] and cation selectivity was related to the hydration energy of the cation. It was noted that the cation with the lowest hydration energy was that most readily transported.[510]

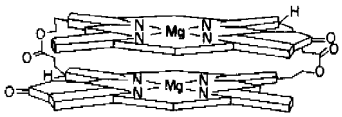
(132) *p-tert*-butylcalix[4]arene

23.5.5 Porphyrins, Phthalocyanines and Chlorophylls

Magnesium complexes of natural origin, the chlorophylls and related pigments, form a vast area of study in both the solid and solution states.[511–513] The chlorophyll ring system is a porphyrin in which a double bond of one of the pyrrole rings has been reduced (**133**); a fused cyclopentanone ring is also present. Chlorophyll is crucial to the process of photosynthesis; photons of light hitting a molecule of chlorophyll provide the energy for a series of redox reactions to occur. The magnesium can be found either centrally bound as in (**133**), or peripherally located on the exterior of the macromolecule. The latter interactions influence molecular aggregation and spectral features, whereas the former siting determines the basic chemistry of the pigment.



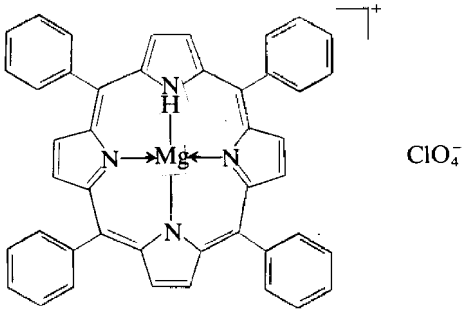
(133) R = Me, chlorophyll *a*
R = CHO, chlorophyll *b*



The molecular structure of ethylchlorophyllide *a* dihydrate,[514] a chlorophyll molecule in which the phytyl side chain has been replaced by an ethyl group, shows one water molecule coordinated to the magnesium and forming a hydrogen bond with the ring V keto group of an adjacent molecule. This in turn has a magnesium-coordinated water molecule hydrogen-bonded to a third molecule and so on to produce a one-dimensional array of overlapping chlorophyll molecules.

Bis-chlorophylls (**134**)[515–517] and 'cyclophane'-chlorophylls (**135**)[518] are reported to exhibit several photochemical properties which mimic the *in vivo* 'special pair' chlorophylls. By

constructing these dimeric units it has been possible to account for the redox and spin delocalization properties of the chlorophyll pairs *in vivo* but not yet to produce the unusually red-shifted spectrum. Such synthetic systems are of interest as evidence relating to the molecular organization of chlorophyll in the photoreactive centres of green plants and photosynthetic bacteria suggest that special pairs of chlorophyll molecules are oxidized in the primary light conversion event in photosynthesis.



(134)

(135)

Studies have also been carried out using porphyrin and phthalocyanine systems as models for the site in chlorophyll. The structure of Mg(tetraphenylporphyrin)·H_2O was solved and showed a disordered system, but it was possible to find the cation in a square pyramidal environment with the water molecule in the apical site.[519] In Mg(phthalocyanine)·H_2O·2py, the magnesium is similarly coordinated, the pyridines not being involved with the metal.[520] The magnesium is displaced from the basal donor plane towards the apical ligand as a common feature. In the latter compound it is a significant displacement of 0.49 Å and is assisted by hydrogen bonding of the water to a proximal pyridine.

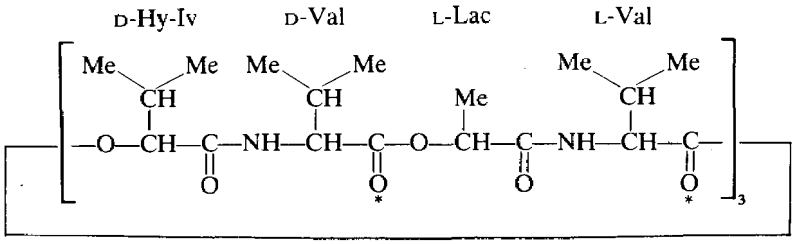
The magnesium porphyrin radical, Mg(tetraphenylporphyrin)ClO_4 (**136**), has been used as a model for the structural and stereochemical consequences of loss of an electron in photosynthetic chromophores.[521] The primary photosynthetic reaction in plants and bacteria consists of a transfer of an electron, in the picosecond time domain, from the chlorophyll phototrap to nearby acceptors yielding chlorophyll π-cation radicals. The structure of (**136**) shows a five-coordinated Mg^{2+} cation which is not quite symmetrically sited in the porphyrin ring but has metal–ligand distances similar to those found in the previous structures. The perchlorate anion is tightly bound (Mg—O = 2.01 Å) in a monodentate mode. It was concluded that the porphyrin can act as an electron sink and that no major effects are found in the bond lengths, or on the stereochemistry, of the macrocycle.

(136)

Phthalocyanines have been found to give other alkali and alkaline earth metal complexes.[522] The reaction of alkali metal amyl oxides (M = Li, Na, K) with phthalonitrile yields M_2(phthalocyanine). In the case of lithium a second, monometallic species believed to be MH(phthalocyanine) is recovered. With the alkaline earth metals Be, Mg, Ca and Ba complexes are available. Be(phthalocyanine) is prepared from the reaction of beryllium and phthalonitrile and gives a dihydrate on standing. The structure of Be(phthalocyanine) shows a unique, square planar environment for the cation.[523] It is likely that in the formation of the dihydrate two bonds in the complex are broken and a tetrahedral (N_2O_2) environment is recovered for the cation. Mg(phthalocyanine) is the only other dihydrated metal derivative of this ligand and it also forms bis adducts with a variety of donor ligands bearing oxygen, nitrogen and sulfur atoms. Mg(tetraphenylporphyrin) behaves in a similar fashion with simple donors; induced Cotton effects in the CD and ORD spectra of Mg(porphyrin) amino acid systems have been interpreted in terms of Mg(porphyrin)·2(amino acid) complexes.

23.6 NATURALLY OCCURRING IONOPHOROUS AGENTS

The 1964 studies, made by Pressman, on the effects of the antibiotic valinomycin on mitochondria showed its ability to induce the selective movement of K^+ into the mitochondria.[28] Valinomycin, and other antibiotics neutral at physiological pH, were considered as discriminatory cation carriers and such species which could carry cations across lipid barriers, such as those found in membranes, as lipid-soluble complexes were collectively termed ionophores, or ionophorous agents.[526] A second group of antibiotics containing carboxylic acid functions was also found to exhibit discriminatory powers, and to reverse the effects of valinomycin.[527] The term ionophore had actually been introduced several years previously in suggested nomenclature for conductance.[528] It was used to designate a species in which ions, and only ions, were present in a crystal lattice; a substance whose molecular crystal lattice produced an electrolyte when dissolved in an appropriate solvent was termed an ionogen. This nomenclature does not appear to have found general use, whereas the more contemporary definition is widely accepted.



Pressman has described his discovery as serendipitous[529] and it is quite remarkable that modern alkali metal coordination chemistry should have as its base the two fortuitous discoveries of Pressman and Pedersen. It is of interest to read the engaging accounts written by these two workers of their early work and to see how work in one area can often lead to major advances in another.[530,531]

There are several excellent reviews concerning ionophorous agents and showing their biological value as well as their structural aspects.[2,226,372,493,529,532–535] Physical studies on these compounds have indicated that the complexation–decomplexation kinetics and diffusion rates of ionophores and their metal complexes across lipid barriers are extremely favourable.[290,493,494] This, along with high cation selectivity, inspired their use as model biological carriers. Representative selectivity sequences for the ionophorous antibiotics, and comparisons with crown ethers are given in Table 11. These sequences correlate well with alkali metal selectivity patterns predicted by Eisenman from studies on ion selective glass electrodes.[536] Using an electromechanical model, it was shown that ion mobility is a function of the ion's mobility in a glass lattice and of its ability to become desolvated and enter the glass. This is not an entirely true analogy as the ionophorous agents are more flexible and mobile than the glass matrix.

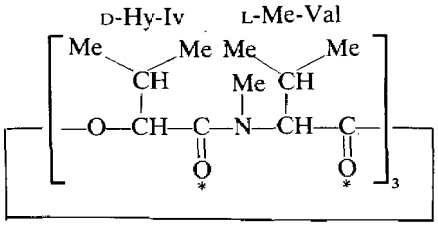


Table 11 Representative Ion Selectivities for Ionophorous Agents and Crown Ethers

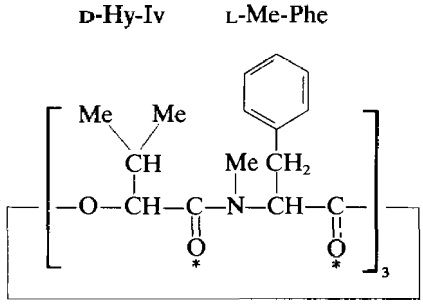
Valinomycin	Rb > K > Cs > Na > Li	Ba > Ca > Sr > Mg
Enniatin A	K > Rb ≈ Na > Cs ≫ Li	
Enniatin B	Rb > K > Cs > Na ≫ Li	
Beauveracin	Rb ≈ Cs > K ≫ Na > Li	
Nonactin	K ≈ Rb > Cs > Na	
Antamanide	Na > Li > K > Rb > Cs	
Monensin	Na ≫ K > Rb > Li > Cs	
Nigericin	K > Rb > Na > Cs > Li	
Lasolocid	Cs > Rb ≈ K > Na > Li	Ba > Sr > Ca > Mg
A 23187	Li > Na > K	Ca > Mg > Sr > Ba
Dianemycin	Cs > Rb ≈ K > Na > Li	Ba > Ca ≈ Mg
Benzo-15-crown-5	Na > K > Cs > Li	
Dibenzo-18-crown-6	K > Cs > Na > Li	
Dicyclohexyl-18-crown-6	K > Cs > Na > Li	



The ionophorous agents have been divided into three groups: neutral ionophores, carboxylic ionophores and quasi-ionophores.[529] Neutral ionophores include cyclodepsipeptides such as valinomycin (**137**), the enniatins (**138**) and beauveracin (**139**); cyclic peptides such as antamanide (**140**); and the macrotetralide actins (**141**). Carboxylic ionophores are comprised of monovalent polyether antibiotics such as monensin (**142**) and nigericin (**143**); monovalent monoglycoside polyether antibiotics such as dianemycin (**144**); divalent polyethers such as lasolocid (X-537A) (**145**); and divalent pyrrole polyether antibiotics such as the antibiotic A 23187 (**146**). The quasi-ionophores are channel-forming species such as the gramicidins, alamethicin and monazomycin.

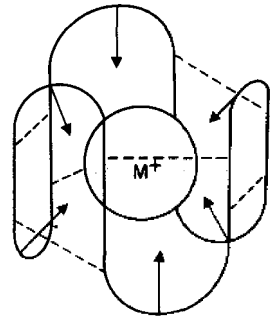
23.6.1 Neutral Ionophores

Valinomycin (**137**) is a macrocyclic dodecadepsipeptide and has shown an unequalled K^+/Na discrimination.[529] As a consequence of this prime ionophorous behaviour many studies have been carried out on both the free ligand and on its metal complexes, and here discussion is restricted to the nature of the metal complexes.

The overall features found in the X-ray structures of (**137**)KX ($X^- = AuCl_4$,[537] I_3/I_5,[538] picrate[539]) are comparable. There is a close to three-fold symmetry of the complex, the cation being located at the centre of the 36-membered ring (Figure 28). The ring is folded around the cation as would three sine waves and these are held in position by six intramolecular hydrogen bonds. The cation is coordinated by six carbonyl oxygens from ester groups in an almost perfectly octahedral arrangement. The cation is thus effectively screened from solvent interaction, although in the structure of (**137**)K(picrate) there is a weak but definite interaction between a picrate oxygen and the cation. All of the lipophilic side chains are orientated on the

periphery of the molecule. The structure of (**137**)$RbAuCl_4$ reveals essentially the same features as in the K^+ complex, K^+ and Rb^+ having similar ionic radii.



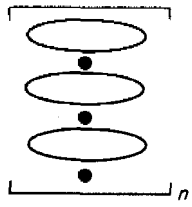


Figure 28 Schematic representation of the valinomycin K^+ complex

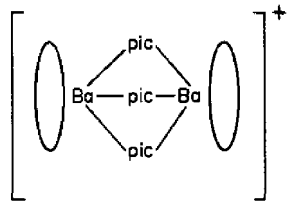

The hydrogen bonding in valinomycin leads to a limited flexibility of the ligand in the complex: the free ligand is much more open, and ellipsoidal in nature.[541] Consequently (**137**) is not able to adjust itself to accommodate ions of different radii, and this helps explain its high K^+/Na^+ discrimination. Solution studies on the Na^+ complex indicate an asymmetry of the ester carbonyl stretching frequencies indicating a non-equivalence of these groups in the structure.[542] The smaller size of Na^+ would lead to this observation as the cation would be unable to interact fully with all six ester carbonyls unless there is an accompanying, unfavourable disruption of the hydrogen bonding. Cs^+ would be too large to fit into the cavity and so again would be discriminated against.[372]

The selectivity ratio $K^+:Na^+$ at 25 °C is of the order $10^4:1$ whereas at 0 °C it is reduced to only 2:1.[543] This dramatic decrease has been interpreted as indirect evidence for the possible role of (**137**) as a carrier in membranes as, if it provided a pore mechanism, this would be unimpaired by freezing. In a carrier mechanism which necessarily involves a mobile ligand to effect incorporation and transfer of the metal freezing would cause a loss of mobility and so impair the mechanism. The high K^+ selectivity of (**137**) has led to its employment in ion-selective electrodes.[543]

The enniatins and beauveracin are cyclic hexadepsipeptides and so are 18-membered macrocycles built up of alternating amino acid and carboxylic acid residues. They exhibit lower selectivity than (**137**) and consequently are more broad spectrum ionophores. The structure of (**138**)KI has been solved[544] but it was not possible to conclude, with certainty, whether the metal is entrapped in the central cavity, as in related cyclic polyether structures (Figure 14a), or whether it occupies a site between two adjacent ligand molecules to give an infinite sandwich (**147**) as has been found in the RbNCS complex of a synthetic LDLLDL isomer of (**138**).[545] Adducts of 1:2 'sandwich' and 2:3 'club sandwich' stoichiometry have been proposed for Cs^+ complexes of (**138**),[546a] and the 1:2 K^+ 'sandwich' complex of (**138**) has been proposed as the species which transports K^+ across lipid layers as it shields the metal effectively from solvent interactions.[546b]

(**147**)

(**148**)

The crystal structure of a barium picrate complex of (**139**) reveals a 2:2 dimeric structure of the form [(**139**)$Ba(picrate)_3Ba$(**139**)]$^+$(picrate)$^-$ (**148**),[547] which is unique as three picrate anions are held in the space between the ligated cations. The cations are not sited within the macrocyclic cavities but are displaced towards the centre of the dimer. This situation is reminiscent of the Cs^+–polyether dimer structure (Figure 15d). The outer surface of the (**139**)$Ba(picrate)_2$ complex is highly lipophilic, and the bulky phenyl residues provide screening for the enclosed anions.

Antamanide is a decapeptide which showed preference for Na^+ and Li^+ in solution and selectivity studies.[548] The crystal structures of (**140**)LiBr·MeCN[549] and (**140**-Phe^4,Val^6)NaBr·EtOH[550] have been solved and show the complexes to be essentially isostructural. The backbone of the antamanide moiety can be described as resembling the periphery of a saddle and the alkali cation is located near the mathematical saddle part. Four carbonyl oxygen atoms coordinate to the metal in an almost coplanar geometry and the complex may be considered as cup-like in this region. A molecule of solvent fills the mouth of the cup and gives the metal a square pyramidal coordination (Figure 29). The cage is stabilized by hydrogen bonding. (**140**) has not yet been observed to act as an ion carrier through membranes.

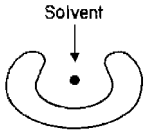

Figure 29 Schematic representation of the antamanide Na^+ complex

The final group of naturally occurring ionophorous agents giving molecular complexes is the macrotetrolide actins (**141**). For this group a more detailed accumulation of structural information allows for a more precise understanding of the selective relationships between the ligands and the cations. The ligands (**141**) are 32-membered cyclic tetralactones, built up of four ω-hydroxycarboxylic acid subunits condensed to each other by esterification. These ionophores exhibit high alkali metal cation selectivity rather like (**137**).[529] Much structural information is available for complexes of nonactin (**141a**) and tetranactin (**141e**).[372] The structures of the free ligands show a large cavity to be present; early consideration of the nature of the alkali metal complexes, based on molecular models, led to the conclusion that the cavity was able to incorporate hydrated cations.[551] However, as in the case of (**137**), the cavity serves as a binding site for the cation and the complexation process is accompanied by much conformational change.

The overall structure found first in the (nonactin)KNCS complex[552] is retained in changing the metal present. The ligand wraps itself around the cation as the seam of a tennis ball (Figure 30) and the cation is thence eight-fold coordinated by the four furanyl and four carbonyl oxygen donor atoms. The periphery of the molecule is lipophilic and the lowered lipophilicity of nonactin relative to tetranactin leads to a diminished transfer of these compounds.

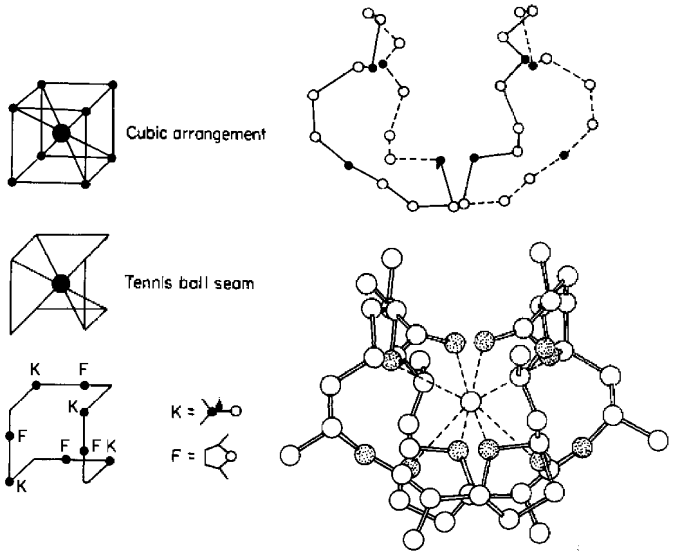

Figure 30 The nonactin potassium complex and the schematic representation of this molecule (reproduced with permission from reference 8)

The different stabilities of the metal nonactin complexes can be rationalized in terms of the interactions within the overall spatial framework. In the K^+ complexes (**141a**)KNCS and (**141e**)KNCS,[553] the distances between the cation and the carbonyl oxygens are slightly less

than those to the ether oxygens (Table 12), and the former are close to the sum of the ionic radius of the cation and the van der Waals radius of oxygen. In the (**141a**)–NaNCS complex the carbonyl oxygen atoms approach the cation but the ether oxygens are restricted in their approach by intramolecular steric hindrance and this is seen in the disparate bond distances.[554] The sodium to ether distances are long (2.70–2.94 Å) and in excess of the sum of the relevant radii (2.35 Å), thus indicating a lowered electrostatic interaction and leading to a distorted cubic coordination geometry. The inability of the ligand to readjust to the required optimum cavity for sodium leads to a reduced stability of the sodium complexes. Complexes of the smaller lithium cation have not yet been observed for (**141**). Incorporation of the larger Rb^+ and Cs^+ cations leads to an expansion of the ligand which involves an outward displacement of the carbonyl oxygen atoms.[553,555] In these species, the observation of bond distances lower than the sum of the component radii suggests the presence of steric strain, which would diminish the stability of the complexes. Solution studies reveal, as with valinomycin, almost identical structures in solution compared with those found in the solid state.[372]

Table 12 Structures of Macrotetrolide Actin Complexes

Complex	*Coordination number*	*Bond distances* (Å) *M—O (carb)*	*M—O (ether)*
Nonactin·NaNCS	8	2.40–2.44	2.74–2.79
KNCS	8	2.73–2.81	2.81–2.88
CsNCS	8	3.13–3.18	3.07–3.16
$Ca(ClO_4)_2$	8	2.33–2.36	2.60–2.61
Tetranactin·NaNCS	8	2.43–2.45	2.70–2.94
KNCS	8	2.75–2.81	2.85–2.92
RbNCS	8	2.88–2.93	2.90–2.98
CsNCS	8	3.06–3.16	3.03–3.10

Data compiled from R. Hilgenfeld and W. R. Saenger, *Top. Curr. Chem.*, 1982, **101**, 1.

The structure of (**141a**)$Ca(ClO_4)_2$ has been solved and shows a close similarity to that of the sodium complex. This is not surprising due to the close similarity in ionic radii between sodium and calcium.[556]

Certain common features may be found in the complexation of alkali and alkaline earth metal cations by ionophorous agents and which aid in cation transport.[8]

(1) The cation sits in the ligand cavity at a centre of optimum electron density provided by the donor atoms of the ligand.

(2) A flexible ligand is required to effect the energetically favoured stepwise removal of the cation solvation sheath. Upon complexation the cation must be stripped of its hydration shell, a process requiring the loss of about 322 kJ mol^{-1} for K^+. This loss must be compensated for by interactions between the cation and the donor atoms of the ligand. Complex formation has been shown to be very fast and stepwise incorporation of the cation by the ligand is essential.[290] Models show that the hydrated K^+ cation could be inserted into the ligand cavity (of **137** and **141**) and held there by hydrogen bonding. Through a series of ligand conformational changes, the water molecules could then be removed and the cation held in the cavity by ion–dipolar interactions.

(3) A lipophilic exterior is presented to facilitate solubilization and cation transport.

(4) A 'best-fit' situation is required with regard to the cavity diameter and the diameter of the incoming cation, but ligand–ligand repulsions must be minimized.

(5) The difference between the energy of the ligation and the energy of solvation must be maximized.

On fulfilment of these requirements, the metal ion is efficiently coordinated, and transported, by the ligand.

An extensive range of synthetic analogues of valinomycin and the enniatins has been prepared and investigated; these studies have been fully described in a monograph.[532] Synthetic peptides have also been prepared and their complexing properties investigated; for example [L-Val-D-Pro-D-Val-L-Pro]$_3$ reacts with potassium picrate to give an isolable 1:1 complex which is expected to have a structure similar to that of the K^+ complex of (**137**).[557] More detailed studies have been made on the complexation properties of the small synthetic peptides [L-Pro-Gly]$_3$ and [L-Pro-Gly]$_4$.

The cation-binding properties of [L-Pro-Gly]$_3$ parallel those of the related naturally occurring ionophores. Solution studies have indicated the availability of 1:1 complexes with Li^+, Na^+, Rb^+, Cs^+ and Ca^{2+}, but Mg^{2+} gave three different stoichiometries, 1:2, 1:1 and 2:1.[558] X-Ray structural studies have been carried out on the magnesium and calcium perchlorate complexes.[559] In the former a 1:1 interaction is found between the peptide and the cation, which is in an octahedral environment provided by three glycyl carbonyl oxygens and three water molecules; these water molecules are hydrogen-bonded to an adjacent peptide and so the molecules are arranged in an infinite stack, and the composite is not unlike a channel or pore. In the Ca^{2+} complex a sandwich structure (1:2) is found and the cation is octahedrally coordinated by six glycol carbonyl oxygens, three from each ring.

[L-Pro-Gly]$_4$ also forms complexes with alkali and alkaline earth cations showing a preference, in solution, for the larger cations. Solution studies revealed 1:1 stoichiometries for Li^+, Na^+, K^+, Cs^+, Ca^{2+}, Mg^{2+} and Ba^{2+} in water, and both 1:1 and 1:2 ratios for these cations in acetonitrile. Na^+ also gave a bimetallic 2:1 complex in acetonitrile.[560] The structure of the Rb^+ complex [L-Pro-Gly]$_4$RbNCS·3H_2O was solved and showed a dimeric structure in which Rb^+ cation was octahedrally coordinated by four glycyl carbonyl oxygens from one ligand, one glycyl carbonyl oxygen from the second ligand and a water molecule.[561]

A further sandwich structure was found for [Gly-L-Pro-L-Pro-Gly-L-Pro-L-Pro]$_2$Mg(ClO_4)$_2$·4MeCN. The cation is in a regular octahedral coordination sphere with two glycyl and one prolyl carbonyl oxygen from each peptide providing the donor groups.[562]

A series of synthetic 32-membered ring macrotetrolides related to the actins have been prepared and show cation transfer ability. The K^+/Na^+ selectivity is however inferior to that of the actins and cyclic polyethers.[563]

23.6.2 Carboxylic Ionophores

These are so described because they are linear and contain a terminal carboxy group, one or two hydroxy groups at the other end of the molecule, and several other oxygen donors provided by the constituents of the chain. In contrast to the neutral ionophores which provide cationic complexes, this group of ligands generally provides neutral salts because, at physiological pH, their carboxy group is dissociated. Carboxylic ionophores have been subdivided according to their ability to coordinate to alkaline earth cations and so those ionophores not capable of transporting divalent cations are termed monovalent polyethers and those capable of transporting divalent cations are termed divalent polyethers, and further subdivisions are available according to the nature of the constituents of these compounds.[529,535]

The ion selectivities displayed by these antibiotics are lower than those of the neutral ionophores, and are given in Table 11. Many studies have been made on the properties of these ionophores, particularly with reference to the calcium-transporting abilities of A 23187 (**146**) and lasolocid (**145**). The search for new antibiotics is ongoing and there is constant addition to a list of about 50 distinct polyether antibiotics which have been isolated from various streptomycetes. Representative structures will be discussed here to illustrate the nature of complexation with alkali and alkaline earth metal cations.

Monensin (**142**) provides examples of complexation by both the anionic and neutral ligand. The structure of the Ag^+ salt was first solved and showed that the monensin anion is wrapped around the cation and that it is held in this conformation by two strong head-to-tail hydrogen bonds between the carboxylate group and the hydroxy functions at the opposite terminus (Figure 31a).[564] The cation is in an irregular six-coordination provided by four ether and two hydroxy oxygen donors. The carboxylates do not interact with the cation but are only involved in the hydrogen bonding. This shows that the cation is encapsulated in a pseudo-cavity, and the ligand provides a lipophilic exterior for the carrier. The crystal structures of the anhydrous and monohydrated sodium salts of (**142**) have extremely similar structures,[565] as does that of the NaBr complex of the acid,[566] where the antibiotic acts as a neutral ligand. The structure of the free acid of (**142**) also reveals a pseudo-cyclic conformation held in place by head-to-tail hydrogen bonding, and having a water molecule located in the ligand cavity.[567] This molecule could provide a route into the cavity for an incoming cation by involvement in the solvation shell of the cation prior to ligand stripping and incorporation. Spectroscopic studies provide comparable results for the conformation of the complexes in solution.[372]

The structural features described for monensin have been found in all the monovalent polyether antibiotic complexes studied. In some instances, *e.g.* nigericin[568] and dianemycin,[569]

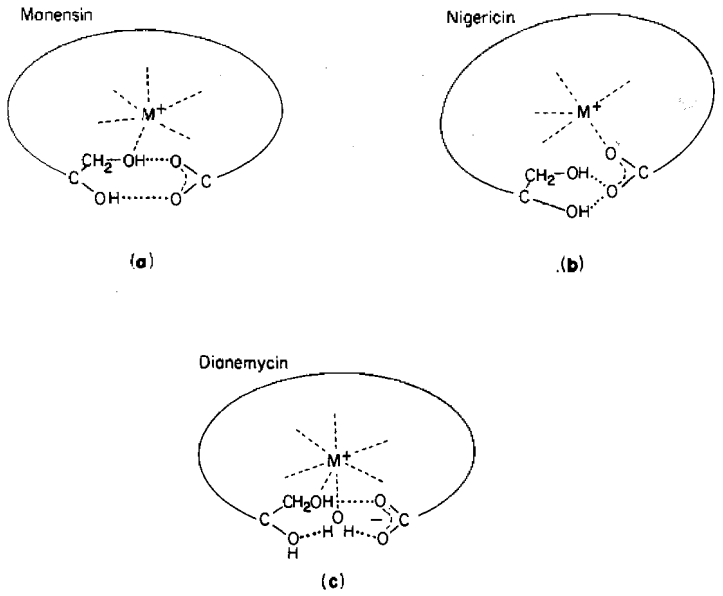

Figure 31 Schematic representations of some metal complexes of acid antibiotics (reproduced with permission from reference 226)

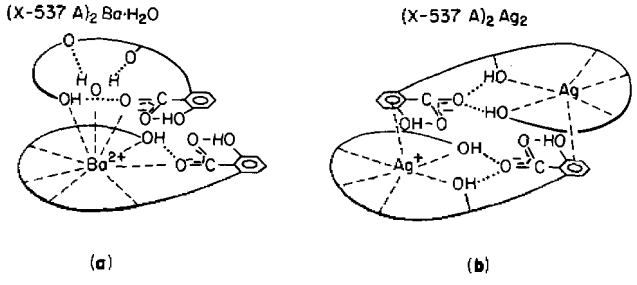
the carboxylic groups are involved in metal complexation as well as in the 'head-to-tail' hydrogen bonding locking scheme (Figure 31b, c). The coordination number of the cation is variable: (monensin)Na^+, 6; (nigericin)Na^+, 5; (nigericin)K^+, 7; (dianemycin)Na^+K^+, 7.[372]

The divalent polyether antibiotics have revealed the existence of dimeric molecules as monomeric complexes in their interaction with alkali and alkaline earth cations. Lasolocid (**145**) forms complexes of the type M^+L^- and these may be monomeric when formed and recovered from methanol, but dimeric when recrystallized from the non-polar carbon tetrachloride. The shortened ligand backbone relative to the monovalent polyethers does not allow complete shielding of the cation from the solvent, and so in non-polar solvents this is overcome by dimerization. If the salicylate and tetrahydropyran moieties present in (**145**) are referred to as the 'head' and the 'tail' of the molecule then two forms of dimerization may be envisaged: 'head-to-tail' and 'head-to-head'.

Discrete dimers of the 'head-to-head' type have been found in the structures of the Ag^+ complex of (**145**)[570] and the Na^+ complex of (**145**)[571] respectively. The complexes were recrystallized from carbon tetrachloride. In both complexes each metal is five-coordinated in the cavity provided by one anion, and there is an additional reaction with the second anion [through an Ag^+–phenyl interaction or an Na^+–carboxylate oxygen atom (Figure 32a)]. When the Na^+ complex was crystallized from a solvent of medium polarity, acetone, the 'head-to-head' dimer was recovered.[571] In contrast, recrystallization from a polar medium, methanol, gave a monomeric complex in which one methanol of solvation was also present.[572] In all of these complexes an intramolecular 'head-to-tail' hydrogen bond was present to hold the ligand in its pseudo-macrocyclic conformation.



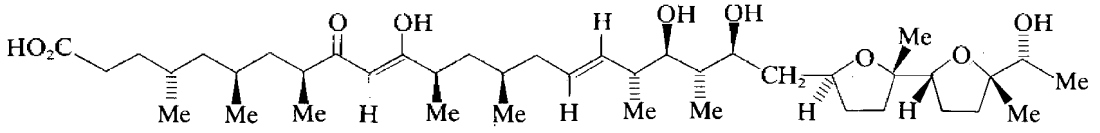


Figure 32 Schematic representations of the structures of the metal complexes of X-537A (reproduced with permission from reference 226)

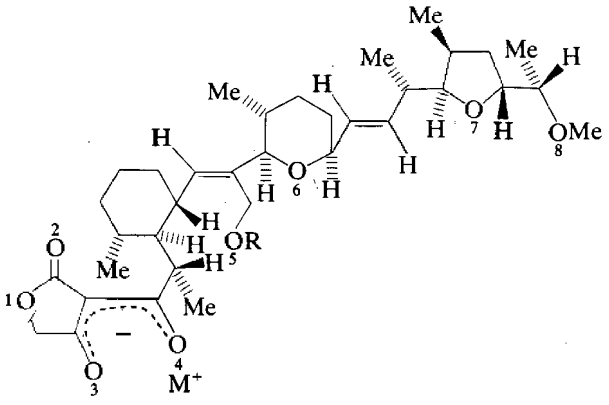
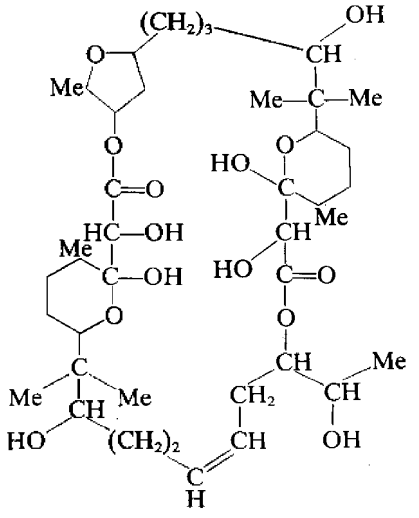


As a consequence of this structural information, the proposal was made that it would be reasonable to consider that the monomeric forms are involved in cation uptake and release in polar media, such exposure being at the surface of a membrane, but that the actual transfer in the medium of low dielectric constant (the lipid phase) would be the dimeric form.[572]

In the Ba^{2+} complex with (**145**), two anions coordinate to the cation in different ways (Figure 32b). The metal ion sits primarily in a cavity provided by one of the anions and is six-coordinated by two ether, two hydroxy, one keto and one carboxylate oxygen atoms. A nine-fold coordination is completed by further coordination to two oxygen atoms from the second anion and a water molecule.[573] A review of the structures of polyether antibiotic complexes is available and includes a compilation of structural data.[372] The stoichiometries of alkali and alkaline earth complexes of (**145**) in methanol, have been determined potentiometrically and show 1:1 neutral complexes for the alkali metal cations, and high stability 1:1 (charged) and 1:2 (neutral) complexes for the alkaline earth cations.[574]



Recent additions to this array of antibiotics include two unusual ionophores: ionomycin (**149**), which efficiently chelates Ca^{2+} as a dibasic acid, the dianion resulting from ionization of the carboxylic acid and β-diketone moieties,[575] and M-139603 (**150**), which has present an acyltetronic acid moiety.[576] A crystallographic study of the calcium complex of (**149**) revealed an octahedral coordination of the cation provided by a carboxylate oxygen, both β-diketonate oxygens, two hydroxy oxygens and one ether oxygen.[575] In the sodium complex (**150**) the cation is six-coordinated through the chelating anion, two ether and one methoxy oxygen atoms of the ligand, and a solvent water molecule.[576] Solution studies on M-139603 reveal the selectivity sequences $Ca^{2+} > Mg^{2+}$ and $Na^+ > K^+ > Rb^+ \gg Li^+$.[577]

(**149**) Ionomycin

(**150**) M = Na, R = H, M 139603

(**151**)

An interesting antibiotic which does not strictly belong to this group, but which exhibits the features of an anionic ion carrier, is a compound derived from the hydrolysis of boromycin by hydrolytic cleavage of D-valine. Boromycin is itself of interest as it is the first well-defined natural organic compound containing boron. The formula, as determined from the X-ray determination of the structures of the Rb^+ and Cs^+ salts of the des-valine product, is (**151**). This molecule is a Boekesen complex of boric acid with a macrodiolide consisting of two almost identical halves. The overall shape of the anion is roughly spherical with a cleft lined by oxygen atoms and a lipophilic surface. The cations are housed in the cleft in an irregular eight-fold coordination (Figure 33).[578]

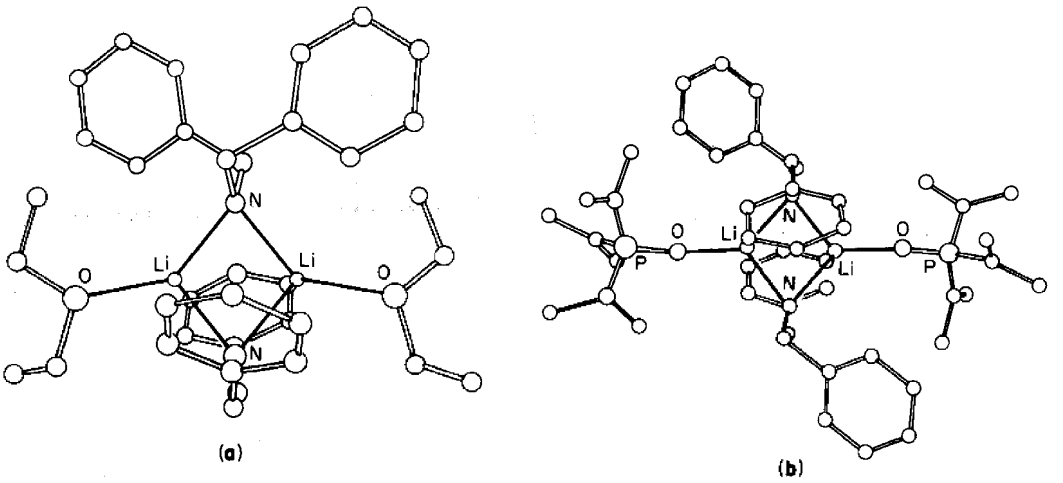
23.7 CONCLUDING REMARKS

During the Second World War, Field Marshall Wavell prepared an anthology of verse and used a sentence from the works of Montaigne as his introduction: 'I have gathered a posie of other men's flowers and nothing but the thread that binds them is my own'. This sentence is also appropriately placed here as with any anthology the choice of contents must be both selective, introducing subjectivity, and appropriate. The coordination chemistry of alkali and alkaline earth metal cations covers a very amorphous area and consequently it has been necessary to prune so that the basic principles are revealed with appropriate examples. As is evident from the references, many reviews of the area now exist and these contain comprehensive compilations of data such as full structural information and the statistical analysis of thermodynamic and kinetic data. It was not deemed appropriate, partly from spatial consideration, to reiterate these tabulations in full in this article. An updating of the area can be found in annual reports presented in *Coordination Chemistry Reviews*[579] and by the Royal Society of Chemistry.[580]

23.8 POSTSCRIPT

Recent progress in the chemistry of alkali and alkaline earth metals has centred on the chemistry of oligomeric coordination compounds of lithium. $[Ph_2C{=}NLi(py)]_4$ and $[ClLi(HMPA)]_4$ have been shown to exist as discrete pseudo-cubane structures in which N and Cl atoms respectively bridge the Li_3 triangular faces.[581] An unprecedented pentanuclear Li_5 cluster anion, having present both μ_3 face and μ_2 edge N to Li bonding, has been found in the structure of $[Li(HMPA)_4]^+[Li_5(N{=}CPh_2)_6(HMPA)_3]^-$.[582] The X-ray structure of dibenzylamidolithium itself has been shown to be a trimeric structure having present an N_3Li_3 core; in contrast the adducts $(PhCH_2)_2NLi{\cdot}OEt_2$ and $(PhCH_2)_2NLi{\cdot}HMPA$ are found to be dimeric with N_2Li_2 cores (Figure 34).[583] Dimeric cores have also been revealed in two isomers of $[\{Ph(2\text{-pyridinyl})NLi\}(HMPA)]_2$, which have N_2Li_2 and O_2Li_2 cores respectively; the latter core uses the donor O atom of the HMPA ligand in a novel bridging mode.[584] A further example of this mode of bonding was then detected in the cation $[Li(H_2O)_2(HMPA)_2]_2^{2+}$ isolated as its chloride salt from the reaction of HMPA with deliberately hydrated LiCl.[585]

Related to $[ClLi(HMPA)]_4$ are the cationic species $[Li_4Cl_2(Et_2O)_{10}]^{2+}$ and $[Li_6Br_4(Et_2O)_{10}]^{2+}$ characterized during studies on the preparation of mixed transition metal–alkali metal anionic clusters.[586,587] These solvated salt clusters are viewed as representing early stages of nucleation and growth of the lithium halide as it crystallizes from the solvent.



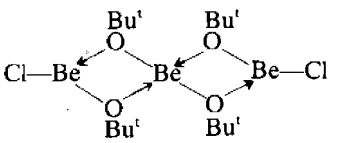


Figure 34 (a) Molecular structure of $[(PhCH_2)_2NLi{\cdot}OEt_2]_2$ and (b) $[(PhCH_2)_2NLi{\cdot}HMPA]_2$ (reproduced with permission from ref. 583)

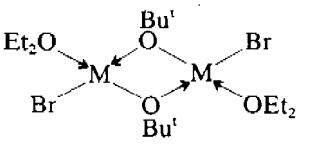
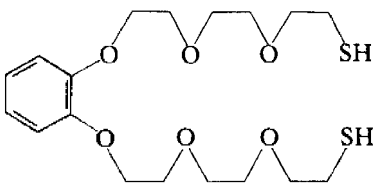
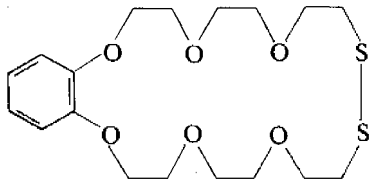


Evidence has been presented for π bonding around a three-coordinate centre in the beryllium dimer (**152**); shortened bond distances from the terminal trigonal Be atoms to the O and Cl atoms are used as the criterion.[588] $(MO)_2$ cores have been found in the complexes (**153**; M = Mg, Be).[589] Further interesting complexes of Mg have been found in the reactions of transition metal halides with $MgCl_2$; these studies have been used to demonstrate that simple molecular complexes can exist in mixtures claimed to be active in Ziegler–Natta catalysis.[590] $MgCl_2{\cdot}2THF$ and $TiCl_4{\cdot}2THF$ react together to give $[Mg_2Cl_3{\cdot}6THF][TiCl_4{\cdot}THF]$, the cation of which is $(THF)_3Mg(\mu\text{-}Cl)_3(THF)_3^+$.[591] The reaction between $MgCl_2$ and $FeCl_3$ in THF gave an unstable complex $[Mg(THF)_5][FeCl_4]$, which on further reaction with THF was reduced to $FeCl_2(\mu\text{-}Cl_2)Mg(THF)_4$.[592] Mixed ligand complexes of Mg^{2+} and Ca^{2+} involving salicylaldehyde, pentane-2,4-dione and *o*-hydroxyacetophenone have been characterized.[593]

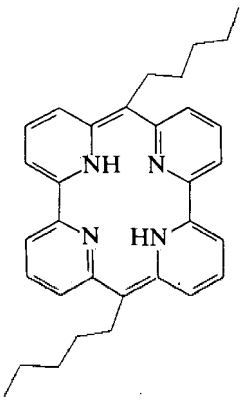
The chemist's ingenuity in devising new coronands and cryptands has been unrelenting and many new systems have been revealed.[594] A representative example is the development of redox-switch crown ethers in which specificity for individual alkali metals accompanies a change in ligand oxidation state; for example (**154**) shows an affinity for Cs^+ only when in the oxidized cyclic form (**154ox**).[595] A further example is the development of an aza macrocycle (**155**) which selectively binds Li^+ and on so doing changes colour from red to colourless.[596] The crystal structure of $[Cs_2(18\text{-crown-6})][Al_3Me_9SO_4]$ shows a Cs^+—Cs^+ interaction only slightly larger than the sum of the ionic radii of the two cations (3.92 Å *cf.* 3.56 Å) and this is close to that for a full bond between the cations.[597]



In the area of bioinorganic chemistry the constitution of a novel carboxylic acid ionophore, griseochelin, has been elucidated.[598] This ionophore forms stable complexes with alkaline earth metal cations in a 2:1 stoichiometry.



(**152**)



(**153**) M = Mg, Be

(**154 red**)

(**154 ox**)

(**155**)

24.1 INTRODUCTION

Tricoordinated boron compounds (boranes) are coordinatively unsaturated and their chemistry is dominated by reactions in which complexes are formed. These complexes are either neutral molecules (borane complexes), anions (borates) or boron cations. Space limitations mean that little or no attention will be paid to complexes containing several boron atoms and to species of the type $L{\cdot}BH_3$, $[BH_4]^-$ and $[L_2BH_2]^+$ (L = neutral ligand), discussed in detail in several books and reviews. Similarly, little attention will be paid to the plethora of metal borates and the cyclic and polymeric amino- and phosphino-boranes.

The whole field of boron chemistry is covered, in a most comprehensive manner, in the 28 volumes on boron of Gmelin's Handbook. Two summarize early results and coordination compounds are dealt with, in part or completely, in recent volumes.[1] Useful chapters, relevant to the coordination chemistry of boron can be found in refs. 2–4. For general information, standard works[5–9] are available while several others contain relevant chapters that will be referred to where appropriate. ^{11}B NMR results are comprehensively surveyed in a recent book,[10] with up to 300 pages of tabulated material, including all the known types of the boron coordination compounds, and serving as a useful guide. In 1964, only one review comprehensively covered the coordination chemistry of boron.[11] Reviews relevant to specialized areas of the field will be referred to under appropriate subheadings.

24.2 NEUTRAL BORANE COMPLEXES

24.2.1 General Considerations and Stability

Since the discovery of $NH_3{\cdot}BF_3$ by Gay-Lussac and Thenard[12] in 1809, many neutral borane complexes have been described, mainly with N, P, As, O and S donor molecules. Their stabilities vary considerably; many are formed at low temperatures only, whereas in other cases

the dissociation of the coordinate bond cannot be observed even at the temperature of decomposition. They are of importance in most reactions of boranes, the first step usually being the formation of some kind of borane complex.

The stability of the coordinative bond in the borane complexes is determined by the electrophilicity of the borane, by the nucleophilicity of the ligand and by steric factors. The electrophilicity of the borane, in turn, depends on the electronegativity of the groups bonded to the boron and on the overlap between the unoccupied p orbital of the boron and the occupied p orbitals of the atoms directly bonded to it (p_π–p_π interaction). The predominance of the latter is reflected by the fact that the relative acidities of halogenoboranes increase in a sense opposite to that expected from electronegativity considerations and is supported by the very weak Lewis acidity of the alkoxy- and amino-boranes. The importance of steric factors is pointed out by Brown and co-workers.[13–15]

In a number of cases, *e.g.* for CO, PH_3, PF_3 and thioethers, the existence of complexes or their surprising stability was explained in terms of a special π bond.[16] However, experimental data and theoretical considerations seem to contradict the assumption that such kinds of π bonds exist.[25] Borane complexes in which donor atoms of appropriate nucleophilicity are part of the group attached to the boron, *e.g.* $BCl_2(NMe_2)$, $BH_2(PMe_2)$, BBr_2SMe, constitute a special case and exist due to intermolecular coordination, in the form of dimers, trimers or polymers.[17–19]

The amine boranes constitute the largest and most extensively studied group of borane complexes. The B—N coordinate bond is generally formulated[17] as having an N^+—B^- polarity as a result of charge transfer from N to B although MO calculations indicate[2,20] the opposite charge distribution. The strength of the coordinate bond in neutral borane complexes is most adequately characterized by the enthalpy change, $\Delta H_{(g)}$ for the dissociation of the adduct in the gas phase into its components.[11,21] Values of $\Delta H_{(g)}$ and heats of reaction for some borane complexes are collected in Table 1.

Table 1 Complex-forming Reactions Heats of Selected Boranes

Base	ΔH[a]	ΔH *values* (kJ mol^{-1}) *for*				*Ref.*
		BH_3[b]	BF_3	BCl_3	BBr_3	
MeCN	ΔH_s	−121.2	−111.0	−144.0	−165.0	1–3
C_5H_5N	ΔH_s	—	—	−234.1	−265.9	4

Based on the data in Table 1, on additional semiquantitative data and upon qualitative observations[2,9,11] the following order of relative stabilities could be established for borane complexes:

(a) for $L{\cdot}BX_3$(X = halogen), $R_3N > R_3P > R_3As > R_3Sb$;
(b) for $L{\cdot}BF_3$, $R_2O > R_2S > R_2Se$;
(c) for $R_3N{\cdot}BX_3$, $BBr_3 > BCl_3 > BH_3 > BF_3 > BMe_3 > B(SMe)_3 > B(OMe)_3$;
(d) for $R_3P{\cdot}BX_3$, $BBr_3 > BH_3 > BCl_3 > BF_3 > BMe_3$.

For borane complexes of intermediate strength the order of relative stabilities can also be estimated from equilibrium data as well, obtained in gas phase or in solution.[11,23] From the temperature dependence of the equilibrium constant for the dissociation in the gas phase the $\Delta H_{(g)}$ values can be determined with great accuracy.[22]

In addition to these limited procedures a number of experimental methods (vibrational spectroscopy, dipole moment measurements, electron diffraction, NMR, *etc.*) have been employed to determine the relative stabilities of these complexes.[11,23] Intense effort has been directed towards establishing some kind of correlation between NMR parameters and stability of the borane complexes. The chemical shifts alone rarely show good correlation. However, complexation shifts (the chemical shift difference between the free and complexed borane or ligand) and various spin–spin coupling constants correlate better with calorimetric data, especially for ligands or boranes belonging to structurally similar series (Table 2).[10,24]

The stability and equilibrium properties of neutral borane complexes are not well known. Instead, the recent chemistry of the borane complexes is predominantly characterized by preparative and structural investigations. This is even more obvious for the charged borane complexes.

24.2.2 Complexes of Hydroboranes

The complexes of borane (BH_3) itself with amines, phosphines, dialkyl sulfides and carbon monoxide, the first representatives prepared only in the 1930s were thoroughly discussed in several books and reviews.[2,9,25–36] Therefore, in this section, only a brief summary will be given outlining the most basic aspects of these compounds, whereas complexes of substituted boranes will be discussed in more detail.

It is generally assumed that the reaction of diborane with neutral Lewis bases (L) results in the formation of $L{\cdot}B_2H_6$ singly bridged complexes ($L{\cdot}BH_2{-}H{-}BH_3$) in the first step. These complexes, which could be positively identified in some cases, generally give rise to the formation of neutral ($L{\cdot}BH_3$) or, rarely, ionic ($[L_2BH_2][BH_4]$) end products.[9,25,34] The amine boranes are, in general, prepared through high-pressure hydrogenolysis of amine trialkylboranes, from alkoxyboranes with H_2 and Al in the presence of NR_3,[2,9] by nucleophilic displacement of weak donors,[9,25,37] by displacement of hydride ion from $[BH_4]^-$ with ammonium salts[9,17,38] or using amines and I_2.[39]

The most characteristic reaction of amine boranes is their conversion into aminoboranes and, subsequently, to borazine at higher temperatures.[9,17] For complexes of low stability, the transfer of H from the boron to the donor is a characteristic process,[11,40] as in the utilization of diborane as an electrophilic reducing agent. The neutral complexes of boranes are fairly stable towards hydrolysis. The key step of the hydrolysis was formerly assumed to involve displacement of BH_3 by a proton, whereas in recent studies ionic intermediates, containing five-coordinated boron ($R_3N{-}BH_4^+$) are also taken into consideration.[41,42] The hydrolytic

stability and good solubility of neutral complexes both contribute to their widespread use as reducing agents.[29,36]

Of the many neutral complexes of borane, $CO{\cdot}BH_3$[11,31,32] and $Me_2S{\cdot}BH_3$[35] deserve special attention. The former is of surprisingly high stability; no other borane(3) is able to form such complexes. $Me_2S{\cdot}BH_3$, being a convenient, stable borane carrier, has an excellent combination of stability and reactivity properties and its use as a borane source[35,36] is on the rise.

The majority of the $L{\cdot}BH_nX_{3-n}$ (X = halogen, R, OR, SR, CN, CO_2H, *etc.*) borane complexes were described in the last 20–25 years. There exist various possibilities for their preparation, summarized in Table 3.

The preparations of complexes of halogenohydroboranes are conveniently achieved through halogenation of the appropriate BH_3 complexes. For some of the halogenating agents the sequence of reactivity is $SbCl_5 \approx SO_2Cl_2 > SbCl_3 > SOCl_2 > HgCl_2 > HCl > [Me_3NH]Cl$, while for the trimethylamine boranes $Me_3N{\cdot}BH_3 > Me_3N{\cdot}BH_2Cl > Me_3N{\cdot}BHCl_2$ applies. Weaker halogenating agents appear to react *via* a polar hydride transfer mechanism, whereas the strongest ones are likely to halogenate by a free radical chain mechanism. The preparation, properties and applications for hydroboration of the THF and Me_2S complexes of halogenoboranes have been reviewed by Brown.[44] The hydrolytic stability of the amine halogenoboranes is fairly high. The rate of hydrolysis for some Me_3N complexes is as follows: $Me_3N{\cdot}BH_2Cl < Me_3N{\cdot}BH_2Br < Me_3N{\cdot}BH_2I$ and $Me_3N{\cdot}BH_3 < Me_3N{\cdot}BHI_2 < Me_3N{\cdot}BH_2I$. These rates are independent of the hydrogen ion concentration. It has been suggested that the rate-determining step is the cleavage of the boron—halogen bond.[45] Hydrolysis of $Me_3N{\cdot}BH_2F$ may occur *via* acid-independent and acid-catalyzed pathways. In the latter case the complex becomes protonated on the fluorine followed by a loss of HF in the rate-determining step.[46]

To obtain complexes of monocyanoborane, a solution of $(BH_2CN)_n$ in Me_2S appears to be the most suitable reagent (Table 3). The complexes of monocyanoborane are extremely stable in acidic media in general and its complexes with tertiary amines are particularly stable in basic media as well. The complexes of primary and secondary amines undergo N—H cleavage in basic media to give the $[BH_2(CN)NR_2]^-$ ion which, in turn, rapidly decomposes *via*, most likely, a dissociative mechanism.[47] Amine complexes of $BH(CN)NC_4H_4$ are even more stable in acidic media, as they become protonated at the α carbon atom of the pyrrole.[48] The CN group in the monocyanoboranes can be transformed into CO_2H, CO_2R or CONHR groups (equations 1–3).[49,50]

$$A{\cdot}BH_2CN \xrightarrow[CH_2Cl_2]{[Et_3O][BF_4]} [A{\cdot}BH_2CNEt][BF_4] \quad (A = \text{amines})$$

$$[A{\cdot}BH_2CNEt][BF_4] \xrightarrow{H_2O} A{\cdot}BH_2CO_2H \quad (1)$$

$$[A{\cdot}BH_2CNEt][BF_4] \xrightarrow{ROH} A{\cdot}BH_2CO_2R \quad (2)$$

$$[A{\cdot}BH_2CNEt][BF_4] \xrightarrow{NaOH} A{\cdot}BH_2CONHEt \quad (3)$$

The amine carboxyboranes may be considered to be analogues of protonated glycine and *N*-substituted glycines. On the basis of structural[49,51] and equilibrium[52] studies, it appears that these analogues differ in several respects from their glycine counterparts. The amine complexes of cyano- and carboxy-borane, as well as the ester and amide derivatives of the latter, display significant antitumor,[49] antiinflammatory[49,50] and antihyperlipidemic[49,53] activity. Recently, some hydroborane complexes containing a chiral boron were synthesized.[48,54] These may be useful for stereoselective transformations of organic compounds. One diastereoisomer of 1-methylbenzylamine-cyanohydropyrrolylborane could be obtained in pure form.[48]

24.2.3 Complexes of Halogenoboranes

As strong Lewis acids, the halogenoboranes are capable of producing a great number of complexes. The largest subgroup in this class is represented by the complexes of trifluoroborane; their first representative was prepared[12] as early as 1809, whereas stable complexes of BI_3 were synthesized[19,20,55] only in the last decades. Some representative halogenoborane complexes and types of reaction used to synthesize them are summarized in Table 4.

Halogenoboranes are capable of giving weak complexes even with unsaturated hydrocarbons.[55] Similarly, weak van der Waals complexes are produced from BF_3 by 'supersonic expansion' with CO, N_2 and Ar.[56]

The stoichiometric composition of the halogenoborane complexes is 1:1, as a rule. However, in some cases, 2:1 and 4:1 complexes are also obtained (Table 4). In the latter instances additional ligands are bonded to the 1:1 complex through hydrogen bonds.[2,11,55] With ammonia only the 1:1 complex is stable, whereas $(H_2O)_2{\cdot}BF_3$ is more stable than $H_2O{\cdot}BF_3$. BF_3 produces 2:1 complexes of similar stability with alcohols and carboxylic acids.[2,55,57] At low temperatures some tertiary amines give complexes with halogenoboranes and complexes of

Table 4 Neutral Complexes of Halogenoboranes and their Preparation

diethyl ether with three halogenoboranes are also known. One borane is bonded through a strong donor–acceptor bond while the others are held by weak halogen bridge bonds.[8,11,55] Halogen-bridged complexes are involved as intermediates in the formation of mixed halogenoborane complexes[24,34] as well as in the halogen exchange reaction between borane complexes and boranes. Complexes with ethers, amines and phosphines of all the conceivable mixed halogenoboranes are obtained in this reaction, under equilibrium conditions, but only a few have been isolated.[24]

The strength of the boron–halogen bond decreases in the order $F \gg Cl > Br > I$, in the complexes as well as in the boranes themselves.[55] This explains the observation that the BF_3 is capable of forming stable complexes, even with molecules containing active hydrogen, whereas the BCl_3, BBr_3 and BI_3 complexes are generally unstable and protonolysis of the trihalogenoboranes occurs.[15,17,18,55,57] Complexes with oxygen donors devoid of active hydrogen, BF_3 complexes excepted, may undergo decomposition with formation of alkyl- or acyl-halogenides or rearrangement with halogen transfer (equations 4–6).[15,55,57] According to X-ray and NMR studies, the complexes of BF_3 with O donors are covalent as solids, whereas some are ionized as liquids or in solution.[2,55,58] In the light of equilibria (7) and (8) it can be understood that BF_3

alone, or in the presence of cocatalysts such as H_2O, ROH, RCO_2H, *etc.*, catalyzes a great number of organic reactions and its use is widespread in the chemical industry.[55,58]

$$R_2O{\cdot}BX_3 \longrightarrow B(OR)X_2 + RX \quad (4)$$

$$MeCOOR{\cdot}BX_3 \longrightarrow MeCOX + B(OR)X_2 \quad (5)$$

$$Ph_2CO{\cdot}BCl_3 \longrightarrow BCl_2OC(Cl)Ph_2 \quad (6)$$

$$ROH{\cdot}BF_3 \rightleftharpoons H^+ + [BF_3OR]^- \quad (7)$$

$$RCOOMe{\cdot}BF_3 \rightleftharpoons RCO^+ + [BF_3OMe]^- \quad (8)$$

$$2L{\cdot}BX_3 \rightleftharpoons [X_2BL_2]^+ + [BX_4]^- \quad (9)$$

$$L{\cdot}BX_3 \rightleftharpoons [X_2BL]^+ + X^- \quad (10)$$

Equilibria of another type are shown in equations (9) and (10).[24,25] For $R_2NH{\cdot}BX_3$ (X = Cl, Br) complexes[59] and for several BI_3 complexes[24,60] equilibrium (9) prevails in solution. The $[X_2BL]^+$ ion is expected[24,55] to form in reactions of BI_3 complexes containing very weak B—I bonds (equation 10). A similar ion was assumed to have formed as an intermediate during the hydrolysis of $Me_3N{\cdot}BCl_3$.[61] The BF_3 complexes rarely enter into ionic equilibria, although with chelating ligands equilibria similar to (9) were detected.[24]

Owing to the strength of the B—F bond, the BF_3 complexes are of widespread use as model compounds, for investigating Lewis acid–base interactions and the nature of the donor–acceptor bond. BF_3 is frequently employed as a standard Lewis acid, for the quantitative characterization of the Lewis basicity of donor molecules.[62,63] The gas-phase equilibrium constants for some BF_3 complexes are shown in Table 5.

Table 5 Trifluoroborane–Base Equilibria in the Gaseous Phase[a]

Base	*K* (bar^{-1})	*Ref.*	*Base*	*K* (bar^{-1})	*Ref.*

The halogenoboranes, unlike BH_3, form more stable complexes with N and O donors than with P and S donors (see Section 24.2.1 and Table 5). Especially stable complexes are formed with N donors; pyridine–trifluoroborane for instance can be distilled at 300 °C without decomposition.[64]

The strength of the coordinative bond in halogenoborane complexes changes in the order $BBr_3 > BCl_3 > BF_3$ for a given base (see Section 24.2.1). Earlier theories based on electronegativity considerations predicted the opposite order.[65] The correct sequence first indicated by the measurements of Laubengayer and Sears[66] became generally accepted, however, only following comprehensive calorimetric studies by Brown *et al.*[11,67] In the absence of calorimetric and equilibrium data the position of BI_3 in the sequence is uncertain.[2] NMR,[10,24,34,68] IR[55,69,70] and displacement reaction invesgitations[71] make it likely that, of all trihalogenoboranes, BI_3 produces the strongest coordinative bond with N, P and As donor molecules. X-Ray data[72] for $Me_3P{\cdot}BX_3$ (X = Cl, Br, I) are in accord with this assumption, while electron diffraction

studies[73] seem not to support it. However, in view of the large atomic radius of iodine it appears likely that BI_3, like BBr_3,[74] displays weaker acceptor ability for bases with larger donor atoms than BCl_3.

24.2.4 Complexes of Boranes with B—O, B—S and B—N Bonds

Owing to the p_π–p_π interaction between the vacant p orbital of boron and the occupied p orbitals of the neighbouring atoms, the majority of these boranes are weak Lewis acids.[15,75] The range of possible substituents at the boron is illustrated in Table 6.

Table 6 Neutral Complexes of Boranes with B—O, B—S and B—N bonds

Of the trialkoxyboranes, only $B(OMe)_3$, $B(OEt)_3$ and $B(OCH_2CH{=}CH_2)_3$ are known to give complexes with strongly basic unhindered amines. The triaryloxyboranes are generally regarded as stronger Lewis acids, for they give, in contrast to the trialkoxyboranes, stable complexes with pyridine. This fact is rationalized[15,76] in terms of resonance interaction between the lone pairs on the oxygen and the π electrons of the aromatic ring. The complexes of the fluoroalkoxyboranes, owing to the inductive effect of the fluoroalkyl group, are more stable than those of their alkyl counterparts; strong complexes are formed even in cases when bulky fluoroalkyl groups are present (Table 6). Despite the bulkiness of the $OTeF_5$ groups, $B(OTeF_5)_3$ forms stable complexes with weak O and N donors (Table 6). In addition to the inductive effect of the TeF_5 groups, an interaction between the oxygen p orbitals and the vacant orbitals on the Te is invoked to explain this behavior.

The alkylthioboranes form more stable complexes than the alkoxyboranes do probably due to a B—S π bond weaker than the B—O π bond.[77,78] This argument is analogous to the one generally accepted for explaining the difference in the Lewis acidity of BF_3 and BCl_3.

The cyanato- and, especially, the thiocyanato-boranes form equally stable complexes with amines, nitriles and ethyl acetate (Table 6). The Lewis acidity of these pseudohalogenoboranes and halogenoboranes, with respect to pyridine and ethyl acetate, follows the order Cl > NCS > NCO > F.[79]

The aminoboranes containing NR_2 groups do not form neutral complexes because the B—N bond possesses a higher π order than B—O and B—S bonds. In contrast, the pyrazol-1-yl and pyrrol-1-yl boranes with sp^2 nitrogens bonded to the boron do give stable amine complexes

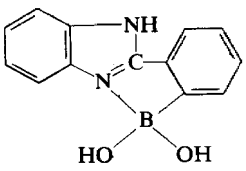
(Table 6). The majority of the complexes in Table 6 are obtained by the reaction of boranes with ligands. Some other methods of synthesis are illustrated by equations (11)–(14).

$$B_2O(OCOR)_4 + (RCO)_2O + 2py \longrightarrow 2py{\cdot}B(OCOR)_3 \quad (11)$$

$$A{\cdot}BBr_3 + 3N_2O_4 \longrightarrow A{\cdot}B(NO_3)_3 + 3NOBr \quad (12)$$

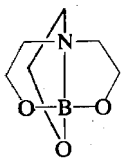
(A = py, 4-Etpy, Me_3N)

$$py{\cdot}BCl_3 + 3LiN_3 \longrightarrow py{\cdot}B(N_3)_3 + 3LiCl \quad (13)$$



$$B(NMe_2)_3 + 3HPz \longrightarrow Me_2NH{\cdot}BPz_3 + 2Me_2NH \quad (14)$$

Pz = pyrazol-1-yl



24.2.5 Chelate Complexes

When a group linked to the boron contains donor atoms (usually O, N) within a distance of four to five bonds from the boron, chelate rings are often formed *via* annular coordination. The majority of the known boron chelates contain BPh_2 or dialkylboron groups[80] but a number of chelates containing BX_2 or BXX′ groups (X and X′ being mostly F and, more rarely, Cl, H, OH, OR, OAc) are also described, as are bicyclic chelates with B—X groups (Table 7). Many chelates are easily obtained *via* reaction of the borane with the proton complex of the ligand

(*e.g.* benzazoles, benzimidazoles, salicylaldehyde and derivatives, 8-hydroxyquinoline). Five-membered monocyclic BF_2 chelate rings are generally stable when stabilizing mesomerism in the chelate ring is possible and/or other factors favor chelate formation,[81] as is the case with *N*-aryl-*N*-acylarylhydroxylamine chelates (Scheme 1). As opposed to the metal chelates, the six-membered BF_2 chelates are more stable than their five-membered counterparts in cases when two double bonds or an aromatic system occurs within the chelate ring (Table 7).[81] Seven-membered chelate rings with mesomeric stabilization are also known; they often display considerable stability.[82]

Scheme 1

The BF_2 chelates are hydrolytically stable (the majority of them may be recrystallized from water) whereas the BCl_2 chelates are easily hydrolyzed. The boric acid ester complex triptych boroxazolidines are also stable towards hydrolysis as are other aminoalcohol esters.[83] A great number of the boron chelates are colored; several spectrophotometric methods are based on chelate formation[81,84] for the analytical determination of boric acid, organoboric acids and chelating organic compounds. The boron chelates are remarkable for their pharmacological properties as well.[84] Various aspects of the boron chelates have been reviewed.[81,83–86]

24.3 ANIONIC COMPLEXES

24.3.1 Hydroborates

The preparation and various aspects of the properties of tetrahydroborates have been comprehensively reviewed.[2,7,9,14,87,88] Therefore, only substituted derivatives of the tetrahydroborates will be dealt with in this section. The methods of synthesis of these compounds are summarized in Table 8.

Of the halogenohydroborates $K[BH_3F]$ and salts of $[BH_2X_2]^-$ and $[BHX_3]^-$ (X = Cl, Br) were obtained in pure form. During the reaction of $[Bu_4N][BH_4]$ with $[Bu_4N][BCl_4]$ or $[Bu_4N][BBr_4]$, redistribution of the ligands occurs with the formation of mono-, di- and tri-halogenohydroborates depending on the molar ratios used.[89] The bromohydroborates are more stable towards disproportionation than the chloro compounds although the monochloro- and monobromo-borates undergo disproportionation equally at 20 °C. The reaction of $[Bu_4N][BH_4]$ with iodine and chlorinated hydrocarbons has been investigated; $[Bu_4N][BH_2Cl_2]$ could be isolated when using CCl_4.[90]

While the reaction of borane with NaSCN results in the formation of monothiocyanatoborate, that of $Na[BH_4]$ with $(SCN)_2$ gives triisothiocyanatoborate. $Na[BH_3SCN]$, which probably contains some B—NCS isomer, displays a higher hydrolytic stability than $Na[BH_4]$ does.[91] Of the hydropseudohalogenoborates, the most extensive studies were made on the cyanoborates. The large −I effect of the CN group confers an exceptionally high hydrolytic stability on the cyanohydroborates. The hydrolysis and H–D exchange of $[BH_3CN]^-$ were studied in detail.[92,93] The hydrolytic stabilities of $[BH_2(CN)_2]^-$ and $[BH(CN)_3]^-$ are even greater; they do not decompose even in concentrated sulfuric acid. The hydrolytic stabilities of $[BH_2(NC)_2]^-$ and $[BH(NC)_3]^-$, on the other hand, are much lower; they can be thermally isomerized into the corresponding cyanoborates.[94] Of all the substituted hydroborates, $Na[BH_3CN]$ is by far the most important one from the practical point of view; it is extensively employed as a reducing agent in organic syntheses.[95]

The existence of hydrohydroxoborates has been the subject of many investigations in connection with the hydrolysis of the $[BH_4]^-$ ion. $[BH_3OH]^-$, $[BH_2(OH)_2]^-$ and $[BH(OH)_3]^-$ ions (Table 8) were all obtained when $Na[BH_4]$ was subjected to partial hydrolysis in strongly acidic media at −78 °C, followed by neutralization. The hydrolysis kinetics of hydrohydroxoborates were studied.[96] The $[BH_3SH]^-$ ion is more stable than the hydroxoborates; $[Et_4N][BH_3SH]$ can be obtained in solid form (Table 8). The trialkoxyboranes can, in general, be converted into trialkoxohydroborates with the aid of alkali metal hydrides. The rate of

reaction of NaH with some of the alkoxyboranes decreases sharply in the order OMe > OEt > OPr^i > OBu. The trimethoxo- and triethoxo-borates undergo disproportionation in THF, whereas the two others are stable. The hydride transfer ability of $K[BH(OPr^i)_3]$ is larger than that of $Na[BH_4]$.[97] The preparation of $Li[BH(SMe)_3]$ is analogous to that of the trialkoxo compounds.[98]

The aminoboranes do not form stable complexes with neutral Lewis bases (see Section 24.2.2), but the amidotrihydroborates, $M[BH_3NR_2]$, are relatively stable. Monophosphidoborates are also known but, apparently, hydroborates with more NR_2 or PR_2 groups are not stable. However, di- and tri-amidoborates derived from amines containing sp^2 N (*i.e.* pyrrole, pyrazole, indole, indazole) are well known.

The amidoborates with NR_2 groups are moderately strong bases.[99] Consequently they are transformed, on treatment with B_2H_6, into μ-amido-bisborate(-1), $[R_2N(BH_3)_2]^-$ [commonly known as bis(borate)amide(1-)]. The phosphidotrihydroborates show analogous reactions (Table 8).

The whole series of pyrrol-1-ylborates, $M[BH_n(NC_4H_4)_{4-n}]$, has been synthesized (Tables 9 and 12). The mechanism of their formation and their hydrolysis kinetics have been studied in detail.[100] The hydropyrazol-1-ylborates are very stable compounds and can be prepared in acid form.[101] The di- and tri-pyrazol-1-ylborates are extensively used as complexing ligands (see Chapter 13.6). The photoelectron spectra of the sodium and thallium(I) hydrotris(pyrazol-1-yl)borates and the electronic structure of the anion itself are reported.[102]

Borates containing hydrocarbon groups have recently been comprehensively reviewed.[4,103] Also known are the Si, Ge and Sn analogues of the monoalkylborates (Table 8). The $[BH_3(COY)]^{n-}$ ions may be mentioned as an interesting subclass of hydroborates with B—C bonds. Because BH_3 and O are isoelectronic,[104] they are isoelectronic with the carbonate, O-alkylcarbonate or carbamate ions (for Y = O, OR, and NR_2, respectively). Hydroborates with three or four different substituents have only recently been synthesized (Table 8). Of these, the $[BH_2(CN)NC_4H_4]^-$ ion shows a remarkable hydrolytic stability, giving rise to the formation of the $C_4H_5N{\cdot}BH_2CN$ complex through reversible protonation, in contrast to the $[BH(CN)(NC_4H_4)_2]^-$ ion which has a much lower hydrolytic stability.[105] The cyanohydropyrazolylpyrrolylborate and the corresponding imidazolylborate (Table 8) are the first representatives of hydroborates containing a chiral boron.

24.3.2 Halogenoborates

The most widely known representatives of this group are the borates with four identical ligands. The simplest way of synthesizing them is to add a suitable halide to the corresponding trihalogenoboranes.[2,55] A large cation is necessary when Cl^-, Br^- or I^- ions are used (equation 15), whereas tetrafluoroborates can be obtained using small cations as well and the reactions can often be performed in aqueous media. The tetrafluoroborates of transition metals are stable compounds, the Ag and Cu^{II} salts being soluble in water and organic solvents.[55,57,106] The $[BF_4]^-$ ion is extensively employed for the isolation of cationic transition metal complexes. Several covalent fluorides, such as BrF_3, ClO_2F, O_2F_2, SF_4, NOF and NO_2F, react with BF_3 to give the appropriate BF_4 salts.[55,57,106] In addition to the inorganic tetrafluoroborates, a great number of organic fluoroborates,[57,106] including ammonium, diazonium, oxonium, sulfonium and carbonium tetrafluoroborates, are known and play an important role in synthetic chemistry.[106] The K, Rb and Cs tetrachloroborates can be prepared without solvent or in appropriate organic solvents, whereas the tetrabromoborates and tetraiodoborates can only be isolated using the ions shown in equation (15).[2,53]

$$MX + BX_3 \longrightarrow M[BX_4] \qquad (15)$$

$$M = [R_4N]^+, [pyH]^+, Ph_3C^+, C_7H_7^+; X = F, Cl, Br, I$$

The relative stabilities of tetrahalogenoborates have been studied by ^{11}B NMR. The ^{11}B chemical shift of the $[BF_4]^-$ ion is independent of the F^- concentration, whereas a marked dependence upon halide ion concentration in organic solvents was observed in other cases. These studies established[24,55] the order of stability as $[BF_4]^- > [BCl_4]^- > [BBr_4]^- > [BI_4]^-$. The heats of formation measured in the gas phase also indicate a significantly higher stability for $[BF_4]^-$ than for $[BCl_4]^-$ (402 and 272 kJ mol^{-1} respectively).[107] The thermal stability of the alkylammonium tetrafluoroborates is fairly high, whereas those with other halogens decompose

to give borazines (equation 16).[55] In accordance with the stabilities of the complexes, the $[BF_4]^-$ ion is only partially hydrolyzed in aqueous medium (*vide infra*), whereas the other tetrahalogenoborates undergo complete and irreversible hydrolysis.[2,55]

$$3[RNH_3][BX_4] \xrightarrow{\Delta} (RNBX)_3 + 9HX \qquad (16)$$

A great number of mixed tetrahalogenoborates are known. While all of the binary mixed halogenoborates, except the $[BF_nI_{4-n}]^-$ ions, have been detected, of the ternary halogen species only a few, such as $[BF_2ClBr]^-$ and $[BFCl_2Br]^-$, are known.[24,108] The mixed halogenoborates are easily identified[24,108] by ^{11}B NMR using the pairwise additivity rule.[109] The majority of mixed halogenoborates exist only under equilibrium conditions. Of the compounds hitherto isolated, only the $[BF_3Cl]^-$ salts[110] have been well characterized.[24]

Derivatives of tetrahalogenoborates, of $[BF_4]^-$ above all, are known in great number; these are summarized in Table 9. $[BF_n(OH)_{4-n}]^-$ ions are formed, *inter alia*, in the course of reversible reactions that take place in a diluted solution of $[BF_4]^-$ ion. The formation and stability of fluorohydroxyborate species have been the subject of several studies[55,111,112] as was the stepwise replacement of OH^- by F^- in the conversion of $[B(OH)_4]^-$ to $[BF_4]^-$. BF_3 with nitrogen oxides (N_2O_3, N_2O_4, N_2O_5) and HNO_3 gives rise to the formation of various ionic complexes containing monodentate NO_3^-, bidentate NO_2^-, or OH^- ligands (Table 9) that can be conveniently used for nitration or nitrosylation.[113]

BF_3 reacts smoothly, in inert solvents, with alkali metal sulfates and phosphates to give stable 2:1 and 3:1 complexes (Table 9), whereas the intermediate complexes that form with NO_3^-, SO_3^{2-} and CO_3^{2-} decompose to $[BF_4]^-$ and B_2O_3.[55] Brownstein *et al.* have established[114] that BF_3 reacts easily with alkylammonium salts in CH_2Cl_2 or liquid SO_2. $[BF_3A]^-$ complex anions are formed with the salts of strong acids (equation 17) whereas complexes with salts of weak acids easily undergo disproportionation (equation 18) and/or conversion into a 2:1

complex (equation 19). Disproportionation proceeds to a small extent for the CN^- ion, but goes to completion with N_3^- ion.[114] Of the 2:1 complexes, an unequivocal structure has been reported only for the cyanocomplex $[F_3BCNBF_3]^-$.[114]

$$[Me_4N]A + BF_3 \longrightarrow [Me_4N][BF_3A] \quad (17)$$
$$(A = ClO_4^-, NO_3^-, SO_3CF_3^-, SO_3F^-)$$

$$[Me_4N]A + BF_3 \longrightarrow [Me_4N][BF_3A] \longrightarrow [Me_4N][BF_4] + [Me_4N][BF_2A_2] \quad (18)$$
$$A = NO_2^-, OAc^-, CF_3CO_2^-, HCOO^-, SCN^-, N_3^-, CN^-$$

$$[Me_4N]A + 2BF_3 \longrightarrow [Me_4N][A(BF_3)_2] \quad (19)$$
$$(A = F^-, OAc^-, PhS^-, CN^-)$$

While BF_3 forms stable complexes with a number of anionic Lewis bases, BCl_3 and BBr_3, although reacting easily with them, rarely give trihalogenoborates.[24,55] Apparently, the $[BX_3OMe]^-$ ions (X = Br, Cl) disproportionate rapidly to give $[BX_4]^-$ ions.[24,55] With pseudohalogenides the BCl_3 generally gives mixed ions, $[BCl_nY_{4-n}]^-$ (Y = CN, NCO, NCS, N_3)[115] and stable trichloroborates $[Me_4N][BCl_3Y]$ (Y = NCO, N_3) could only recently be isolated in liquid SO_2 (Table 9). The preparation of $[Me_4N][BX_3SH]$ (X = F, Cl, Br) in liquid H_2S and that of $[R_4N][BCl_3ClO_4]$ in $CHCl_3$ has been reported (Table 9).

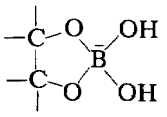
24.3.3 Borates Containing B—O Bonds

Because of the great volume of literature on boron–oxygen coordination compounds, it has been necessary to be highly selective in the choice of material and to confine our attention predominantly to reviews. Of the metal borates[7,116] only those existing in aqueous media will be briefly mentioned and of the complexes of organoboron oxygen compounds,[75] known in a very large number, the most important types only will be included.

24.3.3.1 Hydroxoborates

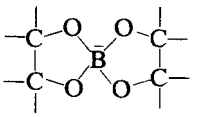
The aqueous chemistry of borates is a relatively neglected area of research; the existence or significance of many ionic species postulated previously should now be regarded with suspicion because of incomplete or unreliable evidence. In dilute solutions or at $pH > 11$ only the monomeric $[B(OH)_4]^-$ exists, while at higher concentrations and at $5 \leq pH \leq 11$ polyborate ions appear, the most important being $[B_5O_6(OH)_4]^-$ with a spiro structure, the monocyclic $[B_3O_3(OH_4)]^-$ and the bicyclic $[B_4O_5(OH)_4]^{2-}$. Other species such as $[B_2O(OH)_5]^-$, $[B_3O_3(OH)_5]^{2-}$ and $[B_4O_5(OH_3)]^-$ have also been postulated.[117]

Of the experimental techniques employed for studying polyborate equilibria, potentiometry has received the greatest attention although incorrect interpretation of the experimental data often led to the postulation of conflicting species. However, vibrational spectroscopy has proved to be a most useful technqiue for identifying the various species in solution.[117]



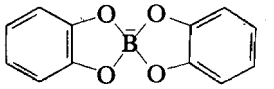
A number of peroxo derivatives of hydroxoborates are well known, the most important being a cyclic borate, $Na_2[B_2(O_2)_2(OH)_4]\cdot 6H_2O$, which possesses, according to crystallographic studies,[118] double peroxo bridges. This compound is in widespread use as a bleaching agent.

24.3.3.2 Alkoxo- and aryloxo-borates

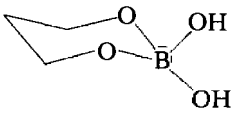


Reaction of trialkoxyboranes with metal alcoholates, alcoholysis or hydride transfer reactions of tetrahydroborates with aldehydes or ketones all result in the formation of tetraalkoxoborates. Steric factors play an important role in these reactions. As a consequence, *sec*-alcohols react very slowly and tetra-*t*-alkoxoborates in general cannot be obtained by any of the reactions above. At elevated temperatures the tetraalkoxoborates revert to the trialkoxyborane and metal alkoxide.[75] Thioalcoholysis of tetrahydroborates can also be effected but, in contrast to the situation in alcoholysis, the last hydrogen atom is more difficult to substitute, probably for steric reasons.[119] Tetraalkoxoborates and tetramercaptoborates are readily hydrolyzed by water or moist air.

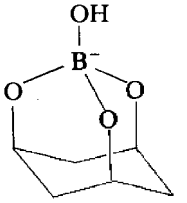
Complexes with polyhydric alcohols or phenols are much more stable than those with monohydric species, probably due to a more favorable entropy contribution attendant upon



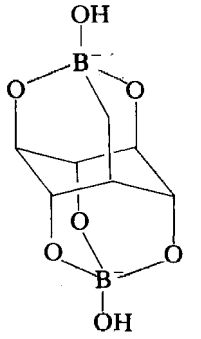
chelate formation. Typical structures of polyolborates are exemplified in (**1**)–(**6**). Unsymmetrical substitution in bisdiolborates [structures (**2**) and (**3**)] creates overall molecular asymmetry so that such derivatives could be resolved into optical isomers.[75]



(**1**)



(**2**)



(**3**)

(**4**)

(**5**)

(**6**)

Diols and polyols can participate in equilibria with boric acid in aqueous solution. The stability of polyolborates is determined by the number of OH groups in *cis* positions. Complexes with polyols are more stable than with diols, and 1,2-diol complexes are more stable than their 1,3-diol counterparts (Table 10) since the resulting five-membered chelate ring is unstrained.[75,120] In the case of 1,3,5-triols stable cage-like structures (**5**) and (**6**) are favored. Open-chain or five-membered cyclic polyols form more stable chelate complexes than their six-membered counterparts.[120] Thus, chelates from alditols and ketohexoses are more stable than the corresponding aldose chelates (Table 10). Many polyols allow quantitative titrimetric determination of boric acid. Of these, mannitol remains the most widely used reagent on the basis of availability, cost and ease of handling.[75]

Table 10 Formation Constants of Polyol Borate Complexes[1,2]

Ligand	$\log \beta_1$	$\log \beta_2$	*Ligand*	$\log \beta_1$	$\log \beta_2$

[1] All data taken from A. E. Martell and R. M. Smith, 'Critical Stability Constants, vol. 3: Other Organic Ligands', Plenum, New York, 1977.
[2] β_1 and β_2 are equilibrium constants for the reactions
$B(OH)_3 + H_2L \rightleftharpoons [B(OH)_2L]^- + H^+$
$B(OH)_3 + 2H_2L \rightleftharpoons [BL_2]^- + H^+$
in 0.1 mol dm^{-3} KCl solutions at 25 °C.

The more stable boron chelates can be isolated even from aqueous solution, whereas those of lower stabilities are only accessible from non-aqueous media. Catechol- and inositol-borates (**3**, **5** and **6**) possesses a well-defined monomeric structure,[75] whereas those obtained from monosaccharides and alditols are polymeric.[121] A crystal structure determination[122] has been carried out for sodium *scyllo*-inositol diborate (**6**).

On the basis of complex-forming properties, boric acid and borates are in widespread use for

synthesis, separation, identification and analysis in the chemistry of carbohydrates, nucleosides, nucleotides, polyphenols, flavonoids and other polyols.[84] Differences in the stabilities of the borate complex can be put to good use, especially in ion-exchange chromatographic separation of sugars and derivatives.[123–125] Polyolborates have also aroused some interest for potential biochemical and pharmaceutical applications.[84,126]

The first natural boron compound, boromycin, isolated in 1967, is the boron complex of a macrocyclic polyol betaine incorporating D-valine ($C_{45}H_{74}BNO_{15}$).[84,127] Its structure has been elucidated by X-ray analysis of the Rb and Cs salt of the fragment obtained after hydrolytic cleavage of the D-valine part.[128] The antimicrobial activity[127,129] and biosynthetic pathway[130] of boromycin have been invesigated. Another antibiotic, containing a BO_4 unit, is aplasmomycin ($C_{40}H_{60}BNaO_{14}$) which has a carbon skeleton devoid of D-valine, but otherwise identical to that of boromycin.[131]

24.3.3.3 Carboxylatoborates

Reaction of $B_2O(OAc)_4$ with sodium acetate results in the formation of $Na[B_2O(OAc)_5]$ with O and OAc bridges, whereas acetatoborates, $M[B(OAc)_4]$ (M = K, Rb, Cs, Tl), are obtained when the reaction is conducted in the presence of acetic anhydride. These borates are easily hydrolyzed; in the case of $[B(OAc)_4]^-$ the rate determining step seems to be dissociation of the complex. Binuclear borates $M_2[B_2O(OAc)_6]$ and $M_2[B_2O_2(OAc)_4]$, were detected, *inter alia*, during thermal decomposition of tetraacetatoborates.[132] The crystal structure of $K[B(OAc)_4]$ has been determined.[133]

Boron gives stable complexes with hydroxycarboxylic and dibasic carboxylic acids when the possibility of the formation of five- or six-membered chelate rings exists. Complexes with 1:1 and 1:2 boron to ligand ratio can both be prepared. 1:1 complexes are generally obtained in aqueous media, preferably with acids (lactic, tartaric, salicyclic and oxalic acids) capable of giving five-membered chelate rings.[75] In non-aqueous media five- and six-membered chelates of hydroxycarboxylic[75] and dicarboxylic acids[134] can be synthesized. Complexes with α-hydroxycarboxylic acids, like those with unsymmetrically substituted bisdiols, display optical isomerism, and resolution through brucine and strychnine salts has been reported in some cases.[75] The crystal structure of potassium bis(*para*-aminosalicylato)borate was reported recently.[135]

24.3.3.4 Borates with anions of oxoacids

Summarized in Table 11 are the compounds known to date with the possible ways of synthesizing them. The majority of these borates has been characterized by IR and NMR and, in some cases, X-ray diffraction. The hydrolytic and thermal stabilities of the tetraalkylammonium tetranitratoborates are surprisingly high, whereas the Rb and Cs salts undergo slow decomposition at room temperature.

The thermochemical properties of tetraperchloratoborates have been studied in detail.[136] The estimated heats of dissociation for $BX_{4(g)}^- \rightleftharpoons BX_{3(g)} + X_{(g)}^-$ decrease in the order F > H > Cl > ClO_4. The sulfatoborates are probably ionic compounds with highly polymeric anions and are sensitive to hydrolysis. The chlorosulfatoborates are stable up to 80–150 °C; their decomposition seems to give, as a first step, $M[BCl_4]$ and SO_3.

24.3.4 Borates with B—N, B—P, B—C and B—Si Bonds

Various kinds of these compounds along with their methods of preparation are summarized in Table 12. The lithium tetraazidoborate is of low hydrolytic stability and detonates easily when it is freed of solvent. The IR spectrum of $Li_3[BN_2]$ is in favor of an $[N{=}B{=}N]^{3-}$ structure isoelectronic and isosteric with the N_3^- and CN_2^{2-} ions. $Li[B(NCS)_4]$ has appreciable stability only in the form of etherate or dioxanate whereas $[(SCN)_3P{=}N{-}P(NCS)_3][B(NCS)_4]$ can be obtained through the reaction of $[Cl_3P{=}N{-}PCl_3][BCl_4]$ with NH_4SCN.[137] The B—NCS bond has been established by IR and ^{11}B NMR studies.

Table 12 Borates with B—N, B—P, B—C and B—Si Bonds and their Preparation

Borate	*Method*	*Ref.*
$Li[B(N_3)_4]$	$Li[BH_4] + HN_3$	1
$Li_3[BN_2]$	$BN + Li_3N$	2
$Li[B(NCS)_4]\cdot 2C_4H_8O_2$	$Li[BH_4] + (SCN)_2$	3
$[Ph_4P][B(NSOF_2)_4]$	$B(NSOF_2)_3 + [Ph_4P]NSOF_2$	4
$K[B(NC_4H_4)_4]$	$K[BF_4] + C_4H_4NMgBr$	5
	$BF_3 + KNC_4H_4$	6
$Na[B(NC_4H_4)_4]$	$Na[BEt_4] + B(NC_4H_4)_3$	7
$K[BL_4]$	$K[BH_4]$ + HL (HL = pirazole, indazole)	8, 9
$Li[B(PEt_2)_4]$	$Et_2O\cdot BCl_3 + LiPEt_2$	10
$M[B(CN)_4]$	BCl_3 + MCN (M = Ag, Cu^I)	11, 12
$Li[B(CN)_3NMe_2]$	$B(CN)_2NMe_2 + LiCN$	11
$Li[B(SiMe_3)_4]$	$B(OR)_3 + LiSiMe_3$	13

Although $Li[B(NHMe)_4]$ exists,[138] most tetraamidoborates contain ligands derived from five-membered heterocyclics such as pyrrole, indole, imidazole, pyrazole and indazole. The thermal and hydrolytic stabilities of these borates are fairly high. When the heterocycle contains two nitrogens the borates can exist in acidic form and the tetraimidazol-1-ylborate can be used for gravimetric determination of the proton.[139] Another type of borate containing a BN_4 unit is represented by bicyclic derivatives formed with *N,N',N''*-trimethylbiuret.[140]

Like the cyanohydroborates, the $[B(CN)_3NMe_2]^-$ and $[B(CN)_4]^-$ ions are extremely stable towards hydrolysis. In the series $Li[B(SiMe_3)_nMe_{4-n}]$, the $^1J(^{29}Si{-}^{11}B)$ coupling constants suggest increasing *s* contribution in the B—Si bond with increasing *n*.

24.4 CATIONIC COMPLEXES

Although some of the cationic chelate complexes have long been known,[141] most of the cationic boron complexes have been synthesized in the last three decades following the

structure elucidation[142] of 'diammoniate of diborane'. Most comprehensively studied are the tetracoordinate cations and, among them, the $[H_2B(NR_3)_2]^+$ species have been the subject of several reviews;[3,34,143] thus we shall not discuss them in detail. The number of tricoordinate boron cations known to date (Table 13) is, however, small. The majority of them have not been isolated and the others are not yet well characterized.[144,145] The unusual dicoordinate cationic boron complexes (Table 13) have only recently been obtained either in solution[146] or in solid form.[144]

Table 13 Types of Cationic Boron Complexes

Complex[a]	*Ref.*	*Complex*[a]	*Ref.*
$[X_2B]^+$		$[H_2B(SMe_2)_2]_2[B_{12}H_{12}]$	7
$[(tmp)BOC_6H_2Bu^t_3]^+ + [AlBr_4]^-$	1	$[(Me_3NBH_2)_2SMe][PF_6]$	10
$[(tmp)BNR_2][AlBr_4]$ (R = Me, Et)	2	$[XHB(NMe_2)_2][PF_6]$ (X = F, Cl, Br)	7
$[(Pr^i_2N)_2B]^+ + [AlCl_4]^-$	3	$[XHB(Me_2pip)][PF_6]$ (X = Cl, Br)	11
$[(tmp)BR][AlBr_4]$ (R = Me, Ph)	2	$[ClHB(PMe_3)PPh_3][PF_6]$	6
$[X_2BL]^+$		$[X_2Bdipy][BX_4]$ (X = F, Cl)	12
$[Cl_2B(4\text{-}Mepy)]^+ + [Al_2Cl_7]^-$	4	$[F_2B(HMPA)_2]^+ + [BF_4]^-$	13
$[(CH_2(Me)N)_2Bpy]^+ + SO_3CF_3^-$	1	$[Cl_2B(OEt_2)_2][FeCl_4]$	14
$[(CH_2(Me)N)_2BNHMe_2]SO_3CF_3$	1	$[(C_6H_4O_2)BL_2]I$ (L_2 = phen, dipy)	15
$[Me_2N(Me)BNHMe_2]I$	5	$[B(acac)_2]Cl$	16
$[X_2BL_2]^+$		$[(Me_2N)_2Bdipy][BPh_4]$	15
$[H_2B(NMe_3)PMe_2Ph][PF_6]$	6	$[HN(BClNH)_2Bpy_2]Cl$	17
$[H_2BL_2][PF_6]$ (L_2 = dppe, dmpe)	6, 7	$[XBL_3]^{2+}$ *and* $[BL_4]^{3+}$	
$[H_2B(AsMe_3)_2][PF_6]$	7	$[HB(4\text{-}Mepy)_2py][PF_6]_2$	18
$[H_2B(OSMe_2)_2]^+ + [BH_4]^-$	8	$[HB(Rpy)_3]Br_2$ (R = H, Me)	19
$[H_2B(THF)_2]^+ + [B_3H_8]^-$	9	$[BL_4]I_3$ (L = Rpy; L_2 = dipy)	20

[a] Ionic form means that the complex exists only in solution; tmp = 2,2',6,6'-tetramethylpiperidino group, Me_2pip = *N,N'*-dimethylpiperazine.

General and specific methods for synthesizing cationic complexes are summarized in equations (20)–(27). Nucleophilic displacement of group X (equations 20 and 21) will be favoured if the B—X bond is weak (*e.g.* B—Br, B—I, B—SR, B—OSO_3CF_3) and an appropriately strong base is used, or if a chelate ring is formed.[143,145] Removal of the X group (equations 22 and 23) can only be effected by the use of strong acceptors (*e.g.* BF_3, BCl_3 $AlCl_3$, $AlBr_3$, SbF_5).[145] Formation of di- or tri-coordinate boron cations is to be expected only when the group bonded to the boron is capable of counterbalancing effectively, by π back-donation, the electron deficiency of the boron (*e.g.* NR_2, OR).[145] Of equal importance is the steric shielding on the boron; bulky groups bonded to the donor atom contribute to the stability (Table 13). Tri- and tetra-coordinate cationic complexes can be obtained through reaction of aminoboranes with the corresponding acids (equations 24 and 25); tricoordinate complexes are formed only when the anion of the acid is of low basicity.[34,145] The methods represented by

reactions (26) and (27) are of limited scope and are useful only for synthesizing four-coordinate complexes.[34,143]

$$L{\cdot}BX_3 \xrightarrow{L} [X_2BL_2]X \xrightarrow{L} [XBL_3]X_2 \xrightarrow{L} [BL_4]X_3 \quad (20)$$

$$BX_3 + L \longrightarrow [X_2BL]^+ + X^- \quad (21)$$

$$L{\cdot}BX_2Y + EY_n \longrightarrow [X_2BL]^+ + [EY_{n+1}]^- \quad (22)$$

$$BX_2Y + EY_n \longrightarrow [X{=}B{=}X]^+ + [EY_{n+1}]^- \quad (23)$$

$$BNMe_2\{N(Me)CH_2\}_2 + HSO_3CF_3 \longrightarrow [\{CH_2(Me)N\}_2BNHMe_2]SO_3CF_3 \quad (24)$$

$$(Me_2N)_2BX + 2HY \longrightarrow [XYB(HNMe_2)_2]Y \quad (25)$$

$X = Cl, H, Me, Et, Ph; Y = Cl, Br$

$$[H_2B(NMe_3)_2]^+ + X_2 \longrightarrow [H_nX_{2-n}B(NMe_3)_2]^+ \quad (26)$$

$n = 1; X = Cl, Br; n = 0, X_2 = F_2, ICl$

$$Me_3N{\cdot}BHBr_2 + 3py \longrightarrow [HBpy_3]Br_2 + NMe_3 \quad (27)$$

The stability of boron cations is very much dependent on the coordination number; the di- and tri-coordinate derivatives exist mainly as equilibrium species, their stability being significantly lower than for those with a coordination number of four. They are converted by even weak bases into neutral compounds or cations with higher coordination numbers.[145] The thermal and hydrolytic stabilities of the tetracoordinate complexes decrease[150] in the order bisamine > trisamine > tetrakisamine; for the $[H_2BL_2]^+$ cations the order of stability is $L = R_3N > R_3P > R_3As > R_2O > R_2S$.[143,147] The bisamine cations are hydrolytically the most stable monoboron species, withstanding concentrated acids and bases without decomposition.[34,143] The bisphosphine complexes, although also stable, undergo slow decomposition in base whereas the bisthioether complexes are rapidly hydrolyzed in water.[143,147] The hydrolytic stability of $[XClB(HNMe_2)_2]Cl$ salts decreases in the order $X = H > F > Cl > Ph$.[143]

The four-coordinate amine complexes are very stable to oxidation;[34,143] they do not react with I_2 and undergo only monosubstitution upon treatment with Br_2 (equation 26). Monohalogenation of bisamine complexes of the $[H_2BLL']^+$ type affords cations containing chiral boron;[34,148] the [XHB(NMe$_3$)4-Mepy]$^+$ (X = Cl, Br) cations were resolved[149] into enantiomers. The crystal structure for X = Br has been reported.[150]

24.5 BORON AS A LIGAND

Various neutral and, especially, anionic boron species are well known as ligands in transition metal complexes. In the majority of cases, however, one or more H, N or other basic atom of the boron compounds is coordinated to the transition metal (*e.g.* Chapters 13.8, 13.6 and 19). In the last 20 years, however, several complexes containing boron–transition metal bonds have been prepared with ligands such as :BX, ·BX_2 or BX_3 (Table 14).

Compounds $[Fe(BX)(CO)_4]$ are, in all probability, dimers with two Fe—B—Fe bonds. $[Fe(BNR_2)(CO)_4]$ (R = Me, Et) could, however, be obtained in monomeric form in low yield. According to IR and ^{11}B NMR studies the :BNR_2 ligand is a weak σ donor but seems to be a better π acceptor than CO. When :BX is a bidentate ligand (Table 14) its bonding properties are similar to those of the ·BX_2 ligands.

Several representatives of boryl–metal compounds containing covalent M–BX_2 bonds are known. ^{11}B NMR and, in the case of carbonyl complexes, IR studies as well indicate back-bonding from the metal atom to the sp^2 boron.[151,152] This may be a reason for the greater stability of boryl carbonylphosphine complexes as compared with boryl carbonyl complexes. The paramagnetic d^7 low-spin complex $[Co(BPh_2)_2(diphos)_2]$ behaves somewhat differently.[152] The Co—B bond is extremely sensitive to oxidation, the BPh_2 group can be exchanged for other metal complexes easily (equation 32), and reduction with sodium smoothly yields the corresponding anionic complex (Table 14). In the case of $[Co(BPh_2)_2(diphos)_2]$ the ^{11}B chemical shift values indicate tetravalent boron which means that the boron carries a unit negative charge, while other boryl–metal complexes behave as molecules with typical trivalent

Table 14 Complexes with a Boron—Metal Bond

Type of boron ligand	*Metal complex or complex unit partner*	*Substituents at the boron*	*Metal–boron ratio*	*Ref.*
BX	$[Mn(CO)_5]$	NMe_2	2:1	1

$$2[FeCl(CO)_2Cp] + [Co(BPh_2)_2(diphos)_2] \longrightarrow 2[Fe(BPh_2)(CO)_2Cp] + [CoCl_2(diphos)_2] \quad (32)$$

X, Y = halogen

Compounds of transition metal complexes possessing a nonbonding electron pair with boranes (BX_3) can be regarded classically as boron complexes with a transition metal ligand. In a broader sense, however, boranes can be classified as acceptor ligands.[154,155] Thus, coordination of a borane results in a decrease of the electron density on the metal atom. In the case of carbonyl complexes this effect is reflected in the increase, by 20–100 cm^{-1}, of the CO stretching frequency.[154–156] It follows from the foregoing that stable coordination of boranes is

to be expected only with transition metal complexes in low oxidation state; this is exemplified by items in Table 14.

Boranes appear to be especially suitable for investigating transition metal basicity[155] but, in spite of this, few relative basicities have been published to date: $[Cr(CO)_3L] < [Mo(CO)_3L] < [W(CO)_3L]$ ($L = Ph_3PC_5H_4$), $[Mn(CO)_5]^- < [Re(CO)_5]^-$, $[Co(CO)_4]^- < [Mn(CO)_5]^-$, $[Mn(CO)_5]^- < [Mn(CO)_4PPh_3]^-$[155,157]. $[Co(NO)_3]$ (Table 14) proved to be an extremely strong base coordinating the weak Lewis acid BMe_3 more strongly than NH_3 or Me_3N does. In the 1:2 complexes, coordination of both boron atoms to the transition metal is certain only in $[Pt(BCl_3)_2(PPh_3)_3]$; a hydrogen bridge structure seems quite plausible in the rhenium complex, $[Re(BH_2—H—BH_3)(CO)_5]^-$, whereas the nature of bonding for the second BF_3 is unknown in the iridium complex (Table 14).

The recently synthesized complexes $K[\mu\text{-}Fe(B_2H_5)(CO)_4]$ and $[\mu\text{-}Fe(B_2H_5)(CO)_2Cp]$ represent the first examples of a substituted diborane (**6**) with a transition metal occupying a bridge site.[158,159] In the case of complexes with $B(NR_2)R_2$ ligands either M←N coordination or ethylenic type π coordination may take place. In the second case boron is also involved in the bonding through M→B back-coordination.[160] Metal–boron bonds also occur in transition metal clusters known in great number, as well as in π-complexes of aromatic boron compounds such as borazines, borabenzenes, *etc.*; all these have been reviewed elsewhere.[161,162]

24.6 APPLICATIONS

In spite of the vast effort and fascinating results in academic and industrial research in the last 30 years industrial applications of coordination compounds of boron have remained fairly limited. Borax, other polyborates and sodium peroxoborate are the only compounds that have acquired major commercial importance to date.[163–165] Borax, the most important boron mineral, is utilized as a starting material for other boron compounds and plays a significant role in the glass industry. The highly water soluble polyborate mixture of stoichiometric composition 1:4 $Na_2O:B_2O_3$ is extensively employed as a plant nutrient[165] and for timber preservation.[165,166] Sodium peroxoborate serves as a bleaching ingredient in household washing.[164] Fluoroboric acid is a metal cleaning agent as well as a catalyst in organic reactions; alkali fluoroborates are utilized in the electroplating industry.[165]

Sodium tetrahydroborate is widely used as a powerful and selective reducing agent in inorganic and organic systems; for instance in organic reductions, in the purification and stabilization of organic materials, bleaching of wood pulp, separation of metals from very dilute solutions, electrodeless plating, particularly of nickel, to produce sodium dithionite from bisulfite, and in the development process for color reversal photographic films.[165,167,168]

Based on the excellent solubility and reducing properties of amine boranes, they are often used for the stabilization and purification of industrial materials. Further, they are applied as additives in hydrocarbon fuels and in lubricating oils, as polymerization catalysts, as ingredients in photographic processing and in the electroplating industry.[169] High stability towards hydrolysis and oxidation makes cationic boron chelates useful as water-soluble dyes.[170]

Detailed investigations are being conducted in the field of boron–nitrogen polymers with N→B coordinative bonds due to their hydrolytic stability (superior to that of the polymers containing tricoordinate boron). Such plastics and elastomers are likely to become candidates for special applications because of the high cross-section of ^{10}B for the (n, α) reaction.[171]

Several complexes have been tested for potential pharmaceutical applications and some of them have been introduced into practice.[84,126] Isolation of antibiotics of boron complex type (Section 24.3.3.2) and results obtained with carboxyborane complexes that are analogues of amino acids (Section 24.2.2) are likely to stimulate further studies. Quite a few boron complexes have found application in ^{10}B neutron capture therapy based on the $^{10}B(n, \alpha)^7Li$ nuclear reaction.[84,126,172]

25.1.1 ALUMINUM: INTRODUCTION

Coordination chemistry of aluminum prior to 1970 was included in Wade and Banister's account of the element.[1] There are thorough reviews of aluminum chemistry with particular reference to oxygen compounds, halides and their adducts, which cover the period prior to 1972.[2] Very early studies of aluminum coordination compounds can be traced through the formula index of Gmelin's Handbook.[3] A 1963 review treats the adducts formed by $AlCl_3$, $AlBr_3$ and AlI_3 and discusses their chemistry in the context of Friedel–Crafts reactions,[4] and the operation of organoaluminum compounds, including halides R_2AlX, as Lewis acids has also been examined.[5,6] Stability constants have been tabulated for a great many Al^{3+} complexes.[7,8]

More specialized studies have examined quantitative aspects of Lewis acidity of the AlX_3 halides and R_3Al molecules using thermochemical measurements[9] and photoelectron spectroscopy.[10] X-Ray emission spectra have been employed to assess the occurrence of σ and π bonding in some important aluminum compounds including alumina, aluminosilicates, cryolite (Na_3AlF_6) and tris(acetylacetonato)aluminum.[11] Specific reference to these and other fundamental studies is made within the following sections which examine aluminum coordination chemistry ligand by ligand.

In this chapter, XRD indicates X-ray diffraction, and ED indicates electron diffraction.

25.1.2 GROUP IV LIGANDS

25.1.2.1 Cyanides

There is an early record of the preparation of $Al(CN)_3 \cdot OEt_2$ and of $LiAl(CN)_4$ by the action of HCN on $LiAlH_4$ in ether at low temperature.[12] They are unstable at room temperature and highly sensitive to O_2 and H_2O. Dicyanoaluminum hydride $AlH(CN)_2$, some polymeric cyanides $(R_2AlCN)_x$, and the anion $(Me_3Al(\mu\text{-}CN)AlMe_3)^-$ have been obtained,[1,13] but there is little recent work.

25.1.2.2 Silicon and Heavier Group IV Ligands

The question of the existence of unsolvated silylaluminum compounds $Al(SiR_3)_3$ was considered some years ago.[14] Subsequently, tetrakis(trimethylsilyl)aluminate was obtained as alkali metal salts, $MAl(SiMe_3)_4$ (M = Li, Na or K),[15] by the action of Me_3SiCl in ether or THF on a 5:1 mixture of the alkali metal and aluminum. This complex, isoelectronic with $Si(SiMe_3)_4$, has been characterized by NMR and IR/Raman spectra. Modification of procedure to use THF/benzene as solvent yields the neutral molecule, as the adduct $Al(SiMe_3)_3 \cdot THF$.[16] Crystal structures of $Al(SiMe_3) \cdot OEt_2$ and $NaAl(SiMe_3)_4$ show Al to be tetrahedrally coordinated with Al—Si distances in the range 244–249 pm.[17] Attempts to isolate base-free $Al(SiMe_3)_3$ have failed. Several catalytic applications of silylaluminum compounds have been investigated.[18]

Germanium analogues of organoaluminum compounds have been postulated and several compounds of this type have been prepared, *e.g.* $MeAl(GeMe_3)_2$, $Al(GeMe_3)_3 \cdot THF$ and $Li(H_3AlGePh_3)$. Some analogous group III–tin derivatives, $Li(Me_3MSnMe_3)$ (M = Al, Ga, In or Tl),[19] are mentioned in Section 25.1.4.1.

25.1.3 NITROGEN LIGANDS

25.1.3.1 Ammonia and Amine Ligands

25.1.3.1.1 Ammonia

Early literature records the preparation of solids $AlX_3(NH_3)_n$ with values of n as high as 9 (X = Cl), 14 (X = Br) or 20 (X = I).[4] $AlCl_3 \cdot NH_3$, obtained from aluminum trichloride using the stoichiometric quantity of ammonia, forms when NH_4AlCl_4 is vaporized.[20] ED measurement reveals a staggered C_{3v} conformation for the H_3NAlCl_3 molecule with the dimensions: Al—N 199.6 pm, Al—Cl 210.0 pm, N—Al—Cl angle 101.2°. The N—Al—Br angle (101.5°) and Al—N distance (199.7 pm) of H_3NAlBr_3 are very similar to those of the chloride. The Al—N distance is shorter than this in $Me_3N \cdot AlCl_3$ (194.5 pm), but longer in $Me_3N \cdot AlH_3$ (206.3 pm) or $Me_3N \cdot AlMe_3$ (209.9 pm); differences here, and in the corresponding gallium compounds, are indicative of trends in the strength of the coordinate nitrogen to metal bond.[21,22] The structure of solid ammonia–aluminum trichloride, H_3NAlCl_3, is the same as that in the gas phase, with Al—N 192.1 pm and Al—Cl (average) 211 pm.[23]

The H_3NAlX_3 molecules have been studied in the gas phase by IR/Raman spectroscopy.[24] NCA yields Al—N force constants of 1.50 N cm^{-1} (X = Cl) and 1.45 N cm^{-1} (X = Br). The analyses of spectra were supported by *ab initio* MO calculations which were also extended to H_3NAlF_3, a molecule which has eluded synthesis. The ammonia adduct of alane (AlH_3) is unknown. A hexaammine $Al(BH_4)_3 \cdot 6NH_3$ is the product of excess ammonia on $KAl(BH_4)_4$.[25] It is believed to contain the cation $Al(NH_3)_6^{3+}$ and it is possible that this species is also present in some of the complexes $AlX_3(NH_3)_n$, noted above, but structural investigation is required.

25.1.3.1.2 Amines

Many complexes of amines with aluminum trihalides, alane and halogenoalanes, AlH_2X and $AlHX_2$, have been described.[26,27] Most are of the form $AlX_3 \cdot$amine although the 1:2 type is also known, particularly when the ligand is trimethylamine. Direct reaction with the aluminum compound in a suitable solvent under anhydrous conditions is the usual way to prepare amine adducts of the halides AlX_3 (X = Cl, Br or I). Amine adducts of organoaluminum compounds are obtained similarly. Primary, secondary or tertiary amines may be used, but primary and secondary amines will often react further, eliminating HX, or an alkane from $R'_3Al \cdot NHR_2$, giving amino $(R'_2AlNR)_x$ or imino $(\text{-}R'AlNR\text{-})_x$ type products (see Section 25.1.3.2).

Amine adducts of alane can be prepared from AlH_3 in ether, the amine displacing the weaker base, Et_2O (equation 1). Alternative methods use $LiAlH_4$, or proceed from $AlCl_3 \cdot NR_3$ retaining the existing Al—N bond (equation 2). $AlH_3 \cdot NMe_3$, m.p. 75 °C, subliming readily, slowly decomposes to polymeric $(AlH_3)_x$ (see equation 3). $AlH_3(NMe_3)_2$ is stable in contact with excess trimethylamine. The reaction of solid $AlH_3 \cdot NMe_3$ with boron trifluoride does not

displace alane, but instead proceeds by a halide–hydride exchange mechanism, forming $BH_3{\cdot}NMe_3$ and AlF_3.[28]

$$AlH_3{\cdot}OEt_2 + R_3N \longrightarrow AlH_3{\cdot}NR_3 + Et_2O \quad (1)$$

$$LiAlH_4 + Me_3NHCl \xrightarrow[-60\,^\circ C]{Et_2O} AlH_3{\cdot}NMe_3 + LiCl + H_2 \quad (2)$$

$$AlCl_3{\cdot}NMe_3 + 3LiH \longrightarrow AlH_3{\cdot}NMe_3 + 3LiCl \quad (3)$$

Reactions of bifunctional amines with aluminum compounds have received some attention. Aluminum isopropoxide with ethylenediamine in benzene solution forms a mixture of species, including polymers.[29] Among these, NMR reveals $(Pr^iO)_3AlNC_2H_4NAl(OPr^i)_3$. The triethylenediamine adduct of alane, $AlH_3{\cdot}N(C_2H_4)_3N$, can be prepared by the action of the base on aluminum metal under a pressure of H_2. It adopts a polymeric structure in the crystal involving five-coordinate aluminum, with planar AlH_3 units linked by diamine molecules using both donor sites.[30] The Al—N distance of 219.5 pm, similar to that in $AlH_3{\cdot}2NMe_3$,[31] is distinctly greater than in four-coordinate adducts. Tetramethylethylenediamine (TMEDA) forms $AlHBr_2{\cdot}$TMEDA which exhibits ν(Al—H) at 1735 cm^{-1}, but in reaction with $AlH_2I{\cdot}NMe_3$ it gives (AlH$_2$TMEDA)I, [ν(Al—H) near 1890 cm^{-1}], believed to contain a four-coordinate complex cation.[32] A structure with the unusual feature of a single N donor atom coordinated to two Al centres has been proposed on NMR evidence for the aluminoxane adduct $(Et_2Al)_2O{\cdot}NMe_2Ph$.[33] The TMEDA adduct of $(Me_2Al)_2O$ is conventional, with the donor atoms of $Me_2NC_2H_4NMe_2$ each attached to an Al atom.[34]

25.1.3.2 N-Heterocyclic Ligands

The formation of molecular complexes between aluminum trihalides and pyridine or alkylpyridines has been the subject of systematic studies.[35,36] Calorimetric data yield bond dissociation energies $D(X_3Al—py)$ of 323, 308 and 264 kJ mol^{-1} for X = Cl, Br and I, respectively, and this same order is found for alkylpyridine adducts, although the Al—N bond is weakened in the case of lutidine by the effects of steric hindrance. For gallium halides the values of $D(X_3M—py)$ are smaller: 248, 237 and 195 kJ mol^{-1} for chloride, bromide and iodide adducts, respectively.

Phase studies reveal the existence of AlX_3py_n (n = 1, 2 or 3 when X = Cl or Br; n = 1 or 3 when X = I). For the $AlCl_3$ system, the 1:1 complex is a simple molecular adduct, while the 1:2 and 1:3 complexes have been shown crystallographically to be *trans*-$AlCl_2py_4^+AlCl_4^-$ and *mer*-$AlCl_3py_3$, respectively.[37] In the cationic species, the Al—N bond length is 207.4 pm (average) and Al—Cl is 227.9 pm (average). In $AlCl_3py_3$, Al—N *trans* to Cl, 209.6 pm, is significantly longer than the other two Al—N bonds of 207.2 pm (average). Vibrational spectra of AlX_3py[38] and AlX_3py_2[39] (X = Cl or Br) had earlier been used to distinguish between the molecular nature of the one and the ionic nature of the other. Al—N force constants in the range 0.7–1.9 N cm^{-1}, with those of $AlBr_3$ adducts greater than those of $AlCl_3$ adducts, were obtained for the 1:1 complexes of several pyridines with AlX_3. Whereas the pyridine complexes of $AlCl_3$ or $AlBr_3$ are usually obtained by direct reaction between the two molecules in a suitable solvent, AlI_3py is conveniently prepared from Al + I_2 + pyridine in ether.[40] There is evidence from phase studies of the $M(OPr^i)_3$/pyridine systems that, whereas gallium forms the expected 1:1 complex, the aluminum compound is of the form $2Al(OPr^i)_3{\cdot}py$.[41]

The 1,10 phenanthroline and 2,2′-bipyridyl ligands form chelate complexes with $Al(ClO_4)_3$[42] and Me_3Al,[43] as well as with the halides $AlCl_3$, $AlBr_3$ and AlI_3.[44] An apparently zerovalent complex $Al(bipy)_3$ is obtained by the action of the lithium salt of the bipyridyl anion on aluminum in THF medium.[45] More recently, N-heterocyclic bases have been shown to react with $AlCl_3$,[46] AlH_3[47] or Me_3Al[46,48] and alkali metals in THF to yield neutral radicals and radical cations, derived from *e.g.* $AlCl_2^+$. Their existence is confirmed by ESR spectroscopy. The 2,2′,2″-terpyridyl adduct of $AlCl_3$ is a 1:1 molecular complex. It is isomorphous with the compounds formed by this ligand with $GaCl_3$, $InCl_3$ and $TlCl_3$.[49] A 1:2 complex of $AlCl_3$ with morpholine consists of discrete molecules in which the Al atom is five-coordinate.[50] Morpholine is attached through nitrogen: the Al—N bond lengths are 206.4 and 209.3 pm, and Al—Cl averages 218.4 pm. ^{27}Al NMR spectroscopy has been used to investigate the species formed by Al^{3+} in aqueous solutions containing the base imidazolidin-2-one. In this system, complexes with 1:1, 1:2 and 1:3 stoichiometry are observed[51] but have not been isolated.

25.1.3.3 Amido and Imido Ligands

Amidoaluminates $MAl(NH_2)_4$ and $M_2Al(NH_2)_5$ are formed as crystalline solids when aluminum is attacked by alkali metals in liquid ammonia. A better synthetic route employs the reactions of NH_3 with $LiAlH_4$ in THF.[52] Structures based on octahedral $Al(NH_2)_6$ units with bridging NH_2 groups were originally proposed on the basis of IR spectra; however, single crystal X-ray analysis reveals approximately tetrahedral $Al(NH_2)_4^-$ ions in $MAl(NH_2)_4$ (M = Na, K or Cs) and $Ca[Al(NH_2)_4]_2 \cdot NH_3$.[53] The Al—N bond distances of the AlN_4 unit average 185 pm. Precipitates from the reactions of $AlH_3 \cdot OEt_2$ with ammonia at various molar ratios, and the materials to which they give rise through partial loss of H_2 on warming to ambient temperature, were investigated some years ago by Wiberg.[1] The final product obtained by heating to 100–150 °C is aluminum nitride. These systems probably have polymeric structures akin to the alkylamino- and alkylimino-alanes considered below.

Dialkylamido complexes[54] are generally more tractable than those containing NH_2 groups. Lithium tetrakis(dimethylamido)aluminate is obtained by the reaction shown in equation (4).[55]

$$LiAlH_4 + 4Me_2NH \xrightarrow{Et_2O} LiAl(NMe_2)_4 + 4H_2 \quad (4)$$

$Al(NMe_2)_3$ is dimeric with bridging ligands (see below). However, $Al(NPr^i_2)_3$ contains a single type of ligand, as indicated by the NMR spectrum over a wide temperature range, and appears to be a monomer.[54] Aluminum is three-coordinate in $Al[N(SiMe_3)_2]_3$ where the AlN_3 unit is planar, with short Al—N bonds of 178 pm.[56] The structure of $Cl_2AlN(Et)C_2H_4NMe_2$ is monomeric, with four-coordinate aluminum.[57] Whereas the coordinate Me_2N—Al distance is 196 pm (a typical single bond value), the Al—NEt bond length is only 177 pm, showing π interaction between planar nitrogen and the Al atom. The complex $LiAl(N{=}CBu^t_2)_4$ is prepared from $AlCl_3 + 4Bu^t_2C{=}NLi$.[58] Two ligands display near-linear C=N—Al geometry with relatively short Al—N bonds, indicating π bonding from N to Al. The remaining ligands form bridges to the Li^+ ion.

Remaining compounds considered here are alkylaminoalanes, R'_2AlNR_2, $R'Al(NR_2)_2$ and $Al(NR_2)_3$, where R′ can be H, alkyl or a halide ligand and R is usually an alkyl group. The structures are usually di- or tri-meric. Also treated are iminoalanes $(R'AlNR)_n$ ($n = 2$–35, commonly 4, 6 or 8) which are polymers with structures based on $(AlN)_x$ rings and clusters. Members of both series, where R′ = H, have been reviewed in the context of aluminum hydride derivatives.[26]

N-Alkylaminoalanes are prepared by the reaction of $AlH_3 \cdot NMe_3$ with a secondary amine (equation 5). Reaction of $LiAlH_4$ in ether with the appropriate amine can also be used. The ease of thermal decomposition of the amine adducts $Et_2(X)Al \cdot NHMe_2$ to form $Et(X)AlNMe_2$ by elimination of ethane depends on the group X in the order Et > Cl > Br > I.[59] Direct synthesis of $Al(NMe_2)_3$ from $Al + 3Me_2NH$ is possible, and the compounds $HAl(NEt_2)_2$ and H_2AlNEt_2 have been prepared from $Al + Et_2NH + H_2$ under pressure.[60] Interaction of $Al(NMe_2)_3$ with $AlH_3 \cdot NMe_3$ gives H_2AlNMe_2 quantitatively. Another route to dialkylaminoalanes is from halogenoalanes by reaction with $LiNR_2$, eliminating LiCl. By carrying out the reaction in stages, mixed ligand products such as $HAl(NR_2)NR'_2$ can be obtained.[26] Of the type $R'Al(NR_2)_2$ is $ClAl(N(Me)SiMe_2)_2NMe$, the first cycloalumadisilatriazane, fully characterized by IR/Raman, NMR, MS and XRD methods.[61] The structure is dimeric so that a central Al_2N_2 ring is present and aluminum attains tetracoordination. The mean Al—N distance (194.7 pm) of the central ring is much longer than the Al—N distance (180.3 pm) to nitrogen of the Al—NMe—Si system, no doubt because this latter N atom is three-coordinate and π bonding is involved.

$$AlH_3 \cdot NMe_3 + 3R_2NH \longrightarrow Al(NR_2)_3 + Me_3N + 3H_2 \quad (5)$$

The NMR spectrum, with two methyl group signals which remain separate up to 150 °C, provided early evidence for the bridged structure of $[Al(NMe_2)_3]_2$.[54] Crystal structure analyses confirm that $[Al(NMe_2)_3]_2$ and $[HAl(NMe_2)_2]_2$ are dimers with four-membered Al_2N_2 rings, whereas $(H_2AlNMe_2)_3$ is a trimer and exists as a six-membered ring of chair conformation.[62] There is a clear difference between exocyclic Al—N bond distances (180.1 to 182.6 pm) and ring Al—N distances (193.7 to 198.0 pm). For the $(H_2AlNMe_2)_3$ trimer there is evidence, from ED in the vapour phase, to suggest transannular interactions between the Al atoms.[63] The molecules $(X_2AlNMe_2)_2$ (X = Cl, Br or I) are dimers of D_{2h} symmetry bridged by the NMe_2

groups, with Al—N bond distances of 190–196 pm.[64] The above compounds react as monomers with pyridine forming 1:1 adducts, *e.g.* $Al(NMe_2)_3 \cdot py$.

Structural data on other alkylaminoalanes are available.[65–67] Of interest is the existence of geometrical isomers where the amido group carries two unlike substituents. For $(Me_2AlNMePh)_2$ variable temperature NMR results yield a value for ΔH of isomerization of 4.5 kJ mol^{-1}.[68] The *cis* isomer with the two phenyl groups on the same side of the Al_2N_2 ring is energetically favoured. $(Et(Br)AlNHBu^t)_2$ exists in solution as a mixture of three isomers, owing to the asymmetry of Al as well as N centres.[69] A single isomer crystallizes, in which both Bu^t and Br pairs are above the plane of the ring.

N-Alkyliminoalanes $(R'AlNR)_n$ are commonly obtained by thermal decomposition of the primary amine adduct of a suitable aluminum compound which proceeds with the elimination of both hydrogens (equation 6). Preparation of some well-defined poly(*N*-alkyliminoalane) oligomers is possible by the direct interaction of Al and RNH_2, with small amounts of $MAlH_4$ as an activator.[70] Alternatively, the reaction of $MAlH_4$ (M = Li or Na) with Bu^tNH_2 has been used. Table 1 gives structural data on various iminoalanes, the structures of which include rings and clusters.[71–79] These clusters have considerable stability; for example, $(HAlNPr^i)_n$ ($n = 4$ or 6) can be chlorinated by HCl or $HgCl_2$ to replace H by Cl substituents.[80] Although tetracoordination of Al is usual, an instance of higher coordination occurs in the cluster $(HAlNPr^i)_2(H_2AlNHPr^i)_2(HAlNCHMeCH_2NMe_2)$.[77] The molecule is built up from four Al_3N_3 and two Al_2N_2 rings. The side-chain NMe_2 group is linked to an Al atom which is thus five-coordinate.

$$nR'_3Al \cdot NH_2R \xrightarrow{\text{heat}} (R'AlNR)_n + 2nR'H \qquad (6)$$

Table 1 Cluster and Cage Structures with an Al–N (or Ga–N) Framework

Compound	*Structure*	*Al–N bond length* (pm)	*Ref.*
$(HAlNBu^t)_4$	Al_4N_4 cube	—	71
$(PhAlNPh)_4$	Al_4N_4 cube	193	1
$(ClAlNMe_2)_4(NMe_2)$	Al_4N_6 tetrahedron	179, 190–194	72
$(HAlNPr^i)_2(H_2AlNHPr^i)_3$	Al_5N_5 bridged ring	190–198	73
$(HAlNPr^i)_6$	Al_6N_6 prism	190, 196	74, 75
$\{HAlNCH(Me)Ph\}_6$	Al_6N_6 prism	189, 198	76
$\{HAlN(CH_2)_3NMe_2\}_6$	Al_6N_6 cage	185–200	77
$(MeAlNMe)_7$	Al_7N_7 cage	196 (average)	78
$(MeAlNMe)_6(Me_2AlNHMe)_2$	Al_8N_8 bridged prism	191 (average)	79
$(MeGaNMe)_6(Me_2GaNHMe)_2$	Ga_8N_8 bridged prism	197 (average)	79
$(MeAlNMe)_8$	Al_8N_8 cage	—	79

Although less familiar than the poly(*N*-alkylamino)alanes $(R'AlNR)_n$, some lower molecular weight iminoalane derivatives have been prepared. Examples are the dimer $[(H_2Al)_2NC_3H_6NMe_2]_2 \cdot THF$[81] and $(Cl_2AlNBu^n)_3Al \cdot NMe_3$.[82] The latter is believed to exist as a symmetrical cluster, although the nature of bonding to the central Al atom is not definitely established.

25.1.3.4 Azide, Cyanate and Thiocyanate Ligands

Aluminum azide is obtained from reacting $AlCl_3$ with NaN_3 in THF, or from the reaction of $AlH_3 \cdot Et_2O$ with HN_3 in ether at low temperature.[83] When trimethylamine adducts of alane are employed, solids thought to be azido complexes are produced (equation 7).[84] Aluminium (and gallium) compounds $X_2M(N_3)$, where X = Br or I, have been prepared by the reaction of MX_3 with the halogen azide XN_3 in benzene.[85] They are polymeric solids which show $\nu(M—N_3)$ modes near 490 cm^{-1} (M = Al), or 430 cm^{-1} (Ga) in the vibrational spectra.

$$MH_3(NMe_3)_n \xrightarrow[\text{cold THF}]{HN_3} (Me_3NH)_nM(N_3)_{3+n} \text{ (M = Al or Ga; } n = 1 \text{ or } 2) \qquad (7)$$

Organoaluminum azides $R_2Al(N_3)$ and $RAl(N_3)_2$ are known; the former type adopts a cyclic structure, $[Me_2Al(N_3)]_n$ where $n = 2$ or 3, based on four-coordinate aluminum with bridging

azido ligands which exchange on the NMR timescale.[86] Related anions have been characterized, for example in the compounds $Me_4N[Me_2M(N_3)_2]$ (M = Al or Ga) and $Cs[Me_3Al(N_3)]$.[87] The crystal structure of the latter reveals Al—N 197 pm, a typical N donor to aluminum bond length. This may be compared with the bridging N_3 group in $K[(Me_3Al)_2N_3]$ where the Al—N distance is 201.5 pm, and ⟨Al—N—Al is 128 °.[88]

Little is known of aluminum cyanates. There are several routes to thiocyanate complexes of aluminum. Aluminum thiocyanate can be prepared as the ether adduct $Al(NCS)_3 \cdot Et_2O$. Reaction of thiocyanogen with $LiAlH_4$ in ether yields $LiAl(NCS)_4 \cdot 2Et_2O$, reported to decompose at −50 °C.[89] $K_3Al(NCS)_6$ is prepared from $AlCl_3$ + 6KNCS, using acetonitrile as the solvent.[90] Complexes of Al^{3+} coordinate to thiocyanate through the nitrogen atom. Alkylaluminum complexes, however, display linkage isomerism. In the salt $Me_4N[Me_2Al(NCS)_2]$ the ligand is S-bound, whereas the crystal structure of $Me_2Tl(Me_2Al(NCS)_2)$ shows NCS coordinated through the N atom with r(Al—N) = 208 pm and also reveals a significant thallium–sulfur interaction.[91] A linear bridging thiocyanate ion is found in $K[(Me_3Al)_2(NCS)]$.[92] The Al—N bond length is normal, 195.1 pm; but Al—S is long, 248.9 pm, indicating a weak interaction. The thiocyanate group is N-bonded to aluminum in $Cs(Me_3AlNCS)$, with the Al—N bond length 194.4 pm.[93]

$Me_4N[(Me_3Al)_2NCSe]$ has been obtained, but reports of selenocyanato complexes of Al are scarce.

25.1.3.5 Nitrile Ligands

The early literature has reports of complexes of aluminum chloride with nitriles $AlCl_3 \cdot n$RCN (R = Me, Et or Ph; n = 0.5, 1 or 2).[4] Aluminum bromide reportedly forms $AlBr_3 \cdot 2$MeCN and $AlBr_3 \cdot n$PhCN (n = 1, 1.5 or 2). X-Ray study of $AlCl_3 \cdot 2$MeCN shows it to be $AlCl(MeCN)_5^{2+}(AlCl_4^-)_2 \cdot$MeCN.[94] Within the cation, four N donors in a plane perpendicular to the Al—Cl bond have an average Al—N distance of 198.6 pm. The unique MeCN *trans* to Cl forms a longer bond, with Al—N = 202.1 pm. The dimensions of a single acetonitrile molecule coordinated to aluminum are revealed in the X-ray structure determination of $Me_3Al \cdot$MeCN.[95] Al—N—C—C is almost exactly linear with Al—N = 202 pm and C≡N = 118 pm (compared with 115.7 pm in the free MeCN molecule). The addition compounds formed by ClCN and BrCN with aluminum halides have been studied by IR/Raman spectroscopy which establish the N-coordinated structure XCN—AlX_3 with C_{3v} symmetry.[96] NCA yields Al—N force constants of 2.0 and 2.8 N cm^{-1} for the chloride and bromide systems, respectively. Halogen exchange occurs when the preparation of $ClCN \cdot AlBr_3$ (or $BrCN \cdot AlCl_3$) is attempted.

Conductimetric measurements of $AlCl_3$ and $AlBr_3$ in MeCN as solvent show that ionic species are formed. IR/Raman and NMR methods have been used extensively to investigate these solutions.[97–101] For the $AlCl_3$–MeCN solutions, ^{27}Al NMR signals are detected for the octahedral species $Al(MeCN)_6^{3+}$, $AlCl(MeCN)_5^{2+}$, *cis*- and *trans*-$AlCl_2(MeCN)_4^+$, as well as the tetrahedral species $AlCl_3(MeCN)$ and $AlCl_4^-$.[100] $AlCl(MeCN)_5^{2+}$ is the major species in terms of concentration. For the $AlBr_3$/MeCN system, it has been deduced from conductivity measurements that $AlBr_2(MeCN)_4^+$ and $AlBr_4^-$ are the most abundant ions.[98]

25.1.4 PHOSPHORUS AND HEAVIER GROUP V LIGANDS

The aluminum halide–phosphine adducts, colorless crystals, $AlX_3 \cdot PH_3$ (X = Cl, Br or I), date from 1932,[102] but not very many complexes of aluminum with other P, As or Sb Lewis bases have been investigated.[4,103] There are 1:1 complexes of $AlCl_3$ and $AlBr_3$ with Ph_3P, various alkylphosphines and their R_3As and R_3Sb counterparts. A 1:2 complex, $AlCl_3(PMe_3)_2$, has been assigned a five-coordinate D_{3h} structure on the basis of IR/Raman spectra.[104] Aluminum borohydride forms both 1:1 and 1:2 adducts with Me_3P, whereas with Me_3As only $Al(BH_4)_3 \cdot AsMe_3$ is obtained.[105] The structure of $Me_3Al \cdot PMe_3$ has been determined in the vapour phase by ED.[106] The Al—P dative bond length of 253 pm is significantly greater than the Al—P distance of 235.7 pm in aluminum phosphide, in which Al is tetrahedrally coordinated by phosphorus.[107]

$AlH_3 \cdot PH_3$ is unknown, and some attempts to prepare $AlH_3 \cdot PMe_3$ were unsuccessful,[108] although the corresponding boron and gallium compounds exist. No reaction occurs in the system Al_2Cl_6/PCl_3; evidently the energy of formation of the Al—P bond is insufficient to offset

that needed to release $AlCl_3$ from the dimer. Reaction does, however, occur with PF_3 and NMR data support the molecular structure F_3P—$AlCl_3$.[109] Subsequently, halogen exchange occurs to produce PCl_3 and AlF_3. Phosphorus(V) compounds PCl_5 and $RPCl_4$ react readily with aluminum chloride to give complex ionic structures, *e.g.* $(PCl_4)(AlCl_4)$, $(RPCl_3)(AlCl_4)$ and $(RPCl_3)(Al_2Cl_7)$.[4] Such compounds are liable to be produced from AlX_3 and a phosphorus(III) molecule if halogen, HX, RX or other reagent capable of oxidative addition is present, whether or not the AlX_3–phosphorus donor complex is stable. (Contrast amine adducts, which are cleaved by hydrogen halides HX, but not usually by halogens or RX.) Arsenic(III) halides do not react appreciably with aluminum halides, although if Cl_2 is admitted to the chloride system, crystals of $AlCl_3 \cdot AsCl_5$ are formed.[110] The likely formulation is $AsCl_4^+AlCl_4^-$. With antimony and bismuth halides, there are reports of $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, $AlBr_3 \cdot BiBr_3$ and $AlI_3 \cdot BiI_3$.[4] Structural investigation of these systems is desirable: it is probable that they are halogen-bridged species, although Al—group V bonds are a possibility.

Adducts of a series of silylphosphine donors have been synthesized.[111] The molecules $Me_2PSiH_nMe_{3-n}$ ($n = 1$ or 2) form adducts with $AlCl_3$ which decompose on heating with loss of the silyl group to give $(Cl_2AlPMe_2)_3$. A structure based on a six-membered Al_3P_3 ring has been proposed, as in the corresponding dimethylamido compounds. Dialkylphosphido compounds of the type $(R_2AlPR'_2)_{2\text{ or }3}$ are known in organoaluminum chemistry.[6] Compounds $(R_2MN(PPh_2)_2)_2$, with R = Me or Et and M = Al or Ga, are obtained from $R_3M + (Ph_2P)NH$, with evolution of alkane. Single crystal X-ray diffraction reveals a structure containing AlNPAlNP rings with Al—P = 253.5 pm and Al—N = 189.4 pm (average values).[112] The diphenylphosphido ligand bridges between $Cr(CO)_5$ and the Al centre in $Cr(CO)_5(\mu\text{-}PPh_2)Al(CH_2SiMe_3)_2 \cdot NMe_3$.[113] The structure, determined by XRD, shows an Al—P bond length of 248.5 pm. The aluminum atom is four-coordinate owing to the presence of the attached molecule of NMe_3 (Al—N bond length = 204.9 pm).

The phosphido complex $LiAl(PH_2)_4$ may be synthesized by reaction of phosphine with $LiAlH_4$.[114] A tetrakis(dimethylphosphido)aluminate $LiAl(PMe_2)_4$ is prepared by metallation of $HPMe_2$ with Bu^nLi in diglyme at −40 °C, followed by reaction with $AlCl_3$.[115] The silyl analogue $LiAl[P(SiH_3)_2]_4$ had been obtained earlier by the action of $P(SiH_3)_3$ on $LiAlH_4$.[116] Finally, mention may be made of a cationic Al—P coordinated species $Al\{P(OMe)_3\}_6^{3+}$ which exists in trimethyl phosphite–water solutions according to NMR evidence.[117]

25.1.5 OXYGEN LIGANDS

25.1.5.1 Oxide, Hydroxide and H_2O as Ligands

Aluminum hydroxide $Al(OH)_3$, frequently encountered as a gelatinous material, is obtained in crystalline form by passing CO_2 into an alkaline aluminate solution at 80 °C. It occurs as gibbsite and in other forms.[1] AlO(OH) is produced as boehmite by adding ammonia to a boiling solution of an aluminum salt, or from gibbsite + water in an autoclave at 300 °C.[118] Alumina, Al_2O_3, is obtained by the dehydration of AlO(OH) or $Al(OH)_3$ in at least six types, of which α-Al_2O_3 (corundum) is the form produced at high temperature and is indefinitely metastable at ordinary temperatures.[1,119] In α-Al_2O_3, the oxide ions form a hexagonal close-packed array in which Al^{3+} ions are distributed symmetrically among octahedral sites.[120] Crystals of gibbsite have a sheet structure based on a double layer of close-packed hydroxyl ions with Al^{3+} in two-thirds of the octahedral interstices.[121] A rarer form of $Al(OH)_3$, nordstrandite, is obtained by controlling the crystallization of the gelatinous hydroxide by adding a chelating agent, ethylene glycol. In crystalline AlO(OH), —Al—O—Al—O— chains are bridged by oxygens of OH groups to a neighbouring chain.

Aluminum forms mixed oxides with many other metals which either replace Al^{3+} in octahedral positions or occupy tetrahedral sites. The spinel structure of $MgAl_2O_4$, an important prototype, has been investigated by photoelectron spectroscopy.[122] Vibrational and solid state NMR methods are also useful for studying aluminate structures.[123–125]

With the alkali metals the simplest mixed oxide type is $NaAlO_2$, prepared by heating Al_2O_3 with the group I oxalate at 1000 °C. The structure of Na_5AlO_4 is orthorhombic: it contains discrete AlO_4 tetrahedra in which r(Al—O) = 176.1–178.9 pm. $Na_7Al_3O_8$, which is triclinic, contains a ring structure derived from six AlO_4 groups linked by oxygen bridges into an infinite chain, whereas $Na_{17}Al_5O_{16}$ has discrete chains of five AlO_4 tetrahedra sharing corners.[126] ^{27}Al NMR spectroscopy applied to polycrystalline aluminates reveals characteristic chemical shifts

for AlO_4, AlO_5 and AlO_6 polyhedra,[125] and the technique also enables the formation of Si—O—Al bonds by AlO_4 groups in aluminosilicate solutions to be monitored.[127] The anion in $Cs_2Al_2O(OH)_6$ is composed to two AlO_4 tetrahedra sharing one O atom.[128] The complex anions $[Al_4(OH)_{16}]^{4-}$ and $[AlO(OH)_2^-]_\infty$ (made up of tetrahedral groups sharing corners) have been identified in XRD studies of barium aluminates.[129] The basic sulfate $Al_2(OH)_4(SO_4)\cdot 7H_2O$ (aluminite) contains the cationic complex $[Al_4(OH)_8(OH_2)_6]^{4+}$ built from four edge-sharing AlO_6 octahedra polymerized in chains and interconnected by SO_4^{2-} ions.[130] The calcium aluminates, which are basic components of Portland cement, have been identified by X-ray crystallography.[131] In another area of applied aluminum chemistry, NMR spectra under magic angle spinning conditions have been used to follow hydration and dehydration of Al sites in ZSM-5 zeolites.[132]

The aquated aluminum cation $[Al(OH_2)_6]^{3+}$ is octahedral. Some crystals in which it is encountered are (average Al—O distances in parentheses): $NaAl(SO_4)_2\cdot H_2O$ (187.8 pm); mellite (187.2 pm); $AlCuCl(SO_4)_2\cdot 14H_2O$ (187.8 pm).[133] These crystals have also been investigated by neutron diffraction and ^1H NMR techniques, which confirm the presence of $[Al(OH_2)_6]^{3+}$ and enable H atoms of the coordinated water molecules to be located.[134] The vibrational modes of $[Al(OH_2)_6]^{3+}$ in alum crystals have been assigned:[135] from the Raman data, $\nu_1 = 542$, $\nu_2 = 473$, $\nu_5 = 347\ cm^{-1}$. Assignments from single crystal Raman measurements of $[Al(OH_2)_6]Cl_3$ place $\nu(Al—O)_{sym}$ at $524\ cm^{-1}$.[136] The aluminyl cation AlO^+ isolated from HF solutions as BF_4^- or SbF_6^- salts shows $\nu(Al—O)$ near $650\ cm^{-1}$.[137]

The Raman bands of very concentrated $Al(NO_3)_3$ solutions are consistent with $[Al(OH_2)_6]^{3+}$ and NO_3^- in the form of solvent-separated ion pairs.[138] Hydration-shell and bulk-water protons can be distinguished by ^1H NMR. ^{27}Al NMR signals distinguish $[Al(OH_2)_6]^{3+}$ from other species, such as $[Al(OH_2)_5(SO_4)]^+$ in sulfate solutions, or $[Al_2(OH)_2(OH_2)_8]^{4+}$ and the more highly polymerized complexes which are produced on the ageing of aqueous aluminate solutions.[139–143] According to Raman[144] and NMR data,[141,145] the cation $[Al_{13}O_4(OH)_{25}(OH_2)_{11}]^{6+}$, which forms a sparingly soluble sulfate and a chloride, persists in aqueous solution. With HCl it decomposes into smaller species, but on adding alkali even higher molecular weight particles can be formed. In strongly alkaline solutions of aluminum compounds, however, the predominant species appear to be mononuclear $[Al(OH)_4]^-$ and dinuclear $[Al_2O(OH)_6]^{2-}$.[146–149] The UV spectra of aqueous solutions of $AlCl_3$, $Al(ClO_4)_3$, $Al(NO_3)_3$ and $Al_2(SO_4)_3$ in which the hexaaqua cation predominates, show an absorption band at 240 nm which is thought to arise from charge transfer involving the Al^{III} dication: $[Al^{III}(OH^-)(OH_2)_5]^{2+} \rightarrow [Al^{II}(OH)(OH_2)_5]^{2+}$.[150]

On the theoretical front, attempts have been made using molecular orbital calculations to elucidate the binding energies and stereochemical constraints associated with the structures of hydrates $[Al(OH_2)_n]^{3+}$ $(n = 1–7)$,[151] and hydroxo complexes $[Al(OH)_4]^-$, $(Al(OH)_5)^{2-}$ or $(Al_2(OH)_8)^{2-}$.[152] MO calculations have also been performed for the molecules H_3AlOH_2 and $(H_2AlOH)_2$.[153] No evidence was found to support π bonding between O and Al. Small molecules of this kind can sometimes be detected by matrix isolation methods. For example, Al atoms react with H_2O under such conditions to give HAlOH, whereas the heavier group III metals form $M\cdot OH_2$ adducts.[154]

25.1.5.2 Alkoxide Ligands: Aluminoxanes and Related Systems

Aluminum alkoxides,[155] known since 1876, are prepared from the alcohol and aluminum, activated by I_2 or $HgCl_2$. Heating $Al + Pr^iOH + MeOC_2H_4OH$ provides a route to $Al(OPr^i)_3$ which avoids the need to introduce mercury. Reaction of $AlCl_3$ with alcohol, using NH_3 to take up the HCl formed, or with a group I metal alkoxide, can also be used to obtain $Al(OR)_3$. Mixing solutions of $Al(OPr^i)_3$ and $AlCl_3$ yields a crystalline material $AlCl(OPr^i)_2$. Alkoxides of higher alcohols can be made from $Al(OPr^i)_3$ by alcohol displacement. By control of the stoichiometry, mixed alkoxides $Al(OR)_n(OR')_{3-n}$ are obtained. The trimethylsiloxide $Al(OSiMe_3)_3$ is capable of controlled hydrolysis to yield polymeric products.[156]

Aluminum alkoxides are soluble in many organic solvents, and exist in various liquid and solid forms depending on the degree of polymerization. All are hydrolyzed readily, liberating the alcohol and giving white solids in which Al—O—Al bonds are a feature. $Al(OBu^t)_3$ and $Al(OPr^i)(OBu^t)_2$ are dimeric with terminal and bridging ligands which can be distinguished in NMR spectra.[157] Others are tri- or tetra-meric, *e.g.* $(Al(OCH_2Ph)_3)_4$, the structure of which contains an eight-membered Al_4O_4 ring.[1] The alkoxide formed by ethylene glycol appears to

contain both four- and six-coordinate Al atoms.[158] The alkoxide oligomers, especially the dimers, are readily cleaved by donor molecules forming adducts, *e.g.* donor·Al[OCH(CF$_3$)$_2$]$_3$ (donor = OEt$_2$, NEt$_3$ or PEt$_3$).[159] A crystallographic study of en·Al(OH)[OCH(CF$_3$)$_2$]$_2$ shows it to consist of OH-bridged dimers with the AlO_4N_2 coordination sphere.[160] Three compounds of empirical formula acac·Al(OR)$_2$ have recently been studied by XRD.[161] When OR = OSiPh$_3$, the compound is a monomer with four-coordinate Al. With OR = OSiMe$_3$ or OPr^i, the products are a dimer and a trimer, respectively, and involve both four- and six-coordinate Al centres.

Aluminum methoxide Al(OMe)$_3$ is a solid which sublimes at 240 °C in vacuum. Aluminum isopropoxide melts in the range 120–140 °C to a viscous liquid which readily supercools. When first prepared, spectroscopic and X-ray evidence indicates a trimeric structure which slowly transforms to a tetramer in which the central Al is octahedrally coordinated and the three peripheral units are tetrahedral.[162,163] Intramolecular exchange of terminal and bridging groups, which is rapid in the trimeric form, becomes very slow in the tetramer. There is MS and other evidence that the tetramer maintains its identity in the vapour phase.[164] Al[OCH(CF$_3$)$_2$]$_3$ is more volatile than Al[OCH(Me)$_2$]$_3$ and the vapour consists of monomers.[165] Aluminum alkoxides, particularly Al(OPr^i)$_3$, have useful catalytic applications in the synthetic chemistry of aldehydes, ketones and acetals, *e.g.* in the Tishchenko reaction of aldehydes, in Meerwein–Pondorf–Verley reduction and in Oppenauer oxidation. The mechanism is believed to involve hydride transfer between R$_2$HCO ligands and coordinated R$'_2$C=O→Al groups on the same Al atom.[1]

Double alkoxides are formed by Al(OR)$_3$ and alkoxides of main group,[166,167] transition[168] or lanthanide elements.[169] The titration of Al(OEt)$_3$ with NaOEt gives a sharp end point to thymolphthalein forming NaAl(OEt)$_4$. This product is salt-like and may contain the [Al(OEt)$_4$]$^-$ anion, whereas other double alkoxides are low melting, volatile compounds and commonly have structures in which alkoxide ligands bridge Al to the other metal. Examples are LiAl(OBu^t)$_4$,[170] Mg{Al(OPr^i)$_4$}$_2$ (m.p. 20 °C) and Mg[Al(OEt)$_4$]$_2$ (m.p. 129 °C)[171] (thought to be dimeric with four-coordinate Mg and Al atoms on NMR evidence).

Alkoxyhydrides, *e.g.* LiAlH$_2$(OBu^t)$_2$,[170] MgAlH$_2$(OPr^i)$_3$[172] and CaAlH$_2$(OPr^i)$_3$[173] have been prepared and shown to have utility as selective reducing agents. Ligand exchange occurs to establish equilibrium between the species AlH$_2$(OR)$_2^-$, AlH(OR)$_3^-$ and AlH$_4^-$.

Alkoxyaluminum compounds ROAlCl$_2$ react with MeAlCl$_2$ to produce materials which contain the Al—O—Al linkage. Similarly, when organoaluminum compounds R$_3$Al (R = Me, Et or Bu^i) are hydrolyzed in ether solution the reaction proceeds in several steps leading to aluminoxane systems. An initial adduct R$_3$Al·OH$_2$ is converted to R$_2$AlOH which then dimerizes. In systems with the R$_3$Al:H$_2$O ratio of 2:1, reaction gives compounds (R$_2$Al)$_2$O which themselves tend to form associated structures.[174] The aluminoxane anion (Me$_2$AlOAlMe$_3$)$_2^{2-}$ consists of a planar Al_2O_2 ring with Me$_3$Al molecules coordinatively linked to the O atoms.[175] The structure has a direct analogy in the chloroaluminate dimer (Cl$_2$AlOAlCl$_2$)$_2^{2-}$ characterized by XRD as a by-product of reductive Friedel–Crafts synthesis.[176] A second complex Cl$_2$AlO(AlCl$_3$)$_2^-$, obtained similarly, contains a quasi-five-coordinate Al atom since a chlorine of each of the AlCl$_3$ groups makes a close approach to this atom. Dimethylaluminum methoxide, (Me$_2$AlOMe)$_3$, the structure of which has an Al_3O_3 ring with the methoxide group acting as a bridging ligand, is obtained by reaction of Me$_3$Al with MeOH. The trimeric structure is well established by IR/Raman and gas phase ED methods.[177] The Al—O distance is 185.1 pm. The formally related compound (Br$_2$AlOSiMe$_3$)$_2$ is dimeric with Al—O bond lengths close to 180 pm.[178] Various aluminoxane type structures are now known[179] and there are parallels between polymeric alkoxides and aluminoxanes, and the related oligomers with (AlN)$_n$ frameworks which occur when amido and imido ligands are present.

25.1.5.3 β-Ketoenolate and Related Ligands

β-Ketoenolates of aluminum are of long standing, and tris(acetylacetonato)aluminum itself was first prepared in 1887.[1] It is obtained as colourless crystals, m.p. 194 °C, b.p. 315 °C, by the reaction of Hacac with Al amalgam; from AlCl$_3$ + Hacac; or by mixing solutions of Al$_2$(SO$_4$)$_3$ and Hacac in aqueous ammonia. Metal atom synthesis can also be employed.[180] Tris(ethylacetoacetonato)aluminum, m.p. 76 °C, is conveniently prepared by heating Al(OEt)$_3$ + 3 mol of ligand.

The structure of $Al(acac)_3$ contains an octahedral AlO_6 core, with Al—O distance of 189.2 pm. Differences of the monoclinic α form and orthohombic γ form (a racemate) lie chiefly in the orientations of molecules within the crystal: bond distances are almost identical.[181] Resolution of the optical isomers of $Al(acac)_3$ has twice been achieved by column chromatography at low temperature.[182,183] The hexafluoro compound, $Al[(OCCF_3)_2CH]_3$, m.p. 74 °C, is more volatile than $Al(acac)_3$. Its structure, determined by vapour phase ED,[184] reveals a slightly distorted AlO_6 unit in which the Al—O distance of 189.3 pm is the same as that in $Al(acac)_3$. Comparative studies have been made of the Raman spectra of $M(acac)_3$ (M = Al, Ga or In)[185] and of other β-diketonates of these metals.[186]

The tris(β-ketoenolato)aluminum compounds are stereochemically non-rigid species and undergo various ligand exchange reactions in solution. A 1976 report[187] summarizes various attempts to establish the stereoisomerization mechanisms and provides access to kinetic and thermodynamic data derived from this work. There is considerable evidence to support an intramolecular twist mechanism, except where fluorocarbon substituents are present. Here, a bond rupture process involving a five-coordinate intermediate is favoured. Later studies[183,188] using variable temperature NMR spectroscopy have estimated the barrier to interconversion between enantiomers to be close to 85 kJ mol^{-1} in a number of β-diketonates. When lanthanide reagents are added to a benzene solution of $Al(acac)_3$, the ^{27}Al NMR signals due to free and complexed molecules can be distinguished and paramagnetic shift data can be obtained.[189]

Acetylacetone complexes have been prepared by the action of acac on $MeAlCl_2$, Me_2AlCl and Me_3Al, and on tetraalkylaluminoxanes R_4Al_2O (R = Me, Et or Bu^i).[190] Mixed ligand derivatives *e.g.* $R_2(acac)_2Al_2O$, tend to disproportionate forming $Al(acac)_3$. Metalla-β-diketones, in which the central CH group is replaced by a transition metal moiety, typically $Mn(CO)_4$ can be effectively coordinated to an aluminum or gallium atom.[191] XRD study of the molecule $Al[(OCMe)_2Mn(CO)_4]_3$ reveals that the acyl CO and Al—O distances, and O—Al—O angles, are not significantly different from the values in $Al(acac)_3$. The cationic complex $(acac)_2Al(OH_2)_2^+$ has been isolated as the picrate,[192] but structural data are lacking.

Tris(tropolonato)aluminum precipitates when tropolone and $AlCl_3$ are mixed in methanol. A significant feature of the ligand coordination, in relation to barriers to isomerization, is the twist angle of 48°, compared to 60° in a regular octahedron.[193] The bond length of 188 pm (average) and estimated bond energy of 250 kJ mol^{-1} from calorimetric measurements[194] make this a rather strong Al—O bond, and photoelectron spectroscopy indicates that there are both σ and π contributions to bonding in the AlO_6 coordination sphere.[195]

25.1.5.4 Oxyanion Ligands

The coordination chemistry of aluminum with oxyanion ligands is chiefly that of the more highly oxidized ions. Nitrites and phosphites are unknown. Arsenites, sulfites, selenites and tellurites are mentioned in the early literature but have received little recent attention.

25.1.5.4.1 Borate, carbonate and silicate

Aluminium borates $(Al_2O_3)_n \cdot B_2O_3$ are solids of some technological interest. Gaseous species AlBO and $AlBO_2$ are generated, along with B_2O_3, when aluminum borates are heated above 1000 °C.[196] $Al_2(CO_3)_3$ is unknown. Basic carbonates of Al are ill-defined materials precipitated from aqueous aluminate solutions in contact with CO_2 gas.[1] Aluminum silicate chemistry, which rests on the variety of structures possible for complex silicate anions, with the added possibility of replacing Si by Al in the lattice, encompasses many naturally occurring and synthetic materials, the structures of which are built up from SiO_4 tetrahedra and AlO_4 and/or AlO_6 units. This vast subject is beyond the scope of the present account.

25.1.5.4.2 Nitrate, phosphate and arsenate

From aqueous nitric acid solutions, aluminum gives hydrates $Al(NO_3)_3 \cdot nH_2O$ (n = 6, 8 or 9) which contain the $[Al(OH_2)_6]^{3+}$ complex (Section 25.1.5.1). A basic nitrate produced when $Al(NO_3)_3 \cdot 9H_2O$ is heated to 136 °C has the composition $Al(OH)_2NO_3 \cdot 1.5H_2O$.[197] Further

heating produces hydrated alumina. IR spectroscopy indicates that NO_3 groups are not coordinated to Al^{3+}, although there is Raman[198] and UV[199] evidence of interaction in aqueous solution. Anhydrous $Al(NO_3)_3$ is prepared with some difficulty from $AlBr_3 + ClNO_3$. $AlCl_3$ with liquid N_2O_4 yields the 'oxide nitrate' $Al_2O(NO_3)_4$ or adducts $Al_2O(NO_3)_4 \cdot xN_2O_4$ which on heating afford $AlONO_3$.[200] Reactions involving N_2O_5 give $Al(NO_3)_3 \cdot N_2O_5$, m.p. 85–98 °C (dec), distillable in vacuum, and believed to crystallize as $NO_2^+[Al(NO_3)_4]^-$.[201] $Et_4N[Al(NO_3)_4]$ is prepared by solvolysis of $AlCl_3 + Et_4NCl$ using excess N_2O_4. The aluminum complex migrates to the anode during electrolysis in nitromethane. Complex salts of the larger group I cations, $MAl(NO_3)_4$ and $M_2Al(NO_3)_5$ (M = Rb or Cs), have been isolated as hygroscopic crystals, stable at room temperature. The crystal structure of $Cs_2Al(NO_3)_5$ shows that the Al atom has distorted octahedral coordination, with the apices occupied by one bidentate and four unidentate nitrate groups.[202] Parameters of the discrete $[Al(NO_3)_5]^{2-}$ anion are as follows: $r(Al–O)_{bident} = 198$ pm; $r(Al–O)_{unident} = 193$ pm (mutually *trans*) and 189 pm (mutually *cis*, but *trans* to bidentate NO_3 linkages). For the unidentate ligands, the Al—O—N angles are close to 125°. Nitrate groups are coordinated to Al in the trimethylaluminum complex ion $(Me_3AlNO_3)^-$ in which NO_3 is unidentate with Al—O distance of 193 pm and angle Al—O—N = 123.3° and $[(Me_3Al)_2NO_3]^-$ in which the nitrato group is bridging (Al–O distances of 195 and 201 pm).[203]

The chemistry of aluminum phosphates,[204,205] which are commercially important as inorganic binding agents, is centred on compounds with Al_2O_3:P_2O_5 molar ratios of 1:1, *i.e.* $AlPO_4$ and hydrates $AlPO_4 \cdot xH_2O$, and 1:3, *i.e.* $Al(H_2PO_4)_3$. Various aluminum poly- and metaphosphates have been characterized. Hydroxyphosphates of Al can be prepared by heating $Al(OH)_3$ with phosphoric acid. Crystalline $AlPO_4$ resembles SiO_2, with tetrahedral coordination around Al, and the structure can exist in quartz-like and other silica isomorphs. NMR (^{27}Al under magic angle spinning conditions) shows a clear distinction between the AlO_4 groups of $AlPO_4$, and the octahedral AlO_6 groups present in various crystalline phosphate complexes.[206] The crystal structure of aluminum trimetaphosphate, $Al(PO_3)_3$, shows it to be built up of infinite chains of PO_4 units, interconnected by AlO_6 octahedra in which the Al—O distance is 188.4 pm (average).[207] In $AlPO_4 \cdot 2H_2O$ the PO_4 tetrahedra share vertices with four $AlO_4(OH_2)_2$ octahedra.[208] The two water molecules are *cis* to one another, with Al—O distances of 189.2 and 195.3 pm. The other four Al—O bonds range from 185.9 to 188.8 pm (average 187.6 pm). Edge-sharing AlO_6 octahedra linked by PO_4 groups are found in the structure of $NaAl_3(PO_4)_2(OH)_2$.[209] The structure of $Al(H_2PO_4)_3$, which can be crystallized from solutions of alumina in phosphoric acid, contains AlO_6 octahedra which share corners with $PO_2(OH)_2$ groups. Several other acid phosphates have been identified in the Al_2O_3—P_2O_5—H_2O system.[210] The compounds $M(PO_2F_2)_3$, where M = Al or Ga, can be prepared from the trihalides and difluorophosphoric acid.[211] Phosphoric acid derivatives of the organometal cations R_2M^+ (M = Al, Ga, In or Tl) have cyclic structures in which the bifunctional M centres are linked through O—P—O groups.[212]

The Al^{3+} ion is strongly complexed by phosphoric acid in aqueous solutions. The complex $[Al(HPO_4)_3]^{3-}$ appears to be the major species present, but the high viscosity of concentrated solutions indicates that polymeric species are also formed. The presence of aquated $[Al(H_3PO_4)]^{3+}$, $[Al(H_2PO_4)]^{2+}$ and complex cations with several acid phosphate ligands has been inferred from ^{27}Al and ^{31}P NMR studies.[213] On addition of fluoride to the solutions, F enters the coordination sphere of Al forming a series of fluorophosphatoaluminum complexes. The solids $AlF(HPO_4) \cdot nH_2O$ ($n = 2$ or 3) have subsequently been characterized.[214] Hydrates of the complex salt $(Me_4N)_3[Al(PO_4)_2]$ have been isolated from aqueous solutions believed to contain the $[Al(PO_4)_2]^{3-}$ anion.[1] Some ATP complexes of aluminum have been studied by NMR.[215] Much remains to be learned about the exact constitution of these solutions.

25.1.5.4.3 Sulfate, selenate and tellurate; tungstate and molybdate

Evaporation of solutions of alumina in sulfuric acid yields crystals of $Al_2(SO_4)_3 \cdot 16H_2O$. If a group I sulfate is also present, the products are alums $MAl(SO_4)_2 \cdot 12H_2O$, in which aluminum exists as $[Al(OH_2)_6]^{3+}$. Analogous selenates but not tellurates have been prepared. Basic salts, *e.g.* $Al_2(OH)_2(SO_4)_2 \cdot 10H_2O$, and solids obtained from aluminum sulfate solutions above 100 °C also contain complex ions in which the coordination sphere of Al^{3+} is occupied by OH groups and/or water molecules rather than sulfate ions. Thermal decomposition of the hydrate $Al_2(SO_4)_3 \cdot 16H_2O$ yields practically anhydrous $Al_2(SO_4)_3$ at 450 °C; further decomposition to

Al_2O_3 and SO_3 occurs above 600 °C.[216] Hydrogen sulfates $M(HSO_4)_3$ (M = Al or Ga) have been prepared (equation 8).[217] Excess water allows the hexahydrates to be formed.

$$M(SO_3Cl)_3 + 3H_2O \longrightarrow M(HSO_4)_3 + 3HCl \quad (8)$$

Anhydrous double sulfates ('alum anhydrides') $M^IM^{III}(SO_4)_2$ are formed by Al and Ga with NH_4 or the alkali metals (M^I).[218] Crystal structure determination establishes that Al^{3+} is coordinated by SO_4 groups, with r(Al—O) = 191 pm.[219] Complexes $M[AlCl_2(SO_4)]$ (M = Li, Na or K) have been prepared.[220] Chlorosulfates of aluminum with the same alkali metals, $M[Al(SO_3Cl)_4]$, are obtained by the solvolysis of $MAlCl_4$ in SO_2 at −15 °C.[221] All are very hygroscopic. The Li compound thermally decomposes to $Al_2(SO_4)_3$, whereas Na or K compounds give $MAl(SO_4)_2$. The sulfate ligand is found in bridging role in $(Me_2Al)_2SO_4$ (from $2Me_2AlCl + Na_2SO_4$), which is monomeric, D_{2d}, in solution but polymeric in the solid state. In aqueous solutions of $Al_2(SO_4)_3$ there is evidence from UV[222] and NMR[223] spectra of coordination of sulfate to the aluminum ion, as $[Al(SO_4)(OH_2)_5]^+$, at concentrations above 0.1 mol^{-1}.

Aluminum forms tungstates $Al_2(WO_4)_3$ and $MAl(WO_4)_2$.[224] Crystals of $Al(WO_4)_3$ are orthorhombic; as in the sulfate, Al^{3+} is octahedrally coordinated, with Al—O distances between 186 and 191 pm.[225] Aluminum can be introduced into the structures of polytungstates and molybdates to prepare $(AlW_{12}O_{40})^{5-}$ and $(AlMo_6O_{21})^{3-}$ for example.[226]

25.1.5.4.4 Chlorate, perchlorate, bromate, iodate and periodate

The salts of these anions are highly hydrated and all are likely to contain the $[Al(OH_2)_6]^{3+}$ complex, although the periodate $Al(IO_4)_3 \cdot 12H_2O$ is reported to decompose above 130 °C to yield the anhydrous iodate $Al(IO_3)_3$.[1] Hydrates $Al(ClO_4)_3 \cdot nH_2O$ (n = 3, 6, 9 or 15) lose water on heating and at 178 °C decompose to $Al(OH)(ClO_4)_2$. Anhydrous $Al(ClO_4)_3$ is obtained from $AlCl_3 + 3AgClO_4$ in benzene. Sparingly soluble perchlorato complexes $M_nAl(ClO_4)_{3+n}$ (M = group I or NH_4 cation; n = 1, 2 or 3) have recently been prepared.[227,228] IR spectra indicate that $[Al(ClO_4)_6]^{3-}$ possesses only unidentate ligands, whereas $[Al(ClO_4)_4]^-$ and $[Al(ClO_4)_5]^{2-}$ contain both uni- and bi-dentate ClO_4. By the same criteria, the compound $Al(ClO_4)_3$ contains bidentate groups, whilst $Al(ClO_4)_3 \cdot 3L$ (L = H_2O, THF or $MeNO_2$) has only unidentate ClO_4 ligands. $Al(ClO_4)_3$ dissolves in MeOH, HOAc or $(AcO)_2O$ with complete replacement of ClO_4 groups by solvent molecules, whereas the perchlorate ligands remain coordinated in MeCN, THF or $MeNO_2$. Mixed ligand complexes $[AlCl_n(ClO_4)_{4-n}]^-$ (n = 1, 2 or 3) have been detected by ^{27}Al NMR in solutions of $AlCl_3 + ClO_4^-$ ions in $CHCl_3$ or CH_2Cl_2, and there is evidence of perchlorate complexing of Al^{3+} in EtOH solutions.[229] Preparations of a salt $Me_4N[AlCl_3(ClO_4)]$,[230] and a molecular adduct $AlCl_2(ClO_4) \cdot 2DME$[231] of the ligand dimethoxyethane, have been reported; both appear to contain perchlorate coordinated to aluminum.

25.1.5.5 Carboxylate Ligands

Aluminum forms carboxylates $Al(O_2CR)_3$, and a range of basic carboxylates, including the mononuclear species $Al(OH)(O_2CR)_2$ and $Al(OH_2)(O_2CR)$, and polynuclear complexes such as $Al_3O(OH)(O_2CR)_6$ obtained from the above by elimination of water.[232] There are many uses in textile, paper and pharmaceutical industries which take advantage of the ability of Al centres to bind O ligands strongly.

Crystallization from concentrated solutions prepared by dissolving freshly precipitated $Al(OH)_3$ in formic acid yields $Al(OH)(O_2CH)_2 \cdot H_2O$. The hydrated triformate $Al(O_2CH)_3 \cdot 3H_2O$ can be obtained from solutions containing an excess of HCO_2H. Basic acetates $Al(OH)_n(O_2CMe)_{3-n}$ (n = 1 or 2) are obtained as white powders from aqueous acetate solutions on partial neutralization. The triacetate $Al(O_2CMe)_3$ is prepared by heating the metal or $AlCl_3$ with acetic acid and acetic anhydride. When heated, $Al(O_2CMe)_3$ loses acetic anhydride forming products with Al—O—Al linkages. The higher carboxylic acids form similar compounds. The trifluoroacetate $Al(O_2CCF_3)_3$ is obtained from Al/Hg and trifluoroacetic acid. A basic salt and the compounds $AlCl_n(O_2CCF_3)_{3-n}$ (n = 1 or 2) have been described.[233] Besides preparations from Al or the trihalides AlX_3, a number of routes to carboxylates employing alkoxides $Al(OR)_3$ or alkyls R_3Al are available.[232] By using the appropriate

stoichiometry mixed alkoxycarboxylates and the compounds $R_2Al(O_2CR')$ and $RAl(O_2CR')_2$ can be obtained.[6]

25.1.5.5.1 Complex ions

Complex salts with a group I metal $MAl(O_2CR)_4$ can be prepared from carboxylate solutions or from $MAlR_4$ (R = various alkyl groups) by reaction with CO_2 under pressure at 200 °C. Acetate complexes of trimethylaluminum have also been prepared, *i.e.* $Me_4N(Me_3AlO_2CMe)$ and $Me_4N[(Me_3Al)_2O_2CMe]$. XRD study of the former shows it to be a four-coordinate aluminum complex, with $r(Al—O) = 183$ pm and the angle C—O—Al = 137 °.[234] The structures of several Al complexes with bridging acetate ligands have been determined.[235]

In aqueous solution Al^{3+} gives complex ions $[Al(O_2CR)]^{2+}$ and $[Al(O_2CR)_2]^{+}$ with formic, acetic, propionic and butyric acids, for which the formation constants have been measured.[236,237] Owing to the influence of chelation, complexes of higher stability are formed by dicarboxylic, amino and hydroxy acids, and both cationic and anionic complexes may be formed.[238,239] Data are available for oxalic, malonic, succinic and lactic, diglycolic, gallic, citric, salicylic, glutamic and aspartic acids.[240–247]

NMR spectra give evidence of polymerization in aqueous solutions of hydroxycarboxylic acid complexes. In lactate (or citrate) solutions the ^{27}Al NMR spectra show distinct peaks for AlL_2^+, AlL^{2+} and AlL_3 complexes.[248] Increased pH leads to substitution of H_2O in the coordination sphere of $Al(OH_2)_6^{3+}$ by lactate and eventual displacement of lactate by OH^-. The citrate ion can function as a uni-, bi- or tri-dentate ligand towards Al^{3+}.[244] A tris(oxalato) complex can be isolated as $K_3Al(O_4C_2)_3{\cdot}3H_2O$.[249] In contrast to oxalato complexes of transition metals, $[Al(O_4C_2)_3]^{3-}$ is highly labile and has defeated attempts at the resolution of optical isomers. Studies of the interaction of Al^{3+} with the carboxylate groups of model membrane systems are leading to a better understanding of physiological processes, especially cumulative toxicity.[250]

25.1.5.6 Ethers and Other Oxygen Donor Ligands

25.1.5.6.1 Molecular complexes

Organic ligands which form O donor complexes with the aluminum trihalides, except AlF_3, include ethers, aldehydes, ketones, esters, nitro compounds, alkyl phosphates, sulfoxides, ureas, acid chlorides and amides.[4] 1:1 is the prevailing stoichiometry, although there are 1:2 AlX_3·ether adducts, some nitro complexes of this form (*e.g.* $AlCl_3{\cdot}2PhNO_2$, $AlBr_3{\cdot}2MeNO_2$), and a few instances of 2:1 type ($Al_2X_6{\cdot}L$). The ether complexes tend to decompose on heating, giving mixtures including AlX_2OR, and as a class the AlX_3 adducts are highly reactive and very susceptible to hydrolysis and nucleophilic attack. X-Ray studies have shown that the crystalline acetyl chloride complex of $AlCl_3$ is ionic, $MeCO^+AlCl_4^-$ (although it has a donor–acceptor structure in dichloromethane solution[251]), whereas the adducts with EtCOCl and PhCOCl are O-linked coordination compounds.[252] Bond lengths are Al—O = 182–185 pm and Al—Cl = 208–209 pm. A decrease in the $\nu(C{=}O)$ stretching frequency shows the carbonyl oxygen to be the donor site in these compounds, and also in the case of esters, amides and anhydrides. Vibrational spectra show that the complexes $AlX_3{\cdot}MeNO_2$ (X = Cl or Br) are simple molecular adducts.[253]

Several of the ether adducts have been investigated in detail. $AlCl_3{\cdot}2THF$ has a molecular structure which is close to trigonal bipyramidal; the tetrahydrofuran ligands are *trans* diaxial with Al—O = 199.0 pm and Al—Cl = 215.3–216.4 pm.[254] There is spectroscopic proof that the ionic complex $AlCl_2(THF)_4^+AlCl_4^-$ can be obtained in the solid state, although it readily isomerizes to the molecular form. A molecular structure $AlX_3{\cdot}THF$ (X = Cl or Br) is found for the solid 1:1 adduct. These species can be detected in solution where the various forms are in equilibrium, and there is evidence of interconversion of *cis* and *trans* forms of $AlCl_3{\cdot}2THF$.[255] The structure of $AlCl_3{\cdot}2diox$ is also based on trigonal bipyramidal coordination.[256] Here, planar $AlCl_3$ units are bridged by 1,4-dioxane to form $(AlCl_3{\cdot}diox)_x$ chains; the second dioxane molecule is merely a solvate. The bond distances [Al—O = 201.7 pm and Al—Cl = 213.9 pm (average)] are close to the values in $AlCl_3{\cdot}2THF$. Diethyl ether gives $AlX_3{\cdot}Et_2O$ (X = Cl, Br or I)[257] whereas Me_2O forms 1:1 and 1:2 types. The complexes $AlHCl_2{\cdot}Et_2O$ and $AlHBr_2{\cdot}Et_2O$

have been examined spectroscopically; ν(Al—O) was close to 330 cm^{-1} and shifted very little on changing Cl for Br.[258]

Coordination takes place through oxygen in the 1:1 and 2:1 sulfone complexes $AlBr_3 \cdot R_2SO_2$ and $2AlBr_3 \cdot R_2SO_2$ which have been studied by means of bromine NQR spectra.[259] A complex of aluminum trichloride with benzo-15-crown-5 is notable as another instance of a 2:1 type, effectively Al_2Cl_6·ether.[260] It is obtained from benzene–diethyl ether solvent; on recrystallization from methanol the more stable 1:1 ($AlCl_3$·ether) adduct is produced. Crystal structures of some related complexes with crown ethers, $(Me_3Al)_n$·ether ($n = 2$ or 4) and $(AlCl_2 \cdot ether)^+$, have been reported.[261] These are useful agents for solubilizing ionic species M^+A^- in aromatic solvents, ultimately affording $M^+AlMe_3A^-$ and $M^+Al_2Me_6A^-$. A general review of etherates of organoaluminum compounds has been given.[262]

Measurements on systems $R_3Al \cdot L$, where L is one of the ethers mono-, di- or tri-glyme, yield low values (*ca.* 25 kJ mol^{-1}) for the activation energy of ligand exchange, suggesting that a bimolecular displacement rather than a dissociative mechanism is operative.[263] NMR measurements in solution confirm the existence of both $AlCl_3 \cdot Me_2O$ and $AlCl_3 \cdot 2Me_2O$ and enable ligand exchange rates to be determined.[264] Competition experiments have shown the following order of ligand strength towards $AlCl_3$: $COCl_2 < MeNO_2 < PhNO_2 < PhCOCl < Me_2O < Ph_2CO < Et_2O < HCO_2Me < MeCN < Cl^-$.[265] Other aspects of the energetics of AlX_3–oxygen donor complexes are compared with those of amine adducts and of the AlX_4^- ions in appropriate sections. Ether adducts of other Al^{III} species, $AlH_3 \cdot Et_2O$ and $Al(NCS)_3 \cdot Et_2O$, are mentioned elsewhere in this chapter.

