A range of other Ru^{III} edta complexes have been prepared starting from '$RuCl_2\cdot xH_2O$' and H_4edta *e.g.* $[RuCl(H_2edta)]$ and $[RuCl_2(H_3edta)]\cdot H_2O$[2540] or $K_2[RuCl_5(OH_2)]$ and $Na_2(H_2edta)$ *e.g.* $K[RuCl(Hedta)]\cdot 2H_2O$ and $K[RuCl_2(H_2edta)]\cdot H_2O$.[2536,2541]

Oxidation of $[Ru^{III}(edta)(OH_2)]^-$ by chlorate ion gives the green mixed valence, μ-oxo dimer $[(edta)Ru^{IV}ORu^{III}(edta)]^{3-}$ which can be reduced at a mercury electrode to $[(edta)Ru^{III}ORu^{III}(edta)]^{4-}$; facile decomposition of the latter to regenerate $[Ru^{III}(edta)(OH_2)]^-$ then occurs.[2542a] A preliminary report on the synthesis of $(Et_4N)_3$ $[LRu(\mu\text{-}OH)(\mu\text{-}O_2)RuL]$ (L = edta, Hedta) has also been published.[2543] The binuclear compound *trans*-$[Ru(NH_3)_4(NCS)LRu(edta)]$ (L = 4-vinylpyridine) has recently been synthesized.[2542b]

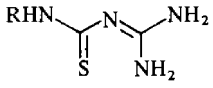
Finally, there is a brief report on the synthesis of the dark brown $[Ru^{IV}Cl_2(H_2edta)]\cdot 3H_2O$ {from $K_2[RuCl_6]$ and $Na_2(H_2edta)$}, which further reacts with acetate ion to give the violet complexes $M_2[Ru^{IV}Cl_2(edta)]\cdot xH_2O$ (M = K^+, x = 3; M = NH_4^+, x = 2).[2540]

45.11.1.6 Triazene 1-oxide complexes

The low spin Ru^{III} triazene 1-oxide complexes (**411**) (R = Et, X = Me, H, Cl, NO_2, CO_2Et; R = Ph, X = Me, H, Cl, CO_2Et) have been synthesized and assigned a meridional RuN_3O_3 coordination sphere. In MeCN, these complexes exhibit a quasi-reversible Ru^{III}/Ru^{II} and a nearly reversible Ru^{IV}/Ru^{III} couple and the electronic spectra of $[RuL_3]^-$ and $[RuL_3]^+$ are reported.[2544]

(411)

Treatment of (**411**) with either aqueous or gaseous HX (X = Cl, Br) gives the diamagnetic *trans,trans,trans*-$[Ru^{IV}X_2L_2]$ complexes, the first example of a Ru^{IV} chelate with centrosymmetric hexacoordination. Redox studies reveal that these compounds undergo stepwise reduction to $[RuX_2L_2]^{n-}$ (n = 1,2) and, furthermore, that the Ru^{III} monoanion loses halide ion to generate the redox active dimer $[L_2XRuXRuXL_2]^-$, ($[L_2RuX_2RuL_2]$).[2545]



45.11.2 N–S Ligands

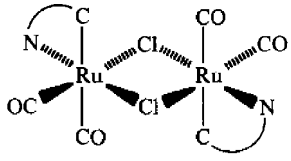
Reaction of $[RuCl_2(diene)]_n$ (diene = nbd, 1,5-cod) with 2(1*H*)-pyridinethione (pyridine-2-thiol), 2(1*H*)-pyrimidinethione or benzothiazole-2-thiol (2-mercaptobenzothiazole) (HL) in hot DMF in

the presence of $Na_2[CO_3]$ gives the chelate complexes $[RuL_2(diene)]$ (one isomer).[2222,2546] Treatment of these compounds with an excess of methyl iodide gives the iodide-bridged dimers $[RuIL(diene)]_2$.[2546] Other pyridine-2-thiol (pySH) and 2-mercapto-benzothiazole (mbtH) complexes such as $[RuCl_2(pySH)_2]_n$, $]Ru(pyS)_2(PPh_3)_2]$, $[Ru(mbt)_2(py)_2(CO)_2]$, $[Ru(mbt)py(CO)_2]_2$ *etc.* are described in Sections 45.5.4.8.i and 45.7.1. Reaction of $[RuCl_2(DMSO)_4]$ with mbtH gives $[RuCl_2(mbtH)_2(DMSO)_2]$. (Scheme 69, Section 45.7.9) while 2-aminothiophenol and $[RuCl_2(PPh_3)_3]$ afford $[Ru(chelate)_2(PPh_3)_2]$.[1706] Reaction of '$RuCl_3 \cdot xH_2O$' and 4-amino-3,5-dimercapto-1,2,4-triazole (H_2amt) gives $[Ru(Hamt)_2]$[2547] whereas 1,3,4-thiadiazole-2,5-dithiol produces polymeric ruthenium(II) and (III) complexes involving only S coordination.[2548] The reactions of 8-mercaptoquinoline with $[RuCl_2(bipy)_2]$ are discussed in Section 45.4.3.1.xiii.

Treatment of '$RuCl_3 \cdot xH_2O$' with 4-benzylamidothiosemicarbazide (btsc) and α-pyridylthiosemicarbazide (apt) gives the Ru^{III} cations $[RuCl_2(btsc)_2]Cl \cdot 2H_2O$ and $[RuCl_2(apt)_2]Cl$ respectively. With 1-benzilidine-4-α-pyridylthiosemicarbazone (bpt), $[RuCl_3(bpt)]$ is produced.[2549,2550]

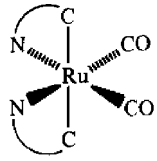
Reaction of '$RuCl_3 \cdot xH_2O$' with *N*-amidinothiourea (Hatu) or *N*-methylamidinothiourea (HNmatu) (**412**) in the presence of NO gives $[Ru^{II}Cl_2(atu)(OH_2)NO] \cdot 2H_2O$ and $[RuCl_2(Nmatu)(OH_2)(NO)] \cdot H_2O$ respectively. Further reaction with aqueous NaOH produces the corresponding nitro complexes $[Ru^{II}(NO_2)atu(OH_2)_3]$[2551] *etc.*

(412)



Thioformamido complexes containing tertiary phosphine ligands are discussed in Section 45.5.4.6.v.

45.11.3 N–C Ligands



Reaction of $[RuCl_2(CO)_3]_2$ with molten azobenzene (azbH) gives the chloride-bridged dimer $[Ru(azb)Cl(CO)_2]_2$ (**413**) which undergoes an extensive range of reactions involving chloride displacement and/or bridge cleavage.[1222,1250] For examples see $[Ru(azb)(CO)_2bipy]^+$ $[Ru(azb)Cl_2(CO)_2]^-$ (**91**) (Section 45.4.3.1.xiii), $[Ru(azb)(SPh)(CO)_2]_2$, $[Ru(azb)(abt)(CO)_2]$ (abt = 2-aminobenzenethiolate) (Section 45.7.1) and reference 3, p. 702.

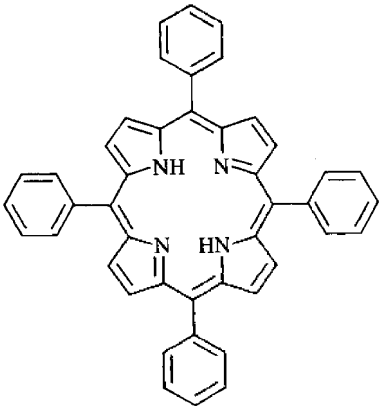
Related cyclometallated complexes $[RuCl(C–N)(CO)_2]_2$ (HC–N = 2-phenylpyridine,[2552] *N*-phenylpyrazole,[2552] PhCH=NMe,[2553] 2-(2-thienyl)pyridine[2554]) can also be synthesized from $[RuCl_2(CO)_3]_2$ and the appropriate ligand.

Some $[Ru(azb)(CO)_3]_2$ is obtained by reaction of $[Ru_3(CO)_{12}]$ with azobenzene,[2555] whereas treatment of $[Ru_3(CO)_{12}]$ with PhCH=NR (R = Me, Ph),[2553] azophenetole[2556] or benzo[*h*]quinolin-10-yl[2557] gives the monomeric $[Ru(C–N)_2(CO)_2]$. An X-ray analysis on the latter confirms structure (**414**).[2558]

(413)

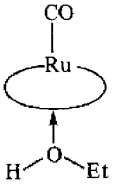
(414)

Finally, reaction of azobenzene with the methanolic ruthenium blue solution gives $[\{Ru(azb)Cl_2\}_2(\mu\text{-PhN=NPh})]$ which on treatment with PPh_3 in MeOH produces $[Ru(azb)Cl(PPh_3)_3]$.[676]



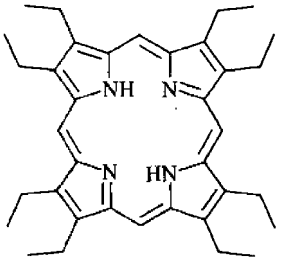
45.11.4 S–O Ligands

Monothio-β-diketonate complexes are described in Section 45.7.7 and monothio-carboxylate, -carbonate and -carbamate complexes in Section 45.5.4.8.5 and SO_2 complexes in Sections 45.4.1.2.iii.c and 45.5.4.8.vi.



45.12 MACROCYCLIC COMPLEXES

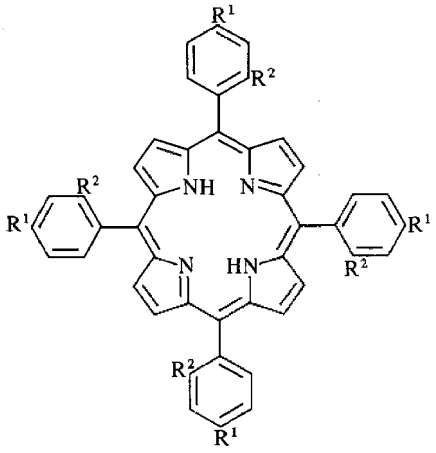
45.12.1 Porphyrins

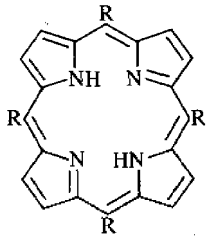


The chemistry of ruthenium porphyrins has been reviewed.[2559–2562] Reaction of $RuCl_3$ with H_2TPP (H_2TPP = *meso*-tetraphenylporphyrin, **415**) in refluxing ethanol/acetic acid under CO for 21 h yields an orange product originally formulated as $[Ru^{III}(TPP)(Cl)(CO)]$ with the ν_{CO} stretching vibration occurring near 1955 cm^{-1}.[2563] The complex was later proposed to be a ruthenium(II) species.[2564] A single crystal X-ray structural analysis of the product reported it to be [Ru(TPP)$(CO)_2$],[2565] but later it was correctly reformulated as the ethanol adduct [Ru(TPP)(CO)(HOEt)] (**416**) with Ru—O = 2.21, Ru—C = 1.77 Å and < RuCO = 175.8°.[2566] In non-coordinating solvents, the complexes [Ru(porph)(CO)(HOEt)] lose EtOH to yield [Ru(porph)CO] (porph = porphyrin dianion), the association constant K for [Ru(OEP)(CO)(HOEt)] (OEP = octaethylporphyrin, **417**) being estimated as 550 M^{-1} at room temperature in CH_2Cl_2 (equation 152).[2567,2568]

(415) H_2TPP

(416)

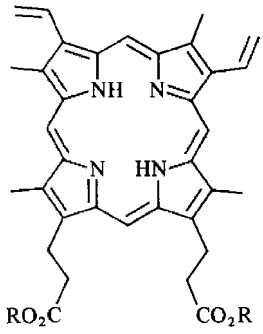




(417) H_2OEP

$$[Ru(OEP)(CO)] + EtOH \overset{K}{\rightleftharpoons} [Ru(OEP)(CO)(HOEt)] \quad (152)$$

Ruthenium(II) carbonyl complexes of the type [Ru(porph)CO] can be prepared by reaction of $Ru_3(CO)_{12}$ with H_2porph in toluene, decalin or benzene,[2566,2568–2576] $[RuCl_2(CO)_3]_2$ or $Ru_3(CO)_{12}$ with H_2porph in acetic or propionic acid,[2564] $RuCl_3$ with H_2porph under CO in 2-methoxy ethanol,[2567,2573,2577] or by reaction of $[Ru(porph)(CN)_2]$ with CO and N_2H_4 in MeOH,[2571] the product being purified by column chromatography. Porphyrin ligands that have been coordinated to ruthenium(II) include H_2TPP (**415**),[2566,2567,2570,2573,2576–2579] H_2OEP (**417**),[2567,2568,2571–2575,2577,2579,2580] substituted derivatives of *meso*-tetraphenylporphyrin, $H_2$4-XTPP (X = CF_3 (**418**),[2575,2580–2583] CH_3 (**419**),[2576,2577,2582,2583] Pr^i (**420**),[2566,2575,2580–2582,2584,2585] Cl (**421**),[2576,2582,2583] Br (**422**),[2576] F (**423**),[2576] MeO (**424**),[2576,2582,2583] Et_2N (**425**),[2582,2583] SO_3^- (**426**)[2569]), $H_2$2-XTPP (X = Me (**427**),[2580,2581] nicotinamide (**428**)[2586]), *meso*-tetramesitylporphyrin (**429**),[2581] *meso*-tetra-*n*-propylporphyrin (TPr^nP, **430**),[2573] *meso*-porphyrin IX dicarboxylic acid (**431**),[2587] dimethyl ester (**432**),[2570,2588–2590] dioctadecyl ester (**433**),[2591] etioporphyrin I (H_2EtioI (**434**)[2592,2593]) and myoglobin.[2587,2594,2595] Adducts [Ru(porph)(CO)L] can be readily prepared by addition of L to [Ru(porph)CO] {L = for example; py,[2566,2572,2578,2581,2585,2591] substituted pyridines,[2580–2585] 3-hydroxyaniline, benzylamine, pyrazole,[2585] 3,5-dimethyl pyrazole,[2584] 4,5-dimethyl pyridazine,[2584] 3,6-dimethyl pyridazine,[2584,2588] aliphatic amines,[2585] imidazole,[2570,2585,2588,2596] substituted imidazoles,[2585,2588] THF,[2575,2580,2583,2585,2592] H_2O,[2583] CO,[2575,2580] PPh_3,[2567,2568] PBu_3^n,[2568,2579] PBu_3^t,[2579] bidentate diphosphines,[2579] RS^- (R = Bu^t, Et, $MeO_2CCH_2CH_2$).[2171] The single crystal X-ray structure of [Ru(TPP)(CO)py] (**435**) shows Ru—C = 1.838 Å, Ru—N(py) = 2.193 Å, average Ru—N(TPP) = 2.052 Å, < RuCO = 178.4°.[2578] The strength of binding of CO to [Ru(porph)CO] is found to decrease in the order porph = OEP ≫ TPP > 4-Pr^iTPP > 4-CF_3TPP (equation 153), [Ru(OEP)$(CO)_2$] (**436**) being stable to loss of CO under vacuum over several hours.[2575]



The rates of phenyl ring rotation and ring current effects in ruthenium complexes of TPP derivatives have been probed by NMR spectroscopy.[2580–2582,2596] Exchange of 4-*t*-butylpyridine in [Ru(porph)(CO)(4-Bu^tpy)] (porph = 4-XTPP; X = Cl, Me, OMe, Et_2N, CF_3) occurs *via* a dissociative mechanism with $\Delta G^{\neq}$ = 77.4–82.8 kJ mol^{-1}, $\Delta H^{\neq}$ = 82.0–92.5 kJ mol^{-1} and $\Delta S^{\neq}$ = 21–42 J K^{-1} mol^{-1}.[2583] Multiple resonance studies on [Ru(porph)(CO)(imid)] show that imidazole tautomerism (equation 154) occurs *via* a dissociative, intermolecular exchange ($\Delta G^{\neq}$ = 76.5 kJ mol^{-1}),[2596] rather than intramolecularly as suggested previously.[2570,2588] Inter- and

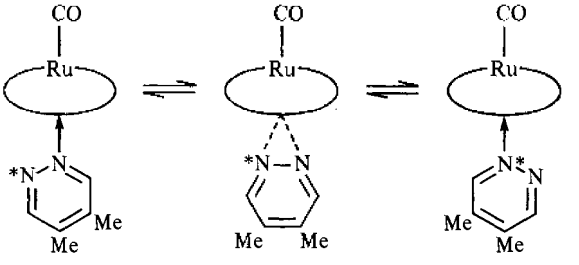
(435)

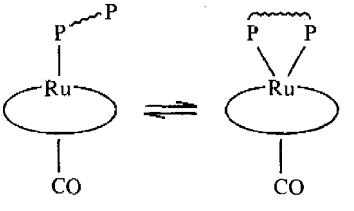
$$[Ru(OEP)CO] + CO \rightleftharpoons [Ru(OEP)(CO)_2] \quad (153)$$



(436)

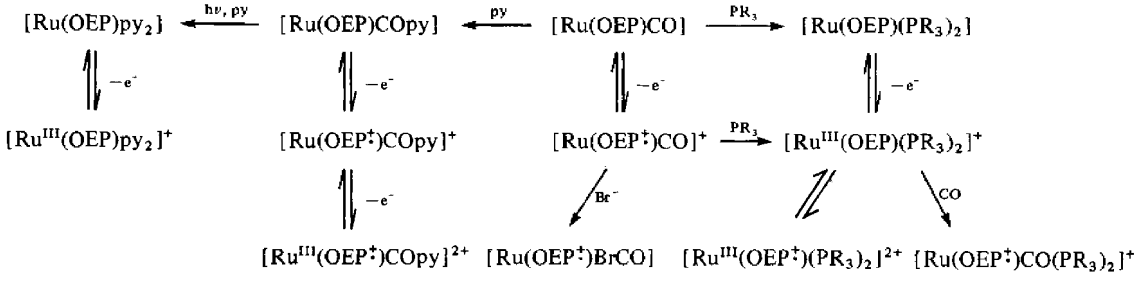
intra-molecular exchange reactions have been observed for 4,5- and 3,6-dimethylpyridazine adducts, intramolecular site exchange *via* a seven-coordinate ruthenium(II) intermediate (**437**) (equation 155) occurring at 20–85 times faster than intermolecular processes.[2584] ^{31}P NMR data for adducts of [Ru(OEP)CO] with bidentate phosphine ligands have been tentatively attributed to the formation of seven-coordinate adducts (**438**) (equation 156).[2579] A molecular orbital scheme for [Ru(porph)(CO)L] has been published.[2592]

The complexes [Ru(porph)(CO)L] generally show two, one electron oxidations and one, one electron reduction. For [Ru(OEP)(CO)(THF)] and [Ru(EtioI)(CO)(THF)], $^1E_{\frac{1}{2}} = +0.61$ and $+0.64$ V *vs.* SSCE respectively[2592] while for [Ru(4-XTPP)CO] (X = H, Me, MeO, F, Cl, Br), $^1E_{ox} =$ 0.74–0.86, $^2E_{ox} = 1.18$–1.27 and $E_{red} = -1.24$ to 1.35 V *vs.* SSCE in DMSO.[2576,2593] On the basis of electronic, IR and ESR data, the first oxidation has been assigned as ligand-based to give the π-cation radical $[Ru^{II}(porph^+)(CO)L]^+$.[2576,2592,2593,2597,2598] Interestingly the osmium analogue $[Os^{II}(OEP)(CO)py]$ is oxidized at the metal centre at $+0.4$ V *vs.* SSCE to afford $[Os^{III}(OEP)$-



(154)

(155)

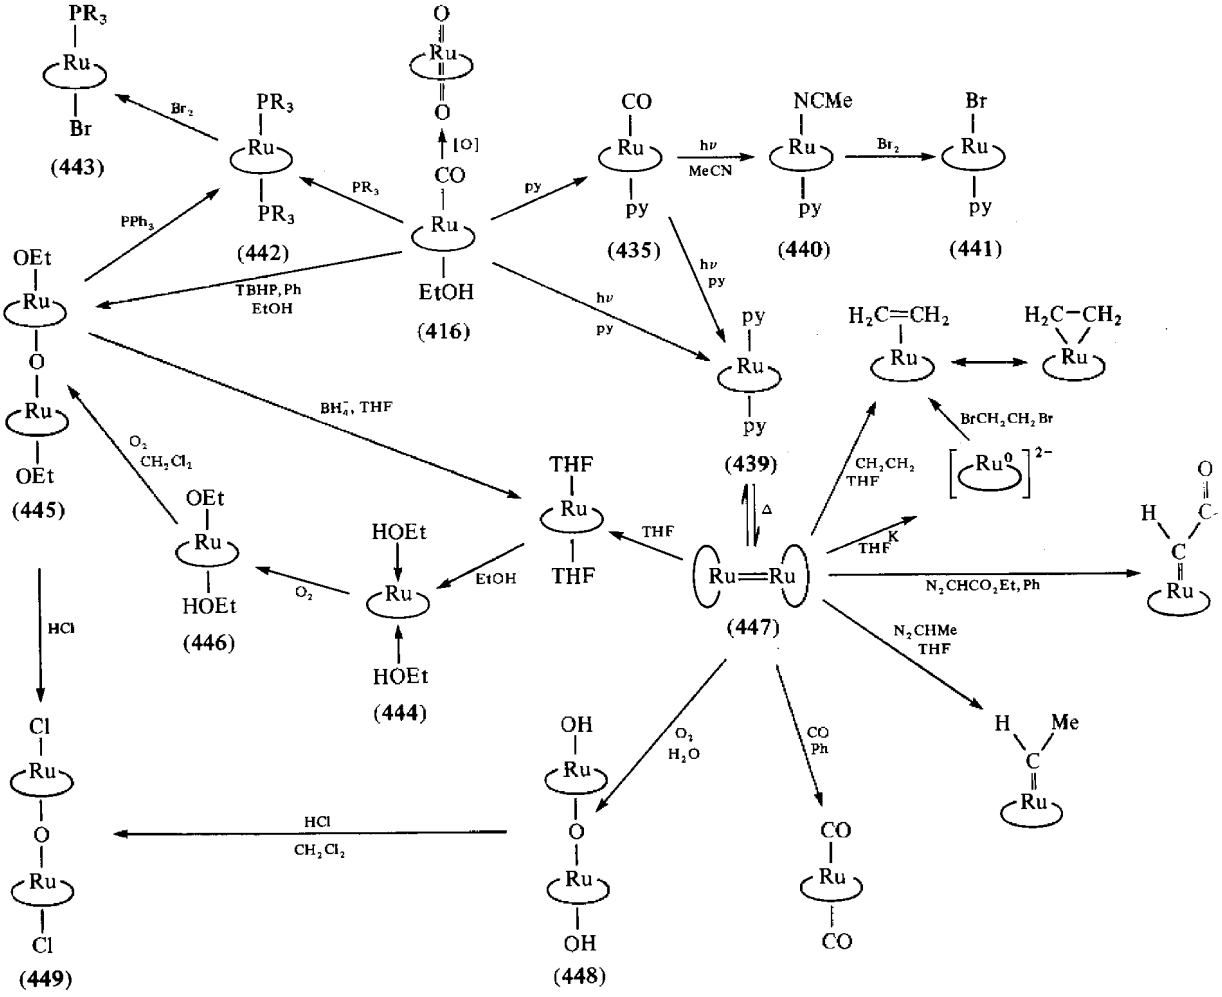


(437)

(156)

(438)

$(CO)py]^+$.[2592] The effect of variation of porphyrin ligand,[2597] solvation and axial ligation[2585,2599,2600] on the porphyrin ring oxidation has been assessed. The ^1H NMR spectra of π-cation radical complexes incorporating OEP and *meso*-porphyrin IX dimethyl ester have been reported and related to data on horseradish peroxidase and myoglobin derivatives.[2598] The second oxidation has been assigned to a metal-based redox couple to yield $[Ru^{III}(porph^+)(CO)L]^{2+}$, with the reduction process being sited on the porphyrin.[2576,2593] The stabilization of ruthenium(I) in the reduced complexes has also been proposed.[2601] For [Ru(4-Et_2NTPP)(CO)(4-Bu^{t}py)] three oxidation couples at $E_{\frac{1}{2}} = +0.50$, $+0.73$ and $+1.06$ V *vs.* SCE in CH_2Cl_2 are observed.[2597] Intramolecular electron transfer reactions between porphyrin and metal centres induced by changes in axial ligation have been studied and are summarized in Scheme 78.[2568,2592,2602,2603] For example, addition of Br^- to purple ($^2A_{2u}$ ground state) $[Ru(OEP^+)CO]^+$ yields green ($^2A_{1u}$ ground state) $[Ru(OEP^+)Br(CO)]$ which can be converted to $[Ru^{III}(OEP)(PBu^n{}_3)_2]^+$ on addition of $PBu^n{}_3$.[2568] Addition of CO to $[Ru^{III}(OEP)(AsPh_3)_2]^+$ yields $[Ru^{II}(OEP^+)(CO)(AsPh_3)]^+$ reversibly.[2603]



Scheme 78

Flash photolysis of [Ru(OEP)CO] has been investigated.[2604] The lifetime of the excited state species [Ru(porph)CO]* (porph = TPP derivatives) has been measured as $\sim 30\,\mu s$ with emission occurring near 730 nm.[2576] Oxidative and reductive quenching of [Ru(TPP)CO]* and related species has been reported, $E_{\frac{1}{2}}$ for the $[Ru(TPP)CO]^{*/+}$ redox couple being assessed as -0.57 V *vs.* SSCE.[2576] [Ru(TPP)CO] photocatalyses the generation of H_2 from H_2O in aqueous micellar solutions in the presence of hydrogenase,[2605] and catalyses the oxidation of sulfides to sulfoxides under O_2 at 100 psi ($7 \times 10^5\,kg\,m^{-2}$) and 100°C.[1375] $[Ru(4\text{-}SO_3TPP)CO]^{4-}$ has been reported to catalyse the water-gas-shift reaction.[2569]

Reaction of two equivalents of [Ru(TPP)CO] with one equivalent of 4,4′-bipy produces the binuclear species $[Ru(TPP)CO]_2 \cdot 4,4'\text{-bipy}$.[2584]

Photolysis of [Ru(porph)(CO)(HOEt)] at 300 nm in the presence of L yields $[Ru(porph)L_2]$ (L = py, porph = TPP,[2564] OEP,[2571,2572,2606–2608] Etio I,[2606] *meso*-porphyrin IX dioctadecyl ester;[2591] L = MeCN, porph = OEP, TPP;[2609] L = DMSO, porph = OEP[2608]). The single crystal X-ray structure of *trans*-$[Ru(OEP)py_2]$ (**439**) shows octahedral ruthenium(II) in the plane of the porphyrin ligand with Ru–N(py) = 2.1 Å.[2608] The resonance Raman spectrum of $[Ru(OEP)py_2]$ has been reported.[2610] Oxidation of $[Ru(porph)py_2]$ (porph = TPP, OEP) at $+0.08$ V *vs.* SSCE yields $[Ru^{III}(porph)py_2]^+$;[2592,2593] $[Ru(TPP)py_2]^+$ has been detected in redox quenching reactions of excited state $[Ru(TPP)py_2]^*$ with $[Ru(NH_3)_6]^{3+}$.[1245] Photolysis of [Ru(OEP)(CO)py] in MeCN yields [Ru(OEP)(NCMe)py] (**440**) which can be converted to [Ru(OEP)Brpy] (**441**) on oxidation with Br_2.[2611] Reaction of [Ru(OEP)Brpy] with $AgPF_6$ in MeCN affords $[Ru(OEP)(NCMe)py]^+$.[2611] Scheme 79 summarizes the synthetic routes to ruthenium porphyrins complexes.[2573,2607,2611]

Scheme 79

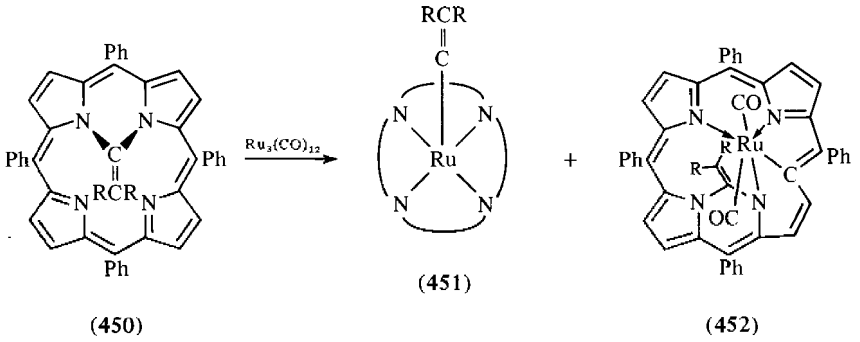
Refluxing solutions of [Ru(porph)(CO)(HOEt)] with phosphines L yields the complexes $[Ru(porph)L_2]$ (porph = OEP, TPP; L = PPh_3, $\frac{1}{2}PPh_3$, PBu^n_3, $P(4\text{-}MeOC_6H_4)_3$, $\frac{1}{2}P(4\text{-}MeOC_6H_4)_3$,[2564,2567,2568] PEt_3, PMe_2Ph, $P(OMe)_3$,[2601] bis(diphenylphosphino)methane (dpm), bis-(diphenylphosphino)ethane, bis(diphenylphosphino)butane, bis{(diphenylphosphino)ethyl}ethyl-

amine;[2579,2612] porph = 4-CF_3TPP, L = $P(OMe)_3$[2580]). The single crystal X-ray structure of *trans*-[Ru(OEP)(PPh_3)$_2$] (**442**) shows six-coordinate ruthenium(II), Ru—P = 2.438, Ru—N = 2.057, 2.044 Å with the central metal atom in the plane of the macrocyclic ring.[2567] An X-ray structural analysis of [Ru(TPP)(dpm)$_2$] shows monodentate dpm ligands with Ru—P = 2.398, Ru—N = 2.038, 2.045 Å.[2612] The dissociation of phosphine ligand L in the complexes [Ru(porph)L$_2$] has been assessed,[2567,2568] equilibrium constant $K = 1.2 \times 10^{-5}$ M for dissociation of [Ru(OEP)(PPh_3)$_2$] in toluene at room temperature (equation 157).[2613] [Ru(TPP)(PPh_3)$_2$] is an efficient catalyst for the decarbonylation of aldehydes.[2614]

$$[Ru(OEP)(PPh_3)_2] \rightleftharpoons [Ru(OEP)(PPh_3)] + PPh_3 \qquad (157)$$

The electrochemistry of bis-phosphine ruthenium porphyrin complexes has been reported (Scheme 78).[2568,2601–2603] Oxidation of [Ru(porph)L$_2$] (porph = OEP, TPP; L = PPh_3, $PBu^n{}_3$) affords the ruthenium(III) species [Ru(porph)L$_2$]$^+$ which converts to [Ru(porph)BrL] in the presence of Br^-.[2568,2602,2611] Likewise direct oxidation of [Ru(porph)(CO)L] or [Ru(porph)L$_2$] with Br_2, or HBr in air gives [Ru(porph)BrL].[2568,2602,2611] The complexes [Ru(OEP)ClL] have been prepared by an analogous procedure using Cl_2, or HCl in air.[2611] The single crystal X-ray structure of [Ru(OEP)BrPPh_3] (**443**) shows ruthenium(III) out of the porphyrin plane by 0.049 Å towards the PPh_3 ligand, with Ru—Br = 2.552 Å, Ru—P = 2.415 Å, Ru—N = 2.025–2.047 Å.[2611] Reduction of [Ru(OEP)BrPPh_3] by zinc amalgam yields [Ru(OEP)PPh_3].[2613] [Ru(OEP)BrPPh_3] in the presence of iodosyl benzene catalyses the oxidation of alkenes, cyclohexane and PPh_3.[2615] The ruthenium(IV) species [Ru(OEP)(O)] and [Ru(OEP$^+$)(O)Br] have been tentatively proposed as intermediates in the oxidation of PPh_3 to $OPPh_3$.[2615] The formation of ruthenium(I) species in the reduction of [Ru(TPP)(PR_3)$_2$] has been proposed.[2601]

Treatment of [Ru(OEP)py$_2$] with KCN over a prolonged period affords [Ru^{III}(OEP)$(CN)_2$]$^-$ which can be converted to [Ru(OEP)(CN)py] on reaction with py.[2574] Reduction of [Ru(OEP)(CN)py] with sodium amalgam in the presence of $CSCl_2$ yields [Ru(OEP)(CS)py]; the species [Ru^{II}(OEP)(CN)L]$^-$ (L = py, CO) have been identified in solution.[2574] Isocyanide adducts [Ru(porph)(CNR)$_2$] (porph = OEP, TPP, R = Bz;[2616,2617] porph = 4-CF_3TPP, R = Bu^t[2580]) can be isolated from reactions of [Ru(porph)CO] with RNC; for [Ru(TPP)(CNBz)$_2$], ν_{NC} = 2148 cm^{-1}.[2617] Addition of L (L = py, 1-methylimidazole, 4-*tert*-butylpyridine) gives [Ru(porph)(CNBz)L].[2616,2617] Kinetic measurements on axial ligand exchange in these compounds indicate that their lability increases in the order Ru(Pc) < Ru(porph) ≪ Fe(Pc) < Fe(porph) (Pc = phthalocyanine).[2616,2617]



Reaction of [Ru(porph)CO] (porph = *meso*-porphyrin IX dimethyl ester) with NO in benzene yields [Ru(porph)$(NO)_2$], ν_{NO} = 1786 and 1838 cm^{-1}.[2589,2590] [Ru(OEP)(CO)py] with NO in MeOH affords [Ru(OEP)(OMe)NO].[2572] The aryldiazonium adducts [Ru(porph)(N_2Ar)solvent]$^+$ (porph = TPP, Ar = Ph, 4-MeOPh, solvent = acetone; porph = TPP, Ar = 4-NO_2Ph, solvent = EtOH; porph = OEP, Ar = 4-NO_2Ph, solvent = EtOH) have been prepared by reaction of [Ru(porph)(CO)(HOEt)] with ArN_2^+ in refluxing CH_2Cl_2.[2618] The stretching vibration $\nu_{N\equiv N}$ occurs near 1800 cm^{-1} for these complexes.[2618]

The binding of O_2 to ruthenium(II) porphyrins has been investigated; the formation of adducts [Ru(porph)(O_2)py] (L = *meso*-porphyrin IX dioctadecyl ester)[2609] and [Ru(OEP)(O_2)(NCMe)][2591] has been reported. [Ru(OEP)PPh_3] and [Ru(OEP)(PPh_3)$_2$] react with O_2 in toluene to give $OPPh_3$, RuO_2 and H_2OEP.[2613] The reaction is thought to occur *via* initial binding of O_2 to [Ru(OEP)PPh_3] and subsequent formation of [Ru(OEP)OH]$_2$O as a proposed intermediate.[2613] An outer-sphere electron transfer between [Ru(OEP)(PPh_3)$_2$] and O_2 to give superoxide and Ru^{III} has been noted.[2611,2613] [Ru(TPP)(HOEt)$_2$] (**444**), prepared by reduction of [Ru(TPP)OR]$_2$O (**445**) with $NaBH_4$ in THF and addition of EtOH, is oxidized by O_2 to [Ru(TPP)(OEt)]$_2$O.[2573] [Ru(TPP)(OEt)(HOEt)] (**446**) can be isolated from the reaction (Scheme 79) and its single crystal X-ray structure shows a centrosymmetric Ru^{III} with Ru—O = 2.019 Å.[2573] Oxidation of [Ru(porph)]$_2$ (**447**) with O_2 in the presence of trace H_2O,[2607] or oxidation of [Ru(porph)CO] (porph = OEP, TPP) with *tert*-butylhydroperoxide[2619] gives the binuclear Ru^{IV} complex [Ru(porph)OH]$_2$O (**448**). An X-ray structural analysis of [Ru(OEP)OH]$_2$O shows a linear RuORu backbone with Ru—O(bridge) = 1.847 Å, Ru—OH = 2.195 Å, Ru—N = 2.067 Å with a staggered conformation of porphyrin rings.[2620] A range of related binuclear Ru^{IV} species [Ru(porph)X]$_2$O (porph = OEP, TPP, TPrP; X = Cl^-, Br^-, $^-$OAc, $CF_3CO_2^-$, HSO_4^-, $^-$OMe, $^-$OEt, 4-$^-OC_6H_4Me$, 2-$^-OC_6H_4OH$) have been prepared.[2573,2607,2619,2621] The single crystal X-ray structure of [Ru(OEP)Cl]$_2$O (**449**) shows a linear RuORu moiety with Ru—O = 1.793, Ru—Cl = 2.320, Ru—N = 2.038 Å,[2621a] while an X-ray structural analysis of [Ru(TPP)OR]$_2$O (OR = 4-OC_6H_4Me) shows < RuORu = 177.8°, Ru—O (bridge) = 1.789 and Ru—OR = 1.964 Å.[2573] Cyclic voltammetry of the binuclear Ru^{IV} complexes

$[Ru(OEP)X]_2O$ (X = Cl^-, Br^-, ^-OH) shows three, two electron redox couples in CH_2Cl_2 assigned to $Ru^{IV}Ru^{IV}/Ru^{III}Ru^{III}$ and $Ru^{III}Ru^{III}/Ru^{II}Ru^{II}$ processes and oxidation of the porphyrin rings.[2619] More recently, oxidation of [Ru(porph)CO] (porph = **429**) with MCPBA or iodosyl benzene has yielded the *trans*-dioxo ruthenium(VI) species $[Ru(porph)O_2]$ which reacts with $P(OMe)_3$ to give two equivalents of Me_3PO and $[Ru(porph)(P(OMe)_3)_2]$. Interestingly, oxidation of the tolyl complex (**419**) yielded the Ru^{IV} μ-oxo dimer, suggesting that steric hindrance of (**429**) is important for the generation of the mononuclear Ru^{VI} oxo derivative.[2621b]

Vacuum pyrolysis (210°C, 10^{-5} torr) of red $[Ru(porph)py_2]$ (**439**) yields a green dimeric product $[Ru(porph)]_2$ (porph = TPP, OEP, 4-MeTPP).[2577,2606–2608] The single crystal X-ray structure of $[Ru(OEP)]_2$ (**447**) shows Ru—Ru = 2.408 Å, Ru—N = 2.050 Å with the Ru^{II} ion 0.30 Å out of the plane of the porphyrin ligands which are twisted by 23.8° with respect to one another.[2577,2622] Paramagnetic shifts in the ^1H NMR spectra of these complexes have been analysed and related to a qualitative molecular orbital diagram suggesting a formal Ru—Ru bond order of two with an electronic configuration $a_{1g}^2 e_u^4 b_{1g}^2 b_{1u}^{*2} e_g^{*2}$.[2577,2622] The binuclear complexes bind CO in the presence of py to yield [Ru(porph)(CO)py].[2608]

The binding of first row metal ions Mn^{III}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} to [Ru(porph)CO] (porph = *meso*-tetra(2-nicotinamidophenyl)porphyrin, **428**) has been investigated by electronic spectra and cyclic voltammetry.[2586] Reaction of $Ru_3(CO)_{12}$ with (**450**) in refluxing THF for 3 h leads to metal insertion to yield (**451**), together with the complex (**452**), formed by oxidative addition of ruthenium into a pyrrole carbon–nitrogen bond (Scheme 80).[2623a] The single crystal X-ray structure of (**452**) shows *cis* carbonyl ligands on six-coordinate Ru^{II} with direct bonding of ruthenium to a carbon atom of the macrocyclic ligand (Ru—C = 2.086 Å) and a non-bonding pyrrole nitrogen atom.[2623a] Very recently, the synthesis of alkylidene and alkene complexes of ruthenium porphyrins has been reported;[2623b,c] reduction of (**447**) with K in THF yields a violet-black precipitate of the ruthenium porphyrin dianion $K_2[Ru^0(porph)]$ (Scheme 79).[2623b]

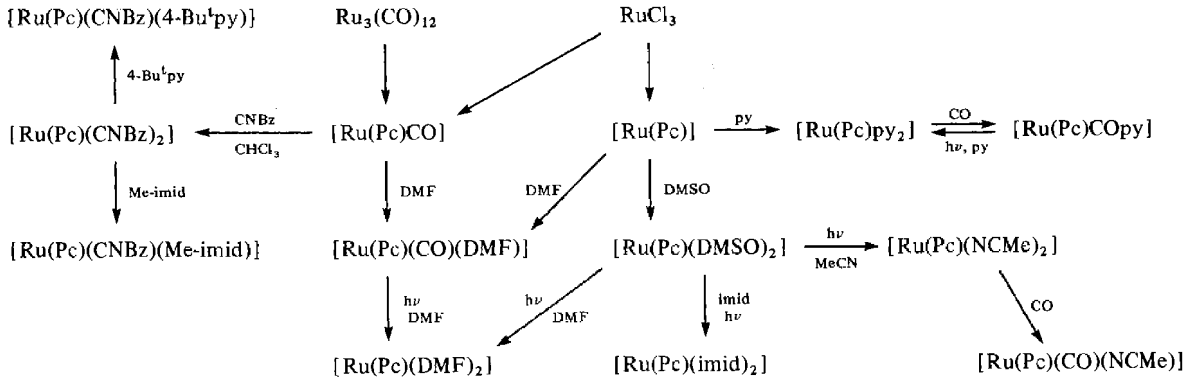


Scheme 80

45.12.2 Phthalocyanines

The coordination chemistry of the phthalocyanine dianion Pc^{2-} (H_2Pc = **453**) has been reviewed.[2562,2624–2626] Early work on the complexation of ruthenium by phthalocyanines reported the reaction of 2-cyanobenzamide or 1,2-dicyanobenzene with $RuCl_3$ to give '[Ru(Pc)]', '[Ru(Pc)Cl]' or '[Ru(ClPc)]'.[2627–2631] More recently treatment of $RuCl_3$ with 2-cyanobenzamide or 1,2-dicyanobenzene at 250°C for 4 h is reported to yield $[Ru^{II}(Pc)]$ together with $[Ru^{III}(Pc)Cl]$ as a minor product and less than 5% yield of [Ru(Pc)CO].[2632] Alternatively [Ru(Pc)] can be prepared by reaction of $RuCl_3$ with 2-cyanobenzamide in naphthalene at 290°C for 1 h,[2633] while the direct synthesis of [Ru(Pc)CO] has been achieved by treatment of $Ru_3(CO)_{12}$ or $RuCl_3$ under CO with 1,2-dicyanobenzene or H_2Pc at elevated tempeatures (greater than 200°C).[2632–2634] Extraction of [Ru(Pc)] and [Ru(Pc)CO] with ligands L affords the adducts $[Ru(Pc)L_2]$ (L = py,[2632,2633] 4-methyl pyridine,[2633] 4-*tert*-butylpyridine,[2633] aniline,[2627,2632] 2-methylaniline,[2627] PBu^n_3, $P(OBu^n)_3$,[2634] DMSO[2635]) and [Ru(Pc)(CO)L] (L = py,[2632,2633] 4-methyl pyridine, 4-*tert*-butyl pyridine[2633]) respectively. The species $[Ru(Pc)(DMSO)_2]$ is likely to incorporate S-bonded sulfoxide and has been found to be a useful precursor to a series of bis-adduct complexes $[Ru(Pc)L_2]$ (L = MeCN, py, imid, DMF) formed by photolysis of the DMSO adduct in the presence of L.[2635] Carbonylation of $[Ru(Pc)L_2]$ affords [Ru(Pc)(CO)L].[2633,2635] Refluxing solutions of [Ru(Pc)] in DMF gives [Ru(Pc)CO(DMF)] which can be converted to $[Ru(Pc)L_2]$ on photolysis in L.[2635] The polymeric pyrazine-bridged species $[Ru(Pc)pz]_n$ has been reported.[2636] Scheme 81 illustrates the synthetic chemistry of ruthenium phthalocyanines.[2617,2635]

(453) H_2Pc

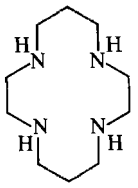
Scheme 81

For [Ru(Pc)COpy] $\nu_{C\equiv O}$ occurs at 1965 cm^{-1} compared with 1939 cm^{-1} for [Ru(TPP)COpy] indicating that back-bonding from Ru^{II} to CO is greater in the latter complex.[2632] Pc complexes are found to be less labile than the corresponding porphyrin species, ligand substitution occurring *via* a dissociative mechanism.[2617,2634]

The complexes [Ru(Pc)(CO)L] and [Ru(Pc)L_2] (L = py, 4-methylpyridine, 4-*tert*-butylpyridine, imid, MeCN, DMF, DMSO) each show a reversible one electron oxidation in CH_2Cl_2; $E_{\frac{1}{2}} = +0.91$ V and $+0.77$ *vs.* SCE for [Ru(Pc)COpy] and [Ru(Pc)py_2] respectively.[2635] Quantitative oxidation gives the π radical cation products [Ru(Pc^+)(CO)L] and [Ru(Pc^+)L_2] which have been characterized by electronic and ESR spectroscopy;[2635] the redox activity of ruthenium phthalocyanines have been compared to the corresponding porphyrin analogues.[2635]

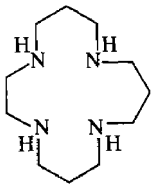
The photochemistry of [Ru(Pc)py_2][2637] and the quenching of excited state species [Ru(Pc)L_2]* (L = DMSO) and [Ru(Pc)(CO)L]* (L = py, DMF)[2638] have been investigated. [Ru(Pc)-{$(CD_3)_2SO$}$_2$] has been used as a ^1H NMR shift reagent.[2639] Protonation of [Ru(Pc)] at uncoordinated N atoms of the macrocyclic ring has been studied;[2628,2640,2641] '[RuPc]' has been found to catalyse the decomposition of H_2O_2,[2629] the oxidation of propene by O_2[2642] and the carbonylation of nitro compounds to isocyanates.[2643]

The exact nature of the complex '[Ru(Pc)Cl]' remains unknown. Formulations of a ruthenium(III) complex with axial Cl^-, [Ru(Pc)Cl],[2628] or a ruthenium(II) species with chlorinated Pc, [Ru(ClPc)],[2644] have been proposed, although ^1H, ^{13}C NMR and electronic spectral data appear to show no evidence for chlorination at the Pc ring.[5,2634] The complexes [Ru(ClPc)L_2] (L = PPh_3, py, methyl imidazole, $P(OBu^n)_3$, $P(Bu^n)_3$) have been reported.[2634,2644] The synthesis of [Ru{Pc-$(SO_3)_4$}]$^{4-}$ (H_2Pc-SO_3H = phthalocyanine tetrasulfonic acid) has been mentioned.[5]



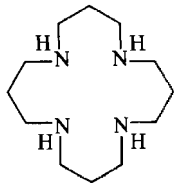
45.12.3 Tetraaza Macrocycles

A range of low spin, octahedral ruthenium(III) complexes incorporating tetraaza macrocyclic ligands have been synthesized. Reaction of $[RuCl_5(OH_2)]^{2-}$ with L in alcoholic solvent under reflux affords *trans*-[$RuCl_2$(L)]$^+$ (L = **454**–**463**).[632a,632b,634,2645–2649] Oxidative dehydrogenation of the coordinated macrocyclic ligand can occur[2646] and has been used to prepare *trans*-[$RuCl_2$(L)]$^+$ (L = **460** and **461**) by aerial oxidation of *trans*-[$RuCl_2$(L)]$^+$ (L = **458** and **459**) respectively.[2648] The single



crystal X-ray structure of *trans*-$[RuCl_2(L)]^+$ (L = **454**) shows distorted octahedral Ru^{III} with Ru—Cl = 2.343, Ru—N = 2.083 Å.[2647] ESR spectra of *trans*-$[RuCl_2(L)]^+$ (L = **454**) have been reported.[635] Reaction of $[RuCl_5(OH_2)]^{2-}$ with cyclam (**454**) in MeOH over three days yields a mixture of *cis*- and *trans*-$[RuCl_2(L)]^+$ which can be separated by ion exchange and gel filtration and characterized by UV–visible spectroscopy.[2645a] The single crystal X-ray structure of the *cis* isomer shows Ru—Cl = 2.371 Å with Ru—N = 2.104–2.117 Å.[2645b] Reduction of these products by zinc amalgam yields the corresponding Ru^{II} species ($E_{\frac{1}{2}} = -0.23$ V, -0.19 V *vs.* NHE for *cis*- and *trans*-$[RuCl_2(L)]^+$ respectively) which react with isn to afford *cis*- and *trans*-$[Ru(L)(isn)_2]^{2+}$.[2645a] *Cis*-$[RuX_2(L)]^+$ may also be prepared by reaction of $[Ru(ox)_3]^{3-}$ with L (L = **454**, **455**) in the presence of HX (X = Cl^-, Br^-).[633] More recently, the complexes *cis*-$[Ru(L)(L')_2]^{2+}$ (L = **454**, L′ = py_2, bipy, phen) have been synthesized.[2645b]

Substitution reactions of *trans*-$[RuCl_2(L)]^+$ to give *trans*-$[RuX_2(L)]^+$ (X = for example, Br^-, I^-, NCS^-, NO_2^-, OAc^-) by direct reaction with X^- or *via* reduction to Ru^{II} have been described.[632a,2646,2648,2649] The kinetics of ligand substitution in $[RuX_2(L)]^+$ and $[RuX_2(L)]$ (X = Cl^-, Br^-) have been measured and suggest a dissociative mechanism for Ru^{III} complexes with the rate of halide release decreasing in the order L = **459** > **458** > **454**.[638,2650] The acid and base hydrolysis of complexes of cyclam (**454**) have been studied and related to data for tetraammine, bis-en and related open chain species, an S_N1cb mechanism being operative for base hydrolysis.[634,636,637,2650]



The electrochemistry of the ruthenium macrocycles *cis*- and *trans*-$[RuX_2(L)]^{n+/(n-1)+}$ (L = **454–462**, X = Cl^-, Br^-, I^-, NCS^-, OH_2, NO_2^-) have been investigated; the $Ru^{III/II}$ couple was found to vary over the range -0.80 to $+0.83$ V *vs.* Ag/Ag^+ and was related to the electronic and steric effects of L and X.[633,639,2647] Kinetic data for the reduction of *trans*-$[RuCl_2(L)]^+$ (L = **454**, **455**, **458**, **459**) by Cr^{II} and V^{II} suggest that electron transfer occurs *via* inner- and outer-sphere mechanisms respectively.[644,645] The variation in redox properties of $[Ru(CN)_6]^{3-/4-}$ in the presence of macrocyclic polyamine receptors has been investigated.[29]

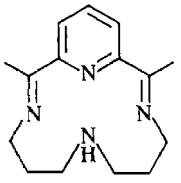
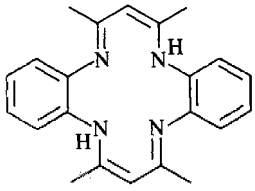
(462)



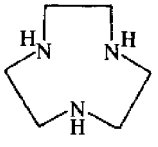
(463)



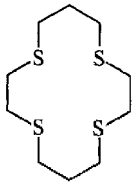
The absorption spectra of *trans*-$[RuX_2(L)]^+$ (L = **454–456**, **458**, **459**, X = Cl^-, Br^-, I^-) show two ligand to metal charge transfer bands. Irradiation at the lower energy CT band leads to stereoretentive aquation of X^-; the effects of L on the photoreactivity of these complexes have been discussed and related to their open chain analogues.[642]

Reduction of $[RuCl_2(L)]^+$ (L = **463**) at -0.20 V *vs.* SCE in aqueous 4-toluene sulfonic acid affords $[Ru(L)(OH_2)_2]^{2+}$ which can be oxidized to $[Ru^{IV}(O)(L)(OH_2)]^{2+}$ with H_2O_2 or electrochemically at 0.6–0.7 V *vs.* SCE. This latter species shows a Ru=O stretching vibration $\nu_{Ru=O}$ at 855 cm^{-1}.[2649a] More recently, this work has been further developed, the single crystal X-ray structures of *trans*-$[Ru^{IV}(O)(L)(NCMe)]^{2+}$,[2649b] *trans*-$[Ru^{IV}(O)(Cl)(L)]^{+}$[2649c] and *trans*-$[Ru^{VI}(O)_2(L)]^{2+}$[2649d] being reported. The chemical and electrochemical interconversion of these products has been achieved, and the oxidative activity of Ru^V analogues assessed.[2649c] The template synthesis of $[Ru(L)(OH_2)](ClO_4)_2$ (L = **464**) has been reported although the exact nature of this product is unknown.[2651a] Reaction of $[Ru_2(OAc)_4Cl]$ with LH_2 (LH_2 = **465**) in ethanol yields the

mixed valence $Ru^{II}Ru^{III}$ binuclear cofacial species $[RuL]_2^+$ (μ_{eff} = 1.55 BM) the single crystal X-ray structure of which shows Ru—Ru = 2.267 Å, with a formal Ru—Ru bond order of 2.5.[2120] Reduction of $[RuL]_2^+$ with $NaBH_4$ in ethanol affords the $Ru^{II}Ru^{II}$ dimer $[RuL]_2$ (μ_{eff} = 2.88 BM) with a Ru—Ru bond distance of 2.379 Å and formal bond order of two.[2120] Reaction with CO and py yields [Ru(L)(CO] and $[Ru(L)py_2]$ respectively.[2120]

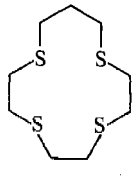


(464)

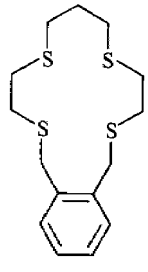


(465)

45.12.4 Triaza Macrocycles



A range of complexes incorporating the triaza macrocycle, 1,4,7-triazacyclononane (**446**), have been synthesized;[2651b] these include $[Ru^{II}Cl(L)(DMSO)_2]^+$, $[Ru^{II}(L)_2]^{2+}$, $[Ru^{III}X_3(L)]$ (X = Cl^-, Br^-) and $[Ru^{III}(ox)(I)(L)]$ and the binuclear species, $[Ru^{III}{}_2(L)_2(\mu\text{-}OH)_2(\mu\text{-}MeCO_2)]^{3+/2+}$, $[Ru^{III}{}_2(L)_2(\mu\text{-}OH)_2Cl_2]^{2+}$ and $[Ru_2(L)_2(\mu\text{-}Cl)_3]^{2+}$. The single crystal X-ray structure of $[Ru^{III}{}_2(L)_2(\mu\text{-}OH)_2(\mu\text{-}MeCO)_2]I_3 \cdot H_2O$ shows a short Ru—Ru bond distance of 2.572 Å, indicating the presence of a single Ru—Ru bond for the diamagnetic complex.[2651b] The electrochemistry of the binuclear complexes was investigated.[2651b]



(466)

(467)

(468)

(469)

45.12.5 Tetrathia Macrocycles

Reaction of $RuCl_3$ or $[RuCl_5(OH_2)]^{2-}$ with L (L = **467**–**469**) in 2-(2-ethoxy)ethanol for two days gives *cis*-$[RuCl_2(L)]^+$.[632a,639,2652] The complexes incorporating (**467**) were originally formulated as *trans* isomers on the basis of IR data,[2652] but were later reformulated as *cis* products;[2653] the single crystal X-ray of *cis*-$[RuCl_2(L)]$ (L = **467**) shows Ru—Cl = 2.471, Ru—S = 2.262, 2.333 Å.[2653] A range of substituted derivatives $[RuX_2(L)]^+$ (X = Cl^-, Br^-, I^-, NCS^-, NO_2^-, N_3^-) have been prepared and their electrochemistry investigated.[639,2652] More recently the reaction of $RuCl_3$ with (**467**) in ethanol for 2 h has been reported to afford a brown product *fac*-$[RuCl_3(L)]$ in which the macrocycle is though to be tricoordinate; treatment with LiBr in acetone yields *fac*-$[RuBr_3(L)]$.[2194]

ACKNOWLEDGEMENT

We are very grateful to Professors M. C. Baird, P. Braunstein, M. I. Bruce, B. Chaudret, D. J. Cole-Hamilton, J. P. Collman, E. C. Constable, F. A. Cotton, P. H. Dixneuf, V. L. Goedken, M. L. H. Green, G. A. Heath, B. R. James, A. Ludi, P. M. Maitlis, R. J. Mawby, D. W. Meek, T. J. Meyer, J. H. Nelson, R. K. Pomeroy, T. B. Rauchfuss, E. A. Seddon, K. R. Seddon, N. Sutin, H. Taube, L. M. Venanzi and G. Wilkinson for reprints and/or preprints of their work.

Osmium

WILLIAM P. GRIFFITH
Imperial College of Science and Technology, London, UK

46.1 INTRODUCTION 522
46.1.1 History 522
46.1.2 Reviews on Osmium 522
46.1.3 General Features of the Coordination Chemistry of Osmium 522
46.1.3.1 Oxidation states 522
46.1.3.2 Coordination numbers 523
46.1.3.3 The ligands in the complexes 524
46.1.3.4 Special aspects of osmium coordination chemistry 524

46.2 MERCURY AS A LIGAND 525
46.2.1 Osmium–Mercury Complexes 525

46.3 GROUP IV COMPLEXES 525
46.3.1 Cyanide Complexes 525
46.3.1.1 Osmium(I) 525
46.3.1.2 Osmium(II) 525
46.3.1.3 Osmium(III) 526
46.3.1.4 Osmium(IV) 526
46.3.1.5 Osmium(VI) 526
46.3.2 Fulminato Complex 526
46.3.3 Osmium–Tin Complexes 526
46.3.3.1 Complexes containing SnX_3^- and halo ligands 527
46.3.3.2 Complexes containing $SnCl_3^-$ and other ligands 527

46.4 NITROGEN LIGANDS 527
46.4.1 Ammine Complexes 528
46.4.1.1 Unsubstituted ammines, $[Os(NH_3)_6]^{n+}$ 528
46.4.1.2 Substituted ammines 529
46.4.2 Complexes with Monodentate Amines 530
46.4.3 Complexes with Bidentate Amines 530
46.4.3.1 Complexes with ethylenediamine 530
46.4.3.2 Complexes with deprotonated ethylenediamine 531
46.4.3.3 A complex of 2,3-butanediimine 533
46.4.4 Complexes with Nitrogen Heterocycles 533
46.4.4.1 Complexes of pyridine and of substituted pyridines 533
46.4.4.2 Complexes with chelating pyridines 534
46.4.4.3 Piperidine ($C_6H_{11}N$) complexes 535
46.4.4.4 Bifunctional heterocyclic donors 535
46.4.4.5 Tetrafunctional ligands 537
46.4.4.6 Polypyridyl complexes of osmium 537
46.4.5 Nitrosyl Complexes 544
46.4.5.1 $[Os(NO)]^5$ and $[Os(NO)]^6$ complexes 545
46.4.5.2 $[Os(NO)]^7$, $[Os(NO)]^8$ and $[Os(NO)_2]^8$ complexes 549
46.4.5.3 $[Os(NO)]^9$, $[Os(NO)]^{10}$ and $[Os(NO)_2]^{10}$ complexes 551
46.4.6 Complex of HNO 551
46.4.7 Diazenido Complexes 551
46.4.8 Thionitrosyl (NS) Complexes 552
46.4.8.1 Osmium(II) 552
46.4.8.2 Osmium(III) 553
46.4.9 Complex of NSCl 553
46.4.10 Dinitrogen (N_2) Complexes 554
46.4.10.1 Mononuclear complexes 554
46.4.10.2 Binuclear dinitrogen-bridged complexes 556
46.4.11 Hydrazine Complexes 556

46.4.12 Hydroxylamine Complex 557
46.4.13 Amino (NH_2) and Organoamido (NR_2) Complexes 557
46.4.13.1 Amino complexes 557
46.4.13.2 Alkanolaminato and diaminato complexes 557
46.4.14 Imido (=NH) and Organoimido (=NR) Complexes 557
46.4.14.1 Complexes with =NH 558
46.4.14.2 Complexes with =NR 558
46.4.15 Nitrido Complexes 560
46.4.15.1 Mononuclear complexes 560
46.4.15.2 Polynuclear complexes 563
46.4.15.3 Polynuclear complexes of mixed oxidation state 565
46.4.16 Triazenido Complexes 565
46.4.17 Azido Complexes 565
46.4.18 Complexes of Pseudohalide Ligands 565
46.4.18.1 Thiocyanato complexes 565
46.4.19 Nitrile Complexes 566
46.4.19.1 Osmium(II) 567
46.4.19.2 Osmium(III) 567
46.4.20 Miscellaneous Nitrogen Donor Complexes 567
46.4.20.1 Biguanide complexes 567
46.4.20.2 Benzotriazole complexes 568
46.4.20.3 Phosphineiminato (NPR_3) and phosphineaminato ($NHPR_3$) complexes 568
46.4.20.4 Other nitrogen donor complexes 569

46.5 PHOSPHORUS, ARSENIC AND ANTIMONY LIGANDS 569

46.5.1 Tertiary Phosphine Complexes 570
46.5.1.1 Phosphine hydrido complexes 570
46.5.1.2 Halo phosphine complexes 572
46.5.2 Tertiary Phosphite Complexes 575
46.5.2.1 Osmium(0) 575
46.5.2.2 Osmium(II) 575
46.5.2.3 Osmium(III) 575
46.5.2.4 Osmium(IV) 575
46.5.3 Phosphorus Trihalide Complexes 575
46.5.3.1 Osmium(−II) 575
46.5.3.2 Osmium(0) 576
46.5.3.3 Osmium(II) 576
46.5.3.4 Osmium(III) 576
46.5.3.5 Higher oxidation states 576
46.5.4 Tertiary Arsine Complexes 576
46.5.4.1 Hydrido arsines 576
46.5.4.2 Halo arsine complexes 576
46.5.5 Tertiary Stibine Complexes 577
46.5.6 Bidentate Phosphine and Arsine Complexes 578
46.5.7 Complexes with Polydentate Phosphines and Arsines 579

46.6 OXYGEN-CONTAINING LIGANDS 579

46.6.1 Aqua and Hydroxo Complexes 579
46.6.2 Osmium Oxo Complexes 579
46.6.2.1 Mononuclear complexes 580
46.6.2.2 Binuclear oxo-bridged complexes 593
46.6.3 Dioxygen, Superoxo and Peroxo Species 596
46.6.4 Alkoxo Complexes 596

46.1 INTRODUCTION

46.1.1 History

Since osmium was first isolated as the tetroxide, one of its most important and celebrated coordination complexes, a brief account of the history of its coordination chemistry is not out of place. The tetroxide, and subsequently the metal, was first isolated in 1803 by Smithson Tennant[1] (1761–1815) by distillation with nitric acid of the black material derived after *aqua regia* treatment of platinum metal concentrates. Of the tetroxide Tennant wrote:

> 'As the smell is one of its most distinguishing characters, I should on that account incline to call the metal *Osmium*'

(from $o\sigma\mu\eta$, a smell). Tennant narrowly escaped being overtaken by Fourcroy and Vauquelin[2,3] in the discovery of osmium. Early work on the coordination chemistry of the element was carried out by Berzelius,[4] but the most extensive of these early studies were those of Claus (1796–1864),[5] who in 1844 had discovered ruthenium.

46.1.2 Reviews on Osmium

The classic works of Gmelin[6,7] give the most extensive coverage of the coordination chemistry of the element, although the volumes on its organometallic chemistry have not yet appeared. The latest edition[7] covers the period 1939 to 1980 and the present author wrote the sections concerned with the coordination chemistry. There are other less comprehensive but useful sources of information. Pascal covers the literature up to 1958[8] while Mellor's treatise is still useful for the older work (up to 1936).[9] The author has written a book on the four rarer platinum metals (osmium, ruthenium, iridium, rhodium) covering the literature to 1967 and a short early review on osmium (1965);[11] Livingstone has written a book on the six platinum metals (1975).[12] There are recent reviews on the high oxidation state chemistry of osmium,[13a] and on standard potentials for osmium and ruthenium.[13b] Other reviews in the osmium chemistry of specific ligands are mentioned at appropriate points in the text. The organometallic chemistry of the element is of course covered up to 1982 in *Comprehensive Organometallic Chemistry* (vol. 4, p. 967).

46.1.3 General Features of the Coordination Chemistry of Osmium

It is hoped that these will become apparent as the text proceeds, so the following comments are very general.

46.1.3.1 Oxidation states

The three elements osmium, ruthenium and rhenium are distinguished from all others by the variety of the oxidation states which they display in their complexes, and of these three osmium is probably the most versatile in this respect. Examples of the main classes of complexes found for each oxidation state are listed in Table 1. It will be seen that all the states from VIII (d^0) to − II (d^{10}) are represented. It is this ability of the element to adopt different oxidation states at the behest of the surrounding ligands which gives osmium chemistry its special flavour and attractions. The principal reason for its versatility in this respect is surely its position within the block of transition metals in the Periodic Table. Its membership of the third row means that its outer ($5d$) orbitals are relatively exposed so that their electronic occupancy is susceptible to the nature of the coordinating ligands, and its central position within that third row means that attainment of the d^0 configuration typical of elements to the left, and of the d^{10} typical of elements to the right, are both possible for osmium. The element can thus be used as a convenient backdrop or exemplar of acceptor properties when discussing the donor properties of ligands. Thus, strong π donors such as F^-, O^{2-} and N^{3-}

favour high oxidation states (Os^{VIII}, Os^{VI}), strong π acceptors such as CO and NO^+ are associated with Os^{II} or Os^0 while NO^+ attains, in a formal sense at least, the Os^{-II} state. 'Conventional' ligands such as halide, ammonia and ethylenediamine tend to favour the III or IV states, while ligands with moderate π-acceptor capabilities (CN^-, bipy, phen) will tend to the Os^{II} (d^6) state.

Table 1 Oxidation States in Coordination Complexes of Osmium

Oxidation state	d^n	*Comments*	*Typical stabilizing ligands*	*Examples*[a]
VIII	d^0	Fairly rare but important	F^-, O^{2-}, N^{3-}	OsO_4, $[OsO_3F_3]^-$, $[OsO_3N]^-$
VII	d^1	Rare	F^-, O^{2-}	OsF_7, $[OsO_4]^-$, $OsOF_5$
VI	d^2	Relatively common	F^-, O^{2-}, N^{3-}	OsF_6, *trans*-$[OsO_2X_4]^{n-}$, $[OsNX_4]^-$
V	d^3	Rare	F^-	$[OsF_6]^-$, $[OsF_5]_4$
IV	d^4	Common	F^-, Cl^-, Br^-, I^-, OH^-, PR_3, OH^-, LR_3	$[OsX_6]^{2-}$, $[Os(NH_3)_4X_2]^{2+}$, *trans*-$Os(LR_3)_2X_4$
III	d^5	Common	Cl^-, Br^-, I^-, NH_3, acac, en, LR_3	$[OsX_6]^{3-}$, $[Os(NH_3)_6]^{3+}$, $[Os\ en_3]^{3+}$, $Os(LR_3)_3X_3$
II	d^6	Common	CN^-, bipy, phen, NO^+, terpy, LR_3	$[Os(CN)_6]^{4-}$, $[Os(bipy)_3]^{2+}$, $[Os(phen)_3]^{2+}$, $[Os(NO)X_5]^{2-}$, *trans*-$Os(LR_3)_4X_2$
I	d^7	Doubtful	? NO^+	$Os(NO)(PPh_3)_2Cl_2$
0	d^8	Fairly rare	CO, $P(OR)_3$, PF_3	$Os(CO)_5$, $Os_3(CO)_{12}$, $Os\{P(OR)_3\}_5$, $Os(PF_3)_5$
−I	d^9	Very rare	NO	$Os(NO)depe_2$
−II	d^{10}	Fairly rare	NO^+, CO, PF_3	$Os(NO)_2(PPh_3)_2$, $[Os(CO)_4]^{2-}$, $[Os(PF_3)_4]^2$

[a] L = P, As or Sb; R = alkyl or aryl; X = Cl, Br, I.

Since the oxidation state concept is so important for osmium we shall make extensive use of it as a means of classification of material within ligand groups, covering the lowest oxidation states first.

46.1.3.2 Coordination numbers

Osmium, and indeed all six platinum group metals, display rather little enterprise and versatility with respect to coordination numbers, although of course the ability to change coordination number lies at the heart of many catalytic reactions of platinum group complexes. The great majority of osmium complexes are octahedral. In Table 2 we give examples of the rarer coordination numbers. There are few examples of eight or seven coordination (nine coordination has not yet been observed for the element although its possibility for osmium has recently been briefly discussed[14]). There are examples of square-based pyramidal geometry, mainly for the higher oxidation states, and trigonal bipyramidal for the lower. Tetrahedral coordination is rare, though found both for osmium(VIII)

Table 2 Unusual Coordination Numbers for Osmium Complexes

Coordination number	*Examples*	*Page in text*	*Shape*
8	$[Os(en-H)_4]I_2$, $[Os(en-H)_3en]I_2$	531	Unknown
	$Os(PMe_2Ph)_2H_6$	571	Unknown
	? OsF_8	612	Unknown
7	$Os(edta)(H_2O)$	602	Monocapped octahedron
	OsF_7	612	Pentagonal bipyramidal
	$Os(PMe_2Ph)_4H_3$, $Os(PEt_2Ph)_4H_3$	571	Distorted pentagonal bipyramidal
	$[Os(PR_3)_4H_3]^+$, $Os(PPh_3)_3HCl_3$	570, 571	Unknown
5	$OsO(O_2R)_2$, $Os_2O_4(O_2R)_2$	584	Square-based pyramidal
	$[OsNX_4]^-$, $OsOCl_4$	563, 584	Square-based pyramidal
	$Os(PPh_3)_3X_2$	573	Square-based pyramidal
	$Os(CO)_5$		Trigonal bipyramidal
	$[Os(PF_3)_4H]^-$	576	Trigonal bipyramidal
	$Os\{P(OMe)_3\}_5$	575	Trigonal bipyramidal
4	OsO_4, $[OsO_4]^-$	588	Tetrahedral
	$[OsO_3N]^-$	562	Tetrahedral
	$Os(NO)_2(PPh_3)_2$	551	Distorted tetrahedral

(in OsO_4 and $[OsO_3N]^-$) and for osmium(−II) in $Os(NO)_2(PPh_3)_2$. Square planar coordination might be expected for osmium(0) (d^8) but does not seem to have been observed for it.

46.1.3.3 The ligands in the complexes

(*i*) *Group VII donors*

All four halide ions from octahedral complexes with the metal. Fluorides or fluoro complexes are known for osmium(VII) to osmium(IV) inclusive, with rather tenuous evidence for OsF_8; OsF_7 is a rare example of seven coordination for the metal. The other halides prefer the IV and III states, though osmium(V) chloride and chloro complexes have recently been made and also $[OsBr_6]^-$. Although $[RuF_6]^{3-}$ is well known there is no osmium analogue, in keeping with the general tendency of third-row elements to display higher oxidation states than their second-row partners.

(*ii*) *Group VI*

The oxo (O^{2-}) ligand is dominant in the coordination chemistry of osmium, participating in the VIII to IV oxidation states inclusive. The tetroxide OsO_4 is the single most important compound of osmium; OsO_4 and the recently discovered $[OsO_4]^-$ ion are tetrahedral. The *trans*-$[O{=}Os^{VI}{=}O]$ 'osmyl' moiety displays an extensive chemistry, comparable with that of the 'uranyl' O=U=O unit, and there is an extensive and unique cyclic oxo-ester chemistry (p. 584). There is surprisingly little information on hydroxo, aqua, sulfato, nitrato or phosphato complexes, but much recent work has been carried out on carboxylato species, and clearly much work remains to be done on the O-donor chemistry of the element. There are a reasonable number of sulfur-donor complexes but few with selenium or tellurium.

(*iii*) *Group V*

There are now a substantial number of nitrido complexes of osmium(VI) and osmium(IV) as well as the 'osmiamate' ion $[Os^{VIII}O_3N]^-$. In addition to the ammine and ethylenediamine complexes, much recent work has been carried out on the bipy, phen and terpy complexes, often in connection with research into the photodissociation of water. The nitrosyl chemistry of the element, though seemingly not as extensive as that of ruthenium, has received much attention, and there has been considerable work on the phosphine, arsine and stibine complexes.

(*iv*) *Group IV*

The wide area of osmium cluster carbonyl chemistry lies beyond the scope of this chapter (see refs. 15 and 16), though a few carbonyl complexes are covered, and of course there is full coverage of the cyanide chemistry of osmium.

46.1.3.4 Special aspects of osmium coordination chemistry

We have already alluded to the diversity of oxidation states, the dominance of oxo chemistry and the cluster carbonyls. Brief mention should be made too of the tendency of osmium (shared also by ruthenium and, to some extent, rhodium and iridium) to form polymeric species, often with oxo, nitrido or carboxylato bridges. Although it does have some activity in homogeneous catalysis (*e.g.* of *cis*-hydroxylation, hydroxyamination or amination of alkenes, see p. 558, and occasionally for isomerization or hydrogenation of alkenes, see p. 571), osmium complexes are perhaps too substitution-inert for homogeneous catalysis to become a major feature of the chemistry of the element. The spectroscopic properties of some of the substituted heterocyclic nitrogen-donor complexes may yet make osmium an important element for photodissociation energy research.

46.2 MERCURY AS A LIGAND

46.2.1 Osmium–Mercury Complexes

These are reported as 1:1 or 2:1 adducts with osmium phosphine or arsine complexes with mercury(II) chloride, but presumably involve Os—Hg—Cl units. They are the black $Os(PMePh_2)_3Cl_2 \cdot HgCl_2$, the white $Os(dppm)_2Cl_2 \cdot HgCl_2$ and the brown $Os(SbPh_3)_4Cl \cdot HgCl_2$, the grey $Os(PPh_3)_4Cl \cdot 2HgCl_2$ and $Os(dppe)_2Cl_2 \cdot 2HgCl_2$, the red $Os(dmpm)_2Cl \cdot 2HgCl_2$ and the black $Os(AsPh_3)_3Cl \cdot 2HgCl_2$. All are made from $(NH_4)_2[OsCl_6]$ and the phosphine, arsine and stibine ligands in water–methanol with $HgCl_2$.[17] Reaction of $Os(PEtPh_2)_3H_4$ and $Os(PEtPh_2)_4H_2$ with $HgCl_2$ gives unidentified species containing Hg:Os ratios of up to 9:1; evidence for the existence of $Os(HgCl)(PR_3)_3H(CO)$ and $Os(HgCl)_2(PR_3)_3(CO)$ (PR_3 = PMe_2Ph, PEt_2Ph) was presented.[18]

46.3 GROUP IV COMPLEXES

The chemistry of osmium is dominated here by the cyanide ligand; there is one fulminato complex, and a number of species containing Os—Sn bonds.

46.3.1 Cyanide Complexes

The cyanide ligand is a good σ donor and a fairly effective π acceptor,[19,20] so it is not surprising that the most stable osmium cyano complex is the d^6 species $[Os(CN)_6]^{4-}$, while $[Os(CN)_6]^{3-}$ (d^5) is fairly strongly oxidizing. In *trans*-$[OsO_2(CN)_4]^{2-}$ (p. 582) and *trans*-$[OsN(CN)_4H_2O]^-$ (p. 562) it is likely that the high oxidation state is sustained by the π-donor oxo ligands (the high ν_{CN} IR frequencies, 2151 cm^{-1} in $[OsO_2(CN)_4]^{2-}$[21] and 2155 cm^{-1} in $[OsN(CN)_4(H_2O)]$,[22] suggest that there is relatively little π bonding in these Os—C linkages).

Cyano complexes of osmium, amongst other transition metals, have been reviewed.[19] There is a brief section on osmium cyano complexes in ref. 16, p. 976.

46.3.1.1 Osmium(I)

A species believed to be $[Os(CN)_5]^{4-}$ can be generated by electron bombardment of $[Os(CN)_6]^{4-}$ in a KCl matrix at 77 K.[23] It was detected by EPR; if genuine it is one of the very few examples of monovalent osmium.

46.3.1.2 Osmium(II)

The potassium, barium, nickel(II) and copper(II) salts have long been known,[24] the normal method of preparation being to treat *trans*-$K_2[OsO_2(OH)_4]$ with excess aqueous potassium cyanide followed by fusion with potassium cyanide.[24,25] A free acid, $H_4[Os(CN)_6]$, can be made by addition of concentrated hydrochloric acid to $K_4[Os(CN)_6]$.[24] It is soluble in alcohol but can be precipitated as an etherate by diethyl ether. A study of its IR spectrum and that of its deuteriate suggests that it contains asymmetric —Os—C—N···H—N—C—Os— hydrogen bonds.[26,27]

There have been a number of studies on the vibrational spectra of $[Os(CN)_6]^{4-}$, mostly on the potassium salt.[28–30]. The latest data are given in Table 3 (with comparative results for $[Fe(CN)_6]^{4-}$ and $[Ru(CN)_6]^{4-}$); the T_{1g} and T_{2u} modes, which are inactive in the Raman and IR, were measured by IETS (inelastic electron-tunelling spectroscopy).[30] The increase in ν_{M-C} (*e.g.* ν_2, ν_4) from Fe to Os is consistent with an increase in M—C π bonding in the same sequence,[31] though it is interesting to note that this is apparently not borne out by ν_1. Electronic spectra of $[Os(CN)_6]^{4-}$ have been measured[32] and assigned;[33,34] the $10Dq$ value for the ion exceeds 34 000 cm^{-1}, much greater than those for $[Fe(CN)_6]^{4-}$ and $[Ru(CN)_6]^{4-}$.[34] Likewise, ^{13}C NMR chemical shifts for $[Os(CN)_6]^{4-}$ compared with $[Fe(CN)_6]^{4-}$ and $[Ru(CN)_6]^{4-}$ are consistent with greater ($\sigma + \pi$) metal–carbon overlap in the former.[35] There are also ESCA,[36] ^{183}Os Mössbauer[37a] and ^{14}N NMR data[25] for $[Os(CN)_6]^{4-}$, and spin–lattice relaxation times for the water molecules in $K_4[Os(CN)_6] \cdot 3H_2O$ have been determined.[37b]

Reaction rates between $[Os(CN)_6]^{4-}$ and $[MnO_4]^-$,[38] and also with OH^-,[39] have been measured. A mixed-valence complex of the Prussian blue type, $KFe^{III}[Os^{II}(CN)_6]$, has been reported.[32]

Table 3 Raman and Infrared data (cm^{-1}) on $[M(CN)_6]^{4-}$ (M = Fe, Ru, Os)[30]

	$[Fe(CN)_6]^{4-}$	$[Ru(CN)_6]^{4-}$	$[Os(CN)_6]^{4-}$
$\nu_1(A_{1g})^a$	2090	2108	2109
$\nu_2(A_{1g})^a$	385	425	458
$\nu_3(E_g)^a$	2055	2068	2061
$\nu_4(E_g)^b$	409	425	449
$\nu_5(T_{1g})^b$	354	344	362
$\nu_6(T_{1u})^c$	2044	2048	2038
$\nu_7(T_{1u})^c$	586	550	555
$\nu_8(T_{1u})^c$	415	371	(390)
$\nu_9(T_{1u})^c$	—	—	—

$\nu_{11}(T_{2g})^a$	(105)	—	—
$\nu_{12}(T_{2u})^b$	474	491	513
$\nu_{13}(T_{2u})$	—	—	—

[a] Raman spectrum, aqueous solution. [b] IETS spectroscopy. [c] IR of $K_4[M(CN)_6]$ in KBr disc.

A few substituted osmium(II) cyano complexes are known (for $[Os(NO)(CN)_5]^{2-}$ see p. 546). Reaction of $(NH_4)_2[OsCl_6]$ and 2,2′-bipyridyl followed by treatment with NaCN gives $Os(CN)_2(bipy)_2 \cdot 2H_2O$ in which the CN groups may be *cis*. Protonation is said to occur in perchloric acid to give $Os(CN)_2(bipy)_2 \cdot 2HClO_4$.[40]

46.3.1.3 Osmium(III)

The salt $(Bu^n_4N)_3[Os(CN)_6]$ is made by an ion-exchange procedure from $[Os(CN)_6]^{4-}$ in air. The magnetic moment is 2.12 BM at 296 K. The electronic spectrum was measured and assigned; 10 *Dq* is 34 950 cm^{-1} for $[Fe(CN)_6]^{4-}$, and 38 000 cm^{-1} for $[Os(CN)_6]^{3-}$.[34] The $[Os(CN)_6]^{3-}/[Os(CN)_6]^{4-}$ couple of +0.634 V compares with +0.356 V for the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ couple and with +0.860 V for $[Ru(CN)_6]^{3-}/[Ru(CN)_6]^{4-}$.[41] A higher value might have been expected for osmium, but apparently the palarographic value of +0.99 V, reported in the earlier literature,[42] may arise from reduction of cyanohydroxo complexes rather than from $[Os(CN)_6]^{3-}$.[19,33,41]

The redox potential for the $[Os(CN)_2(bipy)_2]^+/Os(CN)_2(bipy)_2$ complex is +0.778 V.[40] The species $[Os(CN)_2(OH)_4]^{3-}$ (by electrolytic reduction of an OsO_4/CN^- mixture) and $[Os(CN)_4(OH)_2]^{3-}$ (reduction of *trans*-$[OsO_2(CN)_4]^{2-}$) have been reported.[33,41]

46.3.1.4 Osmium(IV)

Although $[Os(CN)_6]^{2-}$ species have been claimed, it is clear that they are in fact $[Os(CN)_6]^{4-}$ salts.[11]

46.3.1.5 Osmium(VI)

For *trans*-$[OsO_2(CN)_4]^{2-}$ see p. 582; for *trans*-$[OsN(CN)_4(H_2O)]^-$, see p. 562. There are also reports of $[OsO_2(OH)_2(CN)_2]^{2-}$.[41]

46.3.2 Fulminato Complex

The only reported example of an osmium fulminato complex is $(Ph_4As)_2[OsO_2(CNO)_4]$, made by reaction of OsO_4 and potassium fulminate in a sealed tube followed by precipitation with tetraphenylarsonium chloride. The IR spectrum has $\nu(C{\equiv}N)$ at 2297 and 2181 cm^{-1} and ν^{as} (OsO_2) at 824 cm^{-1}.[44]

46.3.3 Osmium–Tin Complexes

Osmium forms relatively few non-organometallic metal–metal-bonded complexes (for species containing Os—Hg bonds see above, p. 525). In common with the other platinum group elements, however, it does form species of the type $[Os(SnX_3)_5X]^{2-}$, and these have received some recent study.

46.3.3.1 Complexes containing SnX_3^- and halo ligands

The known examples are listed in Table 4. The general method of preparation is the treatment of $K_2[OsCl_6]$ with SnX_2 in the presence of HX (for X = F, Cl, Br), while the hydroxo species is made by hydrolysis of the chloro complex.[44,46] The substituted complexes with phosphines, arsines and stibines are similarly made in the presence of the ligand.[17]

Table 4 Complexes Containing Osmium–Tin Bonds

Complex[a]	*Colour*	*Spectroscopic and other studies*
$[Os(SnCl_3)_6]^{4-}$		NMR[53b]
$K_4[Os(SnF_3)_6]$	White	IR, Mössbauer[45]
$(NH_4)_4[Os(SnCl_3)_5Cl]$	Pale yellow	IR,[45,46] UV/vis,[46] X-ray,[47,48] Mössbauer,[45] NMR[50]
$(Me_4N)_4[Os(SnBr_3)_5Br]$	Bright red	IR,[45,46] UV/vis,[46] Mössbauer[45]
$M_4[Os\{Sn(OH)_3\}_5Cl]$		Mössbauer[45]
$(Me_4N)_2[Os(SnCl_3)_4L_2]$	Red	IR, Mössbauer[45]
$(Me_4N)[Os(SnCl_3)_3L_3]$	Red	IR, Mössbauer[45]
$Os(SnCl_3)_3L_3$	Red	IR, Mössbauer[45]
$Os(SnCl_3)(PPh_3)_3Cl$		IR, Raman[17]

[a] L = thiourea.

The best studied of these species is the chloro complex, initially thought[45,47] to be a tetramethylammonium salt since $(Me_4N)Cl$ was used as the cation; subsequent X-ray data, however, showed it to be an ammonium salt or a mixed ammonium–tetramethylammonium salt,[48] so the same may be true for other anionic complexes listed in the table.

The structure shows the presence of two crystallographically independent but very similar anions in which five pyramidal $SnCl_3^-$ groups and a chloro ligand are at the apices of a slightly distorted octahedron. The Os—Cl distance is 2.42(2) Å; the mean Os—Sn distance *cis* to it is 2.580(5) Å and the *trans* Os—Sn distance is 2.530(5) Å. The Os—Cl bond length is some 0.08 Å longer than in other osmium(II) species so there appears to be a *trans* influence by the $SnCl_3^-$ ligand, manifested also in the shorter Os—Sn distance *trans* to the chloro ligand.[48] A force constant analysis was carried out on the molecule.[47,49]

A very high ^{117}Sn–^{119}Sn coupling constant of 18 600 ± 6 Hz was found for $[Os(SnCl_3)_5Cl]^{4-}$.[50] The complex catalyzes alkene isomerization, as does $[Os(SnBr_3)_5Br]^{4-}$.[51]

46.3.3.2 Complexes containing $SnCl_3^-$ and other ligands

Species of the type $Os(SnCl_3)_4L_2$ (L = methyl-, ethyl-, phenyl-, ethylphenyl- and diphenylthioureas and also thioacetamide) have been made from $[Os(SnCl_3)_5Cl]^{2-}$ and L, and the thiourea complexes $Os[SnCl_3)_2L_4]$, $[Os(SnCl_3)_3L_3]^-$, $Os(SnCl_3)_4L_2]^{2-}$ and $[OsL_6](SnCl_3)_2Cl$ can also be obtained.[52] The phosphonium salt $(Ph_3P)_4[Os(SnCl_3)Cl_5]^{4-}$ is obtained from $[Os(SnCl_5)Cl_4]^{4-}$ and Ph_3P or Ph_3PO.[53a]

The reaction of $(NH_4)_2[OsCl_6]$ and tin(II) chloride in concentrated hydrochloric acid and phosphines, arsines or stibines gives $Os(SnCl_3)(PR_3)_2Cl_2$ (PR_3 = $PMePh_2$, PPr^n_2Ph, PPh_3); $Os(SnCl_3)(LPh_3)_4Cl$ (L = As, Sb); $Os(SnCl_3)(L—L)_2Cl$ (L—L = dppm, dppe). IR spectra were measured and also, in the cases of $Os(SnCl_3)(PPh_3)_3Cl_2$, $Os(SnCl_3)(dppe)_2Cl$ and $Os(SnCl_3)(SbPh_3)_4Cl$, Raman spectra.[17]

The ^{119}Sn NMR spectra of $(PPH_4)_4[Os(SnCl_3)_6]$ and of $[OsCl(SnCl_3)_5]^{4-}$ have recently been measured,[53b] and $[Os(SnF_3)_6]^{4-}$ is also known.[45]

For the crystal structure of $(PPh_4)_2[Os(NO)Cl_3(SnCl_3)_2]$ see p. 549 below.

46.4 NITROGEN LIGANDS

Nitrogen is, after oxygen, the most frequently encountered donor atom in the coordination chemistry of osmium. There is a large and growing body of work on the ammine, pyridine, ethylenediamine and porphyrin complexes, but the most popular and rapidly growing field of study at the present time is that of the 'polypyridyls', the 2,2′-bipyridyl, 1,10-phenanthroline and 2,2′,2″,6′-terpyridyl complexes of the metal.

46.4.1 Ammine Complexes

Ammonia forms a number of complexes with osmium (see Table 5), though the only fully established unsubstituted osmium ammine which has been isolated is the hexaammine $[Os(NH_3)_6]^{3+}$; there is, however, electrochemical evidence for the existence both of $[Os(NH_3)_6]^{2+}$ and of $[Os(NH_3)_6]^{4+}$. Amongst the substituted ammines which have been isolated and characterized are several of osmium(II), all with supporting (or stabilizing) π-acceptor ligands, *e.g.* $[Os(NH_3)_5CO]^{2+}$, $[Os(NH_3)_5(NO)]^{3+}$ and $[Os(NH_3)_5(N_2)]^{2+}$.

Table 5 Representative Ammine Complexes

$Os(NH_3)(PPh_3)_2Cl_3$			X-ray[71]

[a] M = magnetic studies; CV = cyclic voltammetry. [b] Bromo and iodo analogues also known.

There is also a wide range of osmium(III) species, *e.g.* $[Os(NH_3)_5X]^{2+}$ (X = Cl, Br, I, OH), *cis*- and *trans*-$[Os(NH_3)_4X_2]^{2+}$ and *mer*-$Os(NH_3)_3X_3$ (X = Cl, Br, I), and in fairly recent work the isolation of the corresponding osmium(IV) ammines has been demonstrated. In the presence of a strongly π-donating ligand such as N^{3-}, $[Os_2^{IV}N(NH_3)_8X_2]^{3+}$ (X = Cl, Br, I, NCS, N_3) and the ill-characterized $[Os^{IV}N(NH_3)_4(H_2O)]^{+}$ are formed, while two oxo ligands suffice to render *trans*-$[Os^{VI}O_2(NH_3)_4]^{2+}$ a stable species.

In this section we consider unsubstituted complexes first, then aqua, hydroxo, halo, carbonyl and phosphine ammines. For nitrido ammines see pp. 562, 563, nitrosylammines p. 546, and dinitrogen ammines p. 554. Other substituted ammines are dealt with under the section concerned with the substituting ligand.

46.4.1.1 Unsubstituted ammines, $[Os(NH_3)_6]^{n+}$

Although both the brown $[Os(NH_3)_6]$ and the yellow $[Os(NH_3)_6]Br$ have been claimed as products of the reaction of $[Os(NH_3)_6]Br_3$ with potassium in liquid ammonia,[54] the products were not well characterized and could be hydrido ammines or mixtures. There is evidence from the polarographic reduction of $[Os(NH_3)_6]^{3+}$ for the existence of $[Os(NH_3)_6]^{2+}$ but it appears to be labile to substitution and has not been isolated:[55] in this respect osmium differs significantly from ruthenium, for $[Ru(NH_3)_6]^{2+}$ is isolable and is in fact a useful synthetic precursor. The tetravalent complex $[Os(NH_3)_6]^{4+}$ has also been detected electrochemically, by cyclic voltammetric oxidation of $[Os(NH_3)_6]^{3+}$;[55] in acidic solution; however, the first product of one-electron oxidation of $[Os(NH_3)_6]^{3+}$ is probably $[Os(NH_3)_5(NH_2)]^{3+}$.[55]

Salts of $[Os(NH_3)_6]^{3+}$ are made from $[OsCl_6]^{2-}$ and ammonia with zinc dust[56] or from $(NH_4)_2[OsBr_6]$ and ammonia under pressure,[57] but a recently devised high-yield procedure involves reaction of $[Os(NH_3)_5(NO)]^{3+}$ with perchloric acid and amalgamated zinc.[55]

The magnetic moment of $[Os(NH_3)_6]Br_3$ has been measured from 77 to 300 K.[58] Both $[Os(NH_3)_6][OsBr_6]$[59] and $[Os(NH_3)_6]Br[OsBr_6]\cdot H_2O$[60] are known; presumably both contain $[Os(NH_3)_6]^{3+}$ though this is not immediately obvious.

46.4.1.2 Substituted ammines

(i) Aqua, hydroxo and triflato ammines

The aqua complex $[Os(NH_3)_5(H_2O)]^{3+}$ is best made from $[Os(NH_3)_5(N_2)]^{2+}$ with $HClO_4$ and cerium(IV);[55] a reversible polarographic reduction, presumably to $[Os(NH_3)_5(H_2O)]^{2+}$, is observed at pH 4.[61] The hydroxopentaammine $[Os(NH_3)_5(OH)]^{3+}$ is made by addition of base to the aqua complex, and this too exhibits a one-electron reversible polarographic reduction to the corresponding osmium(II) species.[61] The aqua complex of osmium(III) is a useful precursor for $[Os(NH_3)_5X]^{2+}$ species (X = Cl, Br, I; see below).

The 'triflato' complex $[Os(NH_3)_5(OSO_2CF_3)]^{2+}$, made from $[Os(NH_3)_5(N_2)]^{2+}$ and triflic acid with bromine, is a very useful precursor for the preparation of mononuclear $[Os(NH_3)_5L]^{n+}$ species (L = pyridine, pyrazine, pyrimidine, *etc.*, see p. 534) and for binuclear pyrazine-bridged complexes (p. 526).[62] For *trans*-$[OsO_2(NH_3)_4]^{2+}$, see p. 582.

(ii) Halo ammines

For convenience we group chloro, bromo and iodo complexes together; no fluoroammines have yet been reported.

(*a*) *Osmium(II)*. Evidence from cyclic voltammetry suggests that $[Os(NH_3)_5X]^{2+}$ (X = Cl, I) can be reduced to the divalent state, presumably to $[Os(NH_3)_5X]^{+}$, but that these are labile to substitution.[63]

(*b*) *Osmium(III)*. The pentaammines $[Os(NH_3)_5X]^{2+}$ are made from $[Os(NH_3)_5(H_2O)]^{3+}$ and HX (X = Cl,[55,64] Br, I[55]). Both *cis* and *trans* isomers are known of $[Os(NH_3)_4X_2]^{+}$; the *cis* species are made from *cis*-$[Os(N_2)_2(NH_3)_4]^{2+}$ and HX,[65] and the *trans* complexes are prepared from *trans*-$[OsO_2(NH_3)_4]^{2+}$ and HX with $SnCl_2$ (X = Cl, Br), while for the iodo complex iron wire replaces $SnCl_2$ as the reducing agent.[55] There is a brief report of the trihalo species *mer*-$Os(NH_3)_3X_3$ (X = Cl, Br, I).[55]

The monoammine complex $K_2[Os(NH_3)Cl_5]$, made by reduction of $K[OsO_3N]$ with $SnCl_2$ in HCl[66] or with vanadium(II) or europium(II),[55] was once thought to be an amide, $K_2[Os(NH_2)Cl_5]$.[67]

Spectral data on osmium(III) haloammines are available (see Table 5); simplified MO theory has been applied to the charge-transfer spectra of $[Os(NH_3)_5X]^{2+}$ and $[Os(NH_3)_4X_2]^{+}$.[68]

(*c*) *Osmium(IV)*. No pentaammine halide species seem to be known of osmium(IV), but *cis*- and *trans*-$[Os(NH_3)_4X_2]^{2+}$ and *mer*-$[Os(NH_3)_3X_3]^{+}$ are made by oxidation of the corresponding osmium(III) complexes with iron(III) in the appropriate acid.[55]

Osmium(IV) ammines have unusually low pK_a values (see Table 5) and so persist only in strongly acidic media; the complexes are more acid by an order of five to six than their platinum(IV) counterparts but only slightly more acidic than the corresponding iridium(IV) complexes. This has been correlated with the decreasing t_{2g} electron occupancy in the series Pt^{IV}–Ir^{IV}–Os^{IV} and attributed to charge transfer from ligands to the empty π orbitals on osmium(IV). The *cis* isomers are more acidic than the *trans*, and this can be correlated with differences between the osmium(III) and osmium(IV) complexes for the isomers.[55]

Nitric oxide reacts rapidly with osmium(IV) di- and tri-haloammines giving, *via* a 'diazotization' reaction, osmium(III) dinitrogen ammine complexes (see p. 555).[64] At higher, pH, di- and tri-haloammines are unstable and undergo disproportionation reactions to osmium(III) haloammines and *trans*-$[OsO_2(NH_3)_4]^{2+}$.[64]

For $[Os(NH_2)X_5][Os(NH_3)_5X]$ (X = Cl, Br), see p. 557.

(iii) Carbonyl and phosphine ammines

Reaction of $[Os(NH_3)_5Cl]^{2+}$ with formic acid and zinc gives $[Os(NH_3)_5(CO)]^{2+}$,[69] and this can be oxidized to $[Os(NH_3)_5(CO)]^{3+}$ with $[IrCl_6]^{2-}$; oxidation of this with cerium(IV) leads to $[Os(N_2)(NH_3)_8(CO)_2]^{4+}$ in which there is a μ-dinitrogen bridge linking two *cis* tetraammine carbonyl osmium(II) moieties (see p. 556).[70]

The reaction of $N_2H_4 \cdot H_2O$ and PPh_3 with *trans*-$K_2[OsO_2(OH)_4]$ yields $Os(PPh_3)_2Cl_3(NH_3)$, and the X-ray crystal structure reveals the structure shown in Figure 1. In this, $a = 2.136(9)$, $b = 2.411(2)$, $c = 2.362(1)$ and the *trans* chloro distance $d = 2.360(3)$ Å. There is some distortion, the Cl(*cis*)—Os—Cl(*cis*) angle being 169.37(1)°.[71]

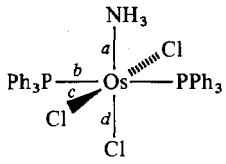

Figure 1 Structure of $Os(PPh_3)_2Cl_3(NH_3)$[71]

Reaction of $Os(PMe_2Ph)_3X_3$ (X = Cl, Br) with ammonia in dry ethanol gives $Os(PMe_2Ph)_3X_2(NH_3)$.[72]

(*iv*) *Miscellaneous ammines*

For *trans*-$[OsO_2(NH_3)_4]^{2+}$, see p. 582, and for $[OsN(NH_3)_4(H_2O)]^{3+}$, see p. 562.

(*v*) *Binuclear ammine complexes*

These constitute an important recent feature of osmium chemistry, but for convenience (and chemical sense) they are considered under the sections dealing with bridging ligands. For such complexes with bridging dinitrogen, see p. 556, with bridging pyrazine, see p. 536, and bridging nitride, see p. 563.

The ill-defined $[Os_2(NH_3)_6Br_4]Br_2$ is formed when $[Os(H_3)_6]Br_3$ is heated to 305 °C; the iodo complex $[Os_2(NH_3)_6I_4]I_2$ is formed when $[Os(NH_3)_6]I_3$ is heated to 234 °C.[75]

46.4.2 Complexes with Monodentate Amines

We consider here the remarkably small number of complexes of osmium with primary and aromatic amines RNH_2; all these involve phosphines as coligands. For complexes of pyridine and its analogues see p. 533; complexes of polydentate amines are considered in the sections which follow this one (p. 534).

Reaction of $Os(PMe_2Ph)_3X_3$ with RNH_2 (X = Cl, R = Me, Et, Pr^n, Pr^i, Bu^n; X = Br, R = Me, Bu^n) gives $Os(PMe_2Ph)_3X_2(RNH_2)$.[72] The *secondary* amines R_2NH give, with $Os(PMe_2Ph)_3Cl_3$, $Os(PMe_2Ph)_3Cl_2(RNH_2)$, which contains the coordinated primary amine (R = Me, Et, Pr^n, Pr^i, Bu^n, ^{n}hexyl, cyclohexyl, piperidine).[72]

46.4.3 Complexes with Bidentate Amines

46.4.3.1 Complexes with ethylenediamine

As ligands for osmium, ammonia and ethylenediamine (en; 1,2-diaminoethane) would be expected to have broadly similar properties, and this is on the whole true — there are stable osmium(III) complexes such as $[Os(en)_3]^{3+}$, *trans*-$[Os(en)_2X_2]^+$ (X = Cl, Br) and $[Os(en)Cl_4]^-$, and more recently the tetravalent $Os(en)X_4$ (X = Cl, Br, I) has been made. There is, however, an interesting chemistry of the 1,2-ethanediaminato-(1 −) and -(2 −) ligands with osmium in the higher IV, V and VI states, and another unusual feature is the existence of the hydride $[OsH_2(en)_2]^{2+}$.

Table 6 Representative Ethylenediamine Complexes

Complex	*Colour*	*Spectroscopic and other studies*[a]
$[Os(en)_3]I_3$	Yellow	IR,[79] M,[77] ESR,[85] CV[76]
$[Os(en)_2Cl_2]Cl\cdot H_2O$[b]		IR, Raman, UV/vis, M[78]
$[Os(en)_2H_2][ZnCl_4]$		IR, ^{1}H NMR, M[81]
$Os(en)Br_4$[c]		IR, UV/vis[79]
$[Os(en-H)en_2]Br_2$	Pink	X-Ray[76]

[a] M = magnetic studies; CV = cyclic voltammetry. [b] Bromo complex also known.[78] [c] Chloro and iodo complexes also known.[79]

We deal first with ethylenediamine complexes, then with 1,2-ethanediaminato-(1 −) and -(2 −) ligands (the so-called (en − H) and (en − 2H)), then related mono- and di-imines, and finally with substituted ethylenediamine complexes (see Table 6).

(*i*) *Osmium(II)*

There is a brief mention in the literature of $[Os(en)_3]^{2+}$, made by a one-electron reduction of $[Os(en)_3]^{3+}$. See also Scheme 1, p. 532.

(*ii*) *Osmium(III)*

The tris chelate $[Os(en)_3]^{3+}$ is most easily made by reduction of $[Os(en - H)(en)_2]^{3+}$ with ethanol, conc. HBr, $Na_2S_2O_4$[76] or $NaHSO_3$.[77] The iodide is paramagnetic with a magnetic moment close to 1.6 BM at room temperature.[77] The two *trans*-$[Os(en)_2X_2]X$ (X = Cl, Br) complexes can be made from $[Os(en)_2H_2]^{2+}$ and HX. The *trans* configuration for the chloro complex is suggested by the Raman and IR spectra, while that for the bromo species is indicated by a Br—Os—Br angle close to 180° from a partly resolved X-ray analysis of the compound. Both complexes are paramagnetic in solution (μ_{eff} = 1.91 and 1.95 BM at 323 K).[78] The salts $Cs[Os(en)X_4]$ (X = Cl, Br) were obtained from $[Os(en)(en - H)_2]Br_2$ and HX (a similar reaction with HI gave '$[Os(en)_3I_2]\ I_4$'). The bromo species with HCl gave $Cs[Os(en)Cl_nBr_{4-n}]$ (n = 1–3).[79] A rate of proton exchange with $[Os(en)_3]^{3+}$ has been given.[80]

(*iii*) *Osmium(IV)*

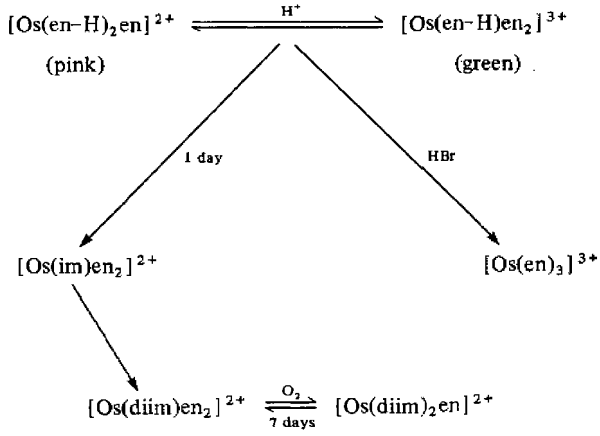
Although $[Os(en)_3]^{4+}$ has not been isolated, it seems possible that an oxidation wave for $[Os(en)_3]^{3+}$ near +2 V may be due to this species; a rate of proton exchange with $[Os(en)_4]^{4+}$ has been given.[80] It is clearly unstable with respect to $[Os(en)(en - H)_2]^{2+}$ and $[Os(en_2)(en - H)]^{3+}$ (p. 532).

There are however several substituted ethylenediamine complexes, the most unusual being the hydride $[Os(en)_2H_2]^{2+}$ which can be obtained as a $[ZnCl_4]^{2-}$ salt (by reaction of $[OsO_2(en)_2]Cl_2$ with zinc in HCl) or as a chloride. The salts are diamagnetic or almost so (μ_{eff} 0.22 BM at 298 K and 0.10 BM at 183 K for the $[ZnCl_4]^{2-}$ salt). Although this is formally an osmium(IV) complex there seems to be no abnormality in the ^{1}H NMR shift (δ_{OsH} = 15.4 p.p.m.); the Os—H stretch lies at 2150 cm^{-1} in the IR.[81]

The species $Os(en)X_4$ (X = Cl, Br) can be prepared from $[Os(en - H)_2(en)]\ Br_2$ and HX; a similar reaction with HI leads to '$[Os(en)_3I_2]\ I_4$', but $Os(en)I_4$ can be obtained from either $Os(en)Cl_4$ or $Os(en)Br_4$ with HI.[79] There is also an oxalato complex $Os(en)ox_2$, obtained from $[Os(en - H)_2(en)]Br_2$ and oxalic acid.[79]

(*iv*) *Osmium(VI)*

The osmyl complex *trans*-$[OsO_2(en)_2]^{2+}$ is discussed on p. 583 (see also Table 21). The only other species in this category is the deep red crystalline '$[Os(en)_3I_2]_4$', obtained by treatment of $[Os(en)(en - H)_2]Br_2$ with HI.[79] Although analytical data fit the formulation reasonably well it seems unlikely that this really is an eight-coordinate osmium(VI) species; an alternative possibility is $[Os(en)(en - H)_2](I_3)_2$.



46.4.3.2 Complexes with deprotonated ethylenediamine

These species, in which the 1,2-ethanediaminato-(1 −) and -(2 −) ligands, $(HN(CH_2)_2NH_2)^-$ and $(HN(CH_2)_2NH)^{2-}$, are denoted by (en − H) and (en − 2H) respectively are relatively common for the higher oxidation states of osmium; indeed the normal preparation of the 'simple' $[Os(en)_3]^{3+}$ cation is by reduction of $[Os(en - H)_2en]^{2+}$. They are in effect π-donating amido ligands and so it is perhaps not surprising that osmium(IV) and osmium(VI) complexes should be formed with them. Precise characterization of some of them is lacking, however, particularly those of osmium(III), but there is a recent X-ray crystal structure of $[Os^{IV}(en - H)_2en]Br_2$.[76]

There is also evidence from NMR of the existence of mono- and di-imine complexes containing the coordinated $HN(CH_2)_2NH_2$ and $HN(CH_2)_2NH$ ligands; these we refer to below as im and diim respectively.

(*i*) *Osmium(II)*

The monoimine complex $[Os(im)(en)_2]^{2+}$ is formed at pH 6–7 by the spontaneous oxidative dehydrogenation of $[Os(en-H)(en)_2]^{3+}$; formation of other iminato complexes is given in Scheme 1.[76] The complexes were detected by electronic and ^1H and ^{13}C NMR spectroscopy.[76]

Scheme 1 Reactions of deprotonated ethylenediamine complexes[76]

(*ii*) *Osmium(III)*

Reaction of $[Os(en)_3]I_3$ with three, two or one moles of potassium amide yields respectively the brown $Os(en-H)_3$, the yellow-brown $[Os(en-H)_2en]I$ and the pink $[Os(en-H)(en)_2]I_2$; the magnetic moment of the latter is 1.58 BM at room temperature.[82] Formulation as iminato complexes would also be possible; structural data on these species would be of interest.

(*iii*) *Osmium(IV)*

The reaction of $(NH_4)_2[OsBr_6]$ and ethylenediamine at 60 °C yields the pink $[Os(en-H)_2en]Br_2$,[77] and this formulation of 1955 as an ethanediaminato(1 –) complex has recently been confirmed by a single crystal X-ray study. The two deprotonated ends of the ligands are *cis* to each other, and the Os—N bond length to these ends (*c* in Figure 2, is 1.90 Å, indicative of some multiple bonding, since the Os—NH_3 bond lengths *a* and *b* are respectively 2.19 and 2.11 Å.[76]

In Scheme 1 the reactions of this and other en – H complexes are depicted; the pK_a for the $[Os(en-H)_2en]^{2+}$–$[Os(en-H)en_2]^{3+}$ equilibrium is about 6.[76]

The pyrophoric species $[Os(en-H)_3]I$ has also been claimed, made by treatment of $[Os(en-H)_2en]I_2$ with potassium amide in liquid ammonia.[82]

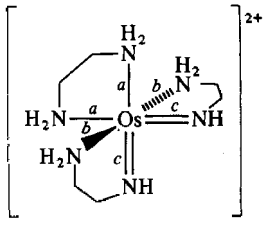


Figure 2 Structure of $[Os(en-H)_2en]^{2+}$[76]

(iv) Osmium(V) and Osmium(VI)

A black microcrystalline material formulated as $[Os(en-H)_3en]I_2 \cdot 4H_2O$ is obtained from $[Os(en-H)_2en]I_2$ and ethylenediamine at 100 °C,[77] and is paramagnetic (μ_{eff} = 1.78 BM).[83] A similar preparative method in the presence of air gives $[Os(en-H)_4]I_2 \cdot 3H_2O$,[77] a green-brown diamagnetic material thought to contain osmium(VI).[83] As formulated both these species presumably contain eight-coordinate osmium, a very rare coordination number for the element, and clearly they merit further investigation.

46.4.3.3 A complex of 2,3-butanediimine

Biacetyl reacts with $[Os(NH_3)_6]I_3$ in alkali, and the diammine-2,3-butanediimine species (Figure 3) is formed as brown-black crystals. The ^1H NMR spectrum is consistent with the *trans* structure.[84]

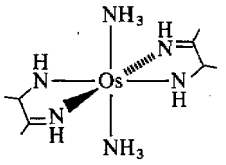

Figure 3 Proposed structure of the 2,3-butanediimine complex[84]

46.4.4 Complexes with Nitrogen Heterocycles

46.4.4.1 Complexes of pyridine and of substituted pyridines

(i) Complexes with pyridine

Osmium forms a number of complexes with pyridine (Table 7), mostly of the II oxidation state although there are examples of osmium(III) and osmium(IV) pyridine complexes. The important osmium(VI) species $Os_2O_6py_4$, a binuclear $\mu\mu'$-oxo 'osmyl' species, is considered on p. 595. There is also some important recent chemistry of osmium nicotinic and isonicotinic acid complexes (the 3- and 4-pyridinecarboxylic acids respectively).

Table 7 Complexes of Pyridine and of Substituted Pyridines

Complex	*Colour*	*Spectroscopic and other studies*[a]

[a] M = magnetic studies; CV = cyclic voltammetry. [b] isonic = *iso*nicotinamide. [c] Also bromo and iodo complexes.

(a) Osmium(II). The reaction of $[OsX_6]^{2-}$ and pyridine gives $Os(py)_4X_2$ (X = Cl, Br);[86] for the iodo complex a *trans* configuration has been postulated.[87] The carbonyl species $Os(py)_3(CO)X_2$ and $Os(py)_2(CO)XI$ (X = Cl, Br) are obtained from $[Os(CO)_2I_4]^-$ with pyridine followed by metathesis —the chloro ligands occupy *trans* position.[88] The dicarbonyls *cis*-$Os(py)_2(CO)_2X_2$ (X = Cl, Br, I) are made from pyridine and *cis*-$[Os(CO)_2X_4]^{2-}$ and their configurations have been determined by vibrational spectroscopy; on heating *in vacuo* the thermodynamically more stable *trans* isomers are formed.[89]

Cyclic voltammetry of $[Os(py)(NH_3)_5]^{3+}$ demonstrated the existence of $[Os(py)(NH_3)_5]^{2+}$,[62,90,91] and the surface-enhanced Raman spectra (SERS) of both species were measured recently,[91,92] with

normal, pyridine-d_5 and ammine-d_3 substitution. The metal–nitrogen, ammine and internal pyridine modes are enhanced; IR spectra were also recorded.[91]

Reaction of pyridine with $OsO_2Cl_2(PPh_3)_2$ yields $Os(py)_3(PPh_3)Cl_2$, which can be reversibly oxidized to the osmium(III) and osmium(IV) derivatives; electrochemical reduction of $Os(py)_2(PPh_3)Cl_3$ gives $[Os^{II}(py)_2(PPh_3)Cl_3]^-$.[93]

(*b*) *Osmium(III).* The iodo complex *mer*-$Os(py)_3I_3$ can be made from $[OsI_6]^{2-}$ and pyridine, and from this the corresponding $Os(py)_3X_3$ species (X = Cl, Br) can be obtained with X_2;[94] *fac*-$Os(py)_3Cl_3$ is made from $[OsCl_6]^{2-}$ and pyridine.[86] The mixed methyl pyrazine (R) complexes $Os(py)_nR_{3-n}X_3$ (n = 3, 1; X = Cl, Br, I) and $Os(py)_2RX_2I$ (X = Cl, Br, I) can be made from $[OsI_6]^{2-}$, pyridine and X^-.[94] The carbonyl halo species *trans*-$[Os(py)(CO)X_4]$ (X = Cl, Br, I) can be made from anhydrous pyridine with $[Os(CO)_2X_4]^{2-}$ or $[Os(CO)X_5]^-$.[95]

Replacement of the dinitrogen ligand in $[Os(N_2)(NH_3)_5]^{2+}$ by pyridine under aerobic conditions[90] or of the weakly bound triflate ligand in $[Os(OSO_2CF_3)(NH_3)_5]^{2+}$ by pyridine[62] yields $[Os(py)(NH_3)_5]^{3+}$; cyclic voltammetric studies show reversible reduction to $[Os(py)(NH_3)_5]^{2+}$ [62,90,91] and the surface-enhanced Raman spectrum[91,92] (SERS) of the complex (both normal and deuteriated) shows Os–N, ammine and internal pyridine vibrational modes. Infrared spectra were also measured.[91]

Reaction of *trans*-$Os(PPh_3)_2Cl_4$ with pyridine yields $Os(py)_2(PPh_3)Cl_3$, which can be oxidized or reduced by one-electron reactions, while electrochemical oxidation of $Os(py)_3(PPh_3)Cl_2$ gives $[Os(py)_3(PPh_3)Cl_2]^+$.[93]

(*c*) *Osmium(IV).* Salts of $[Os(py)X_5]^-$ (X = Cl, Br, I) can be obtained from $[OsX_6]^{2-}$ and pyridine, and the mixed species $[Os(py)Cl_4I]^-$ has also been isolated.[96] The chloro and bromo complexes can be made photochemically in the same way.[97] Electrochemical oxidation of $Os(py)_2(PPh_3)Cl_3$ gives $[Os(py)_2(PPh_3)Cl_3]^+$, and oxidation of $[Os(py)_3(PPh_3)Cl_2]^+$ gives $[Os(py)_3(PPh_3)Cl_2]^{2+}$.[93]

(*ii*) *Complexes of substituted pyridines*

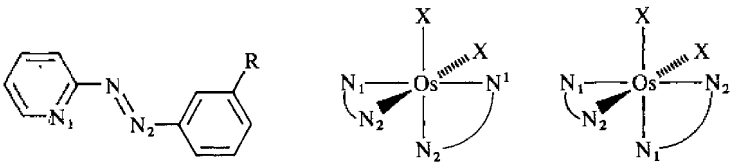
(*a*) *Picoline (methylpyridine) complexes.* The 3- and 4-methylpyridine complexes $Os(pic)_3I_3$ have been made from $[OsI_6]^{2-}$ and the ligand.[94]

(*b*) *Isonicotinic acid (pyridine-4-carboxylic acid) and isonicotinamide complexes.* The dinitrogen ligand in $[Os(N_2)(NH_3)_5]^{2+}$ can be replaced by isonicotinic acid to give $[Os(nic)(NH_3)_5]^{2+}$,[90] and reaction of this ligand or of isonicotinamide with $[Os(N_2)_2(NH_3)_4]^{2+}$ yields $[OsL(N_2)(NH_3)_4]^{2+}$. The latter isonicotinic acid complex $[OsL(N_2)(NH_3)_4]^{2+}$ can be oxidized anaerobically in the presence of HCl to give *cis*-$[OsLCl(NH_3)_4]Cl_2 \cdot H_2O$, while the isonicotinamide complex $[OsL'(N_2)(NH_3)_4]^+$ reacts with $NaNO_2$ and HCl to give a triammine, $[OsL'(N_2)_2(NH_3)_3]Cl_2$. Evidence was also obtained for the existence of $[Os(\text{nicotinic acid})(N_2)(NH_3)_4]^{2+}$.[98]

46.4.4.2 Complexes with chelating pyridines

A number of unusual complexes in which pyridine is substituted in the 2 or *ortho* position with O- or N-donor ligands are known.

(*i*) *2-Hydroxypyridine (hp) complexes*



Reaction of the ligand with $OsCl_3$[103,104] or with $Os_2(OCOMe)_4Cl_2$[105] gives $Os_2hp_4Cl_2S_2$, where S is a solvent molecule. The X-ray crystal structure of $Os_2hp_4Cl_2 \cdot OEt_2$ shows this to have a 'lantern' type of structure similar to that found for $Os_2(OCOR)_4Cl_2$ (R = Me, Et, Pr^n; see Figure 34). In the complex the OsN_2O_2 moieties have a *trans* arrangement and the Os—Os distance is 2.344(2) Å,[103] while in $Os_2hp_4Cl_2 \cdot 2MeCN$ it is 2.357(1) Å.[104] The magnetic moment of $Os_2hp_4Cl_2$ is 1.44 BM at 300 K,[105] larger than that for the carboxylates $Os_2(OCOR)_4Cl_2$ (p. 601), possibly due to a greater population of states derived from configurations such as $\sigma^2\pi^4\delta^2\pi^{*2}$ or $\sigma^2\pi^4\delta^2\delta^*\pi^*$.[106]

Reduction of $Os_2hp_4Cl_2$ with $(\pi\text{-}C_5H_5)_2Co$ gives $[(\pi\text{-}C_5H_5)_2Co][Os_2hp_4Cl_2]$, which contains the Os_2^{5+} core. This olive-green material has a magnetic moment of 2.68 BM at 308 K and of 2.63 BM at 173 K in dichloromethane solution (unlike the corresponding carboxylates for which the moment drops substantially with temperature). The ESR spectrum of the complex was also measured.[107]

The ligand 2-aminomethylpyridine (Rpy) functions as a chelating ligand in its own right or as the monodeprotonated 2-iminomethylpyridine (RpyH) species. This reaction of Rpy with $[OsBr_6]^{2-}$

gives the red osmium(IV) complex $[Os(Rpy)(RpyH)_2]Br_2$, with a magnetic moment of 1.2 BM at room temperature, together with the green $[Os(Rpy)_2(RpyH)](ClO_4)_3$ (μ_{eff} = 1.1 BM) isolated from perchloric acid solution of the reactants. This can be reduced with HSO_3^- to the yellow-green $[Os(Rpy)_3](ClO_4)_3$, an osmium(III) complex (μ_{eff} = 1.8 BM).[108]

Isomeric complexes of 2-(phenylazo)pyridine (pap) and 2-(*m*-tolylazo)pyridine (tap) (Figure 4a) have been prepared from the ligand and $(NH_4)_2[OsX_6]$. These have stoichiometries corresponding to OsL_2X_2 (X = Cl, Br), but exist in various forms such that $Os(pap)_2Cl_2$ and $Os(tap)_2Cl_2$ have structures (b) and (c) shown in Figure 4.[109a] A recent X-ray crystal structure study shows that $Os(tap)_2Cl_2$ has the structure shown in Figure 4(b); mean Os—Cl, 2.394; mean Os—N, 2.06; mean Os—N_2, 1.974 Å.[109b]

(a) tap, R = H; pap, R = Me (b) (c)

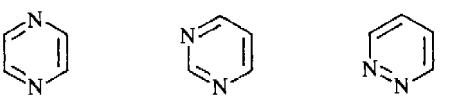


Figure 4 Isomers of 2-(arylazo)pyridine complexes[109a]

46.4.4.3 Piperidine ($C_6H_{11}N$) complexes

For convenience these are placed with pyridine. Only two complexes with osmium seem to have been reported. The ligand reacts with OsL_3Cl_3 (L = PMe_2Ph,[72] $As(p\text{-}MeC_6H_4)_3$[110]) to give OsL_3Cl_2(piperidine).

46.4.4.4 Bifunctional heterocyclic donors

In this section we consider the osmium complexes of the three potentially bifunctional ligands pyrazine (pyz), pyrimidine (pym) and pyridazine (pyd) (Table 8).* All form terminal complexes with

Pyrazine (pyz) Pyrimidine (pym) Pyridazine (pyd)

osmium, but only pyrazine forms binuclear species, the others not doing so presumably for steric reasons. Of particular interest is $[Os_2(pyz)(NH_3)_{10}]^{5+}$, the osmium analogue of the celebrated 'Creutz–Taube' complex $[Ru_2(pyz)(NH_3)_{10}]^{5+}$.[111]

Table 8 Pyrazine Complexes of Osmium

Complex	*Colour*	*Spectroscopic and other studies*[a]
mer-$Os(pyz)_3I_3$[b]	Blue-green	IR, UV/vis[94]

cis-$[Os(pyz)(NH_3)_4Cl]Cl_2$	Orange	UV/vis[98]
$[Os_2(pyz)(NH_3)_{10}]^{4+}$	Violet	UV/vis, CV[114]
$[Os_2(pyz)(NH_3)_{10}]^{5+}$	Red	UV/vis, CV[114]
$[Os_2(pyz)(N_2)(NH_3)_9]^{5+}$		UV/vis, CV[114]
$[Os_2(pyz)(NH_3)_9Cl]^{4+}$		UV/vis, CV[114]
$[Os_2(pyz)(NH_3)_{10}]Cl_6 \cdot H_2O$		UV/vis,[100,114] MCD,[100] CV[113,114]
$[Os_2(pyz)(NH_3)_9Cl]^{5+}$		UV/vis, CV[114]
$[OsRh(pyz)(NH_3)_{10}]$-$Cl_6 \cdot H_2O$		UV/vis, MCD,[100] CV[114]
$[OsRuL(bipy)_4]^{3+}$[c]		UV/vis, CV[112]
$[Os_2(pyz)(NH_3)_{10}]^{6+}$		X-Ray[114b]

[a] CV = cyclic voltammetry. [b] Chloro and bromo complexes also known. [c] L = pyz, pyzc, bpm, pyz, pyzc, bpm.

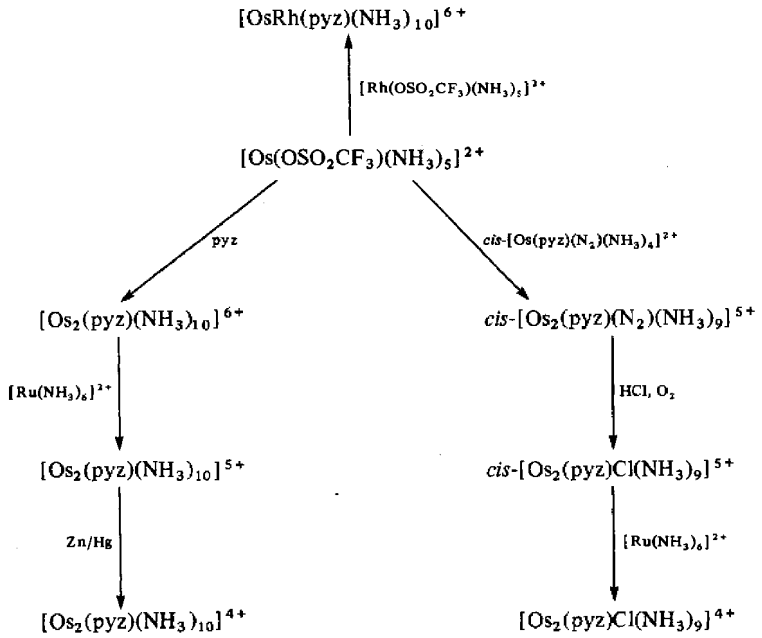
* For bipyridyl, phenanthroline and terpyridyl see p. 537 *et seq.*

(*i*) *Mononuclear complexes*

(*a*) *Osmium(II)*. All three ligands form species of the type $[OsL(NH_3)_5]^{2+}$, these being obtained by electrochemical[62,90] or chemical[90] (zinc) reduction of the corresponding osmium(III) species. In basic solution these osmium(II) complexes are relatively stable in the absence of oxidizing agents, but are less so in acid: the values of pK_a for deprotonation of $[Os^{II}(LH)(NH_3)_5]^{3+}$ are 7.4, 2.1 and 3.7 for pyrazine, pyrimidine and pyridazine respectively, compared with pK_a values of 0.6, 1.3 and 2.33 for the ligands.[90] Recently the surface-enhanced Raman spectra (SERS) of $[Os(pyz)(NH_3)_5]^{2+}$ and of $[Os(pyz)(ND_3)_5]^{2+}$ have been recorded.[91]

The tetraammines *cis*-$[OsL(N_2)(NH_3)_4]^{2+}$ (L = pyrazine or 3,5-dimethylpyrazine) are made from *cis*-$[Os(N_2)_2(NH_3)_4]^{2+}$ and the ligand;[98] complexes of the monoprotonated species *cis*-$[Os(LH)(N_2)(NH_3)_4]^{+}$ (L = *N*-methylpyrazinium, pyrazinium and 3,5-dimethylpyrazinium) are also known.[98]

Recently the complex $[Os(pyzc)bipy_2]^{+}$ (pyzc = 2-pyrazinecarboxylic acid) has been made by reaction of $Os(bipy)_2Cl_2$ with the ligand.[112]



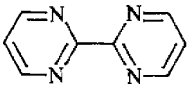
(*b*) *Osmium(III)*. The tris complex OsL_3X_3 (L = pyrazine, methylpyrazine and pyrimidine, X = Cl, Br, I) can be made from $[OsI_6]^{2-}$ and the ligands followed by metathesis where appropriate; *mer* configurations were assigned to $Os(pyz)_3Cl_3$, $Os(pyz)_3I_3$ and OsL_3X_3 (L = *N*-methylpyrazine, X = Cl, Br, I).[94] The mixed species $OsL(py)_2Br_nI_{3-n}$ (n = 1, 2) are made from *mer*-$OsL(py)_2I_3$ (L = *N*-methylpyrazine) and bromine.[113]

Salts of $[OsL(NH_3)_5]^{3+}$ (L = pyrazine, pyrimidine, pyridazine) can be made by displacement of nitrogen from $[Os(N_2)(NH_3)_5]^{2+}$[90] or from the triflato complex $[Os(OSO_2CF_3)(NH_3)_5]^{2+}$ and the ligands.[62] Cyclic voltammetry showed reduction to the osmium(II) species,[62,90] and the surface-enhanced Raman spectra (SERS) of $[Os(pyz)(HNH_3)_5]^{3+}$, $[Os(pyz)(NH_3)_5]^{2+}$ and of their ammine-d_5 derivatives were measured, as were the IR spectra.[91]

Reaction of *cis*-$[Os(pyz)(N_2)(NH_3)_4]^{2+}$ with HX yields *cis*-$[Os(pyz)X(NH_3)_4]^{2+}$ (X = Cl, Br).[98]

(*ii*) *Binuclear pyrazine-bridged complexes*

A number of these have been prepared using the synthetic procedures shown in Scheme 2. Of particular interest is $[Os_2(pyz)(NH_3)_{10}]^{5+}$ which has a radically different electronic absorption spectrum from either $[Os^{II}{}_2(pyz)(NH_3)_{10}]^{4+}$ or $[Os^{III}{}_2(pyz)(NH_3)_{10}]^{6+}$, and is believed to be a class III delocalized mixed-valence dimer, as is the dinitrogen analogue $[Os_2(N_2)(NH_3)_{10}]^{5+}$ (see p. 556). A similar situation probably obtains for $[Os_2(pyz)Cl(NH_3)_9]^{4+}$.[114a]



Scheme 2 Preparation of binuclear osmium ammines[114]

The pyrazine-bridged complex $[OsRu(pyz)bipy_4Cl_2]^{2+}$ has been reported and its electronic spectrum and cyclic voltammetry have been measured; two one-electron oxidations are observed.[112] In recent work the X-ray crystal structure of $[Os_2(pyz)(NH_3)_{10}]Cl_6 \cdot 2H_2O$ has been determined; the Os—N (pyrazine) distance is 2.101(7) Å.[114b]

Reaction of $[Os(pyzc)bipy_2]^+$ (pyzc = 2-pyrazinecarboxylic acid) with *cis*-$Ru(bipy)_2Cl_2$ gives the bridged complex $[OsRu(pyzc)bipy_4]^{2+}$; electronic absorption spectra and cyclic voltammograms were measured. Two one-electron oxidations were observed; the osmium(II) site is oxidized first and then the ruthenium site.[112]

46.4.4.5 Tetrafunctional ligands

The ligand 2,2-bipyrimidine (bpm) has been used to form terminal and bridging complexes with osmium. Reaction of *cis*-$Os(bipy)_2Cl_2$ and the ligand yields $[Os(bpm)bipy_2]^{2+}$, and with *cis*-

$Ru(bipy)_2Cl_2$ this gives the bipyrimidine-bridged complex $[OsRu(bpm)bipy_4]^{4+}$; the electronic absorption spectra and cyclic voltammetric properties were measured. Two one-electron oxidations were observed, the first probably occurring at the Os^{II} site and the second at Ru^{II}.[112]

46.4.4.6 Polypyridyl complexes of osmium

It has now become fashionable to call the bipyridyl, phenanthroline and terpyridyl ligands, and substituted forms of these, the 'polypyridyls' (see Table 9). In section 46.4.4.6.i. we consider the first two together, while terpyridyl complexes are dealt with in Section 46.4.4.6.iii.

Table 9 Properties of Bipyridyl, Phenanthroline and Terpyridyl Complexes

Complex	*Colour*	*Spectroscopic and other properties*[a]
$[Os(bipy)_3]^{2+}$	Green	Resonance Raman,[118,148] UV/vis, CD,[146,147] ^{1}H NMR,[118] CV,[40,157b,158] Mössbauer[184]

$[Os(terpy)_2]^{2+}$		UV/vis,[187] ^{1}H NMR,[188] CV[189]
$[Os(terpy)_2]^{3+}$	Green	CV[189]

[a] CV = cyclic voltammetry; M = magnetic studies. [b] Bromo and iodo complexes also known.

(*i*) *Complexes of 2,2′-bipyridyl and 1,10-phenanthroline*

In accordance with accepted practice we abbreviate these as bipy and phen, and the substituted ligands as Rbipy and Rphen (thus 5-Clbipy is 5-chloro-2,2′-bipyridyl and 4,7-Ph_2phen is 4,7-diphenyl-1,10-phenanthroline). The preparative routes to bipy and phen complexes are in general very similar, as are the chemistries of the two sets of complexes, so it is convenient to deal with them together. We consider first the tris species $[Os(LL)_3]^{2+}$ and $[Os(LL)_3]^{3+}$ and, in the following section, complexes involving LL and other ligands (LL = bipy, Rbipy, Rphen).

Since, like terpyridyl (p. 542), these ligands are good π acceptors by virtue of their considerable ring conjugation, it is the osmium(II) (d^6) state which is the commonest and generally the most stable; thus $[Os(LL)_3]^{3+}$ species are good one-electron oxidants. Nevertheless there are also examples of osmium(IV) and even a few of osmium(V) and osmium(VI) (the 'osmyl' osmium(VI) complexes are considered on p. 581).

The chemistry of these complexes has been extensively researched in the past two decades: the role of $[Os(LL)_3]^{3+}$ and $[Os(LL)_3]^{2+}$ in outer-sphere electron transfer processes has been much studied,

and two early papers in 1964 uncovered a large area of chemistry of bipy and phen complexes with other ligands. Recently, however, some of the considerable current interest in polypyridyl complexes of ruthenium as photosensitizers in the photodissociation of water has stimulated similar work on the corresponding complexes of osmium; as is indicated below it is the mixed complexes of osmium rather than $[Os(LL)_3]^{n+}$ which have excited the most interest. There is also much work likely to be done on electroactive polymeric species containing these ligands as electrode coatings.

(a) The tris complexes $[Os(bipy)_3]^{n+}$, $[Os(phen)_3]^{n+}$, $[Os(Rbipy)_3]^{n+}$ and $[Os(Rphen)_3]^{n+}$

Osmium(II). Salts of the green $[Os(bipy)_3]^{2+}$ ion can be made from OsO_4 and bipyridyl in the presence of hydrazine hydrate,[115] but the commonest procedure is to treat $K_2[OsCl_6]$ or $[Os(bipy)_2Cl_2]Cl$ with bipyridyl at 260 °C;[116] a similar reaction of $(NH_4)_2[OsBr_6]$ with phen at 270 °C gives the dark brown $[Os(phen)_3]^{2+}$.[117] Recent convenient preparations of both species involve refluxing solutions of the ligand with $Os_2(OAc)_4Cl_2$[105] or with $OsCl_3$[118]. Resolution of salts of both ions has been effected with the antimonyl tartrate anion.[117] The substituted complexes $[Os(R\text{-}bipy)_3]^{2+}$ and $[Os(Rphen)_3]^{2+}$ are normally made from $[OsX_6]^{2-}$ (X = Cl, Br) and the ligand (*e.g.* 6-Mebipy,[119] 4,4′-Me_2bipy,[120,121] 5,5′-Me_2bipy,[121] 6,6′-Me_2bipy,[119], 2-Mephen and 2,9-Me_2phen;[119] brief mention has been made of the complexes with 5-Mephen,[122] 4,7-Me_2phen and sulfonated 4,7-Me_2phen).[123]

The $[Os(phen)_3]^{2+}$ cation is said to be formed in aqueous solution from $[OsCl_6]^{2-}$ and the ligand at pH 2.5–5.0; in strong HCl, $Os(phen)_2Cl_2$ is formed.[124a] Recently EPR data on $[Os(bipy)_3]^-$ and $[Os(bipy)_3]^+$ have been reported.[124b]

An X-ray crystal structure determination of $[Os(phen)_3](ClO_4)_2 \cdot H_2O$ shows that the Os—N distances in the cation lie between 2.066(7) and 2.082(7) Å.[125]

Spectroscopic properties: the complexes as photosensitizers. The emphasis of these volumes is on the chemistry of the coordination complexes and so we can provide only a summary and brief guide to recent work on the photophysics and photochemistry of the polypyridyl complexes. Although most bipy and phen complexes of osmium, like their ruthenium analogues, are highly luminescent, it is only comparatively recently that the appropriate spectra have been measured and attempts made to harness their properties for such important applications as the photodissociation of water. The lifetimes of low-lying metal-to-ligand charge transfer (MLCT) excited states of $[Os(LL)_3]^{2+}$ complexes are in general much shorter than those of their ruthenium(II) counterparts.[126,127] This probably arises from the greater spin–orbit coupling in osmium than in ruthenium complexes leading to enhanced radiative and non-radiative decay rates for triplet–singlet transitions which have the effect of shortening the lifetimes of excited states.[127] The electronic absorption and emission spectra and in most cases quantum yields and lifetimes of excited states have been measured for $[Os(bipy)_3]^{2+}$,[119,123,126–137,145] $[Os(bipy\text{-}d_8)_3]^{2+}$,[126, 134,136] $[Os(phen)_3]^{2+}$,[119,123,127–131,134–137,139,145], and the following $[Os(Rbipy)]^{2+}$ and $[Os(Rphen)_3]^{2+}$ species with Rbipy: 6-Mebipy,[119] 4,4′-Me_2bipy,[126,134,137] 6,6′-Me_2bipy,[119] 4,4′-Ph_2bipy;[126] with Rphen: 5-Clphen and 5-Mephen,[126,134] 5,6-Me_2phen,[126,134,137] 5-NO_2phen,[134] 2,9-Me_2phen,[119] 4,7-Ph_2phen;[126,137] also for $[Os(phen)_2(Ph_2phen)]^{2+}$ and $[Os(phen)_2\text{-}SO_2Phphen]^{2+}$.[123] In most cases aqueous media were used but in some micellar solutions of sodium lauryl sulfate were employed.[138,139] The positions of MLCT absorption bands for $[Os(bipy)_3]^{2+}$ are solvent-dependent, this dependence being interpreted on the basis of dielectric continuum theory.[140] The lifetime of excited $[Os(bipy\text{-}d_8]^{2+}$ is approximately three times that for $[Os(bipy)_3]^{2+}$, an effect ascribed to radiationless decay theory.[136] A parametric model, including the effects of spin–orbit coupling, has been developed for the MLCT excited state of $[Os(bipy)_3]^{2+}$.[133]

Quenching of excited states of $[Os(bipy)_3]^{2+}$ and $[Os(5,6\text{-}Me_2phen)_3]^{2+}$ by copper(II) complexes,[143] by iron aqua complexes,[142] by $[Co(phen)_3]^{3+}$, $[Ru(NH_3)_6]^{3+}$, $[Fe(CN)_6]^{3-}$;[141] of $[Os(phen)_3]^{2+}$ by $HgCl_2$,[138] by iron aqua complexes[142] and by cobalt(III) species[144] has been studied. Such quenching by iron aqua species was also studied for $[Os(5,5'\text{-}Me_2bipy)_3]^{2+}$ and for $[Os(5\text{-}Clphen)_3]^{2+}$[142] and by O_2 for $[Os(bipy)_3]^{2+}$,[141,145] $[Os\ phen_3]^{2+}$ and $[Os\ phen_2]^{2=}$ (LL = Ph_2phen, SO_2Phphen)[145].

Circular dichroism spectra for $[Os(bipy)_3]^{2+}$ and $[Os(phen)_3]^{2+}$ have been reported.[146,147] Resonance Raman spectra of $[Os(bipy)_3]^{2+}$ have also recently been measured.[148]

For redox and electron-transfer properties of $[Os(bipy)_3]^{2+}$ and $[Os(phen)_3]^{2+}$ see p. 539.

Osmium(III). Oxidation of $[Os(bipy)_3]^{2+}$ with chlorine yields the violet $[Os(bipy)_3]^{3+}$ ion,[115,149] while the red $[Os(phen)_3]^{3+}$ is similarly prepared by oxidation of $[Os(phen)_3]^{2+}$.[149,150] Resolution of $[Os(phen_3)]^{3+}$ has been achieved by oxidation of the corresponding $[Os(phen)_3]^{2+}$ species.[150]

Spectroscopic properties. The electronic absorption spectra of $[Os(bipy)_3]^{3+}$[136,145,146,151] and of $[Os(phen)_3]^{3+}$[145,146] have been measured, as have their circular dichroism spectra[145–147] and also the spectra of $[Os(4,4'\text{-}Me_2bipy)_3]^{3+}$.[151] The lifetimes of the charge transfer (MLCT) excited states of

$[Os(bipy)_3]^{3+}$ and $[Os(phen)_3]^{3+}$ are some 10^5 to 10^6 times shorter than those of the MLCT states for the corresponding $[Os(bipy)_3]^{2+}$ and $[Os(phen)_3]^{2+}$ species (see also p. 538); it is thought that the excited states of the trivalent complexes are so short-lived that their lower energy ligand field states are too high to be populated. The lifetime for $[Os(bipy\text{-}d_8)_3]^{3+}$ is roughly twice that for $[Os(bipy)_3]^{3+}$[136] (see also p. 538). A brief mention has been made of the use of $[Os(bipy)_3]^{3+}$ for the non-catalytic photooxidation of water in the presence of cobalt(II) hydroxo complexes.[152] The rate of quenching of luminescence of $[Ru(bipy)_3]^{2+}$ by $[Os(bipy_3)]^{3+}$ is close to the diffusion-controlled limit.[153]

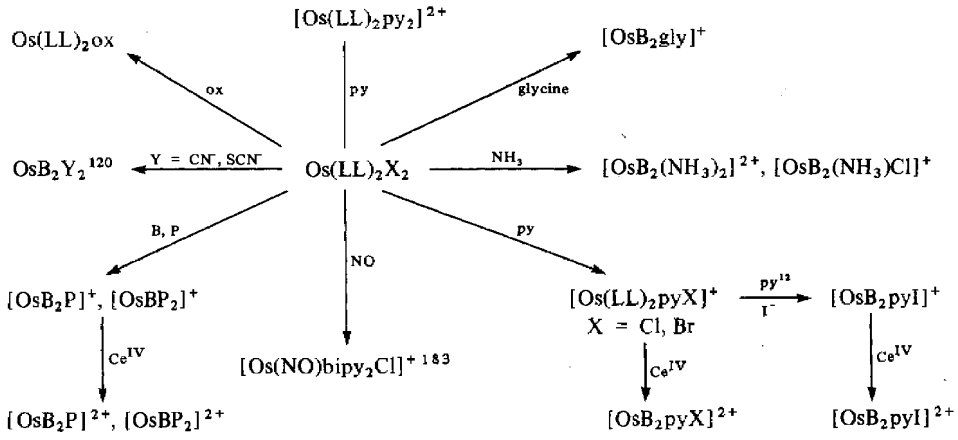
The ^1H NMR spectra of $[Os(bipy)_3]^{3+}$ and of $[Os(phen)_3]^{3+}$ have been measured and contact, pseudo-contact and Fermi-contact shifts studied;[118,149,153] the ESR spectra were also measured.[149] The ^{13}C resonance spectra of $[Os(bipy)_3]^{2+}$, $[Os(4,4\text{-}Cl_2bipy)_3]^{2+}$, $[Os(4,4\text{-}(OEt)_2bipy)_3]^{2+}$, $[Os(4\text{-}OMebipy)_3]^{2+}$ and $[Os(4\text{-}NMe_2bipy)_3]^{2+}$ have been recorded.[153] The resonance Raman spectrum of $[Os(bipy)_3]^{2+}$ has been measured.[118]

Redox and electron transfer properties of $[Os(LL)_3]^{3+}$. There have been a number of determinations of the $[Os(LL)_3]^{3+}/[Os(LL)_3]^{2+}$ couples.[40,156,157a] Values of E_0 of $+0.858$ V for $[Os(bipy)_3]^{3+}/[Os(bipy)_3]^{2+}$ in 0.01 M H_2SO_4 and $+0.855$ V in 0.1 M HCl have been given; for $[Os(phen)_3]^{3+}/[Os(phen)]^{2+}$ it is $+0.859$ V in 0.1 M HCl.[157a]

Polarographic studies show, in addition to oxidation waves for $[Os(bipy)_3]^{2+}$, several reduction waves;[130,158] this is also the case for $[Os(4,4'\text{-}Me_2bipy)_3]^{2+}$, $[Os(5,5'\text{-}Me_2bipy)_3]^{2+}$[121] and $[Os(phen)_3]^{2+}$. Recent cyclic voltammetry and coulombetry studies on $[Os(bipy)_3]^{2+}$ and $[Os(phen)_3]^{2+}$ in liquid SO_2 show successive one-electron oxidations to $[Os(LL)_3]^{3+}$ and $[Os(LL)_3]^{4+}$.[118] There is a small but real difference in the $Os^{III/II}$ redox potential for $[Os(phen)_3]^{2+}$ in aqueous and in non-aqueous sodium lauryl sulfate micellar solutions.[138] Correlations have been made between the oxidation potentials and charge-transfer transition frequencies in complexes $[M(LL)_3]^{2+}$ (Me = Fe, Ru, Os; LL = bipy, 4,4′-Me_2bipy, 5,5′-Me_2bipy).[159]

These high potentials make $[Os(LL)_3]^{3+}$ systems efficient one-electron oxidants, and most of these oxidations proceed *via* an outer-sphere process with second-order rate constants often close to the diffusion-controlled limits. Amongst those reactions which have been studied are $[Os(bipy)_3]^{3+}$ with $[Mo(CN)_8]^{4-}$, $[Mn(NO)(CN)_5]^{3-}$;[160] $[Fe(CN)_6]^{4-}$, $[W(CN)_8]^{4-}$;[161] $[Ru(bipy)_3]^{3+}$, $[IrCl_6]^{2-}$,[161] Fe(phen)$_2$(CN)$_2$;[161] $[Ru(H_2O)_6]^{2+}$;[162] $[Os(LL)_3]^{3+}$ with $[Os(LL)_3]^{2+}$, (LL = bipy, phen,[163] 4,4′-bipy[164]); $[Os(bipy)_3]^{2+}$ with $[Mo(CN)_8]^{3-}$,[165] $[Fe(bipy)_3]^{3+}$;[161] $[Os(phen)_3]^{2+}$ with $[Fe(bipy)_3]^{3+}$, $[Fe(phen)_3]^{3+}$ and $[Fe(4,4'\text{-}Me_2phen)_3]^{2+}$;[166] $[Os(LL)_3]^{2+}$ with $[Fe(LL)_3]^{3+}$ (LL = 4,4′-Me_2phen, 4,7-Me_2phen, 5,6-Me_2phen, 3,5,6,8-Me_4phen).[166]

Detailed kinetics of some of these and other processes have been studied, e.g. oxidation by $[Os(bipy)_3]^{3+}$ of I^-, SCN^-,[167] OH^-;[122] reaction of $[Os(LL)_3]^{3+}$ with OH^- to give O_2 (LL = bipy, phen, 5-Mephen, 4,4-Me_2bipy),[168] oxidation of ascorbic acid by $[Os(LL)_3]^{3+}$ (LL = bipy, 4,4′-Me_2bipy);[169] and the photoinduced electron transfer reactions of acidopentaamminecobalt(III) complexes with $[Os(bipy)_3]^{2+}$.[170] The outer-sphere oxidation of ascorbic acid by $[Os(bipy)_3]^{2+}$ incorporated in a coating on a graphite electrode has recently been reported.[170]



The thermodynamics of formation of outer-sphere complexes in solution, including those of osmium, have been reviewed.[172]

Osmium(IV). Evidence has been obtained from electrochemical oxidation of $[Os(bipy)_3]^{2+}$ and $[Os(phen)_3]^{2+}$ in liquid SO_2 for the existence of $[Os(phen)_3]^{4+}$. Magnetic susceptibility measurements show that $[Os(bipy)_3]^{4+}$ so generated is diamagnetic, and the ^1H NMR spectra and electrochemistry suggest that the oxidation is metal-centred for the bipy complex at least (whereas oxidation for the corresponding iron and ruthenium complexes is likely to be ligand-centred). Resonance Raman spectra of $[Os(bipy)_3]^{4+}$ are more complex than those of $[Os(bipy)_3]^{2+}$ or $[Os(bipy)_3]^{3+}$ suggesting that simple D_3 symmetry is not maintained: a Jahn–Teller splitting leading to inequivalent bond orders amongst the bipy rings was suggested as one explanation for this.[118]

(b) Substituted complexes $[Os(bipy)_xX_y]^{n+}$, $[Os(phen)_xX_y]^{n+}$, $[Os(Rbipy)_xX_y]^{n+}$, $[Os(Rphen)_xX_y]^{n+}$

Monomeric species. There are many of these, and for convenience and brevity we have illustrated the preparation of most of them schematically (see Schemes 3 and 4). The two main precursors are osmium(III) species: $[Os(LL)_2X_2]^-$ (LL = bipy, phen; X = Cl, Br, I), made by treatment of $K_2[OsX_6]$ with the ligands LL in dimethylformamide[173,174] (reduction with $Na_2S_2O_4$ gives $Os(LL)_2X_2$[173]); and $[Os(LL)Cl_4]^-$, made by heating the bipyridinium or phenanthrolinium salts $(LLH)_2[OsCl_6]$ to give $Os(LL)Cl_4$ which is then reduced with H_3PO_2 to $[Os(LL)Cl_4]^-$.[86]

Recently a number of complexes of the form *cis*-$[Os(LL)_2X_2]^{2+}$ (*e.g.* LL = bipy, phen; X = MeCN, $\frac{1}{2}(Ph_2PCH_2PPh_2)$, $\frac{1}{2}(Ph_2PCH{=}CHPPh_2)$, PMe_2Ph) have been made by reaction of

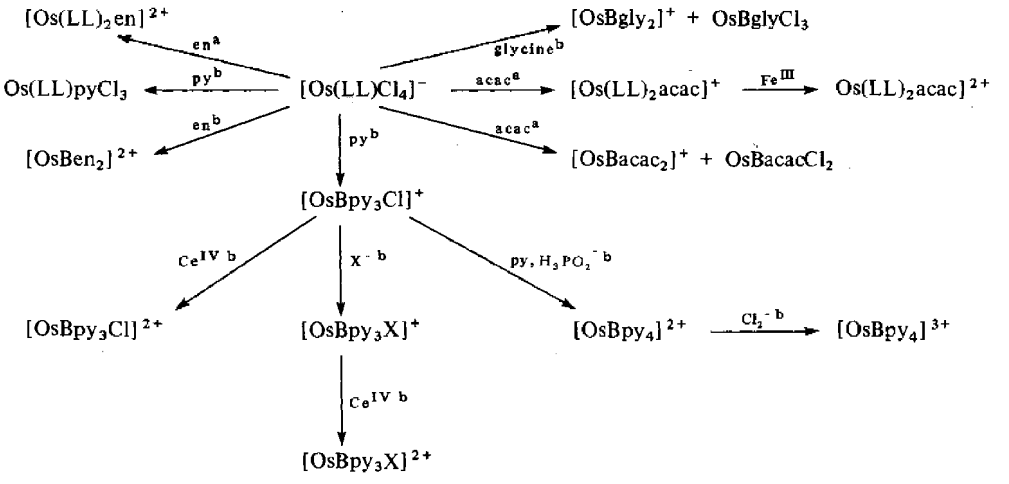
LL = coordinated bipy (B) or phen (P); X = Cl, Br, I. All from ref. 173 unless otherwise indicated.

Scheme 3 Reactions of $Os(LL)_2X_2$

cis-$Os(LL)_2Cl_2$ with X;[127] similar procedures are used to make complexes of the type $Os^{II}(LL)_2XX'$.[127,131,138] Some of these have been used as photosensitizers (see below).

Surface-enhanced Raman spectra (SERS) of $[Os(NH_3)_5bipy]^{3+}$ and its reduced form $[Os(NH_3)_5bipy]^{2+}$ have been measured.[91]

Electronic spectra and redox properties. The electronic absorption spectra of a number of osmium(II) bipy and phen complexes containing other ligands have been studied, *viz.* $[Os(bipy)_2LL]^{2+}$ (LL = phen, en, ox).[120] $Os(bipy)_2X_2$ (X = Cl,[120,172] Br, I,[120] CN[127]), $[Os(bipy)_2py_2]^{2+}$, $[Os(bipy)_2acac]^+$,[120] $[Os(bipy)_2X(py)]^+$ (X = Cl, Br, I),[173] $[Os(bipy)en_2]^{2+}$,[120] $[Os(bipy)en_2]^{2+}$,[151] $[Os(bipy)py_3X]^+$ (X = Cl, Br, I),[86] $Os(phen)_2ox$.[120] Circular dichroism spectra of $[Os(bipy)_2phen]^{2+}$ and of $[Os(bipy)phen_2]^{2+}$ have also been measured.[175]



For electronic spectra of species in this category used as photosensitizers see below.

For redox properties of $[Os(bipy)_2acac]^+$ see p. 541. Polarographic data have been obtained for oxidation and reduction of $Os(bipy)_2X_2$ (X = Cl, Br) and $[Os(bipy)_2L_2]^{2+}$ (L = py, CN, ½en).[158] For electrochemical oxidation of *cis*-$[Os(bipy)_2(H_2O)_2]^{2+}$ see p. 000.[176] In $[Os(phen)_2(Ph_2PCH_2PPh_2)]^{2+}$, $[Os(phen)_2(cis\text{-}Ph_2PCH{=}CHPPh_2)]^{2+}$, $[Os(phen)_2(CO)Cl]^+$ and $[Os(bipy)_2(CNMe)_2]^{2+}$ there are small but real differences in the $Os^{II/III}$ couples in aqueous as compared with aqueous micellar sodium lauryl sulfate media.[138]

Spectroscopic properties: the complexes as photosensitizers. In general, substituted osmium polypyridyl complexes are more reactive electron transfer sensitizers than their ruthenium(II) counterparts and, more significantly, have longer MLCT excited state lifetimes than the corresponding $[Os(LL)_3]^{2+}$ species. The replacement of one of the polypyridyl ligands to enhance the MLCT state lifetime can be accomplished by choosing the ligand X (in $Os^{II}LLX_4$ or $Os^{II}LL_2X_2$) or X and X′ (in Os^{II} LL XX′) in such a way that its π-acceptor capacity controls the lifetime.[127] Species which have been studied in this way include $[Os(phen)py_4]^{2+}$, $[Os(bipy)diars_2]^{2+}$, $[Os(phen)_2py_2]^{2+}$, *cis*-$[Os(LL)_2(CO)Cl]^{2+}$;[131] *cis*-$[Os(LL)_2(CO)Cl]^{2+}$;[131] *cis*-$[Os(LL)_2(NCMe)_2]^{2+}$;[127,131,141] *cis*-$[Os(bipy)_2(NCMe)(PMePh_2)]^{2+}$;[131] *trans*-$[Os(phen)_2(PMe_2Ph)_2]^{2+}$;[127,131] $Os(bipy)_2(CN)_2$;[137] *trans*-$[Os(bipy)_2R_2]^{2+}$ (R = $PMePh_2$, PPh_3); *cis*-$[Os(bipy)_2(PMePh_2)_2]^{2+}$, $[Os(bipy)_2diars]^{2+}$;[131] $[Os(LL)_2dppm]^{2+}$;[127,131] $[Os(LL)_2dppe]^{2+}$;[130,131] $[Os(phen)_2dpp]^{2+}$, $[Os(phen)_2dape]^{2+}$,[131] $[OsL_2(cis\text{-}Ph_2PCH{=}CHPPh_2)_2]^{2+}$;[127,130,131,141] *trans*-$[Os(bipy)_2(trans\text{-}Ph_2PCH{=}CHPPh_2)]^{2+}$, $[Os(LL)_2dape]^{2+}$,[130] $[Os(bipy)_2(Ph_2PC_6H_4PPh_2)]^{2+}$ and $[Os(bipy)_2(Me_2SO)_2]$.[130,131]

The properties of a number of these photosensitizers have been studied in aqueous and sodium lauryl sulfate micellar media,[139] their electronic and emission spectra, electrochemistry and quenching of their luminescence by $HgCl_2$ in both media.[138] In some cases solvent dependence of MLCT excited state lifetimes has been observed, *e.g.* in $[Os(bipy)_2py_2]^{2+}$, $[Os(bipy)_2(NCMe)_2]^{2+}$ and $[Os(bipy)_2(Ph_2PC_6H_4PPh_2]^{2+}$. For these, dielectric continuum theory has been invoked to explain such solvent dependence, and it is necessary to assume that the excited electron in the excited state is localized on one ligand rather than delocalized over all three.[140]

There is a preliminary report of an excited state photoelectrochemical cell based on the reductive quenching of the MLCT excited state of $[Os(bipy)diars_2]^{2+}$ by $N(p\text{-}C_6H_4Br)_3$ in acidic, aerated acetonitrile: it produces H_2O_2 and bromine with high quantum efficiency.[177]

LL = coordinated bipy (B) or phen (P). [a]Ref. 173. [b]Ref. 86.

Scheme 4 Reactions of $[Os(LL)Cl_4]^-$

Osmium(III). The osmium(III) complexes $K[Os(LL)Cl_4]$ (LL = bipy, phen), made by reduction of $Os(LL)Cl_4$ with H_3PO_2 and KCl, are useful precursors for other osmium complexes (Scheme 4). In general, osmium(III) complexes in this category are made by oxidation of the corresponding osmium(II) species with chlorine or with cerium(IV) (see Schemes 3 and 4).

Magnetic susceptibilities of $[Os(bipy)_2Cl_2](ClO_4)$ were measured from 81 to 303 K (μ_{eff} is 1.61 BM at 81 K and 1.87 BM at 303 K); for $(Os(phen)_2Cl_2]ClO_4$ μ_{eff} is 1.61 BM at 85 K and 1.73 BM at 300.3 K.[101]

The complex $[Os(NH_3)_5(4,4'\text{-bipy})]^{3+}$ has been mentioned, and its resonance Raman and IR spectra recorded.[91]

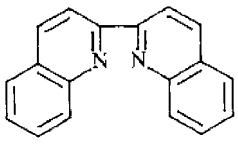
Electronic spectra and redox properties. Electronic spectra have been measured for the following osmium(III) complexes: $[Os(bipy)_2phen]^{3+}$, $[Os(bipy)_2acac]^{2+}$,[151] $[Os(bipy)_2(py)X]^{2+}$ (X = Cl, Br, I),[171] $[Os(bipy)Cl_4]^-$, $[Os(bipy)acac_2]^+$,[151] $[Os(bipy)_2X_2]^+$ (X = Cl, Br, I)[151,172] $[Os(phen)_2X_2]^+$ (X = Br, I)[151,172] and $[Os(bipy)(py)_3X]^{2+}$ (X = Cl, Br, I).[86] Circular dichroism spectra were also measured for $[Os(bipy)_2phen]^{3+}$ and for $[Os(bipy)phen_2]^{3+}$.[175]

The redox potential for $[Os(bipy)_2acac]^{2+}/[Os(bipy)_2acac]^+$ is +0.1539 V as compared with +0.8836 V for $[Os(bipy)_3]^{3+}/[Os(bipy)_3]^{2+}$, showing graphically that osmium(III) is stablized relative to osmium(I) is stabilized relative to osmium(II) by replacement of one bipyridyl ligand.[151] For polarographic oxidation of $Os(bipy)_2Cl_2$, $Os(phen)_2X_2$ (X = Cl, Br), $[Os(bipy)_2LL_2]^{2+}$ (LL = py, ½en) and $[Os(bipy)_2(CN)_2]$ see p. 540, and of *cis*-$[Os(bipy)_2(OH)(H_2O)]^{2+}$, see below.[176] There are also electrochemical (redox) data for $[OsL_2(L—L)_2]^{2+}$ (L—L = $Ph_2P(CH_2)_2PPh_2$, $Ph_2PCH{=}CHPPh_2$, dape) and $[Os(biby)_2X_2]^{2+}$ (X = MeCN, DMSO).[130]

Osmium(IV), (V) and (VI). Heating $(LLH)_2[OsCl_6]$ to 300 °C gives $Os(LL)Cl_4$ (LL = bipy, phen).[86]

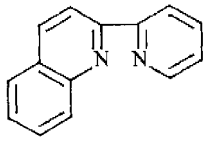
Cyclic voltammetry and differential pulse polarography of *cis*-$[Os(bipy)_2(H_2O)_2]^{2+}$ at pH 1.4 show oxidation to osmium(III) ($E_{\frac{1}{2}}$ + 0.16 V), followed by a two-electron step to osmium(V) ($E_{\frac{1}{2}}$ + 0.61 V) and the one-electron step to Os(VI) ($E_{\frac{1}{2}}$ 0.81 V); in the pH range 2.0–5.5 the Os^{III}–Os^V oxidation was resolved into two reversible one-electron waves showing an intermediacy of Os^{IV}. From pH dependence studies on the complexes the Os^{III} complex is likely to be *cis*-$[Os(bipy)_2(OH)(H_2O)]^{2+}$, the Os^{IV} probably *cis*-$[Os(bipy)_2O(H_2O)]^{2+}$ and the Os^V *cis*-$[Os(bipy)_2O(OH)]^{2+}$, while the Os(VI) species may be *cis*-$[OsO_2bipy]^{2+}$ (see also p. 584). As with the analogous ruthenium complexes the redox system occurs within a remarkably narrow potential window, with $\Delta E_{\frac{1}{2}}$ for $M^{VI/V}$ to $M^{III/II}$.[176,178]

Dimeric species. Reaction of *cis*-$Os(bipy)_2Cl_2$ and $Ph_2PCH_2PPh_2$ (dppm) gives $[Cl(bipy)_2Os^{II}(dppm)Os^{II}(bipy)_2Cl]^{2+}$ which, on oxidation with bromine, yields $[Cl(bipy)_2Os^{III}(dppm)Os^{III}(bipy)_2Cl]^{4+}$; mixture of these two dimers gives the weakly coupled mixed-valence species $[Cl(bipy)_2Os^{II}(dppm)Os^{III}(bipy)_2Cl]^{3+}$. The intervalence transitions were measured.[179] A $\mu\mu'$-hydroxo species $Os_2(OH)_2bipy_2Cl_4$ can be made by prolonged action of hot water on $K[Os(bipy)Cl_4]$.[86]



The near IR and magnetic circular dichroism spectra of $[(NH_3)_5Os(4,4'\text{-bipy})Os(NH_3)_5]^{6+}$ have

been recorded; exchange coupling is likely to occur in this species.[100] The mixed metal species $[OsRu(4,4'\text{-bipy})Cl_2(bipy)_4]^{2+}$ has been prepared from $[Os(4,4'\text{-bipy})Cl(bipy)_2]^{2+}$ and *cis*-$Ru(bipy)_2Cl_2$; cyclic voltammetric and electronic spectral data were recorded.[112]



For the μ and $\mu\mu'$-imido complexes $[Os_2(NH)(bipy)_4]^{4+}$ and $Os_2(NH)_2(bipy)_4$ see p. 558.

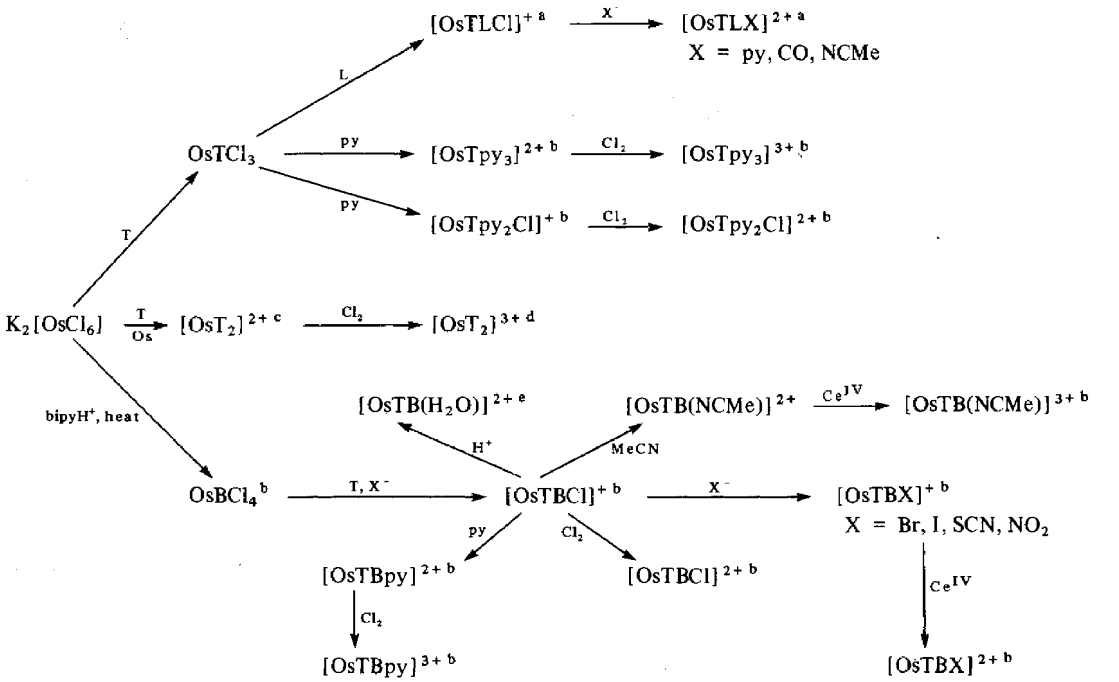
Polymeric species. A field of rapidly growing interest is the reductive electrochemical polymerization of vinyl-containing ruthenium and osmium polypyridyl complexes. For osmium, the starting materials are *cis*-$[Os(bipy)_2L_2](PF_6)_2$ (L = 4-vinylpyridine ($n = 2$). *N*-(4-pyridyl)cinnamamide ($n = 1$)), made from the ligand and *cis*-$Os(bipy)_2(CO_3)$, and *cis*-$[Os(bipy)_2L'Cl](PF_6)$ (L' = 4-vinylpyridine and bis(4-pyridyl)ethylene), made from *cis*-$Os(bipy)_2Cl_2$ and the ligands. These species can be made to form polymeric fibres (homopolymer, copolymer or spatially segregated bilayer) and electrode coatings, and are electroactive because they contain a redox centre in each repeat unit.[180] The redox conduction of the film prepared from electrochemical polymerization of *cis*-$[Os(bipy)_2(N\text{-}(4\text{-pyridyl})\text{cinnamamide})_2]^{2+}$ has been measured by steady-state voltammetry and is close to the E° of the polymer Os^{III}/Os^{II} couple, involving the intermediacy of a mixed-valence state of the polymer.[181a–181c] Coated platinum electrodes using poly-$[Os(bipy)_2(4\text{-vinylpyridine})_2]^{3+}$ have been used to study the kinetically unfavourable oxidations of $Os(bipy)_2Cl_2$ and $[Os(Rphen)_3]^{2+}$ (Rphen = 5-Clphen, 5-NO_2phen and 3,4,7,8-Me_4phen).[182]

(*ii*) *Complexes of 2,2'-biquinoline and 2-(2'-pyridyl)quinoline*

biq

pq

These ligands are clearly related to 2,2'-bipyridyl. They react with $K_2[OsCl_6]$ in refluxing glycerol to give, after addition of sodium perchlorate, black crystals of $[Os(biq)_3](ClO_4)_2 \cdot H_2O$ and $[Os(pq)_3](ClO_4)_2 \cdot H_2O$. The absorption and luminescence spectra were measured; the difference between the energies of the π and π^* bands was less than that found for $[Os(bipy)_3]^{2+}$, as expected from the additional π-electron delocalization in these ligands.[190]



(*iii*) *Terpyridyl (terpy) complexes*

As a tridentate conjugated ligand this would be expected, like 2,2'-bipyridyl and 1,10-phenanthroline, to stabilize osmium(II) and this is indeed the case, with most of the reported complexes containing divalent osmium. The unsubstituted bis complex $[Os(terpy)_2]^{2+}$ is remarkably stable. It seems likely that terpyridyl complexes of osmium(II) are good candidates for further investigation as photosensitizers, having so far received less attention than the corresponding bipyridyl or phenanthroline species.

Osmium(II). The unsubstituted complex $[Os(terpy)_2]Cl_2$ was made in 1937 by fusion of the ligand with a mixture of $K_2[OsCl_6]$ and osmium metal, and is singularly unreactive towards either acids or alkalis.[191] The green chloride gives a red solution. For its redox and spectroscopic properties see below.

A number of substituted terpyridyl complexes have been reported, most of them made by Dwyer and co-workers in 1964.[192] Preparative routes are given in Scheme 5.

Spectroscopic properties: the complexes as photosensitizers. Spectroscopic (absorption and emission spectra),[128,138,187] redox and photochemical properties (MLCT lifetimes, quenching of the Os^{II} MLCT states by $HgCl_2$) have been studied for $[Os(terpy)_2]^{2+}$ in aqueous and in aqueous sodium lauryl sulfate micellar solutions;[138] the solvent accessibility of the complexes correlates with the hydrophilicity of the ligands (other osmium(II) bipy and phen complexes were included in the study).[139] Absolute luminescence, quantum yields and lifetimes of $[Os(terpy)_2]I_2$ in an alcohol glass at 77 K have been determined.[129] The complexes $[Os(terpy)LCl]^+$, $[Os(terpy)LR]^{2+}$ (L = *cis*-$Ph_2PCH{=}CHPPh_2$, dppm; R = py, MeCN, CO), $[Os(terpy)dppm_2]^{2+}$ and $[Os(terpy)(dppm)Cl]^+$ are the first complexes observed to exhibit strong MLCT-based luminescence in fluid solutions at room temperatures;[193] the absorption and emission spectra of $[Os(terpy)(dppm)Cl]^+$ and of

[a] Ref. 193. [b] Ref. 192. [c] Ref. 191. [d] Ref. 189. [e] Ref. 195. [f] Ref. 86.

T = terpyridyl; B = bipyridyl; L = dppm, *cis* $Ph_2PCH{=}CHPPh_2$

Scheme 5 Preparation of terpyridyl complexes

$[Os(terpy)(cis\text{-}Ph_2PCH{=}CHPPh_2)(NCMe)]^{2+}$ at room temperature have been measured.[193]

The ^1H resonance spectrum of $[Os(terpy)_2]^{2+}$ has been recorded.[188]

Redox properties. For oxidation of $[Os(terpy)_2]^{2+}$ see below. Treatment of $[Os(terpy)(bipy)Cl]^+$ with trifluoromethanesulfonic acid gives $[H_2O{-}Os(terpy)bipy]^{2+}$, and it has been shown by electrochemical and spectrophotometric studies (equation 1) to be a member of the series (at pH 7).[194]

$$[H_2O{-}Os(terpy)(bipy)]^{2+} \underset{c^-}{\overset{-e^-}{\rightleftharpoons}} [H_2O{-}Os(terpy)(bipy)]^{3+} \underset{2H^+,c^-}{\overset{-2H^+,-e^-}{\rightleftharpoons}} [O{=}Os(terpy)(bipy)]^{2+} \quad (1)$$

The hydroxo species $[HO{-}Os(terpy)bipy]^{2+}$ can also be made by oxidation of $[H_2O{-}Os(terpy)bipy]^{2+}$.[194] Redox properties of $[Os(terpy)LCl]^+$, $[Os(terpy)LR]^{2+}$ (L = *cis*-$Ph_2PCH{=}CHPPh_2$, R = py, CO, MeCN), $[Os(terpy)dppm\ Cl]^+$ and of $[Os(terpy)dppm]^{2+}$ have been measured.[193]

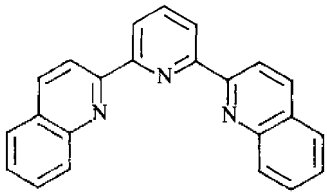
At pH 13, electrochemical reduction of $[OsO_2(terpy)(OH)]^+$ yields $[Os(terpy)O_2(OH)]$, at pH 7, $[Os(terpy)(OH)_3]$, and $[Os(terpy)(H_2O)_3]^{3+}$ at pH 1.[194]

Osmium(III). The unsubstituted $[Os(terpy)_2]^{3+}$ ion can be obtained as a sparingly soluble green perchlorate by oxidation of $[Os(terpy)_2]^{2+}$ with Cl_2.[189]

A number of substituted osmium(III) terpyridyl complexes are known (see Scheme 5).

Redox properties. In general $[M(terpy)_2]^{3+}$ ions are less stable than the corresponding $[M(bipy)_3]^{3+}$ species (M = Os, Ru, Fe); in 0.1 M H_2SO_4 the $[M(terpy)_2]^{3+}/[M(terpy)_2]^{2+}$ potentials are +0.951 (Os), +1.28 (Ru) and +1.08 V (Fe).[189] Although the colour change from green ($[Os(terpy)_2]^{3+}$) to red $[Os(terpy)_2]^{2+}$ is in principle favourable for redox titration purposes the instability of the tripositive complex renders it unsuitable for the purpose.[189] The complex $[HO{-}Os(terpy)bipy]^{2+}$ is obtained by electrochemical reduction of $[O{=}Os(terpy)bipy]^{2+}$ or oxidation of $[HO{-}Os(terpy)bipy]^+$ or $[H_2O{-}Os(terpy)bipy]^{2+}$,[195] and electrochemical reduction of $[OsO_2(terpy)(OH)]^+$ gives $[Os(terpy)(H_2O)_3]^{3+}$ at pH 1, and $Os(terpy)(OH)_3$ at pH 7.[194]

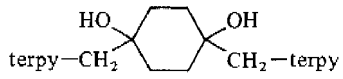
Osmium(IV), (V) and (VI). The existence of $[O{=}Os^{IV}(terpy)bipy]^{2+}$ has already been mentioned (see above).[195] Irreversible electrochemical oxidation of this occurs from pH 1 to 12 at +1.05 V, and the initial product is thought to be $[O{=}Os^{V}(terpy)bipy]^{3+}$ which then loses a bipyridyl ligand and undergoes a further one-electron oxidation to $[OsO_2(terpy)(OH)]^+$. At pH 13.5 a



two-electron, one-proton reduction wave is observed (equation 2), while at lower pH the intermediate is $[HO—Os^{III}(terpy)bipy]^{2+}$.[195]

$$[O{=}Os(terpy)(bipy)]^{2+} \underset{-2e^-,H^+}{\overset{2e^-,H^+}{\rightleftharpoons}} [HO—Os^{II}(terpy)(bipy)]^{+} \quad (2)$$

The osmium(V) species $OsO_2(terpy)(OH)$ has also been detected electrochemically at pH 13, from reduction of $[OsO_2(terpy)(OH)]^+$; the latter is made from *trans*-$K_2[OsO_2(OH)_4]$ and terpy.[194]
Binuclear complexes. For $[Os_2O(terpy)_2(bipy)_2]^{4+}$ and $[Os_2O(terpy)_2(bipy)_2]^{2+}$, see p. 594.[192]



(*iv*) *Complexes of ligands related to terpyridyl*

(*a*) *Bis(2,6-di(2′-quinolyl)pyridine) complexes.* This ligand (dqp) is closely related to terpyridyl. It reacts with $K_2[OsCl_6]$ in refluxing ethylene glycol to give, after addition of sodium perchlorate, the dark purple $[Os(dqp)_2](ClO_4)_2$. The absorption and luminescence spectra were recorded; the luminescence spectrum is similar to that of $[Os(terpy)_2]^{2+}$, the benzo substitution in the dpq complex producing a slight red shift in some of the bands.[196]

dqp

(*b*) *(−)-Tubocurarine complexes.* Reaction of $Os(bipy)(Cl_4$ with (−)-tubocurarine (L) gave the binuclear complex $[Cl(bipy)Os(LL)Os(LL)Os(bipy)Cl]^{2+}$, dichloro-$\mu$-[1,4-cyclohexylbis(2,2′,2″-terpyridyl)-6″-methyl)-1,4-diol]bis(2,2′-pyridyl)diosmium(II) dichloride. The two coordinated chloro ligands can be replaced by pyridine on refluxing this with the complex in aqueous solution. The former complex has potent curariform biological activity[190] and there are possible applications as stains for electron microscopy for the complexes.[197]

L

46.4.5 Nitrosyl Complexes

As with nitrido and oxo complexes we shall consider osmium nitrosyl (NO) complexes as a group, irrespective of the nature of the other ligands present. Just as N^{3-} and O^{2-} are strong π donors and tend to dominate the overall bonding in their complexes, so too the nitrosyl ligand—certainly in its NO^+ guise—is a very effective π acceptor and is the dominant ligand in complexes containing it.

