[a] Rotation, at D line of sodium, or the sign of the rotation at listed wavelength. [b] Absolute configurations based on the helical model proposed by IUPAC.[645]

Amino acid complexes of Rh^{III} are relatively rare,[646] but some $[Rh(en)_2(AB)]^{n+}$ complexes (AB = glycino, alanino, (−)-leucine, (−)-methionine, (−)-valine, (−)-phenylalanine, (−)-tyrosine) have been prepared by reacting equimolar mixtures of *cis* or *trans*-$[Rh(en)_2Cl_2]^+$, OH^- and the appropriate amino acid in an ethanol/water (1/3) solution.[647] In the absence of the reducing ethanol, no reaction is observed; the preparation of the gly and ala complexes using BH_4^- catalysis has been reported.[630] Resolution of such cations, and a comparison of their CD spectra with $(-)_{589}$-$[Rh(en)_3]^{3+}$ (with the Λ configuration) implies that all the $(-)_{589}$-$[Rh(en)_2AB]^+$ ions also have the Λ configuration.[643] The electronic and CD spectra of the methionine complexes suggest that the methionine is bonded through the N and O atoms.[643]

While electronic, IR and ^1H NMR spectra have been used to assign isomeric form for $[Rh(en)_2XY]^{n+}$ ions, ^{13}C NMR has recently been used to unambiguously assign their geometries.[607,648] The ^{13}C chemical shifts for several such compounds are given in Table 37. The *cis* species show more complex spectra than the *trans* isomers, and the ^{13}C signal in *trans*-$[Rh(en)_2XY]^{n+}$ is

relatively independent of the nature of the non-amine ligands, while it is quite sensitive to the nature of X and Y in *cis*-$[Rh(en)_2XY]^{n+}$ ions.[607] Few X-ray structures of these well-characterized ethylenediamine complexes have been reported, but an interesting geometry is displayed by the $HgCl_2$ adduct of *cis*-$[Rh(en)_2Cl_2]Cl$. It has a layered structure with each Hg atom in an environment of six Cl atoms, two each from the adjacent *cis*-$[Rh(en)_2Cl_2]^+$ moieties.[649]

Numerous studies on the substitutions at various $[Rh(en)_2XY]^{n+}$ complexes (equation 123) have been reported. Basolo and co-workers[555] presented a kinetic study of a large variety of $[Rh(N)_4Cl_2]^+$ complexes (*cis* and *trans* complexes for $N_4 = (en)_2$, $(tetrameen)_2$, $(C_2O_4)_2$; *trans* complexes for $N_4 = (NH_3)_4$, $(m\text{-bn})_2$, $(\pm\text{-bn})_2$; and *cis*-$[Rh(trien)Cl_2]^+$, and $[Rh(NH_3)_5Cl]^{2+}$). As with the Co^{III} analogs, the nature and concentration of the incoming nucleophile has little effect on the rate of Cl^- release; for example, the rate constant for Cl^- release from *trans*-$[Rh(en)_2Cl_2]^+$ is between 4.0 and 5.2 ($\times 10^{-5}\,s^{-1}$) for anation by OH^-, NO_2^-, I^-, $^{36}Cl^-$, NH_3 and thiourea.[555] Unlike Co^{III}, however, the Rh^{III} complexes display rates of chloride release which are insensitive to the total charge on the complex, not dramatically catalyzed by hydroxide ions, and which appear to be completely stereoretentive. Basolo suggested that the mechanism for these substitutions is probably more associative than the dissociative route proposed for the Co^{III} analogs, and that a seven-coordinate Rh^{III} intermediate may be involved.

$$trans\text{-}[Rh(en)_2XY]^{n+} + Z^- \longrightarrow trans\text{-}[Rh(en)_2XZ]^{n+} + Y^- \qquad (123)$$

Z = Cl, Br, I; X, Y = halide, H_2O, OH^-, or NH_3

Poë and co-workers have extensively studied the thermodynamics, kinetics and the *trans* effect in the reactivity of such complexes.[623,634,635,638,640,650,653] The thermodynamics of the successive anations of $[Rh(en)_2X(H_2O)]^{n+}$ by halogens suggests that the Rh center is a marginally soft acid, and that its softness is increased by the coordination of a soft base (such as I^-) in a position *trans* to the reaction site; a halide ligand weakens the metal–ligand bond *trans* to itself, and an I^- causes a more dramatic weakening than a Br^-, which has more effect than a coordinated Cl^-.[634,638–640] The spectrophotometrically obtained thermodynamic parameters are summarized in Table 38.

The kinetic parameters for reactions in acidic solution are consistent with the thermodynamic results, and they suggest the *trans*-labilizing series: $I^- > Br^- > Cl^- \approx NH_3 > H_2O$ (Table

39).[623,640,650,651] Poë reminds us that to realistically compare the kinetic *trans* effect of different ligands, one cannot just consider kinetic parameters, but can only compare reactions in which the thermodynamic driving forces are the same; comparisons of ΔH^* (the kinetic term) with the thermodynamic ΔH° can be used to derive a kinetic *trans*-effect series.[651]

Table 40 demonstrates what little effect the incoming nucleophile has on the reaction rate, as well as the large role played by the *trans* ligand. (The rate of halide anation[650] was subsequently taken to be identical to that of direct aquation,[635,639,640,653] although specific data on aquations are not presented.) When the anating ligand has a high kinetic *trans* effect, such as I^-, no evidence of an intermediate aquahalo complex is observed, and the anations proceed directly, with retention of isosbestic points, to the diiodo complex.[650] The similarity of the anation activation parameters to those for the analogous reactions of the pentaammine complexes supports the associative model.[531] Substitutions at *trans*-$[Rh(en)_2(H_2O)_2]^{3+}$ appear unique. However, as the large entropy of activation suggests, a different mechanism (presumably a more dissociative one) operates for this complex.[640] [Chloride anation of $[Rh(H_2O)_6]^{3+}$ is also thought to involve a dissociative mechanism (*vide infra*).[654]] For the anation of *trans*-$[Rh(en)_2XI]^+$ (X = Cl or Br), an interesting catalyzed reaction was noted,[640] but not pursued.

Basolo[555] noted that reactions of Rh^{III} amine complexes were not dramatically accelerated by hydroxide ion, but did show that substitutions in base do follow the standard $k_{obs} = k_1 + k_2[OH^-]$ format, with k_1 representing the first-order aquation observed in acidic solution, and k_2 representing the second-order base-catalyzed path. Poë has studied the kinetics of the base hydrolysis of a variety of *trans*-$[Rh(en)_2XY]^{n+}$ complexes (Table 41). Studies on the base hydrolyses of *trans*-$[Rh(en)_2(OH)X]^+$ (X = Cl, Br, I) showed that the coordinated hydroxide has an intrinsic kinetic *trans* effect comparable to that of Cl^- but that its position in a thermodynamic *trans* effect series is much higher.[635] For *trans*-$[Rh(en)_2X_2]^+$ (X = Cl, Br), virtually complete *trans* → *cis* isomerization occurs upon hydrolysis in base, and *ca.* 50% isomerization is observed when X = I.[653] No such

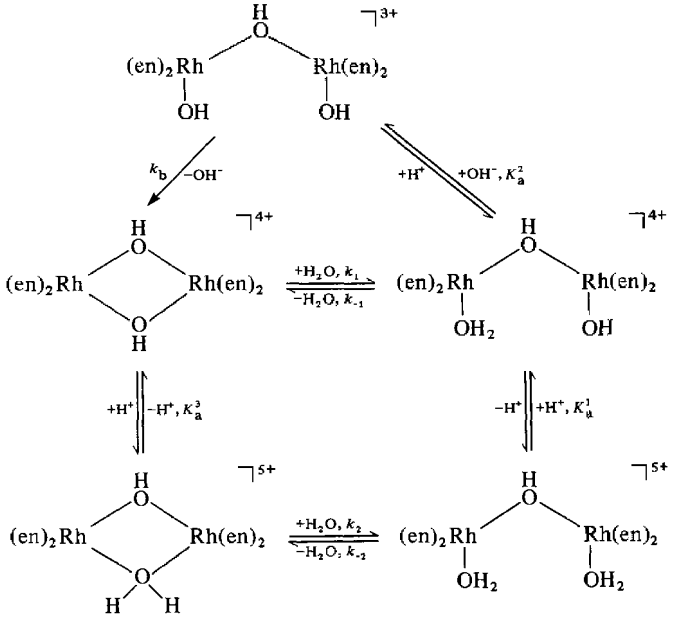
[a] At 50°C.

isomerization is observed upon base hydrolysis of the halohydroxy complexes.[635] It has been suggested[555,655] that an acidic N—H group must be coordinated *trans* to the reaction site in order for k_2 (the OH^- dependent term) to be significant, but *trans*-$[Rh(en)_2Cl(py)]^{2+}$ has a significant $[OH^-]$ dependent term, as do the *trans*-$[Rh(en)_2XY]^{n+}$ ions (Table 41).

Pavelich[624] has presented a thorough study of the chloride anation of *trans*-$[Rh(en)_2(H_2O)_2]^{3+}$ (equation 124), which implies that the conjugate base form (*trans*-$[Rh(en)_2(OH)(H_2O)]^{2+}$) is much more reactive than had previously been thought. Between $[H^+]$ values of 0.02 M to 0.2 M, the observed rate is strongly, and linearly, proportional to $[H^+]^{-1}$. Presumably due to the strong *trans*-labilizing influence of the coordinated hydroxide, the aquahydroxo complex is calculated to be at least three orders of magnitude more reactive than the diaqua ion. Pavelich calculated that at a pH of 1.7 ($[H^+]^{-1} = 50\,M^{-1}$), less than 1% of the complex is deprotonated, but that 95% of the anation still proceeds through this reactive aquahydroxo complex. Addition of the second chloride is 20 times faster still, presumably due to the *trans* influence of the coordinated chloride, so only the dichloro product is observed. The rate of chloride anation is not linearly dependent on $[Cl^-]$. This non-linearity was also observed by Poë for bromide anations of the same complex[623] and is presumed to be due to ion-pairing to both the diaqua (3+) and aquahydroxo (2+) cations. Analysis of this deviation from linearity in the Cl^- system could not be fitted to an interchange stoichiometric mechanism rate law, but could be fitted to a dissociative stoichiometric mechanism rate law. Interestingly, the data were similar to Poë's, but Pavelich reaches the opposite conclusion, and suggests that *trans*-$[Rh(en)_2(H_2O)_2]^{3+}$, and its conjugate base, react *via* a dissociative mechanism.[624]



(124)

Pavelich also points out that there may be valid chemical reasons for the variety of different mechanisms which have been postulated for seemingly straightforward substitutions at Rh^{III} centers. Associative interchanges have been proposed for the pentaammine cations (Section 48.6.2.1.i). Both associative and dissociative interchanges have been proposed for the $[Rh(en)_2XY]^{n+}$ series, and dissociative interchanges, as well as purely dissociative paths, have been proposed for the hexaqua and hexachloro species (Sections 48.6.5.1 and 48.6.7). Such variation in mechanism suggests that the inert ligands have a profound effect on the substitution mechanism of a given rhodium complex. Pavelich speculates that when Rh^{III} is compared to Co^{III}, the increased polarizability of the Rh center (or perhaps its softness) makes it more susceptible to electronic changes induced by the innocent ligands, so that while a wide range of Co^{III} or Cr^{III} complexes may display similar substitution mechanisms, differing mechanisms can be expected for the analogous Rh^{III} or Ir^{III} complexes.[624]

Following from their work on the reactions of pentaammine complexes in liquid ammonia[581–583], Balt and Jelsma studied the kinetics of the ammoniation of some dihalobis(ethylenediamine)-rhodium(III) complexes.[656] While *trans*-$[Rh(en)_2Cl_2]^+$ proved 'too stable toward ammoniation to be studied', the *cis* isomer and *trans*-$[Rh(en)_2I_2]^+$ were both sufficiently reactive. Both cations react in two distinct steps to form $[Rh(en)_2(NH_3)_2]^{3+}$; substitution of the dichloro species goes with retention of the *cis* configuration, while the geometric configuration of the $[Rh(en)_2(NH_3)_2]^{3+}$ formed from the diiodo ion was not determined. In excess NH_4ClO_4, both displayed the rate expression observed in the pentaammine studies: $k_{obs} = k_s + k_b[NH_4^+]^{-1}$. For these complexes, k_s, the rate constant for the 'spontaneous' reaction, is *ca.* 0 for both reactions, and $k_b = k_1 K_{CB}$, where k_1 is the

constant for the rate-determining step, and K_{CB} is the equilibrium constant for the acid–base preequilibrium. (When no NH_4ClO_4 is added, an unusual rate expression is obtained: $k_{obs} = k_1(K_{CB})^{\frac{1}{2}}[Rh]^{-\frac{1}{2}}$.) As observed for the pentaammine complexes, the ΔS^* for base hydrolysis is lower for Rh^{III} than for the Co^{III} analogs, consistent with a more associative conjugate-base mechanism for the Rh complexes.[656]

There are few examples of acid-catalyzed substitutions of $[Rh(en)_2XY]^{n+}$ complexes; attempts to detect H^+-catalyzed aquation of *trans*-$[Rh(en)_2(NO_2)_2]^+$ were unsuccessful.[657] Hancock and co-workers found acid-catalyzed substitutions in a kinetic study of the dinuclear diol, Δ,Λ-$[(en)_2Rh(OH)_2Rh(en)_2]^{4+}$.[628] The synthesis, 'thermal deaquation' and structure of this ion are analogous to $[(NH_3)_4Rh(OH)_2Rh(NH_3)_4]^{4+}$,[595] and the Δ,Λ configuration of the ethylenediamine complex is inferred from X-ray powder patterns, which show it to be isomorphous with the well-characterized Co^{III} and Cr^{III} analogs.[658] In aqueous solution, a ring opening/closing equilibrium is established, as represented in Scheme 18, with rate and equilibrium constant values given in Table 42. The Rh^{III} system is similar to the analogous Cr^{III} system, except that Rh^{III} displays acid catalysis (as does the Co complex). The similarity in ΔH^* and ΔS^* for the k_{-1} and k_{-2} paths suggests that similar mechanisms are operating in the two reactions, and since the nucleophiles are so different (OH^- and OH_2, respectively), it is argued that a dissociative mechanism seems likely. The two pK_a values of the diaquamonool differ by seven orders of magnitude ($pK_a^1 = 2.37$ and $pK_a^2 = 9.13$), too large a difference to be rationalized on the basis of charge considerations (note pK_a values in Tables 31 and 34), and Hancock suggests that the aquahydroxomonool is stabilized by intramolecular hydrogen bonding, as represented in (**47**).[628] A base-catalyzed path was also observed, but it only becomes significant at pH values above 9.5.

(47)

Acid-catalyzed aquations were also observed in a major kinetic study of $[Rh(en)_2(ox)]^+$.[659] The overall reaction studied is given in equation (125), which belies the complexity of the system. All four of the oxalate oxygen atoms exchange with the solvent, but at two kinetically distinct rates. The reactions involved are summarized in Scheme 19, which assumes that there is no direct exchange between an 'inner' oxygen (coordinated to the Rh), and the solvent; an 'inner' oxygen must become an 'outer' oxygen before exchange can occur. There are three possible acid-catalyzed paths for outer oxygen/solvent exchange: two which involve a ring opening step (A → D → A or A → B → D → A, and A → C → A), and one which does not require ring opening (A → B → A). A two-term rate law expression, $k = k_2[H^+] + k_3[H^+]^2$ is needed to describe the reaction shown in equation (125).

$$[Rh(en)_2(ox)]^+ + 2H_3O^+ \rightleftharpoons \textit{cis}\text{-}[Rh(en)_2(H_2O)_2]^{3+} + H_2ox \qquad (125)$$

Scheme 19

Comparison of the kinetic parameters for the reactions in Scheme 19 to those for the analogous reactions of the anionic $[Rh(ox)_3]^{3-}$ (Section 48.6.5.2) is instructive.[660–662] The kinetic parameters (Table 43) for the exchange of the outer oxygens are similar for the two systems, implying that the net charge on the complex has little influence on the kinetics of that step. For the tris(oxalato) complex, the inner/outer oxygen exchange is always slower than the exchange of the outer oxygens with the solvent; in contrast, the rates of inner/outer interchange and outer/solvent exchange are similar for $[Rh(en)_2(ox)]^+$, and reach a crossover point at about 60°C. The faster inner/outer exchange in the latter system is presumably due to the more favourable ΔS^* values (Table 43). In both systems, acid hydrolysis of the oxalato ligand is much slower than the inner/outer exchange at any temperature. For the tris(oxalato) anion aquation proceeds to completion, while with

	Inner/outer oxygen exchange	1.83×10^{-6}	97.9 ± 8.4	-26 ± 25	660
	Acid hydrolysis	$k_2 = 2.5 \times 10^{-8}$	107 ± 8.4	-33 ± 25	660
	$(k = k_2[H^+] + k_3[H^+]^2)$	$k_3 = 1.49 \times 10^{-7}$ ($M^{-2}s^{-1}$)	108 ± 8.4	-12 ± 25	

$[Rh(en)_2(ox)]^+$ equilibrium is established after about 70–75% of the oxalate is aquated, presumably due to the coulombic attraction between ox^{2-} (or Hox^-) and the cationic ethylenediamine complex.[659]

A thorough analysis of the complex kinetics for this system is inappropriate here, and despite the lack of direct evidence for the intermediates in Scheme 19, the predicted acid dependence was observed. (Interestingly, aquation of the analogous $[Co(en)_2(ox)]^+$ ion is not acid catalyzed.[663]) A relative ordering of the reaction rates gives: (a) $k_{CA} \gg k_{BA} > k_{AB} > k_{AC} > k_{DE} \approx k^*_{DE}$; and (b) $k_{CA} \gg k_{CD} > k_{DC} > k_{DE}$.

The chemistry of aqueous solutions of CO_2 in the presence of aquated transition metal complexes has been extensively studied by a group of researchers led by Harris, Palmer and vanEldik, and they have presented extensive kinetic studies on the carboxylation and decarboxylation of a variety of bis(ethylenediamine)carbonato complexes of Rh^{III}.[625,627,641] The decarboxylation of $[Rh(en)_2(CO_3)]^+$ (bidentate carbonate), occurs according to the two-term rate expression $k_{obs} = k_0 + k_1[H^+]$. The kinetic parameters for this reaction are given in Table 44, and the reaction is presumed to occur *via* the route represented in equations (126)–(128). The rapid decarboxylation of the intermediate ion *cis*-$[Rh(en)_2(CO_3H)(H_2O)]^+$ was independently studied, as was the rate of CO_2 uptake by *cis*-$[Rh(en)_2(OH)(H_2O)]^{2+}$ and *cis*-$[Rh(en)_2(H_2O)_2]^{3+}$; the relevant parameters are also given in Table 44. The ΔH^* values for the carboxylation and the decarboxylation of the monodentate carbonate complexes are atypically low for substitutions at Rh^{III} centers, suggesting that these reactions do not involve the cleavage of a Rh—O bond; carboxylation must involve electrophilic attack of the CO_2 at the oxygen atom of the coordinated hydroxo group.[627] The markedly slower rate, and the higher

CO_2 uptake by dihydroxo ion	$k_3 = 215 \pm 29\,M^{-1}s^{-1}$	61.1 ± 0.8	4.6 ± 2.9

[a] Rate constant labels given in equations (126)–(128).

ΔH^* values for the decarboxylation of the bidentate carbonate, imply that the first, rate-determining step in this reaction must involve cleavage of a Rh—O bond as the carbonate ring is opened, and rapid decarboxylation of the monodentate complex can then occur with only C—O bond cleavage.

The *trans* carbonato complexes, *trans*-$[Rh(en)_2(OCO_2)(H_2O)]^+$ and *trans*-$[Rh(en)_2(OCO_2)_2]^-$ were also characterized, and the kinetics of their formation and decarboxylation studied.[625] Scheme 20 represents the complex reaction pattern observed. In the absence of added carbonate, decarboxylation of the monocarbonato complex has a rate expression of the form $k_{obs} = k_1[H^+]/([H^+] + K_3)$ (Scheme 20). Decarboxylation of the bis(carbonato) complex is unusual in that the researchers could find no evidence of an intermediate monocarbonato complex, and concluded that both carbonate ions are lost simultaneously (presumably as $2CO_2$). To support this supposition, they noted that at pH 8.82, CO_2 uptake by *trans*-$[Rh(en)_2(OH)_2]^+$ is proportional to $[CO_2]^2$. The *trans* geometry was maintained throughout these reactions, and the general pattern observed for the *cis* complexes,[627] *i.e.* rapid carboxylation of the Rh—OH^- or decarboxylation of the Rh—OCO_2H moieties, also held for the *trans* complexes.[621] This work was extended to include the kinetics of the formation and decarboxylations of the neutral $[Rh(en)_2(X)(OCO_2)]$ complexes (X = Cl, Br, I), so the effect of changing the ligand *trans* to the reactive site could be monitored.[641] These complexes displayed kinetic rate expressions similar to the *trans* aquacarbonato ions,[625] and a simpler reaction sequence, represented in equations (129) and (130), was observed. The pK_a of *trans*-$[Rh(en)_2(X)(H_2O)]^{2+}$ increases in the order Cl < Br < I, which can be considered as the order of increasing effectiveness for weakening the Rh—O bond, and hence strengthening the O—H bond; as expected, the first-order rate constant for decarboxylation decreases in the order Cl > Br > I. Summarizing the results given in Table 45, the ability of various ligands to labilize a *trans* bicarbonate decreases in the order: $H_2O > OCO_2H^- > OCO_2^{2-} > Cl^- > Br^- \approx NH_3 > I^-$ (the listing for NH_3 is from the *cis* series of complexes — Table 44). A graph of log k_1 *vs.* pK_a for a variety of M—CO_3 complexes shows a strong correlation between the acidity of the parent species and the rate of decarboxylation.

The rate of CO_2 uptake by *trans*-$[Rh(en)_2(X)(H_2O)]^{n+}$ increases in the order X = Cl < Br < I, which is reflected in a steady increase in ΔH^* and ΔS^* (Table 46). When compared with the rates of CO_2 uptake by a variety of aquated metal complexes (including complexes of Cu^{II}, Zn^{II}, Cr^{III}, and Ir^{III}) a clear correlation exists between the pK_a of the coordinated water and the rate of CO_2 uptake.

Thus the rate of uptake does not depend on the nature of the metal, but depends on the nucleophilicity of the bound hydroxide ion, which correlates well with the strength of the O—H bond in the conjugate acid. Isokinetic plots (ΔH^* *vs.* ΔS^*) show parallel lines for CO_2 uptake and decarboxylation, confirming that these complexes share a common mechanism which does not involve cleavage of a metal–ligand bond.[641]

(*iii*) *Other aliphatic bidentate complexes*

The synthesis and reactivities of substituted aliphatic bidentate complexes are similar to the reactions of analogous ethylenediamine complexes. Basolo and co-workers prepared[619] and studied the rates of chloride aquation[555] of a variety of *trans*-$[Rh(NN)_2Cl_2]^+$ complexes (NN = *meso*-bn, where bn = 2,3-diaminobutane; (±)-bn, and tetrameen—both *cis* and *trans* isomers); the rate of chloride release is not dramatically dependent on the nature of the aliphatic amine ligand.

Hancock used the BH_4^--catalyzed path to generate $[Rh(tn)_2(ox)]^+$ (tn = 1,3-diaminopropane), and then showed that substitutions at both *trans*- and *cis*-$[Rh(tn)_2X_2]^+$ occur with retention of geometry (Scheme 21).[664] A kinetic study of the bromide anation and base hydrolysis of *trans*-$[Rh(tn)_2Cl_2]^+$ showed that the alkaline reaction displays the familiar $k_{obs} = k_1 + k_2[OH^-]$ rate expression;[665] the large entropy of activation for the OH^- dependent step ($\Delta S^* = 109 \pm 30\,J\,K^{-1}\,mol^{-1}$ *vs.* $71 \pm 5\,J\,K^{-1}\,mol^{-1}$ for the ethylenediamine analog) was noted, and an S_N1CB path was suggested.[664] When compared to the bromide anation of *trans*-$[Rh(en)_2Cl_2]^+$, the effect of the six-membered ring on the reaction rate is negligible.[665] The *cis* and *trans*-$[Rh(tn)_2(H_2O)_2]^{3+}$ ions have been prepared by Ag^+-induced release of the Cl^- ligands,[666] and these complex ions have electronic spectra and pK_a values (Table 47) comparable to their ethylenediamine analogs.

The ^{15}N NMR (natural abundance) spectra of some Rh^{III} complexes with alkyldiamine and aza aromatic ligands display nitrogen resonances *ca.* 20 p.p.m. upfield from the free ligand for the alkyl complexes, and about 100 p.p.m. upfield for the aza aromatic ligands.[668] This large shift is presumed to be due to the influence of low-lying excited states of the ligands themselves and not to any unusual property of the complexes. No correlation of the chemical shift with the position of the ligands in the spectrochemical series could be found, and non-bonded magnetic interactions are presumed to be involved. Diastereoisomerism was observed for $[Rh(1,2\text{-diaminopropane})_3]^{3+}$, and evidence of two different ligand conformations for the complex ion was also observed.[668]

A variety of substituted ethylenediamine complexes have been resolved, and their ORD, CD and electronic spectra reported (Table 48), with assignments of absolute configurations based on a comparison of their CD spectrum with the CD spectrum of $[Rh(en)_3]^{3+}$.[606] Complexes containing the optically active (*R*)-1,2-propanediamine and (*R*,*R*)-2,3-butanediamine ligands, in which the ligands are locked in the λ configuration by the bulky methyl groups, have also been resolved.[608,669] For $[Rh\{(R)\text{-pn}\}Cl_4]^{-}$ and *trans*-$[Rh\{(R)\text{-pn}\}_2Cl_2]^{+}$, the optical activity must arise from the assymmetry induced by the conformation of the optically active ligand; the effect appears to be additive in these complexes with one and two chiral ligands respectively (Table 48). The Δ configuration is also assigned[670] to the stable form (k,k,k) of $(+)_D$-$[Rh(1,2\text{-diaminocyclohexane})_3]^{3+}$.[671,672] The $[Rh\{(\pm)\text{-bn}\}_3]^{3+}$ ion (bn = 2,3-diaminobutane) has been prepared,[673] and all four diastereomers have been isolated and characterized by ^{13}C NMR.[674] The NMR spectrum of the λ,λ,λ form does not exhibit the broadened methyl group resonance observed for the Co analog, even though the X-ray structure (as the Br^- salt) shows a decreased intraring methyl group contact distance.[674]

48.6.2.3 Photochemistry of monodentate and bidentate amine complexes

The past 15 years have been exciting times for the study of Rh^{III} photochemistry. Photochemical reviews and texts of the late 1960s and early 1970s[676–678] hardly mention Rh^{III}, but as transition metal photochemistry grew in the 1970s, monographs and reviews chronicle the growth of Rh^{III} photochemistry.[679–684] The stability of the 3+ oxidation state and the inaccessibility of Rh^{II} or Rh^{IV}, the stereorigidity and inertness toward substitution of most Rh^{III} complexes in solution, and the photosensitivity of many Rh^{III} amines combined to make Rh^{III} photochemistry the most active Rh^{III} research area of the past 15 years. In general, the photochemistry of non-ammine complexes is discussed in the sections dealing with the specific compounds, but the amount of work presented on the photochemistry of simple monodentate and bidentate amine complexes requires this separate discussion.

(*i*) *The excited state*

Electronic excitation of a low-spin, d^6 Rh^{III} amine shifts electron density to a metal-dominated orbital (e_g) of σ symmetry, which is antibonding with respect to the Rh—ligand bonds. This electron density can come from either a t_{2g} orbital of π symmetry (ligand field excitation) or from a ligand-dominated orbital (ligand to metal charge transfer, or LMCT, excitation). Reduction or oxidation of Rh^{III} amines is difficult, so charge-transfer states are generally higher in energy than ligand field states and, for most complexes, they play little part in Rh^{III} photochemistry. With some exceptions, the quantum yield for photosubstitutions is independent of irradiation wavelength, suggesting that intersystem crossing to the lowest ligand field state occurs with unitary efficiency.[685] Photophysical studies have confirmed that luminescence from Rh^{III} amine complexes generally occurs from the lowest energy ligand field triplet state.[609,686–691] Consistent with rapid population of the ligand field states, the rates of intersystem crossing are extremely rapid and have been estimated to be in the range of $5 \times 10^9\,s^{-1}$ (for $[Rh(NH_3)_5Br]^{2+}$)[692] to $5 \times 10^{11}\,s^{-1}$ (for *cis*-$[Rh(bipy)_2Cl_2]^+$).[693] These findings all point to the generalization that the photochemistry of a Rh^{III} complex can be considered to be the chemistry of its lowest energy ligand field excited state.

Even in rigid media at reduced temperatures, the lifetimes of the luminescing states are short, implying that the thermally equilibrated excited states are extremely reactive.[609,688–691] With nanosecond and subnanosecond laser systems, the luminescence lifetimes under photochemically relevant conditions (fluid solution near room temperature) can now be measured.[692–703] (Emission quantum yields are extremely weak under these conditions, and luminescence quantum efficiencies are estimated to be in the 10^{-6} to 10^{-7} range.[692]) For $[Rh(L)_5X]^{2+}$ (X = Cl or Br, L = NH_3 or ND_3) and *cis*- and *trans*-$[Rh(en)_2Cl_2]^+$, the luminescent states have lifetimes in the range of 1–50 ns. These studies directly support the standard model, in which reactive and non-reactive paths compete for the transient excited state. For example, the rate of deactivation of $[Rh(ND_3)_5X]^{2+}$ is about half that of the undeuterated ions, consistent with the increased photochemical reactivity observed for the deuterated species.[694] It is interesting to note that for $[Rh(cyclam)(CN)_2]^+$, the lifetime of the luminescing state under comparable conditions (326.1 K, 0.001 M aqueous HNO_3 solution) is 2.0 μs, about three orders of magnitude longer than for the less constrained amine complexes.[700] This longevity is presumed to be due to the absence of a reactive decay mode.

The nature of the photoreactive state, as opposed to the luminescing state, is still the source of some debate, as states other than the lowest triplet have been proposed to be important. Evidence that an excited singlet may be involved comes from time-resolved studies of the luminescence of some haloammine complexes, where a weak fluorescence, with a lifetime of about 100 ps, was

observed.[692] A nearby quintet state has also been mentioned[695,701] and Endicott has questioned whether one should even consider this photochemistry to be the reaction of a distinct electronic excited state.[704] He suggests that the photoinduced substitutions and isomerizations may be considered hot ground state processes, with the photoinduced substitutions and isomerizations, not observed upon thermal excitation, resulting when the relaxation trajectory of the distorted excited state goes to a thermally inaccessible region of the ground state free energy surface. Perhaps, he argues, one should focus on understanding the full ground state surface, not the excited state surfaces.[704]

(*ii*) *Photochemistry of* $[Rh(NH_3)_5X]^{n+}$ *ions*

Whatever the nature of the photoreactive state, photolysis of a Rh^{III} amine leads to increased electron density in the metal-centered, σ^* e_g orbitals. Ligand labilization (especially of strongly σ-donating ligands), and subsequent solvolysis, is the anticipated (and observed) reaction. Photoinduced substitutions have now been reported for a large number of Rh^{III} amines, and some of the results are summarized in Table 49.

The first quantitative photochemical study of a Rh^{III} amine was reported by Moggi,[8] who noted that both 254 nm (LMCT) and 365 nm (ligand field) excitation of $[Rh(NH_3)_5Cl]^{2+}$ caused chloride labilization (equation 131). Other early reports include Basolo's study of the photoinduced stereoretentive halide aquation from $[M(en)_2X_2]^+$ (M = Rh, Ir; X = Cl, Br, I),[725] and Broomhead's observation of chloride aquation from $[RhCl_2(phen)_2]^+$.[726] While halide labilization dominates upon photolysis of $[Rh(NH_3)_5Cl]^{2+}$, both bromo and ammine loss occur upon photolysis of the bromo analog (equation 132)[685,707] and ammine is labilized from the iodo analog (equation 133).[708] Biacetyl sensitization of the bromo complex quenches the biacetyl phosphorescence, but not the fluorescence,[707] consistent with a photoreactive triplet state.

$$[Rh(NH_3)_5Cl]^{2+} + H_2O \xrightarrow{h\nu} [Rh(NH_3)_5H_2O]^{3+} + Cl^- \quad (131)$$

$$[Rh(NH_3)_5Br]^{2+} + H_2O \xrightarrow{h\nu} \begin{matrix} [Rh(NH_3)_5H_2O]^{3+} + Br^- \\ trans\text{-}[Rh(NH_3)_4(H_2O)Br]^{2+} + NH_3 \end{matrix} \quad (132)$$

$$[Rh(NH_3)_5I]^{2+} + H_2O \xrightarrow{h\nu} [Rh(NH_3)_4(H_2O)I]^{2+} + NH_3 \quad (133)$$

The photochemical behavior of the $[Rh(NH_3)_5I]^{2+}$ (and *trans*-$[Rh(NH_3)_4I_2]^+$) is unusual, as the quantum yield of ammine labilization decreases as the energy of the irradiating source increases. The quantum yield varies from 0.2 at 254 nm (LMCT region) to 0.9 upon ligand field excitation at 470 nm.[708] In the presence of excess I^- ion, flash photolysis of the LMCT region of $[Rh(NH_3)_5I]^{2+}$ leads to the readily recognizable I_2^- radical anion, suggesting that a redox process, involving the release of I atoms, is involved when the charge transfer state is populated. No I_2^- ions were detectable upon ligand field excitation, and throughout the ligand field region (385–470 nm) the quantum yield of ammine release is constant (0.85). These observations suggest that there are at least two paths to the same overall reaction (equation 133), and the lower quantum yield upon direct LMCT implies that the redox path is not as efficient as the ligand field path, and that energy transfer, from the LMCT state to the extremely reactive ligand field state, is inefficient. A mechanism for the CT path, involving a redox step (equation 134), a complexation (equation 135), and recombination steps (equations 136 and 137) was proposed.[727]

$$[Rh(NH_3)_5I]^{2+} \xrightarrow{h\nu} [Rh(NH_3)_4]^{2+} + NH_3 + I \quad (134)$$

$$I + I^- \longrightarrow I_2^- \quad (135)$$

$$[Rh(NH_3)_4]^{2+} + I + H_2O \longrightarrow [Rh(NH_3)_4(H_2O)I]^{2+} \quad (136)$$

$$[Rh(NH_3)_4]^{2+} + I_2^- \longrightarrow trans\text{-}[Rh(NH_3)_4I_2]^+ \quad (137)$$

Photoinduced ammonium ion release from $[Rh(NH_3)_5I]^{2+}$ absorbed into zeolite Y was studied to monitor the effects of an ion's environment on the photochemical behavior. The same photoreaction occurs in both media, but the quantum yield is reduced by almost a factor of 5 (to 0.18) in hydrated zeolite Y. This was presumed to be due to the steric hindrance of the zeolite walls, which hinder the access of solvent water to the photoexchange site. Consistent with this model, the quantum yield decreases still further (to 0.13) in 'partially dehydrated' zeolite Y.[728]

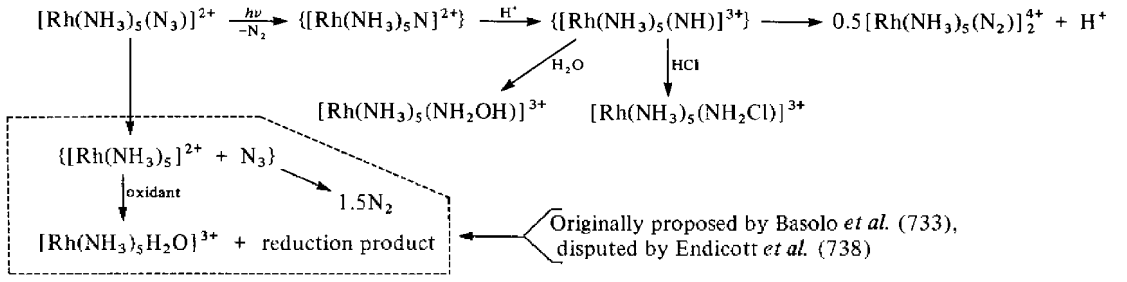
[a] ϕ for NH_3 release $< 10^{-2}$.

One ammine is released upon ligand field excitation of $[Rh(NH_3)_6]^{3+}$, and the deuterated analog is twice as photosensitive.[694,705] The temperature dependence of the quantum yield led to the proposal that temperature independent weak coupling and temperature dependent strong coupling mechanisms were competitive paths for the non-radiative deactivation of the excited state.[705] Another RhN_6^{3+} chromophore, $[Rh(en)_3]^{3+}$, undergoes an inefficient ring opening/anation when photolyzed in the presence of Cl^- (equation 138).[720] Between pH 0 and 8, the quantum yield is pH independent,

and in basic solution, the deprotonated $[Rh(en)_2(monoen)Cl]^{2+}$ forms. Anation by Cl^- must be necessary to prevent ethylenediamine ring closure, as no photochemical reaction is observed in the absence of added Cl^-. Photoanation was also observed upon photolysis of $[Rh(NH_3)_5(H_2O)]^{3+}$ in the presence of Cl^- or Br^-.[709] The direct photolysis of ion pairs (*e.g.* $\{[Rh(NH_3)_5(H_2O)]^{3+}, Cl^-\}$) is evident in that the anation quantum yield is directly proportional to halide concentration. Photoinduced water exchange for $[Rh(NH_3)_5(H_2O)]^{3+}$ is efficient ($\phi = 0.47$), but little photoexchange was observed from the hydroxo complex, $[Rh(NH_3)_5OH]^{2+}$ ($\phi < 0.01$).[709]

$$[Rh(en)_3]^{3+} + HCl \xrightarrow{h\nu} [Rh(en)_2(enH)Cl]^{3+} \quad (138)$$

The ability to measure luminescence lifetimes in fluid solution at ambient temperatures has allowed a much clearer picture of the events which lead to photoinduced substitutions. A recent flurry of activity, led by Ford and Skibsted, has allowed the determination of rate constants for aquations, as well as for radiative and non-radiative decay modes from photoproduced excited states.[667,697,703] For $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br) and *cis*- and *trans*-$[Rh(NH_3)_4XY]^{n+}$ (X = Cl^-, Br^-, H_2O; Y = X, H_2O, OH^-) the rate constants for aquation of the excited states (at 25 °C) range between 6×10^6 to $3.1 \times 10^8\ s^{-1}$,[703] which represents an increase of 13–15 orders of magnitude over the rates of analogous reactions of the ground state complexes. For closely related complexes, the rate of labilization of X generally follows the order $H_2O > Cl^- > Br^- > I^-$, perhaps, Ford suggests, due to the relative abilities of these ligands to form π-bonds with the $t_{2g}^5 e_g^1$ ($\pi^5\sigma^1$) excited states. The influence of Y on the rate of release of Cl^- or Br^- follows the approximate order *cis* X > *trans* $OH^- \approx$ *trans* X > $NH_3 \approx$ *cis* OH^-.[703] The rate of halide release is reversed in *cis*- and *trans*-$[Rh(tn)_2X_2]^+$ (X = Cl, Br) however, as the rate of aquation (and of non-radiative decay) is greater for the bromo than for the chloro complexes.[667] The $[Rh(tn)_2Br_2]^+$ excited states also display rates of aquation and non-radiative decay at least an order of magnitude greater than for the dibromotetraammines. These effects are thought to be due to crowding in the inner coordination sphere by the bulky Br and tn ligands.



Hydroxide ion quenches luminescence from $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br), and reduces, but does not eliminate, the ligand labilizations.[707] For $[Rh(NH_3)_5Br]^{2+}$, ammine labilization is sharply reduced, but Br^- loss is unaffected by the presence of OH^-, leading Adamson to suggest that the two photoreactions originate from two distinct excited states; one which is luminescent, releases NH_3 and is quenched by hydroxide, and a second, non-luminescent state which releases Br^- and is not affected by OH^-.[695] Such a two-excited-state model, orginally proposed by Endicott[707] to account for ammine and bromide release from $[Rh(NH_3)_5Br]^{2+}$, contrasts sharply with the generally held view that Rh^{III} photochemistry originates from a single low-lying excited state (or several states in equilibrium with each other). Hydroxide also quenches NH_3 release from $[Rh(NH_3)_5I]^{2+}$, but increases the efficiency of I^- release by a factor of 5.[702] Ford argues that the enhanced reactivity of I^- is more readily rationalized if the OH^- ion is not considered an 'innocent quencher', but as a reactant which chemically interacts with the photoproduced excited state. A proton transfer, to generate $\{[Rh(NH_3)_4(NH_2)X]^+\}^*$, which is comparable to the reactive intermediate proposed in the S_N1CB reaction of the ground state, is suggested.[702] The reactivity patterns of this new excited species would be unrelated to that of the normal excited state (present in acidic solution), accounting for hydroxide's ability to affect two reaction paths differently, without invoking a distinct excited state species for each reaction.

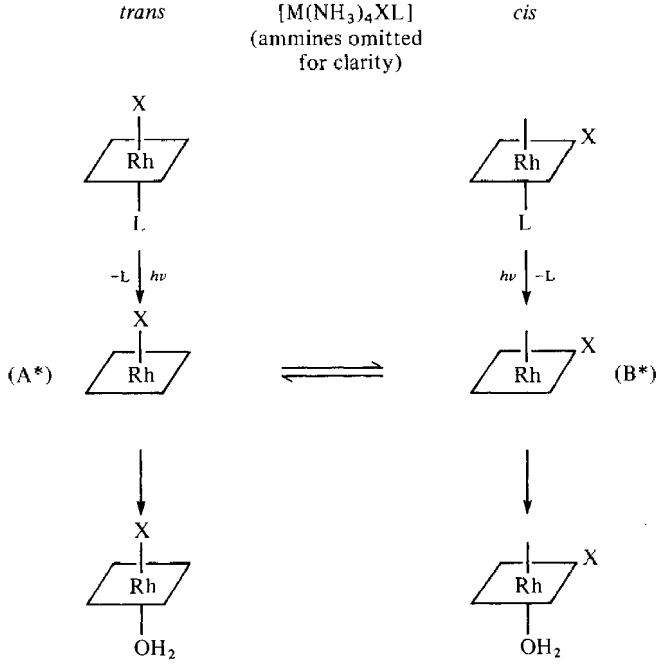
The solvent cage can also influence photochemical reactivity, as studies with $[Rh(NH_3)_5Cl]^{2+}$ in various solvents showed that the identity of the photolabilized ligand, and the rates of radiative, non-radiative and reactive deactivations are solvent dependent. In polar media such as water and formamide, photoinduced Cl^- release dominates, but in less polar media (DMF, DMSO and MeOH), less capable of solvating the resulting Cl^- and Rh^{3+} ions, ammine substitution dominates.[699,730]

Ford and co-workers have also studied the luminescence and photochemistry of a variety of $[Rh(NH_3)_5L]^{3+}$ ions, where L is py, a substituted pyridine or an organonitrile.[713,714] While both ligand field and π–π transitions are apparent in the absorbance spectra, luminescence originates from only the ligand field state. Despite the similarity of the ligand field absorption spectra for all the nitrile complexes, the luminescence spectra depend on the nature of L, and as the energy of the emission band decreases, the quantum yield for nitrile labilization increases. The variation in quantum yield as a function of wavelength again indicates that energy transfer from ligand centered π–π^* states to ligand field states does not occur with unitary efficiency, but the lack of luminescence from the π–π^* states suggests that other, non-radiative paths are available for the normally fluorescence ligands upon coordination to the Rh^{III}.[713]

The photochemical reactivity of $[Rh(NH_3)_5(N_3)]^{2+}$ has proven especially interesting, for HCl solutions of the azidopentaammine ion undergo a ligand-centered reaction, releasing N_2 gas, and generating the chloramine complex (equation 139).[731] Minor products include $[Rh(NH_3)_6]^{3+}$, $[Rh(NH_3)_5(NH_2OH)]^{3+}$ and $[Rh(NH_3)_5(H_2O)]^{3+}$, and the ratio of products depends on the solution conditions and wavelength of irradiation. A coordinated nitrene mechanism, similar to that proposed for the thermal decomposition of Ru^{III}[732] and Ir^{III}[733] azides was proposed,[734] and is represented in Scheme 22. The nitrene intermediate is a soft Lewis acid, and when scavenged by Cl^-, the chloramine is formed; the hydroxylamine results from reaction with H_2O or ClO_4^-. The $[Rh(NH_3)_5(H_2O)]^{3+}$ photoproduct was presumed to result from a redox process involving the formation of transient $[Rh(NH_3)_5]^{2+}$ and the azide radical.[729] (It is interesting to note that only the nitrene path was detected upon photolysis of $[Ir(NH_3)_5(N_3)]^{2+}$,[735] and the azide radical/redox path has been noted for the Co^{III} analog,[736] so a combination of these two paths for the Rh^{III} analog seemed a logical conclusion.) Flash photolysis studies detected a transient N_2^{2-}-linked dimer, $[(NH_3)_5Rh—N—N—Rh(NH_3)_5]^{4+}$,[737] further supporting the nitrene mechanism, but did not find any photoproduced azide radical,[738] calling into question the redox path to $[Rh(NH_3)_5(H_2O)]^{3+}$. Zink suggested[739] photoinduced heterolytic cleavage of the terminal N—N bond in the Rh—N—N—N moiety, releasing N^- to the solution (which would be rapidly attacked by water or HCl to generate NH_2OH or NH_2Cl), and forming the instantly aquated $[Rh(NH_3)_5(N_2)]^{3+}$. While nicely accounting for the aquapentaammine product, Endicott and co-workers showed that virtually no NH_2OH, NH_2Cl, N_3 radical or N_3^- ion was generated in the photolyzed solution. While it seems an anticlimax, they concluded that the nitrene path is the only path available to $[Rh(NH_3)_5(N_3)]^{2+}$, and that the mysterious $[Rh(NH_3)_5H_2O]^{3+}$ must be formed from secondary photolysis of the hydroxylamine or chloramine primary photoproducts.[522]

$$[Rh(NH_3)_5(N_3)]^{2+} + HCl \xrightarrow{H^+,\ h\nu} [Rh(NH_3)_5(NH_2Cl)]^{3+} + N_2 \qquad (139)$$

Scheme 22



(*iii*) *Stereochemical consequences and mechanism*

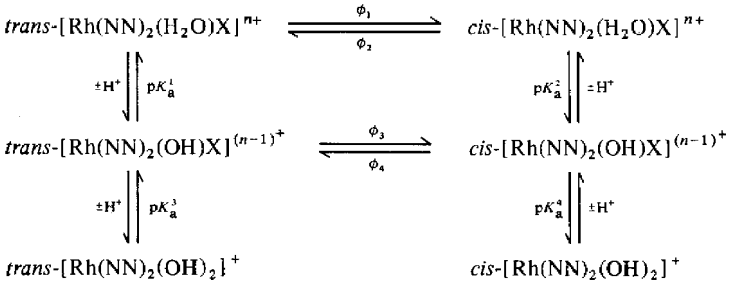
The study of Rh^{III} photochemistry has been stimulated by numerous models which attempt to predict which of six ligands around an octahedrally coordinated metal center will be labilized upon ligand field photolysis. They range from sets of simple empirical rules to molecular-orbital-based theoretical studies,[740–744] and the success of Vanquickenborne's version[743] has made it the current standard. With some exceptions (*e.g.* the nitrene route for the azido complex,[733] the redox chemistry of the iodo,[727] and the effects of various solvents on the chloropentaammine ion[699]) the photochemistry of the $[Rh(NH_3)_5X]^{n+}$ ions discussed in the previous section generally follow Vanquickenborne's model. One recent test of this model used the strong *trans*-labilizing influence of the cyanide ligand to generate *trans*-$[Rh(NH_3)_4(*NH_3)CN]^{2+}$ from the reaction of *trans*-$[Rh(NH_3)_4(CN)Cl]^+$ with $^{15}NH_3$.[626] According to virtually all the models, photolysis of $[Rh(NH_3)_5CN]^{2+}$ should lead to labilization of an ammine in the plane *cis* to the coordinated CN^-, and photolysis (at 254 and 313 nm) does lead to *cis*-$[Rh(NH_3)_4(H_2O)CN]^{2+}$. Virtually all (96% upon 313 nm irradiation) of the photoreleased ammine was unlabeled, confirming that photolysis of this complex leads to regiospecific labilization of an ammine in the equatorial plane.[745]

An interesting challenge to Vanquickenborne's model of regiospecific labilization has been presented by Muir and co-workers,[746] who studied the photoinduced amine aquation from complexes of the form *trans*-$[RhL_4Cl_2]^+$ where L is a heterocyclic amine (pyrazine, pyrazole, pyridine, imidazole, and substituted analogs). Unlike the ammine and ethylenediamine analogs, where chloride loss dominates, both amine and chloride are stereoretentively labilized from these com-

plexes, and the fraction of the reactive decay leading to amine labilization increases with the pK_B of the free amine. An appealingly simple argument suggests that the weaker the amine base, the poorer a σ donor it will be, and the more likely it is to be labilized in the photoproduced excited state.[746]

As it became clear that isomerization often accompanies photoinduced substitution, attempts to predict the stereochemical course of a given photochemical reaction also appeared, with the most successful being that of Vanquickenborne and Ceulemans.[747] In this model, represented in Scheme 23, the photoproduced excited state is presumed to undergo a dissociative loss of the photolabilized ligand, leaving a five-coordinate species in a square pyramidal (SP) geometry. This intermediate is then presumed to undero unimolecular rearrangement to its lowest energy structure, which for d^6 metals is the SP configuration (the trigonal bipyramid arrangement was also considered, and is found to be the stabler geometry in d^3, but not d^6, systems). For a $\{[Rh(NH_3)_4X]^{n+}\}^*$ species, two geometric isomers are possible for the SP configuration, and angular overlap calculations indicate that the stabler species will have the weaker σ-donating ligand in the apical site. (That is, if X is a weaker σ donor than NH_3, excited state A* should be the dominant excited state, while if X is the stronger σ donor, B* should prevail.) Nucleophilic attack, usually by solvent water, at the vacant coordination site of the equilibrated excited state complex completes the photoinduced aquation.

Scheme 23



This model has been tested in numerous studies by Ford (and his even more numerous coworkers), and it has a remarkable record.[747–749] Photoaquation/isomerization studies have been presented for *cis*-$[Rh(NH_3)_4XY]^{n+}$ (X = Cl, Br; Y = H_2O, X),[718] *trans*-$[Rh(NH_3)_4(OH)Y]^+$ (Y = Cl, Br, OH),[642,710] *cis*-$[Rh(NH_3)_4Cl_2]^+$,[717] *trans*-$[Rh(NH_3)_4(CN)Z]^{n+}$ (Z = NH_3, OH),[712] *cis*- and *trans*-$[Rh(en)_2(NH_3)(H_2O)]^{3+}$,[750] and *cis*- and *trans*-$[Rh(en)_2XY]^{n+}$ (X = Cl, Br, I; Y = NH_3, H_2O or X).[637,721,723] In each case, the stereochemical consequences of photolysis are consistent with Vanquickenborne's model. In the study of *cis*-$[Rh(NH_3)_4Cl_2]^+$,[718] the HNO_2-induced aquation of *cis*-$[Rh(NH_3)_4(N_3)Cl]^+$ (which should also generate a $[Rh(NH_3)_4Cl]^{2+}$ species, but in the ground electronic state) was shown to be stereoretentive, yielding *cis*-$[Rh(NH_3)_4(H_2O)Cl]^{2+}$. This implies that the photoinduced *cis* $\rightleftharpoons$ *trans* isomerization is an excited state process.[718]

Skibsted and co-workers have recently presented several studies which rigorously test these stereochemical models. Complexes of the form *cis*- and *trans*-$[Rh(NN)_2XY]^{n+}$, (NN = en or tn (1,3-diaminopropane); X = H_2O, OH; Y = H_2O, OH), plus *cis* and *trans*-$[Rh(tn)_2(H_2O)Z]^{2+}$ (Z = Cl, Br), display similar photochemistries: (a) *cis* to *trans* isomerization dominates for the diaqua and aquachloro ions (in which the H_2O or halide, poorer σ donors than en, occupy the axial site in the SP (square planar) intermediate); (b) *trans* to *cis* photoisomerization dominates for the hydroxoaqua species, as the OH^- ion is a better σ donor than the en nitrogens, and hence occupies an equatorial site; and (c) no photochemistry is observed for the dihydroxo ions.[626,667,724] These results are summarized in Scheme 24 and Table 50.

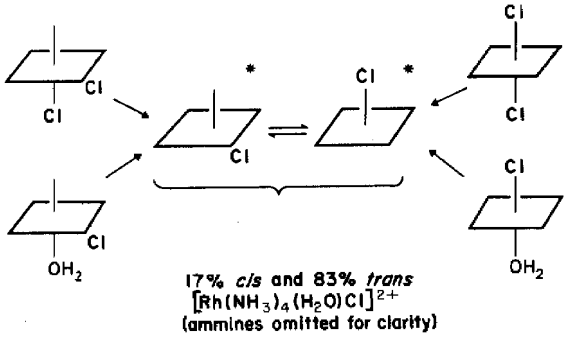
Scheme 24

The excited state intermediates proposed in the Vanquickenborne model[747] are coordinatively unsaturated and usually cationic, and should be powerful Lewis acids immersed in a strongly nucleophilic aqueous environment. Despite this, they are presumed to exist long enough to reach thermal equilibrium, with the stereochemistries of the final products independent of the labilized ligand. This hypothesis has recently been tested,[716,719] as photolysis of *cis*- and *trans*-$[Rh(NH_3)_4Cl_2]^+$, and *cis*- and *trans*-$[Rh(NH_3)_4(H_2O)Cl]^{2+}$ should all lead to the same five-coordinate $\{[Rh(NH_3)_4Cl]^{2+}\}^*$ intermediate, and should therefore all lead to the same photochemical product. Careful reinvestigation of the photochemistry of the *trans*-$[Rh(NH_3)_4Cl_2]^+$,[716] the two *cis* complexes,[719] and a new study of *trans*-$[Rh(NH_3)_4(H_2O)Cl]^{2+}$ [716] showed that in all four cases the photoproduct is the same mixture of $[Rh(NH_3)_4(H_2O)Cl]^{2+}$ isomers (17% *cis* and 83% *trans*; Figure 2). This strongly supports Vanquickenborne's stereochemical model for d^6 systems[747] and suggests that the substitutional photochemistry of these Rh^{III} amines may indeed proceed *via* a purely dissociative mechanism, with a five-coordinate intermediate sufficiently stable to undergo unimolecular isomerization and reach thermal equilibrium between two similar SP structures.

The limiting dissociative mechanism is also supported by studies of the effects of pressure on the photoinduced aquation of *cis*- and *trans*-$[Rh(NH_3)_4X_2]^+$, *cis*-$[Rh(NH_3)_4(H_2O)X]^{2+}$ (X = Cl, Br), *trans*-$[Rh(NH_3)_4(OH)Cl]^+$,[751] $[Rh(L)_5X]^{2+}$ (L = NH_3, ND_3; X = Cl, Br),[752] and $[Rh(NH_3)_5X]^{n+}$ (X = NH_3, I^-, SO_4^{2-}).[711] In the tetraammine series, the volume of activation of photoinduced aquation varies between -8.8 and $+9.3\,cm^3\,mol^{-1}$; in the pentaammine series halide loss has a negative volume of activation (between -10.3 and $-4.2\,cm^3\,mol^{-1}$), while ammine loss has a positive ΔV^* ($+3.4$ to $+12.7\,cm^3\,mol^{-1}$). The effect of pressure on the photochemistry of $[Rh(NH_3)_5Cl]^{2+}$ in formamide, DMF or DMSO allowed an estimation of the volumes of activations for Cl^- labilization, NH_3 labilization, luminescent and non-radiative deactivation paths.[753] Com-



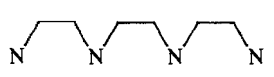


Figure 2 Photolysis of $[Rh(NH_3)_4Cl_2]^+$ and $[Rh(NH_3)_4(H_2O)Cl]$

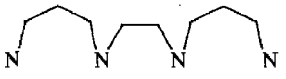
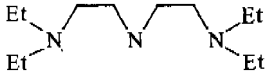
parison of ΔV^* values for reactive and non-reactive paths led to the suggestion of a strong coupling between the two processes.[752] After accounting for the expanded volume of the ligand field excited state, vanEldik and coworkers state that 'a collection of circumstantial evidence points to a limiting dissociative mechanism for the ligand field photosubstitution reactions of rhodium(III) haloammine complexes in aqueous solution'.[753]

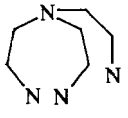
48.6.2.4 Polydentate aliphatic amine complexes



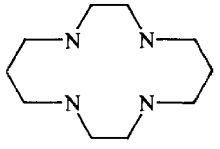
Aliphatic amines with three or more amine functions which form complexes with Rh^{III} are represented in (**48**). These can be subdivided into linear (trien, 2,3,2-tet, *etc.*), branched (tren) and cyclic (cyclam, cyclen, *etc.*) amines, and will be discussed in that order.



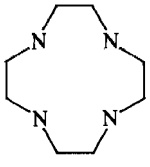
(48a) trien



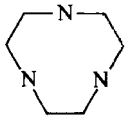
(48b) 2,3,2-tet



(48c) 3,2,3-tet

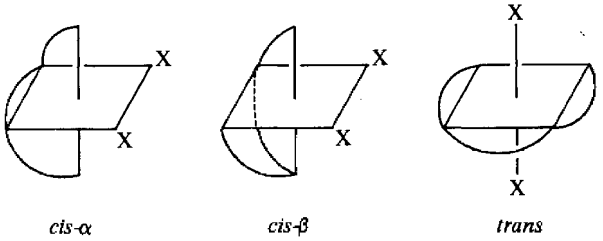


(48d) 1,1,7,7-tetraethyldien



(48e) tren

(48f) cyclam



(48g) cyclen

(48h) [9]aneN$_3$

Two general synthetic paths to Rh^{III} polyamine complexes have emerged: extension of the procedure for the synthesis of $[Rh(en)_2X_2]^+$ [619] (reaction of $RhCl_3 \cdot 3H_2O$ or $[RhCl_6]^{3-}$ with the HCl salt of the appropriate amine), or the reaction of *trans*-$[Rhpy_4Cl_2]^+$ with the appropriate amine.[754] The $[Rh(trien)Cl_2]^+$ ion was first prepared by Basolo and Johnson[619] and later by Gillard and Wilkinson.[755] Three geometric isomers are possible for octahedral complexes with linear tetradentates (**49**), and while isomeric assignment was not made in these initial studies, later work showed

cis-α *cis*-β *trans*

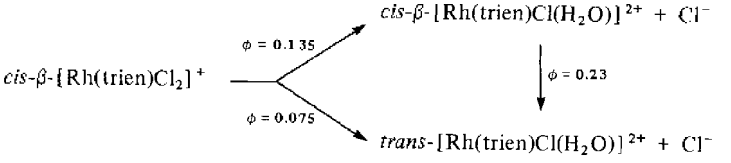
that the *cis*-α isomer had been prepared. Several examples of $[Rh(trien)X_2]^+$ ($X = Cl^-$, Br^-, I^- and N_3^-) have been prepared and the *cis*-α, *cis*-β and unstable *trans* isomers have been separated and identified on the basis of IR and UV/visible spectra (Table 51).[756] Reaction of $[Rh(trien)Cl_2]^+$ (presumably the *cis* isomer) with BH_4^- leads to a brown solution, said to contain the monohydrido *cis*-$[Rh(trien)Cl(H)]^+$; analysis of the *d*–*d* bands suggested that H^- belongs just above F^- in the spectrochemical series.[757]



Kinetic studies of the aquation[619,763] and anation[756] of *cis*-α- and *cis*-β-$[Rh(trien)Cl_2]^+$ and of *cis*-β-$[Rh(2,3,2\text{-tet})Cl_2]^+$[763] have shown that, in the absence of light, substitutions occur with retention of amine configuration, and between 60–80 °C, the aquation rate constants are within an order of magnitude, with the most reactive *cis*-β-$[Rh(trien)Cl_2]^+$, aquating about eight times as rapidly as the least reactive, *cis*-α-$[Rh(trien)Cl_2]^+$. Activation parameters for these reactions, and reactions of other aliphatic polyamine Rh^{III} complexes, are given in Table 52. Photolysis of *cis*-β-$[Rh(trien)Cl_2]^+$ and *cis*-β-$[Rh(2,3,2\text{-tet})Cl_2]^+$ causes efficient release and isomerization, yielding a mixture of *cis*-β- and *trans*-aquachloro products (equations 140 and 141).[758] The *cis*-α-$[Rh(trien)Cl_2]^+$ ion, however, is at least three orders of magnitude less photoreactive than either *cis*-β complex, as no photoinduced reaction could be observed, even after extended photolyses.[758] A similar reactivity pattern was noticed for the *cis* isomers of $[Co(trien)Cl_2]^+$, and steric constraints, induced by the configuration of the trien, were invoked to rationalize the photoinertness of *cis*-α-$[M(trien)Cl_2]^+$ (M = Co or Rh).[766] (Interestingly, the *cis*-α-$[Cr(trien)Cl_2]^+$ ion is quite photosensitive.[767]) A summation of the photochemical reactivity of aliphatic polyamine Rh^{III} complexes is given in Table 53.

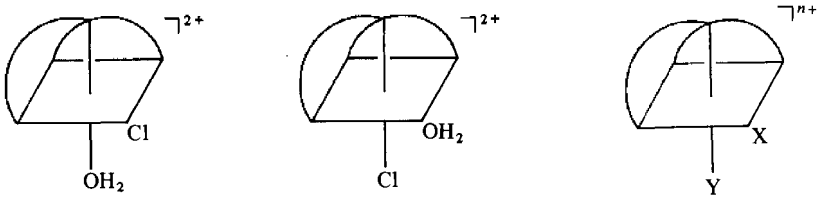
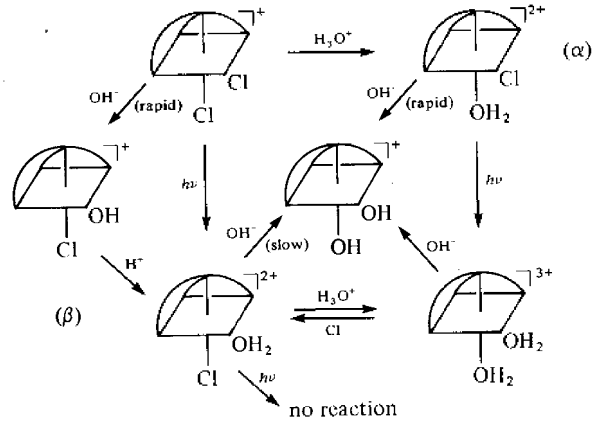
(141)



The stereochemistry of six-coordinte Co^{III} and Rh^{III} complexes with the 3,2,3-tet ligand (**48c**) was thoroughly studied by Bosnich and co-workers.[769] As shown in (**50**), if the six-membered rings are both in a chair conformation, the *trans*-$[Rh(3,2,3\text{-tet})Cl_2]^+$ ion is asymmetric due to the conformation of the five-membered, central ring. Bosnich resolved this ion and studied the solvent-induced changes in the CD spectra, which were attributed to solvation effects, and not to changes of ring configuration.[759,769] The single crystal X-ray structure of $[Rh(1,1,7,7\text{-tetraethyldien})(N_3)_3]$ shows it to be monomeric, with a distorted octahedron, and the substituted dien in a *mer* configuration.[770]



(50)

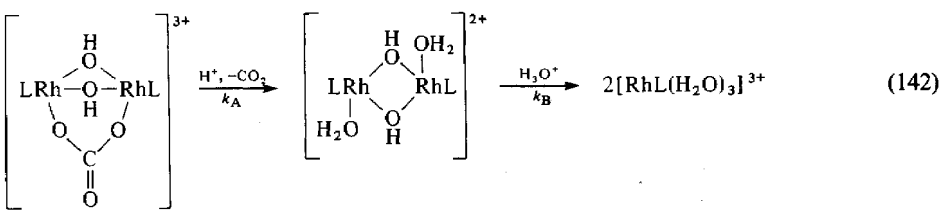
The branched isomer of trien, β,β′,β″-triaminotriethylamine (tren **48e**) can act as a tetradentate toward Rh^{III}, or, as the trihydrochloric acid salt $[(tren3H)^{3+}3Cl^-]$, it can act as a trivalent cation for the precipitation of $[RhCl_3X_3]^{3-}$ (X = Cl, Br, I) and $[RhBr_6]^{3-}$.[771] First reported by Basolo,[619] the aquation kinetics of $[Rh(tren)Cl_2]^+$ were later studied by Madan.[772] Ligand field photolysis of $[Rh(tren)Cl_2]^+$ also causes chloride loss, but the photo and thermally produced $[Rh(tren)Cl(H_2O)]^{2+}$

ions are distinct.[762] It was proposed that the thermal and photochemical reactions produced the two geometric isomers of $[Rh(tren)Cl(H_2O)]^{2+}$ (**51**). Base hydrolysis of $[Rh(tren)Cl_2]^+$ leads to the same isomer produced photochemically,[761] and it has been proposed that this is the α isomer (**51**). Mechanistic arguments, based on the hydrophilic nature of the site *trans* to the tertiary amine, were used to suggest that aquation in acidic aqueous solution (presumably *via* the I_a path), leads to the β isomer. A summary of the reactions of some $[Rh(tren)XY]^{n+}$ complexes is given in Scheme 25. For complexes of the form represented in (**52**), associative processes (aquations, anations) tend to occur at coordination site Y, while dissociative processes (base hydrolysis, photoinduced substitutions) lead to substitutions at site X. Consistent with this model, kinetic studies of the acid hydrolysis of α- and β-$[Rh(tren)X(H_2O)]^{2+}$ show that loss of a halide from site Y involves a small entropy of activation, while aquation of site X involves large positive values of ΔS^* (Table 52).[764]

(51)

Scheme 25

The Rh^{III} complexes containing the 14-membered cyclic tetramine, 1,4,8,11-tetraazatetradecane (cyclam, **48f**), have been extensively studied by Bounsall and Koprich.[773] When the free cyclam ligand is reacted with $RhCl_3 \cdot 3H_2O$ in aqueous solution the dominant product is *cis*-$[Rh(cyclam)Cl_2]Cl$; when the same reaction is run in methanol, the *trans* isomer predominates. Both *cis* and *trans* isomers of a variety of $[Rh(cyclam)XY]^{n+}$ (X and Y = halides, pseudohalides, H_2O, OH^-) have been prepared by direct substitution of the ligand by refluxing the cyclam complex in an aqueous solution of the desired anion.[764,773] With the exception of *cis*-$[Rh(cyclam)I_2]^+$, which isomerizes to the *trans* form when heated, substitutions at $[Rh(cyclam)XY]^{n+}$ occur with retention of geometric configuration.[773] The electronic spectra of a variety of $[Rh(cyclam)XY]^{n+}$ ions, and of other cyclic polyamine Rh^{III} complexes, are recorded in Table 54. Analysis of the IR spectra indicated that the NCS^- ligands are N-bonded, as are the NO_2^- ligands. The *cis* complexes offer an unusual opportunity to study the *trans* bond-weakening effect in a series of closely analogous compounds, as there is a Rh—N bond *trans* to a different ligand in each *cis* complex. Analysis of Rh—N stretching frequencies indicated that the *trans* bond-weakening series is $NO_2^- > I^- > Br^- > Cl^- \approx N_3^-$ > amine N > NCS^-. Photolysis of *trans*-$[Rh(cyclam)X_2]^+$ and the *cis*-dichloro cation causes stereoretentive halide aquation (Table 53).[768] The electrical resistances of compressed samples of *cis*-$[Rh(cyclam)Cl_2](TCNQ)$ (TCNQ = the monoanion of tetracyanoquinoline) are 32 times that of the *trans* isomer.[778] For the more constrained tetramine 1,4,7,10-tetraazacyclodecane (cyclen; **48g**) only the *cis*-$[Rh(cyclen)Cl_2]^+$ ion has been characterized (as the dihydrate of the chloride salt).[775]



The coordination chemistry of the cyclic triamine 1,4,7-triazacyclononane ([9]aneN$_3$; **48h**) has been studied by Wieghardt *et al.* and has proven to be a rich area. In aqueous solution, [9]aneN$_3$

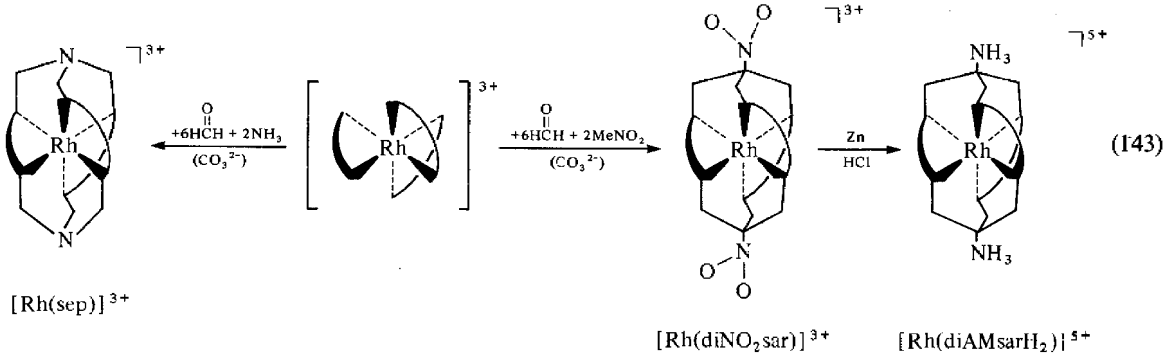
is a tridentate ligand, and a series of doubly and triply bridged hydroxo, carbonato and acetato dimers have been characterized.[775,777,779] As summarized in Scheme 26, $[Rh_2([9]aneN_3)_2(H_2O)_2(\mu\text{-}OH)_2]^{4+}$ is deprotonated at pH values above 8.5 and the resulting conjugate base reacts with carbonate to give a carbonato-bridged dimer.[775,779] A kinetic study of the decarboxylation (equation 142) has shown that both reactions exhibit an acidic dependence.[775] The X-ray structure of the diaquadi-μ-hydroxo tetravalent cation (as the perchlorate salt) confirmed the di-μ-hydroxo geometry.[779] Reaction of $RhCl_3 \cdot 3H_2O$ in ethanol with a methanolic solution of the *N,N′,N″*-trimethyl substituted version of this cyclic triamine (Me_3[9]aneN$_3$) leads to a yellow solid, which, if refluxed in an alkaline perchlorate solution, gives yellow crystals of $[Rh_2(Me_3[9]aneN_3)_2(\mu\text{-}OH)_3](ClO_4)_3$. A preliminary X-ray structure of these crystals confirms the triply bridged hydroxo geometry, and gives an Rh—Rh distance of about 2.96 Å.[777]

(142)



L = [9]aneN$_3$

Sargeson and co-workers have synthesized, characterized and studied the chemistry of a variety of remarkable macrocyclic amine complexes of Rh^{III}, in which the rhodium is virtually isolated

Scheme 26

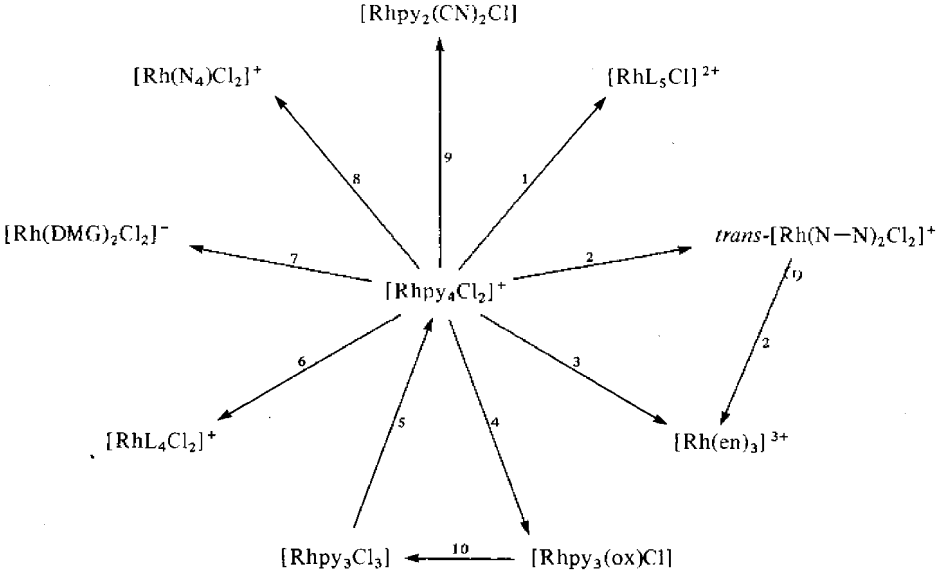
within a cage defined by a six-coordinate aliphatic amine.[767] The syntheses are summarized in equation (143). Reaction of $[Rh(en)_3]^{3+}$ with six equivalents of formaldehyde and two equivalents of ammonia in an alkaline (carbonate) aqueous solution leads to the basic cage complex $[Rh(sep)]^{3+}$. If nitromethane is used instead of ammonia, the $[Rh(diNO_2sar)]^{3+}$ ion is formed; the nitrosyl functions can be reduced to amines with Zn/HCl. The compounds were characterized by UV/visible, IR and ^1H, ^{13}C and ^{103}Rh NMR; the electronic spectra are similar to that of the $[Rh(en)_3]^{3+}$ parent, and the ^1H decoupled ^{13}C NMR shows resonances for two sets of six equivalent methylenes, consistent with D_3 symmetry.

(143)

The effect of the cage on the one-electron reduction of the metal center has been studied in detail. Electrochemical reduction to $[Rh(sep)]^{2+}$ was observed at -1.8 V (*vs.* Ag/AgCl/0.1 M LiCl) in acetone solution, but not in water; reduction is reversible, but further reduction to Rh metal does occur at -2.2 V. The Rh^{II} thus formed is moderately stable, with a half-life of *ca.* 15 ms at 20 °C. As rapid as this decay of the Rh^{II} cage complex may seem, the one-electron reduction of Rh^{III} complexes is normally not reversible, and the Rh^{II} cages do not dimerize, disproportionate or undergo further reduction to the Rh^{I} complex. (While the Rh^{II} state is stabilized by the cage, the photoproduced ^3T excited state of $[Rh(sep)]^{3+}$ decays an order of magnitude more rapidly than the analogous state of $[Rh(NH_3)_6]^{3+}$; $t_{1/2} = 2.8$ μs and 27 μs, respectively.) Pulse radiolysis of $[Rh(sep)]^{3+}$ showed pseudo-first order quenching of the solvated electron ($k = 1.4 \times 10^{10}\ M^{-1}s^{-1}$ at 25 °C), producing $[Rh(sep)]^{2+}$. The authors also comment on the remarkably regiospecific nature of the synthesis of $[Rh(sep)]^{3+}$, as 11 molecules must condense to form the 14-membered ring macrocycle,

and this reaction can reach 90% yields. If chiral $[Rh(en)_3]^{3+}$ is used, the resulting cage is also chiral.[765]

48.6.2.5 N-heterocycle complexes



(*i*) *Pyridine complexes*

Numerous Rh^{III} complexes containing coordinated pyridine and substituted pyridines are known, but this area is dominated by the chemistry of the *trans*-$[Rhpy_4Cl_2]^+$ cation. First characterized by Jørgensen,[780] its chemistry has been studied extensively by Gillard, Wilkinson and co-workers, and it has served as the parent for a host of derivatives.

Attempts to replace the two chlorides by pyridine have been unsuccessful, and the hexapyridinerhodium(III) cation is unknown, although there are several reports of unsuccessful attempts to prepare it.[781] Reaction of *trans*-$[Rhpy_4Cl_2]^+$ in refluxing pyridine leads to *fac*- and *mer*-$[Rhpy_3Cl_3]$; the addition of ethanol leads to a pink residue identified as a chloro-bridged polymer $[Rhpy_2Cl_3]$.[781] Reaction of *trans*-$[Rhpy_4Cl_2]^+$ with Ag^+ (to remove Cl^-) presumably yields $[Rhpy_4(H_2O)_2]^{3+}$, but this material does not pick up even one additional pyridine when refluxed in neat pyridine for four days![781] Early claims for $[Rhpy_6]X_2$ and $[Rhpy_5X]X$ (X = Cl or Br)[782] were later shown to be due to the ubiquitous *trans*-$[Rhpy_4X_2]X$.[781,783]

The standard preparation of *trans*-$[Rhpy_4Cl_2]^+$ is due to Delépine,[784,785] who noticed that reaction of pyridine with $[RhCl_6]^{3-}$ leads to mixtures of $[Rhpy_3Cl_3]$ isomers, but that in the presence of primary or secondary alcohols, *trans*-$[Rhpy_4Cl_2]Cl$ is formed. (The role of the alcohol in this reaction is discussed in more detail in Section 48.6.2.5.iii.) Far IR spectra (pyridine ring vibrations, Rh—N and Rh—Cl stretches) of the *fac* and *mer* isomers of $[Rhpy_3Cl_3]$ confirmed the earlier isomer assignment.[786]

The *trans*-$[Rhpy_4Cl_2]^+$ ion is a convenient starting material, as the pyridines are readily replaced by other donors. Jørgensen's observation[787] that $[Rh(NH_3)_5Cl]Cl_2$ could be recrystallized from boiling pyridine, while NH_3 substitution of py in *trans*-$[Rhpy_4Cl_2]^+$ is facile, has been confirmed.[781] The lability of the pyridine ligands was emphasized in a recent secondary ion mass spectroscopy (SIMS) study of solid *trans*-$[Rhpy_4Cl_2]Cl \cdot 5H_2O$, which indicated that successive pyridine labilization occurred (the ions $[Rhpy_nCl_2]^+$ for $n = 4$, 3, 2 and 1 were detected), while Cl^- was not lost from the parent; no evidence of $[Rhpy_4Cl]^+$ could be detected.[788] Representative examples of the reactions of *trans*-$[Rhpy_4Cl_2]^+$ are given in Scheme 27 and Table 55. Pyridine volatility makes it an exceptionally convenient leaving group, as labilized pyridines can be steam distilled from the reaction flask. The neutral $[Rhpy_3(ox)X]$ complexes (presumably *mer*, X = Cl or Br) display an unusual synergistic solubility, as they are insoluble in both H_2O and pyridine, but are relatively soluble in mixtures of the two solvents, reaching a maximum solubility in 1:1 mixtures of the solvents.[791]

Scheme 27

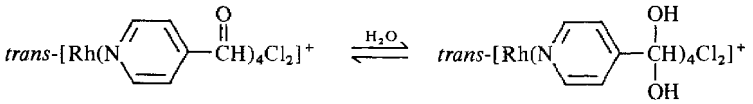


Table 55 Conditions for Reactions Cited in Scheme 27

Reaction	*Reactants*	*Ref.*
1	L = NH_3	789
	L = *N*-methylimidazole	790

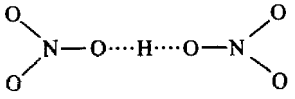
5	Refluxing pyridine	781
6	L = substituted pyridine	781
7	Dimethylglyoxime	601
8	N_4 = trien, 2,3,2-tet	754, 790
	N_4 = 3,2,3-tet	769
9	Aqueous CN^-	794
10	Conc. HCl	791

An extensive number of substituted pyridine analogs of *trans*-$[Rhpy_4Cl_2]^+$ have been prepared *via* the path illustrated in equation (144). For the same reaction, if L = NH_3 or *N*-methylimidazole (miz), pentaamine complexes result. The $[Rh(miz)_4Cl_2]^+$ ion can be prepared by Cl^- anation of $[Rh(miz)_5Cl]^{2+}$ in refluxing aqueous ethanol (pH 3). No reaction is observed for L = α-picoline, 2,4-lutidine or 2-aminopyridine, probably due to steric hindrance. The electronic spectra for all of the $[RhL_4X_2]^+$ ions showed peaks at 409 and 439 nm (±2 nm). Water adds, reversibly, to *trans*-[Rh(4-formylpyridine)$_4$Cl$_2$]$^+$ as shown in equation (145); the analogous 3-formylpyridine complex is unreactive, and may be recovered unchanged from boiling water.[795]

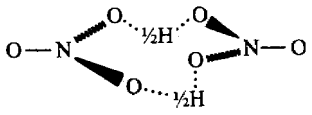
$$RhX_3 \cdot 3H_2O + 4L \xrightarrow[\text{in } H_2O]{30\%\ EtOH} [RhL_4X_2]X \xrightarrow[H_2O]{HY} [RhL_4X_2]Y \qquad (144)$$

L = 3- or 4-substituted pyridine, 3,5-disubstituted pyridine, isoquinoline, pyrimidine, pyrazole or thiazole; X = Cl, Br (and I for L = py); Y = univalent anion



(145)

Halide substitution at *trans*-$[Rhpy_4Cl_2]^+$ is possible, but refluxing *trans*-$[Rhpy_4Cl_2]^+$ in HBr solution (4 M) does not lead to $[Rhpy_4Br_2]^+$, but *trans*-$[Rhpy_4Cl_2](H_5O_2)Br_2$. An unusual fluoride-assisted hydrolysis of *trans*-$[Rhpy_4X_2]^+$ (X = Cl, Br) rapidly leads to $[Rhpy_4X(OH)]^+$. Azide ion readily replaces Cl^- (and py) in $[Rhpy_4Cl_2]^+$, and the compounds $[Rhpy_n(N_3)_{6-n}]^{(n-3)+}$ (n = 2, 3, 4) have been prepared.[795] Thiocyanate does not react with $[Rhpy_4Cl_2]^+$, but NCO^- and NO_2^- each react to give incompletely characterized non-electrolytes.[795]

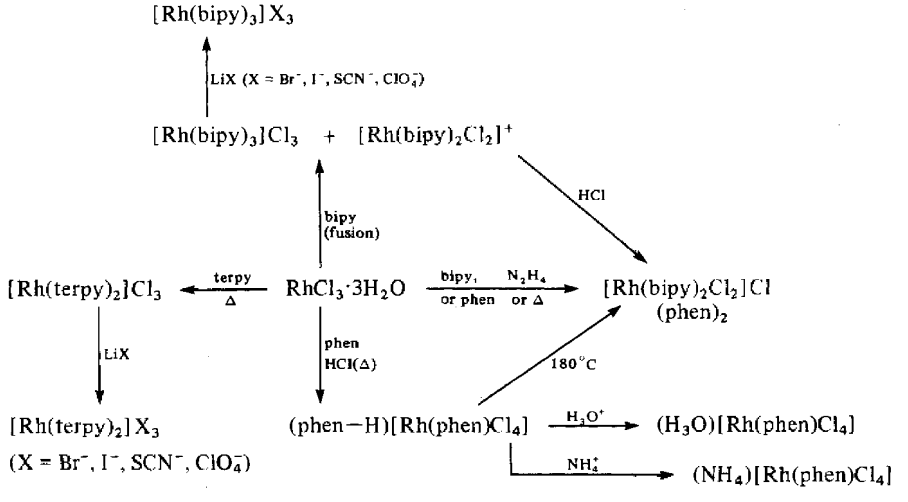


Photolysis (436 and 254 nm) leads to both halide and py labilization from *trans*-$[Rhpy_4X_2]^+$ (X = Cl, Br).[796] The efficiencies of Cl^- and py release are comparable (upon *d–d* excitation at 436 nm), but are uncharacteristically low for photoinduced Rh—Cl bond cleavage. Bromide release dominates over py release upon 254 nm excitation of *trans*-$[Rhpy_4Br_2]^+$. The photoreactions are presumed to proceed with retention of geometry.[796]

The *trans*-$[Rhpy_4Br_2]^+$ ion has been the cationic host to an interesting bit of chemistry concerning the $(HN_2O_6)^-$ anion. The salt was first formulated as $[Rhpy_4Br_2](NO_3)(HNO_3)$ by Poulenc,[797] and it was later proposed, on the basis of a broad IR band near 800 cm^{-1}, that the hydrogen dinitrate anion contains a symmetric H bond.[798] Thermogravimetric and differential thermal analysis showed that a molecule of nitric acid is released at *ca.* 200 °C.[799] A single-crystal X-ray analysis of *trans*-$[Rhpy_4Cl_2][H(NO_3)_2]$ showed that the hydrogen dinitrate anion has two nitrates arranged such that four oxygens (two from each nitrate) form a slightly distorted tetrahedron, with the mean O—O distance about 3.06 Å. The hydrogen atom was not found, but was presumed to be near the center of gravity of the oxygen tetrahedron.[800] The $[As(Ph)_4][H(NO_3)_2]$ salt also contains the hydrogen dinitrate anion, but in this case there is a linear, very short (O—O distance of 2.45 Å) hydrogen bond (**53a**); the anion of the Cs^+ salt has a structure similar to that of the $[Rhpy_4Cl_2]^+$ salt.[801] A neutron diffraction study[802] of *trans*-$[Rhpy_4Cl_2][H(NO_3)_2]$ revealed a disordered structure; the NO_3 moieties form a distorted tetrahedron of oxygen atoms, similar (but not identical) to that observed in the X-ray study,[800] where the hydrogen atoms are disordered between the two closest oxygen atoms (**53b**). The two sites are occupied with equal probability, so that the two non-coplanar nitrate groups may be considered to be bridged by two equivalent H bonds; the O—H—O moiety is bent with a

bond angle near 167.5°. The hydrogen dinitrate ion may, in fact, be a common ion in nitric acid solution, as Gillard and co-workers have prepared and analyzed the IR spectra of a variety of *trans*-$[Rhpy_4Cl_2]^+$ analogs which all contain the $[H(NO_3)_2]^-$ anion.[803] The *trans*-$[Rhpy_4Br_2]Br \cdot HBr \cdot 2H_2O$ crystalline salt has been proposed to contain the $(H_5O_2)^+$ cation with a symmetric O···H···O hydrogen bond between two H_2O moieties.

(53a)



(53b)

Perhaps the most unusual, and potentially important, property of these pyridine–Rh^{III} complexes is their antibacterial activity. The activity is increased by substituting Br for Cl in the *trans*-$[Rhpy_4X_2]^+$ cation, and by adding lipophilic groups to the py ligand (*e.g.* Mepy, Etpy) and is decreased by adding polar groups (*e.g.* HOpy or H_2Npy). The activity seems specific to the *trans*-$[ML_4X_2]^+$ cation (M = Rh, but not Co or Ir; X = Cl, L = py or substituted py, but not NH_3 or $\frac{1}{2}$en).[804]

(*ii*) *Polypyridine complexes*

While not yet as extensive as the chemistry reported for bipy and phen complexes of ruthenium, the chemistry of rhodium polypyridine complexes (especially their excited states) has generated much recent interest. The claim of Lehn and co-workers[805] that excited states of $[Rh(bipy)_3]^{3+}$ are involved in the photoinduced generation of $H_{2(g)}$ from water has sparked renewed efforts to understand the rich excited state chemistry of these complexes.

Synthesis of polypyridine complexes of Rh^{III} generally involves replacing halide ligands with the chelated polypyridyls; fusion of $RhCl_3 \cdot 3H_2O$ and bipy is reported to yield $[Rh(bipy)_3]Cl_3$, and workup of the resulting solid in aqueous nitric acid gives an unreliable yield of $[Rh(bipy)_2Cl_2]$-NO_3.[806] More convenient and reliable syntheses take advantage of the catalytic properties of mild reducing agents (see Section 48.6.2.4.iii) as the reaction of $RhCl_3 \cdot 3H_2O$ with bipy (or phen) in ethanol/2-methoxyethanol solution,[601] or in ethanol with catalytic amounts of hydrazine,[792] gives $[Rh(LL)_2Cl_2]^+$ (or $[Rh(phen)_2Cl_2]^+$) in high yields. An uncatalyzed reaction of $[RhX_6]^{3-}$ (X = Cl, Br) with phen leads to the monosubstituted $[Rh(phen)X_4]^-$ anion, as the $(Hphen)^+$ salt, which can be further substituted to give $[Rh(phen)_2X_2]^+$;[807,808] the chloride form of the latter complex has been resolved on a cellulose column.[807] Mixed complexes of the series $[Rh(bipy)_n(phen)_{3-n}]^{3+}$ (n = 0–3), have been prepared by Crosby and Elfring by bipy or phen substitutions of both chlorides in $[Rh(N{-}{-}N)_2Cl_2]^+$ (N—N = bipy or phen).[809] Scheme 28 summarizes some synthetic paths for the various polypyridine complexes of Rh^{III}.

Scheme 28

The assignment of the geometric configuration for $[Rh(bipy)_2X_2]^+$ (and the phen analog) has been error prone and confusing, as electronic spectra,[601] acid adduct formation,[810] IR and Raman spectra,[808,811,812] ^1H NMR,[808] proposed mechanism of formation,[813,814] and X-ray powder patterns[815] have all been used to make (often conflicting) geometric assignments. It is now clear that these complexes, $[Rh(N—N)_2X_2]^+$ where (N—N) = bipy, phen or methyl or halo-substituted analogs; X = Cl, Br, I, all share the *cis* geometry. The *trans* configuration is unknown for these polypyridyl complexes, while the *cis* configuration is unknown for the monodentate pyridine analogs $[Rhpy_4X_2]^+$. Like the pyridine complexes, bis(bipy) complexes form acid adducts, and thermogravimetric analysis of $[Rh(bipy)_2Cl_2]Cl \cdot HCl \cdot 2H_2O$, implies that the anion should be formulated as $[(H_5O_2)^+(2Cl^-)]^-$.[799]

Recent interest in Rh polypyridyl complexes has centered on the behavior of their excited states; this is an active and complicated research area, and our understanding is less than complete. Discussion here will proceed as follows: (a) the photochemical properties; (b) the chemistry of the reduced polypyridyl complexes; and (c) the role of Rh^{III} polypyridyls as electron-transfer agents in the quenching of photoproduced excited states of $[Ru(bipy)_3]^{3+}$, and the photogeneration of H_2 from water.

In aqueous solution at room temperature, *cis*-$[Rh(N—N)_2X_2]^+$ (N—N = bipy or phen, X = Cl, Br, I) display deceptively simple photochemistry. Upon irradiation between 254 and 436 nm, all undergo stereoretentive halide loss, with the primary photoproduct being the corresponding $[Rh(N—N)_2X(H_2O)]^{2+}$ complex; minor Rh—N bond cleavage also occurs.[796] Halide release quantum yields are about an order of magnitude lower than those generally observed for haloamines of Rh^{III}. In a rigid environment at reduced temperature, these complexes luminesce, and on the basis of lifetime measurements, a heavy-atom perturbation effect, and the large Stokes shifts, the luminescence has been assigned as a spin-forbidden phosphorescence.[816] This assignment was confirmed in a study of the luminescence at 77 K in an alcohol glass matrix (ethanol–methanol, 4:1), in which intrinsic lifetimes, radiative rate constants, and quenching rate constants were determined. The intersystem crossing efficiency to the emitting triplet (a ligand-centered π–π^* state) was found to be 'within 30% of unity', and a semi-empirical spin–orbit-coupling model was used to predict the intrinsic lifetimes of the excited states.[817] DeArmond and Hillis have reported the absorption and emission spectra for several polypyridyl complexes of Rh^{III} (room temperature and at 77 K in ethylene glycol–water 1:1, or ethanol–methanol 5:1 glasses); their spectral results are given in Table 56.[818] The tris(bipy) and tris(phen) complexes show structured emission in the same region as the free ligands, implying that the luminescence is from a ligand-localized π–π^* state, as suggested by Crosby.[820] The bis(bipy) and bis(phen) cations showed broad, structureless emissions at low energy (with short lifetimes), consistent with Crosby's assignment of a d–d,[816] $^3T_1 \rightarrow {}^1A_1$ phosphorescence.[818] The intensity of the ligand-localized phosphorescence again suggests that the intersystem crossing efficiency for the tris-chelated complexes is near unity, but the lower intensity for the bis-chelated complexes suggests that population of the metal-centered $^3T_1$ state is less efficient.[818] Emission from these Rh complexes is generally more efficient than from the Ir analogs.

Emission from the ligand-localized π–π^* state of the tris-chelated complexes was further studied by Crosby, who prepared and showed that the luminescence (77 K, ethanol–methanol 4:1 glasses) from $[Rh(bipy)_n(phen)_{3-n}]^{3+}$ (n = 0–3), displayed long lifetimes (41, 24, 16 and 2.5 ms for n = 0, 1,

$[Rh(en)_2Cl_2]Cl$	469sh (~1.5), 400 (82.2), 284 (123)	690	1.5×10^{-5}

2 and 3, respectively), consistent with phosphorescence from a $^3(\pi-\pi^*)$ excited state.[809] For $n = 0$ and 3, exponential decay of the phosphorescence was observed, but the mixed chelates ($n = 1$ and 2) showed non-exponential behavior. Crosby concludes that intraligand interaction is small in these complexes in both ground and excited states, and that the virtually isolated, ligand-localized, excited states decay independently, the apparent non-exponential decay resulting from the simultaneous, and unrelated, exponential decays from bipy- and phen-centered excited states. Supporting this model, Crosby notes that the absorption spectra of $[Rh(bipy)(phen)_2]^{3+}$ and $[Rh(bipy)_2(phen)]^{3+}$ are virtually indistinguishable from the spectra of appropriate mixtures of the tris(bipy) and tris(phen) complexes.[809]

A study of $[Rh(phen)_3]^{3+}$ confirmed that emission comes from a $^3(\pi-\pi^*)$ state.[819] No emission was observed in fluid solution, but a long-lived excited state occurs in DMF at room temperature, as 290 nm irradiation of $[Rh(phen)_3]^{3+}$ causes the characteristic 780 nm phosphorescence of $*[Cr(CN)_6]^{3-}$ (equation 146). The Sterm–Volmer constant of $3.0 \times 10^3\ M^{-1}$ implies a lower limit for the excited state lifetime of *ca.* 0.30 ms. Sensitization of biacetyl, and the oxidation of diphenylamine (in acetonitrile) and of 1,3,5-trimethoxybenzene are also observed for $*[Rh(phen)_3]^{3+}$, implying that the $^3(\pi-\pi^*)$ state of $*[Rh(phen)_3]^{3+}$ is a powerful oxidant. A potential of 2.00 V is calculated for the $*[Rh(phen)_3]^{3+}/[Rh(phen)_3]^{3+}$ couple,[819] making the excited state of $[Rh(bipy)_3]^{3+}$ a better oxidant than the Ru^{II}, Cr^{III} or Os^{II} analogs.

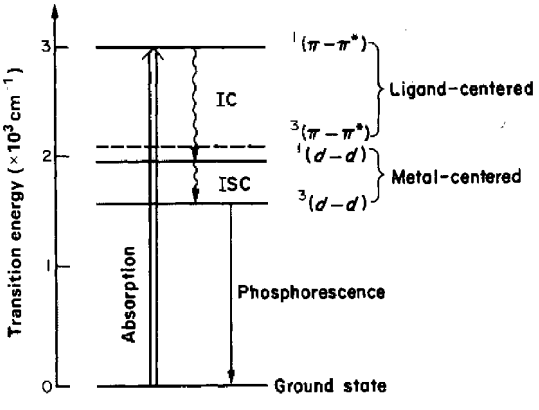
$$*[Rh(phen)_3]^{3+} + [Cr(CN)_6]^{3-} \longrightarrow [Rh(phen)_3]^{3+} + *[Cr(CN)_6]^{3-} \xrightarrow[\text{phosphorescence}]{780\text{ nm}} [Cr(CN)_6]^{3-} \quad (146)$$

In contrast, emission from $[Rh(bipy)_2X_2]^+$ is from a metal-centered, $^3(d-d)$ state. The various low-lying excited states for $[Rh(bipy)_2Cl_2]^+$ are represented in Figure 3, with initial excitation into the $^1(\pi-\pi^*)$ ligand state followed by relaxation and eventual phosphorescence from the $^3(d-d)$ state. The rise times for phosphoresence were reported to be 350–630 ns in room temperature solution and at 77 K,[820] but these values were later found to be artifacts of the detection system.[821] The emitting $^3(d-d)$ states of $[Rh(bipy)_2X_2]^+$ absorb at 580 (X = Cl) and 550 nm (X = Br), and the lifetimes of their transient absorptions (measured by time-resolved absorption spectroscopy in air-saturated ethanol–methanol (4:1) solution at room temperature) were found to be 84 ns (X = Cl) and 54 ns (X = Br).[821] (If the solutions are deoxygenated, the lifetimes increase by about a factor of five.) The presumed relaxation path is represented in equation (147), with the rate of internal conversion (IC) $\approx 4 \times 10^{11}\ s^{-1}$, followed by intersystem crossing (ISC), localized within the *d*-manifold, with the rate constant *ca.* 8×10^{11}.[821]

$$^1(\pi-\pi^*) \xrightarrow{IC} {}^1(d-d) \xrightarrow{ISC} {}^3(d-d) \quad (147)$$

A recent study[822] of the effect of steric interactions on the luminescence of 2,2′-bipyridyl complexes of Rh^{III} found luminescence from both ligand and metal-centered orbitals of $[Rh(dmbpy)_3]^{3+}$ (dmbpy = 3,3′-dimethyl-2,2′-bipyridyl). At 77 K the metal-centered luminescence dominates, but in fluid solution the ligand-centered emission is enhanced. As in the unsubstituted analogs, ligand-centered luminescence dominates under all conditions for $[Rh(dmbpy)_2Cl_2]^+$. Luminescence from fluid solutions of $[Rh(phen)_3]^{3+}$ and $[Rh(bipy)_3]^{3+}$ is consistent with the 77 K behavior,[816] as ligand-centered emission is observed.[822]

Closely tied to the photochemistry of these complexes is their behavior in the presence of reducing agents. Reduction of $[Rh(bipy)_3]^{3+}$ with BH_4^- or Zn amalgam was reported to yield $[Rh(bipy)_2]^+$.[401]



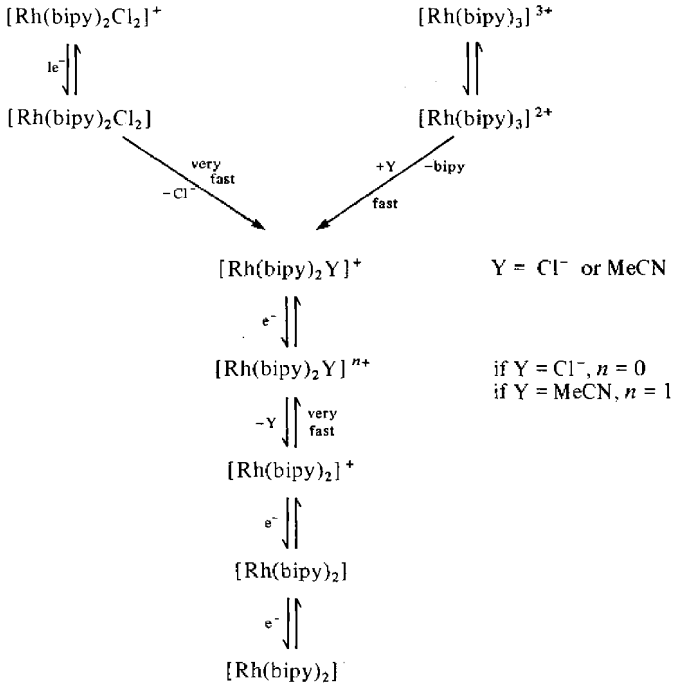


Figure 3 Low-lying excited states of $[Rh(bipy)_2Cl_2]^+$

The kinetics of the reduction of $[Rh(bipy)_2Cl_2]^+$ in alkaline aqueous ethanol (under H_2) revealed a two stage process: an initial induction period, during which time Rh^I species formed, and a faster, autocatalytic region. The kinetics could be fit to the expression: $d[Rh^I]/dt = k[Rh^{III}]^2[Rh^I]$. The reaction rate was retarded by the addition of excess bipy, suggesting the suppression of a dissociation equilibrium, and the rate constant varies with $[OH^-]$, but not with $[Cl^-]$. A five-step mechanism for the autocatalytic process was proposed, involving the formation (*via* an unspecified mechanism) of $[Rh(bipy)_2]^+$, followed by the oxidative-addition of H_2 to $[Rh(bipy)_2]^+$, and chloro-bridged dimeric and trimeric intermediates.[823]

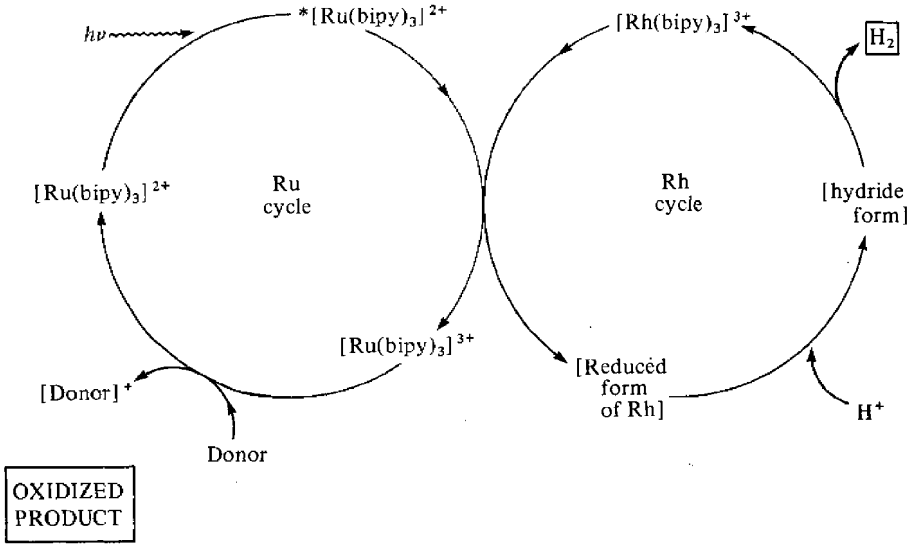
The electrochemical reduction of $[Rh(bipy)_2Cl_2]^+$ and $[Rh(bipy)_3]^{3+}$ in room temperature acetonitrile solutions has been studied by DeArmond and co-workers and is represented in Scheme 29. For both complexes, they claim that the initial one-electron reduction is followed by a 'moderately' fast elimination of a ligand (Cl^- or bipy); if the cyclic voltammetry scans are sufficiently rapid, this reduction is reversible.[824] After ligand labilization, the two paths merge, and there is evidence for two additional one-electron reductions, leading to $[Rh(bipy)_2]$ and $[Rh(bipy)_2]^-$.

Scheme 29

Studies of the reaction of $[Rh(bipy)_3]^{3+}$ with radiation-generated reducing radicals ($e^-_{(aq)}$, $CO_2^{\cdot}$ and Me_2COH) have shown that, however appealing, this relatively simple picture is incomplete.[825] These strong one-electron reductants quantitatively and rapidly ($k = 10^9$–$10^{10}\,M^{-1}s^{-1}$) generate $[Rh(bipy)_3]^{2+}$. This ion has the following properties: (a) it has an absorption maximum at 485 nm ($\varepsilon = 1000$); (b) it slowly loses bipy ($k = 0.45 \pm 0.05\,s^{-1}$ at pH 3–10); (c) it is extremely air-sensitive, and reacts with O_2 ($k = 4.9 \times 10^8\,M^{-1}s^{-1}$); (d) in alkaline solution, $[Rh(bipy)_3]^{2+}$ disproportionates (equation 148), giving the red-violet $[Rh(bipy)_2]^+$ ion and the starting complex; and (e) in very alkaline solutions (pH > 10), $[Rh(bipy)_3]^{2+}$ reduces $[Rh(bipy)_3]^{3+}$, resulting in a redox-catalyzed chain of ligand labilizations.

$$[Rh(bipy)_3]^{2+} + [Rh(bipy)_2]^{2+} \rightleftharpoons \underset{\text{(red-violet)}}{[Rh(bipy)_2]^+} + [Rh(bipy)_3]^{3+} \quad (148)$$

The two-electron reduction product, initially identified as '$[Rh(bipy)_2]^+$' is a most mercurial species, and Hoffman has identified four forms. (a) A red-violet, soluble form [λ_{max} at 518 nm (9500)] identified as $[Rh(bipy)_2(OH)_n]^{(1-n)+}$. This may be dimeric, with OH^- bridges. In neutral solution, the maximum absorbance shifts to 415 nm with a shoulder near 470 nm. (b) A violet, insoluble form, identified as $[Rh(bipy)_2X]$, for $X = Cl^-$, ClO_4^-, *etc.* (c) A transient green form, observed when the red-violet species is acidified. This is presumably $[Rh(bipy)_2(H_2O)_n]^+$. (d) A colorless species formed in acidic solution, which is presumed to be a Rh^{III} hydride, *e.g.* $[Rh(bipy)_2(H)]^{2+}$.

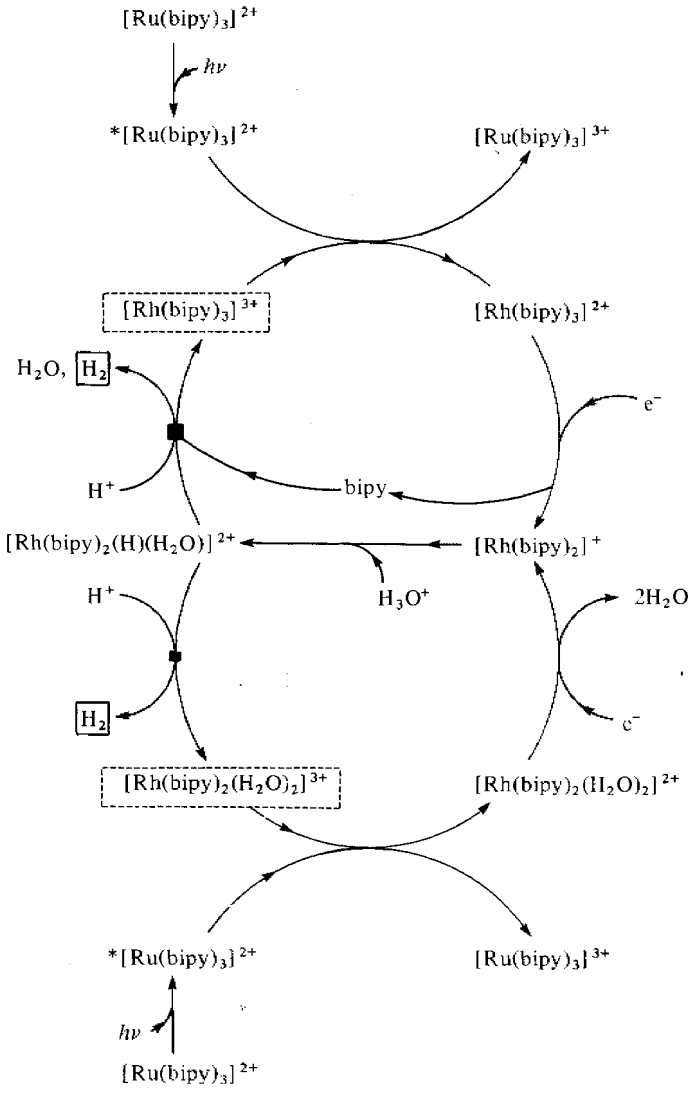


At 'natural pH' (around 5), reduction of $[Rh(bipy)_3]^{3+}$ with these radicals leads to H_2, with an efficiency of about 25%. The dihydrogen precursor is presumed to be the colorless RH^{III}–hydride for $[Rh(bipy)_2]^+$ is stable in an O_2 free environment, and at pH 10 a suspension of $[Rh(bipy)_2]ClO_4$ is stable for at least three months, and does not produce any dihydrogen.[825]

The reaction of radiolytically generated α-hydroxyalkyl radicals ($RR'\dot{C}OH$; R,R′ = H or Me) with $[Rh(phen)_3]^{3+}$ has also been studied, with the emphasis being on the fate of the radicals; equation (149) represents the observed process.[826] An earlier ESR study of such reactions in ethanol glasses found a metal-containing radical for the $[Rh(phen)_3]^{3+}$ system, but not when the starting complex was $[Rh(bipy)_3]^{3+}$.[827]

$$[Rh(phen)_3]^{3+} + RR'\dot{C}OH \xrightarrow{k_a} \text{adduct} \longrightarrow \text{products} \xrightarrow{k} [Rh(phen)_3]^{2+} + R\overset{\overset{O}{\|}}{C}R' \quad (149)$$

The importance of the reduced forms of $[Rh(bipy)_3]^{3+}$ is due to the fact that Rh^{III} polypyridyl complexes oxidatively quench the excited state formed upon visible light irradiation of $[Ru(bipy)_3]^{2+}$ (equation 150). Interest in this redox quenching dramatically increased when Lehn and co-workers demonstrated that aqueous solutions containing $[Ru(bipy)_3]^{2+}$, $RhCl_3 \cdot 3H_2O$, K_2PtCl_6 (or K_2PtCl_4), bipy and triethanolamine (TEOA) generated H_2 when the Ru complex was irradiated.[805] The role of the rhodium in this reaction has been the source of much discussion, as reduced forms of $[Rh(bipy)_3]^{3+}$ are thought to be the precursors to H_2 formation. In a detailed analysis of the mechanism of the H_2 generation, Lehn suggests that there are two catalytic cycles: the $[Ru(bipy)_3]^{2+}$ cycle and the $[Rh(bipy)_3]^{3+}$ cycle.[828] He conjectures that the $[Rh(bipy)_3]^{3+}$ serves as a 'relay species', which mediates water reduction by intermediate storage of electrons. This process is thought to involve a series of one-electron transfers, involving $[Rh(bipy)_2]^+$ and hydrido(bipy)rhodium species. A simplified representation of the relationship of the two catalytic cycles is shown in Scheme 30. Formation of H_2 requires two electrons, but the electrochemical experiments of DeArmond[824] showed that in acetonitrile the first two reduction potentials for $[Rh(bipy)_3]^{3+}$ are close (−0.86 and −1.00 V), so that formation of the ubiquitous $[Rh(bipy)_2]^+$ is facile.



$$*[Ru(bipy)_3]^{2+} + [Rh(bipy)_3]^{3+} \longrightarrow [Ru(bipy)_3]^{3+} + [Rh(bipy)_3]^{2+} \quad (150)$$

Scheme 30

Lehn notes that photolysis of alkaline (pH > 10) solutions of $[Ru(bipy)_3]^{2+}$ in the presence of $[Rh(bipy)_3]^{3+}$ and TEOA (but no Pt) leads to the formation of the 520 nm peak characteristic of $[Rh(bipy)_2]^+$, suggesting that two-electron reduction is possible in this non-complementary system. They conclude that there are at least two paths possible within the Rh cycle, each involving a hydridorhodium(III) species formed *via* the oxidative-addition of H_3O^+ (or H_2O) to $[Rh(bipy)_2]^+$ (equation 151). The two possible paths within the Rh catalytic cycle are presented in Scheme 31.

Other workers have attempted to make sense of this complex set of reactions, and much of the work has concentrated on the nature of the transient $[Rh(bipy)_3]^{2+}$, which is assumed to be the

$$[Rh(bipy)_2]^+ + H_3O^+ \rightleftharpoons [Rh(bipy)_2(H)(H_2O)]^{2+} \overset{H^+}{\underset{OH^-}{\rightleftharpoons}} \quad (151)$$

$$[Rh(bipy)_2(H)(OH)]^+ \rightleftharpoons [Rh(bipy)_2]^+ + H_2O$$

Scheme 31

primary product upon quenching the Ru excited state. No H_2 is generated in the absence of Pt salts, and it has been shown that the Pt prevents the disproportionation of the $[Rh(bipy)_3]^{2+}$ (into Rh^{III} and Rh^{I} species).[829] A detailed study of the electrochemistry and quenching ability of a variety of RhL_3^{3+} ions (L = bipy, 4,4′-Me_2bipy, phen, 5-Clphen, 5-Brphen, 5-Phphen, 5-Mephen, 5,6-Me_2phen and 4,7-Me_2phen) as well as $[Rh(terpy)_2]^{3+}$ showed that all of these cations oxidatively quench the photoproduced $*[Ru(bipy)_3]^{2+}$ (equation 150). Detailed study of quenching by the $[Rh(4,4'\text{-}Me_2phen)_3]^{3+}$ ion suggested that the electron-transfer during the quenching is a facile and endergonic process.[830] Creutz and Sutin showed that a strong correlation exists between reduction potentials obtained in acetonitrile (where the one-electron reduction is quasi-reversible)[824] and those estimated in aqueous solution, implying that data collected in acetonitrile can be used to estimate aqueous behavior. They also argued against DeArmond's interpretation (Scheme 29), and reversed their earlier conclusion,[829] and concluded that the irritating irreversibility of the reduction of $[Rh(bipy)_3]^{3+}$ is due to rapid ligand labilization from the two-electron reduction product (equations 152–154); they estimate that $k_f \approx 5 \times 10^4 s^{-1}$ in H_2O at 25 °C. Pointing to the exceedingly rapid self-exchange between $[RhL_3]^{3+}$ and $[RhL_3]^{2+}$ ($> 10^9 M^{-1} s^{-1}$), they also suggest that the immediate quenching product is not a Rh^{II} species. Rather, they suggest that ligand reduction occurs, generat-

ing a species more appropriately designated as $[Rh^{III}L_2(L^-)]^{2+}$. They recognize a few inconsistencies in this designation, and comment that our current view of the immediate quenching product $[RhL_3]^{2+}$ contains some anomalies which need to be corrected.[830] A more detailed discussion of this interesting ion is presented elsewhere.[831]

$$[Rh(bipy)_3]^{3+} + e^- \longrightarrow [Rh(bipy)_3]^{2+} \quad (152)$$

$$[Rh(bipy)_3]^{2+} + e^- \longrightarrow [Rh(bipy)_3]^{+} \quad (153)$$

$$[Rh(bipy)_3]^{+} \xrightarrow{k_r} [Rh(bipy)_2]^{+} + bipy \quad (154)$$

The current status of our understanding in this area has been succinctly summarized by Hoffman, who commented that '. . .reduction of $[Rh(bipy)_3]^{3+}$ in aqueous solution yields a very rich chemistry. . . Both $[Rh(bipy)_3]^{2+}$ and $[Rh(bipy)_2]^{+}$ are involved in highly complex interlocking ligand-labilization, acid–base, redox, and aggregation reactions'.[825]

(*iii*) *Catalysis of substitutions at Rh^{III}*

Pyridine complexes of Rh^{III} have played a central role in the still poorly understood area of catalyzed substitutions at Rh^{III} centers. Delépine first noted that the consecutive substitution of $[RhCl_6]^{3-}$ by pyridine leads to the neutral, and insoluble, $[Rhpy_3Cl_3]$, but that if the aqueous solvent includes some alcohol, pyridine substitution continues and *trans*-$[Rhpy_4Cl_2]^+$ is the final product (equation 155).[784] Delépine showed that primary alcohols all had comparable effects on the rate of formation of $[Rhpy_4Cl_2]^+$, and that secondary alcohols were less active than primary alcohols.[785] Tertiary alcohols proved to be totally inactive, as are ether, dioxane or acetone. Poulenc had also reported that ethanol catalyzed substitutions at Rh^{III} centers.[793]

$$[RhCl_6]^{3-} \xrightarrow{+py,\ -Cl^-} [Rh(py)_3Cl_3]_{(s)} \xrightarrow[alcohol]{py} [Rh(py)_4Cl_2]Cl \quad (155)$$

Interest in this area was stimulated by a report from Basolo and co-workers,[832] who discussed possible mechanisms for the catalysis. They showed that the alcohols are true catalysts and are not consumed in the reaction (despite the detection of trace amounts of acetaldehyde as a reaction product), and that the substitutions could be catalyzed by a variety of reducing agents (*e.g.* Sn^{II}, BH_4^-, N_2H_4, H_3PO_2). The Co^{II} ion and the $[Rh_2OAc_4]$ dimer are both inactive, and while $[Rh(CO)Cl(PPh_3)_2]$ and $[Rh(CO)(SCN)(PPh_3)_2]$ are inactive, the dimer $[Rh(CO)_2Cl]_2$ is an extremely active catalyst. Kinetic studies were hampered by the evanescence of the catalyst, but Basolo did conclude that the reaction is first-order in Rh and catalyst, zero-order in pyridine (if in excess), and that Cl^- (as well as NO_3^- and ClO_4^-) inhibit the formation of *trans*-$[Rhpy_4Cl_2]^+$. In the presence of soft ligands, alkaline solutions of $RhCl_3 \cdot 3H_2O$ can be reduced to the Rh^I state by alcohols.[833] Basolo concluded that the Delépine catalyst involves a Rh^I species, and suggested a mechanism analogous to Pt^{II} catalysis of substitutions at Pt^{IV} centers (equations 156–158).[834,835]

$$[RhCl_5(H_2O)]^{2-} \xrightarrow{reductant} Rh^I \quad (156)$$

$$Rh^I + 4py \longrightarrow [Rh(py)_4]^+ \quad (157)$$

$$H_2O + [Rhpy_4]^+ + [RhCl_5(H_2O)]^{2-} \rightleftharpoons \{H_2O\text{—}Rhpy_4\text{—}Cl\text{—}RhCl_4OH_2\}^- \xrightarrow{fast} trans\text{-}[Rhpy_4Cl(OH_2)]^{2+} + Rh^I \xrightarrow[fast]{py} trans\text{-}[Rhpy_4Cl_2]^+ \quad (158)$$

With general agreement that a reduced species must be catalyzing substitutions at Rh^{III}, polarographic studies were used to investigate the nature of the reduced (and presumably catalytically active) species. Early work, using pyridine-supporting electrolyte, found the approximate reduction potentials, and provided evidence for a two-electron reduction.[836–838] Gillard and co-workers used DC polarography at a DME to examine many Rh^{III} complexes,[839,840] and proposed a two-electron reduction, noting that complexes with aza aromatic ligands are reduced at significantly more positive potentials than their amine analogs. They suggested Rh^I or Rh^{III}—H species as the primary reduction products. For py-containing complexes, a second reduction wave was observed, which was assigned to pyridine reduction; no second wave was observed for the ethylenediamine-containing ligands. For *cis*-α-$[Rh(trien)Cl_2]^+$, however, two waves were observed, ($E_{\frac{1}{2}} = -0.38$ and -0.75 V; both with $n \approx 2$), and monohydride and dihydride species were presumed to be the

product of these two reductions (equation 159). Reinvestigation[839] of the previously studied[841] reduction of $[Rh(H_2edta)Cl_2]^-$ (initially thought to involve a three-electron reduction) indicated a similar two-wave system ($n \approx 2$ for each wave), presumably also leading to monohydride and dihydrido Rh^{III} species, although the products were not separated, and NMR signals from the resulting hydrides could not be detected.

$$[Rh(trien)Cl_2]^+ \xrightarrow[+H_2O,\ -Cl^-,\ -OH^-]{2e^-,\ E_{\frac{1}{2}} = -0.38\,V} [Rh(trien)Cl(H)]^+ \xrightarrow[+H_2O,\ -Cl^-,\ -OH^-]{2e^-,\ E_{\frac{1}{2}} = -0.75\,V} [Rh(trien)(H)_2]^+ \quad (159)$$

The formation of a single Rh^{III} hydride was questioned in a detailed study of the polarography and coulometry of $[Rhpy_4Cl_2]^+$. In an aqueous pyridine–pyridinium chloride–sodium chloride electrolyte (pH 5.3), this ion displays two distinctive types of polarographic behavior.[842] The 'normal' wave ($E_{1/2} = -0.43$ V *vs.* SCE) is a diffusion-controlled, two-electron reduction at the DME to give an uncharacterized Rh^I product; in solutions with high pyridine concentrations, an 'enhanced' reduction also occurs at the DME surface, which often masked the 'normal' reduction, leading to H^+ consumption and the generation of hydrides. In large-scale reductions of $[Rhpy_4Cl_2]^+$, they observed the consumption of 1.4 mol of H^+ per mol of Rh^{III} species reduced, which is not consistent with a single Rh^{III} hydride product. Their proposed sequence (equations 160–162) does not, however, clearly illuminate what must be a complex reaction sequence.[842]

$$Rh^{III} + 2e^- \longrightarrow Rh^I \quad \text{(normal wave)} \quad (160)$$

$$Rh^I + pyH^+ \longrightarrow Rh^{III} + H^- + py \quad \text{(enhanced wave)} \quad (161)$$

$$xRh^I + yH^+ \longrightarrow \text{products, where } y > x \quad (162)$$

Controlled-potential reduction of aqueous solutions of *trans*-$[Rh(en)_2Cl_2]^+$ in oxygen-free environments leads to the two-electron reduction product *trans*-$[Rh(en)_2(OH)(H)]^+$.[675] In the process of reduction, 2 *F* per Rh atom are consumed, but an intermediate with an absorption band at 338 nm ($\varepsilon = 9000$) reached maximum concentration at *ca.* 0.9 *F* per Rh. This oxygen-sensitive, diamagnetic intermediate does not catalyze substitutions at Rh^{III} centers, which suggests its formulation as the Rh^{II} dimer $[(H_2O)(en)_2Rh—Rh(en)_2(H_2O)]^{4+}$.[843] Atomic absorption analysis of the one-electron reduced solution (reduced at a Hg electrode) revealed the presence of mercury, which led Anson and Gulens to question the Rh^{II} dimer formulation and to propose that mercury leads to a Hg^{2+}-bridged, Rh^I dimer (equation 163). This same species, with the electronic spectra reported by Gillard for the Rh^{II} dimer, could also be prepared by oxidizing *trans*-$[Rh(en)_2(H)(H_2O)]^{2+}$ at mercury electrodes, and by mixing Hg^{2+} solutions with solutions of *trans*-$[Rh(en)_2(H)(H_2O)]^{2+}$. The formation of this trinuclear species can be regarded as a Lewis acid–base complex between Hg^{2+} and the extremely basic $[Rh(en)_2]^+$.[844]

$$2[Rh(en)_2Cl_2]^+ + Hg + 2e^- \longrightarrow \{[Rh(en)_2]_2Hg\}^{4+} + 4Cl^- \quad (163)$$

The two-electron reduction product, *trans*-$[Rh(en)_2(OH)(H)]^+$ displays a sharp ^1H NMR signal at 30.6 τ. The pseudo acid–base equilibrium, represented in equation (164), was proposed to explain the observation that this peak broadens as the pH is raised, disappearing completely by pH 13.

$$[Rh(en)_2]^+ + H_3O^+ \rightleftharpoons [Rh(en)_2(H)(H_2O)]^{2+} \rightleftharpoons [Rh(en)_2(H)(OH)]^+ + H^+ \quad (164)$$

The formation of the hydridohydroxo ion can be considered to be the result of stereoretentive oxidative addition of H_2O across the $[Rh(en)_2]^+$. Acidic solutions of $[Rh(en)_2(OH)(H)]^+$ are stable, even in the presence of O_2, but in alkaline solution it reacts rapidly with oxygen, giving the hydroxoperoxo Rh^{III} monomer, *trans*-$[Rh(en)_2(OH)(OOH)]^+$ (equation 165). Interference from the secondary reaction (equation 166) complicates the overall stoichiometry of the reaction.[675] Concentration of this reaction mixture ($[Rh(en)_2(OH)_2]^+ + [Rh(en)_2(OH)(OOH)]^+$) in the presence of oxygen (pH 9–10) causes a color change to red and then to deep blue, with the formation of the superoxo-bridged Rh^{III} dimer, identified as $[(H_2O)(en)_2RhO_2Rh(en)_2(H_2O)]^{5+}$.[675] The transient red color is reminiscent of the electrochemical reduction of $[Rh(NH_3)_4(OH)(OOH)]^+$, which passes through a pink transient, after the consumption of 1 *F* per Rh, tentatively identified as the hydroxosuperoxo complex.[845]

$$[Rh(en)_2(OH)(H)]^+ + O_2 \longrightarrow [Rh(en)_2(OH)(OOH)]^+ \quad (165)$$

$$[Rh(en)_2(OH)(OOH)]^+ + [Rh(en)_2(OH)(H)]^+ \longrightarrow 2[Rh(en)_2(OH)_2]^+ \quad (166)$$

The catalytic properties of these reduced species have been actively studied by Gillard and co-workers.[601,846–850] Among other things, they have shown that H_2 also initiates Delépine's reaction of $[RhCl_6]^{3-}$,[846] that O_2 dramatically impedes the catalyst,[847] and that halide substitution at *trans*-$[Rhpy_4Cl_2]^+$ (equation 167) is also catalyzed by primary and secondary alcohols.[847] Consistent with the pseudo acid–base equilibrium (equation 164), the rate of catalyzed halide substitution is pH dependent, with little catalytic activity occurring in acidic solutions.[850] There is an induction period for the reaction (the more alcohol in the solution the shorter the period), suggesting that deoxygenation of the solution must occur before the reduced catalyst can be effective.

$$[Rhpy_4Cl_2]^+ + 2Br^- \longrightarrow [Rhpy_4Br_2]^+ + 2Cl^- \quad (167)$$

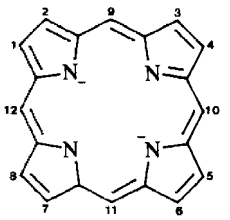
The lack of alcohol catalysis of halide substitutions in the $[Rh(en)_2X_2]^+$ system has been attributed to the relative ease of reduction of the two Rh complexes ($E_{1/2}$ for *trans*-$[Rhpy_4Cl_2]^+$ is -0.39 V, while it is -0.79 V (*vs.* SCE) for *trans*-$[Rh(en)_2Cl_2]^+$), accounting for their differing behavior toward mild reductants.[850] Stronger reducing agents, such as BH_4^- do catalyze halide exchange at $[Rh(en)_2Cl_2]^+$; $[Rh(en)_2(OH)(H)]^+$ (but not $[Rhpy_4]^+$) is also an effective catalyst for halide exchange in neutral, deoxygenated solutions of $[Rh(en)_2X_2]^+$.[850] Kinetic evidence inconsistent with the mechanism proposed by Basolo has led to an alternative mechanism involving catalysis by the poorly characterized Rh^I species, and a $[Rh^I—X—Rh^{III}]$-bridged intermediate. Unlike the Pt^{II}–Pt^{IV} system, where *trans* geometry is needed, BH_4^- catalyzes bromide substitution at *cis*-α- and *cis*-β-$[Rh(trien)Cl_2]^+$, and the reactions proceed with retention of geometric configuration.[851] Gillard and Heaton have summarized the available mechanistic arguments,[851] but the last shoe has yet to fall in this inadequately understood area.

48.6.2.6 Halonitrile complexes

The first examples of halonitrile complexes were reported by Johnson *et al.*,[852] who found that $RhCl_3 \cdot 3H_2O$ reacts readily when dissolved in an alkyl or aryl cyanide to form non-ionic complexes of the form $[RhCl_3(RCN)_3]$ (R = Me, Et, Ph or $MeOCH_2CH_2$). Electronic spectra all show a *d–d* band near 425 nm, and a second band near 370 nm (in nitromethane solution). Under the same conditions, the potentially bifunctional glutaronitrile ($NC(CH_2)_3CN$) reacts with $RhCl_3$ to give an ill-characterized orange solid, which is presumed to be polymeric with bridging nitrile groups.[852] Using 'less extreme conditions', Catsikis *et al.*, prepared *fac*-$[RhCl_3(MeCN)_3]$, characterized by elemental analysis, electronic spectra (Table 57), and IR and proton NMR spectroscopy.[855] Assignment of geometry has been debated, as Johnson used far-IR spectra to assign a *mer* geometry,[856] while Walton later suggested a *fac* structure.[857] Gillard and co-workers used NMR, electronic and Raman spectroscopy to assign the *mer* geometry to a variety of $[RhX_3(RCN)_3]$ complexes (R = CD_3, Et, Pr^n, Pr^i, Ph or $PhCH_2$).[853] They found evidence for a *fac* isomer, but only for $[RhCl_3(MeCN)_3]$.

Anionic halonitrile complexes have been prepared by taking advantage of the insolubility of the $(Et_4N)^+$ salts. If $RhCl_3 \cdot 3H_2O$ is heated with $[Et_4N]Cl$ in a H_2O/MeCN (1:1) solution, *trans*-$[Et_4N][RhCl_4(MeCN)_2]$ is isolated. If $[RhCl_6]^{3-}$ is used as a starting material, and the electrolyte is added after heating, salts of the form $M_2[RhCl_5(MeCN)]$ (M = Cs^+, NH_4^+ or Et_4N^+) can be isolated.[858] Some bromo analogs were similarly prepared.[854] Gillard prepared cationic complexes by the reaction of the neutral $[Rh(MeCN)_3X_3]$ (X = Cl, Br) with $AgNO_3$ (or $AgClO_4$) in acetonitrile

Table 57 Electronic Spectra of some Halonitrile Complexes of Rh^{III}



Compound	λ_{max} (nm) (ε)	*Ref.*
$[RhCl_3(MeCN)_3]$	430 (100), 371 (109)	852[a]
$[RhCl_3(EtCN)_3]$	429 (120), 370 (109)	852[a]
	422	853
$[RhCl_3\{MeO(CH_2)_2CN\}_3]$	425 (136), 376 (142)	852[a]
$[RhCl_3(Pr^nCN)_3]$	429	853
$[RhCl_3(Pr^iCN)_3]$	425	853
$[RhCl_3(PhCN)_3]$	426	853
$[RhCl_3(PhCH_2CN)_3]$	425	853
$(Et_4N)[RhCl_4(PhCN)_2]$	490 (65), 418 (194)	854
$(Et_4N)[RhBr_4(PhCN)_2]$	490 (167), 450 (620), 344 (6200), 304sh (9000), 269 (34 000)	854[b]
$[RhBr_3(MeCN)_2(H_2O)]$	465sh (317), 334 (2960), 266 (4370)	854[b]

solution.[853] Dissolution of this tetrakis(acetonitrile) cation in other nitrile solvents (RCN) leads to nitrile replacement, and is a general route to *trans*-$[Rh(RCN)_4X_2]^+$ cations.[853] The IR spectra of these complexes all showed the expected shift in the ν_{C-N} to higher energy, from 2257 cm^{-1} in pure MeCN to around 2300 cm^{-1} for the coordinated molecules.

48.6.2.7 Porphyrin and phthalocyanine complexes

The chemistry of Rh^{III} complexes with porphyrin and phthalocyanine ligands is quite distinctive, as these rigidly planar, tetradentate amine ligands form complexes *via* unique synthetic routes, and the chemistry of the resulting complexes differs substantially from that of complexes with less constrained ligands. A variety of porphyrin complexes of Rh^{III} have been characterized, and a list of the abbreviations used in this section is found in (**54**) and Table 58.

(54)

Fleischer was an early leader in this area, and found that when the dimeric Rh^I complex $[Rh(CO)_2Cl]_2$ was mixed with mesoporphyrin IX diethyl ester (MePDEE) in glacial acetic acid, a weakly paramagnetic complex, formulated as [Rh(MePDEE)], was generated.[859] The source of the paramagnetism was not explained, and the coordination geometry about the Rh was not discussed, but the IR of the complex showed no N—H or C—O stretches. The two-electron oxidation of a Rh^I complex represents an unusual synthetic route to a Rh^{III} complex, but it has since become a general route to Rh^{III} porphyrins, and was quickly extended[860,861] to include TPP, TPyP and MePDEE analogues. The synthetic path is thought[860] to pass through a $[Rh^I(porph)(CO)Cl]$ (presumably a dianion) intermediate, which is oxidized by O_2 in solution to give the final Rh^{III} species.

All of these porphyrin complexes are intensely colored, with the characteristic α, β and Soret bands near 550, 520 and 400 nm respectively. Fleischer postulated that they are five coordinate (four porphyrin nitrogens and one coordinated H_2O), with the sixth site available for substitution by other ligands.

The source of the weak paramagnetism ($\mu \approx 0.4$ BM)[859] was proposed to be due to the presence of a monomeric Rh^{II} complex, $[Rh^{II}(TPP)]$, formed upon incomplete oxidation of the $[Rh^I(TPP)]^-$ intermediate.[862] Surprisingly, the proposed Rh^{II} monomer did not bind O_2 despite the known reactions of $[Rh(NH_3)_4]^{2+}$ with O_2,[863] and the well-established reactions of Co^{II} and Fe^{II} porphyrin

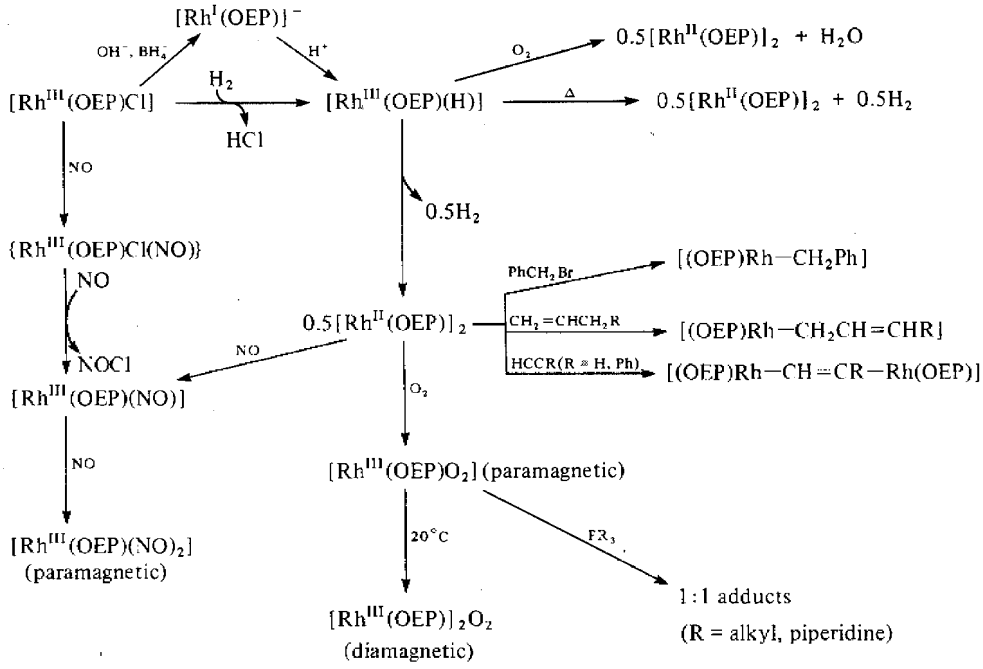
complexes with O_2. Wayland and Newman argued against the existence of a monomeric Rh^{II} porphyrin complex,[864] and proposed that the only Rh^{II} species present was a dimeric $[Rh(porph)]_2$ with a Rh—Rh bond. The diamagnetic $[Rh(OEP)]_2$ dimer, prepared by photolysis of [Rh(OEP)(H)], was convincingly characterized, and while it reacts as if it were a source of the $[Rh^{II}(OEP)]$ moiety, no stable Rh^{II}–porphyrin monomers have yet been thoroughly characterized. The paramagnetism observed by Fleischer and James[859,860,862] was attributed to $[Rh(OEP)(O_2)]$, which forms when $[Rh(OEP)]_2$ is exposed to dioxygen. The complex was characterized by electronic, IR and EPR spectra, and formulated as a Rh^{III}–superoxo complex, with end-on bonding by the O_2^- ligand. The superoxo complex reacts with alkyl phosphines and phosphites,[864] and with piperidine[865] to give 1:1 adducts, and when warmed to 20 °C, its paramagnetism decreases, presumably due to the formation of the peroxo-bridged Rh^{III} dimer.

Wayland has explored the chemistry of the dimeric $[Rh(OEP)]_2$, and found that it reacts with NO to generate [Rh(OEP)NO], which can be subsequently oxidized by O_2 (in air) to give the nitrite (NO_2^-) complex.[865] The same [Rh(OEP)(NO)] can be prepared by the reaction of NO with [Rh(OEP)Cl], although this reaction passes through a metastable intermediate, identified as [Rh(OEP)(Cl)(NO)].[865] Subsequent reaction with NO leads to the stable [Rh(OEP)(NO)] product. The intermediate is characterized as a 'π-cation radical' complex, containing an OEP^- radical ligand, not a Rh^{IV}. Support for the radical anion assignment comes from electrochemical oxidation of a variety of porphyrin-containing species, which revealed that the ease of removing the first two electrons from a porphyrin system is not strongly dependent on the cation bonded to the porphyrin (Table 59), implying that the electron is removed from a ligand-localized orbital which does not interact strongly with the metal. The second electron is also thought to come from a ligand-localized orbital, leaving a diamagnetic, π dication complex.[865]



An interesting series of substitution/redox reactions involving both dimeric Rh^{II} and monomeric Rh^{III} complexes of OEP has been reported.[408,409] In methanolic solution, H_2 reacts with [Rh(OEP)Cl] to generate [Rh(OEP)H] and HCl; borohydride reduction of [Rh(OEP)Cl] leads to a species identified as $[Rh^{I}(OEP)]^-$, which forms the same hydrido species when acidified (ν_{Rh-H} at 2220 cm^{-1}, and when prepared with DCl, ν_{Rh-D} at 1595 cm^{-1}). Dioxygen reacts with [Rh(OEP)Cl] to form the dimeric $[Rh(OEP)]_2$ (an unusual use of O_2 to reduce Rh^{III}); the Rh^{II} dimer can also be formed by heating a degassed toluene or benzene solution of the hydrido complex. The reaction of the $[Rh(OEP)]_2$ dimer with a variety of organic substrates leads to a series of organo-Rh^{III} (OEP) complexes. The reactions described in the past two paragraphs are summarized in Scheme 32.