Of several inorganic ligands which form O-coordinated complexes with $AlCl_3$ or $AlBr_3$, phosphorus oxychloride has been the most fully investigated. The adduct $AlCl_3 \cdot POCl_3$, m.p. 186 °C, is well known and a second adduct has been shown to be $2AlCl_3 \cdot 3POCl_3$ (m.p. 166 °C)[266] (not $AlCl_3 \cdot 2POCl_3$ as in early literature). Unstable crystals $AlCl_3 \cdot 6POCl_3$ decomposing at 42 °C have also been obtained. With other ligands there are reports of $AlCl_3 \cdot COCl_2$, $2AlCl_3 \cdot NO$, $AlCl_3 \cdot NOCl$, $AlCl_3 \cdot 2NOCl$, $2AlCl_3 \cdot SO_2$, $AlCl_3 \cdot SO_2$, $2AlCl_3 \cdot SOCl_2$, and a few analogous complexes of $AlBr_3$ and AlI_3.[1,4,264] All are not necessarily O-bound, for example the 1:1 complex of $AlCl_3$ with NOCl is better formulated as $NO^+AlCl_4^-$ (see Section 25.1.7.2). The aluminum trihalides do not react with carbon monoxide as such, but there are a number of complexes in which the AlX_3 Lewis acid group is attached to a carbonyl group of a transition metal complex,[267] and kinetic studies have shown that coordination to AlX_3 is an effective means of promoting carbonyl insertion reactions.[268] The structure of $[W(CO)_3Cp]_2Al \cdot 3THF$ is a remarkable one; the Al atom is six-coordinate, being attached to O atoms of carbonyls and three THF ligands.[269]

25.1.5.6.2 Cationic complexes

There have been a number of investigations of the species formed by Al^{3+} in polar oxygen-containing solvents. Frequently these are complex cations AlL_6^{3+}; examples which have been characterized by NMR (^1H and ^{27}Al) and other measurements are $Al(DMSO)_6^{3+}$, $Al(DMF)_6^{3+}$, $Al(TMPA)_6^{3+}$, $Al(urea)_6^{3+}$ and $Al(EtOH)_6^{3+}$.[270] Kinetic and thermodynamic parameters have been determined for several of these systems. They show, for example, that $Al(DMF)_6^{3+}$ is a more labile complex than $Al(DMSO)_6^{3+}$, but that all seven species $Al(DMSO)_n(DMF)_{6-n}^{3+}$ ($n = 0$–6) are present at various DMSO:DMF ratios when both ligands are added to a solution of $Al(ClO_4)_3$ in nitromethane. The urea complex has been isolated as a crystalline salt, $Al(urea)_6(ClO_4)_3$, which has been studied crystallographically.[271]

Dimethyl sulfoxide systems have attracted most attention. Ligand exchange of DMSO with the complexes $M(DMSO)_6^{3+}$ (M = Al, Ga or In) has been shown to involve a dissociative mechanism, and rate and activation parameters have been determined for ligand displacement reactions of $Al(DMSO)_6^{3+}$ with H_2O, and with the stronger bases pyridine, bipyridyl and terpyridyl.[272] The halides $AlCl_3$ and $AlBr_3$ form the DMSO complexes $AlX_3 \cdot 1.5DMSO$ and $AlX_3 \cdot 6DMSO$. According to vibrational spectra, both these solids contain the DMSO-coordinated cation and should be formulated as $Al(DMSO)_6^{3+}3AlX_4^-$ and $Al(DMSO)_6^{3+}3X^-$, respectively.[273] Vibrational assignments are also available for the tetramethylene sulfoxide complex $Al(TMSO)_6^{3+}$.[274]

^1H NMR spectra of $AlCl_3$, in either MeOH or EtOH solutions, indicate a solvent coordination number of four which may imply that the species $AlCl_2(ROH)_4^+AlCl_4^-$ predominate.[275] In the cases of $Al(NO_3)_3$ and $Al(ClO_4)_3$ the solvation numbers are five and six,

respectively. For $Al(ClO_4)_3$ in non-aqueous solvents, the addition of trimethyl phosphate produces $Al(TMP)_6^{3+}$, whereas hexamethylphosphoramide gives a tetrahedrally coordinated complex. The kinetics of ligand exchange show that an associative mechanism is followed by the four-coordinate species, which contrasts with the dissociative path to which the six-coordinate species are restricted. If water is also present, the octahedral species $AlL_n(OH_2)_{6-n}^{3+}$ (L = TMP or HMPA) are detected instead.[276]

25.1.6 SULFUR AND HEAVIER GROUP VI LIGANDS

25.1.6.1 Sulfides, Selenides and Tellurides

The compounds Al_2S_3, Al_2Se_3 and Al_2Te_3 are produced by heating the elements in 2:3 proportions.[277] All crystallize in the wurtzite hexagonal lattice of anions with Al^{3+} in two-thirds of the cation sites, although other forms exist, including some high-pressure phases based on a cubic lattice.[278] There are many ternary compounds M^IAlY_2 and $M^{II}Al_2Y_4$ (Y = S, Se or Te),[1,279,280] some of which are less susceptible to hydrolysis and other attack than the corresponding Al_2Y_3. Ternary group III compounds are also known, *e.g.* $InAlS_3$ in which Al is tetrahedrally coordinated by S atoms.[281]

Thiohalides AlSX (X = Cl, Br or I) can be prepared as crystalline compounds by heating Al_2S_3 with AlX_3.[1] They decompose on strong heating and are readily converted to the oxyhalides by moisture and to thioamides $AlSNH_2$ by ammonia. Selenium and tellurium form the analogous AlSeX and AlTeX which react similarly. The structure of AlSX (and AlSeX) deduced from IR/Raman spectra is basically a dimer with a planar Al_2S_2 ring and terminal Al—X.[282] The units are interlinked through halogen bridge bonding. Sulfide ions and $AlCl_4^-$ react in basic $CsCl/AlCl_3$ melts to produce chain-like complex anions $[Al_nS_{n-1}Cl_{2n+2}]^{n-1}$ (n = 2–3 in dilute solution; higher when more concentrated). The polymeric compound $CsAlSCl_2$ can be isolated.[283] Raman spectra of the melts show features attributable to both bridging S and Cl ligands. In acid melts, dissociation to form solid AlSCl occurs.

25.1.6.2 Other Sulfur Donor Ligands

Dialkyl sulfide ligands interact with the halides AlX_3 to form the 1:1 complexes.[257] For $AlCl_3 \cdot SMe_2$, rapid exchange of ligand with excess Me_2S is shown by NMR investigation.[264] $AlI_3 \cdot SEt_2$, obtained by direct reaction of the compounds, has also been characterized by NMR. The dithiocarbamate $Al(S_2CNMe_2)_3$ can be prepared from $Al(NMe_2)_2$ by CS_2 insertion.[284] The structure is monomeric with six-fold coordination of Al by S (Al—S distances = 238.6–240.5 pm). In the case of $ClAl(NMe_3)_2$ the product is the dimer $[ClAl(S_2CNMe_2)_2]_2$. There are two bridging Cl ligands which, with the four S atoms, enable each of the Al atoms in the molecule to be six-coordinate. Various lithium tetrakis(thiocarbamato)aluminates $LiAl(YY'CNHR)_4$ (Y = S, Y' = O or S) have been prepared and characterized by IR spectra.[285] Insertion of CS_2 into the Al—N bond in Me_2AlNPh_2 to yield $Me_2AlS_2CNPh_2$ occurs when the reactants are refluxed together in hexane.[286] The structure of the adduct $Me_3Al \cdot SMe_2$ has been determined by vapour phase ED which yields the Al—S bond length of 255 pm.[287] Reactions of Me_3Al with toluene-3,4-dithiol give a variety of cyclic and polymeric products with Al—S-bonded structures.[288] $(Me_2Al)_2S$, the sulfur analogue of tetramethylaluminoxane, has been reported; it is produced from trimethylaluminum by reaction with lead sulfide or liquid H_2S.[289]

25.1.7 HALOGEN LIGANDS

25.1.7.1 Fluoride Ligand

The AlF_3 molecule, trigonal planar, with Al—F distance of 163 pm, is produced in the gas phase when aluminum trifluoride sublimes (1272 °C at 1 atm).[1] Vibrational frequencies of the monomer, and the Al_2F_6 dimer, are available from matrix isolation studies,[290,291] as is also true for the OAlF molecule.[292]

Crystalline AlF_3 can be obtained from Al_2O_3 and HF at 700 °C. The lattice contains

six-coordinate Al with Al—F = 179 pm. The hydrates $AlF_3 \cdot nH_2O$ ($n = 3$ or 9) are dehydrated with difficulty *via* non-stoichiometric forms. Unlike the other halides, anhydrous AlF_3 is insoluble in inert solvents and only slightly soluble in water. It is more soluble in the presence of HF, forming the complexes AlF_6^{3-}, $AlF_n(OH_2)_6^{3-n}$ and $AlF_3(OH_2)_3$ detectable by NMR and other means.[293–296] Concentrated solutions deposit β-$AlF_3 \cdot 3H_2O$ on standing.

There are many complex fluoroaluminates, both natural and synthetic. Octahedral AlF_6 units are present, either as AlF_6^{3-} or within chain or layer structures where adjacent units share apices. Edge-sharing, which would produce short Al···Al distances, is avoided and Al—F—Al links are close to linear. The solids M_3AlF_6 assume cubic lattices at elevated temperature (the Li salt at 597 °C, Na at 560 °C, K at 300 °C).[1] Structures at ambient temperature are less regular. Recent structural studies include those of alkali metal hexafluoroaluminates, $Ba_3(AlF_6)_2$, $BaZnAlF_9$ (in which Al/ZnF_6 octahedra are linked into tetrameric anions)[297] and $Hg_2AlF_5 \cdot 2H_2O$ (in which AlF_6 octahedra are linked through *trans* fluorines into infinite chains).[298] In $KAlF_4$, layers of AlF_6 groups are connected by four corners. Al—F distances, measured by neutron diffraction, are 181.7 and 175.2 pm.[299]

Na_3AlF_6 'cryolite', which can be synthesized from $Al_2O_3 + HF + NaOH$, forms, with alumina and AlF_3, the basis of the electrolyte in the manufacture of aluminum. There have been critical studies of cryolite,[300] of the liquid phase dissociation $AlF_6^{3-} \rightarrow AlF_4^- + 2F^-$,[301,302] and of the vapour above the melt.[303] In the gas phase, the predominant species $NaAlF_4$ has the structure $Na(\mu\text{-}F)_2AlF_2$, and the $(NaAlF_4)_2$ dimer is also present. MO calculations have been used to compare various possible gas phase structures of $NaAlF_4$, $LiAlF_4$ and $MgAlF_5$.[304]

X-Ray studies[305] established the presence of a linear, symmetrical Al—F—Al bridge with Al—F 178.2 pm in the anion $Me_3Al(\mu\text{-}F)AlMe_3^-$ which is isoelectronic with disiloxane $(Me_3Si)_2O$. Me_2AlF is a cyclic trimer containing the Al_3F_3 ring.[306]

25.1.7.2 Chloride, Bromide, Iodide and Mixed Halide Ligands

Aluminum monohalides AlX are recognized in the high temperature gas phase from which they can be trapped by matrix isolation.[307] AlCl is significant in the chemical transport of aluminum through the equilibrium $Al_{(l)} + AlCl_{3(g)} \rightleftharpoons 3AlCl_{(g)}$. For the AlX_3 monomers, planar trigonal molecules, there are reports of bond distances, and of IR and Raman spectra in the gas phase, or as matrix-isolated species.[308,309] *Ab initio* MO calculations of the geometry of the $AlCl_3$ and Al_2Cl_6 molecules have been performed, and photoelectron spectroscopy has been used to investigate the equilibrium between MX_3 and the M_2X_6 dimers for M = Al or Ga; X = Cl, Br or I.[310] Structural data for the Al_2X_6 molecules are tabulated elsewhere,[1,2] as are the physical properties of the crystalline aluminum trihalides, so that only values which have been subsequently revised are cited here. For example, vibrational spectra of aluminum halide vapours have provided a basis for fresh NCA calculations on the AlX_3 and Al_2X_6 molecules,[308,311] and the Raman spectrum of Al_2Cl_6 in the melt has been reexamined.[312]

Aluminum trichloride is synthesized by heating the metal in chlorine or dry HCl. Various methods of purification have been employed.[1] Crystalline $AlCl_3$, a lattice containing six-coordinate Al, melts at 192 °C under 2.5 atm to give a liquid consisting of Al_2Cl_6 molecules. At 1 atm it sublimes at 150–180 °C, mainly as Al_2Cl_6, although the vapour then contains 1% of the trimer Al_3Cl_9. The dimer dissociates readily (ΔH for $Al_2Cl_6 \rightarrow 2AlCl_3$ is 170 kJ mol^{-1}),[313] and the monomer is the predominant form at 750 °C. Aluminum tribromide (m.p. 98 °C) and aluminum triiodide (m.p. 189 °C) are synthesized from Al and halogen. The standard enthalpies of formation have been redetermined, giving −495 and −280 kJ mol^{-1} for $AlBr_3$ and AlI_3, respectively.[314] The bromide consists of Al_2Br_6 molecules in solid and liquid states. In the vapour, MS detects clusters containing up to 30 atoms, $(AlBr_3)_n$, with strong peaks for $n = 2$, 4 and 6, besides the monomer formed by dissociation.[315] Crystalline AlI_3 has an infinite chain structure with the repeating unit $—AlI_2(\mu\text{-}I)—$.[316] The Al—I distances differ markedly, averaging 272.0 pm (bridging) and 245.3 pm (non-bridging). The Al—I—Al bridge angle is 119°. The liquid is molecular, Al_2I_6, as shown by the IR and Raman spectra.[1] As powerful Lewis acceptors, the trihalides form (with donor molecules) coordination compounds of the type D—AlX_3, and sometimes D_2AlX_3 or DAl_2X_6, discussed at various points in this chapter. $S_2N_2(AlCl_3)_2$ is an example of a compound in which a dibasic species, the S_2N_2 ring, coordinates to two separate $AlCl_3$ units.[317]

The importance of aluminum trichloride (and $AlBr_3$ which is more soluble in hydrocarbons) as a catalyst, particularly for Friedel–Crafts alkylation and acylation of aromatic compounds,

has led to many investigations.[4,318–321] The prime function of $AlCl_3$ is to interact with the RCl or RCOCl molecule to generate cationic alkyl or acyl species with simultaneous production of $AlCl_4^-$ and/or $Al_2Cl_7^-$. With aromatic hydrocarbons (Ar) in the presence of HX, the halides can form $ArH^+Al_2X_7^-$ which is an effective catalyst. Anhydrous aluminum trihalides also interact with aromatic systems in the absence of HX, but the process is imperfectly understood. The alleged formation of a complex of Al_2Cl_6 with benzene has been refuted.[322] Mixtures of the bromide with benzene yield an inclusion compound Al_2Br_6·benzene, the NQR signals of which are similar to those of pure Al_2Br_6.[323] With toluene, Raman spectroscopy gives evidence of a complex throught to have the singly bridged structure $Br_3Al(\mu\text{-}Br)AlBr_2$·toluene,[324] and with mesitylene there is a π complex, $AlBr_3$·mesitylene.[1] Lamellar compounds including C_9·$AlBr_3$·Br_2 and C_{24}·$AlBr_3Br_{0.3}$ are formed when graphite is exposed to $AlBr_3$–Br_2 mixtures.[325]

Chemical transport of the chlorides of many other metals takes place in aluminum trichloride vapour, and this aspect of the Lewis acid behaviour of $AlCl_3$ has received considerable attention, focussing especially on the formulae of the gaseous complexes, their thermodynamic properties and possible applications.[313] The species concerned are molecular complexes which typically have $Al(\mu\text{-}X)_2M$ bridges, such that both Al (as AlX_4 or Al_2X_7) and the other metal, *e.g.* Be, Mg, Fe or Pd, attain a coordination number of four. In $NaAlCl_{4(g)}$ the Na atom is probably above one edge of the $AlCl_4$ tetrahedron, as in $NaAlF_4$.[326] With $CrCl_2$ or $NiCl_2$ the gas phase complex MCl_2·$2AlCl_3$ has the structure $ClAl(\mu\text{-}Cl)_3M(\mu\text{-}Cl)_3AlCl$ in which Al is four-coordinate and the transition metal is six-coordinate. The structures and properties of organoaluminum halides further demonstrate the coordination behaviour of halogen ligands towards Al. Compounds such as R_2AlCl and $RAlCl_2$ (R = Me or Et) are dimeric in the liquid state and tend to dissociate in the vapour.[327,328] The Al–Cl bridge bonds in the $Me_2Al(\mu\text{-}Cl)_2AlMe_2$ molecule (230 pm) are significantly longer than those in Al_2Cl_6 (225 pm).

25.1.7.2.1 Complex halide ions

Aluminum forms the four-coordinate anions AlX_4^- and the bridged species $Al_2X_7^-$, *i.e.* $X_3Al(\mu\text{-}X)AlX_3^-$, both of which are produced when aluminum halide is fused with a metal halide MX.[329] There are recent XRD and spectroscopic studies of the $AlCl_4^-$ ion as crystalline Li, Na, K, Tl and NH_4 salts at ambient and elevated temperatures.[329,330] The Al—Cl distances are 212–214 pm, and various distortions of $AlCl_4^-$ from tetrahedral symmetry are revealed. The corresponding bromides $MAlBr_4$ have also been characterized.[1,331] Near regular $AlCl_4^-$ ions with Al–Cl bond lengths of 212.9 pm occur in $Li(SO_2)_3AlCl_4$[332] and in $NOAlCl_4$[333] (from $AlCl_3$ + NOCl in liquid SO_2). The $AlCl_4^-$ tetrahedra, which interact only weakly with the alkali metal cations, are linked through Cl bridges in the case of some transition metal chloroaluminates, *e.g.* $Cu(AlCl_4)_2$, $Ti(AlCl_4)_2$, $(\eta\text{-}C_6H_6)Ti(AlCl_4)_2$ and $(\eta\text{-}C_6H_6)V(AlCl_4)_3$.[334–336] NQR spectra are able to distinguish between compounds containing ionic AlX_4^- and those in which the groups interact with other metal centres, or form $Al_2X_7^-$.[337–339] The ready formation and low coordinating ability of the AlX_4^- ions has been instrumental in the use of aluminum halides to isolate compounds containing low-valent cluster cations or other unusual species, *e.g.* $Hg_3(AlCl_4)_2$, $Bi_8(AlCl_4)_2$,[340] $C_3X_3(AlX_4)$ (X = Cl or Br),[341] $SCl_3(AlCl_4)$,[342] $PI_4(AlI_4)$ and $P_2I_5(AlI_4)$.[343] In these last two compounds, AlI_4^- has near regular T_d symmetry with Al—I = 251.8 or 252.9 pm, respectively. A notable attempt to utilize $AlCl_4^-$ in isolating a silicon-based cation resulted instead in a compound with $AlCl_3$ coordinated to one of the N atoms of $(Me_2N)_3SiCl$.[344]

Much recent work on $NaCl/AlCl_3$ and related haloaluminate systems has concerned their behaviour as molten salts and non-aqueous electrolytes, and their use as aprotic reaction media.[345–352] $AlCl_3$ with *n*-butylpyridinium chloride, and allied low-melting combinations provide useful model systems for fused salt behaviour and have attracted considerable attention on this account.[353–356] There is evidence, particularly from ^{27}Al NMR spectra, that $Al_2Cl_7^-$ and also $Al_3Cl_{10}^-$ are present in $AlCl_3$-rich systems.[354,355]

The tetrahaloaluminates are hydrolyzed by water; however, the anion $AlCl_4^-$ has been characterized in solution as the complex acid $(Et_2O)_nH^+AlCl_4^-$.[357] This ion and solvated $AlCl^{2+}$ and $AlCl_2^+$ are formed when $AlCl_3$ dissociates in various solvents, such as ethers, $MeNO_2$ and MeCN.[358,359] NMR, IR and Raman spectra have identified the species and have enabled exchange processes between them to be monitored. The ions $[Me_nAlCl_{4-n}]^-$ ($n = 1$–3) have been investigated in benzene solution.[360] Vibrational analyses are available for $MeAlCl_3^-$ and

Me_3AlCl^-,[361] and the crystal structures of $K(MeAlCl_3)$, $Cs(Me_2AlI_2)$ and $Me_4N(Me_3AlI)$ have been determined.[362]

The heptachlorodialuminate ion has been obtained from the reaction of acetyl chloride and Al_2Cl_6 which yields $MeCO^+Al_2Cl_7^-$ in liquid HCl,[363] although the direct reaction yields $MeCO^+AlCl_4^-$.[364] (EtCOCl and $AlCl_3$ form a molecular adduct in which $AlCl_3$ is attached by the CO group of propionyl chloride.) Crystallographic studies of solids containing $Al_2Cl_7^-$, which has been observed in both eclipsed and staggered bent configurations, give the average Al—Cl distances 227.0 pm (bridging) and 208.4 pm (terminal) and a bridge bond angle Al—Cl—Al of 114°.[365] The $Al_2Br_7^-$ anion is similar, having Al—Br = 243 pm (bridging) and 227 pm (terminal) with angle Al—Br—Al = 108° in the NH_4^+ salt.[366] $Et_4N(AlBr_4)$ and $Et_4N(Al_2Br_7)$ are obtained by reactions of $AlBr_3$ with Et_4NBr in acetonitrile.[367] Vibrational spectra of $Al_2X_7^-$ (X = Cl, Br or I in Me_4N^+, K^+ or Cs^+ salts, respectively) indicate higher symmetry with a linear Al—X—Al bridge in the liquid state.[368] In view of the experimental support for both linear and bent structures of $Al_2Cl_7^-$, it is interesting that *ab initio* calculations[369] favour a bent Al—Cl—Al bridge in the species $H_3Al(\mu\text{-}Cl)AlH_3^-$ (in contrast, $Al_2H_7^-$ is predicted to be a linear).

25.1.7.2.2 Mixed halide species

The anions $[AlI_nX_{4-n}]^-$ (X = Cl or Br), readily identifiable by ^{27}Al NMR spectroscopy, are generated from AlI_3 and Pr^n_4NI in CH_2Cl_2 or CH_2Br_2, and the $[AlCl_nI_{4-n}]^-$ series has also been observed in molten salt media.[370] The series $[AlCl_nBr_{4-n}]^-$ and the ions AlX_2YZ^-, containing three different halogens, have been characterized similarly,[371] and equilibrium relationships between these various complexes have been estimated. The chemical shift range which separates $AlCl_4^-$ from AlI_4^- is much smaller than that which separates $GaCl_4^-$ from GaI_4^-, in line with differences in nuclear shielding of the Al and Ga mixed halide species. Raman and NMR spectra of mixtures containing $AlCl_nBr_{4-n}^-$ ($n = 0$–4) have been used to identify the individual ions and MO calculations have been applied to this system.[372] Mixed halide forms of the aluminum trihalide molecules are little known although the reaction of HCl with $AlBr_3$ is said to give mainly $AlCl_2Br$, and both $AlCl_2Br$ and $AlClBr_2$ have been identified by matrix isolation methods.[373]

25.1.8 HYDROGEN AND COMPLEX HYDRIDE LIGANDS

25.1.8.1 Hydride Ligand

Aluminum hydride as polymeric $(AlH_3)_x$, and the trimethylamine complex of alane, $AlH_3{\cdot}NMe_3$, were reported about 1940.[26] Synthesis of aluminum hydride, as a colourless solid, by the reaction of $LiAlH_4$ with $AlCl_3$, appeared in 1947.[374] A route which avoids residual chloride ligands uses the action of sulfuric acid on $LiAlH_4$ in THF.[375] A tested preparation of the complex $AlH_3(OEt_2)_{0.3}$ is available,[376] and some spectroscopic and X-ray data have been reported for this.[377] There are ν(Al—H) bands at 1620–1880 cm^{-1} and ν(Al–O) at 725 cm^{-1}; the crystal is cubic. AlH_3, free of ether, is obtained by running a fresh ethereal solution into pentane. At least six crystalline phases of AlH_3 have been identified.[378] In one modification, isostructural with AlF_3, the Al atoms are each surrounded by an octahedral array of hydrogens. The Al—H distance in this structure is 172 pm.[379] The monomeric AlH_3 and dimeric Al_2H_6 molecules can be generated as vapour phase species above 1000 °C. The Al—H bond energy in $AlH_{3(g)}$ is 340 kJ mol^{-1}, compared to the energy of the electron deficient bridge bond in Al_2H_6, estimated to be 116 kJ mol^{-1}.[380] Whereas AlH_3 is planar, the alane radical anion $^{\cdot}AlH_3^-$ has a pyramidal structure, demonstrated by a combination of matrix isolation and ESR techniques. The molecule $HAlCl_2$ has been generated from AlCl and HCl in an argon matrix under UV irradiation. The vibrational spectrum with ν(Al—H) at 1968 cm^{-1} and ν(Al—Cl) near 475 cm^{-1} favours a planar monomeric structure.[381]

Using *ab initio* procedure, the structure of the $(Me_2AlH)_2$ dimer has been calculated.[382] Similar calculations for $(Me_3Al)_2H^-$, and for the hypothetical species $Al_2H_7^-$, show that the lowest energy corresponds to a linear Al—H—Al bond.[383] The crystal structure of $Na(Me_3Al—H—AlMe_3)$ shows the Al—H distance to be 165 pm, compared to 168 pm in $(Me_2AlH)_2$, and that the Al—H—Al angle is accurately 180°.[384] X-Ray analysis of $K(Me_3AlH)$ reveals a length

of 173 pm for the non-bridging Al—H bond in this anion.[385] Secondary bridging through H and Cl occurs in the complexes formed by $AlH_3{\cdot}OEt_2$, or $AlH_3{\cdot}NMe_3$, with the yttrium chloride dimer $(Cp_2YCl)_2$.[386] This demonstrates both the tendency of the Al—H bond to form bridges, and also the residual unsaturation of the Al centre in $AlH_3{\cdot}L$ systems.

Important aluminum hydride derivatives are the adducts of AlH_3 with Lewis bases; the complex aluminohydrides, notably $LiAlH_4$; and a range of compounds AlH_nL_{3-n}. In this last category are halogenoalanes, AlH_nX_{3-n} (X = Cl, Br or I; $n = 1$ or 2); dialkylaminoalanes, $AlH_n(NR_2)_{3-n}$; iminoalanes, especially the polymeric substances $(—AlH(NR)—)_x$; phosphinoalanes, alkoxyalanes and mercaptoalanes. Aspects of the chemistry of these compounds and adducts of the type $AlH_3{\cdot}NR_3$ and $AlH_3{\cdot}OR_2$ are treated elsewhere in this chapter. There is a good review of work prior to 1970 which charts the early progress of aluminum hydride chemistry.[26]

25.1.8.1.1 Complex aluminohydrides

The principal complex hydrides are alkali metal salts, $MAlH_4$ and M_3AlH_6, especially lithium aluminum hydride. Early accounts described the initial development of these reagents.[387–389] The laboratory preparation and purification of $LiAlH_4$, its manufacture by the Schlesinger process, properties, uses and safe handling were covered. Characteristic reactions of aluminohydrides will not be described now, except for recent work, or where there are aspects of special relevance to aluminum coordination chemistry. Hydridoaluminates can react with metal–halogen, metal–alkoxy and metal–alkyl compounds to form the corresponding metal hydride. Al—H bonds are highly labile and species with such bonds react with active-hydrogen-containing compounds to release hydrogen gas.

Lithium aluminum hydride can be prepared from $AlCl_3$ plus 4LiH in diethyl ether. An alternative route, using $AlH_3{\cdot}NMe_3$ and LiH, illustrates the displacement of coordinated trimethylamine by the more powerful base, H^-. $NaAlH_4$ can be synthesized directly from the elements using THF solvent at 150 °C and 135 atm. The product is obtained by precipitation with toluene, and can be converted to $LiAlH_4$ by reaction with LiCl in Et_2O.

$LiAlH_4$ is stable in dry air below 120 °C, but highly reactive towards moisture and protic solvents. When heated to 100 °C, Li_3AlH_6 is produced by a reaction in which exactly 50% of the total hydrogen is liberated (equation 9).

$$3LiAlH_4 \longrightarrow Li_3AlH_6 + 2Al + 3H_2 \tag{9}$$

Preparative routes to Li_3AlH_6 use $LiAlH_4$ + butyllithium,[390] or $LiAlH_4 + 2LiH$ in the presence of Et_3Al as catalyst.[391] $LiAl_2H_7$ was also reported but not substantiated by further work.[392] $NaAlH_4$ is more stable than the lithium compound, decomposing to Na_3AlH_6 at 220 °C under nitrogen. Above 245 °C further decomposition gives 3NaH + Al + hydrogen.[393] The crystal of $LiAlH_4$ contains tetrahedral AlH_4^- ions with an average Al—H distance of 155 pm. In $NaAlH_4$, the anion has a compressed tetrahedral geometry with the Al—H distance of 153.2 pm. The bond angles are 107.3° and 113.9°.[394] The structures and stabilities of $LiAlH_4$ and the series of complex hydrides $M^IM^{III}H_4$ (M^I = alkali metal, M^{III} = Al, Ga, In or Tl) have attracted recent theoretical as well as experimental attention.[395,396]

The complex hydrides $MAlH_4$ form solvates, *e.g.* $LiH_4{\cdot}nL$, where $L = OEt_2$ or THF and $n = 1$ or 2. $LiAlH_4{\cdot}2THF$ is soluble in benzene and is volatile with some loss of THF. Amine adducts of $LiAlH_4$ are also formed, and are more stable to heat than the parent compound. A hydridoaluminate $NaAlH(OMe)_2OEt$ is manufactured as the benzene-soluble reducing agent 'Red-Al'. Tested procedure is available to prepare a dihydroaluminate which is non-pyrophoric and soluble in aromatic hydrocarbons by the reaction shown in equation (10), using 2-methoxyethanol.[397] This compound probably owes its stability to six-coordinate Al with two H ligands and two chelating groups forming Al—O bonds. Related compounds $Na[AlH_n(OR)_{4-n}]$, where $OR = OC_2H_4NMe_2$ and $n = 1$ or 2 but not 3, are produced by the reaction of 2-dimethylaminoethanol with $NaAlH_4$. Mixed alkoxyhydrides $AlH_n(OPr^i)_{3-n}$ are formed by redistribution reactions of $AlH_3{\cdot}THF$ with $Al(OPr^i)_3$.[398]

$$Na + Al + 2MeOC_2H_4OH \xrightarrow[150\,°C]{H_2,\ 70\text{–}250\ atm} Na[AlH_2(OC_2H_4OMe)_2] \tag{10}$$

The structures of hydridoaluminates have been investigated in solution. Conductance

measurements in ether solutions over a wide concentration range suggest that the ions of $LiAlH_4$ (and $NaAlH_4$) form solvent-separated ion pairs, whereas the ions of Bu_4NAlH_4 are in intimate contact.[399] A slight concentration dependence of the ^{27}Al NMR chemical shift, and the appearance of Al—H coupling below 0.15 mol l^{-1} is consistent with ion-cluster formation at higher concentations, with ion pairs at lower concentrations.[400] Rapid, intermolecular hydride exchange occurs at 25 °C in mono- or di-glyme solutions. No solvent coordination to AlH_4^- is detectable in IR/Raman spectra.[401] NCA of the vibrational data produces an order of M—H stretching force constants in which the aluminum value is less than that for gallium: $AlH_4^- < GaH_4^- < BH_4^-$.

Reaction of hydridoaluminates with $AlCl_3$ forms $AlHCl_2$ and AlH_2Cl as the etherates. The complexes $Li(AlHCl_3)$ and $Li(AlH_2Cl_2)$ also participate.[402] Excess $LiAlH_4$ with $AlCl_3$ in ether at −90 °C can furnish a hydridoaluminate of aluminum itself, $Al(AlH_4)_3{\cdot}OEt_2$, which decomposes to Al + Et_2O + hydrogen between 100 and 200 °C.[403]

25.1.8.2 Borohydride Ligand

Aluminum tris(tetrahydridoborate), $Al(BH_4)_3$, a colourless liquid, f.p. −64.5 °C, b.p. 44.5 °C (extrap.), is the most volatile known compound of aluminum.[1] It is formed by reactions of Me_3Al, AlH_3 or $LiAlH_4$ with diborane. An alternative synthesis is from $AlCl_3 + 3NaBH_4$. Thermal decomposition of $Al(BH_4)_3$ occurs above 70 °C with loss of diborane to form $HAl(BH_4)_2$. Although stable below 25 °C under vacuum, $Al(BH_4)_3$ is a hazardous substance, being oxidized explosively by air and reacting violently with water or any protic agent.

The vibrational spectra of $Al(BH_4)_3$ and $Al(BD_4)_3$ conform to a prismatic structure of D_{3h} symmetry which is maintained in gas, liquid and solid states.[404] NMR spectra show that rapid exchange of ligands is taking place such that bridging and outer protons are equivalent on the NMR timescale at ambient temperature. The dimensions of $Al(BH_4)_3$ have been determined in the vapour by ED.[405] Each BH_4 unit is linked to Al by two three-centre B—H—Al bonds. Similar bridging occurs in the trimethylamine adduct $Al(BH_4)_3{\cdot}NMe_3$, although the Al—H bonds are lengthened considerably from 180 pm in $Al(BH_4)_3$ to 197 pm in the adduct.[406] The Al—N coordinate bond length is 200 pm, a normal distance. A related structure, that of $Al(BH_4)_3{\cdot}NH_3$, has been investigated by single crystal XRD.[407]

Hydridoaluminum tetrahydridoborates $HAl(BH_4)_2$ and H_2AlBH_4 (as ether or amine adducts) are formed by exchange reactions of $Al(BH_4)_3$ with Et_2AlH,[408] or $AlH_3{\cdot}THF$ with B_2H_6,[409] in suitable media. Use of $LiAlH_4$ leads to mixtures of anionic species $[H_{4-n}Al(BH_4)_n]^-$ ($n = 1$–3), some of which appear to be solvated, raising the coordination number of Al above four. Various aluminoboranes of considerable thermal stability are produced by reactions of $Al(BH_4)_3$ with other boron hydrides, *e.g.* B_4H_{10} gives $Al(BH_4)(B_3H_8)_2$.[410] The skeletal structure of $Me_2AlB_3H_8$, determined by vapour phase ED,[411] is analogous to that of B_4H_{10}, the Al atom being linked to each of two boron atoms by a hydrogen bridge, Al—H—B. The Al—H distance is 190.6 pm. In the similar compound of gallium, Ga—H is 198.9 pm. Methylaluminum tetrahydridoborates $MeAl(BH_4)_2$ and $Me_2Al(BH_4)$ can be prepared from $Me_3Al + Al(BH_4)_3$, or from $Me_nAlCl_{3-n} + (3-n)LiBH_4$, where $n = 1$ or 2.[412] Like $Al(BH_4)_3$, they are volatile, monomeric compounds containing bidentate BH_4 ligands, with Al—H distances of 177 pm in four-coordinate $Me_2Al(BH_4)$ and 182 pm in five-coordinate $MeAl(BH_4)_2$.[413] A series of chloroaluminum tetrahydridoborates have been reported, molecular adducts $Cl_{3-n}Al(BH_4)_n{\cdot}OEt_2$ ($n = 1$ or 2) and complex anions, *e.g.* $ClAl(BH_4)_3^-$ as the K^+ salt, having been obtained.[414]

25.1.9 MIXED DONOR ATOM LIGANDS

25.1.9.1 Schiff Base Ligands

A series of pyridoxal amino acid Schiff base complexes have been prepared in which Al is trigonally coordinated by N and two O atoms.[415] These provide a model for the intermediate in the pyridoxal-catalyzed reactions of amino acids. Some Schiff base complexes produced in reactions of the bases with $Al(OPr^i)_3$ have been assigned a structure with five-coordinate aluminum.[416,417]

25.1.9.2 Ligands with N, O and Other Functions

A variety of chelate complexes of Al^{3+} with N and/or O donor atoms are known through stability constant data.[7,8] Their formation illustrates several aspects of Al coordination chemistry. Chelates and other multidentate ligand systems provide a means of regulating the reactivity of aluminum compounds. For example, Al alkoxides can be converted to amino alcohol derivatives to confer water solubility and a degree of hydrolytic stability on otherwise water-sensitive materials.

The edta complex is a particularly stable one: NMR spectroscopy shows that the formation of this complex in solution displaces aqua or hydroxo ligands from Al^{3+}. In other situations, H_2O molecules may be retained in the coordination sphere of the Al atom. A recent example is the six-coordinate complex $AlL(OH_2)_4$ given in solution by the tribasic acid 8-hydroxy-7-[(6′-sulfo-2′-naphthyl)azo]quinoline-5-sulfonic acid (H_3L).[418] The formation of this particular species demonstrates selective coordination to Al by the heterocyclic N and phenolic O atoms, in preference to the azophenol moiety. In another study of multidentate ligand interactions, IR spectra show that complex anions of Al, Ga, In or Tl with oxamic acid $M(NHCOCO_2)_3^{3-}$ are coordinated *via* the carboxyl oxygen and amidic nitrogen, after ionization of one of the hydrogens of the NH_2 group.[419] Similarly, the IR characterization of tris(diethylthiophosphato)-aluminum(III) indicates coordination of Al by both O and S atoms of the ligand.[420]

Molecules in which aluminum forms part of a heterocyclic ring system offer a synthetic challenge likely to lead to developments including Al—N analogues of the boron–nitrogen compounds. Several diazaphosphonia-aluminatacyclobutanes have been characterized in which the unit Al—N—P—N constitutes a four-membered ring.[421] A series of aluminaminophosphines, $R_2AlN(R')PR''_2$, which have been synthesized to act as amphoteric ligands, have been shown to facilitate CO transfer reactions in transition metal complexes. An intermediate has been isolated in which the ligand is part of a ring comprising the CPNAlO sequence.[422]

25.1.10 MACROCYCLIC LIGANDS

There have been several studies of aluminum porphyrins. Octaethylporphyrinatoaluminum hydroxide is readily acetylated and silylated at the OH group.[423] The complex has limited stability in acidic media. Tetraphenylporphinatoaluminum methoxide (TTPAlOMe) promotes the reaction of CO_2 with propylene oxide to produce propylene carbonate under very mild conditions,[424] while TTPAlEt itself reacts with CO_2 under visible light, but not in the dark, and holds interest for investigations of photosynthesis.[425] Phthalocyanine complexes of Al, Ga and In have attracted attention as photocatalysts.[426,427] The conductivity of polymeric materials $(P_cAlF)_n$ increases by factors as high as 10^9 when the structure is doped with iodine to compositions in the range $(P_cAlFI_x)_n$, where $x = 0.01$ to 3.4.

X-Ray studies of crown ether complexes of Al reveal some variation in Al—O coordination with ring size. In particular, 15-crown-5 forms $(Me_3Al)_4$·crown with Al—O = 200.5 pm, whilst dibenzo-18-crown-6 gives $(Me_3Al)_2$·crown with Al—O = 196.7 pm.[428] Other facets of crown ether coordination of aluminum are considered in Section 25.1.5.6.

25.1.11 GALLIUM: INTRODUCTION

Accounts of gallium which include coordination chemistry are those of Greenwood,[429] Sheka *et al.*,[430] and Wade and Banister.[1] Early work on the adducts of gallium trihalides with Lewis bases was documented in 1963,[4] and this area was thoroughly reviewed by Pidcock in 1972.[431] Other aspects of gallium coordination chemistry were examined by Tuck.[431] Stability constants have been tabulated for a number of Ga^{3+} complexes.[7,8]

Three oxidation states of gallium are treated in the following account. Besides the gallium(III) state, it considers the Ga^{I} state, in which Ga^+ retains the $4s^2$ pair of electrons, and the Ga^{II} state which is associated with the presence of a Ga—Ga bond, giving rise to the formal entity Ga_2^{4+} as the nucleus of Ga^{II} coordination compounds. The significance of metal–metal bonding in group III chemistry was explored in 1975.[432]

25.1.12 GALLIUM(I)

25.1.12.1 Oxide, Sulfide and Selenide Ligands

Gallium(I) oxide, Ga_2O, sublimes as a dark brown powder on heating Ga_2O_3 and Ga to 500 °C. It is stable in dry air, but reduces water to hydrogen and H_2SO_4 to H_2S. Molecular species Ga_2O and Ga_4O_2 are trapped when the vapour above heated gallium oxide is condensed in a low temperature matrix. In_2O, GaInO and $Ga_xIn_{4-x}O_2$ molecules were detected similarly.[433] ED studies of $Ga_2O_{(g)}$ give r(Ga—O) = 184 pm and Ga—O—Ga = 140 ± 10°.[1] Gallium or indium superoxide species MO_2 ($\equiv M^+O_2^-$) and M_2O_4 have been observed in frozen matrices.[434]

An apparent Ga^I coordination compound, $Ga(diox)_2Cl$, containing the 1,4-dioxane ligand was studied crystallographically some years ago.[1] This system is due for reinvestigation now that the related dioxane complex of Ga_2Cl_4 has been shown not to contain $Ga(diox)_2^+$, as previously supposed, but to be a molecular complex of Ga^{II} (Section 25.1.13.1).

Examination of the gallium–sulfur and gallium–selenium phase systems reveals Ga_2S and Ga_2Se, respectively.[1] Other compounds identified in these systems, *i.e.* GaS, Ga_4S_5 and GaSe, are materials with Ga—Ga bonds (see Section 25.1.13.2). Gallium(I) sulfide, Ga_2S, is obtained in amorphous form by reducing GaS with hydrogen at 925 °C.

25.1.12.2 Halide Ligands

All four halides GaX (X = F, Cl, Br or I) are known as vapour-phase species, but tend to disproportionate when condensed, producing elementary gallium. The solid once thought to be GaI has been shown to be Ga_2I_3 (below).

Gallium forms a number of mixed valence halides. In these compounds the Ga^+ cation is stabilized by the presence of a non-coordinating anion formed when the strong Lewis acid GaX_3 combines with halide ligands. Examples are the 'dihalides' $Ga^+GaX_4^-$,[435,436] and compounds Ga_3X_7, *i.e.* $Ga^+Ga_2X_7^-$ (X = Cl, Br or I).[437,438] Compounds of the type $Ga^+AlX_4^-$ are analogous to Ga_2X_4.[439] In the subhalides, Ga_2X_3, the stabilizing anion is $Ga_2X_6^{2-}$, the constitution being $(Ga^+)_2Ga_2X_6^{2-}$ (X = Cl,[437] Br[440] or I[441]).

The crystal structure of Ga_2Cl_4 shows Ga^+ surrounded by eight chlorines of the $GaCl_4^-$ counterions. The gallium(I)–chlorine distance is more than 300 pm, to be compared with the Ga–Cl bond length of 219 pm in $GaCl_4^-$, and implies that the Ga^+ cation is not coordinated. When Ga_2Cl_4 is vaporized, the vapour consists solely of GaCl and $GaCl_3$ molecules.[442] Recent structural analyses of Ga_2I_4 and Ga_2I_3 have directed attention to the influence on these structures of the $4s^2$ electron pair of the Ga^+ ion and confirm that iodide is coordinated only to the higher oxidation state centre.[441]

The halides Ga_2X_4 combine with various donor ligands to give products since shown to be molecular adducts of the metal–metal-bonded Ga^{II} state. There are reports of reactions of the halides Ga_2X_4 with alcohols,[443] water,[444] aqueous NaOH, HCl or HF, and H_2S gas.[445,446] Oxidative addition usually occurs, although there is evidence of the initial precipitation of Ga^I-containing solids in the reactions of Ga_2Cl_4 in benzene solution with H_2O or H_2S.

The crystalline solid Ga_2Cl_4 is soluble in benzene. Under regulated conditions, this solution yields crystals which prove to contain the complex $(C_6H_6)_2Ga^+GaCl_4^-$, and X-ray studies show the cation to be the η^6-bis(benzene) complex of Ga^I.[447] The $GaCl_4^-$ ions interact weakly with Ga^+ to provide bridging chlorine atoms between the Ga^I centres. With hexamethylbenzene the related compounds $Ga(C_6Me_6)^+GaX_4^-$ (X = Cl, Br or I) have been prepared.[448]

25.1.13 GALLIUM(II)

25.1.13.1 Nitrogen, Oxygen and Other Donor Ligands

Complexes derived from the 'gallium dihalides' $Ga^+GaX_4^-$ were prepared in 1959 by adding various N, P, As, O or S donor ligands to a solution of Ga_2X_4 in benzene. Originally these were thought to be Ga^I compounds of the form $GaL_4^+GaX_4^-$, where L_4 represents four monodentate, two bidentate or a single tetradentate ligand coordinated to Ga^+. The reaction with these donors has been reinvestigated and products shown to be molecular coordination complexes of the form $Ga_2X_4L_2$, with a covalent Ga—Ga bond.[449] In $Ga_2X_4(diox)_2$ (X = Cl or

Br),[450] 1,4-dioxane ligands function as monodentate ligands so that each Ga atom is four-coordinate, as in the case of the $Ga_2X_6^{2-}$ ions (Section 25.1.13.3). The molecules adopt a partially eclipsed conformation in the crystal structure. Attempts to form $Ga_2Br_4py_2$ by direct reaction of Ga_2Br_4 with pyridine fail owing to disproportionation to Ga metal and the Ga^{III} state, caused by the basic ligand. $Ga_2Br_4py_2$ can, however, be prepared successfully from the dioxane complex by ligand displacement.[451] The molecular structure resembles that of the dioxane complex, although in this case the *trans* conformation is observed.

Intense Raman bands, which are useful for recognizing these M—M-bonded species, are seen in the $Ga_2X_4(diox)_2$ series, at 238 cm^{-1} for X = Cl, 169 cm^{-1} for X = Br and 143 cm^{-1} for X = I.[449] Unstable species which are present in ether extracts from freshly prepared solutions of gallium in hydrobromic acid have been observed in this way. The species are now thought to be the complex acids $(H^+)_2Ga_2Br_6^{2-}$ and $H^+Ga_2Br_5OEt_2^-$, and the ether adduct $Ga_2Br_4(OEt_2)_2$.[432] As anticipated, treatment of the mixture of species with HBr displaces the ether ligands forming $(H^+)_2Ga_2Br_6^{2-}$.

In an interesting further development, the mixed metal compounds $InGaX_4L_2$ (X = various ligands, including py, THF and diox) have been obtained by carefully controlled reactions of $In^+GaX_4^-$ with the various ligands.[452] The salts $(Bu_4^nN)_2InGaX_6$ (X = Cl or Br) could also be prepared. Raman spectra indicate that these compounds contain In—Ga bonds, whilst bearing coordinated halogen and other ligands.

25.1.13.2 Sulfide, Selenide and Telluride Ligands

Gallium forms the golden yellow sulfide GaS, and analogous compounds GaSe and GaTe, which are of interest as semiconductor materials. The structures contain Ga atoms linked in pairs forming the Ga_2^{4+} entity which is bonded by S (Se or Te) ligands to form a layer lattice. The Ga atoms are tetrahedrally coordinated by three group VI atoms and the partnering Ga. There are several modifications of GaS which differ from one another in the stacking of layers and the interlayer spacing,[453–455] but all have essentially the same coordination within the Ga_2S_6 unit. The nature of metal–ligand bonding in GaS, GaSe and GaTe has been investigated by vibrational,[456,457] photoelectron[458] and NQR[459] spectroscopy. The selenogallate $Na_2Ga_2Se_3$, which can be synthesized by heating a 2:2:3 mixture of the elements, is structurally related to GaSe.[455] It contains linked Ga_2Se_6 units with Ga—Ga bonds of 240 pm, a distance slightly less than that in GaS (244.7 pm), GaSe (245.7 pm), GaTe (243.1 pm)[453] or $GaS_{0.6}Se_{0.4}$ (244.7 pm).[454]

25.1.13.3 Halide Ligands

Freshly prepared solutions of gallium metal in aqueous halogen acids act as powerful reducing agents, and this property proves to be due to Ga^{II} halide complexes. The species concerned are the anions $(X_3Ga—GaX_3)^{2-}$ of D_{3d} symmetry which have been isolated as crystalline salts with tetraalkylammonium cations,[460] Ph_4P^+ and Ph_3PH^+.[461] The gallium–halogen distances are similar to those of the GaX_4^- ions, while the Ga—Ga bond length (239 to 242 pm),[441,462] which is almost independent of change of halide, corresponds closely to twice the covalent radius of gallium as observed in the Ga^{III} state. The vibrational specra of all three $Ga_2X_6^{2-}$ ions have been assigned[460] and NQR spectra of $Ga_2Cl_6^{2-}$ and $Ga_2Br_6^{2-}$ have been studied.[463] The Ga NQR frequencies were found to be considerably lower than those of Ga^{III} compounds and the data were used to calculate electron distribution on Ga and halogen atoms as a means of comparing the bonding with that of Ga^{III} complexes. The formation of $Ga_2Cl_6^{2-}$ in gallium-rich chloride melts has been demonstrated by Raman spectroscopy,[437] and anions of this type have also been shown to occur in the low-valent compounds Ga_2X_3 formed in bromide and iodide systems.[437,440,441,464]

Some reactions of the hexahalogenodigallate(II) ions have been investigated.[432] Treatment of a solution of a $Ga_2X_6^{2-}$ salt in nitromethane with a different halide, as solid KY, results in replacement to form mixed halides of gallium(II), $Ga_2(X,Y)_6^{2-}$ which are characterized by strong bands in the 120–250 cm^{-1} region of Raman spectra. The analogous reaction of $Ga_2X_6^{2-}$ with potassium thiocyanate results in only partial replacement of halide by the pseudohalide. IR spectra show the NCS ligand to be coordinated to gallium through the nitrogen atom, as in the case of gallium(III) complexes. The Ga—Ga bond of $Ga_2X_6^{2-}$ ions is stable towards

disproportionation, but readily undergoes scission in reactions with oxidizing agents, for example halogens, Ag^+ or Hg^{2+} ions, to yield gallium(III) complexes. The $Ga_2X_6^{2-}$ ions are slowly attacked by water. Hydrogen is evolved and hydroxo complexes of Ga^{III} are produced.

The formation of complex halides $(X_3GaInX_3)^{2-}$, containing the dinuclear $GaIn^{4+}$ entity,[452] has been mentioned in Section 25.1.13.1, and some dinuclear In^{II} compounds have also been synthesized. Thus, although the molecular form of M_2X_4 is not known in group III (except for boron), stable complexes of these halides can be prepared, either as anions $M_2X_6^{2-}$ or as molecular adducts $M_2X_4L_2$.

25.1.14 GALLIUM(III)

25.1.14.1 Group IV Ligands

25.1.14.1.1 Cyanide ligands

Neither gallium cyanide, $Ga(CN)_3$, nor binary complexes, $Ga(CN)_x^{3-x}$, appear to have been reported. The ion $Me_2Ga(CN)_2^-$ has been prepared as the potassium salt by the reaction of $K_2Hg(CN)_4$ with Me_3Ga.[465] The related complexes $(R_3Ga)_2CN^-$ (R = Me or Et) contain a bridging cyanide group, like the corresponding aluminum species.

25.1.14.1.2 Silicon and heavier group IV ligands

There has been little work on compounds in which gallium is bonded to silicon or a heavier group IV atom. Tris(trimethylsilyl)gallium is produced by treating $GaCl_3 + 3Me_3SiCl$ with lithium in THF, the initial adduct $Ga(SiMe_3)_3 \cdot THF$ being converted to $Ga(SiMe_3)_3$ by vacuum sublimation.[466] $Ga(SiMe_3)_3$ is monomeric, with a planar $GaSi_3$ framework, characterized by vibrational bands $\nu(Ga—Si)_{sym} = 312\ cm^{-1}$ (Raman) and $\nu(Ga—Si)_{deg} = 349\ cm^{-1}$ (IR, Raman). Reaction of Me_2GaCl with $KGeH_3$ leads to $K(H_3GeGaMe_2Cl)$ and, by elimination of KCl, to Me_2GaGeH_3.[467] The compound $Li(Me_3GaSnMe_3)$ readily decomposes to $LiGaMe_4$ (*cf.* In).

25.1.14.2 Nitrogen Ligands

25.1.14.2.1 Ammonia and amine ligands

The gallane complex $GaH_3 \cdot NH_3$ is unknown. Metal fluoride adducts $MF_3 \cdot 3NH_3$ (M = Ga or In) are presumably six-coordinate; above 100 °C step-wise loss of ammonia occurs to give MF_3. For chloride and bromide systems, adducts $GaX_3 \cdot nNH_3$ (X = Cl, n = 1, 3, 5, 6, 7 and 14; X = Br, n = 1, 5, 7, 9 and 14) were reported in 1932.[4] In recent work, exposure of gallium trichloride or tribromide to excess ammonia yielded white powdery substances which proved difficult to characterize, but by restricting the amount of ammonia to one molar equivalent, glassy, low-melting solids, $GaX_3 \cdot NH_3$, were obtained.[468] The vibrational spectra were fully assigned on the basis of C_{3v} symmetry and showed $\nu(Ga—NH_3)$ stretching bands at 498 cm^{-1} (X = Cl) or 480 cm^{-1} (Br). NCA yields Ga—N stretching force constants $k(Ga—N)$ of 2.00 and 1.85 N cm^{-1} for $H_3N—GaCl_3$ and $H_3N—GaBr_3$, respectively. The $H_3N \cdot GaCl_3$ molecule can be observed in the gas phase where ED results have yielded the bond lengths Ga—N = 205.7 pm and Ga—Cl = 214.2 pm. The $GaCl_3$ unit has a rather flat pyramidal strucure suggesting a weaker donor–acceptor interaction than in the aluminum analogue. The Ga—N bond lengthens slightly to 208.1 pm in $H_3N \cdot GaBr_3$.[469] The enthalpies of dissociation of $GaX_3 \cdot NH_3$ [134 kJ mol^{-1} (X = Cl) and 137 kJ mol^{-1} (Br)] are much smaller than those of other nitrogen bases.[470] The trimethylgallium adduct $Me_3Ga \cdot NH_3$ has been thoroughly characterized.[471] A cationic ammonia complex in which gallium appears to be four-coordinate occurs in $[Me_2Ga(NH_3)_2]Cl$.[472]

Amine adducts $GaH_3 \cdot NR_3$ are produced by reaction of $LiGaH_4$ with the base hydrochloride, or by displacing a ligand, such as ether, from a gallane adduct $GaH_3 \cdot L$. Trimethylamine forms $GaH_3 \cdot NMe_3$, m.p. 70 °C, volatile without decomposition, and $GaH_3 \cdot 2NMe_3$, unstable above −60 °C. The second adduct is much weaker (ΔH for dissociation to $GaH_3 \cdot NMe_3$ and Me_3N is 43 kJ mol^{-1}).[1] Structure and bonding in the $Me_3N—GaH_3$ molecules have been studied by

NMR,[473] XRD (Ga—N = 197 ± 9 pm),[1] and more recently by ED, microwave and vibrational spectroscopy.[474] These newer data furnish a length of 212 ± 1 pm and a force constant of 2.44 N cm^{-1} for the Ga—N bond. $GaH_3{\cdot}NMe_3$ undergoes some ligand displacements. *e.g.* with dimethylamine forming $GaH_3{\cdot}NHMe_2$ leading to $(H_2GaNMe_2)_2$ by loss of H_2. The reaction of $GaH_3{\cdot}NMe_3$ with BF_3 apparently involves the initial formation of a five-coordinate complex, $Me_3N{\cdot}GaH_3{\cdot}BF_3$, which decomposes to give $Me_3N{\cdot}BF_3 + Ga + H_2$.[475] The stabilities of gallane adducts decrease in the following order of bases:[1] $Me_2NH > Me_3N >$ pyridine $> Et_3N > Me_2PhN > Ph_3N$.

Gallium trihalides in non-polar solvents, or as ether adducts, react with amines usually in 1:1 stoichiometry. Recrystallization of GaX_3 from trimethylamine gives $GaX_3{\cdot}NMe_3$ when X = Br or I.[476] The chloride initially forms $GaCl_3{\cdot}2NMe_3$ which easily releases one mole of NMe_3. Vibrational spectra have been assigned, and NCA for $Me_3N{\cdot}GaCl_3$ computes a substantial Ga—N force constant of 2.50 N cm^{-1}.[477] For $Me_3Ga{\cdot}NMe_3$, ED results yield r(Ga—N) = 220 pm and Raman spectral data provide k(Ga—N) = 1.6 N cm^{-1}.[478] In reaction with methylamines, the Lewis acid affinity of a series of gallium compounds including $GaCl_3$ decreases in the order $GaCl_3 > Bu^nGaCl_2 > Bu^n_2GaCl > Bu^n_3Ga$.[479] Calorimetric studies of the interaction of various amine bases with $GaCl_3$ have yielded bond dissociation energies $D(GaCl_3—L)$ for the coordinate link of about 290 kJ mol^{-1}. The value for oxygen donors is smaller: *ca.* 235 kJ mol^{-1}. $D(GaCl_3—Cl^-)$ is greater: *ca.* 365 kJ mol^{-1}. Detailed comparisons are available.[435]

In a recent study, $GaCl_3$ has been shown to form a 1:1 complex with hexamethylborazine, in which the conjugated system of the BN heterocycle is disrupted.[480] The ring is no longer planar and contains a tetracoordinate nitrogen linked to $GaCl_3$, with bond distances Ga—N = 206.4 pm and Ga—Cl = 215.3 pm (average). In solution at low temperature, the NMR spectrum indicates a different structure for the adduct, with a bidentate borazine ligand attached to five-coordinate gallium. Leaving aside the rather uncertain crystallographic measurement for $GaH_3{\cdot}NMe_3$, coordinate Ga—N bond distances for amine donors are in the range 205–220 pm. The smallest values are for strong bases coordinated to $GaCl_3$.

25.1.14.2.2 N-Heterocyclic ligands

There are early reports from phase diagram studies of solids $GaX_3(py)_n$ (X = Cl, n = 1 or 2; X = Br, n = 1 or 3) and of some piperidine adducts.[1,3] Recent X-ray study shows that $GaCl_3{\cdot}2py$[481] has the ionic structure $GaCl_2(py)_4^+GaCl_4^-$. The six-coordinate cation adopts a *trans* octahedral structure with r(Ga—N) = 210.8 pm (average). The Ga—Cl distance in the cation is 231.2 pm, compared with 215.7 pm in the four-coordinate anion. Vibrational studies, making use of pyridine-d^5, locate two ν(Ga—py) stretching modes at 248 and 263 cm^{-1}. There is NMR evidence that the strongly basic heterocyclic ligands afford complex cations in MeCN solution, *e.g.* $GaX_2(py)_3^+$ and $GaX_2(phen)_2^+$ (X = Cl, Br or I).[482] Formation of the six-coordinate anions $GaX_3Y(py)^-$ (X = Cl or Br, Y = I'; X = I, Y = Cl or Br) has been claimed.[483] This is remarkable since gallium is usually restricted to a maximum coordination number of four in anionic halide complexes other than fluorides.

With bidentate 1,10-phenanthroline and 2,2'-bipyridyl ligands, gallium forms $Ga(ClO_4)_3{\cdot}3bipy$, $GaCl_3{\cdot}phen$, $GaCl_3{\cdot}2phen$, $GaCl_3{\cdot}bipy$ and $GaCl_3{\cdot}2bipy$.[484,485] A common feature is the presence of a complex cation, *e.g.* $Ga(bipy)_3^{3+}$ or $GaCl_2(bipy)_2^+$. The crystal structure of $GaCl_3{\cdot}bipy$ shows it to be *cis*-$[GaCl_2(bipy)_2]^+GaCl_4^-$.[486] The Ga—N distances of 209.5 and 211.1 pm are very similar to those of the pyridine complex above. In the 1:2 (bidentate) adducts, Cl^- replaces $GaCl_4^-$ as the counteranion. The dimethylgallium derivative $Me_2GaCl(phen)$ is an example of a five-coordinate gallium compound.[487] Ionization to $Me_2Ga(phen)^+Cl^-$ occurs in aqueous solution. The terpyridyl adduct $GaCl_3{\cdot}terpy$ is notable as a molecular complex; in it r(Ga—N) = 211.2 pm (mutually *trans*) and 203.4 pm (*trans* to Cl).[488] The compound $(D_2Ga{\cdot}pyrazol\text{-}1\text{-}yl)_2$ is also a molecular complex.[489] It contains the unit $D_2Ga(\mu\text{-}NN)_2GaD_2$ which assumes the boat conformation.

25.1.14.2.3 Amido and imido ligands

Potassium amidogallate, $K[Ga(NH_2)_4]$, is prepared by dissolving gallium in a solution of KOH in liquid ammonia. Heating this compound to 300 °C under vacuum removes two moles

of ammonia, forming $KGa(NH)_2$.[1] Partial neutralization of the ammonia solution of $K[Ga(NH_2)_4]$ with NH_4Cl yields $Ga(NH_2)_3$. A reported amidogallane, $(H_2GaNH_2)_n$ appears to be polymeric.[1] The anion $[Ga(NH_2)_4]^-$ has tetrahedral symmetry, according to the single crystal Raman spectrum in which ν(Ga—N) appears near 550 cm^{-1}.[490] A more highly coordinated complex, $Na_2[Ga(NH_2)_5]$, has also been prepared. From evidence of IR spectra, this contains six-coordinate gallium, with a structure based on linked $Ga(NH_2)_6$ octahedra with both bridging and non-bridging NH_2 groups.[491]

Dimethylamido compounds $GaCl(NMe_2)_2$ and $Ga(NMe_2)_3$ are obtained from the reaction of $GaCl_3$ with $LiNMe_2$; an excess yields $Li[Ga(NMe_2)_4]$.[492] $Ga(NMe_2)_3$ dimerizes through bridging dimethylamido ligands, but this does not occur in the case of $Ga[N(SiMe_3)_2]_3$, presumably for steric reasons.[493] CS_2 inserts into all of the Ga—N bonds of $Ga(NMe_2)_3$, forming $Ga(S_2CNMe_2)_3$. Volatile compounds $(H_2GaNR_2)_n$ and $[H_2GaN(CH_2)_xCH_2]_n$ ($n = 2$ or 3) result from the reaction of amines or cyclic imines $CH_2(CH_2)_xNH$ with $GaH_3{\cdot}NMe_3$ at room temperature.[494] In $(H_2GaNMe_2)_2$ the Ga—N bond length is 202.7 pm and the central Ga_2N_2 ring is almost square,[495] as it is in related molecules where B, Al or In atoms are bridged by Me_2N ligands. An X-ray study of $[H_2GaN(CH_2)_2]_3$ reveals a Ga_3N_3 ring in the chair conformation, with Ga—N = 197 ± 9 pm.[496] Compounds $RGaCl_2$ (R = Me or Bu) react with two equivalents of $(Me_3Si)_2NH$ to afford $[R(Cl)GaNHSiMe_3]_2$ in which substituents on the Ga_2N_2 ring adopt the *trans-trans* conformation, according to IR and XRD evidence.[497] Reactions of Me_3Ga—base adducts eliminate methane to form $(Me_2GaNMe_2)_2$ from $Me_3Ga{\cdot}NHMe_2$, or $(Me_2GaNH_2)_2$ and $(MeGaNH)_x$ from $Me_3Ga{\cdot}NH_3$. Analogous compounds with P or As ligands in place of N bases are reviewed elsewhere.[498] The structure of an imido complex containing the Ga_8N_8 framework is shown in Table 1 (Section 25.1.3.3).

25.1.15.2.4 Azide, cyanate, thiocyanate and selenocyanate ligands

Azide complexes are formed by Ga^{3+} in aqueous solution.[499] The formation of $Ga(N_3)^{2+}$ is decidedly more exothermic than that of $In(N_3)^{2+}$. The dimethylgallium cation Me_2Ga^+ forms $[Me_2Ga(N_3)]_2$ and $Me_2Ga(N_3)_2^-$, in each of which the gallium atom is four-coordinate.[500] Similarly, Me_3Ga forms $Me_3Ga(N_3)^-$ and $(Me_3Ga)_2(N_3)^-$ (the latter with a bridging azido ligand), as well as the corresponding complexes with NCO, NCS, NCSe or CN ligands.

Little is known of gallium cyanates. There are reports of complex isocyanates $Ga(NCO)_3{\cdot}$bipy and $Ga(NCO)_3{\cdot}$phen and of an unstable compound $(Me_4N)_3Ga(NCO)_6$, thought from spectroscopic evidence to contain cyanate groups bonded through the O atom.[501] Thiocyanato complexes are formed in aqueous solution, *e.g.* $Ga(NCS)^{2+}$ for which the dissociation constant at 25 °C is 4.8×10^{-3}.[502] When excess NCS^- is present, anionic complexes are produced. Gallium can be solvent extracted from these solutions by ethers or by trilaurylamine as $(HB)Ga(NCS)_4$, where HB represents the protonated ether or amine, or by tributyl phosphate or a phosphonate in the form $Ga(NCS)_3L_3$.[503] The hydrate $Ga(NCS)_3{\cdot}3H_2O$ is soluble in ether and in polar organic solvents.[504] The coordinated water molecules can be replaced by diamines to yield $Ga(NCS)_3(H_2O){\cdot}$diam, $Ga(NCS)_3(diam)_n$ ($n = 1.5$ or 2), and (Hdiam)$Ga(NCS)_4{\cdot}$diam, where diam = bipy or phen.[505] Maintaining the first of these complexes under vacuum at 120 °C removes the molecule of water. IR spectra confirm Ga—NCS bonds and suggest that the bidentate amine is also coordinated to the metal. An ethylenediamine adduct of gallium thiocyanate has been formulated with a complex cation, $[Ga(en)_3](NCS)_3$, whereas the acetonitrile complex from $GaBr_3 + 4KNCS$ in MeCN is $K[Ga(NCS)_4{\cdot}MeCN]$[506] and may contain five-coordinate gallium.

Crystalline salts containing tetra-, penta- and hexa-isothiocyanate complex anions can be isolated from aqueous or methanolic solutions.[507] Frequencies ν(Ga—NCS) occur in IR spectra at 350 cm^{-1} in four-coordinate or 250 cm^{-1} in six-coordinate species. Although powder patterns have been reported, single-crystal X-ray data are lacking for gallium thiocyanates. Some gallium selenocyanide complexes $Ga(NCSe)_3L_3$ and $Ga(NCSe)_4^-$ have been prepared.[508] Attempts to obtain $Ga(NCS)_3$ or $Ga(NCSe)_3$ appear to have failed.

25.1.14.2.5 Nitrile ligands

As with aluminum, most recent work on nitrile complexes has been directed to understanding the constitution of solutions of GaX_3 in MeCN. ^1H NMR measurements have been

interpreted in terms of the four-coordinate cations $[GaX_2(MeCN)_2]^+$ and GaX_4^- (X = Cl, Br or I).[509] Later ^{71}Ga NMR studies confirm the presence of $GaCl_4^-$ but favour $[Ga(MeCN)_6]^{3+}$ as the cationic species.[510] The equilibrium

$$4MCl_3(MeCN)_3 \rightleftharpoons M(MeCN)_6^{3+} + 3MCl_4^- + 6MeCN$$

lies further to the right for Ga than Al complexes and this can be attributed to the greater stability of the MCl_4^- ion formed by gallium. For various molecular complexes $GaCl_3 \cdot RCN$, analysis of NQR data shows that approximately half of the charge transferred from the donor molecule is localized on the Ga atom.[511]

25.1.14.3 Phosphorus and Heavier Group V Ligands

Molecular adducts $GaH_3 \cdot L$ have been prepared with Me_3P, Me_2PH, Ph_3P and Ph_2PH, but not with PH_3, by the reaction shown in equation (11). Gas phase displacement reactions indicate that Me_3P has about the same donor strength as Me_3N towards gallane.[512] Analysis of vibrational spectra of these adducts, however, suggests rather different force constants: $k(Ga—P) = 2.0\ N\ cm^{-1}$ in $GaH_3 \cdot PMe_3$,[513] compared with $k(Ga—N) = 2.44\ N\ cm^{-1}$ in $GaH_3 \cdot NMe_3$.[474]

$$LiGaH_4 + R_3P + HCl \longrightarrow GaH_3 \cdot PR_3 + LiCl + H_2 \quad (11)$$

Phosphine reacts with gallium trihalides to form the adducts $GaX_3 \cdot PH_3$ (X = Cl or Br) as glassy solids. In contrast to the behaviour with ammonia, there is no tendency to combine with more than one mole of ligand. Gallium triiodide does not take up phosphine. Alkyl- and aryl-phosphines give 1:1 adducts with $GaCl_3$ and $GaBr_3$, and some GaI_3 adducts have also been prepared.[514] The C_{3v} molecular structure of the phosphine complexes $H_3P—GaX_3$, in solid or liquid states, is substantiated by Raman and IR spectra.[468] NCA applied to the $GaCl_3 \cdot PH_3$ data yields $k(Ga—P) = 1.0\ N\ cm^{-1}$. As might be expected, the bond stretching force constant obtained for $GaCl_3 \cdot PMe_3$ is larger, $k(Ga—P) = 1.75\ N\ cm^{-1}$.[515] NQR data also show Me_3P to be a very good donor towards $GaCl_3$, and in the same study a crystal structure determination has found the $Me_3P—GaCl_3$ molecule to have the unusual staggered conformation: Ga—P = 235.3 pm and Ga—Cl = 217.4 pm.[516]

Vibrational spectra of phenylphosphine adducts $GaCl_3 \cdot PPh_3$ and $GaCl_3 \cdot PPh_nH_{3-n}$ ($n = 1$ or 2) are fully in accord with the presence of a four-coordinate $PGaCl_3$ skeleton in solid and liquid states, and in non-polar solvents.[517–519] However, in acetone or nitromethane, conducting solutions are formed by $GaX_3 \cdot PPh_3$ (X = Cl or Br) which have IR spectra consistent with GaX_4^- ions.[517] A plausible cation is $GaX_2(PPh_3)_2^+$ but confirmation is lacking. There have been a few studies of gallium halide adducts with bidentate P or As ligands. The vibrational spectra of solids $Ga_2X_6 \cdot depe$ (X = Cl or Br) are consistent with a structure in which each phosphorus atom carries a GaX_3 group.[518] The iodide has a markedly different spectrum and may be ionic $GaI_2(depe)^+GaI_4^-$. Nyholm had earlier reported $Ga_2Cl_6 \cdot diars$ and $GaX_3 \cdot diars$ (X = Br or I) and, on the basis of conductivity measurements, had formulated the latter as $GaX_2(diars)_2^+GaX_4^-$.[520] The existence of an apparently six-coordinate complex, with atoms as large as two Br or I and four As ligands, requires checking. Tris(bidentate) complexes $Ga(diars)_3^{3+}$ could not be obtained.

Some P and As donor complexes of organogallium compounds are known.[498] These include $Me_3Ga \cdot PH_3$, $Me_3Ga \cdot PMe_3$,[521] $Ph_3Ga \cdot PPh_3$ and $Ph_2ClGa \cdot PPh_3$[522] investigated by IR/Raman spectra. Pyrolysis of a mixture of Et_3Ga and $HPEt_2$ yields $(Et_2GaPEt_2)_3$, the structure of which is based on a six-membered Ga_3P_3 ring.[523] Me_2GaCl and $HPEt_2$ yield $[Me(Cl)GaPEt_2]_n$, where n indicates a mixture of oligomers, 2 and 3. Fragmentation of these compounds enables GaP to be deposited as a surface coating, significant as a type III–V semiconducting layer. The recently reported compounds $[R_2GaN(PPh_2)_2]_2$ (R = Me or Et)[524] appear to exist in solution as two isomers; one has a six-membered ring GaNPGaNP, the other is eight-membered GaPNPGaPNP. Further developments towards compounds with Ga—N, Ga—P and Ga—As networks can be expected.

25.1.14.4 Oxygen Ligands

25.1.14.4.1 Oxide, hydroxide and H_2O as ligands

Gallium hydroxide $Ga(OH)_3$ is precipitated as a gel from aqueous Ga^{3+} solutions by adding ammonia. It is also produced by the action of acids on solutions of gallates. On standing the hydroxide forms GaO(OH), which is obtained as crystalline material from $Ga(OH)_3$ at 110 °C.[1] The crystal structure is of the six-coordinate diaspore type. In another form, Ga is six-coordinate with the oxygens arranged in the shape of a distorted trigonal prism.[525] Heated above 300 °C, moist gallium hydroxide gives β-Ga_2O_3, the most stable of five oxide modifications.[1] Whereas α-Ga_2O_3 has the corundum structure with a Ga—O distance of 183.4 pm and octahedral coordination, β-Ga_2O_3 consists of vertex-sharing GaO_4 tetrahedra and edge-sharing octahedra, with Ga—O distances of 183 and 200 pm, respectively.[526]

On heating with other metal oxides, gallium oxide forms gallates $M^{I}GaO_2$, $M^{II}Ga_2O_4$ (spinels) and $M^{III}GaO_3$. There are oxides of Ga with aluminum or indium which form solid solutions, $M^{III}_{2-x}Ga_xO_3$. Mixed oxide stoichiometries other than 1:1 (O^{2-}:Ga_2O_3) are quite common. With sodium, there are complex gallates $NaGaO_2$, Na_3GaO_3, $Na_8Ga_2O_7$ and Na_5GaO_4.[527] The structures of these last two are built up from effectively isolated $Ga_2O_7^{8-}$ and GaO_4^{5-} units, the bonding within which has been explored by MO calculations.[528] Some hydrated forms have also been studied, such as $LiGaO_2{\cdot}6H_2O$, effectively $[Li(OH_2)_4]^+[GaO_2(OH_2)_2]^-$, and $LiGaO_2{\cdot}8H_2O$. Here the four-coordinate Ga—O distances are 185–189 pm.[529] $NaGa_{11}O_{16}(OH)_2$ has a complicated structure in which both GaO_4 tetrahedra and GaO_6 octahedra are present, with mean values r(Ga—O) of 185 and 200 pm, respectively.[530] Structures based on GaO_4 tetrahedral prevail among gallates of the divalent metals, *e.g.* $SrGa_2O_4$, $CaGa_2O_4$, $Ca_3Ga_4O_9$ and $Pb_9Ga_8O_{21}$.[531] In $CuGaInO_4$, the Ga atom has trigonal bipyramidal coordination, while that of In is distorted octahedral.[532] Gallium forms oxyhalides GaOX.[1] GaOF is inert to water; the solubility of the others, with extensive hydrolysis, increases in the order GaOCl < GaOBr < GaOI.

Gallium hydroxide is amphoteric, and is a much stronger acid than aluminum hydroxide. For $Ga(OH)_3$ the first acid dissociation constant is 1.4×10^{-7} [for $Al(OH)_3$ the value is 2×10^{-11}].[1] Polymerization occurs in aqueous Ga^{3+} solutions to which OH^- is added,[533] but this tendency is less than in the case of aluminum solutions (Section 25.1.5.1). The formation constants of mononuclear hydroxo complexes of Ga, including $Ga(OH)_4^-$, and the hydrolysis constants of gallium ions have been measured by a competing ligand technique.[534]

In acidic solutions, gallium exists as the hexaaqua cation $Ga(OH_2)_6^{3+}$, which occurs in hydrated crystals of oxyanion salts (Section 25.1.14.4.4). NMR studies employing ^{17}O give $Ga(OH_2)_6^{3+}$ as the hydrated complex.[535] Water exchange at 25 °C is characterized by the rate constant $k_1 = 1.8 \times 10^3\ s^{-1}$. This is much faster than the exchange rate of $Al(OH_2)_6^{3+}$ for which $k_1 = 0.17\ s^{-1}$, reflecting a lesser affinity of Ga^{3+} for oxygen as a ligand. A mechanism of S_N2 type involving $Ga(OH_2)_7^{3+}$ has been suggested.[536] The aquated gallium cation $Ga(OH_2)_6^{3+}$, with K_a of 2.5×10^{-3}, is a stronger acid than $Al(OH_2)_6^{3+}$ ($K_a = 1.1 \times 10^{-5}$).

The $Ga(OH_2)_6^{3+}$ complex is the usual reference state in ^{71}Ga NMR spectroscopy. Compared with this species, the Ga nucleus in $Ga(OH_4)^-$ exhibits a chemical shift of 192 p.p.m. and is more highly shielded.[537] Physical methods, particularly NMR, show that Ga^{3+}, in the form of the aqueous nitrate or perchlorate, continues to be hydrated by six H_2O molecules,[536] even in the presence of a large excess of acetone. Entry of a ligand species into the primary solvent shell can be induced by suitable conditions of temperature and solvent composition. For example, with solutions of gallium chloride in aqueous acetone at −60 °C, an increase in the amount of acetone (not itself coordinated) brings about a progressive fall in the hydration number from 6 to *ca.* 2. The resulting species may be the mixed ligand complex $GaCl_2(OH_2)_2^+$. Dimethylgallium hydroxide is a tetramer $(Me_2GaOH)_4$, and the presence of bridging OH ligands has also been established by X-ray analysis of a dimeric gallium chelate complex.[538]

25.1.14.4.2 Alkoxide ligands

Gallium alkoxides can be prepared by the methods employed for aluminum.[539] $Ga(OMe)_3$, a polymeric material, decomposes without melting but can be sublimed under vacuum. $Ga(OEt)_3$, m.p. 144 °C, $Ga(OPr^n)_3$ and $Ga(OBu^n)_3$ are more volatile than $Ga(OMe)_3$, and these are tetrameric in solution. $Ga(OPr^i)_3$, a liquid, and $Ga(OBu^t)_3$ have dimeric structures

bridged by alkoxide ligands, according to NMR studies.[540] The bulky trimethylsilyl ligand results in $Ga(OSiMe_3)_3$ being monomeric, but does not prevent the formation of a complex anion $Ga(OSiMe_3)_4^-$. Aryloxides, *e.g.* $Ga(OPh)_3$, m.p. 192 °C, are obtained by prolonged heating of Ga metal with the phenol at 180–220 °C.[541] Like group III alkoxides generally, these compounds are Lewis acids and form 1:1 adducts with ammonia, pyridine and other bases. $Ga(OPh)_3$ reacts with boiling MeOH or EtOH to form the corresponding alkoxide.

Reaction of the halide GaX_3 (X = Cl or Br) with less than three moles of alcohol may initially give adducts $GaX_3 \cdot ROH$ but these are readily converted into products $GaX_n(OR)_{3-n}$ ($n = 1$ or 2). These compounds may be di-, tri- or tetra-meric: in all cases alkoxide ligands are bridging. If the halides Ga_2X_4 are used, the reactions involve oxidation of Ga^+ by alcohol (see equations 12 and 13).[443]

$$Ga_2X_4 + 3EtOH \xrightarrow{0\,^\circ C} GaX(OEt)_2 + GaX_3 \cdot EtOH + H_2 \quad (12)$$

$$Ga_2X_4 + 2EtOH \xrightarrow{25\,^\circ C} 2GaX_2(OEt) + H_2 \quad (13)$$

Like the Al compounds, gallium alkoxides are susceptible to hydrolysis giving ill-defined products, including $Ga_2O(OR)_4$ and GaO(OR). Methanolysis of Ga^{3+} ions produces $Ga(OMe)^{2+}$ and $Ga(OMe)_2^+$ in solvated form, as well as polymeric complexes.[542] In reactions with another metal alkoxide, four-coordinate complex anions of the type $Ga(OR)_4^-$ can be formed. Other routes, such as $MGaH_4 + 4ROH$, or $MGaR_4 + 2O_2$, are available. Structural data for gallium alkoxides are in short supply. There are Raman and IR spectra of MeGaCl(OMe) and R_2MOMe (R = Me, or Et; M = Ga or In). The Me_2Ga derivatives are trimeric with a puckered Ga_3O_3 ring.[543]

25.1.14.4.3 β-Ketoenolate and related ligands

Tris(acetylacetonato)gallium(III), m.p. 195 °C, exists in two forms differing slightly in density. Crystal structure determination shows the central GaO_6 octahedron of $Ga(acac)_3$ to be almost regular, with an average Ga—O distance of 195.2 pm.[544] $Ga(acac)_3$ is formed in aqueous solutions of Ga^{3+} and acetylacetonate ions, and is conveniently prepared by adding aqueous ammonia to a solution of $Ga_2(SO_4)_3$ + Hacac. However, at ligand to Ga ratios less than three, hydrolysis leading to the formation of hydroxo complexes must also be considered.[545]

Rates of ligand exchange have been measured for some β-diketonato complexes. Exchange between $Ga(acac)_3$ and ^{14}C-labelled Hacac in THF solution is much faster than in the case of $Al(acac)_3$.[546] A dissociative mechanism proceeds *via* a five-coordinate transition state in which one ligand is unidentate. Coalescence temperatures and activation energies for *cis–trans* rearrangements are conveniently measured by ^{19}F NMR spectroscopy, applied to tris(β-diketonates) with fluoro substituents.[188] The findings place gallium between Al and In in the usual order of a decrease in bond strength of Al—O > Ga—O > In—O, which is also consistent with Raman studies of $M(acac)_3$.[1] When $Ga(acac)_3$ is added to a solution of $Ga(ClO_4)_3$ in dimethylformamide the NMR spectrum shows new signals attributable to $[Ga(acac)(DMF)_4]^{2+}$ and $[Ga(acac)_2(DMF)_2]^+$.[547] The Al^{III} system behaves similarly and the two systems have been compared.

There is a dimethylgallium acetylacetonate $Me_2Ga(acac)$, m.p. 22 °C, and a dimethylgallium tropolonate, the structure of which proves to be dimeric with Ga—O bonds of 197.4 and 202.5 pm to the chelation ligand and distances of 246.3 pm within the central Ga_2O_2 ring of the dimer.[548]

25.1.14.4.4 Oxyanion ligands

(i) Borate, carbonate, silicate and germanate

Gallium borate $GaBO_3$ is unknown. Li_2GaBO_4, m.p. 896 °C (dec), is formed in the $LiBO_2$–$LiGaO_2$ system.[549] There is no carbonate $Ga_2(CO_3)_3$, but a basic carbonato complex $NH_4[Ga(OH)_2CO_3]$ has been characterized in which the CO_3 group is coordinated to Ga in bidentate fashion.[550] Ga_2O_3 and SiO_2 do not react when fused together, but may form ternary compounds in the presence of a third oxide. The products, gallosilicates, are similar to

aluminosilicates, for example, the solids $M^{II}Ga_2Si_2O_8$ (M^{II} = Sr or Ba) are synthetic feldspars.[551] However, unlike the corresponding aluminum compounds, $NaGaSiO_4$ and $Na_4Ga_2Si_2O_9$ are soluble in water.[552] Soluble lithium gallosilicates are also known.[1,553] Gallium oxide combines with germanium oxide GeO_2 to give $Ga_6Ge_2O_{13}$, and various gallogermanates have been synthesized.[1,551]

(*ii*) *Nitrate, phosphite, phosphate and arsenate*

The hydrate $Ga(NO_3)_3 \cdot 9H_2O$, which presumably contains $Ga(OH_2)_6^{3+}$ ions, and a basic nitrate, $Ga_2(OH)_5(NO_3) \cdot 2H_2O$, can be prepared from aqueous solutions. The anhydrous nitrate $Ga(NO_3)_3$ and the complexes $Ga_2O(NO_3)_4$ and $MGa(NO_3)_4$ (M = Na, K or Cs) can be obtained from $GaBr_3/N_2O_5$ or $MBr/GaBr_3/N_2O_5$ mixtures.[554] Vibrational spectra indicate that the nitrate ligands are unidentate in $NO_2^+Ga(NO_3)_4^-$.[555] There are reports of gallium phosphites in early literature.[1] The phosphate $GaPO_4 \cdot 2H_2O$, a highly insoluble compound, is precipitated from aqueous Ga^{3+} solutions by NaH_2PO_4. Above pH 7, basic phosphates are produced. The crystal structure of $GaPO_4 \cdot 2H_2O$ shows Ga to have a coordination number of six: four PO_4 oxygens at a distance of 194 pm and two water molecules at 210 pm.[1] Above 200 °C this solid dehydrates to give $GaPO_4$, in which Ga is four-coordinate, and the Ga—O distance is smaller, *i.e.* 178 pm.

In acidic solutions of gallium phosphate there is evidence of $Ga(HPO_4)^+$, $Ga(H_2PO_4)^{2+}$, $Ga(H_3PO_4)^{3+}$ and possibly other complexes.[556,557] Gallium also forms a pyrophosphate, $Ga_4(P_2O_7)_3$, and various complex phosphates and pyrophosphates.[1,214] Gallium forms $GaAsO_4$ and $GaAsO_4 \cdot 2H_2O$.[1] The latter is precipitated when an acidified Ga^{3+} solution is neutralized in the presence of arsenate ions.

(*iii*) *Sulfate, selenate and tellurate; tungstate and molybdate*

Crystals of $Ga_2(SO_4)_3 \cdot 18H_2O$ lose water in stages, yielding $Ga_2(SO_4)_3$ above 165 °C. Various basic sulfates have been reported.[1] The structure of $H_3O[Ga_3(OH)_6(SO_4)_2]$ contains GaO_6 octahedra with SO_4 groups coordinated to gallium.[558] $Ga(SO_3F)_3$, from $GaCl_3 + S_2O_6F_2$, contains six-coordinate gallium with bridging fluorosulfato groups, according to IR spectra.[559] A chlorosulfate $Ga(SO_3Cl)_3$ and complexes $MGa(SO_3Cl)_4$ (M = Li or Na) have been prepared by the action of SO_3 on $MGaCl_4$.[560] Gallium selenate and tellurate resemble the sulfate.

$Ga_2(WO_4)_3$ is identified in the Ga_2O_3–WO_3 phase diagram. Several gallium tungstates and some polytungstate and molybdate complexes have recently been characterized.[561,562]

(*iv*) *Chlorate, perchlorate, bromate and iodate*

Gallium chlorate and perchlorate crystals obtained from aqueous solutions are hydrated, *e.g.* $Ga(ClO_4)_3 \cdot 6H_2O$. The aqueous solution shows evidence of polymerized cationic species: these are probably hydroxo complexes (Section 25.1.14.4.1) and are unlikely to contain ClO_4 ligands. The same is true of bromate and iodate solutions. $Ga(IO_3)_3 \cdot 2H_2O$ is sparingly soluble in water but readily dissolves in dilute acids. Anhydrous gallium perchlorate is obtained as very deliquescent crystals by the sequences in equation (14).[563] Vibrational spectra show that all three ClO_4 ligands are bidentate, forming a distorted octahedral GaO_6 unit.

$$GaCl_3 + 4Cl_2O_6 \longrightarrow ClO_2^+Ga(ClO_4)_4^- \xrightarrow[\text{vac}]{90\,^\circ C} Ga(ClO_4)_3 \qquad (14)$$

25.1.14.4.5 Carboxylate ligands

Gallium formate can be prepared from $Ga_2O_3 + HCO_2H$.[564] The acetate $Ga(O_2CMe)_3$ is obtained, *via* gallium chloroacetates, from $GaCl_3 + MeCO_2H$. Another preparative route is the slow reaction of the metal with anhydrous acetic acid. The benzoate and phenylacetate can be obtained similarly. Basic carboxylates result if aqueous acids are employed. The reaction of R_3Ga with an acid $R'CO_2H$ can also be applied to carboxylate synthesis. Structural data are lacking for simple formates or acetates of gallium. $MeGa(O_2CMe)_2$ contains both four- and

five-coordinate Ga atoms, with Ga—O distances of 187.3 to 215.3 pm.[565] Gallium tris(trifluoroacetate), $Ga(O_2CCF_3)_3$, has been prepared from $GaCl_3 + CF_3CO_2H$ and shown to form 1:1 adducts with Lewis bases.[566] The complex $Cs[Ga(O_2CCF_3)_4]$ was also reported.

There have been a number of studies of gallium oxalate systems. $Ga(C_2O_4)_3 \cdot 4H_2O$ crystallizes from hot aqueous $Ga(NO_3)_3$ solution containing oxalic acid. On heating above 140 °C, a dihydrate and then anhydrous $Ga_2(C_2O_4)_3$ are produced.[1] The latter decomposes at 200 °C, forming Ga_2O_3. Complex salts containing $Ga(C_2O_4)_2^-$ and $Ga(C_2O_4)_3^{3-}$ anions have been prepared and the formation of these and the cation $Ga(C_2O_4)^+$, presumably hydrated, has been studied to obtain stability constants.[567] Basic complexes may appear in these aqueous solutions. Raman spectra of gallium oxalate solutions confirm the presence of $Ga(C_2O_4)_3^{3-}$. The mode $\nu(M—O)_{sym}$ appears at 573 cm^{-1} [585 cm^{-1} in $Al(C_2O_4)_3^{3-}$].[1] Gallium adopts the coordination number of four in bis(dimethylgallium)oxalate.[568]

There are long-standing reports of Ga complexes with hydroxy acids and related organic chelating agents.[1] The lactate, tartrate and citrate are being used in physiological studies (where Ga^{3+} has affinitities with Fe^{3+}) which involve gallium radioisotopes.[569] According to NMR studies (^1H, ^{13}C and ^{71}Ga) 1:1 Ga:citrate complexes predominate at low pH. Polymerized species exist in the range pH 2–6, and citrate ligands are displaced, forming $Ga(OH)_4^-$, under alkaline conditions.[570] Among other systems of Ga^{3+} and chelating organic acids for which solution equilibria have been studied are those of caprate,[571] various salicylates,[572] some phosphonates and a variety of multidentate ligands.[570,573] Analytical reagents which form complexes with Ga^{3+} include Tiron,[574] pyrocatechol violet,[575] *p*-nitrophenylfluorone,[576] thenoyltrifluoroacetone[577] and flavone kaempferol.[578] A point to emerge from these investigations is that basic complexes are often involved, and the hydrolyzed cation $Ga(OH)^{2+}$ shows enhanced reactivity compared with $Ga^{3+}_{(aq)}$.

The crystal structure of a dimethylgallium salicylaldehyde complex shows it to be dimeric. There is a central Ga_2O_2 ring; the Ga atoms are five-coordinate with distorted trigonal bipyramidal geometry.[579]

25.1.14.4.6 Ethers and other oxygen donor ligands

(i) Molecular complexes

Gallium compounds, especially the trihalides, form coordination complexes by reacting directly with a variety of oxygen donor ligands. Early examples to be characterized were the series $GaCl_3 \cdot L$ (L = Me_2O, Et_2O, Me_2CO, $POCl_3$ or $PhNO_2$) and $GaBr_3 \cdot L$ (L = Me_2O, Et_2O, $POCl_3$ or $POBr_3$).[4,431] The diethyl etherates are low-melting solids: $GaCl_3 \cdot Et_2O$, m.p. 16 °C; $GaBr_3 \cdot Et_2O$, m.p. 21 °C; $GaI_3 \cdot Et_2O$, m.p. 27 °C. Calorimetric measurements show that $GaCl_3$ is a slightly weaker Lewis acid than $AlCl_3$, although the former shows a preference for softer bases, notably S and P donor ligands.[435] Trends in donor bond strength within the $GaCl_3 \cdot L$ series can also be monitored by observing the NQR frequencies of Cl or Ga nuclei.[580] There is a linear correlation: the stronger the donor the lower the NQR frequency.

With the water molecule as ligand, both $GaCl_3$ and $GaBr_3$ form a monohydrate, and several other hydrates have been identified.[581] The highest of these, $GaBr_3 \cdot 15H_2O$, is probably a salt of the $Ga(OH_2)_6^{3+}$ cation with additional water of crystallization. The vibrational spectra of the $GaX_3 \cdot H_2O$ adducts are best assigned in terms of the local symmetry of the units X_3GaO and H_2O rather than the overall C_s symmetry of the molecules.[582] $\nu(Ga–O)$ bands are observed in the region 410–440 cm^{-1} and force constants for the coordinate Ga—O bond are computed to be 1.43 and 1.48 N cm^{-1} in chloride and bromide systems, respectively. The Ga–X stretching modes of these H_2O adducts are similar in frequency to those of complexes $GaX_3 \cdot L$, where L = Et_2O, Me_2S, Et_2S or an N donor ligand, whose constitution has been established earlier by vibrational and NMR spectroscopy.[1] Other 1:1 adducts to have been studied spectroscopically include $GaX_3 \cdot Ph_3PO$ (X = Cl, Br or I),[583] $Me_3Ga \cdot Me_2O$[584] and $GaX_3 \cdot pyO$ (X = Cl or Br).[585] The last of these studies encompassed several substituted pyridine *N*-oxides which exhibit decreases in $\nu(N—O)$ on coordination, showing that the ligand is bound to gallium *via* the oxygen atom. Debate about the structure of acyl chloride adducts $GaCl_3 \cdot RCOCl$ now favours the ionic form $RCO^+GaCl_4^-$ (Section 25.1.14.6.2).

ESR spectra have been used to study interaction of the free radical base 2,2,6,6-tetramethylpiperidine nitroxide (tempo), a weak Lewis base, with $GaCl_3$.[586] This system reveals the expected 1:1 complex $GaCl_3 \cdot$tempo. Only one bridging Cl bond in the Ga_2Cl_6 molecule has

been broken, leaving a vacant site for the oxygen lone pair to coordinate weakly to gallium. $GaCl_3$·1,4-dioxane has recently been shown by XRD to contain five-coordinate Ga.[587] The structure consists of infinite chains in which planar $GaCl_3$ units are linked by dioxane molecules in chair conformation, with Ga—O bonds of length 221.0 pm. The involvement of six-coordinate species $Ga(NCS)_3L_3$, where L represents the O-bonded ligand, has been proposed to account for the solvent extraction of gallium from thiocyanate solutions by phosphonate or trialkylphosphate solvents.[503]

(*ii*) *Cationic complexes*

When gallium salts or the halides GaX_3 dissolve in polar solvents there is a pronounced tendency to ionization, and under these circumstances gallium generally exists as an octahedrally coordinated species. This occurs in aqueous solutions giving $Ga(OH_2)_6^{3+}$ (Section 25.1.14.4.1), in alcohols giving $Ga(ROH)_4^{3+}$ or $Ga(ROH)_6^{3+}$,[588] in dimethylformamide giving $Ga(DMF)_6^{3+}$ and in dimethyl sulfoxide giving $Ga(DMSO)_6^{3+}$.[537,589] In the DMSO complex a characteristic decrease in ν(S—O) confirms coordination through the oxygen. The symmetrical field about the metal nucleus in these species is favourable for Ga NMR spectroscopy, making this an important technique for studying the solution chemistry of these complexes.[537]

25.1.14.5 Sulfur and Heavier Group VI Ligands

25.1.14.5.1 Sulfide, selenide and telluride ligands

Gallium(III) sulfide Ga_2S_3 is prepared by passing H_2S over gallium at 950 °C and subliming the product under vacuum to obtain white crystals. When annealed at 1000 °C, the material is α-Ga_2S_3 which has the wurtzite lattice of close-packed sulfide ions, containing an ordered arrangement of Ga cations. Single crystal IR and Raman spectra of this phase have been assigned to vibrational modes of the GaS_4 groups.[590] Other forms, β- and γ-Ga_2S_3, have a random distribution of the Ga atoms in the wurtzite and zinc blende sulfide lattices, respectively. Ga_2S_3 decomposes slowly in moist air, evolving H_2S. It is soluble in acids, and in strong alkalis, to give gallate and thiogallate species. The compound $Na_2Ga(OH)_3S$ is reported to be formed when aqueous sodium gallate is treated with Na_2S or H_2S.[1]

There is a selenide Ga_2Se_3 and a telluride Ga_2Te_3, and materials can be synthesized which contain two of the group VI elements, *e.g.* Ga_2S_2Te. This compound contains GaS_3Te units linked to give parallel chains: Ga—S and Ga—Te distances are 230.7–235.3 and 255.6 pm, respectively.[591]

Gallium forms a variety of ternary sulfides and selenides. Common types are $M^{I}GaS_2$, $M^{II}Ga_2S_4$ and $M^{III}GaS_3$, and are akin to the mixed oxides. Owing to the unusual electrical properties of these and the corresponding indium compounds, there is an extensive literature concerned with their preparation, physical properties, growth as single crystals and X-ray studies.[592] Examples are $CsGaS_2$, $AgCaS_2$, $TlGaSe_2$, $CdGa_2S_4$ and $LaGaS_3$.[593,594] Compounds of other stoichiometries occur in mixed sulfide systems involving gallium, *e.g.* $Pb_2Ga_2S_4$ (or $2PbS{\cdot}Ga_2S_3$).[595] Extended lattices composed of linked GaS_4 tetrahedra are a feature of these structures. In recent X-ray studies the Ga—S bond distances are within the range 218–236 pm. In $La_{3.33}Ga_6O_2S_{12}$ there are sheets of both GaS_4 and $GaOS_3$ tetrahedra.[596] An adamantane-like cluster anion $Ga_4S_{10}^{8-}$ is found in $K_8Ga_4S_{10}{\cdot}14H_2O$, prepared by the action of aqueous potassium sulfide on Ga_2S_3.[597] The vibrational spectra have been assigned and X-ray structural analysis confirms near-ideal T_d symmetry. Ga—S distances are 228.9 (bridging) and 225.2 pm (terminal). The analogous seleno compound has been synthesized, as have the indium species. The structures have high thermal and solvolytic stability. Layers of Ga_4Se_{10} groups, linked through corners, comprise the structure of the ternary selenide $TlGaSe_2$, already mentioned.[593] Discrete $Ga_6Se_{14}^{10-}$ anions occur in $Cs_5Ga_3Se_7$: in this case six $GaSe_4$ tetrahedra are joined at their edges.[598] The Ga—Se distances range from 235.7 to 249.7 pm. $Cs_6Ga_2Se_6$ obtained as moisture-sensitive crystals, m.p. 685 °C, by reaction of Cs_2Se with Ga_2Se_3, contains the $Ga_2Se_6^{6-}$ anion which consists of just two tetrahedra sharing an edge. Here the Ga—Se distances are 247.0 and 250.5 pm (bridging), 238.5 and 240.7 pm (terminal).[599]

Gallium forms a series of compounds GaYX, where X = Cl, Br or I and Y = S, Se or Te, all of which are highly water sensitive. Crystallographic study of GaTeCl reveals a layer structure

in which the Ga—Te framework resembles that in black phosphorus.[600] Recent investigations have shown that sulfur reacts with $GaCl_3$ in the medium of a CsCl–$GaCl_3$ melt to produce polymeric species $(GaSCl_2^-)_n$.[601] From Raman evidence these appear to have Ga—S—Ga linkages, like the corresponding aluminum complexes.

Alkylthiogallanes $Ga(SR)X_2$ and $Ga(SR)_4^-$ (R = Me or Et) are obtained by the reaction of GaX_3 with Me_3SiSR in benzene.[602] A dimeric structure with bridging thioalkyl ligands has been found. By varying the stoichiometry, $Ga(SR)_2Cl$, $Ga_2(SR)_3Br_3$ and $Ga(SR)_3$ can be prepared. A remarkable structure results from the reaction of Me_2S_2 with Ga_2I_4. The product, $Ga_4(SMe)_4S_2I_4$, is a cluster compound in which four tetrahedrally disposed GaI units are linked along the edges of the tetrahedron by sulfur ligands (four SMe groups and two S atoms). The result is a cage structure similar to that of $Ge_4S_6Br_4$, or to $Ga_4S_{10}^{8-}$ (above). Average bond distances are Ga—I = 251.6, Ga—S (Me) = 233.6 and Ga—S = 220.4 pm.[603]

25.1.14.5.2 Other sulfur-donor ligands

Gallium has a stronger tendency to react with sulfur ligands than has aluminum. This is evident in the chemistry of gallium sulfides and related species, and in the fact that Ga forms compounds with S ligands of which there are no counterparts in Al chemistry. There are adducts GaX_3SR_2 (X = Cl or Br; R = Me or Et), and a dithiolato complex $Ga(mnt)_3^{3-}$ (mnt = *cis*-1,2-$S_2C_2(CN)_2^{2-}$) which resemble those of In^{III} and Tl^{III}.[604] A series of tris(dithiocarbamates) $Ga(S_2CNR_2)_3$ and tris(xanthates) $Ga(S_2COR)_3$ have been prepared from aqueous solutions.[605] Thermal decomposition at 100 °C of two of these compounds is reported to proceed as follows, although the products are not well characterized (equations 15 and 16).

$$Ga(S_2CNH_2)_3 \longrightarrow Ga(NCS)_3 + 3H_2S \quad (15)$$

$$Ga(S_2CNHMe)_3 \longrightarrow Ga(SH)_3 + 3MeNCS \quad (16)$$

The crystal structure of $Ga(S_2CNEt_2)_3$ reveals a monomer, the GaS_6 core of which is closer to prismatic than regular octahedral symmetry. The Ga—S distances are 240.8 to 246.6 pm (average 243.6 pm).[606] The analogous indium compound is known. $(Ph_2GaSEt)_2$ has a structure in which gallium is four-coordinate with bridging EtS ligands.[607] The Ga—S distances are 237.3 and 238.4 pm. A monothio-β-diketonate of gallium has been obtained.[608] Crystal structure analysis to determine the geometry of the central GaO_3S_3 unit would be of considerable interest.

Gallium forms a thiophosphate $GaPS_4$. XRD measurements show that Ga atoms are four-coordinate.[609] The GaS_4 units are distorted tetrahedra, and the Ga—S distances, in the range 226.6–229.7 pm, are appreciably less than those of the GaS_6 group noted above.

25.1.14.6 Halogen Ligands

25.1.14.6.1 Fluoride ligand

The GaF_3 molecule is planar with a Ga—F distance of 188 pm from ED studies.[610] This species and the dimer $(GaF_3)_2$ have been examined in the vapour phase by mass spectrometry.[611] The OGaF molecule has been detected by matrix isolation.[612]

The compound gallium trifluoride GaF_3, colourless needles which are sparingly soluble in water, is produced by thermal decomposition of $(NH_4)_3GaF_6$ or $GaF_3{\cdot}3NH_3$,[613] excluding moisture which brings about the formation of $(NH_4)_2GaF_3(OH)_2$. Solutions of gallium in hydrofluoric acid yield $GaF_3{\cdot}3H_2O$ when evaporated. Stronger heating gives $GaF_2OH{\cdot}xH_2O$, and exposure to NH_3 forms $GaF_3{\cdot}3NH_3$. Aqueous gallium fluoride solutions contain the aquated complexes GaF^{2+}, GaF_2^+, GaF_3 and GaF_4^-;[614] probably all are six-coordinate, *e.g.* $GaF_4(OH_2)_2^-$. The octahedral anion GaF_6^{3-} exists in some fluorogallates for which vibrational analyses are available.[615,616] As with aluminum, there are group I fluorogallates, $MGaF_4$, M_2GaF_5, M_3GaF_6 and MGa_2F_7.[617] Other stoichiometries, *e.g.* $Na_5Ga_3F_{14}$, $BaGaF_5$, $Ba_3Ga_2F_{12}$ and $Ba_{11}Ga_4F_{34}$, are attained by the linking of GaF_6 groups into chains or sheets through bridging fluoride ligands.[618–620] NH_4GaF_4 forms a continuous series of solid solutions with NH_4AlF_4, as does γ-GaF_3 with γ-AlF_3.[621]

Some organogallium fluorides are known. These have cyclic structures $(R_2GaF)_n$, where $n = 3$ or 4,[622] and so differ from the chlorides and bromides $(R_2GaX)_2$ which are halogen-bridged dimers.

25.1.14.6.2 Chloride, bromide, iodide and mixed halide ligands

The trihalides $GaCl_3$ and $GaBr_3$ are usually prepared by burning the metal in a stream of Cl_2 (or Br_2) carried by nitrogen, in apparatus which includes several purification stages and uses all-glass or greaseless connections.[468] GaI_3 can be obtained by dissolving Ga in a refluxing solution of I_2 in CS_2. Gallium chloride and bromide have some advantages over the aluminum trihalides as Friedel–Crafts catalysts, particularly owing to their high solubility in organic solvents. All three halides are colourless, deliquescent, low-melting solids, whose physical properties have been tabulated.[1] In solid and liquid states, and in non-coordinating solvents, the gallium trihalide molecules are dimeric with bridging ligands spanning four-coordinate Ga atoms. In the vapour there is extensive dissociation of Ga_2X_6 to GaX_3. Molecular dimensions are known for monomers $GaBr_3$[623] and GaI_3[1] and dimers Ga_2Cl_6[1] and Ga_2I_6,[624] but precise values are lacking for $GaCl_3$ and Ga_2Br_6. Vibrational assignments are available for the GaX_3 monomers[623,625,626] (from gas phase and matrix isolation studies) and the Ga_2X_6 dimers.[627,628] NQR specra of Ga_2Cl_6 are in accordance with the symmetrical dimer of D_{2h} symmetry.[629]

Halogen-bridging, which enables Ga to be four-coordinate, is also a feature of the dimeric structures of organogallium halides, *e.g.* $(RGaX_2)_2$ where X = Cl, Br or I and R = various alkyl groups; or (Ph_nGaX_{3-n}) ($n = 1$ or 2; X = Cl, Br or I).[630] $(Me_3SiCH_2)_2GaCl$ appears to differ from the usual pattern and to be polymeric in the solid state.[631] In $(HGaCl_2)_2$, IR and Raman spectra establish a chlorine-bridged structure with the terminal ligands in the *cis* arrangement.[632] Structural and spectroscopic data for methylgallium halide anions $[Me_nGaX_{4-n}]^-$ ($n = 0$–4) have been analyzed.[633] A single halogen ligand links the R_3Ga groups in the anions $(R_3Ga)_2X^-$ (X = Cl or Br; R = Me or Et).[634]

$GaCl_3$ forms $GaCl_3{\cdot}BCl_3$,[635] and adducts with some chlorides of the later group elements, *e.g.* $GaCl_3{\cdot}TeCl_4$ and $GaCl_3{\cdot}PCl_5$, which have ionic structures including the $GaCl_4^-$ anion. In $GaCl_3{\cdot}SbCl_3$, XRD reveals a chain structure with Ga—Cl—Ga bridges.[636] The $GaCl_3$–$SnCl_2$ system forms $Sn(GaCl_4)_2$, whereas the $GaCl_3$–$SnCl_4$ system is eutectic and shows no intermediate compound.[637] Germanium is chemically transported in the vapour as $GeGaCl_5$, *i.e.* $Cl_2Ge(\mu\text{-}Cl)_2GaCl$.[638] Kindred vapour-phase species are present in gallium chloride–transition metal chloride systems.[639,640]

Being powerful acceptors, the gallium trihalides react with donor molecules L to form the adducts $GaX_3{\cdot}L$, and in some instances $GaX_3{\cdot}2L$, with a coordinate bond from the group V or VI ligand, which are treated in earlier sections.

(*i*) *Complex halide ions*

With chloride, bromide or iodide as ligand, gallium readily gives the tetrahedral anions GaX_4^-. These exist in aqueous solutions containing excess halide, from which they can be isolated as crystalline salts with a large cation, *e.g.* Bu_4NGaX_4, or by solvent extraction as complex acids $H(solv)^+GaX_4^-$.[357] Crystallographic data for solids containing the GaX_4^- ions are available.[1,486,641,642] Characteristic absorption spectra,[643] vibrational frequencies,[644] NMR chemical shifts[537] and NQR parameters[645] are well established. These properties can be used to study effects such as ligand exchange processes of $GaCl_4^-$ with Cl^-,[646] ion pairing in non-aqueous solutions of alkylammonium chlorogallates,[647] polymorphism of $KGaCl_4$[648] and solid state interactions in the crystalline solids $NO^+GaCl_4^-$[649] and $Ga^+GaCl_4^-$.[437] Bond dissociation energies $D(GaX_3—X^-)$ are 364 and 314 kJ mol^{-1} for X = Cl or Br, respectively.[650]

In dilute aqueous solutions the four-coordinate GaX_4^- ions dissociate, forming $[GaX_n]^{3-n+}$ (aq) ($n = 1$, 2 or 3) and finally $[Ga(OH_2)_6]^{3+}$. Stability constants are available for these equilibria.[7,8] When the solutions are frozen to the glassy state, Raman spectra show that the equilibria are displaced in favour of the aqua cation.[651] The complexes GaX_4^- are formed, together with $Ga_2X_7^-$ (see below), in the systems MX–GaX_3, where MX is a group I chloride or bromide, which have been studied in the solid state or as molten salts. The TlBr–$GaBr_3$ system reveals $TlGa_2Br_7$ and $TlGaBr_4$, whereas the NaBr–$GaBr_3$ system forms $Na_2Ga_2Br_7$, $NaGaBr_4$,

Na_2GaBr_5 and Na_3GaBr_6.[652] These last two probably contain $GaBr_4^-$ and Br^- ions, rather than complexes more highly coordinated than $GaBr_4^-$.

The halide dimers Ga_2X_6 react with MX in 1:2 stoichiometry to form $MGaX_4$, and in 1:1 stoichiometry yielding MGa_2X_7. The crystal structure of KGa_2Cl_7 reveals a bent conformation, the $Cl_3Ga(\mu\text{-}Cl)GaCl_3^-$ anion having C_{2v} symmetry. Vibrational spectra of the solid and molten salt phases have been assigned on this basis,[653] and the bridging and terminal chlorines give distinct NQR signals.[645] Raman studies of molten CsCl–$GaCl_3$ mixtures show the presence of Ga_2Cl_6, $GaCl_4^-$, $Ga_2Cl_7^-$ and possibly higher complexes.[654] The anions $Ga_2X_7^-$ (X = Cl or Br) are present in the mixed valence compounds Ga_3X_7.[437,655] In MI–GaI_3 systems, both $MGaI_4$ and MGa_2I_7 exist when M = Rb or Cs, but only $MGaI_4$ occurs when M = K. Interestingly, the $Ga_2I_7^-$ ion has a linear Ga—I—Ga bridge, vibrational spectra of melts indicating D_{3d} symmetry.[656] For the corresponding bromide systems,[657] there is evidence of a further gallium-rich compound MGa_3Br_{10} for which the Raman spectrum suggests the structure $Br_3Ga(\mu\text{-}Br)GaBr_2(\mu\text{-}Br)GaBr_3^-$. Nyholm and Ulm had prepared $[Ga(diars)_2Cl_2](Ga_3Cl_{10})$ in 1965,[658] although their proposed structure of $Ga_3Cl_{10}^-$, featuring a central six-coordinate Ga atom, can now be discounted.

(ii) Mixed halide species

The molecules $GaCl_2Br$ and $GaClBr_2$ have been observed in the gas phase by Raman spectroscopy.[442] However, attempts to study halogen bridging in mixed halide dimers, *e.g.* $Ga_2Cl_4Br_2$, or in complex anions, such as $Ga_2Cl_6Br^-$, have been defeated by the complexity of the spectra. Mixed halide species RGa_2X_4I have been obtained by the oxidative addition of an alkyl iodide to the halides Ga_2Cl_4 or Ga_2Br_4.[659]

Four-coordinate mixed halide complexes $[GaX_nY_{4-n}]^-$, where X and Y are two of Cl, Br or I, are readily generated in gallium halide systems in solution and solid states. Preparations of $Bu_4P(GaCl_3Br)$, $Ph_4As(GaClBr_3)$, $[(Et_2O)_2H](GaX_3Y)$ and $(py_2H)[GaX_3Y(py)_2]$ (X or Y = Cl, Br or I) have been described.[660,661] Vibrational assignments have been made for most of the ν(Ga—X) and ν(Ga—Y) stretching modes of the GaX_3Y^- anions.[660,662] ^{35}Cl NQR spectra suggest that the solids $Bu^n_4N(GaCl_nBr_{4-n})$ ($n = 0$–4) are individual compounds,[663] although these might have been expected to be disordered phases. The production of mixed halide anions in solution starting from GaX_4^- and GaY_4^- can be followed by Ga NMR spectroscopy and the chemical shifts of the binary mixed halide ions have been measured, as have those of $GaCl_2BrI^-$, $GaClBr_2I^-$ and $GaClBrI_2^-$.[664,665] Halide exchange is rapid in aqueous solution, but slow in CH_2Cl_2, and produces GaX_3Y^- and $GaXY_3^-$ ahead of $GaX_2Y_2^-$. The mechanism of exchange is thought to involve initial dissociation of GaX_4^- and the intermediacy of bridged species such as $X_3Ga—Y—GaX_3^-$.

25.1.14.7 Hydrogen and Complex Hydride Ligands

25.1.14.7.1 Hydride ligand

Gallium forms hydridogallates, $MGaH_4$ and M_3GaH_6, and gallane adducts, *e.g.* $GaH_3{\cdot}NMe_3$. These compounds have some advantages as reducing agents over the corresponding aluminum compounds; however, the chemistry of the gallium hydrides is much less well developed.

Lithium gallium hydride, $LiGaH_4$, a solid which slowly decomposes at 25 °C and a milder reducing agent than $LiAlH_4$, can be prepared in ether solution (equation 17). Tested methods are also available to synthesize Na, K and other salts, and to convert $LiGaH_4$ to $GaH_3{\cdot}NR_3$ by reaction with Me_3N (or Et_3N).[666,667] $LiGaH_4$ forms a dietherate, which is converted to the monoetherate $LiGaH_4{\cdot}OEt_2$ under vacuum. The Raman and IR spectra of alkali metal salts $MGaH_4$ confirm the tetrahedral symmetry of the anion and enable GaH_4^- to be compared with other hydrides.[668]

$$GaCl_3{\cdot}Et_2O + 4LiH \xrightarrow{-78\,^\circ C} LiGaH_4 + 3LiCl \qquad (17)$$

$GaH_3{\cdot}NMe_3$, a solid, is less sensitive to hydrolysis than $AlH_3{\cdot}NMe_3$. Recent measurements of the dimensions of the Me_3N–GaH_3 molecule in the vapour by ED include r(Ga—H) = 149.7 pm.[669] Similarly short terminal Ga—H bonds of 148.7 pm are found in the structure

of $(Me_2NGaH_2)_2$.[495] $GaH_3{\cdot}NMe_3$ can undergo hydride displacement without rupture of the Ga—N bond (equation 18).

$$Me_3N{\cdot}GaH_3 + Me_3NHCl \longrightarrow Me_3N{\cdot}GaH_2Cl + Me_3N + H_2 \quad (18)$$

Following early claims of gallane synthesis, reinvestigation of the reaction of $GaH_3{\cdot}NMe_3$ with BF_3 provides no evidence for uncoordinated GaH_3.[475] MS experiments in which the metal is heated in a hydrogen atmosphere have detected small amounts of gallium hydride as GaH_3^+ (or InH_3^+ when indium is used),[670] but the amounts are much less than in the case of aluminum where both AlH_3^+ and $Al_2H_6^+$ are found. The gallane radical anion $^{\cdot}GaH_3^-$ has been generated in a low temperature matrix and has been shown by ESR study to be pyramidal, like $^{\cdot}AlH_3^-$ and $^{\cdot}SiH_3$.[671]

There are reports of unstable halogenogallanes, the compounds $GaHCl_2$ and $GaHBr_2$ having been prepared from $GaX_3 + Me_3SiH$. $GaHCl_2$ melts at 29 °C (dec), and decomposition to $Ga_2Cl_4 + H_2$ is complete at 150 °C. Evidence from IR/Raman spectra indicates that $GaHCl_2$ is a dimer, probably *cis*-$ClHGa(\mu\text{-}Cl)_2GaHCl$.[632]

25.1.14.7.2 Borohydride ligand

Reaction of $LiBH_4$ with $GaCl_3$ yields hydridogalliumbis(tetrahydroborate) $HGa[(\mu\text{-}H)_2BH_2]_2$. In the gas phase this molecule exhibits five-fold coordination by H atoms which form a distorted rectangularly based pyramid around the Ga atom.[672] As determined by ED, the length of bridge bonds averages 177.4 pm; the terminal Ga—H bond is much shorter, *i.e.* 156.5 pm. $Me_2Ga(BH_4)$, m.p. 5 °C, decomposing to $Ga + H_2$ + methylated borons, can be obtained from $Me_2GaCl + LiBH_4$ (or from $Me_3Ga + B_2H_6$). Its structure shows four-coordinate gallium linked to bidentate BH_4 as $Me_2Ga(\mu\text{-}H)_2BH_2$ with a bridging Ga—H bond length of 179 pm.[673]

25.1.14.8 Mixed Donor Atom Ligands

25.1.14.8.1 Schiff base ligands

A few studies of Schiff base complexes of gallium have been made.[415,674] Frequencies ν(Ga—O) have been located in the range 600–685 cm^{-1}. Modes ν(C=N) are almost unaffected by complexation.

25.1.14.8.2 Amino acids, peptides and proteins

Complexing of Ga^{3+} by simple amino acids has attracted attention as the basis for investigations of more complicated systems.[675,676] IR evidence indicates that both N and O sites are coordinated to the metal. NMR studies of interactions of Ga^{3+} with the bleomycin antibiotics (glycopeptides used in tumour scanning as carriers for the ^{67}Ga radionuclide) have shown that the metal binds by displacing a proton from the α-amino group of the diaminopropionamide fragment of the drug.[677] The conformation of the gallium complex of parabactin has been determined by 300 MHz ^1H NMR spectroscopy, and the sequestering powers of several catechoylamide-type ligands for Ga^{3+} (and In^{3+}) have been investigated as a function of pH to assess the feasibility of the removal of gallium from association with the protein transferin.[678]

25.1.14.8.3 Ligands with N, O and other functions

In gallium complexes with multidentate ligands there is a marked tendency for the coordination number to increase from four to five or six. The reaction of Me_3Ga with ethanolamine yields Me_2GaL_2, where L_2 represents the chelating ethanolamine ligand. Bond distances within the five-membered ring are Ga—O = 191.7 pm, Ga—N = 206 pm.[679] If the ligand is changed to *N,N*-dimethylethanolamine, the resulting chelate dimerizes to form

$[Me_2Ga(OC_2H_4NMe_2)]_2$ with a central Ga_2O_2 ring such that the Ga atoms become five-coordinate. In *N,N'*-ethylenebis(salicylideneiminato)chlorogallium(III) the central Ga atom is again five-coordinate.[680] The geometry approximates to square pyramidal with Cl at the apex. The Ga atom is also five-coordinate in chlorobis(β-hydroxo-2-methylquinolinato)gallium(III) and in some 1:1 complexes of Ga^{3+} or $MeGa^{2+}$ with various O,N,O or O,N,S tridentate ligands.[681,682] Salicylaldimine complexes of Ga are lipophilic species of radiopharmaceutical interest. X-Ray study of one of these reveals the ligand occupying all six coordination sites around Ga, by bonding through three imino N atoms and the deprotonated phenolic O atoms.[683] Ga—N and Ga—O distances are slightly longer than those in four- or five-coordinate Schiff base complexes of gallium, but lie within the established range for octahedral Ga^{III} compounds. The crystal structure of the ethylenediaminetetraacetic acid complex $Ga(Hedta)\cdot H_2O$ shows the ligand bonding in a pentadentate fashion with the water molecule occupying a sixth position.[684] Average bond distances are Ga—N = 214 and Ga—O = 195 pm. The structure of a six-coordinate complex which bears Cl, a tridentate N donor and bridging OH ligands has also been determined.[538]

Stability constants have been evaluated for the complexes formed in aqueous solution between Ga^{3+} and a number of multidentate ligands.[685,686] Some other Ga chelates, including those of hydroxy acids, are treated in Section 25.1.14.4. Investigations by Storr, Trotter and co-workers into the structural chemistry of a series of transition metal complexes, which carry bi- or tri-dentate ligands based on MeGa or Me_2Ga groups (and so can be viewed alternatively as chelate complexes of gallium), are reviewed elsewhere.[687]

25.1.14.9 Macrocyclic Ligands

Gallium porphyrins resemble those of Al, In and transition metal M^{III} atoms. Examples in which the central atom of the GaN_4 kernel also bears a chlorine ligand[688] can be converted into Ga porphyrins with a Ga—C bond.[689] Certain polymeric fluorogallium and aluminum phthalocyanines are of importance on account of their high electrical conductivity (see Section 25.1.9). Crystallographic study of PcGaF[690] has revealed the orientation of the phthalocyanine rings and has established the following bond distances: Ga—F = 193 and Ga—N = 197 pm.

25.2.9 REFERENCES 175

25.2.1 INDIUM: INTRODUCTION

A review of the coordination of indium necessarily begins with reference to the general inorganic chemistry of the element,[1] and to other earlier general works.[2–4] More recent authors have reviewed the adducts of the trihalides and pseudohalides of gallium, indium and thallium,[5] other aspects of the inorganic chemistry of these elements,[6] the coordination chemistry of indium,[7] and the organometallic chemistry of indium.[8] A critical evaluation of the stability constants of indium complexes in solution has also appeared.[9] Each of these articles contains background material and references to earlier work.

25.2.2 INDIUM(I)

The coordination chemistry of indium(I) received little or no attention for many years, largely no doubt because of the lack of suitable starting materials. The indium(I) halides can be easily prepared,[1] but are intractable materials which readily undergo hydrolysis and disproportionation (but see Section 25.2.2.1). The only known organoindium(I) compounds are the cyclopentadienyl and methycyclopentadienyl derivatives,[8] and the former has proven a useful starting point for some synthetic work. Electrochemical methods have been used either to reduce higher states, or to oxidize the metal in the presence of suitable ligands, in order to produce indium(I) species.

25.2.2.1 Nitrogen Ligands

The neutral adducts of InBr and InI with ammonia, $InX{\cdot}nNH_3$ ($n = 1, 2$), are reported to be black insoluble substances which disproportionate in air or in the presence of moisture, and on heating, so that $InI{\cdot}2NH_3$ for example gives $InI_3{\cdot}5NH_3$, indium metal and ammonia.[10] An interesting new development which should open up indium(I) chemistry is that the monohalides InX (X = Cl, Br, I) dissolve in mixtures of aromatic solvents and organic bases.[11] These solutions are relatively stable at low temperature (−20 °C and below), and the dependence of solubility on TMEDA concentration suggests that in the case of InBr or InI, the solute species is InX·3TMEDA in dilute solution, although addition of petroleum ether to the cold solution

precipitates InX·0.5TMEDA. The synthetic usefulness of such solutions is discussed below. Indium(I) halides do not otherwise dissolve in basic solvents and in any case disproportionation is always a major problem, but prolonged refluxing in either aniline or morpholine is reported to give products analyzing as $[In(aniline)_4]X$ and $[In(morpholine)_2]X$ (X = Cl, Br, I), whose formulation depends on the behaviour of the products as 1:1 electrolytes in nitrobenzene.[12] Some structural information on these unusual compounds would be most helpful.

25.2.2.2 Cyanate and Thiocyanate Ligands

Salts of $InCl_2^-$ and InI_3^{2-} (see Section 25.2.2.4) serve as the starting point for the synthesis of salts of $[In(NCS)_2]^-$, $[In(NCO)_2]^-$ and $[In(NCS)_3]^{2-}$ by metathesis in ethanol;[13] the IR spectrum shows that both ligands are N-bonded in structures which are apparently bridged homopolymers in the solid state. No other pseudohalide compounds of indium(I) have been reported.

25.2.2.3 β-Ketoenolates and Related Ligands

The unavailability of suitable starting materials has hindered work in this area, but the reaction of cyclopentadienylindium(I) in Et_2O/benzene mixtures with 4,4,4-trifluoro-1-(thien-2′-yl)butane-1,3-dionate (ttaH) gave the extremely hygroscopic In(tta), and similar derivatives of other bidentate ligands were obtained by this same process.[14] The reactions of the analogous In(oxine) (oxine = 8-hydroxyquinoline anion) show that such InL species are easily oxidized to indium(III) complexes (see Section 25.2.4.8). The insolubility of the product in the reaction mixture is presumably an important factor in this method.

25.2.2.4 Halogen Ligands

The solubility of the indium(I) halides in toluene/TMEDA was noted previously. Electron spectroscopy[15] shows that InCl forms covalent dimers in the gas phase. The *d*-shell electrons can be regarded as being part of the core and play no part in bonding.

Indium monohalides (InX; X = Cl, Br, I) react with the corresponding salt of *N,N′*-dimethyl-4,4′-bipyridylium to form $[Me_2bipy]^{2+}[InX_3]^{2-}$.[16,17] The anions have been formulated as mononuclear C_{3v} species on the basis of Raman spectra, supported by force constant calculations.[18] Electrochemical reduction of In^{III} in concentrated hydrochloric acid did not yield stable In^I species. The reaction of CpIn with HX in the presence of Et_4NX in non-aqueous media[13,19] gave the salts $Et_4N[InX_2]$ whose vibrational spectra indicate the presence of mononuclear C_{2v} anions. With the cation Me_2dppe^{2+} (= 1,2-bis(methyldiphenylphosphonio)-ethane), the salt $Me_2dppe[InI_3]$ was obtained. Metathesis yielded pseudohalide derivatives (see Section 25.2.2.2). The electrochemical oxidation of an indium anode in a non-aqueous solution of Et_4NI and I_2 provides an unusual route to $Et_4N[InI_2]$.[19,20] The oxidation of InX_2^- to $InX_2Y_2^-$ is discussed later.

Aqueous solutions of In^I in low concentration can be prepared by the anodic oxidation of the metal,[21] but the strong reducing properties of $In^+(aq)$ bar this as a route to complexes. The rate of disappearance of In^I in various media has been used to derive stability constants for In^I/X^- species.[22,23]

25.2.2.5 Macrocyclic Ligands

The indium(II) halides, whose solid state structures are $In^+[InX_4]^-$ for X = Br and I (see Section 25.2.2.5), have served as starting points for the preparation of $[In(crown)][InX_4]$(X = Cl, Br, I), $[In(crown)][AlCl_4]$ and $[In(cyclam)][InX_4]$(X = Br, I; crown = dibenzo-18-crown-6; cyclam = 1,4,8,11-tetraazacyclotetradecane).[24] The characteristic vibrational spectra of the InX_4^- anions were important in establishing the solid state structure of these salts of indium(I) cationic complexes. These macrocyclic ligands do not react with suspensions of InX (*cf.* thallium below).

25.2.3 INDIUM(II)

The structure of the few indium(II) compounds identified by early workers is one of the classical problems in group III chemistry, (*cf.* gallium, Section 25.3.3.3). It is now clear that both M—M-bonded compounds and ionic mixed valence species exist, but the factors which govern the relative stability of these species still remain to be elucidated.

25.2.3.1 Nitrogen Ligands

Neutral adducts of the indium dihalides are known with both mono- and bi-dentate nitrogen ligands. Condensation of ligand on to InX_2 (X = Cl, Br, I) cooled in liquid nitrogen gave InX_2L (L = piperidine, piperazine and morpholine). Raman emissions at *ca.* 173 (Cl), 143 (Br) or 105 (I) cm^{-1} were assigned as ν(In—In), leading to the formulation of these compounds as $X_2(L_2)InIn(L_2)X_2$, with the bases acting as monodentate ligands at five-coordinate indium(II)[25] (*cf.* gallium(II) compounds). The reaction between InX_2 (X = Br, I) and various ligands in benzene[26] yielded adducts only with TMEDA and Et_3P (see below); other ligands, and all reactions involving $InCl_2$, lead to disproportionation, either to $In^0 + InX_3$, or to $InX + InX_3$. A later X-ray crystallographic investigation[27] confirmed both the In—In-bonded structure of $In_2Br_3I{\cdot}2TMEDA$, for which r(In—In) = 2.775(2) Å, and five-coordination at indium. Possible reasons for the different behaviour of InX_2 in solution[26] and in the solid state[25] have been discussed[28] and are summarized below (Section 25.2.3.5).

Condensation of pyridine on to InX_2 gives the In—In-bonded compounds $X_2In_2X_4py_4$ (X = Br, I; X = Cl not obtained by this or other methods).[25] Adducts of InI_2 with $EtNH_2$ ($In_2I_4L_5$), and $EtNH_2$ and bipy ($In_2I_4{\cdot}2bipy{\cdot}4EtNH_2$, $In_2I_4{\cdot}Etbipy{\cdot}bipy{\cdot}8EtNH_2$, $In_2I_4{\cdot}Et_4bipy{\cdot}bipy{\cdot}8NH_3$) have also been reported,[29] but unfortunately no structural information is available on these unusual compounds.

25.2.3.2 Phosphorus Ligands

Bis adducts of Et_3P with In_2Br_4 and In_2I_4 have been prepared; vibrational spectra showed these to be $P(X_2)InIn(X_2)P$ species, with a staggered conformation in the solid state.[26]

25.2.3.3 Oxygen Ligands

Adducts of In_2Br_4 and In_2I_4 with THF, tetrahydropyran and DMSO have been prepared by condensing the ligand on to the dihalide.[25] The evidence from vibrational spectroscopy, and the obvious analogies with In_2X_4—nitrogen compounds and with Ga_2X_4 adducts, readily identify these as In—In species.

Two other types of unusual indium(II)–oxygen ligand complexes are known. The polarographic reduction of $In(acac)_3$, $In(tropolonate)_3$ or $In(pyronate)_3$ (pyronate = 3-hydroxy-2-methyl-4-pyronate anion) in non-aqueous solution shows a one-electron reduction in each case,[30] corresponding to the formation of a (formally) In^{II} complex. Similar behaviour was observed with $In(oxine)_3$, and in some cases a second one-electron reduction was also observed, implying the formation of In^{I} species, although in no case was the site of the reduction identified, so that the product may be either $[In^{II}(acac)_3]^-$ or $[In^{III}(acac)_2(acac^-)]^6$ (*cf.* sulfur ligands, Section 25.2.3.4).

Electrolysis in the cell $Pt/MeCO_2H:H_2O(trace)/In$ caused dissolution of the indium anode and formation of fine feathery crystals of the metal on the cathode. This material slowly reacted with the electrolyte to give crystals of $In(OAc)_2$ which could be converted to $In(OAc)_3$ on boiling with glacial acetic acid. It seems likely that the crystal lattice consists of $In^{I} + In^{III} + OAc^-$, but no detailed structure could be obtained.[31] This system warrants further investigation in view of work on the analogous thallium system (see below).

25.2.3.4 Sulfur and Heavier Group VI Ligands

The bis-tetrahydrothiophene adducts of In_2X_4 (X = Cl, Br, I) and the corresponding dimethyl sulfide complexes of In_2Br_4 and In_2I_4 have been prepared.[25]

The polarographic reduction[32] of a number of InL_2^{2-} complexes (L = toluene-3,4-dithiolate) $[InL_2D]^-$ (D = phen, bipy, *etc.*), InL_2^{2-} (L = 1,2-dicyanoethylene-1,2-dithiolate), *etc.*, in non-aqueous solution demonstrated a series of reversible one-electron changes corresponding formally to $In^{III} \rightarrow In^{II} \rightarrow In^{I} \rightarrow In^{0}$, in contrast to the $In^{III} \rightarrow In^{0}$ reduction observed in aqueous solution. As noted above (Section 25.2.3.3), the formal oxidation states are assigned to the metal on the assumption that the ligand itself is not reduced, and this remains to be confirmed experimentally.

Although not true coordination compounds of indium, the compounds In_6S_7 and In_6Se_7 should be noted, since they involve In_2^{4+} in the solid state [r(In—In) = 2.741(2), 2.760(5) Å respectively].[33,34] Similarly, In_4Se_3 and In_4Te_3 contain the catenated In_3^{5+} cation,[35] and might therefore prove useful starting materials for the synthesis of thio complexes of In^{II}. Another intriguing compound in this context is In_5Se_4,[36] in which indium is tetrahedrally coordinated in either $In(In')_4$ or $In(In'S_3)_4$.

25.2.3.5 Halogen Ligands

The solid state structure of In_2I_4 has been shown to be $In^+[InI_4]^-$ by X-ray crystallography,[37,38] isostructural with $GaCl_2$ (see Section 25.2.3.3). Structural work on $InBr_2$ indicates a similar structure,[39] and both this and InI_2 confirm previous assignments based on vibrational spectroscopy.[17] The structure of $InCl_2$ presents a much more complex problem. Vibrational spectra have demonstrated the presence of the $InCl_4^-$ anion in molten indium dichloride,[41,42] but the analogous studies of the room temperature phase are variously interpreted as confirming[43] or denying[41,42] the presence of the tetrahedral anion in the lattice. X-Ray powder studies of the solid are also claimed to support the presence of $InCl_4^-$ in both of two different phases of indium dichloride.[44,45] One explanation of these contradictions may be found in the work of Meyer[46,47] who has shown that the only mixed valence species in the $InCl/InCl_3$ system are In_3Cl_4, In_2Cl_3 and In_5Cl_9; the latter is formulated as $In_3^I[In_2Cl_9]$, with a confacial bioctahedral anion. This work removes much of the uncertainty from the problem, and the conclusion is in keeping with the known tendency of anionic chloro complexes of indium(III) to be six-coordinate, unlike the bromo and iodo compounds (see Section 25.2.4.6.2).

It is clear, then, that none of these molecules contains an In—In bond, and the same is apparently true of the only known indium(II) pseudohalide, $In(CN)_2$, formulated as $In[In(CN)_4]$ from vibrational spectroscopy.[48] The species formed by the coordination of electron donors to In_2X_4 on the other hand are clearly In—In molecules. The structures of the neutral adducts were noted earlier (Section 25.3.2.1). The anionic species $In_2X_6^{2-}$ (X = Cl, Br, I), prepared *via* InX_2,[49] are isostructural with the corresponding gallium(II) anions. In non-aqueous solution, ^{115}In NMR studies[50] show that these molecules disproportionate to $InX_2^- + InX_4^-$. Recent studies of the InX/InY_3 reaction[23] cast some light on these matters, and it appears that kinetic factors, and specifically intramolecular halide transfer, are at least as important as thermodynamic effects in the stability of both $In_2X_4L_2$ and $In_2X_6^{2-}$ species. The importance of phase is shown by the fact that the gas phase above molten InX_2 contains InX, InX_3 and In_2X_6 molecules.[51] Much clearly remains to be done in this area.

25.2.4 INDIUM(III)

As noted in the introduction to this chapter, the coordination chemistry of indium(III) is now firmly based and a number of reviews already exist. The following sections are therefore comprehensive, rather than totally inclusive, in scope.

25.2.4.1 Group IV Ligands

25.2.4.1.1 Cyanide ligands

Indium(III) cyanide is best prepared from InOI and cyanogen, although other methods have been described.[52] An ammonia adduct of $In(CN)_3$ may be formed in the reaction between $Hg(CN)_2$ and indium metal in liquid ammonia, but no other derivatives have been reported.

The efficient extraction of indium from aqueous hydrocyanic acid by long-chain amines implies the formation of anionic In^{III}/CN^- complexes,[53] but no stability constant results are available.[9] Organoindium cyanides have been prepared by reacting Me_3M (M = Ga, In) with Me_3GeCN, eliminating Me_4Ge and forming $[Me_2MCH]_4$[54] to give a structure believed to involve In—C≡N—In bridges.

25.2.4.1.2 Silicon, germanium and tin ligands

The reaction of $InCl_3$ with Me_3SiCl and lithium metal in THF at −30 °C yielded $(Me_3Si)_3In$; NMR and vibrational spectra, and vibrational force constants, have been reported.[55] Indium metal reacts with $(Et_3Ge)_2Hg$ over several days at 50–60 °C to form $(Et_3Ge)_3In$ in 50% yield,[56] and this molecule presumably resembles $(Me_3Si)_3In$ in having a trigonal planar InM'_3 kernel (M′ = Si, Ge). Analogous $In(SnR_3)_3$ compounds have not been prepared to date, but the reaction of $LiSnMe_3$ with Me_3In at low temperature has been shown by NMR methods to produce $Li[Me_3SnInMe_3]$ (*cf.* Al, Ga, Tl), which could not be isolated because of decomposition at room temperature (75% after 2 d).[57] Solutions of InX in toluene/TMEDA[58] do not react with Sn_2Ph_6 (see Section 25.2.4.5.2), but with Ph_3SnX the products are Ph_3SnInX_2·TMEDA (X = Cl, Br, I), in which indium is apparently five-coordinate with an $InSnX_3N_2$ kernel;[59] the anionic complex $Ph_3SnInX_3^-$ has also been prepared by treating such a molecule with R_4NX. The compound $L_2InSnPh_3$ (L = 2-[(dimethylamino)methyl]phenyl ligand) has been prepared[60] from L_2InCl and $NaSnPh_3$, so that a number of In—Sn bonded species are now known.

25.2.4.2 Nitrogen Ligands

25.2.4.2.1 Ammonia and amine ligands

The $[In(NH_3)_6]^{3+}$ cation has been identified in liquid ammonia solution,[61] but attempts to prepare the perchlorate salt were unsuccessful.[62] Mixed complexes such as $[In(NH_3)_5Br]^{2+}$ have been postulated in liquid ammonia,[63] but this has not been confirmed preparatively. Ethylenediamine yields the salt $[Inen_3](ClO_4)_3$ on reaction with $In(ClO_4)_{3(aq)}$ in ethanol,[62] and the analogous nitrate[64] and thiocyanate[65] salts have also been prepared.

Adducts of indium(III) halides or pseudohalides with ammonia have not been reported,[5] which is surprising given that the corresponding Me_3In compounds are known.[66] A number of amine adducts of InX_3 have been reported,[5,7] with stoichiometries InX_3L, InX_3L_2 or InX_3L_3, but structural information is scant; vibrational spectroscopy suggests that InX_3L species probably have D_{3h} symmetry. Adducts of the related bidentate nitrogen donors such as en or TMEDA have not been widely studied, which is unfortunate since here as with bidentate heterocyclic ligands, the question of the balance between neutral and ionic structures is interesting. For example, $InCl_3$/en gives rise[67] to $[Inen_3]Cl_3$ which on heating goes to $[Inen_2Cl_2]Cl$, with no neutral adducts known. With pyrazine, the adduct $InCl_3·L_{1.5}$ is polymeric, with bridging pyrazine and six-coordination at indium.[68] Similar problems have been identified with the corresponding adducts of indium thiocyanate (see Section 25.2.4.2.2). Earlier publications[5,7,8] have listed the adducts formed by inorganic and organic indium(III) species; recent information includes the structures of the compounds $EtInX_2$·TMEDA (X = Br, I) which are five-coordinate neutral mononuclear molecules in both solid and solution.[69]

Little work has been published on hydrazine adducts; the reported compounds $InCl_3·3N_2H_4$ and $InI_3·3N_2H_4$ presumably involve monodentate coordination of the ligand.[70]

25.2.4.2.2 N-heterocyclic ligands

Cationic indium(III) complexes could not be prepared with pyridine, but species such as $[In(bipy)_3]^{3+}$ and $[In(phen)_3]^{3+}$ are known as the perchlorate[62] or nitrate[64] salts, and $[In(terpy)_2](ClO_4)_3$ has also been reported.[67] Stability constants have been measured in the In^{3+}/bipy and In^{3+}/phen systems[71,72] and for some substituted pyridines.[9] The adducts of indium(III) halides and pseudohalides with pyridine and substituted pyridines have been

reviewed previously.[5,7] The stoichiometries of the primary products are either InX_3L_3 or InX_3L_2, but thermal decomposition[73] can lead to loss of ligand yielding InX_3L_2 or InX_3L, depending on X and L (X = Cl, Br, I).

The interaction of ligands such as bipy or phen with InX_3 (X = Cl, Br, I, NCS, NCO) produces either the salts $[InL_3]X_3$[74] or compounds of stoichiometry $InX_3L_{1.5}$.[65,75,76] The structures of these latter have been the subject of several investigations, which have been reviewed previously.[7] In essence, the preparation[77] of salts such as PhAs[$InCl_4$(bipy)] and $[InCl_2(bipy)_2]PF_6 \cdot H_2O$, and the spectroscopic proof that such cationic and anionic indium species exist in solid $InCl_3 \cdot bipy_{1.5}$, have led to the formulation of the latter as the ionic dimer *cis*-$[InCl_2(bipy)]^+[InCl_4(bipy)]^-$ and it seems reasonable to generalize this conclusion to cover other $InX_3 \cdot L_{1.5}$ complexes. The reasons for the existence of these or similar structures, which are to be found in the chemistry of other M^{III} states (*e.g.* Ga, Tl, Ti), is clearly a subject for speculation, but in the absence of crystallographic and thermochemical data no useful arguments can be advanced at present. In addition to the neutral inorganic adducts discussed above, a number of compounds are known involving bipy and/or phen and organometallic compounds,[8] carboxylates and thiolene complexes (see Sections 25.2.4.4.5 and 25.2.4.5.2).

The compounds InX_3(terpy) (X = Cl, Br, I, NCS) are non-ionic,[78] and X-ray[79] studies have confirmed the $InCl_3N_3$ core for X = Cl.

25.2.4.2.3 Amido and imido ligands

The direct reaction of $InCl_3$ with $LiN(SiMe_3)_2$ gives $In[N(SiMe_3)_2]_3$, which is monomeric and has a planar InN_3 kernel;[80] an adduct with Me_3PO has been reported.[81] The established route to amido–indium species is *via* the thermal decomposition of $R'_3In \cdot NR_3$ adducts,[66,82] and in the case of $(Me_2InNMe_2)_2$, a crystal structure determination[83] has confirmed the presence of the In_2N_2 ring, which is also found in $[Me_2InN(Me)Ph]_2$. The isomerization of this compound has been studied in solution.[84] The product obtained from the reaction of $Me_2C{=}NCl$ and Me_3In, namely $[Me_2C{=}NInMe_2]_2$, has a similar In_2N_2 core,[85] being dimeric in both solution (benzene) and solid states. Given the detailed studies of such derivatives of the lighter group III elements, the information here is surprisingly sparse.

25.2.4.2.4 Azide, cyanate, thiocyanate and selenocyanate ligands

Neither neutral nor anionic inorganic azido complexes have been reported, but the organometallics R_2InN_3 are known. Reaction of Et_3In with ClN_3 gives $(Et_2InN_3)_2$, for which a structure based on the In_2N_2 core is proposed,[86] while with Me_3SiN_3 the product is $Me_3SiN_3InMe_3$ which on heating[87] goes to $(Me_2InN_2)_3$. The In_2N_2 bridging is obviously similar to that just discussed (Section 25.2.4.2.3), and the chemistry of such rings should prove interesting.

The parent compound $In(NCO)_3$ has not been isolated, since the reaction between $In_2(SO_4)_3$ and $Ba(NCO)_2$ gave only hydrolysis products, while reactions in alcoholic media between InI_3 and AgCNO produced AgI and an insoluble product which decomposed on heating to give an alkyl urethane derived from the solvent.[76] When adducts of InI_3 were used, the products were the corresponding $In(NCO)_3L_3$ (L = py, DMSO, Ph_3PO), $In(NCO)_3L_2$ (L = Ph_3PO) or $In(NCO)_3L_{1.5}$ (L = bipy, phen). Compounds with different stoichiometries (*e.g.* $In(NCO)_3py_2$, $In(NCO)_3$phen, $In(NCO)_3phen_3$, $In(NCO)_3bipy_3$) have also been reported.[88] The only anionic complex is $[In(NCO)_4]^-$, as the Me_4N^+ salt, and here both terminal and bridging ligands have been postulated on the basis of the vibrational spectrum.[88]

Indium(III) thiocyanate can be prepared by treating $In(CN)_3$ with sulfur,[52] from indium metal and $Hg(NCS)_2$,[52] from $InCl_3 + NaNCS$ in ethanol,[52] or from $In_2(SO_4)_3 + Ba(NCS)_2$ in water.[65] The evidence from IR[65] and X-ray[52] results is that the solid state involves extensive In—NCS—In bridging, with six-coordinate indium. Adducts[65] with both monodentate (py, picoline, urea, DMSO, DMA, Ph_3PO, thiourea) and bidentate (bipy, phen, en) ligands are easily prepared. The monodentate ligand adducts are all of the type $In(NCS)_3L_3$, with the N bonding of thiocyanate shown by IR spectroscopy, while with bipy and phen, $In(NCS)_3L_{1.5}$ compounds are obtained; following the discussion above (Section 25.2.4.2.2), these are formulated as $[InL_2(NCS)_2][InL(NCS)_4]$. With en, the product is $[Inen_3](NCS)_3$, believed to involve the six-coordinate cationic complex described previously (see Section 25.2.4.2.1).

Organoindium thiocyanate derivatives do not appear to have been reported. The results of stability constant measurements for In^{3+}/NCS^- have been reviewed; the recommended values are similar to those for In^{3+}/Cl^- systems.[9]

The anionic thiocyanato complexes prepared[83,84] from $In(NCS)_3$ and different organic cations may be either $[In(NCS)_5]^{2-}$ or $[In(NCS)_6]^{3-}$, apparently depending on the properties of the cation. A subsequent X-ray structural investigation of $(Ph_4As)_3[In(NCS)_6]$ confirmed the N-bonding mode of the ligand, and the presence of an octahedral InN_6 kernel.[91]

A number of selenocyanate compounds formulated as the adducts $In(NCSe)_3L_n$ have been reported[5,92] with L = py ($n = 4$), DMF ($n = 3.5$), Pr_3PO ($n = 3$) and diantipyrylmethane ($n = 2$), but no structural details are available. The compounds $In(NCSe)_3L_3$ (L = bipy, phen) may well be salts of InL_3^{3+} and $NCSe^-$, while the anionic complexes $[In(NCSe)_6]^{3-}$ are reported to involve an N-bonded ligand and six-coordinate indium.[93,94]

25.2.4.2.5 Nitrile ligands

Surprisingly little work has been reported on nitrile derivatives of indium(III), and the neutral adduct $InCl_3 \cdot 2MeCN$ appears to be the only compound of its type subjected to spectroscopic investigation;[95] it seems reasonable to suppose that other such adducts of inorganic and organometallic indium(III) species could be obtained. Neutral adducts of InX_3 have been prepared by the direct electrochemical oxidation of indium metal, giving InX_3L_n (X = Cl, Br, $n = 3$; X = I, $n = 2$),[96] and with mixtures of MeCN and HBF_4/Et_2O the same method gave $[In(NCMe)_6](BF_4)_3$, the salt of a six-coordinate cationic complex.[97]

25.2.4.3 Phosphorus and Arsenic Ligands

The four-coordinate cationic complexes $[InL_4]^{3+}$ (L = Ph_3P, Ph_3As) and $[In(diphos)_2]^{3+}$ were prepared as the perchlorate salts,[62] but could not be obtained from nitrate media.[64] The change in coordination number between nitrogen ligands and the heavier analogues is striking.

Adducts of trialkyl- or triaryl-phosphines, triphenylarsine and diphosphines and diarsines[5,7] with indium trihalides are well known. The structures of $InCl_3 \cdot 2R_3P$ compounds have been generally shown to be trigonal bipyramidal with axial phosphines, and this has been confirmed by X-ray methods in the case of $InCl_3(Ph_3P)_2$.[98] With $InBr_3$ and InI_3, both InX_3L_2 and InX_3L compounds are known as monodentate donors, and interconversion by loss of ligands is often facile.[79] These halides also form 1:1 adducts with diphos, unlike indium trichloride,[5] although the latter does interact with diars to give a compound formulated as $[InCl_2(diars)_2][InCl_4]$.[99] Further crystal structure studies of these compounds would be helpful. Adducts of these group V donors with indium(III) pseudohalides are not known. An interesting reaction of coordinated Ph_3P is the *in situ* oxidation to Ph_3PO to give the Ph_3PO adduct of InX_3,[75] which occurs even in the absence of air; it appears that oxygen is abstracted from the solvent, so that the choice of solvent for the preparation of adducts may be critical.

Adducts of phosphorus and arsenic ligands with organoindium compounds have been reviewed elsewhere.[8] As with the amino derivatives (Section 25.2.4.2.3), one of the important reactions of these compounds involves alkane elimination. In the case of $Me_3In \cdot PH_3$, the product of thermal decomposition is the polymeric $(MeInPH)_n$,[100] while with Me_2PH, Et_2PH or Me_2AsH adducts of Me_3In, the decomposition products are polymeric glasses,[101] which can be sublimed, unlike the compounds derived from $PhPH_2$, $MeAsH_2$ or $PhAsH_2$. With Me_3In and $SbEt_3$ the 1:1 adduct is thermally unstable both to dissociation and decomposition,[102] finally yielding InSb. This route to InM (M = P, As, Sb) compounds is of considerable importance to the electronics industry.

25.2.4.4 Oxygen Ligands

25.2.4.4.1 Oxide, hydroxide and water as ligands

The earlier discussion of complexes of indium(III) with nitrogen ligands emphasized the importance of six-coordination, and in keeping with this, ^1H and ^{115}In NMR studies have identified $[In(H_2O)_6]^{3+}$ as the cation in aqueous solutions of perchloric acid.[103,104] Confirmatory evidence has been obtained from dilatometric[105] and X-ray diffraction[106] methods. Proton

NMR has also been used to demonstrate rapid exchange between coordinated water molecules and the bulk phase,[107] and to show the existence of appropriate mixtures of $[In(H_2O)_6]^{3+}$, $[InL_6]^{3+}$ and $[In(H_2O)_nL_{6-n}]^{3+}$ for L = DMF,[108] acetone,[109] trimethyl phosphate,[110] and also in trimethyl phosphate/acetone/water.[110]

Hydrolysis of the $In^{3+}(aq)$ ion to hydroxy species occurs readily[111] when the pH of the aqueous solution drops below ~3.0, and since the redissolution of any precipitated material may be slow[112] it is important to consider briefly the quantitative aspects of this problem. The first step in the hydrolysis of $In^{3+}(aq)$ is best represented as by equation (1) for which $-\log {}^*K_{1,1} = 4.42 \pm 0.05$ (3 M $NaClO_4$, $\log K_w = -14.22$). The values for ${}^*K_{1,2}$ *etc.* are still uncertain. Enthalpy and entropy changes for equation (1) have also been reported. Polymeric core-linked species generalized as $[In_{n+1}(OH)]^{(n+1)+}$ are believed to form as hydrolysis proceeds, with $In(OH)_3$ as the final product.[9,113,114] The ReO_3 solid state structure of $In(OH)_3$ is distorted by hydrogen bonding between OH ligands of the $M(OH)_6$ octahedra.[115,117] The solubility of the latter in water leads to $K_{sp} = -36.92 \pm 0.01$, although aging of the precipitate is a significant factor.[118] The substance is reported to be soluble in conc. aq. caustic soda, but the nature of the solute species is uncertain. Both $H_2InO_3^-$ and $In(OH)_4^-$ have been proposed[119,120] for the range up to ~1 M NaOH, but at higher OH^- concentrations the solubility of $In(OH)_3$ goes through a maximum (at 11.3 M) above which the solid phase[121] is hydrated $M_3[In(OH)_6]$ (M = Na, Rb). Further study of this topic would seem appropriate. When $In(OH)_3$ is heated with water at high pressure,[122] the product is In(O)OH, which has a deformed rutile structure.[123] The analogous InOX solids (X = F, Cl, Br, I)[1] have been prepared and the lattice parameters tabulated.[124] The possible existence of the related organoindium compounds $(Me_2In)_2O$, MeInO and $(Ph_2In)_2O$ has been discussed elsewhere.[8]

$$In^{3+}(aq) + H_2O \rightarrow In(OH)^{2+} + H^+ \quad (1)$$

Basic species involving both OH^- and halide ligand have been identified in the solid state and in solution. The best defined solution species is $[In(OH)Cl]^+$ for which stability constants have been reported,[9] while the solids[125] include $In(OH)_{1.5}Cl_{1.5}$ and $In(OH)_{1.75}Cl_{1.25}$. No structural work has been reported for these, but the analogous $In(OH)F_2$ has a distorted ReO_3 structure,[126] with octahedral In coordinated by four F and two OH, and this appears to provide a reasonable model for the chlorohydroxo species.

25.2.4.4.2 Alkoxide ligands

Indium(III) alkoxides are readily prepared by the treatment of trihalide with NaOR.[127] The chemistry of these compounds has been little studied, no doubt because they are insoluble materials in which the indium atom optimizes its coordination number by cross-linking *via* oxygen. The isopropoxides of aluminum and gallium react[128] with $In(OPr^i)_3$ to give $In[M(OPr^i)_4]_3$ (M = Al, Ga) which are volatile and monomeric in solution. The structure involves six-coordination at the smaller metal centre.

A number of organometallic alkoxides have been reported. The reaction of In with MeOH gives Me_2InOMe as a glassy polymeric solid, while Bu^tOH gives the dimeric $(Me_2InOBu^t)_2$;[66] with $(CF_3)_2CO$ the product[129] is the analogous $Me_2InOC(Me)(CF_3)_2$. The related compounds $[Me_2InOMMe_3]$ (M = C, Si) are obtained from $Me_3In{\cdot}OEt_2$ and Me_3MOH; the dimeric structure is believed to be based on a four-membered In_2O_2 ring,[130] similar to the In_2N_2 rings discussed earlier (Section 25.2.4.2.3). No structural details are available for the compound $K[Me_2In(OSiMe_3)_2]$, but analogous Al and Ga compounds are known.[131]

25.2.4.4.3 β-Ketoenolates and related ligands

Indium tris(pentane-1,2-dionate), $In(acac)_3$, was first prepared[132] in 1921 by the reaction of Hacac with freshly precipitated $In(OH)_3$, and this remains the essence of later preparations of related compounds, which include derivatives of dibenzoylmethane,[133] fluoro-4-6-octanedione,[134] and various $RCOCH_2COCF_3$ compounds (R = Me, Ph, naphthyl, thienyl, *etc.*).[135] Extraction into an organic solvent such as chloroform is a useful synthetic step in isolating the reaction product from aqueous solution. A direct route involving the electrochemical oxidation of indium metal in a solution of Hacac in methanol offers the advantage of a one-step synthesis.[136] Related compounds with InO_6 kernels include the tropolonate[137] and 3-oxo-2-methyl-3-pyronate derivatives[30] and it is also worth noting the anionic complex

$[In(tropolonate)_4]^-$, prepared as the Na^+ salt,[138] and apparently representing a rare example of eight-coordinate indium(III).

The IR[139,140] and Raman[141] spectra of $In(acac)_3$ and $In(tta)_3$ have been reported, and the ^1H NMR spectrum of $In(acac)_3$ has been discussed by a number of authors.[142–145] The diamagnetism allows a clear interpretation in terms of delocalized electron density in the OCCCO system, but it is not clear whether this bonding extends to the metal itself. The planarity and the InO_6 kernel implicit in these results have been confirmed by X-ray crystallography.[146,14] The preparation of $X_2In(acac)L$ (X = Cl, Br, I; L = 2py, bipy, phen) was achieved by the unexpected oxidation of InX in refluxing Hacac.[148] The crystal structure of $Cl_2In(acac)bipy$ shows that the molecule involves six-coordinate indium, with *cis* chlorides and an essentially planar acac ligand.[149] Dimethylindium acetylacetonate[66] and the corresponding $Me_2In[OC(R)CHC(CF_3)O]$ compounds[150] are easily prepared by the reaction of Me_3In with the parent diketone. These latter molecules are good acceptors, forming monomeric six-coordinate adducts with bidentate nitrogen and phosphorus donors.

The inter- and intra-molecular kinetic behaviour of $In(acac)_3$ and its analogues have been the subject of considerable study. Isomerization is too rapid to allow identification of the individual species in $In(tfa)_3$ ($tfa = CF_3COCHCOMe^-$) and it has generally been accepted that the mechanism involves a five-coordinate intermediate with one monodentate ligand.[151–155] A similar scheme has been used to explain the rapid ligand exchange between InL_3 and HL ($L = CF_3COCHCOR$),[156] and in exchange between Me_2InL and HL.[150] The kinetic orders and activation energies agree with easy change in the coordination number of indium ($6 \leftrightarrow 5$ and $4 \leftrightarrow 5$), which is a common and important feature of much of the coordination chemistry of this element.

The diketonates of indium(III) are thermodynamically stable complexes in non-aqueous solution,[9] and are sufficiently robust to allow studies of polarographic reduction, which has demonstrated one-electron reduction to the formally indium(II) and indium(I) compounds (see Section 25.2.3.3).[30]

25.2.4.4.4 Oxyanion ligands

Stability constant measurements have demonstrated the presence of indium(III) nitrite complexes in methanol, and the crystalline compound $In(NO_2)_3 \cdot MeOH$ has been isolated.[157]

Indium nitrate can be prepared from $InCl_3$ and N_2O_5;[158,159] the dissolution of indium metal in conc. nitric acid yields $In(NO_3) \cdot xH_2O$ ($x = 3, 4, 5$),[7] which has been used as the source of cationic and anionic complexes.[64] Salts of $[In(NO_3)_4]^-$ have been reported,[64,160] and Raman studies[161,162] have demonstrated the presence of In/NO_3^- complexes in solution; the stability constant results have been reviewed.[9]

Indium orthophosphate is essentially insoluble in water, but salts of $[In(PO_4)_2]^{3-}$ and $[In_2(PO_4)_4]^{6-}$ have been prepared,[163] and a solution phase complex with the $H_2PO_4^-$ anion has been identified.[164] The coordination chemistry of In^{3+} with the higher phosphates is at present ill defined. Stability constant measurements,[9] and preparative and spectroscopic studies[7] suggest that InO_6 is the central core of the compounds in the solid state. The same appears to be true for the complexes reported for L = fluorophosphate,[165] methylphosphonate,[166] dichlorophosphate,[167] dimethylthiophosphate,[168] diethylthiophosphinate[169,170] and diisopropylmethylphosphonate.[171]

Indium sulfates have been known for many years, and the literature includes a number of references to double salts which may be reformulated as anionic sulfato complexes.[1,2,7] The existence of indium sulfate complexes in solution has been demonstrated.[9] The solid state structures reveal that bridging by sulfate and/or H_2O is important. By analogy with $RbTl(SO_4)_2$, the salt $NH_4In(SO_4)_2$ was reported to involve infinite chains of $[In(SO_4)_2]^-$, with a distorted trigonal prismatic InO_6 kernel,[172] but in $(NH_4)_3In(SO_4)_3$ the infinite chains consist of InO_6 units in which each oxygen is supplied by a different SO_4^{2-} ligand.[173] Three hydrated salts have been studied by X-ray crystallography,[174,175] namely $NH_4In(SO_4)_2 \cdot 4H_2O$, $HIn(SO_4)_2 \cdot 4H_2O$ and $(H_3O)[In(H_2O)_2(SO_4)_2] \cdot 2H_2O$; all are based on *trans*-$In(OH_2)_2O_4$ units which are linked by sulfate groups. The compound $In(OH)SO_4 \cdot 2H_2O$, which crystallizes from aqueous ethanol solution, has bridged octahedral InO_6 kernels.[177] Here, as elsewhere, the importance of six-coordination of indium(III) by oxygen is a predominant feature of the coordination chemistry.

Indium(III) fluorosulfate, which can be prepared from $InCl_3$ and HSO_3F, is a Lewis acid, and

forms both 1:1 and 1:2 adducts.[178] Indium(III) selenate octahydrate, acid salts and double salts are known, as is the case for tellurate and tellurite, but the only available structural information refers to $NH_4In(SeO_4)_2{\cdot}4H_2O$ which resembles the sulfate in having *trans*-$In(OH_2)_2O_4$ coordination at the metal.[179,180]

The weak complexing of indium(III) with chlorate, bromate and iodate has been studied, and stability constants reported, but no preparative work has been done. Perchlorate ion does not complex with indium(III).[9]

25.2.4.4.5 Carboxylate ligands

Beyond the preparation of many $In(O_2CR)_3$ compounds, the carboxylates have been little investigated. Preparation may be *via* the reaction of oxide or hydroxide with the appropriate acid,[1,31,181] or of $InMe_3$ with excess acid;[182] the latter route also yields $Me_2In(O_2CR)$ when smaller quantities of acid are used (see below). The mode of bonding of the carboxylate (mono, bidentate, bridging) in such compounds has not been settled. Indium(III) acetate, which apparently forms a polymeric lattice, acts as a weak acceptor with pyridine to give a 1:1 complex; with ethanediamine the product is the salt $[Inen_3][OAc]_3$, while R_4N^+ salts of OAc^- and ClO_4^- give the unusual $(Me_4N)_3In(OAc)_6$ and $(Et_4N)_3In(OAc)_3(ClO_4)_3$, whose structures have yet to be elucidated. Indium(III) formate forms a weak 1:1 adduct with pyridine.[31] Anhydrous $In(O_2CCF_3)_3$ is also a Lewis acid, forming 1:3 adducts with py, DMSO and DMF.[183] The bipy and phen adducts of $In(OAc)_3$ show an eight-coordinate InO_6N_2 kernel, with bidentate acetate.[184]

Other than the conclusions drawn from vibrational spectroscopy, there is little definitive structural information on these compounds. The X-ray structure of $Cl_2In(O_2CPh){\cdot}2py$, obtained as one of a number of products from the reaction of InCl with dibenzoyl peroxide, reveals the presence of an $InO_2N_2Cl_2$ kernel, with *cis* chloride and *trans* pyridine ligands;[185] the benzoate is formally bidentate. The structures of Me_2InOAc[186] and Et_2InOAc[187] again show that indium is six-coordinate, with the molecules stacked to produce $InC_2O_2(O')_2$ coordination. These compounds are prepared by the reaction of HOAc and R_3In,[31,188] but the $RIn(OAc)_2$ compounds have not been isolated, although Ph_3In in similar conditions yields Ph_2InOR and $PhIn(OR)_2$ depending on the conditions (R = OCMe, OCEt).[189] Another route is *via* the reaction of R_3M (R = Me, Et) with CO_2, when the product is the dimeric $[R_2M(O_2CR)]_2$, in which the carboxylate ligands bridge two metal atoms to give an $In_2O_2C_2$ ring,[190] so that a variety of modes of bonding of carboxylate to indium(III) must be considered.

The polymeric lattice of Me_2InOAc has important consequences for the coordination chemistry of this substance, which acts as an acceptor giving adducts with stoichiometries 1:1 (DMSO, py; en, diphos) or 2:1 (bipy, phen). The en complex is fluxional in solution. The 2:1 adducts are believed to involve the bidentate ligand bridging the metal atoms of a dimeric Me_2InOAc unit.[191] Similarly the reaction of Me_2InOAc with toluene-3,4-dithiol (H_2TDT) eliminates CH_4 in two separate solvent-dependent processes, and the first product is $[MeIn(OAc)HTDT]_2$, again derived from dimeric Me_2InOAc.[192]

The complex $[In(ox)_2(OH_2)_2]^-$ (ox^{2-} = oxalate anion) was postulated[193] as being the anion present in $NH_4[In(ox)_2(OH_2)_2]$, but recent X-ray studies have shown that the lattice has unusual eight-coordinate indium, with four bridging oxalate ligands giving an Archimedean antiprism.[194] Other solid species include $(NH_4)_3[In(ox)_3]$ and $MIn(ox)_2{\cdot}xH_2O$ (M = NH_4, K, Cs; $x = 3$ or 6); the IR spectra suggest that the oxalate is not bidentate, but do not eliminate the possibility that bridging is again important.[195–197] The structure of $[In_2(ox)_3(H_2O)_4]{\cdot}2H_2O$ is based on pentagonal bipyramidal seven-coordinate indium, oxalate-bridged into infinite chains.[198]

25.2.4.4.6 Ether and other oxygen donor ligands

A number of cationic complexes of the type InL_6^{3+} (L = monodentate oxygen donor) have been prepared,[7] and others are identified in solution by NMR studies (see Section 25.2.4.4.1). These are all readily explained as InO_6 species, with O_h symmetry in the core, again demonstrating the importance of this stereochemistry with hard donor ligands. With Ph_3PO, the product is $[InL_4]^{3+}$ and presumably steric interaction between ligands prevents further coordination.[62] The normal preparative route is by substitution of H_2O in a hydrated salt by excess ligand, but a direct electrochemical route to $[In(DMSO)_6](BF_4)_3$ has been reported.[96]

Adducts of the neutral indium trihalides with oxygen donors have been reviewed previously,[5,7] as have the corresponding organoindium adducts.[8] Stoichiometries of InX_3L_3, InX_3L_2 and InX_3L are known, but any detailed discussion is hindered by the lack of structural and thermodynamic information, although application of the cone angle concept of Tolman[199] has been successful in rationalizing some results.[7] A further complication is that some of the supposedly neutral adducts are in fact ionic dimers, so that $InI_3 \cdot 2DMSO$ is actually *cis*-$[InI_2(DMSO)_4][InI_4]$,[200] and here again there is no explanation of the factors which govern the choice of available structures. Mixed halo-aqua cations and anions are discussed below (Section 25.2.4.6).

25.2.4.5 Sulfur and Heavier Group VI Ligands

25.2.4.5.1 Sulfur and selenide ligands

Thioethers form adducts with indium trihalides,[5,7] but not apparently with organoindium compounds;[8] these compounds show the same range of stoichiometry as do the oxygen analogues. Thiourea complexes have also been studied, and cationic, neutral and anionic derivatives are known.[5,7] Indium tris-phenylthiolate $In(SPh)_3$ has recently been prepared from InX_3 and NaSPh, and adducts with neutral donors, and the anionic complexes $[In(SPh)_4]^-$ and $[XIn(SPh)_3]^-$ (X = Cl, Br, I) can be derived from $In(SPh)_3$.[201] There appears to have been no work on selenium analogues of these compounds. Indium(III) thiolate compounds can also be prepared by the oxidative insertion of InX (X = Cl, Br, I) into R_2S_2 (R = Me, Ph), which gives $(R_2S)_2InX$ and subsequently $(R_2S)_2InX \cdot py_2$ and $[(R_2S)_2InX_2]^-$. Selenide derivatives $(PhSe)_2InX \cdot py_2$ can also be synthesized, but Ph_2Te_2 does not react with InX under the conditions used.[58]

Interesting solid state structures are shown by some stoichiometrically simple In–sulfur compounds. Tetrahedral InS_4 is found in $InPS_4$,[202] but in $KInS_8$ both four- and six-coordinate indium are identified.[203] The basic unit in $Rb_6In_2S_6$ and $Rb_4In_2S_5$ is $In_2S_6^{2-}$, isoelectronic with In_4Cl_6, with both bridging and terminal sulfurs and further bridging gives $In_4S_{10}^{4-}$; indium is four-coordinate in each case.[204] The compounds $In_{2.01}X_3$ (X = S, Se, Te) have been formulated as $In^I[In^{III}oct]_2[In^{III}tet]_{73}X_{115}$, with InX_6 sharing edges with distorted InX_4 tetrahedra.[205] Some of these structures might prove useful in synthetic work (see also In_5S_4, Section 25.2.3.4).

25.2.4.5.2 Bidentate sulfur donor ligands

As part of the development of the coordination chemistry of bidentate sulfur ligands, studies of the appropriate indium(III) complexes have been reported. The In—S_6 analogue of $In(acac)_3$ has not been prepared[7], but a number of related neutral InL_3 chelates are known for L = dithiobenzoate,[206] dithiophenylacetate,[206] diphenyldithioarsenate,[207] *O,O*-diethyldithiophosphate,[208] pentamethylenedithiocarbamate,[209,210] trithiocarbonate and alkyl xanthates.[211,212] The InS_6 kernel has been confirmed by X-ray crystallography; both distorted octahedral[208,212] and trigonal prismatic[210] stereochemistries have been identified, but no doubt the bite of the ligand is a dominant factor. In $In(dithizonate)_3$, indium is five-coordinate (trigonal bipyramidal), with two bidentate and one monodentate ligand.[213] The only analogous In—Se_6 species is the tris-*O,O*-diethyldiselenophosphate complex.[214]

Complexes with anionic dithiolene ligands are prepared by the reaction of $InCl_3$ with the sodium salt of the appropriate ligand, such as MNT^{2-} (= maleonitriledithiolate), TDT^{2-} (= toluene-3,4-dithiolate) or *i*-MNT^{2-} (= 1,1-dicyanoethylene-2,2-dithiolate). The product anions show a range of In—S coordination numbers, from four ($[In(MNT)_2]^-$, $[In(TDT)_2]^-$ to six ($[In(MNT)_3]^{3-}$, $[In(i\text{-}MNT)_3^{3-}]$); the four-coordinate species readily give rise to six-coordinate adducts such as $[In(TDT)_2bipy]^-$. With *i*-MNT^{2-}, no four-coordinate anions were obtained, but $[In(i\text{-}MNT)_2X]^{2-}$ anions (X = Cl, Br, I) were prepared.[32,215] The reduction of these anions was discussed earlier (Section 25.2.3.4). The crystal structure of $(Et_4N)_3[In(MNT)_3]$ established the planarity of the InS_2C_2 ring system, and the distorted octahedral symmetry of the InS_6 kernel.[215,216] 1,2-Ethanediol (H_2EDT) gives the analogous $Et_4N[In(EDT)_2]$, but no six-coordinate species,[217] and the five-coordinate anion $[In(MNT)_2Cl]^-$ can be obtained from aqueous solution;[218] the structure of this anion is intermediate between trigonal bipyramidal and square-based pyramidal.[219]

The reaction of InX (X = Cl, Br, I) with 1,2-bis(trifluoromethyl)dithiete in non-aqueous solution[220] proceeds by insertion of indium into the S—S bond of the dithiete to give polymeric products containing an InS_2C_2 ring. Monomeric derivatives can be obtained by treatment with neutral donors to give adducts formulated as $[InL(DMSO)_4]X$ or $[InL(bipy)_2][InL_2bipy]$ ($L = (CF_3)_2C_2S_2^{2-}$). Similar reactions occur when the dithiete reacts with cyclopentadienylindium,[221] although in this case the neutral adducts are of the type CpInL·bipy. Another route to In—S coordination compounds involves alkane elimination,[222] so that Me_3In reacts with H_2TDT to give polymeric $[MeIn(TDT)]_2$ from which adducts can be obtained in the usual way.

25.2.4.6 Halogen Ligands

25.2.4.6.1 Fluoride ligands

Anhydrous indium trifluoride[223] is an insoluble substance whose lattice involves six-coordinate indium(III).[224] The hydrate $InF_3·3H_2O$ is soluble in water,[225] but insoluble in common organic solvents. The structure has been reported to be based on InF_3O_3 octahedra,[226] but a later study showed sharing of apical H_2O between InF_4O_2 units, with the third H_2O in the lattice.[227] The hydrate is a rare example of an InF_3 adduct.[5] A series of ammonia adducts is known, with 1:1 and 1:3 stoichiometries;[228–230] the 1:1 adduct decomposes on heating to InN.[229] Mixed hydrazine/water adducts have also been prepared,[231] but have been formulated as salts (see below).

Earlier information on the preparation of anionic fluoro complexes from aqueous solutions or in high temperature phases has been reviewed elsewhere.[6,7] Stoichiometries corresponding to $MInF_4$, M_2InF_5 and M_3InF_6 have all been reported, as have the more unusual KIn_2F_7, $K_5In_5F_{14}$[232] and $Rb_2In_3F_{11}$.[233] Early X-ray studies[7] which identified octahedrally coordinated indium in K_3InF_6 and $(NH_4)_2InF_6$ have been confirmed by single crystal work[234] on $Cs_2Na[InF_6]$. Vibrational spectra also confirm this stereochemistry in other InF_6^{3-} salts, and it has been suggested that $MInF_4$ and M_2InF_5 consist of metal ions and InF_6 octahedra sharing edges.[235] In $Rb_2In_3F_{11}$, the $In_3F_{11}^{2-}$ anion has a distorted octahedral InF_6 bridging two pentagonal bipyramidal InF_5 units.[233]

Given the structure of $InF_3·3H_2O$ (see above) and the tendency of indium(III) to be six-coordinate with hard ligands, it is reasonable that the mixed fluoro/aqua anionic complexes should also be $[InF_4(H_2O)_2]^-$ and $[InF_5(H_2O)]^{2-}$. This is compatible with the evidence from aqueous solution chemistry, where stability constants and thermochemical results indicate a series of $[In(H_2O)_{6-n}F_n]^{(3-n)+}$ species.[9] These complexes still await detailed systematic structural investigation.