The normal classification of material by oxidation state is inappropriate for nitrosyl complexes because the oxidation state concept is very much a formalism for them. Instead we shall use the generally accepted $[M(NO)_x]^{n+}$ classification in which x is the number of coordinated NO groups and n the number of metal d electrons, the latter being calculated on the basis that NO^+ is the coordinated moiety. As will be apparent, osmium complexes within each such category do in fact show considerable similarities of structure and reactivity, and also with their ruthenium analogues. Osmium is unusual in forming an $[M(NO)]^5$ type of complex.

Since a far greater number of nitrosyl complexes have been isolated for ruthenium than for any other metal it might be expected that osmium should rival ruthenium in this respect. There seems no reason why this should not be so, and the present disparity in numbers of known osmium and ruthenium nitrosyls simply suggests that much less work has been carried out on the osmium systems.

There are several recent and comprehensive reviews on metal nitrosyl complexes which give good coverage to the osmium complexes;[198] a review on ruthenium nitrosyl complexes is particularly

useful for discussion of bonding aspects and is relevant to the analogous osmium nitrosyls.[199] The reader is also referred to the appropriate section in 'Comprehensive Organometallic Chemistry'.[200]

46.4.5.1 [Os(NO)]^5 and [Os(NO)]^6 complexes

(i) [Os(NO)]^5

The recently reported $[Os(NO)Cl_5]^-$ anion, isolated as NO^+ and PPh_3Me^+ salts from the reaction of Os_2Cl_{10} with nitric oxide, is a rare example of a 17-electron nitrosyl system.[201]

(ii) [Os(NO)]^6

This is the most numerous class and encompasses the widest diversity of coligands. Most of the known species are octahedral and in all the Os—N—O linkage is likely to be essentially linear with the nitrosyl moiety bound as NO^+, giving the osmium a formal oxidation state of II. An interesting area, well investigated for $[Ru(NO)]^6$ species but less studied for the osmium analogues, is that of the attack of the NO group in some of the species by nucleophiles.[199] As with the corresponding ruthenium complexes the N—O stretching frequency (ν_{NO}) lies between 1800 and 1900 cm^{-1} for most of the complexes which behave in this way.

Table 10 Representative Osmium Nitrosyl Complexes

Complex	*Colour*	ν_{NO} *(cm^{-1})*	*Spectroscopic and other properties*
[Os(NO)]^5			
$(PPh_3Me)[Os(NO)Cl_5]$	Golden-yellow	1823	IR[201]

$Os(NO)_2(OEP)$	Red	1778, 1500	IR,[232] UV/vis,[232,255] ^1H NMR[255]

[a] Bromo and iodo complexes also known. [b] Chloro, bromo and iodo complexes also known. [c] Bromo and iodo complexes known, also with arsine and stibine ligands. [d] Methoxo and fluoro complexes also known.[232]

In Table 10 we list representative complexes of the $[Os(NO)]^6$ type; for conciseness we normally give only the potassium salts of anionic species and chloride salts of cationic complexes; for neutral species involving halide ligands we concentrate on the chloro examples. The coverage is representative but not comprehensive.

(*iii*) *Nitrosyl halides*

All four $[Os(NO)X_5]^{2-}$ species are now known. The fluoro complex is made from $[OsX_6]^{2-}$ with excess KHF_2,[202] the reaction yielding $[Os(NO)F_nX_{4-n}]^{2-}$ (X = Cl, Br);[203] stereochemistries of the products were deduced from ^{19}F NMR data.[203] For X-ray data see p. 548. The other nitrosylpentahalogeno complexes have been established longer. They are prepared from salts of *trans*-$[Os(NO)(OH)(NO_2)_4]^{2-}$ together with an excess of HX (X = Cl, Br, I);[204] another useful method is to react salts of $[OsX_6]^{2-}$ with nitrite ion and HX (X = Cl, Br, I).[205] Other salts for which relatively recent preparations have been given include $(NH_4)_2[Os(NO)X_5]$ (X = Cl, Br, I),[206,207] $Rb_2[Os(NO)X_5]$[207] and $Cs_2[Os(NO)X_5]$ (X = Cl,[205,207,208] Br,[205,208] I[205]).

More recently the preparation of $(NO)_2[Os(NO)Cl_5]$ from Os_2Cl_{10} and CCl_3NO has been reported; when the complex is heated to 170 °C the polymeric chloro-bridged species $[Os(NO)Cl_3]_n$ is formed.[209] With PPh_3Me^+, $(NO)_2[Os(NO)Cl_5]$ gives $(PPh_3Me)[Os(NO)Cl_4]$;[210] the X-ray crystal structure of this is described below on p. 548.

Studies on the ^{19}F NMR of $[Os(NO)F_5]^{2-}$ in aqueous solution provide evidence for the existence in such solutions of $[Os(NO)F_4(H_2O)]^-$, *cis*- and *trans*-$Os(NO)F_3(H_2O)_2$, $[Os(NO)F_2(H_2O)_3]^+$ and $[Os(NO)F(H_2O)_4]^{2+}$.[203] The hydrolytic behaviour of $[Os(NO)X_5]^{2-}$ (X = Cl, Br, I) indicates that NO^+ is exerting a *trans* effect in these complexes; the stability decreases from X = Cl to X = I, and the product is initially *trans*-$[Os(NO)(H_2O)X_4]^-$ which then deprotonates to *trans*-$[Os(NO)(OH)X_4]^-$.[211] Irradiation of $[Os(NO)X_5]^{2-}$ (X = Cl, Br) with mercury light gives $[Os(H_2O)X_5]^{2-}$.[211]

There are comprehensive Raman and IR spectroscopic data on $[Os(NO)X_5]^{2-}$ salts (X = Cl, Br, I).[208,212]

(*iv*) *Nitrosyl ammine and nitro complexes*

The chloride, bromide and iodide of $[Os(NO)(NH_3)_5]^{3+}$ are made from the corresponding $[Os(NH_3)_6]^{3+}$ salts and nitric oxide,[56] and X-ray data are available for *trans*-$[Os(NO)(OH)(NH_3)_4]Br_2$, $Os(NO)(OH)(NH_3)Br_2$ and $[Os(NO)(H_2O)(NH_3)_3Cl]Br_2$ (see p. 548). There does appear to be a *trans* influence of the NO group in that the protons in the *trans* ammine group in $[Os(NO)(NH_3)_5]^{3+}$ are acidic; treatment with base yields *trans*-$[Os(NO)(NH_2)(NH_3)_4]^{2+}$, and another product of the reaction is *trans*-$[Os(NO)(OH)(NH_3)_4]^{2+}$. This will react with HX (X = Cl, Br, I) to give *trans*-$[Os(NO)X(NH_3)_4]^{2+}$.[214]

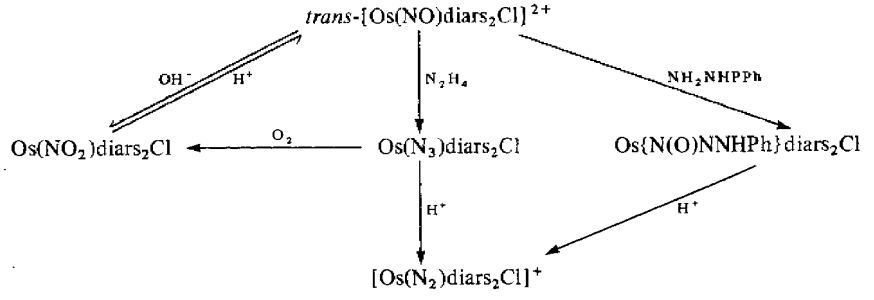
Other substituted ammine complexes such as *cis*-$Os(NO)X_3(NH_3)_2$,$[Os(NO)X(NH_3)_3(H_2)]^{2+}$ (X = Cl, Br, I),[215] *trans*-$Os(NO)Cl_3(NH_3)_2$,[215] $Os(NO)X_2(NH_3)_2(OH)$ (X = Cl, Br,[216,217] I,[217] NO_2,[216] Bu, OAc[217]), *cis*-$Os(NO)Br_2(NH_3)_2Cl$[217] and $[Os(NO)(OH)_2(NH_3)_2(H_2O)]^+$[215] have been prepared.

Salts of '$[Os(NO_2)_5]^{2-}$' have long been reported in the literature[218] with sodium, potassium, ammonium, magnesium, calcium, strontium and barium cations, but the anion in these salts is now known to be *trans*-$[Os(NO)(OH)(NO_2)_4]^{2-}$.[219] The potassium salt, made from $[OsCl_6]^{2-}$ and excess KNO_2,[218] is a useful starting material for other nitrosyl complexes since the NO_2^- groups are easily displaced. The X-ray crystal structure of the anion is discussed below (p. 548). The anion exhibits a complex hydrolytic behaviour, alledgedly in accordance with the *trans* effect of the nitrosyl ligand.[220]

(*v*) *Nitrosyl azido and cyano complexes*

The complex $(Ph_4P)_2[Os(NO)(N_3)_5]$ is made from OsO_4, hydroxylamine and sodium azide. It has an unusually low ν_{N-O} frequency (1715 cm^{-1}). With *o*-phenanthroline, $Os(NO)(N_3)_3$ phen is produced. The red nitrosylpentacyano complex $K_2[Os(NO)(CN)_5]\cdot 2H_2O$ can be made from *trans*-$K_2[OsO_2(OH)_4]$, KCN and nitric acid.[222] The salt, which is unusual in that it is barely soluble in water, is like the nitroprusside ion in that it gives a coloured complex with sulfide ion.[222] With nitric acid it gives a number of species such as *trans*-$[Os(NO)(H_2O)(CN)_4]^-$ and $Os(NO)(CN)_3\cdot 2H_2O$.[223]

For nitrosylcyano complexes with thiourea see p. 608.

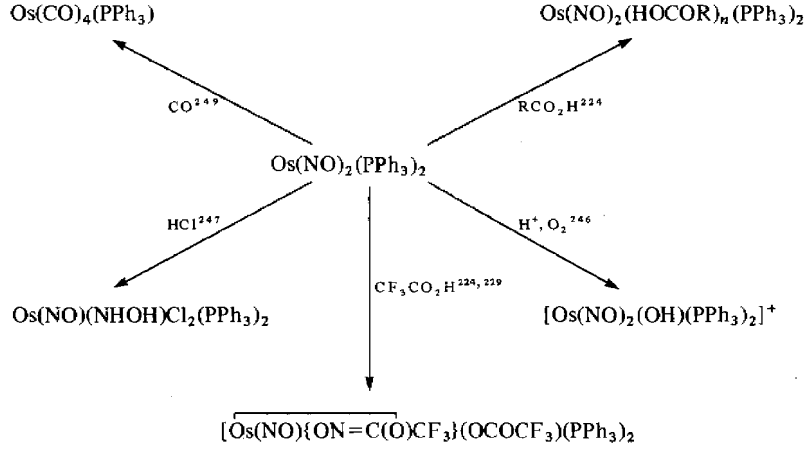


(*vi*) *Nitrosyl complexes with monoteriary phosphines, arsines and stibines*

The hydrido complexes $Os(NO)H(PPh_3)_2(OCOR)_2$ ($R = CF_3$, C_2F_5) have been prepared by reaction of RCO_2H with $Os(NO)H(PPh_3)_3$,[224] and a similar reaction will yield $[Os(NO)H_2(COCF_3)][H(OCOCF_3)_2]$;[224] $Os(NO)_2(PPh_3)_2$ and RCO_2H also give $[Os(NO)H(PPh_3)_2(OCOR)_2]^+$.[225] The neutral hydride is thought to have a structure in which the hydride is *trans* to the nitrosyl group and the monodentate carboxylato ligands are *trans* to each other.[224]

Reaction of $[OsX_6]^{2-}$ (X = Cl, Br) with MNTS (*N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide) in the presence of PR_3 (R = Bu^n, Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, X = Cl, R = Ph, X = Br) yields $Os(NO)X_3(PR_3)_2$;[226] other methods involve reaction of ClNO or BrNO with $OsCl_3$ in the presence of PPh_3[227] or reaction of $[OsX_6]^{2-}$ with nitric oxide and LPh_3 (L = As, Sb), this latter reaction giving $Os(NO)X_3(AsPh_3)_2$, and $Os(NO)X_3(SbPh_3)_2$ (X = Cl, Br, I).[228] The structure for all these species is likely to be that of Figure 12, with NO replacing NS.[226,227]

(*vii*) *With chelating arsines*



Reaction of $Cs_2[Os(NO)X_5]$ and *o*-phenylenebis(dimethylarsine) (diars) gave *trans*-$[Os(NO)(diars)_2X]^{2+}$ (X = Cl, Br, I); *cis*-$[Os(NO)(diars)_2Cl]Cl_2$ is made from $Os(N_3)(diars)_2Cl$ and HCl.[205] The systems provide a good illustration of attack by nucleophiles upon a coordinated nitrosyl group which has some electrophilic properties by virtue of the residual positive charge on its nitrogen atom (see Scheme 6).[205]

Scheme 6 Reactions of nitrosyl diarsine complexes[205]

(*viii*) *Miscellaneous [Os(NO)]^6 species*

Reaction of $Os(NO)_2(PPh_3)_2$ with trifluoroacetic acid gives $Os(NO)(ON{=}C(O)CF_3)(OCOCF_3)(PPh_3)$ (Scheme 7), in which both coordinated trifluoroacetate and *O,O'*-trifluoroacetato-hydroxamate ligands are present (see p. 548 for X-ray structure).[224,229] There are also two metal–metal-bonded species for which X-ray crystal structures have been determined (p. 548):

Scheme 7 Reactions of $Os(NO)_2(PPh_3)_2$

$Os(NO)Cl_2(HgCl)(PPh_3)_2$, made by the action of $HgCl_2$ on $Os(NO)(CO)Cl(PPh_3)_2$,[230] and $(Ph_4P)_2[Os(NO)Cl_3(SnCl_3)_2]$, obtained from $[Os(NO)Cl_3]_n$ and $PPh_4(SnCl_3)$.[231]

Octaethylporphyrin (OEP) affords three osmium nitrosyl complexes: Os(NO)(OMe)(OEP), made from Os(CO)py(OEP), methanol and NO;[232] with HF this yields Os(NO)F(OEP)[232] and with $HClO_4$ it gives $Os(NO)(OClO_3)(OEP)$.[255] The nitrosyl carbonyl complex $[Os(NO)(CO)Cl_2(PPh_3)_2]BF_4$ is made by reaction of $Os(NO)(CO)Cl(PPh_3)_2$ with HBF_4.[223]

Two complexes have recently been reported with polypyridyl ligands: $[Os(NO)(bipy)_2Cl](PF_6)_2$, obtained from $Os(bipy)_2Cl_2$ and nitric oxide with PF_6^-, and $[Os(NO)(terpy)(bipy)](PF_6)_3$, obtained from $[Os(terpy)(bipy)Cl]^+$, NO_2^- and HPF_6. The acid—base equilibrium (equation 3) was compared with that for the ruthenium analogue, and potentials for the $[Os(NO)(bipy)_2Cl]^{3+/2+}$ and $[Os(NO)(terpy)(bipy)]^{3+/2+}$ couples were compared with those for the ruthenium analogues. The differences were attributed to greater Os—NO electronic mixing and greater spin–orbit coupling at the osmium atom.[183]

$$[Os(NO)(terpy)(bipy)]^{3+} + 2OH^- \rightleftharpoons [Os(NO_2)(terpy)(bipy)]^+ + H_2O \quad (3)$$

Reaction of OsO_4 with hydroxylamine hydrochloride and thiocyanate ion gives $[Os(NO)(NCS)_5]^{2-}$; with 2,2′-bipyridyl or 1,10-phenanthroline (LL), $Os(NO)(NCS)_3(LL)$ complexes are formed.[234]

(*ix*) *X-Ray structural studies on* $[Os(NO)]^6$ *complexes*

Until fairly recently there were relatively few structural studies on osmium nitrosyls, but of late the field has received a fair amount of attention. As expected[198] the Os—N—O moiety is essentially linear in all these complexes, and most of them have octahedral coordination. There is evidence for a slight lengthening of the bond *trans* to the nitrosyl (there are more examples of this in the more extensively studied structural chemistry of $[Ru(NO)]^6$ complexes[198]); it has been noted that such *trans* bond shortening is a feature of octahedral $[M(NO)]^6$ complexes where the N—O stretching frequency exceeds 1800 cm^{-1},[198] as it does in all these compounds.

Structurally the simplest complexes to be studied are those of $NaK[Os(NO)F_5]\cdot H_2O$ (I) and $Cs_2[Os(NO)F_5]\cdot H_2O$ (II). For these the Os—N and N—O distances are 1.707(9) and 1.18(1) (I) and 1.675(16) and 1.21(2) Å (II); the mean Os—F (*cis*) distances are 1.991(8) and 1.986(9) Å in (I) and (II) respectively, while the corresponding Os—F (*trans*) distances are 1.966(5) and 1.947(5) Å. The Os—N—O angles are essentially linear in (I) and (II).[235] This slight shortening of *trans* ligands as against *cis* has been noted and discussed for $[Ru(NO)]^6$ complexes of the form $[Ru(NO)X_5]^{n-}$.[198] In $[PPh_3Me][Os(NO)Cl_4]$ there is no *trans* ligand, the structure being square-based pyramidal with an axial nitrosyl ligand (Os—N 1.89(2), N—O 0.90(3) Å, Os—N—O 177(2)°); the four equatorial ligands are at a mean distance of 2.36(1) Å from the osmium, with a mean N—Os—Cl angle of 93.8°.[210] The N—O distance of 0.90(3) Å is described as 'unnaturally short'[210] and presumably would have a more normal value if low-temperature data were obtained. It seems likely that the five-coordinate structure is a consequence of the presence of the large organic cation rather than a marked *trans* effect of the nitrosyl ligand; often 1:1 complexes rather than 2:1 cation:anion species are preferentially formed when the cation is bulky as is the case here (a similar instance is found for $[OsNX_4]^-$ species (X = Cl, Br, I); see p. 560).

Two other structures of highly symmetrical species are those for *trans*-$[Os(NO)(OH)(NH_3)_4]Br_2$ (III)[236] and the anion in *trans,trans*-$[Os(NO)(OH)(NO_2)_4][Ru(NO)(OH)(NH_3)_4]\cdot\frac{1}{2}H_2O$ (IV).[237] Here the Os—N and N—O distances are respectively 1.74(2) and 1.19(3) (III) and 1.762 and 1.15 Å (II);

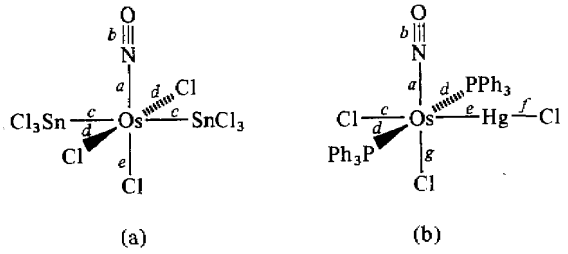


Figure 5 Structures of $[Os(NO)]^6$ complexes containing metal–metal bonds[230,23]

the Os—N—O angles are 176(1)° (I) and 175.7(8)° (IV). The *trans* Os—O (OH) distances are 2.01(2) (III) and 1.943 Å (IV), while the *cis* Os—N distances have mean values of 2.14 and 2.09 Å for (III) and (IV) respectively. For the *trans*-$[Ru(NO)(OH)(NH_3)_4]^{2+}$ cation in (IV) the Ru—N and N—O distances are 1.739 and 1.16 Å with the Ru—N—O angle at 178.4°, the *trans* Ru—O (OH) distance 1.956 Å and the mean *cis* Ru—N (NH_3) distance 2.115 Å.[237]

In $(PPh_4)_2[Os(NO)Cl_3(SnCl_3)_2]$ (V) the *trans* Os—Cl distance (*e*) is slightly but significantly shorter than that for the *cis* (*d*) (Figure 5a) (a = 1.734(2), b = 1.166(21), mean c = 2.648(1), mean d = 2.380(1), e = 2.364(4) Å; Os—N—O angle 180°).[231]

Another species containing a metal–metal bond is $Os(NO)(HgCl)Cl_2(PPh_3)_2$ (VI) (Figure 5b); this is an X-ray structure determination of rather lower accuracy (a = 1.79(4), b = 1.03(6), c = 2.42(2), mean d = 2.39(2), e = 2.577(6), f = 2.39(3), g = 2.37(2) Å, Os—N—O 180°).[230]

In $Os(NO)(OH)(NH_3)_3Br_2$[236,238] (VII) (Figure 6a) and $Os(NO)(H_2O)(NH_3)_3Cl$[236,238] (VIII) (Figure 6b) the bond distances are: a = 1.75(1), b = 1.16(2), mean c = 2.533, mean d = 2.11 e = 1.98(1) Å (for VII) a = 1.64(3), b = 1.21(4), c = 2.343(15), mean d = 2.34, e = 2.13(3).[236]

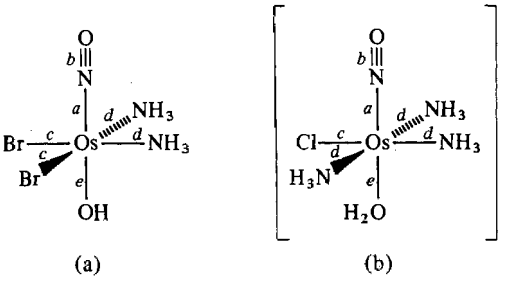

Figure 6 Structures of nitrosyl ammine complexes

In the unusual structure of $\overline{Os(NO)(ON{=}C(O)CF_3)}(OCOCF_3)(PPh_3)_2$ (VII) (Figure 7) the metal—ligand bond lengths between *cis* and *trans* ligands are the most marked for any $[Os(NO)]^6$ complexes, though the nature of the ligands is admittedly different. The coordinating atom *trans* to the nitrosyl group is from an *O,O'*-trifluoroacetohydroxamate ligand. In this a = 1.726(7), b = 1.209(9), c = 2.115(6), d = 2.063(6), e = 2.406(2), f = 2.375(2) and g = 1.984(6) Å[224] (see also ref. 229).

In $[Os(NO)(CO)Cl_2(PPh_3)_2]BF_4$ there is disorder between the carbonyl and nitrosyl ligands; the phosphine groups are *trans* to each other.[233]

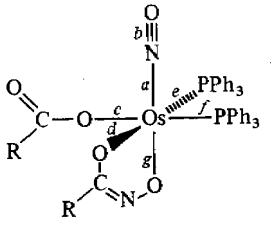

Figure 7 Structure of $\overline{Os(NO)(ON{=}C(O)CF_3)}(OCOCF_3)(PPh_3)_2$[299]

46.4.5.2 $[Os(NO)]^7$, $[Os(NO)]^8$ and $[Os(NO)_2]^8$ complexes

(i) $[Os(NO)]^7$ species

It has recently been shown that $OsCl_2(PPh_3)_3$ reacts with ONCl and ONBr to give $Os(NO)XCl(PPh_3)_2$ (X = Cl, Br); EPR data were reported.[213]

(ii)) $[Os(NO)]^8$ species

There are a few of these, all with phosphines or arsines and with six- or five-coordination. The ν_{NO} frequency in general for these lies lower than for those in $[Os(NO)]^6$ species, in the range 1650–1800 cm^{-1}.

The hydrides $Os(NO)H(PR_3)_3$ ($PR_3 = PMePh_2$, PPh_3) are made from $Os(NO)Cl_3(PR_3)_2$ with ethanolic KOH; the $PMePh_2$ complex may be fluxional in solution.[239]

The complex $Os(NO)Cl(PPh_3)_3$ is made from $Os(NO)(CO)Cl(PPh_3)_2$ in CH_2Cl_2 and air (a procedure giving $Os(NO)Cl(CO_3)(PPh_3)_2$) followed by treatment with PPh_3.[240] It reacts with diazomethane to give the carbene complex $Os(NO)(CH_2)Cl(PPh_3)_2$;[240,241] with the halogenated diazoalkane $IC(N_2)CO_2Et$ an aldoxime dinitrogen complex $Os(N_2)Cl_2\{N(OH)CHCO_2Et\}(PPh_3)_2$ is formed (see p. 556).[241]

The complexes $Os(NO)(NO_2)(PPh_3)_2$ and $Os(NO)Cl(AsPh_3)_2$, made from $OsCl_3$ and, in the first instance, N_2O_3 and PPh_3 and in the second ClNO and $AsPh_3$,[227] have unusually high ν_{NO} frequencies for $[OsNO]^8$ species (Table 10).

The complex $[Os(NO)(dppe)_2]^+$, made from $[Os(NO)(CO)_2(PPh_3)_2]BPh_4$ and dppe[242] will undergo electrochemical reduction in two reversible one-electron steps to give $[Os(NO)]^9$ and $[Os(NO)]^{10}$ species (equation 4).[243]

	$[Os(NO)dppe_2]^{2+}$	$\rightleftharpoons$	$Os(NO)dppe_2$	$\rightleftharpoons$	$[Os(NO)dppe_2]^-$	
$E_{\frac{1}{2}}$ (*vs.* SCE)		−1.33 V		−1.95 V		
ν_{NO} (cm^{-1})	1673		1417		1420	
Colour	Red		Brown		Red	(4)

There are also a number of nitrosyl carbonyl complexes in this category, a representative selection of which are listed in Table 10; general types are $[Os(NO)(CO)PR_3)_2]^+$, $[Os(NO)(CO)_2(PR_3)_2]^+$ and $Os(NO)(CO)X(PR_3)_2$.[242]

In the latter category the chloro complex $Os(NO)(CO)Cl(PPh_3)_2$ is of particular interest. It is made by reaction of $Os(CO)ClH(PPh_3)_3$ with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide, and reacts with HCl to give $Os(HNO)Cl_2(CO)(PMe_3)_2$. This latter complex was shown by X-ray crystal structure analysis to contain an N-bonded HNO group,[233] so presumably electrophilic attack on NO has occurred, possibly *via* a 20-electron intermediate such as $[Os(NO)(CO)Cl_2(PPh_3)_2]^-$. Another curious feature of $Os(NO)(CO)Cl(PPh_3)_2$ is that it exhibits *three* ν_{N-O} frequencies (at 1769, 1629 and 1560 cm^{-1}, shifting to 1742, 1598 and 1534 cm^{-1} on ^{15}N substitution). It has been surmised that the solid may contain more than one form of the species in dynamic equilibrium.[233] Another carbonyl complex of interest is $Os(NO)H(CO)(PPh_3)_2$, made from $Os(NO)(CO)Cl(PPh_3)_2$ and $NaBPh_4$;[244] its X-ray crystal structure has been obtained (see p. 551, Figure 9).

(*iii*) *X-Ray studies on $[Os(NO)]^8$ species*

Two studies have been reported, both on carbonyl nitrosyl complexes, but in both cases disorder prevented the NO and CO groups being distinguished. In $[Os(NO)(CO)_2(PPh_3)_2]ClO_4$, made from $Os(NO)H(CO)(PPh_3)_2$ and $HClO_4$, the trigonal bipyramidal structure has apical phosphine ligands,[244] and this is also the case[245] in $[Os(NO)(CO)(CNR)(PPh_3)_2]ClO_4$[245] (R = *p*-tolyl). In both, however, the Os—N—O unit is essentially linear.

(*iv*) *$[Os(NO)_2]^8$ species*

Few of these are known but there is an X-ray study on one, $[Os(NO)_2(OH)(PPh_3)_2]PF_6$, made by reaction of oxygen with $Os(NO)_2(PPh_3)_2$ in the presence of HPF_6. The crystal structure shows a distorted square-based pyramidal structure in which there is a bent apical nitrosyl group (Os—N—O = 133.6(1)°) and a linear basal nitrosyl ligand (Os—N—O = 177.6(12)°). The bond distances are: a = 1.86(1), b = 1.17(2), mean c = 2.434, d = 1.935(8). e = 1.63(1), f = 1.24(2) Å (Figure 8).[246] The two stretching frequencies of 1842 and 1632 cm^{-1}, recorded for the BF_4^- salt,[247] presumably correspond to those of the linear and bent moieties.

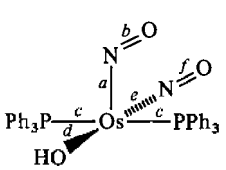

Figure 8 Structure of $[Os(NO)_2(OH)(PPh_3)_2]PF_6$[246]

There is a brief report of $[Os(NO)_2(OCOR)(PPh_3]_2OCOR$ ($R = CF_3$, C_2F_5);[225] reaction of $Os(NO)_2(PPh_3)_2$ with strong non-coordinating acids gives $[Os(NO)_2H(PPh_3)_2]^+$, but the species was not isolated.[247]

46.4.5.3 *[Os(NO)]^9, [Os(NO)]^{10} and [Os(NO)$_2$]^{10} complexes*

(i) [Os(NO)]^9 species

The only example would appear to be $Os(NO)dppe_2$, made by electrochemical reduction of $[Os(NO)dppe_2]^+$ (see below). It is dark brown and very air-sensitive, giving an ESR spectrum which seems to suggest that the unpaired electron is largely localized on the NO ligand. The very low ν_{NO} frequency of 1417 cm^{-1} suggests that it may contain a bent Os—N—O unit.[243]

(ii) [Os(NO)]^{10} species

Again the only example seems to be $[Os(NO)dppe_2]^-$ (see below);[243] the low ν_{N-O} frequency of 1420 cm^{-1} would be consistent with the presence of a bent Os—N—O ligand, equivalent to a coordinated NO^- group (a linear Os—N—O group would give an electron count of 20).

(iii) [Os(NO)$_2$]^{10} species

A very interesting complex is $Os(NO)_2(PPh_3)_2 \cdot \frac{1}{2}C_6H_6$, made from reaction of $Os(NO)H(PPh_3)_3$ with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide; it crystallizes as a hemisolvate from benzene.[248] The X-ray crystal structure shows it to be tetrahedral (N—Os—N = 139.1(3)°, P—Os—P = 103.51(6)°) with two essentially linear Os—N—O moieties (Os—N = 1.771(6) and 1.776(7) Å, N—O = 1.195(8) and 1.211(7) Å; Os—N—O = 178.7(7)° and 174.1(6)°).[248] Although the Os—N—O fragments are linear the ν_{N-O} frequencies are low, as is to be expected in view of competition for π-electron density on the osmium atom. ESCA studies suggest that the effective oxidation state of the osmium lies between II and 0.[248]

The hydrido complex $[Os(NO)_2H(PPh_3)_2]^+$ is formed by the action of strong acids on the complex, and the reaction of CO under pressure with this gives $Os(CO)_4(PPh_3)$, with CO_2 and N_2 as by-products.[249]

Another interesting complex in this category is $Os(NO)_2(OEP)$ (OEP = octaethylporphyrin), made from nitric oxide and Os(CO)py(OEP);[232,255] one ν_{NO} frequency is very low (1500 cm^{-1}) so that one Os—N—O group could be substantially more bent than the other.

46.4.6 Complex of HNO

As mentioned above (p. 550), reaction of $Os(NO)Cl(CO)(PPh_3)_2$ with HCl gives $Os(NHO)Cl_2(CO)(PPh_3)_2$, a rare example of a complex containing a coordinated HNO group. The X-ray crystal structure (Figure 9) has been determined. In this $a = 1.915(6)$, $b = 1.193(7)$, $c = 0.94(11)$, $d = 2.440(2)$, mean $e = 2.434(2)$, $f = 1.899(8)$, $g = 2.429(2)$ Å; ONH = 99(7)°. The ν_{NO} frequency is at 1410 cm^{-1}, shifting to 1393 cm^{-1} in ^{15}N substitution.[233]

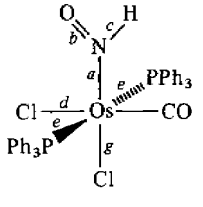

Figure 9 Structure of $Os(HNO)(CO)(PPh_3)_2$[233]

46.4.7 Diazenido Complexes

Reaction of $Os(PPh_3)_3X_3$, LiX and aryldiazonium salts $(RN_2)BF_4$ (X = Cl, R = Ph;[256] X = Br, R = Ph,[256] *p*-C_6H_4Me[257a]) gives $Os(N_2R)(PPh_3)_2X_3$, with the likely structure shown in Figure 10.[256]

ESCA data on $[Os(N_2\text{-}p\text{-}MeC_6H_4)(PPh_3)_2]Br_3$ and on $Os(N_2\text{-}p\text{-}C_6H_4F)(PPh_3)_2Br_3$ suggest that, in the latter case at least, the spectra could distinguish between the two nitrogen atoms.[257b]

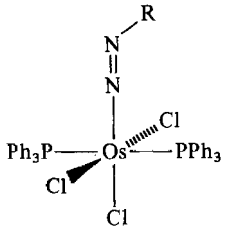

Figure 10 Likely structure of $Os(N_2R)(PPh_3)_2X_3$[256]

46.4.8 Thionitrosyl (NS) Complexes

Despite the relatively large number and diversity of osmium nitrosyl complexes (p. 544) rather few thionitrosyls of the metal are known (see Table 11), and this is clearly a field of potential interest for further study. It should in particular be possible to obtain complexes containing a bent Os—N—S moiety. It is interesting to note that two examples of bis-thionitrosyls, a very rare class of complex, are known with osmium. The formal oxidation state of the metal in all its known thionitrosyls is II with the exception of $(Ph_4As)[Os(NS)Cl_5]$; again by analogy with the nitrosyl chemistry, osmium(0) thionitrosyls might be expected to exist.

Table 11 Thionitrosyl and NSU Complexes

Complex	*Colour*	*M.p. (°C)*	ν_N	*Spectroscopic and other properties*
$Os(NS)_2Cl_4$	Brown		1388, 1326, 1308	IR[261]
$(Ph_4As)[Os(NS)_2Cl\cdot Cl_4]$	Black		1298, 1215	IR, X-ray[261]
$Os(NS)Cl_3(PMe_2Ph)_2$	Green		1285	IR, ^{1}H NMR[262]
$Os(NS)Cl_3(PPh_3)_2$	Green	145–147	1294,[263] 1290[160]	IR,[263] X-ray[260]
$Os(NS)Cl_3(AsPh_3)_2$	Green	150–152	1282,[262] 1290[263]	IR[262,263]
$Os(NS)Cl_3$bipy	Green		1282	IR[262]
$Os(NS)Cl_3py_2$	Green-yellow		1284	IR[262]
$(Ph_4P)_2[Os(NS)(NCS)_5)$	Green-brown		1270	IR[265]
$(Ph_4As)[Os(NS)Cl_5]$	Black		1340	IR[201]
trans-$(Ph_4P)[Os(NS)Cl_4(H_2O)]$	Green		1285	IR, X-ray[264]

Preparative routes involve sulfur abstraction by osmium(VI) nitrido complexes from S_2Cl_2 or SCN^-, though the mechanisms of these reactions are not clear; reaction of halides with $(NSCl)_3$ has also been used.

The subject of thionitrosyl coordination chemistry has recently been reviewed.[258] The NS ligand has been variously described as being a better σ donor and π acceptor[258,259] or a better σ donor but a worse π acceptor than NO.[260]

46.4.8.1 Osmium(II)

(i) Bis thionitrosyls

Two such species are known for osmium. Reaction of Os_2Cl_{10} with $(NSCl)_3$ yields $Os(NSCl)_2Cl_4$ (see p. 553 below) which, with $(Ph_4As)Cl$, gives $(Ph_4As)[Os(NS)_2Cl\cdot Cl_4]$. The X-ray crystal structure of this (Figure 11) shows the thionitrosyl ligands to be *cis* and deviating only slightly from linearity (the OsNS angle is 169.5°). A loosely bound chloro ligand is attached to the sulfur end of an NS group (S···Cl 2.28 Å); in the crystal it is statistically belongs to both sulfur atoms with an occupation probability of 50%.

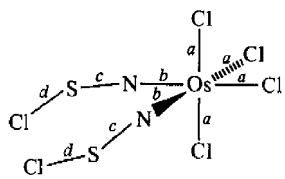

Figure 11 Structure of the anion in $(Ph_4As)[Os(NS)_2Cl\cdot Cl_4]$[261]

The Os—N distance of 1.83 Å is comparable with those found in nitrosyl complexes and is clearly indicative of a measure of back-bonding, but there is no apparent *trans* shortening or lengthening effect on the opposite chloro ligands.[261] In the structure, $a = 2.36$, mean $b = 1.835$, mean $c = 1.46$, mean $d = 2.27$ Å.[261]

Reaction of this material with $GaCl_3$ gave the neutral bis thionitrosyl, $Os(NS)_2Cl_4$. The IR spectrum suggests a *cis* configuration for the complex; although three bands appear in the N—S stretching region (1388, 1326 and 1308 cm^{-1}) the latter two are thought to arise from Fermi resonance. The Os—N stretches appear at 385 and 369 cm^{-1}, though the latter could be an Os—Cl mode.[261]

(*ii*) *Mono thionitrosyls*

The first thionitrosyl complexes of osmium, $Os(NS)X_3L_2$ (X = Cl, Br, L = $AsPh_3$, PMe_2Ph, $\frac{1}{2}$bipy), were made by Chatt by reacting the nitrido species $OsNX_3L_2$ with S_2Cl_2; the pyridine complex $Os(NS)Cl_3py_2$ was made from $[OsNCl_4]^-$, pyridine and S_2Cl_2.[262] The mechanism of the reaction is not at all clear. In the corresponding reaction of S_2Cl_2 with rhenium(V) nitrido complexes to give thionitrosyls it was postulated that nucleophilic attack of S_2Cl_2 at the sulfur atom by the nitrido ligand might occur, but this is less likely for osmium since osmium(VI) nitrido complexes exhibit pronounced electrophilicity at the N^{3-} ligand (p. 561). The ^{1}H NMR spectra of $Os(NS)Cl_3(PMe_2Ph)_2$ was measured and a structure proposed akin to that of Figure 12, with *trans* virtually coupled phosphorus ligands; the complexes are diamagnetic and probably contain linear Os—N—S units.[262]

Reaction of '$OsCl_3$' with $(NSCl)_3$ and L (L = PPh_3, $AsPh_3$) yields $Os(NS)Cl_3L_2$;[263] an improved method for preparation of $Os(NS)Cl_3(PPh_3)_2$ involves the use of $OsCl_2(PPh_3)_3$ and $(NSCl)_3$. The X-ray crystal structure (Figure 12) shows the Os—N—S unit to be linear;[259] the structure is analogous to those for $Os(NO)Cl_3(PPh_3)_2$ and $OsNCl_3(PPh_3)_2$, with $a = 1.779(9)$, $b = 1.503(10)$, mean $c = 2.459(2)$, mean $d = 2.387(3)$ and $e = 2.399(3)$ Å.

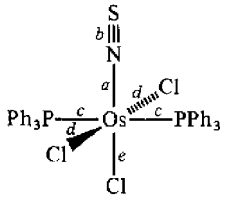

Figure 12 Structure of $Os(NS)Cl_3(PPh_3)_2$

A number of other monothionitrosyls of osmium have recently been reported. Reaction of Os_2Cl_{10} and $(NSCl)_3$ in the presence of $POCl_3$ yields $Os(NS)Cl_4(POCl)_3$ from which $(Ph_4As)[Os(NS)Cl_5]$ can be made,[201] and the latter can also be obtained, as the PPh_4^+ salt, from '$Os(NS)Cl_3$' (a polymer, made from $OsCl_3$, $(NSCl)_3$ and PPh_4^+[264]). Recrystallization of this from water–methanol gives *trans*-$(PPh_4)[Os(NS)Cl_4(H_2O)]$, the structure having been elucidated by X-ray diffraction (Os—N = 1.731(4), N—S = 1.514(5) Å with an Os—N—S angle of 174.9(3)°; Os—O = 2.165(4), mean Os—Cl = 2.356 Å, mean N—Os—Cl = 94.8°).[264]

46.4.8.2 Osmium(III)

Another example of sulfur abstraction by an osmium nitrido complex occurs in the reaction of $[OsNCl_4]^-$ with $(PPh_4)NCS$ to give $(Ph_4P)_2[Os(NS)(NCS)_5]$, in which the thiocyanate groups are thought to be bonded to the metal *via* nitrogen.[265] For reactions of the complex see Scheme 10, p. 563.

46.4.9 Complex of NSCl

The precursor species for $[Os(NS)_2Cl\cdot Cl_4]^-$ and $Os(NS)_2Cl_4$ is $Os(NSCl)_2Cl_4$, a black material obtained by reaction of $(NSCl)_3$ with Os_2Cl_{10}. It is thought to have a *cis* configuration with bent N—S—Cl ligands bound to osmium *via* the nitrogen atoms. The N—S stretching vibration appears at 1335 cm^{-1}.[261]

46.4.10 Dinitrogen (N_2) Complexes

The most stable osmium dinitrogen complexes occur with the metal in the divalent state, as would be expected for this π-acidic ligand, but a substantial number of osmium(III) dinitrogen complexes are also known, though these tend to lose N_2 readily and are kinetically much more labile than their osmium(II) counterparts (see Table 12). A few bis(dinitrogen) species are known with a *cis* arrangement of N_2 ligands; such a configuration is best adapted to π-acidic ligands, there being less competition for the metal t_{2g} orbitals than for the *trans* arrangement. An interesting feature of osmium dinitrogen chemistry is the formation of bridged species containing the Os—N≡N—Os and Os—N≡N—Ru units with apparently mixed oxidation states in some cases.

Dinitrogen complexes of osmium are often synthetically useful because the N_2 group can easily be displaced, especially by acids.

Table 12 Dinitrogen Complexes

Complex	*Colour*	ν_N (cm^{-1})	*Spectroscopic and other properties*[d]
$[Os(N_2)(NH_3)_5]Cl_2$	Yellow	2022	IR,[266,285,286] Raman,[285] UV/vis,[266,268] ESCA[282] X-ray[267]

[a] Bromo and iodo complexes and *trans* isomers also known. [b] L = isonicotinamide. [c] Also PEt_3, $PMePh_2$, PEt_2Ph, $PEtPh_2$, PPr^n_2Ph, $AsMe_2Ph$, $AsEt_2Ph$. [d] CV = cyclic vultammetry.

46.4.10.1 Mononuclear complexes

(*i*) *Complexes with ammines and amines*

(*a*) *Osmium(II)*. Reaction of salts of $[OsCl_6]^{2-}$ with hydrazine hydrate gives $[Os(N_2)(NH_3)_5)^{2+}$;[266] chloride, bromide, iodide, perchlorate, tetrafluoroborate and tetraphenylborate salts have been made. The X-ray crystal structure (Figure 13) shows the *trans* ammine group to be slightly but significantly longer than the *cis* ammines ($a = 1.842(13)$, $b = 1.12(2)$, mean $c = 2.144$, $d = 2.151(15)$ Å) while the Os—N (N_2) distance is clearly much shorter than that expected for a pure σ bond.[267] Photolytic studies on the ion have been reported,[268] and γ irradiation of the complex in methanol generates the OH radical which reacts to give $[Os(N_2)(NH_2)(NH_3)_4]^{2+}$.[269] It is possible that a *trans* effect may be operative such that the *trans* ammine protons become more acidic.

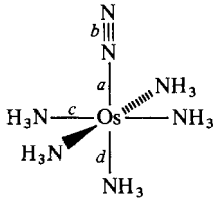

Figure 13 Structure of $[Os(N_2)(NH_3)_5]Cl_2$[267]

Reaction of $[Os(NH_3)_5CO]^{2+}$ with HCl and KNO_2 yields *cis*-$[Os(N_2)(NH_3)_4(CO)]^{2+}$; *trans*-$[Os(N_2)(NH_3)_4I]^+$ is made from $[Os(N_2)(NH_3)_5]^{2+}$ and chromium(II) with HCl and KNO_2. A slightly different route was used to make *cis*- and *trans*-$Os(N_2)(NH_3)_3X_2$ (X = Cl, Br, I), by treating *cis*- or *trans*-$[Os(NH_3)_4X_2]^+$ in HCl with KNO_2 and NO.[64] Complexes of the form *cis*-$[Os(N_2)(NH_3)_4L]^{2+}$ (L = isonicotinic acid, isonicotinamide, pyrazine and substituted pyrazines) are considered on p. 535.

There are also bis(dinitrogen) complexes of osmium(II). The first to be made was *cis*-$[Os(N_2)_2(NH_3)_4]^{2+}$ by a 'diazotization' procedure using $[Os(N_2)(NH_3)_5]^{2+}$ and nitrite in acid solution.[270] Vibrational spectroscopic data using both ^2H and ^{15}N substitution were obtained for the salts,[271] which are useful precursors for other osmium complexes involving pyrazine (see p. 536). A similar preparative procedure involving $[Os(N_2)(NH_3)_4L]^{2+}$ gives *cis*-$[Os(N_2)_2(NH_3)_3L]^{2+}$ (L = isonicotinamide).[98]

(*b*) *Osmium(III)*. Oxidation of $[Os(N_2)(NH_3)_5]^{2+}$ with cerium(IV) gives $[Os(N_2)(NH_3)_5]^{3+}$,[64] and the existence of the ion has also been shown electrochemically.[272] Reaction of *cis*- or *trans*-$[Os(NH_3)_4X_2]^+$ with HCl and NO_2^- gives *cis*- and *trans*-$[Os(N_2)(NH_3)_4X_2]^+$ respectively (X = Cl, Br, I), and a similar method yields *cis*- and *trans*-$[Os(N_2)(NH_3)_3X_2]^+$ from *mer*- and *fac*-$Os(NH_3)_3X_3$ (X = Cl, Br, I); *mer*-$Os(N_2)(NH_3)_2I_3$ was also prepared.[64]

The kinetic stability of these osmium(III) dinitrogen species, while less than that of the corresponding osmium(II) complexes, is far greater than for ruthenium(III) and shows that osmium(III) is capable of effective metal-to-ligand donation. Comparisons have been drawn, using electrochemical and pK_a data, between the π-acceptor properties of CO and N_2 in $[OsL(NH_3)_5]^{3+}$ (L = CO, N_2) species;[64] thus, the pK_a of $[Os(NH_3)_6]^{3+}$ lies near 16,[55] that of $[Os(N_2)(NH_3)_5]^{3+}$ is about 6.6 and that of $[Os(NH_3)_5CO]^{3+}$ about 2.5. In basic solution osmium(III) dinitrogen complexes disproportionate to an osmium(II) dinitrogen species and osmium(VI).[64]

(*c*) *Osmium(IV)*. The possibility of the existence of $[Os(N_2)(NH_3)_5]^{4+}$ has been mentioned.[272]

(*ii*) *Complexes with phosphines and arsines*

(*a*) *Osmium(II)*. These are summarized in Table 12. Most of them take the form *mer*-$(Os(N_2)(LR_3)_3X_2$ and are made by the reaction of $Os(LR_3)_3X_3$ in THF with zinc amalgam and N_2 under pressure.[273] The dinitrogen ligand has weakly basic properties; thus, *mer*-$Os(N_2)(PEt_2Ph)_3Cl_2$ forms a weak complex $Os(NNAlMe_3)(PEt_2Ph)_3Cl_2$ with the etherate of trimethylaluminum.[274] IR data (from comparison of intensities of the N≡N and C≡O stretching frequencies in $Os(N_2)(PEt_2Ph)_3Cl_2$ and $Os(CO)(PEt_2Ph)_3Cl_2$ suggest that N_2 is a weaker σ donor and weaker π acceptor than CO in these complexes.[275]

There are also hydrido dinitrogen complexes. Reaction of $OsH_4(PEtPh_2)_3$ with toluene-*p*-sulfonyl azide yields $Os(N_2)H_2(PEtPh_2)_3$,[276] while monohydrido complexes $Os(N_2)(PR_3)_3HX$ (PR_3 = PMe_2Ph, X = Cl, Br; PR_3 = PEt_2Ph, X = Cl) are made from $Os(N_2)(PR_3)_3X_2$ and sodium borohydride. The structure is thought to involve a *mer* arrangement of phosphine groups with the hydride *cis* to the coordinated dinitrogen.[277] A dinitrogen complex with the chelating phosphine depe, $[Os(N_2)H(depe)_2]BPh_4$, is made from *trans*-$[OsHCl(depe)_2]^+$, nitrogen and sodium tetraphenylboron.[278] With HCl, $Os(N_3)(diars)_2Cl$ gives $[Os(N_2)(diars)_2Cl]Cl$.[205] Two dinitrogen phosphine complexes of osmium have been studied by X-ray methods. Reaction of *mer*-$Os(N_2)(PMe_2Ph)_3Cl_2$ with $Pb(SC_6F_5)_2$ gave *mer*-$Os(N_2)(PMe_2Ph)_3Cl(SC_6F_5)$ which has the structure shown in Figure 14 in which a = 1.909, b = 1.112, mean c = 2.37, d = 2.507, e = 2.37 and f = 2.42 Å.[279]

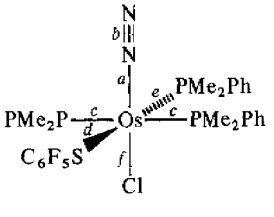

Figure 14 Structure of $Os(N_2)(PMe_2Ph)_3Cl(SPh)$[279]

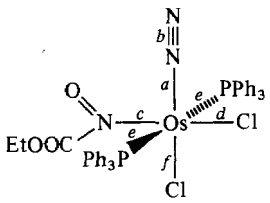
An unusual dinitrogen complex generated from the halogenated diazoalkane $IC(N_2)CO_2Et$ and $Os(NO)Cl(PPh_3)_3$ in the presence of HCl yields $Os(N_2)[N(OH)CHCO_2Et](PPh_3)_2Cl_2$; an X-ray crystal study shows the structure to be that shown in Figure 15 in which a = 1.927(4), b = 1.063(5), c = 2.026(4), d = 2.412(1), mean e = 2.407 and f = 2.431(1) Å.[241]



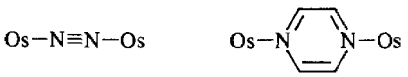


Figure 15 Structure of $Os(N_2)\{N(OH)CHCO_2Et\}(PPh_3)_2Cl_2$[241]

46.4.10.2 Binuclear dinitrogen-bridged complexes

A number of these have been isolated, including species with mixed oxidation states and heteronuclear species with ruthenium. In their general chemistry these remarkable complexes show clear analogies with bridging pyrazine complexes (p. 536):

The best characterized species is $[Os_2(N_2)(NH_3)_{10}]^{5+}$ made as a bromide or as a tosylate from reaction of $[Os(H_2O)(NH_3)_5]^{3+}$ with $[Os(N_2)(NH_3)_5]^{2+}$ in the presence of zinc amalgam. The stability of the mixed valence system (formally Os^{III-II}) has been ascribed to electronic delocalization effects and an MO scheme proposed,[280a] but it is not clear why it appears to be more stable than its reduction product, $[Os(N_2)(NH_3)_{10}]^{4+}$. Magnetic circular dichroism spectra and cyclic voltammetry of the ion have been measured.[280b] A number of other mixed homonuclear species are known, *viz.* $[Os_2(N_2)(NH_3)_9(H_2O)]^{5+}$, $[Os_2(N_2)(NH_3)_9Cl]^{4+}$, $[Os_2(N_2)(NH_3)_8Cl_2]^{3+}$ and $[Os_2(N_2)(NH_3)_9(N_2)]^{5+}$. The latter has one terminal and one bridging N_2 ligand, and is made by reaction of $[Os(N_2)(NH_3)_5]^{2+}$ with *cis*-$[Os(N_2)_2(NH_3)_4]^{2+}$.[281] There is some evidence from ESCA data that the ion $[Os_2(N_2)(NH_3)_8Cl_2]^{3+}$, as the trichloride, is indeed a delocalized Class III mixed valence species.[282a] Another binuclear dinitrogen-bridged complex is $[Os_2(N_2)(NH_3)_8(CO)_2]Cl_4$, made by oxidation of $[Os(NH_3)_5CO]^{2+}$ with persulfate, cerium(IV), permanganate or electrolytically. A possible route for formation of the complex by oxidation of $[Os(NH_3)_5CO]^{3+}$ to a nitrido species of higher oxidation state, possible osmium(V) with coupling of nitrido moieties to give the product, was suggested.[70] The isolation of the blue $[Os_2(N_2)(NH_3)_{10}]^{6+}$ by oxidation of the pentapositive species with chlorine has recently been reported.[282b]

Heteronuclear dinitrogen-bridged complexes are also known. Reaction of *cis*-$[Ru(NH_3)_4(H_2O)_2]^{2+}$ with $[Os(N_2)(NH_3)_5]^{2+}$ yields $[(NH_3)_5Os(N_2)Ru(NH_3)_4(H_2O)]^{4+}$, and this can be oxidized to $[(NH_3)_5Os(N_2)Ru(NH_3)_4(H_2O)]^{5+}$.[283] There is also a very brief mention of $[OsRu(N_2)(NH_3)_{10}]^{n+}$ ($n = 4, 5$).[284]

46.4.11 Hydrazine Complexes

A few of these are known, all with osmium(II) and with phosphine or arsine coligands.

Reaction of $Os(PMe_2Ph)_3Cl_3$ with N_2H_4 or N_2H_3Ph in ethanol yields $Os(PMe_2Ph)_3Cl_2(N_2H_4)$ and $Os(PMe_2Ph)_3Cl_2(NH_2NHPh)$; the use of $Os(PR_2Ph)_3Cl_3$ (R = Et, Bu^n) as starting materials and N_2H_4 under reflux gives apparently binuclear species, $Os_2(PR_2Ph)_4Cl_4(N_2H_4)_2$, with the proposed structure shown in Figure 16.[72]

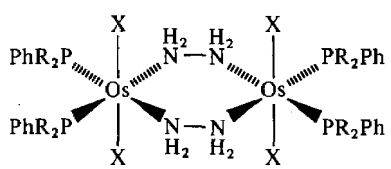

Figure 16 Proposed structure of $Os_2(PR_2Ph)_4Cl_4$[72]

The only reported example of an arsine complex is $Os\{As(p\text{-}MeC_6H_4)_3\}_3Cl_2(N_2H_4)$, made from $Os(As(p\text{-}MeC_6H_4)_3Cl_3$ and N_2H_4.[110]

46.4.12 Hydroxylamine Complex

It seems strange that no hydroxylamine complexes of osmium are established. There is a brief report of a deprotonated complex $Os(NO)(NHOH)Cl_2(PPh_3)_2$, made from $Os(NO)_2(PPh_3)_2$ and HCl. The ν_{NO} band is at 1860 cm^{-1}.[247]

46.4.13 Amino (—NH_2) and Organoamido (—NR_2) Complexes

Relatively few of these are known, though it might be anticipated that more osmium complexes with these ligands should exist.

46.4.13.1 Amino complexes

The only established example is *trans*-$[Os(NO)(NH_2)(NH_3)_4]^{2+}$ (see p. 546); the species $[Os(N_2)(NH_2)(NH_3)_4]^{2+}$ has also been claimed (see p. 554). Further investigation of '$[Os(NH_2)X_5][Os(NH_3)_5X]$' (X = Br, I), made by heating $[Os(NH_3)_6]X_3$,[75] is clearly needed; '$K_2[Os(NH_2)Cl_5]$' is known to be $K_2[Os(NH_3)Cl_5]$ (see p. 529). There is also a need to investigate $Cs_2[Os_2(NH_2)_2X_8]$ and $Cs_2[Os_5(NH_2)_8X_{14}]$ (X = Cl, Br, I), made from HX and $[Os(NH_3)_6][OsBr_6]$.[289] The amido ammine $[Os(NH_2)(NH_3)_5]^{3+}$ may be the first product of the one-electron oxidation of $[Os(NH_3)_6]^{3+}$ in acidic media.[55]

46.4.13.2 Alkanolaminato and diaminato complexes

Reaction of $OsO_2(NBu^t)_2$ with dimethyl or diethyl fumarate gives the osmium(VI) 'esters' $OsO_2(NBu^t(CHCO_2R)_2NBu^t)$ (R = Me, Et); the complex from diethyl fumarate is monomeric in benzene and the structure given in Figure 17(a) was proposed.[290] A related complex $OsO_2(NBu^t(CHCN)_2NBu^t)$ has recently been made from $OsO_2(NBu^t)_2$ and fumaronitrile.[291] Reaction of $OsO(NBu^t)_3$ and dimethyl fumarate gives $OsO(NBu^t)(NBu^t(CHCO_2Me)_2NBu^t)$,[290] presumably having the structure shown in Figure 17(b).

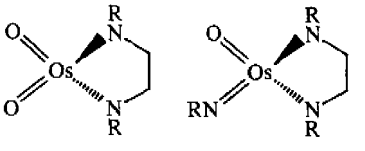

Figure 17 Proposed structures of diaminato complexes[290]

These monomeric and presumably tetrahedral complexes are intermediates in the diamination of alkenes (see p. 559). It is curious that, whereas OsO_4 and $OsO_3(NR)$ react with alkenes R′ to give square-based pyramidal dimers $Os_2O_4(O_2R')_2$ (p. 593) and $[OsO_2(OR'(NR))]_2$ (p. 559) respectively, the reaction products of $OsO_2(NR)_2$ (and presumably of $OsO(NR)_3$) with alkenes are monomeric:[290] there is no obvious reason for this. It is significant that Os—N rather than Os—O bonds are formed in these reactions.[290]

Alkanolaminato complexes $[OsO_2(OR'NR)]_2$ are made from $OsO_3(NR)$ and alkenes R′;[291,300] the X-ray crystal structure of $[OsO_2(OMeCH_2NBu^t)]_2$ shows this to have structure (I), Scheme 8.[291,291a]

46.4.14 Imido (=NH) and Organoimido (=NR) Complexes

This is an interesting area of osmium chemistry which stands much in need of development. Apart from the two incompletely characterized NH complexes, most of the organoimido chemistry is that of osmium(VIII); species such as $OsO_3(NR)$ will undergo oxyamination reactions with alkenic double bonds, and such reactions may be made catalytic. However, because of the high reactivity of osmium(VIII), only a small range of tertiary imido complexes have been prepared (R = Bu^t, Am^t, 1-adamantyl, Oct^t).

There is a good review on organoimide chemistry,[292] and organoimides are also mentioned in the course of a review on nitrido complexes.[293]

46.4.14.1 Complexes with =NH

Two binuclear complexes containing 2,2′-bipyridyl (bipy) have been reported in which the imido ligand appears to function in a bridging role. These are $[Os_2(NH)Cl_2(bipy)_4](ClO_4)_2$, made from $[Os(bipy)_2(NH_3)Cl]^+$ and cerium(IV), and $Os_2(NH_2)(bipy)_4$, made from $Os(bipy)_2Cl_2$ and ammonia.[173] The IR spectrum of the first complex has been recorded.[294] The oxidation states seem too low for these to be true imido complexes and further investigation would certainly be of interest.

46.4.14.2 Complexes with =NR

(i) Osmium(V) and osmium(VI)

It now appears that '$Os(NC_6H_4X)Cl_3(PPh_3)_2$' (X = H, *p*-MeO, *p*-Cl)[295] made from '$OsOCl_3(PPh_3)_2$' (now known to be a mixture containing $OsO_2Cl_2(PPh_3)_2$; see p. 584) are nitrile complexes $Os(NCC_6H_4X)Cl_3(PPh_3)_2$ (see p. 566).[296]

The complex $(PPh_4)[Os(NC(CCl_3)NCCl(CCl_3)Cl_5]$ may perhaps be regarded as an imido complex of osmium(VI); it is made by reaction of Os_2Cl_{10} with trichloroacetonitrile, and X-ray studies show it to have the structure shown in Figure 18. In this, $a = 1.97(1)$, $b = 1.34(1)$, mean $c = 2.32$, $d = 2.279(3)$, Os—N—C = 142.1(8)°. The Os—N distance (*a*) is slightly shorter than that expected for a single bond; the Os—N—C angle is 142.1(8)°.[297]

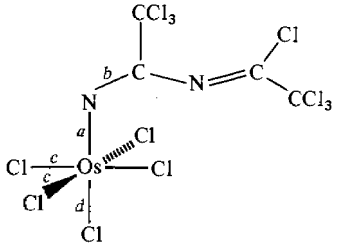

Figure 18 Structure of $(Ph_4P)[Os\{NC(CCl_3)NCCl(CCl_3)\}Cl_5]$[297]

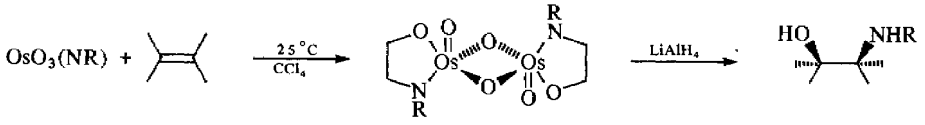
(ii) Osmium(VIII)

The established organoimido complexes all contain osmium(VIII) and are listed in Table 13.

Table 13 Organoimido Complexes



Complex	Colour	*M.p.* (°C)	ν_{OsN} (cm^{-1})	ν_{OsO} (cm^{-1})	Spectroscopic and other properties
$OsO_3(NBu^t)$	Yellow	100	1184	925, 912	IR,[299] UV/vis,[298] ^{13}C NMR[292,309]
$OsO_3(NAm^t)$		57–59	1210	930, 915	IR, ^1H NMR[301]
$OsO_3(NAd)$[a]	Yellow	176–177	1215	925, 915	IR, ^1H NMR,[301] X-ray[302]
$OsO_3(NOct^t)$	Yellow	51.5	1224	928, 910	IR,[291] UV/vis[290]
$[OsO_3(NOct^t)]_2DABCO$[b]	Red		1210	875, 850	Raman, IR, X-ray[308]
$OsO_2(NBu^t)_2$	Yellow	119–120 (d)	1200	888, 878	IR, ^1H NMR, MS,[290] X-ray,[302] ^{13}C NMR[309]
$OsO_2(NAm^t)_2$					
$OsO_2(NAd)_2$	Yellow	209–211	1175	880, 865	IR, ^1H NMR[290]
$OsO_2(NAm^t)(NAd)$	Yellow	72–74	1180	885, 875	IR, ^1H NMR[290]
$OsO(NBu^t)_3$	Yellow	114–116 (dec)	1190, 1100	838	IR, ^1H NMR, MS,[290] ^{13}C NMR[309]
$OsO(NAd)_2(NBu^t)$	Orange	146 (dec)	1160, 1100	838	IR, ^1H NMR[290]

[a] Ad = 1-adamantyl. [b] DABCO = 1,4-diazabicyclo[2.2.2]octane. [c] Not specifically assigned as such in reference.

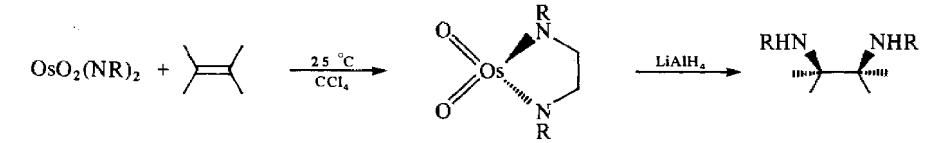
(*a*) *Monoimido species, $OsO_3(NR)$.* The first to be made were $OsO_3(NBu^t)$ and $OsO_3(NOct^t)$, obtained from OsO_4 and the tertiary amine in ligroin.[298] Subsequent preparations of $OsO_3(NBu^t)$ used pentane[299–301] or water[290] as solvent. Other species made by similar routes are $OsO_3(NAm^t)$[290,301] and the 1-adamantyl complex OsO_3(N-1-Ad).[300,301]

The X-ray crystal structure of the latter complex has been determined. The coordination about the osmium is tetrahedral; the Os=N distance of 1.697(4) Å is slightly shorter than the mean Os =O distance of 1.714(4) Å and not much longer than the Os=N distance in terminal nitrido complexes below. The N—C distance is 1.448(6) Å and the Os—N—C angle 171.4(4)°.[302]

The complexes will effect oxyamination reaction with alkenes in a stereospecific reaction (Scheme 8).[290] After reductive cleavage of the intermediate alkanolaminato complex (I) (see below) vicinal amino alcohols (II) are formed. The reaction is unusual in that the new C—N bond is always formed at the least substituted terminal alkenic carbon atom, and there is a clear preference for the imido complex to use its NR group for coordination to the osmium despite the steric restraints of R.[299,300] However, the least sterically hindered part of the alkene moiety is attached to the nitrogen atom.[290,291,300] The yields of amino alcohols in the reaction can be improved by addition of tertiary alkyl bulkhead amines (see below).

(I) (II)

Scheme 8 Oxyamination by $OsO_3(NR)$[300,303]



The oxyamination reactions can be rendered catalytic by using chloramine-T[303–305] or *N*-chloro-*N*-argentocarbamates.[306]

(b) The adducts $OsO_3(NR)\cdot L$ and $[OsO_3(NR)]_2L'$. Just as OsO_4 forms weak adducts with nitrogen donors (see p. 592), $OsO_3(NR)$ (R = Bu^t,[307] 1-Ad, Oct^t)[291] will form 1:1 species $OsO_3(NBu^t)\cdot L$ (L = quinuclidine, 3-quinuclidinone, 3-quinuclidinyl acetate[307]) and $OsO_3(NR)\cdot L$ (R = 1-Ad, Oct^t; L = quinuclidine).[291] There are also 2:1 species $[OsO_3(NBu^t)]_2\cdot L'$ with L′ = hexamethylenetetramine (HMT) or 1,4-diazabicyclo[2.2.2]octane (DABCO)[307] and the same nitrogen donors form similar complexes with $OsO_3(NR)$ (R = Am^t, Oct^t).[291] The X-ray crystal structure of $[OsO_3(NOct^t)]_2\cdot$DABCO has recently been determined; the DABCO ligand bridges two $OsO_3(NOct)^t$ moieties (Os—N = 2.45(1) Å), a little longer than the Os—N distance in $(OsO_4)_2\cdot$HMT due perhaps to a slightly greater *trans* weakening effect of the imido group over the oxo ligand). The osmium atoms have trigonal bipyramidal coordination, the apical positions being occupied by one DABCO nitrogen atom at the imido nitrogen (Os—N = 1.73(1) Å) while the equatorial positions are occupied by the oxo ligands (mean Os=O = 1.71 Å).[308]

(c) Bis imido species, $OsO_2(NR)_2$. Reaction of OsO_4 and *N-tert*-butyltriphenylphosphineimine or *tert*-butyltrimethylsilylamine[302] gives $OsO_2(NBu^t)_2$,[290] and the 1-adamantylimido complex $OsO_2(NAd)_2$ was similarly made; a mixed species $OsO_2(NAm^t)(NAd)$ was prepared from $OsO_3(NAm^t)$ and *N*-1-adamantyltriphenylphosphineimine.[290]

The X-ray crystal structure of $OsO_2(NBu^t)_2$ again shows the expected tetrahedral structure with Os=O at 1.744(6) Å; however, one of the imido groups is essentially linear (Os—N = 1.710(8) Å, Os—N—C = 178.9(9)°) and the other substantially bent (Os—N = 1.719(8) Å, Os—N—C = 155.1(8) Å.[301] The presence of one linear and one bent imido group in the complex has been partly rationalized on electron-counting procedures and MO considerations,[292,301] although both IR and ^{1}H NMR data indicate that both the imido groups are equivalent in solution.[302]

Reaction of $OsO_2(NBu^t)_2$ with alkenes followed by reductive cleavage gives vicinal diamines (IV; Scheme 9), and the intermediate 'ester' (I) (see p. 557) was isolated using dimethyl or diethyl fumarate as the reacting alkene. Again, the preference for Os—N rather than Os—O bond formation is noteworthy.[290]

(III) (IV)

Scheme 9 Diamination by $OsO_2(NR)_2$[290]

Efforts to obtain adducts of $OsO_2(NR)_2$ with nitrogen donors were unsuccessful;[291] this is not surprising since, if the osmium were to be trigonal bipyramidal as in $OsO_4\cdot L$ (p. 592) and $[OsO_3(NR)]_n\cdot L$ (p. 592), there would be considerable steric interaction between L and a necessarily equatorial NR group.

(d) Trisimido species, $OsO(NR)_3$. Reaction of OsO_4, $OsO_3(NBu^t)$ or $OsO_2(NBu^t)_2$ with *N-tert*-butyl-tri-*n*-butylphosphineimine gives $OsO(NBu^t)_3$, and the mixed complex $OsO(NAd)_2(NBu^t)$ can be made from $OsO_2(NAd)_2$ and *N-tert*-butyl-tri-*n*-butylphosphineimine.[290]

With alkenes, $OsO(NBu^t)_3$ effects vicinal diamination; the intermediate ester (III) (see Scheme 9) was isolated from the reaction with dimethy fumarate.[290]

(e) Tetrakisimido species, $Os(NR)_4$. Species of the type $Os(NBu^t)_3(NSO_3Ar)$ have been briefly mentioned (Ar = 2,4,6-trimethylphenyl, 2,4,6-triisopropylphenyl, *p*-tolyl).[292]

46.4.15 Nitrido Complexes

In this section we consider together all the osmium complexes involving the nitrido (N^{3-}) ligand since it appears that this is the dominant factor in the bonding of these complexes (for the same reason all oxo (O^{2-}) and nitrosyl (NO) complexes are grouped together).

Osmium forms a reasonably diverse number of nitrido complexes, particularly in the VI oxidation state (see Table 14); in this it resembles rhenium (as in many other respects). The terminal nitrido ligand is believed to be the strongest (or certainly one of the strongest) π donors[310,311] and will prefer, like the isoelectronic oxo (O^{2-}) ligand, to coordinate to metals in oxidation states of low d electron occupancy (*e.g.* d^0, Os^{VIII}, Re^{VII}; or d^2, Os^{VI}, Re^{V}). Such configurations are readily accessible to rhenium and osmium, placed as they are in the centre of the third row of the transition element block. When in a bridging role the nitrido (and oxo) ligands prefer a d^4 electron configuration and this of course is again readily accessible for osmium, for which the IV state is one of the commonest.

Table 14 Nitrido Complexes

Complex	*Colour*	ν_{OsO} *(cm^{-1})*	*Spectroscopic and other parameters*
$K_2[OsNCl_5]$	Purple	1084	IR,[22,318,325] Raman,[325] Mössbauer,[184]
$K_2[OsNBr_5]$	Purple	1085	IR, Raman[325]
trans-$K[OsNCl_4(H_2O)]$			UV/vis,[357] X-ray[323]
trans-$K[OsNBr_4(H_2O)]$		1109	IR,[318] UV/vis,[357] X-ray[326]
$Ph_4As[OsNCl_4]$	Pink	1123	IR, Raman,[325] UV/vis,[331,357] X-ray[329,330]
$Ph_4As[OsNBr_4]$	Pink	1119	IR, Raman,[325] UV/vis,[332,357] X-ray[331]
$Ph_4As[OsNI_4]$	Deep red	1107	IR,[265] UV/vis,[331] X-ray[332]
$OsNCl_3(PPh_2Me)_2$	Brown	1072, 1063	IR, ^{1}H NMR[315]
$K[OsO_3N]$	Yellow	1021	Raman,[325,340,358] IR,[325,341,358,359] UV/vis,[342,360–362] CV,[363] X-ray[335–338]
$K_3[Os_2NCl_8(H_2O)_2]$[a]	Brown	1137	Raman, IR,[344] UV/vis[344]
$Os_2N(S_2CNMe_2)_5 \cdot C_7H_{16}$	Black	1052	IR, UV/vis, ^{1}H NMR, CV,[350] X-ray[345]
$[Os_2N(NH_3)_8Cl_2]Cl_3$[b]	Yellow	1104	Raman, IR[344] UV/vis[344,353]

[a] Bromo analogue also known. [b] Bromo and iodo analogues also known.

All nitrido complexes of osmium so far reported are diamagnetic, with the exception of $[Os_3N_2(NH_3)_8(H_2O)_6]^{7+}$ (see p. 565).

The subject of transition metal nitrido complexes has been reviewed.[310,311]

46.4.15.1 Mononuclear complexes

(i) Osmium(IV) and osmium(V)

No mononuclear osmium(IV) nitrido complexes have been established, but μ-nitrido species containing a linear Os—N—Os unit are known, and there are trinuclear species of osmium(IV) and of mixed oxidation state containing Os—N—Os—N—Os units. The existence of both types is predictable from bonding considerations. They are dealt with on p. 564.

An osmium(V) nitrido complex $[OsN(CO)(NH_3)_4]^{2+}$ may be involved in the formation of $[Os_2(N_2)(NH_3)_8(CO)_2]^{4+}$ by oxidation of $[Os(NH_3)_5(CO)]^{2+}$.[70]

(ii) Osmium(VI)

This, having a d^2 configuration, is particularly suitable for octahedral mononitrido complexes such as $[OsNCl_5]^{2-}$, to which the Ballhausen–Gray bonding model for vanadyl species can be applied.[312] Taking the nitrido ligand to lie on the z axis the Os≡N triple bond is formed from a σ

bond and two π bonds, the latter being formed by overlap of filled $2p_x$ and $2p_y$ orbitals on N^{3-} with empty $5d_{xz}$ and $5d_{yz}$ orbitals on the osmium, the remaining *d* electrons pairing up in the $5d_{xy}$ orbital. It is curious that, whereas no $[Os^{VI}OX_5]^{n-}$ species are known, *trans* dioxo $[Os^{VI}O_2X_4]^{n-}$ complexes are numerous, the reverse being the case for the nitrido ligand: numerous octahedral osmium(VI) mononitrido complexes exist but no bis nitrido species. It may be that N^{3-} is too powerful a π donor[310,311] for a metal atom to sustain the presence of two such ligands, and indeed, as shown below, in some osmium(VI) nitrido species the ligand has electrophilic properties,[265,313–315] while in the less electronegative but isoelectronic rhenium(V) counterparts the nitrido ligand sometimes has weak nucleophilic properties.[316]

(a) Nitrido halogeno complexes. Reaction of salts of the 'osmiamate' ion $[OsO_3N]^-$ with HCl gives $[OsNCl_5]^{2-}$; the free acid and the potassium, rubidium, caesium and ammonium salts were made by Werner,[317] and more recent preparations of the potassium[299] and cesium[318] salts were described. Similarly, $[OsO_3N]^-$ with HBr gives $[OsNBr_5]^{2-}$; the rubidium and cesium salts have been isolated.[318,319]

The X-ray crystal structure of $K_2[OsNCl_5]$ shows the anion to be severely distorted with an apparently large *trans* weakening effect produced by the nitrido ligand[320] (an earlier X-ray study on '$K_2[OsNCl_5]$'[321,322] was later shown to concern *trans*-$K[OsNCl_4(H_2O)]$[323] and there is also another early, low-accuracy study of $K_2[OsNCl_5]$[324]).

In $K_2[OsNCl_5]$ (Figure 19a) = 1.614(13), mean $b = 2.361(4)$ and $c = 2.605(4)$ Å with an NOsCl (*cis*) angle of 96.5(5)°. The abnormal length of the *trans* Os—Cl bond was attributed to non-bonding steric interactions leading to N···Cl (*cis*) and Cl···Cl (*cis–cis*) distances of *ca.* 3.06 and 3.33 Å respectively.[320]

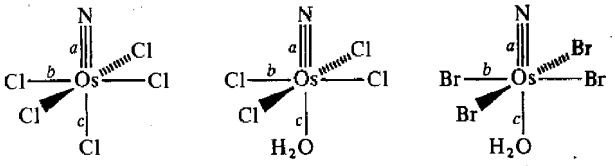


Figure 19 Octahedral halo nitrido complexes

Vibrational spectroscopic data on $[OsNX_5]^{2-}$ (X = Cl, Br) have been given.[325]

It is clear that the nitrido ligand exerts a *trans* weakening influence, however. The *trans* halide atoms in $[OsNX_5]^{2-}$ are easily replaced by water;[319] there are X-ray crystal structural studies on *trans*-$K[OsNCl_4(H_2O)]$ (Figure 19b)[323] and on *trans*-$K[OsNBr_4(H_2O)]$ (Figure 19c).[326] In (b), $a = 1.74(7)$, mean $b = 2.34(2)$ and $c = 2.50(3)$ Å,[323] and in (c) $a = 1.67(5)$, mean $b = 2.486$, and $c = 2.42(3)$ Å. The N—Os—Cl (*cis*) angle is 90.8°[323] and the N—Os—Br angle 101°.[326] Earlier determinations on the chloro complex (then thought to be $K_2[OsNCl_5]$[323,324]) and on the bromo complex are of lower accuracy. The Os—O distances are much longer than in other osmium(VI) species. Thus, Os—O (OH) in *trans*-$K_2(OsO_2(OH)_4]$ is 2.03 Å[327]; clearly a *trans* weakening effect is operative. The axial water molecules are easily removed (leading in the case of the bromo complex to a polymer, $K_n[OsNBr_4]_n$).[318] The larger the cation in *trans*-$M^I[OsNX_4(H_2O)]$ the more labile is the water molecule; salts of $[OsNCl_4(H_2O)]^-$ are known for M = K, Cs or Me_4N, but for M = Et_4N or larger organic cations the five-coordinate $M^I[OsNX_4]$ is formed. Presumably lattice energy forces are responsible for these differences.[328]

The square-based pyramidal halo complexes $[OsNX_4]^-$ can be made from $[OsNX_5]^{2-}$ (X = Cl, Br) with $(Ph_4As)X$,[318] and the deep red, beautifully crystalline iodo complex $Ph_4As[OsNI_4]$ is made from $[OsO_3N]^-$ and HI with $(Ph_4As)^+$.[265] There are X-ray crystal structure analyses of all three $[OsNX_4]^-$ species (Figure 20 and Table 15). They all have a distorted square-based pyramidal structure in which the four halo ligands lie well below the osmium atom, to such an extent that the X···X distances approach the van der Waals interaction distances. It has been suggested that steric N···X repulsion is not the main cause of the distortion since the N···X and X···X distances are virtually identical despite the differences in size between N and X. Rather it is likely to be an

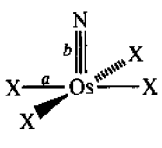

Figure 20 Structure of $[OsNX_4]^-$

Complex	Os—N (Å) (a)	Os—X (Å) (b)	NOsX (°)	N···X (Å)	cis-X···cis-X (Å)	Ref.
$[Ph_4As][OsNCl_4]$	1.604(10)	2.310(2)	104.53(5)	3.125(7)	3.162(4)	329, 330
$[Ph_4As][OsNBr_4]$	1.583(15)	2.457(1)	104.29	3.238(1)	3.364	331
$[Ph_4As][OsNI_4]$	1.626(17)	2.662(1)	103.73(2)	3.433(1)	3.657	332

electronic repulsion effect: the $2p_x^2$ and $2p_y^2$ π electrons on the nitrido ligand are drawn towards the electronegative osmium centre with concomitant repulsive interactions with the lone pairs on the halo ligands.[329,330,332a] Electronic spectral data on $[OsNCl_4]^-$ and $[OsNBr_4]^-$ [331] are consistent with such distortions. Vibrational spectroscopic data on $[OsNX_4]^-$ (X = Cl, Br)[325,331] and $[OsNI_4]^-$[265] have been obtained with ^{15}N substitution data in the case of the chloro and bromo complexes.[325]

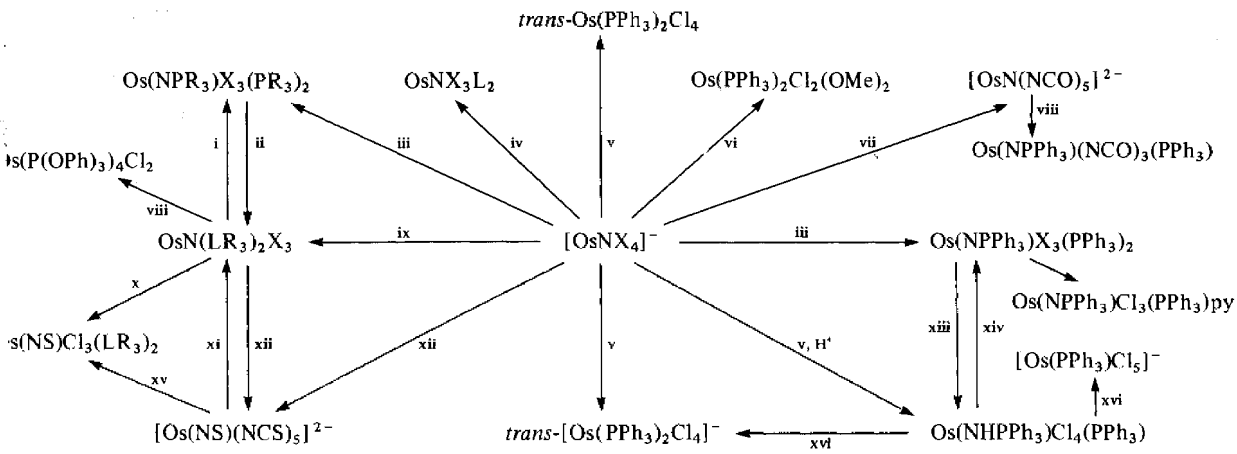
Chemical reactions of $[OsNX_4]^-$ in acetone solution are summarised in Scheme 10. The electrophilicity of the nitrido ligand to phosphines has already been mentioned but it does not extend to arsine, stibine and simple nitrogen donors. Some of the latter, however, do form weak 1:1 complexes with monodentate ligands L and are presumably coordinated in positions *trans* to the nitrido ligand. Bifunctional ligands L′ give 2:1 complexes $[(OsNCl_4)_2L']^{2-}$.[265] The $[OsNCl_4]^-$ ion will abstract sulfur from thiocyanate[265] to give $[Os(NS)(NCS)_5]^{2-}$; another unusual feature is the relative lack of reactivity of $[OsNI_4]^-$ which, with its formal oxidation state of VI, is the highest oxidation state sustained by any transition metal iodo complex. It does not react with phosphines, arsines or aromatic amines, but with $SbPh_3$ it gives $OsNI_3(SbPh_3)_2$[265] in which there must be considerable steric strain and an overall symmetry similar to that of a lump of coal.

In recently reported work it has been shown that $[OsNCl_4]^-$ can be alkylated to $[OsNR_nCl_{4-n}]^-$ with MgR_2, XMgR or AlR_3 (n = 2 or 4, R = CH_2CMe_3 or CH_2CH_2Ph; n = 4, R = Me).[332b]

(b) Nitride complexes with other ligands. The existence of complexes with a water molecule *trans* to the nitride is quite common: thus, reaction of $K[OsO_3N]$ with HCN or oxalic acid gives *trans*-$K[OsN(CN)_4(H_2O)]$ and *trans*-$K[OsN(ox)_2(H_2O)]$, while *trans*-$K[OsNF_2(OH)_2(H_2O)]$ and *trans*-$K[OsN(ox)(OH)_2(H_2O)]$ are also known.[22]

In some osmium(VI) nitrido complexes the N^{3-} ligand is subject to nucleophilic attack by phosphines PR_3 to give phosphineiminato complexes $Os(NPR_3)X_3(PR_3)_2$;[313–315] similar complexes are formed by phosphinites.[265] The formation of these is illustrated in Scheme 10 below, see also p. 568.

The complexes $OsNL_2X_3$ (L = PR_3, AsR_3, $SbPh_3$, ½bipy, ½phen, py; X = Cl, Br) can be made as shown in Scheme 10 and are diamagnetic. IR spectra and, in the case of $OsN(PMe_2Ph)_2Cl_3$, ^1H NMR, suggest a *trans* structure similar to that shown in Figure 12, N replacing NS.[315] The abstraction reaction of sulfur from S_2 by $OsNL_2Cl_3$ (L = PMe_2Ph, $AsPh_3$, ½bipy, ½phen, py)[262] is noteworthy, as is a similar abstraction of sulfur from SCN^- by $[OsNCl_4]^-$ to give $[Os(NS)(NCS)_5]^{2-}$.[265]



The porphyrin complexes *trans*-OsN(OEP)X (OEP = octaethylporphyrin; X = F, $OClO_3$, OMe) are made from OsO_2(OEP) and hydrazine hydrate with HF, $HClO_4$ or MeOH.[255] The existence of *trans*-$[OsN(NH_3)_4(H_2O)]^{3+}$ has been suggested though not fully confirmed.[55] Recently, the preparation of $(Bu^n_4N)[OsN(OSiMe_3)_4]$ has been accomplished by reacting $[OsNCl_4]^-$ with sodium siloxide; the product can be alkylated without cleavage of the Os≡N bond.[322a]

(c) Osmium(VIII). With a few minor exceptions the only established osmium(VIII) nitrido species are the 'osmiamates', salts of the tetrahedral $[OsO_3N]^-$ ion.

The osmiamate in is the source of most other osmium nitrido complexes. The free acid is said to be $OsN(OH)O_2$ in the solid state[22,333,334] and the $Bu^n_4N^+$, Ph_4P^+, Ph_4As^+, lithium, rhodium, potassium, rubidium, cesium, ammonium, silver, thallium, mercury, zinc, barium and lead salts are also known. The preparation of the potassium salt of OsO_4 in concentrated KOH solution with NH_4OH is a simple method for obtaining this useful starting material.[297]

A number of single crystal X-ray studies have been published, on the potassium,[335,336] rubidium[337] and cesium[338] salts. In the potassium and rubidium salts there appears to be a statistical distribution of nitrido and oxo ligands so that Os—N and Os—O bond lengths seem to be equal (*e.g.* 1.72 Å in $K[OsO_3N]$.[336] However, in $Cs[OsO_3N]$, the Os—N and Os—O distances are 1.676(15) and 1.739(8) Å respectively,[338] and an X-ray radial distribution analysis gave the Os—O and Os—N distances in $K[OsO_3N]$ as 1.78(3) and 1.63(3) Å respectively.[339]

Vibrational spectra of normal and isotopically substituted $[OsO_3N]^-$ have been measured (see Table 16).[325,340,341,358–360]

i, *Cl*: PEt_3, PMe_2Ph, $PMePh_2$, PEt_2Ph_2,[a] $P(OEt)Ph_2$;[b] *Br*: PEt_2Ph, $PEtPh_2$;[a] ii, Cl_2, PEt_3, PMe_2Ph, $PMePh_2$, PEt_2Ph, $PEtPh_2$;[a] iii, PPh_3 (Cl, Br);[a] iv, *Cl*: ½bipy;[a] ½phen;[b] *Br*: ½bipy;[a] v, PPh_3;[a] vi, PPh_3, MeOH;[a] vii, NCO^-; viii, PPh_3;[b] ix, *Cl*: $AsEt_3$, $AsPh_3$, $SbPh_3$;[a] *Br*: $AsPh_3$, $SbPh_3$;[a] *I*: $SbPh_3$;[b] x, S_2Cl_2, PMe_2Ph, $AsPh_3$;[c] xi, Cl_2: $AsPh_3$;[b] xii, SCN^-;[b] xiii, H^+;[a] xiv, py;[b] xv, S_2Cl_2, $AsPh_3$;[b] xvi, HCl.[a]

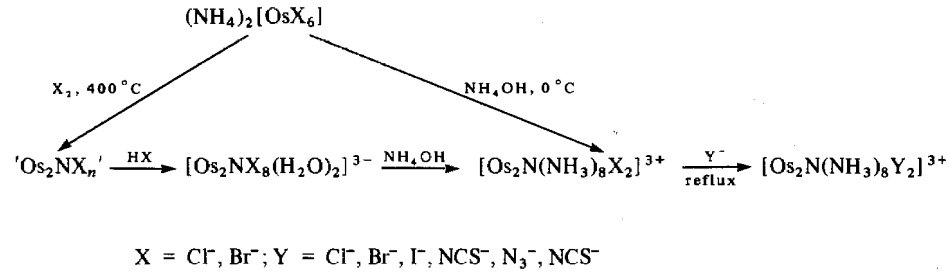
[a] IR data for the solid; others are Raman spectra in aqueous solution.



Electronic spectral data have also been measured for the ion.[342] The only other osmium(VIII) nitrido complexes claimed in the literature are of the type $[OOsN(Rbig)_2]OH \cdot SO_4 \cdot nH_2O$ (Rbig = biguanide, methylbiguanide).[343]

46.4.15.2 Polynuclear complexes

(*i*) *Binuclear species*

(a) Osmium(IV). The known dimers are of the form $[Os_2NX_8(H_2O)_2]^{3-}$ (X = Cl, Br) and $[Os_2N(NH_3)_8Y_2]^{3+}$ (Y = Cl, Br, I, NCS, N_3, NO_3);[344] there is also a dithiocarbamato complex $Os_2N(S_2CNMe_2)_5 \cdot C_7H_{16}$.[345] The first complexes of this type were $[Os_2N(NH_3)_8X_2]X_3$ (X = Cl, Br), made from $(NH_4)_2[OsX_6]$ and ammonia under pressure;[346–348] the routes in Scheme 11 were developed later.[344] The chloro species $[Os_2NCl_8(H_2O)_2]^{3-}$ can also be made in low yield by refluxing an aqueous solution of $K_3[Os(NH_2SO_3)Cl_5]$, and there is some evidence for the existence of $K_5[Os_2NCl_{10}]$.[349] However, although there is a brief mention in a review of an X-ray crystal structure of '$Cs_4[Os_2NCl_{10}]$'[310] this species is nowhere else reported in the literature, and it seems likely that the structure referred to is really that of $Cs_4[Os_2OCl_{10}]$ (see p. 593).

The dimethyldithiocarbamato complex was originally made from $OsCl_3 \cdot nH_2O$ and $Na(S_2CNMe_2)$,[345] and both it and the diethyldithiocarbamato analogue were later prepared from $Os(S_2CNR_2)_3$, $Na(S_2CNR_2)$ and $K_2[OsNCl_5]$.[350] The X-ray crystal structure of the 1:1 heptane

Scheme 11 Preparation of nitrido-bridged binuclear complexes [344]

adduct of $Os_2N(S_2CNMe_2)_5$ shows this to contain a slightly bent, symmetric nitrido bridge accompanied by a bridging dithiocarbamato ligand, the octahedron being completed by the other four chelating dithiocarbamato ligands. The Os—N distance is 1.76(3) Å and the OsNOs angle 164.6(18) °; the mean Os—S distance is 2.39(2) Å.[345]

Structure and bonding. All these osmium(IV) dimers are diamagnetic and Raman and IR spectra of $[Os_2NX_8(H_2O)_2]^{3-}$ and of $[Os_2N(NH_3)_8Y_2]^{3+}$ show no coincidences of fundamental skeletal vibrational modes, indicating a centrosymmetric structure.[344] Although, with the exception of $Os_2N(S_2CNMe_2)_5 \cdot C_7H_{16}$, there are no crystal structure studies on the osmium complexes, that of $K_3[Ru_2NCl_8(H_2O)_2]$ shows that this contains a centrosymmetric anion with a linear, symmetric Ru—N—Ru bridge. The Ru—N distance is 1.720 Å, indicating considerable multiple bonding in the linkage, and the chloro ligands are bent back from the nitrido group (N—Ru—Cl angle = 94.3 °). The long Ru—O (OH_2) distance of 2.175 Å is also suggestive of a *trans* weakening influence by the nitrido ligand.[351] The considerable similarities in the vibrational spectra of the ruthenium and osmium complexes[344] make it very likely that the structures will be similar in both groups. A similar structure has also been found recently from X-ray and vibrational spectroscopic studies on $K_5[Ru_2N(CN)_{10}]$.[352]

The bonding in these species is likely to be similar to that proposed for $[Os_2OCl_{10}]^{4-}$ (p. 594), p_π–d_π interactions for $2p$ orbitals on N^{3-} and $5d_{xz}$, $5d_{yz}$ orbitals on osmium giving rise to the observed diamagnetism.[353]

Raman and IR spectra of $[Os_2NX_8(H_2O)_2]^{3-}$ and $[OsN(NH_3)_8Y_2]^{3+}$ were recorded; isotopic substitution (^2H, ^{15}N) was used to aid assignments for $[Os_2N(NH_3)_8Br_2]Br_3$.[344]

(*ii*) *Trinuclear species*

The known chemistry of these species can all be systematized on the basis of the skeletal structure shown in Figure 21, though there are as yet no single crystal X-ray studies on complexes believed to contain it.

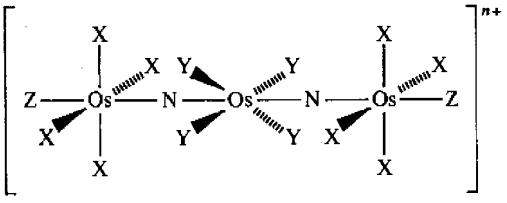


Figure 21 The likely basic structure of $[Os_3N_2X_8Y_4Z_2]^{n+}$ species[354]

Reaction of $(NH_4)_2[OsCl_6]$ or of $[Os(NH_3)_5Cl]Cl_2$ with ammonia gives the diamagnetic purple species $[Os_3N_2(NH_3)_8(H_2O)_6]Cl_6$, 'osmium violet', for which the structure above in Figure 21 (with X = NH_3, Y = Z = H_2O) was proposed; with aqueous cyanide, $[Os_3N_2(CN)_{10}(H_2O)_4]^{4-}$ is formed (X = Z = CN^-, Y = H_2O).[352,354] Resonance Raman and IR spectra were measured, and from these data it appears that the Os_3N_2 unit has considerable multiple bond character.[354] The bonding in the complex can be rationalized by using the molecular orbital scheme for ruthenium red, $[Ru_3O_2(NH_3)_{14}]^{6+}$,[355] and its ethylenediamine analogue $[Ru_3O_2(NH_3)_{10}en_2]^{6+}$.[356]

The complex '$Os_3N_7O_9H_{21}$', made from OsO_4 and ammonia,[344] is possibly $Os_3N_3(OH)_9(NH_3)_4$, with a structure related to that of Figure 21 but having an extra terminal nitrido ligand at the central atom (Y site).[344]

46.4.15.3 Polynuclear complexes of mixed oxidation state

Electrochemical oxidation of $Os_2N(S_2CNR_2)_5$ (R = Me, Et) showed that a reversible one-electron oxidation occurs to $[Os_2N(S_2CNR_2)_5]^+$, an osmium(IV)–(V) species and a further irreversible oxidation, possibly to an osmium(V) dimer.[350]

Trinuclear species apparently containing mixed oxidation states are also known. Reaction of $(NH_4)_2[OsCl_6]$ or $[Os(NH_3)_5Cl]^{2+}$ with air and ammonia gives, in addition to $[Os_3N_2(NH_3)_8(H_2O)_6]^{6+}$, 'osmium brown' $[Os_3N_2(NH_3)_8(H_2O)_6]Cl_7$; the latter is parammagnetic ($\mu_{eff} = 0.87$ BM per trimer unit). IR, resonance Raman and ESCA data are consistent with its formulation as in Figure 21 with X = NH_3 and Y = Z = H_2O. Treatment of 'Claus's salt', obtained from OsO_4 and aqueous ammonia, with cyanide ion gives $[Os_3N_2(CN)_8(H_2O)_6]^{4-}$ (X = CN^-, Y = Z = H_2O),[354] while HX gives $[Os_3N_2X_{11}(NH_3)_3]^{3-}$ (X = Cl or Br, Y = Cl or Br with one H_2O ligand, Z = NH_3).[344] Again, the bonding may be rationalized by the use of MO diagrams for trimeric ruthenium oxo-bridged species.[355,356]

46.4.16 Triazenido Complexes

The trihydro species $OsH_3(RNNNR)(PPh_3)_2$ have been made from $Os(PPh_3)_3H_4$ and the triazenes (R = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4); the complex $OsH_3(p\text{-}MeC_6H_4)NNN(p\text{-}MeOC_6H_4)$ was similarly prepared. These complexes are likely to be seven-coordinate and involve osmium(IV); ^{1}H NMR spectra suggest that they are stereochemically non-rigid. Their remarkable stability (the diphenyl complex is unaffected by boiling with PPh_3 in toluene) may arise from π-delocalization from the triazene to empty metal *d* orbitals.[364]

The osmium(II) species $Os(RNNNR)_2(PPh_3)_2$ (R = Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$) are made from $[OsCl_6]^{2-}$ and the triazene with PPh_3 and KOH. On the basis of IR and ^{1}H NMR data the following structure shown in Figure 22 was proposed.

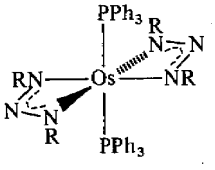

Figure 22 Likely structure of $Os(RNNNR)_2(PPh_3)_2$[364]

46.4.17 Azido Complexes

The only unsubstituted azido complex is $(Ph_4As)[Os(N_3)_6]$, made from NaN_3 and $(Ph_4As)Cl$ with $[OsCl_6]^{2-}$. It is an explosive yellow-orange complex.[365] The μ-nitrido complex $[Os_2N(NH_3)_8(N_3)_2](N_3)_3$ is a brown-yellow material obtained from $[Os_2N(NH_3)_8Cl_2]^{3+}$ and KN_3 under reflux (ν_{NN} = 2077 and 2040 cm^{-1}).[344]

The phosphine complexes $Os(N_3)(PR_3)_3Cl_2$ (PR_3 = PMe_2Ph, PEt_2Ph, $PPr^n{}_2Ph$, $PBu^n{}_2Ph$) are made from NaN_3 and *mer*-$Os(PR_3)_3Cl_3$; these purple complexes have ν_{NN} near 2060 cm^{-1} and probably have the structure shown in Figure 12, N_3 replacing NS.[366] A bis azido complex, *cis*-$Os(N_3)_2(PMe_2Ph)_4$, is a white material made from $Os(PMe_2Ph)_4Cl_2$ and NaN_3; ν_{NN} is at 2050 cm^{-1}.[366] The diarsine complex $Os(N_3)(diars)_2Cl$ is known, prepared from *trans*-$[Os(NO)diars_2Cl]^{2+}$ and $N_2H_4 \cdot HCl$; with HCl it gives the yellow $[Os(N_2)(diars)_2Cl]Cl$.[205]

46.4.18 Complexes of Pseudohalide Ligands

We have already considered azido complexes above; the only other pseudohalide to form complexes with the element is thiocyanate.

46.4.18.1 Thiocyanato complexes

Apart from a rather uncertain report of $[Os(SCN)_4]^{2-}$ the only unsubstituted thiocyanato complex to be fully established is $[Os(NCS)_6]^{3-}$. However, it appears that for the ambidentate NCS^-

ligand osmium(III) lies on the hard–soft boundary so that N or S bonding occurs almost in a random fashion; all the isomers of $[Os(NCS)_n(SCN)_{6-n}]^{3-}$ are known except for $[Os(SCN)_6]^{3-}$ ($n = 0$). This is probably the first system in which linkage isomerism and geometrical isomerism are so intertwined in an otherwise unsubstituted $[ML_6]^{n-}$ system.

(*i*) *Osmium(II)*

The only unsubstituted species claimed are $R_2[Os(NCS)_4]$ (R = diantipyrylmethane, $C_{23}H_{24}N_4O_2H^+$, and diantipyrylpropylmethane, $C_{26}H_{30}N_4O_2H^+$).[367] There are several substituted osmium(II) thiocyanato complexes, however. There is no indication from spectral data whether the ligand is N or S bonded in $(Ph_4P)_2[Os(NO)(NCS)_5]$ (see p. 545);[368] in the thionitrosyl complex $(Ph_4As)_2[Os(NS)(NCS)_5]$ (see p. 562) IR data suggest that there may be Os—N rather than Os—S bonding of the thiocyanate ligand. In $Os(diars)_2(SCN)_2$, made from $Os(diars)_2Cl_2$ and SCN^-, there are no spectral data to indicate the nature of binding of SCN^-,[369] but in $Os(Ph_2AsCH_2AsPh_2)_2(SCN)_2$, made from $(NH_4)_2[OsBr_6]$, SCN^- and the arsine, the IR spectrum is suggestive of S- rather than N-bonded thiocyanate.[370]

The complex $Os(SCN)_2(bipy)_2$ is made from KSCN and $Os(bipy)_2Cl_2$.[120]

(*ii*) *Osmium(III)*

Reaction of $K_2[OsCl_6]$ and KSCN with precipitation of the products by $(Bu^n_4N)^+$ yields $(Bu^n_4N)_3[Os(NCS)_6]$; IR,[371] electronic absorption[372] and Mössbauer spectra were measured,[184] and the magnetic susceptibility was measured from 90 to 295 K ($\mu_{eff} = 1.78$ BM at 295 K).[373] On the basis of the IR spectrum in particular no clear conclusion could be drawn as to whether the thiocyanate ligand was N or S bonded. Subsequent investigation showed that a mixture of isomers $(Bu^n_4N)_3[Os(NCS)_n(SCN)_{6-n}]$ is formed in the reaction,[374] and these may be separated by high-voltage electrophoresis or ion exchange.[375,376]

Of the ten possible isomers of $[Os(NCS)_n(SCN)_{6-n}]^{3-}$ nine have now been separated by ion exchange;[376] at high (refluxing) temperatures the $K_2[OsCl_6]$–KSCN reaction gives *cis* and *fac* complexes, while at lower temperatures (60 °C) the *trans* and *mer* species are formed.[376] In general, longer boiling periods produce a higher degree of N-bonded substitution while shorter reaction times at lower temperatures favour the formation of S-bonded isomers.[375] The only missing species is the fully N-bonded isomer, $[Os(NCS)_6]^{3-}$. The complexes were characterized by their Raman and IR spectra as well as electronic absorption spectra.[375,376] Confirmation of isomer assignment was given by EXAFS measurements on the various salts: the Os—N—C—S bonds are essentially linear while the Os—S—C—N bonds have an Os—S—C angle of approximately 110 °. The Os—N bond length decreases with increasing n in $[Os(NCS)_n(SCN)_{6-n}]^{3-}$ (2.21 Å for $n = 1$, 2.13 for $n = 6$) with the Os—S distance remaining relatively constant at 2.50 Å.[377]

(*iii*) *Osmium(IV)*

Four osmium(IV) complexes have been reported. The salts $[Os_2N(NH_3)_8(NCS)_2]Y_3$ (Y = Cl, NCS) are made from $[Os_2N(NH_3)_8Cl_2]^{2+}$ and NCS^-. The IR and Raman spectra suggest that it contains N-bonded thiocyanate,[344] consistent with the probable 'harder' nature of the $Os^{IV}_2N^{3+}$ moiety (see also p. 563). It has recently been reported, however, that osmium and ruthenium can be separated *via* their $[M(NCS)_6]^{2-}$ complexes using polyurethane foam.[378]

Recently, the isomeric pair $[Os(NCS)Cl_5]^{2-}$ and $[Os(SCN)Cl_5]^{2-}$ have been isolated by ion-exchange separation of the reaction product of $[OsCl_5I]^{2-}$ with $(SCN)_2$. IR, Raman and electronic spectra were measured.[379]

46.4.19 Nitrile Complexes

Surprisingly few osmium nitrile complexes are reported in the literature.

46.4.19.1 Osmium(II)

The reaction of $Os(PMe_2Ph)_3H_4$ and HBF_4 in acetonitrile gives $[Os(NCMe)_3(PMe_2Ph)_3](BF_4)_2$,[380] and there is a brief mention of $Os(NCMe)H_2(PR_3)_2$, made (but not isolated in the pure state) from $Os(PR_3)_3H_4$ (PR_3 = $PMePh_2$, PMe_2Ph, $PEtPh_2$).[276]

For $(PPh_4)[Os(NCMe)(CCl_3)NCCl(CCl_3)Cl_5]$, see under amides, p. 558.

46.4.19.2 Osmium(III)

The complexes $Os(NCAr)Cl_3(PPh_3)_2$ (Ar = Ph, *p*-tolyl) can be made from $OsCl_4(PPh_3)_2$, PPh_3 and ArNC; with MeCN, $Os(NCMe)Cl_3(PPh_3)_2$ is formed. These species are likely, on the basis of IR data, to have the structure shown in Figure 23(a). Reaction of $OsO_2Cl_2(PPh_3)_2$ and of $OsCl_2(PPh_3)_3$ respectively with *p*-toluenenitrile gives *cis*- and *trans*-$Os(NCR)_2(PPh_3)_2Cl_2$ (b and c; Figure 23) respectively.[296]

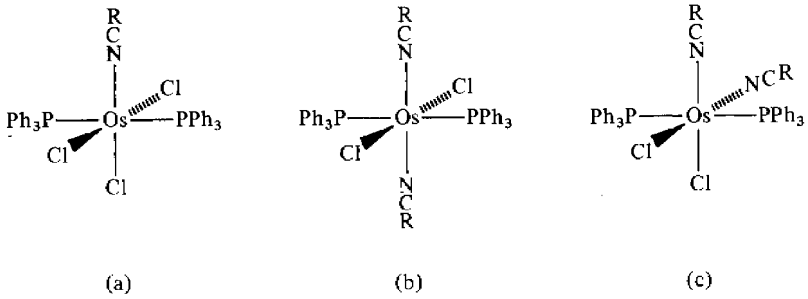

Figure 23 Structures of nitrile phosphine complexes[296]

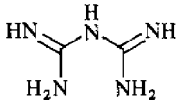

The acetonitrile complex $Os(NCMe)Cl_3(PPh_3)_2$ was found to be paramagnetic (μ_{eff} = 1.87 BM) with a broad room-temperature ESR spectrum (g = 2.16). The cyclic voltammogram showed a one-electron reversible reduction, and there is also a one-electron oxidation.[93]

The salt $(Et_4N)[Os(NCMe)Br_5]$, obtained from $[OsBr_6]^{2-}$ and PbO_2 in acetonitrile, has recently been reported.[381]

A recent X-ray crystal structure determination on *mer*-$Os(NCMe)Br_3(PPh_3)_2$ shows the Os—N distance to be 2.024(10) Å with the bromo ligand *trans* to it at 2.499(1) Å; the mean Os—P distance is 2.419 Å and the *trans* bromo ligands are at 2.490 Å. The complex was made by treating $(Bu^n{}_4N)_2[Os_2Br_{10}]$ in acetonitrile with triphenylphosphine.[382]

46.4.20 Miscellaneous Nitrogen Donor Complexes

46.4.20 Biguanide complexes

There seem to be no unsubstituted complexes of biguanide with osmium, though a few tris species of substituted biguanides have been reported.

(*i*) *Osmium(II)*

The tris complexes $[Os(Rbipy)_3]Br_2$ have been made from $(NH_4)_2[OsBr_6]$ and Rbig·HCl (Rbig = N^1,N^1-dimethylbiguanide, N^1-morpholinebiguanide, N^1-*p*-chlorophenyl-N^5-isopropylbiguanide (paludrine)). Electronic spectra were recorded, and the paludrine complex resolved *via* the antimonyl tartrate.[383]

(ii) Osmium(III)

Paludrine hydrochloride and $(NH_4)_2[OsCl_6]$ give $[Os(paludrine)_3]Cl_3$, or $[Os(paludrine)_3]^{2+}$ can be oxidized with hydrogen peroxide. The magnetic moment of the chloride at room temperature is 2.45 BM. The $[Os(paludrine)_2X_2]X$ complexes (X = Cl, Br) have also been prepared by reaction of $(NH_4)_2[OsX_6]$ with the ligand, and the magnetic moments at room temperature are respectively 1.60 and 1.68 BM. Electronic spectra were recorded.[383]

(iii) Osmium(VI)

Reaction of $(NH_4)_2[OsCl_6]$ and biguanides with alkaline H_2O_2 and OsO_4 with biguanide yields $OsO_2(big)_2$; with H_2SO_4 this gives $[OsO_2(bigH)_2]SO_4 \cdot H_2O$ and HCl yields $[OsO_2(bigH)_2]Cl$. The latter will react with 2,2′-bipyridyl (bipy) to give $[OsO_2(big)(bipy)]^+$. Piperazine biguanide (L′) reacts with *trans*-$[OsO_2(OH)_4]^{2-}$ to give $[OsO_2L'_4]^{2+}$.[384]

46.4.20.2 Benzotriazole complexes

Benzotriazole, $C_6H_4NHN_2$ (btz), forms a few complexes with osmium; fuller characterization would certainly be desirable.

(i) Osmium(III)

Osmium tetroxide in alkali with the ligand in ethanol yields $Os(btz)_3(OH)_3$; $Os(btz)_3X_3$ (X = Cl, Br) can be made from '$[OsO_3btz_4]^{3-}$, and HX.[385] Salts of $[OsO_3(btz)_4]^{3-}$ are said to be formed from the ligand and OsO_4 in alkali; red sodium, potassium, silver, barium, lead and calcium salts were isolated.[385]

46.4.20.3 Phosphineiminato (NPR_3) and phosphineaminato ($NHPR_3$) complexes

A number of osmium(IV) phosphineiminato complexes are known which also contain phosphine or arsine coligands; they are prepared by nucleophilic attack of phosphines on the nitrido ligand in osmium(VI) species. There is also one example of a phosphiteiminato complex, one of a phosphineaminato species, both formally involving osmium(IV), and two examples of osmium(I) aroylphosphineiminato complexes.

(i) Phosphineiminato complexes, $Os(NPR_3)X_3(LR_3)_2$

The preparation and principal properties of these species have been summarised in Scheme 10. They are made by reaction of alkyl aryl phosphines PR_3 (PEt_3, PMe_2Ph, $PMePh_2$, PEt_2Ph, $PEtPh_2$), with $OsN(AsPh_3)_2X_3$ (X = Cl, Br) while the triphenylphosphineiminato complexes $Os(NPPh_3)X_3(PPh_3)_2$ (X = Cl, Br) are best made directly from $[OsNX_4]^-$ and PPh_3. There is one example of a phosphineiminato complex containing an arsine group, $Os(NPPhMe_2)Cl_3(AsPh_3)_2$,[294] and there is a phosphiteaminato species $Os\{NP(OEt)Ph_2\}Cl_3\{P(OEt)Ph_2\}_2$.[265]

The complexes are paramagnetic with moments close to 1.8 BM at room temperature. The ^1H NMR and IR spectra of $Os(NPMe_2Ph)Cl_3(PMe_2Ph)_2$ suggest the *trans* configuration (I; Figure 24)[294] and this is indeed the type of structure found for the analogous ruthenium complex $Ru(NPEt_2Ph)Cl_3(PEt_2Ph)_2$ for which X-ray data have been obtained.[386] These complexes can be oxidized by chlorine to the nitrido species $OsN(PR_3)_2Cl_3$, and the triphenylphosphineiminato species can be protonated successively to $Os(NHPPh_3)Cl_4(PPh_3)$.[294] This bright red material is made by reaction of $[OsNCl_4]^-$ with PPh_3 and HCl, or by addition of one mole of HCl to $Os(NPPh_3)Cl_3(PPh_3)_2$. On the basis of IR data and on the ease of preparation of the complex from species of structure (a), structure (b) was proposed (Figure 24). The complex is readily deprotonated to $Os(NPPh_3)Cl_3(PPh_3)_2$, but its own further protonation by a mole of HCl leads to formation of $(Ph_3PNH_2)Cl$ and salts of $[Os(PPh_3)Cl_5]^-$.[294]

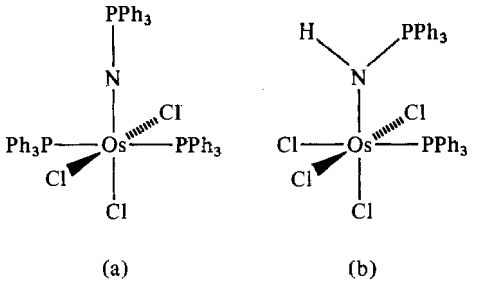

Figure 24 Structures of phosphineiminato and phosphineaminato complexes[294]

(*ii*) *Aroylphosphineiminato complexes, $Os\{NPPh_3C(O)Ar\}Cl_2(PPh_3)_2$*

The *N*-toluolyl and *N*-benzoyl complexes have been made from $OsO_2Cl_2(PPh_3)_2$, the phosphineimine and PPh_3, and the toluolyl complex was also obtained from $Os(PPh_3)_3Cl_2$, toluoylphosphineimine and PPh_3. A structure with the imine functioning as an N,O donor has been proposed (Figure 25).[296]

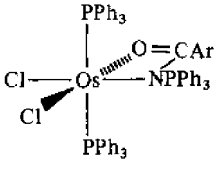

Figure 25 Structure of $Os(NPPh_3COAr)Cl_2(PPh_3)_2$[296]

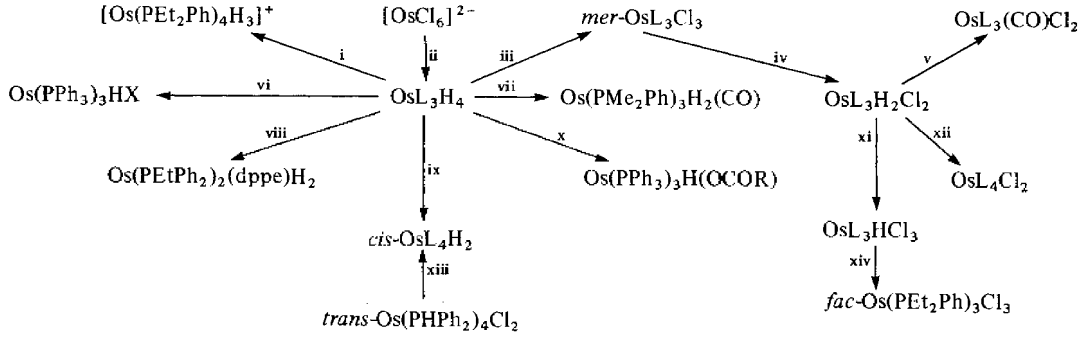
46.4.20.4 Other nitrogen donor complexes

Two complexes have been reported with 8-amino-7-hydroxy-4-methylcoumarin, $NO_3C_{10}H_8$. Reaction of OsO_4 with this ligand in aqueous alkali and ethanol yields $[Os(NO_3C_{10}H_8)_2(OH)_2]\cdot 3H_2O$, a paramagnetic species ($\mu_{eff} = 1.22$ BM at room temperature, suggesting the presence of osmium(IV)). A similar reaction but in acidic aqueous ethanol yields the violet diamagnetic $[OsO_2(NO_3C_{10}H_8)_2]Cl_2$; IR and electronic spectra were measured.[387,388] Reaction of $OsCl_4$ with 4-*p*-dimethylaminoanilino-3-penten-2-one gives grey crystals of $OsL_4\cdot 2H_2O$; the electronic spectrum of this allegedly osmium(IV) complex was measured, but its diamagnetism[389] is unexpected —perhaps it is some type of 'osmyl' complex.

A complex formed between $Na_2[OsCl_6]$ and strychnine sulfate was formulated as $Os(N_2C_{21}H_{22}O_2)_3$[390] but later reformulated as a strychninium salt $(strychnineH)_2[OsCl_6]$.[391,392] For other complexes of osmium with alkaloids see p. 587.

46.5 PHOSPHORUS, ARSENIC AND ANTIMONY LIGANDS

The chemistry of these species with osmium is quite extensive, particularly in the case of the phosphines. In order to keep the sections to a manageable length we concentrate here on the hydrido and halo phosphines, arsines and stibines; when other ligands are involved the material is normally given under that ligand, but cross-references are provided. There are also separate sections on phosphorus trihalide complexes and on tertiary phosphites, while the relatively small sections on chelating phosphines and arsines are considered together. Also, in order to reduce the complexity of the treatment, much use has been made of reaction schemes, and it is in these rather than in the main text that some carbonyl complexes with these ligands are considered. For a fuller treatment of carbonyl phosphines, arsines and stibines the section in 'Comprehensive Organometallic Chemistry' is recommended,[16] as are the reviews of McAuliffe.[393,394]



General chemistry. The commonest oxidation states in the phosphines, arsines and stibines of osmium are II and III, but there are a number of osmium(IV) species and, with oxo, nitrido and hydrido ligands, osmium(VI); with carbonyls there are examples of osmium(0) and with nitrosyls (pp. 549–551) also of the 0 and −II states. Although the stereochemistry is octahedral in most cases

there are examples of eight- and seven-coordination (the latter notably in the case of OsL_3H_4) and five-coordination; steric factors undoubtedly play a role particularly in the latter case. Osmium is not as catalytically active in its phospine, arsine and stibine chemistry as is, for example, ruthenium or rhodium, and most of the examples of catalytic reactions are with the carbonyls which are not covered in this chapter. The element nevertheless exhibits a rich chemistry with these ligands.

46.5.1 Tertiary Phosphine Complexes

46.5.1.1 Phosphine hydrido complexes

A wide variety of these are known, and the principal preparative routes to most of them are indicated in Scheme 12. The examples amongst these of seven- and even eight-coordination — very unusual stereochemistries for osmium — is noteworthy, as is the fact that, in a formal sense at least, some of them contain osmium(IV) or osmium(VI), very high oxidation states for phosphine-containing species.

i, HCl;[276] ii, BH_4^-, PPh_3;[405] iii, BH_4^- with L = PBu^n_3,[404] PMe_2Ph,[404] $PMePh_2$,[276] PEt_2Ph,[404] $PEtPh_2$;[276] iv, Zn and H_2 with L = $PMePh_2$, PEt_2Ph, $PEtPh_2$;[277] v, CO;[277] vi, HX;[397] vii, CO;[276] viii, dppe;[276] ix, L (L = PMe_2Ph, $PMePh_2$, PEt_2Ph, $PEtPh_2$);[276] x, OCOR;[406] xi, HCl with L = $PMePh_2$, PEt_2Ph;[277] xii, L = $PMePh_2$;[277] xiii, $[AlH_2(OH_2)_2OMe)_2]^-$;[407] xiv, heat.[277]

X = Cl, Br, I; R = Me, Et

Scheme 12 Some typical preparations and reactions of osmium hydrido phosphine complexes

The subjects of hydrido[395] and multihydrido[396] complexes have recently been reviewed.

(*i*) *Monohydrido species*

These span the formal oxidation states of II to IV. The carboxylato species $Os(PPh_3)_3H(OCOR)$ (R = Me, Et, CF_3, C_2F_5) are dealt with on p. 600; $Os(PPh_3)_3HX$ (X = Cl, Br, I) have been briefly reported as products of the reaction of $Os(PPh_3)_3H_4$ with HX, and the chloro complex is also made from $Os(PPh_3)_3Cl_2$ and H_2. With CO, $Os(PPh_3)_2HCl(CO)_2$ is formed and pyridine gives $Os(PPh_3)_3HCl(py)_2$. The chloro complex $Os(PPh_3)_3HCl$ catalyzes the homogeneous hydrogenation of terminal alkenes, and in some cases alkene isomerization occurs.[397]

The earlier reported[398] $Os(PBu^n_2Ph)_3HCl_n$ (n = 2 and 3) are now known to be mixtures,[399] but the formally tetravalent $Os(PR_3)_3HCl_3$ (PR_3 = $PMePh_2$, PEt_2Ph)[277] are well established.

For hydrido carboxylato phosphine complexes see p. 601.

(*ii*) *Dihydrido species*

There are two main classes: *cis*-$Os(PR_3)_4H_2$ and $Os(PR_3)_3H_2Cl_2$ (Scheme 12 and Table 17). The *cis* configuration of the former is established, in the case of $Os(PMePh_2)_4H_2$ at least, by phosphorus decoupling NMR experiments;[276] the high-field ^{1}N NMR spectra of $Os(PMePh_2)_2H_2Cl_2$ and of

$Os(PEt_2Ph)_2H_2Cl_2$ suggest that the hydrido ligands are in equivalent environments with respect to the phosphine ligands, a situation possibly caused by coupling effects.[277] The complex *cis*-$Os(PEtPh_2)_4H_2$ catalytically isomerizes and hydrogenates 1-octene, a process much more rapid in the presence than in the absence of hydrogen.[276]

Table 17 Hydrido Phosphine and Arsine Complexes

Complex	*Colour*	*M.p.* (°C)	ν_{OsH} (cm^{-1})	δ_{OsH} (cm^{-1})	τ_{OsH} (*p.p.m.*)	*Ref.*
$Os(PMePh_2)_3HCl_3$	Pink		2216, 2004, 1900		19.42q	277
cis-$Os(PMe_2Ph)_4H_2$		104–108	1950, 1920	830	20.35	276
$Os(PMePh_2)_3H_2Cl_2$	Grey	110–118 (d)	2171, 2029		19.55q	277
$[Os(PEt_2Ph)_4H_3]BPh_4$	White	199–203	–	842	21.09	276
$Os(PEt_2Ph)_3H_4$	White	79–80	2033, 1984, 1864	826	19.52q	404
$Os(PMe_2Ph)_2H_6$	Yellow oil		2028, 1980, 1869		18.60t	404
$Os(AsEtPh_2)_3H_4$		97–99	2041, 1986, 1813	810	19.66	276
cis-$Os(AsEtPh_2)_4H_2$		158–160	1992, 1975	845	23.74	276

Recently the complex *cis*-$Os(PMe_3)_4H_2$ has been obtained by reaction of *trans*-$Os(PMe_3)_4Cl_2$ and $NaC_{10}H_8$; with PF_6^- this gives $[Os(PMe_3)_4H_3]^+$ (see below).[400] Photolysis of $Os(PMe_2Ph)_3H_4$ gives a reactive intermediate $Os(PMe_2Ph)_3H_2$. This reacts with more phosphine to give *cis*-$Os(PMe_2Ph)_4H_2$, and a dimeric product $Os_2(\mu\text{-}H)_2(PMe_2Ph)_6H_2$ also results from the reaction (p. 572).[400]

(*iii*) *Tri- and tetra-hydrido species*

A number have been isolated: $[Os(PEt_2Ph)_4H_3]BPh_4$, made from *cis*-$Os(PEt_2Ph)_4H_2$ and HCl followed by addition of $NaBPh_4$,[276] and $[Os(PMe_3)_4H_3]PF_6$, from *cis*-$Os(PMe_3)_4H_2$ and $NH_4(PF_6)$.[401a] It seems from ^{1}H NMR data on the latter species that is fluxional at room temperature;[401a] an alarming observation on $[Os(PEt_2Ph)_4H_3]BPh_4$ (and its deuteriate) was than no IR band could be found to assign to the Os—H or Os—^{2}H stretches, though a band at 842 cm^{-1} was assigned to an Os—H deformation mode.[276] There is evidence for the existence of $[Os(PEt_2Ph)_2\{Ph_2P(CH_2)_2PPh_2\}H_3]^+$.[276] A recent X-ray crystal structure of $K[OsH_3(PMe_2Ph)_3]$ shows this to contain weak dimers with an H—K interaction; the main Os—H distance is 1.67 Å.[401b]

Tetrahydrido complexes of the form $Os(PR_3)_3H_4$ are the most important phosphine hydrides of osmium. Preparations are shown in Scheme 12 and typical data in Table 17, and some of the reactions are also given in Scheme 14. There is a full neutron diffraction study on $Os(PMe_2Ph)_3H_4$ which shows this to have a distorted pentagonal bipyrimidal structure with two apical and one equatorial phosphine ligand (mean Os—P apical distance 2.312 Å with a P—Os—P angle of 166.1(1)°; the bending occurs presumably as a result of the position of the equatorial phosphine ligand (Os—P = 2.347(3) Å). The hydride ligands are all in the equatorial plane (mean Os—H = 1.663 Å).[396,402] There are preliminary X-ray data on $Os(PEt_2Ph)_3H_4$ which indicate a similar structure (mean axial Os—P distance 2.296 Å, and an equatorial Os—P distance of 2.339 Å[403]). ^{1}H NMR data on the tetrahydrido complex indicate equivalence of the phosphine ligands, an effect which probably arises from fluxionality in solution.[276,404] IR spectra show three or four Os—H stretches in the 1800–2100 cm^{-1} region (though in some cases five stretches are observed in solution).[404] Both ^{1}H NMR and IR data are available for a number of OsL_3H_4 complexes (L = PBu^n_3, PMe_2Ph, PEt_2Ph) and also for $Os(PMe_2Ph)_2L'H_4$ (L′ = $P(OEt)_3$, $P(OMe)_2Ph$, PEt_2Ph, PPh_3, $AsMe_2Ph$); these latter species are made from *mer*-$Os(PMe_2Ph)_2L'Cl_3$ and BH_4^- in methanol.[404]

These OsL_3H_4 complexes have an extensive chemistry, representative examples of which are illustrated in scheme 12. In the presence of hydrogen, $Os(PEtPh_2)_3H_4$ catalyzes the hydrogenation of oct-1-ene.[276] Photolysis of $Os(PMe_2Ph)_3H_4$ gives a reactive intermediate $Os(PMe_2Ph)_3H_2$ (see above).

(*iv*) *Penta- and hexa-hydrido complexes*

Although salts of $[Os(PR_3)_2H_5]^+$ do not seem to have been isolated there is evidence from ^{1}H NMR spectra that $[Os(PMe_2Ph)_2H_5]^+$ is present in solutions of *cis*-$Os(PMe_2Ph)_4H_2$ in trifluoro-

acetic acid.[404] Such an $[OsL_3H_5]^+$ species would be a member of the series WL_3H_6, ReL_3H_5 and IrL_3H_3.[404]

The hexahydrido species $Os(PMe_2Ph)_2H_6$ is made by treatment of $Ph_4As[Os(PMe_2Ph)_2Cl_4]$ with $LiAlH_4$; it was detected by ^1H NMR.[404] The species $OsH_6(PPhPr^i_2)_2$ and $OsH_6(PPhPr^i_2)_2HgCl_2$ have recently been reported.

(v) *Polynuclear hydrido complexes*

Photolysis of $Os(PMe_2Ph)_3H_4$ in benzene or THF yields, amongst other products, red crystals of $Os_2(PMe_2Ph)_6H_4$. The X-ray crystal structure (Fig. 26) shows it to have a short Os—Os bond of 2.818(1) Å, formally a double bond if the electron-count of 18 is to be achieved; the Os_2H_2 bridge appears to be asymmetric with long and short distances of 2.18(10) and 1.59(10) Å respectively, while the Os—H terminal bonds are at 1.61(9) Å. The $Os(PMe_2Ph)_3$ unit about each metal atom has a *fac* geometry; the mean Os—P distance *trans* to the Os_2H_2 plane is 2.259 Å and that *trans* to the terminal hydrido ligand is substantially longer at 2.340(3) Å.[400] Reaction of this complex with HBF_4 leads to $[Os_2(PMe_2Ph)_6H_3]BF_4$, which has a tricapped trigonal prismatic type of structure (akin to that found in $K_2[ReH_9]$) with three bridging hydrido ligands (mean Os—H distance = 1.75(11) Å, Os—Os = 2.558(1) Å) and the mean Os—P distance is 2.291(4) Å. Formally there is an Os—Os triple bond here.[400] Finally, there is ^{31}P NMR evidence for the existence of $Os_2(PMe_2Ph)_5H_4$ in solutions of $Os_2(PMe_2Ph)_6H_4$, in which three hydrido ligands bridge two osmium atoms; one metal atom has three phosphine ligands with a *fac* arrangment and the other similarly bears two phosphine ligands and a terminal hydride ligand.[400]

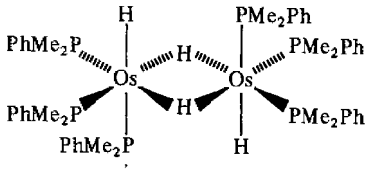


Figure 26 Structure of $Os_2(PMe_2Ph)_6H_4$[400]

46.5.1.2 Halo phosphine complexes

A very substantial number of these are known (examples are given in Table 18); as with the halo-arsines (p. 576) and -stibines (p. 577) the metal oxidation states represented are II, III and IV with a preponderance of the trivalent state; the early-reported '$Os(PPh_3)_3X$' (X = Cl, Br) complexes are now known to be hydrides, $Os(PPh_3)_3HX(CO)$.[408]

[a] $AsPh_3$ and $SbPh_3$ analogues also known.[370]

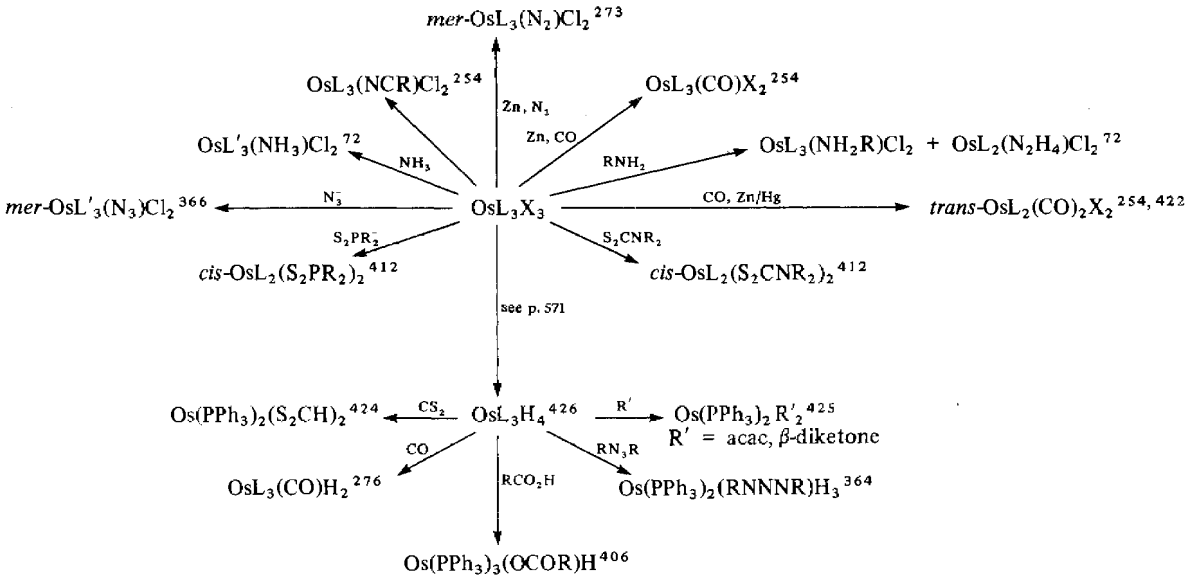
(i) *Osmium(II)*

Examples both of *cis*- and *trans*-$Os(PR_3)_4Cl_2$ and of the five-coordinate $Os(PPh_3)_3X_2$ (X = Cl, Br) are known. Preparations of these are outlined in Scheme 13; in addition, $Os(PMe_2Ph)_2\{P(OMe)_2Ph\}Cl_3$ can be obtained from $P(OMe)_2Ph$ and $Os(PMe_2Ph)_3(N_2)Cl$[409] and

trans-$Os(PMe_3)_4Cl_2$ from $Os(PPh_3)_2Cl_3$ and PMe_3 (a preliminary X-ray study of the complex was reported).[410] The *cis* form of $OsCl_2(PMe_3)_4$ is also known.[401]

i, HX, L (*Cl*: Bu^n_2Ph, Pr^n_2Ph, *Br*: PPr^n_3);[411] ii, Cl_2, L = PMe_2Ph, CCl_4, L = PMe_2Ph, PEt_2Ph;[404] iii, *Cl*: $PMePh_2$, PPr^n_2Ph, PPh_3;[370] iv, BH_4^-, PMe_2Ph, PEt_2Ph;[404] v, HX, L (*Cl*: PEt_3, PPr^n_3, PBu^n_3, PMe_2Ph, PEt_2Ph, PPr^n_2Ph, PBu^n_2Ph,[411] PPh_2(1-naphthyl),[419] *Br*: PPr^n_3, PMe_2Ph, PEt_2Ph, PBu^n_2Ph);[411] vi, N_2H_4 (Cl, PBu_2Ph);[413] vii, HCl, PBu^n_3, PMe_2Ph, $PEtPh_2$;[404] viii, HX, PPh_3 (Cl, Br);[370] ix, Zn, PEt_3, PMe_2Ph, $PEtPh_2$;[254] x, $PMePh_2$, PEt_2Ph, $PEtPh_2$;[420] xi, Zn, HCl, PMe_2Ph;[276] xii, Zn, PMe_2Ph;[276] xiii, HCl;[276] xiv, $PHPh_2$;[407] xv, PPh_3 (Cl,[397,410] Br[421]); xvi, $AgPF_6$;[401] xvii, PMe_3 (Cl).[416]

Scheme 13 Preparative routes for osmium halo phosphine complexes



IR spectra were used to indicate configurations of *cis*- and *trans*-$Os(PHPh_2)_4Cl_2$[407] and of *trans*-$Os(PPh_3)_4Br_2$,[370] while ^{31}P NMR spectra of $Os(PPh_3)_3X_2$ (X = Cl, Br) suggested a square-based pyramidal structure for these in which, however, intramolecular rearangement renders the two phosphorus environments equivalent.[410a] In a recent paper electroreduction of *mer*-$OsCl_3(PMe_2Ph)_3$ to *mer*-$[OsCl_3(PMe_2Ph)_3]^-$ was described; this releases Cl^- to give the five-coordinate *trans*-$OsCl_2(PMe_2Ph)_3$.[410b]

(*ii*) *Osmium(III)*

mer- *and* fac-*OsL_3X_3*. These are important starting materials for other osmium phosphine complexes, particularly the *mer* isomers (see p. 574); general methods of preparation are given in Scheme 13. Other starting materials which have sometimes been used for *mer* complexes are $K_2[OsNCl_5]$, *trans*-$K_2[OsO_2(OH)_4]$ and *trans*-$OsO_2Cl_2(PPh_3)_2$.[411] In some cases *mer*-OsL_3Cl_3 can be converted to *mer*-OsL_3Br_3 with LiBr in refluxing ethanol.[411,412] The species $Os(PMe_2Ph)_2LCl_3$ (L = $P(OMe)_2Ph$, $P(OEt)_3$, PEt_2Ph, PPh_3) are made from *trans*-$Os(PMe_2Ph)_4Cl_2$ and L in hot benzene.[404]

These trivalent complexes are useful starting materials for other osmium phospine complexes, and some of the reactions are indicated in Schemes 13 and 14. In not all of the cases is it clear whether the *mer* or *fac* isomer was used and so we have omitted these prefixes, although it is likely in most cases that the *mer* was in fact the starting isomer. In order to simplify the schemes, general reactions only are indicated.

There is one X-ray crystal structure of a *mer* isomer, *mer*-$Os(PMe_2Ph)_3Cl_3$ (Figure 27). Bond lengths are $a = f = 2.347(6)$, $b = c = 2.408(6)$, $d = 2.350(5)$ and $e = 2.439(6)$ Å.[403] There are IR data on many *mer* and *fac* complexes (*mer*-OsL_3X_3; X = Cl, L = PPr^n_3,[413] PBu^n_3,[404] PMe_2Ph,[404] PEt_2Ph,[404] PBu^n_2Ph;[413] X = Br, L = PPr^n_3;[413] *fac*-OsL_3Cl_3; X = Cl, L = PBu^n_3, PMe_2Ph, PEt_2Ph,[404] PBu^n_2Ph,[413] PPh_3;[370] X = Br, L = PPh_3[370]), and electronic (*mer*-$Os(PPr^n_3)_3Cl_3$,[414] *mer*-$Os(PPr_2Ph)_3Cl_3$,[415] *mer*- and *fac*-$Os(PBu_2^nPh)_3Cl_3$,[414] *mer*-$Os(PBu^n_2Ph)_3Br_3$[414]) and ESR spectra (*mer*-$Os(PMe_2Ph)_3Cl_3$, *mer*-$Os(PEt_2Ph)_3Cl_3$,[102,413] *mer*- and *fac*-$Os(PBu^n_2Ph)_3Cl_3$[413]). Magnetic moments for these complexes lie in the range 1.9–2.1 BM at room temperature.[411] There are ESR data on *mer*-$OsCl_3(PR_3)_3$ (PR_3 = PMe_2Ph, PBu^n_2Ph, $AsMe_2Ph$) and on *mer*-$Os(PBu^n_2Ph)_3Br_3$.[102]

L = phosphine and arsine; L' = phosphine only

Scheme 14 Some reactions of OsL_3X_3 and OsL_3H_4

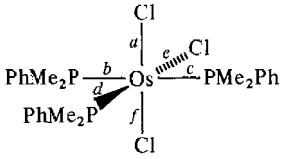


Figure 27 Structure of *mer*-$Os(PMe_2Ph)_3Cl_3$[403]

OsL_2X_3. Only one example of this type is reported; $Os(PPh_3)_2Cl_3$, made by refluxing *fac*-$Os(PPh_3)_3Cl_3$ in *t*-butanol.[416]

trans-*$[OsL_2X_4]^-$*. Apart from the preparative methods given in Scheme 13 *trans*-$Ph_4As[Os(PEt_2Ph)_2Cl_4]$ and *trans*-$Bu^n_4N[Os(PEt_2Ph)_2Br_4]$ are made from the phosphine and the corresponding $[OsNX_4]^-$ salts.[315]

$[Os(PMe_3)_4Cl_2]PF_6$. This is made from $AgPF_6$ and *trans*-$Os(PMe_3)_4Cl_2$, and reacts with CO to give *trans*-$Os(PMe_3)_3Cl_2(CO)$.[401]

$[Os_2L_6Cl_3]^+$. These are made as indicated in Scheme 13, and are likely to have a μ_3-chloro structure.[420]

trans-OsL_2X_4. Apart from the preparative routes outlined in Scheme 13, *trans*-$Os(PPh_3)_2Cl_4$ can be made from $Ph_4As[OsNCl_4]$ with PPh_3 or from $Os(PPh_3)_2Cl_2(NPPh_3)$ and HCl.[315]

A single crystal X-ray structure shows $Os(PMe_2Ph)_2Cl_4$ to have a *trans* configuration, with Os—P = 2.448(3) Å and Os—Cl = 2.319(3) Å.[403] A *trans* configuration in solution is also suggested by IR and ^1H NMR studies on species with L = PMe_2Ph, PEt_2Ph, PPr^n_2Ph and PBu^n_2Ph;[413,417] this is also the conclusion from Raman data on $Os(PMePh_2)_2Cl_4$ and $Os(PPh_3)_2Cl_4$,[370] and IR data on $Os(PMePh_2)_2Cl_4$, $Os(PPr^n_2Ph)_2Cl_4$, $Os(PPh_3)_2Cl_4$[370] and $Os(PPr^n_3)_2Br_4$.[413] There are electronic spectra for $Os(PPr^n_3)_2X_4$ (X = Cl, Br)[414] and ESCA data on $Os(PEt_3)_2Cl_4$, $Os(PMe_2Ph)_2Cl_4$[427] and $Os(PPh_3)_2Cl_4$;[93] magnetic moments are normally between 1.5 and 1.6 BM at room temperature for these complexes.[411]

$[OsLX_5]^-$. The sole example appears to be $Ph_4As[Os(PPh_3)Cl_5]$, a red complex made from $Os(PPh_3)Cl_4(NHPPh_3)\cdot Me_2CO$ and $Ph_4As(H_5O_2)Cl_2$.[315]

Miscellaneous phosphine complexes. For phosphine complexes with other ligands see as follows: acetonato, p. 598; alkoxo, p. 596; ammine, p. 529; azido, p. 565; carboxylato, p. 601; diazenido, p. 601; β-diketonate, p. 597; dinitrogen, p. 555; dithiocarbamate and dithiocarbonate, p. 604; hydrazine, p. 556; complexes with metal–metal bonds, p. 525; nitrile, p. 567; nitrido, p. 562; nitrosyl, p. 547; oxo, p. 584; phosphineiminato, p. 568; phosphinodithionato, p. 605; pyridine and piperidine, p. 533; sulfido, p. 603; triazenido, p. 565; trithiocarbonate, p. 605.

46.5.2 Tertiary Phosphite Complexes

It is a singular circumstance that the known chemistry of the tertiary phosphite complexes of osmium differs quite significantly from that of the tertiary phosphines, arsines and stibines. The closest analogue to $P(OR)_3$ in osmium coordination chemistry would seem to be PF_3, but even here the similarities are not marked. The oxidation states found are 0, II, III and IV (there are no established zerovalent unsubstituted osmium phosphine complexes), and the phosphites form unsubstituted species of the type OsL_5 and $[OsL_6]^{2+}$ which have no counterparts in phosphine chemistry. The reason for these differences must be associated in part at least with the different cone angles and basicities of $P(OR)_3$ ligands as against PR_3. Further similarities and differences between the chemistries of osmium phosphines, phosphites and phosphorus trihalide complexes would obviously constitute a worthwhile study.

46.5.2.1 Osmium(0)

Reaction of $Os\{P(OMe)_3\}_2Cl_4$ and $P(OMe)_3$ with sodium amalgam in THF yields the white $Os\{P(OMe)_3\}_5$. Study of the $^{31}P[^1H]$ NMR spectra showed simultaneous slow exchange of axial and equatorial ligands consistent with a Berry mechanism.[429]

46.5.2.2 Osmium(II)

Amongst the osmium(II) phosphito complexes known are the octahedral $[Os\{P(OR)_3\}_6]^{2+}$, made from $Os(PPh_3)_3Br_2$ and $P(OEt)_3$. The tetraphenylboronate is white; the trimethyl phosphite analogue could not be isolated.[430] Other osmium(II) species include $[Os\{P(OEt)_3\}_5X]^+$ (X = Cl, Br), made from $Os(PPh_3)_3X_2$ and $P(OEt)_3$,[430] $Os\{P(OR)_3\}_4Br_2$ (R = Ph, *p*-ClC_6H_4, *p*-MeC_6H_4), also made from $Os(PPh_3)_3Br_2$ and $P(OR)_3$,[431] and $Os(P(OPh)_3)_4Cl_2$, made from $OsNCl_3(AsPh_3)_3$ and $P(OPh)_3$.[265] For $Os\{P(OMe)_3\}_2$(octaethylporphyrin) see p. 618.

46.5.2.3 Osmium(III)

For $Os(PMe_2Ph)_2\{P(OR)_2Ph\}Cl_3$ (R = Me, Et) see p. 573.

46.5.2.4 Osmium(IV)

Reaction of $Na_2[OsCl_6]$ and $P(OMe)_3$ in the presence of amalgamated zinc gives $Os\{P(OMe)_3\}_2Cl_4$.[429]

46.5.3 Phosphorus Trihalide Complexes

The PF_3 ligand is similar to CO in many aspects of its coordination chemistry, and this is well exemplified by the small area of its osmium chemistry so far explored. The oxidation stages −II, 0 and II are represented, and there is an 'adduct' of osmium(VIII). Little is known about complexes of PCl_3 with osmium.

46.5.3.1 Osmium(−II)

The salt $K_2[Os(PF_3)_4]$ constitutes the most unequivocal instance in which osmium attains this rare oxidation state (it may always be argued for $Os(NO)_2(PPh_3)_2$, which has been crystallographically characterized, that −II is only a formal oxidation state). The salt is made from $Os(PF_3)_4H_2$ and potassium amalgam in ether. It is colourless, and the ^1H NMR and IR spectra are consistent with a symmetrical, presumably tetrahedral, structure.[432]

46.5.3.2 Osmium(0)

Osmium trichloride and Cu metal react with PF_3 at 250 °C under 500 atm to give the colourless $Os(PF_3)_5$, for which a trigonal bipyramidal structure was inferred.[433]

46.5.3.3 Osmium(II)

The dihydride $Os(PF_3)_4H_2$ is a colourless liquid (m.p. −72 °C), prepared from anhydrous $OsCl_3$ and PF_3 at 400 atm with H_2 at 120 atm at 250 °C. Both ^{31}P and ^1H NMR spectra suggest a *cis* structure.[432] With triethylamine $[Os(PF_3)_4H]^-$ is thought to be formed; the species was not isolated, but the ^1H NMR spectrum of a solution containing it was suggestive of a trigonal bipyramidal structure with the hydrido ligand occupying an axial position;[432] However, later ^1H and ^{19}F NMR data suggest that it is fluxional in solution.[434]

A number of tertiary phosphine complexes of osmium(II) substituted by PF_3 have been reported. Thus, reaction of $Os(PPh_3)_3H_4$ and PF_3 yields *cis*-$Os(PF_3)(PPh_3)_2H_2$ and *cis*-$Os(PF_3)(PPh_3)_3H_2$,[435] and the former reacts with HCl to give *cis*-$Os(PF_3)_2(PPh_3)_2HCl$.[436] This in turn with HCl under pressure gives *cis*-$Os(PF_3)_2(PPh_3)_2Cl_2$,[436] and reaction of PF_3 with *mer*-$Os(PMe_2Ph)_3Cl_3$ with zinc will give both the *cis* and *trans* forms of both $Os(PF_3)_2(PMe_2Ph)_2Cl_2$ and $Os(PF_3)(PMe_2Ph)_3Cl_2$.[437]

46.4.3.4 Osmium(III)

For $Os(PMe_2Ph)_2\{P(OR)_2Ph\}Cl_3$ (R = Me, Et) see p. 572. Reaction of osmium metal with PCl_5 at 600 °C gives a brown, volatile solid $OsCl_3 \cdot PCl_3$, the magnetic susceptibility of which was measured from 77 to 373 K; at the latter temperature μ_{eff} is 1.94 BM.[438] Presumably this material has a polymeric structure so as to give it octahedral coordination.

46.5.3.5 Higher oxidation states

At −100 °C OsO_4 will react with PF_3 to give $(OsO_4)_2 \cdot PF_3$; at 60 °C $OsO_4 \cdot PF_3$ is the product. With PCl_3, OsO_4 gives a black material, $OsO_2 \cdot PCl_3$.[439]

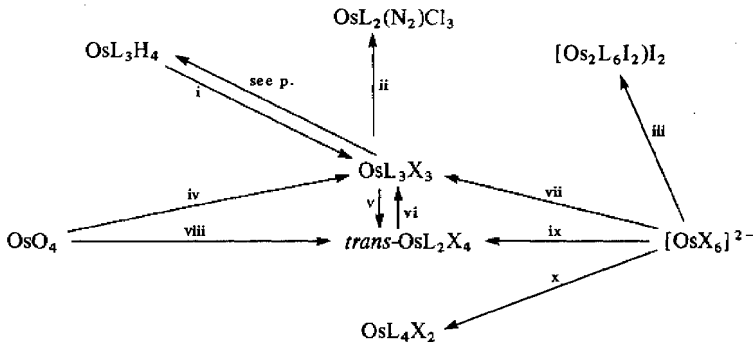
46.5.4 Tertiary Arsine Complexes

A substantial number of these have been reported for osmium, particularly with $AsPh_3$. Predictably the chemistry is quite similar to that for the analogous phosphine species.

46.5.4.1 Hydrido arsines

This is an area which has been much less explored in osmium chemistry than that of the hydrido phosphines. Some physical data are given in Table 17.

No monohydrido arsines seem to be known; reaction of $Os(AsR_3)_3H_4$ and AsR_3 in toluene gives the dihydrido species *cis*-$Os(AsR_3)_4H_2$ (AsR_3 = $AsEt_2Ph$, $AsEtPh_2$), and the ^1H NMR spectra of these suggest a *cis* configuration as is the case for the phosphine analogues.[276] No trihydrido complexes have been reported, but examples of $Os(AsR_3)_3H_4$ are known, made by reaction of *mer*-$Os(AsR_3)_3Cl_3$ with sodium borohydride (AsR_3 = $AsMe_2Ph$,[404] $AsEt_2Ph$,[276,404] $AsEtPh_2$,[276] $AsPh_3$[426]). Carbonylation of $Os(AsEtPh_2)_3H_4$ with CO yields $Os(AsEtPh_2)_3(CO)H_2$.[276]



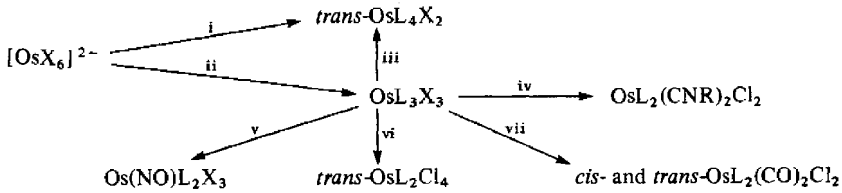
46.5.4.2 Halo arsine complexes

The general chemistry here, though not as extensively investigated as yet, follows the general pattern of the corresponding halo phosphine complexes. (see Table 18). As with these and with the halo stibines, oxidation states of II, III and IV are represented.

Reaction of $[OsX_6]^{2-}$ (X = Cl, Br) with H_3PO_4, HX and $AsMe_2Ph$ or $AsMePh_2$ gives $Os(AsR_3)_4X_2$; although the configurations were not established in this relatively early work[440] it

seems likely that they may be *trans*. The IR spectra of $Os(AsPh_3)_4Br_2$, made by refluxing $(NH_4)_2[OsCl_6]$ and HBr with $AsPh_3$ in 2-methoxyethanol, suggest that this has a *trans* configuration.[370]

There has been a more extensive study of osmium(III) complexes of the form $Os(AsR_3)_3X_3$, and these are summarized in Scheme 15 (see also Table 18).



i, HCl ($AsMe_2Ph$, $AsEt_2Ph$);[404] ii, Zn, N_2 ($AsMe_2Ph$, $AsEt_2Ph$);[273] iii, HI ($AsMe_2Ph$, $AsMePh_2$);[440] iv, HX ($AsPr^n_3$,[411] $AsMe_2Ph$,[411] $AsEtPh_2$[276]); v, CCl_4 ($AsPr^n_3$, $AsMe_2Ph$,[411] $AsEt_2Ph$[404]); vi, N_2H_4 ($AsPr^n_3$);[411] vii, *Cl, Br*: $AsMe_2Ph$,[440] $AsMePh_2$,[422,440] $AsRPh_2$ (R = Et, Pr, Bu);[422] *Br*, $AsPh_3$.[421] viii, HCl ($AsPr^n_3$, $AsEt_2Ph$,[423] $AsPh_3$[370]); ix, $AsPh_3$ (Cl,[370] Br[421]); x, H_2PO_2, HX (X = Cl, Br) ($AsMe_2Ph$, $AsMePh_2$).[440]

Scheme 15 Preparative routes to haloarsine complexes

46.5.5 Tertiary Stibine Complexes

As is the case with most elements the stibine chemistry has been a largely neglected area and this is certainly so for osmium: very few osmium stibine complexes have been isolated. All of the species which have been isolated are with $SbPh_3$, though oxidation states span the range II to IV.

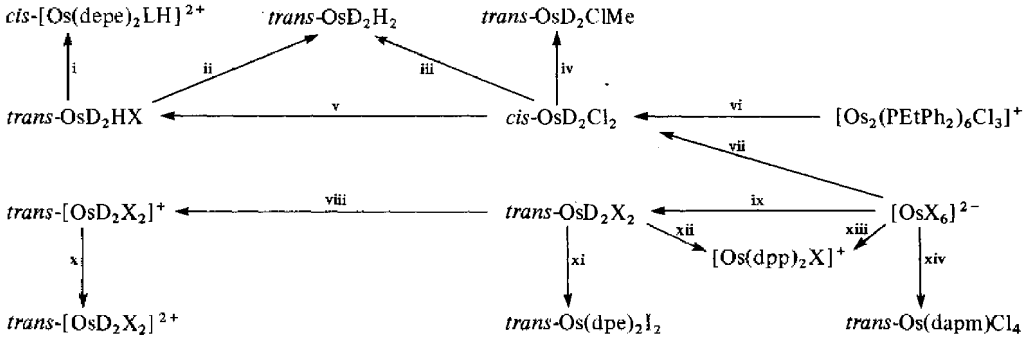
Preparative routes and typical properties are summarized in Scheme 16 (see also Table 18). The claimed *trans* configuration for $Os(SbPh_3)_4X_2$ (X = Cl, Br) and for $Os(SbPh_3)_2Cl_4$ is based at present on the simplicity of the IR spectra and, in the case of the black $Os(SbPh_3)_2Cl_4$, on the ^1H NMR spectrum also.[370] There is confusion however about the structure of $Os(SbPh_3)_3Cl_3$. On the basis of ESR, ^1H NMR and IR data a *mer* configuration has been proposed[370] and this would indeed seem to be the likely structure; an earlier IR study however was interpreted in favour of a *fac* structure.[441] The magnetic moment over a temperature range has been reported (100 to 300 K; μ_{eff} = 1.62 BM at 100 K rising to 1.73 BM at 300 K)[442] (or 1.92 BM at 293 K).[441] The bromo complex $Os(SbPh_3)_3Br_3$, made from $(NH)_2[OsBr_6]$ and $SbPh_3$ in 2-methoxyethanol, is purple, melting at 215 °C[421] or at 185–188 °C;[443] the same preparative route using methanol as the solvent gives a black

i, L (X = Cl, Br);[370] ii, L (X = Cl,[370,441] Br,[370] I[228]); iii, L, BH_4^- (X = Cl);[441] iv, Cl, RNC;[447] v, NO;[228,441] vi, Cl, CCl_4;[370] vii, CO.[441]

L = $SbPh_3$, R = *p*-MeC_6H_4

Scheme 16 Representative preparations and properties of triphenylstibine complexes

form melting at 263–265 °C.[370] On the basis of IR and ^{1}H NMR spectra a *fac* configuration for the black form was suggested;[370] a *mer* configuration for the purple form has been assigned on the basis of its IR spectra.[443] Clearly there is room for some further work in this area.



For nitrido stibines see p. 562, and for nitrosyl stibines see p. 547.

46.5.6 Bidentate Phosphine and Arsine Complexes

For convenience we consider these together. As with tertiary phosphines, arsines and stibines the oxidation states featured in the chemistry of these bidentate ligands are II, III and IV, with the former being predominant.

General preparative routes to these are summarized in Scheme 17. The abbreviations used below, in Scheme 17 and in Table 19 are the conventional ones, namely:

dmpe: bis(1,2-dimethylphosphino)ethane, $Me_2P(CH_2)_2PMe_2$
depe: bis(1,2-diethylphosphino)ethane, $Et_2P(CH_2)_2PEt_2$
dppm: bis(1,2-diphenylphosphino)methane, $Ph_2PCH_2PPh_2$
dppe: bis(1,2-diphenylphosphino)ethane, $Ph_2P(CH_2)_2PPh_2$
dpp: bis(1,2-diphenylphosphino)propane, $Ph_2P(CH_2)_3PPh_2$
pdmp: *o*-phenylenebis(dimethylphosphine), *o*-$C_6H_4(PMe_2)_2$
pdep: *o*-phenylenebis(diethylphosphine), *o*-$C_6H_4(PEt_2)_2$
diars: *o*-phenylenebis(dimethylarsine), *o*-$C_6H_4(AsMe_2)_2$
dapm: 1,2-bis(diphenylarsino)methane, $Ph_2AsCH_2AsPh_2$
dape: 1,2-bis(diphenylarsino)ethane, $Ph_2As(CH_2)_2AsPh_2$

i, BH_4^-, L= $P(OMe)_3$, $P(OPh)_3$, PhCN;[278] ii, $LiAlH_4$, dppe,[449] depm;[448] iii, $LiAlH_4$, pdep;[449] iv, Al_2Me_6, dppm, dppe;[450] v, X^-, $LiAlH_4$; *Cl*$^-$: dmpe, dppe,[449] dppm;[448] *I*$^-$: depe;[449] *SCN*$^-$: depe;[449] vi, dppm, dmpe, depe, dppe, pdep;[420] vii, Na/Hg, depm;[444] viii, *Cl*: $AgBF_4$, dppe, dpp;[445] H_2O_2, pdmp;[451] Cl_2, diars;[369] *Br*: Br_2, diars; *I*, *SCN*: $HClO_4$, I^- or SCN^-, diars;[369] ix, *Cl*: dmpe, dppm, depe, dppe,[420] pdmp,[451] dpp,[445] diars;[369] *Br*: diars;[369] *I*, *SCN*: I^- with X = Br, diars,[369] X = Br, SCN^-;[370] x, HNO_3: *Cl* (pdmp,[451] diars);[369] *Br*, *I*: (diars);[369] xi, I^- (dppe);[420] xii, BF_4^- (Cl, Br) dpp;[445] xiii, Cl, dpp;[445] xiv, dapm.[370]

Scheme 17 General preparations for chelating phosphine and arsine complexes

Table 19 Chelating Phosphine and Arsine Complexes

Complex	*Colour*	*M.p. (° C)*	*Spectroscopic and other properties*[a]
cis-$Os(dppm)_2Cl_2$	Yellow		X-ray[444]
cis-$Os(dppe)_2Cl_2$	Yellow	290–291	D[420]
trans-$Os(dmpe)_2Cl_2$	Yellow	298–300 (d)	UV/vis[453]
trans-$Os(dppe)_2Cl_2$	Yellow	293–296	UV/vis[454]
$[Os(dpp)_2Cl]BPh_4$	Brown	260	IR, UV/vis, ^{31}P NMR,[445] CV[452]
trans-$[Os(pdmp)_2Cl_2]ClO_4$	Purple		UV/vis, EPR, CV[451]

[a] CV = cyclic voltammetry; D = dipole moment

The X-ray crystal structure of $Os(dppm)_2Cl_2 \cdot CHCl_3$ shows this to be *cis*, with mean bond lengths of 2.452(2) (Os—Cl), 2.297 (P *cis* to Cl) and 2.339(1) Å (P *trans* to Cl), and a Cl—Os—Cl angle of 83.08(7)°.[444] The *cis* configuration of $Os(depe)_2Cl_2$ and of $Os(dppe)_2Cl_2$ in solution is demonstrated by the dipole moments of 9.3 and 8.3 D respectively.[420] The *trans* configurations of $[Os(dpp)_2Cl_2]BF_4$[445] and of the arsine complexes OsL_2Cl_2 (L = diars,[446,370] dape[370]) have been inferred from the relative simplicity of their far IR spectra. The complexes $Os(SCN)_2(dapm)_3$ and $OsI_3(dapm)_2$ have been reported; in the former the thiocyanate ligand is thought to be S-bonded.[370]

Magnetic susceptibility measurements on *trans*-$[OsL_2Cl]BF_4 \cdot \frac{1}{2}CH_2Cl_2$ (L = dppe, dpp) give surprisingly high magnetic moments at room temperature (μ_{eff} = 1.98 and 2.07 BM respectively),[455] while moments of $[Os(diars)_2X_2]$ are more normal (1.85 (Cl), 1.88 (Br), 1.93 (I) BM).[369] For the osmium(IV) species $[Os(diars)_2X_2](ClO_4)_2$ they are, not unexpectedly, lower: 1.25 (Cl), 1.22 (Br) and 1.16 (I) BM.[369] Another osmium(IV) complex is *trans*-$Os(dapm)Cl_4 \cdot EtOH$, made from the ligand and $[OsCl_6]^{2-}$ in ethanol.[370]

The IR and ^{31}P NMR spectra of $[Os(dpp)_2Cl]^+$ suggest that this has a trigonal bpyramidal structure in solution with a chloro ligand in an axial position.[445] On electrochemical reduction, it gives $Os(dpp)_2Cl$ (a rare case of osmium(I)) and, on further reduction, the osmium(0) species $[Os(dpp)_2Cl]^-$.[452]

For complexes of bidentate phosphines with metal–metal bonds see pp. 525, 527; for dinitrogen complexes see p. 555.

46.5.7 Complexes with Polydentate Phosphines and Arsines

The 'triphos' ligand (bis(2-diphenyl(phosphinoethyl)phenylphosphine, $[Ph_2P(CH_2)_2]_2PPh$) reacts with $[OsCl_6]^{2-}$ to give the yellow $Os(triphos)Cl_4$,[455] while reaction of bis(*o*-diphenylphosphinophenyl)phenylphosphine (QP) with $[Os(NO)(OH)(NO_2)_4]^{2-}$ and HCl gave the pale yellow $Os(QP)Cl_2$.[456]

One osmium complex of the phosphorus–arsenic chelate As—Pf—As (bis(2-diphenylarsinoethyl)phenylphosphine, $(Ph_2AsCH_2CH_2)_2PPh$) has been made from OsO_4 and the ligand in HCl; it is the orange $Os(As—Pf—As)Cl_3$.[457]

There is one complex with the tetradentate arsine qas (tris(*o*-diphenylarsinophenyl)arsine, $C_{54}H_{42}As_4$): $Os(qas)Cl_2$, made from $K_2[Os(NO)(OH)(NO_2)_4]$ and the ligand with HCl.[456]

46.6 OXYGEN-CONTAINING LIGANDS

46.6.1 Aqua and Hydroxo Complexes

No unsubstituted aqua complexes of osmium seem to have been reported, though we have already referred to a number of species in which H_2O is a ligand. Species such as $[Os(H_2O)_6]^{3+}$ and $[Os(H_2O)_6]^{4+}$ would be expected to exist.

There has also been little work on osmium hydroxo complexes apart from the now well-characterized *cis*-$[OsO_4(OH)_2]^{2-}$ (p. 592), *trans*-$[OsO_2(OH)_4]^{2-}$ (p. 581) and the two μ-hydroxo species structurally characterized, $M[Os_2(OH)O_8]$ (M = Rb, Cs) (p. 596). The $[Os(OH)_6]^{2-}$ species should certainly exist but does not seem to have been mentioned in the literature; even $[Os(OH)_6]^{3-}$ might be expected to be stable in the absence of oxygen. Other hydroxo (and aqua) complexes are considered in sections dealing with the other ligands present.

46.6.2 Osmium Oxo Complexes

The oxo complexes of osmium dominate the chemistry of the element, the cluster carbonyls notwithstanding, and the tetroxide is the single most important compound of the element.

In the area of osmium oxo chemistry there are three main topics of interest: the tetroxide itself, the 'osmyl' complexes which contain the *trans* $O{=}Os^{VI}{=}O$ unit, and the cyclic 'oxo ester' species which contain the Os^{VI} moiety. This is perhaps the most appropriate point at which to comment briefly on the reasons for the stability of these three systems.

Apart from ruthenium, osmium is the only element to form a neutral octavalent tetroxide, and certainly OsO_4 is chemically much more stable than RuO_4. It is a relatively mild oxidizing agent and

undoubtedly owes its stability largely to the ability of osmium, by virtue of its central position in the third row of the transition elements, to sustain the very high VIII oxidation state in the presence of π-donor ligands (O^{2-} alone, O^{2-} with N^{3-}, O^{2-} with F^-). The much greater oxidizing power of RuO_4 must surely derive from the fact that ruthenium is a second-row element and thus barely able to sustain the VIII state, while FeO_4 is unknown.

Whereas OsO_4 and the oxo esters considered below possess certain features unique to osmium, analogues of the 'osmyl' complexes are found for other elements capable of attaining a d^2 configuration (Ru^{VI}, Re^{V}, Tc^{V}, W^{IV}, Mo^{IV}), although it is true that the diversity of the coligands X in *trans*-$[Os^{VI}O_2X_4]^{n-}$ is rivalled only by that in the uranyl system. The reason for adoption of a *trans* geometry is electronic (see p. 579); *cis* dioxo species *cis*-$[MO_2X_4]^{n-}$ are found for the d° state (Re^{VII}, Mo^{VI}, W^{VI}, V^{V}) but are curiously missing from osmium(VIII) and ruthenium(VIII) chemistry.

The cyclic oxo esters are very much a feature of osmium(VI) chemistry but analogous rings are rare with other elements: they have been detected for ruthenium(VI) and manganese(V), but only for chromium(V) has any substantial oxo ester chemistry been uncovered. The osmium species are formed by two main routes: (a) by reaction of OsO_4 with alkenes, dienes or alkynes, in which case two electrons are transferred from the multiple bond to osmium(VIII) which is thus reduced to osmium(VI), or (b) by reaction of *cis*-glycols with *trans*-$[OsO_2(O_2R)_2]$ (R = H, Me) with elimination of water or methanol (see p. 582).

Both routes are facile for osmium and the d^2 osmium(VI) state is particularly stable for oxo species; the redox and kinetic properties of OsO_4 are such as to favour route (a) (whereas for RuO_4, for example, C=C cleavage would occur, and $[ReO_4]^-$ does not possess sufficient oxidizing power for the reaction to occur at all). Route (b) is facile because of the stability of the osmyl system in $[OsO_2(OH)_4]^{2-}$ and $[OsO_2(OMe)_4]^{2-}$ whereas analogues of these species are so far not known for other elements. Nevertheless, oxo ester rings for other elements should surely be commoner than they seem to be; the most fruitful approach to obtain them might be exploitation of a route analogous to (b) with, for example, *trans* dioxo species of ruthenium(VI) or of rhenium(V).

The arrangement of this large section on osmium oxo complexes follows the pattern of other sections in this chapter. We consider mononuclear complexes first, by increasing oxidation state and, within each oxidation state, we consider those complexes with the largest number of oxo ligands first. The same procedure is then followed for binuclear species. For convenience, however, mononuclear and polynuclear oxo esters are considered together.

46.6.2.1 Mononuclear complexes

(i) Osmium(IV) and (V) complexes

(a) Osmium(IV). For $[O{=}Os(terpy)(bipy)]^{2+}$ see p. 543.

(b) Osmium(V). The salt $Li_7[OsO_6]$ has been reported, made by reaction of $Li_5[OsO_6]$ and Li_2O with osmium metal. On the basis of X-ray studies of this hexagonal lattice the Os=O distance was estimated as 2.07 Å, suggesting that this is a lattice compound rather than a true complex.[459] There is a brief report of $Li_3[OsO_4]$[460] but again there is no evidence that $[OsO_4]^{3-}$ tetrahedra are involved.

(ii) Osmium(VI) complexes

As mentioned above the chemistry here is dominated by that of the osmyl species (see p. 581) and by oxo ester complexes (p. 584).

(a) Hexa-, penta- and tetra-oxo species. A substantial number of these have been reported, but in no single case is it certain that they contain discrete mononuclear species. Those reported include $[OsO_6]^{6-}$, $[OsO_5]^{4-}$ and $[OsO_4]^{2-}$ ions. Examples are $Li_6[OsO_6]$, $Na_4[OsO_5]$, $Ba_2[OsO_3]$, $Ba_3[OsO_6]$[460] and $Ba[OsO_4]\cdot nH_2O$;[461] the IR spectrum of $Ba_3[OsO_6]$ has been measured.[462]

For many years the 'osmates' $M^I_2[OsO_4]\cdot 2H_2O$ (M = Na, K)[463] and $Ba[OsO_4]\cdot H_2O$ were regarded as being tetrahedral osmium(VI) species, but it is now known that the sodium and potassium salts at least contain the *trans*-$[OsO_2(OH)_4]^{2-}$ ion;[327,464,465] the barium salt could be $Ba[OsO_2(OH)_4]$ or, possibly, contains the $[OsO_3(OH)_2]^{2-}$ anion (see below).

(b) Trioxo species. Few of these are known for osmium(VI). The species $[OsO_3(OH)_3]^{3-}$ is said to be present in solutions of $[OsO_2(OH)_4]^{2-}$.[466] It is possible that '$Ba[OsO_4]\cdot nH_2O$', made by reaction of $Ba(NO_3)_2$ with $K_2[OsO_2(OH)_4]$,[461] could be $Ba[OsO_3(OH)_2]$ since '$Ba[RuO_4]\cdot 2H_2O$' has been shown by X-ray studies to be $Ba[RuO_3(OH)_2]$ (in which there is a trigonal bipyramidal anion with three oxo ligands in equatorial positions).[467]

A number of trioxo species are claimed in the earlier literature. Thus, '$OsO_3(py)_2$' has long been regarded as such but is now known to be $Os_2O_6(py)_4$[468,469] (though in aqueous solution there is an equilibrium between the monomer and dimer[470,471]). Likewise the claimed 'oxy-oxmyl' salts $[OsO_3X_2]^{2-}$ (X = Cl, Br, NO_2^-, $\frac{1}{2}$ox)[204] are probably $[Os_2O_6X_4]^{4-}$ (see pp. 593 and 595).

(c) Dioxo ('osmyl') species.

As mentioned above (p. 579) this is one of the most important classes of osmium complexes, rivalling in number and diversity the oxo esters to be discussed in the next section. The trivial name 'osmyl' denotes the *trans* $Os{=}Os^{VI}{=}O$ grouping and, like 'uranyl' for $O{=}U^{VI}{=}O$, has passed into common parlance and will be used here.

We have already mentioned that the easily attained d^2 configuration for osmium favours the formation of these species (just as d^0, for other elements but apparently not for osmium, favours the formation of *cis* dioxo species[461,472]). The realization in 1960[464] that the long-known[463] and supposedly tetrahedral '$K_2[OsO_4]\cdot 2H_2O$' was diamagnetic and its consequent reformulation as *trans*-$K_2[OsO_2(OH)_4]$[464] (subsequently confirmed by X-ray studies[327,465]) led to a rationalization of the osmyl complexes.

Almost all osmyl complexes are octahedral (the few exceptions are treated on p. 582) and the great majority have linear or almost linear $O{=}Os{=}O$ systems (Table 20); most are mononuclear but a few are binuclear with a $\mu\mu'$-dioxo bridge.

Table 20 X-Ray Structural Data on 'Osmyl' Complexes

Complex	d_{OsO} (Å)	*OOsO* (°)	d_{OsX} (Å)	*XOsX* (°)	d_{OsY} (Å)	*YOsY* (°)	*Ref.*

[a] Chelating OOsN angle. [b] Chelating acetato ligand.

For $Os_2O_6py_4$ and $K_4[Os_2O_6(NO_2)_4]$ see Table 25 and p. 595; for $Os_2O_4(O_2C_6H_{10})_2(NC_7H_{13})_2$ see Table 25 and pp. 587; for $Os_2O_4(O_4C_8H_{12})py_4\cdot 4H_2O$ see p. 586 and Table 21.

They are all diamagnetic, and this can be attributed to the large tetragonal compression of the octahedron by the *trans* $O{=}Os$ bonds causing the two *d* electrons to pair up in the d_{xy} orbital (assuming the oxo ligands to lie on the *z* axis).[464]

Another approach is to envisage the formation of two three-centre, four-electron MOs involving $2p_x^2$–d_{xz}^0–$2p_x^2$ and $2p_y^2$–d_{yz}^0–$2p_y^2$ orbitals.

We classify here mononuclear osmyl complexes *trans*-$[OsO_2X_4]^{n-}$ by the nature of the ligand X; binuclear osmyl complexes are considered on p. 595.

Osmyl complexes with O-donor ligands. Preeminent amongst these are the 'osmates', sometimes called 'osmiates' in the early literature, and still often incorrectly formulated as salts of '$[OsO_4]^{2-}$'. The sodium, potassium and barium salts were reported in 1844,[474] but it is only recently that the rubidium and cesium salts were prepared.[475] The purple potassium salt is the best known and is a useful starting material for the preparation of other osmyl or osmium complexes. It is easily made from OsO_4 in excess KOH with added ethanol functioning both as reducing and precipitating agent,[464,476] and can also be made from osmium metal by fusion with KOH and KNO_3.[477] The sodium salt, though more soluble, is less easy to characterize and has a variable degree of hydration depending on the amount of ethanol added to the OsO_4–NaOH mixture.[478] The X-ray crystal structure of the potassium salt clearly shows it to have the *trans* structure (I)[327,465] (Table 20) postulated earlier on the basis of its diamagnetism and electronic spectra.[464] The acid dissociation constants of '$H_2[OsO_2(OH)_4]$' have been determined.[479] The possibility that '$Ba[OsO_4]\cdot nH_2O$' (and hence $Ba[OsO_2(OH)_4]\cdot 2H_2O$) could be $Ba[OsO_3(OH)_2]$ has been mentioned above (p. 580).

A closely related species is the olive-green $K_2[OsO_2(OMe)_4]$, made from KOH and OsO_4 in methanol.[480–482] Its use in electron microscopy of biological tissue has been proposed.[482] From it and acetic acid can be prepared the blue $K[OsO_2(OAc)_3]$;[480] on recrystallization from acetic acid this gives $K[OsO_2(OAc)_3]\cdot 2AcOH$ in which the osmyl group is emphatically *not* linear (Figure 28).

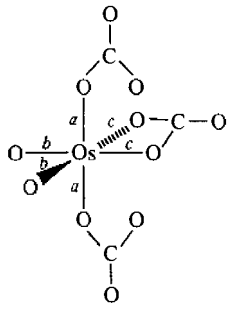

Figure 28 Structure of $K[OsO_2(OAc)_3]\cdot 2AcOH$[483]

The bent osmyl unit (OOsO angle = 125.2(3)°) is *trans* to a chelating acetato ligand, the octahedral coordination being completed by two monodentate acetato ligands. (mean $a = 2.026$, mean $b = 1.711$, mean $c = 2.148$.Å).[483]

The oxalato complex $[OsO_2ox_2]^{2-}$ has long been known as the sodium, potassium, ammonium, rubidium, cesium, magnesium and silver salts; the normal method of preparation is to treat OsO_4 with oxalic acid and the appropriate cation.[204] Recent electronic spectral studies on the tetrabutylammonium salt of $[OsO_2ox_2]^{2-}$ and $[OsO_2(malonate)_2]^{2-}$ show vibrational fine structure.[484] These are clearly true osmyl species, but the ion '$[OsO_3ox_2]^{2-}$'[204] may be better formulated as $[Os_2O_6ox_4]^{4-}$, rather than as the previously suggested $[OsO_2(OH)_2ox]^{2-}$.[21] The salts $M^I_2[OsO_2(salicylate)_2]$ are also reported (M = Na, K, NH_4, Rb, Cs).[485]

The diolato complexes $K_2[OsO_2(O_2R)_2]$ containing oxo ester rings are dealt with on p. 585 (see also Table 21). Formally related to these are the catecholato complexes $[OsO_2(Rcat)_2]^{2-}$, but they differ from them in that the metal–catecholato ring is likely to be planar (see p. 597). These are made for catechol or substituted catechols (Rcat = 4-methyl-, 4-*tert*-butyl-4-nitro-cholato) and $K_2[OsO_2(OH)_4]$. They react with pyridine to give $OsO_2(Rcat)py_2$.[486]

[a] CV = cyclic voltammetry.