Single-crystal X-ray structures of several Rh^{III} porphyrins have been reported. The structure of octahedral $[Rh(Me_2HN)_2(Etio)]Cl \cdot 2H_2O$ showed that the Rh^{III} fits nicely into the plane of the porphyrin nitrogens, with an average Rh—N distance of 2.038 Å; the axial dimethylamine nitrogens are 2.090 Å from the metal.[866] A square-pyramidal complex [Rh(OEP)(Me)] showed similar distances around the metal, with the Rh in the plane of the porphyrin nitrogens, and the apical C atom 2.031 Å from the rhodium.[867] (Ogoshi notes that this Rh—C bond is significantly shorter than the 2.081 Å observed for the Rh—Me distance in another five-coordinate Rh^{III} complex $[Rh(PPh_3)_2(Me)(I)_2]$.[868] The geometries of the two complexes are quite different, however, as the Rh is 0.25 Å out of the plane established by the two P and the two I atoms, but is in the plane of the porphyrin nitrogens.[867] An early report by Fleischer[869] describes the crystal structure of a paramagnetic ($\mu = 1.95$ BM) species, identified as [Rh(TPP)(Ph)(Cl)], which is said to have the 'usual planarity of the pyrrole rings and phenyl rings'. Despite its paramagnetism, the method of synthesis ($[Rh(CO)_2Cl]_2$ is allowed to react with TPP in refluxing benzene) and the Rh—N and Rh—C distances (2.04 and 2.05 Å respectively) are reminiscent of Rh^{III} porphyrins, suggesting that this may be a radical-anion–Rh^{III} complex, not the Rh^{IV} species tentatively proposed by Fleischer.[869]

Table 59 Oxidation Potentials[a] for some Rh^{III} Porphyrins[865]

Complex	*First oxidation*	*Second oxidation*
H_2TPP	0.97	1.25
$[Rh^{III}(TPP)Cl]$	0.98	1.36
$[Rh^{III}(TPP)(NO)]$	0.94	1.36

Scheme 32

Quantitative studies on the reactivity of Rh^{III} porphyrins have centered on substitutions (and proton exchanges) at the fifth and sixth coordination sites in $[Rh(TPPS)(H_2O)]^{3-}$; Ferraudi and co-workers have also presented a detailed study on the photophysics and photochemical reactivity of Rh^{III}–phthalocyanine complexes. Bailey studied the acid–base equilibrium (equation 168) for a variety of metalloporphyrins, and found a pK_{OH} of 5.1 ± 0.1 for [Rh(HMP)], while [Rh(TPPS)] had a pK_{OH} of 6.8 ± 0.1[870] (a pK_{OH} of 7.5 had been reported earlier for the TPPS complex[871]). After analyzing the acid–base behavior of a variety of metalloporphyrins, Bailey found that the results could be most effectively interpreted in terms of a simple crystal field model, and argues that while the porphyrin ligands are certainly delocalized, this need not imply delocalized metal–ligand interactions. He reached the heartening conclusion that his 'observations strongly suggest that metalloporphyrin electronic structure . . . is much simpler than is generally appreciated'.[870]

$$[Rh(porph)(H_2O)_n]^+ \rightleftharpoons [Rh(porph)(H_2O)(OH)] + H^+ \qquad (168)$$

The thermodynamics and kinetics of NCS^-, CN^-,[871] Cl^-, Br^-, NCS^- and I^-[872] substitutions at $[Rh(TPPS)(H_2O)]$ have been reported; the reactions involved are shown in equation (169), and the parameters determined are summarized in Table 60. Spectrophotometric titrations showed two inflection points as OH^- is added to $[Rh(TPPS)(H_2O)_2]^{3-}$, and the consecutive pK_A values (7.01 and 9.80 at 20 °C) correspond to the pK_A values for *fac*- and *mer*-$[RhCl_3(H_2O)_3]$, suggesting that the $TPPS^{6-}$ anion and 3 Cl^- ligands are comparable electron donors toward the Rh center.[872] The trends in the equilibrium constants (Table 60) imply that Rh^{III} is a soft (class B) acid in these complexes; the NCS^- ion is presumed to be sulfur bonded, although no direct evidence is presented to support this assumption.

$$[Rh(TPPS)(L)_2]^{5-} \underset{H_2O}{\overset{H_2O}{\underset{L}{\overset{K_1,\ k\ L}{\rightleftharpoons}}}} [Rh(TPPS)(H_2O)L]^{4-} \underset{H_2O}{\overset{H_2O}{\underset{L}{\overset{K_2\ L}{\rightleftharpoons}}}} [Rh(TPPS)(H_2O)_2]^{3-} \underset{+H^+}{\overset{K_A^1,\ -H^+}{\rightleftharpoons}}$$

$$[Rh(TPPS)(H_2O)(OH)]^{4-} \underset{+H^+}{\overset{-H^+,\ K_A^2}{\rightleftharpoons}} [Rh(TPPS)(OH)_2]^{5-} \qquad (169)$$

The substitutions follow the two-term rate expression: rate $= (k_1[L] + k_{-1})[Rh^{3-}]$. As observed with Co and Cr porphyrins, the rate of ligand substitutions at the Rh^{III}–porphyrin moiety is much faster than for the comparable reactions of non-porphyrin complexes. For example, the rate of Cl^-

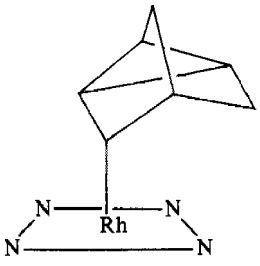
anation of $[Rh(TPPS)(H_2O)_2]^{3-}$ is 10^7 and 10^5 times faster than the rate of Cl^- attack on *trans*-$[RhCl_4(H_2O)_2]^-$, and *trans*-$[Rh(en)_2(H_2O)_2]^{3+}$, respectively. Based on the very negative ΔS^* values observed, an associative interchange (I_a) mechanism for these substitutions was suggested.[872] (Pasternack and co-workers[873] had earlier suggested that a porphyrin could be expected to strongly stabilize a five-coordinate geometry, suggesting that dissociative interchanges would be expected for substitutions at metalloporphyrins.) Studies on the effect of pressure on the rates of NCS^- substitution at $[Rh(TPPS)(H_2O)_2]^{3-}$ support the dissociative model.[874] The ΔV^* of 8.8 $cm^3\,mol^{-1}$ is similar to that observed for the Cr^{III} analog (7.4 $cm^3\,mol^{-1}$), but significantly smaller than observed for Co^{III} (15.4 $cm^3\,mol^{-1}$); this parallels the trend to more negative ΔS^* values for the Cr and Rh analogs. vanEldik concludes that for $[Rh(TPPS)(H_2O)_2]^{3-}$, the 'experimentally observed values are in good agreement with those expected for an interchange mechanism in which the rate determining step is dissociatively activated'; noting the differences between the Co, Cr and Rh systems, he also states that 'the central metal atom seems to control the extent to which the porphyrin can modify the reactivity and mode of the substitution process'.[874]

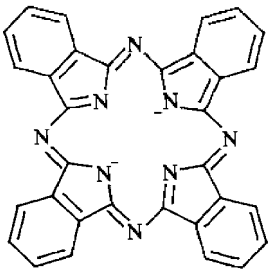
Numerous Rh^I porphyrin complexes have been prepared (*vide supra*), and these have been used to obtain Rh^{III} porphyrins. Sodium ethoxide nucleophilically attacks the C atom of [Rh(TPP)Cl(CO)] (in methylene chloride/ethanol solutions), leading to orange-red crystals of a diamagnetic ethoxycarbonyl(TPP)Rh^{III} complex with a Rh—C σ bond. Reaction of [Rh(TPP)Cl(CO)] with the basic $LiNEt_2$ in diethylamine leads to the analogous $[Rh(TPP)C(O)NEt_2]$, while no reaction of [Rh(TPP)Cl(CO)] is observed with the analogous $NaSEt_2$.[875] Ogoshi and co-workers have studied the reactions of $[Rh^I(OEP)Cl]$ with a variety of reactive organic materials. As summarized in Scheme 33 this Rh^I porphyrin undergoes oxidative



Scheme 33

Scheme 34

additions with an activated cyclopropane,[876] alkyl halides,[877] organolithiums, alkenes and alkynes, and Grignards;[878] all but the Grignards lead to complexes with a Rh^{III}—C σ bond. While Rh^{I} complexes generally catalyze the quadricyclane → norbornadiene valence isomerization, the reaction of [Rh^{I}(OEP)Cl] with quadricyclane leads to the cleavage of only one of the two cyclopropane rings, and the Rh^{III}(OEP) species represented in (**55**). Grigg and co-workers have studied a wide variety of oxidative additions at some dirhodium(I)porphyrin complexes.[879–882] As summarized in Scheme 34, the Rh^{III} products are generally monomeric, five-coordinate species with a Rh—C σ bond.



(**55**)

Sperm whale apomyoglobin, reconstituted with Rh^{III}, leads to stable Rh–myoglobin complexes which are inert to external anions (F^-, OCN^-, N_3^- and CN^-) and to reducing agents (dithionite, borohydride and dihydrogen).[883] The mesoporphyrin–Rh^{III} complex itself, however, is reactive, and readily binds CN^- ion. While the meso—Rh^{III}—Mb resembles the native protein in some ways (its tight binding of the apoprotein and prosthetic group, metal–imidazole bonding, and NMR-determined protein conformation), the inertness of the meso—Rh^{III}—Mb to external anions leads to the supposition that there are no exchangeable aqua ligands coordinated to the Rh^{III}, but that the rhodium binds to both the proximal and the distal imidazoles. This would make the Rh^{III} system a poor ferrimyoglobin model (in which only the proximal histidine is bound to the metal), and a better model of an internal hemichrome. Access to the sixth coordination site is blocked in the reconstituted meso—Me—Rh^{III}—Mb, however, as a methyl group occupies the sixth site; the ^{1}H NMR of the Me resonances are shifted 2 p.p.m. downfield upon incorporation into the myoglobin, due to the compression effect of the amino acid residues at the distal site. (This meso—Me—Rh^{III}—Mb is the first example of a reconstituted hemoprotein with an organometalloporphyrin.) Not surprisingly, the meso—Me—Rh^{III}—Mb is also inert toward substitution and reduction, but the effect of the coordinated methyl group is apparent in studies which compare the ability of meso—Rh^{III} and meso—Me—Rh^{III} to compete with Fe^{III} for coordination within the myoglobin. When meso—Rh^{III} is mixed with Fe^{III}—Mb (at a 4/1:Rh/Fe ratio, 35 °C, pH = 7.0, 24 h), 90% of the resulting prosthetic protohemin in the native myoglobin is replaced by the meso—Rh^{III}. Under similar conditions, only 15% of the meso—Me—Rh^{III} is incorporated, supporting the supposition

that coordination by the distal imidazole occurs in the meso—Rh^{III}—Mb, and that this binding is blocked by the coordinated methyl, decreasing the stability of meso—Me—Rh^{III}—Mb.[883]

Ferraudi and co-workers have presented detailed studies of the photochemical[884,885] and photophysical behavior[886,887] of Rh(phthalocyanine) complexes. Like the porphyrins, the phthalocyanine dianion (ph, **56**) is rigidly planar, with extensively delocalized intraligand bonding around four amine nitrogen donors. Photolysis (254 nm light) of Co^{III} phthalocyanines causes reduction of the metal and oxidation of an axially coordinated ligand, consistent with the population of a ligand-to-metal charge transfer excited state.[888] In contrast, ligand substitutions, without net redox chemistry, were observed when the isoelectronic [Rh(ph)X] (X = Cl, Br, I) complexes were photolyzed under similar conditions. The simplicity of the net reaction belies the complexity observed when the reaction is studied by conventional and laser flash techniques. As Ferraudi states[887] 'the photonic energy is degraded in a complex manner that involves photochemical, radiative and nonradiative paths'. The proposed mechanism for the photochemical path is represented in equations (170)–(177). In the first phase, electron transfer occurs, the anionic ligand is released, and a labile [Rh^{II}(ph)] and a solvent radical are formed (equations 170–172); a Rh^{III}–(radical anion) species is also implicated. Reoxidation of the Rh^{II} involves a complex set of reactions (equations 173–177). Equation (173) has a rate constant of about $10^{10}\,M^{-1}\,s^{-1}$, making the acetonitrile radical ($CH_2CN\cdot$) a poor candidate for the oxidation of the Rh^{II} complex (equation 174). The ESR and the absorbance spectra of the Rh^{III}–ligand radical complex have been recorded,[885] and the absorbance spectrum ($\lambda_{max} \approx 510$ nm) is similar to that observed upon one-electron oxidation of uncoordinated phthalocyanine.[888] This radical–ligand complex is thought to result from population of the $n\pi^*$ ligand-centered states involving the lone electron pairs of the bridging nitrogens of the ph ring.

(56)

$$[Rh^{III}(ph)(MeOH)X] + MeCN \longrightarrow [Rh^{III}(ph\cdot H)(MeOH)X] + CH_2CN\cdot \quad (170)$$

$$[Rh^{III}(ph\cdot H)(MeOH)] \rightleftharpoons [Rh^{III}(ph\cdot)(MeOH)X]^- + H^+ \quad (171)$$

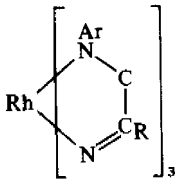
$$[Rh^{III}(ph\cdot)(MeOH)X]^- \rightleftharpoons [Rh^{II}(ph)] + MeOH + X^- \quad (172)$$

$$CH_2CN\cdot + [Rh^{III}(ph)(MeOH)X] \xrightarrow{H^+} MeCN + [Rh^{III}(ph\cdot)(MeOH)X]^+ \quad (173)$$

$$CH_2CN\cdot + [Rh^{II}(ph)] \xrightarrow{H^+} MeCN + [Rh^{III}(ph)(solvent)_2]^+ \quad (174)$$

$$[Rh^{III}(ph\cdot)(MeOH)X]^+ + [Rh^{II}(ph)] \longrightarrow [Rh^{III}(ph)(MeOH)X] + [Rh^{III}(ph)(solvent)_2]^+ \quad (175)$$

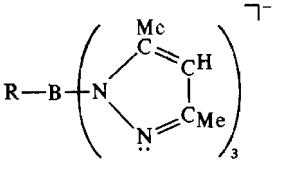
$$CH_2CN\cdot + Me_2CHOH \longrightarrow MeCN + Me_2\dot{C}OH \quad (176)$$



$$[Rh^{III}(ph\cdot)(MeOH)X]^+ + Me_2CHOH \longrightarrow [Rh^{III}(ph)(MeOH)X] + Me_2\dot{C}OH + H^+ \quad (177)$$

In O_2-free solutions, [Rh(ph)(MeOH)Cl] luminesces ($\lambda_{max} \approx 420$ nm, $\phi = 1.3 \times 10^{-3}$) when excited with light of 400 nm or less.[866] Excitation spectra show that the emitting state is well above the lowest π–π^* state, making this an apparent violation of Kasha's rule. Similar luminescence is oberved for the Co^{III}, Ru^{II}, Al^{III}, and weakly observed for Cu^{II} phthalocyanine complexes, and the luminescence is thought to originate from an upper-level, ligand-centered triplet. The action spectrum for photoinduced hydrogen abstraction is independent of X in [Rh(ph)(MeOH)(X)] (X = Cl, Br, I). The photosubstitutions are therefore proposed to originate from a ligand-centered $^3n\pi^*$ state, while emission comes from a ligand-centered upper-level $^3\pi$–π^* state, with another, lower-lying $^3\pi$–π^* state available. Ferraudi presents a detailed investigation of the time dependence

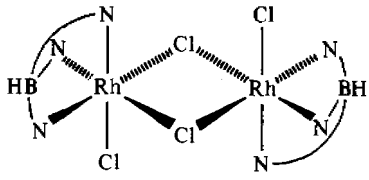
of the two $^3\pi$–π^* states (emission and absorption studies), and of the relationship between the photoemissive and photoreactive states.[888]



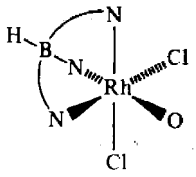
48.6.2.8 Miscellaneous nitrogen ligands

The electronic and IR spectra of $[Rh(NO_2)_6]^{3-}$ are consistent with the expected RhN_6 chromophore, and while ligand field bands were not observed, CT absorbances occur at 317 and 275 nm.[889] Arylazo oximes (N—N) form $[Rh(N—N)_3]$ complexes with Rh^{III} in which the arylazo oxime acts as a bidentate ligand (five-membered rings; **57**).[890] Reaction of $Rh(NO_3)_3 \cdot 3H_2O$ with the appropriate arylazo oxime in ethanol at pH 4 (with CO_3^{2-} used to adjust pH) leads to a precipitate of *fac*- and *mer*-$[Rh(N—N)_3]$. The geometric isomers can be separated on alumina, and ^1H NMR showed that approximately equivalent amounts of the *fac* and *mer* isomers formed (for R = Me or Pr and Ar = Ph). This represents an unexpected (and unexplained) enhancement of the population of the *fac* isomer, as statistically, a *fac*/*mer* ratio of 1/3 would be expected; only the *mer* form was detected for $[Co(N—N)_3]$.[891] These rhodium complexes all display intense absorption bands near 480 and 320 nm, which are presumed to be intraligand bands.[890]

(57) R = H, alkyl, aryl
Ar = aryl



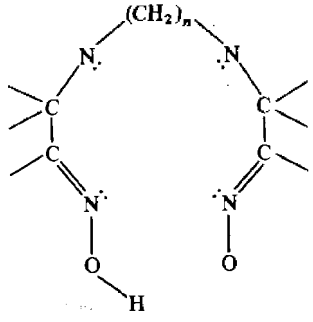
The tripyrazolylborate anion ($RB(pz)_3$, **58**) acts as a tridentate ligand, and frequently results in complexes which are analogous to cyclopentadienyl complexes. The first Rh^{III}–$RB(pz)_3$ complexes were prepared by the oxidative addition of I_2 to $[Rh_2\{RB(pz)_3\}(CO)_3]$, and resulted in octahedral, monomeric complexes $[Rh\{RB(pz)_3\}(CO)I_2]$ (R = H, and, in low yield, for R = pz).[892] For the tetrapyrazolyl species (R = pz) the NMR spectrum showed two, non-interconverting pyrazole environments in a 3/1 ratio, consistent with a tridentate configuration for the borate. The C—O stretch is very high (2090 cm^{-1}), consistent with the formal Rh^{III} designation.[892]



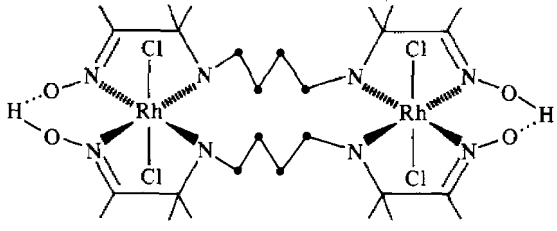
(58) R = H, pz

Powell and co-workers have extensively studied the Rh^{III} chemistry of the hydrotripyrazolylborate anion (R = H).[893] They found that the reaction of equimolar amounts of $Na[HB(pz)_3)]$ with $RhCl_3 \cdot 3H_2O$ in refluxing methanol leads to two types of complexes, depending on reaction conditions. Dilute solutions and short reflux times (*ca.* 1 h) yield chloro-bridged dimeric species (**59a**), while more concentrated solutions, refluxed for longer periods (*ca.* 4 h), generate the methanol-solvated monomer $[Rh\{HB(pz)_3\}Cl_2(MeOH)]$ (**59b**). These two species are convenient starting materials for a variety of reactions, and Powell reported over 60 derivatives.[893] The coordinated methanol can readily be replaced by other neutral monodentates (*e.g.* PR_3, AsR_3, py, NR_3, RNC or CO), and reaction with the appropriate Ag or Tl salts gives $[Rh\{HB(pz)_3\}YCl]$ (Y = acac, hfacac, Et_2NCS_2) and $[Rh\{HB(pz)_3\}Y_2L]$ (Y = Ac^-, no L; Y = $CF_3CO_2^-$, L = H_2O). Reduction of the monomer with H_2/Et_3N leads to the anionic hydride, $[Rh\{HB(pz)_3\}Cl_2(H)]^-$. Similar reactions were observed starting with the dimeric species.[893]

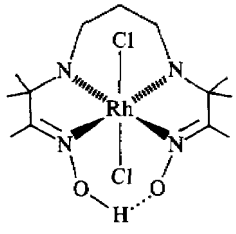
Schlemper and co-workers have reported the X-ray structures of the products of the reaction of $RhCl_3 \cdot 3H_2O$ with a series of similar amine oximes (A–O; **60**). The reaction product is intriguingly dependent on the length of the hydrocarbon chain linking the two amine oxime moieties, and



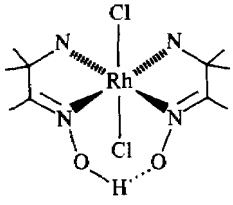
(59a)



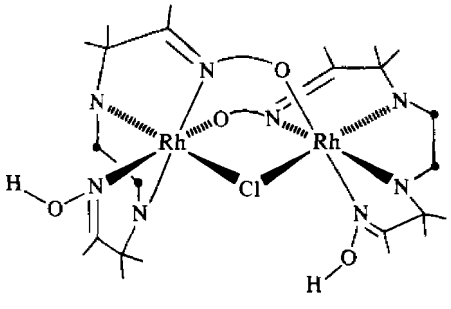
(59b)



representations of the structures are shown in (**61**).[894,895] For the longest hydrocarbon chain ($n = 4$), a binuclear species results, with both (A–O) ligands bridging between the two Rh centers (**61a**). At each end of this molecule there is a very strong hydrogen bond between the two oximes (O—O distance is 2.387 Å).[894] With one less carbon ($n = 3$), the hydrocarbon chain is apparently not long enough to span the two Rh centers, as a monomeric *trans*-[Rh(A–O)Cl_2] complex results (**61b**).[895] Again, a strong hydrogen bond between the two oximes (O—O distance 2.474 Å) makes the (A–O) ligand virtually cyclic. For the even shorter hydrocarbon ($n = 2$), another dinuclear species is formed, but with a chloride and the two oxime moieties bridging the Rh centers (**61d**). There is no evidence of hydrogen bonding in this structure.[894] The last species studied has no hydrocarbon chain (in essence, $n = 0$), but the product has a structure similar to that observed when $n = 3$: a monomeric, *trans*-RhN_4Cl_2 chromophore, with a hydrogen bond between the *cis* oximes (O—O distance of 2.459 Å).[895]

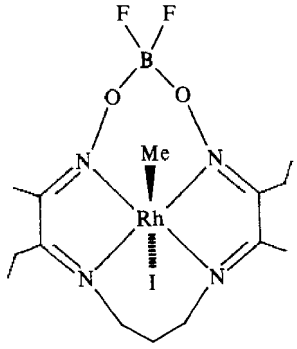


(60)



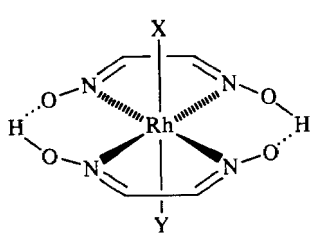
(61a) $n = 4$

(61b) $n = 3$



(61c) $n = 0$

(61d) $n = 2$



The single crystal X-ray structure of *trans*-methyliodo{difluoro[3,3′-(trimethylenedinitrolo)bis(2-pentanone oximato)]borate}rhodium(III) (**62**) shows that the Rh sits in the plane established by the four N atoms, with the I and the Me in the axial positions (2.813 Å and 2.090 Å, respectively). The two six-membered rings resemble a chair conformation, with the BF_2 bridge bent toward the axial methyl group, and the propylene bent toward the iodine atom.[896]

(62)

Complexes of the form $[Rh(RBig)_2Cl_2]Cl$ (RBig = N^1-(*p*-chlorophenyl), N^1-phenyl, N^1-(*o*-tolyl), N^5-isopropylbiguanide) have been prepared in which the biguanide is presumably acting as a N—N bidentate. Substitutions in acidic solution lead to $[Rh(RBig)_2X_2]X$ for X = Br, I, NO_2, CNS and N_3, and oxidation of the dichloro species with $NaClO_2$ is reported to lead to a Rh^{IV} complex $[Rh(RBig)_2Cl_2]Cl_2$.[897]

Dimethylglyoxime (HON=C(Me)CC(Me)=NOH, abbreviated here as HDMG) forms several unbridged Rh^{II} dimers (Section 48.5.2.1.iv) and has a rich chemistry with Co^{III} (the cobaloximes[898]); examples of Rh^{III} complexes are less common, but interest in its Rh^{III} chemistry is growing. As in other metal systems, HDMG, or its monoanionic conjugate base (DMG), acts as a bidentate ligand, bonding through the two nitrogen atoms. Dwyer and Nyholm[899] first reported the preparation of $[Rh(DMG)_2Cl_2]^-$ ion (isolated as the H^+ salt), but this formulation was questioned by Gillard *et al.*[601] who pointed to O—H stretches in the IR spectrum, and suggested that while the $[Rh(DMG)_2Cl_2]^-$ anion undoubtedly exists in solution, the solid state species is more accurately represented as $[Rh(DMG)(HDMG)Cl_2]$.[601] An early report[900] that refluxing HDMG with *trans*-$[Rhpy_4Cl_2]Cl$ leads to *trans*-$[Rh(DMG)_2(py)Cl]$ was also questioned by Gillard[601] who found $[Rhpy_3Cl_3]$ as the major product under the cited conditions. In ethanolic solution in the presence of trace amounts of BH_4^- they precipitated the $[Rh(DMG)_2Cl_2]^-$ anion, either as the pyH^+ or the $[Rhpy_4Cl_2]^+$ salts. The chloropyridine adduct was eventually prepared by adding H_3PO_2 to a hot suspension of $pyH^+[Rh(DMG)_2Cl_2]^-$ in pyridine.[601] Powell has reported the syntheses of many $[Rh(DMG)_2LX]$ complexes [L = PPh_3, $AsPh_3$, $SbPh_3$; X = Cl, Br, I (no $SbPh_3$)], prepared by heating aqueous ethanolic solutions of $RhCl_3 \cdot 3H_2O$, L and HDMG in the presence of the appropriate potassium halide.[901] A similar route was used to prepare $[Rh(DMG)_2(Cl)(ZMe_3)]$ (Z = P or As) and $[Rh(DMG)_2(X)(thiourea)]$ (X = Cl, Br).[902] Single crystal X-ray structures of $[Rh(DMG)_2(Cl)(PPh_3)]$,[903] $[Rh(DMG)_2(Cl)(SbPh_3)]$[904] and $[Rh(DMG)(HDMG)(Cl)(PPh_3)]Cl \cdot CH_2Cl_2$[905] show that these complexes all share a *trans* geometry with the rhodium in the plane established by the bidentate DMG ligands. This geometry is characteristic of bis(DMG) complexes (no *cis* Rh^{III} examples have been reported) as it allows hydrogen bonding between the oxime groups (**63**), so that the two DMG ligands may be considered to form one pseudo-macrocyclic dianion.

(63)

Aqueous substitutions of $[Rh(DMG)_2Cl_2]^-$ have led to $NH_4[Rh(DMG)_2Cl(X)]$ (X = Br, I, NCS), and $[Rh(DMG)_2(thiourea)Cl]$,[906] $[Rh(DMG)_2(NH_3)Cl]$,[907] $[Rh(DMG)_2(H)(PPh_3)]$,[908] and

$[Rh(DMG)_2(Cl)(PPh_3)]$.[909] Reduction of Nyholm's $[Rh(DMG)_2Cl_2]^-$ with BH_4^- in alkaline H_2O/MeOH (1:1) in the presence of MeI leads to methylrhodoxime, *trans*-$[Rh(DMG)_2(H_2O)(Me)]$ (λ_{max} (ε) at 400 (456), 329 (6300), 262 (7690), 225 (11 900) nm).[899,910] A recent kinetic study has shown that the methyl group strongly labilizes the *trans* site.[911] Anation of methylrhodoxime by N_3^-, SCN^-, I^-, py or thiourea is very rapid; about 100 times faster than anations at cobaloxime and six orders of magnitude faster than anations at $[Rh(TPPS)(H_2O)_2]^{3-}$, another complex with a *trans*-$(H_2O)Rh(Me)$ moiety. Activation parameters (for thiourea anation $\Delta H^* = 32.4 \pm 1.3\,kJ\,mol^{-1}$, $\Delta S^* = -61 \pm 4.4\,J\,K^{-1}\,mol^{-1}$) indicate that the lability is due to the low ΔH^* values. The pK_a of the coordinated water (9.78) does not suggest an unusually weak Rh—O bond, so that the low ΔH^* value must arise from a stabilization of the transition state. The anation rates are practically independent of the nature of the nucleophile, suggesting a dissociative process, but the very negative ΔS^* values suggest a mechanism which is more associative than for the cobaloxime.[911]

Espenson has found that the rhodoxime behaves very much like the cobaloxime in its association with iron(III) ion to form the bimetallic $[Rh(DMG)(DMGFe)(H_2O)Me]^{2+}$. Its formation constant (equation 178) is 68.8 ± 4.0 (for cobaloxime, $K_f = 15.3 \pm 0.8$[912]). This unusual cation can be considered to be derived from the structure shown in (**63**), in which X = Me, Y = H_2O, and one of the hydrogen-bonded hydrogens is replaced by an Fe^{3+}. The presence of the iron adduct is readily signalled by an intense absorption near 440 nm ($\varepsilon \approx 47\,000$), and a comparison of the kinetic and thermodynamic parameters shows a strong similarity to the previously studied Fe^{3+} adducts of cobaloxime.[913] Even in the presence of 'forcing concentrations' of Fe^{3+}, there was no evidence of incorporation of a second iron(III) ion.[912]

$$[Rh(DMG)_2(H_2O)Me] + Fe^{3+} \rightleftharpoons [Rh(DMG)(DMGFe)(H_2O)Me]^{2+} + H^+ \qquad (178)$$

Reduction of $[Rh(DMG)_2Cl_2]^-$ in basic aqueous ethanol (to an unspecified Rh^I complex) is autocatalyzed, with a rate expression of the form: rate = $k[Rh^{III}][Rh^I]$.[914] The rate of reduction is not affected by added chloride ion, but varies as the inverse fourth (!) power of $[OH^-]$. A mechanism, involving deprotonation of the DMG ligands, and Cl^--bridged Rh^{III}—Cl—Rh^I intermediates, has been proposed.[914]

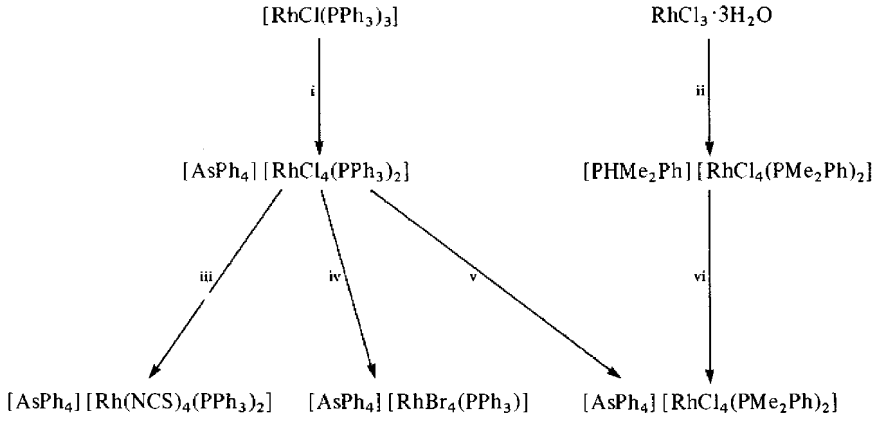
48.6.3 Complexes of Heavier Group V Ligands

There is an extensive chemistry of tertiary phosphine rhodium(III) complexes. However, there are comparatively few complexes of monodentate tertiary arsines, although the complexes of ditertiary arsines are more numerous. There are virtually no tertiary stibine complexes. The two main preparative routes to the complexes described in this section are: (i) direct reaction of the ligands with rhodium trichloride, which usually yields trichloro complexes; and (ii) oxidative addition to rhodium(I) tertiary phosphine complexes, which gives rise to more diverse products of the type $[RhXYZ(PR_3)_n]$. Metathetical reactions on the complexes prepared by either method (i) or (ii) have been used to prepare most of the remaining compounds.

48.6.3.1 Anionic complexes

The anionic complexes containing phosphorus and arsenic ligands are shown in Table 61. It will be noted that there are no anionic complexes containing antimony ligands.

Table 61 Anionic Rhodium(III) Complexes Containing Tertiary Phosphine or Arsine Ligands



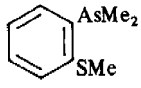
Complex	*Color*	*M.p.* (°C)	*Ref.*
$K[Rh(S_2CO)_2(PMe_2Ph)_2]$	Yellow	195[a]	915
$[AsPh_4][Rh(SCN)_4(PPh_3)_2]$	Lemon yellow	96–98	916
$[AsPh_4][RhCl_4(PMe_2Ph)_2]$	Red-brown	224–26	916
$[NMe_4][RhCl_4(PPh_3)_2]$	Orange-yellow	230–34	916
$[AsPh_4][RhCl_4(PPh_3)_2]$	Orange-yellow	206	916
$[AsPh_4][RhBr_4(PPh_3)_2]$	Yellow-brown	170[a]	916
$[RhCl_2(\mathbf{64})_2][RhCl_4(\mathbf{64})]$	Pale yellow	—	917
$[RhBr_2(\mathbf{64})_2][RhBr_4(\mathbf{64})]$	Yellow-orange	—	917
$[RhI_2(\mathbf{64})_2][RhI_4(\mathbf{64})]$	Brown	—	917

[a] With decomposition.

The most-studied anionic complex is $[AsPh_4][RhCl_4(PPh_3)_2]$. It results from the reaction between tetraphenylarsonium chloride and tris(triphenylphosphine)rhodium(I) complexes. However, if *trans*-$[RhCl(CO)(PPh_3)_2]$ is selected as the starting material then the major product is $[RhCl_3(CO)(PPh_3)_2]$. The less stable tetramethylammonium salt can also be prepared from *trans*-$[RhCl(CO)(PPh_3)_2]$ (equation 179).

$$\textit{trans}\text{-}[RhCl(CO)(PPh_3)_2] + (Me_4N)Cl + HCl \xrightarrow{Me_2CO} (Me_4N)[RhCl_4(PPh_3)_2] \quad (179)$$

The reactions of $[AsPh_4][RhCl_4(PPh_3)_2]$ are shown in Scheme 35; both the chloro and triphenylphosphine ligands of the anion can be substituted by ligands of similar character. For the thiocyanato complex $\nu_{C\equiv N}$ has been found to be 2105 cm^{-1}.[915] Under a nitrogen atmosphere, neat dimethylphenylphosphine slowly displaces the PPh_3 ligands from the complex. The anion $[RhCl_4(PMe_2Ph)_2]^-$ has also been prepared in a 2% yield from $RhCl_3 \cdot 3H_2O$ and PMe_2Ph.[918]



i, $[AsPh_4]Cl \cdot HCl$, Me_2CO;[916] ii, PMe_2Ph, (a) EtOH, (b) Me_2CO;[915] iii, LiNCS, Me_2CO;[916] iv, LiBr, Me_2CO;[916] v, PMe_2Ph, N_2, slow;[916] vi, $[AsPh_4]Cl$, EtOH[915]

Scheme 35 Preparation and reactions of anionic rhodium(III) complexes

It is generally considered that the chloro ligands in the above complexes are not *trans* to the tertiary phosphine ligands by virtue of ν_{Rh-Cl} in their far IR spectra being above 300 cm^{-1}. The PMe_2Ph complex has a ^{31}P NMR spectrum consistent with *trans* tertiary phosphine ligands.[918]

The PMe_2Ph ligands in the bis(dithiocarbonato) complex $K[Rh(S_2CO)_2(PMe_2Ph)_2]$ have been shown to be *trans* by X-ray crystallography.[919] The rhodate(III) salt was prepared by allowing $RhCl_3(PMe_2Ph)_3$ to react with potassium *O*-ethyldithiocarbonate in refluxing ethanol.[916]

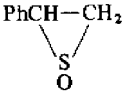
If the thioarsine ligand (**64**) is allowed to react with aqueous rhodium trichloride then the tetrachlororhodate salt is formed. A similar reaction gives rise to the tetrabromo complex (equation 180). The tetraiodo complex can be prepared by addition of LiI to sodium hexachlororhodate(III) and the ligand (equation 181).[916]

(**64**)

$$RhX_3 \cdot 3H_2O + (\mathbf{64}) \xrightarrow{HX_{(aq)}/EtOH} [RhX_2(\mathbf{64})_2][RhX_4(\mathbf{64})] \quad (180)$$

$$Na_3[RhCl_6] + LiI + (\mathbf{64}) \xrightarrow{H_2O/EtOH} [RhI_2(\mathbf{64})_2][RhI_4(\mathbf{64})] \quad (181)$$

48.6.3.2 [RhX₃L] complexes



This is a rare stoichiometry which can be achieved by the coordination of two bidentate anionic ligands. The most authentic examples of this stoichiometry have been prepared by oxidative

addition to rhodium(I) complexes. Three bis(1,3-diaryltriazenido) complexes have been prepared by oxidative addition of the appropriate diaryltriazene to $RhCl(PPh_3)_3$ under mild conditions (equation 182).

$$[RhCl(PPh_3)_3] + ArN_3Ar \xrightarrow[20°C]{C_6H_6} [RhCl(ArN_3Ar)_2(PPh_3)_2] \quad (182)$$

$$Ar = Ph, p\text{-}C_6H_4Me, p\text{-}C_6H_4Cl^{231}$$

The reaction of $RhCl(PPh)_3$ with pentane-2,4-dione (equation 183) is more complex, some *trans*-$[RhCl(CO)(PPh_3)_2]$ is formed as a result of carbonyl abstraction in a side reaction.[920] An even more complex reaction results from the trapping by $RhX(PPh_3)_3$ (X = Cl, Br) of the SO moiety produced in the decomposition of stilbene episulfoxide (**65**; equations 184). The dimeric product is unstable in the presence of PPh_3 and is reduced to the starting material (equation 185).[921]

(65)

$$[RhCl(PPh_3)_3] + acacH \longrightarrow [RhCl(acac)_2(PPh_3)] \quad (183)$$

$$[RhX(PPh_3)_3] + (65) \xrightarrow{CH_2Cl_2} [RhX(SO)(PPh_3)]_2 + OPPh_3 + SPPh_3 + PhCH{=}CHPh \quad (184)$$

$$[RhX(SO)(PPh_3)]_2 + 8PPh_3 \longrightarrow 2OPPh_3 + 2SPPh_3 \quad (185)$$

An even more bizarre example of this stoichiometry is provided by the two dithiophosphorus complexes $[Rh(S_2PPh_2)_3PPh_3]$ and $[Rh\{S_2P(OEt)_2\}_3PPh_3]$. These have been prepared from uncharacterized rhodium(II) substrates by allowing the latter to react with PPh_3 and the sodium salt of the dithioacid. In these two complexes the dithioanion *trans* to PPh_3 is monodentate.

The same nominal stoichiometry is adopted by a few tetrafluoroborate salts of cations which contain similar bidentate thioanions; however, these cations are presumably five-coordinate having the formula $[RhX_2(PPh_3)]^+$ (X = S_2CNMe_2; XH = 2-mercaptobenzothiazole, 2-mercaptopyridine, toluene-3-thiol).[121]

48.6.3.3 [RhX_3L_2] complexes

Complexes adopting this stoichiometry are: (i) genuine five-coordinate complexes, or (ii) six-coordinate complexes containing either a bidentate anionic ligand, or (iii) an uncharacteristically bidentate neutral ligand. The final type of complex in this class is the six-coordinate binuclear complex such as $[RhCl_3(PBu_3)_2]_2$. Examples of the first three types of complex are: (i) $[RhHCl_2(PR_3)_2]$, (ii) $[RhH_2\{S(NPh)CHMe_2\}(PPh_3)_2]$, and (iii) $[RhCl_3\{Me_2As(o\text{-}C_6H_4OMe)\}_2]$.

(*i*) *Five-coordinate complexes*

The many hydrido and dihydrido complexes are a feature of this class. Their coordinative unsaturation undoubtedly arises from the high *trans* effect of their hydrido ligands. In this sense they can be regarded as the rhodium(III) analogs of the $[RhHL_2]$ complexes (Section 48.4.2.1). A lesser number of five-coordinate complexes containing bulky ligands are also known. This latter type can be regarded as the rhodium(III) analogs of the $[RhXL_2]$ complexes from which most can be obtained by suitable oxidative addition reactions.

The dihydrido complexes (Table 62) can be obtained by the oxidative addition of molecular hydrogen to rhodium(I) complexes (equation 186).[10,119,922–926] The tri(*t*-butyl)phosphine complexes can be prepared either from the chlororhodium(I) complex,[923] or rhodium trichloride.[927] The former method seems more reliable since the latter reports the complex as a matt green substance, a color uncharacteristic of tertiary phosphine rhodium(III) complexes. Indeed, Masters and Shaw report that the related tertiary phosphines PBu^t_2R (R = Et, Pr) give green rhodium(II) complexes in this reaction (see Section 48.5.2.1 above).[268,269]

The X-ray crystal structure of $[RhH_2Cl(PBu^t_3)_2]$ (**66**) has been determined.[923] The space group reported[928] for $[RhD_2(PPh_3)_3]$, P_{21}/c, differs from the C_2/c of the former complex.

Table 62 Physical Properties of $[RhH_2XL_2]$ Complexes

The dihydrido complex $[RhH_2Cl(PPh_3)_2]$ is a very important intermediate in the homogeneous catalytic hydrogenation of alkenes.[20] The monohydrido complexes (Table 63) can be made by the oxidative addition of HY species to rhodium(I) complexes (equation 187). Similar complexes can be obtained when bulky tertiary phosphines are allowed to react with alcoholic solutions of hydrated rhodium trichloride.[268,269]

Usually the monohydrido species have the square pyramidal structure (**69**),[268] although the populous and important hydridosilylrhodium(III) complexes have been shown to adopt the trigonal bipyramidal structure (**70**) in the solid state.[934]

(69)

(70)

The five-coordinate monohydrido complexes shown in Table 63 are less reactive and less important catalytically than their dihydrido analogs. One of the few reactions noted is the addition of pyridine to the tricyclohexylphosphine complexes to form six-coordinate products (equation 188).[924] Six-coordinate complexes can also be obtained if the preparation of $[RhH_2Cl(PPh_3)_2]$ is carried out in coordinating solvents.[10]

$$[RhHCl_2(PCy_3)_2] + py \longrightarrow [RhHCl_2(PCy_3)_2py] \quad (188)$$

By contrast the silyl complexes are important catalysts in a variety of hydrosilylation reactions.[20] They can be prepared by the similar oxidative addition of hydrosilanes to rhodium(I) complexes, either directly or in solution (equation 189).[935] However, in the presence of both additional base and triphenylphosphine a hydridorhodium(I) complex results (equation 190).[936] Alternatively in the presence of a large excess of hydrosilane the monohydrido complex is transformed into a dihydrido complex.[922]

$$[RhCl(ZPh_3)_3] + SiHR_3 \longrightarrow [RhHCl(SiR_3)(ZPh_3)_2] + ZPh_3 \quad (189)$$

Z = P, As, Sb; X = Cl, Br, I; R = Cl, OEt

$$[RhCl(PPh_3)_3] + Et_3SiH + Et_3N \xrightarrow[C_6H_6]{PPh_3} [RhH(PPh_3)_4] + Et_3SiCl{-}NEt_3 \quad (190)$$

The complexes produced, although five-coordinate, often contain hydrosilane of crystallization. This additional hydrosilane is not associated with rhodium.[934]

Despite the widespread use of such hydridosilyl complexes in hydrosilylation reactions, only a fraction of those employed have been isolated and characterized (Table 64).

Solutions of the complexes are unstable due to loss of the silyl ligands, which are also readily displaced by other ligands. In the solid state the $[RhHCl(SiX_3)(PPh_3)_2]$ complexes are more stable and only decompose upon heating *in vacuo* above 100 °C (equation 191).[939] The thermal stability of the complexes increases with increasing electronegativity of groups bound to silicon, but decreases with increasing size of tertiary phosphine ligands. Some of the reactions of the silyl complexes are shown in Figure 4.

$$2[RhHCl(SiR_3)(PPh_3)_2] \longrightarrow 2SiHR_3 + [RhCl(PPh_3)_2]_2 \quad (191)$$

The analogous hydridogermyl complexes may be prepared similarly using hydrogermanes.[940,941] However, a 14-fold excess of hydrogermane forms anionic complexes (equation 192). The germyl complexes have a similar structure to their five-coordinate silyl analogs, and, despite being less extensively dissociated in solution, undergo many of the same reactions. Thus, they are decomposed by either carbon monoxide or ethylene (equation 193).

$$[RhCl(PPh_3)_3] + 14GeHCl_3 \longrightarrow [Ph_3PH][Rh(GeCl_3)_6] + H_2 + HCl \quad (192)$$

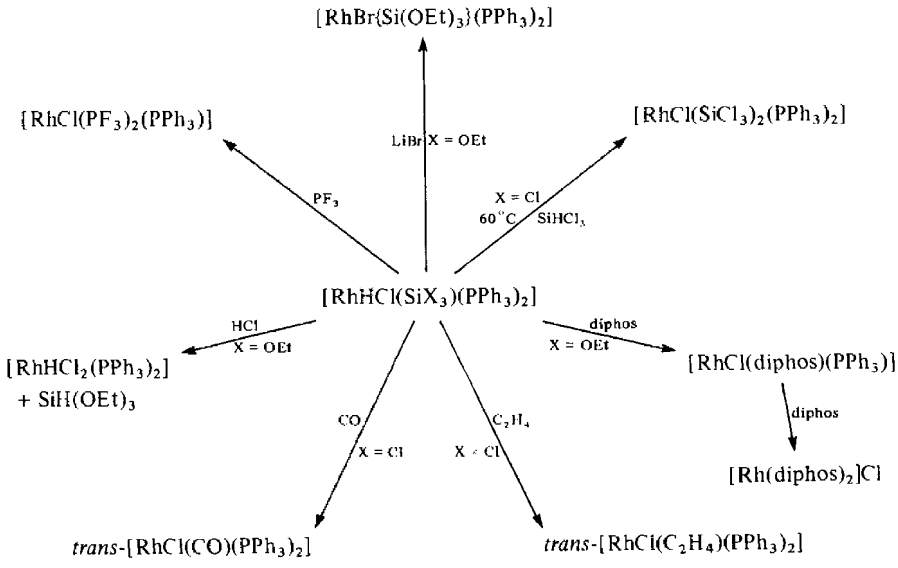

Figure 4 Reactions of $[RhHCl(SiX_3)(PPh_3)_2]$ complexes

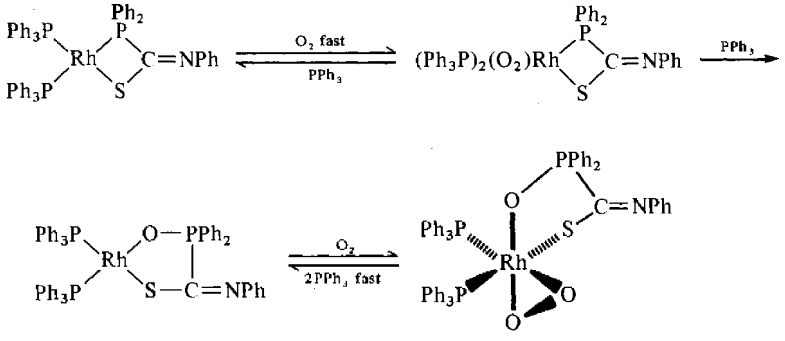

Many rhodium(I) tertiary phosphine complexes react readily with molecular oxygen, although it is not always easy to characterize the products of these reactions.[943,944] The complexes isolated are listed in Table 65.

One problem is that coordinated oxygen oxidizes the tertiary phosphine ligands to form free tertiary phosphine oxide. Often the course of this reaction is solvent dependent; in ethanol the phosphine oxide is more likely to be formed than in hydrocarbon solvents.[945] The oxidation of ligands also occurs in the solid state reaction.[942]

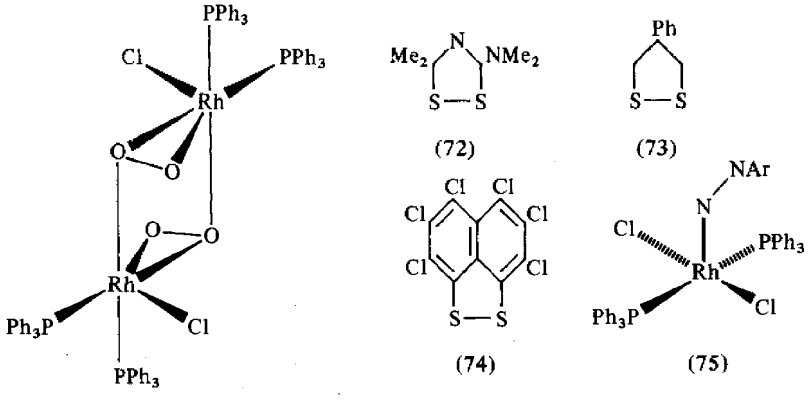
One of the best studies on the oxidation involves the rhodium(I) complex $[(Ph_3P)_2RhS(PPh)C{=}NPh]$. These reactions are shown in Scheme 36. The *N,N*-dimethyldithiocarbamato complex merely undergoes oxidative addition.



Scheme 36 Reactions of $[Rh\{S(PPh_2)CNMe\}(PPh_3)_2]$ with O_2 in the presence of PPh_3

The reaction of dioxygen with $[RhCl(PPh_3)_3]$ has long been known.[930,944,945] The cyano analog reacts similarly.[119] However, the product from the latter reaction may be six-coordinate with bridging dioxygen ligands since both the chloro complex and its dichloromethane solvate adopt structure (**71**).[946,947] The chlorobis(triphenylphosphine) complex is not the sole possible product; under slightly different conditions $[RhCl(O_2)(PPh_3)_3]$ is formed (see Section 48.6.3.5). Most of the dioxygen complexes exhibit bands between 871 and 900 cm^{-1} in their IR spectra, which have been assigned to ν_{O-O}.

There remain a number of other five-coordinate complexes whose physical properties are shown in Table 66. Of these complexes only the $AsCy_3$ complex has been prepared from a rhodium(III) source (equation 194). The remainder have been prepared from oxidative addition reactions of $[RhCl(PPh_3)_3]$. The arylazo complexes have structure (**75**),[948] whilst the sulfinato complexes are bound through sulfur.[950]

$$RhCl_3 \cdot 3H_2O + AsCy_3 \xrightarrow{MeO(CH_2)_2OH} [RhCl_3(AsCy_3)_2] \qquad (194)$$

(*ii*) *Six-coordinate complexes*

The complexes which contain a bidentate anion are listed in Table 67. Two preparative routes exist to these complexes. One involves oxidative addition of two monoanions to a rhodium(I) complex containing a bidentate anion. These are usually complexes containing a disulfur anion (equation 195).[65] Dibenzoylmethane, in contrast to pentane-2,4-dione (see Section 48.6.3.2 above) adds in a similar fashion (equation 196).[920]

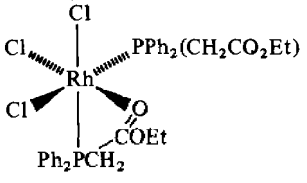
[a] With decomposition.

It is possible that the nitrato complexes $[RhX_2(NO_3)(PMePh_2)_2]$, prepared by the decidedly hazardous addition of concentrated nitric acid to ethanolic solutions of $[RhX_2H(PMePh_2)_2]$, are also six-coordinate but the IR spectrum of the nitrato ligand reputedly gave no clue to its denticity.[953]

Numerous complexes containing bidentate 1,3-diaryltriazenido ligands have been prepared by Robinson and his co-workers. These complexes have been prepared by allowing the 1,3-diaryltriazene to react with a rhodium(I) complex under mild conditions (equation 197)[231,955] or directly from $RhCl_3 \cdot 3H_2O$.[231] The structure (**76**) has been deduced from the ^{31}P and high field ^1H NMR spectra.[231]

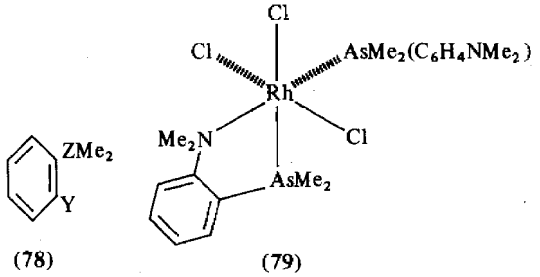
$$[RhH(PPh_3)_4] + ArN_3Ar \longrightarrow [RhH_2(ArN_3Ar)(PPh_3)_2] \quad (197)$$



$$Ar = Ph, p\text{-}C_6H_4Me, p\text{-}C_6H_4Cl$$

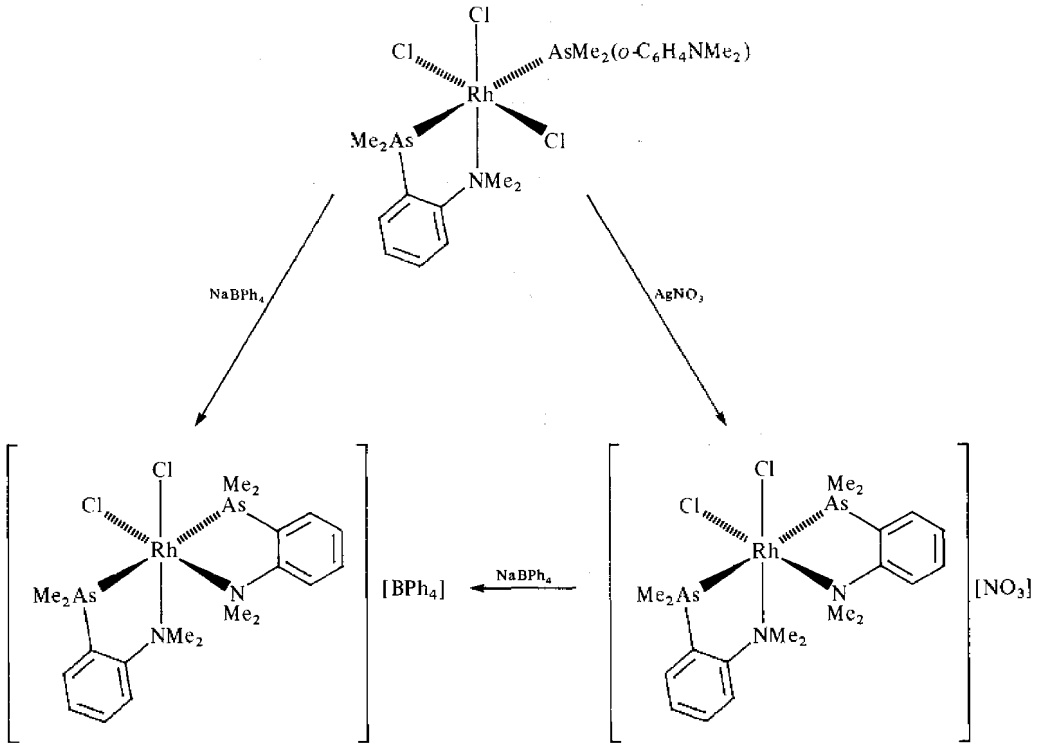
(76)

Besides those complexes which contain bidentate anionic ligands there are also complexes which contain one bidentate neutral ligand. Very frequently this type of complex contains two identical neutral ligands one of which is monodentate and the second bidentate by virtue of complexing to rhodium through a second functional group on the ligand.



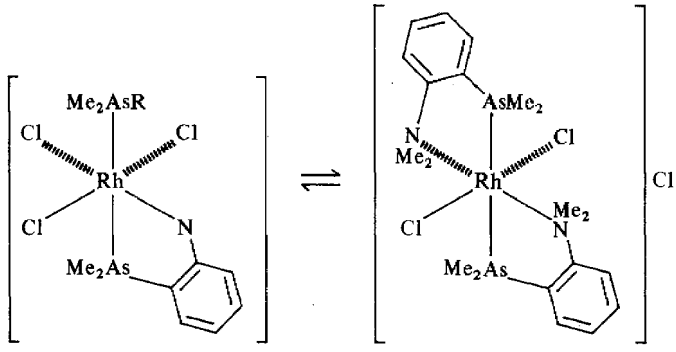
The tertiary phosphine $Ph_2P(CH_2COOEt)$ has been shown by Braunstein and his co-workers to form a rhodium(III) complex when allowed to react with rhodium trihalides. The products are the facial isomers (**77**). This is in accordance with their NMR spectra which show $^2J(P\text{–}P) = 23.5$ Hz.[956]

(77)



This behavior is in contrast to that of the bulky ligands $Bu^t_2P(CH_2)_nCOOEt$ ($n = 2, 3$), which form rhodium(II) complexes under these conditions,[275] and the cyanophosphine $PPh_2(CH_2CN)$, which forms *mer*-$[RhCl_3\{PPh_2(CH_2CN)\}_3]$.[956]

When hydrated rhodium trichloride is allowed to react with (**78**; Y = OMe, NMe_2; Z = As), complexes of empirical formula $[RhCl_3(\mathbf{78})_2]$ are obtained. The orange-red dimethylaminophosphine complex has been shown to have the meridional structure (**79**).[957–959] However, one chloro ligand is labile and can be replaced in the inner coordination sphere by the previously uncoordinated nitrogen atom of the second neutral ligand. This process is enhanced by allowing the complex to react with metal salts whose anions are of low coordinating power (Scheme 37).[957]



(78) (79)

The dark red *o*-anisyl complex can be prepared similarly. It has also been shown to have a meridional structure by X-ray crystallography.[960–962] It too reacts with silver nitrate to form an ionic complex in which all four potential donor atoms of the two neutral ligands coordinate to rhodium.[960]

Scheme 37 Reactions of *mer*-$[RhCl_3\{AsMe_2(o\text{-}C_6H_4NMe_2)\}_2]$[957]

The kinetics of the isomerization (equation 198) and analogous reactions have attracted much attention.[963–969] It is not surprising that the rate of the forward reaction is increased in polar solvents.[969]

(198)

The antimony ligands (**78**; Y = OMe, NMe_2; Z = Sb) also form $[RhX_3(\mathbf{78})_2]$ complexes when allowed to react with hydrated rhodium trihalides, except that rhodium tribromide and the anisyl ligand form the complex $[RhBr_3(\mathbf{78})_3]$. These reddish complexes presumably have similar structures to those of their well-characterized arsenic analogs. Whilst there is no evidence that loss of a halo ligand occurs in 1,2-dichloroethane, silver nitrate displaces one halo ligand. Presumably the *trans*-dihalo nitrate complex is formed.[970] This behavior is confined to antimony ligands of type (**78**). The three ligands $Ph_2Sb(o\text{-}MeOC_6H_4)$, $MeSb(o\text{-}MeOC_6H_4)_2$ and $Me_2Sb(o\text{-}MeOC_6H_4)$ all form $[RhCl_3L_3]$ complexes.[971]

(*iii*) *Dinuclear complexes*

These complexes are produced when rhodium trichloride is allowed to react with two, or less, equivalents of tertiary phosphine or arsine (equation 199). Their physical properties are listed in Table 68, and the complexes have been shown to adopt the non-centrosymmetric structure (**80**).[977] This is in agreement with the dipole moment[972] and ^{31}P NMR spectrum[978] of the tributylphosphine

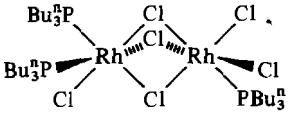
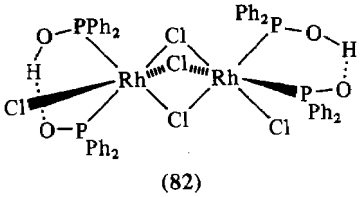
complex. However, working up solutions of this complex causes it to disproportionate (equation 200).[979]

$$RhCl_3 \cdot 3H_2O + 4ZR_3 \longrightarrow [RhCl_3(ZR_3)_2]_2 \quad (199)$$



$Z = P$, $R_3 = Et_3$, Pr_3, Bu_3, $(C_5H_{11})_3$,[972] $EtPh_2$[973]; $Z = As$, $R_3 = Et$,[972] CH_2Ph[974]



(80)

$$3[RhCl_3(PBu_3)_2]_2 \longrightarrow [Rh_2Cl_6(PBu_3)_3] + mer\text{-}[RhCl_3(PBu_3)_3] \quad (200)$$

The trihalobridged structure (**81**) has been confirmed by X-ray crystallography.[980] The disposition of each phosphorus atom *trans* to a different bridging chloro ligand is reminiscent of the structure of the $[Rh_2Cl_5\{Ph_2PO\}_2H_2]^-$ anion (**82**).[981]

(81)

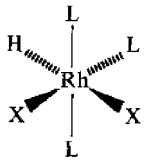
(82)

The trihalobridged species can also be obtained by allowing rhodium trichloride to react with 0.92 equivalents of tertiary phosphine. The trihalobridged complexes revert to dihalobridged complexes in the presence of more ligand (equation 201).

$$[Rh_2Cl_6(PBu_3)_3] + PBu_3 \longrightarrow [RhCl_3(PBu_3)_2]_2 \quad (201)$$

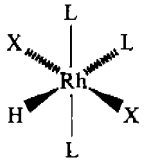
An unstable tri(perfluorophenyl)phosphine complex can be obtained by oxidative addition of chlorine to the dimeric rhodium(I) complex. The ethyldiphenylphosphine complex prepared in this way is more stable (equation 202).

$$[RhCl(PR_3)_2]_2 + Cl_2 \longrightarrow [RhCl_3(PR_3)_2]_2 \quad (202)$$



$R_3 = (C_6F_5)_3$,[73] $EtPh_2$[972]

Apart from the triethylarsine[972] and the tribenzylarsine[974] complexes the remaining tertiary arsine complex is formed by the ditertiary arsine 1,2-$(Ph_2As)_2C_2H_4$; clearly this cannot adopt structure (**80**). However, the ditertiary stibine complexes[976] may well adopt structure (**80**), since their stoichiometry implies that only half the antimony atoms are coordinated to rhodium.



48.6.3.4 [RhH_2XL_3] and [$RhHX_2L_3$] complexes

The dihydrido complexes, despite their catalytic potential, are sparsely represented. It has been shown by X-ray photoelectron spectroscopy that the interaction of hydrogen with solid [$RhCl(PPh_3)_3$] yields the complex [$RhH_2Cl(PPh_3)_3$].[982] This complex has also been detected in solutions containing excess PPh_3 and its NMR spectrum measured.[983] It was noted in Section 48.6.3.3 (i) above that [$RhH_2Cl(PPh_3)_2$] reacts with coordinating solvents to give complexes of this stoichiometry.[10] The lability of the third triphenylphosphine ligand has also enabled the α-methylbenzylamine complex [$RhH_2Cl(PPh_3)_2(PhCHMeNH_2)$] to be prepared and used as a chiral hydrogenation catalyst.[983] The smaller $PEtPh_2$ ligand is less labile and [$RhH_2Cl(PEtPh_2)_3$] can be prepared by oxidative addition of H_2 to [$RhCl(PEtPh_2)_3$] in the presence of excess ligand.[973]

In the monohydrido complexes the neutral ligands adopt the *mer* configuration, thus giving rise to two isomeric forms. The first of these, designated α (**83**), has the hydrido ligand *trans* to an anionic ligand; the β isomer (**84**) has the hydrido ligand *trans* to a neutral ligand. The physical properties of the two series are listed in Tables 69 and 70, respectively.

(83)

(84)

It is not surprising that the α isomers are the more stable, given that the neutral ligands are invariably higher in the *trans* effect series than halogeno ligands. The isomerization from β to α isomers is accelerated by light or by heating, but it is inhibited by the presence of excess neutral ligand. It seems probable, therefore, that a dissociative mechanism is involved.[986]

The ligand *trans* to the hydrido ligand influences the properties of the latter. The rhodium–hydrogen bond is weaker in the β isomer than in the α isomer, ν_{Rh-H} being typically some 100 cm^{-1} lower in the latter (Tables 69 and 70). The ^1H NMR spectra of the isomers are quantitatively similar, consisting of a pair of double triplets in both cases. However, in the spectra of the α isomers all the J(H–P) values are in the range 9–22 Hz, whereas in the spectra of the β isomers the whole spectrum is displaced to lower fields and J(H–P) is about 200 Hz. This is indicative of the hydrido ligand being *trans* to the unique phosphorus ligand.[986]

The complexes have been prepared by several methods. When ethanolic KOH and rhodium

trichloride are allowed to react with $PEtPh_2$ at room temperature α-$[RhHCl_2(PEtPh_2)_3]$ is formed.[987] Piperidine/ethanol mixtures have also been used as the solvent.[988] Prolonged refluxing of the solvent results in carbonyl complexes being isolated. Phosphinic acid has been used as the source of the hydrido ligand in other reactions.[986,989] Zinc dust has also been used as the reducing agent.[990] Alternatively, α-$[RhHCl_2(PMePh_2)_3]$ has been synthesized by the oxidative addition of HCl to the rhodium(I) complex (equation 203).[986] However, treatment of rhodium(III) complexes with phosphinic acid yields the β isomers (equation 204).[986]

$$[RhCl(PEtPh_2)_3] + HCl \longrightarrow \alpha\text{-}[RhHCl(PEtPh_2)_3] \quad (203)$$

$$mer\text{-}[RhX_3(ZMePh_2)_3] + H_3PO_2 \longrightarrow \beta\text{-}[RhHX_2(ZMePh_2)_3] \quad (204)$$

$$Z = P, X = Cl, Br; Z = As, X = Cl, Br, I$$

The tertiary arsine complexes were first prepared by Dwyer and Nyholm,[5] but, before the advent of NMR spectrometry, were erroneously considered to be rhodium(II) complexes.[989] Further investigations have shown that in preparations starting from rhodium trihalides using a higher tertiary arsine:rhodium ratio and lower reaction temperatures favor the formation of the β isomer (equations 205 and 206).[986]

$$RhX_3 \cdot 3H_2O + 2AsEtPh_2 \xrightarrow[78°C]{EtOH/H_2O} \alpha\text{-}[RhHX_2(AsEtPh_2)_3] \quad (205)$$

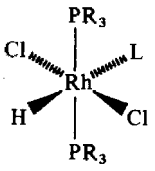
$$RhX_3 \cdot 3H_2O + 3AsEtPh_2 \xrightarrow{0°C} \beta\text{-}[RhHX_2(AsEtPh_2)_3] \quad (206)$$

Few studies have been made of the reactions of this class of complex. The action of bases upon the complexes brings about reductive elimination of hydrogen halide (equation 207).[973] However, if this reaction is carried out in dichloromethane it appears that the hydrido ligand reduces the solvent since, although the base hydrochloride is formed, a rhodium(III) complex results (equation 208).[953] The action of bromine[989] or SO_2[953] also produces hydrogen halide (equations 209 and 210). (The reaction with concentrated nitric acid has already been mentioned in Section 48.6.3.3.ii above.[953])

$$\alpha\text{-}[RhHCl_2(PEtPh_2)_3] \xrightarrow{PhNH_2} [RhCl(PEtPh_2)_3] \quad (207)$$

$$\alpha\text{-}[RhHCl(PEtPh_2)_3] + base \xrightarrow{CH_2Cl_2} [RhCl_3(PEtPh_2)_3] \quad (208)$$

$$[RhHBr(AsMePh_2)_3] + Br_2 \xrightarrow{CH_2Cl_2} [RhBr_3(AsMePh_2)_3] + HBr \quad (209)$$



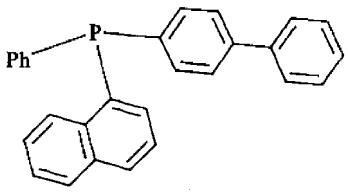
$$[RhHX_2(ZMePh_2)_3] + SO_2 \xrightarrow[78°C]{EtOH} [RhX(ZMePh_2)_3(SO_2)] + HX \quad (210)$$

$$X = Cl, Br; Z = P, As$$

It has been shown that strongly coordinating ligands will displace one tertiary phosphine ligand from β complexes (equation 211). The products have been assigned structure **(85)**.[992]

$$\beta\text{-}[RhHCl_2(PBu^tPr_2)_3] + L \longrightarrow \beta\text{-}[RhHCl_2(PBu^tPr_2)_2L] + PBu^tPr_2 \quad (211)$$

$$L = MeCN, MeNC, py, P(OMe)_3$$



(85)

48.6.3.5 [RhX_3L_3] complexes

This is a populous class of complex: most known tertiary phosphines seem to have been utilized in preparing at least one complex of this type. Meridional isomers are normally the rule, but small tertiary phosphines are also capable of forming facial isomers.

As might be expected, the structures of both isomers are essentially octahedral. However, even in the *mer* complexes, where steric repulsions between tertiary phosphines are minimized, there are slight deviations from orthogonality. Further, in the *mer* complexes the length of the Rh—P bond *trans* to X is less than the length of the mutually *trans* Rh—P bonds. Both these features are apparent from the X-ray crystal structure of *mer*-[$RhCl_3(PEt_3)_3$].[991]

The crystal structure of *mer*-[$RhCl_3(PBu^n_3)_2\{(POMe)_3\}$] has also been determined, and is in accordance with that predicted from its ^{31}P NMR spectrum.[992] The facial and meridional complexes that have been characterized are listed in Tables 71 and 72 respectively.

(86)

Both far IR and ^{31}P NMR spectrometry have been widely used to determine the configuration of the complexes in solution. Generally *mer* complexes have three bands arising from rhodium—halogen stretching, whilst the *fac* isomers only exhibit two such bands in their IR spectra. Such features are also apparent in the solid state Raman spectra of the complexes.[998] Early assignments of IR[94,999] or Raman[998] bands in the 300 cm^{-1} region to ν_{Rh-Cl} are probably erroneous, since bands in this region are found in the spectra of the analogous tribromo or iridium complexes. Goggin and Knight assign these bands in the spectra of [$MX_3(PMe_3)_3$] complexes as PC_3 asymmetric deformation modes.[1000]

The ^{31}P NMR spectra have been recorded with increasing precision with the passing years.[918,993,1001,1002] The work of Shaw's group is regarded as being more accurate since random noise decoupling was employed to enable certain Rh–P couplings in the meridional complexes to be determined.[1002] The spectra of certain trimethylphosphine complexes have also been studied in some detail (see Table 73).[1003,1004]

Both ^1H NMR[1005] and EPR[1006] spectrometry have been used to show that [$RhCl_3(PEt_2Ph)_3$] adopts the meridional configuration. The X-ray photoelectron spectrum of *fac*-[$RhCl_3(PMe_2Ph)_3$]

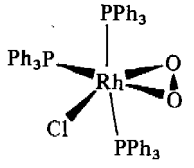
has been obtained and compared with those of similar complexes of second and third transition series elements.[1007] This technique has also been used to show that solid $[RhCl(PPh_3)_3]$ undergoes oxidative addition of hydrogen or oxygen to form $[RhClY_2(PPh_3)_3]$ complexes (Y = H, O).[982]

Perusal of Tables 71 and 72 shows the wide range of complexes that can be obtained. The essential problem is in selecting the correct preparative conditions for the isolation of the required complex in pure form. Many alternative products can be formed from the apparently simple reaction between hydrated rhodium trichloride and tertiary phosphines, some of which are shown in Figure 5. Accordingly many preparative methods have been devised for complexes of this stoichiometry, unfortunately none seem of very wide applicability, and many are specific for only one complex. Those intending their preparation should consult the methods given in the references of Tables 71 and 72, and should be cautioned that slight changes in the preparative methods employed invariably lead to other complexes.

The facial isomers are obtained only from small tertiary phosphines, usually in poor yield. They are both less soluble and less stable than the meridional isomers.

Comparatively little effort has been expended in investigating the reactions of the complexes, as opposed to the application of physical methods in determining their structures. However, in the meridional complexes the halo ligand *trans* to the tertiary phosphine is more labile than the other two and its replacement by other anionic ligands allows the preparation of $[RhX_2X'(PR_3)_3]$ complexes from the trihalo complexes obtained from rhodium(III) halides (equation 212). Prolonged reaction with salts of other anions results in all three halo ligands being replaced (equation 213).[918]



$$mer\text{-}[RhCl_3(PMe_2Ph)_3] + NaS_2Y \xrightarrow[25°C]{MeOH} mer\text{-}[RhCl_2(S_2Y)(PMe_2Ph)_3] + NaCl \quad (212)$$

$$Y = CNMe_2,\ PMe_2$$[915]

$$mer\text{-}[RhCl_3(ZMe_2Ph)_3] + M^IX \longrightarrow [RhX_3(ZMe_2Ph)_3] \quad (213)$$

$$X = Br,\ I,\ NCO,\ SCN,\ N_3$$

It has been shown that the dioxygen complex $[RhClO_2(PPh_3)_3]$, which X-ray crystallography[1008] reveals to have the structure (**87**), decomposes to dimeric $[RhClO_2(PPh_3)_2]_2$ and $OPPh_3$.[1009]

(87)

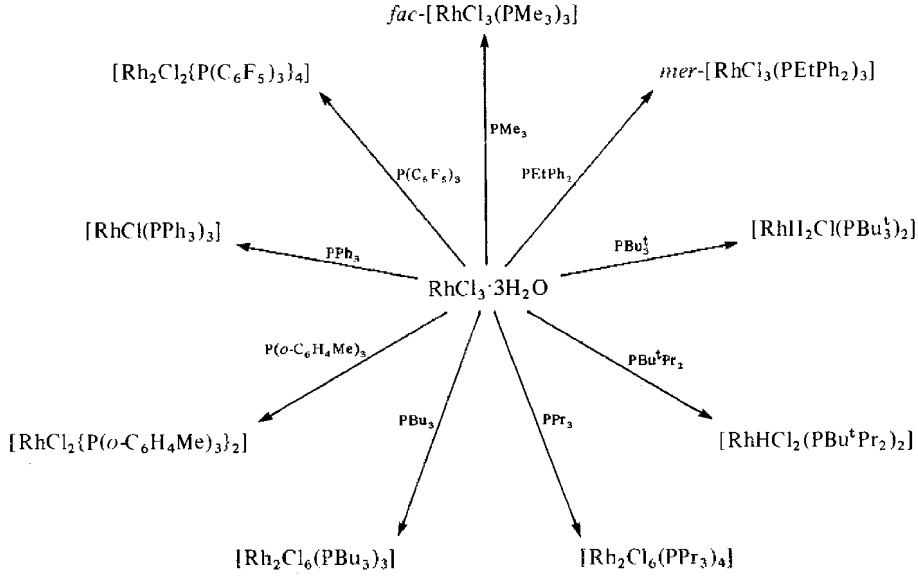


Figure 5 Reactions of $RhCl_3 \cdot 3H_2O$ with tertiary phosphines

The replacement of the tertiary phosphine ligands has seldom been attempted, and the $[RhX_3(PR_3)_2L]$ complexes have usually been prepared by addition of a neutral ligand to the coordinatively unsaturated $[RhX_3(PR_3)_2]$ complexes (see equations 188 and 211). Nevertheless, ditertiary phosphines replace the tertiary phosphine ligands in these complexes (equation 214).[229]

$$mer\text{-}[RhBr_3(PBu_3)_3] + Me_2PCH_2CH_2PMe_2 \xrightarrow[50°C]{C_6H_{14}} cis\text{-}[RhBr_2(Me_2PCH_2CH_2PMe_2)_2]Br + 3PBu_3 \quad (214)$$

The tertiary arsine complexes (Table 74) are much less numerous than those containing tertiary phosphines. They are usually prepared by the interaction of tertiary arsines with rhodium trihalides. The poorer reducing properties of tertiary arsines make it much less likely that rhodium(I) complexes will be formed in this reaction.

The halo ligands of these complexes can be replaced by other anionic ligands.[918] One of the mutually *trans* tertiary arsine ligands can be replaced by other monodentate ligands such as pyridine (equation 215). Two ligands can be replaced by bidentate nitrogen ligands (equation 216);[1014] these latter products are discussed below in Section 48.6.3.6.

$$mer\text{-}[RhX_3(AsMe_2Ph)_3] + py \longrightarrow mer\text{-}[RhX_3(AsMe_2Ph)_2py] \quad (215)$$

$$[RhX_3(AsMe_2Ph)_3] + bipy \longrightarrow [RhX_2(AsMe_2Ph)_2(bipy)]X + AsMe_2Ph \quad (216)$$

One interesting reaction undergone by the tri(styryl)arsine complexes is the bromination of the C=C bond by bromine in CCl_4 (equation 217).[1013] Similar behavior[970] is exhibited by the few tertiary stibine complexes (Table 75) that have been isolated. Few physical properties of these complexes have been investigated, but the ^{121}Sb Mössbauer parameters for both rhodium(III) complexes and the free ligands have been determined.[1016]

$$[RhBr_3\{AsMe_2(C_6H_4CH{=}CH_2)\}_3] + 3Br_2 \xrightarrow[25°C]{CCl_4} [RhBr_3\{AsMe_2(C_6H_4CHBrCH_2Br)\}_3] \quad (217)$$

48.6.3.6 $[RhX_2L_4]X$ complexes

The most numerous complexes of this general type are those containing two bidentate neutral ligands, which are discussed in Section 48.6.3.7 below. These can easily be obtained by the oxidative addition of two anionic ligands to the numerous $[Rh(LL)_2]X$ complexes. There are, however, a considerable number of complexes which contain monodentate neutral ligands. These include the catalytically important $[RhH_2(PR_3)_2(solv)_2]X$ complexes,[1017–1019] and a number of dioxygen complexes.[1020]

The cationic dihydrido complexes (Table 76) were first discovered by Schrock and Osborn during their search for alternative homogeneous hydrogenation catalysts to the ubiquitous $[RhCl(PPh_3)_3]$.[1017–1019] They found that if the cleavage of $[RhCl(diene)]_2$ complexes by PPh_3 was carried out in polar solvents in the presence of a non-coordinating anion, $[Rh(diene)(PPh_3)_2]X$ complexes were formed (equation 218). These complexes in turn underwent oxidative addition of dihydrogen to form rhodium(III) complexes. During the latter reaction the dienes were reduced to alkanes and their place in the coordination sphere occupied by solvent molecules (equation 219). The stability of the dihydrido complex obtained depends markedly upon the tertiary phosphine present. Many complexes readily lose H_2 and revert to rhodium(I) complexes.[1025] Since the dihydrido complexes catalyze the hydrogenation of alkenes by the dihydride route, and the rhodium(I) complexes by the alkene route, their stability and rates of formation are of considerable mechanistic importance.[1026] It has also been shown that their stability is affected by the alkene present.[1027]

$$[RhCl(diene)]_2 + 4PPh_3 \xrightarrow{X^-} [Rh(diene)(PPh_3)_2]X \quad (218)$$

$$[Rh(diene)(PPh_3)_2]X + 3H_2 \xrightarrow{\text{solvent}} [RhH_2(PPh_3)_2(solvent)_2]X + \text{alkane} \quad (219)$$

Unlike the ligands in other normally kinetically inert rhodium(III) complexes, these solvent ligands undergo rapid exchange in the dihydrido complexes with rates of $10^4 s^{-1}$ having been observed. The unusual rapidity of the exchange is due to the geometry of the cation in which the solvent molecules are *trans* to the hydrido ligands. However, the rate of exchange also depends upon the tertiary phosphine ligand present.[1024]

The solvent ligands can be displaced by bidentate ligands, such as bipy,[1019] to form the complex

$[RhH_2(PPh_3)_2(bipy)][ClO_4]$, which had previously been prepared by the borohydride reduction of $[RhRX(bipy)_2][ClO_4]$ complexes in the presence of PPh_3 (equations 220 and 221). Its IR spectrum indicates that the hydrido ligands are *cis*.[1028] Other complexes of this type have been prepared by the oxidative addition of dihydrogen to $[RhL_4]X$ complexes. The hydrido ligands are also *cis* in these complexes. The dihydrido cation $[RhH_2(PPr^i_3)_2(H_2O)_2]^+$ is less well characterized but it has been used in the photochemical production of hydrogen (equation 222).[1029]

$$[RhH_2(PR_3)_2(Me_2CO)_2]X + bipy \longrightarrow [RhH_2(PPh_3)_2(bipy)]X \quad (220)$$

$$R_3 = Ph_3, X = ClO_4; R_3 = Me_2Ph, X = PF_6$$

$$[RhRX(bipy)_2][ClO_4] + 2PPh_3 \xrightarrow[NaBH_4]{MeOH/PPh_3} [RhH_2(PPh_3)_2(bipy)][ClO_4] \quad (221)$$

$$R = Me, Et, Ph, X = I; R = PhCH_2, X = Cl, Br$$

$$[RhH_2(PPr^i_3)_2(H_2O)_2]^+ + H^+ \xrightarrow{h\nu} [RhH(PPr^i_3)_2(H_2O)_3]^{2+} + H_2 \quad (222)$$

There are two monohydrido complexes which have been prepared by the oxidative addition of hydrogen halides to $[Rh\{P(OMe)_3\}_5][BPh_4]$ (equation 223). Two other monohydrido complexes having hydrogen-bonded anions have been prepared by simultaneous substitution of and oxidative addition to dinuclear rhodium(I) complexes (equation 224). The anions give resonances at very low fields in the ^1H NMR spectra of the complexes.[1030] The physical properties of the monohydrido complexes are listed in Table 77.

$$[Rh\{P(OMe)_3\}_5][BPh_4] + HX \xrightarrow[MeOH]{NaBPh_4} [RhHX\{P(OMe)_3\}_4][BPh_4] + P(OMe)_3 \quad (223)$$

$$X = Br, I^{1023}$$

$$[RhClL_2]_2 + PPh_2(OMe) \xrightarrow[CH_2Cl_2]{HX} [RhHCl\{PPh_2(OMe)\}_4](X_2H) \quad (224)$$

$$X = Cl, CF_3CO_2$$

Yet other monohydrido complexes have been prepared by allowing α-$[RhHX_2(PEtPh_2)_3]$ to react with ethanolic perchloric acid and a bidentate ligand (equation 225).[980] Under similar conditions the β isomer forms dihalo complexes but these are better obtained from the trihalo complexes (equation 226).[1014] The coordinatively saturated complex $[Rh\{P(OMe)_3\}_5][BPh_4]$ also forms dihalo complexes upon longer reaction with hydrogen halides (equation 227; *cf*. equation 223 above). The *cis* isomer is also the major product when bromine is allowed to react with the rhodium(I) complex (equation 228). The two isomers can be separated by fractional crystallization, the minor isomer being the least soluble.[1023]

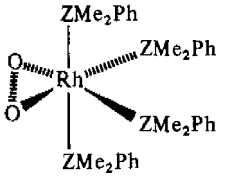
$$\beta\text{-}[RhHX(ZR_3)_3] + LL \xrightarrow[EtOH]{HClO_4} [RhX_2(ZR_3)_2(LL)][ClO_4] \quad (226)$$

$$[Rh\{P(OMe)_3\}_5][BPh_4] + HX \longrightarrow cis\text{-}[RhX_2\{P(OMe)_3\}_4][BPh_4] + P(OMe)_3 \quad (227)$$



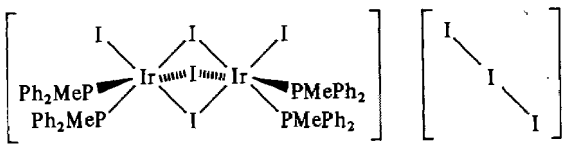
$$[Rh\{P(OMe)_3\}_5][BPh_4] + Br_2 \longrightarrow [RhBr_2\{P(OMe)_3\}_4][BPh_4] + P(OMe)_3 \quad (228)$$

The lability of the halo ligand *trans* to the tertiary phosphine in *mer*-$[RhX_3(PR_3)_3]$ complexes has been exploited in the preparation of substituted cationic complexes (equation 229).[1031]

$$[RhCl_3(PMe_2Ph)_3] + L + AgPF_6 \xrightarrow[Me_2CO]{MeOH\ or} [RhCl_2(PMe_2Ph)_3L][PF_6] \quad (229)$$

$$L = py,\ PMe_2Ph,\ H_2O,\ C_6F_5CN,\ 0.5\ p\text{-}NCC_6F_4CN$$

The dioxygen complexes $[RhO_2(ZMe_2Ph)_4]X$ (Z = P, X = BPh_4; Z = As, X = ClO_4) contain peroxo ligands. In the IR spectra of these complexes ν_{O-O} is about 854 cm^{-1}.[1031] They have been shown to have structure (**88**) by X-ray crystallography.[1032,1033]

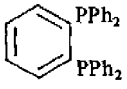


(88)

There are many complexes containing one bidentate and two monodentate neutral ligands. A preliminary crystal study has been made on one of them.[1034] It may finally be noted that the oxidative addition of sundry reagents to rhodium(I) complexes is not an infallible preparative method for complexes of this type. Nitronium tetrafluoroborate, for example, gives only a five-coordinate cation (equation 230).[1035]

$$[RhCl(PPh_3)_3] + [NO_2][BF_4] \xrightarrow{C_6H_6} [RhCl(NO_2)(PPh_3)_3][BF_4] \quad (230)$$

The addition of bromine or iodine to $[RhL_4]^+$ cations gives products whose solutions are poorly conducting. The corresponding iridium complex has been shown to be (**89**). The formation of polyhalogeno anions would explain why no corresponding complexes can be prepared by the oxidative addition of Cl_2.[1036]



(**89**)

48.6.3.7 [RhX₂(LL)₂]X′ complexes

Complexes of this type can be prepared in three principal ways. The most obvious is by allowing hydrated rhodium trichloride to react with the bidentate ligand (equation 231).[229] Unfortunately this method gives rise to both *cis* and *trans* products. However, the reactions between rhodium(III) halides and 1,2-bis(diphenylphosphino)benzene (**90**) yield the *trans* product in the case of the chloride, whilst both the bromide and iodide form the *cis* product.[1037]

$$RhCl_3 \cdot 3H_2O + 2Me_2PCH_2CH_2PMe_2 \longrightarrow [RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Cl \quad (231)$$

(**90**)

Pure samples of the 1,2-bis(dimethylphosphino)ethane complexes can be obtained by using the bidentate ligand to displace monodentate ligands from *mer*-rhodium(III) complexes.[228] Again the larger halo ligands give rise to *cis* products (equations 232 and 233).

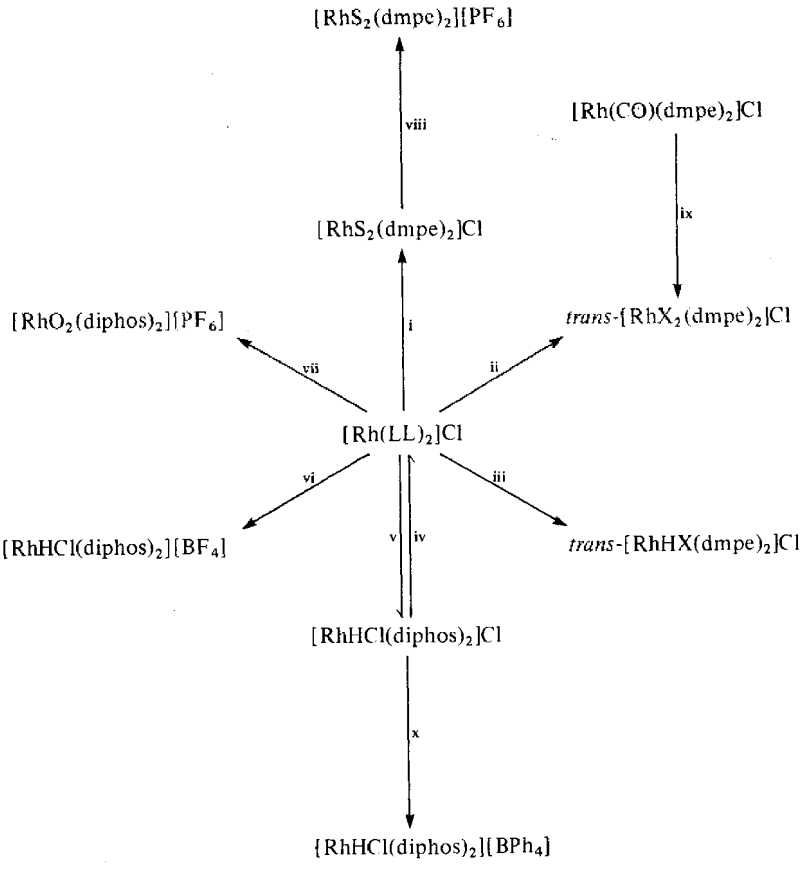
$$mer\text{-}[RhCl_3(PBu_3)_3] + 2Me_2PCH_2CH_2PMe_2 \longrightarrow trans\text{-}[RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Cl \quad (232)$$

$$mer\text{-}[RhBr_3(PBu_3)_3] + 2Me_2PCH_2CH_2PMe_2 \longrightarrow cis\text{-}[RhBr_2(Me_2PCH_2CH_2PMe_2)_2]Br \quad (233)$$

The third preparative method is to oxidize rhodium(I) complexes of the type $[Rh(LL)_2]X'$ (equation 234). Thus, oxidation gives the other geometric isomer to that provided by ligand displacement (equations 232 and 233).

$$[Rh(Me_2PCH_2CH_2PMe_2)_2]Cl \xrightarrow[CCl_4]{Cl_2} cis\text{-}[RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Cl \quad (234)$$

However, although either chlorine or bromine can displace carbon monoxide from the five-coordinate rhodium(I) cation $[Rh(CO)\{(Me_2P)_2C_2H_4\}_2]^+$, chlorine forms the *cis* isomer, whilst bromine forms the *trans* isomer (equations 235 and 236). Similar complexes can be prepared by metathetical reactions involving the ionic halide (equation 237).[229]



$$[Rh(CO)(Me_2PCH_2CH_2PMe_2)_2]Cl + Cl_2 \longrightarrow cis\text{-}[RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Cl + CO \quad (235)$$

$$[Rh(CO)(Me_2PCH_2CH_2PMe_2)_2]Cl + Br_2 \longrightarrow trans\text{-}[RhBr_2(Me_2PCH_2CH_2PMe_2)_2]Br + CO \quad (236)$$

$$trans\text{-}[RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Cl + LiBr \longrightarrow trans\text{-}[RhCl_2(Me_2PCH_2CH_2PMe_2)_2]Br \quad (237)$$

The range of products that can be obtained from oxidative addition reactions is illustrated by those of $[Rh(diphos)_2]Cl$ (Figure 6). Other small molecules besides the halogens add oxidatively to $[Rh(LL)_2]X$ complexes. Hydrogen adds reversibly to $[Rh\{(Me_2P)_2C_2H_4\}_2]Cl$, to form a dihydrido complex (equation 238). The dihydrido complexes have generally been prepared by oxidative addition reactions; their physical properties are listed in Table 79.

Hydrogen chloride, on the other hand, adds irreversibly to both four and five coordinate

i, LL = dmpe, S_8, CH_2Cl_2;[1042] ii, LL = dmpe, X_2 (X = Cl, Br);[228] iii, LL = dmpe, HX (X = Cl, Br);[228] iv, $HClO_4$;[214] v, LL = diphos, HCl;[214] vi, LL = diphos, $NaBF_4$, $HCl_{(g)}$, MeOH;[223] vii, LL = diphos, NH_4PF_6, O_2, MeOH;[1039] viii, NH_4PF_6;[1042] ix, X_2 (X = Cl, Br);[228] x, $NaBPh_4$, EtOH[214]

Figure 6 Oxidative addition and metathetical reactions of complexes containing ditertiary phosphines

$$[Rh(Me_2PCH_2CH_2PMe_2)_2]Cl + H_2 \rightleftharpoons [RhH_2(Me_2PCH_2CH_2PMe)_2]Cl \quad (238)$$

rhodium(I) complexes of this ligand (equation 239). Oxidative additions of hydrogen chloride to other rhodium(I) complexes can be reversed by addition of base to a solution of the resulting monohydrido complex (equation 240).[223]

$$[Rh(Me_2PCH_2CH_2PMe_2)_2]Cl + HCl \longrightarrow [RhHCl(Me_2PCH_2CH_2PMe_2)_2]Cl \quad (239)$$

$$[Rh(LL)_2][BF_4] + HCl \underset{Et_3N/CDCl_3}{\overset{MeOH}{\rightleftharpoons}} [RhHCl(LL)_2][BF_4] \quad (240)$$

LL = $CH_2(PPh_2)_2$, $CHMe(PPh_2)_2$, diphos, $Ph_2P(CH_2)_3PPh_2$

The other hydrogen halides add oxidatively to rhodium(I) complexes of ditertiary phosphines or arsines giving rise to numerous monohydrido complexes, whose physical properties are also listed in Table 79. However, it is possible to prepare certain monohydrido complexes from rhodium(III) halides. One interesting reaction, carried out under an atmosphere of CO, gives rise to dicarbonyldichlororhodate(I) salts (equation 241).[226]

$$RhCl_3 \cdot 3H_2O + 2LL \xrightarrow[C_6H_6/EtOH]{CO,\ 78°C} [RhHCl(LL)_2][RhCl_2(CO)_2] \quad (241)$$

LL = **(19)**, **(91)**, diars

Tetrafluoroborate,[223] tetraphenylborate and iodide[227] salts of a large range of rhodium(I) complex cations react oxidatively with dioxygen (equation 242). The physical properties of the dioxygen complexes are given in Table 80. The claim that a rhodium(I) species containing a ditertiary arsine

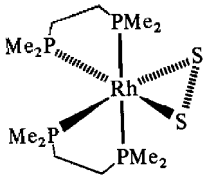
[a] With decomposition. [b] ν_{Rh-S_2}.

The $[RhO_2(diphos)_2][PF_6]$ complex can easily be prepared (equation 243), but it loses oxygen upon dissolution in anaerobic methanol. In the solid state the dioxygen complex is sufficiently stable for its structure to have been determined by X-ray crystallography. The structure (**92**) is best described as trigonal bipyramidal with monodentate dioxygen,[1039] which is in accordance with the NMR evidence.[242] The similarity to a corresponding complex containing monodentate ligands (**88**) is readily apparent. Dioxygen reacts with solid $[Rh\{(Me_2P)_2C_2H_4\}_2]Cl$ to give a material exhibiting a band attributed to ν_{O-O} in its IR spectrum at 845 cm^{-1}, but satisfactory analytical results were not obtained.[229]

$$[Rh(diphos)_2]Cl + O_2 \xrightarrow[MeOH]{NH_4PF_6} [RhO_2(diphos)_2](PF_6) \quad (243)$$

(92)

The analogous $[Rh\{Ph_2P(CH_2)_2SR\}_2][BPh_4]$ complexes also react with dioxygen (equation 244).[242] Disulfur analogs of the dioxygen complexes can be prepared by the oxidative addition of S_2 fragments from cyclooctasulfur (equation 245).



$$[Rh\{Ph_2P(CH_2)_2SR\}_2][BPh_4] + O_2 \longrightarrow [RhO_2\{Ph_2P(CH_2)_2SR\}_2][BPh_4] \quad (244)$$

R = Et, Ph

$$[Rh(LL)_2]Cl + S_8 \longrightarrow [RhS_2(LL)_2]Cl \xrightarrow{NH_4PF_6} [RhS_2(LL)_2][PF_6] \quad (245)$$

LL = $Me_2PCH_2CH_2PMe_2$,[1040,1042] diphos[1040]

Since the structure of $[IrSe_2(diphos)_2]^+$ is similar to (**93**), it may be assumed that the disulfurido-rhodium(III) cation has this structure. Indeed, such a structure has been proposed for the cation $[RhS_2\{(Me_2P)_2C_2H_4\}_2]^+$ on the basis of its IR spectrum, which has a band (attributed to $\nu_{Rh\cdot S\ S}$) at 525 cm^{-1} in both the chloride and hexafluorophosphate salts.[1042]

(93)

The dioxygen complexes undergo a number of interesting addition reactions with the lower oxides of non-metals that give rise to $[RhXX'(LL)_2]X''$ species containing coordinated oxoanions (equations 246 and 247).[230]

$$[RhO_2\{(MePhP)_2C_2H_4\}_2][PF_6] + SO_2 \longrightarrow [Rh(O_2SO_2)\{(MePhP)_2C_2H_4\}_2][PF_6] \quad (246)$$

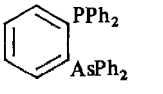
$$[RhO_2\{(MePhP)_2C_2H_4\}_2][PF_6] + N_2O_4 \longrightarrow [Rh(ONO_2)_2\{(MePhP)_2C_2H_4\}_2][PF_6] \quad (247)$$

There remain a number of other complexes of this stoichiometry that have been prepared from rhodium(III) halides; their cations usually contain halo ligands.[235] The number of these complexes has been increased by allowing them to undergo metathetical reactions with sundry metal salts (equations 248 and 249).[214] There are also a number of complexes that have been prepared from the oxidative addition of other compounds to rhodium(I) complexes. Among these are the alkyl or aryl sulfinato complexes that can be prepared by the oxidative addition of suitable sulfonyl chlorides to $[Rh\{(MePhP)_2C_2H_4\}_2][PF_6]$ (equation 250). Whilst methane sulfonyl chloride gave the S-bonded adduct (ν_{S-O} (asym) 1214, 1194; ν_{S-O} (sym) 1035 cm^{-1}), the arene sulfonyl chlorides formed mixtures of *O*- and *S*-sulfinates, the IR spectra of which showed an additional band in the region 1040–1060 cm^{-1} attributable to the latter isomer. Although no isomerization occurred in solution, the proportion of the S isomer in the solids slowly increased over a period of years.[230]

$$RhCl_3 \cdot 3H_2O + 2(Bu^tCH_2)_2PC_2H_4P(CH_2Bu^t)_2 \xrightarrow[EtOH]{NH_4PF_6} [RhCl_2\{(Bu^tCH_2)_2PC_2H_4P(CH_2Bu^t)_2\}_2][PF_6] \quad (248)$$

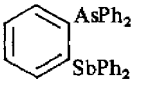
$$[RhHCl(diphos)_2]Cl + NaBPh_4 \xrightarrow{EtOH} [RhHCl(diphos)_2][BPh_4] + NaCl \quad (249)$$

$$[Rh\{(MePhP)_2C_2H_4\}_2][PF_6] + RSOCl \longrightarrow [RhCl(RSO)\{(MePhP)_2C_2H_4\}_2][PF_6] \quad (250)$$



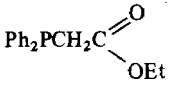
R = Me, *m*-$C_6H_4NO_2$, *p*-C_6H_4Me, 2-$C_{10}H_7$

Since, in the main, complexes of this type are themselves derivatives of other rhodium complexes there seem to have been few investigations of their chemical reactions apart from the metathetical reactions outlined above. Apart from spectral studies there has been little interest shown in their physical properties, although it may be noted that the emission observed from $[RhCl_2\{(Ph_2Z)_2C_2H_4\}_2]Cl$ (Z = P, As) complexes has been attributed to metal-localized phosphorescence.[1043] The ditertiary phosphine complexes are listed in Table 81.



The complexes of this stoichiometry containing ditertiary arsines probably outnumber those of tertiary phosphines. They have been prepared by the same general methods as the tertiary phosphine complexes, although unusually $[RhCl_2(diars)_2]Cl$ has been prepared from $Na_3[RhCl_6]$. Despite the relative antiquity of this method,[1044] it has not been generally adopted (equation 251). The physical properties of the ditertiary arsine complexes are listed in Table 82. It may be noted that the IR spectra of the sulfinato complexes indicate that these are S-bonded like their phosphorus analogs.[230]

$$Na_3[RhCl_6] + diars \longrightarrow [RhCl_2(diars)_2]Cl \quad (251)$$



There are also several complexes containing ditertiary stibines of the type $Ph_2Sb(CH_2)_3SbPh_2$, and there would probably be more were the 1,2-bis(diphenylantimono)ethane ligand known.[1046] Ligands containing two different group V donor atoms also form complexes of this type. These include the ligands (**94**)[1045] and (**95**).[1037] There are also complexes formed by other ligands which contain but one group V donor atom. These include the hexafluorophosphate salt of (**96**),[1047] and the anionic complexes of (**64**), which have been mentioned in Section 48.6.3.1 above.[917]

(94)

(95)

(96)

However, not all bidentate ligands form complexes of this stoichiometry. Although sulfur dioxide displaces CO from a binuclear rhodium(I) complex, the product (**97**) retains a rhodium–rhodium bond.[1048] The complexes of (**98**) form primarily *fac* products when allowed to react with rhodium trichloride.[1049] The strength of the rhodium–sulfur bond is also shown in the failure of diphos or

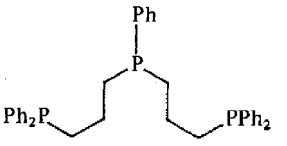
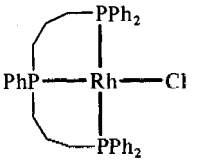
48.6.3.8 Complexes containing polydentate ligands



Polydentate ligands form both rhodium(I) and rhodium(III) complexes. Both oxidation states will be considered in this section since most of the rhodium(I) complexes readily undergo oxidative addition reactions.

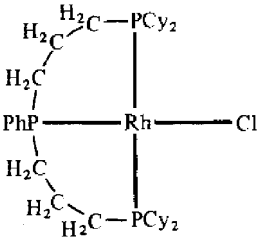
Bis(3-diphenylphosphinopropyl)phenylphosphine (**99**) forms chloro, bromo and iodo rhodium(I) complexes (equations 253 and 254). The bromo complex can be obtained by addition of a large excess of LiBr to $[RhCl(cod)]_2$ prior to addition of the neutral ligand.[1051] The iodo complex has also been prepared from $[RhI(C_8H_{12})]_2$.[1051,1052] The halo complexes (**100**) have been shown to be square planar by X-ray crystallography.[1051]



$$[RhCl(cod)]_2 + (\mathbf{99}) \longrightarrow [RhCl(\mathbf{99})] \quad (253)$$

$$[RhCl(cod)]_2 + (\mathbf{99}) \xrightarrow{LiX} [RhX(\mathbf{99})] \quad (254)$$

$$X = Br, I$$



(99)

(100)

A similar square planar complex (**101**) has been formed by the ligand $PhP\{(CH_2)_3PCy_2\}_2$. The chloro complex has been prepared by synthesizing the ligand on a rhodium(I) template as shown in Scheme 38.[1053] The related tri(tertiary arsine) ligand $PhAs\{(CH_2)_3AsMe_2\}_2$ also forms a complex of similar structure to (**101**). The triarsine complex can be formed by displacement of neutral ligands from other chlororhodium(I) complexes (equation 255).[1054]

(101)

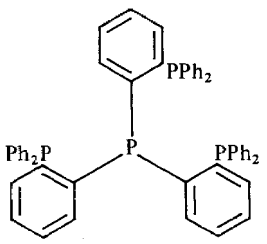
$$[RhCl(cod)]_2 + 2Cy_2P(CH_2)_3Cl \xrightarrow[25\,^\circ C]{C_7H_8} 2[RhCl(cod)\{Cy_2P(CH_2)_3Cl\}] \xrightarrow[Cy_2P(CH_2)_3PHPh]{Et_3N} (\mathbf{101}).$$

Scheme 38 Template synthesis of $[RhP\{(CH_2)_3PCy_2\}_2]$

$$\left.\begin{matrix}[RhCl(PPh_3)_3]\\ [RhCl(C_2H_4)_2]_2\\ [RhCl(cod)]_2\end{matrix}\right\} \xrightarrow{PhAs\{(CH_2)_3AsMe_2\}_2} [RhClAsPh\{(CH_2)_3AsMe_2\}_2] \quad (255)$$

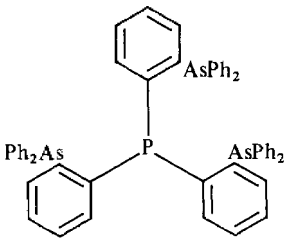
The complexes readily undergo oxidative addition reactions but can easily add additional small neutral ligands to form five coordinate complexes (equation 256).[1055] The structure of the *S*-sulfur dioxide complex has been determined.[1056] The corresponding triarsine complex also forms a sulfur dioxide adduct. The chloro ligand can be replaced by non-coordinating anions (equation 257),[1051] or in the case of the triarsine complex by carbon monoxide.[1054] The ^{31}P NMR spectra of an extensive series of derivatives have been determined, but no preparative details have been given.[1057] The bis(diphenylphosphinosilyl)amide anion functions as a tridentate ligand and displaces the majority of the monodentate tertiary phosphines from rhodium(I) complexes (equations 258 and 259).[1058]

$$[RhCl(\mathbf{99})] + L \longrightarrow [RhCl(\mathbf{99})L] \quad (256)$$



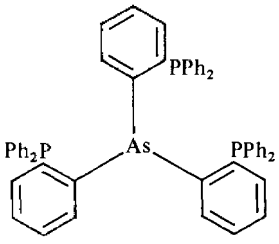
$$L = SO_2, BF_3$$

$$[RhCl(\mathbf{99})] + NH_4PF_6 \xrightarrow{MeCN} [Rh(MeCN)(\mathbf{99})][PF_6] \quad (257)$$



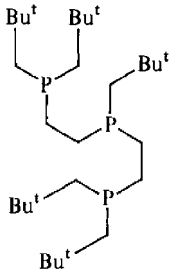
$$[RhCl(PPh_3)_3] + LiN(SiMe_2CH_2PPh_2)_2 \longrightarrow [Rh\{N(SiMe_2CH_2PPh_2)_2\}(PPh_3)] \quad (258)$$

$$[Rh(PMe_3)_4]Cl + LiN(SiMe_2CH_2PPh_2)_2 \longrightarrow [Rh\{N(SiMe_2CH_2PPh_2)_2\}(PMe_3)] \quad (259)$$



Chloro and iodo complexes of the quadridentate ligands (**102**), (**103**) and (**104**) have been prepared. No preparative details are available and the complexes are all too insoluble to confirm the speculation that they are trigonal bipyramidal.[1059]

(102)



(103)

(104)

The rhodium(III) complexes can be prepared either by oxidative addition to the corresponding rhodium(I) complexes or by direct reaction of the ligands with rhodium(III) salts. Normally the reducing properties of tertiary polyphosphines ensure that rhodium(I) complexes are formed; hence the rhodium(III) complexes of these ligands have been prepared *via* oxidative addition reactions. However, the sterically hindered ligand (**105**) fails to reduce hydrated rhodium trichloride even when allowed to react with the latter in refluxing ethanol (equation 260).[235]

(105)

$$RhCl_3 \cdot 3H_2O + (\mathbf{105}) \longrightarrow [RhCl_3(\mathbf{105})] \quad (260)$$

The complexes of $[PhP\{(CH_2)_3PPh_2\}_2]$ (**99**) readily undergo oxidative addition reactions (equations 261–263). Dioxygen forms a rhodium(III) complex which reacts with sulfur dioxide to give a sulfato complex and with carbon monoxide to yield a carbonato complex (equations 264–266).[1051] Similarly, the thermally stable dioxygen complex $[RhCl(O_2)PhAs\{(CH_2)_3AsMe_2\}_2]$, which can be prepared by allowing dioxygen to react with the rhodium(I) complex, is a useful source of other rhodium(III) complexes of this ligand (equation 267). Like the similar diphenylphosphino complex above it reacts with sulfur dioxide to form a yellow sulfato complex and with carbon monoxide to form a yellow-orange carbonato complex. Upon formation of these two complexes the characteristic ν_{O-O} band at 852 cm^{-1} disappears from its IR spectrum and is replaced by bands at 1255, 1140 and 640 cm^{-1} (bidentate sulfato ligand) or bands at 1650 and 1620 cm^{-1} (bidentate carbonato ligand).[1054]

$$[RhCl(\mathbf{99})] + H_2 \longrightarrow [RhH_2Cl(\mathbf{99})] \quad (261)$$

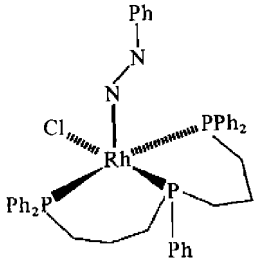
$$[RhCl(\mathbf{99})] + HCl \longrightarrow [RhHCl_2(\mathbf{99})] \quad (262)$$

$$[RhCl(\mathbf{99})] + S_8 \longrightarrow [Rh(S_2)Cl(\mathbf{99})] \quad (263)$$

$$[RhCl(\mathbf{99})] + O_2 \longrightarrow [Rh(O_2)Cl(\mathbf{99})] \quad (264)$$

$$[Rh(O_2)Cl(\mathbf{99})] + SO_2 \longrightarrow [Rh(SO_4)Cl(\mathbf{99})] \quad (265)$$

$$[Rh(O_2)Cl(\mathbf{99})] + CO \longrightarrow [Rh(CO_3)Cl(\mathbf{99})] \quad (266)$$



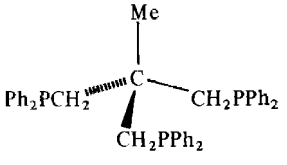
$$[RhClPhAs\{(CH_2)_3AsMe_2\}_2] + O_2 \longrightarrow [Rh(O_2)ClPhAs\{(CH_2)_3AsMe_2\}_2] \quad (267)$$

Tetrafluoroborate species also undergo two fragment oxidative addition reactions to the tritertiary phosphine complex (equation 268). The hydrido complex exhibits ν_{Rh-H} at 2199 cm^{-1}. On heating the square pyramidal[1060] diazonium complex (**106**) it is converted to the hydrido complex.[1052]

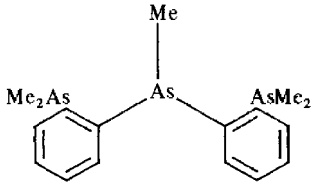
The preparation of the hydrido complex from tetrafluoroboric acid is difficult to reproduce. It has been reported that the preparation from $HBF_4 \cdot Et_2O$ is successful only if ethanol is present. Under these conditions $[RhHCl(L)(EtOH)][BF_4]$ is formed. In THF solution the THF solvate is formed.[1061]

$$[RhCl(\mathbf{99})] + [A][BF_4] \longrightarrow [RhCl(A)(\mathbf{99})][BF_4] \quad (268)$$

A = H, NO, N_2Ph



(106)



The halogens form trihalo complexes when allowed to react with [RhClL] (equation 269).[1051] The trichloro complex containing the tritertiary phosphine (**107**) can be prepared by the oxidative addition of chlorine to a rhodium(I) carbonyl complex (equation 270).[246]

$$[RhCl(\mathbf{99})] + X_2 \longrightarrow [RhX_3(\mathbf{99})] \quad (269)$$

X = Cl, Br, I

(107)

(108)

$$[RhCl(CO)(\mathbf{107})] + Cl_2 \xrightarrow{EtOH} [RhCl_3(\mathbf{107})] \quad (270)$$

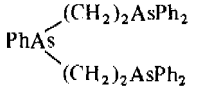
The poorer reducing properties of tertiary arsines usually result in rhodium(III) complexes being formed when these polydentate ligands are allowed to react with rhodium(III) salts. Thus, the tri(tertiary arsine) ligand (**108**) forms mixtures of facial and meridional rhodium(III) complexes (equations 271 and 272). The facial isomer is the more soluble of the two bromo complexes and it can be obtained from the mother liquors after the *mer* complex has crystallized out. Only the *fac* isomer of the iodo complex is known. It can be prepared by addition of lithium iodide to the reaction mixture (equations 273 and 274). The formation of this isomer is, perhaps, surprising on steric grounds, but if the preparation of the meridional complex is essayed by allowing lithium iodide to react with the *mer*-trichloro complex only one chloro ligand is replaced (equation 275). In acid solution the *mer*-tri(nitrato) complex can be obtained from a metathetical reaction (equation 276).

$$RhCl_3 \cdot 3H_2O + (\mathbf{108}) \xrightarrow[EtOH]{12\,M\ HCl} \textit{fac}\text{-}[RhCl_3(\mathbf{108})] \quad (271)$$

$$RhCl_3 \cdot 3H_2O + (\mathbf{108}) \xrightarrow[EtOH]{6\,M\ HCl} \textit{mer}\text{-}[RhCl_3(\mathbf{108})] \quad (272)$$

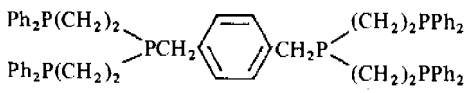
$$RhBr_3 + (\mathbf{108}) \xrightarrow{HBr} \textit{fac}\text{- and } \textit{mer}\text{-}[RhBr_3(\mathbf{108})] \quad (273)$$

$$RhCl_3 \cdot 3H_2O + (\mathbf{108}) + LiI \longrightarrow \textit{fac}\text{-}[RhI_3(\mathbf{108})] \quad (274)$$



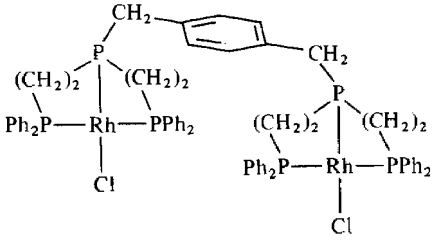
$$\textit{mer}\text{-}[RhCl_3(\mathbf{108})] + LiI \longrightarrow \textit{mer}\text{-}[RhCl_2I(\mathbf{108})] \quad (275)$$

$$\textit{mer}\text{-}[RhBr_3(\mathbf{108})] + AgNO_3 \xrightarrow{HNO_3} \textit{mer}\text{-}[Rh(NO_3)_3(\mathbf{108})] \quad (276)$$



The proposed structures of the two trichloro complexes are based upon their IR spectra. Bands due to ν_{Rh-Cl} occur at 332, 302 and 296 cm^{-1} in the spectrum of the *fac* isomer. The *mer* isomer has bands at 339, 307 and 262 cm^{-1}.

A rhodium(III) perchlorate complex containing two molecules of the tritertiary arsine can also



be prepared (equation 277).[1062] There is also a poorly characterized trichloro complex of the tridentate ligand (**109**).[1063] The hexa(tertiary phosphine) ligand (**110**) displaces neutral ligands, including some that are quite strongly bound, from rhodium(I) complexes, as in equation (278). The low value of 276 cm^{-1} for ν_{Rh-Cl} in the far-IR spectrum has led to the structure (**111**) being proposed for the product. The ligand (**110**) fails to reduce $RhCl_3 \cdot 3H_2O$ when allowed to react with it in ethanolic solution (equation 279). Further evidence for the ionic nature of the product (**112**) is provided by the reaction with NH_4PF_6 (eqution 280).[1064,1065]

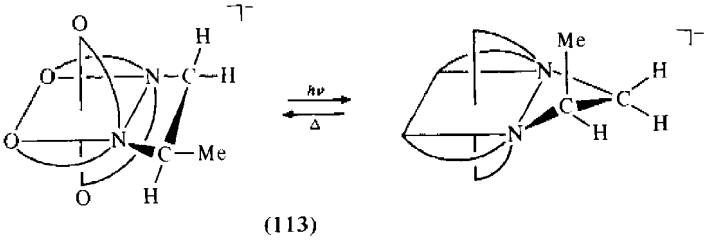
$$[RhCl(CO)(PPh_3)_2] + (\mathbf{110}) \longrightarrow [Rh_2Cl_2(\mathbf{110})] \longleftarrow [RhCl(PPh_3)_3] + (\mathbf{110}) \quad (278)$$

$$2RhCl_3 \cdot 3H_2O + (\mathbf{110}) \xrightarrow{EtOH} [Rh_2Cl_4(\mathbf{110})]Cl_2 \quad (279)$$

$$[Rh_2Cl_4(\mathbf{110})]Cl_2 + NH_4PF_6 \longrightarrow [Rh_2Cl_4(\mathbf{110})][PF_6]_2 \quad (280)$$

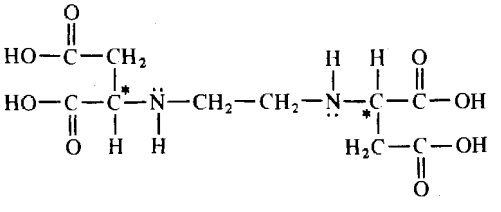
48.6.4 Mixed N—O and N—S Ligand Complexes



48.6.4.1 N—O ligand complexes

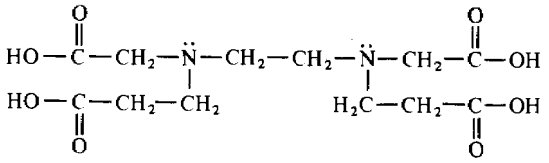
Surprisingly little work has been reported on tris(amino acid) complexes of Rh^{III}. Reaction of $RhCl_3 \cdot 3H_2O$ with sodium bicarbonate causes precipitation of Rh_2O_3, which forms [Rh(D-ala)$_3$] if heated immediately with D-alanine. Fractional crystallization allows separation of *mer*(−) and *mer*(+) isomers, as well as some impure *fac* isomer.[1066] Reaction of the Li salt of DL-methionine ($Li^+MeSCH_2CH_2CH(NH_2)COO^-$) with anhydrous $RhCl_3$ in refluxing ethanol leads to the precipitation of [Rh(DL-methionine)$_3$], in which the methionines act as anionic bidentates, bonded through the O and N atoms.[1067] The solid state reaction of $RhCl_3$ with glycine is reported to lead to [Rh(gly)$_3$], characterized thermogravimetrically and by IR, UV and ^1H NMR spectroscopy.[1068] Several $[Rh(en)_2(\text{amino acid})]^{2+}$ complexes have been prepared and resolved[644,647] (Section 48.6.2.2.ii).[644,647]

Early reports by MacNevin and co-workers[1069–1071] indicated that Rh^{III} did not form complexes with ethylenediaminetetraacetic acid (H_4edta), although MacNevin finally did report indirect evidence of a Rh^{III}–edta interaction.[1072] The first well-characterized complex was reported by Dwyer and Garvan, who overcame the inertness of Rh^{III} by heating the H_4edta with an aqueous solution of $RhCl_3 \cdot 3H_2O$ in an autoclave at 145–150 °C for four hours;[1073] this pressurized 'sealed-tube' technique remains the standard route to aminocarboxylate complexes of Rh^{III}. The resulting complex was shown to have a five-coordinate edta ligand with one uncoordinated carboxyl arm and a water coordinated at the sixth coordination site. The pK_a of the free carboxyl group is 2.32 ± 0.08, while the coordinated water has a pK_a of 9.15 ± 0.02. The complex was resolved by precipitation of the (−)-$[Co(en)_2(NO_2)_2]$(−)-[Rh(edta)(H_2O)] diastereomer, followed by recrystallization of the Rh species as the K^+ salt. Reaction of the monoaqua species with HCl or HBr leads to the tetradentate anions $[Rh(H_2edta)X_2]^-$ (X = Cl, Br) and these complexes were resolved,[1073] compared



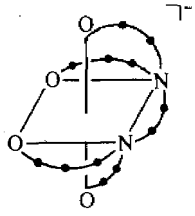
to Co analogs[1074] and characterized by IR spectroscopy.[1075] Other workers have prepared and characterized a variety of NH_4^+, K^+ and Na^+ salts.[1076–1078] NMR spectra were used to confirm that edta is pentadentate in strongly acidic solution, but that in a limited range (pH between 4 and 8), it is hexadentate, as $[Rh(edta)(H_2O)]$ reacts to form $[Rh(edta)]^-$.[1079] A coordinated water is necessary, as ^1H NMR showed that $[Rh(edta)Cl]^-$ remains unchanged between pH 1 and 9 (except for the deprotonation of the free carboxylate). Analysis of the NMR spectra also suggested that the sixth coordination site in these five-coordinate edta complexes is in the diamine plane.[1079] Solid salts of the six-coordiante $[Rh(edta)]^-$ anion have not been reported.

Dwyer and Garvan also prepared and resolved the Rh^{III} complex of 1-propylenediaminetetraacetic acid (pdta), and suggested it was a five-coordinate chelate, forming $[Rh(pdta)(H_2O)]^-$.[1080] Like the edta analog,[1073] resolved samples of the pdta complex rapidly racemize when exposed to light, but unlike the edta ion, the pdta complex spontaneously returns to the resolved form in the dark. This chromophoric behavior was not studied, but ascribed to the reversible formation of a diaqua species.[1080] Wing questioned this, showing that photolysis does not change the acetate portion of the ^1H NMR spectrum,[1081] clearly inconsistent with photoinduced aquation of an acetate arm of the pdta. He proposed that the mutarotation was due to the photoinduced formation of an unstable (axial methyl group) configuration as shown in (**113**); collapse to the stabler (equatorial methyl) configuration then occurs in the dark. The methyl group provides the driving force for this back-reaction, so the edta complex would not be expected to spontaneously re-resolve in the dark, consistent with observation.[1073,1080,1081]

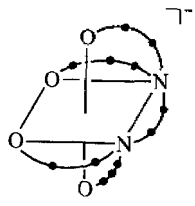


(113)

An isomer of edta with two chiral centers, ethylenediaminedisuccinic acid (edds; **114**) also forms a stable hexadentate complex with Rh^{III}.[1082] The ^1H NMR spectrum of $[Rh(S,S\text{-edds})]^-$ is virtually unchanged between pH 2 and 9, and the IR and NMR spectra are both consistent with a six-coordinate geometry. At pH ≈ 1, $[Rh(S,S\text{-edds})(H_2O)]$ forms, and at pH ≈ 10, the $[Rh(S,S\text{-edds})(OH)]^{2-}$ anion was identified in solution.[1082] The X-ray structure of Co–edta complexes shows that the glycinate rings which are in the plane of the two amine groups (the G rings) are strained, while the out-of-plane rings (R rings) are not strained. For the larger Rh^{III}, such a strain should be enhanced, leading Douglas and co-workers to study Rh^{III} complexes of a variety of aminopolycarboxylates with different chain lengths.[1083–1085] The 'sealed-tube technique' was used to react $RhCl_3 \cdot 3H_2O$ with ethylenediamine-*N*,*N*′-diacetic-*N*,*N*′-di-3-propionic acid (H_4eddda; **115a**) to form *trans*-O_5- and *trans*-(O_5O_6)-Na[Rh(eddda)] (**115b,c**). Isomer assignment was made on the basis of ^1H and ^{13}C NMR, and IR spectra.[1083] The Rh^{III} complex with 1,3-propanediaminetetraacetate (1,3-pdta) is also hexadentate, and, based on CD spectra (Table 83), comparisons to Co analogs and to the CD spectrum of $[Rh(S,S\text{-edds})]^-$, $(-)_D$-$[Rh(1,3\text{-pdta})] \cdot 2H_2O$ has been assigned the Λ configuration. The CD spectra are more intense, and broader than those of the Co^{III} and Cr^{III} analogs, as the low symmetry (C_2) components are not resolved, presumably due to the larger spin–orbit coupling of the Rh.

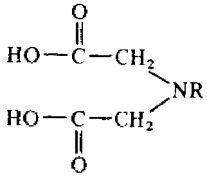


(114)

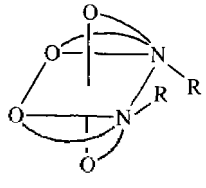


Nitrilotriacetate (NTA), *N*-methyliminodiacetate (MIDA) and iminodiacetate (IDA) (**116**) form a series of 1:1 and 1:2 (metal:ligand) complexes with Rh^{III} (and Co^{III}), which have been characterized by ^1H NMR and electronic spectra.[1087] On the basis of the NMR and a comparison to the Co analog,

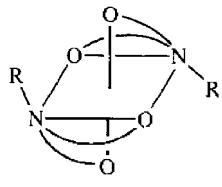
(115a)



(115b) *trans*-(O_5)



(115c) *trans*-(O_5O_6)



an ill-characterized 1:1 adduct of NTA is proposed, $[Rh(NTA)(H_2O)_2]$, in which the NTA is a tetradentate. For all but one of the 1:2 adducts, the ^1H NMR spectra show clean AB patterns, implying the *trans–fac* geometry (**117**). The more soluble isomer of $[Rh(IDA)_2]^-$ shows two AB patterns, consistent with *trans–mer* geometry. The $[Rh(NTA)_2]^-$ ion has two free carboxylate arms (one per NTA), and the NMR shows that averaging of environments between the coordinated and uncoordinated acetates is not observed.[1087]

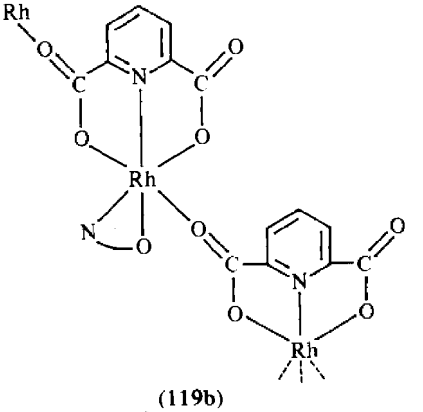
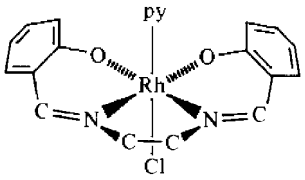
[a] Ligand abbreviations given in text.

M. E. Sheridan *et al.* have recently presented an interesting series of reports on the Rh^{III} complexes formed with the optically active tetradentate, ethylenediamine-*N,N'*-di-*S*-propionate, (*S,S*-eddp).[1088–1091] Four geometric isomers of $[Rh(S,S\text{-eddp})X_2]^{n+}$ are possible (**118**), but for Rh^{III}, only the Δ-*cis*-α and λ-*cis*-β isomers could be detected ($X_2 = 2Cl^-$, $n = -1$; ala^-, $n = 0$; en, $n = +1$). For $[Co(S,S\text{-eddp})(en)]^+$, three isomers were observed, with only the Δ-*cis*-β not formed.[1092] The electronic spectra for the two isomers of $[Rh(S,S\text{-eddp})(en)]^+$ are very similar, but the ^1H NMR is diagnostic of isomeric configuration; the α isomer shows one methyl doublet and one H quartet on the propionate arm, while the β form has dissimilar environments for the propionate arms, and shows two methyl doublets and two H quartets. Substitution of the en by two Cl^- ions occurs with retention of configuration in the Δ-*cis*-α case, and subsequent substitution of the chlorides by *S*-ala, *R*-ala and *S,R*-ala also occurs with retention of the Δ-*cis*-α configuration.[1089,1090] Reaction of λ-*cis*-β-$[Rh(S,S\text{-eddp})Cl_2]^-$ with *R*-ala, *S*-ala or OH^- leads to an unusual (but not unprecedented[1093–1096] in Co systems) isomerization to the Δ-*cis*-α configuration; even the Ag^+-induced chloride hydrolysis of the β isomer occurred with isomerization of the *S,S*-eddp backbone to the Δ-*cis*-α configuration.

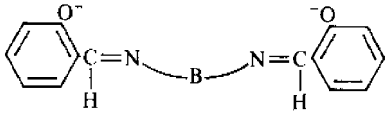


(118)

The dianion of dipicolinic acid (dipic) acts as a tridentate, forming $Na[Rh(dipic)_2]$ and a series of complexes of the form $[Rh(dipic)(N—O)]\cdot nH_2O$ (N—O = an N and O donating bidentate, including the conjugate bases of picolinic acid, nicotinic acid, isonicotinic acid, glycine and aminophenol).[1097] The bis complexes (**119a**) are diamagnetic monomers, characterized by UV/visible and IR spectra, magnetic susceptibility, and conductance measurements. The [Rh(dipic)(N—O)] complexes are presumed to be polymeric, with two oxygen atoms of a dipic carboxylate bonding to two different Rh centers, thus maintaining octahedral coordination of each Rh^{III} (**119b**). The complex $[Rh(L)_2Cl_2]Cl$ (L = isonicotinic acid hydrazide), in which L acts as an N—O bidentate, has been characterized by elemental analysis, conductance, magnetic susceptibility and electronic spectrum.[1098]

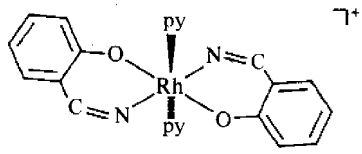


(119a)



(119b)

When a mixture of $RhCl_3\cdot 3H_2O$ with Zn dust is added to a hot pyridine solution containing *N,N'*-ethylenebis(salicylideneiminate) (the Schiff base salen), yellow crystals of [Rh(salen)py(Cl)] (**120**) form.[1099] If the Schiff base is mixed with the $RhCl_3\cdot 3H_2O$ before adding the reducing agent, a pale yellow solid, formulated as [Rh(salen)py], precipitates. The lack of solubility and reactivity of this diamagnetic solid hindered identification, and both polymeric[1099] and dimeric Rh^{II},[413] analogous to $[Rh(DMG)_2(py)]_2$, have been suggested. This same material could be prepared by reacting a methanolic solution of $salenH_2$ in Zn(Hg) with $[Rhpy_4Cl_2]Cl$.[1200] Reaction of [Rh(salen)Cl(py)] with Na(Hg) or BH_4^- in the presence of organic halides leads to [Rh(salen)R(py)] (R = Me, Et, Pr^n,



Pr^i, Bu^n, MeCO, $CH_2{=}CHCH_2$, aniline).[1099] The $[Rhpy_4Cl_2]^+$ ion reacts with a variety of Schiff bases in boiling pyridine solution (in the presence of Zn dust and PF_6^-), to generate a family of complexes of the form $[Rh(SB)py_2]PF_6$ (**121**).[1100] These all formed methyl adducts with Rh^{III}—Me bonds when reacted with methyl iodide.[413] A similar reaction path ($[Rh(py)_4Cl_2]Cl$ + Zn dust + Schiff base) was used to prepare $[Rh(N{-}O)_2py_2]^+$ (**122**). In the absence of Zn dust, $[Rh(py)_4Cl_2]^+$ is unreactive toward Schiff bases, even when refluxed in pyridine for many hours. The best yields are obtained when equivalent amounts of Zn and Rh are reacted.[1100]

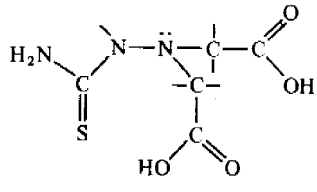
48.6.4.2 N—S bidentate complexes



Cyclohexanone thiosemicarbazide ($C_5H_{10}C{=}N{-}N(H)C{=}SNH_2$ = HL) reacts with $RhCl_3{\cdot}3H_2O$ in refluxing ethanol to form the 3:1 electrolyte $[Rh(HL)_3]Cl_3$, in which the neutral semicarbazide is a sulfur- and nitrogen-bonded bidentate. The conjugate base also forms the non-electrolyte $[Rh(L)_3]$ in which the anionic thiosemicarbazide is again an N- and S-bonded bidentate. These complexes were characterized by conductivity measurements, magnetic susceptibility (both diamagnetic), IR and electronic spectra.[1101] Another N—S bidentate, 6-methyl-2-thiouracil, forms $[Rh(L)_3]Cl_3$ salts (**123a**),[1102] and IR analysis indicates that the thiouracil is bonded through the S and the N (at the 3 position), to form four-membered chelate rings, rather than the S and N-1 bonding observed for $[M(L)_2]^{2+}$ (M = Pt or Pd). A brown diamagnetic solid, which analyzes as $[Rh(tu)_2Cl]$ (tu = the monoanion of thiouracil, where Htu = $C_4H_4N_2S_2$; (**123b**), has been characterized by IR and electronic spectra. It is 'highly insoluble in common organic and inorganic solvents', and IR analysis suggests a polymeric structure, with bridging thiouracil and chloride ligands, with the thiouracil bonded through the N and S atoms, although a specific bonding geometry was not suggested.[1103] Reaction of $RhCl_3{\cdot}3H_2O$ with 4-amino-3,5-mercapto-1,2,4-triazole (H_2TZ) leads to two incompletely characterized complexes: a brick-red solid identified as $[Rh(HTZ)_2Cl(H_2O)]$ and an orange-red $[Rh_2(TZ)_3]$.[1104] Both the HTZ^- and TZ^{2-} ions are presumably acting as bidentates, and weak IR bands near 330 and 430 cm^{-1} are assigned as Rh—S and Rh—N stretches respectively, suggesting coordination through a S and a N atom.

(123a)

(123b)

(124)

Thiosemicarbazidodiacetic acid (H_2L) (**124**) reacts with $RhCl_3{\cdot}3H_2O$ in ethanol in the presence of Lewis bases (B), forming $[Rh(L)(B)Cl]{\cdot}nH_2O$ (B = OH^-, py, α-picolone, PPh_3, aniline); in the presence of bipy or phen (NN), the product is formulated as $[Rh(L)(NN)]Cl$.[1105] Examination of models and IR analysis suggest that the thiosemicarbazide diacetic acid acts as a dianionic tripodal tetradentate, bonding to the Rh through two O, an N and an S atom.

48.6.5 Oxygen Ligands

48.6.5.1 The hexaaqua ion

Early references to Rh perchlorate complexes were presumably the first reports of the $[Rh(H_2O)_6]^{3+}$ ion. When freshly precipitated $Rh(OH)_3$ is reacted with one-third of the indicated molar quantity of perchloric acid, the resulting species in solution was identified as '$Rh(OH)_2^+$',[1106] and recrystallization of $Rh(OH)_3$ from perchloric acid led to a solid identified as '$Rh(OH)_2ClO_4$'.[1107] More recent work[1108] show that reaction of $RhCl_3 \cdot 3H_2O$ with conc. $HClO_4$ leads (after recrystallization) to 'yellow, light, fluffy needles' of $[Rh(H_2O)_6](ClO_4)_3$ with a face-centered cubic lattice. Isotopic dilution studies revealed a hydration number of 5.9 (± 0.4).[1109] It is acidic in aqueous solution (at 64 °C,[111] $K_a = 4 \times 10^{-3}$ and at 25 °C, $pK_a = 3.3$[1110]), and attempts to predict its acidity on the basis of optical basicities shows that outer-sphere solvent molecules significantly affect the experimentally determined pK_a value.[1111] The crystals are hygroscopic, and Forrester noted that replacement of the coordinated waters 'may easily be made by other ligands'.[1108]

Harris and co-workers have extensively studied the kinetics of water substitutions in $[Rh(H_2O)_6]^{3+}$ (equation 281; X = H_2O,[1109] Cl^-,[1112] Br^-[1113]). A two-term rate law was found in all three cases, as was an inverse $[H^+]$ effect. Reaction of the substituting ligand with either $[Rh(H_2O)_6]^{3+}$, or its conjugate base $[Rh(H_2O)_5OH]^{2+}$, accounts for the two-term rate law, while the inverse $[H^+]$ effect occurs because the $[Rh(H_2O)OH]^{2+}$ is several orders of magnitude more reactive than the hexaaqua ion, making the base-catalyzed path the dominant route in all but the most acidic solutions. For Cl and Br anations, the monohalo-substituted species were not isolated, as rapid substitution of a second halide leads to the (presumably *trans*) $[Rh(H_2O)_4X_2]^+$ ions. The kinetic *trans* effect was also cited to explain the reactivity of the $[Rh(H_2O)_5OH]^{2+}$ ion; for the $[Rh(H_2O)_5X]^{2+}$ series, the order of the kinetic *trans* effect induced by X was shown to be $OH \gg Br > Cl$.[1113] Kinetic studies of the anation of $[Rh(H_2O)_6]^{3+}$ by NCS^- (equation 281; X = NCS^-) have been presented by Pilipenko and co-workers;[1114–1116] at 80 °C, $k_{for} = 0.104\ M^{-1}\ s^{-1}$, $k_{rev} = 36.8\ s^{-1}$, $\Delta H^* = 160\ kJ\ mol^{-1}$,[1114], $K = 2.74 \times 10^3$.[1115]

$$[Rh(H_2O)_6]^{3+} + X \rightleftharpoons [Rh(H_2O)_5X]^{n+} + H_2O \qquad (281)$$

48.6.5.2 The tris(oxalato) ion

First prepared by Werner,[1117] the $[Rh(ox)_3]^{3-}$ ion has an electronic spectrum[1118–1120] consistent with an octahedral RhO_6 chromophore. Interest in the chemistry of this ion was piqued by a suggestion, based on solid state broad-line NMR and dehydration data, that what had been called 'hydrated $K_3[Rh(ox)_3]$' was actually $K_6[Rh(ox)_3][Rh(ox)_2(oxH)(OH)] \cdot 8H_2O$,[1121] with one of the six oxalates acting as a monodentate, and an OH^- in the remaining coordination site. This was challenged by Gillard and coworkers,[1122] who noted that aqueous solutions of $[Rh(ox)_3]^{3-}$ are neutral, the NMR shows no rapidly exchanging protons and the Raman, electronic and CD spectra are virtually invariant between pH 2 and 11. Their differential thermal analysis also did not support the monodentate oxalate model.[1122] A single-crystal X-ray structure showed that in the solid state, $K_3[Rh(ox)_3]$ is a tris-chelated, distorted octahedral complex, but that the K^+ ions are unusually close to the Rh center.[1123] Each K^+ ion is coordinated by seven H_2O molecules, and sits directly above a triangular plane of oxygens of the Rh coordination sphere only 3.48 Å from the rhodium; the earlier suggestion[1121] of a monodentate oxalate ligand was readily explained in terms of this structure.[1123]

The $[Rh(ox)_3]^{3-}$ ion was initially resolved as the strychnine salt,[1117] and more recently by precipitation of $(-)[Co(en)_3](-)[Rh(ox)_3]$.[1124] The CD spectrum of $(+)$-$[Rh(ox)_3]^{3-}$ in a crystal of $NaMgAl(ox)_3 \cdot 9H_2O$ is consistent with a trigonal structure in solution, again inconsistent with the monodentate model.[1125] The slow racemization of $[Rh(ox)_3]^{3-}$ was first noticed by Werner,[1117] and Odell *et al.* have studied the acid-catalyzed racemization;[1126] at 44.6 °C in a 1.0 M $HClO_4$ solution, the rate of racemization is $5.03 \times 10^{-5}\ s^{-1}$ with a ΔE^* of 84 kJ mol^{-1}. Odell did not suggest a racemization mechanism, but noted that the 'rate of racemization increases at a rate greater than the stoichiometric acidity'.[1126]

Reaction of $[Rh(ox)_3]^{3-}$ in refluxing perchloric acid leads to *cis*-$[Rh(ox)_2(H_2O)_2]^-$; subsequent substitutions lead to *cis* and *trans* isomers of $[Rh(ox)_2X_2]^{n-}$ (X = H_2O, Cl^-) which have been characterized by electronic and IR spectroscopy.[1120] Exchange of labelled ox^{2-} ion with $[Rh(ox)_3]^{3-}$ proceeds *via* a three-term kinetic expression, with a neutral path ($k = 6 \times 10^{-6}\ s^{-1}$ at 133.2 °C) as

well as acid- ($k_{H^+} = 1.5 \times 10^{-2}\,M^{-1}s^{-1}$) and base-catalyzed paths ($k_{OH^-} = 1.3 \times 10^{2}\,M^{-1}s^{-1}$).[1127] Replacement of one oxalato ligand by two waters (equation 282) was shown to be acid catalyzed, and presumed to involve a rapid acid–base preequilibrium between the $[Rh(ox)_3]^{3-}$ and $[Rh(ox)_2(mono\text{-}ox)(H_2O)]^{3-}$. A related study[1128] found $\Delta H^* = 113\,kJ\,mol^{-1}$ for equation (282).

$$[Rh(ox)_3]^{3-} + 2H_2O \longrightarrow [Rh(ox)_2(H_2O)_2]^{-} + ox^{2-} \quad (282)$$

A series of reports by Milburn and coworkers[660–662,1129] has given a convincing model for the reactivity of $[Rh(ox)_3]^{3-}$. The acid-catalyzed exchange of oxygen atoms (between solvent water and the coordinated oxalato ligands) has been studied for a variety of complexes ($[M(ox)_3]^{3-}$ for M = Co, Cr and for $[Pt(ox)_2]^{2-}$) and in each of these cases all 12 (or eight for Pt) oxygen atoms exchange at indistinguishable rates. For $[Rh(ox)_3]^{3-}$, however, half of the oxygens exchange more rapidly than the other half.[660] The outer oxygens (the more rapidly exchanging, uncoordinated atoms) exchange at a rate similar to those of $[Pt(ox)_2]^{2-}$ and $H(ox)^-$.[661] The rates of inner-oxygen exchange and racemization (of $[Rh(ox)_3]^{3-}$) are also similar.