25.2.4.6.2 Chloride, bromide and iodide ligands

Crystalline indium trihalides are readily prepared from the reaction of the metal and halogen[9] (sometimes in the presence of solvent), from metal + HX, or by the electrochemical oxidation of the metal in a non-aqueous solution of X_2.[20] Indium trichloride and tribromide have indium octahedrally coordinated by halide in the solid state, whereas the triiodide exists as the dimer $I_2InI_2InI_2$ in the solid or in solution; all three halides are dimeric in the vapor phase.[9] The many adducts of these compounds with neutral donors have been extensively reviewed previously.[5,7]

The dominant ion in the mass spectrum of the trihalides[236] is InX_2^+, isoelectronic with CdX_2, and the corresponding organoindium cation $InMe_2^+$ has been identified in solution[237] and in the solid state,[238] and there is also evidence for Ph_2In^+.[239] The symmetry of these R_2M^+ ions and their tendency to go to higher coordinate species have been discussed elsewhere.[8] The existence of cationic complexes such as $[InI_2(DMSO)_4]^+$ and $[InX_2bipy_2]^+$ has been noted earlier (Sections 25.2.4.2.2 and 25.2.4.4.5).

Anionic complexes have been known, if not recognized, for many years as mixed salts of both inorganic and organic cations.[7] In particular, Ekeley and Potratz[240] identified the stoichiometries $CInX_4$, C_2InX_5, C_3InX_6 and C_4InX_7. The role of cation size, solution conditions and ligand properties in determining the coordination number of indium in such anions has been discussed earlier.[7,241,242] It is now clear that with X = I, the only anionic complex is the

tetrahedral InI_4^-,[34,38,199] and at the opposite end of the scale that the crystalline C_4InX_7 compounds involve lattices of $4C^+ + InX_5^{3-} + X^-$ in which InX_6^{3-} (X = Cl, Br) is the octahedral complex,[243,244] also found in $(Me_3NH)_3InCl_6$[245] and in $Cs_2In^I[InCl_6]$.[246] The remaining InX_4^- anions are also tetrahedral in both solid state[247,248] and in non-aqueous solution.[249–251] The detailed symmetry of InX_5^{2-} has been a matter of discussion, but the description as a square-based pyramid will serve for most purposes.[252,253] Compounds of stoichiometry C_2InBr_5 appear to be based on a lattice of $2C^+ + InBr_4^- + Br^-$.[17,242] A meaningful treatment of the interrelationships between these anions is lacking.

The aqueous solution chemistry of indium(III)–halide species has been discussed on the basis of a scheme[9] involving the successive substitution of H_2O by X^- in $[In(H_2O)_6]^{3+}$, in keeping with the evidence on aqua/halogeno species (see below). Raman spectroscopy has supported this model for X = Cl.[254] A second type of coordination equilibria involves the formation of InX_4^- species in aqueous solution from $[InX_4(H_2O)_2]^-$, and appears to be favoured in the order I > Br > Cl[255] (see ref. 9 for a full discussion of this). Changes in the coordination number of indium(III) species in solution have been noted at several points elsewhere in this review, and clearly also play an important part in the chemistry of these halide complexes. The $InCl_5^{2-}/InCl_4^-$ equilibrium has been studied in non-aqueous solution,[256] and other examples have been reported.[241] The aqueous phase substitution scheme is supported by the existence of the anions *cis*-$[InX_4(H_2O)_2]^-$ (X = Cl, Br) and $[InCl_5(H_2O)]^-$, which are known from X-ray studies to be six-coordinate;[257–259] other similar mixed complexes known include $[InCl_4L_2]^-$ (L = urea, thiourea)[260] and $[InCl_4bipy]^-$ (see Section 25.2.4.2.2). Spectroscopic studies of the aqua/halogeno anions have been reported.[261,262]

25.2.4.6.3 Mixed halide ligands

The existence of the mixed halide complexes $InX_{4-n}Y_n^-$ in non-aqueous solution was demonstrated by ^{115}In NMR work for the whole range of $X \neq Y = Cl$, Br, I, and the InX_2YZ^- anions were also identified.[50] The $InX_2Y_2^-$ anions can be prepared by the oxidation of InX_2^- by halogen Y_2, and InX_3Y^- from $In_3X_6^{2-} + Y_2$; detailed vibrational spectral analysis[263] and X-ray analysis of $InCl_3Br^-$ and $InBr_3Cl^-$ confirm the C_{3v} stereochemistry of these anions.[248] Organohalide anions have been reviewed elsewhere.[8]

25.2.4.7 Hydrogen and Hydride Ligands

25.2.4.7.1 Hydride ligands

There is no evidence to support the existence of neutral monomeric InH_3, although an unstable $(InH_3)_n$ is reported to be formed by the decomposition of $LiInH_4$, itself formed by treating $InBr_3$ with LiH ether.[1] No structural information is available. Trimethylindium reacts with MH (M = Li, Na, K) to give the unstable MMe_3InH, and MR_3InH (R = Me, Et) and $NaEt_2InH_2$ have also been described, but again decomposition has barred further work.[8]

25.2.4.7.2 Borohydride and related ligands

Trimethylindium and B_2H_6 yield a solution of $In(BH_4)_3$, which can be obtained as the THF adduct, which decomposes *in vacuo*. The aluminohydride analogue $In(AlH_4)_3$ is even more unstable,[1] and there seems to be little chance of extending the chemistry of indium(III)–hydrido systems.

25.2.4.8 Mixed Donor Atom Ligands

The largest group of mixed donor atom complexes is the tris chelates, of which $In(oxine)_3$ (oxine = 8-hydroxyquinolate) is typical. A number of spectroscopic studies have shown that such compounds contain InO_3N_3 kernels. The analogous InS_3N_3 compounds, such as the 8-mercaptoquinolate, have been used in analytical work and derivatives of monothiodibenzoylmethane are known.[8] Organoindium compounds with such ligands, and others, have been

discussed elsewhere.[8] The structure of $(Ph_4As)_4[In_2(dto)_5]$ (dto = 1,2-dithiooxalate) has one dto ligand bonded to both indium atoms, while others act as bidentate (S_2) ligands to give InS_5O coordination.[264] Another important group of complexes, involving ethylenediaminetetraacetic acid and its analogues, has been extensively studied in solution, and thermodynamic results are available,[9] but the general coordination chemistry of these compounds adds little to what has been discussed previously.

25.2.4.9 Macrocyclic Ligands

The reaction of InX_3 (X = Cl, Br, I) with 18-crown-6 (= L) (*cf.* Section 25.2.2.5) yields In_2X_6L compounds, whose structure is written as $[InX_2L][InX_4]$ on the basis of vibrational spectroscopy.[22] The cation is believed to be involved in *trans*-X_2InL coordination. The corresponding cyclam compounds were also prepared, but the structure of the cations in such molecules is in doubt, since reaction may have occurred at the ring nitrogen atoms.

A series of earlier papers on complexes of indium(III) with porphyrins,[265] and phthalocyanines[266–268] has been summarized earlier.[7] The structures InLX (L = substituted porphyrin; X = Cl, OAc, OPh) imply a square pyramidal stereochemistry with the indium atom situated above the ligand N_4 system, and this has been confirmed by X-ray crystallography for X = Cl[269] and X = Me,[270] but for $X = MeOSO_2$, the indium atom is in the plane of the four nitrogen atoms.[271] A number of Schiff base derivatives have recently been described.[272]

25.2.5 THALLIUM: INTRODUCTION

As with indium, the literature contains a number of surveys of the general inorganic[1] and organometallic chemistry of thallium,[273] and the reviews of this element already cited are also concerned with the adducts of the halides and pseudohalides,[5] and with other aspects of the coordination chemistry.[6] A monograph by Lee provides a most useful treatment of the literature up to 1970.[274] The application of thallium compounds in organic synthesis has been discussed.[275,276]

25.2.6 THALLIUM(I)

One of the classical properties of the main group elements is that the stability of the lower oxidation states increases with atomic number, and the chemistry of thallium is a good example of this effect. In aqueous solution, the Tl^+ ion is stable with respect to oxidation by the solvent and there is accordingly an extensive chemistry of this oxidation state. The similarities between Tl^+ and the corresponding alkali metal cations have resulted in much interest in the use of this ion as a probe in biochemical systems, and the ease with which ^{205}Tl NMR spectra can be recorded has also had an impact on such studies.[277,278]

The similarities between Tl^+ and other M^+ ions have led to the synthesis of many salts and complexes in which Tl^+ serves as a balancing cation, but such compounds will not be included in the present review unless there is some feature of special interest. We may note immediately that the similarity of Tl^+ to, say, K^+ includes poor complexing (*i.e.* weak Lewis acid) behavior in both cases.

25.2.6.1 Group IV Ligands

25.2.6.1.1 Cyanide ligand

The salt TlCN can be prepared by the reaction of thallium(I) acetate and KCN in aqueous solution,[279] but there is no evidence for the formation of cyano complexes in aqueous solution.[280]

25.2.6.1.2 Other Group IV ligands

No compounds containing Tl—MR bonds are known for M = Si, Ge, Sn or Pb, which presumably reflects the dominant ionic character of Tl^+. By way of illustration of this, attempts

to displace mercury from $Hg[Ge(C_6F_5)_2]_2$ by reaction with Tl^0 yielded the compound $Tl[Hg\{Ge(C_6H_5)_3\}_3]$ containing the Tl^+ cation.[281]

It is appropriate to note here some remarkable compounds formed by tin and thallium, although these are not formally thallium(I) compounds. Treatment of the alloy $NaSnTl_{1.5}$ with ethylenediamine gives $Na_5en_2(TlSn_8)$, containing the $TlSn_8^{5-}$ anion for which a *nido* structure is proposed.[282] Similarly, the reaction of KTlSn with en and [2.2.2]cryptate yields $([2.2.2]crypt\text{-}K^+)_3(TlSn_8^{3-}—TlSn_8^{3-})0.5en$, in which the *closo* cluster anions have bicapped square antiprismatic and tricapped trigonal prismatic structures respectively.[283] The existence of such molecules suggests that other Tl—Sn-bonded species might exist.

25.2.6.2 Nitrogen Ligands

Given that the low polarizing power of the Tl^+ ion is similar to that of the heavier alkali metals, it is not surprising that no complexes have been reported with monodentate nitrogen donors such as ammonia. Thallium(I) hydroxide reacts with imidazole (RH) to give TlR, which is apparently a homopolymer linked by covalent Tl—N bonds, rather than a salt,[284] but in the benzotriazole derivative,[285] Tl^+ ions are well separated by the anions, with a distorted trigonal prismatic arrangement of six nitrogen atoms at distances ranging from 2.725 to 3.721 Å. Other than this, there appear to be no monodentate heterocyclic ligand derivatives. The bidentate heterocyclic donors phen and bipy form TlL_2^+ cations, identified as either nitrate or perchlorate salts, and the spectroscopic properties suggest a pseudotetrahedral TlN_4 coordination.[286] The extra stabilization inherent in chelate formation is clearly important here, and in the case of macrocyclic ligands (see Section 25.2.6.7).

Thallium(I) nitride is a highly explosive black solid,[1] but the yellow azide TlN_3 is more stable; the physical properties suggest that there is some covalent Tl—N bonding in the solid state. The mechanism of the decomposition has been reviewed.[287]

The pseudohalides and related compounds have been investigated by a number of workers. Thallium(I) cyanate and thiocyanate are both known, and the latter has been shown to be ionic in the solid state;[288] differing values have been reported for the stability constants in the Tl/NCS^- system in aqueous or mixed water/non-aqueous systems, but the overall evidence is that the complexes are extremely weak.[289] The ionic selenocyanate has been reported, but the chemistry has not been investigated.[1]

25.2.6.3 Oxygen Ligands

25.2.6.3.1 Oxide and hydroxide ligands

Thallium(I) oxide, Tl_2O, is a well-characterized compound and a useful source of Tl^+ salts.[1] Matrix isolation studies of the solid gave structural data in agreement with spectroscopic results.[290,291] The so-called peroxide TlO_2 is obtained electrochemically from aqueous Tl_2SO_4, but the properties include insolubility in water, alkali and some dilute acids, and treatment with dilute HCl yields oxygen. The stoichiometry suggests that the compound is in fact a superoxide, and this has been confirmed by spectroscopic studies on frozen matrices.[292,293]

The reaction of $Ba(OH)_2$ and Tl_2SO_4 in oxygen-free aqueous solution yields aqueous thallium(I) hydroxide, but the solid is best obtained from the metal and aqueous ethanol in the presence of oxygen. The yellow crystalline solid yields an alkaline solution. The mixed oxides MTlO (M = K, Rb) have been prepared by heating M_2O and Tl_2O, but these are apparently not thallate(I) species.[294]

25.2.6.3.2 Alkoxide ligands

Thallium(I) ethoxide has been known for many years, and a series of related alkoxides can be prepared by methods which include Tl + ROH, TlOH + ROH and Tl_2O + ROH.[295] The ethoxide,[296] and a number of other TlOR compounds,[297] are tetrameric in solution, and an X-ray crystallographic study of $(TlOMe)_4$ shows that the structure is based on that of cubane,[298] with no Tl—Tl bonding interactions. The bonding in such molecules has been discussed.[299] Phenoxide, and substituted phenoxides, can be prepared from PhOH + TlOH, while reaction

between Me_3Tl and ROH gives Me_2TlOR (R = Et, Ph).[300–302] The Tl—O bond undergoes insertion by CS_2 and SO_2; the products are TlS_2COPh and TlO_2SOPh from TlOPh, while Me_2TlOR gives RSO_3TlMe_2.[301]

25.2.6.3.3 β-Diketonate and related ligands

Thallium(I) β-diketonates have been known for many years,[303] and are readily obtained by treating the appropriate acid with TlOH or Tl_2CO_3.[1,300,302] The dipole moments of Tl(acac), Tl(hfacac) and Tl(dibenzoylmethane) have been measured, and the two latter compounds shown to be monomeric in benzene.[304] The structure of Tl(hfacac) consists of chelated thallium(I) atoms ($r = 2.62$, 2.72 Å) which are 0.42 Å below the ligand O—C—C—C—O plane; chains of dimers then give pentacoordinate Tl^I, in which the presence of the inert pair is deduced.[305] The oxidative reactions of these compounds might prove interesting. The related Tl(oxinate) has been prepared,[302] but the thioxine analogue could not be obtained by standard methods.[306] Some unusual chelate derivatives of thallium(I) and $Me_3CNSi(Me_2)OCMe_3$ have been reported.[307,308]

25.2.6.3.4 Oxyanion ligands

As noted in the introduction, many thallium(I) salts of oxyacids are known. The preparation and properties of these have been reviewed previously.[1] Some recent structural information from X-ray crystallography includes the identification of two different Tl^I sites in Tl_2SO_3, prepared from $Tl_2CO_3 + SO_2$,[309] the demonstration that Tl^I is seven-coordinate in TlH_2PO,[310] but three-coordinate in Tl_6TlO_6,[311] and the proof of the importance of the inert pair effect in Tl_2HPO_4.[312] In $Tl_4P_4O_{12}$, Tl^+ ions are separated by $P_4O_{12}^{4-}$ rings.[313] The vapor phase of Tl_2SO_4 contains molecules of D_2 symmetry.[314] In a different approach, the shielding anisotropy of ^{205}Tl has been used to investigate solid state effects in $TlNO_3$.[315]

25.2.6.3.5 Carboxylate ligands

Many thallium(I) derivatives of carboxylic acids are known, and can be prepared by standard methods.[1] The electronic spectra[300] have been interpreted as indicating a significant covalent metal–ligand interaction, whereas the IR spectra have been taken to show that the compounds are ionic;[316,317] X-ray diffraction studies should help in setting this point. In Tl(ascorbate), the Tl atoms are far apart (4.05 Å) and the homopolymeric lattice involves oxygen bridging between ligands.[318] Thallium(I) carboxylates can act as Lewis acids, as in the formation of Tl(salicylate)-phen, which consists of dimeric units with pentagonal pyramidal TlN_2O_3 kernels, and again well-separated thallium(I) atoms; the inert pair effect is adduced in explaining this structure.[319] The structure of Tl formate in concentrated aqueous solution is found to be a cubane-like tetramer, with Tl—O—Tl and Tl—OCO—Tl bridging.[320]

Oxidation of TlOAc with bromide in acetic acid gives $Tl(OAc)Br_2$,[321] but as with the alkoxides such reactions have apparently not been investigated in detail. Thallium(I) carboxylates have found considerable application in organic synthesis.[274,275,322]

25.2.6.4 Sulfur and Heavier Group VI Ligands

Thallium(I) sulfide, selenide and telluride are all well-established compounds, and in the case of all three elements, binary compounds other than M^I and M^{III} species and double sulfides are also known, as are Tl salts of trithiocarbonate, azidothiocarbonate, *etc.*[1]

A series of dithiocarbamates can be prepared from a mixture of $R_2NH + CS_2 + Tl^+(aq)$ in alkaline solution. The structure of Pr_2NCS_2Tl consists of dimeric units bonded through a TlS_4Tl octahedron, with these dimers interacting to give chains.[323] In Bu_2NCS_2Tl, dimerization and chains are again found, and in this compound there is some evidence of a stereochemically significant inert pair.[324] Other known related compounds include monothiocarbamates, monothioxanthates,[325] xanthates[326] and *O,O*-substituted dithiophosphates. Derivatives of

i-MNT^{2-} (see Section 25.2.8.5.2) such as $Na_4Tl_2(i\text{-}MNT)_3$, $NaTl_3(i\text{-}MNT)_2$ and $Tl_2(i\text{-}MNT)$ are apparently ionic.[327] (See also Section 25.2.8.4).

The analogous selenium and tellurium chemistry has not been explored. The $[Tl_2Te_2]^{2-}$ anion has been obtained by reacting KTlTe with [2.2.2]cryptate in ethylenediamine to give $[K([2.2.2]crypt)]_2^+[Tl_2Te_2]^{2-}$ en, in which the anion is butterfly-shaped with a 50° fold.[328] The assignment of oxidation numbers is somewhat arbitrary in such systems (*cf.* Section 25.2.6.1.2), but it seems clear that thallium is in a low oxidation state.

Thiourea (tu) adducts of thallium(I) salts have been reported with stoichiometries such as TlX·4tu (X = Cl, Br, I, ClO_4, NO_3, NO_2, ClO_3, NCS), TlF·4tu·$2H_2O$, Tl_2CO_3·8tu and Tl_2SO_4·8tu.[329] The crystal structures of the halides show that these compounds are isostructural with the corresponding alkali halide adducts, while in TlX·4tu (X = NO_3, ClO_4) the coordination of sulfur to thallium involves distances [3.43(1) Å] which are greater than the sum of the ionic radii, so that Tl—S bonding is not an important factor.[330] A similar conclusion emerged from crystal structure studies of TlH_2PO_4·4tu and $Tl(C_6H_5CO_2)$·4tu.[331] A series of analogous selenourea (L) compounds TlX·4L (X = Cl, ClO_4, OAc, Br), TlX·3L (X = NCS, NO_3), and Tl_2SO_4·6L have been prepared and their mode of thermal decomposition studied.[332]

25.2.6.5 Halogen Ligands

25.2.6.5.1 Fluoride ligand

The physical properties of the thallium halides have been tabulated.[1] Crystalline TlF has a distorted rock-salt lattice, with two independent thallium sites.[333–335] The thermodynamic properties of the solid have been reassessed.[336] At high temperature, the vapor phase contains TlF and Tl_2F_2 molecules,[337] and matrix isolation studies have demonstrated the presence of both TlF and Tl_2F_2 in the solid; the dimers have linear symmetry.[338]

Stability constant studies show that in aqueous solution the anions TlF_2^-, TlF_3^{2-} and TlF_4^{3-} are formed;[289] some of these may be aquated. Many double salts have been reported,[1] but it seems that thallium is present in these as the Tl^+ cation rather than as $TlF_x^{(x+1)-}$ anionic complexes.

25.2.6.5.2 Chloride, bromide and iodide ligands

The crystal structures of the three heavier thallium(I) halides have been established[333,334] and lattice energies calculated;[339] the inert pair of Tl^+ is apparently insignificant in terms of the stability of the lattice. The enthalpy of hydration of the Tl^+ ion was also derived. Gas phase (TlBr, TlI) and matrix isolation studies (TlCl, TlBr, TlI) have shown that TlX and Tl_2X_2 species are important.[338,340] Complex formation[289] in aqueous solution decreases in the order Cl > Br > I, and as with the fluorides, the double salts show no evidence of anionic complex formation by Tl^I. Finally, it is important to note that TlI_3 is formulated as $Tl^+(I_3^-)$ from X-ray studies.[341,342] Thermal decomposition yields Tl_3I_4, whose structure has not been reported.

25.2.6.6 Hydrogen and Hydride Ligand

Thallium(I) hydride has been identified spectroscopically in the products of an electric discharge in hydrogen at a thallium cathode, or from thallium and atomic hydrogen.[343] An unstable polymeric solid has also been reported.[344] The borohydride $TlBH_4$ can be obtained by reacting Tl^I compounds with $LiBH_4$, and $TlAlH_4$ is formed similarly;[344] the borohydride, which has an ionic lattice, can also be prepared from KBH_4 and aqueous $TlNO_3$.[345]

25.2.6.7 Macrocyclic Ligands

As noted earlier, the similarities between Tl^+ and alkali metal cations have led to the use of the former as a probe in biological studies, including studies with various macrocyclic ligands, especially those with oxygen donor atoms. The thallium(I) cryptates behave kinetically like the potassium compounds,[346] and the binding constants to 18-crown-6 have been measured by ^{205}Tl NMR methods.[347] Several Tl^I compounds with crown ethers (L) have been prepared; in

addition to TlXL compounds, $(TlL_2)X$ species were obtained, and these are formulated as sandwich structures. There is little evidence of an inert pair effect.[348] Strong interactions are detected between the metal and aromatic rings in the dibenzo-18-crown-6 derivative.[349]

25.2.7 THALLIUM(II)

The problems associated with the M^{II} state of the elements of group III have been noted previously (*cf.* Sections 25.1.13 and 25.2.3). The Tl^{2+} ion has been identified in pulse radiolysis decomposition of aqueous Tl_2SO_4,[350,351] and in γ-irradiated frozen aqueous solutions.[352] Thallium(II) has also been invoked as an intermediate in the photochemical reduction of aqueous Tl^{III} solutions,[353,354] but there is dispute as to its involvement in redox reactions.[355,356] It is safe to conclude that there is no equilibrium aqueous phase chemistry of Tl^{2+}.

The compound Tl_4O_3 is a mixed oxide lattice $(3Tl_2O + Tl_2O_3)$,[357] but the sulfide TlS and selenide TlSe can be formulated as mixed Tl^I/Tl^{III} species, with tetrahedral coordination at Tl^{III} in a $(TlS_2)_n$ chain; the Tl^I ions are then eight-coordinate.[358,359] The sulfide Tl_4S_3 consists of tetrahedral TlS_4^{5-} and Tl^+ ions,[360] while the structure of Tl_2S_5 is made up of Tl^+ and S_5^{2-}. The Tl^+ is coordinated by sulfur atoms from the anion to give pyramidal TlS_3 units, with the remaining site at Tl identified as being occupied by the inert pair.[361] There are both Tl—Te and Tl—Tl interactions in Tl_2Te_3 and Tl_5Te_2;[362,363] many of these compounds might be useful starting materials for synthetic work.

A range of subhalides has been reported in phase studies of TlF/TlF_3 mixtures,[364,365] but structural information is lacking. In the chloride system, the aqueous phase reaction of TlCl and $TlCl_3$ gives $Tl[TlCl_4]$, but the product of the analogous reaction in nitric acid is Tl_2Cl_3, whose structure has been identified as $Tl_3[TlCl_6]$, with $TlCl_6^{3-}$ octahedra [r(Tl—Cl) = 2.50–2.65 Å]; the Tl^+ ions are seven-, eight- or nine-coordinate with long (3.06–3.83 Å) Tl—Cl distances.[366] In the $Tl^I/Tl^{III}/Br^-$ system, $Tl[TlBr_4]$ and $Tl_3[TlBr_6]$ have been identified, and the structure of the former is confirmed by X-ray crystallography.[367] A dioxane (diox) adduct has been shown to be $[Tl(diox)][TlBr_4]$, in which the chains of Tl^+ are formed by dioxane bridging to give TlO_8 dodecahedra; the anion is tetrahedral[368] (*cf.* Section 25.2.8.5.2). The compound $Tl(CN)_2$, which has the structure $Tl[Tl(CN)_4]$, provides a further example of mixed oxidation states giving rise to TlX_2 stoichiometry.[1]

In addition to the halide systems there are a number of thallium(I) salts of thallium(III) complex anions in which the overall stoichiometry implies, incorrectly, the presence of thallium(II) species. These include the sulfate, selenate,[369] acetate[370] and oxalate[371] derivatives. An X-ray determination has confirmed that $Tl(OAc)_2$ is indeed $Tl[Tl(OAc)_4]$, in which the anions are linked through seven-coordinate Tl^+, with some evidence for a stereochemically active inert pair.[370] In $Tl[Tl(OH)(SO_4)_2]$, the structure consists of sheets of linked anions with Tl^+ ions.[372]

25.2.8 THALLIUM(III)

The oxidizing properties of thallium(III) in both aqueous and non-aqueous media obviously preclude the existence of a number of compounds analogous to those found for aluminum, gallium and indium in this oxidation state. Thus, while there is much richer chemistry for thallium in the +I state, there is a concomitant decrease in the detailed information on thallium(III) coordination chemistry.

25.2.8.1 Group IV Ligands

There is some evidence for the formation of Tl^{3+}/CN^- complexes in aqueous solution,[373] but no synthetic study of thallium(III) with this or other group IV ligands has apparently been reported, although the $[Tl(CN)_4]^-$ anion is known in $Tl(CN)_2$ (*cf.* Section 25.2.7). Organothallium(III) compounds are of course well known.[272]

25.2.8.2 Nitrogen and Other Group V Ligands

25.2.8.2.1 Ammonia and amine ligands

Ammoniates of thallium(III) are not stable species, although stability constant measurements suggest that $[Tl(OH)]_2^+$ forms strong complexes with ammonia in conc. ammonium nitrate solution.[374] A number of complexes of TlX_3 (X = Cl, Br, I) with ethylenediamine, 1,3-diaminopropane and similar ligands are known,[5,6] and in the case of X = Cl, Br, NO_3 or ClO_4, for example, the products are of the type $TlX_3 \cdot 3en$, suggesting that these are the ionic species $[Tlen_3]X_3$ with a six-coordinate Tl—N_6 complex cation. Spectroscopic results are available in some cases and have been reviewed elsewhere.[5,6]

25.2.8.2.2 N-heterocyclic ligands

As with amino ligands, adducts of TlX_3 (X = Cl, Br, I) with py, phen, bipy and terpy have been prepared.[5,6] The vibrational spectra of these and related adducts have been extensively reviewed; both neutral (*e.g.* $TlX_3 \cdot py_2$) and ionic formulations (*e.g.* $[Tl_2X_2bipy_2][TlX_4]$) have been proposed.[375] The bipy and phen derivatives are very similar.[375,376] The dimeric structure of $TlCl_3 \cdot phen$ has been shown to involve a TlN_2Cl_4 kernel, in which the phenanthroline nitrogen atoms, the thallium, and two chlorines are in a plane; dimerization involves donation from a neighbouring apical chlorine.[377] The related product $TlCl_3 \cdot phen \cdot DMF$ apparently has the DMF ligand occupying this sixth coordination site.[376]

The compound $TlCl_3 \cdot terpy$ is isomorphous with the gallium analogue (see Section 25.2.4.2.2),[375] although conductivity and spectroscopic results have been interpreted[378] in terms of the structure $[TlCl_2terpy][TlCl_4]$ (but see ref. 379). The problems implicit in using solution phase data to deduce solid state structures have been emphasized earlier, and the conflicts about this compound further illustrate this point. Anionic thallium(III) halogen species, such as $[TlCl_4(quin)_2]^-$ (quin = quinoline) and $[TlCl_3BrL_2]^-$ (L = pyridine, 3-picoline, quinoline) have been prepared,[380] as have the cationic complexes $[Tl(phen)_2X_2]^+$ (X = NO_3, Cl, Br, I).[381] In general, these compounds all point to the predominance of six-coordination in this aspect of the coordination chemistry of thallium(III).

25.2.8.2.3 Other nitrogen ligands

There is little to report here, since the oxidizing properties of thallium(III) prevent the formation of the neutral pseudohalides and similar compounds.[1] On the other hand, adducts of phen and bipy and $Tl(NCS)_3$ have been prepared (*e.g.* $Tl(NCS)_3bipy$) from the trichloride[382] suggesting that the presence of a neutral ligand may stabilize the +III state.

25.2.8.2.4 Other group V ligands

Oxidation of the ligand is again a severe problem in the synthesis of thallium(III) compounds with the heavier group V donors. The reaction of $TlCl_3 \cdot py_2$ with Et_2PhP(= L) yields $TlCl_3 \cdot L_{2.5}$, but attempts to extend this reaction to other phosphines gave thallium(I) species as the main product,[383] and it appears that the combination of oxidizing (Tl^{III}) and reducing (PR_3, AsR_3) reagents is such as to preclude preparative work in this area.

25.2.8.3 Oxygen Ligands

25.2.8.3.1 Oxide, hydroxide and H_2O as ligands

Thallium(III) oxide, Tl_2O_3, has the C—M_2O_3 rare earth sesquioxide structure, in which the metal is six-coordinate.[1] The corresponding hydroxide is apparently unknown. X-Ray studies have shown that $[Tl(OH_2)_6]^{3+}$ exists in solution (Tl—O = 2.235(5) Å),[384] and that the addition of Br^- brings about substitution to *trans*-$[TlBr_2(OH_2)_4]^+$ (Tl—Br = 2.481(2) Å), and $[TlBr_3(OH)_2]^{2+}$ which has a $TlBr_3O_2$ tbp kernel (Tl—O = 2.512(2) Å) (see also below). The solid $Tl(ClO_4)_3 \cdot 6H_2O$ also contains the exactly octahedral $[Tl(OH_2)_6]^{3+}$ cation (Tl—O =

2.23(2) Å),[385] while the tetrahydrates of $TlCl_3$ and $TlBr_3$ are based on distorted trigonal bipyramidal TlX_3O_2 units hydrogen bonded together through the remaining two water molecules.[386] The Tl—OH_2 bond lengths range from 2.428(15) to 2.602(16) Å.

Three oxide halides TlOX (X = F, Cl, Br) are known.[1] Preparations must be carried out at low temperatures[1,387] since the heavier oxyhalides in particular readily decompose. There is no structural information on either TlOCl or TlOBr, but X-ray crystallography shows that TlOF has a calcium fluoride structure, with Tl^{3+} ions in a cube of F^- or O^{2-} ions.[388]

25.2.8.3.2 Alkoxide, β-ketoenolates and related ligands

There appear to be no thallium(III) compounds with such ligands.

25.2.8.3.3 Oxyanion ligands

Thallium(III) nitrate, crystallized from Tl_2O_3 and conc. nitric acid as the hydrate, readily decomposes to $Tl_2O_3 \cdot 2H_2O$, and is a strong oxidizing agent,[389] having been used as such in organic synthesis. The crystal structure of $Tl(NO_3)_3 \cdot 3H_2O$ shows that the nitrate groups are bidentate and asymmetric (Tl—O = 2.299, 2.637 Å), but the water molecules are also bonded to the metal (Tl—O = 2.293 Å), giving a tricapped trigonal prismatic stereochemistry.[390] The anionic complex $NO[Tl(NO_3)_4]$ is formed in the reaction of N_2O_5 and $TlNO_3$.[391]

Thallium(III) orthophosphate, the only known phosphate of this oxidation state, is isostructural with $InPO_4$[392] with the metal atom coordinated by six oxygen atoms from six different PO_4^{3-} groups. The hydrate $TlPO_4 \cdot 2H_2O$ also involves six-coordination, with a $TlO_4(OH_2)_2$ kernel; again each oxygen is provided by a different phosphate.[393] The dichlorophosphate, $Tl(O_2PCl_2)_3$, prepared *via* $TlCl_3 + Cl_2O$ in $POCl_3$, is also believed to involve six-coordinate thallium with bidentate (O-bonded) chelating ligands.[394]

Solutions of Tl_2O_3 in dilute sulfuric acid eventually yield the sulfate $Tl_2(SO_4)_3 \cdot 7H_2O$, which at high pH goes to the basic $Tl_2(OH)_2(SO_4)_2 \cdot 4H_2O$ whose structure is based on chains of TlO_6 octahedra.[395] Crystallization from conc. sulfuric acid gives $Tl_2(SO_4)_2 \cdot 4H_2O$, which on heating reverts to $Tl_2(SO_4)_3$. A number of double sulfates have been reported, and many of these no doubt involve Tl^{III} sulfate complexes (*cf.* Section 25.2.4.4.4) but structural data are lacking at present. Thallium(III) selenate is similar to the sulfate. Thallium(III) tellurate, Tl_6TeO_{12}, consists of TeO_6 octahedra and Tl^{III} coordinated to seven oxygen atoms in a distorted monocapped trigonal prismatic stereochemistry.[311]

Thallium(III) perchlorate is obtained from $TlCl_3 + AgClO_4$, or by the anodic oxidation of $TlClO_4$. Complexing by perchlorate appears very unlikely and the same applies to chlorate, bromate or iodate.[1–3]

25.2.8.3.4 Carboxylate ligands

Thallium(III) carboxylates are readily formed by the reaction of $Tl(OAc)_3$ and the appropriate acid,[1] while $Tl(OAc)_3$ itself is prepared from Tl_2O_3 and glacial acetic acid.[396] The structure of $Tl(OAc)_3$ shows that the thallium atom is coordinated by three chelate acetate groups (Tl—O = 2.30 Å, av.), but two longer Tl—O bonds (2.57 Å) link adjacent molecules into chains of TlO_8 units.[397] The monohydrate is related to the anhydrate, but the eight-coordination is achieved by both acetate and water coordination.[398] The compound $PdTl(OAc)_5$ has palladium bonded directly to thallium but the metals are also bridged by four bidentate carboxylates.[399] There is an extensive literature on the use of thallium(III) carboxylates in organic synthesis.[274,275]

The hydrated double oxalate of rubidium and thallium has been formulated as $Rb[Tlox_2(H_2O)_2] \cdot 2H_2O$. Water is lost on heating, and Tl^{III} undergoes reduction to Tl^I, so that final products are Tl^I oxide and Rb_2CO_3.[400]

25.2.8.3.5 Ethers and other oxygen donor ligands

Relatively few compounds of thallium(III) with simple organic oxygen donors are known, and in particular the adducts of TlX_3 do not appear to have been systematically investigated.[5]

Two recent crystal structures suggest that this situation should be rectified. The adduct $TlCl_3 \cdot L_2$ (L = 4-pyridinecarbonitrile *N*-oxide) has a trigonal bipyramidal structure, with axial oxygen donors,[401] while in $TlBr_3 \cdot$diox the same stereochemistry arises from planar $TlBr_3$ units bridged by 1,4-dioxane molecules in the chair conformation.[402]

Cationic complexes of Tl^{3+} with oxygen donors are known, and can be regarded as substitution products of $[Tl(OH_2)_6]^{3+}$ (*cf.* Section 25.2.8.3.1). The DMSO product has been characterized with various anions,[403] and there seems no reason to suppose that similar compounds cannot be prepared with donor ligands which are resistant to oxidation. The cation $[Tl(pyNO)_8]^{3+}$ (prepared as the perchlorate) may be an indication that eight-coordinate compounds are also accessible in thallium(III) chemistry.[404]

25.2.8.4 Sulfur and other Heavier Group VI Ligands

The oxidizing properties of Tl^{III} are held to be partly responsible for the absence of a binary sulfide Tl_2S_3, although Tl_2Se_3 and Tl_2Te_3 can be prepared by heating the elements,[1] which suggests that oxidation is not the only factor involved. The existence of TlS_4^{5-} tetrahedra in Tl_4S_3 was noted earlier, and the information on Tl_2Te_3 suggests that it is not a simple binary compound (see Section 25.2.7).

Compounds of thallium(III) with monodentate sulfur donors have not been reported, again no doubt because of the redox chemistry involved, but a number of compounds with bidentate sulfur ligands are known. With maleonitriledithiolate (= MNT^{2-}, *cf.* Section 25.2.4.5.2), the anions $[Tl(MNT)_2]^-$, $[Tl(MNT)_2Br]^{2-}$ and $[Tl(MNT)_3]^{3-}$ are all known,[218] implying four-, five- and six-coordination at the metal, although the Tl—S_4 species do not add neutral bidentate nitrogen donors to give Tl—S_4N_2 kernels.[405] Surprisingly, the reaction of TDT^{2-} (the dianion of toluenedithiol) with thallium(I) yields the thallium(III) anion $[Tl(TDT)_2]^-$, suggesting complex redox chemistry in such systems. Stepwise polarographic reduction was not observed for Tl—S_4 or Tl—S_6 complexes.[405] Other anionic complexes reported include $(Ph_4P)_3[Tl(S_2C{=}N{-}C{\equiv}N)_3]$[406] and $R_4N[TlL_2]$ (L = *cis*-ethanedithiolate or 4,5-dithiolate-2,3-xylene).[217] It seems that there are a number of interesting problems awaiting resolution in this area.

25.2.8.5 Halogen Ligands

25.2.8.5.1 Fluoride ligand

Crystalline TlF_3, obtained from the reaction of Tl_2O_3 with F_2, BrF_3 or SF_4,[1] forms orthorhombic crystals in which the Tl^{3+} ions have distorted trigonal prismatic coordination.[407] Stability constant measurements show that Tl^{3+} does not complex with fluoride ion in aqueous solution,[289] while in liquid HF, the equilibrium identified is $TlF_3(s) + F^-(soln) \rightleftarrows TlF_4^-$.[408] In keeping with these solution phase results, the solid phases in the system TlF/TlF_3 do not contain any Tl^{III}/F anionic complexes,[354] and the compounds $MTlF_4$ (M = Li, Na) are true double salts.[409] On the other hand, the compounds M_3TlF_6 (M = Na, K) contain MF_6^{3-} anions;[410,411] a number of other species were identified in these MF/TlF_3 phase studies, including $Na_3Tl_2F_3$, $Na_5Tl_9F_{32}$, $K_5Tl_3F_{14}$ and $K_2Tl_7F_{23}$.[411]

25.2.8.5.2 Chloride, bromide, iodide and mixed halide ligands

Thallium(III) chloride can be prepared by bubbling chlorine through a suspension of TlCl in acetonitrile.[412] The corresponding bromide is unstable in the solid state, and the iodide does not exist[1] (see Section 25.2.6.5.2), and here again the oxidizing properties of the +III state are critical. Hydrates of $TlCl_3$ and $TlBr_3$ can be prepared by oxidation of TlX with X_2; the stable room temperature species are $TlCl_3 \cdot 4H_2O$ and $TlBr_3 \cdot 4H_2O$. Non-aqueous solutions of TlX_3 (X = Cl, Br) can be obtained by similar methods. The structure of the hydrates was discussed earlier (Section 25.2.8.3.1).

Various adducts of TlX_3 have been noted earlier in this chapter, and a number of anionic complexes with coordination numbers of four, five or six have also been prepared. Salts of $TlCl_4^-$ and $TlCl_3X^-$ (X = Br, I) are readily formed from TlX_3 and (say) R_4NCl in non-aqueous

media[412–415] and X-ray studies of a number of such salts[415–417] have confirmed the tetrahedral, or slightly distorted tetrahedral, structure predicted from vibrational[418] and electronic[414] spectroscopy. The five-coordinate anion $TlCl_5^{2-}$ has been identified in aqueous[419] and non-aqueous solution[256] and in the solid state, and is presumably isostructural with $InCl_5^{2-}$ (Section 25.2.4.6.2). The octahedral $TlCl_6^{3-}$ has been identified in a number of salts, although the stoichiometry M_3TlCl_6 is not a sure guide, and X-ray structural studies have been reported.[417,420] The Tl—Cl bond is significantly longer in $TlCl_6^{3-}$ (2.59 Å) than in $TlCl_4^-$ (2.43 Å). The structure of the salt $(pyH)_3Tl_2Cl_9$ is reported to involve $TlCl_4^-$ and $TlCl_5^{2-}$ anions on the basis of Raman and ^{205}Tl NMR spectroscopy,[421] although a previous spectroscopic and normal coordinate analysis of $Cs_3Tl_2Cl_9$ confirmed the $[Cl_3TlCl_3TlCl_3]^{3-}$ structure in this salt.[422] The use of ^{205}Tl NMR to identify $TlCl_5^{2-}$ and $TlCl_6^{3-}$ in both solid and solution should also be noted as an important use of this method.[421,423,424]

Salts of $TlBr_4^-$ can be prepared by the methods outlined above for $TlCl_4^-$. The vibrational spectra in the solid state,[424] and in aqueous[419] and non-aqueous solution,[425,426] support the expected tetrahedral structure, and this has been confirmed by later X-ray studies.[427,428] An interesting result from these experiments is that the salt $RbTlBr_4 \cdot H_2O$ involves $TlBr_4^-$ rather than a five-coordinate hydrated anion. The $TlBr_5^{2-}$ anion has been identified, and the $TlBr_6^{3-}$ anion is assigned O_h symmetry from vibrational spectra.[424,429] The only reported anionic iodo complex is TlI_4^-, for which the tetrahedral geometry has been confirmed by vibrational spectroscopy,[424,425] and by X-ray studies of solid and solution.[430] The preparation of the mixed halogeno complexes $TlCl_3X^-$ was noted earlier and the electronic spectra of these and other $TlX_{4-n}Y_n^-$ have been discussed.[404]

25.2.8.6 Hydrogen and Hydride Ligands

It is likely that the previously reported hydrides TlH_3 and $(TlH_3)_n$ do not exist,[431,432] but the reaction of $TlCl_3$ and LiH in ether at −15 °C yields $LiTlH_4$ which decomposes above ~30 °C,[435] and is the least stable of the group III $LiMH_4$ compounds. The reaction between $TlCl_3$ and $LiMH_4$ (M = Al, Ga) at very low temperatures gives $Tl(MH_4)_3$ which decomposes above −115 °C (Al) or −95 °C (Ga). When $TlCl_3$ is heated with AlH_3 or $LiBH_4$ at −115 °C, the product is $TlCl(MH_4)_2$ (M = B, Al) which decomposes at −95 °C. In these circumstances, it is not surprising that there is no structural information on these very unstable substances.

25.2.8.7 Mixed Donor Atom Ligands

There is nothing significant to report under this heading.

25.2.8.8 Macrocyclic Ligands

Inorganic derivatives of thallium(I) and thallium(III) are not known, but the cationic complex $[TlMe_2(crown)]^+$ (crown = dibenzo-18-crown-6) has been prepared as the picrate salt.[434] X-Ray crystallography has demonstrated the existence of two isomers of the analogous complex with dicyclohexano-18-crown-6; the Me—Tl—Me group is orthogonal to the average ring plane.[435,436]

The porphyrin derivative of thallium(III) has been found[437] to have the metal atom above the N_4 plane by 0.9 Å. Electrochemical two-electron reduction results in reduction to Tl^IL^- (L = porphyrin), and subsequent protonation gives H_2L and Tl^+ in aqueous solution.[438]

26.1 INTRODUCTION

The metalloidal and metallic congeners of carbon in Group IVB exhibit what is probably the most varied coordination chemistry of any similar group of elements in the Periodic Table. Simple reasons for this observation are easy to find including (a) the change in electronegativity on proceeding down the group resulting in a transformation from the classical non-metallic element carbon to the respectably metallic elements, tin and lead, (b) the large increase in atomic radii leading to, *inter alia*, high coordination numbers for the heavier elements, and (c) the emergence of an 'inert pair' effect, leading to the possibility of lone pair stereochemical activity. However, although the principles of VSEPR can in general be applied successfully to predict the geometry of tetravalent and simple bivalent compounds, the factors underlying the stereochemistry of tin(II) and lead(II) compounds in the solid state can often be more subtle, and hence not so readily understood. The extremely wide scope of the structural chemistry in this area therefore only allows a panoramic overview to be described in this chapter, rather than a totally comprehensive treatise.

26.2 GENERAL TRENDS

26.2.1 Electronegativity

Estimated values of the electronegativities of the Group IVB elements are listed in Table 1. The more recently devised scales of Sanderson and Hargattai–Bliefelt (based on analysis of IR band intensitities for $MHCl_3$ and MX_4 molecules and bond distance data in bivalent and tetravalent derivatives) concur with the alternating scale of Allred–Rochow, rather than the original Pauling scale.[1,2] It must be borne in mind, however, that the absolute electronegativity varies significantly upon the particular chemical environment in which the element atom finds itself. The concept of electronegativity is therefore only of utility as a general guide to relative behaviour.

26.2.2 Elemental Structure

Both silicon and germanium crystallize with the diamond structure, although with a substantially lower band gap [*e.g.* (kJ mol^{-1}): 106.8 (Si), 64.2 (Ge); *cf.* ~580 (C)], accounting

Table 1 Element Electronegativity Scales[a]

Element	*Pauling*	*Allred–Rochow*	*Sanderson*	*Hargittai–Bliefelt*
C	2.5	2.5	2.5	2.6
Si	1.8	1.7	1.7	1.9
Ge	1.8	2.0	2.3	2.5
Sn	1.8	1.7	2.0	2.3
Pb	1.9			

[a] Data taken from 'Inorganic Chemistry of the Main Group Elements', The Chemical Society, 1977, vol. 4, p. 145; I. Hargittai and C. Blicfelt, *Z. Naturforsch., Teil B.*, 1983, **38**, 1304; and N. N. Greenwood and A. Earnshaw, 'Chemistry of the Elements', Pergamon, Oxford, 1984, p. 431.

for their semiconducting properties. Tin forms two modifications; white or β-tin, which adopts a tetragonal lattice and is the stable form above the transition temperature of 13.2 °C, and grey or α-tin, which also has the diamond structure and is stable below this temperature.[3] Tetragonal modifications of silicon and germanium have been observed on the application of very high pressures.[4] Lead has a typically metallic face-centred cubic lattice.[3]

26.2.3 Elemental Radii

Estimates of the radii of the Group IV elements in various chemical situations are collected in Table 2. Values increase with increasing atomic number, so that the covalent radii of tin and lead are almost twice that of carbon. 'Ionic' radii are substantially smaller than the corresponding covalent radii, with the M^{II} 'ionic' radii being substantially larger than their M^{IV} counterparts.

Table 2 Elemental Radii (pm)

Element	*Non-bonded radius*[a]	*M^{IV} covalent radius*[b]	*M^{IV} 'ionic' radius*[b]	*M^{II} 'ionic' radius*[b]
C	125	77.2

26.2.4 Bond Energy Data

Data for the single bond dissociation energy, D(M—X), are listed in Table 3. Two sets of values are given, one a general set and the other (in parentheses in Table 3) for trimethylmetal molecules, Me_3MX. Significant variation between the two sets of values occurs (by as much as 100 kJ mol^{-1}), and so only general trends should be noted. In addition, bond dissociation energies vary somewhat between individual molecules, as has been demonstrated for silicon compounds.[5] A steady decrease in bond energy usually accompanies an increase in size of both M and X. However, values for bonds between silicon and oxygen, nitrogen and the halogens are anomalously high, a phenomenon usually ascribed to a manifestation of $(p \rightarrow d)\pi$ reinforcement of the M—X σ bond. Various estimates of the π bond energy of the Si=C and Si=Si double bonds in silaalkenes and disilenes have appeared.[5,6] The most reliable estimate of the Si=C π bond energy in 1,1-dimethylsilaethylene is around 163 ± 21 kJ mol^{-1}.[5] The triple bond energy in the hypothetical species has been calculated to be 324 kJ mol^{-1}.[7] Experimental data afford a lower bound of 69 ± 11 kJ mol^{-1} for the Si=Si π bond energy for disilene, $H_2Si{=}SiH_2$, whereas *ab initio* calculations give a value of 94 ± 8 kJ mol^{-1}. Estimates for substituted disilenes are somewhat greater at around 108 ± 20 kJ mol^{-1}.[8] The Si=Cr bond

dissociation energy in the silylene complex $[(OC)_5Cr{=}Si(OH)H]$ is calculated to be even higher at 128 kJ mol^{-1}.[9]

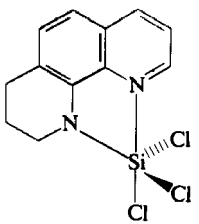
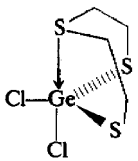
26.2.5 Coordination Geometries



The variety of coordination geometries exhibited by the Group IV elements is illustrated in Table 4, which contains examples of the principal types encountered. The list is extensive, with coordination numbers ranging from one to twelve, but by no means comprehensive. In particular, tin and lead exhibit many irregular coordination geometries of high coordination number. Indeed, except for some esoteric carbides and silicides, compounds with coordination number greater than six are exclusively confined to these metals, consistent with their large covalent radii. Stable, small multiply bonded molecules are formed only by carbon, although a few rather sophisticated molecules containing Si=C, Si=Si, Ge=Ge and Sn=Sn double bonds have been synthesized. Many other silicon and germanium species containing multiple bonds to oxygen, carbon, nitrogen and phosphorus have been postulated as transient intermediates. The only examples of multiple bonding between tin and lead and an electronegative element are the matrix-isolated species, MO and MO_2 (M = Sn, Pb).

Conversely, the stability of compounds of oxidation state +II increases dramatically as the atomic number of the element increases. Carbenes, CX_2, and silylenes, SiX_2, are well established as transient reaction intermediates, and structural data have been obtained in several cases either at high temperatures or by their generation in low-temperature matrices. However, only for germanium, tin and lead are compounds in this oxidation state stable under ordinary conditions. Compounds with the Group IV element in oxidation state +III, the formal oxidation state of the radical species, $R_3M^{\bullet}$, are also usually considered as unstable transients. However, when R is very bulky, these metal-centred radicals, such as for example $Sn[CH(SiMe_3)_2]_3$, have extremely long, perhaps indefinite, lifetimes in solution.



Silicon and germanium are generally tetrahedrally coordinated in their tetravalent derivatives. Although examples of five- and six-coordination are well documented, none are known which contain two or more silicon–carbon bonds. Tetrahedral four-coordination is only observed for tin and lead in R_4M (R = organic group) compounds and R_nMX_{4-n} derivatives which are either sterically crowded or in which the ligand X is weakly electronegative and a poor donor, and higher coordination numbers are achieved wherever possible. For tin and lead compounds with three metal–carbon bonds, coordination saturation invariably occurs at five, although one authenticated example of a six-coordinated complex, $Me_3Sn[(N_2C_3H_3\text{-}1)_3BH]$, has been reported (*vide infra*). For compounds with two or less metal–carbon bonds, coordination saturation is usually achieved at six in an octahedral or distorted octahedral geometry, but a few examples with coordination numbers of seven or eight have been

Table 4 Typical Coordination Geometries Exhibited by the Group IV Elements

Coordination number	*Geometry*	*Examples*

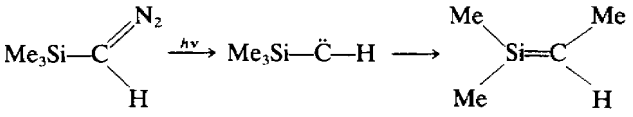
characterized. Of the two five-coordinated geometries, square pyramidal and trigonal bipyramidal, the latter is strongly favoured.[10]

Two factors combine to lend a greater diversity in the stereochemistries exhibited by bivalent germanium, tin and lead compounds, the increased radius of M^{II} compared with that of M^{IV} and the presence of a non-bonding pair of electrons. When the non-bonding pair of electrons occupies the isotropic valence level *s* orbital, as in, for example, the complex cations $Pb[SC(NH_2)_2]_6^{2+}$ and $Pb[antipyrine]_6^{2+}$, or when they are donated to conductance band levels, as in the binary tin and lead selenides or tellurides or the perovskite ternary phases $CsMX_3$ (M = Sn, Pb; X = Cl, Br, I), then the metal coordination is regular. However, in the majority of compounds an apparent vacancy in the coordination sphere of the metal is observed, which is usually ascribed to the presence of the non-bonding pair of electrons in a hybrid orbital and cited as evidence for a 'stereochemically active lone pair'.

Examples of compounds exhibiting the two-coordinated 'bent' geometry are rather sparse and only when the two ligands are very bulky do they occur under ordinary conditions. The preferred coordination geometries for bivalent germanium and tin are the three-coordinate trigonal pyramid and the four-coordinate distorted pseudotrigonal bipyramid, where the stereochemically active lone pair occupies an equatorial coordination site. The latter stereochemistry appears to be favoured when the ligands are very electronegative. Similar three- and four-coordination is also found for bivalent lead, but much higher coordination numbers in a variety of geometries predominate. Although square antiprismatic eight-coordination is quite common, several other types, many of which are irregular, of coordination numbers from seven to twelve are also observed.



26.3 STRUCTURAL SURVEY[11]

26.3.1 Multiple Bonding Involving Silicon, Germanium and Tin

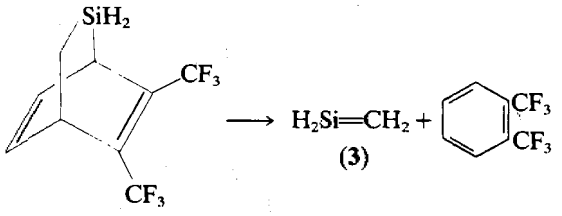
The reluctance of the heavier elements of Group IV to form stable compounds possessing multiple bonds is in sharp contrast to the behaviour of carbon, where $p\pi$–$p\pi$ multiple bond function is a major feature of its chemistry. The quest for multiply bonded compounds involving silicon is by no means new and dates back to the attempts of Frederick Stanley Kipping over 80 years ago to characterize compounds of the type $R_2Si{=}O$, which he termed silicones by analogy with organic ketones.[12] More recently, several multiply bonded silicon and germanium species have been generated as transient intermediates. The list of such intermediates is quite extensive and includes Si=C (silaethylenes; also referred to as silaethenes, silaalkenes and silaolefins), Si=O (silanones), Si=S (silathiones), Si=N (silaimines), Si=Si (disilenes), Ge=C (germaethylenes), Ge=O (germanones), Ge=S (germathiones), Ge=N (germaimines) and Ge=P (germaphosphimines). The evidence for many of these intermediates is indirect and lies only in the strategy of their generation and the nature of the reaction products. However, several have been characterized by physicochemical methods either in low-temperature matrices or at high temperatures. The formation and properties of these types of unstable multiply bonded intermediates were reviewed in 1979.[13] Later data may be found in the main group chemistry reviews.[14]

Various routes to silaethylenes have been devised:

Carbene rearrangement[15,16]

(1)

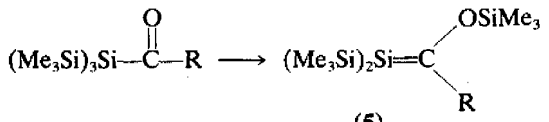
(1)



Silacyclobutane pyrolysis or photolysis[17,18]

(2)

(2)

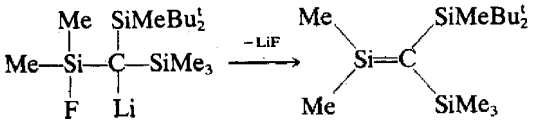


Bridgehead extrusion from bicyclooctadienes[19]

(3)

(3)

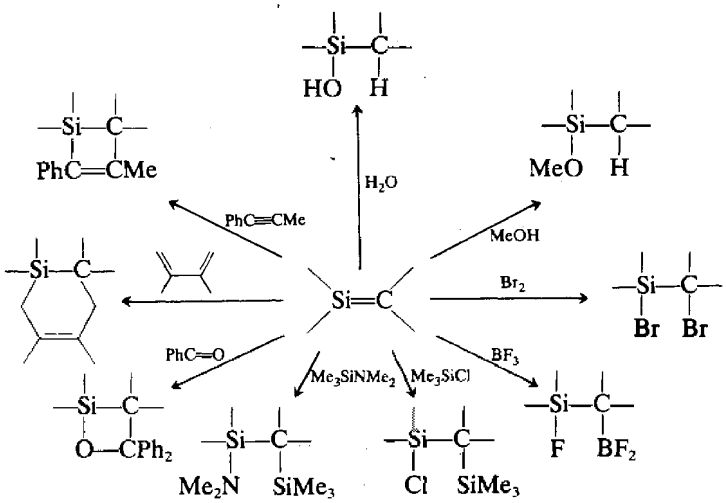
Sigmatropic rearrangement of acylpolysilanes[20]



(4)

(5)

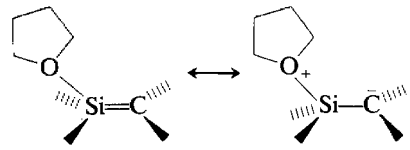
R = Bu^t, adamantyl



Elimination of LiF[21]

(5)

(6)

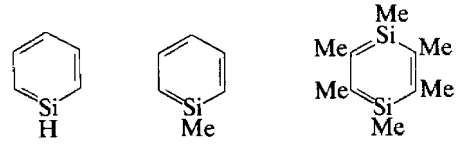


Small unsubstituted silaethylenes, such as (**1**), (**2**) and (**3**) are stable only in low temperature matrices. On warming, 'head-to-tail' dimerization usually occurs. Steric crowding, however, has a dramatic stabilizing effect, and the sterically hindered silaethylenes, (**5**) and (**6**), may be isolated as stable crystalline solids. Nevertheless, the Si=C double bond even in these compounds is very reactive, undergoing aerobic oxidation and many other reactions with both singly and multiply bonded reagents (Scheme 1).[22–26]

Scheme 1 Typical reactions of the Si=C double bond

As expected, experimental determinations of the Si=C double bond distance are lower than the corresponding single bond distance. In the electron diffraction study of $Me_2Si{=}CH_2$,[18] the Si=C double bond is 183(4) pm compared with a value for the Si—C single bond distance of 191(2) pm in the same molecule, and the more precise Si—C single bond distance of 186.7 pm derived for methylsilane from microwave data.[27] This value, however, is significantly higher than calculated values for silaethylene, $H_2Si{=}CH_2$, which fall in the range 163–175 pm.[28,29] That the discrepancy arises because of methyl-for-hydrogen substitution at silicon, proposed by Dewar[32] on the basis of MINDO/3 calculations, has been discounted since the more sophisticated double ζ SCF method predicts exactly the same Si=C distance (169.2 pm) for

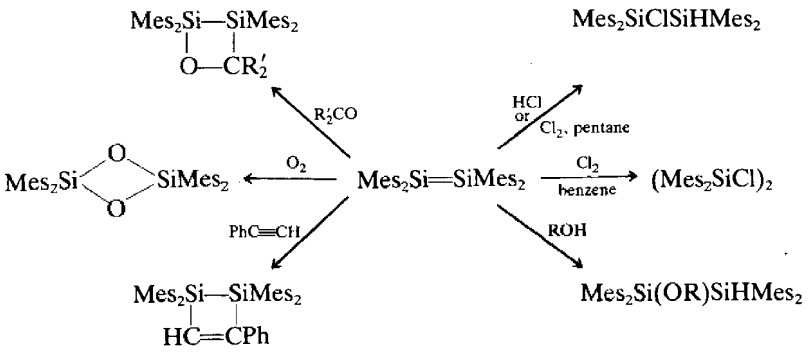
both $H_2Si{=}CH_2$ and $Me_2Si{=}CH_2$.[28] The double bond distances in the two sterically crowded crystalline silaethylenes, $(Me_3Si)_2Si{=}C(OSiMe_3)(C_{10}H_{15})$[20] and $Me_2Si{=}C(SiMe_3)(SiMeBu^t_2)\cdot THF$,[34] are 176.4 pm and 174.7(5) pm respectively, much closer to theoretical estimates. However, it should be noted that in both the silaethylene skeleton is not planar as would be expected for sp^2 hybridization at both silicon and carbon. In the former adamantyl-substituted silaethylene, the molecule is twisted 16° about the Si=C double bond most probably due to the bulky substituents. Such a motion would decrease the efficiency of the $p\pi$–$p\pi$ overlap and lead to a lengthening of the Si=C bond.[35] In crystals of the latter THF solvate, the THF molecule is coordinated to the silicon atom, which adopts a distorted tetrahedral geometry, although the planar geometry persists at carbon. Again the efficiency of $p\pi$–$p\pi$ bonding overlap will be reduced and the adduct is probably best regarded as a zwitterion in which the bonding is described in terms of the resonance formulation as shown in equation (6).



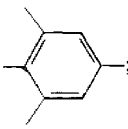
(6)

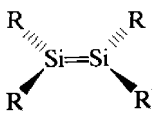
Silaacetylene, HSi≡CH, is predicted to have a *trans* bent equilibrium geometry, with a Si≡C bond distance of 163.5 pm, *i.e.* about 8 pm shorter than the best estimate for the Si=C distance. The bond order has been suggested to be intermediate between two and three.[36]

In the IR, the Si=C stretching vibration has been assigned to a band at 1002 cm^{-1} in the spectrum of $Me_2Si{=}CH_2$[37,38] and to one at 988 cm^{-1} for $MeHSi{=}CH_2$.[39] A later study of the isotopomeric molecules, $Me_2Si{=}CD_2$ and $(CD_3)_2Si{=}CD_2$, however, indicates that two bands, one around 880 cm^{-1} and the other around 1115 cm^{-1}, contribute to this vibration.[40] Significantly, Brook[22] considers the band at 1135 cm^{-1} in the spectrum of the adamantyl-substituted silaethylene (**5**; $R = C_{10}H_{15}$) to be characteristic of silaethylenes. ^{29}Si NMR chemical shifts for the sp^2-hybridized silicon atoms in silaethylenes lie in the rather small range 41–54 p.p.m. As expected, coupling constants involving sp^2-hybridized silicon are greater than those involving sp^3-hybridized silicon.[41]



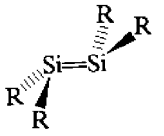
The stabilization of a silicon-containing arene has not as yet been achieved. Nevertheless, silabenzene (**7**), 1-silatoluene (**8**) and hexamethyl-1,4-disilabenzene (**9**) have all been generated as transients.[42–47] Both silabenzene and 1-silatoluene are stable when condensed in argon matrices. The UV spectrum exhibits three bands at 212, 272 and 320 nm expected for a π-perturbed benzene. In its photoelectron spectrum, the lowest ionization energies are at 8.0, 9.3 and 11.3 eV (*cf.* calculated values derived by SCF methods of 8.2, 9.2 and 11.5 eV).[48]





(**7**) (**8**) (**9**)

Disilenes, $R_2Si{=}SiR_2$, vary in stability from short-lived transients to crystalline solids and are indefinitely stable under inert atmospheres depending upon the steric crowding at the Si=Si double bond. Several methods have been employed in the generation of disilenes, including photolysis of linear and cyclic trisilanes,[49–51] photolysis of strained bridgehead molecules such as 7,7,8,8-tetra-*tert*-butyl-7,8-disilabicyclo[2.2.2]octa-2,5-diene[52] and the reduction of 1,2-dihalogenodisilanes using alkali metal naphthalides[53] or lithium wire with simultaneous ultrasonic irradiation.[54] These routes have been employed for the generation of tetraisopropyldisilene, tetra-*tert*-butyldisilene, tetrakis(1-ethylpropyl)disilene and tetraneopentyldisilenes, all of low stability and which may be trapped by the usual types of trapping reagents, and also tetramesityldisilene (**10**), *trans*-1,2-di-*tert*-butyl-1,2-dimesityldisilene (**11**) and tetrakis(2,6-diethylphenyl)disilene (**12**), respectively, which are all stable yellow crystalline solids. The physical and chemical properties of these derivatives indicate that the Si=Si double bond bears a close resemblance to, although distinctly weaker than, the C=C double bond. The most studied compound in this respect is tetramesityldisilene and some typical reactions are shown in Scheme 2. Corroboration of the double bond character comes from UV[49] and ^{29}Si MAS[55]



spectra, and from structural data. The ^{29}Si MAS spectrum exhibits an anisotropy similar to that observed in the ^{13}C spectrum of ethylene (*cf.* the anisotropy in the spectrum of tetramesityldisilane which is much smaller as in the ^{13}C spectra of alkanes). As expected, the Si=Si bond distances in all three stable disilenes are distinctly shorter [216.0(1) pm (**10**), 214.3(1) pm (**11**) and 214.0(2) pm (**12**)] than typical single bond distances (*e.g.* H_3SiSiH_3, 245.3 pm). The two silicon and four carbon atoms in (**11**) are coplanar as in (**13**), but both (**10**) and (**12**) show some distortion. (**12**) exhibits a 10° twist about the Si=Si double bond, while retaining planarity about each silicon atom. The distortion in (**10**) involves a moderate antipyramidalization at the silicon atoms in addition to a slight twisting about the multiple bond as in (**14**).[56,57] In spite of these distortions, the observed Si=Si bond distances in these isolable disilene derivatives fall in the range predicted for disilene, $H_2Si{=}SiH_2$ (212.7–217 pm).[58–60] A further theoretical study has shown that the conformation of disilenes depends strongly upon the central π bond and also on the nature of the substituents.[61]

Scheme 2 Typical reactions of tetramesityldisilene (Mes =  ; R = H, Et; R′ = Me, Ph)

(**13**)

(**14**)

Silanones $[R_2Si{=}O]$,[62–64] silaimines $[R_2Si{=}NR]$,[65–67] siladiimides $[RN{=}Si{=}NR]$,[68] silathiones $[R_2Si{=}S]$,[69] germaalkenes $[R_2Ge{=}CR'R'']$,[70,71] germaarenes $[RC_6H_4GeMe\text{-}1,4]$,[72] germanones $[R_2Ge{=}O]$,[73–77] germathiones $[R_2Ge{=}S]$,[75–78] germaimines $[R_2Ge{=}NR]$[74] and germaphosphimines $[R_2Ge{=}PR]$[74–79] are known only as transients for which no structural data is available. However, double ζ SCF calculations predict planar structures for $H_2Si{=}O$, $H_2Ge{=}O$ and $H_2Ge{=}S$ with double bond distances of 148.5, 163 and 202 pm, respectively.[80,81]

Silicon monoxide is known to be stable at either very high or very low temperatures. The structure of the solid material is very complex. A regular cubic lattice may be formed above 1300 °C, but below this temperature the structure is irregular and comprises a mixture of different atomic arrangements.[82] Molecular SiO as well as several other analogues of multiply bonded carbon oxide molecules have been stabilized in low-temperature matrices. Structural and force constant data are collected in Table 5, from which it would appear that the M=O (M = Si, Ge, Sn) bonds have a generally similar electronic structure to the C=O double bond with bond orders of approximately two. Significantly, the force constants for the MO and MO_2 species for each element are similar, indicating that no further increase in bond order occurs in the two atom molecule (*cf.* CO and CO_2). All the species show a considerable shortening (and strengthening) of the M=O bond compared with typical values for M—O single bonds (*vide infra*). Likewise, the SiS force constant in matrix-isolated SiOS is consistent with a double bond, as in gaseous SiS ($f_{SiS} = 494\ N\ m^{-1}$).[91]

26.3.2 Silylenes, Germylenes and Stannylenes[92]

There has been considerable interest over the past decade in carbene analogues of silicon, germanium and tin. As with the multiply bonded derivatives of these elements, silylenes, germylenes and stannylenes are unisolable transient intermediates, although several have been studied either at high or low temperatures. Electronically, carbenes behave quite differently to their heavier analogues, and invariably have a triplet ($^3B_1$) ground state with the singlet ($^1A_1$) ground state to higher energy.[94,100–106] However, with dihalogenocarbenes,[107,108] silylenes,[109] germylenes[110,111] and stannylenes,[111] the opposite order of energy states is observed and the latter types of intermediate react as such.[112,113] Structurally, all are angular molecules, although the sterically crowded carbene, dimesitylcarbene, has a nearly linear skeleton (*cf.* other diarylcarbenes where the bond angle is *ca.* 150°).[114] Structural data, both calculated and experimental, are collected in Table 6. Consideration of the data confirm the singlet ground state in each case. Particularly diagnostic is the low value of the XMX bond angle, which is calculated to be about 15–25° higher in the triplet first excited state. In addition, the M—X bond distance is reduced in the triplet excited state, which would appear to indicate a greater *p* character for the bonds in the ground state. Vibrational spectra for mixed-isolated SiH_2,[115] $SiMe_2$[116] and halogenated silylenes,[117–120] germylenes and stannylenes[121] confirm the bent C_{2v} geometry for these molecules in this condensed phase. Irradiation of $SiMe_2$ with 450 nm light under these conditions promotes its photoconversion to 1-methylsilene (equation 7).[116]

26.3.3 Bivalent Germanium, Tin and Lead Halide Structures

The C_{2v} geometry characteristic of isolated molecules of bivalent germanium, tin and lead[122] halides in the vapour phase or low-temperature rare gas matrices (*vide supra*) is not preserved in their solid lattices. Rather, variants of close-packed lattices are formed with distortions arising because of the metal non-bonding pair of electrons. The basic structural unit is usually recognizable as a trigonal pyramid (**15**), where the metal forms three quite short bonds with angles of *ca.* 90°, but additional bonds or contacts are often present leading to distorted pseudotrigonal bipyramidal (**16**), octahedral (**17**) or facially capped trigonal prismatic (**18**) coordination geometries.

(15) (16) (17) (18)

The structures of the binary metal(II) halides show a distinct trend to a more ionic type of lattice as the atomic numbers of the metal and halogen increase. Both germanium(II) and tin(II) fluorides have a strongly fluorine-bridged structure in which the structural unit is an $[MF_3]$ trigonal pyramid.[123–125] In GeF_2, these units are fluorine-bridged giving infinite spiral chains in which the germanium atoms have pseudotrigonal bipyramidal geometry (Figure 1a). Crystals of monoclinic SnF_2, however, comprise puckered eight-membered $[Sn_4F_4]$ rings, and each tin atom is coordinated by a highly distorted octahedron of fluorine atoms (Figure 1b). At normal temperatures, PbF_2 crystallizes with the cubic fluorite lattice,[126] but also forms an

orthorhombic modification with the prototype $PbCl_2$-type lattice (**18**) exhibited by anhydrous $SnCl_2$, $SnBr_2$ and $PbBr_2$.[127–129] In this layer-type lattice, the metal atom is surrounded by nine halogen atoms from three different layers, six at the apices of a trigonal prism and three in facially capping positions. The coordination is, however, far from regular, and the metal forms three short bonds (the typical $[MX_3]$ structural unit) together with four additional close contacts. A further two halogen atoms are at even longer distances. Germanium(II) and lead(II) iodides crystallize with the hexagonal anti-CdI_2 lattice, in which the metal atom is surrounded octahedrally by six iodine neighbours, although both compounds exhibit a large number of modifications which differ in the layer sequence.[130,131] Crystals of tin(II) iodide possess a unique layer lattice with the metal atoms occupying two different sites. Two-thirds occupy sites based on the $PbCl_2$-type lattice, each metal atom being coordinated by six iodine atoms at the apices of the trigonal prism, and also by a seventh from a symmetry-related prism in a facial position (Figure 2). The remaining tin atoms are in $PdCl_2$-type chains, which interlock with the $PbCl_2$-type part of the structure to give almost perfect octahedral coordination.[132]

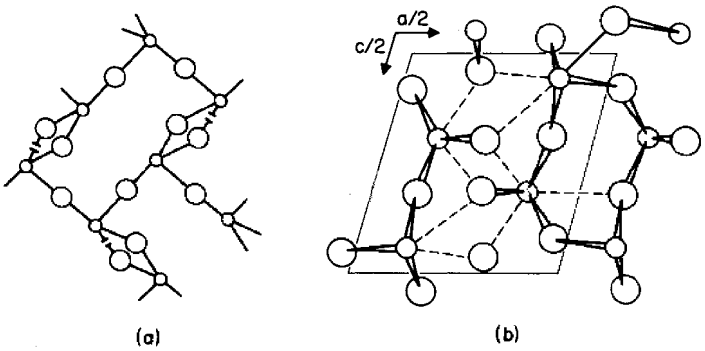

Figure 1 Crystal structures of (a) GeF_2 and (b) the monoclinic modification of SnF_2

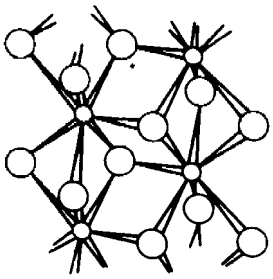

Figure 2 View of the trigonal prismatic sites in SnI_2

A similar range of coordination geometries is also observed for halide complexes and mixed halides. Although many complexes of stoichiometries $MX_2 \cdot L$ and $MX_2 \cdot 2L$ have been synthesized, the structures of only a few are known. Crystals of the *N*-methylbenzimidazole complex of germanium(II) chloride comprise isolated pyramidal adduct molecules.[133] The basic unit of the thiourea complex of tin(II) chloride is again the pyramidal $[SnCl_2 \cdot S{=}C(NH_2)_2]$ adduct, but in this case these units are tightly bound into chains by both chlorine and sulfur bridging.[134] In contrast, the structure of the 1,4-dioxane complex consists of $SnCl_2$ units linked by dioxane ligands to form polymeric chains, with pseudotrigonal bipyramidal geometry for tin (Figure 3).[135]

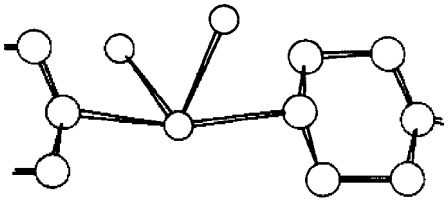

Figure 3 The stereochemistry at tin in *catena*-$SnCl_2$·dioxane

The structures of the tin(II) and lead(II) bromide hydrates, $2SnBr_2 \cdot H_2O$, $3SnBr_2 \cdot H_2O$, $6SnBr_2 \cdot 5H_2O$ and $3PbBr_2 \cdot 2H_2O$, are based upon the trigonal prismatic geometry (**18**) of the anhydrous halides. The metal atoms are surrounded by a trigonal prism of bromine atoms, with bromine atoms, water molecules or vacancies in the facially capping sites. Different coordination types may occur within the same hydrate. For example, in $2SnBr_2 \cdot H_2O$ the tin atoms may experience coordination by either eight bromines, seven bromines and a water molecule, or seven bromines.[136,137] Tin(II) chloride dihydrate has a markedly different structure. One of the water molecules is strongly coordinated to the tin atom forming $[SnCl_2 \cdot H_2O]$ units with typical pyramidal geometry, which form double layers alternating with layers of water of crystallization. Layers are held together by a network of hydrogen bonds.[138,139] The structure of basic tin(II) chloride is very complex indeed. The correct composition is $Sn_{21}Cl_{16}(OH)_4O_6$, and not Sn(OH)Cl as first thought. The structure consists of infinite anionic and cationic nets of stoichiometry $[Sn_5(OH)_6Cl_6]_\infty^{2\infty-}$ and $[Sn_8O_3(OH)_4Cl_5]_\infty^{3\infty+}$, with $[Sn(OH)_3]$, $[Sn(OH)_2Cl]$, $[Sn(OH)_2Cl_2]$ and cubane $[Sn_4O_3(OH)]$ units and intercalated chloride ions.[140] The lead atom in basic lead chloride, Pb(OH)Cl, is surrounded by five chlorine atoms and three hydroxyl groups in a polyhedron best described as a strongly distorted square antiprism.[141]

Several examples of pyramidal $[MX_3]^-$ anions have been characterized, although most involve additional longer contacts. Discrete isolated $[GeCl_3]^-$ and $[SnCl_3]^-$ anions occur in $[C_{11}H_{17}N_2O_2][GeCl_3]H_2O$,[142] and red and green isomers of $[Co(Ph_2PCH_2CH_2PPh_2)Cl][SnCl_3]$[143] and $[Co(en)_3][SnCl_3]Cl_2$.[144] No interaction occurs between the two anions in the latter compound, whereas the closely related compound, $[Co(NH_3)_6][SnCl_4]Cl$, contains discrete pseudotrigonal bipryamidal $[SnCl_4]^{2-}$ anions.[144] An intermediate situation is present in the structure of $[NH_4]_2[SnCl_3]Cl \cdot H_2O$, where significant interaction between the chloride and trichlorostannate(II) ions occurs. However, neighbouring $[SnCl_3 \cdots Cl]$ units are also connected by two longer $Sn \cdots Cl$ bridges forming a chain structure and completing a severely distorted octahedral environment about the tin.[145] A similar distorted octahedral coordination with three short and three much longer metal–halogen distances is also found in $[NH_4][SnF_3]$,[146,147] $RbGeCl_3$[148] and the low temperature forms of $CsGeCl_3$[149] and $CsSnCl_3$.[150] These two latter materials, along with other cesium trihalogenometallates(II), undergo phase transitions to modifications with the cubic perovskite lattice, in which the Group IV metal has ideal octahedral coordination.[151–155] The methylammonium salts, $[MeNH_3][SnBr_xI_{3-x}]$ ($x = 0$–3), $[MeNH_3][PbX_3]$ and $[MeNH_3][Pb_nSn_{1-x}X_3]$ (X = Cl, Br, I) also have the cubic perovskite lattice,[156] and like the alkali metal salts are intensely coloured and exhibit electrical conductivity due to population of lattice conduction bands by the non-bonding electrons of the Group IV metal. Regular octahedral coordination is very common with the larger halogens, presumably largely due to steric reasons, there being little room for metal(II) lone pair stereoactivity, and is found in crystals of orthorhombic $RbPbI_3$,[157] $CsSnI_3$[158] and the hydrates $KPbI_3 \cdot 2H_2O$, $NH_4PbI_3 \cdot 2H_2O$ and $RbPbI_3 \cdot 2H_2O$[159] which all comprise double chains of edge-sharing $[MI_6]$ octahedra held together by the cations and, in the case of the hydrates, water molecules.

Whereas crystals of $[NH_4][SnF_3]$ contain essentially isolated pyramidal $[SnF_3]$ anions,[146,147] the potassium salt $KSnF_3 \cdot \frac{1}{2}H_2O$ consists of infinite $[SnF_3]_\infty^{\infty-}$ chains, in which the tin atoms have a distorted square pyramidal geometry (Figure 4a). Within the chains, each tin atom forms longer bonds to the bridging fluorines, whilst the lone pair is directed away from the basal plane.[160] $NH_4SnBr_3 \cdot H_2O$ has an analogous structure, with water molecules and ammonium ions forming rows between the chains.[161] Intermediate between these two extremes are the $[Sn_2F_5]^-$ and $[Sn_3F_{10}]^{4-}$ anions. The former comprises two $[SnF_3]$ pyramids sharing a common fluorine atom (Figure 4(b)), although a fourth fluorine is located at a distance of only 253 pm from the tin and hence the structure may also be regarded as containing infinite $[Sn_2F_5]_\infty^{\infty-}$ chains.[162] The $[Sn_3F_{10}]^{4-}$ anion consists of three distorted square pyramidal $[SnF_4]$ units similar to those found in $KSnF_3 \cdot \frac{1}{2}H_2O$ (Figure 4(c)).[163]

A number of materials have been characterized which contain cationic fluorotin(II) networks, including Sn_2F_3Cl,[164] Sn_3F_5Br,[165] Sn_2F_3I[166] and $[Sn_5F_9][BF_4]$.[167] In these, the tin atoms enjoy typical pyramidal $[SnF_3]$ or distorted square pyramidal $[SnF_4]$ coordination, with the halide or $[BF_4]^-$ anions occupying large holes within the networks, as illustrated in Figure 5 for Sn_3F_5Br. Closely related to these structures are those of the mixed-valence fluorides, Ge_5F_{12}[168] and Sn_3F_8,[169] where the cationic fluorometal(II) networks are cross-linked by *trans*-bridging octahedral $[M^{IV}F_6]$ units (Figure 6). In contrast, SnFCl[170] and SnF(NCS)[171] have fluorine-bridged ribbon-like structures with pendant chlorine atoms or isothiocyanate groups

from each four-coordinated tin. That of SnFCl is shown in Figure 7. The tin(II) and lead(II) chloride iodides are different still and have a distorted trigonal bipyramidal geometry.[172]

Although many complexes are known in which the trichlorostannate(II) anion functions as a donor to transition metals, very few to main group Lewis acids have been described and no strucural data are available. However, the complexes $B \rightarrow SnX_2 \rightarrow BF_3$ (X = Cl, Br, I; B = NMe_3, bipy, TMEDA and DMSO), in which the tin(II) halide functions simultaneously as both a Lewis acid and a Lewis base, have been reported.[173]

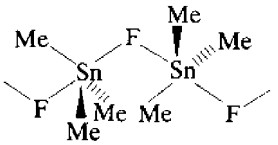
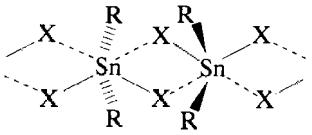
26.3.4 Tetravalent Halides and Halide Complexes

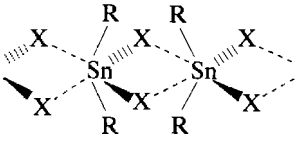


Tetrahedral geometry dominates the structural chemistry of the halides of silicon and germanium, and all the tetrahalides MX_4, hydride halides MH_nX_{4-n} ($n = 1$–3) and organometallic halides, MR_nX_{4-n} ($n = 1$–3; R = alkyl, alkenyl, aryl), exhibit this stereochemistry in all three phases.[174] In contrast, although the analogous tin derivatives are also tetrahedral in the vapour and liquid phases,[196] the solid tin and lead halides show a preponderance for the formation of halogen-bridged lattices. The tetrahedral compounds warrant little comment, although it is notable that the metal–halogen distance increases whilst the metal–carbon distance decreases in the series Me_nMX_{4-n} as the halogen content of the molecule increases, which is consistent with a redistribution of *p* character in the bonds to the more electronegative ligands.

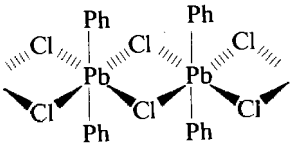
In contrast to the other tin(IV) halides which are tetrahedral molecules, tin(IV) fluoride forms a very strongly fluorine-bridged, two-dimensional sheet structure with octahedrally coordinated tin (**19**).[197] Dimethyltin fluoride[198] (and almost certainly methyltin trifluoride[199]) has a very similar sheet structure in which the non-bridging fluorine atoms in (**19**) are replaced by methyl groups. Fluorine bridging in trimethyltin fluoride results in a one-dimensional chain structure with a planar $[Me_3Sn]$ moiety and trigonal bipyramidal coordination at tin (**20**).[200] These polymeric materials are infusible and insoluble. Other organotin fluorides are similar and only when the organic groups are very large (*e.g.* in $(PhMe_2CCH_2)_3SnF$) does steric hindrance perhaps preclude association. Bridging by the other halogens is much weaker. A loosely associated one-dimensional chain structure similar to that of Me_3SnF has been observed for trimethyltin chloride at 135 K,[201] whereas crystals of Ph_3SnCl,[202] Ph_3SnBr,[203] $[(Me_3Si)_2CH_2]_3SnCl$[204] and $(Me_3SiCH_2)_3SnI$[205] contain discrete isolated molecules. The distortion away from tetrahedral geometry in tricyclohexyltin chloride suggests some intermediate state.[206] Association into one-dimensional chains occurs for dialkyltin dihalides when the alkyl group is very small. Two types of structure have been characterized. In crystals of dimethyltin dichloride[207] and diethyltin dichloride and dibromide,[208] the chains are formed by the two covalently bonded halogen atoms on each tin bridged to two different tin atoms in the chain as in (**21**), whereas in diethyltin diiodide[208] and bis(chloromethyl)tin dichloride[209] the two halogen atoms essentially chelate the next tin atom in the chain as in (**22**). In both, the geometry at tin is highly distorted, and is best regarded as intermediate between tetrahedral and octahedral. No intermolecular interaction appears to be present in crystals of diphenyltin dichloride[209,210] and bis(biphenyl-2)tin dichloride,[211] although both molecules are distorted from tetrahedral geometry. Bridging by chlorine and bromine is much more effective in the organolead halides. Triphenyllead chloride and bromide have an analogous structure to that of trimethyltin fluoride, although as with trimethyltin chloride, the two lead–halogen distances differ substantially.[212] Symmetrical chlorine bridging occurs in diphenyllead dichloride giving rise to



polymeric chains with octahedrally coordinated lead (**23**).[213] Vibrational spectra indicate that the corresponding methyllead halides possess the same structures in the solid, but tetrahedral monomers occur in solution.[214,215]

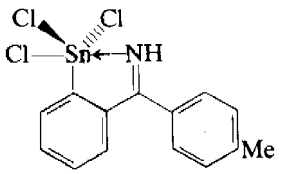


(**19**)

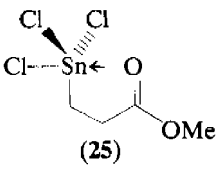


(**20**)

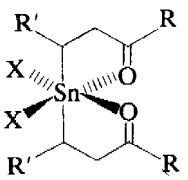
(**21**)



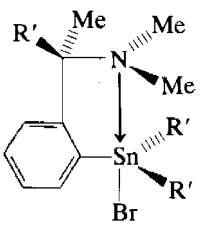
(**22**)



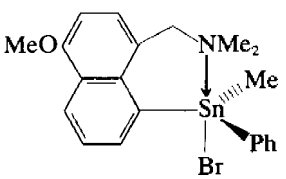
(**23**)



Higher coordination numbers in organotin chlorides can also arise by intramolecular coordination of a donor atom remote in the organic ligand such as in (**24**)–(**28**).[216–222] When two nitrogen atoms are present on the organic group, ionization of halide from tin can occur, as in (**29**).[223] The methylphenyltin homologues, (**27**; R = Me, R′ = Ph) and (**28**), contain chiral tin atoms and exhibit high optical stability since the intramolecular coordination blocks the pathways for stereoisomerization. However, dynamic processes do occur which have been examined by variable temperature NMR and involve Sn—N bond dissociation and inversion at the then uncoordinated nitrogen atom.[222,224] Analogous processes have been observed in the cationic species (**29**),[223] and also in the five-coordinated fluorosilanes (**30**).[225] Intramolecular coordination in the 2-benzoyloxyethylsilanes, $PhCO_2CH_2CH_2SiX_3$ (X = Cl, F), is much weaker than in the analogous tin derivatives such as (**25**), and these compounds can exist in solution as either an acyclic form with four-coordinated silicon or as an intramolecularly five-coordinated heterocycle depending on the concentration and the nature of the solvent.[226] Many other five-coordinated silicon halides have been characterized; (**31**),[227] (**32**)[228] and (**33**)[229] are recent examples illustrating the trigonal bipyramidal geometry typically adopted by such compounds.



(**24**)



(**25**)

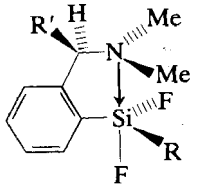
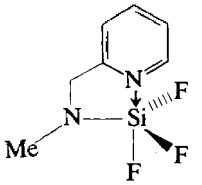
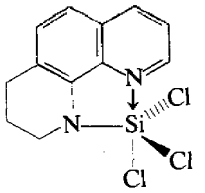
X = Br; R = OEt; R′ = CO_2Et



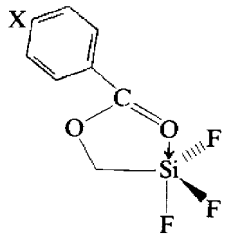
(**27**) R, R′ = Me, Ph; R″ = H, Ph



(**28**)

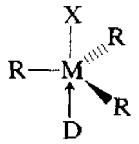


(**29**)

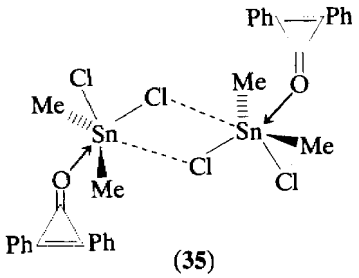


(**30**) R = F, Me

(**31**)

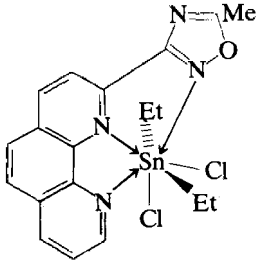


(**32**)



(**33**) X = F, Cl, Br

The silicon(IV), germanium(IV) and tin(IV) halides MX_4 and organometallic halides $R_{4-n}SnX_n$ are good Lewis acids and acceptors of halide and neutral donor molecules. Lewis acidity in these halides increases in the order Si < Ge < Sn < Pb, I < Br < Cl < F and $n = 1 < 2 < 3 < 4$, and is reflected in the stoichiometry and stability of the resulting complexes. Thus, whereas trimethylchlorosilane shows no tendency for complex formation with pyridine,[230] the corresponding tin adduct, $Me_3SnCl{\cdot}C_5H_5N$, was the first authenticated five-coordinated tin complex.[231] Coordination saturation appears to be reached in the trigonal bipyramidal arrangement (**34**) with a planar $[Me_3M]$ moiety for the monohalides, but the dihalides, trihalides and tetrahalides can form 1:2 adducts with an octahedral geometry as well as 1:1 adducts with the trigonal bipyramidal geometry. In the latter, the organic groups always occupy equatorial sites.



(**34**)

Typical examples of five- and six-coordinated complexes and complex anions are listed in Table 7. The 1:1 adduct of dimethyltin dichloride and diphenylcyclopropenone is unusual, and comprises a chlorine-bridged dimer with distorted octahedral geometry for tin (**35**),[232] rather than the usual trigonal bipyramidal geometry found in most other 1:1 complexes such as Ph_2SnCl_2·benzothiazole.[238] Two types of behaviour are observed with terdentate ligands. In some isolated cases, seven-coordinated adducts with a distorted pentagonal bipyramidal geometry such as (**36**) are formed.[234,235] but 2,2′,2″-terpyridine promotes displacement of halogen from tin and the formation of ionic complexes such as $[Me_2Sn(terpy)Cl]^+[Me_2SnCl_3]^-$ containing six-coordinate cations and five-coordinate anions.[236] Ionization of halide takes place more readily with bromine and iodine which are more weakly bonded to the Group IV element. Thus, whereas hexamethylphosphoric triamide forms a neutral, trigonal bipyramidal adduct with trimethyltin chloride, the ionic complex $[Me_3Sn(hmpt)_2]^+[Me_3SnBr_2]^-$ is formed with trimethyltin bromide.[237] Similarly, stable ionic 1:1 adducts of the type $[Me_3Si{\cdot}D]^+X^-$ (X = Cl, Br; D = pyridine, hmpt) have been isolated from the interaction of trimethylbromo- and trimethyliodo-silanes with the donor,[238] whilst all four Si—I bonds are cleaved on dissolution of silicon(IV) iodide in the same solvent, from which the complex $[Sn(hmpt)_6]^{4+}4I^-$ containing octahedrally coordinated silicon was isolated.[239]

(**35**)

(**36**)

Various stereochemical permutations are observed for octahedral tin complexes. Adducts of tin(IV) chloride and bromide generally exhibit the *cis* geometry (**37**),[240–247] although some examples of the *trans* geometry are known.[248–252] Reasons for the preference for the *cis*

geometry are not obvious, but the complexes with the *trans* structure are those with rather bulky donor molecules. Similarly confusing are the structures adopted by the complexes of organotin trihalides and diorganotin dihalides. The two donors are *trans* in the 2:1 pyridine and hmpt complexes of methyltin trichloride as in (**39**), but the analogous DMF complex adopts the *cis* structure (**40**).[253,254] The two organic groups in $R_2SnX_2 \cdot 2L$ complexes are always (to date, anyway!) invariably mutually *trans*, but again the two halide and the two donor molecules can adopt either configuration, (**41**) or (**42**), depending upon the nature of the substituents.[253–262]

IR and NMR spectroscopy are useful techniques for the characterization of complexes which cannot be isolated and for studying solution equilibria. The matrix isolation IR technique has been employed to demonstrate the formation of anions such as SiF_5^-, $MeSiF_4^-$, $Me_2SiF_3^-$ and GeF_5^-, as well as neutral 1:1 adducts such as $SiF_4 \cdot NH_3$.[263–267] ^{19}F NMR shows that the three

species, $[CF_3GeF_5]^{2-}$, *trans*-$[(CF_3)_2GeF_4]^{2-}$ and $[(CF_3)_3GeF_2]^-$, are present in solution when fluoride ion is added to the appropriate trifluoromethylgermanium fluoride $(CF_3)_nGeF_{4-n}$ ($n = 1$–3). Unusually, although the *trans* isomer of the $[(CCF_3)_2GeF_4]^{2-}$ anion exists in solution almost exclusively, crystallization affords the corresponding *cis* isomer (as the potassium salt).[268] ^{119}Sn NMR has been used to demonstrate the facile scrambling of halogen between different tin sites. Thus, all possible isomers occur in solution in mixtures of the tin(IV) halides, the anions SnX_5^- and SnX_6^{2-}, and neutral complexes such as $SnX_4{\cdot}2PBu_3$.[269,270] Formation constants may also be derived by an analysis of NMR chemical shift or coupling constant data.[271–273]

26.3.5 Binary and Ternary Chalcogenide Derivatives

Silica, SiO_2, exists in many different crystalline modifications, the principal ones being the α- and β-forms of quartz, tridymite and cristobalite. Other forms include the rather rare minerals, coesite and stishovite, synthetic forms such as keatite and W-silica, and vitreous silica as found in obsidian. All except for stishovite, which has the rutile structure with six-coordinated silicon, contain the $[SiO_4]$ tetrahedron as the basic structural unit. In α-quartz, the thermodynamically most stable form of silica at room temperature, and the other more common modifications, these tetrahedra are linked together by corner sharing forming infinite arrays. The structure of α-cristobolite is illustrated in Figure 8. Crystals of the two modifications of quartz comprise interlinked helical chains which may be either right- or left-handed so giving rise to the chirality of individual crystals. In the synthetic modification, W-SiO_2, adjacent $[SiO_4]$ tetrahedra are linked not by the corner sharing of single oxygen atoms but by the edge sharing of two oxygen atoms forming infinite parallel chains similar to those found in SiS_2 and $SiSe_2$ (Figure 9). Consistent with this structure, crystals of all three materials[274–277] are fibrous.

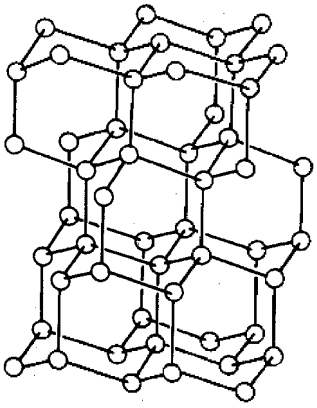

Figure 8 The structure of α-cristobolite illustrating the tetrahedral coordination for silicon.

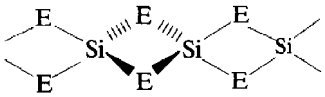

Figure 9 Schematic representation of the chain structures of W-SiO_2, SiS_2 and $SiSe_2$

Germanium(IV) oxide, GeO_2, forms two crystalline modifications. Hexagonal GeO_2 exhibits the β-quartz structure with four-coordinated germanium, whilst the tetragonal modification has a rutile-like structure with six-coordinated germanium and resembles stishovite.[278–280] Both tin(IV) and lead(IV) oxides possess the rutile structure (Figure 10), although another orthorhombic modification of PbO_2 is known with distorted octahedral coordination for lead.[279–283] Limited information is available for the mixed valence tin oxide Sn_3O_4,[284] but the lead analogue, Pb_3O_4, is well characterized and consists of chains of edge-sharing $[Pb^{IV}O_6]$ octahedra linked by pyramidal $[Pb^{II}O_3]$ units.[285–287]

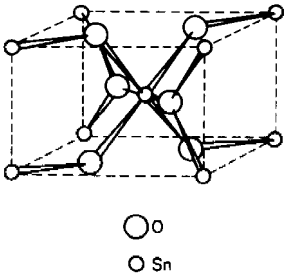

Figure 10 The unit cell of the rutile structure

Germanium(IV) sulfide exhibits two modifications, one with the chain structure illustrated in Figure 9, and the other, like the corresponding selenide, with a distorted CdI_2 lattice.[288] Tin(IV) sulfide and selenide both crystallize with the CdI_2 lattice.[274] The mixed valence tin sulfide, Sn_2S_3, consists of infinite double rutile strands of corner and edge sharing $[SnS_6]$ octahedra connected by tin(II) atoms in typical pyramidal coordination.[289,290]

Tetragonal tin(II) and lead(II) oxides form layer-lattice structures with square pyramidal metal coordination and equal metal–oxygen distances (Figure 11).[291] The metastable orthorhombic modification of PbO has a similar, but more loosely bound layer structure with two short and two longer lead–oxygen distances.[292] Hydrolysis of tin(II) and lead(II) salts yields oxo-metal ions of many different types depending upon the conditions, particularly the pH, some of which have been isolated and characterized crystallographically. The basic tin(II) sulfate, $[Sn_3O(OH)_2]SO_4$, contains discrete $[Sn_3O(OH)_2]^{2+}$ cations in which two of the three tin(II) atoms have distorted square pyramidal four-coordination and the third pyramidal three-coordination.[293,294] The $[Pb_4(OH_4)]^{4+}$ cation, in which the lead atoms occupy the corners of a slightly distorted tetrahedron with the hydroxyl groups capping each face, is present in crystals of $[Pb_4(OH)_4]_3(CO_3)(ClO_4)_{10}\cdot 6H_2O$ and $[Pb_4(OH)_4](ClO_4)_4$.[295] The homologous $[Pb_6O(OH)_6]^{4+}$ cation is present in the α- and β-modifications of $[Pb_6O(OH)_6](ClO_4)_4\cdot H_2O$. This cation is made up of three $[Pb_4]$ tetrahedra sharing common faces, with the oxygen atom located at the centre of the central tetrahedron rather like in the structure of the neutral species $Pb_4O(OSiPh_3)_6$.[296] The six hydroxyl groups are located above each of the six unshared faces of the two terminal tetrahedra.[297,298] From neutral solutions, the hydrate oxides, $3MO\cdot H_2O$ (M = Sn, Pb), may be isolated which contain adamantane-like $[M_6O_8]$ clusters,[299] very similar to those in $[Sn_6O_4(OMe)_4]$.[300]

The influence of the non-bonding pair of electrons on the coordination geometry adopted by the binary metal chalcogenide decreases markedly with increase in size of other Group VI elements. Germanium(II) sulfide and selenide have very distorted NaCl-type lattices with three short and three long contacts.[301–303] Tin(II) sulfide has a structure with parallel zigzag —Sn—S—Sn—S—Sn—S chains, which are connected by short interchain Sn—S contacts giving a basic pyramidal $[SnS_3]$ structural unit. Tin(II) selenide exhibits one phase which is isomorphous with the sulfide, and a second cubic phase with the NaCl lattice, which is also adopted by tin(II) telluride as well as lead(II) sulfide, selenide and telluride.[304–308]

Silicates, together with the closely related aluminosilicates, form what is certainly the largest

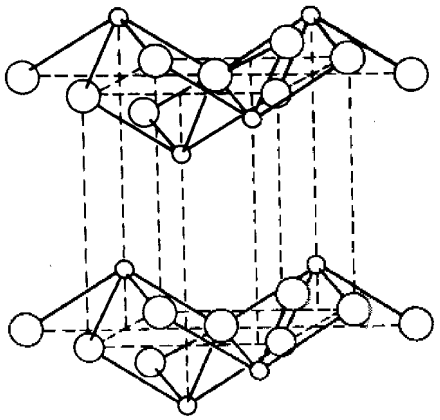

Figure 11 The layer lattice of tetragonal SnO and PbO

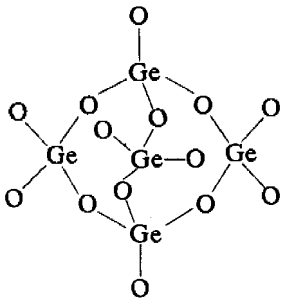


family of compounds known in inorganic chemistry. Many other excellent texts and treatises are available,[274,275,309–311] and hence no more than a cursory account is presented here. Despite the enormous variety of stoichiometries and structural types observed, all follow but a few structural principles: (i) silicon is almost without exception tetrahedrally coordinated by four oxygen atoms, (ii) the overall silicate lattice may be regarded as being made up from the close packing (or very nearly so) of oxygen atoms, in which silicon, aluminum and other metal atoms occupy interstices, (iii) small atoms (Li^{I}, Be^{II}, Al^{III}, Si^{IV}) can occupy tetrahedral interstices, whilst larger metal atoms (Na^{I}, K^{I}, Mg^{II}, Ca^{II}, Fe^{II}, Al^{III}, Ti^{IV}) occupy octahedral holes, (iv) charge balance is accomplished by hydroxyl-for-oxygen or by modification of the metal content of the lattice. Alternatively, silicate structures may be regarded as containing $[SiO_4]$ tetrahedra, which can be 'isolated' as in orthosilicates or *neso*-silicates such as in the olivine minerals or synthetic silicates such as Na_4SiO_4,[312] or form disilicates, chain and cyclic silicates, sheet silicates or infinite three-dimensional networks, by sharing one, two, three or all four oxygen atoms respectively, with other $[SiO_4]$ tetrahedra. Some typical examples are shown in Table 8.

Table 8 Principal Types of Silicate Structures

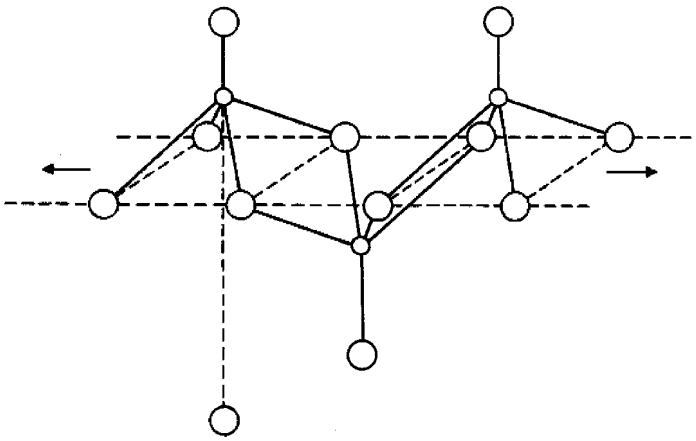
Nomenclature	*Description*	*Examples*
Orthosilicates or *neso*-silicates	Isolated $[SiO_4]$ tetrahedra	Olivine, $(Mg, Fe, Mn)(SiO_4)$ Zircon, $Zr(SiO_4)$
Disilicates or *soro*-silicates	Discrete $[Si_2O_7]$ units formed by two $[SiO_4]$ tetrahedra sharing a common oxygen	Thortveitite, $Sc_2(Si_2O_7)$ Hemimorphite, $Zn_4(OH)_2(Si_2O_7)H_2O$
Cyclic metasilicates or *cyclo*-silicates	Closed rings of $[SiO_4]$ tetrahedra sharing two oxygen atoms	Benitoite, $BaTi(Si_3O_9)$ Beryl, $Be_3Al_2(Si_6O_{18})$ Murite, $[Ba_{10}(Ca, Mn, Tl)_4(Si_8O_{24})\text{-}(Cl, OH, O)_{12}]\cdot 4H_2O$
Chain metasilicates or *ino*-silicates	Chains or ribbons of $[SiO_4]$ tetrahedra sharing two oxygen atoms	Jadeite, $NaAl(Si_2O_6)$ Wollastonite, $Ca_3(Si_3O_9)$ Tremolite, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$
Layer silicates or *phyllo*-silicates	Two-dimensional sheets of $[SiO_4]$ tetrahedra sharing three oxygen atoms	Kaolinite, $Al_4(OH)_8(Si_4O_{10})$ Talc, $Mg_3(OH)_2(Si_4O_{10})$ Muscovite, $KAl_2(OH)_2(AlSi_3O_{10})$
Three-dimensional or *tecto*-silicates	Three-dimensional frameworks of $[SiO_4]$ tetrahedra sharing all four oxygen atoms	Feldspars, zeolites, ultramarines

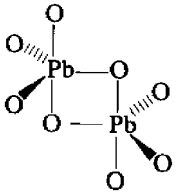
Despite being much less numerous, the structures of germanates bear a striking resemblance to their silicate analogues, and generally comprise lattices formed from basic $[GeO_4]$ tetrahedral units. Thus, the orthogermanates, $BeGeO_4$ and Zn_2GeO_4, contain isolated $[GeO_4]$ tetrahedra, the digermanate, $Sc_2Ge_2O_7$, the $[Ge_2O_7]$ unit, whilst the metagermanates, $BaTiGe_3O_9$ and $CaMgGe_2O_6$, possess cyclic $[Ge_3O_9]$ units and infinite $[GeO_3]_\infty$ chains, respectively. However, several germanates also exhibit octahedral $[GeO_6]$ structural units. For example, the structure of lead α-tetragermanate, α-$PbGe_4O_9$, is based on a mixed Ge—O

lattice with the lead atoms situated in lattice vacancies formed by $[GeO_4]$ tetrahedra and $[GeO_6]$ octahedra,[313] whilst that of $K_2Ba[Ge_4O_9]_2$ consists of rings built up from $[GeO_4]$ tetrahedra, which are linked by $[GeO_6]$ octahedra to form a three-dimensional network.[314] Some germanate species are very unusual and do not have their counterparts in silicate chemistry. The $[Ge_5O_{14}]$ clusters (**43**) found in $Tl_8Ge_5O_{14}$ are formed from five $[GeO_4]$ tetrahedra, three of which share two oxygen atoms whilst the other two each share three.[315]

(**43**)

The structures adopted by the stannates are profoundly different to those of silicates and germanates, in spite of the similarity in stoichiometries. Tin generally is six-coordinated in a regular or slightly distorted octahedral fashion by oxygen atoms, although four- and five-coordination do occur. In addition, a number of hydroxystannate(II) species have been characterized. The sodium salts, $Na_2[Sn_2O(OH)_4]$ and $Na_4[Sn_4O(OH)_{10}]$, contain the $[Sn(OH)_3]^-$ and oxo-bridged $[(HO)_2SnOSn(OH)_2]^{2-}$ anions respectively,[316] whilst the barium salt, $Ba[SnO(OH)]_2$, contains the one-dimensional polyanion, $[SnO(OH)]_\infty^{\infty-}$.[317] All three exhibit typical pyramidal coordination for bivalent tin. Octahedral oxygen coordination about tin is present in all the hydroxystannates(IV), $M[Sn(OH)_6]$ (M = 2Na, 2K, Mg, Ca, Mn, Fe, Co, Ni, Cu, Zn, Cd).[318–326] Potassium orthostannate, K_4SnO_4, is isotypic with K_4GeO_4 and contains discrete, isolated $[SnO_4]$ tetrahedra,[327–329] but other materials of the stoichiometry M_2SnO_4 (M = Mg, Ca, Sr, Ba, Mn, Co, Cd, Zn) are not true orthostannates and contain $[SnO_6]$ octahedra which share common edges to give chain or layer structures.[330–335] Octahedrally coordinated tin is also present in the 'distannates', $M_2Sn_2O_7$ (M = lanthanide elements, Bi),[336–338] and most 'metastannates', $MSnO_3$ (M = Li, Tl, Mg, Ca, Sr, Ba, Mn, Cd, Pb).[339–345] The potassium and rubidium metastannates, however, have unusual square pyramidal five-coordination for tin, and the solid contains infinite $[SnO_3]_\infty^{\infty-}$ polyanions as shown in Figure 12.[346,347]





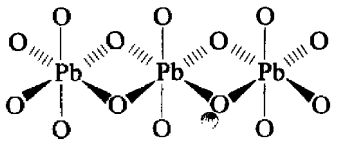


Figure 12 The structure of the infinite $[SnO_3]_\infty^{\infty-}$ polyanions in M_2SnO_3 (M = K, Rb)

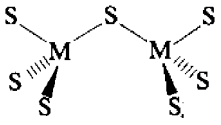
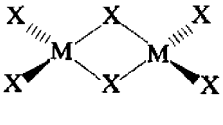
Potassium, rubidium and cesium orthoplumbates M_4PbO_4 (M = K, Rb, Cs) all contain isolated $[PbO_4]$ tetrahedra, as does Rb_3NaPbO_4.[348–350] The structure of the 'metaplumbate', Li_2PbO_3, like Li_2SnO_3, is a variant of the NaCl lattice, with octahedrally coordinated lead,[351]

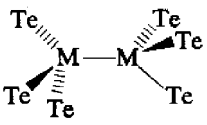
whilst the diplumbate, $K_2Li_2(Pb_2O_8)$,[352] and the triplumbates, $M_2Li_{14}(Pb_3O_{14})$ (M = K, Rb, Cs),[353] contain the discrete $[Pb_2O_8]$ (**44a**) and $[Pb_3O_{14}]$ (**44b**) units respectively. Sodium plumbate(II), Na_2PbO_2, has a layer lattice,[354] although the analogous silver salt contains infinite $[PbO_2]_\infty^{2\infty-}$ chains.[355]



(**44a**)



(**44b**)



The structures of heavier chalcogenide analogues of the silicates, germanates and stannates are largely based upon the tetrahedral $[MX_4]$ unit. Isolated orthothiosilicate anion, $[SiS_4]^{4-}$, and all six orthogermanate and orthostannate anions, $[MX_4]^{4-}$ (M = Ge, Sn; X = S, Se, Te), have been characterized.[356–363] Three types of binuclear anion are known. The $[M_2S_7]^{6-}$ (M = Si, Ge, Sn)[357,364,365] and $[M_2X_6]^{4-}$ (M = Ge, X = S, Se; M = Sn, X = S)[366,367] are formed by the vertex sharing (**45**) and edge sharing (**46**), respectively, of two $[MX_4]$ tetrahedra, but the tellurium derivatives, $[M_2Te_6]^{6-}$ (M = Si, Ge, Sn), contain the metal–metal-bonded arrangement (**47**) with a staggered conformation.[368–370] The metathiometallates, Na_2GeS_3[371] and $K_2SnS_3{\cdot}2H_2O$,[372] form infinite $[MS_3]^{2-}$ chains, whilst $Eu_3Ge_3S_9$[373] contains the cyclic $[Ge_3S_9]^{6-}$ anion. A two-dimensional sheet structure is present in La_2GeS_5,[374] formed as with the metathiometallates by the vertex sharing of tetrahedra. The tetranuclear anions, $[Ge_4S_{10}]^{4-}$, $[Ge_4Se_{10}]^{4-}$ and $[Si_4Te_{10}]^{4-}$, adopt a central adamantane-like framework, but may be more consistently described as being composed of four $[MX_4]$ tetrahedra each sharing two vertices with adjacent tetrahedra.[367,375–378] The $[Ge_4Te_{10}]^{8-}$ anion, however, has the cyclic structure $[Te(GeTe_2)_4Te]$.[379] Not unexpectedly, higher coordination numbers are observed with tin. In $Tl_2Sn_2S_5$, the tin has a five-coordinated distorted trigonal bipyramidal geometry,[380] and a six-coordinated distorted octahedral geometry is observed in the lanthanide thiostannates, La_2SnS_5,[381;382] Fe_2SnS_4[383] and Mn_2SnS_4.[384]

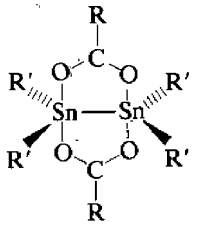
(**47**)

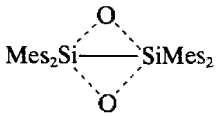
26.3.6 Tetravalent Compounds of Groups IV, V and VI



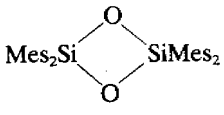
Compounds containing bonds to elements of Groups IV, V and VI illustrate the rather sharp distinction in the structural chemistries of silicon and germanium on the one hand and tin and lead on the other. The coordination chemistries of silicon and germanium are very similar indeed, and tetrahedral four-coordination is overwhelmingly the rule. Tin and lead compounds in contrast endeavour, wherever possible, to adopt structures containing coordination numbers higher than four, the most common being five and six, although examples of seven and eight are known as well.

Compounds containing four bonds to carbon are almost without exception four-coordinate and tetrahedral, although bond distances vary somewhat. Bonds to electronegative organic ligands are generally longer and weaker, and hence more susceptible to cleavage. For example, the Pb–C (cyclopentadienyl) distance in $Ph_3PbC_5H_5$ is 10 pm longer than the bonds to the phenyl groups, and the bond is easily cleaved by protic reagents;[385] whilst the Sn—C bond distances in $Sn[CF_3]_4$ are lengthened by 6 pm compared with those in $SnMe_4$.[386] When electron withdrawal from the metal is accompanied by the presence of a donor atom remote in the ligand, as in the ethyl ester of trimethylplumbylacetic acid, $Me_3PbC(N_2)CO_2Et$, weak intermolecular association with five-coordination for the metal can occur (**48**) in spite of the presence of four lead–carbon bonds.[387]

Similarly, compounds containing metal–metal bonds are four-coordinated, except in the case of the 1,2-bis(dicarboxylato)ditin compounds, $(RCO_2)R'_2SnSnR'_2(O_2CR)$, which have the structure (**49**) where the carboxylato groups span the tin–tin bond.[388,389]



(**48**)



(**49**)

In contrast to other disiloxane derivatives, the SiOSi framework in $Ph_3SiOSiPh_3$ has unexpectedly been found to be linear[390] (*cf.* other disiloxanes and related compounds, *e.g.* $MeH_2SiOSiH_2Me$, $Me_2HSiOSiHMe_2$ and $Me_2SiOSiMe_3$,[391] $Ph_3GeOGePh_3$,[392] $Ph_3SnOSnPh_3$[393] and $Ph_3SiOPbPh_3$[394] which are bent at oxygen). The MOM frameworks in hexabenzyldigermoxane and hexabenzyldistannoxane are also linear, and the phenomenon in all three compounds was attributed to the low electronegativity of the metal coupled with the electron-donating character of the organic group.[395]

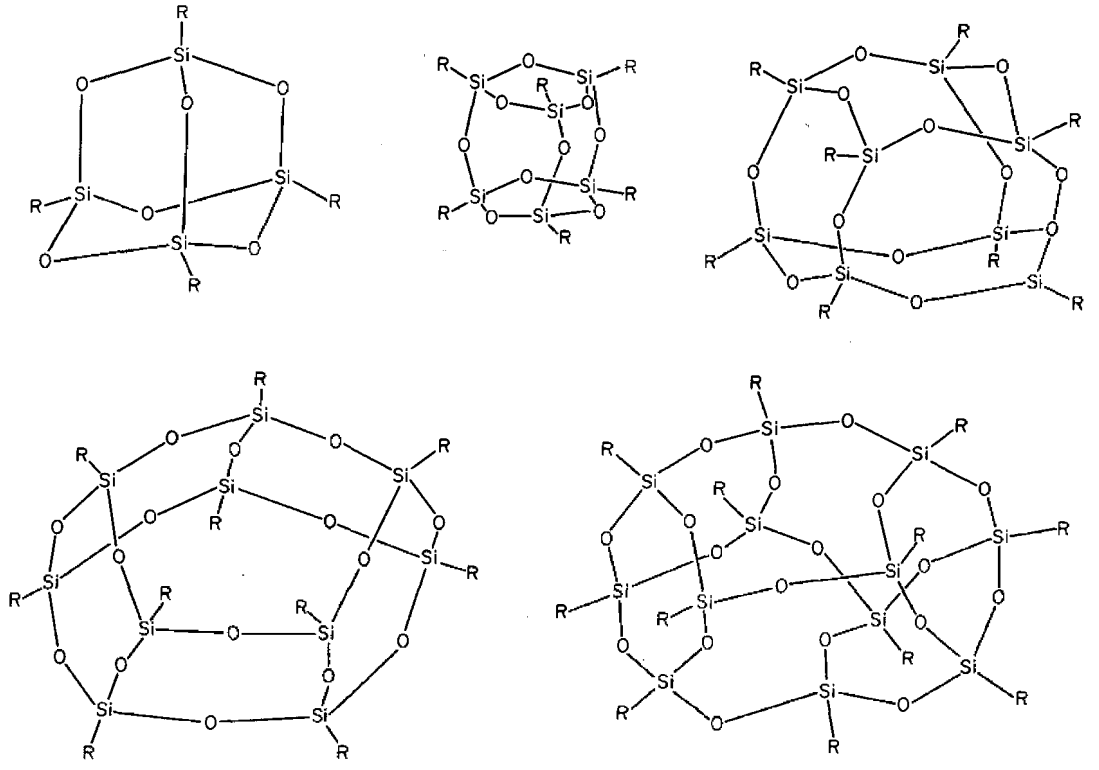
Both di-*tert*-butylsilanediol[396] and the analogous di-*tert*-germanediol[397] form hydrogen-bonded one-dimensional chain structures. Diorganodichlorosilanes and -germanes undergo hydrolysis to form cyclic compounds of composition $(R_2MO)_n$ where $n = 3$, 4, 5, 6, as well as polymeric material. All contain approximately tetrahedrally coordinated metalloid, although the exact conformation adopted by the heterocyclic rings depends upon the organic substituent and the ring size. The four-membered $[Si_2O_2]$ ring compound, tetramesityldisiloxane, obtained by the aerobic oxidation of tetramesityldisilene is rather intriguing. The most striking feature of the molecule is the transannular Si—Si distance (only 231 pm), which is actually shorter than a typical Si—Si bond distance (234 pm), and suggests the retention of some Si—Si bonding. Further, the two Si—O bond distances are longer than usual and unequal, and the SiOSi angle is highly constrained (86°). Further, treatment with lithium naphthalide followed by quenching with water yields the disilane-1,2-diol, $Mes_2Si(OH)—Si(OH)Mes_2$. Hence, the representation (**50**) is probably a truer description of the bonding than a conventional four-membered disiloxane ring (**51**).[398] No analogous transannular Si—Si interactions occur in other four-membered ring systems such as $Ph_2SiNPhSiPh_2NPh$,[399] $(Bu^tO)_2SiSSi(Bu^tO)S$,[400] $Me_2SiSSiMe_2S$,[401] $Cl_2SiCH_2SiCl_2CH_2$[402] and Ph_8Si_4.[403]

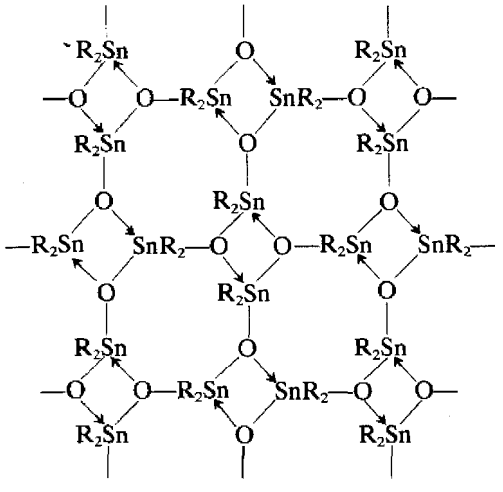
(**50**)

(**51**)

The sesquisiloxanes, $(RSiO_{1.5})_n$ ($n = 4$, 6, 8, 10, 12), adopt a variety of molecular cage structures (Figure 13).[404–408] The *tert*-butylgermanium sesquioxide, $(Bu^tGe)_6O_9$, has the same structure as its silicon analogue.[409]

The sharp antithesis between the molecular structures involving four-coordinated silicon and germanium and the diorgano-tin and -lead oxides, $(R_2MO)_n$ (M = Sn, Pb), and the stannonic and plumbonic acids, $[RM(OH)O]_n$, is astonishing for these latter materials are insoluble and infusible amorphous solids. No X-ray data are available, but the principal structural element in all of them is most probably the four-membered $[M_2O_2]$ ring. The tin compounds are much more studied than their lead counterparts. Indeed, of the plumbonic acids, only PhPb(OH)O has been characterized satisfactorily.[410] Spectroscopic data indicate a cross-linked, three-dimensional network such as (**52**) for the diorganotin oxides, where the stereochemistry of the tin atoms is close to trigonal bipyramidal with equatorial organic groups. The other materials most probably possess similar gross structures exhibiting the same major features. Cross-linking is, however, apparently prevented by bulky ligands, and di-*tert*-butyl- and bis[2,6-diethylphenyl]-tin oxides crystallize as trimeric molecules (**53**) with a planar $[Sn_3O_3]$ ring.[411,412]





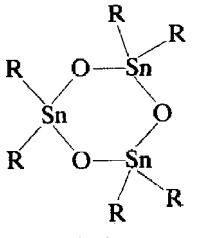


Figure 13 Cage structures formed by organosesquisiloxanes, $(RSiO_{1.5})_n$, where $n = 4$, 6, 8, 10 and 12

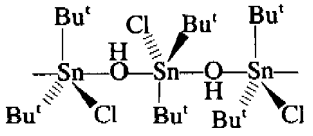
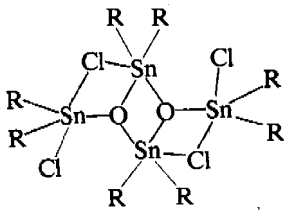
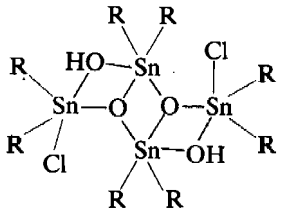


(52)

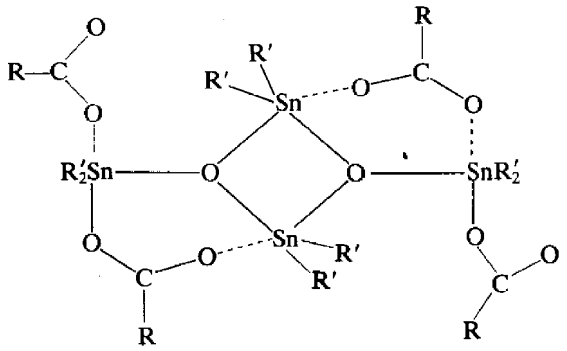


(53)

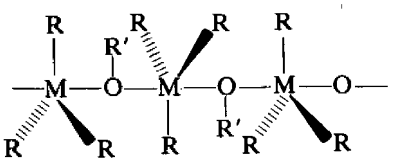
Much better characterized are the intermediates obtained from the hydrolysis of di- and mono-organotin halides or carboxylates. Hydrolysis of di-*tert*-butyltin dichloride gives initially di-*tert*-butyltin chloride hydroxide, $Bu^t_2Sn(OH)Cl$, which has the hydroxyl-bridged chain structure (**54**). Further hydrolysis yields a poorly defined dihydroxide, which readily dehydrates to the oxide. With less bulky organic groups, two intermediates can be isolated from the hydrolysis reaction, the 1,3-dichlorodistannoxanes, $[ClR_2SnOSnR_2Cl]_2$, and the 1-hydroxy-3-chlorodistannoxanes, $[(HO)R_2SnOSnR_2Cl]_2$. Both types are dimeric, with structures (**55**) and (**56**) respectively, and contain the central four-membered $[Sn_2O_2]$ ring and five-coordinated tin.[413,414] In the corresponding dimeric 1,3-dicarboxylatodistannoxanes, $[(RCO_2)R'_2SnOSn'_2(O_2CR)]_2$, one carboxylate group is unidentate, whilst the other functions as a bridging ligand connecting both types of tin atom (**57**).[415–417] Similar 'ladder'-type structures have also been characterized in $[ClPh_2SnOSnPh_2Cl]_2$,[418] $[ClPh_2SnOSnPh_2(OH)]_2$[418] and



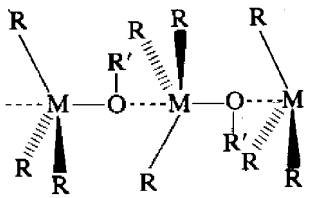
$\{[(NCS)Me_2Sn]_2O\}_2$[419] and the tristannoxane, $\{(N_3)Bu_2SnOSnBu_2OSnBu_3(N_3)\}_2$.[420] Triorganotin and triorganolead hydroxides,[421,422] alkoxides[424–425] and oximes[426] show a marked tendency to associate into one-dimensional chain polymers in which planar $[R_3Sn]$ units are bridged by oxgyen atoms as in (**58**). Steric crowding at either the metal or oxgyen reduces this tendency towards association. Thus, whereas trimethyltin methoxide has the associated structure (**58**), tri-*n*-butyltin methoxide is an oil where association is negligible. Mössbauer spectroscopy may also be used to detect structural changes along homologous series. For example, in the series of cyclohexanone oxime derivatives, $R_3SnON{=}C_6H_{10}$, both the quadrupole splitting and the recoil-free fraction temperature coefficient decrease in the order $Me > Et > Pr^n > Ph$ as the group R increases in size, consistent with a change in structure from the linear polymer (**58**), characterized by crystallography for the trimethyltin derivative, through the more loosely associated structure (**59**) with non-planar $[R_3Sn]$ moieties for the ethyl and *n*-propyl homologues, to ultimately a lattice comprised isolated molecules (**60**) for the phenyl compound.[427,428] Similarly with lead, the triorganolead methoxides, R_3PbOMe, are postulated to have the associated structure (**58**),[424,425] but triphenyl(triphenylsiloxy)lead, $Ph_3PbOSiPh_3$, is monomeric.[429]



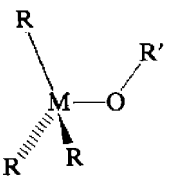
(**54**)



(**55**)



(**56**)



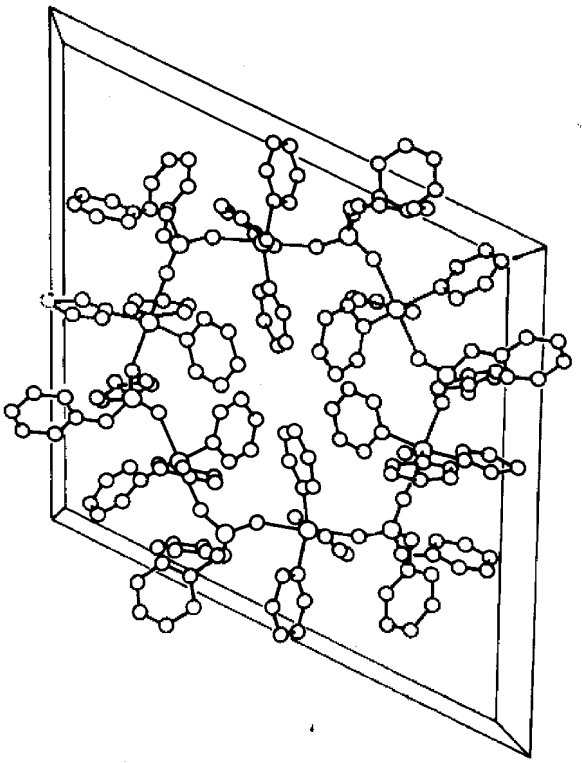
(**57**)

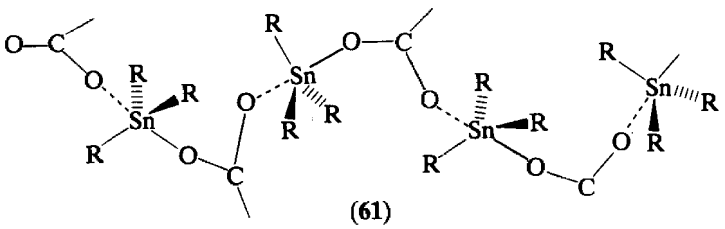
(**58**)

(**59**)

(**60**)

Similar polymeric chain structures are adopted by several other types of triorganotin and triorganolead derivatives including carboxylates, oxyacid derivatives and pseudohalides, and examples are listed in Table 9. Some of the chains are linear, others helical, but the most unusual, and at present unique, solid state structure of this type is the cyclic hexamer formed by triphenyltin diphenylphosphate, $Ph_3SnO_2P(OPh)_2$ (Figure 14).[430] Observed structures of triorganotin carboxylates fall into several categories. The majority, including trimethyl-, trivinyl-, triphenyl- and tribenzyl-tin carboxylates (and also trimethyl- and triphenyl-lead acetates), possess the rather tightly bound one-dimensional polymeric structure (**61**), with the carboxylato groups strongly bridging in the usual *syn,anti* fashion planar triorganotin residues. Tricyclohexyltin carboxylates, although having been previously misrepresented as examples of





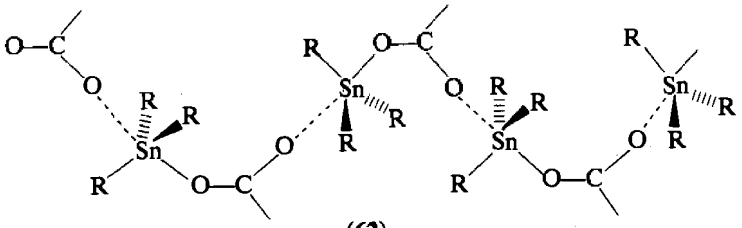


Figure 14 The hexameric structure of $Ph_3SnO_2P(OEt)_2$ (reproduced by permission from *Inorg. Chem.*, 1982, **21**, 960)

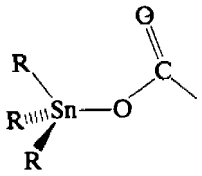

monomeric triorganotin carboxylates with unidentate carboxylato ligands and four-coordinated tin (as in **62**), have a similar one-dimensional structure, although the *syn,anti* bridging is longer and weaker. The only characterized example of a monomeric triorganotin carboxylate is the very sterically crowded, triphenyltin *o*-(2-hydroxy-5-methylphenylazo)benzoate, which adopts not a tetrahedral geometry (**63**) but the distorted trigonal bipyramidal structure (**64**) where the carboxylate group chelates *via* axial and equatorial sites.[431,432]

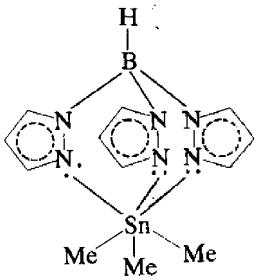
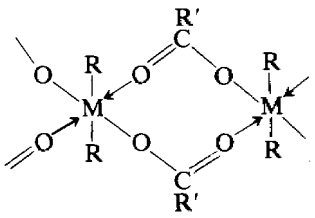
Triorganotin acetylacetonates[433] and *N*-acylhydroxylaminates[434,435] exhibit contrasting behaviour, and have the *cis* trigonal bipyramidal structures, (**65**) and (**66**).

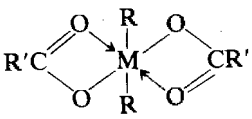


(**65**)

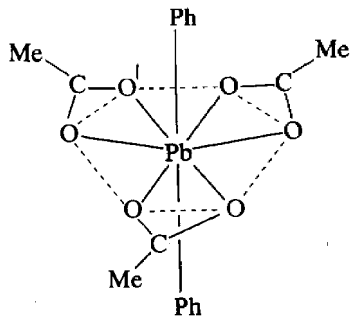


(**66**)

[Tris(pyrazolyl)borate](trimethyl)tin, $[HB(pz)_3]SnMe_3$, (**67**) is unique, being the only authenticated example amongst triorganotin compounds of six-coordination.[436]



(**67**)



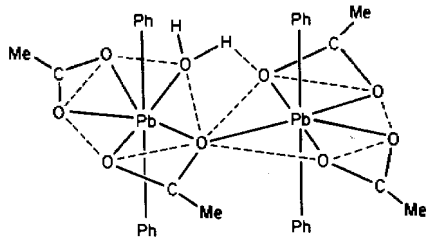
Few structural data are available for the corresponding diorgano-tin and -lead derivatives of these ligands, but their behaviour appears to be broadly similar. Carboxylato and oxyanion ligands form bridged structures, although the nitrate group functions as a chelating ligand, as do the acetylacetonato and *N*-acylhydroxylaminato groups. Thus, the anhydrous dicarboxylates are believed to possess the bridged polymeric structure (**68**) in the solid, which breaks down in solution to the monomeric species (**69**). Both have a *trans* $[SnC_2O_4]$ geometry. The structure of one diorganolead diacetate, $[Ph_2PbCO_2CMe)_2]_2{\cdot}H_2O{\cdot}C_6H_6$, has been determined, although this is probably unrepresentative of the general class of compound, but nevertheless notable. Crystals of this compound comprise binuclear units (Figure 15), in which both the lead atoms have a pentagonal bipyramidal geometry with the phenyl groups occupying axial sites. Each lead is chelated unsymmetrically by two acetate groups, one of which bridges both metals. The water molecule is coordinated to one lead and forms a hydrogen bond with an acetate group chelating the other.[437] Diphenyllead diacetate readily accepts further acetate ion to form the $[Ph_2Pb(O_2CMe)_3]^-$ anion, which has the hexagonal bipyramidal structure (**70**).[438] Dimethyltin bis(fluorosulfonate), $Me_2Sn(OSO_2F)_2$, has a polymeric sheet structure[439] and the dimethyltin phosphate, $(Me_2Sn)_3(PO_4)_2{\cdot}8H_2O$, an infinite 'ribbon' structure,[440] both with *trans* $[SnC_2O_4]$ geometry at tin.

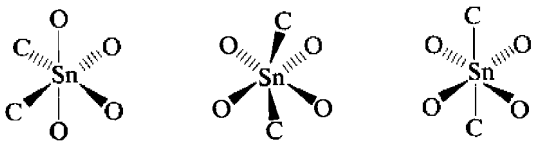
(**68**)

(**69**)

(**70**)

The stereochemistry of molecular six-coordinated dimethyltin derivatives can vary substantially from the *cis* $[SnC_2O_4]$ geometry (**71**), adopted by dimethyltin bis(oxinate)[441] and





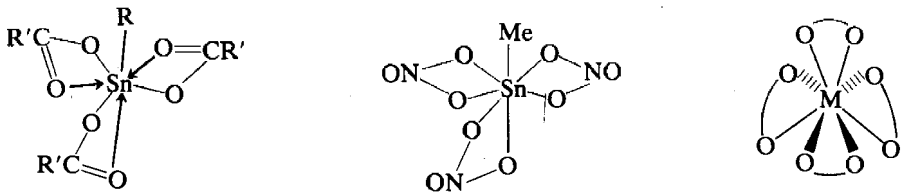


Figure 15 Schematic representation of the structure of $[Ph_2Pb(O_2CMe)_2]_2{\cdot}H_2O$

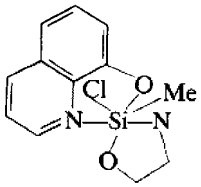
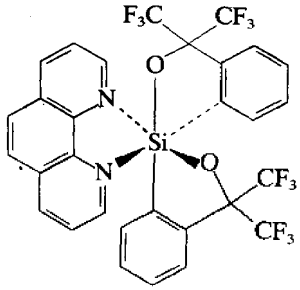
$Me_2Sn(ONHCOMe)_2$,[442] to the *trans* $[SnC_2O_4]$ geometry (**73**) of bis(acetylacetonato)dimethyltin,[443] in which the [CSnC] group is linear and the acetylacetonato group chelate the tin atom symmetrically. A number of compounds, however, exhibit a geometry (**72**) intermediate between these two extremes, including $Me_2Sn(NO_3)_2$,[444] bis{(salicylaldehyde)ethylenediiminato}dimethyltin,[445] $Me_2Sn(ONMeCOMe)_2$[446] and $Me_2Sn(ONHCOMe)_2{\cdot}H_2O$.[442] The difference in stereochemistry between $Me_2Sn(ONHCOMe)_2$ and its monohydrate is quite surprising, and illustrates the rather large effect that hydrogen bonding networks and crystal packing demands can have upon the stereochemistry adopted about the tin atom.

(**71**) (**72**) (**73**)

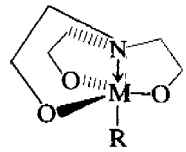


Little is known concerning the structural chemsitry of monoorganotin and monoorganolead derivatives. IR and colligative data suggest the seven-coordinate structure (**74**) for monoorganotintris(carboxylates),[447] similar to that determined for methyltin trinitrate (**75**).[448] Tin(IV) nitrate,[449] and tin(IV) and lead(IV) acetates[450,451] have an eight-coordinated dodecahedral structure (**76**).



(**74**) (**75**) (**76**)

Silicon and germanium compounds with coordination numbers greater than four are much less abundant than for their heavier congeners. Silicon(IV) acetate, $Si(O_2CMe)_4$, is tetrahedral with unidentate acetate groups,[452] but the metalloids are six-coordinated in the anions, $[M(O_2CMe)_6]^{2-}$ (M = Si, Ge).[453] Unusually short intermolecular Si—O, Si---O=C and Si---S=C interactions have been detected in crystalline samples of silyl acetate, H_3SiO_2CMe, and silyl thioacetate, $H_3SiO(S)CMe$, at low temperatures, but under normal conditions silyl carboxylates, like the alkoxides, are monomeric.[454,455] Other examples of five- and six-coordinated compounds, which generally need to contain fewer than two bonds to carbon, include octahedral species such as the $[Si(OH)_2(bipy)_2]^{2+}$ cation,[456] and tris(oxalato)- and tris(acetylacetonato)-metal (2 –) anions,[457–463] and the neutral compounds (**77**)[464] and (**78**),[465] as well as mainly five-coordinated derivatives of chelating ligands. The most widely investigated class of five-coordinated compound are the silatranes and germatranes, which have a trigonal bipyramidal geometry as in (**79**) with short M←N transannular interactions.[466–473] Electron diffraction studies on methylsilatrane, however, indicate that this type of bonding interaction is absent at higher temperatures.[469] Several other related compounds which exhibit transannular M---N interactions are known including [iminobis(ethyleneoxy)]diphenylsilane (**80**),[474] silatranones and germatranones (**81**)[473,475] and 2-carbagermatranes (**82**).[473] Stannatranes are similar, but are associated into the trimeric units (**83**) with octahedrally coordinated tin in both



solution in apolar solvents and the solid phases.[476–480] In donor solvents, this association is broken down, and the mononuclear species (**84**) exist in water and DMSO. In contrast, 1-alkylthiostannatranes are monomeric in all solvents.[478]

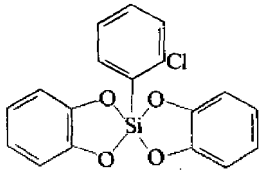
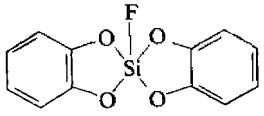
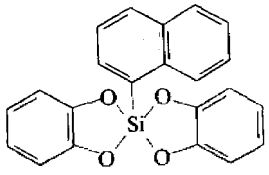
(**81**)

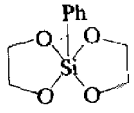
(**82**)

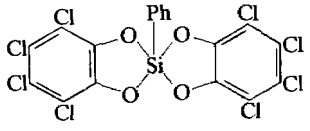
(**83**)

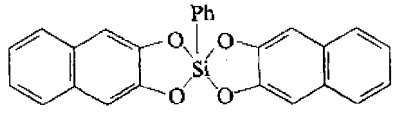


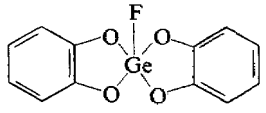


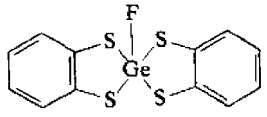


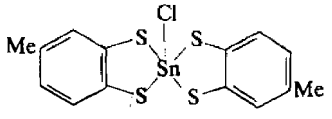




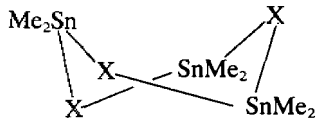








(**84**) D = H_2O, DMSO



The geometry of all the five-coordinated compounds described thus far is, or is very close to, a trigonal bipyramid. Examples of the alternative five-coordinated geometry, the square-based pyramid, are much rarer in Group IV chemistry, although several are known with geometries intermediate between the two extremes along the Berry pseudorotation coordinate.[481–484] Idealized square-based pyramidal geometry is favoured over the trigonal bipyramid by the presence of two large unsaturated chelating ligands with like atoms bonded to the central Group IV element. Thus, the bis(naphthalene-2,3-dioxy)phenylsilane(1 −) has an almost ideal square-based pyramidal structure, being 97.6% displaced along the Berry coordinate. Displacements along the Berry coordinate for other examples are shown in Table 10.

Associated structures are far less prevalent in compounds containing bonds to the heavier chalcogenides. Triorganotin and triorganolead thiolates, R_3MSR' (M = Sn, Pb), are monomeric and tetrahedral like their silicon and germanium counterparts.[485–490] Weak intermolecular Sn---N and Pb---Br interactions do, however, occur in $Ph_3SnSC_5H_4N$-4[491] and $Ph_3PbSC_6H_4Br$-2[489] respectively, causing severe distortion of the geometry at the metal towards a trigonal bipyramid. Likewise, bis(triphenylgermanium)sulfide,[492] and bis(triphenyltin)-sulfide[493] and -selenide[494] are monomeric molecules, which are bent at sulfur or selenium and contain tetrahedrally coordinated metal atoms. The corresponding diorganometal chalcogenides form ring structures (*cf.* the associated polymeric structures formed by diorganotin oxides), most commonly a cyclic trimer (**85**) with a twist-boat conformation.[495] However, with bulky organic substituents, a four-membered ring may be stabilized. Thus, di-*tert*-butyltin sulfide, selenide and telluride, $[Bu^t_2SnX]_2$ (X = S, Se, Te), exist as the dimers (**86**) with a planar central $[Sn_2X_2]$ ring.[496] Some diorganotin sulfides may also exist in a polymeric modification of lower solubility and higher melting than the trimeric form, and probably have the same linear polymeric structure (**87**) as that characterized for diisopropyltin sulfide.[497] The monoorganometal sesquisulfides generally crystallize with the adamantane skeleton (**88**).[498–500]

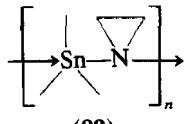
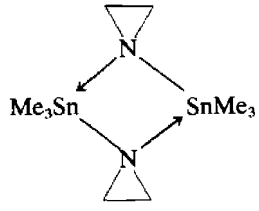
(86)



(87)



(88)

In contrast to a carboxylato and other oxyanion ligands, dithio ligands such as dithiocarbamate and dithiophosphate function as unidentate ligands in their triorganotin and triorganolead derivatives.[490,501–503] When two or less metal–carbon bonds are present, however, chelation by these types of ligands occurs. In the dimethyltin bis(dithiocarbamates), $Me_2Sn(S_2CNR_2)_2$ (R = Me, Et),[504,505] and the diphenyltin and diphenyllead dithiophosphoridates, $Ph_2Sn[S_2P(OEt)_2]_2$,[506] and $Ph_2Pb[S_2P(OPr^i)_2]_2$,[490] the ligands chelate in an anisobidentate fashion allowing the CMC bond angle to close significantly, but in $Ph_2Sn[S_2P(OPr^i)_2]_2$, the [CSnC] linkage is linear and the dithiophosphate groups chelate symmetrically.[507] Methyltin tri(diethyldithiocarbamate) has a distorted pentagonal bipyramidal geometry, in which two dithiocarbamato groups chelate *via* equatorial sites whilst the third spans the remaining equatorial and an axial position.[508]

The most significant feature in the structures of compounds containing bonds to nitrogen is the planar skeleton about nitrogen exhibited by some including, *inter alia*, trisilylamine, $(H_3Si)_3N$,[509] $(MeH_2Si)_3N$,[510] $(F_2P)(H_3Si)_2N$,[511] $(F_2P)_2(H_3Si)N$,[511] $(F_2P)_2GeNH_2$[511] and $(Me_3Sn)_3N$.[512] In these compounds, the metal–nitrogen bond is generally somewhat longer than in others where the geometry at nitrogen is pyramidal, *e.g.* $(Ph_2MeSi)_3N$.[513] In silylamines, $Me_2HSiNMe_2$, MeH_2SiNMe_2 and H_3SiNMe_2, the nitrogen atom has a shallow pyramidal configuration.[514] The similar silylphosphines, $H_3SiPH_nMe_{2-n}$ ($n = 0$–2), are pyramidal at phosphorus.[515–517] Planarity at nitrogen has been attributed to $(p \rightarrow d)\pi$ interactions between the filled p_z orbital on nitrogen and vacant metal *d* orbitals. Theoretical calculations have shown that such interactions are most important for silicon, but even in this case planarity at nitrogen was ascribed principally to electrostatic interactions.[518,519] Unlike other trimethylstannylamines, which according to Mössbauer spectroscopy are monomeric,[520] trimethyltin aziridine is associated in the solid (**89**) but is dimeric in solution (**90**).[521]

(89)

(90)

With phosphorus, a remarkably diverse range of ring and cage frameworks are formed. Three-membered $[MP_2]$ (M = Si, Ge, Sn) rings (**91**) are obtained by steric crowding at phosphorus and the Group IV element.[522–524] That in $Ph_2Si(PBu^t)_2$ is an almost perfect equilateral triangle. Both diastereoisomers of the tetraphospha-3-silaspiro[2.2]pentane (**92a**) and (**92b**) have been characterized.[525] Many different four-, five- and six-membered ring systems have been synthesized, although few structures have been determined. Examples of these, together with some examples of cage frameworks, are illustrated in Figure 16.[526–542] The dimethylsilylarsine derivative, $As_4(SiMe)_6$, has the adamantane structure (**93**).[543]

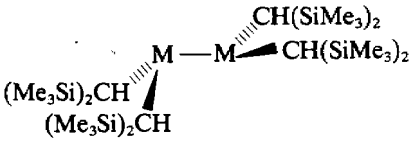
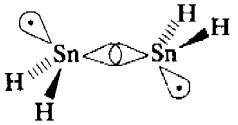
26.3.7 Bivalent Compounds Containing Bonds to Elements of Groups IV, V and VI

Simple σ-bonded bivalent dialkyl or diaryl compounds of germanium, tin and lead of the type R_2M (M = Ge, Sn, Pb) are not stable. Rather, attempts to generate such compounds always result in the formation of isomeric, metal–metal-bonded oligomers (**94**), which contain tetravalent metal atoms.[546–540] Predictably, this facile polymerization process may be precluded by employing a sterically crowded organic group, and bis[bis(trimethylsilyl)methyl-germanium(II) and -tin(II) are monomeric, angular compounds (**95**) in the vapour and in



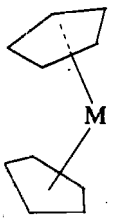
solution.[551–554] In the solid phase, however, dimerization to the *trans* bent structure (**96**) occurs.[551,552,555]

(**94**)

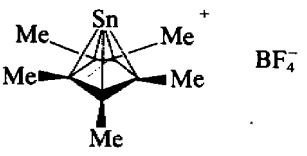


(**95**)

(**96**)



The nature of the metal–metal bond in these compounds is somewhat controversial. Initial interpretation of the bonding in terms of a double 'banana' bond are probably unrealistic,[556] albeit supported by theoretical calculations on the prototype dimetallenes, $H_2M{:}MH_2$ (M = Ge, Sn).[553,557] A more recent theoretical description of distannene, however, favours the singly bonded biradical structure (**97**), in which the unpaired electrons can interact conjugatively across space giving rise to a π or π-type bond, or σ-conjugatively *via* the Sn—Sn σ bond.[558] The corresponding lead compound, $Pb[CH(SiMe_3)_2]_2$, has also been synthesized, but its structure is as yet not known.[552]



(**97**)

Cyclopentadienyl derivatives form the largest class of bivalent organometallic compounds and many are known (Table 11). All the bis(cyclopentadienyl)metal* compounds have the angular sandwich structure (**98**),[559–566] except for bis(pentaphenylcyclopentadienyl)tin[567] in which the two cyclopentadienyl rings are parallel and staggered (Figure 17). Stannocene itself has been the subject of extended Hückel,[559] SCF X_α scattered wave[568] and MNDO calculations,[558] which give generally good agreement between experimentally observed and calculated structural parameters for the angular sandwich geometry and place the non-bonding electron pair in a highly directional orbital *ca.* 2 eV more stable than the HOMO. Calculated metal–carbon distances for the (unstable) isomer with enforced D_{5d} symmetry are, however, substantially shorter (247 pm)[558] than those observed in decaphenylstannocene (268.6–220.5 pm)[567] indicating steric repulsion as the cause of the parallel ring structure in this case. Cyclopentadienylgermanium chloride, C_5H_5GeCl,[569] and pentamethylcyclopentadienylgermanium chloride, C_5Me_5GeCl,[566] also have angular structures in the gas phase, but additional Sn---Cl intermolecular contacts are present for cyclopentadienyltin chloride in the solid.[570]

Cleavage of the rings is very facile.[571–575] Treatment of pentamethylstannocene with tetrafluoroboric acid affords the pentamethylstannocenium salt, $C_5Me_5Sn^+BF_4^-$ (**99**),[559,576] analogous to stannocenium tetrachloroaluminate, $C_5H_5Sn^+AlCl_4^-$, obtained by the reaction of C_5H_5SnCl with aluminum(III) chloride.[577] The germanocenium[569] and stannocenium cations,[558,559] $C_5H_5M^+$ (M = Ge, Sn), too, have been the objects of theoretical study with reasonable agreement with observed data for $C_5Me_5Sn^+$. The two studies of $C_5H_5Sn^+$ do, however, disagree over the ordering of the molecular orbitals.

(**98**)

(**99**)

* The trivial nomenclature germanocene, stannocene and plumbocene appears to have been universally adopted for these compounds.

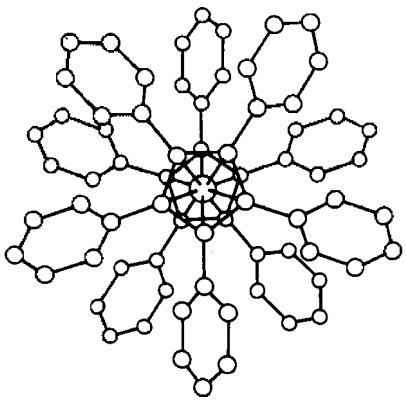

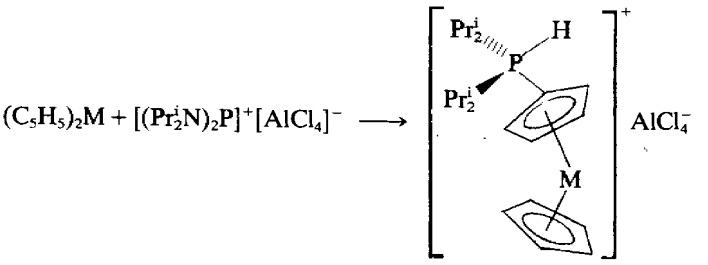

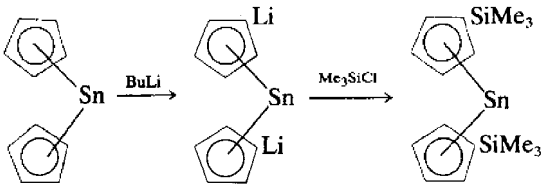

Figure 17 The structure of decaphenylstannocene, $(C_5Ph_5)_2Sn$, viewed along the five-fold axis (reproduced by permission from *J. Am. Chem. Soc.*, 1984, **106**, 4259)

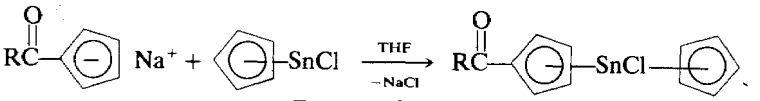
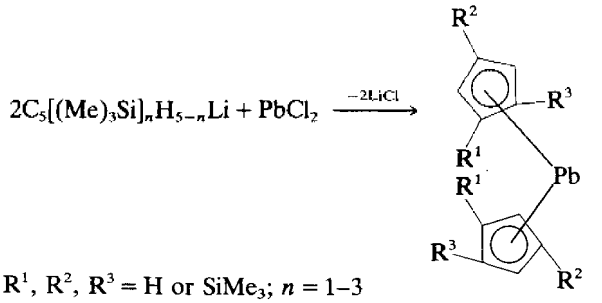
Pentamethylgermanocenium and pentamethylstannocenium salts, $C_5Me_5M^+X^-$ (M = Ge, Sn; $X^- = CF_3SO_3^-$ or BF_4^-), react with nitrogen donors such as pyridine, pyrazine and 2,2′-bipyridine to form adducts. In both of the cations, $[C_5Me_5Sn{\cdot}L]^+$ (L = C_5H_5N, $C_{10}H_8N_2$), the bonding of the cyclopentadienyl ring to the tin atom relaxes from η^5 towards η^2/η^3. The gross structure of the pyridine complex, $[(C_5H_5N)Sn(C_5Me_5)]^+[O_3SCF_3]^-$, is a chain structure in which the anions link adjacent $[(C_5H_5N)Sn(C_5Me_5)]^+$ cations. In contrast, crystals of the corresponding bipyridine salt comprise isolated $[(C_{10}H_8N_2)Sn(C_5Me_5)]^+$ and $[CF_3SO_3]^-$ ions.[578,579]



Functionally substituted stannocene and plumbocene derivatives may be obtained either by ring substitution (equations 8 and 9),[580–582] or by metathesis (equations 10 and 11).[583,584]

Both the bis-alkyl derivatives, $[(Me_3Si)_2CH]_2M$ (M = Ge, Sn, Pb) and the metallocenes, $(C_5H_5)_2M$ (M = Sn, Pb), function as two-electron donors towards both transition metal and main group metal Lewis acid centres forming complexes of the types $[(Me_3Si)_2CH]_2M{:}\rightarrow$



(9)

(10)

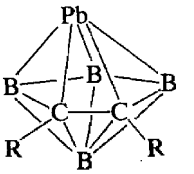
$M^{VI}(CO)_5$ (M = Ge, Sn, Pb; M^{VI} = Cr, Mo, W),[551,552,555,585–588] $(C_5H_5)_2Sn{:}\rightarrow M^{VI}(CO)_5$,[589] $(C_5H_5)_2Sn{:}Mn(CO)_2(C_5H_4Me)$,[590] $[(C_5H_5)_2SnFe(CO)_4]_2$,[591] $(C_5H_4R)_2Sn{:}\rightarrow AlX_3$ (R = H, Me; X = Cl, Br)[592] and $(C_5H_5)_2Pb{:}\rightarrow BF_3$.[593] The constitution of the latter complex, however, must be placed in doubt since the analogous tin complex[594] has been shown by X-ray crystallography to have a very complex polymeric structure, perhaps best formulated as $\{[BF_4]^-(\mu\text{-}\eta^5\text{-}C_5H_5)_2Sn[\mu\text{-}\eta^5\text{-}C_5H_5Sn]^+THF\}_n$.[595]



Closely related to the cyclopentadienyls are carbaborane derivatives, where the bivalent Group IV metal occupies a vertex of the carbaborane framework. The *closo*-dodecacarboranes (**100**) (M = Ge, Sn, Pb) are very stable indeed, and may be sublimed unchanged *in vacuo* at high temperatures.[596] The smaller *C*-trimethylsilyl-substituted stannacarboranes (**101**) (R = H, Me, $SiMe_3$) are also stable enough to be sublimed,[597,598] but the similar plumbacarboranes (**102**) (R = H, Me) decompose at room temperature *in vacuo* although they can be stored indefinitely at 0 °C.[599] The stannacarboranes do not react with either BH_3·THF or BF_3 to form donor–acceptor complexes, indicating that the lone pair occupies an orbital of non-directional character. 1-Stanna-2,3-dimethyl-2,3-dicarba-*closo*-dodecacarborane, $Sn(Me_2)C_2B_9H_9$, can, however, function as a Lewis acid, forming a 2,2′-bipyridyl complex (Figure 18). As with the metallocene adducts, complexation is accompanied by a 'slippage' from η^5 bonding, and this complex may be regarded as an η^3-borallyl complex.

(100)

(101)

(102)

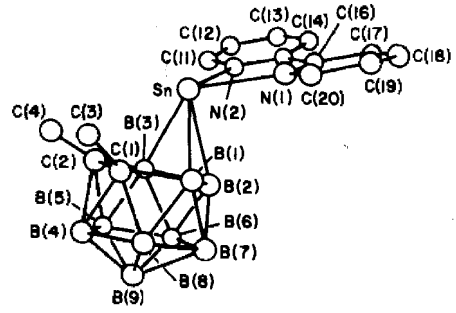


Figure 18 The structure of $Sn(Me)_2C_2B_9H_9$·bipy (reproduced by permission from *J. Chem. Soc., Chem. Commun.*, 1984, 1564)

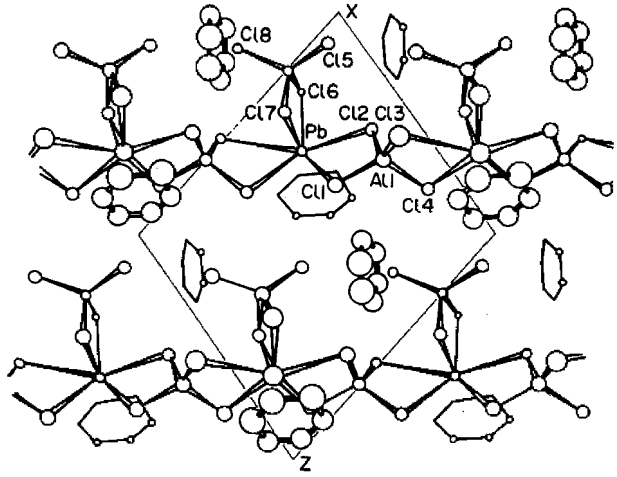
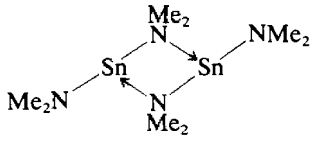
Both tin and lead form η^6-arene complexes, although the arene is much more weakly bound to the metal than in similar complexes of Group VI transition metals. The tin and lead complexes, $[(C_6H_6)M\cdot(AlCl_4)_2\cdot C_6H_6]$ (M = Sn, Pb), are isomorphous, and comprise one-dimensional chain structures (Figure 19) with bridging tetrachloraluminate groups.[600,601] The structure of the related complexes, $[ArSnCl(AlCl_4)]_2$ (Ar = C_6H_6, $C_6H_4Me_2$-1,4), is similar, but contains a central four-membered $[Sn_2Cl_2]$ ring.[602,603]





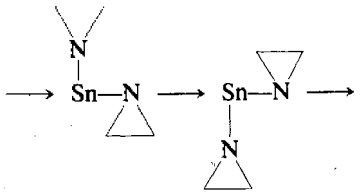


Figure 19 The structure of $[(C_6H_6)Pb(AlCl_4)_2]\cdot C_6H_6$ (reproduced by permission from *Inorg. Chem.*, 1974, **13**, 2429)

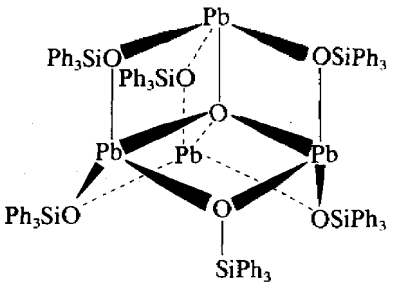
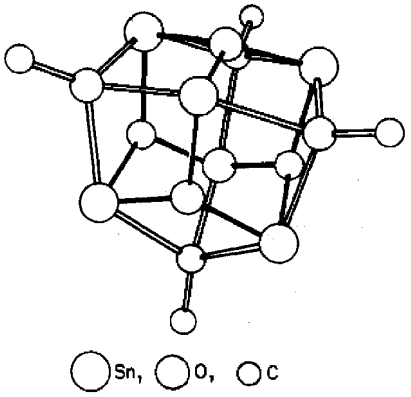
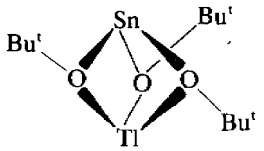
Monomeric amide, alkoxide and thiolate derivatives of germanium(II), tin(II) and lead(II) are only obtained with very sterically crowded ligands. Thus, bis(2,2,6,6-tetramethylpiperidyl)germanium,[604] the bis(trimethylsilyl)amides, $M[N(SiMe_3)_2]_2$ (M = Ge, Sn, Pb),[605] bis(aryloxides), $M(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)$ (M = Ge, Sn, Pb)[606] and the bis(arenethiolato)tin derivative $(SnSC_6H_2Bu^t_3\text{-}2,4,6)_2$[607] are all two-coordinated with an angular, 'V'-shaped geometry. Otherwise, for smaller ligands, association takes place *via* nitrogen, oxygen or sulfur bridging to give dimers, trimers or polymers depending upon the steric demands of the ligand. Thus, tin(II) bis(dimethylamido)tin(II) exists as the dimer (**103**),[608] whereas a polymeric structure such as (**104**) has been proposed for bis(aziridinyl)tin(II).[609] Crystals of the cyclic tin(II) amide, $[SnN(Bu^t)SiMe_2N(Bu^t)]_n$, comprise both monomeric and dimeric units.[610] Similarly, bis(*tert*-butoxy)-germanium(II)[561] and -tin(II),[611] and bis(triphenylsiloxy)-tin(II)[611] and -lead(II)[612] are dimeric, whilst the tin and lead bis(2,6-didisopropylbenzenethiolates) are trimeric, and small alkoxides, $M(OR)_2$ (M = Ge, Sn, Pb; R = Me, Et) are polymeric.[613,614] Bis(triphenylsiloxy)lead(II) is unstable, and readily eliminates hexaphenyldisiloxane affording the cage compound (**105**).[615] Other similar cage compounds such as $Sn_6O_4(OMe)_4$ (**106**) formed by hydrolysis of polymeric tin(II) methoxide,[300] and (**107**)[616] have also been characterized.



A relatively large number of tin–nitrogen cage structures have been characterized. The monomeric diazasilastannetidine, $SnN(Bu^t)Si(Me_2)NBu^t$, is cleaved quantitatively by *tert*-butylamine to give either the 'closed' $[Sn_2SiN_3]$ cage (**108**) or the 'open' cage (**109**). Thermolysis of the latter compound, however, results in conversion to the $[Sn_4N_4]$ cubane

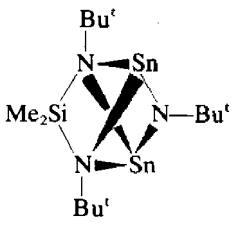


(103)

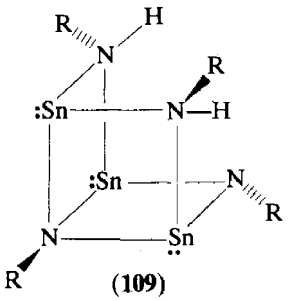


(104)

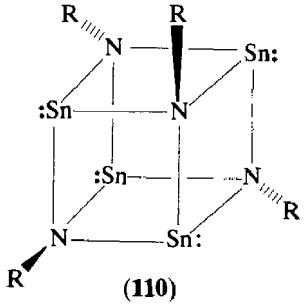
(105)



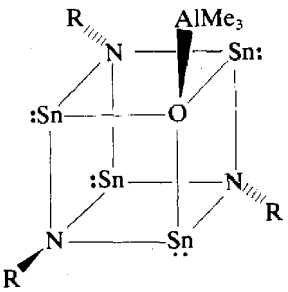
(106)



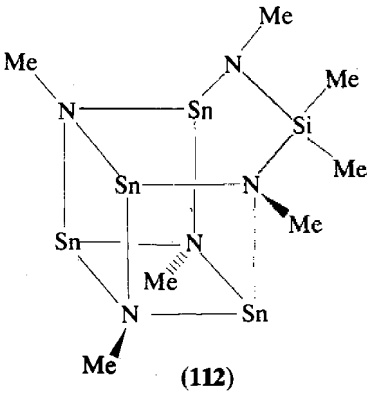
(107)



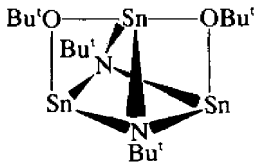
compound (**110**). The analogous $[Sn_4N_3O]$ cubane is obtained by hydrolysis of (**109**) (but not of **110**), and forms the adduct (**111**) with trimethylaluminum. The $[Sn_4N_4]$ core is also present in $(Me_2Si)(NMe)_5Sn_4$ (**112**), where one edge is enlarged by an $[Me_2Si—NMe]$ bridge. The $[Sn_3N_2O_2]$ cage compound (**113**) has a crystallographic plane of symmetry, and may be regarded as a complex between the transient *tert*-butyliminostannanediyl, $[Sn(NBu^t)_2Sn]$, and tin(II) bis(*tert*-butoxide).[617–621]



(108)



(109)



(110)

(111)

(112)

(113)

The proclivity of these types of compound to form associated structures derives from the propensity of bivalent germanium, tin and lead to achieve coordination numbers greater than two. When additional donor sites are available within the ligand itself, coordination saturation at the metal can be achieved either intramolecularly or intermolecularly resulting in the formation, respectively, of discrete monomeric species or polymers. Thus, GeI(acac),[622] $\overline{Ge(OCH_2CH_2)_2NMe}$,[613] $\overline{Sn(SCH_2CH_2)_2E}$ (E = Bu^{t}N, MeN, O, S),[623,624] $Sn(S_2COMe)_2$,[625] *N,N'*-ethylenebis(acetylideneimino)tin(II)[626] and tin(II) derivatives of 1,3-diones and related

compounds[627–629] are all monomeric. Tin(II) and lead(II) carboxylates,[630–636] sulfates[637–639] and phosphates,[640–645] on the other hand, are polymeric in nature. Nevertheless, the coordination polyhedra about the two metals in these types of compound does vary substantially. With bivalent tin, only the usual three-coordinate pyramidal and four-coordinate pseudotrigonal bipyramidal geometries are found, and the anionic groups function solely as bridging ligands. With lead, however, simultaneous chelation and bridging occurs resulting in much higher coordination numbers. Values of six, seven, eight or nine are not atypical, whilst the particular stereochemistry adopted depends upon the individual compound. Thus, for example, whereas tin(II) formate has a two-dimensional sheet structure in which each formate group bridges two adjacent tin atoms (Figure 20),[630] lead(II) formate has a very complex three-dimensional polymeric structure with eight-coordinated lead, in which each formate group now links four different lead atoms (Figure 21).[636] Intermolecular association is much weaker in complexes involving dithio ligands. Thus, crystals of tin(II) and lead(II) dithiocarbonates (xanthates), $M[S_2COR]_2$ (M = Sn, Pb), and dithiocarbamates, $M[S_2CNR_2]_2$, generally comprise discrete molecules with chelating ligands.[646–651] Additional intermolecular interactions are weak or negligible. Lead(II) bis(diethyldithiophosphate), $Pb[S_2P(OEt)_2]_2$, is similar,[652] but the corresponding diisopropyldithiophosphate has a more strongly bonded chain structure.[653] Tin(II) and lead(II) bis(diphenyldithiophosphates) are quite unusual, and possess dimeric structures, where the two metal atoms are linked not only by bridging dithiophosphate groups, but also by an η^6 bonding interaction between the metal and one of the phenyl groups (Figure 22).[654,655]

The two mixed-valence tin carboxylates $[Sn(O_2CC_6H_4NO_2\text{-}o)_4O{\cdot}THF]_2$[656] and $[Sn_2(O_2CCF_3)_4O]_2{\cdot}C_6H_6$,[657] are quite unusual, and exhibit pentagonal pyramidal and square-based pyramidal coordination polyhedra, respectively, for bivalent tin. The former represents

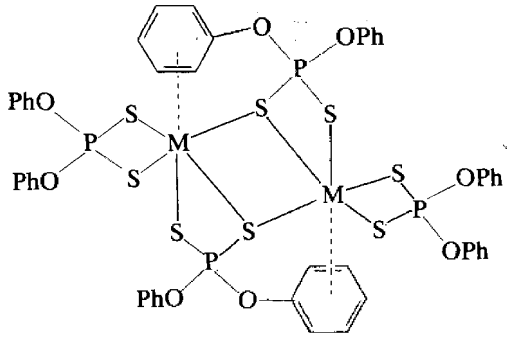

Figure 22 Schematic representation of the dimeric structure of tin(II) and lead(II) bis(*O*,*O'*-diphenyldithiophosphate)

the only example of this stereochemistry in Group IV. The tetravalent tin atoms enjoy typical, almost perfect, octahedral coordination.

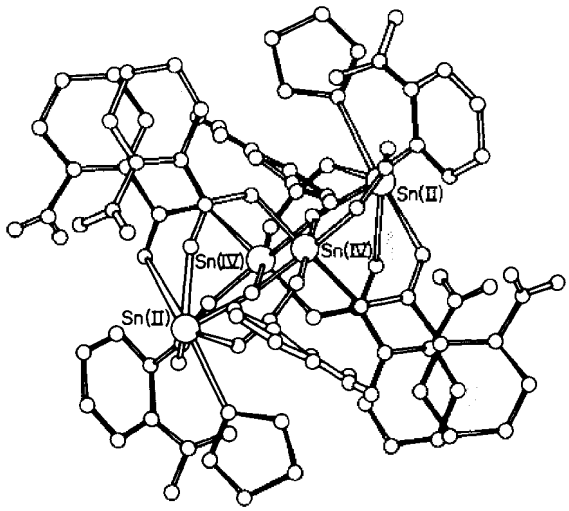

Figure 23 The structure of the mixed-valence tin carboxylate $[Sn_2(O_2CC_6H_4NO_2\text{-}o)_4O]_2 \cdot THF$ (reproduced by permission from *J. Chem. Soc., Dalton Trans.*, 1976, 1602)

Bis(phosphino) and bis(arsino) derivatives of germanium, tin or lead are unknown. However, monophosphino- and monoarsino-germanium and tin halides, Bu^t_2EMX (M = Ge, Sn; E = P, As, X = Cl, Br), have been characterized as thermally stable, though easily oxidized solids, which are thought to be highly associated.[658–663]

29. As Schaeffer points out,[28] the double-ζ SCF calculations of Hood and Schaeffer[30] and Alrichs and Heinzmann,[31] which predict Si=C bond distances of 171.5 pm and 169 pm, are probably the most reliable theoretical estimates. Note that these calculations were reported *before* the electron diffraction study of $Me_2Si{=}CH_2$ appeared.

28.1 INTRODUCTION

This chapter will be divided into three main sections, dealing with the chemistry of arsenic, antimony and bismuth individually, since their interest is intrinsic rather than comparative. However, the Periodic Table trends are important and their main features will be outlined.

The triad As, Sb, Bi has an important place in the history of chemistry, the isolation of the elements being one of the achievements of alchemists in the pre-Scientific Age. An interesting history of their discovery can be found in ref. 1.

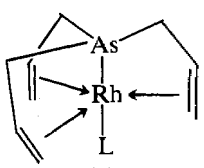
28.2 ARSENIC

The thirty-third member of the Periodic Table has a sinister reputation. Since its isolation in the Middle Ages the main use of arsenic compounds has been the termination of lifeforms. Its use for homicide was widened to include *inter alia* herbicide, fungicide and bactericide (see Section 28.7). Various arsenic compounds have been used from ancient times as pigments, *e.g.* lemon-yellow orpiment, As_2S_3, and red realgar, As_4S_4.

The common oxidation states are −3, +3 and +5, but the simple ions As^{3-}, As^{3+} and As^{5+} are not known. The krypton electronic structure could be attained by gain of three electrons, but there is a high energy requirement. Equally, the loss of five valence electrons to form As^{5+} is unrealizable because of the high ionization enthalpy.

The most common structures of arsenic compounds are tetrahedral and pyramidal, which are similar when the sterically active lone pair is counted. Tetrahedral symmetry holds the potential for chirality and indeed many chiral organoarsenic compounds have been prepared. Arsenic may also use *d* orbitals for $(d–d)\pi$ bonding and for hybridization with s^2 and p^3 orbitals, resulting in trigonal bipyramidal or octahedral structures. In the former the more electronegative substituents occupy the apical position.

28.3 ARSENIC–GROUP 4 BONDS



28.3.1 Carbon Ligands

28.3.1.1 Organoarsenic compounds

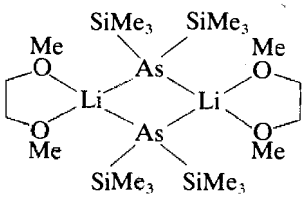
There is a comprehensive review of this area[2] so only a few recent developments will be mentioned here. Organoarsenic intramolecular coordination compounds, *e.g.* (1), have also recently been reviewed,[3] and organoarsenic chemistry is reviewed annually.[4] There is a review containing 102 references on arsonium ylides.[5] The canonical structures of the arsenic ylides are

$$Ph_3As{=}CRR' \longleftrightarrow Ph_3\overset{+}{A}s{-}\overline{C}RR'$$

The overlap of carbon *p* orbitals with arsenic *d* orbitals is less effective than with the *d* orbitals of phosphorus, and so the covalent canonical structure is expected to make less of a contribution to the hybrid structure. This has been confirmed in an X-ray study of 2-acetyl-3,4,5-triphenylcyclopentadienetriphenylarsorane.[6] Yamamoto and Schmidbaur[7] found (^{13}C NMR) that the bonding in arsenic ylides was probably sp^3 (*cf.* phosphorus, which changes from $sp^3 \rightarrow sp^2$), resulting in arsenic pseudotetrahedral geometry (*cf.* phosphorus ylides, which are planar).