Halo osmyl complexes, $[OsO_2X_4]^{2-}$. The potassium, ammonium and cesium salts of $M^I_2[OsO_2Cl_4]$ and potassium and ammonium salts of $M^I_2[OsO_2Br_4]$ are known;[204] no fluoro or iodo osmyl complexes seem to have been reported, although *trans*-$[OsO_2F_4]^{2-}$ would be expected to be stable. Reaction of *trans*-$K_2[OsO_2(OH)_4]$ with HCl gives *trans*-$K_2[OsO_2Cl_4]$,[487] and a convenient preparation for salts of $[OsO_2Cl_4]^{2-}$ or $[OsO_2Br_4]^{2-}$ is to treat $K_4[Os_2O_6(NO_2)_4]$ with HCl or HBr.[204]

The X-ray crystal structure of $K_2[OsO_2Cl_4]$ shows it to have a *trans* structure for the anion (see Table 20).[487]

The so-called 'oxyosmyl' complex '$K_2[OsO_3Cl_2]$' has been made from $K_4Os_2O_6(NO_2)_4]$ and a deficiency of HCl.[204] Although the pyridinium analogue[488] of this has been reformulated as $(pyH)_2[OsO_2(OH)_2Cl_2]$,[461] a more attractive formulation is perhaps $K_4[Os_2O_6Cl_4]$, analogous to its nitro precursor.

The species $[OsO_2Cl_3(H_2O)]^-$ is thought to exist in equilibrium with $[OsO_2Cl_4]^{2-}$ (equation 5).[466]

$$[OsO_2Cl_4]^{2-} + H_2O \rightleftharpoons [OsO_2Cl_3(H_2O)]^- + Cl^- \quad (5)$$

The electrochemical reduction of $[OsO_2Cl_4]^{2-}$ to osmium(IV) and osmium(III) chloroaqua complexes has also recently been studied.[489]

Osmyl complexes with nitrogen donor ligands. The ammine $[OsO_2(NH_3)_4]Cl_2$ was first made by Frémy in 1844[474] and is still sometimes called 'Frémy's salt'. It is most easily made by reaction of *trans*-$K_2[OsO_2(OH)_4]$ with ammonium chloride[490] and is pale yellow and only sparingly soluble in water. On heating it decomposes to hydroxoammine complexes.[491]

The ethylenediamine complex *trans*-$[OsO_2en_2]Cl_2$ is made from *trans*-$K_2[OsO_2(OH)_4]$ and ethylenediamine dihydrochloride.[492] The X-ray crystal structure of the bisulfate salt (Table 20) confirms the *trans* geometry (the O=Os=O grouping, though linear, is not precisely perpendicular to the OsN_4 plane). The rate of exchange of $H_2{}^{18}O$ with *trans*-$[Os^{16}O_2en_2]^{2+}$ is slow but increases with increasing pH.[493] It reacts with $[Fe(H_2O)_6]^{2+}$ to give a deep blue species, possibly $[(H_2O)_5Fe—O—OsOen_2]^{4+}$, for which preliminary X-ray data were given.[494]

Direct reaction of OsO_4 with a series of amino acids in aqueous solution gives *trans*-$OsO_2(an)_2$ (an = glycinato, DL-glycinato, DL-valinato, DL-leucinato, DL-isoleucinato and DL-phenylalaninato), and the X-ray crystal structure of *trans*-$OsO_2(NH_2CH_2CO_2)_2$ has been elucidated (Table 20).[495] There are also X-ray data (Table 20) on $OsO_2(OH)_2phen \cdot 5H_2O$,[469] made by reaction of *trans*-$K_2[OsO_2(OH)_4]$ with 1,10-phenanthroline (phen).[496] The species exists in another monomeric form in which the hydrogen bonding of water molecules is slightly different; there is also a dimer, $Os_2O_6phen_2$.[496] Equilibria for this, and for $OsO_2(OH)_2TMEN \rightleftharpoons Os_2O_6(TMEN)_2$ (TMEN = *N,N,N',N'*-tetramethylethylenediamine), have been studied[496] and there are probably equilibria such as $OsO_2(OH)_2bipy \rightleftharpoons OsO_6bipy_2$ and $OsO_2(OH)_2py_2 \rightleftharpoons Os_2O_6py_4$.[471]

The oxo esters $OsO_2(O_2R)py_2$ are considered on p. 584 but since they are osmyl complexes we list X-ray data for four of these in Table 20; there are also IR data for them.[490,497]

It is worthwhile at this point to note that the O=Os=O moiety is linear only in complexes of the form *trans*-$[OsO_2X_4]^{n-}$, where D_{4h} symmetry exists by virtue of the equivalence of the four X ligands. In species of the type $OsO_2X_2Y_2$ (*e.g.* such as discussed above) it deviates substantially from linearity, by some 10° to 18°, in the complexes which have been studied by X-ray methods. In all cases the distortion is *away* from the relatively short Os—O (ester or hydroxo) bonds and *towards* the longer Os—N bonds. This effect has plausibly been explained on the basis that the π electrons in the O=Os=O system have a powerful repulsive effect towards electrons in the Os—O and Os—N moieties; these are minimized by bending of the O=Os=O system, and are also manifest in a relatively large OOsO angle (*ca.* 85°) and relatively large NOsN angle (*ca.* 94°) (though these are of course affected by ligand bite considerations).[498] There are obvious parallels here with the distortions observed in $OsO(O_2R)_2$ (p. 584),[499,500] $Os_2O_4(O_2R)_2$ (p. 584)[501] and $[OsNX_4]^-$ (p. 561);[329–332] similar effects are operative in the structures of $Os_2O_6py_4$ (Table 25)[469] and $K_4[Os_2O_6(NO_2)_4]$ (Table 25).[502]

The nitro complex '$K_2[OsO_3(NO_2)_2] \cdot 3H_2O$'[204] is not, as previously suggested, $K_2[OsO_2(OH)_2(NO_2)_2]$[21,503] but has been shown by X-ray studies to be $K_4[Os_2O_6(NO_2)_4]$ (p. 595).[502] For $[OsO_2(NO_2)_4]^{2-}$ and $[OsO_2(NO_3)_2(NO_2)_2]^{2-}$, see p. 598. An olive-green octaethylporphyrin (OEP) complex $OsO_2(OEP)$ can be made by oxidation of Os(CO)Cl(OEP) with H_2O_2.[504]

Osmyl complexes with miscellaneous donors. The cyano complex $K_2[OsO_2(CN)_4]$ is made from the action of aqueous KCN solution on OsO_4.[505] There are a number of osmyl complexes with sulfur donors. Reaction of OsO_4 with sodium sulfite in alkali gives $Na_2[OsO_2(SO_3)_4]$;[506] Raman and IR spectra suggest that the sulfite is S rather than O bonded.[507] There are complexes with thiourea, *e.g.*

$[OsO_2\{SC(NH_2)_2\}_2]SO_4$,[508] and dithiocarbamato species have been claimed.[509] Osmyl complexes with thiosemicarbazides are made from the ligand and OsO_4.[510,511] The species originally thought to be $OsOCl_3(PPh_3)_2$ and $OsOBr_3(PPh_3)_2$[512] are now known to be mixtures containing $OsO_2Cl_2(PPh_3)_2$[93,396] and $OsO_2Br_2(PPh_3)_2$;[513] they are made in a pure state by reaction of OsO_4 in HCl or HBr with ethanol, and a number of $OsO_2Cl_2(PR_3)_2$ species ($PR_3 = PMePh_2$, $PEtPh_2$, PEt_2Ph) have been so made.[513]

The 'osmyl' thioether complexes $OsO_2X_2(SR_2)_2$ ($SR_2 = SMe_2$, $MeS(CH_2)_2SMe$, *o*-$C_6H_4A(SMe_2)$, *o*-$C_6H_4(PPh_2)(SMe)$; X = Cl, Br) have recently been reported, made by reaction of the ligand with OsO_4 in concentrated HX. The IR, electronic and ^1H NMR spectra were recorded; the seleno complexes $MeSe(CH_2)_2SeMe$ were also prepared.[514]

One example of a *cis* dioxo complex has been reported, *cis*-$[OsO_2bipy_2](ClO_4)_2$, made by addition of Ce^{IV} to a solution containing *cis*-$[Osbipy_2(H_2O)_2]^{2+}$. The ^1H NMR and IR spectra ($\nu_{as}(OsO_2) = 878$, $\nu_s(OsO_2) = 858\,cm^{-1}$) support this very unusual structure for an osmium(VI) dioxo complex.[176] An X-ray crystal structure would clearly be of great interest.

For osmyl complexes with phthalocyanines see p. 619.

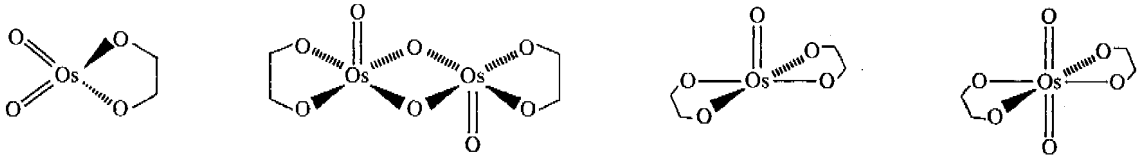
(d) Monooxo species. The simplest of these are the oxotetrafluoride and oxotetrachloride, but the large body of oxo esters come into this category also and are separately considered below.

Oxohalides (see Table 22). The oxotetrafluoride is a blue-green material, made by reaction of OsF_6 and OsO_4 at 175 °C,[523] and is diamagnetic. The oxotetrachloride $OsOCl_4$ is a dark-red diamagnetic liquid, very sensitive to moisture, made by reaction of an 8:1 Cl_2:O_2 mixture on osmium metal at 400 °C,[524] from OsO_4 and thionyl chloride under reflux[525a] or, in a new preparation, from OsO_4 and BCl_3.[525b] The IR spectrum of the gas suggested a square-based pyramidal structure for the compound.[526] It is isoelectronic with $[OsNCl_4]^-$ and so, like the latter, might be expected to undergo nucleophilic attack by phosphines at the axial ligand, but this does not appear to be the case.[265] The compound reacts with cesium fluoride in HCl to give the green '$Cs_2[OsOCl_6]$',[524] an apparently heptacoordinate material which should be further investigated. The so-called 'Os_2OCl_8', also made from osmium with a chloride:oxygen mixture,[527] is probably $OsOCl_4$.[525a]

Table 22 Monooxo Complexes

Complex	*Colour*	$\nu_{Os=O}$	*Spectroscopic and other properties*
$OsOF_4$	Blue-green		Raman[533]
$OsOCl_4$	Deep red	1028	IR,[525b,526] UV/vis[525b]
$OsOF_5$	Green	963	Raman, IR,[534] M,[535] X-ray[535]
$OsO(O_2C_2H_4)_2$	Black	992	IR,[497] X-ray[499,529]
$OsO(O_2C_2Me_4)_2$	Black	978	IR,[497] X-ray[500]

For $Os_2O_4(O_2C_2Me_4)_2$ see p. 000.



Osmium(VI) oxo esters. A large body of osmium(VI) complexes containing the cyclic system OsOCCO is known, generally made by reaction of OsO_4 with an alkene R. It is convenient to deal with these complexes as a group; we abbreviate the above ring as $Os(O_2R)$, the hypothetical O_2R^{2-} 'diolato' unit being derived from an alkene R (or diene or alkyne). Although ring complexes of this type are known for a few other metals it is only with osmium that such wide diversity and chemical stability are achieved.

The early work on the oxidation of alkenes and alkynes by OsO_4 (see p. 590) was little concerned with the osmium-containing intermediates. It was Criegee who showed, in 1936[528] and in 1942,[480] that alkenes R would react with OsO_4 to give isolable 'esters', formulated as $OsO_2(O_2R)$ ('monoesters') and, in some cases, $OsO(O_2R)_2$ ('diesters'); on hydrolysis these gave *cis* diols in high yield. He also showed in 1942 that the reaction of OsO_4 with alkenes was greatly accelerated by the presence of nitrogenous bases L (L = pyridine, isoquinoline) and that this reaction gave $OsO_2(O_2R)L_2$ which, on hydrolysis, gave the *cis* glycol. The possible mechanistic pathways for ester formation from alkenes are briefly considered on p. 590.

In this section we consider first the esters formed without nitrogenous bases (*i.e.* monoesters, diesters and salts of $[OsO_2(O_2R)_2]^{2-}$) and then the even larger body of information on esters containing nitrogenous bases. The latter section is sub-divided according to the Os:L ratio.

Ester complexes formed in the absence of nitrogenous bases. Criegee's 'monoesters' were formed by direct reaction of OsO_4 with the alkene R (*e.g.* tetramethylethylene, cyclopentene, indene, camphene, cholesterol) and were easily isolated.[480,528] He formulated them as presumably tetrahedral species (Figure 29a) (*i.e.* as $OsO_2(O_2R)$). Subsequent work showed them to be dimers, $Os_2O_4(O_2R)_2$ (b),[497] and the complex obtained from tetramethylethylene, $Os_2O_4(O_2C_2Me_4)_2$, was shown by X-ray

diffraction to have an *anti* structure (Figure 29b) the osmium having square-based pyramidal coordination. The terminal oxo ligand adopts the apical positions (Os=O = 1.675(7) Å) with the basal plane being formed by two diolato oxo ligands (mean Os—O = 1.870 Å) and the two bridging oxo ligands (Os—O = 1.922 Å, OsOOs (bridging) angle = 103.9(4)°). The bridging Os_2O_2 ring is planar. The mean O(terminal)OsO(based) angle is 111.1°,[501,529] a distortion comparable to that found in $[Os^{VI}NX_4]^-$ species (see p. 561) and probably arising from the same causes. A study of the ^1H NMR spectra of the complex showed that, in solution, there is a solvent-dependent mixture of the *syn* and *anti* isomers, the former being relatively more stable in solvents of high dielectric constant.[536]

(a) (b) (c) (d)

Figure 29 Strctures proposed for osmium ester complexes[501,529]

It has been shown that the hydrolysis of the monoester of 3-cyclohexenecarboxylic acid in $H_2{}^{18}O$ gave 3,4-dihydroxycyclohexanecarboxylic acid with no ^{18}O incorporation, which implies that cleavage occurs at the Os—O bonds.[530]

The 'diesters' of osmium(VI), $OsO(O_2R)_2$, are normally prepared by reaction of a *cis* diol $R(OH)_2$ with *trans*-$K_2[OsO_2(OMe)_4]$ or $K[OsO_2(OAc)_3]$, the resulting $K_2[OsO_2(O_2R)_2]$ (*vide infra*) then being acidified.[528] In a few cases diesters can be obtained directly from an alkene R with OsO_4[531] or by prolonged reaction of a diol $R(OH)_2$ with OsO_4.[497]

A single crystal X-ray of the species derived from ethylene glycol, $OsO(O_2C_2H_4)_2$, shows this to have a square-based pyramidal structure (Figure 29c).[449,532]

The coordination about the osmium is very similar to that found for the monoesters, the μ,μ'-dioxo bridge being replaced by a second oxo ester ring. The Os=O distance is 1.670(12) Å and the mean O(terminal)OsO(ester) angle is 110.1°; the mean Os—O (ester) distance is 1.885 Å and mean C—O distance 1.452 Å.[499,532] Very similar parameters have been found for $OsO(O_2C_2Me_4)_2$ (Os=O = 1.62, Os—O (ester) = 1.84.Å).[500]

There are a few examples of salts of the type $K_2[OsO_2(O_2R)_2]$, made, as mentioned above, by reaction of diols $R(OH)_2$ with *trans*-$K_2[OsO_2(OMe)_4]$ or $K[OsO_2(OAc)_3]$. No structural data are available but the IR and Raman spectra of $K_2[OsO_2(O_2C_2H_4)_2]$[468] are fully consistent with an osmyl structure (Figure 29d; see Table 21).

Oxo ester complexes with nitrogenous bases (L). Although most of these species contain the osmyl unit there are so many of them that it is appropriate to deal with them in a separate reaction. Most of the complexes have an Os:L ratio of 1:2 (the majority taking the form $OsO_2(O_2R)py_2$) and so we consider such species first and include those complexes of the type $OsO_2(O_2R)(L—L)$, where L—L is a bidentate N donor (usually 2,2′-bipyridyl). Within this first section we consider first the species derived from alkenes R or diols $R(OH)_2$, *viz.* $OsO_2(O_2R)L_2$ or $OsO_2(O_2R)L—L$, and then species derived from dienes, trienes and alkynes. We then deal with the much smaller body of complexes where the Os:L ratio is 1:1.

(1) Species containing OsL_2 or Os(L—L) units.

Complexes $OsO_2(O_2R)L_2$ and $OsO_2(O_2R)L—L$ formed from alkenes R or cis *diols $R(OH)_2$.* Criegee showed that the reaction of alkenes R with OsO_4 was greatly accelerated by the addition of N donors such as pyridine or isoquinoline (L); the products, of stoichiometry $OsO_2(O_2R)L_2$, were easy to isolate and crystallize, and on hydrolysis they would give the pure *cis* diol $R(OH)_2$.[480] Another route to $OsO_2(O_2R)L_2$ is the reaction[480] of a *cis* diol $R(OH)_2$ with 'OsO_3py_2' (now known to be $Os_2O_6py_4$,[469] though in solution the active species may well be OsO_3py_2 or $OsO_2(OH)_2py_2$).[470]

On p. 590 we discuss briefly the mechanism of the OsO_4–alkene–L reaction. The reaction in which *cis* diols $R(OH)_2$ react with 'OsO_3py_2' is thought to proceed *via* nucleophilic attack by the diol on osmium pyridine species. This is consistent with kinetic data and also with ^{18}O-labelling experiments on thymine glycols which demonstrated that there was no C—O bond cleavage.[530]

The reaction between 'OsO_3py_2', and $K_2[OsO_2(OMe)_4]$ or $K[OsO_2(OAc)_3]$ and $R(OH)_2$ normally occurs only with acyclic 1,2-diols and cyclic *cis* 1,2-diols; *trans* 1,2-diols do not react with the exception of *trans*-1,2-cyclohexanediol and *trans*-1,2-cycloheptanediol.[480] Behrman showed that *trans*-thyminediol, *trans*-thymidinediol and *trans*-1,3-dimethylthyminediol did react, albeit slowly,

with 'OsO_3py_2' as did the *cis* analogues;[470] presumably *trans–cis* isomerization had occurred. There are other kinetic data on the reaction of diols with oxoosmium pyridine,[537,538] substituted pyridine,[470] 2,2′-bipyridyl,[470,537,538,540] 1,10-phenanthroline[539] and TMEN[539,541] complexes. Studies have also been made of 'transesterification' reactions with L = pyridine,[537–539] ½bipyridyl,[537–539] ½phenanthroline[539] and ½TMEN.[539,541]

These $OsO_2(O_2R)L_2$ species are of course of the osmyl type; for convenience we give structural and vibrational data in the osmyl section (Table 21, pp. 581 and 582). There are four X-ray structures available (Table 20). In the complexes derived from thymine, $OsO_2(O_2C_5H_6N_2O_2)py_2$,[515] and from 1-methylthymine, $OsO_2(O_2C_6H_8N_2O_2)py_2 \cdot H_2O \cdot 3py$,[498] it is the erstwhile 5,6 double bond of the ligand which is spanned by the osmium, leading to a saturated pyrimidine ring system. The ester ring in the thymine complex has a twisted half-chair conformation[498,515] while that from 1-methylthymine is of a half-chair:[498] this difference may be due to disorder problems, however.[498] In the adenosine complex $OsO_2(O_2C_{10}H_{13}N_5O_4)py_2$ it is the *cis* 2′,3′-diol of the adenosine molecule which is so spanned, the nucleoside in the complex adopting a *syn* conformation rather than the *anti* arrangement in the free nucleoside.[516] The complex $OsO_2(O_2C_{19}H_{12})py_2 \cdot C_7H_8$ is derived from 9-methylbenzanthracene.[517] All of these complexes have O=Os=O units deviating substantially from linearity; this is discussed in the context of the osmyl complexes on p. 583.

The IR spectra of a number of $OsO_2(O_2R)L_2$ complexes (L = pyridine, isoquinoline) have been measured[468,497,519] and, in some cases, ^{18}O labelling used to help in assignments.[497] In general (see Table 21) $\nu_{as}(OsO_2)$ lies near 830 cm^{-1} and $\delta(OsO_2)$ near 300 cm^{-1}, as in other osmyl complexes.

From dienes and trienes. Reaction of OsO_4 and an excess of diene R in the presence of excess or isoquinoline[521] gives $OsO_2(O_2R)L_2$, while a similar reaction but with a 2:1 mole ratio of OsO_4:diene gives $Os_2O_4(O_4R)L_4$.[521] It is likely that $OsO_2(O_2R)L_2$ species have the structure illustrated for cycloocta-1,5-diene in Figure 30(a), since hydrolysis of $OsO_2(O_2C_8H_{12})py_2$ gives cyclooctene-5,6-diol. Raman and IR data are also consistent with this formulation.[521]

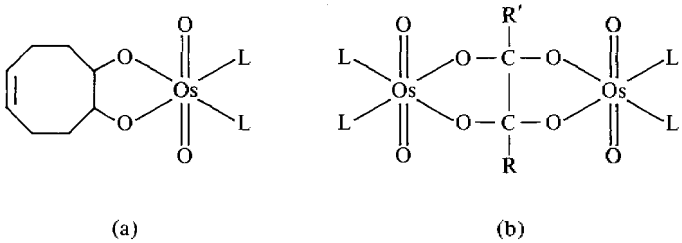


Figure 30 Likely structures of (a) $OsO_2(O_2C_8H_{10})L_2$ and (b) $Os_2O_4(O_2R)L_4$[521]

In the case of $Os_2O_4(O_4C_8H_{12})py_4 \cdot 4H_2O$ a crystal X-ray study shows that, as expected, a binuclear osmyl complex is formed with a bridging tetrolato ring (Figure 31).[522]

The conformation of the central ring is essentially that of a skewed chair–boat form. The osmyl units (Os=O = 1.72 Å) are substantially bent (OOsO angle = 163.5(7)°) from the ester group (Os—O (ester) = 1.95 Å) towards the nitrogen atoms (Os—N = 2.19 Å),[522] as in other osmyl complexes (p. 583).

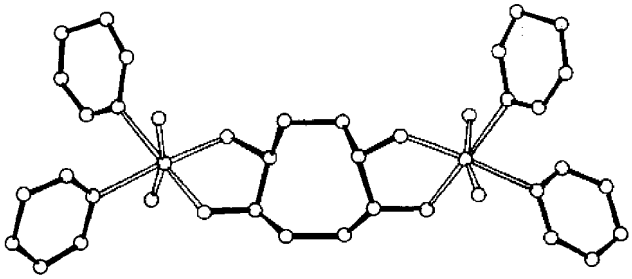

Figure 31 Structure of $Os_2O_4(O_4C_8H_{12})py_4 \cdot 4H_2O$ (reproduced with permission from B. A. Cartwright, W. P. Griffith, M. Schröder and A. C. Skapski, *Inorg. Chim. Acta*, **53**, L129, copyright 1981 Elsevier Sequoia SA)[522]

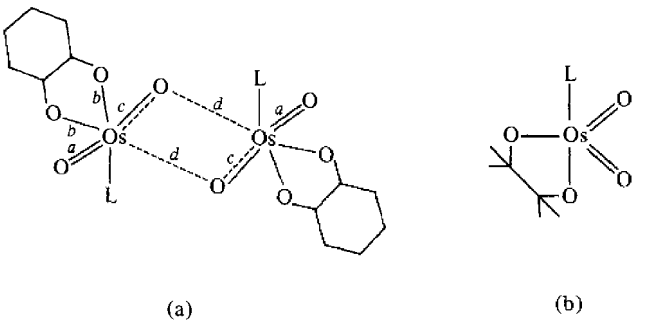

The formation of 1:1 and 2:1 OsO_4:furan oxo esters in the presence of pyridine and of 2,2′-bipyridyl has been studied kinetically using ^1H NMR.[543]

There are a few complexes with trienes. Reaction of methyl linolenate and OsO_4 in excess pyridine gives $Os_3O_6(O_6C_{19}H_{32})py_6 \cdot 2H_2O$ in which it seems that each of the three double bonds is spanned by an OsO_2py_2 moiety;[544] in $OsO_2(O_2C_{28}H_{44})py_2$, made from ergosterol, OsO_4 and pyridine, it seems that only one of the double bonds is so spanned since hydrolysis yields 3,5,6-ergostadientriol.[480]

From alkynes. Reaction of OsO_4 and pyridine[480,497,521] or isoquinoline[480,521] yields $Os_2O_4(O_4R)L_4$. On the basis of IR[497] and Raman, IR and ^1H NMR[521] spectroscopy a tetrolato structure was proposed with the inevitable osmyl unit (Figure 30b).[497,521]

(2) Species containing Os.L units.

(a) From alkenes. The propensity of OsO_4 to form 2:1 or 1:1 adducts with nitrogeneous bases (p. 592) led to a study of reactions of such species with unsaturated organic substrates. The complexes $OsO_4 \cdot L$ (L = pyridine, isoquinoline, phthalazine, quinuclidine) react with alkenes R to give $[OsO_2(O_2R)L]_2$.[519,545] The dimeric formulation derives from an X-ray crystallographic study carried out on $Os_2O_4(O_2C_6H_{10})_2(NC_7H_{13})_2$, the species obtained from cyclohexene with the $OsO_4 \cdot$ quinuclidine adduct. The structure is unusual, showing a weak Os_2O_2 bridge formed by one oxo ligand per metal atom of a distinctly bent osmyl moiety ($a = 1.73$, mean $b = 1.94$, $c = 1.78$, $d = 2.22$ Å; Figure 32a).[546] The OOsO osmyl angle is 154°; the terminal oxo bond length of 1.73 Å is slightly shorter than that involved in the asymmetric bridge (1.78 Å), the two bridge distances being 1.78 and 2.22 Å. The Os—O (ester) distances (1.90, 1.97 Å) and O (ester)OsO(ester) angles are comparable with those found[499,501] for other oxo ester complexes. In solution the complex is monomeric and is thought to have a trigonal bipyramidal structure with the oxo ligand in the equatorial plane (Figure 32b).

(a) (b)

Figure 32 Structure of $OsO_2(O_2R)L$: (a) in the solid state and (b) in solution[545]

Addition of excess ligand L to $OsO_2(O_2R)L$ solution gives $OsO_2(O_2R)L_2$;[545] reaction of 2:1 adducts such as $C_6H_{12}N_4 \cdot 2OsO_4$ formed from hexamethylenetetramine with alkenes R gives a mixture (equation 6).[519]

$$2C_6H_{12}N_4(OsO_4)_2 + 4R \rightarrow 2[C_6H_{12}N_4 \cdot OsO_2(O_2R)] + Os_2O_4(O_2R)_2 \quad (6)$$

It is a consequence of the unusual structure of these complexes in both the solid (dimer) and solution (monomer) states that the IR and Raman spectra show ν(Os=O) frequencies to be higher than in osmyl complexes.[519,545] In particular the IR band assigned to $\nu_{as}(OsO_2)$ lies near 890 cm^{-1} in all these oxo esters containing Os·L units rather than the 830 cm^{-1} absorption typical of those containing OsL_2 or Os(L) units; such behaviour is more typical[461] of *cis* rather than of *trans* dioxo complexes.

Finally we may mention the reaction products of the alkaloids brucine ($N_2O_4C_{23}H_{26}$) and strychnine ($N_2O_2C_{21}H_{22}$) with OsO_4. Initially red 1:1 adducts are formed when these are reacted with OsO_4 (p. 593) but then green osmium(VI) species $OsO_2(O_2R)$ are formed. Since brucine and strychnine (R) contain alkene linkages it is likely that an internal oxo ester has been formed in which an $OsO_4 \cdot N$ unit spans the double bond, with the N donor atoms within the molecule being coordinated to the osmium. Models show that such a structure, which would be analogous to that found for $OsO_2(O_2C_6H_{10})(NC_7H_{13})$ (see above), is feasible. Indeed, OsO_4 with brucine will react with cyclohexene to give $[OsO_2(O_2C_6H_{10})(\text{brucine})]_2$.[545,547a]

Complexes formed from dienes and alkynes. The quinuclidine adduct $OsO_4 \cdot L$ reacts with dienes R to give $Os_2O_4(O_4R)L_2$; this is likely to have a structure analogous to that found for $Os_2O_4(O_4C_8H_{12})py_4$ (p. 586) but with trigonal bipyramidal coordination about the osmium. With cyclooctadiene in excess, $OsO_4 \cdot L$ gives $OsO_2(O_2C_8H_{12})L$ for which vibrational ^1H NMR spectra suggest that only one double bond is spanned by an OsO_2L moiety.[545]

Just as OsO_4 in excess pyridine reacts with alkynes R to give $Os_2O_4(O_4R)py_4$, $OsO_4 \cdot L$ gives $Os_2O_4(O_4R)L_2$; again, there is likely to be trigonal bipyramidal coordination about the osmium.[545]

(iii) Osmium(VII)

(a) Hexa- and penta-oxo species. A few of these have been prepared, *e.g.* $M^I_5[OsO_6]$ (M = Li, Na),[460,547b] $Ba_5[OsO_6]_2$[460] (the IR spectrum of this was measured)[462] and $M^I_3[OsO_5]$ (M = Na, K).[460] On the basis of IR data it was tentatively suggested that $K_3[OsO_5]$ might in fact be $K_6[Os_2O_{10}]$.[462] Magnetic susceptibility measurements were made on $Li_5[OsO_6]$ from 39 to 251 K.[547b]

(b) Tetraoxo species. Recently the salt $(Ph_4As)[OsO_4]$ has been reported, made by reaction of $(Ph_4As)I$ with OsO_4 in CH_2Cl_2 solution. The grey-green complex has a magnetic moment of 1.37 BM at room temperature and the susceptibility follows the Curie–Weiss law from 4.2 to 140 K; (θ = 2.6 K). The low moment has been attributed to spin–orbit coupling effects. Cyclic voltammetric studies in CH_2Cl_2 show a reversible one-electron process for the OsO_4/OsO_4^- couple (E_0 = 0.1 V *vs.* standard calomel electrode). The IR spectrum shows bands at 834 and 852 cm^{-1} assigned to ν_1 (A_1) and ν_3 (F_2), and the deformations ν_2 and ν_4 are at 240 cm^{-1}.[548] The ion functions as an oxidant for activated alcohols, converting primary alcholos to aldehydes.[549]

(c) Monooxo species. The oxopentafluoride $OsOF_5$ is well characterised and is a discrete molecular species. It is made by reaction of osmium with a 5:1 F_2:O_2 mixture at 300 °C under 5 atm.[534] The emerald green crystals melt at 59.2 and boil at 100.5 °C with a transition point at 32.5 °C. The X-ray crystal structure shows it to have the expected C_{4v} structure (Os=O = 1.74, Os—F (*cis*) = 1.78(3), Os—F (*trans*) = 1.72(3) Å).[535] It is interesting that the *trans* fluoro ligand seems to be slightly closer to the metal than the *cis*.

Thermodynamic parameters were collected from vapour pressure data; magnetic susceptibility measurements from 77 to 295 K showed the solid to obey the Curie–Weiss law with θ = 6 °C at μ_{eff} 1.47 BM at 298 K.[535]

The compound OsO_2F_3 is probably polymeric (see p. 596).[533]

(iv) Osmium(VIII)

Obviously the chemistry here is dominated by that of the tetroxide. We briefly consider the hexa- and penta-oxo species, then OsO_4, followed by species of the type $OsO_4 \cdot L$ and $OsO_4 \cdot L_2$. The few tri-, di- and mono-oxo complexes of osmium(VIII) conclude the section. (see Table 23).

Table 23 Osmium(VIII) Oxo Complexes

Complex	ν_{OsO}	*Spectroscopic and other properties*
$Sr[OsO_5(H_2O)]$		X-ray[550]
OsO_4	see Table 24	Raman, IR, UV/vis (see p. 000), Mössbauer,[184] NMR,[583,584] ESCA,[582] X-ray,[561] electron diffraction[562]
$OsO_4 \cdot NH_3$	917, 885	IR[66]
$OsO_4 \cdot py$	928, 915, 907, 885	Raman, IR[468]

For binuclear species see Table 25.

(a) Hexa- and penta-oxo species

Acid dissociation constants of 'H_4OsO_6, $H_{2n}OsO_{4+n}$, H_2OsO_5' and '$H_2OsO_5 \cdot H_2O$' have been published on the basis of measurements of the variation with pH of the electronic spectra of OsO_4 in aqueous solution.[479]

The X-ray crystal structure of the salt $Sr[OsO_5(H_2O)]$ shows this to have a distorted octahedral (C_{4v}) structure with Os=O distances varying from 1.72 to 1.93 Å and an Os—O (H_2O) distance of 2.12 Å.[550] However, it has recently been suggested that this is incorrect and that the salt is $Sr[OsO_3(OH)_2(H_2O)](OH)_2 \cdot H_2O$ (see p. 592).

(b) Tetraoxo species

Osmium tetroxide, OsO_4. This is undoubtedly the most important compound or complex of osmium, and it was as the tetroxide that osmium was first separated and, as explained on p. 522, gave its name to the element. It is industrially important both in the fine organic chemicals industry (for the *cis* hydroxylation of alkenes) and in biological chemistry and medicine for the 'fixation' or

preservation of biological tissue. Its use for the latter purpose can be dated to 1849[551] and for catalytic hydroxylation to 1913.[552] It is also an important precursor for other osmium complexes (p. 590).

The author has written a short general review on OsO_4[553] and there is a good recent review on the chemistry of its reactions with alkenes, dienes and alkynes.[554] In this section we describe its preparation, then its physical properties and chemical reactions.

Preparation. The oxidation of the metal or of any osmium salts will, if vigorous enough, produce the tetroxide; this is very volatile and can be distilled off or extracted from aqueous solution into an inert solvent such as CCl_4. Treatment of the metal at 300 °C with oxygen gives OsO_4,[477] and powdered osmium will also react with aqueous hypochlorite to give it.[497] Various methods of treating osmium residues to give OsO_4 have been described: oxidation with chromic acid and a nitric–sulfuric acid mixture followed by steam distillation;[555] oxidation by permanganate in acid solution[556] or conversion of residues to a thiourea complex followed by oxidation with H_2O_2 gives OsO_4[557] which, in both of these latter methods is then extracted into CCl_4.

Properties. Osmium tetroxide forms pale yellow crystals with a very characteristic odour (a possible description is that of a mixture of ozone and damp hay). It has a considerable vapour pressure at room temperature and so must be kept in stoppered container or (preferably) in sealed ampoules. The vapour is toxic (TLV 2.5 p.p.m.).[558a] The long-term occupational exposure limit (OEL) is 0.002 mg m^{-3}.[558b]

The compound melts at 40.46 ± 0.1 °C and there is a transition point at 72.54 ± 0.4 °C.[559] It is slightly soluble in water to give a very pale yellow solution but is very soluble in organic solvents, polar or non-polar (see below). Thermodynamic data of the compound have been reviewed.[560]

In the solid and gaseous states it is tetrahedral, with X-ray studies on the solid indicating a very slight distortion (two Os=O distances of 1.684(7) and two of 1.710(7) Å, with OOsO angles of 106.7(4) and 110.7(3)°).[561] It seems reasonable to ascribe these very slight distortions to solid-state effects (in the gas phase the Os—O distance is 1.711(3) Å[562]). Raman data (see below) suggest that the tetrahedral symmetry is retained in the pure liquid.[563]

OsO_4 in solution. The solubility of the tetroxide in water at 25 °C is 72.4 g dm^{-3}.[564] Although earlier studies on the partition coefficient of OsO_4 from its aqueous solution with CCl_4 seemed to indicate tht some $[OsO_4]_n$ polymers were present, this is now thought unlikely;[565] certainly the Raman spectrum of the aqueous solution is very similar to that of the solid.[563] There is, however, evidence of aggregation in propane or NF_3 solutions at 90 K.[566] In aqueous solution OsO_4 behaves as a very weak dibasic acid.[479] Extraction constants for OsO_4 in a variety of organic solvents have recently been measured.[567a]

Polarographic and electrochemical studies. Earlier polarographic data for OsO_4 have been reviewed.[567b] Most data concern alkaline aqueous solutions; the reductions $Os^{VIII} \rightarrow Os^{VI}$, $Os^{VI} \rightarrow Os^{IV}$ and sometimes $Os^{IV} \rightarrow Os^{III}$ have been observed, and in oxygen-free alkali the $Os^{VI} \rightarrow Os^{IV}$ and $Os^{IV} \rightarrow Os^{III}$ steps have $E_{\frac{1}{2}}$ values of −0.41 and −1.08 V (*vs.* SCE).[568]

Spectroscopic data. This attractive molecule has long been a favourite for spectroscopic studies and only the most comprehensive or recent data are given here. The four fundamental vibrational frequencies have often been measured for the molecule; since all four are Raman active but only two (the F_2) are IR active we concentrate on the Raman data (Table 24).

Table 24 Vibrational Spectra of OsO_4 (cm^{-1})

	$\nu_1(A_1)$	$\nu_2(E)$	$\nu_3(F_2)$	$\nu_4(F_2)$	*Ref.*
Gas, 373 K	965.2	333.1	960.1	322.7	569
Pure liquid	964	338	953	334	563
Aqueous solution	962	333	952	333	563

IR spectra of gaseous $Os^{18}O_4$ show ν_3 and ν_4 to lie at 911.6 and 321.0 cm^{-1};[570] there are recent IR data on $^{192}OsO_4$.[571] Raman values for ν_1 and ν_2 are, for solutions in CCl_4, 964.5 and 335.2 cm^{-1} for $Os^{16}O_4$ and 909.7 and 316.5 cm^{-1} for $Os^{18}O_4$.[572]

There have been many force contact treatments (see for example ref. 573) and determinations of Coriolis coupling constants.[574] The use of transitions within the OsO_4 molecule as high-precision frequency standards using CO_2 lasers has been described in a number of publications.[575,576]

There have been detailed studies on the electronic absorption spectrum of the gas, and the magnetic circular dichroism spectrum has also been recorded and assigned;[577,578,580] such spectra were also obtained for the aqueous solution.[581] The electronic spectrum of the solid in an argon matrix at 20 K was measured and assigned.[580] An energy level diagram was constructed on the basis of the

gas phase spectrum.[579] There are also studies on the photoelectronic spectra of gaseous OsO_4[582] and the ^{189}Os Mössbauer spectrum was recorded.[184] Using molten OsO_4 a very weak ^{187}Os NMR resonance was observed.[583,584]

Chemical reactions of OsO_4. We concentrate on the important oxidation reactions.

(a) *Oxidation of alkenes.* The subject has been recently and comprehensively reviewed[554] so we give only an outline here.

The first observation that OsO_4 reacted with alkenes was apparently made in 1894;[585] by 1913 Hofmann had established that OsO_4 could be used catalytically for the *cis* hydroxylation of alkenes with ClO_3^- as cooxidant.[552] However, it was Criegee who, in three classic papers,[480,481,528] laid the foundations of our knowledge of this important reaction. He showed that OsO_4 would react with alkenes R to give '$OsO_2(O_2R)$' and in some cases $OsO(O_2R)_2$. The reaction was greatly accelerated by addition of bases such as pyridine to give $OsO_2(O_2R)py_2$.[480,528] Hydroloysis of any of these gave the *cis* glycol $R(OH)_2$. It is now known that '$OsO_2(O_2R)$' is in fact dimeric, $Os_2O_4(O_2R)_2$ (see p. 585).[501,529]

The reaction of alkenes with OsO_4 is commonly thought to involve a concerted six-π-electron cyclization leading directly to a five-membered ring (Figure 29a), accounting for the exclusively *cis* addition to alkenes. However, Sharpless[586] has suggested that the direct nucleophilic attack of carbon on oxygen that this entails is unlikely and that, moreover, the intermediate (Figure 29a) involves an uncomfortable angular strain on the ester ring. The proposed mechanism involves initial formation of an asymmetric oxametallacycle intermediate *via* initial nucleophilic attack of the alkene at the metal rather than at oxygen.[586] This then rearranges and could dimerize to give (b) in Figure 29.[586] The scheme also accounts for the observed[480] rate increase in the OsO_4–alkene reaction consequent on addition of pyridine: attack by the latter would induce a reductive insertion of the Os—C bond of the oxametallacycle into an oxo group giving an ester which then reacts with more pyridine giving $OsO_2(O_2R)L_2$.[586] Unequivocal direct evidence for this appealing mechanism is so far lacking[586–589] though intermediates $[OsO_4 \cdot L]_2$, albeit in dimeric form, have been isolated,[545,546] and there is a report of the existence (but not the isolation) of a complex of OsO_4 with adamantylideneadamantane.[590] Kinetics of the reaction of OsO_4 with alkenes in the absence of nitrogenous bases have been studied[530] as have those of the OsO_4–alkene reaction in the presence of ammonia,[591] pyridine,[537,592,593] substituted pyridines,[530] 2,2′-bipyridyl[537,538,592,594] and TMEN.[594] The OsO_4–alkene reaction is also substantially accelerated by methylamine,[595] cyanide[596] and thiocyanate.[596]

Although OsO_4 is thought of as a specific oxidant for *cis* alkenes there are a few examples of hydroxylation of *trans* alkenes, e.g. *cis*- and *trans*-cyclodecene can be hydroxylated to the respective *cis* and *trans* diols.[597] The OsO_4–alkene–pyridine reaction can be made catalytic by the use of suitable secondary oxidants such as H_2O_2, ClO_3^-, Bu^{t}OOH, *N*-morpholine *N*-oxide, IO_4^-, O_2 and ClO^-.[554]

(b) *Reaction with dienes and trienes.* Criegee noted that ergosterol could be oxidized to 3,5,6-ergostadientriol by OsO_4 and pyridine and he isolated the intermediate ester;[480] there are scattered reports in the literature of the *cis* hydroxylation of dienes and trienes, *e.g.* norbornadiene to *exo-cis*-norbornane-2,3-diol[598] and of *cis,trans*-1,5,9-cyclododecatriene to 8-cyclododecane-*trans*-1,2-diol.[599] The kinetics of reaction of OsO_4–pyridine and OsO_4–bipyridyl to furans have been studied.[543] For a discussion of the oxo esters formed from OsO_4 and dienes, see p. 586.

(c) *Reaction with alkynes.*[544] The first to react OsO_4 with alkynes was Phillips in 1894,[585] and an early analytical method for osmium was based on the reaction of OsO_4 with acetylene.[600] Again it was Criegee who in 1942 noted that acetylene reacted with OsO_4–pyridine to give an 'ester'.[480] Later work showed that alkynes R (acetylene, phenylacetylene, methylphenylacetylene, diphenylacetylene) with OsO_4–pyridine gave $Os_2O_4(O_4R)py_4$; on hydrolysis the esters of the latter three alkenes gave benzil, benzoic acid and 1-phenylpropane-1,2-dione respectively. The reactions can be rendered catalytic by use of an OsO_4–$KClO_3$ reagent.[521] The oxo esters derived from alkynes are considered above (p. 587).

(d) *Reaction with glycols and catechols.* It has been claimed on the basis of electronic spectra that OsO_4 reacts with ethylene glycol, pinacol or trimethylethyleneglycol (R) to give $OsO_2(OH)_2(O_2R)$;[601] kinetics of the oxidation of ethyleneglycol to formaldehyde by OsO_4 have been reported.[602] Certainly the *prolonged* reaction of OsO_4 with ethylene glycol gives $OsO(O_2C_2H_4)_2$, and in the presence of pyridine $OsO_2\{OC_2H_4(OH)\}_2py_2$ is formed.[497] With catechol or substituted catechols (Rcat), species of the form $Os(Rcat)_3$, $[OsO(Rcat)_2]_n$ and *trans*-$[OsO_2(Rcat)_2]^{2-}$ can be isolated (see p. 597).[486]

(e) *Reaction with amino acids, peptides and proteins.* The direct reaction of OsO_4 with amino acids can be difficult owing to the facile oxidation of the NH_2 group[544] but recently a number of osmyl complexes $OsO_2(an)_2$ have been isolated from amino acids and OsO_4 (see p. 583), and an X-ray crystal structure of $OsO_2(glycinate)_2$ has confirmed the osmyl formulation. Earlier studies, perhaps carried out under less rigorous conditions, indicated that amino acid oxidation occurred when

OsO_4[544,592,603] or OsO_4–pyridine[544,603] was used. Blocking of the reactive NH_2 group and esterification of the carboxylate group give complexes of the form $Os_2O_6L_4$ and the kinetics of reaction of OsO_4 and pyridine with 1-methy-α-*N*-acetyl-DL-tryptophan were studied; attack is across the double band of tryptophan.[592] Peptides seem relatively unreactive towards OsO_4[544] though some cleavage may occur.[603]

The reaction of OsO_4 with proteins is a complex subject needing much further study. The evidence so far suggests that OsO_4 can cross-link proteins[544,603] and that the tryptophanyl residue in particular may be implicated.[603] In biological tissue, where OsO_4 reacts with membranous material containing both unsaturated lipids and proteins, there is evidence for lipid–protein cross-linking (see below).[544,604]

(f) *Reaction with nucleosides, nucleotides and nucleic acids.* The literature up to 1977 has been reviewed.[605,606] Of the nitrogenous bases in nucleic acids the ones most likely to react with OsO_4 are the pyrimidines, and indeed there has been much work on its reaction with thymine and its derivatives,[470,539,541] adenine derivatives,[537] cytosine and 3-methylytosine.[594] A sequence-specific osmium reagent for thymine–cytosine pairs has been devised.[607] Nucleosides on their own react slowly with OsO_4 but in the presence of donors such as pyridine[538,608] or 2,2′-bipyridyl[537,538] the reaction is much faster, giving osmyl species $OsO_2(O_2R)py_2$ or $OsO_2(O_2R)$bipy. Reactions of this type are observed with thymidine,[608] cytidine,[538] adenosine[538] or substituted adenosine.[537] We have already discussed the crystal structure of the adenosine complex $OsO_2(O_2C_{10}H_{13}N_5O_4)py_2$ (Table 20 and p. 586).[516] In the presence of pyridine, nucleotides react with OsO_4; kinetic data were obtained for the reaction of desoxythymidine-5′-monophosphate (dTMP),[608] and other nucleotide–OsO_4 reactions were also investigated.[540,608] Polyuridylic acid (poly U) is easily oxidized by OsO_4 with ammonia,[591] and direct visualization of individual osmium atoms in polyuridylic acid treated with OsO_4–bipyridyl has been achieved (shown in the paper in a remarkable series of photographs).[609]

In *in vitro* studies there is little observable reaction between OsO_4 and native deoxyribonucleic acid (DNA), but it does react with denatured DNA, in which the thymine bases have probably been hydroxylated to 5,6-dihydroxythymine *via* an osmium(VI) ester.[610]

(g) *Osmium tetroxide and biological tissue.* The oldest use of OsO_4 is for the 'fixation' or preservation of biological tissue and dates back to 1849,[551] although in 1804 Tennant[1] had noted that it stained the hands; there is a considerable literature on the subject.[611] Osmium tetroxide is unique in having a dual role: applied as a dilute aqueous solution to tissue followed by dehydration and mounting procedures it both preserves the biological material and stains certain parts, particularly membranes, with an osmium-containing material. These stained parts are visible in optical microscopy as black or grey areas but also, by virtue of the electron-scattering power of osmium, delineate those areas in electron micrographs. It has been demonstrated that the uptake of OsO_4 by membranous material in particular is related to the content of unsaturated phospholipids,[612] and this with other evidence has led to the suggestion that cross-linking of double bonds in such lipids could occur[497,613,614] by 'monoester' or 'diester' formation (p. 584). An earlier suggestion that simple hydrogen bonding of OsO_4 was involved[615] has been disproved.[614] It is also possible that proteins and unsaturated lipids are cross-linked in membranes by OsO_4 to give osmyl species;[544,604] the presence of osmium(VI) as well as osmium(IV) and osmium(II) in tissue has been demonstrated by ESCA data,[616] though such data have to be treated with some caution.[617] It is also clear that OsO_4 reacts with catechols ('phenolics') in plant tissue to produce a very deep stain, probably arising from $[OsO(cat)_2]_n$,[486,618] and will almost certainly stain alkaloids.[545,547]

Miscellaneous sections of OsO_4 There is a recent review on the role of OsO_4 in the catalysis of redox reactions,[619] and the OsO_4–catalyzed decomposition of H_2O_2 is thought to proceed *via* peroxo intermediates.[620] With CO_3^{2-} or SO_3^{2-} in aqueous solution OsO_4 gives $[OsO_2(OH)_4]^{2-}$, but with a mixture of SO_3^{2-} and CO_3^{2-} it is said that $[OsO_2(SO_3)_4]^{6-}$ and $[Os(SO_3)_6]^{8-}$ are formed.[621]

(v) *Tetraoxo osmium(VIII) complexes with other ligands*

(a) Oxo hydroxo and oxo aqua species. It has long been known that OsO_4 will react with alkali metal hydroxides to give deep red solutions from which unstable solids can be isolated (called 'perosomates', 'perperosmates' or 'osmenates' in the older literature). Early workers made $M^I_2[OsO_4(OH)_2]$ (M = K,[622,623] Rb,[623] Cs[622,623]) and $Ba[OsO_4(OH)_2]$[622]; the ammonium salt was also claimed[622] (though it might be thought that $(NH_4)[OsO_3N]$ would be the product of the reaction of OsO_4 and NH_4OH). By using a deficiency of M^IOH with OsO_4, $M^I[OsO_4(OH)]$ (M = Rb, Cs[623]) and $Cs[Os_2(OH)O_8]$[623] were claimed. Recent X-ray work has shown the existence of *cis*-$[OsO_4(OH)_2]^{2-}$, $[Os_2(OH)O_8]^-$ and of $[OsO_5(H_2O)]^-$ also.

The X-ray crystal structures of *cis*-$Li_2[OsO_4(OH)_2]$,[624] *cis*-$Na_2[OsO_4(OH)_2]$[625] and *cis*-$M^{II}\{OsO_4(OH)_2\}$ (M = Ca, Sr[626] and Ba[626,627]) have been given, as have improved procedures for the isolation of *cis*-$M^I{}_2$ $[OsO_4(OH)_2]$ (M = Li,[628] Na, K,[628–630] Rb, Cs[629,630]). The anions have *cis* configurations,[629] as predicted by earlier Raman studies.[462] In $Li_2[OsO_4(OH)_2]$ the Os—O (OH) distance is 2.16 Å with mean Os=O 1.75 Å;[624] in the sodium salt there are two Os—O (OH) distances of 2.10 and 2.17 Å with the Os=O bond lengths varying from 1.74 to 1.82 Å;[625] in the barium salt there is disorder between one O—O (OH) and Os=O bond, while the other Os—O (OH) is 2.15 Å and the mean Os=O = 1.73 Å.[627] It has been suggested that the species formulated as $Sr[OsO_5(H_2O)]$ and for which a crystal structure has been reported (p. 588) is in fact $Sr[OsO_3(OH)_3](OH)\cdot 2H_2O$ or $Sr[OsO_3(OH)_2(H_2O)](OH)_2\cdot H_2O$.[629] For $M_2[Os_2O_8(OH)]$ (M = Rb, Cs) see p. 596.

The $[OsO_4(OH)_2]^{2-}$ ion has been implicated in the oxidation of ethylene glycol by OsO_4 in alkali, and a mechanism proposed for this reaction involving the $[OsO_3(OH)_3(OCH_2)_2OH]^{3-}$ ion.[602]

(b) Oxo halo complexes. The yellow $Cs_2[OsO_4F_2]$ has been made from excess CsF and OsO_4[622] and also the rubidium salt;[622] its Raman and IR spectra suggested a *cis* structure for the anion.[462,631] More recently, both it and $Rb_2[OsO_4F_2]$ have been made from RbF and OsO_4.[631] A salt of approximate composition $Cs[OsO_4F]$ has been obtained from OsO_4 and CsF; its Raman and IR spectra suggest that it may contain pentacoordinate osmium.[631]

The isolation and X-ray crystal structure of $(Ph_4)[OsO_4Cl]\cdot CH_2Cl_2$ have been reported. Reaction of OsO_4 in CH_2Cl_2 with $(PPh_4)Cl$ gives the orange-red crystals. The anion is trigonal bipyramidal with the chloro ligand axial; the mean Os—O distance is 1.72 Å and the Os—Cl distance is very long at 2.76(2) Å.[632]

(c) 'Adducts' of OsO_4 with N donors. Although '$OsO_4\cdot py_2$'[633] is now known to be $Os_2O_6py_4$,[469] there are loose 1:1 and 2:1 adducts of OsO_4 with N-donor ligands. These are unusual in that they appear to have very weak, long Os—N bonds such that the symmetry of the OsO_4 fragment is essentially undistorted and retains the reactivity of OsO_4 (see Figure 33 for structures of $OsO_4\cdot NC_7H_{13}$ and $[OsO_4]_2\cdot N_4C_6H_{12}$[634]).

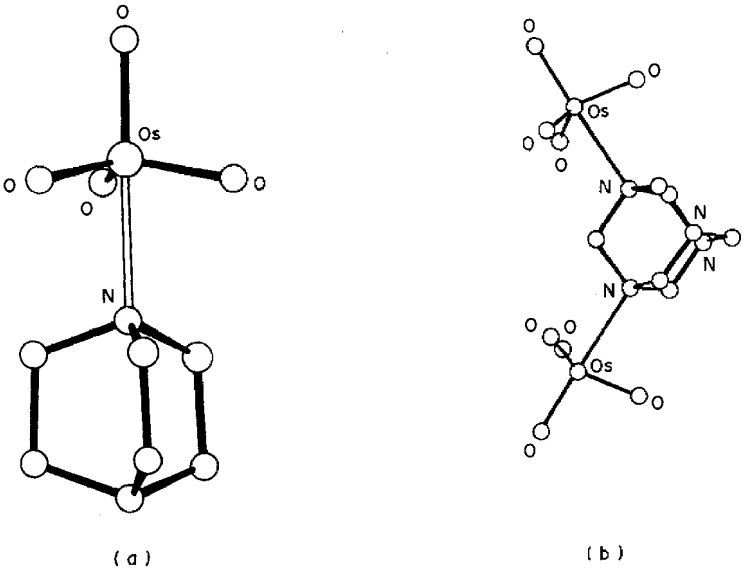

Figure 33 Structures of (a) $OsO_4\cdot NC_6H_{13}$ and (b) $(OsO_4)_2\cdot N_4C_6H_{12}$ (reproduced with permission from W. P. Griffith, A. C. Skapski, K. A. Woode and M. J. Wright, *Inorg. Chim. Acta*, **31**, L413, copyright 1978 Elsevier Sequoia SA)[634]

They are made by reaction of OsO_4 in aqueous solution or emulsion of the amine L to give $OsO_4\cdot L$ (L = pyridine,[468,480,519] NH_3,[66,333] pyridazine, quinuclidine (NC_7H_{13}), phthalazine and isoquinoline,[519] hexamethylenetetramine mandelate[635]) or $Os_2O_8\cdot L'$ (L' = hexamethylenetetramine ($N_4C_6H_{12}$), 1,4-diazabicyclo[2.2.2]octane, 5-methylpyrimidine and pyrazine).[519] With the exception of the pyridine, pyrazine and 5-methylpyrimidine adducts these produce little or no vapour pressure of OsO_4 at room temperature and so can be used as 'safe' forms of OsO_4; indeed, $[OsO_4]_2\cdot N_4C_6H_{12}$ is now commercially used in histochemistry as a replacement for OsO_4.[635]

The X-ray crystal structures of the quinuclidine and hexamethylenetetramine adducts show very long Os—N bonds (2.37 and 2.42 Å respectively) while the symmetry of the OsO_4 unit is little disturbed: the Os—O bond lengths are between 1.697 and 1.722 Å, and the O(axial)OsO(equatorial) angle of 100.6° is close to the tetrahedral angle of 109.47° (Figure 33).[634]

The reluctance of the remaining two nitrogen atoms in hexamethylenetetramine to coordinate may be due to unfavourable angles at these atoms brought about by coordination of the other two donor centres.[519]

It has been noted that a wide variety of alkaloids L containing one or more N-donor atoms will react with OsO_4 to give red solutions which almost certainly contain $OsO_4 \cdot L$ adducts (L = strychnine, brucine, quinine, sparteine, cinchonine, atropine, yohimbine, cocaine, emetine).[545,547] In the cases of strychnine and brucine an internal reaction subsequently occurs to give green osmium(IV) complexes $OsO_2(O_2L)$ (see p. 587). There is also evidence for the formation of 1:1 $OsO_4 \cdot L$ adducts with blocked amino acids (*e.g.* α-*N*-benzoyl-L-histidine, α-*N*-benzoyl-DL-methionine) and imidazoles.[544]

The reactions of $OsO_4 \cdot NC_7H_{13}$ with alkenes,[519,545,546] dienes[545] and alkynes[545] are considered on p. 590 and those of $[OsO_4]_2 \cdot N_4C_6H_{12}$ with alkenes[545] on p. 587.

6.2.1.4.3. Trioxo osmium(VIII) complexes

The salts $M^1{}_3[OsO_3F_3]$ are made by reaction of OsO_4 and KBr, CsBr or $AgIO_3$ in a 1:1 mole ratio with BrF_3,[533] or from MF (M = K, Rb, Cs) and OsO_3F_2.[631] The IR and Raman spectra of the solid cesium salt suggest a *fac* structure,[462] perhaps indicating that O^{2-} is a stronger π donor than is F^- for osmium(VIII) (there are also more recent vibrational data[634]). The postulated dimer $[OsO_3F_2]_2$ is considered on p. 596; the monomeric matrix-isolated OsO_3F_2 has been shown by Raman and IR spectra to have a trigonal bipyramidal (D_{3h}) structure.[636]

Two possible trioxo intermediates have been mentioned: $[OsO_3(OH)_3\{O(CH_2)_2OH\}]^{2-}$, from reaction of ethylene glycol with OsO_4 in base,[602] and $OsO_3(O_2R)$, thought to be formed when monoesters $Os_2O_4(O_2R)_2$ are oxidized with H_2O_2.[528]

6.2.1.4.4. Dioxo and monooxo osmium(VIII) complexes.

Reaction of glycols $R(OH)_2$ with OsO_4 is said to give $OsO_2(OH)_2(O_2R)$ as an intermediate.[601] There is no unequivocal evidence for the existence of these, though in view of the remarkable stability of the $Os^{VI}O_2R$ ring the existence of osmium(VIII) analogues seems feasible; a reductive route from alkenes is not of course possible. Two possible candidates, $OsO_3(O_2R)$ and $OsO_2(OH)_2(O_2R)$, are mentioned above and on p. 590.

The acid dissociation constant of '$OsO_2(OH)_4$' has been given.[479]

46.6.2.2 Binuclear oxo-bridged complexes.

A number of these are known (see Table 25), particularly with osmium(IV) and osmium(VI). It is clear that the bridging oxo ligands are functioning as π donors, particularly in the μ-oxo osmium(IV) dimers.

Table 25 Binuclear Oxo-bridged Complexes

Complex	$\nu_{as}(Os_2O)$	$\nu_s(Os_2O)$	*Spectroscopic and other properties*
$Cs_4[Os_2OCl_{10}]$	852	225	Raman,[640,643,653] IR,[462,640] UV/vis,[643] X-ray[641]
$(Me_4N)_4[Os_2OCl_6Br_4]$	846	223	Raman, IR[462]
$(Et_4N)_4[Os_2OBr_{10}]$	846	237	Raman,[462] IR[294,462]
$Os_2O(dppm)_2Cl_6 \cdot 2CHCl_3$			UV/vis, CV, X-ray[647]
$K_2[Os_2O(\eta^4\text{-chba-Et})_2(OPPh_3)_2$			X-ray[648]
$Os_2O(OAc)_2Cl_4(PPh_3)_2 \cdot Et_2O$			CV, ESCA, X-ray[649]
$Os_2O(OEP)_2(OH)_2$			UV/vis, CV, ^{1}H NMR[650]
$Os_2O_4(O_2C_2Me_4)_2$	981		IR,[497] ^{1}H NMR,[536] X-ray[501,529]
$Rb[Os_2(OH)O_8]$	960–800		IR,[630] X-ray[651]
$Cs[Os_2(OH)O_8]$	960–885		IR,[630] X-ray[629]
$[OsO_4]_2 \cdot N_4C_6H_{12}$	930, 917, 909		Raman, IR,[519] X-ray[634]

$Os_2O_4(O_2C_6H_{10})_2(NC_7H_{13})_2$	903	898		Raman, IR,[545] X-ray[546]
$Os_2O(OEP)_2(OMe)_2$				X-ray[646]

For $Os_2O_4(O_2C_2Me_4)_2$ see p. 000.

(*i*) *Osmium(II) and osmium(III)*

The complex $[Os^{III}_2O(bipy)_2(terpy)_2](ClO_4)_4$ has been claimed (made from reaction of [Os-Cl(bipy)(terpy)]Cl with $HClO_4$); reduction with $Na_2S_2O_4$ is said to give $[Os_2O(bipy)_2(terpy)_2](ClO_4)_2$, while oxidation with ceric ammonium nitrate gives $[Os_2O(bipy)_2(terpy)_2](ClO_4)_5$.[192] These are the only $Os^{II/III}$ μ-oxo complexes so far reported, but iron forms Fe^{III}—O—Fe^{III} and Fe^{III}—N—Fe^{IV} moieties.

(*ii*) *Osmium(IV)*

(a) Halo complexes. The most comprehensively studied example is $[Os_2OCl_{10}]^{4-}$ (isoelectronic with $[Os_2NCl_{10}]^{5-}$, see p. 563).

A number of salts containing $[Os(OH)Cl_5]^{2-}$ (*e.g.* $M^I_2[Os(OH)Cl_5]$; M = Na, K, Rb, Cs and some organic cations)[637] were reported in the earlier literature, but these almost certainly should be reformulated as $M^I_4[Os_2OCl_{10}]$. There is evidence for the existence in solution of the $[Os(OH)Cl_5]^{2-}$ ion, however (see p. 615).

The potassium, cesium and ammonium salts can be made by reaction of OsO_4 in concentrated HCl with OsO_4 in acid, in the presence of $FeSO_4$ functioning as the reducing agent.[638-640] The solids are diamagnetic[639] (this was one of the features which suggested that they were not in fact salts of $[Os(OH)Cl_5]^{2-}$, for which paramagnetism would be expected). The single crystal X-ray structure of $Cs_4[Os_2OCl_{10}]$ shows the anion to have a μ-oxo bridged structure with the equatorial chloro ligands in the eclipsed position. The Os—O distance is 1.778(15) Å with the Os—O—Os angle at 180°; the *cis* Os—Cl distance is 2.370 Å and the *trans* Os—Cl distance is only slightly longer at 2.433 Å.[641] It is instructive to compare the Os^{IV}—O—Os^{IV} grouping with the Os^{IV}—N—Os^{IV} moiety (see p. 615); clearly the nitrido ligand has a more powerful *trans* weakening effect, for the $[Os_2NCl_{10}]^{5-}$ ion has only a tenuous existence, the *trans* ligands being easily replaced by water to give $[Os_2NCl_8(H_2O)_2]^{3-}$.[344,349] The structural parameters for $[Os_2OCl_{10}]^{4-}$ can be compared with those found for $K_4[Ru_2OCl_{10}]$ and $K_3[Ru_2NCl_8(H_2O)_2]$; the Ru—O distance is 1.80 Å with a O—Ru—Cl angle of 94°,[642] while the Ru—N distance is 1.720(4) Å with an N—Ru—Cl angle of 94.7(2)°.[351]

Raman studies have been carried out on the potassium,[640] cesium[640] and ammonium salts[462,643] and on the $[Os_2OCl_{10}]^{4-}$ ion in acid solution;[643] resonance Raman enhancement was observed for the ν_1 (symetric Os—O—Os stretch) mode.[640,643] IR data have also been reported.[462,640] A molecular orbital scheme for the bonding in $[Os_2OCl_{10}]^{4-}$ can be derived from that proposed by Dunitz and Orgel[644] for the analogous $[Ru_2OCl_{10}]^{4-}$ species.[643,645] Such a scheme has been used to interpret the electronic and vibrational spectra of $[Os_2OCl_{10}]^{4-}$.[643]

A few other μ-oxo halo complexes have been reported but incompletely characterized, *viz.* salts of $[Os_2OCl_6Br_4]^{4-}$,[294] $[Os_2OI_{10}]^{4-}$ and $[Os_2OI_2Cl_8]^{4-}$.[518] The species $[Os_2OCl_8(H_2O)_4]^{2-}$ is thought to be a product of the reaction of *trans*-$[Os^{VI}O_2Cl_4]^{2-}$ with $[Os^{III}Cl_4(H_2O)_2]^{2-}$ in acid solution.[489]

There is a recent report of the X-ray crystal structure of *trans*-$Os_2O(OEP)_2]OMe)_2$, a deep violet material made by reaction of Os(OEP)(CO)(OMe) and 2,3-dimethylindole in dichloromethane. The Os—O—Os skeleton is essentially linear (Os—O—Os = 178°, Os—O = 1.808(3) Å); the octaethylporphyrin (OEP) ligands are twisted at a dihedral angle of 23° but are planar (mean Os—N = 2.033(78) Å); the Os—O (OMe) distance is 1.997(29) Å.[646]

(b) Other μ-oxo osmium(IV) complexes. Reaction of $OsCl_3$ in methanol with dppm ($Ph_2PCH_2PPh_2$) followed by recrystallization of the product from ethanol yields $Os_2O(\mu\text{-dppm})_2Cl_6\cdot 2MeCl$, in which a linear Os—O—Os unit (Os—O = 1.792(1) Å) is spanned by two bridging chelating phosphine ligands, the chloro ligands occupying equatorial (*cis* Os—Cl = 2.387(3) Å) and axial (*trans* Os—Cl = 2.307(3) Å) positions. The Os—P distance is 2.443(4) Å. As in $Cs_4[Os_2OCl_{10}]$ the configuration is eclipsed; unlike the interaction in the latter complex, though, the chloro ligands *trans* to the oxo ligand are slightly closer to the metal than are the *cis*. The OOsP angle is 85.51(8)°, brought in presumably by the strained bridge, while the OOsCl (*cis*) angle is 87.57(8)°. The complex could be electrochemically oxidized (presumably to a mixed $Os^{V/VI}$ species) and reduced in two one-electron steps.[647]

Reaction of the tetradentate N,N,O,O ligand 1,2-bis(3,5-dichloro-2-hydroxybenzamido)ethane (abbreviated as H_4chbaEt; see p. 616) with *trans*-$K_2[OsO_2(OH)_4]$ in ethanol yields the osmyl complex $K_2[OsO_2(\eta^4\text{-chbaEt})]$, which can then be reduced by PPh_3 to the μ-oxo-bridged species $K_2[Os_2O(\eta^4\text{-chbaEt})(OPPPh_3)_2]$[648]. As in $Cs_4[Os_2OCl_{10}]$ the equatorial ligands are eclipsed, but the Os—O—Os bridge is not quite linear [OsOOs angle = 175.5°, Os—O (bridged) = 1.795 Å). The *trans* Os—O (PPh_3) distance is 1.971 Å so there is no obvious *trans* lengthening effect.[648].

Another μ-oxo complex containing a bent bridge is $Os_2O(OAc)_2Cl_4(PPh_3)_2$, made from *trans*-$OsO_2Cl_2(PPh_3)_2$ and acetic anhydride (other complexes, such as $Os_2O(OCOR)_2X_4(PR'_3)_2$, R = Me, Et; X = Cl, Br; $PR'_3 = PPh_3$ or PEt_2Ph, were made in similar fashion). In $Os_2O(OAc)_2Cl_4(PPh_3)_2 \cdot Et_2O$ the Os—O—Os moiety (OsOOs angle = 140.2(4)°, Os—O (bridge) = 1.830(10) Å) is spanned by two bridging acetato ligands (Os—O = 2.083(9)), and it is presumably these which cause the very substantial bending of the OsOOs unit and consequent lengthening, in comparison with the other systems, of the Os—O bridge distance. The complex is diamagnetic, and the Os···Os distance is 3.440(2) Å. The equatorial planes, as viewed down the Os···Os axis, are not eclipsed due to the strain imposed by the bridging acetato ligands. Both this and the other $Os_2O(OCOR)X_4(PR'_3)_2$ complexes exhibit a reversible one-electron reduction, and the purple paramagnetic osmium(III)/(IV) complexes $M[Os_2O(OAc)_2Cl_4(PPh_3)_2]$ were isolated (M = Na, Ph_4As); μ_{eff} was 1.3 BM for the sodium salt and 1.7 BM for the $[Ph_4As]^+$ salt.[649]

A number of μ-oxo osmium(IV) porphyrin complexes with octaethylporphyrin (OEP) have been obtained by reaction of $Os^{II}(OEP)(CO)(MeOH)$ with air and 2,3-dimethylindole in dichloromethane. The product is the dark purple $Os_2O(OEP)_2(OMe)_2$; the methoxo group is labile with respect to substitution and both $Os_2O(OEP)_2(OH)_2$ and $Os_2O(OEP)_2(OMe)(OH)$ can be made. The complexes are thought to contain a linear bridge with the methoxo or hydroxo ligands *trans* to the oxo bridge. Cyclic voltammetric studies show that $Os_2O(OEP)_2(OMe)_2$ can be reduced to an Os^{IV}—Os^{III} and then to an Os^{III}—Os^{III} dimer.[650]

The dimeric species Os_2OCl_6, made from OsO_4 and HCl, has been isolated; IR and mass spectral data were obtained.[525] The so-called '$OsBr_3$' may be Os_2OBr_6.[650a]

(*iii*) *Osmium(V)*

The so-called Os_2OCl_8, made from osmium metal and a 15:1 chlorine–oxygen mixture at 700 °C,[527] is thought from its IR spectrum to be $OsOCl_4$ (p. 584).[525]

(*iv*) *Osmium(VI)*

A number of these are known. Most fall into two categories: one, of the type $Os_2O_6L_4$ (A) contains *trans* dioxo osmyl moieties, and the other $Os_2O_4L_4$ (B) contains one terminal oxo ligand per osmium, as in the 'monoesters' already treated on p. 584. In both cases the two metal atoms are linked by a μ,μ'-dioxo bridge in which the Os—O distance is typically *ca.* 1.95 Å. There is clearly far less π bonding in this bridging system than in the linear Os—O—Os system found in osmium(IV) species; this may be a result of the fact that two of the three orbitals suitable for such bonding are used for π bonding to the terminal oxo ligand in these osmium(VI) systems, whereas in the osmium(IV) species two such orbitals are available for π bonding in the Os—O—Os bridge.

The compound $Os_2O_6py_4$, prepared by the reaction of OsO_4 with pyridine in the presence of a little ethanol as reducing agent,[470] is formulated in the older literature as OsO_3py_2[480] (the complex '$OsO_4 \cdot py_2$',[633] made from the slow reaction of OsO_4 with pyridine, is almost certainly $Os_2O_6py_4$[470]). The single crystal X-ray shows it to be a dimer, as previously proposed on the basis of vibrational spectroscopic data,[468] of type (A).[469]

The osmium is octahedral with *trans* osmyl linkages (Os=O = 1.73 Å, the osmyl OOsO angle being bent away from the Os_2O_2 bridge at 163.5(8)°); the Os–N (py) distance is 2.20(2) Å, and the mean Os—O (bridge) distance is 1.94 Å.[469]

There is evidence[471] that, in solution, the dimer is in equilibrium with monomer (equation 7) and there may be such equilibria between monomer and dimer forms with $Os_2O_6L_4$ (L = 3-picoline, 3-chloropyridine),[470] 2,2′-bipyridyl,[471] imidazole,[544] 1,10-phenanthroline[496] and *N,N,N′,N′*-tetramethylethylenediamine (TMEN)[496]). Species of the $Os_2O_6L_4$ type have also been found with imidazoles and α-*N*-benzoyl-L-histidine isobutyl ester.[544]

$$Os_2O_6py_4 \rightleftharpoons 2OsO_3py_2 \qquad (7)$$

Another example of the type (A) structure is $K_4[Os_2O_6(NO_2)_4] \cdot 6H_2O$, a deep brown crystalline material obtained by prolonged reaction at room temperature of KNO_2 with OsO_4 in aqueous solution. It was long formulated as '$K_2[OsO_3(NO_2)_2] \cdot 3H_2O$'[204] and is a useful precursor for other osmium(VI) and osmium(IV) complexes since it releases NO_2 with acids. A single crystal X-ray study showed it to be of type (A) with the osmyl Os=O distance 1.79(1) Å and the osmyl OOsO

angle 164.1°, bent away from the Os_2O_2 bridge; the Os—N distance is 2.17(2) Å and the Os—O bridge distance is 1.99 Å with an OsOOs bridge angle of 102°.[502]

The species formulated[478] as '$Na_4[O_2\{OsO_2(OH)_2\}_2]\cdot nH_2O$', a product of reaction of OsO_4 and NaOH in water–ethanol, could presumably be reformulated as $Na_2[Os_2O_6(OH)_4]\cdot nH_2O$.

An X-ray crystal structure of a type (B) complex, $Os_2O_6(O_2C_2Me_4)_2$, is discussed on p. 584. Other binuclear 'oxo ester' complexes which have been studied by X-ray methods are the 'tetrolato' species $Os_2O_4(O_4C_8H_{12})py_4$,[522] (see p. 586 and Table 21) and the species $Os_2O_4(O_2C_6H_{10})_2(NC_7H_{13})_2$,[546] (p. 587 and Table 25). It is known too that some complexes obtained from OsO_4 and nitrogenous bases are binuclear (p. 592).

(*v*) *Osmium(VII)*

The yellow-green OsO_2F_3, made by reaction of a 1:1 mixture of OsO_4 with OsF_6 at 750 °C, is probably a tetramer or an infinite chain structure with single fluoro bridges.[524]

(*vi*) *Osmium(VIII)*

The binuclear species $M^I[Os_2(OH)O_8]$ (M = Rb, Cs) are prepared by reaction of a deficiency of M^IOH with OsO_4.[629,630] The X-ray crystal structures of the rubidium[651] and cesium[629] salts show the osmium atoms to have a trigonal bipyramidal configuration with the bridging hydroxo ligand in the apical position. The Os=O distances vary from 1.66 to 1.75 Å in the rubidium salt, with the Os—O (OH) distance 2.16 Å and the OsOOs angle 153°.[651] In the cesium salt $Cs[Os_2(OH)O_8]$ the structure is similar (Os=O axial = 1.71(3), mean O=O equatorial = 1.67 Å) linked by a μ-hydroxo ligand constituting the remaining axial positions (Os—O = 2.22(2) Å) in an essentially symmetrical but bent bridge (OOsO angle 133(1)°).[629]

The compound OsO_3F_2 (indistinguishable by X-ray methods from OsO_2F_3)[533] is made by reaction of osmium metal with a 2:1 oxygen–fluorine mixture[523] or from OsO_4 and BrF_3.[524] There is much doubt about its structure, but the compound made at normal temperatures exists in at least three different crystalline forms and polymeric structures seem more likely.[652]

46.6.3 Dioxygen, Superoxo and Peroxo Species

Surprisingly, no non-organometallic complexes containing these ligands appear to have been isolated,[654] though peroxo species in particular might well be involved as intermediates in some reactions (*e.g.* in the OsO_4-catalyzed decomposition of H_2O_2[620]). The complex $Os(O_2)(CO)_2(PPh_3)_2$ is made by slow reaction of O_2 with $Os(CO)_2(PPh_3)_2$,[655] while $Os(O_2)(CO)HX(PCy_3)_2$ (X = Cl, Br) complexes are made from O_2 and $Os(CO)HX(PCy_3)_2$. With SO_2 the chloro species gives a sulfato complex.[656] It is likely that an η^2-peroxo (or 'dioxygen') complex is implicated in ligand oxidations at organic centres, *e.g.* oxidation of $Os(CO)Cl(NO)(PPh_3)_2$ to $Os(CO_3)Cl(NO)(PPh_3)_2$ by oxygen.[657]

46.6.4 Alkoxo Complexes

A few alkoxo complexes are known with phosphine coligands, and the methoxo species *trans*-$K_2[OsO_2(OMe)_4]$ is quite a useful synthetic reagent (see p. 584).

Reaction of $(Bu^n_4N)[OsNCl_4]$ with PPh_3 in methanol gives $Os(PPh_3)_2Cl_2(OMe)_2$,[315] and $Os(OMe_2Ph)_3Cl_3$ and Me_3N in ethanol yields the yellow $Os(PMe_2Ph)_3Cl_2(OEt)$.[72] The ethoxo species *fac*-$Os(PMe_2Ph)_3(S_2CNMe_2)(OEt)$ is made from *mer*-$Os(PMe_2Ph)_3(S_2CNMe_2)Cl$ and $K(S_2COEt)$ in ethanol.[412]

46.6.5 β-Diketonate Complexes

As might be expected for chelating O,O donor ligands it is the intermediate trivalent state of osmium which is stabilized by β-diketonates (as is the case for catechols, p. 597, and tropolonato complexes, p. 597). In the presence of π-acceptor chelates such as bipy, phen and terpy the II state is favoured, while with halides the IV state is preferred. The apparent absence of an osmyl complex, *e.g.* OsO_2acac_2, is surprising.

46.6.5.1 Osmium(II)

Although it has not been isolated, the product of polarographic reduction of $Os(acac)_3$ is probably $[Os(acac)_3]^-$.[658]

Reaction of $Os(PPh_3)_3H_4$ and β-diketonates L gives $Os(PPh_3)_2L_2$ (L = acetylacetonate, trifluoroacetylacetonate, hexafluoroacetylacetonate). A *cis* structure is thought to be likely; IR and ^1H NMR data were obtained.[429]

46.6.5.2 Osmium(III)

The neutral tris complex $Os(acac)_3$ is made from $[OsBr_6]^{3-}$ with acetylacetone under appropriate pH control.[659] It is paramagnetic (μ_{eff} = 1.81 BM at 289 K)[659] and is isomorphous with $Ru(acac)_3$ and $Co(acac)_3$.[660] The near IR spectrum has been measured and assigned.[660,661] A one-electron polarographic reduction wave at −1.244 V is observed (the redox potential for the corresponding thio β-diketonate, $Os(sacsac)_3$ (p. 606), is only −0.151 V); that of $Ru(acac)_3$ occurs at −0.728 V, in keeping with the general tendency of osmium(III) complexes being more difficlt to reduce than ruthenium(III).[658] There are mass spectral data on $Os(acac)_3$.[662]

46.6.5.3 Osmium(IV)

All the known examples also contain halides as coligands. Both *cis* and *trans* isomers of $Os(acac)_2X_2$ (X = Cl, Br, I) can be obtained from $[OsX_6]^{2-}$ and acetylacetone, separation being effected chromatographically;[663] $Os(acac)_2Cl_2$ can also be made by reaction of acetylacetone with $Os_2(OAc)_4Cl_2$[105] (the magnetic moment (1.29 BM) and electronic spectrum of the latter were obtained[105]). There are Raman, IR and electronic spectral data on *cis*- and *trans*-$Os(acac)_2Cl_2$.[663] Salts of $[Os(acac)X_4]^-$ (X = Cl, Br, I) are made from $[OsX_6]^{2-}$ and acetylacetone; IR and electronic spectral data were obtained for them.[664]

46.6.6 Tropolonato Complexes

The monoanion of this, trop, is a good O,O chelate, resembling the catecholato dianion in its platinum group chemistry. Reaction of $[OsCl_6]^{3-}$ (generated from $[OsCl_6]^{2-}$ and silver powder) with tropolone gives the yellow $Os(trop)_3$, for which IR, ^1H and ^{13}C NMR data were obtained. Similar data were obtained for the osmyl complex OsO_2trop_2, made from *trans*-$K_2[OsO_2(OH)_4]$ and tropolone.[665]

46.6.7 Catecholato Complexes

The 'non-innocent' ligand catechol forms very stable osmium(VI) complexes, as do a number of substituted catechols.

46.6.7.1 Tris catecholato complexes, Os(cat)$_3$ and Os(Rcat)$_3$

Reaction of OsO_4 with catechol or substituted catechols Rcat in chloroform yields the deep blue diamagnetic $Os(Rcat)_3$ species (Rcat = catechol, 4-*tert*-octyl-, 4-*tert*-butyl-, 3,5-di-*tert*-butyl-catechol).[486] X-Ray crystal structures of $Os(cat)_3$ and of the tris complex with 3,5-di-*tert*-butylcatechol show these to have D_3 symmetry; the Os—O distances fall within the range 1.947 to 1.985 Å (mean 1.960 Å) and the C—O distances are between 1.30 and 1.35 Å; the catecholato ($O_2C_6H_4$ or $O_2C_6H_2$) rings are essentially planar.[666] For $Os(cat)_3$, IR, Raman, ^1H NMR and electrochemical data were obtained; the latter showed two one-electron reversible reductions, presumably to $[Os(cat)_3]^-$ and $[Os(cat)_3]^{2-}$. The diamagnetism of these formally osmium(VI) species probably arises from the distortion from octahedral to D_3 symmetry.[486]

46.6.7.2 Bis catecholato complexes

Most of these are of the osmyl type, *trans*-$[OsO_2(Rcat)_2]^{2-}$ (Rcat = catechol, 4-methylcatechol, 4-*tert*-butylcatechol, 4-nitrocatechol), made from OsO_4 and the catechol in alkali or from the

catechol and *trans*-$K_2[OsO_2(OH)_4]$; cations were potassium or $(Ph_4P)^+$. The pyridine complexes *trans*-$OsO_2(Rcat)py_2$ were obtained from OsO_4, pyridine and the catechol (Rcat = cat, 4-Me-cat). IR and Raman data on these were measured; $\nu_s(OsO_2)$ appears near 860 cm^{-1} and $\nu_{as}(OsO_2)$ near 820 cm^{-1} (see also Table 21, p. 582).[486] IR and ^1H NMR data were obtained for the existence of $OsO(cat)(O_2C_2Me_4)$ in solution, made from $Os_2O_4(O_2C_2Me_4)_2$ and catechol.[536]

46.6.7.3 Polymeric catecholato complexes

Acidification of solutions containing $[OsO_2(Rcat)]^{2+}$ or direct treatment of the catechol with OsO_4 in acetone gives dark blue, polymeric species $[OsO(Rcat)_2]_n \cdot nH_2O$, thought to contain Os—O—Os—O···chains (R-cat = 4-methylcatechol, 4-*tert*-butylcatechol, 3,5-di-*tert*-butylcatechol). These are remarkably stable species, unreactive even towards boiling pyridine.[486]

46.6.7.4 Complexes with naturally occurring catechols

Preparative methods similar to those above with naturally occurring phenolics, particularly in plant cells, give *trans*-$[OsO_2(Rcat)_2]^{2-}$ (4-methyldaphnetinate), *trans*-$OsO_2(Rcat)py_2$ (gallate, quercetinate) and $[OsO(Rcat)_2]_n \cdot nH_2O$ (catechinate, gallate, digallate and caffeate). The specific site staining of 'phenolic' material (*i.e.* catechol-containing areas in plant tissue by OsO_4 solutions is likely to be due to formation of $[OsO(Rcat)_2]_n \cdot nH_2O$ species.[486,618]

46.6.8 Ketone Complex

The sole example seems to be $[Os(PMe_2Ph)_3Cl_2(OCMe_2)]ClO_4$, made from *mer*-$Os(PMe_2Ph)_3Cl_3$ in acetone in the presence of silver perchlorate.[366]

46.6.9 Oxoanions as Ligands

Some of the complexes in this category are in need of fuller characterization.

46.6.9.1 Nitrato and nitro complexes

There are very few of these for osmium, and no unsubstituted ones.

(*i*) *Nitrato complexes*

The '$K_2[OsO_2(NO_2)_4]$' reported in the early literature,[204] made by reaction of OsO_4 with nitric oxide in an aqueous solution of KNO_2, was later reformulated by the author as an osmyl complex, $K_2[OsO_2(NO_3)(NO_2)_3]$[503] and then, after second thoughts, as a different osmyl species, $K_2[OsO_2(NO_3)_2(NO_2)_2]$.[21]

The nitrato complex $[Os_2N(NH_3)_8(NO_3)_2]^{3+}$ is mentioned on p. 563.

(*ii*) *Nitro complexes*

The '$K_2[Os(NO_2)_5]$' reported in the early literature[204] and made by reaction of $[OsCl_6]^{2-}$ with aqueous KNO_2 is now known to be *trans*-$K_2[Os(NO)(OH)(NO_2)_4]$ (see p. 546).[219]

Recent work has been reported on the nitro complexes $[Os(NO_2)(terpy)(bipy)]^+$, made from $[Os(terpy)(bipy)Cl]^+$ and nitrite ion in ethylene glycol, and on $Os(NO_2)bipy_2Cl$, prepared from $[Os(NO)bipy_2Cl]^{2+}$ and sodium hydroxide. Oxidation of $[Os(NO_2)(terpy)(bipy)]^+$ with cerium(IV) to give $[Os(NO_2)(terpy)(bipy)]^{2+}$ is followed by its disproportionation (equation 8).

$$3[Os(NO_2)(terpy)(bipy)]^{2+} \longrightarrow [Os(NO_2(terpy)(bipy)]^+ + [Os(NO)(terpy)(bipy)]^{3+} + [Os(NO_3)(terpy(bipy]^{2+} \quad (8)$$

The kinetics of this second-order reaction have been studied. The equilibrium shown in

$$[Os(NO_2)terpy\ bipy]^+ + H_2O \rightleftharpoons [Os(NO)(terpy)(bipy)]^{3+} + 2OH^- \quad (9)$$

equation (9) was also measured. The osmium(III) complex $[Os(NO_2)(terpy)(bipy)]^{2+}$ will oxidize triphenylphosphine to Ph_3PO and $[Os(NO)(terpy)(bipy)].^{2+}$ Electronic spectra of $Os(NO_2)bipy_2Cl$ and of $[Os(NO_2)(terpy)(bipy)]^+$ were recorded. Reactions and data were compared with those for the corresponding ruthenium complexes.[183]

For $K_4[Os_2O_6(NO_2)_4]\cdot 6H_2O$ (formerly erroneously believed to be $K_2[OsO_3(NO_2)_2]\cdot 3H_2O$ or *trans*-$K_2[OsO_2(NO_2)_2(OH)_2]$), see p. 595.

46.6.9.2 Phosphato and sulfato complexes

(*i*) *Phosphato complexes*

None have been properly characterized for osmium, though a 1:1 complex between OsO_4 and PO_4^{3-} has been detected spectrophotometrically.[667]

(*ii*) *Sulfato complexes*

Athough sulfato complexes of osmium undoubtedly exist none have been definitely established or characterized.

(a) Osmium(IV). Osmium(IV) sulfato complexes are thought to be present in solutions made by chemical dissolution of osmium in sulfuric acid.[668,669a] Species thought to be $[Os(SO_4)_2(OH)_2]^{2-}$ have also been claimed.[668]

(b) Osmium(VI). Solutions of OsO_4 in H_2SO_4 are said to contain $OsO_2(OH)_2(SO_4)_2$,[669b] presumably an osmyl complex.

46.6.9.3 Sulfito and hydrosulfito complexes

(*i*) *Sulfito complexes*

There are early reports of sulfito complexes of osmium, but only recently has some of this work been reexamined. It appears that osmium binds to the sulfur atom rather than oxygen in SO_3^{2-}, even for the presumably 'hard' osmyl unit in $[OsO_2(SO_3)_4]^{6-}$.

(a) Osmium(II). The salt $Na_4[Os(SO_3)_3]\cdot 6H_2O$ was first made by reaction of osmium(VI) oxoesters with Na_2SO_3.[528] It is not clear whether this should be reformulated as $Na_4[Os(SO_3)_3(H_2O)_3]\cdot 3H_2O$ (with monodentate rather than bidentate SO_3^{2-} ligands) but recent work suggests that the potassium salt is $K_4[Os(SO_3)_3(H_2O)_3]$. It is made by reaction of $KHSO_3$ with $K_2[OsCl_6]$, and its Raman and IR spectra suggest that the SO_3^{2-} ligand functions as a monodentate S donor. The complex is diamagnetic.[507]

Other nominally osmium(II) sulfito species include $Na_6Os_4(SO_3)_7\cdot 24H_2O$, reported as a deep violet material obtained from $Na_2[OsCl_6]$ and $Na_2S_2O_4$.[670]

(b) Osmium(III). Treatment of $[Os(NH_3)_5Cl]Cl_2$ with SO_2 produces the pink-brown $Os(SO_3)(NH_3)_4Cl$; it is paramagnetic ($\mu_{eff} = 1.45$ BM at 294 K), and the Raman and IR spectra suggest a *trans* structure with S-bonded sulfite.[507]

(c) Osmium(IV). The salt $Na_8[Os(SO_3)_6]\cdot 3H_2O$ is reported to result from reaction of $NaHSO_3$ with $[OsCl_6]^{2-}$;[506] another product of this reaction is said to be $Na_6[Os(SO_3)_5(H_2O)]\cdot 4H_2O$.[506] Reaction of $NaHSO_3$ and $Na_2[OsCl_6]$ is also said to give $Na_7[Os(SO_3)_5Cl]\cdot 6H_2O$[506] and $Na_6[Os(SO_3)_4Cl_2]\cdot 10H_2O$.[671] There are also very ill-defined potassium salts: $K_6H_2[Os(SO_3)_6]\cdot 2H_2O$ and '$K_{11}H_3[Os_2(SO_3)_{11}(H_2O)]\cdot 5H_2O$' both being made from reaction of $KHSO_3$ with $K_2[OsCl_6]$.[506] It seems likely[507] that '$K_4H_2[Os(SO_3)_6]\cdot 2H_2O$' is actually $K_4[Os(SO_3)_3(H_2O)_3]$. A complex $K_6H_2[Os(SO_3)_4Cl_4]$ has been claimed as a product of reaction of $K_2[OsCl_6]$ with $KHSO_3$,[671] and OsO_4 with CO_3^{2-} and SO_3^{2-} in solution is said to give $[Os(SO_3)_6]^{8-}$.[621] A product of the K_2OsCl_6–K_2SO_3 reaction is said to be $K_6[Os(SO_3)_5(H_2O)]\cdot 4H_2O$.[506]

Reaction of $[Os_2N(NH_3)_8Cl_2]^{3+}$ with SO_2 gives $[Os_2N(NH_3)_8(SO_3)(H_2O)]Cl_3$; the sulfite is thought to be S-bonded.[507]

(d) Osmium(VI). There are some very ill-defined potassium salts which are said to result from

reaction of OsO_4 with SO_2 in water in the presence of KOH. The osmyl complex $Na_6[OsO_2(SO_3)_4]\cdot 5H_2O$ is well established, however (p. 582),[507] and has long been known.[506]

(*ii*) *Hydrosulfito complex*

The ESCA spectrum of $Na_4[Os(HSO_3)_6]$ has been reported but, irritatingly, no preparation was given.[36]

46.6.9.4 Triflato complex

The coordinated triflato $(SO_3CF_3)^-$ ligand is weakly bound to osmium in $[Os(OSO_2CF_3)(NH_3)_5]^{2+}$, made by reaction of triflic acid with $[Os(NH_{33})_5N_2]^{2+}$.[62] It is a useful reagent for preparation of other osmium pentaammines since triflate is a good leaving group (see p. 529).

46.6.9.5 Carboxylato complexes

In this section we consider the complexes of mono-, di- and poly-carboxylato complexes. There appear to be marked differences from ruthenium carboxylato chemistry particularly in respect of the II/III and III states. A number of osmyl complexes are known with monodentate or bidentate carboxylates (p. 582) but apparently none of ruthenium(VI). On the other hand, the binuclear ruthenium species $[Ru_3O(OCOR)_6L_3]^{n+}$, in which OCOR functions as a bidentate ligand, does not appear to have an osmium counterpart; both elements form 'lantern'-like species containing $[M_2(OCOR)_4]^{n+}$ cores, but again with marked differences between ruthenium and osmium. This is clearly an interesting and rewarding field for further study.

(*i*) *Monocarboxylato complexes*

For amino acids see p. 583.

(a) Monodentate. Few examples are known. The acetato species $K[OsO_2(OAc)_3]\cdot 2AcOH$ has been shown by X-ray studies to contain two monodentate and one bidentate acetato ligands in a plane about a bent osmyl unit (p. 582). The carbonyl complexes $OsH(OCOR)(CO)(PPh_3)_3$ and $Os(OCOR)_2(CO)_2(PPh_3)_2$ must contain monodentate OCOR ligands, and $Os(OCOR)_2(CO)(PPh_3)_2$ presumably contains one mono- and one bi-dentate OCOR group (R = CF_3, C_2F_5).[672]

(b) Bidentate monocarboxylates. A few of these are known, mainly with phosphines. The hydrides $Os(OCOR)H(PPh_3)_3$ are made from $OsH_4(PPh_3)_3$ and the appropriate acid (R = Me, Et,[406] CF_3[672]) and IR and ^1H NMR data suggest that the hydrido ligand is *trans* to the bidentate carboxylate group.[406,672] The bromo species $Os(OCOR)Br_2(PPh_3)_2$ are obtained from $OsBr_2(PPh_3)_3$ and the appropriate acid (R = Ph, *p*-C_6H_4Br, *p*-C_6H_4Me), and their IR spectra suggest that the two phosphine ligands are *trans* to the bidentate carboxylate.[673]

For osmyl salicylato complexes see p. 582, and for other osmyl carboxylato complexes see Tables 20 and 21, and p. 582.

(c) Bridging carboxylato complexes. The ability of carboxylato ligands to function in a bridging role is well exploited by the Group VIII metals. Thus there are many rhodium(II) carboxylates with the 'lantern' structure and a number of species of the type $[Ru_3O(OCOR)_6L_3]^{n+}$, $Re_2(OCOR)_4X_4$ and $Ru_2(OCOR)_4X$ where the carboxylate ligand is bridging. Until recently there have been few such examples with osmium, but new studies suggest that there is a rich chemistry of the element with bridging carboxylates, and that such species have an extensive redox chemistry.

Species containing the Os_2^{5+} core. Reaction of $Os_2(OCOR)_4Cl_2$ (R = Et, Pr^n) and $(\pi\text{-}C_5H_5)_2Co$ yields the salts $[(\pi\text{-}C_5H_5)_2Co][Os_2(OCOR)_4Cl_2]$, and these species are also produced by electrochemical reduction of $Os_2(OCOR)_4Cl_2$. Their magnetic properties in CH_2Cl_2 solution show moments per Os_2 unit higher than for the Os_2^{6+} core species (*e.g.* μ_{eff} of 2.47 BM at 275 K and 2.88 BM at 215 K for $[(\pi\text{-}C_5H_5)_2Co][Os_2(OCOEt)_4Cl_2]$, 2.65 BM at 240 K and 2.85 BM at 190 K for $[(\pi\text{-}C_5H_5)_2Co][Os_2(OCOPr^n)_4Cl_2]$).[674] These are nevertheless lower than moments observed for the analogous $Ru_2(OCOR)_4Cl$ species; this may arise from a greater separation of π^* and δ^* orbitals on Os_2^{5+}.[107]

Species containing the Os_2^{6+} core. Reaction of $[OsCl_6]^{2-}$ with acetic acid in acetic anhydride gives the brown, insoluble $Os_2(OCOMe)_4Cl_2$[105,675] and this will react with propionic or *n*-butyric acids to give $Os_2(OCOR)_4Cl_2$ (R = Et, Pr^n) which are more soluble in organic solvents.[105]

The X-ray crystal structures of the acetato, propionato and *n*-butyrato complexes show these to have the 'lantern' type of structure (Table 26 and Figure 34).

Table 26 Structural Data for Carboxylato Complexes (Å)

Complex	d_{Os-Os}	d_{Os-Cl}	d_{Os-O} *(mean)*	*Ref.*
$Os_2(OCOMe)_4Cl_2$	2.314(1)	2.448(2)	2.009(8)	106
$Os_2(OCOEt)_4Cl_2$	2.316(2)	2.430(5)	2.012(8)	106
$Os_2(OCOPr^n)_4Cl_2$	2.301(1)	2.417(3)	2.016	105, 676

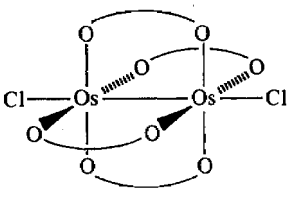

Figure 34 The 'lantern' structure for carboxylato complexes

Despite the short Os—Os distances the complexes are paramagnetic; thus, in solution, μ_{eff} for the butyrate is 1.15 BM per Os atom at 300 K and 1.02 BM at 188 K. It has been suggested that mixing of the triplet $\sigma^2\pi^4\delta^2\pi^{*2}$ or $\sigma^2\pi^4\delta^2\delta^{*1}\pi^{*1}$ states at room temperatures with the singlet ground state arising from $\sigma^2\pi^4\delta^2\delta^{*2}$ may occur, the latter state becoming increasingly favoured at lower temperatures.[105] Contributions from the two former states may, it has also been suggested, account for the greater Os—Os distance of 2.357 Å in Os_2(2-hydroxypyridine)$_4Cl_2 \cdot 2MeCN$ (see p. 534) than in these molecules.[106] The ^1H and ^{13}C NMR spectra of the *n*-butyrato complex show larger contact-shifted resonances to lower frequencies.[105]

Cyclic voltammetric studies show that the propionate and butyrate undergo reversible one-electron reductions ($E^\circ = +0.57$ and $+0.53$ V respectively) to $[Os_2(OCOR)_4Cl_2]^-$,[105,107,677] and there are also irreversible oxidation and reduction waves.

The acetato complex is a useful precursor for other species. In some reactions the bridges are partly or wholly displaced by other bridges, or monomeric osmium-(II), -(III) or -(IV) complexes are formed.[105]

In $Os_2(O_2CR)_2(Ph_2PC_6H_4)_2Cl_2$ [R = Me (made from $Os_2(OAc)_4Cl_2$ and triphenylphosphine) and R = Et (from a similar reaction but using propionic acid)] the phosphine groups function as cobridges with the acetato or propionato bridges; *ortho*-metallation occurs at one of the phenyl rings giving a P—C—C bridge. The short Os—Os distances (2.271(1) Å for R = Me,[678,679] 2.272(2) Å for R = Et[678]) corresponds effectively to a triple bond.[678]

For $Os_2O(OAc)_2Cl_4(PPh_3)_2$ see p. 595 and Table 25.

(*ii*) *Bidentate dicarboxylato complexes*

A few complexes of the oxalato (ox) ligand are known, though no one seems to have succeeded yet in isolating a tris oxalato complex.

In a recent series of papers, very comprehensive Raman, IR and electronic spectral data have been collected for $[Os(ox)X_4]^{2-}$ (X = Cl, Br, I; made from $[OsX_6]^{2-}$ and oxalic acid);[680] for $[Os(ox)Cl_nBr_{4-n}]^{2-}$[681] and for $[Os(ox)Cl_nI_{4-n}]^{2-}$[682] (n = 1–3, all geometrical isomers isolated, made from $[Os(ox)Br_4]^{2-}$ with Cl^- and $[Os(ox)I_4]^{2-}$ with Cl^- respectively). Similar spectroscopic studies were carried out on *mer*-$[Os(ox)(CO)X_3]^{2-}$, made from *trans*-$[Os(CO)_2X_4]^-$ or $[Os(CO)X_5]^{2-}$ with oxalate (X = Cl, Br, I).[683]

The species $Os(ox)bipy_2 \cdot H_2O$ and $Os(ox)phen_2$ are made from the corresponding chloro complexes and sodium oxalate.[173]

(iii) Tetradentate carboxylato complexes

Three edta complexes have been reported, and one of *trans*-1,2-diaminocyclohexane-*N,N,N',N'*-tetraacetate.

(a) Osmium(II). The reaction of OsO_4 with the alkene 3-cyclohexenecarboxylic acid in the presence of H_4edta gives the brown $Na_6H_4[Os(edta)_3]$; maleic acid can also be used as the alkene, and the same species is obtained from $[OsO_2(OH)_4]^{2-}$ and edta. The complex $Na_5H_5[Os(dcta)_3]$ was made from OsO_4, H_4dcta and 3-cyclohexenecarboxylic acid.[684]

(b) Osmium(III). A yellow, paramagnetic 'free acid', $H[Os(H_2edta)Cl_2]\cdot 2\frac{1}{2}H_2O$, is obtained by reaction of $[OsCl_6]^{2-}$ and H_4edta; an anhydrous ammonium salt was also isolated. The material is paramagnetic (μ_{eff} = 1.79 BM at 286 K).[685]

(c) Osmium(IV). On aerial oxidation of $H[Os(H_2edta)Cl_2]\cdot 2\frac{1}{2}H_2O$ black crystals of Os(edta)$(H_2O)\cdot H_2O$ were obtained. An X-ray crystal structure determination showed the osmium to be heptacoordinate, a rare coordination number for the element. It has a distorted capped trigonal prismatic structure, the water occupying the capping position (Os—O (H_2O) = 2.049(7) Å); the four Os—O (edta) bonds form a distorted square (mean Os—O = 2.052 Å) and the two Os—N bonds (mean = 2.159 Å) are under the square, *trans* to the cap.[686]

(iv) Amino acid complexes

For convenience we deal with all the reported osmium complexes of amino acids in this section, apart from the osmyl species (p. 583).

(a) Glycine. The three complexes $[Os(bipy)_2(glycinate)]I\cdot 2H_2O$[173] (made from glycine and Os(bipy)$_2Cl_2$), $[Os(bipy)(glycinate)_2]I\cdot 2H_2O$[86] and Os(bipy)(glycinate)$Cl_2\cdot H_2O$[86] are reported; the latter two were made from glycine with $K[Os(bipy)Cl_4]$. The X-ray crystal structure of OsO_2(glycinate)$_2$ is described on p. 581 (Table 20).

(b) Lysine, arginine, proline and histidine. The methyl ester of α-*N*-benzoyllysine gives an orange solution with OsO_4 likely to contain a 1:1 adduct.[544]

Although α-*N*-benzoyl-L-arginine ethyl ester (L) does not react with aqueous OsO_4, it reacts with the 1-methylimidazole adducts $OsO_4\cdot N_2C_4H_6$ to give $Os_2O_6(N_2C_4H_6)L$; a similar reaction occurs with L-proline methyl ester. The blocked acid α-*N*-benzoyl-L-histidine isobutyl ester (L) gives a species $Os_2O_6L_4$ with OsO_4, and with α-*N*-acetyl-L-cysteine (L′) it gives $OsLL'_2$. With unsaturated lipids R (R = cyclohexene, oleic acid, methyl oleate, cholesteryl acetate) $OsO_2(O_2R)L_2$ is formed.[544]

(v) Miscellaneous acids

Complexes of nicotinic acids and isonicotinic acid with dinitrogen are considered on p. 554.
For methionine, cysteine, cystine and glutathione see pp. 554, 555.

46.6.10 Dimethyl Sulfoxide Complex

The complex $Os(DMSO)_3Cl_3$ is made from $[OsCl_6]^{2-}$ and DMSO under reflux; it is dark green and paramagnetic (μ_{eff} = 1.15 BM at room temperatures). The IR, electronic and ^{1}H NMR spectra were measured and a structure proposed[687] in which there is a *mer* configuration of two O- and one S-bonded DMSO ligands, unlike the rhodium analogue which, despite a similar stereochemistry, has one S- and two O-bonded ligands.[688] This suggests that osmium(III) lies at the borderline of hardness and softness towards DMSO (a similar situation is observed for thiocyanato complexes, *cf.* p. 565).

46.6.11 Complexes with Carbohydrates

In his classic work on the *cis* hydroxylation of alkenes, Criegee used mannitol with osmium(VI) esters (in a 2:1 sugar:osmium ratio) in order to complex the metal and thus hydrolyze the ester to the *cis* diol; the nature of the osmium sugar complex was not investigated.[480]

Reaction of $K_2[OsO_2(OAc)_3]$ with D-glucose[689] and other carbohydrates[690] gave brown, polymeric, largely uncharacterized osmium carbohydrate complexes,[689] called 'osmarins'. It has been suggested that these are osmium(IV) species,[689] although the mode of preparation would suggest that

osmyl complexes are formed. They have been used experimentally for the treatment of arthritis, and may possibly function by scavenging superoxide radicals.[691]

46.7 SULFUR-CONTAINING LIGANDS

Although there are areas of osmium–sulfur chemistry where recent and interesting work has been done (*e.g.* on dithio- and trithio-carbamates), there is also much poor work, often with complicated ligands where little more than the stoichiometry of the complex —and sometimes less— has been established. Much work remains to be done on the osmium chemistry of simple thio (and seleno) ligands.

In general sulfur and selenium, in keeping with their 'soft' character, tend to stabilize the 'intermediate' trivalent state of osmium.

46.7.1 Hydrosulfido and Disulfur Ligands

The species $[Os(SH)_6]^{2-}$ is possibly formed in solution when $[OsCl_6]^{2-}$ in alkali (*i.e.* presumably $[Os(OH)_6]^{2-}$) is treated with H_2S.[692]

Reaction of $Os(PPh_3)_3(CO)_2$ with S_8 gives $Os(S_2)(PPh_3)_2(CO)_2$; the X-ray crystal structure of the selenium analogue has also been determined.[693]

46.7.2 Sulfido Phosphine Complexes

Reaction of $Os(PMe_3)_3H(CH_2PMe_2)$ with S_8 gave $Os(PMe_3)_3S_6$ (dark brown) and $Os(PMe_3)_3S_7$ (orange). In the latter the S_7^{2-} ligand is coordinated in tridentate fashion, and this is shown by its X-ray crystal structure. There is distorted octahedral coordination about the osmium with a *fac* arrangement of phosphine ligands (mean Os—P = 2.235 Å), while the S_7 moiety forms two four-membered rings with S-1, S-4 and S-7 as donors (mean Os—S_1 and Os—S_4 = 2.435 Å, Os—S_4 2.310(2) Å). The rings are not planar; the S—S distances lie between 2.010 and 2.205 Å.[694]

46.7.3 Thioether Complexes

Only one dialkyl sulfide complex has been reported, *fac*-$Os(SEt_2)_3Cl_3$, but recently a number of osmium-(III), -(IV) and -(VI) complexes of chelating thioethers have been prepared. There is also only one DMSO complex, $Os(DMSO)_3Cl_3$ (see p. 602).

46.7.3.1 Dialkyl sulfides

The only example reported is *fac*-$Os(SEt_2)_3Cl_3$, made from $OsCl_4$ and Et_2S in refluxing ethanol. The configuration of this material was deduced from its IR and electronic spectra.[695]

For osmyl complexes with SR_2, see p. 584.

46.7.3.2 Chelating sulfides

A number of complexes of these with osmium(III) and osmium(IV) have appeared in two recent publications; the preferred oxidation state would seem to be IV, although the trivalent species, once made, are quite stable.

(i) Osmium(III)

The trithioether bis(3-methylthiopropyl) sulfide, $S(CH_2CH_2CH_2SMe)_2$ (L), gives $OsLX_3$ (X = Cl, Br) with $[OsX_6]^{2-}$ in addition to $OsLX_4$. The IR spectra in the ν_{OsCl} region suggested that these are *mer* isomers; electronic spectra were also measured. Other osmium(III) complexes of the form $OsL'_{1.5}X_3$ (L' = RSCH=CHSR, $RSCH_2CH_2SR$ (R = Me, Ph) and *o*-$C_6H_4(SMe)_2$; X = Cl, Br)

were made by prolonged reaction of L′ on $[OsX_6]^{2-}$; IR, electronic and ESR spectra were measured. A dithioether-bridged structure was proposed; in solution the chloro complexes have magnetic moments in the range 1.65–1.78 BM.[696]

(ii) Osmium(IV)

Species of the form $OsLX_4$ ($L = S(CH_2CH_2CH_2SMe)_2$, $MeC(CH_2SMe)_3$, X = Cl, Br and X = Cl, $L = S(CH_2)_2S(CH_2)_3S(CH_2)_3$[696]) and $OsL'X_4$[697] (X = Cl, L = RSCH=CHR, $RSCH_2CH_2R$, o-$C_6H_4(SR)_2$, R = Me, Ph; X = Br, L′ = MeSCH=CHSMe, $MeSCH_2CH_2SMe$)[697] have been made from $[OsX_6]^{2-}$ and the ligands. IR and electronic spectra have been reported for all of these, and magnetic moments are in the range 1.3–1.4 BM for most of them.[696,697] The tetrathioether $MeS(CH_2)_2S(CH_2)_2S(CH_2)_2SMe$ (L″) gave a species $Os_2L''Cl_8$.[696]

For osmium(VI) osmyl complexes see p. 584.

46.7.4 Dithiocarbamato ($S_2CNR_2^-$), Trithiocarbamato ($S_3CNR_2^-$), Dithiocarbonato (S_2COR^-) and Phosphinodithionate ($S_2PR_2^-$) Complexes

A number of osmium-(III) and -(IV) complexes involving dithiocarbamato ligands are known; there are some interesting binuclear species involving the ligand in a bridging role. Recently, complexes involving the novel trithiocarbamate and also selenodithiocarbamate ($SeS_2CNR_2^-$) ligands have been synthesized; indeed, they represent the first examples of these ligands in a coordinating role. Much of the work in this area has been carried out by Pignolet and his collaborators.

There is a recent review on the electrochemistry of osmium dithiocarbamato complexes.[698]

46.7.4.1 Dithiocarbamates

(i) Osmium(II)

Electrochemical evidence for the existence of $[Os(S_2CNEt_2)_3]^-$ from reduction of the neutral osmium(III) species $Os(S_2CNEt_2)_3$ has been presented.[699] Reaction of *mer*-$Os(PMe_2Ph)_3Cl_3$ and $Na(S_2CNMe_2)$ gives *cis*-$Os(PMe_2Ph)_2(S_2CNMe_2)_2$,[412] and *cis*-$Os(PPh_3)_2(S_2CNR_2)_2$ (R = Me, Et) can be made from $Os(PPh_3)_3H(OCOCMe)_2$ and $Na(S_2CNR_2)$;[700] *mer*-$Os(PMe_2Ph)_3(S_2CNMe_2)Cl$ is made from *mer*-$Os(PMe_2Ph)_3$ and $S_2CNMe_2^-$, and the *fac* isomer is made from the *mer* with $K_2(S_2COEt)$. Configurations were obtained from ^1H NMR spectra.[412]

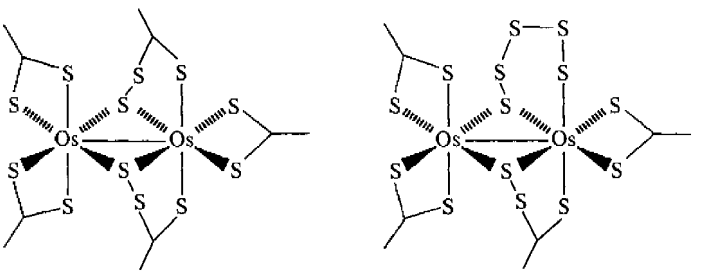
The stable osmium(II) species $Os(S_2CNR)_2(PPh_3)_2$ (R = Me, Et) are made from $OsH(OCOCF_3)(PPh_3)_4$ and $Na(S_2CNMe_2)$.[700] Reaction of *mer*-$Os(PMe_2Ph)_3Cl_3$ with $Na_2(CNMe_2)$ yields *mer*- and *fac*-$Os(PMe_2Ph)_3(S_2CNMe_2)Cl$ and *cis*-$Os(PMe_2Ph)_2(S_2CNMe_2)_2$.[412]

(ii) Osmium(III)

A number of osmium(III) dithiocarbamates are known. The diethyl complex $Os(S_2CNEt_2)_3$ is made by reaction of $(NH_4)_2[OsCl_6]$ and $Na(S_2CNEt_2)$.[350,699] The molecule contains diastereotopic methylene protons and, from a study of the ^1H NMR spectra over a temperature range, rate constants were calculated from the metal-centred optical inversion of the complex.[350] The magnetic moment is 1.61 BM at 25 °C.[350] The dimeric species $Os_2(S_2CNMe_2)_5Cl$ is made from $(NH_4)_2[OsCl_6]$ and $Na(S_2CNMe_2)$.[350]

(iii) Osmium(IV)

The osmium(IV) complex $Os(S_2CNEt)_4$ is also made from the reaction of $(NH_4)_2[OsCl_6]$ with $Na(S_2CNEt_2)$,[699] whilst BF_3 reacts with $Os(S_2CNEt_2)_3$ in dichloromethane to give the paramagnetic $[Os(S_2CNEt_2)_3]BF_4$.[350] In solution $[Os(S_2CNEt_2)_3]PF_6$ (prepared in similar fashion[702]) shows a monomer–dimer equilibrium which has been studied by ^1H NMR and cyclic voltammetry. The X-ray crystal structure of $[Os_2(S_2CNEt_2)_6](PF_6)_2 \cdot nCH_2Cl_2$ (n = 1 or 2) shows the osmium atoms to



have distorted pentagonal bipyramidal coordination such that two sulfur atoms of two dithiocarbamato ligands bridge the metal atoms, one sulfur atom occupying the axial position of one pentagonal bipyramid and the equatorial position of the other. The Os···Os distance of 3.682(1) Å is too long for there to be significant metal–metal interaction. The mean Os—S distance is 2.415(3) Å.[701]

The diamagnetic and apparently seven-coordinate species $Os(S_2CNEt_2)_3X$ (X = Cl, I) were prepared from $Os(S_2CNEt_2)_3$ with HCl and I_2 respectively, and the chloro complex reacts with PPh_3 or MeCN (L) to give $Os(S_2CNEt_2)_3L$, also diamagnetic.[350] Reaction of $Os_2(OAc)_4Cl_2$ with $Na(S_2CNMe_2)$ gives $Os(S_2CNMe_2)_2Cl_2$.[105]

The diamagnetic μ-nitrido species $Os_2N(S_2CNEt_2)_5$ formally contains osmium(IV) and is considered on p. 563. For *fac*-$Os(PMe_2Ph)_3(S_2CNMe_2)(OEt)$, see p. 596.

46.7.4.2 Trithiocarbamates

The first trithiocarbamato complexes to be made were of osmium, and all these complexes are binuclear. In $[Os_2(S_3CNEt_2)_2(S_2CNEt_2)_3]BPh_4$, made from $(NH_4)_2[OsCl_6]$ and $Na(S_2CNEt_2)$ as a by-product in the synthesis of $Os(S_2CNEt_2)_3$, the 'extra' sulfur in $(S_3CNEt_2)^-$ has a bridging role (Figure 35a).[702]

(a) (b)

Figure 35 Structure of (a) $[Os_2(S_3CNEt_2)_2(S_2CNEt_2)_3]BPh_4$ and (b) $Os_2(S_5)(S_3CNEt_2)(S_2CNEt_2)_3$[703]

The mean Os—S (bridge) distances are 2.28 Å and mean Os—S (terminal dithiocarbamate) distances 2.44 Å. The Os···Os distance is 2.791 Å indicating metal–metal interaction which presumably accounts for the observed diamagnetism.[702] Reaction of elemental sulfur with $Os(S_2CNR_2)_3$ (R = Me, Et) in dimethylformamide gives $[Os_2(S_3CNR_2)_2(S_2CNR_2)_3]^+$ and $Os_2(S_5)(S_3CNR_2)(S_2CNR_2)_3$.[703] The X-ray crystal structure of $[Os_2(S_3CNMe_2)_2(S_2CNMe_2)_3]PF_6$ has a very similar structure to that of $[Os_2(S_3CNEt_2)_2(S_2CNEt_2)_3]BPh_4$, again with an Os···Os distance of 2.8782(1) Å and one Os—S (bridge) distance of 2.273 Å. In $Os_2(S_5)(S_3CNEt_2)$-$(S_2CNEt_2)_3$ (Figure 35b) there is a 'half-bridging' cyclic S_5^{2-} ligand, again with an Os···Os distance of 2.785 Å, while the Os—S (bridge) distance is 2.273 Å and the S_5 ring has a mean S—S distance of 2.06. Å.[703] Finally, in the selenodithiocarbamato species $[Os_2(SeS_2CNMe_2)_2(S_2CNMe_2)_3]PF_6$ there is an arrangement similar to that found in the trithiocarbamato analogue as in Figure 35(a) but with seleno instead of thio bridges.[704a]

The Os···Os distance is 2.836(1) Å and the mean Os—Se distance is 2.373 Å. The complex is made from red selenium and $Os(S_2CNEt_2)_3$.[704a]

46.7.4.3 Alkyl dithiocarbonato complexes

There are a few examples of these with phosphine coligands: $K(S_2COEt)$ will react with *mer*-$Os(PMe_2Ph)_3X_3$ (X = Cl, Br) to give *mer*-$Os(PMe_2Ph)_3(S_2COEt)X$, and *cis*-$Os(PMe_2Ph)_2$-$(S_2CNMe_2)(S_2COEt)$ is obtained from *mer*-$Os(PMe_2Ph)_3(S_2CNMe_2)Cl$ and $K(S_2COEt)$. The structures were derived from the ^1H NMR spectra.[412]

46.7.4.4 Alkyl- and aryl-phosphinodithionates

Reaction of *mer*-$Os(PMe_2Ph)_3Cl_3$ and $Na(S_2PMe_2)$ or $NH_4(S_2PPh_2)$ gives *cis*-$Os(PMe_2Ph)_2(S_2PR_2)$ (R = Me, Ph); slight variation of reaction conditions gives *mer*-

$Os(PMe_2Ph)_3(S_2PR_2)Cl_2$. From the methyl complex on recrystallization *trans*-$Os(PMe_2Ph)_2(S_2PMe_2)Cl_2$ and *mer*-$Os(PMe_2Ph)_3(S_2PMe_2)Cl$ can be obtained.[412] Reaction of $(2,4\text{-}Me_2C_6H_3)_2P(S)SH$ (HL) with $(NH_4)_2[OsCl_6]$ gave OsL_3; ESR data indicate distortion from octahedral symmetry.[704b]

46.7.5 Dithiolene Complexes

This is a largely unexplored area of osmium chemistry (in contrast to the situation for iron).

The two best characterized examples are $(Ph_4P)_3[Os(mnt)_3]$ (mnt = *cis*-1,2-dicyanoethylene-1,2-dithiolate), made from $[OsBr_6]^{2-}$ and the sodium salt of the ligand with $Na_2S_2O_4$;[85] $Os(tdt)_3$ (tdt = toluene-3,4-dithiol), a black material made from the liand and $[OsBr_6]^{2-}$ in base, and $(Me_4N)[Os(tdt)_3]$ for which a similar reaction is used but sodium dithionite is used as reducing agent.[705] The ESR spectrum of $[Os(mnt)_3]^{3-}$ has been measured[85] and also IR and electronic spectra on the tdt complexes.[705] Cyclic voltammetric studies on $Os(tdt)_3$ show that the redox system in equation (10) exists.[705]

$$Os(tdt)_3^{2-} \rightleftharpoons Os(tdt)_3^{-} \rightleftharpoons Os(tdt)_3 \rightleftharpoons Os(tdt)_3^{+} \quad (10)$$

An allegedly square planar complex OsL_2 (L = dithiobenzil) was claimed in 1964[706] but was later that year reformulated as the octahedral tris complex OsL_3.[707] No clear preparative details were given of this red complex, but the electronic spectrum and electrical conductance were later reported.[708]

Complexes between OsO_4 and 2,3-quinoxalinedithiol (2:1 and 1:4) have been shown to exist; both were isolated but not analyzed.[709] Further investigation is clearly desirable.

46.7.6 Sulfur Dioxide Complexes

It is surprising that so few of these have been reported for osmium.

The reaction of $[Os(NH_3)_5H_2O]^{3+}$ and $NaHSO_3$ with SO_2 at 80 °C gives $[Os(SO_2)(NH_3)_5]Cl_2$, the IR spectrum of which was measured.[90]

There is also a cyclohexylphosphine (PCy_3) complex: $Os(SO_2)(PCy_3)_2XH(CO)$, made from SO_2 and $Os(PCy_3)_2XH(CO)$ in benzene.[710]

46.7.7 Di- and Mono-thio-β-diketonates

As with much of osmium sulfur chemistry the data are scattered and incomplete; the best characterized complex is the dithioacetylacetonate complex $Os(sacsac)_3$.

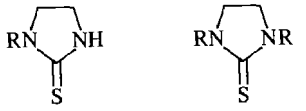
46.7.7.1 Dithioacetylacetonate (4-thiolpent-3-ene-2-thione, $S_2C_5H_7^-$, sacsac)

The reaction between OsO_4 and acetylacetone with H_2S gives dark brown glossy plates of $Os(sacsac)_3$. IR and electronic spectra were recorded for the complex, as well as the ESR spectrum.[711] The magnetic susceptibility from 110 to 290 K shows that μ_{eff} is 1.65 BM at the latter temperature.[703] Polarographic reduction of $M(sacsac)_3$ (M = Ru, Os) shows reversible reduction at −0.01 and −0.151 V (vs. Ag/AgCl electrode),[658,711] while for $Os(acac)_3$ the potential is −1.244 V,[658] *i.e.* $Os(sacsac)_3$ is more easily reduced than $Os(acac)_3$, consistent with the 'softer' nature of sacsac as against acac, but less easily reduced than $Ru(sacsac)_3$, again as to be expected since ruthenium is a second row element.

A dark green complex, $Os(S_2C_6H_9)_3$, is made from 1-ethoxy-1-thiolobut-1-ene-3-thione and $[OsCl_6]^{2-}$.[712]

46.7.7.2 Monothio-β-diketonate complex

Monothiobenzoylmethane reacts with $[OsCl_6]^{2-}$ in aqueous ethanol to give the black complex $Os(SOC_{15}H_{12})_3$, which has a magnetic moment of 1.66 BM at room temperature. The same prepara-



tion but with sodium acetate yields the black $Os(SOC_{15}H_{12})_4$, with a magnetic moment of 1.89 BM.[713]

46.7.8 Monothione Complexes

For the imidazolidine-2-thiones, which have received the most extensive study in this class of complexes, the monosubstituted imidazolidines stabilize osmium(III) while the disubstituted ones stabilize osmium(IV) and osmium(VI).[714]

46.7.8.1 Imidazolidine-2-thiones

The reaction of (I) or (II) with OsO_4 in aqueous ethanol gives $[OsL_6]^{3+}$ (L = (I), R = H, Me, Et)[714,715] and *trans*-$[OsL_2L_4]^{2+}$[716] (L = II, R = Me, Et); IR and electronic spectra were measured[714,715,717] and the kinetics of the reactions followed.[715,717]

The X-ray crystal structure of *trans*-$[OsL_4Cl_2](ClO_4)_2$ (L = II, R = Et, *i.e.* the *N,N'*-diethylimidazolidine-2-thione) confirms the *trans* configuration (Os—Cl = 2.351 Å, mean Os—S = 2.386 Å). The reaction is curious, for the chloro ligands were apparently derived from $HClO_4$ since the reaction was of OsO_4, the ligand and aqueous $HClO_4$. The osmyl complex *trans*-$[OsO_2L_4](ClO_4)_2$ can also be isolated from the reaction mixture.[716]

46.7.8.2 Thiazolidine-2-thione

This ligand (L) will react with OsX_3 (X = Cl, Br) to give OsL_3X_3; IR and electronic spectra of these were measured.[718]

46.7.9 Thiolato Complexes

46.7.9.1 Osmium(III)

The complex $Os(SC_{10}H_{13})_4(CNMe)$ is made from $OsCl_3$, the lithium salt of 2,3,5,6-tetramethylbenzenethiolate and 2,3,5,6-tetramethylphenyl sulfide; it is green-yellow. The X-ray crystal structure of the ruthenium salt shows it to be trigonal bipyramidal, with the acetonitrile in the axial position. The osmium complex is isomorphous; it would seem therefore to be the only example so far reported of a trigonal bipyramidal osmium(IV) complex. In an attempt to make a complex of lower coordination number 2,4,6-triisopropylbenzenethiolate ($SC_{15}H_{23}$) was used but the complex was still pentacoordinate, *i.e.* $Os(S_{15}H_{23})_4(MeCN)$.[719]

46.7.9.2 Osmium(IV)

The species $Na[Os(SNC_4H_{10})(OH)_4]$ and $Os(SNC_8H_{18})_2(OH)_2$ have been claimed, OsO_4 with dimethylaminoethanethiol giving the former[720] while diisopropylaminoethanethiol with 'osmic acid' gives the latter, which supposedly contains osmium(IV) (μ_{eff} is 1.2 BM at room temperature).

46.7.10 Dithiocarboxylate and Thiocarboxylate Complexes

There is some work on dithioformato complexes, but clearly thiocarboxylate osmium chemistry is an area in need of further study.

Complexes of the dithioformate ligand S_2CH^- have been made from $Os(PPh_3)_4H_3$ and CS_2. By analogy with the ruthenium analogue (for which an X-ray crystal structure has been obtained) a

structure involving bidentate S_2CH^- ligands *cis* to each other was proposed for $Os(PPh_3)_2(S_2CH)_2$. Reaction of CS_2 with $Os(PR_3)_3HX(CO)$ (PR_3 = PMe_2Ph, $PMePh_2$, PPh_3; X = Cl, Br) gives two forms of $Os(PR_3)_2(S_2CH)X(CO)$; in one the sulfur atoms are thought to be *trans* to the PR_3 ligands, and in the other the halide and PR_3 ligands are *trans* to the sulfur atoms.[424]

A number of complexes of *p*-chlorodithiobenzoate ($S_2C_7H_4Cl^-$; L) have been claimed, involving osmium(III) and osmium(IV); OsL_3 was isolated.[721] There is also $Os(SO_6C_{16}H_8)_2 \cdot 2H_2O$, a complex of 5,5′-thiodisalicylic acid, made from the ligand and 'osmic acid', and which has a magnetic moment of 1.35 BM at room temperature.[722]

46.7.11 Thiourea Complexes

The principal oxidation states involved in the rather few thiourea (thio) complexes which have been studied are II, III and (as the osmyl complex) VI. In no case is the mode of bonding properly established. In view of the uncertainty surrounding some of these species we consider both unsubstituted and substituted complexes together, using the apparent oxidation state for classification purposes.

46.7.11.1 Osmium(II)

Reduction of $[Os(thio)_6]^{3+}$ with $[Cr(H_2O)_6]^{2+}$ gives $[Os(thio)_6]^{2+}$.[508]

The reaction of thiourea with $[Os(NO)Cl_5]^{2-}$ is said to give a brown, seven-coordinate 'association complex', $K_2[Os(NO)(CN)_5 \cdot thio]$.[723] The X-ray photoelectron spectrum of $OsL_2 \cdot Cl_2$ (L = diphenylthiourea) has been measured.[724]

46.7.11.2 Osmium(III)

It appears that the main reaction product of OsO_4 with thiourea is $[Os(thio)_6]^{3+}$, together with formamidine disulfide, *via* initial formation of $[OsO_2thio_4]^{2+}$.[508,725] The earlier-reported species $[Os(thio)_6](OH)Cl_3$[726] is likely to have contained the osmium(III) species. Salts of $[Os(thio)_6]^{3+}$ with $[Cr(NH_3)_2(SCN)_4]^-$ and $[Cr(SCN)_6]^{3-}$ have been isolated using OsO_4, thiourea and the complex anion in HCl.[727,728] $[Os(thio)_6](SnCl_3)_2Cl$ has been reported;[52] ESCA data on $[Os(thio)_6]Cl_3$ have been given.[616]

The OsO_4–thiourea reaction has recently been investigated kinetically.[726,729]

Reaction of $[Os(NO)(CN)_5]^{2-}$ in hydroxide (which presumably generates $[Os(NO_2)(CN)_5]^{4-}$) and thiourea gives $K_2[Os(thio)(CN)_5]$.[723,730] The X-ray photoelectron spectrum of OsL_2Cl_3 has been measured (L = diphenylthiourea).[724]

46.7.11.3 Osmium(VI)

The osmyl-complex $[OsO_2thio_4]SO_4$ (brown, made from OsO_4 and the ligand in H_2SO_4)[508] and a dark green osmyl complex, made from *N*-α-pyridyl-*N*′-benzoylthiourea and *trans*-$K_2[OsO_2(OH)_4]$, have been reported.[731]

For ethylenethiourea complexes see imidazoline-2-thione, p. 607.

46.7.12 Miscellaneous S,S Donor Ligands

The diisopropyldithiophosphate complex, made by reaction of the ammonium salt of the ligand with $[OsCl_6]^{2-}$, has a dimeric structure with two bidentate $(Pr^iO)_2PS_2^-$ groups per metal atom and two bridging Pr^iP—S—S ligands, according to a preliminary X-ray study.[732]

Complexes of the form $Os(mdtp)_3$ and $Os(ptp)_3$ (mdtp = bis(2-methyl-5-chlorophenyl)dithiophosphinate and ptp is the corresponding *p*-tolyl derivative) were made from $[OsCl_6]^{2-}$ and the sodium salt of the ligand; the ESR data for these species were very briefly described. The complex $(Os(ptp)_2(PPh_3)_2]Cl$ and $[Os(ptp)_2phen]Cl$ were also prepared.[733]

46.8 SELENIUM- AND TELLURIUM-CONTAINING LIGANDS

There are relatively few of these, and it is obviously an area worthy of further investigation, as is that of osmium–tellurium chemistry.

46.8.1 Selenido Complexes

Reaction of $Os(PPh_3)_3(CO)_2$ with Se_8 yields $Os(\eta^2\text{-}Se_2)(PPh_3)_2(CO)_2$, the crystal structure of which shows a distorted octahedral structure. The side-bonded Se_2 ligand (Os—Se = 2.5403(8) and 2.5526(7) Å) with Se—Se = 2.321(1) Å) is *trans* to two carbonyl ligands (mean Os—C = 1.874 Å); the two phosphine ligands are *trans* to each other (mean Os—P = 2.406 Å).[693]

46.8.2 Selenoether Complexes

Reaction of $MeSe(CH_2)_2SeMe$ and also of Me_2Se with HX and OsO_4 gives $OsO_2X_2\{MeSe(CH_2)_2SeMe\}$ (X = Cl, Br); IR, electronic and ^1H NMR spectra were measured.[514]

46.8.3 Diethylselenocarbamato Complex

The species $Os(Se_2CNEt_2)_3$ is obtained from $[OsBr_6]^{2-}$ and $(NH_4)(Se_2CNEt_2)$. The complex has a magnetic moment of 1.63 BM at room temperature.[734]

46.8.4 Imidazolidine-2-selones

Reaction of these with OsO_4 in acid solution gives $[OsL_6]^{3+}$ (L = $SeN_2C_3H_5R$; R = H, Me, Et); the kinetics of the reactions were studied as well as the IR spectra of the complexes.[735]

46.8.5 Tellurium-containing Complexes

Attempts to prepare $OsO_2X_2(TeMe_2)$ (X = Cl, Br) from OsO_4, HX and Me_2Te failed.[514]

46.9 HALOGENS AS LIGANDS

The chemistry of osmium fluorides and fluoro complexes differs sufficiently from that of the chloro, bromo and iodo species to warrant separate treatment here. The early review of Canterford and Colton is still useful for the general halide chemistry of the element.[736]

46.9.1 Fluorides and fluoro complexes

Oxidation states IV to VIII inclusive are represented in the fluorine chemistry of osmium, as compared with III to VI for ruthenium and II and III for iron. Thus the fluorides of the iron–ruthenium–osmium triad well exemplify the greater tendency of second and third row elements to higher oxidation states with π-donor ligands.

The oxofluorides of osmium, amongst others, have recently been reviewed;[731] we have already dealt with them on p. 584.

46.9.1.1 Osmium(IV)

The tetrafluoride OsF_4 is not a discrete molecular species and so is not considered in detail here: it is a yellow material, prepared by reduction of $[OsF_5]_4$ with hydrogen over platinum gauze under UV irradiation at 50 °C.[738]

A number of salts of $[OsF_6]^{2-}$ are known: the free acid[739] (in aqueous solution only), the hydrazinium,[740] tridodecylammonium,[741] sodium,[742] potassium,[739,743] rubidium[739] and cesium[739,743] salts have been isolated. The general method of preparation is to treat the corresponding $[OsF_6]^-$ salt with aqueous alkali;[743] a convenient way of making $K_2[OsF_6]$ is to fuse $K_2[OsX_6]$ (X = Cl, Br or I) with KHF_2 at 400 °C.[744] They are white solids giving stable aqueous solutions.

Lattice parameters have been measured for the sodium, potassium and cesium salts; the sodium salt exists in a metastable orthorhombic form and a stable hexagonal form,[742] while $K_2[OsF_6]$ and $Cs[OsF_6]$ have hexagonal structures related to that of $K_2[GeF_6]$.[739] The IR stretching frequency (ν_3, F_{1u}) of $K_2[OsF_6]$ is 548 cm^{-1}.[745] Electronic spectra have been measured[746] and assigned for solid $K_2[OsF_6]$ and $Cs_2[OsF_6]$; for the $[OsF_6]^{2-}$ ion $10Dq$ is given as 26 000 cm^{-1}.[746,747]

Studies on the magnetic susceptibility of $K_2[OsF_6]$ and $Cs_2[OsF_6]$ from 89 to 291 K have been carried out and show that the molar susceptibility (χ_M) is essentially independent of temperature over this range (see Table 27).[748] The essential invariance of χ_M with temperature has been discussed.[748,749] It would be of considerable interest to study, as has been done for $K_2[OsX_6]$ (X = Cl, Br, I), the effect on the magnetic susceptibility of $M^I_2[OsF_6]$ salts of diluting them in isomorphous diamagnetic host lattices such as $M^I_2[PtF_6]$.

Table 27 Magnetic Data on $[OsX_6]^{2-}$ Complexes[748]

Complex	*Temperature range (K)*	*χ_a over same range (10^{-6} cgsu)*	*μ_{eff} at 300 K (BM)*
$K_2[OsF_6]$	88.9–291.0	713–713	1.31
$Cs_2[OsF_6]$	89.8–278.5	957–937	1.50
$K_2[OsCl_6]$	90–300	941–941	1.51
$Cs_2[OsCl_6]$	91.0–296.5	1257–1162	1.67
$K_2[OsBr_6]$	87.4–295.3	617–603	1.21
$Cs_2[OsBr_6]$	98.0–295.4	1392–1285	1.76
$K_2[OsI_6]$	88.4–296.2	877–789	1.38
$Cs_2[OsI_6]$	90.7–294.4	1191–1132	1.65

Studies on the ^{19}F NMR spectra of solid $M_2[OsF_6]$ (M = K, Rb, Cs) suggest that the anions have distorted structures.[750]

(*i*) *Mixed fluorohalo osmates(IV), $[OsF_nX_{6-n}]^{2-}$*

Many such complexes have been prepared. The fluorochloro series $[OsF_nCl_{6-n}]^{2-}$ has been made from $[OsCl_6]^{2-}$ and BrF_3; both *cis* and *trans* forms of $[OsF_4Cl_2]^{2-}$ were isolted as was *trans*-$[OsF_2Cl_4]^{2-}$.[751]

Recently the reaction of BrF_5 and $[OsCl_6]^{2-}$ has been shown to give all five members of $[OsF_nCl_{6-n}]^{2-}$ with the *cis* isomers for $n = 4$ and 2 and the *fac* isomer of $[OsF_3Cl_3]^-$; reaction of Cl^- with $[OsF_5Cl]^{2-}$ and with *cis*-$[OsF_4Cl_2]^{2-}$ gives *trans*-$[OsF_4Cl_2]^{2-}$, *trans*-$[OsF_2Cl_4]^{2-}$ and *mer*-$[OsF_3Cl_3]^{2-}$. The isomers were separated by ion exchange and their vibrational spectra measured;[752] in earlier work vibrational spectra and unit cell dimensions were listed for some isomers as the potassium salts.[751]

Most members of the series $[OsF_nBr_{6-n}]^{2-}$ and $[OsF_nI_{6-n}]^{2-}$ have been isolated from the reaction of $[OsX_6]^{2-}$ (X = Br, I) and tridodecylammonium fluoride.[753] The salt *trans*-$Cs[OsF_4ClBr]$, made by reaction of $K_2[OsF_5Cl]$ with HBr followed by ionophoresis and addition of cesium ion,[751] has been studied by single crystal X-ray analysis. The mean Os—F distance is 1.94 Å, with Os—Cl = 2.43(1) and Os—Br = 2.49(1) Å.[754]

(*ii*) *Miscellaneous osmium(IV) fluoro complexes*

Reaction of OsF_6 with PF_3 at −196 °C gives a yellow compound, amorphous to X-rays, giving analyses corresponding to $OsF_4 \cdot 2PF_3$. On the basis of IR data the formulation *trans*-$OsF_4(PF_3)_2$ was suggested. The essentially diamagnetic nature of the material (μ_{eff} = 0.3 BM at 300 K) is curious, but possibly it arises from the tetragonal distortion of the complex if it is indeed an osmium(IV) complex containing coordinated PF_3 ligands.[755]

46.9.1.2 Osmium(V)

This is an unusual oxidation state for osmium. We include osmium pentafluoride in our coverage here since it is a discrete molecular species. Osmium pentafluoride, $[OsF_5]_4$, is made by the reduction of OsF_6 with iodine and IF_5 at 55 °C[756] or from the action of silicon on OsF_6.[738] It is a blue-green solid melting at 70 °C to a viscous green liquid which becomes bluer as the temperature rises, boiling at 233 °C to a colourless vapour.[756]

The X-ray crystal structure of the solid shows it to be tetrameric in the solid state with a structure closely akin to that of $[RuF_5]_4$, the metal atoms lying at the corners of a rhombus and linked by *cis* fluoro bridges (Os—F (bridge) = 2.03 Å, mean Os—F(bridge)—Os angle = 137 °). The mean Os—F terminal distance is 1.84 Å (Figure 36).

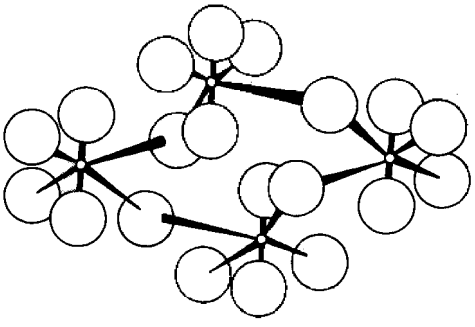


Figure 36 Structure of $[OsF_5]_4$ (reproduced with permission from J. H. Canterford and R. Colton, 'Halides of the Second and Third Row Transition Metals', p. 20, copyright 1968 Wiley)

The substantially bent Os—F(bridge)—Os angle is in agreement with the π-bonding hypothesis put forward by Canterford and Colton.[758] In pentafluorides $[MF_5]_4$ containing *cis* fluoro bridges, the degree of bridge fluoro-to-metal π bonding will be at a maximum if the M—F(bridge)—M angle is 180 ° and M has a d^0 configuration (*e.g.* M = Nb, Ta). As the *d* orbital electron occupancy increases with concomitant lower bridge F to M π bonding the angle is observed to decrease, from d^1 species (Mo, W), d^2 (Tc, Re), to d^3 (Ru, Os) and beyond; thus, in $[OsF_5]_4$, it is likely that such π bonding is of little importance.[758]

Magnetic interactions in $[OsF_5]_4$ have been studied by susceptibility and neutron diffraction measurements; it is magnetically ordered at $T_N = 6$ K.[759] The magnetic moment varies from 1.73 BM at 101.5 K to 2.06 BM at 295.4 K.[756]

(*i*) *Salts of* $[OsF_6]^-$

A number of salts of this ion are known; those of lithium,[760] sodium,[743] potassium,[742] rubidium,[761] cesium,[743] silver,[743,761] NO^+,[762] XeF^+ and $Xe_2F_3^+$[763] and BrF_3^+.[764] The alkali metal salts are made by reaction of a 1:1 $OsBr_4$, MBr mixture with fluorine(Li,[760] Na[742]) or with BrF_3 (K[742], Rb,[761] Cs[742]). These are colourless, decomposing in moist air, and in alkaline solution giving $[OsF_6]^{2-}$. These salts of non-metallic cations are made from OsF_5 or OsF_6 (NO^+,[762] Xe salts[763]).

Unit cell parameters have been measured for the alkali metal salts, which have rhombohedral structures.[760,761] A single crystal X-ray of $K[OsF_6]$ shows this to have a slightly distorted octahedral structure with a mean Os—F distance of 1.82 Å.[765] Raman spectra of $(NO)[OsF_6]$ and $Xe_2F_3[OsF_6]$ have been measured[763] and are listed in Table 28. From the electronic reflectance spectrum of $Cs[OsF_6]$ a value of 36 000 cm^{-1} was obtained for $10Dq$.[747] Magnetic susceptibility data for $K[OsF_6]$ and $Cs[OsF_6]$ show that the magnetic moment is essentially invariant from 115 to 295 K, giving μ_{eff} 3.34 and 3.23 BM for the potassium and cesium salts respectively.[766]

46.9.1.3 Osmium(VI)

(*i*) *Osmium hexafluoride*

OsF_6 is made by the direct fluorination of the metal;[767–769] as noted on p. 612 it now seems quite clear[767,769] that the 'OsF_8' of the early literature[770] is in fact OsF_6. It is a bright yellow solid, melting at 33.9 °C and boiling at 47.5 °C with a triple point at 33.4 °C (at 474.5 mmHg);[768] there is a phase transition at 1.4 °C.[771] In water it disproportionates to OsO_4 and $[OsF_6]^{2-}$.

Electron diffraction data on the vapour at −39 °C show the molecule to be octahedral in the gas phase with an Os—F distance of 1.831(8) Å; it is interesting to note that the Os—F distance for this d^2 species is very close to the value of 1.833(3) Å observed in WF_6 (d^0) and 1.830(8) Å in IrF_6 (d^3).[772] It has been plausibly suggested that this constancy of distance is a consequence of π donation from the fluoro ligands to the metal decreasing from W to Ir because of increased d electron occupancy, this effect being counterbalanced by the shrinkage of the M^{VI} size from left to right brought about by shielding effects.[773] In the solid state OsF_6 is cubic at room temperatures, undergoing a transition at 1.4 °C to a form of lower symmetry (probably orthorhombic).[772] Thermodynamic data have been calculated for the compound on the basis of vapour pressure data.[768]

There has been much work on the vibrational spectroscopy of the molecule; the best data for the vibrational frequencies are given in Table 28,[774] based on the IR spectrum of the gas and the Raman spectra of the liquid[775] and gas.[775–777] Electronic Raman spectra of a solution of OsF_6 in MoF_6 have recently been measured.[778] The unusual breadth and low intensity of the $\nu_2(F)$ and low intensities of combinations involving ν_2 suggest[774–777] that a dynamic Jahn–Teller effect is operative for this t_{2g}^2 molecule. There have been many force constant treatments for the molecule[774,779] and determinations of Coriolis coupling constants.[780,781] Electronic spectra of the gas[782] and its solutions in MoF_6[778] have been measured and assignments proposed. Magnetic susceptibility data were measured from 117 to 297 K and show that the Curie–Weiss law is obeyed ($\theta = 66°$, $\mu_{eff} = 1.47$ BM at 267.8 K).[769] Theoretical interpretions of these data have been given.[783,784]

Table 28 Vibrational Spectra for $[MX_6]^{n-}$ Complexes

Complex		ν_1 (A_{1g})	ν_2 (E_g)	ν_3 (F_{1u})	ν_4 (F_{1u})	ν_5 (F_{2g})	ν_6 (F_{2u})	*Ref.*

[a] Solid. [b] Gas. [c] Solid and solution. [d] Solution. [e] On $[Co\ en_3][OsX_6]$.

The ^{19}F NMR resonance has been measured from 115 to 245 K at different field strengths of solid OsF_6 and spin–lattice relaxation times determined.[785] The electron affinity of OsF_6 has been compared with those of other metal hexafluorides.[762,786,787] The Mössbauer spectrum has been recorded.[184]

The apparently heptacoordinate $(NO)[OsF_7]$ has been made from FNO and OsF_6; it has a cubic structure.[762]

46.9.1.4 Osmium(VII)

The heptafluoride OsF_7 is made by fluorination of the metal at 600 °C under a fluorine pressure of 400 atm. The IR spectra suggest that the complex has a pentagonal bipyramidal (D_{5h}) structure. The magnetic susceptibility was measured from 90 to 195 K and, as with $[OsF_6]^{2-}$ salts, the moment is essentially invariant with temperature over this range ($\mu_{eff} = 1.08$ BM).[788]

46.9.1.5 Osmium(VIII)

The octafluoride OsF_8 was claimed in 1913 to be the product of reaction of Os with fluorine[770] but clearly OsF_6 had been made.[767,769] It is said that some OsF_8, however, may be produced by reaction of osmium with fluorine at very high pressures.[788]

For oxo fluorides and oxo fluoro complexes see p. 584, 588 and 596.

46.9.2 Chloro, Bromo and Iodo Complexes

There is only one binary halide, Os_2Cl_{10}, which can be classed as a 'complex' in the sense that it has a discrete molecular structure, and we consider it on p. 615 below. In this section we consider unsubstituted halo complexes $[OsX_6]^{n-}$, mixed species $[OsX_nY_{6-n}]^{x-}$ (X and Y both halides) and aqua and hydroxo halides. Other halo species substituted with other ligands are considered under the section dealing with the substituting ligand (*e.g.* oxo halo species on p. 584, nitrido halo complexes on p. 563, halo ammines on p. 529).

Although there is a small chemistry of $[OsX_6]^{3-}$ and an even smaller chemistry of $[OsCl_6]^-$, it is the IV oxidation state that predominates in the chloro, bromo and iodo chemistry of osmium, whereas for ruthenium it is probably true to say that the chemistry of $[RuX_6]^{3-}$ is more extensive, or at least has been more extensively investigated, that that of $[RuX_6]^{2-}$. Much work has been done on the mixed halo species $[OsX_xY_{6-n}]^{2-}$.

There is a short review on osmium halo complexes in solution.[789] For carbonyl halides of osmium, see p. 973 of ref. 16.

46.9.2.1 Osmium(III)

There are very early reports of the potassium and ammonium salts of $[OsCl_6]^{3-}$, made from $[OsO_3N]^-$ and HCl or for OsO_4 with NH_4Cl and H_2S,[5] but the compounds were not fully characterized. Reduction of $[OsX_6]^{2-}$ in acid solution with silver powder gives solutions thought to contain $[OsX_6]^{3-}$ (X = Cl, Br, I),[790] and recently the salts $[Co(en)_3][OsX_6]$ have been isolated from such solutions.[791] The potassium salt $K_3[OsBr_6]$ has been isolated by electrolytic reduction of $[OsBr_6]^{2-}$;[792] the $[OsBr_6]^{2-}/[OsBr_6]^{3-}$ couple is +0.31 V in 4 M HBr (*vs.* NHE).[793]

Vibrational spectroscopic data for $[OsX_6]^{3-}$ (X = Cl, Br, I) are given in Table 28,[791] and there are ESR data on apparently uncharacterized $[OsCl_6]^{3-}$ species.[794,795]

Dimeric $[Os_2X_8]^{2-}$ (X = Cl, Br) complexes have recently been made.

46.9.2.2 Osmium(IV)

Salts of $[OsX_6]^{2-}$, especially the chloride as $Na_2[OsCl_6]\cdot nH_2O$ (conveniently soluble in water or polar organic solvents), as $K_2[OsCl_6]$ or $(NH_4)_2[OsCl_6]$, are good precursors for preparations of other osmium complexes; indeed, $Na_2[OsCl_6]\cdot nH_2O$ rivals OsO_4 as a useful starting material.

(*i*) *Unsubstituted $[OsX_6]^{2-}$ species*

For $[OsCl_6]^{2-}$ the free acid[796] and salts with a variety of organic cations are known,[797–800] and the sodium,[801] potassium,[798,802] rubidium,[803] cesium[804] and ammonium[801,805] salts together with a number of heavy metal salts (*e.g.* silver and thallium(I)[806]). The best method of preparation is from OsO_4 and concentrated HCl in the presence of a reducing agent such as ascorbic acid,[798] iron(II) chloride[805] and the appropriate cation. The $[OsBr_6]^{2-}$ ion is obtainable as the free acid in solution[804] and salts of organic cations[797,807,808] as well as sodium,[506] potassium,[804,808] rubidium,[637] cesium[803,804] and ammonium,[809] while $[OsI_6]^{2-}$ is similarly represented by the acid in solution (and also, apparently, as a solid isomorphous with $(NH_4)_2[OsI_6]$[810]), with organic cations[811] and as the potassium[812–814] and ammonium[204] salts. For $[OsBr_6]^{2-}$ and $[OsI_6]^{2-}$ the acids themselves will reduce OsO_4,[809,814] or $[OsCl_6]^{2-}$ can be refluxed with HI.[813]

There is a single crystal X-ray structure of $(Ph_4P)_2[OsCl_6]$ which shows the mean Os—Cl distance to be 2.332 Å,[815] and unit cell data obtained for a number of cubic salts of $[OsCl_6]^{2-}$ and $[OsBr_6]^{2-}$.[816] In a recent paper correlations between Os—Cl distances and Os—Cl stretching frequencies have been made, and similar data presented for rhenium and iridium chloro species.[817] In particular there have been a number of studies on the Raman spectra, both non-resonance and resonance, of $[OsCl_6]^{2-}$[818–822] as well as electronic[823] and electronic resonance Raman spectra;[824] similar studies have been carried out with $[OsBr_6]^{2-}$[818,819,823–826,828,829] and $[OsI_6]^{2-}$[803,821,823,827] (for the latter, magnetic, electronic and Raman spectra and optical activity were also measured[827]). In Table 27 we also

include data on the IR spectra of $[OsCl_6]^{2-}$,[820,828,829] $[OsBr_6]^{2-}$[820] and $[OsI_6]^{2-}$,[791] There have been a number of studies on the electronic absorption spectra of $[OsX_6]^{2-}$ (X = Cl, Br,[790,798,806,811,819,824,830–832] I[811,823,824,831]); vibrational intervals were located in the luminescence spectra of solid $K_2[OsCl_6]$ doped into $K_2[PtCl_6]$.[832]

There have also been NQR[807,834] and ESCA[427] studies on $K_2[OsX_6]$ (X = Cl, Br) and Mössbauer work on $K_2[OsCl_6]$.[184] An MO description of the bonding in $[OsCl_6]^{2-}$ has been given.[835]

(a) Magnetic susceptibility data. The magnetic properties of $K_2[OsX_6]$ and $Cs_2[OsX_6]$ (X = F,Cl, Br, I) were first systematically studied by Earnshaw *et al.*, who found relatively little variation in the atomic susceptibility (χ_a) over a wide temperature range (Table 28).[748]

It was assumed from these data that the relative constancy of X_M with temperature arose from high spin–orbit coupling; where significant variation of χ_M did occur with temperature it was suggested that a small amount of paramagnetic impurity (*e.g.* $[OsX_6]^{3-}$) was perhaps responsible.[748] Later work showed that the susceptibilities of $K_2[OsCl_6]$ and $K_2[OsBr_6]$ diluted in the isomorphous diamagnetic host lattice $K_2[PtCl_6]$ or $K_2[PtBr_6]$ were much higher than for the pure salts, and a 'superexchange' mechanism *via* d_π–d_π metal ligand orbitals for the non-dilute systems was proposed to account for these observations.[836–838] Some of these measurements were repeated[808,839] and susceptibility data presented for $(NH_4)_2[OsX_6]$, $(Bu^n{}_4N)_2[OsCl_6]$ and $(Me_4N)_2[OsBr_6]$, and intermediate coupling schemes proposed.[807,840] Theoretical calculations on the basis of a cubic field successfully fitted experimental results for the susceptibility and electronic absorption spectra of $K_2[OsCl_6]$.[841]

(b) Other data for $[OsX_6]^{2-}$. Kinetics of the reaction shown in equation (11) were measured and compared with those for $[IrCl_6]^{2-}$ and $[IrCl_6]^{3-}$;[842] there are also mechanistic studies on the reactions of $[OsCl_6]^{2-}$ with $[Fe(CN)_6]^{4-}$,[843] bromide[844] and iodide.[845] There are recent thermogravimetric and differential thermal analysis data for $M^I{}_2[OsX_6]$ (M = Rb, Cs; X = Br, I).[846]

$$[OsCl_6]^{2-} + H_2O \rightleftharpoons [OsCl_5(H_2O)]^- + Cl^- \qquad (11)$$

The species $OsCl_4 \cdot 2MCl_4$ (M = S,[847] Se, Te[848]) have been reported; their IR spectra suggest that they contain $[OsCl_6]^{2-}$ ions and so they have been formulated as $(MCl_3)_2[OsCl_6]$.[848]

(*ii*) *Mixed halo complexes, $[OsX_nY_{6-n}]^{2-}$*

Species of this type containing the fluoro ligand have already been considered (p. 610).

(a) $[OsCl_nBr_{6-n}]^{2-}$. All the geometrical isomers in this system, made from HBr and $[OsCl_6]^{2-}$, have been identified; ionophoresis,[849] chromatography[850,851] and HPLC[852] have been used, infrared spectra measured of the various complexes[831] and their stability constants determined.[853] Kinetics of exchange for the eighteen possible ligand exchange reactions were investigated by radiometry.[854,855]

(b) $[OsCl_nI_{6-n}]^{2-}$ and $[OsBr_nI_{6-n}]^{2-}$. Members of the former series were made from HI and $[OsCl_6]^{2-}$, and all the isomers were separated chromatographically,[850] whilst ionophoretic methods were used on the HBr–$[OsI_6]^{2-}$ system to give all the isomers. IR spectra of the members of the $Cs_2[OsBr_nI_{6-n}]$ series have been recorded[856a] as have electronic spectra.[856b] Hydrolysis of $[OsCl_nI_{6-n}]^{2-}$ is catalyzed by mercury(II).[857]

(*iii*) *Dimeric osmium(IV) species*

The dimeric salt $(Bu^n{}_4N)_2[Os_2Cl_{10}]$ can be made by heating $(Bu^n{}_4N)[OsCl_6]$ for a short time to 240 °C. The X-ray crystal structure analysis shows a chloro-bridged dimer structure (Os—Cl(bridge) = 2.411(2), mean Os—Cl *trans* to bridge = 2.306, mean Os—Cl *cis* to bridge = 2.301 Å). The Os···Os distance is 3.626(1) Å. The magnetic susceptibility was measured from 94 to 336 K; it obeys the Curie–Weiss law with $\theta = -6$ and $\mu_{eff} = 1.36$ BM (per metal atom).[858] Recently the bromo analogue has been made by refluxing $(Bu^n{}_4N)_2[OsBr_6]$ in trifluoroacetic acid. The structure is very similar to that of $[Os_2Cl_{10}]^{2-}$; the bridging Os—Br distances are 2.544(4) Å, the mean terminal Os—Br distance is 2.454 Å, and the Os···Os distance is 3.788(3) Å. Although there is clearly no direct Os—Os interaction in either of these complexes the magnetic moment μ_{eff} is remarkably low, 0.26 BM at 296 K.[382]

46.9.2.3 Osmium(V)

(i) Salts of $[OsX_6]^-$ (X = Cl, Br)

The tetraphenylarsonium salt is made from Os_2Cl_{10} and $(Ph_4As)Cl$[859] and tetraethylammonium salt from $(Et_4N)[OsX_4(CO)_2]$ (X = Br, I) and Cl_2 at 120 °C;[833] oxidation of $[OsCl_6]^{2-}$ by PbO_2 gives $[OsCl_6]^-$ [860,861] and $SCl_3[OsCl_6]$ can be got from OsO_4 and SCl_2.[861] The redox potential $[OsCl_6]^-/[OsCl_6]^{2-}$ is 0.8 V (*vs.* Hg/Hg_2SO_4).[833]

The X-ray crystal structures of $(Bu^n{}_4)[Oscl_6]$[858] and $(PPh_4)[OsCl_6]$[815] show these to be octahedral, with mean Os—Cl distances of 2.303 and 2.284 Å respectively. The difference is surprising given that only the cation has changed (see also ref. 861), but both are shorter than the Os—Cl distance of 2.332 Å in $(Ph_4P)_2[OsCl_6]$,[815] as expected in view of their higher oxidation states. The magnetic susceptibility of $(Bu^n{}_4N)[OsCl_6]$ over the range 94 to 336 K obeys the Curie–Weiss law (θ = 18 K, μ_{eff} = 3.03 BM)[858] The Raman, resonance Raman and IR spectra of $[OsCl_6]^-$ were recorded (see Table 28).[833]

Attempts to isolate pure salts of $[OsBr_6]^-$ were not successful, but the ion was generated in solution to form $[OsBr_6]^{2-}$ and solid PbO_2, and electronic spectra were recorded. The $[OsBr_6]^-/[OsBr_6]^{2-}$ potential is + 1.20 V.[860]

(ii) Dimeric osmium pentachloride, Os_2Cl_{10}

This is made by reaction of OsF_6 with BCl_3 at − 196 °C[862] or from OsO_4 and SCl_2.[859] The X-ray crystal struture shows it to be a chloro-bridged dimer with a bridging Os—Cl distance of 2.42 Å, and a mean terminal Os—Cl distance of 2.24 Å. The Os···Os distance is 3.63 Å. The magnetic susceptibility over the range 80 to 293 K obeys the Curie–Weiss law (θ = 230, μ_{eff} = 2.54 BM per Os atom). IR, electronic and ESR spectra were also recorded.[862]

(iii) Substituted halo complexes

(a) Aqua and hydroxo species. Recent work on the electrochemical oxidation of *trans*-$[OsO_2Cl_4]^{2-}$ gives evidence for the existence of labile $[Os^{III}Cl_n(H_2O)_{6-n}]^{(3-n)-}$ species; at high Cl^- concentrations $[OsCl_4(H_2O)_2]^-$ reacts with *trans*-$[OsO_2Cl_4]^{2-}$ to give $OsCl_4(H_2O)_2$.[489]

Although the main product of aquation of $[OsX_6]^{2-}$ appears to be $[OsX_5(H_2O)]^-$ (X = Cl, Br)[842,863] there is evidence for the existence of $[OsCl_5(OH)]^{2-}$,[863] *cis*-$[OsCl_4(OH)(H_2O)]^-$, *fac*-$[OsCl_3(OH)_2(H_2O)]^-$ and *mer*-$OsCl_3(OH)(H_2O)_2$ as well as oxo-bridged dimers in the hydrolysis products of $[OsCl_6]^{2-}$.[864] Evidence for the existence of $OsCl_4(H_2O)_2$,[489,865] $[OsCl_n(H_2O)_{6-n}]^{(4-n)-}$[863,865] and $[OsI_5(H_2O)]^-$ [812,866] has been presented. Studies of the equilibria in equation (12) have been made (X = Cl, Br[863]).

$$[OsX_5(H_2O)]^- + OH^- \rightleftharpoons [OsX_5(OH)]^{2-} + H_2O \quad (12)$$

There are electronic spectral data on $[OsCl_5(H_2O)]^-$.[842,863] The species $OsCl_5(H_2O)$ is probably formed by oxidation of $[OsCl_5(H_2O)]^-$ by Cl_2^-; electronic spectra have been recorded.[867]

The salts of '$[OsX_5(OH)]^{2-}$' (X = Cl, Br) reported in the earlier literature[637] are almost certainly those of the binuclear symmetrically bridged μ-oxo complexes $[Os_2OX_{10}]^{4-}$ (see p. 594), but $[OsCl_5(OH)]^{2-}$ and possibly $[OsCl_4(OH)_2]^{2-}$ are probably present in aqueous solutions of $[Os_2OCl_{10}]^{4-}$.[639]

(b) Aqua and hydroxo complexes of mixed halo species. The equilibria between *cis*-$[OsCl_3I_2(H_2O)]^-$ and *cis*-$[OsCl_3I_2(OH)]^-$ have been studied.[863]

For the mixed halo species see under the appropriate substituting ligand (*e.g.* oxo halo complexes, p. 594; nitrido halo species, p. 563).

46.10 HYDROGEN AND HYDRIDES AS LIGANDS

Hydrido complexes have been dealt with already under the appropriate coligands (*e.g.* hydrido nitrosyls, p. 545; hydrido phosphines, pp. 570, 572; hydrido arsines, p. 576).

In tetrahydroborate and borane complexes the effective ligand is hydrogen so we deal with these small sections here.

46.10.1 Tetrahydroborate Complex

The tetrahydroborato complex $Os(BH_4)H_3\{P(cyclo\text{-}C_5H_9)_3\}_2$ has been made by reaction of $OsH_6\{P(cyclo\text{-}C_5H_9)_3O\}_2$ and the THF adduct of BH_3. The X-ray crystal structure shows it to be distorted pentagonal bipyramidal: the axial ligands are the phosphines (Os—P = 2.346(2) Å, the BH_4^- is bound by two bridging hydrogen atoms (Os—H = 1.90, B—H (bridge) = 1.31, Os—B = 2.30(1), B—H (terminal) = 1.09(7) Å), and the equatorial plane is completed by three terminal hydrido ligands (Os—H = 1.57 Å). At 90 °C there is rapid exchange of the bridging H atoms with the hydrido ligands bound to osmium.[868]

46.10.2 Borane Complex

The *closo*-type 11-vertex metalloborane $(PMe_2Ph)_2OsB_{10}H_8(OEt)_2$ will react with $MCl_2(PPh_3)_3$ (M = Os, Ru) to give the mixed-valence complexes $(PPh_3)_2ClMClOs(PMe_2Ph)B_{10}H_8(OEt)_2$. The Os or Ru atoms are bound exopolyhedrally to the initial metalloborane by two two-electron M $-H_\mu-$B links and an Os—Cl—M four-electron bridge.[869]

46.11 MIXED DONOR ATOM LIGANDS

46.11.1 Bidentate N—O Complexes

46.11.1.1 Benzamido ligand

The benzamidato complex $Os_2Cl_2(NHCOPh)_4$ is made from $Os_2(OAc)_4Cl_2$ and molten benzamide, and $Os_2Br_2(NHCOPh)_4$ from the chloro species and Br^-. The X-ray crystal structures show these to have 'lantern' structures with four bridging benzamido ligands and the halide ligands axial. Each has two closely related molecules in the unit cell with slightly different structures. For the chloro complex the mean distances are Os—Os = 2.367, Os—Cl = 2.491, Os—O = 1.99 and Os—N = 2.02 Å; for the bromo species the mean values are Os—Os = 2.384, Os—Br = 2.610, Os—O = 2.02 and Os—N = 1.93 Å.[870,871]

46.11.1.2 Hydroxybenzamido ligands

An interesting piece of recent research concerns the osmium complexes of 1,2-bis(3,5-dichloro-2-hydroxybenzamide)ethane (H_4chba-Et) and of 1,2-bis(3,5-dichloro-2-hydroxybenzamido)-4,5-dichlorobenzene (H_4chba-dcb) which function as tetradentate tetraanions. They are difficult to oxidize and their amide functional groups tend to stabilize higher oxidation states of metals. The intention is to use complexes of these with osmium as specific oxidants; by controlling the ligands on the metal, control of oxidative properties may be achieved. Reaction of the ligand with *trans*-$K_2[OsO_2(OH)_4]$ gives *trans*-$K_2[OsO_2(\eta^4\text{-chba-Et})$ (characterized analytically, by ^{1}H NMR and by the observation of $\nu_{as}(OsO_2)$ at 820 cm^{-1} in the IR shifting to 788 cm^{-1} on ^{18}O substitution). The structures of the complexes $Os(\eta^4\text{-chba-Et})py_2$, made from pyridine and *trans*-$K_2[OsO_2(\eta^4\text{-chba-Et})]$, and $Os(\eta^4\text{-chba-dcb})$ bipy, made from $Os(\eta^4\text{-chba-dcb})(PPh_3)_2$ and bipyridyl, were established crystallographically.[872] For $K_2[OsO(\eta^4\text{-chba-Et})_2(OPPh_3)_2]$ see p. 594.

For aminocoumarin and aminopentenone complexes, see p. 569; for complexes with amino acids, see p. 583, and with alkaloids, p. 587.

46.11.2 Complexes of Miscellaneous Sulfur-Nitrogen Ligands

46.11.2.1 Sulfamato complexes

The salt $K_2[Os(NH_2SO_3)Cl_5]$ was made as yellow plates from reaction of $[OsCl_6]^{2-}$, $SnCl_2$ and sulfamic acid. The magnetic moment is 2.21 BM at room temperatures, and on the basis of the IR

spectrum it seems likely that the sulfamato ligand is N-bonded to the metal. Another species, $K_3[OsCl_6]\cdot NH_3SO_3$, not fully characterized, was also obtained. Refluxing of $[Os(NH_2SO_3)Cl_5]^{2-}$ in aqueous solution gave a very low yield of $K_3[Os_2NCl_8(H_2O)_2]$ and another nitrido complex, probably $K_5[Os_2NCl_{10}]$.[349]

46.11.2.2 2-Thioamidopyridine complexes

These, $[Os(N_2SC_6H_6)_3]Br_3$ ($\mu_{eff} = 1.71$ BM at room temperature),[873] and the diamagnetic 6-methyl-2-thioamidopyridine complex $Os(SN_2C_7H_8)_2Cl_2$,[874] are made from $[OsX_6]^{2-}$ and the ligands. Complexes of thiazolidine-2-thione ($S_2NC_3H_5$) with OsX_3 (X = Cl, Br) and the ligands, gives the complexes OsL_3X_3. IR and electronic spectra were measured, and the magnetic moments of the thiomorpholin-3-one complex are 1.9 (X = Cl) and 1.8 (X = Br) BM respectively.[718]

46.11.2.3 Miscellaneous sulfur–nitrogen complexes

These, for the most part, lack effective characterization.

The following have also been reported, made from the ligand and OsO_4, sometimes with HCl: $Os(C_7H_5N_2S)_3$ and $Os(C_7H_5N_2S)\cdot(C_7H_3N_2SH)Cl_2\cdot 2H_2O$ (from 2-mercaptobenzimidazole);[875] $Os(C_7H_4NSO)_3$ (from 2-mercaptobenzoxazole);[876] $(pyH)_6[OsO(S_3N_2C_2)_6]$ (from 2,5-dimercapto-1,3,4-thiadiazole and pyridine);[877] $Os(SN_2O_4C_{12}H_{10})(OH)_2$ and $OsO_2(SN_2O_4C_{12}H_{10})Cl_2$ (from 3,3′-diamino-4,4′-dihydroxyphenylsulfone);[878] $[OsO_2(SON_4C_9H_{12})_2]Cl_4$ (from 4-benzylamidothiosemicarbazide);[510] $Os(SNO)_2C_3H_6)_2$ (from cysteine);[544] $Os(SNO_2C_3H_7)_3\cdot L$ and $Os(SNO_3C_5H_9)_2\cdot L$ (from 1-methylimidazole (L) and cysteine or α-*N*-acetylonethylcysteine respectively);[544] $Os(SN_3O_6C_{10}H_{15})_2$ (from glutathione);[544] $OsO_2(SNOC_7H_6)_2$ (from thiosalicylamide).[879]

46.11.3 Complexes of Miscellaneous Sulfur–Oxygen Ligands

There are relatively few of these; as with many of the sulfur–nitrogen donor complexes, little more than the stoichiometries is known.

Thiomorpholin-3-one gives complexes of the type OsL_3X_3 with OsX_3 (X = Cl, Br); their magnetic moments are respectively 1.8 and 2.0 BM at room temperatures.[718] Osmium tetroxide reacts with α-mercaptopropionic acid in NaOH to give $Na_2[Os(OH)_2(OOCSCHMe)_2]$[880], and 'thiovanol' (3-mercapto-1,2-propanediol) gives allegedly tetra- and penta-meric species $[OsL_4]_4$ $[OsL_4]_5$ with OsO_4.[881] Some osmium-(III) and -(IV) complexes with 8-mercaptoquinolines have been reported. The ligands include 2,6-dimethyl-8-mercaptoquinoline,[882] 2,7-dimethyl-8-mercaptoquinoline[883] with osmium(III), 6-methyl-8-mercaptoquinoline[884] with osmium(IV), 5-fluoro- and 5-iodo-8-mercaptoquinolines[885] and 5-alkylthio-8-mercaptoquinoline[886] with osmium-(III) or -(VI). Two species which have been more fully characterized with this type of ligand are $Os(NSC_9H_6)_3$, made from $K_2[OsBr_6]$ and 8-mercaptoquinoline,[887] and $Os(NSC_9H_5Cl)_2$, prepared using 5-chloro-8-mercaptoquinoline.[888]

46.12 MULTIDENTATE MACROCYCLIC LIGANDS

46.12.1 Porphyrin Complexes

The porphyrin ligands impose an N_4 plane on their complexes and, by virtue of the extensive aromaticity of the ligand, are effective π acceptors. Thus it is that most of the osmium complexes are octahedral and of the form *trans*-Os^{II}(porphyrin)L_2 or -Os^{II}(porphyrin)LL'. Most of the work on osmium complexes has been carried out by Buchler and his collaborators using the octaethylporphyrin (OEP^{2-}) ligand. There are two reviews on the subject.[889,890]

We shall deal with complexes of OEP first, and then with those of other porphyrins.

(*i*) *Octaethylporphyrin (OEP) complexes*

(a) Osmium(II). Most of the known complexes involve osmium(II). The two commonest starting materials are Os(OEP)(CO)py, made from H_2(OEP) and $OsCl_3$ under CO in pyridine,[891] from OsO_4,

H_2(OEP), CO and pyridine,[892] or from $Os_3(CO)_{12}$, pyridine and the porphyrin[893] or the dinitrogen complex Os(OEP)(N_2)(THF), prepared from Os(OEP)O_2 and N_2H_4.[894] Many complexes of the form Os(OEP)L_2 have now been isolated (*e.g.* py, OMe, P(OMe)$_3$, NO (p. 551), THF, O (pp. 582, 594 and 595), MeCN, imidazole, 1-methylimidazole, NH_3, NMe_3[890]) and most are made from Os(OEP)(CO)Cl or Os (OEP)py_2 (the latter is prepared from the former by treatment with pyridine).[891]

There are ^{1}H NMR, electrochemical,[890] electronic[232,895] as well as mass spectral data[82] on many of these complexes. A rich resonance Raman spectrum of Os(OEP)py_2 has been measured; many of the porphyrin ligand fundamentals are resonance-enhanced.[896]

Iterative extended Hückel calculations have been carried out on a number of these complexes and used to interpret absorption and emission spectra of Os(OEP)py_2, Os(OEP)(CO)py, Os(OEP)(N_2)(THF) and Os(OEP)$\{P(OMe)_3\}_2$.[895]

(b) Osmium(III). Although no osmium(III) porphyrin complexes seem to have been isolated, electrochemical data indicate the existence of $[Os(OEP)L_2]^+$, made by electrooxidation of Os(OEP)L_2 (L = py, γ-picoline, piperidine, imidazole, 1-methylimidazole, NH_3, NMe_3, P(OMe)$_3$, MeCN). In some cases correlations between $E_{\frac{1}{2}}$ for this oxidation reaction and electronic spectral absorptions could be drawn.[890,897] Similar electrochemical data for Os(OEP)LL′ oxidized to $[Os(OEP)LL']^+$ shows $E_{\frac{1}{2}}$ values intermediate between those for $[Os(OEP)L_2]^+$ and $[Os(OEP)L'_2]^+$; analogies have been drawn between this and the cytochrome system.[897]

46.12.1.1 Osmium(IV)

Few examples are known. One which has been isolated is Os(OEP)Br_2, made from Os(OEP)(N_2)(THF) and CBr_4,[898] and Os(OEP)$(OMe)_2$ obtained from Os(OEP)O_2 and $SnCl_2$ in methanol.[894] In a recent report, reaction of Os(OEP)(CO)Cl with $CHCl_3$ or CCl_4 under photolysis at 365 nm gave Os(OEP)Cl_2. Quantum yields were measured.[899]

46.12.1.2 Osmium(VI)

For the osmyl species OsO_2(OEP) see p. 582 (an improved procedure for its preparation has recently been described[893]).

46.12.1.3 Dimeric complexes

The dimer $[Os(OEP)]_2$ is made by heating Os(OEP)py_2, and a mixed dimer OsRu$(OEP)_2$ is prepared in similar fashion by thermolysis of a mixture of Os(OEP)py_2, and Ru(OEP)py_2. It was suggested that M=M bonds are present in these species.[891]

46.12.1.4 Complexes with other porphyrins

Reaction of $K_2[OsCl_6]$[900] or $OsCl_3$[891] with meso(*p*-tolyl)porphyrin (H_2TTP) with CO in the presence of pyridine yields Os(TTP)(CO)py which with pyridine gives Os(TTP)py_2.[900] On heating this gives a dimer $[Os(TTP)]_2$ which presumably, like its OEP analogue, contains an Os=Os bond.[891]

A number of other complexes of the form Os(porphyrin)(CO)py can be obtained from $K_2[OsCl_6]$, the porphyrin and CO in pyridine, *e.g.* mesoporphyrin-IX dimethyl ester, mesoporphyrin-XI dianion (I) and mesotetraphenylporphyrin;[900] the complex with (I) can also be made from $Os_3(CO)_{12}$, pyridine and the porphyrin.[893]

46.12.2 Phthalocyanine Complexes

Rather surprisingly the phthalocyanine chemistry of osmium is far less developed than that of the porphyrins. Here we use Pc for $[C_{32}H_{16}N_8]^{2-}$.