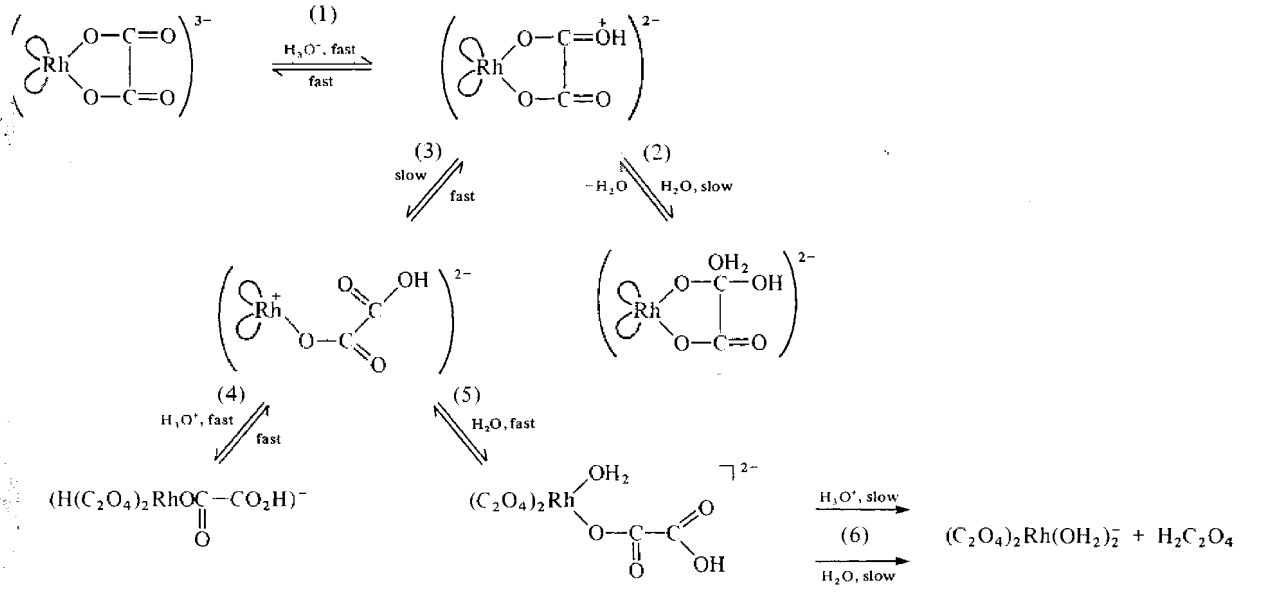
A comprehensive study[662] of the kinetics of racemization and aquation of $[Rh(ox)_3]^{3-}$ showed that both racemization and aquation proceed by two-term rate laws:

$$\text{Rate of racemization} = \{k_{r2}[H^+] + k_{r3}[H^+]^2\}\{[Rh(ox)_3]^{3-}\}$$

$$\text{Rate of aquation} = \{k_{a2}[H^+] + k_{r3}[H^+]^2\}\{[Rh(ox)_3]^{3-}\}$$

Activation parameters for these reactions, and for inner-oxygen exchange, are given in Table 84. The similarity in the rate of inner-oxygen exchange and the second-order racemization term (k_{r2}) suggests parallel mechanisms. The racemization is significantly faster than the aquation (at 56 °C, when 50% of the ions have racemized, only 3% have aquated), and the rate order for the four processes is: outer-oxygen exchange > inner-oxygen exchange ≈ racemization > aquation. This is rationalized in Scheme 39 in which outer-oxygen exchange (steps 1 and 2) does not require ring-opening before exchange, and thus should not be very sensitive to the nature of the metal; the similarity of exchange rates for Rh^{III}, Pt^{II} and H^+ oxalates supports this. Odell's observation[1126] that the rate of racemization increases at a rate greater than the stoichiometry is also rationalized by this scheme.[662]

The one-electron oxidation of $[Rh(ox)_3]^{3-}$ by Ce^{4+} in sulfuric acid solution (1 M) is two orders of magnitude slower than the analogous reaction of $[Cr(ox)_3]^{3-}$, but there are many similarities.[1129] The first step is presumed to be oxidation of coordinated oxalate to the ox^- radical anion, followed by the formation of (presumably *cis*) $[Rh(ox)_2(H_2O)_2]^-$, Ce^{III} and two equivalents of CO_2. A transition state with an oxalate acting as a bridge between Rh and Ce (with bidentate linkages to both metals) was proposed, but is not supported by the large (positive) entropy of activation for the reaction ($\Delta S^* = +146\,J\,K^{-1}\,mol^{-1}$; $\Delta H^* = 136\,kJ\,mol^{-1}$).[1129]



48.6.5.3 Acetylacetonato complexes

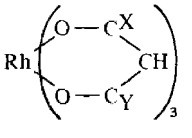
The neutral $[Rh(acac)_3]$ complex was first prepared by reacting $Rh(NO_3)_3$ with acetylacetone in an aqueous (pH 4) solution;[1130] the $[Rh(hfacac)_3]$ and $[Rh(tfacac)_3]$ (hfacac = hexafluoroacetylacetonate; tfacac = trifluoroacetylacetonate) analogs were later prepared in a similar manner.[1131] These complexes are extremely stable, as $[Rh(acac)_3]$ can be recovered unchanged from boiling dilute acid, cold concentrated sulfuric acid, and from 10% caustic soda solutions. The pseudo aromaticity of the chelate rings is demonstrated by the NMR of the ring proton (4.4τ), and by the nitration (using hydrated $Cu(NO_3)_2 \cdot 3H_2O$/acetic anhydride solutions) and monoformylation (using $POCl_3$ in dry DMF) of the chelated rings.[1131] The nitrated species is resistant to reduction,

Table 84 Activation Parameters for Reactions of $[Rh(ox)_3]^{3-}$

Reaction	*Term*[a]	ΔH (kJ mol^{-1})	ΔS (J K^{-1} mol^{-1})	*Ref.*
Racemization	k_{r2}	97.5 ± 6.3	−34.3 ± 17	662
	k_{r3}	112.1 ± 6.3	+24.3 ± 17	662
Inner-O exchange	—	97.9 ± 8.4	−26.4 ± 25	660
Aquation	k_{a2}	106.7 ± 8.4	−32.6 ± 25	662
	k_{a3}	108.4 ± 8.4	−12.1 ± 25	662

[a] Labeled terms given in text.

Scheme 39



as an acidic tin(II) chloride solution leaves the nitro function unaltered, while reaction with Zn/HAc causes decomposition.[1131] IR studies of the adducts $[Rh(acac)_3]\cdot 2(urea)$ and $[Rh(acac)_3]\cdot 3(thiourea)$ indicate that the urea and thiourea are not directly bonded to the rhodium, and that hydrogen bonding is important in the structure of the urea, but not the thiourea, adduct.[1132]

If the reaction between hydrated $RhCl_3$ and hfacac is carried out in dry ethanol, two different species (brown-yellow and red sublimates) of the composition $\{RhCl(hfacac)_2(H_2O)_3\}$ can be separated. While their insolubility makes study difficult, they were assumed to be the two possible geometric isomers of the doubly chloro-bridged dimer $[(hfacac)_2Rh(\mu\text{-}Cl)_2Rh(hfacac)_2]$.[1133]

Electron impact ionization potentials of successively substituted acac complexes $[Rh(acac)_n(3\text{-}NO_2acac)_{3-n}]$ ($n = 1$, 2 or 3) has shown that the first ionization potential is linearly related to the number of nitro substituents, increasing as the number of NO_2- substituted acac ligands increases. The authors argue that such a monotonic relationship implies that ionization occurs from a metal-centered orbital, rather than from the highest filled orbital on any of the ligands.[1134] Ionization from a metal-centered orbital is unexpected, as the lowest energy electronic transitions for these complexes have been assigned to ligand-centered π–π^* transitions (unlike the metal-centered *d*–*d* transitions observed for the analogous Co^{III} and Cr^{III} complexes),[1135] and luminescence of $[Rh(acac)_3]$ occurs from the ligand dominated $\pi^* \rightarrow \pi$ transition.[1136] (Rogerson does note that ionization from ligand orbitals could be rationalized if a delocalized ring model is used.[1134])

Reaction of the dioxygen adduct of $[RhCl(PPh_3)_3]$ with Hacac in room temperature benzene leads to a hydroperoxo complex of Rh^{III}, identified as $[Rh(PPh_3)_2(OOH)Cl(acac)]$. In the presence of triphenylphosphine, triphenyl phosphite is released, with the formation of $[Rh(PPh_3)_2(OH)\text{-}Cl(acac)]$, with *trans* phosphines (geometries were determined by ^{31}P NMR).[1137]

Morris *et al.* have presented an interesting study of the ion dissociation reactions of the molecular ions of $[Rh(acac)_3]$ and fluorinated analogs (**125**) (despite the article's title, which identifies Rh as rhenium).[1138] The ion reactions are surprisingly sensitive to changes in ligand composition. For $[Rh(hfacac)_3]$ over 60% of the metal-containing ions are in the successively formed $Rh(hfacac)_3^+$, $Rh(hfacac)_2^+$ and $Rh(hfacac)^+$ ions. The $Rh(hfacac)^+$ ion is formally a Rh^{II} species, and unlike the Co analog,[1139] it is reduced further, generating numerous Rh^I ions (*e.g.* $Rh(CO)^+$, $RhCF_3^+$). In sharp contrast, $Rh(tfacac)_2^+$ is the base peak in the mass spectrum of the trifluoro analog $[Rh(tfacac)_3]$ and undergoes virtually no reduction to Rh^{II} or Rh^I species. For the unfluorinated $[Rh(acac)_3]$, an ion reaction pattern similar to that of $[Rh(hfacac)_3]$ is observed.

$[Rh(acac)_3]$ Y = X = Me
$[Rh(tfacac)_3]$ X = Me, Y = CF_3
$[Rh(hfacac)_3]$ X = Y = CF_3

(125)

Unlike fluorinated acac complexes of most other metals, there is no evidence of F^- migration to the metal in either of these fluorinated acac complexes of Rh^{III}, but methyl migration does occur in the decomposition of $[Rh(acac)_3]$. Morris comments that Rh is the only example of the metals so far investigated that shows such sensitivity to changes in the ligand composition. When compared to their ruthenium analogs, the authors conclude that bonds to rhodium appear to be more easily broken and formed, an important aspect of the well-known catalytic activity of rhodium.[1138]

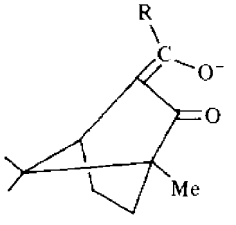
Photolysis of $[Rh(tfacac)_3]$ (tfacac is the unsymmetrically substituted 1,1,1-trifluoromethyl-acac) reveals the existence of two photoinduced reaction paths; the relative efficiency of the two paths is dramatically solvent dependent.[1140] In cyclohexane, *mer* → *cis* isomerization is the only observed photoreaction, but if ethanol or 2-propanol is added to the solvent, the photoisomerization efficiency decreases, and photodecomposition occurs. The nature of the photodecomposition products is not specified, but the enhanced photoreactivity in the presence of tri(*n*-butyl)stannane, a hydrogen atom donor, and flash and continuous photolysis studies in mixed-solvent systems 'strongly implicate hydrogen atom abstraction from the solvent as a key step in the photodecomposition of *mer*-$[Rh(tfacac)_3]$ and suggests that the photoreactive states have considerable radical character'.[1140] Analysis of quantum efficiencies implies that at least two distinct photoproduced excited states must be involved.

48.6.5.4 Dioxygen complexes

Complexes containing the Rh—O_2 moiety are now well known, but there have been a few false starts and misunderstandings along the way. The first claim for an O_2 complex of rhodium was made by Wilkinson and co-workers,[1141] who reported that $[Rh(H)(CN)_4(H_2O)]^{2-}$ reacted with O_2 to give the peroxide-bridged dimer $[(H_2O)(CN)_4Rh—O_2—Rh(CN)_4(H_2O)]^{4-}$. This was later disputed, and the reaction product identified as the protonated, peroxo monomer of Rh^{III}, $[Rh(O_2H)(CN)_4(H_2O)]^{2-}$.[1142] The solid is diamagnetic, and displays O—O stretches at 839 and 825 cm^{-1}, characteristic of an unsymmetric monomer; no such bands appear in the Co–peroxo dimer.[1142]

Reaction of $[Rh(py)_4Cl_2]Cl \cdot 5H_2O$ with O_3 (in O_2) in alkaline ethanol leads to solutions which pass through yellow-orange to green to deep blue.[1143] Addition of perchloric acid and recrystallization from conc. HCl leads to deep blue crystals identified as the superoxo-bridged dimer $[Cl(py)_4Rh—O_2—Rh(py)_4Cl](ClO_4)_3$. Variations on this theme are possible, as analogs have been prepared in which the N-heterocycle is pyridine, 4-methylpyridine or picoline; if the reaction is run in base, chloride is replaced by OH^- (or H_2O, depending on the pH). The dimers are paramagnetic, and have low energy electronic transitions characteristic of O_2^-. They are strong one-electron oxidants in H_2O, and reaction with I^- and Fe^{2+} leads to the peroxo-bridged dimer; the superoxo species is not oxidized by MnO_4^-, Cl_2 or Ce^{4+}, consistent with its assignment as a superoxo species.[1143] The analogous $[Cl(bipy)_2Rh—O_2—Rh(bipy)_2Cl](ClO_4)_3$ has been prepared by the reaction of $[Rh(bipy)_2]ClO_4$ with O_2 and Cl_2 in MeCN solution.[1144] The superoxo assignment is supported by an ESR spectrum showing $S = \frac{1}{2}$ with g factors virtually identical to those of the analogous Co^{III} complexes.[1145]

Photolysis of *cis*-$[Rh(en)_2(NO_2)_2]^+$ in the presence of O_2 leads to a red species, identified as the monomeric superoxo cation $[Rh(en)_2(NO_2)(O_2)]^+$, isolated as the chloride or nitrate salt.[1146] Elemental analyses were not presented, but electronic spectra show a low-energy charge-transfer transition (485 nm) characteristic of the superoxo ligand, and the Raman spectrum shows an O—O stretch at 1052 cm^{-1}. The *cis* isomer is much more reactive than the *trans*, and in the presence of Rh^{III} aqua species, the red-brown monomer reacts to form the familiar blue or purple dimers, $[X(en)_2Rh—O_2—Rh(en)_2X]^{n+}$ (X = Cl^-, NO_2^-, or H_2O). The ESR spectra of a variety of these complexes are consistent with the superoxo assignment.[1147] A molecular-orbital-based bonding model suggests that the unpaired electron is in a π^* orbital located largely on the O_2, consistent with the $[Rh^{III}—O_2^-]$ designation, and with the tendency of the monomeric species to dimerize.[1147]



Reaction of $[Rh(CO)_2Cl]_2$ with tetraphenylporphyrin (TPP) in glacial acetic acid generates a material identified as '[Rh(TPP)]' and the authors state that they found 'no evidence . . . for the formation of oxygen complexes . . .'.[862] This was questioned by Wayland and Newman[864] who found that octaethylporphyrin (OEP) formed a monomeric Rh^{III} superoxo complex $[Rh(OEP)(O_2)]$. Its spectral and chemical properties strongly support the superoxo designation; reexamination of the TPP complex implied that the previously identified Rh^{II} complex [Rh(TPP)] is actually the Rh^{III} superoxo complex $[Rh(TPP)(O_2)]$.[864] Dioxygen (in air) reacts with the (presumably) Rh^{II} dimers

$[Rh(L)]_2$ (L = the tetradentates, salen, salpn or saloph — see Section 48.6.4.1) to form paramagnetic (μ_{eff} = 1.80 BM at room temperature) hyperoxo–Rh^{III} complexes.[414]

48.6.5.5 Miscellaneous oxygen ligands

Solid rhodium sesquioxide, Rh_2O_3, was first identified in 1927,[1148] and has the corundum structure[1149] (hexagonally close packed O^{2-} anions distorted by the presence of Rh^{3+} cations in $\frac{2}{3}$ of the octahedral interstices). Each Rh is surrounded by six oxygens, three at 2.03 Å and three at 2.07 Å. An orthorhombic phase forms above 750 °C.[1150]

There are two examples of chiral O—O chelates (camphor derivatives) which form neutral [Rh(O—O)$_3$] complexes. Reaction of $RhCl_3 \cdot 3H_2O$ with the β-keto aldehyde (+)-hydroxymethylenecamphorate (+hmc; **126a**) in refluxing benzene leads to the two *fac* diastereoisomers D-(−)-[Rh(+hmc)$_3$] and L-(+)-[Rh(+hmc)$_3$],[1151] separable on an alumina column, and characterized by NMR, ORD/CD and UV/visible spectra. Unlike the Co^{III} analog, no *mer* isomers were detected. When $RhCl_3 \cdot 3H_2O$ is suspended in a hot, alkaline solution of (+)-3-acetylcamphorate (+atc; **126b**) for 20 h, four diastereomers (both Δ and Λ forms of both the *mer* and *fac* isomers) of [Rh(+atc)$_3$] were separated *via* silica gel plate chromatography, and identified by NMR, ORD/CD and UV/visible spectroscopy.[1152]

(**126**) **a**: R = H, (+)-hydroxymethylenecamphorate (+hmc)
b: R = Me, (+)-3-acetylcamphorate (+atc)

Several complexes with DMSO ligands have been prepared,[1153–1155] and IR spectra and the ease of formation of $[Rh(DMSO)_2Cl_4]^-$ in Cl^- saturated aqueous solution led to the suggestion that $[Rh(DMSO)_6](BF_4)_3$ has four O-bonded and two S-bonded DMSO ligands.[1154] An X-ray structure of $[RhCl_3(DMSO)_3]$ (prepared by DMSO substitution at *trans*-$[Rh(DMSO)_2Cl_4]^-$) shows that two of the DMSO ligands are S-bonded, while the third is bonded through its oxygen atom.[1155] The chlorides in $[RhCl_3(DMSO)_3]$ lie along a meridional edge, with the two S-bonded DMSO ligands in mutually *cis* sites, in contrast to a calculation which indicated that mutual repulsion would prevent mutually *cis* S-bonded DMSO ligands.[1156]

A study of the thermodynamics and kinetics of the reaction between $[Rh(H_2O)_6]^{3+}$ and the NpO_2^+ ion (equation 283) found an equilibrium constant of 3.31 ± 0.06 at 25 °C ($\Delta H = -15.0 \pm 3.8$ kJ mol^{-1}; $\Delta S = -42 \pm 13$ J K^{-1} mol^{-1}).[1157] In the presence of excess Rh^{III} the reaction is pseudo first order in $[NpO_2^+]$ ($\Delta H^* = 114 \pm 4$ kJ mol^{-1}; $\Delta S^* = 36 \pm 4$ J K^{-1} mol^{-1}). The reaction is also first order in F^- ion, but the role of the fluoride ion is not understood. Fluoride ion does not catalyze water exchange at $[Rh(H_2O)_6]^{3+}$, and the rate of formation of $[ONpORh(H_2O)_5]^{4+}$ is twice as fast as the rate of H_2O exchange at the hexaaqua ion, so it is unlikely that a dissociative ligand exchange is rate-determining in the dissociation of $[ONpORh(H_2O)_5]^{4+}$.[1157] Mössbauer spectroscopy of the ^{237}Np nucleus in the product shows that the Np is in the 5+ oxidation state, is not magnetically split by the Rh atom and that the neptunyl ion maintains its axial symmetry, supporting the suggestion that an oxygen atom of NpO_2^+ simply replaces a water in the inner coordination sphere of the Rh^{III}.[1154] The presence of the actinide gives $[ONpORh(H_2O)_5]^{4+}$ a rich electronic spectrum, but formation of the Np—O—Rh linkage hardly changes the IR and electronic spectra observed in the separate NpO_2^+ and $[Rh(H_2O)_6]^{3+}$ moieties.

$$[Rh(H_2O)_6]^{3+} + O{-}Np{-}O^+ \rightleftharpoons [O{-}Np{-}O{-}Rh(H_2O)_5]^{4+} + H_2O \qquad (283)$$

In an effort to use $[Rh(H_2O)_6]^{3+}$ as a redox-stable, diamagnetic probe, its reactivity with a variety of polyphosphates has been explored.[1159,1160] Several complexes of the form $[Rh(H_2O)_4(PP)]^{n-}$ (PP = $2PO_4^{3-}$, $HP_2O_7^{3-}$, $HP_2O_8^{5-}$, ADP or ATP) have been prepared, and characterized by electronic spectroscopy.[1160] The potential tridentate $H_2P_3O_{10}$ (PPP) is reported to form $[Rh(H_2O)(PPP)]$.[1160]

48.6.6 Sulfur and Heavier Group VI Ligands

48.6.6.1 Monodentate sulfur ligands

Alkyl and aryl sulfides coordinate to Rh^{III}. Dwyer and Nyholm first reported that refluxing aqueous ethanolic solutions of $RhCl_3 \cdot 3H_2O$ and diethyl sulfide leads to the neutral $[RhCl_3(Et_2S)_3]$.[1161] The tribromo and triiodo analogs were also reported; all three complexes are prone to dissociation of the sulfide ligand, as they smell of diethyl sulfide, and cryoscopic measurements in benzene consistently gave less than the theoretical molecular weight values. A study of their dissociation pressures showed that the stability of the Rh—S bond is greatest for the trichloro, and weakest for the triiodo complex.[1162] They are diamagnetic monomers, electronic spectra (ethanol solutions) have been recorded, and X-ray powder patterns show that they are similar to the Ir analogs,[1163] and thus were assigned the *mer* geometry.[1162] Reaction of $[RhCl_3(R_2S)_3]$ (R = Me, Et, Pr) with bipyridyl has led to *fac*- and *mer*-$[Rh(bipy)(R_2S)Cl_3]$ (R = Pr), while reaction with pyridine has generated *fac* and *mer* isomers of $[Rhpy(R_2S)_2Cl_3]$ (R = Me, Et).[1164] Walton prepared complexes of the form $[RhX_3(C_4H_8OS)_3]$ (X = Cl or Br, and C_4H_8OS is the cyclic 1,4-thioxane) and characterized them by far-IR, IR, NMR and electronic spectroscopy.[1165] The far-IR spectra imply a *fac* geometry.

Initial loss of a labile sulfide group is thought to be the first step in the catalytic reactions of $[RhCl_3(Et_2S)_3]$. In a basic solvent (which promotes sulfide labilization) it catalyzes the homogeneous hydrogenation of various alkenic substrates.[1166] The kinetics of the hydrogenation of *trans*-cinnamic acid or maleic acid using $[RhCl_3L_3]$ (L = Et_2S or $(PhCH_2)_2S$) as catalysts have been interpreted to suggest a path involving initial loss of a sulfide, followed by reaction of the coordinatively unsaturated Rh^{III} complex with H_2 and reduction to Rh^I.[1166,1167] The intermediacy of a Rh^{III} hydride was also postulated.

Initial dissociation of a NCS^- ligand is also thought to lead to the electrochemically active $[Rh(SCN)_5]^{2-}$ ion. One irreversible reduction wave ($E_{1/2} = -0.36$ V *vs.* SCE) was observed in a polarographic study of Rh^{III} in aqueous NCS^- solution, but the system was complicated by poisoning of the DME due to catalytic decomposition of SCN^- and sulfate formation.[1168]

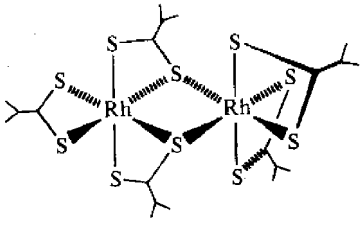
Refluxing $RhCl_3 \cdot 3H_2O$ with a variety of alkyl phenyl sulfides (PhSR for R = Me, Et, Pr^n, Bu^n) in methanol is a straightforward path to both isomeric forms of $[RhCl_3(PhSR)_3]$.[1169] The *mer* forms have been characterized in all four cases, and the *fac* form was cleanly characterized for R = Et and Pr^n; reaction of LiBr (in acetone) with *mer*-$[RhCl_3(PhSEt)_3]$ leads to *mer*-$[RhBr_3(PhSEt)_3]$. The trisulfide, $MeC(CH_2SEt)_3$ reacts with $RhCl_3 \cdot 3H_2O$ in refluxing ethanol to give *fac*-$[RhCl_3\{MeC(CH_2SEt)_3\}]$.[1169]

48.6.6.2 Sulfur chelates

(*i*) *Four-membered rings*

Stimulated by an interest in determining the position of sulfur in the spectrochemical series, Jørgensen prepared and studied the electronic spectra (Table 85) of $[Rh(dtp)_3]$ and $[Rh(dtc)_3]$ (dtp = $(EtO)_2PS_2^-$: dtc = $Et_2NCS_2^-$).[1177] The complexes were prepared by heating an aqueous solution of $RhCl_3 \cdot 3H_2O$ with the sodium salt of the ligand; the addition of a small amount of ethanol to the solution (see Section 48.6.2.5.iii) allows the reaction to proceed at room temperature and yields a cleaner product.

A series of metal dithiocarboxylates (RCS_2^-), including $[Rh(dtb)_3]$, $(NH_4)[Rh(dtb)_2Cl_2]$ and $[Rh(dtpa)_3]$, has been characterized by magnetic measurements, molecular weight determinations and electronic spectra.[1174] Because of the strong intraligand bands, characteristic of dithiocarboxylates, they display rich electronic spectra (Table 85), but the low energy transitions could be assigned to the transitions expected for a high-field, d^6 Rh^{III} center in an octahedral environment. The syntheses involve the straightforward reaction of Rh^{III} salts with the Na salt of the ligand, but of the numerous metals studied, Rh is unique in that the nature of the resulting (dtb) complex depends on the nature of the Rh^{III} starting material. If $RhCl_3 \cdot 3H_2O$ is used, $[Rh(dtb)_3]$ forms, but if $[RhCl_6]^{3-}$ reacts under virtually the same conditions, the product is $[Rh(dtb)_2Cl_2]^-$.[1174]



The N,N-disubstituted dithiocarbamate ligand ($R_2NCS_2^-$) stabilizes high oxidation states of the some first row transition metals, and BF_3 oxidation of $[Rh(Me_2NCS_2)_3]$ was reported to lead to the Rh^{IV} cation.[1178] This was questioned by Hendrickson *et al.*, who showed that the product is actually the dimeric cation $[Rh_2(Me_2NCS_2)_5]^+$.[1179] Characterization was by conductivities, IR and NMR spectroscopy and by a single crystal X-ray structure of $[Rh_2(Me_2NCS_2)_5]BF_4 \cdot 0.5CH_2Cl_2$. The

cation consists of a $[Rh(Me_2NCS_2)_2]^+$ unit coordinated to an octahedral $[Rh(Me_2NCS_2)_3]$ unit through two mutually *cis* sulfur atoms (**127**). The two Rh atoms have opposite absolute configurations, and the long Rh—Rh distance (3.556 Å) indicates that there is no significant metal–metal bonding.[1179] The structure is similar to that of the Co^{III} analog,[1180] but is in sharp contrast to the $[Ru(Et_2NCS_2)_5]^+$ cation, which has two distinct types of bridging dithiocarbamates and a short Ru—Ru distance.[1181]

(127)

Reaction of 'commercial rhodium trichloride' with HS_2PF_2 (solvent unspecified) leads to a sublimate identified as $[Rh(S_2PF_2)_3]$.[1182] A diamagnetic, red-orange solid, it is monomeric in the gas phase. While one of the least reactive of the difluorodithiophosphate metal complexes, it is rapidly hydrolyzed in air. IR analysis implies that the ligands are chelated. Red crystals of $[Rh(S_2PPh_2)_3]$ can be isolated after refluxing rhodium trichloride and diphenyldithiophosphate in $CHCl_3/CCl_4$ solution.[1183]

(*ii*) *Five-membered rings*

Complexes of the form $[Rh(S—S)_2X_2]Y$ (X = Cl, Br; Y = Cl, ClO_4, $0.5S_2O_8$, PF_6 or BPh_4), involving two different S—S bidentate [S—S = 2,5-dithiahexane (dth), $MeSCH_2CH_2SMe$ or 1,2-di(phenylthio)ethane ($PhSCH_2CH_2SPh$)] have been characterized.[1165] The methyl-substituted complexes $[Rh(dth)_2X_2]^+$ are water soluble and insoluble in organic solvents, while the phenyl derivatives are soluble in MeCN and $MeNO_2$; electronic spectra imply both complexes have the *trans* geometry. An incompletely characterized, very insoluble complex of the composition $[Rh(dth)Cl_3]$ was also isolated, and is assumed to be a dichloro-bridged dimer. These dithiahexane complexes

have resisted spirited efforts (both chemical and electrochemical) to oxidize the rhodium center to the 4+ oxidation state. Both $[Rh(dth)_2]BF_4$ and $[Rh(dth)Cl_3]_n$ are unaffected by Cl_2 in chloroform or by Ce^{4+}; $[Rh(dth)Cl_4]^-$ could not be oxidized by Cl_2 or by cyclic voltametry.[1173]

The dynamics of inversion at coordinated sulfur have been studied by variable temperature ^1H NMR for a series of 2,5-dithiahexane complexes, including $[Rh(dth)X_4]^-$ (X = Cl, Br).[1184] At room temperature in DMSO-d^6, the $[Rh(dth)Cl_4]^-$ ion displays two NMR peaks due to the SMe groups in the *meso* and the (±) isomers; as the temperature increases, the peaks broaden and coalescence occurs at 100 °C. An interfering reaction occurs in DMSO (equation 284), resulting in dimeric $[Rh_2(dth)_2Cl_6]$. Detailed interpretation of the NMR of this material was not done (five possible geometric isomers), but a *trans* geometry was assumed. The ΔG^* of coalescence for $[Rh(dth)X_4]^-$ (X = Cl, Br) and $[Rh(dth)_2Cl_6]$ are identical, within experimental error (87.3, 85.5 and 85.3 kJ mol^{-1}, respectively).[1184]

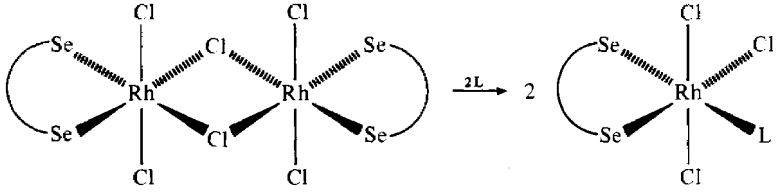
$$[Rh(dth)Cl_4]^- \xrightarrow[-Cl^-]{+DMSO} [Rh(dth)(DMSO)Cl_3] \longrightarrow 0.5[Rh_2(dth)_2Cl_6] + DMSO \qquad (284)$$

The crystal structure of tris-(*S*-methylene-1,2-dithiolato)rhodium(III) ($[Rh(S_2C_3H_5]$) shows it to be octahedral with no intraligand S–S interactions in the chelated ligands.[1185]

(*iii*) *Six-membered rings*

The dithio derivative of acetylacetone (sacsac) forms a neutral, diamagnetic monomer with Rh^{III}. The synthesis of $[Rh(sacsac)_3]$ requires the substitution of sulfur for oxygen in (presumably) coordinated acac ligands (the sacsac ligand has not been isolated in the monomeric state), and is accomplished by bubbling H_2S through an ethanol/HCl solution of $RhCl_3 \cdot 3H_2O$ and acetylacetone at 0 °C.[1175] The resulting $[Rh(sacsac)_3] \cdot 0.5\,Me_2CO$, in the form of red needles, is stable up to 250 °C, and shows two ^1H NMR signals in a 1:6 ratio (ring proton at 6.95 and the six methyl protons at 2.36 δ). Unlike its Fe^{III}, Ru^{III} and Os^{III} analogs, which all undergo a reversible one-electron reduction near 0 V (*vs.* Ag/AgCl), $[Rh(sacsac)_3]$ undergoes an irreversible two-electron reduction at −1.05 V (*vs.* Ag/AgCl).[1186] A single crystal X-ray structure confirmed that the complex is monomeric, and that the large cavities in the lattice are suitable to hold the acetones of crystallization (the acetones were not found in the crystal structure, however).[1187] The complex is a distorted octahedron, with intraligand S—Rh—S angles near 97°, and non-planar chelate rings.

The unsymmetrically substituted dithioacac ligand, *O*-ethylthioacetothioacetate (*O*-Etsacsac), reacts with an ethanolic solution of $RhCl_3 \cdot 3H_2O$ to form $[Rh(O\text{-Etsacsac})_3]$. The orange-red complex is kinetically stable, and its IR and far-IR spectra suggest an octahedral complex with three bidentate ligands in a *fac* geometry.[1188] The authors argue that the position of the methine proton in the NMR spectrum of $[M(sacsac)_3]$ (or an *O*-Etsacsac analog) is not a valid measure of the degree of aromaticity in the chelate ring. A comparison of complexes for a variety of metals shows that the chemical shift of the methine proton is linearly related to the metal's *d* shell population, the molecular geometry, and the nature of the substituent, but is not a reliable measure of the pseudo aromaticity of the sacsac chelate ring.[1188]



(*iv*) *Cyclic polysulfides*

The cyclic, tetradentate thioether (TTP = 1,4,8,11-tetrathiacyclotetradecane) reacts with $RhX_3 \cdot 3H_2O$ in boiling ethanol to generate $[Rh(TTP)X_2]X$ (X = Cl, Br).[1178] If LiI or $LiNO_2$ is added to the $RhCl_3 \cdot 3H_2O$ solution before the addition of the TTP, the corresponding diiodo or dinitro cations were formed. The complexes are 1:1 electrolytes in $MeNO_2$, and display IR and electronic spectra (Table 85) consistent with a *cis* geometry. The ligand field splitting of the sulfur ligands is comparable to the analogous macrocyclic amines. If the ethanol used in the preparation is not boiling, an insoluble material of the composition $[Rh(TTP)Cl]_xCl_{2x}$ forms, presumably a polymer or a chloro-bridged dimer.[1176]

48.6.6.3 Miscellaneous group VI ligands

The thiocyanate and selenocyanate ions (SCN^- and $SeCN^-$) react with $RhCl_3 \cdot 3H_2O$ to form $[RhX_6]^{3-}$ anions.[1170–1172] Both the SCN^- and the $SeCN^-$ are chalcogen-bonded, consistent with the soft character of the Rh^{III} in many complexes.

Two different selenium-containing bidentates have been coordinated to Rh^{III} centers. Reaction of 1,2-diselenocyanatoethane (Se_2E = $SeCNCH_2CH_2NCSe$) with $RhCl_3 \cdot 3H_2O$ in refluxing acetone/ethanol (1:1) solution generates a diamagnetic dimer $[Rh_2(Se_2E)_2Cl_6]$. It is non-conducting in DMSO, and reacts with *p*-toluidine (L) in refluxing MEK to give the diamagnetic monomer $[Rh(Se_2E)(Cl)_3(L)]$ (equation 285).[1189] IR spectra show the ν_{CN} of the $SeCN^-$ is hardly affected by coordination to the Rh^{III}, implying that Se_2E is acting as a bidentate selenium donor. Reaction of $RhCl_3 \cdot 3H_2O$ with the dipotassium salt of 1,1-dicyano-2,2-diselenoethene $(KSe)_2C{=}C(CN)_2$ in aqueous solution containing $(Ph_4P)Cl$ causes precipitation of red 'semi-solid masses', identified as the monomeric $[Ph_4P]_3[Rh\{Se_2C_2(CN)_2\}_3]$, with an octahedral Rh^{III} surrounded by three diselenolate dianionic bidentates.[1190] Conductance measurements indicate it is a 3:1 electrolyte in acetone, but attempts to recrystallize this salt caused decomposition and the formation of solid diselenides.

(285)

Collman and co-workers have presented synthetic routes to a variety of thiolato and selenido complexes of Rh^{III} with the heavy atoms covalently bonded in a linear array; one-dimensional, soluble polymers with a heavy-atom backbone surrounded by organic ligands—complexes which should have unusual electrical properties—are the ultimate goal.[1191] Oxidative addition of diphenyl diselenide to the very reactive square planar Rh^I complex [difluoro-3,3′-(trimethylenedinitrolo)bis(2-pentanone oximato)borate]Rh^I (abbreviated as $[RhL_4]$)[1192,1193] leads to *trans*-$[RhL_4(SePh)_2]$.[1194] A single-crystal X-ray structure shows the phenyl selenides are both bonded to the Rh^{III} through the Se atoms, and are *trans* to each other. Numerous complexes, including *trans*-$[RhL_4X_2]$ (where X = HS, $SGeEt_3$, $SeGeEt_3$ and the monothiol *trans*-$[RhL_4(H)(HS)]$, have also been characterized.[1191]

48.6.7 Hexahalo and Aquahalo Complexes

First reported in 1951, $K_3[RhCl_6]$ was prepared by mixing 'previously ignited NaCl' with finely ground Rh in a combustion furnace at 750 °C while Cl_2 was passed through the mixture.[1195] Work-up in aqueous HCl led to a solution which contained the $[RhCl_6]^{3-}$ ion. This octahedral ion undergoes consecutive aquations in acidic aqueous solution (*vide infra*), but it is unusually photoinert for a Rh^{III} complex. The quantum yield for aquation of the low-energy ligand field band (518 nm) is 0.02, an order of magnitude less than the higher ligand field strength amine complexes.[1196] Raman spectral studies of the analogous $[RhBr_6]^{3-}$ ion show that the ion has an octahedral ground state,[1197] and resonance Raman and far IR studies of $[RhBr_6]^{3-}$ in AgBr crystals are consistent with the expected (cubic) ground state.[1198]

The $[trenH_3]^{3+}$ cation has been used to precipitate the $[RhCl_3X_3]^{3-}$ (X = Cl, Br, I) and $[RhBr_6]^{3-}$ anions;[1199] the electronic spectra are given in Table 86. If a solution of $Na_3[RhCl_6]$ or $RhCl_3 \cdot 3H_2O$ is extracted with a benzene solution of a long chain quaternary ammonium chloride, silica gel separation of the organic layer leads to $(NX_4)_3[Rh_2Cl_9]$ (X = Et or a C_8 to C_{10} aliphatic chain).[1204] Characterized by far IR and UV/visible spectra, the X-ray powder patterns show that $[NEt_4]_3[Rh_2Cl_9]$ is isomorphous with its Cr^{III} analog,[1205] and thus consists of two pyramidally distorted $RhCl_6$ octahedra sharing a face of three Cl ligands.

Hydration of $[RhCl_6]^{3-}$ leads to a variety of aquachloro complexes of the form $[Rh(H_2O)_nCl_{6-n}]^{(n-3)+}$; the spectra and reactivity of these ions have been thoroughly studied, as aqueous solutions of $RhCl_3 \cdot 3H_2O$ vary from yellow to various shades of red and brown. Approximate formation constants have been determined[1200] and synthetic routes to specific isomers have been reported.[1201]

The ubiquitous '$RhCl_3 \cdot 3H_2O$' appears to contain a variety of aquachloro species, as do solutions prepared by aquation of $[RhCl_6]^{3-}$ or 'hydrous rhodium oxide'. Solutions of 'hydrated $RhCl_3$', treated with base, perchloric acid and then with various amounts of LiCl exhibited ^{103}Rh NMR signals which can be assigned to the 10 possible isomers of $[Rh(H_2O)_nCl_{6-n}]^{(n-3)+}$ (n = 0–6).[1206]

[a] Spectra recorded in acidic aqueous solution, except that of $[Rh_2Cl_9]^{3-}$, which was recorded in benzene. [b] Isomer assignment originally not given. Later assigned as *trans* isomer.[1203]

Commercially available samples (from three different suppliers) of '$RhCl_3 \cdot 3H_2O$' (in aqueous solution) initially displayed different ^{103}Rh NMR spectra, with varying amounts of *fac*- and *mer*-$[Rh(H_2O)_3Cl_3]$, *cis*-$[Rh(H_2O)_4Cl_2]^+$ and small amounts of *trans*-$[Rh(H_2O)_4Cl_2]^+$ (the cations presumably as chloride salts).[1200] Overnight at 80 °C, all three solutions give identical ^{103}Rh NMR spectra; solution composition was shown to be independent of the Rh^{III} concentration, implying that monomeric species dominate, and when heated in conc. HCl, all give $[RhCl_6]^3$ as the dominant species.[1206]

Similar aquahalo equilibria have been reported for aqueous hydrofluoric acid solutions of hexafluororhodate(III), and ^{19}F NMR and electronic spectroscopy have been used to identify species in the series, $[RhF_{6-n}(H_2O)_n]^{(n-3)+}$.[1207] In the presence of Cl^- ion, aquachloro complexes form, but there was no evidence of any mixed F–Cl species. (These are the only Rh^{III} complexes which claim to have a Rh—F bond.) All 10 isomers of the $[RhBr_nCl_{6-n}]^{3-}$ series have been identified (^{103}Rh NMR) in solutions prepared by dissolving commercially available hydrated rhodium trichloride in various HCl and HBr solutions.[1208] The ^{103}Rh resonances vary from 7985 p.p.m. for $[RhCl_6]^{3-}$, decreasing by about 150 p.p.m. for each bromide substituent, reaching 7077 p.p.m. for the hexabromo anion. Splitting for the expected *cis*/*trans* ($n = 2$ or 4) and *mer*/*fac* isomers ($n = 3$) was observed, although the claim that the observed 3/1 *mer*/*fac* ratio is the statistically expected ratio[1208] is not valid; statistical arguments would lead to a *mer*/*fac* ratio of 3/2.

The single crystal X-ray structure of $(NH_4)_2[RhCl_5(H_2O)]$ shows it to have the expected octahedral structure, but the Cl *trans* to the water has the shortest Rh—Cl distance, consistent with the known *trans* influence of the chloride ligand.[1209] The solid has significant intermolecular (Rh—O—H···Cl—Rh) hydrogen bonding. Aqueous solutions of $[Rh(H_2O)_nCl_{6-n}]^{(n-3)+}$ catalyze the hydration of acetylene under mild conditions.[1210] The catalytic activity is reported to increase as the number of coordinated chlorides increases, up to five chlorides, with the aquapentachloro complex being the most active, and the hexachloro ion inactive. The immense field of Rh-catalyzed catalytic hydration of unsaturated organics has been covered elsewhere[17] and generally involves π interactions between Rh and C systems, and thus will not be covered here.

Harris, Robb and co-workers have thoroughly studied the kinetics of ligand substitutions of the aquachlororhodium(III) complexes.[1201,1202,1211–1213] The reactions studied are summarized in Scheme 40, and the activation parameters for the labeled reactions are recorded in Table 87. The stereochemical course of these reactions is dominated by the *trans*-labilizing effect of chloride ligands. For

Scheme 40

[a] Values in parentheses determined from original data but analyzed with a different program.[1202] Unparenthesized values from original references. [b] At 50°C, $k = 2.1 \times 10^{-4}$ s^{-1} but a temperature variation study was not reported.

example, aquation of $[RhCl_5(H_2O)]^{2-}$ leads to only *cis*-$[RhCl_4(H_2O)_2]^-$, which undergoes subsequent aquation to yield only *fac*-$[RhCl_3(H_2O)_3]$. With no chlorides *trans* to each other, *fac*-$[RhCl_3(H_2O)_3]$ is extremely resistant to further chloride hydrolysis. Similarly, anations by chloride ion, starting with either $[Rh(H_2O)_6]^{3+}$ or *fac*-$[Rh(H_2O)_3Cl_3]$, occur more readily at a site *trans* to a coordinated chloride.[1202] Such regiospecific substitutions only occur in strongly acidic solutions, where all of the coordinated waters are fully protonated. Since OH^- has a *trans*-labilizing influence comparable to Cl^-,[1201] formation of hydroxo species dramatically alters this sequence; relevant acid dissociation constants are given in Table 88.

The mechanisms of these reactions are discussed by Palmer and Harris, and after allowing for the inevitable uncertainty caused by ion pairing, they conclude that 'the evidence tends to favor a clear dissociative (five-coordinate intermediate) mechanism'.[1202] Additional support for a dissociative mechanism in the substitutions of aquachlororhodium(III) complexes comes from Cl^- isotopic exchange studies of $[RhCl_6]^{3-}$ and $[RhCl_5(H_2O)]^{2-}$, which suggested that the reactions proceed *via*

Table 88 pK_a Values of some Aquachlororhodium(III) Complexes

Complex	pK_a	*Ref.*
$[Rh(H_2O)_6]^{3+}$	3.40	1112
$[Rh(H_2O)_5Cl]^{2+}$	4.86 ± 0.01	1201
cis-$[Rh(H_2O)_4Cl_2]^+$	5.69 ± 0.03	1202
trans-$[Rh(H_2O)_4Cl_2]^+$	6.0 ± 0.1	1202
fac-$[Rh(H_2O)_3Cl_3]$	7.31 ± 0.03	1202
mer-$[Rh(H_2O)_3Cl_3]$	6.96 ± 0.04	1202

initial aquation, followed by anation, rather than *via* the exchange path expected if an associative mechanism were operating.[1212] The rates of bromide and chloride anation of $[Rh(H_2O)_6]^{3+}$ are virtually identical, further suggesting a common (Rh—O bond cleavage) rate-determining step in both reactions.[1112,1113]

Robb and co-workers have studied the kinetics of the anation of $[Rh(H_2O)Cl_5]^{2-}$ by a variety of monoanions (equation 286; X = Cl, Br, I, NO_2, N_3 or NCS).[1213] The rates of anation are relatively independent of the nature of the anating ligand ($k \approx 2.9 (\pm 1) \times 10^{-2} s^{-1}$ at 35 °C), consistent with a dissociative mechanism. The rates of equilibration of the hexachloro, pentachloro and *cis*-tetrachloro anions were studied as a function of chloride concentration and the data were fitted to the kinetic expression: $k_{obs} = k_{aq} + k_{anat}[Cl^-]$. The effect of pressure (1–1500 bar) was also monitored;[1214] for an associative reaction, ΔV^* should be negative (as low as $-18 cm^3 mol^{-1}$) and substrate independent, while a dissociative reaction should show a positive value (up to $+18 cm^3 mol^{-1}$) and be sensitive to changes in the substrate. As shown in Table 89, the results are again consistent with a dissociative mechanism. In addition, the authors note that the ΔV^* values for the aquations and anations are similar to the known partial molar volumes of the leaving groups (Cl^- and H_2O), which implies that the leaving groups are fully solvated in the transition state.[1214] A dissociative process is clearly indicated.

$$[Rh(H_2O)Cl_5]^{2-} + X^- \rightleftharpoons [Rh(X)Cl_5]^{3-} + H_2O \qquad (286)$$

Not surprisingly, Hg^{II} ion enhances the rate of Cl^- aquation from a variety of these complexes. Chan and Harris have presented a detailed kinetic study of the Hg^{II}-induced aquation of *fac*-$[Rh(H_2O)_3Cl_3]$, and the subsequently formed *cis*-$[Rh(H_2O)_4Cl_2]^+$ and $[Rh(H_2O)_5Cl]^{2+}$ ions.[1215] For each of the reactions the data are consistent with a mechanism involving preequilibrium between the Rh—Cl substrate and the Hg^{2+} ion, followed by the rate determining cleavage of the Rh—ClHg bond. For equation (287) (and the analogous reactions of *fac*-$[Rh(H_2O)_3Cl_3]$ or *cis*-$[RhCl_2(H_2O)_4]^+$), the kinetic expression: $k_{obs} = kK[Hg^{2+}]/(1 + K[Hg^{2+}])$ is observed. A double reciprocal plot (k_{obs}^{-1} as a function of $[Hg^{2+}]^{-1}$) was used to determine values for K and k. For the *fac*-trichloro, *cis*-dichloro and monochloro complexes, the values for k (s^{-1}) are 1.07 $(\pm 0.04) \times 10^{-2}$, 4.3 $(\pm 0.3) \times 10^{-5}$ and 8.9 $(\pm 1.8) \times 10^{-6}$ respectively. This decrease in rate constant parallels the rate decrease for the analogous uncatalyzed reactions. The corresponding K values (137 ± 5, 10 ± 1 and 3.0 ± 0.6, respectively), are consistent with a coulombic interpretation, as K decreases as the positive charge on the Rh substrate increases. The association constants for these aquachloro complexes are surprisingly large when one considers that there is no identifiable Hg^{2+} complex formed when Hg^{2+} is added to $[Rh(NH_3)_5Cl]^{2+}$.[1216] The value of K is relatively independent of whether the Cl—Hg moiety is *trans* to a H_2O or a Cl^-, but the rate of the subsequent reaction (k) is markedly increased by the *trans* labilizing influence of a Cl^- ligand. This observation rationalizes the rapid reaction of Hg^{2+} with *mer*-$[Rh(H_2O)_3Cl_3]$, studied by Palmer and co-workers,[1217] who used the same reaction sequence and found the same kinetic scheme for this reaction, but found the association constant (K) for *mer*-$[Rh(H_2O)_3Cl_3]$ is 758 ± 63, significantly

Table 89 Volumes of Activation of some Aquachlororhodium(III) Ions[121]

Substrate	*Reaction*[a]	ΔV^* ($cm^3 mol^{-1}$)
$[RhCl_6]^{3-}$	Aquation (a)	$+21.5 \pm 0.6$
$[RhCl_5(H_2O)]^{2-}$	Aquation (c)	$+14.3 \pm 0.5$
$[RhCl_5(H_2O)]^{2-}$	Anation (b)	$+15.7 \pm 6.5$
cis-$[RhCl_4(H_2O)_2]^-$	Anation (d)	$+14.7 \pm 1.6$

[a] Labeled reactions shown in Scheme 40.

larger than the 137 found for the *fac* isomer.[1215] The Hg^{2+} and $HgCl^{+}$ ions have comparable effects on the reaction rates, but, not surprisingly, $HgCl_2$ does not enhance Cl^- hydrolysis of these complexes.[1217]

$$[Rh(H_2O)_5Cl]^{2+} + Hg^{2+} \overset{K}{\rightleftharpoons} \{Rh(H_2O)ClHg\}^{4+} \xrightarrow{k} [Rh(H_2O)_6]^{3+} + HgCl^{+} \qquad (287)$$

The addition of trace amounts of Rh^{III} halides to photographic emulsions can marginally decrease the sensitivity, but dramatically increase the gradation of the emulsion, and is generally known as 'the rhodium effect'. The mechanism of the rhodium effect is not understood, but the available evidence suggests that the Rh^{III} is chemisorbed on the surface of the Ag halide grains,[1218] and that the Rh^{III} exerts its effect in the formation of the latent image, not in the film development.[1219] Studies monitoring the effects of $[RhX_6]^{3-}$ (X = Cl, Br, CN, SCN), $[Rh(bipy)_2Cl_2]Cl$, $[Rh(NH_3)_5Cl]Cl_2$ and $[Rh(NH_3)_6]Cl_3$, demonstrated that at least one halide (or pseudohalide) must be coordinated to the Rh^{III} for the rhodium effect to occur, suggesting a halide or pseudohalide bridge between Rh^{III} and Ag^{I} centers is involved.[1220] (Of the complexes listed above, only the hexaammine had no measurable effect on either the sensitivity or gradation of the film.) Clearly, study of the chemistry behind this effect deserves further attention.

48.7 RHODIUM(IV) COMPLEXES

Beyond the 3+ oxidation state, rhodium forms a limited number of complexes in the 4+, 5+ and 6+ oxidation states. A recent review[1221] gives an excellent summary of the chemistry of the higher oxidation state chemistry of Rh (as well as Ru, Os, Ir, Pd and Pt). For the 4+ oxidation state, the hexafluoro, hexachloro and trioxo dianions are well characterized. The known neutral species include RhF_4 and some oxides. There are also scattered reports of Rh^{IV} complexes containing substituted biguanides and Schiff base chelates.

48.7.1 Anionic Complexes

The $[RhF_6]^{2-}$ anion has been prepared by several techniques, and a variety of cations have been used to precipitate it. Yellow crystals of $M_2[RhF_6]$ were prepared by the direct reaction of F_2 with $M_2[RhCl_5]$ (M = K, Rb, Cs).[1222] All three salts have room temperature magnetic moments characteristic of one unpaired electron ($\mu_{eff} = 1.98 \pm 0.03$ BM),[1222] consistent with a high field octahedral environment (t_{2g}^5). Mixtures of NaCl and $RhCl_3$ were fluorinated with BrF_3 to yield $Na_2[RhF_6]$ ($\mu_{eff} = 2.0$ BM at room temperature);[1223] X-ray powder patterns show that anhydrous $Cs_2[RhF_6]$ is isomorphous with Na_2PtF_6, and that the earlier reported $Na_3[RhF_7]$[1224] is actually a mixture of NaF and $Na_2[RhF_6]$.[1223] Other monovalent cations used to precipitate $[RhF_6]^{2-}$ have included Li^+[1225] and NO^+.[1226] Yellow or brown salts of divalent cations (Ca, Sr, Ba, Zn, Mg, Ni or Hg) have been prepared,[1227] and the unusual Ag^{2+} ion is stabilized in the black $Ag[RhF_6]$ salt.[1228] The peroxo salt, $[O_2][RhF_6]$ has been prepared,[1226] and in $NOF_{(g)}$ it reacts to give $(NO)_2[RhF_6]$. This latter salt can also be prepared by the reaction of rhodium sponge with a mixture of gaseous NOF and F_2; if a large excess of F_2 is used, the Rh^{V} salt, $(NO)[RhF_6]$ is formed.[1226] The peroxo and nitrosyl salts of $[RhF_6]^{2-}$ have been characterized by Raman spectroscopy.

The K and Rb salts of $[RhF_6]^{2-}$ belong to the $K_2[GeF_6]$ (trigonal) structural type, while the Cs salt exists in both trigonal and hexagonal forms.[1229] With the exception of the Sr and Ba salts, $[RhF_6]^{2-}$ is quite sensitive to hydrolysis; a qualitative listing of rates of hydrolysis of group VIIIB hexafluoro dianions is $PdF_6^{2-} > RhF_6^{2-} > RuF_6^{2-} > PtF_6^{2-} > IrF_6^{2-} > OsF_6^{2-}$, with only the palladium analog more reactive.[1230]

The vibrational spectrum of the potassium salt has been measured (Rh—F stretch at 589 cm^{-1}) and it is consistent with the expected octahedral geometry for $[RhF_6]^{2-}$.[1231] Both solid state absorption spectra[1232] and diffuse reflectance spectra[1233] of $[RhF_6]^{2-}$ salts show two weak, spin-forbidden $^2T_{2g} \rightarrow {}^4T_{1g}$ and $^2T_{2g} \rightarrow {}^4T_{2g}$ transitions at long wavelength (diffuse reflectance maxima at 862 and 625 nm). A variety of stronger, spin-allowed transitions occur at higher energy (521, 472, 362 and 305 nm). Several moderately strong bands below 2500 nm were assigned to transitions between spin–orbit components of the electronic ground state.[1223]

The only other anionic Rh^{IV} halide complex, $[RhCl_6]^{2-}$, has been prepared by the oxidation of an ice-cold aqueous suspension of $Cs_3[RhCl_6]$ by Cl_2 or Ce^{IV}.[1234,1235] The cesium salt is isomorphous with $(NH_4)_2[PtCl_6]$[1234] and $Cs_2[IrCl_6]$.[1236] The reflectance spectrum of $Cs_2[RhCl_6]$ has aroused interest, as

$Cs_2[RhCl_6]$ displays the lowest energy charge-transfer transition of the platinum metal hexachloride dianions.[1237] The Cs salt is paramagnetic (μ_{eff} = 1.7 BM at 298 K),[1238] and the variation in magnetic susceptibility as a function of temperature[1238] and when diluted in a diamagnetic, isomorphous lattice of $Cs_2[PtCl_6]$[1239] was interpreted to imply a significant amount of Rh—Cl bonding in the $[RhCl_6]^{2-}$ ion. The dilution study[1239] also confirmed earlier work[1235] which showed it is exceedingly difficult to prepare pure $Cs_2[RhCl_6]$, as at least one-third of the Rh atoms in each sample studied had been reduced to Rh^{III}.

The $[RhCl_6]^{2-}$ ion is very reactive in solution, and rapidly oxidizes coordinated chlorides to chlorine; this reaction has not been thoroughly studied, but 85–88% of the anticipated Cl_2 has been recovered, and the Rh-containing product is presumably an aquachlororhodium(III) anion.[1238] Attempts to prepare salts other than cesium have not been successful,[1237] presumably because of the rapid internal redox reaction which occurs in solution; the rapid precipitation of the insoluble Cs salt lessens this contamination.

A temperature-jump study of the outer-sphere reduction of $[RhCl_6]^{2-}$ (equation 288) showed that at 10°C the equilibrium constant is 9.08 (μ = 0.05 M) and the rate of both the forward and reverse reactions are approximately diffusion controlled (the lower limit of k_{for} is $2.5 \times 10^9\ M^{-1}\ s^{-1}$).[1240]

$$[RhCl_6]^{2-} + [Ru(phen)_3]^{2+} \rightleftharpoons [RhCl_6]^{3-} + [Ru(phen)_3]^{3+} \quad (288)$$

There are scattered reports of solid salts of Rh^{IV} oxyanions. Early descriptions of a number of uncharacterized 'rhodites' have not been confirmed in recent years; these rhodites, $Na_2O \cdot 8RhO_2$ and $K_2O \cdot 6RhO_2$, were prepared by heating $M_3[Rh(NO_2)_6]$ (M = Na, K) in air at 440 °C.[1241] Heating Rh metal in Na_2CO_3 in air leads to $Na_2[RhO_3]$ with a sodium stannite type lattice.[1242] The Li salt is also reported. The solid state structure of $Sr_4[RhO_6]$ is similar to the well-characterized $Sr_4[PtO_6]$, and has a hexagonal lattice, with each rhodium octahedrally coordinated by six oxygen atoms, and linked in one-dimension through Sr atoms.[1243] The synthesis of this latter compound was not reported, and it was stated that the compound analyzed to be 'oxygen deficient', again suggesting Rh^{III} contamination.

48.7.2 Neutral Complexes

The reaction of anhydrous $RhBr_3$ with BrF_3 was reported to lead to a bromine-contaminated sample (5.8% Br) of a purple-red solid identified as RhF_4.[1223,1224] It is paramagnetic (μ_{eff} = 1.1 BM at room temperature).[1244] There is a more recent report of the preparation of RhF_4 by the direct reaction of $F_{2(g)}$ (2–3 atm, 250 °C) with Rh sponge.[1245] This material was shown to be paramagnetic, very susceptible to hydrolysis in air, and isomorphous with IrF_4 and PtF_4. This latter RhF_4 was identified as 'brown', while the earlier reported material was identified as 'purple-red'.[1223] Attempts to reduce RhF_4 with SeF_4 lead to the formation of a pale pink solid identified as $(RhF_4)_2SeF_4$.[1246] The nature of these adducts has not been reported, but the color calls to mind the pale pink, unstable RhF_4–BrF_3 adduct reported by Sharpe.[1224]

Hydrated RhO_2 has been prepared by the electrochemical or Cl_2 oxidation of Rh^{III} salts.[1247] Little solution chemistry has been reported for this species, but the hydrate is green in alkali, and blue in acetic acid solution; variation in the oxygen analyses suggests that the hydrate may be a peroxide. Thermal treatment causes decomposition of the oxide, not dehydration.[1247] Anhydrous Rh^{IV} oxide has been prepared by heating hydrated Rh_2O_3 in oxygen,[1248] or by heating $Rh(OH)_3$ or $Rh(NO_3)_3 \cdot 6H_2O$ in air at 450 °C.[1249] When heated and squeezed (700 °C, 3000 atm, 24 h) anhydrous RhO_2 forms an undistorted rutile structure, in which the Rh^{4+} ion has an effective radius of 0.62 Å (the effective radius of Pt^{4+} is 0.63 Å).[1250] There is mass spectral evidence for RhO_2, and electron impact measurements suggest an ionization potential of 10.0 eV.[1251]

Some uncharacterized Rh^{IV} complexes, presumably with Rh—O bonds, have been reported. A red solution of Rh^{IV} perchlorate has been claimed,[1252] and chemical and electrochemical oxidation of $Rh_2O_3 \cdot H_2O$ (or $[Rh(H_2O)_6]^{3+}$) in a variety of mineral acids leads to a green solution, which presumably contains some Rh^{IV} species.[1253]

48.7.3 Miscellaneous Rh^{IV} Complexes

Cyclic voltametry of the Rh^{III} complexes [Rh(R)(salen)py] (R = Me, Pr^n, Pr^i; salen = dianion of bis(salicylidene)ethylenediamine) displays reversible one-electron oxidations of the metal center. The ease of formation of the organometallic cation $[Rh(R)(salen)py]^+$ depends on the nature of the

σ-bonded alkyl ligand.[1254] Several complexes of Rh^{IV} (and Ir^{IV}) with the bidentate N^1-*p*-chlorophenyl-N^5-isopropylbiguanide (L) have been reported. The magnetic moments of $[Rh(L)_3]Cl_4$, $[Rh(L)_2X_2]Cl_4$ (X = NH_3, py), and $[Rh(L)_2Y_2]Y_2$ (Y = Cl, NO_2) are consistent with one unpaired electron (μ_{eff} = 1.65–1.82 BM).[1255] The $[Rh(L')_2Cl_2]Cl_2$ (L' = N^1-phenyl or N^1-*o*-tolyl-N^5-isopropylbiguanide) have been prepared by the $NaClO_2$ oxidation of the corresponding $[Rh(L')_2Cl_2]Cl$ salt.[1256]

Oxidation of $[Rh(S_2CNMe_2)_3]$ with BF_3 was reported to lead to '$[Rh(S_2NCMe_2)_3BF_4]$', presumably a Rh^{IV} dithiocarbamate complex.[1257] This was questioned by later work in which cyclic voltammetry was used to show that $[Rh(S_2CNMe_2)_3]$ is irreversibly oxidized (in acetone/Et_4NClO_4) at a potential of 1.24 V *vs.* Ag/AgCl. In dichloromethane or benzene, reaction of $[Rh(S_2CNMe_2)_3]$ with BF_3 leads to the binuclear Rh^{III} complex $[Rh_2(S_2CNMe_2)_5]BF_4$, not a Rh^{IV} monomer (Section 48.6.6.2).[1179] Fleischer has reported[869] that the reaction of $[Rh(CO)_2Cl]_2$ with tetraphenylporphyrin in refluxing benzene leads to the paramagnetic [Rh(TPP)(Ph)(Cl)] molecule. This unusual species was formulated as an organometallic Rh^{IV} complex, but the similarity of its structure and reactivity to other Rh^{III}–porphyrin complexes casts doubt on this oxidation state assignment (Section 48.6.2.7).

Oxidation of the Rh^{II} dimer $[Rh_2(O_2CMe)_4]$ in air with an excess of the disodium salt of 1,1-dicyano-2,2-dithiolatoethylene [in the presence of $(PPh_4)Br$ or $[NBu^n_4]I$, (MX)] affords $[M]_2[Rh\{S_2C{=}C(CN)_2\}_3]$; the same salts could be obtained starting from hydrated rhodium trichloride. While no ESR signal was detected at room temperature, a broad, featureless line was observed at −170 °C, and the anion is paramagnetic (μ_{eff} = 1.1 BM at room temperature). Voltammetric studies showed two oxidation waves, the first of which is a reversible, one-electron oxidation, presumably yielding $[Rh\{S_2C{=}C(CN)_2\}_3]^-$, but no reduction waves between 0.0 and −1.8 V could be detected.[1258]

48.8 RHODIUM(V) COMPLEXES

The complexes of Rh^V are limited to RhF_5, RhF_6^-, and a series of less thoroughly characterized oxide ions.

48.8.1 Anionic Complexes

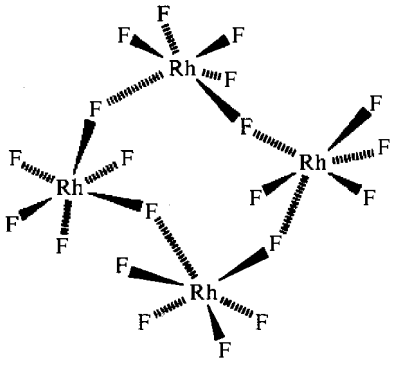
48.8.1.1 $[RhF_6]^-$

Bright yellow, moisture sensitive salts of $M[RhF_6]$ (M = Na, K, Rb, Cs) have been prepared by heating $RhCl_5$ and MCl in IrF_5.[1259] (The Cs^+ salt was elsewhere reported to be 'red-brown'.[1260]) The sodium salt appears to be the most stable, with a room temperature magnetic moment of 2.8 BM, consistent with a high field, t_{2g}^4 electronic configuration for this octahedral cation.[1260] Considerable deviation from Curie behavior was noted for the Na^+ salt, and attempts to prepare the Li^+ salt were unsuccessful. Alkali and alkaline earth salts of RhF_6^- have been prepared using ClF_3 as a vapor phase fluorinating agent.[1261] Non-metal cation salts of RhF_6^-, such as $[XeF_6]^+$, $[KrF_6]^+$,[1262] O_2^+ or NO^+,[1263] have been prepared; some vibrational data are available on the NO^+ salt.[1263]

48.8.1.2 Oxyanions of Rh^V

Various ionic oxides of Rh^V have been reported to result from the oxidation of Rh^{III} salts by hypochlorite, hypobromite or BiO_3^-.[1264–1266] The color of the hypochlorite oxidation product is very pH sensitive, ranging through yellow-orange (pH 11), green (pH 8), blue (pH 6) and purple (pH 2). The blue material is anionic, and tentatively identified as RhO_3^- (or $RhCl_6^-$), while the purple species (pH 2) is cationic, and tentatively identified as RhO_2^+ or RhO^{3+}. The 5+ oxidation state assignment is based on the used of equimolar amounts of Rh^{III} and two-electron oxidants, such as OCl^-.[1265] Perbromate oxidation of $RhCl_6^{3-}$ (excess perbromate) leads to a violet solution at pH 11. Presumably a Rh^{VI} species, this violet solution gradually turns blue (Rh^V). (Use of less OBr^- leads to the yellow-orange Rh^V species discussed above.) The blue Rh^V species is also unstable, and is reported to disproportionate (equation 289).[1265] The most carefully characterized oxyanion of Rh^V is RhO_4^{3-}. First reported by Berzelius[1267] upon chemical oxidation of Rh^{III} salts, it has also been reported to form upon anodic oxidation of Rh^{III}.[1268] In acidic solution the Rh^V oxide is reported to dispropor-

tionate (equation 290), and its oxidation half-reaction (equation 291) has a standard potential of 1.87 V *vs.* NHE.[1269]



$$3Rh^{V} \longrightarrow 2Rh^{VI} + Rh^{III} \quad (289)$$

$$3[HRhO_4]^{2-} + 2H^+ \longrightarrow 2[RhO_4]^{2-} + Rh(OH)_3 + H_2O \quad (290)$$

$$[HRhO_4]^{2-} \longrightarrow H^+ + [RhO_4]^{2-} + e^- \quad (291)$$

48.8.2 RhF_5

The pentafluoride is a dark red, paramagnetic solid (μ_{eff} = 2.93 BM at 298 K) prepared by the reaction of solid RhF_3 and F_2 (6 atm) at 400 °C.[1260] A single-crystal X-ray structure shows that solid RhF_5 has a tetrameric structure analogous to RuF_5 and IrF_5 (**128**).[1270] Each rhodium is coordinated by six fluorine atoms in an approximately octahedral arrangement. The terminal Rh—F distance averages 1.808 Å, while the Rh—F distance is significantly longer (2.01 Å) for the bridging fluorines. This compound is isostructural with the pentafluorides of Ru, Os and Ir.[1271,1272]

(128)

Numerous transition metals form $[MF_5]_n$ species, and there is an interesting correlation between the structure of the pentafluoride and the nature of the metal. All pentafluorides of the metals in Figure 7 have octahedral metal centers with bridging fluorines. Those in group A are tetrameric, with a square structure, featuring linear M—F—M bridges. Group B metals display polymeric chains, with M—F—M angles near 150°, while group C metals have tetrameric structures with M—F—M angles near 135°. All have MF_6 units with close-packed fluorine atoms; group A display distorted c.c.p. lattices, with metals in 1/5 of the octahedral holes, while group C (which includes Rh) are h.c.p. For the left side of Figure 7, bonding can be rationalized with an ionic model, involving $(MF_4^+)(F^-)$ units, while on the right side, covalent bonding is more appropriate, with two-electron/three-center bonds needed to account for the M—F—M bridges.[1270]

The mass spectrum of RhF_5 is not typical of a metal pentafluoride, and is relatively rich in ions containing more than one Rh atom.[1273] For example, as the temperature increases, the concentration of $Rh_2F_9^+$ ion increases at the expense of monomeric RhF_5^+ and RhF_6^+ fragments.

48.9 RHODIUM(VI) COMPLEXES

The 6+ state is the highest formal oxidation state recorded for rhodium, and RhF_6 is the only carefully characterized example. Following the method used to prepare RuF_6,[1274] it can be prepared

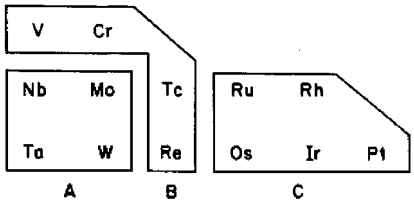


Figure 7 Metals which form $[MF]_n$ species having octahedral metal centers and bridging fluorines

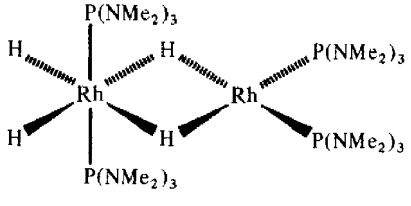
by burning rhodium metal in an atmosphere of F_2/N_2 in a cooled quartz reactor.[1275] Earlier workers[1276] had attempted the direct oxidation of rhodium metal in hot (500–600 °C) F_2, but found the major product was RhF_3, with a red-brown sublimate which contained some impurities of RhF_4 and RhF_5. The highest Rh fluoride obtained using BrF_3 as the fluorinating reagent was RhF_4.[1277]

One of the least stable of the metal hexafluorides, RhF_6, is a black volatile solid ($P_{20\,°C} = 49.5$ Torr). The gas phase is deep red brown and monomeric.[1275] At room temperature it has a body-centered cubic lattice, and, like numerous other hexafluorides, it undergoes a phase change at reduced temperature. The low temperature phase has not been well defined, but is of lower symmetry, and is probably orthorhombic.[1278] For RhF_6 the phase change occurs at -23 °C, which is comparable to the transition temperatures (°C) for other metal hexafluorides:

Mo(−36)	Tc(−19)	Ru(−30)	Rh(−23)		
W(−20)	Re(−22)	Os(−21)	Ir(−11)	Pt(−11)	U(+25)

The electronic spectrum of RhF_6 has not been reported, but ligand field calculations have been used to predict its spectrum.[1279] The IR spectrum of RhF_6 has been reported,[1280] and it is consistent with the expected O_h symmetry. Like IrF_6, the rhodium hexafluoride does not show the Jahn–Teller splittings of the E_g mode observed for the analogous Tc, Re and Os hexafluorides.



Not surprisingly, RhF_6 is a strong oxidizing agent, and, as is its ruthenium analog, is capable of oxidizing Xe.[1281] Virtually everyone who works with RhF_6 comments on its instability, however, which may account for the lack of studies dealing with its use as an oxidant.

There are several reports of Rh^{VI} oxides, but none of the compounds have been thoroughly characterized. There is a brief report of the existence of gas phase RhO_3, with an ionization potential of 11.4 eV.[1282] Differential thermal analysis indicates that RhO_2 (in the rutile form) decomposes to RhO_3 (and presumably to $Rh_{(s)}$) at 850 °C. The trioxide then decomposes to Rh metal and oxygen at 1050 °C.[1250] The most commonly reported Rh^{VI} oxide is the rhodate ion RhO_4^{2-}. The potassium salt was first reported (in 1860) as the blue crystalline product of Cl_2 oxidation of RhO_2 in concentrated KOH solutions.[1283] Brilliant blue solutions, presumed to contain the rhodate ion, have since been reported upon oxidation of alkaline solutions of Rh^{III} salts by hypochlorite,[1284] hypobromite[1285] and persulfates.[1286] Anodic oxidation of RhO_2 in dilute $HClO_4$ has also been reported to yield rhodate solutions. Little is known of the spectra or reactivity of this ion, but the Ba^{2+} salt is reported to be paramagnetic, with a susceptibility characteristic of one unpaired electron,[1286] suggesting that the presumably tetrahedral rhodate ion may exist in the unusual low spin, e_g^3 configuration.

48.10 MISCELLANEOUS RHODIUM COMPLEXES

48.10.1 Complexes of Mixed Oxidation State

There seem to be very few complexes in which there are two rhodium ions in different oxidation states. The best-authenticated examples are the $[RhH_2(PR_3)_2]_2$ complexes [R = NMe_2, $P(OPr^i)_3$]. The dimethylamino complex has been shown to have the structure (**129**) and contains both rhodium(I) and rhodium(III).[1287] The other example is provided by the $[Rh(O_2CMe)_2]^+$ ion in $[Rh(O_2CMe)_2]_2ClO_4$. This ion retains the classic lantern structure of the rhodium(II) carboxylato complexes, but the salt contains both rhodium(II) and rhodium(III).[1288]

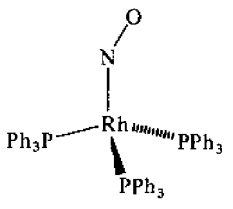
(129)

48.10.2 Nitrosyl Complexes

Nitrosyl complexes are included in this section since, as Feltham and Enemark have noted, the predominantly covalent interactions between nitric oxide and transition metals make assignment of

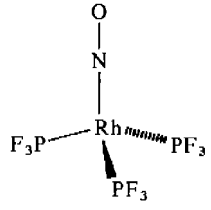
charge to the nitrosyl ligand irrelevant.[1289] The ternary nitrosyl complexes $[Rh(NO)_2X]_n$ can be prepared from the carbonyl halides,[1290–1292] or from rhodium(I) cyclooctadiene complexes (equation 292).[1293] The structures of these polymeric materials are uncertain. Griffiths has speculated that they are tetrameric cubanes rather than halo-bridged dimers.[1291]

$$[RhClL_2]_2 + NO \longrightarrow [RhCl(NO)_2]_x \quad (292)$$



$$L = CO^{1290–1292}, cod^{1293}$$

The reaction between rhodium trichloride and nitric oxide forms another ternary nitrosyl whose formulation is unknown.[1294] However, nitric oxide ligates rhodium(II) acetate (equation 293).[1295] The ternary complexes have been used to prepare other complexes, but these derivatives are commonly prepared from more accessible starting materials.



$$[Rh(O_2CMe)_2]_2 + NO \longrightarrow [Rh(O_2CMe)_2(NO)]_2 \quad (293)$$

48.10.2.1 [Rh(NO)L$_3$] complexes

X-Ray crystallography shows [Rh(NO) $(PPh_3)_3$] to adopt the structure (**130**).[1296] The bent NO group (mean Rh—N—O = 156.7°) is uncharacteristic of the nitrosyl ligand in $\{MNO\}^{10}$ complexes, which normally contain linear nitrosyl groups.[1289] Three independent molecules exist within the unit cell. In each of these three molecules the Rh—N—O plane makes a different angle with the vertical mirror plane containing a Rh—P bond. The electron diffraction study of gaseous $[Rh(NO)(PF_3)_3]$ shows it to have a nominally C_{3v} structure (**131**).[1297] The C_{3v} symmetry exhibited in the gas phase is retained in CCl_4 solution. ^{19}F NMR spectrometry shows ϕF to be 3.8 p.p.m. and coupling constants of $^1J(P–F) + 2^3J(P–F) = 1416$ Hz and $^2J(Rh–F) = 18.0$ Hz have been determined. The approximate value for $^2J(P–P)$ was 85 Hz.[1298] Nevertheless, it has been claimed that the results from X-ray photoelectron spectroscopy are more consistent with their formulation as Rh^INO^- complexes.

(130)

(131)

Nitrosyltris(triphenylphosphine)rhodium(I) was first prepared, in admixture with $[Rh(NO)Cl_2(PPh_3)_2]$, by allowing excess triphenylphosphine to react with $[Rh(NO)_2Cl]$ in tetrahydrofuran.[1299] Since that time four other preparative methods, shown in Scheme 41, have been devised.[199,201,202,1300–1303] Of these methods that using *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide is the most convenient.[199,201,202] The dark crimson-red crystals of the complex start to decompose at 115 °C in air, but at 225 °C in a helium atmosphere.[180]

Tertiary phosphine analogs have been prepared from $[Rh(NO)_2Cl]_x$.[1301] Nitrosyltris(phosphorus trifluoride)rhodium has been prepared from both rhodium(−I) and rhodium(I) complexes (equations 294–296).[1297] Their physical properties are listed in Table 90. The triphenylphosphine complex is quite reactive (Scheme 42). Both electronic[1312] and ^{31}P NMR spectrometry show the equilibrium constant for the reaction (297) to be of the order of 10^{-4} mol dm^{-3} in dichloromethane, benzene[1312,1313] or THF,[1313] so the reactivity of the complex cannot arise from the facile loss of a triphenylphosphine ligand. The invariance of the line width of the doublet at −48.8 p.p.m. ($^1J(Rh–P) = 175$ Hz) with solvent suggests that the species is unsolvated.[1313] This lack of dissociation makes the preparation of the bis(triphenylphosphine) complex to appear erroneous.[1314]

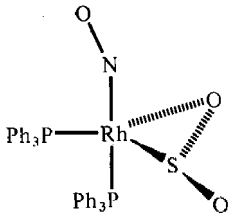
$$[RhCl(PF_3)_2]_2 + PF_3 + NO \longrightarrow [Rh(NO)(PF_3)_3] \quad (296)$$



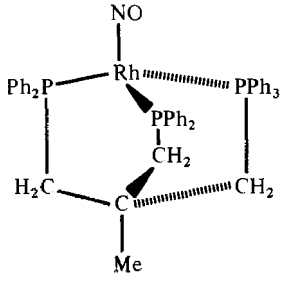
$$[Rh(NO)(PPh_3)_3] \rightleftharpoons [Rh(NO)(PPh_3)_2] + PPh_3 \quad (297)$$

The nitrosyl group is retained in the majority of the reactions. Usually two anionic ligands are added to form analogs of the important complex $[Rh(NO)Cl_2(PPh_3)_2]$ (see Section 48.10.2.2). The complex has also been used to catalyze homogeneous catalytic hydrogenation.[1315] Other reactions include the nitrosylation of iron, cobalt or nickel complexes, and conversion to the cation $[Rh(NO)_2(PPh_3)_2]^+$ by allowing the complex to react with $AgClO_4$.[151]

One reaction in which the oxidation state of the metal remains unchanged is that with sulfur dioxide (equation 298).[1310]

X-ray crystallography has shown that the SO_2 ligand binds through both sulfur and oxygen.[1310,1316] The sulfur dioxide complex (**132**) is easily oxidized by dioxygen in benzene solution to form the sulfato complex $[Rh(NO)(SO_4)(PPh_3)_2]$.[1310,1316] The product distribution when $^{18}O_2$ is the reactant implies that an intermediate sulfur bound sulfato complex is formed.[1316]

$$[Rh(NO)(PPh_3)_3] + SO_2 \xrightarrow{C_6H_6/C_7H_{16}} [Rh(NO)(PPh_3)_2(SO_2)] \quad (298)$$



(132)

Analogs of $[Rh(NO)(PPh_3)_3]$ containing tri(*p*-tolyl)-,[201,1316] tri(*p*-fluorophenyl)-[1301] or tri(*p*-chlorophenyl)-phosphine[201] have been prepared using *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide (equation 299),[201] or from $[Rh(NO)_2Cl]_x$.[1301] Only one of their reactions has been investigated (equation 300). The tritertiary phosphine (**107**) displaces all three PPh_3 ligands when allowed to react with $[Rh(NO)(PPh_3)_3]$ to form the complex (**133**).[1301] The ^{31}P NMR spectra of (**133**) and related complexes have been obtained.[1317]

$$RhCl_3 \cdot 3H_2O + 10PR_3 + p\text{-}MeC_6H_4SO_2N(NO)Me \xrightarrow[78°C]{EtOH} [Rh(NO)(PR_3)_3] \quad (299)$$

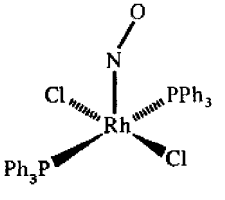
(133)

48.10.2.2 [Rh(NO)X₂L₂] complexes



The most important complex of this type is $[Rh(NO)Cl_2(PPh_3)_2]$, which was first prepared in 1962. The tri(cyclohexyl)phosphine and triphenylarsine analogs were also prepared at this date. The dichloro complexes were precipitated when excess neutral ligand was allowed to react with $[Rh(NO)_2Cl]_x$. The preparative routes available for $[Rh(NO)Cl_2(PPh_3)_2]$ are summarized in Scheme 43. Again *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide is the most convenient source of the nitrosyl ligand.[202,1323]

i, *p*-$MeC_6H_4SO_2N(NO)Me$;[202,1323] N_2, PPh_3, EtOH;[1294] ii, NOCl, CH_2Cl_2;[1319] iii, Cl^-;[1321] iv, HCl;[1304] v, NOCl;[1303] vi, PPh_3, THF;[1299] vii, CH_2Cl_2; $CHCl_3$;[1306] CCl_4;[1294,1306] PhCl; $CH_2{=}CHCH_2Cl$;[1306] HCl, C_6H_6;[1301] viii, HCl;[1309,1330] ix, H_3O^+, KNO_2; NO, $CHCl_3$, H_3O^+;[1320] x, *p*-$MeC_6H_4SO_2N(NO)Me$[201]

Scheme 43 Preparations of $[Rh(NO)Cl_2(PPh_3)_2]$

The dichlororhodium complex adopts the square pyramidal structure (**134**; L = PPh_3). The nitrosyl group is bent but the nitrogen and oxygen atoms lie on the P—Rh—P plane.[1324] The nitrosyl group in $[Rh(NO)Br_2\{P(OPh)_3\}_2]$ is also bent.[1325] Vibrational frequencies of the nitrosyl group in $[Rh(NO)X_2L_2]$ complexes are given in Table 91.

(134)

According to the ^{31}P NMR spectrum $[Rh(NO)Cl_2(PPh_3)_2]$ is not dissociated in solution.[1313]

Many analogs of $[Rh(NO)Cl_2(PPh_3)_2]$ are known since other group V ligands may replace PPh_3, and other monodentate anions the chloro ligands. However, the latter are not derivatives of $[Rh(NO)Cl_2(PPh_3)_2]$ since they have all been obtained from other sources.

If nitrosyl bromide is allowed to react with hydrated rhodium trichloride and PPh_3 in ethanol, the mixed chlorobromo complex is obtained (equation 301).[1303] When $[RhCl(PPh_3)_3]$ is the substrate the dibromo complex is formed (equation 302). This complex can also be obtained from rhodium tribromide, *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide and PPh_3. Replacement of PPh_3 by other tertiary phosphines permits analogous dibromo complexes to be prepared (*cf.* equation 299). Another source of the triphenylphosphine complex is $[Rh(NO)_2Br]_n$. The diiodo complex can be obtained from a similar reaction mixture containing LiI (equation 304).[1293]

$$RhCl_3 \cdot 3H_2O + PR_3 + p\text{-}MeC_6H_4SO_2N(NO)Me \xrightarrow{MI} [Rh(NO)I_2(PR_3)_2] \quad (304)$$

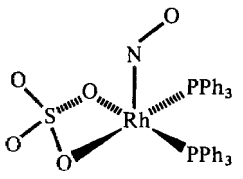
$$M = Li, R = Ph, MeC_6H_4, p\text{-}C_6H_4Cl; M = K, R = Et, Bu$$

The bis(thiocyanato) complex has been obtained by addition of KCNS to $[Rh(NO)_2(PPh_3)_2][ClO_4]$.[1304]

The green chloro(nitro) complex $[Rh(NO)Cl(NO_2)(PPh_3)_2]$ has often been observed as an intermediate in the preparation of $[Rh(NO)Cl_2(PPh_3)_2]$, but it has only been isolated when $[RhCl(PPh_3)_3]$ or *trans*-$[RhCl(CO)(PPh_3)_2]$ have been used as the starting materials (equations 305–308).[244,1318,1325]

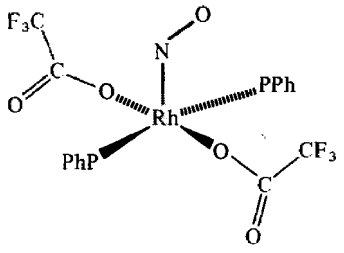
$$[RhCl(PPh_3)_2L] + N_2O_3 \xrightarrow{CH_2Cl_2} [Rh(NO)Cl(NO_2)(PPh_3)_2] \quad (305)$$

$$[RhCl(PPh_3)_3] + 4NO \xrightarrow{PhCl} [Rh(NO)Cl(NO_2)(PPh_3)_2] + PPh_3 + N_2O \quad (306)$$



$$[RhCl(CO)(PPh_3)_2] + NO \xrightarrow{C_6H_6} [Rh(NO)Cl(NO_2)(PPh_3)_2] + CO \quad (307)$$

$$[RhCl(CO)(PPh_3)_2] + NOCl \longrightarrow [Rh(NO)Cl(NO_2)(PPh_3)_2] + CO \quad (308)$$



The IR spectrum of this complex usually shows two nitrosyl absorption bands, which have been ascribed to the presence of isomers. The bands which occur at 1508, 1309 and 816 cm^{-1} arise from the nitro ligand and imply that it is N-bonded.[1325] Whilst the dichloro complex (**134**) has *trans* chloro ligands,[244] the preparation of $[Rh(NO)Cl(NO_2)(diphos)]$, in which the anionic ligands must be *cis*, allows the possibility of geometrical isomerism in $[Rh(NO)Cl(NO_2)(PPh_3)_2]$. *Cis* anionic ligands have been found in the sulfato complex $[Rh(NO)(SO_4)(PPh_3)_2]$ (**135**),[1326] and in the triphenyl phosphite complex $[Rh(NO)Br_2\{P(OPh)_3\}_2]$.[1327] However, the trifluoroacetato complex (**136**) has *trans* basal ligands.[1328]

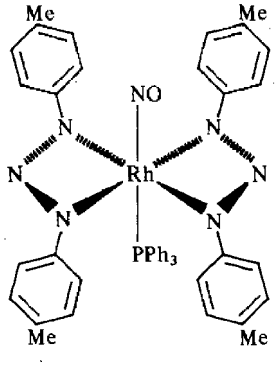
If a green solution of $[Rh(NO)Cl(NO_2)(PPh_3)_2]$ in benzene is allowed to stand, a brown complex is precipitated.[244] This may be the dinitrosyl complex which can be obtained from *trans*-$[RhCl(CO)(PPh_3)_2]$ and nitric oxide when the reaction is carried out in carbon tetrachloride[234] or toluene[1329] solution.

No corresponding dinitro complex is known, but two routes have been discovered to the dinitrato complex $[Rh(NO)(NO_3)_2(PPh_3)_2]$ (equations 309 and 310).[1330,1331]

(135)

(136)

$$[RhH(PPh_3)_3] \text{ or } [RhH(CO)(PPh_3)_3] \xrightarrow{HNO_3} [Rh(NO)(NO_3)_2(PPh_3)_2] \quad (309)$$



$$[Rh(NO)Cl_2L_2(CO)] + AgNO_3 \xrightarrow{CHCl_3} [Rh(NO)(NO_3)_2L_2] \quad (310)$$

The most numerous complexes of this stoichiometry are the bis(carboxylato) complexes. They can be obtained from the reaction between $[Rh(NO)Cl(NO_2)(PPh_3)_2]$ and carboxylic acids in aerated solution (equation 311).[127,1308] The IR spectra of the carboxylato ligands (Table 92) are consistent with their monodentate bonding shown in the structure (**136**).[1328]

$$[Rh(NO)(PPh_3)_3] + RCO_2H \xrightarrow[Me_2CO]{O_2} [Rh(NO)(OCOR)_2(PPh_3)_2] \quad (311)$$

R = Me, Et, *p*-C_6H_4Me, *p*-$C_6H_4NO_2$, *p*-C_6H_4Cl,[127] CF_3, C_2F_5, C_6F_5[1308]

Unlike all the other complexes described in this subsection the bis{di(*p*-tolyl)triazenido} complex (**137**) contains six-coordinate rhodium. It can be prepared from the reaction between the triazene and $[Rh(NO)Cl(NO_2)(PPh_3)_2]$ (equation 312). The single methyl resonance at τ 7.80 in its proton NMR spectrum is the reason for assigning it the symmetric structure.[231]

(137)

$$[Rh(NO)(PPh_3)_3] + (p\text{-}MeC_6H_4)_2N_3 \longrightarrow [Rh(NO)\{(p\text{-}MeC_6H_4)_2N_3\}_2(PPh_3)] \quad (312)$$

Table 92 IR Spectra of $[Rh(NO)(O_2CR)_2(PPh_3)_2]$ Complexes[a]

[a] Data from ref. 127.

Many of the methods that have been used to prepare the $[Rh(NO)X_2(PR_3)_2]$ complexes can be adapted to yield similar tertiary arsine complexes. For example, *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide still functions as a source of the nitrosyl ligand in the presence of tertiary arsines (equations 313 and 314).

$$RhBr_3 + p\text{-}MeC_6H_4SO_2N(NO)Me + AsPh_3 \longrightarrow [Rh(NO)Br_2(AsPh_3)_2] \quad (313)$$

$$RhCl_3 \cdot 3H_2O + p\text{-}MeC_6H_4SO_2N(NO)Me + AsPh_3 \xrightarrow{LiI} [Rh(NO)I_2(AsPh_3)_2] \quad (314)$$

Additionally all three dihalo complexes can be prepared from $[Rh(NO)X_2]_n$ species (equation 315).[1293] The dichloro complex is also produced when $AsPh_3$ is allowed to react with $[Rh(NO)_2Cl]$ (equation 316).[1299]

$$[Rh(NO)X_2]_x + AsPh_3 \longrightarrow [Rh(NO)X_2(AsPh_3)_2] \quad (315)$$

$$[Rh(NO)_2Cl]_x + AsPh_3 \longrightarrow [Rh(NO)Cl_2(AsPh_3)_2] \quad (316)$$

The action of nitrosyl chloride[1303] or dinitrogen trioxide[1318] on $RhCl_3 \cdot 3H_2O$ in the presence of $AsPh_3$ also yields the dichloro complex. There have been reports of the preparation of $[Rh(NO)XL_2]$ complexes.[1329,1332–1334] However, these complexes have only been prepared in the Soviet Union, and it has been claimed that their preparation cannot be repeated.[1335]

48.10.2.3 Cationic complexes

A number of cationic complexes have been prepared. The physical properties of these complexes are shown in Table 93. The first examples were prepared by allowing ammonia or other nitrogenous bases to react with $[RhX(NO)_2]_n$ complexes (equation 317).[1292]

$$[Rh(NO)_2X]_x + L \longrightarrow [Rh(NO)_2L_2]X \quad (317)$$

$$X = Cl, Br; L = NH_3, py, morpholine, 0.5\,bipy$$

They are more usually prepared by the action of nitrosyl compounds on rhodium(I) complexes containing labile ligands.[1336–1339] It has also proved possible in one instance to prepare this type of complex by anion metathesis (equations 318 to 320).[1340]

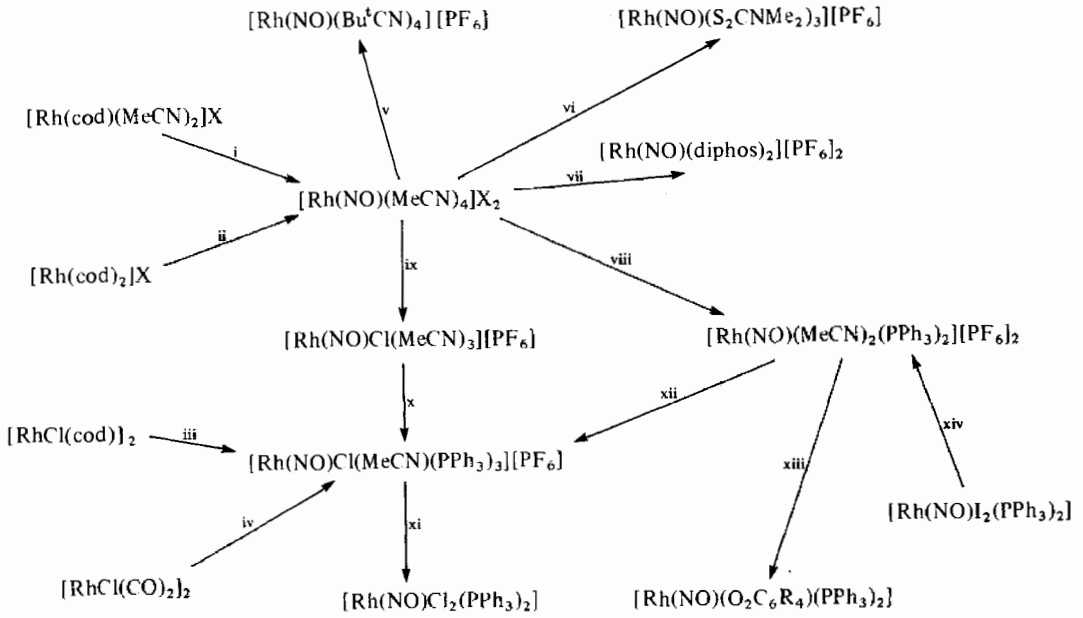
$$[Rh(cod)_2][BF_4] + NOBF_4 \xrightarrow{MeCN} [Rh(NO)(MeCN)_4][BF_4]_2 \quad (318)$$

$$[RhCl(PPh_3)_3] + PPh_3 + NOBF_4 \xrightarrow[C_6H_6]{N_2} [Rh(NO)Cl(PPh_3)_3][BF_4] \quad (319)$$

$$[Rh(bipy)L_2] + NOPF_6 \xrightarrow{MeCN} [Rh(NO)(MeCN)_3(bipy)][PF_6]_2 \quad (320)$$

$$L = CO, cod$$

Table 93 Physical Properties of Cationic Nitrosyl Complexes



Complex	*Color*	ν_{N-O} (cm^{-1})	*Ref.*

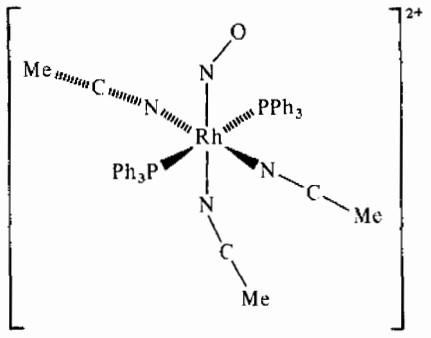
$[Rh(NO)Cl(MeCN)(PPh_3)_2][PF_6]$	Yellow-green	1698	1336
$[Rh(NO)(S_2CNEt_2)(PPh_3)_2][PF_6]$	—	—	1336
$[Rh(NO)(S_2CNMe_2)_3][BF_4]$	Brown	1545	1337
$[Rh(NO)(S_2CNMe_2)_3][PF_6]$	Brown	—	1336

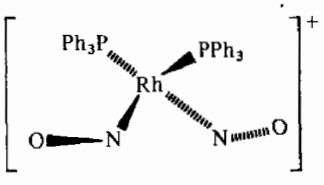
There are two interesting reactions of $[Rh(NO)(CO)(PPh_3)_2][BF_4]_2$ that give rise to complexes of this type. The first can be classed as an esterification whilst the second is a disproportionation (equations 321 and 322).[1341]

$$[Rh(CO)(NO)(PPh_3)_2][BF_4]_2 \xrightarrow[C_6H_6]{ROH,\ -H^+} [Rh(NO)(O_2CR)(ROH)][BF_4] \quad (321)$$



$$[Rh(CO)(NO)(PPh_3)_2][BF_4]_2 \xrightarrow{PriOH} [Rh(CO)_2(PPh_3)_2][BF_4]_3 + [Rh(NO)_2(PPh_3)_2][BF_4] \quad (322)$$

The complexes containing organonitrile ligands themselves undergo a variety of reactions (Scheme 44). Whilst the structures of the five-coordinate cations remain a matter for speculation, the six-coordinate cation $[Rh(NO)(MeCN)_3(PPh_3)_2]^{2+}$ has been shown to have the structure (**138**) by X-ray crystallography.[1343]



i, NOX (X = BF_4, PF_6);[1337] ii, $NOPF_6$, MeCN;[1336,1337] iii, $NOPF_6$, MeCN;[1336] iv, $NOPF_6$, MeCN;[1336] v, Bu^{t}CN;[1337] vi, $Na_2S_2CNEt_2$;[1336] vii, diphos;[1336] viii, PPh_3;[1336] ix, Cl^-;[1336] x, PPh_3;[1336] xi, Cl^-;[1336] xii, Cl^-;[1336] xiii, 1,2-$(HO)_2C_6R_4$ (R_4 = H_4, Br_4, H_3-4-NO_2, H_3-4-CHO, H_3-4-CO_2Me);[1342] xiv, $AgPF_6$, MeCN[1340]

Scheme 44 Preparations and reactions of cationic rhodium nitrosyl complexes

(138)

(139)

The crystal structure of the dinitrosyl cation (**139**) has been determined.[1344] This cation can be prepared from other rhodium nitrosyl complexes (equations 323 and 324).[151,1304]

$$[Rh(NO)(PPh_3)_3] + AgClO_4 \xrightarrow{C_6H_6} [Rh(NO)_2(PPh_3)_2][ClO_4] \quad (323)$$

$$[Rh(NO)_2(NO_2)(PPh_3)_2] + HClO_4 \longrightarrow [Rh(NO)_2(PPh_3)_2][ClO_4] \quad (324)$$

The hexafluorophosphate analog can be prepared from $[Rh(nbd)(PPh_3)_2][PF_6]$ (equation 325). Bis-1,2-(diphenylphosphino)ethane displaces all ligands from the cation, but the reaction is obviously more complex since N_2O and $OPPh_3$ are also produced (equation 326).[234]

$$[Rh(nbd)(PPh_3)_2][PF_6] + NO \longrightarrow [Rh(NO)_2(PPh_3)_2][PF_6] \quad (325)$$

$$[Rh(NO)_2(PPh_3)_2][PF_6] + \text{diphos} \longrightarrow [Rh(\text{diphos})_2][PF_6] + N_2O + OPPh_3 + PPh_3 \quad (326)$$

48.10.2.4 Thionitrosyl complexes

There are a few thionitrosyl complexes of rhodium, many of which contain thionitrosyl bridges. They have been prepared by allowing $[NSCl]_3$ to react with sundry rhodium nitrosyl complexes (equations 327 and 328).

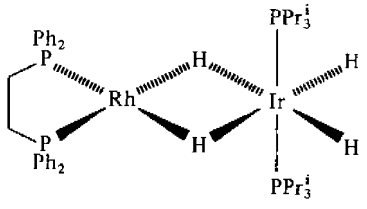
$$[Rh(NO)(PPh_3)_3] + [NSCl]_3 \xrightarrow[CHCl_3]{CCl_4} [Rh(NS)Cl_2(PPh_3)]_2 \quad (327)$$

$$[Rh(NO)Cl_2(ZPh_3)_2] + [NSCl]_3 \xrightarrow[CHCl_3]{CCl_4} [Rh(NS)Cl_2(ZPh_3)]_2 \quad (328)$$

$$Z = As,^{1305}\ P^{1346}$$

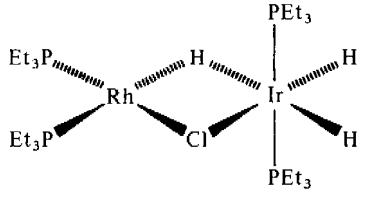
The dihalo complexes are believed to contain thionitrosyl bridges since the band in their IR spectra at *ca.* 840 cm^{-1} disappears when the complexes are cleaved by excess neutral ligand (equation 329). In the latter complexes ν_{N-S} occurs at 1116–1120 cm^{-1}.[1305,1345,1346]

$$[Rh(NS)Cl_2(ZPh_3)]_2 + ZPh_3 \xrightarrow{CH_2Cl_2} 2[Rh(NS)Cl_2(ZPh_3)_2] \quad (329)$$



$$Z = As,^{1305}\ P^{1346}$$

48.10.3 Bimetallic Complexes



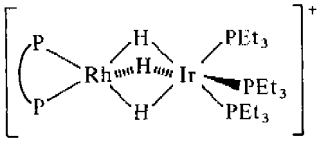
The complexes included in this section are those in which rhodium and at least one other metallic element are present. Normally the second metal is not bound to rhodium although complexes in which a metal–metal bond is supplemented by a bridging ligand are also included.

It has been noted above that the weakly solvated cation $[Rh(diphos)(MeOH)_2]^+$ can be obtained by hydrogenation of $[Rh(diphos)(C_7H_8)][BF_4]$. If the former compound is allowed to react with an equimolar quantity of $[IrH_5(PPr^i_3)_2]$ the di-μ-hydrido complex (**140**) is formed (equation 330). The presence of base merely increases the yield. Only the heavy atoms have been located by X-ray crystallography.[1347]

$$[Rh(diphos)(MeOH)_2]^+ + [IrH_5(PPr^i_3)_2] \xrightarrow[NEtPr^i_2]{MeOH} [(diphos)RhH_2IrH_2(PPr^i_3)_2] \quad (330)$$

(140)

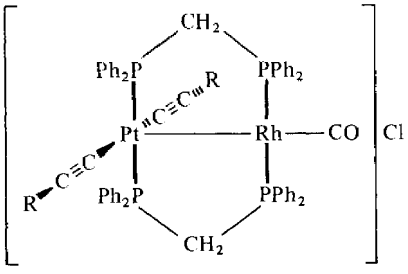
(141)



Two related orange brown μ-hydrido-μ-chloro complexes (**141**) can also be obtained from $[IrH_5(PEt_3)_2]$. Further structural details are available. The ^{31}P NMR spectrum of (**141**) ($PPh_3 = PEt_3$) has a doublet of doublets at 80 p.p.m. and a set of four triplets at 58.8 p.p.m. The latter group arises from the phosphorus atom bound to rhodium which is *cis* to the hydrido bridge.[1348]

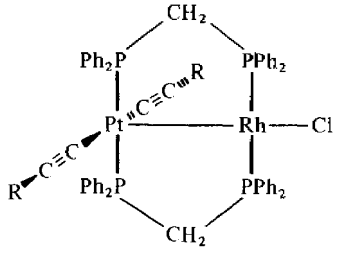
$$[RhCl(PR_3)_2]_2 + [IrH_5(PEt_3)_2] \xrightarrow{C_7H_8} [(R_3P)_2Rh(H)ClIr(PEt_3)_2] \quad (331)$$

$$R_3P = Et_3P,\ 0.5\ \text{diphos}$$



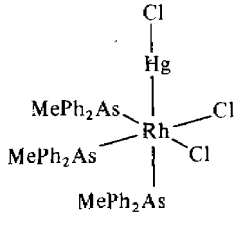
Generation of the $[Rh(diphos)(MeOH)_2]^+$ cation in the presence of *mer*-$[IrH_3(PEt_3)_2]$ gives a dark green cation (**142**) that contains three hydrido bridges (equation 332). Again only the heavy atoms have been located by X-ray crystallography. The ^1H NMR spectrum shows a multiplet at τ 22.0 due to the hydrido ligands. As might be expected the ^{31}P NMR spectrum is complicated, having multiplet peaks arising from the diphos ligand. The IR spectrum of the hydrido ligands shows peaks at 1800 and 1686 cm^{-1}, whilst the corresponding trideuterio complex has peaks at 1300 and 1100 cm^{-1}.[1349]

$$[Rh(diphos)(MeOH)_2]^+ + \textit{mer}\text{-}[IrH_3(PEt_3)_3] \xrightarrow[MeOH]{NaBPh_4} [(diphos)RhH_3Ir(PEt_3)_3][BPh_4] \quad (332)$$



(142)

It is also possible to prepare bimetallic rhodium(I) complexes containing 'A-frame' ditertiary phosphine ligands. However, the majority of these complexes contain carbonyl ligands and have been dealt with in the companion volume.[17] Nevertheless (**143**) upon heating in toluene decarbonylates and forms the bimetallic complex (**144**).[1350]



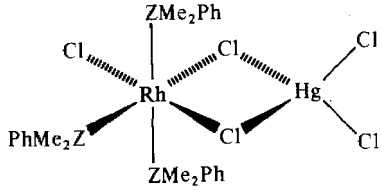
(143)

(144)

Probably the most numerous bimetallic complexes of rhodium are those containing mercury. The complex β-$[RhHCl_2(AsMePh_2)_3]$ reacts with mercury(II) halides,[1351] phenylmercury(II) halides,[1352] or mercury(I) halides[1351,1352] to produce *fac*-rhodium–mercury complexes (**145**) (equation 333). The physical properties of the products are shown in Table 94.

(145)

$$\beta\text{-}[RhHCl_2(AsMePh_2)_3] + HgX_2 \longrightarrow \textit{mer}\text{-}[RhCl_2(HgX)(AsMePh_2)_3] \quad (333)$$



$$X = F, Cl, Br, I, MeCO_2$$

Meridional rhodium(III) complexes also undergo reaction with mercury(II) halides. Unlike the corresponding reaction with rhodium(I) complexes where a rhodium–mercury bond was formed,[186] in these instances the tetrahedral $[HgCl_4]^{2-}$ ion acts as a bidentate ligand (**146**; equation 334). Three bands in the far-IR spectrum of the chloro complex at 345, 310 and 242 cm^{-1} have been assigned to $\nu_{Rh\ Cl\ Hg}$, $\nu_{Hg\ Cl}$ and ν_{Rh-Cl} respectively. However, the reaction between the corresponding tertiary phosphine complex *mer*-$[RhCl_3(PMe_2Ph)_3]$ and $HgCl_2$ also forms a polynuclear mercury complex (equation 335).[1353]

Table 94 Physical Properties of Rhodium–Mercury Compounds

Complex	*Color*	*M.p.* (°C)	*Ref.*
$[RhCl_2(HgF)(AsMePh_2)_3]$	Pale green	195	1351
$[RhCl_2(HgCl)(AsMePh_2)_3]$	Yellow	205	1352
$[RhCl_2(HgBr)(AsMePh_2)_3]$	Orange-yellow	165	1352
$[RhCl_2(HgI)(AsMePh_2)_3]$	Orange	155	1352
$[RhCl_2(HgO_2CMe)(AsMePh_2)_3]$	Yellow	172	1352
$[RhBr_2(HgF)(AsMePh_2)_3]$	Yellow	154	1352
$[RhBr_2(HgCl)(AsMePh_2)_3]$	Yellow	202	1352

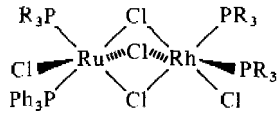
$[RhHgCl_5(AsMe_2Ph)_3]$	Red	156–65[a]	1353

[a] With decomposition.



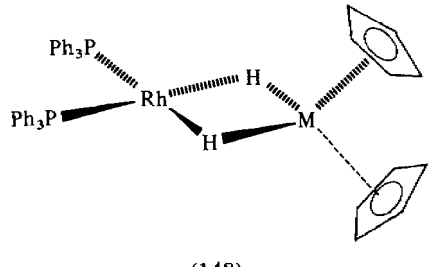
(146)

$$mer\text{-}[RhCl_3(AsMe_2Ph)_3] + HgCl_2 \xrightarrow{MeOH} [RhCl_3(AsMe_2Ph)_3(HgCl_2)] \quad (334)$$

$$mer\text{-}[RhCl_3(PMe_2Ph)_3] + HgCl_2 \xrightarrow[CHCl_3]{MeOH} [Hg_4Cl_8(PMe_2Ph)_2] + [RhCl_3(PMe_2Ph)_3(HgCl_2)] \quad (335)$$

Similar bimetallic complexes to (**146**), except that they contain a bidentate, square planar, anionic ligand of the type $[MCl_3L]^-$ (M = Pt, L = PEt_3, PBu_3, PBu^tPr_2; M = Pd, L = PBu_3) are believed to be formed as intermediates in ligand exchange reactions.[1354]

Trihalo-bridged complexes (**147**) are formed in the reactions between $[RuCl_2(PPh_3)_3]$ and *mer*-$[RhCl_3L_3]$ complexes (equation 336).[1355,1356]



(147)

$$mer\text{-}[RhCl_3(PR_3)_3] + [RuCl_2(PPh_3)_3] \longrightarrow [(R_3P)_2ClRhCl_3RuCl(PPh_3)(PR_3)] \quad (336)$$

$$R_3 = Bu_3, Ph_3, Me_2Ph, Et_2Ph, Bu_2Ph$$

The dihydridobis(cyclopentadienyl) complexes of both molybdenum and tungsten react with $[RhH_2(PPh_3)_2(Me_2CO)_2][PF_6]$ to form deep brown complexes. Their proton NMR spectra indicate that the hydrido ligands are bound to both metals (**148**) since large coupling constants are observed (J(Rh–H) = 29 Hz, J(W–H) = 107 Hz). When the tungsten compound is heated in acetone/D_2O mixtures, deuterium is incorporated in the cyclopentadienyl ligands.[1357]

(148)

$$[RhH_2(PPh_3)_2(Me_2CO)_2][PF_6] + [MH_2(Cp)_2] \longrightarrow [(Ph_3P)_2RhH_2M(Cp)_2] \quad (337)$$

49.1 INTRODUCTION

The coordination chemistry of iridium is concerned primarily with the I, III and IV oxidation states; complexes with iridium in the −I, 0, V and VI oxidation states are also known. Of these latter states, Ir^{-I} and Ir^0 are found in carbonylate anions, oligonuclear and substituted carbonyls, hydrides and ammines. Iridium(V) and (VI) complexes are predominantly hexahalide compounds.

Diamagnetic iridium(I) complexes (d^8) form with π-acid ligands such as tertiary phosphines and arsines, carbonyls, nitrosyls and alkenes, as well as with hydride and halide ions. Several Ir^I complexes undergo oxidative addition reactions to yield six-coordinate octahedral Ir^{III} species. Kinetically inert iridium(III) complexes (d^6) are almost invariably low spin (t_{2g}^6) and six coordinate, though a few five- and seven-coordinate complexes have been reported. By and large, iridium(III) complexes occur with 'soft' ligands, including CO, ER_3 (E = P, As, Sb), R_2S, NO_2^-, NH_3, SCN^-, SO_4^{2-}, SO_3^{2-} and X^- (X = Cl, Br, I). Additionally, there are numerous iridium(III) hydride complexes, usually containing carbonyl, phosphine, arsine and/or stibene ligands. Neutral as well as anionic and cationic iridium(III) complexes exist. A number of six-coordinate paramagnetic

Table 1 Oxidation States and Associated Coordination Numbers and Geometries of Iridium Complexes

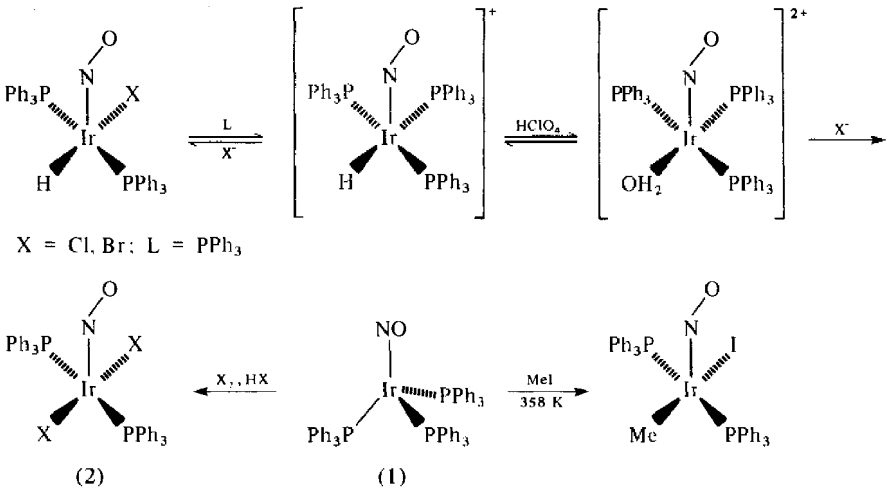
Oxidation state	*Coordination number*	*Geometry*	*Examples*
$-I$, d^{10}	Four	Tetrahedral	$Na[Ir(CO)_3(PPh_3)]$
	Four	Tetrahedral	$[Ir(NO)(PPh_3)_3]$
	Four	—	$K[Ir(PF_3)_4]$
O, d^9	Four	Cluster	$[Ir_4(CO)_{12}]$
	Four	—	$[Ir(CO)(PPh_3)_3]$
	Four	—	$[Ir(NO)(CO)(PPh_3)_2]^+$
I, d^8	Four	Square planar	$[Ir(Cl)(CO)(PEt_3)_2]$
	Five	Trigonal bipyramidal	$[Ir(H)(CO)(PPh_3)_3]$
II, d^7	Four	—	$[Ir(Cl)_2(CO)_2]$
	Five	—	$[Ir(I)_3(CO)_2]$
III, d^6	Five	Trigonal bipyramidal	$[Ir(H)_3(PR_3)_2]$
	Five	—	$[Ir(H)_3(AsPh_3)_2]$
	Six	Octahedral	$[Ir(H)_3(PPh_3)_3]$
	Six	—	$[Ir(H_2O)(NH_3)_5]^{3+}$
	Six	—	$[IrCl_6]^{3-}$
IV, d^5	Six	Octahedral	$[Ir(C_2O_4)_3]^{2-}$
	Six	—	$[IrCl_6]^{2-}$
	Six	—	$M[Ir(OH)_6]$, M = Zn, K_2
V, d^4	Six	Octahedral	$Cs[IrF_6]$
	Seven	—	$[Ir(H)_5(PPhEt_2)_2$
VI, d^3	Six	Octahedral	$[IrF_6]$

iridium(IV) complexes (d^5) are known, in contrast to rhodium(IV). Stable Ir^{IV} complexes are formed with halogen, oxygen and nitrogen donors; these complexes are easily reduced to Ir^{III} with P, As and S donor ligands. Table 1 summarizes the coordination chemistry of iridium in terms of oxidation state and associated coordination numbers and coordination geometries.

This chapter will not deal with iridium complexes in which the coordination chemistry of the iridium–carbon bond is implicated inasmuch as Leigh and Richards[1] have very recently (1982) provided an excellent detailed review on such compounds; organoiridium[2] and iridium carbonyl[3] complexes were also previously reviewed. Iridium complex chemistry has been reviewed (1980) along with rhodium,[4] and in annual reviews.[5] Additionally, iridium complexes have been treated in 'Comprehensive Inorganic Chemistry'.[6]

49.2 IRIDIUM(−I)

49.2.1 Nitrogen Ligands



49.2.1.1 Nitrosyl ligands

Several iridium(−I) nitrosyl complexes are known. Those with the general formula $[Ir(NO)_2X(PPh_3)_2]$ (X = Cl, Br, I) are produced upon reduction of $[Ir(NO)_2(PPh_3)_2]$ with the appropriate lithium halide. IR spectral data for these complexes indicate bridging NO groups, as shown by the low N—O frequencies [ν(N—O) $\approx$ 1540–1490 cm^{-1}].[7] Reaction of $[Ir(NO)_2X(PPh_3)_2]$ with NO results in the oxidation of NO according to reaction (1).[8]

$$[Ir(X)(NO)_2(PPh_3)_2] + 2NO \longrightarrow [Ir(X)(NO_2)(NO)(PPh_3)_2] + N_2O \quad (1)$$

The d^{10} complex $[Ir(NO)(PPh_3)_3]$ (**1**) has been prepared in a variety of ways, including (i) reaction of $[Ir(NO)_2(PPh_3)_2](ClO_4)$ with excess PPh_3;[7] (ii) reaction between $[Ir(NO)(CO)(PPh_3)_2]$ and excess PPh_3;[9] and (iii) the reduction of $[IrCl_3]\cdot 3H_2O$ or $[Ir(Cl)(N_2)(PPh_3)_2]$ with sodium amalgam (or zinc metal) in the presence of PPh_3 and NO.[10] An X-ray crystal structure determination of $[Ir(NO)(PPh_3)_3]$ has shown a tetrahedral geometry about Ir. The Ir—N—O interaction was considered in terms of $[Ir(PPh_3)_3]^-$ and $[NO]^+$ moieties, wherein the NO group serves as a three-electron donor in a σ–π synergistic interaction with Ir.[11] The crystal structure of $[Ir(NO)(PPh_3)_3]\cdot C_3H_6$ has also been determined; presumably, this represents the first reported occurrence of unsubstituted cyclopropane in a crystal structure determined with X-rays.[12] An ESCA study of $[Ir(NO)(PPh_3)_3]$ led to an O(1*s*)—N(1*s*) ionization potential difference of 131.9 eV, indicative of the presence of a linear nitrosyl ligand.[13] Moreover, $[Ir(NO)(PPh_3)_3]$ undergoes oxidative additions with MeI, halogens and stoichiometric amounts of hydrogen halides to yield five-coordinate complexes (**2**) with

tetragonal pyramidal structures in which the NO ligand is bent (see Scheme 1). However, reaction of $[Ir(NO)(PPh_3)_3]$ (**1**) with an excess of HBr and HCl produces $[Ir(NH_2OH)(X)_3PPh_3)_2]$, in which the nitrosyl ligand is converted to a bound hydroxylamine. Also, $[Ir(NO)(PPh_3)_3]$ undergoes protonation with non-complexing acids to yield hydride species.[9] The $[Ir(NO)(CO)(PPh_3)_2]$ complex can be prepared *via* the treatment of $[Ir(H)(CO)(PPh_3)_3]$ with NO.[7] The iridium(−I) dinitrosyl complex $[Ir(NO)_2(PR_3)_2]^+$ has also been reported.[14]

Scheme 1

The tetraazadiene complex $[Ir(NO)(N\text{-}p\text{-tolyl})_4(PPh_3)]$ exhibits a conformational effect, and thereby a temperature dependent ^1H NMR spectrum. Also, this complex readily forms a CO adduct.[15]

49.2.2 Phophorus Ligands

49.2.2.1 Phosphine ligands

The salt $Na[Ir(CO)_3(PPh_3)]$ reduces $[Ni(Cl)_2(PPh_3)_2]$ to yield $[Ir(CO)_3(PPh_3)]_2$ with $[Ni(CO)_2(PPh_3)_2]$. Reaction of the iridium(−I) complex with *trans*-$[Pt(Cl)_2(py)_2]$ (py = pyridine) affords $[M_2(CO)_2(PPh_3)(py)]_n$ where $M_2 = Pt_2$, PtIr or Ir_2.[16]

49.3 IRIDIUM(0)

49.3.1 Nitrogen Ligands

49.3.1.1 Aliphatic amine ligands

Iridium(0) is present in carbonyl and substituted carbonyl complexes, and perhaps in $[Ir(NH_3)_5]$, if indeed this species exists. Although the ammine complex $[Ir(NH_3)_5]$ has been reported,[17] the diamagnetism of this complex suggests an irridium(I) hydride species.

49.3.1.2 Nitrosyl ligands

The iridium(0) nitrosyl complexes $[Ir(NO)(CO)(PPh_3)_2]^+$ and $[Ir(NO_3)_2(NO)_2(CO)(PPh_3)_2]$[18,19] have been synthesized *via* reaction of $[Ir(CO)_3(PPh_3)_2]^+$ with NO and N_2O_4, respectively. The reaction between $[Ir(NO)(PPh_3)_3]$ and RCO_2H reportedly yields $[Ir(O_2CR)(NO)(PPh_3)_2]$, where R is CF_3 or C_2F_5.[20]

The preparation of $[Ir(NO)(PPh_3)]_2O\cdot C_6H_6$ (**3**) involves reaction of *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ and excess $NaNO_2$ under a nitrogen atmosphere. The complex (**3**) is diamagnetic and stable in air, but rapidly decomposes in solution on exposure to air.[21] The dinuclear oxygen-bridged complex $[Ir(NO)(PPh_3)]_2O$ appears to be a good candidate for a strong, considerably bent Ir—Ir bond.

SCF–X_α–SW calculations on this complex have led to the conclusion that the NO ligands are crucial in stabilizing and in determining the exact nature of the substantially bent Ir—Ir bond (2.555 Å). Contour maps suggest the complex to be closer to Ir^I—NO^0 than to Ir^0—NO^+, with square planar coordination about each Ir atom.[22] The X-ray crystal structure of complex (**3**)[23] shows a bent Ir—Ir bond with the NO group π bonded to Ir, with an Ir—N—O angle of 177° and an Ir—N bond length of 1.76 Å suggesting that the Ir—N bond has some double bond character. Complex (**3**) does not undergo oxidative addition reactions with H_2, Cl_2, Br_2, I_2 or HgX_2. However, upon reaction with I_2, $HgCl_2$ or $HgBr_2$, oxidation of the Ir—Ir bond occurs without disruption of the oxygen bridge (reactions 2 and 3). Also, complex (**3**) reacts with tetracyanoethylene to form a 1:1 adduct, wherein the alkene inserts into the Ir—Ir bond with one carbon atom bonded to each Ir atom. With excess PPh_3, complex (**3**) affords $[Ir(NO)(PPh_3)_3]$ and Ph_3PO.[21]

$$(3) + HgX_2 \longrightarrow [Ir(X)(NO)(PPh_3)]_2O^+ + HgX \quad (2)$$

$$(3) + I_2 \longrightarrow [Ir(I)(NO)(PPh_3)]_2O \quad (3)$$

49.3.2 Phosphorus Ligands

49.3.2.1 Phosphine ligands

Several series of dinuclear iridium(0) complexes with tertiary phosphine ligands are known. These include (a) $[Ir(CO)_7(PR_3)]$, where $PR_3 = PPr^n_3$, PPr^i_3, PBu^n_3, PPh_3 and $P(tolyl)_3$; (b) $[Ir_2(CO)_6(PR_3)_2]$, where $PR_3 = PPr^i_3$, PPh_3, $P(OPh)_3$ and $P(tolyl)_3$; (c) $[Ir_2(CO)_5(PR_3)_3]$, where $PR_3 = PPh_3$ or $PPh_2(tolyl)$; and (d) $[Ir_2(CO)_4(PR_3)_4]$, where $PR_3 = PPh_3$ or $P(OPh)_3$.[24,25] The complex $[Ir_2(CO)_6(PPh_3)_2]$ (**4**) reacts with $P(OPh)_3$ to yield $[Ir_2(CO)_4\{P(OPh)_3\}_4]$, from which $[Ir_2(CO)_6\{P(OPh)_3\}_2]$ is obtained on decomposition. Other reactions of these complexes are depicted in reactions (4)–(6).[25] The reduction of $[Ir(Cl)(CO)(PPh_3)_2]$ under 20 atm CO pressure in the presence of $HNEt_2$ affords $[Ir_2(CO)_6(PPh_3)_2]$.[26]

$$(4) + PPh_3 \xrightarrow[303\,K]{C_6H_6} [Ir_2(CO)_5(PPh_3)_3] + CO \quad (4)$$

$$(4) + 2[PPh_2(p\text{-tolyl})] \xrightarrow[reflux]{C_6H_6} [Ir_2(CO)_5(PPh_3)\{PPh_2(p\text{-tolyl})\}_2] + PPh_2 + CO \quad (5)$$

$$(4) + SO_2 \xrightarrow{C_6H_6} [Ir_2(CO)_4(PPh_3)_2(\mu\text{-}SO_2)_2] + CO \quad (6)$$

49.4 IRIDIUM(I)

The coordination chemistry of iridium(I) involves π-acid ligands. Both four- and five-coordinate species form. Iridium(I) complexes are invariably prepared *via* some form of reduction, either from analogous iridium(III) complexes or from halide complexes in the presence of the complexing ligand, or *via* substitution.

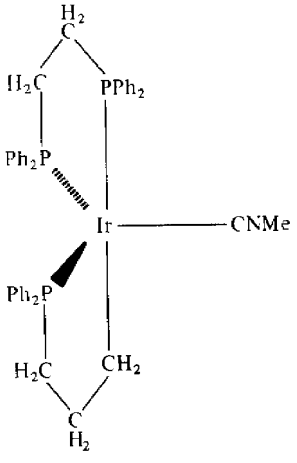
49.4.1 Group IV Ligands

49.4.1.1 Cyanide, isocyanide and fulminate ligands

The yellow iridium(I) complex $[Ir(CN)(CO)(PPh_3)_2]$ has been prepared in two ways; (i) by the action of CN^- on the $[Ir(MeCN)(CO)(PPh_3)_2]^+$ salt; or (ii) by treating $[Ir(Cl)(CO)(PPh_3)_2]$ in a chloroform solution of PPh_3 with an anionic resin in the CN^- form. The IR spectrum of the cyano analogue of Vaska's complex exhibits a $\nu(CN)$ band at 2120 cm^{-1}.[27]

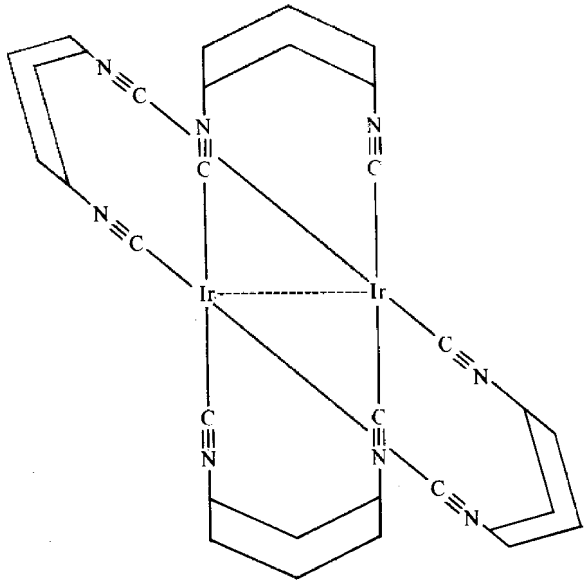
Transition metal complexes containing isocyanide ligands have been reviewed by Malatesta and Bonati.[28] $[\{Ir(Cl)(CO)_3\}_n]$ reacts with alkyl and aryl isocyanides (CNR) to give the iridium(I) isocyanide complexes $[Ir(CNR)_4]^+$, where $R = C_6H_{11}$, p-MeC_6H_4 or p-$MeOC_6H_4$. IR spectra support a square planar structure for $[Ir(CNR)_4]^+$. These complexes undergo *trans* oxidative addition with halogens (X_2) to produce $[Ir(X)_2(CNR)_4]^+$, with MeI to yield $[Ir(I)(Me)(CNR)_4]^+$ ($R = C_6H_{11}$), and with O_2 to give $[Ir(CNR)_4(O_2)]^+$ ($R = C_6H_{11}$). The results indicate that the alkyl isocyanide complexes are more reactive toward oxidative addition than aryl isocyanide complexes.[29] Electronic absorption and MCD spectroscopies have been employed to characterize $[Ir(CNEt)_4]^+$, which exhibits intense visible absorption assigned to MLCT (metal-to-ligand change transfer)

transitions from the occupied metal *d* orbitals to the lowest energy π^* CNEt orbital. The MLCT spectra have been interpreted in terms of a model which involves a single π^* CNEt acceptor orbital and includes metal spin–orbit coupling in the MLCT excited states.[30] IR and electronic absorption spectra of $[Ir(CNR)_4]^+$ (R = Bu^t) are indicative of normal monomeric Ir^I/L_4 complex behaviour. However, $[Ir(CNMe)_4]Cl$ exhibits a very different absorption spectrum, interpreted in terms of an oligomeric species $[Ir(CNMe)_4]_n^{n+}$.[31] Additionally photolysis of this $[Ir(CNMe)_4]_n^{n+}$ species reportedly affords $[Ir(CNMe)_4]^+$.[31] $[Ir(CNR)_4]^+$ and $[Ir(Cl)(CNR)_3(CO)]$ (R = C_7H_7) have also been prepared and characterized.[32] The complexes $[Ir(CNR)_4]^+$ (R = alkyl or aryl) readily undergo oxidative addition to obtain *trans*-$[Ir(X)(Y)(CNR)_4]^+$, where X = Me, Pr, I, Y = I; X = MeCO, σ-C_3H_5, HgCl, $SnCl_3$, $SnPh_3$, Y = Cl; X = Y = Br; X = CN, Y = Br.[33] The reactivity and structures of some tetrakis(aryl isocyanide)iridium(I) complexes have been investigated by Tanaka *et al.*[34]



The addition of HX to $[Ir(CNR)_3(PPh_3)_2]^+$ (R = alkyl or aryl) reportedly proceeds by displacing X^- from the addendum YX to produce an ionic intermediate from which L is subsequently displaced by X^- as depicted in Scheme 2.[35]

$$[Ir(L)_5]^+ + YX \longrightarrow [Ir(Y)(L)_5]^{2+} + X^- \longrightarrow [Ir(X)Y(L)_4]^+ + (L)$$

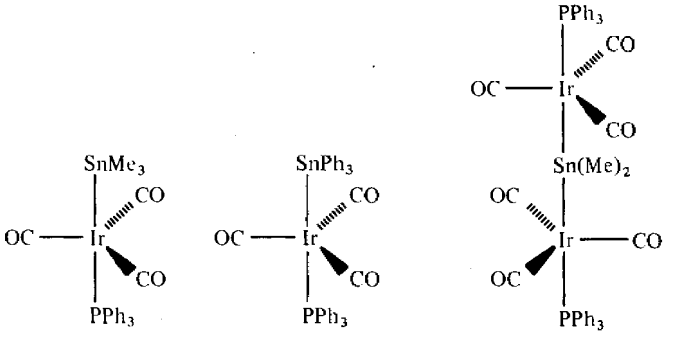


Scheme 2

X-Ray crystal and molecular structures for the stable five-coordinate iridium(I) isocyanide complex $[Ir(CNMe)(dppe)_2]^+$ (**5**) reveal this complex to possess a trigonal bipyramidal geometry. The isocyanide ligand occupies an equatorial position and each dppe chelate bridges one axial and one equatorial site.[36] In contrast to $[Ir(CNR)_3(PPh_3)_2]^+$,[35] the $[Ir(CNR)(P—P)_2]^+$ complexes (where P—P = dppe, dppen and R = Me, *p*-MeC_6H_4) undergo oxidative addition of proton acids (including MeOH), halogens and $HgCl_2$ without loss of a ligand to yield $[Ir(CNR)(P—P)_2Y]^{2+}$ (Y = H, Cl, I, HgCl). However, $[Ir(CNR)(P—P)_2]^+$ does not react with alkyl, allyl or acyl halides. The addition of proton acids yields *cis* products which, on heating, isomerize. Reaction of $[Ir(CNR)(P—P)_2]^+$ with H_2 or O_2 affords *cis*-$[Ir(H)_2(P—P)_2]^+$ and $[Ir(O_2)(P—P)_2]^+$, respectively.[37]

t-Butyl isocyanide (CNBu^t) is known to react with the A-frame complex $[Ir_2(Cl)(CO)(P—P)_2]X$ (P—P = dppm, dpam; X = BPh_4^-, BF_4^-, PF_6^-) affording $[Ir_2(Cl)(CNBu^t)(CO)_3(P—P)_2]X$, $[Ir_2(Cl)(CNBu^t)_2(CO)_2(P—P)_2]X$ (P—P = dppm, X = BPh_4^-; P—P = dpam, X = BF_4^-) and $[Ir_2(CNBu^t)_4(CO)(P—P)_2](BPh_4)_2$. These complexes were characterized by IR, ^{13}C and ^{31}P NMR spectroscopic techniques.[38] Bidentate diisocyanocyclohexane ligands have been prepared. *meso*-1,3-Diisocyanocyclohexane reacts with $[Ir(Cl)(cod)]_2$ to produce $[Ir_2(meso\text{-}1,3\text{-}C_8H_{10}N_2)_4](Cl)_2$ (**6**) for which a windmill structure has been proposed.[39]

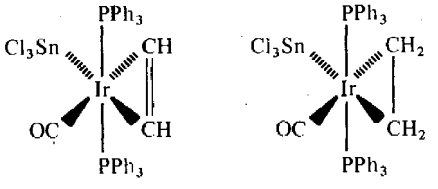
(5)



(6)

49.4.1.2 Sn-containing ligands

The reduction of Vaska's complex, $[Ir(Cl)(CO)(PPh_3)_2]$, with sodium amalgam in THF yields a non-isolable anionic species (**7**; reaction 7). Upon addition of $SnMe_3Cl$, $SnPh_3Cl$ or $SnMe_2Cl_2$, high yields of (**8**)–(**10**), respectively, are obtained.[40] Reaction of (**9**) with Br_2, I_2 or mercury(II) halides results in the cleavage of the Sn—Ir bond. The Ph_3Ge—Ir analogue of (**9**) has also been prepared.[41]



$$trans\text{-}[Ir(Cl)(CO)(PPh_3)_2] \xrightarrow[THF,\ CO]{Na/Hg} Na[Ir(CO)_3(PPh_3)] \quad (7)$$

(7)

(8) (9) (10)

The addition of anhydrous $SnCl_2$ and C_2H_2 or C_2H_4 to *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ yields $[Ir(SnCl_3)(C_2H_2)(CO)(PPh_3)_2]$ and $[Ir(SnCl_3)(C_2H_4)(CO)(PPh_3)_2]$ with structures (**11**) and (**12**), respectively. A five-coordinate structure was assigned to the intermediate product $[Ir(Cl)(SnCl_2)(CO)(PPh_3)_2]$ based on IR spectral data. This five-coordinate complex reacts with H_2, hydrocyanic acid and HX to yield stable products. Addition of HCl yields $[Ir(H)(Cl)(SnCl_3)(PPh_3)_2]$.[42]

(11) (12)

The structure of the complex resulting from the reaction between $[Ir(Cl)(CO)(PPh_3)_2]$ and $SnCl_4$ has been discussed.[43] Recently, the existence of the Sn—Ir bond in the product was questioned.[44] Based on ^{119}Sn NMR data, the iridium(I) complexes from the reaction between $[Ir(Cl)(CO)(PR_3)_2]$ ($PR_3 = P(p\text{-}XC_6H_4)_3$; X = H, F, Cl, OMe) and $SnCl_2$ are isomers of composition $[Ir(Cl)(SnCl_2)(CO)(PR_3)_2]$; they contain bridging halogen ligands and Sn is not coordinated to Ir. When reacted with HCl or H_2, the expected iridium(III) complexes $[Ir(H)(Cl)(SnCl_3)(CO)(PR_3)_2]$ or $[Ir(H)_2(SnCl_3)(CO)(PR_3)]$ are obtained. These iridium(III) complexes do contain an Sn—Ir bond.[44]

Reduction of $[Ir(X)(CO)(PPh_3)_2]$ under the reaction conditions of reaction (7) to yield $[Ir(CO)_3(PPh_3)]^-$, followed by the addition of MX (M = $SnCl_2$, $SnMe_2$; X = Cl), has yielded the dinuclear iridium(I) complex $[\{Ir(CO)_3(PPh_3)\}_2M]$.[45]

49.4.2 Nitrogen Ligands

49.4.2.1 Ammonia and amine ligands

The reduction of $[Ir(Br)(NH_3)_5]$ with potassium in liquid ammonia purportedly yields the yellow iridium(0) complex $[Ir(NH_3)_5]$.[17] However, the diamagnetism of the product is suggestive of an iridium(I) hydride species, $[Ir(H)(NH_3)_5]$.