(1)

28.3.2 Silicon Ligands



The parent compound for this series is H_3SiAsH_2, which was first produced in 1962 in low yield in the gas phase reaction between silane, SiH_4, and arsine, AsH_3, promoted by silent electric discharge.[8] This volatile pyrophoric compound is better prepared from lithium tetraarsinoaluminate and bromosilane.[9] It is also possible to prepare $H_3SiSiH_2AsH_2$ (59%), $MeSiH_2AsH_2$ (57%) and $(Me_3Si)_3As$ (77%) by this route. Trisilylarsine has been shown to have a pyramidal structure by electron diffraction;[10] it is prepared from bromosilane and potassium dihydrogenarsenide at low temperature (−122 to −38 °C).[11]

Higher homologues are coveniently prepared from 'sodium potassium arsenide' and chlorosilanes. The arsenide is a complex mixture formed by mixing a sodium–potassium alloy with powdered arsenic suspended in 1,2-dimethoxyethane (equation 1).[36]

$$ClSiMe_3 + Na_3As/K_3As \longrightarrow As(SiMe_3)_3 \quad (80–90\%) \qquad (1)$$

Tris(trimethylsilyl)arsine is a convenient starting material for the production of $LiAs(SiMe_3)_2 \cdot 2L$ (L = coordinating solvent); see, for example, equation (2) and structure (**2**).

$$As(SiMe_3)_3 + LiMe \xrightarrow{THF} LiAs(SiMe_3)_2 \cdot 2THF + SiMe_4 \quad (2)$$

(**2**)

28.3.3 Other Group 4 Ligands

While many compounds of the type $X_nAs(ER_3)_{3-n}$ ($n = 0$–2; X = any other group, *e.g.* H, Hal, R *etc.*; R = H, alkyl, aryl; E = Ge,[263] Sn,[264] Pb[265]) have been produced, they are mainly of interest to theoreticians and synthesists. They have the expected pyramidal geometry of AsX_3 compounds, and their interest to coordination chemists lies in their behaviour as ligands, which is dealt with elsewhere (Chapter 12.2); there is some special interest in cluster coordination compounds involving As—Ge bonding.

28.4 ARSENIC–GROUP 5 BONDS

Arsenic forms a large number of compounds with other Group 5 members. These are dealt with element by element down the group. However, in the case of arsenic only its catenated and π-bonded compounds are dealt with.

28.4.1 Nitrogen Ligands

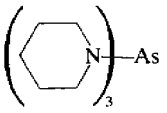
The arsenic–nitrogen bond is not as strong as the As—C, As—O, or As—S bonds and use is made of this in the synthetic chemistry of arsenic. Amongst the wide range of As—N compounds are open-chain aminoarsines, cyclic and macrocyclic compounds of various types, fused ring compounds and three-dimensional fused ring systems of the adamantine type. The calculated As—N bond length from Pauling's covalent single bond radii, and applying the Schomaker–Stevenson correction, is 1.87 Å. This compares with values given for As—N sp^3 bonds from X-ray data.

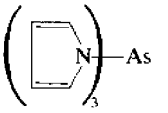
28.4.1.1 Arsenic(III)

(*i*) *Alkylaminoarsines*

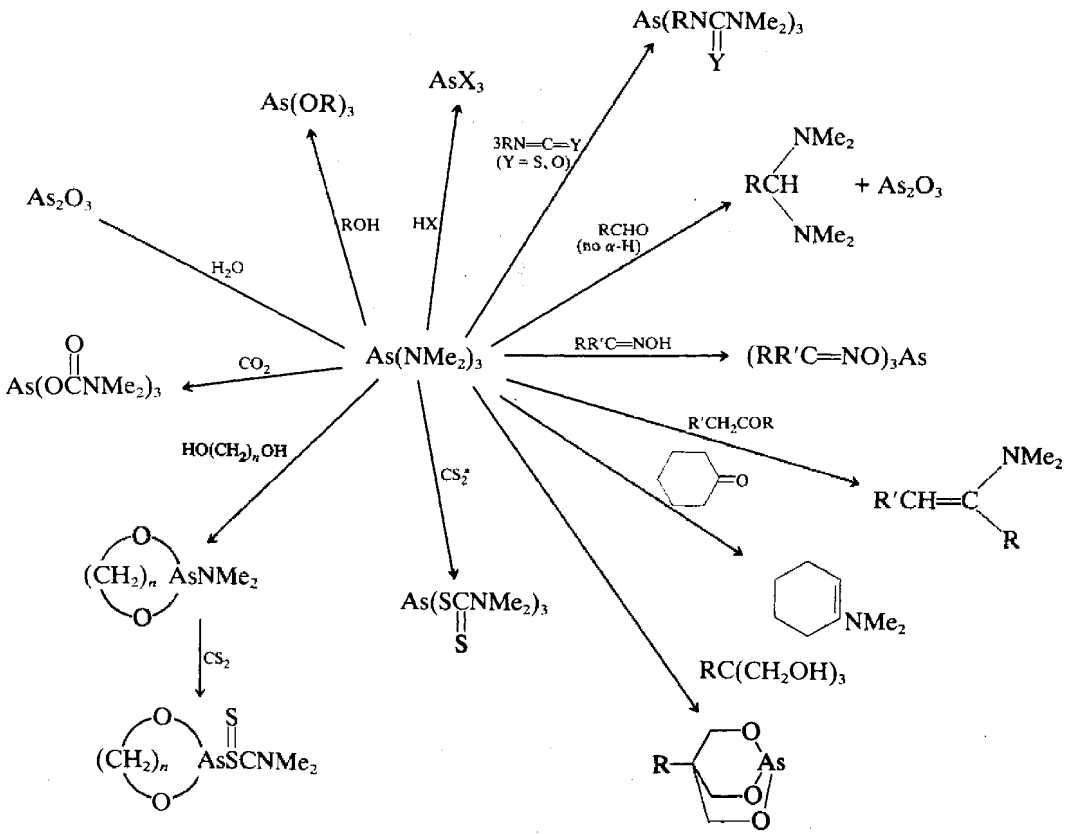
These are readily prepared by adding amines to trihaloarsines in cooled ether solutions. The reaction proceeds stepwise, halogens being successively replaced by alkylamino groups (equations 3–5). Some examples of dialkylaminoarsines are given in Table 1.

$$AsCl_3 + 2Me_2NH \xrightarrow[0\,°C]{Et_2O} Me_2NAsCl_2 + Me_2NH_2^+Cl^- \quad (3)$$





$$Me_2NAsCl_2 + 2Me_2NH \longrightarrow (Me_2N)_2AsCl + Me_2NH_2^+Cl^- \quad (4)$$



$$(Me_2N)_2AsCl + 2MeNH \longrightarrow (Me_2N)_3As + Me_2NH_2^+Cl^- \quad (5)$$

The As—N bond is labile and this has been widely exploited in synthetic arsenic chemistry. Some idea of the versatility[16a] can be seen from Schemes 1 and 2. Refluxing secondary amines with tris(dimethylamino)arsine effects transamination (equation 6). These tris(dialkylamino)arsines undergo the general reactions in Scheme 1, enabling ready access to a wide variety of compounds, many of them finding use as ligands in transition metal complexes (see Chapter 14 of this work).

$$As(NMe_2)_3 + 3HNR_2 \xrightarrow[\text{reflux}]{C_6H_6} As(NR_2)_3 + 3HNMe_2 \quad (6)$$

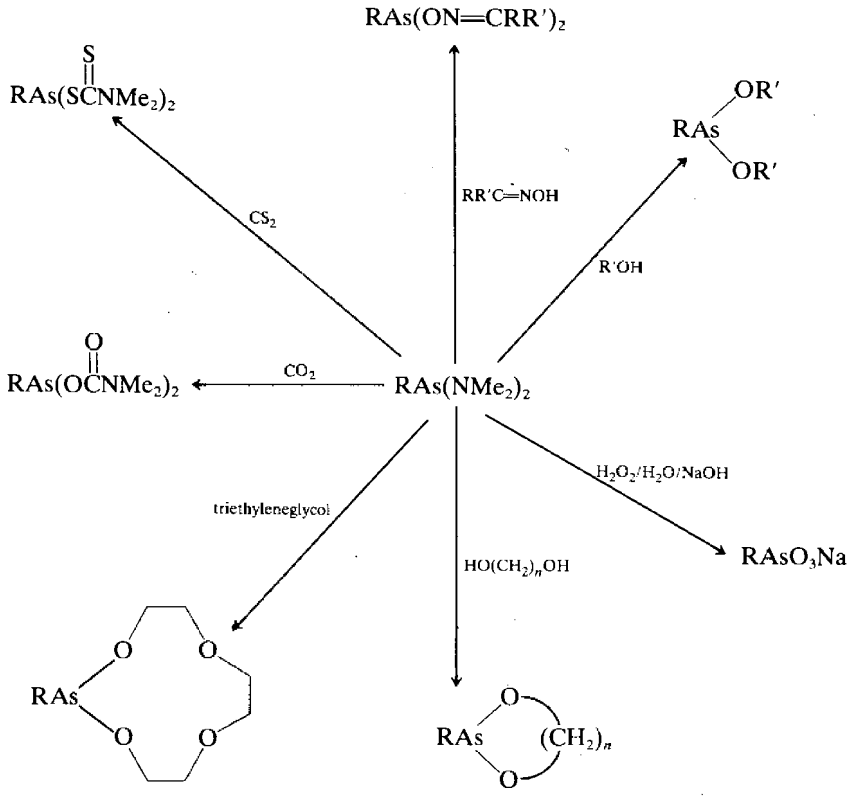


Table 1 Dialkylaminoarsines

Compound	*B.p.* (°C/Torr)	d^{20}	n_D^{20}	*Ref.*

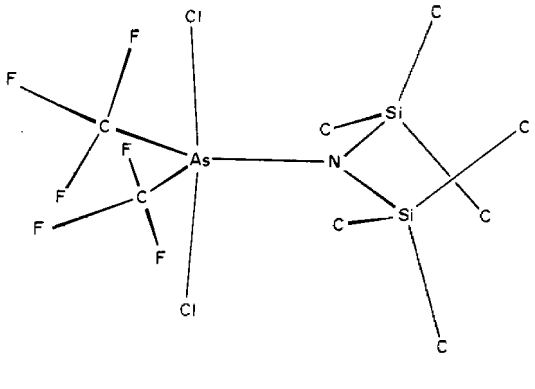
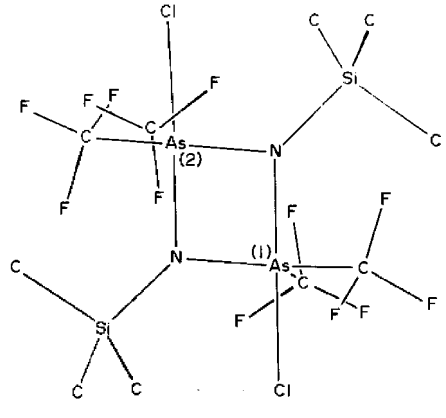
* Reaction with CS_2 is general for tris(dialkylamino)arsines and the tris(dialkyldithiocarbamidato)arsanes may be used for characterization.

Scheme 1



Scheme 2

(*ii*) *Secondary amines and AsF_3*

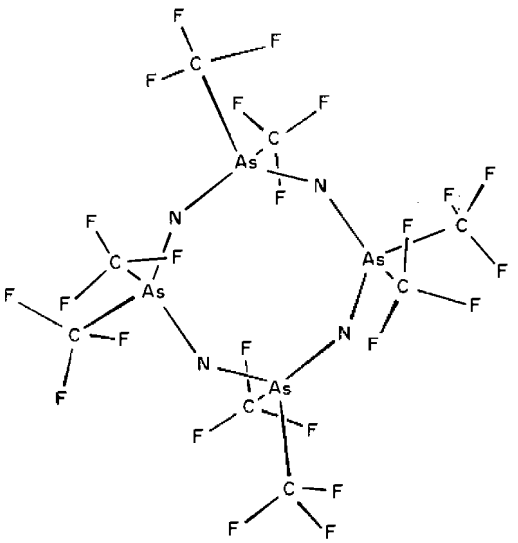


Dialkylaminodifluoroarsines are formed from the reaction of R_2NH with AsF_3. Interestingly, the fluorination of dialkylaminodichloroarsines is unsuccessful using SbF_3, although AsF_3 works.[15]

28.4.1.2 Arsenic(V)

Roesky and co-workers[19,20] have produced an interesting series of compounds which illustrate some general points of arsenic coordination chemistry. When $[(CF_3)_2As\{N(SiMe_3)_2\}]$ is treated in a strict 1:1 ratio with chlorine, $[(CF_3)_2AsCl_2\{N(SiMe_3)_2\}]$ is obtained. This is a trigonal bipyramidal molecule (**3**) with chlorine atoms in axial positions. When $[(CF_3)_2As\{N(SiMe_3)_2\}]$ is treated with an excess of chlorine, the dimer $[(CF_3)_2As(Cl)\{N(SiMe_3)\}]_2$ (**4**) is formed, the first reported example of five-coordinated arsenic

(3)



(4)

in a four-membered ring. The ligands are disposed about arsenic in a distorted trigonal bipyramidal geometry, the longer As—N bonds being axial and the short bonds being equatorial. Once more the chlorine occupies the other axial position instead of one of the CF_3 groups.

When $[(CF_3)_2As(Cl)\{N(SiMe_3)\}]_2$ is refluxed in an inert solvent or pyrolyzed *in vacuo*, trimethylsilyl chloride is derived and expanded heterocycles are formed. The CN of arsenic drops from five to four and the geometry from distorted trigonal bipyramidal to distorted tetrahedral (equation 7). In (**5**) the As and N lie alternately at ±38 and ±63 pm, respectively, from the mean plane through the ring atoms. There are two types of As—N bond, *viz.* at 1.716 Å for bonds on the same side of the plane and the longer 1.732 Å bonds across the plane. The As—N—As angles average 123.5° and the N—As—N angles average 125.0°. The difference in bond lengths, $\Delta = 0.016$ Å, is much less than that found by Glick,[21] $\Delta = 0.12$ Å, for alternating N—As (1.67 Å and 1.79 Å) bonds in the eight-membered ring $[Ph_2AsN]_4$.

$$[(CF_3)_2As(Cl)\{N(SiMe_3)\}]_2 \longrightarrow \underset{\text{six-membered}}{[(CF_3)_2AsN]_3} + \underset{\text{four-coordinate}}{[(CF_3)_2AsN]_4} \quad (7)$$

(**5**)

(**5**)

28.4.2 Phosphorus Ligands

Phosphorus as a ligand to arsenic is discussed in several sections of this work. There is no merit in repeating here under a separate heading that which is more naturally dealt with elsewhere.*

Sufficient to say that, of all the members of Group 5, the analogies between phosphorus and arsenic are closest. When used as coreactant with arsenic compounds, phosphorus compounds may react interchangeably. The recent preparation of P=As compounds by Escudie *et al.*[22] relied on this scrambling of arsenic and phosphorus reactants (equation 8).

$$(Me_3Si)_3CPCl_2 + (Me_3Si)_3CAsCl_2 \xrightarrow{BuLi} \underset{(35)\%}{(Me_3Si)_3CP{=}PC(SiMe_3)_3} + \underset{(30\%)}{(Me_3Si)_3CP{=}AsC(SiMe_3)_3} \quad (8)$$

* Antimony and bismuth bonds to arsenic are dealt with in Sections 28.10.2 and 28.16.2 under antimony and bismuth, respectively.

The interchange of As and P is not necessarily symmetrical. In a study[23] of Group 5 adducts of the type $R_nMX_{3-n}\cdot yM'R'_3$ (X = halogen; R = alkyl or aryl; M, M' = P, As, Sb; $y = 1, 2$) it was found that complexes were formed when M' = P and M = As but not when M' = As and M = P. A few examples of the complexes are given in Table 2. The adducts are probably quaternary salts $[R_2AsPR_2]X$, similar to those of Wolfsberger, $[Me_3P{=}NPMe_2AsMe_2]Cl$.[24]

Table 2 Arsenic–Phosphorus Complexes

Adduct	*Yield* (%)	*M.p.*[a] (°C)	*Conductivity*[b] (10^{-3} S cm^{-1})
$MeAsCl_2\cdot PMe_3$	83	d	37.8

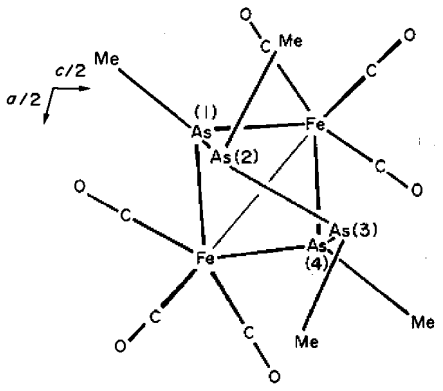
$Me_2AsCl\cdot PMe_3$	82	—	—

[a] d = decomposed. [b] In $MeNO_2$.

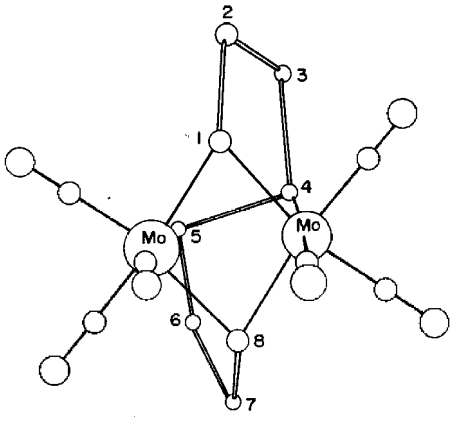
28.4.3 Arsenic Ligands

28.4.3.1 Open-chain arsenic compounds



The first established As—As bond in cacodyl, $Me_2AsAsMe_2$, was also among the earliest of arsenic compounds[25] to be isolated at the beginning of the modern chemical era.[26] However, the building of arsenic chains has not progressed. Arsenic does not appear to form small molecular chain compounds because the thermodynamically stable configurations for three to six arsenic atoms are rings. However, it may be unwise to speculate that such chain compounds will never be produced, since until recently it was thought that As=As systems would never be prepared. The only known exception presently is a red-black polymeric substance of empirical formula $(MeAs)_n$ characterized by Rheingold *et al.*[27] and Daly *et al.*[28]

28.4.3.2 Coordinated open-chain arsenic compounds



While unpolymerized open-chain arsenic compounds are unknown to date, a number of such systems are known when coordinated to transition metals.[29–31] They are prepared by the reaction between transition metal carbonyls and *cyclo*-$(RAs)_n$ ($n = 5, 6$). The reactions go by a variety of mechanisms leading to either the coordination of the unchanged ring,[32] an expanded ring,[31] fragmentamtion of the ring,[33] ring opening and coordination of the open chain without loss of arsenic,[30] or a ring opening and lengthening of the coordinated chain.[31]

When $Fe(CO)_5$ reacts with *cyclo*-$(AsMe)_5$, the ring is opened and the open chain of *four* arsenic atoms is stabilized by ligation (**6**):[29] As(1)—As(2) and As(3)—As(4) bond lengths are 2.453 Å, and the mid-chain As(2)—As(3) bond length is 2.391 Å. The non-bonding arsenics, As(1)···As(4), are 2.888 Å apart. A similarly stabilized open chain of eight arsenic atoms occurs in $[Mo_2(CO)_6(AsPr^n)_8]$ (**7**), formed from $Mo(CO)_6$ and *cyclo*-$(AsPr^n)_5$, *i.e.* chain lengthening (5→8) has occurred. The two terminal As atoms bridge the Mo atoms (Mo—As = 2.554 Å) and two, As(4) and As(5), are only coordinated to one of each of the Mo atoms (Mo—As = 2.623 Å), leaving four uncoordinated As chain atoms, As(2)—As(3) = 2.434 Å. The Mo atoms are seven-coordinate, each lying at the centre of a distorted edge-shared octahedron.

In the case of $\{[CpMo(CO_2)]_2$ [*μ-catena*-$(MeAs)_5]\}$ simple chain opening and subsequent coordination occurred in the reaction between $[Mo(Cp)(CO)_3]_2$ and *cyclo*-$(AsMe)_5$. The mid-chain As—As distances are 2.4335 Å (average) and the terminal As—As distances are 2.449 Å (average) with non-bonding separation between the two terminal arsenics of As(1)···As(5) of 2.835 Å; Mo—As is 2.6285 Å (average).

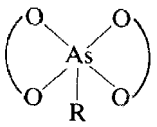
(6) $[Fe(CO)_3]_2(AsMe)_4$ (viewed down the *b* oxis)

(7) $[Mo_2(CO)_6(AsPr^n)_8]$ (*n*-propyl groups are omitted)

28.5 ARSENIC–GROUP 6 LIGANDS

28.5.1 Oxygen Ligands

The chemistries of oxygen, sulfur, nitrogen and halogen ligands of arsenic are quite deeply enmeshed with each other. In this presentation the divisions chosen are not to be thought of as 'the best' but as the most convenient. The oxyhalides are discussed under halogen ligands (Section 28.6). The mixed As/O/S compounds, including oxathia acids, will be included in the sulfur ligand section (28.5.2).



28.5.1.1 Arsenic acid esters and other oxaorganic compounds

Simple esters of arsenic acid, $OAs(OR)_3$, have tetragonal structures; some examples are listed in Table 3. Structurally more interesting are the spiroarsanes (**8**). Goldwhite and Teller[34] initiated the study of the variation in geometry of these complexes from trigonal bipyramidal to rectangular pyramidal. Their findings have been confirmed and the series of structures between the two extremes has been bridged by Holmes and co-workers.[35] The Berry exchange mechanism for a five-coordinate pyramidal system proceeds *via* a rectangular pyramidal intermediate.

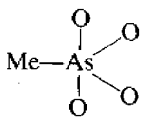


Table 3 Esters of Arsenic Acid, H_3AsO_4[202]

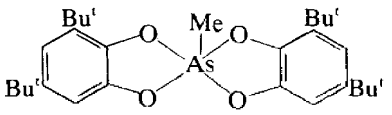
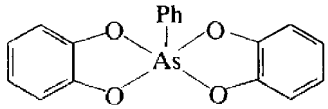
Compound	*B.p.* (°C/Torr)	d^{20}	n_D^{20}
$(MeO)_3AsO$	97–9/13	1.5572	1.4367
$(EtO)_3AsO$	118–120/15.5 235–238/760	1.3023	1.4343
$(PrO)_3AsO$	144–146/14	1.1945	1.4381
$(BuO)_3AsO$	169–171/12	1.1257	1.4421
$(C_6H_{13}O)_3AsO$	189–191/2	1.0496	1.4488



Spiroarsoranes corresponding to many degrees of the transition states are known (**9–11**). Holmes and co-workers studied the variations in substituents and their effect on the percentage displacement from TBP (Table 4).



(**8**) R = alkyl, aryl, OH

(**9**) Distorted trigonal bipyramid (TBP)

(**10**) Almost 45% displaced from TBP to RP

(**11**) Distorted regular pyramid (RP)

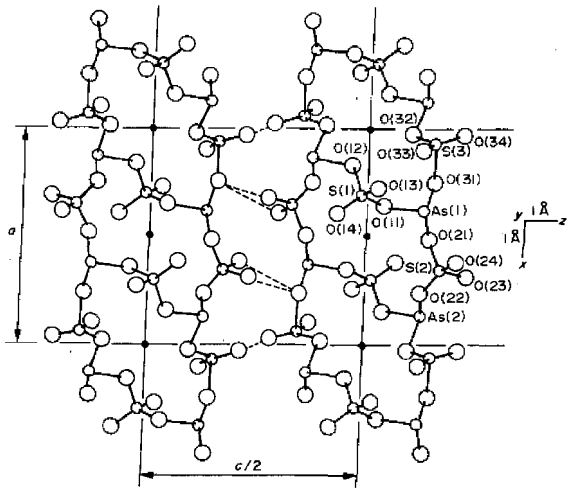
28.5.1.2 Arsenic sulfates

Arsenic does not form true metallic-like salts with sulfuric acid of the type $As_2(SO_4)_3$. However, As_2O_3 dissolves in oleum and crystalline compounds are formed, the compositions of which depend on the concentration of SO_3, *e.g.* $(As_2O_2)(SO_4)_2$, $(As_2O)(SO_4)_2$ and $As(SO_4)_3$.[37] X-Ray studies are listed in Tables 5 and 6. The crystalline compounds consist of AsO_3 pyramids and SO_4 tetrahedra linked by one, two or three oxygen bridges (**12–14**).



(**12**) $(As_2O_2)(SO_4)$

The lone pair on arsenic is sterically active and the arsenic moiety is considered to be AsO_3E (E = lone pair) rather than merely AsO_3. Analysis of the X-ray data[37] enables the definition of

(13) $(As_2O)(SO_4)_2$

(14) $As_2(SO_4)_3$

Table 5 Arsenic(III) Sulfates

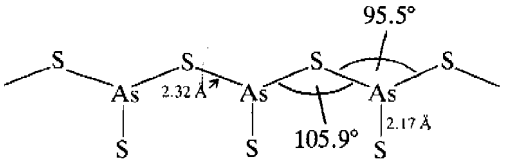
[a] br = bridging. [b] t = terminal. [c] E = lone pair.

the lone pairs in the structures, including estimates of d(As—E) (Table 6). This was considered especially important in the case of $(As_2O_2)(SO_4)$, where the chain structure of the As_2O_2 enables the lone pairs to form tunnels running along the chains and between the sheets. The possibility of utilizing these tunnels for intercalation complexes for electrical applications is being currently investigated.

28.5.2 Sulfur Ligands

28.5.2.1 Thioarsenious acid derivatives



The free acid, $As(SH)_3$, is unknown, but the series of salts M_3AsS_3 is well known; many are minerals. A few examples are listed in Table 7.

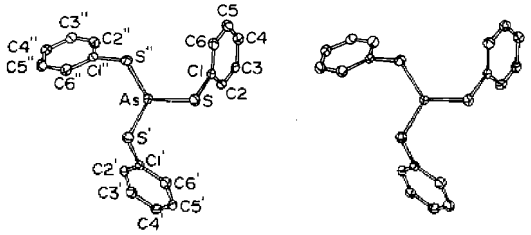
Table 7 Some Thioarsenate Compounds

Compound	*d(As—O)* (Å)	*d(As—S)* (Å)	*Ref.*
K_3AsS_4	—	2.165	247
$Na_3AsS_4 \cdot 8D_2O$	—	2.145–2.173	248
$Na_3AsO_2S_2 \cdot 11H_2O$	1.69	2.14	249
$Na_3AsO_3S \cdot 7H_2O$	1.67	2.14	250
$(NH_4)_3AsS_4$	—	2.20–2.26	251
Cu_3AsS_4	—	2.18	252

The thioarsenite ion is pyramidal[38] in Na_3AsS_3: d(As—S) 2.25 Å, S—As—S 109.9°. The AsS_3^- are stacked to give six sulfur neighbours for Na ions of variable bond distances.

The metathioarsenite ion in $NaAsS_2$ has been shown[39] to be a linear corner-sharing pyramidal polymeric ion (**15**). Similar polymeric structures have been shown for $PbAs_2S_4$ and $TlAsS_2$.

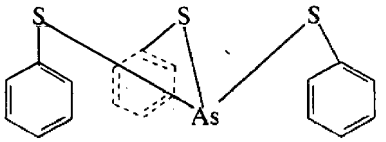
(**15**)



28.5.2.2 Esters of thioarsenious acid

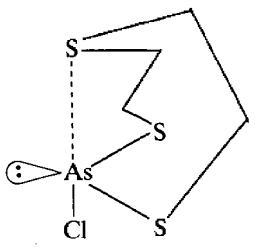
Esters of thioarsenious acid, $As(SR)_3$ (R = Me, Et, Pr^n, Bu^n, Bu^t, Ph), may be obtained by reacting alkali metal thiolates with arsenic halides (equation 9). In difficult cases (steric hindrance) more vigorous methods are used, *e.g.* $(Bu^tS)_3As$ (equation 10).

$$3RSNa + AsX_3 \longrightarrow (RS)_3As + 3NaX \quad (9)$$



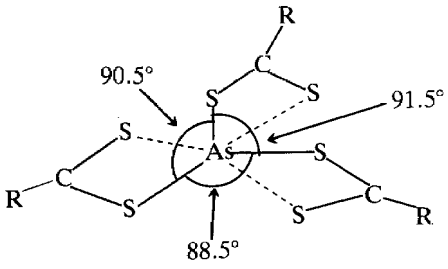
$$AsF_3 + 3Me_3SiSBu^t \longrightarrow (Bu^tS)_3As + 3Me_3SiF \quad (10)$$

Structurally, the esters are pyramidal and an interesting X-ray study of $(PhS)_3As$ has revealed[40] the structure shown in (**16**). The sulfur atoms are in a plane above the arsenic, which



(**16**) Stereoscopic *ORTEP* drawing of $(PhS)_3As$

together with the phenyl rings shield the arsenic atoms (**17**). In solution or in liquid phase the arsenic would be more exposed and available for ligand bond formation with metals, because of thermal inversions at both S and As.



(**17**) View at right angles to sulfur plane

The structure of 2-chloro-1,3,6,2-trithioarsocane shows two interesting features.[41] There is a transannular S–As interaction resulting in the stabilizing of one of the ring conformations. This also results in a pseudotrigonal bipyramidal structure (**18**). Axial bond lengths are As—Cl 2.36 Å and As···S 2.72 Å; equatorial bond lengths are As—S 2.25 and 2.26 Å. Electron donation from the S lone pairs interact with the As *d* orbitals, resulting in sp^3d hybridization and TBP geometry. Raston and White[42] have shown that $As(S_2CNEt_2)_3$ is a six-coordinate arsenic(III) compound (**19**). The crystals are monoclinic and the geometry is grossly distorted towards C_3 symmetry. The mean As—S bond lengths are 2.84 and 2.34 Å. In free Et_2NCS_2 the C—S bonds are of equal length, but when coordinated to As the C—S bonds are 1.68 and 1.76 Å, respectively.

(**18**)

(**19**)

28.5.2.3 Trithioarsenate salts (As^V)

The parent acid H_3AsS_4 has not been isolated, but the partly oxidized acids $H_3AsO_2S_2$ and H_3AsO_3S have been isolated[43] at low temperatures. The thioarsenate ion has the expected four-coordinate tetrahedral geometry. The $(AsO_{4-n}S_n)^{3-}$ anions are well known.

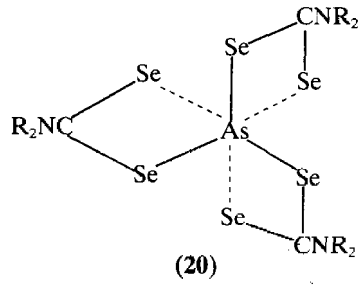
28.5.3 Selenium Ligands

28.5.3.1 Selenoarsenous acid and its salts

Selenoarsenous acid, $As(SeH)_3$, exists only as its salts. Matsumoto and co-workers[44] solved the X-ray crystal structure of silver orthoselenoarsenite: the As atom is pyramidally linked to three Se in $AsSe_3$ units. The silver atoms are bonded to Se making —Se—Ag—Se—Ag— infinite spiral chains; for the $AsSe_3$ pyramids *d*(As—Se)(av) is 2.411 Å, Se—As—Se are 9.81° (av); regarding silver *d*(Se—Ag) (av) are 2.548 Å, 2.527 Å, As—Se—Ag is 107.5°, 97.4°, Se—Ag—Se is 158.8°, Ag—Se—Ag is 79.9°.

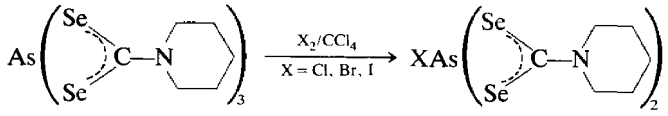
28.5.3.2 Selenoarsenous acid esters

The esters of $As(SeH)_3$ are more difficult to prepare than the oxygen or sulfur analogues. They are all either solids or high boiling oils, and their structures are almost certainly pyramidal. Darmadi *et al.*[45] prepared the trifluoromethyl ester using $Hg(SeCF_3)_2$, which is a yellow oil (m.p. −31 °C) (equation 11).



$$3Hg(SeCF_3)_2 + 2AsBr_3 \longrightarrow 2As(SeCF_3)_3 + 3HgBr_2 \qquad (11)$$

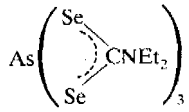
Anderson *et al.* used $Me_3SiSeMe$ as the selenating reagent to give high yields (94–98%) of the arsenic esters (equation 12).

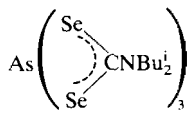


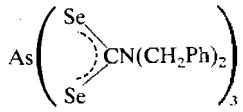
$$R_nAsCl_{3-n} + (3-n)Me_3SiSeMe \longrightarrow R_nAs(SeMe)_{3-n} + (3-n)Me_3SiCl \quad (12)$$

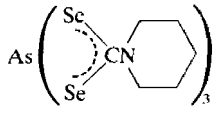
28.5.3.3 Six-coordinate arsenic–selenium compounds

Manoussakis *et al.*[46] have synthesized a series of selenocarbamate six-coordinate complexes of arsenic (**20** and Table 8; *cf.* As—S analogues). By reacting the piperidyl derivative with halogens dissolved in CCl_4 a series of haloselenato carbamate complexes are produced which are probably pentacoordinate (equation 13).









(20)

(13)

Table 8 Diselenocarbamate Complexes of Arsenic(III)

[a] d = decomposed.

28.6 ARSENIC–HALOGEN COMPOUNDS

28.6.1 Three-coordinate Arsenic(III) Halides

Various transient species containing arsenic in low CN with halogens have been recorded spectroscopically, *e.g.* AsI_2 from the photodissociation of AsI_3.[47] The only stable species is the red crystalline iodide, As_2I_4 (m.p. 260 °C),[48] which is decomposed by air or moisture. The

sub-iodide disproportionates when heated above 200 °C (equation 14).[49]

$$3As_2I_4 \overset{300\text{–}350\,^{\circ}C}{\rightleftharpoons} 4AsI_3 + 2As \qquad (14)$$

The arsenic trihalides have been shown by a variety of techniques (Table 9) to be pyramidal molecules in the gas phase. The X—As—X angles increase from X = F 96° to X = I 100°. The *d*(As—X) values increase with increase of temperature,[53] and the X—As—X angle changes in proportion.

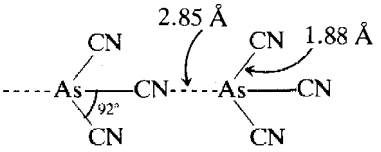
Crystalline arsenic triiodide consists of discrete AsI_3 molecules, which are stacked such that the iodine atoms are hexagonally close packed. The arsenic atoms are octahedrally surrounded by iodine, but with the arsenic off-centre resulting in two sets of *d*(As—I) (Table 9); three bonds of 2.59 Å and three of 3.47 Å (*cf.* AsI_3 vapour, *d*(As—I) 2.56 Å). Arsenic(III) triastatine has not yet (mid-1986) been reported, although it would be surprising if the synthesis has not been attempted.

28.6.2 Reactions of Arsenic(III) Halides

Arsenic(III) halides are not salt-like compounds but typically non-metallic halides comparable to, for example, $GeCl_4$ and SCl_2 besides their predecessors in Group 5, PX_3. However $AsCl_3$ is not as reactive to nucleophilic attack as is PCl_3.

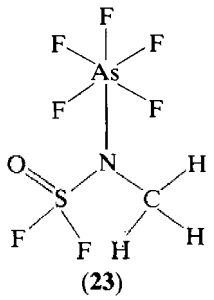


Arsenic trichloride is a Lewis acid, shown by its formation of adducts with bases, *e.g.* $Me_3N{\cdot}AsCl_3$ (**21**), a trigonal bipyramid with a stereoactive lone pair on arsenic.[60b] The d(As—N) is exceptionally long and may be considered to have some ionic character.

(**21**)

28.6.3 Arsenic(III) Pseudohalides

The three known examples of arsenic(III) pseudohalides are $As(CN)_3$,[67] $As(NCO)_3$[68] and $As(NCS)_3$;[69] the thiocyanate is unstable at room temperature. The structure of $As(CN)_3$ (**22**) shows the CN group to be carbon bonded to form a pyramidal $As(CN)_3$ unit. These pyramids are linked together by long As···N 'bonds' to form infinite chains.



(**22**)

28.6.4 Arsenic(V) Halides

28.6.4.1 Arsenic pentafluoride

Arsenic pentafluoride (b.p. −52.8 °C) is the only stable well-characterized arsenic(V) halide. Electron diffraction[49] shows it to be a trigonal bipyramidal molecule, with equatorial d(As—F) 1.656 Å and axial d(As—F) 1.711 Å; ^{19}F NMR shows that the five fluorines are equivalent. The apparent inconsistency displayed by the two techniques is due to the differing time scales of the measured effects. On the slower NMR time scale the axial–equatorial bonds 'rotate' *via* a square pyramidal intermediate resulting in the observed equivalence (pseudorotation).

Arsenic pentafluoride is a Lewis acid capable of forming adducts with basic molecules, *e.g.* (**23**), the adduct with *N*-methyl-*S*,*S*-difluorosulfoximine.[59] Neglecting the methyl group there is a mirror plane through F(ax),As,N,S,O. The methyl C atom lies *ca.* 0.05 Å out of this plane;

(**23**)

the d(As—N) of 1.985 Å is longer than the normal d(As—N) (see Section 28.4.1), but the bond is shorter than that in the $AsCl_3 \cdot NMe_3$ adduct, d(As—N) 2.286 Å.

Arsenic pentafluoride, although outclassed as a 'superacid' component by SbF_5, has still been widely used.[70] Arsenic pentafluoride is a powerful halide acceptor and this property has been utilized in stabilizing various cationic species, *e.g.* $[ClO_2]^+[AsF_6]^-$,[71] $[S_8]^{2+}[AsF_6]_2^-$[58] and $[NS]^+[AsF_6]^-$.[72] The arsenic in AsF_6^- is octahedral, but this is often distorted by the cation field in the crystal unit cell. In the case of $[S_8][AsF_6]_2$ the average d(As—F) is 1.67 Å, *cf.* $KAsF_6$ value of 1.72 Å,[57] but the range of d(As—F) is 1.59–1.72 Å in the four AsF_6^- ions in the crystallographic unit cell. The preparation of several $[AsF_6]^-$ compounds, including the oxidizing agent nitrosyl hexafluoroarsenate $[NO]^+[AsF_6]^-$, is described in detail in 'Inorganic Synthesis', volume 24 (1986).

28.6.4.2 Arsenic pentachloride

While both phosphorus and antimony pentachlorides are stable, $AsCl_5$ is unstable. This anomalous behaviour of arsenic is attributed to d-block contraction; the highest valencies of the p-block elements of the post 3d transition elements are, in general, unstable with respect to other members of their group. In the case of arsenic trichloride the lowering of the energy of the 4s orbital makes the promotion of the $4s^2$ electrons, for further As—Cl bonds to form $AsCl_5$, more difficult. The As—Cl bond strength *per se* in $AsCl_5$ is not thought to be the cause of the molecule's instability.[73] Because of this inherent instability $AsCl_5$ was thought to be one of the so-called non-existent compounds, until the successful proof in 1976 by Seppelt.[74] $AsCl_3$ in liquid chlorine was irradiated with UV light at −150 °C to give $AsCl_5$, a pale yellow solid (m.p. *ca.* −50 °C with decomposition) which was shown by Raman spectroscopy to have a trigonal bipyramidal structure (equation 15).

$$AsCl_3 + Cl_2 \underset{-50\,^\circ C}{\overset{-150\,^\circ C,\ h\nu}{\rightleftharpoons}} AsCl_5 \qquad (15)$$

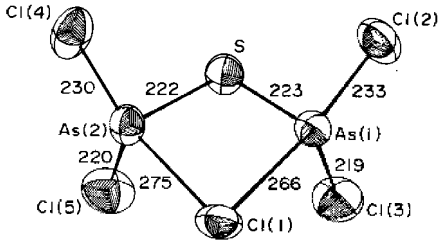
28.6.4.3 Arsenic(V) mixed halides

In the solid state[63] $AsCl_2F_3$ is, in fact, $[AsCl_4]^+[AsF_6]^-$; the $[AsCl_4]^+$ tetrahedron has d(As—Cl) of 2.00 Å and Cl—As—Cl of 109.3° and 109.8°, very near the ideal tetrahedral angles. The $[AsF_6]^-$ bond lengths vary, *viz.* 1.71, 1.68, 1.78 Å, with F—As—F of 90.5° and 89.5°. The arsenic centres in the polyhedra are between 4.84 and 6.03 Å apart.

When $[AsCl_4][AsF_6]$ is pyrolyzed, the mixed halide $AsClF_5$ is formed in preparative quantities.[75] IR studies indicate the chlorine to be in an equatorial position, as expected from its lower electronegativity.

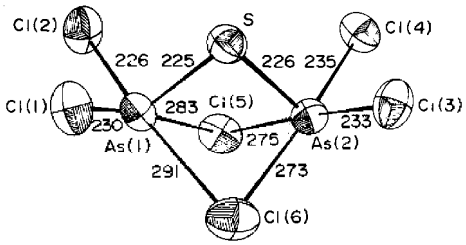
The chlorination of $SbCl_5$ in $AsCl_3$ solution at 80 °C results in the crystallization of a mixed As^V–Sb^V chloride (equation 16). This has been shown by X-ray analysis[66] to be $[AsCl_4]^+[SbCl_6]^- \cdot AsCl_3$. The $AsCl_3$ 'solvate' is slightly distorted, Cl—As—Cl of 97° and 106° (*cf.* 98.5° in free $AsCl_3$). The arsenic tetrahedron and the antimony octahedron are only slightly distorted from the ideal angles (Table 9).

$$SbCl_5 + AsCl_3 + Cl_2 \xrightarrow{AsCl_3} AsCl_5 \cdot SbCl_5 \cdot AsCl_3 \qquad (16)$$



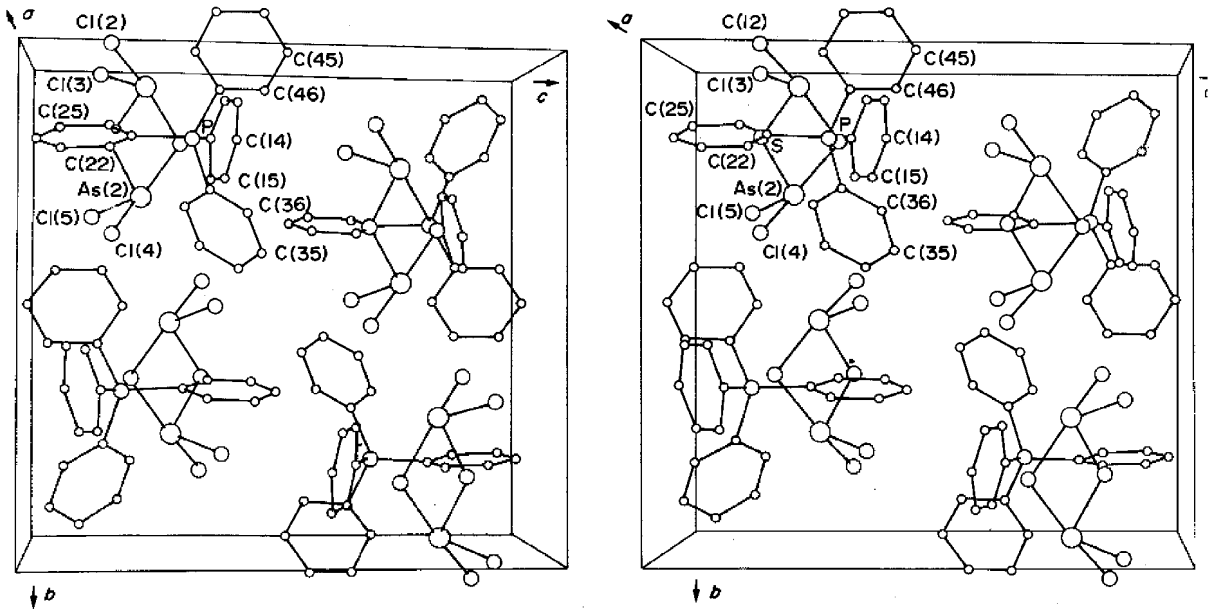
28.6.4.4 Complex arsenic(V) chloride anions

Although arsenic(V) chloride is unstable, the derivative anions are well known, though not as widely studied or used as the corresponding fluorides. In $Cs_3As_2Cl_9$ the highly distorted $AsCl_6$ octahedron has two types of As—Cl bonds, d(As—Cl) at 2.25 and 2.75 Å, the latter suggesting an almost ionic bond.[217]



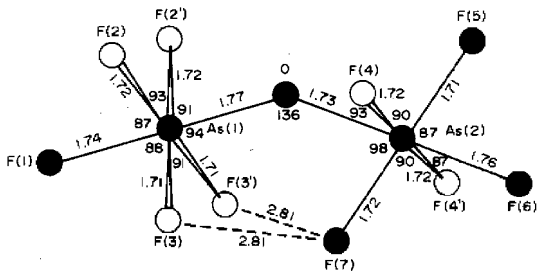
In the thioarsenic halide anions $[As_2SCl_5]^-$ and $[As_2SCl_6]^{2-}$ the As atoms are bridged by S and Cl.[61] In the former the chlorine bridge forms an axial bond with each arsenic atom, which has trigonal pyramidal geometry (**24**).

In $[As_2SCl_6]^{2-}$ the arsenic atoms are bridged by two chlorines and the sulfur ligand; the



arsenic atoms are five-coordinate and have distorted octahedral geometry (**25**). The stereoview shows the unit cell packing of $[Ph_4P][As_2SCl_5]$ and the trigonal bipyramidal disposition of the arsenic ligands is well displayed (**26**).

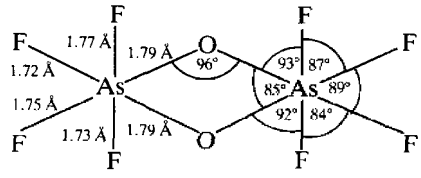
(24)



(25)

(26)

28.6.4.5 Arsenic(V) oxyfluorides



A number of oxygen-bridged arsenic(V) fluoride anions have been studied. In $[As_2F_{10}O]^{2-}$ two AsF_5 groups are bridged[62] by oxygen with an As—O—As angle of 138° and d(As—O) 1.75 Å (av) (**27**). There are small changes in bond lengths and angles when the cation is changed (Table 10).

● = in same plane

(27) $(As_2F_{10}O)^{2-}$ anion in $Rb_2(As_{10}F_{10}O)$

In the $[As_2F_8O_2]^{2-}$ anion[60] there are two bridging oxygens forming a four-membered $(As—O)_2$ ring (**28**) with As—O—As of 96° and O—As—O of 84.9° (av), *d*(As—O) 1.82 Å (av) (Table 10).

28.7 BIOLOGICAL ASPECTS OF ARSENIC

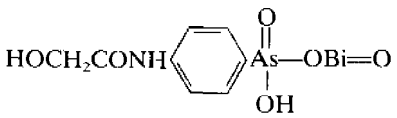
28.7.1 Toxicity of Arsenic

Trivalent arsenic compounds are generally more toxic than the pentavalent compounds; the former compounds inactivate enzymes containing —SH groups. However, arsenate, AsO_4^{3-}, is an analogue of phosphate, PO_4^{3-}, and if present in the body acts as an uncoupler in the oxidation of glyceraldehyde 3-phosphate by forming the highly labile acyl arsenate, 1-arseno-3-phosphoglycerate.[76] Because of its high toxicity the maximum acceptable concentration for an 8 h period has been set at 0.05 p.p.m. for arsine, AsH_3.[77] The lethal human dose is less than 0.25 g As.

In a notorious case in Manchester in 1900–1901 6000 people were affected by drinking beer containing 15 p.p.m. arsenic; 70 people died as a result. The arsenic originated from sulfuric acid containing 1.4% arsenious acid, produced from As-containing iron pyrites. This sulfuric acid was used in a process to manufacture glucose for the brewers, and the glucose contained several hundred parts per million arsenic.

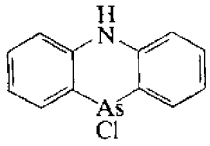
28.7.2 Arsenic in the Environment

Arsenic compounds occur naturally and ubiquitously in nature. The primary sources result from volcanic action and stream waters from arsenic rock strata.



Severe local arsenic pollution can occur adjacent to industrial enterprises producing the various arsenicals used in timber preservation and as agricultural pesticides. Concern expressed by environmental groups has led to a reduction in the use of arsenicals in agriculture over the last decade, and this trend is likely to continue. Waste disposal is the main problem in industrial arsenic production and this problem has been responsible for closing several plants in Western Europe.

28.7.3 Arsenic in Peace and War



Earlier in this century the toxicity of arsenic was utilized in medicine and, later, in warfare. In 1909 Ehrlich developed salvarsan, the first effective antisyphilis agent and one of the first

systematically screened chemotherapeutic agents. While salvarsan was replaced in clinical use by the antibiotics in the 1940s, some specialist arsenical drugs, *e.g.* glycobiarsol (**29**), are still the treatment of choice for amoebic infections.

Amongst the toxic gases, liquids and powders used in World War I there were a few arsenicals. Diphenylchloroarsine, Ph_2AsCl, and diphenylcyanoarsine, Ph_2AsCN, were used as sternutators (irritants to nose and throat, inducing feeling of choking); 10-chloro-5,10-dihydrophenarsazine (**30**), an 'improvement' came 'too late' for use in World War I. Also 'too late' was the vesicant Lewisite, *trans*-$ClCH{=}CHAsCl_2$.

(**29**)

(**30**)

28.7.4 Arsenic in Life

Until recently there was only one word to describe arsenic in relation to life and that was 'lethal'. However, recent work has revealed a new class of bioelements. Beside the bulk elements C, H, O, Ca, P, *etc.* and the trace elements such as Fe, Zn, Br, *etc.*, a new group, the ultratrace elements, has been defined.[78] Among this new class of essential elements is arsenic. Arsenic deficiency signs in experimental animals (fed on rigorously arsenic free diets) include impairment of growth, reproductive and heart function.[79] The detailed role of ultramicrotrace elements is one of the challenges now being addressed by biochemists. It will not be without significance that certain lower marine life forms exhibit a high tolerance for arsenic: up to 175 p.p.m. for prawns, and trimethylarsine has been detected as an off-flavour component of prawns.[80] Arsenic is accumulated in crustacea mainly as the non-toxic arsenobetaine,[81] but this is not the source of the trimethylarsine.

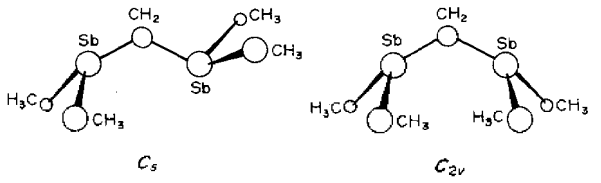
28.8 ANTIMONY

Antimony, the fourth member of the pnictide family, is the only one to exhibit substantial natural isotope variability. The electronic structure of antimony is $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}5s^25p^3$; the Group 5 outer electronic structure of $5s^25p^3$ presages its main valencies of three and five. The CN in its compounds is variable, with six becoming much more common. Simple theory predicts $5p^3$ bonding for Sb^{III} compounds with pyramidal bonds at 90°. In fact three-coordinate antimony(III) compounds have variable angles, usually >90°, indicating a stereoactive lone pair and involving some *s* character in the *p* bonding. The trigonal pyramidal shape for SbX_3 compounds has been shown frequently by X-ray crystallographic studies. Antimony(V) compounds usually involve sp^3d-hybridized orbitals, resulting in trigonal bipyramidal geometry in its pentacoordinate complexes. In six-coordinate compounds sp^3d^2 hybridization is generated, *e.g.* in SbF_6^-. In 'square pyramidal' coordination a stereochemically active lone pair occupies an octrahedral axial position.

28.9 ANTIMONY–GROUP 4 BONDS

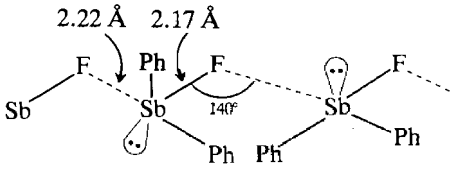
The chemistry of antimony is generally less well developed than that of arsenic and particularly in respect of Group 4 ligands. For the purposes of this discussion organoantimony compounds will be dealt with first and those of silicon, germanium, tin and lead will be taken together.

28.9.1 Carbon Ligands



The synthetic routes developed in arsenic chemistry usually also apply to antimony, but they have not been as fully investigated. A good outline of organoantimony chemistry has been

given by Wardell[82] and an excellent compilation of data and synthetic methods may be found in Gmelin (now in English).[83] For German readers Houben–Weyl will prove useful.[84]



28.9.1.1 Antimony(III) compounds

Stibines, SbR_3, are trigonal pyramidal molecules with C—Sb—C ≈ 90°, but this angle is sensitive to electronic and steric factors, *e.g.* in $Sb(CF_3)_3$, *d*(Sb—C) is 2.202 Å and C—Sb—C is 100°.[85]

Trivinylstibine has been shown to be trigonal pyramidal by IR and Raman spectroscopy,[86] and the bis(stibine) $(Me_2Sb)_2CH_2$ has been shown[87] by NMR to be a mixture of structures with C_s and C_{2v} symmetries (**31**). The halostibine Ph_2SbF[88] is of interest because it exemplifies the tendency of antimony to increase its CN, in this case by bridging Sb···F bonds (**32**). Antimony adopts a trigonal bipyramidal geometry involving a stereoactive lone pair.

(31)

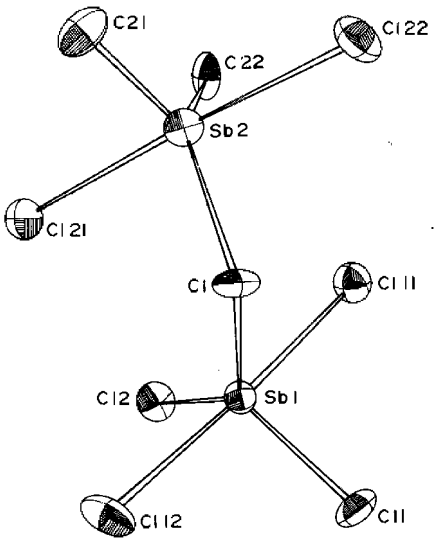
(32)

28.9.1.2 Antimony(V) organohalogen compounds

Stibines may be halogenated by the use of X_2 or by a halogenating agent, *e.g.* trivinylstibine may be chlorinated using sulfuryl chloride (equation 17),[86] and this may be fluorinated using potassium fluoride (equation 18). Both of these compounds are trigonal bipyramidal with apical halogens. Similarly $(Me_2Sb)_2CH_2$, when chlorinated using SO_2Cl_2, afforded the tetrachloro derivative, m.p. 175 °C.[87]

$$(CH_2{=}CH)_3Sb \xrightarrow{SO_2Cl_2} (CH_2{=}CH)_3SbCl_2 \quad (17)$$

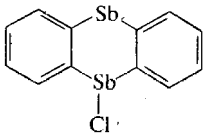
$$(CH_2{=}CH)_3SbCl_2 \xrightarrow{KF} (CH_2{=}CH)_3SbF_2 \quad (18)$$



The trigonal bipyramidal geometry around antimony (**33**) has been shown by X-ray analysis. Some bond lengths are given in Table 11; Cl—Sb—Cl 176.75° (av), Sb—C—Sb 118.2° (rather large for a td angle about carbon).

A halogen atom may be abstracted from haloorganoantimony(V) compounds to form a cation (equations 19 and 20),[86,92] but note the reaction shown in equation (21).[92] The compound $Me_3SbCl_2{\cdot}SbCl_3$ is non-ionic, and an X-ray study has shown the $SbCl_3$ moiety to be chlorine-bridged to three Me_3SbCl_2 moieties, resulting in CNs of six and five, respectively.[92]

$$(CH_2{=}CH)_3SbCl_2 + SbCl_5 \longrightarrow [(CH_2{=}CH)_2SbCl]^+[SbCl_6]^- \quad (19)$$



$$Me_3SbCl_2 + SbCl_5 \longrightarrow [Me_3SbCl]^+[SbCl_6]^- \quad (20)$$

$$Me_3SbCl_2 + SbCl_3 \longrightarrow Me_3SbCl_2{\cdot}SbCl_3 \quad (21)$$

(33) $(Me_2Cl_2Sb)_2CH_2$

Table 11 Bond Lengths and Angles for Some Organoantimony Compounds

Compound	*d(Sb—C)* (Å)	*d(Sb—E)* (Å)	*C—Sb—C* (°)	*Other* (°)	*Ref.*
$Sb(CF_3)_3$	2.202	—	100	—	85
	2.141	2.390 (Cl)	100.2	—	89
$CH_2(SbCl_2Me_2)_2$	2.114 (CH_2) 2.109 (Me)	2.479 (Cl)	90.1 (av)	—	87

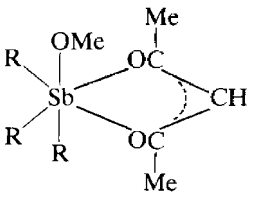
[a] *d*(Si—H) 1.394 Å. [b] Si—Sb—Si



The tendency for antimony to achieve CN six is shown by the behaviour of organohaloantimony(V) compounds to substitution by oxo ligands. Jha *et al.*[93] have employed the bidentate ligands acetylacetone, 8-hydroxyquinoline, salicylaldehyde, *o*-hydroxyacetophenone and 2-hydroxynaphthaldehyde HL (equation 22).

$$R_3SbBr_2 + NaL \xrightarrow[R=Ph,\ Me]{C_6H_6,\ MeOH} R_3Sb(OMe)L + 2NaBr \qquad (22)$$

The complexes produced have been assigned *fac* structures, *e.g.* (**34**). The increasing stability of higher coordination and valency of antimony is shown in the organotrihaloantimony(V) compounds R_2SbCl_3 formed by the oxidative chlorination of monochlorostibines (equation 23). These compounds can be used to prepare pure dihalostibines by thermolysis (equation 24). In the case of Me_2SbCl_3, in solution the methyl groups are equatorial (C_{2v} symmetry), but they become *trans* on reaction with NMe_4Cl.[94]

$$R_2SbCl_2 + Cl_2 \longrightarrow R_2SbCl_2 \qquad (23)$$

$$R_2SbCl_3 \longrightarrow RSbCl_2 + RCl \qquad (24)$$

(34)

28.9.1.3 Other Group 4 ligands (Si, Ge, Sn and Pb)

Silicon forms a series of compounds with antimony analogous to silane. Trisilylstibine, $Sb(SiH_3)_3$, has been shown to be pyramidal by electron diffraction.[95] There was no evidence of bond angle widening, nor bond shortening, thus suggesting the absence of $(p \rightarrow d)\pi$ bonding. The silylstibines are prepared by conventional methods (equation 25).

$$Li_3Sb + 3Me_3SiCl \longrightarrow (Me_3Si)_3Sb \quad (88\%) \tag{25}$$

The silylstibines may be used to prepare germylstibines (equation 26).

$$3Et_3GeH + (Et_3Si)_3Sb \longrightarrow 3Et_3SiH + (Et_3Ge)_3Sb \tag{26}$$

Stannylstibines are prepared[96] by conventional routes (equation 27).

$$3Ph_3SnLi + SbCl_3 \longrightarrow (Ph_3Sn)_3Sb + 3LiCl_3 \tag{27}$$

Tris(organoplumbyl)stibines have been prepared by condensing organolead chlorides with stibine (equation 28).[97]

$$3Me_3PbCl + 3Et_3N + SbH_3 \longrightarrow (Me_3Pb)_3Sb + 3Et_3NHCl \tag{28}$$

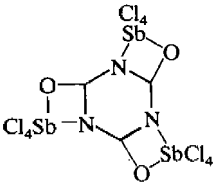
The general coordination chemistry of stibines as donors has been reviewed.[91,98,99]

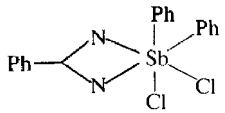
28.10 ANTIMONY–GROUP 5 BONDS

28.10.1 Nitrogen Ligands

The chemistry of antimony and nitrogen is not as rich as that of arsenic and nitrogen. The N—Sb bond mainly exists in compounds where N is but one of a number of donor atoms. These compounds, where significant, will be dealt with under various other headings (mainly oxo and halogen ligands). Some Sb—N bond data are assembled in Table 12.

Antimony trichloride does not react with dimethylamine to give dimethylaminostibines (compare arsenic trichloride). The more vigorous reagent Me_2NLi, however, gives a good yield[100] of tris(dimethylamino)stibine, a colourless, air- and moisture-sensitive liquid (Table 13; equations 29 and 30[103]).





$$SbCl_3 + 3LiNMe_2 \longrightarrow Sb(NMe_2)_3 + 3LiCl_3 \quad (>60\%) \tag{29}$$

$$Me_{3-n}SbCl_n + nMe_3SiNMeLi \longrightarrow \left(\begin{array}{c} Me_3Si \\ \diagdown \\ N \\ \diagup \\ Me \end{array}\right)_n SbMe_{3-n} \quad (50\text{–}70\%) \tag{30}$$

The cyclic aminochlorostibine was synthesized by Wannagat and Schlingmann[104] using milder conditions and triethylamine as HCl acceptor (equation 31).

Scherer *et al.*[105] synthesized the novel bicyclic Sb—N—P ring system (**35**; equation 32). The

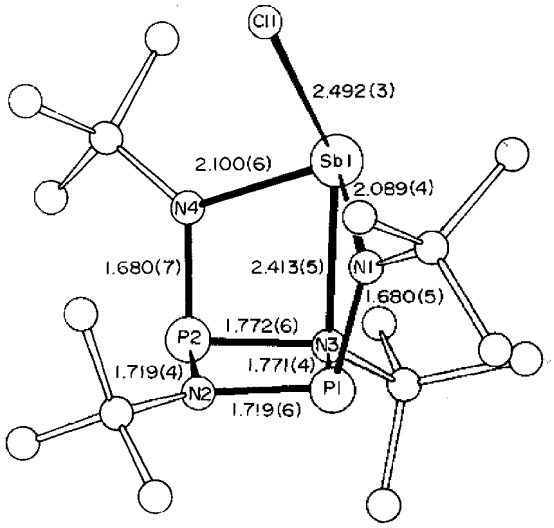
(31)



(32)

Tris(dialkyl)stibines react with sulfur dioxide (equation 33), affording tetraalkylsulfurous diamides and an unidentified antimony/nitrogen compound.[101]

$$Sb(NR_2)_3 + SO_2 \longrightarrow (R_2N)_2SO + 1/n(R_2NSbO)_n \quad (33)$$

There are in the literature some interesting features of antimony chemistry, but which need some crystallographic confirmation, for example the reaction (34). This implies a two-

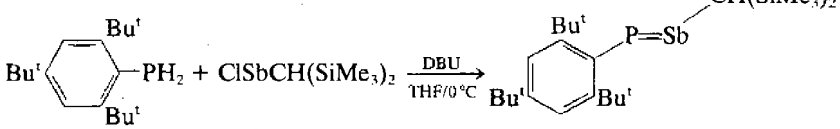
(35)

coordinate antimony.[106] Another unusual reaction is shown in equation (35).[107]

$$R_3Sb + R'SO_2N_3 \longrightarrow RSb{=}NSO_2R' \tag{34}$$

$$SbI_3 + RNH_2 \xrightarrow[\text{reflux}]{\text{MeCN}} RNSbI \tag{35}$$

R = Pr, Bu, $PhCH_2$, Ph



28.10.2 Other Group 5 Ligands (P, Sb and Bi)

Simple antimony–antimony compounds are known, but are less common than those with higher members of Group 5; the Sb—Sb bond energy is 142 kJ mol^{-1}, which is even weaker than the As—As value of 180 kJ mol^{-1}. Several compounds R_2SbSbR_2 (R = Me, CF_3, Et, Bu^t, Ph) are characterized, and all are air sensitive, although the recently prepared $(C_6H_8Sb)_2$ (Table 14) is air stable. This compound[108] is an intensely coloured irridescent purple-blue by reflected light and red by transmitted light. X-Ray analysis revealed the molecular structure to be as expected, *d*(Sb—Sb) 2.835 Å, but with a short intermolecular Sb···Sb distance, 3.625 Å, which is much less than the calculated van der Waals' distance of 4.40 Å. The intermolecular Sb···Sb distance in Ph_2Sb—$SbPh_2$ is 4.88 Å.[90] The intermolecular chains and weak Sb···Sb bond are thought to be responsible for the unusual colouring.

Breunig[109] observed the unusual coupling reaction of tris(trimethylstannyl)stibine when oxidized by air (equation 36).

$$(Me_3Sn)_3Sb \xrightarrow[\text{oxidation}]{\text{air}} (Me_3Sn)_2Sb{-}Sb(SnMe_3)_2 + (Me_3Sn)_2O \tag{36}$$

Antimony–element double bonds are still uncommon. Cowley *et al.*[110] found the stability of P=E (E = P, As, Sb, Bi) falls down the group, *i.e.* P > As > Sb > Bi (equation 37; the Bi analogue could not be prepared). The dark orange solution of the P=Sb compound slowly decomposes to give RP—PR (R = mesityl), making isolation impossible. The arsenic analogue has been characterized by X-ray analysis.[111] The ^{31}P NMR spectrum of the P=Sb compound exhibits an extremely deshielded signal (δ = 620.0 p.p.m.), among the lowest ever recorded.

(37)

28.10.3 Antimony Catenation

Compared to other members of Group 5 antimony displays a marked preference for polymeric structures over cyclic structures (equations 38 and 39[112]). Alkyl primary stibines break down at −78 °C to afford brown/black solids (equation 40).

$$PhEH_2 + PhEI \longrightarrow (PhE)_6 + 6HI \quad (38)$$

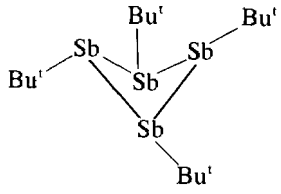
$$E = P, As$$

$$PhSbH_2 + PhSbI_2 \longrightarrow (PhSb)_x + xHI \quad (39)$$

$$RSbH_2 \longrightarrow (RSb)_x + H_2 \quad (40)$$

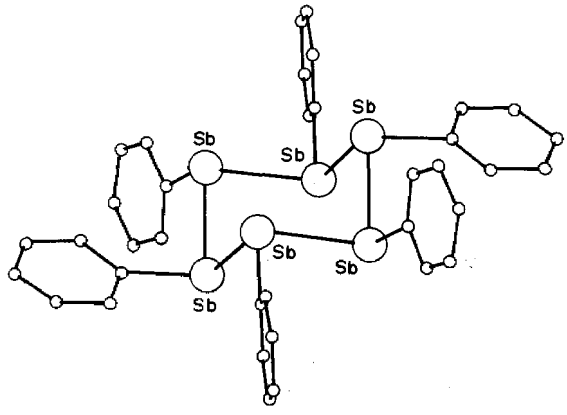
This clear preference for polymeric primary organostibine structures indicates this to be the thermodynamically stable state. Rheingold *et al.*[113] have produced a polymeric material $(MeSb)_x$ by reacting $MeSbH_2$ with Me_2SiCl_2 at −78 °C in toluene. It is thought that the weak Sb—Sb bond and lower steric restrictions because of the size of the Sb atom, together with a lack of transannular stabilizing interactions, significantly favour chain formation over ring formation when alternative reaction pathways are available.

28.10.4 Cyclic Antimony(III) Compounds



Although antimony–antimony compounds tend to form as polymers rather than as cyclic structures, several *cyclo*-antimony(III) compounds have recently been characterized. Ellermann and Veit[114] have synthesized the Sb_3R_4 analogues of the well known three-membered arsenic ring compounds (equation 41).

$$MeC(CH_2SbCl_2)_3 \xrightarrow{Na/THF} Me\text{-}\langle Sb_3 \rangle \quad (41)$$



The four-membered Sb ring with bulky Bu^t stabilizing groups, $(SbBu^t)_4$, has been shown to have the all-*trans* structure (**36**).[115]

Issleib and Balszuweit[116] synthesized a yellow-orange compound thought to be $(PhSb)_6 \cdot C_6H_6$, and Breunig *et al.*[117] have succeeded in isolating $(PhSb)_6 \cdot C_4H_8O_2$ (**37**; equation 42; Table 14).

$$6PhSb(SiMe_3)_2 + 3O_2 + C_4H_8O_2 \longrightarrow (\mathbf{37}) + 6(Me_3Si)_2O \quad (42)$$

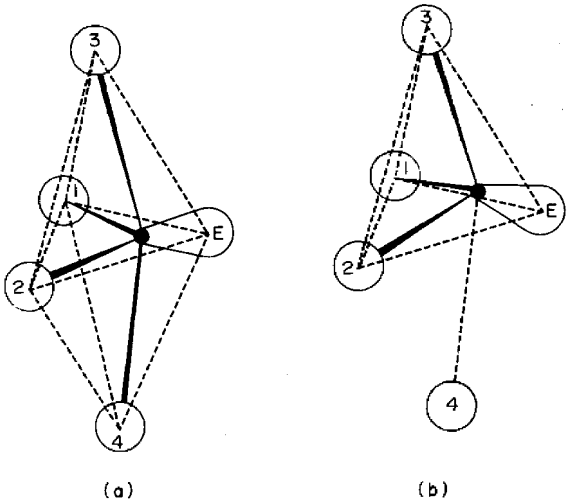
28.11 ANTIMONY–GROUP 6 LIGANDS

28.11.1 Antimony(III) Compounds with Oxoacids

Antimony(III) forms a variety of compounds with oxoacids, some with empirical formulae that may be written in the form of a metal salt, *e.g.* $Sb_2(HPO_3)_3$[118] and $Sb_2(SO_4)_3$,[119] and others as 'basic' salts or mixed oxides, *e.g.* $SbO(H_2PO_4)\cdot H_2O$[120] and $Sb_2O(SO_4)_2$.[121] When the antimony lone pair is involved, the difference between pyramidal and trigonal bipyramidal geometry about Sb is a small change in position (Figure 1 and Table 15). Table 15 was compiled by Bovin[122] and lists typical trigonal bipyramids at the top and typical pyramidal structures (tetrahedral with lone pair) at the bottom. The mean equatorial distance in the first seven compounds listed in Table 15 (Sb-1 and Sb-2) is 2.01 Å and axial (Sb-3 and Sb-4) is 2.22 Å, with mean angles of 92.0° and 148.0°.



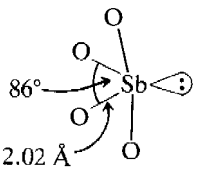


Figure 1 The coordination polyhedra of antimony(III). (a) and (b) show idealized fourfold and threefold coordination, respectively.

The structures of these oxoacid compounds can be complex, *e.g.* $Sb_6O_7(SO_4)_2$,[122] the structure of which consists of distorted tetrahedra (lone pair at the one corner) and *d*(Sb—O) of 1.994–2.207 Å. In these units three different SbO_3 polyhedra share corners and edges to give cylindrical units with SO_4^{2-} tetrahedra between the cylinders. In contrast, antimony(III) phosphite, $Sb_2(HPO_3)_3$, is a fairly simple structure with Sb^{III} coordinated to four isolated HPO_3^{2-} tetrahedra (**38**). The geometry about antimony is trigonal bipyramidal with O(ax)—Sb—O(ax) of 159.4°.[118]

(38)

In the series $Me_3Sb(X)OSb(X)Me_3$ (X = N_3, Cl, ClO_4) trigonal bipyramidal structures were found with X and O in the axial positions. The variation of *d*(Sb—O) with X is given in Table 16.

Table 16 Axial Bond Lengths in $(Me_3SbX)_2O$

Compound	*d(Sb—O)* (Å)	*Axial group*	*d(Sb—X)* (Å)	*Electronegativity of X (Pauling)*
$(Me_3SbCl)_2O$	1.907	Cl	2.628	3.0
$(Me_3SbN_3)_2O$	1.872	N (N_3)	2.344	3.0
$[Me_3Sb(OClO_3)]$	1.862	O (ClO_4)	2.601	3.5

28.11.2 Antimony Oxyhalides

Antimony forms polymeric oxyhalides, and not metallic as in BiOCl. The fluoride, SbOF, has been prepared in two forms: '*L*', with a ladder structure, and '*M*', which has a layered structure. Both forms have a trigonal bipyramidal structure about antimony with three oxygens, one fluorine and one lone pair. Structural parameters are given in Table 15, from which it can be seen that *L*-SbOF heads the table as the nearest to an ideal fit for trigonal bipyramidal geometry.

The oxychlorides SbOCl and $Sb_4O_5Cl_2$ have sheets of Sb—O layers, with chlorines between the layers. The SbOCl layer has one third of the Sb in SbO_4 and two thirds in SbO_2Cl units. In

$Sb_4O_5Cl_2$ one half of the Sb is in SbO_3 coordination and half in SbO_4.[123] Antimony oxoiodides, Sb_3O_4I, $Sb_8O_{11}I_2$ and Sb_5O_7I, also have layered structures.

28.11.3 Antimony(V) Oxide and Derivatives

28.11.3.1 Antimony oxoacids and their salts

Antimonic acid is poorly characterized and reported examples are hydrated Sb_2O_5 of unknown structure. It is known in its salts, however, and these are of the two main types, based on either $[Sb(OH)_6]^-$ or $[SbO_6]^{n-}$ octahedra. The oxyions, *e.g.* $[SbO_4]^{3-}$, do not exist *per se*.

28.11.3.2 Antimonates containing $[Sb(OH)_6]^-$ ions

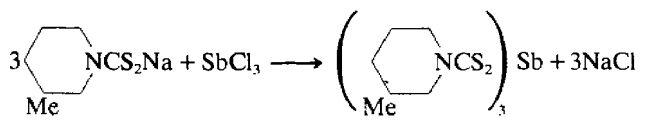
The X-ray crystal structures of sodium pyroantiomonate revealed that the salt should be written $Na[Sb(OH)_6]$, and the silver salt is $Ag[Sb(OH)_6]$. This has led to the reformulation of the older notation (Table 17).

Table 17 Revision of Antimonate Formulae

Old formula	*New formula*
$Na_2H_2Sb_2O_7 \cdot 5H_2O$	$Na[Sb(OH)_6]$
$Mg(SbO_3)_2 \cdot 12H_2O$	$[Mg(H_2O)_6][Sb(OH)_6]_2$
$Cu(NH_3)_3(SbO_3)_2 \cdot 9H_2O$	$[Cu(NH_3)_3(H_2O)_3][Sb(OH)_6]_2$
$LiSbO_3 \cdot 3H_2O$	$Li[Sb(OH)_6]$
$HaF \cdot SbOF_3 \cdot H_2O$	$Na[SbF_4(OH)_2]$

28.11.4 Sulfur Ligands

28.11.4.1 Thioantimonates



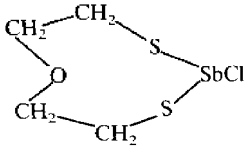
There are a large number of minerals and synthetic materials based on the antimony–sulfur bond. The structures are diverse and are based on trigonal pyramidal, tetragonal, trigonal bipyramidal (usually distorted) or octagonal units. Frequently several of these types of structural unit are used in one structure, *e.g.* Livingstonite, $HgSb_4S_8$, although cases of simple trigonal pyramidal structures are known, *e.g.* Samsonite, $MnAg_4Sb_2S_6$.

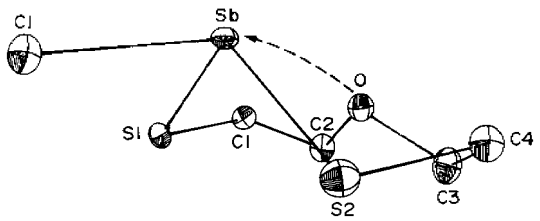
28.11.4.2 Organosulfur ligands

These molecules are usually formed by reacting antimony halides with an organosulfur compound (equations 43,[124] 44[126] and 45[125]).

$$2SbCl_3 + 3Pb(SC_6Cl_5)_2 \xrightarrow[\text{reflux}]{C_6H_6} Sb(SC_6Cl_5)_3 + 3PbCl_2 \quad (73\%) \tag{43}$$

$$SbF_3 + 3Me_3SiBu^t \longrightarrow Sb(SBu^t)_3 + 3Me_3SiF \quad (100\%) \tag{44}$$





(45)

In the case of ligands with larger bite, *i.e.* chains between the sulfur atoms, cyclic disulfides may result, for example 5-chloro-1-oxa-4,6-dithia-5-stibocene,[127] the structure of which consists of antimony in a distorted trigonal bipyramid with Cl and O in axial positions (**39**). A range of crystallographic data is contained in Table 18.

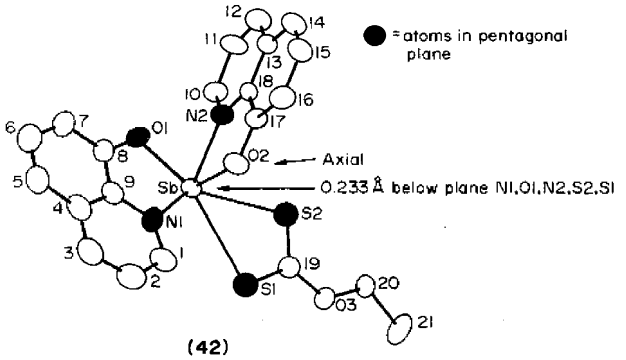
(**39**)

Antimony(III) complexes with bidentate sulfur ligands form an interesting series of structural types. In tris(diethyldithiocarbamate)antimony(III) the sulfur atoms fall into two groups. Firstly, there are three *fac* sulfurs with short *d*(Sb—S) 2.487–2.631 Å bonds, one from each ligand, and then there are three longer bonds *d*(Sb—S) 2.886–2.965 Å (**40**). There is a large gap in the coordination sphere and this has been ascribed[128] to a sterically active lone pair. There is a weak Sb···S 3.389 Å interaction between molecules within van der Waals' radii. Similar results have been obtained for $Sb(S_2CNPr^n_2)$ and tris(1-pyrrolidinecarbodithioato)antimony(III).[129,130] Hoskins *et al.*[133] used the bidentate $EtOCS_2^-$ to prepare analogous SbL_3 species, and found once again that there are three *fac* short Sb—S 2.511 Å bonds and three longer 3.002 Å bonds. The triangles formed by each of these groups of three sulfur atoms (projected into a plane) are rotated at an angle of 41.6° relative to one another (**41**), (*cf.* ideal octahedral geometry of 60°). The thrust of the lone pair on Sb is considered to be in the direction through the centre of the triangle formed by the longer-bonded sulfurs, accounting for the 'splaying out' of that triangle when compared to the short- or primary-bonded sulfur atoms. The S—C—S angle is 123° (*cf.* $(Et_2NCS_2)_3Sb$ S—C—S 118°) and this

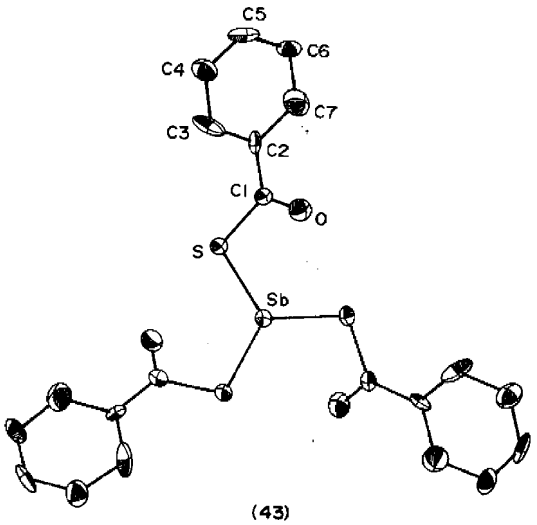


subtle change in bite angle of the ligand may be a factor in the resulting distorted octahedral geometry rather than the pyramidal geometry of $(Et_2NCS_2)_3Sb$. Hoskins *et al.*[133] also adventitiously isolated the mixed ligand complex (*O*-ethylxanthato)bis(quinolin-8-olato)antimony(III), which is pentagonal bipyramidal about antimony (**42**). The oxygen atom of one of the hydroxyquinoline ligands is the apical donor with a short *d*(Sb—O) 2.018 Å. The pyramidal structure is indicated by the angles the other ligand atoms make *via* antimony with this axial oxygen; average angle is 86° (ideal structure, 90°).

(40)

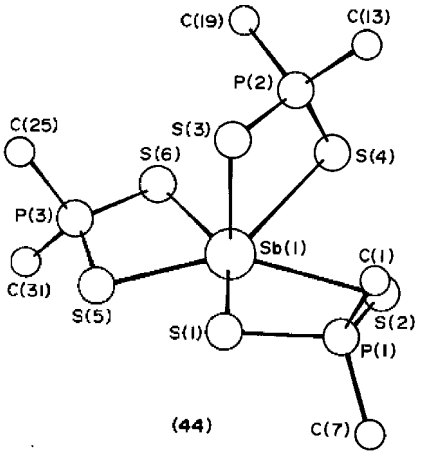
(41)

(42)



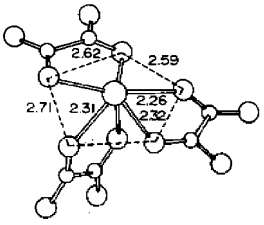
In $Sb(PhCOS)_3$ the shorter bonds are with the sulfur, *d*(Sb—S) 2.493 Å, and the weaker with oxygen, *d*(Sb—O) 2.802 Å. Interestingly, the three oxygen atoms and the antimony are nearly coplanar (**43**). This gives a grossly distorted octahedral geometry which may be thought of as an extreme extension of the type of distortion in $(EtOCS_2)_3Sb$ (**41**) at the threshold of pentagonal bipyramidal geometry.

The geometry about antimony in tris(diphenyldithiophosphinato)antimony(III) is pentagonal pyramidal (**44**) with the lone pair thought to be occupying one of the apical positions in a

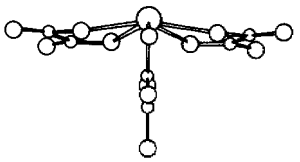


pentagonal bipyramid. This is similar to the structure revealed by Russel *et al.*[135] for the $M_3[Sb(C_2O_4)_3]$ complex (M = NH_4, K; **45**). Sowerby *et al.*[132] have produced $Sb\{S_2P(OR)_2\}_3$ (equation 46).

$$SbCl_3 + 3(NH_4)S_2P(OR)_2 \xrightarrow{EtOH} Sb\{S_2P(OR)_2\}_3 + 3NH_4Cl \qquad (46)$$

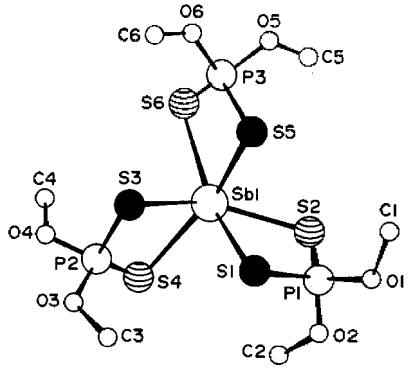


R = Me, Et, Pr^i, Bu^n, Bu^i, Bu^s

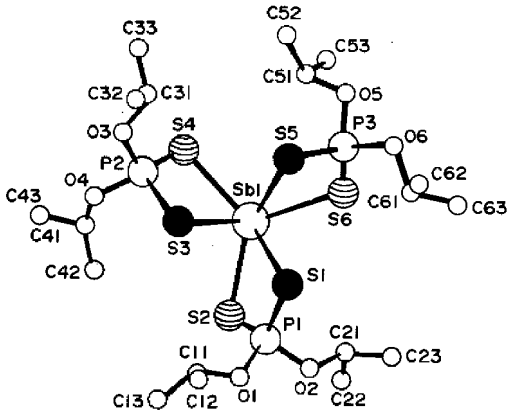


(43)

(44)



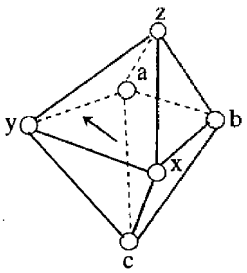
A perspective view of the $[Sb(C_2O_4)_3]^{3-}$ ion



A projection of the $[Sb(C_2O_4)_3]^{3-}$ ion approximately perpendicular to the equatorial plane

(45)

X-Ray structures were produced for the Me (**46**) and Pr^i (**47**) derivatives, both being described in terms of distorted octahedral geometry; the twist angles between the two planes of sulfur atoms are *ca.* 45° in both cases (ideal octahedral twist angle is 60°).



(46)

(47)

In a formal sense in these compounds with sulfur the central antimony atom has a total of seven pairs of electrons. The lone pair then has to occupy a capping position over a triangular face of the octahedron (**48**). The longer Sb—S bonds are then rationalized by the interaction of the lone pair with a group of three *fac* sulfur atoms, say *x, y, z*. However, it could equally well be argued that other geometric imperatives imposed, for example, by small bite ligands or inductive factors by adjacent atoms or groups, or the requirement to minimize intermolecular interaction in the crystal, are responsible. The balance of interactions and their relative importance has not yet been fully worked out.

(**48**)

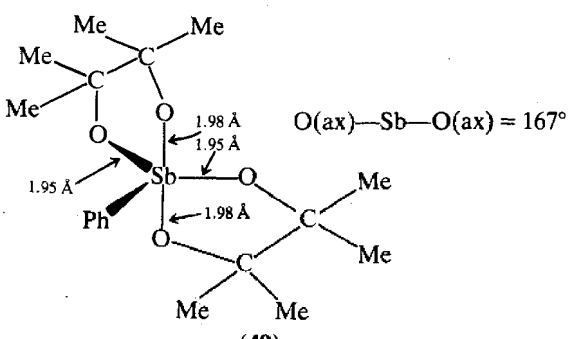
Some interest is being shown in some Sb—S compounds for their pharmacological effect. For example Alonzo *et al.*[136] have prepared $SbL_3 \cdot H_2O$ (LH = L-cysteine), but the structure is not yet known).

28.11.4.3 Organoantimony–sulfur compounds

The known types are well reviewed in Gmelin up to *ca.* 1980, but some representatives will be mentioned here.

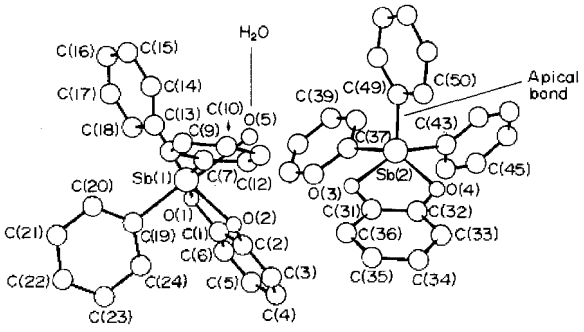
Thioesters are prepared from stibonous esters (equation 47).[137] Thiostibinous esters may be made from the oxo compounds (equation 48).[138]

$$MeSb(OEt)_2 + 2EtSH \xrightarrow[\text{fractionate}]{\text{EtOH, reflux}} MeSb(SEt)_2 \quad (47)$$



b.p. 100 °C/13 mmHg

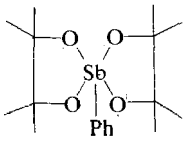
$$(R_2Sb)_2O + 2R'SH \xrightarrow[\text{reflux}]{C_6H_6} R_2SbSR' \quad (48)$$



These are compounds of pharmaceutical interest possessing bactericidal and fungicidal properties and finding use in, for example, paint formulations.

28.11.5 Some Pentacoordinate Molecules

Spiroarsoranes[139] (see p. 245) are distorted towards square pyramidal geometry, so it is surprising that 2-phenyl-4,4,4′4′,5,5,5′5′-octamethyl-2,2′-spirobi(1,3,2)^5-dioxastibolan is found to have a distorted trigonal bipyramidal geometry (**49**).[140]



(**49**)

(50) $(Ph_3SbO_2C_6H_4)_2 \cdot H_2O$

Perhaps the most remarkable five-coordinate compound is bis(triphenylantimony-catecholate)hydrate,[141] which displays six-coordinate octagonal geometry and square pyramidal geometry (Table 19). As seen in (**50**) one molecule of Ph_3Sb(catecholate) is bonded to a water molecule; this bonding is very weak with *d*(Sb—O) 2.512 Å, corresponding to a bond order of 0.17. The oxygens are *fac*. The other molecule of the pair has a base of two carbons, *d*(Sb—C) 2.143, 2.125 Å, two oxygens and an apical *d*(Sb—C) 2.099 Å.

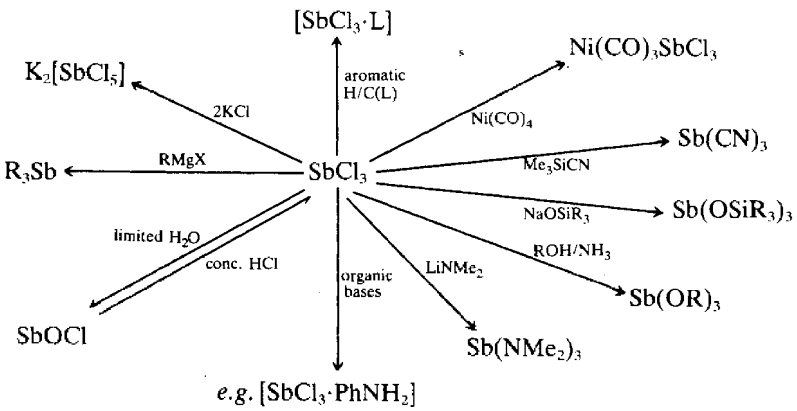
28.12 ANTIMONY–HALOGEN COMPOUNDS

28.12.1 Antimony(III) Halides



The structure of SbX_3 molecules is trigonal bipyramidal in the vapour phase (Table 20) and this symmetry is retained in the crystal state with some variations in bond lengths. In the case of the iodide the *d*(Sb—I) is 2.72 Å (I—Sb—I 99°); the crystal consists of hexagonal close packed assemblies of iodine atoms with antimony in the octahedral interstices, but off-centre, giving two different *d*(Sb—I) distances of 2.87 and 3.32 Å.

Antimony(III) halides are chemically reactive, but less so than their phosphorus or arsenic analogues. Antimony(III) chloride forms a clear solution with water, and there is no evidence for Sb^{3+} ions; dilution results in precipitation of insoluble oxychlorides of various compositions, *e.g.* SbOCl, $Sb_4O_5Cl_2$, $Sb_8O_{11}Cl_2$. Some reactions of $SbCl_3$ are shown in Scheme 3. Antimony(III) fluoride is an important fluorinating agent.

Antimony(III) halides are Lewis acids and will form adducts with Lewis bases. An example is provided by Lipka and Mootz,[149] who prepared an adduct of diphenyl with $SbCl_3$, $2SbCl_3 \cdot PhPh$ (**51**). A molecule of $SbCl_3$ is bonded to each of the biphenyl rings, but there are two differently bonded antimony atoms. One which forms the chain is six-coordinate: there are three chlorine atoms at a normal distance, 2.36 Å (av), and two at the longer distances of 3.443

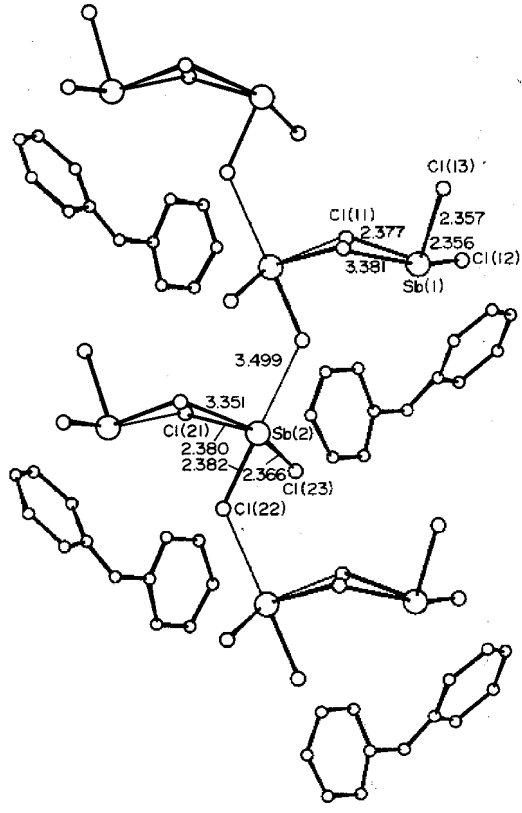
Scheme 3 Representative reactions of antimony(III) chloride

and 3.456 Å; the phenyl ring is the sixth ligand. The other type of Sb only binds to one extra chlorine (3.442 Å) and the other phenyl (3.08 Å), resulting in pentacoordination.

(51)

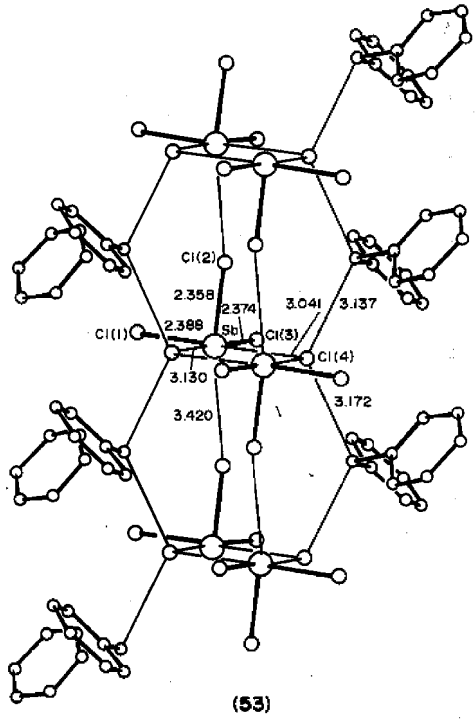
Placing an NH group between the phenyl rings, *i.e.* diphenylamine, resulted in a similar structure, but because of the greater flexibility of the ligand the Sb···Ph distances for the two antimony atoms are approximately the same, 3.08 and 3.09 Å (**52**). However, when the $[PhNH_2]^+Cl^-$ salt is used as the ligand, a completely different structure resulted. Both antimony atoms are in the same environment of a distorted octahedron of six chlorine atoms, and the amine ion is a bridging position between chlorine atoms of the antimony–chlorine-bridged tubular chain (**53**).

These adducts may be usefully compared to that formed by Scruton and Hulme[154] in $SbCl_3 \cdot PhNH_2$. In this case the bonding is with nitrogen and the structure is trigonal bipyramidal with N and Cl apical and two chlorines and the lone pair equatorial. The balance between the factors of the Lewis basicity of the amine *versus* that of the aromatic system together with crystal packing energies must be finely drawn in these systems.



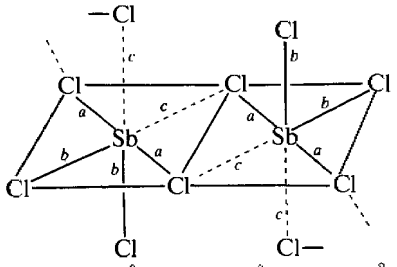
Antimony(III) halides are powerful halide acceptors and form complexes with, for example, monovalent halides to give a variety of interesting structures, *e.g.* (**54**)–(**56**). The tetramethylammonium nonabromodiantimonate(III) dibromine is of interest since the crystal structure contains bromine molecules which bridge the $[Sb_2Br_9]^{3-}$ anions (**56**).[158]

Gillespie and coworkers[164] isolated a 1:1 adduct of SbF_3 and SbF_5 from a reaction mixture of SbF_5 and S_4N_4 in liquid SO_2, the crystal structure of which shows it to be $[Sb_2F_4]^{2+}[SbF_6]_2^-$ (**57**). Similar $[SbF_2]^+$ cations have been described in $M(SbF_2)SO_4$ (M = Rb, Cs)[166] and $K(SbF_2)HPO_4$.[167]



A crystallographically characterized species, $[SbF]^{2+}$, has been described by Mattes and Holz.[165] On mixing 0.1–0.3 M solutions of SbF_3 and MH_2PO_4 the compounds shown in Scheme 4 are isolated. Compound (I) is the same as that produced in $K(SbF_2)HPO_4$ (above), but complexes (II) and (III) have the interesting structure (**58**).

28.12.2 Antimony(V) Halides



Two simple antimony(V) halides are known: SbF_5 (m.p. 8.3 °C, b.p. 141 °C, *d* 3.11 g cm^{-3} at 20 °C) and $SbCl_5$ (m.p. 40 °C, b.p. 140 °C, *d* 2.35 g cm^{-3} at 21 °C). The former is a syrupy viscous liquid (*ca.* 850 centipoise, 20 °C, which is a similar value to glycerol), due probably to the polymeric chains of *cis*-bridged SbF_6 octahedra.[168] The viscosity is greatly reduced by the addition of small amounts of $SbCl_5$, which breaks the Sb—F—Sb bridges. This is of industrial

(57)

importance in processes such as the Swarts reactions. In the crystalline state SbF_5 is a tetramer, **(59)**.[150]

A variety of mixed antimony(V) chloride/fluorides have been described, in the main arising from the fluorination of $SbCl_5$; the product of fluorination is strongly dependent on the fluorinating agent. Bridging fluorides exist in the cyclic tetramer $SbCl_4F$, similar to the $(SbF_5)_4$ **(59)**.[168] One of the products from the HF reaction, $SbCl_3F_2$, is also a tetramer with bridging fluorine, d(Sb—F) 2.07 Å.[155] The other HF fluorination product, $[SbCl_4][Sb_2Cl_2F_9]$, contains the unit $[ClF_4Sb—F—SbF_4Cl]$, with a distorted octahedral geometry about antimony, Sb—F—Sb 163°.[169]

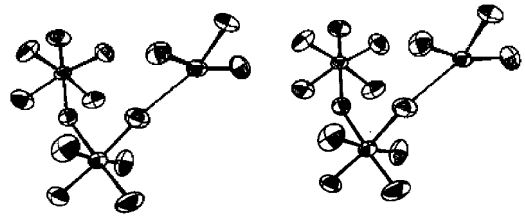
(58)

(59)

Birchall and co-workers[155] found that the fluorination of $SbCl_4F$ gave a product best described as a tetramer of $SbCl_3F_2$ with partial replacement of the fluorine by chlorine and corresponding to the general formula $Sb_4Cl_{12+x}F_{8-x}$ ($x = 0$–4). In the case where $x = 1$ (equation 49) the substitution results in a compound with a disordered crystal structure.

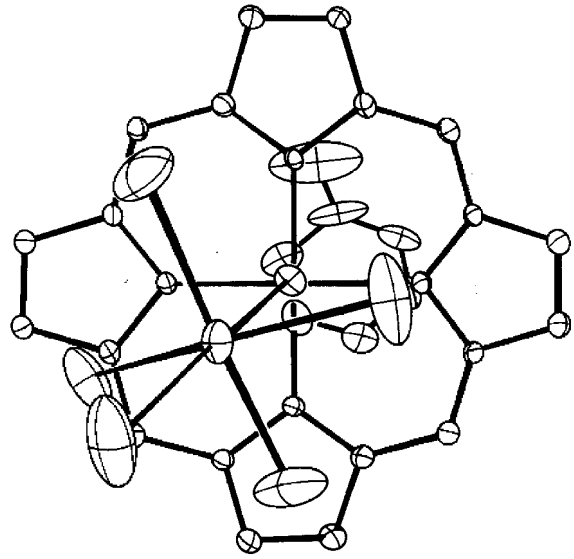
$$SbCl_4F \xrightarrow[SO_2(l)]{SbF_5} Sb_4Cl_{13}F_7 \qquad \text{m.p. } 45\text{–}54\,^{\circ}C \tag{49}$$

One of the more notable features of antimony(V) halide chemistry is the tendency to achieve a CN of six, thus resulting in the facile formation of complex anions, particularly with halide donors (Table 21); the *d*(Sb—F) depends on the nature of the cation. Their structures are related to the F—Sb···F interactions between crystal structure units, which is dependent upon the potential field of the cation.



This powerful halide-abstracting ability results in SbF_5 being the strongest Lewis acid with which HSO_3F forms the strongest 'superacid', the so-called 'magic acid'.[70] The Sb^V halides are excellent Friedel–Crafts catalysts.[269]

Although XeF_4 is a poor F-donor, such is the strength of SbF_5 as a Lewis acid that reaction between them produces $[XeF_3]^+[Sb_2F_{11}]^-$ (**60**), but it should be noted that the nearest approach of an F atom of the anion to the cation is 2.50 Å.[160]



Care must be exercised in interpreting initial data when using SbF_5 to generate $[SbF_6]^-$ anions. An example from the recent literature is that of $Fe(TPP)(FSbF_5)\cdot PhF$.[161] It had been supposed, not unreasonably, that the SbF_6 moiety was an anion, but careful X-ray analysis shows that this moiety is, in fact, a ligand covalently bound to iron (**61**).

Table 21 X-Ray Crystal Data for $M[SbF_6]$

Compound	*Crystal type*	*d(Sb—F)* (Å)	*Ref.*

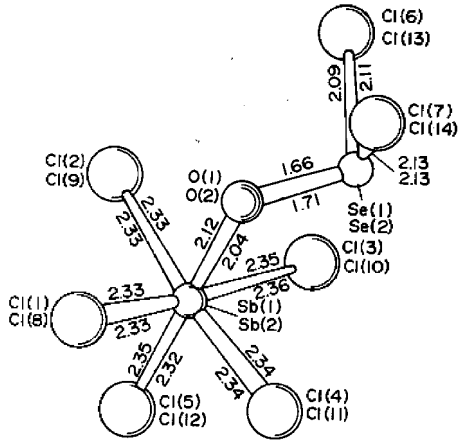
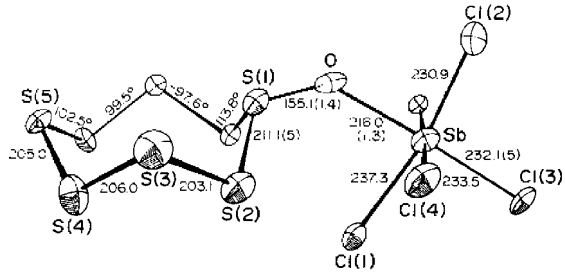
(61) View of $Fe(TPP)(FSbF_5)\cdot PhF$ showing the orientation of the hexafluoroantimonate ligand and the disposition of the fluorobenzene solvate. The porphinato core is in the plane of the paper.

Antimony(V) chloride is also a reactive compound, readily chlorinating and oxidizing a wide variety of compounds. It has a trigonal bipyramidal structure in both the vapour and crystalline forms.[148] Substitution of one of the chlorines by a methoxy group results in an oxygen-bridged dimer (**62**).[156] Two interesting examples of $SbCl_5$ adduct with Lewis bases can be cited. Weber[170] first prepared $SbCl_5\cdot SeOCl_2$ in 1865, but its structure was only solved 100 years later (**63**).[171] Cyclooctasulfur monoxide is an unstable material, but in the orange $SbCl_5$ adduct (**64**), it is stabilized.[172]



28.12.3 Antimony Pseudohalides

The pseudohalides are discussed in the halogen ligand section rather than in the nitrogen ligand section because in the majority of the examples studied the pseudohalide is the minor ligand, *i.e.* one among many—most studied are antimony halide pseudohalides.



Antimony pentachloride reacts with alkali pseudohalides (equation 50). Addition of further KX results in dimer formation, $[SbCl_4X]_2$. The crystal structure of $[SbCl_4N_3]_2$ shows a distorted

(62)

(63)

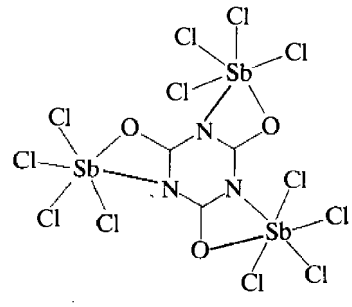
octahedral environment about antimony (**65**).[162]



$$SbCl_5 + KX \longrightarrow K[SbCl_5X] \qquad (50)$$

$$X = CN,\ N_3,\ NCO,\ NCS$$

In the case of $[SbCl_4(NCO)]_2$, however, the material decomposes at 20 °C to a trimer, $[SbCl_4(NCO)]_3$, which is a cyanuric acid derivative (**66**).[163]

(65)

(66)

28.13 BIOLOGICAL ASPECTS OF ANTIMONY

28.13.1 Toxicology

Prudence requires that all antimony compounds should be treated with caution and, until proved otherwise, be considered toxic. While it is true that some studies have shown that, in the short term, antimony oxides may be considered non-hazardous, in the longer term they

have been shown to be carcinogenic in rats. Dusts from the 'natural' antimony oxides are more dangerous than chemically pure Sb_2O_3 because the minerals are often associated with arsenic and lead.

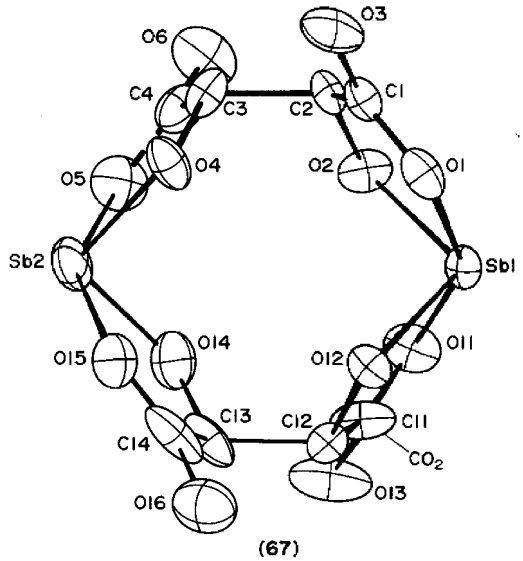
'Antimony spots' are temporary pustular skin eruptions that afflict workers exposed to antimony compounds. Prolonged or acute exposure results in the build up of antimony in the tissues, especially in liver, kidney, adrenals and thyroid. Antimony(III) is considered to be more toxic than antimony(V) because it is relatively slowly excreted. Long term exposures (up to 28 years) have resulted in pneumoconiosis and emphysema, but even after a few months exposure (5–10 mg m^{-3}) to fumes from antimony smelting pathological symptoms were observed, *e.g.* rhinitis, pharyngitis and tracheitis.[174]

Antimony pentachloride, in a case of acute poisoning, caused severe pulmonary oedema in the three victims, two of whom died.[175] Antimony compounds form complexes with thiol groups (see Section 28.11.4), and in enzymes with thiol groups then these processes are blocked.

Evidence is accumulating that antimony is teratogenic and carcinogenic; 30 μl dm^{-3} cause mutations in *Bacillus subtilis*.[176] Antimony has also caused mutations in plants and animals.[177]

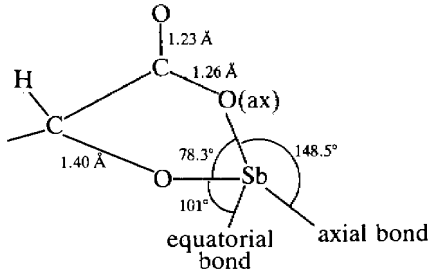
Antimony does not appear to be an essential ultratrace element and does not appear to undergo metabolic reactions analogous to those of arsenic; for example, no biomethylation of antimony has been detected.[178] Antimony trioxide is now suspected to be carcinogenic to humans.

28.13.2 Pharmacology



The hostility of antimony to life has been harnessed by chemical technology in a range of bactericides and fungicides, some of which were mentioned in Section 28.11.4. Since the advent of a rational chemotherapy a rich pharmacology based on antimony has developed. Because of the essential toxicity of antimony, its medical use is of necessity a trade off between the resistance of the patient and the pathogen to antimony poisoning. These drugs are not 'magic bullets'. Nevertheless, the antimony drugs are still the most effective treatment for a number of diseases. The reduction in mortality from 95% to less than 5% in the case of Kala-Azar is due to antimony therapy. Some of the drugs are listed in Table 22.

Table 22 Some Antimony Compounds Used in Medicine



Compound	*Pathogen*	*Human toxicity*	LD_{50} (mg kg^{-1})	*Disease*
Antimony potassium tartrate	*Schistosoma japonicum*	Toxic	48.8 (mouse interperitoneal)	Schistosomiasis (bilharziasis)
Antimony(V) sodium tartrate	*Schistosoma japonicum*	Less toxic than K salt	257 (mouse intravenous)	Schistosomiasis
Sodium antimony(III)bispyrochatecol-3,5-disulfonate)	*Schistosoma haematobium*		80 (rabbit intravenous)	Schistosomiasis
(Stibophen)	*Schistosoma mansoni*		320 (mouse subcutaneous)	Leishmaniasis
Antimony(III) sodium gluconate		Less toxic than tartrates	172 (mouse intravenous)	Schistosomiasis
Sodium antimony(III) dimercaptosuccinate (Stibocaptate)				Schistosomiasis
'Ethylstibamine'[a]				Kala Azar Espudia
Antimony(V) sodium gluconate				Cutaneous leishmaniasis

[a] A mixture of *p*-aminophenylstibonic acid, *p*-acetylaminophenylstibonic acid, antimonic(V) acid and diethylamine.

The structure of crystalline tartar emetic, dipotassium di-μ-(+)-tartrato(4)-bisantimony(III) trihydrate, was first elucidated by X-ray crystallography in China as the (±) salt by H.-C. Mu[179] and further refined by Jacobson and Gress[180] as the (+) isomer by three dimensional X-ray and white radiation neutron diffraction. The structure of $[Sb_2\{(+)\text{-}C_4H_2O_6\}_2]^{2-}$ is shown in (**67**); the coordination about antimony is that of a highly distorted trigonal bipyramid. The axial oxygen atoms are of the carboxylate group and the equatorial is the hydroxyl oxygen (**68**). The bond lengthening between Sb—O(ax) and Sb—O(eq) is on average 0.17 Å. Between the dimers there is a weak Sb—O interaction involving the uncoordinated carboxylate oxygen atom. The dimers are bound loosely to clusters of three water molecules, forming sheets. Potassium ions lie between the sheets holding them in place in the crystal.

(67)

(68)

Finally, an antimony analogue of choline, $HOCH_2CH_2NMe_3^+X^-$, has been synthesized (Scheme 5). The compound acted as a substrate for choline kinase.[181]

$$Me_3Sb + ICH_2CH_2OH \xrightarrow{\text{diglyme}} Me_3SbCH_2CH_2OH^+I^-$$

$$\downarrow \text{ion exchange}$$

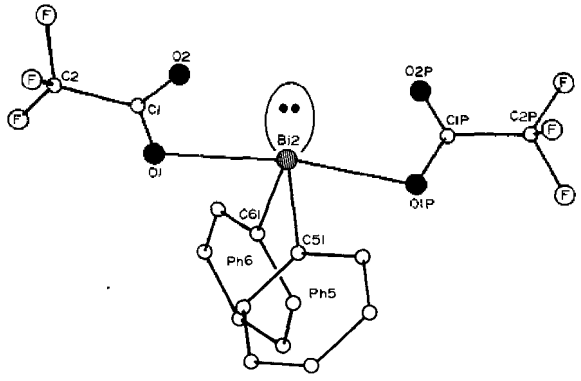
Scheme 5

28.14 BISMUTH

Bismuth was established as an element in 1739 by a Mr Potts. It had been known since the Middle Ages, but had been thought to be a type of lead. It is the heaviest member of Group 5 and has the electronic configuration $[Xe]4f^{14}5d^{10}6s^26p^3$.

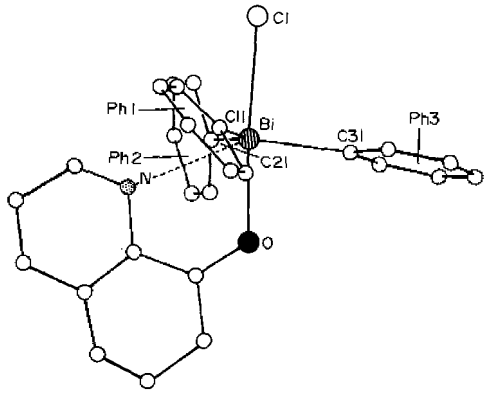
28.15 BISMUTH–GROUP 4 BONDS



28.15.1 Carbon Ligands

Tetraphenylbismuthonium diphenylbis(trifluoroacetato)bismuthate (equation 51)[182] contains a distorted tetrahedral cation and an anion (**69**), the structure of which has been interpreted in terms of a stereochemically active lone pair. This appears to be the only four-coordinate trigonal bipyramidal bismuth structure established to date; in antimony chemistry these types

form polymeric polyanionic structures.



$$Ph_5Bi + PhBi(CF_3CO_2)_2 \xrightarrow{Et_2O} [Ph_4Bi][Ph_2Bi(CF_3CO_2)_2] \quad (51)$$

86%

(69)

X-Ray analysis has shown Ph_3BiCl_2 to have a trigonal bipyramidal structure with axial chlorines.[183] 8-Hydroxyquinoline can displace one chlorine to give $Ph_3Bi(8\text{-HQ})Cl$, which also has a trigonal bipyramidal structure (**70**). The nucleophilic N interaction with bismuth, d(Bi—N) 2.807 Å, causes the twisting of the two nearest phenyl rings.[182]

(70)

28.15.2 Silicon, Germanium and Tin Ligands

28.15.2.1 Silicon ligands

The silicon–bismuth bond has been demonstrated in a number of compounds such as $Bi(SiF_3)_3$, a volatile crystalline compound[184] which decomposes on heating; it is air and moisture sensitive. Germanium–bismuth compounds can be prepared by the use of $Bi(SiEt_3)_3$ (equations 52 and 53).[185]

$$3Et_3SiH + Et_3BI \xrightarrow[15\,h]{165\,^\circ C} (Et_3Si)_3Bi + 3S_2H_6 \quad (52)$$

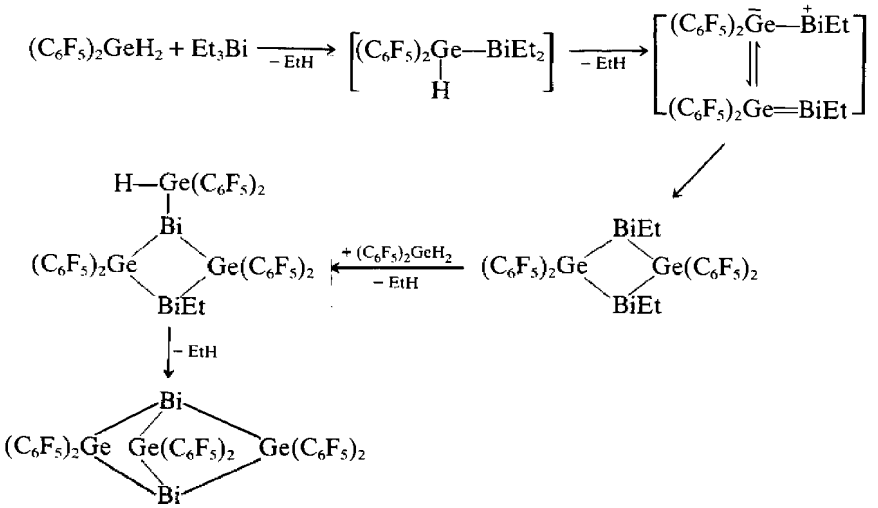
33%

$$(Et_3Si)_3Bi + Et_3GeH \xrightarrow[16\,h]{180\,^\circ C} (Et_3Ge)_3Bi + Et_3SiH \quad (53)$$

73%

The physical properties of some bismuth complexes containing Si, Ge and Sn ligands are listed in Table 23.

Table 23 Some Physical Properties of Si-, Ge- and Sn-containing Bismuthines



Compound	*B.p.* (°C/Torr)	*M.p.*[a] (°C)	*Density* (g cm^{-3})	*Ref.*

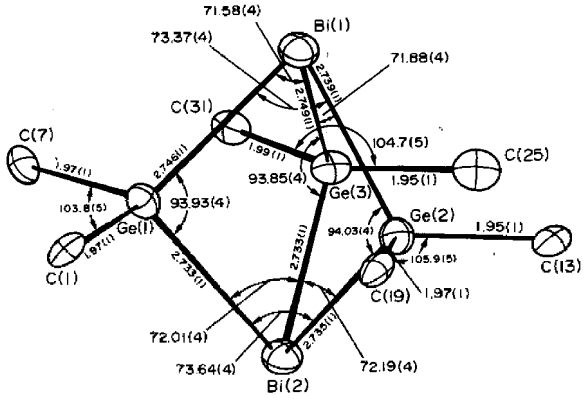
$(Ph_3Sn)_3Bi$		138–142 (d)		190

[a] d = decomposed.

28.15.2.2 Germanium ligands

Germanium–bismuth compounds have been prepared by transmetallation reactions,[185,191] as shown in the previous section (28.15.2.1).

Triethylbismuthine reacts with $(C_6F_5)_3GeH$ to produce[189] mono- and di-substituted germanium compounds, but not the trisubstituted species. If disubstituted germanes are used, an interesting Bi_2Ge_3 ring system is produced (Scheme 6).



Scheme 6

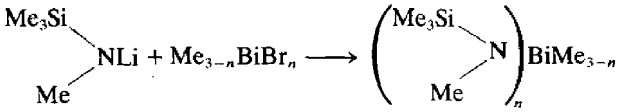
X-Ray analysis has shown the structure of $[(C_6F_5)_2Ge]_3Bi_2$ to be a trigonal bipyramid (**71**) in which Bi has trigonal pyramidal geometry.[192] The average d(Bi–Ge) is 2.739 Å and average angles are Ge—Bi—Ge 72.1° and Bi—Ge—Bi 93.9°.

28.15.2.3 Tin ligands

Tin bismuthines have been prepared in a similar manner to the germanium bismuthines (equation 54).[185,193] The tin bismuthines decompose on heating and are air and moisture sensitive. They have, as yet, found little use.

$$Et_3Bi + Me_3SnH \xrightarrow[5\,h]{100\,^{\circ}C} (Me_3Sn)_3Bi + C_2H_6 \qquad (54)$$

(71)



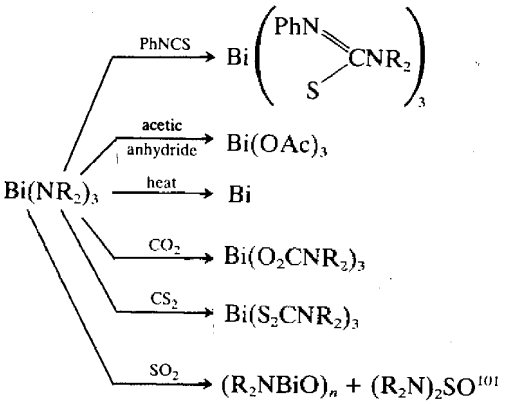
28.16 BISMUTH–GROUP 5 BONDS

28.16.1 Nitrogen Ligands

There are a large number of compounds which contain bismuth–nitrogen bonds, but very few in which such bonding represents the main framework of the bonding. There does exist $BiCl_3$ coordination compounds such as the stable colourless $[BiCl_3(NH_3)_3]$ or the unstable red $[(BiCl_3)_2(NH_3)]$. These compounds are described in more appropriate sections, except where a point about the Bi—N bond is being made.

28.16.1.1 Bismuth(III) compounds

A number of aminobismuthines have been described (Table 24) and are prepared by similar methods to the aminoarsines (equations 55 and 56).[102,194]



$$Me_3Si(Me)NLi + Me_{3-n}BiBr_n \longrightarrow \left(Me_3Si(Me)N\right)_n BiMe_{3-n} \quad (55)$$

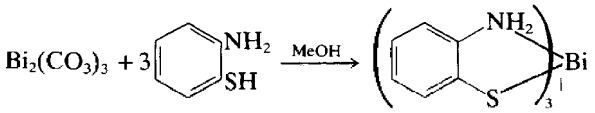
$$BiCl_3 + 3LiNR_2 \xrightarrow{THF} 3LiCl + Bi(NR_2)_3 \quad (56)$$

Table 24 Some Physical Properties of Alkylaminobismuthines

Compound	*B.p.* (°C/Torr)	*M.p.* (°C)	n_{20}^D	*Ref.*
$(Me_2N)_3Bi$	46–49/0.16	40–40.5		194
$(Et_2N)_3Bi$	80–82/0.09		1.5322	194
$(Pr^n_2N)_3Bi$	110–112/0.02		1.4086	194
$\left(Me_3Si(Me)N\right)_3Bi$	90–92/0.1	27–29		102
$\left(Me_3Si(Me)N\right)_2BiMe$	70–71/0.1			102
$Me_3Si(Me)N{-}BiMe_2$	31–32/0.1			102

The bismuth–nitrogen bonds in these compounds are labile and decomposition slowly occurs at room temperature; they may be stored at −78 °C. Some reactions are shown in Scheme 7.

Scheme 7 Some reactions of alkylaminobismuthines



The bismuth–azide bond has received some attention. The synthesis is often surprisingly facile (equation 57).[195] The organobismuthine azides are more unstable, but the azide group displaces an alkyl group from trialkylbismuthine (equation 58).[196]

$$Bi(NO_3)_3(aq) + NaN_3(aq) \longrightarrow BiON_3 \quad (57)$$

$$Me_3Bi + HN_3 \xrightarrow{Et_2O} Me_2BiN_3 + CH_4 \quad (58)$$

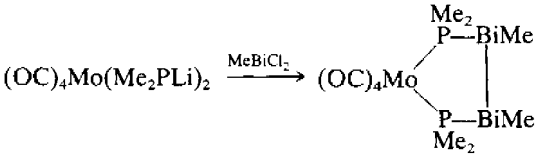
(m.p. 150 °C dec.)

A series of mixed donor ligand complexes involving Bi—N bonds has been developed by Alonzo (equation 59).[197]

(59)

28.16.1.2 Bismuth(V) compounds

The nitrogen–bismuth bond in bismuth(V) compounds is usually found in organobismuth compounds, *e.g.* in the formation of $Ph_3Bi(N_3)_2$, remarkably from aqueous solution, as white crytals, m.p. 95 °C (dec.)[198] (equation 60). The material is metastable at room temperature, slowly decomposing. On heating the diazide decomposes into phenyl azide and the bismuth(III) azide (equation 61). Ph_2BiN_3 is itself unstable with respect to Ph_3Bi and continual heating results in formation of Ph_3Bi.



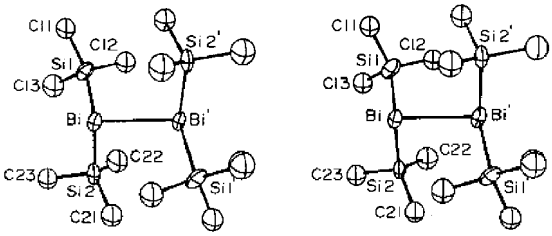
$$Ph_3BiCl_2 + NaN(aq) \longrightarrow Ph_3Bi(N_3)_2 + 2NaCl \quad (60)$$

$$Ph_3Bi(N_3)_2 \longrightarrow Ph_2BiN_3 + PhN_3 \quad (61)$$

28.16.2 Other Group 5 Bonds

Interpnictide bonding is not a well-developed field, with the exception of N—P compounds, although in recent years there have been notable achievements, such as the synthesis of RE=ER compounds. Developments in bismuth–pnictide bonding have not been as successful. However, it may confidently be predicted that analogous compounds will be developed in the near future.

The remarkable five-membered ring (MoP_2Bi_2) was prepared by Stelzer *et al.* (equation 62).[199]



(62)

28.16.2.1 *Bismuth–bismuth bonding*

There are no well-characterized polymeric bismuth catenates, although a black ether-insoluble substance, described as $(PhBi)_x$, results from the reduction of phenylbismuth halides with $LiAlH_4$.[200] A polymeric bismuthine is thought to result from the decomposition of 1,1′-bibismolane.[201] To date, bismuth catenation is limited to Bi_2 in the case of free molecules and to some complex anionic and cationic clusters.

(*i*) *Dibismuthines*

Tetrakis(trimethylsilyl)dibismuthine has a *trans*-staggered conformation, shown to good effect in the stereoview (**72**).[203] The intramolecular d(Bi—Bi) is 3.035 Å and the intramolecular d(Bi···Bi) is 3.804 Å. The Bi—Bi distance averages 2.68 Å. The molecules are linked into chains in the crystal, allowing electronic excitations along the chain, accounting for the green metallic lustrous appearance of these crystals. The compound is red in the liquid state.

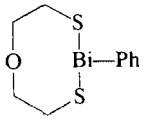
(72)

28.17 BISMUTH–GROUP 6 LIGANDS

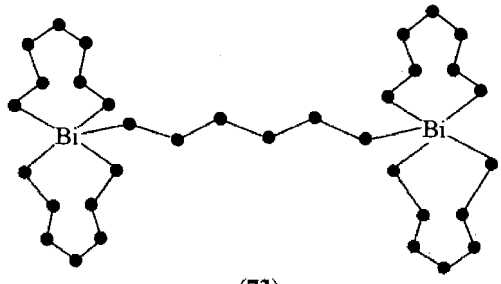
28.17.1 Oxygen Ligands

Bismuth trioxide is a basic oxide and dissolves in mineral acids to give salts such as $Bi_2(SO_4)_3$, $Bi(NO_3)_2{\cdot}5H_2O$ and $BiPO_4$. The hydroxide, $Bi(OH)_3$, may be precipitated by the addition of a base; its composition is variable and compounds such as BiO(OH) have been described, although no structures have been confirmed. Before precipitation takes place complex cations are formed, and at one time it was thought that these were $[Bi_6(OH)_{12}]^{6+}$, but it has subsequently been shown[204] that the most common cation present is $[Bi_6O_4(OH)_4]^{6+}$. An X-ray crystal structure of $Bi_6O_4(OH)_4(NO_3)_6{\cdot}H_2O$ has shown the six Bi atoms to be at the apices of an octahedron at non-bonding separations; the octahedron is face capped by O and OH, forming Bi—O—Bi bridges. A similar structure has been demonstrated for $Bi_6O_4(OH)_4(ClO_4)_6{\cdot}7H_2O$. The lone pairs on the bismuth atoms are directed away from the cage. Each bismuth is bonded to two equatorial oxygen atoms and two axial hydroxide oxygen atoms, resulting in a distorted trigonal bipyramidal structure about bismuth; the bismuth atoms are also weakly bonded to anions in the crystal lattice.

28.17.2 Sulfur Ligands



A truly remarkable bismuth–sulfur compound was recently reported by Muller *et al.* (equation 63).[205] The dark brown compound contains an anion which is essentially two S_7 rings joined by a spiro bismuth atom, and two of these bismuth groups are joined by an S_6 chain (**73**). This bismuth coordination polyhedron is a highly distorted square pyramid, the apex of which is the sulfur of the S_6 chain, d(Bi—S_{apical}) 2.683 Å (av) and d(Bi—S_{eq}) 2.817 Å.



$$Ph_4AsCl + S_8 + BiCl_3 + H_2S \xrightarrow[NH_3]{MeCN} [AsPh_4]_4[Bi_2S_{34}] \quad (63)$$

60%

An eight-membered ring containing bismuth is formed by the condensation of diethoxybismuthines with dithiols (Table 25).[206]

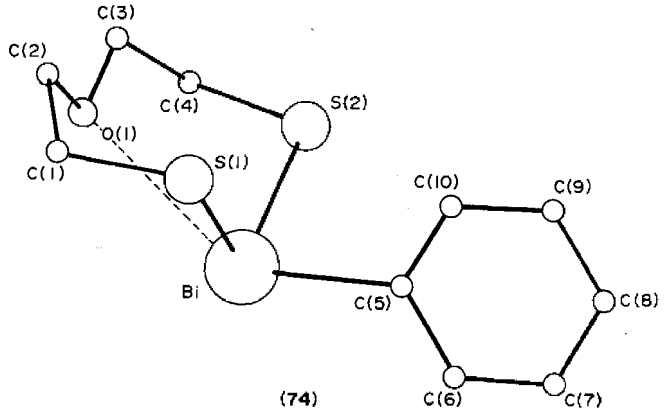


Table 25 Bismuth–Sulfur Bond Lengths and Angles

Compound	*d(Bi—S)* (Å)	*d(Bi—E)* (Å)	*Bond angles* (°)		*Ref.*
	2.581 (av)	2.25 (C) 2.97 (O)	S—Bi—S C—Bi—S	104.2 88.75 (av)	206

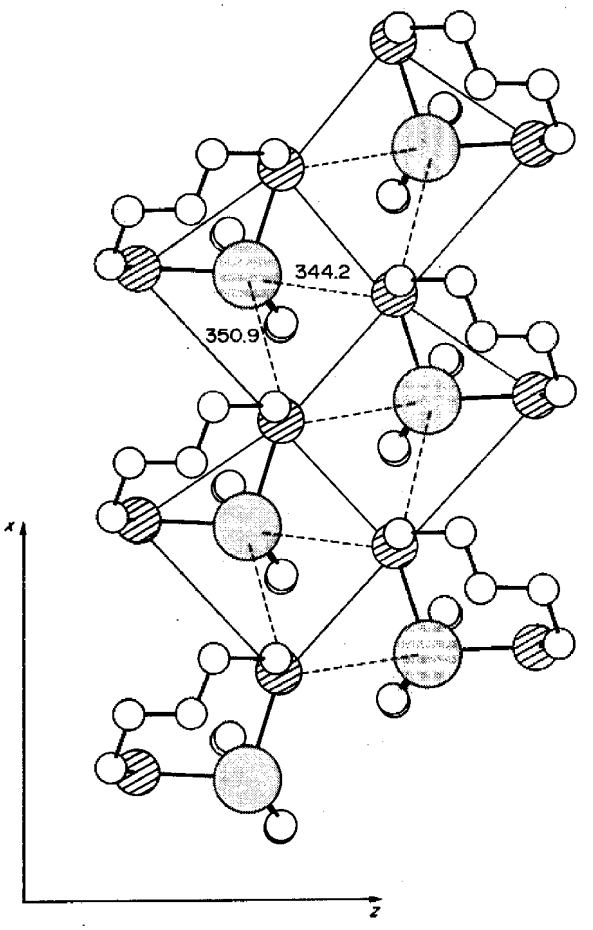
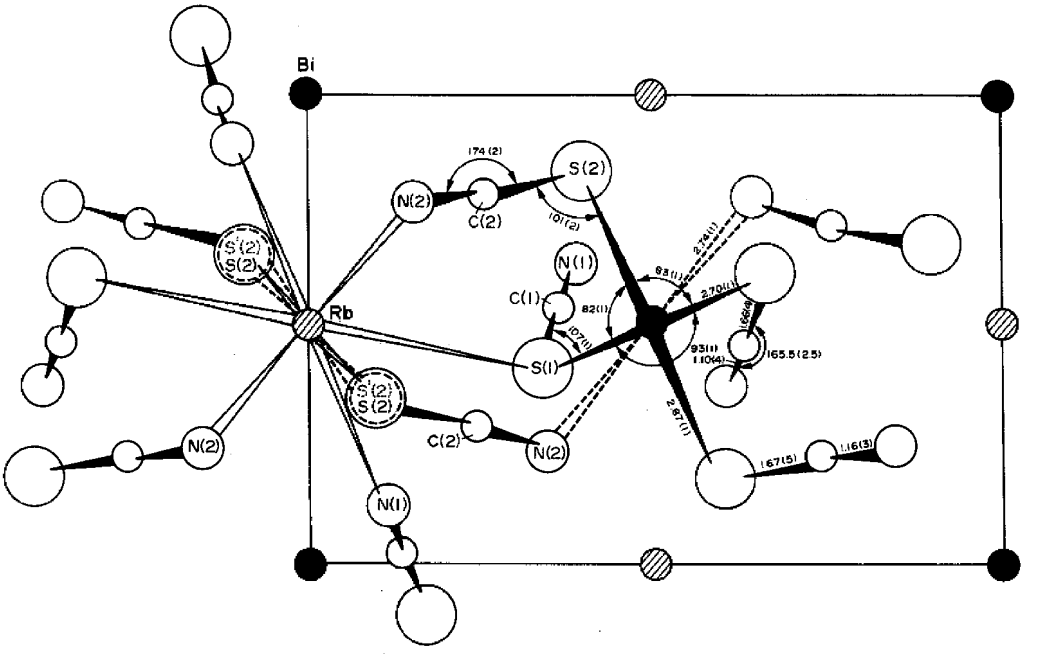
(73)

An X-ray study of 5-phenyl-1-oxa-4,6-dithia-5-bismocane revealed structure (**74**). The Bi—O interaction ensures the conformation shown, in the crystal at any rate. The bismuth coordination sphere is completed by intermolecular sulfur ligands (**75**) and the intermolecular stacking is shown in (**76**).

(74)



(75)

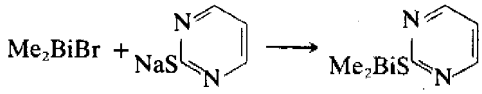


In the case of ambidentate ligands such as thiocyanate, bismuth has a preference for the 'softer' sulfur ligand. This is demonstrated in the X-ray study of $Rb[Bi(NCS)_4]$.[207] Four SCN^- groups coordinate *via* sulfur, *d*(Bi—S) 2.785 Å (av), in a trigonal bipyramidal arrangement, the lone pair occupying an equatorial site. The distortion is shown in the S(ax)—Bu—S(ax) angle of 158.2° (**77**). A weak interaction is suggested by the *d*(Bi· · ·N) of 2.74 Å.

28.17.2.1 Organosulfur ligands

The preference of bismuth for sulfur donor atoms is demonstrated by their method of synthesis. A frequent method used is to displace alkoxide groups by thio-alkyls or -aryls (equation 64). However, one of the problems in syntheses of thiobismuthines is a tendency in some cases to disproportionate, for example the reaction (65) does not occur; instead, the dithiobismuthine is obtained (equation 66).[210] However, in the case of R groups with

(76)



(77) The structure of $Rb[Bi(SCN)_4]_2$ projection along the (001) axis

a 1,3-diaza-2-yl heterocyclic structure, *e.g.* pyrimidin-2-yl, the monosulfide is obtained (equation 67).

$$MeBi(OEt)_2 + 2HSR \longrightarrow MeBi(SR)_2 + 2HOEt \quad (64)$$

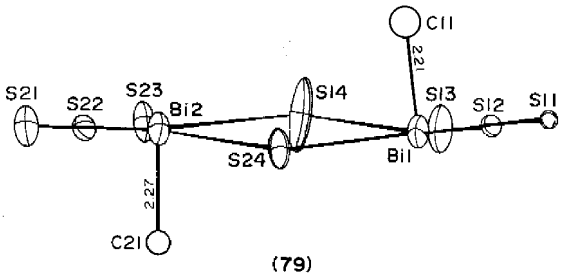
[a] d = decomposed.



Bidentate organosulfur ligands have been synthesized in a similar manner to the simple organosulfur compounds, *e.g.* equation (68).

$$Ph_2BiBr + NaSCOR \longrightarrow Ph_2BiSCOR \quad (68)$$

Some examples of alkylxanthogenato and organodithiocarbamatobismuthines are given in Tables 28 and 29. The crystal structure of isopropylxanthogenatodiphenylbismuth has been solved (**78**).[208] The intermolecular sulfur ligand makes the bismuth coordination polyhedron a trigonal bipyramid (Table 25). In the case of one organo group on bismuth and two bidentate sulfur ligands, *e.g.* bis(diethylthiocarbamato)methylbismuthine,[209] a pentagonal pyramidal structure is adopted in the crystalline state. The compound is monomeric in benzene solution, but crystallizes as a dimer (**79**). The four basal sulfur ligands and the bismuth atom are approximately coplanar, with an apical methyl group (Table 25). It is assumed that the bismuth lone pair is *trans* to the methyl group.

(78)

(79)

In the case of three bidentate sulfur ligands, *e.g.* $[Bi(pedt)_3]_2 \cdot EtOH$ (pedt = 1-pyrrolidinecarbondithioate), more complex structures are formed. The dimer contains two differently coordinated bismuth atoms: one is trigonal prismatic with an extra position on a rectangular face and the other bismuth atom is pentagonal pyramidal. The overall molecular structure is (**80**).[270]

28.17.3 Selenium and Tellurium Ligands

28.17.3.1 Organobismuth–selenium and –tellurium bonds

Selenium–bismuth bonds are formed in the mutual cleavages of dibismuthines and diselenides (equation 69).[218] This particular compound is stable at −30 °C, unlike the tellurium analogue. At room temperature the compound disproportionates to give the diseleno derivative (equation 70). Similar behaviour was noted in the analogous sulfur compounds (Section 28.17.2.1).

$$Me_2BiBiMe_2 + Ph_2Se_2 \longrightarrow Me_2BiSePh \quad (69)$$

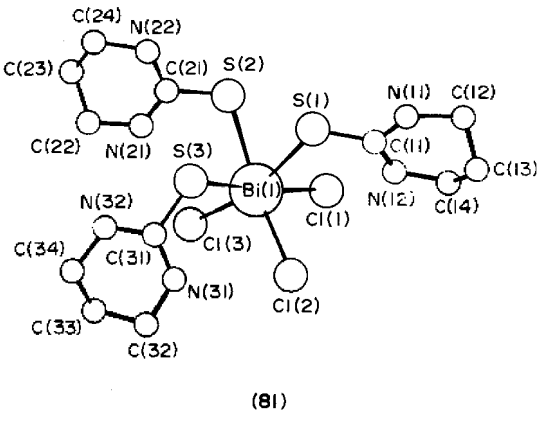
$$Me_2BiSePh \xrightarrow{r.t.} Me_3Bi + MeBi(SePh)_2 \quad (70)$$

28.18 BISMUTH–HALOGEN COMPOUNDS

28.18.1 Bismuth(III) Halides

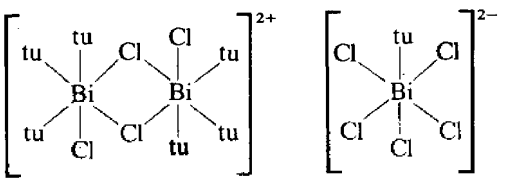
28.18.1.1 Bismuth trifluoride

Reference has been made to the similarity of Bi^{3+} to Y^{3+} and rare earth M^{3+} in properties and structures of their compounds. In this respect BiF_3 is a good example, since its structure is similar to that of YF_3, being a nine-coordinate distorted tricapped trigonal prism with essentially ionic bonding.[219] But, the eight near neighbours are at 2.217–2.502 Å, and the ninth fluorine 'ligand' is at 3.100 Å, as determined by neutron diffraction;[219] BiF_3 is thus best described as eight-coordinate. There are indications, *e.g.* an anomalously large unit cell, that the lone pair is structurally active in BiF_3.



28.18.1.2 Bismuth trichloride

In the gas phase $BiCl_3$ is a pyramidal molecule with d(Bi—Cl) 2.48 Å and Cl—Bi—Cl 100°.[220] In the crystalline state there are five additional near neighbours giving a bicapped trigonal prism for the bismuth atom (Table 30).



Bismuth trichloride readily forms addition compounds, *e.g.* $BiCl_3(NH_3)_3$, $BiCl_3(NO)$, $BiCl_3(NO_2)_2$, $BiCl_2(NOCl)$. These complexes are stable in dry air, but the ligands are displaced by water. It dissolves in organic solvents such as ether, probably forming etherates, $BiCl_3(Et_2O)_n$. Complex halides such as $Cs_2Na(BiCl_6)$ and $(Et_2NH_2)(BiCl_4)$ are known (Table 30).

The ligand 3,4,5,6-tetrahydropyrimidine-2(1*H*)-thione (THPT) forms an S-bonded complex, $BiCl_3(THPT)_3$.[225] The crystal structure (**81**) shows a *fac* octahedron. Interestingly, with bismuth perchlorate $Bi(ClO_4)_3(THPT)_5$ is formed.

As is well known, simple stoichiometry of a compound is not a good guide to the coordination number of the central atom. This is well shown in $(BiCl_3)_3 \cdot 7tu$ (tu = thiourea), where bismuth is octahedrally coordinated to thiourea *via* the sulfur atom.[240] The structure was found to consist of bismuth cations and anions, $[Bi_2Cl_4tu_6]^{2+}[BiCl_5tu]^{2-}$ (**82**).

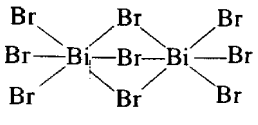
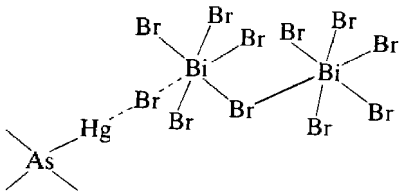
28.18.1.3 Bismuth tribromide



Bismuth tribromide is a pyramidal molecule with *d*(Bi—Br) 2.66 Å. The golden-yellow crystalline $BiBr_3$ occurs in two structural modifications (equation 71). Both modifications are monoclinic. The α-$BiBr_3$ is trigonal pyramidal with three near neighbours, 3 × 2.66 Å, and three more distant bromine ligands, 3 × 3.32 Å. Above 158 °C the structure is an $AlCl_3$ type, *i.e.* polymeric with six bromine near neighbours, 6 × 2.82 Å. Thus, $BiBr_3$ is the only Group 5 trihalide which can assume both a molecular (α-$BiBr_3$) and a polymeric (β-$BiBr_3$) structure.

$$\alpha\text{-}BiBr_3 \overset{158\,^\circ C}{\rightleftharpoons} \beta\text{-}BiBr_3 \qquad (71)$$



The tribromide is prepared in a similar fashion to the chloride (Section 28.18.1.2), and it readily forms complexes. These may be simple octahedra $BiBr_6$, *e.g.* in the case of [2-picH][$BiBr_6$], doubly bridged dimers as in the case of $K_4[Bi_2Br_{10}]$·nH_2O (**83**) and triply bridged dimers as in the case of $[Ph_4P][Bi_2Br_9]$ (**84**).

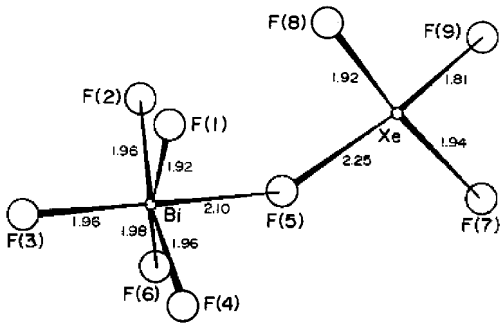
(83)

(84)

(85)

In the case of the singly bridged dimer anion $[Bi_2Br_{11}]^{5-}$, a bromine ligand is 'lost' to the polymeric cation, forming $[Hg_7(HgBr)_2As_4]^{4+}[Bi_2Br_{10}]^{4-}$ (**85**).[236] The anion thus contains bismuth in octahedral and tetragonal pyramidal coordination, and is quite distinct from the $[Bi_2Br_{10}]^{4-}$ anion in $K_4[Bi_2Br_{10}]\cdot 4H_2O$.

28.18.1.4 Bismuth triiodide



The greenish-black crystals of BiI_3 are composed of a hexagonal close packed array of iodine atoms with bismuth atoms in the interstitial spaces, with six nearest neighbours at 3.07 Å. It is prepared by heating the elements in stoichiometric quantities, and purified by subliming under reduced pressure.

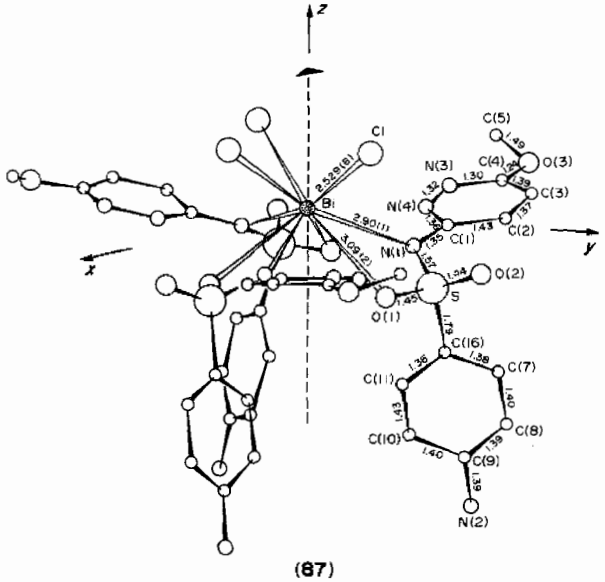
Bismuth triiodide forms similar complexes to its lighter congeners, *e.g.* $KBiI_4$ and K_3BiI_6. The interesting compound $Rb_5I(I_3)(BiI_6)(H_2O)_2$ was formed adventitiously when preparing Rb_3BiI_6 (Table 30).[239]

28.18.2 Bismuth Pentafluoride

The only stable bismuth(V) halide is BiF_5, a white crystalline material, the structure[241] of which consists of BiF_6 octahedra in infinite *trans* chains in the manner of α-UF_5. It reacts explosively with water to form OF_2, O_3 and a brown solid (Bi^V oxyfluoride?) and it is a powerful fluorinating agent.

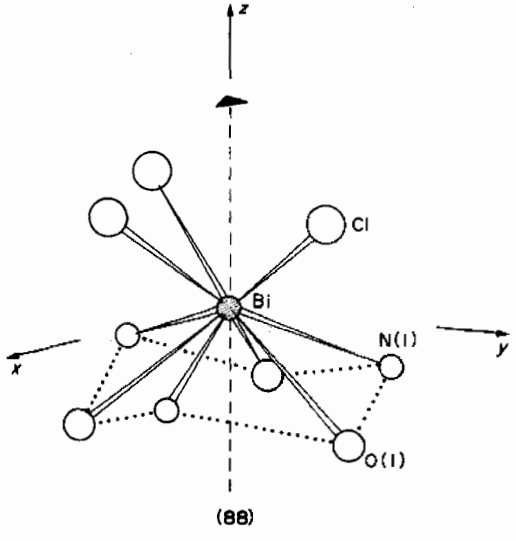
Bismuth pentafluoride is a considerably weaker Lewis acid than is SbF_5, as is seen in the structure of the adduct formed with XeF_4 (**86**).[242] The antimony analogue is described as ionic, $[XeF_3]^+[SbF_6]^-$, on the basis of the 'bridging' fluorine ligand at d(Bi—F) 2.49 Å.[243] In $[XeF_3][BiF_6]$ the μ-F distance, d(Bi—F) 2.25 Å, is shorter and clearly has much greater covalent character than that of the antimony analogue.

(86) The $[XeF_3][BiF_6]$ structural unit



28.19 BIOLOGICAL ASPECTS OF BISMUTH

28.19.1 Pharmacology



Bismuth and its compounds have traditionally been widely used in medicine and veterinary practice. Finely divided bismuth was injected intramuscularly as an aqueous suspension in the

treatment of syphilis and yaws. Its advantage was the slow absorption, possibly as a protein bound complex, giving continuous therapeutic action. The 1982 edition of 'Martindale' lists 18 bismuth compounds used in medical practice,[244] although most of these are not 'drugs of choice', and are mainly used out of traditional sentiment. This tradition has been summarized by Jaenicke.[245]

Trichlorotris(3-sulfanilamido-6-methoxypyridazine)bismuth(III) is a pharmaceutical which contains three nitrogen–bismuth bonds and three weak oxygen–bismuth links (**87**): d(Bi—Cl), 2.529 Å, is similar to that in other coordination compounds; d(Bi—N), 2.90 Å, is longer than the sum of the covalent or ionic radii; d(Bi—O) is long at 3.09 Å. The polyhedron has been described as a distorted octahedron (three chlorine, three nitrogen donors) with three extra positions occupied by the oxygen atoms. The oxygen and nitrogen atoms form a hexagon in a chair configuration (**88**).[272]

(87)

(88)

28.19.2 Toxicology

Bismuth is the least toxic of the As, Sb, Bi triad, which is unusual, since toxicity normally increases down a group, as shown by elements to the left of bismuth, *i.e.* Pb, Tl, Hg. However, it must be emphasized that this is not to say that bismuth is not toxic and experimentalists should avoid contact and ingestion of its compounds.

Table 31 Toxicity of Bismuth Compounds

Compound	*Mammal*	LD_{50}(mg kg^{-1})	LDL_0(mg kg^{-1})	*Method of administration*
Bi metal	Man		221	Not stated
BiOCl	Rat	22		Not stated
$Bi(NO_3)_3$	Mouse		21	Intravenous
$Bi(NO_3)_3$	Mouse		2500	Intraperitoneal
Bi trisodiumthioglycollate	Rabbit	21		Intravenous
Bi potassium sodium tartrate	Rabbit	55		Intravenous
Bi tin oxide	Mouse	178		Intravenous
$BiMe_3$	Dog		233	Oral
	Dog	12		Intravenous
$BiPh_3$	Dog	180		Intravenous

The effects of acute bismuth intoxication include gastrointestinal disturbance, anorexia, headache, malaise, skin reactions, discolouration of the mucous membranes and mild jaundice.[244]

There have been no fatalities in industry attributed to bismuth and it is regarded as relatively non-toxic for a heavy metal.[246] The toxic problems which have been recorded have in the main been iatrogenic illnesses. A characteristic blue-black line on the gums, the 'bismuth line', which may persist for years, is a feature of bismuth overdosage. Soluble salts are excreted *via* urine and may cause mild kidney damage. Less soluble salts may be excreted in the faeces, which may be black in colour due to the presence of bismuth sulfide. Table 31 contains some toxicity data.

29.1 INTRODUCTION

Sulfur, selenium, tellurium and polonium constitute the heavier elements of group VIB of the periodic table and are sometimes referred to as the chalcogens, chalcogenins, chalcogenides or chalconides. Developments in the understanding and interest in the chemistry of these elements have been reviewed at appropriate intervals during the past 20 years.[1–8]

29.1.1 Bonding, Valence and Geometry

The elements have six electrons in their valence shells and show essentially non-metallic covalent character except for polonium and, to a lesser extent, tellurium. Although they may complete the noble gas configuration by forming the chalcogenide ions S^{2-}, Se^{2-} and Te^{2-} it is pertinent to note that these species only exist in the salts of the most electropositive elements. Indeed this divalent state involving two covalent bonds and two lone pairs of electrons is unstable for selenium and tellurium, especially the dihalides, and these species tend to disproportionate to quadrivalent compounds and the elemental state. The elements may also achieve the noble gas configuration by forming two electron pair bonds, *e.g.* hydrogen sulfide, sulfur dichloride and dimethyl sulfide, with the hydrides H_2X decreasing in stability as the group VI element series is descended. The noble gas configuration may also be attained by the formation of ionic species with one bond and one negative charge, *e.g.* RS^-, or three bonds and one positive charge, *e.g.* R_3S^+.

In addition to the divalent species, the elements also form compounds in the formal oxidation state of IV involving two, three, four, five or six bonds. Although the quadrivalent polonium halides are thermally unstable and give the divalent compounds at relatively low temperatures, the quadrivalent state is generally stable for the heavier elements of group VIB particularly in the oxides, oxo acids and halides where, for example, the formation of the hexacoordinated anionic complexes of the type $XHal_6^{2-}$ is increasingly favoured as group VIB is descended. Indeed, six is the characteristic coordination number for tellurium.

The formation of compounds in the formal oxidation state of VI is well established for all four elements, for example, the sexivalent fluorides and the TeF_8^{2-} ion. However, oxidation to this highest valency state becomes progressively more difficult as group VIB is descended since the inert pair effect causes the elements to behave as though two of their valence electrons are absent. Some examples of the compounds formed by the group VIB elements and their stereochemistries are described in Table 1.

Table 1 Compounds of Group VI Elements and their Stereochemistries

Valence	*Number of bonds*	*Geometry*	*Examples*
II	2	Angular	Me_2S, H_2Te, S_n
	3	Pyramidal	Me_3S^+
	4	Square	$Te[SC(NH_2)_2]_2Cl_2$
IV	2	Angular	SO_2
	3	Pyramidal	SF_3^+, OSF_2, SO_3^{2-}, Me_3TeBPh_4
		Trigonal planar	$(SeO_2)_n$
	4	ψ-Trigonal bipyramidal	SF_4, RSF_3, Me_2TeCl_2
		Tetrahedral	Me_3SO^+
	5	ψ-Octahedral (square pyramidal)	$SeOCl_2py_2$, SF_5^-, TeF_5^-
	6	Octahedral	$SeBr_6^{2-}$, PoI_6^{2-}, $TeBr_6^{2-}$
	7	Distorted pentagonal bipyramidal	$TePh(S_2CNEt_2)_3$
	8	Distorted octahedral	$Te(S_2CNEt_2)_4$
VI	3	Trigonal planar	$SO_3(g)$, S(NCR)
	4	Tetrahedral	SeO_4^{2-}, SO_3 (s), SeO_2Cl_2
	5	Trigonal bipyramidal	SOF_4
	6	Octahedral	RSF_5, SeF_6, $Te(OH)_6$
	8 (?)	?	TeF_8^{2-} (?)

The accessibility of the elements from sulfur to polonium to higher oxidation states and coordination numbers, as compared with the four coordination and divalency of oxygen, is a reflection of the availability of *d* orbitals for the formation of σ bonds. It is also notable that sulfur and selenium appear to use $d\pi$ orbitals in the formation of multiple bonds. The strong tendency of sulfur to catenation, which gives rise to compounds with no oxygen, selenium, tellurium or polonium analogues must also be noted, although selenium rings and unbranched elemental chains of selenium and tellurium are an important feature of the chemistry of these elements, as is their tendency to form secondary bonds in crystalline solid compounds.

29.1.2 Group Trends

The greater differences between the chemistry of oxygen and sulfur, as compared with differences between the other group VIB elements, may be associated with a number of features including the lower electronegativities of the elements sulfur to polonium. This tends to lessen the ionic character of compounds which are analogous to those of oxygen, as well as alter the relative stabilities of some bonds and reduce the importance of hydrogen bonding.

Although there are similarities between the chemistry of the chalcogenide elements, the properties of selenium and tellurium clearly lie between those of non-metallic sulfur and metallic polonium. The enhancement in metallic character as the group is descended is illustrated in the emergence of cationic properties by polonium, and marginally by tellurium, which are reflected in the ionic lattices of polonium(IV) oxide and tellurium(IV) oxide and the formation of salts with strong acids.

Finally it is worth noting that, unlike sulfur, selenium and tellurium, neither stable nor long-lived isotopes of polonium are known in nature. The only readily accessible isotope of polonium is polonium-210 which is the penultimate member of the radium decay series and which decays by α-emission with a half-life of 138.4 days.

29.2 COORDINATION COMPOUNDS OF THE GROUP VIB ELEMENTS

A review of the complexes of sulfur and tellurium[9] in 1964 was followed[1] by an extensive survey of the heavy chalcogen complexes in a comprehensive text on the chemistry of selenium, tellurium and polonium in 1966. The subject of coordination in organoselenium and organotellurium chemistry,[10] together with the structural chemistry of complexes of selenium and tellurium with sulfur- and selenium-containing ligands,[11] has received recent attention in

conference proceedings. The group VIB complexes may be conveniently considered within five categories:[4] the anionic halo complexes, the anionic complexes formed by oxo acids, and finally the oxygen, nitrogen and sulfur donor complexes.

29.2.1 Halo Complexes

The complexes of sulfur tetrafluoride with several inorganic fluorides were initially considered[12] in terms of SF_4 acting as a Lewis base giving addition compounds formulated as donor–acceptor complexes of the type $F_4S{\cdot}BF_3$. The stability of these types of compounds was found to decrease in the sequence $SbF_5 > AsF_5 > IrF_5 > BF_3 > PF_5 > AsF_3$. Later investigations of these materials by IR spectroscopy[13] resulted in them being formulated as $SF_3^+BF_4^-$, suggesting that SF_4 acts as a fluoride ion lone-pair donor as opposed to a sulfur lone-pair donor.

The electron acceptor properties of sulfur tetrafluoride are well illustrated by the formation of the stable 1:1 complex with pyridine, $C_5H_5NSF_4$, which is thought to adopt pseudooctahedral or square pyramidal geometry, and the reaction of SF_4 with CsF at 125 °C and Me_4NF at −20 °C to give[14] $CsSF_5$ and $[NMe_4]^+[SF_5]^-$. The square pyramidal structure of the SF_5^- ion in $CsSF_5$ (Figure 1) was deduced from vibrational spectra.[15]

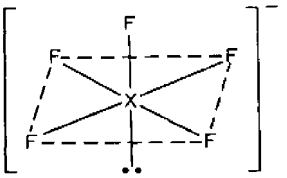

Figure 1 The structure of the SF_5^- ion in $CsSF_5$ (reproduced by permission from *Inorg. Chem.*, 1972, **11**, 1679)

The fluorides of the heavier group VIB elements also form a significant grouping within the halo complexes category, for example the quadripositive elements form complexes of the type MXF_5. For selenium the alkali metal and thallous pentafluoroselenates(IV) are formed as white solids from the dissolution of the metal fluorides in selenium tetrafluoride, but dissociate quite readily at room temperature to the component fluorides.[16] The corresponding pentafluorotellurates(IV) were initially prepared[17] by the addition of cesium fluoride to a solution of tellurium tetrafluoride in hydrogen fluoride and were isolated as colourless crystals which were formulated as $CsTeF_5$. Other pentafluorotellurates(IV), described as $NH_4TeF_5{\cdot}H_2O$, $KTeF_5$ and $Ba(TeF_5)_2{\cdot}2H_2O$, have been isolated from reactions of alkali metal fluoride and tellurium dioxide in hydrofluoric acid[18] or selenium tetrafluoride.[19] The square pyramidal geometry of the pentafluorotellurate(IV) anion has been identified from IR and Raman spectroscopy,[18] and by an X-ray structural determination of the potassium salt.[20]. It is pertinent to note that although the solubility of polonium(IV) hydroxide increases with the concentration of solvent hydrofluoric acid, as might be expected if complex formation were occurring, no complexes have yet been isolated.[21]

The fluoro complex of tellurium with pyridine, $[C_5H_5NH]TeF_5$, has been obtained[22] as a pale green solid by treatment of the pyridine complex $TeF_4{\cdot}py$ with aqueous hydrofluoric acid, whilst a white modification has been reported[18] to be isolated from a mixture of tellurium dioxide and pyridine in hydrofluoric acid.

The nitronium salts of pentafluoroselenate(IV) and pentafluorotellurate(IV) of composition NO_2XF_5 have been prepared[23] from the reaction of selenium or tellurium dioxide with nitryl fluoride.

Other pentahalo anions of group VIB elements have also been identified. For example, studies of solutions of selenium(IV) oxide and tellurium(IV) oxide in hydrobromic acid by Raman spectroscopy[24] have indicated the likely presence of the pentabromo anions, and in non-aqueous solutions there is some evidence that $TeCl_5^-$ and $TeBr_5^-$ might be formed.[25] Although a chloride of this type has been reported[26] a more complex chloro compound $(C_2H_5)_4NTeCl_{13}$, which was obtained from non-aqueous solution and examined by IR and Raman spectroscopy, has been described as $[(C_2H_5)_4N^+(TeCl_3^+)_3]^{4+}Cl_4$. A series of halogeno complexes with urea of the type $[CON_2H_5]TeX_5$, where X = Cl, Br, I, have been prepared[27] and the stability of the $[TeX_5]^-$ anion reported to increase from the chloro to the iodo

complex. Indeed, the chloro complexes were readily converted into the bromo and iodo complexes when treated with the appropriate acid. It is also pertinent to note that the vibrational spectra of the adduct $TeCl_4 \cdot PCl_5$ are consistent[28] with the formulation $PCl_4^+TeCl_5^-$, whereas those of $TeCl_4 \cdot AlCl_3$ are indicative of the formulation $TeCl_3^+AlCl_4^-$.

It is interesting to note the compound $HTeI_5 \cdot 2oxin \cdot 10H_2O$, which has been reported[29] to be isolated from a solution of oxine in hydroiodic acid containing tellurium. The instability constants for some tellurium halo complexes[30,31] and the polonium iodo complexes,[32] including the POI_5^- species, have been reported.

It is also interesting to note the reported[33,34] formation of hydrogen halogeno acids of composition $TeCl_4 \cdot HCl \cdot 5H_2O$, $TeBr_4 \cdot HBr \cdot 5H_2O$, and $TeI_4 \cdot HI \cdot 8H_2O$. The hygroscopic needle-shaped prismatic yellow chloride, red bromide and black iodide were found to lose the hydrogen halide when heated. It is also pertinent to note the identification of the oxide fluorides $TeF_4 \cdot 3TeO_2 \cdot 6H_2O$, $TeF_4 \cdot TeO_2 \cdot 2H_2O$ and $TeF_4 \cdot TeO_2 \cdot H_2O$ and the proposed[33,35] existence of the complex anion $[TeO_2F_2]^{2-}$. In these respects it is also relevant to record that selenium tetrachloride and tellurium tetrachloride both form addition compounds with ammonia and several metal and non metal chlorides,[1] whilst polonium tetrachloride is known[1] to form complexes with nitrosyl chloride, tributyl phosphate and edta.

Selenium oxychloride, $SeOCl_2$, disssolves many metal chlorides, and a number of solvates, for example $FeCl_3 \cdot 2SeOCl_2$, have been reported.[1] An addition compound of $SeOCl_2$ with pyridine, $SeOCl_2 \cdot 2py$, is also known[36] in which the coordination polyhedron around the central selenium atom is a tetragonal pyramid (Figure 2). In this structure two chlorine and two nitrogen atoms (from the pyridine) are bonded in the basal plane with atoms of the same kind in *trans* positions and oxygen atoms at the apex. A tendency to dimerization involving chlorine atoms to give a distorted octahedron around the selenium atoms is observed. It is also relevant to note that selenium dioxide forms addition compounds with hydrogen chloride and hydrogen bromide.[37]

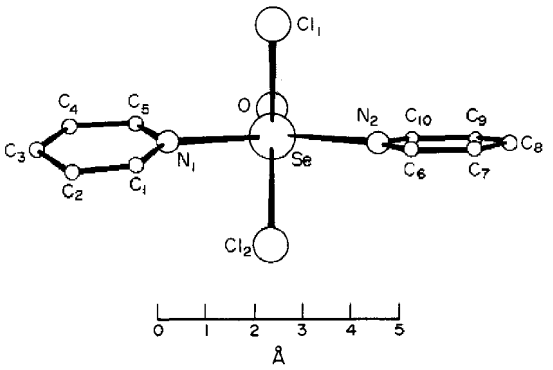

Figure 2 The structure of the addition compound $SeOCl_2 \cdot 2C_5H_5N$ (reproduced by permission from *Acta Crystallogr.*, 1959, **12**, 638)

Tellurium tetrabromide is amphoteric in fused arsenic tribromide, from which complex bromides such as $[(Et)_4N]_2TeBr_6$ and ammine adducts such as $TeBr_4 \cdot 2PhNMe_2$ have been obtained. Addition compounds with pyridine, tetramethylthiourea and piperazine have also been reported.[38,39] Alkali metal salts such as $TeBr_4 \cdot 2CsCl$ and the full brominated complexes of the type M_2TeBr_6 and M_2PoBr_6 are also known.

The tellurium dichlorobromide, $TeCl_2Br_2$, formed by reaction of bromine with tellurium dichloride gives a cream coloured addition compound, $TeCl_2Br_2 \cdot 2py$, with pyridine in ether.[1] The complex dissolves in hot concentrated hydrochloric acid, from which pale orange needles of $(pyH)_2TeCl_4Br_2$ separate on cooling. This compound, as well as the original pyridine complex, dissolves in hot concentrated hydrobromic acid and red needles of the hexabromotellurate(IV), $(pyH)_2TeBr_6$, crystallize on cooling. This is an example of the stability of the hexahalogen complexes (*vide infra*).

A number of hexahalogenotellurates(IV) have been investigated. A few rather unstable hexafluoro complexes are known, for example the nitrosonium compounds of composition $(NO)_2XF_6$ have been obtained[40] from the reaction of nitrosulfuryl fluoride, $NOSO_2F$, with selenium or tellurium tetrachloride. The selenium compound loses nitrosyl fluoride at room temperature to leave the pentafluoroselenate(IV), whereas the tellurium analogue remains

stable to 100 °C. Although the pyridinium hexafluoro complex has been reported[22] to result from the treatment of tellurium dioxide with pyridine in concentrated hydrofluoric acid it must be recalled that (*vide supra*) the pentafluoro complex has been made[18] from the same reaction mixture and that the existence of the hexafluoro complex is therefore a matter of some uncertainty. It is pertinent to note that the fluoro complexes are the least stable of the tellurium(IV) halide complexes.[22]

Tellurium hexafluoride itself has been found to form complexes with potassium, rubidium and cesium fluorides. The cesium compound has a stochiometry approaching Cs_2TeF_8 and, in these types of complexes, the stability of the lattice appears to be inversely related to the polarizing power of the cation and the compounds are only stable in the solid state.[41] Several heptafluorotellurates(VI) have been prepared from the reaction of tellurium with chlorine trifluoride in anhydrous hydrofluoric acid followed by addition of the metal fluoride.[42]

Several hexachloro, hexabromo and hexaiodo complexes of the group VIB elements have been reported.[1] For example, solutions of selenium tetrachloride in concentrated hydrochloric acid contain the hexachloro anion $SeCl_6^{2-}$ from which the ammonium and alkai metal salts can be readily obtained with the cesium salts being the least soluble. The hexahalogenotellurates(IV), such as the chlorides, bromides and iodides of potassium, rubidium and cesium and the chlorides and bromides of ammonium and thallium, have received significant attention.[1] These complexes are generally prepared by precipitation of the complex salt from a solution of the chalcogen dioxide in the concentrated halogen acid. This reaction has also been found[43] to be very effective for the preparation of hexaiodoselenates(IV). Complexes of this type are generally of the form A_2XY_6 in which the anions are octahedrally coordinated. The IR spectra of the selenium and tellurium hexahalogeno anions have been reported.[43] The tellurium-125 Mössbauer chemical isomer shifts, recorded[44] from the hexahalogenotellurates(IV), have been found to be characteristic of the anion and independent of the cation. The data have been associated with the stereochemically inactive lone pair of non-bonding electrons which may be presumed to have considerable *s* electron character and to be highly contracted towards the tellurium nucleus.

The stability of compounds containing $[TeX_6]^{2-}$ ions apparently depends to a considerable extent on the degree of polarization caused by the cation. Hence strongly polarizing hydrogen, lithium and sodium ions may be envisaged as making the $[TeX_6]^{2-}$ anion unstable and thereby mitigate against the isolation of either the free hexahalogeno acids or the lithium and sodium derivatives.

It is pertinent to record that the differences in the properties of compounds of selenium and tellurium in hydrochloric acid solution and the formation of several types of complex ion by these elements are the basis of extraction and ion-exchange methods of separating selenium and tellurium.[1]

29.2.2 Pseudohalide Complexes

The group VIB cyanides, thiocyanates and selenocyanates and their complexes with species such as thiourea have been described.[1,45] For example, the tellurium dithiocyanate complex has been prepared[45] by treatment of tellurium dichloride or tellurium dibromide with ammonium thiocyanate. It seems that little information exists on the preparation of tellurocyanates and there is a sparsity of data on polonium derivatives. Indeed, the only known cyanide of polonium is probably a salt of the quadrivalent element.[1]

29.2.3 Oxo Acid Complexes

The oxo acid complexes of the group VIB elements are largely restricted to those of tellurium and polonium and the information on these types of materials has not changed significantly in recent years.[4]

Tellurium(IV) sulfato complexes of composition $2(2TeO_2 \cdot SO_3) \cdot MHSO_4 \cdot 2H_2O$ have been reported,[46] from which the anhydrous compounds were obtained by calcination. Carboxylic acids have also been found to form anionic complexes with tellurium(IV) and polonium(IV). For example, the silver salts of the citrato- and tartrato-tellurates(IV) have been described[47] as insoluble in water but soluble in nitric acid.

Studies of the solubility of polonium(IV) in formic, acetic, oxalic and tartaric acids have provided evidence of complex formation,[48] with the acetato complex emerging as more stable than the hexachloro anion. Other studies of the solubility of polonium(IV) hydroxide in carbonate[49] and nitrate[50] solution, together with investigations[51] of the ion exchange behaviour of polonium(IV) at high nitrate ion concentration, have been discussed in terms of the formation of anionic complex species.

29.2.4 Oxygen Donor Complexes

There is a sparsity of information on oxygen donor complexes of the group VIB elements. Although sulfur tetrafluoride reacts with oxygen atoms in several species to give materials containing oxygen–sulfur bonds,[8] *e.g.* $SF_4(OSF_5)_2$, the characterization of many of the species as genuine coordination compounds is difficult to assess. Selenium trioxide has been reported[52] to form 1:1 adducts with ether and dioxane. The 1:1 complex of tellurium tetrafluoride with dioxane has been examined[53] by IR spectroscopy and described as $[(\text{dioxane})_2TeF_3]^+[TeF_5]^-$. The 1:1 complex of tellurium tetrachloride with pyridine *N*-oxide (PNO) has similarly been formulated[54] as $[(PNO)_2TeCl_3]^+[TeCl_5]^-$.

Although tellurium tetrachloride has been reported[55] to form a 1:2 complex with acetamide, there appears to be little other information available on the complex. Similarly, the reported tributyl phosphate complex of polonium tetrachloride[56] has received little attention. The formation of a polonium(IV) perchlorate complex with tributyl phosphate has been suggested[57] in the solvent extraction of polonium from perchloric acid.

29.2.5 Nitrogen Donor Complexes

The study of sulfur–nitrogen compounds is currently a very active area of inorganic chemistry research with many new cyclic and acyclic compounds being synthesized which have unusual structures and bonding properties.[8] Indeed, in many cases their description as coordination complexes is difficult to justify without further evidence on their bonding characteristics. The donor properties of nitrogen to sulfur have been referred to previously (Section 29.2.1), *e.g.* during the discussion of the 1:1 stable adduct between pyridine and sulfur tetrafluoride and the formation of $[NMe_4]^+[SF_5]^-$ from the reaction between Me_4NF and SF_4. It is also relevant to note that pyridine forms an adduct with sulfur trioxide.

The selenium tetrachloride complex with pyridine, $SeCl_4 \cdot 2py$, has been discussed[58] in terms of octahedral $[SeCl_3 \cdot 2py]^+$ ions in which the sixth position around selenium is occupied by a lone pair of electrons. It is therefore relevant to recall that the complex $SeOCl_2 \cdot 2py$[36] (Section 29.2.1, Figure 2) may also be described as octahedral with the chlorine atoms and pyridine rings occupying *trans* positions and in which the oxygen atom is *trans* to the lone pair of electrons. It is also pertinent to note that $SeCl_4 \cdot 2py$ is isomorphous with $SnCl_4 \cdot 2py$, which also has a *trans* octahedral configuration, and that conductivity measurements[59] suggest that the complex reacts with the solvent or with impurities. Selenium monobromide dissolved in carbon disulfide has been reported[60,61] to form simple nitrogen donor complexes of composition $Se_2Br_2 \cdot 2L$ with a variety of amines and heterocyclic bases. Although several of the nitrogen donor complexes of the chalcogen tetrahalides have compositions of the type $MX_4 \cdot 2L$, where L is a monodentate ligand, adducts of selenium or tellurium tetrachloride with four molecules of ammonia or two molecules of ethylenediamine which may involve six-coordination, *e.g.* $[(SeCl_2en_2)Cl_2]$, are also well established.[62]

The pentahalo anions which are found in complexes with nitrogen (Section 29.2.1) deserve a little more comment. For example, both mono- and bi-dentate nitrogen donor complexes[53] of composition $TeF_4 \cdot L$ and $2TeF_4 \cdot L$ have been described as $[L_2TeF_3]^+[TeF_5]^-$ or $[L'TeF_3]^+[TeF_5]^-$. The conductivity data recorded[54] from the analogous selenium and tellurium tetrachloride complexes suggest that they are 1:1 electrolytes in non-aqueous solvents and similar evidence recorded[54] from complexes of composition $MY_4 \cdot 2L$, in which the anion may be a simple halide ion, suggests that these are likely to be of a similar nature. Tellurium hexafluoride has been found[63] to form amine complexes of the type $TeF_6 \cdot 2R_3N$ which have been described as eight-coordinate species.