46.12.2.1 Osmium(II)

The polymeric $[OsPc]_n$ has been made by reaction of OsO_4 with pyromellitic dianhydride or with

phthalic anhydride in the presence of ammonium molybdate.[901] An 'osmium phthalocyanine' is said to be formed by reaction of $(NH_4)_2[OsCl_6]$ and phthalonitrile.[902]

46.12.2.2 Osmium(III)

The complex $OsPcClC_6H_4(CN)_2$ is made from $(NH_4)_2[OsCl_6]$ and excess 1,2-dicyanobenzene at 360 °C, and is dark blue. It has a magnetic moment of 1.1 BM at room temperature.[903]

46.12.2.3 Osmium(IV)

The polymeric $[OsPc \cdot SO_4]_n$ has been made by reaction of OsO_4 and excess molten phthalonitrile followed by extraction with H_2SO_4. It is dark blue and diamagnetic;[904] it has however been suggested that it could be an osmyl complex, $OsO_2Pc \cdot C_6H_4(CN)_2$.[903,905] The ion $[Os(PcH)(HSO_4)_2]^+$ may be present in solutions of '$[OsPc \cdot SO_4]_n$' in H_2SO_4,[906,907] and $OsPcX_2$ has been very briefly mentioned (X = Cl, Br, I).[908]

46.12.2.4 Osmium(VI)

Reaction of OsO_4 and 1,2 dicyanobenzene at 180 °C gives the dark blue $OsO_2 \cdot Pc\{C_6H_4(CN)_2\}$ which is paramagnetic (μ_{eff} = 1.4 BM at 20 °C);[903] however, all other osmyl complexes reported (p. 581) are diamagnetic, so this could well be an osmium(IV) or even an osmium(III) species. Another osmyl species claimed is $OsO_2 \cdot Pc \cdot 3PhNH_2$, made from $OsO_2 \cdot Pc \cdot \{C_6H_4(CN)_2\}$ and aniline; no magnetic properties were reported for this.[903]

47.1 INTRODUCTION

47.1.1 General Scope

The coordination chemistry of cobalt can be summed up in three words: *synthesis*, *structure* and *reactivity*, with synthesis being the most important because it comes first. This chapter concentrates on synthetic aspects and its aim is to provide the reader with starting points to the preparation of cobalt complexes in addition to surveying their chemistry.

The chapter deals with complexes formed with groups IV (C, Si), V (N, P, As) and VI (O, S, Se) donor atoms with the following exceptions. Organocarbon chemistry including organocobalt(III) model systems for vitamin B_{12} have been considered by Kemmitt and Russell in the companion series

'Comprehensive Organometallic Chemistry';[1] only CN^-, CO_2 and CS_2 complexes are considered here. The extensive chemistry of cobalt with ammonia and saturated amines is dealt with by House, N-containing heterocyclics by Reedijk, and N macrocycles (porphyrins, corrins, phthalocyanines), polyaza macrocycles, and all-encompassing ligands (cryptands, crown ethers and sepulchrates) by Dolphin, Curtis, and Lehn and Mertes respectively in companion chapters in the present series. Similarly, the mixed O,N donor ligands including Schiff bases are dealt with by Randaccio, Calligaris and Bresciani Pahor.

47.1.2 Synthesis Reference Works

Table 1 lists useful general texts which may be consulted on preparative methods and recipes for cobalt complexes. Table 2 gives references and preparative procedures for some especially useful Co^{III} starting materials and complexes since these are critically important to most investigations; Table 3 gives a more detailed listing of preparations which are to be found in publications which can be relied on for their accuracy and reproducibility. Some comment is appropriate: preparations given in 'Inorganic Synthesis' and Brauer's 'Handbook of Preparative Inorganic Chemistry' can be relied on, but the comprehensive information given in the 1974 edition of Gmelin's 'Handbook of Inorganic Chemsitry' is non-critical in this respect.

47.1.3 Structural Reference Works

A structural index of cobalt complexes is inappropriate since this is readily available from standard data bases.[2] Specific articles and reviews dealing with structures or structurally related aspects are given in Table 4. Structures, where appropriate to the present chapter, are given in the text or in tables but no attempt has been made to be comprehensive.

47.1.4 Properties and Reactivity Reference Works

Table 5 gives references to recent general accounts or reviews of aspects of cobalt chemistry not specifically dealt with in this chapter. Other chapters in the present series also contain much detailed information.

47.2 CARBON LIGANDS

47.2.1 Carbon Dioxide

Whereas the highly basic Ir^I, Rh^I and Ni^0 complexes which are active in CO_2 fixation are monofunctional systems, bifunctional [Co(salen)M] complexes (M = K, Na) which bind CO_2

Table 1 Primary Reference Works: Preparations of Cobalt Complexes or Preparative Methods

Author/editor	*Title, reference*	*Comments*
A. Werner	'Neuere Anschauungen auf dem Gebiete der anorganischen Chemie', 4th edn., Freidrich Vieweg und Sohn, Brunswick, 1920	Earliest account of 'classical' Co^{III} chemistry
G. Brauer	'Handbook of Preparative Inorganic Chemistry', 2nd edn., Academic, New York, vol. 2, 1965	Preparations of several cobalt salts and complexes, *cf.* Table 3
Various (series)	'Inorganic Synthesis', McGraw-Hill, New York, vols. 1 (1939)–17 (1977); Wiley-Interscience, New York, vol. 18 (1978)–	Extensive source of primary preparations; checked, *cf.* Table 3 (complete vols. 1–22)
Gmelin	'Handbuch der Anorganischen Chemie', Springer-Verlag, Berlin; Kobalt, vol. 58, 8th edn.; new supplement series vols. 5–6, 1973	Comprehensive listing of all reported preparations; not checked for reliability
W. G. Palmer	'Experimental Inorganic Chemistry', Cambridge, New York, 1954	A few basic preparations; good early account
G. G. Schlessinger	'Inorganic Laboratory Preparations', Chemical Publishing Co., New York, 1962	A few useful preparations, methods
W. L. Jolly	'Preparative Inorganic Reactions', Interscience, New York, vol. 1, 1964	Preparation methods; a few recipes
M. Shibata	'Topics in Current Chemistry' series, Springer-Verlag, 1983, vol. 110	Co^{III} preparations; some recipes

reversibly have also been described (equation 1).[3,4] It appears that the alkali metal ion acts as a Lewis acid in a concerted acid–base attack on CO_2, with the basic Co^I centre as the other partner. The resultant diamagnetic red or red-brown adducts liberate 1 mol of CO_2 on treatment with acids and have been characterized by IR spectroscopy[3,4] and X-ray crystallography.[4] The solid complexes are, however, unstable in the absence of a CO_2 atmosphere. The structure of $[Co(Pr_2salen)(CO_2)(K)(THF)]_n$ shows that carbon dioxide is C bonded to the cobalt centre with each oxygen bonded to two different K^+ ions. The Co—C distance of 199 pm resembles that found for many alkyl derivatives of [Co(salen)] and the coordinated CO_2 is bent (O—C—O angle 135°) and has C—O distances of 122 and 124 pm. The overall geometry about cobalt is square pyramidal (CoN_2O_2C chromophore). Increased stability of the CO_2 adducts may result from the binding of bases such as pyridine in the vacant sixth position.[3]

$$[Co(salen)M] + CO_2 \rightleftharpoons [Co(salen)(CO_2)M] \quad (1)$$

47.2.2 Carbon Disulfide

The tris (tertiary phosphine) ligand $MeC(dppm)_3$ forms both mono- and di-nuclear cobalt–carbon disulfide complexes.[5] The monomer $[Co\{MeC(dppm)_3\}(CS_2)]$ is formed by the direct reaction of $[Co_2(CO)_8]$ with $MeC(dppm)_3$ and CS_2, or by treating the binuclear Co^I complex $[\{MeC(dppm)_3\}Co]_2(\mu\text{-}CS_2)](BPh_4)_2$ with sodium naphthalenide or with $NaBH_4$ in the presence of excess CS_2. The monomer is an air-stable red solid ($\mu = 1.91$ BM) with the Co atom coordinated to the three phosphorus atoms of $MeC(dppm)_3$ and to CS_2 by a σ bond to C and a π bond to one C=S group. The S—C—S angle (133.8°) and the average length of the C—S bonds (166 pm) approach those found for uncoordinated CS_2 in the $^3A_2$ excited state (135.8°, 164 pm).[6]

The coordinated CS_2 group is electron rich at sulfur and is activated towards attack by electrophiles. Thus treatment of $[Co\{MeC(dppm)_3\}(CS_2)]$ with $[Co(H_2O)_6]^{2+}$ in the presence of $MeC(dppm)_3$ gives the diamagnetic dimer $[\{[MeC(dppm)_3]Co\}_2(\mu\text{-}CS_2)]^{2+}$, and the uncoordinated S atom displaces coordinated THF from $[Cr(CO)_5(THF)]$ and $[Mn(CO)_2(THF)Cp]$ to form $[\{MeC(dppm)_3\}Co(\mu\text{-}CS_2)Cr(CO)_5]$ and $[\{MeC(dppm)_3\}Co(\mu\text{-}CS_2)Mn(CO)_2Cp]$ respectively. Structural data for these binuclear complexes are given in Table 6. The linkage arrangement of the CS_2-bridged dimers is shown by (**1**) and (**2**). In both $[\{[MeC(dppm)_3]Co\}_2(CS_2)]^{2+}$ and $[\{MeC(dppm)_3\}Co(CS_2)Cr(CO)_5]$ the π C=S bond is retained and the bond lengths and angles in the $Co(CS_2)$ units differ little from those found in $[\{MeC(dppm)_3\}Co(CS_2)]$. Apparently π bonding of CS_2 to the Co atom in (**1**) does not greatly influence the σ-bonding capabilities of the sulfur atoms since the bond lengths of the two Co—S σ bonds are nearly identical (~230 pm).

(1)

(2)

With molecular oxygen $[\{MeC(dppm)_3\}Co(CS_2)]$ in THF solution forms the yellow-green dithiocarbonate complex $[Co\{MeC(dppm)_3\}(S_2CO)]$. Related reactions using elemental sulfur or selenium give the corresponding trithiocarbonato and selenodithiocarbonato complexes respectively.[7]

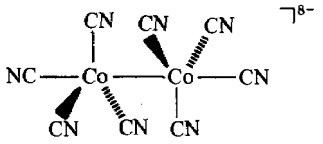
47.2.3 Cyanide

The chemistry of cobalt cyanide complexes has been extensively reviewed by Sharpe.[8]

47.2.3.1 Cobalt(−I) and cobalt(0)

The cyano complexes of cobalt(−I) are restricted to nitrosyl and carbonylnitrosyl mixed ligand complexes, all of which obey the 18-electron rule.

Dark-violet $K_3[Co(CN)_3(NO)]$ results from the action of KCN on $[Co(CO)_3(NO)]$ in liquid ammonia and the intermediate compounds $K[Co(CN)(CO)_2(NO)]$ and $K_2[Co(CN)_2(CO)(NO)]$ may be obtained when the reaction is carried out using stoichiometric ratios of the reactants.[9] The conversion of $[Co(NO)_2Br_2]$ to brown $Na[Co(CN)_2(NO)_2]$ by treatment with ethanolic NaCN has been described,[10] and similar preparations using $[Co(NO)_2BrL]$ reactants (L = PPh_3, $AsPh_3$, $SPPh_3$, $SePPh_3$) give the corresponding $Na_2[Co(CN)(NO)_2L]$ complexes.



The reduction of $K_3[Co(CN)_6]$ by potassium in liquid ammonia affords the air-sensitive brown-violet complex $K_8[Co_2(CN)_8]$,[11] which is the only cyano complex of Co^0 so far described. On the

Table 6 Structures: Cobalt–Carbon Disulfide Complexes[a]

Complex	*Comments*
$[Co(CS_2)\{MeC(dppm)_3\}]$	η^2 linkage; Co—S(1) = 220.6 pm, Co—C = 188 pm; planar $CoCS_2$ fragment

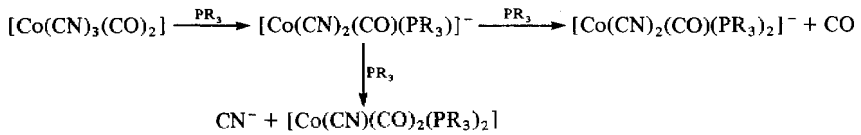
$[\{MeC(dppm)_3\}Co(CS_2)Cr(CO)_5]$	Bridging CS_2, Co—CS(2) bound η^2; Cr octahedral; Cr—S(2) = 244 pm, Co—S(2) = 218 pm, Co—C = 187 pm

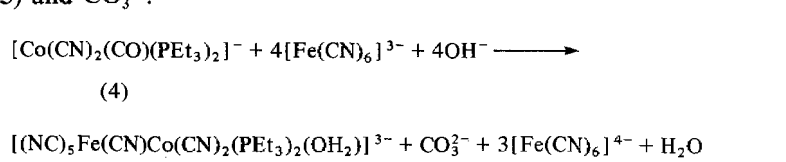
[a] C. Bianchini, C. Mealli, A. Meli, A. Orlandini and L. Sacconi, *Inorg. Chem.*, 1980, **19**, 2968.

basis of IR and Raman spectra bridging CN^- groups appear to be absent and the centrosymmetric structure of D_{3d} symmetry (**3**) has been assigned.[12]



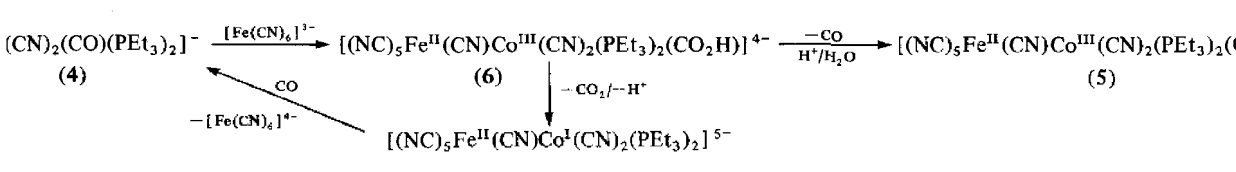
(3)

47.2.3.2 Cobalt(I)



The pentacyanocobaltate(I) ion has been postulated as an intermediate in the electrochemical and chemical reductions of $[CoH(CN)_5]^{3-}$ as well as in the electrochemical reduction of $[Co(CN)_5]^{3-}$. Pulse radiolysis of solutions of $[Co(CN)_5]^{3-}$ produces $[Co(CN)_5]^{4-}$, observable as a transient intermediate which reacts with water to yield $[CoH(CN)_5]^{3-}$. The kinetics of these processes has been studied.[13] The isolation of $K_3[Co(CN)_4]$ as a yellow air-sensitive solid from the chemical reduction of $K_3[Co(CN)_6]$ has been reported but the product has not been fully characterized.[14]

Carbonylation of solutions of $K_3[CoH(CN)_5]$ yields $[Co(CN)_3(CO)_2]^{2-}$, however attempts to isolate pure salts of this species have been unsuccessful owing to its tendency to decompose and disproportionate.[15] On treatment of the product solutions with phosphines moderately stable five-coordinate Co^I complexes of the type $[Co(CN)(CO)_2(PR_3)_2]$, $[Co(CN)_2(CO)(PR_3)_2]^-$ and $[Co(CN)_2(CO)_2(PR_3)]^-$ are obtained (Scheme 1).[16] An alternative route to $[Co(CN)(CO)_2(PR_3)_2]$ complexes (PR_3 = PEt_2Ph, $PEtPh_2$, PPh_3) is provide by direct carbonylation of $[Co(CN)_2(PR_3)_2]$. In $C_2H_4Cl_2$ solution addition of CO gives $[Co(CN)_2(CO)(PR_3)_2]$ initially, which is then reduced by CO to the cobalt(I) product.[17]

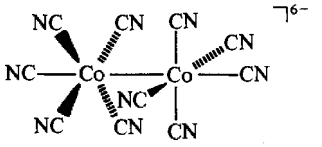


Scheme 1

Oxidation of $[Co(CN)_2(CO)(PEt_3)_2]^-$ (**4**) by $[Fe(CN)_6]^{3-}$ proceeds quantitatively in accordance with Scheme 2 to yield the cyanide-bridged iron(II)–cobalt(III) dimer $[(CN)_5Fe(CN)Co(CN)_2(PEt_3)_2(OH_2)]^{3-}$ (**5**) and CO_3^{2-}.

Scheme 2

Detailed studies of this reaction agree with the mechanism in Scheme 3.[18] The intermediate (**6**) is observable as a transient species (λ_{max} 500 nm, $\varepsilon = 5 \times 10^2$), which may decay by pH-dependent pathways to the final product (**5**), or to the intermediate cyano-bridged iron(II)–cobalt(I) dimer (**7**). The existence of (**7**) is inferred from trapping experiments with acrylonitrile (yielding stable $[Co(CN)_2(PEt_3)(CH_2{=}CHCN)]^-$), or allyl alcohol (yielding the π-allyl complex $[Co(CN)_2(PEt_3)_2(\eta\text{-}C_3H_5)]$. The observation that (**7**) is also trapped by CO provides a basis for the catalytic oxidation of CO to CO_2 (CO_3^{2-}) *via* the cycle (**4**) → (**6**) → (**7**) → (**4**).



Scheme 3

Hydrazine reduction of $[Co(CN)_2(dpe)_2]$ affords the air-sensitive five-coordinate complex $[Co(CN)(dpe)_3]$.[19] This process involves displacement of coordinated cyanide ion accompanied by chelation of the dangling dpe ligand. One diphosphine ligand in the product is readily displaced by CO giving five-coordinate $[Co(CN)(CO)_2(dpe)]$.

47.2.3.3 Cobalt(II)

Light-brown precipitates of cobalt(II) cyanide containing varying amounts of bound water are obtained from addition of stoichiometric quantities of cyanide ion to aqueous solutions of cobalt(II) salts. On heating to 250 °C the hydrates lose water to give blue $\{Co(CN)_2\}_n$.[20] This form of cobalt cyanide possesses the ability to form inclusion compounds with a wide variety of small orgnaic molecules, and X-ray powder patterns indicate an open structure based on a face-centred cube with $a = 1012$ pm.[21] The structure was originally suggested to be related to that of Prussian blue, $KFe[Fe(CN)_6]$, with Co^{2+} replacing K^+ and Fe^{2+} and $[Co(CN)_6]^{4-}$ replacing $[Fe(CN)_6]^{4-}$. However, this structure would need to contain 12 formula units in the unit cell, which is incompatible with the observed crystal density (1.87 g cm^{-3}). Although similarities exist between the structure of $[Co(CN)_2]_n$ and those of both Prussian blue and $Co_3[Co(CN)_6]$, the nature of the differences remains uncertain.[8,20]

The olive-green $[Co(CN)_5]^{3-}$ ion is the predominant cobalt(II) cyanide species in deoxygenated aqueous solutions of cobalt(II) salts to which excess cyanide ion has been added. The pentacyanocobaltate(II) ion is paramagnetic and undergoes rapid exchange of bound CN^-.[22] UV–visible and ESR studies have been interpreted in terms of a purely five-coordinate structure (C_{4v} symmetry),[23] but the anion may be hexacoordinate with a weakly bound water molecule in the sixth position and with C_{4v} symmetry maintained.[24] Studies of the ion in solution are complicated by its tendency to dimerize to diamagnetic violet $[Co_2(CN)_{10}]^{6-}$, the structure of which has been characterized.[25] The dimer possesses D_{4d} symmetry with a Co—Co bond separation of 279.8 pm and with the two sets of equatorial cyanide ligands in staggered conformation (**8**).

(8)

A yellow form of the pentacyanocobaltate(II) ion has been observed in DMF solution. Various monomeric $(NR_4)_3[Co(CN)_5]$ complexes have been crystallized[26] and a structural study on one shows the anion to possess a truly five-coordinate square-pyramidal geometry.[27] Electron irradiation of solid $K_3[Co(CN)_6]$ gives a presumed pentacyanocobaltate(II) ion,[28] the visible spectrum of which is virtually identical with that of $[Co(CN)_5]^{3-}_{(aq)}$. The structural parallels between the green and yellow forms of $[Co(CN)_5]^{3-}$ and isoelectronic $[Co(CNR)_5]^{2+}$ ions indicate that all the green forms observed both in the solid state and in solution are weakly coordinated in the sixth axial position.

The existence of a tetracyanocobaltate(II) ion in aqueous solution has been inferred from studies at high dilution and a brown polymeric complex of composition $K_2[Co(CN)_4]$ has been isolated from solutions of $[Co(SCN)_2]$ and KCN in ammonia.[20] Recently, the monomeric air-sensitive complex $[(PPh_3)_2N]_2[Co(CN)_4]\cdot DMF$ has been crystallized from DMF solution.[29] The complex is essentially square planar but does feature a very weak axial interaction to a neighbouring DMF molecule (Co—O separation 264 pm). The $[Co(CN)_4]^{2-}$ anion appears to be the sole example of a square-planar low-spin ($\mu = 2.15$ BM) cobalt(II) complex containing solely unidentate ligands.

Of the various cobalt(II) cyanide complexes the reactions of $[Co(CN)_5]^{3-}$ have been the most widely studied. Oxidative addition is the characteristic reaction of the low-spin ion, and the driving force for reaction derives from the increase in stability achieved on passing from the 17-valence-electron configuration of the reactant to the closed-shell, 18-valence-electron configuration of the cobalt(III) product. These reactions have been reviewed.[30] Two-electron oxidizing agents with $[Co(CN)_5]^{3-}$ either give bridged $[(NC)_5Co(X)Co(CN)_5]^{6-}$ species (X = O_2,[31] *p*-benzoquinone,[32] C_2F_4,[33] C_2H_2,[34] SO_2,[35] $SnCl_2$[35]) or undergo reductive cleavage with formation of monomeric cobalt(III) products (equation 2, X—Y = H_2,[36] halogen,[37] ICN,[38] H_2O,[39] H_2O_2,[38] alkyl halide,[39] NH_2OH[38]). Except for the reaction of H_2 (and possibly H_2O) these processes occur through a

free-radical stepwise mechanism (Scheme 4).[38,39] For alkyl halides, the rate-determining step is halogen-atom abstraction and the alkyl radicals so produced may combine with $[Co(CN)_5]^{3-}$ giving organocobalt(III) products or may disproportionate to alkanes or alkenes. α,ω-Dihalides are dehalogenated.

$$2[Co(CN)_5]^{3-} + X{-}Y \longrightarrow [Co(CN)_5X]^{3-} + [Co(CN)_5Y]^{3-} \quad (2)$$

$$[Co(CN)_5]^{3-} + X{-}Y \xrightarrow{\text{slow}} [Co(CN)_5X]^{3-} + Y\cdot$$

$$[Co(CN)_5]^{3-} + Y\cdot \longrightarrow [Co(CN)_5Y]^{3-}$$

Scheme 4

Hydrogen absorption by aqueous solutions of $[Co(CN)_5]^{3-}$ was first reported by Iguchi in 1942.[40] H_2 uptake corresponds to 0.5 mol per mol Co and is accompanied by formation of the colourless hydrido complex $[CoH(CN)_5]^{5-}$.[41] The same product results from the reduction of $[Co(CN)_5]^{3-}$ electrolytically or by means of $NaBH_4$. Hydrogenation is reversible with $K = 10^5\,dm^3\,mol^{-1}$ at 25 °C (equation 3). The forward reaction follows third-order kinetics with rate = $k[Co(CN)_5^{3-}]^2[H_2]$. This is consistent with a mechanism involving rate-determining reaction of H_2 with $[Co_2(CN)_{10}]^{6-}$ since the latter exists in rapid equilibrium with $[Co(CN_5]^{3-}$.[30] The further observation that both $[CoH(CN)_5]^{3-}$ and $[CoD(CN)_5]^{3-}$ are produced when the hydrogenation is carried out in D_2O media has been claimed to support a mechanism involving heterolytic fission of H_2.[42] However, homolytic fission with subsequent Co—H/D_2O exchange would lead to the same result and this issue is unresolved.[43]

$$2[Co(CN)_5]^{3-} + H_2 \rightleftharpoons 2[CoH(CN)_5]^{3-} \quad (3)$$

Several low-spin cobalt(II) cyanide complexes containing tertiary or secondary phosphine ligands, and corresponding to the general formula $[Co(CN)_2P_3]$ have been prepared by halide–cyanide exchange (CN^--form anion resin) from tetrahedral $[CoX_2P_2]$ complexes (X = Cl, Br) and an excess of phosphine (Table 7).[44,45] With ditertiary phosphines the reaction gives either diphosphine-bridged binuclear complexes $[(P,P)(CN)_2Co(P,P)Co(CN)_2(P,P)]$ (P,P = dppp, dppb) or mononuclear complexes $[Co(CN)_2(P,P)_2]$ (P,P = dppe) in which one of the diphosphine ligands is monodentate. In all cases the reactions yield orange or red complexes which are five coordinate with a C_2P_3 donor set. In solution ($C_2H_4Cl_2$, benzene) they are frequently unstable and are decomposed by a dissociative process to yellow or green products presumed to be four coordinate.[45]

In many respects the reactions of the monomeric mixed phosphine–cyanide complexes parallel those of $[Co(CN)_5]^{3-}$. Thus, $[Co(CN)_2(dppe)_2]$ undergoes oxidative reactions with SO_2, $SnCl_2$, and alkyl and hydrogen halides, and forms a peroxo dimer on exposure to dioxygen. This latter species is unstable however and in methanol reacts with solvent giving CH_2O and $[Co(CN)_2(dppe)_2]^+$.[46] In $C_2H_4Cl_2$ and in the presence of dioxygen the dimer oxidizes solvent to CO_2 and this process is accompanied by formation of the zwitterionic complex $[(dppe)_2(NC)Co(CN)CoCl_3]$.[47]

47.2.3.4 Cobalt(III)

The preparation and properties of a number of cobalt(III)–cyano complexes are given in Table 8. Many reactions involving formation of cobalt(III)–CN bonds are catalyzed by cobalt(II) species. Adamson[37] first proposed that catalysis of cyanide substitution in $[CoX(NH_3)_5]^{2+}$ ions ($X = Br^-$, I^-) to form $[Co(CN)_5X]^{3-}$ involved the participation of the substitutionally labile $[Co(CN)_5]^{3-}$ (Scheme 5). Subsequent mechanistic studies have been interpreted in terms of inner-sphere electron transfer between $[Co(CN)_5]^{3-}$ and $[CoX(NH_3)_5]^{2+}$ through bridged $[(NC)_5CoXCo(NH_3)_5]^-$ intermediates ($X = Cl^-$, N_3^-, NCS^-, OH^-). For a number of other pentaamminecobalt(III) complexes, including those where $X = PO_4^{3-}$, RCO_2^-, CO_3^{2-}, SO_4^{2-} and NH_3, cyanide substitution, while still catalyzed by Co^{II}, follows a different stoichiometry (equation 4). These processes are believed to proceed *via* outer-sphere electron transfer between $[Co(CN)_6]^{4-}$ (presumed to exist in equilibrium with $[Co(CN)_5]^{3-}$) and the $[CoX(NH_3)_5]^{y+}$ reactant.[8,48] These latter reactions have no real preparative value however and the $[Co(CN)_6]^{3-}$ ion is usually prepared as its potassium salt by aerial oxidation of hot solutions of cobalt(II) salts containing excess KCN. The product is obtained as a pale-yellow crystalline solid, soluble in water but insoluble in common organic solvents. Its parent acid, $H_3[Co(CN)_6]\cdot 0.5H_2O$, is readily obtained by chromatography on acidic-form cation-exchange resin and may be used to prepare various other M^{n+} or quaternary ammonium salts.[49]

$$[Co(CN)_5]^{3-} + [CoX(NH_3)_5]^{2+} \longrightarrow [Co(CN)_5X]^{3-} + [Co(NH_3)_5]^{2+}$$

$$[Co(NH_3)_5]^{2+} + 5CN^- \longrightarrow [Co(CN)_5]^{3-} + 5NH_3$$

Scheme 5

$$[CoX(NH_3)_5]^{n+} + 6CN^- \longrightarrow [Co(CN)_6]^{3-} + X^{n-} + 5NH_3 \quad (4)$$

Strong acids, bases and oxidants leave $[Co(CN)_6]^{3-}$ unaffected and the only substitutions of preparative significance are photosolvation or photoanation. Reduction gives either Co^0– or Co^{II}–cyano complexes depending on conditions.[8]

The spectroscopy and photochemistry of the $[Co(CN)_6]^{3-}$ ion have been studied extensively and have been reviewed.[50] Bands at 312, 260 and 202 nm in the electronic spectrum of aqueous solutions are assigned to the $^1A_{1g} \rightarrow {}^1T_{1g}$, $^1A_{1g} \rightarrow {}^1T_{2g}$ and CT transitions respectively,[51] and similar spectroscopic features are exhibited by solid-state samples.[52] Recent studies have identified a weak absorption band at ~390 nm as being associated with the singlet to triplet $^1A_{1g} \rightarrow {}^3T_{1g}$ transition.[53,54] Crystalline $K_3[Co(CN)_6]$ (and also *cis*-$K_3Na_2[Co(CN)_4(SO_3)_2]$ and *trans*-$Na_5[Co(CN)_4(SO_3)_2]$[55]) exhibits phosphorescence from the $^3T_{1g}$ excited state of the molecule at low temperatures,[56] and laser irradiation of $[Co(CN)_6]^{3-}$ in a glass matrix at 94 K gives rise to a transient spectrum ($t_{1/2} = 1.5 \times 10^{-5}$ s) in the 350 to 500 nm region assigned to absorption by this excited-state species.[54]

In aqueous solution $[Co(CN)_6]^{3-}$ undergoes efficient CN^- photoaquation (equation 5) with a wavelength-independent quantum yield ($\phi = 0.3$) irrespective of whether irradiation occurs in the 254–365 nm region,[57] corresponding to spin-allowed LF absorptions, or in the 405–436 nm region,[58] corresponding primarily to direct triplet excitation. The aquapentacyanocobaltate(III) ion is effectively the terminal product in these processes since it is practically photoinert with respect to further substitution of cyanide. A value of $\Delta V^{\ddagger}$ of $+1.3\,cm^3\,mol^{-1}$ has been reported for the reaction.[59]

$$[Co(CN)_6]^{3-} + H_2O \xrightarrow{h\nu} [Co(CN)_5(OH_2)]^{2-} + CN^- \quad (5)$$

Photolysis of aqueous solutions of $[Co(CN)_5X]^{n+}$ ($X = Cl^-$, Br^-, I^-, N_3^-, SCN^-, H_2O, NH_3) and $[Co(CN)_4(SO_3)Y]^{n-}$ ($Y = SO_3^{2-}$, OH^-, H_2O) in the LF region involves replacement by H_2O of the X and SO_3^{2-} ligands respectively. Unlike the photoreaction of $[Co(CN)_6]^{3-}$, photoaquation efficiencies depend on ionic strength and these reactions appear to occur through dissociative mechanisms involving five-coordinate intermediates. In contrast, photoaquation of $[Co(CN)_6]^{3-}$ is interpreted in terms of a photoactivated interchange mechanism between inner-sphere CN^- and an outer-sphere water molecule.[50] This photoactivated interchange has been shown[60] to be the primary step in the photoanation of $[Co(CN)_6]^{3-}$ by nucleophiles ($Y = I^-$, N_3^-) and photoproduction of $[Co(CN)_5Y]^{3-}$ occurs exclusively from the immediate product $[Co(CN)_5(H_2O)]^{2-}$ (Scheme 6). Irradiation of cobalt(III)–cyano complexes in the CT region results in photoredox processes in parallel with substitutions. The former are comparatively inefficient, presumably because of effective conversion mechanisms from CT to LF states. However, UV irradiation of *trans*-$[Co(CN)_4(SO_3)(H_2O)]^{3-}$,[61] $[Co(CN)_5(NO_2)]^{3-}$ [50] and $[Co(CN)_5(OH)]^{3-}$ [62] produces Co^{II} species, and oxidized acidoligand products have been detected during photolysis of $[Co(CN)_5X]^{3-}$ anions ($X = N_3^-$, I^-, SCN^-).[63,64]

$$[Co(CN)_6]^{3-} + H_2O \xrightarrow{h\nu} [Co(CN)_5(OH_2)]^{2-} + CN^-$$

$$[Co(CN)_5(OH_2)]^{2-} + Y^- \longrightarrow [Co(CN)_5Y]^{3-} + H_2O$$

Scheme 6

Early kinetic measurements on the thermal anation of $[Co(CN)_5(H_2O)]^{2-}$ by anionic nucleophiles ($Y = N_3^-$, SCN^-) indicated that substitution proceeded with a less-than-first-order dependence on [Y] and approached a limiting rate at high concentrations.[65] This, together with the substantial agreement between the limiting rates for the thiocyanate and azide systems and the apparent water-exchange rate on $[Co(CN)_5(H_2O)]^{2-}$, indicated that substitution occurred *via* a limiting dissociative mechanism involving five-coordinate $[Co(CN)_5]^{2-}$ as a reaction intermediate (Scheme 7).

$$[Co(CN)_5(OH_2)]^{2-} \rightleftharpoons [Co(CN)_5]^{2-} + H_2O$$

$$[Co(CN)_5]^{2-} + Y^- \longrightarrow [Co(CN)_5Y]^{3-}$$

Scheme 7

Similar kinetic behaviour is found for substitution of H_2O by CN^- in *trans*-$[Co(CN)_4(SO_3)(H_2O)]^{4-}$.[66] However, a reactive intermediate $[Co(CN)_4(SO_3)]^{3-}$ species generated by loss of H_2O from the coordination sphere need not, in this case, be five coordinate since the possibility exists for rearrangement to a configuration where SO_3^{2-} is bidentate (Section 47.7.4.3).

The reactions of $[Co(CN)_5(H_2O)]^{2-}$ with N_3^- [67,68] and SCN^- [68] have been reinvestigated and important differences found which indicate that the evidence in favour of limiting kinetics is not as clear as originally supposed. In particular, deviations from the simple second-order rate law for anation, rate $= k[Co(CN)_5(H_2O)^{2-}][Y^-]$, appear to be small and the question of reaction mechanism remains somewhat open at present. The effect of solvent on reaction between $[Co(CN)_5(H_2O)]^{2-}$ and N_3^- [69] and the small positive activation volumes for anation by Br^-, I^- and SCN^- [70] are indicative of a dissociative mechanism, but the existence of a long-lived five-coordinate intermediate has not been definitively established.

The thermal reaction between *trans*-$[Co(CN)_4(SO_3)_2]^{5-}$ and $^{13}CN^-$ in aqueous solution results in stereospecific incorporation of label to form *trans*-$[Co(^{13}CN)(CN)_4(SO_3)]^{4-}$, whereas when the reaction is carried out photochemically, labelled cyanide is randomly incorporated.[71] Photodissociative loss of SO_3^{2-} appears to lead to an electronically or vibrationally excited intermediate which has a chemistry quite distinct from the intermediate produced in the thermal reaction. Whatever its exact nature, the photoexcited intermediate has a short configurational lifetime and this causes random introduction of $^{13}CN^-$.

Structural data for cobalt(III)–cyano complexes are given in Table 9. Numerous studies have been carried out on hexacyanobaltates(III) and on Prussian blue analogues of the type $M_3[Co(CN)_6]_2 \cdot 12H_2O$. Various structural models have been proposed for the latter complexes and a discussion of these and the physical changes which occur on dehydration has been given by Beall.[72] In Co^{III} cyanide complexes the Co—C and C—N bond distances (typically 189 ± 2 and 115 ± 2 pm respectively) show little variation irrespective of whether the ligand is terminal or bridging. Better sensitivity to the coordination mode is shown by the stretch frequencies, ν_{CN}, which generally occur at a wavenumber 60–80 cm^{-1} higher for bridging cyanide ligands than for terminal. In a series of related cyanoaminecobalt(III) complexes the respective frequency ranges of 2190 ± 10 cm^{-1} and 2130 ± 10 cm^{-1} are characteristic of these two modes.

Structures have been reported for both the $[(NC)_5Co(CN)Co(NH_3)_5]$ and $[(NC)_5Co(NC)Co(NH_3)_5]$ linkage isomers as well as for $[Co(CN)(DMGH)_2(H_2O)]$ and its isostructural linkage isomer $[Co(NC)(DMGH)_2(H_2O)]$. The electronic spectra of the binuclear complexes do not correspond to those expected for an average environment of CN^- and NH_3 ligands on a single Co^{III} centre but rather to the sum of the spectra of the two cobalt(III) moieties. Similar spectral relationships are found for the thiocyanate-bridged dimers $[(NC)_5Co(SCN)Co(NH_3)_5]$ and $[(NC)_5Co(NCS)Co(NH_3)_5]$.[73] The isocyano complex $[Co(NC)(DMGH)_2(H_2O)]$ appears to be the only Co^{III} complex containing a monodentate isocyano ligand, and is prepared from the reaction of $[Co(DMGH)_2(NH_3)_2]$ with $[Ag(CN)_2]^-$ in aqueous solution.[74] The similar reaction with CN^- in the absence of silver ion yields the corresponding C-bonded isomer. $[Co(NC)(DMGH)_2(H_2O)]$ is hydrolytically stable but is converted to its linkage isomer on heating to 250 °C.

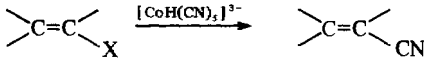
The $[CoH(CN)_5]^{3-}$ ion results from treatment of solutions of $[Co(CN)_5]^{3-}$ with H_2 (Section 47.2.3.3). The hydrido complex is somewhat unstable in solution and salts are obtained with difficulty, however $Cs_2Na[CoH(CN)_5]$ has been isolated as a pure colourless solid which displays $\nu_{CN} = 2113\,cm^{-1}$ and $\nu_{CoH} = 1840\,cm^{-1}$. Freshly prepared solutions of the ion have $\lambda_{max} = 305\,nm$ and a ^1H NMR signal 17.6 p.p.m. upfield from the H_2O resonance.[8]

The $[CoH(CN)_5]^{3-}$ ion has been used extensively as a catalyst in various homogeneous hydrogenations and reviews of the catalytic applications are available.[30,75,76] Under neutral conditions the classes of compounds reduced include conjugated dienes, styrenes, α,β-unsaturated acids (as either salts or esters) and aldehydes, 1,2-diketones and epoxides. Many of these reactions involve σ-complex formation and under favourable conditions stable organopentacyanobaltate(III) products may be isolated.[30] Simple alkenes and alkynes are not reduced but terminal alkynes incorporating an OH function are either selectively hydrocyanated to saturated secondary nitriles or reduced to alkenes (Scheme 8).[77] C_4 allylic alcohols are catalytically hydrogenolyzed to alkenes with the product distributions being highly dependent on reaction conditions.[77] Similar selectivities have been noted in the catalytic hydrogenation of conjugated dienes to monoalkenes.[30]



Scheme 8

Carbonylation of $[CoH(CN)_5]^{3-}$ in strongly alkaline media results in the formation of $[Co(CN)_3(CO)_2]^{2-}$ and the intermediacy of the short-lived tetracyanocobaltate(I) ion $[Co(CN)_4]^{3-}$ in this process has been inferred from mechanistic studies (Scheme 9).[15] Under very similar conditions $[CoH(CN)_5]^{3-}$ catalyzes the cyanation of vinyl halides to form α,β-unsaturated nitriles with retention of configuration (equation 6). Oxidative addition of vinyl halide to the intermediate $[Co(CN)_4]^{3-}$ ion is stereoselective and in the σ complex so produced reductive coupling of the vinyl and cyano ligands gives the stereoretentive organic product and regenerates $[Co(CN)_4]^{3-}$.[78]

47.3 SILICON LIGANDS

47.3.1 Silyl Complexes

A few trialkylsilyl (SiR_3^-) complexes of cobalt are known and a recent account of the reactions of transition-metal trialkylsilanes is available.[79] The cobalt complexes are often prepared *via* oxidative addition of $HSiR_3$ to a low-valent carbonyl or dinitrogen complex (equation 7) or by elimination of H_2 from a cobalt hydride (equation 8). They are usually air sensitive, and unstable with respect to displacement of $HSiR_3$ on heating or on treatment with N_2, H_2 or CO, sometimes in a reversible manner. Deuteration (Scheme 10) provides a useful catalytic route to $DSiR_3$ systems through the intermediacy of the 16-electron $[CoD(PPh_3)_3]$ complex, and O-silylation to give $Si(OR)_4$ species (R = Me, Et) is possible at ambient temperatures *via* $[CoH_2\{Si(OEt)_3\}(PPh_3)_3]$ in the appropriate alcohol.[80]

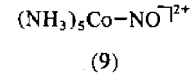
Scheme 10

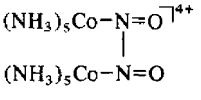
Various substitutions are possible (equation 9)[81] and $[CoH(CO)_4]$ is known to catalyze the addition of $HSiMe_3$ to C_2H_4 at room temperature to give high yields of $SiMe_3Et$.[82] Treatment of $[Co(SiMe_3)(CO)_4]$ with ROH or NH_2R rapidly results in $SiMe_3OR$ or $SiMe_3(NR_2)$ species and $[CoH(CO)]_4$, while GeF_4 and $AsMe_2Cl$ generate $SiMe_3F$ and $SiMe_3Cl$.[82]

$$[Co(SiR_3)(CO)_2(dppe)] \xleftarrow{dppe} [Co(SiR_3)(CO)_4] \xrightarrow{PPh_3} [Co(SiR_3)(CO)_3(PPh_3)] \quad (9)$$



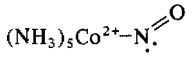
47.4 NITROGEN LIGANDS

47.4.1 Nitrosyl



47.4.1.1 Synthesis

Phosphine complexes containing the NO ligand are considered in Section 47.5.2.3. Most remaining cobalt nitrosyls are simply prepared from the corresponding isolated or *in situ* Co^{II} complex and $NO_{(g)}$ (Table 11). General articles dealing with synthetic methods are available.[83–86] There appears to be no known synthesis *via* oxygen abstraction from coordinated ONO^-, NO_2^- or NO_3^-, or by oxidation of coordinated NH_3 or NH_2OH. Dimeric $[Co(NO)_2X]_2$ (X = Cl^-, Br^-) is a potential starting material for bis(nitrosyl) complexes, but few examples of its use outside the phosphine complexes (Table 34) exist. Most cobalt nitrosyls are diamagnetic with an 18-electron count if NO is considered a three-electron donor in the four- and five-coordinate systems and a one-electron donor in six-coordination; paramagnetic $[Co(NO)\{N(dppe)_3\}](BPh_4)$ (17-electron, tetrahedral) and $[Co(NO)Cl(das)_2](ClO_4)_2$ (17-electron, probably octahedral) are exceptions (Table 11).



The chemistry of the reaction of NO with ammoniacial solutions of $Co^{2+}_{(aq)}$ has had a long and interesting history. As early as 1903, Sand and Genssler[87] demonstrated the existence of two isomeric forms of $[Co(NO)(NH_3)_5]X_2$, a black series (X = Cl^-, NO_3^-, IO_3^-) and a red series (X = Br^-, I^-, NO_3^-, SO_4^{2-}); the former liberated $NO_{(g)}$ rather readily in aqueous solution but the latter was far more stable, especially in dilute acid. Based on empirical evidence, Werner and Karrer[88] considered the black series to be monomeric, designated (**9**), and the red series to be dimeric with a hyponitro structure (**10**). Since that time the reported paramagnetism of the black series has been corrected (both are diamagnetic) but most investigators (and there have been a large number) considered Werner to be wrong and assigned the same or similar structure in the opposite sense. However Werner and Karrer were indeed correct (or nearly so) as the known structures (**11**) and (**12**) testify (Table 12).

$[Co(NO)(DMGH)_2]$	$Co(OAc)_2 \cdot 4H_2O$ + NO + LH_2; MeOH	Black; ν_{NO} 1641 cm^{-1}	6
$[Co(NO)(big)_2(H_2O)]$ (big = biguanide, *N*-amidinothioureas)	$CoCl_2$ + NO + N_2 + bigH; 0 °C, 30 min	Violet; diamagnetic	22
$[Co(NO)(8\text{-quin})_2]$	$CoCl_2 \cdot 6H_2O$ + L + NO; MeOH	ν_{NO} 1650 cm^{-1}	7
$[Co(NO)\{N(dppe)_3\}]$	$[CoH\{N(dppe)_3\}]$ + NO; THF	Brown; ν_{NO} 1620 cm^{-1}; diamagnetic	11
$[Co(NO)\{N(dppe)_3\}](BPh_4)$	$[Co(NO)\{N(dppe)_3\}]$ + $NaBPh_4$; EtOH	Green; ν_{NO} 1680 cm^{-1}; μ = 1.98 BM; tetrahedral structure (Table 12)	11
$[Co(NO)Cl(das)_2](ClO_4)_2$	$[Co(NO)(das)_2](ClO_4)_2$ + Cl_2; MeOH	Green; ν_{NO} 1760 cm^{-1}; μ = 1.90 BM	12
$[Co(NO)X(bipy)_2]Y$ (X = Cl, I, NO_2; Y = ClO_4, PF_6)	$CoX_2 \cdot 6H_2O$ + bipy; EtOH, N_2, NO	Brown, yellow; ν_{NO}, 1642 cm^{-1}; oxidizes in air	19
$[Co(NO)(NH_3)_5]Y_2$ (Y = Cl, NO_3)	$CoY_2 \cdot 6H_2O$ + 0.88NH_4OH; NO; 0 °C, 45 min	Black (monomeric); diamagnetic; ν_{NO} 1170 cm^{-1}; (structure, Table 12)	8, 9
$[Co_2(N_2O_2)(NH_3)_{10}]Y_4$	CoY_2 + 0.88NH_4OH; NO, r.t., 2 h	Red (dimeric); diamagnetic; ν_{NO} 1040–1080 cm^{-1}; (structure, Table 12)	9, 10
$K_3[Co(NO)(CN)_5] \cdot 2H_2O$	'Black' $Co(NO)(NH_3)_5$ Cl_2 + KCN; 0 °C, aq.	Yellow; diamagnetic; ν_{NO} 1130, 1050, 980 cm^{-1}	17

Table 12 Structures: Cobalt–Nitrosyl Complexes

Complex	*Structural details*	*Comments*	*Ref.*
		{CoNO}^{10} systems	
$[Co(NO)_2Cl]_2$	CoNO 176°; Co—NO 173, N—O 112 pm	Dist. tet., dimeric layered structure disordered	14
$[Co(NO)_2I]_n$	CoNO 168°; Co—NO 161, N—O 116 pm	Tet., infinite chains with bridging Co—I—Co	10
$[Co(NO)_2(ONO)]_n$	CoNO 167°; Co—NOO 198, Co—O 215, N—O 113 pm	Bridging CoNOCo (O above N)	11
$[Co(NO)_2(N_2C_5H_7)]_2$	CoNO 161.6, 173.5°; Co—NO 164.6, 168 pm	Dist. tet., dimeric units joined by 3,5-Me_2 pyrazolate ions; NO(ax) bent more than NO(eq)	27
$[Co(NO)(CO)_2(PPh_3)]$	Co—NO(CO) 172–176, Co—P 222.4 pm; PCoCP(NO), 104—106°	Tet., disordered CO, NO	17
$[Co(NO)(CO)(PPh_3)_2]$	Co—NO(CO) 172, Co—P 223 pm; PCoNO(CO) 103.5°, 108°	Tet., disordered CO, NO	17
$[Co(NO)(SO_2)(PPh_3)_2]$	CoNO 169°; Co—P 225–226, Co—NO 168 pm; PCoP 104.8°, PCoN 109–114°	Tet., bending of NO in plane of η^1-planar SO_2	28
$[Co(NO)(1\text{-}CN\text{-}2,6\text{-}Me_2C_6H_3)_3]$	CoNO 177.5°, CoCN 175.9°; Co—N 163, Co—C 184.6–186.5 pm; NCoC 115–120°	Dist. tet., linear NO, CNR coordination	18
$[Co(NO)(CO)_2(AsPh_3)]$	CoNO 177°; Co—NO 174, N—O 114 pm	Tet.	22
$[Co(NO)_2I(PPh_3)]$	CoNO, 163–165°; Co—NO 166, Co—I 257, Co—P 224, N—O, 115 pm	Dist. tet., nearly linear NO coordination (−170 °C study)	5
$[Co(NO)_2I(PPh_2R')]$ ($R' = CH_2CH_2P(O)Ph_2$)	CoNO uncertain; Co—NO 168, N—O 105, Co—P 226, Co—I 225 pm	Dist. tet., disordered NO	7
$[Co(NO)_2(sacsac)]$	CoNO 170°; Co—NO 165, N—O Tet.	12	
$[Co(NO)_2(S_3N)]$	CoNO, 166–167°; Co—N 165–166, N—O 113, 115 pm; NCoN, 112.1°	Dist. tet.	29
$[Co(NO)_2(dppe)](PF_6)$	CoNO, 174.4°; Co—NO 166, N—O 113 pm	Tet.	8
$[Co(NO)_2(PPh_3)_2](PF_6)$	CoNO, 171°; Co—NO 164, N—O 117; NCoN 136–7°	Dist. tet.	9
$[Co(NO)_2(PPh_3)_2](ClO_4)$	CoNO, 171°; Co—NO 166, N—O 115 pm	Dist. tet.	23
		{CoNO}^{9} systems	
$[Co(NO)\{N(dppe)_3\}](BPh_4)$	CoNO 165°; Co—NO 183, N—O 114 pm	Tet.; ν_{NO} 1680 cm^{-1}; μ = 1.98 BM; N^t not coordinated	24
		{CoNO}^{8} systems	
$[Co(NO)(Me_2dtc)_2]$	CoNO 127°; Co—NO 170, N—O 110 pm	Tet. pyr., disordered O in NO ligand	3
$[Co(NO)(Pr^i_2dtc)_2]$	CoNO 129°; Co—NO 171, N—O 111 pm	Tet. pyr., disordered O in NO ligand	4
$[Co(NO)(salen)]$	CoNO 127°; Co—NO 181, N—O 115.5 pm	Tet. pyr.	13
$[Co(NO)(acaen)]$	CoNO 124.4°; Co—NO 182 pm	Tet. pyr.	21
$[Co(NO)(benacaen)]$	CoNO 122.9°; Co—NO 183 pm	Tet. pyr.	21
$[Co(NO)(TPP)]$	CoNO < 128.5°; Co—NO 183, N—O > 110 pm	Sq. pyr. (C_{4v})	19
$[Co(NO)(Cl)_2(PPh_2Me)_2]$	CoNO 165°	Dist. trig. bipyr.; ν_{NO} 1750, 1650 cm^{-1}; equilibrium between bent and linear coordination in soln.	15

$[Co(NO)(das)_2](ClO_4)_2$	CoNO 179°; Co—NO 168, N—O 117 pm	Trig. bipyr.; ν_{NO} 1852 cm^{-1}	1
trans-$[Co(NO)(NCS)(das)_2](NCS)$	CoNO 135°; N—O 101, M—NO 185 pm	Oct.; ν_{NO} 1587 cm^{-1}	1
trans-$[Co(NO)(Cl)(en)_2](ClO_4)$	CoNO, 124.4°; M—NO 182, N—O 104,	Oct.; ν_{NO} 1611 cm^{-1}; long Co—Cl bond	2
trans-$[Co(NO)(OClO_3)(en)_2](ClO_4)$	CoNO 135–141° (or 122–123°); Co—NO 181, Co—OClO, 236, N—O 115 pm	Oct., may contain two disordered NO ligands	6
$[Co(NO)(NH_3)_5]Cl_2$	CoNO 119°; Co—N (*cis*) 198, Co—N (*trans*) 222, N—O 115.4, Co—NO 187 pm	Oct. (black), bent NO	16
$[Co(NH_3)_5NO]_2Br_{2.5}(NO_3)_{1.5}\cdot H_2O$	CoNO 121°, CoNN 117°, CoON 112°; Co—NO 192, Co—ON 187, Co—NH_3 192–197 pm	Oct. (red), bent hyponitrite ligand 	20
	(μ_2-NO) bridges		
$[\{Co(SNNS)\}_2(\mu_2\text{-}NO)](BF_4)$	CoNO 130°; Co—NO 180–182, N—O 121 pm	Oct.; ν_{NO} 1550 cm^{-1}; bridging thiolato (2) and NO	25
$[\{Co(C_5H_5)\}_2(\mu_2\text{-}NO)_2]$	CoNO 139.6°; Co—NO 182, N—O 119	No Co—Co bonding; diamagnetic	26
$[\{Co(C_5H_5)\}_2(\mu_2\text{-}NO)(\mu_2\text{-}CO)]$	CoNO 139.8°; Co—NO 183, N—O 120	No Co—Co bonding; μ = 1.86 BM	26

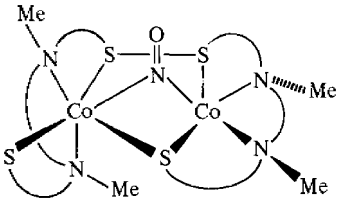
Preparation of the black monomer is achieved at 0 °C after short reaction times; the red dimer is formed at ambient temperatures using longer reaction times (Table 11). Also the red dimer can be prepared from the black monomer and isomer and an intermediate hyponitrito monomer $[Co(N_2O_2)(NH_3)_5]^{2+}$ appears to be involved.[89] Miki and Ishimori[90] suggest that by using ammoniacal solutions which have been pre-exposed to the atmosphere a second hyponitrito isomer, assigned structure (**13**), can be formed. The isomer is less stable in solution giving rise to $[Co(NO_2)(NH_3)_5]^{2+}$ and $Co(OH)_3$ in boiling water and its thermal decomposition appears to differ from the others.[90,91] However structural clarification is necessary.

$$(NH_3)_5Co^{2+}—N{=}O—O{=}N—Co(NH_3)_5^{2+}$$

(13)

Treatment of black $[Co(NO)(NH_3)_5]Y_2$($Y = Cl^-$, NO_3^-) with KCN at 0 °C gives yellow $K_3[Co(NO)(CN)_5]\cdot H_2O$, which may well have a dimeric hyponitrito structure, although direct structural evidence is lacking.[92,93] IR data support a *cis* or skewed hyponitrito bridge and earlier claims that the same compound could be prepared from red $[Co(NO)(NH_3)_5]_2(SO_4)_2\cdot 2H_2O$ have been discounted.[93] Further treatment with CN^- leads to $N_2O_{(g)}$ (equation 10).

Several mixed carbonyl–nitrosyls having the 18-electron count have been prepared from $[Co(NO)(CO)_3]$ or $[Co(NO)_2Br]_2$ (Table 11). All are four coordinate and probably tetrahedral, although the low ν_{NO} for $K_3[Co(NO)(CN)_3]$ (1485 cm^{-1}) may imply square-planar coordination with a bent nitrosyl. Rates of substitution in poorly coordinating solvents (THF, xylene; equations 11 and 12) follow the rate expression $k_{obs} = k_1 + k_2[L]$, with k_1 and k_2 being attributed to dissociative paths involving the sovlent and ligand respectively.[94] For L—L chelates formation of the monodentate species is rate determining.[95]



$$[Co(NO)(CN)_5]_2^{6-} + 2CN^- + 2H^+ \longrightarrow 2[Co(CN)_6]^{3-} + H_2O + N_2O \quad (10)$$

$$[Co(NO)(CO)_3] + L \longrightarrow [Co(NO)(CO)_2L] + CO_{(g)} \quad (11)$$

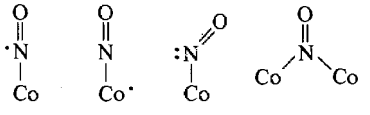
$$[Co(NO)(CO)_3] + L—L \longrightarrow [Co(NO)(CO)(L—L)] + 2CO_{(g)} \quad (12)$$

Oxidative addition of $NONO_2$ was suggested many years ago by Rossi and Sacco[96] for reaction (13) but ^{15}N experiments are necessary to confirm this. However Lippard and coworkers[97] have demonstrated NO^+ addition in the reaction of dimeric $[Co(SNNS)]_2$ (SNNS = $SCH_2CH_2N(Me)CH_2CH_2N(Me)CH_2CH_2S^-$) with $NOPF_6$. Here NO^+ adds across the $(\mu\text{-SR})_2$-bridging dimer to form the triply bridged diamagnetic Co^{III} complex (**14**; Table 12).

$$[Co(NO)(PPh_3)_3] + 7NO \longrightarrow [Co(NO)_2(NO_2)(PPh_3)] + 2OPPh_3 + N_2O + 0.5N_2 \quad (13)$$

(14)

Structures of two other μ_2-bridged nitrosyls $[\{Co(Cp)\}_2(\mu\text{-}NO)_2]$, $[\{Co(Cp)\}_2(\mu\text{-NO,CO})]$ are known (Table 12) and the preparation of $[\{Co(C_5R_5)\}_2(\mu\text{-}NO)_2]^{n+}$ (R = H, Me; n = 0, 1, 2) and $[\{Co(C_5Me_5)\}_2(\mu\text{-NO,CO})]^{n+}$ (n = 0, 1) from $[Co(CO)_2(C_5R_5)]$ and $NOPF_6$ in dichloromethane, and their electrochemistry, have recently been discussed by Connelly, Payne and Geiger.[98]



Reversibility in the coordination of NO to Co^{II} is not as widespread as it is with O_2, and this is supported by theory.[99] The Co—NO bond is stronger than the Co—O_2 bond, particularly in the absence of a sixth ligand, and with spin-pairing complete there is no driving force to form a Co—NO—Co dimer similar to that found with Co—O_2—Co complexes. Reversible coordination is however found in a few cases: in $[Co(NO)Cl(dipy)_2]^+$[100] and in some ill-defined [Co(NO)(amino acid)(base)] species.[101] Nitrosyl transfer from $[Co(NO)(DMGH)_2]$ to various electron-deficient Fe, Co, Ru and Rh complexes (*e.g.* to $[CoCl_2(PPh_3)_2]$,[102] to iron hemoproteins (*e.g.* hemoglobin),[103] and to O_2 leading to $[Co(NO_3)(DMGH)_2]$[104] may result from low concentrations of NO generated in equilibria such as (14) and (15) rather than from the direct addition of coordinated NO.

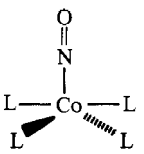
$$[Co(NO)(DMGH)_2] \rightleftharpoons [Co(DMGH)_2] + NO \quad (14)$$

$$[Co(NO)(DMGH)_2] + B \rightleftharpoons [Co(DMGH)_2B] + NO \quad (15)$$

47.4.1.2 Bonding and structure

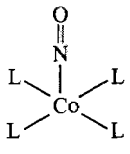
A recent review on structural aspects is available,[105] and accounts of bonding have been given by Enemark and Feltham[106] and Mingos.[107] Three distinguishable coordination modes occur in transition metal nitrosyl: terminal linear (**15**) or (**16**), terminal bent (**17**), and bridging (**18**). These formally correspond to the coordination of NO and NO^+, NO^- and NO^- respectively. Terminal Co—ON coordination has not been found since N is the more basic end of the NO dipole, but it may be possible to form this isomer *via* reactions of Co=O or Co—O_2, or by appropriate cleavage of dimeric Co—N(O)NO—Co systems (see below). Some unusual bridging structures involving O and N coordination are known (Section 47.5.2.3).

(**15**) (**16**) (**17**) (**18**)



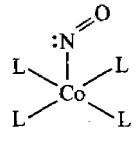
Low-oxidation-state cobalt complexes are invariably four or five coordinate with linear or nearly linear NO bonding. In these (**15**) is considered as NO coordinated to Co^{II} *via* a three-electron bond and (**16**) as NO^+ coordination to d^8 Co^I; the latter description is usually preferred although an overall molecular orbital is involved and individual oxidation states have no reality, and perhaps little usefulness. A general $\{MNO\}^n$ picture has been developed by Mingos[107] and by Enemark and Feltham[108] (n is the sum of electrons associated with the metal d orbitals and the π^*(NO) orbitals of NO groups), and a more specific $\{MNO\}^8$ scheme by Hoffmann and coworkers.[109] Larkworthy and coworkers have recently correlated ^{15}NO and ^{59}Co NMR shifts in five- and six-coordinate cobalt–nitrosyl complexes.[110] Shielding parameters decrease with decreasing MNO angle consistent with the argument that (as a general rule) bent nitrosyl is a weaker ligand than linear nitrosyl.

All known $[Co(NO)L_3]$ systems have close to tetrahedral symmetry (C_{3v}), with linear or nearly linear NO coordination (Table 12) consistent with a closed shell $\{CoNO\}^{10}$ configuration.[107,108,111] A square-planar structure should contain bent NO[108,109] but no example has yet been found. Fenske and coworkers have used extended MO calculations to predict acceptable ionization energies for $[Co(NO)(CO)_3]$,[112] and emphasize the relationship between isoelectronic CO and NO^+ by relating the electronic structure of $[Co(NO)(CO)_3]$ to symmetry lowering in $Ni(CO)_4$ and $Fe(CO)_5$. Evans and Zink use photochemical results to predict a bent NO in the excited state of $[Co(NO)(CO)_3]$.[113] Many four-coordinate systems contain two NO ligands with $[Co(NO)_2Cl]_2$ being tetrahedral and dimeric (Cl bridges), while $[Co(NO)_2I]_n$ is tetrahedral with infinite —I—Co—I— chains and no Co—Co bond (Table 12). Canadell and Eisenstein discuss factors influencing this choice of structure.[114] For tetrahedral monomeric $[M(NO)_2L_2]$ systems, Martin and Taylor have correlated M—N—O bending with the ON—M—NO angle; bending away of the O atoms accompanies larger NCoN angles while smaller angles are found when the nitrosyls point toward each other.[115] This is in agreement with theory,[106] and all $[Co(NO)_2L_2]$ structures are either close to the cross-over point (NCoN = 131 °) or the two nitrosyls point towards each other. However Kaduk and Ibers[116] point out that although available bonding schemes allow rationalization of known structural results, they are not yet able to predict confidently the ground state geometry or more detailed stereochemistry. The 'suck it and see' experimental approach is still of value.



$[Co(NO)\{N(dppe)_3\}](BPh_4)$ has the $\{CoNO\}^9$ configuration and has a slightly distorted tetrahedral structure (Table 12) not unlike that found in high-spin $[CoCl\{N(dppe)_3\}](PF_6)$ (Table 40). The one unpaired electron (μ = 1.98 BM) lies predominantly in a metal-based orbital,[108] which is consistent with the considerable bending in the CoNO grouping (165 °).

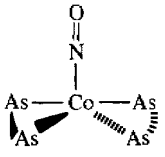
For $\{CoNO\}^8$ systems the following conclusions arise.[109]



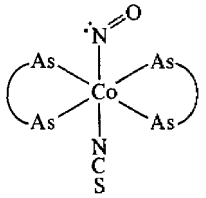
(i) for σ- and π-donating ligands a range of geometries is possible from a strongly bent square pyramid (**21**; C_s) to a less bent trigonal bipyramid (**19**; C_{2v}). A bent nitrosyl will tend to move its Co—N coordination axis in the direction of increased π overlap; in the square pyramid the bent structure (C_s) is favoured over the linear one (**20**; C_{4v}).

(19) C_{2v}

(20) C_{4v}



(21) C_s



(ii) For π-acceptor ligands the trigonal bipyramid is favoured over the square pyramid with NO being equatorial (C_{2v}), and if a nitrosyl bends it will do so in the axial plane rather than in the equatorial plane.

(iii) Linear coordination is expected for axial coordination in a trigonal bipyramid and for basal coordination in the square pyramid. Geometrical deductions have also been made for mixed L systems.[109] Observed structures (Table 12) agree with these conclusions in most instances; thus $[Co(NO)(das)_2](ClO_4)_2$ is trigonal bipyramidal with linear NO coordination, $[Co(NO)(Me_2dtc)_2]$, $[Co(NO)(Pr^i_2dtc)_2]$ and [Co(NO)(salen)] are square pyramidal or tetragonal pyramidal with a bent NO, but $[Co(NO)Cl_2(PPh_2Me)_2]$ adopts an intermediate bent geometry with a stereochemistry of bending at variance with prediction. The second isomer found in the $[Co(NO)Cl_2(PPh_2Me)_2]$ system[117] has not been structurally defined but is thought to be a rotational isomer of the C_{4v} manifold rather than one of the more limiting geometries.[108]

No paramagnetic $\{CoNO\}^8$ systems have been found, but a dramatic change in stereochemistry accompanies the conversion of five-coordinate $[Co(NO)(das)_2](ClO_4)_2$ (**22**), to six-coordinate $[Co(NO)(NCS)(das)_2](ClO_4)$ (**23**).[118] The increased energy of the d_{z^2} orbital shifts the electron pair to the N atom, increasing the tendency to bend with NO^- coordination to Co^{III}.

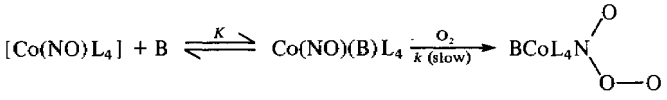
(22) $\nu_{NO} = 1852\,cm^{-1}$
CoNO = 179°

(23) $\nu_{NO} = 1567\,cm^{-1}$
CoNO = 135°

Bent structures (**17**) and (**18**) are favoured for six-coordinate Co^{III} systems (CoNO, 120–130°; $\nu_{NO} \approx 1600\,cm^{-1}$) and are clearly distinguished from the others. Although often synthesized from d^7 Co^{II} complexes (or $Co^{2+}_{(aq)}$ + L) and $NO_{(g)}$, internal redox and coordination of NO^- is clearly indicated with the electron pair on N available for subsequent attack on electron-deficient species (*e.g.* O_2 or NO, see below). In the $\{MNO\}^8$ formalism the bending arises from the higher energy of the d_{z^2} metal-based orbital compared to $\pi^*(NO)$.[107] Noell and Morokuma[119] discuss this in some detail for $[Co(NO)(NH_3)_5]^{2+}$ and predict the observed eclipsing of an adjacent ammonia ligand (Table 12). The large structural *trans* effect in octahedral $\{MNO\}^8$ complexes is well recognized.[120] The *trans* Co—NH_3 bond in $[Co(NO)(NH_3)_5]^{2+}$ is some 24 pm longer than the *cis* Co—NH_3 bonds, and the large majority of bent Co^{III} systems have no *trans* ligand at all (Table 12).

Bridged μ-NO structures are found in a few instances (Table 12) and are in agreement with NO^- coordination and the absence of Co—Co bonding.

47.4.1.3 Reactivity



General accounts of the reactivity of coordinated nitrosyls are available.[106,121–124] A metal ion or metal complex is unable to generate the reactivity of ionic NO^+ towards nucleophiles (*i.e.* OH^-, RS^-, RHN^-) or of NO^- towards electrophiles (*i.e.* H^+, $PhCH_2X$), but it can present NO in a less reactive form under conditions inappropriate to the free ion. Thus linear coordination with $\nu_{NO} > 1886\,cm^{-1}$ may promote nucleophilic reactions at N, and bent coordination with the higher electron density on N ($\nu_{NO} < 1700\,cm^{-1}$) may promote electrophilic attack by H^+, O_2, NO and $PhCH_2Br$.[125] No cobalt nitrosyl is known to undergo nucleophilic attack on the nitrosyl group. Normally linear coordination is associated with four or five coordination and the nucleophile adds to the unsaturated metal instead. However a number of electrophilic reactions are known (Table 13). A recent discussion of these is recommended.[124]

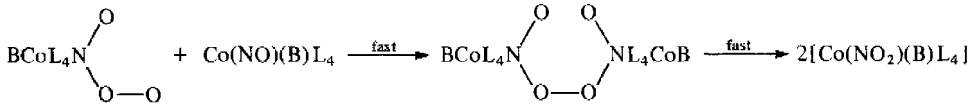


Table 13 Electrophilic Reactions of Cobalt–Nitrosyl Complexes

Complex	ν_{NO} (cm^{-1})	*Electrophile*	*Products*	*Ref.*
$[Co(NO)Br(diars)_2]^+$	1665	HBr	$[Co(HNO)\{Br(diars)_2\}]^{2+}$	1
[Co(NO)(salen)]	1624	O_2/py	$[Co(NO_2)(salen)py]$	2

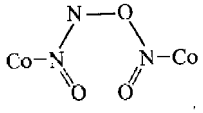
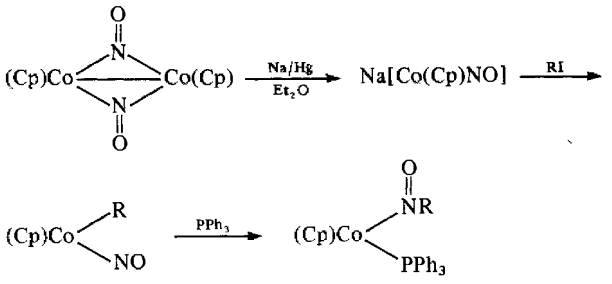
Protonation is found with $[Co(NO)Br(das)_2]^+$, but it remains uncertain whether at N or O. Electrophilic attack by O_2 occurs with most uncharged tetragonal pyramidal five-coordinate systems (Table 13), but prior association with a base ligand such as pyridine appears necessary. The mechanism proposed by Clarkson and Basolo (Scheme 11) is probably general,[126] although neither intermediate has been identified. The function of B appears to be to make the N atom more nucleophilic by promoting the back-bonding component. However it has not been shown that coordinated NO_2 derives directly from coordinated NO, that exchange or reaction with uncoordinated NO is absent, and that only one of the O atoms in the product derives from O_2. Likewise the reaction with an excess of NO remains uncertain in detail although the major product is the same, *i.e.* the coordinated nitro group. In a recent ^{15}N study by Miki[127] on $[Co(NO)(8\text{-quin})_2]$ an 80% yield of $NO[Co(NO_2)(NO_3)(8\text{-quin})_2]$ was obtained (equation 16); liberated N_2O and coordinated NO_3^- derived exclusively from $NO_{(g)}$, while coordinated NO_2^- derived exclusively from coordinated NO. This supports a role for $N_2O_{2(g)}$ and eliminates homolytic N—O fission in an intermediate such as (**24**).



$$\text{rate} = \frac{kK[B][O_2][Co(NO)L_4]}{1 + K[B]}$$

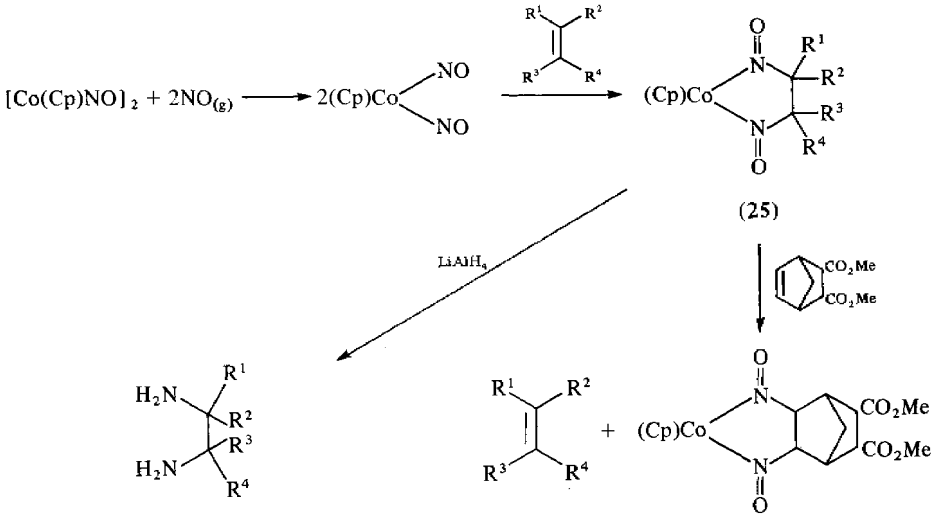
Scheme 11

$$[Co(^{14}NO)(8\text{-quin})_2] + 8\,^{15}NO \longrightarrow {}^{15}NO[Co(^{14}NO_2)(^{15}NO_3)(8\text{-quin})_2] + 3\,^{15}N_2O \qquad (16)$$



(24)

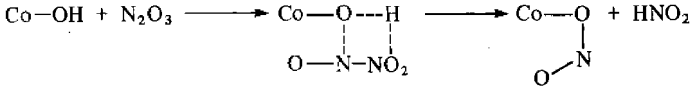
Further studies are required to support and extend these mechanistic aspects. Likewise ^{15}N tracer studies are needed to determine the source of coordinated NO_3^- in $[Co(NO_3)(DMGH)_2py]$ produced in the aerial oxidation of $[Co(NO)(DMGH)_2]$ in the presence of pyridine,[104] and to determine the source of N in N_2 and N_2O produced in the very unusual reduction of NO by NH_3 (or aliphatic amines) as catalyzed by *cis*- and *trans*-$[Co(NO_2)_2(en)_2]X$ ($X = NO_2^-$, NO_3^-).[128]



Bergmann and coworkers have used $[Co(Cp)(\mu\text{-}NO)]_2$ to investigate NO insertion into metal–carbon bonds (Scheme 12; crystal structure, R = Et),[129] and to study addition of coordinated NO to alkenes (Scheme 13).[130,131] The product dinitrosoalkene complex (**25**) can be reduced by $LiAlH_4$ to the primary diamine and can undergo both thermal and photochemical alkene exchange. The catalytic reduction of nitric oxide by amines to $N_2O_{(g)}$ and $N_{2(g)}$ has been found to occur in the presence of *cis*-$[Co(NO_2)_2(en)_2](NO_3)$ and other Co^{III} amines both in aqueous solution and in Y-type zeolites.[128,132] Co^{II} ions incorporated into Y-type zeolites are also effective catalysts in the presence of NH_3 and '$[Co(NO)_2(NH_3)]^{2+}$' has been proposed as a steady-state intermediate.[133] Likewise the catalytic reaction between NO and CO on the surface of Co_3O_4 generating N_2 and CO_2 has considerable interest in the control of nitrogen oxide emissions.[134] A general account of the use of cobalt nitrosyls in pollution control has been given recently by Pandey.[135]

47.4.2 Nitro (NO_2) and Nitrito (ONO)

$[Co(NO_2)(NH_3)_5]X_2$ and $[Co(ONO)(NH_3)_5]X_2$ represent the first examples of linkage isomerism in coordination chemsitry.[136–138] The former nitro isomer is yellow, the latter nitrito is orange, and



Scheme 12

Scheme 13

they are easily prepared.[139] Nitro complexes are usually formed *via* nitrito intermediates and heating a $Co—OH_2^{n+}$ complex with $NaNO_2$ at 60–80 °C in 0.01 M H^+ for 20 minutes is often sufficient to isomerize the latter. For systems where water exchange is rapid, direct displacement of coordinated H_2O by NO_2^- may occur. Some useful preparations are collected in Table 14. $Na_3[Co(NO_2)_6]$ is particularly useful in synthesis since the first four or five nitro groups can usually be displaced successively by other ligands, particularly chelating amines.

Co—ONO complexes are formed by addition of Co—OH to $N_2O_{3(aq)}$. Pearson, Henry, Bergmann and Basolo[140] first described the rate law, rate = $k[CoOH_2][HNO_2][NO_2^-]$, and van Eldik and coworkers have recently confirmed the second-order dependence on $[NO_2^-]_T$ over a wide pH range.[141] Murmann and Taube demonstrated retention of the Co—O bond by ^{18}O tracer methods (equation 17).[142] Other $Co—OH^{n+}$ systems behave similarly and the reaction is relatively fast at room temperature and maximizes at a pH between 3 and 5. Specifically labelled complexes (*e.g.* $Co—^{18}ONO$, $Co—ON^{18}O$) have recently been made.[143]

(17)

Structures of several $Co—NO_2^{n+}$ and $Co—ONO^{n+}$ complexes are known (Table 15, for examples). The $Co—NO_2$ group results in no major structural *trans* influence although Juranic and coworkers[144] report a 5 pm shortening in the $Co—NO_2$ bond when the *trans* ligand is carboxylate.

The $Co—NO_2$ bond is usually very robust and nitro complexes are well known for their stability in aqueous solution. A kinetic *trans* influence of the NO_2 group has not been clearly demonstrated. Hydrolysis is very slow in water but does occur (*cis,trans*-$[Co(en)_2(NO_2)_2]^+$ 3×10^{-8} s^{-1}, 25 °C);[145] heating in strong acids or in NaOH solution results in more rapid hydrolysis. Photolysis of the solid

can result in complete isomerization[146] and this may prove a useful method for the complete removal of the nitro group. Acid hydrolysis of $[Co(NO_2)(NH_3)_5]^{2+}$ follows the rate law $k_{obs} = k(\text{antilog } H_0)$ (H_0 = Hammett acidity constant) and is very slow at ambient temperatures.[147] Jolly and coworkers showed many years ago that the O atom in the $[Co(NH_3)_5OH_2]^{3+}$ product derives from coordinated NO_2^- and suggested $Co—ONO^{2+}$ as a possible intermediate (equation 18).[148] The $[Co(NO_2)_4en]^-$ ion hydrolyzes more rapidly with $k_0 = 2.8 \times 10^{-4}\,s^{-1}$ and $k_H = 2.2 \times 10^{-2}\,mol^{-1}\,dm^3\,s^{-1}$ at 25 °C, $k_{obs} = k_0 + k_H[H^+]$; this reaction is reversible in weakly acidic solution.[149] Murmann and Rahmoeller in a recent elegant study demonstrated the independence of the rate of the NO_2^- exchange reaction of (**26**) on $[NO_2^-]$, solvent and added electrolytes by using ^{15}N- and ^{18}O-labelled NO_2^-;[150] (**26**) is especially labile, and the aqua–nitro complex is known to anate rapidly. The mechanism given by equation (19) probably holds in a general sense.

(**26**)

The Co—ONO bond is less robust and can be cleaved by mild acid (the reverse of its formation) but this appears to occur with O scrambling;[143,151] alternatively, it can be cleaved by the action of HN_3. Acid hydrolysis is markedly catalyzed by Cl^-, Br^-, I^- and SCN^- with major terms in the rate law being $k_{obs} = k_1[H^+] + k_2[H^+][X^-]$.[152] Thus the half-life for aquation of $[Co(ONO)(NH_3)_5]^{2+}$ in $HClO_4$ (0.1 mol dm^{-3}), $LiClO_4$ (0.9 mol dm^{-3}) is *ca.* 1 h at 25 °C, but with the same $HClO_4$ containing LiCl (0.9 mol dm^{-3}) it is *ca.* 1.5 min. A transition state (**27**; equation 20) is proposed.[152] Such Cl^- catalysis could possibly be used in conjunction with the photolytic isomerization of $Co—NO_2^{2+}$ to cause rapid hydrolysis of stable nitro species. The HN_3-promoted reaction has been extensively studied by Seel and coworkers.[152,153] The rate law takes the form $k_{obs} = k_1 + k_2[HN_3]$, where k_1 is the spontaneous isomerization rate (Table 16; $k_2 = 5.53 \times 10^{-3}$ and $2 \times 10^{-2}\,dm^3\,mol^{-1}\,s^{-1}$, 25 °C for $[Co(ONO)(NH_3)_5]^{2+}$[153] and *cis*-$[Co(ONO)_2(en)_2]^+$,[154] respectively). In this case N_3^- attack results in gaseous N_2 and N_2O products (equation 21). The lower $\Delta H^{\ddagger}$ for the assisted reaction (74 *vs.* 93 kJ mol^{-1}) means that isomerization can be prevented at low temperatures (~ 5 °C) by using reasonable N_3^- concentrations.

(20)

(**27**)

(21)

Present interest lies in the Co—ONO to $Co—NO_2$ interconversion. This is spontaneous in the forward direction (Co^{III} favours N and O coordination) and light catalyzed in the reverse. The solid-state reaction has been studied in some detail by Grenthe and Nordin.[155,156] These authors compared the structures of *trans*-$[Co(NCS)(ONO)(en)_2]X$ and *trans*-$[Co(NCS)(NO_2)(en)_2]X$ ($X = I^-$, ClO_4^-) and propose an intramolecular rotation in the Co—ONO plane for the spon-

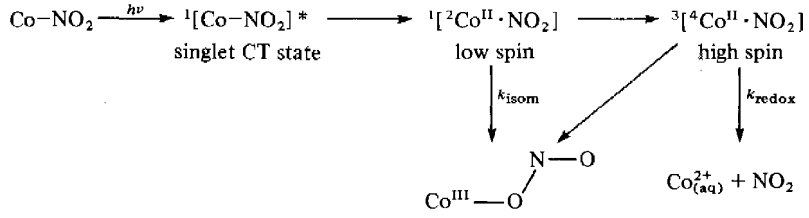
taneous reaction (equation 22).[155] An intermolecular process would involve at least a 400 pm movement of N in the crystal. Powder photography ($X = ClO_4^-$, 293 K) shows a gradual transformation indicating a homogeneous change (*i.e.* separate phases do not appear to coexist in the sample). Photochemical irradiation reverses the process (80% complete) with full retention of crystallinity and of structure. The authors conclude that minimal atomic and molecular movement occurs and that both processes are topochemical. A somewhat more complex solid-state reaction occurs with $[Co(ONO)(NH_3)_5]Cl_2$.[156] A fast spontaneous Co—ONO → Co—NO_2 change is followed by a slower and more substantial structural change to thermodynamically stable crystalline $[Co(NO_2)(NH_3)_5]Cl_2$ (monoclinic, C_2/c_1). The initial isomerization retains the original space group (orthorhombic, $P_{2_1}nb$) but ionic and intermolecular contacts apparently prevent a simple rotation in the Co—ONO plane in this case, and a more complex structural movement is necessary. The reverse photochemical reaction of the stable $[Co(NO_2)(NH_3)_5]Cl_2$ crystal gives a new crystalline modification of $[Co(ONO)(NH_3)_5]Cl_2$, which easily reverts to the original on standing. No ionic Cl^- is incorporated in these processes, and crystal dimensions again imply intramolecular reactions. Johnson and Pashman claim to have observed the 'transition state' complex involving bidentate species (A) in a low temperature photolytic study.[157]

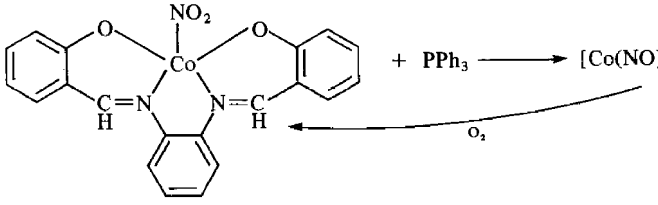
(22)



(A)

The solution chemistry of the Co—ONO to Co—NO_2 isomerization has now been widely studied, mostly with the pentaammine system. Basolo and coworkers initially showed the rate to be independent of added NO_2^- (Table 16) and the intramolecular nature was confirmed by ^{18}O-labelling studies.[142] Murmann earlier had shown that optically active $(+)_{589}$-*cis*-$[Co(NO_2)(ONO)(en)_2]^+$ isomerized with full retention of configuration[158] and this has been confirmed for the OH^--catalyzed reaction in a recent study.[143] The rate for the pentaammine complex has been recently measured in 16 solvents and the 100-fold variation (THF slowest, H_2O fastest) has been interpreted in terms of various solvent parameters; mild catalysis by F^-, AcO^- and NEt_3 is found in Me_2SO.[159] Hg^{2+}, Cd^{2+} and Ag^+ catalyze the reaction in water (Table 16) and in acetone (Zn^{2+} also), and the lack of competitive coordination by H_2O, AcO^- and NO_3^- for the induced path in water again point to a concerted intramolecular process.[159] The rate is also OH^- catalyzed (Table 16), $k_{obs} = k + k_{OH}[OH^-]$, and the large $\Delta V^{\ddagger}$ for k_{OH} ($27 \pm 1.4\,cm^3\,mol^{-1}$) points to the normal S_N1cb mechanism with a large $\Delta\bar{V}$ ($22\,cm^3\,mol^{-1}$) for ammine deprotonation.[143] A similar situation has been found with *cis*- and *trans*-$[Co(ONO)_2(en)_2]^+$ (Table 16).[160] The reaction has also been studied in $NH_{3(l)}$, where $k_{obs} = k[NH_4ClO_4]^{-1}$, indicating isomerization *via* $[Co(NH_2)(ONO)(NH_3)_4](ClO_4)$ (Table 16) and experiments using the specifically labelled *trans*-$^{15}NH_3$ complex show retention of geometrical configuration and the absence of competition for entry by NH_3.[161]

Oxygen scrambling has been demonstrated by Sargeson and coworkers using specifically labelled Co—^{17}ONO and Co—ON^{17}O pentaammine complexes.[151] Acid cleavage results in Co—$^{17}OH_2^{3+}$ from both reactants and this confirms the earlier 50% scrambling result obtained using ^{18}O-labelled complexes.[143] The spontaneous reaction gives a $k(O \rightarrow O)/k(O \rightarrow N)$ ratio of 1.2 indicating a slightly faster rate for the O to O interconversion. This is difficult to reconcile with the intramolecular rotation mechanism (equation 22) proposed for the solid-state reaction and suggests a more complex twist mechanism or momentary complete bond cleavage and re-entry of O and N.



The solution photochemistry of Co—NO_2 leads to both redox decomposition (Co_{aq}^{2+}) and isomerization to Co—ONO ($[Co(NO_2)(NH_3)_5]^{2+}$,[162] *cis*-$[Co(NO_2)_2(en)_2]^+$[163]). The ratio of products is wavelength independent, indicating efficient mixing of reactive LMCT and LF singlet excited states.[164] A semiquantitative model has been described by Endicott.[165] The isomerization pathway is facilitated by increasing solvent viscosity suggesting that the redox process may come at a later stage.[166] A possible mechanism is given by Scheme 14. Scandola and colleagues report acetone

sensitization of both k_{redox} and k_{isom} by an energy-transfer process and have discussed the relative energetics in some detail.[167] No attempt has been made to see if the excited-state species compete for 'spectator' anions (*e.g.* ion-paired NO_3^-) but apparently $Co—OH_2^{3+}$ is not formed. In aerated acetonitrile O_2 acts as a scavenger forming a $Co^{III}—O_2^-$ adduct, while in the absence of O_2 another Co^{III} complex is formed.[168] There has been a report that photolysis of *cis*-$[Co(OC_2O_3)(NO_2)(en)_2]$ leads to *ca.* 10% chelated $[Co(O_2C_2O_2)(en)_2]^+$ as well as $Co^{2+}_{(aq)}$,[169] but whether this results from direct entry of the free carboxylate group in the excited state or from subsequent chelation in the aqua complex is not yet known.

Scheme 14

Unlike Co—NO complexes (Section 47.4.1.3), the reactivity of coordinated nitro and nitrito ligands toward electrophiles is not well explored. However Tovrog and his colleagues at Allied Chemical Corporation have recently shown that (**28**) catalytically oxidizes PPh_3 in a bimolecular transfer of O from coordinated NO_2 (equation 23),[170] and that (**28**) and the similar porphyrin complex $[Co(TPP)(py)(NO_2)]$ both catalyze the oxidation of primary and secondary alcohols to aldehydes and ketones in the presence of the Lewis acids $BF_3 \cdot H_2O$ or $LiPF_6$; non-radical pathways are proposed.[171] Internal redox in $[Co(NO_2)_2(bipy)_2]X$ also occurs on heating, with oxygen transfer, to give the Co^{II} complex $[Co(NO_3)X(bipy)_2]$ and NO ($X = Cl^-$, Br^-, I^-, ClO_3^-, ClO_4^-).[172]

(23)

(28)

47.4.3 Nitriles

47.4.3.1 Cobalt(III)

Cobalt(III) nitrile complexes are easily prepared *via* displacement of a poorly coordinating ligand such as $(MeO)_3PO$, $(EtO)_3PO$ or $CF_3SO_3^-$ by RCN. Thus treatment of $[Co(N_3)_x(NH_3)_{6-x}]^{(3-x)+}$ with NOX ($X = ClO_4^-$, BF_4^-, $OSO_2CF_3^-$) in $(EtO)_3PO$, followed by addition of the nitrile and warming, or addition of the nitrile to $[Co(amine)_x\{(MeO)_3PO\}_{6-x}](ClO_4)_3$ and warming, or dissolution of $[Co(amine)_x(OSO_2CF_3)_{6-x}](CF_3SO_3)_{x-3}$ ($x = 5, 4, 3$) in the appropriate nitrile and warming, leads to excellent yields (Table 17). Jordan, Sargeson and Taube were the first to use such methods,[173] and subsequent reports by Balahura,[174] Sargeson and coworkers[175] and Kupferschmidt and Jordan[188] are recommended for more recent preparations. Most nitrile complexes are stable in neutral to acidic aqueous solution, and have yellow-orange colours characteristic of amine complexes.

The reactivity of coordinated nitriles towards nucleophiles, and electrophiles when deprotonated, has been of major interest. Addition of OH^- to the nitrile carbon occurs readily in alkaline solution, $k_{obs} = k_{OH}[OH^-]$, and the rate is increased some 10^6–10^7 times by coordination (equation 24).[176,177] k_{OH} has values of 1–50 $mol^{-1}\,dm^3\,s^{-1}$ for R = alkyl[177] [*e.g.* 3.4 (Me); 35 ($CH{=}CH_2$)] and varies over a wider range for substituted benzonitriles following a Hammett relationship.[178] For 2-cyanobenzonitrile addition of one equivalent of OH^- is followed by intramolecular amidine formation on treatment with further alkali (**29**), or by rearrangement in acid and hydrolysis to the diamide (**31**), or cyclization to the alternative amidine isomer (**32**; Scheme 17).[179] The alkaline hydrolysis of the

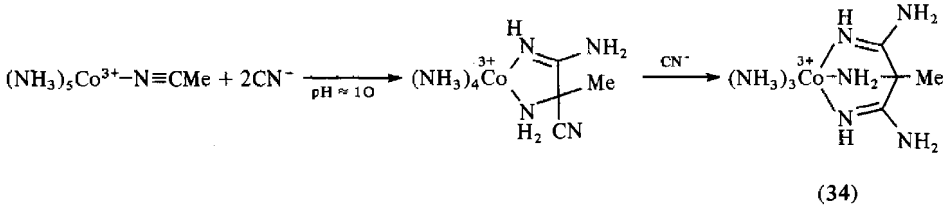
coordinated 2-cyanobenzamide intermediate (**30**) is very fast ($k_{OH} = 5.8 \times 10^6 mol^{-1} dm^3 s^{-1}$ and assistance by the adjacent amide substituent is likely.[179]. Attack by deprotonated coordinated amine centres on nitrile groups of coordinated ligands occurs under mild alkaline conditions to form bidentate amidines (**33**; equation 25).[180] Attack by other nucleophiles such as CO_3^{2-} and CN^- are known,[181,182] with the latter being followed by successive additions of coordinated ammonia and CN^- with the tridentate bis(amidine)aminomethylmalonate complex (**34**) resulting (Scheme 18).[182]

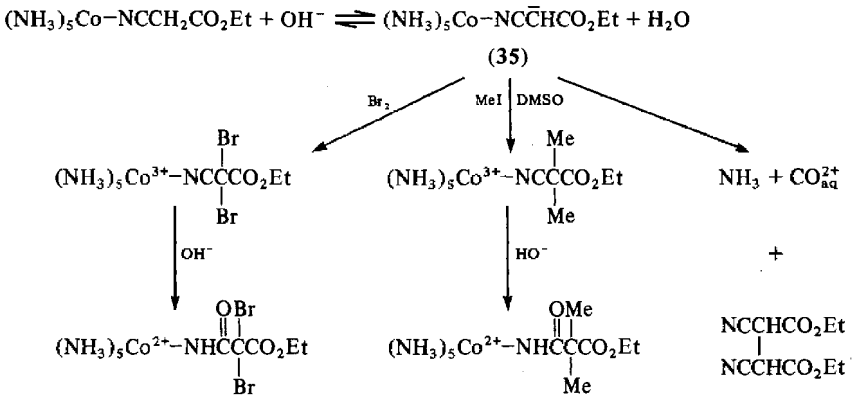
$$(NH_3)_5Co^{3+}—N{\equiv}CR + OH^- \longrightarrow (NH_3)_5Co^{2+}—NHC(=O)R \qquad (24)$$



Scheme 17

(25)

(33)

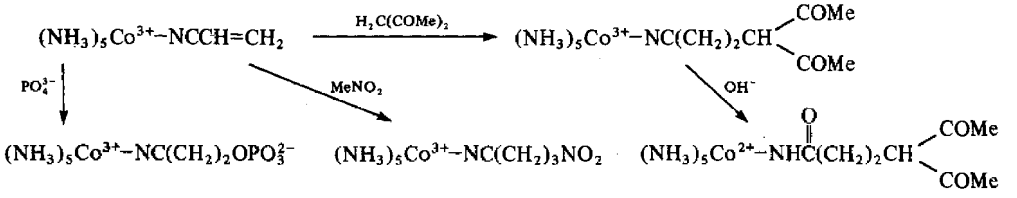


(34)

Scheme 18

Methylene groups adjacent to coordinated nitrile carbon are acidic (*e.g.* for R = CH_2CN, $pK_a = 5.7$) and rapidly undergo base-catalyzed proton exchange (for R = Me this is faster than hydrolysis), and addition of electrophiles other than H^+ to the resulting carbanion (**35**; Scheme 19).

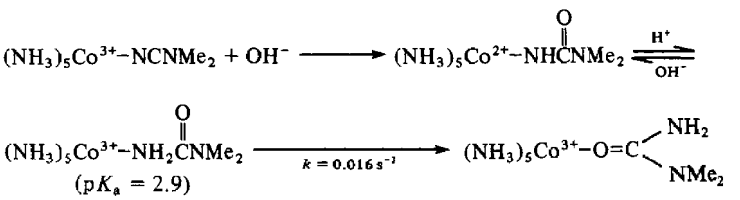
In the absence of an added electrophile the anions undergo spontaneous electron transfer to the metal with release of $Co^{2+}_{(aq)}$ and the nitrile radical, which dimerizes. Alternatively, the coordinated radical anion induces polymerization of methacrylate, styrene, acrylonitrile and methylacrylonitrile monomers under mild non-aqueous conditions.[181]



Reduction of coordinated nitrile to the parent amine can be accomplished with $NaBH_4$ in slightly

Scheme 19

alkaline aqueous solution (equation 26);[183] in acid solution, reduction results in the very rapid formation of $Co^{2+}_{(aq)}$ and Co^0. Adjacent double bonds are activated towards species possessing an acidic H atom. Thus coordinated acrylonitrile adds to acetylacetone, nitromethane and PO_4^{3-} to form saturated nitrile species (Scheme 20).[183]



$$(NH_3)_5Co^{3+}—N{\equiv}CR \xrightarrow[pH \approx 9]{BH_4^-} (NH_3)_5Co^{3+}—NH_2CH_2R \qquad (26)$$

Scheme 20

Coordinated cyanamide does not add OH^- to form the N-bound urea complex since it deprotonates ($pK_a \approx 5.2$) to give the unreactive $[Co(NCNH)(NH_3)_5]^{2+}$ ion, but in acid it readily loses NH_4^+ to form N-coordinated cyanate (equation 27).[183] The analogous dimethylcyanamide complex cannot deprotonate and adds OH^- to form urea (Scheme 21),[185] but this does not proceed further to coordinated carbamic acid and $NHMe_2$ in a process analogous to that suggested for the function of Ni^{2+} in the metalloenzyme jack bean urease (which catalyzes the conversion of urea to these products),[186] nor does it lose $NHMe_2$ to form the cyanato complex as suggested by Balahura and Jordan for the similar urea derivatives (equation 28).[193] Alternatively, in acid solution the protonated urea rapidly isomerizes to the O-coordinated complex ($t_{1/2} \approx 40$ s, 25 °C; Scheme 21).[185] This isomer undergoes OH^--catalyzed hydrolysis at the metal rather than at acyl carbon, so the function of the metalloenzyme has not been duplicated in this system. A similar property is found for O-bound urea (equation 29).[187]

Pathways for reduction of Co^{III}—NCR complexes by M^{2+} reductants ($Cr^{2+} < Eu^{2+} < V^{2+} < [Ru(NH_3)_6]^{2+}$ in a rate sense) are a continuing source of interest.[188–190] Most coordinated nitriles (**36**; equation 30) reduce *via* an outer-sphere pathway (*i.e.* without specific prior attachment of the reductant), but an inner-sphere route becomes available when R = CH_2CO_2H, $CH_2CO_2^-$ in an appropriately substituted aryl species (**37**), especially with $Cr^{2+}_{(aq)}$ ($[Ru(NH_3)_6]^{2+}$ provides a marker rate for the outer-sphere reaction). Some representative data are given in Table 18. Reduction of the corresponding *m*-substituted derivatives (**38**) is some 10 times slower and appears to occur *via* the outer-sphere route.[190] Kupferschmidt and Jordan[188] point out the possibility of an outer-sphere mechanism when the oxidant and reductant can approach each other in flexible intermediates such as (**39**), but this is prevented in (**37**) species. The same authors[191] have come up with the interesting observation that the radical cation intermediate (**40**; equation 31) appears to react preferentially with Cr^{2+} to form $[(NH_3)_5CoNCCH_2Cr(OH_2)_5]^{5+}$ rather than undergo internal reduction to $Co^{2+}_{(aq)}$. This differs from that found with radical anion (**35**). Recently Anderes and Lavallee have shown that the Ru^{II}—Co^{III} dimer (**41**) is very inert ($k < 3 \times 10^{-6}\,s^{-1}$) to electron tunnelling through the insulating bicyclooctane bridge.[192]

$$(NH_3)_5Co^{3+}—NCR + Cr^{2+} \xrightarrow{H^+} Co^{2+}_{(aq)} + 5NH_4^+ + RCN + Cr(H_2O)_6^{3+} \quad (30)$$

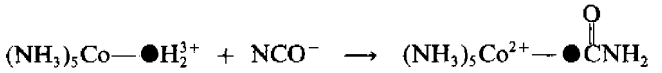
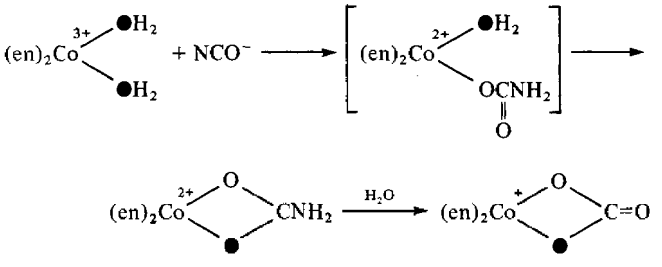
47.4.4 Cyanate, Thiocyanate and Selenocyanate

A review of the coordination chemistry of these ligands is available.[194]



47.4.4.1 Cobalt(III)

Balahura and Jordan[193] first prepared $[Co(NCO)(NH_3)_5](ClO_4)_2$ by heating the aqua complex with urea or a substituted urea in trimethyl phosphate; dimethylacetamide as a solvent gives a better yield (Table 19). Coordination is *via* the N atom. The O-bound isomer has not been reported and is probably unstable to rapid isomerization. Other $CoNCO^{n+}$ complexes have been prepared from the aqua complex, and $K_3[Co(CN)_5(NCO)]$ from the $(EtO)_3PO$ complex (Table 19). $[Co(NCO)(NH_3)_5]^{2+}$ protonates and rapidly adds water to form the carbamic acid complex (**42**). This subsequently aquates, isomerizes to the O-bound carbamate (**43**), and forms $[Co(NH_3)_6]^{3+}$ depending on $[H^+]$ (Scheme 22).[195] Linhard and Flygare[196] showed that treating $[Co(NH_3)_5OH_2]^{3+}$ with NCO^- results in the O-bound carbamate complex (equation 32), and Sargeson and Taube showed that this occurred with retention of the Co—O bond.[197] Similar treatment of *cis*-$[Co(en)_2(OH_2)_2]^{3+}$ finally results in the carbonato chelate $[Co(O_2CO)(en)_2]^+$ *via* the chelated carbamate (Scheme 23).[197]



(42) (43)

Scheme 22

(32)

Scheme 23

Treatment (heating is usually required) of $Co—OH_2^{3+}$ with NCS^- results in the isothiocyanato complex $Co—NCS^{2+}$. These have been known since the beginnings of coordination chemistry and many syntheses are described in 'Inorganic Synthesis' (Table 3). Vinaixa and Ferrer have recently described the preparation of $[Co(NCS)(NH_3)_5]^{2+}$ as an undergraduate experiment in kinetics and preparative chemistry.[198] The Co—NCS group is linear or almost so with a Co—N bond length of ~195 pm; a similar bond length is found in amine complexes. Many crystal structures have been determined, and two recent studies on *trans*-$[Co(NCS)_2(NH_3)_4](OAc)$[199] and $(-)_{589}$-$[Co(NCS)_2(tn)_2]_2(Sb_2(+)tart_2)\cdot 4H_2O$[200] may be consulted for details. The Co—NCS bond is very robust, and most complexes are stable in acidic and alkaline solution for long periods of time.

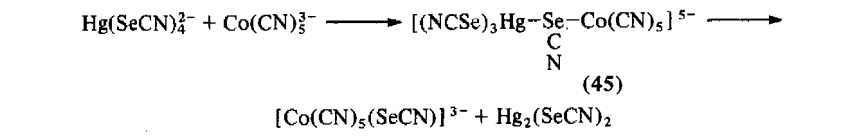
Reversible coordination of heavy metals (Ag^+, Hg^{2+}, Tl^{3+}, Cu^{2+}, Fe^{3+}) can occur to form Co—NCS—M^{n+} species, with an orange to yellow colour change for $[Co(NH_3)_5(\mu\text{-NCS})Hg]^{4+}$.[201]

The thiocyanato linkage isomer Co—SCN^{2+} has been found in several complexes (Table 19). This grouping is bent about the S atom (105°) in $[Co(SCN)(NH_3)_5]Cl_2 \cdot H_2O$ with a Co—S bond length of 225–235 pm. No structural *trans* effect is observed.[202] For the labile $[Co(SCN)(Bu^tpy)(DMGH)_2]$ complex the Co—SCN isomer is favoured by protic solvents (MeOH) and aprotic solvents of low dielectric constant (C_6H_6, CH_2Cl_2), whereas the Co—NCS isomer predominantes in DMF and DMSO.[203] Gutterman and Gray[204] showed that $K_3[Co(CN)_5(NCS)]$ isomerizes to $K_3[Co(CN)_5(SCN)]$ when the solid is heated above 128 °C, whereas the Et_4N^+ salt does the reverse at ambient temperature over 3 d; in solution the S-bonded isomer is favoured by protic solvents, whereas low dielectric solvents (CH_2Cl_2, acetone, nitrobenzene) favour the N-bonded species.[205] $R_3[Co(CN)_5(SeCN)]$ (R = K, Bu^n) follows a similar cation behaviour in the solid and in solution. Rates of dissociation follow the order Co—SCN > Co—SeCN > Co—NCS > Co—NCSe in DMSO. It appears that hard cations (K^+, Cs^+, $MeNH_3^+$) favour S and Se coordination, while soft cations (Me_4N^+, $Bu^n_4N^+$) favour N coordination. Gutterman and Gray put forward a convincing argument for such variations based on polarization effects,[206] but H bonding of the solvent to the N end of NCS^- and Co—SCN seems to play a role.[205] Alkylcobaloximes react with NCX^- (X = Se, S, O) to form labile $[CoR(NCX/XCN)(DMGH)_2]^-$ systems which equilibrate rapidly in solution with a Co—XCN bonding preference Se ≫ S > O. This is in agreement with inert $[Co(XCN)(DMGH)_2(B)]$ systems (B = py, pip).[207]

$[Co(SCN)(NH_3)_5]^{2+}$ isomerizes spontaneously to $[Co(NCS)(NH_3)_5]^{2+}$ in aqueous solution and in the solid chloride salt,[202,208] but some 45% lattice $S^{14}CN^-$ is incorporated on heating $[Co(SCN)(NH_3)_5](S^{14}CN)_2$.[209] The similar isomerization of *t*-$[Co(SCN)(tren)(NH_3)]^{2+}$ in aqueous solution incorporates some $S^{14}CN^-$ into both the Co—SCN^{2+} reactant and Co—NCS^{2+} product[210] so that bond breaking rather than rotation about the ligand π system seems to be involved (equation 33). The reaction is also catalyzed by Hg^{2+},[211] Ag^+ and OH^-,[208] with Co—OH_2^{3+} or Co—OH^{2+} being formed in addition to Co—NCS^{2+}. For the Hg^{2+} and Ag^+ reaction NO_3^- competes for both the Co—NCS^{2+} and Co—OH_2^{3+} products,[210] whereas N_3^- is found to compete for only the Co—OH^{2+} product in the OH^--catalyzed reaction.[208] Some (~0.5%) intramolecular *trans*-Co—SCN^{2+} to *cis*-Co—NCS^{2+} isomerization has been found in the base hydrolysis of *trans*-$[Co(SCN)(NH_3)(en)_2]^{2+}$,[212] but no *t*-Co—$SCN^{2+}$ to *p*-Co—NCS^{2+} isomerization occurs with *t*-$[Co(SCN)(NH_3)(tren)]^{2+}$ under the same conditions and the earlier experiments needs to be re-examined.[210]



(33)

Electron transfer reactions mediated by $[Co(CN)_5]^{3-}$ proceed *via* attack on the adjacent S atom with the rate of reaction (34) being considerably faster than reaction (35), both leading to the S-bonded $[Co(CN)_5(SCN)]^{3-}$ isomer (**44**).[213] Similarly $[Co(CN)_5]^{3-}$ appears to react with $[Hg(SeCN)_4]^{2-}$ *via* the bridged species (**45**, Scheme 24).

$$(NH_3)_5Co^{2+}—SCN + Co(CN)_5^{3-} \longrightarrow Co^{2+} + 5NH_3 + [(NC)_5Co—SCN]^{3-} \quad (34)$$

(**44**)

$$(NH_3)_5Co^{2+}—NCS + Co(CN)_5^{3-} \longrightarrow Co^{2+} + 5NH_3 + [(NC)_5Co—SCN]^{3-} \quad (35)$$

(**45**)

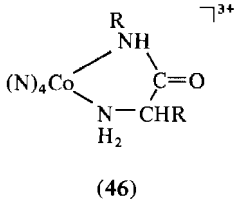
Scheme 24

Bridged complexes containing NCX^- (X = O, S, Se) have been synthesized in both isomeric forms by treating ligand-inert $[Co(XCN)(DMGH)_2(py)]$ (X = S, Se) or $[Co(NCX)(DMGH)_2(py)]$ (X = O, S) with labile $[CoR(DMGH)_2(H_2O)]$ in the presence of an oxidizing agent such as CCl_3Br.[207] Remote attack is suggested (equation 36). The resulting dimer is prone to dissociation

with the rate increasing $CN^- > SCN^- > SeCN^- > NCS^- \gg NCO^-$.[207] Likewise, dimeric complexes $[(L)(DMGH)_2Co—XCN—Co(DMGH)_2XCN]$, involving L = $AsPh_4$, $SbPh_4$, $SbBu^n_4$, have been prepared for X = Se, S.[214]

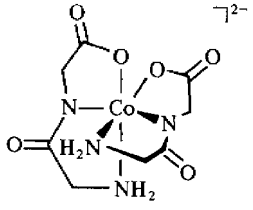
$$[Co(NCS)(DMGH)_2(B)] + [CoR(DMGH)_2(OH_2)] \longrightarrow [(B)(DMGH)_2Co—NCS—Co(DMGH)_2R] + H_2O \quad (36)$$

47.4.5 Ureas, Amides and Peptides



A general review of the coordinating ability of amides is available,[215] as is a more specific article dealing with the reactivity of coordinated esters, amides and peptides.[216]

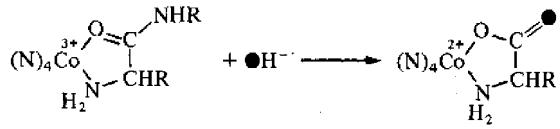
47.4.5.1 Cobalt(III)



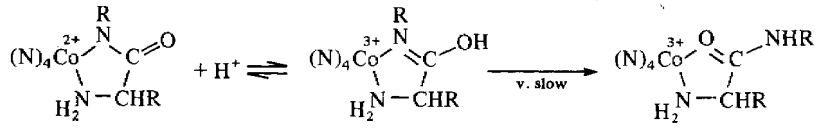
The O-bound urea complex $[Co(NH_3)_5\{OC(NH_2)_2\}](ClO_4)_3$ can be prepared from the aqua or trifluoromethylsulfonate complex (Table 94). It slowly aquates in dilute acid ($k = 4.0 \times 10^{-5}\,s^{-1}$, 25 °C) hydrolyzes in alkali ($k_{OH} = 15.3\,mol^{-1}\,dm^3\,s^{-1}$) largely with Co—O bond fission (equation 37).[187] The N-bound isomer $[Co(NH_3)_5\{NH_2CON(R)_2\}]^{3+}$ has been prepared (R = H, Me) but rapidly isomerizes to the O-bonded species in acid solution ($k_i = 1.6 \times 10^{-2}\,s^{-1}$).[185] A similar property holds for the N-coordinated carbamic acid complex $[Co(NH_3)_5(NH_2CO_2H)]^{3+}$ ($k_i = 8 \times 10^{-2}\,s^{-1}$).[195] Both these 3+ ions are reasonably acidic ($pK_a = 2.9$, -0.4 respectively) with the conjugate base forms being stable to isomerization. However $[Co(NH_3)_5(NHCO_2H)]^{2+}$ gives rise to $[Co(NH_3)_6]^{3+}$ and $CO_{2(g)}$ spontaneously;[195] $[Co(NH_3)_5(NHCONMe_2)]^{2+}$ does not result in $[Co(NH_3)_6]^{3+}$, CO_2 and $NHMe_2$.[185]

$$(NH_3)_5Co^{3+}—O=C(NH_2)(NH_2) \ (pK_a\ 13.2) + \bullet H^- \xrightarrow{97\%} (NH_3)_5Co—\bullet H^{2+} + (NH_2)_2CO$$
$$\xrightarrow{3\%} (NH_3)_5Co—OH^{2+} + (NH_2)_2C\bullet \quad (37)$$

The O-coordinated dimethylformamide and acetamide complexes are susceptible to slower OH^- attack at the carbonyl centre with significant retention of the Co—O bond, *e.g.* equation (38).[217] The reasons for this change in site of attack are not well understood. Likewise, O-chelated amides and peptides are very susceptible to OH^- attack with hydrolysis being accelerated 10^4–10^5 times by coordination.[216] This is the basis of the N-terminal cleavage of small peptide fragments first studied by Buckingham and Collman[218] and extended by others in recent times (equation 39).[219] N-coordinated amides (**46**) are inert to alkaline hydrolysis (they are in fact stabilized by the metal) and this deprotonated form is the preferred bonding mode for Co^{II} and Co^{III} systems in alkaline solution. Coordination results in immediate deprotonation for kinetically labile Co^{II} complexes near pH 10,[220] and protonation of the kinetically more robust Co^{III} complexes ($pK_a \approx 1$) results in the iminol tautomer (**48**), *e.g.* $[Co(Gly\text{-}GlyH)_2](ClO_4)$ (Table 21, crystal structure), rather than the N-bound amide. This protonated amide form slowly reverts to the O-bound amide in $[Co(NH)_3(Gly_4)]^{2+}$ ($k = 2.5 \times 10^{-5}\,s^{-1}$);[221] this property is probably a general one (equation 40).



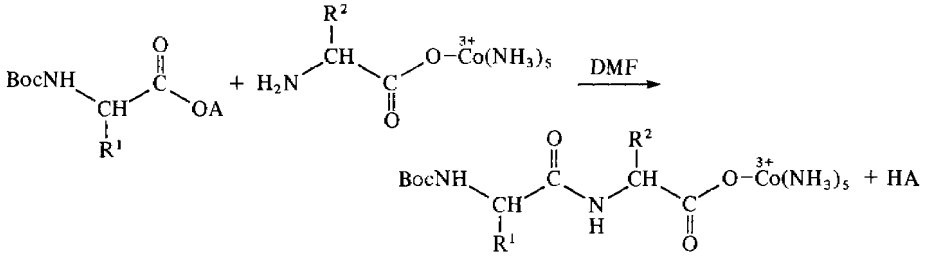
(46)



(47)

$$(NH_3)_5Co^{3+}—O=C(H)(NMe_2) + \bullet H^- \longrightarrow (NH_3)_5Co^{2+}—O\overset{\bullet}{C}H + HNMe_2 \quad (38)$$

(39)



(40)

(48)

Preparations for some Co^{III} amide and peptide complexes are given in Table 20. In oxygen-free aqueous solutions $Co^{2+}_{(aq)}$ forms weak, pink complexes with peptides,[220] chelated *via* the terminal amino N and amide O atoms. Near pH 10 two equivalents of OH^- are consumed and the light-blue solutions containing $[Co(dipeptide)_2]^{2-}$ presumably have the meridional structure (**47**) shown by the analogous Ni^{II} complex.[222] The Co^{II} complexes adopt an electronic configuration of intermediate spin, $\mu \approx 4.1$ BM.[220] Co^{III} peptide complexes have been prepared by several routes and most have been reviewed by Gillard and coworkers.[223] These authors favour using CoO(OH) but Hawkins and his colleagues have used the peroxo decaammine dimer $[\{Co(NH_3)_5\}_2O_2](NO_3)_4$ with considerable success, particularly in preparing mixed ammine–peptide systems.[224] Gillard reports the partial resolution into optical enantiomers of $[Co(Gly\text{-}Gly)_2]^-$ and the separation of other [Co(AA—A′A′)$_2$]$^-$ diastereoisomers by chromatographic methods.[223] Some crystal structures are available (Table 21). The C-terminal methylene residue of $[Co(Gly\text{-}Gly)_2]^-$ undergoes proton exchange in alkali, and Gillard has shown that it reacts with HCHO and MeCHO in the presence of Na_2CO_3 forming $[Co(Gly\text{-}Ser)_2]^-$ and $[Co\{Gly\text{-}(R,S)Thr\}_2]^-$ respectively.[223]

The enhanced reactivity of chelated amino acid esters towards attack by other nucleophiles has been used to advantage in the sequential synthesis of small peptides equation (41).[225] Formation of the amide bond takes only seconds to minutes at room temperature in DMSO as solvent, and the peptide can be easily recovered by reducing the metal to the Co^{II} state. Recent studies have shown that the Λ and Δ diastereoisomeric reactants are selective in their couplings to (*R*) and (*S*) amino acid esters and that mutarotation at the asymmetric centre of the chelated ester reactant varies from 0–6%.[226] Isied and coworkers have described the use of the $Co(NH_3)_5^{3+}$ as a C-terminal protecting group for the sequential synthesis of peptides (equation 42).[227] This procedure has advantages over other methods in some cases.

$$\Lambda\text{-}[Co(AAOMe)(en)_2]^{3+} + A'A'OMe \longrightarrow \Lambda\text{-}[Co(AAA'A'OMe)(en)_2]^{3+} + MeOH \quad (41)$$

(42)

47.4.6 Pyridine, Pyrazine, Triazine and Purine

47.4.6.1 Cobalt(II)

Violet (octahedral, polymeric chain structure) and blue (tetrahedral, monomer) $[CoCl_2(py)_2]$ have been known for a very long time and an early paper by Gill, Nyholm and their colleagues is recommended as an informative starting point to the colours, magnetic properties and structural possibilities of the $[CoX_2(Rpy)_2]$ series (X = Cl, Br, I, NCS).[228] A recent paper by Darby and Vallarino discusses later work.[229] Preparation is easy: addition of an ethanolic solution of anhydrous CoX_2 (sometimes containing dimethoxypropane or triethyl orthoformate as a water scavenger) to a hot solution of the ligand results in blue (tetrahedral) or pink (octahedral) complexes depending on the ratios used. Equilibrium (43) is temperature,[230,231] pressure[231] and solvent[232,233] dependent with the tetrahedral form being stabilized by low pressures and high temperatures. Structures are known

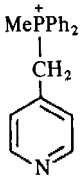
in many instances (Table 22) with little distortion form tetrahedral coordination but with tetragonal distortion and *trans* X ligands for the pink octahedral systems. The magnetic[234] and ESR[235] properties of the latter have been accurately accounted for using the angular overlap MO formalism. Establishment of successive equilibria (equations 44 and 45) have been investigated by T-jump and ^{15}N NMR methods ($k_3 = 3.1 \times 10^3\,mol^{-1}\,dm^3\,s^{-1}$,[236] $k_{-4} = 6.5 \times 10^6\,s^{-1}$)[237] and the $[CoBr_2(py)_3]$ intermediate has been detected in the bromide system.[238] Similarly $[CoCl_3(py)]^-$ can be formed by adding Bu^n_4NCl to $\{CoCl_2(py)_2]$[239] and has been isolated.[240]

$$[CoX_2(Rpy)_2] + 2Rpy \rightleftharpoons [CoX_2(Rpy)_4] \quad (43)$$
blue pink

$$[CoCl_2py_2] + py \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} [CoCl_2py_3] \quad (44)$$

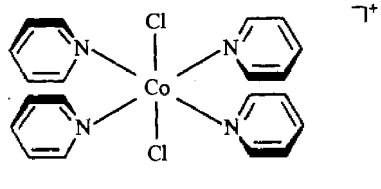
$$[CoCl_2py_3] + py \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} [CoCl_2py_4] \quad (45)$$

Various carboxylate complexes of the type $[Co(O_2CR)_2py_2]$ are known and in general they adopt a distorted octahedral configuration with bidentate carboxyl and *trans* pyridine ligands.[241] *Cis–trans* equilibria in $[Co(O_2CCF_3)_2(Me_xpy)_2]$ have been studied by ^1H NMR line broadening as a function of temperature.[242] Oxidative decarbonylation of $Co_2(CO)_8$ occurs when it is treated with picolinic acid or 2,6-dipicolinic acid with $[Co_2(pic)_3(picH)_3][Co(CO)_4]\cdot 3H_2O$ and bright-purple polymeric $[Co(dipic)]_n$ being isolated from refluxing methanol.[249]



Pyrazine forms pink insoluble $[CoX_2(pyz)_2]$ and $[CoX_2(pyz)]$ complexes (X = Cl, Br, I), which are presumably polymeric and octahedral,[243] but monomeric tetrahedral units are possible with increased methyl substitution. No direct confirmation of bridging pyrazine has been found in these Co^{II} systems. Some orange-red 2-substituted carboxylate and carboxamide pyrazine complexes have been prepared[244] and a distorted octahedral geometry has been confirmed by O'Connor and Sinn, with chelated ligands (Table 22). No well-characterized pyridazine or pyrimidine complexes have been reported.

Pink $[CoX_2(trz)_2]$ and green $[CoX_2(trz)]$ complexes of 1,2,3-triazine are known[245] and bridging triazine is possible. Orange-coloured $[Co(purine)_2](ClO_4)_2\cdot 3H_2O$ has been isolated and a bridging role for at least one purine has been suggested,[246] but the structure of $[Co(OH_2)_4(adenine)_2]^{2+}$ with monodentate *trans* octahedral coordination *via* N-9 of the five-membered purine ring makes this unlikely (Table 25).



$[CoBr_3(L)]$ complexes containing the cationic ligands (**49**) and (**50**) have been reported[247] and many linear and branched ligand systems containing pyridine are known; a recent article by Martell and coworkers may be consulted for details.[248]

Polymers containing the 4-vinylpyridine moiety complexed to cobalt(II) acetate have been used to catalyze the condensation of aldehydes with ketones. High yields of α,β-unsaturated ketones are formed at 80 °C in DMF.[250]

47.4.6.2 Cobalt(III)

Preparations of representative complexes are given in Table 23 and crystal structures in Table 22. Recent preparations of $[CoX_3(py)_3]^{n+}$ and $[CoX(py)_4]^+$ by Schaffer and his colleagues[251–253] have made available a wide range of complexes (Scheme 25). The solvolysis of *trans*-$[CoCl_2(Rpy)_4]^+$ has been studied in water–alcohol mixtures by Elgy and Wells who correlate activation parameters with changes in solvation structure of the transition state.[254] The well-known slow acid-catalyzed hydrolysis of bidentate carbonate in these systems has been studied in some detail by Harris and coworkers for $[Co(CO_3)(py)_4]^+$;[259] the immediate product is thought to be the *trans*-$[Co(OH_2)_2(py)_4]^{3+}$ ion. Utsuno claims to have isolated the asymmetric atropisomer (**51**) by treating *trans*-$[CoCl_2(py)_4]Cl\cdot 6H_2O$ with $(-)_{589}$-Hdibenzoyl tartrate.[255] A large number of mixed-ligand complexes containing oxalate, malonate or carboxylate in addition to pyridine are available, and a recent paper by Fujinami and his colleagues may be consulted for details.[256]

Scheme 25

Table 23 Preparations: Cobalt Complexes Containing Six-Membered N-Heterocyclic Ligands

Complex	*Preparation*	*Comments*	*Ref.*
Cobalt(0)			
$[Co(bipy)_3]$	$CoCl_2 \cdot THF + Li_2$bipy; THF, r.t.	Dark blue; $\mu = 2.23$ BM	3
$[Co(bipy)_2]$	Co + toluene, −196 °C; bipy, warm	Black-green; $\mu = 2.02$ BM	4
Cobalt (I)			
$[Co(bipy)_3]ClO_4$	$[Co(bipy)_3](ClO_4)_2 + bipy + NaBH_4$	Dark blue; 285 nm; ^1H NMR	1, 5
$[Co(phen)_3]ClO_4$	$[Co(phen)_3](ClO_4)_2 + NaBH_4$; EtOH–$H_2O$, −5 °C, vac.	Dark brown	2
Cobalt(III)			
trans-$[Co(Cl)_2(py)_4]Cl \cdot 6H_2O$	$CoCl_2$ + py + MeOH; heat, 15 min.; cool −40 °C, $Cl_{2(l)}$, <25 °C, 40 °C, 4 M HCl	Green; ε_{631} 43; ε_{505} 30	6, 10
trans-$[Co(F)_2(py)_4](ClO_4) \cdot 0.5H_2O$	*trans*-$[Co(Cl)_2(py)_4]Cl \cdot 6H_2O + HF_{(l)}$; −70 °C; $Hg(OAc)_2$; MeOH; 70% $HClO_4$	Red-purple; ε_{567} 27.5; ε_{479} 37.8	6
$[Co(F)_2(H_2O)(py)_3]ClO_4$	$[Co(CO_3)Cl(py)_3] + HF_{(l)}$	Purple; ε_{520} 40.5; ε_{381} 48	6
$[Co(CO_3)Cl(py)_3]$	$CoCl_2 \cdot 6H_2O + KHCO_3 + H_2O_2$; H_2O, 5 °C, py, 12 M HCl, 1 h; stand	Blue-violet; ε_{577} 50; ε_{409} 60	7
$[Co(CO_3)(py)_4]ClO_4 \cdot H_2O$	$[Co(CO_3)Cl(py)_3]$ + py + $Hg(ClO_4)_2$; 50 °C, 45 min; cool	Red; ε_{530} 172; ε_{379} 190	7
trans-$[Co(H_2O)_2(py)_4](ClO_4)_3 \cdot 4H_2O$	$[Co(CO_3)(py)_4]ClO_4 \cdot H_2O$ + 70% $HClO_4$	Brown; ε_{560} 44; ε_{490} 51; $pK_{a(1)}$ 1.37	7
mer-$[Co(Cl)_3(py)_3]$	$[Co(CO_3)Cl(py)_3]$ + 12 M HCl; r.t.	Green; ε_{640} 60.2; ε_{670} 57.7	8
mer-$[Co(H_2O)_3(py)_3](ClO_4)_3$	$[Co(CO_3)(H_2O)(py)_3]ClO_4$ + 12 M $HClO_4$	Purple; ε_{518} 52	8
cis-$K[Co(CO_3)_2(py)_2] \cdot 2H_2O$	$K_3[Co(CO_3)_3]$ + py; 25 °C, 100 h	Purple; ε_{561} 165; ε_{388} 232	9
$[Co(NH_3)_5pyz](ClO_4)_3$	$[Co(NH_3)_5DMSO](ClO_4)_3$ + pyz; DMSO 90 °C, 30 min.	Yellow-orange; ε_{473} 54	11
$[Co(terpy)_2]X_2 \cdot nH_2O$ (X = Cl, Br, NO_3, ClO_4)	CoX_2 + terpy; H_2O heat	Brown-red; ε_{654} 100; ε_{549} 450	12
$[Co(bipy)_3](ClO_4)_2$	$CoCl_2 \cdot 6H_2O$ + bipy; EtOH, heat	Orange; $\mu = 4.85$	13
$[Co(phen)_3](ClO_4)_2 \cdot H_2O$	$CoCl_2 \cdot 6H_2O$ + phen; EtOH	Orange-red	14
$[Co(CO_3)(bipy)_2]ClO_4$	$Na_3[Co(CO_3)_3] \cdot 3H_2O$ + bipy; H_2O, 8 h, $NaClO_4$ to hot soln.	Dark red; ε_{504} 116	15, 16
cis-$[Co(H_2O)_2(bipy)_2](ClO_4)_3 \cdot H_2O$	$[Co(CO_3)(bipy)_2]ClO_4 + HClO_4$; H_2O, 72 h	Orange-red; ε_{490} 60; $pK_{a(1)}$ 4.6; $pK_{a(2)}$ 7.0	15, 16
cis-$[Co(X)_2(bipy)_2]X$	$CoCl_2 \cdot 6H_2O$ + bipy; H_2O or MeOH; O_2 or X_2 oxidation	*cis* (purple) for X = Cl; ε_{538} 58 (*cis*)	17, 18
cis-$[Co(Cl)_2(phen)_2]Cl \cdot 3H_2O$	$CoCl_2$ + phen; MeOH, reflux; −60 °C, $Cl_{2(l)}$; 65 °C, 4 M HCl	Violet; ε_{542} 56.6	18

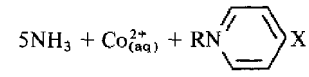
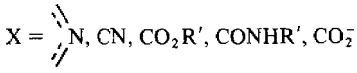
The 2,6-dipicolinic acid complex $[Co(dipic)_2]^-$ has recently been used as a lipophilic oxidant to study electron transfer with cytochromes *c* and c_{551} and with the blue copper centre in stellacyanin, plastocyanin and azurin; penetration of the complex towards the metal centre of the protein is thought to aid electron transfer.[257,271]



Pentaammine complexes may be easily prepared using readily replaceable trimethyl phosphate[173] or trifluromethanesulfonate[175] in $[Co(NH_3)_5L]^{3+,2+}$, using an inert solvent such as sulfolane or trimethyl phosphate. For N-heterocyclic donors, however, reaction (46) is perhaps most convenient since $[Co(NH_3)_5(DMSO)](ClO_4)_3$ is easier to prepare.[260] Chromatographic purification is recommended using ~4 M HCl as eluent. As an example, the work of Leopold and Haim on the preparation of 4,4′-bipyridyl complexes may be consulted.[261] It is likely that *cis*- and *trans*-$[Co(amine)_4(N\ heterocycle)_2]^{3+}$ can be prepared from the corresponding trifluoromethanesulfonate complex using sulfolane or HMPA as solvent.[175] A variety of nicotinamide complexes have recently been made *via* the 'old' method using $[Co(NH_3)_5(OH_2)](ClO_4)_3$ in aqueous solution.[258]



$$[Co(DMSO)(NH_3)_5]^{3+} + \text{N heterocycle} \xrightarrow[DMSO]{90\,^\circ C} [Co(\text{N heterocycle})(NH_3)_5]^{3+} + DMSO \quad (46)$$

Studies on the rates and mechanisms of reduction of $[Co(NH_3)_5L]^{3+}$ species, where L = pyridines, pyrazines, fused bipyridyls and bipyridyls containing ester, acid, nitrile and amide substituents, by metal reductants (Cr^{2+}, V^{2+}, Eu^{2+}) continue to be advanced by Gould and coworkers. For this class of reductants there is good evidence for rapid electron transfer to form a radical oxidant (**52**), with slower subsequent tunnelling of the electron to the Co^{III} centre (Scheme 26). A break in conjugation seriously slows down the k_2 step and sometimes the intermediate can be detected.[360] A representative paper by Gould may be consulted for details.[262] Reduction by $e^-_{(aq)}$, HO· and R· has also been extensively studied,[263,264] while Taube[265] and Haim[266] and their colleagues continue to study the rates of electron transfer in stable bridged species such as (**53**), and in ion pairs such as (**54**). Both adiabatic and non-adiabatic electron transfer appear possible. Marlin, Ryan and O'Halloran have generated the similar intermediate (**55**) and have followed its thermal and photoinduced reactions.[267] Weaver has studied reduction on Hg, Pt and Au surfaces.[268] Such investigations have considerable interest, both as regards understanding more about the barriers to electron transfer by combining theory and experiment and as a means of providing basic knowledge for biological electron transfer. A useful readable account of these studies up to 1975 is provided by Haim,[269] and Taube's small book 'Electron Transfer Reactions of Complex Ions in Solution' provides eloquent background.[270]

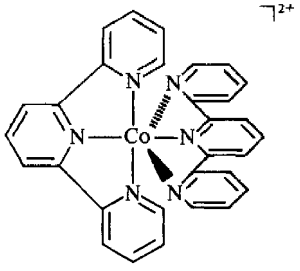
47.4.7 Phenanthroline, Bipyridyl and Terpyridyl



An early review article is available.[272]

47.4.7.1 *Cobalt(−1), cobalt(0) and cobalt(I)*

Low oxidation state complexes have been known for a long time. Vlĉek in 1957 isolated dark blue crystals of $[Co(bipy)_2](ClO_4)$ following $NaBH_4$ reduction of $[Co(bipy)_3](ClO_4)_3 \cdot 3H_2O$ in H_2O–EtOH and showed that the redox process was electrochemically reversible;[273] in the same year Waind and Martin correctly reported this complex as $[Co(bipy)_3](ClO_4)$.[284] Since then the redox chemistry of $[Co(bipy)_3]^{n+}$, $[Co(phen)_3]^{n+}$ and $[Co(terpy)_2]^{n+}$ has been extensively explored, and a crystal structure of $[Co(bipy)_3]Cl \cdot H_2O$ is available (Table 22). Some preparations are given in Table 23. A structure of the intermediate BH_4^- adduct (**56**) is also available (Table 22).

(56)

(57)

The redox chemistry (equations 47 and 48) is largely reversible in acetonitrile (0.1 M Et_4NClO_4)[274–276,282] and appears to be ligand based, although the expected tetragonal distortion is not particularly evident in the crystal structure of $[Co(bipy)_3]Cl \cdot H_2O$. Note the $2e^-$ change for the $[Co(phen)_3]^{+/-}$ process *vs.* the stepwise $1e^-$ changes for the $[Co(terpy)_2]^{+/0/-}$ system.

$$Co(N{-}N)_3^{3+} \overset{e^-}{\rightleftharpoons} Co(N{-}N)_3^{2+} \overset{e^-}{\rightleftharpoons} Co(N{-}N)_3^{+} \overset{2e^-}{\rightleftharpoons} Co(N{-}N)_3^{-} \qquad (47)$$

N—N	$E_{1/2}$ *vs. SCE* (V)	
phen[275]	+0.37	−0.95	−1.64
bipy[282]	+0.30	−0.97	−1.56

$$Co(terpy)_3^{3+} \overset{e^-}{\rightleftharpoons} Co(terpy)_3^{2+} \overset{e^-}{\rightleftharpoons} Co(terpy)_3^{+} \overset{e^-}{\rightleftharpoons} Co(terpy)_3^{0} \overset{e^-}{\rightleftharpoons} Co(terpy)_3^{-}$$

$E_{1/2}$ *vs. SCE* (V)[276] +0.28 −0.77 −1.65 −2.00 (48)

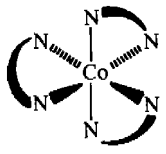
The high-spin character of $[Co(bipy)_3]^+$ ($\mu = 2.53$–2.89 BM)[277,278] and ^1H NMR[279] have been used as evidence for $\sigma_d \rightarrow \pi_{bipy}$ spin delocalization, and the near-UV[279] and near-IR[277] spectra are due to π–π^* transitions in the ligand resulting from this delocalization. Much of the additional electron density in these low-valent complexes clearly resides on the conjugated ligand[272] and the absence of similar reduced $[CoX_2(py)_4]^{n-}$ or $[Co(py)_6]^{+,0}$ species may result in part from conjugation. Apparently $[Co(bipy)_3]^+$ in water produces stoichiometric quantities of H_2 and $[Co(bipy)_3]^{2+}$[280] but the details appear to be complex.[281] The electrochemical properties of related tris{(2-pyridyl)amine}-cobalt(II) complexes have also been discussed.[285]

Metal-vapour-deposition methods have begun to provide new low-valent complexes of uncommon stoichiometry. The preparation of gram quantities of paramagnetic ($\mu = 2.02$ BM) $[Co(bipy)_2]$ has been reported and its reactions with Br_2, tetracyanoethylene and tetracyanoquinodimethane studied.[283] Electrochemically it behaves identically to $[Co(bipy)_3]^{2+}$ (equation 47).[283]

47.4.7.2 *Cobalt(II)*

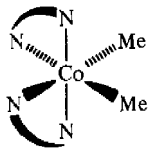
Orange-brown $[Co(N{-}N)_3]^{2+}$ (N—N = bipy, phen) has been known since the days of Burstall and Nyholm,[286] and crystal structures are now available on salts of both (Table 22). They behave as typical high-spin Co^{II}. However $[Co(terpy)_2]X_2$ appears to be at the high to low spin cross-over with $X = Br^-$, NO_3^- having $\mu = 2.96$ BM, and $X = Cl^-$, ClO_4^- being high spin, $\mu = 4.49$, 4.65 BM (300 K).[287] Crystal structures for $X = Cl^-$ and NCS^- (intermediate spin, $\mu = 4.0$ BM; Table 22) suggest the difference, and an X-ray phase transition noted for the NCS complex results from a 10 pm decrease in the Co—N bond length to the central N of an appreciably ruffled tridentate (**57**).[288] A detailed magnetic and spectral (visible–UV, ESR) study suggests that intermolecular cooperative exchange between adjacent Co^{II} sites is a more likely model for spin exchange than

intramolecular thermal excitation.[289] $[Co(bipy)_3]^{2+}$ when trapped in a Y-zeolite matrix shows a similar spin equilibrium[290] although this behaviour is unknown in solid $[Co(bipy)_3]X_2$ salts or in aqueous solution.



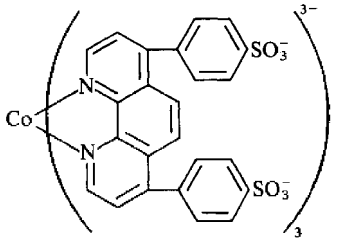
Distorted octahedral *cis*-$[CoX_2(N—N)]$ complexes are well known,[291] and a crystal structure for $X = NCS^-$ is available (Table 22). Very distorted five-coordinate $[CoX_2(terpy)]$ ($X = Cl^-$, NCO^-) is also known (Table 22). Akabori reports that pyrolysis of $(HN—NH)CoCl_4$ salts (N—N = phen, bipy) results in two phases of $[CoCl_2(N—N)]$, one of which is polymeric and octahedral and the other is tetrahedral and monomeric,[293] but such studies need structural clarification.

Watanabe and coworkers have described some Co^{II}–bipyridyl (phenanthroline) catalyzed Michael additions of nitromethane generalized by equation (49) but the catalyzing effect of the complex remains obscure.[292]



$$XCH{=}CHY + HZ \xrightarrow[DMF,\ r.t.]{Co(phen)_x^{2+}} \underset{Z}{XCHCH_2Y} \qquad (49)$$

47.4.7.3 Cobalt(III)



The orange-yellow $[Co(N—N)_3]^{3+}$ ions (N—N = bipy, phen) have been known for a long time (Table 23).[286] The considerable theoretical uncertainty as to their absolute configurations has now been resolved by a crystal structure of $(-)_{589}$-$[Co(bipy)_3][Fe(CN)_6]\cdot 8H_2O$, which has the Δ absolute configuration (**58**).[294] A similar configuration is likely for $(-)_{589}$-$[Co(phen)_3]^{3+}$, which is in agreement with oxidation of $[Co(phen)_3]^{2+}$ in the presence of $(-)_{589}$-malic acid for which evidence exists for Pfeiffer stabilization of the Λ absolute configuration.[295] These species undergo light and halide (I^-, Br^-) induced racemization,[296] and the process is also promoted by $[Co(N—N)_3]^{2+}$,[297] so solutions of the optically active ions should be carefully protected. Thermal racemization of $[Co(phen)_{3-x}(en)_x]X_3$ species ($x = 0$–2; $X = Cl^-$, Br^-, I^-) has been examined in the solid state.[311]

(58) Δ-$(-)_{589}$-$[Co(bipy)_3]^{3+}$

(59)

(60)

The preparation of $(+)_{589}$-$[Co(phen)_3]^{3+}$ by oxidation of the analogous $(+)_{589}$-$[Co(phen)_3]$ $[(+)SbOtart]_2$ complex (Table 23) illustrates the transient optical stability of the Co^{II} cation. The $[Co(phen)_3]^{2+}$ and $[Co(terpy)_2]^{2+}$ ions have been extensively used as stable reductants in outer-sphere redox studies. Recent theoretical[312] and practical[313,314] papers may be consulted for background. Considerable use is now being made of Co^{III}–phen systems in specific labelling of biological enzymes, notably those which have a reductive function. Holwerda, Gray and coworkers have characterized the penetrative ability of $[Co(phen)_3]^{3+}$ for oxidation by measuring the relative rates of reduction, *i.e.* $k[Co(phen)_3^{3+}]/k[Co(C_2O_4)_3^{3-}]$, for several metalloproteins.[315] This varies from 250 for Cu^I stellacyanin to 3.4×10^5 for $HIPIP_{red}$. The hydrophilic oxidants $[Fe(edta)]^{2-}$ and $[Co(C_2O_4)_3]^{3-}$ are considered not to penetrate the protein and are therefore used as marker oxidants. Sykes and coworkers have used $[Co(phen)_3]^{3+}$ and the 4,7-di(benzene-4′-sulfonate) derivative (**60**) in a number of such studies.[316–320] Comparisons are made with other oxidants including $[Fe(CN)_6]^{3-}$, $[Fe(edta)]^{2-}$ and $[Ru(NH_3)_5py]^{3+}$. Studies include reductions of the Fe^{II} heme protein cytochrome b_5 ($k_eK_b = 1.5 \times 10^3\ mol^{-1}\ dm^3\ s^{-1}$ for $[Co(phen)_3]^{3+}$) and some modified derivatives which suggest that the inorganic oxidant acts at a site close to Lys 27 on the right-hand side of the heme edge,[316] high-potential Fe–S protein from *Chromatium vinosum* $HIPIP_{red}$ ($k_eK_b = 2.8 \times 10^{-3}\ mol^{-1}\ dm^3\ s^{-1}$),[317] and the Cu^I proteins parsley plastocyanin PCu(I),[318,319] stellacyanin SCu(I), cytochrome c_2(II), and azurin from *Pseudomonas aeruginosa* ACu(I).[320] For some of these rate-limiting binding to the protein was observed and Table 24 contains some particular information for these. It is clear that although (**60**) binds more strongly it is a poorer oxidant in a kinetic sense since the electron transfer rate is very much reduced compared to $[Co(phen)_3]^{3+}$.

Table 24 Binding Constants (K_b) and Electron Transfer Rates (k_e) for Oxidation of Some Cu^I Metalloproteins[a]

Protein	*Oxidant*	K_b	k_e	k_eK_b
PCu(I)	$[Co(phen)_3]^{3+}$	167	17.9	3000
PCu(I)	$[Co(4,7\text{-DPSphen})_3]^{3-}$	4600	0.041	190
ACu(I)	$[Co(phen)_3]^{3+}$ (pH 9.1)	457	21.3	9700
	$[Co(4,7\text{-DPSphen})_3]^{3-}$	2750	0.21	580
$HIPIP_{red}$	$[Co(phen)_3]^{3+}$	–	–	2800

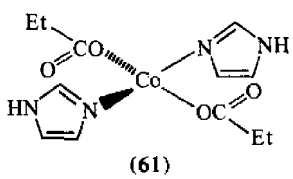
	$[Fe(CN)_6]^{3-}$	(< 10)	–	240

[a] K_b in $dm^3\,mol^{-1}$, k_e in s^{-1}.

Preparations of $[CoCl_2(N{-}N)]Cl$ species were pioneered by Jaeger and van Dijk (bipy) and Pfeiffer and Werdelmann (phen) many years ago but recent work is due to Ablov and Palade[298] and to Schaffer and coworkers.[299] A wide range of complexes is now available some of which are given in Table 23. It appears that green *trans*-$[CoX_2(N{-}N)]^+$ ions ($X = Cl^-$, Br^-) are unlikely despite many earlier claims,[299] and considerable doubt now exists about *trans*-$[Co(OH_2)(OH)(N{-}N)_2]^+$ species.[300] The *cis* configuration may be the only geometry possible sterically. Acid hydrolysis of $[CoCl_2(N{-}N)_2]^+$ is very slow compared to the saturated amine (*e.g.* ethylenediamine) counterparts and previous disagreements have been traced to catalytic impurities.[301] Acid hydrolysis of $[Co(CO_3)(N{-}N)_2]^+$ ions is also slow, $k = k_1\ [H^+] (k_1 = 1.5 \times 10^{-4}\,mol^{-1}\,dm^3\,s^{-1}$ (phen); $2.2 \times 10^{-4}\,mol^{-1}\,dm^3\,s^{-1}$ (bipy), 25 °C), with Co—O bond cleavage for the rate-controlling ring-opening process.[302] Alkaline hydrolysis however is fast[299,301] and must result from an alternative to the normal conjugate base mechanism (S_N1cb) found with saturated amine systems. The mixed chelates $[Co(C_2O_4)_2(N{-}N)]^-$ and $[Co(C_2O_4)(N{-}N)_2]^+$ have been prepared and resolved,[303] and their photochemical[304] and thermal[309] reduction has been studied. Other complexes containing amino acids,[305] ethylenediamine[306,307] and ammonia,[308] and CN^- [308] have been prepared in recent years; some have been resolved into optical enantiomers. The paper by Utsuno and coworkers[308] records ^{13}C resonances for a large number of systems and may be consulted for background references. Some interesting *cis*-dialkyl complexes, *cis*-$[Co(R)_2(bipy)_2](AlR_4)$,[310] have been made (equation 50), and a crystal structure has been reported on (**59**; Table 22). The intermediate $[Co(R)_2(acac)(bipy)]$ was also isolated. Complex (**59**) is stable in aqueous solution, but liberates CH_4 when treated with concentrated H_2SO_4; the chloride salt is even more stable in aqueous solution, however it is rapidly decomposed by UV light, liberating CH_4. ^1H NMR shows no exchange of alkyl groups in $[Co(Me)_2(bipy)_2](AlEt_4)$.[310]

$$[Co(acac)_3] + bipy + AlR_3 \xrightarrow{Et_2O} [Co(R)_2(bipy)_2](AlR_4) \quad (50)$$



R = Me, Et (**59**)

Just as Co^{III}–phenanthroline complexes have been used in metalloprotein electron transfer studies (*vide supra*), Yount and coworkers have utilized $[CoCO_3(phen)_2]^+$ and $CoCl_2$ in the presence of phenanthroline to block the ATPase activity of myosin, and attachment to sulfhydryl groups near the active site is suggested.[321]

47.4.8 Imidazole, Pyrazole, Triazole and Tetrazole

47.4.8.1 Cobalt(II)

Co^{II} complexes of imidazole retain some interest as structural models for biological systems, notably carboxypeptidase A and thermolysin. Vallee and colleagues discuss this with special reference to MCD spectra,[322] and Hodgson discusses stereochemical aspects of purine and metal–nucleotide complexes for similar reasons.[323] Horrocks, Ishley and Whittle have recently described some $[Co(O_2CR)_2(im)_2]$ structural models, *e.g.* (**61**), which have physical properties similar to Co^{II}–substituted carboxypeptidase.[324]

(**61**)

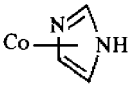
Martin and Edsall were the first to show that the colours and compositions of crystalline Co^{II}–imidazole complexes depend on the pH and conditions of preparation.[325] A general account of the properties of imidazole and histidine complexes is available,[326] and Table 25 lists some structures. Articles by Eilbeck[327] and coworkers and by Davis and Smith[328] may be consulted for preparative details. The complexes are usually easily prepared from the ligand and metal salt in hot ethanol or acetone. An equilibrium between pink (octahedral) and blue (tetrahedral) geometries is found with the unsubstituted ligand, *e.g.* equation 51,[329] and structures are available for each in various salts, as well as for polymeric tetrahedral $[Co(imH)_2]_x$ containing linear chains of bridging imidazolate anions (Table 25). Octahedral complexes containing bidentate NO_3^- or CO_3^{2-} are known (Tabel 25), and a paper by Freeman and coworkers may be consulted for spectral, structural, and magnetic properties of these.[330] Goodgame and coworkers also discuss spectral properties of octahedral and tetrahedral systems.[331] In every case a high-spin electronic configuration obtains with $\mu \approx 5.0$ BM for pink octahedral systems and 4.2–4.5 BM for blue tetrahedral $[CoX_2(im)_2]$ and $[Co(im)_4](ClO_4)_2$ complexes.[328] No structure of imidazole anion with side-on bonding (**64**) is available.

$$\underset{\text{blue, } > 140\,^\circ\text{C}}{[Co(imH)_4][Co(CO)_4]_2} + imH \rightleftharpoons \underset{\text{pink, } < 70\,^\circ\text{C}}{[Co(imH)_6][Co(CO)_4]_2} \qquad (51)$$



Preparative details and background information may be found in the following references: imidazole and substituted imidazoles,[327,332,333] thiazole,[327] benzothiazoles,[334] tetrazoles,[335] pyrazoles.[336] The ligand 2,2′-biimidazolyl (**62**) forms very weak complexes when compared to bipyridyl and phenanthroline but it can be deprotonated to form $[Co(L{-}H)_2]$ species.[337] The very stable complex (**63**) has been known for several years[338] and is characterized by having precise C_{3v} symmetry. White and Faller have pointed out that such a system is ideally suited as a paramagnetic NMR probe.[339] They prepared the R = 4-LiC_6H_4 derivative and have suggested how it might be attached to appropriate sites in target molecules.

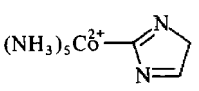
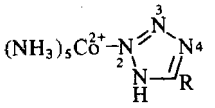
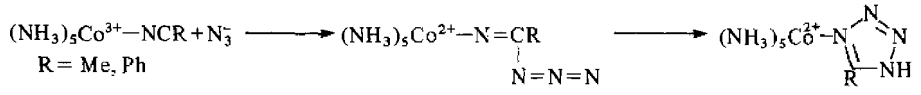
47.4.8.2 Cobalt(III)



Several $[CoL(NH_3)_5]^{3+}$ and *cis*-$[CoL(X)(en)_2]^{2+}$ complexes have been prepared (Table 26) and some crystal structures are available (Table 25). Pentaammine complexes are easily made from $[Co(DMSO)(NH_3)_5](ClO_4)_3$, and there is no need to use a better leaving group.[340,341] The physical properties (^1H NMR, visible–UV, ^{13}C NMR, pK_a) for both systems (L = imH) have been comprehensively documented.[341,342] The acidity of the N_3 proton in (**65**) is enhanced by coordination and the imidazolate anion is readily accessible (pK_a 10.0 *vs.* 14.1 for imH). Several deprotonated bimetallic bridged species have been prepared and structure (**66**) has been put forward as a model for heterobiometallic protein centres.[343] The tetrazole complexes (**68**) exist predominantly in the anionic form (pK_a 1–2)[351] and preparation normally gives the N(2)-bonded form. However Ellis and Purcell[352] have prepared the N(1) isomer by reacting a coordinated nitrile with N_3^- ion at pH ~ 5 (equation 52). Properties of both isomers are available.[351]

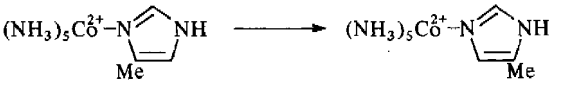


(65)



(66)

(67)



(68)

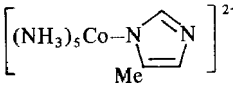
(52)

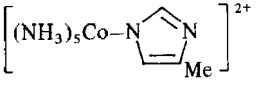
(69)

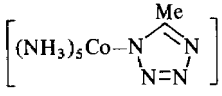
The C(2) proton in (**65**) does not exchange in alkaline aqueous solution in contrast to that of the uncoordinated ligand; the C(2)-bonded mode (**67**) has never been identified. Isomerization in the adjacent 5-Me-substituted complex (**70**) to the more stable 4-Me isomer (**71**; equation 53), occurs *via* the imidazolate anion ($pK_a = 10.46$, $k = 9.6 \times 10^{-4}\,s^{-1}$) although a limiting rate was never achieved;[334] a dissociative but intramolecular pathway *via* the π-bonded ligand (**64**) is preferred. Similar isomerization occurs with N(1)-coordinated 5-methyltetrazole with the protonated ligand now being some 100 times more reactive than its conjugate base (equation 54).[351] Rotation about the double bond similar to that found in Ru^{II} chemistry is more likely in this case. Some comparative intramolecular isomerization rates are given in Table 27.

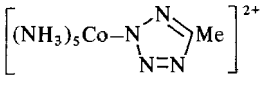
(53)

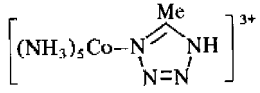
(70) (71)

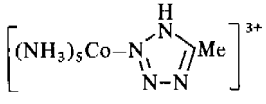






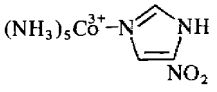






(54)

(74)



Mononitration of $[Co(NH_3)_5(im)]^{3+}$ occurs exclusively at the less-hindered C-4 site and the resulting complex (**72**) is very acidic, $pK_a = 1.66$.[345] Bromination occurs stepwise in acidic aqueous solution with the substitution pattern given by equation (55).[346] Rates of bromination follow the order $k_2 \gg k_3 > k_1$, which is the same as that found with the uncoordinated ligand. Electron transfer in systems (**73**) has been investigated by Isied[349] and Haim,[350] and Table 28 contains some comparative rate data. The imidazolate bridge provides the lowest energy pathway compared to other conjugated systems even though it is the poorest π-acceptor ligand. Szecsy and Haim[350] argue convincingly that the measured value represents k_1 (equation 56), and that subsequent dissociation, k_2, is more rapid. The insulating bis(4-pyridyl)ethane bridge is believed to prevent intraligand transfer and an outer-sphere mechanism is suggested in this case.[350] Reduction of the protonated tetrazole complex (**74**) by $Cr^{2+}_{(aq)}$ has been studied ($k = 19 \pm 2\,mol^{-1}\,dm^3\,s^{-1}$, 25 °C) and an inner-sphere mechanism with coordination of Cr^{II} to N-1 is suggested; the anion form is also reactive.[353] Reduction of $[Co(imH)(NH_3)_5]^{3+}$ by $e^-_{(aq)}$ and the HO· radical results in the diffusion-controlled

production of radical ion intermediates, *e.g.* (**75**), which slowly decay to $Co^{2+}_{(aq)}$ and free ligand ($k = 3 \times 10^3\ s^{-1}$, 25 °C).[354] The barrier to conjugated electron flow from the ligand to the metal is clearly quite high and mechanisms involving restricted overlap of the requisite π-ligand donor and σ-metal acceptor orbitals and an unfavourable equilibrium to form low-spin Co^{II} have been suggested.

47.5 PHOSPHORUS LIGANDS

47.5.1 Phosphorus

The cubane-like $[CoCpP]_4$ unit containing tridentate P atoms has been investigated structurally and semi-theoretically by Dahl and coworkers.[355] This green-black diamagnetic complex has a tetragonally distorted Co_4P_4 core (**76**) with Co—Co bonding (250.4 pm) arising from the requirement to reach the 18-electron configuration. This molecule is related to the series $[P_3Co(CO)_3]$, $[P_2Co_2(CO)_6]$, $[PCo_3(CO)_9]$ in which $Co(CO)_3$ units successively replace a P atom from the structurally similar and electronically equivalent P_4 molecule. The structure of $[Co_2(CO)_5(PPh_3)(\mu\text{-}P_2)]$ (**77**) emphasizes this, while the $[Co_6(CO)_{14}(\mu\text{-}CO)_2P]^-$ anion (**78**) provides a good example of a clathrated phosphide atom (structures, Table 29). Sacconi and his colleagues in a number of reports have made use of the coordinated tricyclic P_3 unit in $[Co\{MeC(dppm)_3\}P_3]$ (**79**) to further coordinate other ML^{2+} units (M = Fe, Co, Ni; L = $MeC(dppm)_3$, $N(dppe)_3$, $MeC(depm)_3$) and to $Cr(CO)_5$

$(PPh_4)[Co_6(CO)_{14}\{\mu\text{-}(CO)_2P\}]$	$Na[Co(CO)_4] + PCl_3$; THF	Structure, P atom coordinated to 6 Co atoms	6
$[Co\{MeC(dppm)_3\}P_3]$	$Co(BF_4)_2 \cdot 6H_2O + L + P_4$; BuOH	Yellow-orange; diamagnetic; structure, δ-P_3 units	1, 5
$[\{Co[Me(dppm)_3]\}(\mu\text{-}P_3)](BF_4)_2$	$Co(BF_4)_2 \cdot 6H_2O + L + P_4$; EtOH, THF, r.t., 1 h, N_2	μ = 2.02–2.20 BM	2
$[\{Co, Ni\{MeC(dppm)_3\}_2\}(\mu\text{-}P_3)](BF_4)_2 \cdot 2(Me)_2CO$	$[Co\{MeC(dppm)_3\}P_3] + NiBF_4 \cdot 6H_2O + L + NaBH_4$; EtOH, CH_2Cl_2, N_2	μ = 3.14 BM; structure, tribridging-P_3 unit	2
$[Co\{N(dppe)_3\}P_3] \cdot 0.5$ THF	$Co(BF_4)_2 \cdot 6H_2O + L + P_4$; THF, EtOH, 50 °C	Red, diamagnetic; structure, δ-P_3 unit	3
$[Co\{MeC(dppm)_3\}(\mu\text{-}P_3)\{MeC(depm)_3\}\text{-}Fe](PF_6)_2 \cdot CH_2Cl_2$	$[Co\{MeC(dpgm)_3\}P_3] + Fe(BF_4)_2$, $6H_2O + L$; EtOH, CH_2Cl_2, N_2	Blue; structure, tribridging δ-P_3 unit	4
$[Co\{MeC(dppm)_3\}(\mu\text{-}P_3)(Cr_2(CO)_{10}]$	$[Co\{MeC(dppm)_3\}P_3] + Cr(CO)_6$; THF; N_2, UV light, 4 h	Structure, two P atoms coordinated to two $Cr(CO)_5$ units	5
$[\{Co[MeC(dppm)_3](\mu\text{-}P_3)\}_2\{CuBr)_6] \cdot 2CH_2Cl_2$	$[Co\{MeC(dppm)_3\}P_3] + CuBr$; CH_2Cl_2, 30 °C, 3 h, N_2	Red-brown; μ-P_3 coordination to hexagonal $(CuBr)_6$ fragment	9

and CuBr units.[356,357,358] These provide good examples of 30-, 31- and 32-electron systems and each example is characterized by a crystal structure (Table 29). Similar δ-As_3 units are possible. Reduction with $NaBH_4$ allows the $[\{Co[MeC(dppm)_3]\}_2(\mu\text{-}P_3)](BPh_4)$ species to be isolated ($\mu = 3.13$ BM),[356] whereas oxidation at Pt generates the bright green diamagnetic $[\{Co[MeC(dppm)_3]\}_2(\mu\text{-}P_3)]^{3+}$ ion.[358] A two-electron reduction product is also reversibly formed at the Pt electrode.[359]

47.5.2 Phosphines

Large numbers of monodentate (PF_3, PR_3, PHR_2, a few PH_2R, and PH_3), bidentate ($NH_2(CH_2)_nPR_2$ and $R_2P(CH_2)_nPR_2$), tridentate and quadridentate (linear, branched) phosphine complexes are known. Much interest lies in their use to catalyze insertion, addition and elimination processes of industrial importance. Review articles covering 1977 are available.[361,362,363]

The σ-donor ability of phosphine ligands varies: $P(alkyl)_3 > P(aryl)_3 > P(OR)_3 > PX_3$ (X = halogen). Basicity ($pK_a(PMe_3) = 8.65$) is an important factor for Co^{III} and Co^{II} but the availability of filled π MOs on the metal for Co^0 and Co^I can modify bonding properties and stereochemsitry. Tollman has discussed the steric requirements of phosphine ligands.[364] Often this factor is of major importance in determining coordination number, stereochemistry and stability. Tollman's steric factor is defined in terms of the 'cone angle' subtended at the metal by the van der Waals' boundaries of the substituents on the P atom; small angles (*i.e.* H, Me and tied-back substituents) favour maximum coordination numbers and maximum stability. A list of cone angles is given in Table 30. Garrou has published a review discussing the use of ^{31}P NMR parameters in determining the chelating ability of phosphine ligands.[365]

Table 30 Minimum Cone Angles for Some P Ligands[1]

Ligand	*Angle* (°)	*Ligand*	*Angle* (°)
PH_3	87 ± 2	PBr_3	131 ± 2
$P(OCH_2)_3CMe$	101 ± 2	PEt_3	132 ± 4
PF_3	104 ± 2	PPh_3	145 ± 2
$P(OMe)_3$	107 ± 2	PPr^i_3	160 ± 10
$P(OEt)_3$	109 ± 2	PCy_3	179 ± 10
PMe_3	118 ± 4	PBu^t_3	182 ± 2
PCl_3	125 ± 2	PPh_3	184 ± 2
		$P(o\text{-tolyl})_3$	194 ± 6

Table 31 Preparations: Phosphine–Hydride Complexes

Complex	Preparation	Properties[a]	Ref.
$[HCo(PF_3)_4]$	$CoI_2 + PF_3$; Cu, H_2 (100 atm), 170 °C	Yellow liquid; diamagnetic; H^- acid of $Co(PF_3)_4^-$; ν_H 1973; ^1H, 20.7	1
$[CoH\{P(OEt)_3\}_4]$	$CoCl_2 + P(OEt)_3 + NaBH_4$; MeOH, N_2, −78 °C	Diamagnetic; soluble in non-polar solvents	2
$[CoH\{P(OPr^i)_3\}_4]$	$CoCl_2 + P(OPr^i)_3 + NaBH_4$; $C_2H_2(OMe)_2$, EtOH, 0 °C	Cream, diamagnetic; ν_H 1945	35
$[CoH\{P(OPh)_3\}_3(CO)]$	$[CoH\{P(OPh)_3\}_4] + CO$; toluene, 150 psi, 100 °C	White	32
$[CoH(N_2)(PPh_3)_4]$	$Co(acac)_3 + PPh_3 + AlR_3 + N_2$	Orange-red; ν_H not observed	4
$[CoH(N_2)\{P(OPr^i)_3\}_3]$	$[CoH_3\{P(OPr^i)_3\}_3] + N_2$; hexane	Near colourless (not isolated)	33
$[CoH(PMe_3)_4]$	$Co^{2+}_{(aq)} + PMe_3 + OH^- + Zn$; aq.	Yellow; ν_H, 1885, not acidic	5
$[Co(BH_4)(PPh_3)_2]$	$CoCl_2 + NaBH_4 + PPh_3$; EtOH, toluene	Green; $\mu \approx 1.2$	8
$[Co(BH_4)(PPh_3)_3]$	$CoX(PPh_3)_3$ (X = Cl, Br, I) + $NaBH_4$	$\mu = 2.71$; monodentate HBH_3^-	7
$[CoH(C_2H_4)(PMe_3)_3]$	$K[Co(C_2H_4)(PMe_3)_3] + H^+$	*Trans* H, P; trig. bipyr.	14
$[CoH(dppv)_2]$	$[CoBr_2(dppv)_2] + NaBH_4$; EtOH	Red; unstable; diamagnetic; ν_H 1885	16
$[CoH(dppe)_2]$	$[CoBr_2(dppe)_2] + NaBH_4$; EtOH	Red; soluble in organic solvents; diamagnetic; ν_H, 1885; unstable soln.	16
$[CoH\{P(dppe)_3\}]$	$Co(acac)_3 + (Bu)_2AlH$; Et_2O		17
	$CoCl_2 + L + NaBH_4$; DMF, reflux	Yellow; diamagnetic; ν_H 1780; air sensitive in CH_2Cl_2	21
$[CoH\{P(dppC_6H_4)_3\}]$	$Co(BF_4)_2 + L + NaBH_4$; DMF, EtOH, 60 °C	Brown-red, diamagnetic; ν_H 1880	24
$[CoH\{N(dppe)_3\}]$	$Co(BF_4)_2 \cdot 6H_2O + L + NaBH_4$; EtOH 50 °C	Red; diamagnetic; ν_H 1870, 1805 (THF adduct)	23
$[CoH(PEt_2R)_4]$ (R = Et, Ph)	$Co(C_8H_{12})(C_8H_{13}) + L + H_2$; benzene, MeCN	Yellow; diamagnetic	25
$[CoH\{P(OMe)_3\}_4]$	$CoCl_2 + L + NaBH_4$; $(MeO)_2C_2H_4$, 0 °C	Yellow; diamagnetic; ^1H 15.09	26
$[CoH\{P(OEt)_2Ph\}_4]$	$CoCl_2 + L + NaBH_4$; EtOH, 60–70 °C	Yellow-orange; diamagnetic; soluble in organic solvents; stable	27
$[CoH\{P(OPh)_3\}_4]$	$Co(NO_3)_2 \cdot 6H_2O + L + NaBH_4$; EtOH	Yellow; no ν_H; fluxional; stable	28
$[CoH\{P(OCH_2)_3CPr^i\}_4]$	$Co(NO_3)_2 \cdot 6H_2O + L + NaBH_4$; EtOH	White	29
$[CoH\{P(Oaryl)_3\}_3(MeCN)]$ (aryl = Ph, tolyl, Pr^iPh, PhPh)	$Co(C_8H_{12})(C_8H_{13}) + L + H_2$; MeCN, r.t.	Yellow; diamagnetic	25
$[Co(H)_2(PPh_3)_3]$	$Co(acac)_2 + PPh_3 + Et_2AlOEt + H_2$; Et_2O	Brown; stable; abs. N_2	12
$[CoH(PMe_3)_4]Cl$	$Co(PMe_3)_4 + HCl$	Fluxional 12-electron system; tet. with added H^-; ν_H 1935 (broad)	6
$[CoH(BH_4)(PCy_3)_2]$	$CoCl_2 + PCy_3 + NaBH_4$	Green; $\mu = 2.15$; dist. sq. pyr. structure (Table 32)	9
$[CoH(BH_3CN)(PPh_3)_3]$	$Co(ClO_4)_2 + PPh_3 + NaBH_3CN$; toluene, EtOH, N_2	Red, $\mu = 1.9$; unstable in soln.	9
$[Co(H)_3\{MeC(dppm)_3\}]BPh_4$	$Co(BF_4)_2 \cdot 6H_2O + L + NaBH_4$; Et_2O	Red; $\mu = 3.29$; stable as solid; ν_H 1700–2200	20
$[CoH\{P(OPh)_3\}_4]PF_6$	$[CoH\{P(OPh)_3\}_4] + Ph_3CPF_6$; CH_2Cl_2	Green; $\mu = 1.96$; no ν_H; unstable	30
$[CoH\{P(OR)_2Ph\}_4]PF_6$ (R = Me, Et)	As above	Green; $\mu = 2.1$–2.4; ν_H 1950; unstable	30
$[Co(H)_3\{P(OPr^i)_3\}_3]$	$[Co(\eta_3\text{-}C_3H_5)\{P(OPr^i_3)_3\}_3] + H_2$; Et_2O	Yellow-brown; diamagnetic	33
$[Co(H)_3(PEt_3)_3]$	$CoCl_2$, PEt_3, $NaBH_4$; EtOH, Ar, 0 °C	Yellow, soluble in benzene, THF; ν_H 1933, 1745	34
$[Co(H)_2\{P(OR)_3\}_4]PF_6$ (R = Me, Et, Pr^i)	$[CoH\{P(OR)_3\}_4] + TFA + NaPF_6$; ROH	White; diamagnetic	35
$Co(H)_3(PPh_3)_3$	$CoCl_2 + PPh_3 + NaBH_4$; EtOH	Yellow; sensitive to air; soluble in non-polar solvents; ν_H 1933, 1745	3
cis-$[Co(H)_2(PR_3)_4]ClO_4$ (R_3 = Me_3, $PhMe_2$, Ph_2H)	$Co(ClO_4)_2 \cdot 6H_2O + PR_3 + H_2$; Pr^iOH	Yellow; ν_H 1900–2000	11

$[CoH(PHR_2)_5](BF_4)_2$ (R_2 = Et_2, EtPh)	$Co(BF_4)_2 + PHR_2$; Pr^iOH	White; diamagnetic; ^1H 24.79	11, 16
trans-$[CoH(X)(PPh_2H)_4]ClO_4$	$Co(ClO_4)_2 \cdot 6H_2O + PPh_2H + HX$	No details; $\nu_H \approx 2000$	11
cis-$[Co(H)_2(PR_3)_2(bipy)]ClO_4$ (R = Bu^n, Pr, Et)	$[Co(bipy)(PR_3)(diene)]^+ + PR_3 + H_2$	Red-orange	13
$[Co(H)_2(dppe)_2]ClO_4$	$[CoH(dppe)_2] + 1.0\,M\,HClO_4$; EtOH, H_2O	Yellow; diamagnetic; ν_H 1940, 1985	18
$[CoH(Cl)(dppe)_2]BPh_4$	$[CoCl(dppe)_2]Cl + NaBH_4$; EtOH; HCl, hexane	Yellow; ν_H 1960	19
$[CoH\{P(OEt)_2Ph\}_4L](PF_6)_2$ (L = RCN, $P(OEt)_2Ph$)	$[CoH\{P(OEt)_2Ph\}_4]PF_6 + Fe(Cp)_2PF_6 + L$; CH_2Cl_2	Yellow; diamagnetic; ν_H 1968	31
trans-$[CoH(X)\{P(OEt)_2Ph\}_4]PF_6$ (X = Cl, Br, I)	$[CoH(H_2O)\{P(OEt)_2Ph\}_4]PF_6 + Fe(Cp)_2PF_6 + LiX$; MeOH	Yellow; diamagnetic; ν_H 1980	31
trans-$[CoH(MeCN)\{P(OEt)_2Ph\}_4](PF_6)_2$	$[CoH\{P(OEt)_2Ph\}_4]PF_6 + Fe(Cp)_2PF_6 + MeCN$; CH_2Cl_2	Yellow, diamagnetic; ν_H 1990; ^1H 29.23	31

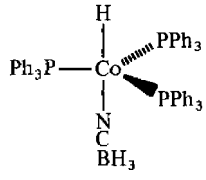
47.5.2.1 Hydrides

General articles concerning transition metal hydrides,[366] their crystallography,[368] and on the preparation and properties of borohydride complexes[369] are available. An overview on the use of $HCo(CO)_4$ and related cobalt hydrides as catalysts in the hydroformylation of alkenes is available.[367]



Complexes containing diamagnetic Co^I (five-coordinate) and Co^{III}, and paramagnetic Co^I (four-coordinate) and Co^{II} are easily prepared (Table 31). Several structures are available (Table 32). The Co—H bond is characteristically strong and normally cannot be titrated by strong bases. Exceptions are $[HCo(PF_3)_4]$, which is a very strong acid in aqueous solution, and $[HCo\{P(OMe)_3\}_4]$, which can be titrated by KH. Acid strength decreases rapidly $[HCo(PF_3)_4] > [HCo\{P(OR)_3\}_4] > [HCo(PR_3)_4]$. Alkyl and aryl phosphine hydrides have properties more in keeping with coordinated H^- (a 'super' halogen). Preparation often involves hydride transfer from BH_4^- to a $CoX(L)_x$ species generated from CoX_2 and L in alcoholic solution, *e.g.* equation (57). Species such as (**80**) and (**81**) are probable intermediates; (**80**) is known, and an analogue of (**81**) has been crystallized as (**82**; Table 32). Other methods of preparation include Zn or Cu reduction of $Co^{2+}_{(aq)}$ in alkaline solution, and the oxidative addition of H_2 or HX to $Co^{2+}_{(aq)}$ or to a low-valent complex (equations 58–61). To avoid the copreparation of dinitrogen complexes Ar should be used as the inert blanket.