49.4.2.2 Nitrosyl ligands

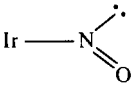
Transition metal nitrosyl complexes have been reviewed by Johnson and McCleverty.[46] The nitrosyl analogue of Vaska's complex $[Ir(Cl)(NO)(PPh_3)_2]^+$, is known,[47] as is $[Ir(NO)(CO)(PPh_3)_2]$.[7] The latter complex is prepared by the action of nitric oxide on $[Ir(H)(CO)(PPh_3)_3]$. $[Ir(Cl)(NO)(PPh_3)_2]^+$ has been obtained[9] from the reaction of $[Ir(H)(Cl)(NO)(PPh_3)_2]$ with $HClO_4$, and undergoes several addition reactions to form five-coordinate nitrosyl complex cations as summarized in reactions (8) through (13).[47] The carbonylation of complexes of the type $[M(NO)(PPh_3)_3]$ reportedly proceeds to mixed nitrosyl–carbonyl species (*e.g.* $[M(NO)(CO)(PPh_3)_3]$). The kinetics of CO absorption by $[Ir(NO)(PPh_3)_3]$ in chlorobenzene to yield $[Ir(NO)(CO)(PPh_3)_2]$ and PPh_3 have been studied.[48] At constant pressure, kinetics first order in $[Ir(NO)(PPh_3)_3]$ were observed. Rate constants and activation parameters for CO absorption are consistent with the mechanism in reactions (14) and (15).

$$[Ir(Cl)(NO)(PPh_3)_2]^+ + CO \longrightarrow [Ir(Cl)(NO)(CO)(PPh_3)_2]^+ \quad (8)$$

$$[Ir(Cl)(NO)(PPh_3)_2]^+ + PPh_3 \longrightarrow [Ir(Cl)(NO)(PPh_3)_3]^+ \quad (9)$$

$$[Ir(Cl)(NO)(PPh_3)_2]^+ + dppe \longrightarrow [Ir(Cl)(NO)(dppe)(PPh_3)_2]^+ \quad (10)$$

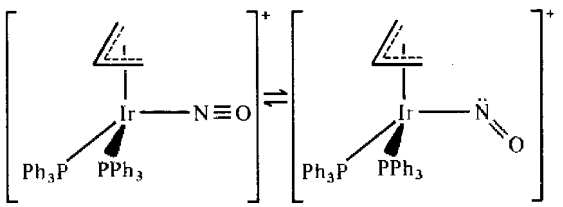
$$[Ir(Cl)(NO)(PPh_3)_2]^+ + Cl_2 \longrightarrow [Ir(Cl)_3(NO)(PPh_3)_2]^+ \quad (11)$$



$$[Ir(Cl)(NO)(PPh_3)_2]^+ + Cl^- \longrightarrow [Ir(Cl)_2(NO)(PPh_3)_2] \quad (12)$$

$$[Ir(Cl)(NO)(PPh_3)_2]^+ + H_2O \longrightarrow [Ir(OH_2)(Cl)(NO)(PPh_3)_2]^+ \quad (13)$$

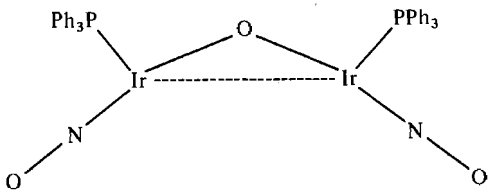
$$[Ir(NO)(PPh_3)_3] \underset{}{\overset{+\text{solvent}}{\rightleftharpoons}} [Ir(NO)(PPh_3)_2(\text{solvent})] + PPh_3 \quad (14)$$



$$[Ir(NO)(PPh_3)_2(\text{solvent})] + CO \longrightarrow [Ir(NO)(CO)(PPh_3)_2] + \text{solvent} \quad (15)$$

Several five-coordination iridium(I) nitrosyl complexes have been reported, including $[Ir(X)_2(NO)(PR_3)_2]$ (X = Cl, Br, I; PR_3 = phosphine) and $[Ir(Cl)(NO)(PPh_3)_2]^+$. The crystal structure of the latter reveals an Ir—N—O angle of 124°. The coordination about Ir is tetragonal pyramidal with the NO ligand at the apex, and Cl, CO and *trans* P atoms in the basal plane. The Ir—N distance is quite long (1.97 Å), suggestive of coordinated NO^- with sp^2 hybridization on the N atom (see **13**).[49] The X-ray crystal structure of $[Ir(I)(NO)(CO)(PPh_3)_2](BF_4)\cdot C_6H_6$ has revealed it to be rather similar to $[Ir(Cl)(NO)(CO)(PPh_3)_2]^+$, with a distorted tetragonal pyramidal geometry about Ir. The Ir—N bond length is 1.89 Å, while the Ir—N—O angle is 125°.[50] The $[Ir(NO)(phen)(PPh_3)_2](PF_6)_2$ complex contains an iridium(I) atom in a trigonal bipyramidal environment with the phen and NO ligands in equatorial positions. The NO ligand is present at NO^+.[4]

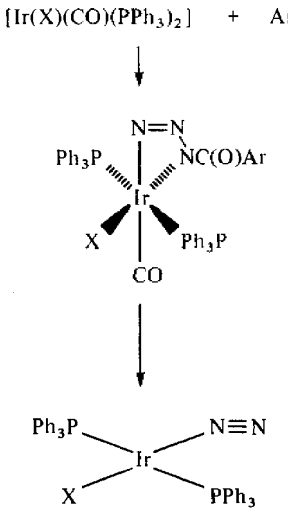
(13)



The complex $[Ir(NO)(PPh_3)_2(\eta^3\text{-}C_3H_5)](PF_6)$ (**14**) can be prepared from the reaction of $[Ir(Cl)(NO)(PPh_3)_2](PF_6)$ and $Sn(C_3H_5)_4$ at 273 K in THF. Repetition of the synthesis employing $[Ir(Cl)(NO)(PPh_3)_2](BF_4)$ afforded $[Ir(NO)(PPh_3)_2(\eta^3\text{-}C_3H_5)](BF_4)\cdot 0.5H_2O$ (**15**). Though evidence for the linear $\rightleftharpoons$ bent equilibrium (**14** $\rightleftharpoons$ **15**) of metal nitrosyl complexes remains scarce, it has been postulated that $[Ir(NO)(PPh_3)_2(\eta^3\text{-}C_3H_5)]^+$ exhibits a facile, well-defined equilibrium. IR and ^1H NMR spectroscopic studies suggest the presence of several dynamic processes in solution. An X-ray crystal structure of complex (**15**) confirmed a bent nitrosyl ligand. Additionally, $[Ir(NO)(PPh_3)_2(\eta^3\text{-}C_3H_5)]^+$ reacts with CO to yield acrolein oxime and $[Ir(CO)_3(PPh_3)_2]^+$, most probably *via* an intramolecular coupling process.[51]

(14) (15)

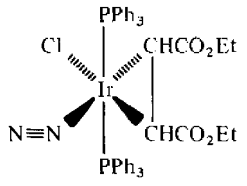
The dinitrosyl cation $[Ir(NO)_2(PPh_3)_2]^+$ (**16**) was synthesized and characterized by X-ray crystallography. A ^{31}P NMR study of complex (**16**) has suggested that phosphine exchange occurs primarily *via* an associative pathway.[52] The X-ray crystal and molecular structures of (**16**) have been determined.[53] Reaction of complex (**16**) with PPh_3 yields $[Ir(NO)(PPh_3)_3]$ and NO^+, though reaction with less bulky phosphines PR'_3 affords $[Ir(PR'_3)_4]^+$.[52] Carbon monoxide reacts with complex (**16**) to give $[Ir(CO)_3(PPh_3)_2]^+$, CO_2 and N_2O; with tertiary phoshines, (PR_3), R_3PO and N_2O are afforded. The carbon monoxide reaction was unexpected, the NO ligand being usually resistant to CO substitution. The proposed mechanism involves the prior formation of a five-coordinate adduct, $[Ir(NO)_2(CO)(PPh_3)_2]^+$, which subsequently and rapidly undergoes oxygen transfer from a coordinated NO ligand to the combined CO, followed by an intramolecular attack of the other NO ligand on the Ir—N system thus produced.[54]



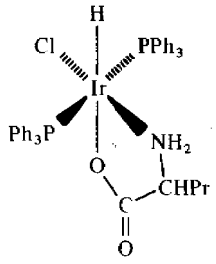
The X-ray crystal structure of $[Ir(Cl)(NO)(PPh_3)]_2O$ (**17**) reveals two identical square planar iridium(I) entities, linked by a common oxygen bridge.[55] $[Ir(X)(NO)(PPh_3)]_2O$ (X = Cl, Br) reacts with excess PPh_3 in CH_2Cl_2 to yield $[Ir(X)_2(NO)(PPh_3)_2]$ and $[Ir(NO)(PPh_3)_3]$.[21]

(17)

49.4.2.3 Dinitrogen, azide, diazo, triazene, tetrazene and selenocyanate ligands

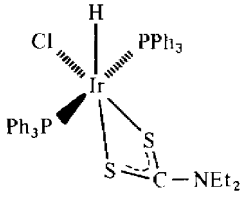


Dinitrogen complexes of the type $[Ir(X)(N_2)(PPh_3)_2]$ (**18**) (X = Cl, Br, I) have been synthesized *via* the mechanism illustrated in Scheme 3. This mechanism is supported by IR spectral and kinetic evidence.[56] Furthermore, complex (**18**) forms the six-coordinate species (**19**) upon reaction with certain alkenes in which the N_2 ligand remains intact. However, reaction of (**18**) with PPh_3, CO or aryl cyanates leads to N_2 displacement.[56] In addition to the dinitrogen analogue of Vaska's complex, $[Ir(Cl)(N_2)(PPh_3)_2]$, impure samples of $[Ir(Cl)(N_2)(PR_3)_2]$, where PR_3 is $PEtPh_2$, PBu^nPh_2, PMe_2Ph or PEt_2Ph, have been obtained.[57] Oxidative addition of HBF_4, CF_3SO_3H or $BuSO_3H$ to *trans*-$[Ir(Cl)(N_2)(PPh_3)_2]$ affords the reactive iridium(III) complexes $[Ir(H)(Cl)(L)(N_2)(PPh_3)_2]$ (L = FBF_3, OSO_2CF_3, OSO_2Bu). The tetrafluoroborate complex $[Ir(H)(Cl)(FBF_3)(N_2)(PPh_3)_2]$ reacts with valinate, diethyldithiocarbamate and PPh_3 to give (**20**), (**21**) and (**22**), respectively.[58]

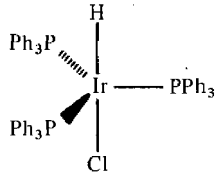


(18)

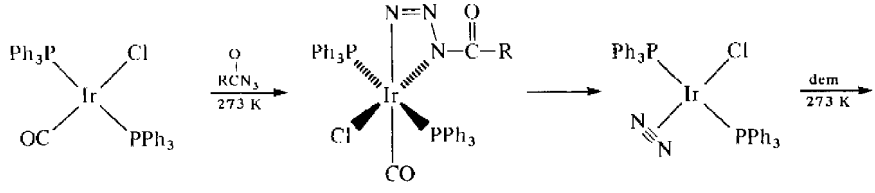
Scheme 3



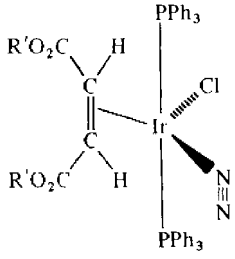
The treatment of $[Ir(Cl)(CO)(PPh_3)_2]$ with an acid azide $RC(O)N_3$ at 273 K has afforded complex (**24**), presumably through the 1,3-dipolar intermediate (**23**) which subsequently eliminates *N*-acyl isocyanate (Scheme 4). Complex (**24**) reacts with diethyl maleate (DEM) to give complex (**25**; see Scheme 4).[59]



(19)

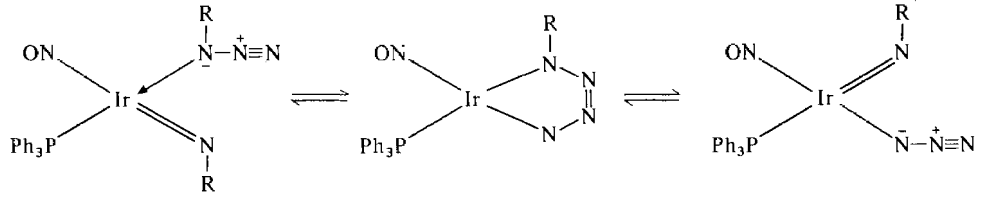


(20)



(21)

(22)

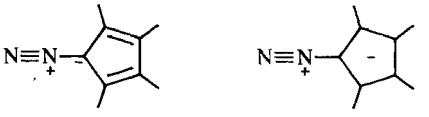


(23) (24)

(25)

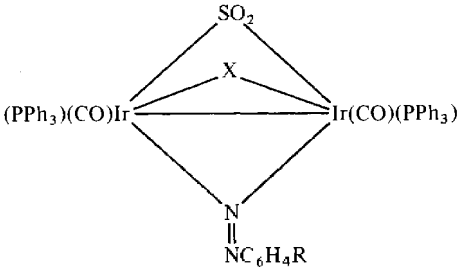
Scheme 4

A complex with the formula $[Ir(NO)(N_4R_2)(PPh_3)]$ (**26**) (R = $SO_2C_6H_4Me$) has been synthesized from $[Ir(NO)(PPh_3)_3]$ and *p*-toluenesulfonyl azide in benzene. The tetrazene complex (**26**) is believed to involve in solution an equilibrium between closed-ring (**26**b) and opened-ring forms (**26**a) and (**26**c). Structure (**26**b) is favoured in the solid state. Complex (**26**) reacts with gaseous HCl to yield $[Ir(Cl)_2(NO)(PPh_3)]$ and the corresponding amide (RNH_2) and azide (RN_3).[19]



(26a) (26b) (26c)

The neutral arenediazo iridium(I) complex $[Ir(Cl)(N_2C_5Cl_4)(PPh_3)_2]$ (**27**) ($N_2C_5Cl_4$ = 2,3,4,5-tetrachlorodiazocyclopentadiene) has been prepared *via* reaction (16). An X-ray crystal structure determination of complex (**27**) reveals a singly bent arenediazo ligand.[60] Further, complex (**27**) is somewhat similar to the cationic complex $[Ir(Cl)(N_2Ph)(PPh_3)_2]^+$,[61] in that both complexes form

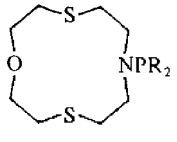


five-coordinate adducts with phosphines and isocyanides. However, reactions with NO^+, CO or N_2Ph^+ are quite different for the two iridium complexes. Complex (**27**) reacts with NO^+, CO, N_2Ph^+, PMe_3, PMe_2Ph, $PMePh_2$ or Bu^tNC (= L) to give the five-coordinate species $[Ir(Cl)(N_2C_5Cl_4)(PPh_3)_2(L)]^+$. Both complex (**27**) and $[Ir(Cl)(N_2Ph)(PPh_3)_2]^+$ have the singly bent diazo linkage perpendicular to the P—P vector.[60,61] The related complexes $[Ir(Cl)(N_2C_5X_4)(PR_3)_2]$ (X = Cl, Br; R = Ph, *p*-FC_6H_4, *p*-MeC_6H_4) have been prepared, wherein iridium is in a square planar environment with mutually *trans* PR_3 ligands and a singly bent $N_2C_5X_4$ ligand. Complex (**27**) reacts with HCl to yield the six-coordinate iridium(III) complex $[Ir(H)(Cl)_2(N_2C_5Cl_4)(PPh_3)_2]$.[62] A square planar environment for Ir has also been observed for $[Ir(Cl)(N_2C_5Cl_4)(PPh_3)_2]\cdot C_7H_8$, having mutually *trans* PPh_3 ligands. The neutral diazo ligand possesses a singly bent geometry in this complex; it appears that there is significant contribution from both canonical structures (**28**a) and (**28**b), though a greater contribution was expected from (**28**b).[63]

$$[Ir(Cl)(CO)(PPh_3)_2] \xrightarrow[CHCl_3/EtOH,\ 273\ K]{ArC(O)N_3,\ N_2C_5Cl_4} [Ir(Cl)(N_2C_5Cl_4)(PPh_3)_2] + CO \qquad (16)$$

(28a) (28b)

$[Ir(CO)_2(PPh_3)(\mu\text{-}SO_2)]_2$ is known to react with *p*-substituted arenediazonium salts, yielding $\{[Ir(CO)_2(PPh_3)]_2(\mu\text{-}N_2C_6H_4R)(\mu\text{-}SO_2)\}^+$ (**29**; R = *p*-tolyl, *p*-methoxy, *p*-fluoro), in which a molecule of SO_2 is replaced by an arenediazonate molecule. The protonated derivatives of (**29**), $\{[Ir(CO)_2(PPh_3)]_2(\mu\text{-}N{=}NHC_6H_4R)(\mu\text{-}SO_2)\}^{2+}$, were obtained by treating (**29**) with HBF_4. Reaction of (**29**) with alkali metal halides, MX, affords the diamagnetic complexes $\{Ir(CO)(PPh_3)]_2(\mu\text{-}X)(\mu\text{-}N_2C_6H_4R)(\mu\text{-}SO_2)\}$ (**30**), which contain halogen atoms (X) bridging the two Ir atoms as shown.[64]



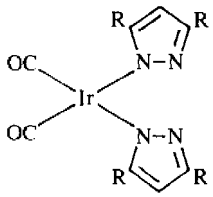
(30)

McGlinchley and Stone[65] have reported the preparation and characterization (^{19}F NMR and IR spectra) of $[Ir(Cl)(CO)(NCF_2CHFCF_3)(PPh_3)_2]$, synthesized from $[Ir(Cl)(CO)(PPh_3)_2]$ and 2H-hexafluoropropyl azide in benzene. Reaction between $[Ir(Cl)(N_2)(PPh_3)_2]$ and $CF_3CHFCF_2N_3$ has afforded the four-coordinate complex $[Ir(Cl)(NCF_2CHFCF_3)(PPh_3)_2]$ and molecular nitrogen.[65]

The crystal and molecular structures of $[Ir(CO)(dtt)(PPh_3)_2]$ (dtt = *p*-$MeC_6H_4NN{=}NC_6H_4Me$-*p*) have been determined by counter data. In this square planar iridium(I) complex, the diaryltriazenido ligand (dtt) is unidentate and *trans* to the CO ligand.[66]

The five-coordinate iridium(I) selenocyanate complex *trans*-$[Ir(CO)(NCSe)(Me_2CO)(PPh_3)_2]$ was prepared *via* metathesis with the corresponding chloro complex $[Ir(Cl)(CO)(PPh_3)_2]$. The complex contains an N-bonded selenocyanate ligand.[67] *trans*-$[Ir(NCS)(CO)(PPh_3)_2]$ has been prepared and contains an N-bonded thiocyanato ligand.[67] The large π-withdrawing character of the *trans* carbonyl ligand in the thiocyanato and selenocyanato complexes probably favours N-bonding.

The aminophosphine ligands (**31a,b**) ($\subset NPR_2$) are prepared from 1-aza-4,10-dithia-7-oxacyclododecane and chlorodiphenylphosphine or chlorodimethylphosphine. Complex (**31**) reacts with $[Ir(Cl)(CO)(cod)]_2$ to produce *trans*-$[Ir(Cl)(CO)(\subset NPR_2)_2]$.[68]



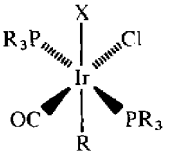
(31a) R = Ph
(31b) R = Me

49.4.2.4 Polypyrazolylborate ligands

Trofimenko[69] has reviewed the preparation of polypyrazolylborate ligands and the syntheses of metal complexes containing such ligands. An update has also appeared.[70]

$[Ir(Cl)(CO)_2]_2$ reacts with bispyrazolylborate anions to yield $[Ir(CO)_2\{H_2B(pz)_2\}]$ and $[Ir(CO)_2\{H_2B(3,5\text{-}Me_2pz)\}]$ (**32**) (pz = 1-pyrazolyl; 3,5-Me_2pz = 3,5-dimethylpyrazolyl).[71] Displacement of a CO ligand by the π-accepting PPh_3 ligand affords $[Ir(CO)\{H_2B(pz)_2\}(PPh_3)]$. These complexes were characterized by ^{1}H NMR, IR and mass spectroscopy.

(32) R = H, Me



49.4.3 Phosphorus and Arsenic Ligands

The chemistry of iridium(I) Vaska-type complexes $[Ir(A)(CO)(PPh_3)_2]$ (A = various anions) has been reviewed,[1,72] and therefore is not exhaustively dealt with here. These complexes are prepared by refluxing an iridium halide in a CO-releasing solvent (alcohol or DMF), or by treating the iridium halide with CO, followed by PPh_3. The analogous complexes $[Ir(A)(CO)(ER_3)_2]$, in which the phosphine ligands are replaced by other group Vb donor ligands are also well known. X-Ray crystal structure, dipole moment and 'virtual coupling' studies have shown that the majority of complexes of the type $[Ir(A)(CO)(L)_2]$ (L = PR_3 or ER_3) possess the *trans* configuration.[73] For complexes with bulky monodentate phosphine ligands (*e.g.* $PR_3 = PMeBu^t_2$), the *trans* configuration is maintained, though there is restricted rotation about the Ir—P bonds as a result of the steric requirements of these ligands.[74] However, the *cis* configuration was found for *cis*-$[Ir(Cl)(CO)(Ph_2AsCH{=}CHAsPh_2)]$,[75] $[Ir(CO)\{N(R)C(Me)CHC(Me)CO\}(PPh_3)]$ (R = *p*-naphthyl, *p*-tolyl),[76] $[Ir\{NHC(CF_3){=}C(CMe{=}CH_2)C(CF_3){=}NH\}(CO)(ER_3)]$ ($ER_3 = PPh_3$, $AsPh_3$),[77] $[Ir(OCRCOCR')(CO)(PPh_3)]$ (R = CF_3, Ph, Me; R' = Me),[76] and $[Ir(Cl)_2(PMePh_2)_2(R)]$ (R = Me, Et, Pr^n).[78]

Bradley and coworkers[79] have examined the electronic absorption spectra at 298 K of a series of d^8 planar complexes with the general formulae $[Ir(A)(CO)(PPh_3)_2]$ (A = OH, F, OCO_2H, ONO_2, Cl, $OReO_3$, $OClO_3$, N_3, NCO, Br, NCS, NO_2, I, NCSe, CN), $[Ir(Cl)(CO)(ER_3)_2]$ (ER_3 = P(*o*-$MeC_6H_4)_3$, PCy_3, $PEtPh_2$, PPh_2Bu, $AsPh_3$, P{*p*-$MeOC_6H_4)_3$}, and $[Ir(CO)(NCBH_3)(PCy_3)_2]$ (Cy = cyclohexyl). The visible spectra reveal three bands; the order of the derivatives noted above corresponds to decreasing energies of the longest-wavelength visible absorption bands and hence to the observed spectrochemical series orders. The two low-lying bands were assigned to the $^1A_1 \rightarrow A_1$, $B_2(^3B_1)$, and $^1A_1 \rightarrow B_1$ transitions, respectively. Similar absorption spectra were obtained from the planar complexes $[Ir(dppe)_2]^+$ and $[Ir(dppen)_2]^+$.[80]

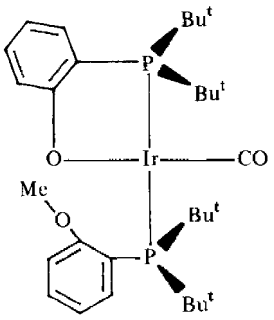
The iridium(I) Vaska-type complexes *trans*-$[Ir(X)(CO)(PPh_3)_2]$ readily undergo oxidative addition with a wide variety of reagents to yield iridium(III) products.[81] Kinetic data for oxidative addition to *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ are usually interpreted in terms of two limiting mechanisms: (i) a concerted process involving a relatively non-polar transition state, resulting in *cis* addition; and (ii) an S_N2 attack by iridium at an electrophilic centre in the substrate molecule involving a polar transition state and usually yielding a *trans* product.[72] With gaseous HX' (X' = Cl, Br, F, HS, *etc.*), solid $[Ir(X)(CO)(PPh_3)_2]$ yields $[Ir(H)(X)(X')(CO)(PPh_3)_2]$; the addition is presumably stereospecifically *cis* (H *trans* to X), based on observations that Ir—H stretching frequencies are sensitive to X and on the absence of H/CO vibrational coupling.[82] *Cis* addition of H_2[83] and O_2[84] to *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ has also been observed. The resulting stereochemistry of the iridium(III) complexes formed as a result of oxidative addition of X_2, HX, RX and acetyl halides to *trans*-$[Ir(Cl)(CO)(PMe_2Ph)_2]$ has been elucidated by NMR and far-IR spectroscopy.[85] Oxidative addition of acyl chlorides, allyl chlorides, methyl bromide and hydrogen halides to *trans*-$[Ir(X)(CO)(PEt_2Ph)_2]$ (X = Cl, Br, I) has been reported.[86] Complexes of the type *trans*-$[Ir(Cl)(CO)(PR_3)_2]$ [$PR_3 = PMe_2$(*o*-$MeOC_6H_4$), PMe_2(*p*-$MeOC_6H_4$)] undergo oxidative addition with MeI, MeCOCl, PhCOCl, or $CH_2{=}CHCH_2Cl$ (RX) to yield octahedral derivatives of the type depicted in (**33**). The reaction rates are faster than that where $PR_3 = PMe_2Ph$; this has been

interpreted in terms of a direct electronic interaction between the methoxy oxygen of PR_3 and the Ir atom.[87] A related paper[88] describes mechanistic studies on the oxidative addition of optically-active α-bromo esters {(*RS*,*SR*)-PhCHFCHBrCO$_2$Et} to *trans*-[Ir(Cl)(CO)(PMe$_3$)$_2$]. NMR spectral data (^{1}H, ^{13}C, ^{19}F) were interpreted in terms of the reactions involving loss of stereochemistry at carbon and proceeding *via* a free radical mechanism, as shown by retarded rates being observed in the presence of electron scavengers. Proton NMR spectroscopy has been employed to monitor the stereochemical changes at carbon during the oxidative addition of alkyl halides to *trans*-[Ir(Cl)(CO)(PR$_3$)$_2$]. Complete loss of stereochemistry at carbon is observed. Two mechanistic pathways were postulated, one having characteristics consistent with a radical chain pathway as exhibited by several saturated alkyl halides, aryl and vinyl halides, and α-halo esters. By contrast, methyl, benzyl and allyl halides, and α-halo ethers react in a different manner, as shown by their insensitivity toward inhibitors.[89]

(33)

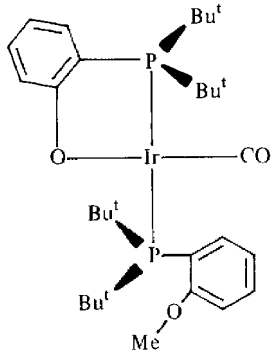
Acyl chlorides, RCOCl, react with [Ir(Cl)(PMePh$_2$)$_3$], or with a solution containing [Ir(Cl)(cod)]$_2$ and PMePh$_2$, to yield the six-coordinate alkyl iridium(III) complexes with mutually *cis* PMePh$_2$ groups, *cis*-[Ir(Cl)(CO)(PMePh$_2$)$_2$(R)] (R = Me, Et, Pr^n). In solution, complexes for which R = Et and Pr^n rapidly equilibrate with the five-coordinate acyl iridium(III) complex [Ir(Cl)$_2$(COR)-(PMePh$_2$)$_2$], which also has mutually *cis* PMePh$_2$ ligands.[78] *trans*-[Ir(Cl)(CO)(PR$_3$)$_2$] and [Ir-(Cl)(CO)(PR$_3$)$_2$] (PR$_3$ = PMe$_2$Ph, PEt$_2$Ph) react with each other, presumably *via* a double-chloro-bridged intermediate, and undergo rapid oxidative addition–reductive elimination. A mixture of *trans*-[Ir(Cl)(CO)(PMe$_2$Ph)$_2$] and [Ir(Cl)$_3$(CO)(PEt$_2$Ph)$_2$] was converted almost completely to *trans*-[Ir(Cl)(CO)(PEt$_2$Ph)$_2$] and [Ir(Cl)$_3$(CO)(PMe$_2$Ph)$_2$] after 15 min at 295 K in C$_6$H$_6$/C$_6$D$_6$.[90] The iridium(I) complex [Ir(CO)(C$_2$Ph)(PPh$_3$)$_2$] (**34**) has been prepared from the reaction of [Ir-(CO)$_3$(PPh$_3$)$_2$]$^+$ and phenylacetylene in acetone, presumably *via* the intermediate species '[Ir(CO)$_2$(HC$_2$Ph)(PPh$_3$)$_2$]$^{+}$'. Complex (**34**) adds SO$_2$, HgCl$_2$, H$_2$, O$_2$, CF$_3$CO$_2$H, MeCO$_2$H, C$_2$(CO$_2$Me)$_2$, MeI and C$_2$(CN)$_4$ *via* attack at the metal centre; in contrast, addition of HX and X$_2$ (X = Cl, Br, I) proceeds by attack at both the metal centre and the alkyne linkage. Thus, addition of Br$_2$ yields [Ir(H)(Br)(CH=CBrPh)(CO)(PPh$_3$)$_2$] and [Ir(H)(Br)(CBr=CHPh)(CO)(PPh$_3$)$_2$].[91]

Titration calorimetry has been employed to determine enthalpies of oxidative addition of RI (= I$_2$, HI, MeI, EtI, Pr^{n}I, Pr^{i}I, PhCH$_2$I, PhC(O)I, MeC(O)I, (*o*-O$_2$C$_6$Cl$_4$), SO$_2$ and C$_2$(CN)$_4$) to complexes of the type *trans*-[Ir(X)(CO)(ER$_3$)$_2$] (X = Cl, ER$_3$ = PMe$_3$;[92,93] ER$_3$ = PPh$_3$, X = F, Cl, Br, I, NCS, N$_3$; X = Cl, ER$_3$ = P(OPh)$_3$, PMe$_2$Ph, PMePh$_2$, PEt$_2$Ph, PPh$_2$Bu^t, PCy$_3$, AsPh$_3$).[94] The enthalpy changes along with other thermochemical data were used to give a relative scale of Ir —R bond energies. The enthalpy of adduct formation between [Ir(Cl)(CO)(PPh$_3$)$_2$] and SO$_2$ was also determined by GLC techniques, permitting tentative characterization of the donor in terms of the E and C model.[95]



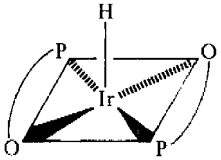
The irreversible electrochemical oxidation of [Ir(X)(CO)(PR$_3$)$_2$] (X = Cl, Br, I; PR$_3$ = PPh$_3$, PPh$_2$Et, PPhEt$_2$, PEt$_3$) on rotating Pt electrodes in Bu$_4$NClO$_4$/CH$_2$Cl$_2$ reportedly proceeds at diffusion-controlled rates. In the redox addition process, atom transferability predominates over complex redox properties. Evidence indicates that the insoluble product of the one-electron oxidation of [Ir(X)(CO)(PR$_3$)$_2$] is a dimeric iridium(II) complex with an iridium–iridium bond.[96]

The reaction of [Ir(Cl)(CO)(PPh$_3$)$_2$] with the hydroperoxide Bu^{t}O$_2$H has yielded [Ir(Cl)(CO)-(PPh$_3$)$_2$(Bu^{t}O$_2$H)$_2$] and a blue Ir/PPh$_3$/Cl substance, along with CO$_2$ and OPPh$_3$. It was proposed that the reaction might occur *via* coordination at a vacant site, with the possibility of oxygen transfer to oxidizable ligands.[97]

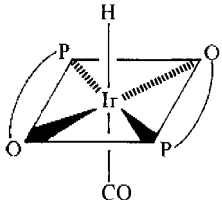


The displacement of MeCN in [Ir(CO)(PPh$_3$)$_2$(MeCN)]$^+$ by the coordinating anions A$^-$ (= CN$^-$, C≡CPh$^-$, SH$^-$, O$_2$CCF$_3^-$, O$_2$CH$^-$, NCS$^-$, NCO$^-$, OH$^-$, F$^-$ and *p*-toluenesulfinate) yields [Ir(A)(CO)(PPh$_3$)$_2$], except where A$^-$ = CN$^-$, and the five-coordinate [Ir(CN)(CO)(PPh$_3$)$_3$] was obtained.[98] Oxidative addition of HCl to [Ir(Cl)(cod)(PEtPh$_2$)] gives [Ir(H)(Cl)$_2$(cod)(PEtPh$_2$)] *via* the intermediate species [Ir(Cl)$_2$(cod)(PEtPh$_2$)]$^-$. Generally, the oxidation of the substrate precedes the nucleophilic attack of the anionic species; in this case, however, it was suggested that the oxidizing step is preceded by the nucleophilic attack affording the intermediate species.[99] [Ir-(Cl)(cod)(PCy$_3$)] has been prepared *via* addition of PCy$_3$ to [Ir(H)(Cl)$_2$(cod)]$_2$. In contrast, the

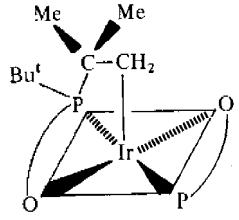
addition of PCy_3 to $[Ir(Cl)(cot)_2]_2$ (cot = cyclooctene) at 293 K in toluene affords $[Ir(H)_2(Cl)\{(P(C_6H_9)Cy_2\}(PCy_3)]$, in which one cyclohexyl group has been dehydrogenated to cyclohexane, the double bond being coordinated to Ir. Under refluxing conditions, the four-coordinate complex $[Ir(Cl)\{P(C_6H_9)Cy_2\}(PCy_3)]$ was formed. The syntheses of $[Ir(Cl)(CO)(PCy_3)_2]$ and $[Ir(H)_2(Cl)(PCy_3)_2]$ have also been reported.[100] The basic and bulky PCy_3 ligand is a potentially good ancillary ligand for a coordinatively unsaturated complex likely to react with small gas molecules. Complexes of the type $[Ir(cod)\{P(p\text{-}RC_6H_4)_3\}_2]A$ (R = Cl, F, H, Me, OMe; A = ClO_4^-, BPh_4^-) have been prepared from $[Ir(Cl)(cod)]_2$ and stoichiometric amounts of the appropriate phosphine, and undergo oxidative and displacement reactions. Thus, $[Ir(cod)\{P(p\text{-}RC_6H_4)_3\}_2]^+$ undergoes oxidative addition with Cl_2, I_2 and MeI, and displacement of cod when reacted with CO or H_2.[101]



Transition metal complexes containing bulky tertiary phosphine ligands are expected to exhibit unusual physical and chemical properties. Complexes of the type *trans*-$[Ir(X)(CO)(PBu^t_2R)_2]$ (**35**; X = Cl, Br; R = Me, Et, Pr^n) have been prepared by passing CO through a solution of $[IrCl_6]^{2-}$ (or $[IrBr_6]^{2-}$) followed by phosphine addition.[102] A modified method has been employed to prepare the O-metallated iridium(I) complex $[Ir(CO)\{PBu^t_2(C_6H_4O)\}\{PBu^t_2(C_6H_4O)Me\text{-}2)\}]$ (**36**).[103] Complexes of the type (**35**) exist as rotational conformers which interconvert at room temperature.[74] For complex (**36**), two rotational conformers are possible (**36a,b**) and thought to interconvert at room temperature.[103] Complex (**36**) can be demethylated to yield $[Ir(CO)\{PBu^t_2(C_6H_4O)\}\{PBu^t_2(C_6H_4OH\text{-}2)\}]$, which on treatment with air yields CO_2 and the paramagnetic iridium(II) complex *trans*-$[Ir\{PBu^t_2(C_6H_4O)\}_2]$ (**37**). Complex (**37**) has been characterized by X-ray structural analysis and magnetic measurements. Presumably, the formation of (**37**) proceeds by initial O_2 uptake to form an 'end-on' species. Hydrogenation of complex (**37**) yields the iridium(III) complex $[Ir(H)\{PBu^t_2(C_6H_4O)\}_2]$ (**38**), which reacts with CO to yield complex (**39**), $[Ir(H)\{PBu^t_2(C_6H_4O)\}_2]$. Complex (**37**) in benzene, when allowed to stand for 24 h, affords the C-metallated iridium(III) complex $[Ir\{PBu^t_2(C_6H_4O)\}\{PBu^t(C_6H_4O)(CMe_2CH_2)\}]$ (**40**).[103]



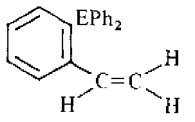
(36a)



(36b)

(38)

(39)



(40)

The bulky phosphine ligand $PBu^t_2(C{\equiv}CPh)$ reacts with $[IrCl_6]^{2-}$ in ethanol to give *trans*-$[Ir(Cl)(CO)\{PBu^t_2(C{\equiv}CPh)\}_2]$. This iridium(I) complex further reacts with HCl to yield $[Ir(H)(Cl)_2(CO)\{PBu^t_2(C{\equiv}CPh)\}_2]$, with sodium propan-2-olate in propan-2-ol to yield $[Ir(CO)\{PBu^t_2[CH{=}C(O)Ph]\}\{PBu^t_2(C{\equiv}CPh)\}]$, and with sodium methoxide to give $[Ir(CO)\{PBu^t_2[CH{=}C(O)Ph]\}\{PBu^t_2[CH{=}C(OMe)Ph]\}]$.[104]

(*o*-Vinylphenyl)diphenylphosphine [*o*-$CH_2{=}CHC_6H_4PPh_2$, spp] and its arsenic analogue [*o*-CH_2

$=CHC_6H_4AsPh_2$, spas} (**41**) form five-coordinate complexes of iridium(I) with the general formula $[Ir(Cl)(L)_2]$ (L = spp, spas). The cationic derivatives $[Ir(L)_2A]^+$ (A = CO, PF_3, $PMePh_2$, py) have been obtained from $[Ir(Cl)(L)_2]$ and $AgBF_4$, NH_4PF_6 or $NaBPh_4$ in the presence of ligand A. All of these complexes are reportedly trigonal bipyramidal with the spp (or spas) ligands in axial sites. The vinyl groups are in equatorial sites and probably lie in the equatorial plane. Proton and ^{31}P NMR data reveal the existence of two isomers (i) a 'symmetric' isomer having equivalent vinyl groups; and (ii) an 'unsymmetric' isomer having inequivalent vinyl groups. The isomerism reportedly arises from the different possible orientations of the vinyl groups with respect to each other.[105]

(**41**) spp, E = P; spas, E = As

The metal-containing phosphine $[PPh_2Fe(CO)_2(\eta\text{-}C_5H_4R)]$ (R = H, Me) reacts with $[Ir(C_8H_{12})(solvent)_x]^+$ to yield a variety of cationic mixed metal cluster species, including $[Ir\{FePPh_2(CO)_2(Cp)\}_2]^+$, $[Ir\{FePPh_2(CO)_2(Cp)\}_2(solvent)_x]^+$, $[Ir(CO)_3\{FePPh_2(CO)_2(Cp)\}_2]^+$, $[Ir(CO)\{FePPh_2(CO)_2(Cp)_2Cl\}]$, $[Ir(X)(CO)\{FePPh_2(CO)_2(Cp)\}_2]^+$ (X = CN, Br, I), $[Ir(Cl)(CO)\{FePPh_2(CO)_2(\eta\text{-}C_5H_4Me)\}_2]$ and $[Ir(I)\{FePPh_2(CO)_2(Cp)\}_2]$. The behaviour of the mixed metal cluster complexes toward CO and H_2 have also been reported.[106]

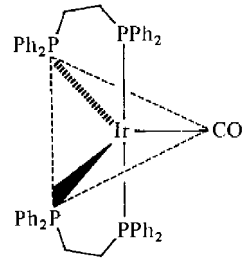
Several iridium(I) complexes containing the secondary phosphine ligands HPR_2 have been prepared. These include $[Ir(HPR_2)_4]^+$, where HPR_2 is $HPEt_2$, HPEtPh, $HPPh_2$, $HPPh(C_6H_{11})$ or $HP(C_6H_{11})_2$, and were prepared from $[Ir(Cl)(C_8H_{14})]_2$ and HPR_2.[107] Reactions of $[Ir(HPR_2)_4]^+$ with CO, H_2 and HCl are summarized in reactions (17)–(19). IR spectral data of the dihydrido iridium(III) complex (reaction 18) were interpreted in terms of a *cis* arrangement of the H ligands; this has been corroborated by ^1H NMR. In contrast, IR and NMR studies of $[Ir(H)(Cl)(HPR_2)_4]^+$ (reaction 19) suggest a *trans* structure.[107] *trans*-$[Ir(Cl)(CO)(HPBu^t_2)_2]$ is formed from hydrated iridium(III) chloride and PBu^t_3 in DMF. This would appear to be the first example of a P—C bond cleavage of a tertiary phosphine resulting in the formation of a secondary phosphine complex.[108]

$$[Ir(CO)(HPR_2)_4]^+ \longleftarrow [Ir(HPR_2)_4]^+ + CO \longrightarrow [Ir(CO)_2(HPR_2)_3]^+ \quad (17)$$

$R_2 = Ph_2, PhC_6H_{11}$ $\qquad$ $R_2 = (C_6H_{11})_2$

$$[Ir(HPR_2)_4]^+ + H_2 \longrightarrow [Ir(H)_2(HPR_2)_4]^+ \quad (18)$$

$$[Ir(HPR_2)_4]^+ + HCl \longrightarrow [Ir(H)(Cl)(HPR_2)_4]^+ \quad (19)$$



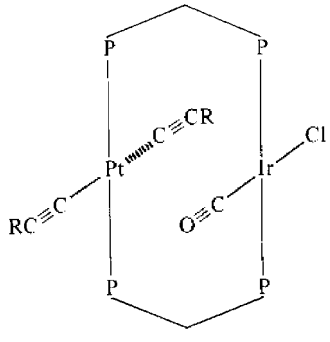
The cationic complexes $[Ir(CO)_2(SbPh_3)_3]^+$ and $[Ir(CO)_2(PR_3)_2]^+$ (R = Ph, C_6H_{11}) have been synthesized from iridium carbonyl halide derivatives with halogen acceptors in the presence of CO.[109]

Several iridium(I) diphosphine complexes have been synthesized with the ligands $Ph_2PCH_2CH_2PPh_2$ (dppe), $Ph_2PCH_2PPh_2$ (dppm), $Ph_2PC_6H_4PPh_2$ (dpbe), $Ph_2PCH_2CH_2AsPh_2$ (arphos), $Ph_2PCH{=}CHPPh_2$ (dppen), $Ph_2AsCH_2CH_2AsPh_2$ (dpae) and $Ph_2P(CH_2)_nPPh_2$ ($n = 3$, 4). Room temperature electronic absorption and MCD spectra of $[Ir(dppe)_2]^+$ and $[Ir(dppen)_2]^+$ reveal intense UV and visible absorptions that have been attributed to MLCT transitions.[110] Excitation polarization of these two luminescent complexes in propan-1-ol at 108 K permitted detailed spectral assignments based on the spin–orbit coupling model for d^8 metal ions complexed with π-acceptor ligands.[111] The absorption and excitation band energies of $[Ir(P{—}P)_2]^+$ and $[Ir(cod)(P{—}P)]^+$ (P—P = dppe, dppen, dpbe, arphos) are relatively insensitive to all ligands except cod. The red shift observed in complexes containing the cod ligand was attributed to destabilization of all the *d* orbitals due to closer approach of the diphosphine ligand to the Ir centre. The emission spectra and lifetimes of $[Ir(P{—}P)_2]^+$ and $[Ir(cod)(P{—}P)]^+$ have been interpreted in terms of a two-level spin–orbit split-triplet manifold.[112]

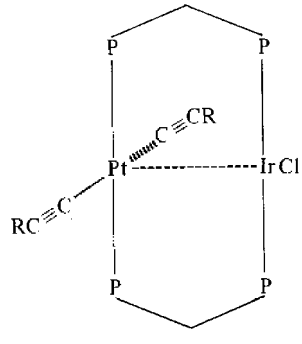
The crystal and molecular structures of the five-coordinate complex $[Ir(dppe)_2(CNMe)](ClO_4)$ have revealed a somewhat distorted trigonal bipyramidal geometry about Ir, with each dppe ligand bridging an axial and an equatorial coordination site.[113] The key structural parameters in this complex are the Ir–isocyanide ligand bond length and the angle in the trigonal plane *trans* to the unique ligand. A discussion of the effects of π-acceptor orbitals on substituents in the equatorial position (CNMe) was consistent with the finding that this iridium(I) complex exhibits the largest

P—Ir—P bond angle (120.36°) when compared to complexes containing NO^+ and CO as the unique ligand. The fluxionality of this complex appears to involve a stereochemically non-rigid TBP structure. However, the geometry of $[Ir(dppe)_2(CNMe)]^+$ is similar to that found for several other dppe complexes of iridium, including $[Ir(CO)(dppe)_2]^+$, $[Ir(dppe)_2(O_2)]^+$ and $[Ir(dppe)_2(S_2)]^+$.[114-116]

$[Ir(dppe)_2(O_2)]^+$ reversibly binds CO in solution.[83] The crystal structure of the CO adduct $[Ir(CO)(dppe)_2]^+$ (**42**) reveals a distorted trigonal bipyramid with CO occupying an equatorial position.[114]



(42)

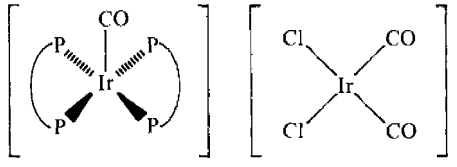


The four- and five-coordinate iridium(I) cations $[Ir(dppe)_2]^+$ and $[Ir(CO)(dppe)_2]^+$ react with $B_{10}H_{14}$, $B_{10}H_{13}$(Cl-6) and $(B_{10}H_{13})^-$ to yield a variety of ionic compounds, some of which are given in reactions (20) and (21).[117] Reaction of *t*-butyl isocyanide with the A-frame complex $[Ir_2(Cl)(CO)_3(P—P)_2](X)$ (P—P = dppm, dpam) affords $[Ir_2(CO)_3(P—P)_2(Bu^tNC)](X)$, $[Ir_2(Cl)(CO)_2(P—P)_2(Bu^tNC)_2](X)$ (P—P = dppm, X = BPh_4; P—P = dpam, X = BF_4) and $[Ir_2(CO)(P—P)_2(Bu^tNC)_4](BPh_4)_2$, as characterized by IR and ^{13}C and ^{31}P NMR spectroscopies.[118] Other neutral and cationic binuclear carbonyl complexes of iridium(I) containing dppm have been reported.[119] The dppm ligand is excellent for stabilizing homo-bimetallic complexes with metal—metal bonds, A-frames, and eight-membered rings. The treatment of *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ with $[Pt(C{\equiv}C\text{-}p\text{-}tolyl)_2(\eta'\text{-dppm})_2]$ in refluxing benzene has yielded $[Pr(C{\equiv}C\text{-}p\text{-}tolyl)_2(\mu\text{-dppm})_2Ir(Cl)(CO)]$ (**43**) in >80% yields. Also, $[Ir(Cl)_2(C_8H_{14})_4]$ reacts with $[Pt(C{\equiv}CPh)_2(\eta'\text{-dppm})_2]$ in benzene at 293 K to give $[(PhC{\equiv}C)_2Pt(\mu\text{-dppm})_2Ir(Cl)]$ (**44**).[120] Dialkynediphosphines of the type $L = Bu^t_2PC{\equiv}C(CH_2)_nC{\equiv}CPBu^t_2$ (n = 4, 5) are known to react with $Na_2[IrCl_6]$ and CO in hot ethanol to yield $[Ir(H)(Cl)_2(CO)(L)]$ (n = 5) which, when treated with NEt_3, gives *trans*-$[Ir(Cl)(CO)(L)]$.[121] Alkynic groups promote the formation of large rings as a result of favourable conformational and entropy effects. The crystal and molecular structures of $[Ir(Cl)(CO)\{Bu^t_2PC{\equiv}C(CH_2)_5C{\equiv}CPBu^t_2\}]$ reveal a distorted planar coordination geometry about Ir with P atoms mutually *trans*.[122]

$$[Ir(dppe)_2]^+ + B_{10}H_{13}X \xrightarrow[X = H,\ 6\text{-}Cl]{} [Ir^{III}(H)(Cl)(dppe)_2][B_{10}H_{12}X] \quad (20)$$

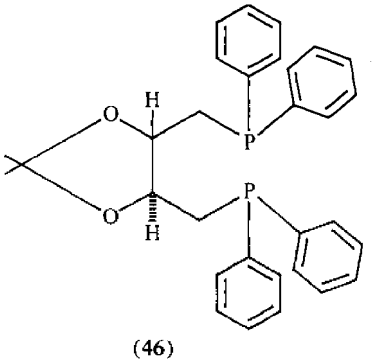
$$[Ir(CO)(dppe)_2]^+ + (NEt_3H)[B_{10}H_{13}] \longrightarrow [Ir^{I}(CO)(dppe)_2][B_{10}H_{13}] + [Ir(H)_2(dppe)_2][B_9H_{14}] \quad (21)$$

(43)



(44)

The double bond present in $Ph_2PCH{=}CHPPh_2$ (dppen) sometimes imparts different character to $[Ir(dppen)_2]X$ and $[Ir(dppen)_2Y]X$ complexes (X = Cl, Br, I, ClO_4, BPh_4; Y = CO, H_2, O_2, HCl, HI) than that present in the corresponding $Ph_2PCH_2CH_2PPh_2$ (dppe) complexes. The different behaviour was attributed[123] to the presence of the double bond. The tendency of the dppen ligand to favour electron delocalization leads to a lowering of its basicity and to a π-bonding ability greater

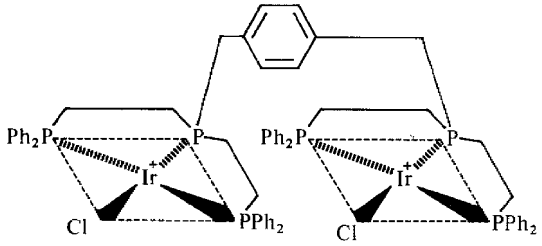


than that of dppe. Thus, the dppen ligand makes less demand for $d\pi$ electrons of Ir, and the back-donation involves mainly the carbonyl group in $[Ir(CO)(dppen)_2]^+$.

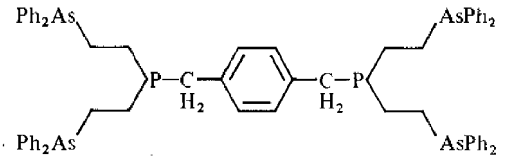
Studies by Shaw *et al.*[124] have shown that the ligands $Bu^t_2P(CH_2)_nPBu^t_2$ ($n \geqslant 9$) bridge rhodium(I) and palladium(II) atoms, but chelate iridium(I) and platinum(II) atoms in a *trans* manner. The diphosphine ligands $Ph_2P(CH_2)_nPPh_2$ ($n = 1$–4) form *trans* carbonyl complexes of iridium(I) with the stoichiometry $[\{Ir(Cl)(CO)(diphosphine)\}_m]$, in which the diphosphine ($m = 1, 3, 4$) bridges the metal atoms. Thus, the complex $[Ir(CO)\{Ph_2P(CH_2)_2PPh_2\}_2][Ir(Cl)_2(CO)]$ forms with the structure (**45**).[119b] The intramolecular barriers to rearrangement of the trigonal bipyramidal complexes $[Ir(CO)\{Ph_2P(CH_2)_nPPh_2\}_2]^+$ decrease with decreasing ring size. This phenomenon has been suggested as a criterion for quantitative assessment of metal-to-ligand bonding.[125]

(45)

The isolation of a series of iridium(I) complexes with the optically-active diop ligand (**46**) [diop = 4,5-bis(diphenylphosphinomethyl)-2,2-dimethyl-1,3-dioxolane] has been reported. Equivalent portions of diop and $[Ir(Cl)(cod)]_2$ in ethanol yield $[Ir(Cl)(diop)(cod)]\cdot EtOH$.[126] The X-ray crystal structure of this complex shows a distorted trigonal bipyramid in which diop serves as an apical–equatorial bidentate ligand. The structure is maintained in solution, as evidenced by ^{31}P NMR data in $CDCl_3$ at 223 K.[127] In acetone solution, reaction between $[Ir(Cl)(cod)]_2$ and two or more equivalents of diop affords $[Ir(diop)_2](BPh_4)$, which reacts with CO to yield $[Ir_2(CO)_2(diop)_3](BPh_4)_2$.[126]



(46)

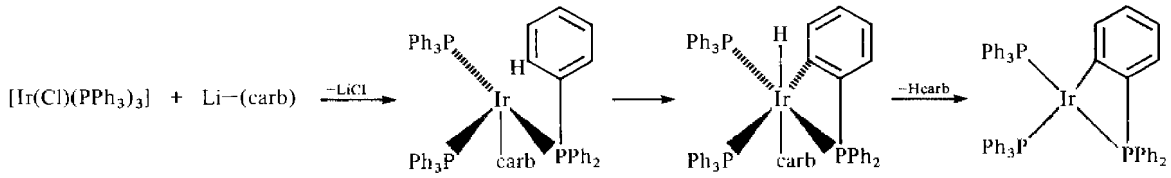


As well as serving as bidentate ligands, dppm, $Bu^t_2PC{\equiv}C(CH_2)_5C{\equiv}CPBu^t_2$ and $Ph_2P(CH_2)_3PPh_2$ are also capable of bridging two iridium atoms. These ligands are incorporated in $[Ir_2(\mu\text{-}Cl)(\mu\text{-}CO)(CO)_2(\mu\text{-}dppm)_2]^+$, $[Ir_2(\mu\text{-}Cl)(\mu\text{-}CO)(CO)_3(\mu\text{-}dppm)_2]^+$, $[Ir(Cl)(CO)\{Ph_2P(CH_2)_3PPh_2\}]_2$ and $[Ir(Br)(CO)\{Bu^t_2PC{\equiv}C(CH_2)_5C{\equiv}CPBu^t_2\}]_2$.[121,128]

The sexidentate ligand P,P,P′,P′-tetrakis-(2-diphenylphosphinoethyl)-α,α′-diphospha-*p*-xylene (TDDX) forms, upon reaction with $[Ir(Cl)(CO)(PPh_3)_2]$, the binuclear diamagnetic non-ionic complex $[Ir_2(Cl)_2(TDDX)]$ (**47**). The TDDX complex is formed *via* complete displacement of CO and PPh_3 from Vaska's complex.[129] The ^1H NMR spectrum of complex (**47**) resembles that of [Ir(triphos)(CO)](Cl),[130] in which the triphos coordinates three coordination sites in the square plane of the Ir ion. Thus, complex (**47**) is likely to be square planar with TDDX as a sexidentate donor binding three coordination positions on each Ir ion of the binuclear complex, as shown.[129] The similar P,P,P′,P′-tetrakis-(2-diphenylarsinoethyl)-α,α′-diphospha-*p*-xylene ligand (TDADX) (**48**) reacts with Vaska's complex in benzene to give [Ir(TDADX)](Cl). In this complex, the potentially sexidentate TDADX ligand appears to bind in a tetradentate manner through the As atoms. Reactions of [Ir(TDADX)](Cl) with H_2, CO and NO are summarized in reactions (22)–(24), respectively.[131]

The internally metallated iridium(I) complex (**51**) results from treatment of $[Ir(Cl)(PPh_3)_3]$ with 1-Li-2R-1,2-$B_{10}C_2H_{10}$ (R = Me, Ph) in ether. The reaction presumably proceeds by initial formation of a carborane iridium(I) complex (**49**), which is transformed to (**51**) *via* the intermediate species (**50**)

(47)



(48)

$$[Ir(TDADX)Cl + H_2 \xrightarrow{CHCl_3} [Ir(H)_2(TDADX)]Cl \quad (22)$$

$$[Ir(TDADX)]Cl + CO \xrightarrow{CHCl_3} [Ir(CO)(TDADX)]Cl \quad (23)$$

$$[Ir(TDADX)]Cl + NO \longrightarrow [Ir(NO)(TDADX)]^{2+} \quad (24)$$

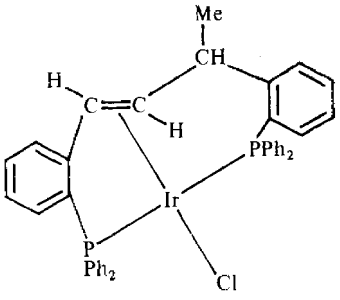
by rapid intramolecular oxidative addition and reductive elimination (see Scheme 5).[132,133] A similar reaction sequence was postulated for $[Ir(PPh_3)_3(Me)]$.[134] Complex (**51**) reacts with CO, H_2 and MeOH in solution according to reactions (25)–(27), respectively, depending on reaction conditions. Proton NMR and IR spectroscopy have been employed to derive the product stereochemistries.[135]

(49) (50) (51)

Scheme 5

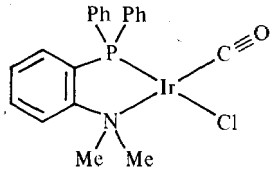
$$(51) + CO \longrightarrow [Ir(CO)\{P(C_6H_4)Ph_2\}(PPh_3)] + PPh_3 \quad (25a)$$

$$(51) + CO \longrightarrow [Ir(CO)\{P(C_6H_4)Ph_2\}(PPh_3)_2] \quad (25b)$$



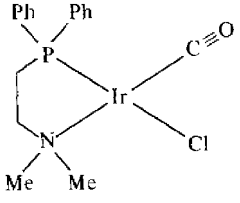
$$(51) + 2CO \longrightarrow [Ir(CO)_2\{P(C_6H_4)Ph_2\}(PPh_3)] \quad (25c)$$

$$(51) + H_2 \longrightarrow fac\text{-}[Ir(H)_3(PPh_3)_3] \quad (26)$$

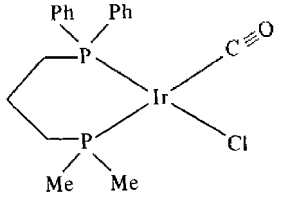


$$(51) + MeOH \longrightarrow [Ir(H)_2\{P(C_6H_4)Ph_2\}(PPh_3)_2] \quad (27)$$

o-$Ph_2PC_6H_4CH{=}^{t}CHCH(Me)C_6H_4PPh_2$-*o* (1-bdpb) reacts with $[Ir(Cl)(cod)]_2$ to yield [Ir(Cl)-(1-bdpb)] (**52**), which exists as a mixture of isomers having differing conformations of the chelate ligand. Possible conformational interconversions have been reported.[136] Complex (**52**) undergoes irreversible oxidative addition at Ir with Cl_2 and HCl, and reversible oxidative addition with H_2.[136] The similar ligands *o*-$Ph_2PC_6H_4(CH_2)_2C_6H_4PPh_2$-*o* (bdpbz) and *o*-$Ph_2AsC_6H_4(CH_2)_2C_6H_4$ PPh_2-*o* (bdabz) are found in [Ir(Cl)(bdpbz)(CO)] and [Ir(Cl)(bdabz)(CO)], respectively. The group Vb donor ligands span *trans* coordination sites. The bdpbz complex isomerizes in solution at room temperature by transferring a benzylic hydrogen atom to Ir and forming a chelate–Ir–carbon σ-bonded complex; the bdabz complex behaves in a similar fashion under more rigorous conditions.[137]



The crystal structure of the square planar complex $[Ir(Cl)(CO)(Ph_2PC_6H_4NMe_2)]$ (**53**) has been determined. IR and ^{31}P NMR spectra for complexes (**53**), (**54**) and (**55**) have suggested that all three complexes possess the same stereochemistry.[138] It was also observed that these complexes are more effective than Vaska's complex for the isomerization of 1-hex-1-ene under hydrogenation conditions.[138]



(52)

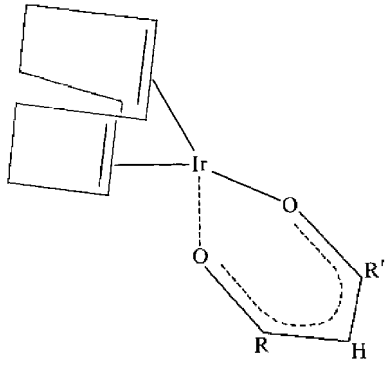
(55)

49.4.4 Oxygen Ligands



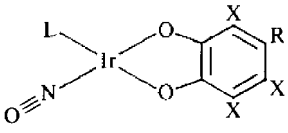
49.4.4.1 β-Diketonate, catecholate and semiquinone ligands

The syntheses and properties of $[Ir(acac)(\eta^5\text{-}C_5Me_5)]$ and $[Ir(hfac)(\eta^5\text{-}C_5Me_5)]$ **(56)** (acac = acetylacetonate, hfac = hexafluoroacetylacetonate) have been reported.[139] These iridium(I) complexes are afforded upon reaction of $[Ir(Cl)_2(\eta^5\text{-}C_5Me_5)]_2$ and the sodium salt of the appropriate acetylacetonate. Under more rigorous conditions, the bis-acac complex $[Ir(acac)_2(\eta^5\text{-}C_5Me_5)]$ **(57)** results, in which the two acac ligands are OO′- and C-bonded to iridium.

(56) (57)

Complexes of the type in **(58)** have been prepared and their properties investigated by IR and ^1H NMR spectroscopy.[140] Proton NMR spectra reveal a regular variation of the chemical shifts of the alkene protons of the cod ligand with the electronic properties of the β-diketonates. Analogous results are obtained from Ir—cod IR frequencies. Treatment of $[Ir(Cl)(C_7H_8)_3]_x$ (C_7H_8 = norbornadiene) with acetylacetone yields a species $[Ir(acac)(C_7H_8)_3]$ **(59)** having two of the norbornadiene units half-linked together with *exo–trans–exo* stereochemistry in a five-membered metallacycle. The crystal structure of complex **(59)** shows the acac ligand to be essentially planar.[141]

(58)



R = R′ = CF_3
R = R′ = Me
R = CF_3, R′ = Me
R = R′ = CMe_3
R = Me, R′ = Ph
R = R′ = Ph
R = Me, R′ = Ph
R = CF_3, R′ = C_4H_3S

IR, Raman and ^{13}C NMR spectroscopic studies have been performed on various $[Ir(acac)(L)_2]$ complexes (L = ethylene, propene, vinyl chloride, vinyl acetate, methyl acrylate, styrene) for the elucidation of the bonding between Ir and the alkene ligand.[142] Also, the square planar iridium(I) acetylacetonate complexes $[Ir(LL)(L')_2]$, where LL is a β-diketonate and L′ is CO or ethylene, have been studied by UVPES.[143] The enthalpies of reaction of the crystalline $[Ir(acac)(L)_2]$ complexes with gaseous CO (reaction 28) have been determined by differential scanning calorimetry. The enthalpies for the gaseous reaction have been derived from these results and Ir—L bond strengths estimated.[143]

$$[Ir(acac)(L)_2](s) + 2CO(g) \longrightarrow [Ir(acac)(CO)_2](s) + 2L(g) \quad (28)$$

IR studies on the photochemistry of the complexes $[Ir(L)(CO)_2]$ (L = acac, hfac, tfac; tfac = trifluoroacetylacetonate) in inert (CH_4·Ar) and reactive (CO, N_2) gas matrices at 12 K have shown that $[Ir(L)(CO)]$, $[Ir(CO)(N_2)]$ and $[Ir(CO)_2(L')]$ (L′ = unidentate form of L) are produced.[144]

The syntheses and characterization of nitrosyl catecholato complexes of the type in (**60**) have been reported.[145] The addition reaction of PPh_3 to various $[Ir(NO)(cat)(PPh_3)]$ (catecholato) complexes to give $[Ir(NO)(cat)(PPh_3)_2]$ has been examined in order to determine if a reversible association of a neutral molecule to a potentially catalytic d^8 four-coordinate complex can be considered as a model of one of the steps involved in the overall catalytic process. The $[Ir(NO)(1,2\text{-}O_2C_6Br_4)(PPh_3)]$ complex has been prepared and characterized. The Ir—O bond length *trans* to the NO ligand is unusually short; this probably results from the bonding effect of having a strong π-acceptor *trans* to a strong π-donor.[147] Studies of the catalytic activity of $[Ir(NO)(1,2\text{-}O_2C_6Br_4)(PPh_3)]$ and $[Ir(NO)(1,2\text{-}O_2C_6H_4)(PPh_3)]$ in the homogeneous hydrogenation of cyclic alkenes, dienes and trienes indicate that the activity is related to the electron density on the central iridium atom.[148]

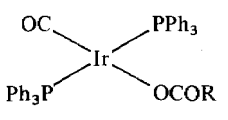
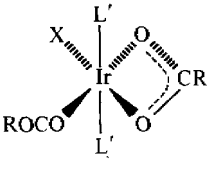
X = H;
R = NO_2, CHO, CO_2Me, CH_2OH, Me



(60)

49.4.4.2 Bicarbonate and carboxylate ligands

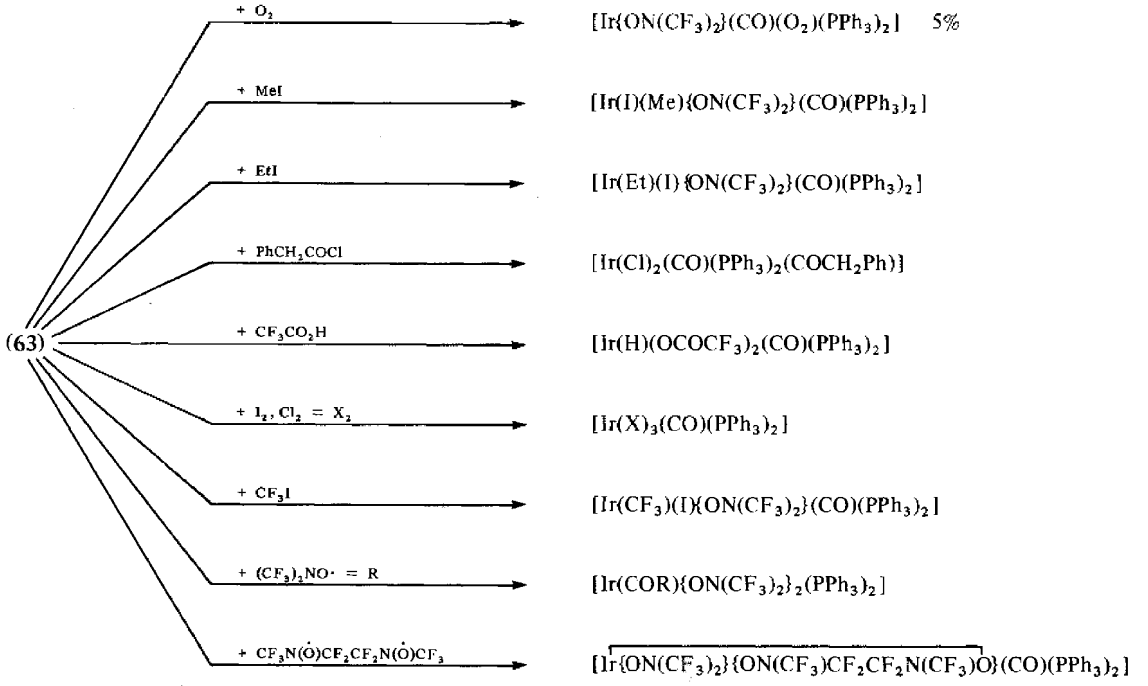


The hydroxy complex *trans*-$[Ir(OH)(CO)(PPh_3)_2]$ reacts with CO_2 in ethanol to produce the monodentate bicarbonato complex $[Ir(OCO_2H)(CO)(PPh_3)_2]$. The rate of reaction is first order in complex and independent of CO_2 and H_2O concentrations.[149,150] The bicarbonato complex reacts with O_2, affording $[Ir(OCO_2H)(CO)(O_2)(PPh_3)_2]$.[149]

$[Ir(CO)(PPh_3)_2(MeCN)]^+$ reacts with the peroxycarboxylic acids RCO_3H in the presence of NEt_3 to yield $[Ir(O_2CR)(CO)(PPh_3)_2]$ (**61**) (R = *m*-ClC_6H_4, Ph, Me). The alkyl peroxy complex (**61**) (R = *m*-ClC_6H_4) reacts with MeI according to reaction (29). Reaction of NaO_2COR' (R′ = *m*-ClC_6H_4) with $[Ir(CO)(PPh_3)_2(MeCN)]^+$ gives an inseparable mixture of $[Ir(O_2CR')(CO)(PPh_3)_2]$, $[Ir(O_2CR')(CO)(O_2)(PPh_3)_2]$, $[Ir(O_3CR')(CO)(PPh_3)_2]$ and $[Ir(O_3CR')(CO)(O_2)(PPh_3)_2]$. However, reaction of NaO_2Bu^t with $[Ir(CO)(PPh_3)_2(MeCN)]^+$ or $[Ir(F)(CO)(PPh_3)_2]$ gave only $[Ir(OH)(CO)(PPh_3)_2]$.[151] $[Ir(X)(L)(L')]$ (L = CO, N_2; L′ = phosphine or arsine) complexes are known to react with RCO_3H to yield $[Ir(X)(O_2CR)_2(L')_2]$ (**62**) (X = Cl, R = *m*-ClC_6H_4, L′ = PPh_3, PPh_2Me, $AsPh_3$; X = Cl, R = Ph, L′ = PPh_3, $AsPh_3$; X = Cl, R = Me, L′ = PPh_3; X = Br, R = *m*-ClC_6H_4, L′ = PPh_3) and CO_2. The complex (**62**) possesses unidentate and bidentate carboxylate ligands, as illustrated.[152]

$$(61) + MeI \longrightarrow [Ir(I)(OCOC_6H_4Cl\text{-}m)(CO)(PPh_3)_2(Me)] \quad (29)$$

(61)

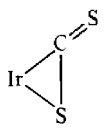


(62)

Perfluorocarboxylic acids R_FCO_2H ($R_F = CF_3$, C_2F_5) are reported[153] to react with $[Ir(NO)(PPh_3)_3]$ in boiling acetone to give $[Ir(NO)(OCOR_F)(PPh_3)_2](OCOR_F)$. The formation of this salt presumably involves successive protonations at the metal centre followed by elimination of

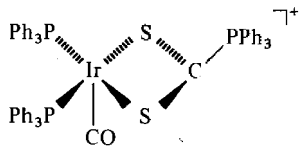
dihydrogen and coordination of the perfluorocarboxylate anion. A similar mechanism has been postulated for the reaction of $[Ir(NO)(PPh_3)_3]$ with HCl.[154]

Metathetical chlorine exchange employing $Na[ON(CF_3)_2]$ and $[Ir(CO)(PPh_3)_2(MeCN)]^+$ has yielded the iridium(I) complex *trans*-$[Ir\{ON(CF_3)_2\}(CO)(PPh_3)_2]^+$ (**63**). This complex undergoes a wide variety of oxidative addition reactions, as revealed in Scheme 6.[155] Complex (**63**) also reacts with the $CF_3\dot{N}(\dot{O})CF_2CF_2N(\dot{O})CF_3$ diradical to yield the seven-membered iridium(III) metallacycle $[Ir\{ON(CF_3)(CF_2CF_2N(CF_3)O\}\{ON(CF_3)_2\}(CO)(PPh_3)_2]$, as given in the last reaction in Scheme 6.[156]



Scheme 6

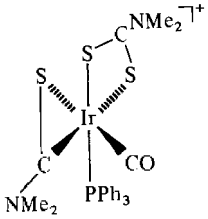
49.4.5 Sulfur Ligands



49.4.5.1 S_2, CS_2, thiocarbamate and related ligands

An investigation of the side-on-bonded disulfur and diselenium complexes $[Ir(P—P)_2(Y_2)]^+$ (P—P = dppe, dmpe; Y = S, Se) has been reported.[157] An X-ray structure of $[Ir(dppe)_2(Se_2)]^+$ revealed it to have a structure very much similar to that of its dioxygen and disulfur analogues. The Se_2 group is side-on bonded to Ir at the equatorial positions of a distorted octahedron. The S_2 or Se_2 groups readily undergo reactions in which they are reduced. Thus, mercury or tertiary phosphines strip S or Se from the complex to form HgS (HgSe) or R_3PS (R_3PSe). $[Ir(dppe)_2(S_2)]^+$ is oxidized by periodate to $[Ir(dppe)_2(S_2O)]^+$ and $[Ir(dppe)_2(SO)_2]^+$.[158] Also, $[Ir(dppe)_2(S_2)]^+$ is methylated at the S_2 group by $MeSO_3F$ to yield $[Ir(dppe)_2(S_2Me)]^+$.[159] The iridium(I) disulfide complexes $[Ir\{S(CH_2CH_2SPh)_2\}(cod)]^+$ and $[Ir(Cl)(cod)(MeSCH_2CH_2SMe)]$ have been prepared from $[Ir(Cl)(cod)]_2$, PPh_3 and the sulfide.[160]

When $[Ir(Cl)(CO)(PPh_3)_2]$ is treated with CS_2, a dark violet solution results and the addition of $NaBPh_4$ leads to the formation of dark violet crystals, which analyze as $[Ir(CO)(CS_2)(PPh_3)_2](BPh_4)$. It was formulated as an octahedral species with a π-bonded CS_2 ligand, as in (**64**). However, when attempts were made to alkylate $[Ir(CO)(CS_2)(PPh_3)_2]^+$ to form the dithioester complex, which should have reacted with acids in an alternative route to the thiocarbonyl complex, the reactions proved unsuccessful. The complex turned out to be $[Ir(CO)(S_2CPPh_3)(PPh_3)_2]^+$ (**65**). $[Ir(CO)(S_2CPPh_3)(PPh_3)_2](BPh_4)$ (**65**) exhibits a distorted trigonal bipyramidal arrangement of donor atoms about the central Ir atom. The (S_2CPPh_3) ligand behaves as a non-planar bidentate zwitterionic species $Ph_3P^+CS_2^-$, in which the S atoms occupy an axial and an equatorial position. The CO ligand occupies the other axial position, while the two PPh_3 groups occupy equatorial sites.

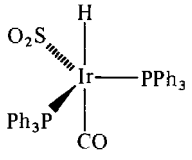


(64)

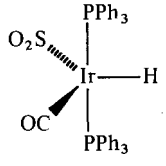
(65)

Very few examples of σ-bonded CS_2 complexes are known in which the CS_2 ligand is bonded to iridium solely through an S atom. $[Ir(Cl)(PPh_3)_3]$ reacts with CS_2 to yield $[Ir(PPh_3)_3(\sigma\text{-}CS_2)(\pi\text{-}CS_2)](BPh_4)$, which slowly decomposes at room temperature or reduced pressures resulting in the isolation of $[Ir(PPh_3)_3(\pi\text{-}CS_2)]^+$.[163] The iridium(I) complex $[Ir(PPh_3)_2(CS)(\sigma\text{-}CS_2)(\pi\text{-}CS_2)]^+$ was initially formed upon reaction of *trans*-$[Ir(Cl)(CS)(PPh_3)_2]$ with CS_2, but the σ-bonded CS_2 ligand was slowly lost to leave the π-CS_2 complex $[Ir(CS)(PPh_3)_2(\pi\text{-}CS_2)]^+$.[164]

The iridium(I) species $[Ir(CO)(\eta^2\text{-}CSNMe_2)(PPh_3)(S_2CNMe_2)](X)$ (**66**; X = Cl, PF_6) is formed upon reaction of $[Ir(Cl)(CO)(PPh_3)_2]$ with $(MeNCS)_2$.[165] Vaska-type complexes presumably react with Me_2NCSCl in a similar manner to yield *trans*-$[Ir(Cl)(CO)(\eta^2\text{-}CSNMe)_2(PPh_3)_2]^+$.

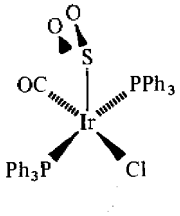


(66)



49.4.5.2 SO_2 and phosphine sulfide ligands

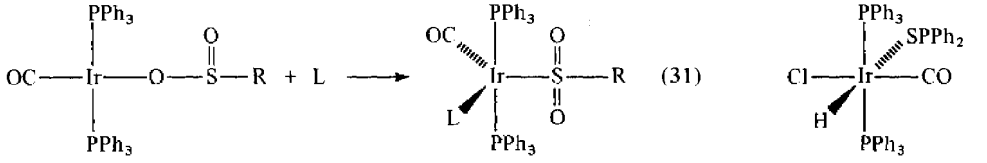
Levison and Robinson[166] have established that SO_2 reacts with $[Ir(H)(CO)(PPh_3)_2]$ to give $[Ir(H)(CO)(PPh_3)_2(SO_2)]$. A tautomeric equilibrium (reaction 30) involving a rapid hydride migration between Ir and the coordinated SO_2 ligand was postulated. A more recent investigation[167] of the reaction of SO_2 with $[Ir(H)(CO)(PPh_3)_3]$ indicates the product to be $[Ir(H)(CO)(PPh_3)_2(SO_2)]$ on the basis of ^1H and ^{31}P NMR evidence. At low temperatures, a six-coordinate hydrido(sulfur dioxide) intermediate, $[Ir(H)(CO)(PPh_3)_3(SO_2)]$, was proposed. The favoured structure for $[Ir(H)(CO)(PPh_3)_2(SO_2)]$ is (**67**), although spectroscopic data also appear consistent with structure (**68**). No evidence (from NMR studies) was obtained in support of equilibrium (30) or for any fluxional process involving the coordination sphere of the five-coordinate d^8 complex.[167] The crystal and molecular structures of $[Ir(Cl)(CO)(PPh_3)_2(SO_2)]$ (**69**) reveal a tetragonal pyramidal coordination geometry around Ir, with CO, Cl and *trans* P atoms in the base and the S of SO_2 at the apex. The O of the CO ligand, Cl and the two P atoms are coplanar, while the Ir—SO_2 moiety is non-planar. The Ir—S vector makes an angle of 31.6° with the normal to the SO_2 plane. The Ir—S interaction (2.49 Å) is weak.[168]



$$[(PPh_3)_2(CO)Ir(H)(SO_2)] \rightleftharpoons [(PPh_3)_2(CO)Ir—SO_2H] \qquad (30)$$

(67)

(68)



(69)

The four-coordinate iridium(I) complex $[Ir(O_2S\text{-}p\text{-tolyl})(CO)(PPh_3)_2]$ (**70**) (O_2S-*p*-tolyl = *p*-toluenesulfinate) has been prepared from $[Ir(CO)(PPh_3)_2(MeCN)]^+$ and sodium *p*-toluenesulfinate.[169] This complex contains an O-bonded sulfinate ligand, as indicated by IR spectral evidence.[98] On addition of methyl iodide to (**70**), an iridium(III) complex with O-bonded sulfinate is formed.

However, uptake of CO or O_2 by (**70**) affords isomerization to S-bonded sulfinate and complex (**71**; reaction 31).[98,169]

The secondary phosphine sulfide Ph_2HPS reacts with $[Ir(Cl)(CO)(PPh_3)_2]$ under mild conditions, giving $[Ir(H)(CO)(PPh_3)_2(SPPh_2)]$ (**72**). ^{31}P NMR data have suggested that the $SPPh_2$ ligand is S-bonded to Ir. Complex (**72**) reactors with MeI or EtI to yield $[Ir(H)(Cl)(I)(CO)(PPh_3)_2]$, most probably by initial S-alkylation of the coordinated Ph_2PS group.[170]

(70) (71) (72)

Reaction of $[\{Ir(Cl)(CO)_3\}_n]$ or $[Ir(Cl)(cod)]_2$ with $(C_6H_{11})_2PSSNH_4$ or $(PhO)_2PSSNH_4$ results in the formation of $[Ir(CO)_2(S—S)]$ (**73**) and $[Ir(cod)(S—S)]$ (**74**) (S—S = $(C_6H_{11})_2PSS$, $(PhO)_2PSS$), respectively. Complex (**74**) reacts with PPh_3 and CO according to reactions (32) and (33), respectively. The dicarbonyl complexes produced in reaction (33) react with PPh_3 and PEt_3 (= L) according to reactions (34) and (35), respectively. The *P,P'*-dithiophosphate ligand of complex (**75**) remains bidentate and iridium is four coordinate. A structure for complex (**76**) was not reported; however, IR spectral data indicate *O,O'*-dithiophosphate ligand behaves as a unidentate ligand. The different behaviour of the dicarbonyl complexes toward L could be rationalized in terms of electronic effects for which the $\{SSP(OPh)_2\}$ ligand is expected to be a stronger π-acceptor than $\{SSP(C_6H_{11})_2\}$ and therefore a stronger Ir—S bond is envisaged. This contrasts with the observed cleavage of the Ir—S bond in reaction (34). Complex (**73**) reacts with 1,2-bis(diphenylphosphine)ethane (dppe) to produce $[Ir(CO)(dppe)_2](S—S)$, in which the $(S—S)^-$ is a counterion. Also, complex (**73**) undergoes oxidative *trans* addition with X_2 (= Cl_2, Br_2, I_2) and MeI to yield $[Ir(X)_2(CO)_2(S—S)]$ and $[Ir(CO)_2(S—S)(MeI)]$, respectively.[171]

$$[Ir(cod)(S—S)] + PPh_3 \longrightarrow [Ir(PPh_3)_2(S—S)] \quad (32)$$

$$[Ir(cod)(S—S)] + CO \longrightarrow [Ir(CO)_2(S—S)] \quad (33)$$

$$[Ir(CO)_2\{SSP(C_6H_{11})_2\}] + L \longrightarrow [Ir(CO)(L)\{SSP(C_6H_{11})_2\}] \quad (34)$$

$$[Ir(CO)_2\{SSP(OPh)_2\}] + L \longrightarrow Ir(CO)_2(L)_2\{SSP(OPh)_2\}] \quad (35)$$

(**76**)

49.4.6 Halogens as Ligands

The iridium(I) halide complexes [IrCl], [IrBr] and [IrI] are believed to exist. Heat treatment (to 1043 K) of $[IrCl_3]$ causes sublimation of [IrCl], which decomposes above 1071 K and is insoluble in both alkaline and acidic media.[172] [IrBr] may be obtained by heating the iridium(III) bromide to 758 K in an HBr atmosphere. The monobromide complex is stable at lower temperatures, and is slightly soluble in water, in acidic and in alkaline media.[173] [IrI] forms upon heating either $[IrI_2]$ or $[IrI_3]$ to 628 K in an HI atmosphere.[173]

49.4.7 Hydrogen and Hydrides as Ligands

The electrochemical reduction of α-$[Ir(H)(Cl)_2(ER_3)_3]$ (ER_3 = PPh_3, $AsPh_3$) in $MeCN/C_6H_6$ solution has afforded $[Ir(H)(PPh_3)_4]$ and $[Ir(H)(AsPh_3)_4]$, respectively. The iridium(I) hydride complexes are stable as solids, but rapidly decompose in solution. Cryoscopic studies have suggested that in solution these complexes dissociate according to reaction (36). IR spectra and elemental analyses support the formulation as $[Ir(H)(ER_3)_4]$.[174] Related iridium(I) hydride complexes may be synthesized *via* replacement of either H_2[175] or HX[176] by a phosphine ligand (reactions 37 and 38), or by phosphine ligand exchange (reaction 39).[177] Alternatively, complexes of this type can be prepared according to reactions (40)(–(43).[14,164,178,179]

$$[Ir(H)(ER_3)_4] \rightleftharpoons [Ir(H)(ER_3)_3] + (ER_3) \quad (36)$$

$$[Ir(H)_2(SiR_3)(CO)(PPh_3)_2] + PR_3 \xrightarrow[298\,K]{C_6H_6} [Ir(H)(CO)(PPh_3)_3] + R_3SiH \quad (37)$$

$$[Ir(H)_2(Cl)(CO)(PPh_3)_2] + PPh_3 + KOH \xrightarrow{EtOH} [Ir(H)(CO)(PPh_3)_3] + KCl + H_2O \quad (38)$$

$$[Ir(H)_3(PPh_3)_3] + P(OPh)_3 \longrightarrow [Ir(H)\{P(OPh)_3\}_4] \quad (39)$$

$$[IrCl_2] + Cu + PF_3 + H_2 \longrightarrow [Ir(H)(PF_3)_4] \quad (40)$$

$$[Ir(Cl)(C_8H_{12})]_2 + PrMgBr + PPh_3 \longrightarrow [Ir(H)(PPh_3)_4] \quad (41)$$

$$[Ir(Cl)(CO)(PPh_3)_2] \xrightarrow{NaBH_4} [Ir(H)(CO)_2(PPh_3)_2] \quad (42)$$

$$[Ir(Cl)(CS)(PPh_3)_2] + NaBH_4 + PPh_3 \longrightarrow [Ir(H)(CS)(PPh_3)_3] \quad (43)$$

$[Ir(H)(CO)_2(PPh_3)_2]$ (from reaction 42) adopts a single structure in the solid state, but appears to exist as an equilibrium mixture of five-coordinate isomers in solution. The isomeric equilibrium is both solvent and temperature dependent.[180] $[Ir(H)\{P(OPh)_3\}_4]$ (from reaction 39) undergoes a reversible ligand–metal hydrogen-transfer with hydrogen elimination and metal–carbon bond formation. In this reaction, an aryl C—H bond in a donor ligand coordinated to Ir reacts with the Ir atom to form a metal–carbon bond; the hydrogen is transferred from the carbon atom to the Ir atom, forming a hydride ligand. This may subsequently be eliminated as H_2.[181] Deuteration studies on rhodium analogues have shown that this intramolecular reaction involves an *ortho* C—H bond of the aromatic phosphorus donor ligand.[182]

49.4.8 Multidentate Macrocyclic Ligands

Few iridium(I) porphyrin complexes are known, owing to the difficulty in incorporating the iridium and the high resistance to reduction of the iridium(III) complex to an iridium(I) complex.

$$[Ir(Cl)(CO)_3]_2 + OEPH_2 \longrightarrow \mu\text{-OEP}[Ir(CO)_3]_2 + [Ir(Cl)(CO)(OEP] \quad (44)$$

(77)

$$[Ir(Cl)(CO)_3]_2 + N\text{-MeOEPH} \longrightarrow N\text{-MeOEP}[Ir(Cl)(CO)_3]_2 \quad (45)$$

(78)

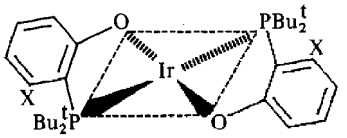
Complexes (**77**) and (**78**) (see reactions 44 and 45) have been synthesized *via* reaction of octaethylporphyrin ($OEPH_2$) or *N*-methyloctaethylporphyrin (*N*-MeOEPH) with $[Ir(Cl)(CO)_3]_2$. The IR and visible spectra of (**77**) are quite similar to those of μ-OEP$[Rh^I(CO)_2]$, indicative of similar structures for the two complexes. No evidence for centrosymmetry in (**77**) was obtained, probably due to the reduction in molecular symmetry by coordination of three CO ligands to each Ir atom.[183]

Complex (**78**) is more readily formed than (**77**), probably the result of the distortion of the porphyrin ring due to N-alkylation of the pyrrolic N—H bond. The spectroscopic properties of (**78**) appear similar to those of *N*-MeOEP$[Rh(Cl)(CO)_2]_2$,[184] and thus similar structures for the Ir^I and Rh^I porphyrin complexes have been proposed, in which the two Ir atoms of the iridium dimer are bonded to the two adjacent nitrogen atoms of the porphyrinato core.[183]

49.5 IRIDIUM(II)

Only a few complexes containing iridium(II) are known, most of which are of a special type as they are either dimeric and diamagnetic or contain non-innocent ligands. More likely, many reported iridium(II) complexes are hydrides of iridium(III) or iridium(III) complexes containing a σ Ir—C bond rather than a supposed π Ir—C bond. Furthermore, iridium(II) complexes, with a d^7 electronic configuration, are expected to be paramagnetic.

49.5.1 Nitrogen Ligands



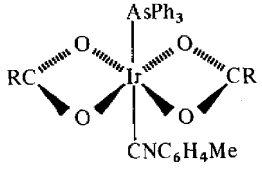
49.5.1.1 Nitrosyl ligands

The iridium(II) complex $[Ir(Br)_3(NO)(PPh_3)_2]$ has been reported by Malatesta and coworkers.[7] A + II oxidation state assignment depends on the formalism used regarding the nitrosyl ligand. The complex is considered iridium(II) if the NO ligand is assigned as $(NO)^+$.

49.5.2 Phosphorus and Arsenic Ligands

49.5.2.1 Phosphine ligands

The syntheses and structures of *trans*-[Ir(Bu$^t_2$PC$_6$H$_4$O)$_2$] and *trans*-[Ir{Bu$^t_2$PC$_6$H$_3$(OMe)O}$_2$] (**79**) have been reported by Mason and Thomas.[185] The iridium(II) state is presumably stabilized by the O,P bidentate ligands. X-Ray analysis of these complexes reveal C_i symmetry and planarity.



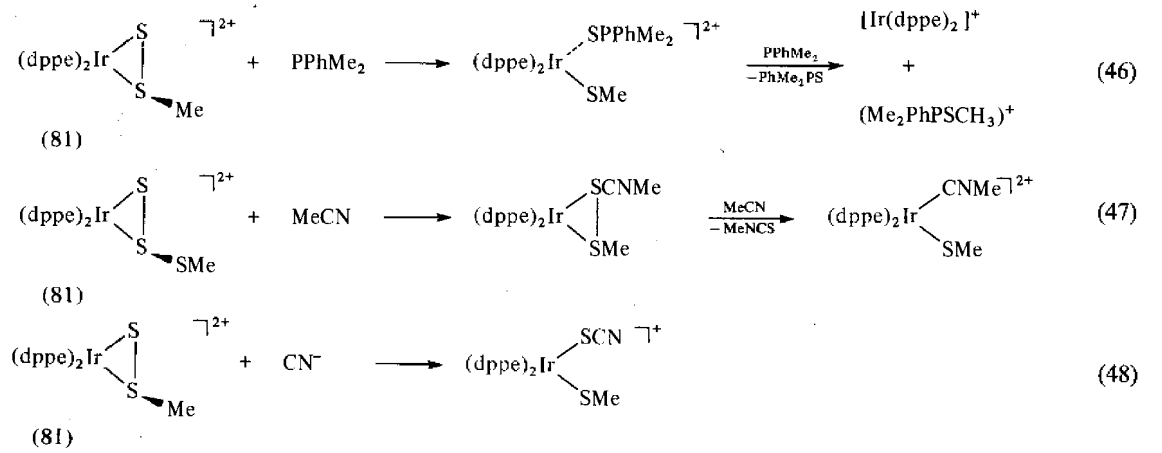
X = OMe

(79)

49.5.2.2 Arsenic ligands

Reaction between [Ir(H)$_3$(AsPh$_3$)$_2$(CNC$_6$H$_4$Me-*p*)] and RCO$_2$H (R = Me, Ar) results in the formation of the iridium(II) complexes [Ir(O$_2$CR)$_2$(AsPh$_3$)(CNC$_6$H$_4$Me-*p*)] (**80**), where R = Me, *p*-ClC$_6$H$_4$, *p*-MeOC$_6$H$_4$, 2,4,6-Me$_3$C$_6$H$_3$ and RCO$_2$ = pentane-2,4-dionate. The complexes are paramagnetic, and, based on EPR spectra, have the structure depicted in (**80**). A tetragonally distorted octahedral geometry was proposed, for which the distortion increases with the ability of the planar ligands to delocalize the electronic charge of the iridium. Thus, complex (**80**) for which R = Me is least distorted. The EPR spectra indicate that the arsine and isocyanide ligands are mutually *trans*.[186]

(80)



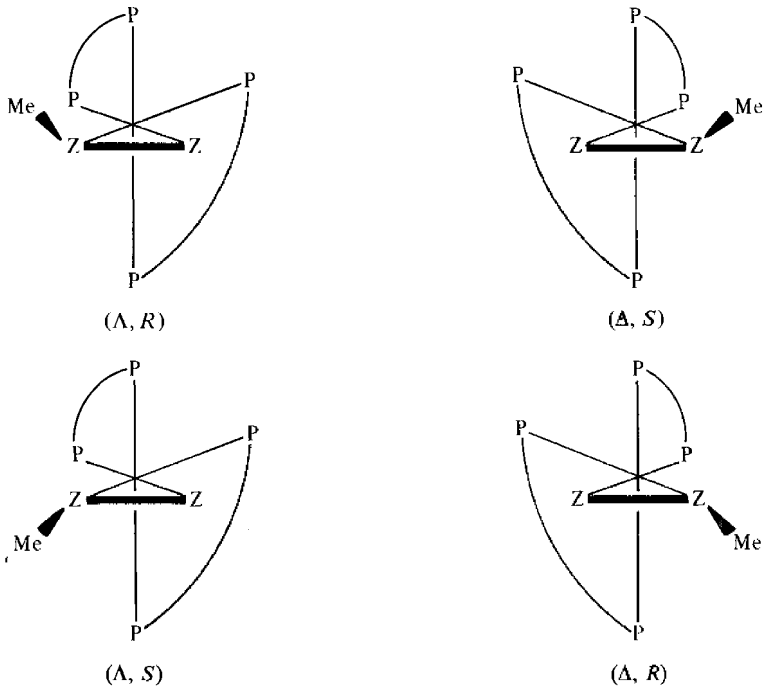
49.5.3 Sulfur Ligands

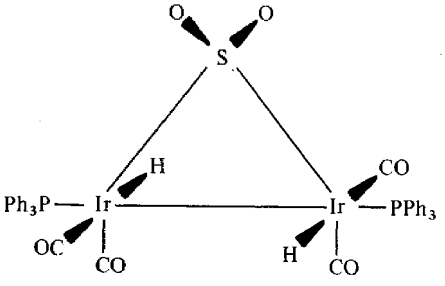
49.5.3.1 Mononuclear complexes

Salts of [Ir(dppe)$_2$(η^2-S$_2$Me$_3$)]$^{2+}$ (**81**) were initially[159] prepared in 1979 *via* the alkylation of [Ir(dppe)$_2$(S$_2$)]$^+$. The geometry about the perthio ligand in complex (**81**) was thought to resemble that found crystallographically in [Os(CO)$_2$(PPh$_3$)$_2$(η^2-S$_2$Me)](ClO$_4$);[187] that is the η^2-S$_2$Me ligand should be structurally and electronically related to other derivatives of the S$_2$ ligand such as in [Ir(dppe)$_2$(S$_2$O)]$^+$.[158b] Hoots and Rauchfuss[188] have recently reported on the stereochemistry and reactivity of [Ir(dppe)$_2$(Z$_2$R)]$^{2+}$ (**82**; Z = S, Se; R = H, Me). In solution, [Ir(dppe)$_2$(Z$_2$Me)]$^{2+}$ exists as a mixture of two diastereomers in a 20:1 (Z = S) and 6:1 (Z = Se) ratio, depending on the disposition of the methyl group relative to the dppe chelate rings. Figure 1 depicts the perspective views of the four stereoisomers of complex (**82**). The (Λ, *S*), (Δ, *R*) pair of enantiomers was thought to predominate, based on steric considerations. Complex (**81**) reacts with the nucleophiles PPhMe$_2$, MeCN and CN$^-$ according to the reactions (46)–(48), respectively.[188]

49.5.3.2 Dinuclear complexes

The dimeric iridium(III) hydride [{Ir$_2$(H)$_2$(CO)$_4$(PPh$_3$)$_2$}(SO$_2$)] (**83**) results from the reaction of [Ir$_2$(CO)$_4$(PPh$_3$)$_2$(μ-SO$_2$)] with H$_2$.[25,189] The SO$_2$ molecule may be considered formally as a diradical, sharing two electrons with Ir to form two covalent bonds; alternatively, SO$_2$ can be thought of as a two-electron acceptor from Ir to form the SO_2^{2-} anion which bridges as a bidentate ligand. Either way, S is sp^3 hybridized. Other complexes containing Ir—S—Ir bridge systems include [Ir$_2$(I)$_2$(CO)$_2$(SCMe$_3$)$_2$(L)$_2$] (**84**),[190] [Ir(CO)(PR$_3$)(μ-SBu^t)]$_2$ (**85**), [Ir(H)(CO)(PR$_3$)(μ-SBu^t)]$_2$ (**86**),[191] [Ir$_2$(Br)$_2$(CO)$_2$(PPh$_3$)$_2$(TTN)] (TTN = tetrathionaphthalene) (**87**),[192] and [Ir$_2$(CO)$_4$(SR)$_2$] (SR = SPh, SBu^t) (**88**).[193] Complex (**85**; R = Me, Ph, NMe, OMe) reacts irreversibly with H$_2$ to





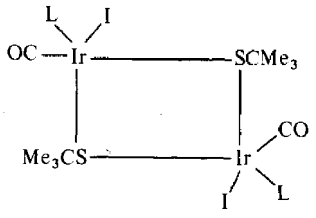


Figure 1 Perspective views of the four stereoisomers of $[Ir(Z_2R)(dppe)_2]^{2+}$ (**82**)

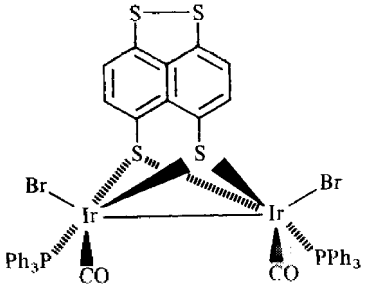
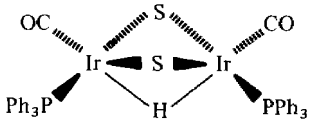


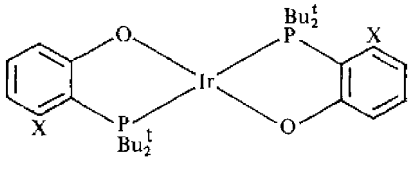
produce complex (**86**). Elemental analyses, NMR and IR spectra, H_2 uptake measurements and molecular weight data reveal that the one-electron oxidative addition of H_2 results in the cleavage of the H—H bond, yielding complex (**86**), wherein each hydrogen atom is bound to a different Ir atom. The formally d^7 Ir^{II} atoms in complex (**86**) are linked together with a single bond, in agreement with the diamagnetic behaviour of complex (**86**).[191a] The reactivity of (**86**) towards protonation (H^+) has been investigated, and reveals the formation of a dimeric monocationic species containing a two-electron three-centre bent Ir—H—Ir bond of the type $\{[Ir(H)(CO)(PR_3)(\mu\text{-}SBu^t)]_2(H)\}^+$ (R = Me, Ph, OMe). A bridging position for the added proton has been postulated on the basis of high-field ^1H NMR and Ir—H stretching frequencies of the product complex and of its deuterated analogue $\{[Ir(D)(CO)(PR_3)(\mu\text{-}SBu^t)]_2(H)\}^+$.[191b] The oxidative addition of I_2 to $[Ir_2(CO)_2(L)_2(SCMe_3)_2]$ (L = CO, PMe_3, $P(OMe)_3$, $PPhMe_2$) affords $[Ir_2(I)_2(CO)_2(L)_2(SCMe_3)_2]$ (**84**).[190] Complex (**87**) is interesting: it is the first tetrathiolene complex in which TTN adopts a six-electron-donating bis-bidentate di(μ-S) bridging configuration, rather than the usual four-electron-donating bis-didentate (μ-TTN) bridging configuration. The $[Ir_2(CO)_4(SR)_2]$ complexes (**88**) possess a butterfly structure with intermolecular associations in the crystal. When treated with PR_3 (= PMe_3, $P(OMe)_3$, PPh_3, $P(NMe_2)_3$), the SBu^t derivative yields $[Ir_2(CO)_4(PR_3)_2(SBu^t)_2]$ and $[Ir_2(CO)_2(PR_3)_2(SBu^t)_2]$. The latter complex reacts with dihydrogen to give $[Ir_2(H)_2(CO)_2(PR_3)_2(SBu^t)_2]$ activation of H_2 at one of the Ir atoms followed by intramolecular H transfer; protonation of this hydride species yields complex (**88**).[193]



(83)

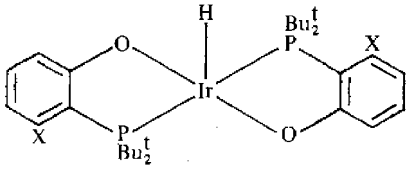
(84)

(87)



(88)

49.5.4 Halogens as Ligands



The existence of iridium(II) halide complexes remains somewhat doubtful, although the preparation of both $[IrBr_2]$ and $[IrI_2]$ has been described.[173] Heating $[IrBr_3]$ at 713 K in a stream of HBr reportedly yields the reddish-brown species $[IrBr_2]$, while $[IrI_2]$ was similarly obtained from the iridium(II) iodide in HI at 603 K. EPR studies on the product of electron irradiation of $[IrCl_6]^{3-}$ in an NaCl matrix reveal a paramagnetic species formulated $[IrCl_6]^{4-}$.[194]

49.5.5 Mixed Donor Atom Ligands

The stable iridium(II) complex $[Ir\overline{\{PBu^t_2(C_6H_4O)\}}\{PBu^t_2(C_6H_4OH)\}(CO)]$ has been synthesized by refluxing 2-methoxyphenyldi-*t*-butylphosphine with $[IrCl_6]^{3-}$ in propan-2-ol under a CO atmosphere. Upon exposure to air, CO_2 evolution occurs, producing the paramagnetic iridium(II) complex (**89**) and the iridium(III) complex (**90**), for which X = H, OMe.[195] A dioxygen adduct of (**89**) (X = OMe) has been isolated.

(89)

(90)

The cyclometallated iridium(II) complex $[Ir\overline{\{PBu^t_2(C_6H_4O)\}_2}]$ (**91**) is afforded when $[Ir\overline{\{PBu^t_2(C_6H_4O)\}}\{PBu^t_2(C_6H_4OH)\}(CO)]$ is exposed to air. Additional air exposure results in hydrogen abstraction from one of the Bu^t groups, yielding a square pyramidal complex containing one cyclometallated and one bicyclometallated ligand. The complex (**91**) forms $[Ir(H)\overline{\{PBu^t_2(C_6H_4O)\}_2}]$ when treated with H_2.[103]

49.5.6 Multidentate Macrocyclic Ligands

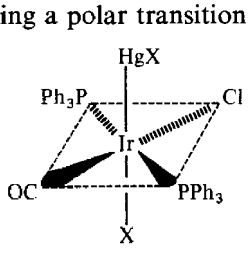
49.5.6.1 Schiff base ligands

The reaction between $[Ir^{III}(H)_3(AsPh_3)_2(CNC_6H_4Me\text{-}p)]$ and the quadridentate Schiff bases *NN'*-ethylenebis(salicylideneimine) (Hsalen) and *NN'*-ethylenebis(acetylacetoneimine) (acacen) yield the iridium(II) complexes $[Ir(AsPh_3)(salen)(CNC_6H_4Me\text{-}p)]$ and $[Ir(AsPh_3)(acacen)(CNC_6H_4Me\text{-}p)]$, respectively.[196]

49.6 IRIDIUM(III)

Iridium(III) complexes (d^6) are diamagnetic and low-spin (t_{2g}^6). The coordination number of most known iridium(III) complexes is six, though a few five- and seven-coordinate complexes have been reported. Iridium(III) forms complexes with 'soft' ligands. The $[Ir(H_2O)_6]^{3+}$ ion is unknown; no solid iridium(III) complexes with coordinated H_2O groups are known with the exception of a few aquachloro complexes.[197]

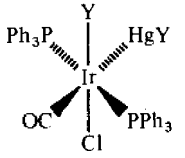
49.6.1 Mercury-containing Compounds as Ligands



Complexes of the type $[Ir(Cl)(HgY)(Y)(CO)(PPh_3)_2]$ (Y = Cl, Br, I, OAc, CN, SCN) and $[Ir(Br)_2(HgBr)(CO)(PPh_3)_2]$ can be formed by the reaction of *trans*-$[Ir(X)(CO)(PPh_3)_2]$ with HgY_2. Oxidation of these Ir—Hg complexes occurs with halogens (I_2, Br_2) and with gaseous HCl, as shown in reactions (49)–(51).[198] Rapid substitution of the halide ions influences the nature of the halide in the reaction products; the halides preferentially coordinate to Ir in the order Cl > Br > I.[199] The hydride complex produced in reaction (51) can also be obtained by oxidizing $[Ir(Cl)_2(HgCl)(CO)(PPh_3)_2]$ with H_2. The physical and chemical properties of these Ir—Hg complexes clearly indicate that they contain a normal covalent Ir—Hg bond. Reaction of $[Ir(Cl)_2(HgCl)(CO)(PPh_3)_2]$ with PPh_3 in benzene results in the elimination of $(PPh_3)_2HgCl_2$ to yield $[Ir(Cl)(CO)(PPh_3)_2]$.[198]

$$[Ir(Cl)(HgI)(I)(CO)(PPh_3)_2] + I_2 \longrightarrow [Ir(Cl)(I)_2(CO)(PPh_3)_2] + HgI_2 \quad (49)$$

$$[Ir(Br)(Cl)(HgBr)(CO)(PPh_3)_2] + Br_2 \longrightarrow [Ir(Br)_2(Cl)(CO)(PPh_3)_2] + HgBr_2 \quad (50)$$



$$[Ir(Cl)_2(HgCl)(CO)(PPh_3)_2] + HCl(g) \longrightarrow [Ir(H)(Cl)_2(CO)(PPh_3)_2] + HgCl_2 \quad (51)$$

Crystal structure investigations of $[Ir(Cl)_2(HgCl)(CO)((PPh_3)_2]$ and $[Ir(Br)(Cl)(HgBr)(CO)(PPh_3)_2]$ have suggested that the oxidative addition of $HgCl_2$ or $HgBr_2$ to *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ is predominantly *trans*, and the two complexes are isomorphous. The X (= Cl, Br) ligands are mutually *cis*, while the PPh_3 ligands are mutually *trans*, as in (**92**). An S_N2 attack by iridium at an electrophilic centre in HgX_2 involving a polar transition state has been proposed.[200]

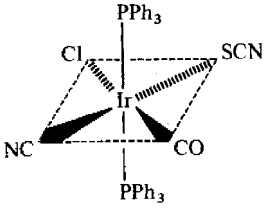
(92)

Oxidative addition reactions of $HgCl_2$ to $[Ir(Cl)(NCF_2CHFCF_3)(PPh_3)_2]$, and of diphenylethynylmercury or di-*n*-heptynylmercury to $[Ir(Cl)(CO)(PPh_3)_2]$ yield $[Ir(Cl)_2(HgCl)(NCF_2CHFCF_3)(PPh_3)_2]$ (**93a**)[65] and $[Ir(Cl)(HgC{\equiv}Y)(CO)(PPh_3)_2(C{\equiv}CY)]$ (Y = Ph, C_5H_{11}; **93b**),[201] respectively. The structures of (**93**), as illustrated, were characterized by IR spectroscopy.

(**93a**) Y = Cl

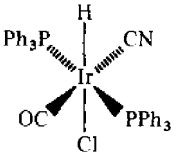
(**93b**) Y = C_5H_{11}, C_6H_5

Electrolysis of $[Ir(Cl)(CO)(PPh_3)_2]$ on anodically polarized mercury electrodes in CH_2Cl_2 leads to the formation of a product mixture of $[\{Ir(Cl)(CO)(PPh_3)_2\}_3Hg]^{2+}$ (**94**) and $[\{Ir(Cl)(CO)(PPh_3)_2\}_4Hg]^{2+}$ (**95**) as perchlorate salts when tetrabutylammonium perchlorate is employed as the supporting electrolyte. In the presence of tetraethylammonium nitrate, the product $[\{Ir(Cl)(CO)(PPh_3)_2\}Hg(NO_3)_2]$ (**96**) is obtained. Complexes (**94**)–(**96**) are converted to $[Ir(Cl)(HgX_2)(CO)(PPh_3)_2]$ (X = Cl, Br, I) on reaction with X^-.[202]



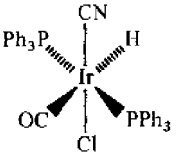
49.6.2 Group IV Ligands

49.6.2.1 Cyanide, isocyanide and fulminate ligands



$[Ir(CN)_3]$ is reportedly obtained by heating $(NH_4)_3[Ir(CN)_6]$ at 603 K, decomposes at 633 K and exhibits ν(CN) at 2202 and 2155 cm^{-1}. On addition of ammonia, $[Ir(CN)_3]$ is converted to $[Ir(CN)_3(NH_3)_2]\cdot 1.5H_2O$.[203] The hexacyano complex $K_3[Ir(CN)_6]$ is obtained on treating $(NH_4)_3[IrCl_6]$ with KCN, followed by crystallization from water.[204] Additionally, a series of complexes of the type $M_3^{III}[Ir(CN)_6]\cdot xH_2O$, where M is Mn to Zn, are known.[205]

$[Ir(CN)_5(H_2O)]^{2-}$ is formed upon UV irradiation of $[Ir(CN)_6]^{3-}$ in aqueous solution. The aquapentacyano anion undergoes thermal anation by Cl^-, Br^-, I^-, OH^- and NCMe (=X), for which the $[Ir(CN)_5X]^{3-}$ anions were isolable in the solid form as $[Co(NH_3)_6]^{3+}$ salts.[206] The lowest energy electronic absorption band in the UV spectra of $[Ir(CN)_5X]^{3-}$ has been assigned to the $^1A_1 \rightarrow {}^3E^a$ and $^1A_1 \rightarrow {}^1E^a$ transitions. The position of these bands established the order of increasing field strength of X as $I^- < Br^- < Cl^- < H_2O < OH^- < NCMe$.



Reaction between $[Ir(Cl)(CO)(PPh_3)_2]$ and $S(CN)_2$ gave $[Ir(Cl)(CN)(NCS)(CO)(PPh_3)_2]$ (**97**) *via* an *S*-thiocyanato intermediate. An X-ray crystal structure of (**97**) shows that the complex is essentially octahedral, and the N—C—S linkage is essentially linear. Of the nine *S*-thiocyanato isomers possible, the crystal structure and IR spectral results appear consistent with those in (**97**).[207] $[Ir(H)(Cl)(CN)(CO)(PPh_3)_2]$ (**98**) and $[Ir(Cl)(CN)(HgCN)(CO)(PPh_3)_2]$ have been prepared from the reaction of Vaska's complex with HCN and $Hg(CN)_2$, respectively.[208,209] Assuming a *cis* addition of HCN, two possible structures of complex (**98**) are possible: (**98a**) and (**98b**). Proton NMR and IR data are best interpreted in terms of structure (**98b**).[208]

(97)

(98a)

(98b)

Those iridium(III) isocyanide complexes obtained from oxidative addition to an iridium(I) isocyanide complex have been treated in Section 49.4.1.1.

The iridium(III) complex $[Ir(H)_3(AsPh_3)_2(p\text{-}MeC_6H_4NC)]$ (**99**) is known to react with HX (or pseudohalides) to yield substitution products $[Ir(H)_2(X)(AsPh_3)(p\text{-}MeC_6H_4NC)]$ (X = Cl, Br, I, N_3).[210] With carboxylic acids or pentane-2,4-dione, complex (**99**) yields the chelated complexes $[Ir(L_2)(AsPh_3)(p\text{-}MeC_6H_4NC)]$ (L_2 = carboxylate or pentane-2,4-dionate) in which Ir^{III} is reportedly reduced to Ir^{II}.[186] Reactions (52)–(60) reveal the utility of complex (**99**) in synthesizing complexes with iridium in various oxidation states.[196]

$$(\mathbf{99}) + HO_2CCH(OH)Me \longrightarrow [Ir^{IV}\{O_2CCH(O)Me\}_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (52)$$

$$(\mathbf{99}) + o\text{-}OHC_6H_4CO_2H \longrightarrow [Ir^{IV}(o\text{-}OC_6H_4CO_2)_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (53)$$

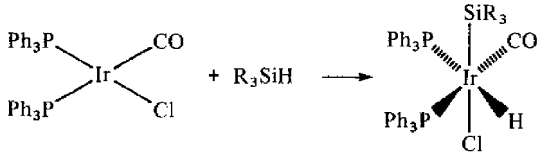
$$(\mathbf{99}) + HO_2CCH(NH_2)CH_2Ph \longrightarrow [Ir^{IV}\{O_2CCH(NH)CH_2Ph\}_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (54)$$

$$(\mathbf{99}) + HOC_6H_4OH\text{-}o \longrightarrow [Ir^{IV}(o\text{-}OC_6H_4O)_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (55)$$

$$(\mathbf{99}) + o\text{-}NH_2C_6H_4OH \longrightarrow [Ir^{IV}(o\text{-}NHC_6H_4O)_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (56)$$

$$(\mathbf{99}) + o\text{-}NH_2C_6H_4CO_2H \longrightarrow [Ir^{IV}\{o\text{-}NHC_6H_4CO_2\}_2(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (57)$$

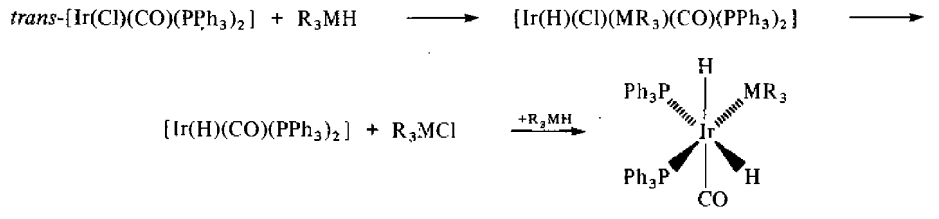
$$(\mathbf{99}) + p\text{-}MeOC_6H_4CO_2H \longrightarrow [Ir^{III}(H)_2(Cl)(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (58)$$



$$(99) + \text{tfac} \longrightarrow [Ir^{III}(H)_2(\text{tfac})(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (59)$$

$$(99) + \text{acac} \longrightarrow [Ir^{II}(\text{acac})(AsPh_3)(p\text{-}MeC_6H_4NC)] \quad (60)$$

Beck and coworkers[211] have reviewed transition metal complexes of the fulminate ion, CNO^-, which bonds to the metal *via* the carbon atom. Fulminate complexes are, in general, similar to those with CN^- ligands. An extensive series of stable, non-explosive fulminates has been examined, including $[Ir(CNO)_6](AsPh_4)_3$. $[Ir(CNO)_6]^{3-}$ was prepared from hydrated iridium(III) chloride and $Hg(CNO)_2$, and characterized by IR spectroscopy.[211d]

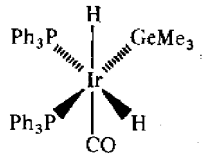


49.6.2.2 Si-, Ge- and Sn-containing ligands

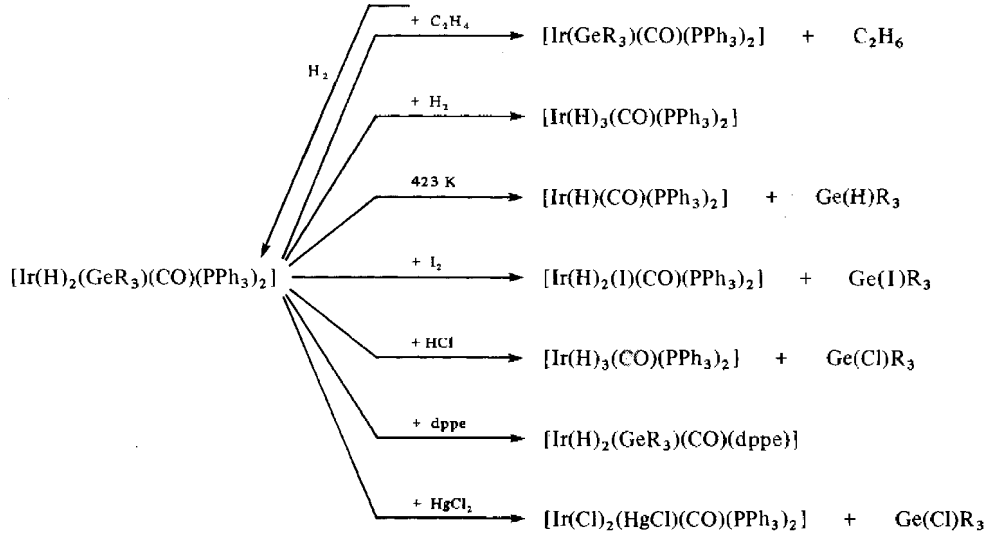
Most iridium(III) complexes containing Group IVb donor ligands are six coordinate and are more stable than their rhodium(III) analogues. The complexes are prepared *via* oxidative addition to an iridium(I) complex. Thus, the facile reaction between Vaska's complex and silanes with electronegative substituents [R_3SiH] gives an iridium(III) complex with an Ir—Si bond. Reaction (61) occurs for $R_3SiH = (EtO)_3SiH$, Cl_3SiH, $EtCl_2SiH$ and $PhCl_2SiH$.[212] Proton NMR and IR

(61)

spectroscopy have been employed to elucidate the structure of the adducts formed between [Ir(X)-(CO)$(PEt_3)_2$] (X = Cl, I) and MN_3Q (M = Si, Q = H, Cl, Br, I,.Me; M = Ge, Q = H, Cl, Br, I). The addition yields *trans*-[Ir(H)(MH_2Q)(X)(CO)$(PEt_3)_2$]. When M = Si, the major product contains H *trans* to Si; and when M = Ge, the major product contains H *trans* to X.[213] Additionally, organosilanes and organogermanes (R_3MH) add to *trans*-[Ir(Cl)(CO)$(PPh_3)_2$] to yield dihydrido complexes, wherein the expected Ir—MR_3 products are intermediates (see Scheme 7).[214,215,216]

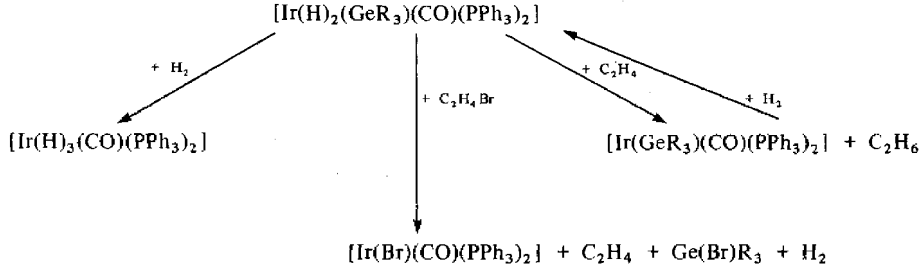


Scheme 7



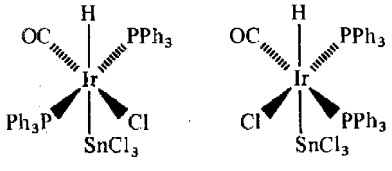
The kinetics of the oxidative addition of silicon hydrides to $[Ir(dppe)_2]^+$ (reaction 62) have been investigated.[217] No conclusive results were obtained on whether reaction (62) proceeds *via* a concerted three-centre transition state or *via* a transition state analogous to that proposed for the Menschutkin reaction. The iridium(I) species *trans*-[Ir(X)(CO)$(PEt_3)_2$] reacts with $Y(SiH_3)_2$ (Y = O, S, Se) in benzene to yield [Ir(H)(I)(SiH_2YSiH_3)(CO)$(PEt_3)_2$] or [{Ir(H)(I)(SiH_2)(CO)$(PEt_3)_2\}_2$Y]. Reaction between *trans*-[Ir(X)(CO)$(PEt_3)_2$] and $P(SiH_3)_3$ affords [Ir(H)(I){$SiH_2P(SiH_3)_2$}-(CO)$(PEt_3)_2$], [{Ir(H)(I)$(SiH_2)_2$(CO)$(PEt_3)_2\}_2$$PSiH_3$] or [{Ir(H)(I)$(SiH_2)(CO)(PEt_3)_2\}_3$P], depending on the proportions of reactants employed. With $N(SiH_3)_3$, *trans*-[Ir(X)(CO)$(PEt_3)_2$] gives [Ir(H)(I){$SiH_2N(SiH_3)_2$}(CO)$(PEt_3)_2$] and [{Ir(H)(I)(SiH_2)(CO)$(PEt_3)_2\}_2$$NSiH_3$]. The reaction products have all been characterized by ^1H and ^{31}P NMR spectroscopy. The oxidative addition reactions are similar to those between *trans*-[Ir(X)(CO)$(PEt_3)_2$] and silyl halides,[213] and similar stereochemistries have also been proposed.[218]

$$[Ir(dppe)_2]^+ + [Si(H)(Me)_n(EtO)_{3-n}] \longrightarrow [Ir(H)(dppe)_2\{SiMe_n(EtO)_{3-n}\}]^+ \quad (62)$$

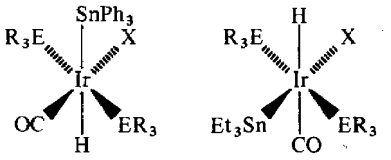


Six-coordinate dihydrido complexes of the type [$Ir(H)_2(GeR_3)$(CO)$(PPh_3)_2$] (R = Cl, Me, Et) can be produced *via* Scheme 7. However, for R = Ph, the five-coordinate complex [Ir(H)-(Cl)$(GePh_3)$(CO)(PPh_3)] is formed. For the complex where R = Me, crystal structural, ^1H NMR and IR spectral data are consistent with structure (**100**).[216] These iridium(III) complexes containing Ge donor ligands undergo several reactions, as summarized in Scheme 8.[216] Furthermore, ethylene is hydrogenated by [$Ir(H)_2(GeR_3)$(CO)$(PPh_3)_2$] to yield the iridium(I) complex [$Ir(GeR_3)$-(CO)$(PPh_3)_2$], as per Scheme 9.

(100)

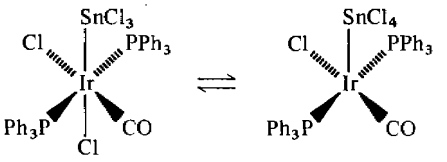


Scheme 8



Scheme 9

$K_2[IrBr_6]$ reportedly reacts with $SnBr_2$ in aqueous HBr solution, from which $(Me_4N)[Ir(Br)_4(SnBr_3)_2]$ was obtained upon addition of Me_4NBr.[4] The syntheses of $[Ir(H)(Cl)(X)(PPh_3)_3]$, $[Ir(H)(Cl)(X)(CO)(PPh_3)_2]$, $[Ir(D)(Cl)(X)(CO)(PPh_3)_2]$, $[Ir(H)_2(X)(CO)(PPh_3)_2]$ and $[Ir(D)_2(X)(CO)(PPh_3)_2]$ (X = $SnCl_3$) *via* oxidative addition of $SnCl_2$ to iridium(I) complexes have been described. $SnCl_2$ serves as a weak σ-donor ligand (*i.e.* $SnCl_3^-$), and exhibits a large *trans* effect due to its ability to form $d\pi$-$d\pi$ bonds to the central Ir atom. IR and ^1H NMR spectral data have been interpreted in terms of structure (**101**) for $[Ir(H)(Cl)(SnCl_3)(CO)(PPh_3)_2]$, although structure (**102**) cannot be excluded.[219] The complexes $[Ir(X)(SnR_3)(CO)(PR'_3)_2]$ (X = Cl, Br, I; R = Me, Et, Ph; PR'_3 = PPh_3, PPh_2Me, $PPhEt_2$) have been prepared and characterized by ^1H NMR and IR spectroscopy. The Ph_3Sn—Ir complexes have been assigned the stereochemistry in (**103**), while the Et_3Sn—Ir complexes are consistent with structure (**104**). Two isomers of the Me_3Sn—Ir complexes were isolable, and assigned to structures analogous to (**103**) and (**104**).[220]



(101) (102)

(103) (104)

Intramolecular oxidation–reduction isomerism involving changes in formal oxidation state at the metal centre are rather uncommon in transition metal chemistry. However, from IR and ^{1}H NMR spectral studies on $[Ir(Cl)(SnCl_4)(CO)(PPh_3)_2]$ and $[Ir(Cl)(SnCl_3Me)(CO)(PPh_3)_2]$, it was concluded that each complex consists of two rapidly interconverting isomers. Further, the available data for the $SnCl_4$—Ir complex are consistent with the isomerism arising from rapidly equilibrating oxidative addition and donor–adduct isomers (**105a**) ⇌ (**105b**).[220]

(105a) (105b)

49.6.3 Nitrogen Ligands

49.6.3.1 Ammonia and amine ligands

The iridium(III) pentaamine complexes $[Ir(X)(NH_3)_5]^{2+}$ undergo octahedral substitution reactions in aqueous solution, similar to Co^{III} and Rh^{III} analogues.[221] $[Ir(X)(NH_3)_5]^{2+}$ (X = NO_3, Cl, Br, I) undergoes aquation (reaction 63) with the reactivity increasing in the order X = Cl < Br < I < NO_3; a linear free energy relationship was observed.[222] The aquation rates of $[Ir(X)(NH_3)_5]^{2+}$ are smaller than those of the cooresponding Rh^{III} complexes, consistent with considerations of crystal field theory. Additionally, $[Ir(Br)(NH_3)_5]^{2+}$ undergoes acid hydrolysis at 298 K with a rate constant $k \approx 2 \times 10^{-10}\,s^{-1}$; $E_a = 113\,kJ\,mol^{-1}$ and $\Delta S^{\ddagger} = -59\,J\,mol^{-1}\,K^{-1}$.[222] The rate constant k_{ex} for the base-catalysed hydrogen exchange of $[Ir(NH_3)_6]^{3+}$ at 298 K in D_2O (reaction 64) has been determined ($k_{ex} = 1.5 \times 10^{-8}\,M^{-1}\,s^{-1}$).[223] The chloride anation of $[Ir(H_2)(NH_3)_5]^{3+}$ is three times faster than the water exchange rate, and has been attributed to an associative interchange mechanism.[224]

$$[Ir(X)(NH_3)_5]^{2+} + H_2O \rightleftharpoons [Ir(H_2O)(NH_3)_5]^{3+} + X^- \quad (63)$$

$$Ir—NH + OD^- \xrightarrow[k_{ex}]{} Ir—ND + OH^- \quad (64)$$

Iridium(III) ammine complexes have been shown to be photoactive.[225,226] Ligand field (LF) excitation (350 nm) of $[Ir(N_3)(NH_3)_5]^{2+}$ leads to efficient decomposition of N_3^- with the formation of $[Ir(NH_2Cl)(NH_3)_5]^{3+}$ and N_2 in aqueous HCl.[226] The principal photoreactions observed on LF excitation (254 or 313 nm) of $[Ir(NH_3)_6]^{3+}$, $[Ir(H_2O)(NH_3)_5]^{3+}$ and $[Ir(Cl)(NH_3)_5]^{2+}$ in aqueous solution at 298 K are summarized in reactions (65) and (66); $[Ir(H_2O)(NH_3)_5]^{3+}$ is virtually unreactive under the conditions employed.[227] The photochemical properties of $[Ir(X)(NH_3)_5]^{2+}$ (X = Cl, Br, I), *trans*-$[Ir(I)_2(NH_3)_4]^+$, *trans*-$[Ir(I)(H_2O)(NH_3)_4]^{2+}$ and $[Ir(L)(NH_3)_5]^{3+}$ (L = H_2O, NH_3, MeCN, PhCN) have been investigated in aqueous solution. LF photolysis leads to ligand photoaquation only, while irradiation of ligand-to-metal charge transfer (LMCT) absorption bands suggest the presence of a redox component as well as aquation. Quantum yields and product distribution are wavelength independent for LF excitation. Also, LF excitation is followed by efficient internal conversion/intersystem crossing to produce a common 'triplet' LF state.[228] Essentially, rhodium(III) and iridium(III) amine complexes behave in a parallel manner.

$$[Ir(NH_3)_6]^{3+} + H_3O^+ \xrightarrow{h\nu} [Ir(NH_3)_5(H_2O)]^{3+} + NH_4^+ \quad (65)$$

$$[Ir(Cl)(NH_3)_5]^{2+} + H_2O \xrightarrow{h\nu} [Ir(H_2O)(NH_3)_5]^{3+} + Cl^- \quad (66)$$

The synthesis and characterization of *cis*- and *trans*-$[Ir(X)_2(en)_2]^+$ (X = Cl, Br, I) and *trans*-$[Ir(X)(Y)(en)_2]^{n+}$ (X = Cl, Y = Br, I, H_2O, OH, NCS, NO_2, ONO; X = Y = NO_3, N_3; en = ethylenediamine) were reported by Bauer and Basolo,[229] following Kida's[230] paper on the synthesis of *cis*- and *trans*-$[Ir(Cl)_2(en)_2]^+$. *trans*-$[Ir(Cl)_2(en)_2]^+$ can be prepared by a catalytic method employing H_3PO_2, while the *cis* isomer is obtained in a high ionic strength medium. Structural assignments were made on the basis of IR spectra and resolution of the *cis* isomer.

Ligand substitution at *trans*-$[Ir(X)_2(en)_2]^+$ occurs without stereochemical change, and with substitution rates independent of the concentration and nature of the incoming ligand and the ionic strength. The substitution mechanism involves an aqua intermediate, as illustrated in Scheme 10.[231] Aquation kinetics of complexes such as *trans*-$[Ir(X)_2(en)_2]^+$ were not directly accessible, the equilibrium in Scheme 10 lying to the left. Table 2 shows various ligand substitution rates and activation parameters for *trans*-$[Ir(X)(en)_2(L)]^+$. The base hydrolysis of *cis*- and *trans*-$[Ir(Cl)_2(en)_2]^+$ also proceeds with stereoretention.

$$[Ir(X)_2(en)_2]^+ \underset{RDS}{\overset{H_2O,\ slow}{\rightleftharpoons}} [Ir(X)H_2O(en)_2]^{2+} \overset{+Y,\ fast}{\rightleftharpoons} [Ir(X)(Y)(en)_2]^{2+}$$

Scheme 10

Table 2 Rates of Ligand Substitution Reactions of *trans*-$[Ir(X)(en)_2(L)]^{+a}$

I	I	58	120	−12.5

[a] Taken, in part, from ref. 231.
[b] At 378 K.

The geometric structure of *cis*-$[Ir(Cl)_2(en)_2]^+$ has been proved by resolution into its optical isomers.[232] Proton NMR studies have shown that the ammination of *cis*-$[Ir(Cl)_2(en)_2]^+$ proceeds with retention of configuration to yield *cis*-$[Ir(en)_2(NH_3)_2]^{3+}$. The absolute configurations of optically-active *cis*-$[Ir(Cl)_2(en)_2]^+$ and *cis*-$[Ir(en)_2(NH_3)_2]^{3+}$ have been inferred by comparing their electronic absorption and CD spectra with those of Co^{III} and Rh^{III} analogues; the Λ configuration has been proposed.[233]

The complexes *trans*-$[Ir(X)_2(en)_2]^+$ (X = Cl, Br, I) in aqueous solution undergo rapid photosubstitution to yield *trans*-$[Ir(X)(en)_2(H_2O)]^{2+}$. LF excitation (350 nm) of *trans*-$[Ir(Cl)_2(en)_2]^+$ affords photoaquation of Cl^- with a quantum yield of *ca.* 0.1 mol einstein^{-1}.[234] Irradiation into the LF bands of *cis*- and *trans*-$[Ir(X)(Y)(en)_2]^+$ (X = Y = Cl, Br, I; X = OH, Y = Cl) in aqueous solution leads to halide photolabilization. For X = Y = Cl, the quantum yields are pH independent. In acidic solution, the *trans* dihalo complexes give *trans*-$[Ir(X)(en)_2(H_2O)]^{2+}$ with complete retention of configuration. But the *cis* analogues undergo simultaneous photoisomerization to yield a mixture of *cis*- and *trans*-$[Ir(X)(en)_2(H_2O)]^{2+}$ with the extent of photoisomerization following the order X = Cl < Br < I.[235] The principal photoreactions observed for these complexes are consistent with theories[236] that propose ligand labilization from the lowest LF excited states being confined to the weak field axis. With an excess of Br^- and I^-, *trans*-$[Ir(Cl)_2(en)_2]^+$ reacts photochemically to yield *trans*-$[Ir(Br)_2(en)_2]^+$ and *trans*-$[Ir(I)_2(en)_2]^+$, respectively.[237]

The photoaquations of X in *trans*-$[Ir(X)_2(en)_2]^+$ provide a useful route for the rapid and clean preparation of various *trans*-$[Ir(X)(Y)(en)_2]^{n+}$ and *trans*-$[Ir(X')_2(en)_2]^+$ complexes (reactions 67–70).[229,237] The products obtained were those expected on the basis of the *trans*-effect behaviour in such systems.

$$trans\text{-}[Ir(Cl)_2(en)_2]^+ \xrightarrow{h\nu,\ I^-} trans\text{-}[Ir(Cl)(I)(en)_2]^+ \longrightarrow trans\text{-}[Ir(I)_2(en)_2]^+ \quad (67)$$

$$trans\text{-}[Ir(I)_2(en)_2]^+ \xrightarrow{h\nu,\ Cl^-} trans\text{-}[Ir(Cl)(I)(en)_2]^+ \quad (68)$$

$$trans\text{-}[Ir(Cl)_2(en)_2]^+ \xrightarrow{h\nu,\ OH^-} trans\text{-}[Ir(OH)_2(en)_2]^+ \quad (69)$$

$$trans\text{-}[Ir(X)_2(en)_2]^+ \xrightarrow{h\nu,\ H_2O} trans\text{-}[Ir(X)(H_2O)(en)_2]^{2+} \xrightarrow{+Ag^+}$$

$$trans\text{-}[Ir(X)(H_2O)(en)_2]^{2+} + AgX(s) \xrightarrow{+Y^-} trans\text{-}[Ir(X)(Y)(en)_2]^+ \quad (70)$$

The kinetics of chloride exchange in *trans*-$[Ir(Cl)_2(trien)]^+$[238] (trien = triethylenetetramine) show behaviour similar to that of *cis*- and *trans*-$[Ir(Cl)_2(en)_2]^+$.[239] Also, the rate constant dependency on chloride concentration is similar for all three complexes. This dependency has been interpreted[238] either in terms of an ion pair or a dissociative mechanism, with the latter being more favourable.

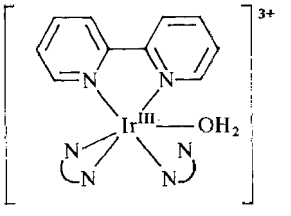
The bis-pyridino complexes *trans*- and *cis*-$[Ir(Cl)_4(py)_2]^-$ and *trans*-$[Ir(Cl)_3(H_2O)(py)_2]$ have been prepared and characterized. The thermal aquation of *cis*-$[Ir(Cl)_4(py)_2]^-$ yields 5% *trans* product, and a trigonal bipyramidal intermediate species is postulated.[240]

trans-$[Ir(Cl)_2(py)_4]^+$[241,242] undergoes photoaquation of Cl^- at 350 and 254 nm irradiation. A significant amount of amine release also occurs during photolysis of this complex.[243] The photochemistry of several pyridine complexes has been reviewed by Balzani and Carassiti,[225] including $[Ir(Cl)_5(py)]^{2-}$,[244] *cis*- and *trans*-$[Ir(Cl)_4)py)_2]^-$,[245,246] *trans*-$[Ir(X)_3(py)_3]$ (X = Cl,[247] Br[248]), and *cis*- and *trans*-$[Ir(Cl)_2(py)_4]^+$.[249]

49.6.3.2 N-heterocyclic ligands

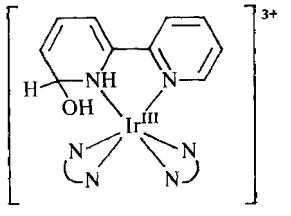
A proton NMR spectroscopic investigation of a complex originally thought to be $[Ir(bipy)_3]^{3+}$ (bipy = 2,2′-bipyridyl) has assigned the complex as *cis*-$[Ir(Cl)_2(bipy)_2]^+$.[250] In agreement, Gillard and Heaton[251] have found that earlier reports of the syntheses of $[Ir(phen)_3]^{3+}$ (phen = 1,10-phenanthroline) and $[Ir(bipy)_3]^{3+}$ were erroneous.

The preparation of *cis*-$[Ir(Cl)_2(4,4'\text{-}Ph_2bipy)_2]^+$, *cis*-$[Ir(Cl)_2(4,7\text{-}Cl_2phen)_2]^+$ and *cis*-$[Ir(Cl)_2(bipy)_2]^+$ (4,4′-Ph_2bipy = 4,4′-diphenyl-2,2′-bipyridyl; 4,7-Cl_2phen = 4,7-dichloro-1,10-phenanthroline) has been reported. The similarities between the UV spectra of the free ligands and the complexes led to an assignment of ligand-localized transitions in this region. Absorption bands in the visible region were assigned to charge-transfer transitions. All three complexes exhibit luminescence at 19.5–21.1 kK at 77 K, ascribed to a charge-transfer ($d\pi^*$) → A_1 transition.[252] Emission quantum yields, lifetimes and spectra, along with photosolvation yields, are reported for *cis*-$[Ir(Cl)_2(bipy)_2]^+$ and its deuterated analogue *cis*-$[Ir(Cl)_2(bipy\text{-}d_8)_2]^+$ in H_2O, DMF, MeOH and MeCN. Both charge-transfer and ligand-field excited states contribute to the decay properties in fluid media. Photosolvation rates are solvent dependent and thus consistent with either a dissociative or a dissociative interchange mechanism.[253]



The luminescence decay curves of *cis*-$[Ir(Cl)_2(phen)(5,6\text{-}Me_2phen)]^+$[254] and *cis*-$[Ir(Cl)_2(phen)(4,7\text{-}Me_2phen)]^+$[255] (5,6-$Me_2$phen = 5,6-dimethyl-1,10-phenanthroline; 4,7-Me_2phen = 4,7-dimethyl-1,10-phenanthroline) have been recorded as a function of excitation and/or emission wavelength. From emission wavelength studies, the total emission spectrum of the 5,6-Me_2phen complex is decomposed into two component spectra, one arising from $d\pi^*$ and the other from $\pi\pi^*$ orbital parentages. Excitation wavelength studies have led to the proposal that upper states of $d\pi^*$ parentage feed the $d\pi^*$ emission while states of $\pi\pi^*$ parentage feed the $\pi\pi^*$ emission. The data obtained from emission wavelength studies of the 4,7-Me_2phen complex best fit a model in which the luminescence occurs as a result of three sets of thermally non-equilibrated levels (lifetimes $\tau = 6.0$, 8.7 and 22 μs), arising from mixed $d\pi^*$–$\pi\pi^*$, $d\pi^*$, and d–d orbital parentages, respectively.

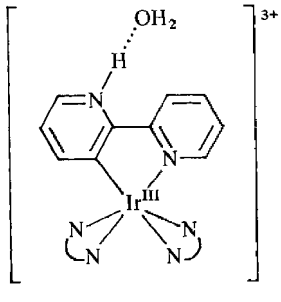
A synthesis of $[Ir(bipy)_3]^{3+}$ has been reported by Flynn and Demas.[256] ^{13}C and proton NMR spectra have confirmed the tris-complex assignment. $[Ir(bipy)_3]^{3+}$ exhibits a phosphorescence at 22.3 kK with a mean lifetime of ~ 80 μs in MeOH/EtOH glass at 77 K; luminescence was assigned as predominantly π–π^* ligand phosphorescence.



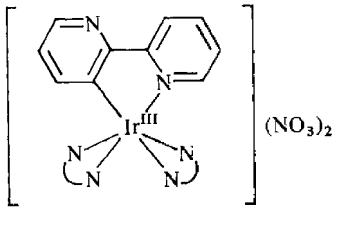
Gillard[257] has summarized many of the so-called 'anomalies' existing for transition metal polypyridyl complexes in aqueous solution, and postulated covalent hydrate formation to explain these 'anomalies'. Nord and coworkers[258] have questioned the validity, and indeed the premise upon which covalent hydration in polypyridyl complexes is based.

The nature of the complex(es) containing three 2,2′-bipyridyls per iridium atom has been the subject of a controversial debate[259–263] since the report by Flynn and Demas[256] of the successful preparation of the $[Ir(bipy)_3]^{3+}$ cation. This species was formulated as having all three bipyridyl ligands ligated to iridium(III) *via* the nitrogen atoms, as demonstrated by ^{13}C NMR spectroscopy (D_3 symmetry, five well-resolved ^{13}C resonances). Later, Watts *et al.*[259] identified another complex also containing three bipyridyl ligands per iridium atom but having distinct absorption and emission spectral properties, as well as different photophysical characteristics from $[Ir(bipy)_3]^{3+}$. The complex exhibits an emission in both acidic and basic media at lower energies than that for $[Ir(bipy)_3]^{3+}$, and

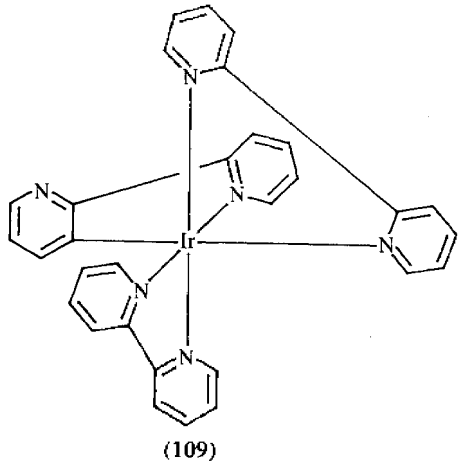
visible absorption bands in these media do not correspond with the tris complex. The complex was described as being comprised of iridium, two bidentate bipy ligands, one water molecule, and one monodentate bipy′, $[Ir(bipy)_2(H_2O)(bipy')]^{3+}$ (**106a**); this complex can be converted to the hydroxo form and isolated by treatment with base. The luminescence spectrum of complex (**106a**) arises primarily from interligand π–π^* transitions of the bipy ligands, with some mixing from charge-transfer from iridium(III) to bipy.[264] The luminescence lifetimes of complex (**106a**) and its hydroxo analogue, $[Ir(bipy)_2(OH)(bipy')]^{2+}$, along with their related emission quantum yields in H_2O and D_2O, have been reported as well.[259] Together with the above information, the IR spectrum of (**106a**) is consistent with a formulation of the complex as the covalently hydrated species (**106b**); however, because there is no facile equilibrium between $[Ir(bipy)_3]^{3+}$ and the covalent hydrate $[Ir(bipy)_2(bipy \cdot H_2O)]^{3+}$ (**106b**), as revealed by the identical emission spectra in both 0.1 M base and 0.1 M acid for $[Ir(bipy)_3]^{3+}$, the nature of the complex isolated by Watts *et al.*[259] cannot be (**106b**). Gillard and coworkers[262] have argued 'because there is no facile equilibrium, it is not to say that no equilibrium exists', and explained the 'puzzling' properties of the complex in terms of the species (**106b**).