29.2.6 Sulfur and Selenium Donor Complexes

Complexes of group VIB elements with sulfur or selenium donor atoms are mainly concerned with complexes of selenium(II), tellurium(II) and tellurium(IV). The structural chemistry of complexes of selenium and tellurium with sulfur- and selenium-containing ligands has been well reviewed in the recent past.[11]

During work on nucleophilic substitution at divalent sulfur,[64,65] a series of tellurium derivatives with sulfur-containing ligands were prepared in a straightforward manner by addition of a warm aqueous solution of, for example, thiourea to tellurium dioxide dissolved in warm hydrochloric or hydrobromic acid, and which involved the reduction of tellurium(IV) to tellurium(II).

Two types of three-coordinate selenium(II) complexes, isolated as the triselenocyanate and the triselenourea salts, and which have essentially similar structures, have been identified.[66] Several three-coordinate tellurium(II) complexes have also been obtained[67] when one of the ligands has a very strong *trans* effect, for example a phenyl group, as in phenylbis(thiourea)tellurium(II) chloride.[68]

Several types of four-coordinate selenium(II) complexes with monodentate ligands have been identified. The isomorphous *cis*-dichloro- and *cis*-dibromo-bis(thiourea) selenium(II) complexes have recently been reported,[69] whilst the dimeric selenium triselenocyanate and trithiocyanate ions have been known for some time.[70–72] The distorted square planar coordination of the $[SeBr_2(tmtu)]$ complex[73] and the selenium dithiocyanate and diselenocyanate complexes[74] is characteristic of the four-coordinate selenium(II) complexes with monodentate ligands. Numerous four-coordinate tellurium(II) complexes with monodentate ligands have been reported,[64] including a large number of square planar complexes with TeS_4, TeS_2S_2 and TeS_4 coordination spheres, some of which may be dimeric. The tellurium tris(ethylenethiourea) cation, $[Te_2(etu)_6]^{4+}$, in the perchlorate salt (Figure 3) is illustrative[75] of the distorted square planar tellurium coordination in these types of complexes. A few square planar complexes with TeS_2X_2 and $TeSX_3$ coordination spheres are also known.[11] The IR and Raman spectra of the tellurium dichloride and dibromide complexes with thiourea have been reported and it appears that the Te–S bond in these compounds is relatively weak.[76]

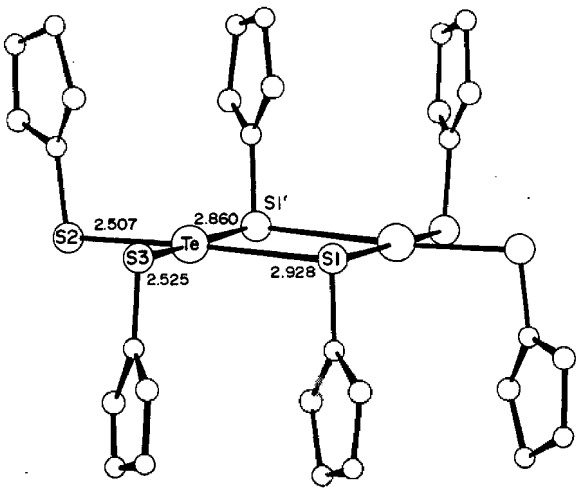

Figure 3 The structure of hexakis(ethylenethiourea)ditellurium(II) perchlorate (reproduced by permission from *Inorg. Chem.*, 1980, **19**, 1050)

Several four-coordinate selenium(II) complexes with bidentate ligands, all of which involve highly distorted square planar SeS_4 or $SeSe_4$ coordination spheres, and some tellurium analogues have been described.[11]

It is pertinent to note the preparation and structure[77] of the tris(ethylxanthato)tellurium(II) anion in its tetraethylammonium salt, $Et_4N^+[Te(EtOCS_2)_3]^-$ (Figure 4), in which the five-coordinate tellurium(II) is coordinated to three ethyl xanthate ligands, one of which is monodentate whilst the other two are anisobidentate. The resulting TeS_5 coordination sphere is pentagonal planar.

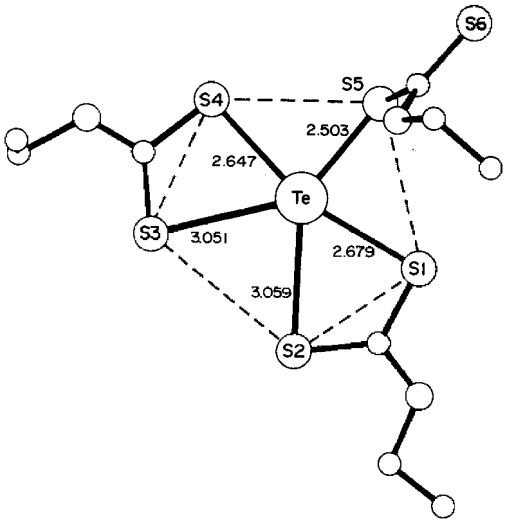

Figure 4 The structure of the tris(ethylxanthato)tellurium(II) anion in its tetraethylammonium salt (reproduced by permission from *Aust. J. Chem.*, 1976, **29**, 2337)

Complexes of both selenium(IV) and tellurium(IV) with sulfur-containing ligands are known although the structural properties appear to have been determined only for the tellurium(IV) species. However, due to the smaller size of selenium(IV) and its poorer acceptor properties, as compared with tellurium(IV), its maximum coordination number appears to be six whilst it has been found to be eight for tellurium.[78] Furthermore, the greater tendency of tellurium to form secondary bonds may cause the structures of similar selenium(IV) and tellurium(IV) compounds to be different.[79] It is also pertinent to note that the reduction of tellurium(IV) to

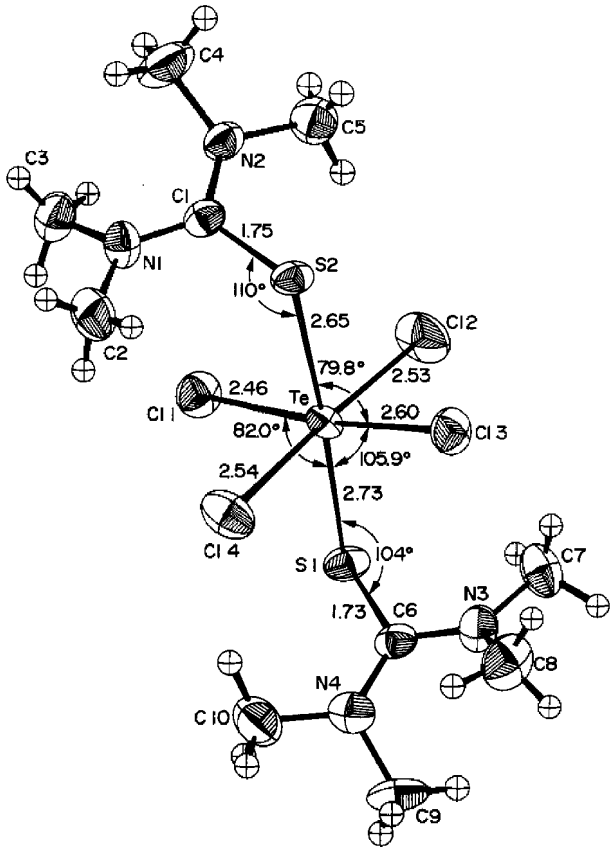

Figure 5 The structure of the monoclinic form of *trans*-tetrachlorobis(tetramethylthiourea)tellurium(IV) (reproduced by permission from *Acta Chem. Scand., Ser. A*, 1975, **29**, 141)

tellurium(II) by sulfur- or selenium-containing ligands does not always occur when strong donor ligands are used.[80,81]

A few four- and five-coordinate tellurium(IV) complexes with sulfur- or selenium-containing ligands are known, but despite the data on the hexahalogenotellurates(IV) (*vide supra*), six-coordinate tellurium(IV) complexes with other ligands are relatively rare. The six-coordinate complexes generally have a TeX_4S_2 coordination sphere, with both *cis* and *trans* isomers, and are considerably distorted from perfect octahedral geometry. The structure[82] of the monoclinic form of *trans*-tetrachlorobis(tetramethylthiourea)tellurium(IV), $[TeCl_4(tmtu)_2]$ (Figure 5) is illustrative of this common distortion from octahedral coordination which may be related to the stereochemical activity of the lone pair of electrons.

Some seven- and eight-coordinate tellurium(IV) complexes with bidentate dialkyldithiocarbamate ligands are known. The eight-coordinate complexes all have dodecahedral D_{2d} structures in which each dodecahedron may be seen as two planar trapezoidal $Te(R_2NCS_2)_2$ groups fused at right angles at the central tellurium ligand. The structure[83] of tetrakis(4-morpholinecarbodithioato)tellurium(IV) (Figure 6) shows the central tellurium atoms to be bonded to all eight sulfur atoms in a slightly distorted dodecahedral configuration.

Complexes of polonium with sulfur donor atoms appear to be less common, although there is some evidence that polonium is complexed by thiourea[84] and of the formation[85] of a volatile polonium diethyldithiocarbamate.

29.3 BIOLOGICAL PROPERTIES

The health hazards and toxicity of selenium and tellurium compounds have been known for some time.[1,2,5] Most selenium compounds are regarded as being toxic and great care has been recommended[1] for the handling of all selenides, organic selenium compounds and soluble selenites and selenates. Ingested selenides are reported[1] to be only slowly released from the body and cause the subject to suffer offensive-smelling breath and perspiration for a long time. Tellurium compounds are also regarded as harmful, although they appear to be rapidly reduced in the body to elemental tellurium which is ultimately excreted in the form of unpleasant smelling organotellurium compounds. Polonium is far more dangerous than selenium or tellurium because of its radioactivity. It appears that all three elements are absorbed in the kidneys, spleen and liver which, in the case of polonium, become the subject of irreversible radiation damage.

30.1 INTRODUCTION

This chapter deals with coordination complexes formed by the elements of both the halogen and noble gas groups, groups VII and 0, of the periodic table. It is convenient and useful to consider these two sets of elements together, since they have many similarities arising from their high electronegativities as the central atoms in complexes, and hence with the rather restricted range of ligands which form such complexes, particularly in the case of the noble gases. Recently[1] the statement has been made, 'It is now widely accepted that noble gas chemistry, which in most cases means nothing but xenon chemistry, must be viewed in relation to the high valency state chemistry of the neighbour elements in the periodic system, especially iodine'.[1]

The general reviews available of the chemistry of the halogens[2b,3–5] and of the noble gases[2c,3–5] are usually concerned with the complete chemistry of the elements and deal with coordination complexes only as part of this chemistry. This is largely due to the difficulty of defining such complexes for these elements. Thus, on the most general definition, almost all compounds containing the central atom in a positive oxidation state could be included. This review will be selective, concentrating on the relationships between the elements of the two groups.

The halogens will be restricted to chlorine, bromine and iodine since fluorine, as the most electronegative element, does not function as the central atom in a complex and astatine has only short-lived, radioactive isotopes, so that very little of its coordination chemistry has been investigated.[2b]

As stated above, noble gas chemistry is almost restricted to that of xenon, with a few krypton compounds of lower stability and with the chemistry of radon largely unexplored, due to the short half-lives of its isotopes. Two reviews[1,6] give good coverage of more recent noble gas chemistry.

30.2 OXIDATION STATES AND COORDINATION GEOMETRY

For both groups of elements the normal oxidation states always differ by two. Thus the halogens form compounds with the odd positive oxidation states I, III, V and VII, while noble gases correspondingly exhibit the even oxidation states II, IV, VI and VIII. These oxidation states vary in their accessibility with different ligands and, as expected, the higher the oxidation state, the more electronegative the ligands needed for stabilization. Thus the only examples of nitrogen ligands bonded to a noble gas atom are found for xenon(II), and these only for a ligand with electron-withdrawing groups attached to the nitrogen atom.

For the halogens the ease of attainment of the higher oxidation states increases as the group is descended from chlorine to iodine, and conversely the lower oxidation states become less accessible down the group.

The coordination geometry of complexes of these elements is most usefully correlated by reference to the valence shell electron pair repulsion (VSEPR) theory.[7] This bonding model, although based on a theoretically doubtful premise, is simple to apply and predicts correctly structures for most of the complexes considered. Only for coordination numbers greater than six does the model run into difficulties, as will be seen later for XeF_6 and $[XeF_8]^{2-}$. Since the structures predicted depend on the number of electron pairs, isostructural arrangements are found for corresponding, isoelectronic, neutral noble gas and anionic halogen species, and for cationic noble gas and neutral halogen species. Some examples of such relationships are shown in Table 1, where the various coordination geometries are listed. The diatomic interhalogens and isoelectronic noble gas cations have not been included.

Table 1 Coordination Geometries Based on VSEPR Theory

Valence shell electrons	*Theoretical arrangement*	*Number of bonds*	*Shape*	*Examples*
8	Tetrahedron	2	Angular	$[BrF_2]^+$
10	Trigonal bipyramid	2	Linear	XeF_2, $[ICl_2]^-$
		3	T-shaped	BrF_3, $[XeF_3]^+$
		4	Distorted square pyramid	$[IF_4]^+$
12	Octahedron	4	Square planar	XeF_4, $[ICl_4]^-$
		5	Square pyramid	IF_5, $[XeF_5]^+$
		6	Octahedral	$[IF_6]^+$
14	Pentagonal bipyramid?	6	Distorted octahedron	XeF_6, $[BrF_6]^-$
		7	Pentagonal bipyramid (fluxional)	IF_7
16	Square antiprism or dodecahedron	7	—	$[XeF_7]^-$
		8	—	$[IF_8]^-$
18	Tricapped trigonal prism?	8	Square antiprism	$[XeF_8]^{2-}$

30.3 COORDINATION COMPOUNDS

No strict definition of coordination compound will be followed for the compounds of these two groups, but coverage will be concentrated on those compounds where inter-group relationships are most obvious. In particular, the halogen oxides and derived oxo ions will not be considered.

The order in which the ligands are discussed will deviate from that generally followed in this series. Complexes with halogen ligands cover such an extensive range of oxidation states and provide so many structural examples for other ligands that they will be considered first. They also provide the largest number of examples of coordination compounds for chlorine and bromine, and the only examples for krypton. Xenon forms some compounds with other ligands, almost all linked to oxygen, and halogen complexes of other ligands are mainly restricted to those of iodine, often with halogen ligands as part of the coordination sphere to enhance stability.

30.3.1 Halogen Ligands

Coordination compounds containing halogen ligands (of which the great majority are fluorides) form the largest group of compounds for these elements. They are best considered as based on the neutral species, with cations and anions, which can be theoretically derived (and usually practically prepared) from the formal self-ionization of the neutral compound.

Considering bromine trifluoride as an example, the self-ionization is shown in equation (1). Dissolution of fluoride acceptors, such as antimony pentafluoride, gives compounds formally containing the difluorobromine(III) cation, and correspondingly, dissolution of fluoride donors, such as potassium fluoride, gives compounds containing the tetrafluorobromate(III) anion.

$$2BrF_3 \rightleftharpoons [BrF_2]^+ + [BrF_4]^- \quad (1)$$

Although the formulation as ionic species appears to correlate well with the known crystal structures for the anionic complexes, the situation is much less clear for the cations, and secondary bonding[8] between the central atom of the cation and atoms of the anion is important. Thus in the structure of difluorobromine(III) hexafluoroantimonate(V) the bromine atom has two fluorine atom neighbours at 1.69 Å and two more, from $[SbF_6]^-$ units, at 2.29 Å, completing a distorted, square planar arrangement of fluorine atoms around the bromine atom.[9]

Similar fluorine bridging in the structure[10] of trifluoroxenon(IV) hexafluorobismuthate(V) leads again to a distorted, square planar arrangement, with three fluorine atoms at 1.81, 1.92 and 1.94 Å from the xenon atom, and the fourth, from the $[BiF_6]^-$ unit, at 2.25 Å.

The interhalogens, noble gas fluorides and derived ions will be treated systematically. The diatomic interhalogens will not be discussed, but the isoelectronic $[XeF]^+$ and $[KrF]^+$ cations will be included due to their important secondary bonding to fluoride to form an asymmetric, two-coordinate arrangement.[6]

30.3.1.1 Halogen(I) and noble gas(II) compounds

These lowest oxidation states can be associated with a coordination number of two and a linear arrangement of the ligands about the central atom. On VSEPR theory these are 10-electron species, with a trigonal bipyramidal arrangement of three lone pairs of electrons in equatorial positions and two halogen ligands in axial positions.

The halogen compounds are the anions derived from the diatomic interhalogens, usually involving the same halogen, symmetrically bonded, as ligands, but, for example with $[BrICl]^-$, the different I—Br (2.51 Å) and I—Cl (2.91 Å) distances giving an asymmetric, linear ion.[11] Generally these anions are prepared by the interaction of the appropriate interhalogen compound with the appropriate halide, with reaction conditions tailored to the properties of reactants and products.

The noble gas compounds include the two difluorides of xenon and krypton and the derived cations $[XeF]^+$ and $[KrF]^+$, if for these latter species the interaction with fluoride in the anion is included. The simplest example of this arrangement occurs in the ions $[Xe_2F_3]^+$ and $[Kr_2F_3]^+$, prepared by interaction of excess difluoride with an acceptor pentafluoride, which can best be described as assemblies of two $[NgF]^+$ ions (Ng = Xe or Kr) with an F^- anion between them, symmetrically placed[12] for Xe, but possibly asymmetrically[13] for Kr. This gives a linear arrangement for Ng and an angular coordination for the central F^-. This asymmetric coordination by two fluorine ligands is also found in the structures of salts of the $[XeF]^+$ cation, investigated by X-ray crystallography,[14–16] and is also indicated for corresponding $[KrF]^+$ salts from spectroscopic measurements.[6] Some representative examples of this coordination arrangement are given in Table 2.

30.3.1.2 Halogen(III) and noble gas(IV) compounds

The species considered for these oxidation states are associated with coordination numbers two, three and four. The corresponding geometrical arrangements are angular for two-coordination in the cationic halogen species, T-shaped for the three-coordinate interhalogens and cationic noble gas species, and square-planar for the anionic halogen complexes and the neutral noble gas fluorides. The situation is complicated by secondary bonding. Thus the

Table 2 Linear Two-coordinate Complexes

	A—*X* (Å)	*X*—*A*—*Y* (°)	*Ref.*
$K^+[ICl_2]^-$	2.55 × 2	180	17
$Cs^+[IBr_2]^-$	2.62, 2.78	178	18
$Cs^+[Br_3]^-$	2.440, 2.698	177.5	19
$[NH_4]^+[BrICl]^-$	2.51(Br), 2.91	180	11
XeF_2	1.983 × 2	180	35
$[XeF]^+[AsF_6]^-$	1.873, 2.212	179	14
$[XeF]^+[RuF_6]^-$	1.87, 2.18	177	15
$[XeF]^+[Sb_2F_{11}]^-$	1.84, 2.35	~180	16
$[Xe_2F_3]^+[AsF_6]^-$	1.90, 2.14	178	12

angular cations for halogens and the T-shaped cations for noble gases can approach the square planar arrangement, as described earlier in this section.

On VSEPR theory the angular cations are eight-electron species with a tetrahedral arrangement of two lone pairs of electrons and two halogen ligands. The T-shaped complexes are 10-electron species, with two lone pairs of electrons in equatorial positions and the halogen ligands in the remaining equatorial and the axial positions. The square planar arrangement is associated with 12-electron species, with two lone pairs *trans* to each other in an octahedral geometry.

The triatomic cations are usually prepared from the corresponding interhalogen, by reaction with a halogen acceptor molecule. This is impossible for some of the more exotic species which have no interhalogen precursor. For example, the $[Br_3]^+$ cation has been characterized[20] in $[Br_3]^+[AsF_6]^-$, formed from the interaction of arsenic pentafluoride and a bromine/bromine pentafluoride mixture and the $[Cl_2F]^+$ cation results from the interaction of antimony pentafluoride with chlorine monofluoride.[21]

Secondary bonding interactions have been shown to give a distorted square planar arrangement for these ions and the variation of this interaction can be correlated with both the acceptor strength of the anion involved and the acceptor strength of the cationic species itself. Thus with the $[SbF_6]^-$ anion the interactions[9] of $[BrF_2]^+$ are stronger than those[22] of $[ClF_2]^+$, and $[ICl_2]^+$ shows[23] one of the shortest iodine to fluorine secondary bonds as yet reported (Table 3).

Table 3 Angular Two-coordinate Halogen Complexes

	Average A—*X* (Å)	*Average A* · · · *X* (Å)	*Ref.*
$[ClF_2]^+[SbF_6]^-$	1.57	2.38	22
$[BrF_2]^+[SbF_6]^-$	1.69	2.29	9
$[ICl_2]^+[SbF_6]^-$	2.268	2.650	23
$[IBr_2]^+[Sb_2F_{11}]^-$	2.423	2.81	24
$[I_3]^+[AsF_6]^-$	2.665	3.04	25
$[ICl_2]^+[SbCl_6]^-$	2.31	2.92	26

The T-shaped geometry is established for the trifluorides of chlorine and bromine in the vapour phase and for[27] solid ClF_3. In the solid state for[28] BrF_3 there is a Br · · · F contact at 2.49 Å, compared with the Br—F distances of 1.72, 1.84 and 1.35 Å, which, although coplanar with the three bonds, is offset from the symmetrical square position. It can be considered as symmetrically placed above the centre of a triangular face, including the two lone pairs of electrons, of the trigonal bipyramidal arrangement. This interaction can be considered too weak to force a rearrangement to the pseudooctahedral form. In contrast, iodine trichloride[29] achieves a close approach to the square planar arrangement by dimerization, and only the longer bridge distances lead to distortion (Table 4).

Although the T-shaped $[XeF_3]^+$ cation forms[10] a coplanar, symmetric secondary bond with the $[BiF_6]^-$ ion, through a very strong contact (Bi · · · F = 2.25 Å), which results in a distorted square planar geometry, the $[SbF_6]^-$[30] and $[Sb_2F_{11}]^-$[31] anions interact more weakly to give the asymmetric arrangement described above for solid BrF_3.

The square planar arrangement found in the anionic halogen complexes and in xenon tetrafluoride is usually regular, although small distortions have been attributed to the influence of the countercations in the halogen compounds. For example, in the compound $[SCl_3]^+[ICl_4]^-$ lengthening of I—Cl bonds[32] can be correlated with the number of secondary bonds to sulfur formed by the particular chlorine atom (Table 4).

Table 4 Planar Four-coordinate Complexes

	A—*X* (Å)	*X*—*A*—*X* (°)	*Ref.*
$K^+[BrF_4]^-$	1.89 × 4	90.9 × 2, 89.1 × 2	33
$K^+[ICl_4]^-H_2O$	2.42, 2.47, 2.53, 2.60	89.2, 89.5, 90.6, 90.7	34
$[SCl_3]^+[ICl_4]^-$	2.439, 2.469, 2.543, 2.603	88.0, 89.5, 91.1, 91.4	32
XeF_4	1.952 × 4	90.0 × 4	35
I_2Cl_6	2.38 × 2, 2.70 × 2	94, 84, 91 × 2	29

30.3.1.3 Halogen(V) and noble gas(VI) compounds

Complexes for these oxidation states are restricted to fluorine ligands, and to xenon for the noble gases, with associated coordination numbers ranging from four to eight. The geometrical arrangements are distorted square pyramidal for four-coordination in the cationic halogen species, square pyramidal for the five-coordinate interhalogens and the cationic xenon species, and distorted octahedral for six-coordinate xenon hexafluoride. For the hexafluoroanions of the halogens, and the heptafluoroxenate(VI) ion, no crystallographic results are available, but the octafluoroxenate(VI) ion has been shown to have a square antiprismatic arrangement.[36]

VSEPR theory correlates the four-coordinate species with a 10-electron, trigonal bipyramidal arrangement of one lone pair of electrons in an equatorial position and four fluorine ligands. The square pyramidal complexes are based on a 12-electron arrangement with one lone pair of electrons. For higher numbers of valence-shell electrons, the VSEPR treatment is less satisfactory. The effect of the lone pair of electrons is certainly seen in the structure of monomeric XeF_6, but this is a fluxional molecule, and the geometry is therefore hard to define. The situation with $[XeF_8]^{2-}$ is difficult to rationalize in terms of VSEPR theory, since the square antiprismatic coordination is only slightly distorted, showing no clear position for the lone pair of electrons.

The tetrafluorohalogen(V) cations are prepared by interaction of the parent fluoride with a good fluoride acceptor molecule, typically SbF_5. The geometry in the solid state has been established for $[BrF_4]^+$ in the $[Sb_2F_{11}]^-$ salt,[37] although the accuracy of the results is low, for $[IF_4]^+$ in the $[SbF_6]^-$ salt,[38] which has a disordered arrangement, and for $[IF_4]^+$ in the $[Sb_2F_{11}]^-$ salt.[39] In the latter, the F—I—F angle between equatorial fluorine ligands is 92.4° and that between axial ligands is 160.3°, as expected from VESPR theory, but there are two pairs of secondary bonds averaging 2.56 and 2.87 Å, grouped around the lone pair position.

The halogen pentafluorides and the $[XeF_5]^+$ cation have a square pyramidal configuration and any weak secondary bonds are found below the base of the pyramid and situated to avoid the axial, lone pair position. These contacts are much more significant for the xenon compounds than for the interhalogens, where they are so weak as to be virtually indistinguishable from normal intermolecular contacts, as seen in the structure of IF_5.[40]

Salts of the $[XeF_5]^+$ cation are synthesized by interaction of XeF_6 with fluoride acceptor molecules in the correct proportions. Excess XeF_6 will produce compounds containing the $[Xe_2F_{11}]^+$ cation. For $[XeF_5]^+$ in combination with $[MF_6]^-$ or $[MF_6]^{2-}$ anions there are either three[41] or four [15] secondary bonds, symmetrically arranged around the lone pair position, with Xe · · · F distances in the range 2.5–3.0 Å. In solid XeF_6, which exists as both tetramers, best represented as $[(XeF_5)^+F^-]_4$, and the corresponding hexamers,[42] the distances are 2.56 Å in the hexamer and 2.23 and 2.60 Å in the tetramer. The $[Xe_2F_{11}]^+$ cation can be represented as $[XeF_5^+ \cdots F^- \cdots XeF_5^+]$ and in the $[AuF_6]^-$ salt[43] has an Xe · · · F^- distance of 2.23 Å and a secondary Xe · · · F bond distance to $[AuF_6]^-$ of 2.64 Å In comparison the overall average Xe—F bond distance in $[XeF_5]^+$ compounds is 1.85 Å.

Compounds with six fluorine ligands have provided structural difficulties. Xenon hexafluoride exists as the monomer in the vapour state and has been shown largely by electron diffraction experiments to be non-octahedral, and also fluxional.[44] Although VSEPR theory might have

predicted a pentagonal bipyramidal arrangement, including the lone pair of electrons, the lone pair is thought to take up a position capping a face of the octahedron of fluorine ligands, and interchanging positions, by moving through the midpoint of an edge. The ions BrF_6^- and IF_6^- result from the interaction of the pentafluorides with alkai metal fluorides as fluoride donors,[45,46] but no definitive crystal structure has been determined. Spectroscopic results indicate a non-octahedral arrangement for the ions.

Interaction of XeF_6 with fluoride donors produces compounds formally containing $[XeF_7]^-$ and $[XeF_8]^{2-}$. The latter anion has been characterized[36] in the compound $[NO]_2^+[XeF_8]^{2-}$, by X-ray crystallography. The Xe—F distances are in the range 1.95–2.10 Å and the structural arrangement is a slightly distorted, square antiprism with no definite position for the lone pair of electrons.

30.3.1.4 Halogen(VII) and noble gas(VIII) compounds

Although in theory the Xe^{VIII} oxidation state might be attainable, no such compounds containing only fluorine ligands have yet been reported. The halogens are represented by iodine heptafluoride and its related $[IF_6]^+$ cation and $[IF_8]^-$ anion. $[ClF_6]^+$ and $[BrF_6]^+$ cations have also been prepared, although lacking their neutral precursors, using the powerful oxidizing properties of platinum hexafluoride or the fluorokrypton(II) cation. Thus interaction of ClF_5 and PtF_6 in a sapphire reactor produces $[ClF_6]^+[PtF_6]^-$ [47a] and warming a solution of $[KrF]^+[AsF_6]^-$ or $[Kr_2F_3]^+[AsF_6]^-$ in liquid BrF_5 or ClF_5 produces $[BrF_6]^+$ [48] $[AsF_6]^-$ or the $[ClF_6]^+$ salt.[47b]

The three hexafluorohalogen(VII) cations have been shown to have octahedral symmetry by spectroscopic methods. This undistorted octahedral geometry is predicted by VSEPR theory, since no lone pairs of electrons are involved.

The heptafluoride has been reported not to have a pentagonal bipyramidal arrangement in the solid state,[49] although the considerable difficulties involved in the crystal structure determination lead to less accurate results than could be desired.[50] In the vapour state electron diffraction results[51] show that the pentagonal bipyramidal arrangement is present but the molecule is non-rigid, with deformation from D_{5h} symmetry, and this may account for the solid state structure.

The octafluoroiodate(VII) ion has been reported[52] to result from the interaction of the heptafluoride with the fluoride donors CsF or NOF, but its structure has not been determined.

30.3.2 Carbon Ligands

This section is concerned almost exclusively with halogen compounds, since although there is an extensive chemistry of halogens in higher oxidation states bonded to carbon in ligands, there is no well-characterized noble gas compound of this type. Mass spectrometer experiments involving *in situ* decay of organic iodides containing ^{131}I have given evidence for the existence of the C—$^{131}Xe^+$ bond,[53] but only one compound has been described on a macroscopic scale. The reaction of XeF_2 with CF_3 free radicals, generated in a plasma, produced a waxy, colourless solid,[54] which was more volatile than XeF_2, and decomposed at room temperature with a half-life of 30 minutes. Handling difficulties and lack of a suitable solvent precluded conclusive identification of the compound.

An extensive review[55] of the chemistry of halogen complexes containing carbon ligands, the 'hypervalent halogen compounds', has been published recently. This is written from an organic chemical viewpoint and includes discussion of the organic chemistry involved in reactions of these compounds. Only aspects directly related to coordination chemistry will be mentioned here.

The review also discusses in detail the bonding in these compounds, in terms of hypercovalent bonds. The gross stereochemistry of these compounds will be related here to the previously described VSEPR model, sufficient for the present discussion.

Although there are a few examples of iodine bonded only to carbon ligands, most complexes contain other, more electronegative ligands in the coordination sphere. There are few examples of chlorine and bromine complexes, and, as yet, no examples even with iodine of oxidation state VII. Most of these complexes, and especially the more stable examples, have aromatic

rather than aliphatic carbon ligands. Classification of these compounds has been in terms of the oxidation state of the halogen and the number of halogen–carbon bonds.

30.3.2.1 Halogen(I) compounds

This class of compound is represented by the dicyanoiodate(I) anion, involving a pseudo-halide rather than an alkyl or aryl ligand. The linear ion, with I—C distance of 2.302 Å, has been characterized in the compound $K[I(CN)_2]C_6H_{12}N_2O_2$, resulting from reaction of an aqueous solution of KCN with an ethanolic solution of ICN. The diimino oxalic acid diethyl ester molecule apparently stabilizes the structure.[56]

30.3.2.2 Halogen(III) compounds

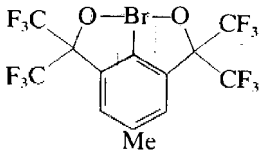
This is the largest group of compounds and, although many examples have been prepared since the original report of phenyliodine(III) dichloride a century ago,[57] few crystal structures have been determined. The compounds have been classified as shown in Table 5.

Table 5 Classification of Organohalogen(III) Compounds

Number of ligands	*Type of ligands*	*Example*
2	Two carbon	PhBr(cyim)[a]
2	One carbon, one heteroatom	PhIO
3	Three carbon	Ph_3I
3	Two carbon, one heteroatom	Ph_2ICl
3	One carbon, two heteroatom	$PhICl_2$

[a] cyim = 3,4-dicyanoimidazolylide.

The compounds with two carbon ligands are halonium ylides, with a formal positive charge on the halogen atom. On VESPR theory they are eight-electron species, with two lone pairs of electrons and an overall tetrahedral arrangement. The C—I—C angles determined are 97.8° in 2-(*o*-chlorophenyliodonium) 4-nitro-6-chlorophenoxide[58] and 98.7° in phenyliodonium 2,5-dicarboethoxy-3,4-dicyanocyclopentadienylide.[59] The C—Br—C angle in the structure of the only bromine compound structurally characterized, phenylbromonium 3,4-dicyanoimidazolylide,[60] is 99.3°. When one carbon atom is replaced by a heteroatom (in practice a multiply bonded oxygen atom) a neutral species of the same stereochemical type results, since the oxygen ligand accounts for the extra pair of electrons in its multiple bond. These compounds are unstable with respect to disproportionation and have not been definitively characterized structurally.



The compounds with three ligands should have the T-shaped stereochemistry characteristic of 10-electron species on VSEPR theory. For three carbon ligands, triphenyliodine, prepared from diphenyliodine(III) iodide and phenyllithium at −80 °C in ether,[61] decomposes at −10 °C, and even more stable compounds, with cyclic structures involving the iodine atom,[62] still decompose over relatively short periods. No crystal structures have been determined, although NMR studies support the structural assignment.[62]

The diphenyliodine(III) halides have dimeric structures in the solid state,[63] directly comparable with that of ICl_3.[29] Thus, these compounds have a planar coordination of the iodine atom by two carbon and two bridging halogen atoms. This corresponds to the 12-electron, octahedral arrangement. The I—Cl bonds in the chloride, of 3.085 Å, are longer than those of 2.70 Å in the trichloride and presumably reflect the significance[63] of the ionic form $\{[Ph_2I]^+[Cl]^-\}_2$.

The characteristic T-shaped coordination is found for compounds with one carbon and two heteroatom ligands. The simplest structure is that of phenyliodine(III) dichloride[64] with I—Cl bond distances of 2.54 Å and Cl—I—C angles of 86°. In general, in the other examples for which structures have been determined,[55] the corresponding angles are less than 90°. Secondary bonding is important in the overall packing of these compounds and has been fully analyzed for two examples.[65]

Recent synthetic work has achieved the preparation of two important bromine(III)

compounds. The interaction of BrF_3 and $C_6F_5SiF_3$ produces[66] $C_6F_5BrF_2$, a thermally stable, but reactive solid. Interaction of this compound with trifluoroacetic anhydride gives the stable carboxylate, $C_6F_5Br(O_2CCF_3)_2$. The much more stable compound (**1**) results from treatment[67] of the diol precursor with BrF_3. This latter compound, which melts at 153–154 °C, is unreactive towards water, dilute hydrochloric acid and dilute sodium hydroxide.

(**1**)

30.3.2.3 Halogen(V) compounds

These compounds are much less common than the halogen(III) compounds and only examples with iodine have been isolated. They have been classified as shown in Table 6. There is a paucity of detailed structural information, with three significant crystal structures and NMR data on some fluoro derivatives.

Table 6 Classification of Organohalogen(V) Compounds

Number of ligands	*Type of ligands*	*Example*
3	One carbon, two heteroatom	$PhIO_2$
4	One carbon, three heteroatom	$PhIOF_2$
4	Two carbon, two heteroatom	Ph_2IOF
5	Two carbon, three heteroatom	Ph_2IF_3
5	One carbon, four heteroatom	CF_3IF_4

The three-ligand class is represented structurally by *p*-chlorophenyliodine(V) dioxide (*p*-chloroiodylbenzene) and the unsubstituted phenyl compound. VSEPR theory would predict pyramidal geometry for these compounds, with multiple bonds to oxygen, and this is found approximately[68] for the *p*-chloro compound, although the accuracy of the determination is low. The angles around iodine are 94, 95 and 103° for the two C—I—O and the O—I—O angles respectively. For the phenyl compound[69] the corresponding angles are 91.1, 76.3 and 147.8° and the distortion in geometry is linked to the effect of the three strong secondary bonds to the iodine atom, which are grouped around the lone-pair position.

Although there is little structural information on four-ligand compounds with two carbon ligands, the structure of '*o*-iodoxybenzoic acid', $C_6H_4CO_2I(O)OH$, provides data for the class with a single carbon ligand.[70] The carboxylate oxygen forms a strong intermolecular bond to iodine of 2.324 Å, to give an arrangement based on a trigonal bipyramid, with the bonds to carbon and the multiply bonded oxygen (I—O = 1.784 Å) in equatorial positions, with the lone pair of electrons, and the intermolecular bond and the I—OH bond of 1.895 Å in axial positions.

For the five-ligand compounds there are no crystallographic data. These compounds are expected to have square pyramidal coordination, based on a 12-electron arrangement. ^{19}F NMR studies have provided some evidence in support of the square pyramidal arrangement. Thus diphenyliodine(V) trifluoride [diphenyl (difluoroiodosyl) fluoride] in nitromethane solution gives a spectrum consisting of two singlets, assigned to the fluorine atom opposite a phenyl ligand (more weakly bonded) and the two equivalent fluorine ligands opposite one another.[71] The lone pair is assumed to occupy the sixth coordination position opposite a phenyl group. Similarly[72] phenyliodine(V)tetrafluoride(tetrafluoroiodobenzene) shows just one singlet in its spectrum, corresponding to the four equivalent fluorine atoms. The corresponding trifluoromethyliodine(V) tetrafluoride[73] [(tetrafluoroiodo) trifluoromethane] has a spectrum typical of an A_3X_4 spin system and shows F—C—I—F coupling, which is consistent with the square pyramidal arrangement.

30.3.3 Nitrogen Ligands

The most significant aspect of chemistry in this section recently has been the characterization of the xenon–nitrogen bond. The carefully controlled reaction between XeF_2 and $HN(SO_2F)_2$ was reported to yield[74,75] the compounds $FXeN(SO_2F)_2$ for 1:1 proportions, and $Xe[N(SO_2F)_2]_2$ for 1:2 proportions, with elimination of HF. This has been confirmed by the subsequent X-ray crystallographic structure determination[76] of $FXeN(SO_2F)_2$ which shows a linear F—Xe—N arrangement with Xe—F and Xe—N distances of 1.967 and 2.200 Å respectively. Reaction of this compound with arsenic pentafluoride forms a bright yellow solid,[77,75] unstable at room temperature, which appears to be $[(FO_2S)_2NXe]^+[AsF_6]^-$ and which decomposes under vacuum to form the pale yellow $[\{(FO_2S)_2NXe\}_2F]^+[AsF_6]^-$, with the cation analogous to $[Xe_2F_3]^+$.

Halogen–nitrogen bonds are rather more common, although research in this area has not been extensive. Most compounds reported are halogen(I) cations, with a linear coordination geometry. Thus, dissolution of I_2, IBr or ICl in pyridine leads[78] to formation of $[py_2I]^+$ cations, and the crystal structure determination[79] of the solid, empirically $py(I_2)_2$, formed from iodine in ethanol solution, has shown the presence of planar $[py_2I]^+$ cations with I_3^- anions and I_2 molecules. The linear $[N—I—N]^+$ unit has an I—N distance of 2.16 Å, the linear arrangement corresponding on VSEPR theory to a 10-electron species.

This linear coordination, but with unequal I—N bonds, has been found in the compound $(bipy)(IN_3)_2$[80] where the I—N(bipy) distance averages 2.44 Å and I—N(azide) averages 2.17 Å, reflecting the difference in the bonding to the two ligands. The two bromine(I) examples studied both show asymmetry of the N—Br—N linear system, although the two ligands are equivalent. Thus in bis(quinuclidine)bromine(I) tetrafluoroborate[81] the Br—N distances are 2.120 and 2.156 Å and in bis(quinoline)bromine(I) perchlorate[82] they are 2.100 and 2.165 Å. The reason for the asymmetry is not obvious.

Although the interaction of pyridine and $ClNO_3$ has been reported[83] to yield the $[py_2Cl]^+$ cation, there is as yet no crystallographic determination on a chlorine(I) compound.

30.3.4 Oxygen Ligands

Apart from the very few examples mentioned previously, oxygen is the only element other than fluorine to form bonds to xenon. For the halogens in positive oxidation states the oxides and oxoanions provide some of the most familiar compounds of these elements, with a very extensive chemistry, adequately reviewed elsewhere.[2] Similarly the oxides and oxoanions of xenon include the simplest examples of compounds of xenon(VIII), with the tetraoxide and the xenate(VIII) (perxenate) ion having the expected, undistorted tetrahedral and octahedral coordination arrangements respectively. In this chapter attention will be concentrated on ligands containing oxygen as the donor atom, rather than the multiply bonded oxide ligand itself. These are mainly oxoacid salts, with earlier work concentrating on such ligands as nitrates and perchlorates and more recent work on the more electronegative species such as the fluorosulfates and particularly the pentafluoroselenates(VI) and pentafluorotellurates(VI). It has been suggested that these latter ligands may be more electronegative than fluorine[84] and the pentafluorotellurate(VI) gives the most thermally stable noble gas compounds of this type.

In general, apart from those involving the more electronegative ligands, the compounds containing Xe—O bonds tend to have limited thermal stability and high chemical reactivity and often to involve explosions. Thus, relatively little crystallographic structure determination has been achieved and spectroscopic techniques have been used to show structural analogies to corresponding interhalogen compounds.

30.3.4.1 Halogen(I) and noble gas(II) compounds

By analogy with the halogen ligand compounds discussed previously, these oxidation states are associated with coordination number two and a linear arrangement of ligands about the central atom. The anionic halogen compounds have been little studied. An IR spectroscopic study[85] of the dinitrato-bromate(I) and -iodate(I) anions was concerned primarily with the denticity of the nitrate ligands, which was not unambiguously determined. Although

$Ag[I(OClO_3)_2]$ is among the products of the low temperature reaction[86] of I_2 with $AgClO_4$ it has not been obtained pure, and no spectroscopic results have been reported.

More interest has been shown in the noble gas compounds, since the majority of these compounds have been prepared for this oxidation state. Compounds are derived from XeF_2 by substitution of one or both fluorine atoms. The order of stability based on the reported decomposition of the mono- and di-substituted species[1] is $OTeF_5 > OSeF_5 > OSO_2F > OPO_2F > OClO_3 > OSO_2CF_3$, OSO_2Me, $OCOCF_3$, OCOMe. The last four ligands lead to explosive products.

The characteristic linear coordination of xenon has been verified crystallographically for two examples. The structure of $FXeOSO_2F$ shows[87] a linear arrangement with Xe—F and Xe—O distances of 1.94 Å and 2.16 Å respectively. Although the structure determination[88] of $Xe(OSeF_5)_2$ shows a disordered arrangement, the O—Xe—O group is linear with an Xe—O distance of 2.12 Å.

The novel cation $[(FXeO)_2SOF]^+$ has been characterized crystallographically as the $[AsF_6]^-$ salt.[89] The bridging fluorosulfate group is analogous to the bridging fluoride in the $[Xe_2F_3]^+$ cation. The Xe—F and Xe—O distances are 1.86 and 2.21 Å respectively.

30.3.4.2 Halogen(III) and noble gas(IV) compounds

The halogen compounds are known for neutral, cationic and anionic species. These should be three, two and four coordinate, with T-shaped, angular and square planar coordination arrangements respectively. No crystallographic work has been reported on the simple species and the spectroscopic results are not always conclusive.

Thus iodine(III) perchlorate[90] and bromine(III) and iodine(III) fluorosulfates[91] are apparently polymeric in the solid state, although the degree of polymerization has not been established. The $[Br(OSO_2F)_2]^+$ and $[I(OSO_2F)_2]^+$ cations have been reported in combination with[92] $[Sn(OSO_2F)_6]^{2-}$ and[93] $[Au(OSO_2F)_4]^-$ anions, and IR and Raman spectra support the formulation as ions, but do not give structural details. The spectra of the anionic species in[91] $K[Br(OSO_2F)_4]$, $K[I(OSO_2F)_4]$, $Cs[I(OClO_3)_4]$[90] and $Rb[Br(OSeF_5)_4]$[94] show features characteristic of the $[BrO_4]$ and $[IO_4]$ square planar units.

A recent structure determination[95] has shown that the compound $I(OSO_2F)_2I$ has the characteristic T-shaped coordination with the I^{III}—I distance of 2.678 Å in the equatorial position and two I—O axial distances of 2.09 and 2.26 Å with O—I—I angles of 91.0° and 85.3°. A secondary I···O bond of 3.05 Å completes a coordination similar to that in the $[XeF_3]^+$ ion described earlier.[30] The only noble gas compound of this class is $Xe(OTeF_5)_4$, prepared from the interaction of XeF_4 and $B(OTeF_5)_3$, for which the Raman spectrum supports the square planar arrangement.[96]

30.3.4.3 Halogen(V) and noble gas(VI) compounds

Although there are some examples of halogen(V) compounds containing oxygen ligands, together with fluoride or multiply bonded oxide, examples with five oxygen ligands are rare and often ill characterized. For example the interaction[97] of IF_5 with $Me_3Si(OMe)$ or $Me_2Si(OMe)_2$ produces the compounds $IF_{(5-n)}(OMe)_n$ for $n = 1$–4, with only tentative identification of $I(OMe)_5$. However, $I(OTeF_5)_5$ has been characterized[84] as well as the substituted species $F_nI(OTeF_5)_{5-n}$ for $n = 1$–4 and $OI(OTeF_5)_3$. The pentakis(pentafluorotellurate) could not be prepared directly from IF_5 but resulted from the oxidation of $I(OTeF_5)_3$ with $Xe(OTeF_5)_2$. The mixed fluoro species were characterized by NMR spectroscopy, all having fluorine in the axial position of the square pyramidal arrangement.

Pentafluorotellurate compounds of xenon(VI) similar to the iodine(V) compounds above have also been prepared.[96] Thus $OXe(OTeF_5)_4$ results from the interaction of $OXeF_4$ with $B(OTeF_5)_3$ and there is NMR evidence from a solution of the pentafluorotellurate in $OXeF_4$ for the species $OXeF_n(OTeF_5)_{4-n}$ for $n = 1$–3. The structures of these compounds are square pyramidal like the iodine compounds above, with the multiply bonded oxide in the apical position. $Xe(OTeF_5)_6$ has been prepared from XeF_6 using the versatile $B(OTeF_5)_3$ reagent at low temperatures. Although it decomposes above −10 °C, powder X-ray diffraction has shown it to have a similar, but significantly different, unit cell to that of $Te(OTeF_5)_6$.[98] From this difference, a distorted octahedral configuration for xenon has been inferred, by comparison

with the undistorted $[TeO_6]$ central unit in the tellurium compound,[96] and the lone pair appears to have some stereochemical effect.

30.3.5 Sulfur and Selenium Ligands

There are no examples of xenon bonded to sulfur or selenium and few for the halogens. The reported compounds involve the thiocyanate[99,100] and selenocyanate[100] ligands acting as pseudohalides, in the anions $I(SCN)_2^-$ and $I(SeCN)_2^-$, for which IR and Raman spectra show the thiocyanate to have a linear S—I—S arrangement but give no definitive results for the selenocyanate, and two examples with more complex thio ligands for which crystal structures have been determined.

For the bis(thiourea) iodine(I) cation,[101] in the iodide salt, there is a linear S—I—S arrangement with the I—S distance of 2.629 Å. The complex cation[102] $[\{(en)_2Co(SCH_2CH_2NH_2)\}_2I]^{5+}$, with the two octahedrally coordinated cobalt complexes linked through an S—I—S bridge, has an S—I—S angle of 173° and an I—S distance of 2.619 Å.

31.1 INTRODUCTION

Titanium is a reasonably common element which has been known for over 170 years. The average titanium content of the earth's crust is 0.63% by weight, which makes it the ninth most abundant element in the earth's crust, 20 times more abundant than carbon, and only outranked by oxygen, silicon, aluminum, iron, magnesium, calcium, sodium and potassium. It is only really in this century that elemental titanium has developed any industrial potential, partly because of difficulties associated with its refinement.

The element was first obtained pure in 1910 by Hunter[1] *via* reduction of the tetrachloride with sodium. In 1925, van Arkel and de Boer[2] obtained a very pure form of the metal by dissociation of the tetraiodide. Nonetheless, the titanium metal industry really dates from the publication of the Kroll process[3] in 1940, which involves reduction of the tetrachloride with magnesium. The principal properties of titanium which recommend it to metallurgists and engineers are its low density, strength and resistance to corrosion.

The most important industrial use of titanium is in the form of the dioxide (rutile or anatase) as a white pigment in the paint industry. Its outstanding property is its capacity or covering power; this, with its relative chemical inertness, has resulted in its almost complete replacement of all other white pigments. Related uses arise in the paper, plastics, rubber, textile and vitreous enamel industries.

31.1.1 Discovery

Titanium was discovered in 1791 by William Gregor, an English clergyman and amateur chemist. He identified it in a black sand (now known to be ilmenite) sent to him for analysis from the Menacchan Valley in Cornwall. Four years later, the famous German chemist Klaproth rediscovered the element in the ore rutile, one form of titanium dioxide. He gave it the name titanium after the Titans who in Greek mythology were the sons of Earth.

Titanium is widely distributed on the earth's surface, and also occurs in the sun, in stars and in meteorites. In the earth's crust the principal ores are ilmenite ($FeTiO_3$) and rutile (TiO_2). An important deposit of ilmenite occurs in the Ilmen mountains in Russia, from which the ore gets its name. Some other minerals are titanomagnetite [Fe_3O_4(Ti)], ramsayite (lorenzenite) ($Na_2(TiO)_2Si_2O_7$), titanite ($CaTiSiO_5$), lamprophyllite [(Ba, Sr, K)Na(Ti, Fe)$TiSi_2$(O, OH, F)$_9$], benitoite [$BaTi(Si_3O_9)$], warwickite [$(Mg, Fe)_3TiB_2O_8$], osbornite (TiN) and perovskite ($CaTiO_3$). Crystallographic details for all these have been tabulated.[4]

31.1.2 Preparation of the Metal

It is not possible to obtain titanium metal by the usual method of reduction of the dioxide with carbon, because a very stable carbide is formed. Moreover the metal is reactive towards nitrogen and oxygen at elevated temperatures, and hydrogen at 900 °C only reduces TiO_2 as far as Ti_3O_5. Reduction of the dioxide with most reducing metals, *e.g.* Na, Al, Ca or Mg, seldom seems to yield a pure product; the most common contaminants, and in some cases the principal products, are lower oxides of titanium. Reduction of the tetrachloride is, therefore, the basis of the preferred methods.

A successful laboratory method is reduction of the dioxide with an excess of calcium hydride in a molybdenum boat. The reaction is carried out at 900 °C in a vacuum or in an atmosphere of hydrogen[5] (equation 1). Most of the hydrogen present can be removed by heating the metal in a vacuum at 1100 °C.

$$TiO_2 + 2CaH_2 \longrightarrow Ti + 2CaO + 2H_2 \quad (1)$$

The first general method involved reduction of the tetrachloride with sodium (equation 2).[1]

The reaction, which is very exothermic, is carried out at 700–800 °C in a steel bomb under an inert atmosphere. The method, which requires very careful control of the temperature, is capable of yielding titanium with a purity of 99.9%. It is also possible to prepare the metal by hydrogen reduction[6] of the tetrachloride at approximately 2000 °C (equation 3). The difficulties of removing hydrogen from the metal, and the high temperatures required, make the method impracticable industrially.

$$TiCl_4 + 4Na \longrightarrow Ti + 4NaCl \quad (2)$$

$$TiCl_4 + 2H_2 \longrightarrow Ti + 4HCl \quad (3)$$

Another important way of producing the metal is the Kroll process, in which magnesium is the reducing agent (equation 4). The magnesium is contained in a molybdenum-coated iron crucible in an atmosphere of argon at 850–950 °C; the $TiCl_4$ is added drop by drop. Towards the end of the addition the temperature is slowly raised to a maximum of 1180 °C, *i.e.* to slightly above the boiling point of magnesium. After cooling the crucible in argon, the magnesium and magnesium chloride are extracted with water and dilute HCl; alternatively, these materials may be removed by volatilization above 1000 °C. The process is clearly expensive, because it involves the prior preparation of the tetrachloride from ilmenite or rutile, followed by fractionation of the $TiCl_4$ to remove any $FeCl_3$.

$$TiCl_4 + 2Mg \longrightarrow Ti + 2MgCl_2 \quad (4)$$

Extremely pure titanium can be made on the laboratory scale by the van Arkel–de Boer method[2] in which TiI_4[7] that has been carefully purified is vaporized and decomposed on a hot wire in a vacuum.[8]

31.1.3 Properties of the Metal

Titanium is dimorphic with a transformation temperature of 882 ± 5 °C. Below this temperature, the metal is hexagonal (D_{6h}—$6/mmc$, $Z = 2$)[4] with lattice parameters at 25 °C of $a = 2.9504$ Å and $c = 4.6833$ Å (α form).[4,9] The second (β) form is cubic (O_h—$Im3m$, $Z = 2$),[9] with the cell parameter[10] of 3.3065 Å at 900 °C. The two forms are isomorphous with the corresponding forms of zirconium.

Titanium is a silvery, ductile metal with important industrial uses because it is less dense than iron, much stronger than aluminum and almost as corrosion resistant as platinum. Although it is unlikely ever to be as inexpensive as steel, its rare combination of properties make it ideal for a variety of uses, particularly in engines, aircraft frames, some marine equipment, in industrial plants and in laboratory equipment. Certain properties may be improved by alloying it with aluminum.

The metal has an enormous affinity for dioxygen, dinitrogen and dihydrogen at elevated temperatures, but only in the case of dihydrogen is the absorption reversible. Moreover, titanium dust is explosive in air, and even the fresh surface of the metal will ignite spontaneously in dioxygen at 25 atm. Traces of oxygen or nitrogen render the metal very brittle and hence of little utility. The kinetics of oxidation of the metal in the range 850–1050 °C have been studied.[11] It is not attacked by mineral acids in the cold or by hot aqueous alkali, but dissolves in HF, hot HCl, hot HNO_3 and hot concentrated H_3PO_4. It reacts with many metals and non-metals forming intermetallic or interstitial compounds, *e.g.* with Al, Sb, Be, Cr, Fe and B.

31.1.3.1 Isotopes of titanium

Titanium has five naturally occurring isotopes with mass numbers ranging from 46 to 50; their percentage isotopic abundances are given in Table 1, with the atomic masses of the individual nucleides.

The atomic weight of titanium is 47.88 (IUPAC; 1971; based on $^{12}C = 12.000$) and was originally determined[12] by the ratio $TiCl_4/4Ag$ and $TiBr_4/4Ag$. Slight separation of the titanium isotopes is possible in the extraction of thiocyanic acid complexes of titanium by ether from aqueous sulfate solutions. The separation factors[13] are $^{50}Ti:^{48}Ti = 1.006$, $^{48}Ti:^{46}Ti = 1.008$ and $^{50}Ti:^{46}Ti = 1.014$.

Table 1 Nuclides of Titanium

31.1.4 General Properties of the Group IV Elements

Titanium is the first member of the 3*d* transition series and has four valence electrons, $3d^24s^2$. The most stable and most common oxidation state, +4, involves the loss of all these electrons. However, the element may also exist in a range of lower oxidation states, most importantly as Ti(III), (II), (0) and −(I). Zirconium shows a similar range of oxidation states, but the tervalent state is much less stable relative to the quadrivalent state than is the case with titanium. The chemistry of hafnium closely resembles that of zirconium; in fact, the two elements are amongst the most difficult to separate in the periodic table.

The ionization energies of the group IV elements are given in Table 2, together with the sum of the first four ionization energies in each case. There is a clear alternation in the ionization energies on passing down the group, this being associated with the alternation in the screening constants and hence the effective nuclear charges (Z^*) of the different atoms. In particular, the third member of a group (Ge in this case) first suffers the transition metal contraction associated with the poor screening of the underlying d^{10} shell, and the fifth member (Pb) first suffers the double contraction associated with the even poorer screening of the underlying f^{14} shell. Consequently, these elements have higher ionization energies than might otherwise have been expected. The elements in group IVA (Ti, Zr, Hf) have uniformly lower ionization energies than those of group IVB, and as a consequence it is believed that the former achieve high coordination numbers with greater facility than the latter. The radii of the elements show these alternations in inverse, as the ionization energy is inversely related to the radius.

Table 2 Ionization Energies (eV) of Group IV Elements[a]

	I_1	I_2	I_3	I_4	$\Sigma_1^4 I_n$
C	11.256	24.376	47.871	64.476	147.98
Si	8.149	16.34	33.46	45.13	103.8
Ge	7.88	15.94	34.21	45.7	103.72
Sn	7.342	14.628	30.49	40.72	93.18
Pb	7.415	15.028	31.93	42.31	96.68
Ti	6.82	13.57	27.47	43.24	91.10
Zr	6.84	13.13	22.98	34.33	77.28
Hf	7.00	14.90	23.20[b]	33.30[b]	78.40

The energy required for the removal of the four valence electrons of titanium is so high that the Ti^{IV} ion does not exist as such; nor do the Zr^{IV} and Hf^{IV} ions. Titanium(IV) compounds are, in general, covalent and bear some resemblance to the corresponding compounds of Si, Ge, Sn and Pb, especially Sn (partly because of the similarities between the ionic and covalent radii of Ti and Sn). For instance TiO_2 (rutile) is isomorphous with SnO_2 (cassiterite), and both become yellow on heating; both $TiCl_4$ and $SnCl_4$ are colourless, distillable liquids which are

rapidly hydrolyzed; both behave as Lewis acids, forming a wide variety of addition compounds. Both $SiCl_4$ and $GeCl_4$ are less powerful acceptor molecules than $TiCl_4$ and $SnCl_4$.

In the lower oxidation states the chemistry of titanium has little or no counterpart in the chemistries of the group IVB elements. The only lower oxidation state of these elements is two, for which the stability order is Ge < Sn < Pb. However, both zirconium(III) and hafnium(III) are similar to if less stable (towards oxidation) than titanium(III) and have comparable although less extensively investigated chemistries.

The most common coordination number of titanium is six (recognized for all oxidation states of the metal), although compounds are known in which the coordination number is four, five, seven or eight. The common oxidation states of titanium with the associated coordination numbers and stereochemistries are summarized in Table 3. The properties of these molecules will be discussed in the appropriate sections. In brief, however, titanium compounds in the +III or lower oxidation states are readily oxidized to the +IV state. Furthermore, titanium compounds can usually be hydrolyzed to compounds containing Ti—O linkages.

Table 3 Oxidation States and Stereochemistry of Titanium

Oxidation state	*Coordination number*	*Geometry*	*Examples*
Ti^{-I}	6	Octahedral	$[Ti(bipy)_3]^-$
Ti^0	6	Octahedral	$[Ti(bipy)_3]$
Ti^{II}, d^2	4	Dist. tetrahedral	$(\eta^5\text{-}C_5H_5)_2Ti(CO)_2$
	6	Octahedral	$TiCl_2$
Ti^{III}, d^1	3	Planar	$Ti\{N(SiMe_3)_2\}_3$
	5	Tbp	$TiBr_3(NMe_3)_2$
	6[a]	Octahedral	TiF_6^{3-}, $TiCl_3(THF)_3$
Ti^{IV}, d^0	4[a]	Tetrahedral	$TiCl_4$
		Dist. tetrahedral	$(\eta^5\text{-}C_5H_5)TiCl_2$
	5	Dist. tbp	$K_2Ti_2O_5$
		Square planar	TiO(porphyrin)
	6[a]	Octahedral	TiF_6^{2-}, $Ti(acac)_2Cl_2$
	7	ZrF_7^{3-} type	$[Ti(O_2)F_5]^{3-}$
		Pentagonal bipyramidal	$Ti_2(ox)_3 \cdot 10H_2O$
	8	Dist. dodecahedral	$TiCl_4(diars)_2$
			$Ti(S_2CNEt_2)_4$

[a] Most common state.

31.1.5 Sources of Information

The main source of information on titanium and its chemistry remains the important review by Clark.[14] References to phosphine and analogous complexes are contained in volumes by McAuliffe and Levason,[15–17] and the update reviews which appear from time to time in *Coordinated Chemistry Reviews*.[18–21] In order to minimize the number of references quoted, much of the early chemistry is referred to in these review sources.

31.2 NIROGEN LIGANDS

31.2.1 Low Valent Titanium Complexes

Although the coordination chemistry of titanium(IV), and to a much lesser extent titanium(III), has been investigated relatively well, few complexes are known in the lower oxidation states −II, −I, O, +I, +II, and all are almost invariably unstable to oxidation.[14,22] Reduction of $TiCl_4$ with excess of dilithium 2,2′-bipyridyl in THF with excess bipyridyl gives $Li[Ti(bipy)_3]\cdot 3.7THF$, as shown in equations (5) and (6). Further reduction to $Li_2[Ti(bipy)_3]\cdot 5.7$ is possible.[14]

$$TiCl_4 + 2Li_2bipy + bipy \xrightarrow{THF} [Ti(bipy)_3] + 4LiCl \quad (5)$$

$$TiCl_4 + 2.5Li_2bipy + 0.5bipy \xrightarrow{THF} Li[Ti(bipy)_3]\cdot 3.7THF + 4LiCl \quad (6)$$

The titanium(II) complexes are somewhat better understood. The deeply coloured $TiX_2(MeCN)_2$ (X = Cl, Br) complexes react with other ligands to yield $TiCl_2L_2$ (L = C_4H_8O, $C_5H_{10}O$, py, $\frac{1}{2}$bipy, $\frac{1}{2}$phen) and $TiBr_2$(bipy), the new species reacting with water to liberate dihydrogen.[23] Reaction of Na_2TiCl_4 with NMe_3 results in oxidation of the halide and the formation of $TiCl_3(NMe_3)_2$.[24] Dialkylamides of titanium(II) have been prepared[25] by the volatility-controlled disproportionation, as shown in equation (7).

$$2Ti^{III} \rightleftharpoons Ti^{II} + Ti^{IV} \quad (7)$$

31.2.2 Titanium(III) Complexes

31.2.2.1 Monodentate ligands

Compounds of many stoichiometries are known, *e.g.* $[TiL_6]^{3+}$, $[ML_4X_3]$ and $[ML_2X_4]^-$. A survey of the range of these compounds and their electronic spectral and magnetic properties is given in Clark's review.[14] Fowles *et al.* have isolated a range of titanium(III) iodide species: TiI_3L_2 (L = NMe_3, α-picoline), TiI_3L_3 (L = py, α-picoline) and $TiI_3(MeCN)_4$, the last being assigned the formula $[TiI_2(MeCN)_4]I$. The magnetic properties of $TiBr_3(NMe_3)_2$[7] and its single crystal X-ray structure have been studied,[28] the latter showing it to be monomeric and basically trigonal bipyramidal. It is possible to use electronic spectroscopy to distinguish the pentacoordinate MX_3L_2 (L = NMe_3, α-picoline) species from the hexacoordinate MX_3L_3 species, since the former have characteristic absorption bands in the near-IR,[29] whereas ESR spectroscopy has been used to show that the $TiCl_3(py)_2$ complex is dimeric and hexacoordinate *via* chloro bridges in pyridine at 77 K.[30]

The reactive Ti^{III}—N complexes of the dialkylamides are useful synthetic reagents, readily reacting with protic reagents such as alcohols (to give alkoxides), unsaturated compounds such as isocyanates to yield ureido derivatives, or metal hydrides to give Ti—M-bonded compounds.[25] Rare three-coordination occurs in $Ti\{N(SiMe_3)_2\}_3$.[31] The He PE spectra of a number of three-coordinate metal amides $M\{N(SiMe_3)_2\}_3$ (M = Sc, Ti, Cr, Fe, Ga, In) show that, whereas the d^0 scandium compound exhibits two bands at IE < 9 eV (assigned to lone-pair orbitals), the spectra of the open-shell compounds are very similar, and it was concluded that bands corresponding to ionization from the metal 3*d* orbitals lie at IE > 9 eV, or are masked by bands due to ionization from nitrogen lone-pair orbitals (>8.1 eV). This was attributed to the strong −I effect of the ligand which, in contrast to compounds of the type $V(NMe_2)_4$, is not counterbalanced by an $\ddot{N}$—M π interaction because of strong competing $\ddot{N}$—Si ($p \rightarrow d$) π bonding.

31.2.2.2 Bidentate and polydentate ligands

The blue en and pn complexes have the formula $[Ti(ligand)_3]^{3+}$, whereas for bipy and phen $[TiCl_2(ligand)_2][TiCl_4(ligand)]$ salts are obtained;[14] the salts $[TiI_2(phen)_2]I$ and $[TiI_2(bipy)_2][TiI_4(bipy)]$ are also known.[26] Whereas most transition metal complexes of tris(2-dimethylaminoethyl)amine (Me_6tren) normally involve all four nitrogens coordinated, in $TiCl_3(Me_6tren)$ only three amines are bound. With terpy all three nitrogens are bound in the octahedral monomeric $TiCl_3$(terpy).[22]

31.2.3 Magnetic Properties of Titanium(III) Complexes

Nearly all titanium(III) complexes exhibit room temperature magnetic moments close to 1.73 BM, and at lower temperatures the fall in value is related not only to the temperature but also to the asymmetry of the ligand field.[14,22,27] Most complexes contain a ground term $^2T_{2g}$ split by ~500 cm^{-1}; the orbital angular momentum is reduced by a factor *k*, which is usually 0.65–0.95. The ESR signals of titanium(III) complexes are almost invariably near the spin-only value of 2.0023.[14,30]

31.2.4 Titanium(IV) Complexes

31.2.4.1 Monodentate ligands

There are a large number of complexes TiX_4 with monodentate nitrogen ligands. For TiF_4 both 1:2 and 1:1 complexes are known, the former being pseudooctahedral and the latter, because of the high Ti—F bond strength, are fluoro-bridge polymers.[14] With $TiCl_4$ and $TiBr_4$ six-coordinate monomers are the commonest adducts, *viz.* TiX_4L_2. The area has been well reviewed.[14] However, reactions between $TiCl_4$ and amines can, unlike reaction with oxygen donor ligands, give rise to $TiCl_3$ derivatives.[14]

More recent work will be described here. Adducts of $TiOCl_2$ with MeCN and NMe_3, for example, form $TiOCl_2L_2$, but with py the adduct $TiOCl_2py_{2.5}$ forms. Only in the case of $TiOCl_2(\alpha\text{-pic})_2$ and $TiOCl_2(NMe_3)_2$ do IR spectra indicate the presence of a terminal Ti=O moiety (978 cm^{-1}), the other complexes presumably having a Ti—O—Ti bridge (*ca.* 890 cm^{-1}), the other complexes presumably having a Ti—O—Ti bridge (*ca.* 890 cm^{-1}). The potentially bidentate *o*-allylaniline complexes only *via* the nitrogen in TiX_4L (X = Cl, Br) to form pentacoordinate monomers; the hexacoordinate $TiBr_4L_2$ is also known.[37]

Titanium(IV) chloride and bromide form $TiX_4(Me_2C{=}N{-}N{=}CMe_2)_2$ in the presence of excess of acetone azine, but when the halides are in excess the products formed are $(TiCl_4)_4(ligand)_3$ and $TiBr_4(ligand)$.[38] Stable azides $[Ti(OPr^i)_2(N_3)_2]$ and $[TiCl(OPr^i)_2(N_3)]$ complexes are known; the azido group can be displaced by reaction with protic reagents and HN_3 is eliminated. The complexes also react with phosphines to form phosphiniminato complexes with N_2 elimination.[39] Mono- and bis-azido complexes have been prepared as shown in equations (8) and (9).[39]

$$[TiCl(OCHMe_2)_3] + Me_3Si(N_3) \longrightarrow [TiCl(OCH_2Me_2)_2(N_3)] + Me_3SiOCHMe_2 \quad (8)$$

$$[TiCl(OCHMe_2)_3] + 2Me_3Si(N_3) \longrightarrow [Ti(OCH_2Me_2)_2(N_3)_2] + Me_3SiOCHMe_2 + Me_3SiCl \quad (9)$$

An X-ray study of $[TiCl_4(N_3)_2]^{2-}$ reveals that the azide groups occupy *trans* positions.[40]

Electrolytic reduction of $TiCl_4$ in the presence of N_2 in DMSO produces a $1:1TiCl_3:N_2$ complex.[41] Two previously reported products from $[ReCl(N_2)(PPhMe_2)_4]$ and $TiCl_3$ have been shown to be derived from $TiCl_4$. $[\{ReCl(N_2)(PPhMe_2)_4\}_2TiCl_4]$ and $[\{ReCl(N_2)(PPhMe_2)_4\}$-$TiCl_4(THF)]$ can be obtained from $TiCl_4$, the former being the first fully characterized example of a trinuclear complex containing two bridging dinitrogen ligands. Titanium tetrachloride in excess reacts with $[ReCl(N_2)(PPhMe_2)_4]$ in Et_2O to yield $[\{ReCl(N_2)PPhMe_2)_4\}(Ti_2Cl_6O)(Et_2O)]$, which exhibits a very low $\nu(N_2)$ at 1622 cm^{-1}.[42]

The X-ray crystal structure of the product of the reaction of $TiCl_4$ with $N(SiMe_3)_3$ shows it to contain planar four-membered $(Ti{-}N)_2$ rings with planar geometry at N apparently with considerable π bonding in the rings. These are linked by chlorine bridges to give five-coordinate Ti atoms in approximately trigonal bipyramidal geometry.[43] The reaction of $TiCl_4$ with an excess of $Li[N(SiMe_3)_2]$ yields $[TiCl\{N(SiMe_3)_2\}_3]$. The resistance to complete chlorine substitution suggests considerable steric crowding due to the bulky $[N(SiMe_3)_2]^-$ ligands. Both X-ray crystallography and ^1H NMR spectroscopy confirm this premise. In the solid state $[TiCl\{N(SiMe_3)_2\}_3]$ has crystallographically imposed C_3 symmetry and a distorted tetrahedral geometry. The ^1H NMR spectrum, which exhibits two equally intense resonances below the coalescence temperature of 34 °C, has been interpreted in terms of restricted rotation about the Ti—N bonds. At low temperatures the three silylamide ligands remain equivalent, but the $SiMe_3$ groups proximal and distal to chlorine are non-equivalent.[44]

The TiF_4 and Pr^i_2NH, Et_2NH, py or NMe_3 systems have been shown to be quite complex by Drago and coworkers.[45] For example, in TiF_4-rich solutions in acetone, high conductance has been explained by equation (10).

$$3TiF_4 + R_2NH \longrightarrow TiF_3(R_2NH)^+ + Ti_2F_9^- \quad (10)$$

31.2.4.2 Bidentate and polydentate ligands

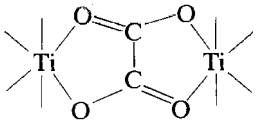
A number of dinitrile ligands (succinonitrile, glutaronitrile, adiponitrile) form $TiCl_4(ligand)$ complexes in which the nitriles bridge two titanium atoms.[46] Reactions of $CH_2(NMe_2)_2$ or $SiMe_2(NMe_2)_2$ with $TiCl_4$ give both chelated $TiCl_4(ligand)$ complexes and $TiCl_3(NMe_2)$ species.[47]

The five-coordinate *meso*-tetraphenylporphyrinato complex [TiF(TPP)] has been synthesized

by reduction of $[TiF_2(TPP)]$ with zinc amalgam. Electrochemical reduction of $[TiF_2(TPP)]^-$, or chemical reduction with sodium anthracenide, gives $[TiF_2(TPP)]^-$. Consistent with its coordinative unsaturation, [TiF(TPP)] adds ligands L (L = THF, PBu_3, pyridine, *N*-methylimidazole, or *N*-methylpyrrolidone) yielding [TiF(L)(TPP)], and adds F^- affording $[TiF_2(TPP)]^-$. All these Ti^{III} complexes have been characterized in solution by EPR spectroscopy; the unpaired electron is believed to reside in the $3d_{xy}$ orbital. Oxidation of [TiF(TPP)] yields a mixture of $[TiF_2(TPP)]$ and the peroxo complex $[Ti(O_2)(TPP)]$. EPR evidence suggests that this reaction proceeds *via* the dioxygen adduct $[TiF(O_2)(TPP)]$, as shown in equations (11) and (12), a species which could be formulated as a superoxotitanium(IV) complex but which appears to have a significant amount of peroxo porphyrin cation radical titanium(IV) character.[48]

$$[TiF(TPP)] + O_2 \rightleftharpoons [TiF(O_2)(TPP)] \quad (11)$$

$$[TiF(TPP)] + [TiF(O_2)(TPP)] \longrightarrow [TiF_2(TPP)] + [Ti(O_2)TPP)] \quad (12)$$



31.3 OXYGEN LIGANDS

31.3.1 Titanium(III) Complexes

31.3.1.1 Electronic spectra

As pointed out by Clark, the $Ti(H_2O)_6^{3+}$ ion has an important historical connection with ligand field theory. In a perfect octahedral field of O_h symmetry, the ^2D ground term of titanium(III) is split into a lower $^2T_{2g}$ term and an upper ^2E_g term. The broad, quite asymmetric band at *ca.* 20 100 cm^{-1} in the visible spectrum of $Ti(H_2O)_6^{3+}$ arises from the $^2E_g \leftarrow {}^2T_{2g}$ transition. The energy of this transition for a complex is a direct measure of the ligand field strength. The splitting of the ^2E_g term is a consequence of the Jahn–Teller effect.

Table 4 is a compilation of some spectral parameters for six-coordinate titanium(III) complexes. There are only a few TiL_6^{3+} complexes of neutral oxygen donor ligands. Addition of chloride to the purple $Ti(H_2O)_6^{3+}$ solution in water causes a continuous shift of the $^2E_g \leftarrow {}^2T_{2g}$ band to lower energy, from 20 100 to almost 14 500 cm^{-1} and probably reflects the formation of such species as $[TiCl(H_2O)_5]^{2+}$, $[TiCl_2(H_2O)_4]^+$, $[TiCl_3(H_2O)_3]$, *etc.* Moreover, the electronic spectra can give a hint to quite subtle structural information. This is illustrated for the compound $NH_4Ti(C_2O_4)_2{\cdot}2H_2O$ which exhibits the $^2E \leftarrow {}^2T_g$ band at 12 800 cm^{-1}, pointing to a weak ligand field generated by bridging oxalate groups, (**1**).[49]

(**1**)

Early workers assumed that alcohol ligands formed $[TiL_6]Cl_3$ complexes, analogous to the hexaaqua species. However, electronic spectra have pointed to these complexes as being of the type $[TiCl_2L_4]Cl$ (Table 4). For THF, dioxane, DMF, MeCN and some other nitrogen ligands the $[TiL_3Cl_3]$ complexes are known, but all of these are very unstable to oxidation.

31.3.1.2 Monodentate and bidentate ligands

Apart from the early interest in monodentate oxygen donors most subsequent work has been with bidentate systems, particularly the oxalates. However, one TiO_6^{3+} system which has been studied is $[Ti(urea)_6]I_3$, the structure having rigorous D_3 point symmetry and essentially linear arrays of iodide ions parallel to the crystallographic threefold axis. The Ti—O distance is 2.014 Å, and there are significant distortions of the coordination polyhedron from the idealized O_h symmetry and from the D_{3d} model often assumed for trigonally distorted octahedral complexes. The three O—Ti—O angles are 90.5, 86.4 and 92.8·. The stability of this compound to aerial oxidation apparently arises from intramolecular hydrogen bonding involving the urea molecules and also hydrogen bonds involving the iodide ions.[50]

Fowles and co-workers have investigated the complexes $KTi(ox)_2{\cdot}2H_2O$, $NH_4Ti(ox)_2{\cdot}2H_2O$

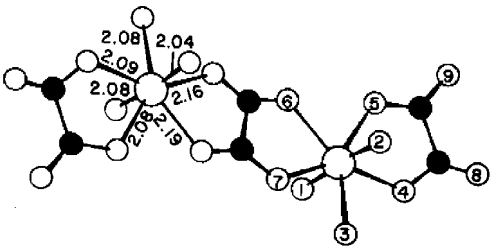


Table 4 Electronic Spectra of Six-coordinate Titanium(III) Complexes

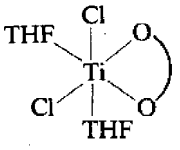
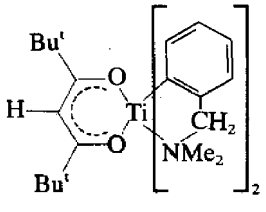
and $Ti_2(ox)_3 \cdot 10H_2O$ (ox = oxalate).[51] The crystal structure of the decahydrate, (**2**), contains a centrosymmetric dimer $Ti_2(ox)_3(H_2O)_6$ and also four non-bonded water molecules. Each metal atom is a seven-coordinate pentagonal bipyramid with two molecules in axial positions and one in an equatorial plane, together with one bridging and one non-bridging oxalate ligand. Further work on the anionic oxalato complexes of titanium(III) has led to the isolation of $Cs[Ti(ox)_2(H_2O)_3] \cdot 2H_2O$, which contains a discrete anion involving again a pentagonal bipyramidal seven-coordinate titanium atom with two non-bridging oxalate chelating ligands in the equatorial plane and the three water molecules occupying the remaining equatorial site and the axial site.[52] Although good crystallographic data are not available for the $K[Ti(ox)_2] \cdot 2H_2O$ complex, an eight-coordination sphere has been proposed, (**3**). Magnetic measurements indicate, not surprisingly, that the bridging oxalate provides an effective path for magnetic exchange between the two titanium(III) atoms; for example in $Ti_2(ox)_3 \cdot 6H_2O$ the intramolecular exchange parameter is rather large, $J = -60\ cm^{-1}$.[54]



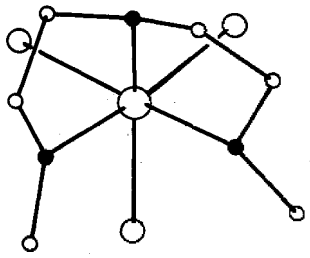
(**2**)



(**3**) Proposed structure for $[Ti(ox)_2]_n^{n-}$; ○ Ti; ○ Oxygen; ● Carbon.

Reaction of $TiCl_3(THF)_3$ with β-diketones gives the deeply coloured Ti(diketonate)$Cl_2(THF)_2$, the ESR spectra of which suggests structure (**4**).[55,56] These complexes react with $LiC_6H_4CH_2NMe_2$, $LiCH_2C_6H_4NMe_2$ and $LiN(SiMe_3)_2$ to give novel air-sensitive organometallic compounds, *e.g.* (**5**).[56] The coordinated THF may readily be displaced by neutral ligands such as PMe_3 or bipy. Magnetic susceptibility measurements on $TiCl_3(THF)_3$ and its thermal decomposition products $TiCl_3(THF)_2$ and $TiCl_3(THF)$ are consistent with monomeric structures for the first two compounds and a polymeric species for $TiCl_3(THF)$.[57]

(**4**)



(**5**)

Polymeric Ti(ligand)$_3$ complexes of diisopropyl phosphate (dipp) and di-*n*-propyl phosphate (dnpp) have been compared to assess steric and inductive effects of alkyl substituents on the strength of the M—O bond in metal complexes with organophosphate ligands. In comparison with the dnpp complex, Ti(dipp)$_3$ exhibits a lower ν(Ti—O), lower ligand field parameters and a higher magnetic moment. These data point to a weaker Ti—O bond in the dipp complex, which is attributable to the steric effect of the $CHMe_2$ substituents, since inductive effects of $CHMe_2$ and Pr groups are about the same. These complexes may have a linear, chain-like, triply bridged $+M(OP(R)_2O_3+_n$ structure.[58]

The tridentate ether ligand diglyme forms $[TiCl_3\{O(CH_2CH_2OMe)_2\}]$ and crystals contain two molecules in the asymmetric unit. In both, the titanium(III) atoms are six-coordinate with a *fac* arrangement of ligands. The metals are bonded to three chlorine atoms (2.31–2.35 Å)

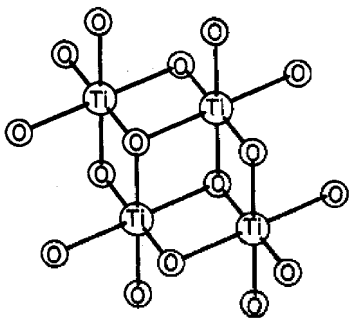
and to the three oxygen atoms of the trioxanonane ligand (2.115–2.182 Å) and the ligand conformation differs in the two molecules, being $\delta\delta$ in one and $\delta\lambda$ in the other, (**6**).[59]

(6)

31.3.2 Titanium(IV) Complexes

31.3.2.1 Monodentate ligands

(*i*) *Alkoxides*



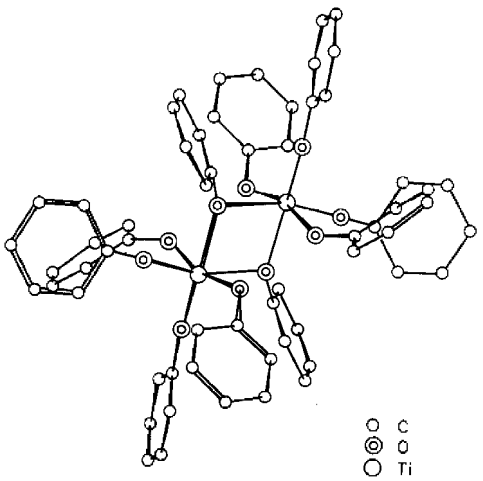
Perhaps the best studied group of titanium(IV) complexes is the alkoxides. The metal alkoxides generally have received a great deal of attention because of their ease of hydrolysis and reactivity with hydroxylic molecules, and their tendency to increase the coordination number of the metal which is opposed by the steric effect of the alkyl group. These properties result in materials, the characteristics of which range from polymeric solids to volatile liquids. The definitive review of this area is that by Bradley.[60]

The original method of preparation involved reaction of the sodium alkoxide and titanium tetrachloride in the appropriate alcohol, as shown by equation (13). However, this is slow and only works for those alcohols which readily form sodium alkoxides. An improved method is shown by equation (14). If a proton-accepting reagent, such as ammonia, is not employed, however, the reaction proceeds only as far as the $TiCl_2(OR)_2$ derivative.

$$TiCl_4 + 4NaOR \longrightarrow Ti(OR)_4 + 4NaCl \quad (13)$$

$$TiCl_4 + 4ROH + 4NH_3 \longrightarrow Ti(OR)_4 + 4NH_4Cl \quad (14)$$

Compounds such as $Ti(OMe)_4$ are usually insoluble polymers, although a soluble tetramer has been isolated, $[Ti(OMe)_4]_4$ (**7**). This complex has the same M_4O_{16} framework as $Ti_4(OEt)_{16}$ and $Ti_4(OMe)_4(OEt)_{12}$. All of these frameworks are centrosymmetric and contain six-coordinate titanium in a group of four edge-sharing octahedra. Each tetrameric unit contains two triply bridging (Ti_3OR), four doubly bridging (Ti_2OR) and ten terminal alkoxy groups. There are two types of Ti atoms: two are coordinated by three bridging and three terminal oxygens and two are coordinated by two bridging and two terminal oxygens. Bradley[60] had discussed the contributions from σ and π bonding in this complex. There is another form of $Ti(OMe)_4$, which is more insoluble and has a different X-ray powder diffraction pattern from the tetramer.[61] Moreover, there are quite large differences in the IR spectra of both species. The insoluble form may well contain no triply bridged OMe groups and thus, of necessity, be more polymeric in nature.



(7)

For $Ti(OEt)_4$ the same tetrameric structure obtains in the solid state. The Ti—O bond lengths reflect the nature of the coordinated oxygen atom, *viz.* Ti_3OEt (2.23 Å), Ti_2OEt (2.03 Å), TiOEt (1.77 Å). This compound is very soluble in organic solvents and may be initially obtained as a supercooled liquid by vacuum distillation. However, over some months of standing at room temperature it solidifies to the tetrameric form. In solution it is probably predominantly trimeric. From ebullioscopic molecular weight measurements a whole series $[Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}]$ $(x = 1, 2, \ldots, \infty)$ has been postulated for the hydrolysis products of $Ti_3(OEt)_{12}$. From solution, crystalline $[Ti_6O_4(OEt)_{16}]$ (*i.e.* $x = 1$) has been obtained.

As mentioned above, the ability of $TiCl_{4-n}(OR)_n$ to function as a Lewis acid decreases as n increases. Few adduct complexes of $Ti(OR)_4$ are known, although $Ti_2(OEt)_8$·en, $Ti_2(OPr^i)_8$·en and $Ti(OPr^i)_4$·en have been reported,[14] but these complexes almost completely dissociate in solution. However, $Ti(OPh)_4$ readily forms 1:1 adducts with PhOH, NH_3, NH_2Me, $NHMe_2$, NMe_3, py, dioxane, $PhNH_2$, Me_2CO. These complexes have been the subject of a review.[62] The difference in the behaviour of the $Ti(OPh)_4$ to the $Ti(OR)_4$ (R = Me, Et) towards Lewis bases is undoubtedly related to the monomeric, and thus the coordinatively unsaturated, nature of the phenoxides in solution.

A range of $TiX_{4-n}(OR)_n$ (R = alkyl, cycloalkyl, alkenyl, aryl; X = halogen; $n = 1, 2, 3$) are known and are best prepared by the direct reaction of the $Ti(OR)_4$ complex with the correct molar ratio of the TiX_4 salt in an inert solvent such as benzene. The nature of the complexes depends upon the degree of replacement of the alkoxy groups by the halide, *e.g.* $[TiCl_3(OBu)_3]_3$, $[TiCl_2(OBu)_2]_2$ and $[TiCl_3(OBu)]$. Both $TiCl_2(OPh)_2$ and $TiCl_2(OEt)_2$ have been shown by X-ray crystallography to be trigonal bipyramidal *via* alkoxy bridges in the solid state, the former having Ti—O_t (1.744 Å), Ti—O_{br} (1.910, 2.122 Å), Ti—Cl (2.209, 2.219 Å)[63] and the latter Ti—O_t (1.77 Å), Ti—O_{br} (1.96 A) and Ti—Cl (2.19, 2.20 Å).[64] Variable temperature ^{13}C NMR studies of $Ti(OR)_4$ (R = Et, Pr^n, Bu^n, Pr^i, Bu^i, Bu^t) suggest the coexistence of trimers and trimer aggregates for the straight chain alkoxides, and monomer–dimer–trimer equilibria for the branched chain derivatives.[65] Recently, $[Ti(Cp)(OPh)_3]$ and $[Ti(Cp)(OPh)_2Cl]$ have been reported.[66] The X-ray crystal structure of $Ti(OPh)_4$·HOPh reveals it to be a dimer of octahedrally coordinated alkoxytitanium molecules (**8**).[67]

(**8**) A view of the dimer projected along the *a* axis

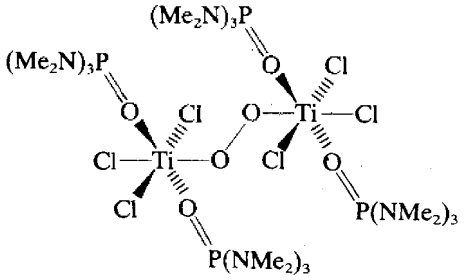
There have been very few reports of alkoxy complexes derived from unsaturated alcohols. A vinoxytitanium derivative can be obtained from the reaction of tetraisopropoxytitanium and acetaldehyde (equation 15).[68] More recently, the dimer $[Ti(OCH_2CHCH_2)_4]_2$ has been isolated from reaction (16).[69]

$$Ti(OCHMe_2)_4 + 2MeCHO \longrightarrow Ti(OCHCH_2)_2(OCHMe_2)_2 + 2Me_2CHOH \quad (15)$$

$$Ti(OCH_2Me)_4 + 4CH_2CHCH_2OH \longrightarrow Ti(OCH_2CHCH_2)_4 + 4Me_2CHOH \quad (16)$$

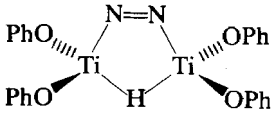
(*ii*) *Other monodentate ligands*

Titanium tetrachloride reacts with trimethylsilanol in the presence of ammonia (equation 17). This complex is a colourless liquid, and the method can be used to produce complexes of



the general type $Ti(OSiR_3)_4$ and $Ti(OSiR_nR'_{3-n})_4$. These complexes have received particular attention because the products of their hydrolysis have potential as polymers.[70]

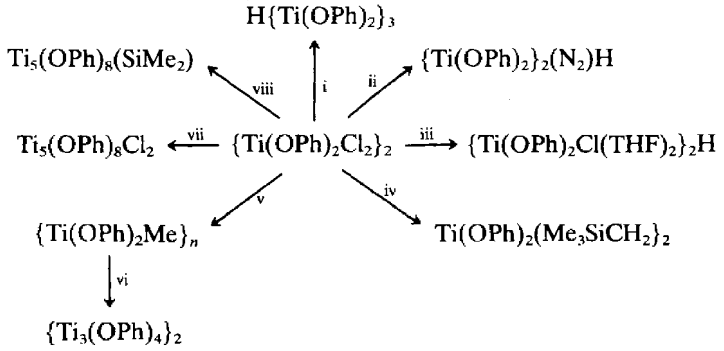
$$TiCl_4 + 4Me_3SiOH + 4NH_3 \longrightarrow Ti(OSiMe_3)_4 + 4NH_4Cl \quad (17)$$



The fact that trifluoromethanesulfonic acid is known to liberate HCl from sodium chloride suggested the reaction of CF_3SO_3H with $TiCl_4$. At 25 °C this results in the formation of a hygroscopic lemon yellow solid $TiCl_3(SO_3CF_3)$. On heating *in vacuo* above 60 °C this complex decomposes, as shown by equation (18), giving another lemon yellow solid which may also be prepared by the reaction of $TiCl_4$ with excess CF_3SO_3H at 25 °C.[71] No higher trifluoromethanesulfonate was isolated. Complexes containing the 2,2,2-trifluoroethoxy, $OCH_2CF_3(OR_f)$ are known, *viz.* $TiCl_2(OR_f)_2$, $TiCl(OR_f)_3$, $Ti(OPr_f)(OR_f)_2$ and $Ti(OPr^i)_3(OR_f)$.[72]

$$2TiCl_3(SO_3CF_3) \longrightarrow TiCl_4 + TiCl_2(SO_3CF_3)_2 \quad (18)$$

Reaction of a purple suspension of $TiCl_3$ in THF with two mol equivalent of HMPA (HMPA = hexamethylphosphoramide) under argon resulted in the formation of a turquoise suspension attributed to $TiCl_3(HMPA)_2$. This suspension was stable to argon, but exposure to air or dioxygen caused the formation of a crystalline yellow solid, (**9**). This contains Ti^{IV}, and a Raman band at 970 cm^{-1} is assigned to the O—O stretch.[73]



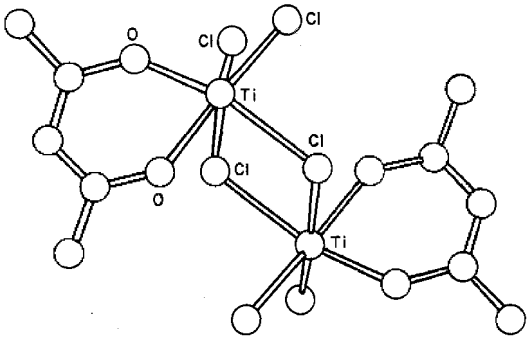
(**9**)

(**10**)

Before leaving this section some special mention should be made of the interesting chemistry developed by Cole-Hamilton and Wilkinson on dichlorodiphenoxotitanium(IV) (Scheme 1),[74] and interesting compounds such as (**10**) were isolated.

Reactions of $(Ti(OPh)_3Cl_2)_2$ i, 2 g-atom of K under argon, toluene, 25 °C; ii, excess of Na/Hg under N_2, THF 25 °C; iii, excess of $NaBH_4$, THF, 25 °C. iv, $(Me_3SiCH_2)_2Mg$, diethyl ether, −10 °C. v, Me_3Mg, diethyl ether, −30 °C. vi, Warm to 25 °C. vii, excess of Zn, toluene, 25 °C. viii, 2 mole equiv. $LiN(SiMe_3)_2$, petroleum, 25 °C.

Scheme 1



31.3.2.2 Bidentate ligands

By far the greatest number of reports have been on the β-diketonate (LH = β-diketone) complexes, and these provide a large series of types TiX_3L, $TiX_4(LH)$, TiX_2L_2, $[TiL_3]^+$, TiOXL, $[TiOL]_2$ (see Table 5 and structures **11**–**15**).

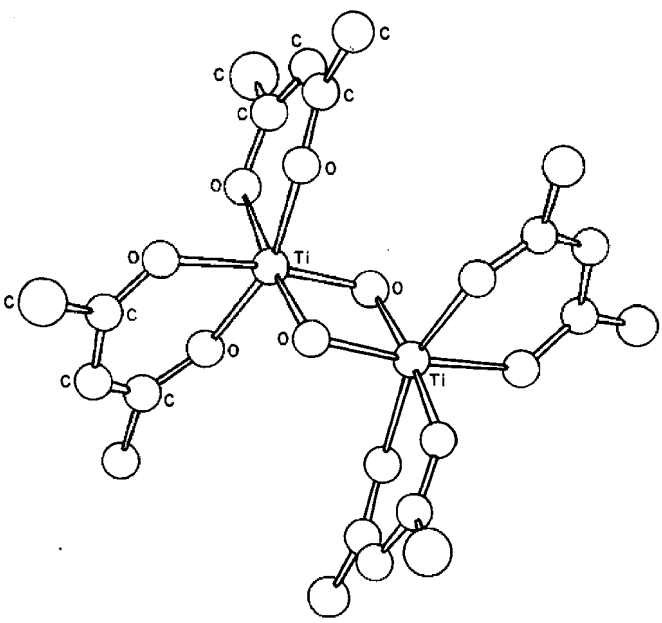
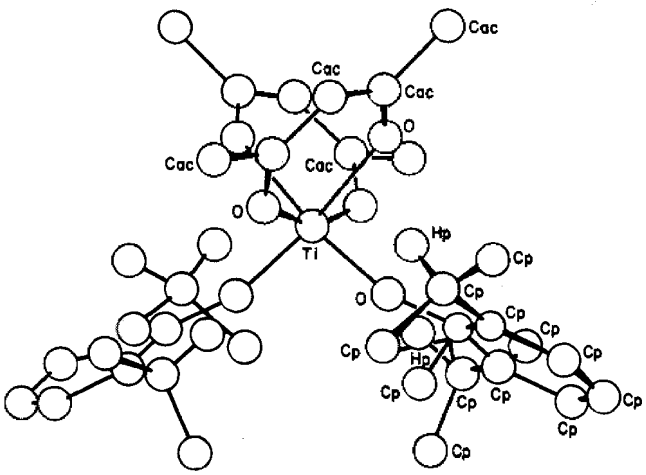
(**11**) $TiCl_3(C_5H_7O_2)$

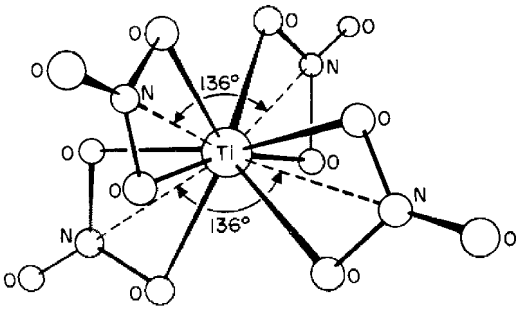


(**12**) $TiCl_3(acac)$

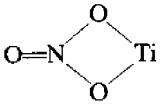


Both bis-oxalato, $[TiO(ox)_2]$,[75] and tris-oxalato, $[Ti(ox)_3]^{2-}$,[76] complexes are known. It is also observed that 1,2-dimethoxyethane (DME) forms chelates $TiX_4(DME)$ (X = F, Cl).[77] The nitrate group is also bidentate in anhydrous $Ti(NO_3)_4$. This complex crystallizes with four $Ti(NO_3)_4$ in each monoclinic unit cell of dimensions $a = 7.80$, $b = 13.57$, $c = 10.34$ Å, $\beta = 125.0°$, and space group $P2_1/c$. The structure, (**16**), consists of individual molecules in each of which four symmetrically bidentate nitrato groups are arranged according to D_{2d} symmetry

(13) $\{TiCl(acac)_2\}_2O$



(14)



(15)

in a flattened tetrahedral manner round the central titanium atom.[78] The dimensions of the nitrato groups differ considerably from those of a typical nitrate ion, having average N—O distances of 1.292 Å for bonds adjacent to the titanium atom and 1.185 Å for the outer bonds. These indicate a high contribution of the bond structure (**17**) to the resonance form of the molecule, consistent with the unusually high IR stretching frequency, 1635 cm^{-1}.

The reaction of titanium(IV) alkoxides with 2-methyl-2,4-pentanedione, pyrocatechol, salicyclic acid or *P,P'*-diphenylmethylenediphosphinic acid (LH_2) yields chelates of type $Ti(OR)_2L$ (R = Et, Pr^i), but instead $Ti(OC_3H_6O)_2$ and $Ti(OR)_4$ are recovered. Replacement of the alkoxy groups in the pyrocatecholate derivatives gives the monomeric $Ti(o\text{-}C_6H_4O_2)(C_5H_7O_2)_2$.[79] The potentially bidentate but-3-en-1-ol forms $TiCl_3(OCH_2CH_2CHCH_2)$, which probably does not contain a Ti–alkene bond. With $TiCl_4$ and 4-methyoxybut-1-ene, a chloride-bridged dimer containing six-coordinate titanium, $[TiCl_4(MeOCH_2CH_2CHCH_2)]_2$, forms.

(16)

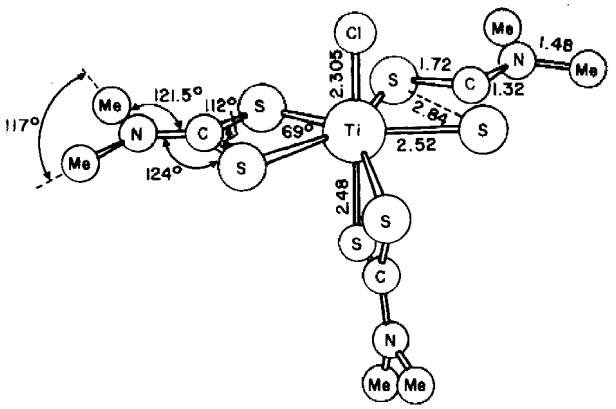
(17)

31.4 SULFUR LIGANDS

31.4.1 Neutral Donors

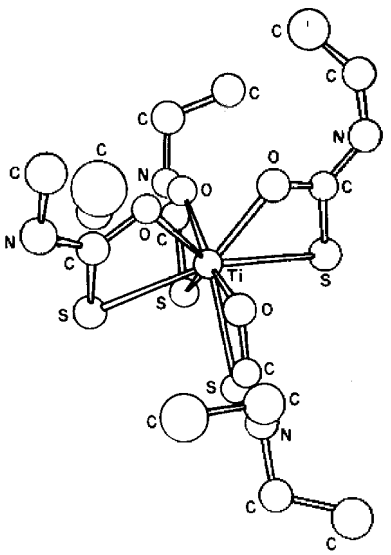
Sulfur complexes of titanium have been only poorly investigated but, nonetheless, there has been some interest in this area. Titanium(IV) must definitely be predicted to be a 'hard' acid, whereas titanium(III) might be expected to show intermediate 'hard/soft' behaviour. However, contrary to expectation, titanium(IV) has been shown to prefer sulfur to oxygen as a donor atom as evidenced by the existence of the Ti—S bonds in the 1,4-thiozen complexes $TiX_4(C_4H_8OS)_2$.[81] Indeed, titanium(IV) halides form stable adducts with a variety of thioethers. Even more puzzling is the fact that this ligand is both sulfur- and oxygen-bound in the titanium(III) derivative $TiCl_3(C_4H_8OS)_x$.[82] Titanium(III) halides also form 1:2 adducts with dimethyl sulfide and tetrahydrothiophene, TiX_3L_2. The chloro complexes are probably dimeric with a direct Ti—Ti bond, whereas the bromo and iodo derivatives are likely to be six-coordinate halogen-bridged dimers.[81] The bidentate 1,2-dimethylthioethane, 1,2-diethylthioethane, 1,2-diphenylthioethane and *cis*-dimethylthiomaleonitrile yield 1:1 adducts TiX_4L (X = Cl, Br).[83]

31.4.2 Anionic Ligands



Attempts to prepare mercaptide complexes of $TiCl_4$ by the use of either thiol and ammonia or sodium mercaptide have not proved successful (equation 19). However, by employing titanium dialkylamides as precursors substitution did occur (equation 20). The insoluble, non-volatile tetramercaptides usually had weakly bound thiol or amine associated with them, *viz.* $Ti(SR')_4{\cdot}(R'SH)_x(R_2NH)_y$. The tetramercaptides are thought to be six-coordinate polymers *via* mercaptide bridges. More controlled addition of ethanethiol or 1-methylethanethiol to $Ti(NR)_4$ gave soluble compounds, *e.g.* $Ti(NMe_2)_3(SEt)$, $Ti(NMe_2)_2(SEt)_2$, $Ti(NMe_2)_3(SPr^i)$ and $Ti(NMe_2)_2(SPr^i)_2$.[84] Titanium tetrachloride reacts with difluorodithiophosphinic acid to give $TiCl_3(S_2PF_2)$ + HCl, but no $TiCl_2(S_2PF_2)_2$ could be isolated.[85]

$$TiCl_4 + 4RSH + 4NH_3 \longrightarrow Ti(SR)_4 + 4NH_4Cl \quad (19)$$



$$Ti(NR_2)_4 + 4RSH \longrightarrow Ti(SR')_4 + 4R_2NH \ (R = Me, Et, Pr^i, R' = Me, Et) \quad (20)$$

There has been tremendous interest in metal complexes of 1,2-dithiolenes[86] and 1,1-dithiolato[87] complexes, arising from both their industrial applications and the bonding in the complexes. The interest in dialkyldithiocarbamate complexes of titanium(IV) was initially because X-ray analysis of $Ti(S_2CNEt_2)_4$ showed it to contain discrete eight-coordinate (dodecahedral) molecules.[88] However, even seven-coordination has been shown[89] to exist in $TiCl(S_2CNMe_2)_3$. Prior to this discovery the existence of seven-coordinate titanium(IV) was, apart from the oxo-bridged dinuclear peroxodipicolinato complex $[TiO_{0.5}(O_2)(C_7H_3O_4N)(H_2O)]_2^-$, not certain. However, Ti(tropolonate)$_3$Cl, Ti(oxine)$_3$Cl and $TiCl_4$(triars) are thought to be seven-coordinate (see refs. quoted in ref. 89). Thus, Fay and co-workers[89] prepared complexes of the type $Ti(S_2CNR_2)_nCl_{4-n}$ ($n = 2$, 3, 4; R = Me, Pr^i, Bu^i; or, when $n = 3$, R = Et) by the reaction of $TiCl_4$ with anhydrous sodium, *N,N*-dialkyldithiocarbamates in refluxing CH_2Cl_2 or benzene. A number of physical techniques

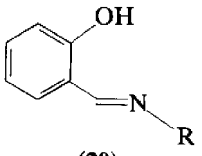
indicate that those complexes are monomeric non-electrolytes in which all of the dithiocarbamate ligands are bidentate. Thus, titanium exhibits coordination numbers six, seven and eight when $n = 2$, 3 and 4, respectively. Coordination number seven has been confirmed for $TiCl(S_2CNMe_2)_3$ (**18**) by X-ray diffraction; the molecule has a pentagonal bipyramidal structure with the chlorine atom in an axial position. Fay and co-workers[90] have examined the low-temperature ^1H NMR of the eight-coordinate monothiocarbamate complexes $Ti(R_2mtc)_4$ (R = Et, Pr^i), which exhibit four methyl resonances of approximately equal intensity, consistent with the dodecahedral *mmmm*-C_{2v} stereoisomer found[91] for $Ti(Et_2mtc)_4$ (**19**) by X-ray diffraction. This isomer has an all-*cis* structure with four sulfur atoms on one side of the coordination group and the four oxygen atoms on the other side. The dipole moment in benzene (4.49 D) is in accord with the highly polar *mmmm*-C_{2v} stereoisomer being the principal species in solution. Variable temperature NMR spectra afford evidence for two distinct kinetic processes: (1) a low-temperature process that involved metal-centred rearrangement, and (2) a high-temperature process that involves hindered rotation about the C—N bond in the ligand. Thus, this complex is sterically rigid on the NMR timescale. Both ν(Ti—O), 558 cm^{-1}, and ν(Ti—S), 313 cm^{-1}, bands have been identified.

(**18**)

(**19**)

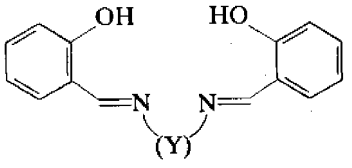
During the period 1965–1975 the chemistry of the 1,2-dithiolene complexes of the transition metals was the subject of considerable study.[86,87,91–98] However, during this period of great activity few complexes of the early transition metals were reported aside from those of vanadium. The problem had much to do with synthetic procedures, since reaction of, say, the anhydrous metal chlorides with the dithiolene or its sodium salt did not prove successful. However, the use of metal dialkylamides[99] did result in clean reactions (*e.g.* equation 21).

$$M(NR_2)_x + (6-x)NaHS_2C_6H_3Me + (x-3)(HS)_2C_6H_3Me \longrightarrow Na_{6-x}M(S_2C_6H_3Me)_3$$
$$M = Ti, Zr, Hf;\ x = 4 \qquad M = Nb, Ta;\ x = 5 \qquad (21)$$



Much of the interest in the bidentate sulfur donor ligands was the discovery that trigonal prismatic as well as octahedral coordination could occur. Thus, X-ray studies of $Re(S_2C_2Ph_2)_3$ and $V(S_2C_2Ph_2)_3$ showed trigonal prismatic geometry. However, Gray and co-workers[100] have concluded from electronic spectral measurements that $Ti(mnt)^{2-}$ (mnt = maleonitriledithiolate) has a severely distorted octahedral structure.

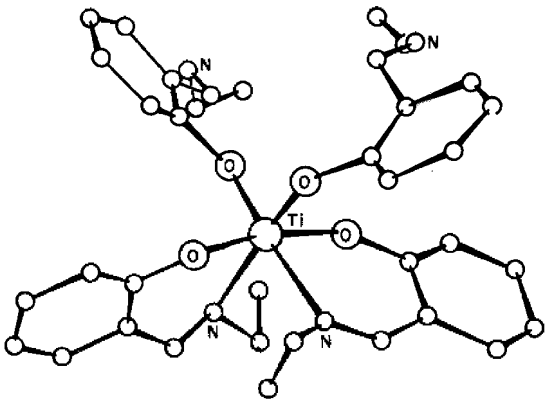
In order to gain some insight into the possible role of π bonding in eight-coordinate complexes involving four symmetrical bidentate ligands, the complexes of dithiobenzoic acid (dtbH) with titanium(IV) and vanadium(V) were examined. A range of complexes $VO(dtb)_3$ and $Ti(dtb)_nCl_{4-n}$ ($n = 2$, 3, 4) were isolated and coordination numbers of six, seven and eight were assigned for the species containing two, three and four dtb ligands. By comparing the electronic spectra of these complexes with the known dithiocarboxylato and dithiocarbamato eight-coordinate species with d^0, d^1, d^2 configurations it was concluded that π bonding interactions of dtb with d^0 systems are much less effective than with d^1 and d^2 systems.



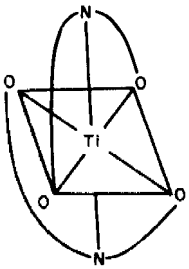
31.5 MIXED DONOR LIGANDS

31.5.1 Schiff Base Ligands

These ligands have been a constant source of interest for inorganic chemists. Both the bidentate type (**20**) (for which, for example, control of tetrahedral–square planar equilibria by the steric effect of the *N*-alkyl group has been studied in bis(chelate)nickel(II) complexes, and for which oxygen bridging has been observed in some *N*-methyl derivatives) and the tetradentate type (**21**) (since the backbone of the ligand, —Y—, can be varied giving either flexibility or rigidity) have been extensively studied.



(20)

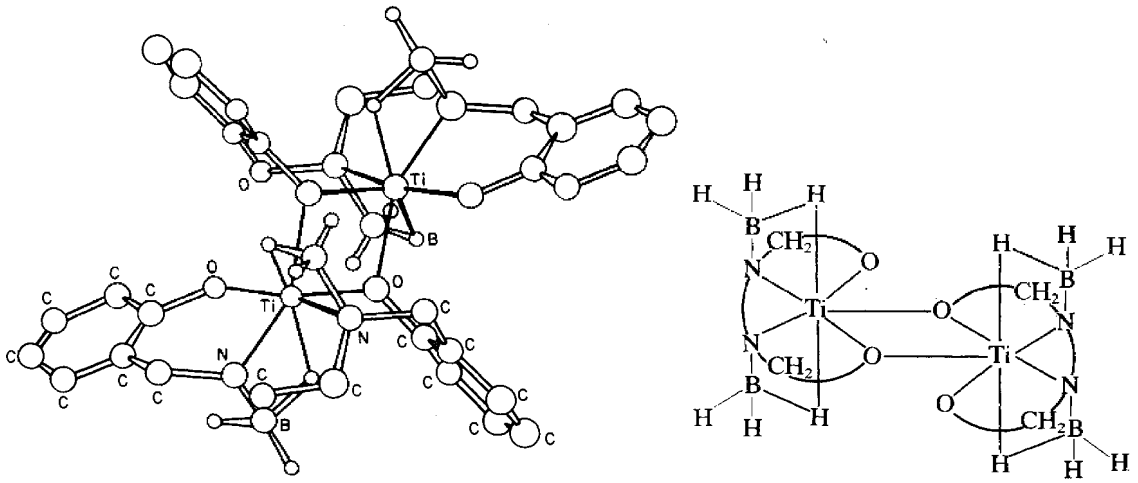


(21)

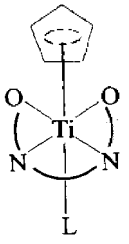
However, despite the potential of these ligands there has been very little work done on titanium systems. Bradley and co-workers[107] were interested to see if four bidentate ligands could bind to titanium(IV) to give an eight-coordination species. They prepared their tetrakis derivatives using Bradley's dialkylamide precursors, as shown in equation (22). The ^{1}H NMR spectrum (R = Et) in $CDCl_3$ solution exhibited broadened methylene, methyl and methine proton resonances at room temperature, which at low temperature split into double peaks suggesting an exchange between two types of ligand in equal proportions. This could mean an eight-coordinate tetrachelated species with a configuration containing the ligands in two distinguishable environments, or a six-coordinate complex containing two bidentate and two monodentate ligands. In the solid state, X-ray crystallography shows that the latter alternative (**22**) obtains. The fact that six-coordination occurs is not surprising, but that two of the Schiff base ligands coordinate as monodentate is wholly surprising. The adoption of the *cis* unidentate configuration recalls the similar behaviour in $Ti(acac)_2(OR)_2$ complexes.[102]

$$Ti(NMe)_4 + 4HOC_6H_4CHNR \longrightarrow Ti(OC_6H_4CHNR)_4 + 4HNMe_2$$
$$R = Me, Et, Bu^t \qquad (22)$$

(22)



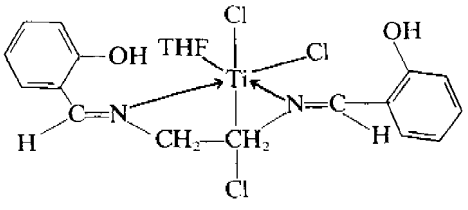
(23)



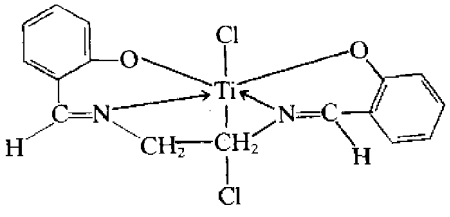
Some complexes with tridentate O_2N donor Schiff base ligands form from the reaction of $OTi(ClO_4)_2$ with H_2L in aqueous methanol. A structure containing four oxygens in the plane of the octahedron and *trans* axial azomethine groups has been assigned (**23**). There is no evidence for the Ti=O group (which is reported to occur in the IR spectrum at *ca.* 1280 cm^{-1}).[103]

Thus far we have seen that Schiff base ligands tend to promote six-coordination, but an unusual reaction has been found to occur between $TiCl_2$(salen) and borohydride. No reduction at titanium is seen, but rather, addition of BH_4^- to the imino function of the ligand occurs to give a dimeric seven-coordinate titanium(IV) compound, (**24**), containing amine–boranes as

donor groups. There is no IR band at *ca.* 1610–1630 cm^{-1}, confirming the reduction of the imino groups.[104] Thus, there is here observed the sexidentate ligand (salen)$(BH_4)_2$ having an $H_2N_2O_2$ set of donor atoms.

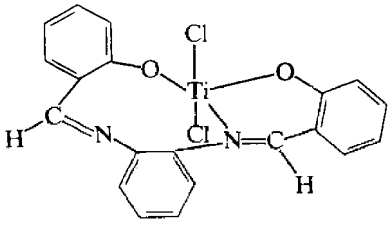


(24)

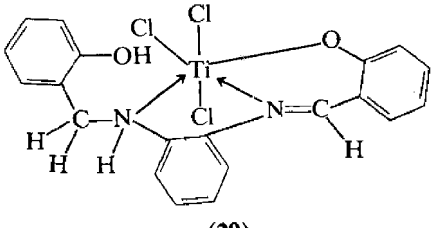


(25)

Employing silyated quadridentate Schiff bases, *e.g.* *O,O'*-bis(trimethylsilyl)-*N,N'*-ethylenebis(salicylideneimine),[105] a range of titanium(IV) complexes Ti(η^5-C_5H_5)(salen)L (**25**; L = Cl, OMe, SMe, NMe_2, $SnPh_3$, acac) have been prepared.

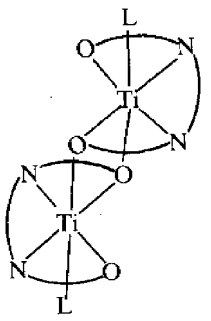


Bowden and Ferguson[106] have obtained a range of interesting complexes starting with $TiCl_3(THF)_3$ and potentially quadridentate Schiff bases. Species (**26**), a titanium(III) complex, initially green, slowly turns red (**27**) on stirring in THF. Complex (**29**) was obtained from the filtrate resulting from the isolation of (**28**). Partial hydrogenation of the Schiff base ligand has occurred. In this complex there occurs another example of a reduced imine function binding to titanium; however, no external reductant was used in producing this species.

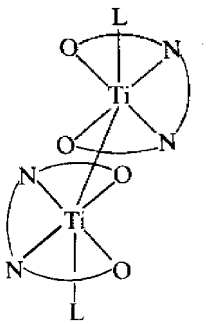


(26)

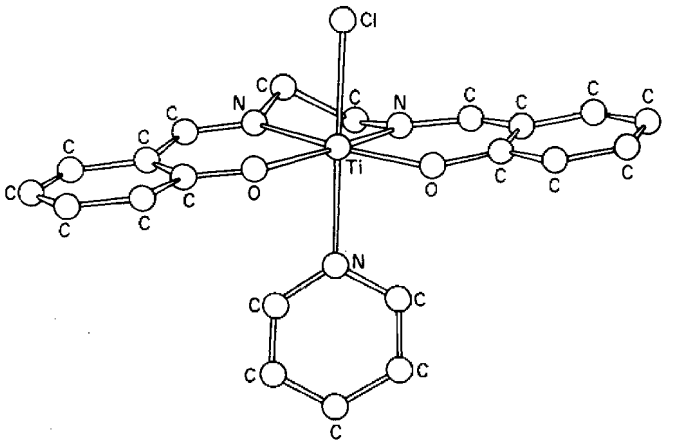
(27)



(28)



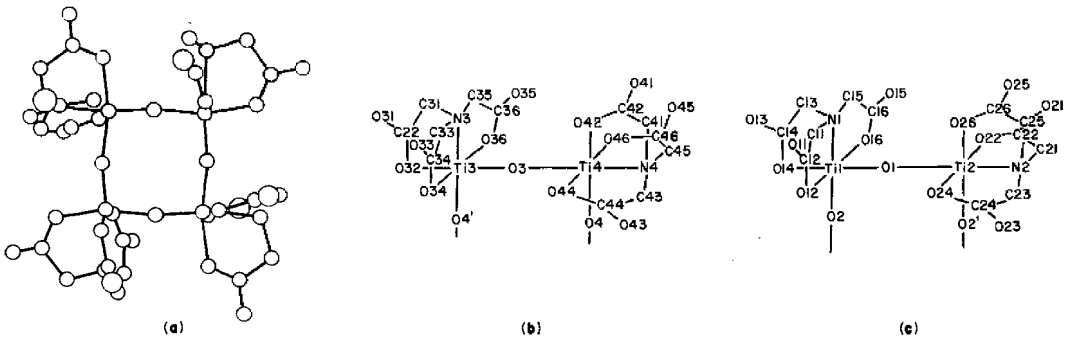
(29)



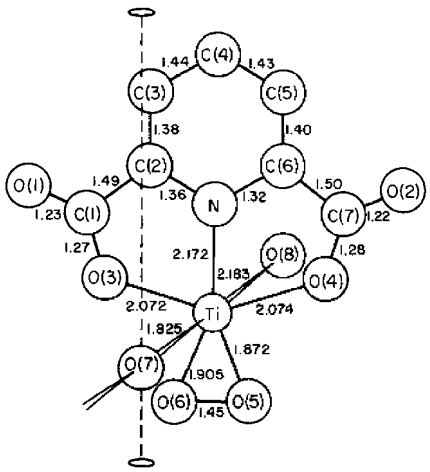
Reduction of the titanium(III) species $[TiCl_2(salen)]$ with zinc dust in THF gives a deep blue solution from which dimeric $[\{Ti(salen)(THF)_2\}][ZnCl_4]$ can be isolated. The reduced paramagnetism of this complex ($\mu_{eff} = 0.96$ BM, 293 K) suggests a strong titanium–titanium interaction (**30a** or **30b**). However, treating this blue solution with pyridine leads to the isolation of the very air-sensitive $[TiCl(salen)(py)]\cdot THF$, whose magnetic moment ($\mu_{eff} = 1.79$ BM, 293 K) corresponds to that expected for a d^1 system. X-Ray analysis of this complex (**31**) confirms the pseudooctahedral coordination around the metal, with salen in the equatorial plane and Cl and py mutually *trans*.[107]

(30a)

(30b)

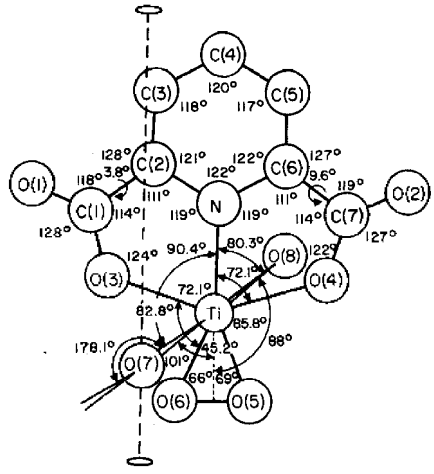


(31)



31.5.2 Aminoacidate Ligands

Recent interest in the peroxo complexes of the early transition metal has resulted in the report of the formation of orange 1:1 peroxo–titanium(IV) species from acidic perchlorate solutions of titanium(IV) and H_2O_2,[108] and Schwarzenbach's group have characterized[109] a number of monomeric and dimeric peroxo–titanium(IV) complexes containing chelating ligands such as pyridine-2,6-dicarboxylate (dipic) and nitrilotriacetate (NTA). Wieghardt and coworkers[110] have isolated $[TiO(dipic)(OH_2)]\cdot 3H_2O$, $[TiO(IDA)(OH_2)]\cdot 2H_2O$ (IDA = iminodiacetate) and $Cs_4[TiO(NTA)]_4\cdot 6H_2O$, which are thought to be precursors to Schwarzenbach's species. The last complex is a tetramer, (**32**), containing four asymmetric μ-oxo bridges, and the titanium atoms are in a distorted octahedral environment. All the above complexes react with H_2O_2 in acid perchloric media to form 1:1 peroxo–titanium(IV) species. Schwarzenbach has isolated the potassium salt of the dipicolinic acid derivative of titanium(IV) in the presence of H_2O_2, *viz*. $K_2Ti_2O_5(dipic)_2\cdot 5H_2O$. This dinuclear complex has C_2 symmetry, and the titanium atoms are coordinated approximately pentagonal bipyramidally sharing an apical μ-oxygen, (**33**). In each bipyramid the peroxy group and the dipic ligand occupy the equatorial sites and the remaining apex is occupied by water. The Ti—O—Ti angle (178.1°) is not significantly different from 180°. The peroxy group, O(5)–O(6), is attached symmetrically to each titanium. The heptacoordination about titanium is similar to that found for other

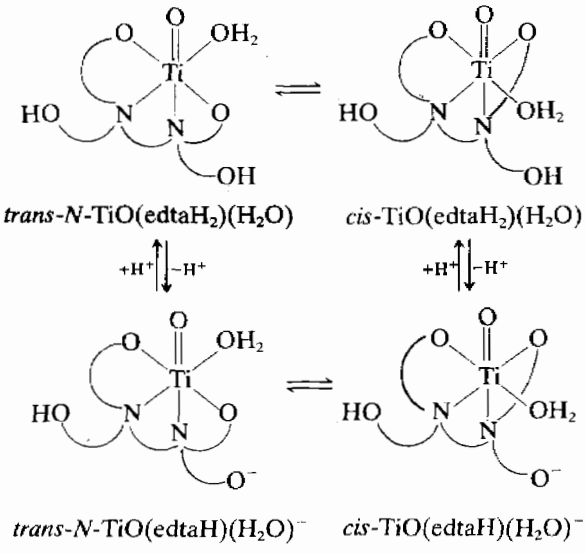


transition metal peroxide complexes.[112] Three of the corners of the pentagon are occupied by the dipic ligand with angles N—Ti—O(3) and N—Ti—O(4) of 72.1 ± 0.3°. The pentagon is distorted mainly because of the short O(5)—O(6) distance. The non-chelated binuclear peroxytitanium complex thus presumably has the composition $[\{Ti(O_2)(H_2O)_4\}_2O]^{2+}$. The Ti—O(7) distance is very short (1.825 Å) but agrees well with that found in the binuclear acac complex of titanium(IV).[113] The O(5)—O(6) distance of 1.453 Å in the peroxy group is equal to the distance found by Busing and Levy in H_2O_2.[114]

(32) (a) Perspective view of the complex $([TiO(NTA)]_4)^{4-}$ anion; (b) and (c) atomic numbering schemes for the two crystallographically independent halves of the tetrameric anions. The open circles represent centres of symmetry.

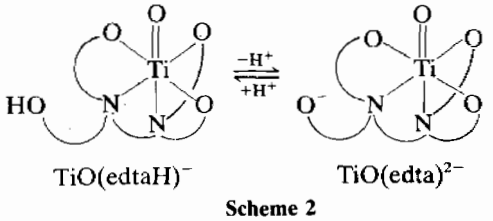
Distances in the complex

Angles in the complex



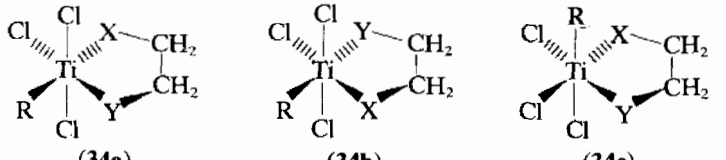
(33)

The peroxy complex of titanium(IV), $Ti(O_2)(edta)^{2-}$, has been used as part of an analytical method for either titanium(IV) or H_2O_2. More recently the structural nature of $TiO(edta)^{2-}$ in solution and the reaction of $TiO(edta)^{2-}$ with H_2O_2 to form $Ti(O_2)(edta)^{2-}$ have been investigated over the pH range 2.0–5.2. Two distinctly different primary coordination spheres in terms of spectral properties and reactivities towards H_2O_2 are observed for $TiO(edta)^{2-}$ solutions in this pH range. As shown in Scheme 2, these are the aquated forms (A), $TiO(edtaH_n)(H_2O)^{n-2}$, having two coordinated carboxylates and two amines and one coordinated water, and the fully chelated forms (B), $TiO(edtaH_n)^{n-2}$, with three carboxylates and two amines coordinated to titanium(IV).[115]



31.5.3 Mixed Ligands Containing Sulfur Donors

Clark and McAlees[116] have prepared a large number of pseudooctahedral complexes of methyltitanium trichloride with symmetrical and unsymmetrical bidentate ligands, **(34)**. It is known that oxidation of $MeTiCl_3$ itself in a hydrocarbon solvent gives a product formulated as $TiCl_3OMe{\cdot}TiCl_2(OMe)_2$, and the oxidation of **(34)** gave the corresponding complexes of methoxytitanium trichloride $TiCl_3OMe(XCH_2CH_2Y)$ (X, Y = OMe, NMe_2, SMe).



A Forms

B Forms

Scheme 2

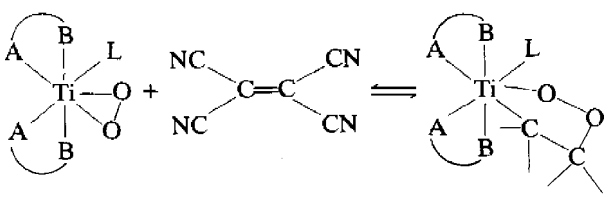
(34a) X = Y = OMe; X = OMe, Y = NMe_2

(34b) X = Y = NMe_2; X = OMe, Y = SMe

(34c) X = Y = SMe; X = NMe_2, Y = SMe

McAlees[117] has also examined some potentially terdentate tripod ligands MeC(X)(Y)(Z) (X = Y = Z = CH_2OMe; X = Y = CH_2OMe, Z = CH_2SMe and CH_2NMe_2; X = CH_2OMe, Y = CH_2SMe, Z = CH_2NMe_2). The precipitates obtained on mixing hexane solutions of equimolar quantities of titanium tetrachloride with these ligands consist of mixtures of products which may include the corresponding 1:1 complex, products in which oxygen–methyl cleavage has occurred to give a titanium alkoxide, and a 3:2 complex. However, the reaction in chloroform medium does give 1:1 products, as it appears that reactions leading to the other types of products take place much more slowly. Variable-temperature NMR shows that all four ligands act only as bidentates towards titanium and that exchange can take place between free and coordinated ligand atoms. The binding to titanium is stronger for nitrogen than for oxygen or sulfur, and oxygen coordination is preferred over sulfur when nitrogen is already bound, whereas sulfur binding is preferred to oxygen coordination when an oxygen is already bound. These observations led McAlees to reexamine the published data[118] on the analogous arsine complex $TiCl_4 \cdot MeC(CH_2AsMe_2)_2$. It had previously been concluded that all three arsenic atoms are coordinated since all the arsenic methyl groups resonate downfield from their resonance position in the free ligand. However, the reinvestigation suggests that one arsenic is uncoordinated.[117]

31.5.4 Other Oxygen–Nitrogen Systems



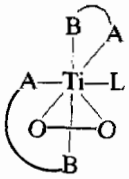
A number of mixed monodentate ligands have been coordinated to titanium(III), *viz.* $TiCl_3(L)(L')$, $TiCl_3(L)_2(L')$ (L = THF, L' = MeCN),[119] and some titanium(IV) alkoxy derivatives of 2-pyrrolidinone have been isolated: $Ti(OR)_3L$, $TiCl(OR)_2L$, $TiCl_2(OR)_2{\cdot}LH$, $TiCl_2(OR)_2{\cdot}2LH$, $TiCl_4{\cdot}LH$ and $TiCl_4{\cdot}2LH$.[120] The starting point for the preparation of the 2-pyrrolidinone complexes is $Ti(OR)_4$ (R = Et, Pr^i), and thus these complexes represent the unusual example of a Ti—O bond being replaced by a Ti—N bond. Moreover, it was found possible to substitute NR_2 by pyrrolidinyl for, on reaction with $Ti(OR)_3(NR)_2$, HNR_2 was evolved. The generalized reaction is shown by equation (23).

$$XTi(OR)_3 + \overline{(CH_2)_3C(O)NH} \longrightarrow \overline{(CH_2)_3C(O)NTi(OR)_3} + XH \qquad (23)$$

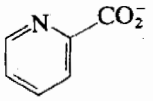
$$(= LH)$$

X = OR, NR_2, Me, but not Cl

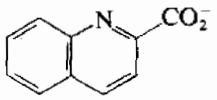
Analogous to the work on dipicolinic acid reported in Section 31.5.2, a range of titanium(IV) peroxo complexes (**35**) have been prepared which encompass an oxygen–nitrogen anionic chelating ligand and hexamethylphosphortriamide.[121] The crystal structure of peroxobis(picolinato)(hexamethylphosphortriamide)titanium(IV) (**36**) reveals that it is another example of a deformed pentagonal pyramid similar to that found for (**32**). The equatorial positions are occupied by the nitrogen atoms of the pyridine-2-carboxylate groups, the oxygen of HMPT and the oxygen atoms of the peroxo group. The axial positions are occupied by one oxygen atom of each pyridine-2-carboxylate group. The peroxo group is, as usual, π bonded to the titanium and the Ti—O(8) and Ti—O(7) bonds are equivalent, and are in the range found by Schwarzenbach[111] and by Guilard in a peroxotitanium(IV) porphyrin adduct.[122] However, the O—O bond is significantly shorter, 1.419 Å, and thus the O—Ti—O angle is smaller, 45.2°. The nitrogen *trans* to the HMPT group (Ti—N, 2.207 Å) is shorter than the Ti—N *trans* to the peroxo group (2.340 Å). Of the complexes prepared, (**35**), all proved to be unusually stable and were reluctant to react with simple alkenes, allylic alcohols and cyclic ketones. Complex (**35a**) did react with tetracyanoethylene (TCNE) to produce '$Ti(O_2)(TCNE)(C_6H_4NO_2)_2(HMPT)CH_2Cl_2$', but as the Ti—$O_2$ IR vibrations disappear the reaction is best viewed according to equation (24).



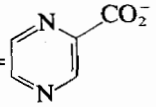
(24)



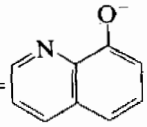
Titanium tetrachloride reacts with 8-quinolinol (oxineH) in 1:2 mol ratio to form the adduct $TiCl_4(oxineH)$, from which two moles of HCl can be eliminated to produce $TiCl_2(oxine)_2$. This compound is a member of a large group of compounds of general formula $MX_2(L)_2$ (M = Ti, Ge, Sn; X = F, Cl, Br, I; L = oxine, acac, salen). The $TiCl_2(oxine)_2$ is only one member of this group, others being $TiCl_4(oxineH)$, $TiCl_4(oxineH)_2$, $TiCl(oxine)_3$ and $TiCl_3(oxine)$.[123] The crystal structure of $TiCl_2(oxine)_2$ shows it to be six-coordinate, (**37**), with *cis* chlorines (Ti—Cl; 2.283 Å), *cis* nitrogens (Ti—N = 2.200 Å) and *trans* oxygens (Ti—O = 1.888 Å). From the reaction of $TiCl_2(oxine)_2$ with oxineH in the presence of NEt_3, $Ti(oxine)_4$ can be isolated. $Ti(sal)_4$ (sal = salicyldehydato) and $Ti(oxine)_2(sal)_2$ can be similarly prepared. The $Ti(oxine)_4$ is probably eight-coordinate.[125,126]



Dimethylglyoxime, $DMGH_2$, forms $TiCl_4(DMGH_2)_n$ (n = 1, 2) in light petroleum. Warming to 40 °C results in the loss of HCl to give $TiCl_3(DMGH)$. Benzil monoxime adducts, $TiCl_4(BMOH)_n$ (n = 1, 2) can also be obtained. The dimethylglyoxime complexes decompose violently on heating, but the benzil monoxime species undergo a Beckmann fragmentation at 120 °C to give phenyl cyanide.[127]



31.6 PHOSPHORUS, ARSENIC AND ANTIMONY COMPLEXES



There are two major reference works to metal complexes containing these donor atoms.[16,17] The chemistry of these donor ligands with titanium is sparse, and clearly there is much scope for exploitation in this area.

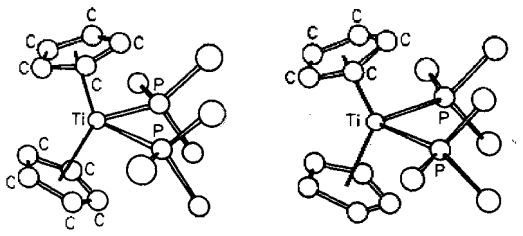
(36)



(37)

31.6.1 Titanium(II) Complexes

Issleib and Weuschuh prepared $Ti(PCy)_2$ by reaction of $TiCl_3$·THF or $TiCl_4$·2THF with $LiPCy_2$. The dark brown product ($\mu_{eff} = 0.60$ BM) was pyrophoric, was decomposed by water and reacted with iodine in benzene to give $TiI_2(PCy_2)_2$ and $TiI_3(PCy_2)_2$.[128] Although somewhat outside the scope of this treatise, an important organometallic complex has recently been prepared $[(\eta^5\text{-}C_5H_5)_2Ti(PMe_3)_2]$.[129] Monomeric titanocene, Cp_2Ti, has always eluded isolation as a discrete compound, since *in statu nascendi* it immediately reacts to form bi- or multi-nuclear species. However, $Cp_2Ti(PMe_3)_2$, synthesized as shown by equation (25), makes accessible the Cp_2Ti unit, since the two phosphine ligands may be replaced by a very large number of substrates under very mild conditions (CO, SPh, C_4H_4, C_4H_8, dmpe, MeCN). The crystal structure of this complex, (**38**), indicates that two crystallographically independent molecules are present, but both molecules possess the same dimensions. The Ti—P distances (2.524, 2.527 Å) are in excellent agreement with the recently reported $(MeC_5H_4)_2Ti(dmpe)$.[130]

$$Cp_2TiCl_2 + Mg + 2PMe_3 \xrightarrow{THF} Cp_2Ti(PMe_3)_2 + MgCl_2 \qquad (25)$$

(38)

31.6.2 Titanium(III) Complexes

When titanium and phosphorus are heated together in the presence of iodine TiI_4 is formed, but rapidly decomposes. The elemental Ti thus created reacts rapidly with phosphorus to give either TiP or TiP_2 (depending on stoichiometry). Iodine is a catalyst in this sequence.[131]

The first titanium(III) complex, $TiCl_3(PEt_3)\cdot C_2H_4$, was prepared by Chatt and Hayter,[132] but more recently monomeric $TiCl_3(PR_3)_2$ ($R_3 = MeH_2$, Me_2H, Me_3, Et_3) have been isolated from direct combination of the components in toluene at 85 °C. At −20 °C there is ESR evidence for $TiCl_3(PR_3)_3$ species for solutions of $TiCl_3$ and $3PR_3$ in toluene.[133] The grey-green $TiCl_3(PEt_3)_2$ is monomeric in solution, and by analogy, the red-brown complexes with the other phosphines are also assumed to be pentacoordinate. The weaker donors, PPh_3 and PCl_3, do not complex with titanium(III).

31.6.3 Titanium(IV) Complexes

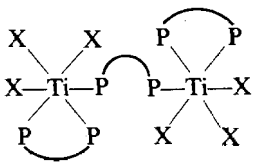
31.6.3.1 Monodentate ligands

The isolation of $TiCl_4(PH_3)$ was first reported in 1832;[134] $TiCl_4(PH_3)_2$ has also been prepared.[135] A large number of $TiCl_4(PR_3)_2$ complexes are now known,[16,17] but only quite recently have $TiBr_4(PPh_3)$ and $TiBr_4(PPh_3)_2$ been prepared, the former having C_{3v} symmetry and the latter a *cis* octahedral structure.[136] There is some evidence for the probable existence of binuclear species of the type $Ti_2Cl_8(PR_3)$.[16,17] Titanium tetrachloride reacts with $Pt(PPh_3)_n$ ($n = 3, 4$) to yield emerald green $(TiCl_4)_2Pt(TiCl_4\cdot PPh_3)_3$, which, on heating *in vacuo* or treatment with more PPh_3, produces $Pt(TiCl_4\cdot PPh_3)_3$. It is thought[137] that the former species is pentacoordinate with two axial $TiCl_4$ and three equatorial $TiCl_4\cdot PPh_3$ moieties bonded to platinum *via* the titanium atoms.

Although $TiCl_4$ and $AsPh_3$ were known to complex as early as 1924, the adduct $TiCl_4(AsPh_3)$ has only been investigated relatively recently.[16,17] The reports of a bis adduct $TiCl_4(AsPh_3)_2$ must be viewed with some suspicion.[138]

The reaction between $SbPh_3$ and $TiCl_4$ in dry benzene initially gives a deep violet solution and ultimately a gummy black solid. It is likely that reduction of $TiCl_4$ has occurred.[139] Although there is a paucity of well-characterized arsine and stibine complexes, a surprisingly large number of patents have dealt with catalyst systems employing these compounds (Table 6) which often contain Lewis acids in addition to Lewis bases. The function of the Lewis acid is often not clearly delineated, but its presence has a pronounced effect on the catalytic activity as does the Lewis base.

31.6.3.2 Bidentate ligands



With 1,2-bis(diphenylarsino)ethane (dpae), $TiCl_4$ forms only a 2:3 complex $[(TiCl_4)_2(dpae)_3]$ although diphos forms 1:1 and 3:2 adducts.[139] Tetramethyldiphosphine and $TiCl_4$ react to form a deep red paramagnetic product of unknown composition, the paramagnetism suggesting that partial reduction to titanium(III) has occurred. With $TiCl_3(THF)_3$ an insoluble, moisture- and air-sensitive complex $(TiCl_3)_2(Me_2PPMe_2)_3$ is produced, for which structure (**39**) has been proposed. Tetraethyldiphosphine does not yield any isolable complex with $TiCl_3(THF)_3$.[17]

Investigations of the diars complexes of the titanium(IV) halides resulted in the first

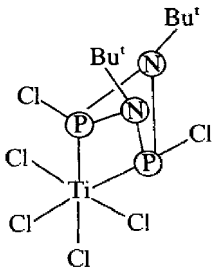
(39)

examples of eight-coordination in the first transition series.[16,17] In $[TiCl_4(diars)_2]$ the dodecahedron contains two diars forming an elongated tetrahedron and four chlorine atoms in a flattened tetrahedron with respect to the fourfold inversion axis, **(40)**.[140] Although numerous attempts have been made to prepare similar complexes with a range of bidentate ligands, only those with the *o*-phenylene or similar backbone have proved successful. Thus 1,2-bis(dimethylarsino)-3-fluoro- or 4-fluoro-benzene form only the hexacoordinate $TiCl_4$(ligand) complexes; presumably the fluorine-substituted ligands are poorer σ donors. Eight-coordination is also not achieved with 1,2-bis(dimethylarsino)-3,3,4,4-tetrafluorocyclobutene ($f_4$fars) or 1,2-bis(dimethylarsino)-3,3,4,4,5,5-hexafluorocyclopentene ($f_6$fars), probably due to

(40)



the larger As—As 'bite' of the ligands, nor with *rac*-*o*-phenylenebis(phenylmethylarsine), due to steric hindrance. However, 1,8-bis(dimethylarsino)naphthalene, which has a short As—As separation, readily forms brown $TiCl_4$(ligand)$_2$. These results reinforce earlier conclusions about the importance of steric factors in promoting eight-coordination, but also suggest that the electronic properties of the ligands are not negligible.[17]

A number of [TiX_4(diars)] (X = Cl, Br), [$(TiF_4)_2$(diars)] and [TiI_4(diars)$_2$] are known.[16,17] No authentic complexes of titanium(III) are known, save for [TiX_3(diars)(H_2O)] (X = Cl, Br).

31.6.3.3 Multidentate ligands

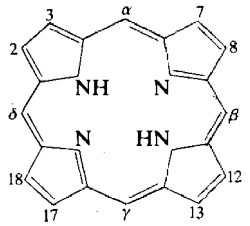
The triarsines (o-$Me_2AsC_6H_4)_2AsMe$ and $MeC(CH_2AsMe_3)_3$ are reported to form seven-coordinate adducts of type $TiCl_4L$, on the basis that they are monomeric and non-electrolytes.[142] However, the complex of the latter ligand has been shown, by NMR studies of McAlees and coworkers,[117] to contain one unbound and two coordinated arsine groups. It is probable that both complexes are hexa-coordinate. Another triarsine, $MeAs\{(CH_2)_3AsMe_2\}_2$, is reported to form a series of complexes $[TiF_4]_3$·L, $[TiCl_4]_2$·L, $[TiBr_4]$·L and $[TiI_3$·L]I.[143] All need further characterization.

Cyclophosphazenes $(RNPX)_n$, especially the diazadiphosphetidines ($n = 2$), have been shown to be capable of acting both as bridging and chelating bidentates through the two phosphorus atoms. It is interesting to see that, once again, the supposed 'hard' acceptor $TiCl_4$ chooses to bind this multidentate ligand *via* the two phosphorus atoms in the *cis* configuration, (**41**).[144] A ν(Ti—P) band is assigned at 435 cm^{-1}, very close to those found for [$TiCl_4$(diphos)] (453, 414 cm^{-1}).

(**41**)

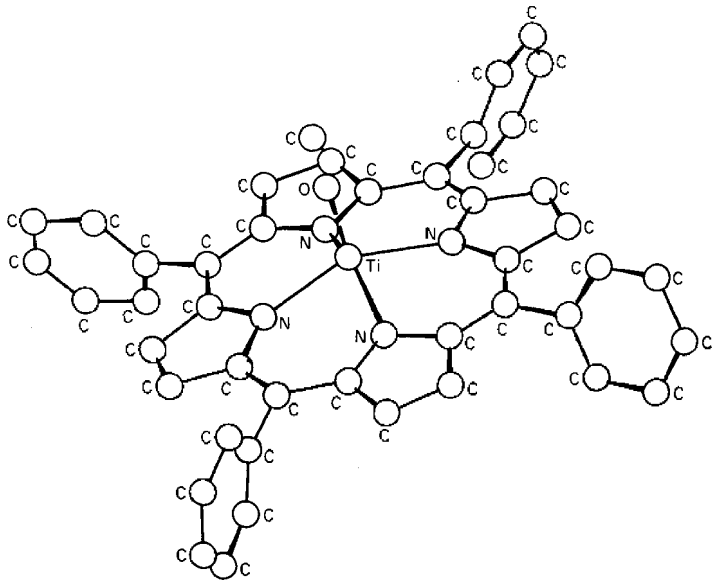
31.7 MACROCYCLIC LIGANDS

31.7.1 Porphyrin Complexes



Although it is just 50 years since Treibs obtained vanadyl deoxophylloerythroetioporphyrin, the major metalloporphyrin in petroleum and shales,[145] it is only relatively recently that Tsutsui obtained the first titanium porphyrin, (*meso*-DME)Ti=O.[146] A review of this general area is available;[147] the nomenclature is given in Table 7.

31.7.1.1 Titanium(III) complexes



Reaction of (por)TiX_2 with zinc amalgam gives the reduced (por)TiX (por = TPP; X = F, Cl, I, SMe) and some hexa-coordinate $[(por)TiF_2]^-$ and [(por)TiF(1-MeIm)] have also been synthesized.[148] For (TPP)Ti(OMe) (**42**), the Ti—N distances (2.12 Å) are very close to those found in analogous titanium(IV) derivatives; in each case the Ti atom lies 0.62 Å out of the plane of the ring.[149] When (TPP)TiF is exposed to dioxygen the reaction shown in equation (26) occurs, and a superoxide intermediate, (TPP)Ti(O_2)F, is thought to exist, from ESR measurements.[148]

$$2(TPP)TiF + O_2 \longrightarrow (TPP)TiF_2 + (TPP)Ti(O_2) \qquad (26)$$

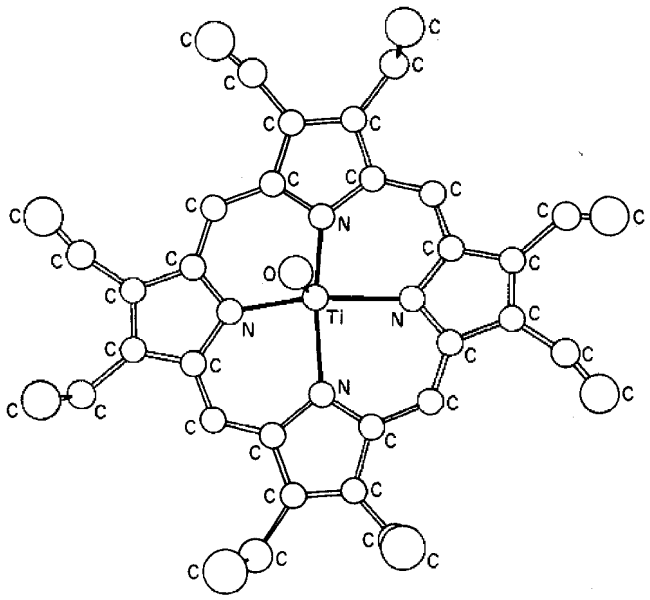
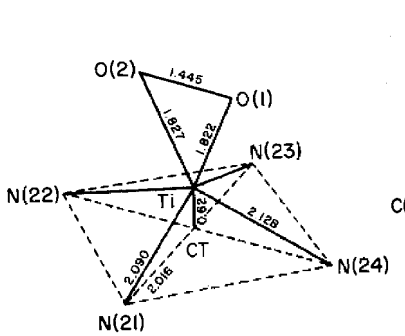
(42)

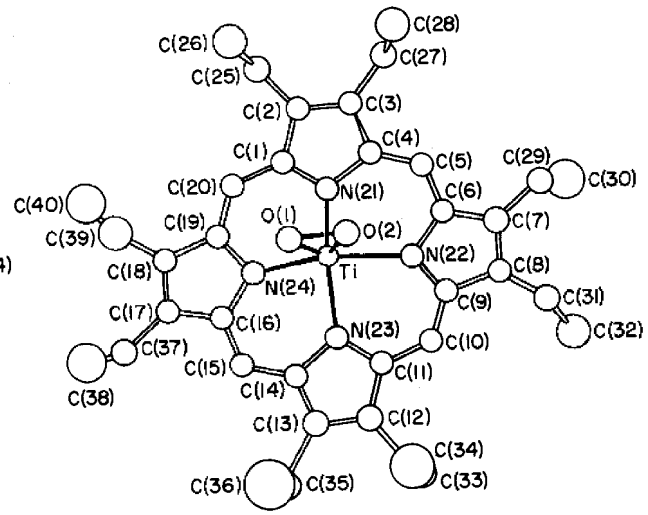


31.7.1.2 Titanyl derivatives

The (por)Ti=O species can be prepared either by the reaction of $(acac)_2TiO$ in phenol 180–240 °C, or $TiCl_4$ in a variety of solvents with the porphyrin. The characteristic ν(Ti= occurs in the range 1050–950 cm^{-1}.



A number of crystal structures are known, *viz.* (OEP)TiO, (TPP)TiO, $(OEPMe_2)$Ti **(43)**.[147] For all these complexes titanium has four nitrogen donors and a double-bonc oxygen, resulting in a classical square pyramid. The information obtained from X-diffraction and EXAFS is in excellent agreement.



31.7.1.3 Peroxotitanium(IV) derivatives

Earlier it has been noted that there is a good deal of interest in peroxo derivatives titanium(IV). It has been shown that (por)TiO can be converted to $(por)Ti(O_2)$ by react with either H_2O_2 or benzoyl peroxide.[150] The crystal structure of $(OEP)Ti(O_2)$ **(44)** reve O—O = 1.445 Å, characteristic of a peroxo moiety, and the Ti—O_2 moiety is generally same as found in other peroxo complexes (Table 8).

(43)

(44)

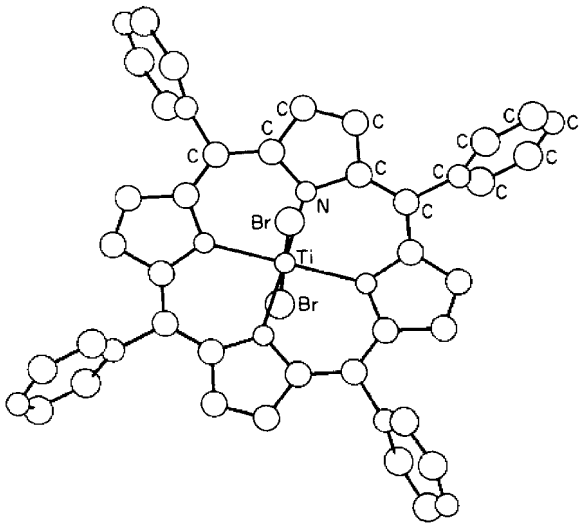


Table 8 Crystallographic Data for some Titanium(IV) Peroxo Complexes

Complex	*Ti—O(1)*	*Ti—O(2)*	*O(1)—O(2)*	*Ti—O(1)—O(2)*	*O(1)—(02)—Ti*	*O(1)—Ti—O(2)*
$[H_2O(dipic)Ti(O_2)]_2O$	1.872(7)	1.905(7)	1.45(1)			45.2(4)
$(H_2O)_2(dipic)Ti(O_2)$	1.834(2)	1.858(2)	1.464(2)	67.50(6)	67.78(6)	46.72(6)
triclinic	1.842(1)	1.862(1)	1.469(1)			
$(H_2O)_2(dipic)Ti(O_2)$	1.833(1)		1.458(2)	66.56(2)		46.88(6)
orthorhombic	1.844		1.477			
$[F_2(dipic)Ti(O_2)]^{2-}$	1.846(4)	1.861(4)	1.463(5)	67.3(2)	66.2(2)	46.5(2)
$[\{(NTA)Ti(O_2)\}_2O]^{4-}$	1.892(2)	1.889(2)	1.469(2)	67.02(6)	67.26(6)	45.72(6)
	1.897	1.898	1.481			
$(OEP)Ti(O_2)$	1.827(4)	1.822(4)	1.445(5)	66.5(2)	66.9(2)	46.7(2)

Fluxional behaviour for (OEP)Ti(O_2) and (TPP)Ti(O_2) has been shown from ^1H and ^{13}C NMR studies. At temperatures down to −50 °C the peroxo ligand undergoes fast exchange between two equivalent sites; the barrier to rotation of the peroxo ligand at the coalescence temperature is 43.9 ± 2.1 kJ mol^{-1} for (TPP)Ti(O_2).

31.7.1.4 Titanium(IV) dihalide derivatives

Oxotitanium(IV) porphyrin complexes react with HX (X = F, Cl, Br) to yield (por)TiX_2. The crystal structure of (TPP)$TiBr_2$ (**45**) has been determined.[151]

(45)

31.7.2 Phthalocyanine Derivatives

Very few complexes have been examined. It is known that (Pc)TiCl can be converted t (Pc)TiO.[152] Dichloro(phthalocyaninato)titanium(IV) can be synthesized *via* equation (27). Th reaction is a convenient one, inasmuch as the titanium(III) furnishes the electrons necessary t convert phthalonitrile to the phthalocyanine anion.[153]

$$2TiCl_3 + 4C_6H_4(CN)_2 \longrightarrow (Pc)TiCl_2 + TiCl_4 \qquad (2$$

31.8 GROUP IV DERIVATIVES

Heintz[154] has reported a dark blue octahedral complex cyanide of titanium(III), $K_3Ti(CN)$ as well as a compound formulated as $K_3Ti(CN)_6KCN$. These complexes were isolated fro aqueous solutions of $TiCl_3$ and KCN under conditions that might be expected to produce on titanium(III) hydroxide. Nicholls *et al.*[155] have repeated these preparations and find the on product of these reactions to contain the dark-blue hydroxide, $[Ti(OH)(H_2O)_5]^{2+}$. Howeve these workers have isolated the grey-green $K_5Ti(CN)_8$ from the reaction of $TiBr_3$ and KCN liquid ammonia; this species is probably a seven-coordinate $K_4Ti(CN)_7 \cdot KCN$ moiety.

Nicholls and Ryan have produced other complex cyanides of titanium: $Rb_5Ti(CN)$ $Cs_4Ti(CN)_7$ and $K_3Ti(CN)_6$. The $K_5Ti(CN)_8$, $Rb_5Ti(CN)_8$ and $Cs_4Ti(CN)_7$ are believed contain seven-coordinate titanium, while $K_3Ti(CN)_6$ is probably six-coordinate. A titanium(I cyanide, $K_2Ti(CN)_4$, was obtained by reduction of $K_3Ti(CN)_6$ with one equivalent of potassiu in liquid ammonia.[156] The extremely reactive titanium(0) cyanide complex, $K_4Ti(CN)_4$, prepared by potassium reduction of a mixture of $TiBr_3$ and KCN in liquid ammonia. Th $Ti(CN)_4^{4-}$ is a powerful reducing agent, converting bipy into $bipy^-$, leaving a brown residue $KTi(NH)_2$. Nicholls and co-workers have also produced evidence for the formation $Ti(CN)_3$.[157]

31.9 TITANIUM ALLOY HYDRIDES

Titanium absorbs dihydrogen reversibly above 300 °C to give, eventually, TiH_2, which is a grey, air-stable powder. Complete desorption occurs at *ca.* 1000 °C. A useful sourcebook is available.[158]

There are usually quite large differences in stability among the protides, deuterides and tritides of a given metal or alloy. Recently, Tanska *et al.*[159] decided to study a series of alloys formed between a single hydride-forming metal and a number of other metals which did not themselves form stable hydrides. Titanium was chosen as the constant constituent since it forms intermetallic compounds or solid solutions with almost every transition element, and many of these alloys are known to form hydrides. The particular interest was the periodic trend of the hydrogen isotope effect as a function of the transition metal alloyed with titanium. The titanium distribution coefficient was defined as in equation (28), and the results obtained are given in Table 9. To place into comparison alloys with stoichiometries other than 1:1, such as $TiMo_2$ and TiCrMn, the electron/atom (e/a) ratio may be plotted *vs.* α, (Figure 1). All the alloys which show significant inverse isotope ratios fall in the range e/a 4.5–5.5. This is not too surprising, in that it is known that the heat of solution of dihydrogen is dependent on the electronic structure of the metal.

$$\alpha = (T/H)\text{solid}/(T/H)\text{ gas} \tag{28}$$

31.10 COMPLEX HALIDES

For general properties of the halides and oxyhalides of titanium, reference to the work by Clark is recommended.[14] The chemistry of the complex halides will be treated here.

31.10.1 Complex Fluorides

The most common form of complex fluoride is that of the TiF_5^- moiety. One method of preparation is to dissolve TiF_4, and to add $[NPr^n_2H_2]F$ and a stoichiometric amount of the donor; a second method involves adding a stoichiometric amount of $[NPr^n_2H_2]_2[TiF_6]$ to a solution of TiF_4L_2.[160] In the ^{19}F NMR spectra of the solutions made by the first method which did not form $[TiF_5L]^-$, a triplet appears at *ca.* −20 ppm with a coupling constant of between 43 and 45 Hz, assigned to $[Ti_2F_{11}]^{3-}$ (**46**). The complexes $[TiF_5L]^-$ and $[Ti_2F_{11}]^{3-}$ are listed in Table 10.

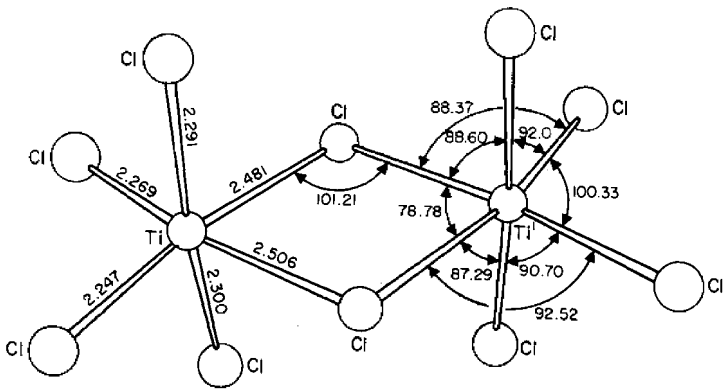
[a] In the gas phase; $ID \approx 3.33 \times 10^{-30}$ C m (from 'Handbook of Chemistry and Physics', ed. R. C. Weast, Chemical Rubber Co., Cleveland, 1973).
[b] In the liquid phase at 25 °C, except where indicated in parentheses (from 'Handbook of Analytical Chemistry', ed. L. Meites, McGraw-Hill, New York, 1963).



A procedure for the fluorination of 1 mm thick wafers of rutile has been developed by Wold and co-workers.[161] The products are $TiO_{2-x}F_x$, and the value of x is an essentially linear function of the fluorination temperature over the range 575–700 °C. For example, $x = 0.002$ for the preparation at 700 °C. Samples with the smallest value of x exhibit the largest photocurrent on irradiation despite having the highest resistance. Under irradiation from a xenon arc source, rutile wafers fluorinated at 575 °C produced almost twice the photocurrent of rutile reduced at the optimum temperature (600 °C).

31.10.2 Complex Chlorides

The $TiCl_6^{3-}$ anion is believed to form when titanium(III) is fused in chloride melts, but it can be isolated from the direct reaction of $TiCl_3$ with an excess of anhydrous pyHCl or by the reaction of $TiCl_3(MeCN)_3$ with pyHCl in chloroform/acetonitrile. However, when Et_4NCl and Et_4NBr are used in the second method the expected hexahalogeno salts are not formed, but $[TiCl_4(MeCN)_2]$ and $(Et_4N)[TiCl_3Br(MeCN)_2]$ were produced. The reaction of $TiBr_3py_3$ with liquid anhydrous hydrogen chloride gives the mixed $(pyH)_3[TiCl_4Br_2]$.[162] Thermal decomposition of $[TiCl_4(MeCN)_2]^-$ gives $[TiCl_4]^-$ species which are six-coordinate polymers and not tetrahedral.[163] Vibrational spectra suggest that $(Et_4N)TiCl_5$ and $(Et_4N)Ti_2Cl_9$ (**47**) have trigonal bipyramidal and chlorine-bridged structures, respectively; ν(Ti—Cl) occurs at 324 cm^{-1} for $TiCl_6^{2-}$.[164] Kyber and Schramm[165] have very usefully collated titanium–chlorine stretching frequency data (Table 11). The $[Ti_2Cl_{10}]^{2-}$ (**48**) species are also known.[166] Adducts of the type $(PCl_5)_n \cdot mTiCl_4$ (n, m = integer) have been known since 1867. Treatment of a PCl_3–$TiCl_4$ solution with chlorine gas led to the complex $PCl_5 \cdot TiCl_4$. A more recent investigation has shown that the reaction of PCl_5 with $TiCl_4$ in $POCl_3$ gives $[PCl_4]_2[Ti_2Cl_{10}]$ (**48**) and in $SOCl_2$ gives $[PCl_4][Ti_2Cl_9]$ (**47**). These anions are unusual examples of face-shared bioctahedra containing transition metal ions in the formal oxidation state +4.[167] The titanium(III) analogue of (**47**) $Cs_3Ti_2Cl_9$ is also known.[168] Optical spectra show evidence for both titanium(III) and titanium(II) in $AlCl_3$–KCl melts ($1.00 \geq X_{AlCl_3} \geq 0.49$) at temperatures 471–894 K and in the LiCl–KCl eutectic melt at 658–1185 K. Titanium(III) is found to be octahedrally coordinated in pure $AlCl_3$(l) and in $AlCl_3$–KCl melts with $X_{AlCl_3} \geq 0.67$, whilst octahedral-tetrahedral equilibria are established at lower $AlCl_3$ contents. Titanium(II) has octahedral coordination at compositions $1.00 \geq X_{AlCl_3} \geq 0.51$, but a disproportionation equilibrium is observed for $X_{AlCl_3} \leq 0.60$, culminating at $X_{AlCl_3} = 0.49$, where titanium(II) is unstable and the spectrum of titanium(III) in an octahedral–tetrahedral coordinated equilibrium is found.[169]

[m] Abbreviations: THF, tetrahydrofuran; D, dioxane; A, acetonitrile; py, pyridine; bipy, 2,2'-bipyridyl; phen, *o*-phenanthroline; B, *o*-phenylenebis(dimethylarsine). For *cis* (C_{2v}) complexes four ν(MCl) are allowed in the IR spectra ($2A_1 + B_1 + B_2$) whereas for *trans* (D_{4h}) complexes only one ν(MCl) mode is allowed (E_u); these complexes are considered to have the *cis* (C_{2v}) structure.

Schram and co-workers have produced a range of unusual titanium chloride species. Treatment of $B_2[NMe_2]_4$ with a six-fold molar excess of $TiCl_4$ afforded $\{[Me_2N]_2BCl\}_2\{TiCl_4\}_3$, small amounts of Me_2NTiCl_3 and $Me_2NBCl \cdot Ti_2Cl_6$.[170] The last complex contains coordinated dimethylamino moieties and the pentacoordinate structure (**49**) is proposed.[165] Treatment of this compound with HCl produced $\{[Me_2NH]_2BCl_2\}^+\{Ti_2Cl_7\}^-$, and pyrolysis of this complex affords Me_2NBCl_2 and $\{Me_2NH_2\}\{Ti_2Cl_7\}$.[171] As well as IR criteria for coordination numbers (Table 11), Kyker and Schram have also proposed that charge-transfer spectra can also be used as an indication of coordination number (Table 12).

(**49**)

The reaction of $TiCl_4$ with $Pt(PPh_3)_n$ ($n = 3, 4$) was mentioned in Section 31.6.3.1, the product being $(TiCl_4)_2Pt(TiCl_4 \cdot PPh_3)_3$, from which $Pt(TiCl_4 \cdot PPh_3)_3$ can be obtained by heating *in vacuo* or addition of further PPh_3.[137] Schram has also isolated the $Ti_3Cl_{11}^-$ ion in the

$[(Ph_3P)_3PtCl]^+[Ti_5Cl_{11}]^-$ salt. Little is known about the structure of this mixed oxidation state cluster anion; addition of $TiCl_4$ affords $[(Ph_3P)_3PtCl]^+[Ti_5Cl_{19}]^-$.[172]

31.10.3 Complex Bromides

Concomitant with his work on the chloride system[165,170,171] Schram has produced $\{[Me_2N]_2BBr\}_2\{TiBr_4\}_3$, proposing the following type of coordination:[173]

$$Br_4Ti \leftarrow N(Me)_2B(Br)(Me)_2N \rightarrow TiBr_4 \leftarrow N(Me)_2B(Br)(Me)_2N \rightarrow TiBr_4$$

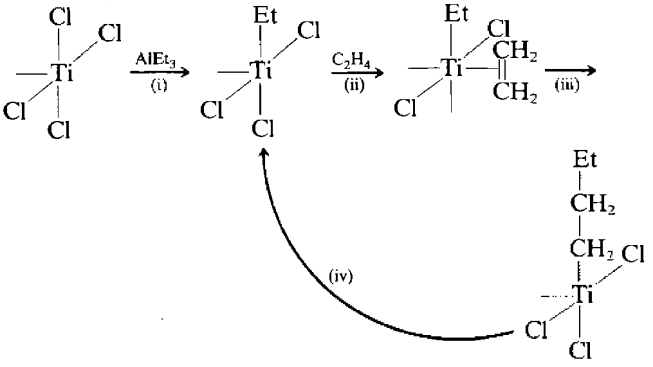
Treatment of $TiBr_4$ with $B_2[NMe_2]_4$ produces $B_2Br_2[NMe_2]_2 \cdot TiBr_3$, for which the dinuclear structure (**50**) is proposed.[174] Complexes $M_2[TiBr_5(H_2O)]$ (M = Cs, Rb, pyH) are known.[175]

(**50**)

31.10.4 Complex Iodides

It would be predicted that TiI_6^{2-}, analogous to TiX_6^{2-}(X = Cl, Br), would not be a very stable complex, and because of the electronic spectra of the latter species, it would also be predicted that TiI_6^{2-} would be black. When $[Et_4N]_2TiCl_6$ is treated with liquid HI a very black material, resembling carbon, is produced. This material is very unstable in air and changes in colour to the dark red-brown of I_3^- in the time required to pour it quickly from one container to another. The complex is unstable in almost all solvents; it was only possible to obtain the reflectance spectrum of $[Et_4N]_2TiI_6$ (Table 13).

Table 13 Electron-transfer Spectra of TiX_6^{2-} [a]



$TiCl_6^{2-}$	(25.0) [1300], (29.6) [~17 000], 31.8 [22 000], 43.8 [30 000]
$TiBr_6^{2-}$	(17.7) [~700], (21.7) [~8 000], 24.9 [16 000], (27) [~12 000], 36.1 [20 000]
$[Et_4N]_2TiI_6$	(9.5) [0.3], 12.1 [0.65], 14.3 [0.65], (18.7) [0.8], 23.2 [1.0]

[a] Wavenumbers in kilokaisers with shoulders in parentheses. For $TiCl_6^{2-}$ and $TiBr_6^{2-}$ values in brackets are molar extinction coefficients and for $[Et_4N]_2TiI_6$ values are intensities relative to the strongest listed transition taken equal to 1.0.

31.11 ZIEGLER–NATTA CATALYSIS

Ziegler and Natta were jointly awarded the Nobel Prize for Chemistry in 1963. It was Ziegler[177] who first showed that ethylene can be induced to polymerize under ambient conditions in the presence of a mixture of $TiCl_4$ and $AlEt_3$, and Natta[178] demonstrated that by suitably modifying these catalysts stereoregular polymers of alkenes can be produced. Prior to these discoveries, the polymerization of ethylene involved high temperatures and pressures. The most likely mechanism is shown in Scheme 3,[179] involving (i) replacement of a coordinated chloride by an ethyl group derived from $AlEt_3$; (ii) a vacant coordination site on the surface and an ethylene molecule becoming bound; (iii) '*cis* insertion' as the ethylene migrates to the ethyl group; and (iv) another ethylene becoming bound at the vacant coordination site.

Processes (ii) and (iii) are repeated.

Scheme 3

Quite apart from the economic advantage of being able to polymerize alkenes under ambient conditions, another advantage is that with propylene, for example, the polymerization is regular and not atactic.

31.12 MISCELLANEOUS

This chapter has been devoted to the coordination chemistry of titanium and has made no attempt to describe the more basic chemistry of this element. References to alloys, to the simple halides and oxyhalides, the oxides, sulfides, selenides, tellurides, nitrides, azides, phosphides, arsenides and antimonides are well reviewed by Clark,[14] and the recent text by Greenwood and Earnshaw[180] contains a good section on titanium.

32.1 INTRODUCTION

The coordination chemistry of zirconium and hafnium is dominated by oxidation state IV and by higher coordination numbers, especially coordination number eight. Oxidation states and coordination geometries are summarized in Table 1.

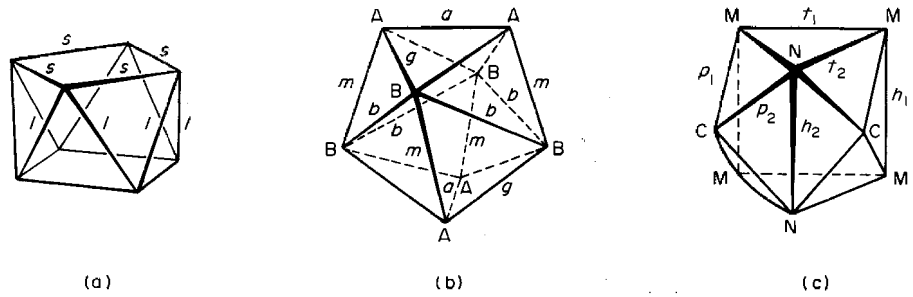
Only a small number of zirconium(III) and hafnium(III) complexes are known. Nearly all of these are metal trihalide adducts with simple Lewis bases, and few are well characterized. Just one zirconium(III) complex has been characterized structurally by X-ray diffraction, the chlorine-bridged dimer $[\{ZrCl_3(PBu_3)_2\}_2]$. Although a number of reduced halides and organometallic compounds are known in which zirconium or hafnium exhibits an oxidation state less than III, coordination compounds of these metals in the II, I or 0 oxidation states are unknown, except for a few rather poorly characterized Zr^0 and Hf^0 compounds, *viz.* $[M(bipy)_3]$, $[M(phen)_3]$ and $M'Zr(CN)_5$ (M = Zr or Hf; M' = K or Rb).

The preference of zirconium(IV) and hafnium(IV) for higher coordination numbers follows from the relatively large size and high charge of the +4 ions. Because these ions have electronic configuration d^0, there are no stereochemical preferences arising from a partly filled *d* shell. Consequently, Zr^{IV} and Hf^{IV} exhibit a great variety of coordination geometries. The three idealized coordination polyhedra for the most common coordination number, coordination number eight, are shown in Figure 1; polyhedral edges and vertices are labeled according to the nomenclature of Hoard and Silverton[1] and Porai-Koshits and Aslanov.[2] The eight vertices of the D_{4d} square antiprism are equivalent, while the D_{2d} dodecahedron has two sets of inequivalent vertices (A and B) and the C_{2v} bicapped trigonal prism has three sets of vertices (M, N and the capping sites, C). In Table 1, and throughout this chapter, the stereochemistry of tetrakis chelate complexes is indicated by specifying the polyhedral edges that are spanned by the bidentate ligands. The most common stereoisomer for tetrakis chelates is the dodecahedral *mmmm* isomer. The square antiprismatic *ssss* isomer is less common, and the bicapped trigonal prismatic $t_1t_1p_2p_2$ stereoisomer and dodecahedral D_2-*gggg*, S_4-*gggg* and *abmg* stereoisomers are rare. Of the three eight-coordination polyhedra, the dodecahedron is preferred.

A survey of the ligands which coordinate to zirconium and hafnium indicates that complexes with metal–oxygen bonds are most abundant. Complexes with metal–halogen and metal–nitrogen bonds follow in decreasing order of abundance. The chemistries of zirconium and hafnium are closely similar, more similar than for any other pair of elements. Because of the lanthanide contraction, zirconium–ligand and hafnium–ligand bond lengths are nearly identical. Based on a limited amount of thermochemical data, hafnium–ligand bonds appear to be slightly stronger than zirconium–ligand bonds.

Zirconium and hafnium complexes are highly fluxional. NMR studies indicate stereochemical nonrigidity, facile exchange of terminal and bridging ligands, and rapid intermolecular ligand exchange.

This chapter reviews the literature up to approximately January 1984. Previous comprehensive reviews of the chemistry of zirconium and hafnium are available,[3–6] and annual surveys of the inorganic and coordination chemistry of these elements have been published since 1981.[7–9] The present treatment emphasizes the chemistry of discrete, isolable complexes, although some attention has been given to the extremely complex aqueous solution chemistry of Zr^{IV} and Hf^{IV}. In general, zirconium forms slightly more stable complexes in solution than does hafnium; stability constants may be found in standard compilations.[10–13] In cases where the structural chemistry of discrete complexes is closely related to that of chain, layer or extended three-dimensional structures, the discussion of the discrete complexes has been set in the broader context; the section on fluorometallate complexes is a case in point. Organometallic compounds of zirconium and hafnium[14] have been excluded almost entirely.