(80)

(81)

(82)

$$CoCl_2 + PR_3 + NaBH_4 \longrightarrow [CoCl(PR_3)_3] \xrightarrow{NaBH_4} [Co(H)_3(PR_3)_2] \quad (57)$$

$$Co^{2+}_{(aq)} + PMe_3 + Zn \xrightarrow{OH^-} [CoH(PMe_3)_4]$$
$$cis\text{-}[Co(H)_2(PR_3)_4] \xleftarrow{H_2} Co^{2+}_{(aq)} + PR_3 \xrightarrow{HX} trans\text{-}[CoH(X)(PR_3)_4]^+ \quad (58)$$

$$[Co(dppv)_2]BF_4 + H_2 \longrightarrow [Co(H)_2(dppv)_2]^+ \quad (59)$$

$$[Co(PMe_3)_4] + HCl \longrightarrow [CoH(PMe_3)_4]Cl \quad (60)$$

$$K[Co(C_2H_4)(PMe_3)_3] + H^+ \longrightarrow [CoH(C_2H_4)(PMe_3)_3] \quad (61)$$

Phosphite ester complexes $[CoH\{P(OCH_2)_3CR'\}_4]$ (R′ = Me, Pr^i; tied-back substituents) and $[CoH\{P(OR)_3\}_4]$ (R = Me, Et, Pr^i, Ph) can be prepared in a similar fashion, and are yellow or white crystalline solids (Table 31). They are mostly diamagnetic and show less hydride character than $[CoH(PR_3)_4]$ due to the more electronegative phosphite ligand. They are not nearly as acidic as $[HCo(PF_3)_4]$ or $[HCo(CO)_4]$ but for R = Me, Et can be deprotonated by the very strong base KH (equation 62).[370]

$$[CoH\{P(OMe)_3\}_4] + KH \xrightarrow{THF} K[Co\{P(OMe)_3\}_4] + H_2 \quad (62)$$

Some properties of hydrido-phosphine complexes have been summarized.[366,371] For Co^I systems $\nu_H \approx 1870$–1900, for Co^{II} $\nu_H \approx 1930$, and for Co^{III} $\nu_H \approx 1950$–$2000\,cm^{-1}$; but sometimes ν_H is not observed. Often the hydride can be titrated with aqueous HCl, and complete decomposition in this manner has been used for analysis (equation 63), but this is not universal (Scheme 26).[372,373] D is retained in $[Co(D)_2(dppe)_2](ClO_4)$ on adding OH^-, and HD rather than D_2 is evolved on treatment with acids.[373] $[CoH(dppe)_2]$ reduces CCl_4 to $CHCl_3$[373] and $[Co(H)_2(PPh_3)_2]$ reduces 1-heptene to heptane,[374] but $[CoH(Cl)(dppe)_2]Cl$ oxidizes EtOH to acetaldehyde in alkaline solution (equation 64).[372] The interesting paramagnetic $[Co_2(H)_3\{MeC(dppe)_3\}_2](BPh_4)$ ($\mu = 3.29$ BM) is dimeric with three μ-H bridges (**83**; Scheme 27), and most (if not all) hydride complexes react with CO to give dimeric diamagnetic carbonyl systems (equations 65 and 66). The two *cis* hydrides in $[Co(H)_3(PPh_3)_3]$ can easily be eliminated by Y = CO or N_2 and the resulting Co^I complex has a distorted trigonal bipyramidal geometry with axial H and Y groups (equation 67).[376]

Table 32 Structures: Phosphine–Hydride Complexes

Complex	*Ligand*	*Structure*[a]	*Ref.*

Scheme 27

All $[CoH(PR_3)_4]$ complexes (R = F, alkyl, aryl, OR) have near C_{3v} microsymmetry with a distorted tetrahedral CoP_4 skeleton and H^- fluxionally disposed between tetrahedral faces. In solution $[HCo(PF_3)_4]$ shows a limiting ^{31}P spectrum (3:1 ratio of PF_3 groups) at $-160\,^{\circ}C$[377] and its solid state structure shows an almost tetrahedral CoP_4 unit (H^- not located) (Table 32).[378] Limiting slow exchange is not shown by $[CoH\{P(OR)_3\}_4]$ at $-140\,^{\circ}C$ (R = Me, Et, Pr^i),[379,380] $\Delta G^{\ddagger} < 25\,kJ\,mol^{-1}$, but $[CoH\{P(OEt)_2Ph\}_4]$ with the more bulky phosphonite ligand shows a temperature-dependent collapse of the symmetrical high field ^{31}P quintet, and its crystal structure shows H^- to be located on a distorted tetrahedral face (Table 32).[381] It is likely that the cone angle of the ligand is important in determining the coalescence temperture for these species. $[CoH\{P(OR)_3\}_4]$ complexes (R = Me, Et, Ph) readily add CO to form five-coordinate trigonal bipyramidal $[CoH(CO)\{P(OR)_3\}_3]$ (Table 31), and H–D exchange occurs in acid solution *via* the *cis*-$[CoH(D)\{P(OR)_3\}_4]^+$ intermediate. This species is relatively unstable but has been examined by ^1H NMR,[382] and has been isolated as the PF_6^- salt.[383]

Oxidation to give Co^{II} and Co^{III} hydride complexes has been achieved in a number of instances (Table 31). $[CoH\{P(OPh)_3\}_4]$ and $[CoH\{P(OR)_2Ph\}_4]$ (R = Me, Et) can be readily oxidized to the analogous Co^{II} cation using trityl salts, and green paramagnetic $[CoH\{P(OEt)_2Ph\}_4](PF_6)$ may be further oxidized in the presence of L = H_2O, RCN, $P(OEt)_2Ph$ to the Co^{III} complex *trans*-$[CoH(L)\{P(OEt)_2Ph\}_4](PF_6)_2$ (Scheme 28). *trans*-$[CoH(H_2O)\{P(OEt)_2Ph\}_4]PF_6$ is especially interesting as it appears to be the only phosphine complex containing both hydride and aqua ligands.[384]

$[CoH\{P(OEt)_2Ph\}_4] \xrightarrow{Ph_3C^+PF_6^-} [CoH\{P(OEt)_2Ph\}_4]PF_6 \xrightarrow{CCl_4}$ *trans*-$[CoH(Cl)\{P(OEt)_2Ph\}_4]PF$ (yellow, diamagnetic)

$[CoH\{P(OEt)_2Ph\}_4]PF_6 \xrightarrow{Fe(Cp)_2^+PF_6^-} [CoH\{P(OEt)_2Ph\}_4](PF_6)_2$ (L)

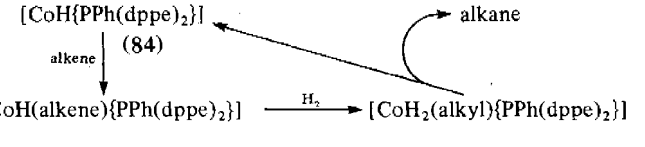
trans-$[CoH(L)\{P(OEt)_2Ph\}_4](PF_6)_2 \xrightarrow[(L = H_2O\ only)]{LiX}$ *trans*-$[CoH(X)\{P(OEt)_2Ph\}_4]PF_6$ (yellow, diamagnetic; X = Cl^-, Br^-, I^-)

Scheme 28

Reductive elimination of H_2 occurs when $[Co(H)_2\{P(OR)_3\}_4]^+$ salts are treated with CO or $P(OR')_3$ and the reaction is not measurably reversible, $p(H_2) = 1$ atm (equation 68).[383] This contrasts with that found for isoelectronic $[Fe(H)_2\{P(OR)_3\}_4]$. Also, the hydrogen exchange reaction (69) occurs without H–D scrambling and both reactions have been interpreted in terms of a dissociative $[Co\{P(OR)_3\}_4]^+$ intermediate.[383]

$$[Co(H)_2\{P(OR)_3\}_4]^+ + L \longrightarrow [CoL\{P(OR)_3\}_4]^+ + H_2 \quad (68)$$

$$[Co(H)_2\{P(OR)_3\}_4]^+ + D_2 \longrightarrow [Co(D)_2\{P(OR)_3\}_4]^+ + H_2 \quad (69)$$



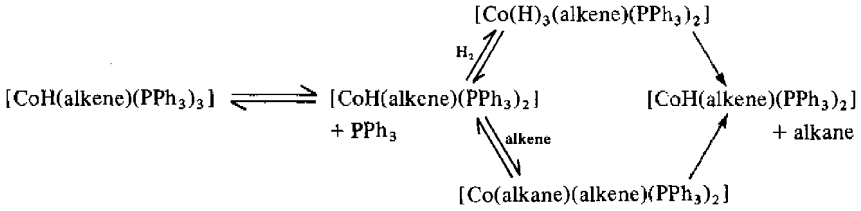
Ligand substitution rates in $[CoH\{P(OR)_3\}_4]$ have been studied by Muetterties and Hirsekorn who found that exchange is slow in non-polar solvents (benzene) taking 4–6 weeks at 100 °C (R = Me > Et > Ph; equation 70).[382] However in polar solvents it is faster, being 100 times faster in MeCN. A dissociative process to give $[CoH\{P(OR)_3\}_3]$ is suggested as being rate determining, but CO displacement is 10–100 times faster under the same conditions so that an associative process also appears to be possible. Conder and coworkers have shown that CO substitution is photocatalyzed with reaction (71) being complete within 20 minutes in CO-saturated tethyhydrofuran at ambient temperature; the reverse of reaction (71) was not photocatalyzed.[385]

$$\begin{array}{l} [CoH\{P(OR)_3\}_4] + P(OR')_3 \rightleftharpoons [CoH\{P(OR)_3\}_3\{P(OR')_3\}] + P(OR)_3 \\ \quad \text{CO} \downarrow \\ [CoH\{P(OR)_3\}_3CO] \xrightarrow{CO} [CoH\{P(OR)_3\}_2(CO)_2] \end{array} \quad (70)$$

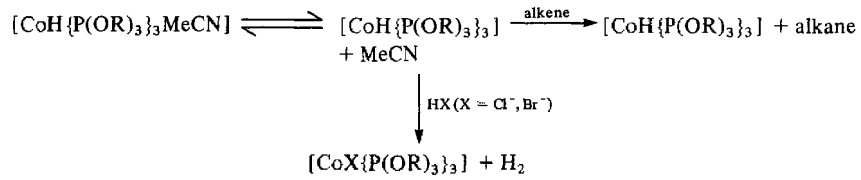
$$[CoH\{P(OPh)_3\}_4] + CO \xrightarrow{h\nu} [CoH\{P(OPh)_3\}_3CO] + P(OPh)_3 \quad (71)$$

Cobalt hydrido phosphine and phosphite complexes can be useful catalysts in hydrogenations. Thorn and Hoffman[386] have discussed the MO consequences of hydride insertion into alkenes and its catalysis by d^8 metals. The requirement appears to be the ability to generate a vacant coordination site for the substrate. Thus the five-coordinate systems $[CoH(PR_3)_4]$ and $[CoH\{P(OR)_3\}_4]$ are rather sluggish, although laser excitation of $[CoH\{P(OEt)_2Ph\}_4]$ has been shown to generate a coordinatively unsaturated species, presumed to be $[CoH\{P(OEt)_2Ph\}_3]$ (ε_{580}(max), 17 000), which reacts rapidly with $P(OEt)_2Ph$ ($1.4 \times 10^8\ M^{-1}s^{-1}$) and 1-hexene ($1.1 \times 10^8\ M^{-1}s^{-1}$).[387,389] However $[CoH(N_2)(PPh_3)_3]$ is an excellent catalyst for alkene hydrogenation,[390] the dimerization of C_2H_4[391] and $MeCHCH_2$[392,288] and the isomerization of alkenes;[393] it readily loses N_2 in the presence of the alkene (equation 71). Likewise the stereochemically rigid $[Co(H)_3\{PhP(dppp)_2\}]$ and $[Co(H)_3\{PhP(dppe)_2\}]$ readily catalyze the hydrogenation of 1-octene *via* the initial loss of H_2 to form the reactive four-coordinate 16-electron intermediate (**84**), which coordinates alkene (Scheme 29),[394] whereas $[Co(H)_3(PPh_3)_3]$ generates the coordinatively unsaturated intermediate $[Co(H)_3(PPh_3)_2]$ by loss of PPh_3.[395] $[Co(H)_3\{P(OPr^i)_3\}_3]$ has likewise been shown to be an effective catalyst for the hydrogenation of both terminal and internal alkenes at 0 °C and $p(H_2) = 1$ atm, and selectively hydrogenates α,β-unsaturated ketones and amides *via* a reaction involving displacement of H_2 (equation 73).[406]

$$\underset{\text{yellow}}{[CoH(N_2)(PPh_3)_3]} + \text{alkene} \rightleftharpoons \underset{\text{red-brown}}{[CoH(\text{alkene})(PPh_3)_3]} + N_2 \quad (72)$$



Scheme 29

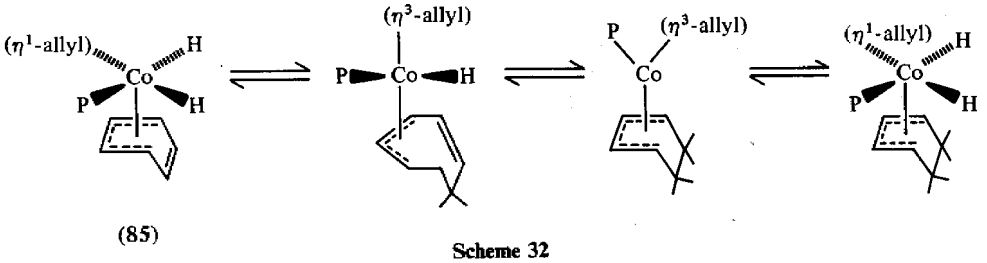


$$[Co(H)_3\{P(OPr^i)_3\}_3] + \text{alkene} \rightleftharpoons [CoH\{P(OPr^i)_3\}_3(\text{alkene})] + H_2 \quad (73)$$

Various kinetic studies on these processes have been carried out.[388,391,393,395,396] For example alkene hydrogenation in $[CoH(alkene)(PPh_3)_3]$ follows the rate law $k_{obs} = k[H_2][alkene][PPh_3]^{-1}$ and this has been interpreted in terms of a dual pathway originating from the coordinatively unsaturated $[CoH(alkene)(PPh_3)_2]$ intermediate (Scheme 30),[396] but other mechanisms are possible. Similarly

$[CoH\{P(OPh)_3\}_3MeCN]$ rapidly catalyzes the hydrogenation of 1-butene (no isomerization) and it reacts spontaneously with HX generating H_2;[397] facile dissociation of MeCN generating an unsaturated system is again likely (Scheme 31), since stable systems such as $[CoH\{P(OR)_3\}_4]$ are unreactive under similar conditions. Similarly $[CoH(N_2)(PPh_3)_3]$ reacts with HX, and will oxidize PPh_3 in the presence of air, presumably *via* the initial loss of N_2 and coordination of H^+ and O_2 respectively (equation 74). Likewise N_2O can be reduced to N_2 in the presence of PPh_3, which is oxidized to Ph_3PO.

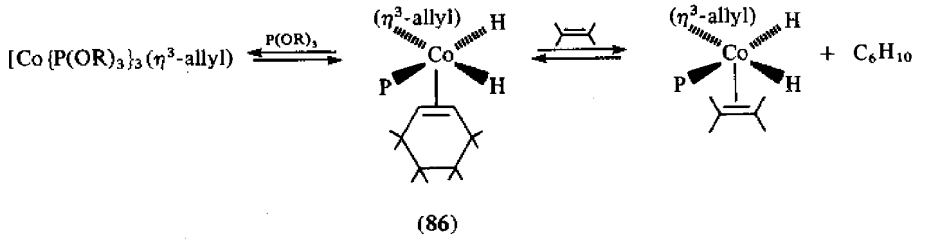
Scheme 30



Scheme 31

$$[Co(X)_2(PPh_3)_2] + N_2 + H_2 + PPh_3 \xleftarrow{HX} [CoH(N_2)(PPh_3)_3] \xrightarrow[\text{catalytic}]{PPh_3} Ph_3P{=}O \qquad (74)$$

Hydride complexes have been shown to be present in the selective *cis* hydrogenation of arenes accidentally discovered by Muetterties and Hirsekorn in 1973.[398] Muetterties and coworkers have since shown in an impressive series of papers[399] that the parent catalyst $[Co\{P(OMe)_3\}_3(\eta^3\text{-}C_3H_5)]$ and a number of other π-allyl phosphite Co^I systems are possibly unique in their ability to hydrogenate aromatic hydrocarbons (room temperature, $p(H_2) = 1$ atm), and to a degree they are chemoselective. Requirements for catalysis include the ability to undergo rapid reversible $\eta^3 \rightleftharpoons \eta^1$ coordination of the allyl group (thereby generating vacant coordination sites on the metal) and the ability to undergo $Co^I \rightarrow Co^{III}$ oxidative addition of H_2. The catalyst prepares itself as given in equation (75)[400] followed by successive $\eta^1 \rightarrow \eta^3 \rightarrow \eta^1$ allyl changes which generate vacant coordination sites and allow the binding of the arene (Scheme 32). The initial reactive intermediate appears to be the strained η^4-arene (**85**), and by successive hydrogenation steps ($Co^{III} \rightarrow Co^{II} \rightarrow Co^I$) and oxidative additions of H_2 reduction takes place without the dissociation (or scrambling) of semireduced products (*i.e.* C_6H_6 gives $C_6H_6D_6$, and unreacted C_6H_6 essentially no D); however alkenes can compete for the final η^2-cyclohexene hydrogenation step (**86**; Scheme 33). The structure of $[Co(\eta^3\text{-cyclooctenyl})\{P(OMe)_3\}_3]$ (**87**) establishes its square-pyramidal geometry if the allyl is considered as a bidentate ligand; a similar structure is found for $[Co(\eta^3\text{-}C_3H_5)\{P(OMe)_3\}(CO)_2]$ and a somewhat more distorted structure for $[Co(\eta^3\text{-benzyl})\{P(OMe)_3\}_3]$ (**88**). A wide variety of benzene derivatives, cyclohexadienes and cyclohexenes are reduced but steric, electronic and acidic properties interfere (*e.g.* F, CN and NO_2 substituents deactivate); hydrogenation rates are low (one turnover per hour for C_6H_6) but the larger phosphite ligands improve this,[401,402,406] *e.g.* $[Co(H)_3\{P(OPr^i)_3\}_3]$ (equation 73). Janowicz and Bergman[403] provide evidence to support an alternative autocatalytic bimolecular pathway for the hydrogenation of Me in $[Co(PPh_3)(Me)_2(Cp)]$ (equation 76). If the $[Co(PPh_3)_2(Cp)]$ product is introduced at the beginning of the reaction (45 °C, benzene) the normal induction period disappears, and the inhibition in rate on adding PPh_3 implies a role for coordinatively unsaturated $[Co(Me)_2(Cp)]$ and $[Co(PPh_3)(Cp)]$. It is proposed that H_2 adds to the latter, which then reacts with the former.



$$[Co\{P(OR)_3\}_3(\eta^3\text{-allyl})] \rightleftharpoons [Co\{P(OR)_3\}_3(\eta^1\text{-allyl})] \xrightleftharpoons{H_2} [Co\{P(OR)_3\}_3(H)_2(\eta^1\text{-allyl})] \qquad (75)$$

Mirbach and coworkers have investigated the use of $[CoH(CO)_3(PBu^n_3)]$ in catalyzing the formation of straight-chain aldehydes from propene and 1-octene (equation 77).[404] The catalyst is produced photochemically from $[Co(CO)_3(PBu^n_3)][Co(CO)_4]$, and the mild experimental conditions and polar solvents used (MeOH, 80 °C, 80 bar) make such ionic complexes useful alternatives to the

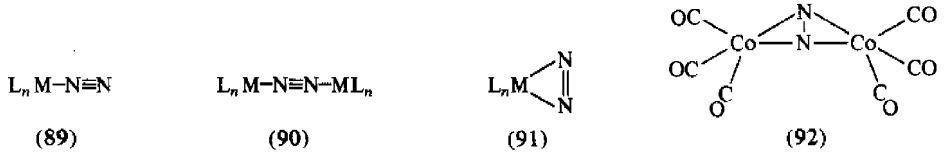
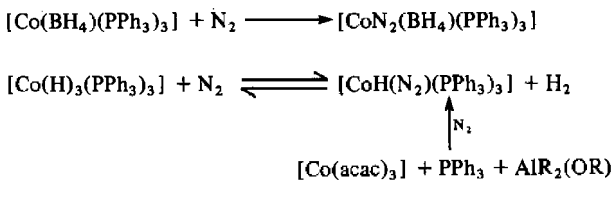
$$[Co(PPh_3)(Me)_2Cp] + H_2 + PPh_3 \longrightarrow [Co(PPh_3)_2Cp] + 2CH_4 \quad (76)$$



normal cobalt or rhodium carbonyl catalysts. Thus Murata and coworkers have shown that $[Co_2(CO)_8]$ in the presence of the ligand dppe catalyzes the hydroformylation of propene at 135 °C in a water gas shift process (equation 78).[405]

$$RCH{=}CH_2 + CO + H_2 \xrightarrow{\text{catalyst}} RCH_2CH_2CHO \quad (77)$$

$$MeCH{=}CH_2 + CO + H_2O \xrightarrow{\text{catalyst}} MeCH_2CH_2CHO \quad (78)$$



47.5.2.2 Dinitrogen

Dinitrogen usually coordinates in an end-on fashion, (**89**) or (**90**), and sometimes in a side-on π-bonded mode (**91**). Hoffmann and coworkers consider that side-on coordination to two metal centres such as (**92**) is possible,[407] and Yamabe and coworkers have also considered theoretical aspects in relation to possible reduction to hydrazine or ammonia.[408]

(89) (90) (91) (92)

Dinitrogen complexes can be prepared by the addition of N_2 to a Co hydride or borohydride complex, by reduction under N_2 of $CoCl_2$ or $[Co(acac)_3]$ using Mg or $R_2Al(OR)$ in the presence of PR_3 (R = Ph, Me), or by displacement of a coordinated alkene (Schemes 34 and 35; Table 33).

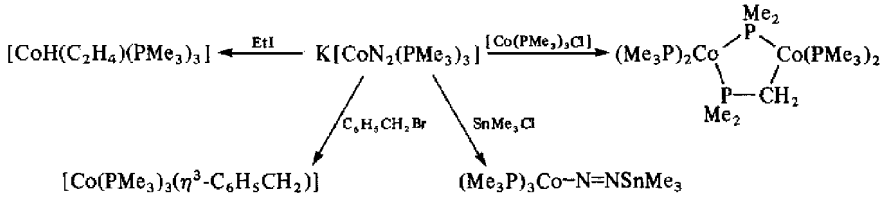
Scheme 35



$[CoH(N_2)(PPh_3)_3]$ has been extensively studied;[409] it has the distorted trigonal-bipyramidal structure (**93**; Table 32). The end-on coordinated N_2 is reversibly displaced by H_2, C_2H_4 and NH_3, and is irreversibly displaced by CO and PF_3 with retention of geometry (**94**). It also reacts with formaldehyde to give the *trans* complex (**95**) (structure, Table 32).

$K[Co(N_2)(PMe_3)_3]$ and $[Mg(THF)_4][Co(N_2)(PMe_3)_3]_2$ are unstable in non-polar solvents giving rise to the paramagnetic $[Co(N_2)(PMe_3)_3]$ intermediate, and ultimately to Co, $[Co(PMe_3)_4]$ and N_2 (equation 79).[410] Structures are available (Table 35). Although the reduction of coordinated N_2 has not yet been demonstrated in these systems, end-on coordination occurs with the above cations stabilizing the linear $Co{=}N^{\delta+}{=}N^{\delta-}{-}{-}{-}M^{n+}$ array. Addition, or oxidative addition, to $[Co(N_2)(PMe_3)_3]^-$ is also known (Scheme 36).[411] Miura and Yamamoto report that coordinated N_2 in $[Mg(THF)_2][Co(N_2)(PR_3)_3]_2$ is converted to N_2H_4 and a small amount of NH_3 on hydrolysis.[412] Mason and Ibers report that the bridged N_2 dimer $\{[Co(PEt_2Ph)_3]_2(\mu\text{-}N_2)\}$ and $Na[Co(N_2)(PEt_2Ph)_3]$ react with dry CO_2 to give ill-defined Co—CO and $Co(CO_3)$ products *via* some sort of reductive disproportionation process.[413]

$$[CoN_2(PMe_3)_3]^- \xrightarrow{-e^-} [CoN_2(PMe_3)_3] \longrightarrow [Co(L)_2(PMe_3)_2] + PMe_3 + N_2 \qquad (79)$$

47.5.2.3 Nitrosyl

Non-phosphine-containing nitrosyl complexes are considered in Section 47.4.1.

$[Co(NO)(PR_3)_3]$ (R = Ph, alkyl, OEt) can be directly prepared from $CoX_2 \cdot 6H_2O$ salts ($X = Cl^-$, NO_3^-) and PR_3 under appropriate conditions (Table 34). A tetrahedral structure is inferred from IR and NMR evidence for these $\{CoNO\}^{10}$ diamagnetic systems, and is indeed found for

$[Co(NO)\{N(dppe)_3\}]$	$[CoH\{N(dppe)_3\}] + NO$; THF	Brown; ν_{NO} 1620; diamagnetic	15
$[Co(NO)\{P(OEt)_2Ph\}_3]$	$[Co(NO)_2\{P(OEt)_2Ph\}_2]BPh_4 + L$; acetone	Red; ν_{NO} 1673	9
$[Co(NO)(Cl)_2(dppe)]$	$[Co(NO)_2(dppe)]Cl + dppe$; benzene	Brown; ν_{NO} 1676	4, 6, 16
$[Co(NO)(X)_2(PR_3)_2]$ (X = Cl, Br, I; R = Et, Bu^n, Ph)	$[Co(X)_2(PR_3)_2] + NO$; benzene	Dark brown, unstable in air	7
$[Co(NO)L(PPh_3)_2]$ (L = 1,4-napthaquinone, maleic anhydride, fumaronitrile)	$[Co(NO)(PPh_3)_3] + I_2$; THF	Brown-green, diamagnetic	5
	$[Co(NO)(PPh_3)_3]$ + alkene; Et_2O		11
$[Co(NO)(PR_3)SR']_2$	$[Co(NO)(CO)_2(PR_3)] + R'SH$	RS-bridged dimer	13
$[Co(NO)(dppe)_2]X_2$	$Co(NO_3)_2 \cdot 6H_2O + P(OR)_3 + NO$; EtOH	Pink, unstable in polar solvents; diamagnetic; linear CoNO (^{1}H NMR)	13, 15
$[Co(NO)\{P(OR)_3\}_4](BPh_4)_2$ (R = Me, Et)	$[Co(NO)\{P(OR)_3\}_4](BPh_4)_2 + LiX$; EtOH	Green-brown; unstable to disproportionation; diamagnetic	3, 8
$[Co(NO)X\{P(OR)_3\}_3]Y$ (X = Cl, Br, I; Y = BF_4, BPh_4)	$[Co(NO)_2X]_2 + PR_3$	Dark brown; diamagnetic	9
$[Co(NO)_2X(PR_3)]$ (R = Ph, Cy, Et; X = Cl, Br, I)	$[Co(NO)Cl(PPh_3)] + PPh_3$; EtOH, $NaClO_4$	Brown; diamagnetic (structure Table 36)	10
$[Co(NO)_2(PPh_3)_2]X$ (X = Cl, ClO_4, BPh_4, PF_6)	$[Co(NO)_2Cl]_2 + KPPh_2$	Ph_2P-bridged dimer	13
$[Co(NO)_2(PPh_2)]_2$	$[Co(NO)\{P(OR)_3\}_4]^{2+} + NO$		14
$[Co(NO)_2\{P(OR)_3\}_2]BPh_4$	$[Co(Cl)_2(dppv)_2]Cl + NaNO_2$; MeOH, N_2, reflux	Red; ν_{NO} 1800, 1858	9, 16
$[Co(NO)_2(dppv)]ClO_4$	$[Co(NO)_2Cl]_2 + dppe$; benzene	Red; ν_{NO} 1850, 1795	
$[Co(NO)_2(dppe)]Y$ (Y = Cl, ClO_4, BPh_4)	$CoCl_2 + L + NEt_3 + NO$; EtOH, $NaBPh_4$	Brown; ν_{NO} 1855	16
$[Co(NO)_2(PPh_3)_2]BPh_4$

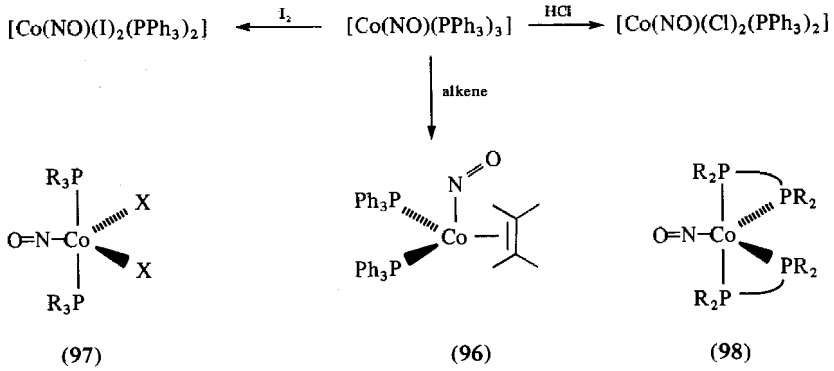
Table 35 Structures of Monodentate Phosphine Complexes



Complex	*Data*[a]	*Comments*	*Ref.*
$[Co(PPh_3)_2(NO)_2]PF_6$	CoN 164.5; CoP 226.6; MCoN 136.7°; CoNO 171°	Dist. tet., flattened towards planar	1
$[Mg(THF)_4][Co(N_2)(PMe_3)_3]_2$	CoN 172; NN 118; MgN 204; NNMg 158°	Dist. tet., long NN bond; N_2 evolved in low polarity solvents	3
$K[Co(N_2)(PMe_3)_3]$	NN 116–118; CoN 170–1; KN 276–293	Hexameric, linear Co—NN—K	4
$[Co(PPh_3)(CpZn)_2(Cp)]$	CoZn 229; CoP 212	Dist. tet., $CpZn^+$ ligands	8
$\{Li[Co(PMe_3)_3C_2H_4]\}_3$	CoLi 238; LiC 231–261; CoC 200	Dist. oct., trimeric with bridging Li	24
$[Co(NO)(CO)_2(PPh_3)]$	CoP 222; NCoC 111–116°	Dist. tet., Co and NO disordered	14
$[Co(NO)(CO)(PPh_3)_2]$	CoP 223; NCoC 120°	Dist. tet (as above)	14
$[Co_2(PPh_3)_2(NO)(SO_2)]$	CoS 202.1; CoN 168; CoNO 169	Dist. tet., planar $CoSO_2$	23
$[Co_2(PMe_3)_2(CO)_4(C_2H_2)]$	CoCo 246.4; CoCO 178; CoC 196	Dimeric, C_{2v} sym., bridging C_2H_2 unit	9
$[Co(PMe_3)_3(PhCCPh)]BPh_4$	CoCo 185.2; CoP 212.7, 221.2; CoC 126.5	Dist. tet., bonded to triple bond	26
$[Co_2(PMe_3)_4(\mu\text{-}OMe_2)(PMe_2CH_2)]$	P=CH_2 171; PCCo, 88°	Dist. tet., dimeric oxidation product of $[Co(N_2)(PMe_3)_3]^-$; bridging PMe_2, PMe_2CH_2	5
$[Co_2(PMe_3)_2(Me_2PCH_2PMe_2)_2PMe_2]$	CoCo 260.3; $CoPMe_2$ 214.4; CoPCo 74.8°	Dist. tet. pyr.; dimeric with diphosphine bridge; μ-PMe_2	20
$[Co(PPh_2Me)_2(NO)Cl_2]$	CoN 171; CoP 226; CoCl 226–229; CoNO 164.5°	Dist. trig. bipyr., NO (slightly bent) equatorial; another isomer detected in solid and soln.	6
$[Co(PMe_3)_3(Ph)(C_2H_4)]$	CoP 119–121; CoC(Ph) 200; CoC(ethylene) 204–5; PCoP 97.9°; PCoC(Ph) 81.6°; PCoC(Et) 92.6°	Dist. trig. bipyr., equatorial coplanar Ph, C_2H_4; axial PMe_3	7
$[Co\{P(OMe)_3\}_3(C_8H_8)]$	CoP 211–213; P(1)CoP 103.5–106.2°; PCoP, 97.4°	tet. pyr.; η^3-cyclooctenyl ligand spans base edge; catalyst for arene hydrogenation; axial $P(OMe)_3$	16
$[CoH(BH_4)(PCy_3)_2]$	CoP 222; CoH 135; PCoP 158°; CoH(**B**) 180, 187(ax)	Dist. sq. pyr., bidentate BH_4^-	10
$[Co(PMe_3)_3(MeCN)C_2H_4]BPh_4$	CoC 202.3, 203; CC 141; CON 191.3; CoP 217.5–224	Dist. trig. bipyr.; equatorial C_2H_4, MeCN	25
$[Co(PMe_3)_2(MeCN)PhCCPh]BPh_4$	CoC 197.7, 198.1; CC 126.7; CoN axial MeCN	Dist. trig. bipyr.; equatorial PhCCPh, axial MeCN	26
$[CoH(PPh_3)_3(NCBH_3)]$	CoH 142; CoN 190.4; CoP(ax) 229	Dist. sq. pyr. with H axial	11
$[Co(X)_2(PPh_3)_2]$ (X = Cl, Br)	CoX 221(Cl), 235(Br); CoP 238; XCoX 115(Cl), 117°(Br)	Tet., high spin	12
$[Co(PEt_3Ph)_2(mesityl)_2]$	CoP 223.4; CoC 199.4; CCoP 89.6°	Planar, low spin, apical sites blocked, *trans* PR_3	13
$[Co(Cl)_2(PMe_3)_3]$	CoCl 226, 238; CoP 221–224; PCoP 87–96°, 169°	Dist. trig. bipyr. Cl(eq)	15
$[Co(Br)_2(PPhF_2)_3]$	CoP(ax) 216; CoP(eq) 212; CoBr 237–8; BrCoBr 126°; P(1)CoP(2), 172.5°	Trig. bipyr., Br(eq)	17
$R[Co(Cl)_3(PPh_3)]$	CoCl 222–227; CoP 239; ClCoCl 113–116°; ClCoP, 103–105°	Tet.	19
$[Co_4(\mu_3\text{-}PPh)_4(PPh_3)]_4$	CoCo 257–258; CoCoCo 59.6–60.1°	Tet., Co_4 cluster with PPh-coordination on faces, terminal PPh_3; also Co_4^+ cluster	19
$[Co(Br)_2(PPh_2H)_3]$	CoBr 233, 254; CoP 220–223; BrCoBr 125.6; PCoP 175.9°	Trig. bipyr., Br(eq)	22
$\{CoCl(PMe_3)_4\}BF_4$	CoCl 231; CoP 225–229; PCoCl 84°; PCoP 86–97°, 167°	Dist. trig. bipyr., Br(eq)	15
$[Co_2(CN)_4(PMe_2Ph)_5(O_2)]$	CoP(ax) 229–230; CoP(eq) 220–224; CoC(t) 190–1; CoC(b) 185; CoN 195; CoO 189–191; CO 144	Co^{III} dimer from $Co(CN)_2^-$, $(PMe_2Ph)_3 + O_2$; bidentate O_2^{2-}	18
$[Co(Cl)_2(PPh_3)(Me_4EtCp)]$	CoP 229; CoCl 226, 229; CoC 209–214; ClCoCl 94	Dist. oct., Me_4EtCp occupies three coordination sites	21
		Octa. long trans bond to PPh; Co displaced 11.2 pm	2

$[CoCl(DMGH)_2(PC_y)]\cdot$toluene	CoP 236.9; CoCl 229.4	Oct., Co displaced 10 pm above dist. N_4 plane	2
$[Co(NO_2)(DMGH)_2(PPh_3)]$	$CoNO_2$ 198; CoP 239.2	Oct.	27
$[Co(Cl)(DMGH)_2(PBu_3)]$	CoCl 229.5; CoP 227.1; CoN 188.9	Oct.	28
$[Co(Cl)(DMGH)_2P(OMe)_3]$	CoCl 227.2; CoP 216.5; CoN 184–194	Oct.	28
$[Co(CH_2Br)(DMGH)_2(PPh_3)]$	CoP 239.9; CoC 199.8; PCoC 175°	Oct.	29
$[Co(CH_2CN)(DMGH)_2(PPh_3)]$	CoP 239.1; CoC 204.3; PCoC 177.7°	Oct.	29
$[Co(CH_2CMe_3)(DMGH)_2(PMe_3)]$	CoP 231.6; CoC 208.4; CCoP 173.7°; $CoCH_2C$ 130.2°	Oct.	30
$[Cp(Me)(DMGH)_2(PR'_3)]$ (R′ = Ph, OMe)	CoP 242.8, 226.8; CoC 203.3, 204.1	Oct.	31
$[Co(Pr^i)(DMGH)_2\{P(COH_2)_3CMe\}]$	CoP 227; CoC 212–3; PCoC 169.9°	Oct.	32

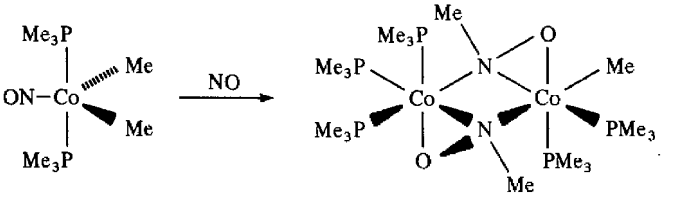
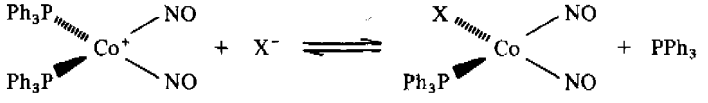
$[Co(NO)(PR_3)_{3-n}(CO)_n]$ ($n = 1,2$; Table 35). They undergo addition reactions to form five-coordinate $\{CoNO\}^8$ systems,[414] and alkene replacement to give (**96**), which may not be tetrahedral (Scheme 37).[415] Replacement of PPh_3 by SO_2 gives tetrahedral $[Co(NO)(SO_2)(PPh_3)_2]$ with coplanar Co—SO_2 and linear Co—NO coordination (structure, Table 35). The interesting paramagnetic $[Co(NO)\{N(dppe)_3\}](BPh_4)$ complex ($\mu = 1.98$ BM) also has the tetrahedral structure (Table 35) and this is one of the few examples of a paramagnetic nitrosyl complex.



(97) (96) (98)

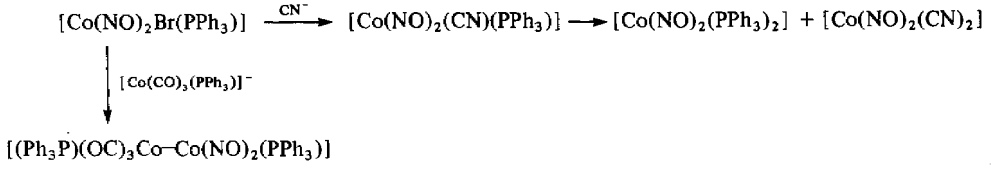
Scheme 37

Addition of NO to the high-spin tetrahedral Co^{II} species $[CoX_2(PR_3)_2]$ ($X = Cl^-, Br^-$; structure, Table 35) gives the $\{CoNO\}^8$ species (**97**), which for $R_3 = Ph_2Me$, $X = Cl^-$ (structure, Table 35, CoNO = 164.5°) appears to be close to the crossover between tetragonal pyramidal (C_s) with a bent CoNO and trigonal bipyramidal (C_{2v}) with linear CoNO. Thus (**98**) has been shown by ^{31}P NMR to be fluxional.[416] An analogue of (**97**) is (**101**), which is formed by addition of NO to $[Co(Me)_2(PMe_3)_3]$, but in this case the complex is unstable to further insertion into the Co—Me bond forming the bridged nitrosomethane Co^{III} complex (**102**; equation 80).[417] $[Co(NO)\{P(OR)_3\}_4]^{2+}$ (R = Me, Et; $P(OEt)_2Ph$) has been prepared from $CoX_2 \cdot 6H_2O$ (Table 34) and ^1H NMR at −60 °C supports equatorial coordination in a trigonal-bipyramidal cation (**99**).[418] No structures are apparently available on these systems. Further reaction with NO gives $[Co(NO)_2\{P(OR)_3\}_2]^+$, and CO and CNR can displace coordinated NO. Reduction to the 19-electron system $[Co(NO)\{P(OR)_3\}_4]^+$ results in loss of $P(OR)_3$ followed by further reduction to $[Co(NO)\{P(OR)_3\}_3]$. Likewise addition of NO to $[CoX\{P(OR)_3\}_4]^+$ or to $[Co(X)_2\{P(OR)_3\}_2]$, or of LiX (or HX) to $[Co(NO)\{P(OR)_3\}_4]^{2+}$ gives $[Co(NO)X\{P(OR)_3\}_3]^+$ (Table 34). IR (ν_{NO}, 1780–1800 cm^{-1}) and NMR evidence again support trigonal-bipyramidal equatorial coordination (**100**) with no evidence for a second isomer. Further reaction with NO gives $[Co(NO)_2\{P(OR)_3\}_2]$ and $[Co(NO)_2\{P(OR)_3\}]$ and reaction with I^-, PR_3, CO and CNR gives a variety of products.[419] Loss of halide occurs on reduction of $[Co(NO)X\{P(OR)_3\}]^+$ at platinum ($X = Cl^-, I^-$) with $[Co(NO)\{P(OR)_3\}_3]$ being formed; oxidation results in $[Co(NO)_2\{P(OR)_3\}_2]^+$ and $[Co(NO)_2X\{P(OR)_3\}_2]$ and species containing no nitrosyl ligand.[430]



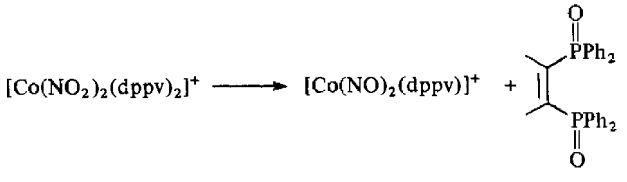
(99) (100)

(101) (102) (80)

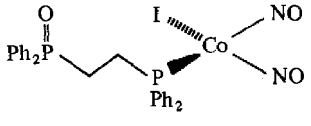


Hydrolysis and alcoholysis at the coordinated P atom have been found to occur with $[Co(NO)(PF_3)_3]$ giving $[Co(NO)(PF_3)_{3-n}(PF_2O)_n]^{n-}$ ($n = 1, 2$) and $[Co(NO)\{P(OR)_3\}_3]$ respectively,[420] and Sacco and his colleagues have shown that the nitrosyl ligand in $[Co(NO)(PPh_3)_3]$ can be transferred to a variety of Co^{II} and Ni^{II} phosphine complexes.[431]

Dinitrosyl–phosphine complexes can be prepared in a number of ways. Treatment of the diamagnetic halide-bridged dimer $[Co(NO)_2X]_2$ with PR_3 gives an equilibrium distribution of tetrahedral (**103**) and (**104**), with the former (structure, Table 35) being favoured by excess PR_3 and large non-coordinating counterions (ClO_4^-, BPh_4^-, PF_6^-) and the latter by excess halide ($X = Cl^-$, Br^-; equation 81). ^{59}Co NMR data for $[Co(NO)_2X(L)]$ have been interpreted in terms of decreasing π-acceptor power in the series $L = P(OR)_3 > P(NR_2) \sim P(alkyl)_3$.[421] Both (**103**) and (**104**) can be readily reduced by $NaBH_4$ to $[Co(NO)(PPh_3)_3]$, and heating $[Co(NO)_2(PPh_3)_2](ClO_4)$ with KNO_2 produces the nitrito complex $[Co(NO)_2(PPh_3)(ONO)]$. On the other hand Br^- in (**104**) can be displaced by other basic species such as CN^- and $[Co(CO)_3(PPh_3)]^-$ (Scheme 38).[422] $[Co(NO)_2(vpp)]^+$ has been prepared *via* internal redox in the unstable yellow-brown cobalt(III) intermediate $[Co(NO_2)_2(dppv)_2]^+$ (equation 82).[423] Treatment of $[Co(NO)_2X]_2$ ($X = Cl^-$, Br^-, I^-) with dppe results in products which depend on the amount of dppe used:[424] $[Co_2(X)_2(dppe)(NO)_4]$ containing possible bridging N_2O_2 (or dppe),[425] $[Co(NO)_2(dppe)]X$, and, in the presence of excess ligand, $[Co_2(NO)_2(dppe)_3]$ and $[Co(X)_2(dppe)(NO)]$. Treatment of $[Co(NO)_2(dppe)](PF_6)$ with Et_4NI in THF results in oxidation at one P centre and monodentate phosphine coordination (**105**).[426]



(81)



(103) (104)

Scheme 38

(82)

(105)

Major structural interest in $[Co(NO)_2(PPh_3)_2]^+$ lies in its nearly tetrahedral stereochemistry (Table 35; NCoN, 137.6°) and linear CoNO bond (171°); this is to be compared with its more distorted Rh^I (NRhN, 157.5°; RhNO, 158.9°) and Ir^I (154.2°, 163.5°) analogues.[427,428] The latter two complex ions undergo the potentially valuable redox reaction shown in equation (83), and the failure of the Co^I complex to do so is thought to arise from the more acidic character of the metal orbitals in the $\{Co(NO)_2\}^{10}$ framework. A tetrahedral structure is likewise found for $[Co(NO)_2(dppe)](PF_6)$ (Table 12) but there is some suggestion based on NMR evidence that both tetrahedral and square-planar structures exist for $[Co(NO)_2\{P(OR)_3\}_2]^+$ in solution.[419] Direct confirmation of this is required. Both reduction ($E_{1/2} \approx -0.4$ V, -1.5 V) and oxidation (~ 0.8 V) of $[Co(NO)_2\{P(OEt)_3\}_2]^+$ have been observed with the first reduction wave being reversible; impure paramagnetic $[Co(NO)_2\{P(OEt)_3\}_2]$ has been isolated, and there is IR evidence suggesting bending of the nitrosyl in this 19-electron system.[429]

$$[M(NO)_2(PPh_3)_2]^+ + 4CO \longrightarrow [M(CO)_3(PPh_3)_2]^+ + N_2O + CO_2 \quad (83)$$

47.5.2.4 *Monodentate phosphines*

(*i*) *Cobalt(−I)*

Yellow-orange diamagnetic $[Co(PMe_3)_4]^-$ is formed by the low-temperature reduction of $[Co(PMe_3)_4]$ (equation 84; Table 36) and equilibrium electron electron transfer may be involved.[432] This ion is almost certainly tetrahedral and is one of the strongest reducing agents known ($E^\circ = -2.5$ to -3 V). It is also a powerful nucleophile reacting with both inorganic (*e.g.* H^+) and organic electrophiles *via* an oxidative (possibly free radical) process.[432] Similar properties hold for alkene-substituted systems (Scheme 39), and this leads to the possibility of industrially important catalytic processes.[445] Semireduced $K_2[Co(C_2H_4)(PMe_3)_3]_4$ has been isolated and shown to be a convenient source of reducing power in organic solvents at room temperature.[477] A similar property holds with $Li[Co(C_2H_4)(PMe_3)_3]$ whose structure (Table 35) shows weak interactions with the metal and alkene in a distorted trimeric octahedral arrangement.

$$[Co(PMe_3)_4] \xrightarrow[-70\,^\circ C]{M} [Co(PMe_3)_4]^- \xrightarrow[-70\,^\circ C]{RCl} [CoR(PMe_3)_4] + Cl^- \quad (84)$$

M = Li, Na, K; R = H, alkyl

$$[Co(PMe_3)_3] + \text{alkene} \longrightarrow [Co(\text{alkene})(PMe_3)_3] \xrightarrow{K}$$

green, $\mu = 1.85$ BM

$$[Co(\text{alkene})(PMe_3)_3]^- \xrightarrow{RCl} \text{Me}_3\text{P}(\text{R})\text{Co}(\text{alkene})(\text{PMe}_3)_2$$

orange-brown

alkene = C_2H_4, C_3H_7, cyclopentene

Scheme 39

Unlike $[Co(PMe_3)_4]^-$ less basic $[Co(PF_3)_4]^-$ and $[Co\{P(OR)_3\}_4]^-$ can be prepared by deprotonation of the parent hydride (equation 85; Table 36). Such species also readily undergo oxidative addition reactions.[433] The hydrides $[HCo(PF_3)_4]$, $[HCo\{P(OMe)_3\}_4]$ and $[HCo(PMe_3)_4]$ can be considered as H^+ conjugate acids of d^{10} bases. However their acidity decreases dramatically in the above order with $[HCo(PF_3)_4]$ being easily titrated by most bases in aqueous solution; the latter two hydrides cannot be titrated with LiR or KH and are better considered as hydride complexes of Co^I (*cf.* Section 47.5.2.1). $Hg[Co\{P(OMe)_3\}_4]_2$ retains C_{3v} trigonal-bipyramidal symmetry even at 100 °C (it has a strong axial Co—Hg—Co framework) but the phosphite ligands are stereochemically fluxional among the remaining coordination sites ($E_a \approx 42$ kJ mol^{-1}).[434] Likewise $[HCo(PF_3)_4]$ is stereochemically non-rigid,[433] as is $[CoR(PMe_3)_4]$, R = H, Me (Section 47.5.2.1).

$$HCo\{P(OR)_3\}_4 + KH \xrightarrow{THF} K[Co\{P(OR)_3\}_4] + H_2 \quad (85)$$

R = Me, Et; colourless

(*ii*) *Cobalt(0)*

Reduction of Co^{II} halides with Na/Hg or Hg/Grignard (but not $NaBH_4$) in the presence of PR_3 under Ar (N_2 complexes are usually formed in the presence of N_2) forms dark-coloured paramagnetic C_{3v}-distorted $[Co(PR_3)_4]$ complexes (Table 36). The ESR spectrum of $[Co(PMe_3)_4]$ shows a well-resolved eight-line pattern characteristic of axial symmetry.[435] $[Co(PPh_3)_4]$ has apparently not been made but $[Co(PPh_2Me)_4]$ and $[Co(DBP)_4]$ have, so steric constraints may not be important. Intermediate paramagnetic '$Co(PR_3)_3$' species (PR_3 = PMe_3, DBP) have been observed and are synthetically useful (see below).

These 17-electron systems are excellent nucleophiles and undergo a variety of displacement, dimerization and oxidative addition reactions; $[Co(PMe_3)_4]$ is especially reactive (Scheme 40).[435]

Table 36 Preparations: Monodentate Phosphine Complexes

Complex	*Preparation*	*Properties*[a]	*Ref.*
Cobalt(−I)			
$M[Co(PMe_3)_4]$	$[Co(PMe_3)_4] + M$; Ar, THF	Yellow-orange; diamagnetic; very reactive nucleophile	1
(M = Li, Na, K)			
$[Mg(THF)_4][Co(PMe_3)_3N_2]_2$	$CoCl_2 + PMe_3 + Mg$; THF, N_2, 3 d, 20 °C	Orange-yellow; ν_{NN} 2068(s)	2
$K[Co\{P(OR)_3\}_4]$	$[HCo\{P(OR)_3\}_4] + KH$; THF	Colourless; rapidly gives $[Co(H)\{P(OR)_3\}_4]$ in H^+ media	3
(R = Me, Et)			
$K[Co(PF_3)_4]$	$[HCo(PF_3)_4] + K/Hg$; $E^c_{1/2}$	Colourless; diamagnetic	4
Cobalt(0)			
$[Co(PMe_3)_4]$	$CoCl_2 + PMe_3 + Mg$/THF (or Na/Hg); Ar	Brown; μ = 1.70; very reactive nucleophile	7
$[Co(PPh_2Me)_4]$	$[CoCl_2(PPh_2Me)_2] + PPh_2Me$	Brown-black; μ = 1.71	8
$[Co(DBP)_4]$	$CoCl_2 \cdot 6H_2O + DBP + NaBH_4$; boiling EtOH	Red-brown; diamagnetic; possibly dimeric	9
$[Co(C_2H_4)(PMe_3)_3]$	$[Co(PMe_3)_3] + C_2H_4$	μ = 1.85	12
$[Co(C_2H_4)(PPh_3)_3]$	Et_2O, ArCo(acac) + $Et_2Al(OEt)$ + PPh_3 + Et_2O, Ar[3], 0 °C	Orange; μ = 1.90	22
Cobalt(I)			
$[CoX(PPh_3)_3]$	$CoX_2 \cdot 6H_2O + PPh_3 + NaBH_4$; EtOH, N_2	Green (X = Cl); tet.	14, 9
(X = Cl, Br, I)	$[CoX_2(PPh_3)_2] + LiPPh_3$; THF		15
$[CoX(PMe_3)_3]$	$CoX_2 + PMe_3 + Na/Hg$; Et_2O	Blue-violet; μ = 3.1–3.4; tet.	9, 16
(X = Cl, Br, I)	$[Co(PMe_3)_4] + CoX_2 + PMe_3$		17
	$[Co(Me)(PMe_3)_4] + NH_4Cl$		18
$[CoX(PPhF_2)_4]$	$CoCl_2 + PPhF_2$		21
(X = Cl, Br)	$[CoBr_2(PPhF_2)_3] + PPhF_2$	Brown-orange; dimagnetic	22
$[Co(Me)(PPh_3)_3]$	$[Co(acac)_3] + Me_2Al(OEt) + PPh_3$; toluene, −5 °C	Orange; unstable giving CH_4	
$[Co(Me)(PPh_3)_2]$	$[Co(acac)_3] + Me_2Al(OEt) + PPh_3$; Et_2O, Ar, 0 °C, 4 h		7
$[Co(Me)(PMe_3)_4]$	$[CoCl(PMe_3)_3] + LiMe + PMe_3$; Et_2O, −78 °C	Diamagnetic	19
$[Co(PPh_3)_{2,1}(CNR')_{3,4}](PF_6)$	$[Co(PR_3)_2Cl_2] + RNC(N_2H_4)$; EtOH	Orange; diamagnetic; trig. bipyr. (^1H NMR, IR); fluxional	
(R′ = alkyl, aryl)	$[Co(CNR)_5]X + PPh_3$; CH_2Cl_2		
Cobalt(II)			
$[Co(X)_2(PMe_3)_2]$	$CoX_2 + PMe_3$; EtOH	Blue, red (X = NCS); μ = 3.9–4.4 (2.15, X = NCS); tet.	35
$[Co(X)_2(PR_3)_2]$	$CoX_2 + PR_3$; EtOH	Blue (Cl); blue-green (Br); brown (I); μ = 4.4–4.7	5
(X = Cl, Br, I; R = Et, Ph)	$CoX_2 + PPh_3$; NBu^n_4X; acetone	Blue (Br); green (I); μ = 4.5–4.6	23
$(NBu^n_4)[Co(X)_3(PPh_3)]$	$Co(NCS)_2 + PEt_3$; EtOH	Red-brown; μ = 2.21; dimeric; dissociates in CH_2Cl_2 soln.	36
(X = Cl, Br, I)	$CoX_2 + PCy_3$; EtOH	Blue-green; μ = 4.40	37
$[Co(NCS)_2(PEt_3)_2]$			
$[Co(X)_2(PCy_3)_2]$			
(X = Cl, Br, NCS)

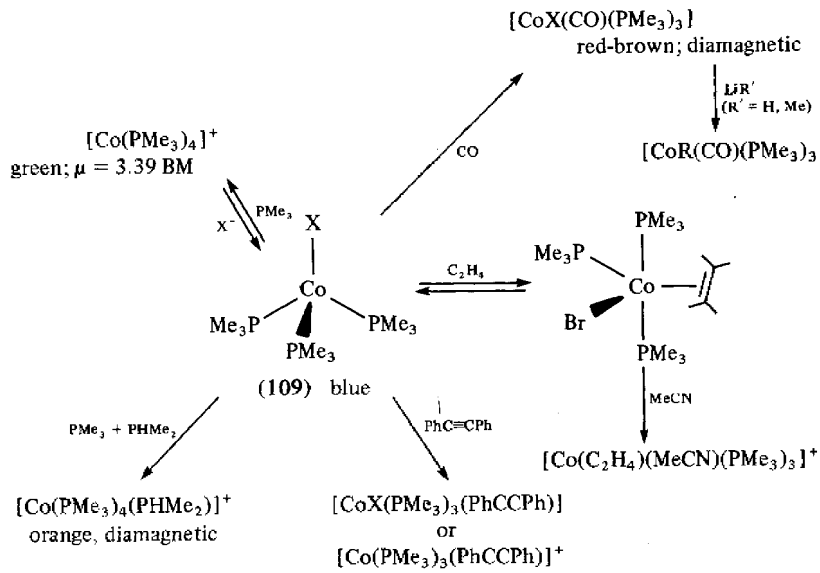
Addition of $Me_2PCH_2PMe_2$ in THF at room temperature leads to the red-brown paramagnetic dimer (**106**), which has an unusually short Co—Co bond (bond order 1.5; structure, Table 35) with each Co being formally at the 0.5 oxidation level. $[Co(PEt_3)_4]$ also adds to the B,C skeleton of *closo*-carbonates to form paramagnetic (**107**) and diamagnetic (**108**) clusters (equation 86).[436] Many uses for these electron-rich species will be found.

Scheme 40

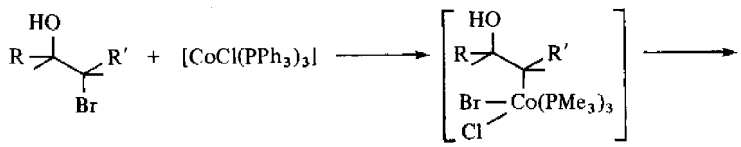
(**106**)



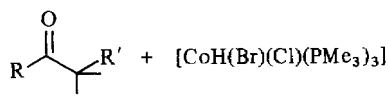
(**107**) (**108**) (86)

(iii) Cobalt(I)

Cautious reduction of CoX_2 in the presence of PR_3 or of $[Co(Cl)_2(PR_3)_2]$ at low temperature produces $[CoX(PR_3)_3]$ species (X = Cl^-, Br^-, I^-, O_2CMe ; Table 36). The four-coordinate 16-electron systems (**109**) are typically high spin (μ = 3.1–3.4 BM) and tetrahedral (probably C_{3v}) with high fluxional lability. With R = Ph or other aryl they are not very stable in solution (THF, CH_2Cl_2, C_6H_6) and oxidize readily to ill-defined products. With R = Me they are more stable and readily add electron pairs generating diamagnetic trigonal-bipyramidal systems (Scheme 41).[437] Addition of C_2H_4 to $[CoBr(PMe_3)_3]$ is reversible forming $[CoBr(C_2H_4)(PMe_3)_3]$ with equatorial Br and C_2H_4 ligands,[475] whereas treatment with PhCCPh leads to trigonal-bipyramidal $[CoBr(PhCCPh)(PPh_3)_3]$ in toluene and some tetrahedral $[Co(PhCCPh)(PPh_3)_3]Br$ in acetone;[476] a structure of the latter is available (Table 35). Addition of MeCN to these products results in $[Co(MeCN)(R)(PMe_3)_3]^+$ (R = C_2H_4, PhCCPh) with equatorial R (structures, Table 35). Displacement of Br^- and PMe_3 occurs readily in acetonitrile at −80 °C (equations 87 and 88).[475] $[CoCl(PPh_3)_3]$ and $[CoCl_2(PPh_3)_2]$ have been shown to be effective catalysts in the oxidation of cyclic $B_3H_8^-$ to $B_3H_7PPh_3$ (and lower



homologues) possibly *via* initial displacement of halide and chelation of borate, and for the oxidation of bromohydrins to ketones *via* a β-hydroxylalkyl cobalt(III) intermediate[439] in a manner reminiscent of the vitamin-B_{12}-catalyzed dehydration of 1,2-diols (equation 89). $[CoX(PPh_3)_3]$ ($X = Cl^-, Br^-, I^-$) also catalyzes the dimerization of ethylene to an isomeric mixture of butenes[440] and of methyl acrylate to dimethyl adipate;[441] Co^I complexes are again proposed as intermediates and are probably similar to those outlined by Klein.[442]



Scheme 41

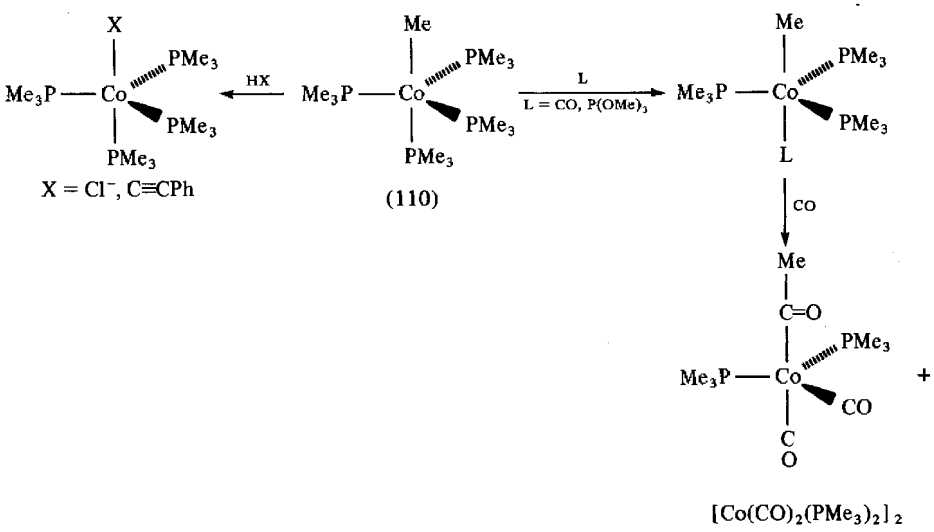
$$[CoBr(PMe_3)_3] + MeCN \longrightarrow [Co(MeCN)_2(PMe_3)_3]^+ + Br^- + PMe_3 \quad (87)$$

$$[Co(PMe_3)_4]^+ + MeCN \longrightarrow [Co(MeCN)(PMe_3)_4]^+ + PMe_3 \quad (88)$$

(89)

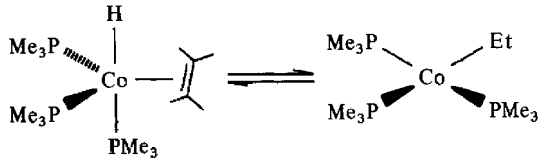
Diamagnetic $[Co(Me)(PPh_3)_3]$ and the 14-electron $[Co(Me)(PPh_3)_2]$ can be prepared by treating $[Co(acac)_3]$ with Me_3Al or $Me_2Al(OEt)$ in toluene (Table 36). These electron-deficient compounds are rather unstable and readily transfer the Me group (equation 90). $[Co(Me)(PPh_3)_3]$ also catalyzes the aldol condensations of acetone (to give mesityl oxide) and of methyl ethyl ketone (to give isomers of hepten-5-ones)[443] and spontaneously evolves biphenyl and $PMePh_2$ in non-polar solvents (migration of Me from Co to P).[444] $[Co(Me)(PMe_3)_3]$ does not appear to exist.

$$[CoX(PPh_3)_3] + CH_4 \xleftarrow{HX} [CoMe(PPh_3)_3] \xrightarrow{PhC\equiv CPh} \underset{(cis\ +\ trans)}{\overset{Me}{\overset{|}{PhC}}=CHPh} \quad (90)$$



$[CoR\{(PMe)_3\}_4]$ species (R = H, alkyl) may be readily prepared by substitution on $[CoCl(PMe_3)_4]$ or by oxidative addition to $[Co(PMe_3)_4]^-$ (equations 91 and 92);[435,445] these 18-electron systems have a distorted trigonal bipyramidal geometry with axial R (**110**). ^1H and ^{31}P spectra demonstrate fluxional character at ambient temperatures with a coalescence temperature of −52 to −75 °C. With more bulky alkyl or aryl ligands, or phosphines, stereochemical rigidity in $[CoR(PR'_3)_4]$ is maintained to higher temperatures. The *trans* influence of axial R causes substitution by Y (CO, $P(OMe)_3$) to occur in the axial position, but with HX methane is liberated (Scheme 42).[435]

These systems offer promise for the insertion of alkenes (or CO) into M—H or M—C bonds. Klein and coworkers[442] have demonstrated reversibility in the system (**111**), (**112**) by observing complete deuteration *via* $[Co(D)(C_2H_4)(PMe_3)_3]$; 1-pentene is also converted into 2-pentene (*cis*:*trans* = 9:1). However methyl migration in $[Co(Me)(1\text{-pentene})(PMe_3)_3]$ was not observed but on warming solutions of $[Co(Ph)(C_2H_4)(PMe_3)_3]$ in C_2H_4 at 50 °C biphenyl is produced. Some mixed phosphine–isocyanide complexes of the type $[Co(PR_3)(RNC)_4]^+$ and $[Co(PR_3)_2(RNC)_3]^+$ with axial phosphine ligands have been prepared (Table 36) and their oxidation studied.[446,447] Some of the most interesting systems involve NO coordination; these are considered in Sections 47.4.1.2 and 47.5.2.3 but in the case of $[Co(Cl)_2(NO)(PPh_3)_2]$ there is good IR (1750 cm^{-1}, 1650 cm^{-1} NO stretches) and photoelectron evidence for the existence of both linear and bent CoNO isomers in both the solid and in solution.[448,117]

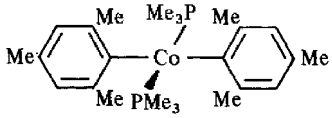


$$K[Co(PMe_3)_4] \xrightarrow[-70\,^\circ C]{RX} [CoR(PMe_3)_4] \xleftarrow{LiR} [CoX(PMe_3)_4] \qquad (91)$$

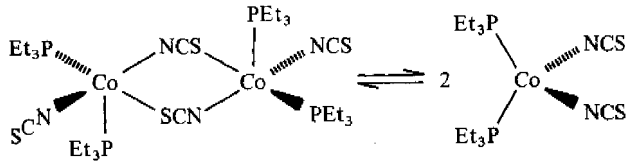
$$X = Cl^-, Br^-, I^-$$

$$[Co(C_2H_4)(PMe_3)_3]^- \xrightarrow[R = H, Me]{RCl} \text{yellow-orange} \xleftarrow[R = Me, Ph]{LiR} [Co(C_2H_4)Cl(PMe_3)_3] \qquad (92)$$

Scheme 42



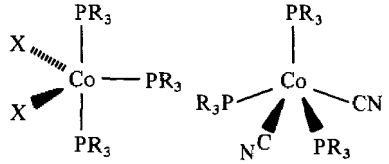
(iv) Cobalt(II)



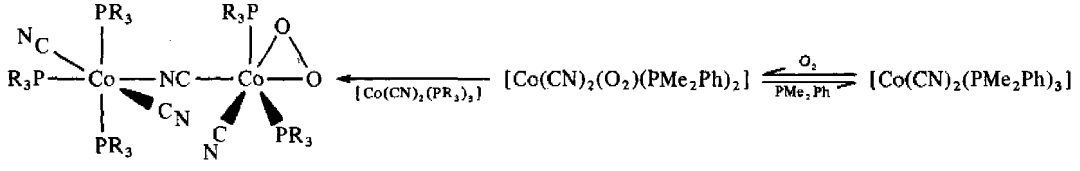
High-spin tetrahedral or pseudo-tetrahedral (C_{2v}) $[Co(X)_2(PR_3)_2]$ (R = alkyl, aryl; X = Cl^-, Br^-) complexes are easily prepared from CoX_2 and PR_3 in hot EtOH (Table 36). Addition of a large cation can lead to the isolation of the $[Co(X)_3(PR_3)]^-$ anion, and $[Co(X)(PMe_3)_4](BPh_4)$ has been isolated (Table 36). Crystal structures are available (Table 35). Care must be taken to avoid ligand oxidation, especially for R = aryl. $[Co(X)_2(PR_3)_2]$ and $(NBu^n_4)[Co(X)_3(PR_3)]$ have ESR and NMR characteristics consistent with a fast spin–lattice relaxation process ($T_1 \approx 6 \times 10^{13}\,s^{-1}$)[450] and use of

this has been made to study by NMR methods the ion pairing of large cations.[451] Temperature- and pressure-dependent shifts have been used to follow PPh_3 exchange in $[Co(Br)_2(PPh_3)_2]$ and the parameters $\Delta H^{\ddagger} = 32 \pm 2\,kJ\,mol^{-1}$, $\Delta S^{\ddagger} = -80 \pm 13\,J\,mol^{-1}\,K^{-1}$, $\Delta V^{\ddagger} = -12.1 \pm 0.6\,cm^3\,mol^{-1}$ have been interpreted in terms of an associative process *via* the known $[Co(X)_2(PR_3)_3]$ species.[452,453]

Complexes of the type $[Co(R)_2(PR_3)_2]$ appear to be stable only when R is an *o*-disubstituted or very bulky *o*-substituted aryl (R = alkyl are unknown) and their low spin ($\mu = 2.3$–2.7 BM) and zero dipole moment have been associated with the planar *trans* structure (**113**; Table 36) in which the two axial sites are blocked by the Me substituents. Gerloch has considered the theoretical aspects of bonding in these systems.[454] Another example of (**113**) may be low-spin $[Co(NCS)_2(PMe_3)_2]$ ($\mu = 2.15$ BM),[468] but $[Co(NCS)_2(PEt_3)_2]$ is dimeric in the solid with NCS bridges and exists in equilibrium with the high-spin tetrahedral monomer in CH_2Cl_2 solution (equation 93).



(113)

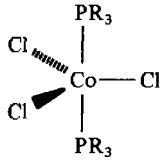


(93)

$\mu = 2.2$ BM $\qquad\qquad$ $\mu = 4.4$ BM

The 17-electron five-coordinate $[CoX_2(PR'_3)_3]$ systems (X = halide, Me; $R'_3 = Me_3$, Me_2Ph, HR^1R^2) are again easily prepared (Table 36), but with the exception of the PMe_3 complex partially dissociate to $[Co(X)_2(PR'_3)_2]$ in the absence of excess phosphine; steric effects are considered to be important.[455] These low-spin complexes have the trigonal bipyramidal structure (**114**) for X = halide, Me (structures, Table 35); $[CoH(PMe_3)_4]^+$ probably has a tetrahedral skeleton with an appended hydride (ν_H, 1935 cm^{-1}), and for X = CN^-, SCN^- the complexes have the tetragonal-pyramidal structure (**115**) with *trans* X groups (ESR).[456] The X = CN^-, SCN^- and F^- complexes absorb O_2 (reversibly at low temperature) releasing PR_3, and eventually form the Co^{II} dimer (**116**; Scheme 43).[437,457]

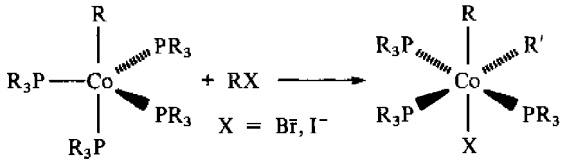
(114) $\qquad$ (115)



(116)

Scheme 43

Treatment of $CoBr_2$ with PHR_2 ($R_2 = Et_2$, EtPh, MePh) in the presence of $NaBPh_4$ results in low-spin light-green $[CoBr(PHR_2)_4](BPh_4)$, while octahedral $[Co(Br)_2(PHR_2)_4]$ is apparently formed in its absence.[455]



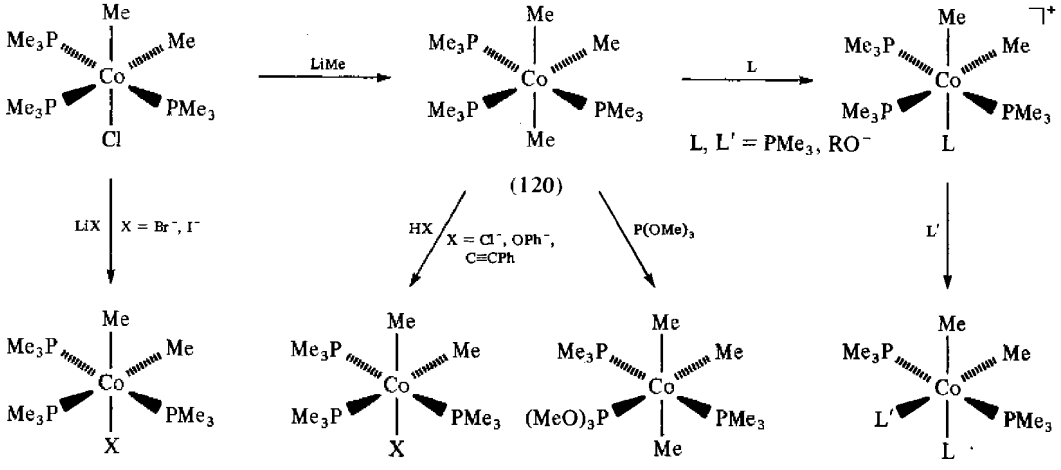
(v) *Cobalt(III)*

An increasing number of monodentate phosphine complexes of Co^{III} are becoming available (Table 36); few structures are known (Table 35). Many years ago Jensen[458] prepared the high-spin five-coordinate $[Co(X)_3(PR_3)_2]$ complexes ($\mu = 3.0$ BM; X = Cl^-, Br^-) and their monomeric nature and zero dipole moment imply a trigonal-bipyramidal structure (**117**). Oxidative addition of HX or RX to electron-deficient four-coordinate Co^I (equation 94) or to five-coordinate Co^I (**118**; equation 95) or to Co^{II} (equation 96) provides additional routes to octahedral Co^{III} systems of type (**119**; Table 36). The formation of the analogous hydrido–Co^{III} systems (Section 47.5.2.1) is often reversible (equations 97 and 98).

(117)

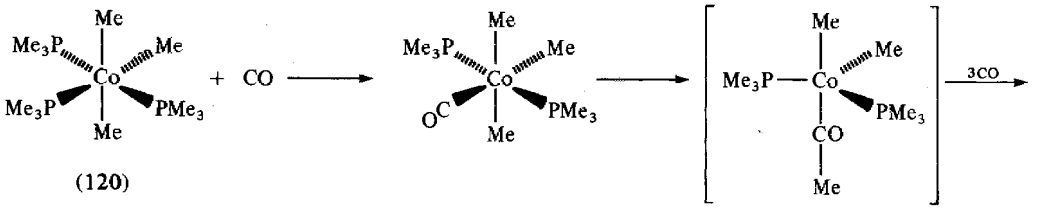
$$2[CoI(PMe_3)_3] + MeI \longrightarrow [CoI(Me)_2(PMe_3)_3] + [Co(I)_2(PMe_3)_3] \quad (94)$$

(118) (119) (95)



$$[Co(Me)_2(PMe_3)_3] + X_2 \xrightarrow[X=Br^-,I^-]{} [CoX(Me)_2(PMe_3)_3] \quad (96)$$

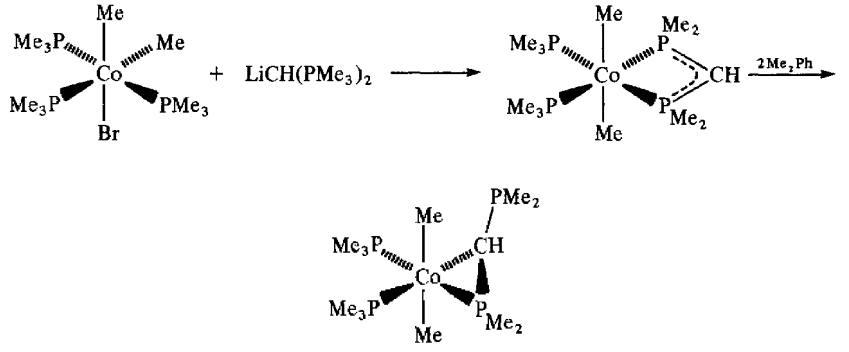
$$[CoH(PPh_3)_3] + H_2 \rightleftharpoons [CoH_3(PPh_3)_3] \quad (97)$$



$$[Co(PHR_2)_5] + H^+ \rightleftharpoons [CoH(PHR_2)_5]^{2+} \quad (98)$$

red white

Subsequent substitutions in these systems are often regiospecific (Scheme 44).[459,460,461] Unlike the reductive elimination of *cis* hydrides in $[Co(H)_3(PPh_3)_3]$, ethane is not formed from *cis* Me groups in (**120**; Scheme 44), but for L = CO insertion into the Co—Me bond occurs with the release of acetone (Scheme 45); no intermediates have been observed.[459] Using the diphosphomethamide anion as an analogue of allyl an interesting bonding isomerization has been observed (**121** to **122**; Scheme 46).[462]



Scheme 44

Scheme 46

Bergman and coworkers have investigated in some depth the $[Co(Me)_2(PPh_3)(Cp)]$ system, which provides low-temperature routes to carbonylation, hydroformylation and polymerization processes.[471–474] An overview of this work is available.[478] Methyl scrambling occurs between similar $[Co(Me)_2(PPh_3)(Cp)]$ units in THF at 60 °C and PPh_3 dissociation from one appears to be a prerequisite.[471] In another study this dissociation (Scheme 47) was shown to occur with $k = 4 \times 10^{-4}\,s^{-1}$ in toluene at 30 °C with the $[Co(Me)_2(Cp)]$ product reacting rapidly with PMe and CO. The latter product (**123**) gives rise to acetone without scrambling (intramolecular) in 0.05 M solution (some scrambling occurs at higher concentration).[472] Reactions with PhCCPh (dimerization, methyl migration; equation 99) and with C_2H_4 (equation 100) have also been investigated by Bergman in some depth extending earlier work by others and having some bearing on the chain-growth step in Ziegler–Natta polymerization.[472,473] The authors have also shown that the similarly substituted Co^{III} dialkyl complex (**124**) undergoes cyclopentadienyl exchange with the Co^{I} complex (**125**) in THF.[474] Equilibrium was reached (67%, **126**; 33%, **124**) within 48 h at 62 °C (equation 101). These Co^{I} bis(phosphine) complexes readily undergo phosphine exchange *via* dissociation to the unsaturated intermediate (**127**; equation 102).[475] For the PPh_3 complex $k = 1.15 \times 10^{-3}\,s^{-1}$ at −60 °C and the intermediate prefers PMe_3 to PPh_3 by a factor of about four over PPh_3.

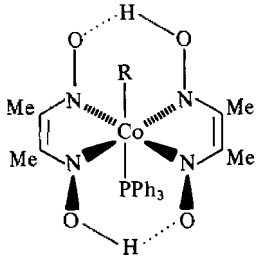
$$[Co(Me)_2(PPh_3)Cp] + CH_2{=}CH_2 \longrightarrow [Co(C_2H_4)(PPh_3)Cp] + CH_4 + MeCH{=}CH_2 \quad (100)$$

(101)

(124) (125) (126)



(102)

(127)

Shibata and coworkers[463,464] have used $[Co(acac)_3]$, $K[Co(CN)_2(acac)_2]$ and $K_3[Co(CN)_5I]$ to prepare a wide range of the more classical Co^{III} complexes: *cis*- and *trans*-$[Co(acac)_2(PR_3)_2]^+$, $[Co(CN)_2(acac)(PR_3)_2]$, and *trans*-$[Co(CN)_4(PR_3)_2]^-$ (R = alkyl, aryl; Table 36). They report ^1H, ^{31}P and visible–UV spectra and some simple reactions. *trans*-$[Co(acac)_2(PMe_2Ph)_2]^+$ aquates to blue-green *trans*-$[Co(acac)_2(PMe_2Ph)(H_2O)]^+$ in aqueous ethanol, and in the presence of charcoal it isomerizes to an equilibrium mixture containing mostly the *cis* isomer.

A number of vitamin B_{12} analogues containing dimethylglyoxime (**128**) have been prepared,[465] and ^1H and ^{13}C NMR spectra of $[Co(DMGH)_2(PR_3)R']^{0,+}$ (R′ = Cl^-, NO_3^-, CN^-, CH_2R^-, Ph^-, Me^-, $PO(OR)_2$, MeOH) have been correlated with the size and electronic properties of the phosphine. ^{13}C shifts are accounted for largely by through-bonding effects and ^1H shifts by spatial effects. The latter increase in the order oxygen donors < halides ≈ CN^- ≈ SR^- ≈ PR_3 < alkyl, aryl.[466] Dissociation of R′ occurs readily, and an equilibrium is often established in poor donor solvents. Randaccio and Bresciani-Pahor, and Marzilli and coworkers have carried out a series of structural characterizations in an attempt to correlate the structural *trans* effect of the phosphine ligand on the Co—C bond (Table 35).

(128) R = Me, Et, Ph

47.5.2.5 Bidentate phosphines

(*i*) *Cobalt(−I) and cobalt(0)*

A few low-valent complexes containing bidentate phosphines are known. Paramagnetic $[Co(dppe)_2]$ can be made by reducing $[Co(Br)_2(dppe)_2]$ with Na (Table 37); it is an excellent reducing agent, reducing Sn^{2+} to the metal and H_2 to $[CoH(dppe)_2]$.[479] Some exotic systems with poor σ donors such as (**129**; Scheme 48) are known. King and coworkers have shown that the $[Co_2\{MeN(PF_2)_2\}_3]$ structural unit containing a Co—Co bond (271–277 pm) is very stable. Stepwise substitution of terminal CO groups by other neutral Lewis bases[497] and by halogens[496] is possible (Scheme 48) as well as reduction to the radical anion and dianion.[498] Structures are known for several of these complexes (Table 38). Similar treatment of $[Co_2(CO)_8]$ with $MeN\{P(OMe)_2\}_2$ forms (**130**).[499]

Table 37 Preparations: Bidentate Phosphine Complexes

Complex	*Preparation*	*Properties*[a]	*Ref.*
Cobalt(0)			
$[Co(dppe)_2]$	$[CoBr_2(dppe)_2]$ + Na; benzene	Dark red; dipole moment 1.2	11
Cobalt(I)

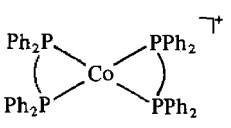
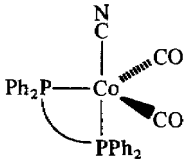
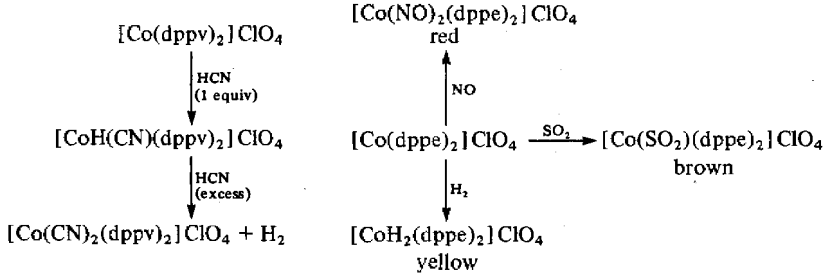


Scheme 48

(ii) Cobalt(I)



The dark $[Co(P—P)_2]ClO_4$ complexes (Table 37) (P—P = dppe, dppv) are diamagnetic and this, with their electronic spectra, suggests the uncommon planar structure (**131**) (planar structures are known for the analogous Rh and Ir complexes).[480] Being coordinatively unsaturated they readily add basic ligands and undergo oxidative addition (Scheme 49). Thus $[Co(dppv)_2](ClO_4)$ rapidly adds O_2 and H_2 (Section 47.5.2.5.ii; equation 106), NO, SO_2, and HCN to form octahedral Co^{III} systems.



(130)

(131)

(132)

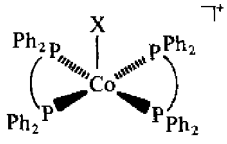
Scheme 49

Low-spin five-coordinate $[CoX(P—P)_2]$ ($X = Br^-$, CN^-; Table 37) probably have a square-pyramidal (C_{3v}) structure. For $X = Br^-$ the complex appears to be extensively dissociated into (**131**) in solution. These complexes readily undergo substitution and oxidative addition (equations 103 and 104).[481,482] The preparation of five-coordinate $[CoR(P—P)_2]$ species (R = alkyl, aryl) has not been reported, but $[Co(PMe_3)(dmpm)_2]Cl$ has been made and its disproportionation studied (equation 105).[483]

$$[CoBr(dppe)_2] + L \longrightarrow [Co(CO)(dppe)_2]Br \quad (103)$$

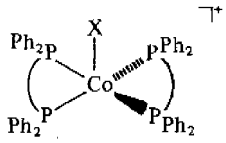
L = CO, PhCOCl; yellow

$$[CoH(CN)(dppv)_2]ClO_4 \xleftarrow{H_2} [Co(CN)(dppv)_2] \xrightarrow{CO} [Co(CO)_2(dppv)_2]ClO_4 \quad (104)$$



(**132**)

$$[Co(PMe_3)(dmpm)_2]Cl \xrightarrow{THF} [CoCl_2(PMe_3)(dmpm)] + [Co(PMe_3)(dmpm)_2]_2PMe_2 \quad (105)$$

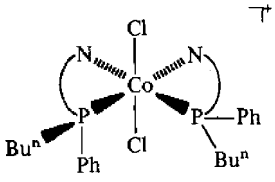


orange

(*iii*) *Cobalt(II)*

High-spin ($\mu = 4.4$ BM) $[Co(X)_2(P—P)]$ and low-spin five-coordinate ($\mu = 1.9$–2.3 BM) $[CoX(P—P)_2]^+$ are easily prepared (Table 37). The detailed structure of the former is uncertain but it appears to be pseudo tetrahedral, and does not contain CoX_4^{2-}.[484] $[CoX(P—P)_2]^+$ species are more robust and their magnetic moment indicates some orbital mixing. ESR studies show that $[CoX(P—P)_2]^+$ species with P—P = dppm, dppv have a different electronic ground state than those with P—P = dppe.[485] $[CoX(dppe)_2]^+$ adopts both square-pyramidal (**133**) and trigonal-bipyramidal (**134**) structures in the solid state, and an equilibrium between them (mostly **134**) is quickly established in solution; major spectral differences occur only at *ca.* 660 nm.[486] $[Co(NCS)_2(diphos)]$ ($\mu = 2.5$ BM) is reported to contain terminal isothiocyanate ligands and may be planar,[487] and $[Co(Cl)_2(diphos)_2]$ ($\mu = 1.97$ BM) is octahedral.[488] With $[Co(CN)_2(dppe)_2]$ (Table 37) it is proposed that both cyanides are coordinated with one dppe remaining monodentate, while with dppp and dppb dimeric $[Co(P—P)_{1.5}(CN)_2]_2$ units with bridging phosphine chelates have been suggested.[45] Considerable electronic and structural variation apparently exists in the paramagnetic ions with chelate ring flexibility probably making a significant contribution to the ground-state geometry.

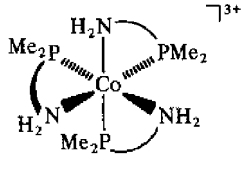
(**133**) red



(**134**) green

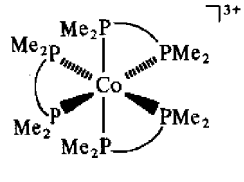
$[Co(P—P)_2]^{2+}$ (P—P = dppe, dppv, diphos) has been prepared (Table 37) and although no structure has been reported, a planar geometry with a $^2A_1$ electronic ground state (unpaired electron in d_{z^2} orbital) is inferred from ESR studies.[489,490] Substitution into $[CoCl(dppe)_2]^+$ by the chelating ligands L = bipy, phen, 2,9-Me_2phen follows the rate law $k = k_1k_3[L]/(k_2 + k_3[L])$, which implies a dissociative process with a limiting rate for ring opening of $k_1 = 62.5\,s^{-1}$, 25 °C.[491] $[Co(dppv)_2](ClO_4)$ readily adds two equivalents of CN^- to form $[Co(CN)_2(dppv)_2]$, and $[Co(CN)_2(dppe)_2]$ is oxidized by half an equivalent of O_2 to diamagnetic $[Co(CN)_2(dppe)]ClO_4$. The latter complex induces unusual oxidation processes (Section 47.5.2.5.iv; Scheme 50).

(*iv*) *Cobalt(III)*



A large number of bidentate chelates of the type *trans*-$[CoX_2(P—P,N—P)_2]^+$ have been prepared by halogenation or air oxidation of $CoCl_2 \cdot 6H_2O$ in the presence of the phosphine, or by halogenation of a five-coordinate Co^{II} complex, *e.g.* $[CoCl(dppv)_2]^+$ (Table 37). *Cis* coordination must occur in $[Co(CO_3)(P—P)_2]^+$, but addition of acid results in isolation of only the *trans* diaqua product. The synthesis of *trans*-$[Co(Cl)_2(dppe)_2]^+$ by routine methods has not been successful but many *trans*-$[Co(Cl)_2(N—P)_2]^+$ systems have been prepared and the importance of steric crowding about the P atom is clearly shown by several crystal structures such as (**135**; Table 38).[492] The PCoP angle in (**135**) is extended (99°, 103°) and the NCoN angle reduced (85°, 88°) even allowing for the longer CoP

bond (225 pm) compared to CoN (202 pm). It is interesting that in structures (**135**), (**136**) and (**137**) (Table 38) the donor P atoms are mutually *cis*. Apparently the structural *trans* effect of P (Δ_r = 5–7 pm) results in a *trans* labilizing effect with the stronger bonding N donor being preferred in the *trans* position. This influence must outweigh the increased steric requirements that result. Steric problems are minimized using dmpe, and the tris complex $[Co(dmpe)_3]Br_3$ (**137**) has been prepared;[493] it is not very stable, is insoluble in water and has not been produced in optically active forms. It appears to be the only $[Co(P—P)_3]^{3+}$ chelate known.

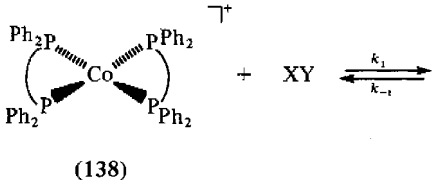


(135)

trans-$[CoCl_2\{(S)\text{-abppe}\}_2]^+$

(136)

Δ-*fac*-$[Co(adme)_3]^{3+}$

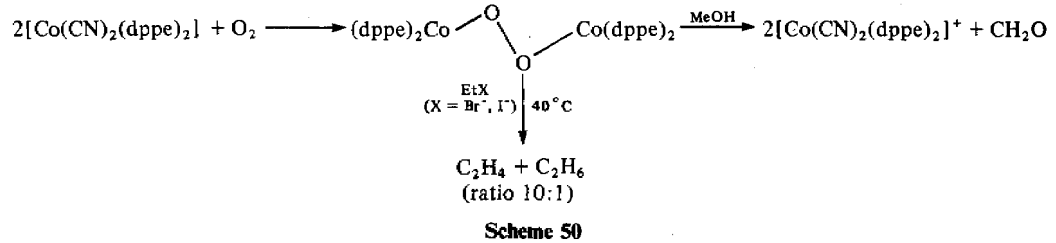


(137)

Δ, Λ-$[Co(dmpe)_3]^{3+}$

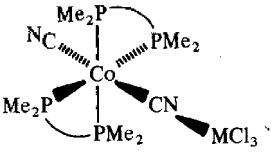
A variety of mixed (P—P), (N—P) chelates containing acac$^-$, CO_3^{2-}, $C_2O_4^{2-}$ and 2,3,2-tet have been prepared (Table 37); some have been resolved into optical enantiomers by conventional or chromatographic means (Table 37), and ^1H, ^{31}P, CD and electronic spectra have been reported. Metathesis of *trans*-$[Co(Cl)_2(P—P)_2](ClO_4)$ with NaX in methanol leads to other *trans*-$[Co(X)_2(P—P)_2]^+$ complexes (X = N_3^-, NCO^-, NCS^-, CN^-); however NO_2^- addition to *trans*-$[Co(Cl)_2(dppv)_2](ClO_4)$ results in the isolation of the unsaturated 14-electron complex $[Co(NO)_2(dppv)]$ and oxidized ligand.[423]

Complexes containing $R_2P(CH_2)_nPR_2$ (R = Ph, aryl) are unstable and have not been isolated, but diamagnetic $[Co(Cl)_2(diphos)_2](ClO_4)$ has (ε_{560}, 78).[488] Yellow *trans*-$[Co(CN)_2(P—P)_2](ClO_4)$ systems are easily formed *via* oxidation of $[Co(CN)_2(P—P)_2]$ or by addition of excess HCN to $[Co(P—P)_2](ClO_4)$. Oxidative addition of O_2, H_2 and HCN (1 equiv) to $[Co(dppv)_2](BF_4)$ (**138**) results in diamagnetic $[Co(Y_2)(dppv)_2](BF_4)$ (**139**; equation 106),[481,494] and for $Y_2 = O_2$ the side-on bonding mode of the peroxide moiety has been verified (Table 38).[495] Oxidative addition appears to occur only with planar diamagnetic d^8 systems; $[CoCl(PPh_3)_3]$, $[Co(dppe)_2]^+$ (both tetrahedral) and five-coordinate $[Co(CN)(dppv)_2]$ either do not react or slowly decompose to give the oxidized ligand (with O_2).



(106)

(138)

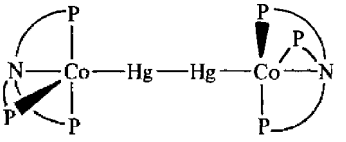


(139)

XY	k_1 ($mol^{-1}\ dm^3\ s^{-1}$)	*K*
O_2	1.7×10^4	$>10^9$
H_2	1.2×10^5	$>10^{10}$

Oxygenation of $[Co(CN)_2(dppe)_2]$ in MeOH or CH_2Cl_2 as solvent, or oxygenation in the presence of EtI, produces CH_2O, CO_2 and C_2H_4 respectively (Scheme 50). An unusually reactive peroxo Co^{III} dimer has been suggested as the important intermediate.[46] Also the cyano ligand has been shown to act as a bridging ligand to other divalent metals,[47] *e.g.* (**140**).

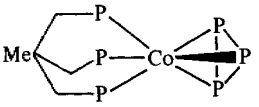
Scheme 50



(140) M^{II} = Co, Mn, Fe, Ni, Zn

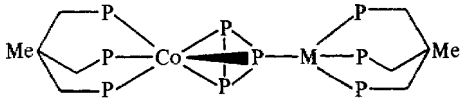
47.5.2.6 Tri- and multi-dentate phosphines

(i) Cobalt(−1) and cobalt(0)



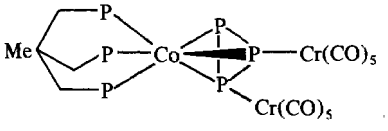
Reduction of $[CoCl(L)](BPh_4)$ (L = N(dppe)$_3$, P(dppe)$_3$) with Na/Hg in THF results in red-brown dimeric $[Co(L)]_2(Hg_2)$ species (**141**) in which Hg_2^{2+} is linearly coordinated between two Co^{-1} centres.[500] These unstable diamagnetic trigonal-bipyramidal complexes (structure, Table 40) react with CO and CO_2 at ambient temperatures in an apparent redox process (equation 107).[500]

(141)



$$[Co(CO)\{N(dppe)_3\}]^+ + Hg \xleftarrow{CO} [Co\{N(dppe)_3\}]_2\text{-}\mu(Hg)_2 \xrightarrow{CO_2} [Co(CO)\{N(dppe)_3\}]^+ + Hg + CO_3^{2-} \quad (107)$$

Sacconi and coworkers[501,502] have prepared some interesting *cyclo*-P_3 ligand systems of the type $[Co(P_3)L]$ containing formally d^9 Co^0 by reacting $Co(BF_4)_2 \cdot 6H_2O$ with $MeC(CH_2PPh_2)_3$ or $N(CH_2CH_2PPh_2)_3$ in alcoholic THF (Table 39). The diamagnetic orange-yellow $[Co(P_3)\{MeC(dppm)_3\}]$ and red $[Co(P_3)\{N(dppe)_3\}]$ are stable as solids with the former being soluble and stable in THF, CH_2Cl_2 and nitroethane. Their structures (Table 40) show a staggered arrangement of the two tridentate P_3 chelates but with the Co atom lying closer to the phosphine-P_3 plane (**142**). The similar $[Co(P_2S)\{MeC(dppm)_3\}](BF_4)$ complex has recently been prepared from P_4S_3 and its structure (Table 40) closely resembles the others.[503]



(142)

$[Co(P_3)\{MeC(dppm)_3\}]$ retains considerable basic character and is capable of donating electron pairs to other $[M\{MeC(dppm)_3\}]^{2+}$ units (**143**), $[M\{MeC(depm)_3\}]^{2+}$, or to one or more $Cr(CO)_5$ units, *e.g.* (**144**).[356,504,505] In all these complexes the *cyclo*-P_3 unit can be viewed as being linked to Co^0 *via* three localized electron-pair σ bonds; an MO framework involving all the sandwiched atoms is however likely.

(143) M = Ni, Co

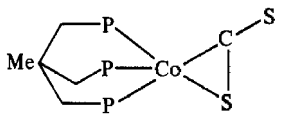
Table 40 Structures: Di- and Multi-dentate Phosphine Complexes



Complex	*Ligand*	*Structure*[a]	*Ref.*
Cobalt(−I)			
$[Co_2L_2Hg_2]$	$N(CH_2CH_2PPh_2)_3$	Trig. bipyr.; CoHg 243; HgHg 265; CoN 210; HgCoN 179.9°; dimeric with Hg_2^{2+} bridge	18
Cobalt(0)			
$[CoL(P_3)]$	$MeC(CH_2CH_2PPh_2)_3$	Dist. oct.; CoP 219; CoP_3 230	20
$[CoL(P_3)]$	$N(CH_2PPh_2)_3$	Dist. oct.; CoP 224–226; CoP_3 231–232	21
$[CoL(P_3)NiL](BPh_4)_2 \cdot$ acetone	$MeC(CH_2PPh_2)_3$	Dist. oct.; CoP 222–224; CoP_3 230	22
$[CoL(CS_2)]$	$MeC(CH_2PPh_2)_3$	Five-coordinate (π-CS_2); CoP 222–225; CoC 188; CoS 221; CSS 133.8°	23
$[CoL(P_3)[Fe\{MeC(depm)_3\}]]PF_6 \cdot CH_2Cl_2$	$MeC(CH_2PPh_2)_3$	Dist. oct.; CoP 220–222; CoP_3 227–230	24
Cobalt(I)			
[CoHL]	$P(o\text{-}C_6H_4PPh_2)_3$	Trig. bipyr., CoP(ax) 209; CoP 213; CoH 143	26
$[CoL]BF_4$	$N(CH_2CH_2PPh_2)_3$	Trig. pyr., CoP 225–227; CON 220.7; axial site vacant	1
$[CoL(P_2S)]BF_4$	$MeC(CH_2CH_2PPh_2)_3$	Dist. oct.; CoP 221; CoP_2S 227	17
Cobalt(II)			
$[CoL(CO)Br]BPh_4$	$MeC(CH_2CH_2PPh_2)_3$	Dist. sq. pyr.; CoBr 237; CoC 179; CoP 224–229	15
$[Co_3L_2Cl_6]$	$MeC(CH_2PPh_2)(CH_2CH_2PPh_2)$	Dist. tet. (trimer); CoCl 220, 223; CoP 235–239	25
$[Co_2L_2(OH)_2](BPh_4)_2 \cdot$ acetone	$MeC(CH_2PPh_2)_3$	Trig. bipyr., dimeric (OH bridges); CoP 224–229; CoX 191–199, CoCO 306	2
$[CoL(OAc)](BPh_4) \cdot$ acetone	$MeC(CH_2PPh_2)_3$	Sq. pyr.; CoP 221–228; CoX 200, 203	2
$[CoLBr]PF_6$	$[Ph_2P(CH_2)_2N(Me)(CH_2)]_2$	Sq. pyr.; CoP 222; CoBr(ax) 254; CoN 203	3
$[CoLCl]PF_6$	$[Ph_2P(CH_2)_2]_2N(CH_2)_2OMe$	Dist. trig. bipyr.; CoN 242; CoO 203; CoP 241–244; CoCl 225 [NCS complex sq. pyr. (low spin)]	4
$[CoLCl]PF_6$	$N(CH_2CH_2PPh_2)_3$	Tet. trig. bipyr.; high spin; CoN 268 (partial bonding)	5
$[CoLBr]PF_6 \cdot EtOH$	$N(CH_2CH_2PPh_2)_3$	Dist. trig. bipyr.; CoP 226–240; CoBr 236; high spin	6
[CoLI]I	$N(CH_2CH_2PPh_2)_3$	Dist. sq. pyr. (ap. P); CoP 223–228; CoI 258; CoN 212; low spin	19
$[CoLI]BPh_4$	$N(CH_2CH_2PPh_2)_3$	Dist. trig. bipyr.; CoP 235–237; CoI 247; CoN 272; high spin	6
$[CoLBr]PF_6$	$P(CH_2CH_2PPh_2)_3$	Dist. sq. pyr. (ap. P); CoP 216–229; CoBr 238; low spin	7
$[CoLCl]BPh_4$	$P(o\text{-}C_6H_4PPh_2)_3$	Dist. sq. pyr.; CoP 206 (ap), 226–232; CoCl 231	8
$[CoL(OH)]BF_4 \cdot EtOH$	$P(CH_2CH_2PPh_2)_3$	Dist. sq. pyr. (ap. P); CoP 213–229; CoO 187	9
$[CoL(H_2O)](BF_4)_2 \cdot$ acetone	$P(CH_2CH_2PPh_2)_3$	Dist. sq. pyr. (ap. P); CoP 215-231; CoO 210	9
[CoLI]I	$(Ph_2PCH_2CH_2)_2NCH_2CH_2NEt_2$	Dist. trig. bipyr.; CoP 242, 245; CoI 265; CoN 244, 218	10

$[CoL(NCS)_2]$	$Ph_2PCH_2CH_2NHCH_2CH_2NEt_2$	Dist. trig. bipyr.; CoP 232; CoN 210, 207; CoN(CS) 204, 192	11
$[CoL(NCS)_2]$	$Ph_2PCH_2CH_2N(Me)CH_2CH_2NEt_2$	Dist. trig. bipyr.; CoP 240; CoN 236, 214; CoN(CS) 214	11
$[CoL(NCS)_2]$	$Ph_2P(CH_2)_2NH(CH_2)_2NEt_2$	Low temp. form: dist. sq. pyr. (120 K); high temp. form: dist. trig. bipyr. (298 K)	12
$[CoLCl]BF_4 \cdot 0.8H_2O$	$NH_2(CH_2)_3P(Ph)(CH_2)_3P(Ph)(CH_2)_3NH_2$ (*meso*)	Sq. pyr. (Cl axial); CoN 204–2-5; CoP 219–218; CoCl 243; PCoP 89.5°; PCoN 92.7°; NCoN 86.4°	13
$[Co_3L_4](BF_4)_6$	$N(CH_2CH_2PMe_2)_3$	Trig. bipyr.; CoN 205; CoP 225–226; NCoP 177.3°; trimeric	14
$[CoL](BPh_4)_2$		Three structures known	16

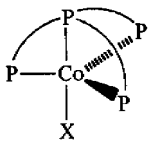
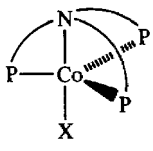
Likewise an air-stable CS_2 adduct $[Co(CS_2)\{MeC(dppm)_3\}]$ can be prepared from $Co_2(CO)_8$ (Table 39). The Co atom is coordinated to the three P atoms and one π linkage to CS_2 (**145**).[505] This 17-electron system is capable of adding other electrophilic species such as $[Co\{MeC(dppm)_3\}]^{2+}$, $Cr(CO)_5$, $Mn(Cp)(CO)_2$, and structures on the former two are available, *e.g.* (**146**).[5]

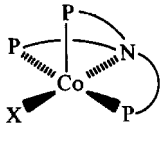


(145)

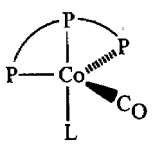


(146)

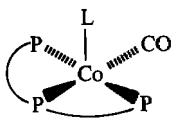
(ii) Cobalt(I)



Several complexes with tripod ligands of the type $RC(P_3)$, $N(P_3)$ and $P(P_3)$ have been prepared (Table 39). With $RC(P_3)$ high-spin tetrahedral [Co(L)X] are formed; these are air sensitive and not very stable. With $P(P_3)$ the five-coordinate [Co(L)X] systems are trigonal bipyramidal (**147**) and low spin for all X (halides, NCS^-, CN^-, H^-, CO), but for $N(P_3)$ high-spin (μ = 3.2–3.3 BM) complexes occur with the more electronegative ligands ($X = Cl^-$, Br^-, I^-, NCS^-) and low-spin trigonal-bipyramidal structures for more nucleophilic X (CN^-, H^-, CO). Structures for high-spin $[Co\{N(P_3)\}X]$ are not available but it is likely that the symmetry is lifted from C_{3v} (**148**) towards C_{2v} (**149**). For the electronically identical d^8 Ni^{II} complexes (**148**) is found for all X in $[Ni\{N(P_3)\}X]^+$ but a cross-over to high-spin (**149**) occurs at about $[Ni(N_2P_2)X]^+$; for the lower-charged Co^I systems this cross-over apparently requires a higher ligand field. Sacconi has related the electronegativity and nucleophilic ability of ligands to spin-pairing energy and structure for d^7 and d^8 systems in an important publication.[506] Du Bois and Meek[522] have investigated the stereochemical properties of $[Co\{PhP(dppe)_2\}(CO)L]^+$, $[Co\{PhP(dppp)_2\}(CO)L]^+$ and $[Co\{MeC(dppm)_3\}(CO)L]^\bullet$ (L = CO, $P(OMe)_3$, PPh_2H, PPh_2Me, PEt_3, PPh_3) by ^{31}P NMR spectroscopy. $[Co\{PhP(dppe)_2\}(CO)L]^+$ has the rigid structure (**150**), whereas $[Co\{PhP(dppp)_2\}(CO)L]^+$ with the large chelate bite adopts the rigid structure (**151**) with L in the apical position (L = CO adopts structure **150**). $[Co\{MeC(dppm)_3\}(CO)L]^+$ on the other hand is fluxional at room temperature with rapid intramolecular switching of L and CO in the trigonal-bipyramidal structure (**150**); only $[Co\{MeC(dppm)_3\}(CO)\{P(OMe)_3\}]^+$ gives a limiting spectrum at $-100\,^\circ C$. Monodentate phosphine exchange with the free ligand is fast with $[Co\{PhP(dppp)_2\}(CO)(PPh_2H)]^+$, $[Co\{PhP(dppe)_2\}(CO)(PPh_3)]^+$ and $[Co\{MeC(dppm)_3\}(CO)(L)]^+$ ($L \neq P(OMe)_3$) *via* a dissociative process.

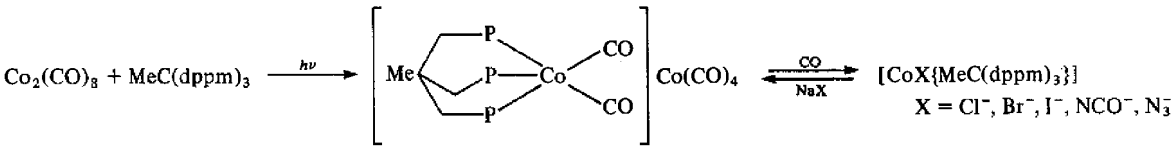


(147)



(148)

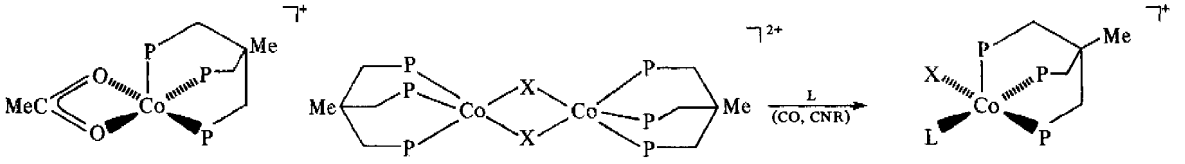
(149)



(150)

(151)

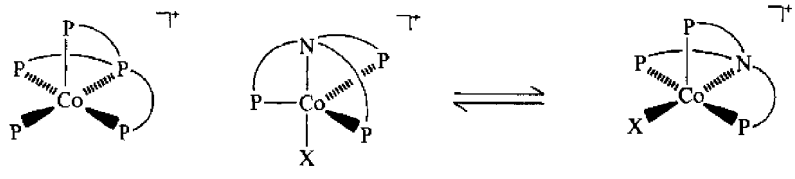
The above five-coordinate complexes can best be made *via* the hydride (equation 108), while treatment of $[Co\{MeC(dppm)_3\}(CO)_2][Co(CO)_4]$ with NaX leads to paramagnetic ($\mu \sim 3$ BM) tetrahedral $[Co(X)\{MeC(dppm)_3\}]$ (Scheme 51) whose reactions with CO, O_2 and phenanthroline have been reported.[507] Similar treatment of $[Co\{N(dppe)_3\}](BF_4)$, whose trigonal-bipyramidal structure has a vacant coordination site (see Table 40) with CO gives $[Co(CO)\{N(dppe)_3\}](BF_4)$.[508]



$$[CoH(CO)\{MeC(dppm)_3\}] + NH_4BF_4 + L \longrightarrow [CoL(CO)\{MeC(dppm)_3\}](BF_4) + H_2 + NH_3 \quad (108)$$

Scheme 51

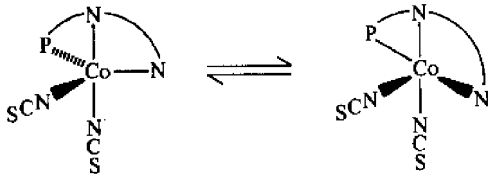
(*iii*) *Cobalt(II)*



Branched P_3 donor ligands such as $MeC(dppm)_3$, $MeP(dppe)_2$, $PhP(dppe)_2$ and $PhP(dppp)_2$ form distorted square-pyramidal low-spin monomeric $[Co(X)_2(L)]$ ($X = Cl^-$, Br^-) or $[CoX(L)]^+$ ($X = NO_3^-$, AcO^-, $acac^-$) complexes, *e.g.* (**152**), or dimeric trigonal-bipyramidal systems $[CoX(L)]_2^{2+}$ (**153**) in which the low magnetic moment is believed to result from exchange coupling *via* the X bridges.[509] Table 39 gives some representative preparations. Monomeric $[Co(X)_2(L)]$ is sensitive towards O_2 and is inclined to dissociate to tetrahedral species in solution, whereas the dimeric systems are more stable.

(152) (153)

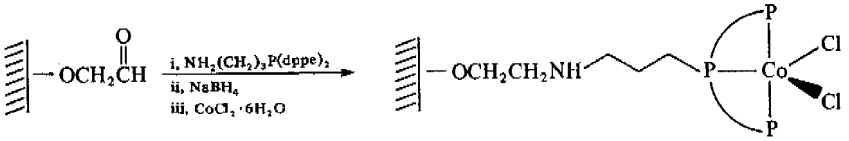
The stronger ligand field provided by P_4 donors results in low-spin ($\mu \approx 2.0$ BM) distorted trigonal-bipyramidal $[CoX(L)]^+$ systems for both linear and tripod donors with a decided square-pyramidal tendency, *e.g.* $[CoBr\{P(dppe)_3\}](PF_6)$ and $[CoCl\{P(dppC_6H_4)_3\}](BPh_4)$ (**154**). This switch from trigonal-bipyramidal (D_{3h}) to square-pyramidal (C_{4v}) geometry is expected for the d^7 configuration on increasing the ligand field. Venanzi and coworkers,[510] and Higginson, McAuliffe and Venanzi[511] have correlated such ligand-field effects with spectral and magnetic properties, and discuss the structural consequences in terms of static Jahn–Teller distortions. This distortion of C_{3v} microsymmetry is also expected on removing one electron from a diamagnetic d^8 Co^I complex and can be seen in the structures of $[CoH\{P(dppC_6H_4)_3\}]$ (trigonal bipyramidal) and $[CoCl\{P(dppC_6H_4)_3\}]BPh_4$ (square pyramidal).



The intermediate-strength $N(dppe)_3$ ligand forms high-spin trigonal-bipyramidal $[CoX\{N(dppe)_3\}]^+$ (**155**) with $X = Cl^-$, Br^-, OH^-, H_2O, but low-spin distorted square-pyramidal structures (**156**) with the harder ligands NCS^-, I^-, and CN^-. An interesting situation exists with $[CoI\{N(dppe)_3\}]Y$, which is high spin with a distorted trigonal-bipyramidal structure for $Y = BPh_4^-$ in the solid state, but low spin with a distorted square-pyramidal structure for $Y = I^-$ (Table 40). This spin-state change is also seen in nitroethane solution for $Y = I^-$, where the visible spectrum shows a preference for the trigonal-bipyramidal structure at higher temperatures,[512] and for solid $[CoX\{N(dppe)_3\}](BPh_4)$ ($X = Cl^-$, Br^-), where increasing the pressure to 35 kbar gives spectra characteristic of low-spin square-pyramidal (**156**).[513] Di Vaira discusses these changes in MO terms,[514] but lattice forces must decide the issue at cross-over points which can be approached gradually from either side. With the more bulky $N\{CH_2CH_2P(Cy)_2\}_3$ ligand high-spin trigonal-bipyramidal $[CoX\{N(dCype)_3\}]Y$ species exist for $X = Cl^-$, Br^-, I^-, NCS^- in the solid state but when $Y = X = Cl^-$ partial ligand dissociation to form tetrahedral $[Co(Cl)_2P_2]$ occurs in nitroethane.[515] With more basic $N(CH_2CH_2PMe_2)_3$ trimeric $[\{CoN(dmpe)_3\}_3N(dmpe)_3](BF_4)_6$ has been isolated. This contains three trigonal-bipyramidal $CoN(dmpe)_3^{3+}$ units coordinated in axial positions to the P atoms of an additional $N(CH_2CH_2PMe_2)_3$ ligand.[516]

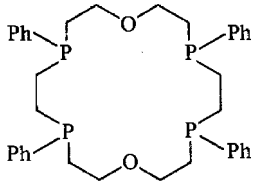
(154) (155) (156)

As further P donors are replaced by N the decreasing ligand field of the chelate favours high-spin trigonal-bipyramidal structures (Table 40). However steric consideration also play a part. Thus with the linear PNNP and NPPN ligands $Ph_2PCH_2CH_2N(Me)CH_2CH_2N(Me)CH_2CH_2PPh_2$ and *meso*-$H_2N(CH_2)_3P(Ph)(CH_2)_3P(Ph)(CH_2)_3NH_2$, low-spin square-pyramidal $[CoX(L)]Y$ ($Y = PF_6^-$, BF_4^-) are still favoured, but with the branched ligands $(Ph_2PCH_2CH_2)_2NCH_2CH_2NEt_2$ and $(Ph_2PCH_2CH_2)_2NCH_2CH_2OMe$ high-spin trigonal-bipyramidal $[CoX(L)]^+$ ions result (Table 40). The linear PNN tridentates $Ph_2PCH_2CH_2N(R)CH_2CH_2NEt_2$ (R = H, Me) form trigonal-bipyramidal $[Co(X)_2(L)]$ complexes in the solid state with some dissociation to tetrahedral species in



solution depending on R.[517] For X = NCS^-, R = H, an interesting temperature-dependent high–low spin equilibrium exists, which is accompanied by spectral (visible, IR) changes consistent with the structural forms (**157**) and (**158**) (equation 109). Structural studies at 120 K and at room temperature confirm this proposal.[518,519] Furthermore, the low-temperature form (**158**) appears to react with O_2 more rapidly than (**157**) with the ultimate formation of $[Co(NCS)_3L]$ containing Co^{III} and $[Co(NCS)_2(LO)]$ containing the oxidized ligand.[517] This agrees with the known reactivity of square-planar and square-pyramidal Co^{II} systems.

(109)

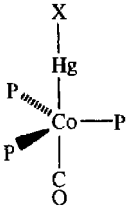


(**157**) μ = 4.32 BM, 418 K (**158**) μ = 2.16 BM, 79 K.

Uriarte and Meek have attached NPP and $NP(P_2)$ ligands to derivatized glass beads (equation 110),[520] and such hybrid polymer-supported catalysts offer advantages over homogeneous systems.

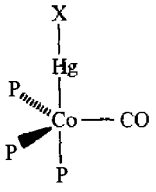
(110)

Co^{II} complexes of all five diastereoisomers of the phosphorus-containing crown ether (**159**) have been isolated[521] and crystal structures are available on three of them (*RS,RS,RS,RS,*(δ); *RSRS,SR,*(α); *RS,RS,SR,SR,*(β); Table 40). No enantiomeric systems have been separated. All five complexes are low spin (μ = 2.0–2.5 BM), consistent with planar coordination of the four P donors, but the ligand geometry determines how many oxygen atoms are coordinated. $[CoL_\beta](BPh_4)_2$ and $[CoL_\delta](BPh_4)_2$ are essentially octahedral with both O atoms coordinated in a *trans* arrangement, while $[CoL_\alpha](BPh_4)_2$ is square pyramidal with only one O bound. The $[CoL_\varepsilon]^{2+}$ ion containing the (*RS,SR,RS,SR*) diastereoisomer is also expected to be square pyramidal on spectral grounds, while L_γ = (*RS,SR,SR,RS*) gives $[CoCl(L_\gamma)]^+$ in which the fifth coordination site is occupied by Cl^-.[521] This is consistent with the chemistry of (N,P) and (all-N) macrocycles where the ligand geometry is largely responsible for determining the coordination stereochemistry.



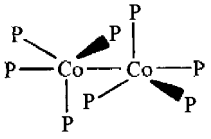
(**159**)

47.5.2.7 Phosphites, phosphonites and phosphinites



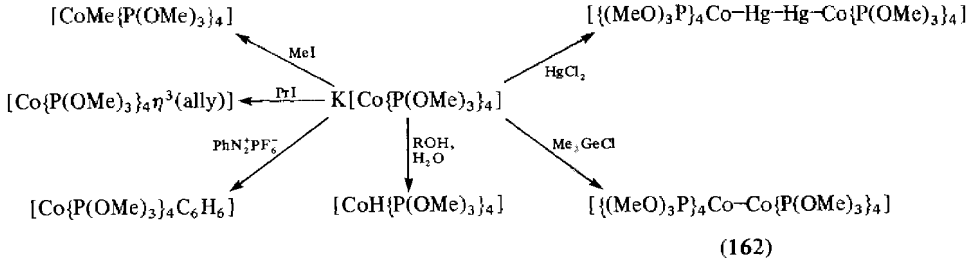
Hydride and dinitrogen complexes containing these ligands are considered in Sections 47.5.2.1 and 47.5.2.2. The electronegative OR substituent reduces σ-donor strength but increases electron delocalization from the metal, stabilizing low oxidation states. The cone angle for $P(OR)_3$ is smaller than for PR_3 (Table 30) but it may still be restrictive in the preparation of $[Co\{P(OR)_3\}_5]^+$ species with bulky R.[526] Weiss and Verkade have correlated ^{59}Co NMR shifts for a series of $[Co\{P(OR)_3\}_3\}_6]^{3+}$ complexes in terms of increasing ligand field with decreasing σ basicity or increasing phosphorus π acidity.[536]

(i) Cobalt(−1)



The $[Co\{P(OR)_3\}_4]^-$ ions have been produced by reaction of $[CoH\{P(OR)_3\}_4]$ with KH, by Na/Hg reduction of $CoCl_2$ in the presence of $P(OR)_3$, or electrochemically (Table 41). Rakowski and Muetterties have reported a very soluble $Na[Co\{P(OPr^i)_3\}_5]$ species which has two different ^1H resonances for $P(OPr^i)_3$ in the ratio of 4:1 and which does not rapidly exchange coordinated and free ligand.[406] A number of yellow-orange monomeric $[Co\{P(OPh)_3\}_4(HgX)]$ and $[Co\{P(OPh)_3\}_x(CO)_{4-x}(HgX)]$ species have been prepared from $[CoH\{P(OPh)_{3,4}\}(CO)_{1,0}]$ and HgX_2 with the latter having properties consistent with both axial (**160**) and equatorial (**161**) CO isomers.[535]

(160)



(161)

(162)

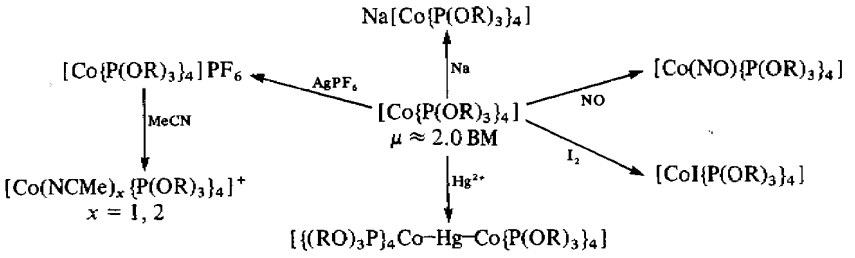
The chemistry of the d^{10}, presumably tetrahedral, $[Co\{P(OMe)_3\}_4]^-$ ion demonstrates some typical reactions with the products (Scheme 52) being in general more robust than their PR_3 analogues.[382]

(162)

Scheme 52

(ii) Cobalt(0)

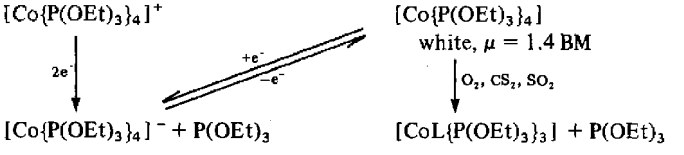
Several paramagnetic $[Co\{P(OR)_3\}_4]$ complexes (R = Me, Et, Pr^i, Ph) have been prepared by the controlled reduction of $CoCl_2$ in the presence of excess $P(OR)_3$,[406] or by controlled electrochemical oxidation of $[Co\{P(OEt)_3\}_4]^-$ [527] or reduction of Co^{II} in the presence of excess $P(OR)_3$ (Table 41).[532,533] There appears to be some uncertainty in colour with Rakowski and Muetterties reporting orange-red $[Co\{P(OPr^i)_3\}_4]$ and Zecchin and coworkers white or pale yellow $[Co\{P(OR)_3\}_4]$ (R = Et, Pr^i, Ph). They are very sensitive to traces of moisture and O_2 and readily undergo ligand displacement in a good donor solvent such as acetonitrile (Scheme 53).[532] Dimeric $[Co_2\{P(OR)_3\}_8]$ (R = Me, Et, Pr^i) has been prepared by treating $K[Co\{P(OR)_3\}_4]$ with Me_3GeCl (Scheme 52),[382] or by reducing $CoCl_2$ with Na/Hg in the presence of $P(OPr^i)_3$ (Table 41),[534] and its structure (R = Me) shows a staggered arrangement of axially bridged trigonal bipyramids (**162**). This species is not formed by the radical dimerization of $[Co\{P(OR)_3\}_4]$ and the dimer does not dissociate to the monomer below 70 °C. Neither monomer nor dimer reacts with H_2 at ambient temperatures or abstracts H from solvent. Photolysis forms $[Co\{P(O)(OMe)_2\}\{P(OMe)_3\}_4]$, and photolysis in the presence of H_2 gives $[CoH\{P(OMe)_3\}_4]$.



(iii) Cobalt(I)

Some $[CoCl\{P(OR)_3\}_3]$ complexes of tetrahedral symmetry are known ($\mu \approx 3$ BM; Table 41); these dissociate one $P(OR)_3$ ligand in solution. $[Co\{P(OR)_3\}_5]^+$ ions (R = Me, Et; $P(OCH_2)_3CMe$) are fluxional at room temperature but the A_2B_3 spectrum (^{31}P NMR) obtained at low temperature (−122 to −200 °C) establishes a trigonal-bipyramidal ground state (D_{3h} symmetry) with $\Delta G^{\ddagger}$

Table 41 Preparations: Phosphite, Phosphonite and Phosphinite Complexes



Complex	*Preparation*	*Properties*	*Ref.*
$[CoH\{P(OR)_3\}_4]$ (R = Me, Et)	$CoCl_2$ + L + $NaBH_4$; $(RO)_2C_2H_4$, 0 °C	Yellow; diamagnetic	4
$K[Co\{P(OR)_3\}_4]$ (R = Me, Et)	$[CoH\{P(OR)_3\}_4]$ + KH; THF, 65 °C, vac.	White; diamagnetic insoluble in inorganic solvents	4
$Na[Co\{P(OPr^i)_3\}_5]$	$CoCl_2$ + L; THF, Na/Hg	White; diamagnetic, two kinds of L	14
$Na[Co\{P(OPh)_3\}_4]$	CPE of $[Co\{P(OPh)_3\}_4]$ at −1.00 V; $C_2H_4(OMe)_2$, −30 °C	White	15
$[Co\{P(OEt)_3\}_4]$	CPE of $(Et_4N)[Co\{P(OEt)_3\}_4]$; MeCN	White; μ = 1.4 BM, v. reactive	8
$[Co\{P(OPr^i)_3\}_4]$	$CoCl_2$ + L + Na/Hg; THF	Orange-red; μ = 2.0 BM	14
$[Co\{P(OPh)_3\}_4]$	Co^{2+} + L + $NaClO_4$; MeCN; CPE at −1.10 V	Pale yellow	15
$[CoR\{P(OR)_3\}_4]$ (R = Me, Ph)	$K[Co\{P(OR)_3\}_4]$ + RI; THF	Yellow; diamagnetic	4
$[Co\{P(OPh)_3\}_x(CO)_{4-x}(HgX)]$ (X = Cl, Br, I; x = 4, 3, 2)	$[CoH\{P(OPh)\}_x(CO)_{4-x}]$ + HgX_2; acetone	Orange-yellow	16
$[CoCl\{P(OEt)_3\}_3]$	$[Co\{P(OEt)_3\}_5]Cl$; vac., 90 °C	Brown; μ = 3.15; tet	5
$[CoCl\{P(OPr^i)_3\}_3]$	$CoCl_2$ + Zn + L; THF	Purple; μ = 2.9 BM, soluble in non-polar solvents	14
$[Co\{P(OMe)_3\}_5]Y$ (Y = BF_4, BPh_4)	$Co(BF_4)_2 \cdot 6H_2O$ + L; acetone; $(MeO)_2CHEt$	Yellow; soluble in THF, DMF, acetone; insoluble in Et_2O, ROH, RH	1
$[Co\{P(OEt)_3\}_5]Y$ (Y = Cl, BPh_4)	$CoCl_2$ + L + NEt_3; EtOH, H_2O, r.t.	Yellow; diamagnetic	5
$[Co\{P(OCH_2)_3CMe\}]Y$ (Y = NO_3, ClO_4)	$Co(ClO_4)_2 \cdot 6H_2O$ + L; EtOH, 0 °C	Yellow; diamagnetic	2
$[Co\{P(OR)_3\}_5]BPh_4$ (R = Me, Et; $P(OCH_2)_3CMe$)	$[Co(C_8H_{12})(C_8H_{13})]$ + L; MeOH; MeCOCl, $NaBPh_4$	Yellow	6
$[Co(CO)_n\{P(OMe)_3\}_{5-n}]BPh_4$ (n = 0–3)	$Co_2(CO)_8$ + L; pentane	Yellow-white; diamagnetic	7
$[Co\{P(OR)_3\}_3(\eta^3\text{-}C_3H_5)]$ (R = Me, Et, Pr^i)	$K[Co\{P(OMe)_3\}_4]$ + PrI; THF, evap.	Orange; diamagnetic, fluxional	4, 13
$[Co\{P(OR)_3\}_3(\eta^3\text{-}C_8H_{13})]$ (R = Me, Et, Pr^i)	$[Co(C_8H_{12})(C_8H_{13})]$ + L; pentane, 16 h, evap.	Orange-brown; diamagnetic	12
$[Co\{C_2H_2(CO_2Et)_2\}\{P(OR)_3\}_3]$ (R = Me, Et, Pr^i)	$[Co(MeCN)_2\{C_2H_2(CO_2Et)_2\}_2]$ + $P(OR)_3$; toluene, N_2	Yellow; ethyl fumarate, maleic anhydriude (structure, Table 42)	17
$[CoX\{P(OEt)_2Ph\}_4]BPh_4$ (X = Cl, Br, I, NCS)	CoX_2 + L; EtOH, $NaBPh_4$	Green; μ = 2.0–2.3 BM; stable under N_2; soluble in organic solvents	9
$[Co(Cl)_2\{P(OEt)_nEt_{3-n}\}_2]$	$CoCl_2$ + 2L; benzene	Blue-green; μ = 4.23–4.66 BM	10
$[Co(Cl)_2\{P(OEt)_nEt_{3-n}\}_3]$	$CoCl_2$ + 3L; benzene	Green-black; μ = 2.03–2.48 BM; dissociates in benzene	10
$[Co\{P(OMe)_3\}_6]Y_3$ (Y = ClO_4, BF_4, BPh_4)	$Co(ClO_4)_2 \cdot 6H_2O$ + L; EtOAc; DMSO, H_2O	Colourless; diamagnetic; ε_{350} 200; ^1H and ^{59}Co NMR	3
$[Co\{P(OCH_2)_3CMe\}_6](ClO_4)_3$	$Co(ClO_4)_2 \cdot 6H_2O$ + L	Colourless; diamagnetic	2
cis-$[Co(NCS)_2\{P(OR)_3\}_4]BPh_4$ (R = Me, Et)	$Co(SCN)_2$ + L; MeOH, $NaBPh_4$	Yellow; diamagnetic	11
trans-$[Co(NCS)_2(L)_4]BPh_4$ (L = $P(OMe)_3$, $P(OMe)_2Ph$)	$[Co(NCS)(L)_4]BPh_4$ + NO; CH_2Cl_2	Red; diamagnetic (structure Table 42)	11

Scheme 53

for intramolecular exchange of phosphite ligands > 40 kJ mol^{-1} (*vs.* < 20 kJ mol^{-1} for $[CoH\{P(OR)_3\}_4]$; Section 47.5.2.1).[526] Dissociation and intermolecular ligand exchange occur at higher temperatures. Oxidation of $[Co\{P(OR)_3\}_4]$ with $AgPF_6$ leads to $[Co\{P(OR)_3\}_4](PF_6)$ (R = Me, Et, Pr^i, Ph),[406] and the reverse reduction to Co^0 and Co^{-1} has been achieved electrochemically with the latter couple being reversible.[527] Preparation of $[Co\{P(OR)_3\}_5]Y$ can be achieved by disproportionation of Co^{2+} in the presence of $P(OR)_3$,[523] photolysis of $[Co(CO)\{P(OMe)_3\}_4]^+$ in the presence of $P(OMe)_3$,[524] and the displacement of cyclooctadiene from $Co(C_8H_{12})(C_8H_{13})$ using excess $P(OR)_3$ followed by the addition of one equivalent of acetyl chloride (Table 41).[525] Protonation of $[Co(Me)\{P(OMe)_3\}_4]$ leads to CH_4 *via* the intermediate hydride $[Co(H)(Me)\{P(OMe)_3\}_4]$ (equation 111).[383]

Scheme 54

$$[CoMe\{P(OMe)_3\}_4] + H^+ \longrightarrow [Co\{P(OMe)_3\}_4] + CH_4 \qquad (111)$$

(*iv*) *Cobalt(II)*

Five-coordinate low-spin Co^{II} species $[CoX\{P(OEt)_3\}_4]^+$ have been prepared (Table 41), but dissociation to tetrahedral $[CoX\{P(OEt)_3\}_3]^+$ occurs in solution.[528] Similarly low-spin $[Co(Cl)_2\{P(OEt)_nEt_{3-n}\}_3]$ have been prepared (n = 3, 2, 1; n = 3 in solution only; Table 41) and these dissociate one ligand in organic solvents (benzene, nitrobenzene) to form high-spin tetrahedral $[Co(Cl)_2\{P(OEt)_nEt_{3-n}\}_2]$ (equation 112). Stability constants suggest maximum stability with phosphinite and phosphonite ligands (n = 1, 2) and this has been rationalized in terms of increasing cone angle and decreasing σ-donor ability.[529] Both the high-spin four-coordinate and low-spin five-coordinate complexes react with O_2 in benzene solutions or as solids producing phosphine oxide products (equation 113). The rate for L = $P(OEt)_3$ is slower than that for the phosphonite and phosphinite complexes (0.038 *vs.* 0.36–0.68 dm^3 mol^{-1} s^{-1} for $P(OEt)_nEt_{3-n}$, n = 1–3) and a green $[Co(Cl)_2(L)_2(O_2)]$ intermediate has been investigated.[530]

$$[CoCl_2(L)_2] + L \rightleftharpoons [CoCl_2(L)_3] \qquad (112)$$

$$\mu = 4.2\text{–}4.7\,BM \qquad \mu = 2.0\text{–}2.5\,BM$$

$$[CoCl_2(L)_2] + O_2 \longrightarrow [CoCl_2(LO)_2] \qquad (113)$$

(*v*) *Cobalt(III)*

The few Co^{III} phosphite complexes that have been prepared (Table 41) have resulted from disproportionation reactions (equations 114, 115 and 116). Phosphite ester hydrolysis has been found to occur with *trans*-$[Co(DMGH)_2(Cl)\{P(OMe)_nPh_{3-n}\}]$ (n = 3, 2, 1) with the formation of the corresponding phosphonato complex anion *trans*-$[Co(DMGH)_2Cl\{P(O)(OMe)_{n-1}Ph_{3-n}\}]^-$. This most interesting reaction requires the presence of a nucleophilic agent such as halide (or a nitrogen

heterocycle) which becomes alkylated in the process. An S_N2 displacement at the ester carbon centre of the coordinated phosphite has been proposed.[531]

47.5.2.8 Phosphates, cobalt(III)

The structures of several Co^{III}–phosphate complexes are known (Table 46), but their chemistry is not well understood and is not considered here.

(*i*) *Orthophosphates*

Preparations are given in Table 45 and structures in Table 46. Monodentate and bidentate coordination is very slow and occurs by water exchange at the metal (k_{ex}) rather than by attack of coordinated water or hydroxide at phosphorus(V). It is therefore expected that there will be some sort of correlation between k_{ex} and the rate of anation k_{an}. An ion-pair mechanism is likely in all cases, and rather large K_{ip} values and limiting kinetics have been observed (Scheme 55, Table 43). k_1 is some 10–10^2 times slower than k_{ex}, and this can be accounted for by unusually strong H bonding in the ion pair, and by orientation effects.[537] Other oxyanions behave similarly where substitution (*i.e.* oxygen exchange) at the metal is slow.

$$\underset{(cis + trans)}{[Co(HO)(H_2O)(en)_2]^{2+}} + HPO_4^{2-} \overset{K_{ip}}{\rightleftharpoons} \underset{(cis + trans)}{[Co(HO)(H_2O)(en)_2]^{2+}HPO_4^{2-}} \xrightarrow{k_1}$$

$$[Co(O_2PO_2)(en)_2]^+ + H_2O + OH^-$$

$$k_{an} = \frac{k_1K_{ip}[HPO_4^{2-}]}{1 + K_{ip}[HPO_4^{2-}]}$$

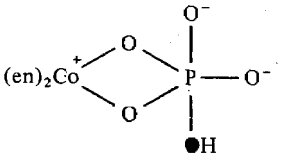
Hydrolysis of monodentate phosphate is also very slow and Co^{III}–OPO_3H_n species ($n = 3$–0) can be considered inert at room temperature (k_0, Table 44). As expected, hydrolysis occurs by substitution at the metal and without exchange into the phosphate (equation 117). Acid catalysis is interpreted in terms of aquation of the acid conjugate of the complexed phosphate (Table 44). $[Co\{OP(OH)_3\}(NH_3)_5]^{3+}$ ($pK_a \approx -0.7$) hydrolyzes some 10^2 times slower than $[Co\{OP(OMe)_3\}(NH_3)_5]^{3+}$, which suggests that protonation at the bound O atom is not important. Base hydrolysis is also very slow (Table 44), occurs *via* substitution at the metal, and an S_N1cb process is likely *via* prior deprotonation of an ammine ligand (equation 118).

$$[(NH_3)_5Co—OPO_3H]^+ + H_2● \xrightarrow{k_0} [(NH_3)_5Co—●H_2]^{3+} + HPO_4^{2-} \quad (117)$$

$$[(NH_3)_5Co—OPO_3] + ●H^- \xrightarrow{k_{OH}} [(NH_3)_5Co—●H]^{2+} + PO_4^{3-} \quad (118)$$



Ring opening in bidentate orthophosphate complexes is both fast and reversible. The inherent stability of chelate rings compared to their acyclic analogues is offset in this four-membered chelate by distortion at the tetrahedral P centre (98.7°), at octahedral Co^{III} (76°), and possibly by the close approach of Co to P. Strain is obvious in the crystal structure of $[Co(O_2PO_2)(en)_2]$ (Table 46). Lincoln and Stranks[538] carried out a careful study of the hydrolysis of this complex. In dilute acid (pH < 4) ring opening occurs *via* protonation and Co—O bond fission. In neutral and alkaline

conditions some O—P bond cleavage was initially believed to occur (35–40%),[538] but recent ^{18}O and ^{17}O experiments have shown exclusive Co—O bond cleavage in 0.4 mol dm^{-3} NaOH[1216] and at pH ≈ 8.[1217] A phosphorane intermediate or transition state (**163**) is therefore not involved in this reaction.

(163)

Scheme 56

Scheme 56 gives the current state of affairs, and it is clear that the chelate is only stable in neutral to slightly alkaline conditions; in acidic solution (pH < 4) the monodentate form predominates. Similar chemistry obtains with [Co(O_2PO_2)(cyclen)].[539]

(ii) Orthophosphate esters and halides

Preparations are given in Table 45. Schmidt and Taube[540] pioneered the early work in this area by preparing and studying the hydrolysis of the $OP(OMe)_3$, $OP(OBu)_3$ and $^-O_2P(OMe)_2$, pentaammine complexes. The triesters (R = Me, Et, Bu^n) are not good ligands and are relatively easily displaced in aqueous solution (equation 119). They have also been used in poorly coordinating solvents to prepare other pentaammine complexes.[173] Recent studies[187] establish that both aquation (10^{-3} mol dm^{-3} HCl) and base hydrolysis (0.1 mol dm^{-3} OH^-) occur exclusively by substitution at Co rather than at P. A similar result is likely for all alkyl and aryl monodentate (or bidentate) phosphate esters unless the metal can force unusually large strain at the P centre. A rather more complex situation occurs with *p*-nitrophenylphosphate.[541] In 0.05–1.0 mol dm^{-3} OH^- about 50% hydrolysis at Co occurs (*p*-nitrophenylphosphate is released) but the remainder occurs *via* a phosphoamidate intermediate generated by attack of a deprotonated ammine ligand with release of *p*-NO_2PhOH (Scheme 57). Ultimately this path leads to free $NH_2PO_3^{2-}$ without incorportion of solvent label. It appears that a single Co^{III} centre cannot provide sufficient activation at P for attack at this centre, even when an excellent leaving group is provided. However, attachment of two oxygen atoms to form a four-membered chelate can provide sufficient activation to allow hydrolysis at P to occur (probably as a result of distortion of the OPO angle). With $[Co\{O_2PO(OC_6H_4NO_2)\}(en)_2]^+$ only hydrolysis at Co is observed but with $[Co\{O_2PO(OC_6H_4NO_2)\}(tn)_2]^+$ sufficient flexibility about Co^{III} results and about 35% hydrolysis at P is found (Scheme 58).[542] Production of the *p*-nitrophenolate ion in the pH range 6.5–13.5 follows the rate $k_{obs} = k_1 + k_2[OH^-]$ ($k_1 = 7 \times 10^{-5}$ s^{-1}, $k_2 = 5.1$ mol^{-1} dm^3 s^{-1}) and the initial fast release of *p*-nitrophenol (35% of total) is followed by a slower reaction presumably *via* leakage back from the monodentate complex. The same rate was found using excess *trans*-$[Co(OH)(tn)_2(H_2O)]^{2+}$ and $Na_2O_3POC_6H_4NO_2$ at pH 7.54, which implies complete coordination of the substrate, and the 100% production of *p*-nitrophenol in this case implies recycling of released ester. This study, which provides an acceleration of 10^4–10^9 (depending on pH) over hydrolysis of the uncoordinated ester, was not the first to report the Co^{III}–promoted hydrolysis of a phosphate ester but it does provide some important mechanistic detail.[543] Clearly bidentate attachment to a metal ion is a minimum requirement and this parallels organic chemistry where five-membered ring phosphate esters are remarkably reactive.[544] It also supports the associative nature of nucleophilic displacement at phosphorus(V) with accelerated reactions being found only when distortion of the ground state of the P centre (both electronic and steric) is provided.

$[(NH_3)_5Co(\mu\text{-}PO_4H)Co(NH_3)_5](ClO_4)_4$	$[Co(OPO_3)(NH_3)_5]$ + $[Co(NH_3)_5OH_2](ClO_4)_3$; H_2O, pH 2.5–3, 70 °C, 4 h	^{31}P NMR	16

Intramolecular hydrolysis by Co^{III}-coordinated hydroxide in *cis*-$[Co(OH)\{OPO_2(OC_6H_4NO_2)\}(en)_2]$ has also been demonstrated (Scheme 58a) and a phosphorane intermediate analogous to (**163**) is suggested.[1216] The advantages of metal-coordinated hydroxide over alkoxide in facilitating such cyclizations and hydrolyses are discussed in this report.

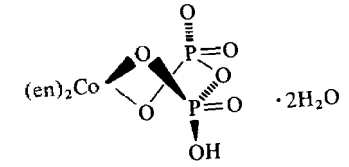
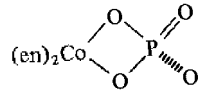
Table 46 Structures: Cobalt Phosphate, Phosphonate, Phosphite, ADP and ATP Complexes



Complex	*Data*[a]	*Comments*	*Ref.*
$Co_3(PO_4)_2$	$P2_1/n$	Dist.; CoO_6, CoO_5 units	1
$Co_2(PO_4)Cl$	$C2/c$; CoO 194–224; CoCl 243.5–254.2	Dist.; CoO_4Cl_2 polyhedra with one face shared with two adjacent polyhedra; 3D network	16
$K_4Co(P_3O_9)_2 \cdot 7H_2O$	$Fm2m$; ionic structure	3D network of P_3O_9 rings linked by Co^{2+}, K^+	2
$Na[Co\{OPH(O)(OH)_3\}] \cdot H_2O$	$Pbca$; CoO 206–215	3D network; oct.; five O(P), one OH_2 donors; two O(P) bridges	3
$[Co(O_3PCH_2NH_3)_2(H_2O)_2]$	$P2_1/c$; CoO 210, 212; OPC 108.6 °C; OPO (bridge) 111.9 °	Dist. oct.; two OH_2 (*trans*); two $O(PO_2R)$, two bridging $O_2(POR)$ (*trans*); prep. from $CoCl_2 \cdot 6H_2O$ in aq. soln.	4
	$P2_1$; β,γ coord., six-membered chelate; OCoO 93.7 °; CoOP 129, 130 °; CoO 193, 194; H-bond between amine and oxygens	Derived from HIO_5 cleavage of $(NH_3)_4$CoATP; *S*-chirality at P (same as in Mg(ATP) substrate for PRPP synthetase)[b]	5, 8
	$P2_1/n$; α,γ coord., eight-membered chelate; H-bonds between ammines to β,γ oxygens OCoO 94.6 °; CoOP 140, 151 °; CoO 192, 193	Boat configuration (P-1 O-1 P-2 O-2 almost coplanar); many H-bonds; More folded P_3O_{10} structure than in β,γ isomer (above)	6
	$P4_2/mbc$; α,β,γ coord.; two six-membered chelates; OCoO 88.3, 92.9 °; CoO 192, 194	Two chelate rings are mirror images; phosphate units sharply folded.	7
	*Cc*; monodentate pyrophosphate; CoO 192; CoOP 139 °; PO_3P 131.3 ° (unconstrained)	Intramolecular H bonds between ammines and O-1, O-2	8

$P2_1/c$; six-membered chelate; OCoO 92.5°; CoOP 126, 127°; CoO 193.6, 193.9; H bonds between axial ammines and oxygens.

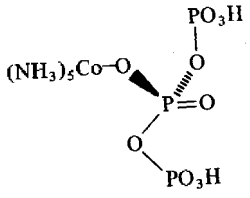
Distorted boat conformation with more packed chelate than in β,γ P_3O_{10} chelate



8

$P2_1/c$; six-membered chelate; OCoO 92.8°; CoOP 125, 127°; CoO 193, 195; H bonds between axial ammines and oxygens

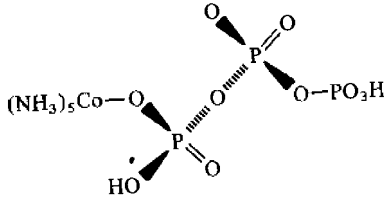
Skew-boat conformation, stabilized by H bonding; similar bond lengths to ionic $P_2O_7^{4-}$



9

$P1$; two independent molecules in unit cell; OCoO 76.0°; CoO 194.8, 193.3; CoOP 92.5, 92.8°; OPO 98.7°

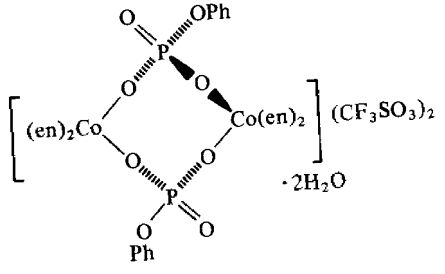
Constrained angles at Co, P in four-membered chelate; discrete $\Delta(\lambda\lambda)$, $\Lambda(\delta\delta)$ chains held together by H bonds



10

$P2_12_12_1$; β-coord. of $H_2P_3O_{10}^{3-}$ ligand; CoO 193.6

Two H bonds with ammines; extended phosphate chain

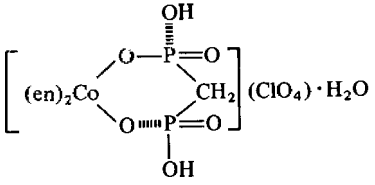


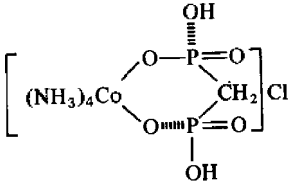
11

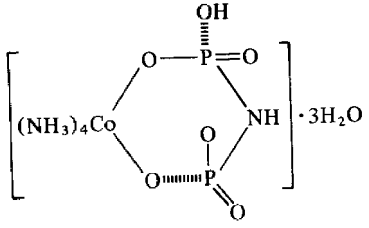
$P2_12_12_1$; γ-coord. of $H_2P_3O_{10}^{3-}$ ligand; CoO 191.2

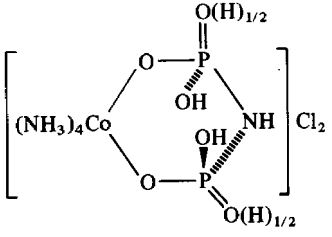
No intramolecular H bonds; helical conformation of phosphate

11









$P2_1/c$; bridging coord. of phosphate ester; CoO 192.2, 195.6; OCoO 94.1

meso (Δ,Λ) isomer formed from $[Co(en)_2Cl_2]ClO_4$ + Ag_2O_3POPh in Me_2SO

12

Table 46 (*continued*)

Complex	*Data*[a]	*Comments*	*Ref.*
	OCoO 94.3°; OPC 109.7°; CoO 193.1	Racemic crystal; no distortion about Co or P	13
	CoO 194; CoOP 131–137°; PO 152; OPC 111°	ATP analogue	14
	$P2_1/c$; OCoO 91.8°; CoO 1.91	Chair conformation; trianionic chelate	15
	$P2_12_12_1$; OCoO 94.4°; CoO 1.93–1.94	Boat-twist boat conformation; monoanionic chelate	15

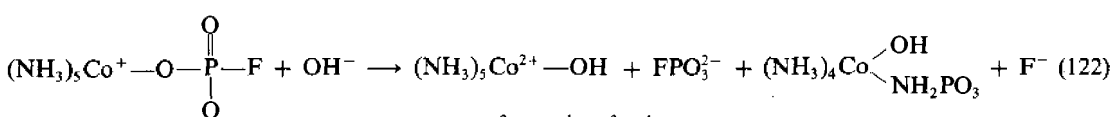
to (**163**) is suggested.[1216] The advantages of metal-coordinated hydroxide over alkoxide in facilitating such cyclizations and hydrolyses are discussed in this report.[1216]

$$(NH_3)_5Co{-}OP(OMe)_3^{3+} + \bullet H_2/\bullet H^- \longrightarrow (NH_3)_5Co{-}\bullet H_2^{3+}/\bullet H^{2+} + PO(OMe)_3 \quad (119)$$



Ligands closely related to orthophosphate esters include acetylphosphate, acetylphenylphosphate and fluorophosphate. Alkaline hydrolysis of $[Co\{OP(O)_2OCOMe\}(NH_3)_5]^+$ occurs exclusively at the carbonyl centre, and the acceleration provided by cobalt(III) four atoms removed is minimal (10 times, equation 120).[546] This is a good comparative example of phosphoryl *versus* acyl hydrolysis, since an excellent leaving group at P is provided (AcO^-) and P is two atoms closer to the activating metal. Likewise the coordinated-hydroxide-promoted hydrolysis of acetylphenylphosphate occurs exclusively at C (equation 121), but the rate enhancement over solvolytic OH^- is in this case significant (10^2 for a 10 mM Co^{III} solution).[546] Hydrolysis at P does not occur even with O-bound monofluorophosphate, with *ca.* 50% hydrolysis occurring at Co^{III} and the remainder involving intramolecular attack of a coordinated amide ion (equation 122).[547] The latter path presumably involves a four-membered chelated amidate intermediate and an enhancement of *ca.* 10^{10} over hydrolysis of FPO_3^{2-} is calculated for this part. Attack by phosphate species such as is found in ADP and ATP synthetases is more difficult. Apparently heating $[Co\{OP(O_2H)F\}(NH_3)_5](ClO_4)_2$ with a solution of NaH_2PO_4 leads to some pyrophosphate complex $[Co(OP_2O_6H)(NH_3)_5]$ but the published details are not very clear.[548]

$$k = 0.53\,mol^{-1}\,dm^3\,s^{-1},\ 25\,^{\circ}C,\ I = 1.0\,M \quad (120)$$

$$k = 3.3 \times 10^{-3}\,mol^{-1}\,dm^3\,s^{-1}$$

(iii) Pyrophosphates, triphosphates, ADP and ATP

Preparations are listed in Table 47. Main interest lies in determining how metal ions catalyze the hydrolysis of ADP and ATP. ATP plays a crucial role in the energy metabolism of all living cells and divalent metal ions (Mg^{2+}, Mn^{2+} and Ca^{2+}) play an important role in these phosphoryl transfer processes.[549] Divalent metal ions such as Mg^{2+}, Ca^{2+}, Zn^{2+}, Cu^{2+} and Mn^{2+} provide only modest *in vitro* catalysis[550–554] and stronger, more specific coordination to phosphate units appears to be required by the enzyme. Co^{III} (and Cr^{III}) complexes of ADP and ATP have been shown to mimic many of the biological functions of the Mg^{2+} enzyme, and since the cobalt(III)–phosphate coordination remains intact, the specificity of alternative coordination sites, and the stereochemical requirements at phosphorus, have been elucidated in some cases.[555] Often the Co^{III}–enzyme species is biologically active and several enzymic functions of ATP have been examined in this manner.

$HP_2O_7^{3-}$ coordinates to Co^{III} either as a monodentate ligand (terminal O^-) or as a bidentate chelate (six-membered $^-O,O^-$). The complexes are easily made in aqueous solution (equation 123),[556] or by heating sparingly soluble $[Co(N)_{6-n}(H_2O)_{n-6}](HP_2O_7)$ (N = NH_3, en, tn) under a good vacuum at ~100 °C.[557] Chromatographic separation on Dowex or Sephadex anion–cation resins leads to pure species (Table 47). Crystal structures of $[Co\{OP(O)_2OPO_3H\}(NH_3)_5]\cdot H_2O$, $[Co\{O_2P_2O_4(OH)\}(NH_3)_4]\cdot 2H_2O$ and Δ,Λ-$[Co\{O_2P_2O_4(OH)\}(en)_2]\cdot 2H_2O$ are available (Table 46) with the six-membered chelates showing no apparent strain about the Co or P centres. The alternative four-membered ring isomer has not been identified and is unlikely to occur in an equilibrium sense because of chelate ring strain.

This lack of ring strain in the six-membered chelate stabilizes the system towards hydrolysis at

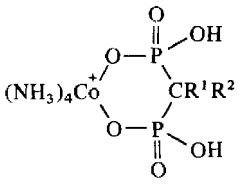
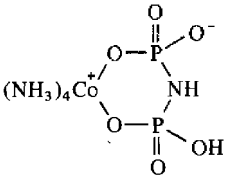
$$\underset{0.01\,M}{[Co(H_2O)_2(NH_3)_4]^{3+}} + \underset{0.01\,M}{H_2P_2O_7^{2-}} \xrightarrow[80\,^\circ C,\ 10\,min]{pH\,3} [Co(O_2P_2O_5H)] \qquad (123)$$

P, and for $(N)_4 = (NH_3)_4$, $(en)_2$, tren and $(tn)_2$ (equation 124), hydrolysis is unimportant over the wide range pH 3–14. At pH values above 11 hydrolysis at Co occurs with the ultimate release of unaffected (no O exchange) $P_2O_7^{4-}$. The monodentate intermediate appears to have some stability since it has been observed, but not isolated. For $(N)_4 = (NH_3)_4$ (equation 124), reduction to Co^{II} becomes an increasing problem at high pH.

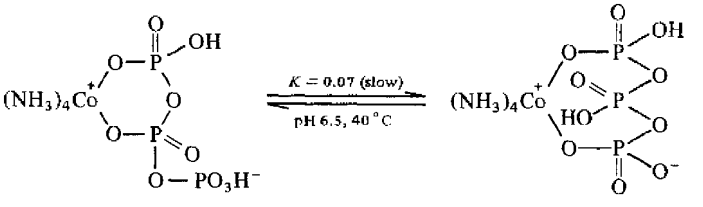


(124)

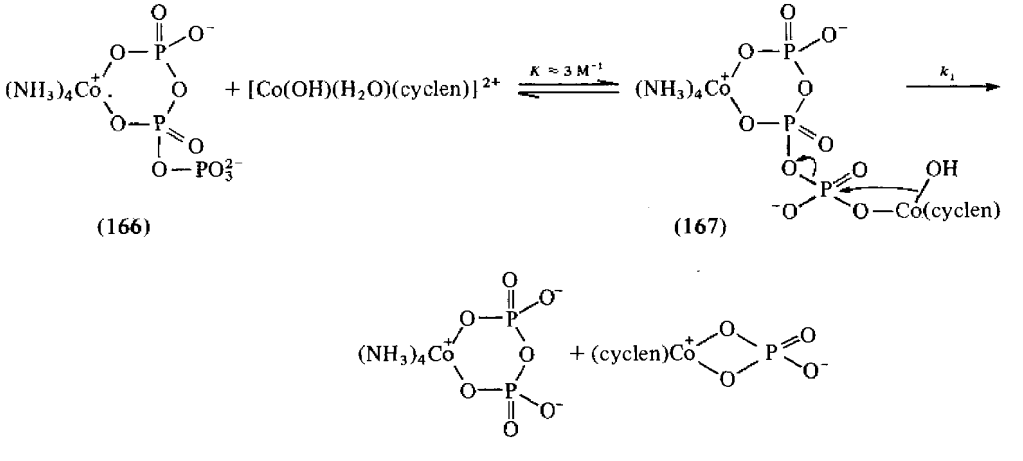


Using ^{31}P NMR in a semi-quantitative sense Hubner and Milburn[558] have shown that with the labile $(N)_4 = (tn)_2$ system multiple coordination to the $HP_2O_7^{3-}$ unit is possible when excess Co^{III} reagent is present. Then hydrolysis at P (probably stoichiometric rather than catalytic) ensues with a maximum rate at pH $\approx$ 7. This suggests $[Co(OH)(H_2O)(tn)_2]^{2+}$ is the reactive ingredient. At pH 5 ($[Co] = 0.3$, $[H_2P_2O_7^{2-}] = 0.1$ mol dm^{-3}) a half-time for $H_2PO_4^-$ production of about 1 h compared to 10 years for the uncoordinated ligand demonstrates the accelerating effect of the additional Co^{III} unit(s). Although no reactive species have been identified, Scheme 59 gives some of the possibilities. Crystal structures are available for the diphosphonate (PCP) and diphosphoamidate (PNP) analogues (**164**) and (**165**) (Table 46) and these have been used as probes for H transfer, Ca^{2+} binding, and cleavage patterns in phosphoryl transfer. Thus the potato enzyme apyrase catalyzes the hydrolysis of $[Co(PXP)(NH_3)_4]$ species (X = O, N) to give $[Co(OPO_3)_2(NH_3)_4]$ with the possible intermediacy of $[Co(OPO_3)(OPO_2NH_3)(NH_3)_4]$ in the case of X = N.[573]

Scheme 59



(164) R^1, R^2 = H, Me, OH, Bu^t, NH_2, Cl, NMe_2



(165)

$H_2P_3O_{10}^{3-}$ can act as a monodentate (terminal O^-), bidentate (β,γ, six membered; α,γ, eight membered) and tridentate (α,β,γ, six membered) ligand system (crystal structures Table 46). The β,γ six-membered chelate is particularly interesting since it is the only structure to have an asymmetric P centre. Although prepared from $[Co(NH_3)_4(OH_2)_2]$ and $H_2P_3O_{10}^{3-}$ as a racemic mixture, the crystal structure was carried out on the isomer isolated from $[Co(ATP)(NH_3)_4]$ by periodate cleavage, and has the absolute (*S*) chirality. All structures (Table 46) indicate little or no strain at either Co or P, although sharply folded units are often involved. As with chelated $HP_2O_7^{3-}$ little or no accelerated hydrolysis at P occurs in the absence of additional metal activation and this appears to be independent of ring size (equation 125).[559,560,561] This is consistent with the absence of distortion at the tetrahedral P centres. Some accelerated hydrolysis at alkaline pH values results from the slower hydrolysis for the parent $P_3O_{10}^{5-}$ compared to the protonated species rather than from a significant increase in k_{obs} for the chelate. Table 48 gives some hydrolysis data for $[Co(O_2P_3O_8)(NH_3)_4]^{2-}$ and the β and γ isomers of $[Co(OP_3O_9)(NH_3)_4]^{2-}$. The presence of additional Co^{III} reagent significantly accelerates the reaction, especially with species having two available *cis* coordination sites.[562,563] The pH variation in k_{obs} has been interpreted as intramolecular hydrolysis by coordinated hydroxide in the bifunctionalized system (**167**; Scheme 60) and the derived rate $k_1 = 0.01\ s^{-1}$ represents an acceleration of $\sim 3 \times 10^4$ compared to the initial chelate (**166**) and 5×10^5 compared to $P_3O_{10}^{5-}$, so considerable activation has been achieved. $[Co(OH)_2(cyclen)]^+$ also initiates hydrolysis in monodentate β- and γ-$[Co(OP_3O_9)(NH_3)_5]^{2-}$ systems[564] (formation of PO_4^{3-} + $[Co(OP_2O_7)(NH_3)_5]^-$ is 50-fold faster for the β isomer) but the effect is considerably smaller and does not appear to show the same pH variation. None of the reactive intermediates have been isolated in these studies, or indeed clearly identified, so that considerable uncertainty remains as to details. However distortion about the P centre undergoing hydrolysis seems a necessary requirement, and it is likely that this can only be achieved in four-membered chelates.

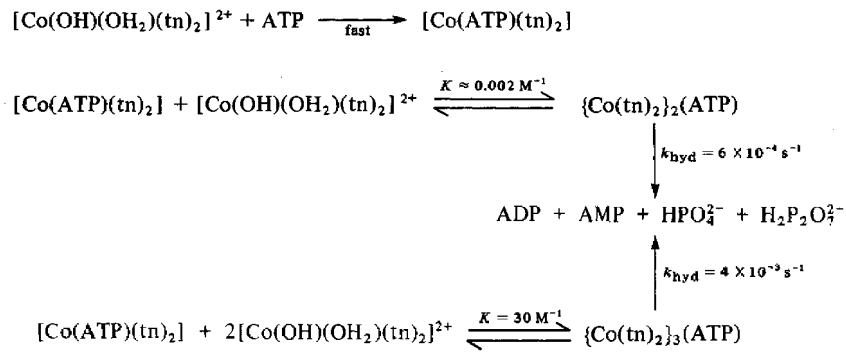
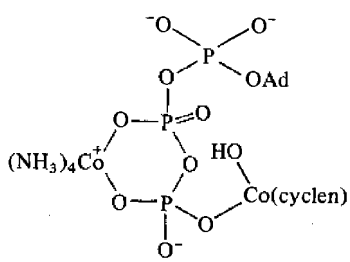
2. $[Co(NH_3)_4O_2P_3O_8]^{2-}$ = 25 mM; [activating complex] = 20 mM.
3. At pH 6 $k_{hyd} = 2.3 \times 10^{-7}\ s^{-1}$ (40 °C).
4. For β-$[Co(NH_3)_5OP_3O_9]^{2-}$ $k_{obs} < 10^{-6}s^{-1}$ and for γ-$[Co(NH_3)_5OP_3O_9]^{2-}$ $k_{obs} < 10^{-8}\ s^{-1}$ (*i.e.* little or no acceleration over free ligand). T. P. Haromy, P. F. Gilletti, R. D. Cornelius and M. Sundaralingam, *J. Am. Chem. Soc.*, 1984, **106**, 2812.

Several complexes of the $[Co(HATP)(NH_3)_n]$ (n = 2, 3, 4) and $[Co(ADP)(NH_3)_n]$ (n = 4, 5) variety have been prepared and isolated (as solids or as aqueous solutions; Table 47). Spectral data (^1H and ^{31}P NMR, UV–visible) have been reported.[556] Likewise the diastereoisomeric ADP(αS) coordinates with a preference for (O,S) binding (equation 126).[565] No crystal structures are available, but the configuration of the inactive form of $[Co(HATP)(NH_3)_4]$, isolated from the yeast-hexokinase-mediated synthesis of glucose 6-phosphate ADP, has been characterized following periodate cleavage and a crystal structure on the resulting $[Co(O_2P_3O_8H_2)(NH_3)_4]$[566] is available (Table 46; Scheme 61). The (*S*) configuration at P requires the (*R*) diastereoisomer of β,γ-$[Co(HATP)(NH_3)_4]$ to be the active ingredient in the enzymic process.[567] This strongly implies similar β,γ coordination and an (*R*) configuration for MgATP. Likewise, phosphoribosyl-pyrophosphate (PRPP) synthetase specifically utilizes the β,γ-$(-)^{CD}_{550}$-(*S*)-$[Co(ATP)(NH_3)_4]$ diastereoisomer in the phosphorylation of ribose 5-phosphate[568] but in this case the phosphorylated ribose product containing the metal has the opposite CD from the starting material implying that inversion at P has occurred (Scheme 62). The (*R*)- and (*S*)-α,β-$[Co(ADP)(NH_3)_4]$ diastereoisomers have been separated on cycloheptaamylose[566] and assignments of configuration follow the above ATP complexes.

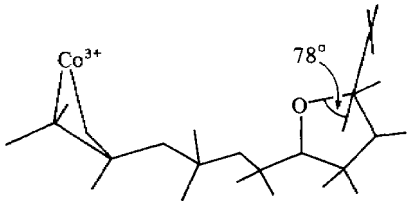


Scheme 61



Scheme 62

As found with $H_2P_2O_7^{2-}$ and $H_2P_3O_{10}^{3-}$ hydrolysis of ATP and ADP can be accelerated by $[Co(OH)(OH_2)(N)_4]^{2+}$ species[570,571] and by the hydrolysis products of $[Co(Cl)_3(dien)]$.[572] The $(N)_4 = (tn)_2$ complex shows no acceleration for a 1:1 ratio, but the 2:1 metal:ATP mixture (0.1–0.01 mol dm^{-3} ATP) shows $\sim 10^5$ enhancement at pH 7. Scheme 63 summarizes these findings. At high pH hydrolysis of the Co^{III} complex predominates. $[Co(cyclen)(H_2O)_2]^{3+}$ also catalyzes the hydrolysis of $[Co(NH_3)_4(ATP)]^-$ at pH 8–9, and (**168**) has been claimed as the reactive species.[581] In all these studies however no intermediates have been positively identified, and the immediate products, coordinated or otherwise, also lack definition.

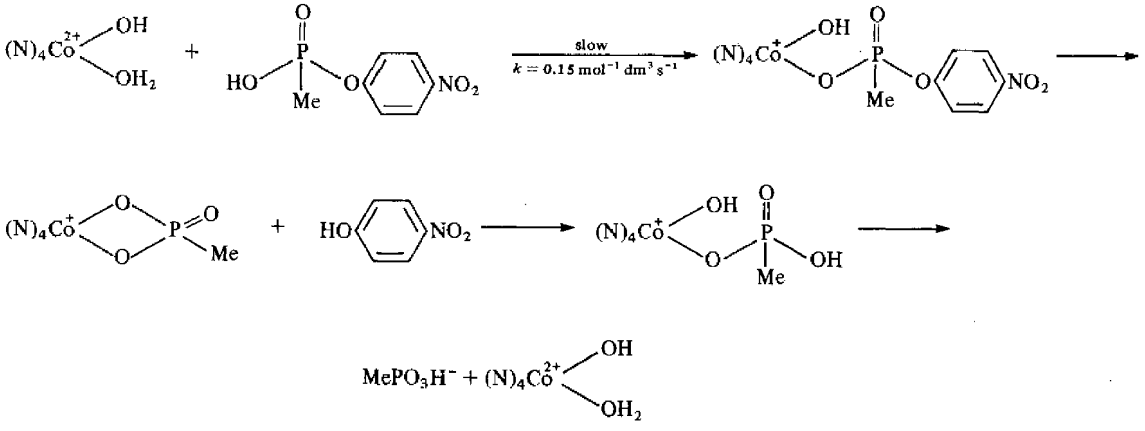


Scheme 63

(**168**)

Stable Co^{III} ADP and ATP complexes have been used as competitive inhibitors in a number of enzymic studies and some progress has been made at unravelling the requirements of the active sites. Steady-state kinetic studies show β,γ-$[Co(ATP)(NH_3)_4]$ to compete with MnATP for $(Na^+ + K^+)$, Mg^{2+} and Ca^{2+} ATPases derived from kidney medulla.[574] K_i values for β,γ-$[Co(ATP)(NH_3)_4]$ are similar to the K_m values for MnATP for both the $(Na^+ + K^+)$ and Mg^{2+} enzymes, and ^{31}P NMR shows that the Co^{III} complex acts as a substrate for the Mg^{2+} and Ca^{2+} systems. Likewise,

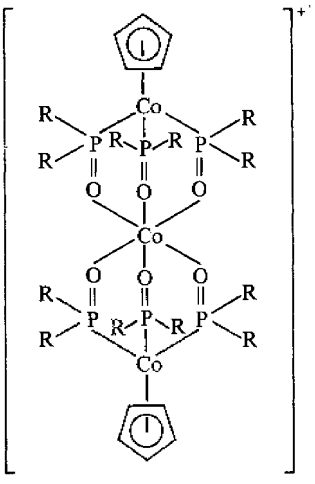
$(-)_{505}$-[Co(ATP)$(NH_3)_4$] and $(-)_{532}$-[Co(ADP)$(NH_3)_3(H_2O)$] compete with MgADP for the active site of creatine kinase although they are not as effective in this role as similar Cr^{III} species.[575] Werber and coworkers have used an uncertain Co(phen)ATP complex to probe the active ATPase site of the energy-releasing myosin enzyme.[376,377] A more recent publication suggests that the initial inhibitor may be a $Co^{II}(phen)_x$ species and that the site of inactivation is not the true active site of the enzyme.[578] The paramagnetic effects of enzyme-bound Mn^{2+} on the ^1H and ^{31}P T_1 relaxation rates of β,γ-[Co(ATP)$(NH_3)_4$] have been used to describe the active site of cAMP-dependent bovine-heart kinase.[579,580] β,γ-[Co(ATP)$(NH_3)_4$] competes with MgATP (and MnATP) for the nucleotide binding site in the enzyme and the T_1 data suggest that Mn^{2+} (attached to an adjacent inhibitory site) coordinates to either all three α,β,γ or the α,γ phosphates of β,γ-[Co(ATP)$(NH_3)_4$]; the latter possibility is favoured.[579] A decision on the two possible orientations of the adenosine ring about the glycosidic bond has been made possible by nuclear Overhauser studies, with the antiglycosidic structure shown by (**169**) being favoured.[580]



(**169**) Co(ATP)$(NH_3)_4$-bound protein kinase

(*iv*) *Phosphonates, phosphoamidates, phosphites and their esters*

Busch and Pennington have prepared the $[Co\{OP(O_2H)CH(Me)NH_3\}(NH_3)_5]^{2+}$ ion containing O-bound 1-aminoethylphosphoric acid, but it remains to be isolated and fully characterized.[582] The terminal amine group has a pK_a of 3.2 and the deprotonated complex acts as a bridge for intersphere electron transfer with $Cr^{2+}_{(aq)}$.[582] A series of diphosphonate chelates of type (**164**) have been prepared (Table 47) and fully characterized.[583] Crystal structures on the parent (R^1, R^2 = H) bis(ethylenediamine) and tetraammine complexes are available (Table 46). Complex (**164**) binds Ca^{2+} strongly (K varies from 4×10^3 to 2×10^6 mol dm^{-3}), particularly when R = OH, and this implies a similar role for radioactive ^{99m}Tc-bound pyrophosphonates and pyrophosphates, which are used as skeletal imaging reagents.[584]

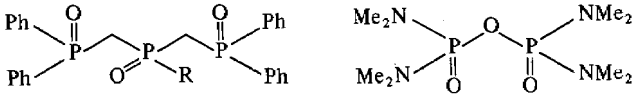


N-bound phosphoamidate in $[Co(NH_2PO_3H)(H_2O)(NH_3)_4]Cl_2$ has been prepared by treating O-bound $[Co\{OP(O_2H)PhNO_2\}(NH_3)_5]^{2+}$ with 3 mol dm^{-3} NaOH.[541] It is easily removed from the metal by treating with acid, but further characterization seems desirable; O,O-chelated amidates such as (**165**) have been prepared and a crystal structure is available (Table 46).

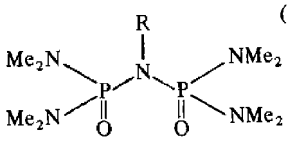
Several $[Co(OH)(OH_2)(N)_4]^{2+}$ systems catalyze the hydrolysis of *p*-nitrophenylmethylphosphonate (PMP) and its ethyl ester (EPMP) [$(N)_4$ = tme > tn > trien ≫ bipy], possibly *via* the sequence shown by Scheme 64 with rate-determining coordination of the ester.[584] This involves an acceleration of $> 10^4$ at pH 7.6 (1.5 mM complex) but none of the intermediates have been characterized. Recycling of the $[Co(OH)(OH_2)(N)_4]^{2+}$ reagent appears to be involved.

Scheme 64

Klaui has recently described the first clear example of a $^5T_2$ (high spin) $\rightleftharpoons$ $^1A_1$ (diamagnetic) spin equilibrium in an octahedral Co^{III} complex using the phosphito complex $[Co(OPR_2)_3Cp]$ (R = OR, Et) as a tridentate ligand.[585,586] Complex (**170**) has been isolated (ClO_4^- and PF_6^- salts) following electrochemical oxidation of the neutral Co^{II} complex. The six phosphite oxygens provide a ligand field about the central metal intermediate between H_2O (low spin) and F^- (CoF_6^{3-}, high spin) with the complexes being green and paramagnetic at elevated temperatures (μ = 4.1 BM, R = Et, 393 K) and yellow and diamagnetic below 200 K. The behaviour is reversible, occurs both in the solid and in solution, and is R dependent.[586] ^{31}P NMR studies show little solvent influence on the spin equilibrium, with $\Delta H^\circ = 24\,kJ\,mol^{-1}$, $\Delta S^\circ = 70\,J\,mol^{-1}\,K^{-1}$ in four different solvents.[587] It is concluded that inner-sphere electronic effects are responsible for the equilibrium position.



(170)

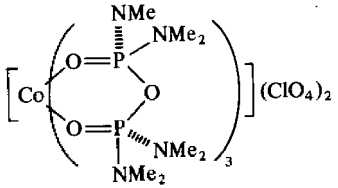


(*v*) *Phosphine oxides, phosphoramides and phosphinates*

These are largely restricted to Co^{II} and Co^{III}. The former are invariably tetrahedral and the latter octahedral, sometimes with ligand-induced distortion. An early paper by Goodgame and Cotton discusses some spectroscopic properties[588] and MCD spectra have been investigated by Kato and Akimoto.[589] A review covering recent chemistry is available.[590] Table 49 lists some structural information.

Co^{II} complexes containing phosphoramides ($O = P(NR^2)_3$)[591] iminophosphoranes ($RN = PPh_3$)[592] and phosphinates ($^-O_2PR^1R^2$)[593] are known, as are distorted octahedral complexes containing the neutral chelating ligands (**171**),[594] (**172**)[595] and (**173**).[596]

(171) (172)



(173)

47.6 ARSENIC LIGANDS

The softer and larger As atom results in weaker coordination to all first-row transition elements. $As(OR)_3$ and AsX_3 (X = halogen) coordination to cobalt has not been well characterized. Arsines (AsR_3) form longer and weaker bonds with the σ-donor power decreasing in the order NR_3

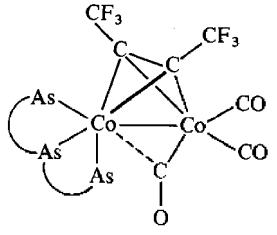
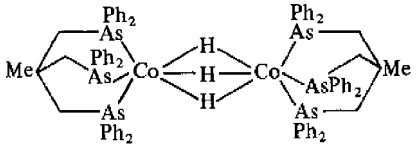
(Co—L ≈ 200 pm), PR_3 (225), AsR_3 (233). Few low-oxidation-state complexes have been reported and no crystal structures. The alkyl-substituted arsines of Co^{II} are usually easily air-oxidized to Co^{III} complexes, but this is difficult with phenyl- and aryl-arsines. Further oxidation to Co^{IV} does not appear to be possible.



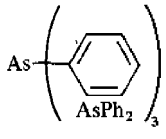
47.6.1 Cobalt(−I), Cobalt(0) and Cobalt(I)

$AsPh_3$ displaces alkene from $[Co(C_8H_{13})(C_8H_{12})]$ under H_2 to form $[HCoH(AsPh_3)_4]$, and under suitable conditions $[CoH(N_2)(AsPh_3)_3]$ and $[Co(H)_3(AsPh_3)_3]$ can be obtained.[598] Several Co^0 complexes containing CO and NO ligands in addition to AsR_3 are known. $[Co(NO)(L)_{1,2}(AsR_3)_{2,1}]$ and $[Co(NO)_2L(AsR_3)]$ are tetrahedral or close to tetrahedral with linear or nearly linear bonding of NO. Some preparations are given in Table 50 and structures in Table 51.

Several nominally Co^0 complexes containing chelated arsines are known and a recent study of the coordination of **(174)** to $[Co_2\{C_2\{CF_3\}_2\}(CO)_6]$ resulting in structure **(175)**[599] typifies organocobalt work in this area.



(174) ttas



(175)

Diamagnetic $[Co\{MeC(dpam)_3\}(CO)_2](BPh_4)$ containing the tridentate arsine tris(diphenylarsinomethyl)ethane is formed on treating the paramagnetic Co^{II} dimer **(176)** with CO, and a similar five-coordinate complex $[Co\{As(dpap)_3\}(CO)](BPh_4)$ containing ligand **(177)** has been prepared from $[Co_2(CO)_8]$ (Table 50). Structures of these monomeric systems are not known.

(176)

(177)

47.6.2 Cobalt(II)

Unlike their phosphine analogues monotertiary arsines do not readily combine with simple Co^{II} halides. Anhydrous CoX_2 with $AsEt_3$ *in vacuo* forms unstable $[Co(X)_2(AsEt_3)_2]$ species,[600] and $[Co(I)_2(AsPh_3)_2]$ has been isolated from nitromethane solution.[601]

Bidentate arsines form more stable complexes and some preparations are given in Table 50. The electronic spectrum of red-brown $[Co(I)_2(dpav)]$ **(178)** is inconsistent with a tetrahedral geometry and it may be planar (μ = 2.9 BM), but $[Co(X)_2(dpae)]$ **(179)** (X = Cl^-, Br^-, I^-) is almost certainly tetrahedral.[487] The asymmetric phenyl analogue forms $[Co(mpae)_2](CoX_4)$ as the solid and a planar structure is possible for the cation (μ = 2.1 BM for the ClO_4^- salt).[602] Bis(diphenylarsino)methane forms green $[Co_3(dpam)_4I_6]$ of unknown structure and low stability. Four-coordinate planar structures for complexes $[Co(As—As)_2](ClO_4)_2$ have not been positively identified with the poorer aryl or vinyl As donors (see below) but dark green $[Co(dmav)_2](CoCl_4)$ is probably planar (μ = 2.6 BM for cation).[603] Attempts to prepare five-coordinate $[CoX(diars)_2]^+$ complexes (diars = **180**) have not been successful for X = Cl^-, Br^-, I^-, but for X = NCS^- excess ligand results in $[Co(NCS)(As—As)_2]^+$ (As—As = dpav, dpae), and using a 1:1 ratio of ligand to metal the non-electrolyte $[Co(NCS)_2(diars)_2]$ has been isolated which may be planar (μ = 2.6 BM).[487] Irradiation of a mixture of *cis* and *trans* bis(dimethylarsine)ethylene with CoX_2 results in $[CoX(dmav)_2]X$, which is five-coordinate; a 1:1 electrolyte in solution (X = Cl^-, Br^-, I^-), its magnetic moment in the solid state

(μ = 1.96–2.16 BM) is consistent with pentacoordination.[603] $[CoX_2(das)_2]$ (das = **181**) is likely to be *trans* octahedral in the solid state although magnetic data are in the range found for five-coordinate Co^{II}.[604] The structure of $[Co(OClO_3)_2(das)_2]$ shows long bonds in the axial positions of a tetragonally distorted octahedraon (Table 51). In ionizing solvents such as nitromethane a planar geometry for $[Co(das)_2]^{2+}$ is possible, although Bosnich, Jackson and Lo suggest dimerization in acetonitrile.[606] The related ligand (**182**) forms green paramagnetic $[Co(nas)_3](CoCl_4)$ and yellow diamagnetic $[Co(nas)_3](ClO_4)_2$, and dimerization is possible for the latter and octahedral coordination for the former.[607] Reduction of $[Co(H_2O)_2(das)_2](ClO_4)_3$ with primary alcohols leads to the dimer (**183**), which is essentially diamagnetic (μ = 0.7 BM).[606]

The branched ligand (**184**) forms unstable $[Co\{MeAs(dmap)_2\}_2]^{2+}$ salts with possibly the apical As remaining uncoordinated,[608] but no Co^{II} complexes have been reported with the softer ligand (**185**) (the apical phosphine analogue $PhP(dmap)_2$ forms square-pyramidal $[CoCl_2\{PhP(dmap)_2\}]$,

Section 47.5.2.6.iii). Reduction of $Co(BF_4)_2$ with $NaBH_4$ in the presence of (**186**) forms the mauve μ_3-hydrido-bridged dimer (**176**)[375] (structure Table 51), which reacts with HCl or CO generating 3 mol of H_2 and Co^{2+} or $[Co\{MeC(dpam)_3\}(CO)_2](BPh_4)$ respectively.