(106a)



(106b)



Another source of controversy about the formulation of this iridium(III) complex rests on its ^1H and ^{13}C NMR spectra.[263] The data from these spectra preclude the existence of structure (**106b**) and were taken as consistent with structure (**106a**).[259] A single crystal X-ray structural study[265] on the ClO_4^- salt of this complex has demonstrated unequivocally that the species contains neither a monodentate nor a covalently hydrated bipyridyl ligand, at least in the solid state. All three bipyridyl ligands are chelated to iridium(III), but one bipy ligand is chelated *via* the nitrogen of one ring and the C-3 carbon of the other ring, reminiscent of *o*-metallated complexes. It has been proposed[267] that the data[259–262] can be understood in terms of, and are all consistent with, structure (**107**). Clearly, for complexes where monodentate or covalently hydrated species have been postulated, renewed consideration must be given in the light of (**107**) or equivalent species. Watts[268] has reconsidered the ^1H and ^{13}C NMR data, as has Seddon.[269] Furthermore, recent studies by Serpone *et al.*[270] reveal that the nitrate salt of this cation contains two NO_3^- units per iridium(III), consistent with structure (**108**). A very recent crystal structure determination of the red complex [Ir(bipy-N,N')$_2$(bipy-C^3, N')]$^{2+}$ (**109**) has revealed that each Ir atom is coordinated, in a distorted octahedron, to five nitrogen atoms and one carbon atom of the bipy ligands. In both N-bonded bipy rings and the C-bonded ring, the C(2)—N and C(6)—N distances are short, suggestive of rings 5, 7 and 13 being bonded to Ir *via* carbon (three $Ir(bipy)_3^{3+}$ units per asymmetric unit). Proton NMR and UV spectra of complex (**109**) were in accordance with the crystal structure analysis depicted in (**109**).[271] Also, Spellane *et al.*[272] have recently cited some ^1H and ^{13}C NMR data for [Ir(Hbipy-C^3, N')(bipy-N,N')$_2$]$^{3+}$ in DMSO-d_6 which indicate the presence of a C-bonded ring to Ir. Experiments employing a lanthanide shift reagent confirmed the presence of a site of Lewis basicity on the carbon-bonded pyridine ring.[272]

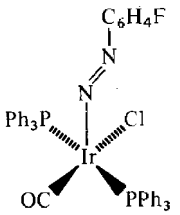
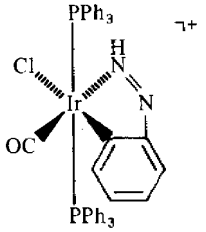
(108)



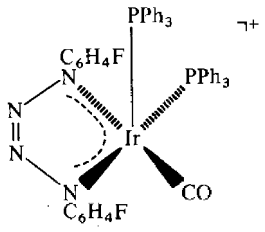
(109)

49.6.3.3 Diazenato and diazo ligands

Transition metal complexes of aryldiazenato ($ArN{=}N^-$) and aryldiazene ($ArN{=}NH$) ligands serve as valuable models of the catalytic activation of N_2 and for its preliminary reduction to N_2H_2. Aryldiazenato and aryldiazene derivatives of *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ have been investigated by several groups.[273] $[Ir(X)(CO)(PPh_3)_2]$ (X = Cl, Br) reacts with arenediazonium tetrafluoroborates in the presence of LiCl to give $[Ir(Cl)(X)(CO)(N{=}NAr)(PPh_3)_2]$. In the absence of LiCl, the cationic complex $[\{Ir(X)(CO)(N{=}Ar)(PPh_3)_2\}_n]^+$ is obtained. A crystal structural analysis of $[Ir(Cl)_2(CO)(N{=}NC_6H_4NO_2\text{-}o)(PPh_3)_2]$ confirmed the presence of a 'doubly-bent' aryldiazenato ligand (**110**).[274] The N-ligand appears to exert a strong *trans* influence. The five-coordinate cation $[Ir(Cl)(CO)(N{=}NC_6H_4F)(PPh_3)_2]^+$ (**111**) also contains a doubly-bent ArN_2^- ligand. Further addition of neutral or negative ligands affords six-coordinate iridium(III) complexes.[275]

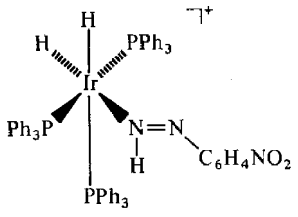


(110)

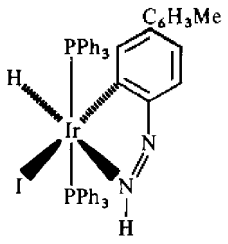


(111)

The reaction between $[Ir(Cl)(CO)(PPh_3)_2]$ and diazonium ions in the presence of ethanol or propan-2-ol affords the *o*-metallated diazene (**112**)[276] and the iridium(III) tetrazene complex (**113**).[277] A mechanism for the synthesis of (**113**) has been presented.[278]



(112)



(113)

$[Ir(Cl)_2(NH{=}NAr)(PPh_3)_3]^+$ and $[Ir(Cl)_3(NH{=}NAr)(PPh_3)_2]$ have been synthesized from $[Ir(H)(Cl)_2(PPh_3)_3]$.[279] Insertion of diazonium ions into *mer*-$[Ir(H)_3(PPh_3)_3]$ yields $[Ir(H)_2(NH{=}NAr)(PPh_3)_3]^+$; a preliminary X-ray investigation has suggested the structure (**114**).[280] The crystal and molecular structures of $[Ir(H)(I)(NH{=}NC_6H_3Me\text{-}p)(PPh_3)_2]$ (**115**) have been elucidated.[281] More recently, it was shown that reaction between $[Ir(H)_3(PPh_3)_2]$ and *p*-substituted arenediazonium salts gives $[Ir(H)_2(NH{=}NC_6H_4R)(PPh_3)_2]^+$ at low temperatures (263 K) and the *o*-metalated complexes $[\overline{Ir(H)(NH{=}NC_6H_3R)}(PPh_3)_2]^+$ (**116**; R = F, OMe) at higher temperatures (313–323 K). The *o*-metallated complexes (**116**) react with CO, PPh_3, NaI and HCl according to reactions (71–74), respectively.[282]

(114)

(115)

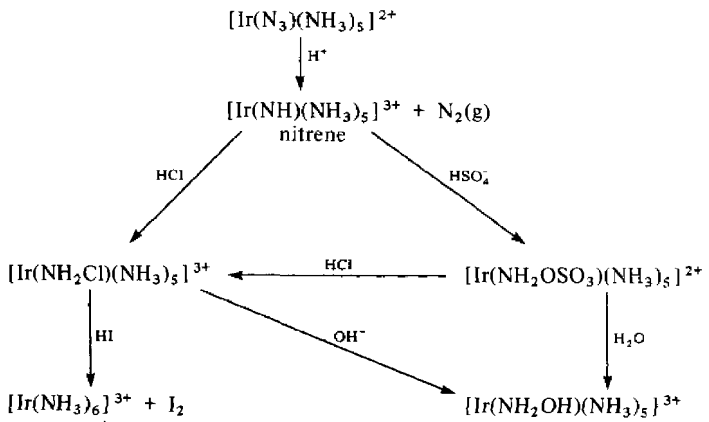
$$(116) + CO \longrightarrow [\overline{Ir(H)(CO)(NH{=}NC_6H_3R)}(PPh_3)_2]^+ \quad (71)$$

$$(116) + PPh_3 \longrightarrow [\overline{Ir(H)(NH{=}NC_6H_3R)}(PPh_3)_3]^+ \quad (72)$$

$$(116) + NaI \longrightarrow [\overline{Ir(H)(I)(NH{=}NC_6H_3R)}(PPh_3)_2] \quad (73)$$

$$(116) + HCl \longrightarrow [\overline{Ir(H)(Cl)_2(NH{=}NC_6H_3R)}(PPh_3)_2] \quad (74)$$

49.6.3.4 Azide ligands



The synthesis of the iridium(III) azide complex $(Bu^n_4N)_3[Ir(N_3)_6]$ occurs *via* reaction (75). The visible and near-UV absorption and reflection spectra of this complex have been recorded; the assignment of bands in this and rhodium(III) azide complexes has led to the location of the N_3^- ligand in the spectrochemical and nephelauxetic series.[283]

$$Na_3[IrCl_6]\cdot 12H_2O + NaN_3 \xrightarrow[Bu^n_4N^+]{H_2O/EtOH} (Bu^n_4N)_3[Ir(N_3)_6] \quad (75)$$

trans-$[Ir(N_3)(en)_2]^+$ readily reacts with acid to liberate N_2 gas.[229] Subsequent investigation of this system suggested that the reaction occurs *via* a low-energy metal–nitrene (M—NH) pathway.[284] $[Ir(N_3)(NH_3)_5]^{2+}$ also liberates gaseous N_2 upon reaction with acid,[285] presumably by way of reaction (76). Kinetic studies were consistent with a nitrene intermediate pathway. Scheme 11 shows some reactions of $[Ir(N_3)(NH_3)_5]^{2+}$, all of which are in agreement with a nitrene path; furthermore, the coordinated nitrene serves as a powerful electrophile. Basolo[284] has given a brief review of the preparation and reactivity of transition metal nitrene complexes. Photolysis of $[Ir(N_3)(NH_3)_5]^{2+}$ in aqueous HCl proceeds by reaction (77). A mechanism consistent with steady state and flash photolysis results is given in Scheme 12.[284]

$$[Ir(N_3)(NH_3)_5]^{2+} + 2H^+ + X^- \longrightarrow [Ir(NH_3)_5(NH_2X)]^{3+} + N_2(g) \quad (76)$$

$$[Ir(N_3)(NH_3)_5]^{2+} + 2H^+ + Cl^- \xrightarrow{h\nu} [Ir(NH_3)_5(NH_2Cl)]^{3+} + N_2(g) \quad (77)$$

$[Ir(NH)(NH_3)_5]^{3+} + Cl^- \longrightarrow [Ir(NHCl)(NH_3)_5]^{2+}$

$[Ir(NH)(NH_3)_5]^{2+} + ClO_4^- \longrightarrow [Ir(NHOClO_3)(NH_3)_5]^{2+} \longrightarrow [Ir(NH_2OH)(NH_3)_5]^{3+}$

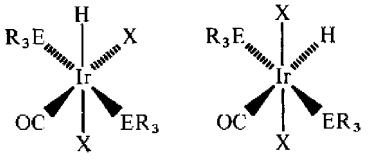
$[Ir(NHCl)(NH_3)_5]^{2+} + H^+ \longrightarrow [Ir(NH_2Cl)(NH_3)_5]^{3+}$

Scheme 12

Zink[286] has applied a molecular orbital approach to photochemical assignments of excited states of iridium(III) azide complexes. The observed products of 250–400 nm irradiation of $[Ir(N_3)(NH_3)_5]^{2+}$ are $[Ir(NH_3)_5(NH_2Cl)]^{3+}$ and N_2, the same products expected on the basis of populating the LL (ligand-localized $\pi_{non} \rightarrow \pi^*$) excited state. It was suggested, therefore, that the photoreaction originates in the LL excited state. The formation of a coordinated nitrene intermediate has been ascribed to a combination of LMCT and LL states rather than to the LL state alone.

49.6.3.5 Polypyrazolylborate ligands

From a structural point of view, the complex chemistry of the tripyrazolylborate anion frequently resembles that of cyclopentadienyl or pentamethylcyclopentadienyl complexes. The iridium(III) tripyrazolylborate complexes $[Ir(Cl)_2\{HB(3,5\text{-}Me_2pz)_3\}]_2$, $[Ir(Cl)_2\{HB(3,5\text{-}Me_2pz)_3\}(AsPhMe_2)]$, $[Ir(CF_3CO_2)_2\{HB(3,5\text{-}Me_2pz)_3\}(H_2O)]$ and $[Ir(acac)(Cl)\{HB(3,5\text{-}Me_2pz)_3\}]$ have been prepared and characterized by ^1H NMR spectroscopy. None of these complexes exhibited a ν(B—H) mode in the region of *ca.* 2500 cm^{-1}, as do their rhodium analogues.[287]



49.6.4 Phosphorus, Arsenic and Antimony Ligands

49.6.4.1 Unidentate ligands

Iridium(III) phosphine complexes obtained *via* the oxidative addition to Vaska-type iridium(I) complexes have been discussed (Section 49.4.3).

The stereochemistries of $[Ir(X)_n(ER_3)_3(Me)_{3-n}]$ (X = Cl, Br, I; ER_3 = PMe_2Ph, $AsMe_2Ph$; n = 0, 1, 2) have been assigned from the methyl resonance patterns of their ^1H NMR spectra.[288] Structural assignments of *trans*-$[Ir(X)_4(PMe_3)_2]$, *mer*- and *fac*-$[Ir(X)_3(PMe_3)_3]$ and *trans*-$[Ir(X)_2(PMe_3)_4]$ (X = Cl, Br) have been made on the basis of IR and Raman (< 800 cm^{-1}) spectral data; additionally, the significance of the Ir—P and Ir—Cl stretching frequencies has been discussed.[289]

Tri-*t*-butylphosphine reacts with hydrated iridium(III) chlorides to yield $[Ir(H)_2(Cl)(PBu^t_3)_2]$.[290] The two isomeric series, α and β, of hydrido carbonyls of the type $[Ir(H)(X)(CO)(ER_3)_2]$ (X = Cl, Br; ER_3 = $AsMePh_2$, $AsEtPh_2$) have been prepared. The structures of the α and β configurations are shown in (**117a**) and (**117b**), respectively.[291] Other complexes containing unidentate As donor ligands have been prepared *via* oxidative addition and characterized, including $[Ir(H)_3(AsPh_3)_2(CO)]$[292] and $[Ir(H)(X)(CO)(ER_3)_2]$ (ER_3 = $AsPh_3$, $AsMe_2Ph$).[293] Reaction between $[Ir(H)_3(AsPh_3)_2(CNC_6H_4Me\text{-}p)]$ (**118**) and HX (or pseudohalides) leads to the substitution products $[Ir(H)_2(AsPh_3)_2(CNC_6H_4Me\text{-}p)(X)]$ (X = Cl, Br, I, N_3).[210] With carboxylic acids and pentane-2,4-dione, complex (**118**) yields the chelated complexes $[Ir(L)_2(AsPh_3)(CNC_6H_4Me\text{-}p)]$ (L = carboxylate or pentane-2,4-dionate), in which Ir^{III} is reportedly reduced to Ir^{II}.[186] Reactions (78)–(86) reveal the utility of complex (**118**) in synthesizing complexes with iridium in various oxidation states.[196]

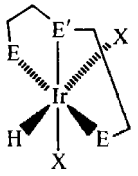
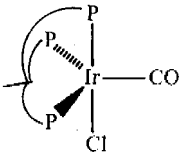
(**118**) + $HO_2CC_6H_4OH\text{-}o$ ⟶ $[Ir^{IV}(O_2CC_6H_4O\text{-}o)_2(AsPh_3)(CNC_6H_4Me\text{-}p)]$ (82)

(**118**) + $HO_2CCH(NH_2)CH_2Ph$ ⟶ $[Ir^{IV}\{O_2CCH(NH)CH_2Ph\}_2(AsPh_3)(CNC_6H_4Me\text{-}p)]$ (83)



$$(\mathbf{118}) + HOC_6H_4OH\text{-}o \longrightarrow [Ir^{IV}(OC_6H_4O\text{-}o)_2(AsPh_3)(CNC_6H_4Me\text{-}p)] \quad (84)$$

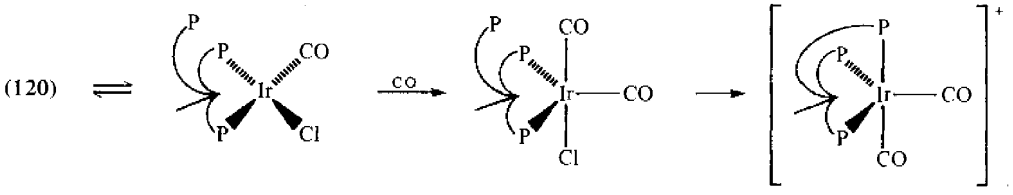
$$(\mathbf{118}) + HOC_6H_4NH_2\text{-}o \longrightarrow [Ir^{IV}(OC_6H_4NH\text{-}o)_2(AsPh_3)(CNC_6H_4Me\text{-}p)] \quad (85)$$



$$(\mathbf{118}) + HO_2CC_6H_4NH_2\text{-}o \longrightarrow [Ir^{IV}(O_2CC_6H_4NH\text{-}o)(AsPh_3)(CNC_6H_4Me\text{-}p)] \quad (86)$$

49.6.4.2 Polydentate ligands

Reaction of $[Ir(H)(X)_2(PPh_3)_2]$ (X = Cl, Br) and the potentially tridentate ligands $(o\text{-}Ph_2EC_6H_4)_2E'Ph$ (TP: E = E′ = P; PDAS: E = As, E′ = P; ASDP: E = P, E′ = As; TAS: E = E′ = As] has afforded complexes of the type $[Ir(H)(X)_2(L)]$ (**119**), where L = TP, PDAS, ASDP or TAS. The syntheses and characterizaton of complexes (**119**) by ^1H and ^{31}P NMR spectroscopy have revealed the meridional isomer, as shown, to be preferred.[294] The tripodal ligand 1,1,1-tris-(diphenylphosphinomethyl)ethane ($MeC(CH_2PPh_2)_3$ = TDPME) reacts with $[Ir(Cl)(CO)(PPh_3)_2]$ in benzene to yield [Ir(Cl)(CO)(TDPME)], for which a trigonal bipyramidal structure (**120**) was tentatively assigned. The reaction of complex (**120**) with CO has been postulated as proceeding by way of Scheme 13 to give complex (**121**).[295]



(119)

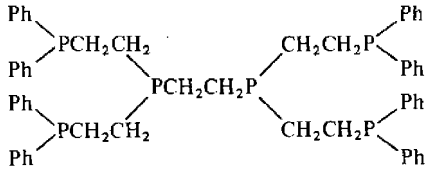
TP: E = E′ = P
PDAS: E = As; E′ = P
ASDP: E = P; E′ = As
TAS: E = E′ = As

(121)

Scheme 13

Reaction of $[Ir(H)(Br)_2(PPh_3)_3]$ with the tetradentate ligand tris(*o*-diphenylphosphinophenyl)-phosphine, QP (**122**), gives $[Ir(H)(Br)(PPh_3)(QP)](BPh_4)$, which was assigned a seven-coordinate structure.[296] With the similar tetradentate ligands ASTP, PTAS and QAS (**122**), $[Ir(H)(X)_2(PPh_3)_2]$ (X = Cl, Br) reacts to produce $[Ir(PPh_3)(ASTP)]^+$, $[Ir(PPh_3)(PTAS)]^+$ and $[Ir(PPh_3)(QAS)]^+$, respectively.[297] Under the conditions employed $[Ir(X)(PPh_3)_3]$ (X = Cl, Br) reacted with QP according to reaction (87), and [Ir(Cl)(PPh$_3$)(cod)] reacted with QP to give [Ir(Cl)(QP)] and $[Ir(PPh_3)(QP)]^+$. [Ir(Cl)(QP)] reacts with HCl and Cl_2 according to reactions (88) and (89), respectively.[297]

(122)



QP: E = E′ = P

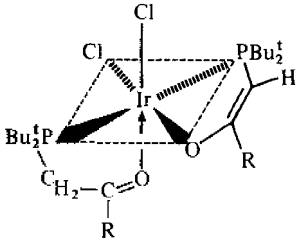
PTAS: E = As; E′ = P
QAS: E = E′ = As

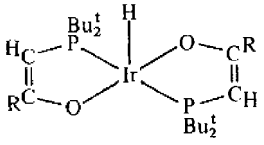
$$[Ir(X)(PPh_3)_3] + QP \longrightarrow [Ir(PPh_3)(QP)]^+ + [Ir(X)(QP)] \quad (87)$$

$$[Ir(Cl)(QP)] + HCl \longrightarrow [Ir(H)(Cl)(QP)]^+ \quad (88)$$

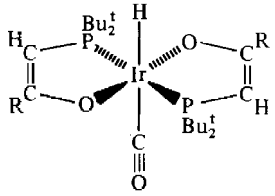


$$[Ir(Cl)(QP)] + Cl_2 \longrightarrow [Ir(Cl)_2(QP)]^+ \quad (89)$$

The trinuclear derivative $[Ir_3(Cl)_9\{P_2(-Pf)_4\}_2]$ results from the reaction between hydrated iridium(III) chloride and the hexatertiary phosphine $(Ph_2PCH_2CH_2)_2PCH_2CH_2P(CH_2CH_2PPh_2)_2$ $(=P_2(-Pf)_2)$ (**123**). Far-IR spectra for the trinuclear complex were interpreted in terms of three Cl atoms of each $IrCl_3$ moiety occupying meridional positions in an octahedron, and the $P_2(-Pf)_4$ ligand bridging the three $IrCl_3$ groups. Also, bridging Cl atoms could be present.[298]



(123)



The bulky β-ketophosphine ligands $PBu^t_2(CH_2COPh)$ (Q) and $PBu^t_2(CH_2COBu^t)$ (Q′) are known to behave as either (i) unidentate ligands through the P atom; (ii) bidentate ligands through the P atom and the keto group; or (iii) bidentate enolate ions. Iridium trichloride reacts with Q and Q′, affording the six-coordinate complexes (**124**). Complex (**124**) reacts with $NaNO_2$ to give the five-coordinate square-pyramidal hydride complexes (**125**), which take up CO to yield (**126**).[299] Carbonylation of $Na[IrCl_6]$ followed by the addition of Q yields (**127**) with an uncoordinated keto group. On treatment of complex (**127**) with NaOEt, a mixture of (**126a**) and (**128**) was reportedly formed. Proton and ^{31}P NMR spectroscopic data were employed to elucidate the structures.[299]

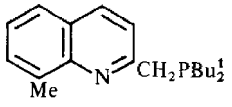
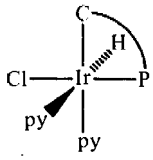
(128) R = Ph

The cyclometallated chlorohydrido iridium(III) complex (**129**) is obtained upon treatment of $[Ir(Cl)(PPh_3)_3]$ with organometallic derivatives of either the unsubstituted 1,2- and 1,7-carborane (-2-H-1,2-$B_{10}C_2H_{10}$) or the C(7)-methyl- and -phenyl-substituted carborane (-7-R-1,7-$B_{10}C_2H_{10}$) (R = H, Me, Ph). Proton NMR spectral data revealed evidence that the H ligand is *trans* to Cl and mutually *cis* to three non-equivalent P nuclei.[133] In MeCN, $[Ir(PMe_2Ph)_4]^+$ reacts with H_2 to yield *cis*-$[Ir(H)_2(PMe_2Ph)_4]^+$; however, on refluxing for 6 h in the absence of H_2, the complex *fac*-$[Ir(H)(PMe_2C_6H_4)(PMe_2Ph)_3]^+$ (**130**) results.[300] *o*-Metallation in $[Ir(H)(X)_2\{P(OPh)_3\}_3]$ (X = Cl, Br) apparently proceeds *via* a reductive elimination of HX to produce $[Ir(X)\{P(OPh)_3\}_3]$ followed by an internal oxidative addition process. For the iodo analogue, $[Ir(H)(I)_2\{P(OPh)_3\}_3]$, a mixture

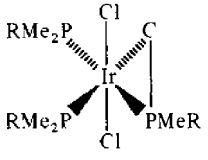


of H_2 and HI is eliminated, which might suggest that a pathway which does not involve prior generation of an iridium(I) species is plausible.[301] Duff and Shaw[302] have reported on the *o*-metallation of six-coordinate iridium(III) dimethylnaphthylphosphine complexes, for which a 1,2-hydrometallation of coordinated ligand followed by H_2 elimination was postulated to account for *o*-metallation in a coordinatively saturated complex. The 8-methylquinoline derivative mqp (**131**) reacts with $[Ir(Cl)(cot)_2]_2$ and [$^2H_5$]-pyridine in hexane to produce $[Ir(H)(Cl)(mqp\text{-}H^3)(NC_5D_5)_2]$ (**132**), one of three possible isomers being illustrated.[303] Analogous complexes have been obtained employing R_2PCH_2Ph (R = Bu^t, C_6H_{11}).[304] An oxidative addition–reductive elimination sequence was favoured for the *o*-metallation of the coordinatively unsaturated methyl iridium(III) complexes $[Ir(Cl)(X)(PPh_3)_2(Me)]$ (X = Cl, Br) to yield $[Ir(Cl)(X)\{PPh_2(C_6H_4)\}(PPh_3)]$.[305]

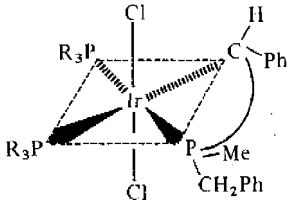


(129)

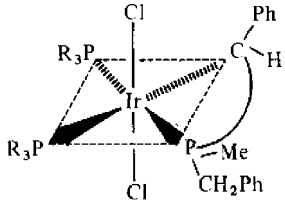
(130)



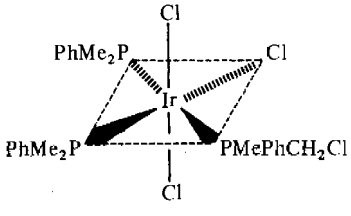
(131)



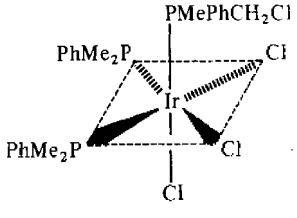
(132)



The treatment of *mer*-$[Ir(Cl)_3(PMe_2R)_3]$ (R = Ph, Me) with strong bases (*e.g.* $LiNPr^i_2$, LiBu^n or $Li(CH_2)_5Li$) affords the three-membered ring metallacycles $[Ir(Cl)_2(CH_2PMeR)(PMe_2R)_2]$ (**133**). The crystal structural data of complex (**133**) (R = Ph) prompted Al-Jibori *et al.*[306] to suggest that the base removes a proton from a methyl group of coordinated PMe_2Ph to yield a carbanion, which subsequently attacks the metal with removal of the labile Cl ligand *trans* to PMe_2Ph. The geometrical isomers (**134a**) and (**134b**), together with their corresponding enantiomers, were thought to be produced upon reaction of *mer*-$[Ir(Cl)\{PMe(CH_2Ph)_2\}_3]$ and $LiNPr^i_2$.[306] On exposure to excess dry HCl, complex (**133**) is rapidly and quantitatively converted to *mer*-$[Ir(Cl)_3(PMe_2R)_3]$. When treated with Cl_2, complex (**133**) (R = Ph) undergoes ring opening to give *mer*-$[Ir(Cl)_3(PMe_2Ph)_2(PMePhCH_2Cl)]$ (**135**). Complex (**135**) converts to the corresponding *fac* isomer (**136**) on exposure to visible radiation.[306]

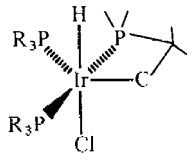


(133)

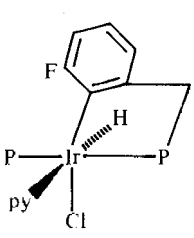


(134a)

(134b)

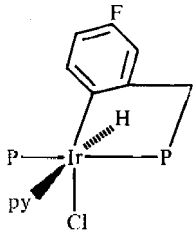


(135)



(136)

Four- and five-membered ring metallacycles (*e.g.* **137**) have been synthesized *via* reaction of tertiary aliphatic phosphines (*e.g.* $PBu^t_2Pr^n$, $PBu^t_2Bu^n$, PBu^t_3, PPr^i_3) with $[Ir(Cl)(cot)_2]_2$ in the presence of γ-picoline or MeCN. The steric effects of the phosphines and the coligand were observed to determine the composition and the stereochemistry of the products.[307] The reaction of the alkenic phosphine P(allyl)R_2 (R = Bu^t, C_6H_{11}) with $[Ir(Cl)(cot)_2]_2$ in the presence of γ-picoline produces the metallated complexes $[Ir(H)(Cl)(CH{=}CHCH_2PR_2)(R_2PCHCH{=}CH_2)(NC_6H_7)]$. For the complex in which R = Bu^t and γ-picoline was absent, the five-coordinate complex $[Ir(H)(Cl)(CH{=}CHCH_2PR_2)(R_2PCHCH{=}CH_2)]$ was obtained. The product stereochemistries



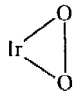
were inferrred from ^1H and ^{31}P NMR and IR spectral data.[308] Reaction between $[Ir(Cl)(cot)_2]_2$ and *m*-$FC_6H_4CH_2P(C_6H_{11})_2$ affords two isomers in an 8:1 molar ratio; NMR (^{31}P and ^{19}F) spectroscopic data have been interpreted in terms of structures (**138a**) and (**138b**), and a nucleophilic mechanism.[304]

(137)

(138a)

(138b)

The tertiary phosphine $PBu^t_2\{C_6H_3(OMe)_2\text{-}2,6\}$ is known to react with iridium(III) chloride in propan-2-ol to yield the five-coordinate hydride complex $[Ir(H)\{OC_6H_3(OMe\text{-}3)(PBu^t_2\text{-}2)\}_2]$ (**139**), which converts, in air, to the paramagnetic iridium(II) species $[Ir\{OC_6H_3(OMe\text{-}3)(PBu^t_2\text{-}2)\}_2]$, which reversibly adds O_2 and reacts with NO. The dioxygen adduct $[Ir(O_2)\{OC_6H_3(OMe\text{-}3)(PBu^t_2\text{-}2)\}_2]$ slowly converts to the coordinatively unsaturated C-cyclometallated iridium(III) complex $[Ir\{CH_2CMe_2PBu^tC_6H_3(OMe\text{-}6)O\}\{OC_6H_3(OMe\text{-}3)PBu^t_2\text{-}2)\}]$. Complex (**139**) also reversibly adds pyridine and CO.[309]



49.6.5 Oxygen Ligands

49.6.5.1 Hydroxy ligands

$[Ir(OH)_3]$ precipitates as a result of the reaction between $K_3[IrCl_6]$ and KOH under a CO_2 atmosphere. The product is usually colloidal, and ranges in colour from yellow-green to blue-black. Iridium(III) hydroxo species (including $[Ir(OH)_6]^{3-}$ and $[Ir(OH)_5(H_2O)]^{2-}$ are thought to be present in alkaline solutions of Ir_2O_3.[310]

49.6.5.2 Dioxygen ligands

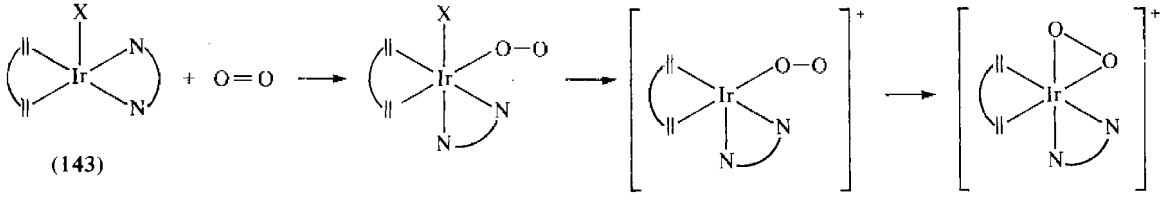
Molecular oxygen adducts of transition metal complexes are of interest and importance to catalytic processes and commercial oxidation processes, as well as being intermediates in oxidation reactions. Vaska[311] has reviewed the nature of dioxygen bound to transition metal complexes. All known iridium dioxygen complexes possess the 'peroxo' structure (**140**). Experimental data reveal that the formation of covalent Ir—(O_2) bonds on dioxygen addition to IrL_x is accompanied by extensive redistribution of electrons, and the electron transfer is from the iridium to dioxygen. SCF–X_α–SW calculations on $[Ir(O_2)(Ph_3)_4]^+$ and $[Ir(Ph_3)_4]^{3+}$ indicate 'peroxo'–metal bonding.[312]

(140)

Relative rates of O_2 uptake by *trans*-$[Ir(X)(CO)(PPh_2R)_2]$ (X = F, Cl, Br, I; R = Ph, Et, Me) in CH_2Cl_2 follow the order R = Me > Et > Ph and X = I > Br > Cl > F.[313] If dioxygen addition is considered as an acid–base reaction (metal complex = Lewis base), then factors which increase the electron density at the metal centre should (in the absence of unfavourable steric effects) enhance the addition of O_2 (reaction 90). The results suggest that as the basicity of the phosphine ligand increases and the electronegatively of X decreases, the rate of O_2 addition also increases.[313] The X-ray crystal structure of $[Ir(Cl)(CO)(O_2)(PPh_2Et)_2]$ reveals a side-on coordination with the O_2 centre, CO and Cl moieties defining the equatorial plane, or a distorted octahedral iridium(III) system with O_2^{2-}.[314]

$$ML_x + O_2 \rightleftharpoons O_2 \cdot ML_x \quad (90)$$

The structures of $[Ir(X)(CO)(O_2)(PPh_3)_2]$ (X = Cl, I[315–317]) have similar inner coordination spheres, the only significant difference being the considerably longer O—O internuclear distance in the iodo complex (1.51 Å for X = I *vs.* 1.30 Å for X = Cl). Based on internuclear distance criteria, the chloro complex could be viewed as a 'superoxo' complex with iridium in the II oxidation state, and the iodo complex as a 'peroxo' complex with iridium in the III oxidation state. However, both complexes are diamagnetic, and other similarities between the two complexes leads to an iridium(III) 'peroxo' assignment. CNDO-type molecular orbital calculations on these complexes have shown that the iridium ion has a formal charge of +3, and that the O_2 molecule coordinates to the metal ion through oxidative addition.[318]



Dioxygen addition to $[Ir(A)(CO)(PPh_3)_2]$ (A = F, OH, NCO, NCS, O_2CH, O_2CCF_3, SH, C, CPh and *p*-toluenesulfinate) gives the iridium(III) complexes $[Ir(A)(CO)(O_2)(PPh_3)_2]$.[319] The readily reversible O_2 uptake by $[Ir(SCN)(CO)(PPh_3)_2]$ probably accounts for a previous report[317] that $[Ir(SCN)(CO)(O_2)(PPh_3)_2]$ does not form.

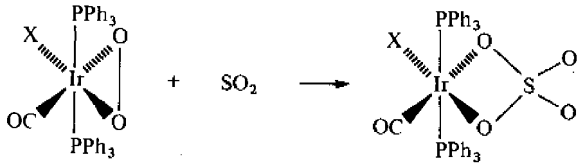
X-Ray crystal structure determinations of $[Ir(dppe)_2(O_2)]^+$,[320,321] and $[Ir(O_2)(PPhMe_2)_4]^+$[322] have implied that the O—O bond length is essentially independent of the metal and the basicity of the phosphine ligand. Analogous rhodium complexes exhibit similar structures.[322] A comparison[320] of the crystallographic data for $[Ir(dppe)_2(O_2)]^+$ and $[Ir(X)(CO)(O_2)(PPh_3)_2]$ led to the following conclusions: (i) a short O—O bond length (1.30–1.42 Å) corresponds to reversible O_2 uptake, while a long O—O bond (1.50–1.625 Å) corresponds to irreversible O_2 uptake; and (ii) increasing the donor strength of the phosphine ligand favours longer O—O bond lengths. Conclusion (ii) was determined to be invalid based on a comparison of $[Ir(dppe)_2(O_2)]^+$[320,321] and $[Ir(O_2)(PPhMe_2)_4]^+$ (see above).[322] Conclusion (i) is invalidated inasmuch as the O—O bond length (1.46 Å) in $[Ir(Cl)(CO)(O_2)(PPh_2Et)_2]$ would seem to indicate irreversible O_2 uptake, though reversible O_2 uptake was observed.[323] Furthermore, a redetermination[321] of the structure of $[Ir(dppe)_2(O_2)]^+$ indicates that the unusually long O—O bond distance reported previously is actually an artifact caused by crystal decomposition during irradiation.[320]

The preparation of $[Ir(X)(CO)(ER_3)_2(O_2)]$ (ER_3 = $AsMePh_2$, $AsEtPh_2$; X = Cl, Br),[291] and crystal structures of $[Ir(O_2)(PMe_2Ph)_4]^+$, $[Ir(PMe_2Ph)_4]^+$[324] and the PF_6^- and ClO_4^- salts of $[Ir(dppm)_2(O_2)]^+$[325] have been reported. In the latter complex, identical O—O bond lengths (within experimental error) are observed, as well as similar geometries around iridium. Only different packings were observed for the PF_6^- and ClO_4^- salts of this complex.

The conclusions to be drawn from dioxygen uptake reactions and crystal structure investigations of the resultant dioxygen complexes include: (i) the O—O bond length is constant, regardless of the metal or the other ligands present in the inner coordination sphere; (ii) the short and long O—O bond lengths observed are most likely artifacts caused by disorder and crystal decomposition; (iii) there is no correlation between O—O bond length and reversibility of O_2 uptake; and (iv) O_2 uptake can be viewed as an oxidation process, even if it is reversible.

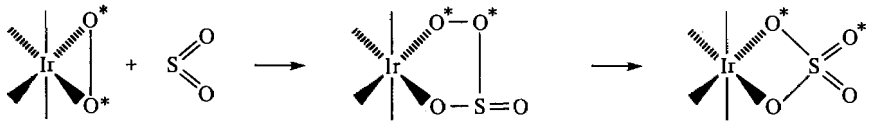
Kinetic measurements have indicated that O_2 reacts more rapidly with the five-coordinate complex [Ir(I)(phen)(cod)] (**141**) than with the four-coordinate complex $[Ir(phen)(cod)]^+$ (**142**) to yield $[Ir(O_2)(phen)(cod)]^+$. The analysis was consistent with complex (**141**) being more susceptible to oxygenation than complex (**142**).[326] The reaction of complex (**142**; Cl^- salt) with O_2 in methanol was investigated kinetically in the presence and absence of SCN^- and I^-. On addition of NaX (X = SCN, I), the five-coordinate complex [Ir(X)(phen)(cod)] (**143**) forms. An 'end-on' oxidative addition of O_2 to complex (**142**) has been proposed (see Scheme 14).[327]

(143)



Scheme 14

An investigation of the thermal deoxygenation of solid $[Ir(Cl)(CO)(O_2)(PPh_3)_2]$ in nitrogen has revealed two rate-controlling steps, depending on the temperature. The steps are associated with the nucleation and growth of product, and a phase boundary mechanism.[328]



Complexes of the type $[Ir(CO)(PPh_3)_2(Ar)]$ undergo reaction with dioxygen to yield [Ir-

$(CO)(O_2(PPh_3)_2(Ar)]$ wherein Ar = Ph, *m*-MeC_6H_4 and *p*-MeC_6H_4. However, complexes with *o*-substituted Ar ligands do not react with O_2, reportedly due to steric shielding of the metal centre.[329]

The stoichiometric reaction of SO_2 with coordinated O_2 to form coordinated sulfate appears to be general for dioxygen complexes. ^{18}O isotope substitution and IR spectroscopy have been employed to study the reaction betwen $[Ir(X)(CO)(O_2)(PPh_3)_2]$ (X = Cl, Br, I) and SO_2 (reaction 91). IR spectral results are consistent with a bidentate sulfate ligand. The mechanism proposed for sulfate formation involves a peroxosulfate intermediate, that is insertion of SO_2 into one of the Ir—O bonds and bond formation between S and the leaving O, with subsequent rearrangement of the peroxo–sulfite intermediate thus generated (see Scheme 15).[330,331]

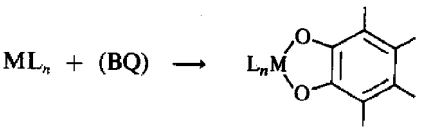
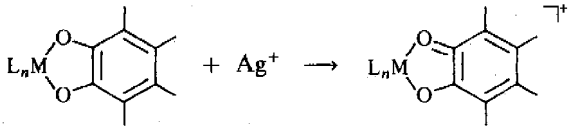
Scheme 15

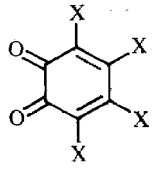


49.6.5.3 β-Diketonate, catecholate and semiquinone ligands

The syntheses and stereochemical assignments of $[Ir(H)_2(L)(PPh_3)_2]$ (**144**) (L = acac, tfac, hfac) and $[Ir(H)(Cl)(acac)(PPh_3)_2]$ have been reported.[332,333] The dihydride complex (**144**) is prepared *via* reaction of $[Ir(H)_3(PPh_3)_2]$ with the appropriate β-diketone. IR spectral data for this complex are consistent with the β-diketonate ligands coordinated to Ir as bidentate ligands, and, combined with ^1H NMR data, are consistent with structure (**144**). Both complexes have *trans* PPh_3 ligands. Reaction of the iridium(I) complex $[Ir(acac)(C_2H_4)_2]$ with alkenic phosphines in the presence of γ-picoline and acetonitrile produces the six-coordinate metallated iridium(III) complex $[Ir(H)(L)(CH_2CH{=}CH)(R_2P)]$ (R_2P = Bu^t_2P, $(C_6H_{11})_2P$; L = γ-picoline, MeCN). The ligand L is displaced by CO, CNR and $P(OMe)_3$.[334] Reaction between allene and the iridium(I) complex $[Ir(acac)(\eta\text{-}C_8H_{14})_2]$ at 195 K, followed by treatment with pyridine in heptane at 243 K, yields the iridium(III) complex $[Ir(acac)(C_3H_4)_3(py)]$ (**145**) with evolution of allene. The crystal structure of complex (**145**) reveals a distorted octahedral coordination geometry in which the acac ligand and an allene dimer serve as chelating ligands with a pseudo-*fac* configuration relative to each other. The coordination about Ir is completed by one of the double bonds of the allene molecule and by pyridine.[335]



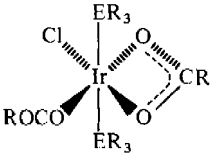
(144)



Transition metal complexes containing catecholate and semiquinone ligands have been reviewed by Pierpont and Buchanan.[336] The syntheses of catecholate adducts of platinum group metals by oxidative addition of benzoquinone (BQ) have been reported (reaction 92).[337] The coordinated catechol can then be oxidized to the semiquinone with silver ion (reaction 93). In reactions (92) and (93), L_nM = $[Ir(Cl)(CO)(PPh_3)_2]$ and the benzoquinones (BQ) are shown in (**146**). The oxidative addition of phenanthrenequinone to $[Ir(Cl)(CO)(PPh_3)_2]$ has also been cited.[338]

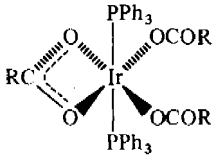
(92)

(93)



(146) X = Cl, Br

On coordination to metals, the quinone–CO stretching frequency shifts at least 200–300 cm^{-1}, which infers a formal reduction to catechol with oxidation of the metal. The possibility of an intermediate radical anion coordination mode for *o*-benzoquinones has been demonstrated[339] by the reversible chemical and electrochemical oxidation of reduced quinone complexes. ESR spectra of $[Ir(Cl)(1,2\text{-}O_2C_6Cl_4)(CO)(PR_3)_2]$ ($PR_3 = PPh_3$, $PMePh_2$) indicate that the unpaired electron is localized in the semiquinone ligand. The quinone coordination mode is strongly affected by the oxidizing ability of the quinone and the nature of the complex itself.



49.6.5.4 Carboxylate, chelating carboxylate CO_3^{2-}, CO_4^{2-}, RCO_2^- and oxalate ligands

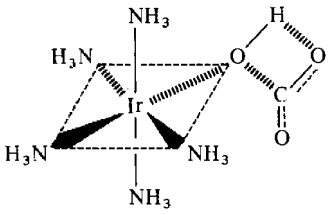
Iridium(I) complexes of the type *trans*-$[Ir(X)(CO)(PR_3)_2]$ ($PR_3 = PEt_3$, PPh_3, $PPhMe_2$; X = Cl, Br, I) undergo rapid oxidative addition with carboxylic acids RCO_2H (R = H, Me, CF_3, Ph, 1-naphthyl) to yield the iridium(III) complexes $[Ir(H)(X)(O_2CR)(CO)(PR_3)_2]$ corresponding to both formal *cis* and *trans* addition of RCO_2H to the Ir^I complex. In solution, the carboxylato complexes undergo rapid anion exchange such that at equilibrium two additional hydride complexes, $[Ir(H)(X)_2(CO)(PR_3)_2]$ and $[Ir(H)(O_2CR)(CO)(PR_3)_2]$, are present. For all the complexes, the phosphine ligands are mutually *trans*, the H and CO ligands are mutually *cis*, and O_2CR is unidentate.[340] The ease of protonation of the Ir^I complexes by RCO_2H to yield the Ir^{III} complexes has been observed[341] to be dependent on the nature of PR_3, yielding an order of ligand basicity $PMe_3 > PMe_2Ph > PMePh_2 > PPh_3$.

$[Ir(X)(ER_3)_2(L)]$ (L = N_2, CO) is known to react with peroxycarboxylic acids, RCO_3H, affording the carboxylato complexes $[Ir(X)(O_2CR)_2(ER_3)_2]$ (**147**; X = Cl, R = 3-ClC_6H_4, $ER_3 = PPh_3$, PPh_2Me, $AsPh_3$; X = Cl, R = Ph, $ER_3 = PPh_3$, $AsPh_3$; X = Cl, R = Me, $ER_3 = PPh_3$; X = Br, R = 3-ClC_6H_4, $ER_3 = PPh_3$) and CO_2. These complexes possess one unidentate carboxylate ligand and one bidentate ligand yielding a coordination number of six. The stereochemistry is revealed in (**147**). In contrast, reaction between $[Ir(I)(CO)(PPh_3)_2]$ and RCO_3H has yielded $[Ir(O_2CR)_3(PPh_3)_2]$ (**148**; R = Ph, 3-ClC_6H_4), and a mixture of $[Ir(O_2CPh)_3(CO)(PPh_3)_2]$ and $[Ir(I)_3(CO)(PPh_3)_2]$ with RCO_3H = dibenzyl peroxide. A tentative stereochemical assignment for complex (**148**) has been shown.[152]

(147)

(148)

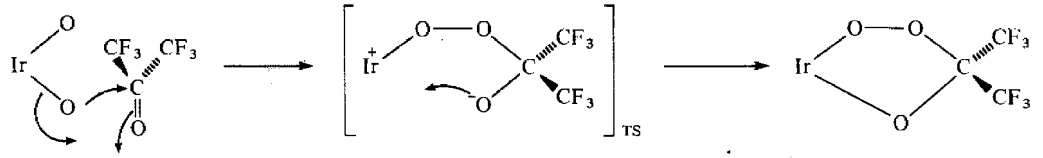
The formation and decarboxylation kinetics of $[Ir(OCO_2)(NH_3)_5]^+$ have been studied as a function of pressure, based on activation volumes for CO_2 uptake ($\Delta V^{\ddagger} = -4.0\,cm^3\,mol^{-1}$) and decarboxylation ($\Delta V^{\ddagger} = +2.5\,cm^3\,mol^{-1}$), and partial molar volume measurements. The suggested mechanism for the formation and decarboxylation is given in Scheme 16. Bond formation during CO_2 uptake and bond breaking during decarboxylation were believed to be *ca.* 50% completed in the transition state (**149**) of these processes.[342]



The peroxocarbonato iridium complexes $[Ir(OCO_3)(CO)(PPh_3)_2(R)]$ (R = Me, Ph) have been synthesized from $[Ir(CO)(O_2)(PPh_3)_2(R)]$ and liquid CO_2, probably *via* external attack by CO_2 on

$$[Ir(OH_2)(NH_3)_5]^{3+} \overset{K_A}{\rightleftharpoons} [Ir(OH)(NH_3)_5]^{2+} + H^+$$

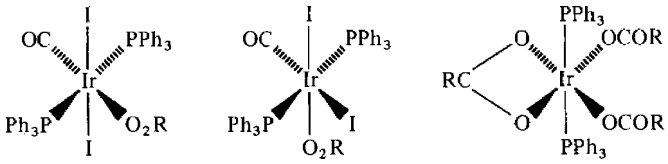
$$[Ir(OH)(NH_3)_5]^{2+} + CO_2 \overset{k_1}{\underset{k_2}{\rightleftharpoons}} [Ir(OCO_2H)(NH_3)_5]^{2+}$$



$$[Ir(OCO_2H)(NH_3)_5]^{2+} \overset{K_B}{\rightleftharpoons} [Ir(OCO_2)(NH_3)_5]^{+} + H^+$$

Scheme 16

(149)

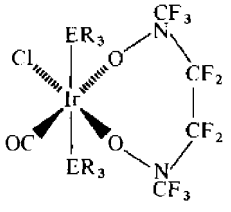


coordinated O_2.[343] The reaction mechanism was thought to be similar to that proposed for the reaction of hexafluoroacetone with $[Ir(Cl)(CO)(O_2)(PPh_3)_2]$.[344] The mechanism of the addition of hexafluoroacetone ($CF_3C(O)CF_3$) to $[Ir(X)(CO)(O_2)(PPh_3)_2]$ presumably involves direct nucleophilic attack of $CF_3C(O)(CF_3$ on the coordinated O_2 ligand to give the iridium(III) ozonide product (**151**) *via* an ionic transition state (**150**; see Scheme 17).[344]

(150) (151)

Scheme 17

The bis(alkylperoxy) iridium(III) complexes $[Ir(X)(O_2Bu^t)_2(CO)(ER_3)_2]$ (**152**; X = Cl, ER_3 = PPh_3, $AsPh_3$, PPh_2Me; X = Br, ER_3 = PPh_3, $AsPh_3$) and $[Ir(X)(O_2CPhMe_2)_2(CO)(ER_3)_2]$ (**153**; X = Cl, ER_3 = PPh_3, $AsPh_3$; X = Br, ER_3 = PPh_3) have been prepared *via* reaction of Bu^tO_2H or $PhMeCO_2H$ with the appropriate *trans*-$[Ir(X)(CO)(ER_3)_2]$ (X = Cl, Br) complex. The analogous reaction with *trans*-$[Ir(I)(CO)(PPh_3)_2]$ affords $[Ir(I)_2(O_2CR)(CO)(PPh_3)_2]$ (**154**) (R = Bu^t, $PhMe_2$). The diiodide complex reveals IR and ^1H NMR spectra interpreted in terms of the two PPh_3 ligands being mutually *trans*, and possessing either structure (**154a**) or (**154b**).[345] Spectroscopic data on complexes (**152**) and (**153**) suggest the structure in (**155**).[152] Treatment of (**152**) or (**153**) with organic acids $R'CO_2H$ results in the substitution of only one of the alkylperoxy ligands, with formation of $[Ir(X)(OCOR')(O_2R)(CO)(PPh_3)_2]$ (X = Cl, R = Bu^t, R′ = CF_3, CCl_3, $CHCl_2$, CO_2H, *cis*-CH=CHCO$_2$H, Ph, H; X = Cl, R = CMe_2Ph, R′ = CF_3; X = Br, R = Bu^t, R′ = CF_3, H).[346] The related complexes $[Ir(X)(Y)(O_2Bu^t)(CO)(PPh_3)_2]$ (X = Y = Cl, Br; X = Cl, Y = Br, NO_3) have been prepared *via* reaction of $[Ir(X)(O_2Bu^t)_2(CO)(PPh_3)_2]$ (X = Cl, Br) with HCl, HBr or HNO_3 at 273 K.[346]



(154a) (154b) (155)

Several iridium(III) oxalato (ox) complexes have been reported, including $K_3[Ir(ox)_3]_n \cdot H_2O$, $KH_2[Ir(ox)_3] \cdot 4H_2O$, $K_3[Ir(Cl)_3(NO_2)(ox)] \cdot 2H_2O$, $M_3[Ir(Cl)_4(ox)]$ (M = Na, Rb, Cs, NH_4), $M_3[Ir(Cl)_2(ox)_2] \cdot nH_2O$, $M_3[Ir(Cl)_2(NO_2)_2(ox)] \cdot nH_2O$ (M = Li, Na, K, Rb, Cs, NH_4) and $H_3[Ir(ox)_3] \cdot n$-

H_2O.[310] The synthesis of $K_3[Ir(ox)_3]$ has been reported by several groups.[347] More recently, Flynn and Demas[348] have reported a simple high-yield preparation of this complex with a novel solvent extraction step. Various methods, including IR, Raman and ^1H NMR spectroscopy, thermogravimetry and pH invariance results, have been employed to determine the role played by water in the structures of crystalline transition metal oxalato complexes. For $K_3[Ir(ox)_3]\cdot 4.5H_2O$, a tris-chelated structure with one water molecule hydrogen bonded in a unique fashion has been postulated.[347c] The rates of racemization of $[Ir(ox)_3]^{3-}$ have been measured,[349] as well as the circular dichroism.[350] While $K_3[Ir(Cl)_2(ox)_2]$ exists as *cis* and *trans* isomers (*cis*-$[Ir(Cl)_2(ox)_2]\cdot 3H_2O$ and *trans*-$[Ir(Cl)_2(ox)_2]\cdot 4H_2O$) $K_3[Ir(ox)_3]\cdot 4.5H_2O$ has been resolved into optical enantiomers which do not racemize in hot water.[351]

Addition of the bis(trifluoromethyl)nitroxy radical $[(CF_3)_2NO\cdot]$ to $[Ir(Cl)(CO)(ER_3)_2]$ yields the complexes $[Ir(Cl)(CO)(ER_3)_2\{ON(CF_3)_2\}]$ ($ER_3 = PPh_3$, PPh_2Me, $AsPh_3$).[155] Several iridium(III) complexes containing the $ON(CF_3)_2$ ligand have been prepared *via* oxidative addition to $[Ir(CO)(PPh_3)_2\{ON(CF_3)_2\}]$.[155] The stable diradical $CF_3N(\dot{O})CF_2N(\dot{O})CF_3$ reacts with *trans*-$[Ir(Cl)(CO)(ER_3)_2]$ ($ER_3 = PPh_3$, PPh_2Me, $AsPh_3$) and *trans*-$[Ir(CO)(PPh_3)_2\{ON(CF_3)_2\}]$ to form the seven-membered metallacyclic iridium(III) complexes $[\overline{Ir\{ON(CF_3)CF_2CF_2N(CF_3)O\}}(Cl)(CO)(ER_3)_2]$ (**156**) and $[\overline{Ir\{ON(CF_3)CF_2CF_2N(CF_3)O\}}\{ON(CF_3)_2\}(CO)(PPh_3)_2]$. IR spectra have been interpreted in terms of structure (**156**) for the former complex; the iradacycle is presumably fluxional.[156]

(156)

49.6.5.5 Nitrito–nitro and nitrate ligands

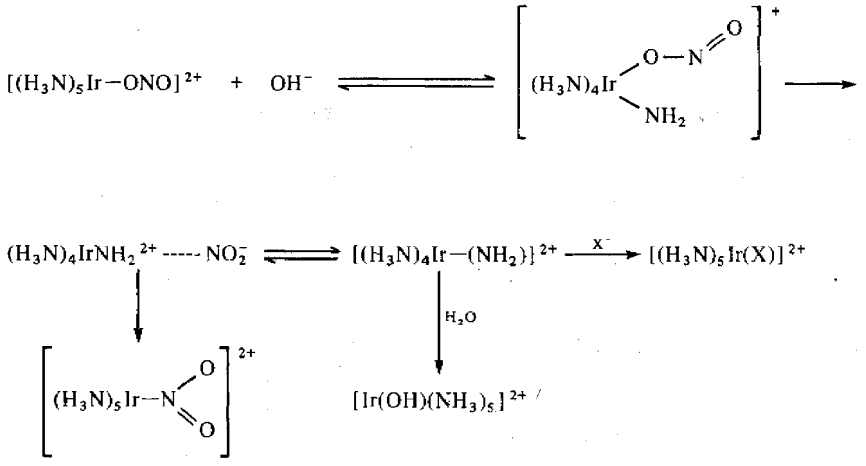
Several iridium(III) complexes containing the nitrito (NO_2) ligand have been prepared *via* reaction of N_2O_4 (or NO_2^-) with an iridium(I) complex, as per reactions (94)–(99).[352] The nitrito ion $[Ir(ONO)(NH_3)_5]^{2+}$ rearranges to the nitro form $[Ir(NO_2)(NH_3)_5]^{2+}$ in aqueous base according to equation (100), for which $k_s = 3.0 \times 10^{-5}\,s^{-1}$ and $k_{OH} = 2.7 \times 10^{-5}\,dm^3\,mol^{-1}\,s^{-1}$. A base-catalyzed pathway was proposed[353] for the Co^{III}, Rh^{III} and Ir^{III} complexes, as depicted in Scheme 18. The temperature and pressure dependencies of the rates of linkage isomerization of $[Ir(ONO)(NH_3)_5]^{2+}$ in aqueous solution indicate $\Delta V^{\ddagger} = -5.9 \pm 0.6\,cm^3\,mol^{-1}$, $\Delta H^{\ddagger} = 95.3 \pm 1.3\,kJ\,mol^{-1}$ and $\Delta S^{\ddagger} = -11 \pm 4\,J\,K^{-1}\,mol^{-1}$.[354] The similarity between these results and those previously obtained for Rh^{III} and Co^{III} analogues[355] are indicative of an intramolecular mechanism.

$$\left.\begin{matrix}[Ir(Cl)(CO)(PPh_3)_2] \\ [Ir(Cl)(NO)(CO)(PPh_3)_2]^+\end{matrix}\right\} + N_2O_4 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (94)$$

$$[Ir(Cl)(CO)(PPh_3)_2] + 3NO_2 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (95)$$

$$[Ir(H)(CO)(PPh_3)_2 + N_2O_4 \longrightarrow [Ir(H)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (96)$$

$$[Ir(Cl)(NO)(CO)(PPh_3)_2]^+ + N_2O_4 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (97)$$



$$[Ir(CO)_3(PPh_3)_2]^+ + N_2O_4 \longrightarrow [Ir(NO_2)(NO_3)_2(CO)(PPh_3)_2] \quad (98)$$

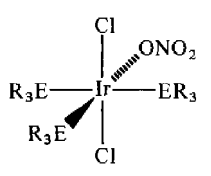
$$[Ir(dppe)_2]^+ + N_2O_4 \longrightarrow [Ir(NO_2)_2(dppe)_2]^+ \quad (99)$$

$$k_{obs} = k_s + k_{OH}[OH^-] \quad (100)$$

$[Ir(NO_3)_3]$ is as yet unknown, though the $[Ir(NO_3)_6]^{3-}$ complex anion is documented. The latter complex is afforded upon dissolution of $[IrCl_3]$ in concentrated HNO_3 at 373 K.[356]

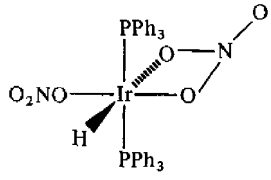
Treatment of $[Ir(H)(CO)(PPh_3)_3]$ in benzene with warm, concentrated HNO_3 yields a yellow crystalline solid formulated as $[Ir(NO_3)_3(PPh_3)_2]$.[357,358] The white crystalline complex $[Ir(Cl)(NO_3)_2$-

Scheme 18



$(CO)(PPh_3)_2]$ results from oxidative addition of NO_3^- to $[Ir(X)(CO)(PPh_3)_2]$. Several reaction pathways have been cited, including (i) reaction of $[Ir(Cl)(CO)(PPh_3)_2]$ with concentrated HNO_3 in THF at 313 K;[359] (ii) reaction between $[Ir(X)(CO)(PPh_3)_2]$ (X = Cl, Br, N_3, NCO, NCS) and $(NH_4)_2[Ce(NO_3)_6]$, $[Cu(NO_3)_2]$ or $[Fe(NO_3)_3]$ in the presence of NO_3^- at ambient temperatures;[360] or (iii) reaction of the dioxygen adduct of $[Ir(Cl)(CO)(PPh_3)_2]$ with NO_2/N_2O_4.[361] The related complex $[Ir(Cl)(NO_3)_2(CO)(AsPh_3)_2]$ was prepared *via* pathway (iii).[361]

The green iridium(III) complex $[Ir(NO_3)_2(NO)(PPh_3)_2]$ is formed by the action of ethanolic HNO_3 on $[Ir(NO)(PPh_3)_3]$ or $[Ir(NO)(CO)(PPh_3)_2]$. A bent Ir—N—O moiety has been proposed on the basis of the low $\nu(NO)$ in the IR spectrum.[358]



Reaction of *mer*-$[Ir(Cl)_3(ER_3)_3]$ (ER_3 = PMe_2Ph, PEt_2Ph, $AsMe_2Ph$) and $AgNO_3$ in acetone/water solutions forms $[Ir(Cl)_2(NO_3)(ER_3)_3]$, with the structure in (**157a**). In a similar fashion, $[Ir(I)_2(NO_3)(PMe_2Ph)_3]$ has been synthesized from *mer*-$[Ir(I)_3(PMe_2Ph)_3]$.[362]

Complexes of the type $[Ir(Cl)(NO_3)(X)(PPh_3)_2]$ (X = Cl, Br, I, N_3, NCO, NCS) are prepared *via* electrophilic attack by O_2 on the bent NO ligand in $[Ir(Cl)(X)(NO)(CO)(PPh_3)_2]$ in benzene solution at ambient temperature. The rates of oxygenation decrease with X as I > Br > Cl > NCS > NCO > N_3,[363] which approximates the decreasing electron release by X.

When $[Ir(NO_3)_2(NCO)(CO)(PPh_3)_2]$ is allowed to react in $EtOH/CH_2Cl_2$ solutions exposed to air, yellow crystals of $[Ir(H)(NO_3)_2(PPh_3)_2]$ (**157b**) result. An X-ray crystal structural analysis of complex (**157b**) reveals the PPh_3 ligands as mutually *trans*, with one unidentate and one bidentate nitrate ligand (see structure **157b**). Complex (**157b**) reacts with CO to yield $[Ir(H)(NO_3)_2(CO)(PPh_3)_2]$, in which both NO_3^- ligands are unidentate.[364] The related iridium(III) cation $[Ir(NO_3)_2(CO)(PMePh_2)_3]^+$ (isolated as the BF_4^- or ClO_4^- salt) has been synthesized by the reaction of NO_2/N_2O_4 with $[Ir(CO)(O_2)(PMePh_2)_3]^+$.[365] Other iridium(III) nitrato complexes which have been prepared are outlined in reactions (101)–(106).[366]

(157a)

(157b)

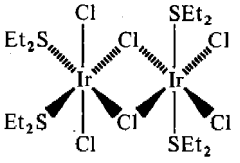
$$[Ir(Cl)(CO)(PPh_3)_2] + N_2O_4 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (101)$$

$$[Ir(Cl)(NO)(CO)(PPh_3)_2]^+ + N_2O_4 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (102)$$

$$[Ir(Cl)(CO)(PPh_3)_2] + 3NO_2 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (103)$$

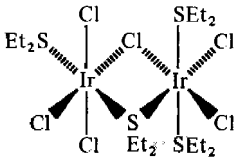
$$[Ir(H)(CO)(PPh_3)_3] + N_2O_4 \longrightarrow [Ir(H)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (104)$$

$$[Ir(Cl)(NO)(CO)(PPh_3)_2]^+ + N_2O_4 \longrightarrow [Ir(Cl)(NO_2)(NO_3)(CO)(PPh_3)_2] \quad (105)$$



$$[Ir(CO)_3(PPh_3)_2]^+ + N_2O_4 \longrightarrow [Ir(NO_2)(NO_3)_2(CO)(PPh_3)_2] \quad (106)$$

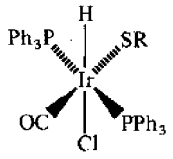
49.6.6 Sulfur Ligands



49.6.6.1 Sulfide ligands

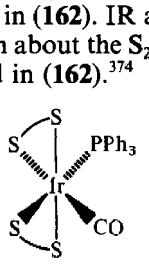
Reaction between H_2S and *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ in CH_2Cl_2 leads to the formation of one of the first iridium(III) complexes containing an SH ligand, namely $[Ir(H)(Cl)(SH)(CO)(PPh_3)_2]$. This complex possesses a pseudooctahedral coordination geometry with *trans* PPh_3 ligands and *trans* H—Ir—Cl and HS—Ir—CO arrangements. The oxidative addition of H_2S to Vaska's complex is *cis* addition.[367]

$[Ir(Cl)_2(SEt_2)_4][Ir(Cl)_4(SEt_2)_2]$ and *fac*-$[Ir(Cl)_3(SEt_2)_3]$ can be prepared from an iridium(III) halide and a monosulfide. The anion $[Ir(Cl)_4(SEt_2)_2]^-$ can be oxidized to *trans*-$[Ir(Cl)_4(SEt_2)_2]$.[368] Irradiation of *fac*-$[Ir(Cl)_3(SEt_2)_3]$ gives $[Ir_2(Cl)_6(SEt_2)_4]$, which exists in two isomeric forms.[160] Also, the complexes $[Ir(Cl)_3(SEt_2)_{3-n}(py)_n]$ ($n = 1, 2$), $[Ir(Cl)_3(SMe_2)_2]$ and $[Ir_2(Cl)_5(SR_2)_4]$ (R = Me, Et) have been reported[160] though not well characterized. Photolysis (*d–d* excitation) of *mer*-$[Ir(Cl)_3(SEt_2)_3]$ in benzene or toluene solution yields a mixture of $[Ir_2(Cl)_4(\mu\text{-}Cl)_2(SEt_2)_4]$ (**158**) and $[Ir_2(Cl)_5(\mu\text{-}Cl)(\mu\text{-}SEt_2)(SEt_2)_3]$ (**159**).[369] The unusual bridging SEt_2 group in (**159**) was identified by the absence of rapid inversion at the tetrahedrally coordinated S atom in the ^1H NMR spectrum. The crystal structures of complexes (**158**)[370] and (**159**)[371] have been determined.

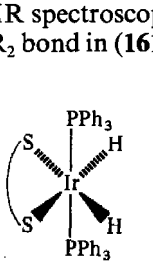


(158)

(159)



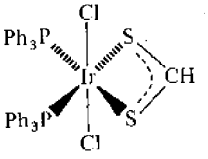
Hydrogen sulfide, 4-methylbenzenethiol and 4-methylbenzene-1,2-dithiol add to *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ to yield the iridium(III) complex $[Ir(H)(Cl)(CO)(PPh_3)_2(SR)]$, wherein SR is SH, SC_6H_4Me or SC_6H_3MeSH, respectively. Spectroscopic data are consistent with the structure (**160**) with CO and SR groups *trans* to each other.[372]



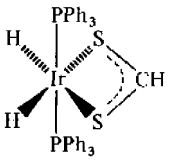
(160)

49.6.6.2 Dithiocarbamate and CS_2-based ligands

The X-ray crystal and molecular structures of the iridium(III) dithiocarbamate complex $[Ir(S_2CNC_4H_8)_3](C_6H_5)_{0.5}$ shows a trigonally-distorted octahedral metal–ligand coordination sphere. A comparison with analogous Fe^{III} and Cr^{III} complexes indicates that the iridium complex is closest to octahedral in its environment.[373] The dithiocarbamato and *O*-dithiocarbamato derivatives $[Ir(H)_2(S—S)(PPh_3)_2]$ (S—S = $R_2NCS_2^-$, $ROCS_2^-$; R = Me, Et) were prepared by treating the appropriate chloro or carboxylato complex with sodium salts of the S—S ligands. $[Ir(S_2CNMe_2)_2(CO)(PPh_3)_2]^+$ formed upon reaction of Vaska's complex with tetramethylthiuram disulfide; the assigned stereochemistry is that illustrated in (**161**).The stereochemistry assigned to $[Ir(H)_2(S—S)(PPh_3)_2]$ is depicted in (**162**). IR and NMR spectroscopy have confirmed the presence of a substantial barrier to rotation about the $S_2C—NR_2$ bond in (**161**), but nothing comparable was observed for the $S_2C—OR$ bond in (**162**).[374]

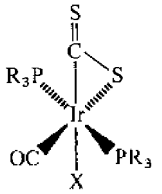


(161)

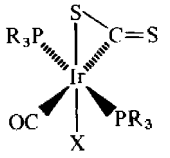


(162)

The iridium(III) hydrides *trans*-$[Ir(H)(Cl)_2(PPh_3)_3]$ and *mer*-$[Ir(H)_3(PPh_3)_3]$ react with CS_2 to yield the dithioformato complexes $[Ir(Cl)_2(S_2CH)(PPh_3)_2]$ (**163**) and $[Ir(H)_2(S_2CH)(PPh_3)_2]$ (**164**), respectively. Both complexes exhibit IR absorption at *ca.* 1215–1235 and 900–930 cm^{-1}, attributable to $\nu(S_2CH)$. Proton NMR spectra established the stereochemistry of these complexes, as shown in (**163**) and (**164**).[375,376] The equivalent coupling of the dithioformate proton to two ^1H nuclei (as in **164**) clearly favours the symmetrical structure for the dithioformate ligands, as opposed to any asymmetric alternatives.



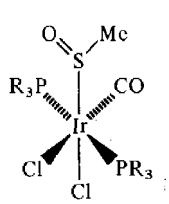
(163)



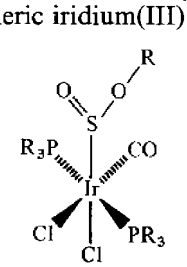
(164)

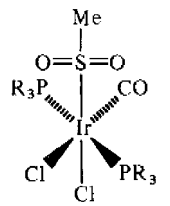
Insertion of CS_2 into $[Ir(H)(CO)(PPh_3)_3]$ has been monitored by NMR spectroscopy. A definitive assignment of the product, either $[Ir(S_2CH)(CO)(PPh_3)_2]$ or $[Ir(CS_2H)(CO)(PPh_3)_2]$, could not be made owing to the lack of documentation on the SH proton chemical shift. However, the observed signal at $\delta = 5.0$ p.p.m. may be indicative of $[Ir(CS_2H)(CO)(PPh_3)_2]$.[377]

Carbon disulfide reacts with $[Ir(H)(CO)_2(PPh_3)_2]$ to yield an iridium(III) species containing two CS_2 molecules bonded to each Ir atom. The proposed formulations for this species included $[Ir(SSCH)(CO)(PPh_3)_2(\pi\text{-}CS_2)]$ and $[Ir(CSSH)(CO)(PPh_3)_2(\pi\text{-}CS_2)]$. Here again, no definitive structural assignment was put forward as no NMR signal was observed nor an analysis reported.[377] However, the dithioformato ligand is most likely unidentate in either case. It has been proposed[378] that the complex obtained by the addition of CS_2 to $[Ir(I)(CO)(PPh_3)_2]$ has the orientation isomers of configuration (**165**) and (**166**). However, Deeming and Shaw[379] have suggested that $[Ir(Cl)(CO)(PMe_2Ph)_2(CS_2)]$ exists as only one of these isomers in solution, as well as in the solid state.

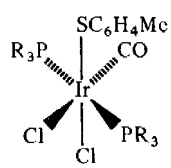


(165)



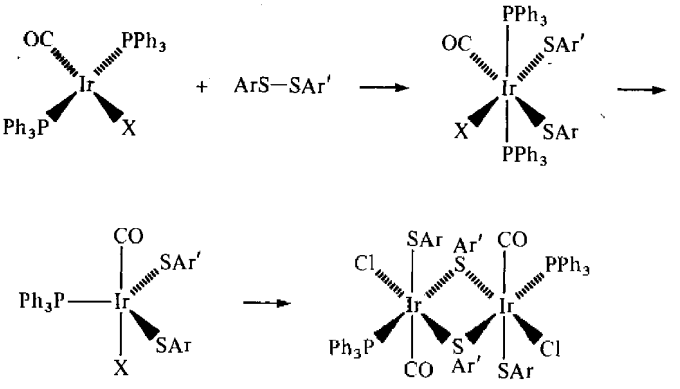


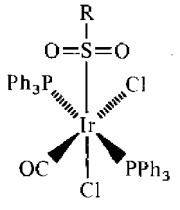
(166)



49.6.6.3 Other S-containing ligands

The first sulfenato and alkylsulfenato complexes of iridium(III) were prepared by George and Watkins.[380] The sulfenato complexes $[Ir(Cl)_2(MeSO)(CO)(PR_3)_2]$ (**167**; $PR_3 = PPh_3$, PPh_2Me) were prepared from $[Ir(Cl)(CO)(PR_3)_2]$ and MeS(O)Cl; the alkylsulfenato complexes $[Ir(Cl)_2(ROSO)(CO)(PR_3)_2]$ (**168**; $PR_3 = PPh_3$, R = Me, Et; $PR_3 = PMe_2Ph$, R = Me) were obtained *via* reaction of $[Ir(Cl)(CO)(PR_3)_2]$ and the appropriate ROS(O)Cl. These complexes do not rearrange to yield sulfinato complexes. The preparation of the sulfinato complex $[Ir(Cl)_2(MeSO_2)(CO)(PPh_2Me)_2]$ (**169**) and the thio complex $[Ir(Cl)_2(SC_6H_4Me\text{-}p)(CO)(PR_3)_2]$ (**170**; $PR_3 = PPh_3$, PPh_2Me) have also been reported.[380] Their stereochemistries were assigned on the basis of ^1H NMR and IR spectral data. Oxidative-elimination products of the type $[Ir(X)(SC_6H_4Y)\{SC_6H_3(NO_2)_2\}(CO)(PPh_3)]_2$ (**171**) were prepared from *trans*-$[Ir(X)(CO)(PPh_3)_2]$ (X = Cl, Br, I) and a series of 2,4-dinitrophenyl 4-Y-phenyl disulfides (Y = NO_2, Br, F, H, Me, MeO; reaction 107). The S—S bond in the unsymmetrical disulfide ArS—SAr′ is cleaved by Vaska's complex, and the resulting fragments then coordinate to Ir to form a dimeric iridium(III) complex, as depicted in Scheme 19.[381]

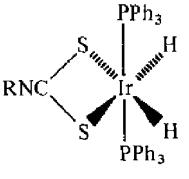




$$2[Ir(X)(CO)(PPh_3)_2] + 2ArS{-}SAr' \longrightarrow [Ir(X)(CO)(PPh_3)(SAr)(SAr')]_2 + 2PPh_3 \quad (107)$$

(171)

Scheme 19



The oxidative addition of sulfonyl chlorides [RSO_2Cl] to Vaska's complex gives the iridium(III) sulfinate complex $[Ir(Cl)_2(RSO_2)(CO)(PPh_3)_2]$ (**172**; R = Me, Et, Pr^n, *p*-MeC_6H_4, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$) in which the SO_2 group is bound to Ir through the S atom. A tentative structure (**172**) was suggested based on ^1H NMR spectral interpretation.[382] From the addition of RSO_2 to $[Ir(Cl)(CO)(PMe_2Ph)_2]$, $[Ir(Cl)_2(RSO_2)(CO)(PMe_2Ph)_2]$ is obtained, with stereochemical arrangements analogous to (**172**).[379]

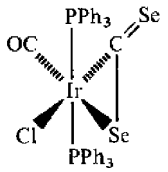
(172)

The organoperthio group RSS^- is capable of complexing with *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ to form $[Ir(Cl)_2(SSC_6F_5)(CO)(PPh_3)_2]$.[387] The reaction is analogous to the addition of RSH,[383] RSSR[381] and RSCl[380] to square planar iridium(I) complexes.

The monomeric iridium(III) complexes $[Ir(S{-}S)_2(\eta\text{-}C_5Me_5)]$ (S—S = S_2CNMe_2, S_2PMe_2) have been prepared *via* reaction of $[Ir(Cl)_2(\eta\text{-}C_5Me_5)]_2$ and excess dithioacid anion $S{-}S^-$. Analytical and IR, ^1H, ^{13}C and ^{31}P NMR spectroscopic results were interpreted in terms of the occurrence of uni- and bi-dentate dithioacid exchange, probably *via* a dissociatively controlled intramolecular mechanism.[384] Another report[385] on the preparation of $[Ir(S_2CNMe_2)_2(\eta\text{-}C_5Me_5)]$ suggests that the complex contains one uni- and one bi-dentate dithio ligand. The preparation of $[Ir\{S_2C_2(CN)_2\}(\eta\text{-}C_5Me_5)]$ was also reported.[385] Complexes of the type $[Ir(H)_2(Rdtc)(ER_3)_2]$ (**173**) [ER_3 = PPh_3, $AsPh_3$; Rdtc = piperidine dithiocarbamate (Pipdtc), piperazine dithiocarbamate (Pzdtc), *N*-methylpiperazine dithiocarbamate (Me—Pzdtc), morpholine dithiocarbamate (Timdtc)] have been prepared and characterized by IR and ^1H NMR spectroscopy. The stereochemistry proposed for these complexes is shown in (**173**).[386]

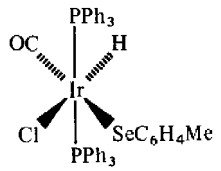
(173)

49.6.7 Selenium Ligands



The electrochemical behaviour of the iridium(III) complexes $[Ir(dppe)_2(L_2)]^+$ (L_2 = Se_2, S_2, O_2) has been investigated,[388] revealing the dissociation of L_2^- consequent to the addition of one electron to the antibonding orbital of the π component of the Dewar–Chat–Duncanson model for ML_2 bonding. The mechanism for the electrolytic reduction is given in Scheme 20. The progression of the

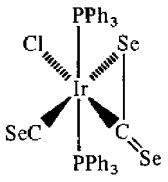
first reduction wave (A) to more negative potential for $L_2 = Se_2 \rightarrow S_2 \rightarrow O_2$ was taken to be indicative of the π-back-bonding interaction enhancing in the same direction; thus, a stepwise destabilization of the lowest unoccupied molecular orbital follows the same order. Two iridium complexes containing Se donor ligands have been prepared *via* oxidative addition of carbon diselenide and areneselenols to *trans*-[Ir(Cl)(CO)(PPh_3)$_2$].[389] As such, addition of CSe_2 to Vaska's complex produced [Ir(Cl)(CO)(CSe_2)(PPh_3)$_2$] (**174**), while addition of *p*-MeC_6H_4SeH resulted in [Ir(H)(Cl)(CO)(PPh_3)$_2$(SeC_6H_4Me-*p*)] (**175**). The IR spectrum of complex (**174**) exhibits a low ν(Ir—Cl) value, suggesting that the Cl ligand is *not trans* to CO. However, the IR data are consistent with the configuration in (**174**), and are analogous to those reported for [Ir(Cl)(CO)(CS_2)(PPh_2Me)$_2$].[379] The ^{1}H NMR spectrum of complex (**175**) is consistent with a structure in which the two PPh_3 ligands are *cis* to the hydride ligand and *trans* to each other. The suggested configuration of [Ir(H)(Cl)(CO)(SeC_6H_4Me-*p*)(PPh_3)$_2$] is that given in (**175**), based on ^{1}H NMR and IR spectral interpretation.[389]



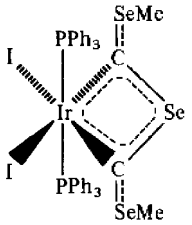
$$[Ir(X)_2(dppe)_2]^+ \xrightarrow[1e^-]{(A)} [Ir(X)_2(dppe)_2]^0 \xrightarrow{k_d} [Ir(dppe)_2]^+ + X_2^- \xrightarrow{1e^-}$$

$$[Ir(dppe)_2]^0 \xrightarrow{k_H} [Ir(H)(dppe)_2]$$

Scheme 20

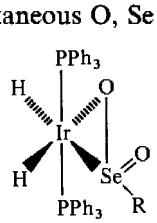


(174)



(175)

[Ir(Cl)(CSe)(PPh_3)$_2$] readily undergoes oxidative addition with Cl_2, O_2 and $AgClO_4$ in MeCN to yield [Ir(Cl)$_3$(CSe)(PPh_3)$_2$], [Ir(Cl)(CSe)(O_2)(PPh_3)$_2$] and [Ir(CSe)(PPh_3)$_2$(MeCN)](ClO_4), respectively. However, reaction of [Ir(Cl)(CSe)(PPh_3)$_2$] with BH_4^- and PPh_3 affords the Ir—Se complex [Ir(H)$_2$(SeMe)(PPh_3)$_3$]. Also, reaction between [Ir(Cl)(CSe)(PPh_3)$_2$] and CSe_2 gives the complex shown in (**176**), which on reaction with MeI leads to complex (**177**).[390]



(176)

(177)

The seleninato iridium(III) complexes [Ir(H)$_2$(XPhSeO$_2$)(PPh_3)$_2$] (X = H, *p*-Cl, *m*-Cl, *m*-Br, *m*-NO_2) have been synthesized from [Ir(H)$_3$(PPh_3)$_2$] and the appropriate sodium benzeneseleninate salt. The monomeric diamagnetic complexes have the hydride ligands in a *cis* arrangement and the $RSeO_2$ ligand coordinated through simultaneous O, Se bonding, as in structure (**178**).[391]

(178)

49.6.8 Halogens as Ligands

Iridium(III) fluoride is prepared by reducing [IrF_6] with metallic iridium at 323 K. [IrF_3] is black, possesses a hexagonal close-packed structure and is relatively inert toward water.[310]

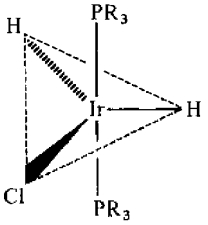
The red octahedral complex $[IrCl_3]$ results from direct chlorination of metallic iridium at 773 K;[310] two forms of $[IrCl_3]$ are known, both water insoluble.[392] The dark green hydrate, $[IrCl_3]\cdot 3H_2O$, is obtained upon heating the oxychloride $[Ir(Cl)_2(OH)]\cdot 3H_2O$ in HCl.[343]

Ferguson and Rankin[394] have recently reviewed the various preparative routes and structural chemistry of iridium(III) chloro and bromo complexes. In general, iridium(III) chloro complexes of the type $M_3[IrCl_6]\cdot 12H_2O$ (M = Li, Na), $M_3[IrCl_6]\cdot H_2O$ (M = K, Rb, Cs, NH_4), $M_3[IrCl_6]$ (M = Na, K, NH_4) and $M_2[Ir(Cl)_5(H_2O)]$ (M = K, Rb, Cs, NH_4) are prepared *via* the reduction of $M_2[IrCl_6]$ by reagents such as Fe^{2+},[395] ethanedioate (oxalate),[396–398] or hydrogen sulfide.[399,400] Factors affecting product composition include chloride ion concentration, choice of M, method of recrystallization and solution age. The crystal structures of iridium(III) chloro complexes depend on M as well as the presence or absence of water of crystallization. Single-crystal X-ray structures of $K_3[IrCl_6]$, $K_3[IrCl_6]\cdot H_2O$ and $(NH_4)_3[IrCl_6]\cdot H_2O$ reveal them to be isostructural with their rhodium analogues, though each complex belongs to a different space group.[394b]

The aquation of $[IrCl_6]^{3-}$ yields $[Ir(Cl)_5(H_2)]^{2-}$, $[Ir(Cl)_4(H_2O)_2]^-$ and $[Ir(Cl)_3(H_2O)_3]$.[401] The activation entropy associated with this reaction was suggestive of a dissociative mechanism. In the presence of added salts, the calculated activation entropies were attributed to the orienting effect of the cation (*e.g.* Li^+) on the water adjacent to the $[IrCl_6]^{3-}$ anion.[402] Irradiation of $K_3[IrCl_6]$ doped into NaCl reportedly yields $[IrCl_6]^{4-}$, based on ESR data.[403]

The reddish-brown $[IrBr_3]$ is also known, and thought to be formed upon treatment of '$[IrBr_2]$' with bromine.[393] More likely, however, is that $[IrBr_3]$ is grey-brown in colour and obtained *via* direct bromination of metallic iridium at 843 K under 8 atm pressure.[404] Additionally, the hydrated complexes $[IrBr_3]\cdot H_2O$, $[IrBr_3]\cdot 3HBr\cdot 3H_2O$ and $[IrBr_3]\cdot H\beta r\cdot H_2O$ are thought to exist.[310]

Iridium(III) bromo complexes of the type $M_3[IrBr_6]$, $M_3[IrBr_6]\cdot 12H_2O$, $M_3[IrBr_6]\cdot H_2O$ and $[Co(NH_3)_6][IrBr_6]$ have been cited. They are, in general, prepared *via* reduction of $[IrBr_6]^{2-}$,[310] treatment of $[Ir(OH)_3]$ with HBr,[405] or treatment of the iridium(III) chloro analogue with HBr.[394,406,407] The hydrated complexes $K_3[IrBr_6]\cdot 4H_2O$[405] and $K_3[IrBr_6]\cdot 3H_2O$[408] are thought[394a] to actually be $(H_3O)K_8[IrBr_6]_3\cdot 9H_2O$.



A single-crystal X-ray structure determination of $Rb_3[IrBr_6]\cdot H_2O$ has shown it to be isostructural with $(NH_4)_3[IrCl_6]\cdot H_2O$.[394b] X-Ray powder photographs, along with comparative analyses, suggest that the complexes $[Co(NH_3)_6][IrX_6]$ (X = Cl, Br) crystallize in the cubic space group P_a3.[394b] Preliminary single-crystal X-ray studies[394b] on $(NH_4)_3[IrBr_6]\cdot H_2O$, $Cs_3[IrBr_6]\cdot H_2O$ and $(H_3O)K_8[IrBr_6]_3\cdot 9H_2O$, as well as $Rb_3[IrBr_6]\cdot H_2O$, have revealed the $[IrX_6]^{3-}$ anions to be distorted as a consequence of the non-spherical packing of the cations and, in some cases, of the water molecules surrounding the anions.

The reaction between Ir_2O_3 and HI presumably gives $[IrI_3]$, while $[IrI_6]^{3-}$ can be synthesized from $[IrI_3]\cdot 3H_2O$ and KI.[310,401] Additionally, the hydrated complex $[IrI_3]\cdot 3H_2O$ has been reported.[310]

The dinuclear complexes $M_3[Ir_2(Cl)_9]$ (M = Rb, Cs) and $M_3[Ir_2(Br)_9]$ (M = Rb, Cs, Me_4N) have recently been prepared. Heating $M_2[Ir(Cl)_5(H_2O)]$ under vacuum to 623 K, followed by cooling and treating with water, led to the isolation of impure samples of $M_3[Ir_2(Cl)_9]$. The $M_3[Ir_2(Br)_9]$ complexes result from treatment of $M_3[IrCl_6]\cdot H_2O$ or $M_2[Ir(Cl)_5(H_2O)]$ with HBr.[394b]

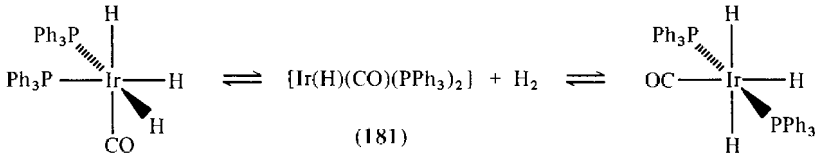
49.6.9 Hydrogen and Hydrides as Ligands

The five-coordinate iridium(III) dihydrates $[Ir(H)_2(Cl)(PR_3)_2]$ (PR_3 = PBu^t_3, PBu^t_2Ph) have been synthesized from $IrCl_3\cdot xH_2O$ and PR_3, and have the structure depicted in (**179**). Reactions of complex (**179**) with NaI, CO and H_2 are summarized in reactions (108)–(110).[290b] Hydride complexes of the type $[Ir(H)_n(Cl)_{3-n}(PRBu^t_2)_2]$ (n = 1, R = Me; n = 2, R = Bu^t) react with $NaBH_4$ to yield the non-fluxional complexes $[Ir(H)_2(BH_4)(PRBu^t_2)_2]$.[290b] In toluene, $[Ir(Cl)(N_2)(PPh_3)_2]$ and HCl react to yield $[Ir(H)(Cl)_2(PPh_3)_2]$; in ethanol, however, CO is abstracted from the solvent affording $[Ir(H)(Cl)_2(CO)(PPh_3)_2]\cdot EtOH$.[409] Reaction between $[Ir(Cl)(cod)]_2$ and HCN produced the unusual five-coordinate species $[Ir(H)(Cl)(CN)(cod)]$.[410]

(179)

$$[Ir(H)_2(Cl)(PBu^t_2Ph)_2] + NaI \longrightarrow [Ir(H)_2(I)(PBu^t_2Ph)_2] \quad (108)$$

$$[Ir(H)_2(Cl)(PBu^t_2Ph)_2] + CO \longrightarrow [Ir(H)_2(Cl)(CO)(PBu^t_2Ph)_2] \quad (109)$$



$$[Ir(H)_2(Cl)(PR_3)_2] + H_2 \xrightarrow{Na(propan\text{-}2\text{-}olate)} [Ir(H)_5(PR_3)_2] \quad (110)$$

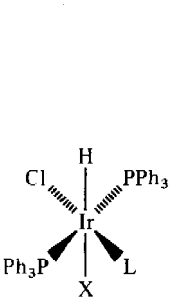
Oxidative addition of H_2 to iridium(I) complexes yields a variety of six-coordinate iridium(III) dihydrides. Dihydrogen reacts with $[Ir(Cl)(CO)(PPh_3)_2]$ in benzene at 298 K to produce $[Ir(H)_2(Cl)(CO)(PPh_3)_2]$;[411] the reaction is reversible and a kinetic investigation has been reported.[412] $[Ir(Cl)(PPh_3)_3]$ reacts with H_2 at 298 K and atmospheric pressure to give $[Ir(H)_2(Cl)(PPh_3)_3]$.[413] The four-coordinate iridium(I) complex $[Ir(dppe)_2]^+$ reversibly reacts with H_2, affording $[Ir(H)_2(dppe)_2]^+$.[414]

The addition of hydrogen halides (*e.g.* HCl) to iridium(I) complexes also affords iridium(III) hydrides. The stereochemistry of these additions to $[Ir(Cl)(CO)(PPh_3)_2]$[414b] and related complexes has been studied in some detail.[415–417] In the solid state or in non-polar solvents *cis* adducts are formed, while the use of polar solvents gives mixtures of *cis* and *trans* adducts. Reaction between $[Ir(Cl)(PPh_3)_3]$ and HCl gives $[Ir(H)(Cl)_2(PPh_3)_3]$; the corresponding arsine and stibene complexes are similarly obtained.[413] $[Ir(dppe)_2]^+$ undergoes oxidative addition with HCl to yield $[Ir(H)(Cl)(dppe)_2]^+$.[414] Oxidative addition of HCN to $[Ir(Cl)(CO)(PPh_3)_2]$ gives $[Ir(H)(Cl)(CN)(CO)(PPh_3)_2]$.[418] Additionally, pentafluorobenzenethiol oxidatively adds to $[Ir(Ph)(CO)(PPh_3)_2]$ to produce $[Ir(H)(Ph)_2(CO)(PPh_3)_2]$, and to $[Ir(Cl)(CO)(PPh_3)_2]$ under mild conditions to give the same product.[419]

Five-coordinate iridium(I) complexes may react with hydrogen halides (HX) to eliminate a ligand and form Ir—H and Ir—X bonds. Both $[Ir(CO)(PMe_2Ph)_4]^+$ and $[Ir(CO)_2(PMe_2Ph)_3]^+$ react with HCl to yield $[Ir(H)(Cl)(CO)(PMe_2Ph)_3]^+$.[420] Dimethylphenylarsine is displaced from $[Ir(CO)(AsMe_2Ph)_2(PMe_2Ph)_2]^+$ by HCl, yielding $[Ir(H)(Cl)(AsMe_2Ph)(CO)(PMe_2Ph)_2]^+$.[420] Thiophenol reacts with $[Ir(Cl)(CO)(PPh_3)_2]$, from which $[Ir(H)(Cl)(Ph)(PPh_3)_2]$ is obtained.[419] Substituted thiophenols react similarly with Vaska's complex.[410,419,421] Salts of $[Ir(H)_2(CO)_2(ER_3)_2]^+$ (ER_3 = tertiary phosphine or arsine) have been prepared *via* reversible hydrogen displacement of CO from $[Ir(CO)_3(ER_3)_2]$.[422]

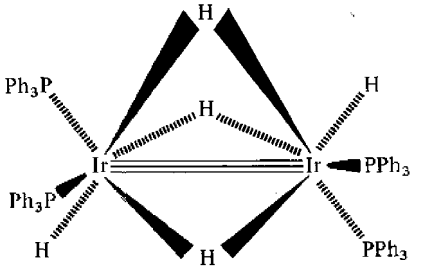
The preparation and interconversion of two isomeric iridium(III) trihydrides, *fac*- and *mer*-$[Ir(H)_3(CO)(PPh_3)_2]$ (**180**), have been studied. Under a hydrogen atmosphere, both isomers undergo spontaneous interconversion to a dynamic equilibrium. The kinetic data obtained from the interconversion and H_2 displacement from both isomers by PPh_3 suggest that the interconversion process occurs *via* a reversible reductive elimination–oxidation sequence. Both processes are believed to involve the intermediate species $[Ir(H)(CO)(PPh_3)_2]$ (**181**). It has further been postulated that the interconversion process proceeds by slow unimolecular loss of H_2 (reductive elimination), followed by a rapid readdition of H_2 to the coordinatively unsaturated intermediate species (**181**), as depicted in Scheme 21.[423]

(180) (181) (180)



Scheme 21

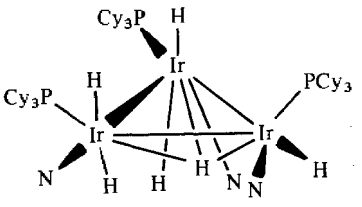
The addition of $Na_3[IrCl_6]$ to a hot ethanolic solution of PPh_3 followed by $NaBH_4$ addition gives *mer*-$[Ir(H)_3(PPh_3)_3]$ on cooling; *fac*-$[Ir(H)_3(PPh_3)_3]$ is obtained by evaporating the filtrate obtained under reduced pressure.[424] The structure of *mer*-$[Ir(H)_3(PPh_3)_3]\cdot 0.5C_6H_6$ shows a very distorted octahedral coordination geometry about Ir with three adjacent sites occupied by P atoms.[425] Both *fac*- and *mer*-$[Ir(H)_3(PPh_3)_3]$ react with carboxylic acids in boiling 2-methoxyethanol to give $[Ir(H)_2(O_2CR)(PPh_3)_3]$ (R = Me, *p*-tolyl, *p*-ClC_6H_4, *p*-$NO_2C_6H_4$).[426]



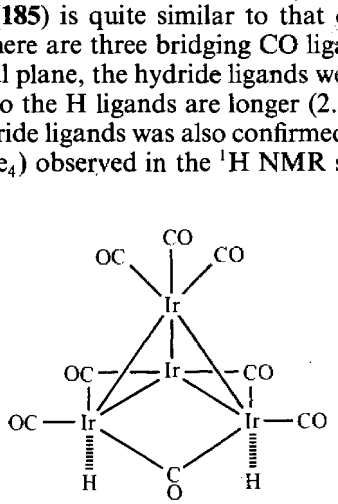
The oxidative addition of HBF_4, CF_3SO_3H and $BuSO_3H$ to *trans*-$[Ir(Cl)(L)(PPh_3)_2]$ (L = CO, N_2) has afforded the highly reactive iridium(III) complexes $[Ir(H)(Cl)(X)(L)(PPh_3)_2]$ (X = BF_4, CF_3SO_3, $BuSO_3$) (**182**), in which X can easily be substituted by σ and π donors. The stereochemistry of the hydride complex (**182**) is shown.[58]

The dimeric hydrido complex $[Ir(H)(X)_2(CO)(PR_3)]_2$ (X = Cl, Br; PR_3 = PEt_3, PPh_3) has been synthesized by carbonylation of iridium halides followed by phosphine addition; the complex

contains halide bridges.[427] Hydride bridges are present in $[Ir_2(\mu\text{-}H)_3(H)_2(PPh_3)_4](PF_6)$ (**183**) for which X-ray structural, IR and ^1H NMR spectral data have been interpreted in terms of the presence of an iridium–iridium triple bond (2.518 Å).[428]

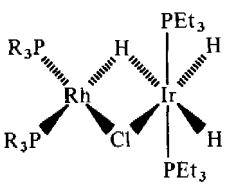


(182)

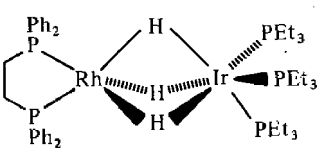


(183)

The trimeric complex $[\{Ir(H)_2(PCy_3)_3(C_5H_5N)\}_3(\mu\text{-}H)]^{2+}$ (**184**; N = Pyridine) has been characterized by X-ray crystallography, IR and ^1H NMR spectroscopy, and found to contain a tricoordinate hydrogen ligand within a triangle of iridium atoms.[429] The tetranuclear complex anion $[Ir_4(H)(CO)_{11}]^-$ has been isolated as the tetraalkylammonium salt by treating $[Ir_4(CO)_{12}]$ with K_2CO_3 and CO in methanol.[430] The dihydride species $[Ir_4(H)_2(CO)_{11}]$ was produced upon treatment of the anion with acetic acid.[430] In concentrated H_2SO_4, slow dissolution of $[Ir_4(CO)_{12}]$ gives rise to a non-isolable solution thought to contain $[Ir_4(H)_2(CO)_{12}]^{2+}$.[431] The dihydrido anion $[Ir_4(H)_2(CO)_{10}]^{2-}$ (**185**) was synthesized in two stages: $[Ir_4(CO)_{12}]$ reacts with RO^- in ROH (R = Me, Et) to yield $[Ir_4(CO_2R)(CO)_{11}]^-$, which, when added to alkaline hydroxide, gives the dianion.[432] The X-ray crystal structure of complex (**185**) is quite similar to that of $[Rh_4(CO)_{12}]$, wherein the iridium atoms form a tetrahedron and there are three bridging CO ligands. Inasmuch as two terminal CO ligands are missing from the basal plane, the hydride ligands were suggested to occupy these positions. The two Ir—Ir bonds *trans* to the H ligands are longer (2.802 Å) than the remaining Ir—Ir bonds (2.71 Å). The presence of hydride ligands was also confirmed by the hydride NMR resonance ($\delta = -16.15$ p.p.m. relative to $SiMe_4$) observed in the ^1H NMR spectrum of the dianion (**185**) in CD_3CN.[432]

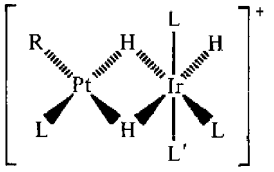


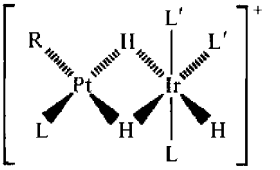
(184)



(185)

The hydrido-bridged dinuclear complex $[(PR_3)_2Rh^I(\mu_2\text{-}H)(\mu_2\text{-}Cl)Ir^{III}(H)_2(PEt_3)_2]$ (**186a**; $PR_3 = PEt_3$, or $2PR_3$ = dppe) was produced upon treatment of $[Ir(H)_5(PEt_3)_2]$ with $[Rh(\mu\text{-}Cl)_2(PR_3)_2]_2$. An X-ray crystal structure determination reveals a distorted octahedral geometry about Ir and a distorted square planar geometry around Rh.[433] The similar complex $[(dppe)Rh^I(\mu_2\text{-}H)_2Ir^{III}(H)_2(PPr^i_3)_2]$ has been prepared and characterized by X-ray crystal structure and NMR analyses. Its structure is similar to that of complex (**186a**).[434] Another hydrido-bridged dinuclear complex, $[(dppe)Rh(\mu_2\text{-}H)_3Ir(PEt_3)_3]^+$, has the structure shown in (**186b**).[435]





(186a)

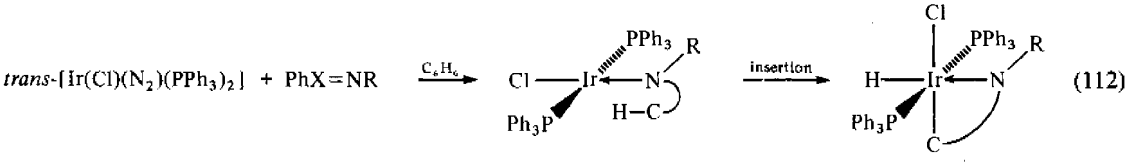
(186b)

Reaction between $[Ir(H)_2(OCMe_2)_2(PPh_3)_2]^+$ and $[M(H)_2(Cp)_2]$ (M = Mo, W) has yielded $[(PPh_3)_2(H)Ir(\mu\text{-}H)_2(\eta\text{-}\sigma\text{:}1\text{-}5\text{-}\eta\text{-}C_5H_4)M(Cp)]^+$. Intermediate formation of $[(PPh_3)_2(H)_2Ir(\mu\text{-}H)_2M(Cp)_2]^+$ was reportedly observed, and kinetic parameters were obtained for the C—H insertion reaction. Reversible hydride bridge cleavage for M = W occurs with pyridine and acetonitrile.[436] The hydrido-bridged bimetallic complexes (**187**)–(**190**) have been synthesized from *trans*-$[Pt(L)_2(MeOH)(R)]^+$ and $[Ir(H)_5(L')_2]$. Complex (**187**) reacts with CO at room temperature to yield $[Ir(H)_2(CO)(PEt_3)_3]^+$. Reaction of complex (**187**) with ethylene gives (**190b**); complex (**190**) reacts with H_2 at moderate temperatures and pressures to produce $[(PEt_3)_2Pt(\mu\text{-}H)_2Ir(H)_2(PEt_3)_2]^+$.[437]

(187a) R = H, L = L′ = PEt_3 (187b) R = H, L = L′ = PEt_3

(188a) R = Ph, L = L′ = PEt_3 (188b) R = Ph, L = L′ = PEt_3

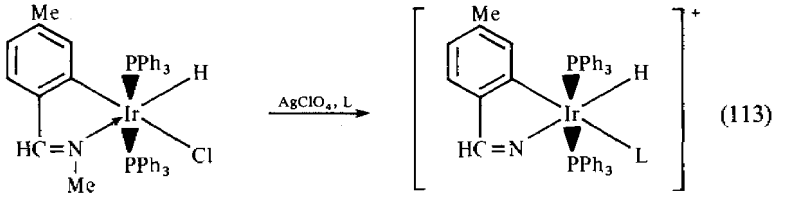
(189a) R = H, L = PEt_3, L′ = PPr_3 (190b) R = Et, L = L′ = PEt_3



(190a) R = Et, L = L′ = PEt_3

49.6.10 Mixed Donor Atom Ligands

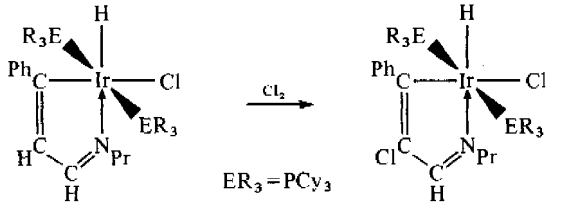
49.6.10.1 Bidentate N–C ligands



Organometallic intramolecular coordination complexes consist of those which have at least one M—C bond and at least one group forming an intramolecular coordination bond. Iridium(III) complexes containing an N donor intramolecular coordination bond are well known, and conform to the five-membered ring structure theory first proposed by Matsuda *et al.*:[438] organometallic intramolecular coordination complexes tend to form five-membered ring structures. Transition metal organometallic intramolecular coordination complexes containing an N donor ligand have been reviewed by Omae.[439]

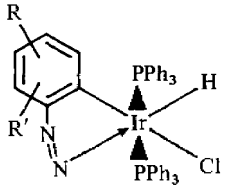
Reactions of *trans*-$[Ir(Cl)(N_2)(PPh_3)_2]$ with benzylideneamines have afforded the *o*-metallated complexes (**191**) for X = CH, N (see reaction 112).[440] Whereas square planar palladium(II) benzylideneamine complexes are formed *via* a substitution reaction of the metal with the hydrogen at the *ortho* position, octahedral iridium(III) analogues are more probably formed by an insertion reaction arising from the affinity of the Ir atom to the H atoms (reaction 112). The insertion mechanism involves $\sigma(N)$ coordination of the imine ligand, which brings an *ortho* or alkenic CH group close to the Ir atom, followed by oxidative addition of the *ortho* or alkenic CH group to the Ir atom. Treatment of complex (**191**) with $AgClO_4$ and then with $C_6H_{11}NC$ or CO (= L) gives rise to the formation of complex (**192**) with the metallacyclic ring remaining intact (see reaction 113).[441]

(112)



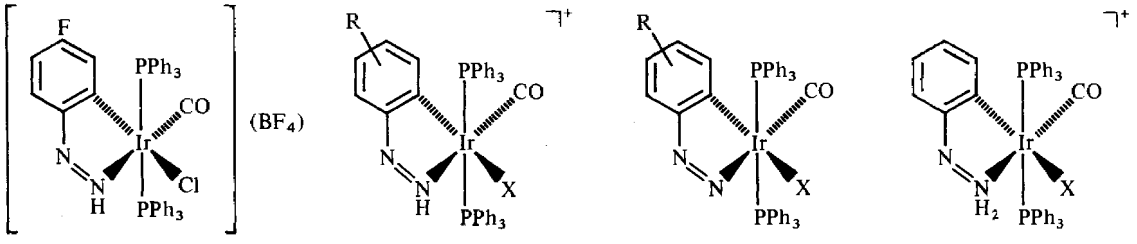
(191)

(113)



(191) (192)

Five-membered cyclometallated complexes similar to (**191**) are produced from the reaction between alkenic imines and iridium complexes. The reaction of alkenic imines with $[Ir(Cl)(C_8H_{14})_2]_2$ in the presence of cyclohexylphosphine yields complex (**193**),[442] which, when treated with Cl_2, undergoes substitution without Ir—C bond rupture to give (**194**; reaction 114).[441] Azobenzene or its derivatives react with $[Ir(Cl)(C_8H_{14})_2]_2$ in the presence of PR_3 (R=Ph, cyclohexyl) according to reaction (112) to yield the cyclometallated complex (**195**).[441,442]



(114)

(193) (194)

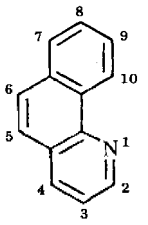
(195) R = Ph, Me, tolyl, xylyl; R′ = H, Me

Two products are formed *via* the reaction of *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$ with *p*-fluorobenzenediazonium tetrafluoroborate.[443,444] One is a red, air-stable, diamagnetic tetrazene complex,[445,446] while the other is the yellow, air-stable diamagnetic complex (**196**). The X-ray crystal structure of the acetone solvate of complex (**196**) has been determined. Various substituted arene diazonium ions react with $[Ir(Cl)(CO)(PPh_3)_2]$ and its analogues in the presence of lithium chloride, benzene/ethanol, or benzene/propan-2-ol to yield *o*-metallated aryldiazene complexes (**197**) (where X = Cl, Br, F, I, $OClO_3$; R = H, F, Br, Cl, Me, CF_3, NH_2, NO_2, OMe; and Y = BF_4^-, ClO_4^-).[447–448] The complex (**197**) may undergo deprotonation, affording an aryldiazenato complex (**198**), as well as hydrogenation in the presence of a palladium catalyst to produce an *o*-metallated arylhydrazine complex (**199**). The X-ray crystal structure of (**196**) and (**197**), dichloro(4-methoxyphenyldiimide)-C^2,N^1-bis(triphenylphosphine)iridium–chloroform (1:1), has been determined. The iridium atom displays a distorted octahedral coordination and is bonded to the terminal nitrogen atom.[449]

(196) (197) (198) (199)

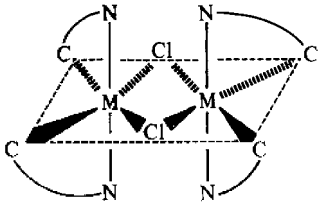
An insertion product is obtained upon reaction of $[Ir(H)_3(PPh_3)_3]$ with *p*-anisolediazonium tetrafluoroborate, and undergoes *o*-metallation to yield $[Ir(H)(NHNC_6H_3OMe)(PPh_3)_3]^+ (BF_4)^-$ (**200**).[450] The neutral complex $[Ir(H)(X)(NHNC_6H_3OMe)(PPh_3)_2]$ (**201**) results from the action of halides X^- on complex (**200**). The reaction of complex (**201**) with halogens, X_2, affords $[Ir(X)_2(NHNC_6H_3OMe)(PPh_3)_2]$.

The syntheses of phenyldiimide complexes have been reported by Toniolo and coworkers.[451] One example is the *o*-metallation reaction of the aryldiazenato iridium(III) complex (**202**) with phenylacetylene (reaction 115) to yield complex (**203**).



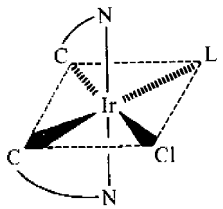
$$[Ir(Cl)(CO)(N_2C_6H_4R\text{-}p)(PPh_3)_2](BF_4) + HC{\equiv}CH \xrightarrow{\text{EtOH or } C_6H_6/\text{acetone}} \quad (115)$$

(**202**)



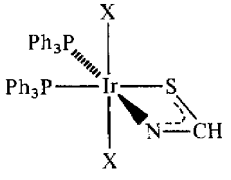
$$[Ir(Cl)(CO)(NH{=}NC_6H_4R\text{-}p)(PPh_3)_2(C{\equiv}CPh)]^+(BF_4)^-$$

(**203**)

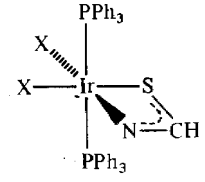


The reaction of $Na_3[IrCl_6]$ in 2-methoxyethanol with benzo[*h*]quinoline (bhqH; **204**) yields $[Ir(Cl)(bhq)_2]_2$ (**205**), in which the bhq ligand is coordinated at N-1 and C-10 atoms. Proton NMR and IR spectra support a structure similar to that of the rhodium(III) analogue (**205**). Complex (**205**) reacts with L (= PBu^n_3, SEt_2) to give $[Ir(Cl)(bhq)_2(L)]$ (**206**).[452]

(204)



(205) M = Rh, Ir

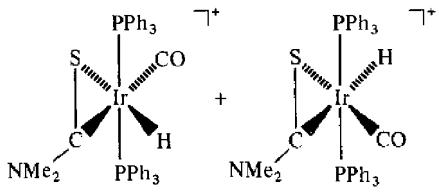


(206)

49.6.10.2 Bidentate N–S ligands

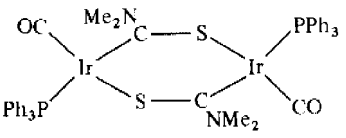
Alkyl and aryl isothiocyantes, RCNS, parallel CS_2 in their capability to insert into M—H bonds and yield products having the *N*-alkyl- or *N*-aryl-formamide chelate ligand RN===CH===S. The iridium(III) complexes $[Ir(X)_2(RN{=}{=}{=}CH{=}{=}{=}S)(PPh_3)_2]$ (**207**; X = Cl, Br; R = Me, Et, Ph) can be prepared from *trans*-$[Ir(H)(X)_2(PPh_3)_2]$ and the appropriate alkyl or aryl isothiocyanate. Two isomeric forms of (**207**) were deemed plausible, with (**207a**) the preferred stereochemistry for the alkyl products and (**207b**) for the aryl products.[453]

(207a)



(207b)

49.6.10.3 Bidentate S–C ligands



The X-ray crystal structure of $[Ir(CO)(PPh_3)(\eta^2\text{-}SCNMe_2)_2]^+$ (as the BF_4^- salt) reveals that both $IrSCNMe_2$ units are virtually planar and coordinated *via* C and S, with bond distances comparable to other η^2-$SCNMe_2$ complexes. The coordination geometry about Ir is a distorted octahedron.[454] IR spectra on the products of reactions (116) and (117) have also been interpreted in terms of η^2 coordination of the $SCNMe_2$ ligand, *via* C and S.[454] Interestingly, the product of reaction (117), *trans*-$[Ir(Cl)(CO)(PPh_3)_2(\eta^2\text{-}SCNMe)_2)]^+$, has been reported[455] to be formed in the absence of additional Cl^-; whereas, in the presence of Cl^-, $[Ir(Cl)_2(CO)(PPh_3)_2(\eta^1\text{-}SCNEt)]$ was formed.[377] Thus, it would appear that $SCNMe_2$ is capable of η^2 coordination *via* displacement of Cl^- from Ir^{III}, whereas SCNMe is not. The reaction of $[Ir(H)(CO)(PPh_3)_3]$ with $Me_2NC(S)Cl$ results in immediate precipitation of an intermediate complex, $[Ir(H)(CO)(PPh_3)_2(\eta^2\text{-}SCNMe_2)]^+$, that exists in two isomeric forms (**208a**) and (**208b**). Reaction of complex (**208**) with Et_3N in C_6H_6 affords complex (**209**), $[Ir(CO)(PPh_3)(\mu\text{-}SCNMe_2)]_2$, as in reaction (118).[454] In the complex analogous to (**208**), $[Ir(H)(Cl)(CO)(PPh_3)_2(\eta^1\text{-}SCNMe)]$, η^1 coordination of SCNMe is present and Cl^- is not displaced from the coordination sphere.[455]

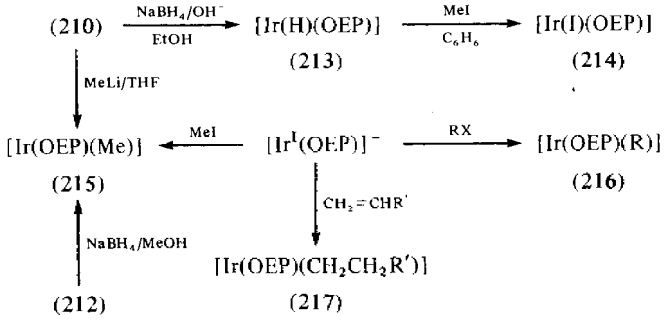
$$[Ir(Cl)_2(PPh_3)_2] + Me_2NC(S)Cl \xrightarrow{C_6H_6} cis\text{-}[Ir(Cl)_2(\eta^2\text{-}SCNMe_2)(PPh_3)_2] \quad (116)$$

$$[Ir(Cl)(CO)(PPh_3)_2] + Me_2NC(S)Cl \xrightarrow{C_6H_6} trans\text{-}[Ir(Cl)(\eta^2\text{-}SCNMe_2)(CO)(PPh_3)_2]^+ \quad (117)$$

(208a) (208b)

(209)

(118)



49.6.11 Multidentate Macrocyclic Ligands

The iridium(III) octaethylporphyrin (OEP) complexes (**210**)–(**212**) have been prepared and characterized spectroscopically by Ogoshi *et al.*[183] (reactions 119–121). Scheme 22 depicts various reactions of complexes (**210**) and (**212**) to yield hydrido- (**213**) and organo-iridium(III) (**214**)–(**217**) porphyrin complexes. The preparation and influence of axial ligands on the central iridium atom of several iridium(III) octaethylporphyrin complexes has been reported. The complexes investigated include [Ir(X)(CO)(OEP)] (**218**; X = Cl, Br, ClO_4, CN, BF_4, Me) and [Ir(L)(OEP)(Me)] (**219**; L = no ligand, *N*-methylimidazole (mim), pyridine, NH_3, CN). For the carbonyl complexes (**218**), the CO stretching frequencies and absorption peak wavenumbers varied in the order Me^-, $Br^- \approx Cl^-$, $ClO_4^- \approx BF_4^-$, that is in the order of decreasing electron-donating tendency of the axial ligand X. Proton NMR studies were employed to determine the *cis* and *trans* influence of the porphyrin ligand. A linear correlation between the chemical shift of the *meso* protons (*cis* influence) and the reversible redox potential (Ir^I/Ir^{III}) in the range +0.4 to +1.3 V has been observed. These results were explained[456] in terms of the change of electron density caused by chelation of the axial ligands depending on their electron-donating tendency; the order to this tendency varies for complexes (**218**) and (**219**) as: CO < no ligand < py < NH_3 < mim < CN^- < $ClO_4^- \approx BF_4^-$ < $Cl^- \approx Br^-$ < Me^-.

$$[Ir(Cl)(CO)_3]_2 + OEPH_2 \longrightarrow \underset{(\mathbf{210})}{[Ir(Cl)(CO)(OEP)]} + \mu\text{-}OEP[Ir(CO)_3]_2 \quad (119)$$

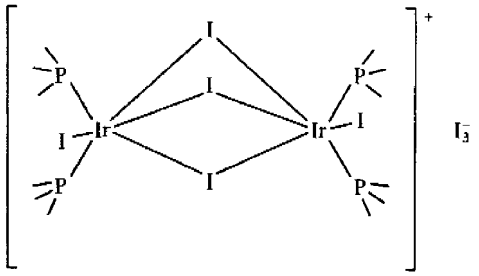
$$[Ir(Cl)(cod)]_2 + OEPH_2 \longrightarrow \underset{(\mathbf{211})}{[Ir(cod)(OEP)]} + \underset{(\mathbf{210})}{[Ir(Cl)(CO)(OEP)]} \quad (120)$$

$$[Ir(Cl)(cod)]_2 + N\text{—}Me\cdot OEPH \longrightarrow \underset{(\mathbf{212})}{[Ir(Cl)_2(N\text{—}Me\cdot OEP)]} \quad (121)$$

Scheme 22

The reaction of *meso*-porphyrin IX diethyl ester with $[Ir(Cl)(CO)_3]_2$ or $[Ir(Cl)(CO)(cot)_2]$ yields the iridium(III) porphyrin derivative [Ir(CO)(HePDEE)] (HePDEE = hematoporphyrin diethyl ester).[457] This complex, along with the dimethyl ester derivative, has been characterized by electronic, IR, electron spin resonance and mass spectroscopic techniques as well as magnetic susceptibility measurements. The iridium complexes differ from their rhodium analogues in that they retain a CO ligand in the coordination shell.

49.7 IRIDIUM(IV)



49.7.1 Phosphorus and Arsenic Ligands

The paramagnetic iridium(IV) complexes *trans*-$[Ir(Cl)_4(ER_3)_2]$ (ER_3 = tertiary phosphine or arsine) have been prepared *via* chlorine oxidation of $(ER_3H)[Ir(Cl)_4(ER_3)_2]$.[458] These iridium(IV) complexes are considered attractive as potential oxidizing agents inasmuch as they are soluble in a variety of organic solvents and thus as oxidizing agents of organic molecules and organometallic complexes.[459] Chlorine oxidation of $[Ir(Cl)_4(PMe_3)_2]^-$ in $CHCl_3$ yields *trans*-$[Ir(Cl)_4(PMe_3)_2]$, for which IR spectra were interpreted in terms of *trans* Cl ligands.[460] The electronic and MCD spectra of the D_{4h} iridium(IV) complexes *trans*-$[Ir(Cl)_4(ER_3)_2]$ (Er_3 = PMe_2Ph, PEt_2Ph, $AsPr^n_3$) have re-

vealed LMCT bands occurring at exceptionally low energies. These transition energies aid in the approximation of the bonding orbitals of ER_3 with respect to the metal; and from these energies, correlations were made between the energy of the ligand σ orbital and the Ir—ER_3 bond stability. The LMCT transition parallels the reducing power of ER_3.[461] The *trans*-$[Ir(Cl)_4(PMe_2Ph)_2]$ complex is reduced to *trans*-$[Ir(Cl)_4(PMe_2Ph)_2]^-$ at 0.90 V (*vs.* Ag–AgCl) in MeCN. The utility of this complex as an oxidizing agent with $[M(Cp)_2]$ (M = Ni, Fe), $[Pt(C_2H_4)(PPh_3)_2]$ and *trans*-$[Pd(Cl)_2(AsMe_3)_2]$ has been investigated.[462] For example, with $[Pt(C_2H_4)(PPh_3)_2]$, the iridium(III)–platinum(II) complex $[(Cl)_2(PMe_2Ph)_2Ir(\mu\text{-}Cl)_2Pt(PPh_3)_2]^+$ is formed.[459]

The iridium(IV) complexes $[Ir(R'CO_2)_2(ER_3)(RNC)]$ (ER_3 = $AsPh_3$; RNC = *p*-MeC_6H_4NC; R′ = $MeCH(O)CO_2$, *o*-$OC_6H_4CO_2$, $PhCH_2CH(NH)CO_2$, *o*-$NHC_6H_4CO_2$), $[Ir(o\text{-}C_6H_4O)_2(ER_3)(RNC)]$ and $[Ir(o\text{-}NHC_6H_4O)_2(ER_3)(RNC)]$ have been prepared from the iridium(III) complex $[Ir(H)_3(AsPh_3)_2(p\text{-}MeC_6H_4NC)]$.[196]

On treating $[Ir(ER_3)_4]^+$ (ER_3 = $P(OMe)Ph_2$, $PMePh_2$) with excess I_2 in CH_2Cl_2 or acetone, a complex of stoichiometry $[Ir(I)_4(ER_3)_2]$ is obtained. An X-ray structure determination of the complex of $[Ir(I)_4(PMePh_2)_2]$ established this compound as a salt of formula $[Ir_2(I)_5(PMePh_2)_4]^+(I)_3^-$, as depicted in (**220**).[463] The coordination about Ir is a distorted octahedron, and the complex has a triple I bridge with three I atoms shared by both Ir atoms. There is no Ir—Ir bond (> 3.5 Å).[463]

(220)

49.7.2 Oxygen Ligands

49.7.2.1 Hydroxy ligands

The complex $K_2[Ir(OH)_6]$ can be synthesized by treating $Na_2[IrCl_6]$ with KOH, and has been characterized by absorption spectroscopy, thermogravimetric analysis and voltage–current curves.[464] $Cd[Ir(OH)_6]$ possesses a tetragonal structure and serves as a magnetically dilute insulator, while $Zn[Ir(OH)_6]$ has a cubic structure and exhibits an anomalous magnetic behaviour.[465]

49.7.2.2 Oxalate ligands

The oxidation of $[Ir(ox)_3]^{3-}$ by cerium(IV) in aqueous acidic sulfate or perchlorate media has given $[Ir(ox)_3]^{2-}$. That the product is indeed $[Ir(ox)_3]^{2-}$ and not $[Ir^{III}(ox)_2(C_2O_4^-\cdot)]^{2-}$ finds support from the slow reaction observed in the presence of excess cerium(IV); free or coordinated oxalate radical anion would be expected to react rapidly with Ce^{IV}. In solution, $[Ir(ox)_3]^{2-}$ undergoes slow pseudo-first-order reaction to yield the highly reactive intermediate $[Ir^{III}(ox)_2(C_2O_4^-\cdot)]^{2-}$.

49.7.2.3 Nitrato ligands

The iridium(IV) nitrato complexes $M_2[Ir(NO_3)_6]$ (M = K, Rb, Cs), isomorphous with $K_2[Pt(NO_3)_6]$ and possessing magnetic moments consistent with a d^5 electronic configuration, are attained from the reaction of $M_2[IrBr_6]$ with N_2O_5. ESR spectra at 77 K reveal extensive π bonding between Ir and the NO_3 ligands.[467] The ESR spectrum of $K_2[Ir(NO_3)_6]$ in $K_2[Pr(NO_3)_6]$ was found to be isotropic at 77 K, indicating that any ^2T_g ground state Jahn–Teller term must be dynamic. Considerable $Md \rightarrow L_\pi^*$ delocalization was shown by the hyperfine constants. The presence of symmetrically bidentate NO_3 groups in $K_2[Ir(NO_3)_6]$ was supported by IR, Raman and ESR spectroscopic analyses.[468] The solution properties, IR spectra, magnetic properties and X-ray powder diffraction data for $M_2[Ir(NO_3)_6]$ have been reported more recently.[469]

49.7.3 Sulfur Ligands

Chlorine oxidation of the iridium(III) anions $[Ir(Cl)_5(SPh_2)]^{2-}$, $[Ir(Cl)_4(SPh_2)]^-$, *cis*- and *trans*-$[Ir(Cl)_4(SMe_2)_2]^-$ and $[Ir(Cl)_4(L)]^-$ (L = $RS(CH_2)_nSR$, RSCH=CHSR, 1,2-$C_6H_4(SR)_2$; R = Me, Ph; $n = 2$, 3) has led to the formation of the corresponding iridium(IV) complexes. The Ir^{IV} complexes $[Ir(Cl)_4(L)]$ have a *cis*-octahedral geometry. All complexes have been characterized on the basis of IR, Raman and electronic absorption spectra, as well as ^1H NMR spectra.[470]

49.7.4 Halogens as Ligands

The IV oxidation state is the most stable for iridium halogeno complexes. The preparation of $[IrF_4]$ has been reported,[471] though the actual product is probably $[IrF_5]$. A subsequent paper[472] reported the formation of $[IrF_4]$ from $[IrF_5]$ and iridium metal; on heating $[IrF_4]$ disproportionates to $[IrF_3]$ and $[IrF_5]$. Additionally, the formation of $[IrF_4]$ in high yields (95–100%) was reportedly obtained upon hydrogen reduction of $[IrF_6]$ or $[IrF_5]$. Polyisotopic mass spectra, visible and IR spectra, as well as chemical analyses and X-ray powder patterns support the proposed composition.[473] $(NO)_2[IrF_6]$ has been synthesized by the action of NOF and F_2 on metallic iridium, and analyzed by resonance Raman spectroscopy.[474]

Hexachloroiridates(IV) may be prepared by (i) chlorinating a mixture of iridium powder and an alkali metal chloride; (ii) in solution, by the addition of an alkali metal chloride to a suspension of hydrous IrO_2 in aqueous HCl;[475] or (iii) by the oxidation of $[IrCl_6]^{3-}$ by O_2 in acidic media.[476–478] Oxidation by O_2 probably occurs *via* reaction (122), with $E^0 = +0.21$ V.[14] Fine[479] has suggested that the reverse of reaction (122) occurs in alkaline media. The black crystalline sodium salt $Na_2[IrCl_6]$ is water soluble, and is the usual starting material for the synthesis of other iridium(IV) coordination complexes. The resonance Raman spectrum of $(NBu_4)_2[IrCl_6]$ reveals anomalous polarization of all bands; this has been ascribed to Jahn–Teller distortions present in the excited electronic state.[475] The single-crystal electronic spectra of various $[IrCl_6]^{2-}$ salts have also been reported.[480]

$$4[IrCl_6]^{3-} + O_2 + H^+ \longrightarrow 4[IrCl_6]^{2-} + 2H_2O \quad (122)$$

Reduction of $[IrCl_6]^{2-}$ by a variety of agents has been cited. The reduction of $[IrX_6]^{2-}$ (Cl, Br) by 2-thiouracil and 2-thiopyrimidine follows second-order rate laws, first-order with respect to both the concentration of the oxidant and the reductant. A pH–rate profile as well as activation parameters have been presented, and a free radical mechanism proposed.[481] Reduction in aqueous alcoholic solution by aquated electrons, hydrogen and alkyl radicals was investigated by pulse radiolysis, and found to result in the production of $[IrCl_6]^{3-}$.[482] A kinetic examination of reaction (123) in aqueous solution shows that this outer-sphere electron transfer reaction proceeds by parallel paths first and second order in substrate (SCN^-).[483] The kinetics of the oxidation of hydrazine by $[Ir(Cl)_4(H_2O)_2]$, $[Ir(Cl)_5(H_2O)]^-$, $[IrCl_6]^{2-}$, as well as $[IrBr_6]^{2-}$, in aqueous acidic perchlorate solution have been investigated.[484]

$$6[IrCl_6]^{2-} + SCN^- + 4H_2O \longrightarrow 6[IrCl_6]^{3-} + SO_4^{2-} + CN^- + 8H^+ \quad (123)$$

The *j–j* model has been employed to assign ligand-to-metal charge-transfer bands in the absorption and MCD spectra of $(NBu_4)_2\{trans\text{-}[Ir(Cl)_4(Br)_2]\}$ and $(NEt_4)_2\{trans\text{-}[Ir(Br)_4(Cl)_2]\}$.[485] Irradiation of CT or *d–d* absorption bands of $[IrCl_6]^{2-}$ results in substitution and redox processes.[486] Irradiation at 254 nm (CT bands) produces $[Ir(Cl)_5(H_2O)]^-$ and $[Ir(Cl)_5(H_2O)]^{2-}$; by contrast, *d–d* band irradiation yields only $[Ir(Cl)_5(H_2O)]^-$, except in the presence of added Cl^- when $[IrCl_6]^{3-}$ is formed.

Salts of $[IrBr_6]^{2-}$ are obtained by repeated treatments of the corresponding chloro complexes with HBr. The reaction between $[IrBr_6]^{2-}$ and Cr^{II} proceeds, at least in part, through an inner-sphere redox mechanism in two stages. Initially, Ir^{IV} and Cr^{II} react *via* parallel inner- and outer-sphere paths to give $[(Br)_5Ir^{III}BrCr^{III}(H_2O)_5]$, and $[IrBr_6]^{3-}$ and $[Cr(H_2O)_6]^{3+}$, respectively. Subsequently, the binuclear species dissociates *via* a parallel bond-rupture process to yield $[Ir(Br)_5(H_2O)]^{2-}$ and $[Cr(Br)(H_2O)_5]^{2+}$.[487] The reaction between $[IrCl_6]^{2-}$ and Cr^{II} also proceeds through parallel inner- and outer-sphere reactions.[488] A kinetic investigation of reaction (124) in aqueous solution reveals a similar mechanism to that exhibited in reaction (123).[483]

$$2[IrBr_6]^{2-} + 2I^- \longrightarrow 2[IrBr_6]^{3-} + I_2 \quad (124)$$

49.8 IRIDIUM(V) AND IRIDIUM(VI)

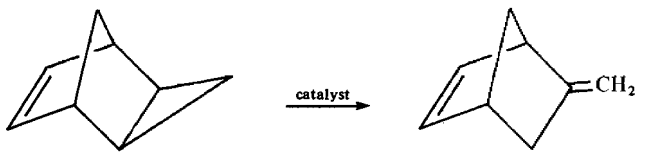
49.8.1 Iridium(V)

Very few iridium(V) (d^4) complexes are known; for those known, hydride or halogen ligands are usually present.

The iridium(V) fluoro complex $[IrF_5]$ has been prepared *via* reduction of $[IrF_6]$ with silicon or dihydrogen.[473] In the gas phase, $[IrF_5]$ possesses D_{3h} symmetry,[489] while in the solid state, a fluoride-bridged polymeric structure with bridges mutually *cis* is indicated on the basis of IR[473] and ^{19}F NMR studies.[490] $M[IrF_6]$ (M = alkali metal) has been obtained from the reaction of $[IrBr_3]$, KBr and BrF_3.[491] $(NO)[IrF_6]$, $[SeF_4][IrF_5]$ and $[SeF_4][IrF_5]_2$ have also been reported.[492]

The pentahydride complexes $[Ir(H)_5(PR_3)_2]$ ($PR_3 = PMe_3$,[493] PEt_2Ph[494]) have been prepared and characterized by IR and NMR spectroscopy. $[Ir(H)_5(PMe_3)_2]$ exhibits one of the most intense Ir—H absorptions at 1920 cm^{-1}. The ^{31}P NMR spectrum of this complex established the presence of five magnetically equivalent hydride ligands.[493] The IR and ^1H NMR spectra of $[Ir(H)_5(PEt_2Ph)_2]$ have also been reported.[494]

49.8.2 Iridium(VI)



Direct fluorination of metallic iridium at 543 K has produced the rather unstable, yellow d^3 complex $[IrF_6]$, which is isomorphous with its osmium(VI) analogue. $[IrF_6]$ tends toward dissociation, yielding fluorine and lower iridium fluorides. The octahedral $[IrF_6]$ species decomposes in water; this is accompanied by ozone liberation. The magnetic moment of $[IrF_6]$ is $\mu_{eff} = 3.3$ BM at 300 K.[492b]

49.9 CATALYTIC ACTIVITY OF IRIDIUM COORDINATION COMPLEXES

Iridium coordination complexes are known to serve as homogeneous catalysts in a wide variety of reactions, including hydrogenation of C—C multiple bonds, isomerization of alkenes, dienes and alkynes, and oxidation of various organic substrates. In general, the iridium complex catalysts are less active than their rhodium analogues, presumably due to the increased activation energy required for substance coordination as well as the rearrangement within the coordination sphere.

Iridium(I) complexes are well suited for hydrogenation catalysis owing to their ready capability to undergo addition. Vaska-type complexes, $[Ir(X)(CO)(PPh_3)_2]$, iridium(I) and iridium(III) hydride complexes have been shown to catalyze such reactions efficiently; the substrates catalytically hydrogenated by these complexes are collected in Table 3. The isomerization of alkenes and dienes, as well as the oxidation of several organic substrates, are catalyzed by iridium complexes in homogeneous solution; these are summarized in Tables 4 and 5, respectively. Several other types of reactions are catalyzed by iridium complexes in homogeneous solution as well; among them are ring-opening, disproportionation, deuterium exchange, cyclotrimerization, SO_2 elimination, C—H bond activation, decarbonylation (and carbonylation) and hydrogen transfer processes.

In the presence of catalytic amounts of $[Ir(Cl)(CO)(PPh_3)_2]$, *exo*-tricyclo[3.2.1.$0^{2,4}$]oct-6-ene (**221**) rearranges selectively and quantitatively to 5-methylenebicyclo[2.2.1]hept-2-ene (**222**) upon heating at 403 K in benzene (reaction 125).[495] Under similar conditions, *exo,exo*-tetracyclo[3.3.1.$0^{2,4}$.$0^{6,8}$]nonane (**223**) rearranges to *exo*-6-methylenetricyclo[3.2.1.$0^{2,4}$]octene (**224**) (reaction 126).[495]

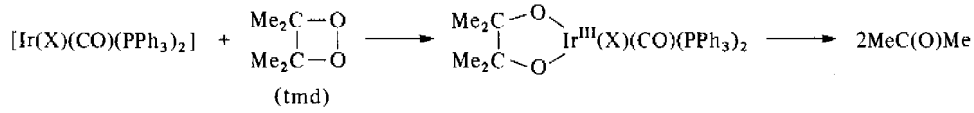
$[Ir(Cl)(CO)(PPh_3)_2]$	NO, CO	544, 545
$[Ir(Cl)(CO)_2(PPh_3)_2]$	NO, CO	544, 545
$[Ir(Cl)(PPh_3)_3]$	NO, CO	544, 545
$[Ir(CO)_3(PPh_3)_2]^+$	NO, CO	544, 545
$[Ir(Cl)(N_2)(PPh_3)_2]$	NO, CO	544, 545
$[Ir(CO)(PPh_3)_2(solvent)]^+$	NO, CO	544, 545
$[Ir(Br)(NO)_2(PPh_3)_2]$	NO, CO	544, 545
$[Ir(NO)_2(PPh_3)_2]^+$	NO, CO	544, 545
$[Ir(C)(XO)(O_2)(PPh_3)_2]$	α-Methylstyrene, cyclohexene	546
$[Ir(Cl)(cod)]_2$	Cyclooctene	547

The disproportionation of cyclohexa-1,4-diene to benzene and cyclohexane is catalyzed by $[Ir(X)(CO)(PPh_3)_2]$ (X = Cl, I), $[Ir(Cl)(CO)(AsPh_3)_2]$ and $[Ir(H)_2(Cl)(CO)(PPh_3)_2]$.[496] The iridium(I) complex $[Ir(cod)(MeCN)_2]^+$ reportedly catalyzes both the disproportionation of cyclohexa-1,3-diene to benzene and cyclohexene, as well as the isomerization of cyclohexa-1,4-diene to the conjugated isomer.[497] $[Ir(Cl)_2(C_5Me_5)]_2$ catalyzes the disproportionation of acetaldehyde to acetic

acid and ethanol in water in the absence of base.[498] The disproportionation of $PhMeH_2$ is also catalyzed by Vaska's complex.[499]

Barefield *et al.*[493] report that $[Ir(H)_5(ER_3)_2]$ (ER_3 = $PPhEt_2$, PEt_3, PMe_3) catalyzes the exchange between D_2 and benzene, probably *via* oxidative addition of the C—H bond to a coordinately unsaturated intermediate species. Also, Vaska's complex catalyzes the exchange between D_2 and C_2H_4, concomitantly with hydrogenation.[500]

$[Ir(Cl)(N_2)(PPh_3)_2]$ reacts with dialkyl acetylenedicarboxylates to form complex (**225**) *via* N_2 displacement. The complex (**225**) may react with an alkyne at 383 K to yield the iradacyclopentadiene complex (**226**) and then hexasubstituted benzenes (Scheme 23).[501]



Scheme 23

The elimination of sulfur dioxide from arenesulfonyl chlorides is catalyzed by Vaska's complex,[502] while this same iridium complex apparently catalyzes the aromatization of various 1,4-dihydro derivatives of aromatic hydrocarbons.[503]

The diphosphine complexes $[Ir(dppe)_2]^+$ and $[Ir(dppe)(cod)]^+$ reportedly catalyze the decarbonylation of aldehydes.[504,505] Methanol carbonylation is catalyzed by $[Ir(Cl)_4]\cdot H_2O$ to yield acetic acid. The active species is thought to be an acetyl iridium(III) species, wherein the rate-determining step involves electrophilic attack of this species on methanol. The effects of added iodide ion on reaction rates have also been investigated.[506]

Hydrogen transfer reactions are catalyzed by several iridium complexes, including the dimethyl sulfoxide (DMSO) complexes *cis*- and *trans*-$[Ir(Cl)_4(DMSO)_2]^-$, $[Ir(Cl)_3(DMSO)_3]$ and $[Ir(H)(Cl)_2(DMSO)_3]$,[507] as well as the cyclooctadiene (cod) complexes $[Ir(Cl)(cod)]_2$[508] and $[Ir(3,4,7,8\text{-}Me_4phen)(cod)]^+$,[509] and *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$.[510] Vaska's complex catalyzes the conversion of *p*-methoxybenzoyl chloride to the corresponding aldehyde.[510] The dimethyl sulfoxide iridium(III) complexes catalyze hydrogen transfer from propan-2-ol to unhindered cyclohexanones to yield cyclohexanols,[507] while the cod complexes serve as catalysts in the transfer of hydrogen from propan-2-ol to alkenes, ketones[508] and α,β-unsaturated ketones.[509]

Additionally, $[Ir(X)(CO)(PPh_3)_2]$ (X = Cl, Br) catalyzes the cleavage of tetramethyl-1,2-dioxetane (tmd), presumably *via* reactions depicted in Scheme 24.

Scheme 24

The redistribution of siloxanes has been observed[512] to be catalyzed by Vaska's complex. The water-gas shift reaction is homogeneously catalyzed by iridium complexes, including $[Ir(L)_2(cod)]^+$ where $(L)_2$ is $(PMePh_2)_2$, $(PPh_3)_2$, dppe, phen, 4,7-Ph_2phen, 4,7-Me_2phen, 3,4,7,8-Me_4phen or phenS (phenS = 4,7-diphenyl-1,10-phenanthrolinesulfonate). The catalytic activity increases for those catalysts with bidentate (L_2) ligands and is sensitive to temperature.[513]

49.10 AD INTEGRATUM

The activity in the chemistry of iridium remains unabated. Since the writing of this chapter, several hundred papers have been published that are germane. These have been integrated below in terms of ligands bound to Ir.

49.10.1 Nitrosyl Ligands

The iridium(I) nitrosyl complex $[Ir(NO)(PPh_3)_3]$ reacts with perfluorocarboxylic acids RCO_2H in the presence and absence of O_2 to yield $[Ir(NO)(O_2CR)_2(PPh_3)_2]$. A crystal structure determination of the trifluoroacetate derivative $[Ir(NO)(O_2CCF_3)_2(PPh_3)_2]$ reveals an essentially trigonal bipyramidal coordination about Ir, with an equatorial linear NO ligand, unidentate carboxylate ligands and axial PPh_3 ligands.[548] NMR spectroscopy and gas uptake/evolution measurements have elucidated the role of O_2 in the conversion of $[Ir(NO)(PPh_3)_3]$ to $[Ir(NO)(O_2CCF_3)_2(PPh_3)_2]$.[549] The reaction of $[Ir(NO)(dppn)(PPh_3)_2](PF_6)_2$ or $[Ir(X)(NO)(dppn)(PPh_3)_2](PF_6)$ (dppn = bis(2′-pyridyl)pyridazine; X = Cl, Br, I) with $[Pd(Cl)_2(PhCN)_2]$ or with $[Pt(I)_2(cod = cyclooctadiene)$ gives mixed metal binuclear species, *e.g.* $[Ir(NO)(dppn)(PPh_3)_2(PdCl_2)](PF_6)_2$. IR and ^{31}P NMR spectroscopic results and conductivity measurements suggest a structure possessing a bridging NO, *i.e.* [Ir—N(O)—Pd].[550]

49.10.2 Nitrogen

The compounds $[Ir(cod)L_2](BF_4)$ have been prepared for which L is benzonitrile (bzn), phenylacetonitrile ($PhCH_2CN$), 4-methoxybenzonitrile (4-MeObzn) and 2-chlorobenzonitrile (2-Clbzn).[551] IR spectra are consistent with the coordination of the benzonitrile ligand *via* the free electron pair of the nitrogen atom. Also, the complexes $[Ir(cod)L_2]A$, where L = 2-methylpyridine, 2-ethylpyridine, 5-nitro-6-methylquinoline, quinoline, 4,7-dichloroquinoline and [Ir(cod)(L—L)]A, where L is succinonitrile, 8-aminoquinoline, ethylenediamine, 1,2-diphenylethylenediamine, and *N,N,N′,N′*ptetramethylethylenediamine, have also been synthesized.[551] Nitriles, $Na(RCN)_4$, add to azide ligands of $[Ir(N_3)(CO)(PPh_3)_2]$ to give the 5-R-tetraazolato complexes $[Ir(CO)(N_4CR)(PPh_3)_2]$ (R = Me, CF_3).[552] Amino-, phosphino- and thionitriles also add, *via*, 1,3-cycloaddition, to azide ligands of $[Ir(N_3)(CO)(PPh_3)_2]$ to give corresponding 5-*R*-tetraazolato complexes.[553]

The dinuclear iridium(I) complex $[Ir(CO)(PPh_3)(\mu\text{-pz})]_2$ (pzH = pyrazolyl, $C_3N_2H_4$) is afforded *via* reaction between $[Ir(Cl(CO)(PPh_3)_2]$ and Napz.[554] The analogous complex $[Ir(cod)(\mu\text{-pz})]_2$ is obtained by reaction of $[IrCl(cod)]_2$ with pzH, followed by CO and PPh_3 treatment. The product reacts with I_2 or Br_2 to form $[IrX(CO)(PPh_3)(\mu\text{-pz})]_2$ (X = I, Br), and with Cl_2 to give $[Ir(Cl)(CO)(PPh_3)(4\text{-Clpz})]_2$.[555] The synthesis and characterization of a number of iridium(I) complexes containing the bidentate, chelating pyrazolylgallate ligand Me_2Gapz has been reported.[556] Crystal structural studies of $[Ir(cod)(Me_2Gapz)]$, $[Ir(CO)_2(\mu\text{-pz})]_2$ and $[Ir(CO)_2(\mu\text{-3,5-Me}_2pz)]$ have confirmed the expected boat conformations for the six-membered M—(N—N)$_2$—Ir rings (M = Ir, Ga).