32.2 ZIRCONIUM(0) AND HAFNIUM(0)

32.2.1 Group IV Ligands

Air- and moisture-sensitive complex cyanides of composition $M'_5Zr(CN)_5$ (M' = K or Rb) have been prepared by reaction at −50 °C in anhydrous ammonia of zirconium(III) bromide with an excess of either KCN or RbCN. In the case of the reaction involving KCN, the 1:3 distribution of zirconium between the gray, ammonia-insoluble $K_5Zr(CN)_5$ and the soluble zirconium(IV) products is in accord with the disproportionation shown in equation (1). The

magnetic moment of $K_5Zr(CN)_5$ is 2.69 BM at room temperature and its ESR spectrum shows a signal with $g = 1.986$. The absence of free KCN in the product has been confirmed by X-ray powder diffraction. The IR spectrum of $K_5Zr(CN)_5$ exhibits at least five bands in the C≡N stretching region at 2195, 2173, 2112, 2097 and 2073 cm^{-1}, suggesting a rather low symmetry structure.[15]

$$4ZrBr_3 + 5KCN + 6NH_3 \longrightarrow K_5Zr(CN)_5(s) + 3ZrBr_3(NH_2) + 3NH_4Br \quad (1)$$

32.2.2 Nitrogen Ligands

The tris(2,2′-bipyridyl) and tris(1,10-phenanthroline) complexes, $[M(bipy)_3]$ and $[M(phen)_3]$ (M = Zr or Hf), can be synthesized in ~80% yield by sodium amalgam reduction of $ZrCl_4$ or $HfCl_4$ in THF solutions that contain a stoichiometric amount of the ligand. These compounds are dark colored, extremely air-sensitive, monomeric and diamagnetic in solution.[16] $[Zr(bipy)_3]$ has also been prepared by using $Li_2(bipy)$ as the reducing agent. This procedure afforded copper-colored crystals that have an effective magnetic moment of 0.31 BM.[17] Further reduction of $[Zr(bipy)_3]$ in THF gives $Li[Zr(bipy)_3]\cdot 4THF$ (dark violet crystals, $\mu_{eff} = 1.70$ BM) and $Li_2[Zr(bipy)_3]\cdot 8THF$ (dark colored crystals, $\mu_{eff} = 1.10$ BM).[18] The formal oxidation state of zirconium in the $[Zr(bipy)_3]^{n-}$ ($n = 0, 1$ or 2) could be regarded as 0, −I or −II, respectively; however, because of the likelihood of electron delocalization on to the aromatic ligands, there are the usual problems here in assigning formal oxidation states.

32.3 ZIRCONIUM(III) AND HAFNIUM(III)

The coordination chemistry of zirconium(III) is an ill-defined and relatively unexplored area.[19] Only one magnetically dilute zirconium(III) complex has been isolated, $[ZrCl_3(tfars)]\cdot MeCN$ [tfars = 1, 2-bis(dimethylarsino)-3,3,4,4-tetrafluorocyclobutene $(CF_2)_2C_2(AsMe_2)_2$][20] and the first structurally characterized zirconium(III) complex $[\{ZrCl_3(PBu_3)_2\}_2]$ has just recently been reported.[21] The known zirconium(III) complexes and their physical properties are listed in Table 2. Even less is known about the coordination chemistry of hafnium(III). Just one complex, $HfCl_3(py)_4$, has been reported.[22]

32.3.1 Nitrogen Ligands

The ammonia adduct $ZrBr_3(NH_3)_6$ has been obtained as a dark brown crystalline solid upon treatment of $ZrBr_3$ with liquid ammonia.[15]

Fowles *et al.*[23,24] have prepared a number of adducts of ZrX_3 (X = Cl, Br or I) with pyridine, 2,2′-bipyridyl, 1,10-phenanthroline and acetonitrile (Table 2). These highly colored, air-sensitive compounds have unusual stoichiometries and low magnetic moments. The metal-to-ligand ratio is 1:2 for $ZrX_3(py)_2$ (X = Cl, Br or I) and $ZrBr_3(bipy)_2$, 1:1.5 for $Zr_2X_6(bipy)_3$ (X = Cl or I) and $Zr_2Cl_6(phen)_3$, and 1:2.5 for $Zr_2X_6(MeCN)_5$ (X = Cl, Br or I). The magnetic properties of these compounds suggest dinuclear or oligonuclear structures with some electronic interaction between neighboring Zr atoms. For example, halogen-bridged dimeric

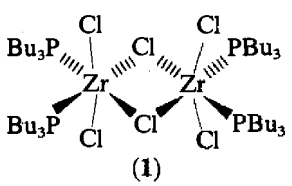
structures, $[(py)_2X_2ZrX_2ZrX_2(py)_2]$ and $[(MeCN)_3X_2ZrX_2ZrX_2(NCMe)_2]$, have been proposed for the pyridine and acetonitrile adducts. However, because the complexes are too insoluble for molecular weight measurements, structural proposals are necessarily speculative. Conductance measurements (Table 2) indicate that the iodide complexes and $Zr_2Cl_6(phen)_3$ behave as 1:1 electrolytes in acetonitrile; species such as $[ZrI_2(py)_2(MeCN)_2]^+I^-$, $[ZrI_2(bipy)_2]^+[ZrI_4(bipy)]^-$ and $[ZrCl_2(phen)_2]^+[ZrCl_4(phen)]^-$ may be formed.

In a thesis, Wasmund[22] has reported the reduction of $ZrCl_4$ and $HfCl_4$ with alkali metals in pyridine to give MCl_3–pyridine adducts having stoichiometries $ZrCl_3(py)_3$ and $HfCl_3(py)_4$, respectively. The zirconium complex is weakly paramagnetic ($\mu_{eff} = 0.39$ BM) and the hafnium compound is diamagnetic, but ESR spectra of both complexes in pyridine are said to indicate the existence of 'a paramagnetic species of unknown character.'

Larsen and Henzler[25] have described the preparation of $ZrCl_3(3,5\text{-lutidine})_2$ and $ZrCl_3(2,4\text{-lutidine})_{1.2-1.3}$ by slow reaction of crystalline $ZrCl_3$ with benzene solutions of the appropriate lutidine at room temperature over periods of up to 30 days. These investigators view the lutidine adducts as intercalation compounds, in which the lutidine is inserted into the solid between the chains of $ZrCl_6$ octahedra present in crystalline $ZrCl_3$. The frequencies of the ν(Zr—Cl) IR band and visible absorption bands of the lutidine complexes (Table 2) are appreciably shifted from the values of 333 cm^{-1} and 17 400 cm^{-1} found for $ZrCl_3$. The magnetic susceptibilities of the complexes are nearly independent of temperature, but they are very dependent on field strength. It is interesting that the more sterically hindered 2,6-lutidine did not react with $ZrCl_3$.



Olver and co-workers[26,27] have studied the polarographic reduction of $ZrCl_4$ and $HfCl_4$ in acetonitrile with 0.1 M $[NEt_4][ClO_4]$ as the supporting electrolyte. Three plateaus were interpreted in terms of reduction to the III, II and metallic states. However, controlled potential electrolysis of $ZrCl_4$ led to soluble $[ZrCl_6]^{2-}$ ions and poorly characterized precipitates, and no evidence for stable concentrations of Zr^{III} complexes could be found. Evidently, the Zr^{III} is rapidly oxidized by perchlorate, solvent or residual water.

32.3.2 Phosphorus and Arsenic Ligands

Dinuclear zirconium(III) complexes of the type $[\{ZrCl_3(PR_3)_2\}_2]$ (R = Et, Pr or Bu) have been prepared in high yield by reduction of $[ZrCl_4(PR_3)_2]$ with one equivalent of sodium amalgam.[21] The less soluble methyl derivative $[\{ZrCl_3(PMe_3)_2\}_2]$ was obtained by photolysis of $[Zr(CH_2CMe_3)_2Cl_2(PMe_3)_2]$.[28] Molecular weight measurements suggest that the $[\{ZrCl_3(PR_3)_2\}_2]$ complexes undergo reversible phosphine dissociation according to equation (2), and ^1H and ^{31}P NMR spectra indicate that coordinated and free phosphine exchange at a rate on the order of the NMR time scale. NMR data are included in Table 2. A weak ESR signal for toluene solutions of $[\{ZrCl_3(PR_3)_2\}_2]$ and free phosphine, which becomes more intense when excess phosphine is added, has been interpreted in terms of formation of the mononuclear complex $[ZrCl_3(PR_3)_3]$ (equation 3). $[\{ZrCl_3(PBu_3)_2\}_2]$ has a centrosymmetric chlorine-bridged structure (**1**), with distortions from regular octahedral geometry that include bending back of the four terminal Zr—Cl bonds away from the central $Zr(\mu\text{-}Cl)_2Zr$ unit; (terminal Cl)—Zr—(terminal Cl) = 165.1°. The Zr—Zr bond length is 3.182(1) Å, close to that in zirconium metal (3.1789 Å) and somewhat longer than that in β-$ZrCl_3$ (3.07 Å). Thus the Zr—Zr bond is long and presumably weak. Reactions of the $[\{ZrCl_3(PR_3)_2\}_2]$ complexes with ethylene, propylene and butadiene have been studied.[21]

$$[Zr_2Cl_6(PR_3)_4] \rightleftharpoons [Zr_2Cl_6(PR_3)_3] + PR_3 \quad (2)$$

$$0.5[\{ZrCl_3(PR_3)_2\}_2] \rightleftharpoons [ZrCl_3(PR_3)_2] \underset{-PR_3}{\overset{PR_3}{\rightleftharpoons}} [ZrCl_3(PR_3)_3] \quad (3)$$

(**1**)

Prolonged reaction of $ZrCl_4$ with 1,2-bis(dimethylarsino)3,3,4,4-tetrafluorocyclobutene,

$(CF_2)_2C_2(AsMe_2)_2$ (tfars), in acetonitrile (sealed tube, eight days at 100 °C, six months at room temperature) yields $[ZrCl_3(tfars)]\cdot MeCN$ as a brown solid. A weak IR band at 2255 cm^{-1} indicates that the acetonitrile is not coordinated to the metal. This compound is a nonelectrolyte in acetonitrile and exhibits a magnetic moment at room temperature of 1.73 BM. It appears to be the first magnetically dilute zirconium(III) complex to have been reported.[20]

32.3.3 Oxygen Ligands

No zirconium(III) complexes with oxygen donor ligands have been isolated. However, the electronic absorption spectra of aqueous solutions of ZrI_3 have been interpreted in terms of the formation of aqua complexes (equation 4).[29] The spectrum of a freshly prepared solution of ZrI_3 exhibits a band at 24 400 cm^{-1}, which decays over a period of 40 minutes, and a shoulder at 22 000 cm^{-1}, which decays more rapidly. The 24 400 cm^{-1} band has been assigned to $[Zr(H_2O)_6]^{3+}$, and the 22 000 cm^{-1} shoulder has been attributed to an unstable intermediate iodo–aqua complex. If it is assumed that the absorption band of $[Zr(H_2O)_6]^{3+}$ is due to the $^2T_{2g} \rightarrow {}^2E_g$ ligand-field transition, the value of Δ is 24 400 cm^{-1}. This corresponds to a Δ value of 20 300 cm^{-1} for $[Ti(H_2O)_6]^{3+}$ [30] and 17 400 cm^{-1} for the octahedral $ZrCl_6$ chromophore in zirconium(III) chloride.[25]

$$ZrI_3 \xrightarrow{\text{fast}} [ZrI_n(H_2O)_{6-n}]^{3-n} \xrightarrow{\text{slow}} [Zr(H_2O)_6]^{3+} \xrightarrow[\text{oxidation}]{\text{slow}} Zr^{IV} \qquad (4)$$

32.3.4 Halogen Ligands

K_2ZrF_5 has been mentioned by Ehrlich.[31] It is described as a white solid which can be sublimed and which exhibits slight temperature-independent paramagnetism.

Reduction of Zr^{IV} in ZrX_4–Al_2X_6 (X = Cl, Br or I) melts, with either zirconium or aluminum metal, yields soluble blue species. These species were not isolated, but they have been formulated as $Zr(X_2AlX_2)_3$ complexes on the basis of their electronic spectra. Absorption bands at 17 400 (X = Cl), 16 000 (X = Br) and 14 000 cm^{-1} (X = I) may be assigned to the $^2T_{2g} \rightarrow {}^2E_g$ transition of Zr^{III} in an octahedral environment of halide ions. The solid zirconium(III) halides exhibit ligand-field bands at closely similar frequencies.[32]

32.4 ZIRCONIUM(IV) AND HAFNIUM(IV)

32.4.1 Group IV Ligands

32.4.1.1 Cyanides

Very little is known about cyanide complexes of zirconium(IV) or hafnium(IV). Just one compound has been reported. $[Hf(CN)\{N(SiMe_3)_2\}_3]$ (m.p. 170–172 °C dec.; ν(CN) 2160 cm^{-1}) has been prepared by reaction of $[HfCl\{N(SiMe_3)_2\}_3]$ with Me_3SiCN in toluene at reflux.[33]

32.4.1.2 Tin-containing ligands

$Zr(SnPh_3)_4$ has been obtained as a yellow solid (m.p. 70–73 °C; sintering at 65 °C) by reaction of $Zr(NEt_2)_4$ with four equivalents of Ph_3SnH. The related compound containing nine metal atoms, $(Ph_3Sn)_3ZrSnPh_2Zr(SnPh_3)_3$, was prepared *via* the sequence of reactions in equations (5)–(7). The transamination with *N*-phenylformamide (equation 6) is necessary in order to prevent diethylamine-catalyzed decomposition of Ph_2SnH_2 in the next reaction step. After purification by chromatography, the product was obtained in 22% yield as a yellow solid which melted at 100 °C (sintering at 85 °C).[34]

$$Zr(NEt_2)_4 + 3Ph_3SnH \longrightarrow (Ph_3Sn)_3Zr(NEt_2) + 3Et_2NH \qquad (5)$$

$$(Ph_3Sn)_3Zr(NEt_2) + HNPhC(O)H \longrightarrow (Ph_3Sn)_3ZrNPhC(O)H + Et_2NH \qquad (6)$$

$$2(Ph_3Sn)_3ZrNPhC(O)H + Ph_2SnH_2 \longrightarrow (Ph_3Sn)_3ZrSnPh_2Zr(SnPh_3)_3 + 2HNPhC(O)H \qquad (7)$$

32.4.2 Nitrogen Ligands

32.4.2.1 Ammonia and amines

The reactions of ammonia and aliphatic amines with zirconium(IV) chloride and hexachlorozirconate(IV) salts have been reviewed by Fowles.[35] Early work on ammonia adducts of zirconium tetrahalides is summarized in the monograph by Blumenthal.[3] Compounds of the type $ZrCl_4 \cdot nNH_3$ ($n = 8$, 4 or 2)[36] and $ZrBr_4 \cdot 4NH_3$[37] were prepared more than 80 years ago by reaction of the tetrahalides with gaseous ammonia. Thermal decomposition of $ZrCl_4 \cdot 8NH_3$ in argon gives stepwise formation of $ZrCl_4 \cdot 6NH_3$, $ZrCl_4 \cdot 4NH_3$ and finally $ZrCl_4$.[38] Tensimetric studies indicate that the $ZrCl_4 \cdot 8NH_3$ obtained upon reaction of $ZrCl_4$ with liquid ammonia is a mixture of $ZrCl_3(NH_2) \cdot 6NH_3$ and NH_4Cl.[39] The ammonolysis product can be freed of NH_4Cl by washing with liquid ammonia, and the resulting $ZrCl_3(NH_2) \cdot nNH_3$ is converted to $ZrCl_3(NH_2) \cdot NH_3$ by heating *in vacuo* at 100 °C.[40] The same ammonolysis products are obtained upon reaction of liquid ammonia with M'_2ZrCl_6 ($M' = NH_4$, Rb or Cs).[41] The reaction of gaseous $ZrCl_4$ with ammonia at 300 °C yields $ZrCl_4 \cdot 2NH_3$, which has a cubic unit cell with $a = 10.13$ Å.[42]

Zirconium(IV) and hafnium(IV) halides form adducts with a variety of monodentate and polydentate amines. Typical complexes are listed in Table 3. In general, these compounds are air- and moisture-sensitive white solids (yellow when the halide is iodide), thermally stable and insoluble in most organic solvents.

Tertiary amines yield MX_4L_2 or MX_4L complexes, depending on the steric bulk of the substituents on the nitrogen atom. Trimethylamine gives well-characterized monomeric $[MX_4(NMe_3)_2]$ (M = Zr or Hf; X = Cl, Br or I) complexes that have been assigned an octahedral *cis* or *trans* structure on the basis of the number of ν(M—X) bands in their IR spectra. On the other hand, 1:1 adducts were obtained upon reaction of $ZrCl_4$ with triethylamine, *N,N*-dimethylaminomethylferrocene or diethylaminoacetonitrile. The IR spectrum of $[ZrCl_4(Et_2NCH_2CN)]$ and a molecular weight measurement on the analogous titanium complex suggest that Et_2NCH_2CN behaves as a bidentate ligand, coordinating to the metal through the amine nitrogen atom and the triple bond of the nitrile group.

While zirconium(IV) chloride forms simple adducts with tertiary and secondary amines, aminolysis takes place with primary amines yielding amonobasic chlorides such as $ZrCl_2(NHMe)_2 \cdot NH_2Me$ and $ZrCl_3(NHR) \cdot NH_2R$ (R = Et, Pr or Bu).[43] The reactions of amines (A = Me_3N, Et_3N, Me_2NH, Et_2NH or $EtNH_2$) with the corresponding alkylammonium hexachlorozirconates $[AH]_2[ZrCl_6]$ have also been studied.[44] No reaction was observed with the tertiary amines; very slow aminolysis occurred with the secondary amines; and relatively rapid aminolysis of one Zr—Cl bond took place with ethylamine (equation 8).

$$[EtNH_3]_2[ZrCl_6] + 2EtNH_2 \longrightarrow [EtNH_3]_2[ZrCl_5(NHEt)] + [EtNH_3]Cl \quad (8)$$

Diamines such as ethylenediamine, tetramethylethylene diamine and $SiMe_2(NMe_2)_2$ give 1:1 adducts with zirconium(IV) and hafnium(IV) halides. The ν(M—X) region of IR spectra of $[MX_4(TMEDA)]$ (X = Cl or Br) and $[MCl_4\{(NMe_2)_2SiMe_2\}]$ complexes is consistent with an octahedral *cis* (C_{2v}) structure. The presence of two *N*-methyl resonances in ^{1}H NMR spectra of $[ZrCl_4\{(NMe_2)_2SiMe_2\}]$ suggests the presence of a non-planar ZrN_2Si chelate ring; the two resonances coalesce to a broad singlet at 100 °C owing to a rapid ring-inversion process. Pale yellow solid adducts, $[MCl_4\{Ti(NMe_2)_4\}]$ (M = Zr or Hf), have been prepared by displacement of trimethylamine from *n*-pentane suspensions of $[MCl_4(NMe_3)_2]$. IR spectra of the $[MCl_4\{Ti(NMe_2)_4\}]$ complexes suggest an octahedral *cis* structure about zirconium or hafnium in which $Ti(NMe_2)_4$ behaves as a bidentate chelating ligand (**2**).

(**2**)

The tripod ligand tris(2-dimethylaminoethyl)amine (Me_6tren) also displaces trimethylamine from $[MCl_4(NMe_3)_2]$ yielding 1:1 adducts $MCl_4 \cdot Me_6$tren (M = Zr or Hf). On the basis of IR and ^{1}H NMR data these compounds have been formulated as $[MCl_2\{Me_6tren\}]Cl_2$ salts in which Me_6tren behaves as a tetradentate ligand. Unfortunately, conductance studies proved unreliable.

32.4.2.2 N-heterocyclic ligands

Monodentate N-heterocyclic amines such as pyridine, substituted pyridines, benzoquinolines, imidazoles and indazoles, and bidentate amines such as 2,2′-bipyridyl and 1,10-phenanthroline react with zirconium(IV) and hafnium(IV) halides to give moisture-sensitive, diamagnetic adducts that are generally insoluble in most organic solvents. Typical complexes are listed in Table 4. They may be prepared by prolonged stirring of a solution of the ligand and a suspension of the metal halide in an inert solvent such as benzene or dichloromethane. Alternatively, the adducts may be precipitated by mixing solutions of the ligand and metal halide in a donor solvent such as acetonitrile, ether or ethyl acetate.

Octahedral 1:2 adducts $[MX_4L_2]$ are the usual products of the reaction of zirconium(IV) or hafnium(IV) halides with monodentate N-heterocyclic amines. However, there are exceptions. Both 1:2 and 1:3 adducts have been reported for X = Cl and L = pyridine; the $MCl_4(py)_3$ (M = Zr or Hf) complexes are converted to $[MCl_4(py)_2]$ upon heating *in vacuo* for seven hours at 65–75 °C.[45] While 3,5-lutidine and 2,4-lutidine react with ZrX_4 (X = Cl, Br or I) to give the expected 1:2 adducts, the more sterically hindered 2,6-lutidine yields 1:1 adducts. IR and ^{1}H NMR spectra of $ZrCl_4$(2,6-lutidine) suggest that this complex may have a symmetrical, chlorine-bridged dimeric structure.[25] 5,6-Benzoquinoline also gives a 1:1 adduct with zirconium(IV) chloride, whereas 3,4-benzoquinoline yields the expected 1:2 complex.

X-Ray structures of these complexes are not yet available. However, the $[MX_4L_2]$ adducts have been assigned octahedral *cis* or *trans* structures on the basis of the number of metal–halogen stretching bands in IR spectra. *cis*-$[MCl_4L_2]$ complexes exhibit two or more ν(M—Cl) bands in the region 275—360 cm^{-1},[45] while *trans*-$[MCl_4L_2]$ compounds show a single ν(M—Cl) band at about 335–350 cm^{-1}.[25] Both *cis* and *trans* isomers are observed (Table 4), and the preferred configuration is not easily rationalized in terms of the structure of the ligand.

Table 4 Complexes of Zirconium(IV) and Hafnium(IV) Halides with N-heterocyclic Ligands

Ligand	*Complex*[a]	*Physical method*[b]	*Structure (ligand donor atom)*	*Ref.*
Pyridine	$[MCl_4(py)_2]$	P, IR, ΔH	*cis*	1–7

IR spectra are also useful in identifying the ligand donor atom in the case of complexes that contain ambidentate or potentially bidentate ligands. Thus, 3-cyanopyridine, 2-acetylpyridine and nicotinamide behave as monodentate ligands in $[MCl_4L_2]$ complexes, coordinating to the metal only through the pyridine nitrogen atom. Imidazoles bind to metal tetrachlorides at the unsaturated nitrogen atoms, while indazoles are attached at the pyrrole nitrogen atom. The absence of a band at 960 cm^{-1} in the IR spectra of $ZrX_4(pyrazine)_2$ (X = Cl or Br) complexes indicates that, at least in the solid state, both pyrazine nitrogen atoms are coordinated. Evidently pyrazine bridges between two metal atoms. The molar conductance of a $\sim 10^{-3}$ M acetonitrile solution of $ZrCl_4(pyrazine)_2$ is close to that expected for a nonelectrolyte; the small

conductance observed may be due to slight dissociation (equation 9). Unfortunately, the low solubility of the $ZrX_4(pyrazine)_2$ complexes precluded molecular weight measurements.

$$ZrCl_4(pyrazine)_2 + MeCN \rightleftharpoons [ZrCl_3(MeCN)(pyrazine)_2]^+ + Cl^- \quad (9)$$

Zirconium(IV) fluoride reacts with 2,2′-bipyridyl to give $[ZrF_4(bipy)_2]$, whereas zirconium(IV) and hafnium(IV) chlorides yield $[MCl_4(bipy)]$ or $MCl_4(bipy)_{1.5}$, depending on the stoichiometry of the reaction mixture. Only the 1:1 adduct $[ZrBr_4(bipy)]$ is known in the case of the bromide. $[ZrF_4(bipy)_2]$ has been assigned an eight-coordinate structure on the basis of IR spectra and conductance measurements. This compound exhibits ν(Zr—F) bands at 483 and 504 cm^{-1}, consistent with the two IR-active Zr—F stretching modes ($b_2 + e$) expected for a D_{2d} dodecahedral structure.[46] An ionic structure, $[MCl_2(bipy)_3][MCl_6]$, has been suggested for the isomorphous $MCl_4(bipy)_{1.5}$ (M = Zr or Hf) complexes, but attempts to isolate the eight-coordinate cation by preparation of the perchlorate or tetrafluoroborate salts were unsuccessful.[46] The ν(M—X) region of IR spectra of the $[MX_4(bipy)]$ (M = Zr or Hf, X = Cl; M = Zr, X = Br) complexes is consistent with an octahedral *cis* (C_{2v}) structure. The structure of the $[MX_4(phen)]$ analogues may be more complex since IR spectra of the $[MCl_4(phen)]$ complexes exhibit five ν(M—Cl) bands.[45] Molar conductances of the $[ZrX_4L]$ (L = bipy or phen) complexes in acetonitrile are much less than expected for a 1:1 electrolyte, but slight dissociation in this solvent (equation 10) is indicated.[47]

$$[ZrX_4L] + MeCN \rightleftharpoons [ZrX_3L(MeCN)]^+ + X^- \quad (10)$$

Oxozirconium(IV) complexes of the type $ZrOX_2L_n$ (L = pyridine, α-picoline, 2-aminopyridine, 2,4-lutidine, 2,6-lutidine or quinoline; $n = 4$ when X = Cl, Br, I or ClO_4; $n = 2$ when X = NO_3 or NCS) have been reported.[48–50] The corresponding 2,2′-bipyridyl and 1,10-phenanthroline complexes have stoichiometries $ZrO(ClO_4)_2L_3$, $ZrOX_2L_2$ (X = Cl, Br or I) and $ZrOX_2L$ (X = NO_3 or NCS). All of these compounds are monomeric nonelectrolytes in nitrobenzene except for the perchlorate derivatives, which behave as 1:2 electrolytes. The structures of these complexes are unknown. However, several conclusions have been drawn on the basis of IR studies: (i) the nitrate ligands are bidentate; (ii) the NCS ligands bond to zirconium through the nitrogen atom; and (iii) the perchlorate compounds contain uncoordinated ClO_4^- ions. A weak IR band in the 900–980 cm^{-1} region has been assigned to ν(Zr=O),[50] but the presence of the zirconyl group needs to be confirmed by X-ray diffraction since this species rarely occurs[51–54] (see Section 32.4.4.1).

Zirconium and hafnium cyanate, thiocyanate, and selenocyanate complexes that contain N-heterocyclic ligands are discussed in Sections 32.4.2.5.iii, 32.4.2.5.iv and 32.4.2.5.v.

32.4.2.3 Hydrazine and nitro ligands

The reaction of zirconium(IV) fluoride with excess anhydrous hydrazine yields the 1:2 adduct $ZrF_4(N_2H_4)_2$, which loses one molecule of hydrazine at 230–245 °C. $ZrF_4(N_2H_4)_2$ and $ZrF_4(N_2H_4)$ have been characterized by their IR spectra.[55]

Hydrazine and substituted-hydrazine complexes of the type $ZrOX_2(NH_2NHR)_4$ (R = H, Me or Ph; X = Cl, Br, I, NCS or NO_3) have been synthesized by addition of six equivalents of the hydrazine to an ethanol solution of the appropriate zirconyl salt. An IR band at ~970 cm^{-1} assigned to ν(N—N) indicates the presence of bidentate chelating or bridging hydrazine ligands; these complexes may be polymeric since they are insoluble in common organic solvents.[56]

Substituted phenylhydrazido(1−) complexes $[XC_6H_4NHNH_3]_2[ZrCl_{6-n}(NHNHC_6H_4X)_n]$ (X = Cl, Br, I or NO_2; $n = 1$, 2, 3, 4 or 6) are formed upon reaction in alcohol or dioxane of $ZrCl_4$ with $XC_6H_4NHNH_2$ or the corresponding hydrazine hydrochloride. The thermal decomposition of these compounds has been studied.[57–59]

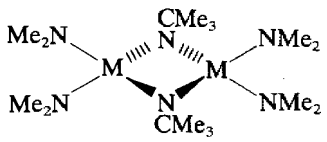
Nitro complexes $[M(NO_2)_4(DMF)_2]$ (M = Zr or Hf) have been prepared by reaction of $ZrCl_4$ with four equiv. of $AgNO_2$ in dimethylformamide–acetonitrile. Addition of 2,2′-bipyridyl or 1,10-phenanthroline to solutions of $[M(NO_2)_4(DMF)_2]$ yields the corresponding $[M(NO_2)_4(bipy)]$ or $[M(NO_2)_4(phen)]$ complexes. The reaction of $[Zr(NO_2)_4(DMF)_2]$ with $(NBu_4)Br$ gives $(NBu_4)_2[Zr(NO_2)_6]$. IR spectra of these complexes indicate that the nitro group is coordinated through the nitrogen atom.[60]

32.4.2.4 Dialkylamido-, bis(trimethylsilylamido)- and bis(amido)-silane ligands

(*i*) *Dialkylamido ligands*

Metal dialkylamides were reviewed by Bradley in 1972.[61] A comprehensive list of all zirconium and hafnium amides reported prior to 1979 may be found in the book by Lappert *et al.*[62]

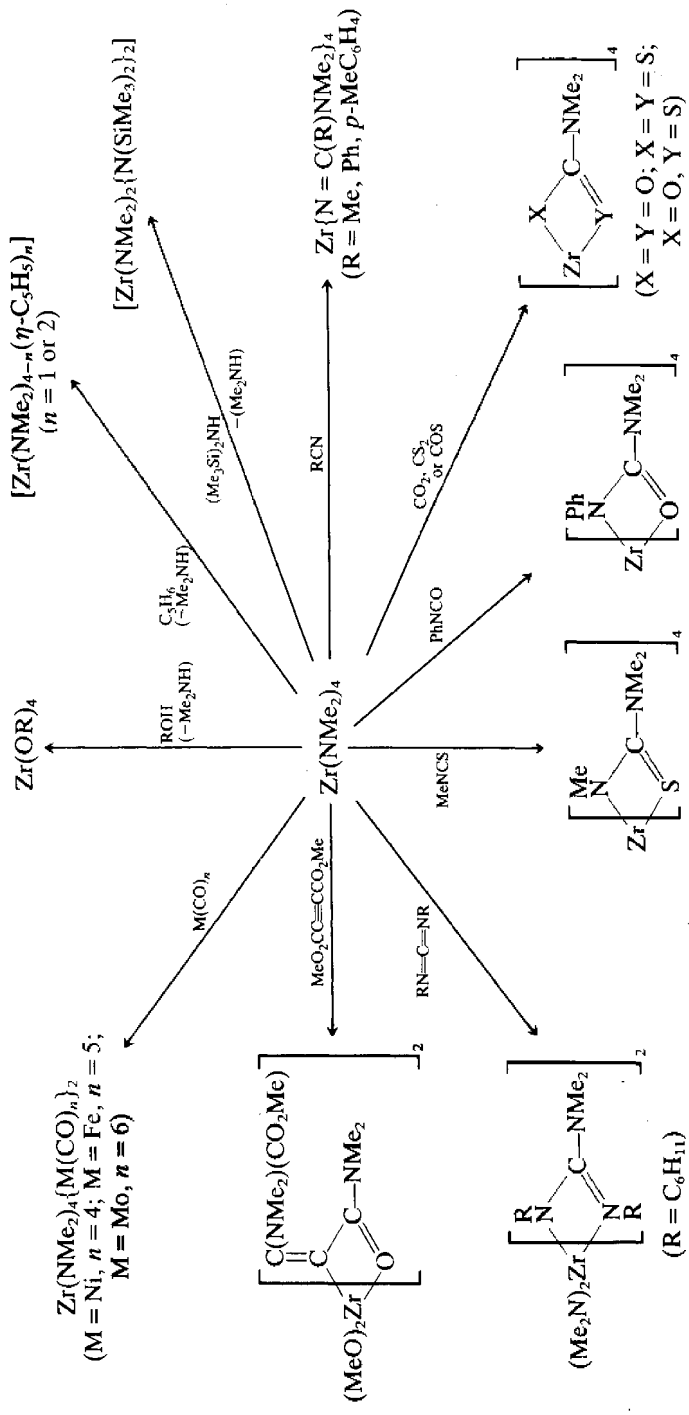
Dialkylamido complexes of the type $M(NR_2)_4$ (M = Zr or Hf; R = Me, Et, Pr, Bu, $CHMe_2$ or CH_2CHMe_2; $R_2 = NC_5H_{10}$, NC_5H_9Me or $NC_5H_8Me_2$) may be prepared by reaction of the metal tetrachloride with the appropriate lithium dialkylamide (equation 11) or by transamination between $M(NR_2)_4$ (R = Me or Et) and a higher boiling secondary amine (equation 12).[63–66] The transamination approach may also be used to prepare mixed ligand complexes such as $[Zr(NMe_2)_2\{N(CHMe_2)_2\}_2]$ or $[Zr(NEt_2)_3\{N(CHMe_2)_2\}]$.[63] The $M(NR_2)_4$ complexes are moisture-sensitive, volatile liquids or low-melting solids that can be distilled or sublimed at ~0.1 mmHg. Originally, some of these compounds were said to be green or blue,[63] but it now appears that the pure compounds are generally colorless or yellow.[6,64–66] Molecular weight measurements in boiling benzene indicate that $Zr(NMe_2)_4$ is partly polymerized; the degree of association is 1.22 in benzene, and ^1H NMR studies in dichloromethane show that the degree of association increases with decreasing temperature.[63,65] $[Zr(NEt_2)_4]$ is monomeric in boiling benzene, and complexes that contain higher amides are presumably monomeric as well.



$$4MCl_4 + 4LiNR_2 \longrightarrow M(NR_2)_4 + 4LiCl \quad (11)$$

$$M(NR_2)_4 + 4R'_2NH \longrightarrow M(NR'_2)_4 + 4R_2NH \quad (12)$$

He^I photoelectron spectra of $[M(NR_2)_4]$ (M = Zr or Hf; R = Me or Et) have been recorded, and the lowest energy band has been assigned to ionization from molecular orbitals having nitrogen 'lone pair' character. Splitting of this band indicates that free rotation about the M—N bond is not occurring in these compounds.[67] Calorimetric measurements on alcoholysis reactions of $[Zr(NR_2)_4]$ (R = Me or Et) and $[Hf(NEt_2)_4]$ have afforded the following values for the mean thermochemical bond energies (kJ mol^{-1}): Zr—N, 377; Hf—N, 397.[68] IR spectra of the $[M(NR_2)_4]$ complexes exhibit a single M—N stretching frequency (at 530–680 cm^{-1}), consistent with the local T_d symmetry of the MN_4 core.[65]



Zirconium and hafnium dialkylamides are highly reactive compounds. They undergo (i) protolytic substitution reactions with reagents such as alcohols, cyclopentadiene and bis(trimethylsilyl)amine;[63,64] (ii) insertion reactions with CO_2, CS_2, COS, nitriles, phenyl isocyanate, methyl isothiocyanate, carbodiimides and dimethyl acetylenedicarboxylate;[69–72] and (iii) addition reactions with metal carbonyls.[73] These reactions are summarized with reference to $Zr(NMe_2)_4$ in Scheme 1.

Transamination between $[Zr(NEt_2)_4]$ and primary amines does not give stable $Zr(NHR)_4$ complexes; the reaction of $[Zr(NEt_2)_4]$ with RNH_2 (R = Et, Pr, Bu or Ph) in hydrocarbon solvents at 0–5 °C yields precipitates of composition $Zr(NR)(NHR)_2$.[74] The dinuclear *t*-butylimido derivatives $[\{M(NCMe_3)(NMe_2)_2\}_2]$ (M = Zr or Hf) (**3**) have been prepared by heating a hexane solution of $M(NMe_2)_4$ under reflux with one equivalent of Me_3CNH_2, followed by removal of the solvent and sublimation of the residue at 150 °C *in vacuo*. The dimeric structure of (**3**) has been confirmed by an X-ray study of the zirconium complex. The geometry about the Zr atom is roughly tetrahedral, with the Zr—N bonds to the nearly planar dimethylamide ligands (average 2.060 Å) and the symmetrically bridging *t*-butylimide ligands (average 2.066 Å) being nearly identical. The molecule is centrosymmetric, and the Zr_2N_2 ring is planar.[75]

(**3**)

Acylamido complexes of the type $Zr(NHCOR)_n(OCHMe_2)_{4-n}$ ($n = 1, 2, 3$ or 4; R = Me, Ph or C_5H_4N) have been prepared in quantitative yield by reaction of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with stoichiometric amounts of acetamide, benzamide or nictotinamide. These compounds are insoluble in common organic solvents, nonvolatile and probably polymeric. IR spectra show

[Zr(NMe2)4−n(η-C5H5)n]
(n = 1 or 2)
[Zr(NMe2)2{N(SiMe3)2}2]
Zr{N = C(R)NMe2}4
(R = Me, Ph, p-MeC6H4)

Scheme 1

unperturbed ν(C=O) vibrations, indicating that the NHCOR ligands coordinate through the nitrogen atom.[76]

Reaction of an excess of imidazole with tetrabenzylzirconium in THF at 52 °C yields $Zr(C_3N_2H_3)_4$ as a yellow crystalline solid.[77] The pyrrolyl complex $[Na(THF)_6]_2[Zr(\eta^1\text{-}NC_4H_4)_6]$ has been prepared by reaction of $[ZrCl_2(\eta\text{-}C_5H_5)_2]$ with (pyrrolyl)sodium in THF at reflux temperature. The $[Zr(\eta^1\text{-}NC_4H_4)_6]^{2-}$ ion is octahedral (crystallographic point group symmetry $\bar{3}$) with N—Zr—N bond angles near 90°. Short Zr—N bond lengths (2.198 Å) and Zr—N—(centroid η^1-NC_4H_4) angles of 179° are indicative of considerable d_π–p_π character in the Zr—N bonds.[78]

(*ii*) *Bis(trimethylsilylamido) ligands*

Chlorobis(trimethylsilyl)amido complexes $[MCl\{N(SiMe_3)_2\}_3]$ and $[MCl_2\{N(SiMe_3)_2\}_2]$ (M = Zr or Hf) have been prepared by reaction of the metal tetrachloride with a stoichiometric amount of lithium or sodium bis(trimethylsilyl)amide.[79–81] The $[MCl\{N(SiMe_3)_2\}_3]$ complexes are surprisingly inert to substitution reactions; they do not react with dioxygen, water, dilute mineral acids, aqueous $AgNO_3$, $LiCH_2SiMe_3$, $LiBH_4$ or excess $Na[N(SiMe_3)_2]$. However, they do react with methyllithium, yielding $[M\{N(SiMe_3)_2\}_3(Me)]$,[79] and $[HfCl\{N(SiMe_3)_3\}]$ is conveniently converted to $[HfX\{N(SiMe_3)_2\}_3]$ (X = Br, I, N_3 or CN) by reaction for 12 hours in refluxing toluene with the appropriate trimethylsilyl halide or pseudohalide (equation 13).[33]

$$[HfCl\{N(SiMe_3)_2\}_3] + Me_3SiX \longrightarrow [HfX\{N(SiMe_3)_2\}_3] + Me_3SiCl \quad (13)$$

The corresponding $[MCl_2\{N(SiMe_3)_2\}_2]$ (M = Zr or Hf) complexes are considerably more reactive than the $[MCl\{N(SiMe_3)_2\}_3]$ analogues. The dichlorobis(silylamides) are air- and moisture-sensitive. They can be converted to $[MCl(BH_4)\{N(SiMe_3)_2\}_2]$ (M = Zr or Hf) and $[HfCl(OSiMe_3)\{N(SiMe_3)_2\}_2]$ derivatives, and they serve as starting materials for the preparation of a variety of alkyl complexes of the type $[M\{N(SiMe_3)_2\}_2R_2]$, $[Hf\{N(SiMe_3)_2\}_2RR']$ and $[HfCl\{N(SiMe_3)_2\}_2R]$.[81,82]

Physical and spectroscopic properties of the inorganic bis(trimethylsilylamido) complexes are listed in Table 5. These compounds are relatively low-melting, colorless or white crystalline solids; they have been characterized by IR, ^1H NMR and $^{13}C\{^1H\}$ NMR spectroscopy.

Table 5 Bis(trimethylsilylamido) Complexes of Zirconium(IV) and Hafnium(IV)

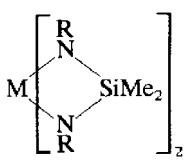
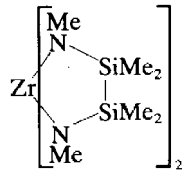
X-Ray and NMR studies[80] of the $[MCl\{N(SiMe_3)_2\}_3]$ (M = Zr or Hf) complexes indicate the presence of considerable steric crowding due to the bulky $N(SiMe_3)_2$ ligands. In the solid state, these compounds have a distorted tetrahedral structure (**4**) of crystallographically imposed C_3 symmetry [Zr—Cl = 2.394(2), Zr—N = 2.070(3), Hf—Cl = 2.436(5), Hf—N = 2.040(10) Å].

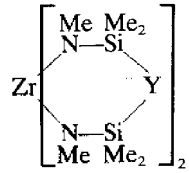


Crowding is evidenced by the Cl—M—N angles being 10–13° less than the N—M—N angles, and by the M—N—Si angles proximal to Cl being 8–10° less than the M—N—Si angles distal to Cl. ^{1}H NMR spectra, which exhibit two equally intense resonances below the coalescence temperature of 4–5 °C, are consistent with structure (**4**), and the observed line broadening has been interpreted in terms of restricted rotation about the M—N bonds. The unusual stability of the $[MCl\{N(SiMe_3)_2\}_3]$ complexes is no doubt due to the steric bulk of the bis(trimethylsilyl)amide ligands, which protect the metal atom from attack by potential reactants.



(**4**)

(iii) Bis(amido)silane ligands



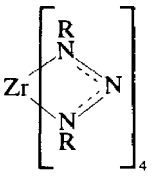
Reaction of zirconium or hafnium tetrachlorides with the lithium-substituted bis(amido)silanes $Me_2Si\{N(Li)R\}_2$, $\{SiMe_2N(Li)Me\}_2$ or $Y\{SiMe_2N(Li)Me\}_2$ yields the spirobicyclic amides (**5**)–(**11**).[83–87] These compounds are colorless or light yellow, low-melting, volatile solids. They have been characterized by mass spectra, IR and Raman spectra, and ^{1}H and ^{29}Si NMR spectra. An X-ray study of compound (**5**) has established a spirobicyclic structure of approximate D_{2d} symmetry with planar $\{ZrN_2Si\}$ rings (Zr—N = 2.053 Å, N—Zr—N bite angle = 77.9°).[83] Compounds (**9**)–(**11**) are monomeric in freezing benzene.[87]

(**5**) M = Zr, R = CMe_3
(**6**) M = Zr, R = $SiMe_3$
(**7**) M = Hf, R = $SiMe_3$

(**8**)

(**9**) Y = NMe
(**10**) Y = O
(**11**) Y = CH_2

The spirobicyclic compounds are cleaved by $ZrCl_4$ or $HfCl_4$, yielding the corresponding dichloro-monocyclic compounds (equations 14 and 15).[84,87] The dichloro compounds are oligomeric or polymeric; IR spectra suggest chlorine-bridged structures, and cryoscopic molecular weight measurements on $ZrCl_2\{(NMeSiMe_2)_2O\}$ in benzene indicate a degree of association of ~4.



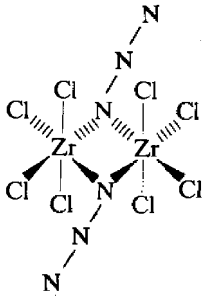
$$[M\{(NSiMe_3)_2SiMe_2\}_2] + MCl_4 \longrightarrow 2MCl_2\{(NSiMe_3)_2SiMe_2\} \quad (14)$$
(**6**) or (**7**) (M=Zr or Hf)

$$[Zr\{(NMeSiMe_2)_2Y\}_2] + ZrCl_4 \longrightarrow 2ZrCl_2\{(NMeSiMe_2)_2Y\} \quad (15)$$
(**9**), (**10**) or (**11**) (Y=NMe, O or CH_2)

32.4.2.5 Triazenes, azides, cyanates, thiocyanates, selenocyanates and related ligands

(i) Triazenes

The dark red tetrakis(1,3-diphenyltriazenido)zirconium(IV), $[Zr(dpt)_4]$ (m.p. 230 °C), has been prepared by reaction of $ZrCl_4$ and Ag(dpt) in diethyl ether.[88] The analogous, orange 1,3-dimethyltriazenido derivative, $[Zr(dmt)_4]$ (m.p. 120 °C), was synthesized from $ZrCl_4$ and Mg(dmt)I.[89] Both compounds are monomeric in benzene and are presumably eight-coordinate (**12**).



(12) R = Me or Ph

(ii) Azides

Highly explosive $ZrCl_3(N_3)$ is obtained from the reaction of $ZrCl_4$ with iodine azide in dichloromethane (equation 16). IR spectra indicate that this compound is polymeric, having both azide and chlorine bridges. The reaction of $ZrCl_4$ with one and two equivalents of $[PPh_4][N_3]$ yields the thermally and mechanically stable complexes $[PPh_4]_2[\{ZrCl_4(N_3)\}_2]$ and $[PPh_4]_2[ZrCl_4(N_3)_2]$, respectively. $[PPh_4]_2[\{ZrCl_4(N_3)\}_2]$ contains centrosymmetric dimeric anions (**13**) in which the zirconium atoms are linked by the α-nitrogen atoms of the nearly linear azide groups; average bond lengths and angles are: Zr—Cl = 2.407 Å, Zr—N = 2.203 Å, N—Zr—N = 66.7°, Zr—N—Zr = 113.3°. IR spectra suggest that $[ZrCl_4(N_3)_2]^{2-}$ has an octahedral *trans* structure.[90]

$$ZrCl_4 + IN_3 \longrightarrow ZrCl_3(N_3) + ICl \tag{16}$$

(13)

(iii) Cyanates

Three kinds of cyanate complexes have been reported: (i) $ZrCl_3(NCO)$;[91] (ii) $[NEt_4]_2[M(NCO)_6]$ (M = Zr or Hf);[92] and (iii) $M(OCN)_4L_2$ (M = Zr or Hf; L = DMSO, py, 0.5bipy or 0.5phen).[93] These compounds have been prepared from the metal tetrahalides by the reactions outlined in equations (17)–(21).

$$ZrCl_4 + IOCN \xrightarrow[-30\,°C]{CH_2Cl_2} ZrCl_3(NCO) + ICl \tag{17}$$

$$MCl_4 + 2[NEt_4][NCO] \xrightarrow{MeCN} [NEt_2]_2[MCl_4(NCO)_2] \tag{18}$$

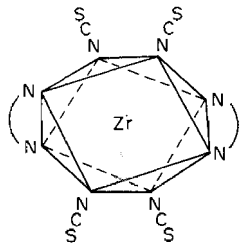
$$[NEt_4]_2[MCl_4(NCO)_2] + 4AgNCO \xrightarrow{MeCN} [NEt_4]_2[M(NCO)_6] + 4AgCl \tag{19}$$

$$MCl_4 + 2Pb(NCO)_2 \xrightarrow{THF} M(OCN)_4 + 2PbCl_2 \tag{20}$$

$$M(NCO)_4 + 2L \xrightarrow{THF} M(OCN)_4L_2 \tag{21}$$

An N-bonded attachment of the cyanate ligands in $ZrCl_3(NCO)$ and $[M(NCO)_6]^{2-}$ has been established by vibrational spectra, which exhibit a shift of the ν(C—O) mode to higher

frequency upon complex formation.[91,92] IR spectra of the $M(OCN)_4L_2$ complexes suggest that the cyanate ligands in these compounds may be coordinated through the oxygen atom;[93] however, this needs to be confirmed by structural studies. Conductance measurements show that the $M(OCN)_4L_2$ complexes dissociate according to equation (22) upon dissolution in DMF.[93]



$$M(OCN)_4L_2 + DMF \longrightarrow [M(OCN)_3L_2(DMF)]^+ + [NCO]^- \quad (22)$$

(*iv*) *Thiocyanates*

Two classes of salts containing complex thiocyanate anions have been isolated from aqueous solutions: (i) $A_2[M(NCS)_6]\cdot nH_2O$ (M = Zr or Hf; A = tetraalkylammonium or pyridinium cation)[94–98] and (ii) $A[MO(NCS)_3(H_2O)]\cdot H_2O$ (A = NH_4, C_5H_5NH, K, Rb or Cs when M = Zr; A = Cs when M = Hf).[97–100] The related oxohafnium complexes, $[C_5H_5NH][HfO(NCS)_3(H_2O)]$ and $(C_5H_5NH]_3[(HfO)_2(NCS)_7]\cdot H_2O$, have also been reported.[98,100] All of these compounds exhibit a ν(C—S) IR band at higher frequency (787–879 cm^{-1}) than in KSCN (749 cm^{-1}), indicative of an N-bonded attachment of the thiocyanate ligands. The oxometal complexes display a characteristic band at 913–927 cm^{-1} (M = Zr) or 934–940 cm^{-1} (M = Hf), which is not present in spectra of the $[C_5H_5NH]_2[M(NCS)_6]$ salts. This band may be due to the M=O stretching mode[99,100] (see Section 32.4.4.1).

Oxozirconium complexes of the type $ZrO(NCS)_2L_2$, where L is an N or O donor ligand, are discussed in Sections 32.4.2.2, 32.4.2.3 and 32.4.4.1.

The complexes $[M(NCS)_4(DMF)_4]$ and $K_2[M(NCS)_5]\cdot nDMF$ ($n = 6$ when M = Zr; $n = 4$ when M = Hf) have been prepared by mixing saturated DMF solutions of KSCN and the metal tetrachloride. IR spectra indicate that the thiocyanate ligands are N-bonded and DMF is coordinated through the carbonyl oxygen atom in the eight-coordinate $[M(NCS)_4(DMF)_4]$ complexes.[101] Related $[M(NCS)_4(bipy)_2]$ and $M(NCS)_4(phen)_3$ complexes have been reported,[102] and the X-ray structure of $[Zr(NCS)_4(bipy)_2]$ has been determined.[103] The structure (**14**) features an N-bonded attachment of the linear, monodentate thiocyanate ligands (Zr—NCS = 2.182 Å) and a square antiprismatic coordination polyhedron of crystallographically imposed D_2 symmetry. The 2,2′-bipyridyl ligands (Zr—N = 2.412 Å) span an opposite pair of lateral edges. The coordination polyhedron is slightly distorted in the direction of a D_{2d} dodecahedron; the corresponding dodecahedral stereoisomer would have the bipy ligands on the *a* edges and the NCS groups in the B sites.

(**14**)

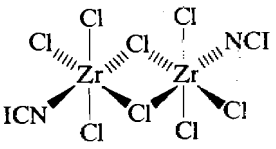
In aqueous solution, zirconium(IV) and hafnium(IV) form complexes $M(NCS)_n^{4-n}$, where $n = 1$–8.[104] Selective extraction of hafnium thiocyanate complexes from acidic aqueous solution by methyl isobutyl ketone is a widely used industrial method for the separation of zirconium and hafnium. Separation methods have been reviewed by Vinarov.[105]

(*v*) *Selenocyanates*

Tan colored $K_2[M(NCSe)_6]$ (M = Zr or Hf) complexes have been prepared by extracting the metal tetrachlorides into an acetonitrile solution of KSeCN. IR spectra indicate an N-bonded attachment of the NCSe ligands.[106]

Treatment of a THF solution of $K_2[M(NCSe)_6]$ with 2,2′-bipyridyl or 1,10-phenanthroline yields the complexes $M(NCSe)_4(bipy)_2$ and $M(NCSe)_4(phen)_3(THF)$ (M = Zr or Hf).[107] Radial

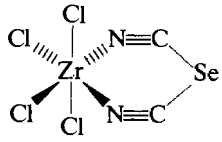
distribution curves for the hafnium compounds based on X-ray powder data show maxima assigned to Hf···Se at 4.8–4.85 Å. These data are consistent with coordination of the NCSe ligand through the nitrogen atom.[102]



The reaction of $ZrCl_4$ with freshly prepared $(SeCN)_2$ in CS_2 at −60 °C yields the substitution product $ZrCl_3(NCSe)$ (equation 23). IR spectra suggest that the SeCN group acts as a bridging ligand, coordinating through the nitrogen and selenium atoms.[108]

$$ZrCl_4 + (SeCN)_2 \longrightarrow ZrCl_3(NCSe) + ClSeCN \quad (23)$$

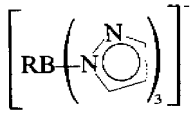
(vi) Halogenoids, interhalogen–halogenoids and interhalogenoids



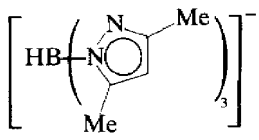
Zirconium(IV) chloride reacts with freshly prepared oxycyanogen $(OCN)_2$ in dichloromethane at −70 °C to give the 1:1 adduct $ZrCl_4(NCO)_2$. IR spectra suggest that the NCO—OCN ligand is attached to the metal through the nitrogen atoms. The nitrogen atoms appear to occupy *cis* positions in the $ZrCl_4N_2$ coordination group,but it is not known whether this compound is a monomer or a polymer.[109]

Cyanogen iodide forms a 1:1 adduct with $ZrCl_4$ in which ICN is N-bonded; a dimeric C_{2h} structure (**15**) has been proposed on the basis of IR and Raman spectra.[110] X-ray powder patterns show that the 1:2 adducts $[MCl_4(NCCl)_2]$ (M = Zr or Hf) are isostructural with $[ZrCl_4(NCMe)_2]$, and the ν(C≡N) and ν(M—Cl) regions of IR spectra confirm an octahedral *cis* geometry. The $[MCl_4(NCCl)_2]$ complexes lose one molecule of ClCN at 95–125 °C to give $MCl_4(NCCl)$ complexes, which are stable up to 190 °C.[111]

(**15**)



Vibrational spectra indicate that $ZrCl_4$ adducts with $S(CN)_2$ and $Se(CN)_2$ adopt rather different structures. The 1:2 adduct $[ZrCl_4\{S(CN)_2\}_2]$ has been assigned an octahedral *cis* structure in which the $S(CN)_2$ ligands are S-bonded. $[ZrCl_4\{Se(CN)_2\}]$, a 1:1 adduct, appears to contain an N-bonded $Se(CN)_2$ ligand, and a chelate structure (**16**) has been suggested.[112] However, oligomeric structures in which $Se(CN)_2$ acts as an N-bonded bridging ligand may be more likely in view of the geometry of $Se(CN)_2$.[113]



(**16**)

32.4.2.6 Poly(pyrazolyl)borates

Poly(pyrazolyl)borate complexes of the type $[ZrCl_3(RBPz_3)]$ (R = H, $CHMe_2$, Bu or Pz) and $[ZrCl_3\{HB(3,5\text{-}Me_2Pz)_3\}]$ have been prepared by reaction of sodium or potassium salts of the ligands (**17**) and (**18**) with two equivalents of $ZrCl_4$.[114,115] Treatment of these complexes with one equivalent of $KOCMe_3$ in toluene yields the mono-*t*-butoxide derivatives $[ZrCl_2(OCMe_3)(RBPz_3)]$ and $[ZrCl_2(OCMe_3)\{HB(3,5\text{-}Me_2Pz)_3\}]$. The $[ZrCl_2(OCMe_3)(RBPz_3)]$ complexes are fluxional on the NMR time scale ($\Delta G^{\ddagger} = 56 \pm 2$ kJ mol^{-1} for R = Bu), while the sterically more crowded $[ZrCl_2(OCMe_3)\{HB(3,5\text{-}Me_2Pz)_3\}]$ is stereochemically rigid at temperatures up to 140 °C. These rearrangements appear to take place by a trigonal twist mechanism.[115] $[ZrCl_2(OCMe_3)\{HB(3,5\text{-}Me_2Pz)_3\}]$ serves as the starting material for preparation of stable alkyl derivatives $[Zr(OCMe_3)R_2\{HB(3,5\text{-}Me_2Pz)_3\}]$ (R = Me, CH_2Ph or C≡CMe).[116] Di- and tri-*t*-butoxide derivatives $[ZrCl_{3-n}(OCMe_3)_n\{HB(3,5\text{-}Me_2Pz)_3\}]$ (n = 2 or 3) have also been reported.[115,116]

(17) $[RBPz_3]^-$

(18) $[HB(3,5\text{-}Me_2Pz)_3]^-$

Asslani *et al.*[117] have described the synthesis of the tetrakis(pyrazolyl)borate complexes $[ZrCl_2(BPz_4)_2]$, $[ZrBr_2(BPz_4)_2]$ and $[Zr(BPz_4)_4]$. Analytical and ^1H NMR data were reported for these compounds, but Reger and Tarquini[115] have been unable to reproduce the NMR data.

32.4.2.7 Nitriles

Zirconium(IV) and hafnium(IV) chlorides and bromides form 1:2 adducts of the type $[ZrX_4(RCN)_2]$ (R = Me, Et, Pr or Ph; X = Cl or Br) and $[HfX_4(MeCN)_2]$ (X = Cl or Br).[118–124] These complexes may be prepared by (i) direct reaction of the metal tetrahalide with an excess of the nitrile[120,123] or (ii) electrochemical oxidation of zirconium or hafnium metal in the presence of a solution of chlorine or bromine in acetonitrile.[118] The adducts are moisture-sensitive, white solids, insoluble in nonpolar solvents, but soluble in acetonitrile. In the later solvent, $[ZrBr_4(MeCN)_2$ behaves as a nonelectrolyte.[122]

IR (4000–180 cm^{-1}) and Raman (4000–10 cm^{-1}) spectra of $[MCl_4(MeCN)_2]$ and $(MCl_4(CD_3CN)_2]$ (M = Zr or Hf) have been reported, and normal coordinate calculations have been performed using a modified Urey–Bradley force field. Four ν(M—Cl) frequencies were observed in the region 375–310 cm^{-1}, consistent with an octahedral *cis* structure.[124] A shift of the ν(C≡N) band to higher frequencies upon complexation seems to be characteristic of coordination through the lone pair of electrons on the nitrile nitrogen atom.[120,121] UV spectra of the $[ZrX_4(RCN)_2]$ (R = Me or Et; X = Cl or Br) complexes exhibit intense bands that have been attributed to halogen → metal and nitrile → metal charge-transfer transitions.[122]

IR spectra suggest different structures for the $ZrCl_4$ complexes with diethylcyanamide and diethylaminoacetonitrile. $[ZrCl_4(Et_2NCN)_2]$ is a typical octahedral *cis* complex in which Et_2NCN coordinates through the nitrile nitrogen atom.[125] However, in $[ZrCl_4(Et_2NCH_2CN)]$, a 1:1 adduct that exhibits an 80 cm^{-1} shift of ν(C≡N) to lower frequency upon complexation, Et_2NCH_2CN appears to behave as a bidentate ligand, coordinating to zirconium through the amine nitrogen atom and the triple bond of the nitrile group.[126] IR spectra of $ZrCl_4\{(NCCH_2C_5H_4)Fe(C_5H_5)\}$ indicate that cyanomethylferrocene coordinates to zirconium through the nitrile nitrogen atom.[127]

The dinitrile complexes $[ZrCl_4(NCCH_2CN)_2]$ and $ZrCl_4\{NC(CH_2)_nCN\}$ ($n = 4$ or 8) were obtained as white solids from the reaction of excess nitrile with a suspension of $ZrCl_4$ in dichloromethane. These complexes exhibit high-frequency shifts of ν(C≡N) upon complexation, characteristic of coordination through the nitrile nitrogen atoms. The $ZrCl_4\{NC(CH_2)_nCN\}$ adducts were formulated as chelate compounds or coordination polymers, while $[ZrCl_4(NCCH_2CN)_2]$ is an ordinary 1:2 adduct in which chelation is precluded by the short length of the chain between the two nitrile groups.[128] The IR spectrum of the pale yellow phthalonitrile adduct $[ZrCl_4\{C_6H_4(CN)_2\}_2]$ suggests that phthalonitrile behaves as a monodentate ligand.[129]

32.4.2.8 Ureas

A few zirconium tetrahalide adducts with urea and its derivatives have been reported. Known compounds include $[ZrF_4\{(Me_2N)_2CO\}]$,[130] $[ZrCl_4\{(H_2N)_2CO\}_2]$[131] and $[ZrCl_4\{RC(O)NHC(O)NH_2\}]$ (R = Me or Ph).[132] IR studies indicate that urea coordinates to zirconium through the carbonyl oxygen atom.[131] The acylureas coordinate through both oxygen atoms, giving a chelate structure.[132]

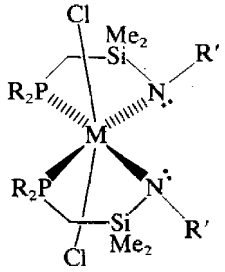
32.4.3 Phosphorus and Arsenic Ligands

32.4.3.1 Ligands containing only P or As donor atoms

Zirconium and hafnium tetrahalides form six-, seven- and eight-coordinate adducts with polydentate phosphine and arsine ligands. The 1:1 adducts $[MX_4(dppe)]$ and $[MX_4(dpae)]$ (M = Zr, X = Cl or Br; M = Hf, X = Cl; dppe = $Ph_2PCH_2CH_2PPh_2$, dpae = $Ph_2AsCH_2CH_2AsPh_2$) have been prepared in benzene media. IR spectra of the $[MCl_4(dppe)]$ complexes exhibit four ν(M—Cl) modes in the 353–278 cm^{-1} region, consistent with a six-coordinate octahedral structure.[45]

Eight-coordinate 1:2 adducts $[MX_4(diars)_2]$ (M = Zr or Hf; X = Cl or Br) are obtained from the reaction of the metal tetrahalides with *o*-phenylenebis(dimethylarsine).[133,134] These compounds are isomorphous with the corresponding titanium complex $[TiCl_4(diars)_2]$, which has a D_{2d} dodecahedral structure with the chlorine atoms in the B sites and the bidentate diarsine ligands spanning the polyhedral *a* edges.[135] The analogous $[ZrCl_4(dmpe)_2]$ (dmpe = $Me_2PCH_2CH_2PMe_2$) complex has been reported recently.[136]

Reaction of the tritertiary arsine ligand methylbis(3-dimethylarsinopropyl)arsine, $MeAs\{(CH_2)_3AsMe_2\}_2$ (tas), with $ZrBr_4$ in acetonitrile yields the 1:1 complex $[ZrBr_4(tas)]$, which is believed to be seven-coordinate on the basis of IR and conductance evidence. The methyl rocking modes at 890 and 852 cm^{-1} in the complex are at higher frequencies than in the free ligand, consistent with a tridentate attachment of the arsine ligand, and the molar conductance of a 10^{-3} M solution of $[ZrBr_4(tas)]$ in nitrobenzene indicates little dissociation of bromide ions. However, conductance studies in nitrobenzene, nitromethane, acetone and acetonitrile indicate increasing dissociation upon dilution (equation 24).[137]



$$[ZrBr_4(tas)] + \text{solvent} \rightleftharpoons [ZrBr_3(tas)(\text{solvent})]^+ + Br^- \quad (24)$$

Zirconium(IV) chloride reacts with $P(NCO)_3$ in benzene and with $P(CN)_3$ in benzene–diethyl ether to give the substitution products $ZrCl_3\{P(NCO)_2\}$ and $ZrCl_3\{P(CN)_2\}$, respectively (equation 25). These compounds have been obtained as somewhat impure, very hygroscopic solids. On the basis of IR evidence, the $P(NCO)_2$ and $P(CN)_2$ ligands are believed to be coordinated through the phosphorus atom.[138]

$$ZrCl_4 + PX_3 \longrightarrow ZrCl_3(PX_2) + ClX \quad (25)$$
(X = CN or NCO)

32.4.3.2 Ligands containing mixed donor atoms

The reaction of $LiN(SiMe_2CH_2PR_2)_2$ with either $ZrCl_4$ or $HfCl_4$ yields $[MCl_2\{N(SiMe_2CH_2PR_2)_2\}_2]$ (M = Zr or Hf; R = Me or Ph) as colorless, air- and moisture-sensitive crystalline solids. ^1H and $^{31}P\{^1H\}$ NMR spectra of these complexes are consistent with a chiral, octahedral structure (**19**) in which the bulky $N(SiMe_2CH_2PR_2)_2$ ligands are bidentate, with the two uncoordinated $SiMe_2CH_2PR_2$ groups being disposed to opposite sides of the equatorial plane. Structure (**19**), of approximate C_2 symmetry, has been established for $[ZrCl_2\{N(SiMe_2CH_2PMe_2)_2\}_2]$ by a single-crystal X-ray study; averaged bond distances are Zr—P = 2.798, Zr—N = 2.096 and Zr—Cl = 2.460 Å.[139]

(**19**) R′ = $SiMe_2CH_2PR_2$

The $[MCl_2\{N(SiMe_2CH_2PR_2)_2\}_2]$ complexes are unreactive towards nucleophiles. However,

$[HfCl_2\{N(SiMe_2CH_2PMe_2)_2\}_2]$ disproportionates in the presence of excess $HfCl_4$, yielding the 'mono' amide complex $[HfCl_3\{N(SiMe_2CH_2PMe_2\}_2]\cdot HfCl_4]_x$, which can be converted to the monomeric complex $[Hf(BH_4)_3\{N(SiMe_2CH_2PMe_2)_2\}]$ and $[Hf(BH_4)_4]$ upon reaction with excess $LiBH_4$. Treatment of $[Hf(BH_4)_3\{N(SiMe_2CH_2PMe_2)_2\}]$ with Lewis bases (NEt_3 or PMe_3) generates the dinuclear trihydride $[\{Hf[N(SiMe_2CH_2PMe_2)_2]\}_2(H)_3(BH_4)_3]$.[140]

32.4.4 Oxygen Ligands

32.4.4.1 Water, hydroxide and oxide

The extremely complicated aqueous solution chemistry of Zr^{IV} and Hf^{IV} has been reviewed by Larsen,[5] Solovkin and Tsvetkova,[51] and Clearfield.[52] Zirconium(IV) and hafnium(IV) ions undergo extensive hydrolysis, and the predominant solution species are polynuclear, even in dilute ($>10^{-4}$–10^{-3} M) solutions of high acidity (1–2 M). Spectrophotometric,[141] ultracentrifugation,[142–144] and light scattering[145] studies point to trinuclear and tetranuclear hydrolysis products; complexes such as $[M_3(OH)_4]^{8+}$ and $[M_4(OH)_8]^{8+}$ have been suggested. The mononuclear ions M^{4+} are predominant solution species only at trace metal ion concentrations ($<\sim 10^{-4}$ M). A recent potentiometric determination of hydrolysis constants, $K_h = [M(OH)^{3+}][H^+]/[M^{4+}]$, for Zr^{4+} and Hf^{4+} in perchlorate media ($[H^+] = 0.5$–4 M) confirms that Zr^{4+} ($K_h = 0.28 \pm 0.05$) is more strongly hydrolyzed than Hf^{4+} ($K_h = 0.08 \pm 0.03$).[146]

Direct evidence for the existence of tetranuclear hydroxo complexes comes from X-ray diffraction studies of the zirconyl halides, $ZrOX_2\cdot 8H_2O$ (X = Cl or Br).[147,148] These isomorphous compounds contain the $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ cation (Figure 2) in which four Zr atoms at the corners of a slightly puckered square are connected by double hydroxo bridges. Each zirconium atom is attached, in addition, to four water molecules, giving an eight coordination polyhedron best described as a distorted dodecahedron. Averaged Zr—O bond distances are Zr—OH_2 = 2.272 and Zr—OH = 2.142 Å.[148] Subsequent studies[149,150] of X-ray scattering from concentrated aqueous solutions of zirconium(IV) and hafnium(IV) halides and zirconium(IV) perchlorate are consistent with a predominant tetranuclear solution species, $[M_4(OH)_8(H_2O)_{16}]^{8+}$ (M = Zr or Hf), with a structure similar to that of the cation in the crystalline zirconyl halides.

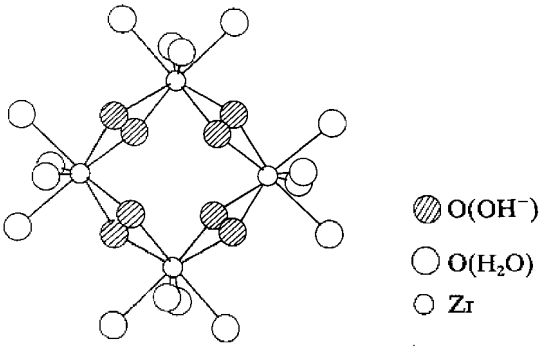


Figure 2 Structure of the $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ cation

^1H NMR spectra of zirconyl perchlorate in water–acetone mixtures at −70 °C indicate that Zr^{IV} has an average hydration number of ~four.[151] This is in accord with $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ if it is assumed that only the bound water molecules are observed; the lack of an NMR signal for the hydroxy protons could be due to rapid proton exchange.

Raman spectra of acidic aqueous solutions of $MOCl_2\cdot 8H_2O$ (M = Zr or Hf) have been examined in an effort to detect the zirconyl and hafnyl ions, $M{=}O^{2+}$. No evidence for a ν(M=O) Raman band in the region 800–1000 cm^{-1} was found.[152–154] A broad IR band centered at ~1000 cm^{-1} is observed in the multiple attenuated internal reflectance spectrum of a concentrated $ZrOCl_2$ solution.[154] However, this band shifts to lower frequency upon deuteriation, indicating that the solution species contains hydroxo bridges, and not zirconyl groups. Bands due to δ(ZrOH) in the 910–1030 cm^{-1} region of the IR spectrum of crystalline

$ZrOCl_2 \cdot 8H_2O$ exhibit similar isotopic shifts in the deuteriated analogue.[154,155] Raman spectra of 2.5 M $ZrOCl_2$ in 5 M HCl show a polarized band at 580 cm^{-1}, a depolarized band at 450 cm^{-1} and a shoulder at ~420 cm^{-1}. The former two bands are assigned to totally symmetric and non-totally symmetric ν(Zr—OH) vibrations of the $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ ion, and the 420 cm^{-1} band is tentatively assigned to a ν(Zr—OH_2) vibration. Upon addition of NaOH, the 420 cm^{-1} band decreases in intensity and a new band appears at ~530 cm^{-1}, probably due to ν(Zr—OH) vibrations involving terminal hydroxyl groups of a more highly hydrolyzed species such as $[Zr_4(OH)_8(OH)_4(H_2O)_{12}]^{4+}$.[154]

When perchloric acid solutions of Zr^{IV} are diluted from $[Zr^{IV}] \simeq 10^{-2}$ M to $[Zr^{IV}] \leq 10^{-4}$ M and the $HClO_4$ concentration is increased from 0.5 M to 2–4 M, $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ is converted to the mononuclear ion, presumably $[Zr(H_2O)_8]^{4+}$. The kinetics of this process, abbreviated $Zr_4 \rightarrow Zr$, follow the simple rate law $k_H[H^+][Zr_4]$; at ionic strength 2.0 M ($NaClO_4$): $k_H(25\,°C) = 0.95 \times 10^{-3}\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 55.2$ kJ mol^{-1}, and $\Delta S^{\ddagger} = -117 \pm 8$ J K^{-1} mol^{-1}. Acids HX, such as H_3PO_4, $H_2C_2O_4$ and HF, also induce $Zr_4 \rightarrow Zr$ conversion, giving the rate law $k_H[H^+][Zr_4] + k_{HX}[HX][Zr_4]$.[156]

X-Ray diffraction studies have established the presence of coordinated water molecules and bridging hydroxo ligands in normal and basic Zr (Hf) salts and in certain neutral and anionic complexes. Water- and hydroxo-containing compounds that consist of discrete complexes are listed in Table 6. Averaged metal–oxygen bond lengths to coordinated water molecules and bridging hydroxo ligands are in the ranges 2.20–2.29 and 2.10–2.14 Å, respectively. Structures of these complexes, mostly dodecahedral, are discussed in later sections dealing with the other ligands.

Table 6 Structural Data for Aqua and Hydroxo Complexes of Zirconium(IV) and Hafnium(IV)

Structural formula	*Coordination polyhedron*[a]	*Averaged bond lengths* (Å) *Zr—OH_2*	*Zr—OH*	*Ref.*

Very little X-ray data is available for zirconium or hafnium complexes that contain oxo ligands. The only X-ray evidence for the existence of the zirconyl or hafnyl group, $M{=}O^{2+}$, comes from a structural study of K_2ZrO_3.[157] This compound contains chains of ZrO_5 square pyramids that share basal edges. The Zr—O distance to the apical oxygen atom (1.92 Å) is appreciably shorter than the sum of ionic radii (2.20 Å), the sum of the covalent radii (2.22 Å)

and the Zr—O distances to the four basal, bridging oxygen atoms (2.13 Å). In his 1973 review of the structural chemistry of zirconium compounds, MacDermott[54] identifies the apical Zr—O bond in K_2ZrO_3 as the only probable example of a zirconium–oxygen double bond yet reported. He adds, 'There is no doubt that the 'zirconyl' group as a persistent species in solution is mythical.'

Planalp and Anderson[158] have recently reported the structure of $[\{ZrME[N(SiMe_3)_2]_2\}_2O]$, a centrosymmetric oxo-bridged dinuclear complex having a linear Zr—O—Zr bridge and a short Zr—O bond distance (1.950(1) Å). μ-Oxo compounds of the type $[\{MX(\eta\text{-}C_5H_5)_2\}_2O]$ (M = Zr or Hf; X = Cl, Me or SPh) are common in organometallic chemistry.[14] These compounds exhibit a characteristic IR band associated with the M—O—M unit at ~750–800 cm^{-1} and M—O bond distances in the neighborhood of 1.95 Å. The Zr—O bond lengths (average 1.959(3) Å) in the cyclic trinuclear complex $[\{ZrO(\eta\text{-}C_5H_5)_2\}_3]$ are similar to those in the dinuclear complexes, indicative of an appreciable amount of zirconium–oxygen $d\pi$–$p\pi$ bonding.[159]

Numerous attempts have been made to identify the zirconyl or hafnyl group in solid compounds on the basis of vibrational spectroscopy. Barraclough, Lewis and Nyholm[160] found that compounds known to have an M=O bond exhibit a strong, sharp IR band in the region 900–1100 cm^{-1} while polymers with an —M—O—M—O— chain structure give a broad band at somewhat lower frequency. Kharitonov and Zaitsev[161] suggested the range ~800–1000 cm^{-1} for ν(Zr=O) and ν(Hf=O), and noted that δ(MOH) deformation modes can give rise to strong bands in the same region. Thus, study of deuteriated compounds is necessary in order to avoid incorrect assignments. A case in point is $ZrOCl_2 \cdot 4H_2O$. This compound exhibits a sharp IR band at 918 cm^{-1}, assigned to ν(Zr=O) by Spasibenko and Goroshchenko.[162] However, Powers and Gray[155] showed that the 918 cm^{-1} band is displaced to 697 cm^{-1} in the spectrum of $ZrOCl_2 \cdot 4D_2O$, and therefore it cannot be assigned to the zirconyl group.

The IR spectrum of anhydrous $ZrOCl_2$, prepared by reaction of $ZrCl_4$ with Cl_2O, exhibits an intense band at 877 cm^{-1} and a broad band at 538 cm^{-1}. The 877 cm^{-1} band was assigned to the ZrO^{2+} cation, and the 538 cm^{-1} band to the —Zr—O—Zr—O— chain of a polymeric $\{ZrOCl_4^{2-}\}_n$ anion.[163] The same bands have been observed in the IR spectrum of an amorphous form of anhydrous $ZrOCl_2$ obtained from the reaction of $ZrCl_4$ with Sb_2O_3.[164] On the other hand, anhydrous $ZrOCl_2$ prepared by (i) thermal decomposition of $Zr_2OCl_6 \cdot 4MeCN$[165] or (ii) partial dehydration of $ZrOCl_2 \cdot 8H_2O$ with thionyl chloride followed by heating *in vacuo* at 200 °C[166] showed no bands that could be assigned to the zirconyl group.

Several oxochloro complexes of zirconium have been reported. These compounds are listed in Table 7 along with frequencies of IR bands that have been assigned to zirconium–oxygen stretching modes. The acetonitrile and dioxane adducts of Zr_2OCl_6, $[Zr_2OCl_8]^{2-}$ and $[Zr_2OCl_{10}]^{2-}$ are believed to contain Zr—O—Zr bridging units. The strong, sharp band at 1104 cm^{-1} in the spectrum of $Zr_2OCl_6 \cdot 4POCl_3$ has been cited as evidence for a Zr=O group, and both Zr=O groups and —Zr—O—Zr—O— chains have been suggested for $(C_5H_5NH)_2ZrOCl_4$.

Table 7 Zirconium—Oxygen Stretching Frequencies for Oxo–Chloro Complexes of Zirconium(IV)

Compound	$\nu(ZrO)$ (cm^{-1})	*Ref.*

Kharitonov and coworkers have presented IR evidence for the existence of the M=O group in two classes of zirconyl (hafnyl) compounds: (i) oxyfluorides such as $ZrOF_2$, $KZrOF_3 \cdot 2H_2O$, $Zr_4F_{10}O_3$, $HfOF_2$, $Hf_4F_{14}O$ and $Hf_4F_{12}O_2$;[167] (ii) isothiocyanates such as $A[ZrO(NCS)_3(H_2O)] \cdot H_2O$ (A = NH_4, C_5H_5NH, K, Rb or Cs), $A[HfO(NCS)_3(H_2O)] \cdot H_2O$ (A = C_5H_5NH or Cs) and $[C_5H_5NH]_3[(HfO)_2(NCS)_7] \cdot H_2O$.[99,100] However, Selbin[53] has been unable to duplicate the oxyfluoride work and Clearfield[52] has suggested that the intense, but rather broad, IR band reported for the oxyfluorides in the region 833–896 cm^{-1} could be assigned to an M—O—M vibration instead of an M=O mode. The isothiocyanate complexes display a sharp, rather intense band at 913–927 cm^{-1} (M = Zr) or 934–940 cm^{-1} (M = Hf),[99,100] and this has been confirmed by Selbin[53] for $A[ZrO(NCS)_3(H_2O)] \cdot H_2O$ (A = Cs or NMe_4). However, the corresponding deuteriated compounds have not been studied, and therefore it is possible that the 913–927 and 934–940 cm^{-1} band arises from a δ(MOH) vibration rather than a ν(M=O) mode.[161] Lipatova and Semenova[168] have reported that this band disappears when $Cs[MO(NCS)_3(H_2O)] \cdot H_2O$ (M = Zr or Hf) is dissolved in acetone, and reappears when the solvent is evaporated. This observation was interpreted in terms of a reversible hydrolysis of the M=O group of the solid compound, giving an $M(OH)_2$ moiety in solution. The mode of attachment of the oxygen atom in the $A[MO(NCS)_3(H_2O)] \cdot H_2O$ complexes remains uncertain, and X-ray studies are needed to establish the structure of these compounds.

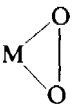
The zirconyl group has also been said to be present in oxo zirconium(IV) complexes of the type $[ZrOX_2L_2]$ (X = Cl, Br, NO_3 or NCS), $[ZrOL_4]I_2$, and $[ZrOL_6][ClO_4]_2$, where L is an oxygen donor ligand such as diphenyl sulfoxide,[169,170] tetramethylene sulfoxide,[171] pyridine *N*-oxide,[172] 2-methylpyridine *N*-oxide,[173] 2,6-lutidine *N*-oxide,[172] triphenylphosphine oxide[174] or hexamethylphosphoramide[175] and in the analogous 2,2′-bipyridine 1,1′-dioxide complexes $[ZrOX_2(bipyO_2)] \cdot 2H_2O$ (X = Cl, Br, NO_3 or NCS), $[ZrO(bipyO_2)_2]I_2 \cdot 2H_2O$ and $[ZrO(bipyO_2]_3[ClO_4]_2 \cdot 2H_2O$.[176,177] In general, the chloro, bromo, nitrato and isothiocyanato complexes are monomeric nonelectrolytes in ionizing organic solvents, while the iodide and perchlorate compounds behave as 1:2 electrolytes. IR spectra of these compounds show that (i) the nitrate ligands are bidentate, (ii) the NCS ligands are attached to zirconium through the nitrogen atom, and (iii) the perchlorate compounds contain uncoordinated ClO_4^- ions. A weak IR band in the 900–980 cm^{-1} region has been assigned to the ν(Zr=O) mode, but the low intensity of this band argues against such an assignment. On the other hand, the molecular weight and conductance data are consistent with mononuclear structures that contain a Zr=O group. Unfortunately, no X-ray structural data are available. Other compounds of unknown structure that may possibly contain a Zr=O group include oxozirconium(IV) complexes with N-heterocyclic ligands (Section 32.4.2.2), tridentate Schiff bases (Section 32.4.9.1.i) and 1,10-phenanthroline mono-*N*-oxide (Section 32.4.9.3).

Previous reviewers [51–54] have maintained a healthy skepticism concerning the existence of the $Zr{=}O^{2+}$ and $Hf{=}O^{2+}$ ions. There is no evidence for the existence of these species in aqueous solution and IR evidence for the presence of Zr=O and Hf=O groups in solid compounds is equivocal. These structural units appear to be rare, and only X-ray studies can provide really convincing evidence for their existence.

Relatively insoluble, high-melting oxometal complexes are likely to have polymeric structures based on —M—O—M—O chains. IR bands assignable to ν(Zr—O—Zr) vibrations suggest structures of this type for $ZrO(O_2CR)_2 \cdot nRCO_2H$ (R = Me, Et, Pr, CH_2Cl or Ph),[178] $ZrO(O_2SeC_6H_4X)_2$ (X = 4-Cl, 3-Cl or 3-Br), and $ZrO(O_2SeC_6H_4\text{-}3\text{-}NO_2)_2 \cdot 2H_2O$.[179] The carboxylato complexes exhibit a broad band of medium intensity in the 800–865 cm^{-1} region, and the benzeneseleninato complexes show a medium or strong band at 739–750 cm^{-1}.

32.4.4.2 Peroxide and hydroperoxide

A variety of peroxo and hydroperoxo complexes of zirconium(IV) and hafnium(IV) have been isolated from aqueous or aqueous methanolic hydrogen peroxide solutions that contain additional ligands such as sulfate, oxalate or fluoride. Examples of recently reported complexes are listed in Table 8 along with characteristic vibrational frequencies and the pH employed in the aqueous preparations. Earlier work on peroxo compounds has been reviewed by Connor and Ebsworth[180] and by Larsen.[5]



The peroxo complexes are white solids, soluble in mineral acids, but insoluble in common organic solvents. They are relatively stable at room temperature; however, they lose active oxygen at elevated temperatures. Several of the compounds in Table 8 were isolated with

variable amounts of lattice-held water of crystallization. The distinction between lattice-held and coordinated water molecules was made on the basis of thermogravimetric analysis. These complexes exhibit characteristic IR and Raman bands in the regions 840–880 and 500–600 cm^{-1} (Table 8). The band at 840–880 cm^{-1}, observed in both IR and Raman spectra, has been assigned to the O—O stretching mode of the bidentate peroxo ligand in the triangularly linked MO_2 group (**20**).[181–184] Two bands in the 500–600 cm^{-1} region have been attributed to the symmetric and asymmetric metal–oxygen stretching vibrations, $\nu_s(MO_2)$ and $\nu_{as}(MO_2)$, although this assignment is somewhat uncertain for the peroxofluoro complexes owing to the presence of ν(M—F) modes in the same frequency region.[181,185]

(**20**)

Jere and Gupta[182] have reported two ν(O—O) bands for $[Zr_2(O_2)_3(SO_4)(H_2O)_4]\cdot(4–6)H_2O$, a band at ~870 cm^{-1}, fairly strong in both IR and Raman spectra, which has been assigned to a triangularly linked bidentate peroxo ligand, and a band at 840 cm^{-1}, strong in the Raman spectrum but very weak in the IR, which was attributed to a bridging peroxo group. In principle, one should be able to distinguish these two modes of attachment since ν(O—O) of a triangular MO_2 group is both IR and Raman active, while ν(O—O) of an M—O—O—M group is active in the Raman spectrum but inactive (C_i symmetry) or only weakly allowed (C_2 symmetry) in the IR spectrum. However, Gerasimova *et al.*[185] have noted that ν(O—O) of a

triangular MO_2 group may also be very weak in the IR, and thus distinguishing the two modes of peroxide attachment may be problematic.

Structures have been suggested for some of the peroxo complexes on the basis of the vibrational spectra.[182–184] However, no X-ray structures are yet available.

The hydroperoxo complexes $K_2MF_5(O_2H)$ (M = Zr or Hf) may be distinguished from the peroxo complexes on the basis of a unique IR band of moderate intensity at ~1450 cm^{-1}. This band has been assigned to $\delta(O_2H)$.[185] X-Ray powder patterns indicate that $[NH_4]_3[MF_6(O_2H)]$ and $[NH_4]_3[MF_7]$ (M = Zr or Hf) are isostructural. Since $[MF_7]^{3-}$ has a pentagonal bipyramidal structure, the $[MF_6(O_2H)]$ ions may be assigned an analogous seven-coordinate structure, with the O_2H^- group behaving as a monodentate ligand.[185]

32.4.4.3 Alkoxides, trialkysilyloxides and aryloxides

Metal alkoxides have been extensively reviewed by Bradley[61,186–188] and by Mehrotra.[188–191] Zirconium and hafnium tetraalkoxides may be prepared by (i) reaction of alcohols with the anhydrous metal chlorides or pyridinium hexachlorometallates in the presence of ammonia (equations 26 and 27), (ii) alcoholysis or alcohol interchange (equation 28), (iii) transesterifications (equation 29) or (iv) reaction of alcohols with metal dialkylamides or metal acetylacetonates (equations 30 and 31). A preferred method for preparation of many $M(OR)_4$ (M = Zr or Hf) compounds in a high state of purity involves alcoholysis of $M(OCHMe_2)_4 \cdot HOCHMe_2$ in benzene solution; the isopropanol solvate can be purified by recrystallization from isopropanol, and the isopropanol produced in the alcoholysis is conveniently removed by fractional distillation of the benzene–isopropanol azeotrope. This approach, however, is inefficient for synthesis of the *t*-butoxides because of the small (~0.2 °C) difference in boiling points for isopropanol and *t*-butanol. The *t*-butoxides are better prepared from the tetrakis(diethylamide) (equation 30) or by transesterification between $M(OCHMe_2)_4 \cdot HOCHMe_2$ and *t*-butyl acetate.

$$MCl_4 + 4ROH + 4NH_3 \longrightarrow M(OR)_4 + 4NH_4Cl \quad (26)$$

$$[C_5H_5NH]_2[MCl_6] + 4ROH + 6NH_3 \longrightarrow M(OR)_4 + 6NH_4Cl + 2C_5H_5N \quad (27)$$

$$M(OR)_4 + 4R'OH \longrightarrow M(OR')_4 + 4ROH \quad (28)$$

$$M(OR)_4 + 4MeCOOR' \longrightarrow M(OR')_4 + 4MeCOOR \quad (29)$$

$$Zr(NEt_2)_4 + 4Me_3COH \longrightarrow Zr(OCMe_3)_4 + 4Et_2NH \quad (30)$$

$$Zr(acac)_4 + 4ROH \longrightarrow Zr(OR)_4 + 4Hacac \quad (31)$$

The reaction of alcohols with $ZrCl_4$ in the absence of ammonia yields chloride alkoxides $ZrCl_3(OR) \cdot nROH$ and $ZrCl_2(OR)_2 \cdot nROH$. Mixed alkoxides such as $Zr(OR)(OCMe_3)_3$ and $Zr(OR)_2(OCMe_3)_2$ (R = Me or Et) have been obtained from alcoholysis reactions between (i) $Zr(OR)_4$ and *t*-butanol or (ii) $Zr(OCMe_3)_4$ and ROH. The monomethoxy complex is dimeric, $[\{Zr(OMe)(OCMe_3)_3\}_2]$, and probably has a methoxy-bridged structure.

Boiling points and molecular association data for the tetraalkoxides are listed in Table 9. The methoxides are insoluble, polymeric solids of low volatility; $Zr(OMe)_4$ sublimes in a molecular still at 280 °C. $Ti(OMe)_4$ is a tetramer, but the structures of $Zr(OMe)_4$ and $Hf(OMe)_4$ remain unknown. Most of the other tetraalkoxides are volatile liquids, which are soluble in organic solvents. Two forms of zirconium isopropoxide (liquid b.p. 160 °C/0.1 mmHg and crystalline m.p. 135 °C) have been described.[192] For tetraalkoxides that contain the same number of carbon atoms, the boiling point and the degree of association (*n*) in boiling benzene decrease with increasing branching of the alkyl chain. Thus, in the case of the eight isomeric zirconium amyloxides, the primary amyloxides have values of *n* in the range 3.7–2.4, while the secondary amyloxides are dimers and the tertiary amyloxide $Zr(OCMe_2Et)_4$ is a monomer. The tertiary alkoxides are monomeric because steric hindrance prevents alkoxide bridging, which causes oligomerization of the primary and secondary alkoxides. Careful vapor pressure measurements on $M(OCMe_3)_4$ and $M(OCMe_2Et)_4$ have shown that volatility increases as M varies in the order Ti < Zr < Hf; the increase in volatility with increasing molecular weight has been attributed to an entropy effect.[193,194] $Ti(OCMe_2Et)_4$ and $Hf(OCMe_2Et)_4$ have been separated by gas chromatography, but attempts to separate $Zr(OCMe_2Et)_4$ and $Hf(OCMe_2Et)_4$ were unsuccessful.[195]

^1H NMR spectra of the trimeric isopropoxides $M(OCHMe_2)_4$ (M = Zr or Hf) indicate rapid exchange of terminal and bridging isopropoxide groups; ^1H NMR spectra of mixtures of

$M(OCMe_3)_4$ and *t*-butanol evidence rapid intermolecular exchange of *t*-butoxide ligands.[196] IR spectra of zirconium and hafnium tetraalkoxides exhibit a strong ν(C—O) band near 1000 cm^{-1} and one or more ν(M—O) bands in the region 520–590 cm^{-1}.[197,198] Calorimetric measurements have afforded the following values for mean thermochemical bond energies (kJ mol^{-1}) in $Zr(OCHMe_2)_4$ and $Hf(OCHMe_2)_4$: Zr—O, 552; Hf—O, 573.[68] No X-ray structural data are available for the tetraalkoxides except for a preliminary report of a study of the isopropanol solvates $M(OCHMe_2)_4 \cdot HOCHMe_2$ (M = Zr or Hf). These complexes have a dimeric structure in which two MO_6 octahedra share an edge.[199]

Zirconium and hafnium tetraalkoxides are highly reactive compounds. They react with water, alcohols, silanols, hydrogen halides, acetyl halides, certain Lewis bases, aryl isocyanates and other metal alkoxides. With chelating hydroxylic compounds HL, such as β-diketones, carboxylic acids and Schiff bases, they give complexes of the type $ML_n(OR)_{4-n}$; these reactions are discussed in the sections dealing with the chelating ligand.

Partial hydrolysis of zirconium alkoxides yields polymeric oxozirconium alkoxides such as $Zr_3O_4(OR)_4$ (R = Et or CMe_3), $Zr_2O_3(OCHMe_2)_2$ and $Zr_2O_3(OCMe_3)_2 \cdot 4HOCMe_3$;[200,201] complete hydrolysis gives hydrated zirconium dioxide. An X-ray study[202] of an oxo zirconium methoxide hydrolysis product has shown that the crystals contain molecules of $[Zr_{13}O_8(OMe)_{36}]$. This complex has a $\bar{3}m(D_{3d})$ structure (Figure 3) consisting of a cubic close packed arrangement of 13 Zr atoms, three above and three below a plane of seven. The central

Zr atom is surrounded by a slightly distorted cube of eight oxygen atoms (at 2.19 and 2.23 Å), each of which is attached to three of the other Zr atoms. The 12 peripheral Zr atoms are seven-coordinate, being bonded to two bridging oxygen atoms (at 2.15–2.19 Å), four bridging methoxide ligands (at 2.12–2.21 Å) and one terminal methoxide ligand (at 2.00 and 2.03 Å). An alternate route to oxozirconium alkoxides is the reaction of alcohols with $ZrOCl_2 \cdot 2MeCO_2H$ in the presence of piperidine. This approach has been used to prepare compounds of the type $ZrO(OR)_2 \cdot nROH$ and $ZrOCl(OR) \cdot nROH$ (R = Me, Et, $CHMe_2$ or CMe_3; $n = 0.5$–2.0.[203]

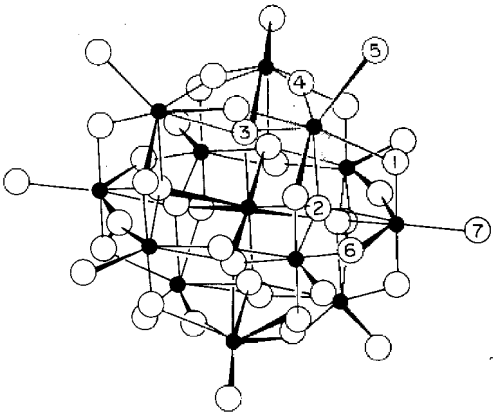

Figure 3 The arrangement of zirconium atoms (solid circles) and oxygen atoms (open circles) in molecules of $[Zr_{13}O_8(OMe)_{36}]$; O(2) and O(3) are bridging oxygen atoms while the other oxygen atoms are part of methoxide groups (reproduced by permission from ref. 202)

The synthetic utility of alcoholysis reactions of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ has been mentioned already. Additional examples are the preparation of glycoxides of the type $Zr\{O(CR_2)_xO\}(OCHMe_2)_2$, $Zr\{O(CR_2)_xO\}_2$ and $Zr\{O(CR_2)_xO\}\{O(CR_2)_xOH\}_2$ (R = H or Me)[204] and *N*-methylaminoalkoxides of the type $Zr(OR)_n(OCHMe_2)_{4-n}$ ($R = CH_2CH_2NHMe$, $CH_2CH_2NMe_2$ or $CHMeCH_2NMe_2$; $n = 1$, 2, 3 or 4)[205] from stoichiometric amounts of $ZrO(OCHMe_2)_4 \cdot HOCHMe_2$ and the appropriate glycol or aminoalcohol. The *N*-methylaminoalkoxides are monomeric in boiling benzene except for $Zr(OCH_2CH_2NHMe)_n(OCHMe_2)_{4-n}$ ($n = 1$ or 2), which are dimeric.

Silanolysis of $Zr(OR)_4$ ($R = CHMe_2$ or CMe_3) (equation 32) gives the corresponding trialkylsilyloxides $Zr(OSiR'_3)_4$ (Table 9). These compounds are colorless liquids or white solids that can be distilled or sublimed under reduced pressure. They are less susceptible to hydrolysis and possess greater thermal stability than the corresponding *t*-alkoxides. It is interesting to note that the trialkylsilyloxides are slightly more associated than the *t*-alkoxides, presumably because steric effects of the R_3SiO group are smaller that those of the R_3CO group; $Zr(OSiMe_3)_4$ is a dimer in boiling benzene.

$$Zr(OR)_4 + 4R'_3SiOH \longrightarrow Zr(OSiR'_3)_4 + 4ROH \quad (32)$$

Halide alkoxides $ZrX_n(OR)_{4-n}$ (X = Cl or Br) are formed in reactions of zirconium alkoxides with hydrogen halides or acetyl halides. Thus $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ reacts with acetyl chloride in 1:1, 1:2 and 1:3 mole ratios yielding isopropyl acetate and $ZrCl(OCHMe_2)_3 \cdot HOCHMe_2$, $ZrCl_2(OCHMe_2)_2 \cdot HOCHMe_2$ and $ZrCl_3(OCHMe_2)$, respectively. When an excess of acetyl chloride is used, the product is $ZrCl_4 \cdot 2MeCO_2CHMe_2$.[206]

Relatively few coordination compounds are known in which zirconium or hafnium alkoxides bond to Lewis bases. Zirconium isopropoxide forms 1:1 adducts with isopropanol, pyridine, hydrazine and ethylenediamine, but it does not bond to donors such as diethyl ether, dimethylamine, triethylamine, 2,2′-bipyridyl or thiourea.[207,208] Halogen substitution in the alkoxide ligand appears to increase the Lewis acid character; thus $Zr(OCH_2CCl_3)_4$ forms a 1:2 adduct with acetone. Chloride alkoxides $ZrCl_n(OR)_{4-n}$ ($n = 1$, 2 or 3) and $ZrOCl(OR)$ are better Lewis acids than the corresponding $Zr(OR)_4$ and $ZrO(OR)_2$ compounds. $ZrOCl(OCHMe_2)_2 \cdot 2HOCHMe_2$ reacts in dichloromethane with a variety of Lewis bases yielding adducts of the type $ZrOCl(OCHMe_2) \cdot L$ (L = py, bipy, quinoline, DMF, dimethylacetamide or phthalimide) and $ZrOCl(OCHMe_2) \cdot 3DMSO$, whereas the corresponding dialkoxides $ZrO(OR)_2 \cdot ROH$ (R = Me, Et or $CHMe_2$) failed to react.[209]

Zirconium tetraalkoxides $Zr(OR)_4$ (R = Pr, $CHMe_2$ or CMe_3) react with stoichiometric

amounts of phenyl or naphthyl isocyanate to give the insertion products $Zr\{NR'C(O)OR\}_n(OR)_{4-n}$ (R' = Ph or $C_{10}H_7$; $n = 1, 2, 3$ or 4).[210]

Reaction of zirconium and hafnium alkoxides with alkali metal, alkaline earth metal, aluminum and gallium alkoxides yields bimetallic alkoxides of the type: $M'Zr(OCMe_3)_5$, $M'M_2(OR)_9$ and $M'_2M_3(OR)_{14}$ (M' = alkali metal; M = Zr or Hf; R = alkyl); $M''\{M_2(OCHMe_2)_9\}_2$ and $M''M_3(OCHMe_2)_{14}$ (M'' = Mg, Ca, Sr or Ba); $M'''M(OCHMe_2)_7$ and $M'''_2M(OCHMe_2)_{10}$ (M''' = Al or Ga).[188,190] The bimetallic alkoxides are volatile, covalent compounds that can be sublimed or distilled under reduced pressure. Most of these compounds are monomeric in boiling benzene, though some tend to dimerize. Structures have been suggested on the basis of molecular weight data, ^{1}H NMR spectra, and the products of alcoholysis reactions, but no X-ray structural data are yet available. A recent study of solubility in the $Al(OCHMe_2)_3$–$Zr(OCHMe_2)_4$–L (L = THF or $HOCHMe_2$) system has confirmed the existence of $AlZr(OCHMe_2)_7$, but failed to provide evidence for $Al_2Zr(OCHMe_2)_{10}$.[211] The existence of bimetallic alkoxides $M'''Zr_3(OCHMe_2)_{15}\cdot 3HOCHMe_2$ has been established in the $M'''(OCHMe_2)_3$–$Zr(OCHMe_2)_4$–$HOCHMe_2$ (M''' = Y or La) systems.[212,213]

Compounds of composition $[C_5H_5NH]_2[MCl_4(OMe)_2]$ (M = Zr or Hf), $[C_5H_5NH]_2[ZrCl_5(OEt)]$ and $[C_5H_5NH]_2[ZrCl_2(OEt)_4]$ have been prepared by reaction of the metal tetrachlorides with methanol or ethanol in the presence of pyridine.[214]

The reaction of $ZrCl_4$ with Li(tritox) in diethyl ether yields $[ZrCl_3(tritox)_2\cdot Li(OEt_2)_2]$, where tritox is the sterically bulky tri-*t*-butylmethoxide ligand, $(Me_3C)_3CO$. An X-ray study of this compound revealed trigonal bipyramidal coordination about the zirconium atom, with the two tritox ligands in equatorial sites and three chlorine atoms in the remaining sites. The equatorial chlorine atom and one of the axial chlorine atoms bridge to the lithium atom, which is also attached to two diethyl ether molecules. The Zr—O bond lengths (average 1.895 Å) are exceptionally short and the Zr—O—C angles (average 169°) are nearly linear, indicative of strong $p\pi$–$d\pi$ bonding. It has been suggested that the neutral $(Me_3C)_3CO\cdot$ ligand may function as a five-electron donor, like a cyclopentadienyl group. Extraction of $[ZrCl_3(tritox)_2\cdot Li(OEt_2)_2]$ with hexane yields $ZrCl_2(tritox)_2$, which can be converted to $ZrMe_2(tritox)_2$ by reaction with MeLi.[215]

Conductometric titration of $ZrCl_4$ with KOPh in nitrobenzene indicates the formation of $Zr(OPh)_4$, $ZrCl_3(OPh)$ and $ZrCl_2(OPh)_2$, which have been isolated and characterized by chemical analysis. The Lewis acidity of $Zr(OPh)_4$ and $ZrCl_2(OPh)_2$ has been demonstrated by isolation of adducts with py, bipy, phen and their *N*-oxides.[216]

$ZrCl_4$ and $HfCl_4$ react with LiOAr (OAr = 2,6-di-*t*-butylphenoxide) in benzene or diethyl ether to give the aryloxide complexes $[MCl(OAr)_3]$ (M = Zr or Hf). Attempts to prepare the corresponding $MCl_2(OAr)_2$ compounds were unsuccessful. $[HfCl(OAr)_3]$ has a sterically congested, tetrahedral structure with bond distances Hf—Cl = 2.365(1) Å, Hf—O = 1.938(3), 1.925(2) and 1.917(3) Å, and Hf—O—C bond angles in the range 152–159°. Low-temperature ^{1}H NMR spectra exhibit inequivalent *t*-butyl groups proximal and distal to the chlorine atom owing to a slowing at ~ −60 °C of rotation about the Hf—O—Ar bonds. Because the sterically bulky *t*-butyl groups tend to protect the metal atom from nucleophilic attack, the $[MCl(OAr)_3]$ complexes are not easily alkylated though $[HfCl(OAr)_3]$ does react with MeLi to give $[HfMe(OAr)_3]$.[217]

32.4.4.4 β-Ketoenolates, tropolonates, catecholates and quinones; ethers, aldehydes, ketones and esters

(i) β-Ketoenolates

Tetrakis(acetylacetonato) complexes of zirconium and hafnium were reported in 1904[218] and 1926,[219] respectively, and a large number of β-diketonate derivatives have been described subsequently (Table 10). These compounds are of the type $[M(dik)_4]$, $[M(dik)_3X]$, $[M(dik)_2X_2]$, $M(dik)X_3$ and $[M(dik)_3]Y$ (dik = β-diketonate anion; X = Cl, Br, I, NO_3, or alkoxide; Y = $[FeCl_4]$, $[AuCl_4]$, $\frac{1}{2}[PtCl_6]$ or $\frac{1}{2}[Zr(SO_4)_3]$). Additional β-diketonate compounds include the anionic complex $[NEt_4][Zr(bzbz)F_4]$ (bzbz = dibenzoylmethanate)[220] and the 1:1 $ZrCl_4$–diketone adducts $[ZrCl_4(MeCOCR_2COMe)]$ (R = H or Me).[221,222] Early work on zirconium and hafnium β-diketonates has been reviewed by Larsen,[5] Bradley and Thornton,[6] Fackler[223] and Mehrotra *et al.*[224]

The following methods have been employed for preparation of zirconium and hafnium

Table 10 β-Diketonate Complexes of Zirconium(IV) and Hafnium(IV), $[M(RCOCR'COR'')_nX_{4-n}]$

β-diketonates, and the application of these methods to specific compounds is documented in Table 10: (A) reaction of a hydrated metal salt and the β-diketone in aqueous or nonaqueous media, often in the presence of a base such as carbonate or triethylamine; (B) extraction of a hydrochloric acid solution of the metal ion with a benzene solution of the diketone; (C) reaction of a metal tetrahalide with the diketone (or diketonate anion) in an organic solvent at reflux (equation 33); (D) exchange of diketonate ligands between a metal diketonate and a less volatile β-diketone (*e.g.* equation 34); (E) reaction of a metal alkoxide with a stoichiometric amount of the diketone in benzene at reflux (*e.g.* equation 35); (F) ligand exchange between metal complexes, *e.g.* $M(dik)_4$ and MX_4 (equation 36) or $M(dik)_4$ and $M(dik)_2X_2$ (equation 37); (G) conversion of $[M(dik)_4]$ to $[M(dik)_3Cl]$ by reaction with acetyl chloride. The physical methods that have been used to characterize zirconium and hafnium diketonates are also listed in Table 10.

$$MX_4 + n\text{Hdik} \longrightarrow [M(dik)_nX_{4-n}] + n\text{HX} \quad (n = 2,\ 3 \text{ or } 4) \tag{33}$$

$$[Zr(acac)_4] + 4\text{Hbzbz} \xrightarrow[25\ mm\ Hg]{100\ ^\circ C} [Zr(bzbz)_4] + 4\text{H(acac)} \tag{34}$$

$$Zr(OCHMe_2)_4 \cdot HOCHMe_2 + n\text{Hdik} \xrightarrow[\text{reflux}]{C_6H_6} Zr(dik)_n(OCHMe_2)_{4-n} + (n+1)HOCHMe_2 \quad (n = 1,\ 2,\ 3 \text{ or } 4) \tag{35}$$

$$3[Zr(acac)_4] + ZrI_4 \xrightarrow{THF} 4[Zr(acac)_3I] \tag{36}$$

$$[Zr(acac)_4] + [Zr(acac)_2(NO_3)_2] \xrightarrow[\text{reflux}]{C_6H_6} 2[Zr(acac)_3(NO_3)] \tag{37}$$

(*a*) *Tetrakis(diketonates)*, $[M(dik)_4]$. X-Ray crystal structures have been reported for $[Zr(acac)_4]$[225] and $[Zr(bzbz)_4]$.[226] Both complexes have an eight-coordinate square antiprismatic structure (Figure 4) in which the bidentate β-diketonate ligands span *s* edges of the antiprism to give the D_2-*ssss* stereoisomer. The antiprism is slightly distorted, in the direction of a C_{2v} bicapped trigonal prism in the case of $[Zr(bzbz)_4]$, and in the direction of a D_{2d} dodecahedron in the case of $[Zr(acac)_4]$. These distortions have been analyzed in some detail by Chun *et al.*[226] The Zr—O bonds in $[Zr(bzbz)_4]$ fall into two symmetry-inequivalent sets in accord with the idealized D_2 symmetry of the coordination group. The Zr—O bonds to the 'outer' sites (1, 3, 6 and 8 in Figure 4) (average 2.153 Å) are significantly shorter than the bonds to the 'inner' sites (average 2.192 Å). The averaged length of all eight Zr—O bonds in $[Zr(bzbz)_4]$ (2.172 Å) is 0.026 Å less than the averaged Zr—O bond length in $[Zr(acac)_4]$ (2.198 Å). X-ray powder patterns have shown that $[Hf(acac)_4]$ is isostructural with $[Zr(acac)_4]$, and time differential perturbed angular correlation measurements on $[Hf(acac)_4]$ are consistent with a D_2-*ssss* square antiprismatic structure.[227]

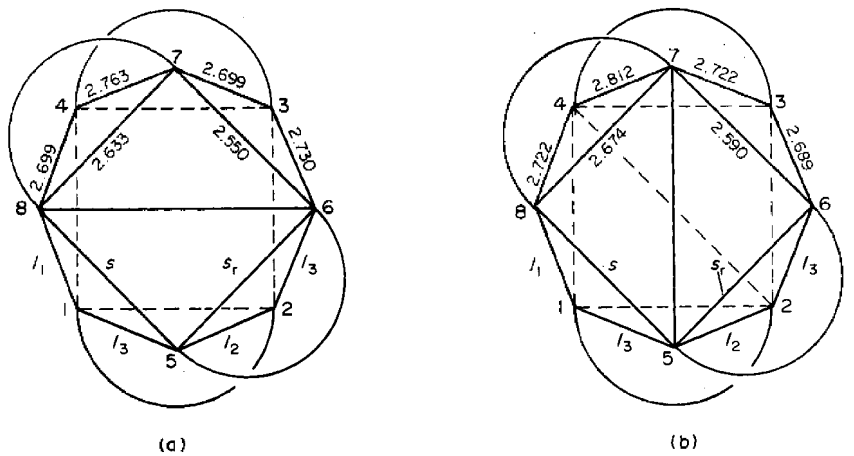

Figure 4 Structures of (a) tetrakis(1,3-diphenyl-1,3-propanedionato)zirconium(IV) and (b) tetrakis(2,4-pentanedionato)zirconium(IV). Dimensions of the coordination polyhedra are averaged in accord with approximate D_2-222 symmetry. Distortions of the square antiprisms involve slight folding of the quadrilateral faces about the indicated face diagonals (reproduced by permission from reference 226)

^1H and ^{19}F NMR spectra of Zr^{IV} and Hf^{IV} tetrakis(β-diketonates) have been investigated in $CHClF_2$ solution at temperatures down to −170 °C, and several complexes have been identified which become stereochemically rigid on the NMR time scale at temperatures in the range −115 to −170 °C.[228] Spectra of [Zr(acac)$_4$] and [Hf(acac)$_4$] in the slow-exchange limit exhibit two methyl proton resonances of equal intensity, consistent with the *D*$_2$-*ssss* stereoisomer found in the solid state. ^{19}F spectra of [Zr(tfacac)$_4$] (tfacac = MeCOCHCOCF$_3$) show that more than one geometric isomer is present in solution. The kinetics of intramolecular rearrangement of several of these complexes have been studied by NMR line-shape analysis; kinetic data are summarized in Table 11. Tetrakis(diketonates) are highly fluxional; for [Zr(acac)$_4$], the extrapolated rate constant at 25 °C for exchange of methyl groups between the two inequivalent sites of the *D*$_2$-*ssss* stereoisomer is $4.7 \times 10^5\ s^{-1}$ and the rearrangement barrier $\Delta H^{\ddagger}$ is only 17 kJ mol^{-1}.

[a] In $CHClF_2$ solution. [b] Methyl group exchange. [c] *t*-Butyl group exchange; dmh = MeCOCHCOCMe$_3$.

Intermolecular exchange of β-diketonate ligands is also a rapid process. Ligand exchange between [M(acac)$_4$] and [M(tfacac)$_4$] (M = Zr or Hf) is fast on the ^1H NMR time scale at temperatures above ~70 °C.[229] ^1H and ^{19}F NMR spectra of [Zr(acac)$_4$]–[Zr(tfacac)$_4$] mixtures indicate the presence in solution of all five [Zr(acac)$_n$(tfacac)$_{4-n}$] (n = 0, 1, 2, 3 or 4) complexes, with the mixed-ligand complexes being favored at the expense of the parent complexes.[229,230] It is interesting to note that equilibrium constants K_n for formation of the mixed-ligand complexes (equation 38) depend strongly on the difference in the degree of fluorination of the two diketonate ligands dik and dik′. Thus, observed values of K_n for the [Zr(acac)$_4$]–[Zr(bzbz)$_4$] system are slightly less than the statistical values for random scrambling of ligands ($K_1 = K_3 = 4$; $K_2 = 6$), while values of K_n for the [Zr(acac)$_4$]–[Zr(hfacac)$_4$] and [Zr(dpm)$_4$]–[Zr(hfacac)$_4$] (dpm = Me$_3$CCOCHCOCMe$_3$) systems are ~10^3–10^5 times the statistical values.[231] Values of K_n for the [Zr(acac)$_4$]–[Zr(tfacac))$_4$] system are intermediate, ~4–7 times the statistical values. In the [Zr(acac)$_4$]–[Zr(tfacac)$_4$] system, deviations from random scrambling of ligands are due to entropy effects,[230] while in the [Zr(acac)$_4$]–[Zr(hfacac)$_4$] system, enthalpy effects are the principal causes of the nonstatistical behavior.[231] Minacheva and Brainina[232] have reported the isolation of a number of mixed-ligand complexes, including [M(acac)$_2$(bzbz)$_2$] (M = Zr or Hf).

$$\frac{n}{4}[M(dik)_4] + \frac{4-n}{4}[M(dik')_4] \overset{K_n}{\rightleftharpoons} [M(dik)_n(dik')_{4-n}] \quad (n = 1, 2 \text{ or } 3) \tag{38}$$

The kinetics of ligand exchange between [M(dik)$_4$] (M = Zr or Hf; dik = acac or tfacac) and the corresponding free β-diketones have been studied by Adams and Larsen.[233] [Zr(acac)$_4$] exchanges ligands with a polystyrene resin functionalized with acetylacetonate groups to give a polymer-bound zirconium complex.[234]

[M(acac)$_4$] (M = Zr or Hf) complexes react with *N*-bromosuccinimide yielding the 3-bromo-2,4-pentanedionate derivatives [M(acac)(3-Bracac)$_3$] and [M(3-Bracac)$_4$]; the products depend on the reaction conditions and often are isolated as succinimide adducts.[235] [Zr(bzac)$_4$] (bzac = MeCOCHCOPh) and [Zr(bzbz)$_4$] are not brominated under the same reaction conditions. The reaction of bromine with [M(acac)$_4$] results in both electrophilic substitution on the chelate ring and replacement of two acetylacetonate ligands; the products M(3-Bracac)$_2$Br$_2$·nH$_2$O (n = 1 or 2) were isolated as hydrates due to the presence of traces of moisture.[236] Only ligand replacement occurs in reactions of bromine with [M(bzbz)$_4$]; products

are $[M(bzbz)_2Br_2]$ (M = Zr or Hf) and $[Zr(bzbz)_3Br]$.[237] With iodine, $[Zr(acac)_4]$ forms a 1:1 charge-transfer complex, which has been studied in solution by spectrophotometric methods.[238] IR studies indicate extensive hydrogen bonding between $[Zr(acac)_4]$ and $CDCl_3$ in CCl_4 solution, presumably involving the acetylacetonate oxygen atoms.[239]

Many $[M(dik)_4]$ complexes are volatile, especially those that contain fluorinated diketonate ligands. Mass spectra and gas chromatographic behavior of several of these complexes have been studied (see Table 10). Isenhour and coworkers[240,241] have employed fluorinated diketonates in mass spectrometric procedures for determination of Zr and Zr/Hf ratios in geological samples. The most intense peak in mass spectra of $[M(dik)_4]$ complexes is $[M(dik)_3]^+$. Sievers *et al.*[242] have used gas chromatography of metal trifluoroacetylacetonates to separate Zr from Al, Cr and Rh. However, attempts to separate $[Zr(tfacac)_4]$ and $[Hf(tfacac)_4]$ by gas chromatography were unsuccessful. Zirconium and hafnium can be separated by solvent extraction procedures that employ fluorinated diketones.[105] $[M(dik)_4]$ (M = Zr or Hf; dik = acac, dpm, tfacac or hfacac) have been used as volatile source materials for chemical vapor deposition of thin films of the metal oxides.[243,244]

(*b*) *Tris(diketonates)*, $[M(dik)_3X]$. Known compounds of this type have X = halide, nitrate or alkoxide. The methods used to prepare these complexes are indicated in Table 10.

IR and Raman spectra, dipole moment data, and molecular weight and conductance measurements point to seven-coordinate structures for the halo complexes $[M(acac)_3X]$ (M = Zr or Hf, X = Cl or Br; M = Zr, X = I). The vibrational spectra exhibit metal–halogen stretching bands (Table 12) and indicate that all of the carbonyl groups are coordinated.[245] Dipole moments of ~5–6 D in benzene solution are in good agreement with the values expected for a seven-coordinate structure.[246] The $[M(acac)_3X]$ (X = Cl or Br) complexes are monomeric nonelectrolytes in ionizing solvents,[247,248] but $[Zr(acac)_3I]$ is ~10% dissociated in 1,2-dichloroethane and ~26% dissociated in nitrobenzene.[247] The dissociated species of $[Zr(acac)_3I]$ in 1,2-dichloroethane are markedly stabilized by tetrahydrofuran, probably due to coordination by the THF (equation 39). Crystallization of $[Zr(acac)_3I]$ from THF yields a $Zr(acac)_3I \cdot THF$ adduct, which loses THF upon heating for 5 h at 80 °C *in vacuo*.

$$[Zr(acac)_3I] + THF \rightleftharpoons [Zr(acac)_3(THF)]^+ + I^- \quad (39)$$

[a] This region obscured by solvent absorption. [b] p = polarized; dp = depolarized.

A seven-coordinate structure for $[Zr(acac)_3Cl]$ has been confirmed by X-ray diffraction.[249] This complex has distorted pentagonal bipyramidal geometry with the chlorine atom in an axial position (Zr—Cl = 2.472(6) Å). The axial Zr—O bond is ~0.06 Å shorter than the averaged length (2.14 Å) for the five, quite uniform equatorial Zr—O bonds. Because of close O···O contacts in the equatorial plane, the pentagonal girdle of oxygen atoms is appreciably puckered. In solution, $[Zr(acac)_3Cl]$ is stereochemically nonrigid on the NMR time scale at temperatures down to −130 °C.[247]

It is interesting to note that $[Zr(acac)_3Cl]$ can be recrystallized unchanged from hot acetylacetone.[250] An NMR study[247] has shown that substitution of the chlorine atom is very slow under anhydrous conditions; heating $[Zr(acac)_3Cl]$ with neat acetylacetone for 24 h at 80 °C yields a product which is only ~20% $[Zr(acac)_4]$. In the presence of water, $[Zr(acac)_3Cl]$ is readily converted to $[Zr(acac)_4]$,[250,251] evidently due to preliminary hydrolysis of the Zr—Cl bond. In anhydrous media, the ease of complete substitution is dependent on the nature of the diketone; certain aryl-[252] and trifluoromethyl-substituted[253] diketones readily react with $ZrCl_4$ to give the tetrakis(diketonates).

The dibenzoylmethanate complex $[Zr(bzbz)_3Cl]$ reacts with iron(III) chloride, gold(III) chloride or chloroplatinic acid in chloroform or glacial acetic acid yielding $[Zr(bzbz)_3]Y$ (Y = $[FeCl_4]$, $[AuCl_4]$ or $0.5[PtCl_6]$).[248,250] $[Hf(bzbz)_3][FeCl_4]$ is also known.[248] The tetrachloroferrate and tetrachloroaurate salts behave as 1:1 electrolytes in nitromethane or nitrobenzene.

IR spectra of the 3-cyano-2,4-pentanedionate complex $(Zr(3\text{-}CNacac)_3Cl$ suggest that one of the three cyano groups is coordinated to a second Zr atom, thus increasing the coordination number of zirconium to eight. Coordination of one of the cyano groups also occurs in the dichloro complex $Zr(3\text{-}CNacac)_2Cl_2$.[254]

Several $[M(dik)_3(NO_3)]$ complexes are known (Table 10). $[Zr(acac)_3(NO_3)]$ has an eight-coordinate structure in which the bidentate nitrate ligand spans an *a* edge and the three acetylacetonate ligands span *b*, *m* and *g* edges, respectively, of a distorted D_{2d} dodecahedron. This unusual *abmg* ligand wrapping pattern (Figure 5) is preferred over the commonly observed *mmmm* wrapping pattern because the bite of the acetylacetonate ligand is too large to permit two acac ligands to be located on the same trapezoid of a ZrO_8 dodecahedron. The acac ligand bite shows significant variation with the type of polyhedral edge it spans: *m*(2.618(2) Å) < *g*(2.689(2) Å) < *b*(2.786(2) Å). Zr—O bonds to the acac ligands (average 2.141(1) Å) are systematically shorter than Zr—O bonds to the nitrate ligands (average 2.366(2) Å).[255] In solution, $[Zr(acac)_3(NO_3)]$ is a monomeric nonelectrolyte which is stereochemically nonrigid on the NMR time scale at temperatures down to at least −144 °C.[228,255] The monoalkoxy complexes $[Zr(dik)_3(OR)]$ (Table 10) are monomeric in solution and presumably are seven-coordinate.

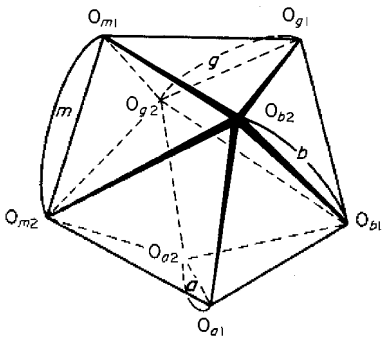

Figure 5 Ligand wrapping pattern in $[Zr(acac)_3(NO_3)]$. The ligands are labeled *a*, *b*, *m* or *g* according to the dodecahedral edge which the ligand spans (reproduced by permission from ref. 255)

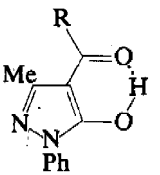
(*c*) *Bis(diketonates)*, $[M(dik)_2X_2]$. The best characterized compounds in this class (Table 10) are $[M(acac)_2X_2]$ (M = Zr or Hf; X = Cl or Br) and $[Zr(acac)_2(NO_3)_2]$. The $[M(acac)_2X_2]$ complexes are monomeric nonelectrolytes in nitrobenzene.[247] In benzene solution, they possess dipole moments of ~8 D.[246] Vibrational spectra of the $[M(acac)_2X_2]$ complexes exhibit coincident metal–ligand stretching bands in IR and Raman spectra (Table 12), and the $[M(acac)_2Cl_2]$ complexes display two ν(M—Cl) IR bands.[245] These data point to an octahedral *cis* structure. In vibrational spectra of the series of compounds $[M(acac)_2X_2]$, $[M(acac)_3X]$ and $[M(acac)_4]$ (Table 12), the ν(M—O) and ν(M—X) bands exhibit systematic shifts to lower

frequency, and the ν(C···O) bands show corresponding shifts to higher frequency, as the coordination number of the metal increases from six to seven to eight. The $[M(acac)_2X_2]$ complexes are highly fluxional in solution; a single time-averaged methyl proton resonance was observed for $[Zr(acac)_2Cl_2]$ at temperatures down to −130 °C.[247] X-Ray powder patterns indicate that the $[Zr(acac)_2X_2]$ and $[Hf(acac)_2X_2]$ complexes which contain the same halogen are isomorphous.

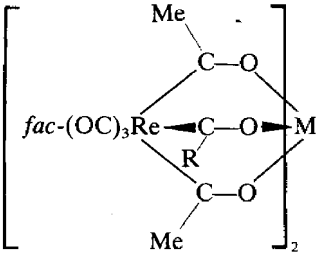


$[Zr(acac)_2Cl_2]$ reacts with two equivalents of PhMgBr, two equivalents of PhLi or one equivalent of Ph_2M (M = Mg, Cd or Hg) in THF at low temperatures yielding $Zr(acac)_2ClPh$. This compound was formulated as a chlorine-bridged dimer, but no molecular weight data were reported.[256] Treatment of $[Zr(acac)_2Cl_2]$ with four equivalents of PhLi results in phenyl substitution of the chelate ring (equation 40).

$$[Zr(acac)_2Cl_2] + 3PhLi \longrightarrow Zr(3\text{-}Phacac)_2ClPh + LiCl + 2LiH \quad (40)$$

$[Zr(acac)_2(NO_3)_2]$ has an eight-coordinate structure in which bidentate acetylacetonate and bidentate nitrate ligands span the *m* edges of distorted D_{2d} dodecahedron.[257] The observed stereoisomer is the C_2-*mmmm* isomer having one acetylacetonate ligand and one nitrate ligand on each BAAB trapezoid. Averaged Zr—O bond distances are Zr—O(acac) = 2.096 Å and Zr—O(nitrate) = 2.295 Å. Within a particular chelate ring, Zr—O bond lengths involving dodecahedral A sites exceed those involving B sites by 0.015–0.051 Å (5σ–17σ) and these differences appear to be propagated in the C—O and N—O bond lengths in the ligands. $[Zr(acac)_2(NO_3)_2]$ is a monomeric nonelectrolyte in solution, and retention of coordination number eight is suggested by the similarity of solid-state and solution-state IR spectra. ^{1}H NMR spectra in $CHClF_2$ solution[228] indicate that $[Zr(acac)_2(NO_3)_2]$ becomes stereochemically rigid on the NMR time scale at temperatures below −144 °C, and the spectra in the slow-exchange limit are consistent with the C_2-*mmmm* structure found in the solid state. Kinetic data for exchange of acetylacetonate methyl groups between the two inequivalent sites of the C_2-*mmmm* stereoisomer are included in Table 11.

(*d*) *Mono(diketonates), M(dik)X*$_3$. A few $M(dik)Cl_3$ complexes (Table 10) have been isolated as 1:1 adducts with THF following ligand exchange reactions between $[M(dik)_4]$ and MCl_4 in THF.[258,259] Several $Zr(dik)(OCHMe_2)_3$ compounds have been prepared by reaction of equimolar amounts of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ and the β-diketone. The complexes that contain fluorinated diketonate ligands (Table 10) appear to be monomeric[260] and presumably five-coordinate, while those that contain acac, bzac or bzbz ligands have a tendency to dimerize.[261] A structure having six-coordinate zirconium and two isopropoxy bridges has been suggested for the dimer. Reaction of $Zr(acac)(OCHMe_2)_3$ with *t*-butanol affords $Zr(acac)(OCMe_3)_3$, which has only a small tendency to dimerize.



(*e*) *Miscellaneous β-diketonates and related compounds.* Heterocyclic tetrakis(β-diketonates) of the type $Zr(dik)_n(OCHMe_2)_{4-n}$, where dik is the anion of a 4-acyl-3-methyl-1-phenyl-2-pyrazol-5-one (**21**) and $n = 1$, 2, 3 or 4, have been prepared by reaction of stoichiometric amounts of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ and the pyrazolone in benzene at reflux.[262] These compounds are monomeric in boiling benzene, except for the $Zr(dik)(OCHMe_2)_3$ complexes, which tend to dimerize. The $Zr(dik)_n(OCHMe_2)_{4-n}$ complexes exchange alkoxide ligands with *t*-butanol yielding the corresponding $Zr(dik)_n(OCMe_3)_{4-n}$ complexes, and they undergo insertion reactions with phenyl isocyanate giving $Zr(dik)_n\{NPhC(O)OCHMe_2\}_{4-n}$ ($n = 1$, 2 or 3). Additional synthetic routes have been reported for preparation of $[Zr(dik)_4]$, where dik is the anion of (**21**; R = Ph or CF_3).[263,264]

(**21**) R = Me, Et, Ph, 3-ClC_6H_4

Tetrakis(salicylaldehydato)zirconium(IV), tetrakis(3-methoxysalicylaldehydato)zirconium-(IV) and tetrakis(ethyl acetoacetato)zirconium(IV) have been synthesized by reaction of $[Zr(acac)_4]$ with salicylaldehyde, 3-methoxysalicylaldehyde or ethyl acetoacetate, respectively.[265,266] The reaction of $ZrCl_4$ with salicylaldehyde in diethyl ether gives the addition compound $ZrCl_4 \cdot 2\{2\text{-}OC_6H_4CHO\}$ at −15 °C, and the substitution product $[Zr\{2\text{-}OC_6H_4CHO\}_2Cl_2]$ at reflux temperature.[221] Salicylaldehyde reacts with $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ in benzene at ambient temperature yielding $Zr\{2\text{-}OC_6H_4CHO\}_n(OCHMe_2)_{4-n}$ ($n = 1$ or 2). When these reactions are carried out in refluxing benzene, the products undergo Meerwein–Ponndorf reduction yielding compounds such as $Zr_2\{2\text{-}OC_6H_4CH_2O\}\{2\text{-}OC_6H_4CHO\}(OCHMe_2)_5$ and $Zr_2\{2\text{-}OC_6H_4CH_2O\}_3(2\text{-}OC_6H_4\text{-}CHO\}(OCHMe_2)$.[267] Several β-keto ester complexes have been synthesized from $Zr(OCHMe_2)_4 \cdot HOCHMe_2$; these include $Zr(PhCOCHCO_2Et)_n(OCHMe_2)_{4-n}$ ($n = 1$, 2, 3 or 4)[261] and $[Zr(MeCOCHCO_2Me)_3(OCHMe_2)]$.[268] The reaction of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with bis(acetoacetates), $MeCOCH_2CO_2(CH_2)_nO_2CCH_2COMe$ ($n = 2$, 4 or 5) yields oligo-nuclear products.[269]

Neutral bis-chelate complexes of the type $[\{fac\text{-}(OC)_3Re(MeCO)_3\}_2Zr]$ and $[\{fac\text{-}(OC)_3Re(MeCO)_2(RCO)\}_2Hf]$ (R = Me, $CHMe_2$ or $PhCH_2$) have been prepared by reaction of $[RC(O)Re(CO)_5]$ with MeLi in THF, followed by addition of a THF solution of $ZrCl_4$ or $HfCl_4$. The $[fac\text{-}(OC)_3Re(MeCO)_3]^{2-}$ dianion is the formal, metalla analogue of the tri-acetylmethanate anion. The Zr and Hf complexes were obtained in rather poor yields as pale yellow air-sensitive solids. IR and ^1H NMR spectra are consistent with tridentate coordination (**22**) of the triacetylmetallate ligands.[270]

(**22**)

(*ii*) *Tropolonates*

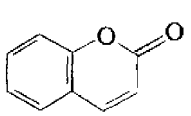
Tetrakis(tropolonato) complexes $[MT_4]$ (M = Zr or Hf; T = $C_7H_5O_2$) have been prepared by reaction of tropolone with (i) $ZrCl_4$ or $HfCl_4$ in chloroform,[271] or (ii) a Zr^{IV} or Hf^{IV} salt in 50% water–methanol.[272] The $[MT_4]$ complexes tend to form solvates when crystallized from polar organic solvents. X-Ray diffraction studies of $[ZrT_4] \cdot 2.25CHCl_3$[273] and $[HfT_4] \cdot DMF$[274] have established that both crystals contain eight-coordinate $[MT_4]$ complexes. The bidentate tropolonate ligands span the *m* edges of a D_{2d} dodecahedron. As is often observed in dodecahedral complexes, averaged bond lengths to the dodecahedral A sites are slightly longer than averaged bond lengths to the B sites (Zr—O_A = 2.194, Zr—O_B = 2.174, Hf—O_A = 2.188, Hf—O_B = 2.176 Å). A very strong band at 288.0 cm^{-1} in the IR spectrum of $[^{90}ZrT_4]$, which shifts to 283.9 cm^{-1} in $[^{94}ZrT_4]$, has been assigned to Zr—O stretching; the corresponding ν(Hf—O) mode in $[HfT_4]$ is at 245 cm^{-1}.[272] Quadrupole coupling parameters for $[HfT_4]$, obtained from time differential perturbed angular correlation measurements, have been interpreted in terms of a square antiprismatic or dodecahedral structure of D_2 symmetry.[275,276] However, more recent measurements on $[HfT_4]$, $[HfT_4] \cdot CHCl_3$ and $[HfT_4] \cdot DMF$[277] have shown that the quadrupole coupling parameters are strongly influenced by intermolecular interactions between $[HfT_4]$ and dipolar solvent molecules.

^1H NMR studies of the corresponding α-, β- and γ-isopropyl-tropolonato complexes $[M(C_{10}H_{11}O_2)_4]$ (M = Zr or Hf)[278] indicate that these complexes are stereochemically nonrigid on the NMR time scale at −85 to −100 °C. The $[M(C_{10}H_{11}O_2)_4]$ complexes and the free ligand undergo intermolecular ligand exchange at elevated temperatures; the approximate rates for $[M(\gamma\text{-}C_{10}H_{11}O_2)_4]$ (M = Zr or Hf) are 50 s^{-1} at 140 °C in tetrachloroethane. These ligand exchange rates are slower than those for analogous β-diketonate complexes.[233]

(*iii*) *Catecholates and quinones*

Colorless crystals of $Na_4[Hf(O_2C_6H_4)_4]\cdot 21H_2O$ have been isolated following addition of an O_2-free aqueous solution of hafnium tetrachloride to an O_2-free alkaline solution of catechol. The crystals contain discrete eight-coordinate $[Hf(O_2C_6H_4)_4]^{4-}$ anions having $\bar{4}$ site symmetry. The coordination polyhedron is a D_{2d} dodecahedron, and the bidentate catecholate ligands span the *m* polyhedral edges; Hf—O_A = 2.220(3) and Hf—O_B = 2.194(3) Å.[279]

The $[Hf(O_2C_6H_4)_3]^{2-}$ anion has been prepared in THF by reaction of $[Hf(NEt_2)_4]$ with one equivalent of catechol and two equivalents of the sodium salt $NaOC_6H_4OH$. The complex was isolated from acetonitrile–ether as $[NEt_4]_2[Hf(O_2C_6H_4)_3]$, which behaves as a 2:1 electrolyte in acetonitrile and exhibits a ligand-to-metal charge-transfer band at 33 900 cm^{-1}.[280] Aqueous solutions that contain zirconyl chloride, catechol and excess ammonia yield precipitates of composition $(NH_4)Zr(OH)(O_2C_6H_4)_2$, $[NH_4]_2[Zr(O_2C_6H_4)_3]$ or $[NH_4]_2[Zr(O_2C_6H_4)_3]\cdot C_6H_4(OH)_2\cdot 1.5H_2O$, depending on the catechol/Zr^{IV} ratio in the initial solution.[281] Anhydrous $ZrCl_4$ reacts with molten catechol yielding a colorless crystalline powder of composition $H_2Zr(O_2C_6H_4)_3$. Related compounds of the type $ZrL_2(amine)_2$ (L = $C_{12}H_8O_2$, $C_{20}H_{12}O_2$ or $C_{10}H_6O_2$; amine = Et_3N, Et_2NH or C_5H_5N) have been prepared by reaction in methanol of $ZrCl_4$ with 2,2′-dihydroxybiphenyl, 2,2′-dihydroxybinaphthyl, or 1,8-dihydroxynaphthalene followed by addition of the appropriate amine. The amine-free compound $Zr(C_{12}H_8O_2)_2$ is obtained by reaction of $ZrCl_4$ with molten 2,2′-dihydroxybiphenyl.[282]



Formation of zirconium and hafnium complexes with polyhydroxyaromatic compounds in aqueous solution has been studied by potentiometric, spectrophotometric and ion exchange methods. Much of this work has been reviewed by Larsen.[5] A potentiometric and light-scattering study of the zirconium(IV)–Tiron (Tiron = disodium 1,2-dihydroxybenzene-3,5-disulfonate) system provides evidence for mixed hydroxo–Tiron chelates at Tiron/Zr^{IV} ratios less than 2.5, but at higher Tiron/Zr^{IV} ratios the unhydrolyzed complexes $[Zr_2L_5]^{12-}$ and $[ZrL_4]^{12-}$ (L = tetranegative anion of 1,2-dihydroxybenzene-3,5-disulfonic acid) are present.[283,284]

Quinones such as alizarin red S (1,2-dihydroxyanthraquinone-3-sulfonate) and chloroanilic acid have long been used as analytical reagents for spectrophotometric determination of zirconium.[285,286] These reagents form 1:1 complexes with Zr^{IV} in strongly acidic solutions.[287–289] The binding site in alizarin red S has been a matter of some controversy,[288–290] but it now appears, on the basis of voltametric and spectrophotometric evidence, that Zr^{IV} coordinates to alizarin red S through the two adjacent phenolic oxygen atoms.[288,289]

(*iv*) *Ethers, aldehydes, ketones and esters*

Zirconium and hafnium tetrahalides react with ethers, aldehydes, ketones and esters in solvents such as carbon tetrachloride, dichloromethane, benzene, acetyl chloride or liquid sulfur dioxide to give moisture-sensitive solid adducts of the type MX_4L and $[MX_4L_2]$ (Table 13). The more common 1:2 adducts are obtained when two equivalents or an excess of the Lewis base is used, while synthesis of the 1:1 adducts generally requires strict adherence to 1:1 stoichiometry. Procedures for preparation of $[MCl_4(THF)_2]$ (M = Zr or Hf) have been published in *Inorganic Syntheses*.[291] The adducts are thermally stable at room temperature but decompose at elevated temperatures. They are insoluble in most organic solvents, though they show some solubility in benzene and in nitrobenzene in which they behave as nonelectrolytes. Complex formation is accompanied by characteristic changes in the ν(C—O—C) frequency of the ethers and the ν(C=O) frequency of the aldehydes, ketones and esters; the IR bands due to these modes are shifted to lower frequency in the adducts.

Many of the 1:2 adducts have been assigned an octahedral *cis* structure on the basis of dipole moment data[292–297] (Table 13), and this has been confirmed for $[ZrCl_4(MeCO_2Et)_2]$ by IR spectroscopy.[298] On the other hand, $[HfCl_4(THF)_2]$[299] and $[ZrCl_4L_2]$ [L = naphthaldehyde[300] or coumarin[301] (**23**)] have been assigned an octahedral *trans* structure on the basis of the number of ν(M—O) and/or ν(M—Cl) bands in IR spectra.

IR spectra also provide information about the coordination site in these adducts. In $[ZrCl_4L_2]$ (L = furanaldehyde[300] or coumarin[301]), only the carbonyl oxygen atom is attached to the Zr atom. All three carbonyl groups, and none of the nitrile groups, appear to be coordinated in the pyruvonitrile complexes $[MCl_4(MeCOCN)_3]$ (M = Zr or Hf), suggesting that these compounds are seven-coordinate.[302] Among the compounds in Table 13, the $[MCl_4(MeCOCN)_3]$ complexes are the only 1:3 adducts to have been reported. IR spectra indicate that both the carbonyl oxygen atom and the nitrile nitrogen atom are coordinated in the 1:1 ethyl cyanoacetate adduct, $ZrCl_4(NCCH_2CO_2Et)$. A structure having a six-membered chelate ring has been suggested,[303] but because of the geometry of the ligand, a polymeric structure with ethylcyanoacetate bridges seems more likely.

Not all of the compounds listed in Table 13 have been isolated in the solid state. The existence of some of the ester adducts has been inferred from electric polarization and cryoscopic molecular weight measurements on 1:1 and 1:2 stoichiometric mixtures of the metal tetrahalide and the ester in benzene solution. The concentration dependence of the polarizations and molecular weights[294–297,304] indicates that the 1:1 complexes tend to dimerize in the more concentrated solutions and the 1:2 complexes tend to dissociate (equation 41) in

the more dilute solutions. Dissociation of the $[ZrX_4(RCO_2R')_2]$ complexes increases as X varies in the order Cl < Br < I. Thus, estimated equilibrium constants for dissociation of the $[ZrX_4(MeCO_2Et)_2]$ complexes according to equation (41) are $\sim 5 \times 10^{-4}$ (X = Cl), 2×10^{-2} (X = Br) and 3.5×10^{-1} (X = I). Dimerization of the $[ZrX_4(RCO_2R']$ complexes increases as X varies in the reverse order (I < Br < Cl). The ease of dissociation of the $[ZrX_4(RCO_2R')_2]$ complexes also depends on the size of the R group. Thus, the ethyl formates $[ZrX_4(HCO_2Et)_2]$ (X = Cl or Br; $\mu = 7.63$ and 7.85 D, respectively) are hardly dissociated, while the ethyl butyrates $[ZrX_4(PrCO_2Et)_2]$ (X = Br or I; apparent $\mu = 3.80$ and 3.07 D, respectively) are essentially completely dissociated to $[ZrX_4(PrCO_2Et)]$ and $PrCO_2Et$. These dissociation reactions complicate interpretation of the dipole moment data in Table 13. The polarization and molecular weight measurements provide no evidence for dissociation of the 1:1 complexes, and they indicate that the 1:2 complexes do not bind additional ester molecules in the presence of an excess of the ester.

$$[ZrX_4(RCO_2R')_2] \rightleftharpoons [ZrX_4(RCO_2R')] + RCO_2R' \quad (41)$$

Table 13 includes heats of formation for some of the adducts; values of ΔH, determined calorimetrically, refer to equation (42). In formation of the $ZrX_4(RCO_2Et)_n$ (R = H, Me or Pr, $n = 1$ or 2) complexes, ΔH for addition of the first ester molecule is much larger than ΔH for addition of the second ester molecule,[305] consistent with the ease of dissociation of the 1:2 complexes.

$$MX_4(s) + nL(l) \longrightarrow MX_4L_n(s \text{ or } l) \quad (42)$$
$$(n = 1 \text{ or } 2)$$

Also included in Table 13 are zirconium and hafnium tetrahalide adducts with diethers, dialdehydes, diketones and diesters. 1,4-Dioxane gives both 1:1 and 1:2 adducts; the 1:1 complexes may be polymeric.[120,306] Phthalaldehyde, 3,3-dimethylacetylacetone, and diethyl phthalate yield 1:1 adducts with MCl_4 (M = Zr or Hf); IR and molecular weight data suggest that these complexes have an octahedral *cis* structure in which the Lewis base behaves as a chelating ligand. ZrX_4 (X = Cl or Br) form 1:1 adducts with diethyl oxalate and diethyl malonate and both 1:1 and 2:1 (*i.e.* $\{ZrX_4\}_2\{diester\}$) adducts with diethyl succinate and diethyl adipate.[307] Apparently conflicting molecular weight data have been reported for the 1:1 complexes[307,308] and the structure of these compounds remains uncertain.

32.4.4.5 Oxoanions as ligands

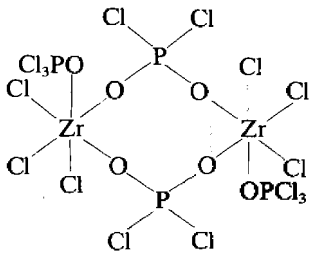
(*i*) *Nitrate*

Anhydrous zirconium(IV) nitrate has been prepared by reaction of $ZrCl_4$ with liquid dinitrogen pentoxide at 30 °C (equation 43). This compound is a covalent, hygroscopic, colorless crystalline solid which sublimes at 100 °C *in vacuo* and is extremely soluble in polar organic solvents.[309] IR and Raman spectra of $[Zr(NO_3)_4]$ have been interpreted[310] in terms of the eight-coordinate, D_{2d}-dodecahedral *mmmm* structure that has been established by X-ray diffraction for $[Ti(NO_3)_4]$[311] and $[Sn(NO_3)_4]$.[312] Nitrogen–oxygen stretching bands in the 1576–1650, 1223–1280 and 986–1028 cm^{-1} regions have been assigned to ν(N=O), $\nu_{as}(NO_2)$ and $\nu_s(NO_2)$, respectively. The ν(N=O) and $\nu_{as}(NO_2)$ modes arise from splitting of the ν_3 (E') mode of the D_{3h} $[NO_3]^-$ ion, and the large difference between the frequencies of these two modes is consistent with bidentate coordination of the nitrate ligands.[313] Hafnium(IV) nitrate has been prepared by reaction of hydrated hafnium nitrate with liquid N_2O_5. Sublimation of the reaction product at 100 °C *in vacuo* afforded the addition complex $Hf(NO_3)_4 \cdot N_2O_5$.[314]

$$ZrCl_4 + 4N_2O_5 \longrightarrow [Zr(NO_3)_4] + 4NO_2Cl \quad (43)$$

The reaction of $[NMe_4]_2[MCl_6]$ (M = Zr or Hf) with N_2O_4 in acetonitrile at room temperature yields white, moisture-sensitive hexanitrato complexes $[NMe_4]_2[M(NO_3)_6]$.[315] A similar reaction between $Cs_2[ZrCl_6]$ and liquid N_2O_5 gives a mixture of $CsNO_3$ and $[Zr(NO_3)_4]$. The $[NMe_4]_2[M(NO_3)_6]$ complexes are thermally unstable, slowly evolving nitrogen oxides at 130 °C (M = Zr) or 230 °C (M = Hf). They exhibit ν(N—O) IR bands in the regions 1517–1600,

1269–1294 and 981–1021 cm^{-1}. The splitting between the bands arising from the ν_3 (E') mode of $[NO_3]^-$ is substantial, though not as large as for $[Zr(NO_3)_4]$. The $[NMe_4]_2[M(NO_3)_6]$ complexes probably contain monodentate nitrate ligands, but their structures have not yet been determined.



Quite large splittings of the ν_3 (E′) mode have been observed for the hydrated tetranitrates $M(NO_3)_4(H_2O)_4$ (M = Zr or Hf)[166,316] and the basic nitrates $MO(NO_3)_2(H_2O)_2$, $MO(NO_3)_2(H_2O)_6$, $M_2O_3(NO_3)_2(H_2O)_5$ (M = Zr or Hf)[317] and $Zr(OH)(NO_3)_3(H_2O)_3$,[166] indicative of strong nitrate coordination; however, the mode of attachment of the nitrate ligands is unknown. Bidentate attachment has been proposed for the $[ZrO(NO_3)_2L_2]$ (L = N-heterocyclic or O-donor ligand) complexes mentioned in Sections 32.4.2.2 and 32.4.4.1, and this has been established by X-ray diffraction for the β-diketonate complexes $[Zr(acac)_3(NO_3)]$[255] and $[Zr(acac)_2(NO_3)_2]$[257] discussed in Section 32.4.4.4.i.

(*ii*) *Dichlorophosphate*

Dichlorophosphates of the type $ZrCl_3(O_2PCl_2)\cdot POCl_3$ and $MOCl(O_2PCl_2)\cdot POCl_3$ (M = Zr or Hf) have been synthesized by reaction of the metal tetrachlorides with dichlorine monoxide in $POCl_3$ (equations 44 and 45). IR and Raman spectral studies suggest that $ZrCl_3(O_2PCl_2)\cdot POCl_3$ has a centrosymmetric dimeric structure (**24**), while the very insoluble $MOCl(O_2PCl_2)\cdot POCl_3$ compounds are assumed to have an oxo-bridged polymeric structure.[318]

$$ZrCl_4 + 2POCl_3 + Cl_2O \longrightarrow ZrCl_3(O_2PCl_2)\cdot POCl_3 + 2Cl_2 \quad (44)$$

$$ZrCl_4 + 2POCl_3 + 2Cl_2O \longrightarrow MOCl(O_2PCl_2)\cdot POCl_3 + 4Cl_2 \quad (45)$$

(**24**)

(*iii*) *Sulfate, fluorosulfate and selenate*

Zirconium(IV) and hafnium(IV) form a plethora of crystalline sulfates. The normal sulfates include five anhydrous phases, four monohydrates, a tetrahydrate, three pentahydrates and a heptahydrate. The structural relationships and transformations among these compounds have been reviewed by Bear and Mumme.[319,320] Of the normal zirconium sulfates whose structures have been determined thus far, only α-$Zr(SO_4)_2(H_2O)_5$,[321] β-$Zr(SO_4)_2(H_2O)_5$[322] and $Zr(SO_4)_2(H_2O)_7$[323] contain discrete complexes. All three of these compounds contain the centrosymmetric dinuclear $[Zr_2(SO_4)_4(H_2O)_8]$ molecule in which each Zr atom is dodecahedrally coordinated by one bidentate chelating sulfate ligand, two bridging sulfate ligands and four water molecules; Zr—O bond lengths are in the ranges 2.16–2.28 Å (chelating sulfate), 2.06–2.18 Å (bridging sulfate), and 2.16–2.27 Å (water). $Zr(SO_4)_4(H_2O)_4$,[324] α-$Zr(SO_4)_2(H_2O)$[325] and γ-$Zr(SO_4)_2(H_2O)$[326] have layer structures, while anhydrous α-$Zr(SO_4)_2$[327,328] has an extended three-dimensional structure. The Zr atom exhibits square antiprismatic eight-coordination in the tetrahydrate and tetragonal base–trigonal base seven-coordination in the monohydrates and the anhydrous sulfate. The sulfate ligands in these compounds are variously bidentate chelating, bidentate bridging, tridentate bridging or tetradentate bridging. X-Ray data indicate that the corresponding hafnium sulfates[329] are isostructural with the zirconium compounds.

Basic zirconium sulfates[5,6] are unlikely to contain discrete complexes. $Zr(OH)_2SO_4$[330] and $Zr_2(OH)_2(SO_4)_3(H_2O)_4$[331] have three-dimensional framework structures that feature hydroxo and sulfato bridges.

Numerous complex sulfates of the type $M'_2M(SO_4)_3(H_2O)_x$, $M'_4M(SO_4)_4(H_2O)_x$ and

$M'_6M(SO_4)_5(H_2O)_x$ (M' = Na, K, Rb, Cs, or NH_4; M = Zr or Hf) have been isolated from aqueous sulfuric acid solutions,[332–340] and related oxalato-, carbonato- and fluoro-containing mixed-ligand complexes such as $(NH_4)_2Zr(C_2O_4)(SO_4)_2(H_2O)_5$,[341] $(NH_4)_6Zr_2(CO_3)_6(SO_4)(H_2O)_6$,[341] $M'_2ZrF_2(SO_4)_2(H_2O)_x$ and $M'_2ZrF_4(SO_4)(H_2O)_x$ (M' = K, Rb, Cs or NH_4)[342] have also been reported. Recent X-ray studies have shown that the complex sulfates can have mononuclear, dinuclear or polynuclear structures. The tetrasulfato complexes $Na_4[Hf(SO_4)_4(H_2O)_2]$[343] and $[NH_4]_4[Hf(SO_4)_4(H_2O)_2]\cdot 2H_2O$[344] contain discrete mononuclear anions in which the Hf atom is dodecahedrally coordinated by eight oxygen atoms from two bidentate sulfate ligands, two monodentate sulfate ligands and two water molecules. In the pentasulfato complex $Na_6[Hf(SO_4)_5(H_2O)]$,[345] the Hf atom is attached to two bidentate sulfate groups, three monodentate sulfate groups and one water molecule; the geometry of the HfO_8 coordination group in this complex does not closely approximate that of any of the common eight-coordination polyhedra. Hf—O bond distances in these complexes are in the ranges 2.15–2.33 Å (bidentate sulfate), 2.07–2.17 Å (monodentate sulfate) and 2.18–2.33 Å (water). The trisulfato complex $K_2Zr(SO_4)_3(H_2O)_2$ contains centrosymmetric $[Zr_2(SO_4)_6(H_2O)_4]^{4-}$ anions in which the eight-coordinate Zr atoms are held together by two bidentate bridging sulfate ligands; the ZrO_8 coordination polyhedron has been variously described as dodecahedral[346] or bicapped trigonal prismatic.[347] Still another type of structure has been found for the isostructural complexes $Na_2M(SO_4)_3(H_2O)_3$ (M = Zr[348] or Hf[349]). In these compounds the metal atom is attached to two water molecules, two bidentate chelating sulfate ligands, and two bidentate bridging sulfate ligands, giving infinite spiral chains in which the repeating unit is $[M(SO_4)_3(H_2O)_2]^{2-}$. The chains are held together by Na^+ cations and water molecules. $Cs_2Hf(SO_4)_3(H_2O)_2$[350] has a similar chain structure.

Cation exchange, solvent extraction and Raman spectroscopic studies of highly acidic zirconium sulfate solutions suggest that these solutions contain a mixture of solution species having from one to four sulfate ligands per Zr atom.[153,351] The sulfato–zirconium complexes appear to be somewhat more stable than the analogous hafnium complexes.[351]

Zirconium(IV) fluorosulfates $Zr(SO_3F)_4$, $ZrO(SO_3F)_2$, $Zr(O_2CMe)_2(SO_3F)_2$ and $Zr(O_2CMe)_3(SO_3F)$ have been prepared by reaction of fluorosulfuric acid with $Zr(O_2CCF_3)_4$, anhydrous $ZrOCl_2$ or $Zr(O_2CMe)_4$. IR spectra suggest that the fluorosulfate ligands are bidentate in the first three compounds and tridentate (C_{3v} symmetry) in $Zr(O_2CMe)_3(SO_3F)$. All four compounds are good Lewis acids and form complexes with pyridine, 2,2'-bipyridyl and triphenylphosphine oxide.[352]

Mixed-ligand selenato complexes of the type $K_2MF_2(SeO_4)_2(H_2O)_3$, $K_2MF_2(SO_4)(SeO_4)(H_2O)_3$ and $M'_2M_2F_8(SeO_4)(H_2O)_3$ (M = Zr or Hf; M' = K or Rb) have been isolated from aqueous selenic acid solutions. Possible polymeric and dimeric structures have been proposed for these compounds on the basis of IR spectra.[353,354]

(*iv*) *Molybdate*

Alkali metal zirconium and hafnium molybdates have been isolated from high-temperature melts, and X-ray structures of representative compounds have been determined. The isostructural $K_8[M(MoO_4)_6]$ (M = Zr or Hf) complexes[355] contain discrete $[M(MoO_4)_6]^{8-}$ anions that are linked together by K^+ cations. The Zr (Hf) atoms are octahedrally coordinated by six oxygen atoms (mean Zr—O = 2.08, mean Hf—O = 2.05 Å) which are corner-shared with six MoO_4 tetrahedra. $Cs_8[Zr(MoO_4)_6]$[356] crystallizes in a different space group but contains the same complex anions (mean Zr—O = 2.11 Å). In the structure of $Cs_2Hf(MoO_4)_3$,[357] each Hf atom is again surrounded octahedrally by six MoO_4 tetrahedra. However, the molybdate groups bridge between adjacent Hf atoms giving infinite columns of HfO_6 octahedra and MoO_4 tetrahedra with repeating unit $[Hf(MoO_4)_3]^{2-}$.

(*v*) *Perchlorate*

Anhydrous zirconium(IV) and hafnium(IV) perchlorates have been prepared by reaction of $ZrCl_4$ or $HfCl_4$ with a solution of Cl_2O_7 in anhydrous perchloric acid at −10 °C.[358,359] $[Zr(ClO_4)_4]$ (m.p. 95.5–96.0 °C) and $[Hf(ClO_4)_4]$ (m.p. 104.5–105.0 °C) are volatile, hygroscopic, colorless crystalline solids. The vapor pressure of $[Zr(ClO_4)_4]$ varies from 0.8 mmHg at 25 °C to 210.8 mmHg at 95.7 °C,[360] while that of the even more volatile $[Hf(ClO_4)_4]$ ranges

from 2.2 mmHg at 30.5 °C to 37.9 mmHg at 60.9 °C.[361] Above 100 °C, the $[M(ClO_4)_4]$ complexes decompose to $MO(ClO_4)_2$ (M = Zr or Hf). IR and Raman spectra of $[Zr(ClO_4)_4]$[358] and $[Hf(ClO_4)_4]$[359] have been interpreted in terms of an eight-coordinate structure that contains bidentate chelating perchlorate ligands. A large frequency difference between the terminal and bridging ν(Cl—O) bands indicates a considerable amount of covalent character in the metal–perchlorate bonds. IR spectra of gaseous $[M(ClO_4)_4]$ (M = Zr[360] or Hf[361]) are not significantly different from spectra of crystalline $[M(ClO_4)_4]$, indicating no significant change in molecular structure upon vaporization.

$[Zr(ClO_4)_4]$ and $[Hf(ClO_4)_4]$ react with cesium or rubidium perchlorates in $HClO_4$–Cl_2O_7 yielding (perchlorato)metallates of the type $Cs_n[Zr(ClO_4)_{4+n}]$ ($n = 1$, 2, 3 or 4),[362] $Cs_n[Hf(ClO_4)_{4+n}]$ ($n = 1$, 2 or 3)[363] and $Rb_n[Hf(ClO_4)_{4+n}]$ ($n = 1$ or 2).[363] IR spectra suggest that, as n increases, the number of bidentate perchlorate ligands decreases and the number of monodentate perchlorate groups increases, thus maintaining a coordination number of eight for the metal atom.

32.4.4.6 Carboxylates, carbamates, carbonates and oxalates

(*i*) *Carboxylates*

Zirconium carboxylates have long been known,[3] but these compounds are still not very well characterized and no X-ray structural data are available. Known compounds include normal carboxylates $M(O_2CR)_4$, mixed-ligand compounds $Zr(O_2CR)_nX_{4-n}$ (X = Cl or $OCHMe_2$) and a variety of basic carboxylates such as $MO(O_2CR)_2(H_2O)_x$, $Zr(OH)_3(O_2CR)$, $Zr_2O(O_2CR)_6$ and $M_2O(OH)(O_2CR)_5(H_2O)_x$ (M = Zr or Hf).

The following normal carboxylates have been prepared by reaction of $ZrCl_4$ or $HfCl_4$ with an excess of hot, anhydrous carboxylic acid: $Zr(O_2CR)_4$ (R = H, Me, Et, Pr, $CHMe_2$, $C_{15}H_{31}$, $C_{17}H_{35}$, CH_2Ph, Ph, CH_2Cl, $CHCl_2$ or CCl_3)[221,364–371] and $M(O_2CCF_3)_4$ (M = Zr or Hf).[372] Temperature control appears to be an important factor in these syntheses since intermediate products are obtained at low temperatures and thermal decomposition occurs at high temperatures. Thus Ludwig and Schwartz[366] reported that the reaction of $ZrCl_4$ with RCO_2H at −15 °C in carbon tetrachloride yields the addition compounds $ZrCl_4(RCO_2H)_2$ (R = Et, Pr or $CHMe_2$). In xylene solution, the reaction products are the mixed-ligand complexes $Zr(O_2CR)_2Cl_2(RCO_2H)_2$ at 60–65 °C, and the tetrakis(carboxylates) $Zr(O_2CR)_4$ (R = Me, Et, Pr or $CHMe_2$) at 125 °C. Paul *et al.*[365] have synthesized $Zr(O_2CR)_4$ (R = Me, Et, CH_2Cl, $CHCl_2$ or CCl_3) by heating at reflux a mixture of $ZrCl_4$ and an excess of the pure carboxylic acid under reduced pressure at temperatures below 80 °C. If the reactants are allowed to reflux at 1 atm pressure, the thermal decomposition products $ZrO(O_2CR)_2$ are obtained.

Brainina *et al.*[373] have prepared $Zr\{O_2C(CH_2)_nX\}_4$ ($n = 4$, 5, 6, 11, 15 or 17 when X = H; $n = 10$ when X = Cl) from $Zr(acac)_4$ and the fatty acid (equation 46), the acetylacetone being removed by heating the reaction mixture in a stream of dry dinitrogen at reduced pressure. A similar approach has been employed for synthesis of $M(O_2CR)_4$ (M = Zr or Hf; R = Pr, Ph, 4-$C_6H_4NO_2$, or 4-$C_6H_4NH_2$).[374–377]

$$Zr(acac)_4 + 4RCO_2H \longrightarrow Zr(O_2CR)_4 + 4Hacac \qquad (46)$$

The tetrakis(carboxylates) rapidly hydrolyze in moist air and thermally decompose to oxocarboxylato compounds at elevated temperatures. They are nonelectrolytes in nitrobenzene and acetonitrile. Because of their insolubility in most organic solvents, they have been assumed to be polymeric,[365] and this is supported by molecular weight data for $M(O_2CPr)_4$ (M = Zr or Hf).[374] On the other hand, more recent molecular weight measurements on $Zr(O_2CMe)_4$ in antimony(III) chloride,[367] $Zr(O_2CEt)_4$ in propionic acid, and $Zr(O_2CPr)_4$ and $Zr(O_2CCHMe_2)_4$ in the corresponding butyric acids and in carbon tetrachloride[366] indicate that all four compounds are monomeric. Moreover, IR spectra of $Zr(O_2CMe)_4$, which exhibit $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ bands at 1540 and 1455 cm^{-1}, respectively, suggest that the acetate ligands are chelating rather than bridging.[378] Therefore, the tetrakis(carboxylates) may be discrete eight-coordinate chelate complexes; this needs to be confirmed by X-ray diffraction. $Zr(O_2CCCl_3)_4$ behaves as a Lewis acid, forming $Zr(O_2CCCl_3)_4L_2$ adducts with pyridine, pyridine *N*-oxide and triphenylphosphine oxide.[371]

Mixed-ligand compounds of the type $Zr(O_2CCH_2Ph)_nCl_{4-n}$ ($n = 2$ or 3)[369] and

$Zr(O_2CR)_n(OCHMe_2)_{4-n}$ (R = $C_{15}H_{31}$ or $C_{17}H_{35}$; n = 1 or 2)[368] have been prepared by reaction of stoichiometric amounts of the carboxylic acid with $ZrCl_4$ or $Zr(OCHMe_2)_4 \cdot HOCHMe_2$, respectively. Similar reactions of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with furan-2-carboxylic acid, indole-3-acetic acid or indole-3-butyric acid yield the heterocyclic carboxylato complexes $Zr(O_2CR)_n(OCHMe_2)_{4-n}$ (R = C_4H_3O, C_9H_8N or $C_{11}H_{12}N$; n = 1, 2 or 3); IR spectra of these complexes exhibit an 80–120 cm^{-1} separation between the $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ bands, suggesting a symmetrical bidentate attachment of the carboxylate ligands.[379] The reaction of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with fatty acids present in excess in refluxing benzene yields the basic carboxylates $Zr_2O(O_2CR)_6$ (R = C_9H_{19}, $C_{11}H_{23}$, $C_{15}H_{31}$ or $C_{17}H_{35}$).[368]

Basic carboxylates are generally obtained from reactions of $MOCl_2 \cdot 8H_2O$ (M = Zr or Hf) with carboxylic acids or acyl chlorides.[178,380–383] Compounds of the type $MO(O_2CEt)_2(H_2O)$ and $M_2O(OH)(O_2CR)_5(H_2O)_n$ (R = H or Me; n = 1 or 2) have been studied extensively by Russian workers,[381–386] and some, as yet unconfirmed, tetranuclear and octanuclear structures have been proposed on the basis of IR and molecular weight data. Dicarboxylic acids precipitate Zr^{IV} from aqueous zirconyl chloride solutions at pH 2–3 yielding polymeric complexes of composition $Zr(OH)_3(O_2CCH{=}CHCO_2H)$, $Zr(OH)_3(O_2CC_6H_4CO_2H)$ and $Zr(OH)_3\{O_2C(CH_2)_nCO_2H\}$ (n = 1, 2 or 4).[387,388]

Amino acid complexes of the type $[M_4(OH)_8(O_2CCHRNH_3)_8]X_8 \cdot 12H_2O$ (M = Zr or Hf; R = H or Me; X = Cl, Br or NO_3) have been prepared in aqueous solution from glycine or α-alanine and the appropriate zirconyl (hafnyl) salt. IR and X-ray photoelectron spectra indicate that (i) the amino acid ligands are in the zwitterionic form, $^-O_2CHRNH_3^+$, and are coordinated through the carboxylate oxygen atoms, and (ii) the X^- ions are not coordinated. The tetrameric structure of $[Zr_4(OH)_8(H_2O)_{16}]Cl_8 \cdot 12H_2O$ is assumed to be preserved in the amino acid complexes.[389–392]

(*ii*) *Carbamates*

Tetrakis(*N*,*N*-dimethylcarbamato)zirconium(IV), an air- and moisture-sensitive white crystalline solid, has been prepared by reaction of CO_2 with $Zr(NMe_2)_4$ in toluene.[70] This compound is monomeric in benzene, and IR studies indicate that the carbamato ligands are bidentate. An eight-coordinate dodecahedral structure like that found for the analogous monothiocarbamato complex $[Zr(SOCNEt_2)_4]$ (Section 32.4.5.2) is likely. ^1H NMR spectra of $[Zr(O_2CNMe_2)_4]$ at −120 °C in 1:1 dichloromethane–Freon 11 exhibit only a single methyl resonance. In the absence of accidental degeneracy, this observation would indicate that $[Zr(O_2CNMe_2)_4]$ is stereochemically nonrigid at −120 °C.

(*iii*) *Carbonates*

Carbonato complexes of the type $K_4[M(CO_3)_4] \cdot nH_2O$, $[C(NH_2)_3]_4[M(CO_3)_4] \cdot H_2O$ and $[Co(NH_3)_6]_4[Zr(CO_3)_4]_3 \cdot 11H_2O$ (M = Zr or Hf; n = 2 or 6) have been isolated from aqueous solutions that contain $MOCl_2 \cdot 8H_2O$ and appropriate carbonate salts.[393,394] The potassium and guanidinium salts exhibit molar conductances in aqueous solution that are close to the value expected for a 4:1 electrolyte.[393] IR spectra show strong bands in the regions 1580–1620, 1280–1360 and 1012–1060 cm^{-1} due to stretching vibrations of bidentate carbonato ligands.[395] The $[M(CO_3)_4]^{4-}$ ions are assumed[393–395] to have an eight-coordinate dodecahedral structure like that of $[Zr(C_2O_4)_4]^{4-}$ (Section 32.4.4.6.iv).

IR and conductance data also suggest the likelihood of mononuclear eight-coordinate anions in the mixed-ligand complexes $[C(NH_2)_3]_6[Zr(CO_3)_4(C_2O_4)] \cdot 1.5H_2O$, $[C(NH_2)_3]_6[Zr(CO_3)_3(C_2O_4)_2] \cdot 7H_2O$, $K_6[Zr(CO_3)(C_2O_4)_4] \cdot 7.5H_2O$,[396] $[NH_4]_4[Zr(CO_3)_2F_4]$[341] and $K_4[M(CO_3)(C_2O_4)_2F_2] \cdot 5H_2O$ (M = Zr or Hf).[354] In the $[Zr(CO_3)_n(C_2O_4)_{5-n}]^{6-}$ (n = 1, 3 or 4) complexes, some of the ligands are bidentate and some are monodentate; IR spectra indicate that the carbonato–metal chelate rings are more stable than the oxalato–metal chelate rings.

Pospelova and Zaitsev[393] have reported a series of basic carbonato complexes of zirconium in which the metal-to-carbonate ratio varies from 1:1 to 1:3. Typical compositions are: $M'_nZr_2O(OH)_{6-n}(CO_3)_n(H_2O)_x$ (n = 2, 3, 4 or 6) and $M'_4Zr_2O(CO_3)_5(H_2O)_x$ (M′ = Na, K, NH_4, $C(NH_2)_3$, *etc.*). Analogous carbonato-oxalato complexes such as $M'_6Zr_2O(CO_3)_n(C_2O_4)_{6-n}(H_2O)_x$ (n = 2 or 4) are also known.[396] IR studies have shown that the basic carbonato complexes contain bidentate carbonate ligands,[395] but only the 1:3 complexes

of composition $K_6Zr_2O(CO_3)_6(H_2O)_7$ and $(NH_4)_6Zr_2O(CO_3)_6(H_2O)_5$ have been characterized structurally by X-ray diffraction.[397,398] These complexes, properly formulated as $K_6[Zr_2(OH)_2(CO_3)_6]\cdot 6H_2O$ and $[NH_4]_6[Zr_2(OH)_2(CO_3)_6]\cdot 4H_2O$, both contain a centrosymmetric dimeric anion (Figure 6) in which each Zr atom is dodecahedrally coordinated by two bridging hydroxo groups (Zr—O = 2.07–2.13 Å) and three bidentate carbonate ligands (Zr—O = 2.16–2.29 Å). The two dodecahedra share an *m* edge, and the carbonate ligands span the remaining six *m* edges. Analogous hafnium complexes, $K_6[Hf_2(OH)_2(CO_3)_6]\cdot 6H_2O$ and $[C(NH_2)_3]_6[Hf_2(OH)_2(CO_3)_6]\cdot 2H_2O$, have been reported by Dervin *et al.*[394]

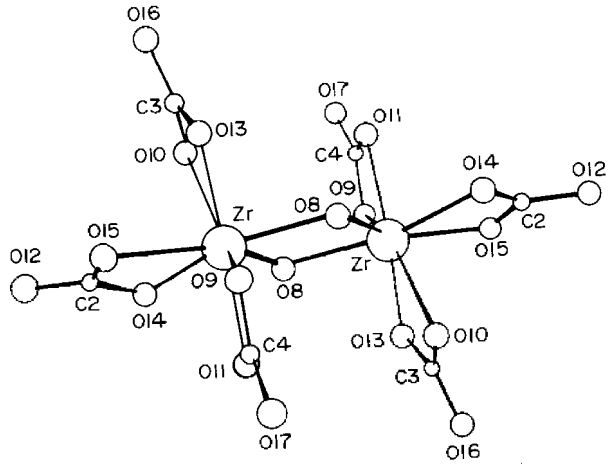


Figure 6 Structure of the centrosymmetric anion in $[NH_4]_6[Zr_2(OH)_2(CO_3)_6]\cdot 4H_2O$ (reproduced by permission from ref. 398)

(*iv*) *Oxalates*

Oxalato complexes of zirconium have been known for many years.[3,399] The best characterized is the $[Zr(C_2O_4)_4]^{4-}$ ion, which has been isolated in alkali,[399] alkaline earth,[400,401] cadmium and lead[401] salts. High-yield procedures for preparation of $K_4[M(C_2O_4)_4]\cdot 5H_2O$ (M = Zr or Hf) have appeared in *Inorganic Syntheses*.[402] The preparations involve addition of an aqueous solution of $MOCl_2\cdot 8H_2O$ to a solution containing potassium oxalate and oxalic acid, followed by addition of ethanol to precipitate the product. X-Ray studies of the isostructural $Na_4[M(C_2O_4)_4]\cdot 3H_2O$ (M = Zr or Hf) salts[403] and the isostructural $K_4[M(C_2O_4)_4]\cdot 5H_2O$ (M = Zr or Hf) salts[404,405] have shown that the $[M(C_2O_4)_4]^{4-}$ ion has a slightly distorted D_{2d} dodecahedral structure in which the virtually flat, bidentate oxalate ligands span the *m* polyhedral edges. Averaged metal–oxygen bond lengths (Table 14) to the dodecahedral A sites are 1.6–2.9% longer than those to the B sites. Perturbed angular correlation measurements of the electric field gradient at the metal site in $M'_4[Hf(C_2O_4)_4]\cdot nH_2O$ (M' = Na, K, Rb, Cs, or NH_4) complexes indicate significant ligand→metal π bonding involving the oxygen atoms in the dodecahedral B sites and the metal $d_{x^2-y^2}$ orbital.[406] Metal–oxygen stretching bands in IR spectra of $K_4[Zr(C_2O_4)_4]\cdot 5H_2O$ (321.5 cm^{-1}) and $K_4[Hf(C_2O_4)_4]\cdot 5H_2O$ (280 cm^{-1}) have been assigned on the basis of metal isotopic substitution studies [$\nu(^{90}Zr—O) = 324.0\,cm^{-1}$; $\nu(^{94}Zr—O) = 316.6\,cm^{-1}$].[407] The lability of $[M(C_2O_4)_4]^{4-}$ (M = Zr or Hf) complexes with respect to ligand exchange has been demonstrated by studies of aqueous solutions of $K_4[M(C_2O_4)_4]\cdot 5H_2O$ and ^{14}C-labeled oxalic acid; complete exchange of oxalate ligands occurs within the few minutes required to complete the experiment.[408]

Tris(oxalato) and pentakis(oxalato) complexes of the type $M'_2Zr(C_2O_4)_3\cdot nH_2O$ (M' = NH_4 or K), $(NH_4)_3H_3Zr(C_2O_4)_5\cdot nH_2O$ and $(NH_4)_6Zr(C_2O_4)_5\cdot nH_2O$ have also been reported.[399] $(NH_4)_6Zr(C_2O_4)_5\cdot nH_2O$ was obtained by passing ammonia over the acid salt $(NH_4)_3H_3Zr(C_2O_4)_5\cdot nH_2O$. The other compounds were isolated from aqueous and/or alcoholic solutions of zirconyl chloride that contain various amounts of $H_2C_2O_4$ or $[HC_2O_4]^-$. The $M'_2Zr(C_2O_4)_3\cdot nH_2O$ salts are 2:1 electrolytes,[399] and IR spectra indicate that all of the oxalate ligands are bidentate.[409] It has been suggested, based on the structure of $[Zr(C_2O_4)_4]^{4-}$, that the tris(oxalato) complexes contain an eight-coordinate $[Zr(C_2O_4)_3(H_2O)_2]^{2-}$ anion.[409] In addition to the IR bands characteristic of bidentate oxalate ligands, $(NH_4)_6Zr(C_2O_4)_5\cdot nH_2O$ shows a band at ~1600 cm^{-1},

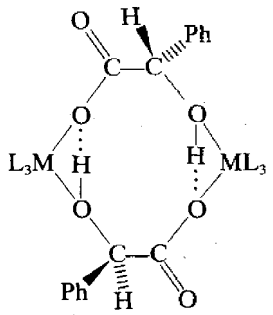
which has been assigned to the $\nu_{as}(CO_2)$ mode of 'uncombined CO_2' groups. A structure for $[Zr(C_2O_4)_5]^{6-}$ having three bidentate and two monodentate oxalate ligands is favored.[409]

Mixed-ligand sulfato-oxalato and carbonato-oxalato complexes were mentioned in Sections 32.4.4.5.iii and 32.4.4.6.iii. A variety of fluoro-oxalato complexes have also been reported. Typical compositions are: $M'_4M(C_2O_4)_3F_2(H_2O)_n$, $M'_3M(C_2O_4)_2F_3(H_2O)_3$, $M'_2Zr(C_2O_4)F_4(H_2O)_n$, $M'_2Zr_2(C_2O_4)F_8(H_2O)_4$ and $K_{14}M_4(C_2O_4)_5F_{20}(H_2O)_2$ (M′ = alkali metal; M = Zr or Hf).[341,410,411]

Zaitsev and coworkers[412–414] have prepared basic oxalates such as $M'_2ZrO(C_2O_4)_2\cdot nH_2O$ (M′ = K, NH_4, or 0.5 Ba) and $M'Zr(OH)_3(C_2O_4)\cdot nH_2O$ (M′ = Na, K, NH_4, or 0.5 Ba) and have suggested that these complexes may have tetranuclear structures based on the $\{Zr_4(OH)_8^{8+}\}$ unit found in $[Zr_4(OH)_8(H_2O)_{16}]Cl_8\cdot 12H_2O$. In recent years, divalent metal zirconyl oxalates have been of interest as precursors for the preparation of ceramic materials; $M''ZrO(C_2O_4)_2\cdot nH_2O$ complexes decompose at elevated temperatures yielding metal zirconates $M''ZrO_3$ (M″ = alkaline earth, Zn, Cd or Pb).[415,416]

32.4.4.7 Aliphatic and aromatic hydroxy acids

α-Hydroxycarboxylic acids $RR'C(OH)CO_2H$ such as glycolic (R = R′ = H), lactic (R = H; R′ = Me), malic (R = H; R′ = CH_2CO_2H), tartaric (R = H; R′ = $CH(OH)CO_2H$), trihydroxyglutaric (R = H, R′ = $CH(OH)CH(OH)CO_2H$), and citric (R = R′ = CH_2CO_2H) acids form stable complexes with Zr^{IV} and Hf^{IV}, even in strongly acidic solutions.[417–419] The greater complexing ability of the hydroxy acids relative to that of the corresponding carboxylic acids is attributed to the formation of five-membered chelate rings (**25**). A recent study by Hala and Londyn[419] indicates that Hf^{IV} in 1.0–3.0 M $HClO_4$ media forms 1:1 and 1:2 complexes with glycolic, tartaric and citric acids and 1:1, 1:2, and 1:3 complexes with lactic and malic acids. The stability of the 1:1 complex increases in the order tartrate < malate < glycolate < citrate < lactate. Earlier, Ryabchikov *et al.*[417,418] found that the Hf^{IV} complexes are somewhat less stable than the Zr^{IV} analogues.