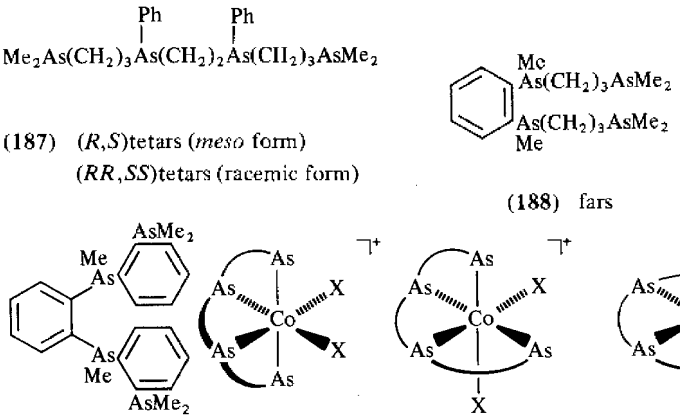
(185)

(186)

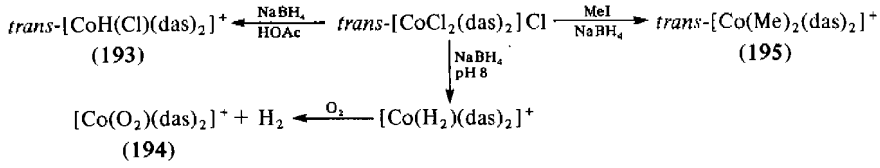


47.6.3 Cobalt(III)

Few monotertiary arsine complexes are known for Co^{III}. Displacement of *trans* sulfito groups from $Na_5[Co(CN)_4(SO_3)_2]$ gives $Na[Co(CN)_4(AsPh_3)_2]$, which presumably also has the *trans* configuration.[609] Some $[CoY(DMGH)_2(AsR_3)]$ cobaloximes are also known (R = Me, Ph; Y = Cl^-, $SnPh_3^-$)[610] as are some σ-bonded $R^1R^2As^-$ and $R^1R^2(O)As$ complexes (see below).

Bidentate diarsines are more common and Nyholm many years ago reported the preparation of several *trans*-$[CoX_2(das)_2]^+$ complexes by air oxidation of the corresponding Co^{II} systems (X = Cl^-, Br^-, I^-, NCS^-).[611] He also isolated $[Co(das)_3](ClO_4)_3$. Subsequently, the *cis*-$[CoX_2(das)_2]^+$ isomer was prepared, initially following treatment of *trans*-$[CoI_2(das)_2]I$ with Ag^+,[612] and later *via* $[Co(CO_3)(das)_2]ClO_4$.[613] In this later work Bosnich and coworkers resolved *cis*-$[Co(Cl)_2(das)_2]^+$ using (+)-arsenyltatrate and showed optical retention in various substitutions with H_2O, CO_3^{2-}, NO_3^-, NO_2^- and $C_2O_4^{2-}$. Racemization in dry MeOH occurs with some 80% conversion to the *trans* isomer.[613] Some preparations are given in Table 50 and crystal structures in Table 51. The green *trans* complexes are usually tetragonally distorted in the solid state but the *trans* configuration is thermodynamically favoured in solution. Peloso and Dolcetti have followed rates of substitution (Cl^- exchange, NCS^-) and isomerization for *cis*- and *trans*-$[Co(Cl)_2(das)_2]^+$,[614] and Jackson, McLaren and Bosnich report an interpretation of their CD spectra.[615] Some unusual self-induced catalytic substitution and racemization processes have also been reported and solutions should be protected from the light.[613] The *cis*-diaqua, hydroxyaqua, and dihyroxy ions do not racemize rapidly although water and hydroxide exchange occurs within hours at 25 °C.[613] Green, presumably *trans*, $[Co(X)_2(dmav)_2]X$ complexes have also been prepared, as has $[Co(dmav)_3](BF_4)_3$ (Table 50). Bubbling NO through methanol solutions of *trans*-$[Co(X)_2(das)_2]X$ results in *trans*-$[CoX(NO)(das)_2](ClO_4)$ and trigonal-bipyramidal $[Co(NO)(das)_2](ClO_4)$ (Table 50), and Brant and Feltham have recently correlated their photoelectron spectra with those of other Co and Fe nitrosyls. A linear correlation between ν_{NO} and the N 1*s* binding energy was demonstrated as well as insensitivity of the As 3*d* binding energy to the other ligands.[616]

A number of multidentate arsine complexes have been prepared by air oxidation of the corresponding Co^{II} complexes (Table 50). Perhaps the most interesting work in this area is that of Bosnich and his colleagues using the quadridentates (**187**), (**188**) and (**189**); all contain two central chiral As atoms. Air oxidation of $CoCl_2$ in acidified MeOH in the presence of (**187**) gives five $[Co(Cl)_2(tetars)]Cl$ isomers, three containing the racemic (*RR,SS*) ligand and two the *meso* (*RS*) form.[617] Resolution of α-$[Co(Cl)_2(RR,SS\text{-tetars})]^+$ followed by reduction using KCN gives the optically-active (*SS*) ligand, which is optically stable and stereospecific in its subsequent coordination to Co^{III}. However an interesting and unexplained halide-induced racemization process was found for the complexes in acetonitrile. Metathesis leads to a wide range of complexes (X = CO_3^{2-}, H_2O, Br^-, NO_2^-, NCS^-, CN^-, N_3^-) with retention at the chiral As centres but with changes in stereochemistry between isomers (**190**), (**191**) and (**192**).[618] The *meso* ligand prefers the *trans* structure (**192**) but the racemic ligand exists in all three forms. A rationalization of their CD spectra has also been reported.[619] Reduction of α-$[Co(Cl)_2(RR,SS\text{-tetars})]Cl$ with $NaBH_4$ in MeOH–H_2O mixtures produces a yellow solution which absorbs O_2 forming β-$[Co(O_2)(RR,SS\text{-tetars})](ClO_4)$ containing side-on-bonded dioxygen (**204**; Table 51). A similar property holds for *trans*-$[Co(Cl)_2(R,S\text{-tetars})]Cl$ and *trans*-$[Co(Cl)_2(das)_2]Cl$. If the solutions are kept acidic hydrido complexes *trans*-$[CoH(Cl)(As—As)_2](ClO_4)$ are formed (**193**; Scheme 65). Use of excess $NaBH_4$ at pH 8 leads to almost white $[Co(H)_2(das)_2](ClO_4)$, which slowly absorbs O_2 in the solid forming pink $[Co(O_2)(das)_2](ClO_4)$ (**194**).[620] Likewise treatment with MeI results in (**195**). The *trans*-labilizing effect of hydride is seen in the very facile exchange of aqua ligand in $[CoH(H_2O)(das)_2]^{2+}$.[620] A similar study using fars (**188**) and qars (**189**) has given the *meso* and optically active ligands and



interconversions similar to the above are possible.[621] The (*RR,SS*) qars ligand forms only the α stereochemistry (**190**) due to the rigid ligand backbone but fars gives α, β- and *trans* complexes. Reduction of *trans*-[Co(Br)$_2$(*RR,SS*-fars)]Br with $NaBH_4$ in basic solution and subsequent O_2 absorption forms [Co(*RR,SS*-fars)O_2]$^+$, while in acidic solution *trans*-[CoH(Br)(*RR,SS*-fars)]$^+$ is formed. A stable dihydride [Co(H)$_2$(*RR,SS*-qars)](ClO_4) was also isolated.[621]

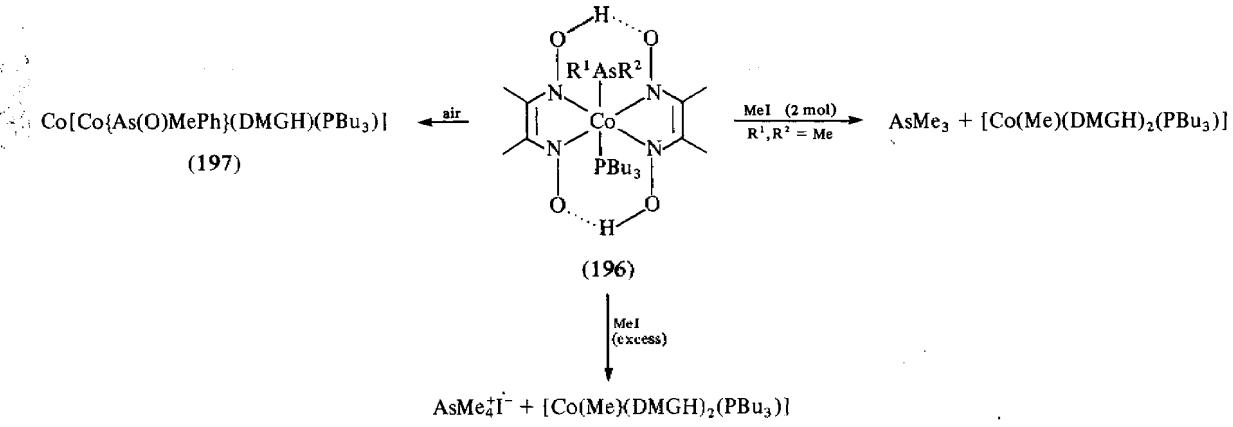
Scheme 65



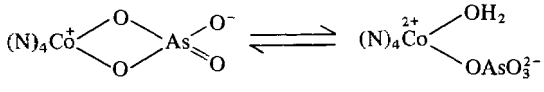
Few mechanistic studies on ligand replacement have been reported. Nanda and Tobe many years ago studied the displacement of Cl^- by $Y = Br^-$, NCS^- in [Co(Cl)$_3${MeAs(dmap)}], and the independence of rate on the nature and concentration of Y^- suggested rate-limiting dissociation. Also it appears that [CoX(solv)(As—As)$_2$]$^{2+}$ species rapidly undergo anation by X^- (halide, pseudohalide). The rate is very much faster than for the corresponding amine complexes.

Some interesting σ-bonded $R_2(OH)As$ complexes containing As^{III} result from treating [Co(DMGH)$_2$] with Ph_2AsCl or MePhAsCl in methanol, and a structure on [CoCl{As(OH)MePh}-(DMGH)$_2$]·H_2O (Table 51) establishes a Co^{III}—As bond.[623] Treatment of Co^I cobaloximes with R^1R^2AsX (X = Cl, I) leads to $R^1R^2As^-$ coordination. Thus addition of [Co(DMGH)$_2$py]$^-$ to $AsMe_2Cl$ and [Co(DMGH)$_2$(Bu^{t}py)]$^-$ to $AsMe_2I$ in methanol gives a product which approximates to [Co(DMGH)$_2$($AsMe_2$)·MeOH. This is thought to be polymeric with $AsMe_2$ bridges.[624] Using [Co(DMGH)$_2$(PBu^n_3)]$^-$ as the nucleophile R^1R^2AsCl forms green solutions (R^1, R^2 = Me, Ph) thought to be (**196**), which air oxidize to (**197**; Scheme 66). A crystal structure (Table 51) shows two [Co(DMGH)(PBu^n_3){As(O)MePh}] units joined to a central Co^{II} ion.[624] Complex (**196**) also reacts with MeI, or [Co(DMGH)$_2$(py)Me], to form $AsMe_3$ (Scheme 66), and this is seen as a possible model for the aerobic biological methylation of arsenic.

47.6.4 Arsenates

Comparisons with phosphate (and other oxyanions) can be made with reference to Section 47.5.2.8.(i).

Substitution at As^V is much faster than that at P^V due to its more polarizable nature and readiness to expand its covalency from four to five or six. Thus O exchange in $AsO_4H_n^{(3-n)-}$ is considerably faster than in P analogues and this is paralleled by their ability to react with $CoOH_2^{n+}$ species with displacement at As rather than at the metal. The reaction given by equation (127) is reasonably fast in the forward direction ($k_f = 5 \times 10^{-3}\ s^{-1}$ in 0.1 mol dm^{-3} arsenate, pH 6)[597] and when assumptions are made concerning ion pairing the rate for displacement at As within the ion pair is somewhat faster (*ca.* 10 times) than that for the unassisted O exchange in $HAsO_4^{2-}$ (k_{ex}; Table 74). Proton

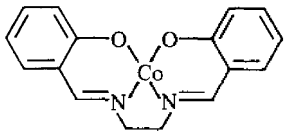


Scheme 66

transfers in a transition state of type (**253**) have been proposed with the lower reactivity of $H_2AsO_4^-$ being attributed to the smaller ion-pairing constant.[597] The reverse hydrolysis reaction (k_{hyd}; Table 74) is fastest with $[Co(OAsO_3H_3)(NH_3)_5]^{2+}$ ($pK_a \approx 3.3$), and an acid-catalyzed route *via* $[Co(OAsO_2H_3)(NH_3)_5]^{3+}$ ($pK_a \approx -0.5$) is also available. The more basic complexes are relatively stable in aqueous solution. Comparison of k_{hyd} and k_{ex} (Table 74) shows that the CoO—AsO_3H_n bond is more inert than the HO—AsO_3H_n bond.

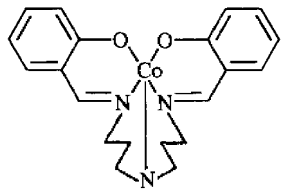
$$[(NH_3)_5CoOH_2]^{3+} + [HAsO_4]^{2-} \underset{k_{hyd}}{\overset{k_f}{\rightleftharpoons}} [(NH_3)_5CoOAsO_3H]^{+} + H_2O \qquad (127)$$

The chelate form of arsenate (equation 128) has not been clearly identified. It is more likely than phosphate to dissociate to the monodentate form in aqueous solution.



(128)

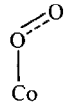
47.7 OXYGEN LIGANDS



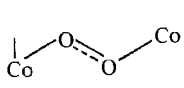
47.7.1 Superoxo and Peroxo

Cobalt–dioxygen chemistry has its origins with Fremy[625] who, in 1852, reported that the exposure of ammoniacal solutions of cobalt(II) salts to air resulted in the formation of brown 'oxo-cobaltiates'. However, it was not until 1898 that these cobalt–dioxygen complexes were correctly formulated by Werner and Mylius as containing the $[(NH_3)_4Co(O_2)Co(NH_3)_4]^{4+}$ cation.[626] In the late 1930s Tsumaki[627] observed that solid samples of the cobalt(II)–Schiff-base complex [Co(salen)] possessed the capacity to bind dioxygen reversibly. This discovery prompted a widespread and continuing interest in the oxygen-carrying ability of cobalt chelates. Much of the early work in this area concerned solid state cobalt(II)–Schiff-base systems, in particular the square-planar complexes derived from [Co(salen)] (**198**) and the trigonal-bipyramidal complexes derived from [Co(salpr)] (**199**). Both types of compound can be prepared in active and inactive forms, with dioxygen-carrying ability being dependent on purification procedures and the methods of preparation employed. Calvin and his coworkers prepared, characterized and tested for dioxygen-carrying properties a total of 57 Co–Schiff-base complexes[628] and many more were examined by Diehl.[629] Compounds of type (**198**) bind 1 mol of O_2/mol of Co while those of type (**199**) bind 0.5 mol O_2/mol of Co. Oxygenation can be reversed either by heating or by evacuation, however after many oxygenation–deoxygenation cycles dioxygen-carrying ability decreases. In the solid state [Co(3-Fsalen)] deteriorates to ~60% of its original activity after 1500 cycles,[630] and this deterioration is linked to irreversible oxidation or to strain imposed on the crystal leading to inactive modifications. In non-aqueous solution oxygen uptake by both the type (**198**) and (**199**) chelates was complicated by problems of irreversibility and the failure of the complexes to appreciably oxygenate under oxygen pressures sufficient to cause oxygenation in the solid state.[631] A significant development came with the discovery of Burk, Hearon, Caroline and Schade[632] that the cobalt(II)–amino-acid complex

[Co(his)$_2$] combined reversibly with dioxygen in aqueous solution. This was an important result, for [Co(his)$_2$] was the first synthetic compound to undergo reversible oxygenation in aqueous solution and it was evident that oxygenation was a general rather than an isolated phenomenon. This early chemistry of cobalt–dioxygen complexes has been reviewed.[630,633–635]

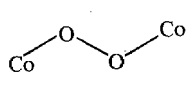


(198)



(199)

It is now recognized that cobalt dioxygen complexes may be classified according to their molecular geometries and electronic distributions into four related categories. These structural classes were originally proposed by Vaska[636] in his general review on dioxygen–metal complexes and allow the cobalt systems to be viewed as either superoxo (types Ia and Ib) or peroxo complexes (types IIa and IIb) of cobalt(III). This formalism is supported by the collective experimental evidence for cobalt–dioxygen adducts, which indicates that binding of O_2 to cobalt involves considerable electron transfer from the metal to the coordinated dioxygen moiety. Unlike the situation with chromium– and iron–O_2 adducts the degree of electron transfer, and consequently the nature of the bonding in the cobalt–dioxygen complexes, is relatively clear.



(Ia)

(Ib)

(IIa)

(IIb)

One of the best measures of the degree of charge transfer to dioxygen is the stretching frequency ν_{O_2}, and selected data for cobalt–dioxygen complexes are given in Table 52. Several early assignments of ν_{O_2} are known to be incorrect but the increasing use of isotopic substitution ($^{18}O_2/^{16}O_2$) and Raman and resonance-Raman techniques has now eliminated many of the problems and ambiguities associated with the measurements. The frequency ranges 1075–1195 cm^{-1} and 790–932 cm^{-1} are widely recognized as diagnostic for superoxo and peroxo complexes respectively[636] and virtually all stable cobalt–dioxygen adducts are found to have stretch frequencies lying in one or the other of these ranges. The unstable complexes formed between cobalt(II) porphyrins and O_2 doped into Ar matrices have recently been shown[637,638] to have ν_{O_2} values ($\sim$ 1280 cm^{-1}) significantly greater than the upper limit of the superoxo range.

Single-crystal X-ray structures have now been determined for a large number of cobalt–dioxygen complexes and comparisons of the observed O—O bond lengths with those of superoxide anion or peroxide dianion (O—O separation = 128 pm, KO_2; 149 pm, Na_2O_2) also form a reliable guide to classification.

Recent reviews on the chemistry of metal–dioxygen complexes with particular relevance to cobalt systems include a number dealing with general properties,[636,639–641] binuclear superoxo and peroxo complexes,[642,643] reversible oxygenation,[644–646] complex stability,[647,648] catalytic oxidation[649,650] and electronic[651] and EPR[652] spectral properties.

47.7.1.1 η^1 Superoxo

The 1:1 dioxygen adducts of cobalt(II) complexes containing tetradentate ligands have been widely studied. In these systems dioxygen binding requires the presence of a Lewis base in the coordination site *trans* to the dioxygen moiety, which gives rise to six-coordinate adducts. Complexes of this type include those with Schiff bases, porphyrinato and various other macrocyclic ligands. Other ligand types are also suitable however. Certain pentadentate ligands provide the additional donor atom to eliminate the need for an external Lewis base, and a stable six-coordinate cobalt–dioxygen adduct containing solely unidentate ligands has been reported,[26] five-coordinate

cobalt(II)–trisphosphine complexes bind dioxygen but dissociate a phosphine ligand in the process to form five-coordinate terminally bound dioxygen complexes.[456]

In many systems there is a marked tendency for μ-peroxo dimer formation (Scheme 67) but the 1:1 adducts may be stabilized by the use of polar solvents and by bulky groups in the ligand which hinder the dimerization step. They may also be stabilized kinetically by use of low temperatures, however bases with the ability to hydrogen bond will accelerate dimerization[653] and σ basicity is also important. Detailed discussions of the factors influencing stability are available.[644,646]

$$(B)(L_4)Co + O_2 \underset{}{\overset{K_{O_2}}{\rightleftharpoons}} (B)(L_4)Co(O_2)$$

$$(B)(L_4)Co(O_2) + Co(L_4)(B) \xrightarrow{k} (B)(L_4)Co(O_2)Co(L_4)(B)$$

Scheme 67

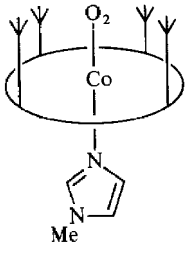

Table 53 gives a list of a number of cobalt(III)–superoxo complexes which have been isolated as crystalline solids. There is a marked preponderance of complexes of the type $[Co(SB)(B)(O_2)]$ (SB = Schiff base). The base adducts of simple Co^{II} porphyrins have low affinities for dioxygen at room temperature and consequently their 1:1 adducts with O_2 are not isolable. In contrast, exposure of a solid sample of Collman's picket fence porphyrin system [Co(TpivPP)(*N*-Meim)] to 1 atm of dioxygen for 24 h produces [Co(TpivPP)(*N*-Meim)(O_2)] (**200**).[654] The pivalamido pickets in this compound exercise control of solvation about the coordinated dioxygen moiety and the stability is comparable with that of $CoMbO_2$,[655] where the globin protein environment performs the same function.

Virtually all water-soluble cobalt dioxygen complexes are binuclear but $(NR_4)_3[Co(CN)_5(O_2)]$ (R = Et, Pr^n) complexes may be obtained following the reaction of O_2 with $[Co(CN)_5]^{3-}$ in DMF

solution,[26] and oxygenation of ethanolic solutions of *cis*-[$Co(Cl)_2$(*s*-Me_2en)$_2$] gives *cis*-[CoCl(*s*-Me_2en)$_2$(O_2)]$^+$ isolated as its PF_6^- or ClO_4^- salt.[656] That the monomeric rather than the dimeric complexes are obtained appears to be due to the influence of solvent in the first case and to steric hindrance in the ligand in the second. The five-coordinate Co^{II}–Schiff-base complexes [Co(salpr)] and [Co(*N*-Mesalpr)] differ only by substitution of H for Me at the axial nitrogen atom, yet on oxygenation in non-polar solvents the former gives a stable μ-peroxo dimer, [{Co(salpr)}$_2$(O_2)],[657] while the latter gives the unusual superoxo complex [Co(*N*-Mesalpr)(O_2)]·[Co(*N*-Mesalpr)].[658] Clearly, the balance between formation of the mononuclear and binuclear complexes is delicate.

Structural studies on the monomeric dioxygen complexes have often been hampered by solid-state disorder or excessively high thermal motion of the coordinated dioxygen moiety. Despite these problems a number of structures have been reported (Table 54) and with one exception the O—O bond distances all lie within the relatively narrow range 124 to 135 pm. Both the O—O bond lengths and the Co—O—O bond angles (range 117° to 153°) are consistent with the formulation of these 1:1 adducts as cobalt(III)–superoxo complexes. The variation in the Co—O—O bond angles has been attributed to packing forces.[644]

Magnetic susceptibility measurements on $[Co(L_4)(B)(O_2)]$ complexes correspond to the presence of one unpaired electron and EPR spectra exhibit a well-defined eight-line ^{59}Co hyperfine spectrum with a peak separation of ~12 G. Studies using $^{17}O_2$-labelled [Co(bzacen)(py)(O_2)] show the two oxygen atoms to be non-equivalent in the solid state and in frozen solution,[659] but equivalent in fluid solution.[660,661] The equivalence may be due to a rapid equilibrium between two bent conformations: $Co—(O_AO_B) \rightleftharpoons Co—(O_BO_A)$. These experiments also showed the electron to be localized essentially on dioxygen. The commonly held view that there is a formal transfer of an electron from the cobalt metal centre to a dioxygen π^* orbital in the cobalt–dioxygen adducts ($Co^{III}—O_2^-$) has been challenged by Tovrog, Kitko and Drago.[662] On the basis of EPR experiments they suggest that on combination of a Co^{II} complex with dioxygen only partial transfer occurs, with the degree of transfer being dependent on the ligand environment about the metal. For a series of cobalt(II) complexes containing a range of different ligand types they estimate between 0.1 and 0.8 electrons transferred to the coordinated dioxygen fragment. The proposed alternative bonding interaction involves the spin pairing of unpaired electron in an antibonding orbital of O_2 with an unpaired electron in a d_{z^2} orbital on cobalt(II).[663] That the unpaired electron in the adducts resides in an oxygen π^* orbital is not in dispute. Smith and Pilbrow[652] have discussed the merits of this proposal, but have concluded from a recent analysis of the EPR spectra of several cobalt–dioxygen complexes that electron transfer cannot be estimated reliably at present.[664] The results of EPR studies on a wide range of η^1 cobalt–dioxygen complexes, including $CoHbO_2$, $CoMbO_2$ and the dioxygen adduct of vitamin B_{12r}, have been summarized in recent reviews.[644,652]

Several η^1 cobalt–dioxygen adducts have been studied theoretically. These investigations include studies on $[Co(Cl)_4(B)(O_2)]$ systems (B = none, NH_3, py, im) by Boca[665] and the construction of Walsh diagrams by Teo and Li[666] for the interaction of O_2 with the fragments $[Co(CN)_5]^{3-}$ and $[Co(PH_3)_4]^+$. Calculations on [Co(acacen)(B)(O_2)] (B = none, H_2O, CN^-, CO, im) by Veillard and

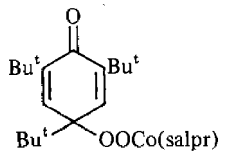
coworkers[667] show the bent η^1 geometry to be more stable than the η^2 by 190–340 kJ mol^{-1} depending on **B**, and also preferred over the linear η^1 arrangement. In agreement with the related calculations of Fantucci and Valenti on [Co(acacen)(NH_3)(O_2)][668] the unpaired electron is found to be localized essentially in a π_g^* orbital of dioxygen. Veillard's calculations[667] also show a relationship between the σ-donor ability of the axial ligand **B**, the ease of oxidation of cobalt(II) to cobalt(III), and the ease of oxygenation.

Qualitative support for this result comes from the observation by Carter, Rillema and Basolo[669] that for a number of complexes of the type [Co(SB)(B)] (SB = Schiff base) a linear correlation exists between log K_{O_2} (K_{O_2} = [Co(SB)(B)(O_2)]/[Co(SB)(B)]pO_2) and the oxidation potential cobalt(II) to cobalt(III). The correlation holds both for variation in B within the [Co(bzacen)(B)] series and for variation in the Schiff base within the [Co(SB)(py)] series, thus giving a measure of the effects of axial and in-plane ligands on the stability of the [Co(SB)(B)(O_2)] adducts. Basolo[669] suggested the correlations exist because the oxidation potentials provide a measure of the charge density on the cobalt centre. The greater the charge density on Co the greater will be the electron transfer from cobalt to dioxygen, and consequently the more stable the dioxygen complexes. The correlation between K_{O_2} and the base strength of axial phosphine ligands in [Co(porphyrin)(PR_3)] complexes[670] also relates to the amount of electron density at the cobalt metal centre. An analogous correlation relating electronic effects arising from substitution in the in-plane ligand to the dioxygen-binding ability of [Co(porphyrin)(py)] complexes has been described by Walker, Beroiz and Kadish.[671]

The reduction of $[Co(CN)_5(O_2)]^{3-}$ by Mo^V species in aqueous solution produces the bimetallomer (**201**), which is slowly decomposed in organic solvents to the η^2-Mo(O_2) species (**202**).[672] Tracer studies using $^{18}O_2$ show however that the peroxo bridge in (**202**) does not derive from $[Co(CN)_5(O_2)]^{3-}$.[673]



(201)

(202)

Kumar and Endicott[673] have examined the one-electron oxidation–reduction of [Co([14]aneN$_4$)-(H_2O)(O_2)]$^{2+}$ in aqueous solution. Reduction competes successfully with dimerization in this system and even mildly reducing metal ions such as Fe^{2+} react *via* an inner-sphere process. Presumably this pathway is preferred owing to the large free-energy changes associated with formation of the μ-peroxo adducts. With Fe^{2+} the adduct is observable as a transient CoOOFe species, which decays to Fe^{3+} and unspecified cobalt products.

The coordination of O_2 to Co^{II} centres not only enhances the basicity of the dioxygen fragment but also increases its tendency to undergo free-radical reactions. The radical nature of η^1 cobalt–dioxygen complexes is now well established and is particularly demonstrated through their participation in hydrogen-abstraction reactions. The autooxidation of phenols to the corresponding *p*-quinones and diphenoquinones catalyzed by cobalt(II) complexes provides the best example. Nishinaga[675] has demonstrated that the dioxygen complex [Co(salpr)(O_2)] activates 2,4,6-tri-*t*-butylphenol *via* hydrogen abstraction by following the simultaneous decrease in the Co—O_2 EPR signal and appearance of the phenoxy radical signal. The product of the reaction of [Co(salpr)] with the radical has since been isolated and found to have the structure (**203**).[649] Similar H-atom abstractions are observed for [Co(salen)(py)O_2)] and the dioxygen adduct of vitamin B_{12r} with 1,4-dihydroxybenzene, and with *N,N'*-tetramethyl-*p*-phenylene.[676] Drago and coworkers have also examined the oxidation of phenols catalyzed by cobalt(II)–Schiff base complexes[677,678] and report a high selectivity toward *p*-quinone production over solution analogues when the complex is bound to a polymer support.[678] A further illustration of the radical character of the η^1 Co—O_2 complexes has been given by the reaction of [Co(*N*-Mesalpr)(O_2)] with the spin trap 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) to form a stable Co—O—O—DMPO spin adduct.[679]

(203)

The role of cobalt–dioxygen complexes in autooxidations other than phenol oxidation is less certain, and ostensibly similar reactions appear to follow radically different pathways. Thus, in the oxidation of thiols to disulfide catalyzed by Co^{II} species catalysis by the phthalocyanine complex $[Co^{II}(TSPc)]^{4-}$ apparently proceeds *via* a Co^{I} intermediate and without participation of Co—O_2 species,[680] whereas catalysis by $[Co^{II}(TPP)]$ appears to involve initial formation of an η^1 cobalt–dioxygen complex from which O_2^- is displaced by thiolate.[681] Several reviews giving extensive coverage to oxidations catalyzed by cobalt(II) complexes are available.[649,650,682,683]

There have been a number of reports describing the formation of η^1 cobalt–dioxygen complexes by reactions not involving oxygenation of cobalt(II) chelates. Ligand substitution at the axial positions of the cobalt(III) complex aquacobalamin (vitamin B_{12a}) is sufficiently rapid to allow coordination of electrochemically generated O_2^- ion in DMF solution.[684] The product displays an EPR spectrum identical with that of the dioxygen adduct of the Co^{II} complex vitamin B_{12r}. Condensation of $[Co(CO)_4]$, produced from the thermal dissociation of $[Co_2(CO)_8]$, and O_2 at 77 K produces $[Co(CO)_4(O_2)]$,[685] which has the EPR characteristics of an η^1 cobalt–dioxygen adduct. The same product is reported from the cocondensation of Co atoms with CO/O_2 mixtures at 10–12 K.[686] Simic and Hoffman[687] have found that O_2^- adds to both $[Co(4,11\text{-dieneN}_4)(H_2O)_2]^{2+}$ and $[Co(1,3,8,10\text{-tetraeneN}_4)(H_2O)_2]^{2+}$ in aqueous solution to produce transient species displaying intense charge transfer bands. The spectra do not correspond to Co^{I} or Co^{III} complexes, excluding O_2^- as a simple electron transfer agent. It is concluded that O_2^- adds to the Co^{II} centre at a labile axial site.

47.7.1.2 η^1:η^1 Superoxo

The only μ-superoxo complexes to have been characterized are those which contain cobalt. They are readily prepared by treatment of the corresponding μ-peroxo complexes with strong oxidants. Thompson and Wilmarth[688] observed that MnO_4^-, HOCl, Br_2, BrO_3^- and NO_3^- are all effective oxidants toward $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{3+}$ in acidic solution whereas Fe^{3+}, H_2O_2, Ag^+ and $Cr_2O_7^{2-}$ are not. In other systems Cl_2, PbO_2, persulfate and Ce^{IV} in nitric acid solution have also effected oxidation.[642] A number of well-characterized μ-superoxo cobalt(III) complexes are listed in Table 55. There are no reports of μ-superoxo complexes containing Schiff base ligands and all that are known contain either terminal amine or cyano groups.

The μ-superoxo cobalt(III) complexes are usually green light-sensitive compounds and their measured magnetic susceptibilities ($\mu \approx 1.6$ BM) correspond to the presence of one unpaired electron. Werner[689] originally formulated the complexes as containing a peroxide group briding Co^{III} and Co^{IV} centres, however the equivalence of the two metal atoms has been demonstrated by EPR experiments. Room temperature EPR spectra of both the single-bridged μ-superoxo[690,691] and μ-amido-μ-superoxo[690,692] ions are well-defined isotropic spectra consisting of 15 lines with $A_{iso} \sim 10$ G. This is the expected spectrum for two magnetically equivalent cobalt nuclei with the unpaired electron residing primarily on the dioxygen bridge. A theoretical study of $[(NH_3)_5Co(O_2)Co(NH_3)_5]^{5+}$ using SCCC methods[693] is in agreement with this result.

Several structural studies on the μ-superoxocobalt(III) complexes have been undertaken (Table 56) and the observed O—O bond lengths (range 124 to 135 pm) also support the structural formalism $Co^{III}(O_2^{2-})Co^{III}$. Recently, Raman spectroscopy has allowed the determination of O—O stretching frequencies for a number of single-bridged superoxo complexes.[694,695] As is the case for the corresponding μ-peroxo species, this vibration is IR inactive, presumably because the molecular symmetry is such that dipole changes due to this vibration are small. A general discussion of the Raman and IR spectra of μ-superoxocobalt(III) complexes has been given[694] and values of ν_{O_2} appear in Table 52.

The purple salt $[(NH_3)_5Co(O_2)(NH_3)_5][(NC)_5Co(O_2)Co(CN)_5]$ has been prepared[690] and is stable in the solid state, whereas $[(NH_3)_5Co(O_2)Co(NH_3)_5](ClO_4)_5$ decomposes with loss of oxygen within 2 to 3 d at room temperature.[696] In acidic solution $[(NH_3)_5Co(O_2)Co(NH_3)_5]^{5+}$ and the doubly bridged $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4]^{4+}$ ion decompose by pH independent paths to yield Co^{III} and Co^{II} species in equal amounts. These processes appear to be simple aquations at cobalt(III), following which the leaving group is further decomposed.

Valentine and Valentine[698] found that irradiation of the LMCT bands of $[(NH_3)_5Co(O_2)$-$Co(NH_3)_5]^{5+}$ and $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4]^{4+}$ gives efficient decomposition into 1:1:1 mixtures of $[Co(NH_3)_5(H_2O)]^{3+}$, $Co^{2+}_{(aq)}$ and O_2 independent of the temperature, acidity or ionic strength of the solutions. Attempts to trap electronically-excited intermediates gave negative results and the quantum yields fall sharply if the ammine ligands are replaced by chelating amines such as tetren.[699]

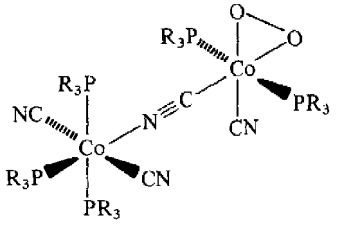
Photolysis of $[(NC)_5Co(O_2)Co(CN)_5]^{5-}$ gives $[Co(CN)_5(OH_2)]^{2-}$, O_2 and H_2O_2[698] with quantum yields being dependent on the wavelength of excitation.[700] Superoxide ion appears to be generated in the primary photolysis step.

Kinetic data have been reported for reduction of μ-superoxo complexes by Fe^{2+},[701] Mo^{V},[702] Co^{II}[703] and Ru^{II} complexes,[704] and V^{2+}, Cr^{2+} and Eu^{2+}.[705] These processes involve outer-sphere electron transfer and in some cases[703,706] the Marcus theory has been applied to the rate constants obtained. Electron transfer quenching of the excited state of $[Ru(bipy)_3]^{2+}$ by various μ-superoxo cobalt(III) complexes leads to production of $[Ru(bipy)_3]^{3+}$ and the corresponding μ-peroxo species.[706]

47.7.1.3 η^2 Peroxo

Few examples of this type are known and all appear to be formed irreversibly. Oxygenation of the planar Co^{I} complex $[Co(vpp)_2](BF_4)$ either in the solid state or in solution gives $[Co(vpp)(O_2)](BF_4)$, which shares with $[Co(bzacen)(py)(O_2)]$[707] the distinction of being the first monomeric cobalt–dioxygen complex to be structurally characterized.[495] Bosnich[708] found that the similar reaction of O_2 with the Co^{I} species produced by BH_4^- reduction of *cis*-α-[Co(Cl)$_2$(*R,R*:*S,S*-tetars)]$^+$ gave red *cis*-β-[Co(*R,R*:*S,S*-tetars)(O_2)]$^+$ for which a structural study[709] has also confirmed the η^2-bonded mode of the dioxygen moiety (**204**). This complex is also produced exclusively when an equilibrium mixture of the *cis*-α and *cis*-β isomers of [Co(*R,R*:*S,S*-tetars)$(H_2O)_2]^{3+}$ in water is treated with H_2O_2. This specificity appears to arise through Co^{II}–catalyzed isomeric equilibration of the products since the H_2O_2 reaction is far faster than the *cis*-α- to *cis*-β-diaqua isomerization. The corresponding reaction with *cis*-[Co(diars)$_2(H_2O)_2]^{3+}$ gives *cis*-[Co(diars)$_2(O_2)]^+$, which is also formed quantitatively when *cis*-[Co(H)$_2$(diars)$_2$](ClO$_4$) in neutral methanol solution is exposed to dioxygen. Bosnich[708] reports an alternative method of preparing η^2-dioxygen adducts *via* the base-induced cleavage of Co—Co bonds in dimers of the type *trans,trans*-[(X)(As$_4$)Co—Co(As$_4$)(X)]$^{4+}$ (X = H_2O or MeCN; As$_4$ = (diars)$_2$, *R,S*-tetars, *R,R*-tetars). The yields are always less than 50% and the reactions involve heterolytic cleavage of the Co—Co bonds to produce Co^{III} complexes and the O_2 sensitive Co^{I} species (Scheme 68).



(204)

Scheme 68

Under certain conditions two one-electron-donor Co^{II} centres can interact with dioxygen as if they were a single two-electron donor. This occurs in the formation of $[Co_2(CN)_4(PMe_2Ph)_5(O_2)]$ (**205**) from the reaction of dioxygen with $[Co(CN)_2(PMe_2Ph)_3]$.[457] In this case the binuclear complex arises from a cyanide-bridged inner-sphere electron-transfer reaction between $[Co(CN)_2(PMe_2Ph)_3]$ and the immediate O_2-substituted product $[Co(CN)_2(PMe_2Ph)_2(O_2)]$. The formal oxidation states of the final product thus correspond to $Co^{III}NCCo^{III}(O_2^{2-})$. All the η^2-dioxygen adducts are kinetically robust, which is surprising in view of the small bite angles ($OCoO \approx 45°$) reported for these species (Table 57).

(205)

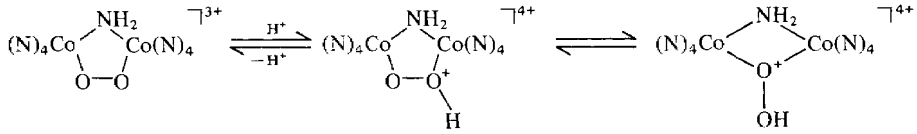
47.7.1.4 η^1:η^1 Peroxo

The reaction of cobalt(II) complexes with dioxygen in aqueous solution normally produces diamagnetic μ-peroxocobalt(III) complexes, and isotopic labelling shows the peroxo bridge to be derived entirely from the O_2 used in the preparation.[710] Formation of the dimer is preceded by formation of a monomeric superoxo species (Scheme 69), which may be stabilized by steric hindrance in the ligand. Generally the kinetic and/or energy balance favours the dimer. The ligands include simple monodentates (H_2O, NH_3, CN^-, NO_2^-, halide), aminocarboxylates, polyamines and various macrocycles.

$$[(L_5)Co]^{n+} + O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(L_5)Co(O_2)]^{n+}$$

$$[(L_5)Co(O_2)]^{n+} + [Co(L_5)]^{n+} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [(L_5)Co(O_2)Co(L_5)]^{2n+}$$

Scheme 69



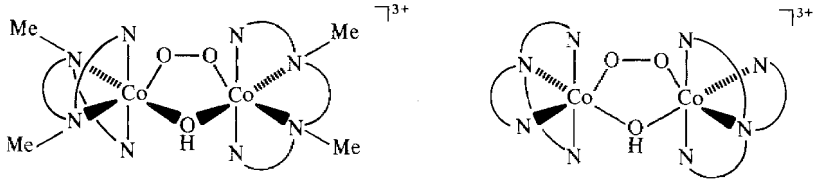
Under basic conditions acidic ligands (H_2O, NH_3) *cis* to the peroxo group can be deprotonated to form dibridged μ-(OH,O_2) or μ-(NH_2,O_2) species. The effect of the second bridge is to stabilize the peroxo dimer toward dissociation. However, while the amido bridge is stable in acidic solution the μ-hydroxo bridge is readily cleaved. Ethylenediamine[711] and tren[712] dibridged μ-peroxo species have also been reported. The one-electron oxidation of the usually brown μ-peroxo cobalt(III) complexes with strong oxidants such as Ce^{IV}, Cl_2 or $S_2O_8^{2-}$ affords green paramagnetic μ-superoxo complexes. Table 55 gives details of the preparation of water-soluble μ-peroxo and μ-superoxo complexes where these have been isolated as crystalline solids. Ligand exchange on many of the μ-peroxo complexes is rapid and the facile substitution of monodentate ligands frequently provides an alternative to direct oxygenation as a synthetic route, *e.g.* equation (128).

$$[(NH_3)_5CoO_2Co(NH_3)_5]^{4+} + 2\text{dien} \longrightarrow [(NH_3)_2(\text{dien})Co(O_2)Co(\text{dien})(NH_3)_2]^{4+} + 6NH_3 \quad (128)$$

It has recently been shown that the rates of substitution of NH_3 ligands in $[\{(en)_2(NH_3)Co\}_2(O_2)]^{4+}$ [713] and dioxygen exchange in $[\{(tren)(MeNH_2)Co\}_2(O_2)]^{4+}$ [714] are identical with the pH-independent rates of decomposition of these complexes to cobalt(II) species and dioxygen. Similarly, the rates of formation of μ-hydroxo bridges, following loss of amine ligand, in $[\{(tren)(NH_3)Co\}_2(O_2)]^{4+}$,[715] $[\{(en)_2(NH_3)Co\}_2(O_2)]^{4+}$ [713] and $[\{(tren)(MeNH_2)Co\}_2(O_2)]^{4+}$ [714] are found to be identical with the rates of decomposition of the complexes to cobalt(II) and O_2. Thus the fast ligand-exchange rates observed for the μ-peroxo complexes arise from the lability of the cobalt(II) species produced *via* Scheme 69.

Not all singly bridged μ-peroxo complexes decompose as indicated by the reverse pathways of Scheme 69. It has long been known that in acidic solution $[\{(NC)_5Co\}_2(O_2)]^{6-}$ is cleaved quantitatively to $[Co(CN)_5(H_2O)]^{2-}$ and hydrogen peroxide,[31] and a number of other μ-peroxo complexes behave similarly. Also, in acidic media *trans*-$[\{(SCN)([14]aneN_4\}Co)_2(O_2)]^{2+}$ is quantitatively converted to *trans*-$[Co(SCN)_2([14]aneN_4)]^+$ in the presence of SCN^- in a process which produces H_2O_2.[716] Solutions of $[\{(H_2O)([14]aneN_4)Co\}_2(O_2)]^{4+}$ possess both oxidizing and reducing properties[717] and it is probable that H_2O_2 formation in this reaction is due to an outer-sphere electron transfer between the oxidizing Co^{III}—(O_2) and reducing Co^{II} species produced in the first step of peroxo-dimer decomposition.

Concentrated solutions of strong acids protonate the peroxo bridge to produce red μ-hydroperoxo complexes. Protonation of $[(N_4)Co(\mu\text{-}NH_2,O_2)Co(N_4)]^{3+}$ ions $[(N_4) = (NH_3)_4, (en)_2$; Scheme 70] initially gives the orange intermediate (**206**), which slowly isomerizes to the red isomer (**207**).[710,718] Crystallographic studies on (**207**) for $(N_4) = (en)_2$[719] confirm the end-on coordination mode for the hydroperoxo group and give the O—O bond distance as 142 pm. The three bonds to the bridging oxygen atom are not coplanar.



(206) (207)

Scheme 70

Zehnder and Fallab[720] have demonstrated peroxo bridge formation *via* anation of *cis*-$[Co(en)_2(H_2O)_2]^{3+}$ with H_2O_2. Reaction at pH 4.8 initially gives the hydroperoxo complex *cis*-$[Co(OOH)(en)_2(H_2O)]^{2+}$, which at higher pH reacts with $[Co(OH)(en)_2(H_2O)]^{2+}$ to yield racemic $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$. Crystal structures of the dibridged species are available for the *meso*[721] and racemic[722] forms.

The question regarding isomer distributions in μ-peroxo complexes containing multidentate ligands has been addressed by Fallab and coworkers. In the formation of $[(trien)Co(\mu\text{-}OH,O_2)Co(trien)]^{3+}$ eight chemically distinct isomers are possible of which three are observed.[723] Methylation at the secondary nitrogens of the trien ligand destablizes isomers with the β configuration and oxygenation of $[Co(Me_2trien)(H_2O)_2]^{2+}$ in alkaline solution gives the dibridged complex (**208**)[723] with an α,α configuration. Three achiral isomers of $[(tren)Co(\mu\text{-}OH,O_2)Co(tren)]^{3+}$ are possible, however only (**209**) is formed by oxygenation of $[Co(tren)(OH_2)]^{2+}$.[724]

(208) (209)

The electronic spectra of μ-peroxo cobalt(III) complexes are dominated by LMCT transitions from filled $\pi^*(O_2^{2-})$ orbitals to empty Co^{III} $d\sigma^*$ orbitals, giving rise to intense broad bands in the near UV region.[725] Ligand field bands often appear as poorly defined shoulders on the rising UV absorption but are resolved for certain [14]aneN$_4$ complexes.[716] The monobridged μ-peroxo dimers often exhibit two band maxima at ~ 320 and 380 nm, whereas the dibridged complexes $[\mu\text{-}(OH,O_2)$, $\mu\text{-}(NH_2,O_2)]$ display one intense band at 360 nm with a shoulder at higher energies. These features arise from splitting of the $\pi^*(O_2^{2-})$ level and are related to the planarity of the $Co(O_2)Co$ unit.[651] Electronic[716] and ^{59}Co NMR[726] spectral studies indicate that the μ-peroxo group possesses normal spectrochemical properties for an oxygen donor ligand bound to Co^{III}.

Selected structural data for μ-peroxo cobalt(III) complexes are included in Table 57. Orbital diagrams constructed for Co—O—O bonds in $N_4Co(O_2)CoN_4$ species show that *trans* bent bonds are the most stable[727] and this is what is observed for the monobridged complexes. Dibridging forces the μ-peroxo group to adopt a skewed *cis* geometry except in cases (*e.g.* $[(tren)Co(\mu\text{-}tren,O_2)Co$-

Table 57 Structures: Monomeric and Dimeric Cobalt(III)–Peroxo Complexes

(tren)]$^{4+}$) where the additional bridging ligand possesses sufficient conformational flexibility to allow the *trans* structure. The O—O bond lengths (mean 147 pm) are comparable with that found for ionic peroxide in Na_2O_2 (149 pm).[728] In the solid-state structures hydrogen-bonding effects, packing forces and the nature of the counterion play a role in determining the planarity of the Co—O—O—Co unit.[644,729]

Rate studies on the oxygenations of cobalt(II) complexes in aqueous solution are numerous. According to Scheme 69, and assuming a steady state in $L_5Co(O_2)$, production of the μ-peroxo complex follows equation (129), which for $k_2[CoL_5] \gg k_1$ reduces to equation (130) and k_1 is obtained directly. At ambient concentrations of O_2 this is generally the case, implying that for most Co^{II} complexes formation of the monomeric L_5CoO_2 species is rate determining under these conditions. Values of the rate constant k_1 (Table 58) mainly lie in the relatively narrow range 10^3 to 10^5 dm^3 mol^{-1} s^{-1} at 25 °C irrespective of the nature of the ligands on the Co^{II} reactant. This

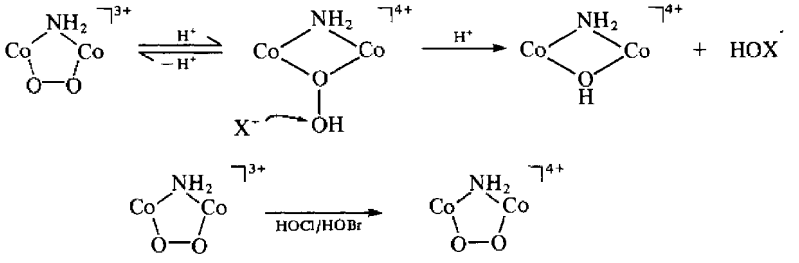
constancy appears to arise, at least in part, from a mechanism dominated by water exchange; however the oxygenation rates are slower than the estimated rates of water exchange at Co^{II} centres by a factor of $\sim 10^3$, and the data indicate that there is a strict orientation requirement of the O_2 moiety in the substitution process. It is of some interest to find that the low-spin $[Co([14]aneN_4)(OH_2)_2]^{2+}$ and high-spin $[Co([15]aneN_4)(OH_2)_2]^{2+}$ ions combine with O_2 at comparable rates.[730] Since reaction of the latter complex requires a change in spin multiplicity, the intrinsic barrier to adduct formation appears not to be sensitive to the spin state of the Co^{II} reactant.

$$d[L_5Co(O_2)CoL_5]/dt = k_1k_2[CoL_5]^2[O_2]/(k_{-1} + k_2[CoL_5]) \quad (129)$$

$$d[L_5Co(O_2)CoL_5]/dt = k_1[CoL_5][O_2] \quad (130)$$

A recent kinetic study has monitored oxygenation of the primary Co^{II} photoproduct produced following flash photolysis of *cis*-$[Co(NO_2)_2(en_2]^+$ in air-saturated acetonitrile solution.[731]

Hyde and Sykes[732] have carried out a detailed study of the Cr^{II} reduction of $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{3+}$. The reaction proceeds in five identifiable stages; the first involving inner-sphere attack by Cr^{2+} on the peroxo bridge to give a Cr^{III}—$(O_2)^{2-}$—Co^{III} species. The stepwise reduction is complicated, with isomerization and decomposition being involved in the intermediate stages before final Cr^{2+} reduction of the Co^{III} centre. The Fe^{2+} reduction of $[(N_4)Co(\mu\text{-}OH,O_2)Co(N_4)]^{3+}$ ions in acidic solution is slower than hydrolysis of the OH bridge, and the previously reported Fe^{2+} reduction of the doubly bridged species[733] has been shown to be in error.[734]



Fallab[735] has shown that reaction of I^- with $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$ gives $[Co(en)_2(OH_2)]^{3+}$ and I_2 in acidic solution. Hydrolysis of the OH bridging group is followed by I^- attack on the mono-bridged species. The latter process is related to that occurring when I^- reacts with $[(N_4)Co(\mu\text{-}NH_2,O_2)Co(N_4)]^{3+}$ ions to produce $[(N_4)Co(\mu\text{-}NH_2,OH)Co(N_4)]^{4+}$ species,[736] and to the Cl^-- or Br^--catalyzed disproportionation of the μ-amido-μ-peroxo complexes to produce the correspond-

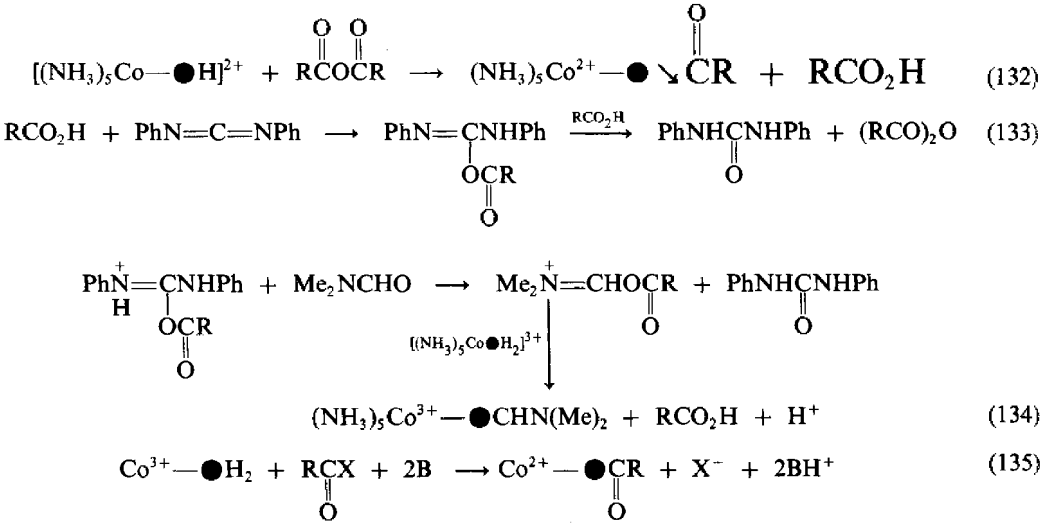
ing μ-amido-μ-hydroxo and μ-amido-μ-superoxo species.[737] In those systems it is likely that the reactive form of the complex is the hydroperoxo species, which undergoes initial attack by halide ion at the non-bridging oxygen atom (Scheme 71). Sulfite and nitrite ions with $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{3+}$ give respectively $[(en)_2Co(\mu\text{-}NH_2,SO_4)Co(en)_2]^{3+}$ and $[(en)_2Co(\mu\text{-}NH_2,NO_2)Co(en)_2]^{4+}$.[738]

Scheme 71

Reduction potentials for μ-superoxo/μ-peroxo–cobalt(III) couples have recently been obtained by cyclic voltammetry.[739,740] Decomposition or dissociation of one or the other of the components of the couple, which frustrated measurements by other techniques, may be overcome by the use of fast scan rates. Protonation of the μ-peroxo group stabilizes the complex and $E^{\ominus}$ values are pH dependent below pH 3. A similar stabilization on protonation of the peroxo bridge has been noted in the Cr^{2+}-, V^{2+}- and Eu^{2+}-promoted reduction[705] of the $[(NH_3)_5Co(O_2)Co(NH_3)_5]^{4+}$ ion. The protonated species has $K_a \sim 10\,dm^3\,mol^{-1}$ at 25 °C.[705]

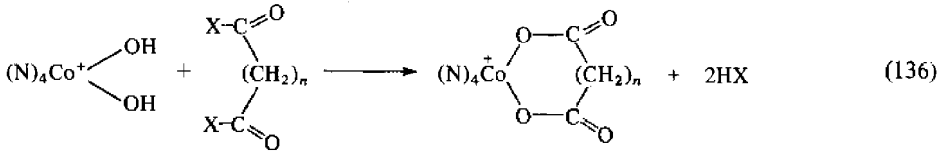
Dimeric cobalt porphyrins linked at the porphyrin periphery to provide a cofacial configuration, and capable of forming μ-bridged oxygen adducts, have been reported.[742,743] Chang[742] demonstrated that peroxo-bridge formation occurred on exposure of a dicobalt porphyrin to dioxygen and that the μ-peroxo complex was readily oxidized to the corresponding μ-superoxo species. More recently, Collman's group[743] has investigated electroreducing properties of a number of dicobalt porphyrins bound to graphite electrodes in acidic aqueous solution. Electroreduction of O_2 to H_2O_2 or H_2O is observed in all cases with the mode of catalytic activity being dependent on the degree of separation of the two Co centres. One possible mechanism for the four-electron reduction of dioxygen to water in this system is shown in (Scheme 72), but it should be emphasized that bridging dioxygen species have not been directly observed in this process.

Scheme 72



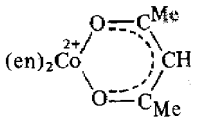
47.7.2 Carboxylates

47.7.2.1 Synthesis, cobalt(III)



Until recently the heating of Co—OH_2^{n+} species with RCO_2H or RCO_2Na in neutral aqueous solution, first used by Gibbs and Genth,[744] was the recognized method of preparation. Gould,[745–747] following earlier work by Sebra and Taube,[74] prepared numerous $[Co(OCOR)(NH_3)_5]^{2+}$ ions by this method (equation 131). Some improvement is possible using $[Co(DMF)(NH_3)_5](ClO_4)_3$ or $[Co(DMSO)(NH_3)_5](ClO_4)_3$ in DMF or DMSO, by using $[Co(OH_2)(NH_3)_5](ClO_4)_3$ in ethylene glycol, and by using $[Co(OCO_2)(NH_3)_5](NO_3)$ in diglyme[746] or methanol.[747] The Ag^+-induced removal of Cl^- from $[CoCl(NH_3)_5]Cl_2$ or *cis*-$[Co(Cl)_2(en)_2](ClO_4)$ in MeOH at room temperature[750,751] is another possibility but is not recommended.

$$[Co(OH_2)_{6-x}(amine)_x]^{3+} + RCO_2^- \longrightarrow [Co(OCOR)_{6-x}(amine)_x]^{(3-x)+} + (6-x)H_2O \quad (131)$$



The new method, rediscovered by Jackman, Scott and Portman,[752] originates with Werner who prepared $[Co(OCOR)(NH_3)_5](NO_3)_2$ (R = Me, Et) using a heterogeneous mixture of solid $[Co(OH)(NH_3)_5](NO_3)_2$ and the appropriate anhydride (equation 132).[753] Jackman and coworkers use non-aqueous conditions and have extended the reaction to include a large number of acid anhydrides, with the hydroxo complex being generated *in situ* by adding the sterically hindered base $N(Me)_2Bz$.[754] The rate law for reaction (132) in aqueous solution takes the form $k_{obs} = kK_a[Co]_T/(K_a + [H^+])$, which is consistent with Co—OH^{2+} being the reactive species (K_a = acidity constant for Co—OH_2^{3+}). The reaction is normally quite fast ($k = 3.1\,mol^{-1}\,dm^3\,s^{-1}$ for R = Et, 25 °C $I = 1.0$) and ^{18}O tracer experiments confirm that the oxygen atom in the coordinated carboxylate derives from the hydroxo ligand.[755] The difficulty with using aqueous solutions in a preparative sense is the ready hydrolysis of many anhydrides. In non-aqueous solvents (DMF, DMSO, $(MeO)_3PO$) the anhydride can often be generated *in situ* from the parent acid (equation 133), but in DMF it is important to generate the Co—OH species before adding RCO_2H (*i.e.* add the sterically hindered base before adding RCO_2H) otherwise Co—DMF^{3+} is formed in rather large amounts (equation 134).[756] Such side reactions can also be fast and occur *via* nucleophilic attack of Co—OH at the unsaturated C centre.[757] This new preparative method has general utility since any acyl compound with a good leaving group can be used (equation 135). This probably includes dicarboxylic acid species (monodentate or bidentate) but such preparations (equation 136) have not been examined in detail. However chelated acetylacetonate (**210**) has been prepared in this manner.[758] The recent preparations of *cis*- and *trans*-$[Co(NO_2)(OC_2O_3)(en)_2]$ uses displacement of the aqua ligand by $C_2O_4^{2-}$.[169]

$X = Cl^-, PhO^-, p\text{-}NO_2C_6H_4O^-, RCO_2^-$; B = NEt_3, or similar non-nucleophilic base

$X = Cl^-, p\text{-}NO_2C_6H_4O^-$

(210)

47.7.2.2 Monocarboxylates

(*i*) *Formato, cobalt(I)*

The reaction of CO_2 with $[CoH(N_2)(PPh_3)_3]$ or $[Co(H)_3(PPh_3)_3]$ in benzene containing excess phosphine leads to the green formato complex $[Co(O_2CH)(PPh_3)_3]$.[409] In the absence of excess ligand only brown $[Co(CO)(PPh_3)_3]$ and a cobalt(II) formate species, which converts to $Co(HCOO)_2 \cdot 2H_2O$ on exposure to moist air, are formed. Attempts to insert CO_2 into the Co—H bonds of $[CoH(dppe)_2]$ and $[CoH(dppv)_2]$ lead to poorly defined products which release CO_2 on treatment with H_2SO_4 and which do not contain coordinated formate.[759] By contrast, $[CoH(N_2)(RR'_2P)_3]$ and $[Co(H)_3(RR'_2P)_3]$ (R = Et, R′ = Ph; R = Ph, R′ = Et) both give formate complexes on treatment with CO_2. These are less stable than the corresponding PPh_3 complexes but few experimental details are available. $[CoH(PMe_2Ph)_4]$ does not react with CO_2 in the solid state but in benzene solution it takes up CO_2 reversibly to give $[Co(O_2CH)(PMe_2Ph)_3]$.[760] This has antisymmetric and symmetric vibrations of the CoOCHO group at 1610 and 1360 cm^{-1}. A general scheme for the insertion of CO_2 into Co—H bonds involving initial formation of cobalt–carbon dioxide adducts has been proposed (Scheme 73).[760]

$$[CoH(L)_4] + CO_2 \rightleftharpoons [CoH(CO_2)(L)_3] + L$$

$$[CoH(CO_2)(L)_3] \rightleftharpoons [Co(OCHO)(L)_3]$$

Scheme 73

(*ii*) *Formato, cobalt(III)*

$[Co(O_2CH)(NH_3)_5](ClO_4)_2$ containing O-bonded formate has been prepared *via* $[Co(OH_2)(NH_3)_5](ClO_4)_3$ (pink, ε_{500} 69.6),[761] but it can undoubtedly be made *via* $[Co(OH)(NH_3)_5]^{2+}$ and MeO_2CH (equation 135), or by using $[Co(DMSO)(NH_3)_5](ClO_4)_3$ and NaO_2CH. The carbonyl O undergoes H^+-catalyzed exchange, $k = 6.2 \times 10^{-5}$ mol^{-1} dm^3 s^{-1},[762] but the complex is quite stable in aqueous solution (Table 59). The *cis*-$[Co(O_2CH)(H_2O)(en)_2]^{2+}$ ion has been reported in aqueous solution (λ_{max} 300, 500 nm).[761]

Major interest lies in the oxidation of Co^{III}—OC(O)H species to CO_2, its use in electron transfer, and its photochemistry. Candlin and Halpern showed that oxidation by MnO_4^- (1.0–0.1 mol dm^{-3} H^+, ~0 °C) followed the rate law $k_{obs} = k[MnO_4^-]$ ($k = 2.5 \times 10^{-2}$ mol^{-1} dm^3 s^{-1}) but with the $[Co(NH_3)_5(OH_2)]^{3+}$ product showing an additional $[MnO_4^-]$ dependence over the less abundant $Co^{2+}_{(aq)}$ product (ratio ≈ 3.5 in 10^{-2} mol dm^{-3} MnO_4^-).[763] This was interpreted in terms of Scheme 74 with the primary act being H atom abstraction to give the formate radical anion (**211**). Presumably the k_2 path leads to Co^{III}—O=C=O or Co^{III}—CO_2, which rapidly aquates. More recently Brezniak and Hoffman generated (but did not directly observe) the same radical intermediate (**211**) using pulse radiolysis methods with H atom abstraction by HO· and H·.[764] Only $Co^{2+}_{(aq)}$ was observed in this study ($k \sim 2 \times 10^9$ mol^{-1} dm^3 s^{-1}) and using an estimate of $k_3 > 10^6$ s^{-1} for the electron-tunnelling process (equation 137) they estimate k_2 of Scheme 74 as $> 3 \times 10^8$ mol^{-1} dm^3 s^{-1}. Clearly the CO_2^- radical coordinated to Co^{III} is a powerful reducing agent. Photolysis at 254 nm also leads to $Co^{2+}_{(aq)}$ and CO_2 (also H_2 by a secondary process),[761] and a long-lived intermediate, assigned as the C-bonded formato isomer (**212**; Scheme 75), has been characterized.[765] This species is attributed to a pathway involving ligand excitation (Scheme 75) and has a $pK_a = 2.6$. It is much more stable than the radical anion, existing for at least one minute in acidic solution but more rapidly decaying at pH 5 (~50 s^{-1}).[765]

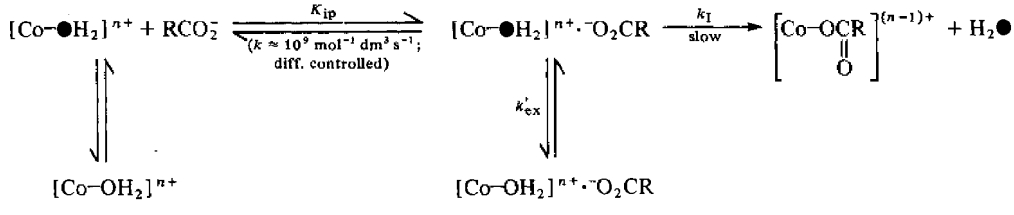
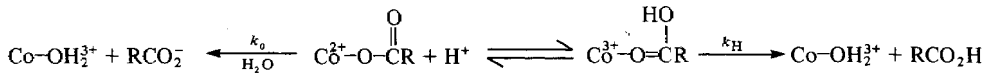
(*iii*) *Alkyl and aryl monocarboxylates, cobalt(III)*

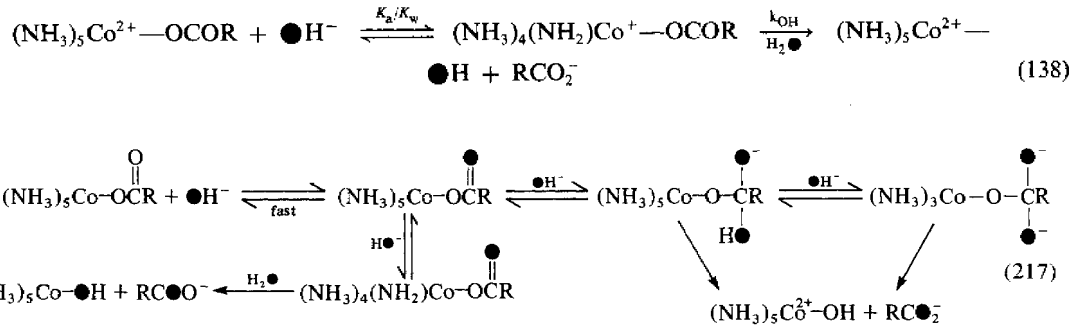


Both monomeric (**213**), chelated (**214**) and bridged dimeric (**215**) and (**216**) complexes are known. The latter were first prepared by Werner[689] and in the last decade have received some attention in relation to remote attack and outer-sphere electron transfer (see below). The monomeric complexes

Scheme 75

(**213**) are very abundant and simple to prepare (Section 47.7.2.1). Formation *via* anation of Co—OH_2^{n+} by RCO_2H or RCO_2^- is slow and occurs *via* displacement of coordinated water (Scheme 76). Table 43 contains some recent kinetic data and extensive compilations are to be found elsewhere.[772,773] Saturation kinetics are often encountered, $k_{obs} = k_I K_{ip}[RCO_2^-]/(1 + K_{ip}[RCO_2^-])$, with rate-determining substitution from within the ion pair (the alternative possibility of non-reactivity of the ion pair would be counter productive).[771] A dissociative mechanism is implied since k_I bears some resemblance to the water-exchange rate and has never been known to exceed it, but whether a totally dissociative process is involved within the ion pair with the five-coordinate intermediate existing long enough for unfavourably positioned ions to reorient themselves is not known.



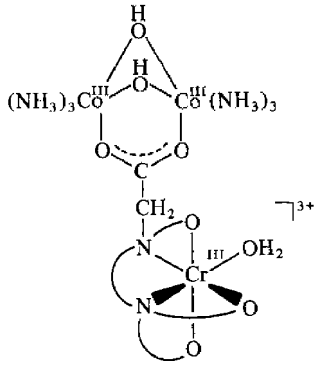


Scheme 76

The reverse hydrolysis in acidic to neutral solution often follows the rate law $k_{obs} = k_0 + k_H[H^+]$ and the reaction is again very slow; usually such studies are carried out at elevated temperatures. Table 59 contains some relevant data and extensive compilations are available.[772,773] k_H is regarded as solvolysis of the protonated substrate (Scheme 77) and represents the reverse of the anation by RCO_2H. Acid-catalyzed O exchange into the coordinated acyl function is generally slower than hydrolysis except for electronegative R (H, CF_3, CO_2H) where it is faster.[762] However, Jackman and coworkers have found intramolecular scrambling between the O atoms in $[Co\{OC(O)Me\}(NH_3)_5]Y_2$ both in solid and in solution.[757] In the solid it is about one-third complete in 90 d at 23 °C, and is two-thirds complete after 15 min at 50 °C in aqueous solution. It is not known whether this process is H^+- or OH^--catalyzed[774] and it may well resemble Co—SCN/Co—NCS isomerization (Section 47.4.4.1). O scrambling has not been observed in chelate complexes of type (**214**), probably because rotation about the acyl function is now more difficult. Alkaline hydrolysis is also slow, but is faster than acid hydrolysis; it follows the rate law $k_{obs} = k_{OH}[OH^-]$ in most complexes (Table 59). An S_N1cb mechanism is generally accepted with aquation of the amine-deprotonated conjugate and cleavage of the Co—O bond (equation 138).[772,773] For some electronegative R (CF_3, CCl_3, $CHCl_2$, CO_2^-) $k_{obs} = k_{OH}[OH^-] + k'_{OH}[OH^-]^2$ with OH^- attack at the acyl function and both Co—O and CoO—C bond cleavage, the latter *via* the deprotonated addition intermediate (**217**; Scheme

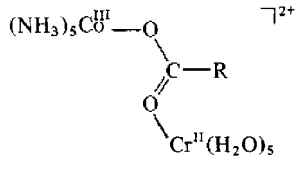
78).[774–776] OH^--catalyzed exchange of carbonyl oxygen is generally slower than alkaline hydrolysis for most alkyl groups with monodentate systems,[777] but for the above electronegative species it is comparable.[774,775]

Scheme 77



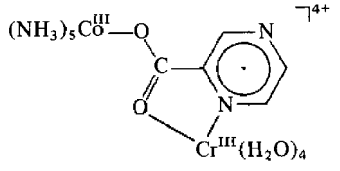
(138)

(217)



Scheme 78

The bridged complexes (**215**) and (**216**) are generally prepared from μ-(OH) species (Table 60).[781] Thus the rate law for the formation of $[\{Co(NH_3)_4\}_2(\mu\text{-}NH_2,O_2CMe)]^{4+}$ in the $[H^+]$ range 0.1–1.5 takes the form $k_{obs} = (k_1 + k_2[H^+])[MeCO_2H]$ with $k_1 = 1.4 \times 10^{-6}\,mol^{-1}\,dm^3\,s^{-1}$, $k_2 = 6.5 \times 10^{-6}\,mol^{-2}\,dm^6\,s^{-1}$ at 25 °C.[768] Initial anation at one Co^{III} centre is considered to be rate determining with rapid subsequent bridging. Protonation of the bridging μ-(OH) also plays a part. The reverse hydrolysis is also H^+-catalyzed and is somewhat slower.[768] Recently the novel $Co_2^{III}Cr^{III}$ complex (**218**) has been reported[767] and obvious extensions are possible.



Carboxylate–Co^{III} systems have been extensively used to study electron transfer. Taube and Gould pioneered this work and have remained major contributors.[270,748] A recent review by Pennington is recommended,[769] and articles by Haim (bridged activated complexes), Meyer (excited state), Sutin (theory), Endicott (structural and photochemical probes), Ford, Wink and DiBenedetto (photochemical), Espenson (free radical) and Creutz (mixed valence complexes) in a volume dedicated to Taube[770] provides up-to-date background. Inner-sphere paths using a Cr^{2+} reductant probably proceed *via* an intermediate such as (**219**), while if R contains a coordination centre then radical intermediates such as (**220**) have been observed.[778] The same or similar reduced-ligand intermediates have also been directly generated *via* pulse-radiolysis studies.[779,780] With bridged carboxylates (**216**), an outer-sphere mechanism is more likely since both oxygens are already coordinated but if R contains an available coordination site then bridged intermediates are again observed and are probably the reactive entity.[360] Other reductants, such as the photoexcited $[Ru(bipy)_3^*]^{2+}$ species, are thought to act by both outer-sphere and ligand-reduced inner-sphere mechanisms.[782]

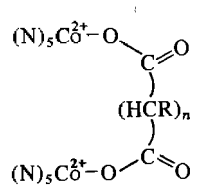
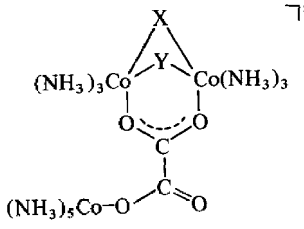
47.7.2.3 Dicarboxylates, cobalt(III)



As well as regular monodentate complexes (**213**), R = $(CH_2)_nCO_2H$, two types of chelate have been prepared (**221**) and (**222**), and one other bidentate (**223**). Some preparations are given in Table 60 and some structures in Table 61. The extended dimeric complexes (**223**) were first reported by Duff[804] and his method has been recently improved and extended to include a number of symmetrical systems,[805] but asymmetric or heterometal complexes are possible. Sykes and coworkers have prepared μ-bridged chelated oxalato complexes of type (**226**) but also including (**224**) and (**225**) (X, Y = NH_2, OH).[806] Wieghardt has made similar complexes with other dicarboxylic acids[807] and Nishide and Saito some related oxalato and carbonato complexes containing 2-aminopropanol.[808] Complex (**226**) aquates slowly to the ring-opened species $[(NH_3)_5CoOCOCOOCo(NH_3)_4(H_2O)]^{4+}$ in 1.0 mol dm^{-3} $HClO_4$, and this is representative of others.



(221)

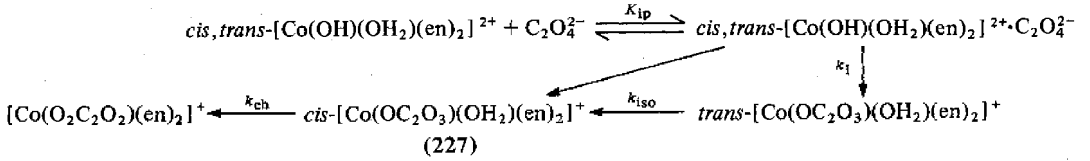
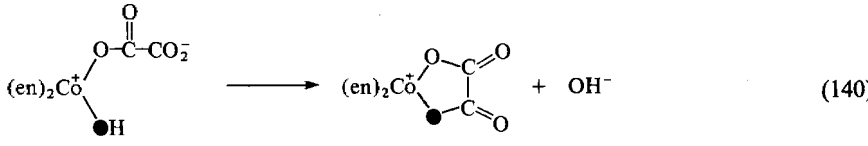
(225)



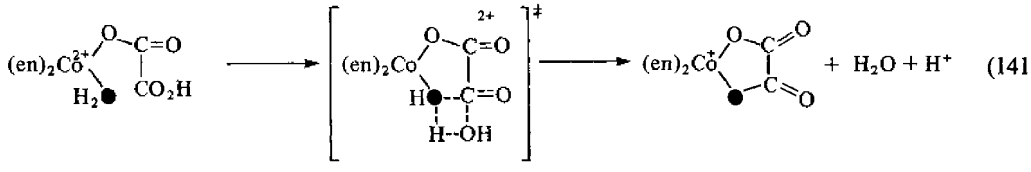
(226)

Simple bidentate chelates (**221**) have been extensively studied. Their formation *via* anation of *cis*-$Co(OH_2)_2^{n+}$ systems is slow (Table 60), but saturation rates consistent with the intervention of ion pairs (Scheme 76) are observed, especially with $C_2O_4^{2-}$.[783] Both monodentate and bidentate coordination are possible. With $[Co(OH_2)(N)_5]^{3+}$ and oxalate $[Co(OC_2O_3H)(N)_5]^{2+}$ is formed [(N)$_5$ = $(NH_3)_5$,[784] $(en)_2(NH_3)$].[785] With *cis*-$[Co(OH_2)_2(N)_4]^{3+}$ the chelate $[Co\{O_2C_2(CH_2)_n\}(NH_3)_4]^+$ is the final outcome but intermediate monodentate carboxylates $[Co\{OCO(CH_2)_nCO_2\}(N)_4(OH_2)]^+$ become increasingly stable as the subsequent chelation step slows down. This occurs with increasing ring size ($n > 1$) and steric requirement.[792] With $H_2C_2O_4$ and $HC_2O_4^-$ biphasic kinetics are not observed however (*cis*-$[Co(H_2O)_2(en)_2]^{3+}$,[786,787] *cis*-$[Co(OH_2)_2(NH_3)_4]^{3+}$,[788] pH < 1) and $[Co(O_2C_2O_2)(N)_4]^+$ appears to be the only observed product (equation 139). In 2.0 mol dm^{-3} H^+ marked catalysis by NO_3^- has been found,[787,789,790] but this is not apparent with $[Co(OH_2)(N)_5]^{3+}$. The effect is not understood and marked H^+ catalysis is also involved.[791] Possible decomposition products such as HNO_2, N_2O_3 or $H_2NO_2^+$ may be formed under the acid conditions and elevated temperatures (50–70 °C) or the water-exchange rate (k_{ex}, k'_{ex}; Scheme 76) may be increased by the presence of nitrate species. A biphasic reaction is however found with $C_2O_4^{2-}$ in the pH range 3–7 ($[Co(OH)(H_2O)(en)_2]^{2+}$,[793] *cis*-$[Co(H_2O)_2(NH_3)_4]^{3+}$).[794] For $[Co(OH)(H_2O)(en)_2]^{2+}$ water exchange has been increased significantly over that for $[Co(H_2O)_2(en)_2]^{3+}$ and the resulting increased anation rate for both *cis* and *trans* reactants leads to *cis*- and *trans*-$[Co(OC_2O_3)(OH_2)(en)_2]^+$ intermediates (Scheme 79).[793] These intermediates have been recovered and studied independently with the *trans* isomer isomerizing to *cis* ($k_{iso} = 8 \times 10^{-6}\,s^{-1}$) before chelating ($k_{ch} = 4.6 \times 10^{-5}\,s^{-1}$).[795] An ^{18}O tracer study has shown that chelation in the *cis* monodentate (**227**) proceeds partly (~30–40%) *via* attack by coordinated water, while *cis*-$[Co(OC_2O_3)(OH)(en)_2]$ reacts entirely by this path (equation 140).[796] Under acidic conditions (pH < 2) the cyclization of *cis*-$[Co(OC_2O_3H)(en)_2]^{2+}$ has increased three-fold over that at pH 5 and



the reaction is also believed to occur exclusively *via* intramolecular oxygen exchange at the carboxyl centre rather than at the metal (equation 141).[796]

$$[Co(OH_2)_2(N)_4]^{3+} + H_2C_2O_4/HC_2O_4^- \overset{K_{ip}}{\rightleftharpoons} [Co(OH_2)_2(N)_4]^{3+}\cdot H_2C_2O_4/HC_2O_4^- \xrightarrow[slow]{k_1} [Co(O_2C_2O_2)(N)_4]^+ + 2H_2O + 2H^+ \quad (139)$$



(227)

Scheme 79

(140)

(141)

Both monodentate and chelated oxalato complexes undergo H^+- and OH^--catalyzed exchange of O atoms. For $[Co(OC_2O_3/H)(NH_3)_5]^{+,2+}$ this is faster (H^+) or comparable (OH^-) with hydrolysis of the complex, while for $[Co(O_2C_2O_2)(en)_2]^+$ the two exocyclic O atoms exchange much faster than chelate ring opening. Some O-exchange data are given in (Table 62).

Hydrolysis of chelated oxalate and malonate is very slow and both systems can be considered inert at ambient temperatures. There is no report of H^+- or M^{n+}-catalyzed ring opening; there is no easy point of attachment of the catalyst in such systems. Acid hydrolysis of monodentate complexes at elevated temperatures (Table 59) often follows the rate law $k_{obs} = k_1 + k_2[H^+]$ with k_2 corresponding to hydrolysis of $[Co\{OC(O)(CH_2)_nCO_2H\}(N)_5]^{2+}$. The acid-catalyzed pathway becomes less important with increasing n.[797,798] Metal ions (Fe^{3+}, Al^{3+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Mn^{2+}) catalyze the reaction in the same manner by coordinating to the free carboxylate function.[799,803] Dash and Harris have studied this initial rapid binding of Fe^{3+} species to $[Co(OC_2O_3)(NH_3)_5]^+$.[800]

Alkaline hydrolysis is somewhat faster and generally follows the rate law $k_{obs} = k_{OH}[OH^-] + k'_{OH}[OH^-]^2$, although sometimes k'_{OH} is not observed (Table 59). For $[Co(OC_2O_3)(NH_3)_5]^+$, k_{OH} corresponds to Co—O and k'_{OH} to C—O bond cleavage.[776] Dash and

coworkers have carried out a number of kinetic studies.[801] For chelated $[Co(O_2C_2O_2)(en)_2]^+$, Andrade and Taube showed that close to three O atoms had exchanged on complete alkaline hydrolysis[775] and recent studies by Buckingham and coworkers have demonstrated that two of these exchange rapidly in the chelate before hydrolysis, and that both the k_{OH} and k'_{OH} paths for chelate cleavage occur with substantial (60% and 100% respectively) C—O bond fission (Scheme 80). The subsequent hydrolysis of the monodentate *cis* hydroxo product occurs entirely *via* Co—O bond cleavage.[796] Similar mechanisms have been suggested for the alkaline hydrolysis of other chelated dicarboxylate complexes.[802]

Scheme 80

The photochemistry of Co^{III} oxalate complexes was studied and reviewed at an early stage.[809] Thermally unstable green $K_3[Co(O_2C_2O_2)_3]$ and $K[Co(O_2C_2O_2)_2en]$ undergo photoredox decay both in solution and in the solid with the $C_2O_4^-$ radical being a major product (Scheme 81). An intermediate bidentate oxalate radical coordinated to high-spin Co^{II} (**228**) has been identified.[813] Endicott and coworkers have shown by studying the photolysis of monodentate $[Co(OC_2O_3)(NH_3)_5]^+$ and chelated $[Co(O_2C_2O_2)(en)_2]^+$ that an additional pathway exists (Scheme 82) whereby excitation results in heterocyclic C—C cleavage and the formation of CO_2 and a C-bonded formato complex of Co^{III} (**229**);[812] this latter species spontaneously decays *via* internal electron transfer to $Co^{2+}_{(aq)}$ and $\cdot CO_2H$ or CO_2^- radicals. More stable Co^{II} products are formed in the photolysis of $[Co(O_2C_2O_2)(N—N)_2]X$ (N—N = phen, bipy), with $[Co(O_2C_2O_2)(N—N)_2]$ and $[Co(X)_2(N—N)_2]$ being identified.[810] Some MO calculations on these latter systems have been described.[811]

$$[Co(O_2C_2O_2)_3]^{3-} \underset{}{\overset{h\nu}{\rightleftharpoons}} \underset{(228)}{[Co^{II}(O_2C_2O_2\cdot)(O_2C_2O_2)_2]^{3-}} \longrightarrow [Co(O_2C_2O_2)_2]^{2-} + C_2O_4^-$$

$$[Co(O_2C_2O_2)_3]^{3-} + C_2O_4^- \longrightarrow [Co(O_2C_2O_2)_2]^{2-} + C_2O_4^{2-} + 2CO_2$$

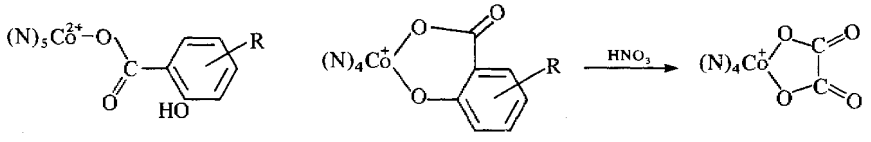


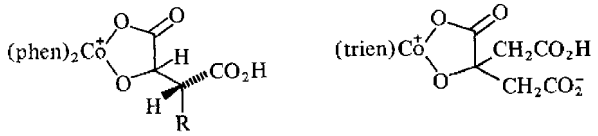
Scheme 82

47.7.2.4 Hydroxycarboxylates: cobalt(III)

(*i*) *Salicylate*

The formation and hydrolysis of monodentate salicylate complexes (**230**) parallels other carboxylates (Tables 60 and 59, respectively). Metal-ion-accelerated hydrolysis (Fe^{3+} species,[814]

Al^{3+}[815]) is also found, and a pathway *via* the phenolate anion ($pK_a \sim 11.2$) exists for both aquation and alkaline hydrolysis.[816] Chelated salicylates (**231**) are known [$(N)_4 = (NH_3)_4$, $(en)_2$, β-(trien)] and $[Co(sal)(en)_2]^+$ has been resolved into enantiomeric forms (Table 60). These chelates are very stable in aqueous solution and hydrolysis is very difficult. O-exchange studies do not appear to have been carried out. Garbett and Gillard have noted an interesting oxidation–decarboxylation of $(-)_{589}$-$[Co(sal)(en)_2]^+$ in concentrated HNO_3 in which the five-membered oxalate chelate (**232**) is formed in ~90% yield together with picric acid.[817] Nitration of the chelate precedes ring oxidation and Yamamoto and coworkers have carried out an extensive study on the green nitro product first noted by Morgan and Smith.[818] Green $[Co(5\text{-}NO_2sal)(N)_4]^{2+}$ is paramagnetic ($\mu = 1.6$–1.9 BM) and appears to be formed during the nitration since similar treatment of authentic orange $[Co(5\text{-}NO_2sal)(NH_3)_4]^+$ does not appear to lead to the paramagnetic species.[819] Yamamoto has investigated a number of such systems [$(N)_4 = (NH_3)_4$, $(en)_2$, (trien), $(phen)_2$] and has shown that the related nitroso species $[Co(5\text{-}NOsal)(NH_3)_4]^+$ and its brown paramagnetic oxidation product $[Co(5\text{-}NOsal)(NH_3)_4]^{2+}$ are not formed as intermediates in the nitration process.[817,820] Photoelectron spectroscopy indicates substantial ligand as opposed to metal oxidation.[820,821]



(230) (231) (232)

(*ii*) *Tartrate, malate and citrate*

Some preparations using these hydroxy acids are given in Table 60 and some structures are listed in Table 61.

An early report[822] of the stereospecific reaction between (*R*)(+)-tartaric or (*R*)(+)-malic acid and $[Co(CO_3)(phen)_2]Cl$ at ambient temperature has been refuted and both Δ- and Λ-$[Co\{(R)L\}(phen)_2]^+$ ions (**233**) are formed.[823,824] The distribution ratio $\Delta(R)/\Lambda(R) = 0.38$ for the (*R*)-tartrate complex. Using $[Co(Cl)_2(phen)_2]Cl$ at 60 °C and Na(+)-tartrate the ratio is 0.70, but thermodynamic distributions remain unknown. Δ(*R*) and Λ(*R*) diastereoisomers of both acids have recently been isolated and characterized by CD and 360 MHz ^1H NMR.[825] The reaction of *meso*-tartaric acid results in four diastereoisomeric possibilities (depending on which asymmetric carbon is in the chelate ring) and all four have been separated ($\Delta(S)R$:$\Lambda(S)R$:$\Delta(R)S$:$\Lambda(R)S$ = 26:24:27:23).[824] From these results it appears likely that the reported stereospecific reaction of $[Co(CO_3)(en)_2]Cl$ with (*S*)(−)-tartaric acid resulting in only Λ-$[Co\{(S)tart\}(en)_2]Cl$[826] is in error. The reaction of sodium citrate with $[Co(Cl)_2(trien)]Cl$ also leads to a preference for the five-membered chelate involving the hydroxyl group (**234**) as has recently been shown by a crystal structure of β-$[Co(cit)(trien)]\cdot 5H_2O$.[827]

R = H [(*R*)-mal]

(234)

47.7.2.5 Tridentates and quadridentates, cobalt(III)

Variations in ligand type and geometrical configuration provide an almost endless array of possibilities, and far too many to consider here. Bernauer[828] considers such possibilities and some recent preparations are given in Table 63, and crystal structures in Table 61.

Main interest centres on correlating alterations in stereochemistry with CD and ^1H NMR spectra, and $[Co(edda)XY]^{n+}$ systems figure prominently in this regard. An early review is available[829] and a selected study[830] may be consulted. $Na[Co(edda)(CO_3)]$ serves as a good starting material for many

complexes.[831] The potential tri- and quadri-dentate hydroxy acids (malic, tartaric and citric) show bidentate chelation and are considered in Section 47.7.2.4.(ii).

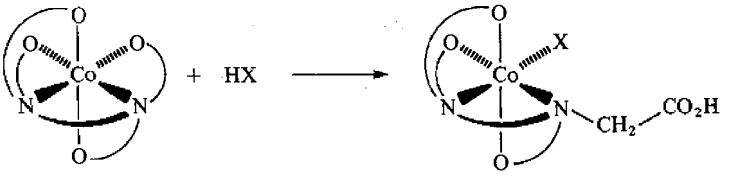
47.7.2.6 Quinquedentates and sexidentates, cobalt(III)

Brintzinger, Thiele and Muller appear to have been the first to prepare a sexidentate polycarboxylate cobalt(III) complex when they reported $Na[Co(edta)]\cdot 4H_2O$.[832] The sexidentate nature of the ligand was confirmed by a crystal structure of $NH_4[Co(edta)]\cdot 2H_2O$.[833] Busch and Bailar first reported the resolution of $[Co(edta)]^-$ into its enantiomeric forms[834] and its absolute configuration (**235**) was assigned by comparisons with $K(+)_{546}$-[Co{(*R*)pdta}] (**236**) (the (*R*)-methyl substituent prefers the equatorial disposition)[835] and by its reaction with ethylenediamine, which leads to a preponderance of Λ-$(+)_{589}$-$[Co(en)_3]^{3+}$.[836] Such stereospecific effects have been discussed by Sargeson.[837] Subsequently other methods of preparation and resolution have become available and these are collected in Table 64. A crystal structure of $(-)_{546}$-$K[Co(edta)]\cdot 2H_2O$ has confirmed its enantiomeric configuration as (**235**).[838] Koine and Tanigaki report the isolation, resolution and 400 MHz ^1H NMR spectrum of $(-)_{546}$-[Co{(*R*)pdta}]$^-$ containing the axial (*R*)-methyl orientation and confirm that it is present to only 0.1% at equilibrium.[839] Similar stereospecific effects are found with [Co{(*R*,*R*)-cdta}]$^-$ containing *trans*-1,2-cyclohexanediaminetetraacetate;[835,837] oxidation of Co^{II} with H_2O_2 in the presence of excess ligand leads to a 1:2 Co^{III}:cdta complex of unknown structure.[840] Lengthening the $N—(CH_2)_n—N$ chain to $n = 4$ gives $[Co(bdta)]^-$ (Table 64) but no suitable oxidizing agent has been found for $n = 6$.[841] Proton assignments in the ^1H NMR spectrum of $[Co(edta)]^-$ have recently been confirmed by Overhauser enhancement studies.[862]

(235) $(+)_{546}$-$[Co(edta)]^-$

(236) $(+)_{546}$-[Co{(*R*)-pdta}]$^-$

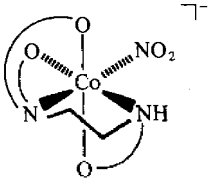
An early general account of the properties and some reactions of $[Co(Y)]^-$ (Y^{4-} = edta, pdta, cdta) has been given by Garvan,[842] and Bernauer[843] has discussed more recent stereospecific effects of related sexidentates. ^1H NMR assignments and proton exchange data are available.[844] Some reversible E° values and stability constants have been reported by Ogino and Ogino[845] and are given in Table 65. A good parallel exists between the stability of the Co^{II} and Co^{III} complexes.



The crystal structures of $NH_4[Co(edta)]\cdot 2H_2O$[833] and $(-)_{546}K[Co(tdta)]\cdot 2H_2O$[838] imply that equatorially placed acetate arms are more strained than axial ones and can be displaced to form quinquedentate complexes (**237**) containing a free carboxylic acid $[CoX(HY)]^-$ or carboxylate $[CoX(Y)]^{2-}$ residue (equation 142). Preparations exist for X = Cl^-, Br^-, NO_2^-, H_2O, OH^- (Table 64) and extension is obviously possible. Schwarzenbach[846] first reported the preparation of the quinquedentate complexes and the uncertainty in the geometrical purity of $[CoBr(Hedta)]^-$ has now been traced to the use of $CoCl_2\cdot 6H_2O$ as starting material.[847] Some have been resolved into optical isomers in their own right (Table 64) but reaction (142) occurs largely (75%; Y = edta; X = Cl^-),

Table 65 Redox and Stability Constant Data for Some Co^{II}/Co^{III} Polycarboxylate Complexes[a]

Couple	E° (mv)[b]	$\log K_{Co^{II}Y}$	$\log K_{Co^{III}Y}$
$[Co(edta)]^{-/2-}$	0.374	16.03	40.92
$[Co(tdta)]^{-/2-}$	0.295	15.39	41.70
$[Co(bdta)]^{-/2-}$	0.547[c]	15.58	37.6
$[Co(pdta)]^{-/2-}$	0.367	17.40	42.4
$[Co(m\text{-}bdta)]^{-/2-}$	0.339	16.9	42.4
$[Co(cdta)]^{-/2-}$	0.356	18.73	43.9
$[Co(Heedtra)(H_2O)]^{0/-}$	0.507	14.8	37.5



[a] Data taken from H. Ogino and K. Ogino, *Inorg. Chem.*, 1983, **22**, 2208.

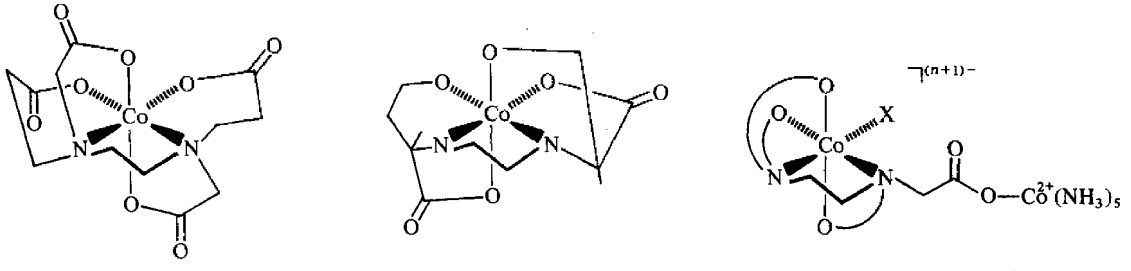
[c] 1.0 mol dm^{-3} $NaClO_4$.

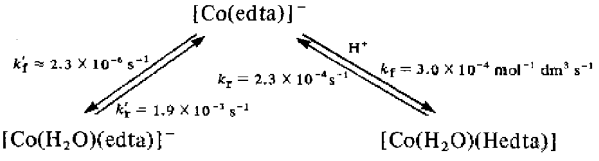
or completely (Y = pdta, cdta) with retention of absolute configuration. The exclusive disengagement of one equatorial acetate arm is suported by ^{1}H and ^{13}C NMR data[848,849] and by a structure on $K[Co(NO_2)(Hedtra)]\cdot 1.5H_2O$ (**238**).[850] However the reactions of $(+)_{546}$-$[Co(edta)]^-$ and $(-)_{546}$-$[CoX(edta)]^{2-}$ (X = Cl^-, Br^-) of the same absolute configuration with ethylenediamine to give an excess of $\Delta(-)_{589}$-$[Co(en)_3]^{3+}$,[851] and the similar reactions of $(-)_{546}$-$[Co\{(S)pdta\}]^-$ with ethylenediamine to give $\Lambda(+)_{589}$-$[Co(en)_3]^{3+}$, and with (*R*,*S*)-propylenediamine to give $\Lambda(+)_{589}$-$[Co\{(S)\text{-}pn\}_3]^{3+}$,[852] suggest that a rather specific complete unravelling occurs.[861]



(142)

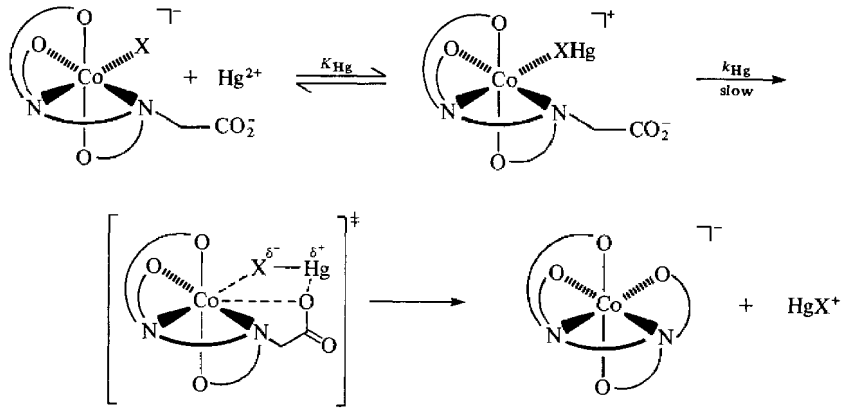
$(+)_{546}$-$[Co(Y)]^-$ (237) $(-)_{546}$-$[Co(HY)X]^-$

(238)



Including two six-membered chelates as in (**239**) appears to position these in the equatorial plane,[853] and a similar result is found in the crystal structure of the ethylenediaminedisuccinic acid (edds) complex (**240**).[854] Removal of these less-strained equatorial chelates to form quinquedentate complexes (equation 142) appears to be difficult. Substitution of methyl groups on two of the acetate arms seems to force these into axial positions.[855] The free acetate arms of $[CoX(edta)]^{n-}$ (X = H_2O, NH_3, NO_2^-) can coordinate to other metal ions and (**241**) has been prepared.

(239) Δ-$[Co(eddda)]^-$ (240) Λ-$[Co\{(S,S)\text{-}edds\}]^-$ (241)



Higginson and coworkers[856] have investigated the rates and equilibria of ring closure and have shown that protonation of the acetate arm (pK_a = 3.1) results in considerable stabilization of the quinquedentate chelate (> 50% in 1.0 mol dm^{-3} H^+). A related equilibrium is found with the *N*-hydroxyethyl derivative.[857] The faster chelation rate for the anion (k_r') compared to the protonated carboxylic acid (k_r; Scheme 83) was considered to demonstrate anchimeric assistance in removing the coordinated water molecule. However the corresponding rates for $[Co(H_2O)(cdta)]^-$ and $[Co(H_2O)(Hcdta)]$ are 7×10^{-4} s^{-1} and 1.6×10^{-2} s^{-1},[857] which is contrary to the above interpretation; a change in mechanism is possible. Some relevant data are given in Table 66. Spontaneous halide removal from $[CoX(HY)]^-$ and $[CoX(Y)]^{2-}$ (X = Cl^-, Br^-) in aqueous solution is slower than chelation of the aqua complex so that a decision as to whether the immediate product is $[Co(H_2O)(Y)]^-$ or $[Co(Y)]^-$ cannot be made. However studies by Wilkins and coworkers using quinquedentates which do not contain a free carboxylate arm and hence must form $[Co(H_2O)(Y)]$ suggest that the sexidentate $[Co(Y)]^-$ is the immediate product in the aquation with loss of X^- being assisted by the carboxylate arm in some fashion (Table 66).[858] Many M^{2+} and some M^{3+} ions catalyze the removal of Cl^-, and for Hg^{2+} and Ag^+ the induced reactions lead directly to

the coordinated carboxylate with full retention of configuration (*i.e.* $[Co(H_2O)(Y)]^-$ is not formed). Higginson and coworkers relate the relative abilities of M^{2+} (M^{3+}) to bind the carboxylate and coordinated halide in $[CoX(Y)]^{2-}$ with assistance from both being considered important (Scheme 84).[859,860] With Hg^{2+} and several M^{3+} ions (In^{3+}, Sc^{3+}, La^{3+}) limiting rates of reaction were observed with K_{Hg} being independent of protonation of the carboxylate residue but with k_{Hg} being considerably faster for the anion. This suggests strong binding to chloride in an equilibrium sense but with assistance in its subsequent removal by carboxylate.

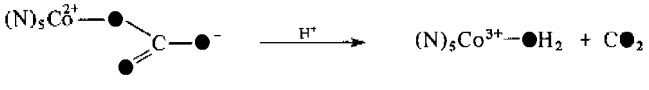
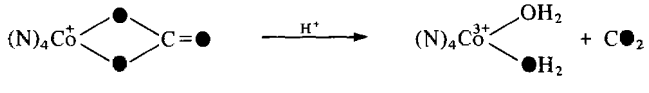
Rates and mechanisms for the reduction of $[Co(edta)]^-$, $[Co(H_2O)(Hedta)]$, $[CoX(edta)]^{2-}$, $[Co(edta)(NH_3)_5]^-$ and $[Co(NH_3)_5\{Co(edta)(H_2O)\}]^{2+}$ by Cr^{2+}, Fe^{2+}, $Fe(CN)_6^{4-}$, $Ru(NH_3)_6^{2+}$ and Ti^{3+} have been investigated by many research workers and an article by Pennington[769] is recommended for background reading. Recent studies by Ogino and coworkers[866,867,868] and by Marec and Orhanovic[869] are also relevant.

The photochemistry of $[Co(edta)]^-$ and $[CoX(Hedta)]^-$ has been investigated by Natarajan and Endicott.[864] Besides a small amount of photoaquation the limiting yields of Co^{2+}_{aq} and CO_2 differ ($\phi_{Co} = 0.025, 0.14$) but for the quinquedentate complex ϕ_{Co} is nearly independent of X ($X = Cl^-$, Br^-, NO_2^-) over the excitation range 300 nm $> \lambda \geqslant$ 229 nm. This suggests a rapid thermal equilibration between singlet excited states with rate-determining competitive formation of products and unreactive reactant states of lower energy.[865]



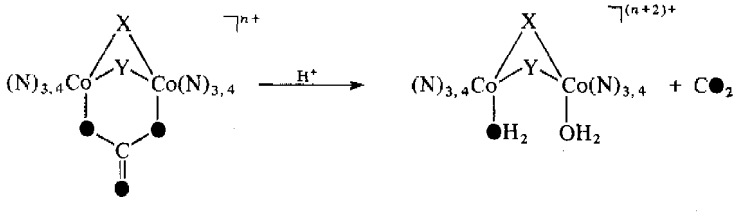
47.7.3 Carbonate

47.7.3.1 Cobalt(II)



Few well-defined Co^{II}–carbonate complexes are known. The two structures given in Table 68 are probably representative of chelated and monodentate carbonate. $K_2[Co(CO_3)_2(H_2O)_4]$ crystallizes as rose-coloured plates from warm solutions of Co^{II} salts in the presence of K_2CO_3[870] and contains *trans* monodentate carbonate. Bidentate carbonate in $[Co(CO_3)(H_2O)_2(imH)_2]$ appears to exert a measurable structural *trans* influence on the *trans* water molecules (CoO, 216.6 pm *vs.* 209.4 in $Co(H_2O)_6^{2+}$)[330] and a similar effect is found in Co^{III}–carbonato complexes. Violet crystals of $[Co(CO_3)(H_2O)_2(NHpy_2)]$ have been isolated on reacting $Na_3[Co(CO_3)_3]$ with 2,2′-bipyridylamine and presumably contain chelated carbonate (IR; $\mu = 5.23$ BM).[871]

47.7.3.2 Cobalt(III)



Cobalt(III)–carbonato complexes provide a very useful starting point for the preparation of other cobalt(III) complexes so that high yield synthetic methods are of great practical importance. Table 67 lists preparations for the major structural types **(241)**–**(244)** and variations for substituted or related ligand systems are based on these. Recent reviews covering the wider aspects of transition metal carbonates are available.[872–874]

The usefulness of cobalt(III)–carbonato complexes derives from their acid lability, with CO_2 and the Co^{III}–aqua complex being rapidly generated in most cases (equations 143, 144 and 145), with full retention of geometric and optical configuration. The coordinated water molecule can then be replaced by the ligand of choice. In non-aqueous solvents the cleavage pattern (equations 143, 144 and 145) would predict an easy route to $[Co(solv)(H_2O)(N)_4]^{3+}$ systems, and if finely divided $[Co(CO_3)(N)_4]X$ ($N_4 = (NH_3)_4$, $(en)_2$) is suspended in dry acetone and concentrated HX added ($X = Cl^-$, Br^-, $CF_3SO_3^-$), $[CoX(OH_2)(N)_4]X_2$ results. However dissolution in concentrated HX invariably results in largely $[Co(X)_2(N)_4]X$.

$Na_3[Co(CO_3)_3]$,[876] or the $[Co(CO_3)_3]^{3-}$ ion prepared *in situ*, has been extensively used for prepar-

ing $[Co(CO_3)_2(AB)]^{n-}$ complexes, and from these, mixed $[Co(CO_3)(AB)(A'B')]$ systems, especially where AB, A'B' are bidentate ligands such as oxalate, amino acids, phen, bipy and related chelating diamines. Shibata and colleagues have been largely responsible for developing this area and a recent account of their work is available.[877] The green $[Co(CO_3)_3]^{3-}$ ion has been resolved into its optical forms but racemizes rapidly,[878] and it is only moderately stable between pH 8 and 10 in the presence of 0.1–1.0 mol dm^{-3} HCO_3^-;[879] it is best prepared and used immediately. Many of the $[Co(CO_3)(AB)_2]^+$ and $[Co(CO_3)(macrocycle)]^+$ systems can be prepared directly from $CoCl_2$ or $Co(OAc)_2$ and the ligand and $NaHCO_3$, others from $[Co(X)_2(AB)_2]^+$ or $[Co(X)_2(macrocycle)]X$, where X = Cl^-, Br^-, using Ag_2CO_3, and still others by oxidation of the Co^{II} complexes in the presence of CO_2 (Table 67). For the macrocycles cyclam,[880,881] [15 or 16]aneN_4,[882] *trans*[14]dieneN_4[883] and tet b,[884] $[Co(CO_3)(macrocycle)]^+$ is particularly valuable since bidentate carbonate requires adjacent *cis* coordination sites and this forces a strained stereospecific geometry on the macrocycle, *e.g.* (**245**). This forced configuration is retained on removing the carbonate moiety in acid solution. This property is valuable since it can present a Co^{III} centre to potential ligands in an alternative configuration and it might be useful in the investigation of biological active sites.

(**245**) $[Co(CO_3)\{trans(S,R)[14]dieneN_4\}]^+$

Monodentate systems $[Co(OCO)_2(N)_5]^{n+}$ are easily formed by saturating an aqueous solution of the aqua complex with CO_2 at pH ≈ 6. Under such conditions maximum concentrations of dissolved CO_2 occur and many $[Co(OH_2)(N)_5]^{n+}$ complexes have pK_a values in this range. It is the complexed hydroxo conjugate which is the reactive species (equation **146**)[875] and if the pK_a is a little higher (*i.e.* the complex is somewhat less acidic) then the reaction is a little slower under any pH condition. The reaction of HCO_3^- and CO_3^{2-} (pH 8–10) is very slow by comparison and can generally be disregarded for those complexes which have slow water exchange rates. But contributions by such species have been found.[886] The rate law takes these factors into consideration and some rate constants corresponding to equation (**146**) are given in Table 69. A recognizable Brönsted relationship exists between $\log k$ and the pK_a of the $Co—OH_2^{n+}$ complex,[885] and the β value of ~0.15 suggests control by the properties of $CO_{2(aq)}$ rather than by the nucleophilic ability of coordinated hydroxide. A $\Delta V^{\ddagger}$ study gives a value of $-10.1 \pm 0.6\,cm^3\,mol^{-1}$ for the pentaammine system and this has been interpreted in terms of significant bond formation in the transition state.[887]

$$[(N)_5Co—\bullet H]^{2+} + CO_{2(aq)} \xrightarrow{k} [(N)_5Co—\bullet \searrow CO_2]^+ + H^+ \qquad (146)$$

Four basic structural types have been found: monodentate (**241**), bridging monodentate (**244**), bridging μ-bidentate (**243**) and the four-membered chelate (**242**). Some structures are given in Table 68. Koshy and Dasgupta have recently reinvestigated the preparation of (**244**) $[(N)_5 = (NH_3)_5]$[888] but its very rapid hydrolysis to $[Co(OCO_2H)(NH_3)_5]^+$ and $[Co(OH_2)(NH_3)_5]^{2+}$ still leaves some doubt as to its structure. Churchill and colleagues have described the structure of μ-bridged $[\{(NH_3)_3Co\}_2\{\mu\text{-}(OH)_2CO_3\}]SO_4 \cdot 5H_2O$ together with preliminary data on its acid hydrolysis and reconstitution.[889] The cleavage patterns for the two structural types (**243**) and (**244**) have not been described in any detail.

Monodentate complexes (**241**) are well characterized (Table 67) but only one structure, that of $[Co(OCO_2)(NH_3)_5]Br \cdot H_2O$, is available (Table 68). Considerable unsaturation into the coordinated O atom is suggested by the similar C—O bond lengths. These complexes undergo rapid acid-catalyzed decarboxylation (reverse of equation 146) and some rate data are given in Table 69. Acyl–O bond cleavage has been established for $[Co(OCO_2H)(NH_3)_5]^{2+}$,[890] and the rapidity of the reactions makes this certain in a general sense. Bidentate (**242**) shows some 10 pm longer bond lengths for C—O in the chelate ring with 68–70° angles at the metal (Table 68), which indicates considerable strain. Acid catalysis follows the rate law $k_{obs} = k_0 + k_1[H^+]$ with k_0 and k_1 values of $1–8 \times 10^{-4}\,s^{-1}$ and $0.1–1\,mol^{-1}\,dm^3\,s^{-1}$ respectively for tetraammine systems and $\sim 10^{-5}\,s^{-1}$ and $10^{-4}–10^{-5}\,mol^{-1}\,dm^3\,s^{-1}$ for the aromatic amines py, phen, bipy.[874] Note the very much slower k_1 values for the complexes containing aromatic amines. ^{18}O tracer experiments have established

Co—O bond cleavage for k_1 in $[Co(CO_3)(NH_3)_4]^+$ (Scheme 85)[892] followed by faster O—CO_2H hydrolysis of the monodentate (Table 69). In strongly acidic solutions k_1 can exceed k_H for the monodentate with a limiting rate (k'_H in Scheme 85) being approached. In this case the monodentate is observed as an intermediate.[896] The reverse ring closure for $[Co(OCO_2)(OH_2)(N)_4]^+$ is fast ($k_{-0} = 0.02$–$0.1\ s^{-1}$, Scheme 85). For $[Co(CO_3)_2(en)]^-$ and $[Co(CO_3)_2(py)_2]^-$ loss of the first carbonate chelate is very fast and rate data are only available for the intermediate $[Co(CO_3)(H_2O)_2(N)_2]^+$ species [$(N)_2$ = en,[897] $(py)_2$[898]].

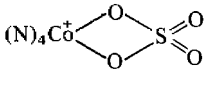
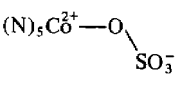
Scheme 85

Under alkaline conditions pathways first order in $[OH^-]$ become available for both ring opening and subsequent hydrolysis of the monodentate carbonate intermediate (equation 147). Both reactions are quite slow ($k_{OH} = 3.6 \times 10^{-3} mol^{-1} dm^3 s^{-1}$, $k'_{OH} = 8.2 \times 10^{-6} mol^{-1} dm^3 s^{-1}$ for $[Co(CO_3)(tren)]^+$).[893] Both reactions involve Co—O cleavage for $(N)_4 = (en)_2$ and probably occur *via* S_N1cb cleavage in the deprotonated amine base conjugate.[894] Endicott and coworkers have discussed this reaction in some detail[895] and Dasgupta and Sadler report a recent example using $[Co(CO_3)(cyclam)]^+$.[903] The reverse cyclization is also very slow under alkaline conditions ($k_{-OH} = 6.5 \times 10^{-5} s^{-1}$ for $(N)_4 = (en)_2$) and the ring-opened form (**246**) is stabilized for $[OH^-] > 0.01 mol dm^{-3}$. Carbonate exchange in monodentate (**241**) and chelate (**242**) systems therefore nearly always occurs *via* hydrolysis and Co^{III}–hydroxo attack on solvated CO_2. Dobbins and Harris have discussed this for chelate systems[899] and Francis and Jordan for $[Co(OCO_2)(NH_3)_5]^+$.[900] However, displacement of carbonate in $[Co(CO_3)_3]^{3-}$ by pyridine, diamines and SO_3^{2-} is thought to occur both directly as well as *via* $[Co(CO_3)_2(H_2O)(OCO_2H)]^{2-}$ species.[901,902]



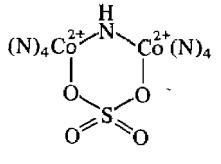
(147)

47.7.4 Oxyanions of Cobalt(III)



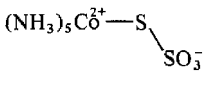
47.7.4.1 Sulfate, selenate and tellurate

The group oxidation state anions SO_4^{2-}, SeO_4^{2-} and $TeO_2(OH)_4^{2-}$ show an increasing tendency to polymerize with SO_4^{2-} being relatively inert to oxygen exchange and dimerization, while $TeO_2(OH)_4^{2-}$ rather easily dimerizes to $Te_2O_6(OH)_4^{4-}$.[904] The racemic chelate $[Co\{O_2Te(OH)_4\}(en)_2]^+$ also rapidly equilibrates to the dimer $[Co(en)_2\{O_2Te(OH)_4O_2\}(en)_2Co]^{2+}$ in aqueous solution and tetrameric $[\{Co(en)_2\}_2(O_4TeO_2TeO_4)\{(en)_2Co\}_2]Cl_4$ has also been isolated.[905] This increasing tendency to raise the valence of the non-metal by substitution with other oxy species increases the possibility of Co^{III}—OH_2 or Co^{III}—OH attack. Some preparations are listed in Table 70.

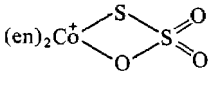


SO_4^{2-} coordinates in three structural modifications (**247**), (**248**) and (**249**) with the chelate (**247**) being unstable towards pH-independent ring opening [$(N)_4 = (en)_2$, $k = 7.3 \times 10^{-5}\,s^{-1}$].[906] The monodentate (**248**) is quite stable but undergoes slow aquation, $k_{obs} = k_1 + k_2[H^+]$, and base hydrolysis (Table 44). Ring opening and hydrolysis almost certainly occur without S—O bond cleavage.[907] Formation of monodentate sulfato complexes $[Co(OSO_3)(NH_3)_5]^+$ and $[Co(OSO_3)(H_2O)(en)_2]^+$ is also very slow (Table 43) and assumes a rate independent of $[SO_4^{2-}]$ above 0.02 mol dm^{-3} indicative of strong ion pairing.[908,909] Bridged species (**249**) are easily formed by bubbling SO_2 through a solution of the μ-superoxo dimer $[(N)_4Co\{\mu\text{-}(O_2,NH_2)\}Co(N)_4]^{4+}$ [$(N)_4 = (NH_3)_4$, $(en)_2$] with oxidation at S and reduction at O occurring rapidly.[910] A corresponding μ-selenato complex can be formed in a similar manner using SeO_2 but the reaction is slower.[911] Selenate analogous of (**247**) and (**248**) appear to be unknown. As mentioned above the preparation of the Te^{VI} chelate $[Co\{O_2Te(OH)_4\}(en)_2]Cl\cdot H_2O$ corresponding to (**247**) has been reported and it has been resolved into its optical enantiomers.[905]

(247)



(248)



(249)

47.7.4.2 Thiosulfate

Some interesting chemistry is now available on the mono sulfur analogue of sulfate, the thiosulfate ion. Both S- and O-bound isomers of $[Co(S_2O_3)(NH_3)_5]^+$ are known, and a structure on the former (Table 72) confirms it, *i.e.* (**250**), as the stable form. Preparations are given in Table 70. The O-bound isomer has been observed as a minor product (*ca.* 3%) in the alkaline hydrolysis of $[Co(OSO_2R)(NH_3)_5]^{2+}$ (R = Me, CF_3) in 1.0 M $Na_2S_2O_3$.[947] It rather rapidly isomerized intramolecularly in solution to the *S*-bound isomer ($t_{1/2} \approx 27$ min). The O,S chelate (**251**) has been prepared by Deutsch and coworkers but is unstable towards hydrolysis to monodentate *trans*-$[Co(SSO_3)(OH_2)(en)_2]^+$.[948] Such hydrolysis is some four times faster than that for the sulfato chelate $[Co(O_2SO_2)(en)_2]^+$, which suggests a small *trans* influence for the coordinated sulfur (*cf.* Section 47.8.5). Oxidation of *cis*-$[Co(SSO_3)_2(en)_2]^-$ with an excess of I_2 leads to *trans*-$[Co\{S(S)SO_3\}(OH_2)(en)_2]^+$ containing the stabilized disulfane monosulfonate anion (**252**), possibly *via* an unstable tetrathionate intermediate (equation 148). The product was isolated as *trans*-$[Co\{S(S)SO_3\}Cl(en)_2]$ and shows *trans* labilizing effects.[949] Stoichiometric oxidation of *trans*-$[Co(SSO_3)_2(en)_2]^-$ using I_3^- gives *trans*-$[Co(SSO_3)(H_2O)(en)_2]^+$, and anation of this ion with NCS^-, NO_2^-, NCO^-, Cl^- and $C_2O_4^{2-}$ is fast, consistent with the kinetic *trans* labilizing order SO_3^{2-} > RSO_2^- > SSO_3^{2-} (*cf.* Section 47.8.5).[950,951] Aquation of the resulting *trans*-$[Co(SSO_3)(Y)(en)_2]$ is also fast.

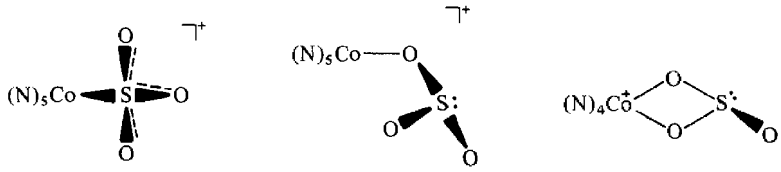
(148)

(252)



47.7.4.3 Sulfite and selenite

The lower oxidation state group IV anions SO_3^{2-} and SeO_3^{2-} rapidly undergo substitution and oxygen exchange and associative interchange processes involving expansion of covalency are attractive routes to their metal complexes.[912] Coordination is often much faster than the unassisted water exchange at the metal, and proton transfer and bond making in associated transition states of the type (**253**) and (**254**) are important for Co^{III}.

(253) (254)

Tetrahedral SO_3^{2-} is known to coordinate to Co^{III} in three ways (**255**), (**256**) and (**257**), although structures are only confirmed for (**255**; Table 72). Preparations to some O-bonded complexes are given in Table 70 and some S-bonded systems in Table 71. Since SO_3^{2-} can be removed by treatment with hot concentrated acid, S-bonded complexes (**255**) can sometimes be useful in synthesis but reduction to $Co^{2+}_{(aq)}$ is often a competing problem.[913] They are reasonably stable in alkali. Baldwin many years ago prepared orange-brown $[Co(O_2SO)(en)_2]X$ ($X = Cl^-, ClO_4^-, NO_3^-$) and on the basis of molecular weight and IR data represented them as chelates (**257**).[914] More recently some phenanthroline and bipyridyl complexes of similar constitution have been prepared (Table 71). The chelate structure has not been confirmed but Baldwin's observations suggest that it is quite robust.

(255) (256) (257)

The O-bonded isomer (**256**) has been examined recently by Harris and his colleagues[915,916] and can be easily prepared by the addition of the aqua complex to $Na_2S_2O_5$ or $NaHSO_3$ solutions at pH ~ 5–6 (Table 71). These species are much less stable, undergoing reduction to Co^{II} or hydrolyzing in acid solution (pH < 5), and isomerizing to the S-bound isomer in alkali. Addition of $SO_{2(aq)}$ to Co^{III}—OH is fast at pH ≈ 5 where the concentration of the two reactants is maximized. Compared to the reaction with $CO_{2(aq)}$ reaction (149) is some 10^6 times faster. Some kinetic data are collected in Table 73. The resulting red-brown products (Table 70) are typical of other O-bound group VI anions, and a recent ^{17}O experiment verifies the source of the O atom.[917] The reverse hydrolysis is subject to H^+ catalysis as required by equation (149; Table 74). For the pentaammine system reduction to Co^{II} also occurs at pH < 5 but the O-bound isomer is stable in alkaline solution and apparently isomerizes to $[Co(SO_3)(NH_3)]^+$; this latter aspect has not been described in much

Table 71 Preparations: Some S-Bonded Sulfito, Sulfinato Complexes of Cobalt(III) (Monodentate)

Complex	*Preparation*	*Properties*	*Ref.*
α,β-$[Co(SO_3)(tetren)](ClO_4)\cdot H_2O$	$[CoOH_2(tetren)](ClO_4)_3 + Na_2S_2O_5$; r.t.	Orange-yellow; ε_{444} 236, ε_{281} 16900	11

detail.[915] The α,β-$[Co(OSO_2)(tetren)]^+$ ion is more stable toward reduction and isomerizes to α,β-$[Co(SO_3)(tetren)]^+$ at a pH-independent rate (pH 6–7.5, $2.7 \times 10^{-4}\,s^{-1}$, 25 °C). This is some 10^3 times faster than the related isomerization of O-chelated sulfinate in $[Co(cystO_2)(en)_2]^{2+}$ (Section 47.8.2.2.iii). The resulting S-bound isomer undergoes slow hydrolysis in alkali, $k_{OH} = 8.15 \times 10^{-5}\,mol^{-1}\,dm^3\,s^{-1}$.[916] $[Co(OSO_2)(OH_2)(tren)]^+$ reduces to Co^{II} in the pH range 2.9–5.4 ($k_{OH} \approx 1.0 \times 10^{-3}\,s^{-1}$) but adds a second SO_3^{2-} ligand in the pH range 7.2–8.9 to form $[Co(SO_3)_2(tren)]^-$.[918] Unlike $[Co(NO_2)(NH_3)_5]^{2+}$ and S-bound $[Co(cysO_2)(en)_2]^+$, $[Co(SO_3)(NH_3)_5]^+$ shows no signs of photoisomerization.[919]

$$(NH_3)_5Co^{2+}—\overset{\diagup}{\bullet}H + SO_{2(aq)} \underset{k_{hyd}}{\overset{k_f}{\rightleftharpoons}} (NH_3)_5Co^{2+}—\bullet\!\!<^{O}_{SO_2^-} + H^+ \qquad (149)$$

The direct reaction of Co^{III}—OH_2 or Co^{III}—OH species with SO_3^{2-}, as distinct from the above reaction with $SO_{2(aq)}$, is not well documented but appears to be moderately fast. Stranks and coworkers[920] many years ago found that *trans*-$[Co(OH)(OH_2)(en)_2]^{2+}$ reacts with SO_3^{2-} to form *trans*-$[Co(SO_3)_2(en)_2]^-$ within one second at pH 7.5, which is faster than expected for substitution at the metal centre, and Spitzer and van Eldik[919] have recently discussed the relatively fast reaction of $[Co(OH)(NH_3)_5]^{2+}$ with SO_3^{2-} at pH 9–10 to form *trans*-$[Co(SO_3)_2(NH_3)_4]^-$ (Table 71). It is very likely that these reactions occur by the addition of coordinated water or hydroxide to the sulfur atom of SO_3^{2-} with subsequent isomerization of O-bound sulfite to the favoured S-bound isomer (equation 150).

Crimson-red selenito complexes are formed within milliseconds by the addition of $CoOH_2^{n+}$ species to Na_2SeO_3 at pH values between 3 and 6.[921–923] Bidentate chelates of type (**247**) do not

$$(N)_5Co^{3+}—OH_2 + SO_3^{2-} \longrightarrow (N)_5Co^{2+}—O(SO_2^-) \xrightarrow{fast} (N)_5Co^{+}—SO_3 \qquad (150)$$

coexist with the monodentate (**248**) at equilibrium and equilibrium constants for formation of the monodentate are such that the monodentate is stabilized in solutions above pH 3. Rate data have been interpreted in terms of addition of $CoOH_2^{3+}$ and $CoOH^{2+}$ to $HSeO_3^-$ (Table 74) and for the aqua complexes rate saturation can be attributed to ion pairing.[921] The fast rate for $CoOH_2^{3+}$ is attributed to efficient proton transfer to selenite oxygen in the associative transition state (**253**). The reaction of SeO_3^{2-} is some 15–24 times slower if OH^- is considered the leaving group on Se. Dimeric selenite species become important contributors to the reaction at pH > 7.[923]

It is well known that S-bonded SO_3^{2-} complexes (**255**) labilize monodentate ligands *trans* to them in octahedral coordination. Thus Siebert and Wittke showed that $[Co(SO_3)(NH_3)_5]^+$ could be prepared and purified only in solutions containing an excess of $NH_{3(aq)}$, otherwise *trans*-$[Co(SO_3)(OH_2)(NH_3)_4]^+$ was isolated.[924] This *trans* labilizing effect is also discussed in Section 47.8.5. It is found in the reactions of $[Co(SO_3)(NH_3)_5]^+$,[925,926,930] *trans*-$[Co(SO_3)(H_2O)(en)_2]^+$,[927] *trans*-$[Co(SO_3)X(DMGH)_2]^{0,+}$,[928,929,931] and with *trans*-$[Co(SO_3)(CN)_4(OH_2)]^{3-}$.[66,932] The large body of evidence suggests that SO_3^{2-} promotes an S_N1(lim) displacement mechanism with complete dissociation of the *trans* group prior to interaction with the incoming ligand, especially with *trans*-$[Co(SO_3)(CN)_4(OH_2)]^{3-}$ (Scheme 86). The alternative dissociative interchange process with saturation of the rate being attributed to saturation within a preformed ion pair (Scheme 87) is possible for cationic systems with the rate variation being ascribed largely to variation in K_{ip}.[927] However the S_N1(lim) mechanism seems certain for $[Co(SO_3)(CN)_4(OH_2)]^{3-}$ where ion pairing with Y^{n-} should not cloud the issue and where k_1 is independent of the concentrations and identity of Y^{n-} over a wide range of entering groups (SO_3^{2-}, CN^-, NCS^-, NH_3, py; $k_1 \approx 2.5 \pm 0.5\,s^{-1}$; $\Delta H^{\ddagger}$ 92.4 kJ mol^{-1}, $\Delta S^{\ddagger}$ 73 J $mol^{-1}K^{-1}$).[932] Wilmarth's contributions to this area have now been suitably acknowledged.[933] Perhaps the $[Co(SO_3)(CN)_4]^{3-}$ intermediate is stabilized as the chelated octahedral ion (**258**). Such a species would allow the solvent cage to reach or approach the equilibrated state, but its subsequent preference for other ligand donors over H_2O, *e.g.* 140 (NH_3), 340 (py), remains a mystery. Studies such as these establish the dissociative influence of coordinated SO_3^{2-}, whereas the similar influence of coordinated CN^- is now open to question.[67] Farrell and Murray report the possibility of O entry in the reaction of $[Co(SO_3)(OH_2)(en)_2]^+$ with SO_3^{2-} at pH 7.1 with the $[Co(OSO_2)(SO_3)(en)_2]^-$ product rearranging subsequently to $[Co(SO_3)_2(en)_2]^-$.[934]

$$[Co(SO_3)(CN)_4(OH_2)]^{3-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Co(SO_3)(CN)_4]^{3-} + H_2O$$

$$[Co(SO_3)(CN)_4]^{3-} + Y^- \xrightarrow{k_2} [Co(SO_3)(CN)_4Y]^{4-}$$

$$[Co(SO_3)(en)_2(OH_2)]^+ + Y^- \overset{K_{ip}}{\rightleftharpoons} [Co(SO_3)(en)_2(OH_2)]^+ \cdot Y^- \xrightarrow{k} [Co(SO_3)(en)_2Y] + H_2O$$

Scheme 87

(258)

47.7.4.4 Chromate, molybdate and tungstate

A relatively rapid red–orange colour change accompanies the addition of Na_2CrO_4 to $[Co(NH_3)_5(OH_2)]^{3+}$ in acid solution and this can be attributed to equilibrium (151). Equilibrium studies indicate the existence of a very stable ion pair $[Co(NH_3)_5(OH_2)]^{3+} \cdot CrO_4^{2-}$ in addition to the inner-sphere complex (**256**) ($K_c = k_f/k_{hyd} = 3.07 \times 10^5$) and limited kinetic data indicate a rate first order in both Cr^{VI} and $[H^+]$ (Table 74).[935] Hydrolysis of $[Co(OCrO_3)(NH_3)_5]^+$ is reasonably rapid ($t_{1/2} < 7$ min, 5 °C). Early reports on the preparations of chelate complexes $[Co(O_2MO_2)(NH_3)_4]X$ and monodentate $[Co(OMO_3)(NH_3)_5]X$ need to be reexamined. It is likely that the fast rate of oxygen exchange at M (Cr,[936] Mo,[937,938] W[939]) makes the chelates (**247**) unstable with respect to the monodentate $[Co(OMO_3)(H_2O)(NH_3)_4]^+$ and these complexes need to be isolated and carefully characterized.

$$(NH_3)_5Co^{3+}—OH_2 + HCrO_4^- \underset{k_{hyd}}{\overset{k_f}{\rightleftharpoons}} (NH_3)_5Co^+—OCrO_3 + H_3O^+ \quad (151)$$

(256)

Anation of $[Co(OH)(NH_3)_5]^{2+}$ by MoO_4^{2-} in the pH range 7.1–8.0 is in the stopped-flow range indicating rapid oxygen displacement at Mo^{VI}.[940] Rate data have been interpreted in terms of $[Co(OH_2)(NH_3)_5]^{3+}$ and $[Co(OH)(NH_3)_5]^{2+}$ reacting with $HMoO_4^-$ (Table 74) even though the pK_a of the latter is 3.53. Both reactions are faster than water exchange (k_{ex}) although slower than substitution by anionic species at $HMoO_4^-$. Reaction (152) is reversible ($K = 475\,mol^{-1}\,dm^{-3}$) with the acid-catalyzed path being the reverse of $HMoO_4^{2-}$ addition. It is clear that exchange of Co^{III}-coordinated molybdate is reasonably fast.

$$(NH_3)_5Co^{3+}—OH_2 + MoO_4^{2-} \underset{k_{hyd}}{\overset{k_f}{\rightleftharpoons}} (NH_3)_5Co^+—OMoO_3 + H_2O \quad (152)$$

Subsititution by $[Co(OH)_{2,1}(OH_2)_{0,1}(en)_2]^{+,2+}$ into WO_4^{2-} in the pH range 8.0–9.0 is in the stopped-flow range indicating a very fast attack by Co—OH or Co—OH_2 at W^{VI}.[941] Rate data given in Table 74 are for substitution into HWO_4^- even though its $pK_a = 3.5$. The alternative of $[Co(H_2O)_2(en)_2]^{3+}$ and $[Co(OH)(H_2O)(en)_2]^{2+}$ reacting with WO_4^{2-} gives forward rates (6.60×10^2 and $2.8 \times 10^4\,mol^{-1}\,dm\,s^{-1}$), which suggest exchange within the ion pair in excess of 66 and $560\,s^{-1}$. These values are very much faster than the unassisted water exchange rate ($0.44\,s^{-1}$) and an associative interchange process (see **253**) is again likely.

47.7.4.5 Iodate, perrhenate, chlorite and perchlorate

O exchange into IO_3^-, ReO_4^- and ClO_2^- is fast and their cobalt(III) complexes are formed by the addition of Co—OH_2 to the group VII centre. The immediate red–purple colour change which accompanies the addition of $NaIO_3$ to $[Co(OH_2)_2(en)_2]^{3+}$ must be followed by relaxation methods.[942] Both the forward and reverse reactions (equation 153) are acid catalyzed ($[H^+] = 0.03$–$0.005\,mol\,dm^{-3}$) and have been interpreted in terms of addition of coordinated water to HIO_3 (Table 74). Using a value of $0.3\,mol^{-1}\,dm^3$ for the association constant, the formation rate within the associated reactant (**253**) is $5 \times 10^4\,s^{-1}$, which is almost 10 times faster than unassisted water exchange into HIO_3. Clearly IO_3^- exchange on Co^{III} is very fast and it has not been possible

to isolate solid iodate complexes.[943] Early reports in the literature of isolated cobalt(III) complexes containing IO_3^-, BrO_3^- and ClO_3^- are probably erroneous.

$$(en)_2(H_2O)Co^{3+}—OH_2 + HIO_3 \underset{k_{hyd}}{\overset{k_f}{\rightleftharpoons}} (en)_2(H_2O)Co^{2+}—OIO_2 + H_3O^+ \quad (153)$$

Addition of perrhenate to $CoOH_2^{n+}$ or $CoOH^{(n-1)+}$ complexes has not been studied in detail but heating $[Co(OH_2)(NH_3)_5](ReO_4)_3$ results in displacement of coordinated water (Table 70). Both $[H^+]$ and $[OH^-]$ paths for O—Re bond cleavage in $[Co(OReO_3)(NH_3)_5]^{2+}$ exist (Table 74) and these processes are strongly catalyzed by acetic acid and by acetate and biphthalate ions.[944]

The chlorito complex $[Co(OClO)(NH_3)_5](NO_3)_2$ has been prepared by ClO_2 oxidation of Co^{II} in the presence of ammonia (Table 70); it is stable for considerable periods when protected from light.[945] The reverse reaction is acid catalyzed. Attempts to prepare a chlorato complex by oxidation were unsuccessful. Reduction using Fe^{2+}, HSO_3^-, or VO^{2+} results in substantial retention of the Co—O bond (equation 154), but oxidation with $Co^{3+}_{(aq)}$ results in some 66% Co—O bond cleavage.[945]

$$[(NH_3)_5CoO—ClO]^{2+} + SO_3H^- + 2H^+ \longrightarrow [(NH_3)_5CoOH_2]^{3+} + HSO_4^- + Cl^- \quad (154)$$

Few cobalt complexes exist containing coordinated tetrahedral perchlorate, and those which do show weak coordination. Table 75 gives some structural data. Early reports on the isolation of $[Co(OClO_3)(NH_3)_5](ClO_4)_2$ are erroneous but Sargeson and coworkers have prepared it as pink crystals by nitrosation of $[CoN_3(NH_3)_5](ClO_4)_2$ in concentrated $HClO_4$.[946] Coordinated perchlorate is rapidly displaced by water in aqueous solution ($t_{1/2} \approx 7$ s) and cobalt in any oxidation state prefers almost any other donor atom over perchlorate oxygen.

47.7.4.6 Polyoxyanions of Nb^V, Mo^{VI}, W^{VI} and I^{VII}

Some interesting chemical and structural patterns are beginning to emerge in the coordination of cobalt with oxyanions of these elements. Together with V^V, Ta^V and Cr^{VI} the simple oxyanions readily condense to form structural units based on MO_6 octahedra by sharing an edge or a trigonal face.[952,953] CoO_6 or CoO_4 units fit into these polyhedra as integral parts and the high group valence often stabilizes Co^{III} octahedra. The structural unit is often large but is robust and many have been known for a long time. Some preparations are given in Table 76 and structures in Table 77.

Several Co^{III} complexes containing the $Nb_6O_{19}^{8-}$ unit have been prepared (Table 76). $Nb_6O_{19}^{8-}$ (**259**) consists of six NbO_6 octahedra condensed by edge sharing and one of the triangular faces coordinates as a tridentate to form *fac*-$[Co(Nb_6O_{19})L_3]^{3-}$ complexes. $K_7[Co(Nb_6O_{19})(CO_3)(NH_3)]$ has been prepared from $K[Co(CO_3)_2(NH_3)_2]$ and has been used to coordinate (*S*)-aspartate, glycinate, (*S*)-valinate and (*S*)-alaninate, with the last two being resolved into enantiomeric forms.[954] When

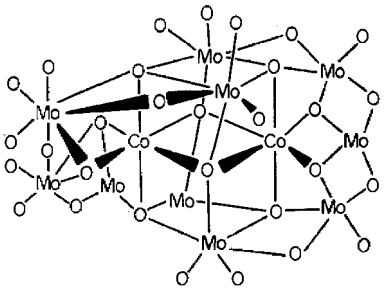
solutions of $Co^{2+}_{(aq)}$ are mixed with the stable $Mo_7O_{24}^{6-}$ ion in the presence of an oxidizing agent such as Br_2 the central Mo^{VI} atom is replaced by Co^{III} and the remarkably stable, emerald-green $[Co\{Mo_6O_{18}(OH)_6\}]^{3-}$ ion results (Table 76). Its structure is presumably the same as that of the analogous Cr^{III} species[955] (**260**) with four-membered chelates surrounding a Co^{III} centre in a symmetric configuration. Treating (**260**) with activated charcoal or Raney nickel forms the racemic dimeric unit (**261**)[956] and this has been resolved into its enantiomeric forms using $(+)_{589}$-$[Co(en)_3]^{3+}$.[957] Heteropoly complexes based on IO_6^{5-} units have been surveyed[958] and the structure of $[Co_4I_3O_{24}H_{12}]^{3-}$ (**262**; Table 77) shows a central CoO_6 octahedron surrounded by alternating CoO_6 and IO_6 octahedra. The three terminal Co^{III} centres contain *cis*-aqua ligands, which can be readily replaced by NH_3, ethylenediamine or amino acids (Table 76). The $[Co_4I_3O_{18}(OH_2)_4\{(S)ala\}]^{4-}$ ion has been separated into its diastereoisomeric forms by chromatography on Sephadex.[959]



The $[CoW_{12}O_{40}]^{5-}$ ion has the classic 'Keggin' structure with a central tetrahedrally situated Co^{III} atom surrounded by four W_3O_{12} clusters making up an almost regular cubo-octahedron (**263**).[953] This unit is structurally very stable, does not undergo rapid O exchange at pH 1–2,[960] and can be used as an outer-sphere electron transfer oxidant in both inorganic[961] and organic[965] reactions.

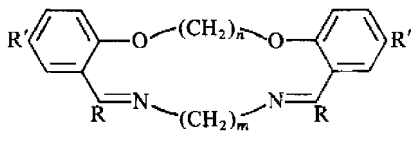
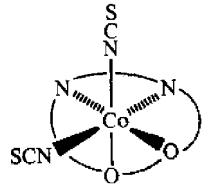
Recent oxidations to be studied include those of *p*-methoxytoluene,[962] glutathione[963] and cysteine and related mercapto acids.[964]



47.7.5 Ethers, Cobalt(II)

Well-defined crystalline complexes possessing cobalt(II)–ether oxygen bonds are comparatively rare. There are no authenticated examples of monodentate ether complexes. Light blue or lavender adducts of cobalt(II) halides with 1,4-dioxane are formulated as containing six-coordinate cobalt(II) and bridging dioxane ligands[966] but have not been fully characterized. Only one example of bidentate ether oxygen coordination has been reported. Addition of $SOCl_2$ to a solution of $Co(CF_3COO)_2$ in 2-dimethoxyethane (dme) gives the red trimeric complex $[Co_3(Cl)(SO_4)(CF_3COO)_3(dme)_3]$ in which dme acts as a chelating group and the remaining ligands bridge octahedral metal centres.[967] Octahedral coordination is also found in the dimeric complex $[Co(Cl)(diglyme)]_2(SbCl_6)_2$ (diglyme = triethyleneglycol dimethyl ether), where the chlorides act as bridging ligands and the coordination sphere of each metal is completed by binding of one molecule of the tetradentate polyether.[968]



Lindoy and coworkers[969,970] have reported cobalt(II) complexes of various 14- to 17-membered macrocycles with O_2N_2 donor sets. For ligands of type (**264**) high spin $[CoX_2(macrocycle)]$ complexes (X = Cl^-, Br^-, NCS^-) are octahedral for 15- and 16-membered ring systems, but tetrahedral and without Co—O (ether) bonds for the 17-membered ligand. The complexes $[CoX_2(macrocycle)]$ of the ligand (**265**; R = R′ = H; $n = 2$; $m = 3$) have been isolated as orange and purple isomers for X = NCS^-. IR studies indicate thiocyanate to be N bound in both species and a crystal structure on the purple isomer confirms a six-coordinate geometry in which the quadridentate is folded about the Co atom giving a *β-cis* configuration (**266**).

There are now several structural studies on cobalt(II) crown ether and cryptand complexes (Table 78), which show the coordination mode to be markedly sensitive to the macrocycle cavity diameter. Both 12-crown-4 and 15-crown-5 (cavity diameters 120–150 pm and 170–220 pm respectively) can include Co^{2+} ions to form structures in which every ether oxygen atom is bound to the metal.[971] In contrast Co—O (ether) bonding is destabilized in the larger 18-crown-6 and dicyclohexyl-18-crown-6 polyethers. In the blue complexes obtained from the reaction of these compounds with $CoCl_2$ the role of the cyclic polyether is to solvate discrete $[Co(H_2O)_6]^{2+}$ cations and $[CoCl_4]^{2-}$ anions and there are no direct Co—O (ether) bonds.[972,973] A similar effect is seen in the Co^{II} complex of a 27-membered-ring macrocycle where the pentacoordinate structure (**267**) features only one long Co—O (ether) bond.[974]

(267)

47.8 SULFUR LIGANDS

47.8.1 Sulfides and Disulfides

Monomeric cobalt complexes containing SH^- or S^{2-} as ligands are comparatively rare since there is a tendency toward formation of binary sulfides. Di Vaira, Midollini and Sacconi[975] showed that tri(tertiary phosphines), when used as coligands, are capable of stabilizing Co—S bonds and were able to prepare the five-coordinate complexes $[Co(SH)\{P(dppe)_3\}](BPh_4)$ and $[Co(SH)\{N(dppe)_3\}](BPh_4)$. These species are low spin with trigonal-bipyramidal geometries, and with the sulfur atom in an axial position. Treatment of $[Co(SH)\{N(dppe)_3\}](BPh_4)$ with NaOEt produces the diamagnetic complex $[\{N(dppe)_3\}Co(\mu\text{-}S)Co\{N(dppe)_3\}]$ which features a linear Co—S—Co bridge and tetrahedral sp_3 coordination about each Co atom. Diamagnetism in this complex appears to arise through superexchange coupling of two d^8 metal centres.[976]

Binuclear ions containing only disulfide as a bridging ligand are also rare but oxidation of $[Co(CN)_5]^{3-}$ by elemental sulfur leads to $[(NC)_5Co(S_2)Co(CN)_5]^{6-}$, isolated as its potassium salt, and the same species is formed on treatment of $[Co(CN)_5(OH)]^{3-}$ or $[(NC)_5Co(O_2)Co(CN)_5]^{6-}$ with H_2S. The selenium analogue $[(NC)_5Co(Se_2)Co(CN)_5]^{6-}$ has also been reported.[977] A recent study[978] suggests that the bridging disulfide ligand in $[(NC)_5Co(S_2)Co(CN)_5]^{6-}$ is slowly oxidized on exposure to air to thiosulfite (SSO_2^{2-}) but the preparation appears to suffer from problems of poor reproducibility. A crystal structure of $K_6[(CN)_5Co(SSO_2)Co(CN)_5]$ characterizes the product as containing a μ-(thiosulfito-*S*,*S*′) unit indicating that oxidation of the sulfide bridge does not involve Co—S rupture.

Both sulfide and disulfide are more commonly encountered as bridging ligands in cobalt clusters. There are few systematic syntheses. For example, $[Co_2(CO)_8]$ reacts at room temperature with CS_2 either neat or in the presence of hydrocarbon solvents to form $[Co_3(S)(CO)_9]$, $[Co_6(C)(S)_2(CO)_{12}]$ and at least three other sulfur-containing derivatives in addition to sulfur-free species such as $[Co_3(C)(CO)_9]$.[979] Similarly, $[Co_2(CO)_8]$ with elemental sulfur in hydrocarbon solvent gives $[Co_3(S)(CO)_9]$, $[Co_4(S)_2(CO)_{10}]$, $[Co_6(S)_8(CO)_6]$ and $[Co_6(S)_4(CO)_{14}]$,[980] with the product distribution dependent on the reaction conditions. Details of several cluster preparations are given in Table 79 and structural data in Table 80.

Single crystal EPR studies of paramagnetic $[Co_3(X)(CO)_9]$ species (**268**; X = S, Se) diluted in the diamagnetic $[FeCO_2(X)(CO)_9]$ analogues[981] demonstrate that the unpaired electron in (**268**) resides in an antibonding orbital. The antibonding nature of the HOMO is also demonstrated by the lengthening of the M—M bonds in (**268**) relative to those in $[FeCo_2(X)(CO)_9]$ species, which contain one electron less.[982] The effect of electron occupancy of antibonding orbitals on Co—Co bond

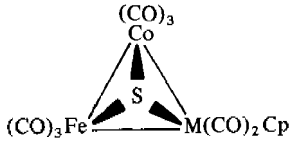
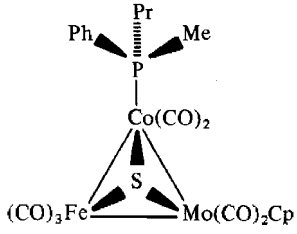
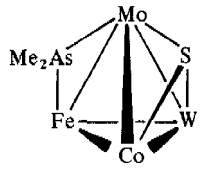
lengths is also seen in the family of clusters $[Co_3(S)(X)(Cp)]^{n+}$ (**269**; X = CO, *n* = 0; X = S, *n* = 1; X = S, *n* = 0).[983] Approximate MO calculations using Fenske–Hall procedures have been carried out on these systems.[984]



(268)



(269)



Vahrenkamp[985] first synthesized the chiral tetrahedrane type clusters (**270**), which have been resolved for M = Mo *via* the diastereoisomeric phosphane (**271**),[986] and a directed synthesis[987] has achieved the construction of the μ_3-S-bridged tetranuclear CoFeMoW cluster (**272**).

(270) M = Mo, W, Cr

(271)

(272)

A chemistry of cobalt–sulfide–thiolate molecular clusters comparable with that of iron systems has also begun to emerge. Treatment of $[Co_4(\mu\text{-SPh})_6(SPh)_4]^{2-}$ with HS^- in acetone affords the octanuclear cluster $[Co_8(\mu_4\text{-S})_6(SPh)_8]^{4-}$ isolated as its $Pr^n_4N^+$ salt.[988] In MeCN solution the complex is red-purple with intense sulfur-core charge transfer bands which obscure the Co^{II} *d–d* transitions. This behaviour contrasts with that of both mono- and poly-nuclear cobalt^{II}-thiolate complexes, which all display LMCT bands below 440 nm and have well-developed ν_2 and ν_3 features. The $[Co_8(\mu_4\text{-}S_6)]^{4+}$ core sustains reversible one-electron oxidation and reduction ($E_{1/2} = -0.54$, -1.18 V, MeCN) and chemical reduction with sodium acenaphthylenide in THF gives $[Co_8(\mu_4$-

$S_6)(SPh)_6]^{5-}$, which has also been structurally characterized (Table 80). A similar Co_8S_6 core unit is found in the synthetic mineral pentlandite, Co_9S_8.[989]

In systems containing cobalt(II) salts, sulfide and thiolate substitution of the bidentate S_2-*o*-xyl^{2-} ligand (S_2-*o*-xyl^{2-} = *o*-xylene-α,α'-dithiolate) for monofunctional thiolate directs cluster assembly away from the Co_8S_6 core and toward the $Co_3(\mu_3\text{-S})$ unit. A high yield preparation (50%) of the complex $(Et_4N)_2[Co_3(\mu_3\text{-S})(S_2\text{-}o\text{-xyl})_3]$ has been reported[990] and structural studies[990,991] show the pyramidal $Co_3(\mu_3\text{-S})$ unit to be unsupported by additional metal–sulfur bonding. The solution properties of the complex (^{1}H NMR, UV–visible spectra and magnetic moments) are consistent with magnetically coupled tetrahedral CoS_4 chromophores.

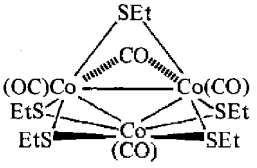
Structural studies on $[Co_6(\mu_3\text{-S})_8(CO)_6]\cdot 3S_8$[992] and $[Co_6(\mu_3\text{-S})_8(PEt_3)_6](BPh_4)$[993] show the cluster components to consist of Co_6 octahedra encapsulated in S_8 cubes. This geometry is the inverse of that found for $[Co_8(\mu_4\text{-S})_6]^{4+/3+}$ cores, where Co_8 cubes are circumscribed by S_6 octahedra.

47.8.2 Thiolates, Sulfenates and Sulfinates

A useful review of the stereodynamic possibilities for inversion at chiral and prochiral sulfur (and Se, Te) in metal complexes is available.[994]

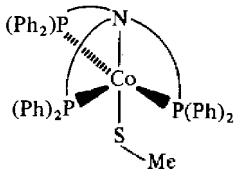
47.8.2.1 Low oxidation states of cobalt

Structural data for Co—SR complexes are given in Table 81; selected data for Co—S—Co systems are included in Table 80.



Klumpp, Marko and Bor[980] described the synthesis of presumed $[Co_4(SEt)_7(CO)_5]$ and $[Co_4(SEt)_3(CO)_7]$ from the reaction of $[Co_2(CO)_8]$ with EtSH in hexane. However subsequent X-ray structures by Wei and Dahl[995,996] have shown the products to be $[Co_3(SEt)_5(CO)_4]$ (**273**) and

Table 81 Structures: Cobalt(II)–Thiolate Complexes



Complex	*Comments*	*Ref.*
$(Pr^n_4N)[Co(SC_{10}H_{13})_3(NCMe)]$	Monomeric, tetrahedral CoS_3N; CoS = 228 pm, CoN = 204 pm	1
$[Co(Cl)_2(SC_5H_4N)_2]$	Monomeric, distorted tetrahedral CoS_2Cl_2; CoS = 232 pm, CoCl = 227 pm	2
$[Co(SC_4H_6N_2)_4](ClO_4)$	Monomeric, tetrahedral CoS_4; CoS = 230 pm	3
$(Me_4N)_2[Co_2(S_2\text{-}o\text{-xyl})_3]$	Dimeric, $Co_2(\mu\text{-S})_2$ core; CoCo = 279 pm, $CoS_{b,t}$ = 230 pm	4
$(Ph_4N)_2[Co(SPh)_4]$	Monomeric, distorted tetrahedral CoS_4; CoS = 232–234 pm	5
syn- and *anti*-$[Co_2(SEt)_6]^{2-}$	Dimeric, $Co_2(\mu\text{-S})_2$ core; CoCo = 305 pm (*anti*), 302 pm (*syn*); CoS_b = 235–238 pm, CoS_t = 226–229 pm	6
$(Me_4N)_2[Co_4(SPh)_{10}]$	$Co_4(\mu\text{-S})_6$ core; CoCo = 387 pm, CoS_b = 232 pm, CoS_t = 226 pm	7
$[Co_3(SEt)_5(CO)_4]$	$Co_3(\mu\text{-SEt})_5(\mu\text{-CO})$ core; CoCo = 255 pm, CoS = 220–223 pm	8
$[Co_4(SEt)_8(CO)_4]$	$Co_4(\mu\text{-SEt})_8$ core; each pair of Co atoms joined by two briding SEt groups; CoS = 224–229 pm; minimum CoCo = 250 pm	9
$[Co_5(SEt)_5(CO)_{10}]$	A $Co_3(\mu\text{-SEt})_2(\mu\text{-CO})_2(CO)_3$ fragment connected by two (μ_3-SEt) bridges to a $Co_2(\mu\text{-SEt})(\mu\text{-CO})(CO)_4$ residue	10

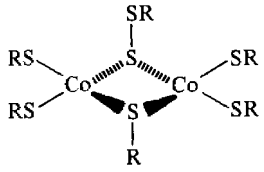
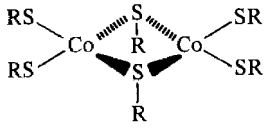
$[Co_6S(SEt)_4(CO)_{11}]$ respectively (Table 80). In the absence of solvent $[Co_2(CO)_8]$ and EtSH form $[Co_5(SEt)_5(CO)_{10}]$[997] for which a crystal structure is also available.[998] In these cobalt–carbonyl–thiolate systems the S atoms doubly or triply bridge metal centres and there appears to be no examples where RS^- functions as a monodentate ligand.

(273)



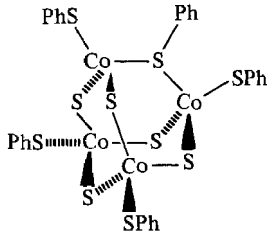
(274)

Early attempts to prepare Co^{II}—SR complexes by the reaction of RS^- (R = Et, Pr^i, Bu^t, Ph) with cobalt(II) salts in ethanolic solution produced only poorly characterized coordination polymers.[999] Subsequently, Sacconi and coworkers[975] isolated stable monomeric methylthio complexes $[Co(SMe)(L)](BPh)_4$ (L = $N(dppe)_3$, $P(dppe)_3$) by reacting the tetradentate ligand with Co^{II} in the presence of MeSH. A crystal structure of low-spin $[Co(SMe)\{N(dppe)_3\}](BPh_4)$ shows the expected trigonal-bipyramidal geometry (**274**). Dance[1000] showed that the equilibria of Scheme 88 are established in MeCN, and that tetrahedral $[Co(SPh)_4]^{2-}$ and the molecular cluster $[Co_4(\mu\text{-}SPh)_6(SPh)_4]^{2-}$ could be crystallized by treatment with R_4N^+ salts. Alternatively, $(Ph_4P)_2[Co(SPh)_4]$ can be obtained by reacting $[Co(S_2COEt)_3]$ with KSPh and Ph_4PCl.[1001]



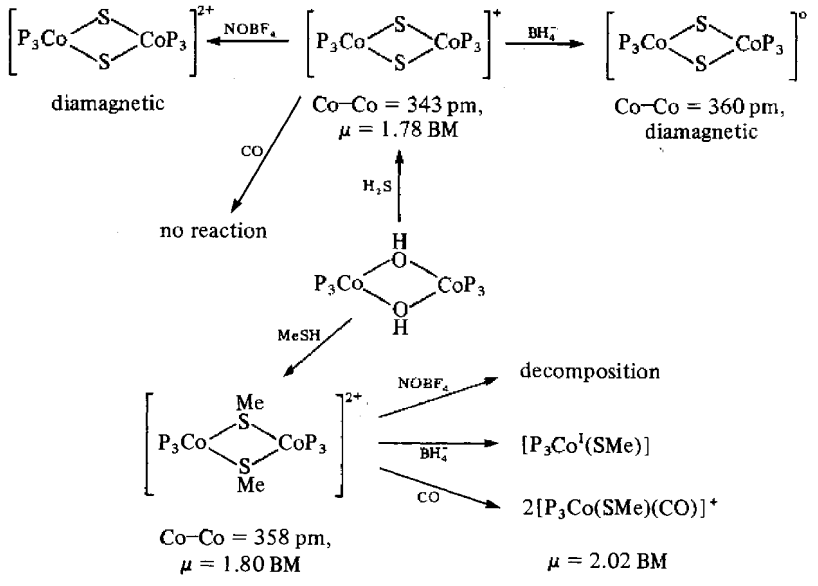
$$Co^{2+} + 4PhS^- \rightleftharpoons Co(SPh)_4^{2-} \rightleftharpoons [(\mu\text{-}PhS)_2\{Co(SPh)_2\}_2]^{2-} \rightleftharpoons [Co_4(\mu\text{-}SPh)_6(SPh)_4]^{2-}$$

Scheme 88



The $[(\mu\text{-}RS)_2\{Co(SR)_2\}_2]^{2-}$ anion, anticipated but not isolated in the thiophenolate systems, has now been obtained in both *anti* (**275**) and *syn* (**276**) forms for R = Et.[1002] Salts of $[Co(SEt)_4]^{2-}$, $[Co_4(\mu\text{-}SEt)_6(SEt)_4]^{2-}$ and $[Co_4(\mu\text{-}SPh)_6(Cl)_2(SPh)]^{2-}$ have also been isolated.[1000,1002] The adamantane-like core in $[Co_4(\mu\text{-}SPh)_6(SPh)_4]^{2-}$ (**277**) is maintained by bridging thiolate ligands rather than by direct Co—Co bonding, and the bridges are thermodynamically stable; added halides (Cl^-, Br^-) displace terminal rather than bridging PhS^- and the core is not disrupted in donor solvents (H_2O, py, DMSO). Bridging thiolate gives rise to a characteristic MCD spectrum for the ν_3 transition and this property has been utilized in the assignment of ligational modes (*b* or *t*) to RS^- in Co^{II} complexes of cysteine peptides and for Co^{II}-substituted metallothioneins.[1003]

(275)



(276)

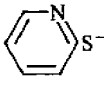
(277)

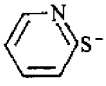
The reaction of $[\{MeC(dppm)_3\}_2Co_2(\mu\text{-}OH)_2](BPh_4)_2$ with MeSH in acetone in the presence of air produces the thiolate-bridged species $[\{MeC(dppm)_3\}Co_2(\mu\text{-}SMe)_2](BPh_4)$. Replacement of MeSH with H_2S in the reaction results in $[\{MeC(dppm)_3\}_2Co_2(\mu\text{-}S)_2](BPh_4)$. The redox and substitution chemistry of these systems has been examined in some detail and considerable crystallographic data are available.[1004] Some of these aspects are summarized in Scheme 89, where P_3 = $MeC(dppm)_3$. A feature of the dinuclear species is the planar nature of the Co_2S_2 unit and the insensitivity of the Co—Co separation on the formal oxidation state. In contrast to the stability of the μ-sulfido dimer the $[Co_2(\mu\text{-}SMe)_2]^{2+}$ structure does not survive reducing or oxidizing conditions, and ligand substitution by CO leads to monomeric products.

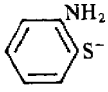
Scheme 89

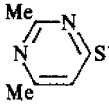
No sulfenate complexes of low-valent cobalt appear to be known but some sulfinate systems have been described. Treatment of $Na[Co(CO)_3(PPh_3)]$ with CF_3SO_2Cl gives stable monomeric $[Co(SO_2CF_3)(CO)_3(PPh_3)]$ in which $CF_3SO_2^-$ acts as a monodentate S donor.[1005] Blue tetrahedral $(PPh_4)_2[Co(O_2SR)_4]$, formed on treating $(PPh_4)[CoCl_4]$ with RSO_2Ag salts (R = Me, Ph, *p*-MePh), is hydrolyzed in water to octahedral (usually rose-red) $[Co(O_2SR)_4(H_2O)_2]$.[1006] The stereochemistry of these six-coordinate species is uncertain but IR studies indicate bidentate *O,O′* sulfinate, and their limited solubility in water and organic solvents is consistent with polymeric structures.[1007] An alternative route to their preparation involves the addition of NaO_2SR salts to solutions of cobalt(II) halides.[1007,1008]

Prolonged acetone extraction of $[Co(bipy)_3](O_2SR)_2$ (R = *p*-MePh) results in the formation of $[Co(O_2SR)_2(bipy)_2]$ linkage isomers involving O- and S-bonded monodentate sulfinate.[1009] The yellow S-bonded isomer is difficult to isolate (8%) owing to its tendency to decompose in the solid, but like the orange O-bonded form it displays spectral and magnetic properties consistent with an octahedral high-spin configuration.



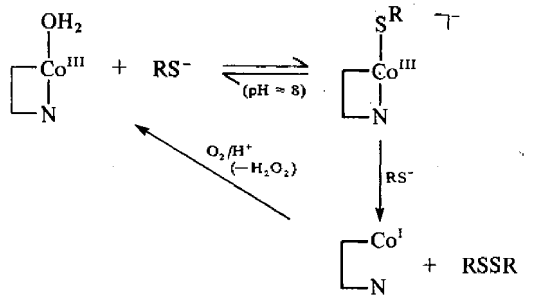






47.8.2.2 Cobalt(III)

A general account of the work of Sargeson's group up to 1979 is available[1010] as is an account of the oxidation of coordinated thiolate by Deutsch's group.[1011] X-Ray photoelectron spectroscopy provides a useful tool for determining the oxidation of coordinated sulfur by comparing $S2p_{3/2}$ binding energies with authentic systems.[1012]



(*i*) *Monodentate systems*

Authentic monodentate thiolate complexes of Co^{III} amines are unknown. Treatment of Co^{II} salts or Co^{III} amines with alkene- or arene-thiols, especially in the presence of air, should be avoided. Disproportionation and reduction of the Co^{III} complex and polymerization and oxidation of the thiol occurs. An intractable mess usually results. Thiolate complexes of cobaloximes and cobalamines are however well known. Treatment of $[Co(DMGH)_2py(Cl)]$ with a stoichiometric amount of NaOH and RSH (R = Me, Et) results in dark-green $[Co(DMGH)_2py(RS)]$ and similar treatment of the Co^{II} dimer $[Co(DMGH)_2py]_2$ with PhSH results in black $[Co(DMGH)_2py(PhS)]$ (Table 82). Solutions of $[Co(DMGH)_2py(RS)]$ are sensitive to air and in the presence of alkali decompose to RSSR and a mixture of cobaloxime(I) and [Co(DMGH)(OH)py]. In the presence of air cobaloximes and cobalamines catalyze thiol oxidation (Scheme 90),[1013] and visible light has been shown to sproduce $H_{2(g)}$ catalytically when $[Co(DMGH)_2py(PhS)]$ is irradiated in the presence of excess PhSH (Scheme 91).[1014]

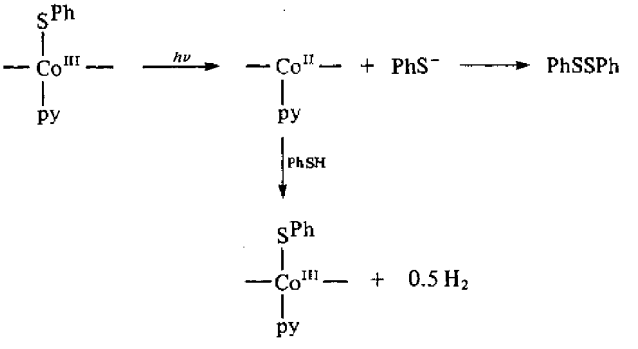


Table 82 Preparations: Monodentate and Bidentate Thiolate Chelates of Cobalt(III) (Not Containing Mixed Ligand Systems)

Complex	*Ligand*	*Preparation*	*Ref.*
Monodentate			
$[Co(DMGH)_2py(PhS)]$	PhS^-	$[Co(DMG)_2py]_2$; MeOH, r.t.	13

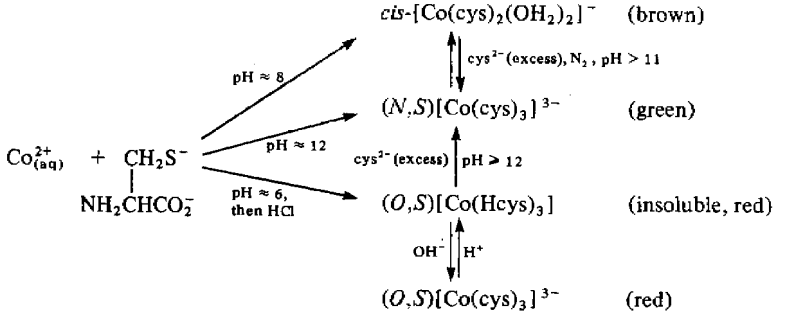
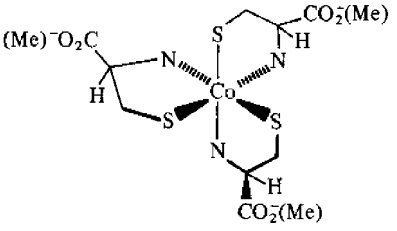


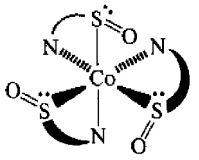
Scheme 90

Scheme 91



(*ii*) *Tris(bidentate) chelates*

The chemistry of bidentate thiols containing five- and six-membered chelates is now quite extensive. Table 82 summarizes some preparations. There is an interesting history to these complexes and some uncertainty still remains. Harris seems to be the first to have investigated cobalt—thiolate systems,[1015] and Michaelis and Schubert used Co^{II} salts in strongly alkaline aqueous media in the presence of air to prepare solutions of uncertain Co^{III} complexes containing cysteine and thioglycolic acid.[1016,1017,1018] Schubert then isolated dark-brown, green and red complexes[1019] and these were described in detail by Neville and Gorin,[1020,1021] sometimes with internal disagreements but with obvious difficult in reproducing the earlier work. The preparations and interconversions are outlined in Scheme 92 and should be reexamined in the absence of atmospheric oxygen since we now know that oxidation of thiolate sulfur both prior and subsequent to coordination is relatively easy. However green (N,S) and red(O,S) coordination of cysteine seems certain with the latter $Na_3[Co(cys)_3]\cdot 6H_2O$ complex in alkaline solution having an identical absorption spectrum to $[Co(O_2CCH_2CH_2S)_3]^{3-}$. The use of the Co^{III} reagents $Na_3[Co(CO_3)_3]\cdot 3H_2O$, $[Co(NH_3)_6]Cl_3$ and CoO(OH) in an N_2 atmosphere gives better yields of green or blue-green $[Co(cys)_3]^{3-}$, $[Co(tga)_3]^{3-}$ and $[Co(cyst)_3]$ (cyst = $NH_2CH_2CH_2S^-$; Table 82). With (*R*)-cysteine or its *O*-methyl ester[1024] the *fac*-(*N*,*S*)-Δ configuration of $[Co\{(R)\text{-cys}\}_3]^{3-}$ (**278**) appears to be formed stereospecifically with equatorially oriented uncoordinated carboxylate functions. The Δ absolute configuration about

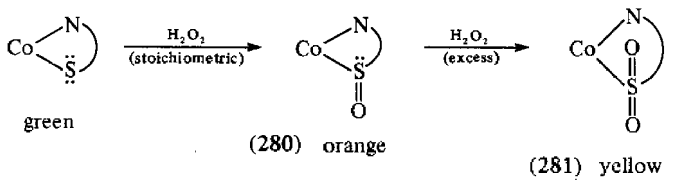


Scheme 92

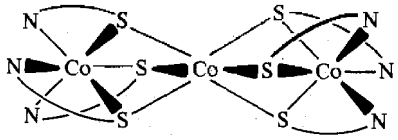
Co^{III} has been confirmed by comparing CD spectra[1022,1024] with that for resolved Λ-[Co(cyst)$_3$] whose absolute configuration is known from a structure (**279**) of its semi-oxidized [Co(cystO)$_3$]·(+)-tartaric acid mixed salt.[1025] Using Λ-[Co(en)$_3$]Br$_3$ as starting material partially resolved Λ-[Co(cyst)$_3$] has been prepared[1024] and it may be possible to extend this type of synthesis to other optically-active tris(N,S) systems. These green and blue-green complexes (Table 82) have been assigned the symmetrical *fac*-(N,S) geometry with the exception of brown [Co(pyt)$_3$] (pyt = pyridine-2-thiolate) which has been assigned the *mer*-(N,S) configuration on the basis of its more complex ^{13}C spectrum.[1026]

(278)

Δ-*fac*(*N*,*S*)-(+)$_{400}$-[Co{(*R*)-cys}$_3$]$^{3-}$



(279)



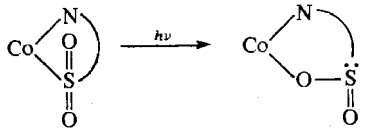
Λ-*fac*(*N*,*S*)-(+)$_{500}$-[Co(cystO)$_3$]

Such tris(N,S) chelates appear to be only moderately stable in neutral aqueous solution with [Co(cys)$_3$]$^{3-}$ being stable only at pH > 11 in the presence of excess cysteine; the oxidized sulfenate and sulfinate chelates are more stable (see below). Reexamination of brown *cis*-[Co(cys)$_2$(OH$_2$)$_2$]$^-$, the dimer [H$_2$Co(tga)(OH)]$_2$, black insoluble Na$_3$[Co(edt)$_3$]·3H$_2$O and green Na$_3$[Co(tga)$_3$]·6H$_2$O (Table 82) seems warranted. The tris(penicillamine) complex does not appear to have been made. Little is known about their optical and configurational stability, and no ligand replacement studies appear to have been undertaken. Heber and coworkers report the preparation of [Co(SCH=CHS)$_2$(PR$_3$)] (R = Ph, Bu, OPh) containing apparently Co^{IV},[1027] and the diamagnetic thioether complex [Co(SCH=CHSR)$_3$] (R = Me, Et, Bu),[1028] but further study to confirm their composition and to determine their structure is necessary.

Oxidation of coordinated thiolate to the sulfenic (**280**) and sulfinic (**281**) acid chelates can be readily achieved and the accompanying green–orange–yellow colour change is very striking (equation 155); it was used over 50 years ago by Michaelis and Yamaguchi as a sensitive test for H_2O_2[1016] and it was first correctly described by Schubert.[1019] The oxidized forms are much more stable and structural characterization has largely been done using them. Oxidation occurs without breaking the Co—S bond and the semi-oxidized sulfenate is asymmetric on sulfur (*i.e.* coordinated thiolate is prochiral). Four diastereoisomeric possibilities therefore exist for a single Δ-*fac*-(N,S)[Co(N—S)$_3$] configuration and steric arguments suggest oxidation will occur preferentially at the equatorial lone pair. Oxidation of Δ-[Co(cys)$_3$]$^{3-}$ is said to form only the Δ-(*S*,*S*,*S*) and Δ-(*R*,*S*,*S*)-[Co(cysO)$_3$]$^{3-}$ possibilities with the latter subsequently mutarotating to the former.[1024] This selectivity agrees with the chromatography of Δ-[Co{(*R*)MecysO}$_3$] where only one isomer is observed,[1024] and with the structure of Λ-(*R*,*R*,*R*)-[Co(cystO)$_3$]·C$_4$H$_6$O$_6$·H$_2$O,[1025] but it places the oxygen atom over an adjacent chelate ring rather than between chelates (**279**). Further investigations of this stereospecific or stereoselective effect would be useful. No similar studies appear to have been carried out on the oxidation products of Na$_3$[(tga)$_3$]. Few quantitative data are available on the rates and rate laws for oxidation. Qualitatively it is known that it is difficult to stop it at the tris(sulfenato) stage.[1024] Oxidation using non-oxygen-transferring agents (V^V, Ce^{IV}, HNO$_3$, Co^{3+}_{aq}) usually produces a disulfide. This remains coordinated if more than one electron is transferred (*cf.* Section 47.8.4) but it can be released to the solvent *via* an internal redox process with formation of Co^{II} and free ligand. Deutsch and coworkers have examined these aspects in some detail and a general account of this work is available.[1011] Oxidation of [Co(cyst)$_3$] using HNO$_3$ produces (**282**) and internal electron transfer in a semi-oxidized intermediate is proposed (Scheme 93).[1061]

green (280) orange (281) yellow (155)

(282)



$$[Co(cyst)_3] + ox \longrightarrow [Co(cyst)_2(cyst^+)] + red \xrightarrow[\text{internal electron transfer}]{H^+} Co^{II} + cyst + cyst\text{-}cyst$$

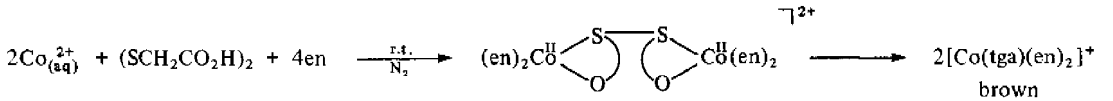
$$Co^{II} + 2[Co(cyst)_3] \longrightarrow [\{Co(cyst)_3\}_2\mu_6(Co^{II})]^{2+} \xrightarrow{\text{oxidation}} [\{Co(cyst)_3\}_2\mu_6(Co^{III})]^{3+}$$

(282)

Scheme 93

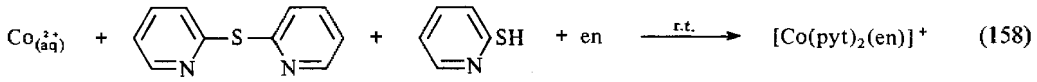
Dollimore and Gillard observed a yellow (406 nm) to red (490 nm) colour change on standing solid K_3-$\Delta(+)_{400}$[Co{(*R*)cysO_2}$_3$], or an aqueous solution of it, in bright sunlight.[1022,1023] This is likely to result from isomerization to the O-bound sulfinato complex (**283**) containing the six-membered chelate (equation 156).[1029] This O-bound sulfinate is now asymmetric on sulfur leading to further isomers, and inversion at S is synchronous with the exchange between coordinated oxygens. The unknown five-membered (N,O)carboxylate-bound chelate may be more stable in this case with release of the oxidized sulfur donor. No corresponding photolytic study has been reported for the sulfenate chelate, and it is not known if the isomerization given by equation (156) is thermally reversible.