Oxidative addition of MeI to the iridium(I) complex $[Ir(\mu^2\text{-}C_8H_{14})\{N(SiMe_2CH_2PR_2)_2\}]$ (R = Ph, Pr^i) yields monomeric, five-coordinate complexes of the type $[Ir(I)(Me)\{N(SiMe_2CH_2PR_2)_2\}]$. Spectroscopic and crystallographic measurements reveal the complexes to have a square pyramidal geometry with the methyl ligand in an apical position. In the presence of H_2, these complexes rapidly form the iridium(III) amine hydrides $[Ir(I)(H)(Me)\{NH(SiMe_2CH_2PR_2)_2\}]$ with a stereochemistry corresponding to an overall *trans* addition of H_2.[557] It appears that H_2 activation by these iridium complexes occurs *via* an oxidative addition/reductive transfer pathway rather then a direct heterolytic cleavage of H_2.

$[Ir(Cl)_3(PPh_3)_3]$ reacts with NaN_3 in alcoholic solution giving *cis*-$[Ir(H)_2(N_3)(PPh_3)_3]$; on exposure to light, the product releases H_2 and $[Ir(N_3)(PPh_3)_3]$ in a reversible manner. The crystal structure of the dihydride shows one H ligand is *trans* to N_3 and the other H ligand is *trans* to a PPh_3 ligand.[558]

Base hydrolysis of *cis*-$[Ir(Cl)_2(en)_2](Cl)$ gives *cis*-$[Ir(OH)(en)_2(H_2O)](S_2O_6)$ in 80% yields. By contrast, a 3:2 mixture of *cis*- and *trans*-$[Ir(OH)(en)_2(H_2O)](ClO_4)_2$ is obtained from the base hydrolysis of *trans*-$[Ir(Cl)_2(en)_2](Cl)$, as indicated by chemical analyses, electronic spectra and potentiometric titrations. The concentration acidity constants are: $K_{a1} = 10^{-6.290\pm0.007}$ and

$K_{a2} = 10^{-8.097\pm0.009}$ mol l^{-1} for the *cis* isomer, and $K_{a1} = 10^{-4.798\pm0.004}$ and $K_{a2} = 10^{-7.856\pm0.010}$ mol l^{-1} for the *trans* isomer.[559] The properties of the iridium(III) species $[Ir(en)_3]_2[Cu_2Cl_8]Cl_2 \cdot 2H_2O$ were characterized by EPR spectroscopy, magnetic susceptibility measurements and X-ray diffractometry. The crystal structure suggests layers of magnetically inequivalent $Cu_2Cl_8^{4-}$ dimers with antiferromagnetic intradimer coupling. The dimers appear well separated by large $[Ir(en)_3]^{3+}$ dimagnetic complexes.[560]

Complexes of the type $[Ir(H)_2L'(PPh_3)_2]A$ (L′ = 8-methylquinoline, caffeine) each posses a C—H---Ir bridge, structurally characterized for the methylquinoline case where A = SbF_6. On the basis of the C—H + M → C—M—H reaction trajectory, the authors propose that for a given metal species capable of breaking C—H bonds,[561] conformational and steric effects will play an important role in determining whether cyclometallation or attack on an external substrate (*e.g.* alkane) will occur. Moreover, it would seem that sterically uncongested metal systems will favour the occurrence of alkane activation, rather than cyclometallation.[561] The triply *o*-metallated complex *fac*-$[Ir(ppy)_3]$ (ppy = 2-phenylpyridine) has been characterized in its ground and luminescent excited states.[562] The dichloro-bridged dimers $[Ir(Cl)L_2]_2$ (L = 2-phenylpyridine (ppy), benzo[*h*]quinoline (bzq)] were investigated by ^{13}C and ^1H NMR and by absorption and luminescence spectroscopy. The NMR results confirm previous formulation of the complex as dichloro-bridged *o*-metallated dimers in halocarbon solvents, but indicate they are cleaved to monomeric species of the type $[Ir(Cl)L_2(S)]$ (S = solvent, *e.g.* DMF) in ligating solvents S. Comparison of the results suggests that the *o*-metallated ligands are considerably higher than bipy or phen in the spectrochemical series.[563] The observations are consistent with the synergistic function of the *o*-metallated ligands as both strong σ donors and π acceptors.

cis-$[Ir(bipy)_2(OSO_2CF_3)_2](CF_3SO_3)$ has been isolated and employed in the synthesis of new hydrido complexes of iridium(III): *cis*-$[Ir(H)(bipy)_2(PPh_3)](PF_6)_2$ and *cis*-$[Ir(H)_2(bipy)_2](PF_6)$. Additionally, an improved high-yield synthesis of $[Ir(bipy)_3](PF_6)_3$ has been reported.[564] The two *bis* bipyridyl complexes have interesting spectral and electrochemical properties. Ohashi and Nakamura[565] have obtained the emission decay curves of *cis*-$[Ir(Cl)_2(bipy)_2](Cl)$, *cis*-$[Ir(Cl)_2(phen)_2](Cl)$, *cis*-$[Ir(Cl)_2(4,7\text{-}Me_2phen)_2](Cl)$ and *cis*-$[Ir(Cl)_2(5,6\text{-}Me_2phen)_2](Cl)$. The spectra exhibit a dependency on the solvent character of the DMF/H_2O mixed solvents at 77 K and at 298 K. It appears there are at least two kinds of emitting states for these species in DMF/H_2O solvents. The iridium(III) bipyridyl complex $[Ir(C^3,N'\text{-bipy})(bipy)_2]^{2+}$ is an attractive photosensitizer in aqueous bromide solutions. Based on product analysis, steady-state emission and pulsed laser experiments, the photosensitization proceeds along a mechanism that involves two exciplexes and the transients $Br_2^- \cdot$ and HO_2.[566]

The complexes of *p*-dimethylaminoanil and of 3-acetyl-4-hydroxycoumarin glyoxal with some third row transition metal ions (Ir^{3+}, Pr^{4+}, UO_2^{2+}) have been produced, and $[Ir(C_{19}H_{15}O_4N_2)_2](Cl)$ has been characterized by IR spectroscopy and magnetic measurements.[567]

The thermally stable, Schiff base complexes $[M(PPD)(Cl_x] \cdot yH_2O$ (M = Ir, Pt; $x = 4$; PPD = *p*-$Me_2C_6H_4CH{=}N(CH_2)_3NH_2$) have been prepared; characterization by IR spectroscopy shows the dimethylamino and free amino groups to be the coordinating sites. Further characterization by magnetic moment measurements and NMR and electronic spectral data indicates the iridium(IV) complex to be octahedral.[568]

49.10.3 Phosphorus Ligands

The complexes *trans*-$[Ir(Cl)L\{P(CHMe_2)_3\}_2]$ (L = CO, py, MeCN) were prepared from $[Ir(Cl)(cod)_2]_2$ *via* the intermediate $[Ir(Cl)\{P(CHMe_2)_3\}_2]$ complex. *trans*-$[Ir(Cl)(CO)\{P(CHMe_2)_3\}_2]$ reacts with LiC_2Ph to give *trans*-$[Ir(C_5Ph)(CO)\{P(CHMe_2)_3\}_2]$, which, on treatment with HX, yields $[Ir(H)(X)C_2Ph(CO)\{P(CHMe_2)_3\}_2]$ (X = Cl, CF_3CO_2). *trans*-$[Ir(Cl)(N_2)\{P(CHMe_2)_3\}_2]$ is obtained from the carbonyl complex and 2-furfuryl azide.[569] Some new mono- and di-nuclear iridium(I) complexes containing the *bis*(tertiary phosphine) ligands $Ph_2P(CH_2)_nPPh_2$ ($n = 2$, dppe; $n = 3$, dppp) have been prepared, and the formation of iridium(III) hydrides by H_2 oxidative addition has been studied by Fisher and Eisenberg.[570] The dinuclear complexes $[Ir(X)(CO)(dppp)]_2$ (X = Br, I) possess *trans* phosphine donors, with the dppp ligands bridging the iridium(I) centre. All the dppp complexes are mononuclear, with dppp serving as a chelating ligand. The complexes $[M(CN)_2(dppmP)_2]$ (M = Pt, Pd), when treated with $[Ir(Cl)(CO)_2(NH_2C_6H_4Me\text{-}p)]$ or *trans*-$[Ir(Cl)(CO)(PPh_3)_2]$, give the heterometallics $[Ir(Cl)(CO)(\mu\text{-dppm})_2M(CN)_2]$.[571] The treatment of $[Ir(CNB^t)_2(\mu\text{-dppm})]_2(Cl)_2$ with dppm gives labile systems at 293 K. At 213 K, ^{31}P–^1H NMR spectroscopy reveals complete conversion to the *tris*-monodentate dppm complexes

$[Ir(CNBu^t)_2(dppmP)_3](Cl)$. Reaction of $[Ir(Cl)(cod)_2]_2$ with four equivalents of dppm, six equivalents of Bu^tCN, and two equivalents of $[Au(Cl)(PPh_3)]$ yields the fluxional molecule $[Ir(CNBu^t)_3(\mu\text{-dppm})_2Au](Cl)_2$; however, reaction between $[Ir(CO)(dppmPP')_2](Cl)$ and $[Ag(Cl)(CNBu^t)]$ affords $[Ir(CNBu^t)(CO)(\mu\text{-dppm})_2Ag(Cl)]$.[572]

Some novel five-coordinate iridium(I) complexes of the type $[Ir(CO)(chel\text{-}P_3)(R)]$ (chel-P_3 = $PhP(CH_2CH_2CH_2PPh_2)_2$, R = CH_2CMe_3, CH_2SiMe_3; chel-P_3 = $MeP(CH_2CH_2CH_2PPh_2)_2$, R = CH_2SiMe_3; chel-P_3 = $PhP(CH_2CH_2PPh_2)_2$, R = CH_2SiMe_3, 4-MeC_6H_4) have been synthesized from $[Ir(CO)(PPh_3)_2(R)]$ and the respective triphosphine. ^{31}P NMR studies show these complexes to be stereochemically rigid at normal temperatures.[573] Reaction between $[Ir(\eta^4\text{-cod})(\eta^3\text{-}2\text{-}XC_3H_4)]$ (X = Me, H) and di-*t*-butylphosphine gives $[Ir(\eta^4\text{-cod})(\eta^3\text{-}C_3H_5)\{PH(Bu^t)_2\}]$. X-Ray crystallographic investigations suggest that where X = Me the complex possesses the square pyramidal geometry with the phosphine ligand in an axial position.[574]

In the complex $[Ir(\eta^2\text{-}o\text{-}BrC_6H_4PPh_2)(cod)](SbF_6)$, $o\text{-}BrC_6H_4PPh_2$ chelates to Ir *via* P and the Br bound to the aromatic ring. The complex reacts with Cl^- to give $[Ir(Cl)(\eta'\text{-}BrC_6H_4PPh_2)(cod)]$, with MeCN to produce $[Ir(\eta'\text{-}BrC_6H_4PPh_2)(cod)(MeCN)](SbF_6)$, and with H_2 to yield $[Ir(H)_2(\eta^2\text{-}o\text{-}BrC_6H_4PPh_2)(cod)(SbF_6)$.[575] Reaction between Vaska's complex and the phosphine–thiol chelate (diphenylphosphino)ethanethiol (PSH) gives $[Ir(H)(CO)(PS)(PSH)](Cl)$.[576] Two equivalents of *o*-(diphenylphosphino)benzoylpinacolone (HacacP) react with $[Ir(Cl)(CO)_2(p\text{-}NH_2C_6H_4Me)]$ giving $[Ir(Cl)(CO)(HacacP)_2]$, which undergoes smooth metallation with copper(II) carboxylates to give $[Ir(Cl)(CO)\{Cu(acacO)_2\}]$. The *trans*-$[Ir(Cl)(CO)\{Zn(acacP)_2\}]$ complex can be synthesized by treating $ZnEt_2$ with two equivalents of HacacP followed by $[Ir(Cl)(CO)_2(p\text{-}H_2NC_6H_4Me)]$. EPR data for the Ir—Cu complex indicate the formation of an enolate bridge between Ir and Cu.[577]

The solid state structure of $[Ir(Cl)(PF_3)_2]_2$ consists of infinite zigzag chains of Ir atoms with short inter- and intra-molecular Ir---Ir contacts. By contrast, related complexes containing PF_2NMe_2, *e.g.* $[Ir(Cl)(PF_2NMe_2)_3]$ and $[Ir(Cl)(PFNMe_2)_2]_2$, do not appear to have extended metal–metal interactions.[578] ^{31}P spin–lattice relaxation times T_1, and ^{31}P–^1H nuclear Overhauser enhancement values for $CDCl_3$ solutions of the compounds $P(C_6H_4\text{-}p\text{-}X)_3$, $[Ir(Cl)(CO)\{P(C_6H_4\text{-}p\text{-}X)_3\}_2]$ (X = H, Me, F, Cl, OMe) and $[Au(Cl)\{P(C_6H_4\text{-}p\text{-}X)_3\}]$ (X = H, OMe) have been determined.[579] For the uncoordinated tertiary phosphines T_1 = 26–28 s, except for X = OMe, where T_1 = 14 s. For the iridium(I) complexes, T_1 = 4.4–8.7 s, whereas for the gold(I) compounds, T_1 = 15.7 s (H) and 11.3 s (OMe). Differing relaxation mechanisms within each class of compound seem to be indicated by the data.[579]

Vaska's complex reacts with F-*t*-butyl hypochlorite to yield a complex tentatively postulated as $[Ir(Cl)(CO)\{(CF_3)_3CO\}_2(L)_2]$, where L presumably is a complex ligand containing $(CF_3)_3CO$ and Cl groups.[580] Stang and coworkers[581] have determined the k_H/k_{D3} (= secondary kinetic deuterium isotope effect) values for the reaction of $[Ir(Cl)(CO)(PPh_3)_2]$ with MeI (k_H/k_{D3} = 0.93) and MeO-SO_2CF_3 (k_H/k_{D3} = 1.13) at 308 K in toluene. The values are consistent with a Menschutkin-type S_N2 displacement process. Reaction of Vaska's complex with $Li[W(CO)_5(PPh_2)]$ yields the dinuclear complex $[IrW(\mu\text{-}PPh_2)(CO)_6(PPh_3)_2]$. Also, reaction between Vaska's complex and $Li[W(CO)_4(PPh_2H)(PPh_2)]$ gives $[IrW(H)(CO)_5(\mu\text{-}PPh_2)_2(PPh_3)_2]$, characterized by X-ray diffractometry. The hexacarbonyl complex above adds H_2 and CO at the Ir centre, while the pentacarbonyl complex reacts with LiPh and LiMe to yield the acyl–halide derivatives $[Li(THF)_x][IrW(H)(CO)_4(\mu\text{-}PPh_2)_2(PPh_3)C(O)R]$ (R = Ph, Me) with the acyl ligand terminally bound to W and the hydride to Ir.[582] PH_3 adds oxidatively in toluene to *trans*-$[Ir(X)(XO)(PEt_3)_2]$ (X = Br, Cl) to give $[Ir(X)(H)(CO)(PEt_3)_2(PH_2)]$. The $[Ir(X)(H)(CO)(PEt_3)_2(AsH_2)]$ complexes have also been isolated. The complexes were characterized by ^1H and ^{31}P NMR spectroscopy. $[Ir(H)(CO)(PEt_3)_2(PH_2)(PH_3)]^+$ is produced upon reaction of *trans*-$[Ir(X)(CO)(PEt_3)_2]$ and PH_3 in CH_2Cl_2 at 180 K, followed by internal oxidative addition at greater than 230 K.[583]

Dimethyl- and diethyl-phosphine oxide, methylphosphonite, and ethylmethylphosphonite all add oxidatively to $[Ir(Cl)(Me_2PhP)_3]$ to produce hydrido(dialkylphosphinito) or alkyl(alkylphosphinito) iridium(III) complexes, $[Ir(Cl)(H)(PPhMe_2)_3\{P(O)RR'\}]^+$. The nature of these species was ascertained by ^1H and ^{31}P NMR.[584] $[Re(H)_3(\eta^4\text{-}C_5H_6)(PPh_3)_2]$ reacts with $[Ir(Br)(CO)(dppe)]$ in C_6D_6 to give $[Re(H)_2(Cp)(PPh_3)_2]$ and $[Ir(Br)(H)_2(CO)(dppe)]$. The isomer of the iridium complex formed exclusively is the thermodynamically favoured isomer having H *trans* to P and Br. The driving force for the dehydrogenation of the Re complex by the Ir complex is attributed to the stronger M—H bond for iridium and the greater thermodynamic stability of the dehydrogenated product $[Re(H)_2(Cp)(PPh_3)_2]$.[585]

Homobimetallic iridium(I) complexes containing the binucleating PNNP ligand undergo oxidative addition and reductive elimination reactions with acetyl chloride and methyl iodide. Thus,

$[Ir_2(\mu\text{-}PPh_2)(CO)(PNNP)]$ reacts in two successive irreversible oxidative addition steps with either acetyl chloride or methyl iodide to give the diacyl $[Ir_2(\mu\text{-}PPh_2)(CO)_2(PNNP)(MeCO)_2(Cl)_2]$ and dimethyl $[Ir_2(\mu\text{-}PPh_2)(CO)_2(PNNP)(Me)_2(I)_2]$ complexes, respectively, in which iridium is Ir^{III}.[586]

The hydrido-bridged dinuclear complexes $[Ir(Cl)(L)_3(\mu\text{-}H)(\mu\text{-}Cl)Rh(dppe)]^+$ can be prepared by reacting $[Rh(acetone)_2(dppe)]^+$ with *mer,trans*-$[Ir(Cl)_2(H)(L)_3]$ (L = PMe_2Ph, PEt_2Ph, PEt_3, dppe). The X-ray crystal structure of the dinuclear complex shows a distorted octahedral coordination around Ir. In a similar manner, one can produce the isoelectronic complex $[Ir(H)(PEt_3)_3(\mu\text{-}Cl)(\mu\text{-}H)Rh(dppe)](BF_4)$ from *mer,cis*-$[Ir(Cl)(H)_2(PEt_3)_3]$.[587] $[Ir(H)_5(PEt_3)_2]$ reacts with complexes containing the 'RhClL$_2$' moiety (L = PEt_3 or L_2 = dppe) to give $[Ir(H)_2(PEt_3)_2(\mu\text{-}Cl)(\mu\text{-}H)Rh(L)_2]$. The crystal structure of $[Ir(H)_2(PEt_3)_2(\mu\text{-}Cl)(\mu\text{-}H)Rh(PEt_3)_2]$ indicates a distorted octahedral geometry about Ir, with the bridging chlorine atom asymmetrically bonded to both Ir and Rh.[588]

Reaction of Vaska's complex with the functionalized silanes $PPh_2CH_2CH_2SiR'R''H$ (R′ = R″ = Me, Ph; R′ = Me, R″ = Ph; R′ = Me, Ph, R″ = H) yields the iridium(III) adducts $[Ir(Cl)(^nH)(CO)(PPh_2CH_2CH_2SiR'R'')(PPh_3)]$ (n = 1, 2). The complexes are chiral at Ir; however, while the complexes with R′ = R″ = Me and R′ = R″ = Ph are enantiomeric, those with R′ = Me, R″ = Ph, R′ = Me, R″ = H, and R′ = Ph, R″ = H are diastereomeric.[589] The five-coordinate iridium(III) complex $[Ir(Cl)(PPh_2CH_2CH_2SiMe_2)_2]$, prepared *via* reaction of $[Ir(Cl)(cod)]_2$ and excess $PPh_2CH_2CH_2SiMe_2H$ in THF solution, has been characterized by IR and ^1H NMR spectroscopy and by X-ray diffractometry. The complex reacts with NaX (X = Br, I) in acetone to give $[Ir(X)(PPh_2CH_2CH_2SiMe_2)_2]$.[590] Auburn *et al.*[591] have described the synthesis of a chelate-silyl iridium(I) complex from iridium(III) *via* reductive elimination. Thus, photolysis of $[Ir(H)_2(CO)(PPh_2CH_2CH_2SiMe_2)(PPh_3)]$ evacuated in THF gives < 30% yield of $[Ir(CO)(PPh_2(CH_2CH_2SiMe_2)(PPh_3)]$. In a CO atmosphere, the same reaction gives > 80% yield of the same product. Crystal structural studies of the iridium(I) complex show a five-coordinate Ir atom with Si in an axial position *trans* to PPh_3, and two CO ligands in the equatorial plane.[591]

Rhodes and coworkers[592] have reported on the unexpected results of reaction between Cu^I and the *mer* and *fac* isomers of $[Ir(H)_3(P)_3]$, where P is PMe_2Ph. ^1H NMR spectroscopy has identified $[\{mer\text{-}Ir(H)_3(P)_3\}_2Cu](PF_6)$ as the product of reaction between $[Cu(MeCN)_4](PF_6)$ and two equivalents of *mer*-$[Ir(H)_3(P)_3]$ in THF. In the addition of $[Cu(MeCN)_4(PF_6)$ to $[\{fac\text{-}Ir(H)_3(P)_5\}_2Cu](PF_6)$, there is no conversion of the *fac* to the *mer* isomer in MeCN at 298 K over several hours. The Ag^I adduct of *fac*-$[Ir(H)_3(P)_3]$ has also been synthesized.[592] The stoichiometric protonation of *fac*-$[Ir(H)_3(P)_3]$ in $CDCl_3$ using $HBF_4 \cdot Et_2O$ shows complete conversion to $[Ir(H)_4(P)_3]^+$. The latter possess a pentagonal bipyramidal structure at 193 K. Protonation of *mer*-$[Ir(H)_3(P)_3]$ yields an identical product. Although spectroscopically undetectable, H_2 elimination from $[Ir(H)_4(P)_3]^+$ would seem to give rise to $[Ir(H)_2(L)(P)_3]^+$ (L = N_2, CO, MeCN). In essence, what has occurred is reductive elimination (Ir^V to Ir^{III}).[593] An investigation of the Cu^+/*fac*-$[Ir(H)_3(PMe_2Ph)_3]$ system at Ir:Cu stoichiometries of less than 2:1 has led to evidence of an unexpected yet isolable aggregate. At an Ir:Cu ratio of 2:3, the product is consistent with the formulation $[Ir_2Cu_3(H)_6(MeCN)_3(PMe_2Ph)_6](PF_6)_3$.[594]

The X-ray crystal structure of $[Ir(Cl)_2(C_3H_5)(CO)(PMePh_2)_2]$[595] and $[Ir_4(CO)_8(PMe_2Ph)_4]$[596] have been determined.

49.10.4 Arsenic and Antimony Ligands

Pentacoordinate iridium(I) complexes of the general formula $[Ir(Cl)L_2(TFB)]$ or $[Ir(Cl)(L{-}L)(TFB)]$ (TFB = tetrafluorobenzobicyclo[2.2.2]octatriene; L = PPh_3, $AsPh_3$, $SbPh_3$; L—L = dppe, bipy, phen) have been synthesized from $[Ir(Cl)(TFB)_2]$ and the appropriate ligand.[597] Bis(diphenylphosphinomethyl)phenyl arsine, dpma, reacts with $[Ir(Cl)(CO)(p\text{-toluidine})]$ to give $[Ir_2(Cl)_2(CO)_2(\mu\text{-dpma})_2]$. The latter dimeric complex subsequently reacts with bis(benzonitrile)palladium(II) chloride in CH_2Cl_2 to obtain $[Ir_2Pd(Cl)_3(CO)_2(\mu\text{-dpma})_2](BPh_4)$. The dpma ligand is sufficiently flexible for it to accommodate a range of metal–metal interactions within the polynuclear units.[598]

49.10.5 Oxygen Ligands

Homo- and hetero-dinuclear bis(di-μ-amide or -oxo)iridium(I) complexes of formula $[MM'(\mu\text{-}L)(cod)_2]$ (L = 1,8-$(NH_2)_2$naphthalene, 1,8-$(O)_2$naphthalene, 2,3-$(O)_2$naphthalene) have been synthesized and characterized by IR spectroscopy.[599] Two different routes to the preparation of the first

iridium(I) carbon-bonded diketonate complex, [Ir(acac-C^3)(cod)(phen)], have been reported.[600] The crystal structure of this complex reveals pentacoordinate iridium in a distorted pyramidal stereochemistry. The synthesis and characterization of binuclear complexes containing the flexible bridging bis(2,4-pentanedionato) ligand have been cited.[601] Thus, $[Ir(cod)]_2\{xyl(acac)_2\}]$ is afforded upon reaction of $[Ir(\mu\text{-Cl})(cod)]_2$ with *p*-silylenebis[3-(2,4-pentanedione)], xyl(Hacac)$_2$. The methylene complexes $[Ir(I)(CO)(=CH_2)(PPh_3)_2]$ and $[Os(Cl)(NO)(=CH_2)(PPh_3)_2]$ form 1:1 adducts with SO_2, and an X-ray crystal structure determination of the osmium complex shows the sulfene fragment in $[Os(Cl)(NO)\{CH_2S(O)O\}(PPh_3)_2]$ to be C,O-bound forming a non-planar, four-membered ring with the S atom having pyramidal geometry.[602]

49.10.6 Boron Ligands

Reaction between $K[B_4H_9]$ and *trans*-$[Ir(Cl)(CO)(PMe_2Ph)_2]$ in the presence of an additional equivalent of KH gives $[Ir(\eta^4\text{-}B_4H_9)(CO)(PMe_2Ph)_2]$. In the crystalline state, this iridapentaborane consists of an open five-atom cluster in which the $[Ir(CO)(PMe_2Ph)_2]$ fragment occupies an apical vertex site and is bound to the four boron atoms of the $(\eta^4\text{-}B_4H_9)$ ligand.[603] $Li[CB_8H_{13}]$ reacts with $[Ir(Cl)(PPh_3)_3]$ in diethyl ether to produce several products, including *closo*-[1-PPh_3)-2,2,2-$H(PPh_3)_2$-2,10-$IrCB_8H_8$]. An X-ray diffraction study of this *closo* complex shows the ten-vertex cage to have bicapped Archimedean square antiprismatic geometry, with Ir in an equatorial position. The apical sites are occupied by the carbon, and a boron covalently bonded to the P of a PPh_3 ligand.[604] NMR spectroscopy characterized the *arachno*-6,9-dimetalladecarborane complex $[(PMe_3)_2Pt\text{-}B_8H_{10}Ir(H)(PMe_3)_2(CO)]$, obtained on deprotonation of an *arachno*-4-iridanoborane with KH followed by reaction with *cis*-$[Pt(Cl)_2(PMe_3)_2]$. Mild thermolysis or UV photolysis of the *arachno*-4-iridanoborane produces the corresponding *nido*-2-iridanoborane. This is the first *nido* nine-vertex metalloborane to be structurally characterized. The *arachno* → *nido* transformation, occurring *via* dihydrogen loss, follows first-order kinetics.[605]

49.10.7 Sulfur and Selenium Ligands

Claver and coworkers[606] have prepared the cationic iridium(I) complexes $[Ir(cod)(\mu\text{-L})]_2(ClO_4)_2$ and $[Ir(cod)\{\mu\text{-(L—L)}\}]_2$, where L is SMe_2, SEt_2, tetrahydrothiophene (tht), or trimethylene sulfide (tms), and (L–L) is 1,4-dithiacyclohexane (dt), $(SBu^t)_2(CH_2)_2$ (tmdto), or $(SMe)_2$. These same authors have also isolated the mononuclear complexes $[Ir(cod)(L)_2](ClO_4)$ (L = tht, tms) and [Ir(cod)(L—L)](ClO_4) (L—L = dth).[607] These react with H_2 to give the corresponding iridium(III) dihydride complexes, with $[Ir(cod)(L)_2]^+$ (L = tht, tms) react with one or two moles of PPh_3 to yield the pentacoordinate derivatives $[Ir(cod)(L)_2(PPh_3)]^+$ or $[Ir(cod)(L)(PPh_3)_2]^+$.

The thiolato-bridged dinuclear iridium(I) complexes $[Ir(CO)(L)(\mu\text{-}SBu^t)]_2$ react with dihalomethane to produce $[Ir(X)(CO)(\mu\text{-}SBu^t)]_2(\mu\text{-}CH_2)$ (X = I, L = CO, $P(OMe)_3$, PPh_3, PPh_2Me, PMe_2; X = Br, L = PPh_3). A crystal structure determination of $[Ir(I)(CO)(\mu\text{-}SBu^t)\{P(OMe)_3\}]_2(\mu\text{-}CH_2)$ reveals Ir to be octahedrally coordinated to one CO, one $P(OMe)_3$, one I, two bridging S atoms of the thiolato ligands, and the bridging C atom of the CH_2 group. The phosphite ligands are mutually *trans*, as are the carbonyl ligands.[608] $[Ir(dppe)_2(S_2O)]^+$ reacts with $MeOSO_2F$ to yield $[Ir(dppe)_2(\eta^2\text{-}S_2OMe)]^{2+}$, which has been characterized by X-ray crystallography, and which can be converted to $[Ir(dppe)(MeCN)(\eta^1\text{-SOMe})]^{2+}$ upon reaction with two equivalents of MeCN.[609] Teo and Snyder-Robinson[610] have elucidated the crystal structure of $[Ir(X)(CO)(PPh_3)_2(TCTTN)]\cdot C_6H_6\cdot MeCN$ (X = Cl, H; TCTTN = tetrachlorotetrathionaphthalene, $C_{10}Cl_4S_4$). The Ir atom is octahedrally coordinated to two *trans* PPh_3 ligands, two S atoms from TCTTN, one CO ligand and one X ligand. Crystallographic studies have characterized $[Ir(Cl)(H)(CO)(PPh_3)_2(SH)]$, obtained *via* reaction of Vaska's complex with H_2S in CH_2Cl_2 solutions.[611]

The stepwise oxidation of $[Ir(dppe)_2(\eta^2\text{-}S_2)](PF_6)$ with *m*-chloroperbenzoic acid gives $[Ir(dppe)_2(\eta^2\text{-}S_2O)](PF_6)$ and $[Ir(dppe)_2(\eta^2\text{-}S_2O_2](PF_6)$. Oxidation of $[Ir(dppe)_2(\eta^2\text{-}Se_2)](PF_6)$ with peracetic acid affords $[Ir(dppe)_2(\eta^2\text{-}Se_2O)](PF_6)$. Though the preparation of η^2- or η^2-OSO complexes *via* selective sulfur-abstraction reactions is not possible, the unsymmetrical dichalcogenide complex $[Ir(dppe)_2(\eta^2\text{-SSe})]^+$ can be prepared from $[Ir(dppe)_2](Cl)$ and $[Ti(Cp)_2S_xSe_{5-x}$ $(x \approx 3)$.[612] Complete reduction of the selenocarbonyl ligand of $[Ir(Cl)(CSe)(PPh_3)_2]$ by $NaBH_4$ in the presence of PPh_3 produces $[Ir(H)_2(PPh_3)_3(SeMe)]$. Additionally, CSe_2 reacts with $[Ir(Cl)(CSe)(PPh_3)_2]$ to form the iridium(III) adduct $[Ir(Cl)(\eta^2\text{-}CSe_2)(CSe)(PPh_3)_2]$.[613]

49.10.8 Halide Ligands

$[Ir(Cl)_6(H)_2]$ can be prepared *via* the electrochemical dissolution of powdered iridium in HCl. The rate of dissolution was studied as a function of current density, HCl solution concentration, temperature, and as a function of the number of bipolar electrodes.[614] The first Cl-containing compound of iridium(V) has been isolated from reaction between $[Ir(Cl)_6]^{2-}$ and BrF_3 in liquid HF giving $[Ir(Cl)_{6-n}(F)_n]^-$ ($n = 1$–6). The deep red $Cs[Ir(Cl)(F)_5]$ has been characterized by IR and Raman spectroscopy.[615]

49.10.9 Hydride Ligands

Oxidative addition of H_2 to the iridium(I) chelates $[Ir(X)(CO)(dppe)]^{n+}$ ($n = 0$, X = Cl, Br, I, CN, H; $n = 1$, X = PPh_3, dppe) proceeds with > 99% stereoselectivity to yield a *cis*-dihydride product with one H *trans* to P(dppe) and the other H *trans* to CO. The addition reaction is controlled by electronic factors of the CO and X ligands. Where X is Cl, Br or I, the stereoselectivity has a kinetic origin with subsequent conversion of the initially formed isomer to the more stable *cis*-dihydride isomer. The basis for the electronic factor is attributable either to (i) enhanced overlap in the π-back-bonding interaction between metal *d* and $\sigma^*(H_2)$ orbitals; or (ii) preferred bonding of one set of *trans* ligands as the reaction proceeds.[616] $[Ir(H)(CO)_2(PPh_3)_2]$ reacts with the coordinatively unsaturated dihydride cluster $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ to yield $[Os_3(H)_3(CO)_{11}\{Ir(PPh_3)\}]$. The X-ray crystal structure of the product reveals that the Ir atom caps the Os_3 triangle to form a distorted tetrahedral metal framework.[617] Reaction between an acetone solution of $[IrAu_3(NO_3)(PPh_3)_5](BF_4)$ and 1 atm H_2 yields the hydride cluster complex $[IrAu_4(H)_2(PPh_3)_6](BF_4)$. The two hydride ligands in this complex could not be located by X-ray analysis; they are believed to be bridging-Ir–axial-Au bonds. ^1H NMR spectral data support this assignment, though a terminal Ir—H bonding description also appears plausible.[618]

Trimethylphosphine reacts with $[Ir(C_5Me_5)]_2(\mu\text{-}H)_3A$ (A = PF_6, BF_4) to give the monohydride-bridged dimer $[Ir(H)(C_5Me_5)(PMe_3)]_2(\mu\text{-}H)A$. The product for which A = BF_4 reacts with a third equivalent of PMe_3 at elevated temperatures to produce the monomeric species $[Ir(H)_2(C_5Me_5)(PMe_3)]$ and $[Ir(H)(C_5Me_5)(PMe_3)_2](BF_4)$. Deprotonation of $[Ir(H)_2(C_5Me_5)(PMe_3)]$ with LiBu^t/pmdeta leads to $[Ir(H)(C_5Me_5)(PMe_3)][Li(pmdeta)_x]$, which reacts with alkylating agents to yield complexes of the type $[Ir(H)(C_5Me_5)(PMe_3)(R)]$ (R = alkyl).[619] $LiBH_4$ reacts with $[Ir(C_5Me_5)]_2(\mu\text{-}H)_3(PF_6)$ to give the borohydride-bound dimer $[\{Ir(C_5Me_5)\}_2(H)_3](BH_4)$, while $LiEt_3BH$ reacts with $[Ir_2(C_5Me_5)]$ to yield the mononuclear salt $[Ir(H)_3(C_5Me_5)][Li(THF)_x]$. The anion of the latter product can be hydrolyzed to the iridium(V) complex $[Ir(H)_4(C_5Me_5)]$. Hydrolysis of $[\{Ir(C_5Me_5)\}_2(H)_3](BH_4)$ leads to the iridium(IV) dimer $[Ir(H)_3(C_5Me_5)]$.[620]

Crabtree and coworkers[621] have synthesized $[Ir(H)_2(MeCN)_2(PPh_3)_2]^+$ from $[Ir(H)_5(PPh_3)_2]$ and HBF_4 in MeCN, and $[Ir(H)_2(PPh_3)_2(S)_2]^+$ (S = H_2O, Me_2CO, MeOH). The crystal structural analysis of $[Ir(H)_2(Me_2CO)_2(PPh_3)_2]^+$ shows an unusually long Ir—O distance (2.220–2.235 Å). The crystal structure of $[Ir(H)_3(PMe_2Ph)_2]_2$ reveals molecules as $(\mu\text{-}H)_2$-bridged dimers possessing strict crystallographic inversion symmetry. The Ir atom is approximately octahedrally coordinated by four H (two bridging) and two phosphine ligands. In solution, the dimers exhibit fluxional behaviour.[622] Vibrational and NMR spectroscopic data have recently been reported for $[Ir(CN)_5(H)]^{3-}$.[623]

$[\{Ir(C_5Me_5)\}_2(Cl)_4]$ reacts with $SiEt_3$ to form $[Ir(Cl)(H)_2(C_5Me_5)(SiEt_3)]$, which, under more drastic conditions, reacts further to give $[Ir(H)_2(C_5Me_5)(SiEt_3)_2]$. The $[Ir(Cl)(H)_2(C_5Me_5)(SiEt_3)]$ complex is also obtainable *via* reaction of $SiEt_3H$ with $[\{Ir(C_5Me_5)\}_2(Cl)_2(H)_2]$. This is an example of the highly unusual oxidative addition of iridium(III) to iridium(V).[624]

49.10.10 Catalytic Activity of Iridium Coordination Complexes

Complexes of the type $[Ir(bzn)(cod)(L)](ClO_4)$ (bzn = benzonitrile; L = tricyclohexylphosphine, neomenthyldiphenylphosphine) catalyze the homogeneous hydrogenation of tetrasubstituted prochiral amido alkenes $R^1R^2C{=}CR^4N'$. Under very mild conditions, the catalysis occurs for $N' = NHCOR^3$, $R^3 = CO_2Me$; $R^1 = R^2 = Me$, $R^4 = Me$, Ph; $R^1 = Me$, $R^2 = Ph$, $R^4 = Me$, Ph; $R^1 = Ph$, $R^2 = Me$, $R^4 = Ph$.[625] $[Ir(cod)(PCy_3)(py)](PF_6)$ serves as a catalyst in the hydroxyl-directed hydrogenation of cyclic and acyclic alkenic alcohols, wherein the reaction shows diastereoselectivity dependent on catalyst substrate stoichiometry.[626] Park *et al.*[627] have noted that the iridium(I)

complex $[Ir(CO)L(PPh_3)_2]^+$ and the iridium(III) complex $[Ir(H)_2(CO)L(PPh_3)_2]^+$ (L = *cis*-MeCH=CHCN, *trans*-MeCH=CHCN, CH_2=$CHCH_2CN$) play an important role in the catalytic hydrogenation and isomerization of the corresponding L. The homogeneous catalysis of cyclohexene hydrogenation by iridium and rhodium complexes has been accomplished by Khan and coworkers.[628]

Kinetic studies of the oxidation of nickel(II) dimethylglyoximate by periodate, catalyzed by iridium(IV), has been published recently.[629] Additionally, the kinetics and mechanism of iridium(III)- and ruthenium(III)-catalyzed oxidation of isopropyl alcohol by iodosoacetate have been elucidated.[630]

The integrated system made up of $[Ir(Cl)(cod)]_2$ and $P(C_6H_4OMe\text{-}2)_3$ catalyzes selective transfer hydrogenation of the CO group in $CH_2CHCH_2CH_2COMe$.[631] The resulting yield of unsaturated alcohol, CH_2=$CHCH_2CHMeOH$, is maximum at high P:Ir ratios. This may be understood in terms of an intramolecular interaction between the substrate and the OMe groups of the phosphine. The same system reacts with PhCH=CHCOMe to give the unsaturated alcohol, along with the saturated ketone and alcohol. While hexan-2-one can be reduced to the alcohol, the sterically crowded Me_2C=$CHCH_2CH_2COMe$ gave only unsaturated alcohol on reduction.[632] The selective reduction of α,β-unsaturated carbonyl compounds with alcohols is known to be catalyzed by iridium(I) complexes containing 2,2′-bipyridyl, 1,10-phenanthroline and substituted derivatives.[633] Homogeneous catalytic dehydrogenation of cyclooctane into cyclooctene is effected with $[Ir(H)_5(PPr^i_3)_2]$ and $[Ir(H)_5\{P(C_6H_4\text{-}F\text{-}p)_3\}_2]$ at 423 K in the presence of an alkene that can serve as the hydrogen acceptor.[634] Hydrogen transfer reactions from cyclopentanol to substituted cyclohexanones are catalyzed by iridium complexes containing nitrogen donor chelating ligands.

The species $[Ir(cod)(PPh_3)(pz)]$ or $[Ir(cod)(pz)]_2$ in the presence of PPh_3 (pz = pyrazolato) dissolves in acetone to yield catalytic solutions which partially hydroformylate and hydrogenate alkynes and alkenes.[635] Results were reported for the hydroformylation of hept-2-yne. The hydrosilylation of styrene by $[Si(Cl)_2(H)Me]$ is catalyzed by complexes of the type $[ML_nL'_m]$ (M = Ir, Co, Ni, Ru, Rh, Os, Pd, Pt; L = halide, NO_2^-, SCN^-; L′ = DMSO, Et_2SO, Et_2S, NH_3). The catalytic activity and regioselectivity of these catalysts have been examined after immobilization on AV17X8 or KU 2X8 anion exchangers.[636]

$[Ir(Cl)_3]$ catalyzes the isomerization of methyl formate at 473–508 K/33–250 bar CO in the presence of an MeI promoter. The major product is acetic acid, with methyl acetate as a by-product.[637] The synthesis of PhNCO *via* carbonylation of $PhNO_2$ at 398 K under 80 atm CO pressure can be catalyzed by $[Ir(CO)_2(PPh_3)_2]^+$.[638]

44.1.1 GENERAL SURVEY

44.1.1.1 Introduction

Iron is the most abundant transition metal in the earth's crust, occurring to the extent of some 5% in igneous rocks.[1] It is thought metallic iron is a major component of the earth's core.[2] Iron has a rich coordination chemistry and many of its complexes find use in practical applications.

44.1.1.2 Iron Complexes in Analysis

The widespread occurrence of iron ores, coupled with the relative ease of extraction of the metal, has led to its extensive use as a constructional material with the result that the analysis of steels by both classic 'wet' and instrumental methods has been pursued with vigour over many years.[3] Iron complexes are themselves widely used as the basis of convenient analytical methods for the detection and estimation of iron down to parts per million. Familiar tests for iron(III) in aqueous solution include the formation of 'Prussian blue' as a result of reaction with $[Fe(CN)_6]^{4-}$, and the formation of the intensely red-coloured $[Fe(H_2O)_5SCN]^{2+}$ on reaction with thiocyanate ion.[4] Iron(II) forms particularly stable red tris chelates with α,α'-diimines such as 1,10-phenanthroline or 2,2′-bipyridine that have been used extensively in spectrophotometric determinations of iron and in the estimation of various anions.[5] In gravimetric estimations, iron(III) can be precipitated as the insoluble 8-hydroxyquinoline or α-nitroso-β-naphthol complex which is then ignited to Fe_2O_3.[6] In many situations the levels of free $[Fe(H_2O)_6]^{3+}$ may be controlled through complex formation by addition of edta.

44.1.1.3 Biological Systems

The versatility of the chemistry of iron is reflected by the variety of roles it plays in biological systems where it is frequently found at the active centres involved in processes such as oxygen and

electron transport in nitrogenase, many oxidases and in metalloenzymes such as hydrogenases and reductases. While sustained research over the last two decades has provided much detailed information about the coordination environment of iron in several important natural systems (*e.g.* haemoglobin, ferredoxins and cytochromes), there are still many cases in which the exact location of the iron is not known.

44.1.1.4 Organometallic Chemistry

There have been rapid developments in the organometallic chemistry of iron and during recent years a huge amount of work has been published in this area, as can be judged from there being some 2000 references concerned with iron compounds in the companion work 'Comprehensive Organometallic Chemistry'.[7] As a result of the effort that has gone into the biological and organometallic areas, the basic coordination chemistry of iron has been rather overshadowed and there have been relatively few reviews or books published on the subject in recent years.

44.1.1.5 Iron Mössbauer Spectroscopy

There are few direct spectroscopic probes for iron; for instance, in most complexes charge transfer bands obscure the *d–d* transitions and magnetic measurements cannot provide information on low-spin iron(II) complexes. Therefore when the Mössbauer technique became generally available in the late 1960s, it was widely used for the study of iron complexes. The effect[8] arises from the resonant absorption of γ-rays by the ^{57}Fe nucleus, which has a natural abundance[9] of $\sim 2\%$. When the γ-ray source and sample nuclei are in different environments, the shift in the energy of resonant absorption is expressed as a velocity relative to some arbitrary zero such as stainless steel or $Na_2[Fe(CN)_5NO]\cdot 2H_2O$. Whilst the value of the shift is temperature dependent, it is also affected by the electronic environment.

The chemical or isomer shift (δ) arises from the interaction of electrons with the ^{57}Fe nucleus. This interaction is strong for electrons with zero angular momentum, that is *s* electrons, and δ is a linear function of *s* electron density at the nucleus. The contribution of the outer *s* orbitals make δ sensitive to the chemical environment. In high-spin complexes δ depends markedly on oxidation state, and Mössbauer spectroscopy may be used to indicate the oxidation state of high-spin iron complexes. At room temperature δ varies from $+1.0$ to $+1.6\,mm\,s^{-1}$ for high-spin iron(II) complexes, and from $+0.45$ to $+0.75\,mm\,s^{-1}$ for high-spin iron(III) complexes (Figure 1). The chemical shifts of high-spin complexes also depend on the nature of the bound ligands. For example, the effect of ligand electronegativity on δ is in the same order as the nephelauxetic series.[10] Such large effects are not seen in low-spin complexes. Both iron(II) and iron(III) low-spin complexes have δ values between 0.0 and $+0.3\,mm\,s^{-1}$ (relative to $Na_2[Fe(CN)_5NO]\cdot 2H_2O$) illustrating the importance of back donation.[11] Indeed, π bonding effects appear to be the main cause of chemical shift variation in low-spin complexes. Bancroft and coworkers derived 'partial isomer shifts' (PIS) for a number of ligands, which allow the chemical shift to be calculated for a range of low-spin iron(II) complexes.[12] As expected the values of PIS are in the same order as the spectrochemical series.

The Mössbauer effect has its origin in the nuclear $I = \frac{1}{2}$ to $I = \frac{3}{2}$ spin transition. This transition is split by the electric quadrupole interaction to give a two line spectrum. Figure 2 illustrates the relevant transitions together with the six line spectrum which results from the simultaneous interaction of a magnetic field. The electric field gradient at the iron nucleus can arise from both asymmetric occupation of the *d* orbitals and asymmetry of the ligand field. There are therefore a number of factors affecting the quadrupole splitting energy ΔE_Q.

In high-spin d^5 complexes where the coordinated ligands are identical, the symmetric population of the *d* levels normally results in very small values for ΔE_Q. In contrast, high-spin d^6 centres with one spin-paired $3d$ orbital have sufficient field gradient at the nucleus for a two line Mössbauer spectrum to be observed. Low-spin d^6 complexes have a symmetrical configuration and, for example, $[Fe(CN)_6]^{4-}$ displays a single line spectrum, whilst the incomplete t_{2g} set in low-spin d^5 iron(III) creates a field gradient which induces splitting similar to that observed in high-spin iron(II) complexes. In complexes where the ligand environment is not symmetrical, a field gradient is created and electric quadrupole splitting is observed. There are many low-spin iron(II) complexes which show two line spectra and a range of compounds of the type $[FeA_4B_2]$, $[FeA_5B]$ and $[FeB_4A_2]$ have been investigated.[16] Theoretically the relation in equation (1) would be expected and this has been

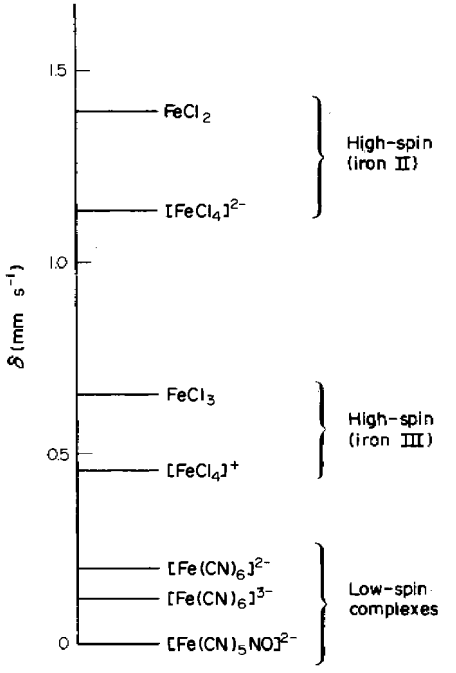

Figure 1 Variation of chemical shift (δ) at 25 °C with oxidation state for low-spin cyanide and high-spin chlorides. Data from refs. 13–15

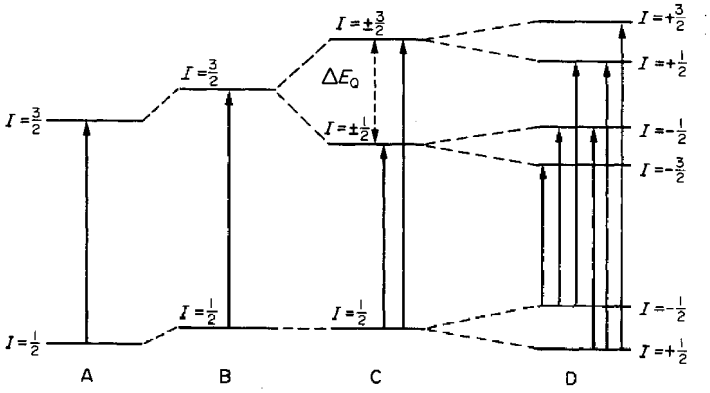

Figure 2 Schematic description of some ^{57}Fe Mössbauer spectra showing original nuclear energy levels (A) slightly perturbed through interaction with S electron density (B) giving rise to a chemical shift (δ) resulting from quadrupole interactions (C) and magnetic splitting of the ground and excited states (D). Arrows indicate transitions responsible for one, two and six line Mössbauer spectra

observed within the limits of experimental error. Thus observed ΔE_Q values may support structural assignments, as well as helping to define oxidation state and spin state. Much of the chemically important information to be derived from Mössbauer spectroscopy is obtained from the chemical shift and the quadrupole splitting energy. Additional information can be obtained by measuring the spectrum of the sample in a magnetic field which further removes nuclear spin degeneracy[17] and often results in a six line spectrum.

44.1.1.6 Oxidation States and Coordination Numbers

Iron compounds are known in which the oxidation state of the metal ranges from $-$II (d^{10}) to

VI (d^2), and the examples in Table 1 illustrate the kinds of complexes formed and their stereochemistries. Several of these oxidation states are not well characterized; the −I and V states are rare, while I is not common. The most frequently encountered oxidation states in complexes of a conventional coordination type (particularly in aqueous media) are II (d^6) and III (d^5): the ferrous and ferric states respectively. The preferred nomenclature, and that used here, indicates these oxidation states as iron(II) and iron(III).

Table 1 Selected Examples of Iron Complexes Illustrating the Range of Oxidation States and Coordination Geometries

Oxidation state	*Coordination number*	*Complex*	*Coordination geometry*	*Comments*	*Ref.*
-II (d^{10})	4	$[Fe(CO)_4]^{2-}$	Tetrahedral	Uncommon oxidation state, but familiar as Collman's reagent $Na_2[Fe(CO)_4]$ and other carbonyl anions	1
0 (d^8)	5	$[Fe(CO)_3(PPh_3)_2]$	Trigonal bipyramidal	Uncommon oxidation state in classical complexes but extensively found in organometallic compounds	2
I (d^7)	5	$[Fe(dppe)_2H]^a$	Square pyramidal	Very few paramagnetic iron(I) complexes have been reported	3
II (d^6)	4	$[FeBr_2(PPh_3)_2]$	Tetrahedral	Common oxidation state in aqueous solution.	4
	5	$[FeBr(Me_6tren)]^+$	Trigonal bipyramidal	Stabilized by high-field ligands, otherwise easily oxidized to iron(III). Octahedral geometry is most	5
	5	$[Fe(ClO_4)(OAsMe_3)_4]^+$	Square pyramidal	common.	6
	6	$[Fe(phen)_3]^{2+}$	Octahedral		7
	7	$[Fe(HPAP)(H_2O)_2]^{2+d}$	Pentagonal bipyramidal		8
	8	$[Fe(1,8\text{-naph})_4]^{2+b}$	Dodecahedral		9
III (d^5)	3	$[Fe\{N(SiMe_3)_2\}_3]$	Trigonal	Most iron(III) complexes are octahedral but	10
	4	$[FeCl_4]^-$	Tetrahedral	tetrahedral and square pyramidal geometries are also	11
	5	$[FeCl(dtc)_2]^c$	Square pyramidal	important. In aqueous media, Fe^{3+} readily hydrolyzes and bridged dimeric species are common.	12
	5	$[Fe(N_3)_5]^{2-}$	Trigonal bipyrimidal	Low-spin complexes are only obtained with the strongest field ligands	13
	6	$[Fe(phen)_3]^{2+}$	Octahedral		14
	7	$[Fe(edta)(H_2O)]^-$	Pentagonal bipyramidal		15
	8	$[Fe(NO_3)_4]^-$	Dodecahedral		16
IV (d^4)	4	$[Fe(l\text{-norbornyl})_4]$	Tetrahedral	Iron(IV) is not common; known in mixed oxides.	17
	6	$[Fe(diars)_2Cl_2]^{2+}$	Octahedral	Most easily prepared complexes are those with dithiocarbamate ligands	18
V (d^3)	4	FeO_4^{3-}	Tetrahedral	Only known in the solid oxides M_3FeO_4 and not well characterized	19
VI (d^2)	4	FeO_4^{2-}	Tetrahedral	Blue FeO_4^{2-} is very strongly oxidizing, finds uses in organic chemistry	20

[a] dppe = 1,2-bis(diphenyphosphino)ethane.
[b] 1,8-naph = 1,8-naphthyridine.
[c] dtc = dithiocarbamate.
[d] HPAP = macrocycle from 2,9-di(1-methylhydrazino)-1,10-phenanthroline and 2,6-diacetylpyridine.

44.1.1.6.1 Low oxidation states

As expected, the lower oxidation states of iron are stabilized by π acceptor ligands such as phosphines and carbon monoxide, and there is a large volume of 'organometallic' chemistry involving what are formally iron(0) centres.[7] There are very few examples of iron in the oxidation states $-$II (d^8) and $-$I (d^9). While the $-$II oxidation state is rare, the pale yellow compound $Na_2[Fe(CO)_4]$ (best prepared by reducing $[Fe(CO)_5]$ with sodium amalgam in THF) and other derivatives of $[Fe(CO)_4]^{2-}$ are familiar because they are being increasingly used in the synthesis of aldehydes and ketones.[18,19] The $[Fe(CO)_4]^{2-}$ anion is isoelectronic and isostructural[20] with tetrahedral $[Ni(CO)_4]$. Many iron(0) compounds are known, most of which are best regarded as organometallic compounds.[7] However, species such as $[Fe(CO_3)L_2]$ (L = PPh_3, $AsPh_3$ *etc.*) are considered in this chapter. Reduction of conventional iron coordination complexes can yield species containing iron(0). For instance, alkali metal reduction[21] of red $[Fe(bipy)_3]^{2+}$ affords black $[Fe(bipy)_3]$, but care is necessary when assigning oxidation states in such complexes without complete spectroscopic characterization, since reduction of the ligand (rather than at the metal) may take place where extensively delocalized ligand systems are involved such as with the macrocyclic porphyrins[22] and phthalocyanines.[23]

While not common, a number of iron(I) complexes have been isolated and characterized, although as might be expected, disproportionation to the more stable iron(0) and iron(II) will take place in many situations. Several iron(I) complexes with phosphine ligands such as the trigonal bipyramidal $[FeCl(dppe)_2]$ have been reported. Alkali metal reduction of iron(II) phthalocyanine ([FePc]) gives $[FePc]^-$ that contains iron(I). More highly reduced species may also contain iron in the same oxidation state with additional electrons being localized on the ligand.[23] Several nitric oxide complexes are considered to contain iron(I) centres, including the coloured species $[Fe(H_2O)_5NO]$ of the nitrate 'brown ring test'. Assignment of oxidation state in these complexes is often not straightforward, and accordingly it has not been firmly established in many instances. Therefore, in this chapter nitric oxide complexes have been grouped together rather than divided according to oxidation state. A number of more or less transient iron(I) complexes have also been generated using electrochemical or radiolysis techniques and characterized *in situ* by spectroscopic methods.

44.1.1.6.2 Iron(II)

An extremely large number and wide range of iron(II) and iron(III) complexes are known. These d^6 and d^5 configurations represent the most important oxidation states of iron. Most iron(II) complexes have an octahedral geometry, although there are examples of four-, five- and even eight-coordination. Salts of tetrahedral $[FeCl_4]^{2-}$ are readily obtained with large cations;[24] other tetrahedral complexes include $[Fe(OPPh_3)_4]^{2+}$, $[Fe\{OP(NMe_2)_3\}_4]^{2+}$ and the iron(II) centre in the rubredoxins with four sulfur donors. Some tetrahedral rubredoxin model compounds have also been characterized.[25] Square planar iron(II) complexes are formed with tetradentate nitrogen donor macrocycles of which the most familiar are phthalocyanine and the porphyrins, to which in recent years have been added a large number of additional 'synthetic' macrocycles.[26] The magnetic properties of some of these complexes indicate the relatively unusual intermediate spin ($S = 1$) ground state. There is a strong tendency for all of these compounds to acquire two axial ligands (usually nitrogen donors) and become six-coordinate and low-spin. Carbon monoxide and dioxygen adducts are also formed with these complexes[27] and it is now understood how, *via* kinetic or steric effects, to inhibit oxidation to μ-oxo iron(III) species so mimicking the behaviour of haemoglobins and related oxygen carriers.

Numerous five-coordinate high-spin iron(II) complexes, with tetradentate nitrogen donor macrocyclic ligands, have been reported in which the fifth coordination site is occupied by a halide ion. Other five-coordinate complexes include $[Fe(terpy)X_2]$ (refs. 28–30) and examples with tripod ligands, such as $[Fe\{N(CH_2CH_2PPh_2)_3\}X]^+$. High-spin and low-spin complexes with tripod ligands are known,[31] as well as those displaying spin cross-over.

The iron(II) $^5D_2$ ground state is split by octahedral fields into $^5T_{2g}$ and ^5E_g states. High-spin octahedral iron(II) complexes have magnetic moments typically about 5.2 BM and show broad $^5T_{2g}$ to ^5E_g transitions[32] occurring in the visible/near-IR region of the spectrum. Thus salts of the familiar $[Fe(H_2O)_6]^{2+}$ ion are pale green in solution, with an absorption peak at 10 400 cm^{-1} and a shoulder at $\sim$8300 cm^{-1} that may result from a Jahn–Teller effect.[32] Most simple iron(II) salts are susceptible

to air oxidation, a process catalyzed by copper(II) and palladium(II) that has been extensively studied.[33] With very strong-field ligands, like cyanide ion and α,α′-diimines, spin pairing can take place with the result that complexes such as $[Fe(phen)_2(CN)_2]$ are essentially diamagnetic, although some temperature independent paramagnetism, amounting to rather less than 1 BM, is commonly reported.[34,35] These low-spin complexes are usually intensely coloured (typically red or purple) due to strong metal–ligand charge transfer[36] bands that obscure *d–d* transitions. An important feature of low-spin octahedral iron(II) complexes, which is in accord with crystal field stabilization energy considerations,[37] is their stability and kinetic inertness. As a result of this, though not as extensive as that of the isoelectronic, highly inert cobalt(III) centre, a considerable amount of work on their preparation and the kinetics and mechanisms of their reactions has been accumulated. While $[Fe(phen)_2(CN)_2]$ is low-spin, most complexes of the type $[Fe(phen)_2X_2]$ are high-spin. However, by appropriate choice of the anion X^-, it is possible to obtain complexes having strongly temperature-dependent magnetic moments that cross over from being low-spin to high-spin as the temperature is increased. A number of other iron(II) complexes display similar behaviour.[38] Moreover, complexes such as $[Fe(phen)_2(ox)]$ have two unpaired electrons,[39] an unusual situation for a d^6 centre that results from deviation from strict octahedral symmetry.

Although very high coordination numbers are rare for iron(II), eight-coordination is well characterized in the red-orange high-spin complex with 1,8-naphthyridine, $[Fe(naph)_4]^{2+}$, which in the perchlorate salt has a distorted dodecahedral geometry.[40,41] Seven-coordination is more common than eight-coordination, and is known in several macrocyclic complexes.[42]

44.1.1.6.3 Iron(III)

As with iron(II), most iron(III) complexes are octahedral; however, four- (tetrahedral) and five-coordination are also well known (see Table 1). There are also examples of higher coordination number that include the relatively uncommon seven-coordination found in some iron(III) nitrogen macrocycle complexes[43] and in $[Fe(edta)(H_2O)]^-$ (ref. 44). Eight-coordination is exemplified[45] by $[Fe(NO_3)_4]^-$. Iron(III) has a strong affinity for oxygen ligands and a marked tendency to form oxo-bridged complexes. With μ-oxo bridges, as for instance in $[\{Fe(salen)\}_2O]$ (ref. 46) and $[(FeCl_3)_2O]^{2-}$ (ref. 47) that contain two five- and two four-coordinate centres respectively, there is strong antiferromagnetic coupling that results in low and temperature dependent magnetic moments. Monomeric five-coordinate complexes such as $[Fe(S_2CNR_2)_2X]$ have[48] three unpaired electrons. A large number of iron(III) complexes with sulfur donors are known.

In most octahedral monomeric complexes, iron(III) is high-spin, for instance $[Fe(acac)_3]$, and these complexes have magnetic moments close to the expected spin-free value. Complexes containing very high field ligands, as in $[Fe(CN)_6]^{3-}$ and $[Fe(phen)_3]^{3+}$, are low-spin and they display higher than predicted room temperature magnetic moments due to large orbital contributions. As expected in this situation, the observed magnetic moment decreases as the temperature is lowered. Like low-spin iron(II) complexes, low-spin iron(III) centres are significantly more kinetically inert than their high-spin analogues.

As previously noted, spin cross-over behaviour is well established in iron(II) complexes and there are also examples involving iron(III) species. For example, a variety of iron(III) dithiocarbamate complexes of the type $[Fe(S_2CNR_2)_3]$ having a trigonally distorted octahedral geometry display high-spin/low-spin cross-over behviour.[49,50] Little is known about the spin forbidden *d–d* transitions of iron(III) complexes due to near-UV charge transfer bands that 'tail' into the visible part of the spectrum. Even simple iron(III) salts in aqueous media are yellow.

44.1.1.6.4 Iron(II)–iron(III) redox behaviour

The $[Fe(H_2O)_6]^{2+}$ cation is oxidized by molecular oxygen to $[Fe(H_2O)_6]^{3+}$. The usually quoted potential for the $Fe^{3+/2+}$ couple is +0.77 V, but the latest discussion[51] gives +0.738 V. The standard electrode potential is strongly influenced by the nature of the ligands involved, and a wide range of E^0 values is covered depending on the complex concerned. Indeed, it is this ability of iron to span a wide range of redox potential that is exploited in a number of biological systems. Figure 3 illustrates the standard electrode potentials of some typical complexes. In general the high field α,α′-diimine ligands stabilize iron(II) relative to the aqua cations when a low-spin complex is formed,

and the importance of back-bonding in these complexes is emphasized by the significant stabilizing effect of *electron withdrawing* substituents in the ligand.

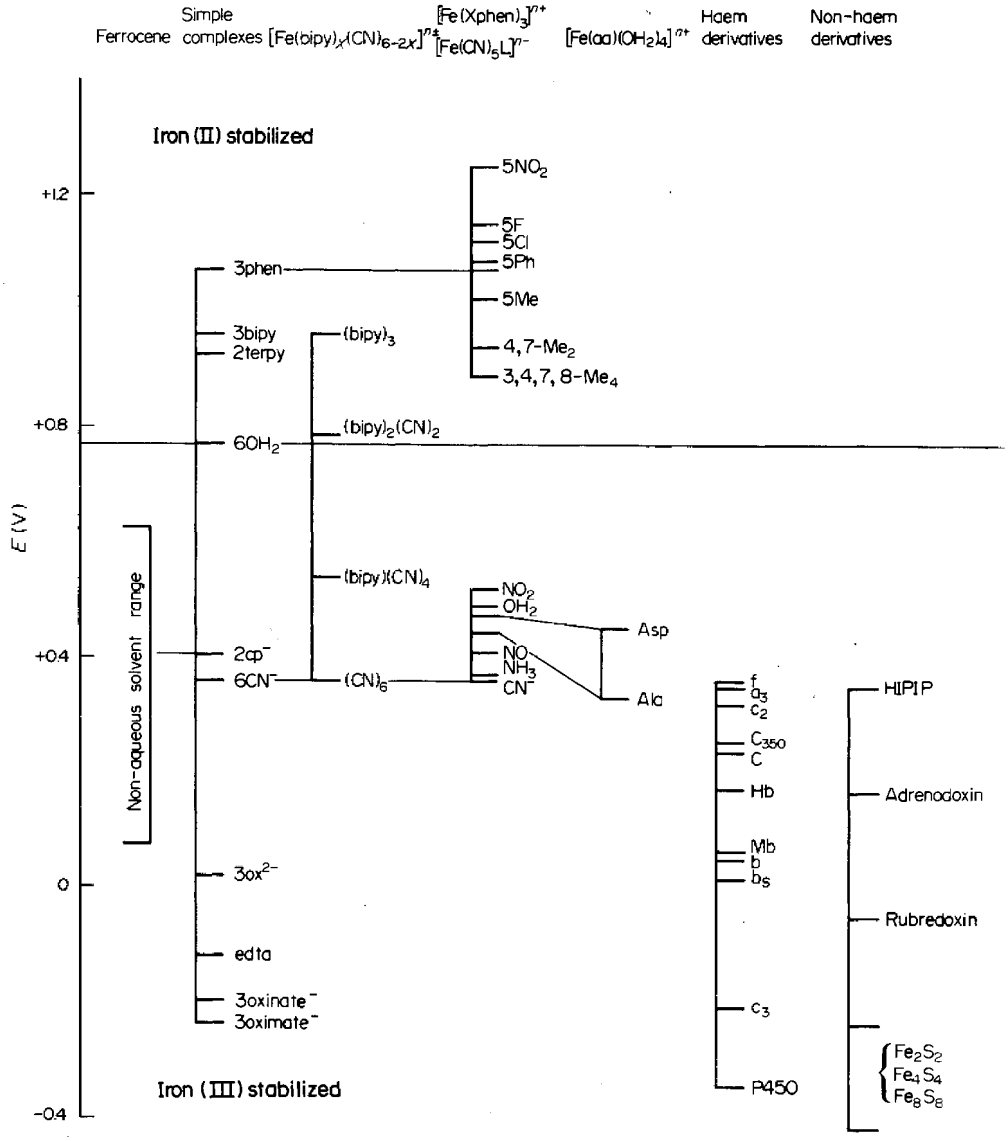

Figure 3 Standard oxidation potential for iron complexes in aqueous solution

The anionic cyano iron(III) complexes $[Fe(CN)_6]^{3-}$ and $[Fe(bipy)(CN)_4]^-$ are more stable than the iron(II) forms relative to the aqua cations. This is at variance with the expectation of the iron(II)–cyanide bond having greater strength than the iron(III)–cyanide bond. It appears that in these instances the electrode potentials are influenced by the large negative entropies of hydration of the anionic iron(II) complexes, and it is this that destabilizes them with respect to the higher oxidation state.[52,53] That is, the higher bond strength (enthalpy) of the iron(II) complex is outweighed by a hydration (entropy) term which no doubt involves structure-forming hydrogen bonding between the cyanide nitrogen atoms and the solvent water. In keeping with this proposal, the iron(III) oxidation state becomes progressively more stable along the series $[Fe(bipy)_2(CN)_2]^{0/+}$, $[Fe(bipy)(CN)_4]^{2-/-}$ and $[Fe(CN)_6]^{4-/3-}$ as the number of cyanide ligands increases.

In the solid state, iron complexes can display interesting internal redox behaviour as a result of applying high pressure.[54] Reduction of iron(III) to iron(II) on the application of pressure is well documented and is usually monitored by Mössbauer or optical spectroscopy. For instance, conversion to iron(II) in $[Fe(acac)_3]$ proceeds continuously with pressure over the range above 30 kbar,

but does not go to completion. After the pressure is released and mechanical strain removed by grinding the sample, iron(III) is reformed. In examples of this kind it appears it is the ligand that is being oxidized. Application of high pressure to solid complexes that are high-spin, but close to the cross-over point, can cause them to go low-spin (*e.g.* $[Fe(phen)_2(SCN)_2]$) but there are examples where application of pressure causes a low-spin complex to become high-spin. Thus at pressures approaching 200 kbar low-spin $[Fe(CN)_6]^{4-}$ becomes high-spin, and $[Fe(phen)_3]^{2+}$ similarly displays a Mössbauer spectrum characteristic of high-spin iron(II). Clearly, in order to interpret these results the overall total volume for the different forms has to be considered, as well as the spin-transition energetics.

44.1.1.6.5 Mixed iron(II)–iron(III) complexes

Both delocalized and localized Fe^{II}/Fe^{III} mixed valence complexes are known, the most comprehensively investigated being Prussian blue which has the limiting formula $Fe_4^{III}[Fe^{II}(CN)_6]_3 \cdot 14H_2O$. The single crystal structure has been reported,[55] and the degree of valence delocalization has been extensively probed.[56] Recently, thin films of insoluble Prussian blue have been intensively studied because of their electrochromic behaviour; electrochemical oxidation gives continuous mixed valence composition (up to complete oxidation) while reduction to Prussian white takes place cleanly at a critical potential.[57] A number of other delocalized systems have been studied involving aromatic bridging ligands. In contrast, the mixed valence compound $Fe_2F_5 \cdot 2H_2O$ is a nonmolecular solid with a three-dimensional network structure with distinct Fe^{II} and Fe^{III} coordination sites, in which the water is bound to the Fe^{II} centres.[58]

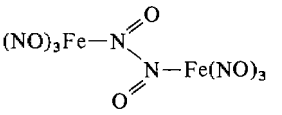
44.1.1.6.6 Higher oxidation states

The IV, V and VI oxidation states of iron are all known in oxyanions. However, relatively few well-characterized complexes with iron in an oxidation state higher than three are known. A review[59] concerned with these oxidation states was published in 1974. Complexes containing iron(IV) are not large in number. This appears to be the highest oxidation state of iron in the catalases,[60] and a considerable body of information has been collected on the strongly oxidizing iron(IV) porphyrins.[61,62]

The green/black low-spin d^4 $[Fe(diars)_2X_2]^{2+}$ (X = Cl, Br) obtained by oxidation of $[Fe(diars)_2X_2]^+$ with concentrated nitric acid[63] appears to have a *trans* configuration and is not very stable. More recent examples of well-characterized (X-ray) iron(IV) species involve dithiocarbamate ligands.[64,65] For example, low-spin $[Fe(S_2CNEt_2)_3]^+$ is obtained by merely treating the corresponding iron(III) complex with an excess of iodine.[66,67] The interpretation of the Mössbauer spectra of these complexes is based on that applied to d^5 and d^6 systems.[68] An organometallic compound of the type $[FeR_4]$ has been reported[69] with R being the particularly favourable 1-norbornyl group, and this could be thought of as being an iron(IV) derivative. This 'oxidation state' is, however, rare in organometallic compounds.

The +5 oxidation state is not well defined and seems only to exist in M_3FeO_4 (M = alkali metal), but even these compounds have not been obtained pure.[70] The +6 oxidation state is more familiar. Deep red/purple salts, containing discrete tetrahedral FeO_4^{2-} units, are obtained by anodic oxidation, or the hypochlorite oxidation of freshly precipitated iron(III) hydroxide.[71] Water soluble potassium ferrate(VI) (K_2FeO_4) is fairly stable in basic solution, but gives iron(III) and oxygen in neutral or acid solution. It is more strongly oxidizing than permanganate and has some application in organic oxidations. Other than these oxyanions there appear to be no stable coordination complexes of iron(V) or iron(VI).

44.1.2 NITRIC OXIDE COMPLEXES



44.1.2.1 Introduction

The nitric oxide molecule shows many similarities to carbon monoxide in its ability to form complexes with transition metals. Nitric oxide has an extra electron, occupying a π^* antibonding orbital, which is relatively easily lost. In the case of terminally bound NO, simple MO theory predicts that whilst $M—NO^+$ will be linear, $M—NO^-$ may be a 'bent' bond. The potential thus

exists to establish the formal oxidation state of the metal centre in nitric oxide complexes by examining their IR spectra. Although well-authenticated examples of bent M—NO bonds exist,[72] they are rare and there have been numerous discussions of the bonding in transition metal nitrosyl complexes.[73–81] Iron nitrosyl complexes have not been classified by oxidation state but are discussed here separately.

44.1.2.2 Simple and Binary Nitrosyls

Reports in the older literature suggested the existence of $[Fe(NO)_4]$. However, this is likely to be a dimeric compound[82] containing a bridging hyponitrite ligand (**1**). One electron reduction of the complex $[Fe(NO)_2Cl]_2$, chemically[83] or electrochemically,[84] leads to a species which acts as a catalyst for the cyclodimerization of dienes. This has been described as '$Fe(NO)_2$', which probably exists in THF solution as $[Fe(NO)_2(THF)_n]$. Aqueous solutions of ferrous salts absorb nitric oxide to give the familiar colour of the 'brown ring test', which is due[85] to the complex ion $[Fe(H_2O)_5NO]^{2+}$.

(1)

44.1.2.3 Nitrosyl Carbonyls

(i) $[Fe(CO)_2(NO)_2]$

Several preparations of dicarbonyl dinitrosyl iron have been reported including treatment of $[Fe_3(CO)_{12}]$ or $[Fe_2(CO)_9]$ with nitric oxide,[86,87] acidification of a mixture of $[HFe(CO)_4]^-$ and nitrite ion,[88] reaction of iron pentacarbonyl with nitrosyl chloride[89] and acidification of a mixture of $[Fe(CO)_3NO]^-$ and nitrite ion[90] as in equations (2) and (3).

$$[Fe(CO)_5] + NaNO_2 + 2NaOH \xrightarrow{H_2O} Na[Fe(CO)_3NO] + CO + Na_2CO_3 + H_2O \quad (2)$$

$$Na[Fe(CO)_3NO] + NaNO_2 + 2MeCO_2H \longrightarrow [Fe(CO)_2(NO)_2] + CO + 2MeCO_2Na + H_2O \quad (3)$$

Red crystalline $[Fe(CO)_2(NO)_2]$ has a distorted tetrahedral geometry. It is somewhat air sensitive, melts at 18 °C and is readily transferred in the vapour phase in a vacuum system. The IR spectrum in cyclohexane solution contains strong carbonyl bands at 2083 and 2034 cm^{-1} and strong nitrosyl bands at 1810 and 1756 cm^{-1}. A full IR assignment has been reported.[91] $[Fe(CO)_2(NO)_2]$ reacts with a wide variety of ligands with preferential CO displacement; both monomeric and dinuclear complexes result. A kinetic study of CO displacement reactions of $[Fe(CO)_2(NO)_2]$ by phosphines, phosphites and triphenylarsine supports[92] a bimolecular displacement mechanism where the entering ligand attacks the 'soft' iron atom to give a five-coordinate transition state. The substitution can be catalyzed by various hard bases.[93] This is thought to occur *via* attack on a carbonyl carbon atom which destabilizes the M—CO bond so making carbonyl a better leaving group.

(ii) The $[Fe(CO)_3NO]^-$ anion

The $[Fe(CO)_3NO]^-$ anion is formed by the reaction of $[Fe(CO)_5]$ with nitrite ion in methanol, and isolated as $[Hg\{Fe(CO)_3NO\}_2]$ by reaction with aqueous mercurous cyanide[90,94] but many other salts are also known.[95–97] The anion can be conveniently prepared in high yield[98] as the bright yellow salt $[(Ph_3P)_2N][Fe(CO)_3NO]$ by the reaction of $[(Ph_3P)_2N](NO_2)$ with $[Fe(CO)_5]$ in THF (ν_{CO}, 1982 m, 1876 s; ν_{NO}, 1650 m cm^{-1}). IR studies suggest that in the mercury derivative the three metals are bonded in a linear fashion, each iron atom having trigonal bipyramidal geometry.[99] Carbon monoxide is readily displaced by π acceptor ligands[100–102] in benzene at room temperature to give $[Hg\{Fe(CO)_2(NO)L\}_2]$ (L = R_3P, R_3As, R_3Sb, $(RO)_3P$) in which the geometry of the iron and mercury atoms remains unchanged.[101] In the case of reaction with pyridine (or other N bases and isocyanides) however,[100] disproportionation yields a mixture of $[Fe(py)_6][Fe(CO)_3NO]$ and

$[Fe(py)_2(NO)_2]$. Interestingly, $[Hg\{Fe(CO)_3NO\}_2]$ reacts slowly with tris(dimethylamino)phospine (Tdp) in refluxing benzene[94] to give first partial then complete substitution of CO (equation 4). Mercury iron nitrosyl complexes are the basis for two routes[103,104] to iron–tin, iron–germanium and iron–lead bonds. These are illustrated in equations (5) and (6).

$$[Hg\{Fe(CO)_3NO\}_2] + (Me_2N)_3P \xrightarrow[\text{benzene}]{\text{reflux}} \begin{cases} \xrightarrow{6\,h} [Fe(Tdp)_2(CO)_2NO][Fe(CO)_3NO] \\ \xrightarrow{20\,h} [Fe(Tdp)_2(NO)_2] \end{cases} \quad (4)$$

$$[Hg\{Fe(CO)_2(NO)(PPh_3)\}_2] + 2SnCl_4 \xrightarrow[25\,^\circ C]{\text{benzene}} [Cl_3SnFe(CO)_2(NO)(PPh_3)] + HgCl_2 \quad (5)$$

$$[Hg\{Fe(CO)_2(NO)(P(OPh)_3)\}_2] \xrightarrow[THF]{Na/Hg} Na[Fe(CO)_2(NO)(P(OPh)_3)] \xrightarrow{Ph_3GeBr} \xrightarrow{Ph_3GeBr} [Ph_3GeFe(CO)_2(NO)(P(OPh)_3)] + NaBr \quad (6)$$

The $[Fe(CO)_3NO]^-$ anion reacts with LAuX (L = $(MeO)_3P$, Me_3P, Ph_3P, $(p\text{-}ClC_6H_4)_3P$) to give complexes $[LAuFe(CO)_3NO]$ containing gold–iron bonds[105] which undergo CO substitution reactions in a fashion similar to $[Hg\{Fe(CO)_3NO\}_2]$ as in equation (7), where L = $(PhO)_3P$, Ph_3P. Conductimetric titration has been employed to study[106] the reduction of $[Fe(CO)_3NO]^-$ through to $[Fe(CO)_3NO]^{5-}$ although the oxidation state of the metal at any particular stage is uncertain.

$$[Ph_3PAuFe(CO)_3(NO)] + L \xrightarrow[25\,^\circ C/dark]{\text{benzene}} [Ph_3PAuFe(CO)_2(NO)L] \quad (7)$$

44.1.2.4 The Nitroprusside Ion

Sodium nitroprusside ($Na_2[Fe(CN)_5NO]\cdot 2H_2O$), possibly the best known of all nitrosyl complexes,[107] is made either by the action of nitric acid (equation 8) or sodium nitrite (equations 9 and 10) on the hexacyanoferrate(II) anion. The equilibria (9) and (10) are driven to the right by the addition of barium chloride to the reaction mixture and by removing HCN in a stream of CO_2 passing through the hot solution. The overall process[108] is shown in equation (11).

$$[Fe(CN)_6]^{4-} + 4H^+ + NO_3^- \longrightarrow [Fe(CN)_5NO]^{2-} + CO_2 + NH_4^+ \quad (8)$$

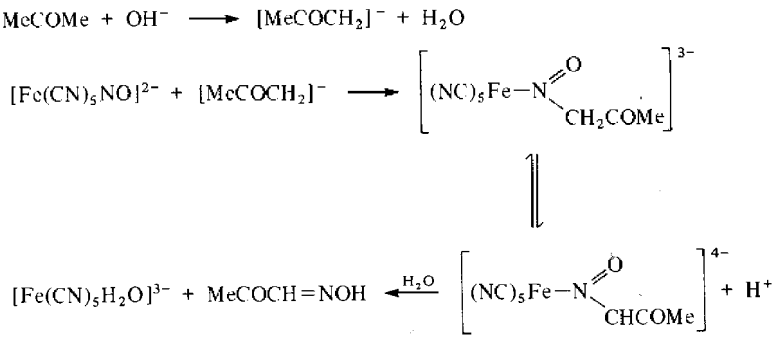
$$[Fe(CN)_6]^{4-} + NO_2^- \rightleftharpoons [Fe(CN)_5NO_2]^{4-} + CN^- \quad (9)$$

$$[Fe(CN)_5NO_2]^{4-} + H_2O \rightleftharpoons [Fe(CN)_5NO]^{2-} + 2OH^- \quad (10)$$

$$2[Fe(CN)_6]^{4-} + 2NO_2^- + 3Ba^{2+} + 3CO_2 + H_2O \longrightarrow 2[Fe(CN)_5NO]^{2-} + 2HCN + 3BaCO_3 \quad (11)$$

Red crystals of sodium nitroprusside are readily soluble in water and ethanol; aqueous solutions undergo a complex decomposition process in light.[109] Low-spin (diamagnetic) $[Fe(CN)_5NO]^{2-}$, as the sodium, iron(II), copper(II) and zinc(II) salts, shows considerable conversion to the high-spin state at 20–110 °C under high pressure.[110] The nitroprusside anion has an N—O bond length of 1.13 Å, an Fe—NO angle of 180 ° and an NO stretching frequency of 1947 cm^{-1} indicating an NO^+ complex of iron(II) with extensive π bonding. However, the Mössbauer spectrum and shortness of the Fe—N bond (1.63 Å) argue[111] for a less positively charged NO ligand and indeed the X-ray photoelectron spectrum[112] indicates a positive charge on NO of approximately +0.35. One-electron reduction of $[Fe(CN)_5NO]^{2-}$ by sodium in liquid ammonia,[113] or a variety of radicals formed in aqueous solution in radiolysis experiments,[114] results in the formation of $[Fe(CN)_5NO]^{3-}$, which undergoes a first order decay with loss of cyanide to give $[Fe(CN)_4NO]^{2-}$. Both the tetragonal pyramidal structure[115] of $[Fe(CN)_4NO]^{2-}$ and the likelihood that it is a *cis*-cyanide which is lost in both this transformation and reactions involving nucleophilic attack on nitroprusside are predicted from INDO molecular obital calculations[116] based on recent structure determinations. Multielectron

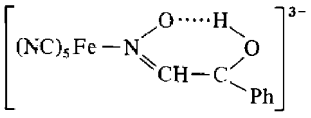
electrochemical reduction in nonaqueous solvents results[117] in the formation of $[Fe(CN)_5NH_2OH]^-$.



The nitroprusside ion is attacked by hydroxide to yield the corresponding nitro compound $[Fe(CN)_5NO_2]^{4-}$. The rate of formation of $[Fe(CN)_5NO_2]^{4-}$ is first order in OH^- and nitroprusside concentrations[118] and electrochemical studies suggest[119] the formation of the transient intermediate $[Fe(CN)_5(N(=O)OH)]^{3-}$ (equations 12 and 13).

$$[Fe(CN)_5NO]^{2-} + OH^- \xrightarrow{slow} [Fe(CN)_5NO_2H]^{3-} \quad (12)$$

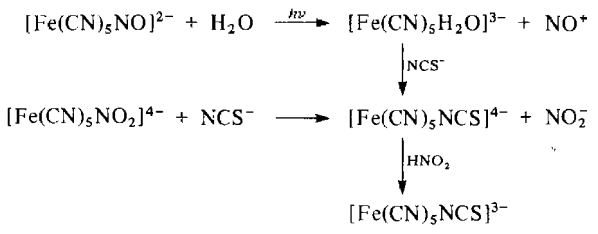
$$[Fe(CN)_5NO_2H]^{3-} + OH^- \xrightarrow{fast} [Fe(CN)_5NO_2]^{4-} + H_2O \quad (13)$$



The yellow solid $Na_4[Fe(CN)_5NO_2]$ is prepared[120] by the reaction of concentrated aqueous NaOH with a methanolic solution of sodium nitroprusside at 2 °C. The kinetics of the hydrolysis equilibrium (14) have been investigated.[118] $[Fe(CN)_5H_2O]^{3-}$ is also the usual product in the reaction of nitroprusside ion with ketones, and molecules containing active methylene groups, in alkaline solution.[109] The reaction with acetone has been studied in some detail[121] and the overall reaction in Scheme 1 proposed. Salts of the type (**2**) shown in Scheme 1 can be isolated. The red ion $[Fe(CN)_5N(O)CHCOPh]^{4-}$ formed in the reaction of nitroprusside with acetophenone can be protonated[122] to yield a blue, isolable complex thought to have structure (**3**).

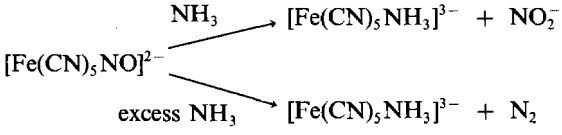
$$[Fe(CN)_5NO_2]^{4-} + H_2O \rightleftharpoons [Fe(CN)_5H_2O]^{3-} + NO_2^- \quad (14)$$

(2)



Scheme 1

(3)

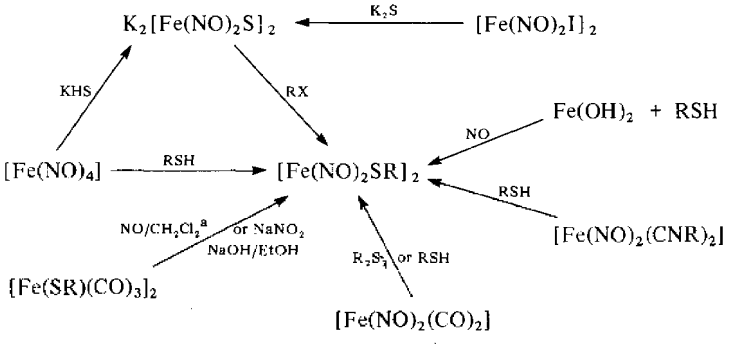


Colour reactions of the nitroprusside ion such as these have been known for many years.[123] Most of these reactions involve nucleophilic attack on the coordinated NO group resulting in either displacement of NO or the formation of an unusual ligand bound to the iron. In the Gmelin test for SH^- a purple-violet colour is formed. This has been reported[124] as being due to the ion $[Fe(CN)_5NOS]^{4-}$; however this is probably an oversimplification[125] and no definite structural assignment has been made. Na_2Se and Na_2Te react with nitroprusside to give[126] respectively blue-green and black colours. Alkaline solutions of mercaptans react with nitroprusside to form purple-red colours[127] and thus this reaction has been used to identify cysteine in mildly basic solution.[128] Thiourea and its derivatives react with nitroprusside[129] to give red coloured adducts which, in the case of thiourea, slowly becomes blue. The structures of these adducts are uncertain but the final blue colour[130] may be due to $[Fe(CN)_5(NCS)]^{3-}$, which can be produced by the photolysis of nitroprusside ion in the presence of aqueous thiocyanate, or by acidification of alkaline solutions of $[Fe(CN)_5NO_2]^{4-}$ containing thiocyanate. The reaction path shown in Scheme 2 has been proposed.[131]

Whilst crystals of $[Fe(CN)_5(NCS)][Bu_4N]_3$ are orange, the colours of the salt vary[107] from orange in acetone, to purple in ethanol and blue or purple in aqueous solutions. The analagous selenium compound $[Fe(CN)_5(NCSe)][Bu_4N]_3$ is formed[132] in the reaction of $Na_3[Fe(CN)_5NH_3]$ with *n*-butyl ammonium chloride and KNCSe in acetone.

Scheme 2

Nitroprusside ion reacts with ammonia[133] at pH 11.0–12.5 to give $[Fe(CN)_5NH_3]^{3-}$ and nitrite as in equation (15); with higher concentrations of ammonia nitrogen is evolved, presumably following attack on the NO ligand by ammonia. Similar behaviour is observed with primary aliphatic amines.[134] In liquid ammonia nitroprusside is attacked by NaNHPh to give $Na_4[Fe(CN)_5\{(N{=}O)NPh\}]$, whereas only $Na_3[Fe(CN)_5NH_3]$ is isolated[135] following the reaction with NaNRR′.

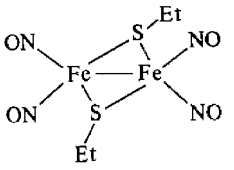


(15)

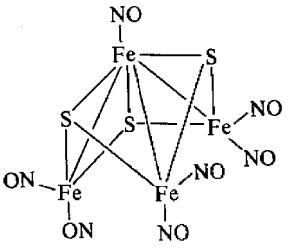
Sodium nitroprusside is a rapidly acting peripheral vasodilator which has been known[136,137] for some time to lower blood pressure swiftly in emergencies. Whilst useful for controlling blood pressure during surgery, only low doses have been recommended because sodium nitroprusside apparently forms free cyanide *in vivo*. The concentrations of CN^- measured in the past may, however, have been an artefact[138] due to photodecomposition during lengthy colorimetric analysis. The reactions of sodium nitroprusside with amines have been investigated[139] as part of a study to identify its mode of biological action.

44.1.2.5 Complexes Containing Nitric Oxide and Sulfur Donors

The most familiar complexes in this class are Roussin's red and black salts[140] obtained as a mixture from the reaction of iron(III) sulfide with nitric oxide and an alkali metal sulfide.[141] The dimeric and diamagnetic red salt, $K_2[Fe(NO)_2S]_2$ gives rise to a series of stable esters $[Fe(NO)_2SR]_2$ (R = Me, Et, Ph *etc.*) which are also diamagnetic, dark red and soluble in organic solvents. Some preparative routes[142] to the red salt and its esters are shown in Scheme 3.



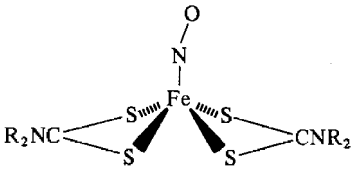
[a] A. R. Butler, C. Glidewell and J. McGinnis, *Inorg. Chim. Acta*, 1982, **64**, L77.



Scheme 3

The structure of the red ethyl ester[143] (**4**) has two iron and two sulfur atoms in a planar configuration, the iron atoms being approximately tetrahedrally coordinated by two bridging sulfur and two nitrosyl ligands. The angle at sulfur is 73.7°, the Fe—Fe distance 2.72 Å and the N—Fe—N bond angle 117°. The X-ray structure[143] reveals the presence of only the C_{2h} isomer whereas NMR measurements in d^8-toluene show both C_{2h} and C_{2v} forms.[144] The activation energies for the interconversion of the two forms (typically $\Delta G^{\neq} = 75.3\,kJ\,mol^{-1}$) have been derived for a variety of alkyl substituents.

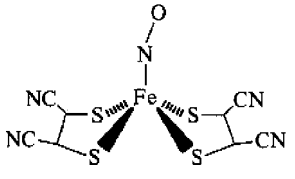
The black salts $M[Fe_4S_3(NO)_7]$ (M = Na, K, Cs, $AsPh_4$) are classically prepared[141] from $NaNO_2$, KHS and iron(II) sulfate. They may also be prepared in good yield[144] by nitrosylation of $[Fe_2S_2(CO)_6]$, $[Fe_2S_2(CO)_6]^{2-}$ or $[Fe_3S_2(CO)_9]$ by reaction with sodium nitrite in a refluxing solution of sodium hydroxide in aqueous ethanol. The structure (**5**) consists of a trigonal pyramid of iron atoms with triply-bridged sulfur atoms and iron–iron bonds between the apical Fe—NO group and three basal $Fe(NO)_2$ groups. The three $Fe(NO)_2$ groups are also joined by the triply bridging sulfur atoms. An early structural study[145] found the Fe—N bond length shorter in the apical group. More recent work[146] on the $AsPh_4^+$ salt, prepared by Na/Hg reduction of $[Fe_4(NO)_4(\mu_3\text{-}S)_4]$ in THF, has however shown that all Fe—N and N—O bond lengths in the black monoanion are essentially the same. This observation prompted a reexamination of the bonding in both the red and black salts in comparison with the closely related $[Fe_4(NO)_4(\mu_3\text{-}S)_4]$ clusters. The black salt can be formally constructed[146] from the dimensionally similar groupings present[147,148] in the red salt and in $[Fe_4(NO)_4(\mu_3\text{-}S)_4]$. The bonding models developed for these two molecules suggest that the bonding in the monoanion of the black salt can be analagously described under C_{3v} symmetry.



(4)

(5)

The preparation of the five-coordinate iron nitrosyl dithiocarbamate complexes $[Fe(NO)(S_2CNR_2)_2]$ was first reported[149] by Cambi and Cagnasso. These compounds may be prepared[150] by reacting a solution of a divalent iron salt and NaS_2CNR_2 with NO in methanol. Crystal structures of $[Fe(NO)(S_2CNR_2)_2]$ (R = Et, (**6**), at room temperature[151] and subsequently for R = Me at −80 °C) show[152] a square pyramidal geometry with an approximately linear apical iron nitrosyl group (Fe—N—O = 174° and 170° respectively) in contrast to the bent (M—N—O = 135°) metal nitrosyl group in the isomorphous complex[153] $[Co(NO)(S_2CNMe_2)_2]$. Both iron complexes are paramagnetic. ESR and Mössbauer spectra of $[Fe(NO)(S_2CNR_2)_2]$ have been interpreted[154–156] in terms of a formal iron(I) species in which the unpaired electron resides in the iron d_{z^2} orbital. This conclusion is supported[157] by a study of 14 iron nitrosyl dithiocarbamate complexes with differing organic substituents. The pK_a of the corresponding dialkylammonium ion was shown to be an effective measure of the mesomeric effect of the $-NR_2$ groups of the dithiocarbamate ligand which in turn affects ν_{NO} and the Fe—N bond length.



(6)

Green-black five-coordinate $[FeNO(S_2CNR_2)_2]$ is reportedly[158] converted into the dark brown six-coordinate molecule $[Fe(NO)_2(S_2CNR_2)_2]$ by action of NO in chloroform. Subsequent investigation,[159] however, has failed to confirm this although some evidence for the existence of the molecule as an intermediate was gained from $^{14}N/^{15}N$ exchange studies.

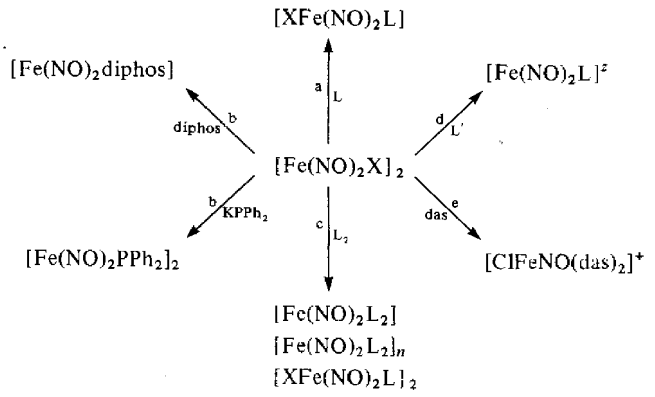
Direct oxidation of $[Fe(NO)(S_2CNMe_2)_2]$ at room temperature[160] leads to *cis*-$[Fe(NO)(S_2CNMe_2)_2X]$ (X = Br, I, NO_2) whilst at −78 °C *trans*-$[Fe(NO)(S_2CNMe_2)_2(NO_2)]$ is formed.[159] In this case, the *trans* isomer is the kinetic product which isomerizes at 5 °C to the thermodynamically favourable *cis* isomer. *Trans* products are apparently favoured by ligands such as MeCN and $-NCS^-$ which are relatively weak σ donors and poor π acceptors. Ligands which have either strong σ donor (and strong π acceptor) properties such as MeNC and NO_2^-, or which are able directly to donate from large π orbitals into vacant *cis* π^* orbitals (such as halides) favour a *cis* configuration.[159] In the *cis* nitro compound, NO and NO_2^- undergo[161] a novel intramolecular exchange reaction. The *cis* octahedral geometry of the halogeno derivative $[Fe(NO)(S_2CNEt_2)_2I]$ has been confirmed[162] by

magnetically perturbed Mössbauer spectroscopy at 4.2 K. Whilst the bis-nitrosyl bis-dithiocarbamate complex has not been substantiated, an analagous complex *cis*-$[Fe(NO)_2(Sacsac)_2]$ (Sacsac = dithioacetylacetonate) has been reported[163] (ν_{NO} = 1765, 1790 cm^{-1}).

Other examples of the stabilization of an iron nitrosyl complex by chelating sulfur ligands are the bis-dithiolene complexes[164] $[Fe(NO)(S_2C_2R_2)_2]^Z$ ($Z = 0, -1, -2, -3$; $S_2C_2R_2$ = disubstituted *cis*-ethylene-1,2-dithiolates, tetrachlorobenzene-1,2-dithiolate, toluene-3,4-dithiolate). These complexes have square pyramidal geometry, analagous to the iron nitrosyl bis-dithiocarbamate complexes discussed above, as exemplified in a crystal structure[165] of $[Fe(NO)\{S_2C_2(CN)_2\}_2]$ (**7**). The Fe—N—O bond angle (measured at room temperature) is reported to be 168°. These complexes undergo a series of one-electron transfer reactions[164] which have been investigated voltammetrically. The half-wave potential for each redox step is dependent on the dithiolene ligand, becoming more positive as the ligand becomes more electron withdrawing; the order $S_2C_2(CN)_2 > S_2C_2(CF_3)_2 > S_2C_6Cl_4 > S_2C_6H_3Me > S_2C_2Ph_2$ has been observed.[164] The effect is also seen in substituted diaryldithiolenes,[166] half-wave potentials becoming more positive as substituents on the aryl group become more electron withdrawing. The complexes $[Fe(NO)(S_2C_2R_2)_2]$ undergo ligand exchange reactions, $[Fe(NO)\{S_2C_2(CN)_2\}(S_2C_2Ph_2)]^-$ for example resulting[167] from mixing the two corresponding bis-dithiolene monoanionic complexes.

(7)

In the formation of $[Fe(NO)(S_2C_2Ph_2)_2]$ by the reaction between $[Fe(S_2C_2Ph_2)_2]_n$ and NO in cold chloroform, a purple complex[168] $[Fe_2(NO)_2(S_2C_2Ph_2)_3]\cdot CHCl_3$ can also be obtained. The monoanion can be isolated as a green solid by reaction of the neutral complex with $NaBH_4$. The Mössbauer spectrum of the neutral complex[169] shows that the two iron atoms are not equivalent, possibly due to interaction with the chloroform molecule. Interesting structure-related effects are also observed[170] in the complexes $[Fe(NO)(S_2CO_2Me_2)(P,P)]$ (P,P = diphos, $2PPh_3$). ESR spectra indicate that the unpaired electron may reside in different metal orbitals depending on the steric influence of the phospine ligands on the basic square pyramidal geometry of the complexes.



44.1.2.6 Nitrosyl Halides

$[Fe(NO)_3X]$ and $[Fe(NO)_2X]_2$ (X = Cl, Br, I) are known, although the former is highly unstable. $[Fe(NO)_3Cl]$ is prepared[171] by the action of NO on $FeCl_2$ at 70 °C in the presence of iron powder; the bromide and iodide analogs are prepared[172] from their respective tetracarbonyl halides as in equation (16). The more stable diamagnetic halides $[Fe(NO)_2X]_2$ are nonpolar and dissolve in organic solvents. The iodide, which has been studied in the most detail, may be prepared by direct reaction of NO with FeI_2 at elevated temperature, from $[Fe(NO)_2(CO)_2]$ by carbon monoxide displacement[172] with iodine or by the room temperature reaction[173] of NO with FeI_2 in acetone in the presence of iron powder. The dimeric nature of $[Fe(NO)_2X]_2$ has been confirmed by a crystal structure determination of the iodide (**8**).[174] The iron atoms are essentially tetrahedrally coordinated with iodine bridges. Although the bond is long (3.05 Å) there is a considerable iron–iron interaction. Both types of halide react with a variety of ligands to form monomeric complexes $[Fe(NO)_2LX]$.

$$[Fe(CO)_2X]_2 + Fe + 6NO \longrightarrow 2Fe(NO)_3X + 4CO \qquad (16)$$

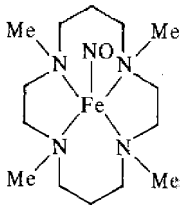
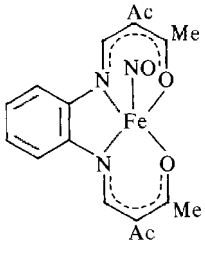
Scheme 4



Some reactions of $[Fe(NO)_2X]_2$ are illustrated in Scheme 4. The complexes $[Fe(NO)_2X_2]$ and $[FeNOX_3]$ are also known. $[Fe(NO)_2X_2][N(PPh_3)_2]$ is prepared[175] by the reaction of alkyl halides with $[Fe(CO)_3NO][N(PPh_3)_2]$ (X = Cl, Br or I). Reaction of the carbonyl nitrosyl with halogens affords[175] $[FeX_3(NO)][N(PPh_3)_2]$ (X = Cl, Br) or $[FeX_2(NO)_2][N(PPh_3)_2]$ (X = I).

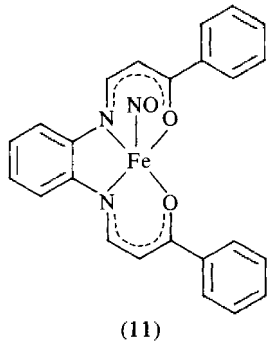
44.1.2.7 NO Adducts of Complexes Containing Polydentate Ligands

There are few examples of simple nitrosyl complexes containing σ N donor ligands. The Fe—NO moiety requires to be stabilized by appreciable d–π interaction and this is at odds with the classically 'hard' nature of N donor bases. In cases where iron nitrosyls are stabilized in coordination with a nitrogen (or oxygen) donor ligand, there is usually a degree of π acceptor character associated as, for example, with delocalized planar systems.[176] Nitric oxide reacts with solid β-iron phthalocyanine[177] to yield a 1:1 adduct (from which NO is readily displaced by pyridine). A similar route has been used to prepare nitrosylmyoglobin[179] and nitrosylhaemoglobin[178] for single crystal ESR studies which have been interpreted on the basis of a bent metal–nitrosyl bond. Iron nitrosyl complexes of tetraphenylporphyrin (TPP) have been investigated as possible models for the haem protein systems. The five-coordinate[180] complex [Fe(NO)TPP] has an Fe—NO bond angle of 151°, whereas[181] in [Fe(NO)(TPP)(1-MeIm)] (MeIm = 1-methylimidazole) it is 142°. The analogous complex [Fe(NO)(TPP)(4-MePip)] (4-MePip = 4-methylpiperidine) was found to crystallize in two distinct forms, with and without chloroform solvate,[182] in which the Fe—NO angles are 138.5° and 143.7° respectively. A structural correlation has been noted[182] between the stretching frequency of the coordinated nitrosyl and the length of the *trans* Fe—N bond.



Nitrosyl (*meso*-2,3,7,8,12,13,17,18-octaethyl-5-nitroporphyrinato)iron(II) has been shown[183] to dimerize at high concentration at 9 K. This observation implies an explanation of the ESR spectrum of the NO-haem-salicylate system, which is in turn a model of the observation that the interaction of oxyhaemoglobin with salicylate causes enhanced oxygen uptake in the presence of a substrate such as ascorbate. An interesting example of an iron nitrosyl complex with an N donor ligand without a delocalized π system is provided[184] by the complex $[Fe(TMC)(NO)]^{2+}$ (**9**) (TMC = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane). The complex is stabilized with considerable distortion from tetragonal pyramidal towards trigonal bipyramidal geometry.

Nitric oxide reacts with an ethanolic solution of [Fe(salen)] [salen = *N*,*N*′-ethylenebis(salicylideniminato)] at room temperature to give the black complex [Fe(salen)NO]. This compound exhibits[185] an $S = \frac{3}{2}$ to $S = \frac{1}{2}$ spin cross-over at 175 K. The corresponding complex of the 5-chloro-salen ligand [Fe(5-Cl-salen)NO], however, shows no sharp spin cross-over transition but a steady decrease in magnetic moment from 3.8 to 0.5 BM over the temperature range 4–100 K, indicative[186]



(9)

of an antiferromagnetic interaction and this implies a different lattice arrangement than in [Fe(salen)NO], possibly involving dimer formation. [Fe(TMC)NO] also exhibits an $S = \frac{3}{2}$ to $S = \frac{1}{2}$ spin transition although without a sharp transition temperature. Interestingly the $S = \frac{3}{2}$ to $S = \frac{1}{2}$ interconversion rate is considerably slower in [Fe(salen)NO]. The spin state equilibria have also been described for [Fe(salphen)NO] {salphen = *N,N'-o*-phenylenebis(salicylideniminato)} and here as in [Fe(salen)NO] hysteresis accompanies the spin cross-over at around 175 K. Indeed the existence of $S = \frac{3}{2}$ to $S = \frac{1}{2}$ spin equilibria are a feature of iron nitrosyl complexes of quadridentate Schiff bases and analogous compounds. For example the complex [Fe(J-ph)NO] (**10**) shows a sharp transition[187] in μ_{eff} from 2.0 BM at 90 K to 3.2 BM at 70 K whilst [Fe(bza-ph)NO] (**11**) shows[187] a gradual transition in μ_{eff} from 2.1 BM at 90 K to 2.6 BM at 300 K. Recently iron nitrosyl complexes of the bidentate ligand Q (Q = 8-quinolinolate) have been isolated.[188] [Fe(5-chloro-Q)$_2$(NO)(DMF)] and [Fe(2-methyl-Q)(NO)$_2$] have magnetic moments of 4.21 BM and 1.97 BM respectively, whilst μ_{eff} for [Fe(Q)$_2$NO]$_2$ varies[188] from 4.4 at 285 K to 4.0 BM at 83 K.

(10)

(11)

44.1.3 IRON(0) AND LOWER OXIDATION STATES

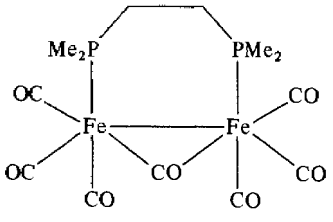
44.1.3.1 Introduction

The zero and lower oxidation states are relatively unimportant in the classical coordination chemistry of iron. With increased electron density on the iron, *d–d* and *d–π* interactions are particularly important, and systems with π acceptor orbitals are the dominant ligand species. Amongst the most common ligands encountered are carbon monoxide, phosphines, phosphites and unsaturated hydrocarbons. There are, however, a few relatively well-characterized iron(0) complexes derived from the reduction of higher oxidation state complexes containing N donor ligands possessing delocalized π systems.

44.1.3.2 Nitrogen Ligands

Herzog and co-workers[189] reduced $[Fe(bipy)_3]^{2+}$ to the zerovalent complex with Li_2bipy. Reduction of $FeCl_3$ in the presence of 2,2′-bipyridine also results in the formation of $[Fe(bipy)_3]$ as in equation (17). The black crystalline complex $[Fe(bipy)_3]$ dissolves in THF, dioxane or benzene to give red-violet solutions, while in protic solvents such as water, dilute acid or alcohols the complex is oxidized to $[Fe(bipy)_3]^{2+}$ with liberation of hydrogen. $[Fe(bipy)_3]$ decomposes at 145 °C *in vacuo* to iron and 2,2′-bipyridine. The compound appears to be paramagnetic[190] although its magnetic susceptibility has not been reported since the measurement is distorted by traces of metallic iron. Conductance and ESR measurements ($g_{av} = 2.075$) are in agreement[190] with a d^8 configuration with

neutral ligands. If an excess of reducing agent is used[191,192] a species is generated which apparently contains iron(−1) as in equation (18). However, ESR evidence suggests that the unpaired electrons in Na[Fe(bipy)$_3$] occupy molecular orbitals composed mainly of ligand orbitals. A similar reduction route can be used to prepare [Fe(terpy)$_2$] and related iron(0) complexes.[193] [Fe(bipy)$_3$] and coordinatively unsaturated [Fe(bipy)$_2$] can also be prepared[194] by the thermal decomposition of the alkyl complex [Et$_2$Fe(bipy)$_2$]; the tris derivative is formed when the decomposition takes place in the presence of free 2,2′-bipyridine.



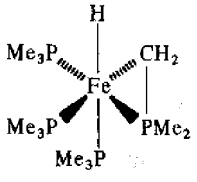
$$2FeCl_2 + 6bipy + 3Li_2bipy \xrightarrow{THF} 2[Fe(bipy)_3] + 4LiCl + 3bipy \quad (17)$$

$$3Nabipy + [Fe(bipy)_3]Cl_2 \longrightarrow Na[Fe(bipy)_3] + 3bipy + 3NaCl \quad (18)$$

The reduction of the classic iron(II) tris α,α′-diimine chelates has also been investigated electrochemically.[195,196] Whilst the first two reduction steps to the one and zero oxidation states are well understood, the nature of further reduced species is unclear. Such studies, however, do appear to demonstrate a limit to which increased electron density at the iron can be supported before charge becomes resident on the ligands. In the case of [Fe(bipy)$_3$] the increased electron density at iron must be stabilized by *d*-π back-donation. The structure of [Fe$_2$(CO)$_7$(bipy)] demonstrates[197] that 2,2′-bipyridine is a poorer π acceptor than two carbon monoxide ligands. Substitution of two carbon monoxide ligands in [Fe$_2$(CO)$_9$] by bipy leads to this complex which has one not three bridging CO groups. This is explained[197] in that bridging CO is a poorer π acid than terminal CO. The structure generated has a reduced number of bridging CO (increased number of terminal CO) ligands to make up for the poorer π acidity of bipyridine. Whilst the π acceptor properties of 2,2′-bipyridine represent a limit to the formation of less than zerovalent complexes with neutral ligands, the structure and spectra of [(η^6-toluene)Fe(bipy)] clearly demonstrate[198] that 2,2′-bipyridine does have considerable ability to accept π electron density from iron(0). The strength of the interaction is apparent from the Fe—N distance of 1.9 Å and the inertness of the toluene ligand which is only displaced by a very strong π acid such as dppe.

44.1.3.3 Phosphorus Ligands

Commonly, many iron(0) compounds containing phosphorus donor ligands are thought of as 'organometallic' rather than coordination complexes. Nonetheless, a brief discussion of some of their more important structural features is appropriate. Iron carbonyls react thermally[199,200] or photochemically[201] with PPh_3 to yield a mixture of [Fe(CO)$_4$PPh$_3$] and [Fe(CO)$_3$(PPh$_3$)$_2$]. Especially bulky phosphines such as P(Bu^t)$_3$ or P(EMe$_3$)$_3$ (E = Ge, Si, Sn) produce[202] only [Fe(CO)$_4$PR$_3$]. [Fe(CO)$_3$(PR$_3$)$_2$] are stable pale yellow complexes which can also be obtained from a variety of organometallic compounds containing the Fe(CO)$_3$ moiety. IR and Mössbauer spectra of [Fe(CO)$_3$(PR$_3$)$_2$] are consistent with a trigonal bipyramidal structure and these complexes are only known as the *trans* isomers. [Fe(CO)$_5$] reacts with bidentate phosphines to give mononuclear products containing mono and bidentate phosphine ligands, and binuclear complexes containing bridging phosphine ligands. The complex [Fe(CO)$_3$dmpe] (dmpe = 1,2-dimethylphospinoethane) has a geometry intermediate between square pyramidal and trigonal bipyramidal because of the small ligand 'bite'. The iron atoms in the dinuclear bridged complex (**12**) are coordinated in a trigonal bipyramidal geometry with the phosphorus ligands occupying *cis* axial positions.



(12)

The carbonyl ligands in [Fe(CO)$_3$(PR$_3$)$_2$] compounds are rather inert towards substitution, but these compounds do find use as starting materials for a number of complexes *via* an oxidative route (*vide infra*). Although [Fe(CO)$_3$(PPh$_3$)$_2$] is only sparingly soluble in most common organic solvents,

it is rather more soluble in concentrated sulfuric acid giving a yellow solution shown by NMR spectroscopy to contain a protonated species. Careful halogenation of $[Fe(CO)_3(PR_3)_2]$ affords[201] $[Fe(CO)_3(PR_3)X_2]$. The controlled one-electron oxidation of $[Fe(CO)_3(L)_2]$ complexes generates deep green iron(I) complexes, some of which can be isolated and are useful in the preparation of novel iron(II) complexes. These reactions are discussed in Section 44.1.4.3. *trans*-$[Fe(CO)_3L_2]$ complexes react with mercury(II) halides to form adducts (L = PPh_3 adduct is 1:1, L = $P(OPh)_3$ adduct is 1:2). Carbon monoxide is displaced photochemically from $[Fe(CO)_3(PEt_3)_2]$ by sulfur dioxide to give $[Fe(CO)_2(PEt_3)_2(SO_2)]$, which undergoes oxidative[204] elimination with HI to yield $[Fe(CO)_2(PEt_3)_2I_2]$. The analogous complex $[Fe(CO)_2(Ph_3)_2I_2]$ has been shown[205] to contain *cis* iodides, *cis* carbonyls and *trans* phosphines. The analogous phosphite complexes $[Fe(CO)_2\{P(OR)_3\}_2X_2]$, however, are thought[206] to have *cis* carbonyl, *cis* phosphite and *cis* halides for X = I but *trans* halides for X = Br.

Higher degrees of carbonyl substitution by phosphorus donor ligands in iron(0) complexes may be obtained by reduction of the corresponding halide in the presence of free ligand, or by direct synthesis using iron atoms. Thus reduction of $\{Fe(dmpe)_2Cl_2]$ by sodium naphthalenide in THF yields[207] red-brown air sensitive $[Fe(dmpe)_2]$. Sodium amalgam reduction of $[Fe\{P(OMe)_3\}_3Cl_2]$ in the presence of $P(OMe)_3$ gives[208] the very air sensitive yellow complex $[Fe\{P(OMe)_3\}_5]$. This complex reacts with carbon monoxide in ether to yield the remaining two members of the series $[Fe(CO)_x\{P(OMe)_3\}_{5-x}]$, namely $[Fe(CO)\{P(OMe)_3\}_4]$ and $[Fe(CO)_2\{P(OMe)_3\}_3]$. Reduction of $[FeCl_2(PMe_3)_3]$ with sodium amalgam in THF in the presence of excess PMe_3 under argon gives $[Fe(PMe_3)_4]$ (**13**) in which a hydride transfer has taken place to yield[209,210] an octahedral iron(II) species.

(13)

Iron pentacarbonyl reacts with PF_3 at elevated temperature and pressure giving the series of complexes $[Fe(CO)_{5-x}(PF_3)_x]$. $[Fe(PF_3)_5]$ may also be made by the direct reaction[211] of iron atoms with PF_3 at low temperature. This route enables the novel binuclear complex $[(PF_3)_3Fe(PF_2)_2Fe(PF_3)_3]$, not available by other means, to be obtained. The metal atom technique[212] has been extended to the synthesis of a number of d^8 iron complexes[213–215] with phosphorus donor ligands. In the low temperature reaction[216] of iron atoms with cycloocta-1,5-diene (1,5-cod), the very temperature-sensitive and highly reactive compound $[Fe(1,5\text{-cod})_2]$ is formed. This compound reacts with PMe_3 to yield $[Fe(1,5\text{-cod})(PMe_3)_3]$ but with $P(OMe)_3$ to yield $[Fe(1,3\text{-cod})\{P(OMe)_3\}_3]$. $[Fe(1,5\text{-cod})_2]$ reacts with dppe in ether/methylcyclohexane at −20 °C to yield, presumably, $[Fe(dppe)_2]$, which decomposes above 0 °C but reacts[216] with nitrogen to give the five-coordinate dinitrogen complex $[Fe(dppe)_2N_2]$.

44.1.4 IRON(I)

44.1.4.1 Introduction

Although isoelectronic with cobalt(II), d^7 iron(I) complexes show a marked instability, particularly with respect to disproportionation to iron(0) and iron(II) complexes. Accordingly few iron(I) compounds have been isolated and characterized. It is therefore not appropriate to group iron(I) complexes by the ligand classification used for other complexes. The scheme which has been adopted is to discuss reports of iron(I) complexes under the headings of: carbon monoxide and arsine ligands, phosphorus-containing ligands, cyanide ligands, complexes of macrocyclic ligands and organometallic complexes.

44.1.4.2 Carbon Monoxide and Arsine Ligands

There are several examples of iron(I) complexes in which the +1 oxidation state is stabilized by coordination of carbon monoxide or arsine ligands. In an early paper[217] Hieber and Lagally

described the formation of $[Fe(CO)_2I]$ by heating $[Fe(CO)_2I_2]$ in a stream of CO_2 as in equation (19). Careful oxidation of $[Fe(CO)_3pdma]$ with iodine in benzene/nitrobenzene (equation 20) under nitrogen has been reported[216] to give brown yellow $[Fe(CO)_3pdma]^+I^-$ (pdma = *o*-phenylenebis-dimethylarsine).

$$[Fe(CO)_2I_2] \longrightarrow [Fe(CO)_2I] + \tfrac{1}{2}I_2 \quad (19)$$

$$[Fe(CO)_3pdma] + \tfrac{1}{2}I_2 \longrightarrow [Fe(CO)_3pdma]^+ I^- \quad (20)$$

Amongst dimeric organometallic compounds which formally contain iron(I) is the well-known[219] diamagnetic dimeric carbonyl complex $[Fe(\eta\text{-}C_5H_5)(CO)_2]_2$. Recently a series of paramagnetic monomeric iron carbonyl hydrides has been generated[220] by UV irradiation of dilute solutions of $[Fe(CO)_5]$ in pentane under hydrogen at low temperatures. The iron(I) species $[HFe(CO)_4]$ was characterized by ESR spectroscopy ($g = 2.0120$). One-electron electrochemical oxidation of $[Fe(CO)_5]$ in trifluoroacetic acid is reported[221] to yield transient $[Fe(CO)_5]^+$ (half-life = 50–500 ms). The naked ion Fe^+ has been observed in ion cyclotron resonance studies of its interaction with alkanes.[222] Fe^+ was generated in the gas phase by electron impact on $[Fe(CO)_5]$.

44.1.4.3 Phosphorus Ligands

In much of the reported chemistry of iron(I) the low oxidation state is stabilized by coordination to phosphorus-containing ligands. Thus, Sacco and co-workers prepared[223] the paramagnetic iron(I) hydride $[FeH(dppe)_2]$ (dppe = 1,2-bis(diphenylphosphino)ethane) by the sodium reduction of $[FeHCl(dppe)_2]$ in benzene under nitrogen as in equation (21) and also by its reaction with $[Co(N_2)(PEt_2Ph)_3]Na$ in THF. Deep red crystalline $[FeH(dppe)_2]$ is soluble in benzene and toluene but insoluble in pentane. The compound is paramagnetic both in the solid state and in solution and obeys the Curie–Weiss law between 97 K and 297 K ($\theta = 14.5°$). It is isomorphous[224] with $[CoH(dppe)_2]$ and shows a strong ESR signal at room temperature in toluene solution centred[225] at $g = 2.085$. Under a nitrogen atmosphere $[FeH(dppe)_2]$ reacts with trityl salts (Ph_3CX; X = BF_4, ClO_4) in benzene to yield $[FeH(N_2)(dppe)_2]X$ as in equation (22) and with stoichiometric amounts of HCl or $HClO_4$ in ethanol to yield respectively $[FeHCl(dppe)_2]$ and $[FeH(N_2)(dppe)_2]^+ClO_4^-$. The reaction with acids appears to proceed *via* the oxidative addition of a proton to give an unstable iron(III) dihydride $[FeH_2(dppe)_2]^+$. With a large excess of hydrochloric acid at 80 °C $[FeCl_2(dppe)_2]$ is formed. The reduction of $[FeCl_2(dppe)_2]$ with stoichiometric amounts of sodium in the presence of free phosphine as in equation (23) yields the analogous iron(I) halide $[FeCl(dppe)_2]$.

$$[FeHCl(dppe)_2] + Na \longrightarrow [FeH(dppe)_2] + NaCl \quad (21)$$

$$[FeH(dppe)_2] + Ph_3CX + N_2 \longrightarrow [FeH(N_2)(dppe)_2]X \quad (22)$$

$$[FeCl_2(dppe)_2] + Na \longrightarrow [FeCl(dppe)_2] + NaCl \quad (23)$$

The red crystals of this complex have a bulk magnetic moment of 2.11 BM ($\theta = 8$ K) and in toluene solution a strong ESR signal with a partially resolved hyperfine structure[226] is centred at $g = 2.075$. The complexes $[FeX(dppe)_2]$ (X = Br, I) have also been prepared. Reaction of $[Fe(dppe)_2]$ with $AlEt_3$, $AlEt_2Cl$ or $Al(Bu^i)_2H$ affords $[Fe(dppe)_2]^+X^-$ ($X^- = AlH_2R_2^-$ or $AlCl_2R_2^-$). These four-coordinate iron(I) complexes react with ligands L to give the five-coordinate cations $[FeL(dppe)_2]^+$ (L = C_2H_4, CO, N_2, MeCN).[227] The ESR spectra of a range of iron(I) bis-dppe complexes have been measured; the reported g values (Table 2) are sensitive to both coordination number and the nature of the additional ligand. On the basis of their ESR spectra the complexes $[FeH(dppe)_2]$ and $[FeCl(dppe)_2]$ have been assigned respectively square pyramidal and trigonal bipyramidal coordination geometries.[227]

In deaerated methanolic solution, iron(II) hydrido complexes of the type $[FeH(L)(dppe)_2]^+$ (L = MeCN, $MeCH_2CN$, $CH_2{=}CHCN$, PhCN and *p*-MeC_6H_4CN) are reduced to $[FeH(L)(dppe)_2]$ by solvated electrons produced by γ-radiolysis of the solvent.[228] In pulsed radiolysis studies $[FeH(L)dppe_2]$ decays to five-coordinate $[FeH(dppe)_2]$ (half-life $\leqslant$ 1 s). In continuous radiolysis however, $[FeH(dppe)_2]$ is not the final product and here as in its reaction with acids it is suspected that oxidative addition of a proton yields an unstable iron(III) dihydride which decom-

Table 2 ESR g values for dppe Complexes of Iron(I)[a]

$[Fe(C_2H_4)(dppe)_2]^+$	2.085
$[Fe(CO)(dppe)_2]^+$	2.0515
$[Fe(MeCN)(dppe)_2]^+$	2.0981
$[Fe(dppe)_2]^+$	2.21

[a]dppe = 1,2-bis(diphenylphosphino)-ethane; data from M. Gargano, P. Giannoccaro, M. Rossi, G. Vassapollo and A. Sacco, *J. Chem. Soc., Dalton Trans.*, 1975, 9.

poses to hydrogen and $[Fe(dppe)_2]^+$. Further oxidation yields $[FeH(dppe)_2]^{2+}$ which is itself reduced by the iron(I) species $[FeH(dppe)_2]$ to $[FeH(dppe)_2]^+$. This coordinatively unsaturated species then binds the neutral ligand present in solution and so regenerates the starting complex.[228] Pulsed radiolysis studies of the complexes $[FeH(L)(dppe)_2]^+$ (L = $P(OMe)_3$, CO) in deaerated methanol solution showed the existence of a novel five-coordinate iron(I) intermediate $[FeH(L)(dppe)_2]$ in which one dppe is monodentate. Ring closure by dppe with elimination of L results in the familiar[229] iron(I) complex $[FeH(dppe)_2]$. These processes are outlined in Scheme 5. Interestingly, pulse radiolysis techniques have also been used to generate transient iron(I) species in aqueous solution.[230]

$$[FeH(L)(dppe)_2]^+ \xrightarrow[e^-]{\text{pulsed } \gamma \text{ radiolysis}} [FeH(L)(dppe)_2] \longrightarrow [FeH(dppe)_2] + L \xrightarrow[MeOH_2^+]{\text{continuous } \gamma \text{ radiolysis}}$$

$$[FeH_2(dppe)_2]^+ \longrightarrow [FeH(dppe)_2]^+ + H_2 \xrightarrow{MeOH_2^+} [FeH(dppe)_2]^{2+} \xrightarrow{[FeH(dppe)_2]} [FeH(dppe)_2]^+$$

Scheme 5

Cyclic voltammetric studies of $[Fe(CO)_3L_2]$ {L = PPh_3, $PMePh_2$, $P(NMe_2)_3$, $P(OPh)_3$; L_2 = dppe, dppm (dppm = bis(diphenylphosphino)methane)} in dichloromethane showed reversible one-electron oxidation to $[Fe(CO)_3L_2]^+$, which was identified spectroscopically.[231,232] Oxidation of $[Fe(CO)_3(AsPh_3)_2]$ is apparently not reversible but the corresponding iron(I) cation was identified by ESR and IR spectroscopy. The complexes $[Fe(CO)_3L_2]^+$ are generated chemically as deep green solutions[231] by the oxidation of $[Fe(CO)_3L_2]$ with $[N(C_6H_4Br\text{-}p)_3]^+PF_6^-$ in dichloromethane (formed by the reaction between $N(C_6H_4Br\text{-}p)_3$ and $AgPF_6$ followed by filtration to remove metallic silver) (equation 24). The salt $[Fe(CO)_3(PPh_3)_2]^+PF_6^-$ was isolated as the hemidichloromethane solvate, which is soluble in polar solvents. Reaction with halogens (X_2, X = Cl, Br, I; 1:1 ratio Fe:X) in dichloromethane (equation 25), is rapid to give $[FeX(CO)_3(PPh_3)_2]^+$. With halide ions $[Fe(CO)_3(PPh_3)_2]^+$ (1:1 molar ratio) forms the paramagnetic intermediate $[FeX(CO)_3(PPh_3)_2]$ which disproportionates to give $[Fe(CO)_3(PPh_3)_2]$ and $[FeX_2(CO)_{4-n}(PPh_3)_n]$, (X = I, n = 1; X = Br, n = 1, 2; X = Cl, n = 2). The iron(I) species $[FeX(CO)_3(PPh_3)_2]$ is an intermediate in the oxidative elimination reactions of $[Fe(CO)_3(PPh_3)_2]$ with halogen. It is not clear whether this species contains an Fe—X bond or a halogen–acyl group.[231]

$$[Fe(CO)_3L_2] + N(C_6H_4Br\text{-}p)_3^+ \longrightarrow [Fe(CO)_3L_2]^+ \quad (24)$$

$$[Fe(CO_3)L_2]^+ + X_2 \longrightarrow [FeX(CO)_3L]^+ + X^- \quad (25)$$

The electrochemical reduction of a series of cationic iron(II) hydrido complexes *trans*-$[FeH(L)(dppe)_2]^+$ (L = N_2, C_5H_5N, PhCN, CH_2CHCN, MeCN, $P(OMe)_3$, $P(OEt)_3$, CO) has been shown to proceed *via* transient d^7 iron(I) species which lose one of the neutral ligands. Further reduction of the resulting five-coordinate intermediates yields stable d^8 iron(0) anionic hydrides.[233]

The oxidative substitution and radical coupling reactions of $[Fe(CO)_3(PPh_3)_2]^+$ have led to a number of unusual iron(0) and iron(II) complexes, *e.g.* equation (25), which cannot be obtained[234] from its diamagnetic precursor $[Fe(CO)_3(PPh_3)_2]$. The iron(I) species is relatively unstable, probably due to poor charge delocalization by the phosphine ligands. The presence of an imidazolidinylidene

[b] L = $\overbrace{CN(Me)CH_2CH_2NMe}$

ligand allows more efficient charge delocalization.[235] Several carbenecarbonyl–iron(I) complexes have been isolated by oxidation of $[Fe(CO)_3(L)(L')]$ (L = :CN(Me)CH_2CH_2NMe; L′ = PPh_3, PEt_3, ½dppe, $P(OPh)_3$) using a variety of agents (I_2, $AgBF_4$, $AlCl_3$, MeI, Ph_3CCl, TCNE, AgCN, $AgPF_6$, $AgSbF_6$) in THF or dichloromethane under argon. Nine crystalline complexes have been reported, and these are listed in Table 3 together with some of their properties. The iron(I) salts are susceptible to neutral ligand exchange reactions, in particular CO displacement as for example in equation (26). When a THF solution of an allyl iron halide $[Fe(\eta\text{-}C_3H_5)(CO)_2L'(X)]$ (X = Br or I; L′ = CO, phosphine or the carbene ligand L above) is stirred with the electron rich alkene L_2, the neutral iron(I) complexes $[Fe(\eta\text{-}C_3H_5)(CO)_2L']$ are formed (equation 27). These green complexes have been characterized spectroscopically in THF solution and data are given in Table 4.

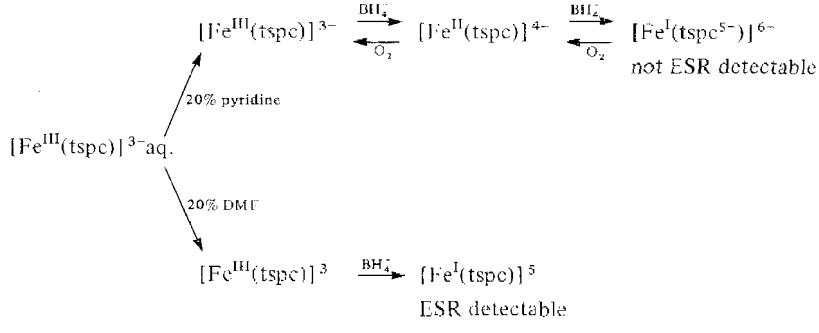
44.1.4.4 Cyanide Complexes

Treadwell and Huber reported[236] the electrolytic reduction of aqueous $K_4[Fe(CN)_6]$ in the presence of excess KCN yielding a colourless solution which reduces one mole of $[Fe(CN)_6]^{3-}$. This was interpreted as indicating the formation of an iron(I) cyano complex, although the possible formation of a hydrido species such as $[Fe(CN)_5H]^{3-}$ has not been ruled out by subsequent chemical studies.[237] The complex ions $[Fe(CN)_6H]^{4-}$ and $[Fe(CN)_5]^{4-}$ have been observed in pulse radiolysis studies of aqueous hexacyanoferrate(II) solutions.[238] γ-Irradiation of single crystals of alkali halides doped with hexacyanoferrate(II) ions have yielded ESR spectra characteristic of a number of iron(I) species.[239,240] These include $[Fe(CN)_5]^{4-}$, $[Fe(CN)_5(H_2O)]^{4-}$, $[Fe(CN)_5Cl]^{5-}$, $[Fe(CN)_4Cl_2]^{5-}$, $[Fe(CN)_5Br]^{5-}$ and $[Fe(CN)_4Br_2]^{5-}$. The spectra of the pentacyano species contain some evidence for a 'bent' cyanide ligand.[239]

44.1.4.5 Macrocyclic Ligands

There have been a number of reports of iron(I) complexes generated by the reduction of iron phthalocyanine compounds. The assignment of metal oxidation state is complicated by the ability of the phthalocyanine ring to undergo reduction. Progressive reduction of iron(II) phthalocyanine with sodium in THF first yields a purple solution which shows a strong ESR spectrum centred at $g = 2.01$, and on further reduction the solution turns blue and the ESR signal collapses. A final reduction stage yields a green solution whose ESR signal[241] is a single isotropic line at $g = 2.003$. Subsequently further electrochemical investigation of this sequence identified a fourth (earlier) stage

in the sequential reduction though this stage could not be reproduced using Na/THF.[242] These authors postulate the sequence shown in Scheme 6.



$$\underset{\text{green}}{[Fe^{II}pc]} \xrightarrow{e^-} \underset{\text{pink}}{[Fe^{II}pc]^-} \xrightarrow{e^-} \underset{\text{purple}}{[Fe^{I}pc]^{2-}} \xrightarrow{e^-} \underset{\text{blue-violet}}{[Fe^{I}pc]^{3-}} \xrightarrow{e^-} \underset{\text{green-blue}}{[Fe^{I}pc]^{4-}}$$

Scheme 6

The redox couple $[Fe^{II}pc]/[Fe^{I}pc]$ is sensitive to solvent since the extent of π back-donation to phthalocyanine is influenced by the electron donating ability of axial solvent ligands. Thus the iron(II) complex is more easily reduced in solvent systems where π back-donation is minimized. The ease of reduction of $[Fe^{II}pc]$ lies in the sequence pyridine > DMSO > DMF as solvents.[242] By contrast the Fe^{II}/Fe^{I} redox potentials of iron(II) porphyrin complexes show little solvent dependence because their capability for π back-donation is relatively small.[242]

The iron(I) anion [Fe(TPP)]$^-$ (TPP = tetraphenylporphine dianion) is produced[243] by the reduction of μ-oxo-bis(tetraphenylporphineiron(III)) with Na/Hg in THF. The product appears to exist in different spin states in THF solution (200–300 K) and frozen THF matrix at 77 K. A recent study, however,[244] is unequivocal about the d^7 Fe^{I} nature of the complex in the presence of pyridine.

Carbon monoxide reacts with [Fe(TPP)]$^-$ to form a five-coordinate complex [Fe(TPP)CO], which can be reduced electrochemically to the corresponding iron(I) species from which, however,[245] CO spontaneously dissociates. The Fe—CO interaction is stabilized by the presence of hydrocarbon chains bound by amide linkages to the *ortho* position of the TPP phenyl rings. Carbon monoxide adducts of iron(I) complexes of a number of these 'superstructured' porphyrins have been reported.[245] The chemistry of these highly reduced species is of relevance to understanding[246] the reactions of cytochrome P-450 and the peroxidases.

Scheme 7

Deep blue [iron(III)(tspc)] (tspc = 3,10,17,24-tetrasulfonatophthalocyanine) is reduced in aqueous solutions to give two iron(I) tspc species[247,248] as shown in Scheme 7. Stoichiometric sodium reduction[249] of $[Fe^{II}(salen)]$ in THF affords high-spin d^7 [Fe(salen)]$^-$. At room temperature this complex has a magnetic moment of 3.7 BM and the Curie-Weiss law is obeyed down to 90 K ($\theta = -46\,^\circ$). The sodium salt is freely soluble in THF forming air and moisture sensitive deep green solutions. The [Fe(salen)]$^-$ anion is a strong nucleophile reacting, as in equation (28) for instance, with benzyl chloride at $-60\,^\circ$C to give the corresponding iron(III) benzyl derivative[249] which is high-spin.

$$[Fe(salen)]^- + PhCH_2Cl \longrightarrow [PhCH_2Fe(salen)] + Cl^- \qquad (28)$$

Controlled potential electrolysis of the iron(II) complex $[Fe(L)(MeCN)_2]^{2+}$ (L = Me_6[14]1,3,8,10-tetraeneN_4, see Section 44.1.5.12.3) in acetonitrile at the first reduction plateau gives[250] the purple iron(I) cation $[Fe(L)]^+$, isolable in high yield as the $CF_3SO_3^-$ salt. The ESR spectrum in frozen acetonitrile is characteristic of low-spin d^7 iron(I) having a rhombic distortion from octahedral geometry. The effective magnetic moment measured by an NMR technique is 2.3 BM. A second quasi-reversible reduction step yields the analogous iron(0) complex; however, repeated scanning of this redox system results in hydride abstraction from the supporting electrolyte $Bu^n_4NBF_4$ to form a second iron(I) complex [FeH(L)(MeCN)]. The purple-black product also shows the appropriate ESR spectrum for low-spin d^7 iron(I) (μ_{eff} = 2.1 BM). An Fe—H stretching vibration is observed as a sharp IR absorbtion at 1890 cm^{-1}. The iron(I) alkyl and aryl derivatives [FeR(L)] result[250] from the sequential reaction of the iron(II) complex $[Fe(L)Cl]^+$ with two equivalents of the appropriate lithium alkyl or aryl as in equations (29) and (30). ESR and magnetic data are again consistent with

d^7 iron(I) and the unpaired electron occupies a molecular orbital which is predominantly metal ion in character.

$$[Fe(L)Cl]^+ + LiR \longrightarrow [Fe(L)Cl] + Li^+ + \tfrac{1}{2}R{-}R \quad (29)$$

$$[Fe(L)Cl] + LiR \longrightarrow [Fe(L)R] + LiCl \quad (30)$$

44.1.4.6 Organometallic Complexes

The oxidation state of +1 in iron chemistry is interesting for its rarity and so it is appropriate to include a description of some compounds which would not classically be regarded as coordination complexes. The iron(I) complexes $[(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6Me_6)]$, $[(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6Et_6)]$ and $[(\eta^5\text{-}C_5Me_5)Fe(\eta^6\text{-}C_6Me_6)]$ are obtained by Na/Hg reduction of the corresponding cationic compounds[251] in DME at 20 °C. The parent compound $[(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6H_6)]$ is highly unstable with respect to dimerization through the arene ring which is preceded by intramolecular electron transfer to an arene carbon atom.

A catalytically active species containing iron(I) has been postulated[252,253] in the cross coupling of 1-bromopropene with a variety of alkylmagnesium bromides in the presence of a reagent derived from the reduction of tris(dibenzoylmethido)iron(III). At intense ESR signal centred at $g = 2.08$ is observed on treating $[Fe(DBM)_3]$ with excess ethylmagnesium bromide in THF at −40 °C. A similar spectrum is observed on treating $FeCl_3$ and $[Fe(acac)_3]$ in this way. The existence of an iron(I) intermediate has been postulated in certain systems studied for the fixation of molecular nitrogen. Thus, an ESR signal at $g = 2.01$ observed[254] on mixing $FeCl_3$ and LiPh in ether was assigned to d^7 iron(I).

44.1.4.7 Nitric Oxide Complexes

One of the earliest assignments of an oxidation state of +1 for an iron complex was that of Wilkinson and co-workers[85] based on the magnetic susceptibility, IR and absorbtion spectra of $[Fe(H_2O)_5NO]^{2+}$. The potential for nitric oxide to act as either a two or three electron donor in its coordination to transition metal ions, however, has led to much controversy. For this reason iron nitrosyl complexes are discussed separately in Section 44.1.2.

44.1.5 IRON(II)

44.1.5.1 Introduction

For many years the coordination chemistry of iron(II) was overshadowed by the Werner complexes of its isoelectronic neighbour cobalt(III). Compared with cobalt(III) a substantially higher ligand field is needed to produce low-spin iron(II) complexes; once formed, however, they are usually thermodynamically very stable and kinetically inert. Complexes of this type are easily prepared, and a number have been known for a long time. Classic examples include mixed oxidation state cyanides (Prussian blues) and tris-(α,α′-diimine) complexes ('ferroins'). More recent examples include complexes containing phosphorus and sulfur donors. With weaker field ligands oxidation to iron(III) species is a common preparative problem, and no doubt this has been one of the reasons for the slow early development of what has become such a rich area. In complexes having intermediate ligand field strengths thermally induced spin transitions become possible and these have been extensively investigated. With strong field tetradentate macrocyclic ligands the relatively unusual $S = 1$ spin state is often observed. A major objective has been to devise complexes that mimic the behaviour of the natural iron(II) oxygen carrying proteins, and a range of synthetic porphyrin complexes are now available that do this. Another important biologically relevant area is that of the iron/sulfide clusters that provide convincing models for several electron transfer systems.