(**25**)

Hydroxo(glycolato) complexes of composition $M_2O(OH)_2(CH_2OHCO_2)_4\cdot nH_2O$ and $M(OH)(CH_2OHCO_2)_3\cdot nH_2O$ (M = Zr or Hf; n = 3–7) have been isolated by mixing 1 M solutions of $MOCl_2\cdot 8H_2O$ and glycolic acid in 1:1, 1:2, 1:3 and 1:4 molar ratios.[420] IR spectra indicate that the carboxylate and hydroxyl oxygen atoms are attached to the metal atom, but the detailed structures of these compounds are unknown. The lactato complexes $Zr(MeCHOHCO_2)_4$ and $Zr(OH)(MeCHOHCO_2)_3$ have been obtained from 3–5 M HCl solutions; $Zr(MeCHOHCO_2)_4$ is very easily hydrolyzed.[421]

Ermakov *et al.*[422] have isolated compounds of composition $Zr(C_4H_2O_6)\cdot 2H_2O$ and $Zr(C_5H_4O_7)\cdot 3H_2O$ from 0.5 M $ZrOCl_2$ solutions that were treated with one equivalent of tartaric acid or trihydroxyglutaric acid, respectively. A similar experiment with citric acid gave

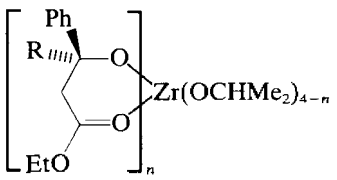
a mixture of $Zr(C_6H_4O_7)\cdot 4H_2O$ and $Zr_2(OH)_4(C_6H_4O_7)\cdot 2H_2O$. IR studies of the tartrate and citrate complexes suggest that complex formation involves the carboxylate and the hydroxyl groups and is accompanied by loss of the hydroxy protons.

Mandelic acid and its derivatives have long been used as analytical reagents for determination of zirconium and hafnium.[285,286] The tetrakis(mandelates) $M\{(\pm)\text{-}PhCHOHCO_2\}_4$ are precipitated when a solution of (±)-mandelic acid is added to a hot (80–90 °C) 5 M hydrochloric acid solution of the metal oxychloride. Larsen and Homeier[421] have proposed that the $M\{(\pm)\text{-}PhCHOHCO_2\}_4$ complexes have a polymeric structure in which eight-coordinate metal atoms are linked by (±) pairs of bridging mandelate ligands (**26**). The stability of this structure was attributed to short, double-minimum hydrogen bonds involving the hydroxyl protons and the carboxylate oxygen atoms, and it was suggested that these hydrogen bonds can only form when a (±) pair of ligands is present in the bridge. Evidence for this polymeric structure includes: (i) the very low solubility and lack of volatility of the $M\{(\pm)\text{-}PhCHOHCOO)\}_4$ complexes, (ii) the presence of broad ν(O—H···O) IR bands centered at 2600, 2300 and 1850 cm^{-1}, and (iii) the fact that the tetrakis(mandelato)-complexes could only be prepared when the ligand was (±)-mandelate; attempts to prepare $Zr\{(+)\text{-}PhCHOHCHO_2\}_4$ and $Zr\{(-)\text{-}PhCHOHCO_2\}_4$ yielded basic mandelates $Zr(OH)_x(PhCHOHCO_2)_{4-x}$. The presence of broad, low-frequency ν(O—H···O) bands in IR spectra of $M\{(\pm)\text{-}PhCHOHCO_2\}_4$ (M = Zr or Hf) has been confirmed by Karlysheva *et al.*,[423] although these workers have suggested a monomeric tetrakis(chelate) structure.

(**26**) L = $PhCHOHCO_2^-$

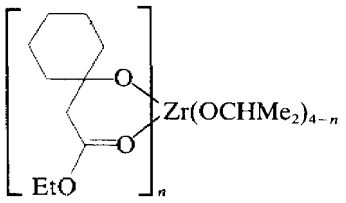
$M\{(\pm)\text{-}PhCHOHCO_2\}_4$ precipitates dissolve in solutions of weak bases such as ammonia, organic amines and sodium bicarbonate. The dissolution reaction is consistent with enhanced acidity of the OH groups in a chelate structure and has been attributed by Hahn and coworkers[424,425] to salt formation, *e.g.* equation (47). Larsen and Homier,[421] however, have questioned the identity of Hahn's reaction products and have suggested that the dissolution reaction involves attack by bases on the hydrogen bonds of a polymeric structure.

$$M\{\pm\text{-}PhCHOHCO_2\}_4 + 4NH_3 \longrightarrow [NH_4]_4[M\{\pm\text{-}PhCH(O)CO_2\}_4] \quad (47)$$



The reaction of mandelic acid with $ZrCl_4$ in acetonitrile yields a mixture of $[Zr\{(\pm)\text{-}PhCHOHCO_2\}_3Cl]$ and $[Zr\{(\pm)\text{-}PhCHOHCO_2\}_4]$.[421] The latter soluble product is believed to be a monomeric, seven-coordinate isomer of the polymeric tetrakis(mandelate) obtained in aqueous media; it exhibits an IR band at 1700 cm^{-1}, which is attributed to ν(C=O) of a monodentate mandelate ligand.

Mandelic acid reacts with $Zr(OCHMe_2)_4\cdot HOCHMe_2$ in refluxing benzene to give $Zr\{PhCH(O)CO_2\}(OCHMe_2)_2$, $Zr(PhCHOHCO_2)\{PhCH(O)CO_2\}(OCHMe_2)$ or $Zr(PhCHOHCO_2)_4$, depending on the stoichiometry of the reaction mixture. $Zr(PhCHOHCO_2)\{PhCH(O)CO_2\}(OCHMe_2)$ loses isopropanol when heated under reduced pressure, yielding $Zr\{PhCH(O)CO_2\}_2$, and is converted to $Zr(PhCHOHCO_2)_2(OCHMe_2)_2$ when treated with isopropanol in benzene. Reaction of $Zr(PhCHOHCO_2)\{PhCH(O)CO_2\}(OCHMe_2)$ with 1-butanol in refluxing benzene gives the butoxide derivative $Zr(PhCHOHCO_2)\{PhCH(O)CO_2\}(OBu)$.[426]

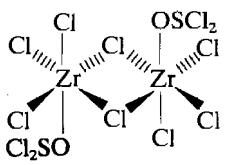


Reactions between salicylic acid and $Zr(OCHMe_2)_4\cdot HOCHMe_2$ in benzene yield similar products; $Zr(2\text{-}OC_6H_4CO_2)(OCHMe_2)_2$, $Zr(2\text{-}HOC_6H_4CO_2)(2\text{-}OC_6H_4CO_2)(OCHMe_2)$, $Zr(2\text{-}OC_6H_4CO_2)_2$ and $Zr(2\text{-}HOC_6H_4CO_2)_2(2\text{-}OC_6H_4CO_2)$ have been isolated, depending on the

reaction temperature and the stoichiometry of the reaction mixture. The reaction of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with excess methyl salicylate gives the tetrakis complex $Zr(2\text{-}OC_6H_4CO_2Me)_4$.[427] In aqueous media, salicylic acid and its derivatives precipitate Zr^{IV} in the form of basic salicylates.[286,428,429]

The reactions of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ with the β-hydroxy esters $PhCR(OH)CH_2CO_2Et$ (R = H or Me) and $C_6H_{10}(OH)CH_2CO_2Et$ in 1:1, 1:2, 1:3 and 1:4 molar ratios in benzene at reflux afford monomeric, viscous liquid complexes of the type (**27**) and (**28**). IR spectra and molecular weight measurements indicate that the Zr atom has a coordination number of five, six, seven or eight when n is 1, 2, 3 or 4, respectively. The complexes that contain $OCHMe_2$ groups can be converted to the corresponding t-butoxide derivatives by reaction of (**27**) and (**28**) ($n = 1$, 2 or 3) with Me_3COH in benzene at reflux.[430] Chloro(hydroxyester) complexes of the type $Zr\{MeCH(O)CO_2Et\}_2Cl_2$, $Zr\{PhCH(O)CO_2Me\}_2Cl_2$ and $Zr(2\text{-}OC_6H_4CO_2Me)_nCl_{4-n}$ ($n = 2$ or 3) have been known for many years.[221]

(**27**) $n = 1$, 2, 3 or 4



(**28**) $n = 1$, 2, 3 or 4

32.4.4.8 Sulfoxides, selenoxides, amides, N-oxides, P-oxides and related ligands

Zirconium(IV) and hafnium(IV) halides react with sulfoxides, selenoxides, amides, *N*-oxides, *P*-oxides and related ligands to give moisture-sensitive solid adducts that are generally insoluble in common organic solvents. Typical examples are listed in Table 15. Use of two equivalents or an excess of Lewis base ordinarily yields octahedral 1:2 adducts $[MX_4L_2]$, some of which have been assigned *cis* or *trans* configurations on the basis of the number of metal–halogen stretching bands in vibrational spectra. For example, IR and Raman spectra and normal coordinate calculations[431] have established a *cis* structure for $[MCl_4(POCl_3)_2]$ (M = Zr or Hf) complexes, which exhibit four ν(M—Cl) modes in the region 370–305 cm^{-1}.

A few 1:1 adducts have been reported. For example, thermal decomposition of $[MCl_4L_2]$ (M = Zr or Hf; L = $POCl_3$ or $POFCl_2$) under reduced pressure yields solid MCl_4L complexes[432] that have been shown to be monomeric in nitrobenzene when L = $POCl_3$.[433] Vapor pressure measurements in the $ZrCl_4$–$POCl_3$ system have shown that $[ZrCl_4(POCl_3)]$ exists in the gas phase as well.[434] On the other hand, the thionyl chloride adduct $[\{ZrCl_4(SOCl_2)\}_2]$ is a centrosymmetric dimer (**29**) in which each Zr atom is octahedrally coordinated by two bridging chlorine atoms (at 2.58 ± 0.01 Å), three terminal chlorine atoms (at 2.34 ± 0.02 Å) and the thionyl chloride oxygen atom (at 2.273(13) Å).[435] Phthalimide forms a 1:1 adduct with $ZrCl_4$, which is a monomeric nonelectrolyte in nitrobenzene but which may be polymeric in the solid state since IR spectra suggest that both carbonyl groups are coordinated to the metal.[436]

(**29**)

The reactions of zirconium and hafnium tetrahalides with an excess of dimethyl sulfoxide or a primary amide yield MX_4L_n compounds having values of n as large as 10 (see Table 15). IR studies of $MCl_4(DMSO)_8$[437] and $ZrCl_4(HCONH_2)_4$[438] indicate the presence of both coordinated and noncoordinated Lewis base ligands; the formamide complex has been formulated as $[ZrCl_4(HCONH_2)_2] \cdot 2HCONH_2$. On the other hand, IR spectra of the 2,6-lutidine *N*-oxide complex $[ZrCl_4(2,6\text{-}Me_2C_5H_3NO)_3]$ suggest that all three *N*-oxide ligands are attached to a

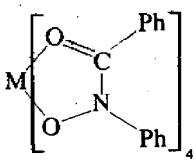
seven-coordinate Zr atom.[439] It is interesting to note that the reaction of excess 2,6-lutidine *N*-oxide with $ZrCl_4$ yields a 1:3 complex, while the analogous reaction with $HfCl_4$ gives the 1:2 adduct *cis*-$[HfCl_4(2,6\text{-}Me_2C_5H_3NO)_2]$.

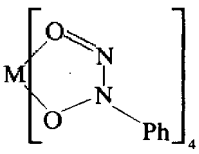
Formation of the adducts in Table 15 is accompanied by characteristic low-frequency shifts in the IR bands of ligand vibrations that involve stretching of bonds to the oxygen atom; typical low-frequency shifts upon coordination to MCl_4 (M = Zr or Hf) are ~100 cm^{-1} for ν(SO) in DMSO,[437] ~60 cm^{-1} for ν(SeO) in Ph_2SeO,[440] ~15 cm^{-1} for ν(C=O) in DMF[120] and 115–155 cm^{-1} for ν(P=O) in phosphine oxides, phosphinates, phosphonates and phosphates.[441] These data indicate that the Lewis bases are coordinated through the oxygen atom. Coordination through the carbonyl oxygen atom in $[ZrBr_4(DMF)_2]$ is supported by the presence of two methyl resonances in the ^1H NMR spectrum.[442] The C≡N group is not coordinated in the cyanoacetamide complex $[ZrCl_4(NCCH_2CONH_2)_2]$; this compound is a monomeric nonelectrolyte in nitrobenzene, and IR spectra are consistent with six coordination, the $NCCH_2CONH_2$ being attached to zirconium through the carbonyl oxygen atom.[443]

Several lines of evidence suggest that the Lewis acid strength of zirconium and hafnium tetrahalides toward oxygen donor ligands increases in the order $ZrX_4 < HfX_4$: (i) metal–oxygen stretching force constants in *cis*-$[MCl_4(POCl_3)_2]$ are 0.344 mdyn $Å^{-1}$ (M = Zr) and 0.434 mdyn $Å^{-1}$ (M = Hf);[432] (ii) $\Delta H°_{298}$ values (kJ mol^{-1}) for conversion of $MCl_4(POCl_3)_2$(s) to $MCl_4(POCl_3)$(s) and $POCl_3$(g) are 67 ± 8 for M = Zr and 88 ± 8 for M = Hf;[444] and (iii) $\Delta H°_{298}$ values (kJ mol^{-1}) for formation of $MX_4(DMSO)_2$(s) from MX_4(g) and 2DMSO(g) are: −379 ($MX_4 = ZrCl_4$), −392 ($HfCl_4$), −367 ($ZrBr_4$), −399 ($HfBr_4$).[445]



Oxozirconium(IV) complexes of the type $[ZrOX_2L_2]$ (X = Cl, Br, NO_3 or NCS), $[ZrOL_4]I_2$ and $[ZrOL_6][ClO_4]_2$, where L is sulfoxide, *N*-oxide or *P*-oxide, have been discussed in Section 32.4.4.1. In all of these compounds, the Lewis base is coordinated to the metal through the oxygen atom. Additional complexes of this type include $[ZrO(DMSO)_6][ClO_4]_2 \cdot n$DMSO ($n$ = 0 or 2)[446,447] and $[ZrOL_6][ClO_4]_2$ (L = pyridine *N*-oxide or quinoline *N*-oxide).[448,449]

Paul *et al.*[450] have prepared amide complexes of the type $ZrOCl_2(HCONH_2)_4$ and $ZrOCl_2L_2$ (L = DMF, $MeCONH_2$, MeCONHMe, MeCONHPh, $MeCONMe_2$, or $PhCONH_2$) by addition of the amide to an acetone solution of anhydrous $ZrOCl_2$. Kharitonov *et al.*[451] have isolated DMF complexes of composition $MOCl_2(DMF)_2(H_2O)_2$, $MO(OH)(NO_3)(DMF)$, $M(SO_4)_2(DMF)_4$ and $MO(SO_4)(DMF)(H_2O)$ (M = Zr or Hf) from DMF solutions of hydrated zirconium and hafnium salts; they have suggested mononuclear, tetranuclear and polynuclear structures for some of these compounds on the basis of IR spectra. Savant *et al.*[452] have reported $ZrO(antipyrine)_3(ClO_4)_2$ and $Zr(antipyrine)_6(ClO_4)_4$; these complexes are electrolytes in $PhNO_2$, $MeNO_2$ and DMSO, with the extent of dissociation depending on the solvent. For all of these compounds, IR spectra indicate that the amide or antipyrine ligand is coordinated through the carbonyl oxygen atom.



$MOCl_2 \cdot 8H_2O$ (M = Zr or Hf) and $ZrO(ClO_4)_2 \cdot 8H_2O$ react with the potentially tridentate phosphine oxide, phosphinate and phosphinic acid ligands L = $\{Ph_2P(O)CH_2\}_2P(O)R$ (R = Ph, OEt or OH) yielding complexes of composition $M(OH)_2LCl_2(H_2O)_8$ and $Zr(OH)_2L(ClO_4)_2(H_2O)_8$, respectively. The perchlorate compounds are electrolytes in $PhNO_2$, while the chloro complexes are nonelectrolytes. Reaction of $ZrCl_4$ with L gives the $ZrCl_4(L)$ complexes (Table 15), which are also nonelectrolytes in $PhNO_2$. Low-frequency shifts of 60–90 cm^{-1} in ν(P=O) upon complex formation indicate that the phosphorus ligands are coordinated through the phosphoryl oxygen atoms.[453] Phosphine oxides and organic phosphates, particularly tri-*n*-octylphosphine oxide and tri-*n*-butyl phosphate, are important complexing agents in solvent extraction procedures for separation of zirconium and hafnium from other metals.[286]

32.4.4.9 Hydroxamates, cupferron and related oxygen ligands

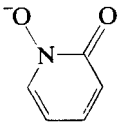
N-Benzoyl-*N*-phenylhydroxylamine and cupferron (the ammonium salt of *N*-nitroso-*N*-phenylhydroxylamine) have long been used as analytical reagents for gravimetric determination of zirconium.[286] Addition of these reagents to moderately acidic aqueous solutions of Zr^{IV} or Hf^{IV} precipitates the tetrakis chelates (**30**) and (**31**). Bhatt and Agrawal[454] have prepared $\{Zr\{ON(Ph)COPh\}_4]$ at pH 5.5, but Karlysheva and Sheka[455] report that basic cupferrates of variable composition are obtained if the acid concentration is less than 1 N. $[M\{ON(Ph)COPh\}_4]$ (M = Zr or Hf) complexes have also been isolated from benzene solution following extraction of Zr^{IV} or Hf^{IV} from 1–3 M $HClO_4$ or 1–5 M HCl; extraction from 6–9 M HCl affords the chloro complexes $[M\{ON(Ph)COPh\}_3Cl]$.[456]

(**30**) M = Zr or Hf

(**31**) M = Zr or Hf

An X-ray structural determination[457] has shown that $[Hf\{ON(Ph)COPh\}_4]$ (**30**; M = Hf) exists in the solid state as the unusual S_4-*gggg* dodecahedral stereoisomer. Because the four *g* edges spanned by the ligands (average 2.527 Å) are appreciably shorter than the other four *g* edges (2.869 Å), the BAAB trapezoids of the dodecahedron are somewhat twisted; the ligating oxygen atoms are displaced from the mean trapezoidal planes by 0.08–0.20 Å. The PhCO oxygen atoms occupy the dodecahedral A sites and the PhNO oxygen atoms take the B sites, in accord with Orgel's rule for d^0 complexes.[458,459] As expected, the averaged Hf—O_A bond distance (2.258 Å) is longer than the Hf—O_B distance (2.116 Å), but the ratio Hf—O_A/Hf—O_B (1.067) is unusually large.

Zirconium(IV) cupferrate (**31**; M = Zr) exists in the solid state as the more usual D_{2d}-*mmmm* dodecahedral stereoisomer.[460] In this structure, the PhNO oxygen atoms are located in the A sites and the nitroso oxygen atoms are found in the B sites; averaged bond lengths are Zr—O_A = 2.168 Å, Zr—O_B = 2.212 Å, Zr—O_A/Zr—O_B = 0.980. If the PhNO oxygen atom carries more of the ligand's negative charge than the nitroso oxygen atom, this structure would appear to be a violation of Orgel's rule. However, the two N—O bond lengths within the chelate ring are equal (1.30 Å), suggesting that the charge on the two oxygen atoms may not be significantly different.

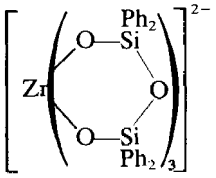


The difference in ligand wrapping pattern for $[Hf\{ON(Ph)COPh\}_4]$ and $[Zr\{ON(Ph)NO\}_4]$ is interesting. Tranqui *et al.*[457] have noted the close interpenetration of adjacent molecules in the crystal structure of $[Hf\{ON(Ph)COPh\}_4]$ and have suggested that the molecular structure may be influenced by crystal packing effects. Another factor that may be of importance is a difference in the normalized bites of the hydroxamate and cupferrate ligands, 1.155 in (**30**; M = Hf) and 1.108 in (**31**; M = Zr); the D_{2d}—*mmmm* wrapping pattern becomes less stable as the normalized bite of the ligand increases.[461]

Time differential perturbed angular correlation (TDPAC) measurements on the solid compounds (**30**; M = Hf) and (**31**; M = Hf) have been interpreted[275] in terms of two different hafnium environments, a conclusion which is not in accord with the X-ray crystal structures.[457,460] A more recent TDPAC study[462] provides information about π bonding involving the hafnium $d_{x^2-y^2}$ orbital and the oxygen atoms in the dodecahedral B sites. The charge transferred into $d_{x^2-y^2}$ has been estimated to be ~20% of the overall charge donated by the ligands in (**30**; M = Hf) and ~16% in (**31**; M = Hf). The overall charge donated by the ligands into the metal valence orbitals is in the range −0.7 to −1.2 e; thus the Hf—O bonds are still quite highly ionic.

Mixed-ligand hydroxamato complexes of the type $Zr(ONHCOR)_n(OCHMe_2)_{4-n}$ (R = Ph or CH_2Ph; *n* = 1, 2, 3 or 4) have been prepared by reaction of the appropriate hydroxamic acid with $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ in benzene at reflux; the value of *n* depends on the stoichiometry of the reaction mixture.[463] Zirconium(IV) alkyls ZrR_2Cl_2 (R = CH_2SiMe_3) or ZrR_4 (R = CH_2SiMe_3 or CH_2CMe_3) react with nitric oxide to give the six- or eight-coordinate *N*-alkyl-*N*-nitrosohydroxylaminato complexes $[Zr(ONRNO)_2Cl_2]$ or $[Zr(ONRNO)_4$, respectively.[464]

Zirconium(IV) forms a tetrakis chelate with the hydroxamate-related 1-oxy-2-pyridonate



ligand (**32**); the chloroform solvate $Zr(C_5H_4NO_2)_4 \cdot CHCl_3$ was isolated from chloroform–ethanol.[465]

(**32**)

32.4.4.10 Miscellaneous oxygen donor ligands

The diethylammonium salt of the tris(tetraphenyldisiloxanediolato)zirconate(IV) anion (**33**) has been obtained in very low yield from the reaction of $[Zr(NEt_2)_4]$ with diphenylsilanediol in THF. The ligand results, under the basic reaction conditions, from condensation of two $Ph_2Si(OH)_2$ molecules. Anion (**33**) has an octahedral tris-chelate structure with a twist angle (46.9°) that indicates some distortion towards trigonal prismatic geometry.[466]

(**33**)

Tetrakis(perfluoroalkanesulfonates) $Zr(R_FSO_3)_4$ ($R_F = CF_3$ or C_2F_5) have been prepared by reaction of $ZrCl_4$ with an excess of the perfluoroalkanesulfonic acid.[467] The mode of attachment of the perfluoroalkanesulfonate ligands is unknown.

Bis(benzeneseleninato)oxozirconium(IV) complexes, $ZrO(O_2SeC_6H_4X)_2$ (X = 4-Cl, 3-Cl or 3-Br) and $ZrO(O_2SeC_6H_4\text{-}3\text{-}NO_2)_2 \cdot 2H_2O$ have been synthesized in aqueous solution by reaction of a 1:4 molar ratio of $Zr(NO_3)_4$ and the sodium salt of the ligand. IR spectra indicate an *O,O'*-bidentate attachment of the $O_2SeC_6H_4X$ ligands and an oxo-bridged polymeric structure. The presence of just one ν(Zr—O—Zr) IR band (739–750 cm^{-1}) and two ν(Zr—O) bands for the bonds to the $O_2SeC_6H_4X$ ligands (405–504 cm^{-1}) suggests an octahedral trans environment for the Zr atom.[179]

$Zr(acac)_4$ reacts with four equivalents of diphenylphosphinic acid at 300 °C yielding $Zr\{OP(O)Ph_2\}_4$, which is dimeric at 100 °C in 1,2-dichlorobenzene. IR spectra of this compound exhibit ν(P=O) bands due to coordinated and uncoordinated P=O groups, suggesting the presence of bridging and monodentate diphenylphosphinate ligands. $Zr\{OP(O)Ph_2\}_4$ has remarkable thermal stability, not melting up to 490 °C. A polymeric, diphenylphosphinate-bridged compound $ZrCl_2\{OP(O)Ph_2\}_2$ has been obtained by reaction of $ZrCl_4$ with two equivalents of diphenylphosphinic acid in *n*-butanol.[468] Di-*n*-butylphosphates of the type $Zr(NO_3)_2\{OP(O)(OBu)_2\}\{HOPO(OBu)_2\}_n$ ($n = 0$, 2 or 4) are also known.[469]

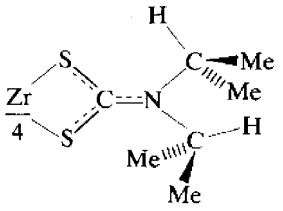
32.4.5 Sulfur Ligands

32.4.5.1 Thiolates and thioethers

Only one zirconium thiolate coordination compound is known; the blue $Zr(SPh)_4$ has been prepared by reaction of $ZrCl_4$ with $Al(SPh)_3(Et_2O)$.[470] The dithiolates $Zr(SCH_2CH_2S)(OCHMe_2)_2$ and $Zr(SCH_2CH_2S)_2$ have been obtained as white solids from the reaction of stoichiometric amounts of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$ and ethanedithiol in benzene at reflux.[471]

The following metal halide–thioether adducts have been reported: $[ZrCl_4(Me_2S)_2]$,[472] $[MCl_4(THT)_2]$ and $[ZrBr_4(THT)_2]$ (M = Zr or Hf; THT = tetrahydrothiophene),[473] $[ZrCl_4(MeSCH_2CH_2SMe)_2]$[474] and $ZrCl_4$(1,4-oxathiane).[306] These relatively insoluble compounds are generally prepared by prolonged stirring of a mixture of the metal halide and the thioether in an inert solvent such as benzene or cyclohexane.

Thermochemical measurements[473] indicate that $[ZrBr_4(THT)_2]$ is less stable than $[ZrCl_4(THT)_2]$, presumably because of steric hindrance. Although $[ZrCl_4(THF)_2]$ and



$[HfCl_4(THF)_2]$ exhibit closely similar heats of adduct formation, $[HfCl_4(THT)_2]$ is more stable than $[ZrCl_4(THT)_2]$, indicating that Hf^{IV} has more class b character than Zr^{IV}.

IR spectra show that the conformation of 1,2-dimethylthioethane changes from predominantly *trans* to *gauche* on formation of $[ZrCl_4(MeSCH_2CH_2SMe)_2]$.[474] This is consistent with an eight-coordinate structure in which $MeSCH_2CH_2SMe$ coordinates through both sulfur atoms. A high coordination number for zirconium is also indicated by the low frequencies of the ν(Zr—Cl) and ν(Zr—S) IR bands, 305 and 275 cm^{-1}, respectively. In the six-coordinate, probably polymeric compound $ZrCl_4$(1,4-oxathiane),[306] ν(Zr—Cl) is at 345 cm^{-1}. The IR spectra indicate that 1,4-oxathiane is in the chair form and both the sulfur and the oxygen atoms are coordinated to zirconium atoms.

32.4.5.2 Dithiocarbamates and monothiocarbamates

Eight-coordinate *N,N*-dialkyldithiocarbamato complexes $[Zr(S_2CNR_2)_4]$ (R = Me, Et, Pr) have been prepared by reaction of $[Zr(NR_2)_4]$ with CS_2 in cyclohexane.[69] The isopropyl derivative $[Zr\{S_2CN(CHMe_2)_2\}_4]$ was obtained from the reaction of $ZrCl_4$ with $Na\{S_2CN(CHMe_2)_2\}$ in the presence of triethyl phosphite.[475] $[Zr(S_2CNEt_2)_4]$ is isomorphous with $[Ti(S_2CNEt_2)_4]$, which has been shown by X-ray diffraction to have a D_{2d}-*mmmm* dodecahedral structure.[476] The mass spectrum of $[Zr(S_2CNEt_2)_4]$ exhibits a peak for the parent ion; the base peak is $[Zr(S_2CNEt_2)_3]^+$.[477] Low-temperature ^1H, ^{13}C and ^{19}F NMR spectra of $[Zr(S_2CNR_2)_4]$ (R = Et or Pr), $[Zr\{S_2CN(Me)(Pr)\}_4]$ and $[Zr\{S_2CN(Me)(C_6F_5)\}_4]$ indicate that these complexes undergo very rapid intramolecular rearrangement. No evidence of stereoisomers or inequivalence of A-site and B-site *N*-alkyl groups was observed at temperatures down to −140 °C.[478,479] Intermolecular ligand exchange between $[Zr(S_2CNPr_2)_4]$ and $[Ti(S_2CNPr_2)_4]$ is slow on the NMR time scale at 80 °C.[478]

Variable temperature ^1H NMR spectra of $[Zr\{S_2CN(CHMe_2)_2\}_4]$ (**34**) show that the isopropyl groups are inequivalent owing to hindered rotation about the C—N single bonds. Rate constants for this process range from 20 s^{-1} at −25.0 °C to 670 s^{-1} at 21.0 °C; $\Delta H^{\ddagger} = 45 \pm 1$ kJ mol^{-1} and $\Delta S^{\ddagger} = -39 \pm 5$ J mol^{-1} deg^{-1}.[475]

(**34**)

Five-, six-, seven- and eight-coordinate complexes of the type $[M(S_2CNRR')_nCl_{4-n}]$ (n = 1, 2, 3 or 4; M = Zr or Hf; R = Et, R′ = 3-C_6H_4Me; R = H, R′ = cyclopentyl or cycloheptyl) have been synthesized by reaction of stoichiometric amounts of MCl_4 and anhydrous $Na(S_2CNRR')$ in dichloromethane at reflux. These complexes are monomeric nonelectrolytes in solution, and IR spectra indicate a bidentate attachment of the dithiocarbamate ligands.[480,481] The same ligands react with aqueous solutions of $MOCl_2$ (M = Zr or Hf) to give compounds of composition $MO(S_2CNRR')_2{\cdot}2H_2O$; these complexes contain bidentate dithiocarbamate ligands, but their structures are unknown.[482] Six-coordinate complexes, $[Zr(S_2CNR_2)_2(OPh)_2]$ and $[Zr(S_2CNRR')_2(OPh)_2]$ (R = Me, Et or $CHMe_2$; R′ = cyclohexyl), have been prepared from $Zr(OPh)_2Cl_2$ and $Na(S_2CNR_2)$ or $Na(S_2CNRR')$ in THF at reflux.[483]

ZrX_4 (X = F or Cl) reacts with the sodium salt of piperazine-1,4-dicarbodithioate to give complexes of composition $ZrF_2\{S_2CN(CH_2CH_2)_2NC(S)SH\}_2$ and $Zr_2Cl_6\{S_2CN(CH_2CH_2)_2NCS_2\}$ respectively.[484,485] On the basis of IR evidence, the fluoride complex has been assigned an octahedral *trans* structure in which one CS_2^- group is bidentate while the other CS_2^- group is attached to a proton.[484] IR spectra indicate that the piperazine-1,4-dicarbodithiolate behaves as a tetradentate ligand in the chloride complex.[485]

Two recent papers on $[(\eta\text{-}C_5H_5)M(S_2CNMe_2)_3]$ (M = Zr or Hf)[486] and $[(\eta\text{-}C_5H_5)_2ZrCl(S_2CNR_2)]$ (R = Me or Et)[487] are mentioned in passing to provide an entry into the current literature on organo-zirconium and -hafnium dithiocarbamato complexes.

The moisture-sensitive monothiocarbamato complexes $[Zr(SOCNR_2)_4]$ (R = Me, Et or

$CHMe_2$) may be prepared by reaction of $ZrCl_4$ with $Na(SOCNR_2)$ in dry acetonitrile.[488] $[Zr(SOCNMe_2)_4]$ has also been synthesized by insertion of carbonyl sulfide into the Zr–N bonds of $[Zr(NMe_2)_4]$.[70] An X-ray study[489] has established that $[Zr(SOCNEt_2)_4]$ exists in the solid state as the dodecahedral stereoisomer that has an *mmmm* ligand wrapping pattern and a C_{2v} arrangement of the sulfur and oxygen atoms. This isomer is one of six possible stereoisomers having the *mmmm* ligand wrapping pattern (Figure 7). In the C_{2v} isomer, two of the sulfur atoms occupy A sites and two occupy B sites so as to give a highly polar all-*cis* arrangement with the four sulfur atoms clustered on one side of the coordination polyhedron; Zr—S_A = 2.689(1), Zr—S_B = 2.669(1), Zr—O_A = 2.200(2), Zr—O_B = 2.180(2) Å. The dipole moment of $[Zr(SOCNEt_2)_4]$ (3.61 ± 0.16 D) is relatively large, indicating that the C_{2v} isomer is the predominant solution species as well.[488] This isomer may be stabilized by a *trans* effect;[489] one of the two D_{2d} stereoisomers (Figure 7) would have been expected on the basis of Orgel's rule.[458,459]

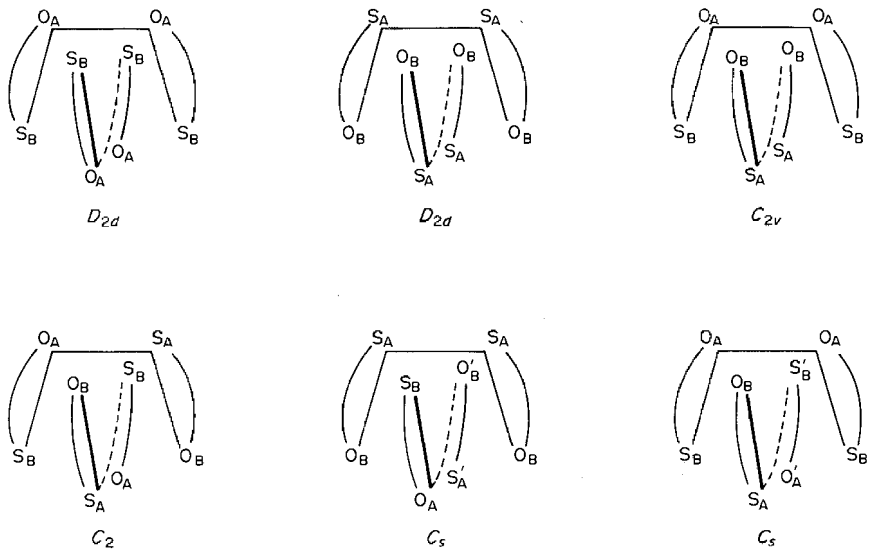


Figure 7 Schematic representation of the six possible dodecahedral stereoisomers of a $[Zr(SOCNR_2)_4]$ complex. The two mutually perpendicular trapezoids of the D_{2d} dodecahedron are outlined, and the A- and B-site occupancy of the sulfur and oxygen atoms is shown (reproduced by permission from ref. 488)

The low-temperature ^1H NMR spectrum of $[Zr(SOCNMe_2)_4]$ can be interpreted in terms of four overlapping methyl resonances, a spectrum consistent with that expected for the C_{2v} stereoisomer. Variable-temperature ^1H NMR spectra[490] exhibit evidence of two distinct kinetic processes: (i) a low-temperature process (LTP) that involves metal-centered rearrangement and (ii) a high-temperature process (HTP) that involves rotation about the C···N partial double bond in the monothiocarbamate ligand. Coalescence temperatures for the LTP and HTP are −53.5 and +78.2 °C, respectively. Activation parameters (kJ mol^{-1} or J mol^{-1} deg^{-1}) are: $\Delta G^{\ddagger}(-53.5\,°C) = 47.1 \pm 0.2$, $\Delta H^{\ddagger} = 40 \pm 1$, and $\Delta S^{\ddagger} = -34 \pm 5$ for the LTP; $\Delta G^{\ddagger}(78.2\,°C) = 82.7 \pm 0.5$, $\Delta H^{\ddagger} = 99 \pm 5$, and $\Delta S^{\ddagger} = 47 \pm 15$ for the HTP. The greater stereochemical rigidity of $[Zr(SOCNMe_2)_4]$ in comparison with $[Ti(SOCNMe_2)_4]$ and analogous $[M(S_2CNR_2)_4]$ (M = Ti or Zr) complexes is evidence for a polytopal rearrangement mechanism for the metal-centered process.

32.4.5.3 Dithiolenes and related ligands

The tris(dithiolene) complexes $[M(S_2C_6H_3R)_3]^{2-}$ (M = Zr, R = H; M = Zr or Hf, R = Me) have been synthesized in THF solution by reaction of the metal diethylamide with a mixture of benzene-1,2-dithiol (or toluene-3,4-dithiol) and its sodium salt (equation 48). The complexes were isolated as moisture-sensitive, red or orange $[NEt_4]_2[M(S_2C_6H_3R)_3]$ salts following addition of $(NEt_4)Br$ to the THF solution of the sodium salt. The $[NEt_4]_2[M(S_2C_6H_3R)_3]$ complexes exhibit a strong ν(M—S) IR band at 311–321 cm^{-1}, and they show an intense ligand $(\pi_v) \rightarrow$ metal $(d_{x^2-y^2}, d_{xy})$ charge-transfer transition in electronic spectra at 20 000–27 800 cm^{-1}.

^1H and ^{13}C NMR spectra of $[NEt_4]_2[Zr(S_2C_6H_3Me)_3]$ gave only a single, sharp (time-averaged?) methyl resonance. Polarographic reduction of $[Zr(S_2C_6H_3Me)_3]^{2-}$ in MeCN was highly irreversible.[491]

$$[M(NEt_2)_4] + 2NaHS_2C_6H_3R + (HS)_2C_6H_3R \longrightarrow Na_2[M(S_2C_6H_3R)_3] + 4HNEt_2 \quad (48)$$

The $[Zr(S_2C_6H_4)_3]^{2-}$ anion in $[NMe_4]_2[Zr(S_2C_6H_4)_3]$ has a structure (Figure 8) that is intermediate between octahedral and trigonal prismatic; the trigonal twist angle is 37°. Averaged distances are Zr—S = 2.543, S···S (intraligand) = 3.265, S···S (interligand) = 3.584 Å. The averaged S—C bond length (1.765 Å) is close to that expected for an S—C single bond, indicating that $[Zr(S_2C_6H_4)_3]^{2-}$ is best formulated as a dithiolatozirconium(IV) complex. It is interesting to note that the isoelectronic complexes $[Nb(S_2C_6H_4)_3]^-$ and $[Mo(S_2C_6H_4)_3]$ are trigonal prismatic. The change in geometry as the metal *d*-orbital energies decrease in the series $Zr^{IV} > Nb^{V} > Mo^{VI}$ has been rationalized in terms of increasing ligand $(\pi_v) \rightarrow$ metal $(d_{x^2-y^2}, d_{xy})\pi$ bonding.[492]

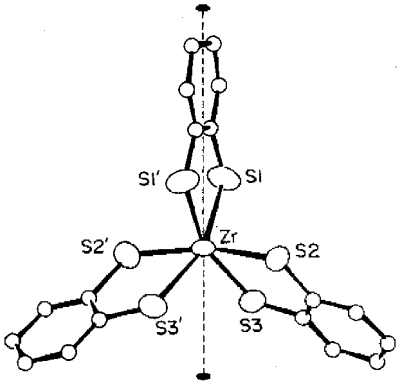

Figure 8 A perspective view of the $[Zr(S_2C_6H_4)_3]^{2-}$ anion. The complex is located on a crystallographic twofold axis

Tris(*o*-mercaptophenolato) complexes, $[NEt_4]_2[M(SOC_6H_4)_3]$ (M = Zr or Hf),[280] have been prepared by a method similar to that used for the analogous dithiolates. A compound of composition $Zr(SOC_6H_4)(HSOC_6H_4)_2$ has been obtained from the reaction of $ZrCl_4$ with three equivalents of *o*-mercaptophenol.[493]

32.4.5.4 Other sulfur donor ligands

Reaction of $Na\{S_2P(OEt)_2\}$ with $ZrCl_4$ in toluene affords the tetrakis(diethyldithiophosphate) $[Zr\{S_2P(OEt)_2\}_4]$.[494] An X-ray study[495] has established that the corresponding diisopropyl derivative $[Zr\{S_2P(OCHMe_2)_2\}_4]$ has an eight-coordinate D_{2d}-*mmmm* dodecahedral structure, with Zr—S_A = 2.746(3) and Zr—S_B = 2.653(3) Å. This structure is somewhat surprising[461] in view of the rather large S···S bite (3.178(5) Å) of the dithiophosphate ligand; the normalized bite is 1.177 Å.

Zirconium and hafnium tetrachlorides form 1:1 and 1:2 adducts with thiourea. IR spectra indicate that the 1:1 adducts contain terminal and bridging chlorine atoms and S-bonded thiourea ligands. A chlorine-bridged dimeric structure $[\{H_2N)_2CS\}Cl_3MCl_2MCl_3\{SC(NH_2)_2\}]$ has been proposed.[496] The IR spectra and calorimetric measurements suggest that only one thiourea ligand is coordinated to the metal in the 1:2 adducts; the second ligand appears to be attached to the complex *via* hydrogen bonds.[496,497]

The reaction of $ZrCl_4$ with triphenylphosphine sulfide in benzene at reflux affords a 1:1 adduct, which has been assigned a μ_2-chlorine-bridged structure on the basis of molecular weight, conductance and IR data.[498] An insoluble red-brown thiophene adduct of composition $ZrCl_4(C_4H_4S)_2$ has been obtained by prolonged shaking of a 4:1 mixture of thiophene and $ZrCl_4$ in benzene.[292]

32.4.6 Selenium Ligands

The reaction of $ZrCl_4$ with $Al(SePh)_3$ in ether–benzene yields the phenylselenolate $Zr(SePh)_4$ as a turquoise, microcrystalline product.[499]

32.4.7 Halogens as Ligands

32.4.7.1 Tetrahalides

Zirconium(IV) and hafnium(IV) halides are high-melting crystalline solids, which do not contain discrete complexes. α-ZrF_4[500] and β-ZrF_4[501] have extended three-dimensional structures in whch ZrF_8 dodecahedra (α form) or square antiprisms (β form) are linked together by sharing fluorine atoms. Crystalline $ZrCl_4$ consists of infinite zigzag chains of $ZrCl_6$ octahedra which share non-opposite edges; $ZrBr_4$, $HfCl_4$ and $HfBr_4$ are isostructural with $ZrCl_4$.[502] In zirconium(IV) iodide, ZrI_6 octahedra share non-opposite edges so as to give a helical chain structure with an identity period of six octahedra.[503] Hafnium(IV) iodide has yet another type of chain structure in which sharing of non-opposite edges of HfI_6 octahedra results in folded chains with an identity period of four octahedra.[504] Much useful information on the preparation and properties of zirconium(IV) and hafnium(IV) halides may be found in previous reviews[5,6] and in the monograph by Canterford and Colton.[505]

In the gas phase, the tetrahalides exist as monomeric regular tetrahedral molecules. This has been established by electron diffraction and vibrational spectroscopy. Bond lengths and vibrational frequencies are listed in Table 16. Force constants for M—X bond stretching are slightly larger for the hafnium tetrahalides than for the zirconium analogues; the force constants decrease appreciably as X varies in the order Cl > Br > I.[506]

Table 16 Bond Lengths (Å) and Vibrational Frequencies[a] (cm^{-1}) in Gaseous Zirconium(IV) and Hafnium(IV) Halides

Compound	*Bond length*	ν_1 (a_1)	ν_2 (e)	ν_3 (t_2)	ν_4 (t_2)	*Ref.*
ZrF_4	1.902(4)	633 (ED)[b]	185 (ED)	668 (IR)	187 (ED)	1–3
HfF_4	1.909(5)	659 (ED)	187 (ED)	645 (IR)	179 (ED)	1–3
$ZrCl_4$	2.32(1)	377	98	418	113	3–8
	2.32(2)	380.5		423 (IR)		
				421 (IR)		
$HfCl_4$	2.316(5)	382	101.2	390	112	3, 5, 6, 9
	2.33(2)			393 (IR)		
$ZrBr_4$	2.465(4)	225.5	60	315	72	6, 10
$HfBr_4$	2.450(4)	235.5	63	273	71	6, 10
ZrI_4	2.660(10)	158	43	254	55	6, 10
HfI_4	2.662(8)	158	55	224	63	6, 10

[a] Raman frequencies, unless indicated otherwise. [b] Calculated from electron diffraction data and the ν_3 (t_2) IR frequency.

Metal tetrahalide adducts with Lewis bases (*cf.* Tables 3, 4, 13, 15 and 23) are discussed in other sections. The tetrafluorides form stable hydrates $MF_4(H_2O)_n$ (n = 1 or 3), in contrast to the other tetrahalides which react with water to give oxyhalides. It is interesting to note that $ZrF_4(H_2O)_3$ and $HfF_4(H_2O)_3$ have rather different structures. The zirconium compound[507,508] consists of discrete, centrosymmetric $[Zr_2F_8(H_2O)_6]$ complexes in which two dodecahedral $ZrF_5(H_2O)_3$ units are joined by sharing an F···F *m* edge. The three water molecules (Zr—O = 2.263–2.323 Å) and a bridging fluorine atom (Zr–F = 2.214 Å) occupy the dodecahedral A sites, while the other bridging fluorine atom (Zr—F = 2.118 Å) and the three terminal fluorines (Zr—F = 1.996–2.032 Å) take the B sites. Occupation of the B sites by the better π-donor ligand is in accord with Orgel's rule.[458,459] In the hafnium compound,[509] $HfF_6(H_2O)_2$ units share two F···F polyhedral edges giving a chain structure with repeating unit $HfF_4(H_2O)_2$; the uncoordinated water molecule is held between the chains by hydrogen bonds. The monohydrate $ZrF_4(H_2O)$ has a three-dimensional network structure[510] in which $ZrF_6(H_2O)_2$ dodecahedra share six corners (four fluorine atoms and two water molecules) with six adjacent dodecahedra.

32.4.7.2 Fluorometallates

Zirconium and hafnium form a vast array of complex fluorides, $M'_xM_yF_z$, where *M* is Zr or Hf, and M′ is an alkali, alkaline earth, divalent transition metal, or lanthanide cation, or the conjugate acid of a nitrogen base. The number of fluorine atoms per Zr (Hf) atom is commonly eight, seven, six or five, but non-integral ratios are also found, as in $Na_3Zr_2F_{11}$, $Na_5Zr_2F_{13}$, $Li_3Zr_4F_{19}$, $Rb_5Zr_4F_{21}$ and $Na_7Zr_6F_{31}$. The variety of alkali fluorometallates is illustrated in Table 17.

Table 18 summarizes structural data for fluorozirconates whose structures have been determined by diffraction methods. In some cases, the analogous fluorohafnates are known to be isomorphous with the fluorozirconates. The compounds are grouped according to the coordination number of the Zr atom (six, seven or eight); individual structures are discussed in the following sections. In general, there is no simple relation between structure and stoichiometry. Fluorine bridging between Zr atoms is common, resulting in oligonuclear, chain, layer and extended three-dimensional structures in which the coordination number of the metal exceeds that expected on the basis of the simplest formula. A variety of coordination polyhedra have been found in fluorozirconate structures; the more common ones are the octahedron for coordination number six, the pentagonal bipyramid and C_{2v} monocapped trigonal prism for

coordination number seven, and the D_{2d} dodecahedron, D_{4d} square antiprism, and C_{2v} bicapped trigonal prism for coordination number eight. Averaged Zr—F bond lengths (Table 18) are in the ranges 1.98–2.04, 2.04–2.08 and 2.10–2.13 Å for coordination numbers six, seven and eight, respectively. In compounds that contain Zr—F—Zr bridges, the averaged Zr—F (bridging) bond length is as much as 0.1 Å larger than these values, and the averaged Zr—F (terminal) bond length is correspondingly smaller. The following discrete anions have been characterized structurally: $[ZrF_6]^{2-}$, $[ZrF_7]^{3-}$, $[ZrF_8]^{4-}$, $[Zr_2F_{12}]^{4-}$, $[Zr_2F_{10}(H_2O)_2]^{2-}$, $[Zr_2F_{13}]^{5-}$, $[Zr_2F_{14}]^{6-}$ and $[Zr_4F_{24}]^{8-}$.

Table 18 Structural Data for Complex Fluorozirconates

Compound	*Structural description*[a]	*Average Zr—F bond length* (Å)	*Ref.*
Coordination number 6			
$Li_2[ZrF_6]$	Isolated $[ZrF_6]^{2-}$ octahedra	2.016	1
$Rb_2[ZrF_6]$	Isolated $[ZrF_6]^{2-}$ octahedra	2.04	2
$Cs_2[ZrF_6]$	Isolated $[ZrF_6]^{2-}$ octahedra	2.04	2
$[Cu(H_2O)_4][ZrF_6]$	$[ZrF_6]^{2-}$ octahedra	1.996	3
$FeZrF_6$	Three-dimensional network; ZrF_6 and FeF_6 octahedra share corners	1.991 (cubic) 1.995 (trigonal)	4
$CuZrF_6$	Three-dimensional network; ZrF_6 and CuF_6 octahedra share corners	1.995 (cubic)	5
$SmZrF_7$	Three-dimensional network; ZrF_6 octahedra and SmF_8 polyhedra share corners	2.006	6
Coordination number 7			
$[NH_4]_3[ZrF_7]$	Isolated $[ZrF_7]^{3-}$ PBP; dynamically disordered	2.02	7, 8
$[H_3NC_2H_4NH_3]_3[ZrF_7]_2{\cdot}2H_2O$	Isolated $[ZrF_7]^{3-}$ CTP	2.059	9
$[NMe_4]_2[Zr_2F_{10}(H_2O)_2]$	Centrosymmetric dimer; two $ZrF_6(H_2O)$ PBPs share an equatorial F···F edge	2.045	10
$[H_3NC_2H_4NH_3]_2[Zr_2F_{12}]$	Centrosymmetric dimer; two ZrF_7 PBPs share an equatorial edge	2.062	11
$K_2[Cu(H_2O)_6][Zr_2F_{12}]$	Centrosymmetric dimer; two ZrF_7 PBPs share an equatorial edge	2.063	12
α-$BaZrF_6$	Centrosymmetric $[Zr_2F_{12}]^{4-}$; two ZrF_7 CTPs share an edge	2.082	13
$Na_5[Zr_2F_{13}]$	C_{2h} symmetry; two ZrF_7 CTPs share the capping site	2.06	14
γ-Na_2ZrF_6	ZrF_7 irregular polyhedra share two F atoms	2.065	15
Coordination number 8			
$Li_6[BeF_4][ZrF_8]$	Isolated $[ZrF_8]^{4-}$ DD	2.10	16
$[Cu(H_2O)_6]_2[ZrF_8]$	Isolated $[ZrF_8]^{4-}$ SAP	2.103	17
$[Cu(H_2O)_6][Cu_2(H_2O)_{10}][Zr_2F_{14}]$	Centrosymmetric dimer; two ZrF_8 SAPs share an *s* edge	2.109 2.105	18 19
K_2ZrF_6	Chain structure; ZrF_8 DDs share *m* edges	2.114	20
$MnZrF_6{\cdot}5H_2O$	Chain structure; ZrF_8 DDs share *a* edges	2.12	21, 22
β-$BaZrF_6$	Chain structure; ZrF_8 DDs share *a* edges	2.126	23
$PbZrF_6$	Isostructural with β-$BaZrF_6$	2.10	24
$(N_2H_6)ZrF_6$	Zigzag chain structure; ZrF_8 BTPs share t_1 edges	2.12	25
$TlZrF_5$	Layers of $(ZrF_5^-)_n$; ZrF_8 BTPs share edges and corners	2.112	26
$Mn_2ZrF_8{\cdot}6H_2O$	Layer structure; ZrF_8 SAPs and $MnF_4(H_2O)_3$ PBPs share F···F edges	2.11	27
$Cd_2ZrF_8{\cdot}6H_2O$	Isostructural with $Mn_2ZrF_8{\cdot}6H_2O$	2.114	28
$Na_7Zr_6F_{31}$	Three-dimensional network; ZrF_8 SAPs share corners and edges	2.113	29
Coordination numbers 6, 7 and 8			
$Rb_5Zr_4F_{21}$	Cross-linked structure containing:		30
	ZrF_6 octahedra	1.98	
	ZrF_7 polyhedra (CO/PBP)	2.06	
	ZrF_7 polyhedra (CO/PBP)	2.08	
	ZrF_8 irregular antiprisms	2.13	

[a] PBP = pentagonal bipyramid; CTP = C_{2v} monocapped trigonal prism; CO = monocapped octahedron; DD = dodecahedron; SAP = square antiprism; BTP = bicapped trigonal prism.

(*i*) *Alkali metal salts*

Alkali fluorometallates may be obtained by crystallization of MF_4—M′F melts (M = Zr or Hf; M′ = alkali metal), or by reaction of a suitable Zr^{IV} or Hf^{IV} compound with an alkali fluoride in hydrofluoric acid, water, acetic acid or methanol. References to the preparation of specific compounds are given in Table 17.

Phase equilibria in MF_4–M′F systems are rather complex, and polymorphism is common. For example, the following compounds have been identified in the ZrF_4–NaF system: $NaZrF_5$, $Na_3Zr_2F_{11}$, $Na_3Zr_4F_{19}$, $Na_7Zr_6F_{31}$, two polymorphic forms of Na_3ZrF_7 and $Na_5Zr_2F_{13}$, and at least three polymorphs of Na_2ZrF_6.[511,512]

From aqueous MF_4–M′F systems, the usual products are M'_3MF_7, M'_2MF_6 or $M'MF_5{\cdot}H_2O$ depending on the stoichiometry of the reaction mixture. The hexa- and penta-fluorometallates can be recrystallized from water, but crystallization of the heptafluorometallates requires the presence of excess alkali fluoride. For the aqueous MF_4–CsF system, the highest fluorometallate obtained, even in the presence of excess CsF, is Cs_2MF_6.[513,514] Synthesis of the cesium heptafluorometallates Cs_3MF_7 is accomplished by crystallization of a 1:3 MF_4—CsF melt. The pentafluorozirconate that crystallizes from aqueous ZrF_4—NH_4F—HF solutions depends on temperature and the concentration of HF; at 20 °C and HF concentrations less than 5 wt%, $(NH_4)ZrF_5{\cdot}H_2O$ is obtained, while at higher HF concentrations or at elevated temperatures, anhydrous $(NH_4)ZrF_5$ is formed.[515] $(NH_4)ZrF_5$ may also be prepared by thermolysis of $(NH_4)_3ZrF_7$[516,517] and by reaction of $(NH_4)_2ZrF_6$ with XeF_2.[518] Other routes to anhydrous fluorometallates include (i) reaction of HfF_4 with M′F in anhydrous acetic acid,[519,520] (ii) reaction of $ZrBr_4$ with M′F in methanol[521,522] and (iii) reaction of ZrO_2 or HfO_2 with NH_4F at 130 °C.[517,523]

The thermodynamic properties of ammonium fluorozirconates have been determined[515,516] from heat of solution measurements; values of ΔH_f° (kJ mol^{-1}) at 298 K are -3386 ± 3 for $(NH_4)_3ZrF_7$, -2918 ± 3 for α-$(NH_4)_2ZrF_6$, -2217 ± 3 for $(NH_4)ZrF_5$ and -2728 ± 3 for $(NH_4)ZrF_5{\cdot}H_2O$. The heat of dehydration for the pentafluorozirconate (equation 49) is 54 ± 2 kJ mol^{-1}, and the equilibrium water vapor pressure associated with this reaction is 16.1 mmHg at 20 °C. These values indicate very weak bonding of the water. Thermal decomposition of ammonium fluorozirconates[524] occurs in a stepwise manner, with the decomposition temperatures depending on pressure; the steps in equation (50) have been identified at 1 atm pressure.

$$(NH_4)ZrF_5{\cdot}H_2O(s) \longrightarrow (NH_4)ZrF_5(s) + H_2O(g) \quad (49)$$

$$(NH_4)_3ZrF_7 \xrightarrow{297\,^\circ C} (NH_4)_2ZrF_6 \xrightarrow{357\,^\circ C} (NH_4)ZrF_5 \xrightarrow{410\,^\circ C} ZrF_4 \quad (50)$$

Raman spectra of aqueous solutions of $(NH_4)_3HfF_7$ and $(NH_4)_2HfF_6$[525] are identical (ν_1 589, ν_5 230 cm^{-1}), and are similar to spectra of crystalline Cs_2MF_6 (M = Zr or Hf) salts, which are known to contain $[MF_6]^{2-}$ anions. Therefore, $[HfF_7]^{3-}$ dissociates in solution into $[HfF_6]^{2-}$ and F^-. Paper chromatographic studies[526] have shown that $[ZrF_7]^{3-}$ is similarly dissociated. Raman spectra of ZrO_2 and HfO_2 in 5 M HF indicate that the $[MF_6]^{2-}$ anions are the predominant species in solution.[152]

^{19}F NMR spectra of 1 M aqueous solutions of $(NH_4)_2ZrF_6$ and $(NH_4)_2HfF_6$[525] exhibit a single, rather broad resonance (line width ~8 Hz for $[ZrF_6]^{2-}$ and ~40 Hz for $[HfF_6]^{2-}$), which broadens and shifts upfield upon addition of excess F^-. These observations have been interpreted in terms of rapid fluoride exchange, probably proceeding *via* an $[MF_7]^{3-}$ intermediate. For a solution 0.25 M in $[ZrF_6]^{2-}$ and 1.5 M in F^-, which gave a ^{19}F linewidth of 1550 Hz, the average lifetime of a fluorine nucleus in the $[ZrF_6]^{2-}$ and F^- sites was estimated to be $\sim 1.4 \times 10^{-5}$ s. The ^{91}Zr NMR spectrum of $(NH_4)_2ZrF_6$ in D_2O[527] also consists of a single, broad line (minimum linewidth 50 Hz); no Zr—F coupling is observed, in accord with rapid fluoride exchange.

Because K_2HfF_6 is ~1.7 times more soluble in water than K_2ZrF_6,[528] zirconium and hafnium can be separated by fractional crystallization of the hexafluorometallates. This approach is used on an industrial scale in the USSR.[286] Conductance measurements on aqueous solutions of M'_2MF_6 (M' = K, Rb, or Cs) indicate very little hydrolysis of the $[MF_6]^{2-}$ ions.[529] Alkaline hydrolysis of potassium and ammonium fluorozirconates yields crystalline $M'ZrF_3(OH)_2 \cdot H_2O$ complexes, which are easily dehydrated to $M'ZrF_3(OH)_2$.[530]

The coordination number of the Zr (Hf) atom in the crystalline hexafluorometallates varies from six to eight depending on the alkali cation. Li_2ZrF_6[531] and the isomorphous rubidium and cesium salts M'_2MF_6[532] contain the octahedral $[MF_6]^{2-}$ anion. The Zr atom in γ-Na_2ZrF_6 is surrounded by an irregular polyhedron of seven fluorine atoms, two of which are bridging.[533] The isomorphous K_2MF_6 salts[532] contain chain anions which are built up from MF_8 dodecahedra that share opposite *m* edges, i.e. all four bridging fluorine atoms are located on one trapezoid of the dodecahedron (Zr—F terminal = 2.038, 2.077; Zr—F bridging = 2.111, 2.231 Å).[534] Still another structure (space group *Pmma*) is adopted by the isomorphous $(NH_4)_2MF_6$ and Tl_2MF_6 salts. In these compounds, the Zr (Hf) atom may have a pentagonal bipyramidal environment; however, the locations of the fluorine atoms are not well defined by the X-ray data.[532]

The isomorphous, cubic heptafluorometallates $(NH_4)_3MF_7$ and K_3ZrF_7 contain dynamically disordered $[MF_7]^{3-}$ ions. Both capped octahedral[535] and pentagonal bipyramidal[536] models have been suggested, and the latter is supported by single-crystal X-ray and neutron diffraction studies of $(NH_4)_3ZrF_7$.[537,538] The averaged Zr—F bond length in $(NH_4)_3ZrF_7$ (2.02 Å) appears to be a bit too short in comparison with Zr—F bond lengths in other seven-coordinate structures (Table 18). The sodium salts Na_3MF_7 crystallize in the tetragonal system (space group *I*4/*mmm*) and are also dynamically disordered; the Zr (Hf) atom appears to be surrounded by a cube of F-atom sites, one of which is vacant.[539] The dynamics of F-atom motion in alkali heptafluorometallates have been studied by ^{19}F NMR spectroscopy[540,541] and by perturbed angular correlation measurements.[542,543]

The coordination environment of the Zr atom in Li_4ZrF_8 is unknown, but the $[ZrF_8]^{4-}$ anion has been found in Li_6BeZrF_{12}. This compound, which is obtained from a LiF—BeF_2—ZrF_4 melt of stoichiometric composition, contains tetrahedral $[BeF_4]^{2-}$ and dodecahedral $[ZrF_8]^{4-}$ anions ($Zr—F_A = 2.16$, $Zr—F_B = 2.05$ Å).[544] Eight-coordinate Zr atoms are also found in the pentafluorozirconate $TlZrF_5$. In this compound, ZrF_8 bicapped trigonal prisms share one edge and four corners so as to give $(ZrF_5^-)_n$ layers that are held together by Tl^+ cations.[545]

The sodium salt $Na_5Zr_2F_{13}$ contains $[Zr_2F_{13}]^{5-}$ anions of C_{2h} symmetry in which two ZrF_7 monocapped trigonal prisms share the F atom that occupies the capping site (Zr—F terminal = 2.00–2.10, Zr—F bridging = 2.10 Å).[546]

$Rb_5Zr_4F_{21}$ has a complex cross-linked chain structure that contains four crystallographically independent Zr atoms having three different coordination numbers. The structure is built up from edge- and/or corner-shared ZrF_6 octahedra, ZrF_8 irregular antiprisms and two independent ZrF_7 polyhedra.[547] Application of the dihedral angle criteria of Muetterties and Guggenberger[548] indicates that both ZrF_7 polyhedra are midway between a capped octahedron and a pentagonal bipyramid.

$Na_7Zr_6F_{31}$ contains octahedral arrays of six ZrF_8 square antiprisms which share corners in such a way as to give Zr_6F_{36} units. These units in turn share external edges with six neighboring Zr_6F_{36} units, giving an extended three-dimensional anion with formula $(Zr_6F_{30}^{6-})_n$. The 'extra'

F^- ion is located within the cuboctahedral cavity surrounded by the six ZrF_8 square antiprisms.[549]

Mixed-ligand fluorometallates that contain peroxide, sulfate, selenate, carbonate or oxalate ligands are discussed in Sections 32.4.4.2, 32.4.4.5.iii, 32.4.4.6.iii and 32.4.4.6.iv.

(*ii*) *Hydrazinium, alkylammonium and guanidinium salts*

Hydrazinium(2+) salts, $(N_2H_6)MF_6$ and $(N_2H_6)_3M_2F_{14}$ (M = Zr or Hf), have been isolated from hydrofluoric acid solutions of the metal oxides and hydrazinium(2+) fluoride.[550,551] $(N_2H_6)ZrF_6$ contains infinite zigzag chains of ZrF_8 bicapped trigonal prisms which share the two t_1 edges on the quadrilateral face.[552] The reaction of $(N_2H_6)MF_6$ with XeF_6 at room temperature yields thermally unstable compounds $nXeF_6{\cdot}MF_4$ ($n \leqslant 6$) which decompose *in vacuo* at room temperature to white, moisture-sensitive solids of composition $XeF_6{\cdot}MF_4$. Vibrational spectra suggest that these compounds contain $[XeF_5]^+$ cations and polymeric $(MF_5^-)_n$ anions.[553] A hydrazinium(1+) salt of composition $(N_2H_5)_3Zr_4F_{19}{\cdot}3H_2O$ has been prepared by reaction of ZrF_4 and hydrazinium(1+) fluoride in aqueous solution.[55]

Large, colorless, prismatic crystals of $[NMe_4]_2[Zr_2F_{10}(H_2O)_2]$ have been isolated from dilute HF solutions of $ZrF_4(H_2O)_3$ and tetramethylammonium fluoride. The $[Zr_2F_{10}(H_2O)_2]^{2-}$ anion is a centrosymmetric dimer in which two $ZrF_6(H_2O)$ pentagonal bipyramids share an equatorial F···F edge (Zr—F terminal = 1.972–1.997; Zr—F bridging = 2.143, 2.184 Å); the water molecule occupies an equatorial site (Zr—O = 2.271 Å). The following metal–ligand stretching bands are observed in the IR spectrum: ν(Zr—F terminal) 520, 480, 420; ν(Zr—F bridging) 325; ν(Zr—O) 385 cm^{-1}.[554] The hexafluorometallates $[NEt_4]_2[MF_6]{\cdot}2H_2O$ have been prepared by direct electrochemical oxidation of zirconium or hafnium anodes in PhCN solutions that contain $[NEt_4]F{\cdot}3HF$.[555]

The ethylenediammonium fluorozirconates $(H_3NC_2H_4NH_3)(ZrF_5)_2{\cdot}H_2O$, $(H_3NC_2H_4NH_3)ZrF_6$ and $(H_3NC_2H_4NH_3)_3(ZrF_7)_2{\cdot}2H_2O$ have been prepared in aqueous solution by reaction of various molar ratios of $(H_3NC_2H_4NH_3)F_2{\cdot}HF$ and $H_2ZrF_6{\cdot}2H_2O$. The presence of ν(Zr—F terminal) and ν(Zr—F bridging) in the 600–380 cm^{-1} region of IR spectra of the pentafluorozirconate indicates that this compound probably contains polymeric $(ZrF_5^-)_n$ anions.[556] Crystals of $(H_3NC_2H_4NH_3)ZrF_6$ contain centrosymmetric $[Zr_2F_{12}]^{4-}$ ions in which two pentagonal bipyramidal ZrF_7 groups share a common equatorial edge (Zr—F terminal = 1.960–2.073; Zr—F bridging = 2.146, 2.154 Å),[557] while $(H_3NC_2H_4NH_3)_3(ZrF_7)_2{\cdot}2H_2O$ contains two crystallographically independent monocapped trigonal prismatic $[ZrF_7]^{3-}$ ions.[558]

The following guanidinium and aminoguanidinium fluorozirconates have been isolated from aqueous media and have been characterized by IR spectroscopy and X-ray diffraction: $(CN_3H_6)_2ZrF_6$, $(CN_3H_6)_3ZrF_7$, $(CN_4H_7)_2ZrF_6$, $(CN_4H_8)ZrF_6{\cdot}0.5H_2O$ and $(CN_4H_8)ZrF_6{\cdot}H_2O$. The IR and X-ray studies indicate the presence of $[ZrF_6]^{2-}$ in $(CN_4H_7)_2ZrF_6$, $[Zr_2F_{12}]^{4-}$ in $(CN_3H_6)_2ZrF_6$ and $[Zr_4F_{24}]^{8-}$ ions in $(CN_4H_8)ZrF_6{\cdot}0.5H_2O$. Comparison of IR spectra of $(CN_3H_6)_3ZrF_7$ and $(CN_4H_8)ZrF_6{\cdot}H_2O$ with spectra of compounds of known structure suggests that the former compound contains $[ZrF_7]^{3-}$ ions while the latter probably contains $(ZrF_6^{2-})_n$ chain anions like those in K_2ZrF_6. Thermal decomposition of the $(CN_4H_8)ZrF_6{\cdot}nH_2O$ compounds involves loss of water at 100–120 °C and elimination of HF at 130–190 °C; the latter process yields the pentafluorozirconate $(CN_4H_7)ZrF_5$.[559]

(*iii*) *Divalent metal fluorometallates*

Several types of divalent transition metal fluorometallate hydrates have been obtained by slow, room-temperature evaporation of aqueous HF solutions of MO_2 or MF_4 (M = Zr or Hf) and the divalent metal fluoride $M''F_2$. A 1:1 molar ratio of $M''F_2$ and MO_2 gives well-formed crystals of $M''MF_6{\cdot}6H_2O$ (M'' = Fe, Co, Ni or Zn), $MnMF_6{\cdot}5H_2O$ or $CuMF_6{\cdot}4H_2O$, while a 2:1 ratio of $M''F_2$ and MF_4 in water, slightly acidified with HF, yields crystals of $M''_2MF_8{\cdot}12H_2O$ (M'' = Co, Ni, Cu or Zn). From HF solutions of CdF_2 and MO_2, crystals of $Cd_2MF_8{\cdot}6H_2O$ are obtained, regardless of the molar ratio of CdF_2 and MO_2.[560,561]

The $M''MF_6{\cdot}6H_2O$ compounds are isostructural with $FeSiF_6{\cdot}6H_2O$ (space group $R\bar{3}m$), which is known to contain octahedral $[Fe(H_2O)_6]^{2+}$ and $[SiF_6]^{2-}$ ions in a slightly distorted CsCl structure.[560,561] The structure of $CuZrF_6{\cdot}4H_2O$ consists of square planar $[Cu(H_2O)_4]^{2+}$ and octahedral $[ZrF_6]^{2-}$ ions (Zr—F = 1.982–2.007 Å), which are arranged in infinite

$\cdots[ZrF_6]^{2-}\cdots[Cu(H_2O)_4]^{2+}\cdots[ZrF_6]^{2-}\cdots$ chains. Thus the coordination polyhedron about copper is a tetragonally distorted octahedron, with two rather long (2.246 Å) *trans* Cu···F interactions.[562] The structure of $MnZrF_6{\cdot}5H_2O$ contains infinite chains of ZrF_8 dodecahedra, which are threaded on the twofold (*c*) axis of the monoclinic crystal (Figure 9). Each ZrF_8 dodecahedron shares the two *a* edges with neighboring ZrF_8 dodecahedra and shares two B vertices with two $MnF_2(H_2O)_4$ octahedra. An additional uncoordinated water molecule is present in the lattice. Averaged bond lengths are $Zr—F_A = 2.21$ and $Zr—F_B = 2.03$ Å.[563,564]

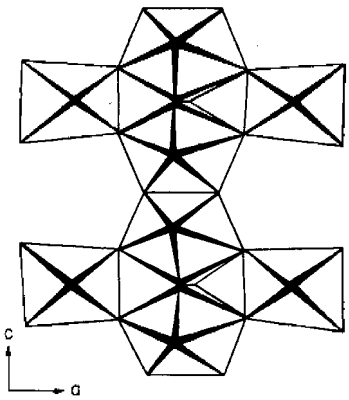

Figure 9 Projection of part of the structure of $MnZrF_6{\cdot}5H_2O$ on the *ac* plane showing ZrF_8 dodecahedra and $MnF_2(H_2O)_4$ octahedra

The isostructural octafluorozirconates $M''ZrF_8{\cdot}6H_2O$ (M″ = Mn or Cd) have a layer structure in which ZrF_8 square antiprisms and $M''F_4(H_2O)_3$ pentagonal bipyramids are linked together by sharing F···F polyhedral edges.[565,566] On the other hand, $Cu_2ZrF_8{\cdot}12H_2O$ contains isolated square antiprismatic $[ZrF_8]^{4-}$ anions and $[Cu(H_2O)_6]^{2+}$ cations.[567]

The heptafluorozirconate $Cu_3(ZrF_7)_2{\cdot}16H_2O$, isolated from 40% hydrofluoric acid, contains $[Cu(H_2O)_6]^{2+}$, $[Cu_2(H_2O)_{10}]^{4+}$, and $[Zr_2F_{14}]^{6-}$ ions, which are held together by a three-dimensional network of hydrogen bonds. The $[Zr_2F_{14}]^{6-}$ ion is a centrosymmetric dimer in which two ZrF_8 square antiprisms are joined together by sharing an *s* polyhedral edge (Zr—F terminal = 2.048–2.107; Zr—F bridging = 2.171, 2.185 Å).[568,569] The structure of $K_2Cu(ZrF_6)_2{\cdot}6H_2O$ consists of K^+, $[Cu(H_2O)_6]^{2+}$, and centrosymmetric $[Zr_2F_{12}]^{4-}$ ions. In $[Zr_2F_{12}]^{4-}$, two ZrF_7 pentagonal bipyramids share an equatorial edge (Zr—F terminal = 1.967–2.064; Zr—F bridging = 2.156, 2.161 Å).[570]

Anhydrous alkaline earth and transition metal hexafluorometallates $M''MF_6$ are generally prepared from $M''F_2$ and MF_4 by crystallization of a melt or by prolonged annealing of the metal fluorides. Most of these compounds exist in two polymorphic forms, depending on the temperature. The low temperature (α) form of $BaZrF_6$ contains centrosymmetric $[Zr_2F_{12}]^{4-}$ anions in which two ZrF_7 monocapped trigonal prisms share the F···F edge that joins the capping site to an adjacent vertex (Zr—F terminal = 1.999–2.079; Zr—F bridging = 2.155, 2.254 Å).[571] The structure of the high-temperature (β) form of $BaZrF_6$ contains infinite chains of *a*-edge-shared ZrF_8 dodecahedra, similar to the chains in $MnZrF_6{\cdot}5H_2O$ (Figure 9); bond lengths in β-$BaZrF_6$ are $Zr—F_A = 2.242$ and $Zr—F_B = 2.010$ Å.[572] α-$SrZrF_6$, α-$EuZrF_6$, and $PbZrF_6$ are isostructural with β-$BaZrF_6$; a single-crystal study of the lead compound gave $Zr—F_A = 2.19$ and $Zr—F_B = 2.00$ Å.[573] In studies of phase equilibria for the SrF_2–MF_4 (M = Zr or Hf) systems, the compounds α- and β-Sr_2MF_8 and Sr_3MF_{10} have been identified in addition to α- and β-$SrMF_6$.[574]

$M''MF_6$ (M″ = Mn, Fe, Co, Ni or Cu) exist in several crystalline forms, the most common being a high-temperature, cubic ordered ReO_3 structure and a low-temperature, trigonal $LiSbF_6$ structure. Both modifications consist of octahedra which share corners in three dimensions and which are centered alternately by M″ or M.[575–577] The isostructural lanthanide fluorometallates $LnMF_7$[578] also have an extended three-dimensional structure; an X-ray study of $SmZrF_7$[579] has shown that the structure is built on corner sharing of ZrF_6 octahedra and irregular SmF_8 polyhedra.

(iv) *Vibrational spectra of fluorometallates*

The vibrational spectra of alkali fluorometallates have been examined in considerable detail. In the hexafluorometallates Li_2ZrF_6 and M'_2MF_6 (M' = Rb or Cs; M = Zr or Hf) the octahedral $[MF_6]^{2-}$ anion occupies a site of D_{3d} symmetry,[531,532] and consequently the triply degenerate normal modes [$\nu_3(t_{1u})$, $\nu_4(t_{1u})$, $\nu_5(t_{2g})$ and $\nu_6(t_{2u})$ in O_h] are split into *a* and *e* components. Vibrational frequencies (Table 19) have been assigned on the basis of polarized Raman[580,581] and polarized IR reflectance[581] spectra of single crystals, and assignments have been confirmed by normal coordinate analyses.

Table 19 Vibrational Frequencies for Solid Alkali Hexafluorometallates

Compound	ν_1 a_{1g}	ν_2 e_g	ν_3 e_u	ν_3 a_{2u}	ν_4 e_u	ν_4 a_{2u}	ν_5 a_{1g}	ν_5 e_g	ν_6 e_u	Ref.
Li_2ZrF_6	585	580 (?)	560	498	246	187	303	251		1
Rb_2ZrF_6	589		537	522	240	192	258	244		2
Cs_2ZrF_6	579	585 (?)	535	502	229	190	245	233	142 (?)	1
Cs_2HfF_6	572		498	490	217	187	257	247		2

2. I. W. Forrest and A. P. Lane, *Inorg. Chem.*, 1976, **15**, 265.

Far IR spectra of solid K_2MF_6, $(NH_4)_3ZrF_7$, $(NH_4)_2ZrF_6$, $(NH_4)ZrF_5$ and $(NH_4)ZrF_5{\cdot}H_2O$ exhibit broad band systems in the region 550–150 cm^{-1}. These spectra are more complex and less well defined than spectra of $[MF_6]^{2-}$. The broad bands have been attributed to metal–fluorine vibrations of complex anions of low site symmetry.[582,583] The close similarity between the spectra of $(NH_4)ZrF_5$ and $(NH_4)ZrF_5{\cdot}H_2O$ in the Zr—F stretching region strongly suggests that the water molecule is not attached to the Zr atom.[583]

Attempts have been made to correlate the frequency of the Raman-active symmetric stretching mode of crystalline fluorozirconates of known structure with the coordination number of the Zr atom.[584,585] The data in Table 20 show that, for the alkali metal salts, ν_s(Zr—F) decreases with increasing coordination number, although the interpretation of this trend is complicated by fluorine-bridging in the seven- and eight-coordinate compounds. No correlation exists when all of the data are considered; values of ν_s(Zr—F) for the isostructural eight-coordinate β-$BaZrF_6$, $PbZrF_6$ and α-$SrZrF_6$ vary considerably among themselves and are more similar to ν_s(Zr—F) frequencies for the six- and seven coordinate fluorozirconates of alkali metals. Raman spectra of LiF—NaF—ZrF_4 melts have been examined, and composition-dependent systematic variations in Raman frequencies have been interpreted in terms of an equilibrium distribution of $[ZrF_8]^{4-}$, $[ZrF_7]^{3-}$, $[ZrF_6]^{2-}$ and possibly species in which the Zr atom has a coordination number less than six.[584]

Table 20 Coordination Numbers of the Zirconium Atom and ν_s(Zr—F) Raman Frequencies for Crystalline Fluorozirconates

Coordination number	Compound	ν_s (Zr—F) (cm^{-1})	Ref.
6	Li_2ZrF_6	585	1
	Rb_2ZrF_6	589	2

3. Y. Kawamoto and F. Sakaguchi, *Bull. Chem. Soc. Jpn.*, 1983, **56**, 2138.

An IR spectral criterion for identification of dinuclear anions having pentagonal bipyramidal coordination about zirconium has been proposed by Davidovich *et al.*[554] These workers have noted that the $[Zr_2F_{12}]^{4-}$ anion in $[H_3NC_2H_4NH_3]_2[Zr_2F_{12}]$ and $[CN_3H_6]_4[Zr_2F_{12}]$ and the $[Zr_2F_{10}(H_2O)_2]^{2-}$ anion in $[NMe_4]_2[Zr_2F_{10}(H_2O)_2]$ exhibit an intense ν(Zr—F bridging) band in the 300–400 cm^{-1} region and a characteristic triplet of ν(Zr—F terminal) bands in the 400–600 cm^{-1} region; the central band of this triplet, located at 470–490 cm^{-1}, is more intense than the other two.

32.4.7.3 Chlorometallates, bromometallates and iodometallates

In contrast to the great variety of fluorometallates, nearly all of the known chloro-, bromo- and iodo-metallates are salts that contain the simple, octahedral $[MX_6]^{2-}$ anion. The best characterized alkali metal salts are listed in Table 21. The hexachloro complexes M'_2MCl_6 may be prepared (i) by fusing a stoichiometric mixture of M'Cl and MCl_4 at elevated temperatures,[586,587] (ii) by heating M'Cl in the presence of MCl_4 vapor at ~1 atm pressure[588,589] or (iii) by reaction of stoichiometric amounts of M'Cl and MCl_4 or $MOCl_2{\cdot}8H_2O$ in concentrated hydrochloric acid saturated with hydrogen chloride gas.[41,590,591] The recently reported M'_2MX_6 (X = Br or I) complexes were obtained by fusing or sintering a stoichiometric mixture of M'X and MX_4. Analogous ammonium salts $(NH_4)_2MCl_6$ have been isolated from hydrochloric acid solutions of NH_4Cl and $MOCl_2{\cdot}8H_2O$.[590,591]

The M'_2MX_6 compounds are moisture-sensitive, high-melting, white (X = Cl or Br) or yellow (X = I) crystalline solids that decompose at elevated temperatures to solid M'X and gaseous MX_4. The thermal stability of the M'_2MCl_6 compounds, as measured by the decomposition temperature T_{dec} (Table 21), increases with increasing size of the alkali cation. Values of ΔH_c, the enthalpy of the complexing reaction in equation (51), indicate that $[HfCl_6]^{2-}$ is slightly more stable than $[ZrCl_6]^{2-}$, but $[HfBr_6]^{2-}$ is appreciably more stable than $[ZrBr_6]^{2-}$, thus illustrating the enhanced class b character of Hf^{IV}. The thermodynamic data in Table 21 and data for related Nb^{IV} and Sn^{IV} complexes suggest that halogen $p\pi \rightarrow$ metal $d\pi$ bonding is important in $[ZrX_6]^{2-}$ and $[HfX_6]^{2-}$ complexes.[587,592]

$$2M'X(s) + MX_4(s) \longrightarrow M'_2MX_6(s) \quad (51)$$

X-Ray powder patterns indicate that M'_2MCl_6 (M' = K, Rb, Cs, or NH_4),[591] M'_2MBr_6 (M' = K or Cs),[592] and Cs_2MI_6[593] have the cubic K_2PtCl_6 structure (space group $Fm3m$), which contains regular octahedral anions. The powder data afford Zr—Cl bond lengths of 2.44(10) Å for Rb_2ZrCl_6 and 2.45(10) Å for Cs_2ZrCl_6.[594] An averaged Hf—Cl bond length of 2.446 Å in the octahedral $[HfCl_6]^{2-}$ ion has been obtained from a single-crystal study of $Bi^+[Bi_9^{5+}][HfCl_6^{2-}]_3$.[595] The Hf—I distance in Cs_2HfI_6 is 2.829(2) Å.[593] Interestingly, the Na_2MCl_6 complexes are not cubic; X-ray powder data for Na_2HfCl_6 have been indexed assuming a tetragonal cell with $a = 15.99$ and $c = 13.21$ Å.[596]

Quite a number of hexachlorozirconates and some hexachlorohafnates, hexabromozirconates and hexabromohafnates of nitrogen bases have been reported. These compounds are of the type A_2MX_6 (A = R_4N, R_3NH, R_2NH_2, RNH_3 or C_5H_5NH; R = alkyl or aryl). They may be prepared by (i) reaction of MX_4 with a substituted ammonium halide in thionyl chloride,[597–599] acetyl chloride,[600] benzoyl chloride[601,602] or acetonitrile;[603] (ii) reaction of $[MX_4(EtCN)_2]$ with the ammonium halide in chloroform;[604] or (iii) reaction of MX_4 with an amine in ethanol saturated with hydrogen chloride gas.[44,46,605] $[NEt_4]_2[MBr_6]$ complexes have been obtained by electrochemical oxidation of zirconium or hafnium metal in the presence of bromine and $[NEt_4]Br$ in benzene; however, analogous oxidation in the presence of chlorine and $[NPr_4]Cl$ in thionyl chloride gave the pentachlorometallates $[NPr_4][MCl_5]$.[118] $[C_5H_5NH]_2[ZrCl_6]$ reacts with NaOEt in ethanol at reflux yielding the substitution product $[C_5H_5NH]_2[ZrCl_5(OEt)]$.[605] Aminolysis reactions of alkylammonium hexachlorozirconates were mentioned in Section 32.4.2.1.

Vibrational spectra of $Cs_2(MCl_6)$,[599] $[NEt_4]_2[MX_6]$,[599,606] and $[Et_2NH_2]_2[MX_6]$[603] (X = Cl or Br) have been reported. Raman (ν_1, ν_2 and ν_5) and IR (ν_3 and ν_4) bands have been assigned and force constants determined. Frequencies for the NEt_4^+ salts, taken from the most complete study to date,[599] are listed in Table 22. Far IR spectra of M'_2ZrI_6 (M' = Li, Na, K, Rb or Cs) display a strong band in the region 195–175 cm^{-1}; the analogous M'_2HfI_6 complexes exhibit a similar band at 165–145 cm^{-1}.[607] Electronic spectra of $[Et_2NH_2]_2[ZrX_6]$ (X = Cl or Br) have been recorded, and UV bands have been assigned to halogen $p\pi \rightarrow$ metal d charge-transfer transitions.[604]

Table 22 Vibrational Spectral Data for Solid $[NEt_4]_2[MX_6]$ (X = Cl or Br) Complexes[1]

Compound	ν_1 (a_{1g})	ν_2 (e_g)	ν_3 (t_{1g})	ν_4 (t_{1u})	ν_5 (t_{1g})
$[NEt_4]_2[ZrCl_6]$	321s	250w, sh	293s	152s	151s
$[NEt_4]_2[HfCl_6]$	326s	257w, sh	275s	145s	156s
$[NEt_4]_2[ZrBr_6]$	194s	144w, sh	223s	106m	99s
$[NEt_4]_2[HfBr_6]$	197s	142w, sh	189s	102m	101s

1. W. van Bronswyk, R. J. H. Clark and L. Maresca, *Inorg. Chem.*, 1969, **8**, 1395.

Other hexachlorometallates that have been characterized by vibrational spectroscopy include $[SbPh_4]_2[ZrCl_6]$,[608] $[NO]_2[MCl_6]$ (M = Zr or Hf),[609] and $[SCl_3]_2[ZrCl_6]$.[610] The $[NO]_2[MCl_6]$ complexes were prepared by treating a concentrated solution of the metal tetrachloride in thionyl chloride at 0 °C with NOCl gas; their IR and Raman spectra exhibit the bands expected for $[MCl_6]^{2-}$ and show a strong $\nu(NO^+)$ band at 2191–2199 cm^{-1}. $[SCl_3]_2[ZrCl_6]$ was obtained by reaction of sulfur, chlorine and $ZrCl_4$ in a sealed tube; Raman frequencies of $[ZrCl_6]^{2-}$ in this compound were identified at 324 (ν_1), 258 (ν_2) and 154 cm^{-1} (ν_5).

Raman spectra of $ZrCl_4$–PCl_5 mixtures reveal the presence of at least one chlorozirconate species in addition to $[ZrCl_6]^{2-}$. The new Raman frequencies have been attributed to trigonal bipyramidal $[ZrCl_5]^-$, which is formed as a result of the equilibrium in equation (52).[611] IR evidence for the presence of solvated $[ZrCl_5]^-$ in acetonitrile solutions of $ZrCl_4$ and $[NEt_4]Cl$ has been presented by Olver and Bessette,[27] and $[NEt_4][ZrCl_5(MeCN)]$ has been isolated from acetonitrile by Feltz.[612] This compound loses acetonitrile *in vacuo* at 90 °C yielding $[NEt_4][ZrCl_5]$.

$$[ZrCl_6]^{2-} + [PCl_4]^+ \rightleftharpoons [ZrCl_5]^- + PCl_5 \quad (52)$$

The reaction of $ZrCl_4$ with *t*-butyl chloride and phosphorus(III) chloride in carbon disulfide gives $[Me_3CPCl_3][Zr_2Cl_9]$ as a moisture-sensitive, insoluble solid. IR and Raman spectra of the anion are consistent with a D_{3h} structure in which two $ZrCl_6$ octahedra share a common face; ν(Zr—Cl terminal) 350–387, ν(Zr—Cl bridging) 240–315 cm^{-1}.[613]

32.4.8 Hydroborates and Hydrides as Ligands

Zirconium(IV) and hafnium(IV) tetrakis(tetrahydroborates) $M(BH_4)_4$ are of interest as extremely volatile, covalent complexes that contain tridentate BH_4^- ligands and exhibit rapid intramolecular exchange of bridging and terminal hydrogen atoms.[614,615] These compounds were prepared initially from $NaMF_5$ (M = Zr or Hf) and excess $Al(BH_4)_3$ (equation 53),[616] but they are obtained more conveniently from the reaction of the anhydrous metal tetrachloride with excess lithium tetrahydroborate (equation 54), either in the solid state[617,618] or in the presence of a small amount of diethyl ether.[619]

$$NaMF_5 + 2Al(BH_4)_3 \longrightarrow M(BH_4)_4 + 2AlF_2(BH_4) + NaF \quad (53)$$

$$MCl_4 + 4LiBH_4 \longrightarrow M(BH_4)_4 + 4LiCl \quad (54)$$

$Zr(BH_4)_4$ and $Hf(BH_4)_4$ have very similar properties. Both are low-melting (m.p. 29 °C), colorless crystalline solids that exhibit a vapor pressure of 15 mmHg at 25 °C. They are highly reactive, spontaneously inflaming in dry air, detonating on contact with water, and slowly decomposing with liberation of hydrogen gas on standing at 25 °C. The solid complexes are very soluble in nonpolar solvents.

The chemical reactions of $M(BH_4)_4$ complexes have received very little attention. Both compounds behave as Lewis acids in reactions with tetraalkylammonium and lithium tetrahydroborates, yielding $[(C_8H_{17})_3NPr][M(BH_4)_5]$, $[NBu_4][M(BH_4)_5]$ and $LiM(BH_4)_5$.[620] $Zr(BH_4)_4$ reacts with $LiAlH_4$ in ether to give $Zr(AlH_4)_4$, an unstable white solid, which decomposes within several hours at room temperature to a pyrophoric black solid.[617]

Tridentate coordination of the BH_4^- ligand in $M(BH_4)_4$ complexes was first established by a low-temperature (−160 °C) single-crystal X-ray study of $Zr(BH_4)_4$.[621] A very recent single-crystal neutron diffraction study (at −163 °C) of the isostructural $Hf(BH_4)_4$ analogue[622] has afforded accurate positions for the bridging hydrogen atoms. The regular tetrahedral $Hf(BH_4)_4$ molecule (Figure 10) occupies a site of crystallographic $\bar{4}3m$ (T_d) symmetry, and the BH_4^- ligands adopt the conformation in which the Hf—H bonds to one BH_4^- ligand are staggered with respect to the Hf—B bonds to the other three BH_4^- ligands. Bond lengths are Hf—B = 2.281(8), Hf—H_b = 2.130(9), B—H_b = 1.235(10) and B—H_t = 1.150(19) Å, where H_b and H_t denote the bridging and terminal hydrogen atoms, respectively. An electron diffraction study[623] has afforded the following bond lengths for the gaseous $Zr(BH_4)_4$ molecule: Zr—B = 2.308 ± 0.010, Zr—H_b = 2.21 ± 0.04, B—H_b = 1.27 ± 0.05 and B—H_t = 1.18 ± 0.12 Å. The electron diffraction data suggest that the gaseous molecule may have only *T* symmetry, with the tridentate BH_4^- ligands being rotated out of the exactly staggered conformation (Figure 10) by an averaged torsion angle of 22°.

IR and Raman spectra of $Zr(BH_4)_4$ and $Hf(BH_4)_4$ have been assigned in terms of both T_d and *T* models,[624–627] and assignments have been supported by deuterium isotopic substitution studies[625–627] and normal coordinate analyses.[626–629] The vibrational spectra have not provided unequivocal evidence for a choice between these two closely related point groups. However, the spectra strongly support a tridentate attachment of the BH_4^- ligands.[615,630] Characteristic IR and Raman bands for $Zr(BH_4)_4$ and $Hf(BH_4)_4$ occur in the following frequency regions:

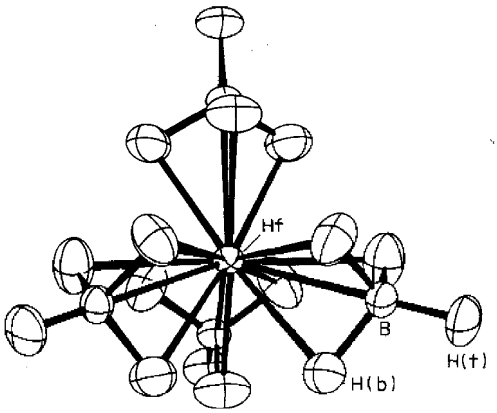

Figure 10 The structure of $Hf(BH_4)_4$ (reproduced by permission from ref. 622)

ν(B—H_t) 2560–2580, ν(B—H_b) 2100–2200, bridge deformation 1200–1300 and ν(M—BH_4) 480–560 cm^{-1}. The Raman studies[626] and normal coordinate analyses[626,627] suggest that direct metal–boron bonding interactions may be important.

He(I) and He(II) photoelectron spectra of $M(BH_4)_4$ (M = Zr or Hf) have been reported. Assignments were made on the basis of qualitative molecular-orbital models[631,632] and an LCAO–HFS(Xα) calculation on $Zr(BH_4)_4$.[632]

^1H and ^{11}B NMR spectra of $M(BH_4)_4$ (M = Zr or Hf)[618,633–636] and ^{91}Zr NMR spectra of $Zr(BH_4)_4$[636] at 25 °C indicate the equivalence of all of the hydrogen atoms owing to rapid intramolecular exchange between the bridging and terminal positions. ^1H and ^{11}B spectra of the zirconium and hafnium compounds are closely similar. The ^1H spectra consist of a quartet of equally intense lines due to spin–spin splitting by boron-11 ($I = \frac{3}{2}$; $J(^{11}B—H) = 90$ Hz), with some additional weaker lines due to splitting by boron-10 ($I = 3$; $J(^{10}B—H) = 30$ Hz). The ^{11}B spectra exhibit a 1:4:6:4:1 quintet ($J(^{11}B—H) = 90$ Hz). The inner nine lines of the anticipated 17-line spectrum have been observed in the ^{11}B-decoupled ^{91}Zr spectrum of $Zr(BH_4)_4$; the averaged coupling constant J(Zr—H) is 28 Hz.

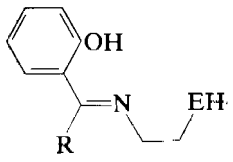
On cooling solutions of $M(BH_4)_4$ to −80 °C, the ^1H resonance lines are markedly broadened. This effect was originally attributed to a slowing of the rate process that exchanges hydrogen atoms between the bridging and terminal sites.[634] However, it was later shown that the observed line-shape changes are due to quadrupolar effects and that the hydrogen-atom exchange rate is still rapid (probably $> 10^4$ s^{-1}) at −80 °C.[635]

Variable temperature, solid-state ^1H NMR studies of $M(BH_4)_4$[637] have provided evidence for two intramolecular motional processes. The higher temperature process has been assigned to exchange of bridging and terminal hydrogen atoms; for M = Zr, $E_a = 21.8 \pm 1.3$ and $\Delta G^{\ddagger}$ (−73 °C) = 30.5 kJ mol^{-1}; for M = Hf, $E_a = 35.1 \pm 1.3$ and $\Delta G^{\ddagger}$ (−59 °C) = 33.9 kJ mol^{-1}. The lower temperature process has been interpreted in terms of rotation of the BH_4^- ligands about the threefold (M—B—H_t) axis; for M = Zr, $E_a = 22.6 \pm 0.8$ and $\Delta G^{\ddagger}$ (−149 °C) = 18.0 kJ mol^{-1}; for M = Hf, $E_a = 19.2 \pm 0.8$ and $\Delta G^{\ddagger}$ (−140 °C) = 19.2 kJ mol^{-1}.

The methyltrihydroborato complex $Zr(BH_3Me)_4$ has been prepared by reaction of $ZrCl_4$ and $LiBH_3Me$ in chlorobenzene. It has a tetrahedral structure, like $Zr(BH_4)_4$, with tridentate attachment of the BH_3Me^- ligands (Zr—B = 2.335(3), average Zr—H_b = 2.06, average B—H_b = 1.14 Å).[638]

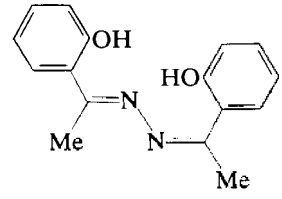
The mixed-ligand complexes $[MCl(BH_4)\{N(SiMe_3)_2\}_2]$ (M = Zr or Hf) and $[Hf(BH_4)_3\{N(SiMe_2CH_2PMe_2)_2\}]$ were mentioned in Sections 32.4.2.4.ii and 32.4.3.2 respectively. IR and ^1H NMR studies of the $[MCl(BH_4)\{N(SiMe_3)_2\}_2]$ complexes indicate that the BH_4^- ligand is tridentate and exchange of bridging and terminal hydrogen atoms is fast on the NMR time scale at −80 °C.[81] On the other hand, $[Hf(BH_4)_3\{N(SiMe_2CH_2PMe_2)_2\}]$ contains bidentate BH_4^- ligands as evidenced by two ν(B—H_t) (2470 and 2420 cm^{-1}) and two ν(B—H_b) (2110 and 1950 cm^{-1}) IR bands. ^1H and ^{11}B NMR spectra of this complex indicate rapid exchange of inequivalent BH_4^- ligands as well as rapid exchange of bridging and terminal hydrogen atoms.[140]

Treatment of $[Hf(BH_4)_3\{N(SiMe_2CH_2PMe_2)_2\}]$ with Lewis bases (NEt_3 or PMe_3) yields the dinuclear trihydride $[\{Hf[N(SiMe_2CH_2PMe_2)_2]\}_2(H)_3(BH_4)_3]$. This complex is fluxional; ^1H and selectively decoupled ^{31}P NMR spectra show the presence of three equivalent hydrides coupled to four equivalent phosphorus nuclei.[140]



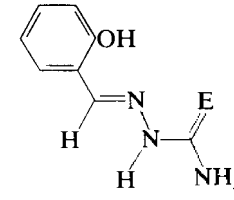
32.4.9 Mixed Donor Atom Ligands

32.4.9.1 Open polydentate ligands

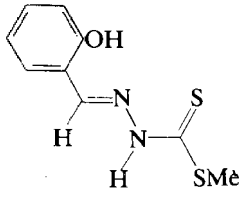


Zirconium(IV) forms a rather large number of complexes with ONO- and ONS-tridentate Schiff base ligands, ONNO- and SNNS-tetradentate Schiff base ligands, and related species such as diacyl hydrazines. Relatively few hafnium analogues have been reported thus far.

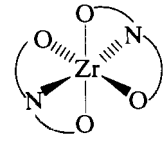
(i) ONO- and ONS-Tridentate Schiff base ligands



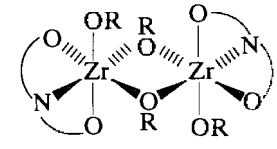
$Zr(OCHMe_2)_4 \cdot HOCHMe_2$ reacts in benzene at reflux with a variety of dibasic tridentate Schiff bases H_2L in 1:1 and 1:2 mole ratios to give complexes of the type $Zr(OCHMe_2)_2(L)$ and $Zr(L)_2$, respectively. The Schiff bases that undergo these reactions include aldimines and ketamines derived from carbonyl compounds and hydroxyalkyl amines (**35**)[639–641] or mercaptoalkyl amines (**36**),[642] azines (**37**),[643] semicarbazones (**38**),[644] thiosemicarbazones (**39**),[645] and Schiff bases derived from *S*-alkyldithiocarbazates (**40**);[646] one example of each type of ligand is shown in (**35**)–(**40**). The carbonyl compounds from which these Schiff base ligands are derived are commonly salicylaldehyde, 2-hydroxy-1-naphthaldehyde, acetylacetone or 2-hydroxyacetophenone. With but a few exceptions, the $Zr(L)_2$ complexes are monomeric in solution, while the $Zr(OCHMe_2)_2(L)$ analogues are dimeric. IR spectra indicate that $(L)^{2-}$ behaves as an ONO- or ONS-tridentate ligand, and six-coordinate structures have been suggested, for example (**41**) and (**42**). The $Zr(OCHMe_2)_2(L)$ complexes undergo alkoxide exchange reactions with alcohols such as *t*-butanol, 2-methylpentane-2,4-diol ($C_6H_{14}O_2$), or benzene-1,2-diol ($C_6H_6O_2$) yielding the $[Zr(OCMe_3)_2(L)]$, $[Zr(C_6H_{12}O_2)(L)]$ and $[Zr(C_6H_4O_2)(L)]$ derivatives, respectively; these complexes are monomeric in solution and presumably five-coordinate.



(**35**) H_2L; R = H or Me, E = O
(**36**) H_2L; R = H or Me, E = S

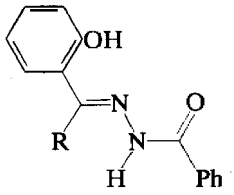


(**37**) H_2L



(**38**) H_2L; E = O
(**39**) H_2L; E = S

(**40**) H_2L

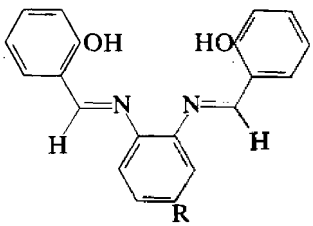


(**41**)

(**42**) R = $CHMe_2$

Mixed-ligand complexes [Zr(L)(L')] that contain dinegative anions of two different ONO-tridentate Schiff base ligands have been prepared in benzene at reflux by reaction of a 1:1:1 mole ratio of $Zr(OCHMe_2)_4 \cdot HOCHMe_2$, H_2L and H_2L'.[647] Several $[Zr(L)_2]$, $[\{Zr(OCHMe_2)_2(L)\}_2]$, $[Zr(C_6H_{12}O_2)(L)]$ and $[Zr(C_6H_4O_2)(L)]$ complexes that contain the dinegative anions of ONS-tridentate Schiff bases have been synthesized from benzothiazolines.[648]

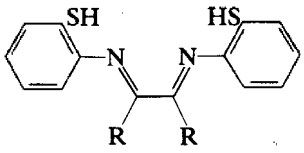
The reaction of $Hf(OCHMe_2)_4 \cdot HOCHMe_2$ with stoichiometric amounts of the *S*-methyldithiocarbazate (**40**) or the dibasic benzoyl hydrazones (**43**) yields analogous hafnium complexes $Hf(L)_2$ and $Hf(OCHMe_2)_2(L)$.[649,650] Only the disubstitution products $HfCl_2(L)$ could be obtained from the reaction of $HfCl_4$ with (**40**) or (**43**). The $HfCl_2(L)$ complexes are moisture-sensitive, insoluble, yellow solids and are probably polymeric.[651,652] On the other hand, a monomeric trigonal bipyramidal structure with *trans* chlorine atoms has been suggested for thiosemicarbazone complexes of the type $ZrCl_2(L)$; these compounds exhibit a single ν(Zr—Cl) IR band at ~290 cm^{-1}.[653] Unfortunately, both the $HfCl_2(L)$ and $ZrCl_2(L)$ complexes are too insoluble for molecular weight measurements.



(**43**) H_2L; R = H or Me

Zirconyl chloride (or acetate) reacts in methanol at reflux with tridentate Schiff bases prepared by condensation of substituted salicylaldehydes with ethanolamine,[654] *o*-hydroxybenzylamine,[655] *o*-aminobenzyl alcohol[656] or salicylhydrazide[657] to give 1:2 metal:ligand complexes of the type $[ZrO(HL)_2]$. IR spectra indicate that the Schiff bases behave as monobasic ONO- tridentate ligands; for example, (**35**) coordinates to zirconium through the phenolate oxygen, azomethine nitrogen and hydroxylic oxygen atoms. The complexes are monomeric nonelectrolytes in solution, and they exhibit a medium intensity IR band in the region 880–945 cm^{-1}, which has been attributed to $\nu(Zr{=}O)$. If these compounds do contain a Zr=O group, the Zr atom would be seven coordinate.

Dibasic tridentate Schiff bases derived from salicylaldehydes and 2-aminobenzoic acid[658] or 1-amino-2-mercaptobenzene[659] react with aqueous zirconium nitrate to give monomeric complexes of the type $[Zr(OH)_2(L)(H_2O)]$. IR spectra of these compounds support an ONO- or ONS-tridentate attachment of the $(L)^{2-}$ ligands.



(*ii*) *ONNO- and SNNS-Tetradentate Schiff base ligands*

The eight-coordinate complex $[Zr(dsp)_2]$, where $(dsp)^{2-}$ is the dianion of the tetradentate Schiff base (**44**), has been prepared by condensation of tetrakis(salicylaldehydato)zirconium(IV) $[Zr(sal)_4]$ with *o*-phenylenediamine, and its structure has been determined by X-ray diffraction.[266] This complex has a dodecahedral coordination polyhedron with nitrogen atoms in the A sites and oxygen atoms in the B sites. The tetradentate ligands span the *mam* polyhedral edges, and the trapezoidal planes are very nearly perpendicular (dihedral angle = 89.2°). The Zr—N bonds (mean 2.43 Å) are appreciably longer than the Zr—O bonds (mean 2.10 Å). The corresponding $[Zr(dspeb)_2]$ complex, where $(dspeb)^{2-}$ is the dianion of (**45**), is of interest as a possible starting material for synthesis of coordination polymers.[660] A glossy red polymer of approximate molecular weight 20 000–40 000 has been prepared by condensation of $[Zr(sal)_4]$ and 1,2,4,5-tetraaminobenzene.[661]

(**44**) H_2dsp; R = H
(**45**) H_2dspeb; R = CO_2Et

The reaction of $Zr(OCHMe_2)_4{\cdot}HOCHMe_2$ with dibasic ONNO-tetradentate Schiff base ligands derived from diaminoalkanes and salicylaldehyde, 2-hydroxy-1-naphthaldehyde, acetylacetone or 2-hydroxyacetophenone yields dimeric $[\{Zr(OCHMe_2)_2(L)\}_2]$ and monomeric $[Zr(L)_2]$ complexes,[662] analogous to the ONO-tridentate Schiff base complexes discussed in the previous section. Monomeric $[Zr(OCHMe_2)_2(L)]$ and $[Zr(L)_2]$ complexes, where $(L)^{2-}$ is the dianion of the SNNS-tetradentate Schiff bases (**46**) have been prepared from $Zr(OCHMe_2)_4{\cdot}HOCHMe_2$ and the appropriate benzothiazoline.[648] A few compounds of composition $ZrCl_2(L)$[663,664] and $ZrO(L)(H_2O)_3$[665] have been synthesized in methanol by reaction of ONNO-tetradentate Schiff bases and zirconyl chloride.

(**46**) H_2L; R = H or Me

(iii) Diacyl hydrazines

With diacyl hydrazines, zirconium tetrafluoride and tetrachloride form 2:1, 1:1 and 1:2 adducts of the type $(ZrF_4)_2(RCONHNHCOR')$ (R = 4-C_5H_4N, R' = Me or Ph),[666] $ZrF_4(RCONHNHCOR')$ (R = R' = H or Me; R = Me, R' = Ph),[667] and $ZrCl_4$-$(MeCONHNHCOPh)_2$.[668] In addition, zirconium tetrachloride undergoes substitution reactions yielding $ZrCl_2(RCONNCOR')$ (R = R' = H, Me or Ph; R = Me, R' = Ph; R = 4-C_5H_4N, R' = Me or Ph).[666,668] All of these compounds may be polymeric since they have high decomposition temperatures and are insoluble in common organic solvents. IR spectra suggest that the diacyl hydrazines function as ONNO-tetradentate ligands.

32.4.9.2 Aminopolycarboxylates

Zirconium(IV) and hafnium(IV) form numerous stable chelate complexes with the anions of aminopolycarboxylic acids. Among the compounds that have been isolated in the solid state are $K_2[Zr(nta)_2]$,[669] $[M(edta)(H_2O)_2]\cdot 2H_2O$[670] and $H[Zr(dtpa)]\cdot 3H_2O$[671] (M = Zr or Hf; nta = nitrilotriacetate; edta = ethylenediaminetetraacetate; dtpa = diethylenetriaminepentaacetate). These compounds are prepared by concentration of hot, acidic aqueous solutions that contain stoichiometric amounts of an M^{IV} salt and the chelating ligand. Solid complexes of the type $M'Hf(OH)(edta)\cdot 2H_2O$ and $M'Hf(OH)(cdta)\cdot 2H_2O$ (M' = Na or NH_4; cdta = 1,2-cyclohexanediaminetetraacetate) are also known.[672]

Eight-coordinate dodecahedral structures have been established for $[Zr(nta)_2]^{2-}$[673] and $[Zr(edta)(H_2O)_2]$[674] by single-crystal X-ray studies. $[Zr(nta)_2]^{2-}$ exhibits a ligand wrapping pattern (Figure 11) in which the two nitrogen atoms occupy dodecahedral A sites, in accord with Orgel's rule; the three glycinate groups of each tetradentate nta ligand span *a*, *g* and *m* polyhedral edges. In comparison with cubic, square antiprismatic, and other dodecahedral stereoisomers, the observed stereoisomer is ideally suited for minimizing nonbonded repulsions and chelate-ring strain. Zr—O bonds to the dodecahedral A sites (2.251(7) Å) are significantly longer than Zr—O bonds to the B sites (2.124(9), 2.136(8) Å), and the Zr—N bonds are extraordinarily long (2.439(9) Å). In $[Zr(edta)(H_2O)_2]$ (Figure 11), the two nitrogen atoms and the water molecules occupy the dodecahedral A sites, while the four oxygen atoms of the hexadentate edta ligands take the B sites, again in accord with Orgel's rule (Zr—N = 2.43(2); Zr—O = 2.12(2), 2.14(2); Zr—OH_2 = 2.27(2) Å).

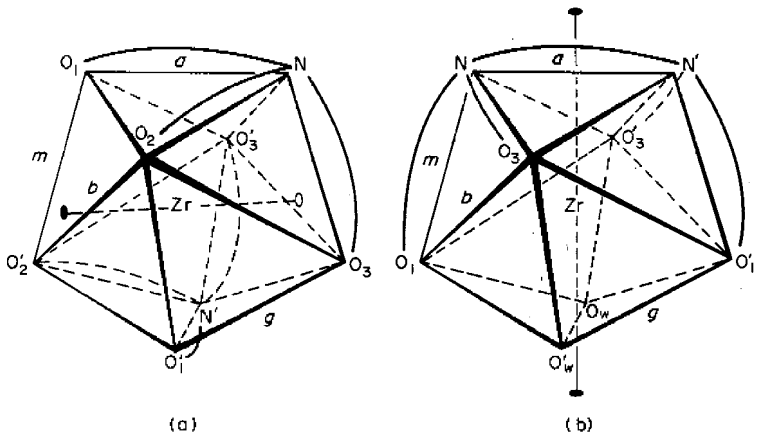


Figure 11 Ligand wrapping pattern in (a) $[Zr(nta)_2]^{2-}$ and (b) $[Zr(edta)(H_2O)_2]$. Primed and unprimed symbols are related by the indicated crystallographic twofold axes

The existence of a wide variety of zirconium(IV)-aminopolycarboxylate complexes in solution was established by the potentiometric titration studies of Intorre and Martell.[675–677] This work and related solution studies have been reviewed by Larsen.[5] Zirconium(IV) forms 1:1 and 1:2 complexes with tetradentate aminopolycarboxylates, 1:1 complexes with hexadentate and octadentate aminopolycarboxylates, and mixed ligand complexes with aminopolycarboxylates and various bidentate ligands, for example 1:1:1 Zr–edta–Tiron and 1:1:2 Zr—nta–Tiron complexes (Tiron = 1,2-dihydroxybenzene-3,5-disulfonate). The stoichiometries of these complexes are consistent with the tendency of zirconium to achieve a coordination number of eight.

^{1}H NMR spectra of the 1:1 Zr–edta and Hf–edta complexes in the pH range 1–3.5 exhibit an AB pattern for the inequivalent glycinate protons and a single resonance for the ethylene protons.[678,679] The spectra are not as complex as might have been expected on the basis of the low (C_2) symmetry of the dodecahedral $[Zr(edta)(H_2O)_2]$ molecule; evidently the inequivalent glycinate groups undergo rapid exchange, but the rate of Zr—N bond rupture is slow on the NMR time scale. Changes in the NMR spectra above pH 3.5 have been interpreted in terms of hydrolysis and polymerization.

Thermodynamic parameters for formation of M(edta) and $M(nta)^+$ (M = Zr or Hf) from M^{4+} and $(edta)^{4-}$ or $(nta)^{3-}$ have been determined at 15, 25 and 35 °C from calorimetric measurements.[680–683] Results for Zr(edta) at 25 °C are $\Delta G° = -187.2 \pm 0.3$ kJ mol^{-1}, $\Delta H° = -2.6 \pm 0.6$ kJ mol^{-1} and $\Delta S° = 618.8 \pm 2.5$ J mol^{-1} deg^{-1}. The large positive entropy change is associated with the effects of dehydration of the highly charged reacting ions.

32.4.9.3 NO-, NS- and OS-bidentate ligands

Zirconium(IV) and hafnium(IV) halides from a variety of 1:1 and 1:2 adducts with NO- and NS-bidentate ligands (Table 23). These compounds are generally prepared by mixing solutions or suspensions of the components in a polar organic solvent at room temperature. They are moisture-sensitive, white or yellow solids, insoluble in most organic solvents. Structures of the adducts have not been established; however the mode of coordination of the ligands is suggested by frequency shifts in characteristic IR bands upon complexation. Most of the ligands in Table 23 behave as NO- or NS-bidentate ligands, but 8-quinolinol and the *N*-arylsalicylaldimines appear to coordinate only through the nitrogen atom. IR spectra suggest that only one of the two benzaldehyde thiosemicarbazone ligands is attached to the metal in $MCl_4(PhCH{=}NNHCSNH_2)_2$ (M = Zr or Hf). Coordination of the hydroxylic oxygen atom of 3- and 4-aminophenol in the 1:4 adducts $MCl_4(H_2NC_6H_4OH)_4$ is uncertain.

Anhydrous zirconyl chloride forms insoluble, yellow 1:2 adducts, $ZrOCl_2(2\text{-}HOC_6H_4CH{=}NC_6H_4R)_2$ (R = H, 4-Me, 4-Cl or 4-OMe), with *N*-arylsalicylaldimines. Five-coordinate structures in which the salicylaldimines behave as N-bonded monodentate ligands have been suggested on the basis of IR spectra.[684]

The reaction of $ZrCl_4$ with two equivalents of ethanolamine or diethanolamine in ethyl acetate yields the substitution products $ZrCl_2(OC_2H_4NH_2)_2$ or $ZrCl_2(OC_2H_4NHC_2H_4OH)_2$, respectively, while the analogous reaction with triethanolamine gives the 1:4 adduct $ZrCl_4\{N(C_2H_4OH)_3\}_4$. IR spectra indicate that $(OC_2H_4NH_2)^-$ behaves as an NO-bidentate ligand.[685]

The following moisture-sensitive substitution products have been prepared by prolonged heating (in refluxing chloroform, THF or dichloromethane) of stoichiometric amounts of $ZrCl_4$ or $HfCl_4$ and benzoyl hydrazine, 4-pyridinecarboxylic acid hydrazide, benzoylhydrazones or Schiff bases derived from *S*-methyldithiocarbazate: $ZrCl_2(PhCONNH_2)_2$,[668] $ZrCl_3(4\text{-}NC_5H_4CONNH_2)$,[666] $HfCl_3(L)$ and $HfCl_2(L)_2$ (L = RR′C=NNC(O)Ph or RR′C=NNC(S)-SMe).[651,652] IR spectra indicate that these ligands act as monobasic NO- or NS-bidentate ligands, forming five-membered chelate rings upon complexation. The complexes are insoluble in most organic solvents, and they may be polymeric. The *N*-phenylsalicylaldiminato derivative $ZrCl_2(2\text{-}OC_6H_4CH{=}NPh)_2$ has been synthesized by condensation of aniline and dichlorobis(salicylaldehydato)zirconium(IV).[686]

$ZrCl_4$ and $HfCl_4$ react with 8-quinolinol (eight equivalents) in THF at reflux or in the absence of solvent at 140 °C to give the hydrolytically and thermally stable, isomorphous tetrakis chelates $[M(8\text{-O-quin})_4]$ (M = Zr or Hf). These compounds can be sublimed at ~350 °C/0.05 mmHg.[687] Precipitation of Zr^{IV} from aqueous solutions with 8-quinolinol often gives products of variable composition, but pure $[Zr(8\text{-O-quin})_4]$ can be obtained from hot

Table 23 Complexes of Zirconium(IV) and Hafnium(IV) Halides with NO- and NS-Bidentate Ligands

Ligand	*Complex*[a]	*Ligand donor atom(s)*	*Ref.*

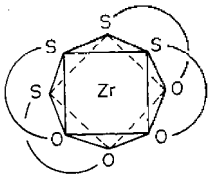
solutions that contain an excess of oxalate.[688] The structure of $[Zr(8\text{-}O\text{-}quin)_4]$ is dodecahedral with the nitrogen atoms in the A sites and oxygen atoms in the B sites, in accord with Orgel's rule (Zr—N = 2.405(8), Zr—O = 2.106(6) Å). The molecule adopts the rather uncommon D_2-*gggg* ligand wrapping pattern, presumably to avoid steric crowding of *o*-hydrogen atoms along the *a* edges of the more common D_{2d}-*mmmm* stereoisomer.[689]

Tetrakis(*N*-ethylsalicylaldiminato)zirconium(IV) $[Zr(2\text{-}OC_6H_4CH{=}NEt)_4]$ has a closely related dodecahedral structure with nitrogen atoms in the A sites and oxygen atoms in the B sites, but in this case the bidentate ligands span the *g* edges so as to give the very rare S_4-*gggg* stereoisomer. The Zr—N bond length (2.539(9) Å) is extraordinarily long, and the Zr—O bond length (2.055(7) Å) is unusually short. $[Zr(2\text{-}OC_6H_4CH{=}NEt)_4]$ and the *N*-isopropyl and *N*-*t*-butyl analogues were prepared by reaction of the appropriate salicylaldimine with $Zr(NMe_2)_4$.[690]

The *N*,*N*-diethylhydroxylamido(1 −) complex $[Zr(ONEt_2)_4]$ has been prepared from $Zr(OCHMe_2)_4{\cdot}HOCHMe_2$ and excess Et_2NOH. An X-ray study of the analogous titanium(IV) compound shows that the complex exists as the expected dodecahedral D_{2d}-*mmmm* stereoisomer with nitrogen atoms in the A sites and oxygen atoms in the B sites. Coalescence of the NMR resonances of the diastereotopic methylene protons of $[Zr(ONEt_2)_4]$ at 42 °C indicates rapid cleavage of the Zr—N bonds ($\Delta G^{\ddagger} = 69 \pm 6$ kJ mol^{-1}).[691]

Numerous NO-bidentate Schiff base complexes and a few NS-bidentate Schiff base complexes of the type $M(OCHMe_2)_{4-n}(L)_n$ (M = Zr or Hf; $n = 1$, 2, 3 or 4) have been synthesized by reaction of stoichiometric amounts of $M(OCHMe_2)_4{\cdot}HOCHMe_2$ and the Schiff base (HL) in refluxing benzene. The known zirconium complexes contain ligands such as *N*-arylsalicylaldimines, *N*-arylnaphthylaldimines[692,693] and *N*-(2-pyridyl)salicylaldimine.[694,695] In some cases, only two or three of the isopropoxy groups could be replaced by the Schiff base ligand. The $Zr(OCHMe_2)(L)_3$ and $Zr(L)_4$ complexes are monomeric in solution, but association, presumably involving isopropoxy bridges, is sometimes observed for the $Zr(OCHMe_2)_3(L)$ and $Zr(OCHMe_2)_2(L)_2$ complexes. Benzoyl hydrazone and *S*-methyldithiocarbazate Schiff base complexes of hafnium, $Hf(OCHMe_2)_{4-n}\{RCH{=}$

$NNC(O)Ph\}_n$ and $Hf(OCHMe_2)_{4-n}\{RCH{=}NNC(S)SMe\}_n$ (R = Ph or C_4H_3O), have been reported by Verma *et al.*[649,650]



Oxozirconium(IV) *N*-arylsalicylaldiminato complexes of composition ZrOCl(L) and $ZrO(L)_2$ (L = 2-$OC_6H_4CH{=}NAr$) have been prepared by reaction of 1:1 and 1:2 mole ratios of $ZrOCl_2{\cdot}8H_2O$ and the Schiff base in MeOH–Et_2O. The ZrOCl(L) complexes can also be obtained from a 1:1:1 molar mixture of $ZrOCl_2{\cdot}8H_2O$, salicylaldehyde and aromatic amine.[696]

Treatment of a hot methanol solution of appropriate zirconyl salts with 1,10-phenanthroline mono-*N*-oxide (phenNO) yields the oxozirconium(IV) complexes $[ZrO(phenNO)X_2]$ (X = Cl, Br, NO_3 or NCS), $[ZrO(phenNO)_2]I_2$ or $[ZrO(phenNO)_3][ClO_4]_2$.[697] These compounds are analogues of the 2,2′-bipyridine-1,1′-dioxide complexes discussed in Section 32.4.4.1.

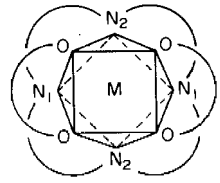
Insertion of phenyl isocyanate or methyl isothiocyanate into the metal-nitrogen bonds of $M(NMe_2)_4$ gives the tetrakis (NO- or NS-bidentate) chelates $[M\{NPhC(O)NMe_2\}_4]$ (M = Zr or Hf) or $[Zr\{NMeC(S)NMe_2\}_4]$.[72] Analogous insertion into the Zr—C bonds of $Zr(CH_2Ph)_4$ yields $[Zr\{NPhC(O)CH_2Ph\}_4]$ or $[Zr\{NMeC(S)CH_2Ph\}_4]$,[698] while insertion of phenyl or naphthyl isocyanate into the Zr—O bonds of zirconium alkoxides gives $Zr\{NR'C(O)OR\}_n(OR)_{4-n}$ (R′ = Ph or $C_{10}H_7$; R = Pr, $CHMe_2$ or CMe_3; *n* = 1, 2, 3 or 4).[210]

A few complexes have been reported in which zirconium(IV) or hafnium(IV) is attached to an OS-donor bidentate ligand. Alkyl thioglycolates, $Zr(OCHMe_2)_2(L)$ and $Zr(L)_2$ (L = $[SCH{=}C(OR)O]^{2-}$; R = Me or Et), have been synthesized from stoichiometric amounts of $Zr(OCHMe_2)_4$ and the alkyl thioglycolate, H_2L. The isopropoxy groups of $Zr(OCHMe_2)_2(L)$ are replaced by *t*-butoxy groups when the isopropoxy complex is heated under reflux with an excess of Me_3COH in benzene. Molecular weight measurementts and IR spectra indicate that the $Zr(OR)_2(L)$ complexes have alkoxy-bridged dimeric structures.[699] Related $Zr(OCHMe_2)_2(L)$ and $Zr(L)_2$ (L = $[SCH_2CH_2O]^{2-}$, $[SCH_2CH_2CO_2]^{2-}$ or $[2\text{-}SC_6H_4CO_2]^{2-}$) complexes have been reported.[471,700] Reactions of stoichiometric amounts of zirconium isopropoxide and 2-mercaptopropionic acid yield $Zr(OCHMe_2)(L)(HL)$ and $Zr(L)_2$.[471]

Tetrakis(thioacetylacetonato)zirconium(IV) $[Zr(Sacac)_4]$ has been prepared by reaction of stoichiometric amounts of $ZrCl_4$ and Na(Sacac) in dichloromethane. $[Zr(Sacac)_4]$ has a square antiprismatic structure (**47**) in which the ligands span the *s* polyhedral edges in such a way as to cluster the sulfur atoms in all-*cis* positions. The observed C_2-*ssss* stereoisomer is distorted in the direction of the dodecahedral C_1-*mmgg* and bicapped trigonal prismatic C_1-$t_1t_1p_2p_2$ stereoisomers. Consistent with the former distortion, the averaged Zr—O and Zr—S bond lengths fall into two classes (Zr—O_A = 2.185, Zr—O_B = 2.132, Zr—S_A = 2.724, Zr—S_B = 2.665 Å).[701]

(**47**)

The sulfur atoms are also clustered in all-*cis* positions in the $t_1t_1p_2p_2$ bicapped trigonal prismatic structure of tetrakis(*N*-methyl-*p*-thiotolylhydroxamato)hafnium(IV) $[Hf\{MeC_6H_4\text{-}C(S)N(O)Me\}_4]$. Averaged metal–ligand bond distances are Hf—O = 2.150 and Hf—S = 2.678 Å.[702]



Monothiocarbamato complexes are discussed in Section 32.4.5.2.

32.4.10 Multidentate Macrocyclic Ligands

32.4.10.1 Porphyrins

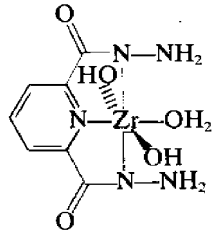
Octaethylporphinato complexes of the type $[M(OEP)(O_2CMe)_2]$ (M = Zr or Hf) have been prepared by reaction of H_2OEP and $[M(acac)_4]$ in molten phenol at 210–240 °C followed by crystallization from pyridine–acetic acid–water mixtures. The complexes have been characterized by IR and mass spectra[703,704] and by electronic absorption and emission spectra.[705] They have an eight-coordinate square antiprismatic structure (**48**) in which the four porphinato nitrogen atoms occupy the coordination sites on one square face and the two bidentate acetate

ligands span *s* edges on the opposite (rectangular) face. Bond lengths in the hafnium complex of C_{2v} symmetry are Hf—O = 2.278(3), Hf—N_1 = 2.266(5) and Hf—N_2 = 2.248(3) Å; the zirconium and hafnium complexes are nearly isodimensional.[706]

(48)

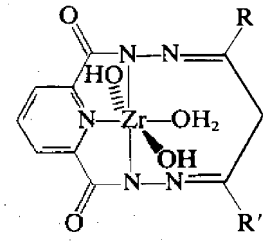
The red-violet mixed-ligand complex [Zr(OEP)(acac)(OPh)] has been isolated from the reaction of H_2OEP and [Zr(acac)$_4$] in molten phenol, and has been converted to bis(β-diketonato) derivatives [Zr(OEP)(dik)$_2$] (dik = acac or bzbz) by reaction with an excess of the β-diketone in boiling pyridine. The hafnium analogues [Hf(OEP)(dik)$_2$] (dik = acac or bzbz) were prepared from the β-diketone and [Hf(OEP)(O_2CMe)$_2$]. ^{1}H NMR spectra of the [M(OEP)(bzbz)$_2$] complexes at 0 °C (M = Zr) or −40 °C (M = Hf) exhibit two triplets and two quartets for the porphinato ethyl groups, consistent with a C_{2v} structure like (**48**).[707]

The *meso*-tetraphenylporphyrin complex [Zr(TPP)Cl_2] has been prepared by reaction of H_2TPP with $ZrCl_4$ in boiling benzonitrile. The electronic spectrum of [Zr(TPP)Cl_2] and the facile kinetics of TPP dissociation in acidic media suggest that the zirconium atom lies considerably out of the plane of the TPP ligand with both chlorine atoms being located on the same side of the TPP plane.[708]



32.4.10.2 Phthalocyanines

The bluish chlorophthalocyanine complexes [M(PcCl)Cl_2] (M = Zr or Hf; PcCl = [$C_{32}H_{15}ClN_8$]$^{2-}$) have been synthesized by reaction of the metal tetrachlorides with *o*-phthalonitrile at 280 °C (equation 55).[709] Treatment of the [M(PcCl)Cl_2] complexes with boiling acetic acid gives the dichroic red-violet/dark blue acetato analogues [M(PcCl)(O_2CMe)$_2$],[709] while treatment of the [M(PcCl)$_2$] complexes with ethanol and then warm water yields the blue hydroxo derivatives M(PcCl)$(OH)_2$·$2H_2O$.[710] These complexes exhibit enormous thermal stability. [Zr(PcCl)(O_2CMe)$_2$] can be sublimed in high vacuum at 500 °C.[709] [Hf(Pc)$_2$] (Pc = [$C_{32}H_{16}N_8$]$^{2-}$) sublimes at 540–560 °C and does not decompose until ~686 °C.[711]



$$ZrCl_4 + 4C_8H_4N_2 \longrightarrow [Zr(PcCl)Cl_2] + HCl \qquad (55)$$

32.4.10.3 Other polyaza macrocycles

$ZrOCl_2$·$8H_2O$ reacts with 2,6-dipicolinoyl dihydrazine (H_2dpdh) yielding a 1:1 complex that has been formulated as ZrO(dpdh)$(H_2O)_2$ or Zr$(OH)_2$(dpdh)(H_2O) (**49**). The free NH_2 groups of compound (**49**) condense with the carbonyl groups of β-diketones affording compounds (**50**) that are believed to contain 12-membered macrocyclic rings.[712]

33.1 GENERAL INTRODUCTION

The element was recognized in 1831, when N. G. Sefström was able to isolate and characterize the oxide; the name vanadium was derived from Vanadis, a goddess in Scandinavian mythology. The beautiful colours of vanadium compounds had been observed as early as 1801, by A. M. del Rio in his experiments with a new element he called erythronium because of the red colour after treatment with acid.[1]

Some tribulations in the experimental work and the variety of colours observed in early vanadium chemistry can now be explained as due to the formation of various coordination compounds, early symptoms of a rich and challenging chemistry.

There are vanadium compounds with formal oxidation states from −3 up to +5 with the exception of −2. Under ordinary conditions, the most stable states are +4 and +5. Suitable sources of information for the early chemistry of vanadium are Mellor's[2] and Sidgwick's[3] books. More recent work is covered by several reviews.[4–9]

The coordination chemistry of vanadium is strongly influenced by the oxidizing/reducing properties of the metallic centre, and the chemistry of vanadium ions in aqueous solution is limited to oxidation states +2, +3, +4 and +5, although V^{2+} can reduce water. Redox potentials are given in Table 1 and an *E vs.* pH diagram is shown in Figure 1.

The oxidation state −3 has been observed only in organometallic compounds, and until now there have been no reports of compounds with oxidation state −2, although there is no reason

Table 1 Standard Potentials of Vanadium Couples in Aqueous Solutions at 25 °C

Couple	*Standard potentials* (V) *in Strongly acid solutions*	*Weakly acid solutions*	*Neutral and basic solutions*
V^{V}–V^{IV}	1.000	0.723	0.991
V^{IV}–V^{III}	0.337	0.481	0.542
V^{III}–V^{II}	−0.255	−0.082	−0.486
V^{II}–V^{0}	−1.13	−1.13	−0.820

Data from Y. Israel and L. Meites, in 'Standard Potentials in Aqueous Solution', ed. A. J. Bard, R. Parsons and J. Jordan, Dekker, New York, 1985.

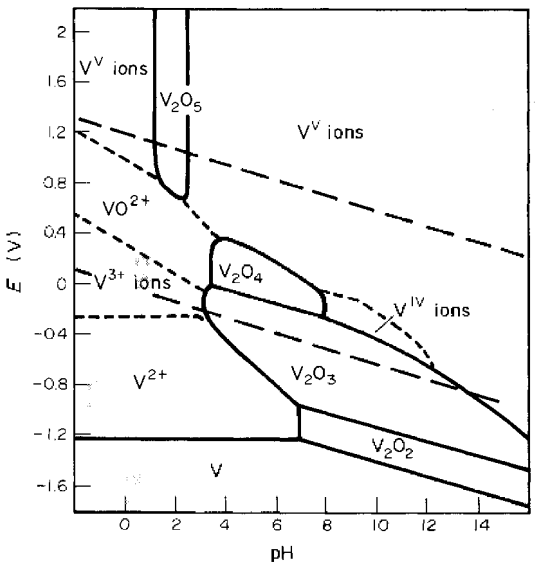

Figure 1 Potential *versus* pH diagram for the vanadium–water system at 25 °C. The dashed lines indicate the domains of relative predominance of the dissolved forms of the metal, but the various dissolved forms for each oxidation state are not explicit. The solid lines correspond to saturated solutions with a total vanadium concentration of 0.51 g dm^{-3}. The long dashed lines correspond to oxidation and reduction of water (for E° values of 1.23 and 0.00 V respectively) (adapted from E. Deltombe, N. Zoubov and M. Pourbaix, in 'Atlas d'Equilibres Electrochimiques', ed. M. Pourbaix, Gauthier-Villars, Paris, 1963)

to believe that such compounds cannot exist. Coordination compounds with formal oxidation states from −1 up to +2 are usually octahedral; for some it is not possible to ascertain a formal oxidation state as the bonding scheme may alternatively be explained by coordination of the reduced ligand. The ability of V^{2+} to reduce water and the instability of most of the complexes in these low oxidation states explains the small number of compounds. On the other hand, the reducing properties of vanadium(II) ions and their complexes have been used in many preparative methods, and among such reactions, the dinitrogen reduction deserves special attention.

Although many vanadium(III) complexes are unstable towards air, there are quite a few compounds in this oxidation state, most with octahedral geometry. However, remarkable seven-coordinate complexes were also characterized.

High concentration of vanadium in the blood of some tunicates has been a long-standing problem of biochemistry. That vanadium(III) ions are part of the respiratory pigment has been ruled out recently. The efficient mechanism used to concentrate vanadium from sea water is now understood but the utility of vanadium for these living organisms is still an intriguing question.

The +4 oxidation state is the most stable under ordinary conditions and the majority of vanadium(IV) compounds contain the VO^{2+} unit (vanadyl ion), which can persist through a variety of reactions. Its complexes typically have square pyramidal or bipyramidal geometry

with the vanadyl oxygen apical and the V atom lying above the plane defined by the equatorial ligands. Trigonal bipyramidal complexes are also known.

The VO^{2+} entity bonds most effectively to the more electronegative atoms, *e.g.* F, Cl, O, N (and also S and P).

Many vanadyl complexes are not air stable and generally they can be easily hydrolyzed and/or oxidized to the +5 oxidation state.

Table 2 gives examples of the coordination geometry adopted by each oxidation state.

Table 2 Oxidation States and Stereochemistries of Vanadium Complexes

Oxidation state	*Coordination number*	*Stereochemistry*	*Examples*
−3	6		$(Et_4N)_2[(Ph_3Sn)V(CO)_5]$
	7	Monocapped octahedral	$(Et_4N)[(Ph_3Sn)_2V(CO)_5]$
−1	6	Octahedral	$[V(bipy)_3]^-$
0	6	Octahedral	$[V(bipy)_3]$
1	6	Octahedral	$[V(bipy)_3]^+$
Low but not defined	6	Trigonal prismatic	$[V(S_2C_2Ph_2)_3]$
2	6	Octahedral	$[V(CN)_6]^{4-}$, $[V(H_2O)_6]^{2+}$
3	3	Planar	$[V\{N(SiMe_3)_2\}_3]$
	4	Tetrahedral	$[VCl_4]^-$
	5	Trigonal bipyramidal	*trans*-$[VCl_3(NMe_3)_2]$
	6	Octahedral	$[V(H_2O)_6]^{3+}$, $[V(C_2O_4)_3]^{3-}$
	7	Pentagonal bipyramidal	$K_4[V(CN)_7]\cdot 2H_2O$
4	4	Tetrahedral	$[VCl_4]$
	5	Trigonal bipyramidal	$[VOCl_2(NMe_3)_2]$
		Square pyramidal	$[VO(acac)_2]$, $[VS(acac)_2]$
	6	Octahedral	$[VO(acac)_2(dioxane)]$, $[V(catecholate)_3]^{2-}$, $[V(acac)_2Cl_2]$
	8	Dodecahedral	$[V(MeCS_2)_4]$, $[VCl_4(diars)_2]$
5	4	Tetrahedral	$[VOCl_3]$, $[V(Me_3SiO)_3(adamantylimido)]$
	5	Trigonal bipyramidal	VF_5 (g), VCl_5 (g)
		Square pyramidal	$[VOF_4]^-$
	6	Octahedral	$[VO(OMe)_3]$, $[VO_2(ox)_2]^{3-}$, $[VOCl_3(benzonitrile)_2]$
	7	Pentagonal bipyramidal	$[VO(NO_3)_3(MeCN)]$, $[V(dipic)(H_2NO)(NO)(H_2O)]^-$
	8	Dodecahedral	$[V(O_2)_4]^{3-}$

Many vanadium(V) compounds are oxo complexes containing the VO^{3+} or the VO^{2+} entity, and the *cis* geometry in dioxo complexes has been confirmed by structure determinations. A great number of oxo complexes containing halides, alkoxides, peroxide, hydroxamates and aminocarboxylate have been characterized. The oxidation of ligands by vanadium(V) prevents the isolation of a larger number of complexes. On the other hand, the oxidizing properties of vanadium(V) compounds are useful for many preparative reactions, namely for the catalysis of oxidations. Important examples are catalysts used for the oxidation of SO_2 to SO_3 in the industrial production of sulfuric acid, and there is great concern over the presence of small concentrations of vanadium in fuels (coal and petroleum) because of this ability of vanadium to catalyze the oxidation of sulfur dioxide.

Some similarities between vanadate and phosphate explain the biological activity of the metal in the oxidation state +5. The most remarkable example is the strong inhibition of the Na^+ pump (Na^+, K^+-ATPase). This and other problems in the bioinorganic chemistry of vanadium are likely to continue as areas of active research.

The great recent development in electrochemical techniques will certainly be helpful for the study of redox processes of a metal which can occur in so many oxidation states. Multinuclear NMR spectrometers will allow increased use of ^{51}V resonance as a routine method for the characterization of complexes in solution. Other recent developments are the study of polynuclear complexes, metal clusters (homo and hetero-nuclear) and mixed valence complexes, and it can be anticipated that these topics will soon become important areas of vanadium coordination chemistry, although the isolation of compounds with such complex

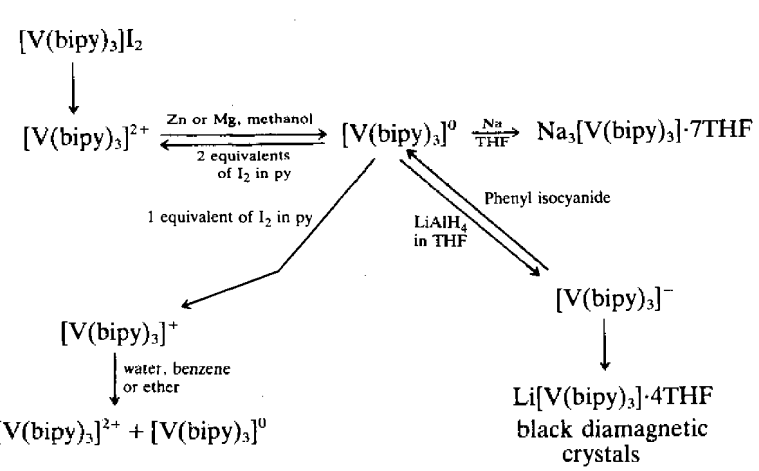
structures is again symptomatic of the difficulties that may be found in the chemistry of this metal.

33.2 LOW OXIDATION STATES (BELOW +2)

33.2.1 Introduction

The low oxidation states (from −3 to +1) are less usual; ligands in these complexes are those capable of stabilizing low oxidation states of other metals.

The derivatives of the pentacarbonylvanadate(-III) ion have the lowest formal oxidation state known for vanadium. Solutions of $[Na(diglyme)_2][V(CO)_6]$ are reduced by sodium to $[V(CO)_5]^{3-}$. Various salts were isolated by using the alkali iodide or onium halide;[10] Rb^+ and Cs^+ salts are rather thermally stable. $[V(CO)_5]^{3-}$ with R_3EX (R = alkyl or aryl; E = Sn, Pb; X = halide) leads to $[(R_3E)V(CO)_5]^{2-}$ and $[(R_3Sn)_2V(CO)_5]^-$. The IR spectra of crystalline $(Et_4N)[(Ph_3Sn)_2V(CO)_5]$ and its solutions are inconsistent with a pentagonal bipyramidal geometry and X-ray methods showed[11] that the anion structure is approximately a monocapped octahedron: the Sn—V lengths are 2.757(3) and 2.785(3) Å with ∠SnVSn 137.9(1)°. The corresponding compounds with oxidation number −2 have not been isolated.



33.2.2 Cyanide Complexes

VBr_3, potassium and potassium cyanide react in liquid ammonia.[12] The brown product, $K_2V(CN)_2 \cdot 0.5NH_3$, was paramagnetic (1.86 BM) and extremely pyrophoric. ν(CN) at 1905 cm^{-1} is consistent with a low oxidation state; the UV reflectance spectrum was recorded: 45.0, 36.0 sh, 28.0 sh, 20.0 br ($cm^{-1} \times 10^3$).

33.2.3 Nitrogen Ligands

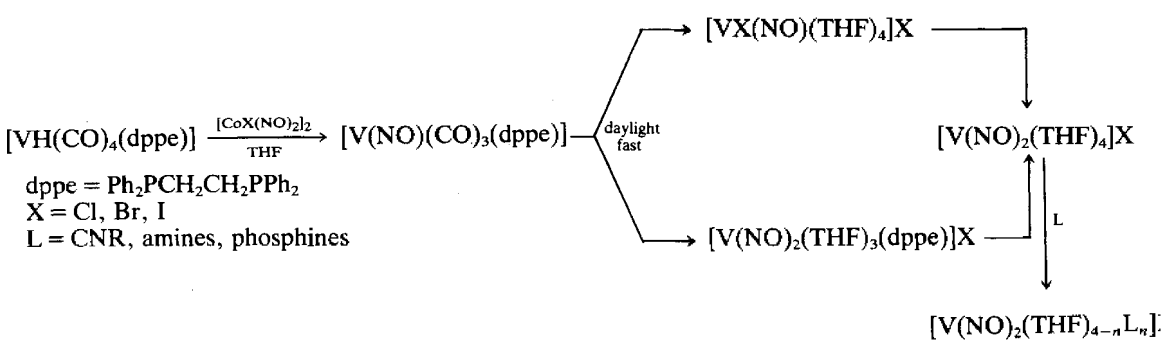
33.2.3.1 Bipyridyl, o-phenanthroline and terpyridyl

Complexes with formal oxidation states from +2 to −3 were reported by Herzog and co-workers in classic experiments; those for the bipyridyl complexes are in Scheme 1. Solutions of $[V(bipy)_3]I_2$ in 50% methanol on reduction by magnesium or zinc yield $[V(bipy)_3]$.[13] This had $\mu_{eff} = 1.9$ BM and a two-dimensional X-ray study[14] indicated that the nitrogen atoms were at the corners of a distorted octahedron with V—N 2.10 ± 0.03 Å and ∠NVN 73.6 ± 1.5°. ESR spectra[15] also suggested trigonal symmetry and an electronic structure analogous to that for $[VS_6C_6Ph_6]$ (Section 33.2.5).

Scheme 1 Preparation and interconversions of bipy complexes in low oxidation states

Solutions of $[V(bipy)_3]^+$ can be obtained by partial oxidation of $[V(bipy)_3]$ with iodine but the solid obtained with empirical formula $[V(bipy)_3]I\cdot\frac{1}{2}py$ was suggested[16] to be a mixed crystal of the similar compounds of vanadium(0) and vanadium(II). $Na_3[V(bipy)_3]\cdot 7THF$ was obtained[17] on reducing the tris(bipy) complex with sodium. This air-sensitive compound has $\mu_{eff} = 2.76$ BM. The corresponding tris(phenanthroline) complexes were obtained[18] on reducing a $[V(phen)_3]I_2$ solution in THF with Li_2benzophenone to $[V(phen)_3]$ which could be reoxidized with two equivalents of I_2 back to $[V(phen)_3]^{2+}$. Further reduction of $[V(phen)_3]$ with Li_2benzophenone led to $[V(phen)_3]^-$ and $Li[V(phen)_3]\cdot 3.5THF$ was isolated. Similarly, black $[V(terpy)_2]$ was isolated when $[V(terpy)_2]I_2$ was reduced with magnesium or $LiAlH_4$.[19]

The reduction of VCl_3 by sodium amalgam in the presence of a suitable ligand has been proposed[20] as an improved method for the preparation of several zerovalent complexes VL_3 (L = 2,2′-dipyridyl disulfide, 2,2′-dipyridylamine, di-*t*-butyldiimine). The magnetic moments were 1.82, 1.71 and 1.79 BM. Such similarity of magnetic properties is in favour of similar bonding. An alternative description considers that the electrons of the reduced species are located in π^* orbitals of the ligand. Reduced forms of bipy ($bipy^-$ and $bipy^{2-}$) are known.



The UV-vis spectra of $[V(bipy)_3]$ were interpreted[21] as indicating the existence of partially reduced ligand ($bipy^-$ or $bipy^{2-}$) at least in the excited states, but were also interpreted[22] as indicating V^0 bonded to neutral bipy. By comparing IR spectra of $[V(bipy)_3]^z$ ($z = 2+, 0$) and Li(bipy), $[V(bipy)_3]$ should be considered[23] as a complex of the reduced ligand $bipy^-$ or a complex of collectively reduced ligands.[24]

The ESR spectrum of $[VL_3]$ [L = benzilbis(*N*-phenylimine)] shows[25] hyperfine splitting due to ^{51}V, corresponding to a d^5 low-spin configuration with 80–90% of the charge of the unpaired electron at the metal.

Polarography and cyclic voltammetry[26] of $[V(bipy)_3]^z$ ($z = 2+, 1+, 0, 1-, 2-, 3-$) gave $E_{1/2}$ values of −0.8, −1.01, −1.11, −1.55 and −2.23 V for these five steps, and smaller polarographic waves at −2.10 and −2.6 V were attributed to the reduction of free bipy. From comparison of the $E_{1/2}$ values for the bipy complexes with those for 4,4′-dimethyl-2,2′-bipy and 5,5′-dimethyl-2,2′-bipy, the electron added (or removed) in the reactions of $[V(L)_3]^z$ ($z = 2+, 1+, 0$) was at t_{2g} orbitals.[26] On the other hand, for $V(bipy)_3/V(bipy)_3^-$ and $V(bipy)_3^-/V(bipy)_3^{2-}$ the added electron would occupy orbitals with a predominant π^* character. However, $[V(bipy)_3]$ is diamagnetic, and an intermediate character has been proposed for it.

33.2.3.2 Nitrosyl

Using $[Co(X)(NO)_2]_2$ as a nitrosylating agent, Rehder and co-workers synthesized various nitrosyl and dinitrosyl complexes as depicted in Scheme 2.[27,28] An extensive study of ^{51}V NMR of solutions of nitrosylvanadium species has been published.[27] THF molecules in *cis*-$[V(NO)_2(THF)_4]$ are easily replaced by other L leading to *cis*-$[V(NO)_2(THF)_{4-n}L_n]X$ (L = several ligands such as py, phen, MeCN, $OPEt_3$, thiophene, acetone; $n = 2$ to 4; X = Cl, Br, I). For L = CNR (R = cyclohexyl, Pr^i, Bu^t), $[VX(NO)_2L_3]$ are also formed and the presence of coordinated X was established[27] by the normal halogen dependence (Cl < Br < I) of ^{51}V shielding in ^{51}V NMR.

Scheme 2 Preparation of dinitrosyl complexes

A cyanonitrosyl complex, $K_3[V(NO)(CN)_5]\cdot 2H_2O$, was obtained[29] from VO_4^{3-} and CN^- in alkaline medium using hydroxylamine as the source of NO. Its structure[30] is tetragonally distorted octahedral: the mean V—C distance is 2.17 Å, there is a short V—N bond (1.66 Å) and the VCN and VNO linkages are almost linear. By conducting nitrosylation in H_2S,[31] $K_4[V(NO)(CN)_6]\cdot H_2O$ was isolated and $K_4[V(NO)(CN)_6]\cdot\frac{1}{2}KOH\cdot\frac{1}{2}H_2O$ studied by diffraction.[32] $[V(CN)_6(NO)]^{4-}$ has approximately pentagonal bipyramidal geometry with the nitrosyl group axial. The mean V—C bond length is 2.15 Å and the V—N bond length is 1.68 Å. These complexes have been used to prepare $K_2[V(NO)(CN)_4L]$ from $K_4[V(NO)(CN)_6]$ with L = bipy or phen[33] and $[V(NO)_2(L)_2]^+$ derivatives from $K_3[V(NO)(CN)_5]$.[34]

Using an excess of hydroxylamine in the reductive nitrosylation of VO_4^{3-} forms the dinitrosyl anion $[V(NO)_2(CN)_4]^{2-}$, and on treatment with bipy (or phen), complexes of formula $[V(NO)_2(CN)_2L]\cdot H_2O$ were isolated.[35]

Magnetic moments ($\mu_{eff} = 1.5$ and 1.6 BM for bipy and phen derivatives) confirmed the existence of one unpaired electron and ESR (no ^{51}V–^{15}N or ^{51}V–^{13}C superhyperfine splitting) indicated that it is located in a metal orbital. Two strong ν(N—O) bands at 1650 and 1520 cm^{-1} confirm the *cis* NO groups.

A brown polynuclear dichlorotrinitrosylvanadium(−I) was isolated[36] from a solution of $[VCl_4]$ in carbon tetrachloride by reaction with dry NO, and Beck and co-workers reported[37] that the same product was obtained from $[V(CO)_6]$ with NOCl. A trigonal bipyramidal arrangement with terminal and bridging chloro ligands was proposed for this compound $[V(NO)_3Cl_2]_n$, which reacts with solvents losing NO and forming mononitrosyls $[V(NO)L_4Cl_2]$ (L = MeCN, Ph_3PO, $\frac{1}{2}$phen). Herberhold and Trampisch[38] used sodium amalgam or zinc powder to prepare $[V(NO)_2L_2Cl]_x$ (L = acetonitrile, methyl isonicotinate) and $[V(NO)_2(Bu^tNC)_4]PF_6$. IR and ^{51}V NMR indicate that a single *cis* dinitrosyl species is the intermediate. The extensive work with ^{51}V NMR is summarized in Figure 2.

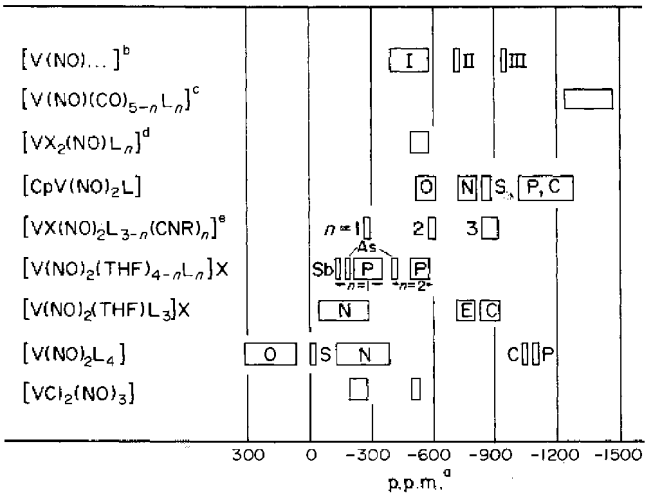


Figure 2 ^{51}V NMR shift ranges of nitrosyl vanadium complexes. Ligand abbreviations: N = NR_3, NCR; O = OCR_2, OR_2, OPR_3; P = PR_3, As = AsR_3, Sb = SbR_3, E = P, As, Sb; S = SR_2; X = Cl, Br, I, PF_6. (a) ^{51}V shielding increases from left to right; shift values are measured taking $VOCl_3$ as standard. (b) I = [V(nitrilotripropanolato)(NO)L]$^-$ (L = O ligand); II = [V(dipicolinato)(NO)$(ONH_2)(H_2O)$]$^-$; III = $[V(CN)_4(NO)(ONH_2)]^{3-}$. (c) L = P, As or CO. (d) L = O ligand or acetonitrile. (e) L = THF or acetonitrile. (f) I and II are respectively the di- and mono-nitrosyl derivatives formed in acetonitrile solution; III, resonance measured in CD_3NO_2 solution (data taken from refs. 27 and 38)

33.2.3.3 Dinitrogen complexes

Complexes of vanadium(0) with dinitrogen were obtained by co-condensations. $[V(N_2)_6]$ has been prepared[39] in frozen matrices; this formulation was based on the similarity of IR and UV-vis spectra with the corresponding $[V(CO)_6]$. By increasing the vanadium concentration, changes in the IR were explained as due to a dimer, $[V_2(N_2)_{12}]$.[39] Dinitrogen is acting as a weak ligand compared with CO, *i.e.* a poorer σ donor and a poorer π acceptor.[40]

33.2.4 Phosphorus Ligands

The dropwise addition of sodium naphthalenide to THF containing vanadium trichloride and 1,2-bis(dimethylphosphino)ethane (dmpe) causes changes of colours suggesting a stepwise reduction from +2 to 0. Brown $[V(dmpe)_3]$ was isolated[41] ($\mu_{eff} = 2.10$ BM) and IR data suggest octahedral coordination. The same complex was synthesized by a metal vapour technique.[42] The ESR was that expected and the unit cell is cubic with $a = 11.041(3)$ Å.

$[Et_4N][V(PF_3)_6]$ was prepared[43,44] by UV irradiation of $[Na(diglyme)_2][V(CO)_6]$ in diglyme saturated with PF_3 and studied[45] by multinuclear (^{19}F, ^{31}P, ^{51}V) NMR. The well-resolved spectra confirmed a (non-ideal) cubic geometry for the complex and V—PF_3 is weaker than V—CO.

Other V—P bonds may be found in phosphinehydrido complexes. The heptacoordinate $[V(H)(PF_3)_6]$ was prepared[43] from $[V(PF_3)_6]$ on heating with phosphoric acid. Reaction of a THF slurry of $[V_2(\mu\text{-}Cl)_3(THF)_6]_2Zn_2Cl_6$ with $PMePh_2$ followed by addition of $LiBH_4$ yielded a dark red air-sensitive material, a Zn_2V_2 aggregate with a V=V double bond and hydrogen bridging V to Zn atoms (Figure 3).[46]

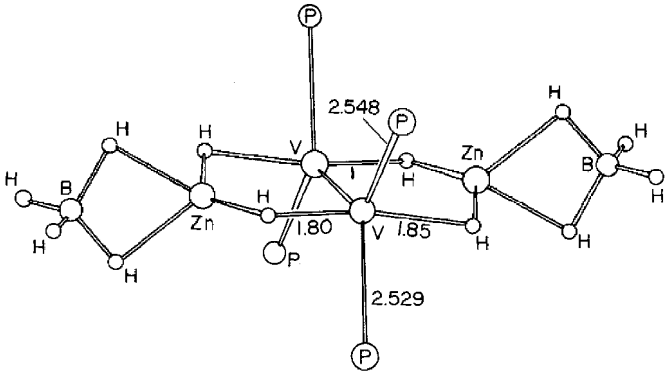

Figure 3 Structure of the phosphinohydrido complex $V_2Zn_2H_4(BH_4)_2(PMePh_2)_4$. The V—V distance of 2.400(2) Å was interpreted as corresponding to a double bond[46]

33.2.5 Tris(dithiolene) and Tris(diselenolene) Complexes

'Dithiolene complexes' was the name suggested by McCleverty[47] for complexes of unsaturated 1,2-dithiols without implying any particular ligand structure or valence formalism. The dithiolene complexes described differ from the vanadium(III) dithiolates (Section 33.4.6) reported by three independent groups.[48]

The charge at the vanadium in the usual dithiolene complexes may be estimated[49] as less than 2, and these complexes are therefore included in the section on low valence states. Various tris(dithiolene) complexes have been isolated and one-electron oxireductions studied by polarographic and voltammetric techniques. Table 3 summarizes methods of preparation and electrochemical behaviour. Schrauzer and co-workers[50] correlated electrochemical data with Taft's constants: the observed linear correlation reflected the ligand π orbital origin of the orbitals involved in the redox process.

$[V(S_2C_2Ph_2)_3]$ is trigonal prismatic, slightly distorted by a trigonal twist of 8.5°.[51] $[V(S_2C_2Ph_2)_3]^-$ was also trigonal prismatic as its electronic spectrum is similar to the isoelectronic $[Cr(S_2C_2Ph_2)_3]$,[51] which was isomorphous with $[V(S_2C_2Ph_2)_3]$. $(Me_4N)_2[V(S_2C_2(CN)_2)_3]$ was studied by diffraction[52] and a structure between octahedral and trigonal prismatic was proposed for the anion $[V(S_2C_2(CN)_2)_3]^{2-}$.

The C=C stretching frequencies of the $S_2C_2Ph_2$ and $S_2C_2H_2$ complexes increase with the negative charge of the complexes, *i.e.* the sulfur ligands become more 'dithiolate' in character.[53] The dithiolene complexes have several intense transitions in the visible, whose assignment is not yet complete. Using previous work as well as the resonance-Raman spectra for $[V(S_2C_2Ph_2)_3]^{0,1-}$ and $[V(S_2C_2(CN)_2)_3]^{2-}$, a set of assignments was produced (Figure 4).[54]

The ESR of $[V\{S_2C_2(CN)_2\}_3]^{2-}$ doped in single crystals of isomorphous

$[AsPh_4]_2[Mo\{S_2C_2(CN)_2\}_3]$ was fitted by an axially symmetric spin Hamiltonian with $g_\parallel = 2.000$, $g_\perp = 1.974$, $A_\parallel = 10$ G and $A_\perp = -100$ G, interpreted in terms of a $^2A_1$ ground state in D_3 symmetry.[49] The unpaired electron has predominantly metal d_{z^2} character. A molecular orbital scheme (Figure 4) was proposed for the dithiolene complexes.[55] This scheme has been used in the discussion of ESR results,[49] and electronic and resonance-Raman spectra.[54]

Tris(diselenolene) complexes derived from $Se_2C_2(CF_3)_2$ have been prepared by similar methods.[56]

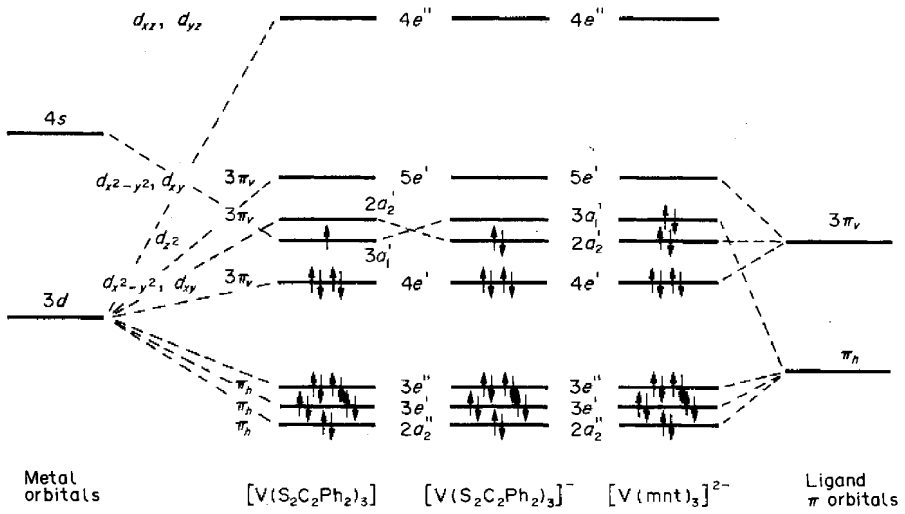

Figure 4 Electronic configurations of vanadium tris(1,2-dithiolene) complexes (from ref. 54, based on the scheme in ref. 55)

33.2.6 Hydrido Complexes

Hydridophosphino complexes have been described previously (Section 33.2.4). The bond dissociation energy of 209 kJ mol^{-1} has been measured[57] by ion beam mass spectrometry using the reaction in equation (1). The bond energies between V^+ and other atoms were compared with the corresponding carbon bonds: the energy of the bond to vanadium is about one half that of the corresponding carbon bond.

$$V^+ + H_2 \longrightarrow VH^+ + H \qquad (1)$$

33.3 VANADIUM(II)

33.3.1 Introduction

The small number of vanadium(II) compounds may be explained by (i) difficulties in keeping the compounds (they are very often easily oxidizable) and (ii) difficulties in characterization (because of contamination by higher oxidation state(s)). Although the easy oxidation may be inconvenient in the isolation and handling of compounds of vanadium(II), there are many examples of applications of vanadium(II) as a reducing agent for a large variety of both organic and inorganic species (see Section 33.3.8), usually behaving as a one-electron reducing agent.

Vanadium(II) compounds are usually prepared by reduction of acidic solutions of higher oxidation states. The usual geometry is octahedral and the electronic spectra often show three d–d spin-allowed bands. These spectra, as well as those of tetrahedral and linear complexes, have been reviewed.[58] For this d^3 configuration, a spin-only magnetic moment of 3.87 BM is expected. Slow substitution can be predicted for vanadium(II) complexes but such reactions are not as slow as those for the isoelectronic Cr^{III} ions.

33.3.2 Cyanides and Isocyanides

A solution of VCl_3 reduced with zinc and added to saturated KCN gave yellow $K_4[V(CN)_6]$. The structure[59] is almost a regular octahedron with V—C having a mean value of 2.161(4) Å and C—N a mean value of 1.153(7) Å, comparable to other cyano complexes of vanadium. The value 3.78 BM[60] for the room temperature magnetic moment is consistent with vanadium(II) and the spectrum showed[60] two d–d bands at 22.3×10^3 and 27.7×10^3 cm^{-1}. A purple powder[14] $K_2V(CN)_4$ was obtained by reaction of $K_2V(CN)_2 \cdot 0.5NH_3$ with NH_4CN in liquid ammonia. Its low magnetic moment (3.2 BM) and high ν(CN) were due to a polymeric cyanide-bridged structure.

$[V(CNBu^t)_6]^{2+}$ has been prepared by reduction of $V(CNBu^t)_3Cl_3$ or oxidation of $[V(CO)_6]^-$ in the presence of an excess of *t*-butyl isocyanide. In red $[V(CNBu^t)_6][V(CO)_6]_2$,[61] the octahedral cation has V—C 2.10(1) Å comparable to 2.161(4) Å for the hexacyanide.

33.3.3 Nitrogen Ligands

33.3.3.1 Ammonia and amines

Vanadium(II) chloride does not react with liquid ammonia at −33 °C, but at room temperature, it reacts slowly giving purplish brown $V(NH_3)_{5.4}Cl_{1.9}$ with a magnetic moment of 3.70 BM.[62] $[V(NH_3)_6]Br_2$ was isolated[63] from solutions of $[V(H_2O)_6]Br_2$ in ethanol by bubbling dry NH_3, or by condensing ammonia on to the hexahydrate. The magnetic moment is ~3.9 BM and the powder photograph has been indexed in terms of a face-centered cubic unit cell of side 10.5 Å, isomorphous with $[Ni(NH_3)_6]Br_2$. The three bands in the diffuse reflectance spectrum (32 000, 21 200 and 14 800 cm^{-1}) have been interpreted in terms of octahedral symmetry. Methylamine and VCl_2 in a Carius tube at 160 °C formed purple-brown $V(MeNH_2)_6Cl_2$.[64]

Complexes $[VL_3]X_2$ (L = en, 1,2-diaminopropane, 1,3-diaminopropane; X = Cl, Br, I) and $[V(dien)_2]X_2$ were prepared by mixing ethanolic solutions of amine and of vanadium(II) halide. The magnetic moments (3.66–3.91 BM) and electronic spectra were typical of octahedral vanadium(II) and there was no halogen coordination.[65]

33.3.3.2 N-heterocyclic ligands

Vanadium(II) alcoholates in ethanol[66] or hydrated vanadium(II) halides in *n*-butanol[67] were used to prepare complexes $[VL_6]X_2$ and $[VL_4X_2]$ (L = pyrazole, imidazole, dimethylimidazole, 1-methylimidazole, 2-methylimidazole, benzimidazole and isoquinoline; X = Cl, Br, I). [V(benzimidazole)$_2$Cl$_2$]·0.5butanol has been obtained[67] and the reflectance spectrum was consistent with an essentially octahedral environment. The magnetic moment (2.41 BM at 298 K decreasing with temperature) also suggests a polymeric structure. On heating the green V(1-methylimidazole)$_6$Cl$_2$ under vacuum, violet compounds formulated as V(1-methylimidazole)$_n$Cl$_2$ (n = 4, 5) were obtained.

(*i*) *Polypyrazolyl ligands*

Mani and co-workers[68] synthesized complexes of polypyrazolylborates $H_nB(pz)_{4-n}^-$ (n = 0, 1, 2) with vanadium(II). For n = 0 or 1, $[VL_2]$ were obtained with electronic spectra (and magnetic moments) consistent with an octahedral geometry and $HB(pz)_3^-$ and $B(pz)_4^-$ as tridentate ligands. For n = 2, $K[V(H_2B(pz)_2)_3]\cdot EtOH$ was isolated: the anion has a slightly distorted octahedral geometry with a mean V—N of 2.169(19) Å.[68] The isoelectronic poly(1-pyrazolyl)methane ligands have been used to synthesize vanadium(II) complexes.[69] The potentially bidentate ligands $H_2C(pz)_2$ and $H_2C(Me_2pz)_2$ react with vanadium(II) salts giving different stoichiometries, depending on the coordinating power of the anions: VL_2X_2 (L = $H_2C(pz)_2$, X = Cl, Br, I, NSC; L = $H_2C(Me_2pz)_2$, X = Br, NCS) and $[VL_2Cl]Y$ (L = $H_2C(pz)_2$, Y = BPh_4; L = $H_2C(Me_2pz)_2$, Y = PF_6, BPh_4).

They were octahedral with the exception of $[V(H_2C(Me_2pz)_2)_2Cl]Y$ (Y = PF_6 or BPh_4): these two have moments of 3.82–3.83 BM, virtually independent of temperature, and are monomeric and five-coordinate. The potentially tridentate $HC(pz)_3$ formed $[VL_2]Y_2$ (Y = Br, PF_6) and $[VL_2]_2[V(NCS)_6]$, with octahedral coordination.

Complexes of tris(1-pyrazolylethyl)amines (shown in Figure 5 and abbreviated as tpea) have been characterized. Complexes $[V(NCS)_2L]$ (L = tpea, R = H,[70] Me[71]) possess a slightly distorted octahedral geometry, the complex [VClL]BPh_4 (L = tpea, R = H) (μ_{eff} = 3.54 BM at 295 K and 2.93 at 90 K) has a polymeric structure with bridging chlorine atoms.

(*ii*) *Pyridine and related ligands*

$[V(py)_6][V(CO)_6]_2$ precipitated by adding solid $[V(CO)_6]$ to a toluene solution containing an excess of pyridine. By dissolving it in CH_2Cl_2, an isocarbonyl-bridged complex

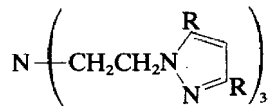

Figure 5 General formula of the tris(1-pyrazolylethyl)amine ligands

$[V(py)_4][V(CO)_6]_2$ is formed.[72] $[VL_4][V(CO)_6]_2$ (L = β- or γ-picoline) were obtained by reaction of $V(CO)_6$ and the ligand in benzene.[73]

$V(py)_4Cl_2$ has a *trans* structure with a mean V—N of 2.189 Å.[74] On heating it at 170 °C under vacuum, red-brown $V(py)_2Cl_2$ was detected and finally $V(py)Cl_2$ is formed. The formulae of complexes with pyridine, β-picoline and γ-picoline are listed in Table 4 with magnetic moments and thermal decomposition data.

Table 4 Complexes of Vanadium(II) with Pyridine and Picolines

Data taken from M. M. Khamar, L. F. Larkworthy, K. C. Patel, D. J. Phillips and G. Beech, *Aust. J. Chem.*, 1974, **27**, 41.

Complexes like $[V(L)_3]I_2$ (L = bipy, phen) and $[V(terpy)_2]I_2$ (already mentioned as starting materials for low-valent compounds) were isolated from solutions of VSO_4 by adding the corresponding ligand and iodide. The spectrum of $V(bipy)_3(ClO_4)_2$ shows[21] three bands due to *d–d* transitions with much metal-to-ligand charge-transfer character. The fine structure was due to vibrational interactions, evidence for electron delocalization within the excited states. $[V(aminoquinoline)_3]X_2 \cdot 2H_2O$ (X = Cl, Br, I) were synthesized[65] and showed spectra resembling those of the bipy complex.

Pyridine (and derivative) complexes $[VL_4(NCS)_2]$ have been isolated from aqueous ethanol; IR spectra indicated *trans* structures. On the other hand, $[VL_2(NCS)_2]$ with L = phen or bipy exhibit split CN absorptions suggestive of *cis* structures.[75]

33.3.3.3 Isothiocyanates

$K_4[V(NCS)_6] \cdot EtOH$ was prepared from VSO_4 solution in the presence of an excess of potassium thiocyanate,[76] and other counterions (NMe_4^+, NEt_4^+, Hpy^+) have been reported.[77] Thiocyanato groups are N-bonded and the moments are near the spin-only value. The electronic spectra have been interpreted on the basis of an octahedral d^3 ion although the splitting observed in the ν_2 band makes the assignment uncertain. On the other hand, X-ray powder photographs showed[77] that $[NEt_4]_4[V(NCS)_6]$ is isomorphous with the nickel complex, suggesting an octahedral geometry. In aqueous solutions, $[V(H_2O)_6]^{2+}$ reacts with the NCS^- ion;[78] the results from the thermodynamic and kinetic studies of this equilibrium have been summarized in Table 5.

33.3.3.4 Acetonitrile

The $[V(NCMe)_6]^{2+}$ ion was first obtained[73] in a solid $[V(NCMe)_6][V(CO)_6]_2$ as a product of the disproportionation of $[V(CO)_6]$. More recently, the structure of the

hexakis(acetonitrile)vanadium(II) ion has been determined[79] in $[V(NCMe)_6][ZnCl_4]$ obtained from the reduction of VCl_3 with $ZnEt_2$ in acetonitrile. The vanadium is surrounded by the six acetonitrile nitrogen atoms in near octahedral geometry (with mean V—N of 2.11 Å) and the VNC bond angle (173.4° av.) shows a slight deviation from linearity.

33.3.4 Phosphines

Bis(triethylphosphine)vanadium(II) chloride may be prepared by the zinc reduction of $VCl_3(PEt_3)_2$ or from '$VCl_2(THF)_2$' upon addition of triethylphosphine. The solid has a low value of 1.98 BM consistent with a polymeric structure and μ_{eff} remained unchanged in benzene; cryoscopy in benzene showed a dimer.[80] The spectra of such solutions contain three d–d transition bands at 10 040 ($\varepsilon = 21$), 15 120 ($\varepsilon = 19$) and 22 500 cm^{-1} ($\varepsilon = 30$).

$[V_2(\mu\text{-}Cl)_3(THF)_6]_2[Zn_2Cl_6]$ was used to synthesize other dinuclear compounds with bridging chlorine atoms, bridging diphosphine ligands and bidentate tetrahydroborates: $[V(\mu\text{-}Cl)(\mu\text{-diphos})BH_4]_2$ (diphos = bis(diphenylphosphino)methane[81] or bis(dimethylphosphino-methane[82]). The structures of these two were very similar; the bisdimethylphosphine complex is represented in Figure 6. The V—V distances (respectively 3.112(3) Å and 3.124(2) Å) are too long to suggest any significant metal–metal bonding.