(156)



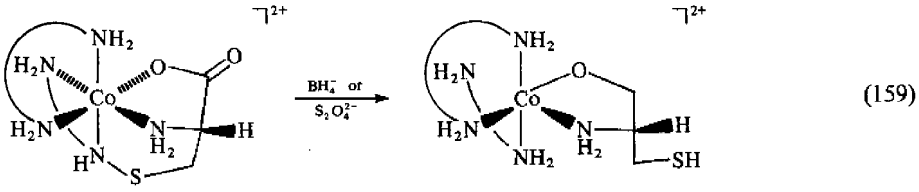
(283)

The $\Delta(+)_{400}$-[Co{(*R*)cysO_2}$_3$]$^{3-}$ anion forms sparingly soluble yellow salts with a number of 3+ cations[1019] and Dollimore and Gillard[1022] have shown it to be an excellent resolving agent for a wide variety of Co^{III}, Cr^{III} and Rh^{III} complexes.



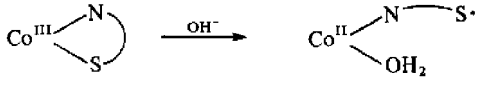
(*ii*) *Mixed bidentate chelates*

The mixed bidentate thiolato complexes $[Co(N—S)(en)_2]^{2+,1+}$ and $[Co(O—S)(en)_2]^+$ have received considerable attention over the last decade. Having only one coordinated S atom they provide ideal starting points for investigating the spectral and structural properties of different oxidation states of sulfur as well as for studying the reactivity of coordinated sulfur. Originally poor yields of these complexes were obtained by treating *trans*-[Co(Cl)$_2$(en)$_2$]Cl with (*R*)-cysteine, cysteamine and thioglycolic acid in aqueous alkaline solution[1030–1032] but Lane and Bennett[1033] discovered that oxidation of $Co^{2+}_{(aq)}$ using the disulfide of the thiol in the absence of air gave excellent yields (equation 157). This stoichiometry provides the basis of the modern method for preparing these complexes (Table 83). Some minor modification is necessary for aromatic thiols. The Cr^{III} analogues can be made in an identical manner.[1034] The excellent yield probably derives from internal redox within a Co^{II}–disulfide intermediate (**284**), although such a species has never been observed. The bidentate nature of the ligand probably stabilizes (**284**) and no successful preparations have been reported using disulfides which lack this capacity. The method also appears to be applicable to $[Co(N—S)_2(en)]^+$ and $[Co(O—S)_2(en)]^-$ chelates, and green $[Co(pyt)_2(en)](ClO_4)$ has been prepared using a mixture of the disulfide (1 mol equiv) and thiol (2 mol equiv) in ethanol (equation 158).[1035] A *trans*-(*S*) structure has been proposed. This particular complex is unstable in hot aqueous solution giving rise to $[Co(pyt)_3]$, but the preparative method can probably be extended to other systems. With (*R*)-cysteine the thermodynamically least stable diastereoisomer Λ-(*N*,*S*)[Co{(*R*)cys}(en)$_2$]-



(ClO_4) crystallizes in 96% yield in a second-order asymmetric manner. The solution actually contains the equilibrium mixture $\Delta(R):\Lambda(R) = 7:3$.[1036] Both $Co^{2+}_{(aq)}$ and OH^- effect rapid mutarotation about the metal in this complex but not about the chiral carbon. With (*S*)-penicillamine a similar equilibrium obtains ($\Lambda:\Delta[Co\{(S)pen\}(en)_2]^{2+} = 7:3$) but preferential crystallization does not occur.[1037] X-Ray structures confirm equatorial and axial dangling carboxylate functions in Λ-$[Co\{(R)cys\}(en)_2](ClO_4)$ and Δ-$[Co\{(R)cys\}(en)_2](ClO_4)\cdot H_2O$ respectively.[1037] (N,S) bonding seems to be preferred in (N,S,O) systems (cysteine, penicillamine) but (N,O)$[Co\{(R)cys\}(en)_2]^{2+}$ has been prepared by reduction of the tridentate sulfenamide complex (**285**; equation 159).[1038] This (N,O) chelate lacks the extended charge transfer absorptions in the near UV characteristic of thiolate coordination.

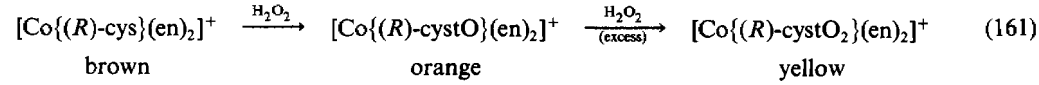
(157)



(158)

(159)

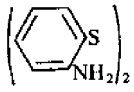
(285)

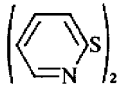


Thiolate sulfur in $[Co(cyst)(en)_2]^{2+}$ can be protonated in strong acid without dissociation from the metal[1039] but all thiolate chelates seem to be unstable in strongly alkaline solutions undergoing slow thermal reduction *via* an inner-sphere electron-transfer process (equation 160).[1056]

(160)

Spectral and structural data are given in Table 84 and Table 85 and methods of resolving enantiomeric systems in Table 86. Photodecomposition ot $Co^{2+}_{(aq)}$ occurs without photoaquation and is wavelength independent.[1049]





Oxidation to coordinated sulfenate and sulfinate (equation 161) was first reported by Sloan and Krueger[1040] who isolated the orange sulfenate and yellow sulfinate as their perchlorate salts. Similar oxidized products have now been isolated for several systems; these are given in Table 87. Generally the sulfenate complexes aquate or decompose slowly in neutral aqueous solution and the reaction is acid catalyzed. They also decompose to unknown products in strongly alkaline conditions. Reversible O-protonation occurs in acid ($pK_a \approx -1$) without mutarotation at S (see below). The sulfinate complexes are more stable in neutral and acid solution but they also decompose in alkali. One mole equivalent of oxidizing agent generates the sulfenate exclusively with excess reagent and longer times being necessary to form the sulfinate (this differs from the tris(thiolate) systems, Section 47.8.2.2.ii). Stabilization of sulfenate S is not found in uncoordinated sulfenic acids. Lydon and Deutsch have discussed these properties in a general article.[1043]

(161)

Two-electron oxidizing reagents are the best ($S_2O_8^{2-}$, Br_2, NaOCl, MnO_4^-, H_2O_2) and the reaction of H_2O_2 follows a two-term rate law, $k_{obs} = k_1[H_2O_2] + k_2[H_2O_2][H^+]$, with k_2 being interpreted as attack by $H_3O_2^+$; this term is important only when $[H^+] > 0.1\,mol\,dm^{-3}$. Comparative data are given in Table 88. A similar situation holds for $S_2O_8^{2-}$. Coordinated thiolate is about as nucleophilic as NCS^- and the reduced nucleophilicity of coordinated sulfenate is probably why it is stabilized relative to organic sulfenates. The ligand field strength of sulfur increases with formal oxidation

state, thiolate(II) < sulfenate(IV) < sulfinate(VI); $^1A_{1g} \rightarrow {}^1T_{1g}$ transitions at 470–520 nm (brown), 470–490 (orange) and 430–440 (yellow) (Table 84).

Metal sulfenates are formally analogous to organic sulfoxides being asymmetric at S; the [Co(N—SO)(en)$_2$]$^{n+}$ systems are therefore diastereoisomeric. Oxidation of Λ-[Co{(*R*)cys}(en)$_2$]$^+$ occurs preferentially at the axial lone pair (**286**),[1036] probably because the prochiral centre is more accessible to H_2O_2 and the carboxylic acid substituent of cysteine prefers to be equatorial. But oxidation is not stereospecific with Λ(*S*):Λ(*R*) ≈ 2.5 for the 1+ reactant (at pH ≈ 5) and 1.3 for the 2+ reactant (at pH < 2). More sterically hindered oxidizing agents increase this ratio.[1036] The more rapid further oxidation of the remaining axial lone pair in Λ(*R*)-[Co{(*R*)cysO}(en)$_2$]$^+$ compared to the slower oxidation of the equatorial lone pair in Λ(*S*)-[Co{(*R*)cysO}(en)$_2$]$^+$ supports this idea.[1041] However the structure of Δ(*S*)-[Co(cystO)(en)$_2$](SCN)$_2$ (**287**; Table 87) clearly shows that oxidation in this complex has occurred at the equatorial site. The specificity in this latter system has not been detailed.[1042] Equatorial oxidation is also found with [Co(cyst)$_3$] (Section 47.8.2.2.ii), so some flexibility is possible. The *p*- and *t*-[Co(cystO)(tren)]$^{2+}$ ions having S^{IV} as the only centre of asymmetry have been resolved into their (*R*) and (*S*) enantiomers (**288**) and (**289**).[1045] This is the first reported resolution of enantiomeric sulfenate complexes in which coordinated sulfur is the only source of asymmetry.

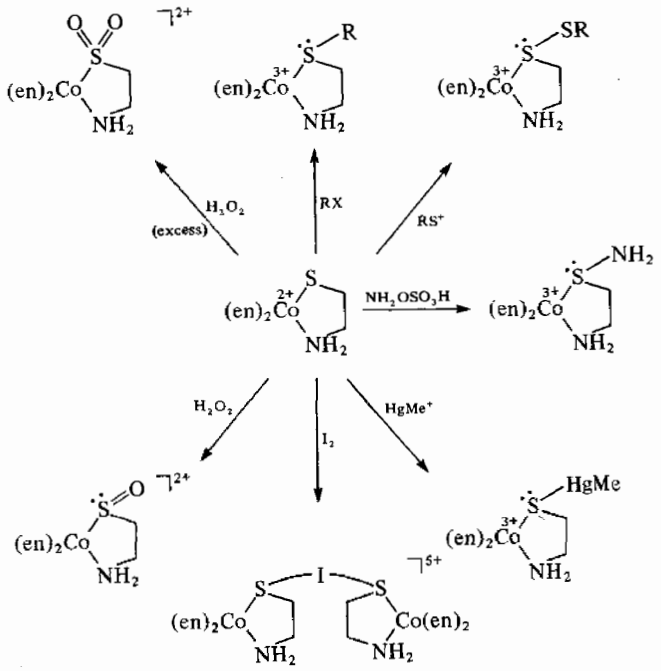
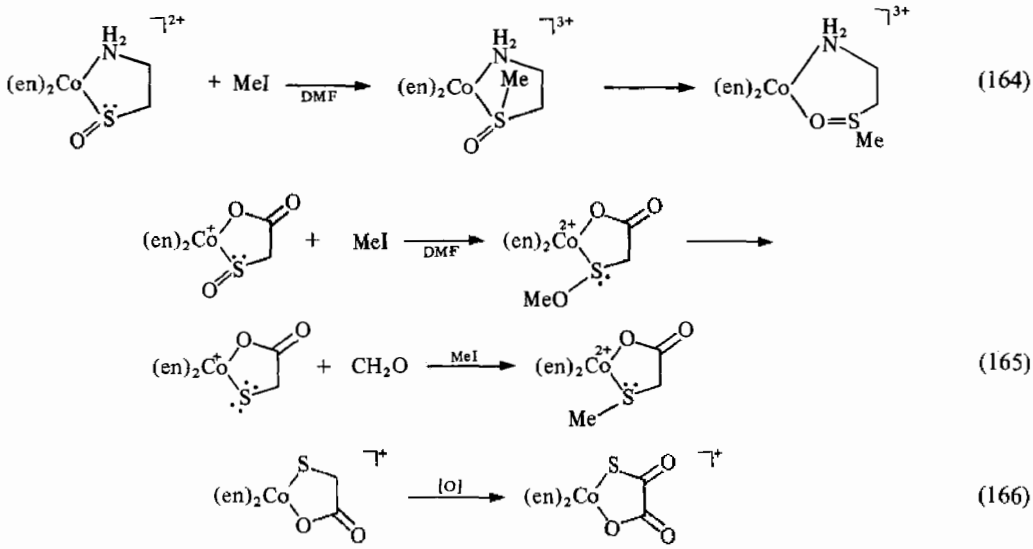
p(*S*)-[Co(cystO)(tren)]$^{2+}$

Mutarotation at coordinated sulfenate S is slow, which is analogous to the situation with organic thiols. Introduction of the S=O group imparts a high resistance to inversion. Racemization in *p*-(*S*)-$[Co(cystO)(tren)]^{2+}$ occurs at the rate $9.92 \times 10^{-5}\,s^{-1}$ (30 °C; pH independent) and the *t*-(*S*) isomer is some 80 times slower.[1045] Other diastereoisomeric sulfenate systems have also been shown to be optically very stable. Protonation to form Co—S(OH)R ($pK_a \approx 0$) does not alter this, but addition of alkali does with mutarotation of Λ(*S*)-$[Co\{(R)cysO\}(en)_2]^{+}$ being rapid at both S and Co in 0.1 mol dm^{-3} OH^- (but not at C). This may occur *via* a labile Co^{II}—SO(R) intermediate.[1036]

Mutarotation at S is also reported to be catalyzed by light,[1041] possibly *via* an O-bound sulfenate intermediate (equation 162). Adamson and coworkers report that photodecomposition to $Co^{2+}_{(aq)}$ is the final outcome.[1049] For sulfinate complexes donor S to O isomerization occurs[1029,1049] and red O-bound (N,O)$[Co(cystO_2)(en)_2](ClO_4)_2 \cdot H_2O$ has been isolated.[1029] This process (equation 163; *hν* 350–450 nm) is thermally reversible ($t_{1/2} \approx 600$ h, r.t.) but which O atom is involved, axial or equatorial, is not known. The O-bound form is now asymmetric, and some specificity might be expected.



(162)



(163)

Root and Deutsch discuss other oxidations of coordinated thiolate[1059] and Scheme 94 outlines some of these. Nucleophilicity towards MeI is similar to that of uncoordinated RSH or RSR. Some crystal structures of the oxidized products are given in Table 87. The reactivity of sulfenic acids is masked by coordination to the metal and these complexes are reasonbly stable in neutral or weakly acidic solutions, but strong acid gives mostly $Co^{2+}_{(aq)}$. Unlike organic sulfoxides (which preferentially O-alkylate and then slowly rearrange to the sulfoxonium ion R_3SO^+) only S-methylation is observed when $[Co(cystO)(en)_2]^{2+}$ is treated with MeI (it may however initially occur at O).[1044] This product then isomerizes to the O-bound isomer (equation 164). Both processes occur with full retention of configuration at S and Co and the six-membered ring is apparently more stable than the five-membered chelate. Treatment of $[Co(tgaO)(en)_2]^+$ with MeI however gives rise to the thioether $[Co(tgaMe)(en)_2]^{2+}$ rather than the sulfoxide possibly *via* disproportionation of the intermediate *O*-methyl ester to the thiolate and formaldehyde (equation 165), the process being activated by the acidic α-carbon centre.[1043,1044] Other oxidants may react to give oxidation at the adjacent C atom rather than at coordinated S. Thus treatment of $[Co(tga)(en)_2]^+$ with *N*-chlorosuccinimide[1057] or acetic anhydride[1058] in DMF or DMSO leads to the monothiooxalate chelate (**290**; equation 166).

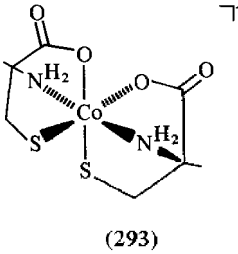
(*iv*) *Tridentate, quadridentate and sexidentate chelates*



The (S,O,N) tridentate ligands (*R*)-cysteine, (*R*)-methionine and (*R*)-penicillamine coordinate stereospecifically but often give several geometric isomers of $[Co\{(R)L\}_2]^{-,+}$. Table 89 lists some preparations and Table 85 some structures. All three isomers (**291**), (**292**) and (**293**) of $[Co\{(R)cys\}_2]^-$ have been isolated and their visible and CD and ^1H NMR spectra compared.[1046,1047] Isomerization to a common equilibrium slowly occurs in aqueous solution. Treatment of *trans*(*N*)-$[Co\{(S)pen\}_2]^-$ with Me_2SO_4 in aqueous solution results in all three geometric thioether complexes $[Co\{(S)penMe\}_2]Br$,[1047] whereas similar treatment of the three $[Co\{(S)pen\}(dien)]^+$ isomers appears to proceed with geometric integrity.[1048] ^1H NMR also suggests that methylation at the asymmetric S atom is stereospecific. The isolation of the tridentate $[Co\{(R)cys\}_2]^-$ has not been reported (*cf.* Section 47.8.2.2.ii for $[Co\{(R)cys\}_3]^{3-}$). Some mixed-ligand complexes are included in Table 89. The quadridentate ligand $HS(CH_2)_2N(Me)CH_2CH_2N(Me)(CH_2)_2SH$ forms two $[Co(eddt)(en)]^+$ isomers (**294**) and (**295**), and a crystal structure establishes stereospecific coordination of the sexidentate thioether ligand *N*,*N*′-ethylenebis{(*R*)-cysteine-Me} (**296**; Table 89).

(*v*) *Metal binding to coordinated thiolate*

Soft metals such as Ag^+, Cu^+ and $MeHg^+$ coordinate to $Co^{III}SR^{n+}$ complexes and uncoordinated thioethers with about equal ease. Thus it seems that Co^{III} and R^+ have similar effects on the binding power of RS^-, reducing it by about 10^{10} (Table 90; equation 167). This property has implications for electron transfer since ligation of coordinated thiol to a second metal centre is probably the first step in inner-sphere electron transfer. Data given in Table 90 demonstrate that Co^{III}—SR^{n+} retains some Lewis basicity towards soft metals. These studies have utilized $[Co(R—S)(en)_2]^{+,2+}$ systems (R—S = cyst, tga)[1050] but the metals Fe^{III},[1051,1052] Ru^{III}[1052] and Co^{III}[1053] also form very stable $[Co(cyst)_3]_2M^{3+}$ cations *via* bonding to the trigonal faces of two $Co(cyst)_3$ octahedra,[1052] and Zn^{II}, Cu^{II} and Cd^{II} form $\{[Co(cyst)_3]_2M\}MBr_4$ species which are thought to involve μ-Br bridges.[1053] Resonance Raman studies show two strong absorptions which have been assigned to the somewhat weakened stretching and bending modes of the $Co(cyst)_3$ moiety,[1054] and oxidation by H_2O_2 appears to be modified by the presence of the second metal.[1060] The prochiral S centre generates two diastereoisomeric possibilities in a CoS(R)M product. Structure (**297**; Table 85) shows the axial lone pair to be more nucleophilic generating $\Lambda(S),\Lambda(S)$ and $\Delta(R),\Delta(R)$ dimers. The Ag^+ ion lies on a two-fold symmetry axis and the dimer unit is chiral with two units existing in the crystal related by a centre of inversion. Both lone pairs are involved in the binding of Cu^I (structure **298**; Table 85). This red-brown dimer has been suggested as a model for ESR-silent type 3 copper in multicopper oxidases.[1055]

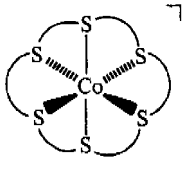
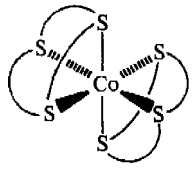
47.8.3 Thioethers

The coordination chemistry of thio-, seleno- and telluro-ethers in transition metal complexes has recently been reviewed in detail.[1094]



47.8.3.1 Cobalt(II)

Co^{II} is generally regarded as forming only weak bonds to thioether sulfur. This is indicated by the absence of complexes containing monodentate thioether and by only a few reports dealing with bidentate thioether complexes. The latter are of the $[Co(X)_2\{RS(CH_2)_2SR\}_2]$ type (R = Me, Et, Pr; $X = Cl^-, Br^-, I^-, NCS^-$)[1062,1063] and they display spectral and magnetic properties consistent with a *trans* octahedral geometry. This has been verified for $[Co(ClO_4)_2\{MeS(CH_2)_2SMe\}_2]$, which incidently was the first complex containing coordinated perchlorate to be structurally characterized (Table 75).[1064] Its magnetic properties resemble Co^{II} in a square-planar environment due to the weak coordination of ClO_4^- and have been interpreted in terms of a doublet–quartet equilibrium.[1063]

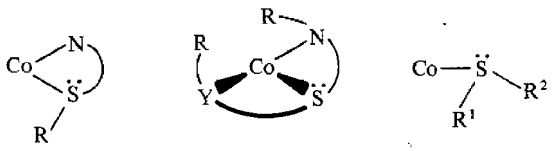


Various mixed-donor bidentate systems have been investigated. N—S bidentates generally form high-spin octahedral $[Co(X)_2(N—S)_2]$ complexes but increasing ligand bulk can result in tetrahedral $[Co(X)_2(N—S)]$. Ligands investigated include 2-(methylthio)aniline (mta),[1065] 2-[(methylthio)methyl]aniline (mtma),[1066] 2-{(methylthio)methyl}pyridine (mtmp)[1067] and *trans*-2-(ethylthio)cyclopentylamine (etcp).[1068] Tris complexes containing these ligands are rare but $[Co(mtmp)_3](ClO_4)_2$ has been reported.[1067]

The structure of *trans*-$[Co(Cl)_2\{HO(CH_2)_2S(CH_2)_2OH\}_2]$ shows the potentially tridentate thioether acting as a bidentate with normal Co—O bonds (207 pm) but long Co—S bonds (251 pm).[1069] Structural studies have also been carried out on high-spin Co^{II} complexes of alkylthioacetate ($RSCH_2COO^-$) ligands.[1070,1071] With Ph_2P(2-MeSPh) and $Ph_2P(CH_2)_3S(CH_2)_3S(CH_2)_3PPh_2$ low-spin five-coordinate $[CoX(P—S)_2]^+$ and $[CoX(PSSP)]^+$ have been characterized by magnetic and spectral studies.[604,1072] Similar complexes exist with the related As—P and Se—P ligands. The NSN tridentate $Me_2N(CH_2)_2S(CH_2)_2S(CH_2)_2NMe_2$ (Me_4daes) forms high-spin (μ = 4.4–4.5 BM) five-coordinate $[Co(X)_2(Me_4daes)]$ complexes ($X = Cl^-, Br^-, I^-$) and visible spectra indicate trigonal bipyramidal structures in the solids.[1073] This geometry also occurs with $[CoBr(Bu^t\text{-}NS_3)]PF_6$ ($Bu^t\text{-}NS_3 = N(CH_2CH_2SBu^t)_3$). All three sulfur atoms lie in the equatorial plane with the Co atom displaced 35 pm toward the apical bromine (Co—S, 238 pm).[1074]

Cobalt(II) complexes of polythioethers include those of 1,2-bis-(*o*-methylthiophenylthio)ethane,[1075] and the macrocyclic ligands 1,4,7-trithiacyclononane ([9]aneS$_3$)[1076] and 1,4,7,10,13,16-hexathiacyclooctadecane ([18]aneS$_6$).[1077] The structure of $[Co([18]aneS_6)](picrate)_2$ shows the cobalt atom in a distorted octahedral environment with each three-sulfur segment coordinated facially to give the *meso* geometry (**299**). Facial coordination of the trithia ligands is also found in the tetragonally distorted CoS_6 complex $[Co([9]aneS_3)_2](BF_4)_2$ (**300**),[1076] but here $Co—S_{eq} > Co—S_{ax}$, whereas the reverse occurs with $[Co([18]aneS_6)](picrate)_2$.[1077] The low spin ($\mu$ = 1.8 BM) of the latter complex is unusual since thioether donors are normally regarded as relatively weak-field ligands. However this is the only $Co(SR)_6^{2+}$ system for which magnetic and ESR data have been reported.

(299)



(300)

47.8.3.2 Thioethers, sulfoxides and sulfones, cobalt(III)

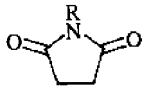
Thioether complexes are mostly of the bidentate (**301**) or multidentate (**302**) type. Monodentate systems (**303**) are rare but are known (equation 167a),[1078] and in such cases they provide useful starting materials since the thioether ligand is easily displaced.

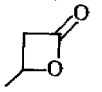
$$Co(NO_3)_2 + 2DMGH_2 + NaBr + Me_2S \xrightarrow[EtOH,\ heat]{O_2} \underset{\text{brown}}{trans\text{-}[CoBr(Me_2S)(DMGH)_2]} \quad (167a)$$

(301) (302) (303)

Coordinated thioether S is often asymmetric. In (**302**) the asymmetry is frozen by the configuration of the attached chelate rings but in (**301**) it is not and inversion is fast. Conventional resolution *via* diastereoisomeric salts has never been substantiated for a purely enantiomeric Co—SR^1R^{2n+} system devoid of other chirality. ^{13}C and ^1H studies on diastereoisomeric systems[1079] however show that inversion rates are normally of the order $0.1–10\,s^{-1}$, which makes coordinated thioethers decidedly more configurationally labile than organic sulfonium salts. The effects of asymmetry in (**302**) are readily seen in diastereoisomeric systems where the lone pair on S is often stereospecifically orientated. It usually directs stereochemical change and ligand replacement processes.

(*i*) *Bidentates*

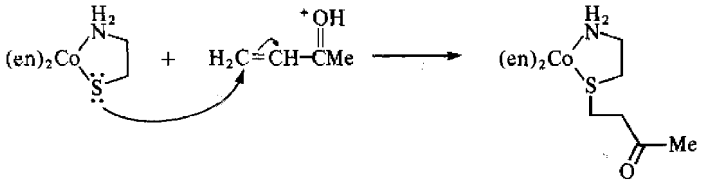




Kolhari and Busch were the first to describe the alkylation of Co^{III}—SR when they treated (N,S)[Co(cys)$(en)_2$]I with MeI in aqueous methanol.[1030] However they incorrectly described the product as (N,O)[Co(cysMe)$(en)_2$]I_2 containing carboxylate rather than thioether coordination. The (N,S) and (N,O) chelates have subsequently been clearly distinguished (equations 168 and 169), and the methylation reaction gives the (N,S) isomer with retention of the Co—S bond.[1080] Deutsch and coworkers in a comprehensive investigation of alkylating reagents describe the versatility of this reaction.[1081,1082] Some of this information is collected in Table 91. Primary and secondary alkyl groups, activated double bonds, carbocations, and strained groups have been added. Alkylation of $[Co(cyst)(en)_2]^{2+}$ with methyl vinyl ketone is first order in both reactants and in $[H^+]$, consistent with the mechanism given by equation (170).[1082] Where crystal structures are available (Table 85) they show alkylation occurs stereospecifically at the axial lone pair with the R group directed between adjacent ethylenediamine chelates,* *e.g.* (**304**). Subsequent mutarotation does not usually occur.

$$\Lambda\text{-}(N,S)[Co\{(R)\text{-cys}\}(en)_2]ClO_4 + MeI \xrightarrow{DMSO} \underset{\text{brown}}{\Lambda\text{-}(N,S)[Co\{(R)\text{-cysMe}\}(en)_2](ClO_4)_2} \quad (168)$$

$$cis\text{-}[Co(DMSO)_2(en)_2](ClO_4)_3 + (R)\text{-HcysMe} \xrightarrow{DMSO} \underset{\text{orange}}{\Delta,\Lambda\text{-}(N,O)[Co\{(R)\text{-cysMe}\}(en)_2](ClO_4)_2} \quad (169)$$



Bidentate thioether complexes are reasonably stable in neutral and acidic aqueous solutions but readily hydrolyze in alkali, and the process appears to be reversible. Oxidation to the sulfoxide is difficult but once thioether S is dissociated from the metal becomes relatively easy (Scheme 95).

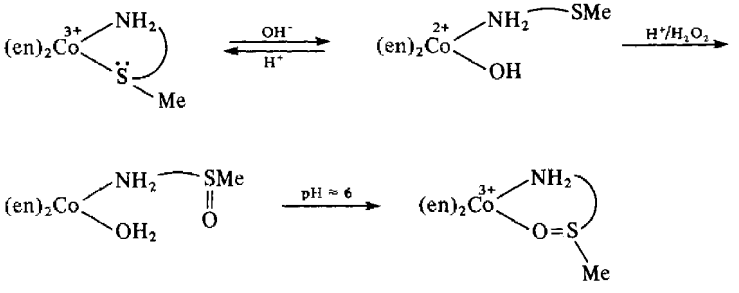
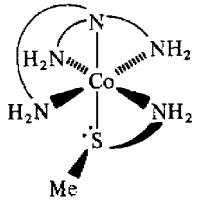
*The IUPAC designation (*S*) or (*R*) at sulfur depends on the nature of the substituent. When R = H, Me, Et, the Λ-[Co$(NH_2\text{-SR})(en)_2]^{3+}$ complex takes the (*R*) configuration but for heavier substituents (*e.g.* O, S) the configuration is (*S*). For the sake of consistency with the sulfenate and disulfide complexes we will designate the substituent as taking precedence in all cases, *i.e.* (*S*) for all substituents.



(170)

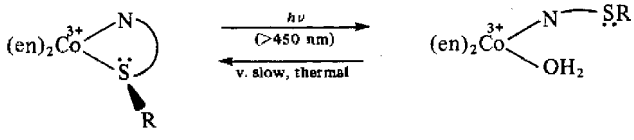
(304)



$\Lambda(S)$-$[Co(H_2N{-}SR)(en)_2]^{3+}$

Subsequent coordination now ocurs *via* the O atom, probably with displacement of coordinated water. This chemistry resembles that of organic sulfonium salts (R_3S^+) and thioethers.

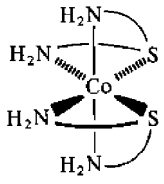
Scheme 95



Inversion at Co^{III}—SR^1R^2 is fast (0.1–10 s^{-1}) but diastereoisomeric systems have been detected by ^1H and ^{13}C NMR spectroscopy. Thus (**305**) shows clearly resolved signals of the tren ligand arising from the chiral thioether.[1079] Also the related *t*-(N,S)[Co{(*R*)cys}(tren)]$^{3+}$ chelate shows immediate ^1H-NMR spectral changes on deprotonation of the dangling equatorial carboxylate arising from rapid (< 5 s) mutarotation of the (*R*)S(*R*)C, (*S*)S(*R*)C diastereoisomeric mixture. Thus inversion appears to be 10^5–10^7 times more rapid than for uncoordinated sulfonium salts, a result in keeping with other M—SR^1R^2 systems.[1083]

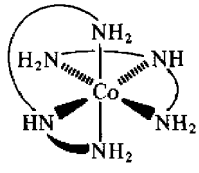
(305)

t-[Co(cystMe)(tren)]$^{3+}$



Photolysis in the ligand field region leads to photoaquation (equation 171), while irradiation in the charge-transfer region leads to some reduction to $Co^{2+}_{(aq)}$.[1049] The thioether S atom in [Co$(RSCH_2CH_2NH_2)(en)_2]^{3+}$ (R = alkyl, aryl) has been shown to act as a lead-in centre for inner-sphere reduction of the metal by $Cr^{2+}_{(aq)}$, with more bulky R slowing down the rate and carboxylate substituents increasing the rate by chelating to the reductant.[1097]

(171)



(*ii*) *Multidentates*

Preparations and structures are given in Tables 92 and 93 respectively. Bridging thioether (**302**) prefers the bent configuration with adjacent chelate rings in different planes. Thus $[Co(daes)_2]^{3+}$ adopts only the *u-fac* configuration (**306**), whereas the analogous all N system prefers the *mer* geometry (**307**). Similarly, $[Co(X)_2(eee)]^{n+}$ is *s-cis* (**308**) for X = Cl^-, Br^-, NO_2^-, NCS^-, $C_2O_4^{2-}$, bipy, as is $[Co(Cl)_2(tet)]^+$, while $[Co(X)_2(ete)]^{n+}$ prefers the *u-cis* geometry (**309**) but does adopt *trans* (**310**) for X = Cl^- (60% *u-cis*, 40% *trans* at equilibrium).[1084] The corresponding all-N complexes $[Co(Cl)_2(trien)]^+$, $[Co(Cl)_2(3,2,3\text{-tet})]^+$ and $[Co(Cl)_2(2,3,2\text{-tet})]^+$ adopt *s-cis*, *u-cis* and *trans,trans*, and *trans* configurations respectively. This stabilization of the bent geometry at S is not well understood but may be connected with its larger size. The reader is referred to a recent article by Abel, Bhargava and Orrell on such aspects.[994] In (**308**) the lone pair on S is stereospecifically orientated and only $\Lambda(R,R)$ and $\Delta(S,S)$ configurations obtained, but for (**309**) and (**310**) the planar S may be (*R*) or (*S*). This can direct subsequent stereochemical change.[1084,1085] Thus inversion at S must occur for the stereochemical change (**309**) *R,S* to (**308**) *R,R*, and (**310**) *R,R* gives stereospecific (**309**)-$\Lambda(R,R)$ and (**308**)-$\Lambda(R,R)$ products if the asymmetry at S is maintained. Little is known about such processes compared to the well-documented chemistry for coordinated N. Worrell and colleagues have synthesized several thioether chelates in order to study the effects of the long Co—S bonds on inner-sphere electron transfer reactions *via trans* ligands.[1089,1090] The cations (**311**) and (**312**) show increased rates of reduction by $Fe^{2+}_{(aq)}$ compared to their all N analogues.[1090,1096] One recent study[1086] serves to highlight the ease of inversion at thioether S and suggests that the restriction of geometrical configuration resultant upon retention at S is not as certain here as it is in N multidentates. The ready interconversion of the optically active brown (**313**) and green (**314**) isomers of [Co{1,10-bis(salicylideneamino)-4,7-dithiadecane}]$^+$ (equation 172), can be accomplished *via* a trigonal twist process with simultaneous inversion at both chiral S centres. The alternative possibility of retention at S would require a complex series of edge displacements and predicts the opposite absolute configuration about the metal. Rapid (0.1–10 s^{-1}) inversion at coordinated S allows for flexible rearrangement in such multidentates. The structure of (**313**; Table 93) contains the very unusual planar thioether ligand.

Cyclic 14- and 15-membered tetrathioether ligands (**315**) and (**316**) also form $[CoX_2(S_4)]^+$ complexes with (**315**) preferring the *cis* geometry and (**316**) being *trans* with planar S donors (Table 92). *cis*-$[CoCl_2(ttp)]^+$ undergoes normal metathetical reactions to form *cis*-$[CoX_2(ttp)]^+$ species but *trans*-$[CoCl_2(ttx)]^+$ decomposes readily in hot water to give Co^{2+}_{aq}.[1095]

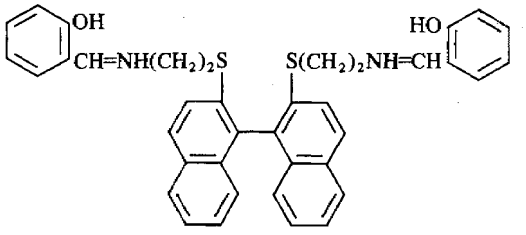
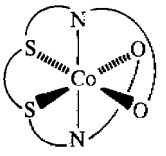
(316)

Steric or conformational restraints imposed by substituents on the ligand can impose stereoselectivity or can enforce some stereospecificity. Thus (*R*)-epe stereospecifically forms (**317**) with the methyl group equatorial rather than axial,[1087] and (*S,S*)-pep also prefers (65%) the Λ configuration (**318**) with the methyl groups adjacent to X.[1088] In both systems the configuration about Co and S

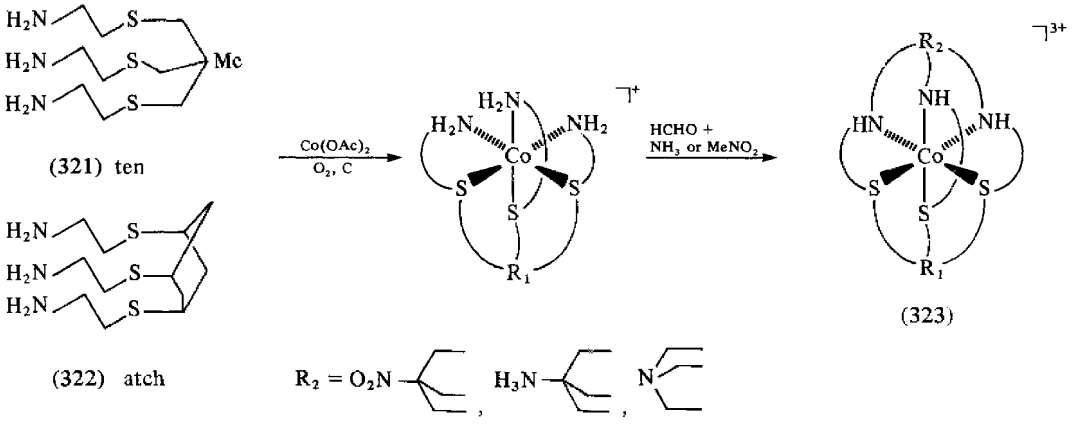


(317) Λ-(*R,R*)-[CoX$_2${(*R*)-epe}]$^+$



(318) Λ-(*R,R*)-[CoX$_2${(*S,S*)-pep}]$^+$

is maintained in various displacements of X. Gahan and O'Connor have used the optically-active binaphthyl fragment (**319**) to stereospecifically form the cobalt sexidentate (**320**) in which the two S donors have the (*S*) configuration.[1091]

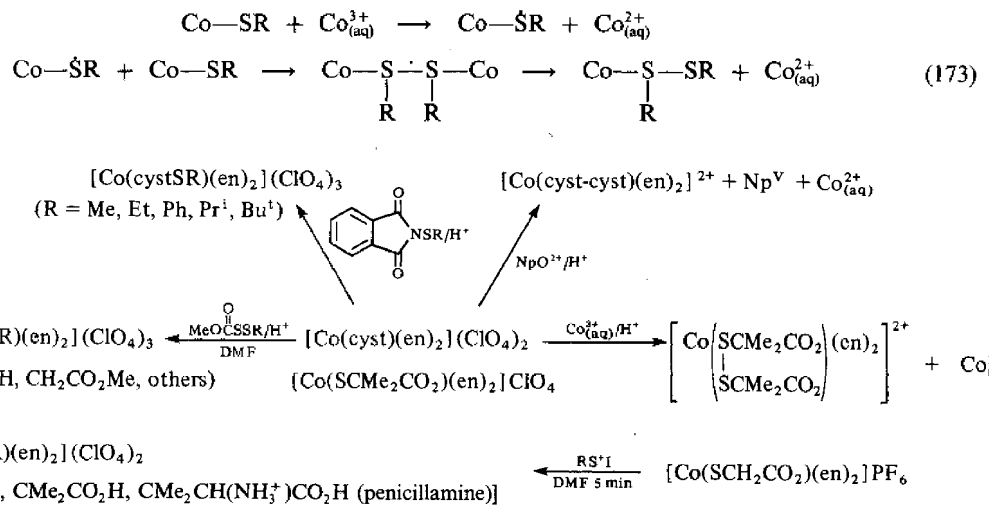


(319)

(320)

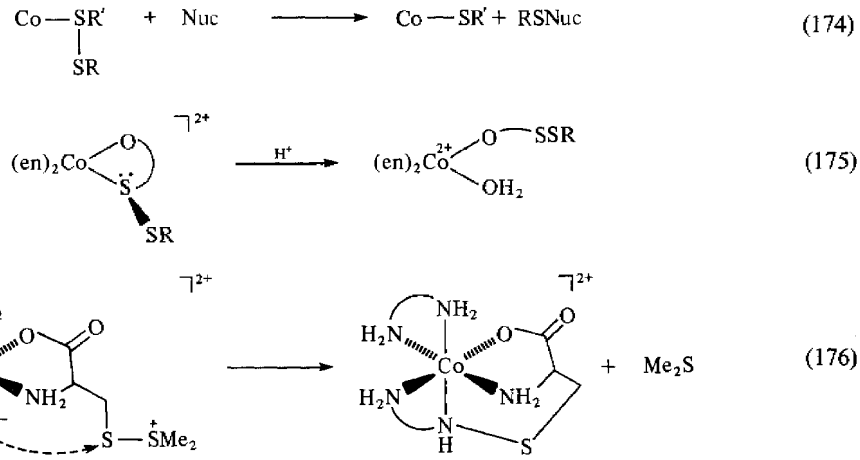
Λ-(+)$_{546}$-[Co{(*S*,*S*)-nmep}]$^+$

Sargeson and coworkers have synthesized a number of thioether cryptate sexidentates including (**321**)[1092] and (**322**)[1093] condensing the appropriate trithiol with aziridine. The trigonally positioned amine groups in their Co^{III} complexes (Table 92) have been capped by condensation with HCHO and an appropriate nucleopile to form the totally encapsulated complexes (**323**; Scheme 96). These have been resolved into their optical enantiomers which can be reduced to the chiral Co^{II} chelates and reoxidized by O_2 with full retention of chirality. Indeed it is very difficult to remove the metal from within the cage under any condition.



Scheme 96

47.8.4 Disulfides (RSSR), Cobalt(III)



Interest in these systems stems largely from the influence of metals on the thiolate–disulfide redox couple found in blue copper proteins. The synthesis of Co^{III} disulfides has been largely due to Deutsch and coworkers.[1098] Single-electron oxidation of Co^{III}—SR^{n+} by Np^{IV}, $Co^{3+}_{(aq)}$, or $Fe^{3+}_{(aq)}$ leads to symmetrical disulfides containing only one coordinated S atom. The reaction (equation 173) is generally fast and is considered to proceed *via* a free radical mechanism. Unsymmetrical disulfides may be generated using potent RS^+ species such as *N*-thiophthalimides, sulfonyl iodides, and methoxycarbonyl alkyl disulfides, with the latter being possibly the most useful because of their generality and ease of preparation. The reactions proceed *via* bimolecular attack of the coordinated thiolate on RS^+Y^-; examples are given in Scheme 97. The coordinated S atom is asymmetric in the product (**323**; equation 173) and structural studies (Table 85) suggest that with diastereoisomeric systems only the axial lone pair is used with the added SR group being located between chelate rings, that is the thioalkylation is probably stereospecific at coordinated S. However, there is no information on the optical stability of the coordinated disulfide. Electronegativity arguments would place RS^+ somewhere between R^+ and O^{2-}, and whereas Co^{III}–thioether systems invert fairly rapidly (*cf.* Section 47.8.3.2.i). Co^{III} sulfenates are optically stable. Mutarotation or racemization at Co^{III}–disulfide probably lies somewhere in between.

Coordinated disulfides are very susceptible to nucleophilic cleavage and this is often an obstacle to their preparation. Nucleophiles such as OH^- and RSH cause rapid regeneration of the Co^{III} thiol

Scheme 97

except when the S—S bond is protected by bulky groups (equation 174). Thus when R = Bu^t and $C(Me)_2CO_2H$, the $[Co(tga\text{-}SR)(en)_2]^{2+}$ complex is reasonably stable and hydrolysis of the Co—S bond now becomes a competitive process.[1098] The S—S bond is more inert in acidic solution but hydrolysis of the Co—S bond occurs (equation 175). The susceptibility of the S—S bond to nucleophilic attack is displayed by the intramolecular formation of a coordinated sulfonamide *via* a sequence of reactions including that with the solvent DMSO (equation 176).[1099] The last step in this process involves attack of deprotonated coordinated ethylenediamine on the activated disulfide.

47.8.5 *Trans* Effect of Coordinated Sulfur

Sulfur ligands have a tendency to labilize groups *trans* to them in octahedral cobalt(III) complexes. In recent years structural and NMR evidence has been correlated with rates of substitution to justify semiquantitatively the statement that a longer than normal bond represents a weaker bond in a kinetic sense; that is ground-state destabilization is a major factor influencing rates of substitution. Recent publications in this area may be consulted for details.[426,927,1100] Crystal structure data (Table 72) clearly show longer *trans*-NH_3 bonds compared to *cis*-NH_3 in S-bonded SO_3^{2-} complexes and this is extended and correlated (Scheme 98).[1081] For SO_3^{2-} and $S(O)_2R^-$ complexes rates of replacements of the *trans* ligand have been correlated with this lengthening in both amine[426,927] and dimethylglyoxime[1100,1101] complexes. Such studies assume a purely dissociative reaction, with loss of *trans*-L (k_1 for loss of NH_3 in equation 177) being a measure of the observed rate. This gives $k(SO_3^{2-})/k\{S(O)_2R^-\} \approx 150$ corresponding to a Δr of ~ 3 pm. A comparison of the type $k(SO_3^{2-})/k(NH_3$ or $H_2O)$ is more difficult, but Yandell and Tomkins[927] estimate a value of $\sim 10^8$ corresponding to $\Delta r = 9$–10 pm. SO_3^{2-} is not the best *trans*-labilizing ligand in octahedral Co^{III}

chemistry and, although structural evidence is lacking, the extended kinetic *trans* effect given by Scheme 99 has been obtained from dimethylglyoxime complexes with labilization of *trans*-MeOH.[1100]

$$SO_3^{2-} > S(O)_2R^- \geqslant S(O)R^- > SR^- > SSO_3^{2-} \approx S(R)R \approx S(SR)R$$

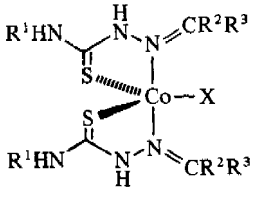
Oxidation state of sulfur	IV	II	0	−II	−II	−II	−I
Δr (pm) = (*trans* Co–N bond length) − (*cis* Co–N bond length)	9	≈6	5–7	≈4	≈1	1–0	1–0

Scheme 98

$$[Co(SO_3)(NH_3)_5]^+ \xrightarrow[\text{slow}]{k_1} [Co(SO_3)(NH_3)_4]^+ + NH_{3(aq)} \xrightarrow[\text{fast}]{Y^-} \textit{trans}\text{-}[Co(SO_3)Y(NH_3)_4] \quad (177)$$

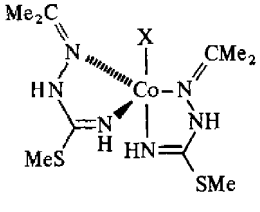
$$CH_3^- > C_6H_5^- > SO_3^{2-} > (MeO)_2P(O)^- > RS(O)_2^-$$

Δk_1 (equation 177)	900	300	100	50	1



Scheme 99

The absence of a structural effect for SSO_3^{2-}, S(R)R and S(SR)R is consistent with a lack of formal negative charge on the coordinated S atom. This results in a decreased σ-donor ability and a longer Co—S bond, with the *trans* Co—N bond returning to its normal value of ~195 pm (Table 85). However anation of *trans*-$[Co(SSO_3)(H_2O)(en)_2]^+$ is some 10^4 times faster than anation of similar amine complexes[950] demonstrating that kinetic effects are more sensitive than structural ones.

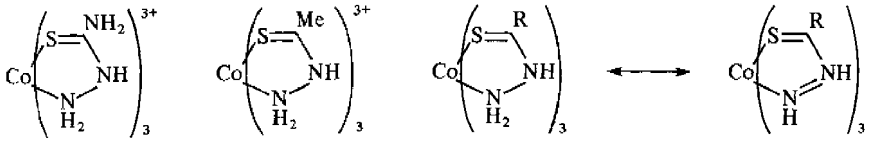


Deutsch and coworkers have used a simple harmonic oscillator model to relate the kinetic effects (as measured by activation enthalpies) to the energy necessary to stretch the *trans* N bond, $\Delta H^{\ddagger}S(O)_2R^- - \Delta H^{\ddagger}(SO_3^{2-}) = k^1\{(r^{\ddagger} - r\{S(O)R_2^-\})^2 - (r^{\ddagger} - r(SO_3^{2-})^2\}$, which gives $r^{\ddagger} = 320$ pm for the transition-state complex.[426] This represents a stretching of some 120 pm. This value may be used to estimate $\Delta H^{\ddagger}$ for other (perhaps hypothetical) dissociation processes. More general articles on the *trans* effect emphasizing its structural and electronic aspects are available.[1102–1104]

47.8.6 Thiosemicarbazones, Cobalt(II)

A variety of CoX_2L_2 complexes have been prepared[1105,1106] where L = $R^1NHCSNHN{=}C(R^2)(R^3)$ and X = Cl^-, Br^-, I^-. When R^2 and R^3 are alkyl, the ligand is (S,N) bidentate and the complexes are five coordinate with a trigonal-bipyramidal stereochemistry (**324**). However if R^2 and/or R^3 are aryl, they are tetrahedral with S_2X_2 donor arrangements. Structures are known for both five-coordinate $[CoXL_2]X$ (L = $H_2NCSNHN{=}C(Me)_2$, X = Cl^-;[1107] L = $PhNHCSNHN{=}C(Me)_2$, X = Br^-)[1106] and four-coordinate $[Co(I)_2L_2]$ [L = $H_2NCSNHN{=}C(Ph)(Me)$] systems.[1108] Structural investigations on the cobalt(II) complexes of acetone *S*-methylthiosemicarbazone have shown that the ligand is an (N,N) bidentate and that both five-coordinate[1109,1110] (**325**) and octahedral geometries obtain.[1111]

(324)

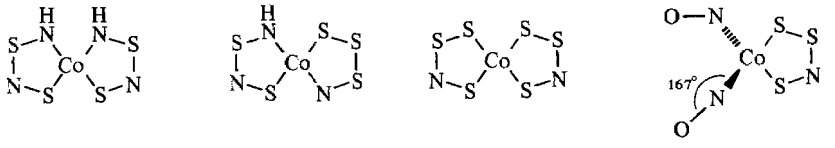


(325)

47.8.7 Thiosemicarbazides, Cobalt(III)

Tris complexes of $H_2NCSNHNH_2$ (Htsc) were first reported by Jensen and Rancke-Madsen,[1112] and Sadykova and coworkers investigated complex formation using various Co^{II} salts in aqueous solution. They found that the cation formed was in fact $[Co(Htsc)_3]^{3+}$ (**326**).[1113] Samus and Ablov[1114]

separated the violet (ε_{429} 414) facial and green (ε_{420} 1900) meridional isomers and Sun and Harris[1115] resolved both with the $(+)_{589}$-SbOtartrate anion and assigned geometric structures from comparisons of electronic spectra and absolute configurations from CD and ORD measurements. Gabel and Larsen[1116] have likewise prepared and resolved the tris(thioacethydrazide) complex $[Co(Htah)_3]^{3+}$ (**327**), and on the basis of a single methyl ^1H NMR signal have assigned it as the *fac* isomer. The complexes can be easily deprotonated (pK_a = 4.77, 6.17, 7.53 for *fac*-$[Co(Htsc)]^{3+}$; 1.4, 3.17, 4.63 for *fac*-$[Co(Htah)_3]^{3+}$) to give the neutral species (**328**), but *fac* to *mer* isomerization then slowly occurs, which on addition of acid results in *mer*-$[Co(Htsc)_3]^{3+}$. This isomer slowly reconverts to the more stable *fac*-$[Co(Htsc)_3]^{3+}$ ion with inversion of configuration.[1115,1116]



(326) (327) (328)

47.8.8 Thionitro and Thionitrosyl

Addition of $(NSCl)_3$ to $[CoH\{P(OPh)_3\}_4]$ dissolved in THF under argon forms the green thionitrosyl $[Co(NS)(Cl)_2\{P(OPh)_3\}_2]$, which on exposure to oxygen changes to yellow-green $[Co(NSO)(Cl)_2\{P(OPh)_3\}_2]$ containing the thionitro monoanion.[1117] This reaction resembles the oxidation of coordinated nitrosyl to coordinated nitro (Section 47.4.1.3) and the thionitro group is presumably coordinated as Co—N(S)O. A crystal structure of $[Co(NSF)_6](AsF_6)_2$ is available and demonstrates Co—N bonding.[1118]

The reaction of $CoCl_2$ with S_4N_4 in refluxing MeOH under N_2 produces a mixture of $[Co(S_2N_2H)_2]$ (**329**), $[Co(S_2N_2H)(S_3N)]$ (**330**) and $[Co(S_3N)_2]$ (**331**), which have been separated by preparative TLC and crystallized as dark black solids.[1119] Subsequent attempts to prepare $[Co(S_3N)_2]$ by the direct reaction of $CoBr_2$ with $(PPN)(S_3N)$ met with only limited success.[1120] IR assignments support bidentate (S,S) coordination with *cis* square-planar geometries.[1119] The reaction of $[Co_2(CO)_8]$ with S_4N_4 in deoxygeneated benzene gives a black explosive solid formulated either as polymeric $[Co_2(CO)(N_4S_4)]$[1121] or as $[CoN_4S_4]$.[1122] The absence of obvious Co—S stretch frequencies infers Co—N bonding of the N_4S_4 unit. Treatment with refluxing acetone gives $[Co(S_2N_2H)_2]$, while nitrosation in pentane leads to readily sublimable violet $[Co(NO)_2(S_3N)]$.[1123] The IR spectrum of this latter complex shows two NO stretching absorptions (1836, 1778 cm^{-1}) characteristic of a pseudotetrahedral geometry and this has been confirmed by its structure (**332**; Table 12).

(329) (330) (331) (332)

47.8.9 Sulfamates, Sulfonamides and Isothiocyanates, Cobalt(III)

Preparations are given in Table 94. The N-bound sulfamate complex $[Co(NH_2SO_3)(NH_3)_5]^{2+}$ (pK_a, 5.83) is easily made but it spontaneously isomerizes in aqueous acid to the O-bound isomer $[Co(OSO_2NH_3)_5]^{2+}$,[1125] ($pK_a \approx 13.1$), which itself aquates primarily by an acid-catalyzed path, $k = k_1 + k_2[H^+]$ (equation 178). In alkaline solution both the N-bound sulfamate and its conjugate base undergo OH^--catalyzed hydrolysis (equation 179), with the latter reaction being very slow.[1126] The O-bound isomer is more reactive under the same conditions (k_{OH} = 20 $mol^{-1}\,dm^3\,s^{-1}$).[907] The protonated sulfamide complexes $[Co(NH_2SO_2NHR)(NH_3)_5]^{3+}$ aquate more rapidly ($k = 1.3 \times 10^{-2}\,s^{-1}$, R = H; $k > 0.11\,s^{-1}$, R = *p*-MeC_6H_4) but their acidity, $pK_a = -0.24$ (R = H), makes this apparent only in acid solutions; the basic forms appear to be quite stable.[1126] Their reduction by $Cr^{2+}_{(aq)}$ in acid solution is considered to occur *via* a bridged outer-sphere intermediate.[1127]

Table 94 Preparations: Sulfamate, Sulfamide, Sulfonamides, Ureas, Carbamates of Cobalt(III)

Complex	*Ligand*	*Preparation, properties*	*Ref.*

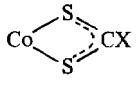
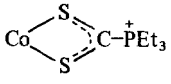
$$[(NH_3)_5Co{-}NH_2SO_3]^{2+} \underset{k=1.1\times10^{-3}\,s^{-1}}{\rightleftharpoons} [(NH_3)_5Co{-}OSO_2NH_2]^{2+} \xrightarrow{k_2=3.0\times10^{-5}\,mol^{-1}\,dm^3\,s^{-1}}$$
$$[(NH_3)_5Co{-}OH_2]^{2+} + NH_2SO_3H \quad (178)$$



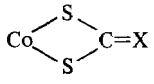
$$[(NH_3)_5Co{-}NH_2SO_3]^{2+} \underset{(pk_a=5.83)}{\overset{OH^-}{\rightleftharpoons}} [(NH_3)_5Co{-}NHSO_3]^{+}$$
$$(k_{OH} = 0.01\,mol^{-1}\,dm^3\,s^{-1}) \searrow^{OH^-} \qquad HO^- \swarrow (k_{OH} = 2.5\times10^{-7}\,mol^{-1}\,dm^3\,s^{-1}) \quad (179)$$
$$[(NH_3)_5Co{-}OH]^{2+} + NH_2SO_3^-$$

Treatment of phenyl isothiocyanate with $[Co(OH_2)(NH_3)_5](ClO_4)_3$ in the presence of a base leads to the S-bound isomer rather than the O-bound form (Table 94). The latter is possibly formed as an intermediate (equation 180).[1124]



$$[(NH_3)_5Co{-}OH]^{2+} + S{=}C{=}NPh \xrightarrow{slow} [(NH_3)_5Co{-}O(C{=}S)NHPh]^{2+} \longrightarrow [(NH_3)_5Co{-}S(C{=}O)NHPh]^{2+} \quad (180)$$

47.8.10 1,1-Dithioacids and 1,1-Dithiolates



General articles and reviews are available.[1128–1131] Dithioacid complexes are of the type **(333)**, where X is alkyl or aryl (dithiocarboxylates), NR_2 (dithiocarbamates), OR (xanthates) and SR (thioxanthates). The $CS_2 \cdot PEt_3$ adduct **(334)** is also of this type although it acts as a zwitterion in its coordination. These systems are formally monoanion chelating agents. The 1,1-dithiolates **(335)**, where X = CR_2 (alkyl, aryl), NR (dithiocarbimates), S^- (trithiocarbonate), O^- (dithiocarbonate), are dianion chelating agents.

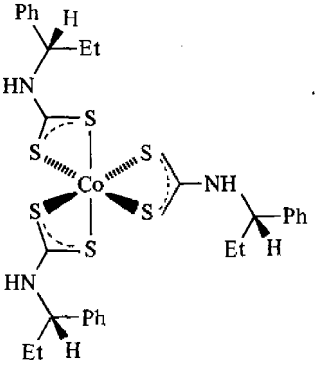
(*i*) *Dithiocarboxylates*

Both Co^{II} and Co^{III} complexes are known (Table 95). The dark-green or red-brown diamagnetic $[Co(S_2CR)_3]$ systems[1148,1149] appear to contain bidentate (S,S) coordination, although no structures are available and they have not been resolved into enantiomeric forms. This differs from monodentate coordination for their all-O analogues. The electrochemical reduction of the tris(dithiobenzoate) system has been studied.[1149]

(*ii*) *Dithiocarbamates and thioselenocarbamates*

Dithiocarbamic acid itself and its alkali metal salts are unstable towards hydrolysis but metal chelates are known and a structure of $[Co(S_2CNH_2)_3]$ is available (Table 96). This complex is probably unstable towards hydrolysis giving $[Co(S_2CO)_3]^{3-}$. Salts of dithiocarbamates derived from primary amines are also unstable under alkaline conditions, although N(3)-substituted dithiocarbazic acid forms green tris(S,S) chelates (**336**).[1133] The similar N(3)-unsubstituted acids form (N,S) chelates (**337**) which can be deprotonated when R = H with possible isomerization to the (S,S) dithiocarbimate chelate (**339**).[1133] The (N,S) chelate (**338**) has been positively identified by a crystal structure of its *S*-methyl ester, R = H (Table 96).[1134]



(336) R = Me, Ph (337) (338) (339)

Ammonium salts of diseleno- and thioseleno-diethylcarbamic acid have been made and Heber and coworkers have reported the preparation of olive-green, diamagnetic $[Co(SeSCNEt_2)_3]$ and mention $[Co(Se_2CNEt_2)_3]$.[1157]

Tris(dialkyldithiocarbamate)Co^{III} complexes can be easily prepared in water using $Na^+R_2dtc^-$ and $CoCl_2$ in the presence of O_2,[1135] or by oxidation of Co^{II} using the disulfide dimer; the former method is preferable (equation 185). Representative examples are given in Table 95. A very large number of these green or green-brown, neutral water-insoluble complexes have been prepared. Normally the diamagnetic tris Co^{III} chelate results even when O_2 is rigorously excluded but a few $Co(R_2dtc)_2$ have been reported when R is large (Table 95). These Co^{II} species are paramagnetic with one unpaired electron and probably have a square planar structure. Their stability is surprising and must reside in steric factors; no structural information is available.

$$CoCl_2 + Na^+R_2NCS_2^- \xrightarrow{O_2} [Co(S_2CNR_2)_3] \longleftarrow CoCl_2 + R_2NC(=S)SC(=S)NR_2 \qquad (185)$$

O'Connor and coworkers have synthesized several optically-active $[Co(R_2dtc)_3]$ complexes using $(+)_{546}$-K[Co(edta)] or $(+)_{546}$-K[Co{(−)pdta}] as the asymmetric cobalt source.[1135] The latter gives $(+)_{546}$ species for all R (assigned Δ-$[Co(R_2dtc)_3]$), while the former gives $(+)_{546}$ for R = Me, Et, Bu^n, pyrr, Ph, Bz, and $(-)_{546}$ for R = Pr^i, Bu^i. Recrystallization results in considerable racemization[1135] and this has been followed in a number of solvents over the temperature range 50–70 °C.[1151] ^1H NMR studies confirm a rapid intramolecular process at 170 °C in $C_6D_5NO_2$.[1137] A $\Delta V^‡$ study has been interpreted in terms of a trigonal-twist mechanism without bond breaking for R = pyrr ($\Delta V^‡$, 9.8 $cm^3 mol^{-1}$ in ethanol) and one-ended dissociation for R = Ph ($\Delta V^‡$, −2 to −9.3 $cm^3 mol^{-1}$ in several solvents).[1136] Woon and O'Connor have prepared the optically-active (*S*)-2-carboxypyrrolidine derivative, which in its deprotonted form is water soluble.[1156] This was resolved on DEAE cellulose into its $(+)_{546}$-Δ(*SSS*) and $(-)_{546}$-Λ forms and CD spectra were used to assign configurations. Similarly, Haines and Chan have used optically-active *S*(−)-1-phenylethylamine to prepare $(+)_{660}$-[Co{(*S*)PhEtdtc}$_3$] *via* a second-order asymmetric procedure.[1138] The $(-)_{660}$ diastereoisomer is apparently also formed but is more soluble in water and mutarotates to the $(+)_{660}$ isomer which slowly precipitates. The latter is assigned the Λ configuration (**340**) and ^1H NMR shows only one sharp doublet at 1.49 p.p.m. for the methyl group. When dissolved in non-polar solvents (CH_2Cl_2, CS_2, C_6H_6) this isomer apparently mutarotates completely to the Δ-$(-)_{660}$-[Co{(*S*)PhEtdtc}$_3$] diastereoisomer (Me doublet, 1.44 p.p.m.). Enantiomeric results were obtained using the (*R*)-(+)-PhEtdtc ligand. Rate constants for inversion ($2.1 \times 10^{-4} s^{-1}$ (CH_2Cl_2), $8.5 \times 10^{-5} s^{-1}$ (CS_2) at 25 °C) and activation parameters [$\Delta H^‡$ 80 kJ mol^{-1}, $\Delta S^‡$ −39 J $K^{-1} mol^{-1}$ (CH_2Cl_2)] are in general agreement with other studies. Kida and his colleagues have found that $[Co(en)_3]^{3+}$ reacts with dithiocarbamates (R = Et, C_2H_4OH) in aqueous alkaline solution in the presence of light.[1152] Substitution is quite rapid (3 h in room light at ambient temperatures is sufficient) and quantum yields are in excess of 1.0. A primary photoredox process followed by a chain reaction involving Co^{II} species is proposed.[1152]

(**340**)
Λ-$(-)_{660}$-[Co{(*S*)-PhEtdtc}$_3$]

Several crystal structures of $[Co(R_2dtc)_3]$ complexes are available (Table 96) and they all show a distorted octahedral geometry with a bite angle of ~76° at the metal. There is no suggestion of distortion towards a trigonal prismatic structure. For R = H there is some suggestion of electron redistribution within the ligand but this may result from H bonding in the lattice. Much of the early structural work was aimed at verifying a zwitterionic component to the bonding (*i.e.* [Co($S_2C{=}NR_2$)]) and this appears to have been partly realized (*cf.* Section 47.8.10.2.i).

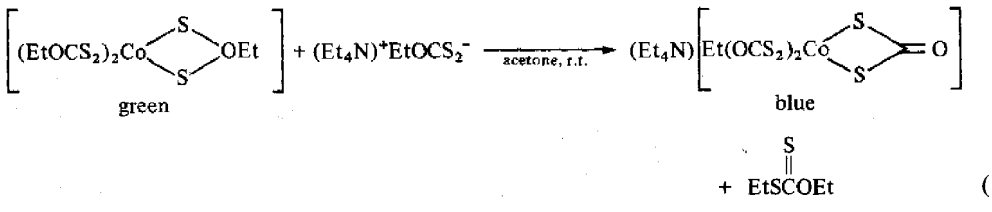
Gahan and O'Connor have noted rapid photoracemization of $[Co(R_2dtc)_3]$ when solutions in organic solvents are exposed to sunlight.[1151] Light of wavelength less than 400 nm appears to be necessary and the process is very rapid in $CHBr_3$. No decomposition occurs and preliminary flash photolysis studies indicate a transient intermediate with $\lambda_{max} = 500$ nm. This optical instability contrasts with the apparent reluctance of $[Co(R_2dtc)_3]$ and $[Co(R_2'dtc)_3]$ to exchange ligands in nitrobenzene when heated at 195 °C for several hours[1139] and with the inability of $[Co(Et_2dtc)_3]$ to react with the $[Co(SEt)(S_2CSEt)]_2$ dimer in refluxing $CHCl_3$.[1145] However, it has been reported that $[Co(Et_2dtc)_3]$ and $[Co(S_2CSEt)_3]$ form $[Co(Et_2dtc)_2(S_2CSEt)]$ on refluxing in $CHCl_3$ for 10 minutes.[1140] Clearly these ligand exchange processes need to be reexamined.

Early uncertainty in the redox chemistry of $[Co(R_2dtc)_3]$ has now been resolved.[1141,1142] BF_3 oxidation leads to $[Co_2(R_2dtc)_5]^+$ dimers containing Co^{III} rather than a Co^{IV} species. Here a $Co(R_2dtc)_3$ unit is *cis* chelated to a second $Co(R_2dtc)_2^+$ fragment of opposite chirality *via* sulfide bridges (Table 96). These bridges form longer and less robust bonds to the metal and the dimer can be easily cleaved with the incorporation of acetylacetone, dithioacetylacetone, ^-S_2COR and ^-S_2CNR to form unsymmetrical tris chelates (equation 186; Table 95). Also, neutral ligands such as ethylenediamine and its *N*-alkyl derivatives, and several dithiooxamides (equation 187) result in well-defined mixed chelates (Table 95). These products are diamagnetic and appear to be monomers. Some kinetic data are available.[1154,1155]

$$[Co_2(R_2dtc)_5]BF_4 + Y{-}Y^- \longrightarrow [Co(R_2dtc)_3] + [Co(R_2dtc)_2(Y{-}Y)] \quad (186)$$

$$[Co_2(R_2dtc)_5]BF_4 + R_2NC(=S)C(=S)NR_2 \longrightarrow [Co(R_2dtc)_3] + \left[(Et_2dtc)_2Co\begin{smallmatrix} S & NR_2 \\ S & NR_2 \end{smallmatrix}\right]BF_4 \quad (187)$$

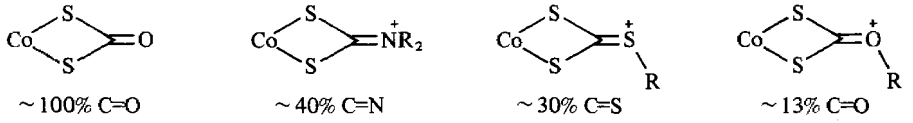
Oxidation to the formally cobalt(IV) species $[Co(R_2dtc)_3]^+$ is difficult ($E^\circ = 0.96$ V (cyclohexyl), 1.22 V (benzyl), acetone solvent) but at Pt in CH_2Cl_2 it is electrochemically and chemically reversible with controlled potential electrolysis resulting in monomeric $[Co(Cy_2dtc)_3]^+$ ($\lambda_{max} \approx 410$ nm).[1142] However attempts to isolate this complex were unsuccessful with the $[Co_2(Cy_2dtc)_5]^+$ dimer being the only product. These E° values suggest a Co^{III}-oxidized ligand formalism and the monomer is apparently unstable. The first one-electron reduction to give $[Co(R_2dtc)_3]^-$ is also not easy ($E_{1/2} = -0.80$ V (benzyl), -1.13 V (cyclohexyl), acetone solvent) but shows considerable chemical reversibility at Pt and Hg in acetone[1142] or DMSO.[1153] Further reduction leads to Co^0 (equation 188). Both the electrochemistry and the stability of the oxidized and reduced species are sensitive to the nature of the R group, the solvent and the redox procedure.[1142]



$$Co(R_2dtc)_3 + e^- \longleftrightarrow Co(R_2dtc)_3^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Co(R_2dtc)_2 + R_2dtc^- \xrightarrow{2e^-} Co + 2R_2dtc^- \quad (188)$$

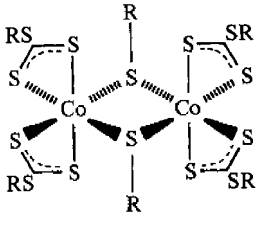
(*iii*) *Xanthates and thioxanthates*

There are suggestions that the early preparations of Compin and Delepine[1143] give rise to impure products. $[Co(S_2COR)_3]$ can be prepared from either $[Co(CO_3)_3]^{3-}$ (equation 189), or $[Co(NH_3)_6]^{3+}$ (equation 190; Table 95), with recrystallization of the green water-insoluble products from an organic solvent. Care is needed since dealkylation is easy in the presence of an excess of ligand anion.[1146] This presumably occurs *via* nucleophilic attack at O (equation 191). The structure of the resulting $(Et_4N)[Co(S_2COEt)_2(S_2CO)]$ complex shows short Co—S and C—O bonds in the dianionic dithiocarbonate chelate (Table 96) indicating substantial 1,1-dithiolate character. By using 2-sulfonatoethyl xanthate Hansen and Harnung have resolved the resulting $[Co(S_2COC_2H_4SO_3)_3]^{3-}$ anion (Table 95) and have assigned charge transfer and ligand field absorptions using CD and MCD spectra.[1150] This appears to be the only example of separated enantiomers.



$$[Co(CO_3)_3]^{3-} + 3ROCS_2^- \longrightarrow [Co(S_2COR)_3] + 3CO_3^{2-} \quad (189)$$

$$[Co(NH_3)_6]Cl_3 + 3K^+ROCS_2^- \xrightarrow{0\text{-}5\,^\circ C} [Co(NH_3)_6](ROCS_2)_3 \xrightarrow{60\,^\circ C} [Co(S_2COR)_3] + 6NH_3 \quad (190)$$



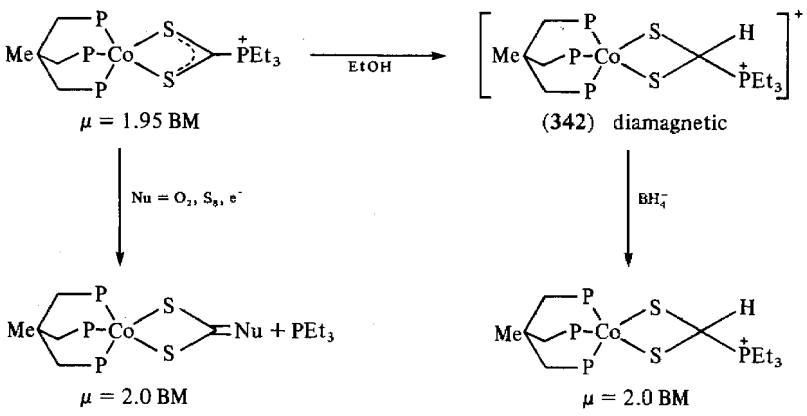
(191)

The above method using $[Co(CO_3)_3]^{3-}$ can also be used to prepare the tris(thioxanthates) $[Co(S_2CSR)_3]$ but these can also be made from Co^{II} salts and $Na^+RSCS_2^-$ provided a little $FeCl_3$ is present to prevent dimerization (Table 95). Crystal structures of $[Co(S_2COEt)_3]$ and $[Co(S_2CSEt)_3]$ (Table 97) show a resemblance to that of $[Co(Et_2dtc)_3]$ with a 76° bite angle at the metal and similar bond lengths within the four-membered chelates. The more electronegative *exo* O and S atoms (when compared to N in the dithiocarbamates) have been rationalized in terms of less zwitterionic character (Scheme 100).

Scheme 100

Green water-insoluble $[Co(S_2CSR)_3]$ are diamagnetic and rather unstable to heat, eliminating CS_2 in organic solvents giving brown thiolate-bridged diamagnetic dimers (**341**).[1144] The sulfide bridges adopt a symmetrical anticonfiguration (Table 97) and it has so far not been possible to isolate asymmetric systems using mixed-ligand or mixed-metal reactants. Preparation *via* Co^{II} salts in the absence of $FeCl_3$ leads largely to the dimer (except for R = Bu^t). The terminal thioxanthate ligands undergo stepwise nucleophilic displacement at C when $NHEt_2$ is used, resulting in mixed dithiocarbamate–thioxanthate dimers (equation 192).[1145] A similar reaction occurs with $[Co(S_2CSMe)\{MeC(dppm)_3\}](BPh_4)$.[1161]

(341)



$$[Co(SEt)(S_2CSEt)_2]_2 + NHEt_2 \xrightarrow[CHCl_3]{heat} [Co(SEt)(S_2CNEt_2)_n(S_2CSEt)_{2-n}]_2 \quad (192)$$
$$2n = 1\text{–}3$$

The $[Co(S_2CSR)_3]$ monomer undergoes reversible reduction ($E \approx -0.80$ to -1.0 V in CH_2Cl_2) but irreversible oxidation ($E \approx 1.5$ V). The $[Co(SR)(S_2CSR)_2]_2$ dimer undergoes irreversible reduction ($E \approx -1.0$ V) and oxidation ($E \approx 1.4$–1.6 V).[1144]

(*iv*) *Trialkylphosphine dithioacids*

Immediate addition of BPh_4^- to a solution of $MeC(dppm)_3$, S_2CPEt_3 and $Co^{2+}_{(aq)}$ in ethanol results in the crystallization of brown five-coordinate $[Co(S_2CPEt_3)(MeC(dppm)_3)](BPh_4)_2$[1147] (Table 97). However if the solution is left to stand or if it is refluxed, internal redox occurs and the red-brown distorted square-pyramidal Co^{III} complex (**342**) containing the reduced ligand is obtained (structure, Table 96; Scheme 101). This process may occur *via* H^- abstraction from the solvent followed by oxidation at the metal, or by H atom abstraction by the Co^{III} radical anion. Complex (**342**) may be reduced by BH_4^- to an orange-brown Co^{II} complex containing the reduced ligand (Scheme 101). Other nucleophiles also add readily to the C atom of the initial Co^{II} complex (Nu = O_2, S_8, e^-) with

displacement of PEt_3, forming S_2CO^{2-} (structure, Table 96), S_2CS^{2-} and π-CS_2 chelates respectively. As the authors[1147] point out this chemistry provides a useful synthetic route to a variety of 1,1-dithiolato systems and to a potential source of metal-activated CS_2 (Nu = e^-).

Scheme 101

47.8.10.2 1,1-Dithiolate complexes

A general account of this area is available.[1158] These complexes include di- and tri-thiocarbonates (OCS_2^{2-}, SCS_2^{2-}), unsaturated alkene systems ($R_2C{=}CS_2^{2-}$), and dithiocarbimates ($RN{=}CS_2^{2-}$). K_2CS_3 can be prepared as a yellow solid by adding CS_2 to an alcoholic solution of KOH which has been saturated with H_2S,[1159] and as a solution in DMF by adding KOH to CS_2.[1160] Relatively few cobalt complexes of these localized dithiols are known (Table 98).

(i) Di- and tri-thiocarbontes, cobalt(III)

Cleavage of the C—P bond in $[Co\{S_2CP(Et)_3\}\{MeC(dppm)_3\}](BF_4)_2$ by O_2 and S_8 has already been noted (Scheme 101). The resulting $[Co(S_2CO)\{MeC(dppm)_3\}]$ and

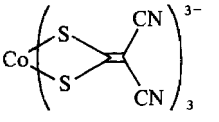
$[Co(S_2CS)\{MeC(dppm)_3\}]$ complexes[1147] are five coordinate and a crystal structure of the former (Table 96) shows a distorted square-pyramidal P_3S_2 donor set. As with the π-CS_2 complexes (Section 47.2.2) the uncoordinated S atom in $[Co(S_2CS)\{MeC(dppm)_3\}]$ is nucleophilic and will displace halide ion from alkyl halides or weakly bound ligands from organometallic derivatives. This gives thioxanthate (*e.g.* $[Co(S_2CSMe)(\{MeC(dppm)_3\})]^+$) and CS_3-bridged binuclear (*e.g.* $[\{MeC(dppm)_3\}Co(\mu\text{-}CS_3)Cr(CO)_5]$) complexes respectively.

(*ii*) *Di- and tri-thiocarbonates, cobalt(III)*

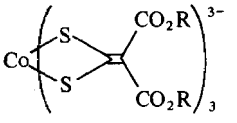
Olive-green $[Co(S_2CS)_3]^{3-}$ has been prepared and isolated (Table 98) and a brown-green complex of composition $[Co_2(C_2S_7)(NH_3)_6]$ precipitates from ammoniacal $CoSO_4$ when treated with Na_2CS_3.[1162] IR data for the latter have been interpreted in terms of structure (**343**),[1163] and $[Co(S_2CS)_3]^{3-}$ (**344**) probably contains the bidentate S_6 donor set although it is less stable than the unstable all-oxygen analogue $[Co(CO_3)_3]^{3-}$ (Section 47.7.3.2).

(343)



(344)

(*iii*) *Alkenedithiolates and dithiocarbimates*



The preparation and properties of known cobalt(II) and cobalt(III) complexes are given in Table 98. The dithiocyclopentadienyl anion is a resonance hybrid and the low spin (μ = 2.55 BM) and ESR of (**345**) suggest a distorted planar structure. The 1,1 analogue of maleonitriledithiolate (**346**) has reduced electron delocalization and McCleverty and his colleagues have investigated the electrochemistry of the mixed $[Co\{S_2C_2(CN)_2\}_2(S_2C{=}X)]^{3-}$ system.[1164] Only one-electron oxidation is possible in CH_2Cl_2 at Pt (equation 193), and chemical oxidation with I_2 has resulted in the isolation of $(Ph_4P)_2[Co\{S_2C_2(CN)_2\}(S_2C{=}X)]$ (X = $CHNO_2$, $C(CN)CO_2Et$). Likewise diamagnetic (**347**) can be reversibly oxidized ($E_{1/2}$ = 0.14 V).[1165] The dithiocarbazic acid anion $[Co(S_2C{=}NNH_2)_3]^{3-}$ has been discussed in Section 47.8.10.1. (i) and the corresponding nitrile $[Co(S_2C{=}NCN)_3]^{3-}$ has been isolated (Table 98).

(345)

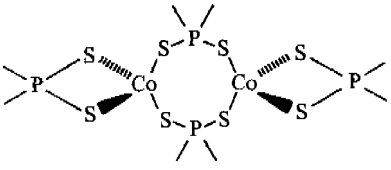
(346)

(347)

$$[Co\{S_2C_2(CN)_2\}_2(S_2C{=}X)]^{3-} \underset{E_{1/2}=0.02 \text{ to } -0.11\,V}{\longleftrightarrow} [Co\{S_2C_2(CN)_2\}_2(S_2C{=}X)]^{2-} + e^- \quad (193)$$

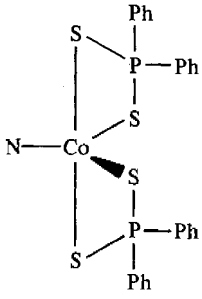
47.8.10.3 Thiophosphinates and selenophosphinates

These ligands can be easily made (equations 194 and 195), but obviously extreme care is necessary with the Se compound.[1174,1175]



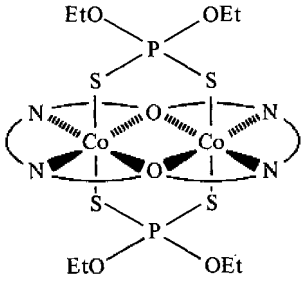
$$P_2S_5 + 4EtOH \xrightarrow[N_2,\ heat]{} 2(EtO)_2PS_2H + H_2S \quad (194)$$

$$PPh_2Cl + S_8 \longrightarrow Ph_2PSCl \xrightarrow{NaHS} Ph_2PS_2^-Na^+ \quad (195)$$



(i) Cobalt(II)

The synthesis of $[Co(S_2PR_2)_2]$ (R = alkyl, aryl, OEt, CF_3) involves addition of the sodium or ammonium salt of the ligand to solutions of Co^{II} halides, or the reaction of Co metal with the acid ligand (R = F, CF_3; Table 99).[1166,1168,1169] $[Co\{S_2P(OEt)_2\}_2]$ has also been made by photoreduction of the Co^{III} complex (equation 196).[1179] Although many of these tetrahedral species are quite soluble in organic solvents, this is not the case for R = Me, Ph, and the former complex at least is polymeric in the solid state.[1169] In contrast the structure of $[Co(S_2PEt_2)_2]_2$ consists of dimeric units (**348**).[1169] Benzene solutions of this complex appear to be associated into larger polymeric units with retention of tetrahedral geometry about the metal. Attempts to prepare $[Co(S_2PMe_2)_2]$ in aqueous solution lead to $[Co(S_2PMe_2)(SOPMe_2)]$ but with other dialkyldithiophosphinates this substitution of O for S is not stoichiometric. Monomeric $[Co(S_2PR_2)_2]$ is stabilized towards oxidation at the metal by the formation of trigonal-bipyramidal five-coordinate (**349**) and octahedral adducts with unidentate amines and phosphines (Table 99).[1170,1171] Dimeric structures such as (**350**) are also known.[1172]



$$2[Co\{S_2P(OEt)_2\}_3] \longrightarrow [Co\{S_2P(OEt)_2\}_2] + (EtO)_2P(S)—S—S—P(S)(OEt)_2 \quad (196)$$

(348)

(349)

Cobalt(II) complexes of the mixed thiophosphinic and selenophosphinic ligands R_2PXY^- (X = S, Se; Y = S, Se, O) were first investigated by Kuchen and coworkers,[1166,1167] and Calligaris and his group describe the structure of polymeric $[Co(SOPPh_2)_2]_n$ as chains of alternate single- and triply-bridging Ph_2PSO units coordinated to distorted tetrahedral Co atoms.[1173] Their preparation is similar to the dithiophosphinate complexes (Table 99) and polymerization in solution appears to be extensive.[1173,1167] They are susceptible to hydrolysis and oxidation but can normally be stored for extended periods in sealed tubes.

The preparation and spectral properties of $[Co(Se_2PPh_2)_2]$ have been reported[1174] and $[Co\{Se(O)PEt_2\}_2]$ has been described.[1167] Both are rather unstable.

(*ii*) *Cobalt(III)*

Dark green $[Co\{S_2P(OR)_2\}_3]$ can be prepared from the ligand and CoF_3[1175] or by oxidation of $[Co\{S_2P(OR)_2\}_2]$ with H_2O_2 (Table 99).[1176] The analogous Se complex forms red crystals having a distorted octahedral stereochemistry.[1177] Indigo-coloured (**351**; Scheme 102) reacts with diphenylphosphine[1178,1150] and diphenylarsine[1178] chelates in acetone or CH_2Cl_2 in two stages with the second stage involving transfer of a methyl group to the released $(MeO)_2PS_2^-$ nucleophile.[1150]

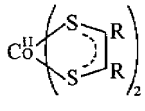
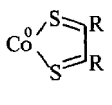
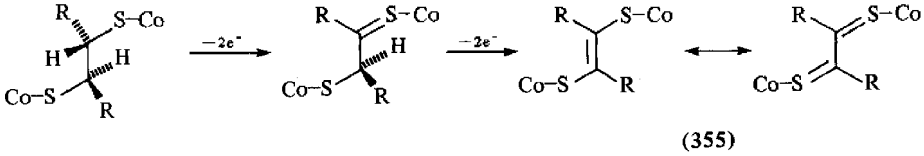


Scheme 102

47.8.11 1,2-Dithiolates



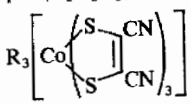
Well-documented articles and reviews are available.[1129,1180–1184] These ligands form five-membered chelates with most metals. Early interests lay in the difficulty in assigning a formal oxidation state to the metal (**352**)–(**354**), the discovery of the rare trigonal-prismatic structure for several neutral tris complexes (but not for Co) in some facile one- and two-electron transfer reactions, and in some unusual five- and six-coordinate adducts, including some with bonding to saturated carbon. No monodentate 1,2-dithiolate system is known and the *trans* configuration (**355**) has not been described. No attempted oxidation of *trans* dithiol–metal complexes has been described and it might be expected that (**355**) would be quite stable with rotation about the C—C bond occurring only in one tautomer.

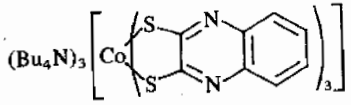


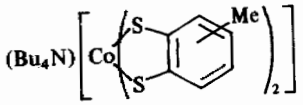
(352) dithiolate

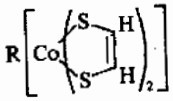
(353) dithiene

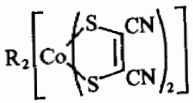
(354) dithiolene

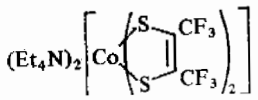


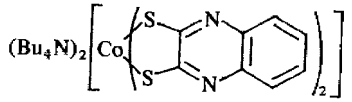












(197)

(355)

Cobalt forms diamagnetic $[Co(S_2C_2R_2)_3]^{3-}$, a series of monomeric square planar $[Co(S_2C_2R_2)_2]^{n-}$ ions (n = 1–3) and square-pyramidal dimeric $[Co(S_2C_2R_2)_2]_2^{n-}$ species (n = 0–2). All are highly coloured, indicating extensive electron delocalization, and all are reasonably labile both in a geometric sense and towards the displacement of one or more dithiolate ligands by other chelating groups. The square planar $[Co(S_2C_2R_2)_2]^-$ ion adds both monodentate and bidentate ligands forming five- and six-coordinate complexes. Their lability, wide range of oxidation states, and the rather rare square-planar $[Co(S_2C_2R_2)_2]^-$ ion distinguishes these complexes.

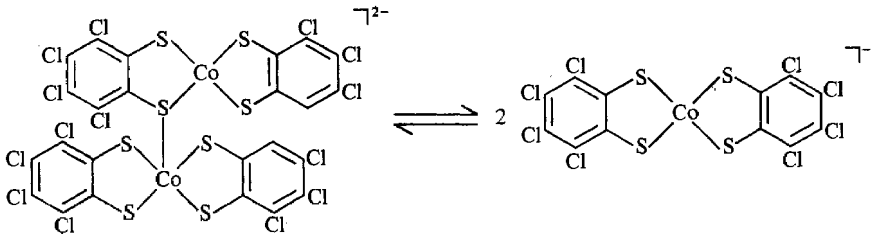
47.8.11.1 Tris(1,2-dithiolates)

Representative preparations are given in Table 100 and structural information in Table 101.

Diamagnetic $[Co(S_2C_2R_2)_3]^{3-}$ can be prepared from $Na_3[Co(CO_3)_3]$ or $[CoBr(NH_3)_5]^{2+}$ by heating with $Na_2S_2C_2R_2$ in water or alcohol or by adding excess ligand to the more stable square-planar monoanion (**356**; equation 198). $[Co(S_2C_2R_2)_3]^{3-}$ tends to dissociate to $[Co(S_2C_2R_2)_2]^-$ in the absence of excess ligand and to $[Co(S_2C_2R_2)_2]^{2-}$ in sunlight. It is probably octahedral, although no structure is available; $(Ph_4As)_3[Co\{S_2C_2(CN)_2\}_3]$ is isomorphous with the Cr^{III} complex, and the analogous Fe^{IV} complex is octahedral. In general the more reduced or negatively charge $[M(S_2C_2R_2)_3]^{n-}$ systems appear to be octahedral while the oxidized or neutral systems (*e.g.* of Re^{IV}, V^{VI}, Mo^{VI}) have the uncommon trigonal-prismatic structure (**357**; equation 199), possibly because the dithiolene structure would prefer to be *trans*, *e.g.* (**355**). $[V\{S_2C_2(CN)_2\}_3]^{2-}$ adopts an intermediate distorted geometry. Attempts to resolve $[Co(S_2C_2R_2)_3]^{3-}$ into its enantiomers have failed and the suggestion is that the trigonal-prismatic geometry (**357**) provides a low-energy pathway to intramolecular racemization (equation 199).[1185] Spectrally, however, these complexes resemble $[Co(thiooxalato)_3]^{3-}$, which has been resolved. The reduction potential, $E_{1/2} \approx -0.6$ V, suggests considerable reductive stability in neutral solution but the reduced $[Co(S_2C_2R_2)_3]^{4-}$ ion rapidly dissociates to $[Co(S_2C_2R_2)_2]^{2-}$ and free ligand. Oxidation is unknown although likely. Compared to the more common O- and N-donor octahedral chelates $[Co(S_2C_2R_2)_3]^{3-}$ is rather labile.

(356) green-brown (198)

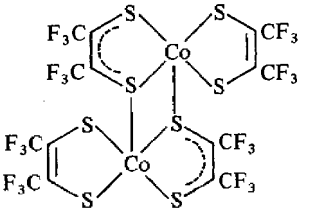


Λ-$[Co(S_2C_2R_2)_3]^{3-}$ (357) Δ-$[Co(S_2C_2R_2)_3]^{3-}$ (199)

47.8.11.2 Bis(dithiolates)

The $[Co(S_2C_2R_2)_2]^-$ ion can be prepared by the stoichiometric addition of $Na_2S_2C_2R_2$ to $CoCl_2 \cdot 6H_2O$ in EtOH or MeOH, or by the careful oxidation (*e.g.* I_2) of $[Co(S_2C_2R_2)_2]^{2-}$ (Table 100). This ion is chemically more robust than $[Co(S_2C_2R_2)_3]^{3-}$, although dimerization does occur and is usually rapid and reversible (equation 200). The equilibrium position depends on substituents with electron-withdrawing groups (CF_3, Ph, CN) stabilizing the dimer, and R = H, *p*-MeC_6H_4, giving monomeric products. Thus $[Co(p\text{-}MeC_6H_4dithiolate)_2]$ is monomeric and square planar both as a solid and in non-coordinating solvents, while the tetrachlorobenzene derivative $[Co(S_2C_6Cl_4)_2]_2^{2-}$ is diamagnetic and dimeric with a square-pyramidal geometry in the solid. In THF solution the latter dissociates to give the full spin-triplet ($S = 1$) ground state monomer (equation 201). Structures of both the square-planar monomer and square-pyramidal dimer (Table 101) show similar bond lengths to Co in the bridges and in the chelate rings with no Co–Co interaction. With $[Co\{S_2C_2(CF_3)_2\}]_2$ Co is 37 pm out of the basal plane of the square pyramid. The monomer unit has two unpaired electrons, the dimer is diamagnetic. Reversible oxidation (R = CF_3, Ph) is possible (equation 202), and the intermediate product $(Et_4N)[Co\{S_2C_2(CF_3)_2\}_2]_2$ has been isolated ($\mu = 1.91$ BM, Table 100). The fully oxidized $[Co(S_2C_2R_2)_2]_2$ systems (R = CF_3, Ph) are diamagnetic and adopt a square-pyramidal geometry (**358**), presumably because this allows the pairing up of spins in the semi-oxidized ligands. Thus both the electronic nature of the substituent and the oxidation state of the complex as a whole appear to control the structure and magnetic behaviour.

The tendency of $[Co(S_2C_2R_2)_2]^-$ to dimerize is paralleled by its ability to add additional ligands, those systems with electron-withdrawing substituents (R = CN, CF_3, halogenated phenyl) forming

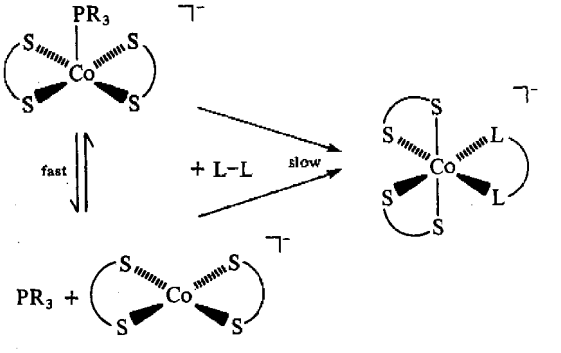


$$2[Co(S_2C_2R_2)_2]^- \rightleftharpoons [Co(S_2C_2R_2)_2]_2^{2-} \quad (200)$$

(201)

$$[Co(S_2C_2R_2)_2]_2^{2-} \underset{E_{1/2}\,0.5\,V}{\overset{-e^-}{\rightleftharpoons}} [Co(S_2C_2R_2)_2]^- \underset{E_{1/2}\,1.24\,V}{\overset{-e^-}{\rightleftharpoons}} [Co(S_2C_2R_2)_2] \quad (202)$$

$(CH_2Cl_2, Ag/AgI)$



(358)

stable five- and six-coordinate systems but the others doing so only with difficulty (Table 102). Ligand addition is both fast and reversible. Addition to the square-planar monomer (**359**; equation 203) is rate determining (L = PPh_3, $AsPh_3$, py, phen).[1186,1187] With L = phen the process is two stage with chelation and stereochemical rearrangement following formation of the five-coordinate square pyramid. Subsequent reaction of $[Co(S_2C_2R_2)_2L]^-$ with chelating ligands such as phen, mnt^{2-}, bipy appears to occur *via* both associative and dissociative routes (Scheme 103). Green or tan five-coordinate $(Bu_4N)[Co\{S_2C_2(CN)_2\}_2L]$ (L = pip, morph) and six-coordinate $(Bu_4N)[Co\{S_2C_2(CN)_2\}_2L_2]$ (L = py, imH, NH_3, $BuNH_2$, $PhNH_2$) are representative of these systems.[1188] Crystal structures of two L = phen complexes (Table 101) show typical octahedral stereochemistries and these six-coordinate systems are spin paired and diamagnetic. The five-coordinate $[Co\{S_2C_2(CN)_2\}_2L]^-$ ion appears to be on the borderline between spin-triplet ($S = 1$) and diamagnetic ground states although there seems to be some uncertainty on this point.[1188,1189] The monodentate six-coordinate systems may adopt *cis* (preferred) and/or *trans* geometries.

$$[Co(S_2C_2R_2)_2]_2^{2-} \overset{fast}{\rightleftharpoons} 2[Co(S_2C_2R_2)_2]^- \overset{+L\ slow}{\rightleftharpoons} 2[Co(S_2C_2R_2)_2L]^- \quad (203)$$

(**359**)

Scheme 103

Ligand addition to the fully oxidized diamagnetic dimer $[Co(S_2C_2R_2)_2]_2$ (R = CF_3, Ph) cleaves the bridge forming spin-triplet $[Co(S_2C_2R_2)_2L]$ monomers of presumed square-pyramidal geometry (equation 204). These may be considered as Co^{IV} dithiolates or as Co^{III} complexes containing the

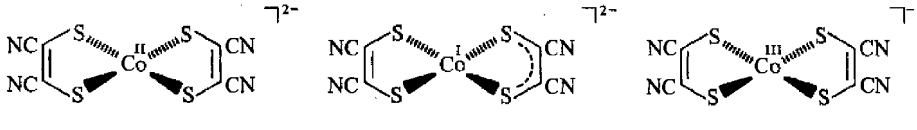
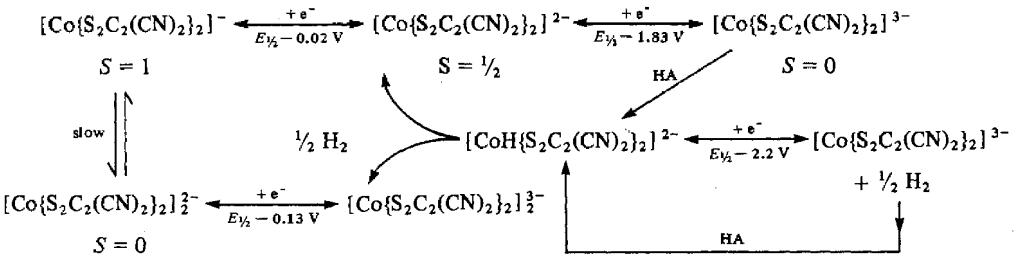
oxidized ligand (more likely). Ligand exchange studies using mixtures of the reduced dimers $[Co(S_2C_2R_2)_2]_2^{2-}$ have shown[1190] that the monomer–dimer equilibrium is rapidly set up, that ligand exchange at the metal is slow (several hours) and probably occurs intramolecularly within the mixed dimer, and that dithiolate exchange does not occur in the five-coordinate system formed on adding L (Scheme 104).



$$[Co(S_2C_2R_2)_2]_2 + 2L \longrightarrow \quad (204)$$

$R = CF_3, Ph$

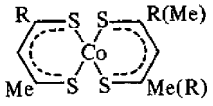


Scheme 104

The fully reduced monomeric anion $[Co(S_2C_2R_2)_2]^{2-}$ can be prepared from $CoCl_2 \cdot 6H_2O$ or $Co(OAc)_2 \cdot 6H_2O$ and $Na_2S_2C_2R_2$ in alcohol providing air is excluded (Table 100). Solutions are orange to red, the solids are paramagnetic with one unpaired electron and the structures are square planar. The complexes do not appear to dimerize and show a marked reluctance to add additional ligands except when the latter is a good π acceptor (*e.g.* $(Ph_4P)_2[Co\{S_2C_2(CN)_2(NO)\}]$ has been isolated). The photochemical oxidation of $[Co\{S_2C_2(CN)_2\}_2]^{2-}$ has been reported to be strongly wavelength dependent.[1191] The electronic structure of square planar $[Co(S_2C_2R_2)_2]^{2-}$ formed part of the considerable debate in the 1960s as to the extent of electron delocalization in the 1,2-dithiolene complexes, *i.e.* is $[Co\{S_2C_2(CN)_2\}_2]^{2-}$ d^7 Co^{II} with two dianionic dithiolate ligands (**360**) or is it spin-paired Co^{I} with an odd-electron dithiene radical anion (**361**).[1192,1193] The general consensus now seems to be that (**360**) is more correct with the odd electron being largely metal based but with some ligand character.[1182] The intense colour is consistent with extensive electron delocalization. Likewise MO calculations on the oxidized $[Co(S_2C_2R_2)_2]^{-}$ ion conclude that the two unpaired electrons are also largely metal based[1194] making these species examples of very rare square-planar paramagnetic d^6 Co^{III} (**362**) (*cf.* discussion above).

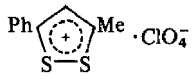
(360) (361) (362)

Electrochemical oxidation of $[Co\{S_2C_2(CN)_2\}_2]^{2-}$ in THF produces initially monomeric $[Co\{S_2C_2(CN)_2\}_2]^{-}$, which quickly dimerizes to $[Co\{S_2C_2(CN_2\}_2]_2^{2-}$ (Scheme 105). In DMSO this subsequent dimerization is only slight.[1187] Further reduction to $[Co\{S_2C_2(CN)_2\}_2]^{3-}$ is possible and weak acids are reduced to H_2 by this ion. A metal-based protonation mechanism (Scheme 105) has been proposed.[1197]



Scheme 105

Attempts to alkylate on sulfur in $[Co\{S_2C_2(CN)_2\}_2]^{2-,1-}$ have been unsuccessful. Reaction of MeI in THF with the former leads to decomposition while the latter appears to be unreactive.[1196]



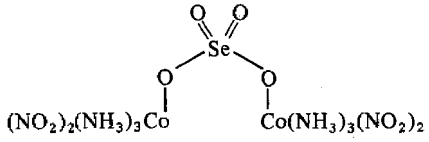
47.8.12 1,3-Dithiolenes

The syntheses and general properties of 1,3-dithiolene transition metal complexes have been discussed in a recent review.[1198]

Martin and Stewart[1199] first described the preparation of the deep-violet complex $[Co(SacSac)_2]$ (**363**; R = Me) from the reaction of $CoCl_2$ with acetylacetone (acacH) and H_2S. A similar synthesis[1200] where CF_3acac is substituted for acac yields $[Co(CF_3SacSac)_2]$ (**363**; R = CF_3). The preparation of $[Co(PhSacSac)_2]$ *via* BH_4^- reduction of the dithiolium salt (**364**) in the presence of $CoCl_2$ has also been reported.[1201]

(363)

(364)



The magnetic properties of $[Co(SacSac)_2]$ (μ = 2.35 BM, 290 K; 2.30 BM, 112 K)[1198] are consistent with the known square-planar geometry in which the Co atom is precisely coplanar with the four S donor atoms.[1202] Low-spin five-coordinate base adducts $[Co(SacSac)_2B]$ (B = py, piperazine, $BiPh_3$, $SbPh_3$, $AsPh_3$, PPh_3) have been reported,[1203,1204] and oxidative addition of amines (phen, bipy) gives octahedral Co^{III} complexes $[Co(SacSac)_2(N{-}N)]^+$.[1205] With nitric oxide $[Co(SacSac)_2]$ yields two nitrosyls; dark brown, weakly paramagnetic $[Co(SacSac)_2(NO)]$ and red-brown, diamagnetic $[Co(SacSac)(NO)_2]$. The mononitrosyl is unstable in solution and disproportionates to the dinitrosyl and $[Co(SacSac)_3]$.[1206] A crystal structure of tetrahedral $[Co(SacSac)(NO)_2]$ is available.[115]

Dark-brown $[Co(SacSac)_3]$ is prepared by aerial oxidation of solutions of $[Co(SacSac)_2]$ in the presence of acetylacetone and H_2S.[1207] The initial product is $[Co(SacSac)_2(Sacac)]$ which converts to $[Co(SacSac)_3]$ under forcing conditions.

47.9 SELENIUM LIGANDS

47.9.1 Selenate and Selenite

These have been discussed together with oxyanions (Section 47.7.4), specifically SeO_4^{2-} (Section 47.7.4.1) and SeO_3^{2-} (Section 47.7.4.3). An early report on the preparation of (**365**)[1208] requires further confirmation.

(365)

47.9.2 Selenolate, Selenenate and Seleninate

47.9.2.1 Cobalt(II)

Pink-violet seleninato complexes $[Co(O_2SePhX)_2(H_2O)_2]$ (X = H, *m*-, *p*-Cl, *m*-, *p*-Br, *p*-Me, *p*-NO_2) can be obtained by the addition of cobalt(II) salts to aqueous solutions of substituted benzeneseleninato anions;[1209] IR studies indicate that the arylseleninato groups are (O,O) chelated to the metal. Reaction with N,N-bidentate ligands (phen, bipy) gives octahedral orange-yellow $[Co(O_2SeArX)_2(N,N)_2]$ species in which the $RSeO_2^-$ groups are bonded *via* a single oxygen donor.[1210]

47.9.2.2 Cobalt(III)

Co(III)—Se chemistry is in its infancy. Only a few compounds are known and those which are have been prepared *via* the oxidative Bennett approach[1033] using the diselenide and Co^{II} (equation 205, Table 103). Deutsch and coworkers were the first to make selenolate complexes.[1211] Generally they resemble their S counterparts, with H_2O_2 oxidation to the orange-yellow selenenato ($^-Se(O)R$) and seleninato ($^-Se(O)_2R$) complexes being even easier, and methylation with Me_2SO_4 in water giving selenoether Co—Se(Me)R complexes (Table 103).[1212] The structural *trans* effect of Co—SeR is somewhat greater than Co—SR (Δr = 6.3 *vs.* 4.1 pm) and all Co—Se complexes show intense charge-transfer spectra tailing into the visible.[1211,1212] The O atom in Co—Se(O)R is more basic than the corresponding oxygen atom in Co—S(O)R ($pK_a \approx 4$ *vs.* ≈ -1).[1213] This is in keeping with a longer Co—Se bond compared to Co—S (~236 pm *vs.* 224 pm).

$$2Co(ClO_4)_2 + 5en + (H_3N^+CH_2CH_2Se)_2SO_4^{2-} \xrightarrow[N_2,\ r.t.,\ H_2O]{} 2[Co(cystSe)(en)_2](ClO_4)_2 \quad (205)$$

One important difference from S is in the isomerization from Co—$Se(O_2)$R bonding to Co—OSe(O)R on standing an aqueous solution of $[Co(cystSeO_2)(en)_2](NO_3)_2$ for 1 d in a refrigerator.[1213] The structure of the resulting spontaneously resolved $\Delta(S)$-$(-)^{CD}_{500}$-$[Co\{cystSeO(O)\}(en)_2](NO_3)_2$ complex (**366**) gives the (*S*) configuration on Se with the *exo* O atom over an ethylenediamine ring.[1214] The longer Co—Se bond makes dissociation from the metal easier and this fact will probably limit the coordination chemistry of Se with Co. The lower energy of the ligand field absorption compared to S analogues (~10 nm shifts in the 490–500 nm absorption) is in keeping with this view. The corresponding sulfinate complex requires strong light for isomerization from S to O coordination (*cf.* Section 47.8.2.2.iii).

The Se atom becomes asymmetric on oxidation to Co—Se(O)R or on methylation to Co—Se(Me)R. Comparisons of CD spectra suggest that Se in Λ-$[Co\{cystSe(O)\}(en)_2]^{2+}$ takes on the

equatorial (*R*) configuration (**367**) but this remains unconfirmed.[1213] ^1H and ^{13}C spectra suggest the opposite Λ(*S*) configuration* for the selenoether, and a stereospecific product.[1210] The long Co—Se bond should allow greater flexibility in this respect. Protonation at the O atom in Λ(*R*)-[Co{cysSe(O)}$(en)_2$]$^{2+}$ is easy ($pK_a \approx 4$) and appears to result in mutarotation at Se possibly *via* ready dissociation from the metal. Unlike thioether sulfur where racemization or mutarotation is reasonably fast ($0.1–10\ s^{-1}$) the two optical Se isomers, (*S*)- and (*R*)-*t*-[Co{cystSe(Me)}(tren)]$^{2+}$ (**368**) have been separated on SP-Sephadex.[1215] The mutarotation rate, $\sim 2 \times 10^{-4}\ s^{-1}$, demonstrates that inversion at Se is much slower than at S. The similar *p* complex could not be resolved chromatographically and it appears that the analogous *p*-(*R*)-[Co{cystSe(O)}(tren)]$^{2+}$ complex (**369**) racemizes some 50 times faster than its *t* congener. This may result from the greater lability of the Co—Se bond, or from differing rates of inversion at the metal. Photolysis of Co—SeR complexes leads to photoreduction at all wavelengths.

48.1 INTRODUCTION

Rhodium, as befits an element of the platinum metal sextet, occurs mainly as a minor constituent of platinum group metal ores. Thus, it occurs as a component of the ore deposits at Sudbury, Ontario, in the Merensky reef at Rustenberg in the Republic of South Africa, and in the platinum metals' ore deposits in the Ural range of the USSR. The major production centers are the Urals and South Africa, since the Sudbury ores in particular have a very low rhodium content. Minor deposits of the metal ores which contain some rhodium also occur in British Columbia, the United States of America, Columbia, Spain, Borneo and Australia. Nevertheless, rhodium is an exceedingly rare element with an abundance in the earth's crust of some 10^{-9}%.

The element was first isolated by Wollaston in 1804 who obtained it from crude platinum. The crude platinum was of Spanish origin and Wollaston complained of the mercury added by the Spaniards in an attempt to remove the gold from the material.[1]

Within a decade the first rhodium complex, $[RhCl(NH_3)_5]Cl_2$, had been prepared by Vauquelin.[2] Later this complex was studied by Claus whose name is often associated with the salt.[3] The naming of a complex after a later worker in the field has since become something of a tradition in rhodium chemistry.

The stereochemistry of rhodium(III) complexes was established by Werner who prepared the cation $[Rh(en)_3]^{3+}$ and resolved the racemate *via* its (+)-3-nitrocamphorate or (+)-tartrate salts.[4]

However, progress in rhodium complex chemistry was slow, and it was not until the early 1940s that Dwyer and Nyholm[5,6] prepared further examples of rhodium complexes. These included the

tertiary arsine complexes, which were later to exert such an important influence on the direction rhodium chemistry would take.

Again rhodium chemistry languished for two decades. In the 1960s four disparate lines of research suddenly burgeoned, making the chemistry of the element one of the most active research areas of the past two decades.

The kinetic and thermodynamic studies on the octahedral rhodium(III) complexes[7] suddenly gained momentum. This field was later to give rise to the important discovery of the photosensitivity of rhodium complexes.[8]

A totally new field of rhodium chemistry was opened up by the discovery of the remarkable catalytic properties of $[RhCl(PPh_3)_3]$ by Wilkinson's school.[9,10] This important complex has stimulated a rapid expansion in the chemistry of the lower oxidation state complexes. Much of this interest has, inevitably, spilled over into the organometalic chemistry of the element and is thus outside the scope of this chapter.

The facile changes of oxidation state exhibited by rhodium complex catalysts pointed the way to the employment of rhodium complexes in the photochemical decomposition of water.[11]

The interest in the lower valence states of rhodium also led to the synthesis of the rhodium(II) carboxylates,[12] which, although shown to be diamagnetic, excited little interest until the end of that momentous decade when an X-ray crystal structure revealed the source of the diamagnetism to be their rhodium—rhodium bonds.[13]

However, the rapid pace of rhodium chemistry has not been fully reflected in the review literature. The two extant English language reference works have been well overtaken by events.[14,15] There is an invaluable compendium of the early work by Griffith,[16] and a new edition of Gmelin's handbook has been published very recently.[17] However, apart from these last two books and the ever increasing space devoted to the chemistry of the element in undergraduate texts there has been no systematic attempt to review the chemistry of this element apart from its organometallic compounds, which form the subject of the companion series.[18]

To some extent this situation has been rectified by a number of reviews of more limited range. Among these are the review by Robinson on the rhodium(II) carboxylates,[19] and the reviews on the chemistry of $[RhCl(PPh_3)_3]$[20] and $[RhH(CO)(PPh_3)_3]$.[21] The tertiary phosphine, arsine and stibine complexes of the element have also been covered in two reviews of these ligands' complexes with the transition elements.[22]

Apart from catalytic reactions in organic and industrial chemistry there are few practical applications of rhodium complexes. Recently some interest has been shown in the use of rhodium(II) carboxylates in chemotherapy. Generally it appears that the rhodium(II) complexes are less effective than those of platinum(II),[23] although they also appear to induce less unwelcome side effects than do the platinum(II) complexes. They may have some promise as radiation sensitizers, although this is more probably due to the high atomic number of rhodium than any specific pharmaceutical properties.

As might be expected, the lipophilicity increases with increasing chain length of the carboxylato ligands' alkyl group. This increases the body burden of rhodium, which in turn increases both the toxicity and antitumor activity of the rhodium complex. However, it has been stated that too great an increase in the chain length (*i.e.* beyond the pentanoate) reduces the therapeutic properties.[24] It seems that optimal properties are shown by the butyrate.[25,26]

The mode of action of the carboxylates is, as yet, uncertain. It is believed that acetate is mainly decomposed in the liver. The labelled acetate produces $^{14}CO_2$, but only 5% of the rhodium is eliminated in the urine in the first 24 hours after administration.[27] The acetate, propionate[28] and butyrate[29] inhibit DNA and RNA syntheses. This has been demonstrated for the butyrate by *in vivo* studies on Erlich tumor cells in mice. It is possible that rhodium(II) acetate owes its antineoplastic activity to its inhibition of the enzymatic deamination of arabinosylcytosine. The latter is an antineoplastic agent in its own right, and it has been suggested that its joint administration with rhodium(II) acetate might prove efficacious.[30]

The complexes of rhodium will primarily be considered in order of increasing oxidation state. However, complexes in which the oxidation state of the metal is uncertain (*e.g.* nitrosyls) or dinuclear complexes of mixed oxidation state will be dealt with last.

The complexes will be assigned to sections according to the number of neutral ligands they contain. Polydentate ligands will, for the purposes of assignation, be considered to be equivalent to the number of donor atoms. However, polydentate ligands' complexes will normally be considered after those of similar monodentate ligands. For example, discussion of the properties of $[Rh(NH_3)_6]^{3+}$ will precede that of the reactions of $[Rh(en)_3]^{3+}$. Mononuclear complexes will precede bridged complexes. Within these classes the donor atom will determine the order to citation and

within each of these sub-classes the anionic ligand will then determine the order. Polyatomic anions will be cited in the order appropriate to their central atom. The final determinant of precedence will be increasing relative molar mass, which can generally be equated with complexity of the ligand set. For example *mer*-$[RhCl_3(PMe_3)_3]$ will be discussed before *mer*-$[RhCl_3(PPr_3)_3]$, which in turn will be followed by *mer*-$[RhCl_3(PPr^i_3)_3]$. To this end, invoking the complexity criterion, PR_3 complexes will, for example, precede $PR'R_2$ complexes. All complexes will be included at the first opportunity. Thus, $[RhCl_5(H_2O)]^{2-}$ would be considered to be the complex of an oxygen ligand rather than of five chloro ligands.

This order will be adhered to except where its slavish implementation would lead to extensive cross referencing and unnecessary duplication of material. The bald order will be supplemented by sundry reaction schemes since, historically, many areas of rhodium chemistry have been developed by preparing derivatives of some dozen or so key complexes, and it would be unwise to discard this aspect of the subject.

48.2 RHODIUM(−I) COMPLEXES

With one exception the only non-carbonyl complexes in this oxidation state are those of the $[Rh(PF_3)_4]^-$ ion. Complexes of this ligand were reviewed by Nixon in 1970.[31]

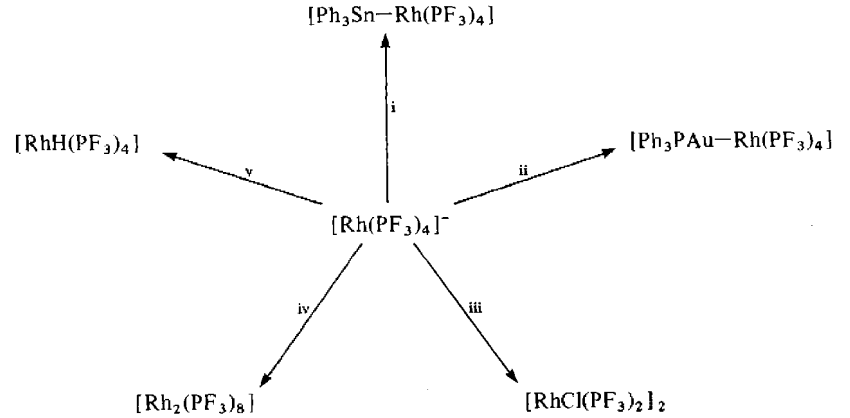
The salts of this ion, which is presumably tetrahedral like the isoelectronic anion $[Co(CO)_4]^-$, can be obtained by neutralizing $[RhH(PF_3)_4]$ with bases (equation 1).[32]

$$[RhH(PF_3)_4] + py \longrightarrow (pyH)[Rh(PF_3)_4] \quad (1)$$

The potassium salt can be prepared by reducing $[Rh_2(PF_3)_8]$ with potassium amalgam (equation 2),[32–35] or by allowing the latter reagent to react with the hydridorhodium(I) complex (equation 3).[32,35]

$$[Rh_2(PF_3)_8] + 2K/Hg \longrightarrow 2K[Rh(PF_3)_4] \quad (2)$$

$$[RhH(PF_3)_4] + 2K/Hg \longrightarrow 2K[Rh(PF_3)_4] + H_2 + Hg \quad (3)$$



The dimeric chloro complex $[RhCl(PF_3)_2]_2$ can be similarly reduced.[36]

Large cations form isolable salts of the $[Rh(PF_3)_4]^-$ anion (equations 4 and 5).[32]

$$[Rh(PF_3)_4] + [Fe(phen)_3]^{2+} \longrightarrow [Fe(phen)_3][Rh(PF_3)_4]_2 \quad (4)$$

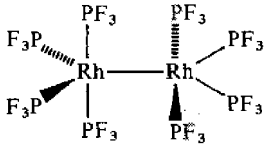
$$[RhH(PF_3)_4] + [Co(Cp)_2]^+ \longrightarrow [Co(Cp)_2][Rh(PF_3)_4] \quad (5)$$

The reactions of the $[Rh(PF_3)_4]^-$ anion are showing in Scheme 1. The most noteworthy reactions include the formation of metal–metal bonds with tin[33,36] and gold.[33] Other $[L_nM—Rh(PF_3)_4]$ complexes can be prepared by different routes (see Section 48.10.3). The anion is oxidized by $SnCl_4$, $TlCl_3$ or $[RhCl(PF_3)_2]_2$.[33]

i, Ph_3SnCl;[36] ii, $[Ph_3PAuCl]$;[33] iii, $TlCl_3$ or $SnCl_4$;[33] iv, $[RhCl(PF_3)_2]_2 + PF_3$;[33] v, 50% H_2SO_4[34]

Scheme 1 Reactions of $[Rh(PF_3)_4]^-$

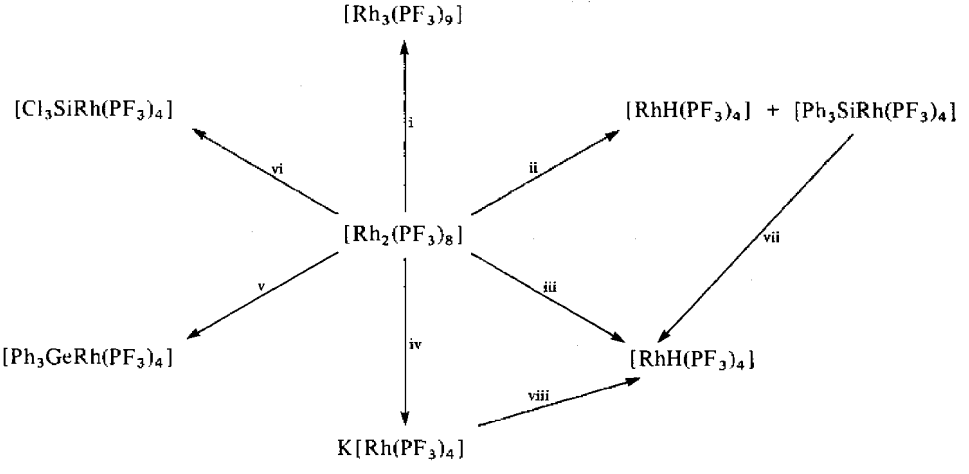
The only other non-carbonyl rhodium(−I) complex that has been isolated is the closely related $[Rh(PF_2NMe_2)_4]^-$. The potassium salt can be obtained by reducing $[RhCl(PF_2NMe_2)_3]$ with potassium amalgam.[37]



48.3 RHODIUM(0) COMPLEXES

48.3.1 $[Rh_2(PF_3)_8]$

This complex can be prepared by allowing PF_3 to react with anhydrous rhodium trichloride and copper powder under severe conditions (equation 6).[34,35]



$$RhCl_3 + 6Cu + 8PF_3 \xrightarrow[150°C]{250\,atm} [Rh_2(PF_3)_4]_2 + 6CuCl \quad (6)$$

A more convenient preparation is to oxidize $K[Rh(PF_3)_4]$ with $[RhCl(PF_3)_2]_2$ (Scheme 1, Section 48.2 above).[33] The diamagnetic, orange-red crystals of the product melt at 92.5°C.[35] The dimeric formulation (**1**) is consistent with its diamagnetism, and with the ^{19}F and ^{31}P NMR spectra recorded at temperatures below −15°C.[33,38] Poor crystal quality prevents the solid state structure being determined.[38]

(1)

The rhodium(0) complex reacts instantaneously with hydrogen and abstracts it from several hydrides (Scheme 2). On heating $[Rh_2(PF_3)_8]$ to 170°C, it decomposes forming $[Rh_3(PF_3)_9]$. The trimer has been characterized by mass spectrometry, but there is the possibility it may be the mixed Rh^I/Rh^0 species $[Rh_3(PF_2)(PF_3)_8]$.[33]

i, 170°C;[33] ii, Ph_3SiH;[33] iii, H_2;[33] iv, K/Hg;[34] v, Ph_3GeH;[33] vi, $SiHCl_3$;[33] vii, H_2;[33] viii, 50% H_2SO_4[34]

Scheme 2 Reactions of $[Rh_2(PF_3)_8]$

48.3.2 $[Rh(PPh_3)_n]$ Complexes

Pale green $[Rh(PPh_3)_4]_2$ can be prepared by the polarographic reduction of $[RhCl(PPh_3)_3]$ in acetonitrile. The product is believed to be dimeric since it is diamagnetic. Attempts to demonstrate the presence of an Rh—H bond in the material failed.[39,40] The complex can also be prepared by electrochemically reducing solutions of $RhCl_3 \cdot 3H_2O$ in the presence of triphenylphosphine.[40]

There is a patent claiming that magnesium amalgam reduced $[RhCl(PPh_3)_3]$ to $[Rh(PPh_3)_2]_2$.[41] However, since the high field ^1H NMR spectra of these complexes have not been obtained, there

must be some doubt as to their authenticity. They may be hydridorhodium(I) complexes or even *o*-metallated rhodium(I) complexes.

48.3.3 [Rh(diphos)$_2$]

The ionic complex [Rh(diphos)$_2$]Cl can be reduced electrochemically in a variety of solvents to form the reactive species [Rh(diphos)$_2$]. The usual fate of this species is to abstract a hydrogen atom from the solvent and form [RhH(diphos)$_2$].[42] There is one instance where attack on the electrolyte, [Bu$_4$N][ClO$_4$], has been observed.[43] Another school disputes this mechanism of [RhH(diphos)$_2$] formation, and rightly questions the validity of deuterium labelling experiments which use alkaline mixtures of H_2O and D_2O.[44]

48.4 RHODIUM(I) COMPLEXES

48.4.1 Anionic Complexes

Rhodium does not readily form anionic complexes in its lower oxidation states, probably because π-acid ligands are usually required to disperse the electron density from the metal in neutral or even cationic complexes. It is not surprising, therefore, that the few examples of rhodium(I) anionic complexes contain powerful π-acid ligands.

The $[RhCl(SnCl_3)_2]_2^{4-}$ anion can be obtained by allowing $[SnCl_3]^-$ — to reduce rhodium trichloride (equation 7). The tetramethylammonium salt has been isolated.

$$2RhCl_3 + 6[SnCl_3]^- \xrightarrow{3M\ HCl} [RhCl(SnCl_3)_2]_2^{4-} + 2[SnCl_5]^- \quad (7)$$

Tetramethylammonium chloride cleaves the dimeric complex $[RhCl(PF_3)_2]_2$ and forms $[Me_4N][RhCl_2(PF_3)_2]$.[36]

48.4.2 [RhXL$_2$] Complexes

There are three principal types of complex which share this stoichiometry. The first consists of authentic three-coordinate complexes containing three monodentate ligands. The second type comprises complexes of mononegative bidentate anions. In the last type rhodium achieves four coordination by forming bridged species of general formula $[RhXL_2]_2$. Complexes where one of the neutral ligands is untypically bidentate are discussed in Section 48.4.2.4.

48.4.2.1 Three-coordinate complexes

These complexes (see Table 1) are formed by very bulky, electron-donating tertiary phosphine ligands since even relatively large ligands of this type from $RhXL_3$ complexes (*e.g.* $[RhCl(PPh_3)_3]$). Electron-withdrawing ligands give rise to halo-bridged complexes, for example $[RhCl\{P(C_6F_5)_3\}_2]_2$. There has been considerable interest in the synthesis and properties of such three-coordinate complexes since they are isolable analogs of the important catalytic intermediate $[RhCl(PPh_3)_2]$.

Bis(tricyclohexylphosphine) complexes are probably the most accessible and hence widely inves-

Table 1 Physical Properties of $[RhXL_2]$ Complexes

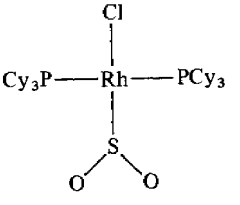
Complex	*Color*	*M.p.* (°C)	*Ref.*
$[RuH(PPr^i_3)_2]$	Orange	80[a]	55
$[RhH(PBu^t_3)_2]$	Dark brown	160[a]	55
$[Rh\{N(SiMe_3)_2\}(PPh_3)_2]$	Green	128–30	58, 59
$[RhF(PCy_3)_2]$	Red	—	46
$[RhCl(PCy_3)_2]$	Lilac	—	46
$[RhBr(PCy_3)_2]$	Lilac	—	46
$[RhI(PCy_3)_2]$	Lilac	—	46

[a] With decomposition.

tigated three-coordinate complexes. Numerous PCy_3 complexes can be prepared from $[RhF(C_8H_{14})_2]_n$ (equation 8).[46,47]

$$[RhF(cod)]_2 + 4PCy_3 \longrightarrow 2[RhF(PCy_3)_2] \xrightarrow{NaX} [RhX(PCy_3)_2] \quad (8)$$
$$X = Cl, Br, I, N_3$$

The bromo and iodo complexes can also be prepared from $[RhCl(C_8H_{14})_2]_2$.[47] The ^{31}P NMR spectrum shows $[RhCl(PCy_3)_2]$ to be in equilibrium with $[RhCl(PCy_3)_2]_2$.[46]



The bis(tricyclohexylphosphine) complexes are 14-electron species and are highly reactive. They are easily oxidized by air,[48] and even decompose when stored in an inert atmosphere. However, they will readily coordinate an additional small ligand. Many of these small ligands bind through carbon and are, therefore, outside the scope of this review. Both dinitrogen[46,49] and sulfur dioxide form adducts (equations 9 and 10).[50]

$$[RhX(PCy_3)_2] + N_2 \xrightarrow[25°C]{C_6H_6} [RhX(PCy_3)_2N_2] \quad (9)$$
$$X = Cl, Br, I$$

$$[RhCl(PCy_3)_2] + SO_2 \longrightarrow [RhCl(SO_2)(PCy_3)_2] \quad (10)$$

The fluoro complex does not react with dinitrogen, but the degree of reactivity increases with the atomic number of the halo ligand.

The sulfur dioxide complex (**2**) has been shown to contain an S-bound sulfur dioxide ligand.[51]

(2)

The $RhXL_2$ complexes can also be prepared by expelling one neutral ligand from $RhXL_3$ complexes. Tricoordinate or weakly solvated square planar complexes are known to exist in solution,[52,53] but unsolvated examples have seldom been isolated. The phenolate complex $[Rh(OPh)(PPh_3)_2]$ can be prepared by recrystallizing the tris(triphenylphosphine) complex from toluene, but it may be dimeric with anion bridges.[54] The best examples of this method of preparation are those of $[RhHL_2]$ complexes. These three-coordinate hydrido complexes are obtained due to the high *trans* effect of the hydrido ligand labilizing the third neutral ligand in the four-coordinate precursor. Several $[RhH(PR_3)_2]$ complexes can be obtained from the dinitrogen complexes $[RhH(N_2)(PR_3)_3]$.[55,56] The corresponding PCy_3 complex can be obtained by decomposing *trans*-$[RhHN_2(PCy_3)_2]$ at 60°C (equation 11).[55]

$$[RhH(N_2)(PR_3)_2] \longrightarrow [RhH(PR_3)_2] + N_2 \quad (11)$$
$$R_3 = Bu^t_3,[54,55]\ Bu^t_2Ph[54]$$

At lower temperatures dinitrogen coordinates to $[RhH(PCy_3)_2]$ forming the four-coordinate mononuclear complex $[RhH(N_2)(PCy_3)_2]$.[46,47,49,55,56]

Less commonly, three-coordinate complexes can be obtained containing a large anion. The yellow three-coordinate complex $[Rh\{N{=}C(CF_3)_2\}(PPh_3)_2]$ can be prepared by allowing $[Me_3Sn\{N{=}C(CF_3)_2\}]$ to react with $[RhCl(PPh_3)_3]$.[57] Poorer yields are obtained when $[LiN{=}C(CF_3)_2]$ is used. Presumably the anion is bound solely through nitrogen as it is in $[Rh\{N{=}C(CF_3)_2\}\{C(NMeCH_2)_2\}(PPh_3)_2]$ whose structure has been determined by X-ray crystallography.[58]

The green bis(trimethylsilyl)amido complex can be prepared by allowing $[RhCl(PPh_3)_3]$ to react with $LiN(SiMe_3)_2$ in THF.[59] It will be noted that neither of these anions can undergo β-hydride abstraction reactions that destroy simpler amido complexes.

48.4.2.2 Complexes containing bidentate anions

The pentan-2,4-dionato (acac) complexes may be prepared either by cleaving dinuclear pentan-2,4-dionato complexes with tertiary phosphines,[60,61] or by displacing the halo ligands in bridged, triphenyl phosphite or $PF_2(NEt_2)$ complexes (equations 12–16).[61,62]

$$[Rh(acac)(C_2H_4)_2]_2 + 4PR_3 \longrightarrow 2[Rh(acac)(PR_3)_2] + 4C_2H_4 \quad (12)$$

$R_3 = Ph_3, Ph_2Me$[60]

$$[Rh(acac)(C_8H_{14})_2]_2 + 4PR_3 \longrightarrow 2[Rh(acac)(PR_3)_2] + 4C_8H_{14} \quad (13)$$

$R_3 = PF_2NEt_2, PF(NMe_2)_2$[61]

$$[Rh(acac)(CO)_2] + 2PR_3 \longrightarrow [Rh(acac)(PR_3)_2] + 2CO \quad (14)$$

$R_3 = PF_2NEt_2, P(NMe_2)_3$[61]

$$[RhX\{P(OPh)_3\}_2]_2 + 2acacH \longrightarrow 2[Rh(acac)\{P(OPh)_3\}_2] \quad (15)$$

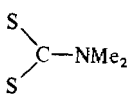
X = Cl, Br[62]

$$[RhCl(PF_2NEt_2)_2]_2 + 2acacH \longrightarrow 2[Rh(acac)(PF_2NEt_2)_2] \quad (16)$$

Closely similar is the preparation of the *N*-methylsalicylaldiminato complexes (equation 17).[63]

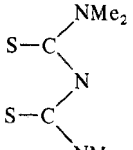
$$[RhCl(C_2H_4)_2]_2 + 2Tl(SalNMe) + 4PR_3 \xrightarrow{Et_2O} 2[Rh(SalNMe)(PR_3)_2] + 2TlCl + 4C_2H_4 \quad (17)$$

$R_3 = Ph_3, Ph_2Me$[63]



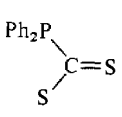
Orange crystals of the trifluoroacetato complex $[Rh(O_2CCF_3)\{P(OMe)_3\}_2]$ can be obtained if the trimeric hydrido complex $[RhH\{P(OMe)_3\}_2]_3$ is allowed to react with CF_3CO_2H in diethyl ether.[64]

Generally, however, this class of complex is the preserve of the disulfur anion. If $[RhCl(PPh_3)_3]$ is allowed to react with ammonium dialkyldithiophosphinates or diaryldithiophosphates in benzene, the products are $[Rh(S_2PCy_2)(PPh_3)_2]$ and $[Rh\{S_2P(OPh)_2\}(PPh_3)_2]$ respectively (equation 18).[65]



$$[RhCl(PPh_3)_3] + NH_4S_2PR_2 \longrightarrow [Rh(S_2PR_2)(PPh_3)_2] + PPh_3 + NH_4Cl \quad (18)$$

R = Cy, OPh[65]



Other di- or mono-thioanions (**3**)–(**8**) form complexes.[66] The secondary phosphinethiol $MeCH(SH)CH_2PHPh$ also displaces the chloro and one triphenylphosphine ligand from $[RhCl(PPh_3)_3]$ when it is dissolved in aqueous ethanolic ammonia.[67] The structures of these complexes have been inferred from their ^1H and ^{31}P NMR spectra.

48.4.2.3 Bridged complexes

These complexes can be prepared from phosphorus ligands that are themselves substituted by electron-withdrawing groups. It is often beneficial, however, to employ a low ratio of phosphorus ligand to rhodium since in several instances excess ligand cleaves the halo bridges and forms four-coordinate monomeric complexes. Table 2 lists those complexes of this structure that have been isolated.

Many of the complexes can be prepared by displacing ethylene from Cramer's compound (equation 19). However, it is more difficult to displace all the cycloocta-1,5-diene from $[RhCl(cod)]_2$ (equation 20); unless excess ligand is used an intermediate cyclooctadiene complex is formed.[77]

Table 2 Physical Properties of $[RhXL_2]_2$ Complexes

[a] With decomposition. [b] $R = (MeSiO)_2MeSiCH_2CH_2$.

$$[RhCl(C_2H_4)_2]_2 + 4L \longrightarrow [RhClL_2]_2 + 4C_2H_4 \quad (19)$$

$$L = P(p\text{-}C_6H_4Me)_3,^{70}\ PPh_2CH_2CH_2SiMe(OMe)_2,^{72}\ PF_2NMe_2,^{81}\ PF_2NEt_2^{82}$$

$$[RhCl(C_8H_{12})]_2 + 4L \longrightarrow [RhClL_2]_2 + 2C_8H_{12} \quad (20)$$

$$L = P(OMe)_3,^{76}\ P(OPh)_3,^{62}\ PF_2(OPr)^{76}$$

The enthalpies of these exothermic reactions have been determined for chloro, bromo and iodo species.[86] Other complexes that have been obtained from the cyclooctadiene complex include $[RhCl(PF_3)_2]_2$,[36] $[RhCl\{P(OMe)_3\}_2]_2$ and $[RhCl\{PF_2(OPr)\}_2]_2$.[76]

It is even more difficult to prepare $[RhClL_2]_2$ complexes from $[RhCl(CO)_2]_2$ (equation 21). Only the stronger π-acid ligands are capable of totally displacing the carbonyl ligands of the starting material. The triphenyl phosphite[78] and PF_3 complexes[79] can be made in this way.

$$[RhCl(CO)_2]_2 + 4L \longrightarrow [RhClL_2]_2 + 4CO \quad (21)$$

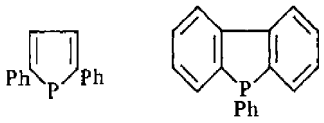
$$L = PF_3,^{79}\ P(OPh)_3,\ P(p\text{-}OC_6H_4Me)_3,\ P(p\text{-}OC_6H_4Cl)_3^{78}$$

The mixed ligand complex $[Rh_2Cl_2(PF_3)_2(PhN_2Ph)_2]$ was prepared by equilibrating the two dimeric complexes (equation 22).[85]

$$[RhCl(PF_3)_2]_2 + [RhCl(PhN_2Ph)_2]_2 \longrightarrow 2[RhCl(PF_3)(PhN_2Ph)]_2 \quad (22)$$

The complexes can also be prepared from other monomeric rhodium(I) complexes. Both the triphenylphosphine and the tri(*p*-tolyl)phosphine complexes can be prepared by refluxing solutions of the appropriate $[RhCl(PAr_3)_3]$ complex in an inert atmosphere (equation 23).[68,70] Alternatively one ligand of an $[RhXL_3]$ complex can be oxidized (equation 24).[87,88]

$$2[RhCl(PAr_3)_3] \rightleftharpoons [RhCl(PAr_3)_2]_2 + 2PAr_3 \quad (23)$$



$$Ar = Ph,^{68}\ p\text{-}C_6H_4Me^{70}$$

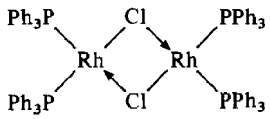
$$2[RhCl(CO)(PPh_3)_2] + Bu^tOOH \longrightarrow [RhCl(PPh_3)_2]_2 + 2Ph_3PO \quad (24)$$

Finally several complexes can be prepared by utilizing the ligand to reduce hydrated rhodium trichloride in homogeneous solution (equation 25).[71,73–75,83,84]

$$2RhCl_3 \cdot 3H_2O + 6L \xrightarrow{EtOH} [RhClL_2]_2 + 2LO \quad (25)$$

L = (9), (10),[71] $P(C_6F_5)_3$,[73,74] $PPh_2(C_6F_5)$,[74] $PPh_2(C_6Cl_5)$[75]

(9) (10)



The kinetics of the formation of $[RhCl(PPh_3)_2]_2$ from $[RhCl(PPh_3)_3]$ have been studied.[91,92] The dimeric complex has the planar structure (11); this is similar to that found for $[RhCl(cod)]_2$, but differs from the folded structure adopted by $[RhCl(CO)_2]_2$.[93] Details of the far IR spectra, which indicate similar halo-bridged structures are collected in Table 3.

Of all the complexes detailed above, those containing fluorine-substituted ligands have been the most studied. Their ^{31}P NMR spectra are summarized in Table 4.

The dimeric complexes can undergo bridge cleavage, neutral ligand exchange, or anionic ligand exchange when allowed to react with suitable reagents. Again the reactions of $[RhCl(PF_3)_2]_2$ have been most widely studied. These reactions are summarized in Scheme 3.

Triphenyl phosphite complexes undergo several of the reactions of the PF_3 complexes and, unlike the latter, are cleaved by treatment with excess ligand (equation 26). In the presence of a non-complexing anion the chloro ligand is displaced.[62]

Excess triphenyl phosphite will convert $[RhCl\{P(C_6F_5)_3\}_2]_2$ to the triphenyl phosphite complex (equation 27). Triphenylphosphine reacts similarly.[73,74]

(11)

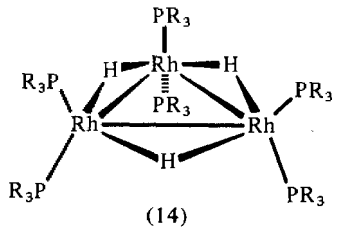
$$L = P(OPh)_3,^{73}\ PPh_3^{74}$$

The chloro ligands of $[RhCl\{P(OPh)_3\}_2]_2$ can also be displaced by pentan-2,4-dione.[62,77]

The dialkylamidodifluorophosphine complexes are also cleaved when allowed to react with excess ligand. However, these reactions are easily reversed.

The yellow dimethylamidophosphine complex is also cleaved by triphenylphosphine and reduced by potassium amalgam.[37]



The triphenylphosphine dimer is not very soluble, and this together with its ready reaction with oxygen has deterred investigations of its chemical properties. Whilst liquid sulfur dioxide cleaves the molecule and forms $[RhCl(SO_2)(PPh_3)_2]$,[96] solutions of SO_2 in ethanol/chloroform yield the centrosymmetric dimer (**12**),[97] whose structure has been determined by X-ray crystallography.[98] Closely similar to this complex is the cation (**13**) which can be prepared by passing sulfur dioxide into a methanolic solution of $[RhCl(cod)]_2$, $NaClO_4$ and PPh_3. The orange perchlorate salt has had its structure determined by X-ray crystallography.[99]

(12) (13)

The allyl complex $[Rh(\eta^3\text{-}C_3H_5)(cod)]$ reacts with trialkyl phosphites to form $[RhHL_2]_n$ complexes. The dimeric triisopropyl phosphite complex has already been mentioned. Trimethyl and triethyl phosphite, however, form trimeric products.[64,100] The structure of the trimethyl phosphite complex (**14**) has been determined by X-ray crystallography.[100–102]

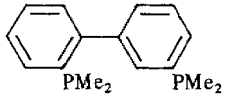
Finally there is a report of an ill-characterized benzothiazole complex $[RhCl(C_7H_5NS)_2]_2$. The benzothiazole ligands may be N-bound.[103]

(14)

48.4.2.4 [RhX(LL)] complexes

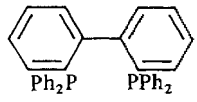
There are a few analogs of the bridged complexes described above which contain bidentate neutral ligands in place of the four monodentate neutral ligands.

They may be prepared by careful displacement of cycloocta-1,5-diene ligands from $[RhX(cod)]_2$ (equation 29).[104,105] Other complexes have been prepared by removing the single cyclooctadiene ligand from $[RhCl(LL)(cod)]_2$ complexes by hydrogenation (equation 30).[106]



$$[Rh(PPh_2)(cod)]_2 + 2LL \longrightarrow [Rh(PPh_2)LL]_2 + C_8H_{12} \quad (28)$$

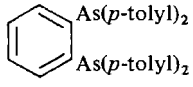
LL = $Ph_2PCH_2PPh_2$, diphos, $Ph_2P(CH_2)_3PPh_2$, $Ph_2P(CH_2)_2AsPh_2$[104]



$$[RhCl(cod)]_2 + (\mathbf{15}) \xrightarrow{C_6H_6} [RhCl(\mathbf{15})]_2 + 2C_8H_{12} \quad (29)$$

$$[RhLL(cod)]Cl + H_2 \longrightarrow [RhClLL]_2 + C_8H_{14} \quad (30)$$

LL = diphos, (**16**), diop[106]



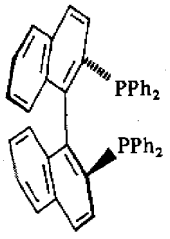
(15)

(16)

When the diarsine ligand (**17**) is allowed to react with rhodium trichloride in refluxing DMF, the bridged complex $[RhCl(\mathbf{17})]_2$ is formed (equation 31).[107]

$$RhCl_3 \cdot 3H_2O + (\mathbf{17}) \xrightarrow[\text{reflux}]{DMF} [RhCl(\mathbf{17})]_2 \quad (31)$$

(17)

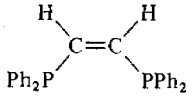


The complexes prepared by hydrogenation of their cyclooctadiene precursors may be solvated ionic monomers. This type of complex is formed if the anion is non-coordinating. For example, complexes of the ligand (**18**) can be obtained containing two methanol ligands (equation 32). However, the unsolvated complex $[Rh_2(\mathbf{18})_2][ClO_4]_2$ is the minor product in the reaction. It seems quite likely that this complex contains an η^6-phenyl group, as has been demonstrated for the corresponding diphos complex.[108,109]

$$10[Rh(\mathbf{18})(nbd)]ClO_4 + 20H_2 \xrightarrow{MeOH} 8[Rh(\mathbf{18})(MeOH)_2]ClO_4 + [Rh(\mathbf{18})]_2[ClO_4]_2 + 10C_7H_{12} \quad (32)$$

Recently, hydrogenation of the η^3-allyl complex $[Rh\{C_2H_4P_2(OR)_4\}(\eta^3\text{-}C_4H_7)]$ (R = Me, Et, Pr^i) has yielded $[RhH\{C_2H_4P_2(OR)_4\}]_n$ complexes (R = Me, Et, $n = 4$; R = Pr^i, $n = 2$) (equation 33).[110]

$$[Rh\{(RO)_2P(CH_2)_2P(OR)_2\}(\eta^3\text{-}C_4H_7)] \xrightarrow[C_7H_8]{H_2\ 3\,atm} [RhH\{(RO)_2P(CH_2)_2P(OR)_2\}]_n \quad (33)$$



If the anion is bidentate then bidentate neutral ligands form [RhX(LL)] complexes. Strangely, only one example of such a complex is known. The orange 5-methyl-8-hydroxyquinolinato complex

(18)

can be prepared if its rhodium(I) dicarbonyl complex is allowed to react with the unsaturated ditertiary phosphine (**19**) (equation 34).

$$[Rh(C_{10}H_8NO)(CO)_2] + (\mathbf{19}) \longrightarrow [Rh(C_{10}H_8NO)(\mathbf{19})] + 2CO \quad (34)$$

(19)

The ^{31}P NMR spectrum shows $^{1}J_{Rh-P} = 160$ Hz.[111]

48.4.3 [$RhXL_3$] Complexes

This is the most populous class of rhodium(I) complex. Interest in this type of complex has undoubtedly been inspired by the important catalytic applications of [$RhCl(PPh_3)_3$].[10,20] All complexes of this stoichiometry are 16-electron compounds and are formally coordinately unsaturated. However, for steric reasons they do not readily add a fifth ligand and pentacoordinate rhodium(I) complexes are rare. Many of the complexes undergo important oxidative addition reactions. The rhodium(III) products from these reactions are described in Section 48.6.

Isolable complexes of this stoichiometry are listed in Table 5.

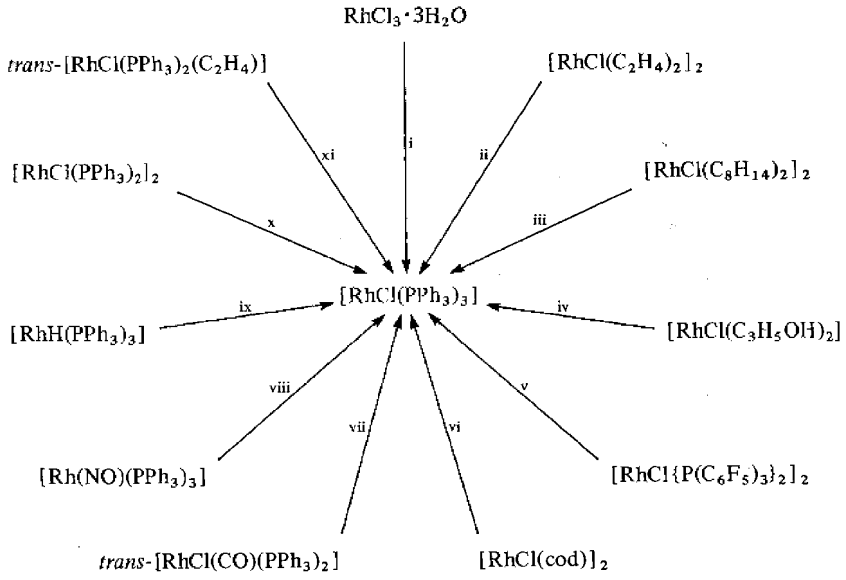
[a] With decomposition. [b] R = $(MeSiO)_2MeSiCH_2CH_2$. [c] Ethanol hemisolvate.



The neutral ligands usually possess some π-bonding capacity and it is rare, even in complexes containing two different neutral ligands, for a purely σ-bonding neutral ligand to coordinate to rhodium.

The anionic ligand can be virtually any uninegative ion. Anions of low coordinating power, however, do not form complexes of this stoichiometry and structure. There is an ionic perchlorate complex $[Rh(PPh_3)_3]ClO_4$ in which the cation is 'T' shaped.[144] It has been calculated that a cation of this structure lies near an energy minimum.[145] Two ionic PMe_3 complexes are also known.[146]

The complexes can be prepared by a wide variety of routes. The important complex $[RhCl(PPh_3)_3]$ has probably received the most attention, and preparations of this complex are shown in Scheme 4.

The main preparative routes to other complexes of this class usually involve the displacement of less firmly bound ligands from other rhodium(I) complexes (equations 35 and 36). This method has proved popular in catalytic studies since it enables the catalyst to be prepared *in situ* and obviates the necessity of isolating the catalytic complex.

A limited range of tertiary phosphine complexes can be prepared by reducing hydrated rhodium trichloride with the ligand itself (equation 37). Triarylphosphines containing electron-withdrawing substituents do not form monomeric complexes. Tris(perfluorophenyl)phosphine, for example, forms a dimeric complex (equation 25), and even heating the latter compound with neat ligand in a Carius tube for 24 hours does not form a mononuclear complex.[74] Under other conditions certain other tertiary phosphines can form a wide range of products which embraces rhodium(III), rhodium(II), and hydrido or carbonyl complexes.

[a] Asymmetric. [b] Symmetric.

The hydrido complex $RhH(PPh_3)_3$ is also a good starting point for preparing other complexes. Upon treatment with acids it eliminates hydrogen and forms an $[RhX(PPh_3)_3]$ complex (equation 38).

$$[RhH(PPh_3)_n] + HX \longrightarrow [RhX(PPh_3)_3] + H_2 \quad (38)$$

$n = 3, 4$; X = OPh,[54,126] O_2CMe,[127,128,154] O_2CEt, $p\text{-}O_2CC_6H_4NO_2$, $p\text{-}O_2CC_6H_4Cl$[127]

The carboxylato complexes (Table 6; equation 39) can also be prepared from the uncharacterized dimeric rhodium(II) species obtained by treating rhodium(II) acetate with HBF_4.[121]

$$\{Rh_2^{4+}\} + LiO_2CR + PPh_3 \longrightarrow [Rh(O_2CR)(PPh_3)_3] \quad (39)$$

R = Me, Et, Pr, C_5H_{11}, Ph, CH_2Cl, $CClF_2$, CF_3, C_2F_5

If rhodium(III) acetate were known, it would be possible to believe the patent claim that $[Rh(O_2CMe)(PPh_3)_3]$ can be prepared from it.[155]

Chlorotris(triphenylphosphine)rhodium(I) is also the precursor of numerous chloro complexes which may be obtained by exchanging PPh_3 for other ligands. The main use of this reaction, however, is to prepare $[RhXL_2L']$ complexes (see Section 48.4.3.1 below). The triphenylphosphine substitution reactions of $[RhCl(PPh_3)_3]$ are shown in Scheme 6.

The hydrido complex, $[RhH(PPh_3)_3]$, is obtained in a number of anion exchange reactions of $[RhCl(PPh_3)_3]$ due to hydride abstraction from the anions (equation 40).

$$[RhCl(PPh_3)_3] + MX \longrightarrow [RhH(PPh_3)_3] \quad (40)$$

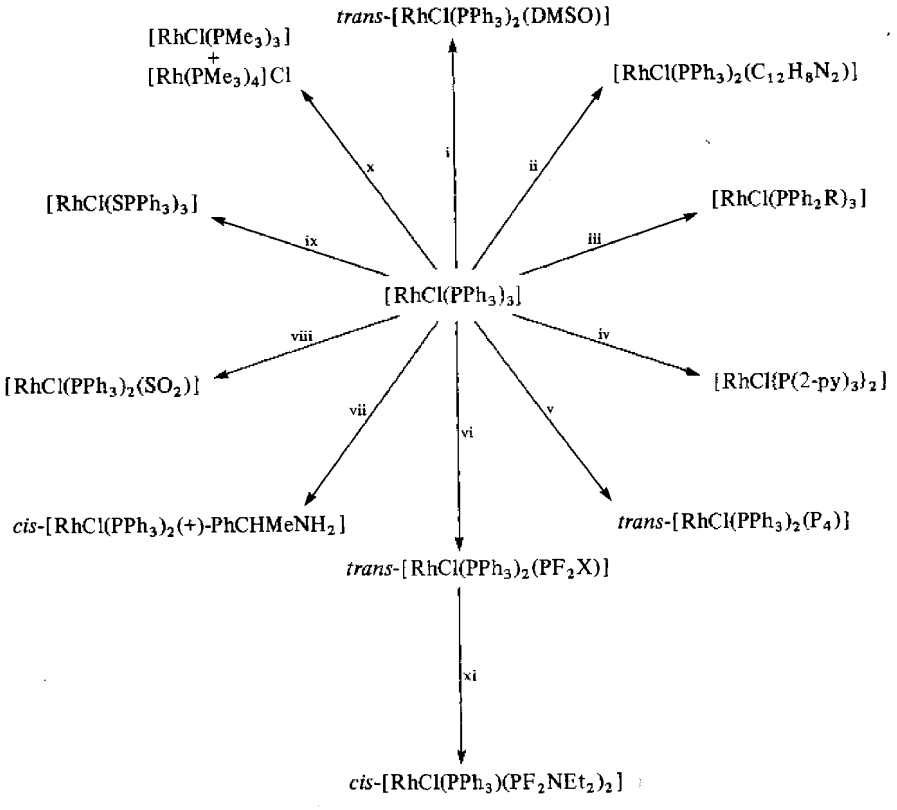
MX = $NaBH_4$,[153] $AlPr^i_3$,[54,118] $LiNHPr^i$,[160] $LiNMe_2$, $LiNPr^i_2$,[161] KOH/EtOH[152]

The trialkyl or triaryl phosphite complexes are more accessible than those of tertiary phosphines. The phosphite ligands complex strongly to rhodium, and easily displace alkene,[161] alkadiene[77,162] and even carbonyl[78] ligands from $[RhCl(CO)_2]_2$ (equations 41 and 42), a displacement that cannot be achieved by tertiary phosphines. Indeed, even tertiary phosphine ligands themselves can be displaced by the phosphite ligands (equation 43).[162] The phosphite complexes can also be prepared by cleaving $[RhX\{P(OR)_3\}_2]_2$ complexes with additional ligand (equation 26).

$$[RhCl(C_8H_{12})]_2 + 6L \longrightarrow 2[RhClL_3] + 2C_8H_{12} \quad (41)$$

L = $P(OMe)_3$,[76] $P(OPh)_3$[62,77]

$$[RhCl(CO)_2]_2 + 6P(OR)_3 \longrightarrow 2[RhCl\{P(OR)_3\}_3] + 4CO \quad (42)$$



R = Ph, $p\text{-}C_6H_4Me$, $p\text{-}C_6H_4Cl$[78]

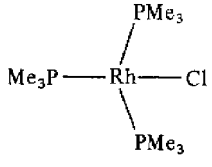
$$[RhCl(CO)(ZPh_3)_2] + \text{excess } P(p\text{-}OC_6H_4Cl)_3 \longrightarrow [RhCl\{P(p\text{-}OC_6H_4Cl)_3\}_3] + 2ZPh_3 + CO \quad (43)$$

Z = P, As, Sb[162]

By contrast tertiary arsine and stibine ligands do not displace alkadiene ligands[163] and are only able to displace weakly bound alkene[140,143] or allyl[141] ligands from other rhodium(I) complexes.

Few of the $[RhXL_3]$ complexes have had their physical properties investigated in great detail. As

i, DMSO, 100°C;[156] ii, benzo[*c*]cinnoline, C_6H_6;[90] iii, PPh_2R (R = C_7H_{15}, $C_{16}H_{33}$,[137] *m*-$C_6H_4SO_3Na$);[138] iv, P(2-py)$_3$, C_6H_6, 25°C;[157] v, P_4, CH_2Cl_2, −78°C;[158] vi, PF_2X (X = F,[80,89] CCl_3,[80] NMe_2, NEt_2[82]); vii, (+)-PhCHMeNH$_2$;[159] viii, $SO_{2(g)}$, C_6H_{14};[96] ix, $SPPh_3$;[84] x, PMe_3, C_6H_{14};[116] xi, PF_2NEt_2[80]



Scheme 6 Triphenylphosphine substitution reactions of [RhCl(PPh$_3$)$_3$]

in the case of their chemical properties nearly all interest has been focussed on the commercially and catalytically important [RhCl(PPh$_3$)$_3$].

A few of the complexes have had their structures determined by X-ray crystallography. Both the red[164,165] and orange[165] isomers of [RhCl(PPh$_3$)$_3$] have been investigated, as has [Rh(O$_2$CPh)(PPh$_3$)$_3$].[129,166] The latter compound was probably investigated because of its unusual preparation (equation 44).[129]

$$[RhPh(PPh_3)_3] + CO_2 \longrightarrow [Rh(O_2CPh)(PPh_3)_3] \quad (44)$$

The structures of the tris(triphenylphosphine) complexes are somewhat distorted from a true square planar arrangement of ligands. However, the structure of [RhCl(PMe$_3$)$_3$] (**20**) also deviates significantly from square planar geometry and this is unlikely to arise from interligand repulsions.[116] As might be expected, the large PPh$_3$ ligands of [RhH(PPh$_3$)$_3$] encroach severely upon the small hydrido ligand which has not been accurately located.[167]

(**20**)

The structure of [RhBr(PPh$_3$)$_3$] has been investigated by the relatively untried technique of X-ray absorption. It was concluded that its RhBrP$_3$ core was similar to the RhClP$_3$ cores of the chloro complexes.[168] The deviations of the cores from orthogonality are also indicated by the ^{31}P NMR study of solid [RhCl(PPh$_3$)$_3$]. The spectrum is complicated due to the many side bands caused by the ^{31}P chemical shift anisotropy, but is sufficiently well resolved to detect the inequivalence of the two *trans* PPh$_3$ ligands.[169]

The solution chemistry of $[RhCl(PPh_3)_3]$ has been dominated by the catalytically engendered interest in the dissociation of triphenylphosphine from the complex. The degree of dissociation has proved difficult to determine. Early results were erroneous due to aerial oxidation of the solutions,[68,131] and anaerobic isopeistic methods failed to provide an answer due to the slow precipitation of $\{RhCl(PPh_3)_2\}_2$.[170] However, more recent experiments in which oxygen has been rigorously excluded have shown the degree of dissociation in unadulterated solutions to be small.[171–173] The exchange of PPh_3 with $P(p\text{-}C_6H_4Me)_3$ has been shown to proceed by a dissociative mechanism.[174]

Data from the ^{31}P NMR spectra of some $[RhXL_3]$ complexes are collected in Table 7. The ^{103}Rh NMR spectrum of $RhCl(PPh_3)_3$ has also been obtained. In addition to the coupling constants recorded in Table 7 the additional coupling constant $^3J[P(1)\text{–}Rh\text{–}P(2)]$ was evaluated as -38 Hz.[176] The NMR data have been used in Hückel molecular orbital calculations for some $[RhCl(PR_3)_3]$ species.[177]

The X-ray emission spectrum of $[RhCl(PPh_3)_3]$ has been recorded.[178] However, X-ray photoelectron spectroscopy is claimed to show that the complex is 40% contaminated with a dioxygen rhodium(III) species.[179] This seems highly unlikely since two independent X-ray crystal structure determinations have been made.

The thermal decomposition of $[RhCl(PPh_3)_3]$ has been investigated twice. The first investigation revealed that the complex reacted with oxygen between 100 and 165°C, but decomposed in a helium atmosphere at 210°C.[180] The second proposed that biaryls were formed when $[RhCl(PPh_3)_3]$ and its congeners were heated above 140°C.[181]

48.4.3.1 [RhXL$_2$L′] complexes

The $[RhXL_2L']$ complexes exist in two isomeric forms. The *trans* complexes are listed in Table 8, and the few *cis* complexes in Table 9.

The *trans* complexes predominate since L′ is usually smaller than L and the *trans* disposition of the L ligands is of lower energy than the *cis* arrangement. The complexes can be prepared by a few general routes. The first of these involves cleaving $[RhXL_2]_2$ complexes with L′ or the addition of L′ to the three coordinate, monomeric complexes $[RhXL_2]$ (equation 46). In another method (equation 47), one neutral ligand is displaced from $[RhXL_3]$ complexes by L′ (see Scheme 6 for displacement of triphenylphosphine ligands from $[RhCl(PPh_3)_3]$).

$$[RhXL_2]_2 + 2L' \longrightarrow 2[RhXL_2L'] \quad (45)$$

X = Cl, L = PF_3, L′ = PPh_3,[34] L = PF_2NEt_2, L′ = PPh_3;[82] X = Cl, Br, I, L = PPh_3, L′ = $SO_{2(l)}$[96]

$$[RhX(PCy_3)_2] + N_2 \longrightarrow [RhX(PCy_3)_2(N_2)] \quad (46)$$

X = Cl, Br, I[46]

$$[RhXL_3] + L' \longrightarrow [RhXL_2L'] + L \quad (47)$$

Less commonly, treatment of the dimeric complexes with excess ligand both cleaves the dimers and displaces one of the original neutral ligands (equation 48). Some dinitrogen complexes can be prepared in a single reaction from hydrated rhodium trichloride (equation 49). Other dinitrogen complexes can be prepared by displacing cyclooctene from $[RhCl(C_8H_{14})_2]_2$ with PPr^i_3 under nitrogen (equation 50).[183] The most ingeneous preparation of a dinitrogen complex is the low temperature reaction of [*trans*-$RhCl(CO)(PPh_3)_2$] with butanoyl azide (equation 51).[184]

$$[RhClL'_2]_2 + 4L \longrightarrow 2[RhClL_2L'] + 2L' \quad (48)$$

$$L' = PF_3,\ L = PPh_3,\ AsPh_3{}^{89}$$

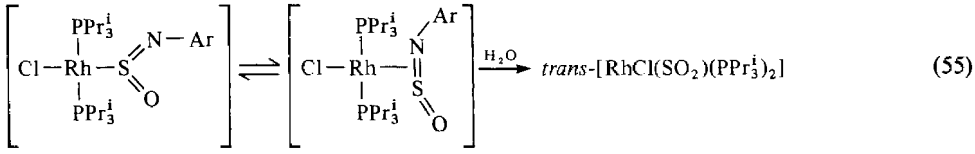
$$RhCl_3 \cdot 3H_2O + \text{excess } PR_3 \xrightarrow[THF]{Na/Hg,\ N_2} [RhH(PR_2)_2(N_2)] \quad (49)$$

$$R_3 = Bu^t_3,{}^{55}\ PhBu^t_2{}^{55,185}$$

$$[RhCl(C_8H_{14})_2]_2 + 4PPr^i_3 \xrightarrow{N_2} 2[RhCl(N_2)(PPr^i_3)_2] + 4C_8H_{14} \quad (50)$$

$$\textit{trans}\text{-}[RhCl(CO)(PPh_3)_2] + PrCON_3 \longrightarrow [RhCl(N_2)(PPh_3)_2] \quad (51)$$

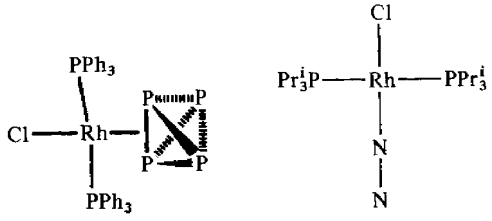
Tetrakis(trimethylphosphine)rhodium(I) chloride loses two trimethylphosphine ligands when allowed to react with PPh_3 at elevated temperatures (equation 52). The ionic compound also undergoes a more complex reaction with benzene and sodium. In this a trimethylphosphine ligand is converted to a PMe_2Ph ligand (equation 53).[186] The geometry adopted by both these complexes



is unknown. When $[RhCl(PPh_3)_3]$ is allowed to react in refluxing benzene with 1-aryltetrazoline-5-thiones (equation 54), two PPh_3 ligands are replaced by two thione molecules. These are believed to be S-bonded, but again information on the geometry around rhodium is lacking.[187] Similar remarks apply to the geometry of $[RhCl(PPh_3)_2(MeCN)]$[188] and $[RhCl(PPh_3)_2SnCH(SiMe_3)_2]$.[189]

$$[Rh(PMe_3)_4]Cl + PPh_3 \xrightarrow[\text{reflux}]{C_7H_8/THF} \textit{trans}\text{-}[RhCl(PMe_3)_2(PPh_3)] + 2PMe_3 \quad (52)$$

$$[Rh(PMe_3)_4]Cl + Na \xrightarrow{C_6H_6} [RhCl(PMe_3)_2(PMe_2Ph)] \quad (53)$$



$$[RhCl(PPh_3)_3] + ArN_3NHCS \xrightarrow[\text{reflux}]{C_6H_6} [RhCl(PPh_3)(ArN_3NHCS)_2] + 2PPh_3 \quad (54)$$

By a similar reaction to that shown in equation (50), the unusual complex $[RhCl(PPr^i_3)_2(p\text{-}MeC_6H_4NSO)]$ can be prepared. In the solid state the ligand is S-bound but isomerization to a μ-bonded species occurs in solution. The latter compound is hydrolyzed by water to a sulfur dioxide complex (equation 55).[190]

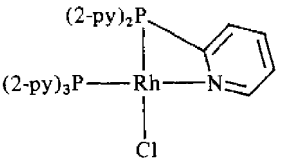
(55)

Other complexes whose crystal structures have been determined include the tetraphosphorus complex (**21**),[191] and the dinitrogen complex (**22**).[182] The latter complex was originally believed to contain a sideways-on dinitrogen ligand;[183] however, once corrections were made for disorder and anisotropy of the dinitrogen ligand, the more usual end-on coordination was proposed.[182]

(21) (22)

The hydrido dinitrogen complexes, whilst failing to fulfill the modern alchemists' dream of a catalyst for the low temperature low pressure ammonia synthesis, have been thoroughly investigated and some of their spectroscopic properties are listed in Table 10.

Bidentate ligands very seldom form related complexes of the type [RhXL(LL)], possibly because one of the bidentate ligand's donor atoms must be *trans* to a tertiary phosphine, a factor that also accounts for the small number of [*cis*-$RhXL_2L'$] complexes known. A rare example of a complex containing a bidentate ligand is provided by the orange complex (**23**), which can be obtained from $[RhCl(PPh_3)_3]$ (Scheme 6).[157]



There are also a few dimeric complexes containing a bridging bidentate ligand. Particularly noteworthy are the binuclear dinitrogen complexes $[\{RhH(PR_3)_2\}_2N_2]$ (R = Pr^i,[55] Cy[55,56]).

Finally it should be noted that there are a few ionic $[RhL_3]X$ complexes besides $[Rh(PPh_3)_3](ClO_4)$

mentioned above.[144] Surprisingly these contain the smallest tertiary phosphine, PMe_3, rather than very large ligands whose bulk might be expected to favor three-coordinate cations. Even more surprisingly the complexes have been obtained directly from $[Rh(PMe_3)_4]Cl$ rather than $[RhCl(PMe_3)_3]$ (equation 56).[116,146]

$$[Rh(PMe_3)_4]Cl + KX \longrightarrow [Rh(PMe_3)_3]X + PMe_3 + KCl \quad (56)$$

$$X = BPh_4, PF_6^{116,146}$$

48.4.4 $[RhXL_4]$ Complexes

48.4.4.1 $[RhHL_4]$ complexes

There are three limiting forms of structure for hydrido complexes of this stoichiometry: trigonal bipyramidal, square pyramidal and monocapped tetrahedra. The structure of a given complex is difficult to classify since, in addition to the hydrido ligand being difficult to locate by X-ray crystallography, many of the complexes suffer radiolytic damage during data collection. This damage reduces the quantity and accuracy of the data available. However, examination of the structure of the rhodium ligand core gives a clue to the overall structure.

Similar difficulties occur in attempts to study solution structures by NMR spectrometry. Here ligand exchange is the problem. A further difficulty in ^1H NMR spectrometry is the multiple splitting of the hydride resonance by both ^{103}Rh and ^{31}P nuclei in the molecule. The ultimate example is found in $[RhH(PF_3)_4]$ where every nucleus in the molecule has a non-integral spin. It has been calculated that the hydrido resonance should be split into 130 peaks![192]

In the solid state $[RhH(PPh_3)_4]$[193] and the isomorphous $[RhH(PPh_3)_3(AsPh_3)]$[118] have been shown to have monocapped tetrahedral structures, and $[RhH(PPh_3)_3(PF_3)]$[194] is a trigonal bipyramidal species. It has been stated that the solution structures, at low temperatures, of $[RhH(PF_3)_4]$ and $[RhH\{P(OEt)_3\}_4]$,[195] and $[RhH\{P(OCH_2)_3CPr\}_4]$[196] are all monocapped tetrahedra. However, these three complexes clearly exhibit fluxional behavior in solution and pass through intermediate structures which can be represented as distorted trigonal bipyramids.[195,197] This stereochemical non-rigidity may account for their J(Rh–H) values of 9–9.5 Hz,[195] which may be compared with the coupling constant of the square pyramidal complex $[RhH(PPh_2Me)_4]$ of 7 Hz[118] (see below). Nevertheless, it has been found that the ^1H NMR spectrum of $RhH(PPh_3)_4$ (J(Rh–H) = 0 Hz) is similar (see Table 11) to that of the known trigonal bipyramidal species $[RhH(CO)(PPh_3)_3]$ (J(Rh–H) = 0.8 Hz). The ^1H NMR spectrum of $[RhH(PPh_2Me)_4]$ shows only the *cis* P–H coupling of 18 Hz, without any *trans* P–H coupling being observed. Additionally, J(Rh–P) is 7 Hz, which implies that $[RhH(PPh_2Me)_4]$ is square pyramidal in solution.[118] The triaryl phosphite complexes

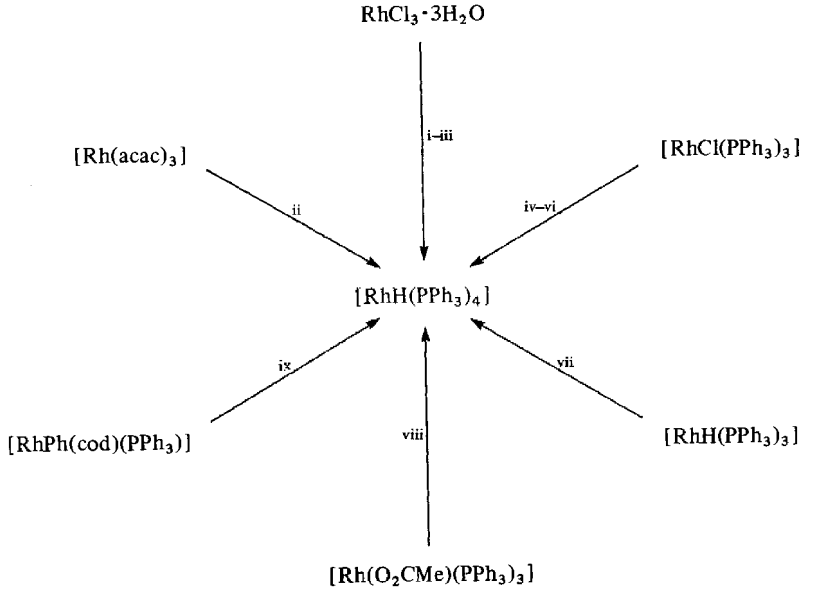
$[RhH\{P(OAr)_3\}_4]$ have similar coupling constants and are probably also square pyramidal in solution.

One of the more important complexes in this class is $[RhH(PPh_3)_4]$. It can be prepared from a variety of starting materials (Scheme 7).

The four PPh_3 ligands form a tetrahedron around rhodium. The hydrido ligand could not be located by X-ray crystallography.[193]

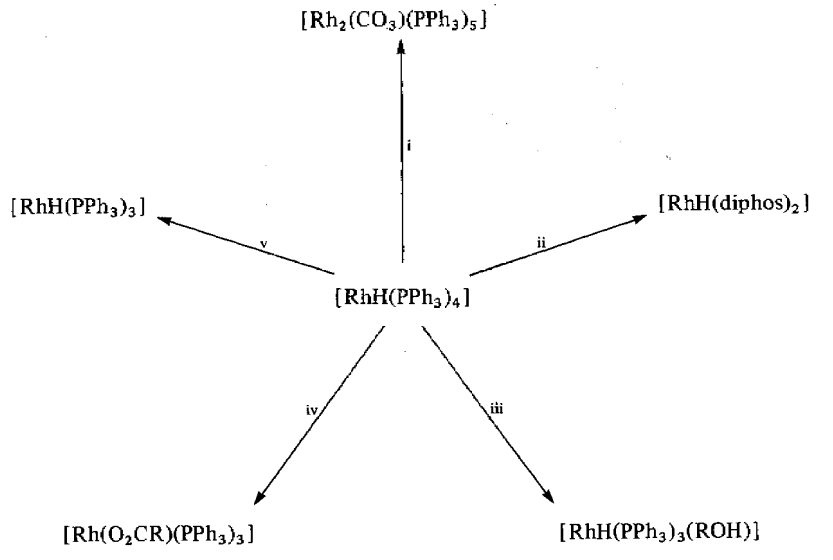
The complex is very reactive; the hydrido ligand can be replaced by other anionic ligands (Scheme 8) and the lability of the triphenylphosphine ligands allows other complexes of this stoichiometry to be prepared. The most interesting product from these reactions is the dirhodium carbonato complex (**24**). This is the product when $[RhH(PPh_3)_4]$ is allowed to react with carbon dioxide in toluene at 25°C.[205] Originally the product was thought to be a CO_2 complex,[206] but X-ray crystallography showed it to be (**24**).[205] The additional oxygen atom may arise from traces of moisture or oxygen in the gas stream. ^{31}P NMR studies on benzene solutions of (**24**) imply that the dimeric structure is retained in solution.