A notable feature of the literature concerned with iron chemistry is that while a number of excellent reviews are available that deal with specific topics, there are none that deal with the whole coordination chemistry of iron(II). The present review first deals with cyanide complexes followed by complexes containing simple monodentate nitrogen donors. The huge amount of work published

on diimine and related complexes is covered in several subsections before considering complexes with phosphorus, oxygen and sulfur donors. Then halide complexes are discussed before finally considering the N donor macrocyclic systems.

44.1.5.2 Cyanide Complexes

44.1.5.2.1 The hexacyano complex

The exceptionally high affinity[255] of iron(II) for cyanide ion is reflected in the heat of formation[256,257] of the $[Fe(CN)_6]^{4-}$ anion (equation 31). The stability of this, the ferrocyanide ion, is illustrated by the nature and history[258] of its iron(III) salt, Prussian blue, possibly the first isolated coordination complex, which is discussed in Section 44.1.5.2.4.

$$[Fe(H_2O)_6]^{2+} + 6CN^- \longrightarrow [Fe(CN)_6]^{4-} + 6H_2O \qquad \Delta H_f^0 = -358.9\,kJ\,mol^{-1} \qquad (31)$$

The addition of aqueous cyanide to a solution containing an excess of an iron(II) salt results[259] in the precipitation of an impure iron cyanide. On the other hand, the addition of excess cyanide to iron(II) solutions rapidly gives the hexacyanoferrate(II) ion. The rate of uptake of the sixth cyanide ion is significantly slower than for the previous five due to low-spin $[Fe(CN)_5H_2O]^{3-}$ being kinetically inert. This second order stage of the reaction has[260] an activation energy of 104 kJ mol^{-1} and an equilibrium constant of $\sim 10^8$. In fact, these data relate to the formation of $[Fe(CN)_6]^{4-}$ from both $[Fe(CN)_5H_2O]^{3-}$, itself very stable, and $[Fe_2(CN)_{10}]^{6-}$, both of which are present in the reacting solution. The inner sphere reduction of $[Fe(CN)_6]^{3-}$ with a variety of mild reducing agents readily forms $[Fe(CN)_6]^{4-}$. Such reactions may be mechanistically complex, as for example in the reduction with sulfite ion which involves[261] an intermediate formed from $[Fe(CN)_6]^{3-}$ and SO_3^- radical anion as shown in Scheme 8. The octahedral geometry of the ferrocyanide ion has been established[262] in $K_4[Fe(CN)_6]\cdot 3H_2O$. When ammonium hexacyanoferrate(II) is heated to 320 °C *in vacuo*, a pale green substance of empirical formula 'Fe(CN)$_2$' results about which little is known.

$$[Fe(CN)_6]^{3-} + SO_3^{2-} \longrightarrow [Fe(CN)_6]^{4-} + SO_3^-$$

$$[Fe(CN)_6]^{3-} + SO_3^- \longrightarrow [Fe(CN)_5(CN\cdot SO_3)]^{4-}$$

$$[Fe(CN)_5(CN\cdot SO_3)]^{4-} + H_2O \longrightarrow [Fe(CN)_6]^{4-} + SO_4^{2-} + 2H^+$$

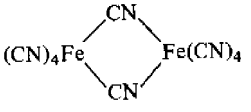
Scheme 8

With the exception of the barium salt, which is only sparingly soluble, the ferrocyanides of the alkali and alkaline earth metals are easily soluble in water though not in alcohols. All these soluble salts separate from aqueous solution as well-defined pale yellow crystals. Large numbers of sparingly soluble salts of general formula $K_2M^{II}[Fe(CN)_6]$ and $KM^{III}[Fe(CN)_6]$ are obtained by precipitation, as are the salts of most transition metal ions. These have polymeric structures involving M—N≡C—Fe coordination. In some cases linkage isomerization has been demonstrated, for example $KFeCr(CN)_6$ is less stable than $KCrFe(CN)_6$ which has been shown[263] to contain Cr—N≡C—Fe linkages. Many of the insoluble transition metal salts of $[Fe(CN)_6]^{4-}$ are useful ion exchange materials and the copper(II) salt has a classic use as a semipermeable membrane in the measurement of osmotic pressure. The alkali metal salts may also be made *via* the acid $[H_4Fe(CN)_6]$, which is obtained in aqueous solution by ion exchange. This strong tetrabasic acid can be precipitated as an ether addition compound by adding ether to a strongly acid solution of $[Fe(CN)_6]^{4-}$. Subsequent removal of the ether is readily accomplished to afford $[H_4Fe(CN)_6]$ as a white powder which slowly becomes blue in moist air and is soluble in water and ethanol. The protons have been shown[264,265] to be bound to the nitrogen atoms of the CN groups. The acid dissolves without decomposition in liquid hydrogen fluoride[266] to give $[Fe(CNH)_6]^{2+}$. An X-ray crystal structure[267] of $[Fe(NCD)_6]^{2+}$ as the $[FeCl_4]^-$ salt reveals tetrahedral $[FeCl_4]^-$ and octahedral $[Fe(NCD)_6]^{2+}$ moieties joined together by Fe^{II}—NCD···Cl—Fe^{III} deuterium bonds. The rigidity of the linear N—C—D group results in some tetragonal distortion of the FeN_6 octahedron. The acid $[H_4Fe(CN)_6]$ decomposes[268] on heating in various atmospheres to form Prussian blue type compounds. Both the acid and the potassium salt react[269] with BF_3 to give adducts whose IR and Mössbauer spectra are consistent with the Lewis acid bound to the nitrogen atoms of the cyanide as in equations (32) and (33).

$$[Fe(CN)_2(CNH)_4] + 2BF_3 \longrightarrow [Fe(CNH)_4(CN\cdot BF_3)_2] \quad (32)$$

$$K_4[Fe(CN)_6] + 6BF_3 \longrightarrow K_4[Fe(CN\cdot BF_3)_6] \quad (33)$$

The kinetic inertness of $[Fe(CN)_6]^{4-}$ is typified by the extremely slow thermal displacement of CN^- by α,α'-diimines. Such reactions are however catalyzed[270] by a variety of metal ions such as Hg^{2+} and the stability constants for some of the intermediate heteropolynuclear complexes have been determined.[271]



44.1.5.2.2 Pentacyano complexes

On a small scale, photolysis of $[Fe(CN)_6]^{4-}$ in aqueous solutions[272,273] affords some $[Fe(CN)_5H_2O]^{3-}$. When the reaction is carried out in the presence of nitrosobenzene the loss of cyanide is accelerated resulting in the formation of the violet PhNO complex. The rate of this process is also enhanced by the presence of certain metal ions, for example Hg^{2+} or Pb^{2+}. Larger scale preparations usually involve[274] reductive removal of NO from the nitroprusside ion in the absence of potential donor ligands other than water. Thus the reaction of $[Fe(CN)_5NO]^{2-}$ with hydroxylamine in the presence of sodium carbonate yields a yellow deliquescent powder formulated as $Na_3[Fe(CN)_5H_2O]$. The violet PhNO complex $[Fe(CN)_5PhNO]^{3-}$, which has $\lambda_{max} = 528$ nm in aqueous solution, is formed when this salt reacts with nitrosobenzene. In common with many other $[Fe(CN)_5L]^{3-}$ ions, reaction[275] with an excess of cyanide yields $[Fe(CN)_6]^{4-}$.

Solutions resulting from the preparation of $[Fe(CN)_5H_2O]^{3-}$ by reducing nitroprusside ion contain dimeric species, as indeed may solutions resulting[276] from the photolysis of $[Fe(CN)_6]^{4-}$. Two dimers have been identified, as $[Fe_2(CN)_{10}]^{6-}$ and $[Fe_2(CN)_{11}]^{7-}$. The structure proposed for $[Fe_2(CN)_{10}]^{6-}$ requires[277] two non-linear cyano bridges. A single equivalent oxidation of $[Fe_2(CN)_{10}]^{6-}$ yields a green complex $[Fe_2(CN)_{10}]^{5-}$ ($\lambda_{max} = 1200$ nm; $\varepsilon = 10^4$) and a second equivalent oxidation gives a purple ion $[Fe_2(CN)_{10}]^{4-}$ ($\lambda_{max} = 560$ nm; $\varepsilon = 1600$). The UV and visible spectra[278,279] of $[Fe_2(CN)_{10}]^{6-}$ and $[Fe_2(CN)_{10}]^{4-}$ are similar to those of the single bridged dinuclear complexes $[Fe_2(CN)_{11}]^{7-}$ and $[Fe(CN)_{11}]^{5-}$. The structure of the dimeric species derived from $[Fe(CN)_5H_2O]^{3-}$ has not been fully resolved despite recent work. Structures (**14**) and (**15**) have been proposed containing one or two cyanide bridges respectively.

$[(NC)_5Fe-CN-Fe(CN)_4H_2O]^{6-}$

(14)

(15)

Competition ratios for the reaction of the dimer with several nucleophiles have been determined[280] and the similarity between the ratios for the dimer and for $[Fe(CN)_5H_2O]^{3-}$ suggests the presence of an aqua ligand in the former. $[Fe(CN)_5H_2O]^{3-}$ is also generated by dissociation of $[Fe(CN)_5NH_3]^{3-}$ or $[Fe(CN)_5SO_3]^{5-}$ in aqueous solution; it then equilibrates with the dimeric species. In the case of the ammine complex[277] the dimerization step is rate determining in acidic solution (rate constant: 1.1 $dm^3\,mol^{-1}\,s^{-1}$ at 298 K) whilst in alkaline solution it is the reaction of $[Fe(CN)_5H_2O]^{3-}$ with another $[Fe(CN)_5NH_3]^{3-}$ which is the slowest step. $[Fe(CN)_5H_2O]^{3-}$ also reacts[278] with a variety of $[M(CN)_6]^{n-}$ complexes to give bridged dimeric species $[FeM(CN)_{11}]^{m-}$ (*e.g.* M = Fe, $m = 7$, M = Co, $m = 6$). The formation of binuclear species also takes place through bound organonitriles, for example $[Fe(CN)_5H_2O]^{3-}$ reacts[283] with $[Co(NH_3)_5L]^{3+}$ (L = 3- or 4-cyanopyridine) to form $[(NC)_5Fe(\mu\text{-}L)Co(NH_3)_5]$ which then undergoes intramolecular electron transfer to give iron(III). The ease with which oligomeric species are formed in this system has probably contributed to the difficulty in fully characterizing the products. In the absence of oxygen $[Fe(CN)_5H_2O]^{3-}$ decomposes[284] on heating to give $[Fe(CN)_6]^{4-}$ and $[Fe(H_2O)_6]^{2+}$.

44.1.5.2.3 Reactions of $[Fe(CN)_5L]^{3-}$

Useful starting materials for the synthesis of $[Fe(CN)_5L]^{3-}$ are the aquapentacyanoferrate(II) ion $[Fe(CN)_5H_2O]^{3-}$ and the amminepentacyanoferrate(II) ion $[Fe(CN)_5NH_3]^{3-}$. These react with a variety of ligands with displacement of H_2O or NH_3 by L to give $[Fe(CN)_5L]^{3-}$ (*e.g.* CO displaces

NH_3 to give $[Fe(CN)_5CO]^{3-}$). $[Fe(CN)_5NH_3]^{3-}$ is best prepared[285] from the nitroprusside ion by standing in a solution of concentrated ammonia buffered with sodium acetate as in equation (34).

$$[Fe(CN)_5NO]^{2-} + 2NH_3 + OH^- \longrightarrow [Fe(CN)_5NH_3]^{3-} + N_2 + H_2O \quad (34)$$

$$[Fe(CN)_5NO]^{2-} + 2RNH_2 + OH^- \longrightarrow [Fe(CN)_5RNH_2]^{3-} + N_2 + ROH + H_2 \quad (35)$$

Nitroprusside may also be reduced with Na/Hg to give $[Fe(CN)_5NH_3]^{3-}$. Complexes containing primary amines can also be made[286] from the nitroprusside ion in the presence of sodium acetate with the formation of nitrogen and the corresponding alcohol as in equation (35). The ammonia ligand in $[Fe(CN)_5NH_3]^{3-}$ is rapidly hydrolyzed ($t_{\frac{1}{2}} \sim 40$ s, 25 °C). If the reaction is carried out in the presence of a small amount of ascorbic acid, to prevent aerial oxidation to iron(III), this represents a convenient route to $[Fe(CN)_5H_2O]^{3-}$. The kinetics of ligand dissociation from pentacyanoferrates(II), $[Fe(CN)_5L]^{n-}$, have been extensively investigated. These reactions proceed through a limiting dissociative mechanism. Variation of the rate constant with different incoming ligands has been reported in relatively few cases. The dependence of reactivity on the nature of the leaving ligand, however, has been examined in detail. Whilst charge effects are small, solvation effects are important. The strength of the iron–ligand bond is paramount in determining dissociation rates and attempts have been made to assess the σ and π bonding contributions from metal–ligand charge-transfer bands and ligand pK_a values. Table 5 contains data for the formation of $[Fe(CN)_5L]^{n-}$ complexes from $[Fe(CN)_5H_2O]^{3-}$ and Table 6 contains kinetic parameters for dissociation of L from $[Fe(CN)_5L]^{n-}$ complexes.

Photolysis of six-coordinate $[Fe(CN)_5en]^{3-}$ results in the loss of one cyanide to give[287] the chelated complex $[Fe(CN)_4en]^{2-}$ in high quantum yield. With ligands such as the cyanopyridines that have two donor sites $[Fe(CN)_5L]^{n-}$ complexes have been observed to exhibit coordination isomerization. Several such compounds have been studied[288,289] and interestingly some of the isomerizations involve an intramolecular mechanism.

Prussian blue (PB) respectively. They are identical mixed oxidation state polymeric complexes having the idealized composition $Fe_4[Fe(CN)_6]_3$, *i.e.* iron(III) ferrocyanide. If precipitation is rapid in the presence of potassium ions, these are incorporated with the formation of a so-called 'soluble PB' that is readily peptized. Prussian blue is an historically important salt which is amongst the first identified coordination compounds. Its early isolation is due in part to the especially strong affinity of iron(II) for cyanide and to the stability of the resulting complexes. Small almost black crystals of PB, free from alkali metal ions, separate slowly when $FeCl_3$ reacts[290] with $[H_4Fe(CN)_6]$ in 10 M HCl (approximately ten weeks). X-Ray and neutron (powder) diffraction studies[291] confirm that the structure (analogous to other polynuclear cyanides) consists of a cubic $Fe^{III}NCFe^{II}$ framework where a quarter of the iron(III) sites are vacant. The average compositon[292] of the pseudo-octahedral coordination sphere of iron(III) is $FeN_{4.5}O_{1.5}$. In the ideal stoichiometry of $Fe_4[Fe(CN)_6]_3 \cdot 14H_2O$, six of the water molecules occupy coordination sites around the iron(III) atoms whilst eight occupy uncoordinated interstitial sites. Recent studies employing DTA and NMR techniques appear[293] to show a third type of water molecule in the Prussian blue structure. These authors[293] conclude that of the eight uncoordinated water molecules four are 'lattice' water molecules in the second coordination sphere and four are 'zeolitic' water molecules in the third coordination sphere of the paramagnetic iron(II) centres. Mössbauer and magnetic measurements

on a series of Prussian blue analogues, $M_j^A[M^B(CN)_6]_k \cdot mH_2O$, show[294] that the ions bound to the carbon end of the cyanides (M^B) are low-spin and all ions in M^A sites are high-spin. As in Prussian blue itself the analogues are characterized by well-defined octahedral cyanide sites, extensive water of hydration and variations in the M^A sites.

Individual iron atoms in Prussian blue appear to have well-defined electronic configurations with lifetimes of around 10^{-7} seconds. An interpretation[295] of the electronic spectrum suggests that the blue colour arises from electron transfer between the $[Fe(CN)_6]^{4-}$ and iron(III) ions and that the relevant electrons reside on the ferrocyanide moiety in the ground state. Vacuum pyrolysis of Prussian blue can result in valence reversal to give[296] iron(II) ferricyanide, which has also been identified[297] in aqueous solution, the complex previously thought to have been 'Turnbull's blue'.

The redox chemistry of the Prussian blue family (Table 7) has attracted considerable attention. The generation of thin films of Prussian blue[298] has led to studies of its mediation in electron transfer reactions[299] and of the electrochemical processes[300,301] involved in its deposition and redox reactions. This work has been spurred by its electrochromic properties which have been used in prototype electronic display devices based, for example,[302] on Prussian blue modified SnO_2 electrodes. A recent review[303] deals with the electrochemistry of electrodes modified by depositing thin films of PB and related compounds on them. Interestingly, true Prussian blue is somewhat difficult to process and modern 'iron blue' pigments such as Milori blue are derived from the oxidation of 'Berlin white' $\{Fe(NH_4)_2[Fe(CN)_6]\}$ to give iron(III) ammonium ferrocyanides.

Table 7 The Prussian Blue Family

Trivial name	*Idealized formula*	*Ref.*
Soluble Prussian blue	$KFe^{III}[Fe^{II}(CN)_6]$	1
Insoluble Prussian blue	$Fe^{III}_4[Fe^{II}(CN)_6]_3$	1
Prussian brown / Berlin green	$Fe^{III}[Fe^{III}(CN)_6]$	2, 3, 4
Prussian green	$KFe_3^{III}[Fe^{II}(CN)_6][Fe^{III}(CN)_6]_2$	2, 3
Prussian white / Everitts salt	$K_2Fe^{II}[Fe^{II}(CN)_6]$	2

44.1.5.2.5 Isocyanide complexes

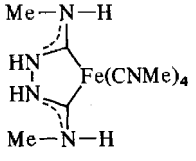
Organic isocyanides react directly with iron(II) salts to form complexes containing no more than four isocyanide ligands. Thus FeX_2 reacts in alcoholic solution to give[304] the stable diamagnetic complexes $[FeX_2(CNR)_4]$ (X = Cl, Br, I, SCN; R = alkyl, aryl). Both *cis*[305] and *trans* isomers[306] exist and these can easily be separated by chromatography on alumina. In some cases the *cis*/*trans* ratio is determined by the temperature of the reactant solution.[307] The addition of isocyanides to $Fe(ClO_4)_2$ in the absence of solvent yields diamagnetic $[Fe(CNR)_4](ClO_4)_2$, which apparently contains four-coordinate iron(II). A wide range of iron(II) isocyanide complexes is obtained by the alkylation of the corresponding low-spin cyanides. As early as 1888 Freund[308] synthesized $[Fe(CN)_2(CNEt)_4]$ by the alkylation of silver ferrocyanide with ethyl iodide (equation 36).

$$Ag_4[Fe(CN)_6] + 4EtI \longrightarrow [Fe(CN)_2(CNEt)_4] + 4AgI \quad (36)$$

This and related reactions were studied by Hartley[309,310] who obtained[311] some $[Fe(CNMe)_6]$ by methylation of $Ag_3[Fe(CN)_6]$ with MeI. Originally these complexes were incorrectly formulated and were not recognized as coordination compounds until 1933. An early X-ray structure determination was reported[312] in 1945 for $[Fe(CNMe)_6]Cl_2$. Transalkylation of iron(II) isocyanide complexes can be accomplished[313] by reacting the CNR complex with alkyl halide R'X that has a higher boiling point than RX which is continuously distilled from the reaction mixture. The reaction is general for aliphatic iron(II) isocyanide complexes and yields up to 80% are possible although usually several products are formed which require chromatographic separation. Although $[Fe(CNMe)_6]^{2+}$ results from the reaction[314] of ferrocyanide with dimethyl sulfate as in equation (37), the product of the reaction between diazomethane and ferrocyanic acid[315] is $[Fe(CN)_2(CNMe)_4]$ as shown in equation

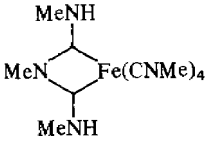
(38). On heating (150 °C, 10 h) $[Fe(CNMe)_6]Cl_2$ is converted[316] to a mixture of *cis*- and *trans*-$[FeCl_2(CNMe)_4]$. Somewhat surprisingly, $[H_4Fe(CN)_6]$ reacts with aliphatic alcohols to form $[Fe(CN)_2(CNR)_4]$ and other complexes. Intermediate species formed during this reaction can polymerize with the evolution of hydrogen cyanide. Addition of HCN displaces isocyanide, however, and so constitutes a catalytic cycle for the synthesis[313] of RNC from HCN and ROH.

$$[Fe(CN)_6]^{4-} + 3Me_2SO_4 \longrightarrow [Fe(CNMe)_6]^{2+} + 3SO_4^{2-} \quad (37)$$



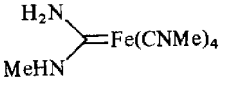
$$[H_4Fe(CN)_6] + 4CH_2N_2 \longrightarrow [Fe(CN)_2(CNMe)_4] + 4N_2 \quad (38)$$

Controlled alkylation of $[Fe(CN)_2(CNMe)_4]$ with one equivalent of MeI (90 °C, 4 h) affords $[Fe(CN)(CNMe)_5]I$ in 70% yield.[317] Iron(II) complexes containing more than four isocyanide ligands can also be obtained by the reaction of free ligand with an iron compound in another oxidation state. Thus $[Fe(CNMe)_6][FeCl_4]_2$ results[318] from the room temperature reaction between $FeCl_3$ and CNMe. The cation $[Fe(H)(CNBu^t)_5]^+$ is obtained by protonation of $[Fe(CNBu^t)_5]$ which is formed[319] by sodium amalgam reduction of $FeBr_2$ in the presence of an excess of the isocyanide (equation 39). The structure of $[Fe(CNBu^t)_5]$ differs from the ideal trigonal bipyramidal configuration, and the equatorial ligands are non-linear[320] having a CNC angle of 135° as in $[FeCl_2(CNMe)_4]$ for which an angle of ~166° was reported.[306] In contrast, the reported[312] CNC angle in $[Fe(CNMe)_6]^{2+}$ is 173°.



$$FeBr_2 \xrightarrow[CNR]{Na/Hg} [Fe(CNR)_5] \xrightarrow{HBF_4} [Fe(H)(CNR)_5]BF_4 \quad (39)$$

Hydrazine reacts with $[Fe(CNMe)_6]^{2+}$ to form the chelate (**16**) in which addition to two adjacent isocyanide ligands has taken place.[321] Methylamine reacts[322] in a related way to give (**17**), while reaction with ammonia results in the formation[323] of a monodentate carbene complex (**18**). Methylation of $[Fe(CN)_2(phen)_2]$ with Me_2SO_4 yields $[Fe(CNMe_2)(phen)_2]$,[26] which reacts with hydrazine to give[323] the tris chelate (**19**) in a similar fashion to the formation of (**16**).



Amongst the aromatic isocyanide iron(II) complexes, those containing benzyl isocyanide are the best studied. Coordination influences the reactivity of the ligand resulting[324] in rapid nitration which, in common with sulfonation and bromination, takes place at the *para* position.[313,325] This effect may result from anchimeric assistance as shown in structure (**20**). This argument is supported by the effect being destroyed in the presence of a strong Lewis acid which prevents the participation of the nitrogen lone pair. Aliphatic aldehydes in 96% sulfuric acid alkylate the aromatic ring to give substituted benzyl alcohols, which subsequently react to form polymeric materials.[325]

44.1.5.3 Alkyl Cyanides

Metallic iron reacts with nitrosyl tetrafluoroborate in acetonitrile to yield[327] off-white $[Fe(NCMe)_6](BF_4)_2$ (μ_{eff} = 5.2 BM). The $[Fe(NCMe)_6]^{2+}$ cation is readily formed when iron is oxidized by a number of strong oxidizing agents in rigorously anhydrous and oxygen free acetonitrile. Early workers investigated the use of chlorine, bromine and iodine[328] as oxidizing agents, whilst more recent work[329] has employed high oxidation fluorides such as WF_6, MoF_6 or PF_5. Oxidation of $[Fe(NCMe)_6]^{2+}$ with chlorine in acetonitrile yields $[Fe(NCMe)_6][FeCl_4]_2$. This salt and its bromine analog are reduced[328] by refluxing over iron wire to give complexes with the stoichiometry $[FeX_2(NCMe)_2]$. Some properties of these complexes are given in Table 8. The hexakis acetonitrile iron(II) cation reacts with $P(OMe)_3$ [but not under similar conditions with PF_3 or $P(OPh)_3$] in acetonitrile solutions[329] with stepwise replacement of MeCN by $P(OMe)_3$. The final species obtained at room temperature is $[Fe(NCMe)\{P(OMe)_3\}_5][PF_6]_2$; four intermediate cations can be positively identified by NMR spectroscopy and a fifth tentatively assigned. Formation of $[Fe(NCMe)_5P(OMe)_3]^{2+}$ is very rapid[330] and cross-over from high- to low-spin iron(II) probably

occurs with the next step, *i.e.* formation of $[Fe(NCMe)_4\{P(OMe)_3\}_2]^{2+}$, which is thought to have a *cis* configuration. This red species creates the initial colour seen on mixing $P(OMe)_3$ with an acetonitrile solution of $[Fe(NCMe)_6]^{2+}$. Subsequent substitutions are far slower and give rise to colour ranges from red to orange and finally yellow on standing for several days. As expected the crystal structure of $[Fe(NCMe)_6][FeCl_4]_2$ reveals octahedral $[Fe(NCMe)_6]^{2+}$ cations and tetrahedral $[FeCl_4]^-$ anions.[331,332]

Table 8 Properties of selected MeCN Complexes[a]

Compound	*Colour*	μ_{obs} (BM)	*IR* (cm^{-1})
$[FeCl_2(NCMe)_2]$	Off-white	—	2275, 2285
$[FeBr_2(NCMe)_4]$	Brown	—	—, —
$[Fe(NCMe)_6][FeCl_4]_2$	Yellow	5.92	2270, 2290
$[Fe(NCMe)_6][FeBr_4]_2$	Red	5.89	2285, 2305
$[Fe(NCMe)_6][FeI_4]_2$	Dark green	5.48	2270, 2290

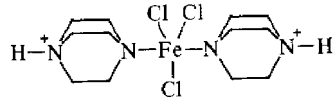
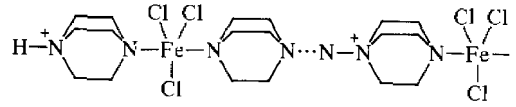
44.1.5.4 Simple Amines

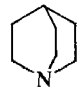


44.1.5.4.1 Saturated and primary aromatic amines

Although not commonly encountered because of their facile oxidation to brown compounds of uncertain composition, iron(II) hexaammine salts can be prepared[333] under carefully controlled conditions. Thus, addition of ammonia to freshly prepared $FeBr_2$ under an atmosphere of hydrogen gives a green precipitate which is converted with excess ammonia to light blue-grey crystals of $[Fe(NH_3)_6]Br_2$. Principal IR absorbances are 1595m, 1159vs, 625vs cm^{-1} (NH_3) and 315s cm^{-1} (Fe—N).[334] In common with other +2 transition metal ions, iron(II) forms stable complexes with a wide range of simple amines, and these are generally high-spin and sensitive towards oxidation. Iron(II) chloride reacts directly[335] with excess anhydrous primary amines (NH_2R, R = Me, Et, Pr^n and Bu^n) to form the complexes $[Fe(NH_2R)_2Cl_2]$. Interestingly, $FeCl_3$ is reduced[335] by primary amines to form the same white air sensitive microcrystalline solids, which are thought to have tetrahedral geometry.



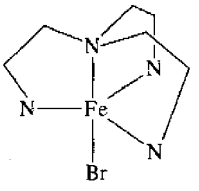
Complexes of stoichiometry $[Fe(SO_4)(L)_2]$ are formed[336] by the direct reaction of iron(II) sulfate and aniline or *para*-toluidine. The unusual monodentate, monoprotonated ditertiary amine ligand dabcoH$^+$ (**21**) reacts[337] with FeX_2 in anhydrous ethanol to yield complexes $[FeX_3(dabcoH^+)_2]X$ which have trigonal bipyramidal geometry (**22**), unusual[338] for high-spin complexes of monodentate ligands (X = Cl, μ_{eff} = 5.21 BM; X = Br, μ_{eff} = 5.13 BM). Hydrogen bonding and electrostatic forces play an important part in directing the stereochemistry of these compounds. Other workers[339] using the same method have obtained $[FeCl_3(dabco)(dabcoH^-)]$ (**23**), which upon heating (184 °C) loses dabco to form tetrahedral $[FeCl_3(dabcoH^+)]$. Under the appropriate conditions[340] this complex may be formed from the reaction between $FeCl_2$ and dabcoH$^+$ in the presence of Cl^-. Under carefully controlled conditions the less stable $[FeX_3(dabcoMe^+)(H_2O)]$ and $[FeX_3(dabcoMe^+)(NH_3)]$ (X = Cl, Br) can also be obtained.[341] In contrast, with FeI_2 the four-coordinate pseudotetrahedral $[FeI_3(dabcoH^+)]$ is the only species detected.[340] With the analagous monotertiary amine[342] quinuclidine (**24**) in which electrostatic hydrogen bonding effects are essentially absent, only pseudotetrahedral $[FeCl_2(quin)_2]$ is formed.



(21)

(22)

(23)



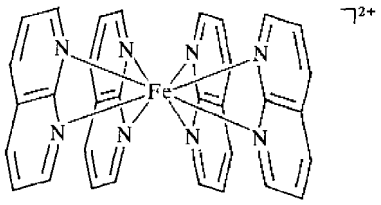
(24)

Unlike the reactions of pyridine and other tertiary amines with $[Fe(CO)_5]$ that give products such as $[Fepy_6][Fe_4(CO)_{13}]$, primary and secondary amines under anhydrous conditions form adducts prior to reaction giving $[Fe(CO)_4(amine)]$. In some instances two amine molecules are invovled in adduct formation and one of these is thought to attack a CO ligand whilst the other is hydrogen bonded to the complex.[343,344]

Iron(II) forms[345] stable complexes with a range of polyethyleneamine and related polydentate amines. There has been considerable research effort[346] devoted to the measurement of the thermodynamics of formation of these complexes in aqueous solution. Thus, for example, ethylenediamine[347] forms mono, bis and tris complexes in aqueous media with successive enthalpies of reaction being 21.1, 43.5 and 66.3 kJ mol^{-1} respectively. Similar thermochemical measurements have been made on a number of other polydentate amines, for example diethylenetriamine,[348] 2,2′,2″-triaminotriethylamine,[349] triethylenetetramine,[350] tetraethylenepentamine[351] and *N,N,N′,N′*-tetra(2-aminoethyl)ethylenediamine.[352]

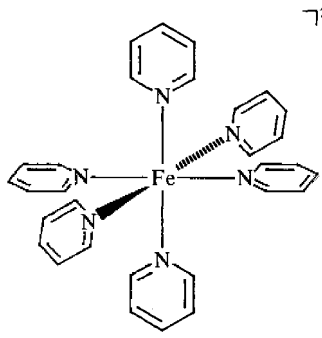
Many aliphatic polydentate amines form stable iron(II) octahedral complexes and in some instances these are obtained directly from Fe^{III} precursors. Thus anhydrous ethylenediamine or propylenediamine react with $FeCl_3$ to give octahedral $[Fe(en)_3]Cl_2$ and $[Fe(pen)_3]Cl_2$ respectively.[353] In contrast bis(2-dimethylaminoethyl)methylamine reacts[354] with $FeCl_2$ in hot butanol to yield amethyst, air sensitive crystals of high-spin ($\mu_{eff} = 5.2$ BM) five-coordinate $[Fe(dien)Cl_2]$. A number of similar iron(II) complexes have been isolated with tri- or tetra-dentate amines.[355,356] For example, the trigonal bipyramidal coordination geometry (**25**) of $[Fe(Me_6tren)Br]Br$ (Me_6tren = tris(2-dimethylaminoethyl)amine) has been confirmed[357] by an X-ray crystal structure determination.

(25)



Interestingly an attempt[358] to measure the heat of formation of the nonmethylated propyl derivative (3,3′,3″-triaminotripropylamine) in aqueous solution failed because of hydroxide precipitation in advance of any complex formation. Stability constants for a range of metal(II) ions with Me_6tren and Me_5dien in aqueous solution have been interpreted[355] as showing that six-coordinate octahedral geometry is the preferred configuration for iron(II); presumably five-coordination results from steric factors. When possible, the donor atoms of these polydentate ligands are compressed into octahedral symmetry. Thus tetren (tetraethylenepentamine) reacts with $FeSO_4$ under acid conditions to form a solution which when alkalized to pH 8.5 takes up carbon monoxide to form[359] six-coordinate $[Fe(tetren)CO]^{2+}$. A large number of high-spin six-coordinate iron(II) complexes of di-and tri-dentate polyamines have been synthesized[360] having picrate counterions.

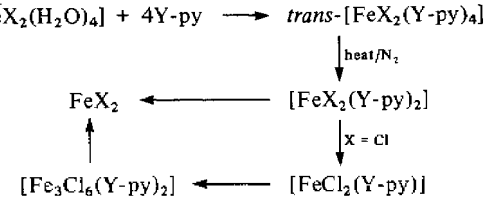
44.1.5.4.2 1,8-Naphthyridine



When a solution of 1,8-naphthyridine (napy) in ethyl acetate is added to $[Fe(H_2O)_6](ClO_4)_2$ in refluxing 2,2-dimethoxypropane/ethanol, a red–orange product may be isolated[361] which has the stoichiometry $[Fe(napy)_4](ClO_4)_2$ (**26**). The complex has been shown[362] to possess an eight-coordinate iron(II) centre with distorted dodecahedral geometry. Eight-coordination is rare in transition metal complexes having a more than half filled *d* shell and in this case gives rise to unusual Mössbauer effects,[363,364], for example an extremely high quadrupole splitting of 4.49 mm s^{-1} (at 77 K). The four-membered chelate ring having a 'bite' of 2.2 Å is maintained in iron(II) complexes of substituted naphthyridines (2,7-dimethyl-1,8-naphthyridine = dmnapy; 2-methyl-1,8-naphthyridine = mnapy). However, the markedly lower quadrupole splittings observed in $[Fe(mnapy)_4](ClO_4)_2$ and $[Fe(dmnapy)_3](ClO_4)_2$ are interpreted[365] as being derived from an octahedral coordination geometry.

44.1.5.5 Monodentate Aromatic Amines

Although pyridine has relatively weak coordinating properties,[366] a very large number of iron complexes containing one or more pyridine ligands are known.[367] In dilute aqueous solution it appears that only two molecules of pyridine are bound to Fe^{2+}_{aq} with formation constants[368] of $\log_{10}K_1 = 0.6$ and $\log_{10}\beta_2 = 0.9$. Increasing the pyridine concentration decreases the dielectric constant of the medium so favouring the formation of inner-sphere complexes with anions. Thus in concentrated solutions $[FeX_2py_4]$ complexes are obtained (see below). Steric effects are not an important factor here since the $[Fepy_6]^{2+}$ cation can be formed in the absence of other potential ligands. The reaction of $[Fe(CO)_5]$ and $[Fe_3(CO)_{12}]$ with pyridine was first investigated by Hieber and coworkers in 1930, and the products formulated as $[Fe_2(CO)_4py_3]$ and $[Fe(CO)_3py]$ respectively.[369,370] Subsequent work showed that only one complex salt is formed in these reactions, $[Fepy_6]^{2+}[Fe_4(CO)_{13}]^{2-}$ having a magnetic moment in keeping with a high-spin iron(II) centre (5.47 BM).[371,372] The X-ray crystal structure of this salt shows[373] that in the $[Fepy_6]^{2+}$ cation (**27**) the pyridine ligands occupy three mutually perpendicular planes with each pair of *trans* pyridine rings being coplanar. The $[Fepy_6]^{2+}$ cation is also obtained from reaction of $[C_4F_7Fe(py)_2(CO)_2I]$ with pyridine.[374]



(26)

(27)

Yellow *trans*-$[FeCl_2py_4]$ is precipitated[375] when a saturated aqueous solution of $FeCl_2$ is added to an excess of pyridine in the absence of air. This complex is isotypic[376] with the analogous cobalt and nickel complexes known to have *trans* configurations. Being significantly more stable towards oxidation than simple iron(II) salts, and since $[FeCl_2py_4]$ has moderate solubility in common organic solvents, it is a convenient source of iron(II) for the preparation of other complexes. When heated under nitrogen solid *trans*-$[FeCl_2py_4]$ loses pyridine, successively forming three polymeric pyridine complexes.[377] Related complexes *e.g.* $[FeCl_2(4\text{-Mepy})_4]$, $[Fe(NCS)_2py_4]$) form only a single well-defined intermediate phase containing two pyridine ligands as shown in Scheme 9.

Scheme 9

The enthalpy for loss of two molecules of pyridine from $[FeCl_2py_4]$ has been estimated[378] to be $113.0 \pm 1.7\,kJ\,mol^{-1}$ and $128.0 \pm 1.3\,kJ\,mol^{-1}$ for loss of the remaining two pyridine molecules to form $FeCl_2$. *trans*-$[FeX_2(Y\text{-}py)_4]$ complexes containing a wide range of anions and substituted pyridines have been prepared[379] and their IR spectra reported.[380–384] The main features are strong sharp bands characteristic of coordinated pyridine. The complexes *trans*-$[FeI_2py_4]\cdot 2py$ and *trans*-$[Fe(NCO)_2py_4]\cdot 2py$ display bands due to coordinated and free pyridine and are therefore formulated as written.[383] All of these complexes have absorptions in the near IR assignable to *d–d* transitions, and splitting of the ^5E_g level is in accord with a tetragonally distorted octahedral structure.[384] Magnetic properties and Mössbauer spectra of these complexes have been interpreted on this basis.[384,385] Only the splitting of the e_g orbitals can be obtained from the electronic spectra,

but from measurement of ΔE_Q in the Mössbauer spectra the splitting of the t_{2g} orbitals has been estimated[386] for $[FeX_2L_4]$ where X = Cl, Br, I, NCS; L = py, 4-Mepy, isoquinoline. Table 9 lists properties of a number of $[FeX_2L_4]$ complexes. The complex $[Fe(NCS)_2py_4]$ can be obtained in yellow[387] and black[388] forms that have been claimed[389] to be *trans* and *cis* isomers. However, their magnetic moments are similar[390] and Mössbauer spectroscopy indicates they are not different isomers.[391,392] X-Ray crystallography[393] confirms that the yellow complex has the *trans* configuration with N-bound thiocyanate ligands. It appears the black form contains small amounts of Fe^{III} impurity, which is readily formed since the Fe^{3+}/Fe^{2+} and $(SCN)_2/SCN^-$ redox potentials are similar. In keeping with this explanation solutions of yellow *trans*-$[Fe(NCS)_2py_4]$ do not darken, even over long periods under oxygen-free conditions[391,392] and dark violet solutions formed by exposure to air are reconverted to the yellow form by sulfur dioxide.[392]

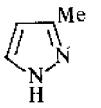
As with pyridine, β-picoline, γ-picoline and isoquinoline, complexes of the type $[FeX_2(amine)_4]$ (X = Cl, Br, I) are obtained by adding a slight excess of the free amine to an aqueous solution of the iron(II) halide.[385,394] In contrast the less basic ligands 4-cyanopyridine and 3,5-dichloropyridine, which are solids and therefore have to be added as an alcoholic solution, afford[385] complexes of the type $[FeX_2(ligand)_2]$ (X = Cl, Br). With X = NCO, $[Fe(NCO)_2(4\text{-}CNpy)_4]$ and $[Fe(NCO)_2(4\text{-}CNpy)_2]$ have been isolated as have the corresponding 3-cyanopyridine complexes. It appears that the bis complexes have polymeric tetragonal structures.[395] Sterically crowded quinoline forms tetrahedral complexes, $[FeX_2(quinoline)_2]$ (X = Cl, Br, I, NCS) whose Mössbauer, electronic and IR spectra have been extensively investigated.[396,397] A high-spin hydrated δ-amino-2-methylquinoline sulfate iron(II) complex has been isolated that is thought to be octahedral and monomeric with a monodentate sulfate ligand.[398]

Another sterically demanding ligand, 2-methylimidazole (2-Meimid), forms brown tetrahedral complexes $[Fe(2\text{-}Meimid)_4]X_2$ ($X = ClO_4^-$, BF_4^-) that are not well characterized, while with halides neutral complexes are obtained.[399] The complexes $[FeX_2(Me_2imid)_2]$ (X = Cl, Br) are formed[400] with the equally bulky 1,2-dimethylimidazole (Me_2imid). However, when the anion is thiocyanate the tetragonal complex $[Fe(NCS)_2(Me_2imid)_4]$ is obtained.[400] In contrast to the behaviour of the more sterically hindered pyridine, imidazole itself[401,402] and its *N*-alkyl derivatives[403–405] readily form yellow/orange salts of the type $[Fe(imid)_6]^{2+}$ that are easily isolated with anions such as NO_3^-, Br^-, I^- and ClO_4^-. The physical properties of these solid high-spin air sensitive complexes are well documented (Table 10), and in methanol solution proton NMR isotropic shifts of $[Fe(imid)_6](ClO_4)_2$ indicate the cation has O_h symmetry.[406]

Several simple iron(II) complexes containing pyrazoles (pz) have been prepared, usually from ethanol solutions dehydrated with a small addition of triethyl orthoformate. Thus light yellow $[Fe(pz)_6]X_2$ ($X = BF_4^-$, ClO_4^-) are high-spin complexes[401] with room temperature magnetic moments of 5.4 BM. With the tautomeric ligand 3(5)-methylpyrazole, (**28**) (Mepz), tetragonal complexes of the type $[Fe(Mepz)_4X_2]$ (X = Cl, Br, I) are formed[406] with magnetic moments ~5.6 BM. The complex formulated as $Fe(Mepz)_7(ClO_4)_2$ that has a room temperature magnetic moment of 5.43 BM undoubtedly contains the $[Fe(Mepz)_6]^{2+}$ cation.[407] Table 10 lists magnetic and Mössbauer parameters for several monodentate aromatic nitrogen donor complexes.



Several iron(II) triazole complexes are known and the unsubstituted ligand forms bridged species *via* the 2- and 4-nitrogen atoms. Addition of 1,2,4-triazole (**29**) (trz) to a slightly acidified solution of $FeCl_2$ and NH_4SCN in the presence of SO_2 [to prevent formation of iron(III)] affords pale green crystals of $[Fe(NCS)_2(trz)_2]$. This polymeric complex has an interesting layer structure[408] containing somewhat distorted N_6 octahedra, with the layers separated by hydrogen-bonded NCS^- groups.

(29)

Magnetic properties are anisotropic with antiferromagnetic intralayer exchange.[409] In contrast, with the sterically hindered 4-substituted derivatives (particularly *t*-butyl) the ligand is forced to be monodentate or bidentate *via* the 1,2-nitrogen atoms, and an asymmetrical dinuclear complex, $[Fe(NCS)_2(Butrz)_4]\cdot H_2O$, is formed[410a] that is readily oxidized to iron(III). Protonation of the 2,6-dimethylpyrazine complex $[Fe(CN)_5(dmpz)]^{3-}$ brings about dramatic spectral changes associated with the metal to ligand charge transfer. This shifts from 440 nm to 600 nm, and the pK_a of the coordinated ligand (**30**) is 2.80 compared with 1.9 for the free ligand.[410b]

44.1.5.6 Diimines and Related Ligands

44.1.5.6.1 Introduction

Good σ donor properties and appropriate π back-bonding abilities, supplemented by the chelate effect, result in most α,α'-diimines being high-field bidentate ligands which, when steric effects do not interfere as in, for example, 2,9-dimethylphenanthroline,[411,412] are comparable in strength with cyanide ion. Consequently most complexes of the type $[Fe(\alpha,\alpha'\text{-diimine})_3]^{2+}$ are low-spin and essentially diamagnetic, displaying but a small temperature independent paramagnetism of ~ 1 BM. Metal-to-ligand charge transfer results in characteristic[413,414] intense absorption in the visible region of the spectrum ($\varepsilon \sim 10^4$), and their magnetic circular dichroism spectra have been studied[415] down to 4.2 K. Since the tris complexes are readily formed in dilute solution (with extremely large stability constants — see Table 11) they have been used extensively for the spectrophotometric determination of iron.[416] Another analytical application is the use of large $[Fe(\alpha,\alpha'\text{-diimine})_3]^{2+}$ cations to precipitate anions in gravimetric procedures. These complexes have also found application as reversible high potential (~ 1.1 volt) redox indicators since in solution the iron(III) complexes are virtually colourless in comparison with intensely coloured iron(II) species.[417]

The redox potentials of a very wide range of substituted $[Fe(LL)_3]^{3+/2+}$ complexes in aqueous

media have been reported[418] but there is little data available on the effect of the solvent.[419] Preparatively the iron(III) complexes are easily obtained from the corresponding iron(II) cations using cerium(IV) in acid solution. The optically active iron(III) complexes can be prepared from the corresponding optically active iron(II) complexes. They racemize slowly in the solid state, but only take a few minutes in solution.[420]

As expected from crystal field considerations[421] the low-spin iron(II) complexes are substitution inert, and thermodynamically very stable with respect to Fe^{2+} and the free ligand; overall formation constants (β_3) can be as large as 10^{23}. The consecutive formation constants for iron(II) 2,2′-bipyridine and 1,10-phenanthroline complexes derived by Irving and Mellor[422] are not in the usual order $K_1 > K_2 > K_3$, but rather $K_1 > K_2 \ll K_3$ (Table 12) and this was attributed to spin pairing on addition of the third ligand since $[Fe(H_2O)_2(LL)_2]^{2+}$ and $[Fe(H_2O)_4(LL)]^{2+}$ will be high-spin by analogy with the corresponding chloro complexes. While this behaviour is consistent with enhanced stability of the low-spin tris complexes, Brisbin and McBryde[423] have cast considerable doubt on the numerical significance of the reported K_2 values. There is no doubt, however, that in these systems $K_1 \ll K_2K_3$. With 2-methyl-1,10-phenanthroline steric hindrance is responsible for the tris complex being high-spin and the more usual order $K_1 > K_2 > K_3$ is observed.[424]

Over recent years there have been a number of publications concerned with formation constants of $[Fe(\alpha,\alpha'\text{-diimine})_3]^{2+}$ complexes at various temperatures. Consequently additional $\Delta H°$ and $\Delta S°$ values are now available (Table 13),[425-428] and some data concerning mixed solvents have also been reported.[424,429-431] Most of the substitution reactions of the tris ligand, low-spin, intensely coloured complexes proceed at rates conveniently monitored by conventional spectrophotometric techniques, and a considerable body of literature dealing with these kinetic and mechanistic aspects has been published. The most important α,α'-diimine ligands are 2,2′-bipyridine and 1,10-phenanthroline, and their iron(II) complexes are dealt with first before considering complexes of other α,α'-diimines.

44.1.5.6.2 2,2′-Bipyridine and 1,10-phenanthroline

(*i*) *Tris complexes*

The intensely red cation $[Fe(bipy)_3]^{2+}$ was first described by Blau[432] in 1888 who obtained 2,2′-bipyridine (**31**) by pyrolyzing copper(II) picolinate. Ten years later Blau reported[433] the synthesis of 1,10-phenanthroline (**32**) and showed that it forms a similar tris complex with iron(II). He also noted some of the redox properties of these complexes. It was not until 1931 that they were introduced as reversible high potential redox indicators.[434] In 1912 Werner demonstrated the octahedral geometry of $[Fe(bipy)_3]^{2+}$ by the successful resolution of its optical isomers.[435] More recent studies showed that complexes related to $[Fe(phen)_3]^{2+}$ have biological activity.[436] Solutions containing $[Fe(bipy)_3]^{2+}$ or $[Fe(phen)_3]^{2+}$ are obtained by addition of a slight excess of the ligand in ethanol, methanol or acetone to an aqueous solution of an iron(II) salt. The red solutions so obtained are indefinitely stable at pH ~7; addition of a concentrated solution containing a large anion such as ClO_4^-, Br^- or I^- precipitates the cations, and the complex salts can be recrystallized from organic solvents. However, when the anion (X) is a moderately good ligand, complexes of the type $[Fe(NN)_2X_2]$ can result on recrystallization (see below). The small ligand bite in $[Fe(phen)_3]^{2+}$ results in a slight compression along the pseudo-three-fold axis as well some twist distortion from O_h geometry.[437,438] In $[Fe(phen)_3]I_2 \cdot 2H_2O$ each complex is surrounded by four others with one of the ligands protruding into the 'pockets' of the neighbouring complexes.[438]

(31)

(32)

Optically active $[Fe(phen)_3]^{2+}$ and $[Fe(bipy)_3]^{2+}$ are readily obtained (*via* the antimony *d*-tartrate[439]). Racemization in the solid-state is very slow and available kinetic results have been discussed in a recent review.[440] The volume of activation for racemization of crystalline $[Fe(phen)_3](ClO_4)_2$ has been estimated[441,442] to be -0.9 ± 0.1 cm^3 mol^{-1} at room temperature. The volume of activation for racemization in solution is positive and large (14.2 ± 0.3 cm^3 mol^{-1} in

0.01 M HCl[443]) and similar to that for dissociative acid aquation,[444] possibly implying a common mechanism. However, the rate of racemization is some nine times faster than dissociation, arguing against a common mechanism (see below). Mechanisms involving excitation of the low-spin iron(II) centre to the high-spin $^5T_2$ state, and twist processes have been considered for the racemization process, which is enhanced by the presence of organic cosolvent.[445,446] Very recently it has been reported[446a] that the iron(II) complex of sulfonated 4,7-diphenyl-1,10-phenanthroline, $[Fe\{(SO_3Ph)_2phen\}_3]^{4-}$, dissociates and racemizes at the same rate in water (15–35 °C) but the addition of a cosolvent affects these processes differently. In all but extremely dilute solutions of mineral acid, protonation of free ligand causes $[Fe(phen)_3]^{2+}$, $[Fe(bipy)_3]^{2+}$ and related complexes to dissociate in an attempt to restore equilibrium conditions as in equation (43). As a result the intensely coloured solutions fade, obeying simple first order kinetics and become colourless over a period of minutes to hours depending on temperature and the complex concerned. Being easily monitored[447] these reactions have been the subject of numerous kinetic studies. Dissociation can also be induced by the presence of a large amount of metal ion such as Hg^{2+} that forms a relatively stable colourless complex with the α,α′-diimine ligand.[444,448] Dissociation also takes place when a high concentration of a ligand is added that complexes with the iron and successfully competes with the α,α′-diimine. The latter approach is particularly effective with polycarboxylates under mildly oxidizing conditions (*e.g.* with air), when iron(III) polycarboxylates result.[449] First order rate constants for the acid aquation of $[Fe(phen)_3]^{2+}$ and tris complexes of substituted 1,10-phenanthrolines not having ionizable groups only vary slightly (decreasing) with acid concentration. In keeping with a dissociative mechanism, activation energies are as high as 125 kJ mol^{-1} and entropies of activation are large and positive (Table 14).[450] Variations in aquation rate for complexes such as $[Fe(NH_2phen)_3]^{2+}$ with acid concentration are attributed to protonation equilibria involving the substituent.[451]

Table 14 Rate Constants and Activation Parameters for Aqueous Solutions of Complexes of the Type $[Fe(Xphen)_3]^{2+}$ in 1 M Sulfuric Acid

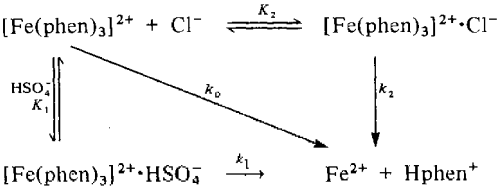
$$[Fe(LL)_3]^{2+} + 3H^+ \longrightarrow Fe^{2+}_{aq} + 3LLH^+ \quad (43)$$

The behaviour of $[Fe(bipy)_3]^{2+}$ towards acid aquation is not the same as $[Fe(phen)_3]^{2+}$. In the presence of sufficient mineral acid $[Fe(bipy)_3]^{2+}$ dissociates, the rate of aquation increasing with acid concentration until a rate limit is reached[452] at ~2 N. This is interpreted[453,454] in terms of a mechanism involving species containing monodentate protonated 2,2′-bipyridine as illustrated in Scheme 10, rather than the original suggestion[455] of a protonated intermediate with six iron–nitrogen bonds (although related species have been claimed[456]). The 1,10-phenanthroline ligand appears too rigid to easily form monodentate protonated species so the acid dependent path ($k_3[H^+]$ in Scheme 10) is not available for $[Fe(phen)_3]^{2+}$. It has been deduced that the only low-spin species in Scheme 10 is $[Fe(bipy)_3]^{2+}$ itself.[457] This scheme does not, however, account for all of the reported observations. In concentrated hydrochloric acid $[Fe(bipy)_3]^{2+}$ dissociates[458] but in other concentrated acids the situation is more complex.[459] In fact it is difficult to obtain the iron(II) complexes in concentrated solutions of nitric or sulfuric acids due to oxidation to iron(III), and the overall pattern of behaviour may be related to the activity of water in the concentrated acids.[460] In this connection it is interesting to note that rates of dissociation are significantly less in D_2O/HCl than in H_2O/HCl solutions.[461] A considerable amount of work, notably by Burgess,[462] has made use of these dissociation reactions as a probe for structure in mixed solvent systems.

Both $[Fe(phen)_3]^{2+}$ and $[Fe(bipy)_3]^{2+}$ and their substituted derivatives undego relatively rapid reactions with strong nucleophiles such as OH^-, CN^- and N_3^- to give nucleophile dependent products. With cyanide ion the low-spin first formed product[463] is $[Fe(CN)_2(LL)_2]$, which after long reaction periods is converted[464] to $[Fe(CN)_4(LL)]^{2-}$ as in equation (44). These cyanide complexes show strong solvatochromatic charge-transfer bands.[465–467] For instance the absorption maximum of $[Fe(CN)_2(bipy)_2]$ in the visible region in water is 515 nm while in pyridine it is 629 nm; there are also

Scheme 10

$$[Fe(LL)_3]^{2+} \xrightarrow{CN^-} [Fe(CN)_2(LL)_2] \xrightarrow{CN^-} [Fe(CN)_4(LL)]^{2-} \quad (44)$$



correspondingly large changes in extinction coefficient. Reaction of $[Fe(LL)_3]^{2+}$ complexes with hydroxide ion leads to complete displacement of the ligand from the iron and formation of iron(III) hydroxide[468] as in equation (45). It appears that formation of highly insoluble iron(III) hydroxide provides the thermodynamic driving force for the overall reaction. Addition of edta to chelate the iron(III) prevents precipitation of $Fe(OH)_3$ while not inhibiting the reaction. In the absence of oxygen there is no reaction. The effect of micelles on the aquation and base hydrolysis of $[Fe(phen)_3]^{2+}$ has been reported.[469] Reactions with both cyanide and hydroxide ions under pseudo first order conditions follow the second order rate law shown in equation (46). At very high nucleophile concentrations higher orders in nucleophile have been reported[470] (*e.g.* $k_3[X^-]^2$ and $k_4[X^-]^3$), and it seems likely these result from specific ion effects. The k_1 term is assigned to ligand independent rate determining dissociation of the complex, and the k_2 term to associative reaction with the nucleophile.[471–473] The latter second order path is usually dominant and surprisingly is associated with a positive volume of activation.[474] Since there are no ionizable hydrogens present, a conjugate base mechanism is not possible, so the observed kinetic behaviour might result from direct nucleophilic attack on the metal centre, or perhaps through a mechanism involving ion-pairs (see below). Support for the second order reactions involving attack on the iron centre comes from the reaction of optically active $[Fe(phen)_3]^{2+}$ with CN^- which gives[475] some *inverted* $[Fe(CN)_2(phen)_2]$. Both retention and inversion paths are involved and although interpretation of the kinetic data is not straightforward, it is concluded that the optical inversions are true chemical inversions.[476,476a] Curiously, however, the reaction of optically active $[Fe(bipy)_3]^{2+}$ with CN^- involves some *retention* of activity[477] with a greater dependence on $[CN^-]$ than is the case for inversion of $[Fe(phen)_3]^{2+}$. An alternative, and interesting, mechanism involving an initial reaction of the nucleophile with the coordinated α,α′-diimine ligand was postulated[478] by Gillard in 1975. By analogy with reaction of some quaternary nitrogen heterocyclic compounds[479,480] it was suggested the second order path corresponds to nucleophilic attack on the coordinated (*i.e.* quaternary) ligand at a position close to the metal which is followed by rapid transfer of the nucleophile to the metal.

$$[Fe(LL)_3]^{2-} + OH^-/O_2 \longrightarrow Fe(OH)_3 + 3LL \quad (45)$$

$$k_{obs} = k_1 + k_2[X^-] \quad (46)$$

It was further suggested that in some situations water might add across the C=N bond (covalent hydration) with subsequent deprotonation in alkali leading to formation of a pseudo base that rapidly undergoes intramolecular shift of the OH from ligand to metal. These suggestions stimulated much work both by Gillard's group and others, most of which has been reviewed,[481] but there remains disagreement concerning the importance of covalent hydration and pseudo base formation in reactions of iron(II) α,α′-diimine complexes and also complexes of other metals.[482,483] It appears that the best evidence for nucleophilic attack on the ligand in iron(II) 2,2′-bipyridine and 1,10-phenanthroline complexes involves 5-nitro-1,10-phenanthroline. However, this results from Meisenheimer complex formation with attack taking place on the 6-position, which is remote from the iron centre rather than adjacent to it.[484,485]

The participation of reaction paths involving ion pairs has been proposed to explain the second order behaviour of $[Fe(LL)_3]^{2+}$ complexes with OH^- and CN^-. Margerum first suggested[486] the $[Fe(phen)_3]^{2+}\cdot nOH^-$ ion pairs are likely to dissociate at rates different from $[Fe(phen)_3]^{2+}$ itself, and pointed out that other anions such as Cl^-, F^-, NO_3^-, ClO_4^- *etc.* might be expected to form ion pairs as readily as OH^-, though none of these ions significantly enhance the rate of dissociation in aqueous media.[445,487] This could be due to a number of factors including hydration/steric effects and unfavourable competition with dipolar interactions. Ion pairing of $[Fe(LL)_3]^{2+}$ cations with a range of common anions in nonaqueous media is well established and in some instances hydrophobic effects are operative.[488] They have been used over a number of years as a means of concentrating these complex cations (*via* solvent extraction into an immiscible liquid) in spectrophotometric determinations.[489–494] There are reports of enhanced rates of acid solvolysis of $[Fe(bipy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ by common anions in dimethyl sulfoxide[495] and methanol.[496] In the latter solvent the effectiveness in accelerating the rate is $Cl^- \gg Br^- \sim MeC_6H_4SO_3^- > HSO_4^- \sim NO_3^- > ClO_4^-$. In $DMSO$, acid solvolysis of $[Fe(phen)_3]^{2+}$ is dramatically increased by Cl^- (added in the form of LiCl or $Et_3\overset{+}{N}CH_2PhCl^-$) and this effect is inhibited by HSO_4^-. These observations were quantitatively accounted for by the competitive ion-pair formation mechanism shown in Scheme 11 involving a reactive ion pair with Cl^- and a more inert $[Fe(phen)_3]^{2+}\cdot HSO_4^-$ ion pair.[497]

Scheme 11

Similar ion-pair competition has been reported for the reaction of CN^- with $[Fe(phen)_3]^{2+}$ in water where addition of I^- inhibits the reaction by formation of a relatively inert iodide ion pair.[498] In this instance there is independent evidence for ion-pair formation with iodide.[499] There is, however, criticism of ion-pair mechanisms although the observed kinetic behaviour is not in accord with the proposed[500] alternative mechanism involving a preequilibrium to form a bis chelate. A recent lengthy paper[501] dealing with reaction of several $[Fe(LL)_3]^{2+}$ complexes with CN^- highlights the importance of other effects in some instances. $[Fe(LL)_3]^{2+}$ (LL = phen, bipy), in the presence of long chain alkyl sulfonates, are readily extracted into chloroform,[502] and dissociation and racemization rates are enhanced *via* specific interactions.[503]

(*ii*) *Bis complexes*

Complexes of the type $[FeX_2(LL)_2]$ (LL = phen, bipy) where X is a unidentate anionic ligand have been studied extensively[504] because they display a range of spin states depending on the nature of X. $[Fe(CN)_2(LL)_2]$ complexes are low-spin ($^1A_1$) and kinetically inert. Weak field ligands (X^-) result in high-spin complexes ($^5T_2$), while with some ligands, notably NCS^- and $NCSe^-$, the $^5T_2$ to $^1A_1$ spin transition can be observed in the form of abrupt changes in magnetic and spectral properties over a fairly narrow temperature range.[505] Low-spin *cis*-$[Fe(CN)_2(phen)_2]$ is obtained from the reaction of $[Fe(phen)_3]^{2+}$ with CN^- in aqueous solution. There has been controversy over its stereochemistry with some IR data suggesting *cis* and *trans* isomers exist, but Mössbauer experiments[506] indicate the existence of a single isomer ($\Delta E_Q = 0.58\ mm\ s^{-1}$, $\delta = +0.27$ relative to stainless steel). The *cis* complex is only very slightly soluble in water, but readily extractable with chloroform or nitrobenzene and as noted previously it exhibits remarkable solvatochromic properties (Table 15). In aqueous solution it is orange and in chloroform or nitrobenzene it is violet. The reaction of $[Fe(phen)_3]^{2+}$ with CN^- has been recommended for the selective and sensitive determination of cyanide.[507] If excess $[Fe(phen)_3]^{2+}$ is present only $[Fe(CN)_2(phen)_2]$ is formed, with excess CN^- reaction to give $[Fe(CN)_4(phen)]^{2-}$ is so extremely slow at room temperature that it does not interfere.

The cyanide ligands in $[Fe(CN)_2(LL)_2]$ (LL = phen, bipy) are sensitive towards protonation: successive protonation of both cyanide ligands causes the colour of the complex to change from violet through orange-red to yellow.[508,509] Protonation in liquid hydrogen fluoride has also been examined in detail,[510] and a *cis* configuration confirmed for the diprotonated cation. Both

$[Fe(CN)_2(phen)_2]$ and the corresponding bipy complex can be oxidized to give iron(III) complexes.[511] They are useful as indicators for titration of weak bases in nonaqueous solvents, and also for redox titrations. The reaction of $[Fe(CN)_2(bipy)_2]$ with hydroxide ion follows a first-order rate law with rates *independent* of $[OH^-]$ to give, presumably, hydrated iron(III) oxide *via* air oxidation.[512] Other low-spin complexes of the $[FeX_2(LL)_2]$ (LL = phen, bipy) type[504] are with $X^- = NO_2^-$ and CNO^-, while most others are high-spin. In this respect the halide complexes are typical with magnetic moments of ~ 5.3 BM at room temperature. They are obtained from reaction of the anhydrous iron(II) salt with the diimine in a low polarity solvent,[513] or from the corresponding tris complex by extraction or refluxing with hot organic solvent, or pyrolysis in the absence of oxygen. Thermal decomposition of the tris complex as in equation (47) achieved by refluxing or extracting with a hot solvent such as chloroform, benzene, or methylcyclohexane, can be satisfactory although long reaction times are necessary in some instances.[513,514] This procedure does not make use of water or methanol, because in these solvents most of the high-spin bis ligand species are not stable. They usually dissociate forming the tris complex according to equation (48), although there are instances where, depending on the nature of X^-, recrystallization from methanol or ethanol affords the bis complex.

$$[Fe(LL)_3]X_2 \longrightarrow [Fe(LL)_2X_2] + LL \quad (47)$$

$$3[FeX_2(phen)_2] \longrightarrow 2[Fe(phen)_3]^{2+} + Fe^{2+} + 6X^- \quad (48)$$

Japanese workers[515] have reexamined the pyrolysis of $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$, a means of making $[FeX_2(LL)_2]$ complexes originally investigated by German[516] and later by American groups.[517,518] Using Mössbauer spectroscopy they found[515] $[FeCl_2(bipy)_2]$ is obtained in the temperature range 140–200 °C with dissociation of the bipy ligand taking place at ~ 140 °C before dehydration is complete. However volatilization of the dissociated ligand from the solid proceeds only slowly below 200 °C. The room temperature Mössbauer parameters of $[FeCl_2(bipy)_2]$ ($\delta = 1.01$ mm s^{-1}, $\Delta E_Q = 2.98$ mm s^{-1}) obtained in this way are the same as previously reported[519–521] for $[FeCl_2(bipy)_2]$ made in acid aqueous solution from the ligand and Fe^{2+}.

While most $[FeX_2(LL)_2]$ (LL = phen, bipy) complexes are high-spin ($^5T_2$) and a few low-spin ($^1A_1$), some, such as $[Fe(ox)(phen)_2]$ (ox = oxalate) and $[FeF_2(phen)_2]$, are claimed[512,522] to be of intermediate spin. Of particular interest are those complexes (notably when $X^- = NCS^-, NCSe^-$) in which the high-spin to low-spin transition can be observed in the form of an abrupt change in magnetic and spectral properties over a fairly narrow temperature range.[504,505] These complexes can be obtained from the red precipitates formed when aqueous solutions of Fe^{2+} and the anion are treated with the calculated amount of ligand. These red hydrated compounds on dehydration afford, for example,[523] purple *cis*-$[Fe(NCS)_2(phen)_2]$. The red compound containing phen dissolves in solvents such as dimethyl sulfoxide and nitromethane, but not in diethyl ether or dioxane. In acetonitrile rapid isomerization takes place[524] to give the insoluble purple *cis*-$[Fe(NCS)_2(phen)_2]$. This behaviour is consistent with the red compound being $[Fe(phen)_3]_2[Fe(NCS)_4](NCS)_2 \cdot nH_2O$ and this formulation is supported by Mössbauer and IR spectra as well as other measurements.[524] Equations (49) and (50) represent the process taking place. At room temperature the magnetic

$$3Fe^{2+} + 6SCN^- + 6phen \longrightarrow [Fe(phen)_3]_2[Fe(NCS)_4](NCS)_2 \quad (49)$$

$$[Fe(phen)_3]_2[Fe(NCS)_4](NCS)_2 \longrightarrow 3\ cis\text{-}[Fe(NCS)_2(phen)_2] \quad (50)$$

moments of $[Fe(NCS)_2(phen)_2]$, $[Fe(NCSe)_2(phen)_2]$ and $[Fe(NCS)_2(bipy)_2]$ are in the range characteristic of high-spin complexes (4.9 to 5.2 BM) but at lower temperatures abruptly decrease (*e.g.* in $[FeX_2(phen)_2]$ at 174 K for $X^- = NCS^-$; at 232 K for $X^- = NCSe^-$). The observed magnetic moments tend to approach values more typical of low-spin complexes at 77 K. The existence of several polymorphs complicates the situation, but spectroscopic studies, and in particular Mössbauer data (Table 16) conclusively show that the transition involves a change from the $^5T_2$ to $^1A_1$ spin state. However, a simple model based on a 'pure' Boltzmann distribution over a fixed set of energy levels is an inadequate interpretation of the experimental results. It seems likely that solid state effects such as domain size have an important role in this behaviour. Thus samples of $[Fe(phen)_2(NCS)_2]$, prepared by precipitation in methanol and by acetone extraction of $[Fe(phen)_3](NCS)_2$, show a number of differences resulting from different crystal size and quality. The spin transition in the sample obtained from methanol is gradual while that of the extracted sample is abrupt. Their thermal behaviour (DTA) and temperature dependent X-ray diffraction patterns also show significant differences.[525]

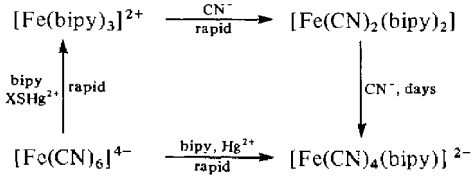
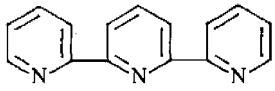
(*iii*) *Mono complexes*



In solution yellow iron(II) species containing one α,α'-diimine ligand can be obtained[526] from an excess of Fe^{2+} in an acidified solution of the ligand (which controls the amount of available free ligand *via* protonation). Formation constants for many such complexes of substituted 1,10-phenanthrolines have been reported and tabulated.[425] The rate of formation of $[Fe(phen)(H_2O)_4]^{2+}$ is rapid and has a very unfavourable entropy of activation ($E_a = 53.6$ kJ mol^{-1}, $\Delta S^{\neq} = -66.9$ J K^{-1} mol^{-1}.[527] Kinetics of the corresponding reactions with 2,2′-bipyridine have also been reported.[528] Reaction of $[FeF_2py_4]$ with 1,10-phenthroline in pyridine affords violet $[FeF_2(phen)]$ (4.4 BM) which is no doubt polymeric.[513] Other dihalo complexes can be obtained by pyrolysis of the corresponding tris complexes. From $[Fe(bipy)_3]Cl_2 \cdot 5H_2O$ two $[FeCl_2(bipy)]$ isomers have been characterized by Mössbauer spectroscopy.[515] The orange isomer originally thought to be monomeric and possibly tetrahedral ($\delta = 0.93$ mm s^{-1}; $\Delta E_Q = 3.58$ mm s^{-1} at 293 K) is obtained from the first formed $[FeCl_2(bipy)_2]$, on further heating it is converted to a rose-red polymeric form. This is similar to that prepared from $FeCl_2$ and the ligand in hydrochloric acid,[519] for which the Mössbauer data are consistent with the presence of polymeric, chloride-bridged, octahedral high-spin iron(II), as are IR spectra and magnetic moments. It has been suggested the corresponding 5,5′-dimethyl-2,2′-bipyridine complex is probably a dimer containing five-coordinate iron(II).[517] Very recently, however, the orange isomer of $[Fe(bipy)Cl_2]$ has been obtained from ethanol solutions of $FeCl_2 \cdot 4H_2O$ and a deficiency of bipy, and on the basis of low temperature magnetic data structure (**33**) comprising a chain of five-coordinate iron(II) centres with single chloro bridges was proposed.[520]

The $[Fe(CN)_4(LL)]^{2+}$ (LL = bipy, phen) complexes have not been extensively studied. They are low-spin, and the proton NMR spectra of the complexes with LL = bipy and 5,5′-Me_2bipy are consistent with the expected two-fold symmetry of the diimine. With LL = phen an unexpected

(33)

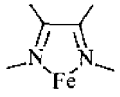


inequivalence has been observed that was postulated to be due to addition of water to an imine double bond.[529] Like $[Fe(CN)_2(LL)_2]$, the anionic mono diimine complexes exhibit solvatochromatic effects. $[Fe(CN)_4(LL)]^{2-}$ complexes can be obtained by prolonged (days) reaction of $[Fe(LL)_3]^{2+}$ with cyanide ion, but a better route is from $[Fe(CN)_6]^{4-}$, which reacts with bipy in the presence of a deficiency of Hg^{2+} to form predominantly $[Fe(CN)_4(bipy)]^{2-}$. With an excess of Hg^{2+} only $[Fe(bipy)_3]^{2+}$ is formed (Scheme 12).[530] The pyrolysis of $[Fe(CN)_4(LL)]^{2-}$ complexes, including the diprotonated species, has been studied extensively by Hungarian workers.[531–533]

Scheme 12

44.1.5.6.3 2,2′:6′,2″-Terpyridine

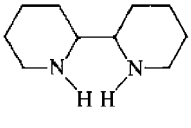
The terdentate ligand 2,2′:6′,2″-terpyridine, terpy (**34**), forms mono and bis complexes with iron(II). On the basis of a comparison of X-ray powder data it was suggested[534] that $[Fe(terpy)X_2]$ (X = Br, I) has a five-coordinate structure similar to that of $[Zn(terpy)Cl_2]$. In spite of early reports[535,536] claiming that the chloro complex is isomorphous with the zinc analogue, its X-ray powder pattern is different and it has been reformulated[537] as $[Fe(terpy)_2][FeCl_4]$, which is in accord with an observed[538] magnetic moment of 4.60 BM, well below the spin-only value.



(34)

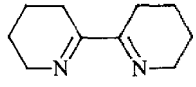
Fe^{2+}_{aq} in the presence of an excess of terpy forms[539,540] the very stable low-spin complex $[Fe(terpy)_2]^{2+}$, for which $\log \beta_2 = 20.4$, $\Delta H = -113\,kJ\,mol^{-1}$ and $\Delta S = -13\,J\,K^{-1}\,mol^{-1}$. The rate of ligand exchange is slow and has been examined using tritium-labelled terpy.[541] In acid solution, ligand dissociation takes place[542] and the observed kinetic behaviour as a function of acid concentration is complex.[543] Reaction of $[Fe(terpy)_2]^{2+}$ with CN^- follows second order kinetics to give $[Fe(terpy)(CN)_3]^-$ whose maximum absorption in the visible region (metal–ligand ct) varies markedly with the nature of the solvent.[543] Oxidation of $[Fe(terpy)_2]^{2+}$ yields the iron(III) complex (~1.1 V), while controlled reduction affords the +1 and 0 formal oxidation states.[544,545]

44.1.5.6.4 Other diimines and related ligands

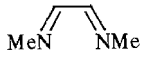


The basic iron(II) α-diimine five-membered unsaturated chelate ring (**35**) is a key unit in iron chemistry. In this review the classic ligands important in the early development of the area have been allocated separate sections: 2,2′-bipyridine and 1,10-phenanthroline (44.1.5.6.2), and 2,2′:6′,2″-terpyridine (44.1.5.6.3). The closely related dioximes are discussed in Section 44.1.5.7, while the many macrocyclic systems containing such linkages are covered in later sections. Once it was appreciated that only the basic structure (**35**) rather than a fully aromatic ligand is necessary to obtain stable, highly coloured (metal-to-ligand charge transfer[546a]) complexes, many ligands containing this moiety were synthesized and their iron(II) complexes prepared. Some of the most readily

accessible complexes are obtained *via in situ* Schiff base formation, and several useful reviews concerned with them are available.[546b–546e] These species are discussed first, before dealing with complexes of fully aromatic ligands. Most of these complexes are red or purple, and many with six nitrogen donors are low-spin and not of particular interest unless they display unusual ligand reactivity or because they have been the subject of kinetic studies. Several of these complexes can be obtained *via* oxidation/dehydrogenation of the corresponding saturated complex and this illustrates the thermodynamic stability of (**35**) in low-spin complexes. There has also been considerable interest in those complexes that exhibit spin transitions as a result of steric or electronic effects causing a weakening of the ligand field strength.



(35)



Blau reported[547] in 1898 that the *saturated* α,α′-dipiperidine (**36a**) forms a purple iron(II) complex. This surprising finding was later shown by Krumholz[548] to be due to air oxidation of the ligand in the presence of Fe^{2+} to give the tris chelate of (**36b**). He also demonstrated the template reaction of methylamine with glyoxal or biacetyl in the presence of Fe^{2+} that affords red tris complexes of the diimines (**37a**) and (**37b**). Although the free ligands are unstable, these complexes are very stable with respect to dissociation in acid but rather less so towards alkali. Their visible spectra are similar to those of $[Fe(bipy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$. For $[Fe(\mathbf{37b})_3]^{2+}$, $\lambda_{max} = 568$ ($\varepsilon = 1.07 \times 10^4$) and as with related complexes, on the high frequency side of this electronic band there are shoulders. These have been assigned to metal-to-ligand charge transfer,[547] while a later Raman study indicated they are largely due to vibronic transitions.[550] The range of complexes obtainable *via* this template synthesis is illustrated by the selected examples in equation (51). The isomer shifts of the tris complexes in their Mössbauer spectra[551] do not differ greatly ($\delta \sim -0.06\,mm\,s^{-1}$ at 298 K relative to $^{57}Co/Cu$) and the quadrupole splitting values fall within the range 0.5 to $0.6\,mm\,s^{-1}$ except for complexes with phenyl groups. These have $\Delta E_Q \sim 0.9\,mm\,s^{-1}$, that may result from steric effects or increased π acceptor ability. The former is favoured. The tris chelate derived from glyoxal and methylamine, $[Fe(\mathbf{37a})_3]^{2+}$, has been resolved and its racemization kinetics studied.[552] Racemization involves both intramolecular twist and bond breaking paths (~70% *via* twist at 69.4 °C). The activation enthalpy for bond breaking, as with $[Fe(bipy)_3]^{2+}$, is lower than that for twist racemization. In contrast with the more rigid $[Fe(phen)_3]^{2+}$, the activation enthalpy for dissociative bond breaking is larger than that for racemization.

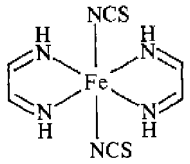
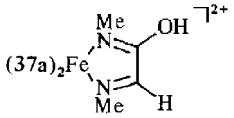
(36b)

(37a)

(37b)



(51)

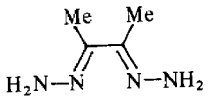


R = H; R′ = H, Me, Ph
R = Me; R′ = Me, Et, Ph
RR′ = $(CH_2)_6$

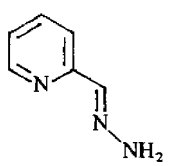
Calculations[553] on complex (**38**) confirm metal-to-ligand back-donation is important and indicate that HOMOs in complexes of this type have considerable ligand character. The latter result is relevant to the behaviour of related complexes upon oxidation. Oxidation of tris{(glyoxal)bis(methylimine)}iron(II), $[Fe(\mathbf{37a})_3]^{2+}$, by cerium(IV) is not like the reaction involving phen or bipy that simply gives the corresponding iron(III) complexes. Here oxidation of the coordinated ligand takes place to give two or more products including complex (**39**). It appears[554] that this reaction does not proceed *via* direct attack on the ligand but rather at the metal centre giving an intermediate iron(III) complex, which decomposes to give several products. Electrochemical and spectrophotometric monitoring of the reaction in 4.07 M H_2SO_4 led to evidence[555] supporting a mechanism in which intramolecular electron transfer in the first formed iron(III) complex is

assisted through nucleophilic attack by water on the ligand. This proton abstraction takes place at Me or CH, explaining the observed ligand oxidized products. However, these radicals may react with water at the same time reducing a molecule of $[Fe(\mathbf{37a})_3]^{3+}$. The basic correctness of this complicated mechanistic scheme was confirmed by electrochemical studies[556] that yielded values of the rate constants for some of the faster processes. As acidity is increased the thermodynamic stability of the iron(III) complex increases with respect to iron(II), and in strong sulfuric acid (> 10 M) $[Fe(\mathbf{37a})_3]^{3+}$ does not undergo ligand oxidation. Under these conditions activation parameters[557a] for the Ce^{IV} oxidation are $\Delta H^{\neq} = 43.9 \pm 4.2\,kJ\,mol^{-1}$ and $\Delta S^{\neq} = -33.5 \pm 8.4\,J\,K^{-1}\,mol^{-1}$.

(38)

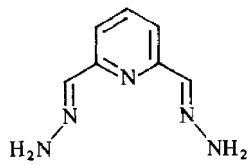


(39)

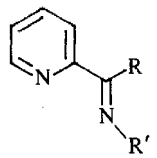


In acetonitrile electrochemical reduction gives iron(I) and iron(0) species.[557b] In this solvent ligand oxidation reactions are almost absent, but they are not completely avoided due to the presence of small amounts of water.[558] This problem was overcome by using a totally anhydrous low temperature (25 °C) molten salt comprising aluminum chloride and ethylpyridinium bromide (2:1 mole ratio). In this medium, reversible one-electron electrochemical oxidations take place[559] with $[Fe(\mathbf{37a})_3]^{2+}$, $[Fe(\mathbf{37b})_3]^{2+}$ and a number of related complexes.[560] Here the iron(III) form is thermodynamically more stable than is iron(II), whereas in aqueous solutions the reverse is true.

Addition of $[Fe(\mathbf{37a})_3]^{2+}$ to the Fe^{3+}_{aq}-catalyzed decomposition of hydrogen peroxide inhibits oxygen evolution by competing with Fe^{3+}_{aq} for $HO_2^{\cdot}$ radicals.[561] Thus the iron(II) complex is a trap for $HO_2^{\cdot}$, itself becoming oxidized in regenerating H_2O_2. In acid solutions $[Fe(\mathbf{37b})_3]^{2+}$ undergoes autooxidation through a free radical process. The reaction is first order in complex and half order in oxygen, suggesting protonation is involved in a preequilibrium step. The main product results form the oxidation of C-methyl to a hydroperoxide, and oxidation only takes place when a C-methyl or C-methylene group is present.

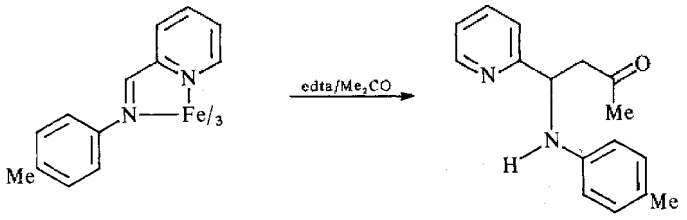


Dihydrazones of α-diketones can form low-spin tris complexes with iron(II). Thus the complex with biacetyldihydrazone (**40a**) is well characterized and related tris complexes derived from benzil and glyoxal are also low-spin,[563,564] while bis complexes of the type $[FeX_2(NN)_2]$ are paramagnetic[565] with magnetic moments of ~ 3 BM. These unusual values might be indicative of the complexes being incorrectly formulated. The bidentate and tridentate hydrazones (**40b**) and (**40c**) derived from pyridine aldehydes form low-spin tris and bis complexes respectively.[566] However, considerably more work has been carried out on the related Schiff bases (**41**) obtained from pyridine aldehydes[567] or ketones[568] and a primary amine (that can be aliphatic or aromatic). In both cases the resulting Schiff bases acts as a bidentate ligand and the low-spin tris iron(II) complexes are deep purple. They are prepared by adding a solution of an iron(II) salt to a mixture of a pyridine-2-carbaldehyde (or ketone) and the amine. This facile template synthesis can be used to prepare the free ligand *via* subsequent demetallation with edta. This is conveniently carried out in aqueous methanol, but if aqueous acetone is used, addition of acetone to the C=N bond takes place,[569] as shown in equation (52). When the complexes are formed in the presence of halide, green bis complexes $[FeX_2(NN)_2]$ result that are high-spin.[570] Extraction of these compounds with refluxing chloroform or cyclohexane yields mono complexes $[Fe(NN)X_2]$ that undoubtedly contain halide bridges.



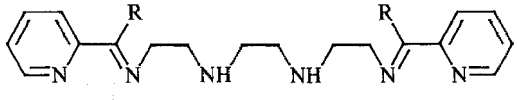
(40a)

(40b)



(40c)

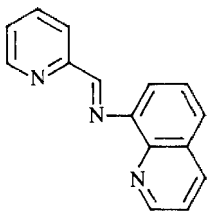
(41)



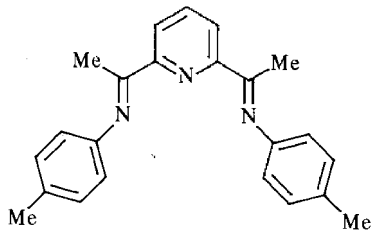
Acid dissociation of several iron(II) tris complexes of (**41**) has been well studied. For R = H, R′ = alkyl or phenyl the variation of rate with acid concentration is small,[567,571] like that for $[Fe(phen)_3]^{2+}$. This is surprising since these ligands might be expected to be flexible, and so form a monoprotonated intermediate in the way $[Fe(bipy)_3]^{2+}$ does. Perhaps this is due to the partially

(52)

dissociated intermediate having a very short life. Substitution in the phenyl ring does affect the dissociation rate in a way that can be correlated with Hammett constants. In contrast to the behaviour of most of these complexes, those with ligands derived from nitroanilines or pentafluoroaniline dissociate at rates that depend on acid concentration. Moreover, the results[571] are consistent with a rate law containing an [acid]^2 term that has been interpreted in terms of a rapid protonation preequilibrium, or hydrogen bonding with H_3O^+. With R = Ph isomeric complexes are obtained that dissociate at different rates,[568] and similar effects have been observed[572] with R = H, R′ = Me, Pr; and R = R′ = Me.[573] These and related complexes react with hydroxide ion[574] and cyanide ion in second order reactions. Iron(III) hydroxide is the product of the former and dicyano complexes of the latter. Like $[Fe(CN)_2(phen)_2]$ the analogous Schiff base complexes are low-spin, and display strong charge-transfer spectra that are very solvent dependent.[575a] Reaction of $[Fe(\mathbf{41})_3]^{2+}$ (R = Ph, R′ = 3,4-dimethylphenyl) with hydroxide ion has $\Delta V^{\neq} \sim 11\,cm^3\,mol^{-1}$, and this increases markedly as the solvent is made increasingly methanol rich highlighting the role of solvation.[575b] Complexes of the $[Fe(\mathbf{41})_3]^{2+}$ type react with hydrogen peroxide[574] at a rate independent of $[H_2O_2]$ that is limited by ligand dissociation. With peroxodisulfate in some instances two parallel reactions take place, one being independent, and the other dependent on the oxidant concentration. Thus, for R = R′ = Ph a single term rate law applies, whereas when R = H, R′ = Ph there is a two term rate law.[576] Oxidation of $[Fe(\mathbf{41})]^{2+}$ (R = R′ = Me) with the more powerful cerium(IV) is more complicated, and the reaction depends on acidity. Oxidation of the metal is followed by intramolecular reduction back to iron(II) with concomitant radical formation at the ligand that is assisted by water and retarded by acid.[577] Under appropriate conditions the major product is $[Fe(\mathbf{41})_3]^{2+}$ with R = CHO, R′ = Me.

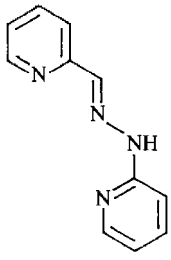


A large number of polydentate Schiff base ligands have been reported, and of particular interest are the iron(II) complexes of ligands such as (**42**) (R = H, Ph) because they are low-spin, even though they contain only two diimine units.[578] The rate of acid aquation of $[Fe(\mathbf{42})]^{2+}$ is slow, but this depends on acid concentration. Reaction with hydroxide ion is second order, as is that with cyanide ion. The product of the last reaction is not $[Fe(CN)_6]^{4-}$, but $[Fe(CN)_4(\mathbf{42})]^{2-}$ that has only one diimine bound to the metal. Related ligands have been prepared and much of the early work has been reviewed.[546b–546e]

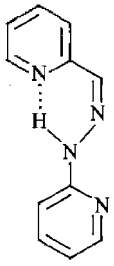


(42)

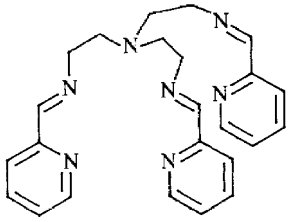
The tridentate ligands (**43a**) and (**43b**) form low-spin bis ligand complexes. The kinetics of several reactions of these, and related complexes have been studied.[579a] The *cis*/*trans* isomers (**43c**) and (**43d**) of pyridine-2-carbaldehyde 2-pyridylhydrazone can be isolated and both form iron(II) complexes.[579b] A tris complex is obtained with (**43d**). In water this is yellow, and when an acid solution is boiled it is converted to the bis complex $[Fe(\mathbf{43c})_2]^{2+}$. This complex is exceptionally stable (log $\beta_2 = 16.7$) and it is acidic so that in alkaline solution it forms a neutral complex.[579c] The hexadentate ligand (**43e**) forms a well-characterized purple low-spin complex,[579d] but substitution of methyl groups in the pyridine rings adjacent to the nitrogen atoms results in a complex displaying spin cross-over.[579e] The dynamics of this spin change have been monitored using laser temperature-jump methods.[597f]



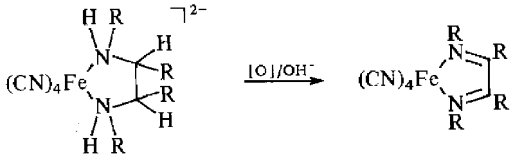
Iron(II) complexes containing saturated amines can undergo oxidative dehydrogenation to give thermodynamically more stable imine complexes. Mention has been made earlier in this section about the behaviour of α,α′-dipiperidine in this respect.[548] One of the most well-studied systems involves yellow diamagnetic 1,2-diamine complexes of the type $[Fe(CN)_4(diamine)]^{2-}$. Upon oxidation in alkaline solution these give red diimine complexes as in equation (53). The reaction goes *via* an iron(III) intermediate that can be isolated under acidic conditions. In the presence of base this gives complexes containing mono- and di-imine linkages.[580] The electrochemical and ferricyanide



(43a)

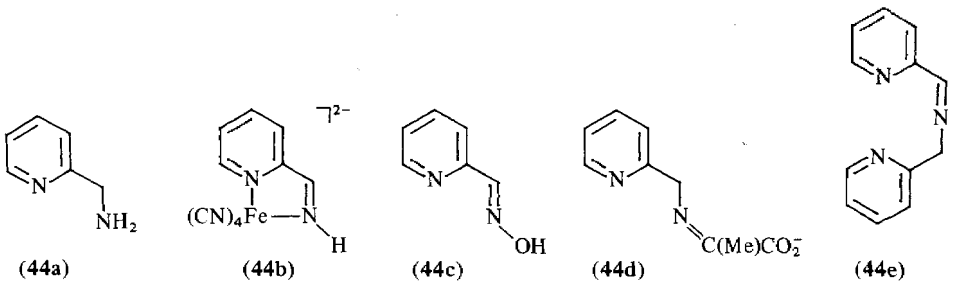


(43b)

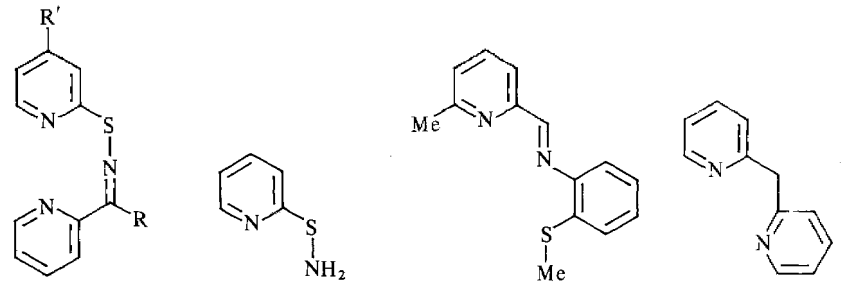


(43c)

(43d)

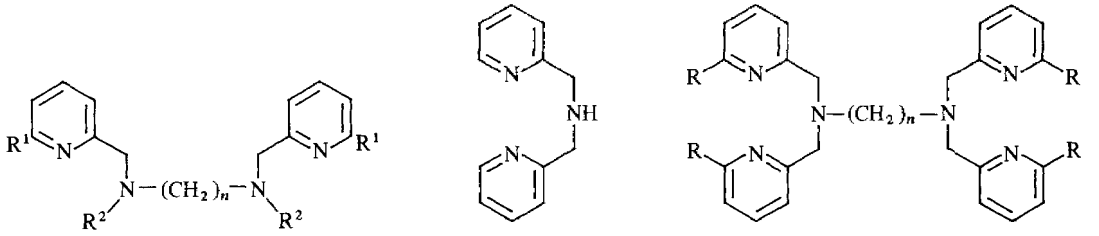


(43e)

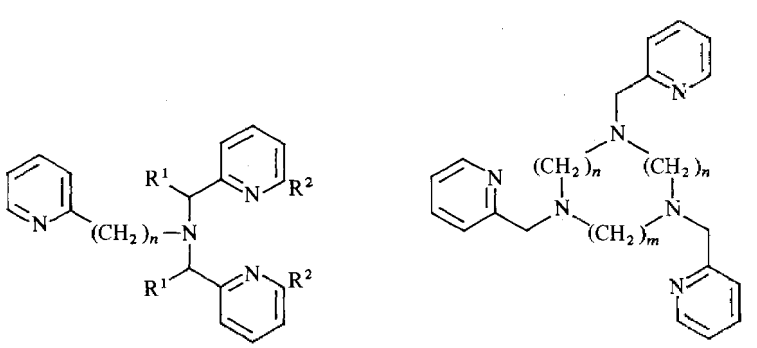


(53)

oxidation of the ethylenediamine complex $[Fe(CN)_4(en)]^{2-}$ has been studied in detail.[581] Reaction of the first formed low-spin iron(III) complex with OH^- leads to NH_2 deprotonation that is followed by internal electron transfer giving iron(II) with a NH radical, that forms the Fe^{II}=NH linkage on further oxidation. Tetracyano complexes containing optically active diamines have been prepared,[582] and their CD spectra recorded. Treatment with basic hydrogen peroxide gives the expected red diimine complexes. A large amount of work has been done on iron(II) complexes containing 2-aminomethylpyridine (α-picolylamine) (**44a**) and its derivatives. The tetracyano complex $[Fe(CN)_5(\mathbf{44a})]^{2}$ is smoothly oxidized to the imine complex (**44b**) that is quite stable in mildly acid solution.[583] In alkaline solution further oxidation gives the corresponding oxime (**44c**) complex together with uncharacterized decomposition products. Reaction of (**44a**) and sodium pyruvate with Fe^{2+}_{aq} does not give the expected complex containing (**44d**) because isomerization to the conjugated imine takes place that is followed by transamination with another molecule of (**44a**) to give the complex containing the tridentate ligand (**44e**) and α-alanine.[584] The related sulfur ligand (**44f**) forms a low-spin bis chelate,[585a] whereas the tris complex with (**44g**) has a magnetic moment of 2.8 BM. The mixed donor ligand (**44h**) forms a low-spin bis complex, and high-spin complexes of the type $[FeX_2(\mathbf{44h})]$ that may be five-coordinate.[585b] 2,2′-Dipyridylmethane (**44i**) appears[586] to form only high-spin iron(II) complexes but these are of the type $[FeCl_2(\mathbf{44i})_2]$ that has μ_{eff} = 5.3 BM. 2-Aminomethylpyridine (**44a**) itself forms $[Fe(\mathbf{44a})_3]^{2+}$, which exists in different colours and spin forms. As a methanol solvate, the high-spin chloride salt adopts the *mer* configuration whereas it is a *fac* isomer as the dihydrate (due to hydrogen bonding?) that is low-spin.[587a] The difference in Fe—N bond lengths in these complexes is large (~0.19 Å). The alcohol solvates of the bromide and chloride salts display sharp spin transitions to low-spin forms in the region 130–110 K, but removal of solvent molecules causes the transitions to become very gradual.[587b] The iodide salt contains two isomers in the lattice: the *mer* isomer has Fe—N = 2.20 Å and the *fac* form (with Fe—N = 2.06 Å) exists as a mixture of interconverting high- and low-spin species at room temperature.[587c] At room temperature the ethanol solvate of the chloride salt is yellow, but at liquid nitrogen temperature it is red. X-Ray structure work carried out at 298, 150 and 90 K shows the average Fe—N bond distances in the high- and low-spin forms are 2.195 Å and 2.013 Å respectively. The N—Fe—N bite angle increases by about 6° on going from high- to low-spin, and there are small changes in N—C distance consistent with increased d–π interaction.[587d] As suggested by Mössbauer work,[587e] the disorder of the alcohol molecules also varies with the spin transition, and their ordering may act as a trigger for the spin transition.



(44a) (44b) (44c) (44d) (44e)



(44f) (44g) (44h) (44i)

Danish workers have synthesized several polydentate ligands derived from (**44a**) that illustrate the sensitivity of the spin transition to small ligand modifications and indicate that the chelate effect may be as important as conjugation in the ligand. Thus, with (**44j**; $n = 2, 3$ and $R^1 = R^2 = H$) low-spin complexes of the type $[Fe(NCS)_2(\mathbf{44j})]$ are obtained, but if R^1 or R^2 is methyl, high-spin complexes result.[588a] The bis complex of the tridentate ligand (**44k**) is red and low-spin,[588b] as is the complex of the hexadentate ligand (**44l**) when $n = 3$ and R = H, but high-spin for $n = 2$, R = Me, while complexes of closely related ligands display magnetic moments that are strongly temperature dependent.[588c] Complexes containing the tetradentate ligand (**44m**) similarly display a variety of spin behaviour.[588d] With $n = 1$, $R^1 = H$, $R^2 = Me$ $[Fe(NCS)_2(\mathbf{44m})]$ is high-spin whereas spin transition is observed when $n = 1$, $R^1 = H$, Me, $R^2 = H$. Triaza macrocycles (**44n**) with pendent pyridylmethyl groups making them hexadentate have been reported.[588e] When $n = m = 2$ the pseudooctahedral $[Fe(\mathbf{44n})]^{2+}$ is low-spin, but the complex with the somewhat expanded ligand having $n = m = 3$ the complex is high-spin.

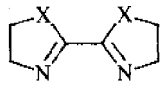
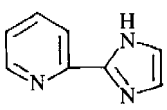
(44m) (44n)

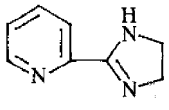


Ligands of the type (**45a**; X = NH, S, O) form a bridge between simple cyclic diimines and the fully aromatic ligands containing two heteroatoms. The tris complex with X = S is low-spin and the kinetics of its ligand dissociation reactions involving acid, hydroxide, peroxydisulfate, and heavy metals such as Ag^+, Hg^{2+} have been studied. Interestingly there is no catalysis by the heavy metals.[589a] The mixed ligand complex $[Fe(NCS)_2(\mathbf{45a})_2]$ (X = S) is high-spin at room temperature, but when the temperature is lowered it undergoes spin cross-over.[589b] The tris complex with X = NH displays a spin transition at the relatively high temperature of ~310 K, and its Mössbauer spectrum at 293 K has a poorly resolved quadrupole-split doublet centred at 0.29 mm s^{-1} (relative to natural iron) attributable to the major low-spin component. At 77 K only the resonance due to this form is present.[589c] The rapid (stopped-flow) reaction of $[Fe(\mathbf{45a})_3]^{2+}$ X = O (λ_{max} = 500, $\varepsilon = 1.6 \times 10^3$) with OH^- has been reported to involve attack by OH^- on the coordinated ligand followed by ligand decomposition and finally precipitation of $Fe(OH)_3$. The first stage is a preequilibrium for which thermodynamic data have been presented.[589d] The related tris complex of 2,2′-bipyrazine (**45b**) behaves similarly, and reaction rates for this and related complexes have been compared with charge densities based on INDO molecular orbital calculations.[589e] In contrast the tris complex with (**45c**; X = NH) is high-spin[589f] down to ~115 K, and when X = O the complex remains high-spin over the complete temperature range investigated.[489c] In acetonitrile $[Fe(\mathbf{45c})_3]^{2+}$ reacts with oxygen to form water and an iron(III) complex in which one of the ligands is deprotonated. The mechanism of this reaction is not fully resolved, but it is thought an intermediate containing coordinated oxygen may be involved.[589g]

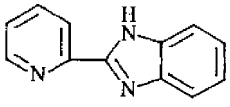
(45a)



(45b)

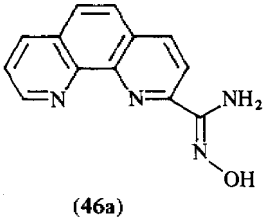


(45c)

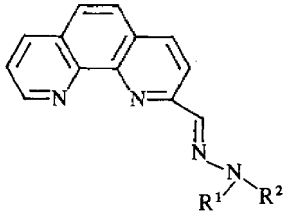


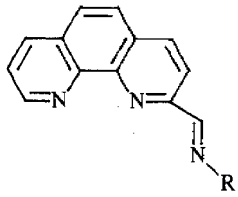
Octahedral tris ligand complexes containing the pyridylimidazole ligand (**45d**) or related ligands (**45e**) and (**45f**) display spin cross-over behaviour that in most instances is sensitive to both the nature of the anion and the number of molecules of water of crystallization. Several groups have examined[590a–590c] the deep red hydrated $[Fe(\mathbf{45d})_3](ClO_4)_2$ that is high-spin at around room temperature, but whose magnetic moment gradually decreases as the temperature is lowered until at about 100 K it rapidly falls to ~1 BM. As in other spin cross-over systems this behaviour cannot be described adequately by a simple Boltzmann distribution with a fixed energy difference.[590b]

(45d)



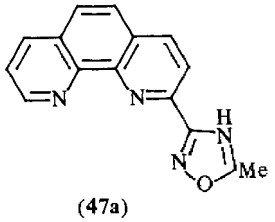
(45e)



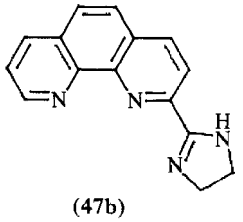


(45f)

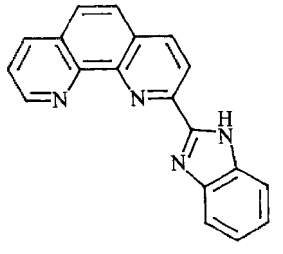
Mössbauer spectra recorded[590c] down to 4.2 K readily distinguish between the low-spin and high-spin forms. $[Fe(\mathbf{45e})_3](ClO_4)_2$ exists in dark blue and dark purple forms.[590b] The former is low-spin and the latter high-spin at room temperature (5.25 BM at 295 K). The magnetic moment of the high-spin complex decreases rapidly at around 120 K. The complex $[Fe(\mathbf{45f})_3]^{2+}$ was first investigated for possible use in the spectrophotometric determination of iron, and although its extinction coefficient is not particularly large, it has the advantage of being extractable into isoamyl alcohol.[590d] This complex is expected to have a relatively stable high-spin form as a result of steric effects, and in fact with some of its salts it is not possible to characterize the low-spin ground state magnetically.[590e–590g] Mössbauer spectra show the coexistence of high- and low-spin forms that have a *mer* configuration, indicating that there is a substantial difference between the coordinated pyridine and benzimidazole nitrogen atoms. Rather surprisingly the bis diimine complex $[Fe(NCS)_2(\mathbf{45f})_2]$ is fully high-spin down to 4.2 K (ref. 590g). The dynamics of the spin equilibria in solution for $[Fe(\mathbf{45d})_3]^{2+}$ and $[Fe(\mathbf{45f})_3]^{2+}$ have been investigated using laser Raman temperature-jump[590h] and photochemical perturbation with a Q-switched laser. Recently volumes of activation have been determined for both forward and reverse processes. Both complexes show a marked solvent dependence for $\Delta V^{\neq}$ (high → low), but $\Delta V^{\neq}$ (low → high) is not very sensitive to the nature of the solvent. The former are negative, as are corresponding values of $\Delta S^{\neq}$, in agreement with there being substantial Fe—N bond contraction in the activation step.[590i,590j]



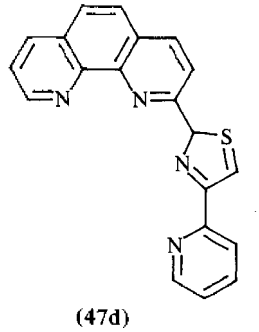
Just as bidentate ligands have been formed by attachment of an imine containing group, or other suitable donor, to the 2-position of a monodentate pyridine, so tridentate ligands have been obtained from 1,10-phenanthroline. Thus, the 2-amidoxime (**46a**) has a fairly strong ligand field and $[Fe(\mathbf{46a})_2]^{2+}$ is low-spin,[591a] but the spin cross-over point is approached in the bis ligand complexes of the hydrazones (**46b**). Magnetic properties of these complexes depend on the nature of R^1 and R^2, and are most pronounced when $R^1 = R^2 = Ph$. This complex has a sharp spin change near room temperature,[519b] and this is associated with X-ray powder diffraction pattern changes.[591c] Similar steric effects operate in the bis complex of the 2-carbaldehyde imines (**46c**). With R = Bu^t the complex is high-spin and there is a gradual spin cross-over as the temperature is lowered, but with almost all other R groups the complex is low-spin at room temperature.[591d]



(46a)



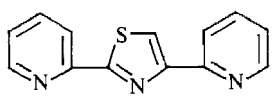
(46b)



(46c)

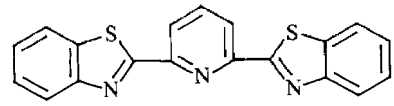
Several 1,10-phenanthroline derivatives with a five-membered heterocyclic group in the 2-position have been prepared, and most of their bis iron(II) complexes display temperature dependent behaviour. Salts of $[Fe(\mathbf{47a})_2]^{2+}$ are high-spin and they undergo a spin change at low temperature, but this is so gradual it seems likely that solid-state effects are involved.[592a] However, no changes in the powder X-ray diffraction pattern are evident. The bis ligand complex of the imidazoline derivative (**47b**) is predominantly low-spin at room temperature (~1.8 BM) but the magnetic moment gradually increases as the temperature is raised.[592b] Both salts of the benzimidazole analogue complex $[Fe(\mathbf{47c})_2]^{2+}$ and its neutral deprotonated form, are low-spin at room temperature, and their magnetic moments only increase slightly at higher temperatures. A number of complexes of related ligands with 2-thiazole groups have been prepared and these usually display temperature dependent magnetic moments. At first sight however, it is rather surprising that $[Fe(\mathbf{47d})_2]^{2+}$ is high-spin over the entire experimental temperature range (83–363 K). This behaviour is attributed to the steric effect of the uncoordinated pyridyl group.[592c]

(47a)



(47b)

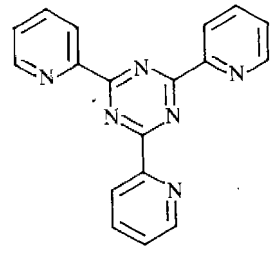
(47c)



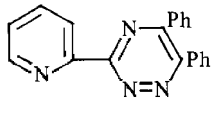
(47d)

Most heterocyclic tridentate ligands related to terpyridine (Section 44.1.5.6.3) have a smaller ligand field, and so salts of the bright red $[Fe(\mathbf{48a})]^{2+}$ are high-spin (~5.5 BM) at room temperature. Their magnetic moments decrease only gradually to ~3.3 BM at 80 K. At ~100 K the colour changes to intense purple, and the reason for the high limiting magnetic moment might be due to only half of the molecules becoming low-spin.[593a] Introduction of a methyl group adjacent to one of the pyridine nitrogen atoms results in the bis complex becoming fully high-spin.[593b] The dibenzothiazole (**48b**) forms reddish purple $[Fe(\mathbf{48b})_2]^{2+}$ that is high-spin at room temperature (4.49 BM at 313 K). The magnetic moment decreases as the temperature is lowered but some paramagnetism remains at 83 K (2.23 BM). When a solution of $FeBr_3$ is added to one of (**48b**) in alcohol the black crystalline salt $[Fe(\mathbf{48b})_2][FeBr_4]Br$ is obtained,[593c] in which it was deduced the magnetic moment of the iron(II) cation only varies slightly with temperature.

The tripyridyl-*s*-triazine ligand (**49**) is also tridentate and forms a very stable low-spin bis complex with iron(II) for which $\log \beta_2 = 11.05$ at 23 °C (ref. 594a). It proved possible to separate the stepwise

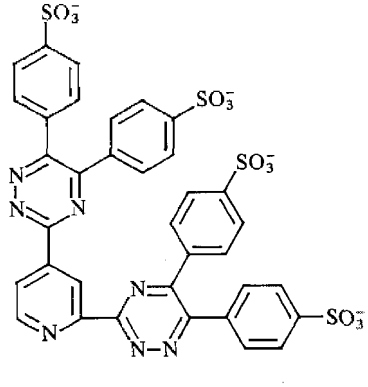


(48a)

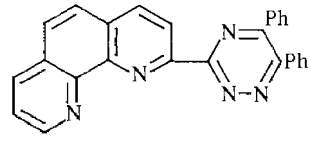


(48b)

formation constants, and the value of K_2 (log $K_2 = 6.26$) is significantly larger than K_1 (log $K_1 = 4.81$), in keeping with the mono complex (presumably $[Fe(\mathbf{49})(H_2O)_3]^{2+}$) being high-spin. The kinetics of formation and dissociation of $[Fe(\mathbf{49})_2]^{2+}$ have been studied[594b] and surprisingly it appears that addition of the first ligand to $[Fe(H_2O)_6]^{26}$ is rate determining, while as expected, formation of the mono complex is rate determining in the dissociation. As expected for dissociation of a basic tridentate ligand, and as found[543] for $[Fe(terpy)_2]^{2+}$, the acid dissociation kinetics are complex—particularly so because of the uncoordinated basic nitrogen sites. Reaction of $[Fe(\mathbf{49})_2]^{2+}$ with hydroxide ion is first order in both complex and hydroxide, and it has been suggested[594c,594d] this is due to a rapid preequilibrium with CN^- or OH^- which is followed by ligand dissociation. The derived activation parameters support this proposal. Electrochemical reduction of $[Fe(\mathbf{49})_2]^{2+}$ affords neutral $[Fe(\mathbf{49})_2]$, that has been suggested[595] contains anionic ligands.

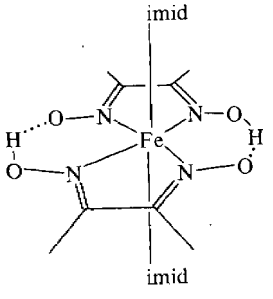


(49)

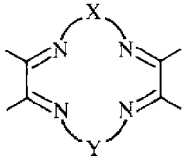


The unsymmetrical 1,2,4-triazine ring is present in several ligands recommended for use in the spectrophotometric determination of iron. Sulfonation of **(50a)** affords[596] a water soluble reagent that is bidentate forming a tris diimine complex with $\beta_3 \sim 4.9 \times 10^{15}$, for which an extinction coefficient as high as 2.86×10^4 ($\lambda_{max} = 652$ nm) has been reported.[597] The course of its reaction with hydroxide ion proceeds[598a] *via* an intermediate (formed by some ligand reaction) that in turn undergoes dissociation. Reaction with cyanide ion follows a simple pattern in water,[598b] but this is not the case in aqueous DMSO. Here spectral evidence suggests cyanide ion attacks one ligand, while parallel ligand displacements take place.[598c] The related sulfonated ligand **(50b)** is claimed[599a] to be the most sensitive chromogen for iron(II) with $\varepsilon = 3.22 \times 10^4$ ($\lambda_{max} = 565$ nm). The presence of the sulfonic acid groups has little effect on the absorption maximum or extinction coefficient of the iron(II) tris ligand complex.[599b] Reaction of $[Fe(\mathbf{50b})_3]^{10-}$ with cyanide ion is complex, there being several intermediate species. The tridentate derivative of 1,10-phenanthroline with a 2-(1,2,4-triazine) ring (**51**) forms a deep purple low-spin complex $[Fe(\mathbf{51})_2]^{2+}$.[600]

(50a)



(50b)

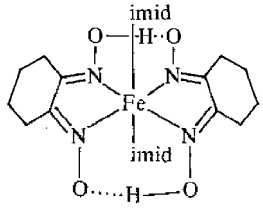


(51)

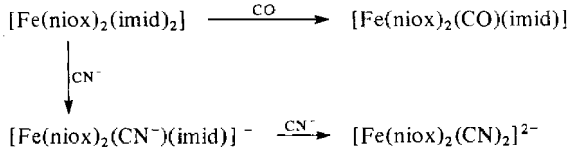
44.1.5.7 Dioximes

In the absence of a reducing agent and strong axial ligands, $[Fe(DMG)_2]$ (DMG = dimethylglyoxime) is unstable. Hydrazine can fulfil both of these roles, and red $[Fe(DMG)_2(N_2H_4)_2]$ (λ_{max} 525 nm, $\varepsilon \sim 10^4$) is an air stable low-spin complex.[601] The structure of the analogous $[Fe(DMG)_2(imid)_2]$ (**52**) has been determined[602] by X-ray diffraction; the two DMG ligands are planar and the six nitrogen atoms bound to the low-spin iron(II) centre exhibit the expected tetragonal distortion from octahedral symmetry. Bis-methylimidazole complexes of iron(II) dimethylglyoxime systems have been synthesized[603] with varying degrees of ring closure that extend to macrocycles and in such complexes one axial imidazole ligand may be substituted by either carbon monoxide or benzyl isocyanide. For the complexes [Fe(**53**)(Meimid)(CO)]$^{n+}$ the order of CO lability is: DMGH < DOHpn < DOHen < TIM < TAAB, 14aneN$_4$ < porphyrin, phthalocyanine < 15aneN$_4$.

(52)



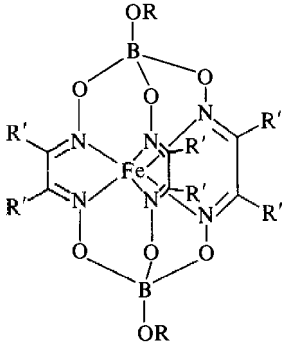
(53)



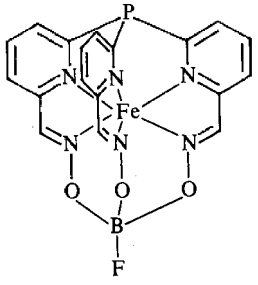
DMGH: X = Y = O·HO
DOHpn: X = $(CH_2)_3$
Y = O·HO
DOHen: X = $(CH_2)_2$
Y = O·HO
TIM: X = Y = $(CH_2)_3$

Increasing net positive charge on the iron results in increased lability of the π acceptor carbon monoxide ligand. The cationic complexes of TIM, TAAB and 14aneN$_4$ show very similar CO dissociation rates despite large variations in ring size and ligand unsaturation. The larger rings achieve the environment needed to stabilize low-spin iron(II) by puckering to avoid conformational strain. There is an underlying trend with ring size however as shown by the sharp increase in CO dissocation rate for the 15aneN$_4$ complex.

The structure of the 1,2-cyclohexanedione dioxime (niox) complex, $[Fe(niox)_2(imid)_2]$ (**54**), which is more soluble than the analogous DMG complex, has also been determined,[604] but because of disorder in the cyclohexyl rings some of the important structural parameters were ill defined. However, the Mössbauer spectra of $[Fe(niox)_2L_2]$ (L = py, imid, NH_3, $BuNH_2$) and related complexes have been studied in detail and are consistent with considerable tetragonal distortion.[605,606] $[Fe(niox)_2(imid)_2]$ reacts with CN^- to give $[Fe(niox)_2(CN)_2]^{2-}$, and by using only one equivalent of CN^- $[Fe(niox)_2(CN)(imid)]^-$ can be obtained.[605] Reaction with CO affords $[Fe(niox)_2(imid)(CO)]$ as in Scheme 13.



(54)



Scheme 13

Iron(II) complexes of monooximes derived from pyrazole-4,5-dione have been reported.[607] These are high-spin with the iron coordinated to oxygen donors. The preparation has been reported[608] of oligomeric iron(II) tetraoxime complexes having molecular weights between 2600 and 3100. These oximes have aliphatic backbones which are very flexible and as a result the FeN_4 units appear to be independent of one another with protons α or β to the oxime groups undergoing no shift upon complexation. Other related oxime complexes are discussed in a review.[609] However, of more interest are the encapsulated complexes obtained by capping oxime oxygen atoms of the, formally intermediate, tris oxime complexes with suitable groups. Thus reaction[610] of $FeCl_2$ with dimethylglyoxime (R′ = Me) or 1,2-diphenylethane-1,2-dione dioxime (R′ = Ph) and boric acid in refluxing alcohol (ROH, R = H, Me, Et, Pr^i, Bu^n) affords red low-spin complexes (**55**). No doubt these complexes, like their Co^{III} analogues, approach a trigonal prismatic configuration.[611,612] Russian workers[613] obtained the corresponding 1,2-cyclohexanedione dioxime complex capped with BF by using BF_3 in acetonitrile in place of boric acid in alcohol. Alcoholysis of this complex affords the BOR derivatives. Experimental methods for the substitution of a wide variety of groups have subsequently been developed.[614]

(55)

A correlation has been established between the iron(II)/iron(III) redox couple of such complexes and the substituent on the apical boron atoms; no corresponding trend in ^{11}B NMR shifts has been observed, however. The related dark red low-spin, non-octahedral complex (**56**) is obtained[615] by encapsulation of the preformed hexadentate ligand with BF_3. X-Ray crystallography reveals[616] that the coordination geometry deviates by approximately 21.5° from the ideal trigonal prismatic configuration in this complex which has a formally 'chiral' iron centre. The analogous complex $[Fe(py_3TPN)]^{2+}$ is closer to an idealized octahedral geometry[617] having an 'angle of twist' of 17°. An analysis[618] of a number of crystal structures suggests that geometry may be rationalized on the basis that ligand rigidity favours trigonal prismatic coordination. Amongst the most 'octahedral' of such complexes is $[Fe(py_3tren)]^{2+}$ which shows a high ⇌ low spin transition both in the solid state and in solution.[618] A variable temperature X-ray structure analysis shows that steric interactions between methyl groups and neighbouring pyridine rings is responsible for variations in magnetic behaviour as the number of methyl groups varies. Additionally, it was noted that the Fe—N bond distance contracted by approximately 0.12 Å in the solid state transition from high-spin (μ_{eff} = 5.0 BM, 300 K) to intermediate-spin (μ_{eff} = 2.3 BM, 205 K).

(56)

44.1.5.8 Phosphorus and Arsenic Donors

44.1.5.8.1 Monodentate ligands

A considerable number of stable organometallic iron(0) compounds containing phosphorus donors are known, but comparatively few with arsenic donors have been reported. In contrast many simple iron(II) phosphine complexes tend to be unstable, and undergo dissociation in solution. It appears that phosphites (notably trimethyl phosphite) tend to form more stable simple iron(II) complexes than do the corresponding phosphines. However, with polydentate phosphines more stable complexes result, and five-coordination is relatively common. Complexes in several spin states, including some displaying spin-equilibrium behaviour, are known. Diamagnetic octahedral complexes of the type $[FeX_2(PP)_2]$ are well characterized, and interesting bis carbonyl complexes containing monodentate or polydentate phosphorus donors are obtained upon reaction with carbon monoxide under surprisingly mild conditions. Few iron(II) complexes containing arsenic donors have been well characterized.

Colourless needles, assumed to be $[FeCl_2(PEt_3)_2]$, have been isolated[619] from $FeCl_2$ and the phosphine in benzene. In ethanol, apparently, there is no reaction[620] which illustrates the relatively poor affinity of iron(II) for trialkylphosphines. Refluxing anhydrous FeX_2 with a tertiary phenylphospine PR_3 ($R_3 = Ph_3$, Ph_2Et, $PhEt_2$) in benzene affords[619] the high-spin complexes $[FeX_2(PR_3)_2]$ for which magnetic moments over the range 4.8–5.3 BM have been reported; this and the electronic spectrum of $[FeBr_2(PPh_3)_2]$ are consistent with a tetrahedral configuration.[621] Iron(II) halides react with the secondary phosphines HPR_2 (R_2 = MePh, EtPh, Et_2) in anhydrous ethanol to form complexes of the type $[FeX(HPR_2)_4]^+$ that have been isolated as their BF_4^- and PF_6^- salts.[622] These red/violet complexes are paramagnetic (~3 BM) with triplet ground states. In solution, some phosphine dissociation takes place to form tetrahedral complexes. With carbon monoxide at room temperature bis carbonyl complexes are formed as in equation (54); they are yellow and appear to have *trans*-carbonyl ligands in solution. '$Fe(PF_6)_2$' and $Fe(BF_4)_2 \cdot 6H_2O$ react with an excess of secondary phosphine (HPR_2, R_2 as above) in 2-propanol to give yellow or yellow/brown $[Fe(HPR_2)_5]X_2$ (X = PF_6, BF_4). These complexes are paramagnetic with μ_{eff} in the range 1.3–2.5 BM, but the presence of paramagnetic impurities makes it difficult to establish the actual ground state. Reaction of $[Fe(HPR_2)_5](PF_6)_2$ with carbon monoxide takes place in two stages:[622] addition of the first CO is rapid with subsequent phosphine substitution being relatively slow to give diamagnetic *trans*-$[Fe(HPR_2)_4(CO)_2]$ as in equation (55).

$$[FeX(HPR_2)_4]^+ + 2CO \longrightarrow [FeX(CO)_2(HPR_2)_3]^+ + HPR_2 \quad (54)$$

$$[Fe(HPR_2)_5]^{2+} \xrightarrow{CO} [Fe(HPR_2)_5CO]^{2+} \xrightarrow{CO} \textit{trans}\text{-}[Fe(HPR_2)_4(CO)_2]^{2+} + HPR_2 \quad (55)$$

While the secondary phosphine PCy_2H forms the colourless tetrahedral complex $[FeCl_2(PCy_2H)_2]$ (5.12 BM) with $FeCl_2$, the complex $[FeCl_2(PEt_2H)_2]$ is red with a magnetic moment of 3.61 BM, which is claimed to be consistent with a square planar structure.[623] With $FeCl_2$ or $FeBr_2$ and the primary phosphine $PPhH_2$, the orange/red square planar complex $[Fe(PPhH_2)_4]X_2$ can be formed,[624] but $PCyH_2$ is said to be anomalous in forming $[FeBr_2(PCyH_2)_3]$ (3.48 BM), while with $FeCl_2$ square planar $[FeCl_2(PCyH_2)_2]$ results.[625] The phosphides $[Fe(PCy_2)_2]$ and $Li[Fe(PCy_2)_3]$ are formed from the reaction[626] of $FeBr_2$ with$LiPCy_2$.

Carbon monoxide reacts with mixed alkyl/aryl phosphine iron(II) complexes (but not those of PPh_3) to give well-defined high-spin complexes of the type $[FeCl_2(PR_3)_2(CO)_2]$.[619] The IR spectra of $[FeX_2(PEt_3)_2(CO)_2]$ (X = NCS, Cl, Br, I) have been recorded.[627] Carbonylation of a mixture of $FeCl_2$ and diphos in benzene affords[628] $[FeCl_2(diphos)(CO)_2]$, which on the basis of its IR spectrum has *cis* CO ligands. However, when THF is the solvent a different isomer results that has *trans* CO ligands, and refluxing the *cis* isomer in acetone causes it to isomerize to the *trans* form.[628] A wide range of low-spin iron(II) complexes of the type $[FeX_2(CO)_2P_2]$ have been reported and characterized in which P = phosphine or phosphite.[629] Readily available $P(OMe)_3$ is a good ligand due to the low steric requirements associated with strong σ donor and π acceptor properties. In many respects, $P(OMe)_3$ mimics the behaviour of isocyanides, and many low-spin iron(II) complexes containing CO and $P(OMe)_3$ have been reported.[630] Reaction of $FeCl_2$ with $P(OMe)_3$ in benzene or methanol produces an uncharacterized, readily oxidized mixture which may contain $[Fe\{P(OMe)_3\}_6]^{2+}$, $[FeCl_2\{P(OMe)_3\}_4]$ and other products. However, $FeCl_2$ and $P(OMe)_3$ with $SnCl_2$ react in stoichiometric amounts to give *cis*-$[Fe(SnCl_3)Cl\{P(OMe)_3\}_4]$, which reacts with $NaBPh_4$ in methanol to give $[Fe(SnCl_3)\{P(OMe)_3\}_5]$ as a yellow precipitate.[630] In the presence of $NaBH_4$, reaction of $FeCl_2$ with an excess of $P(OMe)_3$ affords a high yield of sightly soluble off-white

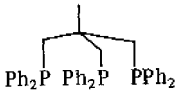
material said to be $[Fe\{P(OMe)_3\}_6]$, but complete analytical results supporting this formulation were not reported.[630] In contrast, sodium amalgam reduction of $[FeCl_2\{P(OMe)_3\}_3]$ in the presence of free $P(OMe)_3$ affords[208] yellow crystals of $[Fe\{P(OMe)_3\}_5]$ (see Section 44.1.3.3) that reacts with NH_4PF_6 according to equation (56). On the NMR timescale the hydride so formed is kinetically inert with respect to exchange reactions, but reaction with CF_3CO_2H gives hydrogen and ostensibly $[Fe\{P(OMe)_3\}_5]^{2+}$ that was characterized[632] by NMR. It also reacts[210] with MeI to give $[FeMe\{P(OMe)_3\}_5]^+$.

$$[Fe\{P(OMe)_3\}_5] + NH_4PF_6 \longrightarrow [FeH\{P(OMe)_3\}_5]PF_6 + NH_3 \quad (56)$$

$$FeCl_2 + NaBH_3(CN) + P(OR)_3 \xrightarrow{MeOH} \textit{trans}\text{-}[Fe(BH_3CN)_2\{P(OR)_3\}_4] \quad (57)$$

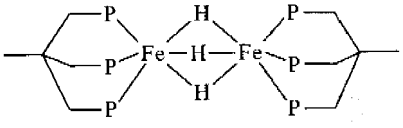
Reaction of hydrated $FeCl_2$ with excess $Na(BH_3CN)$ and $P(OR)_3$ (R = Me, Et) in methanol gives[631] low-spin *trans*-$[Fe(BH_3CN)_2\{P(OR)_3\}_4]$ as in equation (57). However, a mixture of *cis* and *trans* isomers resulted when the iron was obtained by electrolytic dissolution in acetonitrile, and it appears both solvent effects and the nature of the phosphite are important in determining the isomer ratio. Diethylphenyl phosphonite ($P(OEt)_2Ph$) reacts[632] with $FeCl_2$ in ethanol to give well-characterized, light yellow, diamagnetic *cis*-$[FeH_2\{P(OEt)_2Ph\}_4]$ as in equation (58). The product has Fe—H distances of 1.51 Å, with a geometry intermediate between octahedral and tetrahedral. It is indefinitely stable under argon or nitrogen, but the crystals turn brown after a few days exposure to air. The related, though less well-characterized, trimethyl phosphite dihydride complex $[FeH_2\{P(OMe)_3\}_3]$, as well as a tetrahydride, have also been described.[210]

$$FeCl_2 + P(OEt)_2Ph \xrightarrow{BH_4^-/EtOH} \textit{cis}\text{-}[FeH_2\{P(OEt)_2Ph\}_4] \quad (58)$$



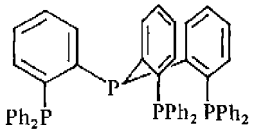
44.1.5.8.2 Polydentate ligands

Many iron complexes having interesting structures and reactions are formed with polydentate arsenic and phosphorus ligands.[633] However, in the present context the coordination chemistry of the arsines is considerably less extensive than that of the phosphines, and there are many examples when it is not possible to prepare the corresponding arsine analogue of a well-characterized phosphine complex. The most well-known ditertiary arsine is *o*-phenylenebis(dimethylarsine), (diars) and the complexes $[FeX_2(CO)_2(diars)]$ (X = Br, I) and $[FeI_2(diars)]$ are readily obtained by halogen oxidation of appropriate iron(0) species.[218] Nitric acid oxidation[63] of $[FeCl_2diars]$ affords the iron(IV) complex $[FeCl_2(diars)]^{2+}$. Iron powder reacts with *o*-phenylenebis(diethylphosphine) ($C_6H_4(PEt_2)_2$) under an atmosphere of hydrogen at 200 °C to give[634] small amounts of the dihydride *trans*-$[FeH_2\{C_6H_4(PEt_2)_2\}]$. The monohydride complex[635–637] *trans*-$[FeHCl(depe)_2]$ (depe = 1,2-bis(diethylphosphino)ethane) reacts with $NaBPh_4$ in acetone under nitrogen to give the relatively stable cationic dinitrogen complex *trans*-$[FeH(N_2)(depe)_2]^+$, as in equation (59), which was isolated as the BPh_4^- salt.[638] The same reaction carried out in the presence of a wide range of ligands (L), including phosphites, affords[639] the complexes *trans*-$[FeHL(depe)_2]^+$. Mössbauer spectra obtained at 4.2 K in a high applied magnetic field permit discussion of the bonding in these complexes. It is concluded[640] that the instability of N_2 complexes is associated mostly with the weak σ donor properties of N_2. Even though the related complex *trans*-$[Fe(\eta^2\text{-}H_2)(H)(diphos)_2]^+$ is stable to loss of hydrogen up to 50 °C, it must be stored under hydrogen or argon since it slowly reacts[641] with molecular nitrogen to give *trans*-$[FeH(N_2)(diphos)_2]^+$. The reactant η^2-H_2 complex undergoes intramolecular exchange of terminal hydride with the hydrogens of the η^2-H_2 ligand,[642] for which the activation parameters are $\Delta H^{\neq} = 58.2 \pm 2.9\,kJ\,mol^{-1}$ and $\Delta S^{\neq} = -4.2 \pm 12.6\,J\,K^{-1}\,mol^{-1}$. The X-ray structure of *trans*-$[Fe(\eta^2\text{-}H_2)(H)(diphos)_2]BF_4$ has been determined.[642] Reaction of this complex with good donor ligands gives complexes of the type *trans*-$[FeH(L)(diphos)_2]^+$, like those of depe previously discussed. The bidentate phosphines $R_2PCH_2CH_2PR_2$ (R = Me, Et) readily form octahedral low-spin *trans* dichloro complexes, *trans*-$[FeCl_2(R_2PCH_2CH_2PR_2)_2]$. They have been the subject of high precision X-ray structure determinations[643] that show Fe—P distances (~2.2 Å) are dramatically shorter than in related high-spin complexes. For example, the polytertiary phosphine $(Ph_2PCH_2CH_2)_2PPh_2$ acts as a bidentate ligand in the distorted octahedral $[FeCl_2\{(Ph_2PCH_2CH_2)_2PPh_2\}_2]$ that is high-spin with Fe—P distances[643] in the range 2.66–2.71 Å.



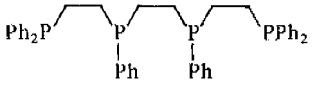
The tripod ligand (**57**) reacts with iron(II) salts in the presence of $NaBH_4$ to give the structurally novel diamagnetic binuclear iron(II) complex (**58**), which contains two octahedra sharing a face

$$\textit{trans}\text{-}[FeHCl(depe)_2] + NaBPh_4/N_2 \longrightarrow \textit{trans}\text{-}[FeH(N_2)(depe)_2]BPh_4 + NaCl \quad (59)$$

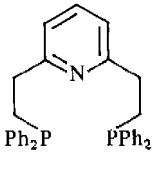


having three hydride ligands at the edges.[644] Thus, the iron centres are bridged by three hydrides. As expected, treatment with hot acid gives hydrogen and liberation of the tripod ligand. No complex was isolated when the corresponding arsenic ligand was used. Similarly the arsenic analogue of the tetrateritary phosphine (**59**) does not appear[645] to complex with iron(II). Reaction of (**59**) itself with anhydrous $FeCl_2$ in ethanol gives an intense purple solution containing five-coordinate $[FeCl(\mathbf{59})]^+$, and similar complexes are formed with other halides that have magnetic moments of ~3.1 BM. With NCS^- and CN^-, however, six-coordinate diamagnetic complexes of the type $[FeX_2(\mathbf{59})]$ are obtained.[645]

(57)



(58)



(59)

In contrast, the more flexible tripod ligand $P(CH_2CH_2CH_2PMe_2)_3$ reacts rapidly with anhydrous iron(II) halides to give deeply coloured solutions which afford violet crystals of $[FeX_2P(CH_2CH_2CH_2PMe_2)_3]$ that are diamagnetic and non-electrolytes.[646] X-Ray structure determination confirms these complexes have *cis* halides with a slightly distorted octahedral geometry, rather than the five-coordinate trigonal bipyramidal structures[646] of the cationic complexes formed with (**59**) and $P(CH_2CH_2PPh_2)_3$. The reason for the change in geometry from five- to six-coordination for the halide complexes on going from the more rigid ligands to $P(CH_2CH_2CH_2PMe_2)_3$ is no doubt associated with the flexibility of the C_3 chains that provides a larger chelate bite angle {(**59**) has only 84 ± 2°} and enhanced Fe—P overlap. Like ligand (**59**), $P(CH_2CH_2PPh_2)_3$ forms[647] a diamagnetic six-coordinate dithiocyanate complex $[Fe(NCS)_2P(CH_2CH_2PPh_2)_3]$. In contrast to the triplet ground state of the five-coordinate halide complexes of the tripod ligand (**59**), the corresponding complexes of the linear tetradentate ligand (**60**), $[FeX(\mathbf{60})]^+$ (X = Cl, Br, I; isolated as their BPh_4^- salts) have room temperature magnetic moments between those expected for $S = 0$ and $S = 1$. Spin equilibria between a singlet ground-state and low-lying triplet state could be responsible for the non-Curie–Weiss temperature behaviour.[647] An X-ray structure determination of the five-coordinate bromo complex shows it to have distorted trigonal bipyramidal geometry.[648] As with ligand (**59**), the dithiocyanato complex $[Fe(NCS)_2(\mathbf{60})]$ is diamagnetic and presumably octahedral.[647] The mixed donor ligand 2,6-bis(2-diphenylphosphinoethyl)pyridine (**61**) forms a series of 1:1 five-coordinate complexes with iron(II) halides.[649] The yellow chloride and bromide complexes $[Fe(\mathbf{61})XY]$, (X = Y = Cl, Br) are high-spin (~5.35 BM) and obey the Curie–Weiss law over the entire temperature range studied (93–293 K). However, the corresponding brown diiodo complex (X = Y = I) and the red mixed iodo–thiocyanate (X = I, Y = NCS) show anomalous behaviour with their magnetic moments abruptly falling at low temperatures, but even at the lowest temperature employed (93 K) neither complex completely reached the low-spin state.[649]

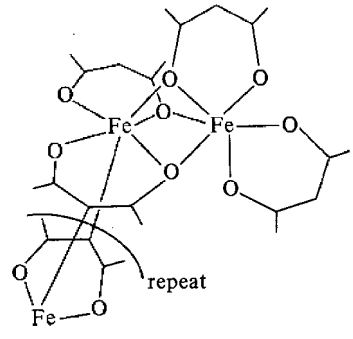
(60)

(61)

44.1.5.9 Oxygen Donors

With simple oxygen donor ligands, iron(II) complexes are high-spin and usually easily oxidized by air to iron(III) species. The number of complexes studied containing oxygen donors is much less than those having nitrogen donors. However, some mixed donor complexes involving oxygen are particularly important, and the most notable of these are the iron(II) nitrogen macrocycles which bind dioxygen. These are considered in the section concerned with porphyrins (44.1.5.12.5).

44.1.5.9.1 Water



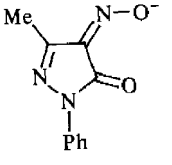
Dissolution of iron in dilute mineral acid affords $[Fe(H_2O)_6]^{2+}$. Although thermodynamically unstable towards air oxidation, the process is slow unless a strong oxidizing agent is used. In alkaline solution however, iron(II) is strongly reducing and is readily oxidized by atmospheric oxygen, and there is evidence that it will even reduce N_2 to ammonia.[650] Iron(II) oxide species are also active in the photoassisted reaction of water with nitrogen to give ammonia.[651] White $Fe(OH)_2$ is much more soluble that its Fe^{III} counterpart and in the presence of air darkens rapidly through oxidation. Solutions of the $[Fe(H_2O)_6]^{2+}$ are only slightly acidic (equation 60), so that iron(II) carbonate precipitates on addition of Na_2CO_3 and no carbon dioxide is evolved. Aqueous solutions of $[Fe(H_2O)_6]^{2+}$ are pale blue-green and this octahedral cation is present in many hydrated iron(II) salts such as the sulfate and the perchlorate. In the double salt $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$ (Mohr's salt or Tutton's salt), which is rather more resistant to oxidation than the simple sulfate, the octahedron has principally a tetragonal distortion whilst in $FeSiF_6 \cdot 6H_2O$ the hexaaqua complex has a trigonal distortion.[652] In natural waters, iron is mostly present as insoluble iron(III) hydroxide. However, decomposition of inorganic matter, particularly in subsurface waters, can reduce iron(III) to iron(II) (lowering pH), whose hydroxide is relatively soluble, and this phenomenon can cause difficulties in water purification. The common method for removing iron from domestic water supplies involves aeration, which increases the pH by removing CO_2 and provides enough oxygen for the oxidation of iron(II) to iron(III) as shown in equation (61). The kinetics of this oxidation have been studied by several groups and a number of different rate equations proposed.[653–657] The reaction is catalyzed by copper(II) compounds[658–661] and it is particularly rapid in the presence of aquapalladium(II) ions.[33] The oxidation of $[Fe(H_2O)_6^{2+}]$ by molecular oxygen in perchloric acid solution yields a green intermediate complex having an absorption band at 337 nm. This green complex consists of one iron(II) and three iron(III) octahedra linked by oxo bridges.[662]

$$[Fe(H_2O)_6]^{2+} + H_2O \rightleftharpoons [Fe(H_2O)_5(OH)]^+ + H_3O^+ \qquad K_1 = 10^{-9.5} \tag{60}$$

$$2Fe^{2+} + 5H_2O + \tfrac{1}{2}O_2 \longrightarrow Fe(OH)_{3(s)} + 4H^+ \tag{61}$$

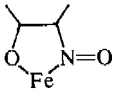
44.1.5.9.2 Acetylacetonate

In the presence of piperidine, *trans*-$[FeCl_2(H_2O)_4]$ reacts with acetylacetone in degassed water under nitrogen, to form[663] hydrated bis(2,4-pentanedionato)iron(II). This classic neutral coordination complex is, however, coordinatively unsaturated and has an unusual tetrameric structure. X-Ray crystallography[664] reveals that the structure (**62**) consists of a pair of asymmetric Fe_2 units linked by rather long Fe—C bonds (2.785 Å). The $acac^-$ ligand which contains the bonding carbon atom also has an oxygen atom which bridges two iron atoms within the asymmetric unit. It is therefore somewhat unusual in having four coordination bonds to three separate metal atoms. The zero field Mössbauer spectrum of the tetramer consists[665] of two overlapped quadrupole doublets representing the two metal environments. The hyperfine splitting observed between 16.0 and 1.67 K, low temperature susceptibility[666] data (approaching the spin only value at 4.2 K), and the tetrameric structure indicate the unusual phenomenon of slow paramagnetic relaxation.



(62) $[Fe_4acac_8]$

Magnetic data for other iron(II) β-diketonates, *e.g.* 1-(3-pyridyl)-1,3-butanedione and 4,4-trifluoro-1-(3-pyridyl)-1,3-butanedione, indicate[667] the complexes to be polymeric. These com-



pounds are all highly air-sensitive, although the hexafluoroacetylacetone complex $[Fe(F_6acac)_2(H_2O)_2]$ is somewhat more stable.[668] $[Fe(acac)_2]$ itself reacts with a variety of bases to form hexacoordinate adducts.[669,670] Where the base is a heterocyclic diamine such as 4,4′-bipyridine, some polymeric products are observed and the 1:1 adducts are highly stable.[671] The polymeric species can be oxidized with iodine to give[672] a mixture of iron(II) and iron(III) centres and the ratio of the oxidation states is characterizable by Mössbauer spectroscopy. The choice of diamine, and in particular its degree of electron delocalization, has a marked influence on the conductivity of the polymeric materials. This allows a strategy for the accurate control of the conductivity of a low dimensional coating material.