Using 1,2-bis(dimethylphosphino)ethane (dmpe) mononuclear *trans*-$VX_2(dmpe)_2$ (X = Cl or Me) were obtained[83] and the *trans* structure of the dichloro complex was confirmed: the mean V—Cl and V—P were 2.44 and 2.50 Å respectively.

33.3.5 Oxygen Ligands

33.3.5.1 Water

A hydrolysis constant of 10^{-7} has been assumed[84] from the colour changes in VCl_2 titrated with base, and a pK value of 6.49 was determined from pH measurements in solutions of

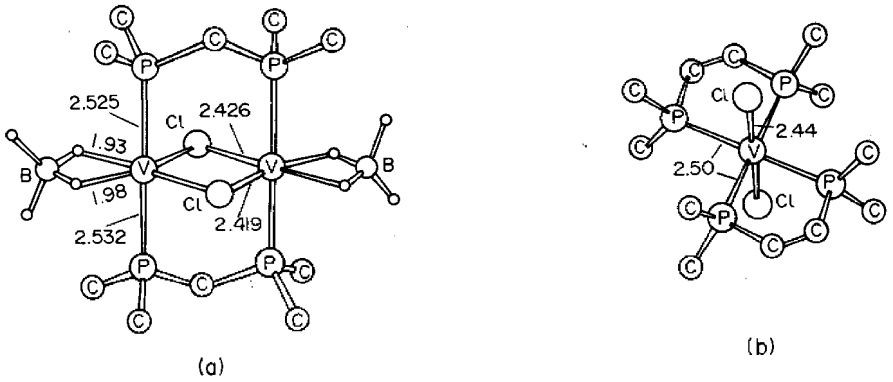

Figure 6 Structure of the phosphine complexes. (a) The complex with bis(dimethylphosphino)methane. A similar structure is found in the corresponding complex with bis(diphenylphosphino)methane.[82] (b) The complex with bis(diphenylphosphino)ethane[83]

VSO_4.[85] Polarography suggested dimeric species.[86] Baes and Mesmer[87] criticized the value for the hydrolysis constant, since it is difficult to avoid oxidation of the metal by water. Contamination with higher oxidation states would lead to high values of the constant. Molecular orbital studies[88] of hexahydrated divalent metals show that $pK > 10$ comparable to manganese(II) ions should be expected. Exchange in $[V(H_2O)_6]^{2+}$ has been studied by ^{17}O NMR:[89] $k_m^{298} = 87 \pm 4\ s^{-1}$, $\Delta H^* = 61.8 \pm 0.7\ kJ\ mol^{-1}$, $\Delta S^* = -0.4 \pm 1.9\ J\ mol^{-1}\ K^{-1}$ and $\Delta V^* = -4.1 \pm 0.1\ cm^3\ mol.^{-1}$ This negative volume of activation was evidence of an associative interchange mechanism.

On reducing V_2O_5 in sulfuric acid by electrolysis, sodium amalgam or zinc, $[V(H_2O)_6]SO_4$ may be isolated, isomorphous with zinc sulfate. Tutton's salts are double sulfates $M_2[V(H_2O)_6](SO_4)_2$ ($M = NH_4^+$, K^+, Rb^+, Cs^+); in $(NH_4)_2[V(H_2O)_6](SO_4)_2$, the $[V(H_2O)_6]^{2+}$ have mean V—O of 2.15 Å.[90]

Several hydrated halides have been prepared[91] by dissolving V_2O_5 in acid (hydrochloric, hydrobromic or hydroiodic) and reducing by electrolysis: $[V(H_2O)_6]X_2$ (X = Br or I), $[V(H_2O)_4X_2]$ (X = Cl, Br or I) and $[V(H_2O)_2X_2]$ (X = Cl or Br). The hexa- and tetra-hydrates are magnetically dilute, with moments near the spin-only value and invariant with temperature. On the other hand, the dihydrates have moments which indicate a polymeric structure.

33.3.5.2 Alcohols and ethers

Green $[V(MeOH)_6][V(CO)_6]_2$ was prepared by reacting methanol with $[V(CO)_6]$.[92] Vanadium(II) chloride methanolates were prepared by electrolytic reduction of VCl_3 in methanol.[93] The hexasolvated vanadium(II) complex was converted to tetrakis and bis methanolates by careful heating. $[VCl_2(MeOH)_2]$ has μ_{eff} lower than the spin-only value and a polymeric structure (with Cl bridges) may be assumed.[94] In $[V(MeOH)_6]Cl_2$, the VO_6 unit has almost ideal octahedral geometry with average V—O 2.132(3) Å.[95] The electronic spectrum confirms a slightly weaker field for methanol compared to water. An alternative route[66] for vanadium(II) alcoholate synthesis involved treatment of ethanolic solutions of hydrated vanadium(II) salts with triethyl orthoformate. Several solids were isolated ($VBr_2 \cdot 6EtOH$, $VCl_2 \cdot 4EtOH$, $VCl_2 \cdot 2EtOH$).

The V^{II} cation in $[V(THF)_4][V(CO)_6]_2$ was shown to have octahedral coordination:[96] four THF molecules are in a planar array with V—O 2.170 Å. The axial positions are occupied by oxygen atoms of the two hexacarbonylvanadate(−I) anions with V—O(CO) 2.079 Å.

33.3.5.3 β-Diketones

A basic solution with a large excess of acetylacetone is strong blue. Complexes have been studied ($\log \beta_1 = 5.383$, $\log \beta_2 = 10.189$, $\log \beta_3 = 14.704$). A potential of −1.0 V *vs.* SHE was measured for the reduction of the V^{III} tris complex.[84] Mixed complexes $V(L)_2(py)_2$ (L = acac, trifluoroacetylacetonato or dibenzoylmethanato) isolated from solutions containing VSO_4 and the appropriate ligand[97] show intense absorption in the region 700–300 nm.

33.3.5.4 Oxalate and carbonate

$V(C_2O_4)\cdot 2H_2O$ may be obtained[98] from VCl_2 solution and sodium oxalate or oxalic acid; its thermal decomposition under a CO_2 atmosphere (~3000 bar) was shown[99] to occur at 262 ± 2 °C and by 280 °C the conversion into V_2O_3 is complete. The vanadium(II) carbonate was prepared from a VSO_4 aqueous solution and Na_2CO_3.[99] Amorphous $VCO_3\cdot 2H_2O$ was isolated. When this was heated in CO_2 (~3500 bar), the water content was lowered and crystalline products were obtained.

33.3.6 Halides

A compound obtained from reduction of VCl_3 by zinc metal in THF was shown to be $[V_2(\mu\text{-}Cl)_3(THF)_6]_2[Zn_2(\mu\text{-}Cl)_2Cl_4]$. Its structure has been determined at −105 °C[100,101] and −160 °C[102] avoiding the extensive and detrimental disorder in the THF ligands. Figure 7 shows the $[V_2(\mu\text{-}Cl)_3(THF)_6]^+$ ion. At −105 °C, the mean V—Cl and V—O distances are 2.478(3) and 2.147(7) Å. The V—V (2.99 Å) corresponds to some interaction, and antiferromagnetic behaviour was observed with an exchange integral $-J = 75\ cm^{-1}$. The visible spectra in dichloromethane with a few drops of THF show a strong sharp doublet at *ca.* 25 000 cm^{-1},[101] assigned as a double spin-flip transition of the coupled pair of V^{2+} ions.

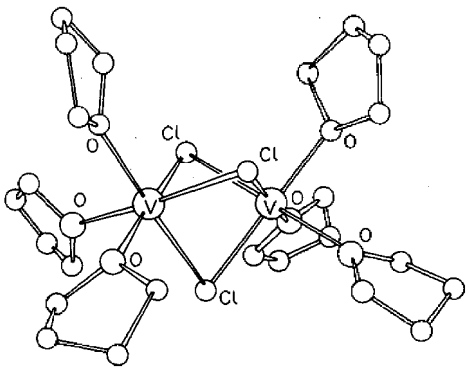

Figure 7 Structure of the $[V_2(\mu\text{-}Cl)_3(THF)_6]^+$ cation[101–102]

Vanadium(II) dihalides and complex halides are prepared by high temperature dry routes. The preparation, structure and properties were reviewed.[103] Blue crystals of VF_2 have a rutile-type structure: the V—F distances (2.073 and 2.092 Å) are near the sum of the ionic radii.[104,105] Complex fluorides MVF_3 (M = Na, K or Rb) have been obtained from VF_2 and the appropriate fluoride by heating at 1200 °C and separating the crystals by means of a microscope[106] or heating at 800 °C and treating the crystals with dilute acid solution.[107] $NaVF_3$ has a distorted perovskite-type structure[106,107] and KVF_3 and $RbVF_3$ have a cubic structure of the ideal perovskite type.[107] By replacing some V^{2+} ions by V^{3+} in KVF_3, new compounds having the general formula $K_xV^{II}_xV^{III}_{1-x}F_3$ or K_xVF_3 may be isolated,[108,109] with structures similar to the potassium tungsten bronzes.

VCl_2 can be prepared by such methods as reduction of VCl_3 with hydrogen at 675 °C,[110] or the mixing of stoichiometric quantities of VCl_3 and V powder in a quartz tube under vacuum and slowly heating to 800 °C.[111] Crystals have a CdI_2-type structure.[112]

Using dry high temperature procedures, several complexes have been isolated: $KVCl_3$,[98,113] $CsVCl_3$,[98,113] NH_4VCl_3[114] and $TlVCl_3$.[114] $RbVCl_3$ has been obtained by careful dehydration of $RbVCl_3\cdot 6H_2O$.[115] All these have $CsNiCl_3$-type structures[98,113–115] with a slightly distorted octahedron of chloride ions.

VBr_2 can be prepared by reduction of VBr_3 with hydrogen[116] and VI_2 by reaction of stoichiometric amounts of the elements at 160 °C.[116] The diiodide may form black crystals by using an excess of iodine but red crystals are obtained by sublimation at 750 °C with vanadium in excess.[117] The dibromide[118] and the red form of vanadium diiodide[117] have structures of the CdI_2 type while the black form of VI_2 exhibits a $CdBr_2$-type structure.[117] The complexes $CsVBr_3$[113] and $CsVI_3$,[119] prepared by heating stoichiometric amounts of dihalide and the Cs halide at 700 °C in sealed quartz tubes, have structures similar to the chloride complexes (*i.e.*

$CsNiCl_3$-type). Table 6 summarizes results on electronic spectra. The three spin-allowed transitions are usually observed and extensive vibrational contribution has been observed in single crystal spectra.[120,121] Intense spin-forbidden transitions may also be observed[122] due to exchange interactions in the solid phase. The diiodide[123,124] and the complex halides[121] show trigonal distortion.

The magnetic properties have been studied by means of magnetic susceptibility and specific heat measurements; some results are in Table 7. In VF_2 there are strong exchange interactions (antiferromagnetic) between the vanadium atoms.[104,125] In the lamellar dihalides (VCl_2, VBr_2 and VI_2), the predominant interactions take place between atoms in the same plane. There are relatively strong antiferromagnetic interactions at low temperature, which decrease from the chloride to the iodide.[118] In the complex fluorides there are strong antiferromagnetic interactions due to superexchange couplings between the vanadium ions. The vanadium(II) complex halides of the $CsNiCl_3$ type (chloride, bromide and iodide) do not obey the Curie–Weiss law. The molar susceptibilities are weak and increase significantly from chloride to iodide. The strongly negative antiferromagnetic interactions in these halides result from either direct t_{2g}–t_{2g} or superexchange t_{2g}–t_{2g}–t_{2g} and e_g–s–e_g coupling.[113,126]

33.3.7 Macrocyclic Ligands

By reacting the appropriate halide with the ligand in anhydrous DMF, VLX_2 (L = Me_2[14]aneN$_4$, X = Cl; L = Me_6[14]aneN$_4$, X = Cl, Br, I) were obtained.[127] All have moments close to spin-only, the reflectance spectra can be interpreted assuming a tetragonally distorted octahedral structure, and the IR spectra confirm that the ligands adopt a planar arrangement of the four nitrogen atoms, the halides occupying the *trans* axial positions.

The chemistry of vanadium porphyrins has been reviewed.[128] Reduction of dihalogenovanadium(IV) porphyrins produced the corresponding vanadium(II) complexes *trans*-[V(por)L_2] (por = OEP, TPP, TpTP, TmTP; L = THF, $PPhMe_2$). The structures of [V(OEP)$(THF)_2$] and [V(OEP)$(PPhMe_2)_2$] have been determined.[129] In both, the vanadium is in the plane defined by the four porphyrin nitrogens and V—N are 2.051(4) Å in [V(OEP)$(PPhMe_2)_2$] and 2.046(4) Å in [V(OEP)$(THF)_2$]. V—O in the THF complex is 2.174(4) Å and the V—P bond in the phosphine complex is 2.523(1) Å, comparable with lengths of V—O in other THF complexes (Sections 33.3.5.2 and 33.3.6) and V—P in complexes with diphosphine ligands (Section 33.3.4).

33.3.8 Vanadium(II) as Reducing Agent

Vanadium(II) has been the reducing agent for a large variety of organic and inorganic substrates and both aqueous and nonaqueous solutions have been used. The solutions of vanadium(II) can be conveniently obtained by electrolysis (Section 33.3.5), from reduction of V_2O_5 with zinc metal[130] and by reduction of VCl_3 with lithium tetrahydroaluminate in anhydrous THF.[131]

The reduction of organic compounds by low valent metals has been reviewed[132] and Table 8 shows examples for vanadium(II). Vanadium acts as a one-electron reducing agent and usually the reactions involve the formation of organic radicals. For instance,[133] [$VCl_2(py)_4$] was rapidly oxidized by several aryl and alkyl halides RX to vanadium(III) and an almost quantitative yield of R—R obtained. Initial attack on the V^{II} complex by the aralkyl halide *via* an outer-sphere mechanism probably forms a radical which rapidly reacts with a further V^{II} yielding an aralkyl vanadium(III) intermediate. The coupled products are formed by oxidation of this by another molecule of RX. The reduction of organic radicals has also been studied: the rapid reduction of methyl radical by vanadium(II) was observed[134] in the reaction of V^{2+} with hydrogen peroxide and Me_2SO: methane (~25% based on the amount of H_2O_2) was formed with traces of ethane (<2%). The formation of methane was assumed to occur according to Scheme 3.

The oxidation of hexaaquavanadium(II) by aliphatic radicals has been studied by kinetic competition based on the homolytic decomposition of organopentaaquachromium(III) cations.[135] $[V(H_2O)_6]^{2+}$ is oxidized to V^{3+} by organic radicals such as ·CMe_2OH or ·CHMeOEt with formation of Me_2CHOH and Et_2O respectively. The rate constants measured for the reactions were 2.1×10^5 (3.6×10^4 in 92% D_2O) and 5.9×10^4 $M^{-1}s^{-1}$. Two mechanisms have been suggested:[134,135] either the formation of a seven-coordinate organovanadium intermediate or the direct abstraction of a hydrogen atom from a water molecule coordinated to a vanadium(II) ion.

33.3.8.1 The reduction of N_2 and related compounds

Shilov and collaborators discovered[136] considerable yields of hydrazine and ammonia when dinitrogen reacts with a suspension of freshly prepared V^{II} and Mg^{II} hydroxides. The magnesium is essential and yields of hydrazine and ammonia depend on temperature, pH, dinitrogen pressure and solvent (Scheme 4). The system has been used to reduce acetylene to ethylene and ethylene to ethane.[137] Shilov and collaborators assumed a multinuclear structure for the centre where N_2 reduction occurs and suggested the mechanism shown in Scheme 5.

An alternative explanation by Schrauzer and collaborators[138,139] assumes mononuclear vanadium(II) as a two-electron reductant: dinitrogen would be reduced in a first step to N_2^{2-}. N_2 and hydrazine would be obtained by disproportionation of N_2H_2 (diazene), inside the $Mg(OH)_2$ lattice, which would protect the diazene from rapid decomposition to the elements. On reducing acetylene in deuterated media, the resulting ethylene was exclusively *cis*.[139]

Solutions of vanadium(II) complexes of catechol (1,2-dihydroxybenzene) can reduce

Table 8 Examples of Reductions of Organic Compounds by Vanadium(II) Ions

$$6V(OH)_2 + N_2 + 6H_2O \longrightarrow 6V(OH)_3 + 2NH_3$$

Scheme 4 Dinitrogen reduction by vanadium(II) hydroxide

Scheme 5 Mechanism suggested for the reduction of dinitrogen by the suspension of freshly prepared V^{II} and Mg^{II} hydroxide

dinitrogen to ammonia in the pH range 8.5–13.5.[140] There is parallel reduction of solvent with dihydrogen evolution. The yield of NH_3 increases with the dinitrogen pressure up to 75% of the reducing agent: the other 25% are used in the simultaneous reduction of the solvent. In the limit, the stoichiometry of the reaction is as shown in equation (2), which is remarkable as the same stoichiometry is found in the biological fixation of dinitrogen (catalyzed by nitrogenase). This vanadium system has other similarities with the biological systems: (i) carbon monoxide is also reduced[141] and inhibits the formation of ammonia but not of dihydrogen;[142] (ii) acetylene is reduced to ethylene, and *cis*-deuteroethylene is obtained from C_2D_2;[143] (iii) if the reaction is stopped, there is an intermediate from which hydrazine can be obtained by acid.

$$8V^{2+} + N_2 + 8H_2O \longrightarrow 8V^{3+} + 2NH_3 + H_2 + 8OH^- \quad (2)$$

$$\frac{d[V^{(II)}]}{dt} = k_1[V^{(II)}]^2[N_2] + k_2[V^{(II)}]^{1/2} \quad (3)$$

A spectrophotometric method was used to study[144] the rate equation (3). The first term corresponds to the reduction of dinitrogen to ammonia and the second to the reduction of the protons of solvent to H_2.

The stoichiometry (equation 2) requires eight electrons transferred from vanadium(II) ions to dinitrogen atoms (six electrons) and hydrogen atoms (two electrons) and this kinetic equation (3) was interpreted as evidence for a polynuclear structure of the transition state during the reduction of dinitrogen. An alternative mechanism was suggested.[145]

For several α,ω-dicarboxylates and polymeric carboxylates the highest yield of hydrazine was found for $—O_2C(CH_2)_nCO_2—$ with $n = 5$ or 6.[146]

The most important contributions to studies of these reactions came from the groups of Schrauzer[147] and Shilov;[148] there has been a long controversy about the mechanism.

Aprotic media containing vanadium as the reducing species have also been proposed for dinitrogen reduction. Combinations of $[VO(acac)_2]$ with organometallic compounds (EtMgBr, Bu^nLi, Bu^i_3Al) react with dinitrogen.[149] On reacting VCl_3 in THF with Mg under N_2, nitrogen-containing complexes were found and it was suggested that the reduction occured *via* Scheme 6.[150] The reducing species is divalent. However, for $[VCl_3]$ or $[VCl_4]$ in THF with an excess of Li(naphthalenide)[151,152] and Li_2(naphthalenide),[153] ESR experiments suggested that V^I or V^0 may be responsible. $[VCl_4]$ with Mg under dinitrogen gave a reaction similar to that with $[VCl_3]$.[150] After the dinitrogen fixation, the atmosphere was replaced by carbon dioxide and one molecule was fixed per vanadium: $[(THF)_3Cl_2Mg_2OV(NCO)]$ precipitated.[154] The reaction of trimethylchlorosilane with lithium in THF in the presence of VCl_3 under an N_2 atmosphere leads to tris(triethylsilyl)amine.[155]

$$\{V\}_2 + N_2 \rightleftharpoons \{VN_2V\}$$

$$\{VN_2V\} \xrightarrow{Mg} \{VN_2V\}\,(Mg) \xrightarrow{3Mg} \begin{cases} V_2N_2Mg_4Cl_4(THF)_2 \\ \text{or} \\ VNMgCl_2(THF) \end{cases}$$

Scheme 6 Mechanism suggested for the reduction of dinitrogen by VCl_3 and Mg in THF

33.3.8.2 The reduction of H_2O, H_2O_2 and O_2

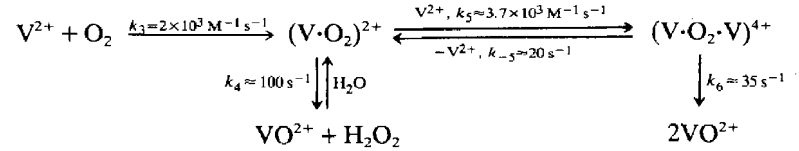
$V(OH)_2$ is a strong reducing agent and freshly prepared $V(OH)_2$ reacts with water with dihydrogen evolution. In acidic solution, reduction of water may be induced by UV radiation.[138] From solutions containing complexes with catechol there is evolution of dihydrogen with simultaneous oxidation of the metal to vanadium(III). The reaction is first order in vanadium(II) and autocatalytic (Scheme 7).[145]

$$V^{II}(pyrocat) + H^+ \longrightarrow \left[—V—H\right] \xrightarrow{H^+} \left[—V—H---H^+\right] \longrightarrow V^{IV}(pyrocat) + H_2$$

$$V^{IV}(pyrocat) + V^{II}(pyrocat)_n \longrightarrow 2V^{III}(pyrocat)$$

Scheme 7 Mechanism suggested for the reduction of water by $V^{(II)}$ pyrocathecolate complexes

Dihydrogen evolves from vanadium(II)-cysteine at pH 6.0–9.5. This reduction is first order in V^{II} and independent of pH in the range 7.5–8.5. If cysteamine or cysteine methyl ester is used, dihydrogen is still evolved. The reaction with serine is 1000 times slower than with cysteine even though the half wave potentials are comparable.[156] This reaction may be explained by a hydride pathway similar to that proposed for catechol complexes or alternatively Scheme 8.



$$H^+ + H\text{—}V^{IV}(cys)_n \xrightarrow{fast} H_2 + V^{IV}(cys)_n$$

$$V^{II}(cys)_m + V^{IV}(cys)_n \longrightarrow 2V^{III}(cys)_n$$

Scheme 8 Alternative mechanism suggested for the reduction of water by V^{II} cysteinato complexes

The reduction of H_2O_2 was studied[157] by stopped flow confirming evidence for a one-electron path.[158] A Fenton-type mechanism is likely.[134]

The reaction with oxygen was studied[157] by stopped flow; the results and mechanism are in Scheme 9.

Scheme 9 Kinetics and mechanism of oxidation of vanadium(II) by molecular oxygen

A polymeric Schiff base complex gave reversible dioxygen addition:[159] the oxygen could be liberated in vacuum and above 200 °C.

33.3.8.3 The reduction of metal complexes

There are examples of outer and inner sphere mechanisms.[160] Many cobalt(III) complexes have been substrates. For halogenopentaamminecobalt(III), the rate constants ($k_F = 3.95$, $k_{Cl} = 10.2$, $k_{Br} = 30.0$, $k_I = 127\ M^{-1}\ s^{-1}$) show a systematic trend.[161] Comparisons with the outer-sphere reductant hexaammineruthenium(II) (k_{Ru})[162] or with $Cr(bipy)_3^{2+}$ (k_{Cr})[161] show linear correlation (equations 4 and 5).

$$\log k_V = 0.89 \log k_{Ru} - 0.64 \quad (4)$$

$$\log k_V = 1.18 \log k_{Cr} - 6.1 \quad (5)$$

The reduction of carboxylatopentamminecobalt(III) complexes by vanadium(II) is predominantly inner-sphere.[163] From $[Co(en)(C_2O_4)_2]^-$ and $[Co(C_2O_4)_3]^{3-}$, $V(C_2O_4)^-$ and V^{3+} ions are primary products.[164] For N-bonded glycinato- and β-alaninato-pentaamminecobalt(III), there is an intermediate with V^{II} attached to the unprotonated carboxylate group.[165]

The reduction of diamminebis(dimethylglyoximato)cobalt(III) is a substitution-controlled inner-sphere process while the monohalogeno complexes (amminebromo and amminechloro) react by an outer-sphere mechanism.[166] The activation entropies are -46.0 ± 1.7, -129.7 ± 1.7 and $-137.7 \pm 1.7\ J\ K^{-1}\ mol^{-1}$. In the cationic cobaloximes $[Co(HDMG)_2L_2]^+$ (L = $EtNH_2$, $PhNH_2$, py or 3,5-Me_2py), a plot of $\Delta G^{\neq}$ *vs.* $E_{1/2}$ illustrates progression from inner- to outer-sphere mechanism (Figure 8). $[Co(HDMG)_2(NH_3)X]$ (X = N_3^-, NCS) have $\Delta S^{\neq}$ values of -73.0 ± 3.0 and $48.6 \pm 4.0\ J\ K^{-1}\ mol^{-1}$.[167]

Several azidoammines react *via* inner-sphere pathways, except *trans*-$Co(NH_3)_4(H_2O)(N_3^-)^{2+}$ ($k \approx 100\ M^{-1}\ s^{-1}$).[168]

Some reactions with cobalt(III) complexes show autocatalysis by the unbound ligand released during the primary reaction,[169] *via* reduction to a radical, Lig·, which reduces another cobalt(III) and regenerates the ligand (Scheme 10).

Tris(picolinato)vanadate(II) reduces $[Co(edta)]^-$, $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$ and $[Co(sep)]^{3+}$ (sep = sepulchrate) with second-order rate constants of 7.7×10^4, 8.0×10^3, 8.2×10^2 and 8.4×10^4.[170] $k_{11} = 3.1 \times 10^6\ M^{-1}\ s^{-1}$ for self exchange of $V(pic)_3^{0/-}$,[170] eight orders

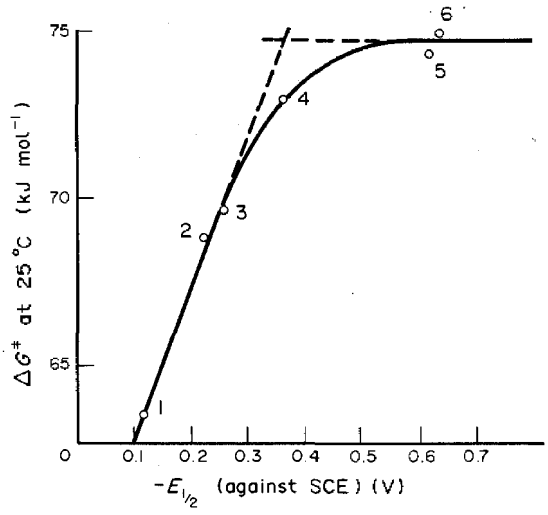


Figure 8 Free energy for the $V^{2+}(aq)$ reduction of cobaloximes $[Co(HDMG)_2LL']$ compared with their polarographic reduction

$$\text{Lig} + V^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Lig}\cdot + V^{3+}$$

$$\text{Lig}\cdot + Co^{III}\text{ complex} \xrightarrow{k_2} \text{Lig} + Co^{II}\text{ complex}$$

Scheme 10 Mechanism of the autocatalysis observed in the reduction of cobalt(III) complexes by vanadium(II)

of magnitude larger than for $[V(H_2O)_6]^{3+/2+}$ but comparable to $[V(bipy)_3]^{3+/2+}$; a more difficult rearrangement is associated with electron transfer for $[V(H_2O)_6]^{3+/2+}$.

The reduction of platinum(IV) complexes involves two one-equivalent changes $Pt^{IV} \rightarrow Pt^{III} \rightarrow Pt^{II}$; the first step is rate-determining. Second-order rate constants with vanadium(II) (k_V) and with hexaammineruthenium(II) (k_{Ru}) show linear correlation (equation 6).[171]

$$\log k_V = 0.89 \log k_{Ru} - 1.68 \tag{6}$$

A wide variety of microorganisms synthesize powerful iron(III) chelators (siderophores). Their reduction (ferroxamine B, ferrichrome and ferrichrome A) has been studied.[172]

33.3.9 Biological Dinitrogen Fixation

The isolation of a vanadium nitrogenase suggests that vanadium may have a more important role in the nitrogen cycle than was recognized.[173] This vanadium enzyme may have similarities with the chemical systems described in Section 33.3.8.1.

33.4 VANADIUM(III)

33.4.1 Introduction

Vanadium(III) compounds are usually prepared from V^V or V^{IV} by electrolytic reduction; many complexes were prepared using VCl_3 as starting material. Usually, vanadium(III) complexes are unstable towards air or moisture and have to be prepared under an inert atmosphere. Many have octahedral coordination and their electronic spectra are typical of d^2 ions with three spin-allowed d–d transitions:

$$\nu_1 = {}^3T_{2g}\,(F) \longleftarrow {}^3T_{1g}\,(F)$$
$$\nu_2 = {}^3T_{1g}\,(P) \longleftarrow {}^3T_{1g}\,(F)$$
$$\nu_3 = {}^3A_{2g}\,(F) \longleftarrow {}^3T_{1g}\,(F).$$

Usually, the third band is not observed as it is weak and frequently masked by charge-transfer transitions.

33.4.2 Cyanide and Isocyanide

Several procedures for the preparation of cyanide complexes have been reported. The heptacyanovanadate(III) ion has been shown to be a pentagonal bipyramid from a crystallographic study of $K_4V(CN)_7 \cdot 2H_2O$.[174,175] The averaged V—C distance is 2.15(1) Å, and there is no significant difference between the equatorial and the axial V—C distances. The coordination number seven is unusual in complexes of monodentate ligands. The crystal field stabilization energy cannot explain the pentagonal bipyramidal geometry as a cubic configuration has a nearly equivalent stabilization energy.[176]

The observed structure has been rationalized in terms of the 'nine-orbital' or the '18-electron' rule.[175] The two electrons of the paramagnetic $[V(CN)_7]^{4-}$ ion ($\mu_{eff} = 2.8$ BM) will occupy two degenerate orbitals of the metal ($3d_{xz}$ and $3d_{yz}$) and the seven orbitals of the ligands containing the donated electrons achieve the 'nine orbitals' of the rare gas krypton. A molecular orbital treatment of this species also suggested large interactions between orbitals on adjacent equatorial ligands not encountered in octahedral symmetry.[177]

A monohydrate[60] of $K_4[V(CN)_7]$ and the preparation of the anhydrous material have also been reported.[178] The geometry of the anions in all cases has been suggested to be the same.[179] The IR spectrum of the dihydrate shows two bands (2100 and 2070 cm^{-1}) similar to those in solution (2104 and 2027 cm^{-1}). Therefore the anion in solution must be $[V(CN)_7]^{4-}$ with a pentagonal bipyramidal geometry. Attempted studies[179,180] of the ESR spectrum have been unsuccessful due to the disproportionation products: $[VO(CN)_5]^{3-}$ and $[V(CN)_6]^{4-}$.

The energy ordering of the $3d$ metal orbitals is $d_{xz}, d_{yz} < d_{x^2-y^2}, d_{xy} < d_{z^2}$ predicted in a crystal field approach[181] or by a molecular orbital treatment.[176] $K_4[V(CN)_7] \cdot 2H_2O$ in a Nujol mull at liquid nitrogen temperature shows[185] three absorption bands at 20 600, 22 800 and 28 600 cm^{-1},[181] assigned as $^3A_2' \rightarrow {}^3E_2''$, $^3A_2' \rightarrow {}^3E_1[(e_1'')(e_2')]$ and $^3A_2' \rightarrow {}^3A_1''[(e_1'')(a_1')]$.

VCl_3 treated with Bu^tNC produces *mer*-$[VCl_3(CNBu^t)_3]$. The structure was determined by X-ray diffraction.[182] The ^1H NMR spectra in $CDCl_3$ showed that the free ligand exchanges more rapidly with the isocyanide *trans* to chloride than with the *trans* isocyanide groups. Therefore, the kinetic *trans* effect of chloride ion is larger than that of isocyanide.

33.4.3 Nitrogen Ligands

33.4.3.1 Ammonia, amines and amides

On reaction of ammonia with vanadium(III) halides there is ammonolysis of one V—X bond. The amidohalides $VX_2(NH_2) \cdot nNH_3$ (X = Cl[62,183] or Br,[183,184] $n = 4$–5) have an ammonia content that depends on the temperature. A similar compound $V(NCS)_2(NH_2) \cdot 4NH_3$ has been prepared from $V(NCS)_3$ in THF with NH_3.[185] These amidohalides are polymeric.[6,185]

VCl_3 with primary amines gave similar derivatives containing one coordinated amide and one or more molecules of amine,[64] but ethylenediamine[186,187] and propylenediamine[186] give $[V(L)_3]Cl_3$ (L = en, pn). These are isomorphous with the chromium(III) complexes; the chlorine atoms are ionic, and the cations are tris-bidentate.

Tetrahedral blue-black compounds $[VL_4](SCN)_3$ (L = en or Me_4en) were prepared[188] from $K_3[V(NCS)_6]$ and their electronic spectra are comparable to other tetrahedral vanadium(III) complexes with substituted pyridines (see Section 33.4.3.2).

$VCl_3(NMe_3)_2$ reacts in benzene with lithium bis(trimethylsilyl)amide to give $[V\{N(SiMe_3)_2\}_3]$.[189] Similarity of spectroscopic properties led to the suggestion of a trigonal structure similar to that of the iron(III) complex.[190] The complex is paramagnetic ($\mu_{eff} = 2.38$ BM) but shows no electron paramagnetic resonance. Bands at 19 200, 15 900 and 12 000 cm^{-1} have been assigned to d–d transitions.[191]

On reacting vanadium(IV) chloride or vanadium(III) bromide with trimethylamine $VX_3(NMe_3)_2$ (X = Cl or Br) were obtained.[192] The driving force for the reduction of $[VCl_4]$ is the formation of $VCl_3(NMe_3)$.[193] This chocolate brown compound has been isolated from the solution remaining after extraction of the pink-mauve $[VCl_3(NMe_3)_2]$ whose structure has been determined and as shown in Figure 9 is a trigonal bipyramid.[194]

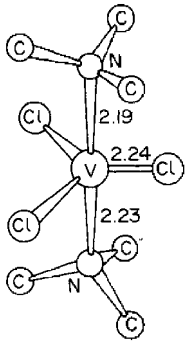

Figure 9 Structure of $[VCl_3(NMe_3)_2]$[194]

The electronic spectra of these bipyramidal species are more complex than the related octahedral chromophores and two characteristic spin-allowed bands are predicted in the near IR region: $^3A_2' \rightarrow {}^3A_1'', {}^3A_2''$ and $^3A_2' \rightarrow {}^3E''$ respectively at 4900 and 7100 cm^{-1} in $[VCl_3(NMe_3)_2]$.[195] In benzene, it decomposes irreversibly to $V_2Cl_6(NMe)_3$ with a second-order rate constant of 0.0166 l mol^{-1} s^{-1}.[196] The IR spectrum shows V—Cl terminal and bridging bands and the magnetic moment (2.55 BM) is significantly smaller than for a magnetically dilute vanadium(III) complex.

33.4.3.2 N-heterocyclic ligands

Complexes $V(L)Cl_2 \cdot 2EtOH$ (LH = guanine)[197] and $V(LH)L_2Cl \cdot EtOH$ (LH = purine or adenine)[198] have been isolated after refluxing VCl_3 with the ligand in a mixture of ethanol and triethyl orthoformate.

$VCl_3(py)_3$ has been prepared[187,199] and binding energies measured by ESCA:[200] 514.1 (for V $2p^{3/2}$ level), 196.7 (for Cl 2*s*) and 398.0 eV (for N 1*s*). On reacting $K_3[V(NCS)_6]$ in Pr^iOH with pyridine or alkylpyridines, tetrahedral blue-black compounds $[VL_4](SCN)_3$ have been isolated although they were unstable,[188] forming the corresponding octahedral complexes by liberating amine on rearrangement. Their spectra have been studied.[201] For example, $[V(py)_4](NCS)_3$ has three bands at 9500, 16 200 and 25 000 cm^{-1} assigned as $^3A_2 \rightarrow {}^3T_2$, $^3A_2 \rightarrow {}^3T_1(F)$ and $^3A_2 \rightarrow {}^3T_1(P)$.

A similar preparative procedure was used to isolate tetrahedral complexes of bidentate donors (L = bipy or phen) $[VL_2](SCN)_3$. However, complexes of vanadium(III) chloride or bromide with these same bidentate donors have stoichiometries depending on conditions.[199] With excess of bipy or phen, complexes $[VX_2L_2]X$ were obtained. In EtOH or in MeCN two series of complexes were isolated:[202] VCl_3LL' (L = bipy or phen; L' = EtOH or MeCN) and $[VCl_2L_2]^+ + [VCl_4L]^-$. In the reaction of vanadium(III) with phenanthroline[202,203] or bipyridine[204] there is evidence for extensive hydrolysis. Spectrophotometry was used to estimate the equilibrium constant ($K_{eq} = 0.43$) for the reaction in equation (7).[203]

$$V(OH)^{2+} + 2phenH^+ \rightleftharpoons [V(OH)(phen)_2]^{2+} + 2H^+ \quad (7)$$

For $[V] > 2 \times 10^{-3}$ M, an increase in absorptivity indicates dimerization. The nature of the dimer has been discussed.[204]

33.4.3.3 Thiocyanate, selenocyanate and azide

From spectrophotometry, the formation constant of $V(NCS)^{2+}$ is $\sim 10^2$.[205] Complexes containing $[V(NCS)_6]^{3-}$ have been isolated and the structure of $K_3[V(NCS)_6] \cdot 12H_2O$ determined by X-ray diffraction,[206] confirming that thiocyanate coordinates *via* the N atom (the mean V—N distance in this complex is 2.044(2) Å).

When VCl_3 in acetonitrile reacts with ammonium thiocyanate, a progressive exchange occurs.[207] Complexes with various stoichiometries were isolated: $VCl_2(NCS) \cdot 3MeCN$, $VCl(NCS)_2 \cdot 3MeCN$, $V(NCS)_3 \cdot 5MeCN$ and $Ct_3[V(NCS)_6] \cdot 2MeCN$ ($Ct = K^+$, NH_4^+, pyH^+,

piperidinium, Ph_4P^+, $MePh_3As^+$ or Me_3S^+). Similar complexes containing bromide and thiocyanate were also isolated as well as a mixed complex of NCS^- and $NCSe^-$ formulated as $M_3[V(NCS)_3(NCSe)_3]\cdot 2MeCN$ ($M = K^+$ or Na^+). Complexes $Ct_3[V(NCSe)_6]$ ($Ct = Ph_4As^+$, Me_4N^+, Et_4N^+ or K^+) have also been prepared.[208,209]

Several azido species have been detected in acetonitrile: $V(N_3)^{2+}$, $V(N_3)_3$ and $V(N_3)_6^{3-}$.[210] $(Bu_4N)_3[V(N_3)_6]$ has been isolated.[208] As expected for octahedral V^{III}, the magnetic moments are slightly lower than spin-only values and there is a marked temperature dependence at low temperatures.[211]

33.4.3.4 *Nitriles*

Anhydrous vanadium trichloride or tribromide reacts with acetonitrile to yield green or red-brown solutions. Complexes $[VX_3(MeCN)_3]$ ($X = Cl$ or Br) crystallize with varying amounts of acetonitrile in the lattice,[212] where the IR spectra show the free (2253.5 cm^{-1}) and coordinated (2292 cm^{-1}) acetonitrile.

In acetonitrile, vanadium trichloride reacts with large organic chlorides to yield cream-yellow complexes of the type $Ct[VCl_4(MeCN)_2]$ ($Ct = Et_4N^+$, $MePh_3As^+$ or Ph_4As^+). Bromide-containing complexes have also been isolated: $(Et_4N)[VBr_4(MeCN)_2]$ and $(Et_4N)[VCl_3Br(MeCN)_2]$. The acetonitrile molecules of $(Ph_4As)[VCl_4(MeCN)_2]$ may be removed at 100 °C under vacuum.[213] Acrylonitrile and propionitrile complexes have been described.[214]

33.4.3.5 *Silazanes*

Hexamethylcyclotrisilazane, $(Me_2SiNH)_3$, and octamethylcyclotetrasilazane, $(Me_2SiNH)_4$ (shown in Figure 10 and abbreviated as HMT and OMT respectively), form octahedral complexes. VCl_3 reacted with HMT in THF to form $VCl_3(HMT)$,[215] which dissolves in dichloromethane giving a nonconducting solution. The ligand is terdentate and two V—Cl bands (at 358 and 326 cm^{-1}) confirm the facial geometry for the chlorine atoms. On reacting $[VCl_3(THF)_3]$ with OMT in benzene $[(VCl_3)_2(OMT)(THF)_2]$ was obtained,[216] with both coordinated and uncoordinated NH groups and with bridging chlorine atoms.

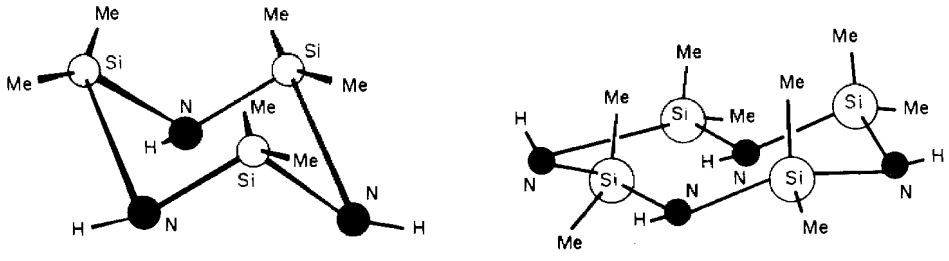

Figure 10 Formulae of silazanes: (a) hexamethylcyclotrisilazane (HMT), (b) octamethylcyclotetrasilazane (OMT)

33.4.4 Phosphines and Arsines

VCl_3 reacted with Et_3P or Pr_3P in THF to form trigonal bipyramidal $[VCl_3L_2]$.[217] $[VCl_3(Me_2PCH_2CH_2PMe_2)(THF)]$ was prepared by reaction of $[VCl_3(THF)_3]$ with ligand.[218] Five-coordinate $[VCl_3(PMePh_2)_2]$ has been synthesized from $[VCl_3(THF)_3]$ and phosphine upon reflux in benzene.[219] X-Ray diffraction has shown that the crystalline solid contains two independent but nearly identical molecules, each of them trigonal bipyramidal (Figure 11).[219]

On refluxing in THF, VCl_3 reacted with triarsines to yield red-brown complexes $[VCl_3(TAS)]$ (TAS = bis(dimethylarsinophenyl)methylarsine or 1,1,1-tris(dimethylarsinomethyl)ethane).[220] These are non-electrolytes, and the ligand is terdentate. Both have a facial structure.

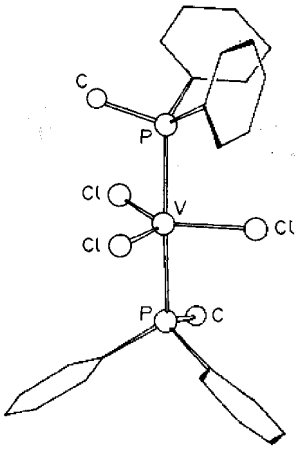

Figure 11 Structure of $[VCl_3(PMePh_2)_2]$. The V—Cl distance to the underlined atom (2.17 Å) is shorter than the average of the other V—Cl bonds (2.25 Å). Another distortion of the trigonal bipyramid is the observed P—V—P bending (166.6°). The small difference in V—P bond lengths (2.547 and 2.525 Å) has no chemical significance[219]

33.4.5 Oxygen Ligands

33.4.5.1 Aqua species, OH^-

The characterization of $[V(H_2O)_6]^{3+}$ has been done on the cesium alum $CsV(SO_4)_2 \cdot 12H_2O$[221] and on $[V(H_2O)_6](H_5O_2)(CF_3SO_3)_4$;[222] the VO_6 unit has an octahedral geometry. When hydrogen atoms of the coordinated water molecules are considered, the symmetry is lowered from O_h to D_{3d}. Two remarkable features are underlined in Figure 12: (i) the water molecules are nearly flat, *i.e.* for each coordinated water the vanadium centre, the oxygen and the two hydrogen atoms are lying in the same plane; (ii) the six hydrogen atoms of three mutually *cis* water molecules are essentially coplanar (the deviations from the mean plane are less than 0.1 Å with an average absolute deviation of 0.056 Å).

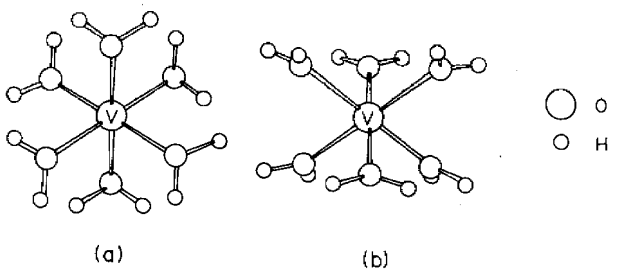

Figure 12 Structure of the $[V(H_2O)_6]^{3+}$ ion. The oxygen atoms are octahedrally coordinated with an average V—O distance of 1.995(4) Å. (a) The ion viewed down the C_3 axis; (b) a view perpendicular to the C_3 axis[222]

In the IR spectrum of the cesium alum, two bands were assigned to antisymmetric metal–ligand stretch ν_3 (532 cm^{-1}) and antisymmetric metal–ligand bend ν_4 (607 cm^{-1}),[223] and in the oriented single-crystal Raman spectrum, the totally symmetric stretching mode of the cation occurs at 525 cm^{-1}.[224]

The electronic spectra of the cesium alum and of vanadium(III) in perchloric acid solutions are very similar ($\nu_1 = 17\,800$ and $\nu_2 = 25\,700\ cm^{-1}$) and it was concluded that vanadium(III) existed as the hexaaqua ion in such solutions.[225] The coordination number six was confirmed by NMR.[226] Water exchange has been studied by ^{17}O NMR spectroscopy as a function of temperature (255–413 K) and pressure (up to 250 MPa):[227] $k_{ex} = (5.0 \pm 0.3) \times 10^2\ s^{-1}$ (at 298 K), $\Delta H^{\neq} = (49.4 \pm 0.8)\ kJ\ mol^{-1}$, $\Delta S^{\neq} = -(28 \pm 2)\ J\ K^{-1}\ mol^{-1}$, $\Delta V^{\neq} = -(8.9 \pm 4)\ cm^3\ mol^{-1}$ and the compressibility coefficient of activation $\Delta\beta^{\neq} = -(1.1 \pm 0.3) \times 10^{-2}\ cm^3\ mol^{-1}\ MPa^{-1}$.

Table 9 Data on Hydrolysis and Oxoreduction of Vanadium(III)

1. F. Brito and J. M. Gonçalves, *An. Quím.*, 1982, **78**, 104; solutions 3 M in KCl at 25 °C with total vanadium concentration in the range 0.006–0.160 M and $0 < \bar{n} < 0.85$.
2. E. L. Yee, R. J. Cave, K. L. Guyer, P. D. Tyma and M. J. Weaver, *J. Am. Chem. Soc.*, 1979, **101**, 1131; solution 0.2 M $LiClO_4$ (pH 1–1.8) at 25 °C.

The hydrolysis has been studied by potentiometric[228] and spectrophotometric[229] techniques and below pH 3.2 may be described by the reactions and equilibrium constants of Table 9.

The magnetic susceptibilities of solutions of hydrolysis products were consistent with the binuclear complex in such solutions having a double hydroxide bridge $[V(OH)_2V]^{4+}$ rather than an oxo bridge $[V—O—V]^{4+}$.[230]

The solids from systems $VX_3 + MX + HX + H_2O$ (X = Cl, Br; M = K, NH_4, Rb, Cs) depend on the concentration of the halide and on the temperature during precipitation.[231]

There was evidence for the existence of green $[V(H_2O)_4X_2]^+$ in $[V(H_2O)_4X_2]X{\cdot}2H_2O$ (X = Cl, Br), $Rb[VCl_2(H_2O)_4]Cl_2{\cdot}2H_2O$ and $Cs_2[V(H_2O)_4X_2]X_3{\cdot}nH_2O$ (X = Br, $n = 1$; X = Cl, $n = 0$). The red $[VCl_5(H_2O)]^{2-}$ may be found in $M_2[VCl_5(H_2O)]$ (M = Cs, Rb, K, NH_4) prepared by dehydration of the corresponding double salts containing the $[VCl_2(H_2O)_4]^+$ ion. The structure of *trans*-$[V(H_2O)_4X_2]^+$ has been confirmed by X-ray diffraction in $[V(H_2O)_4X_2]X{\cdot}2H_2O$ (X = Br or Cl),[232] $Cs_2[V(H_2O)_4X_2]X_3$ (X = Br or Cl)[233] and $Cs_3[VCl_2(H_2O)_4]Cl_4$.[234] The low temperature crystal electronic and IR spectra of $Cs_3[VCl_2(H_2O)_4]{\cdot}Cl_4$ have been reported.[234]

33.4.5.2 Dioxygen

Dioxygen oxidizes VCl_3 or VCl(salen) to vanadium(IV) with the intermediate formation of dioxygen adducts,[235] with equilibrium constants of the order of 10^2; they are involved in the catalysis of oxygenation of 3,5-di-*t*-butylpyrocatechol.[236]

33.4.5.3 Alcohols and ethers

VCl_3 reacted with several alcohols to form $[VCl_2(ROH)_4]Cl$ or $[VCl_3(ROH)_3]$ depending on the preparation and on the alcohol.[237] The complexes dissolved in parent alcohol behave as 1:1 electrolytes; electronic spectra are consistent with the $[VCl_2(ROH)_4]^+$ ion. The IR spectra show two V—Cl frequencies and a *cis* geometry has been suggested.[237] The fluorescence and photochemistry of the charge-transfer band in alcoholic solutions have been reported.[238]

THF and 1,2-dimethoxyethane react with VX_3 (X = Cl or Br) to form $[VX_3(THF)_3]$ and $VX_3{\cdot}1.5C_4H_{10}O_2$.[239]

A *trans* structure proposed for $[VCl_3(THF)_3]$ from the IR spectrum was confirmed by X-ray diffraction.[100] The dimethoxyethane complex loses dimethoxyethane on heating to give $VX_3{\cdot}C_4H_{10}O_2$. Both complexes of dimethoxyethane were polymeric.[239]

33.4.5.4 β-Ketoenolates and catecholate

For vanadium(III) β-diketonates the recommended preparation is reduction with the dithionite of compounds such as oxovanadium(IV) sulfate, vanadium(V) oxide or ammonium vanadate followed by the addition of the β-diketone in alcohol.[240]

$[V(acac)_3]$ crystallizes in two forms.[241] The vanadium atom is surrounded by an octahedron

of oxygen atoms with V—O lengths of 1.979 and 1.982 Å for the α and β forms. There is a slight trigonal distortion of these octahedra: the intraring OVO angles are 88.0 and 87.3° respectively.

The d–d transitions in the electronic spectrum (~18 200 and 21 700 cm^{-1} in solution in ethanol) are difficult to locate as they occur as shoulders on a strong charge-transfer band.[242] Molecular orbital calculations were used in the interpretation of the spectra of $[V(acac)_3]$;[243] charge-transfer and Rydberg transitions may contribute at energies higher than 40 000–50 000 cm^{-1}. The He-I photoelectron spectra of $[V\{(CF_3CO)_2CH\}_3]$ have been studied to elucidate the energies of the metal d and ligand orbitals.[244] Based on core binding energies,[245] the metal d orbitals are not involved in bonding.

Raman spectra of $[V(acac)_3]$ suggest that the contributions of dative π bonding should be small.[246] In IR spectra, the shifts of ν(M—O) bands were related to the electronic effects of the substituents.[247]

NMR techniques are suitable for the study of solutions containing vanadium(III) complexes. Ligand exchange is catalyzed by acids and inhibited by bases.[248] The facial and meridional isomers of complexes with unsymmetrically substituted ligands (*e.g.* 1,1,1-trifluoroacetylacetone) could be detected.[249] The same technique was used in the study of the stereochemistry and rearrangement of tris(β-diketonato) complexes[250] as well as those of the related ligands dehydroacetic acid, methyl acetoacetate and ethyl acetopyruvate.[251] In many systems, measured *fac*/*mer* ratios were smaller than the statistical 1:3. The rearrangement (isomerization) in a number of diketonate complexes is intramolecular, but the NMR data are consistent with twisting or bond rupture.[248] However, a bond breaking mechanism should be catalyzed by acid and such catalysis was not observed.

The β-diketonates are usually thermally stable and may be fused or volatilized with little or no decomposition. These complexes were tested by gas–liquid chromatography without evidence for on-column degradation.[252] However, some retention of fluorodiketonato complexes was due to reaction in the stationary phase or with active sites.[253] The sublimation enthalpy of tris(trifluoroacetylacetonate)vanadium(III) is 118 ± 2 kJ mol^{-1} and the evaporation enthalpy is 77.8 ± 0.8 kJ mol^{-1}.[254] At 300–470 °C there is decomposition of $[V(acac)_3]$; acetone, CO and CO_2 are the products.[255]

$K_3[V(catecholate)_3]\cdot 1.5H_2O$ has been synthesized from VCl_3 and catechol in ammonia solution, on adding a solution of KOH. The vanadium is surrounded by six oxygen atoms of catecholate ions: the average V—O bond length is 2.013(9) Å.[256] A tris(*o*-semiquinone)vanadium(III) complex[257] from $V(CO)_6$ and quinone was better formulated as bis(catecholate)(*o*-semiquinone)vanadium(V).[256]

33.4.5.5 Oxoanions

Several complexes $[V(OR_2P{=}O)_3]_x$, $[V\{O(RO)R'P{=}O\}_3]_x$ and $[V\{O(RO)_2P{=}O\}_3]_x$ (R = alkyl or aryl) were prepared from VCl_3 and phosphinates ($R_2(RO)P{=}O$),[258] phosphonates ($R(RO)_2P{=}O$)[259] and phosphate alkyl esters ($(RO)_3P{=}O$).[260]

Tris(organoseleninate) complexes have been synthesized and, in DMF or nitromethane, are non-conducting.[261] The ligands act as bidentate *O*,*O'*-seleninate and the complexes have an octahedral configuration with D_3 symmetry.

The electronic spectrum of vanadium(III) ions in concentrated sulfuric acid with λ_{max} at 13 600 (ε = 7.8), 21 800 (ε = 11) and 29 000sh cm^{-1} has been interpreted as due to octahedral coordination.[262] The solid methyl sulfate $V(MeSO_4)_3$ has been isolated (μ_{eff} = 2.68 BM) as well as complexes of methyl sulfate containing three molecules of pyridine and one or two molecules of bipy.[263]

Sodium sulfinates $NaRSO_2$ (R = Me, Ph or MeC_6H_4) reacted in ethanol with VCl_3 and tris(*O*,*O'*-sulfinato) complexes were obtained.[264] The IR spectra are consistent with the sulfinato ions as bidentate. The electronic spectra show two d–d transitions: ν_1 in the range 14 700–14 930 cm^{-1} and ν_2 = 22 990 cm^{-1}.

33.4.5.6 Carboxylic acids

There have been several reports on monocarboxylate complexes although different formulae and various structures have been produced. After boiling VCl_3 with anhydrous formic acid, a

solid $V(O_2CH)_3 \cdot HCO_2H$ was isolated and at 180 °C green $[V(O_2CH)_3]$ was obtained.[265] VCl_3 and acetic acid under reflux gave a solid $V_3(OH)(O_2CMe)_8$ or $H[V_3O(O_2CMe)_8]$.[266] Later, a different formulation was proposed, $[V_3O(O_2CMe)_7(HOCMe)]_n$, *i.e.* a polymeric structure with a bridging acetate joining the $[V_3O(O_2Me)_6]$ clusters.

$[V_3O(O_2CCH_2Cl)_6(H_2O)_3]ClO_4 \cdot 3H_2O$ contains the planar V_3O group and there is no metal–metal bonding in this oxo-centered cluster.[267]

There was an earlier claim for the synthesis of $[V_2(O_2CR)_6]$ (R = Me or Ph) using vanadium diboride as starting material (equation 8).[268]

$$2VB_2 + 6RCO_2H \longrightarrow V_2(O_2CR)_6 + 3H_2 + 4B \quad (8)$$

$[VCl_3(THF)_3]$ and sodium benzoate in dichloromethane produced green $[V_3O_3(THF)(O_2CPh)_6]$, characterized by X-ray diffraction.[269]

It is likely that the oxidation to vanadium(IV) occurred during the crystallization, with intermediate trimeric vanadium(III) benzoate complexes.

Another example of a complicated polynuclear complex is an octanuclear basic benzoate containing four vanadium(III) and four zinc(II) atoms: $[VZnO(O_2CPh)_3(THF)]_4 \cdot 2THF$.[270] The crystal structure shows that the distances between these four vanadium atoms are just below 3 Å and therefore some V—V bonding may occur.

Values for the formation constants of $[V(C_2O_4)]^+$ and $[V(C_2O_4)_2]^-$ were respectively 1.6×10^7 and 3.5×10^{12}.[271] By irradiation of these solutions at 254 nm, there is a photodecomposition of the oxalate sensitized by the oxalato vanadium(III) complex; the resulting products were equimolar amounts of CO and CO_2. $K_3[V(C_2O_4)_3] \cdot 3H_2O$ can be easily crystallized from aqueous solutions containing ammonium vanadium alum and potassium oxalate. The measured magnetic moment is 2.78 BM and this compound obeys the Curie law quite closely.[272] The thermal decomposition has been studied.[273]

By adding the resolving ions (+)-$[Co(en)_3]^{3+}$ and (−)-$[Rh(en)_3]^{3+}$ to solutions of the labile $[V(C_2O_4)_3]^{3-}$ ion, the diastereoisomeric salts $[M(en)_3][V(C_2O_4)_3]$ (M = Co or Rh) have been isolated and the CD spectra were measured as dispersions in CsCl discs.[274] The ORD and CD spectra of solutions containing $[V(C_2O_4)_3]^{3-}$ could be observed by adding (+)-cinchonine hydrochloride.[275] Although $[V(C_2O_4)_3]^{3-}$ is labile, partial resolution occurs. The structure of the *trans*-diaquabis(oxalato)vanadate(III) ion has been determined in $Cs[V(C_2O_4)_2(H_2O)_2] \cdot 4H_2O$ and $(MeNH_3)[V(C_2O_4)_2(H_2O)_2] \cdot 4.5H_2O$.[276] In both, the oxalate groups are coplanar, with V—O bond lengths of 2.005(2) and 2.017(4) Å respectively.

$K_3[V(malonate)_3]$ may be prepared by a procedure similar to that of the trisoxalato complex.[272] The kinetics of ligand exchange have been studied by NMR line broadening:[277] $k_{ex} = 50\ s^{-1}$ at 70 °C.

33.4.5.7 *Hydroxy acids*

Vanadium(III) and tartaric acid (H_4t) in aqueous solution form 1:1 and 1:2 complexes with various degrees of protonation:[278] $V(H_2t)^+$, $V(H_2t)_2^-$, $V(Ht)^0$, $V(Ht)_2^{3-}$ and $V(Ht)_3^{6-}$. The formation constants of complexes 1:1, 1:2 and 1:3 were estimated by NMR relaxation in solutions containing vanadium(III) and lactic ($\beta_1 = 1.1 \times 10^2$, $\beta_2 = 2.0 \times 10^4$ and $\beta_3 = 1.8 \times 10^6$) or mandelic acids ($\beta_1 = 1.2 \times 10^2$, $\beta_2 = 2.2 \times 10^4$ and $\beta_3 = 1.5 \times 10^6$).[279] The reactions between vanadium(III) and salicylic, *p*-aminosalicylic and 5-nitrosalicylic have been studied.[280]

33.4.5.8 *Dimethyl sulfoxide and amides*

Dimethyl sulfoxide saturated with SO_2 reacts with vanadium[281] or V_2O_5[282] to form $[V(DMSO)_6](S_2O_7)_{3/2}$ which loses DMSO up to 170 °C giving $V(S_2O_7)_{3/2}$. DMSO coordinates through oxygen while the disulfate is present as an anion.[283] Earlier work reported the $[V(DMSO)_6]^{3+}$ perchlorate.[284]

Vanadium was allowed to react with bromine in DMF; $V(DMF)_6(Br_3)_3 \cdot 0.3(DMF)$ was isolated,[285] for which $10Dq = 17\,300\ cm^{-1}$.

$[V(urea)_6]I_3$ crystallizes from a solution of the sulfate on adding potassium iodide. The oxygen atoms of the urea molecules form an octahedron twisted 7° about the three-fold axis with V—O lengths of 1.98 Å.[286] The magnetic susceptibility of the iodide and perchlorate salts

of $[V(urea)_6]^{3+}$ ion and the magnetic anisotropy of the iodide have been measured. The electronic spectrum of the perchlorate has been reinterpreted.[287]

33.4.6 Sulfur Ligands

33.4.6.1 Thioethers

Vanadium trichloride or tribromide reacts with thioethers giving $[VX_3L_2]$ (X = Cl or Br; L = SMe_2, tetrahydrothiophene or SEt_2).[288,289] The complex with di-*n*-propyl sulfide could not be isolated.[288] These compounds are oxidized very easily. Solubility, molecular weights and conductance show that they are monomeric and non-ionic. Dipole moments, IR and electronic spectra are consistent with *trans* trigonal bipyramidal structures.

The similarity of properties for $[VX_3 \cdot (SEt_2)_2]$ in solution or solid indicates that the solid is also five-coordinate bipyramidal.[289]

33.4.6.2 Dithiocarbamates

$[V(S_2CNR_2)_3]$ (R = Me, Et, Pr^n or Bu^i) were obtained by oxidation of $VBr_2 \cdot 6H_2O$ with diethylammonium dialkyldithiocarbamates in anaerobic ethanol/triethyl orthoformate.[290] Complexes $[VL_3]$ and $[VClL_2]$ of cyclic substituted dithiocarbamates L (L = piperidino, morpholino, thiomorpholino and *N*-methylpiperazino) were reported;[291] their properties are consistent with bidentate dithiocarbamate.

The diethyldithiocarbamato complex is isomorphous with the iron(III) complex and must have an approximate octahedral symmetry. As expected for octahedral vanadium(III), two bands (ν_1 and ν_2) appeared in the diffuse reflectance spectra. $[V(S_2CNRR')_3]$ (RR' = MePh or BzBz) were prepared from VCl_3 and a sodium or lithium salt of the dithiocarbamate; IR spectra in CS_2 confirm the tris(bidentate chelate) coordination. By NMR,[292] two processes can be observed for $[V(S_2CNMePh)_3]$ in CD_2Cl_2: *cis–trans* isomerization causing line broadening between −89 and −61 °C and metal-centred optical inversion without *cis–trans* isomerization causing broadening below −97 °C.

33.4.6.3 Dithiolate and dithiophosphinates

Although dithiolene complexes have been known for some time (see Section 33.2.5), the first 'pure' dithiolate complexes of vanadium have only recently been characterized.[48] Structures of $(Et_4N)_2[V_2(SCH_2CH_2S)_4]$, $(Ph_4P)_2[V_2(SCH_2CH_2S)_4]$ and $(Ph_4P)_2[V_2(SCH_2CH_2S)_4] \cdot 4MeOH$ were published almost simultaneously. The three independent reports agree on the structure of the $[V_2(SCH_2CH_2S)_4]^{2-}$ ion (Figure 13). The vanadium atoms are bridged by the four S atoms of two dithiolate ions and the V—V distance (2.60 ± 0.02 Å) suggests metal–metal bonding, confirmed by the observed diamagnetic behaviour.

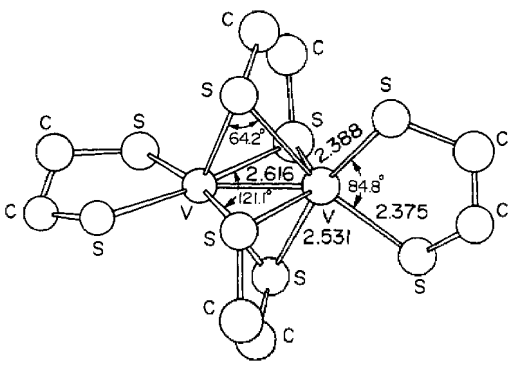

Figure 13 Structure of $[V_2(edt)_4]^{2-}$ with selected bond distances and angles

Dithiophosphinate complexes $[V(S_2PX_2)_3]$ (X = F, CF_3, Me, Ph, OEt) were reported[293] and the structure where X = OEt has been determined.[294] The six sulfur atoms form a trigonally distorted octahedron around vanadium with the average V—S distance 2.45 ± 0.02 Å. Visible spectra (in CH_2Cl_2 or an oriented crystal) show four bands: a charge-transfer band is observed at 22 700 and 23 300 cm^{-1} in the solution and crystal. The others at 12 820, 18 080 and 26 400 cm^{-1} (13 200, 18 400 and 26 400 in the crystal) are the expected transitions for octahedral V^{III}.

33.4.7 Halides

Several solvated vanadium(III) halides have been described in the previous sections and those with water, alcohol, acetonitrile or THF have been useful starting materials for the synthesis of vanadium(III) complexes.

A great number of anionic complexes containing four, five or six halide ions have been characterized. However, in aqueous solutions containing V^{III} ions and F^-, the potentiometric technique using a fluoride selective electrode has shown no indication of any complex other than VF^{2+} (stability constant: $\log \beta = 5.00 \pm 0.03$ at 25 °C in 1.0 M $NaClO_4$ solution).[295]

Salts of hexafluorovanadate can be obtained by high temperature techniques or from solutions containing hydrofluoric acid. For instance, X-ray patterns and DTA were used for the characterization of 17 double fluorides obtained by solid state reactions in the systems $VF_3 + MF$ (M = Li, Na, K, Rb, Cs, Tl) and seven double fluorides in the systems $VF_3 + MF_2$ (M = Ca, Sr, Ba, Pb),[296] and the lattice constants[297,298] and magnetic properties[298] of $A_2B[VF_6]$ (A, B = Cs, Rb, Tl, K, Na, Li) were also reported. The structure of the high temperature β phase of Li_3VF_6 has been determined and compared with the cryolite-type stable α form. The vanadium atoms have an octahedral coordination.[299]

K_3VF_6 can be obtained by reacting V_2O_5 and KI with hydrofluoric acid on a steam bath[300a] or by heating at 800 °C powdered vanadium and potassium hydrogen fluoride;[300b] the magnetic moment at 20 °C was 2.79 BM.[300a] X-Ray powder data have been given for its three solid forms.[301] Predicted transition energies[302] were compared with those observed at 10 200, 14 800 and 23 250 cm^{-1}.[303]

The standard enthalpy of formation of $K_3VF_6(c)$ is -3026 kJ mol^{-1}.[304] The calculated ligand field stabilization has been compared with those of the elements from scandium to gallium. The ligand field effect has also been discussed for the IR spectrum of $[Cr(NH_3)_6][VF_6]$ and isomorphous $[Cr(NH_3)_6][MF_6]$ (M = Sc, Ti, Cr, Mn or Fe).[305]

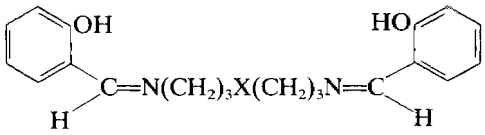
Hydrazinium fluorovanadates $(N_2H_5)_3VF_6$[306] and $(N_2H_6)VF_5$[307] and their thermal decomposition were reported.[308]

$(NH_4)_3VF_6$ can be crystallized from $VF_3 \cdot 3H_2O$ and ammonium fluoride in water.[309] It has a moment of 2.79 BM[300a] and on reaction with XeF_2 forms a V^V complex with coordination of more than six fluoride ions.[309] On thermal decomposition the final product is VF_3 at ~450 °C. There was no intermediate formation of NH_4VF_4 but a method for the preparation of this has been reported.[310]

Several studies[311,312] appeared on the phase transitions at 135, 413 and 482 K in the perovskite-type $RbVF_4$, in which vanadium is octahedrally coordinated. In $Rb[VF_4(H_2O)_2]$ the water molecules are *trans* and hydrogen bonds form chains of VF_4O_2 octahedra.[313] Complexes $M_2VF_5 \cdot H_2O$ (M = K, Rb, Cs) were precipitated from solutions containing $VF_3 \cdot 3H_2O$, HF and KF, and on heating in vacuum, M_2VF_5 (M = K, Rb, Cs) formed.[314]

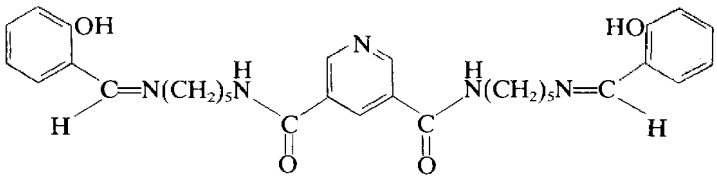
The chloride complexes have also been prepared with various stoichiometries. Green $MVCl_4 \cdot 6H_2O$ (M = K, Rb, Cs) precipitated from cold solutions (−30 to −10 °C) of VCl_3 and MCl saturated with HCl.[315] From such solutions at high temperature (100–120 °C) red $M_2VCl_5 \cdot H_2O$ (M = K, Rb, Cs) are obtained.[316]

In both solid compounds (containing large cations each as Ph_4P^+, Ph_4As^+) and in solutions $[VCl_4]^-$ has distorted tetrahedral symmetry as suggested by spectra in benzene:[317] 8300 and 9250 cm^{-1} assigned as $^3A_2 \rightarrow {}^3E$, 10 000 cm^{-1} as $^3A_2 \rightarrow {}^3A$ and 15 030 cm^{-1} ($\varepsilon = 260$) as $^3A_2 \rightarrow {}^3T_1(P)$. X-Ray powder patterns show the tetrachlorovanadates to be isomorphous with other known tetrahedral MCl_4 species and IR data suggest a distorted tetrahedral symmetry.[318] Magnetic data show antiferromagnetic interaction of the vanadium atoms; these magnetically dilute species are completely different from $(NEt_4)VCl_4$ which is similar to $(NEt_4)_3V_2Cl_9$. Therefore a polymeric structure was suggested for $(NEt_4)VCl_4$ with octahedral vanadium. Its electronic spectrum is very different from the tetrahedral complexes,[319] consistent with a distorted octahedral geometry.



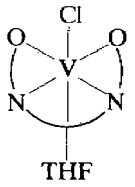
$Cs_3V_2Cl_9$ was prepared by heating a stoichiometric mixture of VCl_3 and CsCl.[320] The similarity of the powder pattern to that of the corresponding Cr complex suggests similar structures: $V_2Cl_9^{3-}$ consists of octahedra sharing a trigonal face. The moment at 300 K (2.74 BM) is consistent with little metal–metal interaction.

Green crystals of $Ct_2VBr_5{\cdot}5H_2O$ (Ct = Rb, Cs, Hpy) were prepared in hydrobromic acid[321] and, on thermal decomposition, successively dehydrated *via* $Ct_2VBr_5{\cdot}3H_2O$ and $Ct_2VBr_5{\cdot}H_2O$ to the corresponding anhydrous Ct_2VBr_5 (Ct = Rb, Cs, Hpy).



33.4.8 Mixed Donor Atom Ligands

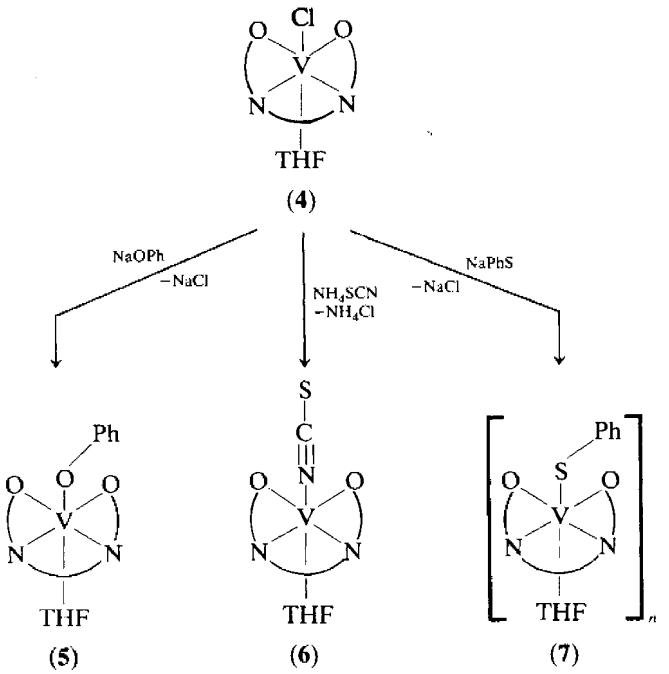
33.4.8.1 Schiff bases



By allowing salen to react with anhydrous VCl_3 in pyridine under high purity nitrogen, a brown solid formulated as [VCl(salen)(py)] precipitated.[235] The geometry is probably octahedral with Cl^- and py *trans*.[322] Conductance showed it to be a 1:1 electrolyte. Oxidation with O_2 resulted in the corresponding VO^{2+} compound, [VO(salen)(py)], *via* a dioxygen adduct (Section 33.4.5.2). Complexes with ligands (**1**) and (**2**) and with the structurally related (**3**) have been prepared by adding the THF adduct of VCl_3 to solutions of the corresponding ligands, with subsequent addition of potassium *t*-butoxide or in the presence of triethylamine.[323] They are red-brown monomers [VCl(SB)] (SB = Schiff bases (**1–3**). IR indicates coordination by phenolic oxygen and azomethine nitrogen and the visible spectra and magnetic moments (2.5–2.7 BM) are consistent with pseudooctahedral V^{III}.[323] Oxidation of [VCl(SB)] (SB = **1**) by O_2 produces the VO^{2+} compound.[323] If $TlBF_4$ is added to [VCl(SB)] (SB = **3**) in acetone, TlCl precipitates and an orange solid is isolated, formulated as [V(SB)(acetone)]BF_4 from displacement of chloride by O-coordinated acetone.[323] This needs confirmation.

(**1**) X = N
(**2**) X = P

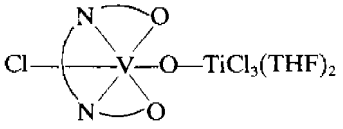
(**3**)



(**4**)

In one synthesis of [V(acen)Cl(THF)] (**4**), a THF suspension of Na_2acen is allowed to react with $[VCl_3(THF)_3]$.[324] A second method involves reductive deoxygenation of [VO(acen)] (equation 9); once [VO(acen)] has been synthesized, it is a straightforward procedure.

$$[VO(acen)] + TiCl_3(THF)_3 \xrightarrow[-TiOCl_2]{\text{reflux in THF}} (\mathbf{4}) \qquad (9)$$



The chloride in (**4**) can be easily replaced and several derivatives [V(acen)(X)(L)] (X = OPh, SPh, NCS^-; L = solvent molecule, *e.g.* THF, py) have been prepared.[325] Complex (**4**) has been used for synthesis of organometallic derivatives.[325] The structures of several (X = Cl^- (**4**), OPh^- (**5**) and NCS^- (**6**)) have been determined,[324] and consist of discrete molecules containing the same [V(acen)(THF)] unit. The coordination geometry can be described as a square bipyramid whose equatorial plane is formed by the N_2O_2 atoms of the tetradentate ligand, with oxygen from THF at one apex, the other apex being occupied by Cl^-, O from OPh^- or N from NCS^- (Scheme 11). The N_2O_2 core is not exactly planar, and the V atom is displaced out of the N_2O_2 'plane' towards X (0.143, 0.151 and 0.082 Å for **4**, **5** and **6**).

Complex (**7**) may be either monomeric or dimeric (as observed for formally five-coordinate V^{III} in $[V(acen)(CH_2Ph)]_2$).[325]

Scheme 11

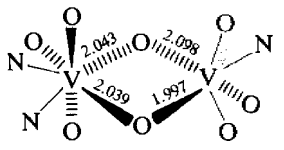
When reaction (**9**) is started at room temperature for a few minutes, then cooled to −30 °C and later to −70 °C, a different complex (**8**) may be isolated, whose structure consists of binuclear $[V^{IV}(Cl)(acen)O\{TiCl_3(THF)_2\}]$ in which an O atom bridges the [VCl(acen)] and $TiCl_3(THF)_2$ units.[324] The V—Cl distance (2.352 Å) is similar to that of (**4**). For the bridging O atom, *d*(V—O)(1.937 Å) is longer than in other μ-oxo vanadium complexes.[324]

(**8**)

33.4.8.2 Amino acids

Simple and mixed complexes of V^{III} with aspartic and glutamic acids and with methionine have been reported[326] although their elemental analysis cannot be considered entirely satisfactory. These green, water soluble compounds were prepared from VCl_3 solutions (normally obtained *in situ* by reduction of V_2O_5 by Zn), addition of the amino acid(s) and precipitation with acetone. Complexes with L-Ser, L-Thr and L-Leu have been isolated and studied by IR, UV-vis, CD and thermogravimetric measurements.[327] The location of ν(V—Cl) bands in the region 350–395 cm^{-1}, the magnetic moments and other considerations led to formulations $VCl(Ser)_2 \cdot H_2O$ (μ_{eff} = 2.79 BM), $VCl_2(Thr)(ThrOH) \cdot 2H_2O$ and $VCl_2(Leu)(LeuOH) \cdot 3H_2O$ (μ_{eff} = 2.31 and 2.39 BM, respectively), with polymeric structures (note that low μ_{eff} values can result from VO^{2+} impurities).[327] $[VCl_3(Gly)_3]$[328] and $[V(H\text{-}Had)_3]$ (H-Had = *N*-formyl-*N*-hydroxylglycine[329]) have also been prepared. Further structural studies are needed.

Preparation of complexes with amino acids in the pH range 4–7 is difficult as V^{III} is partially hydrolyzed and can be easily oxidized. This also makes solution studies difficult. At low pH (1.5–3) complexes $[VL(H_2O)_5]^{2+}$ are believed to form,[327-331] with, at higher pH, $[V(Gly)_2]$ and $[V(Glu)_2]^-$ (pH *ca.* 3.5 and 4–4.5, respectively).[332] From potentiometry, $\log \beta_1$ of 8.8, 8.4 and 9.0 and $\log \beta_2$ of 15.4, 14.8 and 16.3 were determined for Ser, Thr and Leu. With cysteine, complexation of V^{III} is faster than that of V^{II} by three orders of magnitude (same pH).[156]



Enthalpies of activation are comparable but entropies differ. The maximum number of ligands is two, and the formation constants determined (equation 10) were $\beta_1 = 10^{13}$ and $\beta_2 = 10^{20}$.[156]

$$V^{(III)}(aq) + n\overset{+}{N}H_3CH(CO_2^-)CH_2SH \overset{\beta_n}{\rightleftharpoons} [V(NH_2CH(CO_2^-)CH_2S)_n] + 2nH^+ \quad (10)$$

33.4.8.3 Complexones

Complexes of NTA formulated as $[V(NTA)(H_2O)_2]\cdot 5H_2O$ and $Cs_3[V(NTA)_2]$ have been prepared.[333] The pK_a of the coordinated water molecule in the former is 6.2. Although $Cs_3[V(NTA)_2]$ exhibits no tendency to form hydroxo complexes in aqueous solution, the second NTA^{3-} is markedly more weakly bound than the first ($\log \beta_1 = 13.4$ and $\log \beta_2 = 22.1$ at 20 °C and $I = 0.1$ M).

Schwarzenbach *et al.*[334] prepared $Na[V(edta)]\cdot 4H_2O$ by reduction of the VO^{2+} complex with sodium amalgam and determined the formation constant of $[V(edta]^-$ as $10^{25.9}$. The formation constant for reaction (**11**) in Scheme 12 ($L = edta^{4-}$ and $n = 2$) was $10^{4.4}$. In the V^{III} dimer $(H_2en)[V(Hnhet)]_2\cdot 2H_2O$, the anion (**9**) displays several uncommon features.[335] Each V^{III} was seven-coordinate, having a distorted pentagonal bipyramidal configuration. The bridging atoms are the alkoxy oxygens formed by deprotonation of the *N*-hydroxyethyl functionality of the parent $nhet^{3-}$ ligand ($nhet^{3-}$ = *N*-(hydroxyethyl)ethylenediaminetriacetate). The V—V distance is 3.296 Å and the angles of the $\{V_2O_2\}$ core (VOV = 108°; OVO = 72°) suggest little strain is present.

(**9**)

The binuclear complex (**9**) may be produced from monomeric [V(nhet)] by two paths: (i) by combination of two molecules of $[V(nhet)(OH)]^-$ or $[V(nhet)(OH)]^-$ and $[V(nhet)(H_2O)]$,[336] or (ii) by a cross-redox reaction between $[V^{IV}O(nhet)]^-$ and $[V^{II}(nhet)]^-$ (see also Section 33.5.9.3).[337,338] The unusually intense spectral features of $[V^{II}V^{IV}O(nhet)_2]^{2-}$ originate in oxo bridging between V^{II} and V^{IV} in the cross reaction.[336–338] This intermediate has a short lifetime (~25 ms), but it is unusually long by comparison with other inner-sphere systems.

The cross-redox reaction discussed above and formation of the V^{III} dimers has also been reported in the case of the edta complexes. Scheme 12 summarizes part of the equilibria proposed to explain potentiometric and spectroscopic data at $t = 25$ °C and $I = 0.20$ M in $NaClO_4$.[336–338] The polarographic behaviour of V^{III} complexes of edta and 'analogous' ligands has also been studied.[339]

$$[VL(H_2O)]^{1-n} + H_2O \overset{K_a}{\rightleftharpoons} [VL(OH)]^{n-} + H_3O^+ \quad (11)$$

$$2[VL(H_2O)]^{1-n} + 2H_2O \overset{K_D}{\rightleftharpoons} [V^{III}\,\text{dimer}] + 2H_3O^+ \quad (12)$$

$$2[VL(OH)]^{n-} \overset{K_d}{\rightleftharpoons} [V^{III}\,\text{dimer}] + H_2O \quad (13)$$

If $L = edta^{4-}$ then $n = 2$, $pK_a = 10.16$, $pK_D = 16.71$ and $pK_d = -3.62$; if $L = Hedta^{3-}$ then $n = 1$, $pK_a = 6.4$, $pK_D = 9.05$ and $pK_d = -3.7$[335]

Scheme 12

Reaction (**14**) has been studied.[340,341] The equilibrium constant K_R is of the order 10^{-10} so that comparable concentrations of the reactant and product coexist at pH ~5. The reaction goes to completion at higher pH values (5.4–7.1) and is quantitative in the reverse direction at pH 2.5–4.0, where mixtures of the Fe^{III} and V^{III} complexes are stable in the absence of O_2.

$$[Fe^{III}(edta)]^- + [V^{III}(edta)]^- \overset{K_R}{\rightleftharpoons} [Fe^{II}(edta)]^{2-} + [V^{IV}O(edta)]^{2-} + 2H^+ \quad (14)$$

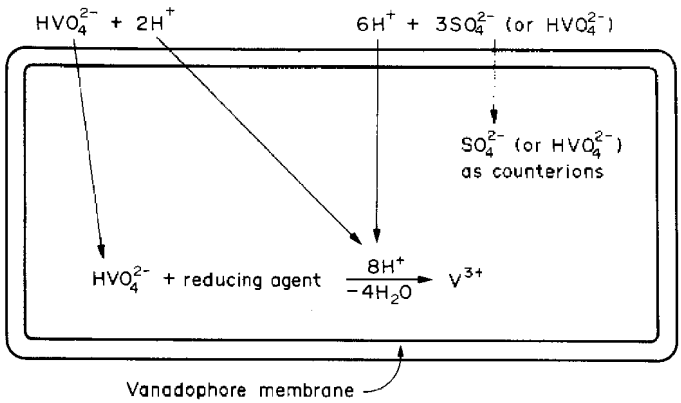
In the redox reaction between [Ti(nhet)(H_2O)] and [VO(nhet)]$^-$, a binuclear species containing Ti^{IV} and V^{III} appears by a substitution after the electron transfer step.[342] The orange [$Ti^{IV}V^{III}$(nhet)$_2$] forms in the pH range 2.5–7.5, and can also be generated by combination of [V(nhet)(H_2O)] and [TiO(nhet)]$^-$.

33.4.9 Vanadium in Tunicates

The sea squirts or tunicates are fascinating marine creatures, their name being derived from the tunic made of cellulosic material that surrounds the body of the animal. In 1911, Henze discovered vanadium in the blood of *Phallusia mammillata* C.[343] He later found the same with other ascidians (a class of tunicates). In vanadium-accumulating species, most vanadium is located in the vacuoles—vanadophores—of certain types of blood cells—the vanadocytes. The concentration in the vanadophore can be as high as ~1 M and this value must be compared with concentrations of the order of 2×10^{-8} M for vanadium in sea water.[344] Kustin *et al.* have reviewed the work done to understand the efficient accumulation and the possible biological roles of the metal.[345]

Although local concentrations of the metal may be very high, isolation is difficult due to the sizes of the vanadophores (2 μm) and the vanadocytes (8 μm). It was thought that vanadium was bound to a protein named hemovanadin[346] but later it was found that this was an artefact during hemolysis and isolation. Proton NMR spectra of living blood cells show that the vanadium(III) concentration range of the vanadophores is sharply limited and the spectra were consistent with a labile vanadium(III) aqua complex.[347] X-Ray absorption spectroscopy of the vanadocytes has shown that only a small amount (<10%) of the vanadium is present as VO^{2+} in the vanadocyte and that the vanadium(III) ions are surrounded by a single shell of six oxygen atoms at an average distance of 1.99 Å, ruling out N ligands such as porphyrin or imidazole.[348] The combined NMR and EXAFS were consistent with vanadophores containing a simple vanadium(III) aqua complex probably with another small oxygen ligand like sulfate that exists in high concentration in the vanadocyte. ESR confirmed the existence of concentrations of vanadium(IV) of the order of 10^{-2} M,[349] compared with the estimated total of vanadium in the vanadophore (1.4 M). Again, the data were consistent with most vanadium existing as $V(SO_4)(H_2O)_{4-5}^+$.

For the vanadophore region, the sulfate concentration has been estimated to be of the order of 1.3 M and pH ~2.[349] With no evidence for a stable complex within the vanadocyte, Figure 14 depicts an interesting mechanism proposed for vanadium and sulfate accumulation.[350] Anionic vanadium(V) (as HVO_4^{2-}) and sulfate ions enter the cell. Provided that within the vanadophore there is a strong reducing agent, vanadium can be reduced to vanadium(IV) and vanadium(III), cationic at the low pH in the vanadophore. If the vanadophore membrane is permeable to anions but not cations, the reduced vanadium remains trapped.



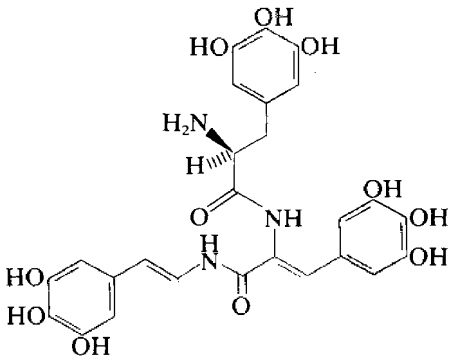


Figure 14 Mechanism of vanadium accumulation in the vanadophore assuming a membrane permeable only to anions

Recently, a reducing blood pigment named tunichrome B-1 (**10**) was isolated from the tunicate *Ascidia nigra* L. and characterized.[351] It has a structure derived from three (3,4,5-trihydroxy)phenylalanine units and the trihydroxyphenyl group is suitable for reducing the metal.

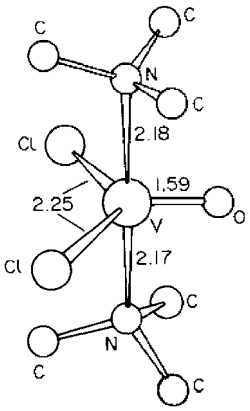
(10)

The uses of the metal for the living creature have been the subject of much speculation but the possibility that vanadium(III) is involved in oxygen transport has been ruled out experimentally.[352] The role of the high concentrations of vanadium in tunicates remains tantalizing.

33.5 VANADIUM(IV)

33.5.1 Introduction

This oxidation state is the most stable under ordinary conditions.[353] Important compounds contain the VO^{2+} unit (vanadyl(IV) ion or oxovanadium(IV) ion), which can persist through a variety of reactions and is considered the most stable oxycation of the first row transition ions.[354] It forms stable anionic, cationic and neutral complexes with all types of ligands, and has one coordination position occupied by the vanadyl oxygen (Figure 15).



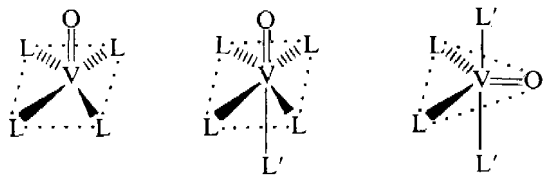


Figure 15 Square bipyramidal geometry of vanadyl(IV) complexes; more common ranges of bond lengths (Å) are indicated. The V atom lies above the plane of the four L ligands

The complexes typically have square pyramidal (**11**) or bipyramidal structure (**12**) with vanadyl oxygen apical, the vanadium atom lying 0.035–0.055 Å above the plane defined by the equatorial ligands.[354] There have been reports of five-coordinate 'trigonal bipyramidal' complexes (**13**) with structures determined by X-ray diffraction techniques.

(11) **(12)** **(13)**

Only three general reviews on vanadium(IV) complexes have been given;[355–357] others deal with subnormal magnetic complexes,[358] ESR spin probes,[354] vanadium(IV) halides,[6] optical spectra and phosphorus donor ligands,[359] vanadium porphyrins[128] and annual reviews for 1979, 1980 and 1981.

Many publications discuss ordering of molecular orbitals based on ESR or optical spectra. Although assignment of the bands has been a matter of controversy,[355,360–375] most interpret them in terms of the energy level scheme proposed by Balhausen and Gray (Figure 16).[364] Although developed for $VO(H_2O)_5^{2+}$ (assuming C_{4v} symmetry), it has been applied to other complexes. Its universality has been questioned because the order of orbitals will probably vary from complex to complex and will depend on symmetry. In this model, the unpaired electron resides in a largely nonbonding d_{xy} orbital (the z axis is taken as the vanadyl bond) with lobes pointing between the equatorial ligands; ESR measurements are generally consistent with this.[354] The interaction of d_{xz},d_{yz} with the ligand may be π acceptor in character and the relative order of the B_2 and E orbitals could be inverted.[374] Usually three optical bands are observed in the visible,[356] assigned (C_{4v} symmetry) to $(I)^2B_2\,(d_{xy}) \rightarrow {}^2E\,(d_{xz},d_{yz})$; $(II)^2B_2\,(d_{xy}) \rightarrow {}^2B_1\,(d_{x^2-y^2})$; and $(III)^2B_2\,(d_{xy}) \rightarrow {}^2A_1\,(d_{z^2})$ (or a charge-transfer transition). For some complexes four bands are observed, possibly arising from splitting of the d_{xz},d_{yz} levels in low symmetry (Figure 16c) and band III is often obscured by intense absorption tailing in from the UV. Transition $III(d_{xy} \rightarrow d_{z^2})$ may be at 125–200 nm.[362,370] However, it will most likely be at 330–400 nm if not obscured by charge transfer. This is discussed by Lever[368] and further evidence is given by weak bands at ~360 nm in the CD spectra of complexes with (*R*)-lactate[372] and (*S*)-peida[373] (peida = *N*-[1-(2-pyridyl)ethyl] iminodiacetate).

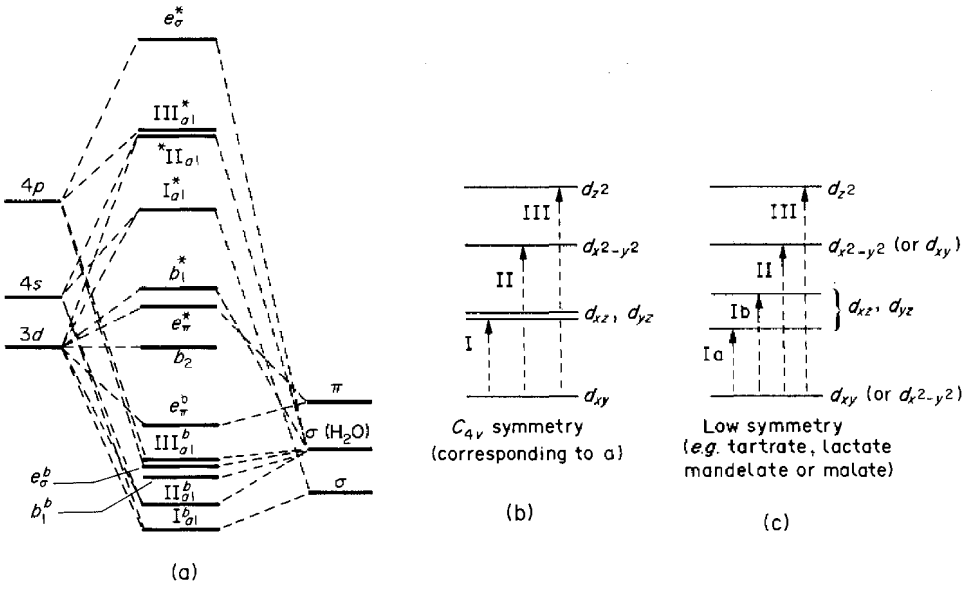

Figure 16 (a) Molecular orbital scheme for $[VO(H_2O)_5^{2+}]$ (C_{4v} symmetry) according to Balhausen and Gray;[364] (b), (c) splitting of the vanadium *d* levels (b_2, *e* and b_1 considered mainly as V orbitals)

Mabbs and co-workers studied the single crystal polarized spectra of pentacoordinate VO^{2+} compounds at 298 and 5 K and of poly(dimethylsiloxane) mulls of six VO^{2+} compounds (five- and six-coordinate complexes).[369] Ligand-field strengths ranged from that of cyanide to that of bromide. Transitions I and II were assigned to $3d_{xy} \rightarrow 3d_{x^2-y^2}$ and to $3d_{xy} \rightarrow 3d_{xz},3d_{yz}$. Spectra of six-, five- and four-coordinate compounds of vanadium(IV), *e.g.* $[VCl_6]^{2-}$, $[VCl_4]^+\cdot[VCl_5]^-$ and VCl_4, are in Lever's textbook.[368]

According to the Ballhausen and Gray model,[364] the vanadium–oxygen bond is triple and it has been explicitly considered as such by several authors.[376–378] In most textbooks and publications, including this one, the structures of oxovanadium(IV) compounds are reported with a double bond between vanadium and oxygen.

ESR spectroscopy is a particularly useful technique as it provides information on the stereochemistry, ligand type and degree of covalency of V^{IV} complexes. The fundamental ESR properties of VO^{2+} complexes have been reviewed.[354] Petrakis and co-workers have shown that

the ESR spectra of various vanadyl complexes yield A_0 (isotropic hyperfine splitting constant) and g_0 (isotropic g) values in reasonably well-defined ranges characteristic of the types of metal–ligand bonds, *i.e.* g_0 increases and A_0 decreases in the series VOO_4, VON_2O_2, VOS_2O_2, VON_4, VOS_4.[379] ENDOR studies of complexes randomly oriented in a matrix can provide valuable data.[380–383] The hyperfine and quadrupole tensor components of ligand nuclei identify ligands and give more insight than that provided by ESR studies alone.

The V=O stretching frequency is an important characteristic of oxovanadium(IV) complexes, generally observed at $985 \pm 50\,cm^{-1}$.[353,355] It is quite sensitive to the nature of the ligands. Donors that increase the electron density of the metal reduce its acceptor properties towards O, the V—O multiple bond character and the stretching frequency. For complexes $VOL_5^{n\pm}$, ν(V=O) falls in the order $L = H_2O > NCS^- > CN^- > DMSO \sim F^-$; this series bears no obvious relation to the spectrochemical and nephelauxetic series.[353]

Although most oxovanadium(IV) complexes are blue, some Schiff base complexes may vary from yellow to maroon. Earlier suggestions that such colours, together with reductions in the V—O frequencies from 950–1000 to 800–850 cm^{-1}, indicate polymerization or VO · · · VO · · · VO interaction are erroneous. Even for coordination environments which are very similar, the V=O lengths may be very different, the vanadyl oxygens being exposed to the influence of the neighbouring molecules in the crystal.[384]

VO^{2+} bonds most effectively to electronegative atoms, *e.g.* F, Cl, O and N, and bonds to S and P are also known.[359] Fluoro and oxygen complexes are specially stable. Complexes with oxygen donors follow the expanded Irving–Williams series:[354] $VO^{2+} > Cu^{2+} > Ni^{2+} > Co^{2+} > Fe^{2+} > Mn^{2+}$. The presence of one or two nitrogen donors places VO^{2+} lower in the series.

Vanadyl compounds hydrolyze much more easily than any other metal chelates of the first transition series, and in some conditions the vanadyl 1:1 chelates prefer combination with hydroxyl to a second ligand molecule.[385] Unless otherwise stated formation constants β_{xyz} presented in this review correspond to the reaction shown in equation (15).

$$xVO^{2+} + yL + zH^+ \rightleftharpoons (VO)_x(L)_y(H)_z \qquad \beta_{xyz} = \frac{[(VO)_x(L)_y(H)_z]}{[VO^{2+}]^x[L]^y[H^+]^z} \tag{15}$$

33.5.2 Group IV Ligands

Most complexes of vanadium(IV) with group IV ligands are normally organometallic compounds, which have been reviewed.[9]

In cyanide complexes, several bonding modes are available but CN^- will show more basic character when coordinating through the carbon lone pair.[386] No stable cyanide complexes exist in acid solution, but complexes $M_3[VO(CN)_5]$ ($M = Et_4N^+$, Me_4N^+ or Cs^+) have been isolated; apparently the large cation provides the necessary crystal stability. They are prepared from aqueous $VOSO_4$ and NaCN (6 M) on addition of salts of the corresponding counterion.[387] ν(V=O) was in the range 952–956 cm^{-1} (with a shoulder at 965–968 cm^{-1}).[388]

An old compound, $K_2V(CN)_6$,[389] was reformulated as $K_3[VO(CN)_5]$,[390] based on a band at 935 cm^{-1} assigned to ν(V=O). Mabbs and co-workers assigned ν(V=O) at 930 cm^{-1}, which probably reflects high electron density in the vanadium from the CN^-;[369] ESR studies of $[VO(CN)_5^{3-}]$ anion indicate significant covalency.[356] UV-visible spectra of solutions containing VO^{2+} and cyanide do not support the existence of $V(CN)_6^{2-}$.[391]

33.5.3 Nitrogen Ligands

33.5.3.1 Ammonia and aliphatic amines

Complexes $[VOCl_2L_n]$ (L = monodentate or bidentate neutral ligand; $n = 1$, 2 or 3) are made by methods including controlled hydrolysis of vanadium(IV) chloride adducts,[392,393] controlled oxidation of vanadium(III) chloride adducts,[394,395] reaction of ligand with aqueous $VOCl_2$,[396,397] with $VOCl_3$,[398,399] $VOBr_3$[400,401] or with $VOCl_2(MeOH)_3$ in methanol.[402] Methods for the related $Ct_2[VOCl_4]$ (Ct = monopositive cation) include reaction of $[VOCl_2(diox)_2]$ (diox = 1,4-dioxane) with CtCl in liquid SO_2,[403,404] thermal decomposition of hydrates or ethanenitrile adducts,[403–407] reaction of $VOCl_2(MeCN)_2(diox)_{0.5}$ with CtCl in ethanenitrile[403,404] and direct reaction between $VOCl_2$ and CtCl in $CHCl_3$.[408] A general synthetic procedure for

$[VOCl_2L_n]$ and $Ct_2[VOCl_4]$ is more reproducible and gives fewer problems from solvolysis and thermolysis.[409] The method consists of ligand displacements in solutions of $[VOCl_2(MeCN)_2]$ (very simple to prepare on a large scale) in THF or ethanenitrile according to equations (16) and (17). $[VOCl_2(Me_3N)_2]$ was prepared by this method and bands at 404 and 383 cm^{-1} were assigned to ν(V—Cl).[410] Two strong IR bands in $[VOCl_2L_2]$ indicate geometry of type (**13**);[409] when there is only one ν(V—Cl) band, the geometry is of type (**11**). For $VOBr_2L_2$,[401] one class gives two strong ν(V—Br) stretches (the higher in the region 360–340 cm^{-1}); the other shows only one ν(V—Br), 340–320 cm^{-1}.

$$VOCl_2(MeCN)_2 \xrightarrow[\text{THF or MeCN}]{L} VOCl_2L_n \qquad (16)$$

$$VOCl_2(MeCN)_2 \xrightarrow[MeCN]{CtCl} Ct_2[VOCl_4] \qquad (17)$$

Wood and co-workers prepared $[VOCl_2(Me_3N)_2]$ by reduction of $VOCl_3$ with Me_3N under strictly anhydrous conditions.[398] After redissolution in trimethylamine, blue crystals suitable for X-ray work formed. The geometry around the vanadium atom is trigonal bipyramidal (**13**) (see Figure 17), probably due to steric effects of the bulky Me_3N. Several similar compounds have been prepared by reduction of $VOCl_3$ with the appropriate amine (see Table 10). With methylamine, the reduction is slower than with the others; the silvery grey product is probably polymeric. A compound formulated as $VOCl_2 \cdot 5NH_3$ had a room temperature moment of 1.62 BM and obeyed the Curie–Weiss law with $\theta = 60$ K.[411]

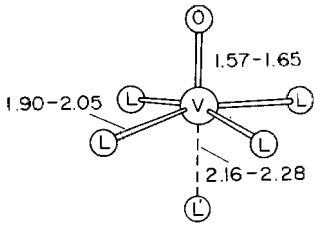

Figure 17 A perspective view of $[VOCl_2(Me_3N)_2]$. The bond lengths are in Å. The angles in the equatorial plane are 120°.[398]

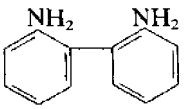
Table 10 $VOCl_2 \cdot n$(amine) Complexes

Amine	$\nu(V{=}O)$ (cm^{-1})	$\mu^{r.t.}$ (BM)	$\nu(V{-}Cl)$ (cm^{-1})	*Ref.*
NMe_3 ($n = 2$)	990	1.73	404, 383	1, 2
$NHMe_2$ ($n = 2$)	1000	1.68		1
NH_2Me ($n = 4$)	972	1.72		1

1. K. L. Baker, D. A. Edwards, G. W. A. Fowles and R. G. Williams, *J. Inorg. Nucl. Chem.*, 1967, **29**, 1881.
2. J. Cave, P. R. Dixon and K. R. Seddon, *Inorg. Chim. Acta*, 1978, **30**, 349.

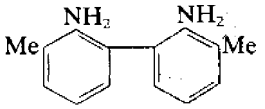
The tetrahalides $[VX_4]$ are Lewis acids and produce adducts with a variety of donors, namely aliphatic amines or amides. The common coordination number is six, although this and the precise geometry have not often been determined. VCl_4 reacts with amines and, in rigorously anhydrous conditions, gives satisfactory products like VCl_4NHMe_2, $VCl_2(NHMe)_2 \cdot 4NH_2Me$, VCl_4NMe_3 and $VCl_3 \cdot 2NMe_3$.[412] A compound formulated $VCl_4 \cdot 2EtNH_2$ has been obtained in a vapor-phase reaction;[413] $VCl_4 \cdot 2L$ (L = MeCN, $PhCH_2CN$, EtCN) have been prepared,[6] and VCl_4(dibenzylamine)$_2$.[414] An adduct formulated $VCl_4(MeCOCN)_2$ was prepared by reaction of VCl_4 with an excess of ligand in petrol.[415] With VCl_4 in excess, $(VCl_4)_2(MeCOCN)_3$ was obtained. With benzoyl cyanide, only $(VCl_4)_2(PhCOCN)_3$ was obtained pure. IR spectra suggest nitrogen coordination. VCl_4 normally forms 1:2 adducts with unidentate ligands. Octahedral as well as tetragonal structures have been proposed. Solutions of such adducts are not common, but $[VCl_4(RCN)_2]$ give brown solutions in benzene and molecular-weight measurements indicate extensive dissociation.[6] $[VF_4NH_3]$ (probably polymeric, with $\mu_{eff}^{r.t.} = 1.83$ BM) readily gives a brown aqueous solution.[416]

The chloride of $[VCl_4]$ may be substituted by amide. With primary and secondary amines at room temperature, aminolysis stops at the dichlorodiamides. The ammonia-insoluble, presumably polymeric $[V(NH_2)_2Cl_2]$ dissolves in NH_4Cl in liquid NH_3; complex anions are formed.[6] The green $VCl_2(RHN)_2{\cdot}4RH_2N$ (R = Me, Et, Pr^n, Bu^n), insoluble in benzene and the parent amines, are probably polymeric.[412,417] They release two molecules of amine at 60 °C, leaving purple $[VCl_2(RHN)_2{\cdot}2RH_2N]$. Products from secondary amines $[VCl_2(R_2N)_2]$ (R = Me, Et, Pr^n) are more soluble and molecular weights in benzene indicated a mixture of monomer and dimer.[417]



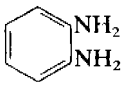
Complete replacement of halogen can be achieved using lithium dialkylamides. $[VCl(Et_2N)_3]$[418] and the dark green liquid $[V(Et_2N)_4]$ have been obtained as well as $[V(Me_2N)_4]$.[418,419] $[V(Et_2N)_4]$ obeys the Curie–Weiss law with small θ; $\mu_{eff} = 1.71$ BM. ESR and absorption spectra are consistent with monomeric $[V(Et_2N)_4]$.[419] The metal–nitrogen bond in these complexes is sensitive to protic reagents HL (where L = OH, OR, $OSiR_3$, halide, HNR, NR_2, SR, C_5H_5, C≡CR, *etc.*) and this has been put to synthetic use, originally by Bradley and Thomas,[420–422] who prepared vanadium(IV) alkoxides and trialkylsilyloxides (equation 18).

$$V(R_2N)_4 + yHL \longrightarrow VL_y(R_2N)_{4-y} + yNHR_2 \tag{18}$$



$$VCl_4 + \underset{\text{(Slight excess)}}{\text{amine}} \xrightarrow[\text{ii, vacuum dry, } CaCl_2]{\text{i, } CHCl_3,\ -0\,^\circ C} VCl_4{\cdot}(\text{amine})_n \tag{19}$$

The complex of tetrakis(aminomethyl)methane was studied by ESR at 77 K[423] and the triplet state spectrum at ~1500 G, due to $\Delta M_I = 2$, interpreted assuming dimeric oxovanadium(IV) with V—V of 5.7 Å.

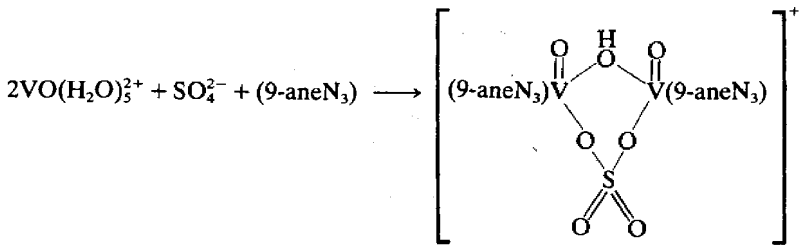


From the reaction (equation 19) of anilines and naphthylamines, $[VCl_4L_2]$ were obtained,[414,424] and with diamines (**14**)–(**16**), compounds VCl_4L' result. They are hygroscopic, insoluble in $CHCl_3$, CCl_4, benzene and nitrobenzene and slightly soluble in acetone and dioxane.

(**14**)

(**15**)

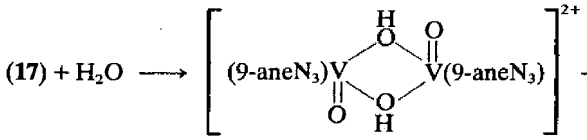
(**16**)



Ethylenediamine oxovanadium(IV) complexes in water have been reported[355] and dark brown '$[V(en)_3]F_4$' has been prepared by adding VF_5 to the diamine at low temperature.[425]

Further studies are required to sort out whether the fluorides really are only counterions.

$VOSO_4{\cdot}5H_2O$ with 1,4,7-triazacyclononane (9-aneN_3) (1:1) in H_2O at 50 °C yields blue acidic solutions (equation 20), from which a blue perchlorate was precipitated, by $NaClO_4$. With NaI, a blue iodide was obtained for which ν(V=O) was at 950 cm^{-1};[426] absorptions at 1210, 1140 and 1030 cm^{-1} were assigned to μ-sulfato.



Attempts to recrystallize (**17**) from aqueous solutions resulted in the release of sulfate and formation of species (**18**) (equation 21). Upon addition of $NaClO_4$, NaBr or NaI, grey salts of (**18**) were obtained. From the temperature dependence of χ_M, $J = -177$ cm^{-1}, indicating strong antiferromagnetic coupling of the two V^{IV}; ν(V=O) = 950 cm^{-1}, and a new band at 540 cm^{-1} was assigned to ν(V—O) of the μ-hydroxo bridges. The crystal and molecular structure of the bromide of (**18**) consists of discrete binuclear cations with the V^{IV} centres in a distorted octahedral environment. The $V(\mu\text{-}OH)_2V$ four-membered ring is planar and V···V is 3.033 Å. The oxo groups are mutually *trans*; VO is 1.603 Å, much shorter than the V—OH bond lengths of ~1.96 Å. The vanadyl O atoms influence the *trans* V—N bond (~0.15 Å longer than the equatorial V—N distances).

For the dimer (**18**), at 200 K, the ESR powder spectrum shows an intense central signal and a strong half-field absorption.[427] Below 200 K, well-resolved hyperfine structure appears. The hyperfine constant for the half-field transition, 84 G, is approximately half of the A_z value for the monomers. From single crystal ESR,[427] the exchange integral $J_{xy,x^2-y^2} \approx -410$ cm^{-1}, compared to the value from magnetic susceptibility: $J_{xy,x^2-y^2} \approx 354$ cm^{-1}.[426]

(20)

(18)

(21)

33.5.3.2 *N-heterocyclic ligands*

Adducts of $VO(acac)_2$ with pyridines have been extensively studied (see Section 33.5.5.4.ii). Adducts $VOF_4 \cdot py$[416] and $VOCl_4 \cdot L_n$ with L = py, PhN=NPh, pyrrole, pyrazine, 2,6-dimethylpyrazine, bipy and phen have been discussed.[6] A $[VCl_4L_2]$ complex (L = carbazole) has been reported.[414] Again, the rule is the formation of 1:2 adducts with monodentate nitrogen donors and 1:1 adducts with bidentate donors. IR and solubility data have been used to decide whether bidentate ligands are chelated or bridging.

The stoichiometry of products from $VOCl_2 \cdot 3MeOH$ with aliphatic and heterocyclic nitrogen donors[402] depends on pK_a, bulk of the ligand and the reaction conditions (see also Section 33.5.5.3). The ligands included N-heterocyclic and other nitrogen bases (*e.g.* Et_2NH, Et_3N and *N,N,N',N'*-tetramethyl-1,2-diaminoethane). The complexes isolated have the stoichiometries $VOCl_2 \cdot xL$ ($x = 2$ and 3), $VOCl_2 \cdot xL \cdot yMeOH$ ($x = 1, 2$; $y = 1, 2$), $VOCl_2 \cdot B$, $2VOCl_2 \cdot 3B'$, $(LH)[VOCl_2(OMe)]$, $(BH_2)[VOCl_2(OMe)]_2$, $(B'H)[VOCl_2(OMe)]$, $VO(OMe)_2 \cdot 2LHCl$, $VO(OMe)_{2...} \cdot BH_2Cl_2$, $VOCl(OMe) \cdot xL$ ($x = 1$ and 2) and $VOCl(OMe) \cdot 2L \cdot L' \cdot HCl$ where L and L' are monodentate (ligands), and B and B' are bidentate chelating and bridging ligands respectively. $VOCl_2 \cdot xL$, $VOCl_2 \cdot B$ and $(Ct)_2[VOCl_4]$ ($Ct = Hpy^+$, L = py ($x = 2, 3$), bipy and phen) have been prepared by the general procedure in equations (16) and (17).[409] When $(LH)[VOCl_2(OMe)]$ (L = 2,6-lutidine or *N,N*-dimethylaniline, bulky ligands with low pK_a values) react with py, a simple adduct $VOCl_2 \cdot 2py$ forms. In contrast, reactions of complexes where the base has a high pK_a (*e.g.* Et_3N) give $VOCl(OMe) \cdot 2py \cdot LHCl$.[402]

VOF_2 combines readily with water or fluoride. It has less tendency to combine with nitrogen or sulfur, but many complexes of these donors and oxygen donors were easily prepared by reaction (**22**).[428] The products containing N-heterocyclic donors are listed in Table 11, with some properties.

$$VOF_2 \cdot H_2O + nL \xrightarrow{EtOH} VOF_2(L)_n(H_2O)_m \quad (22)$$

$n = 1$ or 2, $m = 0$ or 1

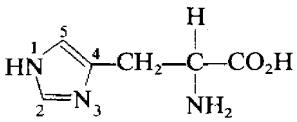
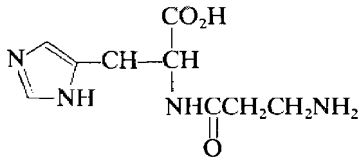
At room temperature, the reaction (equation 16) between Hpy·Cl and $[VOCl_2(MeCN)_2]$ in MeCN gives the expected green $(Hpy)_2[VOCl_4]$ with spectra similar to other square pyramidal $Ct_2[VOCl_4]$ compounds.[409] However, at −30 °C, a blue compound of identical composition forms, with different diffuse reflectance typical of a trigonal bipyramidal structure. The compound undergoes temperature-dependent ($C_{2v} \leftrightarrow C_{4v}$) reversible transformation like that of $(Et_4N)_2[VOBr_4]$ (Section 33.5.8.1, equations 52).[400] The C_{4v} green form is the stable isomer at room temperature and the blue form is stable at room temperature for only a few days.

Polycrystalline $[VOBr_2(py)_2]$ and $[VOCl_2(MeCN)_2]$ give single-line ESR spectra as does $(Hpy)_2[VOCl_4]$, while the spectrum of $(Et_4N)_2[VOCl_4]$ shows fine structure.[409] In nonaqueous solvents at room temperature, ESR spectra of $[VOX_2L_n]$ show the occurrence of ligand dissociation and displacement; for example, the following reaction shown in equation (23) occurs.[409] Even in non-coordinating solvents, then, the electronic spectra of $[VOX_2L_n]$ may be open to doubt in the absence of a careful study of the species present in solution. $[VOBr_2L_n]$ have been prepared by reduction of $VOBr_3$ (see Table 11).[401] The reactions liberate Br_2 when 1:2 ratios of $VOBr_3$ to ligand are used, so cyclohexene was used as solvent.



$$VOBr_2(py)_3 \overset{\text{toluene}}{\rightleftharpoons} VOBr_2(py)_2 + py \qquad (23)$$

Solutions from the reactions of $[VO(L)SO_4]$, $[VO(L)_2SO_4]$ (L = bipy or phen) and $[VO(bzim)_2]^{2+}$ (bzim = benzimidazol-2-olate) with $SOCl_2$ or $SOBr_2$ gave similar ESR spectra after several hours at reflux. The deoxygenated vanadium(IV) compounds formed (see Section 33.5.5.7) are almost certainly *cis*-dihalogeno dichelates because of steric hindrance due to the α protons of the chelates.[429]



Imidazole (im) (**19**) complexing oxovanadium(IV) has been studied by ESR and proton and nitrogen ENDOR spectra.[383] Changes in orientation of the im plane, imposed by geometric constraints of multidentate ligands, such as in histidine (**20**), are reflected in the proton as well as the nitrogen ENDOR spectra. Four im ligands are bound to VO^{2+} and are oriented in a similar fashion, all making the same angle with the equatorial plane.

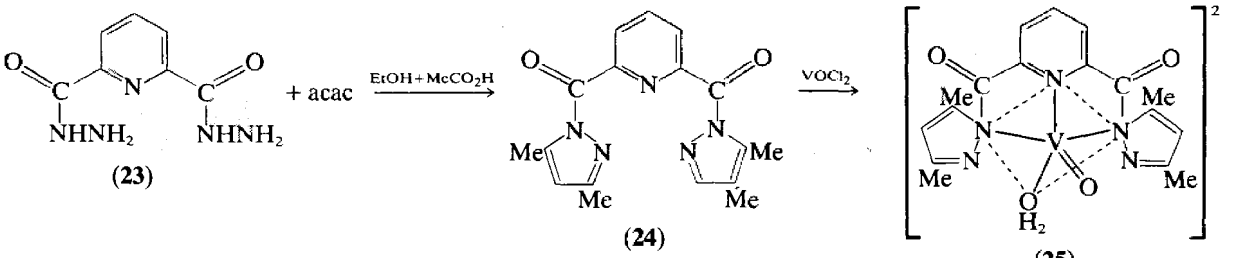
(**21**)



33.5.3.3 Hydrazine and related ligands

$[VOX_2L_4]$ (X = Cl, Br, I; L = N_2H_4, $PhNHNH_2$, Me_2NNH_2) exhibit subnormal moments (1.26–1.36 BM) and may be polymeric but further structural studies are needed.[431] VO^{2+} and 2,6-dipicolinoyl dihydrazine (DPH) (**23**) give $[VO(DPH)_2]$ and $[VO(DPH)X_2]$ (X = Cl^- or $\frac{1}{2}SO_4^{2-}$) (*cf.* Section 33.5.9.4.i).[432] They react with β-diketones according to Scheme 13. The β-diketones were acac, Prac (R = Et, R′ = Me) and Bzac (R = Ph, R′ = Me). (**25**) is obtained when $VOCl_2$ is added to the condensation product of DPH and acac (Scheme 14). VO^{2+} induces the cyclization; this template effect is 'kinetic'.[433] Complexes of (**26**) and (**27**) have been prepared,[434] for use in treatment of arteriosclerosis and to lower blood pressure.

33.5.3.4 Thiocyanate

Thiocyanato oxovanadium(IV) complexes have been extensively studied. Table 12 summarizes the isolated complexes containing NCS^-. In the thiocyanato thiourea complexes, IR shows that all ligands are coordinated through nitrogen.[435] The thiocyanato complexes $(Ct)_2[VO(NCS)_4(H_2O)]\cdot 4H_2O$ ($Ct = K^+$, NH_4^+) have been studied by X-ray techniques.[436] Prepared by the addition of the appropriate thiocyanate to aqueous $VOSO_4$, the complex is extracted with ethyl acetate. The geometry around the vanadium is shown in Figure 18. The NCS^- coordinates as isothiocyanate and the structure may be regarded as chains of anions linked by the two ammonium ions *via* the vanadyl oxygen and one water. The bond distance to the axial H_2O in $[VO(NCS)_4(H_2O)]^{2-}$(2.22 Å) is shorter than in $[VO(H_2O)_5]^{2+}$(2.4 Å).[356] Probably the stronger ligand NCS^- weakens V=O sufficiently to allow a stronger *trans* attachment by H_2O. ν(V=O) values support this idea, with values of 982 and 963 cm^{-1} for the thiocyanato complex and 1000 and 975 cm^{-1} for the aqua ion.[388]

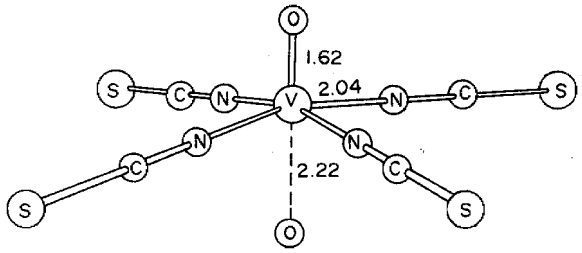

Figure 18 Geometry and internuclear distances (Å) in the complex $(NH_4)[VO(NCS)_4(H_2O)]\cdot 4H_2O$[436]

Smith and Martell tabulate stability constants ($\log \beta_{110} = 3.32$ and $\log \beta_{120} = 3.68$, at 25 °C)[437] and Che and Kustin determined the rate constant for NCS^- complexation ($k_1 \approx 1 \times 10^3\ M^{-1}\ s^{-1}$, at 25 °C and $I = 0.05\ M\ KNO_3$).[438] Thiocyanate complexes have high formation constants, and find use for photometric determination of vanadium.[435,439–441]

33.5.3.5 Nitriles

The exchange of ligands having different π donor/acceptor properties with $[VOCl_2(MeCN)_2]$ and $[VO(DMSO)_4](ClO_4)_2$ was studied by ESR in MeCN;[442] coordinated MeCN could be substituted readily but large excesses of fairly strong donors (*e.g.* DMSO) were required to substitute the chlorine atoms. $VOBr_3$ and acetonitrile in cyclohexene give $[VOBr_2(MeCN)_3]$; with pyridinium bromide in acetonitrile $(Hpy)[VOBr_3(MeCN)_2]$ is obtained.[400] $[VOF_2(MeCN)(H_2O)]$ was prepared by the procedure described in Section 33.5.3.2 for $[VOF_2L_n]$.[429]

For malonodinitrile (maldn) and succinodinitrile (sucdn), $VO(maldn)SO_4\cdot 2H_2O$ and $VO(sucdn)SO_4\cdot 2H_2O$ were prepared according to reaction (24).[443]

$$VOSO_4 + \begin{matrix}\text{maldn}\\ \text{or}\\ \text{sucdn}\end{matrix} \xrightarrow[5\text{ h reflux}]{\text{DMF}} \text{complex} \qquad (24)$$

33.5.3.6 Biguanide and related ligands

Complexes of biguanide and substituted derivatives (big = $R^1R^2C(=NH)NHC(=NH)NH_2$) formulated as $[VO(big)_2(H_2O)]$ have been prepared from $VOSO_4$ and an excess of biguanide in alkaline solution.[444] The bluish green to light green crystalline products (see Table 13) are hydrolyzed by water. Room temperature moments are near the spin-only value. Syamal studied the ESR, IR and electronic spectra of polycrystalline complexes of biguanide, several dibiguanide derivatives and of *o*-methyl-1-amidinourea (Table 13).[445] The pure samples exhibited a single line at $g \approx 1.97$ but magnetic dilution in the corresponding diamagnetic Ni^{II} complexes resolved the hyperfine splitting, an axial spectrum (eight parallel and eight perpendicular lines) being obtained. The low values of $\nu(V{=}O)(\sim 940\ cm^{-1})$ are consistent with the presence of strong out-of-plane $d_\pi - p_\pi$ bonding. The electronic spectra were recorded in mulls and bands at ~590, 430 and 400 nm were assigned to bands I, II and III (see Figure 16b).[74] Complexes of guanylalkylureas appear as silky bluish green to rose-violet precipitates (Table 13). They were formulated as $[VO(gua)_2]$ complexes involving nitrogen coordination.[446]

33.5.4 Phosphorus and Arsenic Ligands

Only a few non-organometallic complexes with V—P bonds have been studied. The first oxovanadium(IV) phosphine complexes obtained pure were the green compounds $VOX_2\cdot L\cdot H_2O$ (X = Cl, Br; L = $Ph_2PCH_2CH_2PPh_2$) and $VOBr_2\cdot L'\cdot H_2O$ (L' = $Ph_2PCH_2PPh_2$),[447] prepared from $VOCl_2$ or $VOBr_2$ in carefully degassed solvents. In spite of precautions, some phosphine oxide compounds were formed. Table 14 summarizes some properties. $[VOBr_2(Ph_3P)_2]$ was prepared by substitution in THF from $[VOBr_2(MeCN)_3]$.[401]

ESR spectra of powdered $[VOCl_2(Ph_3P)_2]$ show some fine structure.[409] Spectra for $VOCl_2$

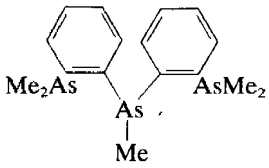
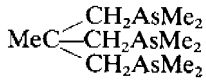
solubilized in toluene by an excess of phosphine R_3P show that each of the eight lines of the $^{51}V^{IV}$ nucleus is split into a 1:2:1 triplet.[448] This structure can be attributed to two equivalent phosphorus nuclei and was thus ascribed to $[VOCl_2(R_3P)_2]$. Varying the bulk of R, the spectra show increasing line width with increasing molecular volume and it was suggested that the trigonal bipyramid is the more probable configuration for $[VOCl_2(R_3P)_2]$.[448] This agrees with a suggestion that $[VOCl_2L_2]$ with trigonal bipyramidal structure should give two strong ν(V—Cl) IR-active bands;[409] in fact these were observed for $[VOCl_2L_2]$ (L = Ph_3P and Ph_2MeP; Table 14). As in $[VOX_2L_n]$ where L is a nitrogen ligand, ESR spectra with phosphines in non-aqueous solvents provide evidence for the occurrence of ligand dissociation and displacement.[409] For example, reaction (25) proceeds even in non-coordinating solvents and this again emphasizes the need for examination of species in solution when interpreting the electronic spectra (and other properties) of $[VOX_2L_2]$ complexes.



$$VOBr_2(Ph_3P)_2 \underset{Ph_3P}{\overset{THF}{\rightleftharpoons}} VOBr_2(THF)_2 + 2Ph_3P \qquad (25)$$

A dicyclohexylphosphide (Cy_2P) complex, $[Li(DME)][V(Cy_2P)_4]$ (DME = 1,2-dimethoxyethane) was isolated by the addition of a THF solution of $LiCy_2P$ to a suspension of a vanadium halide THF adduct at −80 °C, addition of DME and cooling to −30 °C.[449] The detailed structure was not determined; oxidation with $[Cp_2Fe](BF_4)$ gives the thermally unstable $[V(Cy_2P)_4]$.



The first compound with arsenic donors was orange $[VCl_4(diars)_2]$.[450] With the similar ligand detars (**28**), brown-black $[VCl_4(detars)]$ was obtained;[451] with tritertiary arsines (**29**) and (**30**) $[VCl_4L]$ were obtained.[452] The complexes were prepared by adding the arsines to VCl_4 in CCl_4; extreme care must be taken to avoid formation of the vanadyl species. Hydrolysis of (**28**) forms no complexes with definite composition, unlike the case of bipy and phen which form $[VOCl_2L]$.[451] However, with (**29**) and (**30**), similar VO^{2+} complexes were obtained by hydrolysis,[452] but were not well characterized. $[VCl_4(detars)]$ has $\mu_{eff} \sim 1.76$ BM (~293 K) and IR and solubility suggest that detars acts as a bidentate chelate (not a bridge).[6] A dodecahedral structure with bidentate arsines was suggested[6] for $[VCl_4(diars)_2]$ as it is isostructural with the corresponding titanium complex. When diars reacts with VCl_4 the only product is the eight-coordinate $[VCl_4(diars)_2]$, while with detars Clark[451] reported that $[VCl_4L]$ is obtained and in no circumstances was another molecule added to the six-coordinate complex. The tritertiary arsines (**29**) and (**30**) in $[VCl_4L]$ were originally considered terdentate;[452] thus V^{IV} would be seven-coordinate. Further structural studies are needed.

(**28**)

(**29**)

(**30**)

Attempts to prepare $[VOCl_2L_n]$ (L = Ph_3As and Ph_3Sb) were unsuccessful and only the As-containing compound $(Ph_4As)_2[VOCl_4]$ was obtained.[409] The ESR and the single ν(V—Cl) band (346 cm^{-1}) suggest a square pyramidal structure.[409]

33.5.5 Oxygen Ligands

33.5.5.1 Oxovanadium(IV) in aqueous solutions

(i) The vanadyl ion. Rate of exchange

In moderately acidic solutions, oxovanadium(IV) exists as VO^{2+} (or $VO(H_2O)_5^{2+}$) commonly called 'vanadyl ion' (Figure 19). The four water molecules of the tetragonal bipyramid have long residence time (see Table 15), and the axial water exchanges rapidly with the solvent. The 'labilization' of the *trans* water has been explained as a result of π bonding.[454] Water exchange is slow compared to other doubly charged ions.[455] The high charge of vanadium is important not only in the formation of the vanadyl group but also in the coordination of the water molecules.

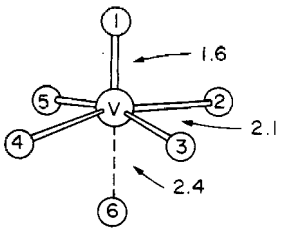


Figure 19 Schematic representation of $[VO(H_2O)_5^{2+}]$ and average internuclear distances (Å) from electron spin echo modulation (ESEM), electron nuclear double resonance (ENDOR) and X-ray diffraction studies[453]

Proton and deuteron relaxation show that relatively slow hydrogen exchange occurs in neutral solutions. The exchange is, however, acid catalyzed. Rivkind interpreted increased spin–spin relaxation rate with increasing acidity as due to protonated vanadyl and estimated

the constant $\beta_p = [VOH^{3+}]/([VO^{2+}][H^+])$.[456] However, the similarity of the activation parameters for the proton-catalyzed proton exchange of VO^{2+} and that of Ni^{2+} and Cr^{3+} is a strong argument against Rivkind's interpretation.[457] The hydrogen lifetime in the first coordination shell of VO^{2+} ions is determined by chemical exchange of the equatorial water.[458,459] Nágypál *et al.* studied equilibrium (**26**) by spectrophotometric methods at constant $[ClO_4^-]$ (6 M) and interpreted NMR relaxation at 2.5 and 100 MHz taking into account both chemical environments and reaction pathways.[460] The UV spectrum of solutions cannot be explained by protonation of the vanadyl oxygen: the protonation site is a coordinated water, contrary to Rivkind's interpretation. The protonation constant for reaction (**26**) is 0.23 ± 0.05. Variations in absorption spectra have also been explained through anation by the acid (including ClO_4^- [461]). For high acid concentrations, V^{IV} may be oxidized. Ballhausen and Gray explained the resistance of VO^{2+} to protonation in terms of the M.O. bonding scheme.[364]

$$VO^{2+} + H^+ \rightleftharpoons VOH^{3+} \tag{26}$$

Considering values in Table 15 and other kinetic data, Nishizawa and Saito classified the rates of substitutions into five categories (Figure 20):[462] (1) very rapid apical substitution, (2) fairly rapid intramolecular rearrangement from apical to basal, (3) rather slow direct basal substitution, (4) slow chelate formation of a bidentate ligand coordinated as a unidentate and (5) very slow exchange of the oxo ligand. According to this view, regioselectivity between *trans* (apical) and *cis* (basal) sites on substitution reaches 10^9.[462]

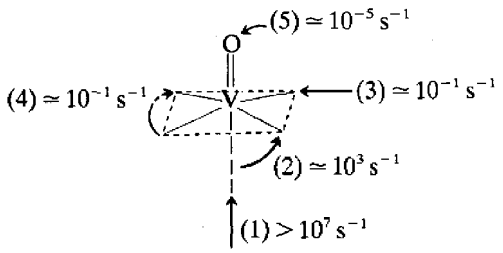

Figure 20 Different substitution rates at various coordination sites of oxovanadium(IV) ion (see text), with approximate first-order rate constants at room temperature

(*ii*) *Hydrolysis in solution*

From potentiometry, calorimetry (Table 16) and ESR spectroscopy,[463–465] there is agreement about the species in moderately acidic solutions. On the other hand, the nature of species present in neutral or basic solutions is still controversial.

In moderately acid solutions, oxovanadium(IV) exists mainly as $[VO(H_2O)_5]^{2+}$. As pH

increases (but pH $\lesssim$ 4), evidence for the formation of $[VO(OH)]^+$ and $[(VO)_2(OH)_2]^{2+}$ is strong. Table 16 summarizes the relevant constants (β_{np} is defined according to equation 27).

$$n VO^{2+} + pH_2O \rightleftarrows (VO)_n(OH)_p^{2n-p} + pH^+ \qquad \beta_{np} = \frac{[(VO)_n(OH)_p^{2n-p}]}{[VO^{2+}]^n[H^+]^p} \tag{27}$$

Oxovanadium(IV) is amphoteric but only a few quantitative studies exist on vanadium(IV) in neutral or basic solutions. Ducret explained his observations by the existence at pH $\geq$ 8–9 of $[(VO)_2(OH)_5]^-$.[466] Britton and Welford[468] also suggested $[(VO)_4(OH)_{10}]^{2-}$ to explain titration in basic solutions and Lingane and Meites[469] interpreted polarographic data in terms of $[(VO)_2(OH)_6]^{2-}$ and $[(VO)_4(OH)_{10}]^{2-}$. Ostrowetsky also assumed the formation of $[(VO)_4(OH)_{10}]^{2-}$ in neutral and basic solutions and obtained brown reddish crystals, $(NH_4)_2V_4O_9$.[470] Chasteen remarked that species in the pH range 7–11 are ESR silent[471] and suggested that polymeric $[VO(OH)_3]_n^-$ exist at pH ~ 7.[354]

Virtually all amphoteric oxides are converted to monomeric anions in sufficiently strong basic media. Rieger and co-workers studied strongly basic oxovanadium(IV) solutions by ESR, optical and Raman spectroscopy.[472] Raman absorption at 987 cm^{-1} confirms the presence of the vanadyl group in solution, and from ESR spectra and titration, the authors concluded that vanadium(IV) exists as a monomer $[VO(OH)_3]^-$ for pH $\geq$ 12.

In Figures 21(a) and 21(b), speciations of solutions with two different total oxovanadium(IV) concentrations are presented assuming that the predominant soluble species in the pH range *ca.* 6–11 is $[(VO)_2(OH)_5]^-$. Further research is required to sort out the species and equilibria existing in neutral and basic solutions.

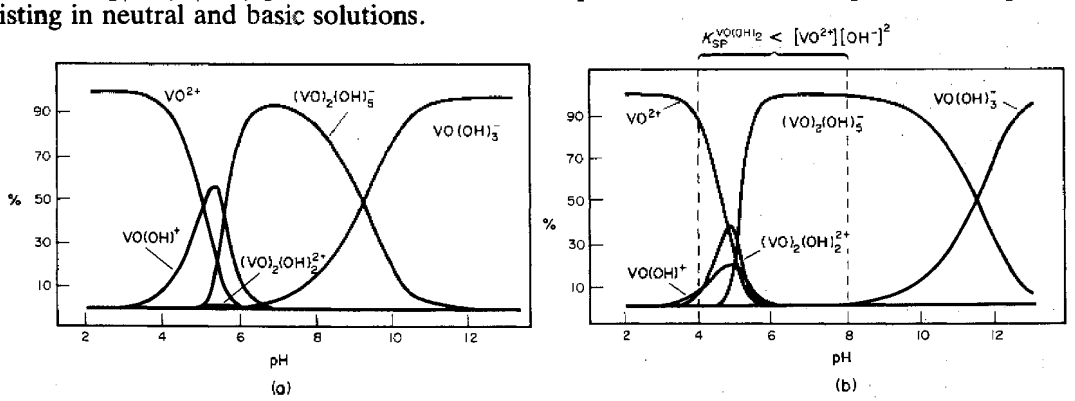

Figure 21 Speciation in oxovanadium(IV) aqueous solutions: (a) $C_{VO} = 10^{-5}$ M and (b) $C_{VO} = 2 \times 10^{-3}$ M. Formation constants β_{11}, β_{22} and β_{25} are those reported by Komura *et al.* for 0.1 M $LiClO_4$ and 25 °C.[467] For pH $\geq$ 5 these speciations should only be used as a guide in order to give an idea of what may probably be the relative importance of the total concentrations of species $[(VO)_2(OH)_5^-]_n$ and $[(VO)_2(OH)_6^{2-}]_m$. For pH $\geq$ 12 apparently only $[VO(OH)_3^-]$ predominates. Note that the ratio $C_{monomeric}:C_{polymeric}$ increases as the C_{VO} decreases and that in (b) $K_{sp} \lesssim [VO^{2+}][OH^-]^2$ in the pH region *ca.* 4–8. In the calculations β_{13} was assumed to be 1×10^{-18}

(iii) Redox behaviour of oxovanadium(IV) solutions

Because of the multiple and slow equilibria, the elucidation of all the species present and the hydrolysis and redox equilibria is a difficult task. Redox behaviour of oxovanadium(IV) will not be discussed here: detailed information is given by Pourbaix,[474] Hepler and co-workers,[475] 'Gmelins Handbuch'[357] or Baes and Mesmer.[87]

The most important half-cell reactions are shown in equations (28) and (29).[476] Oxovanadium(IV) can be oxidized by O_2, more easily as pH increases; in acidic solutions, the blue VO^{2+} solutions are stable to air. Air oxidation in alkaline solutions (0.006–3.8 M NaOH) is rapid at 15 °C.[477] The initial rate is proportional to $[OH^-]$. Fe^{III} catalyzes the reaction while Cr^{III} inhibits it. With $[V] > 0.002$ M, the rate is controlled by diffusion of oxygen. When VO^{2+} is chelated, oxidation may be considerably retarded and—as a rule—the more stable the complexes, the more pronounced this 'retardation effect'. However, in 1:1 solutions of oxovanadium(IV) and tartrate at pH ~ 8, the oxidation is rapid.[478] The dissolved oxygen was depleted within a few seconds.

$$VO_2^+(aq) + 2H^+ + e^- \rightleftharpoons VO^{2+}(aq) + H_2O \qquad E^0 = 1.00\,V \tag{28}$$

$$VO^{2+}(aq) + 2H^+ + e^- \rightleftharpoons V^{3+}(aq) + H_2O \qquad E^0 = 0.359\,V \tag{29}$$

A study of several VO^{2+}–complexone–aqua complexes with a few outer-sphere oxidants proved the importance of an equatorial H_2O or OH^- ligand.[479] The products certainly have a hexacoordinate *cis*-dioxo structure. Presumably the aqua ligand can change into a new oxo ligand without changing its site, and the other donors are retained without rearrangement or partial dissociation. Further, significant regioselectivity exists:[479] *cis*-oxo-hydroxo complexes are much more rapidly converted into *cis*-dioxo complexes (V^V compounds) than *cis*-oxo-aqua complexes or those without hydroxo or aqua *cis* to the vanadyl oxygen.

(iv) Mixed-valence species

Ostrowetsky studied solutions containing V^V and V^{IV} and concluded:[481] (i) at pH ≳ 10, no mixed-valence complex forms; (ii) at 8 ≲ pH ≲ 10, one forms with a V^{IV}/V^V ratio of 2, and at least six vanadium atoms; a solid, $Na_3[V_2^VV_4^{IV}O_{15}H]$, was isolated; (iii) at 4 ≲ pH ≲ 6.5, six different mixed-valence complexes form but only those with V^{IV}/V^V ratios of 3/7 and 7/3 are stable; (iv) a compound containing eight V^V and two V^{IV} transforms into the more stable 7/3 compound in a few minutes; (v) all these compounds contain a V_{10} group in the molecule.

Deep violet crystalline $[Et_4N]_2[V_5O_{14}H_2]$ was prepared from CH_2Cl_2 (or similar) solutions containing $[VO(acac)_2]$, Et_4NCl and $[Cu(acac)_2]$.[359,482] Why it forms is not understood. It was formulated as $[Et_4N]_4[V_8^VV_2^{IV}O_{28}H_4]$. Two types of mixed-valence vanadium compounds are known: the very inert bronzes and the aqueous decavanadates. This compound appears intermediary, somehow related to both types.[482] Its colour, hardness and metallic lustre are similar to the bronzes. Yet it is soluble in water, producing a green solution with a spectrum similar to one of the 7/3 decavanadates described by Ostrowetsky.[481] Robin and Day also discuss the formation of the stable 7/3 species proposed by Ostrowetsky and assume that all these anions almost certainly retain the $V_{10}O_{28}$ skeleton.[483]

33.5.5.2 Peroxide ligand

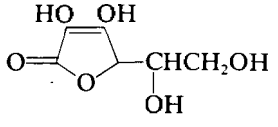
Orange-red oxoperoxovanadates(IV) $(Ct)[VO(O_2)F(H_2O)_2]$ ($Ct = NH_4^+$, K^+, Rb^+, Cs^+) were synthesized from $(Ct)[VOF_4]$ with H_2O_2 in the molar ratio 1:12 (pH ~ 4).[484] Insoluble in common organic solvents, they decompose in water. Redox titrations indicate the presence of O_2^{2-} coordinated to the V^{IV} of VO^{2+}. The $\mu_{eff}^{r.t.}$ are 1.70–1.75 BM and the optical spectra showed three absorptions at *ca.* 476 (or lower), 565 and 855 nm, the first obscured by strong charge transfer.[484] $\nu(V{=}O)$ of compounds $(Ct)[VO(O_2)F(H_2O)_2]$ was in the range 950–970 cm^{-1}.

33.5.5.3 Alcohols

Alcohols and phenols cleave two bonds of VCl_4 forming dichloroalkoxides. Those formed by aliphatic alcohols are dark green and dimeric in boiling benzene.[6] At 150 °C (0.1 mmHg) they yield $[V_2OCl_3(OR)_3]$. The *t*-butyl and *t*-amyl alkoxide chlorides are made by alcohol exchange on the isopropoxides.[6] $[VCl_2(OR)_2{\cdot}ROH]$, where R = *n*- or *t*-butyl, give well-resolved ESR spectra with $g_{av} = 1.95$.[485] While alkali metal alkoxides do not usually effect complete cleavage of V—Cl bonds, pale blue $[V(OSiPh_3)_4]$ may be obtained in the reaction of VCl_4 with sodium triphenylsilanolate.[486] The liquid analogue $[V(OSiEt_3)_4]$ forms from $[V(NEt_2)_4]$ and triethylsilanol in benzene.[420]

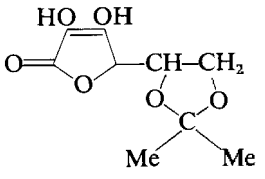
Complete replacement of the halogen atoms in VCl_4 can be achieved using lithium dialkylamides. As described in Section 33.4.3.1.i, VCl_4 with $LiNEt_2$ gives the dark green liquid $[V(NEt_2)_4]$. This and $[V(NMe_2)_4]$ react vigorously with alcohols to give moisture-sensitive tetraalkoxides $[V(OR)_4]$.[420] Molecular weight measurements in benzene show that the tertiary alkoxide complexes are monomeric liquids, the secondary are predominantly monomeric and the primary are associated.[487] An eight-line partially resolved ESR spectrum was obtained with pure $V(OBu^t)_4$ at 303 K.[487,419] The ESR parameters from room temperature[487] and frozen solutions[420,488] indicate distorted D_{2d} symmetry with a $d_{x^2-y^2}$ ground state; the compound is magnetically dilute with $\mu_{eff} = 1.69$ BM independent of temperature. Solid vanadium tetramethoxide gave a very broad ESR spectrum. The results are consistent with a trimeric species $[V_3(OMe)_{12}]$. It shows significant temperature variation of μ_{eff}.[419] Dimeric $[V_2(OEt)_8]$ also gave a broad ESR spectrum consistent with an orbital singlet ground state with magnetic dipole interaction. NMe_4^+ and NH_4^+ salts of $[VCl_5(OR)]^{2-}$ (R = Me, Et, Pr^n, Bu^n) gave μ_{eff} values near the spin-only value for a d^1 system with negligible temperature variation.[489]

$VOCl_2{\cdot}3MeOH$ may be prepared when VCl_4 reacts with MeOH[490] (*cf.* Section 33.5.3.2). Several other complexes $[VO(L)_n(X)_m]$ where L is a relatively strongly bound ligand (*e.g.* Cl^-) and X is alkoxide or alcohol have been included in early reviews,[6,355,356] *e.g.* $[NMe_4][VOCl_4(EtOH)]$. Some are discussed in other sections according to the nature of L. Glycerol inhibits V^{IV} oxidation in alkaline solutions and prevents precipitation in the whole pH range. Absorption spectra indicate coordination of glycerol.[491]



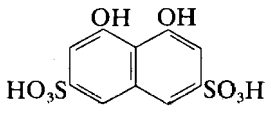
The stability constants with ascorbic (**31**) and 5,6-*O*,*O*′-isopropylideneascorbic acids (**32**) have been estimated and are almost independent of the nature of the ligands,[492] which are unidentate, the hydroxyl groups in the lactone ring being involved in the coordination. A vanadyl ascorbate has been synthesized, formulated $[VO(C_6H_7O_6OH)]{\cdot}2H_2O$.[493]

33.5.5.4 Catecholate, polyketonate, hydroxyaldehydate and hydroxyketonate ligands



(i) Catecholates

Aromatic polyalcohols act as strong coordinating agents and Table 17 summarizes reported formation constants. The complexes are quite stable; this behaviour has been used for the qualitative and quantitative determination of vanadium (*e.g.* refs. 494 and 495). At pH 3–4, an initial vanadyl catechol complex slowly converts to a tris complex.[496] In fact complexes with 1:3 metal–ligand stoichiometry have been isolated (see below), but since in the equilibrium (30) no protons are consumed or liberated, $[VO(cat)_2]^{2-}$ and $[V(cat)_3]^{2-}$ are not distinguishable by potentiometric studies.



$$VO(cat)_2^{2-} + H_2cat \rightleftharpoons V(cat)_3^{2-} + H_2O \qquad (30)$$

Although 1:2 complexes may be isolated, formation of 1:3 complexes and displacement of the vanadyl oxygen seem to be favoured. This effect is probably due to the exceptional chelating ability of 1,2-dihydroxybenzenes which appear particularly good σ and π donors, an effect that stabilizes metal and ligand without a change in formal change. An interesting comparison can be made for $K_3[V^{III}(cat)_3]$,[497] $(Et_3NH)_2[V^{IV}(cat)_3]$[256] and $Na[V^{V}(DTBcat)_3]$[256] (cat = $C_6H_4O_2^{2-}$, $H_2DTBcat$ = **35**); $d(V—O)_{av}$ are 2.013, 1.942 and 1.91 Å, and the ionic radii are 0.78, 0.72 and 0.68 Å, respectively.

From equation (30), whether a tris chelate is formed depends on the donor ability of the ligand. Several vanadium(IV) complexes with 1,2-dihydroxybenzenes formed from solutions of the ligand, $VOSO_4$ and thallium(I) acetate.[498] The compounds are of two types: (I) $Tl_2[V(RC_6H_3O_2)_3]$ (R = H, 3-Me, 4-Me, 3-MeO) and (II) $Tl_2[VO(RC_6H_3O_2)_2]$ (R = CHO).

The crystal and molecular structures of $(Et_3NH)_2[V(cat)_3]\cdot MeCN$ (**37**) and $K_2[VO(cat)_2]\cdot EtOH\cdot H_2O$ (**36**) were determined. Complex (**36**) has a square pyramidal geometry; $d(V{=}O) = 1.616$ Å (longer than usual in complexes with geometry of type (**41**)) and $d(V—O(cat)) = 1.956$ Å. Complex (**37**) has an approximately octahedral coordination geometry. $(Et_3NH)_2[VO(L)_2]\cdot 2MeOH$ (L = **35** and **37**) were prepared by displacement using $[VO(acac)_2]$ and adding the appropriate catechol.[256] A similar method was used for $Na_2[VO(DTBcat)_2]$ (**38**).[500] Its absorption spectrum in CH_2Cl_2 is dominated by intense change transfer which results in a bronze-coloured solution. When one equivalent of $SOCl_2$ is added to one of (**38**) in CH_2Cl_2, the solution immediately changes to blue. The resulting blue $Na_2[VCl_2(DTBcat)_2]$ (**39**) can also be formed by the same procedure as for the synthesis of (**38**), but with $VCl_2(acac)_2$ in place of $[VO(acac)_2]$.

In contrast with catechol[498,501,502] and norepinephrine[501] complexes where V^{IV} seems to be the stable oxidation state, V^{III} and V^{IV} DTBcat complexes are oxidized to V^{V} by protic solvents.[500] However, observation of V^{IV} ESR does not necessarily imply complete reduction of V^{V} by catechol;[256] either partial reduction or even adventitious V^{IV} could yield a similar result.

Redox chemistry of vanadium–catechol systems is complicated; References 256, 497 and 499–508 discuss this subject in detail. In complexes, the metal centre may be in the +5, +4, +3 (and +2) formal oxidation state and quinones complex in three localized electronic forms:

catecholate, semiquinolate and quinolate. A complex containing mixed charged ligands, $[V^{V}O(DTBSQ)(DTBcat)]_2$ (DTBSQ = semiquinonate of **35**), has been characterized structurally and the formation of $[V(Cl_4SQ)(Cl_4Q)_2]$[497] (Cl_4Q = tetrachloroquinonato and Cl_4SQ = tetrachlorosemiquinonato) has also been suggested.

(*ii*) *β-Diketonato ligands*

In addition to the very stable, commercially available, crystalline blue-green $[VO(acac)_2]$, several other $[VO(\beta\text{-diketonato})_2]$ complexes have been prepared;[509,510] they vary from yellow to green and brown. The $\mu_{eff}^{r.t.}$ values are in the range 1.71–1.76 BM and normally decrease slightly in the range 300–380 K.[509]

$[VO(acac)_2]$ may be prepared by several methods (*e.g.* by one-electron reduction of V^{V} by ethanol or mixing the diketone with $VOSO_4$) and its crystal and molecular structure has been determined.[511] It consists of discrete molecules of $[VO(acac)_2]$ in which vanadium presents a nearly square pyramidal geometry (Figure 22). Some internuclear distances are in Table 18. The crystal structure of $[VO(bzac)_2]$ (bzac = 1-phenyl-1,3-butanedionato) has also been determined.[512a] The ligands are arranged in a square pyramidal geometry with a *cis* configuration and each phenyl ring is nearly coplanar with its chelate ring. Some distances are in Table 18. IR and Raman spectra of $[VO(acac)_2]$ were studied.[512b]

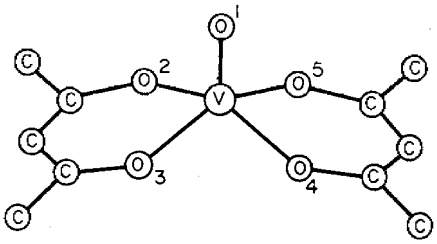

Figure 22 Perspective view of $VO(acac)_2$ molecule.[511] Internuclear distances are given in Table 18

In many solvents, particularly water and alcohols, $[VO(\beta\text{-diketonato})_2]$ are slowly oxidized by atmospheric O_2,[513] but very rapidly with H_2O_2.[355]

The constant for reaction (**31**) for β-diketones in tautomeric keto (HK) and enol (HE) forms, can be partitioned between K_K and K_E (reactions **32** and **33**). At equilibrium, equations (34) and (35) hold, and values obtained are given in Table 19.[514] Kinetics showed that the reaction occurs through the enol form by parallel acid-independent and inverse-acid paths (Scheme 15).[514]

$$VO^{2+} + HL \overset{K_1}{\rightleftharpoons} VO(L)^{+} + H^{+} \quad (31)$$

$$VO^{2+} + HK \overset{K_K}{\rightleftharpoons} VO(E)^{+} + H^{+} \quad (32)$$

$$VO^{2+} + HE \overset{K_E}{\rightleftharpoons} VO(E)^{+} + H^{+} \quad (33)$$

$$\frac{1}{K_I} = \frac{1}{K_E} + \frac{1}{K_K} \tag{34}$$

$$\frac{[HE]}{[HK]} = \frac{K_K}{K_E} \tag{35}$$

Scheme 15

In dichloroethane the ligand exchange of $[VO(acac)_2]$ with Hacac [^{14}C] occurs without side reactions and the rate may be expressed by $R = k_2[VO(acac)_2][Hacac]$, where [Hacac] is the concentration of the free acac in enol form.[515]

Electrochemistry of $[VO(acac)_2]$ in DMSO has been studied by cyclic voltammetry and controlled-potential coulometry at a platinum electrode.[516] $[VO(acac)_2]$ is irreversibly reduced by one electron at −1.9 V *vs.* SCE (saturated calomel electrode) to a stable V^{III} product. In the presence of an excess of ligand, $[VO(acac)_2]$ is reduced by two electrons to $[V(acac)_3]^-$ with the V^{III} species mentioned above and $[V(acac)_3]$ as intermediates. The one-electron oxidation of $[VO(acac)_2]$ at +0.81 V *vs.* SCE gives a V^V product.

The room temperature ESR spectrum of $[VO(acac)_2]$ in toluene consists of the eight lines expected for an atom of spin $\frac{7}{2}$, with $g = 1.971$ and an average coupling constant of 120 G.[517,518] In frozen (77 K) toluene solution, molecular tumbling ceases, different molecular axes of the axially symmetric $[VO(acac)_2]$ are oriented along the applied field and the spectrum splits into two overlapping eight-line spectra. The single crystal spectra of *cis*-$[VO(bzac)_2]$ show anomalous fine structure.[519]

Solvent effects and adduct formation of $[VO(acac)_2]$ and other $[VO(\beta\text{-diketonato})_2]$ complexes have been studied by several methods[361,366,520–532] and in coordinating solvents $[VO(acac)_2]$ is known to add a sixth ligand according to equation (36). Older reports include a spectrophotometric and calorimetric study of $[VO(acac)_2]$ and $[VO(tfacac)_2]$ adducts.[521] With $[VO(acac)_2]$ in nitrobenzene, the enthalpy change for reaction (**36**) ranges from 44.3 kJ mol^{-1} for *n*-decylamine to 24.3 kJ mol^{-1} for methanol. Equilibrium constants K were between 1000 and ~0.6. $[VO(acac)_2]$ is not a sensitive indicator of relative base strength.[521] For $[VO(acac)_2]$, A_0 decreases by ~3 G (and g_0 increases by ~0.0004) as amine adducts are formed.[522]

$$VO(acac)_2 + \text{ligand} \overset{K}{\rightleftharpoons} VO(acac)_2(\text{ligand}) \tag{36}$$

Equilibrium constants for reaction (**36**) have been estimated from spectrophotometry. In some studies, visible spectra of solutions containing $[VO(acac)_2]$ at constant concentration and base in variable concentration show an isosbestic point, which suggests but does not prove that

there are only two absorbing species. However, in all cases the results were interpreted according to equation (36).

Table 20 summarizes results from several spectroscopic equilibrium studies of adduct formation $[VO(acac)_2]$.[525,532–534]

In early work, solvent effects were explained by coordination at the vacant axial position. This was questioned by Guzy *et al.* who measured spectra of $[VO(acac)_2]$ in numerous solvents and pointed out that, especially for hydrogen-bonding solvents, there might be interaction with vanadyl oxygen.[361] Selbin concluded that for alcohols (and $CHCl_3$ and CH_2Cl_2), the H-bonding effect is greater with the vanadyl oxygen than with the acac oxygens.[359] The interaction of $[VO(acac)_2]$ with solvents has been measured by the ^{51}V hyperfine coupling in mixtures of ethanol and CCl_4 as a function of solvent composition.[529]

IR studies with pyridine derivatives[535,536] showed the existence of adducts with the sixth ligand bound *cis* rather than *trans* to the oxygen; an X-ray study of the 4-phenylpyridine (Phpy) adduct confirmed this (Figure 23a).[537] Interaction of ligands (solvent or a dissolved molecule) with $[VO(acac)_2]$ may involve (i) coordination in a sixth position *trans* to the vanadyl oxygen, (ii) coordination in a sixth position *cis* to the vanadyl oxygen, and (iii) hydrogen bonding to the oxygen (or atoms of the ligand).

While type (ii) was observed with the 4-phenylpyridine adduct, interaction of type (i) exists between $[VO(acac)_2]$ and 1,4-dioxane (diox) or 4-picoline. With diox, a substantial change in the $\nu(V{=}O)$ stretch is observed when it is added to $[VO(acac)_2]$ in $CHCl_3$[538] but only small effects for the visible spectra in nitrobenzene.[521] In the complex $[VO(acac)_2(diox)]$, from X-ray analysis, the oxygen atoms of diox are coordinated *trans* to the vanadyl oxygen (Figure 23b).[539] The crystal structure of $[VO(acac)_2(4\text{-picoline})]$ consists of discrete molecules with 4-picoline in the *trans* position and a very short V=O of 1.557(17) Å.[540]

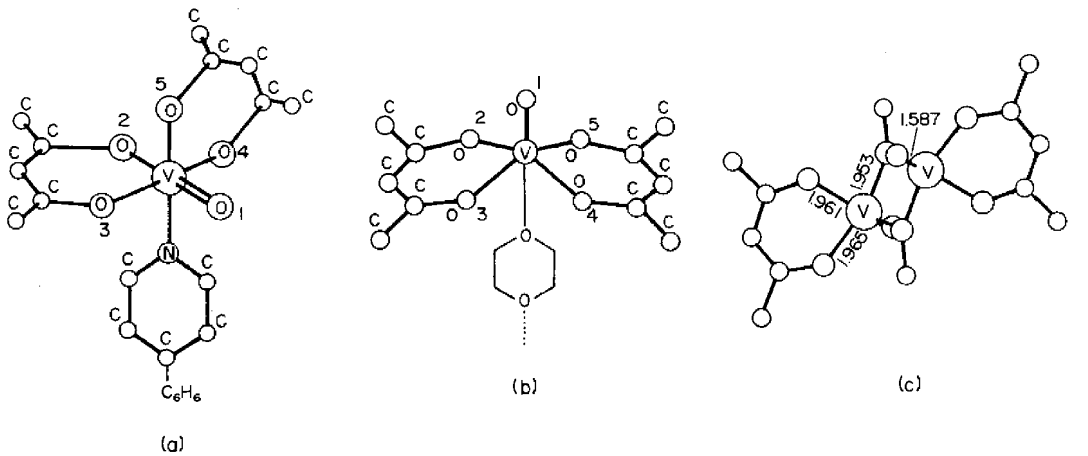

Figure 23 Schematic representation of the molecular structure of (a) $[VO(acac)_2(4\text{-phenylpyridine})]$,[537] (b) $[VO(acac)_2(1,4\text{-dioxane})]$[539] (a dioxane molecule bridges two $[VO(acac)_2]$ groups) and (c) $[VO(OMe)(acac)]_2$.[553] Some internuclear distances are included in Table 18

Besides the structure of $[VO(acac)_2(Phpy)]$[537] and IR evidence,[535,536] ENDOR studies (see Section 33.5.1) suggest formation of *cis* adducts and/or the existence of *cis* and *trans* isomers.[527] For $[VO(acac)_2]$ with methanol and substituted pyridines in frozen $CHCl_3$/toluene solutions, there must be a well-defined binding site for $CHCl_3$, most likely *via* a hydrogen bond to the vanadyl oxygen, and methanol is at the vacant axial position. For $[VO(acac)_2]$ and substituted pyridines in $CHCl_3$, complexation induced constant shifts of $31 \pm 3\ cm^{-1}$ and/or $51 \pm 3\ cm^{-1}$ (Table 21)[535] attributed to *cis* ($31\ cm^{-1}$ shift) and/or *trans* ($51\ cm^{-1}$ shift) adducts. However, the IR of solid $[VO(acac)_2(substituted\ py)]$ (Table 22) were interpreted on the reverse assumption that *cis* coordination produces the larger shift of $\nu(V{=}O)$.[536] Kirsk and van Willigen consider that the group of pyridines that coordinate in the *cis* position induces a larger shift in $\nu(V{=}O)$;[527] accepting this, they find a good correlation between the solution IR data[535] and their own ENDOR. In a number of instances, the isomer that is present in the solid state[536] may not predominate in liquid[535] and frozen solution. Other investigations emphasize subtle factors controlling equilibrium between different conformation.[526,531,541] For example, Mannix and Zipp[526] studied the visible spectra of $[VO(acacX)_2]$ (X = Cl or Br) in several solvents with a

wide range of donor properties and obtained a linear relationship between the energy differences of the first two visible bands, $D_{1,2}$, and the solvent donor number.[542] However, the $[VO(acacX)_2]$ compounds were found to be poorer acceptors than $[VO(acac)_2]$; this is surprising.

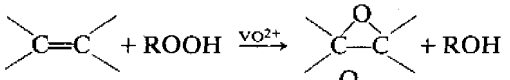
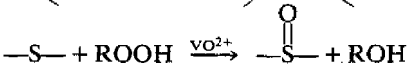
A rather different study of the kinetics of decomposition of solid complexes of $[VO(dbm)_2(L)]$ (dbm = dibenzoylmethanato, L = py and several methyl-, dimethyl- and amino-pyridines) used differential scanning calorimetry (DSC).[531] Using the temperature that corresponds to the loss of the molecule L in equation (37), a linear relationship was found between it and the basicity of L, except for 4-amino- and 4-methyl-pyridine.

$$VO(dbm)_2L \longrightarrow VO(dbm)_2 + L \qquad (37)$$



In the coordination of 4-picoline *N*-oxide (MPNO) to a series of $[VO(\beta\text{-diketonato})_2]$

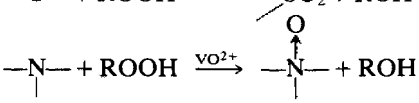
complexes, IR spectra and equilibrium constants for adduct formation followed the order: tftacac > tfacac > dbm > bzac > acac > dpm (dipivaloylmethanato). A similar order was found with several other neutral bases.[524] For $[VO(acac)_2]$, the MPNO coordinates *trans* but for $[VO(bzac)_2]$ and others the coordination is *cis*. A similar trend was found in compounds $[VO(\beta\text{-diketonato})_2(L)]$ with acac or tfacac and L = py, phen, α- and β-naphthoquinoline (α- and β-nq).[543] $[VO(acac)_2(phen)]\cdot 2MeOH$ was prepared from an excess of phen with $[VO(acac)_2]$ in methanol. The same reaction in CH_2Cl_2 results in V^{IV} oxidation and $[VO_2(acac)(phen)]$ is obtained,[544] while $[VO(tfacac)_2(phen)]$ is produced in both solvents if the starting material is $[VO(tfacac)_2]$. In the two $[VO(\beta\text{-diketonato})_2(phen)]$ complexes, phen was said to be unidentate and a *cis* octahedral structure was proposed for $[VO(tfacac)_2(L)]$ complexes (L = py, phen, α-nq, β-nq).[543]



Early publications on $[VO(\beta\text{-diketonato})_2]$ have been reviewed.[355] More recently, complexes with benzoyl *m*-nitroacetanilide, benzoyl acetanilide[545] and 1,1′-(1,3-phenylene)-bis(butane-1,3-dione[546] have been synthesized. Other $[VO(\beta\text{-dik})_2]$ adducts have been isolated, for example $[VO(acac)_2]$ adducts with a series of pyridine *N*-oxides[547] and several pyridine carboxamides,[548] and $[VO(bzac)_2]$ adducts with pyridine, methylamine, isoquinoline and 4-picoline.[549] Equilibrium constants of 1:1 and 2:1 adducts of pyrazine with $[VO(tfacac)_2]$ have been determined (equation 38).[550] In the 2:1 complex, the pyrazine bridge between two equatorial sites of adjacent vanadium atoms promotes a weak exchange interaction. The nitroxide radical 2,2,6,6-tetramethylpiperidinyl *N*-oxide also forms an adduct with $[VO(hfacac)_2]$ in which there is a strong interaction between the electrons on the metal and nitroxide.[551]

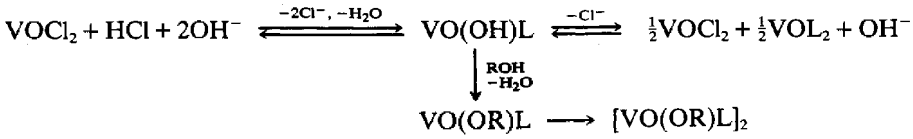
$$VO(tfacac)_2 + pz \underset{}{\overset{K=1.5\times10^6}{\rightleftharpoons}} VO(tfacac)_2pz \overset{K=2\times10^3}{\rightleftharpoons} [\{VO(tfacac)_2\}_2pz] \qquad (38)$$

Oxidation of alkenes, sulfides, sulfoxides and amines by alkyl hydroperoxides (ROOH) is catalyzed by $[VO(acac)_2]$ (equations 39–42),[552] and mechanisms involving association of ROOH with $[VO(acac)_2]$ forming V^V compounds have been suggested.[552] The reactions of phenoxyl, iminoxyl, nitroxyl, peroxyl and alkoxyl radicals with $[VO(acac)_2]$ in solution were studied by kinetic ESR spectroscopy[552] and the net reaction was found to be catalytic reduction of the radical, probably also involving initial formation of a V^V compound.



(39)

(40)



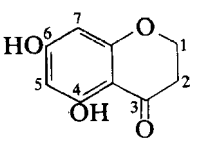
(41)

(42)

The reaction in alcoholic medium of a β-diketone, a base and $VOCl_2$ in 1:2:1 molar ratios leads to compounds $[VO(alkoxy)(\beta\text{-diketonato})]_2$.[553] This is an interesting result since $[VO(\beta\text{-diketonato})_2]$ form if the reaction with the same species is carried out in molar ratios of 2:2:1 or 1:1:1. Therefore, the stoichiometry in which the reagents are mixed will drive the reaction towards one product or the other. This behaviour was rationalized assuming Scheme 16 where an intermediate [VO(OH)L] (not isolated) forms and is irreversibly transformed to the corresponding [VO(OR)L] compound.

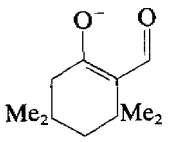
Scheme 16

Several complexes $[VO(OR)_2(\beta\text{-dik})]_2$ were prepared including $[VO(OMe)(acac)]_2$; for its crystal structure,[580] see Figure 23(c).[553] It consists of dimeric units with a chair-like



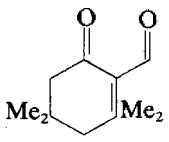
arrangement and the geometry around the vanadium atom was best described as tetragonal bipyramidal. The vanadium lies 0.60 Å above the plane of two β-diketone oxygens and two bridging alkoxy oxygen atoms. The $\mu_{eff}^{r.t.}$ is 1.80 BM, *i.e.* magnetic exchange is much greater in the Cu^{II} analogues. V—V is 3.102 Å. Although the compositions, homogeneity and molecular weights of the polymers obtained using $[VO(OR)(\beta\text{-dik})]_2$ complexes as Ziegler–Natta catalysts are almost the same as those obtained using the commercial catalysts $[V(acac)_3]$ and $[VOCl_3]$, the latter show higher activities.

A few $[VO(OMe)(\beta\text{-diketonato})]_2$ and $[VO(L)]_2$ complexes (L = polydentate O-coordinating ligands) also have a high catalytic activity for the oxygenation of catechols (namely 3,5-di-*t*-butyl-1,2-dihydroxybenzene)[554] and this reaction was considered similar to the one catalyzed by pyrocatechase.



A different group includes vanadium^{IV} hexacoordinate complexes with no vanadyl bond. Complexes $[VO(L)_n]$ (L = tetradentate or two bidentate ligands) react under mild conditions with $SOCl_2$ or $SOBr_2$ producing $[V(L)_nCl_2]$ or $[V(L)_mBr_2]$ hexacoordinate V^{IV} complexes.[429] The same deoxygenation can be accomplished in dioxane by PCl_5, which is even more reactive than $SOCl_2$.[555] Complexes $[V(\beta\text{-diketonato})X_2]$ (X = Cl, Br) have been studied with acac, bzac, dbm, tfacac: *cis* and *trans* isomers may form, in relative abundances which are solvent dependent. In non-polar solvent, the abundance of the *trans*-dichloro isomer decreases in the order tfacac > acac > bzac > dbm.[429] All these dark compounds are rapidly hydrolyzed in air to vanadyl complexes.

(*iii*) *Hydroxyaldehydato and hydroxyketonato ligands*



Several VO^{2+} salicylaldehydato (and derivative) complexes $[VO(L)_2]$ have been prepared although practically no work is recent. The early work has been reviewed[355,357b] and includes salicylaldehyde (Hsal) and the derivatives 5-Cl-, 5-Br-, 3,5-Br_2-, 3,5-Cl_2-, 4-phenyl- and 4-amino-salicylaldehyde. The oxovanadium(IV) complex of β-hydroxynaphthaldehyde was also reported.[556,559] More recent studies include the synthesis of compounds formulated as $[VO(L)_2]$ with L = (**46**; R = 3-MeO, 5-Cl),[557,558] (**47**), 3,7-dimethyl-7-hydroxyoctan-1-al[560] and 4,6-dihydroxycoumaran-3-one (**40**).[561] IR spectra of the last suggests that coordination involves the 3- and 4-oxygen atoms. No magnetic data are given and $\nu(V{=}O) = 965\ cm^{-1}$.

After mixing for a few hours a solution of (**42**) in CH_2Cl_2 with a solution of $VOSO_4$ (pH 3) in H_2O under N_2, a chelate with the β-ketoaldehyde (**41**), formulated as $[VOL_2]$, was obtained from the organic phase.[562] ESR showed $A_0 = 105$ G. Similarly formulated complexes with the nitroxides (**43**) and (**44**) were observed in solution. $[VO(tropolonato)_2]$ (tropolone = **45**) and the deoxygenated compounds obtained by reaction with $SOCl_2$ and $SOBr_2$ (Section 33.5.5.4.ii) $[VX_2(tropolone)_2]$ (X = Cl, Br), have been studied.[429] A trigonal prismatic structure is proposed with the chelate ligands occupying two vertical edges.

33.5.5.5 Oxoanions as ligands

(i) Sulfate

Hydrated sulfates $VOSO_4 \cdot xH_2O$ are one of the most common starting materials for the preparation of oxovanadium(IV) compounds. Several forms have been characterized; some are in Table 23, which shows that V=O is 1.58–1.59 Å and is longer in α- and β-$VOSO_4$ where the VO^{2+} group is involved in $\cdots V{=}O \cdots V{=}O \cdots$ chains; the H_2O molecules are either free or coordinated to the vanadium atom and the oxygens of VO_6 octahedra belong to water molecules, to SO_4 groups or to other VO_6 octahedra.

Table 23 Anhydrous and Hydrated Forms of Vanadyl Sulfates $VOSO_4 \cdot xH_2O$: X-Ray Diffraction Data

	V—O internuclear distances (Å)				
x	*Vanadyl oxygen*	*Equatorial oxygens*	*Axial oxygen*	*Type of vanadium environment*	*Ref.*
0 (β form) (unstable)	1.594	2.056, 2.005 2.05, 2.016	2.284	Three-dimensional network with chains of VO_6 distorted octahedra connected pairwise by an SO_4 group *via* corner sharing	1
0 (α form)	1.63	2.04[a] (×4)	2.47	A VO_6 octahedron has four SO_4 tetrahedra in the equatorial plane	2
				 (48)	3
3	1.576	2.033, 2.048 2.003[a], 2.001[a]	2.280	 (49)	4, 5
5	1.591	2.048, 2.037 2.035, 1.983[a]	2.223	 (50)	6
5	1.584	2.008, 2.019 2.006, 1.994[a]	2.181		7
5 (β form) unstable)	1.591	2.031, 2.031 2.018, 2.018	2.218	 (51)	8
6	1.586	2.023, 2.021 2.160, 2.004	2.029		9

Neutron powder data on $VOSO_4 \cdot 3D_2O$ improved the location of hydrogen in the structure.[563] In $2VOSO_4 \cdot H_2SO_4$, X-ray techniques show VO_6 octahedra linked by monodentate SO_4 tetrahedra into polymeric $[VOSO_4]_\infty$ layers joined together by sulfuric acid molecules.[564] Several $(VO)_2H_2(SO_4)_3$ hydrates have been reported.[357a]

Oxovanadium(IV) sulfate solutions were studied by Ducret who concluded that $[VO(SO_4)]$ and $[VO(SO_4)_2]^{2-}$ form and reported $[VOSO_4]/([VO^{2+}][SO_4^{2-}]) = 63$.[466] Others obtained 2.4×10^2.[565] Pressure jump relaxation techniques on $VOSO_4$ solutions were explained according to equation (43): $K = (3.0 \pm 0.5) \times 10^2$.[566] Grigor'eva studied vanadium(IV) solutions over a wide range of H_2SO_4 and SO_4^{2-} concentrations.[567]

$$VO^{2+} + SO_4^{2-} \underset{\text{very fast}}{\rightleftharpoons} \underset{\text{(outer sphere complex)}}{VO(H_2O)SO_4} \overset{k_d \simeq 10^3}{\rightleftharpoons} \underset{\text{(inner sphere complex)}}{VOSO_4} \qquad K = \frac{[VO(H_2O)SO_4] + [VOSO_4]}{[VO^{2+}][SO_4^{2-}]} \tag{43}$$