44.1.5.9.3 Pyridine N*-oxide*

$[Fe(H_2O)_6](ClO_4)_2$ reacts with pyridine *N*-oxide in methanol to form[673] dark red crystals of $[Fe(pyO)_6](ClO_4)_2$, whose IR spectrum has been analyzed in some detail.[674,675] Analogous complexes are formed with a variety[676] of substituted pyridine *N*-oxides, for example 2-, 3- and 4-cyanopyridine *N*-oxides form[677] octahedral hexakis complexes. A number of complexes containing bidentate oxygen donors have been reported; the oxime of pyrazoledione, for example, forms[678] a bis iron(II) complex. Thus, iron(II) ammonium sulfate reacts with (**63**) to form the turquoise complex $[Fe(\mathbf{63})_2 \cdot H_2O]$, whose magnetic moment decreases with temperature; it has a large negative Weiss constant and is almost certainly polymeric. The complex reacts with pyridine to form $[Fe(\mathbf{63})_2(py)_2]$, whose magnetic behaviour is the opposite of the starting material suggesting it is a monomeric pseudooctahedral complex.[678] Iron(II) oxime complexes with the basic coordination illustrated in structure (**64**) occur in the green biological pigment ferroverdin.[679] The reaction between $[Fe(H_2O)_6]^{3+}$ and catechol provides a series of complexes whose iron(II)/iron(III) redox reactions have been investigated[680] by Mössbauer spectroscopy as a model system for the microbial transport of iron by enterobactins. In contrast, hydrated iron(II) perchlorate reacts with a number of phosphate esters to yield stable high-spin five-coordinate complexes. Thus the perchlorate hydrate, dehydrated by treatment with triethyl orthoformate, reacts with dimethyl-methylphosphonate (DMMP) to form an oil which when extracted with ether yields buff $[Fe(DMMP)_5](ClO_4)_2$ ($\mu_{eff} = 5.14$ BM).[681] In an analagous preparation trimethyl phosphate (TMP) yields first the monohydrate $[Fe(TMP)_5H_2O](ClO_4)_2$, which is readily dehydrated[682] to the five-coordinate complex, which is stable in air ($\mu_{eff} = 5.12$ BM). In anhydrous acetone the iron(II) salt also reacts with trimethylphosphine oxide or trimethylarsine oxide to yield[683,684] high-spin five-coordinate complexes $[FeL_4(ClO_4)](ClO_4)$ (L = Me_3AsO, $\mu_{eff} = 4.94$ BM). In the case of the more sterically bulky ligand diphenylmethylarsine oxide, a compound with the stoichiometry $FeL_4(ClO_4)_2$ was formed, but the IR spectrum[685] did not show the presence of coordinated perchlorate ion. Indeed, the electronic spectrum and magnetic data point to an essentially tetrahedral structure.[686] A four-coordinate tetrahedral structure is also observed[687] for the complex $[Fe(HMPA)_4](ClO_4)_2$ (HMPA = hexamethylphosphoramide) ($\mu_{eff} = 5.19$ BM). The neutral four-coordinate complex $[Fe(TPO)_2Cl_2]$ is formed when $FeCl_2$ is refluxed in an acetone solution of triphenylphosphine oxide under nitrogen.[688]

(63)

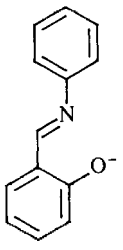
(64)

44.1.5.9.4 Miscellaneous oxygen donors

When an iron(II) salt is added to an aqueous solution of iron(III) citrate, the greenish yellow colour intensifies and a mixed valence complex containing one iron(II) and three iron(III) centres together with one citrate ion has been described.[689] In aqueous solution iron(II) reacts with oxalic acid to form a precipitate having a stoichiometry of $FeC_2O_4 \cdot 2H_2O$, for which two crystalline habits have been identified.[690] In methanol, a monomethanolate complex with stoichiometry $[FeC_2O_4(MeOH)H_2O]$ is formed, the hexacoordinate iron(II) has a symmetric tetragonal distortion in the

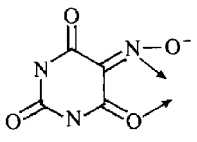
hydrate but the position of the iron atom is not symmetric in the latter complex.[691] The perchlorate salt of hexaaqua iron(II) reacts[692] with DMSO in acetone to give the pale green complex $[Fe(DMSO)_6](ClO_4)_2$, which explodes on heating. Iron(II) halides react with a variety of ethers (THF, 1,2-dimethoxyethane, 1,4-dioxane) to yield adducts which have been studied by electronic and IR spectroscopy, and magnetic methods.[693] Decomposition of $FeSO_4 \cdot 6H_2O$ on heating involves stepwise loss of water, and when heated in air, anhydrous $FeSO_4$ gives $Fe(OH)SO_4$ that decomposes to give $Fe_2O(SO_4)_2$.

44.1.5.9.5 Mixed donor ligands containing oxygen



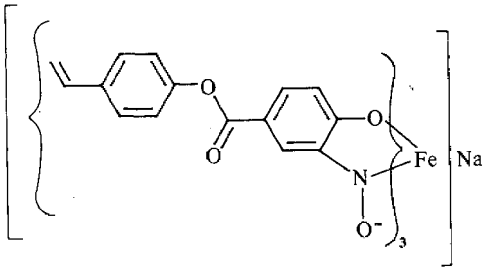
This class of complex comprises mostly mixed O and N donors. Bidentate donors such as the Schiff base derived[695] from salicylaldehyde and aniline (**65**) form unusually stable complexes with iron(II). In the case of 1,10-phenanthroline *N*-oxide[696] however, the iron(II) complex $[Fe(phenNO)_3](ClO_4)_2$ is high-spin ($\mu_{eff} = 5.47$ BM) in contrast to $[Fe(phen)_3]^{2+}$ (Section 44.1.5.6). Amino acids are N,O donors and form a series of iron(II) complexes.[697] They are high-spin, hexacoordinate and are thought to have extended carboxylate-bridged structures. Interestingly, the sulfur-containing amino acid methionine is also a bidentate N,O donor to iron(II). Here again, a carboxylate-bridged polymer structure has been proposed.[698] A low-spin iron(II) complex is formed with the violurate ion (**66**) and X-ray structural analysis[699] shows $[FeV_3](NH_4)$ to have *fac* geometry similar to ferroverdin (**67**), a tris-nitrosophenyl iron(II) complex.[700] Ferroverdin was the first naturally occurring nitrosophenyl complex observed. Early reports on the extremely air sensitive Schiff base complex of iron(II) (**65** and **68**) have in some cases been shown[701] to have involved oxidation products. Their Mössbauer and electronic spectra show (for closely related systems) a linear relation between isomer shift and quadrupole splitting. The temperature dependence of the splitting implies[701] a large axial distortion in these six-coordinate complexes. Temperature dependence has also been observed[702] for at least one quinone adduct of [Fe(salen)], $[Fe(salen)_2(C_6H_4O_2)]$ (salen = **68**, R = $(CH)_2$). However, the Curie–Weiss behaviour and magnetic susceptibility of this complex ($\mu_{eff} = 5.76$ BM, 297 K) suggest that it is in fact d^5 high-spin iron(III). Of greater interest however, is the nitrosyl adduct of [Fe(salen)]. This complex has been observed[703] to have a relatively rare $S = \frac{3}{2}$ to $S = \frac{1}{2}$ spin cross-over near 175 K. An X-ray crystal structure[704] has established a square pyramidal geometry relatively undistorted towards trigonal bipyramidal, unlike the macrocyclic complex $[Fe(Me_4 14aneN_4)NO]$.[705] The latter complex has an essentially linear NO group, whilst in the salen complex it is bent. These features persist through the spin transition.[706] There are a series of ligands known as 'strati-Schiff bases' which form complexes of iron(II).[707] These ligands are being explored as potential models for enzyme systems in which metal coordination sites are 'stacked'.

Tridentate mixed O,N donors include (**69**) and (**70**)[708] and the sulfur-containing system TAN. A crystal structure[709] of $[Fe(TAN)_2]$ (**71**) shows the two ligands to be nearly planar with the two planes essentially perpendicular to one another and the ligands in *mer* coordination. The tetradentate O_2N_2 ligand H_2acacen forms a dimeric high-spin iron(II) complex [Fe(acacen)$_2$] ($\mu_{eff} = 4.84$ BM, 294 K). An X-ray structure has confirmed[710] that the pentacoordination of iron(II) is maintained on reaction with EtONa when a tetranuclear Fe_2Na_2 complex is formed in which the iron atoms are doubly bridged by EtONa (**72**). A five-coordinate complex is also obtained with the terdentate ligand[711] Me_4daeo, $[Fe(Me_4daeo)Cl_2]$ (**73**), $\mu_{eff} = 5.26$ BM, 295 K, and the quinquedentate ligand[712] bis(salicylidinimine-3-propyl)amine (SALRDPT, **74**). This and related complexes have been discussed as model systems for oxygen transport and activation.[713]

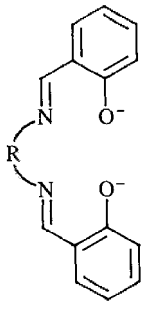


The pentadentate N_3O_2 ligand 2,6-diacetylpyridenebissemicarbazone forms a seven-coordinate iron(II) complex having axial chloride and water ligands. The ligand is formed *in situ* as an alcohol solution of diacetylpyridine and $FeCl_2$ is treated with semicarbazide hydrochloride. X-Ray structural analysis[714] shows the ligand to be planar. The unusual planar hexadentate N_4O_2 ligand (**75**) forms[715] binuclear iron(II) complexes $[Fe_2(\mathbf{75})L_4]^{2+}$ (L = py, im, Meim). These high-spin complexes (L = Meim, $\mu_{eff} = 4.71$ BM, 298 K) show a marked antiferromagnetic exchange interaction. Analysis shows that there is little difference in the magnitude of this interaction between the six-coordinate and comparable five-coordinate complexes.

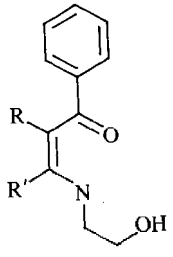
44.1.5.10 Sulfur Donors



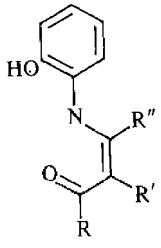
Iron–sulfur chemistry has developed over recent years to become a very rich area. A feature of many complexes is their redox behaviour, with more than one oxidation state being important. This



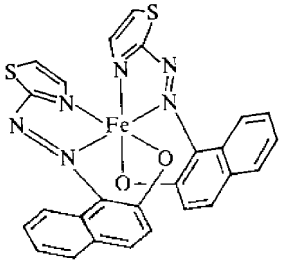
(65)



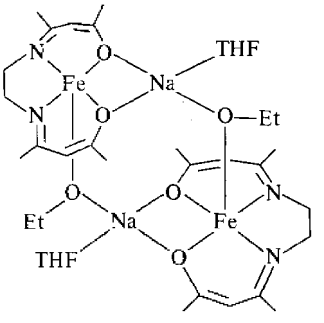
(66)



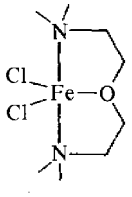
(67)



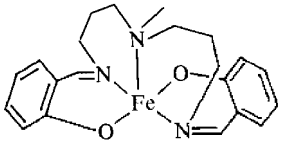
(68)



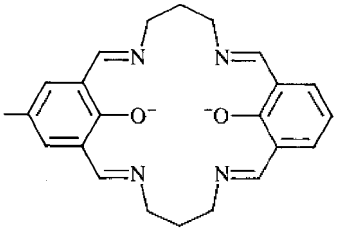
(69)



(70)

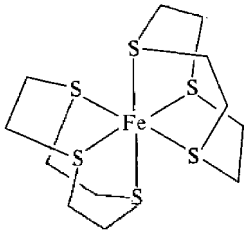


(71)



(72)

(73)



(74)

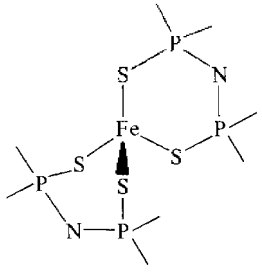
(75)

section is mainly concerned with iron(II) complexes but inevitably some iron(III) complexes are discussed (notably in mixed oxidation state clusters). Similarly, some iron(II) sulfur donor complexes are included in Section 44.2.5, which deals with higher oxidation states, and accordingly readers should consult both sections. Those sulfur complexes containing nitric oxide are contained in Section 44.1.2.5.

With the recent availability of 1,4,7-trithiacyclononane ([9]aneS$_3$) *via* an elegant template synthesis[716] there has been inerest in comparing its complexing ability with that of the surprisingly high-field ligand [9]aneN$_3$ that forms an octahedral low-spin iron(II) complex.[717] Purple $[Fe([9]aneS_3)_2]^{2+}$ is also low-spin and its stability is such that it is obtained when Fe^{II} and Fe^{III} salts are reacted with the free ligand. Its electronic spectrum exhibits two *d–d* transitions typical of Fe^{II} in an octahedral ligand field, that are not obscured by intense charge-transfer bands. X-Ray structure determination[718] confirmed an octahedral geometry shown in (**76**).

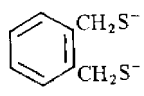
(76)

44.1.5.10.1 Binary sulfides



Iron(II) sulfide is ordinarily dark grey to brown, but when very pure it has been reported to form almost colourless crystals.[719] It is quite insoluble in water, and its reaction with oxygen is exothermic to give Fe_2O_3 or Fe_3O_4 depending on conditions. Rarely is the iron to sulfur ratio unity and formulae ranging from Fe_6S_7 to $Fe_{11}S_{12}$ have been assigned to these iron deficient non-stoichiometric phases. There are a number of iron(II) sulfide minerals which contain an approximately octahedral environment of sulfur atoms. Troilite, stoichiometric FeS, is hexagonal with the NiAs superstructure[720] having Fe—S bond lengths[721] ranging from 2.38 to 2.72 Å with an average of ~2.5 Å. Pyrrhotite $Fe_{1-x}S$ exists in hexagonal and monoclinic forms, with the Fe—S bond lengths[722] in the latter ranging from 2.37 Å to 2.67 Å. The cubic disulfide pyrite FeS_2 contains a regular FeS_6 octahedron with Fe—S bond lengths of 2.26 Å;[723] marcasite, a tetragonal polymorph of FeS_2 has an octahedral geometry distorted by elongation along the *c* axis. In both pyrite and marcasite the anions are disulfide (S_2^{2-}) and not sulfide (S^{2-}). Troilite (FeS) and pyrrhotite ($Fe_{1-x}S$) are high-spin, but pyrite (FeS_2) is low-spin and each have been studied by Mössbauer spectroscopy.[724] Application of high pressure converts the high-spin forms to low-spin, and the transition is reversed when the applied pressure is removed.[725,726]

Molecular orbital/energy band calculations have been performed for a range of iron(II) sulfides[727,728] and there is interest in the band-like valence-electron states in FeS_2[729] and also in their bulk and surface properties typified by studies using Auger spectroscopy[730] and X-ray absorption.[731–733] The extensive work in this area published during the period 1960–1969 is contained in an excellent review by Ward.[734] Unfortunately, discussion about the fascinating tricyclic iron(III) polysulfide anion $[Fe_2S_{12}]^{2-}$[735] and its reactions with, for example, activated alkynes[736] are outside of the scope of this section.



44.1.5.10.2 Iron sulfur clusters

Tetrahedral iron sulfide species that can have two or more charge states are involved in many electron transfer proteins.[737] The core structures that have been identified in proteins include the single iron centres of rubredoxin, and the two iron/two sulfide and four iron/four sulfide centres of various ferredoxins. A wide range of model complexes have been prepared and characterized, and the results of this work, as well as that on the natural system, have been extensively reviewed.[737,744]

Trimethylarsine sulfide forms[745] two types of tetrahedral iron(II) complexes $[Fe(SAsMe_3)_4](ClO_4)_2$ and $[FeX_2(SAsMe_3)_2]$ (X = Cl, Br), but one of the first structurally well-characterized tetrahedral iron(II) sulfur complexes was $[Fe(SPMe_2NPMe_2S)_2]$ (**77**) that has a magnetic moment of 5.25 BM in the solid state and 4.99 BM in dichloromethane solution.[746] The measured[747] Fe—S bond lengths range from 2.339 to 2.380 Å and the S—Fe—S bond angles from 100.5° to 114.9°. Simpler synthetic analogues of the single iron centre of bacterial rubredoxins have been prepared using PhS^-, *i.e.* $[Fe(SPh)_4]^{2-}$, but the best characterized species involve the *o*-xylyldithiolate ligand (**78**). Discrete tetrahedral complexes of both iron(II) and iron(III) have been isolated.[748] Thus reaction of $[FeCl_4]^{2-}$ with excess *o*-xyl$(SH)_2$ affords orange $[Fe(S_2\text{-}o\text{-xyl})_2]^{2-}$, whereas use of a 2:1 ligand to metal ratio gives the dimer $[Fe_2(S_2\text{-}o\text{-xyl})_3]^{2-}$, which on treatment with excess thiol is converted to the monomer. Controlled aerial oxidation of $[Fe(S\text{-}o\text{-xyl})_2]^{2-}$ affords the iron(III) complex $[Fe(S_2\text{-}o\text{-xyl})_2]^-$, which is readily isolated as the Et_4N^+ salt. The structures of both complexes have been determined by X-ray methods.[748] The mean Fe^{II}—S bond length is 2.356 Å, which is some 0.09 Å longer than that of the Fe^{III} monomer.

(77)

(78)

The oxidation state of the iron centres within a sulfide cluster can be the same or formally inequivalent. However, in all oxidation states antiferromagnetic spin coupling can take place directly or *via* bridging sulfur atoms. The $[Fe_2S_2]$ core is present in spinach ferredoxin, and a number of model complexes of the type $[Fe_2S_2(SR)_4]^{2-}$ containing iron(III) have been prepared and fully characterized. In particular salts of $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$ and $[Fe_2S_2(S\text{-}p\text{-tol})_2]^{2-}$ (prepared from $FeCl_3$, NaSH and ArSH in the presence of NaOMe) have been the subject of high resolution X-ray structure determinations.[749,750] In this oxidized form the iron(III) centres are in an approximately tetrahedral environment of sulfur ligands, but at low temperatures the complexes are diamagnetic and display no ESR signals due to antiferromagnetic coupling. At room temperature, population of the $S = 1$ level can give rise to some paramagnetism. One-electron reduction of $[Fe_2S_2(SR)_4]^{2-}$ produces inequivalent iron centres on the Mössbauer timescale. The isomer shifts correspond to the presence of Fe^{II} and Fe^{III} centres that are both high-spin and antiferromagnetically coupled. Work on the corresponding reduced natural spinach ferredoxin continues,[751] and its chemistry parallels that of these model complexes. In contrast however, under conditions used to prepare $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$, 1,2-ethanedithiol forms a black iron(III) dimer, $[Fe_2(edt)_4]^{2-}$, that contains no sulfide.[752] Moreover, the iron environment is not tetrahedral, but consists of five sulfur atoms with a distorted trigonal bipyramidal geometry.[753] Although iron sulfur complexes are usually kinetically labile with respect to exchange, $[Fe_2(edt)_4]^{2-}$ fails either to undergo thiolate ligand substitution reactions or to incorporate sulfide ion. Unlike the sulfide-containing dimers that undergo two one-electron reductions, $[Fe_2(edt)_4]^{2-}$ exhibits a single two-electron reduction.[752] This difference may reflect the relatively long Fe—Fe distance in $[Fe_2(edt)_4]^{2-}$.

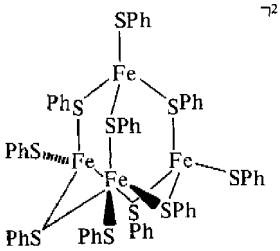
A considerable number of ferredoxins are known that contain one or more $[Fe_4S_4]$ clusters. At low temperatures these are diagmagnetic in the oxidized form but weak ESR signals can often be detected and the reduced forms display strong ESR signals. The structural features of the cubane-like $[Fe_4S_4]$ core have been well defined in several proteins, and a series of thermodynamically stable model complexes of the type $[Fe_4S_4(SR)_4]^{2-}$ have been prepared and thoroughly investigated.[739,740] In the natural systems SR is a cysteine ligand. Three overall charge levels are accessible as indicated in equation (62).

$$\underset{\text{'}3Fe^{II}1Fe^{III}\text{'}}{[Fe_4S_4(SR)_4]^{3-}} \rightleftharpoons \underset{\text{'}2Fe^{II}2Fe^{III}\text{'}}{[Fe_4S_4(SR)_4]^{2-}} \rightleftharpoons \underset{\text{'}1Fe^{II}3Fe^{III}\text{'}}{[Fe_4S_4(SR)_4]^{-}} \qquad (62)$$

It appears that no single protein in aqueous media will undergo reversible redox reactions between all three oxidation levels. The '$3Fe^{II}1Fe^{III}$'/'$2Fe^{II}2Fe^{III}$' couple is found in many bacterial proteins, while the '$2Fe^{II}2Fe^{III}$'/'$1Fe^{II}3Fe^{III}$' couple is only found in the so-called high-potential iron protein from photosynthetic bacteria. In marked contrast to the dimeric '$Fe^{II}Fe^{III}$' complexes that display two pairs of doublets in their Mössbauer spectra that are typical of isolated iron(II) and iron(III) centres in tetrahedral environments, the Mössbauer spectra of $[Fe_4S_4(SR)_4]^{2-}$ complexes show them to be largely valence delocalized.[754] Only limited spin delocalization, which is more readily detected, is present in the paramagnetic complexes $[Fe_4S_4(SR)_4]^{3-}$ and $[Fe_4S_4(SR)_4]^{-}$. Simple molecular orbital descriptions of these complexes have been presented.[755] Preparatively they are easily obtained from $FeCl_3$, NaSR, NaSH and MeONa in methanol. Usually the reaction is carried out in two stages;[756] $FeCl_3$ is reacted with NaSR to give an insoluble (if R = aryl) polymeric dark green sulfide, which is then treated with NaHS/MeONa to give the corresponding disulfide and the desired mixed oxidation state cluster $Na_2[Fe_4S_4(SR)_4]$. The overall reaction is illustrated in equation (63). A wide variety of thiols have been used in these reactions including β-mercaptopropionic acid ($R = CH_2CH_2CO_2H$), which affords[757] the water soluble $[Fe_4S_4\{S(CH_2)_2CO_2\}_4]^{6-}$, which has a half-wave potential[758] (0.58 V *vs.* SCE) similar to that of natural ferredoxin.

$$4FeCl_3 + 6NaSR + 4NaSH + 4NaOMe \longrightarrow Na_2[Fe_4S_4(SR)_4] + RSSR + 4MeOH + 12NaCl \qquad (63)$$

Thiolate exchange reactions of the dimeric iron(III) and the iron(II)/iron(III) cubane tetramers, $[Fe_2S_2(SR)_4]^{2-}$ and $[Fe_4S_4(SR)_4]^{2-}$, have been studied[750,759] in some detail and provide routes to several related complexes. Exchange takes place with other thiols (R'SH) as in equation (64).



$$[Fe_nS_n(SR)_4]^{2-} + mR'SH \longrightarrow [Fe_nS_n(SR)_{4-m}(SR')_m]^{2-} + mRSH \quad n = 2, 4;\ m = 0\text{–}4 \qquad (64)$$

Phenols also react to give the corresponding complexes, *e.g.* $[Fe_4S_4(OPh)_4]^{2-}$, salts of which have been isolated.[760] With benzoyl chlorides the fully substituted clusters $[Fe_4S_4Cl_4]^{2-}$ ($n = 2, 4$) are obtained, which have been structurally characterized.[761,762] The tetramer $[Fe_4S_4Cl_4]^{2-}$ and related iron(II)-containing cubane complexes are discussed in more detail later in this section.

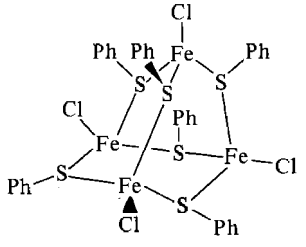
Since the initial work on $[Fe_4S_4(SR)_4]^{2-}$ clusters, spectrophotometric and NMR studies have provided further insight into routes to their formation, and highlighted the importance of solvent effects in these reactions. The route from $FeCl_3/RS^-$ and HS^- may be summarized[763] as in equation (63). With methanol or acetonitrile as solvent, in the absence of HS^-, and with the ratio $PhS^-:Fe = 3.5:1$ reaction (65) takes place to give the insoluble adamantane-like[764] iron(II) cluster $[Fe_4(SPh)_{10}]^{2-}$ (79) in high yield. This is oxidized by elemental sulfur in a surprisingly smooth reaction, in view of the degree of reorganization involved, to give the '$2Fe^{II}2Fe^{III}$' cubane complex $[Fe_4S_4(SPh)_4]^{2-}$ according to equation (66).

$$4FeCl_3 + 14PhS^- \longrightarrow [Fe_4(SPh)_{10}]^{2-} + 2PhSSPh + 12Cl^- \quad (65)$$

$$[Fe_4(SPh)_{10}]^{2-} + \tfrac{1}{2}S_8 \longrightarrow [Fe_4S_4(SPh)_4]^{2-} + PhSSPh \quad (66)$$

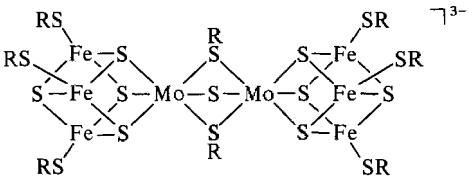
(79)

However, in acetonitrile with the ratio $PhS^-:Fe \leqslant 5:1$, the mononuclear tetrahedral iron complex $[Fe(SPh)_4]^{2-}$ is formed first, which reacts with sulfur to form the iron(III) dimer $[Fe_2S_2(SPh)_4]^{2-}$ according to equations (67) and (68). No further reaction takes place, but addition of methanol facilitates the reductive elimination of PhSSPh from the dimer to give the '$2Fe^{II}2Fe^{III}$' cubane complex as in equation (69). Although this series of reactions has been written for PhS^-, it appears similar reactions take place with alkyl as well as aryl thiolates.



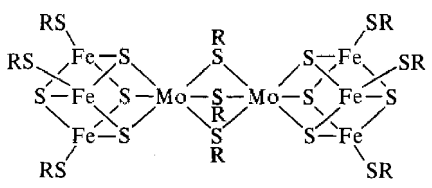
$$2FeCl_3 + 10PhS^- \longrightarrow 2[Fe(SPh)_4]^{2-} + PhSSPh + 6Cl^- \quad (67)$$

$$2[Fe(SPh)_4]^{2-} + \tfrac{1}{4}S_8 \longrightarrow [Fe_2S_2(SPh)_4]^{2-} + PhSSPh + 2PhS^- \quad (68)$$

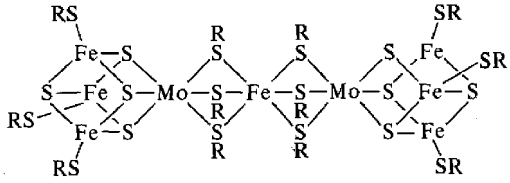


$$2[Fe_2S_2(SPh)_4]^{2-} \longrightarrow [Fe_4S_4(SPh)_4]^{2-} + PhSSPh + 2PhS^- \quad (69)$$

The convenient route to $[Fe_4S_4(SR)_4]^{2-}$, using $FeCl_3$, RS^- and sulfur, depends on thiolate reducing half of the iron(III) to iron(II), and all of the sulfur to sulfide. As a result more thiolate is required than with procedures starting with sulfide ion. This requirement can be reduced by using an iron(II) salt[765] rather than iron(III). The overall reaction is then as in equation (70).



$$4FeCl_2 + 4S + 10RS^- \longrightarrow [Fe_4S_4(SR)_4]^{2-} + 8Cl^- + 3RSSR \quad (70)$$

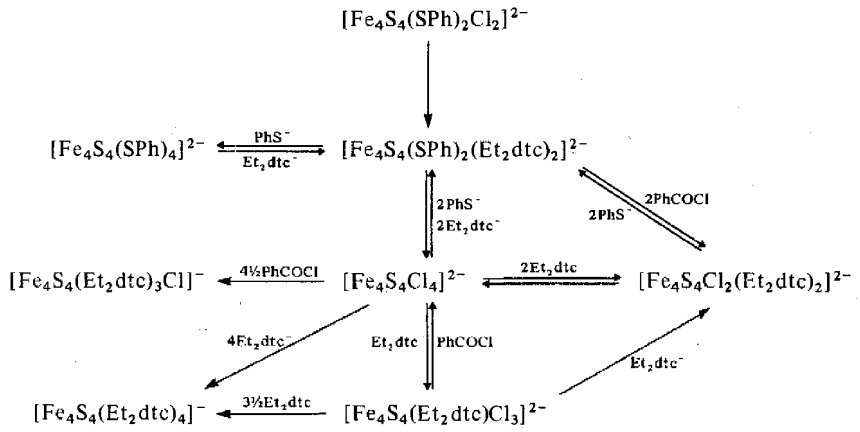


(80)

(81)

(82)

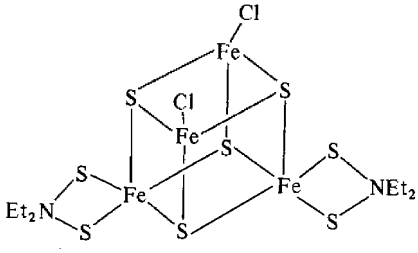
(83)



A further oxidative addition reaction of $[Fe(SPh)_4]^{2-}$ is that with organic trisulfides to give $[Fe_2S_2(SPh)_4]^{2-}$ in high yield.[766] $[Fe(SPh)_4]^{2-}$ also reacts with additional $FeCl_2$ or $FeBr_2$ (1:2.4 molar ratio) to give the paramagnetic clusters $[Fe_4(SPh)_6X_4]^{2-}$ (**80**), which have been isolated as their PPh_4^+ salts. The X-ray structure of $[Fe_4(SPh)_6Cl_4](PPh_4)_2$ shows[766] a nearly regular tetrahedron of iron atoms within a slightly irregular octahedron of bridging sulfur atoms in an adamantane type of cage. The mean Fe—Fe and Fe—S bond distances are 3.94 Å and 2.36 Å respectively. A series of novel bridged cluster complexes result from the reaction of MoS_4^{2-} with RS^- and $FeCl_3$ in methanolic solution containing quaternary ammonium cations. Depending on reaction conditions, yields of three such complexes as their R_4N^+ salts can be optimized:[767–770] $[Mo_2Fe_6S_9(SR)_8]^{3-}$ (**81**), $[Mo_2Fe_6S_8(SR)_9]^{3-}$ (**82**) and $[Mo_2Fe_7S_8(SR)_{12}]^{3-/4-}$ (**83**). The first complexes of this type were reported in 1978 by two research groups simultaneously; these were $[Mo_2Fe_6S_9(SEt)_8]^{3-}$[767] and $[Mo_2Fe_6S_8(SPh)_9]^{3-}$.[771,772] The iron atoms in the $[Mo_2Fe_6S_8(SR)_9]^{3-}$ anions are similar to those in the $[Fe_4S_4(SR)_4]^{2-}$ clusters and their Mössbauer spectra are consistent with extensive delocalization over the metal centres. Tungsten analogues have been prepared, and the properties of these complexes are similar to those containing molybdenum.[773,774] Amongst the most extensively investigated complexes in this series are (**82**) and (**83**), and analogues containing bridging methoxide ligands have also been isolated.[773] Equations (71) and (72) give the overall stoichiometries for formation of structures (**82**) and (**83**) respectively. The first identifiable complex formed in these reactions is the sulfur-bridged dimer $[(RS)_2Fe(S)_2MoS_2]^2$, which is well characterized.[775,776] A growing number of related trimers containing Fe_2Mo or $FeMo_2$ centres with bridging sulfides have been reported. Much of the work on these and their tungsten counterparts has been reviewed by Coucouvanis.[777]

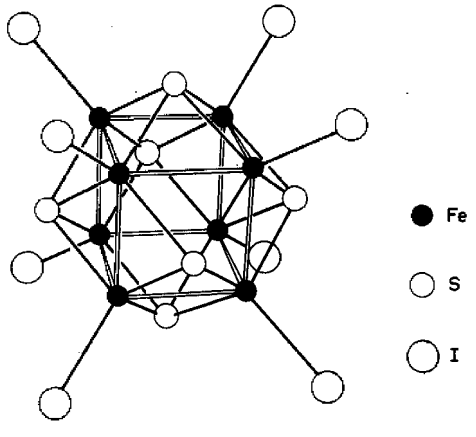
$$2MoS_4^{2-} + 6FeCl_3 + 17RS^- \longrightarrow [Mo_2Fe_6S_8(SR)_9]^{3-} + 4RSSR + 18Cl^- \quad (71)$$

$$2MoS_4^{2-} + 7FeCl_3 + 20RS^- \longrightarrow [Mo_2Fe_6S_8(SR)_{12}]^{3-} + 4RSSR + 21Cl^- \quad (72)$$



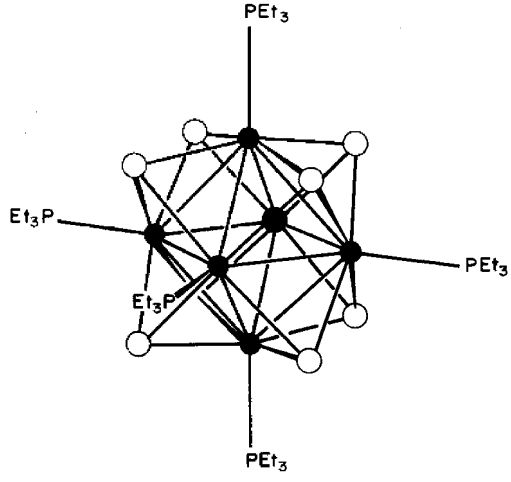
A number of iron sulfide/nitrosyl complexes are known; these include $[Fe_2S_2(NO)_4]^{2-}$, $[Fe_2(SR)_2(NO)_4]$ and the black tetramer $[Fe_4S_3(NO)_7]^-$ (Roussin's salts), as well as neutral $[Fe_4S_4(NO)_4]$. All these are diamagnetic and are discussed in Section 44.1.2.5, which is concerned with iron nitrosyl complexes. A variety of other iron/sulfide clusters are known and their range is illustrated by the following examples. Amongst the first Fe_4S_4 complexes to be structurally well characterized was $[Cp_4Fe_4S_4]$ obtained from reaction of $[Cp_2Fe_2(CO)_4]$ with elemental sulfur.[778] A related complex is $[Cp_2Fe_2S_2(SEt)_2]$, obtained from reaction of $[Cp_2Fe_2(CO)_4]$ with ethyl polysulfide in refluxing methylcyclohexane.[779] This dark green diamagnetic complex contains an unusual planar FeSSFe bridge,[780] and its electrochemical behaviour suggests the diamagnetism results from a unique electron pair coupling.[781] The planarity of the FeSSFe bridge is retained on one-electron oxidation to $[Cp_2Fe_2S_2(SEt)_2]^+$ and following further one-electron oxidation (nonreversible) $[Fe_2Cp_2(NCCH_3)_2(SEt)_2]^{2+}$ was isolated.[781] As previously noted, benzoyl chloride reacts with $[Fe_2S_4(SR)_4]^{2-}$ to give $[Fe_4S_4Cl_4]^{2-}$, which has bridging sulfides and terminal chloride ligands. Salts of this black anion are air sensitive, and its cubane core structure is similar to that of the thiolate precursor. There is a departure from ideal cubic symmetry with the Fe_4 portion being essentially tetrahedral.[762] Treatment of $[Fe_4S_4Cl_4]^{2-}$ with sodium iodide affords the iodo complex $[Fe_4S_4I_4]^{2-}$. The bromo analogue is obtained in the same way, but not the fluoro complex.[761] Electrochemical reduction of the dimer $[Fe_2S_2Cl_2]^{2-}$ gives[761] the corresponding tetramer as in equation (73). A similar scheme accounts for the behaviour of the analogous thiolate complexes. Their reduced dimers are sufficiently stable for the 3 −/4 − process involving dimers to be observed together with that for the 3 −/4 − and 2 −/3 − tetramers.[782] A range of mixed halide/diethyldithiocarbamate (Et_2dtc) cubane clusters have been prepared[783,784] from $[Fe_4S_4Cl_4]^{2-}$, PhS^- and Et_2dtc^- *via* the series of reactions shown in Scheme 14.

$$2[Fe_2S_2Cl_4]^{2-} \underset{[FeCp_2]^+}{\overset{e^-}{\rightleftharpoons}} [Fe_4S_4Cl_4]^{2-} + 4Cl^- \quad (73)$$



Scheme 14

Structures of the complexes $[Fe_4S_4(Et_2dtc)_nX_{4-n}]^{2-}$ ($X = Cl^-$, PhS^-; $n = 1$, 2) have been determined[784] and each have the familiar iron/sulfur core. There are relatively long distances between the five-coordinate iron atoms bound to Et_2dtc ligands, as for example in $[Fe_4S_4Cl_2(Et_2dtc)_2]^{2-}$ (**84**).



(84)

A number of large and structurally interesting iron sulfide/halide clusters have been isolated and characterized. Refluxing a mixture of iron, sulfur and Et_4NI in THF for 24 hours[785] gives a moderate yield of $(Et_4N)_2[Fe_6S_6I_6]$ in the form of small black platelets, as in equation (74). The formal oxidation state of the iron is +2.67, that is '$4Fe^{III}2Fe^{II}$'. This reacts further with iron and I_2/I^- in dichloromethane over a protracted period to give $(Et_4N)_3[Fe_8S_6I_8]$ according to equation (75). The eight iron atoms in this complex (**85**) form an almost perfect cube with terminal iodide ligands and μ_4-bonded sulfides on each face.[786] A Fe_6 cluster with triply bridging sulfide ligands is obtained by reaction of $Fe(BF_4)_2$ and PEt_3 (1:3 molar ratio) with H_2S in an acetone/ethanol mixture. After several days in air the green solution becomes black, and addition of $NaBPh_4$ deposits crystals of $[Fe_6S_8(PEt_3)_6](BPh_4)_2$. This iron(III) cationic complex (**86**) contains an octahedral arrangement of iron atoms with terminal phosphine ligands.[787]

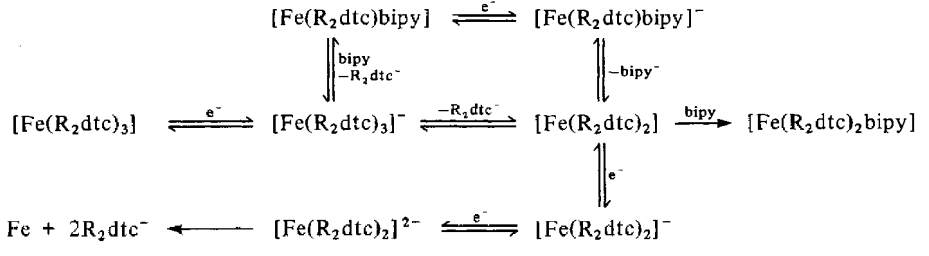
$$6Fe + 6S + 2I_2 + 2I^- \longrightarrow [Fe_6S_6I_6]^{2-} \quad (74)$$

$$[Fe_6S_6I_6]^{2-} + 2Fe + I^- + \tfrac{1}{2}I_2 \longrightarrow [Fe_8S_6I_8]^{3-} \quad (75)$$



44.1.5.10.3 Dithio ligands

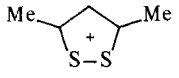
This section is concerned with 1,1-, 1,2- and 1,3-dithio chelates typified by dithiocarbamates (**87**), the dithiolenes (**88**) and dithoacetylacetonates (**89**) together with the $[FeX_4]^{2-}$ dithiolinium salts. All of these iron complexes are of interest because of both their novel electronic structures and redox processes involving high and low oxidation states. Relatively few monothiocarbamate transition metal complexes have been prepared and the limited chemistry of polymeric $[Fe(SOCNMe_2)_2]$ is discussed in a recent review.[788] In contrast, many transition metal dithiocarbamates are known and their chemistry has recently been reviewed.[789] Very large quadrupole splittings ($\sim 4.2\ mm\ s^{-1}$) in the Mössbauer spectra of $[Fe(R_2dtc)_2]$ complexes indicate a dimeric structure in the solid state and magnetic susceptibility measurements show antiferromagnetic coupling (Néel temperature = 110 K).[790,791] The X-ray structure of $[Fe(Et_2dtc)_2]$ (**90**) confirms it is dimeric and shows the two dithiocarbamate ligands; each bridges one axial and one equatorial position of the trigonal bipyramidal geometry around the iron atoms.[792] Generally, in solution these iron(II) complexes are extremely air sensitive being rapidly oxidized[791–793] to the iron(III) complex $[Fe(R_2dtc)_3]$. In the presence of excess R_2dtc^- the tris complex $[Fe(R_2dtc)_3]^-$ is formed.[794] This is also air sensitive and its stability depends on the cation. Oxidation of the iron(III) complex in benzene by air[795] or iodine[796,797] affords the corresponding iron(IV) complex. Electrochemical reduction of the iron(III) complex $[Fe(R_2dtc)_3]$ in acetone and acetonitrile using platinum electrodes gives[798] the high-spin tris iron(II) complex *via* a process indicated by cyclic voltammetry to be reversible. Measurements obtained during controlled potential electrolysis, however, indicate that there is some loss of ligand on reduction. With mercury electrodes additional reduction reactions have been observed.[799,800]

(87) (88) (89) (90)

$[Fe(R_2dtc)_3]^-$ is formed first, followed by loss of R_2dtc^- and sequential reduction to give $[Fe(R_2dtc)_2]^-$ and $[Fe(R_2dtc)_2]^{2-}$ as shown in Scheme 15. In the presence of bipy, reduction of $[Fe(R_2dtc)_3]$ gives[800] the well-characterized iron(II) mixed ligand complex $[Fe(R_2dtc)_2(bipy)]$, and this process can generate $bipy^-$ radical anion. The iron(I) complex $[Fe(CO)_3(PPh_3)_2]^+$ undergoes[801] oxidative substitution with R_2dtc^- (and $^-S_2CPPh_2$) to give the cationic dicarbonyl complexes *cis,trans*-$[Fe(CO)_2(PPh_3)_2(S_2CNR_2)]^-$. The same complex is obtained with $Me_2NC(S)SS(S)NMe_2$. Golden yellow $[Fe(Me_2dtc)_2(CO)_2]$ is obtained from the reaction of $[FeBr_2(CO)_4]$ with Me_2dtc^- in acetone.[802] The UV photoelectron spectra of several $[Fe(R_2dtc)_2(CO)_2]$ complexes have been examined.[803] In the vapour phase CO is lost to give $[Fe(R_2dtc)_2]$. The analogous cyclopentamethylene dtc dicarbonyl complex is the product from addition of the corresponding disulfide to $[Fe(CO)_5]$ in THF. In crystals of this complex analyzed by X-ray crystallography,[804] only one of the possible structural isomers was present, resulting from the relative orientation of the chair-form piperidine rings.

Scheme 15

Whilst little information is available concerning iron(II) xanthates, the preparations of $[Fe(S_2COEt)_2]$ and $[Fe(S_2COEt)_3]^-$ have been described[805] and addition of potassium xanthate to a solution of $FeCl_2$ and 1,10-phenanthroline (2:1:1 ratio) yields $[Fe(S_2COEt)_2(phen)]$. If 1,10-phenanthroline is replaced by 2,2′-bipyridine, two crystalline modifications of $[Fe(S_2COEt)_2(bipy)]$ are formed.[805] Pyridine reacts with iron(III) xanthates to form[806] high-spin iron(II) complexes as in equation (76).

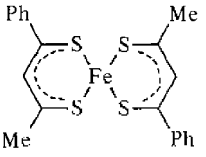


$$2[Fe(S_2COR)_3] + 4py \longrightarrow 2[Fe(S_2COR)_2py_2] + ROC(S)SSC(S)OR \quad (76)$$

The thioxanthate complex $[Fe(S_2CSEt)_3]^-$ is obtained from reaction of *trans*-$[FeCl_2(H_2O)_4]$ with potassium ethylthioxanthate in methanol or THF. Initially, a violet/red-brown solution is obtained although this can become bluish-green at high ligand-to-metal ratios. However, addition of R_4N^+ yielded only one product, namely the tetraalkylammonium salt of $[Fe(S_2CSEt)_3]^-$. An X-ray crystal structure analysis[807] shows the FeS_6 core to be distorted from a regular octahedron towards a trigonal prism with an average Fe—S distance of 2.52 Å. The blue colour of dilute solutions of $Et_4N[Fe(S_2CSEt)_3]$ in acetonitrile fades over a period of a few days at 10 °C to give some brown material and black crystals of an unusual iron(III) trithiocarbamate $(Et_4N)_2[Fe(SEt)(S_2CSEt)(CS_3)]_2$. This complex has a relatively short Fe—Fe distance. The iron atoms are bridged[808] by two ethylthio and two ethylthioxanthate ligands. The very reactive high-spin complex $[Fe(S_2PF_2)_2]$ is formed[809] in the absence of air and water from iron metal or $FeCl_2$ with anhydrous HS_2PF_2.

Oxidation states higher than +2 are favoured by the presence of dithiolene ligands and these complexes are discussed in Sections 44.2.5.2 and 44.3. In the present section, discussion is restricted to the reaction of $[Fe(Et_2dtc)_2]$ with $S_2C_2(CF_3)_2$. In THF solution in the absence of air this reaction yields the complex $[Fe(Et_2dtc)_2\{S_2C(CF_3)_2\}]$ as in equation (77). The geometry of this complex is slightly distorted[810] from an octahedron towards a trigonal prism. As is frequently the case with complexes of this type, the assignment of oxidation state to the metal ion is somewhat ambiguous. Nonetheless, there is a high degree of Fe^{II} character associated with the structural data. Magnetic data for both the solid complex and in solution are consistent with a singlet/triplet spin equilibrium. In solution two stereochemical rearrangements are observed[811] on the NMR timescale: inversion ($\Delta H^{\neq} \sim 37.7\,kJ\,mol^{-1}$) and C—N bond rotation ($\Delta H^{\neq} \sim 66.9\,kJ\,mol^{-1}$). In electrochemical experiments in acetonitrile solution, two reduction and one oxidation steps have been observed.[812]

$$[Fe(Et_2dtc)_2] + S_2C_2(CF_3)_2 \longrightarrow [Fe(Et_2dtc)_2\{S_2C_2(CF_3)_2\}] \quad (77)$$

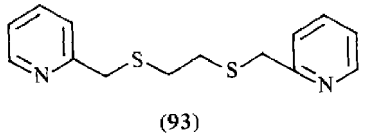


The complex $[Fe(SPMe_2NPMe_2S)_2]$ containing an unusual 1,3-dithio ligand has a tetrahedral structure, and is discussed in Section 44.1.5.10.2. Early reports[813,814] of attempts to prepare complexes of dithioacetylacetone describe a reaction mixture of Fe^{3+}, acetylacetone, HCl and H_2S in ethanol, which somewhat surprisingly yielded a deep purple 3,5-dimethyl-1,2-dithiolinium salt (**91**) of the $[FeCl_2]^{2-}$ anion. Simple $[FeX_4]^{2-}$ salts are pale cream and dithiolinium cations have no appreciable absorption in the visible region. Thus many workers[815] suspected the presence of Fe—S bonds. The discrete $[FeCl_4]^{2-}$ ion has, however, been demonstrated in an X-ray structure determination.[816] The intense colour of this and related salts is due to a broad absorption (around $20\,000\,cm^{-1}$) arising from charge transfer between the sulfur-containing cation and the reducing tetrachloroferrate anion. The structure of $(\mathbf{91})_2[FeCl_4]$ contains several potential S · · · Cl interactions. Each cation participates in three relatively short S—Cl contacts which represent a ready route for charge transfer. A variety of substituted 1,2-dithiolinium tetrachloroferrate(II) salts have been characterized, and their charge-transfer behaviour rationalized in terms of a combination of steric and electronic effects. Chemical reduction of $(\mathbf{91})_2[FeCl_4]$ (*e.g.* with $NaBH_4$ or $Na_2S_2O_4$) gives[817] a moderate yield of the low-spin neutral iron(III) dithio-β-diketone complex $[Fe(C_5H_7S_2)_3]$.

(91)

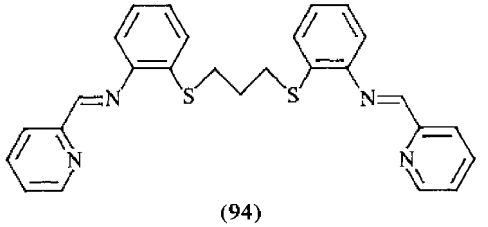
Red-brown crystals of this complex dissolve in chloroform and are reduced further, on shaking the solution with aqueous $Na_2S_2O_4$, to give the bis-dithio-β-diketone iron(II) complex $[Fe(C_5H_7S_2)_2]$, which is very sensitive to reoxidation. A similar complex is postulated by Japanese workers,[818] resulting from the reduction of 3-methyl-5-phenyl-1,2-dithiolium perchlorate in the presence of Fe^{2+}. The exact structure is unknown but is thought to be as shown in (**92**). $[FeCl_4]^{2-}$ forms[819] a

related charge-transfer complex with the dication of *N,N'*-dimethyl-4,4'-bipyridine (paraquat). EPR spectroscopy shows the presence of some completely reduced radical cation pq^+ although the Mössbauer spectrum indicates that the majority of iron is present as iron(II) in the complex. The X-ray powder diffraction pattern is very similar to that for an equivalent cobalt salt whose X-ray crystal structure shows[820] the paraquat cation to be planar.



(92)

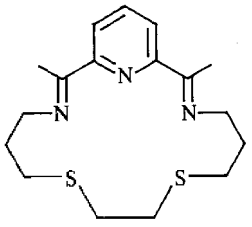
44.1.5.10.4 Mixed sulfur nitrogen donors



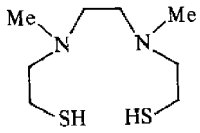
A variety of iron(II) complexes with sulfur and nitrogen donors are known. Many have unusual coordination geometries and interesting magnetic behaviour. The iron(II) complexes of (**93**) with stoichiometry [Fe(**93**)Y_2] (Y = Cl, Br, I, NCS) are high-spin and their magnetic moments, in the range 5.3–5.4 BM, are consistent with octahedral coordination. The halide complexes are orange or yellow, whilst the thiocyanate is dark green. The complexes dissociate in nitromethane and reaction (78) has been proposed[821] for which the equilibrium constant increases in the order Cl ~ NCS < Br < I.

$$[Fe(\mathbf{93})Y_2] + CN_3NO_2 \longrightarrow [Fe(\mathbf{93})Y(CH_3NO_2)]^+Y^- \qquad (78)$$

In contrast, the more delocalized hexadentate ligand (**94**), which provides an S_2N_4 donor set, forms[822] a low-spin iron(II) complex. Here, the higher degree of conjugation demands that the geometry of each NNS sequence must at least approximate to being planar with the result that only two enantiomeric forms are possible. The stability of this iron(II) complex is illustrated by its formation from iron(III) salts. If excess $FeCl_3$ is used, the product is blue [Fe(**94**)][$FeCl_4$]$_2$, whereas excess $FeCl_2$ affords [Fe(**94**)][$FeCl_4$].

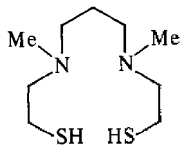


(93)

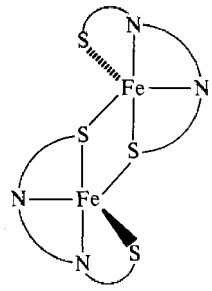


(94)

The Schiff base condensation of 2,6-diacetylpyridine with 4,7-dithiadecane-1,10-diamine yields the macrocyclic ligand (**95**), which has an S_2N_3 donor set. The six-coordinate complexes [Fe(**95**)Y]$^+$ can be high- or low-spin depending on the nature of Y, for example magnetic moments for Y = Cl, Br, I and NCS are 5.2, 5.3, 0.3 and 0.6 respectively. Three distinct structural modifications of the stoichiometry Fe(**95**)$(NCS)_2$ have been characterized in the solid state. In acetonitrile solution, however, there appears to be a common structure. Two of the solid state structures are high-spin and the other low-spin; no doubt these involve different conformations of the macrocyclic ligand. X-Ray crystal structure analysis of the low-spin complex shows[823] the macrocycle wrapped around the iron(II) centre as a pentadentate ligand with a nitrogen bound NCS^- group completing a distorted octahedral geometry. The neutral bis complexes of the linear aliphatic ligands (**96**) and (**97**) are both high-spin and have slightly distorted trigonal bipyramidal structures involving dimercapto-bridged dimers. The extent of distortion from the trigonal bipyramidal dimer structure (**98**) is greater for the ligand (**96**) (which is the less flexible of the two) than for (**97**). The two iron atoms are sufficiently close (3.2 Å) for significant antiferromagnetic exchange to occur by direct overlap of iron[824] orbitals. Because of the closeness of the participating nuclei and the orbital dependence of the effect, it is possible to evaluate[825] electron pair exchange parameters for the temperature dependence of the magnetic susceptibility of the complexes [Fe(**96**)]$_2$ and [Fe(**97**)]$_2$.

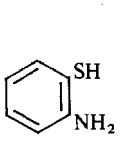


Neutralization of an alcoholic solution of *o*-aminobenzenethiol (**99**) with a slight deficiency of

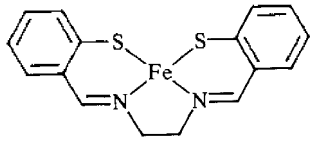


(95)

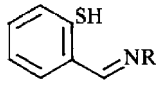
(96)



(97)

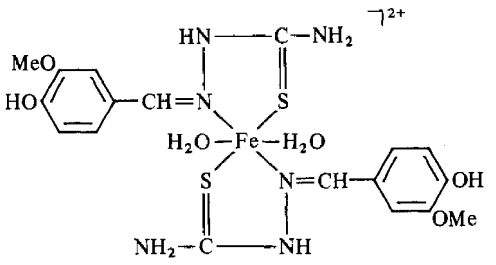


(98)



NaOH in the presence of $FeSO_4$ affords a pale yellow precipitate of $[Fe(SC_6H_4NH_2)_2]$. It is insoluble in most common solvents but slightly soluble in DMF. This iron(II) complex is not well characterized; it is antiferromagnetic with a well-defined Néel point of 138 K and a magnetic moment of 3.95 BM (rather low due to exchange). The reflectance spectrum of the complex indicates six-coordination and it may be assumed that its structure is polymeric and involves sulfur bridges. Ethylenediamine reacts with bis(thiosalicylideniminato)iron(II) to give[827] (**100**), which has a magnetic moment of 1.9 BM. The well-known oxygen analogue of this complex, [Fe(salen)], has in contrast a spin-only value of 4.77 BM.[282] The low temperature Mössbauer spectrum of (**100**) is compatible with the intermediate $S = 1$ spin state, while the temperature dependence of its magnetic moment between 4.2 K and 300 K is consistent with coupling in a polymeric structure. The complex reacts with oxygen in pyridine at room temperature, affording the corresponding iron(III) μ-oxo dimer. The room temperature UV spectrum of (**100**) in pyridine is similar to that in dichloromethane, but at $-23\,^{\circ}C$ a dramatic change from blue-black to red ($\lambda = 508$ nm) takes place. This has been ascribed[829] to pyridine coordination. When carbon monoxide is passed into such a solution it also becomes red and the complex [Fe(**100**)(CO)(py)] is formed. This has been characterized by X-ray crystal structure determination,[830] which shows the pyridine and carbon monoxide ligands to be *trans* to each other. A variety of complexes have been prepared[829] with ligands formally similar to (**100**) but with the CH_2CH_2 moiety exchanged for different groups. Some of these also have the unusual $S = 1$ spin state.[831] In contrast the neutral bis-ligand complexes of the bidentate (**101**) are high-spin (magnetic moments approximately 5.1 BM)[829] and the assignment of an $S = 2$ spin state is supported by Mössbauer data.[831]

(99)



(100)

(101)

The quadrupole splitting in the Mössbauer spectrum of the thiosemicarbazide complex $[Fe(NH_2NHCSNH_2)_2]SO_4$ is particularly large[832] (4.65 mm s^{-1}) and an X-ray crystal structure showed[833] an unusual chain-like polymer formed by SO_4^{2-} bridges between *cis*- and *trans*-$[Fe(NH_2NHCSNH_2)_2]^{2+}$ units. These are thus two different iron environments and the Mössbauer spectrum observed is less complex than expected. The origin of the large quadrupole splitting remains unclear. A vanillin thiosemicarbazone iron(II) complex (**102**) has been reported[834] and its fungicidal properties investigated. Cysteine reacts with Fe^{2+} under acidic or neutral conditions to give a light brown complex of 1:1 stoichiometry. This complex probably involves bonding through the carboxylate oxygen atoms. If, however, the reaction is carried out in alkaline solution, a 1:2 (FeL_2) complex is formed. Under the same conditions and in the presence of carbon monoxide, a red dicarbonyl $[FeL_2(CO)_2]$ results. The IR and Raman spectra of these complexes have been recorded.[835] The $[FeL_2]$ complex has a polymeric structure[836] with antiferromagnetic coupling[837] which probably occurs *via* thiolate bridging groups. The Mössbauer spectra of these complexes have also been reported;[838] however, their structures are not known with any certainty.

(102)

44.1.5.11 Halides

44.1.5.11.1 Fluorides

Iron difluoride is an off-white sparingly soluble material, which may be prepared by the reaction of metallic iron with HF,[839,840] dehydration of the tetrahydrate,[841] displacement[842] of chlorine in $FeCl_2$ by HF, reduction of $FeF_3 \cdot xH_2O$[843] or reaction of Fe_2O_3 with carbon and HF.[841] It has been shown[844] to be monomeric in the gas phase between 692 °C and 876 °C. The solid has the rutile structure in which FeF_6 octahedra are tetragonally distorted with iron–fluorine bond distances[845] of 1.99 Å (× 2) and 2.12 Å (× 4). Structural transformations have been observed at very high pressures.[846] Above 100 K, FeF_2 has a magnetic moment of 5.56 BM.

Iron difluoride tetrahydrate is a white solid which browns in air. It may be prepared by dissolving metallic iron in warm hydrofluoric acid and precipitating with ethanol. The structure[847] is described as an array of discrete $[FeF_2(H_2O)_4]$ octahedra in which H_2O and F^- are randomly distributed over 12 possible sites, each site being occupied by an average of $\frac{1}{3}O$ and $\frac{1}{6}F^-$. A saturated aqueous solution of the hydrate forms[848] a yellow precipitate of composition $Fe_2F_5 \cdot 7H_2O$ on standing in air for several days. This complex is dehydrated at 100 °C in nitrogen to give $Fe_2F_5 \cdot 2H_2O$ and completely dehydrated at 180 °C to give the grey mixed oxidation state salt Fe_2F_5. The structure of the hydrate contains distinct Fe^{II} and Fe^{III} centres.[849]

44.1.5.11.2 Chlorides

Iron dichloride is a hygroscopic white solid readily soluble in water and ethanol. It may be prepared by reaction of metallic iron with HCl at red heat,[850] under mild conditions in THF[851] or methanol,[852] or with a mixture of the acid and chlorine at 700 °C. The trichloride decomposes[854] at 300 °C *in vacuo* or may be reduced for example with H_2[842] or H_2S[855] to yield $FeCl_2$. Thermal decomposition of $FeCl_3$ aids purification of $FeCl_2$ by vacuum sublimation. Anhydrous $FeCl_2$ may also be prepared by dehydration of $[FeCl_2(H_2O)_4]$ and the reaction of metallic iron with CCl_4.[857]

Whilst the vapour of $FeCl_2$ is monomeric ($\nu = 492\,cm^{-1}$) at lower temperatures,[850] an increasing proportion of dimer ($\nu = 430 cm^{-1}$)[858,859] is present as the temperature is raised. Crystalline $FeCl_2$ has the $CdCl_2$ structure[860] under normal conditions. The packing geometry of the $FeCl_6$ octahedra appears to be dependent on the mode of crystallization. At high pressures structural changes occur; a magnetically observable change to a CdI_2 structure is seen[861] at low temperatures at 2 kbar pressure and the structure undergoes a similar modification[862] at 5.7 kbar at room temperature. The anhydrous dichloride has a magnetic moment of $\mu_{eff} = 5.87$ BM at 300 K. $FeCl_2$ reacts readily with a wide variety of ligands to form $[FeCl_2L_n]$ complexes, many of which are discussed elsewhere in this chapter.

Also of interest is the tetrahedral anion $[FeCl_4]^{2-}$ found in a number of complexes. Tetrachloroferrates may be prepared by the reaction of alkali metal chlorides with $FeCl_2$ in the melt[863] or, for example, the reaction of triphenylmethylarsonium chloride or tetraethylammonium chloride with $FeCl_2$ in deoxygenated ethanol.[864] The tetrachloroferrate(II) anion is less common than its iron(III) counterpart and there have been few structural determinations. The geometry of $[FeCl_4]^{2-}$ is frequently complicated by interaction with other species, as for example in the case of the complex $\{[Fe(\eta^5\text{-}C_5H_5)(CO)_2]_3SbCl\}_2[FeCl_4] \cdot CH_2Cl_2$ in which hydrogen bonding between $[FeCl_4]^{2-}$ and chloroform is thought[865] to cause a significant distortion from perfect tetrahedral symmetry. In $[NMe_4]_2[FeCl_4]$, which is isostructural with the analogous cobalt, nickel and zinc salts which have

no close interactions, the anion is nearer to ideal tetrahedral symmetry.[866] Interestingly the bond lengths (Fe—Cl = 2.29 Å) in the iron(II) anion are 0.11 Å longer than those found in the iron(III) anion $[FeCl_4]^-$. This is in contrast to the octahedral case where, for equivalent spin states, bond lengths differ[866] by about 0.04 Å between the iron(II) and iron(III) oxidation states. This difference has important implications in the study of iron–sulfur proteins where oxidation state changes in tetrahedral iron anions are frequently observed. The interesting charge transfer observed between $[FeCl_4]^{2-}$ and dithiolium cations is discussed in Section 44.1.5.10.3. A number of other complex binary iron chlorides exist, often poorly characterized. The $[FeCl_6]^{4-}$ anion is found as the mineral rinneite[867] in potash deposits. The tetrahydrate $[FeCl_2(H_2O)_4]$ may be prepared[868] by dissolving metallic iron in aqueous HCl and crystallizing the product at room temperature. The distorted octahedral structure[869] has *trans* chloride ligands and there is extensive hydrogen bonding in the crystal lattice (Fe—Cl = 2.38 Å; Fe—O = 2.09, 2.5 Å). Crystallization at 75° yields the dihydrate,[870] which can also be prepared by careful dehydration of the tetrahydrate. The structure of $FeCl_2 \cdot 2H_2O$ consists of chains of $[FeCl_4(H_2O)_2]^{2-}$ octahedra with *trans* aqua ligands which are linked by two bridging chlorine atoms[870] (Fe—O = 2.075 Å; Fe—Cl = 2.488, 2.542 Å).

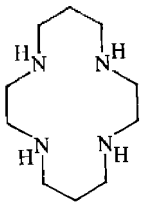
44.1.5.11.3 Bromides

Iron dibromide is a pale yellow-to-brown hygroscopic solid that is soluble in water, ethanol, ether and acetonitrile. It is prepared[871] by the reaction between metallic iron and bromine in a flow tube at 200 °C. $FeBr_2$ is purified from $FeBr_3$ by sublimation in nitrogen or under vacuum. Other preparative routes include the reaction of metallic iron with HBr in methanol,[852] hydrobromination of Fe_2O_3[872] in a flow tube at 200 °C–350 °C and dehydration[873] of $[FeBr_2(H_2O)_4]$. $FeBr_2$ crystallizes in a layer lattice of the CdI_2 type[873] and has a magnetic moment of 5.71 BM at 295 K. Like the chloride, $FeBr_2$ readily forms adducts with a wide range of donor molecules including amines, pyridines, phosphines, arsines and oxygen donor ligands. A series of hydrates may be crystallized from aqueous solution at different temperatures,[874] a 9-hydrate below −29.3 °C, a 6-hydrate[875] at room temperature, a tetrahydrate above 49 °C and a dihydrate above 83 °C.

44.1.5.11.4 Iodides

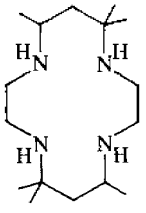
FeI_2 is a red-black crystalline solid which is hygroscopic, very soluble in water and also soluble in ethanol and ether. It may easily be prepared[876–878] from elemental iron and iodine because of the non-existence of the triiodide. Anhydrous FeI_2 has the CdI_2 structure[879] and a magnetic moment of 5.75 BM at 295 K. As with the dibromide, a series of hydrates are obtainable from aqueous solutions of FeI_2; for example, the green tetrahydrate results from evaporation at room temperature. FeI_2 also forms a wide range of adducts with suitable donor ligands. Recent work has identified significant advantages[877] in the use of high purity FeI_2 in discharge lamps.

44.1.5.12 N Donor Macrocycles



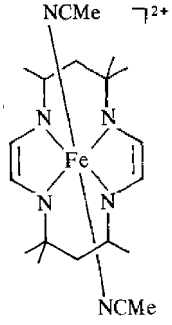
44.1.5.12.1 Introduction

There is a particularly extensive and rich coordination chemistry associated with iron(II) N donor macrocycles. The coordination chemistry of the biologically important iron porphyrin complexes has been of interest since the classic studies of Fischer, and over recent years there has been a resurgence of work on these and also on a wide range of related synthetic macrocyclic complexes. This section concentrates on their coordination chemistry, and where appropriate highlights enhanced ligand reactivity specifically induced by the iron(II) centre. First saturated ligands are discussed and then the unsaturated systems, with the particularly well-studied porphyrins and phthalocyanines being dealt with in separate subsections.



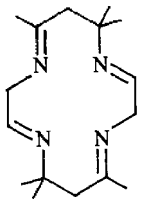
44.1.5.12.2 Saturated macrocycles

This section is concerned with complexes formed by macrocycles which are effectively polydentate ethylene or propylene amines. The prototype ligand is 'cyclam' or [14]aneN$_4$[880,881] (**103**) (1,4,8,11-

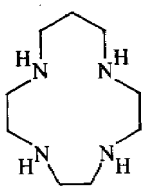


tetraazacyclotetradecane). Thus, when $FeCl_2 \cdot 4H_2O$ is added to a warm solution of Me_6[14]aneN$_4$ (**104**) in DMF, a tan precipitate of [Fe(Me_6[14]aneN$_4$)Cl$_2$] forms[882] on cooling to room temperature. A similar complex with axial acetonitrile ligands results[883] from the reaction of Me_6[14]aneN$_4$ with iron(II) acetate or perchlorate in anhydrous acetonitrile. This complex is low-spin, highly air sensitive and, in acetonitrile solution, is progressively oxidized to yield the diimine complex [Fe(Me_6[14]1,3,8,10-tetraeneN$_4$)]$^{2+}$ (**105**).

(103)

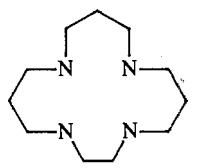


(104)



(105)

Reactions of [Fe(hfpd)(H_2O)$_2$] (hfpd = 1,1,1,5,5,5-hexafluoro-2,4-pentanedionato) with (**104**) and related macrocycles in rigorously anaerobic conditions afford[884] complexes of the type [Fe(L)(hfpd)] (L = **104**). Mössbauer spectroscopy indicates six-coordinate high-spin iron(II), but the nature of the bonding of the axial ligands is not fully resolved. TMC (tetramethylcyclam), the tetra-*N*-methyl derivative of (**103**), reacts[885] readily with [Fe(NCMe)$_6$](BF$_4$)$_2$ in acetonitrile to give the five-coordinate high-spin iron(II) complex [Fe(TMC)(NCMe)](BF$_4$)$_2$. Substitution of the co-ordinated acetonitrile yields [Fe(TMC)X]$^+$ (X = Br, Cl, NCS$^-$, N$_3^-$), which are also five-coordinate. All these complexes react in the solid state with moist ambient air to give dark red-brown compounds which are reported[885] to be six-coordinate $S = 1$ iron(II) species, having a water molecule in the sixth coordination position. Complex (**105**) shows three well-defined reversible electrochemical reduction steps,[883] corresponding to Fe^{I}, Fe^{0} and Fe^{-I} oxidation states, whereas in acetonitrile [Fe(Me_6[14]aneN$_4$)(MeCN)$_2$]$^{2+}$ reduces irreversibly. The saturated nitrogen atoms in such ligands are relatively 'hard' but complexes with strong field axial ligands tend to be low-spin. Thus when the axial acetonitrile ligands in purple, low-spin [Fe(Me_6[14]aneN$_4$)(MeCN)$_2$](BF$_4$)$_2$ are removed *in vacuo*[886,887] a powder-blue high-spin species [Fe(Me_6[14]aneN$_4$)(BF$_4$)](BF$_4$) containing coordinated BF_4^- is formed. A series of complexes [Fe(Me_6[14]aneN$_4$)X$_2$] have been synthesized.[887] In the order of the spectrochemical series, low-spin complexes were observed for X = CN$^-$, NO$_2^-$ (and MeCN as BF_4^- and PF_6^- salts), high-spin complexes for X = MeCO$_2^-$ ($\mu_{eff} = 5.7$ BM) Cl$^-$ (5.95), Br$^-$ (5.47), I$^-$ (5.37) and BF_4^- (5.7, five-coordinate). The X = NCS$^-$ complex exists in a mixture of spin states having a room temperature magnetic moment of 1.5 BM and a weak ESR signal at $g = 2.285$. The stabilization of iron(II) in complexes having predominantly saturated nitrogen donor ligands is unusual, and may be ascribed to the conformation of the macrocycle, which maintains the planarity of the donor set, and hence a relatively high ligand field strength. Significantly increasing ligand field strength, however, results in the formation of five-coordinate high-spin complexes, probably because the metal ion is then too large to fit inside the plane of the high-field ligand. Thus, with relatively weak-field axial ligands such as halide, the tetraimine (**106**) forms[888] a five-coordinate complex [Fe(Me_6[14]1,4,8,11-tetraeneN$_4$)(Cl)](ClO$_4$). Mössbauer studies have shown[889] that the π-accepting power of the tetradentate macrocyclic amines increases with the degree of unsaturation and that π bonding to iron(II) is especially important for ligands containing the α-diimine moiety. Iron(II) complexes of a range of saturated macrocyclic amines of varying ring size, *i.e.* [13]aneN$_4$ (**107**), [15]aneN$_4$ (**108**) and [16]aneN$_4$ (**109**), have been synthesized[890] in addition to those of the non-methylated ligand cyclam [14]aneN$_4$ (**103**). The ligand field strength of the macrocycle varies markedly with ring size, being greater in smaller rings. This difference is demonstrated[890] by the spin states of tetragonal iron(II) complexes with rings of differing size (Table 17).



Interestingly, the presence of methyl substituents on the saturated tetraaza macrocycles also affects the properties of their iron(II) complexes. Whilst [Fe(Me_6[14]aneN$_4$)(NCS)$_2$] shows a $^1A_{1_g} \rightleftharpoons {}^5T_{2_g}$ spin transition, [Fe([14]aneN$_4$)(NCS)$_2$] is low-spin. Furthermore, [Fe([14]aneN$_4$)(MeCN)$_2$](PF$_6$)$_2$ does not lose MeCN to form a five-coordinate species which is in contrast to the analogous complex [Fe(Me_6[14]aneN$_4$)(MeCN)$_2$](BF$_4$)$_2$. A further example of the

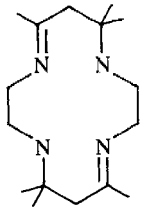
5. Compound has stoichiometry $[Fe([16]aneN_4)(NO_2)]NO_2$.

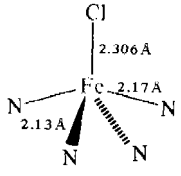
effect of ring size is given[891] by the reversible uptake of carbon monoxide by low-spin $[Fe([14]aneN_4)(MeCN)_2]^{2+}$ and high-spin $[Fe([15]aneN_4)(MeCN)_2]^{2+}$. The latter complex becomes low-spin on substitution of one MeCN by CO, which was the first example of a non-haem complex changing spin state on binding CO. The relatively weaker ligand field of $[15]aneN_4$ and the proximity of the CO complex to the spin cross-over contributes to a 2000-fold increase[891] in the lability of CO in $[Fe([15]aneN_4)(CH_3CN)(CO)]^{2+}$ over the analogous $[14]aneN_4$ complex.

The macrocyclic triamine $[9]aneN_3$ (**110**) can only coordinate 'facially', in contrast with common open chain polyamines and macrocycles of larger ring size. Reaction[892] of the free ligand with $FeCl_2$ leads to the precipitation of blue $[Fe([9]aneN_3)_2]Cl_2$, which may easily be converted to the bromide. Surprisingly, this complex is diamagnetic and stable in aqueous solution although air sensitive. The formal redox potential at 3 °C in 0.1 M KCl is +0.13 V. Thus the iron(III) complex is but a weak oxidant.



(110)

44.1.5.12.3 Partially unsaturated macrocycles



Interest in complexes of new synthetic macrocyclic ligands (and especially amines) was sparked by the discovery of the so-called Curtis ligands (**111**) first observed[893] as the product from the

reaction of tris(ethylenediamine)nickel(II) with acetone. The ligand (**111**) (Me_6[14]dieneN$_4$) forms[894] stable, high-spin complexes of the type [Fe(Me_6[14]dieneN$_4$)X](ClO$_4$) with X = Cl, Br, I. An X-ray crystal structure determination[895] shows five-coordinate iron(II) in [Fe(Me_6[14]dieneN$_4$)Cl]I. The macrocycle however is not planar but adopts a puckered configuration. Steric constraints prevent the high-spin iron(II) from fitting inside a plane containing the four nitrogen atoms and the iron sits slightly proud of the ring as illustrated in structure (**112**) with one axial chloride. The ligand is too rigid to allow coordination of a second *cis* halide.

The *d–d* electronic spectrum of this complex in solution is the same as the solid-state spectrum and this, together with the fact that the iron(II) centre remains high-spin, indicates that the unusual five-coordinate structure persists in solution. A related series of complexes have been prepared,[896] which show that the spin state and coordination number of the iron are dependent on the non-macrocyclic ligand (Table 18). The acetonitrile complex [Fe(Me_6[14]dieneN$_4$)(MeCN)$_2$]$^{2+}$ exists as two distinct isomers (which have different IR, visible and NMR spectra) that are interconvertible and derive from the *meso* and racemic forms of the asymmetric nitrogen atoms in the macrocyclic ligand. Interestingly, in the case of [Fe(Me_6[14]dieneN$_4$)(phen)](ClO$_4$)$_2$ the phen ligand is constrained to coordinate in a *cis* fashion if it is to be bidentate. This complex shows a thermal $^1A_{1g} \rightleftharpoons {}^5T_{2g}$ spin equilibrium. The UV/visible spectrum contains mainly strong charge transfer bands, and as the marked dependence of magnetic moment on temperature suggests, spectral characteristics also change with temperature. Thus at room temperature the complex is purple-black, whilst at 150 °C it undergoes a reversible change to a pink-red colour.

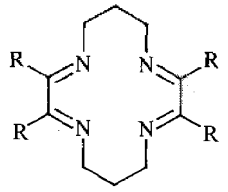
These complexes are very sensitive and many decompose rapidly on exposure to air. Controlled reaction of low-spin six-coordinate complexes with oxygen, however, can lead to oxidative dehydrogenation of the ligand forming iron(II) complexes of tetraaza macrocycles,[897] which in some cases are isolable as the free ligand (Scheme 16). The high-spin five-coordinate halide complexes [Fe(Me_6[14]dieneN$_4$)X]$^+$ react with controlled amounts of oxygen to yield[830] intense blue precipitates in which oxidative dehydrogenation of the ligand is apparently accompanied by the tautomerization of the β-diimine to the α-diimine. This tautomerization also occurs to some extent during the oxidation of low-spin six-coordinate complexes with strong field axial ligands such as CN^-, NCS^- or imidazole.

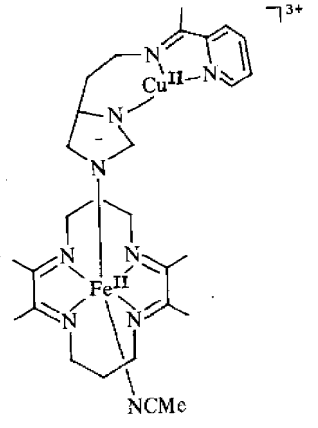
Scheme 16



Oxidative dehydrogenation of the fully saturated 14-membered tetraaza macrocycle iron(II) complex affords different products. Thus when $[Fe(Me_6[14]aneN_4)(MeCN)_2](BF_4)_2$ is oxidized in acetonitrile solution, the resulting complex contains[898] a macrocyclic tetraazatriimine ligand with one α-diimine group. If the BF_4^- salt is exchanged with NH_4PF_6, the resulting red-violet complex is further oxidized in basic acetone with the solution becoming deep blue. Extraction of the resulting mixture with chloroform, followed by acidification in acetonitrile and crystallization from ethanol saturated with NH_4PF_6, yields the violet complex of the corresponding tetraazatetraimine having two α-diimine groups as shown in Scheme 17. The axial acetonitrile ligands in the triimine complex **A** in Scheme 16 are readily exchanged[898] to give highly air sensitive products which are dehydrogenated by molecular oxygen to the corresponding tetraimine complexes (L = imidazole, SCN^-, NO_2^-, CN^-, CNH, CNMe and Cl^-).

Scheme 17

The analogous complexes $[Fe(TIM)L_2](PF_6)_2$ (TIM = **113**, R = Me; L = MeCN, imidazole) may be synthesized[899] from iron dichloride/tin dichloride and the reaction product of 2,3-butanedione and 1,3-diaminopropane in methanol followed by addition of acetonitrile. The X-ray crystal structure of $[Fe(TIM)(MeCN)_2](PF_6)_2$ has been determined[900] and the iron shown to be coplanar with the ligand. Both acetonitrile ligands in the burgundy-red low-spin complex may be exchanged for imidazole, or a single acetonitrile exchange for CO. Substituents on the macrocyclic ligand influence the redox potential[901] such that the iron(III) oxidation state is stabilized with increasing σ donor strength of the ring. The iron(II) oxidation state is stabilized with increasing π acceptor ability.



An $[Fe(TIM)L_2]^{2+}$ complex forms the starting point for the synthesis[902] of novel bimetallic

(113)

complex (**114**) in which an imidazole group bridges Cu^{II} and Fe^{II} atoms. It is thought such a system might mimic the interaction between the haem a_3 centre and the Cu(β) protein compounds of cytochrome oxidase. The kinetics of axial acetonitrile substitution by *N*-methylimidazole have been investigated[903,904] for the complexes $[Fe(TIM)L_2](PF_6)_2$ (R = Me, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, Ph; L = MeCN). The reactions proceed *via* a dissociative mechanism but whether the loss of the first or second acetonitrile is the rate determining step is the subject of discussion.

Activation parameters for this process are given in Table 19 together with data for the same reaction of complexes with two related macrocycles. For these complexes there is a linear free energy relationship between $\Delta S^{\neq}$ and $\Delta H^{\neq}$ but data for the equivalent complexes with ligands (**106**) and (**121**) (Table 19) are not within this correlation. However, there appears to be a relationship[905] between $\Delta H^{\ddagger}$ (or k_1) and the donor ability of the macrocyclic ligand as measured by the half-wave redox potentials of the complexes.

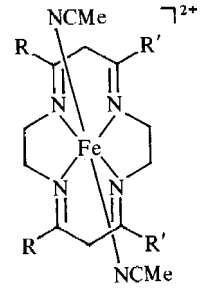
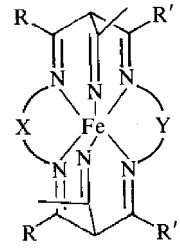
Iron(II) complexes of the dianion of the macrocycle Ph_2[14]tetraeneN_4 (**115**) have been prepared[906] by the convenient reaction of anhydrous iron(II) acetate with the free ligand in DMF. The iron(II) complex of the analogous Ph_2[16]tetraeneN_4 ligand is prepared in the same way but the preparation of the complex of the macrocycle of intermediate ring size Ph_2[15]tetraeneN_4 requires the presence of two equivalents of pyridine to assist in incorporation of the metal. Interestingly, these complexes are well-defined examples of intermediate spin state ($S = 1$) and have reduction potentials (in DMF at 25 °C) in the range −3.2 to −3.7 V. Oxidation of these complexes with Br_2 in chloroform affords the equivalent iron(III) complexes and reaction with diphenyl sulfide (with a catalytic amount of PhSH) gives the iron(III) benzene thiolate complexes in good yield.



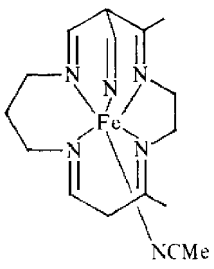
(115)



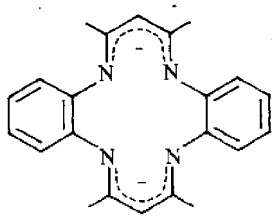
The macrocyclic ligands (**116**) may be synthesized by a modified Jaeger method (Ni^{II} template synthesis). These ligands react differently according to their ring size to form[907] complexes of iron(II). When the 14-membered ligands react with $[Fe(NCMe)_6]^{2+}$, a complex containing axial *trans* acetonitrile groups and a bis-β-diimine macrocyclic ligand (**117**) is formed. In the corresponding experiment with the 15- and 16-membered ligands however, acetonitrile molecules undergo an electrophilic reaction with the apical carbon atoms of the six-membered β-diimine moieties in the complex. The resulting compound is an iron(II) complex of a partially cyclized bis-β-triimine hexadentate ligand (**118**). The X-ray crystal structure[908] of (**118**) (R = Me, R′ = H, X = Y = $(CH_2)_3$) shows the six imine nitrogen donors to form a slightly distorted octahedron. The double bonds are localized (C—N average = 1.26 Å) and the macrocycle is folded to accommodate *cis* coordination of the iminoethyl groups.

(116)

(117)

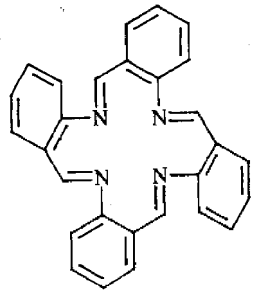


(118)



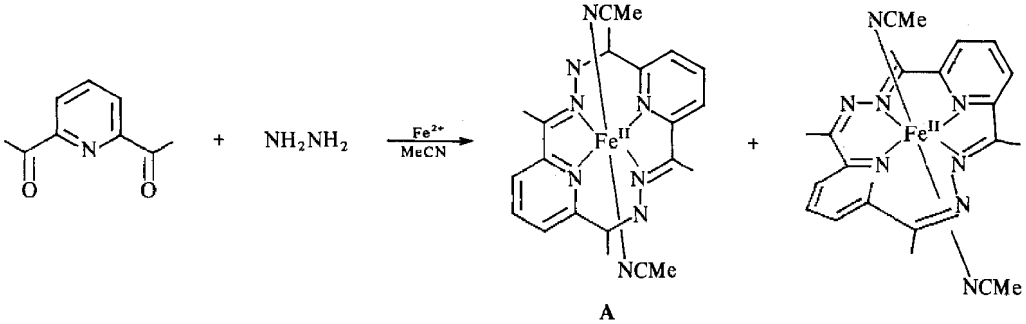
Both complexes (**117**) and (**118**) may be deprotonated (*e.g.* complex (**117**) by reaction with triethylamine in acetonitrile, complex (**118**) by reaction with Bu^tOK in Et_2O) to yield[909] novel square planar complexes of the corresponding dianionic tetraaza macrocyclic ligands. These unusual complexes exist in an intermediate $S = 1$ ground state. Subsequent reprotonation of the square planar complex of the 14-membered ring system [Fe(Me_2[14]tetraeneato(2−)N_4)] in acetonitrile regenerates complex (**117**). However, similar treatment of [Fe(Me_2[15]tetraeneato(2−)N_4)] yields a *trans* acetonitrile pentaimine iron(II) complex (**119**), whilst in the case of [Fe(Me_2[16]tetraeneato(2−)N_4)] the *trans* hexaimine analog of complex (**118**) is formed. Similar reactions in the presence of pyridine generate the expected *trans* pyridine tetraaza macrocyclic iron(II) complexes. Novel iron(III) complexes are generated[910] by the oxidation of the square planar tetraaza macrocyclic dianion iron(II) species.

The X-ray crystal structure[911] of the square planar complex of the dianion (**120**) shows that the ligand has a saddle shape, resulting from interaction between the methyl groups and the benzene rings. The structure of the free neutral ligand is remarkably similar to its structure in the complex. The average Fe—N bond distance is 1.92 Å (noticeably shorter than in equivalent $S = 0$ or $S = 1$ iron(II) porphyrin complexes) and the ligand conformation helps to place the iron atom 0.114 Å above the plane of the donor set. Iron(II) complexes of this ligand readily form[912] monocarbonyl complexes, with or without a second axial ligand. The geometry of the ligand allows for geometric isomers to be formed for complexes [Fe(L)(CO)(L′)] (L = **120**, L′ = amine *etc.*) depending upon which side of the ligand CO is coordinated to iron. For both L′ = NH_2NH_2 and the five-coordinate complex [Fe(L)CO], the CO ligand is located on the side of the macrocycle toward which the planar benzene rings are inclined. (This orientation is also observed[913] in the case of the iron(III) complex [Fe(L)Cl], L = **120**). In the case where L = py however, an X-ray crystal structure confirms[912] that



the CO is coordinated on the opposite side of the ligand. It is thought that this isomer may be more stable because steric interactions between the α-hydrogen atoms of pyridine and the macrocyclic ring are thus minimized. Iron(II) complexes of the tetraaza macrocycle (**121**) are reportedly formed[914] in low yield from the tetramerization of *o*-aminobenzaldehyde.

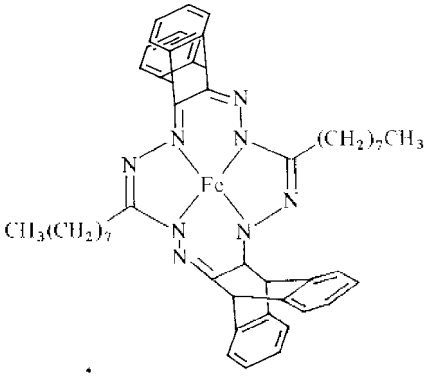
(119)



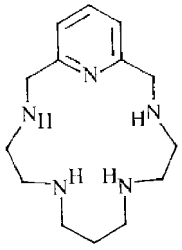
(120)

(121)

'Template condensation' has been used to obtain other fully conjugated macrocycles as their iron(II) complexes shown in Scheme 18. The reaction takes place readily over 20 minutes with the dropwise addition of hydrazine to a solution of 2,6-diacetylpyridine and $Fe(ClO_4)_2 \cdot 6H_2O$ in acetonitrile. The product separates as an intense blue-green precipitate.[915] Other six-coordinate low-spin complexes of these ligands are obtained with a variety of other axial ligands (NO_2^-, CO, Cl^-, Br^-, NCS^-, N_3^-). An X-ray crystal structure of complex **A** (Scheme 18) shows[915] that the macrocycle ligand is planar. The iron–nitrogen distances are somewhat compressed (1.899 Å and 1.892 Å) and the bond lengths of the macrocycle ring show a conjugated rather than an aromatic structure. The electronic spectrum argues for considerable delocalization, beyond that which would be expected based solely on the α-diimine linkages present in the molecule. The planarity of the macrocycle can, however, be disturbed[915] by the coordination of a bidentate ligand such as phen or bipy. In this case the 'puckering' of the ring causes the electronic spectrum to revert toward that characteristic of a tris-α,α′-diimine complex. The macrocycle (**120**) results from the template condensation of *o*-phenylenediamine with pentane-2,4-dione on nickel(II) after Jaeger. The hydrochloride salt of (**120**) (obtained free of Ni after treatment with HCl) forms[916] mono carbon monoxide complexes [Fe(L)(base)CO] (L = **120**, base = MeCN, py, 4-picoline, hydrazine) on reaction with anhydrous iron(II) salts under an atmosphere of carbon monoxide. An X-ray crystal structure of $[Fe(L)(NH_2NH_2)CO]$ shows[916] that, here too, the macrocycle is slightly saddle shaped (non-planar) as a result of steric interactions (*vide supra*[911]). The carbon monoxide is linear and shows a CO stretching frequency for a series of such complexes (1930–1940 cm^{-1}) slightly lower than that of carbon monoxyhaemoglobin (1951 cm^{-1}).

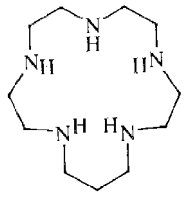


A



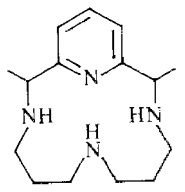
Scheme 18

The ability to exchange small ligand molecules in tetraaza macrocyclic complexes of iron(II) is relevant to the well-known reversible binding of molecular oxygen to haemoglobin.[917] The first such reversible binding of O_2 to an iron(II) complex was observed in 1973. Previously molecular oxygen was bound to iron(II) complexes irreversibly, usually with oxidation to iron(III) which was thought to proceed *via* the formation of an O_2-bridged dinuclear intermediate. The complex (**122**) was designed[918] to have a steric cage which would allow entry to O_2 but effectively prevent sufficiently close approach on the part of another iron(II) centre to form the bridged intermediate. The dark

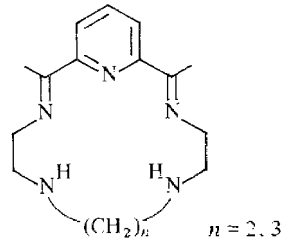


blue-black complex (**122**) reacts with one molecular equivalent of oxygen in THF/dimethoxyethane containing 4% pyridine to form a cherry red solution. When the complex was dissolved in toluene/1% pyridine and oxygen take-up was monitored by optical spectroscopy, it was found[918] to be reversible over a number of freeze–thaw cycles. An X-ray crystal structure[919] of complex (**122**) shows the iron coordination geometry to be essentially square planar with two relatively short Fe—N bond lengths (1.846 and 1.826 Å). The short bonds are probably due in part to the constricting nature of the macrocycle, which is itself slightly puckered. The deep 'pocket', which effectively prevents the formation of the dinuclear species, is evident. This has subsequently been shown to be a useful feature (though not a necessary one) for reversible oxygen uptake as is demonstrated by this behaviour in, for example, tetraphenylporphyriniron(II) (see Section 44.1.5.12.5). Iron(II) complexes of the ligands (**123**) and (**124**) have been prepared. The pyridine ring in (**123**) greatly stabilizes the reversible formation of a pink-violet oxygen adduct formulated[920] as $[(\{FeL\}^{2+})_2O_2]$ (L = **123**) in aqueous solution. By contrast the complex of the fully saturated ring (**124**) yields a very short lived oxygen iron(II) adduct and autooxidation is very rapid.

(122)



(123)



(124)

There are a series of macrocyclic ligands incorporating the pyridine moiety. The 14-membered macrocycle (**125**) forms[921] a series of high-spin five-coordinate iron(II) complexes $[Fe(L)X]^+$ (L = **125**; X = Cl, Br, I). The corresponding complexes where the monodentate ligands are azide or bidentate acetate are also high-spin but six-coordinate whilst the dithiocyanate complex is low-spin and six-coordinate (Table 20). The coordination numbers were identified on the basis of Mössbauer spectroscopy. Large ΔE_Q values in five-coordinate complexes of iron(II) are thought to arise from a combination of the nonspherical electron distribution about the iron nucleus and the dissymmetry of the ligand field. The assignment of a $^5B_2$ rather than a ^5E ground state (derived from the tetragonal distortion of an octahedral field) to iron in these complexes is supported by a magnetically perturbed Mössbauer study[922] on the five-coordinate high-spin complex $[Fe(Me_6[14]dieneN_4)Cl]ClO_4$. The ΔE_Q value for the acetate complex is similar to that found for high-spin six-coordinate iron(II) and it is assumed that the bidentate acetate ion causes some folding of the macrocycle. ΔE_Q values for the azide and thiocyanate complexes are consistent with high-spin six-coordinate and low-spin six-coordinate iron(II) complexes respectively.

Examples of seven-coordination in pyridine-containing macrocycles have also been osberved. Thus the iron(II) complexes $[Fe(L)X_2]\cdot xH_2O$ (L = **126**; X = halide or pseudohalide) are formed[923] when the corresponding seven-coordinate iron(III) complexes are reduced with aqueous sodium dithionite in the presence of excess NaX or by the direct template synthesis with 2,6-diacetylpyridine and the corresponding tetramine in the presence of iron(II). The triimine moiety gives rise to a strong

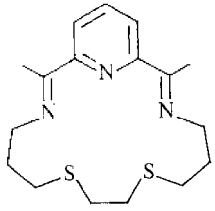
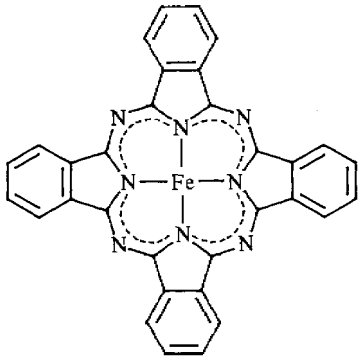
visible absorption derived from metal-to-ligand charge transfer; the complexes are deep blue or blue-green. An X-ray crystal structure[924] of the iron(II) dithiocyanate complexes of the 15- and 16-membered macrocycles (**126**) confirms seven-coordination with a distorted pentagonal bipyramidal geometry. The thiocyanate ligands occupy the axial positions and the macrocycle is somewhat puckered. Replacement of the anionic thiocyanate ligands with neutral water molecules makes almost no difference[925] to the structure.



The substitution of 3,6-dioxaoctane-1,8-diamine for 3,6-diazaoctane-1,8-diamine in a template synthesis with 2,6-diacetylpyridine on iron(II) yields the mixed donor macrocycle (**127**). This molecule also forms[926] a seven-coordinate iron(II) complex $[Fe(L)(NCS)_2]$ (L = **127**). This blue high-spin complex (room temperature magnetic moment = 5.44 BM) exhibits an electronic spectrum and electrochemical behaviour which indicate that the complex of the mixed donor oxygen-containing macrocycle stablizes the +2 oxidation state to a greater extent than the same complex of the corresponding macrocyclic pentamine. The seven-coordinate high-spin iron(II) complex $[Fe(L)(H_2O)_2]$ (L = **128**) of the related macrocycle (**128**) is formed by the condensation of 2,9-di-(1-methylhydrazino)-1,10-phenanthroline with 2,6-diacetylpyridine in the presence of fresh $FeCl_2 \cdot 4H_2O$. The X-ray crystal structure[927] of this complex clearly shows that the iron(II) atom is coplanar with the macrocyclic donor set.

(127)

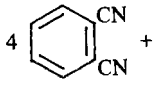
(128)



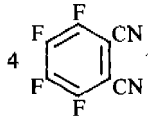
(129)

The Schiff base condensation of 2,6-diacetylpyridine with 4,7-dithiadecane-1,10-diamine yields the similar N_3S_2 macrocycle (**129**). This ligand is able to form complexes with iron(II) but its mode of coordination adapts to the monodentate coligand. Thus X-ray crystal structures[928] show that in $[Fe(L)(NCS)]^+$ and $[Fe(L)(MeOH)Cl]^+$ (L = **129**) the iron atom has a distorted octahedral geometry. In the first complex the macrocycle is quinquedentate and wraps around the iron atom. In the second complex the macrocycle is quadridentate with one sulfur atom weakly coordinated and one free. A compound with the formulation $[Fe(L)(NCS)_2]$ (L = **129**) has been observed[928] and evidently exists in three different forms (from IR, Mössbauer and magnetic data). Although X-ray structural data are not available on these isomers it is likely that they also reflect different ligand conformations of the N_3S_2 macrocycle.

44.1.5.12.4 Phthalocyanine



Iron(II) phthalocyanine (**130**) was originally discovered[929,930] by chance during the manufacture of phthalimide at the Grangemouth works of Scottish Dyes Ltd (subsequently part of ICI plc). Commercially, phthalocyanines are an important class of blue/green pigments and they are also used in some dyestuffs, having very good colour intensity with excellent light fastness as well as thermal stability and chemical inertness.[931–934] The iron(II) complex can be obtained by the heterogeneous reaction of iron salts with the parent macrocycle(metal-free)phthalocyanine[935,936] (PcH_2) in a high boiling basic solvent as in equation (79), or from the metal exchange reaction of Fe^{2+} with Li_2Pc in acetone[937] (equation 80). However, the best laboratory procedure makes use of the reductive cyclization of phthalonitrile with very finely divided iron generated from $[Fe(CO)_5]$ as in equation (81) in a high boiling solvent such as 1-chloronaphthalene.[938] Good yields of pure product are obtained over about an hour, and extensive washing with organic solvent removes remaining reactants and by-products. The same procedure enables the perfluoro derivative to be obtained from tetrafluorophthalonitrile (equation 82). Unlike the unsubstituted compound, the perfluoro derivative is soluble in several organic solvents, including acetone, to give intensely deep blue solutions.[839]

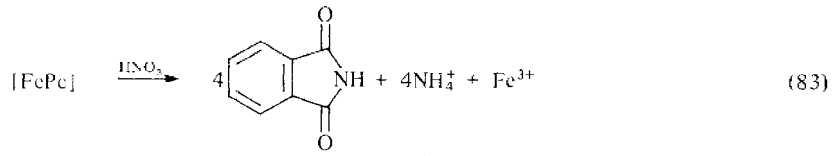


(130)

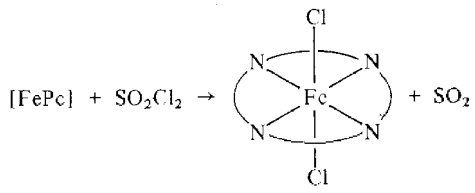
$$PcH_2 + Fe^{2+} \longrightarrow [FePc] + 2H^+ \quad (79)$$

$$PcLi_2 + Fe^{2+} \longrightarrow [FePc] + 2Li^+ \quad (80)$$

$$+ [Fe(CO)_5] \rightarrow [FePc] + 5CO \quad (81)$$



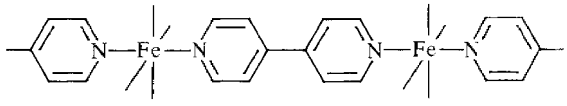
$$+ [Fe(CO)_5] \rightarrow [Fe(PcF_{16})] + 5CO \quad (82)$$



Solid phthalocyanine complexes of the first row transition metals exist in at least two well-characterized forms (α and β) that differ in the relative orientation of the macrocycle planes.[940,941] In the iron(II) complex, the resulting different intermolecular interactions give rise to differences in their Mössbauer spectra.[942] The most stable β-form is obtained as long purple needles by slow high-vacuum sublimation and the physical properties of this material have been studied in detail by many workers. Several groups have examined the magnetic properties of [FePc] and although all the measurements confirm the $S = 1$ intermediate spin state, there is some disagreement about the electronic configuration. One of the more exact Mössbauer determinations on a powdered sample over the temperature range 4.2–100 K was interpreted in terms of a ^3E_g ground state,[943,944] while other low temperature magnetic measurements are consistent with the $^3B_{2g}$ ground state.[945] However, the directly determined electron density distribution mapped from a set of accurate X-ray reflections collected at 100 K indicates ^3E_g as being the major contributor to the ground state.[946,947] This study also shows a deficiency of iron electron density along the axis perpendicular to the molecular plane, with an excess density along the diagonals of the Fe—N(pyrrole) directions. Magnetic circular dichroism spectra of [FePc] in dichlorobenzene could support a $^3A_{2g}$ ground state[948] and bands at 714 nm and 800 nm were assigned to metal–ligand charge transfer, although such spectra could be associated with protonated species.[949,950] Nevertheless, it may be possible that the ground state is not the same in the solid as in poorly coordinating solvents.

Iron(II) phthalocyanine is insoluble in most non-coordinating organic solvents but it does dissolve in very strong acids such as sulfuric and chlorosulfonic acids due to protonation of the basic bridging aza nitrogen atoms.[951,952] Although not soluble in hot hydrochloric acid, a reaction occurs which produces a dark material originally called[953] 'chloroferric phthalocyanine' and formulated [ClFePc]. Since this material is formed in the absence of air,[954] and even from gaseous hydrogen chloride,[955] it appears likely that it is a hydrochloride of iron(II) phthalocyanine ($FePcH^+Cl^-$) in which a bridging aza nitrogen atom is protonated. There is, however, evidence[956] indicating that when the reaction with hydrochloric acid is carried out in air some iron(III) species are formed, and it is possible that mixtures of protonated iron(II) complexes together with μ-oxo iron(III) dimers can be formed (see below). In warm concentrated nitric acid the first formed, purple, cationic radical species degrade to phthalimide and ammonium ion (equation 83).

Reaction of [FePc] with thionyl chloride produces [$FePcCl_2$], as in equation (84), which is considered to contain iron(III) and the oxidized macrocycle Pc^-, with chloride ions in the axial positions.[956,957] The overall oxidation level is confirmed by oxidative titration and the observed magnetic moment (3.1 BM) indicates a low-spin $S = \frac{1}{2}$ state. Considerable care is needed to exclude



(83)

(84)

traces of water during the preparation of [FePcCl$_2$] to avoid formation of the hydrochloride. However, once formed [FePcCl$_2$] appears stable towards water.[956] Although α-[FePc] does not react with nitric oxide, the β form after a long period at room temperature forms [FePcNO], which is quite stable.[177,958] [FePcNO] reacts with pyridine forming [FePcpy$_2$] and when heated at 250 °C [FePc] is reformed. The IR spectrum (ν_{NO} 1737 cm^{-1}) suggests it should be regarded as an Fe^{III}–NO$^-$ complex.

Addition of ligands in the axial positions of [FePc] takes place readily in solution to form six-coordinate low-spin complexes. Thus, [FePc] dissolves in pyridine to form a deep green complex [FePcpy$_2$] that is easily isolated and has moderate solubility in solvents such as chloroform and toluene.[959,960] Interesting one-dimensional polymeric bridged complexes (**131**) result when bidentate aromatic amines such as pyrazine or 4,4′-bipyridine are used.[961,962] In solution [FePcpy$_2$] reacts with CO to form [FePcpy(CO)],[963] as shown in equation (85), and diamagnetic red-violet crystals of [FePc(DMF)(CO)] are formed from phthalonitrile and [Fe(CO)$_5$] at moderate temperatures[964] in DMF, as in equation (86).

(131)

$$[FePcpy_2] + CO \longrightarrow [FePcpy(CO)] + py \quad (85)$$

$$[Fe(CO)_5] + 4o\text{-}C_6H_4(CN)_2 \xrightarrow{DMF} [FePc(DMF)(CO)] \quad (86)$$

[FePc(DMF)(CO)] is only stable in air for a few minutes, but it is stable under an atmosphere of carbon monoxide. In a vacuum at ~ 80 °C it decomposes to a mixture of α- and β-[FePc]. In DMSO, [FePc(DMSO)$_2$] reacts[965] with a large excess of carbon monoxide to form [FePc(DMSO)(CO)] at a rate given by $k_{obs} = k_f[CO] + k_r$ with an equilibrium constant of $\sim 1 \times 10^4$ dm^3 mol^{-1} at 20 °C. Related monocarbonyl complexes with *N*,*N*-diethylacetamide, pyridine, piperidine, hexamethylphosphoramide and Ph$_3$PO *trans* ligands have been reported.[966] Exposure of [FePc] in a hydrocarbon solvent to carbon monoxide at high pressure affords [FePc(CO)$_2$]. Other mixed ligand complexes of the type [FePcLL′] containing a range of ligands have also been isolated or characterized in solution (Table 21).[967–969] The structure of [FePc(4-Mepy)$_2$] has been determined[970] by X-ray methods and an Fe—N(4-Mepy) distance of 2.00 Å reported. A similar bond length of 1.94 Å was derived for the axial Fe—N in [FePc(BuNH$_2$)$_2$] from the induced shift of NMR proton resonances.[971] These structural determinations are in agreement with Mössbauer spectra of [FePcL$_2$] complexes.[972–974] Relatively large quadrupole splitting (Table 22) is in accord with a tetragonal structure with the in-plane ligand field being greater than the axial field. Moreover, with π acceptor ligands the π interaction is generally only weak. In the essentially diamagnetic [FePc(DMSO)$_2$] (0.74 BM) the iron is coordinated to the *sulfur* atoms of the axial DMSO ligands.[975] The in-plane Fe—N bond distances are similar to those in [FePc(4-Mepy)$_2$] and [FePc] itself, while the Fe—S distance of 2.31 Å suggests there is very little π back-donation.

The thermodynamics and mechanisms of axial ligand exchange in [FePcLL′] complexes shown in equations (87) and (88) have been extensively studied using visible spectroscopy. For L′ = substituted pyridines (L = DMSO) the binding strength order is 4-NH$_2$py > 4-Mepy > pyridine > 4-MeCOpy > 4-CNpy, which follows the Lewis basicity of the ligands and highlights the importance of σ bonding.[976] With nitrogen ligands of different types the order is imidazole > piperidine > pyridine indicating that π bonding must be important with the relatively poorly basic imidazole. But

with carbon monoxide, bonding is considerably weaker[963] than in iron(II) porphyrin complexes where π bonding is generally considered important. As expected, steric effects in [FePcLL′] complexes are important. Thus 2-methylpyridine and 2-methylimidazole only form very weakly bound complexes. This may indicate that displacement of the iron from the macrocycle core is more difficult with phthalocyanine than porphyrins. The rates of ligand exchange reactions in [FePcLL′] are moderately fast and must be studied by rapid mixing techniques such as stopped flow.[977–979] These reactions (equations 89 and 90) are dissociative in nature involving the coordinatively unsaturated [FePcL]. As evidenced by the ratio of the rate constants k_{-1}/k_2 the intermediate does discriminate between ligands, again suggesting the geometry to be square pyramidal with the iron centre in the macrocycle plane. Thus no spin change is required, which would be the case if the metal moved out of the plane. Depending on the relative values of the rate constants involved, this mechanism can result in reaction rates that are independent of the concentration of the incoming ligand [L″], (k_2[L″] > k_{-1}[L′]) or first order in [L″] (k_{-1}[L′] > k_2[L″]) and examples of both kinds of behaviour have been reported.[977–981] The rates of these reactions are significantly slower than the corresponding reactions of porphyrin complexes, which may be due to a higher charge on the iron atom, or the phthalocyanine being more rigid than the porphyrin ring system.

Reaction of [FePc] with sodium metal or dilithium benzophenone in THF affords reduced solvated species of the type M_n[FePc]·mTHF (n = 1–4). Magnetic and ESR measurements

suggest[982,241] the first formed product contains iron(I) and the more highly reduced compounds iron(0) with additional electrons being located on the macrocycle ligand. However, electronic spectra were subsequently interpreted[983] in terms of only iron(I) centres being present. The reduced compounds undergo oxidative addition reactions with organic halides to produce interesting organometallic iron species[982,241] and this work has recently been reviewed.[984] A recent electrochemical/ESR study of [FePc] indicates the first reduction product (purple) is a five-coordinate iron(I) species. The voltage between the first and second reduced species is significantly solvent dependent (~0.2 V in pyridine and ~0.6 V in dma), and again it is concluded the second product is an iron(I) complex of the reduced ligand Pc^{3-}, but not all of the earlier observations are completely explained.[244]

(132)

Among the water soluble derivatives of [FePc] the tetrasulfonated complex (**132**; R = SO_3^-) is the most studied although many aspects of its chemistry are not completely resolved. Direct sulfonation of [FePc] is not clean,[985] and it is better to start with 4-sulfophthalic acid in a cyclization procedure. Weber and Busch[986] formulated their product obtained in this way as the iron(II) complex $Na[FePc(SO_3H)_3(SO_3^-)]\cdot 3H_2O$, but other workers favour a mixture of iron(III) complexes,[987] $Na_3[FePc(SO_3^-)_4]\cdot 7H_2O$ and $Na_4[FePc(SO_3^-)_4(OH)]\cdot 2H_2O$. In solution a magnetic moment of 1.8 BM was reported and that of the solid 3.0 BM.[996] In solution, as with other phthalocyanines,[988] dimerization takes place, but here perhaps involving μ-oxo Fe^{III} dimers. When Fe^{2+} is added to a neutral solution of the tetrasulfonated metal-free ligand $\{H_2Pc(SO_3H)_4\}$ a green solution is formed[989] that has a visible spectrum characteristic of a first row transition metal complex (λ_{max} 671 nm), with a strong absorption at 425 nm similar to well-characterized $[FePcL_2]$ complexes. At pH = 6.5 this reacts with oxygen according to the 1:2 (O_2 to Fe) stoichiometry shown in equations (91) and (92). New bands at 637 nm and 344 nm due to the oxygenated complex disappear when the solution is purged with nitrogen at 70 °C. These results[989] favour the participation of an iron(II) rather than an iron(III) complex and it is of interest that it is possible to obtain reconstituted haemoglobins with tetrasulfonated iron phthalocyanine in the place of haem,[990] and furthermore that these complexes reversibly combine with oxygen. Continuous UV irradiation of sulfonated iron phthalocyanine in solution causes low quantum yield degradation of the macrocycle with liberation of Fe^{3+}, but in the presence of 2-propanol iron(I) species result.[991]

$$[FePc(SO_3^-)_4(H_2O)_2]^{4-} + O_2 \rightleftharpoons [FePc(SO_3^-)_4(H_2O)(O_2)]^{4-} + H_2O \quad (91)$$

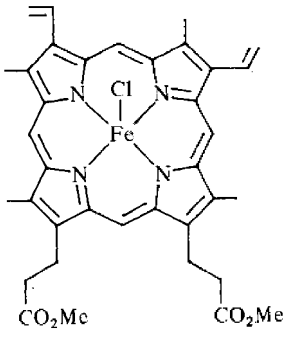
$$[FePc(SO_3^-)_4(H_2O)(O_2)]^{4-} + [FePc(SO_3^-)_4(H_2O)_2]^{4-} \rightleftharpoons$$

$$[(SO_3^-)_4PcFe(H_2O)(O_2)(H_2O)FePc(SO_3^-)_4]^{8-} + H_2O \quad (92)$$

The nature of products resulting from the reaction of oxygen with [FePc] itself has only recently been clarified. In 1965 Weber and Busch reported that the solid sulfonated complex reacts reversibly with oxygen.[986] The rigorously dried complex in the absence of oxygen displayed a magnetic moment of 4.80 BM, but only 3.08 BM in air. In contrast to the reversible oxygen carrying behaviour in solution discussed above,[989] Weber and Busch found the complex was oxidized in aqueous solution.[986] Reexamination of this system also led to the conclusion that irreversible oxidation takes place.[992] While very dilute solutions ($\sim 10^{-5}$ M) of [FePc] in DMSO slowly fade at a rate proportional to the concentration of oxygen,[977,978] more concentrated solutions form a precipitate[993] on standing which was subsequently identified as a Fe^{III} μ-oxo dimer.[994] In sulfuric acid, a kinetic study showed[995] the initial reaction of [FePc] with oxygen is reversible and the species formed decomposes irreversibly with formation of Fe^{3+} and oxidation of the macrocycle. Two crystalline forms of the μ-oxo dimer have been claimed on the basis of X-ray powder patterns and magnetic properties,[996] but the results of Mössbauer experiments indicated[997] that one of these is in fact a mixture of two species —perhaps a small amount of the μ-oxo dimer with an unidentified low-spin iron(II) complex. The quadrupole splitting for $[(FePc)_2O]$ is the smallest so far reported for a μ-oxo-bridged iron dimeric species. ESR data have also been interpreted[998] in terms of only one species. However, other evidence has very recently been presented[999] for the presence of two compounds. Preparatively, solid $[(FePc)_2O]$ is best obtained by the interaction of oxygen with [FePc] suspended in DMF or other solvents. The soluble substituted complex $[FePcR_4]$ (R = dodecylsulfonamide) forms $[(FePcR_4)_2O]$, which when irradiated with visible light is photoreduced to the iron(II) complex.[1000] Reaction with bases such as imidazole similarly causes reduction, and bis-base iron complexes are formed.[1000] $[(FePc)_2O]$ itself oxidizes PPh_3 to $OPPh_3$ in the presence of pyridine under mild conditions[1001] as in equation (93), and [FePc] is a catalyst for PPh_3 oxidation at room temperature if high pressures of oxygen are used.[1002]

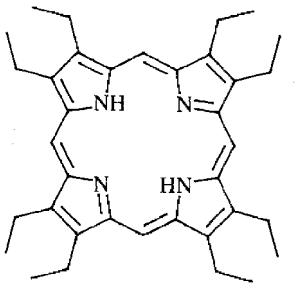
$$[(FePc)_2O] + PPh_3 \xrightarrow{py} 2[FePcpy_2] + OPPh_3 \quad (93)$$

Reaction of $[(FePc)_2O]$ or [FePc] with NaN_3 in 1-chloronaphthalene affords[1003] the highly insoluble, but stable, nitrido-bridged complex $[(FePc)_2N]$, which is more resistant to reduction than $[(FePc)_2O]$. Oxidation of $[(FePc)_2N]$ by strong oxidizing agents causes one-electron oxidation, and a PF_6^- salt can be crystallized in the presence of pyridine: $[(pyFePc)_2N]^+PF_6^-$. The electrochemistry of both $[(FePc)_2O]$ and $[Fe(Pc)_2N]$ in pyridine has been examined in considerable detail.[1004] A range of six-coordinate iron(III) phthalocyanine complexes of the type $[FePcL_2]^-$ ($L = OH^-$, OPh^-, NCO^-, NCS^-, N_3^-, CN^-) have been reported[1005–1007] that are low-spin with magnetic moments 2.05–2.49 BM. With halide and oxygen donor ligands five-coordinate complexes are formed [FePcX]



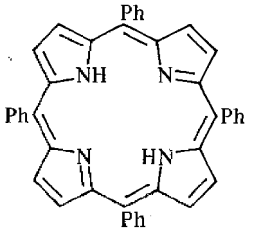
(X = Cl, Br, I, RCO_2, RSO_3) that have magnetic moments 3.9–4.53 BM indicative of $S = \frac{3}{2}$ or mixed spin states ($S = \frac{3}{2}, \frac{5}{2}$). Work on iron(III) phthalocyanine complexes has been hampered by their intractable nature and the use of derivatives soluble in organic solvents is likely to facilitate characterization. Recent examples of such ligands include a phthalocyanine having a long chain ester substituent (**132**) with R = $O_2C(CH_2)_9Me$. On the basis of magnetic (4.4 BM in CH_2Cl_2 and 5.0 BM in $CHCl_3$) and ESR results, the iron complex is assigned the +3 oxidation state. The mono-imidazole complex is also high-spin, but the bis-imidazole species is low spin. The formation constants for this process have $K_1 \gg K_2$.[1008,1009] The iron(III) complex of (**132**) (R = $O_2C(CH_2)_9Me$) and related phthalocyanines appears[1010] to coexist in high- and low-spin forms. Much needed X-ray structural data on iron(III) phthalocyanine complexes is now becoming available, for instance the structure of $[FePc(CN)_2]^-$ has been reported.[1011] Others are the products of [FePc] oxidation by iodine in hot chloronaphthalene: [FePcI] and a dimer $[FePcCl]_2I_2$. The former is a one dimensional molecular conductor that is best formulated as $[FePc]^{1/3+}$ $\frac{1}{3}(I_3^-)$ in which there are I_3^- chains. The dimer has a structure in which the chlorine atoms have been abstracted from the solvent. In this five-coordinate iron(III) complex, the iron atom is 0.3 Å above the plane of the inner nitrogens and the phenylene rings are slightly bent away from the iron atoms.[1012]

44.1.5.12.5 Porphyrins



The iron porphyrins and related compounds constitute an extremely important class of coordination complex due to their chemical behaviour and involvement in a number of vital biological systems. Over recent years a vast amount of work on them has been published. Chapter 21.1 deals with the general coordination chemistry of metal porphyrins, hydroporphyrins, azaporphyrins, phthalocyanines, corroles, and corrins. Low oxidation state iron porphyrin complexes are discussed in Section 44.1.4.5 and those containing nitric oxide in Section 44.1.4.7, while a later section in this chapter (44.2.9.2) is mainly concerned with iron(III) and higher oxidation state porphyrin complexes. Inevitably however, a considerable amount of information on iron(II) complexes is contained in that section as well as in Chapter 21.1. Therefore in order to prevent excessive duplication, the present section is restricted to highlighting some of the more important aspects of the coordination chemistry of the iron(II) porphyrins while the related unusually stable phthalocyanine complexes are discussed in the previous section.

Much of the older work (including some useful practical procedures) concerned with natural iron porphyrins is contained in Falk's classic book 'Porphyrins and Metalloporphyrins', which was published in 1964.[1013] Subsequently an enlarged multiauthor edition appeared[1014] that covered the literature to the end of 1974. Since then a number of reviews concerned with iron porphyrins have been published.[1015–1022] The most important recent books are the seven volumes entitled 'The Porphyrins' edited by Dolphin,[1015] and 'Iron Porphyrins' edited by Lever and Gray,[1016] while Berezin's book[1017] is a useful guide to some of the less familiar Russian literature.



The most widely studied natural complexes are those of protoporphyrin IX whose chloro iron(III) complex is readily available. This is often used as its dimethyl ester which is also commercially available and is known as hemin ester (**133**) and which is soluble in organic solvents. However, this and related compounds suffer irreversible photodegradation in the presence of oxygen, while water soluble derivatives are susceptible to acid-catalyzed hydration of the reactive vinyl substituents (the so-called mesoporphyrin has ethyl groups instead of vinyl groups). Moreover, until comparatively recently the exact nature of the species present in aqueous solutions was often poorly defined. Therefore the use of more stable and better characterized synthetic porphyrins in nonaqueous media has usually been preferred. The iron complexes of octaethylporphyrin (**134**) (OEP), 5,10,15,20-tetraphenylporphyrin (**135**) (TPP) and its derivatives are among the most widely studied, with TPP complexes being the most popular. A further problem with many metalloporphyrins is that they dimerize or aggregate in solution. The extent and type of aggregation depend on several parameters, but in general TPP complexes do not show these effects as markedly as natural porphyrins.[1023] Purple H_2TPP and its derivatives are prepared[1024] by the often vigorous reaction of pyrrole with benzaldehyde or another aromatic aldehyde. Although simple to perform, these reactions afford only moderate yields of product that may be freed from chlorin by chromatography on alumina. It is usual to insert iron(III) into the preformed macrocycle using acetic acid or DMF as solvent. Reduction of [XFeTPP] (typical X = Cl) by chromium(II),[1025] borohydride[1026] *etc.* gives the iron(II) complex. This can also be obtained[1027] from the free ligand *via* reaction with freshly prepared iron(II) propionate in propionic acid. Solid [FeTPP] is best purified by vacuum sublimation, which gives lustrous dark blue crystals; in noncoordinating solvent it is air sensitive.[1028] The solid-state

(133)

(134)

(135)

structure[1029] of [FeTPP] crystallized from benzene/ethanol has Fe—N bond lengths (1.97 Å) characteristic of an intermediate $S = 1$ spin state that is consistent with a room temperature magnetic moment of ~4.4 BM and low temperature Mössbauer data obtained in large magnetic fields. The structure has a slightly ruffled core with the phenyl rings rotated ~10° from being perpendicular to the porphyrin core. Other iron(II) four-coordinate porphyrins also have $S = 1$. The magnetic behaviour of readily purified [FeTPP] has been thoroughly investigated and this work has recently been reviewed.[1030] The structure of iron(II) octaethylporphyrin has been reported[1031] and compared with that of the corresponding chlorin. Both, like [FeTPP], have intermediate $S = 1$ spin states. Overall, however, there is surprisingly little published magnetic data for iron(II) porphyrins compared with that available for the iron(III) complexes.

Like related complexes, [FeTPP] reacts with many nitrogen bases to give low-spin bis-base species. The stability of these complexes is such that even refluxing iron(III) [ClFeTPP] in piperidine affords[1032] [Fe(TPP)(pip)$_2$] *via* a poorly understood process which may involve an axial radical ligand.[1033,1034] In the presence of pyridine addition of OH^- also induces reduction.[1035] This may involve addition of OH^- to coordinated pyridine.[1036] The structure of [Fe(TPP)(pip)$_2$] has been determined[1037] by X-ray methods and the rather long Fe—N(pip) bond distance of 2.127 Å attributed to steric interaction involving the piperidine NH. With bases having even stronger steric effects, such as 2-methylimidazole, mono-base high-spin five-coordinate complexes result[1038] that in this instance have a significantly shorter Fe—N(base) distance of 2.014 Å. In this complex the iron centre is displaced from the porphyrin core by about 0.5 Å, and there is also substantial doming of the porphyrin core itself.[1039] The molecular packing of [Fe(TPP)(2-Meimid)] has been examined in considerable detail[1040] The iron is similarly displaced from the macrocycle in [(ON)Fe(TPP)] (about 0.2 Å), which has a bent NO and is best described as a low-spin iron(II) complex.[1041,1042] Nitric oxide complexes of this type are capable of binding[1043] an axial nitrogen or sulfur ligand so becoming six-coordinate. The Mössbauer spectra of several five-coordinate protoporphyrin IX iron(II) complexes in frozen aqueous solutions display[1044] large quadrupole splittings (4.0 to 4.4 mm s^{-1}). The largest value is with acetone, but this complex is incompletely formed. The splitting order for the more stable complexes is F^- > catechol < phenol. In dichloroethylene the formation constant for the reaction[1045] of F^- with [Fe(TPP)] is ~600 M^{-1}. In organic solvents such as chloroform and benzene, iron(II) porphyrins are free of axial ligands and there have been several studies concerned with the thermodynamics of binding axial nitrogen bases, both in non-coordinating and donor solvents that are ligand replacement reactions (equations 94 and 95). The results of some early work[1046] concerned with measuring stability constants for these reactions may be in error due to incomplete reduction of iron(III) by hydrazine monohydrate. The successive equilibrium constants[1047] for binding pyridine to [Fe(TPP)] in benzene are $K_1 \sim 1.5 \times 10^3\ M^{-1}$ and $K_2 \sim 1.9 \times 10^4\ M^{-1}$ respectively. The larger value for K_2 is in keeping with the monopyridine complex being high-spin and the extra stability of the final product being associated with a transition to the low-spin state. In this instance the monopyridine intermediate is five-coordinate and may have a structure similar to that of [Fe(TPP)(2-Meimid)] with the iron centre displaced from the porphyrin plane. The redox self exchange rates for [Fe(por)B$_2$] complexes are rapid and rate constants for this process $\{Fe^{III}/Fe^{II}\}$ do not vary in a regular fashion with steric hindrance on the periphery of the macrocycle,[1052] although it is thought[1048,1049] electron transfer takes place *via* the edge of the macro-

$$[Fe(por)] + B \longrightarrow [Fe(por)B] \quad (94)$$

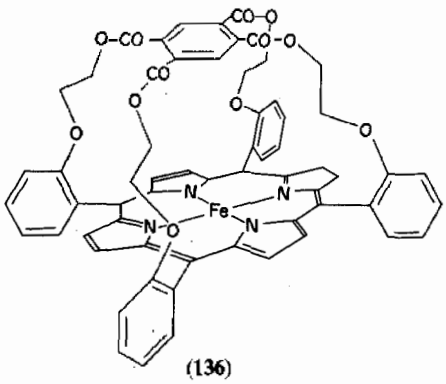
$$[Fe(por)B] + B \longrightarrow [Fe(por)B_2] \quad (95)$$

cycle in natural systems such as cytochromes.[1050,1051] The rates of thermal ligand substitution reaction are within the stopped flow range[1053] but photodissociation is extremely rapid and it appears only one ligand is released on excitation of the six-coordinate complex,[1054] in the primary process. The overall recombination kinetics can be complex due to spontaneous dissociation of the first formed five-coordinate complex.

Cyanide ion binds strongly[1056] to iron(II) porphyrins to give complexes typified by $[Fe(por)(CN)_2]^{2-}$ that are low-spin. In DMSO the intermediate complex $[Fe(por)(CN)(DMSO)]^-$ appears relatively stable. The self exchange rate for $[Fe(TPP)(CN)_2]^{2-/-}$ in DMSO is $5.8 \times 10^7 M^{-1}s^{-1}$ (27 °C) while cyanide exchange is relatively slow. The bis(isocyanide) complex $[Fe(TPP)(Bu^tNC)_2]$ has Fe—C bond distances of 1.90 Å and the Fe—C—N angle is significantly less than 180°, which may result from packing effects.[1058] Sulfur donors may also act as axial ligands; the X-ray structure analysis of the thioether complex $[Fe(TPP)(THT)_2]$ shows an Fe—S distance of 2.338 Å, very similar to that in related iron(III) systems.[1059,1060] With weak field axial oxygen donor ligands iron(II) porphyrins are usually high-spin, kinetically labile and susceptible to air oxidation (see below). In THF it appears [FeTPP] is mainly in the form of the five-coordinate species [Fe(TPP)(THF)].[1047] However, it is possible to crystallize $[Fe(TPP)(THF)_2]$ and, as might be expected, it contains[1061] substantially longer Fe—O bonds (2.31 Å) than do related low-spin complexes. Both bis-phosphite and bis-phosphine iron(II) porphyrins are low-spin, and Mössbauer data for a series of these complexes have been interpreted[1062] in terms of changes of the axial ligands causing substantial changes in the iron–porphyrin bonding. Thus the macrocycle ligand tends to act as an electron sink.[1063,1064] Aliphatic hydroxylamines react with [Fe(TPP)Cl] in the presence of pyridine to give[1065] the corresponding iron(II) pyridine nitroso complex. This reaction is shown in equation (96) for isopropylhydroxylamine, and treatment of the product with additional pyridine liberates acetone oxime with formation of $[Fe(TPP)(py)_2]$ as in equation (97).

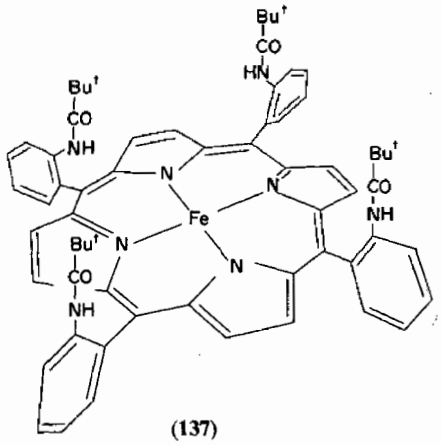
$$[Fe(TPP)Cl] + Me_2CHNOH/py \longrightarrow [Fe(TPP)(py)(Me_2CHNO)] \quad (96)$$

$$[Fe(TPP)(py)(Me_2CHNO)] + py \longrightarrow [Fe(TPP)(py)_2] + Me_2CNOH \quad (97)$$



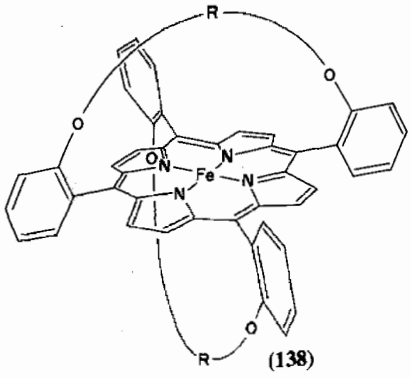
Carbon monoxide reacts[1066] with [Fe(TPP)] in toluene to give apparently low-spin [Fe(TPP)CO] and $[Fe(TPP)(CO)_2]$ with successive equilibrium constants of 6.6×10^4 and 140 respectively at 20 °C. Similar values have been reported for reaction of carbon monoxide with natural porphyrins.[1028,1067,1068] Simple bis-nitrogen base iron(II) porphyrins in noncoordinating solvents react with carbon monoxide as in equation (98) to give monocarbonyl complexes. The thermodynamics and kinetics for por = TPP have been studied[1069] in detail as well as for more complex sterically hindered porphyrins (see below). Considerable attention has been given to the reversible oxygenation of iron(II) porphyrins due to the importance of haemoglobin and related natural systems.[1070] (For an excellent review of the non-haem oxygen carrier hemerythrin, see ref. 1071). The unliganded iron(II)–porphyrin complexes, in the absence of a reducing agent, react with oxygen to form iron(III) μ-oxo dimers. The dimer $[(FeTPP)_2O]$ is now well characterized[1072] and intermediate adducts of the type $[Fe(TPP)O_2]$ have been observed[1073] using matrix isolation techniques. In the presence of excess nitrogen base there is no reaction with oxygen, but the simple bis complexes $[Fe(por)L_2]$ in dichloromethane at low temperatures (−79 °C) undergo oxygenation according to equation (99) that is reversed when the solution is purged with nitrogen. Solvent effects are important in this process. Thus in contrast to the behaviour in dichloromethane, oxygenation of $[Fe(TPP)py_2]$ is not complete in toluene under 1 atm oxygen pressure.[1069]

$$[Fe(por)L_2] + CO \longrightarrow [Fe(por)(CO)L] + L \quad (98)$$

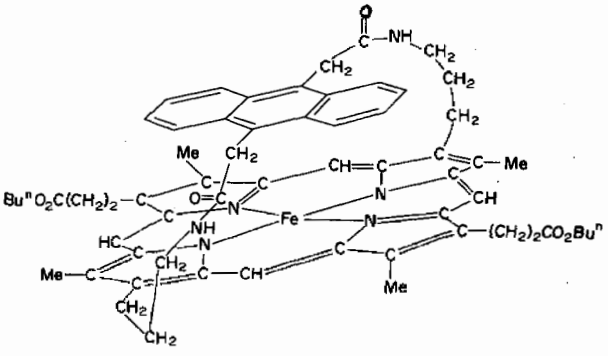


$$[Fe(por)L_2] + O_2 \longrightarrow [Fe(por)(O_2)L] + L \quad (99)$$

The rate determining step in these reactions with oxygen or carbon monoxide is dissociative loss of nitrogenous base from $[Fe(por)L_2]$ to generate a five-coordinate intermediate that rapidly reacts with either oxygen or carbon monoxide to generate the product. The five-coordinate intermediate shows no marked kinetic preference for nitrogen base or oxygen, reflecting the high reactivity of this species. However, in the presence of oxygen and carbon monoxide the five-coordinate intermediate has a kinetic preference for oxygen, although this first formed species subsequently converts to the thermodynamically favoured carbonyl product.[1069] The displacement of oxygen from $[Fe(TPP)(L)(O_2)]$ is also dissociative[1074] with the kinetic *trans* effect of L being pyridine > piperidine ≫ 1-methylimidazole. However, as solutions of the oxygenated complexes are

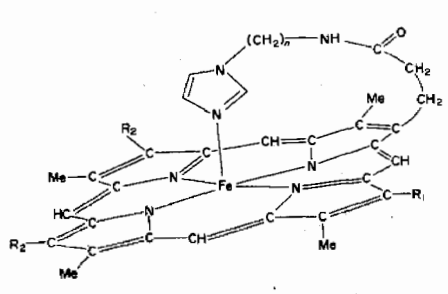


warmed to room temperature, oxidation rather than oxygenation becomes increasingly important. Embedding the porphyrin in a polymer matrix[1075,1076] or attachment to a surface[1077] inhibits μ-oxo dimer formation by physical separation of the iron centres and can yield systems capable of reversibly binding oxygen. Steric protection of the oxygen binding site itself can also inhibit the reactions that result in formation of iron(III) μ-oxo dimers. Examples of such complexes are the 'capped' porphyrins (**136**),[1078–1080] 'picket fence' porphyrins (**137**),[1081] 'basket handle' porphyrins (**138**)[1082] and the 'cyclophane hemes' (**139**)[1083] that have been extensively studied in connection with the biological iron(II) oxygen carriers myoglobin and haemoglobin.

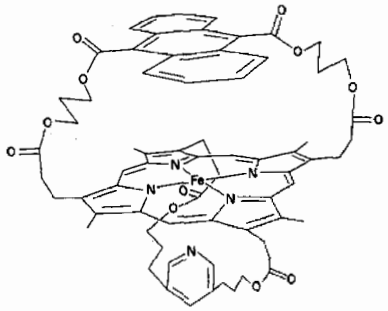


(136)

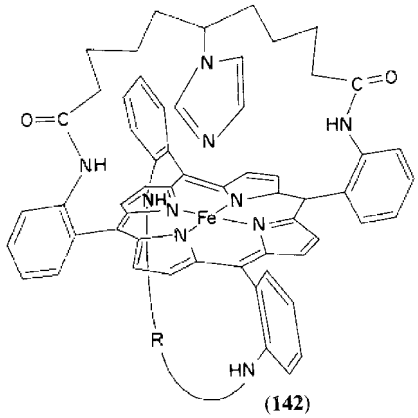
(137)



(138)



(139)

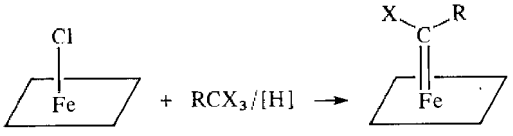


Reversible oxygenation of these complexes in solution usually requires the presence of an added axial ligand such as pyridine or 1-methylimidazole which coordinates to the unprotected face of the porphyrin, and so stops μ-oxo-dimer formation taking place from this side. Thiolate can also fulfil this role[1084–1087] as it does in cytochrome P-450. This fifth ligand site can be conveniently occupied by a nitrogen donor covalently bound to the macrocycle so effectively making the ligand quinquedentate. Complexes of this type include the 'tail base' or 'chelate heme' (**140**),[1088,1089] while those that involve two links to the base forming a more rigid system are typified by the 'double strapped' (**141**)[1090] and 'hanging base' (**142**) complexes.[1091–1093] Rigidity of the strapping groups can favour four- or five-coordination so eliminating the undesired oxidation reactions, but if too rigid, motion of the iron(II) centre can be inhibited resulting in decreased affinity for molecular oxygen.[1094]

(140)

(141)

(142)



The oxygen-binding properties of model complexes are similar to those of myoglobin and haemoglobin, although their affinity for carbon monoxide is much less than it is for most model complexes. It appears[1095,1096] this is due to steric constaints in the natural oxygen carriers that demand a bent or tilted geometry of the diatomic ligand. This is satisfactory for the inherently bent Fe—O—O group, whereas the linear Fe—C≡O group is significantly destabilized. This 'distal-side' steric hindrance involves imidazole and isopropyl groups in the globin chain. Similar effects have been observed with some sterically demanding model complexes.[1097] The rates of reaction of carbon monoxide with a range of five-coordinate iron(II) porphyrin species have[1098] reduced equilibrium constants for systems with severe steric effects. This is caused by slower reaction with CO rather than a change in the rate of dissociation from the six-coordinate complex.

However, a variety of quite subtle electronic and steric effects may be operative in these processes, including free movement of the iron (and if appropriate doming or ruffling of the macrocycle) when forming the five-coordinate intermediate, polarity and specific interactions such as hydrogen bonding at or near the binding site, as well as the electronic behaviour of the porphyrin and the influence of solvation. The importance of polarity is demonstrated by an amide strapped complex that has an affinity for oxygen an order of magnitude greater than that of the ether analogue,[1099] presumably due to enhanced stabilization of the charged $\{Fe^{III}(O_2)^-\}$ contribution to the oxygenated species. However, care in interpretation in such situations is needed because quite small steric changes can also be important. The nature of the *trans* axial base may also influence the O_2 affinity of iron(II) porphyrins. Early reports[1074,1100] suggested pyridine produces a weaker iron/O_2 interaction than does imidazole. This could be due to the decreased π basicity of pyridine compared with that of imidazole.[1101] With various 'capped' porphyrins the reverse is true[1102] and it has been concluded[1103] that, generally, substitution of pyridine for imidazole does not have large effects on carbon monoxide affinities. However, the relative differences induced by changing the base differ[1104] for binding CO and O_2. Clearly care is needed when trying to separate the importance of small electronic and steric changes in these systems. Often in these studies different solvents have been used. It has been shown[1105] for both an unprotected and a bis-pocket porphyrin[1106] whose 1,2-dimethylimidazole adduct has moderate affinity for reversible oxygenation, that solvent polarity enhances oxygen affinity but decreases carbon monoxide affinity. Here ΔG for oxygenation correlates well with empirical solvent parameters such as π^*. Earlier, it was noted[1107] that π donor/acceptor interactions involving the macrocycle do not influence carbon monoxide binding rates. As expected, the very large binding constants for nitric oxide to a series of iron(II) 'capped' porphyrins to form [Fe(por)(B)(NO)] (with bent Fe—N—O) correlate well with oxygenation data implying similar steric effects.[1108] In the absence of an axial base [Fe(por)(NO)] reacts with excess nitric oxide to give a product formulated[1109] as $[Fe(por)(NO^-)(NO_2^+)]$ as shown in equation (100).

$$[Fe(por)(NO)] + 3NO \longrightarrow [Fe(por)(NO)(NO_2)] + N_2O \qquad (100)$$

Several iron porphyrin carbenes are known[1110] that are obtained by the general reaction of the chloro iron(III) complex with RCX_3 (X = Cl, Br) in the presence of iron powder or sodium dithionite as in equation (101). The air sensitivity of the product depends on the nature[1111,1112] of R. Formally these complexes could be described as iron(II) species. They are diamagnetic, and can bond an additional axial ligand. The structure of the dichlorocarbene complex $[Fe(TPP)(CCl_2)(H_2O)]$ has been determined by X-ray methods,[1113] which showed a short Fe—C distance of 1.83 Å. This complex is reactive and, for instance, with primary amines a coordinated

isocyanide results. A novel bridged, or 'double carbene' [{Fe(TPP)}$_2$C] has been obtained from the use of CBr_4 in the reductive procedure shown in equation (101). Alkyl radicals react with iron(II) porphyrins to form [Fe(por)(R)]. Methyl radicals are captured rapidly, but chloromethyl radicals react slowly and it has been suggested[1114] this is a possible cause for the toxicity of chloromethyl compounds. Reaction of chloro iron(III) complexes with Grignard reagents also affords alkyl derivatives. Chemical oxidation of the phenyl complex [Fe(por)(Ph)] causes migration of the aryl group onto a pyrrolic nitrogen to form an iron(III) N-substituted complex. Reduction induces the reverse reaction, while the metal free N-substituted porphyrin is obtained on demetallation.[1115,1116] These transformations may be viewed as initial oxidation of the metal centre to Fe^{IV}, with the reverse reduction involving oxidative addition of NPh to an iron(I) centre. These and other reactions of an organometallic nature are the subject of a recent review.[1117]

Subject Index

Acetic acid, ethylenediaminetetra-, 253
Alkenes
  oxidation
    osmium tetroxide, 590
Alkynes
  reactions
    osmium tetroxide, 590
Amino acids
  reactions
    osmium tetroxide, 590
Analysis
  iron complexes, 1180
Aromatization
  iridium catalysts, 1160

Benzaldehyde, *o*-amino-
  self-condensation, 257
Bonds
  iron–germanium, 1189
  iron–lead, 1189
  iron–tin, 1189
  rhodium–rhodium, 903
    cleavage, 950

Catalases, 263, 264
Catechol dioxygenases, 230
Catechols
  reactions
    osmium tetroxide, 590
Chloromethyl compounds
  toxicity, 1270
Cobalt complexes, 635–882
  ADP, 760
  amides, 682
  arsenates, 774
  arsenic ligands, 767–775
  ATP, 760
  bipyridyl, 691
  bis(dithiolates), 876
  carboxylates, 790
  cyanates, 679
  cyanides
    reduction, 646
  disulfides, 829
  1,2-dithiolates, 871
  1,3-dithiolenes, 880
  nitriles, 674
  nitrito, 666
  nitro, 666
  nitrosyl, 657
    bonding, 663
    reactivity, 664
    structure, 663
    synthesis, 657
  oxygen ligands, 775–829
  peptides, 682
  peroxo, 775, 784, 785
  phenanthroline, 691
  phosphinates, 767
  phosphine oxides, 767
  phosphines, 701
    dinitrogen, 709
    hydrides, 704
    nitrosyl, 711
  phosphinites, 746
  phosphites, 704, 746, 766
  phosphoamidates, 766
  phosphonates, 766
  phosphonites, 746
  phosphoramides, 767
  phosphorus ligands, 699–767
  properties, 637
  pyrophosphates, 760
  reactions, 637
  selenates, 880
  selenites, 880
  selenium ligands, 880
  selenocyanates, 679
  selenophosphinates, 869
  silyl, 655
  structure, 637
  sulfenates, 833
  sulfides, 829, 849
  sulfinates, 833
  sulfur ligands, 829–880
    trans effect, 856
  superoxo, 775, 776, 781
  synthesis, 637
  terpyridyl, 691