(24)

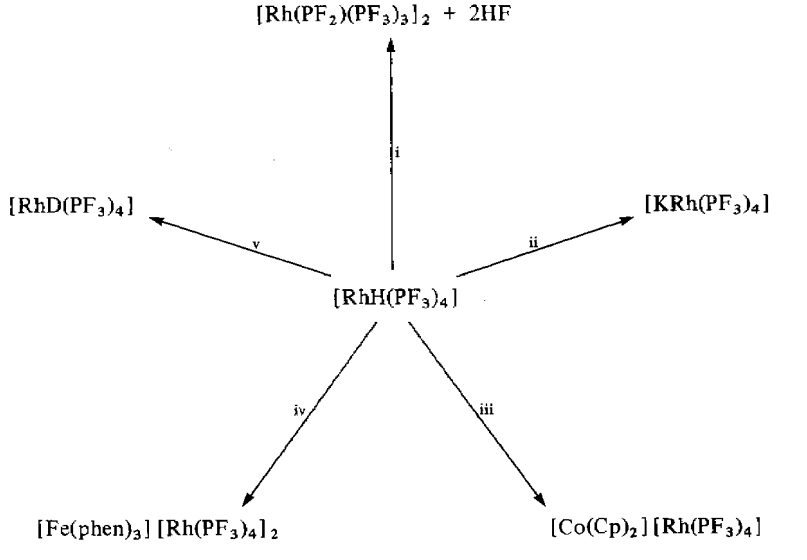
The action of PF_3 and hydrogen at high temperatures and pressures upon mixtures of anhydrous rhodium trichloride and copper forms (equation 57) the colorless liquid $[RhH(PF_3)_4]$ (b.p. 89°C/725 torr).[32,35,208] The liquid decomposes slowly at 20°C to form $[Rh(PF_2)(PF_3)_3]_2$, but on heating to 140°C it decomposes to rhodium metal.[32] The hydrido complex can also be formed by the action of strong acids on the potassium salt $K[Rh(PF_3)_4]$ (equation 58).[34]

$$RhCl_3/Cu + PF_3 + H_2 \xrightarrow[70°C]{200\ atm} [RhH(PF_3)_4] \quad (57)$$



$$K[Rh(PF_3)_4] + H_2SO_4 \longrightarrow [RhH(PF_3)_4] \quad (58)$$

The complex behaves as a strong acid (Scheme 9). The deuterio complex can be prepared by treating the hydrido complex with D_2SO_4.[32] The exchange of hydrogen is much easier than in the case of $[RhH(PPh_3)_4]$ which only exchanges very slowly with deuterium gas (equation 59).[209]



i, $NaBH_4$, PPh_3, EtOH;[198,199] ii, Et_3Al, PPh_3;[200] iii, EtOH/KOH, reflux;[201,202] iv, $NaBH_4$, PPh_3;[153] v, N_2H_4, PPh_3, C_6H_6/EtOH, H_2, reflux;[118] vi, $NaOPr^i$, PPh_3, Pr^iOH;[125] vii, PPh_3;[118,153] viii, H_2, PPh_3, C_6H_6;[203] ix, H_2, PPh_3[204]

Scheme 9 Reactions of $[RhH(PF_3)_4]$

$$[RhH(PPh_3)_4] + D_2 \xrightarrow{C_6H_6} [RhD(PPh_3)_4] + HD \quad (59)$$

The next most important complexes of this type are trialkyl or triaryl phosphite complexes. These are best prepared by allowing the ligands to react with $[RhH(CO)(PPh_3)_3]$ (equations 60 and 61).

$$[RhH(CO)(PPh_3)_3] + 4PX_3 \longrightarrow [RhH(PX_3)_4] + 3PPh_3 + CO \quad (60)$$

$$X_3 = Et_3,[197] Ph_3,[210] Ar_3,[198] PrC(CH_2O)_3[196]$$

$$[RhCl\{PPh(OEt)_2\}_4] + PPh(OEt)_2 \xrightarrow[EtOH]{NaBH_4,\ Ar} [RhH\{PPh(OEt)_2\}_4] \quad (61)$$

Little is known of their chemical properties. If the electrochemical reduction of $[RhH\{P(OPh)_3\}_4]$ is essayed, loss of a phosphite ligand occurs before reduction to $[RhH\{P(OPh)_3\}_3]^-$ takes place. The anionic complex is unstable and *o*-metallates, eliminating hydrogen.[211]

Apart from $[RhH(PPh_2Me)_4]$, which can be prepared from $[RhCl(PPh_2Me)_3]$ by treating it with hydrazine (equation 63),[118] and $[RhH(PMe_3)_4]$, which is prepared by reducing the rhodium(III) complex $[RhH_2(PMe_3)_4]Cl$ with sodium amalgam (equation 62),[186] the remaining example of this type of complex is the dibenzophosphole complex $[RhH(\mathbf{10})_4]$ (equation 64). The last complex dissociates readily in solution (equation 65).[52,133,212]

$$[RhH_2(PMe_3)_4]Cl \xrightarrow[THF,\ 25°C]{Na/Hg} [RhH(PMe_3)_4] \quad (62)$$

$$[RhCl(PPh_2Me)_3] + PPh_2Me \xrightarrow[EtOH/C_6H_6]{N_2H_4,\ H_2,\ 80°C} [RhH(PPh_2Me)_4] \quad (63)$$

$$RhCl_3 \cdot 3H_2O + (\mathbf{10}) \xrightarrow{NaBH_4} [RhH(\mathbf{10})_4] \quad (64)$$

$$[RhH(\mathbf{10})_4] \rightleftharpoons [RhH(\mathbf{10})_3] + (\mathbf{10}) \quad (65)$$

The one complex of this stoichiometry not to have a set of four phosphorus ligands is $[RhH(PPh_3)_3(AsPh_3)]$. This can be prepared by allowing $AsPh_3$ to react with $[RhH(PPh_3)_3]$ (equation 66). It has been shown to be isomorphous with $[RhH(PPh_3)_4]$. Phosphorus and arsenic randomly occupy the coordination sites.[213] The corresponding tris(triphenylarsine) complex can be prepared from $[RhPh(cod)(PPh_3)]$ (equation 67).[204]

$$[RhH(PPh_3)_3] + AsPh_3 \longrightarrow [RhH(PPh_3)_3(AsPh_3)] \quad (66)$$

$$[RhPh(cod)(PPh_3)] + AsPh_3 + H_2 \longrightarrow [RhH(AsPh_3)_3(PPh_3)] \quad (67)$$

48.4.4.2 Other [RhXL$_4$] complexes

Very few complexes of this type are known. Some $[RhX(PF_3)_4]$ complexes can be prepared from $[RhX(PF_3)_2]_2$ but these readily lose PF_3 on warming to room temperature.[89] The complexes containing PF_2NR_2 ligands are slightly more stable. The complexes $[RhCl(PF_2NMe_2)_4]$, $[RhCl(PF_2NEt_2)_4]$, and $[RhI(PF_2NEt_2)_4]$ have been isolated. Their decomposition temperatures have been reported to be 79, 28, and 58°C respectively. The difluorodimethylaminophosphine complex is yellow and the others orange. They have been prepared by addition of excess ligand to various dimeric rhodium(I) complexes (equations 68–70).[61]

$$[RhCl(CO)_2]_2 + \text{excess } PF_2NMe_2 \xrightarrow{-78°C} [RhCl(PF_2NMe_2)_4] \quad (68)$$

$$[RhCl(PF_2NEt_2)_2]_2 + \text{excess } PF_2NEt_2 \xrightarrow{-78°C} [RhCl(PF_2NEt_2)_4] \quad (69)$$

$$[RhI(cod)]_2 + PF_2NEt_2 \longrightarrow [RhI(PF_2NEt_2)_4] \quad (70)$$

The yellow diethyl phenylphosphonite complex is also known. It can be prepared directly from hydrated rhodium trichloride (equation 71).[195]

$$RhCl_3 \cdot 3H_2O + NaBH_4 + \text{excess } PPh(OEt)_2 \xrightarrow{EtOH} [RhCl\{PPh(OEt)_2\}_4] \quad (71)$$

48.4.4.3 [RhH(LL)$_2$] complexes

Despite the isolation of numerous $[RhHL_4]$ complexes only two of the corresponding complexes containing bidentate ligands have been prepared. The first complex $[RhH(diphos)_2]$ may be prepared by the displacement of neutral ligands from $[RhH(PPh_3)_4]$ (equation 72),[200] or by allowing the chloride salt to react with $[BH_4]^-$ (equation 73). This reaction is reversed when the hydrido complex is dissolved in carbon tetrachloride. The deuterio complex can be prepared similarly from $Li[AlD_4]$. The hydrido complex eliminates hydrogen when allowed to react with $HClO_4$ (equation 74).[214]

$$[RhH(PPh_3)_4] + 2diphos \longrightarrow [RhH(diphos)_2] + 4PPh_3 \quad (72)$$

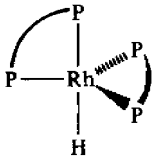
$$[Rh(diphos)_2]Cl \underset{CCl_4}{\overset{NaBH_4,\ N_2,\ EtOH}{\rightleftharpoons}} [RhH(diphos)_2] \quad (73)$$

$$[RhH(diphos)_2] + HClO_4 \longrightarrow [Rh(diphos)_2]ClO_4 + H_2 \quad (74)$$

The hydrido complex is formed as an intermediate in the electrochemical reduction of [Rh(diphos)$_2$]Cl,[42] but is itself oxidized in the system (equation 75).[215]

$$[Rh(diphos)_2]Cl \xrightarrow[MeCN]{e^-} [Rh(diphos)_2]^0 \xrightarrow{MeCN} [RhH(diphos)_2] \xrightarrow{-e^-} [RhH(diphos)_2]^+ \xrightarrow{-H_2} [Rh(diphos)_2]^+ \quad (75)$$

The light orange hydrido complex melts with decomposition at 280°C. Since the hydrido ligand is coordinated to rhodium (ν_{Rh-H} 1902 cm^{-1}, ν_{Rh-D} 1465 cm^{-1}), the complex is coordinatively saturated and exhibits poor catalytic properties.



The second complex of this type has been prepared directly from hydrated rhodium trichloride (equation 76).[216] Later work has shown that the addition of formaldehyde is superfluous.[217] An alternative preparation uses $[BH_4]^-$ as the reducing agent (equation 77).[218]

$$RhCl_3 \cdot 3H_2O + (+)\text{-diop} \xrightarrow[HCHO_{(aq)}]{KOH/EtOH} [RhH\{(+)\text{-diop}\}_2] \quad (76)$$

$$RhCl_3 \cdot 3H_2O + (+)\text{-diop} \xrightarrow{NaBH_4} [RhH\{(+)\text{-diop}\}_2] \quad (77)$$

The yellow complex decomposes at 210°C. Upon recrystallization from dichloromethane the monosolvate is formed which melts at 185°C. In solution the complex exhibits fluxional behavior. The high field ^{1}H NMR spectrum shows the hydride resonance to be composed of a quintet of doublets centered at $\tau \approx 28.4$. In benzene solution $[\alpha]_D^{25} = -3.4°$.[218]

In the solid state $\nu_{Rh-H} = 2040\,cm^{-1}$.[218] X-Ray crystallography shows the complex to have the trigonal bipyramid structure (**25**).[219]

(25)

48.4.5 [RhL$_4$]X Complexes

48.4.5.1 Complexes containing monodentate ligands

There are comparatively few complexes of this type, which, given the populous nature of the related [Rh(LL)$_2$]X class (see Section 48.4.5.2 below), seems a little strange. However, the small bite of the bidentate ligands causes fewer steric problems than the accommodation of four large, monodentate ligands around the central rhodium atom. As a consequence, isolable complexes of this stoichiometry usually contain small or medium sized neutral ligands (see Table 12).

The complexes can be prepared from other ionic rhodium(I) complexes (equation 78)[221] or, in the presence of non-coordinating anions, they can be prepared by allowing excess neutral ligand to react with other rhodium(I) complexes (equation 79).[220,222]

$$[Rh(PPh_3)_2(cod)]PF_6 + PR_3 \longrightarrow [Rh(PR_3)_4]PF_6 \quad (78)$$

R_3 = Ph_2Me, Me_2Ph, $Ph(OMe)_2$[221]

$$[RhCl(PPh_3)_3] + PHPh_2 \xrightarrow[50°C,\ MeOH]{X^-} [Rh(PHPh_2)_4]X \quad (79)$$

X = BF_4, PF_6, ClO_4[221]

In general, the complexes are stable and unreactive. Their simple ^{31}P NMR spectra are unchanged upon addition of free ligand, showing the inert nature of the complexes. Their main reactions are

oxidative addition. The complexes prepared by way of equation (78) oxidatively add molecular hydrogen, in contrast to the complexes of secondary phosphines, which are unreactive even at high hydrogen pressures.[220]

Tetrakis(trimethylphosphine)rhodium(I) is more reactive, but tends to lose a PMe_3 ligand readily (see equations 52, 53 and 56).

48.4.5.2 Complexes containing bidentate ligands

A very large number of complexes of this stoichiometry have been prepared. Isolable complexes are listed in Table 13. Like the analogs containing monodentate ligands, the cations are somewhat inert and many of their reactions involve anion exchange.

The most accessible complex appears to be $[Rh(diphos)_2]Cl$ which can be obtained from a variety of starting materials (Scheme 10). The ligand will reduce rhodium(III) chloride or displace other ligands from many rhodium(I) complexes. Unlike tertiary monophosphines it will totally displace carbon monoxide from $[RhCl(CO)_2]_2$ (equation 80). It does, however, require excess ligand to bring about the reaction.[214,233] Less diphos forms an unstable carbonyl complex,[233] which slowly disproportionates (equation 81).[244]

$$[RhCl(CO)_2]_2 + 2\text{diphos} \longrightarrow 2[RhCl(CO)(\text{diphos})] + 2CO \quad (80)$$

$$4[RhCl(CO)(\text{diphos})] \xrightarrow{1\ \text{week}} 2[Rh(\text{diphos})_2]Cl + [RhCl(CO)_2]_2 \quad (81)$$

The other complexes are prepared similarly by utilizing the power of the bidentate ligands to displace (equations 82 and 83) monodentate ligands from rhodium's coordination sphere.

$$[RhCl(cod)]_2 + 4LL \longrightarrow 2[Rh(LL)_2]Cl + 2cod \quad (82)$$

LL = $PhMePCH_2CH_2PPhMe$, *cis*-$(Ph_2P)CH{=}CH(PPh_2)$, diars, *cis*-$(Ph_2As)CH{=}CH(AsPh_2)$[226]

$$[RhCl(C_8H_{14})_2]_2 + 4LL \longrightarrow 2[Rh(LL)_2]Cl + 4C_8H_{14} \quad (83)$$

LL = $(Ph_2P)_2CH_2$, $(Ph_2P)CH_2CH_2CH_2(PPh_2)$, $(Ph_2P)(CH_2)_4(PPh_2)$, (+)-diop[224]

Other ionic complexes which have a non-complexing anion can be prepared from chloro complexes and an inorganic salt of the anion (equations 84 and 85).

$$[RhCl(cod)]_2 + 4LL + 2MX \longrightarrow 2[Rh(LL)_2]X + 2cod + 2MCl \quad (84)$$

MX = $NaBPh_4$, LL = $(Ph_2P)_2NCH_2CO_2Me$, $(Ph_2P)_2NCHPr^iCO_2Me$,[236] $Ph_2PCH_2CH_2SEt$,[242]

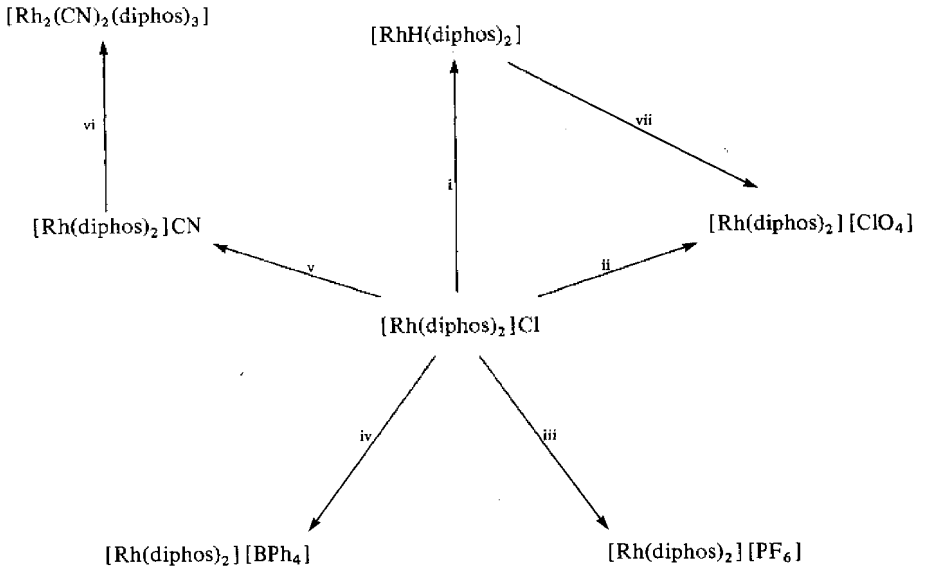
Although $(Bu^tCH_2)_2P(CH_2)_2P(CH_2Bu^t)_2$ forms a typical $[Rh(LL)_2]^+$ complex when allowed to react with $[RhCl(cod)]_2$ and NH_4PF_6 (equation 84),[234] the closely related ditertiary phosphine $Bu^t_2P(CH_2)_3PBu^t_2$ forms complexes which contain hydrido ligands or the diphosphine bound additionally to rhodium through carbon.[248,249]

Apart from anion exchange reactions the complexes are inert. One of the few reagents to bring about a change in the coordination sphere is sulfur dioxide which coordinates to rhodium without displacement of a bidentate ligand. However, the product is not well characterized and the crystals contain clathrated sulfur dioxide.[250]



If $[Rh(diphos)_2]Cl$ is allowed to react with an anion exchange resin in the cyanide form, the corresponding cyanide complex (ν_{C-N} 2089 cm^{-1}) is formed. Upon dissolution of the product in benzene a diphos ligand is lost and $[Rh_2(CN)_2(diphos)_3]$ is formed.[119] The dinuclear product probably contains a bridging diphos ligand (*cf.* $[Cu_2(N_3)_2(diphos)_3]$[251]). These reactions and the anion exchange reactions of $[Rh(diphos)_2]Cl$ are shown in Scheme 10a.

By way of contrast, the unsaturated ditertiary phosphine complex $[Rh\{cis\text{-}(Ph_2P)CH{=}CH(PPh_2)\}_2]ClO_4$ forms a five-coordinate cyano complex (ν_{C-N} 2070 cm^{-1}) when allowed to react with an anion exchange resin.[252]

The structure of $[Rh(diphos)_2]ClO_4$ has been determined. X-Ray crystallography showed the RhP_4 core to be planar, but the aliphatic carbon atoms of the ligands do not lie in this plane.[253]

The electronic spectra of several of the complexes have been studied and attempts have been made to correlate the absorption bands with the energy levels of proposed molecular orbital diagrams.[254,255] An Rh–P coupling constant of 133 Hz has been observed in the ^{31}P NMR spectrum of $[Rh(diphos)_2]^+$.[256]

Many complexes of this type (*e.g.* $[Rh\{(HOCH_2)CH(PPh_2)CH_2PPh_2\}_2][BF_4]$[257]) have been prepared *in situ* and used as homogeneous catalytic hydrogenation catalysts, but have never been fully characterized.

Scheme 10(a) Reactions of $[Rh(diphos)_2]Cl$

48.4.6 $[RhL_5]X$ Complexes

In this type of complex rhodium(I) achieves its maximum coordination number with neutral ligands. As might be expected, very few complexes of this type are known. The isolable examples are unstable and easily lose neutral ligands. The complexes so far isolated contain five trialkyl phosphite ligands. These ligands have high π-acidity but are poor σ-donors. All six $[Rh\{P(OR)_3\}_5]X$ complexes are white. They ionize in acetone solution. Their physical properties are shown in Table 14.

The salts have been prepared by adding excess trialkyl phosphite to $[RhCl(cod)]_2$ in the presence of an inorganic salt of a non-complexing anion (equation 90).

$$[RhCl(cod)]_2 + \text{excess } P(OR)_3 + 2MX \longrightarrow 2[Rh\{P(OR)_3\}_5]X + 2cod + 2MCl \quad (90)$$

$$R = Me, Et, Bu^i, Bu^n, MX = NaBPh_4; R = Me, MX = NH_4PF_6; P(OR)_3 = P(OCH_2)_3CMe, MX = NaBPh_4$$[222]

The ^1H NMR spectra of the complexes show the ligands to be labile. There is the further possibility that the cation is fluxional, having trigonal bipyramid and square pyramid configurations as limiting forms.

The ligands can be displaced by alkenes, and the trimethyl and triethyl phosphite complexes lose three ligands from the cation to yield η^6-tetraphenylborato complexes. In the case of the $P(OMe)_3$ complex the reaction can be reversed by adding excess $P(OMe)_3$ (equations 91a and 91b).[222]

48.5 RHODIUM(II) COMPLEXES

Despite the vast number of cobalt(II) complexes known, the dipositive oxidation state is rare for rhodium. The bulk of the rhodium(II) complexes known are dimeric, the classic examples being the diamagnetic carboxylato complexes that adopt the classic lantern structure (**26**). However, even the aqua complex is dimeric so the bridging carboxylato ligands are not essential for the formation of the rhodium–rhodium bond.

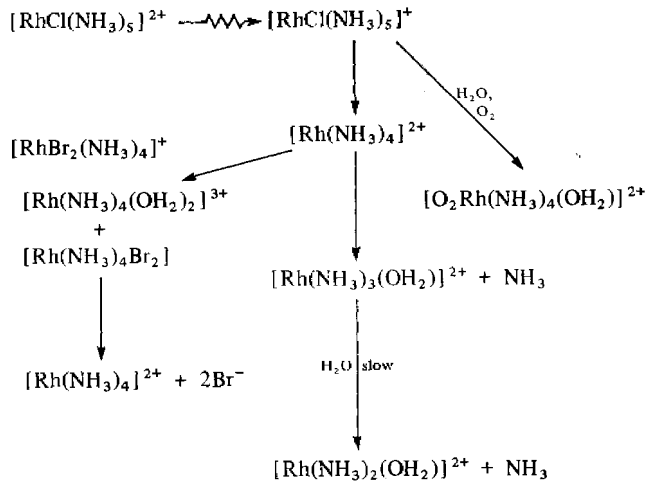
(26)

Rhodium(II) complexes with tertiary arsines were erroneously reported over 40 years ago. These complexes were, with the advent of NMR spectrometry, later proved to be hydridorhodium(III) complexes. Nevertheless, the only stable isolable monomeric rhodium(II) complexes are those containing tertiary phosphine and other similar group VB ligands.

A further difference between rhodium(II) and cobalt(II) complexes becomes apparent from a study of the monomeric complexes. Whereas virtually all cobalt(II) complexes are high spin d^7 species, with the exception of $[Co(CN)_5]^{3-}$ and related species, the rhodium(II) complexes are all low spin complexes. Thus, because of the lack of spin reorientation required in forming a low spin rhodium(III) complex, they are excellent reducing agents. The stability of the rhodium–rhodium bond in the dimers prevents their facile oxidation.

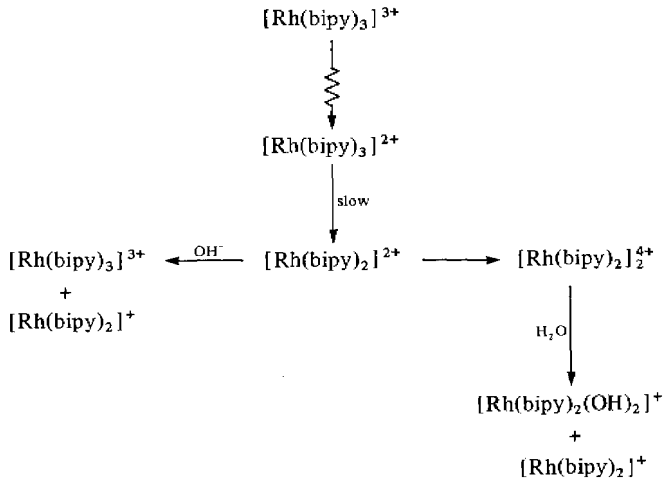
Because of the great differences in behavior between the few monomeric complexes and the dimeric complexes, this section is divided principally into two parts.

48.5.1 Monomeric Complexes



Few monomeric rhodium(II) complexes, other than those stabilized by group VB ligands, have anything but a transient existence. Whilst the former can be prepared by reduction of rhodium(III) salts with the group VB ligand, the latter are generated by photolytic or radiolytic methods. The short lifetimes of these species have occasionally been extended by trapping them within a crystal lattice.

It has been demonstrated that $RhBr_3$-doped AgBr crystals give rise to Rh^{2+} centers upon exposure to light. These rhodium(II) centers become more stable with decreasing temperatures and at 35 K it was shown that the low spin Rh^{II} center was in a D_{4h} environment.[258] However, it was believed that the D_{4h} symmetry observed for photolytically generated Rh^{2+} centers in LiH or LiD lattices was an artifact of site symmetry.[259] It is reasonable to assume less than ideal geometry for a $t_{2g}^6 e_g^1$ ion since Jahn–Teller effects will be prominent for such an electronic configuration and a static Jahn–Teller effect has been observed for Rh^{2+} in a CaO matrix at 4.2 K.[260]



Gamma irradiation of Rh^{3+}-doped NH_4Cl crystals again gives rise to Rh^{2+} centers of D_{4h} symmetry. In this system further reduction to Rh^0 was also observed.[261] Pulse radiolysis has proved to be a powerful tool for the investigation of the behavior of rhodium(II) species in aqueous solution. Various reducing agents in the system can bring about the reduction of rhodium(III) complexes besides the ubiquitous solvated electron.[262]

Both $[RhCl(NH_3)_5]^+$ generated from $[RhCl(NH_3)_5]^{2+}$, and $[Rh(bipy)_3]^{2+}$ generated from $[Rh(bipy)_3]^{3+}$, have been studied. The former (Scheme 11) shows that Jahn–Teller effects persist in the solution chemistry of rhodium(II).[263] The principal reactions of the latter (Scheme 12) involve disproportionation to Rh^I and Rh^{III}.[262,264]

The complexes described in this section contain either (i) tertiary phosphines or stibines in

Scheme 11 Generation and reactions of $[RhCl(NH_3)_5]^+$

Scheme 12 Generation and reactions of $[Rh(bipy)_3]^{2+}$

conjunction with halo ligands, or (ii) bidentate tertiary monophosphine ligands. They are clearly different in nature from the $[Rh_2(O_2CR)_4(ZX_3)_2]$ (Z = P, As, Sb) complexes, which are best regarded as derivatives of carboxylatorhodium(II) complexes (Table 14a).

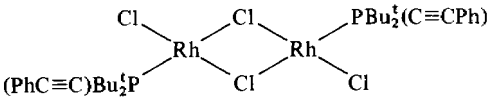
[a] R = $—CH_2(2\text{-}Me\text{-}5\text{-}OMeC_6H_3)$. [b] With decomposition.

48.5.1.1 *Tertiary phosphine complexes*

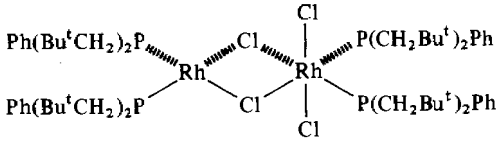
Many large tertiary phosphines fail to reduce hydrated rhodium trichloride and form rhodium(I) complexes. Under mild conditions they usually reduce the salt to paramagnetic rhodium(II) complexes. This was first discovered when $P(o\text{-}C_6H_4Me)_3$ was employed, as in equation (92).[265]



$$RhCl_3 \cdot 3H_2O + P(o\text{-}C_6H_4Me)_3 \xrightarrow[EtOH]{0°C} RhCl_2\{P(o\text{-}C_6H_4Me)_3\}_2 \quad (92)$$

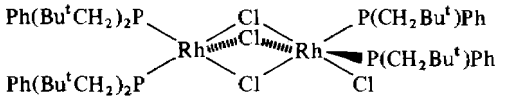
The blue-green complex is paramagnetic ($\mu = 2.3$ BM) and has a single band due to $\nu_{Rh\text{-}Cl}$ in its far IR spectrum. Accordingly it has been assigned the *trans* configuration. If the preparative reaction is carried out at 0°C, or if CH_2Cl_2 solutions of the blue-green complex are evaporated *in vacuo*, purple crystals of a less stable and less well characterized isomer are obtained. The purple isomer is also paramagnetic (see Table 14b for magnetic and IR spectral data).

If these preparations are carried out at high temperatures, or if either of the above complexes is heated, *o*-metallation occurs. No reduction to rhodium(I) complexes was observed [265,266] It has been claimed that the attempted borohydride reduction of the dichloro complex in ethanol forms the unstable diamagnetic rhodium(II) complex $[RhH(BH_4)\{P(o\text{-}C_6H_4Me)_3\}]$.[212]



The large steric requirements of the tricyclohexylphosphine ligand are presumably responsible for the isolation of $[RhX_2(PCy_3)_2]$ (X = Cl, Br) complexes under mild conditions. Both the red-brown chloro complex and the green bromo complex are paramagnetic.[267]

The ligands PBu^t_2R (R = Me, Et, Pr) also yield *trans*-rhodium(II) complexes when allowed to react with ethanolic solutions of $RhCl_3 \cdot 3H_2O$. If the reaction is carried out above 25°C *o*-metallation does not occur, instead $[RhHCl_2(PBu^t_2R)_2]$ complexes are formed.[268,269] The closely related alkynylphosphine ligand $PBu^t_2(C{\equiv}CPh)$ also forms a hydridorhodium(III) complex when allowed to react with hydrated rhodium trichloride. Upon dissolution in chloroform, however, the red rhodium(III) hydrido complex decomposes and forms the orange binuclear rhodium(II) complex (**27**).[270]



(27)

Tri(neopentyl)phosphine and phenyldi(neopentyl)phosphine also form complexes of this stoichiometry. However, these complexes are apparently diamagnetic. In their ^{1}H NMR spectra the resonances of the *t*-butyl groups are well defined. Accordingly they have been formulated as mixed Rh^I/Rh^{III} complexes. They may adopt either structure (**28**) or (**29**).[271]

(28)

(29)

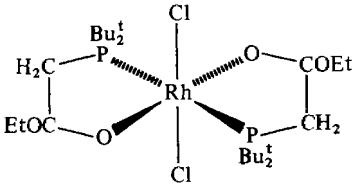
Emerald green crystals of *trans*-$[RhCl_2(PR_3)_2]$ can be obtained from the tertiary phosphine and hydrated rhodium trichloride at room temperature. The NMR spectrum is degraded and multiple peaks from ν_{Rh-Cl} in the far IR spectrum suggest that the product is a *trans* rhodium(II) complex.[272]



The closely related ligand, $PBu^t_2(o\text{-}C_6H_4OMe)$, also forms a paramagnetic rhodium(II) complex. However, in the reaction the ligand is demethylated, and the product has a totally different structure to the halo complexes so far described in this section.[273]

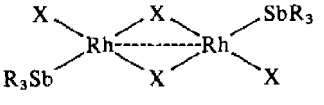
A similar reaction takes place between $RhCl_3 \cdot 3H_2O$ and the keto phosphine $PBu^t_2(CH_2COPh)$, except that a rhodium(III) complex is first formed containing the phosphaenolate. In the presence of sodium methoxide this rhodium(III) complex is reduced to the paramagnetic rhodium(II) species (**30**).[274]

The carbethoxy tertiary phosphine $Bu^t_2P(CH_2)_nCO_2Et$ ($n = 1$) forms an octahedral, cationic rhodium(III) complex (**31**), in which the carbonyl group coordinates to rhodium. Homologous ligands ($n = 2$, 3) from four-coordinate rhodium(II) complexes in which the ligands are only phosphorus bound.[275]

(30)

(31)

Although hydrated rhodium(II) propionate merely has its axial aqua ligands replaced when it is allowed to react with PPh_3, both the formate and acetate form orange mononuclear complexes under mild conditions.[276]



If diphos is allowed to react with the η^3-2-methallyl complex $[RhCl_2(\eta^3\text{-}C_3H_4Me)]$ in the presence of hydrogen the gray-green complex $[RhCl_2(diphos)]$ is formed.[277]

48.5.1.2 Tertiary arsine complexes

There are no tertiary arsine complexes of rhodium(II). Early reports of such complexes are erroneous.[5,6] The complexes have been shown to be hydridorhodium(III) species.

48.5.1.3 Tertiary stibine complexes

Rhodium(III) halides form $[RhX_2\{Sb(o\text{-}C_6H_4Me)_3\}]$ complexes when allowed to react with tri(*o*-tolyl)stibine. Despite their stoichiometry and diamagnetism there is no evidence for their being either *o*-metallated or hydridorhodium(III) complexes. It is believed they have the planar dimeric structure (**32**). Intramolecular interactions in such dimers could account for their diamagnetism and the non-equivalence of the methyl protons in their ^1H NMR spectrum.[278]

(32)

48.5.2 Dimeric Complexes

In 1960, Chernayev and co-workers reported that refluxing $[RhCl_6]^{3-}$ in aqueous formic acid leads to a stable, dark green compound.[279] Despite its initial formulation as a Rh^I formate, a formulation quickly retracted[280] when an X-ray study of the acetate analog showed it to be dimeric,[281] this dark green material is generally acknowledged to be the first well-characterized complex containing the Rh_2^{4+} moiety. Since then, interest in the structures, the metal–metal and metal–ligand bonding, and the reactions (*e.g.* substitutions, electrochemistry, chemotherapy, catalytic properties) of these complex has caused an explosion of research activity. These complexes

contain what is now generally recognized as a Rh—Rh single bond, and most, but not all, contain four ligands which span the Rh—Rh bond. They will be considered according to the type of bridging ligands, followed by brief discussions of the bonding and reactions of these complexes. Numerous excellent reviews have appeared recently and while overlap is unavoidable, the discussion here concentrates on work presented since their appearance.[282–286]

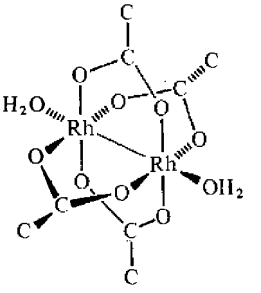
48.5.2.1 Synthesis and structure

(*i*) *Oxo-bridged dimers*

The prototypical Rh^{II} dimer is $[Rh_2(O_2CMe)_4]$ and is readily prepared by refluxing $RhCl_3 \cdot 3H_2O$ and $(Na^+/H^+)O_2CMe$ in ethanol, a mildly reducing solvent (equation 93).[287,288] Recrystallization of the dark green precipitate from methanol gives the dimethanol adduct, $[Rh_2(O_2CMe)_4(MeOH)_2]$, which forms the parent $[Rh_2(O_2CMe)_4]$ when heated to 100°C for 30 min. Yields as high as 85% (based on initial $RhCl_3$) have been reported.[289]

$$RhCl_3 \cdot 3H_2O + (Na^+/H^+)(O_2CMe^-) \xrightarrow{EtOH} [Rh_2(O_2CMe)_4] \quad (93)$$

The dimeric Rh^{II} acetates, readily soluble in a wide variety of solvents, are air-stable Lewis acids which readily form 1:1 and 1:2 adducts with many Lewis bases. They generally display two visible absorption bands at ~600 and ~450 nm. The 450 nm band is reasonably unaffected by adduct formation, while the position and intensity of the low energy band is extremely sensitive to the number and nature of the axially bonded ligands; two other characteristic transitions in the UV region near 250 and 220 nm are also axial-ligand dependent.[290,291] (Spectral assignments are discussed in Section 48.5.2.2.) The thermal stability of $[Rh_2(O_2CMe)_4L_2]$ is dependent on the nature of the adduct L, and on the nature of the carboxylate bridges.[292–294]



Much of our current understanding of $[Rh_2(O_2CMe)_4L_2]$ complexes comes from numerous single crystal X-ray structures. Table 15 lists, in order of increasing Rh—Rh bond length, the Rh—Rh and average Rh—L bond lengths for the tetraacetate complexes whose X-ray structures have been reported. The Rh—Rh bond is short and remarkably invariant within this series, with less than 0.08 Å difference between the longest and shortest examples. The structure of the dihydrate (**33**)[297] is representative of the structure of all of these tetracarboxylato species. The $[Rh_2(O_2CMe)_4]$ core has approximately D_{4h} symmetry, with the Lewis base adducts H_2O in (**33**) coordinated to the sites *trans* to the Rh—Rh bond. There is little evidence of strain, as the average bond angles (*e.g.*

Rh—Rh—O_{eq}, 88.07°; Rh—O—C, 119.50°; Rh—Rh—O_{ax}, 176.03°) suggest a comfortable fit of the acetates around the Rh_2^{4+} moiety.[297] The softness of the Rh^{II} center is apparent, as both DMSO and PhN(H)C(OMe)S are sulfur bonded, and the nitrite ion is bonded through the nitrogen atom (Table 15). The binding to the axial sites is relatively weak, and long Rh—L bond lengths are a general feature of these tetracarboxylate dimers; for example, in $[Rh_2(O_2CMe)_4(H_2O)_2]$, the Rh—OH_2 axial bonds are 0.27 Å longer than the Rh—O_{eq} bonds from the acetate bridges.

(33)

The readily prepared $[Rh_2(O_2CMe)_4]$ is the starting point for the synthesis of many other oxo-bridged Rh^{II} dimers. While the mechanisms of these reactions are not known, a carboxylate exchange must occur, as heating $[Rh_2(O_2CMe)_4]$ in an excess of the desired carboxylate, usually in the protonated form, generally leads to virtually quantitative conversion to the substituted carboxylate (equation 94). Substituted carboxylate dimers have also been prepared by refluxing ethanolic solutions of $RhCl_3 \cdot 3H_2O$ with the desired carboxylate, analogous to equation (93). As shown in Table 16, X-ray studies have shown that there is still little variety in the Rh—Rh bond length, and excluding the phosphate-bridged species, the difference between the shortest and longest Rh—Rh bond in this series is only 0.031 Å.

$$[Rh_2(O_2CMe)_4] + 4HO_2CR \longrightarrow [Rh_2(O_2CR)_4] + 4HO_2CMe \quad (94)$$

While X-ray structures have not been reported, numerous $[Rh_2(Q)_4L_2]$ complexes have been reported with a variety of bridging ligands.[282,283,286] Recent examples include complexes where Q is the conjugate base of glutaric acid $[^-O_2C(CH_2)_3COOH]$, α-propionic acid,[318] or mandelic acid (with L = H_2O, NH_3, N_2H_4, thiourea, DMSO, $PhNH_2$);[319] the CD spectrum of the tetramandelate $[Rh_2(L\text{-}(+)\text{-}O_2CC(OH)HPh)_4(H_2O)_2]$ has been reported.[320] Reaction of $RhCl_3 \cdot 3H_2O$ with ethanolic solutions of sodium cinnamate (*trans*-PhCH=CHCOO$^-$ Na^+) leads to $[Rh_2(\text{cinnamate})_4]$, which forms 1:2 adducts with DMF, MeCN and pyridine when dissolved in these solvents.[321]

Cotton recently reported the single crystal X-ray structures of two $[Rh_2(O_2CR)_4L_2]$ complexes, where R is a bulky hydrocarbon (R = 1-adamantane or 2-(PhC_6H_4).[308] The structures show little

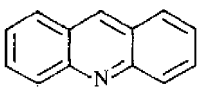
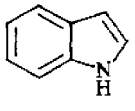
[a] See (35). [b] 2-BPC = 2-biphenylcarboxylate.

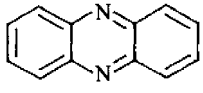


evidence of steric crowding, as the bulky groups are far from each other at the tips of the bridges. When R = CPh_3, a mixed bridged species $[Rh_2(O_2CMe)_2\{O_2CCPh_3\}_2(MeCN)_2]$ forms (see Section 48.5.2.1.iii).

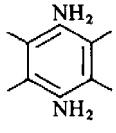
The salicylate ion (sal = o-$O_2CC_6H_4OH^-$) forms, *via* a bridge-exchange with $[Rh_2(O_2CMe)_4]$, complexes of the form $[Rh_2(sal)_4L_2]$ (L = NH_3, py, aniline, en, urea, $MeC(S)NH_2$ and N_2H_4).[322] Reaction of salicylate with $RhCl_3 \cdot 3H_2O$ in aqueous EtOH, followed by recrystallization of the solid product from absolute ethanol, leads to the interesting diadduct species $[Rh_2(sal)_4(C_2H_5OH)(H_2O)]$, which has been characterized by a structural study.[314] Bonding to the Rh_2 core is through the carboxyl oxygens, the phenyl rings are coplanar with the Rh—Rh bond, and three of the salicylate hydroxyl groups face toward one end of the dimer. This 3,1 geometry is presumed to be sterically determined, as the ethanol is bonded to the Rh at the end of the complex with the three hydroxyl groups, while the water is coordinated at the more open end; there is evidence of hydrogen bonding between the phenyl hydroxides and the bridging carboxyl oxygens as in (**34**).[312]



(34)

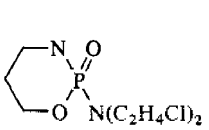


Steric crowding is more evident when bulky ligands occupy the axial sites. Cotton has presented[312] the single crystal X-ray structures of $[Rh(O_2CEt)_4(L)_n]$ (**35**; L = acridine (ACR), 7-azadine (AZA), phenazine (PHZ), or 2,3,5,6-tetramethyl-*p*-phenylenediamine (DDA); n = 1 or 2). For L = ACR or AZA (monobasic ligands), n = 2 and the normal coordination geometry occurs, consisting of discrete dimeric units with an ACR or an AZA bonded to each end of the Rh_2 core. In contrast, the dibasic ligands (L = PHZ or DDA) serve as bridges between Rh_2 units, and complexes of the stoichiometry [Rh(prop)$_4$L] are formed. For L = PHZ, almost linear chains occur (the Rh—Rh—N angle is *ca.* 174°), while the approximately tetrahedral amine of the DDA results in zigzag chains of —[Rh—Rh]—DDA—[Rh—Rh]—DDA—[Rh—Rh]—.[312]

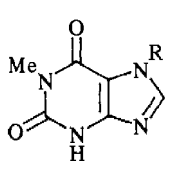


ACR = acridine

AZA = 7-azaindole

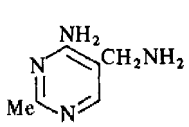


PHZ = phenazine

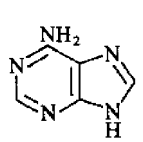


DDA = 2,3,5,6-tetramethyl-*p*-phenylenediamine

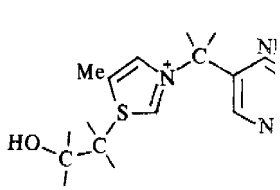
(35)



Interest in the antitumor properties of $[Rh_2(O_2CMe)_4]$ has led to studies of adduct formation with bases of biological importance. Cyclophosphamide (**36a**) does not generally coordinate with metal systems, but adducts of the form $[Rh_2(O_2CR)_4L_2]$ (R = Me, Et, Pr; L = cyclophosphamide) have been reported[323] although the nature of the phosphamide—Rh bond is not clear. Single crystal X-ray structures of $[Rh_2(O_2CMe)_4L_2]$ (L = theophylline, caffeine; **36b**) show they have the normal Rh^{II} dimeric structure.[298] The surprising feature of the theophylline complex is that bonding to the theophylline is through N(9), rather than the N(7) generally observed for other theophylline–metal complexes. It is suggested that the repulsion between the carbonyl oxygen at C(6) and the bridging carboxyls of $[Rh_2(O_2CMe)_4]$ hinders axial coordination at the N(7) site. Coordination through N(9) is also observed for the caffeine complex, where the methyl group prevents coordination at N(7).[298] Coordination at N(9) and at C(8) are observed in Cu^{II}–caffeine complexes,[324,325] and C(8) coordination is observed in the $[Ru^{III}(caffeine)(NH_3)_3Cl_2]^+$ ion.[326]

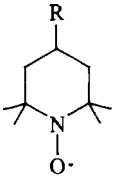


(36a) cyclophosphamide

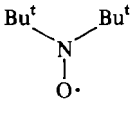


(36b) theophylline, R = H
caffeine, R = Me

(36c) AAMP



(36d) adenine



(36e) thiamine

Aoki has shown that AAMP (4-amino-5-aminomethyl-2-methylpyrimidine; **36c**) reacts with $[Rh_2(O_2CMe)_4]$ to form the 1:1 adduct $[Rh_2(O_2CMe)_4(AAMP)]\cdot 3.5\,H_2O$, a one-dimensional polymer reminiscent of the DDA complexes.[304] Coordination to the Rh_2 units is through the N(1) and the amino group from N(5), and does not involve the basic N(3) site. The bonding is end to end, with two amine nitrogens [from N(5)] bonded at each end of the same Rh_2 unit, and two pyrimidine N(1) atoms bonded at either end of the next unit; this can be represented as: $--N^1)$—[Rh—Rh]—$(N^1—N^5)$—[Rh—Rh]—$(N^5—N^1)$—[Rh—Rh]—$(N^1--$. Lack of binding by N(3) is attributed to steric crowding induced by the carboxylate oxygens, and suggests why $[Rh_2(O_2CMe)_4]$ does not react with polycytidlic acid bases, where the N(3) ring nitrogen is flanked by bulky carbonyl and amino groups; it also led Aoki to suggest that $[Rh_2(O_2CMe)_4]$ could develop into a useful probe for estimating the adenine (**36d**) containing regions of nuclei acids, as it should bind adenine much more strongly than the other nucleic acid bases. Aoki also reports the preparation of $[Rh_2(O_2CMe)_4(thiamine)(H_2O)]Y$ (**36e**; $Y = NO_3^-$, PF_6^-, BF_4^-, ClO_4^-); the electronic spectrum of this cation suggests the thiamine is N bonded to the Rh, with N(1) favored over N(3) for the same steric reason.[304]

Use of fluorinated carboxylates as bridges between Rh^{II} centers began with a report from Drago's group of the ESR spectrum of the 1:1 adduct of $[Rh_2(O_2CCF_3)_4]$ and 2,2,6,6-tetramethylpiperidine *N*-oxide (Tempol; **37a**).[327] Not surprisingly, the electron-withdrawing bridges enhance the Lewis acidity of the Rh centers. Numerous perfluorinated carboxylate dimers have been structurally characterized (Table 17), and while the variation in Rh—Rh bond lengths is a bit longer than that observed for the unfluorinated carboxylates, the total range is still small (0.086 Å). The increased acidity of the Rh centers is evident, as such weak bases as dimethyl sulfone (the first example of a structurally confined sulfone complex)[328] and nitroxide radicals (**37b**)[330,332] form structurally characterized adducts. Unless the axial ligands are similar, it is inappropriate to compare the structures of fluorinated and unfluorinated carboxylate-bridged complexes, but for the H_2O and alcohol adducts, the complexes with the electron-withdrawing bridges have marginally longer Rh—Rh, and shorter Rh—O_{ax} bonds.

(**37a**) Tempo, R = H
Tempol, R = OH

(**37b**) t-butyl nitroxide

The electron-withdrawing fluorides also seem to harden the Rh centers. For the soft phosphine and phosphate adducts, fluorinated bridges have the opposite effect on the Rh—L_{ax} bond lengths, as the Rh—P bonds are longer with the fluorinated bridges than with the electron-donating hydrocarbon substituents. More dramatic evidence of the effect of the electronegative bridges comes from studies of the potentially ambidentate DMSO adducts. Numerous DMSO adducts of unfluorinated tetracarboxylates have been reported[290,291,293,305,313,314,334–337] and the electronic and IR spectra of these orange complexes suggest sulfur coordination. In contrast, the DMSO adduct of $[Rh_2(O_2CCF_3)_4]$ is blue. Structural studies of $[Rh_2(O_2CR)_4(DMSO)_2]$ (R = Me, Et, CF_3) have confirmed the ambidentate nature of DMSO, as it is S-bonded in the unfluorinated complexes,[305,313] but is O-bonded when R = CF_3.[313] An interesting 'structural isotope effect' is observed in the

structures of $[Rh_2(O_2CCF_3)_4(L)_2]$ (L = Me_2SO or $(CD_3)_2SO$), as these complexes crystallize in different space groups, and the deuterated adduct has a surprisingly shorter Rh—Rh bond (0.012 Å). Such large packing modifications upon substitution of D for H are unusual, and may reflect the effect of the smaller size of the CD_3 group.[331]

Other sulfur-bonding adducts of the Rh_2^{4+} core have been reported for thiols,[338] thioethers,[305,335] alkyl sulfides,[291,293,336] thiourea derivatives,[339–341] and benzothiadiazole.[342] Reaction of NCX^- (X = S, Se) with $[Rh_2(O_2CMe)_4]$ is reported to lead to the anionic 1:1 adduct $[Rh_2(O_2CMe)_4(NCX)]^-$.[343] A structure has not been reported, but based on analytical data, one-dimensional chains with bridging NCX^- anions were proposed.[343]

The nitroxyl radical adducts (Table 17) are dramatic evidence of the increased acidity of Rh centers when encased by the fluorinated bridges. Hendrickson did variable temperature magnetic studies on $[Rh_2(O_2CR)_4(Tempo)_2]$ (R = CF_3, Pr, Ph) and $[Rh_2(O_2CCF_3)_4(Tempol)_2]$.[332] For the Tempo biradicals, an 'astonishingly large antiferromagnetic exchange interaction' between the biradical centers was observed. At 342 K, the magnetic moment is 1.06 BM, but by 80 K the complexes are essentialy diamagnetic; the fact that the biradical centers are *ca.* 6.8 Å apart makes this exchange all the more unusual. (The *J* values are 2–3 orders of magnitude greater than those observed for the tetrafluorocarboxylate dimer of molybdenum.) The significance of this biradical coupling to our understanding of the bonding in Rh^{II} dimers is discussed in Section 48.5.2.2.

Dirhodiumtetracarboxylates with N-donor adducts have been reported for numerous monodentate and bidentate bases, varying in complexity from ammonia through nucleic acids and adenine nucleosides and nucleotides; Table 18 lists references for studies on such N-donating adducts. The structures of a variety of these complexes have been determined (*vide supra*), and while the range of Rh—Rh bond distances is greatest for N-donating bases, the range is still only 0.067 Å.[282] Straightforward correlations between the Rh—Rh bond length and a specific property of the axial ligands have not yet appeared.

Carbon-bonded adducts include cyanide ions[356] and isocyanides.[357] The structure of $[Rh_2(O_2CMe)_4(MeNC)_2]$ is reported to confirm the formation of an axial Rh—C bond.[299] Interest in the CO adduct has been sparked by the question of whether σ or π bonding is involved in the Rh—L_{ax} bond. A structural study shows that in $[Rh_2(O_2CMe)_4(CO)_2]$ the CO is linearly bonded through the carbon atom, and that the C—O bond is 0.03 Å *longer* than in free carbon monoxide.[352] This is difficult to understand, as several groups have reported that a small (between 39 and 60 cm^{-1}) *decrease* in the $\nu_{C\ O}$ stretching frequency occurs upon coordination to the Rh_2^{4+} moiety.[335,352,358,359] The different experimental conditions used in the spectroscopic studies may account for the different C—O stretching frequencies, but it is difficult to rationalize the apparent contradiction in the IR and structural information.

Bridging by carbonate, sulfate and dihydrogenphosphate (O_2CR, for R = O^{2-}, SO_2^{2-} or $P(OH)_2^-$) have also been observed in dirhodium(II) complexes. The first report of a carbonate-bridged species came from Chernyaev's group,[360] and Wilson and Taube later prepared $[Rh(CO_3)_4]^{4-}$ by the reaction of aqueous carbonate with the unbridged dimer $[Rh_2(H_2O)_{10}]^{4+}$ (abbreviated as $Rh_{2(aq)}^{4+}$).[289] The similarity in the electrochemical properties of the carbonate and the acetate complexes led Taube to propose a carbonate-bridged dimeric structure, which was confirmed by structural studies on the diaqua and dichloro adducts (Table 16).[315] Bicarbonate-bridged complexes (R = OH^-) have been reported,[289,361] but have not been confirmed by structural studies. Taube also noted that the mobility of $Rh_{2(aq)}^{4+}$ on a cation-exchange column was markedly increased when sulfuric acid was used

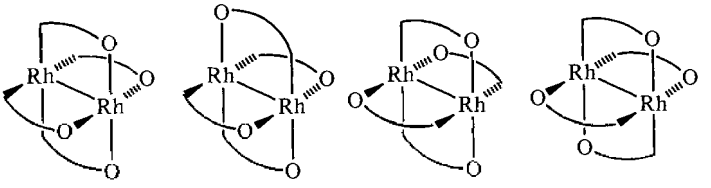
as the eluant;[364] elution of $Rh_{2(aq)}^{4+}$ with $(NH_4)_2SO_4$ led to the isolation of the presumably sulfato-bridged $(NH_4)_4[Rh_2(SO_4)_4]\cdot 4.5H_2O$. The diaqua adduct $[Rh_2(SO_4)_4(H_2O)_2]^{4-}$, isolated as the Cs^+ salt, can also be prepared by heating $[Rh_2(O_2CR)_4]$ (R = H or Me) in sulfuric acid.[363] A variety of $H_2PO_4^-$-bridged species have been reported,[319,364,365] and structural studies on $[Rh_2(H_2PO_4)_4(H_2O)_2]$ confirm the standard dioxo-bridged Rh core, but with an unusually long Rh—Rh bond.[317]



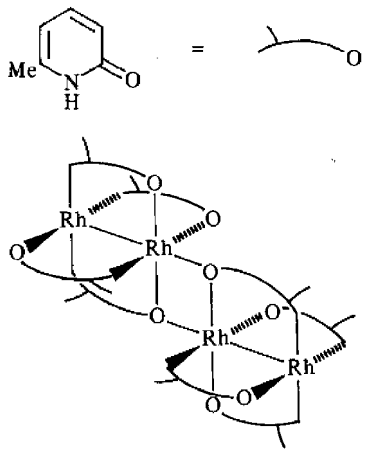
(*ii*) *Asymmetrically bridged dimers*

The dimers discussed so far have been bridged by four identical oxo ligands, with D_{4h} symmetry of the primary coordination sphere. Following work with Cr and W, a new class of Rh^{II} dimers with substituted 2-oxypyridine bridges (**38**) has been developed. These oxypyridines are prototypes for the bridging ligands with two different coordinating sites, considered in this section. This ligand asymmetry introduces the possibility of geometric isomerization in the tetrabridged dimer; as shown in (**39**), the four possible isomers can be labelled the 4,0 (C_{4v}), 3,1 (C_s), 2,2-*trans* (D_{2d}), and 2,2-*cis* (C_s) isomers. Examples of all four of these forms have now been characterized.

(**38**)

mhp = 6-methyl-2-oxypyridine, X = Me
chp = 6-chloro-2-oxypyridine, X = Cl
fhp = 6-fluoro-2-oxypyridine, X = F

4,0 3,1 2,2-*trans* 2,2-*cis*



(**39**)

Synthesis of oxypyridine-bridged dimers can be achieved by the direct reaction of $RhCl_3\cdot 3H_2O$ with the appropriate ligand in a mildly reducing solvent, as in equation (93), or by bridge exchange (equation 94), with the ubiquitous $[Rh_2(O_2CMe)_4]$ as the common starting material. Data from structural studies on a variety of asymmetrically-bridged dimers are presented in Table 19. Initial studies of $[Rh_2(Q)_4]$ (Q = mhp or chp) showed that as with the Cr adducts steric crowding of the pyridine methyl groups hinders coordination at the axial sites, and the complex adopts the 2,2-*trans* geometry.[366,367] The 1:1 adducts of imidazole, acetonitrile and Hmhp with $[Rh_2(mhp)_4]$, and the imidazole adduct of $[Rh_2(chp)_4]$ have been structurally characterized, and all adopt the 3,1 geometry.[368,369] With three methyl groups around one end of the molecule, the Lewis base is able to bond at the less-crowded end. Synthesis of $[Rh_2(mhp)_4(Hmhp)]$, by reaction of $[Rh_2(O_2CMe)_4(MeOH)_2]$ with Na(Hmhp), also generates a tetrameric complex, $[Rh_2(mhp)_4]_2\cdot 2CH_2Cl_2$. This tetramer consists of two $[Rh_2(mhp)_4]$ units, each in a 3,1 geometry, with the open ends joined by two Rh—O bonds between the Rh (at the open end of each dimer), and an oxygen from one of the bridging oxypyridines.[369] This structure is represented in (**40**). The 12.65 MHz ^{103}Rh NMR spectrum (in CD_2Cl_2/CH_2Cl_2 at ~300 K) had a single resonance at 5745 p.p.m. for $[Rh_2(mhp)_4]$, while the tetramer had a pair of doublets (split by 35 Hz) centered at 7644 and 4322 p.p.m., consistent with the presence of two sets of inequivalent Rh atoms.[373]

[a] TFA = conjugates base of trifluoroacetamide = $CF_3C(O)NH^-$.

(40)

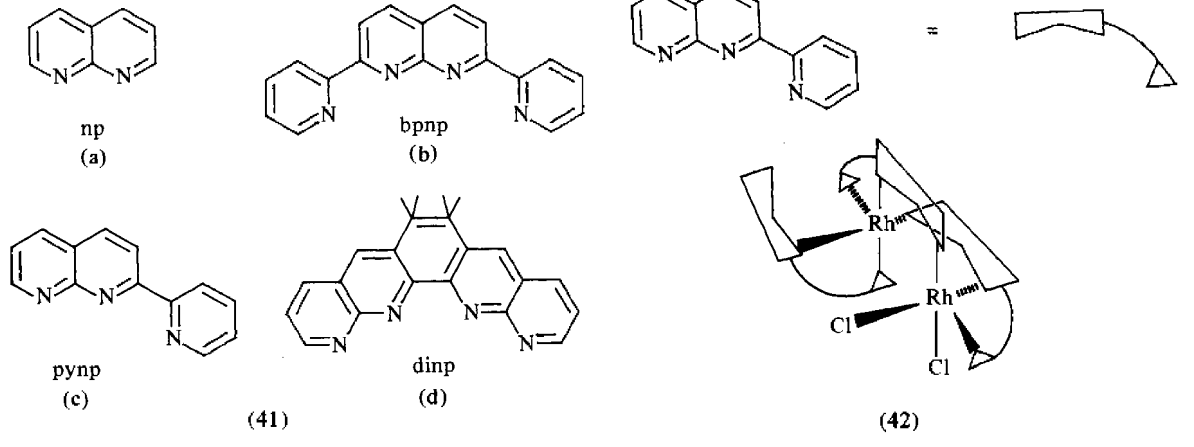
The complexity of the tetramer's structure convincingly demonstrates the power of single crystal X-ray studies as a primary analytical tool. Perhaps an even more dramatic recommendation comes from the three imidazole adducts listed in Table 19, as imidazole was not a reagent used in their syntheses. The dimers were all prepared from a solid melt of $[Rh_2(O_2CMe)_4]$ + Hmhp (or Hchp) under argon, and the resulting solids were recrystallized from various solvents. The imidazole was identified by assigning atomic scattering parameters for either N or C to the different atoms in the ring; the only configuration with reasonable thermal ellipsoids was that of imidazole. The authors do not speculate (in print) about the source of the imidazole, and invite rational suggestions as to its origin.[368]

The 4,0 geometry is observed for $[Rh_2(fhp)_4(DMSO)]$ (**38**; X = F).[371] As observed with the Cr, Mo and W analogs,[374] the four fluorine atoms form a square around one end of the Rh_2 core, with a short F—F distance of 2.925 Å. The DMSO is S-bonded, with an unusually short Rh—S bond (2.332 Å *vs.* 2.449 Å for $[Rh_2(O_2C)_4(DMSO)_2]$).

Bear and co-workers have recently presented several reports on the chemistry of $[Rh_2(tfaa)_4]$, where tfaa is $CF_3C(O)NH^-$, the conjugate base of trifluoroacetamide.[372,375,376] The tfaa bridge can be considered to be a trifluoroacetate with a coordinated oxygen replaced by an isoelectric NH group, and represents the first N—O bidentate bridges of Rh_2 not based on the oxypyridine system. Similar to the carboxylate-bridged dimers in gross structure and adduct formation the tfaa dimers display some distinctive properties. Reaction of $[Rh_2(mhp)_4]$ with Htfaa leads to a mixture of products, separable into four bands by HPLC. The approximate distribution of Rh in the four bands as 4%, 94%, 2% and < 1%; NMR analysis of the first 4% band suggests the 3,1 isomer of $[Rh_2(tfaa)_4]$. Structural studies of the bis(pyridine) adduct of the second band showed it had the 2,2-*cis* geometry with a relatively long Rh—Rh bond.[372] (This structural study was marred by an unidentified 'mysterious' diatomic molecule, which occupied ~ 15% of the axial sites.) An analogous bridge-exchange of $[Rh_2(O_2CMe)_4]$ with *N*-phenylacetamide (MeCONHPh), also leads to four HPLC separable products. NMR analysis suggests that the four products correspond to the four geometric isomers (**39**) of $[Rh_2(PhNOCMe)_4]$, with the predominant product being the 3,1 isomer.[376] Much of the work with $[Rh_2(tfaa)_4]$ and its adducts centers on its interesting electrochemical properties, which are discussed in Section 48.5.2.3.(ii).

Bridge exchanges between $[Rh_2(O_2CMe)_4]$ and 2,4-dithiouracil (dtu)[377] or thiobenzoic acid (tbz)[378] generate the diamagnetic complexes $[Rh_2(Q)_4(L)_2]$ (L = H_2O for Q = ttu; L = py, thiourea, DMSO or DMF when Q = tbz). IR analysis indicates that a dtu nitrogen is deprotonated upon coordination, and that the dtu exhibits N and S bonding to the Rh_2 core, although a specific geometry is not suggested. Reaction of $RhCl_3 \cdot 3H_2O$ with 5,5′-thiodisalicylic acid in acid (pH 1) solution is reported to give an ill-characterized, paramagnetic (μ = 2.60 BM) brown complex of stoichiometry $[Rh(C_{14}H_8O_6S) \cdot 4H_2O]$.[379]

(*iii*) *Mixed-bridge dimers*



Recently, Rh^{II} dimers with more than one type of bridging ligand in the same complex have been characterized; these will be considered along with a few complexes with less than four bridging

ligands. Reaction of the Rh^{I} dimer $[Rh_2Cl_2(\mu\text{-}CO)(DPM)_2]$ (DPM = bis(diphenylarsino)methane = $Ph_2AsCH_2AsPh_2$) with HA ($A^- = Cl^-$, SO_3Ph^-, Me^-, BF_4^-) does not cause the expected oxidative addition, but leads to $[Rh_2Cl_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2(A)]$.[380] The single crystal X-ray structure of the HCl adduct, $[Rh_2Cl_3(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]$ shows it to have two mutually *trans* bridging DPM ligands; the mutually *trans* H and the CO also serve as bridges, and the IR bands (ν_{CO} between 1748 and 1818 cm^{-1} and ν_{Rh-H} between 1230 and 1267 cm^{-1}) suggest that all of these complexes have structures similar to the trichloro complex. The Rh—Rh distance (2.7464 Å) is long, but still within the bonding range. This complex is unique among Rh^{II} dimers in several ways, as it has three different bridging ligands, and has three axial ligands (Cl^-), two at one end and the third at the other end of the dimer.[380] Oxidative addition across the Rh^{I}—Rh^{I} core (a transannular oxidative addition) does occur when I_2 reacts with $[Rh^{I}_2(CO)_2Cl_2(DPM)_2]$, generating the (DPM)-bridged Rh^{II} dimer, $[Rh(CO)_2Cl_2I_2(DPM)_2]$.[381] Similar reactions have led to the diamagnetic dimers, $[Rh_2(CNR)_4(X_2)(DPM)_2]$ (X = I, Br),[382] and $[Rh_2(CNR)_4(Ph_2AsCH_2AsPh_2)I_2]$, and $[Rh(CNR)_4(DPM)_2(SCF_3)_2]$.[383]

Mixed-bridge complexes based on a bridging carboxylate frame have been obtained from the products of the bridge exchange between $[Rh_2(O_2CMe)_4]$ and Hmhp.[368] Five different complexes apparently crystallized from this single brew (*vide supra*), and two of them were $[Rh_2(O_2CMe)_2(mhp)_2(im)]$ and $[Rh_2(O_2CMe)_2(mhp)_2(im)]\cdot 2CH_2Cl_2$. Both complexes exhibit mutually *trans* acetates and oxypyridines, with both pyridine-methyl groups pointing toward the same end of the dimer; the imidazole is coordinated to the other, more open, end. As with the $[Rh_2(mhp)_4(im)]$ (*vide supra*) the source of the imidazole is unknown.[368] All five members of the series $[Rh_2(O_2CMe)_n(NH(O)CMe)_{4-n}]$ ($n = 0, 1, 2, 3, 4$) have been prepared *via* bridge exchange between $[Rh_2(O_2CMe)_4]$ and $MeC(O)NH^-$.[384] The five complexes were separated by HPLC, but the exact geometric structure of the substituted species was not determined.

In their studies of $[Rh_2(O_2CR)_4]$ with bulky R groups, Cotton and Thompson noted that the bridge exchange between $[Rh_2(O_2CMe)_4]$ and $Ph_3CCO_2^-$ generates $[Rh_2(O_2CMe)_2(O_2CCPh_3)_2(MeCN)_2]$.[308] Other bulky substituents (R = 2-PhC_6H_4 or 1-adamantane) replaced all four acetate bridges, and it is not clear why the reaction with triphenylcarboxylate stops after the replacement of only two acetates. (Kinetic studies of acetate replacement by trifluoroacetate in $[Rh_2(O_2CMe)_4]$ indicate that the reaction slows markedly after replacement of two acetate bridges,[385] so a kinetic factor may be involved.) Steric crowding cannot be important, as $[Rh_2(O_2CMe)_2(O_2CCPh_3)_2(MeCN)_2]$ has the *cis* configuration, and there is adequate room for two additional triphenylcarboxylate bridges. Cotton points to a stacking of the phenyl groups from adjacent bridges as a possible contribution to the stability of the *cis* geometry.[308]

A new series of mixed-bridge dimers, recently characterized by Ford and his group, are based on a 1,8-naphthyridine frame (**41**).[386–388] Upon mixing the crescent-shaped bpnp with $[Rh_2(O_2CMe)_4]$ (in acidic methanol under argon in the presence of NH_4PF_6), substitution of one acetate bridge occurs, and the 'croissant complex' $[Rh_2(O_2CMe)_3(bpnp)]PF_6$ can be isolated. A single-crystal X-ray study (Table 20) reveals that the bpnp acts as a bridge, through the 1,8-naphthyridine nitrogens, allowing the pendant pyridines to bond to the axial sites at either end of the Rh_2 core. Other complexes in this series include $[Rh_2(O_2CMe)_3(L)]^+$ (L = dinp or pynp), $[Rh_2(np)_4]Cl_4$, $[Rh_2(O_2CMe)_2(pynp)_2]^{2+}$,[387] and $[Rh_2(pym)_3Cl_2](PF_6)_2$.[384] NMR analysis of $[Rh_2(O_2CMe)_2(pynp)_2]^{2+}$ indicates that the acetates and the pynp bridges have a mutually *cis* geometry.[387] A single-crystal X-ray study of $[Rh_2(pynp)_3Cl_2](PF_6)_2$ revealed its unusual geometry, represented in

[a] $C_{22}H_{22}N_4$ = 7,16-dihydro-6,8,15,17-tetramethyldibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecinate (a macrocyclic dianion); im = imidazole; mhp = 2-oxy-6-methylpyridine; DPM = bis(diphenylphosphino)methane; bpnp = 2,7-bis(2-pyridyl)-1,8-naphthyridine (**41b**); pymp = 2-(2-pyridyl)-1,8-naphthyridine (**41c**).

(**42**), as it has only two bridging ligands. The pyridines pendant to the pynp bridges act as the axial donors, while the other pynp acts as a non-bridging bidentate ligand; the two chlorides bond in equatorial positions to the other Rh atom.[388] The two naphthyridine-bridged complexes characterized to date have longer Rh—Rh bonds than observed for the purely acetate-bridged complexes, but the length is still within the range of a Rh—Rh single bond.

Two other complexes with only two bridging ligands have been characterized by X-ray studies. $[Rh_2(O_2CH)_2(phen)_2]Cl_2$ is a 1:2 electrolyte in aqueous solution, suggesting that the chlorides are not axially bonded, or that they are readily labilized in aqueous solution.[389] This bis(bridge) complex has a Rh—Rh bond (2.576 Å) which is *ca.* 0.2 Å longer than that observed for the tetracarboxylate-bridged dimers, but is comparable to the 2.618 Å observed for the other bis(bridge) complex, $[Rh_2(O_2CMe)_2(DMG)_2(PPh_3)_2]$.[390]

While its structure has not been determined, the first well-characterized bis(bridge) complex was characterized by Ugo and co-workers, who noted that the reaction of $[Rh_2(O_2CMe)_4(H_2O)_2]$ with acac, trifluoroacetylacetone, or hfacac (Q) gives complexes of the form $[Rh_2(O_2CMe)_2(Q)_2]\,(H_2O)_2$. Adducts with py, 2-methylpyridine and 2-chloropyridine were characterized, and analysis of electronic and IR spectra, and the ^1H and ^{31}P NMR led Ugo to propose bridging acetates, with the acacs each chelated to a single metal.[397] Mixed acetate/salicylate,[398] acetate/phosphate[399] and formate/bipy[400] complexes have also been reported, but the nature of the bridging has not been determined.

(*iv*) *Dimers without bridging ligands*

Several claims could be supported for the first preparation of a Rh^{II} dimer with only the Rh—Rh bond to hold the dimer together. In 1961 Martin and co-workers reported that sodium amalgam reduction of $[Rh(bipy)_2Cl_2]X$ ($X = NO_3^-$, ClO_4^-) leads to red-violet solids with the stoichiometry $[Rh(bipy)_2Cl(X)]_2\cdot 4H_2O$ ($X = NO_3^-$, ClO_4^-).[401] They are diamagnetic, and were presumed to be chloro-bridged dimers; the preponderance of Rh^{II}—Rh^{II} bonds discovered since 1961, and the lack of halogen-bridged dimers, suggests that this work should be reinvestigated. In 1967, Shchepinov and co-workers used BH_4^- to reduce $[Rh(DMG)_2Cl_2]^+$ in the presence of PPh_3, generating $[Rh_2(DMG)_4(PPh_3)_2]$, a diamagnetic, air-stable solid.[402] Shchepinov's suggestion that $[Rh_2(DMG)_4(PPh_3)_2]$ contained a Rh—Rh bond was confirmed in a structural study, which found a long (2.936 Å) Rh—Rh bond, the longest Rh^{II}—Rh^{II} bond yet determined.[393] The nearly planar bidentate DMG ligands are staggered on the two Rh atoms, and are bent towards each other and away from the axial PPh_3 ligands; steric repulsions between the DMG ligands are thought to be responsible for the long Rh—Rh bond.[393] Keller and Seibold prepared $[Rh_2(DMG)_4]$ by reacting

HDMG with $[Rh_2(O_2CMe)_4]$, an interesting bridge → no bridge conversion.[403] Complexes with DMG derivatives, and the py and THF adducts, were prepared by this same route.[404] An X-ray photoelectron study of several DMG-containing Rh^{II} and Rh^{III} complexes has been reported.[405]

Soon after the preparation of $[Rh_2(DMG)_4(PPh_3)_2]$, Maspero and Taube reported that $Cr^{2+}_{(aq)}$ reduces $[Rh(H_2O)_5Cl]^{2+}$ to give a species with cation exchange behavior which implied a charge greater than 3+ (equation 95).[362] This complex was formulated as the $[Rh_2(H_2O)_{10}]^{4+}$ dimer [λ_{max} at 630 (ε39.8), 412 (59.1) and 250 nm (10 600)]. Attempts to isolate a solid with a variety of anions (PF_6^-, BF_4^-, BPh_4^-, $B_{10}H_{10}^{2-}$, $B_{12}Cl_{12}^{2-}$ and $[Fe(CN)_6]^{4-}$) failed, and halide-catalyzed disproportionation to Rh^{I} and Rh^{III} also interfered. A solid salt of this important cation has not yet been reported. The complex is reported to be 'slightly paramagnetic', which led Taube to suggest that the dimers are in equilibrium with the paramagnetic monomer.[362] Ziolkowski later suggested that the paramagnetism may result if the HOMOs are two degenerate π^* orbitals populated by two unpaired electrons,[406] and a study of the magnetic susceptibility of a variety of tetraacetate-bridged dimers also showed that a small temperature independent paramagnetism (μ_{eff} near 0.5 BM) was a common feature of these Rh^{II} dimers.[407]

$$2[Rh(H_2O)_5Cl]^{2+} + [Cr(H_2O)_6]^{2+} \longrightarrow [Cr(H_2O)_5Cl]^{2+} + [Rh_2(H_2O)_{10}]^{4+} \quad (95)$$

Reduction of [Rh(OEP)Cl] (OEP = octaethylporphyrin) with $H_{2(g)}$ leads to the Rh^{III} hydride [Rh(OEP)H], which, when heated in benzene or oxidized with O_2, forms the brown diamagnetic $[Rh_2(OEP)_2]$ (equation 96).[408,409] The OEP ligand is a rigidly planar cyclic dianion, so ligand bridging is impossible. The dimer undergoes a variety of reactions with substituted hydrocarbons, leading to complexes with Rh^{III}—C bonds (Section 48.5.2.3.iii).

$$2[Rh(OEP)Cl] + H_2 \longrightarrow 2[Rh(OEP)(H)] \begin{cases} \xrightarrow{\frac{1}{2}O_2} [Rh_2(OEP)_2] + H_2O \\ \xrightarrow{\Delta,\ C_6H_6} [Rh_2(OEP)_2] + H_2 \end{cases} \quad (96)$$

During studies on a series of Rh^{I} isonitriles, Olmstead and Balch found that a series of dimeric Rh^{II}–isonitrile complexes could be generated by the reaction of appropriate Rh^{I} and Rh^{III} complexes (equation 97).[410] This reaction was found to be quite general (for X = I, R = Me, Bu^n, Ph, C_6H_{11}; and R = C_6H_{11} for X = Cl), but not universal, as no reaction is observed if R = Bu^t and X = Br or I. A halogen-bridged dimer would require little atomic motion, but IR analysis supports a Rh—Rh bond, with axial halides.[410] Support for this proposed structure came when it was shown that analogous compounds can be prepared by the transannular oxidative addition of monomeric $[Rh(p\text{-}MeC_6H_4NC)_4]PF_6$,[392] or dimeric $[Rh_2(bridge)_4]^{2+}$ (bridge = 1,3-diisocyanopropane).[411] Irradiation of $[Rh_2(bridge)_4]^{2+}$ in conc. HCl causes H_2 formation and the generation of a similar dimer $[Rh_2(bridge)_4Cl_2]^{2+}$.[394] A single-crystal X-ray structure confirmed the traditional Rh—Rh bonded structure, with short non-bonded interactions between eclipsed C—N groups on adjacent Rh atoms contributing to the length of the Rh—Rh bond (2.837 Å).[394] Another (presumably bridged dimer) has been prepared by the two-electron electrochemical oxidation of $[Rh_2(dimen)_4]^{2+}$ (dimen = 1,8-diisocyanomenthane). In the presence of axially coordinated Cl^-, oxidation occurs at low potentials, and in the presence of PF_6^- (in MeCN or CH_2Cl_2) a yellow salt, identified as $[Rh_2(dimen)_2Cl_2](PF_6)_2$, has been isolated.[412]

$$[Rh(RNC)_4]^+ + [Rh(RNC)_4X_2]^+ \rightleftharpoons [Rh_2(RNC)_8X_2]^{2+} \quad (97)$$

While studying Schiff base complexes of Rh^{III} (see Section 48.6.4.1 for a discussion of structures), West and co-workers reported that if $RhCl_3 \cdot 3H_2O$ or $[Rhpy_4Cl_2]Cl$ (in pyridine) is mixed with methanol solutions of *N,N'*-ethylenebis(salicylideneiminate) (H_2salen) and a reducing agent (Zn dust), a diamagnetic, pale yellow solid, formulated as [Rh(salen)py], forms.[413] This complex remains ill characterized, and while it displays an uncharacteristic chemical inertness, West suggested that it may be an unbridged Rh^{II} dimer, analogous to the bis(DMG) complexes.[413] Reaction of equimolar mixtures of $[Rh(CO)_2Cl_2]_2$, salenH_2 and a base (Et_3N or $NaHCO_3$) in refluxing methanol leads to a weakly paramagnetic (μ_{eff} = 0.90 BM) material formulated as Rh(salen).[414] The corresponding Schiff bases with 1,2-propylene (salpn) and *o*-phenylene (saloph) chains between the two salicylideneiminato groups also form 1:1 complexes with Rh, but both $[Rh(salpn)]_2$ and $[Rh(saloph)]_2$ are diamagnetic, suggesting that they are undissociated dimers, while $[Rh(salen)]_2$ is in equilibrium with its monomeric form. All three react with O_2 in air to give paramagnetic oxygen adducts (*e.g.* $[Rh(salen)O_2]$), formulated as hyperoxo Rh^{III} species.[414]

The O_2 oxidation of $[Rh(CO)_2Cl_2]_2$ in dimethylacetamide ($Me_2NC(O)Me$ = DMA) in the

presence of LiCl and Ph_4As^+ leads to a solid identified as $(Ph_4As)_2[Rh_2Cl_6(DMA)_2]$.[415] The solid has a low magnetic moment ($\mu = 0.95$ BM), and is a 2:1 electrolyte in DMA, although in $CHCl_3$ its molecular weight is *ca.* 23% lower than expected. Further oxidation leads to $[Rh_2Cl_9]^{3-}$, a characterized anion in which two pyramidally distorted $RhCl_6$ octahedra share an octahedral face (Section 48.6.7). This led to the proposal that the two Rh atoms in $[Rh_2Cl_6(DMA)_2]^{2-}$ are bridged by a pair of chloride atoms (two $[RhCl_4(DMA)]$ square pyramids sharing a basal edge).[415] If true, this is a unique Rh^{II} dimer; an alternate structure with a Rh—Rh bond is not difficult to imagine.

48.5.2.2 Bonding and electronic structure in Rh^{II} dimers

Two related features of Rh_2^{4+} dimers of obvious interest are the metal—metal bond, and the range of colors displayed by various adducts. The colors range from blue to green for oxygen donors, red to orange for nitrogen and sulfur donors, and red to yellow for phosphorus donors. The spectra generally consist of two relatively weak (ε 200–300) transitions centered near 600 nm (Band I) and 450 nm (Band II). The position of Band I is very dependent on the number and nature of axially bound ligands, while Band II is virtually invariant to the presence or absence of numerous ligands. Two intense bands (Band III near 250 nm and Band IV near 220 nm with $\varepsilon > 10\,000$) occur in the UV. These two bands undergo a ligand-dependent red shift as the axial ligands become more tightly bonded. Structural studies have shown that the Rh—Rh bond length varies by more than 0.5 Å, from 2.371 to 2.936 Å (see Table 17 and 21). To understand the spectra and structural features of these complexes clearly requires an understanding of their electronic structure. Few areas in rhodium chemistry have received such heated discussion, and while a consensus seems to have emerged on the Rh—Rh bond order, questions remain to be resolved.

The original report (in 1962) on the structure of $[Rh_2(O_2CMe)_4(H_2O)_2]$[281] suggested a Rh—Rh single bond; the Rh—Rh bond length (2.45 Å) and the observed diamagnetism could be rationalized with such a formulation. In 1970, Martin used extended Hückel calculations to arrive at an electronic configuration for the Rh_2 core ($14\,e^-$) of $\pi^4, \sigma^2, \delta^2, \delta^{*2}, \pi^{*4}$,[290] supporting the single bond hypothesis. The axial-ligand dependent absorption (Band I, 600 nm) was assigned as a $\pi^* \rightarrow \sigma^*$ (Rh_2^{4+}) transition. Band II, relatively unaffected by axial ligands, was assigned as a $\pi \rightarrow (\delta, \sigma^*)$ or $\pi \rightarrow (\delta^*, \sigma^*)$ transition, again within the Rh_2 core.

Just before Martin's extended Hückel analysis, Cotton and co-workers suggested that the manifold of occupied frontier orbitals included two non-bonding orbitals which were essentially the $5s$ and $5p_z$ orbitals of the Rh atoms (the Rh–Rh axis generally defines the z-axis). This led to a $14\,e^-$ core configuration of $\sigma^2, \pi^4, \delta^2, \sigma_n^2, \sigma_n'^2, \delta^{*2}$, with two empty π^* and an empty σ^* orbitals, and a Rh—Rh triple bond.[393,416,417] This configuration also accounted for the diamagnetism, and was soon supported by a reevaluation of the Rh—Rh bond length in $[Rh_2(O_2CMe)_4(H_2O)_2]$. The new value, 2.3855 Å,[297] was *ca.* 0.065 Å shorter than the earlier reported length,[281] and more than 0.5 Å shorter than the only other Rh—Rh bond length known at the time (2.936 Å in $[Rh_2(DMG)_4(PPh_3)_2]$).[390] An estimate of the Rh^{II} covalent radius (1.40–1.45 Å)[418] set a 'rather firm lower limit of 2.80 Å' for the Rh^{II}—Rh^{II} single bond.[297,393] Any bond which is 15% shorter than the minimum single bond length must be considered a serious candidate for a multiple bond.

The triple bond formulation did not receive theoretical support, however, as in 1978 Norman and Kolari presented their SCF–X^α–SW calculations on $[Rh_2(O_2CH)_4]$ and $[Rh_2(O_2CH)_4(H_2O)_2]$.[419] Their calculations indicate that the non-bonding $5s$ and $5p_z$ Rh-centered orbitals, important in Cotton's analysis, are at high energy and remain unoccupied. Their 14-electron core is $\sigma^2, \pi^4, \delta^2, \pi^{*4}, \delta^{*2}$ with only the σ^* unoccupied; this represents a single, σ bond, as predicted by Martin.[290] The electronic transitions were assigned as: Band I, $\pi^* \rightarrow \sigma^*$ (within the Rh_2 core); Band II, $\pi^* \rightarrow \sigma^*$ (Rh—O_{eq}); Band III, $\sigma \rightarrow \sigma^*$ (Rh_2); and Band IV, $\sigma(L) \rightarrow \sigma^*$, in reasonable agreement with Martin's earlier assignment.[290] Norman notes that the electronic spectra for the unbridged $Rh_{2(aq)}^{4+}$, and the bridged $[Rh_2(CO_3)_4]^{4-}$ and $[Rh(SO_4)_4]^{4-}$ ions are very similar to the spectra of the carboxylate-bridged dimers, and suggests analogous electronic configurations for the ions.[419]

When water molecules are brought in along the Rh–Rh axis, Norman's analysis indicates that there is very little π interaction with the metal, and that the π and δ MOs of the metal–metal bond are virtually unperturbed by the presence of the H_2O. As for σ bonding, within a_{1g} symmetry axial binding by water stabilizes both the Rh—OH_2 σ-bonding and antibonding orbitals so that both are fully occupied, and virtually no net bonding results. In a_{2u} symmetry, the Rh—Rh bond destabilizes the Rh—Rh σ^* orbital, lessening its interaction with the σ orbitals on the water. This nicely accounts for the observations that the metal–axial-ligand bonds are significantly weaker than normal in these Rh_2^{4+} dimers, and that the stronger the metal–metal bond (that is the higher in energy the Rh—Rh

σ^* orbital) the weaker the metal–axial-ligand bond. Thus, there is a mutual interaction, as the presence of axial ligands weakens the Rh—Rh bond, while the Rh—Rh bond weakens the Rh–axial-ligand bond.[419]

This analysis also accounts for the observed changes in the electronic spectra. Axial ligands strongly influence the energy of the Rh—Rh σ^* orbital, so the energy of Band I [$\pi^* \rightarrow \sigma^*$ (Rh_2)] would be expected to be dependent on the number and nature of the axial ligands. Band II ($\sim$450 nm) was assigned to the $\pi^* \rightarrow \sigma^*$ (Rh—O_{eq}), which is virtually unaffected by the presence or absence of axial ligands. The axial-ligand dependency and the greater intensity of Bands III and IV are consistent with their assignment as $\sigma \rightarrow \sigma^*$ transitions. These spectral assignments were supported by a single crystal polarized absorption study.[420]

In 1981, Nakatsuji *et al.* presented the results of an *ab initio* SCF study on [$Rh_2(O_2CH)_4$], various adducts, and the corresponding cations.[421] While their proposed electronic configuration was not exactly the same as that suggested by Norman and Kolari, they did agree that a Rh—Rh single bond of σ symmetry exists in these dimers. Their analysis showed just how sensitive the electronic configuration is to the nature of the axial ligands, for when there are no axial ligands, or when L = H_2O or NH_3, they put the electronic configuration of the 14-electron core (for [$Rh_2(O_2CH)_4(L)_2$] at π^4, δ^2, π^{*4}, δ^{*2}, σ^2); when L = PH_3, the ordering of the two lowest levels in the Rh_2 core reverses with the net result still being a single σ bond. This analysis was extended to the monocation radical dimer,[422] and the calculations are consistent with ionization of an electron from the HOMO σ orbital, leading to a cation with the unpaired electron in an orbital of σ symmetry. This assignment is supported by ESR studies.[423,424]

The differences caused by axial coordination by P, *vs.* bonding by either N or O, was also explored in an SCF–X^α–SW molecular orbital calculation by Bursten and Cotton.[425] These studies are of special interest, as Drago has presented several studies (*vide infra*) which imply the importance of π back bonding in phosphine adduct formation. Neither the X^α calculations of Cotton[425] nor the *ab initio* calculations of Nakatsuji[421,422] supports the existence of any significant amount of π bonding, as the only effective Rh—P bonding is through the Rh d_{z^2} orbital, and is thus of σ symmetry. The ESR spectra on [$Rh_2(O_2CR)_4(PX_3)_2$]$^+$ cations also imply the dominance of Rh—P σ bonds.

Gray and co-workers have recently presented a single-crystal polarized spectral analysis for [$Rh_2(O_2CMe)_4(H_2O)_2$] and for $Li_2[Rh_2(O_2CMe)_4Cl_2]\cdot 8H_2O$, and propose new assignments for the visible absorptions.[300] Both complexes showed similar spectra, with Band I split into two electric-dipole-allowed transitions near 650 (*z*-polarized) and 600 nm (*x,y*-polarized). The 650 band was assigned to a $\delta^*(Rh_2) \rightarrow \sigma^*$(Rh—O) band, while the band at *ca.* 600 nm was assigned as $\pi^*(Rh_2) \rightarrow \sigma^*$(Rh—O). Weak but structured transitions ($\varepsilon \approx$ 10–20) between 800 and 650 nm are assigned to the spin-forbidden components of these δ^*, $\pi^* \rightarrow \sigma^*$(Rh—O) transitions. The assignment of Band I as a $Rh_2 \rightarrow$ Rh—O transition, rather than the previously assigned Rh_2 core transition,[290,419,420] is based on the *x,y*-polarization of the major 600 nm band and the 300 cm^{-1} vibrational spacing, which corresponds to a Rh—O, not a Rh—Rh, stretch. The reasons for the sensitivity of Band I to axial ligands is not as straightforward as in the previous assignment, and is proposed to be due to axial-ligand-induced variations in the energy of the occupied π^* orbital. Band II is assigned to π(Rh—O) $\rightarrow \sigma^*$(Rh—O). Isotropic (solution) spectra were then used to assign the two UV bands to the $\sigma(Rh_2) \rightarrow \sigma^*(Rh_2)$ and σ(Rh—L) $\rightarrow \sigma^*(Rh_2)$.[300]

Use of vibronic spacing for electronic band assignment depends on knowledge of stretching frequencies, and estimates of the Rh—Rh stretching frequency in Rh_2^{II} carboxylates have varied: 155 cm^{-1} for [$Rh_2(O_2CMe)_4$][426], 170 cm^{-1} for [$Rh_2(O_2CMe)_4(MeOH)_2$][427] and between 288 and 351 cm^{-1} for a variety of carboxylates, with 320 cm^{-1} assigned to the Rh—Rh stretch in the diaquatetraacetate dimer.[428] In light of work with Ru_2 tetracarboxylate dimers (with significantly shorter metal–metal bonds)[429] and the value of 184 cm^{-1} for the Rh—Rh stretch in [$Rh_2(mhp)_4$],[430] Gray questions the 288–351 cm^{-1} range proposed by Oldham[428] and suggests that a range of 150–170 cm^{-1} is more resonable.[300] Gray then makes the interesting observation that this is the same region as the Rh—Rh stretch in [$Rh_2(bridge)_4X_2$]$^{2+}$, which has a Rh—Rh bond $\sim$0.4 Å longer than the tetracarboxylate complexes. This represents an unusual, but explicable, breakdown of Badger's rule, which correlates a given bond length with the cube root of its force constant.[431] (It is ironic that in the same manuscript Gray invokes Badger's rule to dispute the 288–351 cm^{-1} assignments of Rh—Rh stretching frequencies.[300])

Electronic transitions in [$Rh_2(O_2CMe)_4L_2$], and in its cation radical, have been qualitatively interpreted in terms of a molecular orbital model which assumes that metal–ligand interactions are larger than intermetallic interactions.[432] The intense near UV bands (Bands III and IV) are assigned to intermetallic $\sigma \rightarrow \sigma^*$ transitions; the bonding model qualitatively accounts for the observed red shift as ligand σ-donating ability increases. This is in agreement with the assignments of Gray *et al.*[300]

Table 21 Proposed Models for the Rh—Rh Bond in Rh^{II} Tetracarboxylate Dimers

Proposer (Ref.)	*Method used*	*Rh—Rh bond order*	*Molecular orbitals ordering*
Dubicki, Martin (290)	Extended Hückel	1	$\pi^4\sigma^2\delta^2\delta^{*2}\pi^{*4}$
Cotton *et al.* (416, 417)	Qualitative MO and empirical arguments	3	$\sigma^2\pi^4\delta^2\sigma_n^2\sigma'^2_n\delta^{*2}$
Norman, Kolari (419)	SCF–X^α–SW	1	$\sigma^2\pi^4\delta^2\pi^{*4}\delta^{*2}$
Nakatsuji *et al.* (421)	*Ab initio*–SCF	1	If L = H_2O, NH_3, or no L $\pi^4\delta^2\pi^{*4}\delta^{*2}\sigma^2$ If L = PH_3 $\sigma^2\pi^4\pi^{*4}\delta^{*2}\sigma^2$
Nakatsuji *et al.* (423)	*Ab initio*–HF	—	For cation radical, if L = H_2O, NH_3 $\sigma^2\pi^4\pi^{*4}\delta^{*2}\sigma^1$ For cation radical, if no L singly occupied δ^*

and Norman and Kolari.[419] For the cation radical, however, the corresponding transition does not show the same ligand dependency, leading Kawamura[423,424] to suggest that the odd electron in the cation radical is not accommodated in the Rh—Rh σ bond, directly contradicting the conclusions reached by Nakatsuji.[421,422]

To summarize the current position on the Rh—Rh bond, the 'triple-bond windmill'[368] seems to have stopped spinning, and workers in the area seem to have reached a consensus, and refer to a Rh—Rh single bond. Agreement ends at that point however, as generally accepted electronic configurations and spectral assignments have not yet emerged, and will doubtless remain a contested and stimulating subject for some time. Table 21 summarizes the conclusions reached by the major theoretical studies on Rh^{II}–Rh^{II} systems.

The nature of the bond between Rh and an axially coordinated ligand (L_{ax}) has also been debated in recent years. There is no argument that axial Rh—L bonds are significantly weaker and longer than bonds to the equatorial bridges, and that the ligands at axial sites are more readily replaced than the bridging ligands. The strong *trans* effect (and influence) of the Rh—Rh bond is often invoked to account for these observations.[282] Debate has centered around whether the Rh—L_{ax} bond involves σ or π bonding.

The opening salvo came from Drago and coworkers, who studied the thermodynamics of the formation of the 1:1 and 2:1 adducts of eight different bases with [Rh(buty)$_4$] (buty = $C_3H_7CO_2^-$) in benzene solution (equation 98).[359] They found K_1 was approximately three orders of magnitude larger than K_2; if uncoupled, statistical arguments would have $K_1 = 4K_2$.[359] Despite the differences between K_1 and K_2, $\Delta H_1 \approx \Delta H_2$, implying a large entropy effect. Drago suggested that [Rh_2(buty)$_4$] forms 2:1 adducts with benzene when dissolved in that solvent, but that coordination of an added base to one end causes the release of both benzenes (equation 99); the large entropy increase of this step contributes to the first equilibrium constant. Also noting that in benzene solution both acetonitrile and carbon monoxide form adducts with a decrese in C—N and C—O stretching frequencies respectively, Drago suggested that extensive π back-bonding must be involved in the Rh—L_{ax} bonding. The simplified MO diagram (Figure 1) shows that π bonding lowers the π^* level, and increases the energy of the $\pi^* \rightarrow \sigma^*$ transition. The presence of π back-bonding was supported by an analysis of the reduction potentials of the oxidation products $[Rh_2(buty)_4L_n]^+$ (n = 0, 1, 2)[359] and by a similar thermodynamic study in CH_2Cl_2, a non-coordinating solvent.[433]

$$[Rh_2(buty)_4] \underset{-L}{\overset{K_1}{\rightleftharpoons}} [Rh_2(buty)_4L] \underset{-L}{\overset{K_2}{\rightleftharpoons}} [Rh_2(buty)_4L_2] \quad (98)$$

$$[Rh_2(buty)_4] \overset{C_6H_6}{\rightleftharpoons} [Rh_2(buty)_4(C_6H_6)_2] \overset{L}{\rightleftharpoons} [Rh_2(buty)_4L] + 2C_6H_6 \quad (99)$$

Bursten and Cotton then presented the results of an X^α–SW molecular orbital calculation on $[Rh_2(O_2CH)_4(PH_3)_2]$ in which they found no evidence of Rh → P back-bonding, and commented that the 'evidence on the occurrence of π-bonding is neither extensive nor straightforward'.[425] Other theoretical studies have implied that Rh—L_{ax} bonding is predominantly σ.[421,422] The X-ray photoelectron spectra of [$Rh_2(O_2CMe)_4$] and its 1:1 adduct with 4-cyanopyridine show that the adduct displays lower binding energies (Rh $3d_{5/2}$ and Rh $3p_{1/2}$) than the parent complex. If extensive back-bonding to the 4-cyanopyridine existed, a decrease in electron density of the Rh_2 core (and an increase in binding energies) would be expected; this was interpreted to point to the dominance of

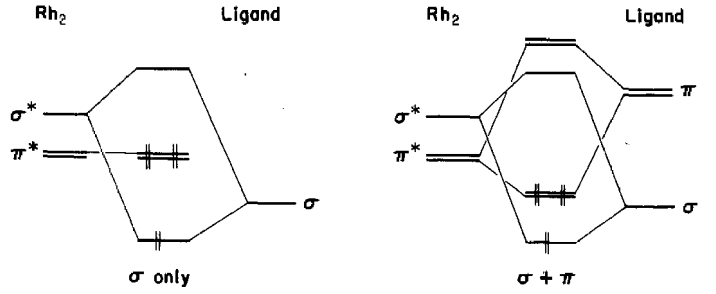

Figure 1 Simplified MO diagram for adducts of $[Rh(buty)_4]$ with bases in benzene solution

σ effects over any π back-bonding.[434] (Interestingly, the two Rh^{II} centers were indistinguishable in the 1:1 adduct with 4-cyanopyridine.)

Drago has presented additional thermodynamic arguments and a comparison between Rh_2^{4+} and Mo_2^{4+} systems to support the position that for some ligands, the admittedly weak Rh—L_{ax} bond can have a significant π component.[435-437] A recent ESR study of a variety of 1:1 and 2:1 adducts of the oxidized $[Rh_2(buty)_4L]^+$ ion led to the suggestion that the ordering of the filled molecular orbitals depends on the nature of the axial ligands, and that for the 2:1 phosphine adducts the HOMO is singly degenerate (presumably a σ^* orbital), while for the 1:1 phosphine adducts, or for complexes with weak donors, the HOMO is the doubly degenerate π^* level.[437]

The debate over the importance of π bonding of axially coordinated ligands has not yet been resolved, but the case for the existence of some π interaction seems to be growing. For example, Bear and coworkers determined the equilibrium constants for the 1:1 and 2:1 adducts of $[Rh_2(O_2CMe)_4]$ with a variety of di- and tri-peptides, substituted pyridines and imidazole, and found that the stability of the L—Rh bond does not correlate with the base strength of the entering ligand; this led Bear to suggest that more than σ bonding is involved, and that π bonding must be crucial.[438] Ironically, a recent study of the thermodynamics of the formation of 1:1 adducts between $[Rh_2(O_2CCF_3)_4]$ and 11 different alkenes found that the K_{form} values (between 6.1 for styrene and 578 for 2-methylpropane) do not correlate with association constants between these alkenes and more traditional π donors such as Rh^I, Pd^{II}, Pt^{II} and Ag^I.[439] Activation by the electron-withdrawing fluoroacetates is necessary, as no reaction is observed between alkenes and $[Rh_2(O_2CMe)_4]$, suggesting that back-donation from the Rh—Rh system may not have a dominant influence on Rh—L_{ax} stability. The case for π bonding is supported by the large antiferromagnetic exchange interaction between radical centers in $[Rh(O_2CR)_4(Tempo)_2]$ (R = CF_3, Pr, C_6F_5) which was rationalized in terms of a strong π interaction between the Rh and the axial radicals.[332] (The Mo—Mo π^* orbitals would be empty in the Mo analog, making such a π interaction impossible, consistent with the negligible antiferromagnetic exchange observed in $[Mo(O_2CCF_3)_4(Tempo)_2]$.[332]

48.5.2.3 Reactivity of Rh^{II} dimers

The reactivity of Rh^{II} dimers cannot be divided cleanly into substitution and redox processes, as the presence of the very stable +1 and +3 oxidation states means that processes which might be expected to cause substitution can lead to redox processes.

(*i*) *Substitutions at Rh^{II} dimers*

The most obvious reaction of Rh^{II} dimers is the formation of adducts by ligand substitution in the axial sites. An outline of the various bases which have been reported to coordinate to the Rh_2 core is given in Section 48.5.2.1. Numerous studies concerning the kinetics and thermodynamics of axial substitutions have been presented.[335,348,349,440-443] In general, adduct formation occurs in two kinetically separable steps at rates which suggest that the Rh—Rh bond has a strong *trans*-labilizing influence. The stability of the adducts is dependent on the nature of the bridging ligands, and Bear and co-workers have shown that for the reactions of $[Rh_2Q_4]$ (Q = acetate, propionate and methoxyacetate) with a variety of ligands, both K and k values follow the order propionate > acetate > Me-acetate.[436-438] This order was rationalized in terms of a desolvation effect of the bridging groups, and parallels the order observed in antitumor studies. The lability of the axial

site led Bear to use $[Rh_2(benzoate)_4]$ suspended in squalene as the stationary stage in GLC columns, which were used to separate alkene mixtures and various ethers, ketones and esters.[444] A multi-temperature study of the ^1H, ^{13}C, ^{31}P and ^{103}Rh NMR of the trimethyl phosphite (TMP) adducts of $[Rh_2(O_2CMe)_4]$ was able to detect the 1:1 and 2:1 adducts, and found rapid TMP exchange at 298 K.[445]

Few kinetic studies on bridge substitutions have been presented, but studies of the reaction of CF_3COOH with $[Rh_2(O_2CMe)_4]$ showed that the relative rates of bridge exchange is 80:40:2:1.[446] The geometry of the unisolated $[Rh_2(O_2CMe)_2(O_2CCF_3)_2]$ was not determined, but it is interesting to note that after substitution of the first two fluorinated bridges, the rate of further exchange slows dramatically.

There is no characteristic reaction in acidic solution, as the reaction depends on the nature of the conjugate base of the acid used. Bridge exchange is observed in carboxylic, thiocarboxylic, sulfuric and orthophosphoric acids, while arenesulfinic acids (RSO_2H) cause oxidation to $Rh(RSO_2)_3$ species.[447] Hydrochloric and hydrobromic acids cause disproportionation to Rh metal and RhX_3.[448,449] The potential bridge, dipicolinic acid, reacts with $[Rh_2(O_2CMe)_4]$, generating a structurally uncharacterized material identified as $Rh(dpc)\cdot 3H_2O$.[450] An early report[287] indicating that reaction of $[Rh_2(O_2CMe)_4]$ with perchloric, trifluoromethylsulfonic or fluoroboric acids leads to $Rh^{4+}_{2(aq)}$, was later questioned by Taube[451] and Pinnavaia[452] who showed that the products are $[Rh_2(O_2CMe)_3]^+$ and $[Rh_2(O_2CMe)_2]^{2+}$. In acetonitrile solutions of CF_3SO_3H or $HBF_4\cdot Et_2O$ (both strong, non-complexing acids), $[Rh_2(O_2CPr)_4]$ loses butyric acid and generates the cationic $[Rh_2(O_2CPr)_2]^{2+}$ dimer, although acetonitriles are presumably coordinated. The product gives no ESR signal, implying negligible amounts of monomeric radicals, but attempts to precipitate the dication with sulfide ion leads to black, intractable solids.[453]

In the presence of oxidizing agents the bridged dimers show surprising stability as $[Rh_2(O_2CMe)_4]$ does not react with O_2, but does react with ozone to form the trimeric $[Rh_3(\mu\text{-}O)(O_2CMe)_6(H_2O)_3]^+$.[454] A structural study of the perchlorate salt shows a central oxygen atom surrounded by a triangle of Rh atoms,[455] and is discussed in Section 48.5.2.4. Oxidation to $[Rh_2(O_2CMe)_4]^+$ has been reported with Cl_2, PbO_2 and Ce^{4+}, while basic peroxide and persulfate oxidations lead to Rh^{III} species.[451]

In the presence of H_2, the unbridged $Rh^{4+}_{2(aq)}$ is reduced to Rh metal, and the strongly reducing environment of H_2 over a THF solution containing PMe_3 and Na(Hg) causes the decomposition of $[Rh_2(O_2CMe)_4]$.[456] Low pressure CO leads to the formation of a labile CO adduct,[299,306,359] but under extreme conditions (up to 300 atm and 120°C) reduction to $Rh_6(CO)_{16}$ occurs.[358]

In a fluoroboric acid/methanol solution, PPh_3 reduces $[Rh_2(O_2CMe)_4]$ to $[Rh(PPh_3)_3(BF_4)]$,[457] while oxidation occurs in the presence of PMe_3, yielding *fac*-$[Rh(PMe_3)_3(H)(O_2CMe)_2]$.[458] In the presence of $P(Me)_3$, Grignards react with $[Rh_2(O_2CMe)_4]$ to generate monomeric Rh^{III} alkyls and Rh^{I} σ aryls.[457]

Little is known of the reactivity of the $Rh^{4+}_{2(aq)}$ ion, although Ziolkowski and Taube point out that it is probably labile, as it can be prepared by the Cr^{2+} reduction of $[Rh(NH_3)_5Cl]^{2+}$. No ammonia is retained in the primary coordination sphere of the resulting Rh^{II} dimer.[459] The dimer reacts with dihalogens (X_2) to give $[Rh(H_2O)_5X]^{2+}$ (X = Cl, Br, I),[362,460] and with O_2 to give $[Rh(H_2O)_6]^{3+}$ with a green transient, identified as the peroxo-bridged dimer $[(H_2O)_5Rh—O_2—Rh(H_2O)_5]^{4+}$.[459]

(*ii*) *Electrochemistry of Rh^{II} dimers*

The lack of Rh^{II} complexes generated from the reduction of Rh^{III} species was noted by Taube in 1968[362] and in his recent review Felthouse notes that electrochemical studies of other metal–metal bonded systems have been 'a fertile area for study... although relatively few studies have been reported on dirhodium(II) compounds.'[282] That is rapidly changing, as Rh^{II}_2 electrochemistry has become a vigorously pursued research area.

Wilson and Taube first reported that while $Rh^{2+}_{2(aq)}$ is not oxidizable by cyclic voltammetry, the tetraacetato-, tetracarbonato- and tetrasulfato-bridged dimers undergo reversible one-electron oxidations at 1.225 V, 1.022 V (in *p*-toluenesulfonic acid solution), and 1.112 V (0.2 M H_2SO_4) *versus* NHE respectively.[289] Oxidation of $[Rh_2(O_2CMe)_4]$ at a bright Pt electrode in 1.0 M $HClO_4$ leads to $[Rh_2(O_2CMe)_4]^+$, and the precipitation of uncharacterized solids $[Rh_2(O_2CMe)_5]$ and $[Rh_2(O_2CMe)_4Cl]$.[461] ESR and IR spectra of $[Rh_2(O_2CMe)_4]^+$ showed (within the time of the experiments) that the two Rh nuclei had identical electronic environments,[461] suggesting a $[Rh^{2.5}]_2$ formulation rather than $[Rh^{II}—Rh^{III}]$. This was supported by the X-ray photoelectron spectroscopy, which

showed a single binding energy for the Rh $3d_{5/2}$ orbitals (310.1 eV) in $[Rh_2(O_2CMe)_4]^+$, implying identical Rh atoms within the time scale of the XPS experiment.[434]

Bear and coworkers have shown that a reversible, one-electron oxidation is a general phenomenon for numerous $[Rh_2(O_2CR)_4]$ complexes (R = $C(Me)_3$, C_5H_9, Pr, Et, Me, $PhCH_2$, $MeOCH_2$, $PhOCH_2$, MeCHCl), but not when R = CF_3.[462] The oxidation potential is dependent on the nature of R, as dimers with electron-donating bridges (R = $C(Me)_3$, C_5H_9) are oxidized near 0.90 V (*versus* SCE in DMF solution) but *ca.* 1.28 V is needed to oxidize the complex with the electronegative R = MeCHCl bridge; oxidation was not observed (up to 1.7 V) for R = CF_3.[462] None of these complexes showed a second oxidation wave (up to 1.7 V), but all were irreversibly reduced (between −1.04 and −1.68 V); further electron absorption was observed, leading to uncharacterized reduction products. Again, the reduction potentials are dependent on the nature of the bridge, with complexes containing electron-withdrawing bridges the easiest to reduce. Bear showed[462] that the half-wave potentials (both oxidation and reduction) could be linearly correlated to the polar substitution parameters of Taft.[463] Bridges which effectively withdraw electron density from the Rh_2 core stabilize the higher oxidation state, making reduction of $[Rh_2(O_2CR)_4]$ easier and oxidation more difficult, while the electron-donating bridges stabilize the lower oxidation state, and the opposite trend in oxidation potentials is observed.[462] A more recent study of the one-electron oxidation of $[Rh_2(Q)_4]$ (Q = pivolate, butyrate, acetate, benzoate, methoxyacetate and chloroacetate) also found a LFER between $E_{\frac{1}{2}}$ and the Taft polar substituent parameters. Similar relationships were also observed for several 1:1 and 2:1 axially substituted adducts.[464]

Bear,[462] Bottomley[464] and Drago[359] have noted that the oxidation potential of $[Rh_2(O_2CR)_4L_2]$ is also sensitive to the nature of the axial ligands (L), and that axial coordination reduces the oxidation potential of the dimer. Increases in the σ donor strength (as mesured by pK_{BH^+}) of the axially bonded ligand should destabilize the d_{z^2} molecular orbital, leading to the observed cathodic shift in oxidation potential. Adduct stabilization of the cation was supported by estimates of the equilibrium constants for the reactions shown in equations (98), for L = py, and (100) as K_1 and K_2 (8.20 and 4.38) were three orders of magnitude less than for the analogous reactions involving the cation ($K_1^+ \approx 11$, and $K_2^+ \approx 8$).[464] The electrochemical reactions observed for $[Rh_2Q_4]$ can be summarized in equation (101).

$$[Rh_2(buty)_4]^+ \underset{-L}{\overset{K_1^+}{\rightleftharpoons}} [Rh_2(buty)_4L]^+ \underset{-L}{\overset{K_2^+}{\rightleftharpoons}} [Rh_2(buty)_4L_2]^+ \qquad (100)$$

$$[Rh_2Q_4]^+ \overset{1e^-}{\rightleftharpoons} [Rh_2Q_4] \overset{1e^-}{\rightleftharpoons} [Rh_2Q_4]^- \overset{ne^-}{\rightleftharpoons} \text{products?} \qquad (101)$$

Cannon and co-workers have used stopped-flow techniques to study the kinetics and thermodynamics of axial substitutions at $[Rh_2(O_2CMe)_4]^+$.[485] Their results are summarized in Table 22. The monoadduct $[Rh_2(O_2CMe)_4Br]$ was detected by rapid scanning stopped-flow spectrophotometry, with λ_{max} between 520 and 530, and between 790 and 800 nm. Oxidation of $[Rh_2(O_2CMe)_4]$ by Cl_2 (reaction 5 in Table 22) is independent of $[H^+]$ and $[Cl^-]$, indicating that Cl_2 (not HOCl or OCl^-) is the actual oxidizing agent.[465] Rates of reduction of $[Rh_2(O_2CMe)_4]^+$ with cationic reductants (to hinder the inner-sphere path) vary between 10.7 $M^{-1}s^{-1}$ with Fe^{2+}, to 6.0×10^4 $M^{-1}s^{-1}$ for Ce^{4+}.[466] Marcus analysis of these electron transfer rates allowed Cannon to estimate the rate of self-exchange between $[Rh_2(O_2CMe)_4]$ and $[Rh_2(O_2CMe)_4]^+$ (equation 102) at $k = 16\,M^{-1}s^{-1}$.[466]

$$[Rh_2(O_2CMe)_4] + [Rh_2(O_2CMe)_4]^+ \rightleftharpoons [Rh_2(O_2CMe)_4]^+ + [Rh_2(O_2CMe)_4] \qquad (102)$$

Bear, Kadish and co-workers have led a recent burst of activity centered on the electrochemical behavior of Rh^{II} dimers bridged by trifluoroacetamide (tfaa = $HN(O)CCF_3$). First prepared *via* bridge exchange[375] with $[Rh_2(O_2CMe)_4]$, $[Rh_2(tfaa)_4]$ undergoes one-electron oxidation between +0.91 V and +1.08 V (*vs.* SCE) in a variety of non-aqueous solvents.[375,467] The oxidations are reversible in $MeNO_2$, RCN (R = Ph, Me, Pr), acetone, THF and DMF, but are not reversible in

Table 22 Kinetic and Thermodynamic Parameters (From ref. 465)

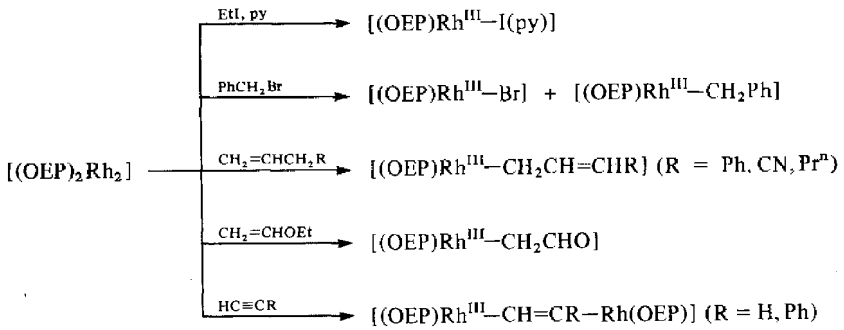
Reaction	k_f ($M^{-1}s^{-1}$)	k_{rev} (s^{-1})	K
$[Rh_2(O_2CMe)_4]^+ + Cl^- \rightleftharpoons [Rh_2(O_2CMe)_4Cl]$	$4.7(\pm 1.6) \times 10^3$	60 ± 14	80
$[Rh_2(O_2CMe)_4]^+ + Br^- \rightleftharpoons [Rh_2(O_2CMe)_4Br]$	$16.4(\pm 0.5) \times 10^3$	18 ± 3	890
$[Rh_2(O_2CMe)_4Br] + Br^- \rightleftharpoons [Rh_2(O_2CMe)_4Br_2]^-$	—	—	150
$[Rh_2(O_2CMe)_4Br_2]^- \rightleftharpoons [Rh_2(O_2CMe)_4]^+ + Br_2^-$	6.0×10^2	—	—
$[Rh_2(O_2CMe)_4] + Cl_2 \rightleftharpoons [Rh_2(O_2CMe)_4]^+ + Cl_2^-$	120	—	—

py or MeCN/py solutions; in py, the K_{form} of $[Rh_2(tfaa)_4(py)]$ is *ca.* 250, implying that the irreversibility is due to a rapid reaction of the oxidized 1:1 py adduct, although 'the exact nature of the irreversibility has not been identified'.[467] Unlike the acetate-bridged dimers, the tfaa dimers are not reduced at potentials as low as -1.9 V. Electrochemical oxidation of $[Rh_2\{NH(O)CCF_3\}_4]$ contrasts with the behavior of the trifluoroacetate analog, which could not be oxidized electrochemically. The generalization—electron-withdrawing bridges destabilize the cationic species, making the oxidation potential more positive, while electron-donating bridges make oxidation less difficult—applies here, as the effect of the electron-donating nitrogen offsets the electron-withdrawing effects of the CF_3 group. The net effect is that the oxidation behavior of $[Rh_2(tfaa)_4]$ compares to that of $[Rh_2(O_2CEt)_4]$.[467]

This generalization was further explored in a study of the electrochemistry of the five dimers $[Rh_2(O_2CMe)_n(HN(O)CMe)_{4-n}]$ ($n = 0$, 1, 2, 3, 4).[384,468] Prepared by bridge exchange with $[Rh_2(O_2CMe)_4]$ and separated by HPLC, the oxidation potentials vary linearly with the number of amidate ligands. In acetonitrile solution the oxidation potential of $[Rh_2(O_2CMe)_4]$ is $+1.19$ V (*vs.* SCE), and is reduced by 0.25 ± 0.04 V for each amidate ligand which replaces an acetate; oxidation of $[Rh_2\{NH(O)CMe\}_4]$ occurs at 0.15 V.[384] All of the oxidations are reversible (or 'quasi-reversible'), and a second oxidation wave was observed for $[Rh_2(O_2CMe)\{NH(O)CMe\}_3]$ and $[Rh_2\{NH(O)CMe\}_4]$ at 1.65 and 1.41 V respectively. Study of the mixed acetate–amidate complexes (where $n = 0$ and 1) in the presence of various axial ligands and in different solvent systems supports the existence of a π interaction between the Rh_2 core and potential π acceptors such as DMSO and PPh_3. The sensitivity of the orbital structure to the nature of the bridging ligands is emphasized by the observation that the nature of the HOMO changes as n goes from 0 ($[Rh_2(O_2CMe)_4]$) to 1 ($[Rh_2(O_2CMe)_3\{NH(O)CMe\}]$).[368]

The effects of *N*-substituted phenyl groups has also been explored in electrochemical studies of $[Rh_2\{PhN(O)CMe\}_4]$.[376,469] Bridge exchange from $[Rh_2(O_2CMe)_4]$ followed by HPLC separation leads to a green isomer, identified by NMR analysis as the 3:1 isomer (see Section 48.5.2.1.ii), and a blue isomer, a 1:1 water adduct of unknown geometry. Both complexes undergo two reversible one-electron oxidations. The oxidations ($+0.55$ and $+1.65$ V (*vs.* SCE) for the blue isomer; $+0.53$ and $+1.63$ V for the green form) are separable in CH_2Cl_2, MeCN and PrCN, and the two-electron oxidation product is stable within the time of the cyclic voltammetry experiment, although a slow reaction to Rh^{III} products occurs. This suggests the interesting possibility that with very electron-donating bridges, stable Rh_2^{III} species might be prepared.[469]

(*iii*) *Miscellaneous reactions of Rh^{II} dimers*



One obvious reaction of Rh^{II} dimers which has been little explored is the cleavage of the Rh—Rh bond. Taube suggested that the slight paramagnetism of $Rh_{2(aq)}^{4+}$ may be due to the dimer $\rightleftharpoons$ 2(monomer) equilibrium,[362] but the small paramagnetism (μ_{eff} near 0.5 BM) of tetraacetatodirhodium(II) complexes,[407] where Rh—Rh bond cleavage is unlikely, led Taube to suggest[289] that the paramagnetism of $Rh_{2(aq)}^{4+}$ is due to some other phenomenon. Espenson has shown that flash or continuous photolysis (visible irradiation) of $[Rh_2(DMG)_4(PPh_3)_2]$ homolytically cleaves the Rh—Rh bond, generating the $[Rh(DMG)_2PPh_3]$ radical monomer.[470] This monomer may play an important role in $FeCl_3$ oxidation of $[Rh_2(DMG)_4(PPh_3)_2]$ (equation 103) as the reaction is first order in $[Rh_2^{4+}]$ and zero order in $[Fe^{3+}]$ ($\Delta H^{\ddagger} = 85.6 \pm 2.6$ kJ mol^{-1}, $\Delta S^{\ddagger} = 19.2 \pm 7.7$ J K^{-1} mol^{-1}), implying that the reaction proceeds *via* rate-determining cleavage of the Rh—Rh bond, followed by rapid oxidation of the resulting radical monomers.[470] For the reaction (dimer) $\rightleftharpoons$ 2(monomer), Espenson estimated that $K \approx 1.5 \times 10^{-10}$, with $\Delta H^{\circ} \approx 86$ kJ mol^{-1} and $\Delta S^{\circ} \approx 100$ J K^{-1} mol^{-1}. Ignoring solvent effects, this ΔH° value is an estimate of the Rh—Rh bond dissociation energy when the Rh—Rh bond distance is 2.97 Å; in Rh metal, the Rh—Rh bond is 2.68 Å long, with a bond energy of 93 kJ mol^{-1}.[471]

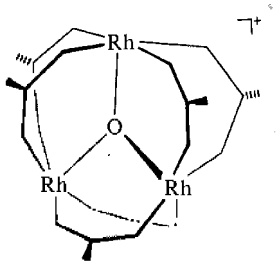
$$[Rh_2(DMG)_4(PPh_3)_2] + 2FeCl_3 \longrightarrow 2[Rh(DMG)_2(PPh_3)Cl] + 2FeCl_2 \qquad (103)$$

There are scattered reports of the catalytic activity of Rh^{II} dimers, although this field is dominated by the thoroughly studied catalytic activity of Rh^{I} monomers. Rempel and coworkers investigated the $[Rh_2(O_2CMe)_4]$-catalyzed hydrogenation of terminal alkenes, substituted ethylenes and ethylene in DMF solution,[472] and found that only one of the Rh atoms is involved in the reaction, which is proposed to proceed *via* a hydride complex. Hydrogenation activity has been reported for $[Rh_2(phen)_2(O_2CMe)_2Cl_2]$,[389] and Rh^{II} (and Pd^{II}) carboxylates efficiently catalyze the cyclopropane

tion of alkenes by diazoesters.[473] A more thorough discussion of the catalytic activity of Rh^{II} dimers is in the companion series.[17]

The unbridged $[Rh_2(OEP)_2]$ undergoes a variety of reactions with substituted hydrocarbons in which the Rh—Rh bond is cleaved, and organometallic Rh^{III} complexes are formed. Several such reactions are represented in Scheme 13.[409] These reactions are intimately tied to reactions of Rh^{III} OEP complexes, discussed in Section 48.6.2.7.

Scheme 13



Interest in the chemistry of tetracarboxylate Rh^{II} dimers has doubtless been spurred by the observation that $[Rh_2(O_2CMe)_4]$ has shown antitumor activity against L1210 leukemia and Ehrlich ascites tumors in mice.[385,474–478] The rate of formation and the stability of 1:1 adducts in $[Rh_2(Q)_4]$ follows the order Q = propionate > Q = acetate > Q = methyl acetate, paralleling their antitumor activity.[441–443] Preliminary screening of the cyclophosphamide adducts of the tetrapropionate and tetrabutyrate dimers indicate that the complexes are inactive.[323]

48.5.2.4 Miscellaneous polynuclear complexes of Rh^{II}

Coordination complexes with more than two Rh^{II} are relatively rare. Numerous Rh-bridged (bridge = 1,3-diisocyanopropane) polynuclear species, and other organometallic clusters, involving Cp, CO (often as bridges), and phosphine ligands have been characterized. These have been efficiently reviewed by Felthouse[282] and are outside the scope of this report. Haines has reported the structure of a unique dimer containing Rh^{II}, $[Rh_2(CO)(L)_2Cl_2]\cdot 2CHCl_3$ (L = $(PhO)_2PN(Et)$-$P(OPh)_2$— a neutral symmetric diphosphorus bridge),[479] which nicely evades classification. One of the Rh atoms is in a square planar environment, coordinated to two mutually *cis* phosphite bridges, a CO and the other Rh atom; it has bond lengths and a coordination geometry characteristic of Rh^0. The other Rh is five coordinate, being bonded to two mutually *cis* phosphite bridges, two *cis* chlorines, and the other Rh atom. Its geometry and bond distance are characteristic of Rh^{II}. The Rh^0—Rh^{II} bond distance of 2.661 Å is well within the range observed for the more traditional Rh^{II} dimers.

An interesting compound, prepared by the ozonization of $[Rh_2(O_2CMe)_4]$, and formulated as $[Rh_3(O)(O_2CMe)_6(H_2O)_3]ClO_4$ was reported by Wilkinson and coworkers.[454] On the basis of electronic, IR and NMR spectra, they proposed a Rh_3O core; such M_3O cores were then known for Cr,[480] Mn,[481] Fe[480a,482] and Ru.[483] The same trimer was also prepared by reacting $RhCl_3\cdot 3H_2O$ with AgO_2CMe, and was shown to be isomorphous with the Cr analog.[484] A single crystal X-ray structure confirmed the presence of the planar Rh_3O core with the Rh atoms in an almost equilateral triangle around the central O atom (**43**).[455] While formally a Rh^{III} trimer, assuming a central O^{2-}, it is instructive to compare this structure to the numerous structures of Rh^{II} dimers discussed in Section 48.5.2.1. Each Rh pair in the trimer is bridged by two acetate groups, but the average Rh—Rh distance (3.33 Å) precludes the possibility of strong Rh—Rh interaction. The average distance between the Rh and the O atom of the bridging acetates (2.020 Å) is similar (even a bit shorter) than that observed in $[Rh_2(O_2CMe)_4(H_2O)_2]$ (2.039 Å[297]) despite a Rh—Rh distance which is almost 1 Å longer in the trimer. This is dramatic evidence that the acetate is a most accommodating bridge,[303] and that the C—O—Rh bond is flexible, expanding from *ca.* 119.5° in the dimer to *ca.* 132° in the trimer. Such clear evidence of flexibility confounds the problem of explaining why the Rh—Rh bond is so consistently short in the tetracarboxylate dimers, as the carboxylate bridges do not appear to be all that constraining. The average Rh—OH_2 distance in the trimer (*ca.* 2.13) is significantly

shorter (*ca.* 0.18 Å) than the Rh—O_{ax} distance in $[Rh_2(O_2CMe)_4(H_2O)_2]$, or in any of these axially bonded dimers. In the trimer, the Rh—OH_2 bond is not *trans* to a Rh—Rh bond, while the characteristically long Rh—O bonds in the dimers are directly *trans* to a Rh—Rh bond, clearly illustrating the often-cited *trans* influence of the Rh—Rh bond.

(43)

48.6 RHODIUM(III) COMPLEXES

48.6.1 Group IV Ligands

48.6.1.1 Cyano complexes

The hexacyanorhodate(III) anion was first prepared by the fusion of $[Rh(NH_3)_5Cl]Cl_2$ with KCN,[485] and Schmidtke prepared it by reacting $RhCl_3 \cdot 3H_2O$ with a five-fold excess of CN^-; aqueous KCN workup of the resulting '$Rh(CN)_3 \cdot 3H_2O$' leads to $K_3[Rh(CN)_6]$.[486] Wilkinson and co-workers reported that the reaction of an aqueous solution of CN^- with $[Rh(CO)_2Cl]_2$ leads to $[Rh(CN)_4(H)(H_2O)]^{2-}$,[487] but Jewsbury later identified the product as $[Rh(CN)_5(H)]^{3-}$.[488] An intermediate in this reaction was said to be polymeric $[Rh(CO)_2CN]_n$,[487] while Jewsbury later spoke of $[Rh(CO)_2(CN)Cl]^-$, *trans*-$[Rh(CO)_2(CN)_2]^-$ and $[Rh(CO)(CN)_3]^{2-}$ as intermediates in the same reaction.[488] A stopped-flow kinetic study of the reaction of CN^- with $[Rh(CO)_2Cl]_2$ indicated that successive CN^- substitutions lead to the tetracyanorhodate(I) anion, $[Rh(CN)_4]^{3-}$, which then undergoes oxidative addition with HCN to give $[Rh(CN)_5(H)]^{3-}$.[489] In the presence of MeI, pentacyanoalkylrhodium complexes are formed.[489]

The $[Rh(CN)_5(H)]^{3-}$ anion forms adducts with O_2, NO_2 and C_2F_4, although the nature of the oxygen adduct has been disputed.[487,490] Reaction of *trans*-$[Rh(py)_4Cl_2]Cl$ with excess KCN in boiling water gives a yellow solid, identified as the first mixed cyano complex of Rh^{III}, $[Rhpy_2(CN)_2Cl] \cdot 2H_2O$. Its insolubility in a variety of solvents and its IR spectrum suggest that it is a cyano-bridged dimer.[491]

Gray and co-workers showed that photolysis (254 nm) of $[M(CN)_6]^{3-}$ (M = Rh, Ir) in acidic aqueous solution leads directly to $[Rh(CN)_5(H_2O)]^{2-}$, and even extended photolysis leads to the loss of only one CN^-.[492] Thermal anation of the resulting aquapentacyanorhodate(III) anion provides a convenient synthetic path to $[Rh(CN)_5X]^{n-}$ (X = Cl^-, Br^-, I^-, OH^- and NCMe). The electronic spectra of the resulting complexes are given in Table 23; the spectrum of the $[Rh(CN)_6]^{3-}$ ion has

Table 23 Electronic Spectra of some Cyano Complexes of Rh^{III} (from Ref. 492)

Complex	λ_{max} (nm)(ε)	*Assignment*
$K_3[Rh(CN)_6]$	260sh (170)	$^1A_{1g} \rightarrow (^3T_{1g}, {}^3T_{2g})^a$
	225 (555)	$^1A_{1g} \rightarrow {}^1T_{1g}$
$K_2[Rh(CN)_5NCMe]$	245 (550)	$^1A_{1g} \rightarrow {}^1E^a$
$[Rh(CN)_5H_2O]^{2-}$	265 (605)	$^1A_{1g} \rightarrow {}^1E^a$
$[Rh(CN)_5OH]^{3-}$	258 (500)	$^1A_{1g} \rightarrow {}^1E^a$
$K_3[Rh(CN)_5Cl]$	277 (425)	$^1A_{1g} \rightarrow {}^1E^a$

$K_3[Rh(CN)_5I]$	313 (1500)	$^1A_{1g} \rightarrow {}^1E^a$
	258 (4200)	π-LMCT
	220 (42 000)	σ-LMCT

[a] Also assigned[494] to $[Rh(CN)_5(H_2O)]^{2-}$ contamination.

been the source of some controversy.[486,493-495] Schmidtke[486] originally assigned the 225 nm band to the spin-allowed $^1A_{1g} \rightarrow {}^1T_{1g}$ transition, and the weak shoulder at 260 nm to the spin-forbidden $^1A_{1g} \rightarrow ({}^3T_{1g}, {}^3T_{2g})$ transition. Gray and co-workers agreed[494] with the 225 nm band assignment, but suggested that the ill-defined shoulder near 260 nm, as well as the 325 nm (initially thought to be the $^1A_{1g} \rightarrow {}^1T$ band[494]), is due to contamination by the $[Rh(CN)_5(H_2O)]^{2-}$ ion.[492]

48.6.1.2 Miscellaneous group IV complexes

Acyl chlorides oxidatively add to $[RhCl(L)_3]$ (L = PMe_2Ph) to generate $[RhCl_2(COR)L_3]$ (R = Me or Et).[496] In the absence of oxygen, reaction of $[RhCl_2(COR)L_3]$ with NH_4PF_6 gives a square pyramidal Rh^{II} acyl salt $[RhCl(COR)L_3][PF_6]$ with an apical acetyl group.[496] In the presence of oxygen, however, the same conditions lead to a dirhodium, triply-chloro-bridged acetyl Rh^{III} cation $[Rh_2Cl_3(COR)_2L_4]PF_6$.[497] A single-crystal X-ray structure of this dimer shows both rhodiums to be octahedrally coordinated by three shared chlorides, two phosphines and the carbon atom of the acetyl group. The *trans* influence of the acyl group is apparent, as the Rh—Cl bond distance for the Cl *trans* to the acyl group is significantly longer (about 0.2 Å) than those *trans* to the phosphines. The long (3.328 Å) Rh—Rh distance suggests there is no metal–metal bond. A mechanism for the formation of the dimer, involving the dimerization of an unisolated $[RhCl(L)_2(Me)(CO)]^+$ ion, is proposed.[497]

The $SnCl_3^-$ moiety acts as a monoanionic ligand toward Rh^{III}, forming complexes with Rh—Sn bonds. Following the method of Kimura *et al.*,[498] $Cs_3[RhCl_4(SnCl_3)_2]$ and $(Me_4N)_3[RhX_n(SnX_3)_{6-n}]$ (X = Cl, Br; n = 1, 2, 3) have been prepared and characterized by conductivities, far IR spectra (Rh—Sn stretches found near 210 cm^{-1}), ^{119}Sn Mössbauer spectroscopy and by their reactions with water and iron(III) ion.[499] All of the complexes are diamagnetic, and SnX_3^- shows a strong *trans*-labilizing effect. Mössbauer spectra show a significant decrease in the density of the 5*s* electrons at the Sn^{II} atoms, suggesting σ donation to the Rh center, while the quadrupole splitting suggests the SnX_3^- ligand is also a π acceptor.[499] The three anions $[RhCl_{6-m}(SnCl_3)_m]^{3-}$ (m = 1, 2 or 3), have been studied by ^{119}Sn NMR spectroscopy. The ^{117}Sn satellite peak intensity is directly related to the number of coordinated tin atoms, and these satellites also reveal that fast intramolecular scrambling of the ligand occurs.[500] Reaction of these Rh^{III} complexes with a six-fold excess of Sn^{II} leads to a Rh^I complex with five Sn^{II} ligands.

The reaction of DMF with HCl solutions of $RhCl_3 \cdot 3H_2O$ in the presence of excess $SnCl_2$ leads to a Rh^{III} complex with one hydrido ligand, and four equivalent (by ^{119}Sn NMR) $SnCl_2$DMF ligands. Occupancy of the sixth coordination site is uncertain.[501] An X-ray analysis of blue-violet crystals of the composition $[RhL_6][Rh(SnCl_3)_4(SnCl_4)][SnCl_6] \cdot 4H_2O$ (L = NH_3 or 0.5 en) has been presented;[502] such salts have been used as hydrogenation or alcohol dehydrogenation catalysts. An X-ray analysis of $Cs_4[RhSn_6F_{19}(H_2O)_6]$ has shown that the structure consists of Cs^+ ions, H_2O molecules and $[Rh\{SnF_2(H_2O)_2\}_2[Sn_4F_{15}\}]^-$ anions.[503] The Rh atom is coordinated to the six Sn atoms, with the two mutually *cis* $SnF_2(H_2O)_2$ groups, and a tetradentate Sn_4F_{15} group held together by fluoride bridges between the 4 Sn atoms.

48.6.2 Nitrogen Ligands

48.6.2.1 Monodentate amines

(*i*) *Pentaammine complexes*

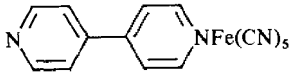
Complexes of the form $[Rh(NH_3)_5X]^{n+}$ have been studied and restudied for many years, and the work continues. Firmly bonded to the Rh^{III}, the five ammines are thermally quite inert, leaving the sixth site for ligand substitution studies. Numerous thermodynamic and kinetic studies of ligand substitutions have been reported and the reactivity at the sixth site is generally, but not always, between Co and Ir. Ligands at the sixth site are often susceptible to photoinduced substitution, but not to redox processes, making $[Rh(NH_3)_5X]^{n+}$ complexes popular candidates for photochemical studies.

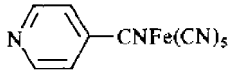
(*a*) *Synthesis and characterization.* The starting material for this family of complexes is almost always the yellow $[Rh(NH_3)_5Cl]Cl_2$, initially prepared by Vauquelin[2] and Claus[3] but most modern references are to the methods of Johnson and Basolo[504] or Wilkinson and co-workers.[505] The former

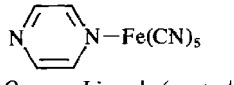
is adapted from the method of Lebedinski,[506] and involves the direct reaction of $RhCl_3 \cdot 3H_2O$ with $(NH_4)_2CO_3/NH_4Cl$ in aqueous solution (equation 104). This leads to chloride salts of the chloropentaammine and dichlorotetraammine cations, but these are easily separated as $[Rh(NH_3)_5Cl]Cl_2$ is insoluble in cold water, while the dichlorotetraammine is quite soluble.[504] The latter synthesis takes advantage of the ability of reducing agents to catalyze substitutions at Rh^{III} centers (Section 48.6.2.5.iii), as an aqueous ethanolic solution of $RhCl_3 \cdot 3H_2O$ reacts rapidly with aqueous NH_3 to generate, in 80% yields, pure $[Rh(NH_3)_5Cl]Cl_2$.[505]

$$RhCl_3 \cdot 3H_2O + (NH_4)_2CO_3/NH_4Cl \xrightarrow[\Delta]{H_2O} [Rh(NH_3)_5Cl]Cl_2 + [Rh(NH_3)_4Cl_2]Cl \qquad (104)$$

Generation of other pentaammines $[Rh(NH_3)_5X]^{n+}$ generally involves simply heating an aqueous solution containing $[Rh(NH_3)_5Cl]^{2+}$ and an excess of X. Direct substitution of the chloride, without significant ammine labilization, is the rule, although a claim has been made that heating solid $[Rh(NH_3)_5Cl]Cl_2$ to 296°C causes ammine labilization, cleanly yielding $[Rh(NH_3)_4Cl_2]Cl$.[507] This was later questioned, as significant decomposition, yielding Rh metal and N_2 gas, was also observed under these harsh conditions.[508]







The chloride is readily removed by boiling a solution of $[Rh(NH_3)_5Cl]Cl_2$ with Ag^+ (usually as the nitrate or perchlorate salt), generating $[Rh(NH_3)_5(H_2O)]^{3+}$ and the easily removed AgCl; the aquapentaamminerhodium(III) cation can then be isolated, if desired, as the perchlorate salt.[509] The coordinated water is weakly acidic (cited pK_a values range from 6.14[510] to 6.24 in 0.47 M $NaClO_4$,[511] to 6.93 in 1.0 M $NaClO_4$[512]), and the free energy, enthalpy and entropy of neutralization are similar to those for the Co^{III} analog.[513] Replacement of the coordinated water proceeds more readily than removal of the chloride (the mechanisms of such direct anations are discussed below). The coordinated oxygen atom is also a reaction site in itself, and some of the apparent anations involve oxygen attack, and do not involve cleavage of the Rh—O bond (*e.g.* reaction with CO_2 to yield CO_3^{2-},[514,515] SO_2 to yield SO_3^{2-},[516] NO_2^-[517] and acetate[518]). These reactions are also discussed below.

A variety of ligands have occupied the sixth site of the pentaamminerhodium(III) moiety. The electronic absorption spectra for many of the resulting complexes are recorded in Table 24. Some of the more unusual and/or useful ligands merit mention here. Reduction of $[Rh(NH_3)_5Cl]^{2+}$ with BH_4^-[536] has been reported to yield the monohydrido complex $[Rh(NH_3)_5H]^{2+}$, although later reports say that reduction with Zn in ammonia is a more convenient preparative route.[505,541] The hydride ligand has a strong *trans*-labilizing effect, so the hydridopentaamminerhodium(III) cation is a convenient starting material for the synthesis of a variety of complexes, as both H^- and NH_3 labilization can be effected.[542]

The conjugate base of trifluoromethanesulfonic acid, $OSO_2CF_3^-$, nicknamed 'Triflate', is becoming a popular ligand as it is an excellent leaving group. If $[Rh(NH_3)_5Cl]Cl_2$ is heated (90–110°C) in neat trifluoromethanesulfonic acid, the chloride-free solid, identified as $[Rh(NH_3)_5(OSO_2CF_3)](OSO_2CF_3)_2$, is generated. The ^1H NMR spectrum shows two peaks in a 4:1 ratio (3.16 p.p.m. *vs.* 3-(trimethylsilyl)propanesulfonate for the *cis* protons, and 2.90 p.p.m. for the *trans* protons), and the electronic spectrum (Table 24) suggests that the triflate ligand exerts a weak ligand field.[539] Its uses as a leaving group were demonstrated by Taube and co-workers,[543] who reacted $[Rh(NH_3)_5(OSO_2CF_3)]^{2+}$ with $[Os(NH_3)_5(pyrazine)]^{3+}$, and isolated the pyrazine-bridged $[(NH_3)_5Rh(pyrazine)Os(NH_3)_5]Cl_6$. Triflate's versatility was shown by Jackman and co-workers,[544,545] who reacted a DMF solution of $[Rh(NH_3)_5(OSO_2CF_3)]^{2+}$ with acetic anhydride in the presence of *N,N*-dimethylbenzylamine (DMB). The resulting acetylation, forming acetatopentaamminerhodium(III), is thought to proceed in two steps, with the basic DMB initially reacting with the triflate ligand, to generate the hydroxo complex, which then rapidly reacts with the acetic anhydride to form the acetatopentaamminerhodium(III) cation.

The hexaammine can be prepared by heating $[Rh(NH_3)_5Cl]Cl_2$ dissolved in concentrated aqueous ammonia in a sealed tube at 100°C for several days.[519,546,547] Detailed IR studies of the deuterated hexaammine,[548] and of $[Rh(NH_3)_6]^{3+}$ as the GaF_6^{3-}, ScF_6^{3-}[549] and MnF_6^{3-}[550] salts provide evidence of significant hydrogen bonding between the ammine hydrogens and the hexafluorometalate anions. Emission studies of crystalline powders of $[Rh(NH_3)_6][Rh(CN)_6]$, and the deuterated analog, suggest that the luminescent $^3T_{1g}$ excited state exhibits Jahn–Teller distortions.[551] An alternative route to the hexaammine involves the acid hydrolysis of $[Rh(NH_3)_5(NCO)]^{2+}$;[520] the details of this reaction and the synthesis of a series of organonitrilepentaammineRh(III) complexes are discussed below.[528]

Photolysis of $[Rh(NH_3)_5(N_3)]^{2+}$ can be used to generate $[Rh(NH_3)_5(NH_2Cl)]^{3+}$, or the NH_2OH analog;[522,523] the proposed mechanisms are discussed in Section 48.6.2.3.

One of the more unusual pentaamminerhodium(III) complexes was reported by Wieghardt,[552] who reacted the monodentate oxalatopentaamminerhodium(III) cation with $[Co_2(\mu\text{-}OH)_3(NH_3)_6]^{3+}$ to generate the $[Co_2Rh]^{5+}$ trimer, isolated as the bromide salt (**44**). IR spectra in the C—O stretching region for several oxalatopentaamminerhodium(III) complexes, and the deuterated analogs, are also recorded.[552]

(44)

The ^1H NMR spectra of a variety of $[Rh(NH_3)_5X]^{n+}$ ions dissolved in concentrated H_2SO_4 show only one ammine proton peak, at −3.82, −4.13, −3.78 and −3.65 p.p.m. (*vs.* external TMS) for $X = NH_3$, HSO_4^-, Cl^- and Br^- respectively.[547] The Ir analogs also have only one ammine resonance, but the Co species display two peaks in the expected 4:1 ratio. Neither intraligand nor proton exchange with the solvent could be used to explain the missing peaks; the magnitude of the 'diamagnetic' and 'paramagnetic' shielding in the heavier metals was cited to account for the single peak in the Rh and Ir cases. This is not a universal phenomenon, however, as other $[Rh(NH_3)_5X]^{n+}$ complexes do show two ammine peaks in the expected 4:1 ratio.[539]

(b) Reactions of $[Rh(NH_3)_5X]^{n+}$. The aquation and anation of $[Rh(NH_3)_5X]^{n+}$ in acidic aqueous solution (equation 105), was first studied by Lamb[553] who used conductance changes to monitor the 'interconversion of acido and aqua rhodium complexes', for the chloro and bromopentaammine-rhodium(III) cations. He found that both aquation and anation are first-order in $[Rh^{III}]$, and that the hydrolysis is accelerated by the presence of OH^-. The forward form of equation (105) (aquation) has since been studied for $X = Cl^-$,[554,556] Br^-, I^-,[531,556] OH_2,[557–559] SO_4^{2-},[560] NO_3^-[561] and N_3^-.[562] Representative results for the aquation of various pentaammine salts are given in Table 25. For aquations of halides or nitrate ions, rate expressions which are first-order in [Rh] and zero-order in $[H^+]$ are found. Poë[531] gives a detailed discussion of the thermodynamic, kinetic and intrinsic-kinetic *trans* effects, and compares the aquation and anation of $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br and I) with the $[Rh(en)_2XY]^+$ system. When $X = SO_4^{2-}$, a two-term rate expression was observed

$$[Rh(NH_3)_5X]^{n+} + H_2O \overset{H^+}{\rightleftharpoons} [Rh(NH_3)_5H_2O]^{3+} + X^{(3-n)-} \qquad (105)$$

(rate $= k_1 + k_2[H^+]$), implying significant acid catalysis as well as the normal, first-order aquation.[560]

The reverse of equation (105), the anation of aquapentaamminerhodium(III), has also been extensively studied. After Lamb's initial observations,[553] the first detailed study was reported by Poë and co-workers (for $X = Cl^-$, Br^-, I^- and NCS^-),[531] but was quickly followed by anation studies for $X = Cl^-$,[531,555,565] Br^- and SO_4^{2-},[565] propionate,[538] oxalate,[535] NO_3^- and $MeCOO^-$.[566] The results are summarized in Table 26. Interpretation of the kinetic results is complicated by unavoidable interference from ion-pairing, and while some differences exist, most systems showed: (a) ΔS^* values near zero; (b) rates which are less than, or comparable to, the rates of water exchange; and (c) rates which depend on the ionic strength and the nature of the nucleophile. The general consensus of these workers is that anation of pentaamminerhodium(III) complexes is associative in nature, and while not purely associative, the anations, and by implication the aquations, are probably more associative than the analogous reactions of $[Co(NH_3)_5(H_2O)]^{3+}$; the I_a designation is the most commonly used description. In the oxalate system, vanEldik points to the very negative values for ΔS^* (Table 26), the similarity in rates of anation by $H_2C_2O_4$, $HC_2O_4^-$ and $C_2O_4^{2-}$, and their relative unreactivity

when compared to anation by halides, sulfate, azide, *etc.*, to argue that a different mechanism (he suggests I_d) is operating during oxalate anation.[537]

A powerful technique for exploring the mechanisms of such ligand replacements is the determination of the volume of activation, ΔV^*, by monitoring the effect of pressure on the reaction rate. Swaddle first reported the ΔV^* for the water exchange of aquapentaamminerhodium(III) had a negative value ($-4.1 \pm 0.4\,cm^3\,mol^{-1}$),[563] comparable to values determined for aqua exchange at aquapentaamminechromium(III) ($-5.8\,cm^3\,mol^{-1}$) or hexaaquachromium(III) ($-9.3\,cm^3\,mol^{-1}$); such anations of Cr^{III} centers are generally thought to react *via* an associative path. The contrast to the more dissociative $[Co(NH_3)_5(H_2O)]^{3+}$ was also sharp ($\Delta V^* = +1.2\,cm^3\,mol^{-1}$), further supporting the idea that substitutions at Rh^{III} centers are more associative than those at Co^{III} (Table 27).

The effects of pressure on the kinetics of the anation of aquapentaamminerhodium(III) by Cl^- were also studied by vanEldik *et al.*[567] They assumed an ion-pairing mechanism, represented in equation (106), but could not determine K_x under the high ionic strength conditions used. They concluded that the value of K_x was 'immeasurably small', and discounted the importance of ion-pairing during the anation of aquapentaamminerhodium(III) under high ionic strength conditions. (vanEldik commented on the difficulty in distinguishing between I_a and I_d mechanisms on the basis of kinetic interpretations. At low ionic strengths, one can determine the value of K_x, but will not have enough nucleophile present to determine k; but with high ionic strengths, k, but not K_x, can be determined.) A positive ΔV^* ($+3.0 \pm 0.7\,cm^3\,mol^{-1}$) was found, similar to the values found for Co^{III} anations, but much more positive than the NCS^- anation of aquapentaamminechromium(III) ($-4.9\,cm^3\,mol^{-1}$). For the rhodium system, vanEldik disagreed with Swaddle's earlier conclusion,[563] and spoke of a 'dissociatively activated transition state'.[527]

$$[L_5RhH_2O]^{3+} + Cl^- \overset{K_x}{\rightleftharpoons} \{[L_5RhH_2O]\cdot Cl^-\}^{2+} \overset{k}{\rightleftharpoons} [L_5RhCl]^{2+} + H_2O \qquad (106)$$

Swaddle has determined the partial molar volumes[568] and reexamined the effects of pressure on the water exchange of $[M(NH_3)_5(H_2O)]^{3+}$ (M = Co, Rh, Ir and Cr).[569] The partial molar volume of the transition state, ($\Delta\bar{V}^*$) was defined to be the difference between the volume of activation and the partial molar volume of the ground state ($\Delta\bar{V}^* = \Delta V^* - \Delta\bar{V}°$). While earlier studies[563] showed that the volume of activation (ΔV^*) did vary as the central metal changed, the partial molar volume of the transition state ($\Delta\bar{V}^*$) is quite insensitive to the nature of the central metal (Table 27). Swaddle concludes that 'contrary to intuition. . . the transition states of a series of aqua exchange reactions must resemble one another surprisingly closely, regardless of detailed mechanism'.[569]

Pavelich has taken a different approach to kinetic studies of aquapentaamminerhodium(III) anations, and argues that the common practice of doing kinetic studies at high ionic strength is invalid, as ion pairing with the 'inert' electrolytes (typically perchlorates) confuses the interpretation of the results. He has presented a study of Cl^- anation of aquapentaamminerhodium(III) at low ionic strength, with the only anion added to the solution being the anating ligand. Ion-pairing was treated by potentiometric and spectral data, and was combined with kinetic data on the formation of $[Rh(NH_3)_5Cl]^{2+}$. A complex modeling analysis (to fit idealized *A*, *I* and *D* mechanisms) was used and Pavelich concluded that the reaction could most effectively be modeled assuming an interchange (*I*) path.[570] The activation parameters cited in Table 26 are based on that assumption.

It is fair to conclude that the mechanism of substitutions in acidic solution of $[Rh(NH_3)_5X]^{n+}$ has not yet been settled. The recent trend has been to question the earlier assignment of an I_a process, and to just refer to it as an interchange *I*, with less credence given to experimentally verifiable differences between I_a and I_d mechanisms.

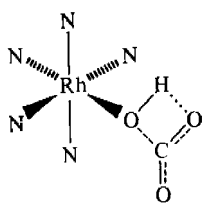
The Hg^{2+} ion induces aquation of $[Rh(NH_3)_5X]^{2+}$ (X = Cl, Br and I) and numerous kinetic studies have been presented.[572–577] The mechanisms represented in equation (107) appear to occur;

the rate of aquapentaammine formation is proportional to $[Hg^{2+}]$ for X = Cl and Br, but approaches a constant value for X = I.[573] The $[Rh(NH_3)_5I—Hg]^{4+}$ intermediate has been detected (λ_{max} at 370 nm), and the K_{form} of this intermediate at 11.4 °C is 225 ± 16.[572] At that temperature, the Hg^{2+}-induced aquation is about seven orders of magnitude faster than the spontaneous aquation, and the rate constant for the dissociation of $[Rh(NH_3)_5I—Hg]^{4+}$ is $1.26 \times 10^{10} \exp(-66\,500 \pm 5000)/RT$ (at 25 °C, $k = 2.75 \times 10^{-2}\,s^{-1}$).[573] The enthalpy of activation for the Hg^{2+}-induced aquation of the bromopentaammine complex is 32 kJ mol^{-1} lower than for the spontaneous aquation.[574] The ΔV^* is negligible (-1.0 ± 0.4 cm^3 mol^{-1}) for the Hg^{2+}-induced aquation of $[M(NH_3)_5X]^{2+}$ (M = Co, Rh, Ir; X = Cl, Br, I), suggesting that the rate-determining step is not purely dissociative, but better described as an interchange.[575,576] A $t_{2g}^5 e_g^1$ configuration for the Rh^{III} center has been suggested for the $[Rh(NH_3)_5X—Hg]^{4+}$ intermediate.[573] A full kinetic study of the Hg^{2+}-induced aquation of *trans*-$[Rh(NH_3)_4Cl_2]^+$ has also been presented;[577] the rate of release of the first chloride is significantly greater than for the second chloride.

$$[L_5RhX]^{2+} + Hg^{2+} \overset{K}{\rightleftharpoons} [L_5Rh—X—Hg]^{4+} \xrightarrow{k} [L_5Rh]^{3+} + HgX^+ \xrightarrow[H_2O]{\text{fast}} [L_5RhH_2O]^{3+} \quad (107)$$

Lamb[553] first noted that OH^- ion accelerates the hydrolysis of $[Rh(NH_3)_5Cl]^{2+}$, but the increase is not as dramatic as observed for Co^{III} complexes. Kinetic studies have revealed a rate law of the form: $k_{obs} = k_{aq} + k_{OH}[OH^-]$ for the hydrolysis of $[Rh(NH_3)_5X]^{n+}$ for X = Cl^-, Br^-, I^-,[578] SO_4^{2-},[560] NO_3^-[561] and N_3^-.[533] Isokinetic plots (E_a plotted as a function of log A) are linear for halopentaammine complexes, but the data from the base hydrolysis of $[Rh(NH_3)_5N_3]^{2+}$ are well off the line, for both Rh^{III} and Co^{III} pentaammines, suggesting the azido complexes have some unspecified 'distinguishing feature' in their mechanisms.[533] For carboxylato complexes (X = RCO_2^-), a three-term equation is needed to account for the kinetic results: $k_{obs} = k_2[OH^-] + k_3[OH^-]^2$. The third-order path (second order in $[OH^-]$) was attributed to a path involving OH^- attack of the coordinated acetate.[579] For most systems, the base-catalyzed reaction is presumed to proceed *via* the well-known dissociative conjugate-base mechanism, S_N1CB. Palmer reported that the pressure dependence of the rates of base hydrolysis of $[Rh(NH_3)_5X]^{2+}$ (X = Cl^-, Br^-, I^-, NO_3^-) are consistent with an I_d model for X = Cl and Br, although he questions the utility of trying to draw fine distinctions between I_a and I_d steps. For X = I^- the volume data suggested some ion-pairing between the I^- and the coordinatively unsaturated conjugate base, $[Rh(NH_3)_4(NH_2)]^{2+}$, while for X = NO_3^- an I mechanism was favored.[580] Table 28 summarizes some of the kinetic parameters determined for the base hydrolysis of pentaammine complexes of Rh^{III}.

The kinetics of substitutions at pentaamminerhodium(III) in ammonia solutions have been studied by Balt and Jelsma.[581–583] For the two-step reaction represented in equation (108), they invoke an associative conjugate-base mechanism (S_N2CB) as the reaction appears more associative than the Co analog.[582] A major study of the ammoniation of $[Rh(NH_3)_5X]^{2+}$ (for X = Br^- or NO_3^-) revealed a two-term rate expression, $k_{obs} = k_s + k_b[NH_4^+]^{-1}$, with ΔS^* values for the rate-determining step which are *ca.* 420 J K^{-1} mol^{-1} less than for the Co analogs, again suggesting a mechanism more associative than for Co.[583] For $[Rh(NH_3)_5(NO_2)]^{2+}$, the hydrolysis follows the pattern observed for the Co^{III} analogs, with NH_3 being released in acidic solution, and NO_2^- being released in base. This was interpreted in terms of the kinetic *trans* effect of the nitrite ion.[581] Balt concludes that the acid reaction (ammine loss) 'proceeds *via* the same mechanism in the Co^{III} and Rh^{III} complexes (*i.e.* dissociative interchange), whereas aquation with loss of NO_2^- is probably more associative for Rh^{III}.[581]



$$[Rh(NH_3)_4(OH)_2]^+ \xrightarrow[NH_{3(aq)}]{68–80\,^\circ C} [Rh(NH_3)_5OH]^{2+} \xrightarrow{112–142\,^\circ C} [Rh(NH_3)_6]^{3+} \quad (108)$$

Several of the apparent aquations and anations at the pentaamminerhodium(III) moiety have been shown to be reactions of the coordinated ligands, and do not involve cleavage of the rhodium–ligand bond. The aquation of $[Rh(NH_3)_5(RCOO)]^{2+}$ (RCOO = Ac^-, Bu^tCOO^- or CF_3COO^-) has a two-term kinetic expression, characteristic of a reaction proceeding *via* an uncatalyzed and a catalyzed path, $k_{obs} = k_{aq} + k_H[H^+]$.[518] Indirect evidence suggests that in the acid-catalyzed reaction (but not the uncatalyzed path), carbon–oxygen cleavage leads to the final aquapentaammine-rhodium(III) product.[518] More detailed kinetic studies of the uptake of CO_2[514] and SO_2[516] by aquapentaamminerhodium(III) have been presented. The reactive species in both cases is the hydroxopentaammine complex, and as shown in Table 29, the rates of decarboxylation of $[M(NH_3)_5(CO_3)]^+$ are very rapid, and virtually invariant for M = Co, Rh or Ir.[514] This mechanism is supported by volume of activation studies,[535] which also suggest that both C—O bond formation

uptake, and C—O bond cleavage during decarboxylation are approximately 50% complete in the transition state. This suggests a transition state represented by (**45**).[535]

(**45**)

The classic example of an apparent aquation/anation which does not involve cleavage of a metal–ligand bond involves the $[M(NH_3)_5NO_2]^{2+}$ ion. First reported (for M = Rh^{III}, Ir^{III} and Pt^{IV}) by Basolo and Johnson,[517] the rate of formation of $[Rh(NH_3)_5NO_2]^{2+}$ from $[Rh(NH_3)_5H_2O]^{3+}$ followed the rate expression: rate = $k[[Rh(NH_3)_5H_2O]^{2+}][NO_2^-][HNO_2]$. Such kinetic behavior is reminiscent of the nitrosation of amines, and suggests a mechanism involving NO^+ attack at the coordinated hydroxyl oxygen (equation 109–111), followed by intramolecular linkage isomerization of the resulting nitrito complex (equation 112) to the stable N-bonded nitropentaammine-

Table 29 Parameters for the Decarboxylation of $[M(NH_3)_5CO_3]^+$ (25°C, $\mu = 0.5$ M) (from ref. 514)

$$[M(NH_3)_5CO_3]^+ + H^+ \overset{K_c}{\rightleftharpoons} [M(NH_3)_5(CO_3H)]^{2+} \overset{k}{\rightleftharpoons} [M(NH_3)_5OH]^{2+} + CO_2$$

rhodium(III).[517] Aquation in acid solution of both the nitro and nitritopentaamminerhodium(III) complexes are consistent with this mechanism.[564] The nitro complex is hydrolyzed by the loss of NO^+ ion from the transition state, and the entering water is not involved in the transition state. Aquation of the nitrito complex is less straightforward, and reacts *via* a mechanism involving both mono- and di-protonated species. Results with Rh parallel the results for other pentaammine complexes (Cr, Ir and Co), confirming that these reactions do not involve cleavage of the metal —ligand bond.[564]

$$[(NH_3)_5Rh\text{-}H_2O]^{3+} \rightleftharpoons [(NH_3)_5RhOH]^{2+} + H^+ \quad (109)$$

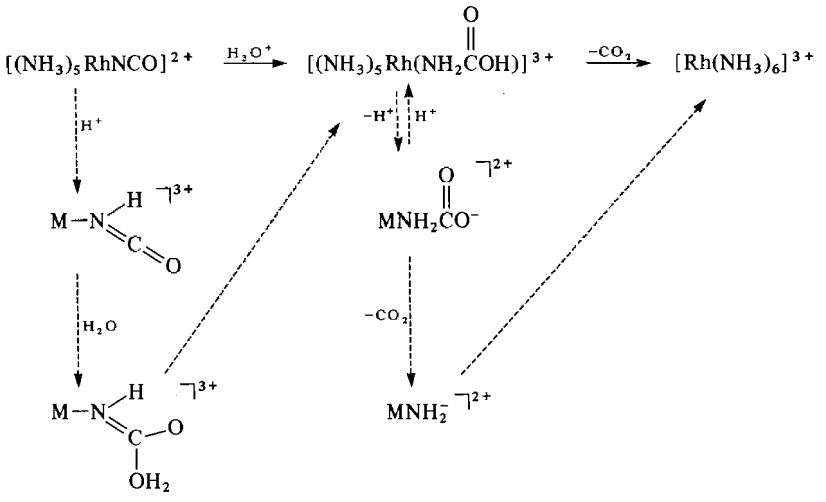
$$[(NH_3)_5Rh{-}OH]^{2+} + N_2O_3 \longrightarrow \left[(NH_3)_5Rh{-}\overset{H}{O}{-}\overset{+}{N}{-}O \;\; NO_2^-\right]^{2+} \longrightarrow [(NH_3)_5Rh{-}ONO]^{2+} + HNO_2 \quad (111)$$

$$[Rh(NH_3)_5{-}ONO]^{2+} \longrightarrow [Rh(NH_3)_5{-}NO_2]^{2+} \quad (112)$$

The spontaneous isomerization from the nitrito (—ONO) to the nitro ($-NO_2$) pentaammine-rhodium(III) complex has been well studied, and compared to the isomerizations of the analogous Co, Ir and Cr complexes. Isomerization was shown to occur in both the solid state and, about an order of magnitude more rapidly, in aqueous solution.[517] The volume of activation (ΔV^*) in aqueous solution is comparable for $[M(NH_3)_5ONO]^{2+}$ (M = Co, Ir and Rh, $\Delta V^* = -6.7$, -5.9 and $-7.4 \pm 4\,cm^3\,mol^{-1}$ respectively), which is consistent with the anticipated intramolecular isomerization.[584] The linkage isomerization is catalyzed by OH^-,[585] and by Hg^{2+}.[586] In alkaline solution, the linkage isomerization of nitritopentaamminerhodium(III) obeys the rate expression: rate = $k_s + k_{OH}[OH^-]$, and at 25°C, $k_s = 9.6 \pm 0.2 \times 10^{-4}\,s^{-1}$, $k_{OH} = 7.6 \pm 0.2 \times 10^{-3}\,M^{-1}\,s^{-1}$, $\Delta H_s^* = 85 \pm 2.5\,kJ\,mol^{-1}$, $\Delta H_{OH}^* = 96 \pm 2\,kJ\,mol^{-1}$, $\Delta S_s^* = -18 \pm 9\,J\,K^{-1}\,mol^{-1}$ and $\Delta S_{OH}^* = +38 \pm 6\,J\,K^{-1}\,mol^{-1}$.[585] For both the spontaneous and base-catalyzed paths, the rates of isomerization for the three pentaammines follow the order Rh > Co > Ir; for the base-catalyzed path the reaction rates are of the order 278:217:1, while for the spontaneous path (k_s), the relative rate constants are 32:2.3:1. The greater reactivity of the Rh complex, attributed to a lower ΔH^* for both the spontaneous and base-catalyzed paths, contrasts sharply with the order generally observed for the aquation of d^6 pentaammines. For example, for M = Co, Rh and Ir, the aquation of $[M(NH_3)_5Br]^{2+}$ in acidic solution occurs with relative rate constants of 4:1:0.001.[587] The ordering is not always Co > Rh ≫ Ir, however, as the rates of water exchange in aquapentaammine complexes in the Rh triad have relative rates of 0.53:1:0.0059,[559] and the relative rates of acid aquation of the $[M(NH_3)_5(CO_3)]^+$ ions are 1:1:0.02.[518]



Linkage isomerization has also been observed in the $[Rh(NH_3)_5(urea)]^{3+}$ ion.[521] The direct substitution of urea into $[Rh(NH_3)_5(OSO_2CF_3)]^{2+}$ in sulfolane solution leads to $[Rh(NH_3)_5(urea)]_2(S_2O_6)_3 \cdot 3H_2O$, with both N- and O-bonded ureas. Recrystallization leads to the pure O-bonded isomer. The pK_a of the N- and O-bonded isomers are 13.19 and 13.67, respectively, compared to a pK_a of about 14 for free urea. The ^1H NMR suggests that the N-bonded form is in the imidol, not the amide form (**46**). In alkaline solution, the O form isomerizes to give the deprotonated N-bonded ureapentaammine complex and $[Rh(NH_3)_5OH]^{2+}$. In acidic solution, both the N- and O-bonded forms lead to $[Rh(NH_3)_5H_2O]^{3+}$ and $[Rh(NH_3)_6]^{3+}$, with the latter complex coming from a $[Rh(NH_3)_5NCO]^{2+}$ intermediate (*vide infra*). The isomerizations and the hydrolyses of both the N- and O-bonded urea complexes showed spontaneous and base-catalyzed paths. As with the Co^{III} analog, there was no evidence for the 'substantial production of $[Rh(NH_3)_5(OOCNH_2)]^{2+}$'; formamide is the product of urease-catalyzed hydrolysis of urea, and apparently the Rh^{III} does not polarize the C—O bond to the extent of the Ni^{2+} in the urease. Formation of the hexaammine does represent a 30 000 fold increase in the rate of urea hydrolysis, and is presumed to proceed through a Rh—NCO intermediate.[521]

$$\underset{\text{imidol form}}{[(NH_3)_5Rh{-}\overset{H}{N}{=}\overset{OH}{C}{-}NH_2]^{3+}} \qquad \underset{\text{amide form}}{[(NH_3)_5Rh{-}NH_2{-}\overset{O}{\overset{\|}{C}}{-}NH_2]^{3+}}$$

(46)

This last reaction, the hydrolysis of coordinated nitriles, has been extensively studied by Ford and co-workers; acidic hydrolysis of $[Rh(NH_3)_5NCO]^{2+}$ has been used as an alternate route to the hexaammine (equation 113).[520] The reaction was shown to go through a carbamic acid intermediate, which was isolated and characterized. The kinetic study of the hexaammine formation was complicated by the presence of these two consecutive reactions, and by two different reaction paths. The mechanism proposed for the hydrolysis of the coordinated cyanate is shown in Scheme 14; at low acid concentrations (0.005 to 0.025 M) the rate determining step is H_2O attack of the protonated species leading to a rate expression which is first-order in $[H^+]$: rate $= k_1[Rh][H^+]$. At higher acid concentrations (0.2 to 1.0 M), decomposition of the carbamic acid complex is rate determining, and a more complex rate law is observed: rate $= k_0[Rh] + k_{-1}[Rh][H^+]^{-1}$. At 25°C, $k_1 = 0.62\,M^{-1}s^{-1}$ (almost four times as reactive as the Co analog, and an order of magnitude faster than the Ru analog), $k_0 = 2.1 \times 10^{-3}\,s^{-1}$, $k_{-1} = 9.6 \times 10^{-4}\,M\,s^{-1}$.[522]

$$[Rh(NH_3)_5(NCO)]^{2+} + H_3O^+ \longrightarrow [Rh(NH_3)_6]^{3+} + CO_2 \qquad (113)$$

Scheme 14

In basic solution, however, the hydrolysis of benzonitrilepentaamminerhodium(III) ion (equation 114) is two orders of magnitude slower than the Ru^{III} analog, yet still represents a major rate enhancement (about six orders of magnitude) over the rate of hydrolysis of the free ligand. For the free ligand and the benzonitrilepentaammine complexes of Ir^{III}, Rh^{III}, Co^{III} and Ru^{III}, the relative rate constants are $1, 2.9 \times 10^5, 6.5 \times 10^6, 2.5 \times 10^6$ and 2.8×10^8 respectively.[524,525] The reaction is first-order in both [Rh complex] and $[OH^-]$. The intermediate amino complex can be protonated, but only at low pH, as its pK_b is 11.8.[524]

$$[(NH_3)_5Rh{-}N{\equiv}CPh]^{3+} + OH \longrightarrow [(NH_3)_5Rh{-}\underset{\text{amido form}}{\overset{H}{N}}{-}\overset{O}{C}Ph]^{2+} \qquad (114)$$

A kinetic study of the nitrous-acid-induced aquation of $[Rh(NH_3)_5N_3]^{2+}$ indicated that the reaction cannot be interpreted in terms of a single reaction mechanism.[588] The results suggest the mechanism proposed for the Co analog. As shown in equations (115)–(119), a series of nitrous acid preequilibria is followed by attack at the coordinated azide with $\{Rh(NH_3)_5N_3, NO\}^{3+}$ proposed as a likely intermediate. The $[Rh(NH_3)_5N_3]^{2+}$ ion is a factor of four less reactive than the Co analog,[526] and at least an order of magnitude less reactive than HN_3.[589]

$$H^+ + HNO_2 \rightleftharpoons NO^+ + H_2O \qquad (115)$$

$$H^+ + HNO_2 \rightleftharpoons H_2NO_2^+ \qquad (116)$$

$$2HNO_2 \rightleftharpoons N_2O_3 + H_2O \qquad (117)$$

$$[Rh(NH_3)_5N_3]^{2+} + H_2NO_2^+ \longrightarrow [Rh(NH_3)_5H_2O]^{3+} + N_2O + N_2 \qquad (118)$$

$$[Rh(NH_3)_5N_3]^{2+} + N_2O_3 \longrightarrow [Rh(NH_3)_5H_2O]^{3+} + N_2O + N_2 + NO_2^- \qquad (119)$$

The electrochemical reduction of $[Rh(NH_3)_5OH]^{2+}$ has been studied in buffered ammoniacal solutions, and leads to a hydroperoxo species (equation 120).[590] Using a DME, $E_{\frac{1}{2}}^0 = -1.10$ V (*vs.* saturated calomel), but below pH 9.4, the pH dependence of the reduction potential led to the conclusion that a rapid proton uptake (presumably to give the aquapentaammine ion) occurs before electron transfer could occur. Gross electrolysis (−1.19 V, Hg cathode) leads to $[Rh(NH_3)_5H]^{2+}$, although a Rh^I intermediate is thought to be involved. Curtis *et al.* measured the reduction potentials of a large number of $[Rh(NH_3)_5X]^{n+}$ complexes in 0.1 M $NaClO_4$ solution and irreversible reductions occurred between −0.86 and −1.45 V.[591] Despite several references to apparent correlations between reduction potentials and numerous other physical properties of coordination complexes, Curtis could find no correlation between the reduction potentials and absorption spectra, ^1H NMR, or rates of aquation or base hydrolysis. The reduction potentials for the complexes studied are given in Table 30. Generally, the Rh^{III} complexes are *ca.* 0.8 ± 0.1 V more difficult to reduce than their Co analogs, and about 0.7 V easier to reduce than the corresponding Ir complexes. Early reports of some correlation between reduction potential and the wavelength of maximum *d–d* absorption[592,593] were assumed to be based on limited data as no such correlation could be found in this huge study involving dozens of pentaammine complexes of Co^{III}, Rh^{III} and Ir^{III}.[591] When carefully considered, the lack of such correlation is really not surprising, and is carefully rationalized by Curtis *et al.*

$$[Rh(NH_3)_5OH]^{2+} + O_2 \xrightarrow[NH_3/NH_4^+]{e^-} [Rh(NH_3)_4(OH)(O_2H)]^+ \quad (120)$$

(*ii*) *Other monodentate amine complexes*

The ubiquitous NH_3 ligand also forms a variety of tetraammine complexes, $[Rh(NH_3)_4XY]^{n+}$, but the chemistry of these complexes is closely related to that of the bis(ethylenediamine) analogs and relevant references will be included there. The acid dissociation constants for $[Rh(NH_3)_4(H_2O)X]^{n+}$ (X = NH_3, H_2O, OH^-, Cl^-, or Br^-; Table 31) have been determined from potentiometric titrations; the acidity of the coordinated H_2O can be rationalized in terms of electrostatic and σ and π bonding effects.[512] Heating solid *cis*-$[Rh(NH_3)_4(OH)(H_2O)]S_2O_6$ at 120°C for 15 hours leads to 'thermal deaquation' (equation 121) and the formation (after recrystallization from NH_4Br solution) of the bis(hydroxo) bridged salt, $[(NH_3)_4Rh(OH)_2Rh(NH_3)_4]Br_4$,[595] which is isomorphous with the well known Co^{III} and Cr^{III} analogs. The electronic spectra of these complexes, and other monodentate amine complexes not covered in the pentaammine section (Section 48.6.2.1.i), are given in Table 32.

$$cis\text{-}[Rh(NH_3)_4(OH)(H_2O)]S_2O_6 \xrightarrow{120°C,\ Br^-} [(NH_3)_4Rh(OH)_2Rh(NH_3)_4]Br_4 + 2H_2O \quad (121)$$

Monodentate amines other than NH_3 also form complexes with Rh^{III}. Edwards and co-workers prepared and characterized 12 complexes of the form $[Rh(Az)_3X_3]$, $[Rh(Az)_4X_2]^+$, $[Rh(Az)_5X]^{2+}$, $[Rh(Az)_6]^{3+}$, $[Rh(NH_3)_5Az]^{3+}$ and $[Rh(Az)_3(H_2O)_2(OH)]^{2+}$, where Az = aziridine (azacyclopropane), $NH(C_2H_4)$, and X = halide.[596] Prepared by the direct reaction of $RhCl_3 \cdot 3H_2O$ with aziridine, these complexes are similar to the well-studied ammine complexes; the aziridine acts as a typical monodentate ligand, halide aquation occurs in aqueous solution, and Br^- substitution of coordinated Cl^- was noted. Reaction of $[Rh(Az)_4Cl_2]^+$ with I^- causes reduction to $[Rh(Az)_3I]$, and HCl does not open the aziridine ring, suggesting that coordination to the Rh^{III} stabilizes the three-membered aziridine ring, presumably by saturating the N atom, and hindering the standard

ring-opening reactions. The electronic spectra (Table 32) are difficult to interpret, as no information on the geometric configuration of these complexes is given; an unusual feature is suggested, as a band identified as the spin-forbidden $^1A_{1g} \rightarrow {}^3T_{2g}$ transition, previously observed for $[RhCl_6]^{3-}$, $[Rh(C_2O_4)_3]^{3-}$ and $[Rh(NH_3)_5Br]^{2+}$,[597] is also observed for $[Rh(Az)_3Cl_3]$ and $[Rh(Az)_4I_2]I$ (488 nm). All the aziridine complexes showed strong intraligand transitions (217–227 nm), and IR peaks (850–890 cm^{-1}), confirming that the aziridine ring is intact. The molar absorption constants for several of these complexes were reported to increase upon dilution, but no explanation for this phenomenon was suggested.[596]

A series of monomeric and chloro-bridged oligomeric (or perhaps polymeric) allylamine complexes $[RhCl_3L_n]$ ($L = H_2NCH_2CH{=}CH_2$; $n = 1, 2, 3$) have been characterized (for $n = 1$ a coordinated H_2O is also present) and have been shown to undergo a variety of inter- and intra-molecular reactions.[598] As shown in Scheme 15, the reactions are thought to begin by a breakdown of the chloro bridges, followed by coordination of the unsaturated C=C moiety of the allylamine, H

transfer, and rapid collapse to the final products. (The organic products were identified by GLC, but the exact nature of the Rh^{III} product was not indicated.) Coordination to the Rh^{III} has no effect on the stretching frequency of the C=C double bond of the allylamine, showing that they are N-bonded. Analogous complexes with the saturated *n*-propylamine were prepared: $[RhCl_3L'_n]$ (n = 1, 2, 3) and $[RhL'_5Cl]Cl_2$ (L' = $H_2NCH_2CH_2Me$); while similar to the allyl complexes, the saturated ligands do not undergo the reactions represented in Scheme 15.[598]

Scheme 15

Swaddle has studied the H^+- and OH^--induced aquation of $[Rh(NH_2R)_5Cl]^{2+}$ (R = H or Me), and found, contrary to expectations, that $[Rh(NH_2Me)_5(H_2O)]^{3+}$ is more acidic (pK_a = 6.10) than the pentaammine complex (Table 31), suggesting that methylamine is a poorer electron-donor than ammonia.[511] Methyl substitution of the amine only slightly retards the acid hydrolysis of $[Rh(NH_2R)_5Cl]^{2+}$; the difference is in the ΔS^* term ($-50.2\,J\,K^{-1}\,mol^{-1}$ for R = Me *vs.* $-44\,J\,K^{-1}\,mol^{-1}$ for the pentaammine) not the ΔH^* (101.9 kJ mol^{-1} for R = Me *vs.* 102 kJ mol^{-1} for the pentaammine). In addition, the change in ΔS^* upon methyl substitution is opposite to the change observed for the analogous Co^{III} system, further supporting the assignment of an I_d mechanism for the aquation of Co^{III} amines in acidic aqueous solution, and a more associative (I_a) path for the Rh^{III} analogs. In contrast, methyl substitution accelerates the OH^- induced aquation of $[Rh(NH_2R)_5Cl]^{2+}$ by a factor of 29, consistent with a dissociative rate-determing step which is accelerated by steric crowding. The S_N1CB (or D_{CB}) mechanism is suggested.[511]

48.6.2.2 Bidentate aliphatic amines

(*i*) *$[Rh(en)_3]^{3+}$*

Werner first reported that the $[Rh(en)_3]Cl_3$ salt results when hydrated ethylenediamine reacts with $Na_3[RhCl_6]$,[4] and Jaeger showed that it could be formed when 50% en/H_2O reacts with $RhCl_3\cdot 3H_2O$.[599,600] Wilkinson and co-workers,[601] and Gasbol,[602] have taken advantage of the catalytic properties of ethanol to prepare $[Rh(en)_3]^{3+}$ by reacting $RhCl_3\cdot 3H_2O$ with ethylenediamine in aqueous ethanol, and Watt has used the direct reaction of 98% ethylenediamine with solid $RhCl_3\cdot 3H_2O$ with some success.[603] The electronic spectrum has been reported by a variety of workers,[601,602,604–606] and is consistent with a RhN_6 chromophore (Section 48.6.2.2.ii; Table 35). Werner resolved it as the 3-nitro-(+)-camphor and (+)-tartrate salt,[4] and the tartrate resolution has been repeated.[602,606] The (−)-$[Rh(en)_3]^{3+}$ ion is isostructural with (+)-$[Co(en)_3]^{3+}$ and (+)-$[Cr(en)_3]^{3+}$ and has the Λ configuration.[610]

Several researchers have used ^1H NMR to analyze configurational interactions of the ethylenediamine bidentates in $[Rh(en)_3]^{3+}$.[611–615] Hawkins noted[612] that the non-equivalence of protons in such tris(ethylenediamine) complexes is not necessarily due to conformational differences, for even if

Table 33 Population of Δ-$[Rh(en)_3]^{3+}$ Conformers (from ref. 615)

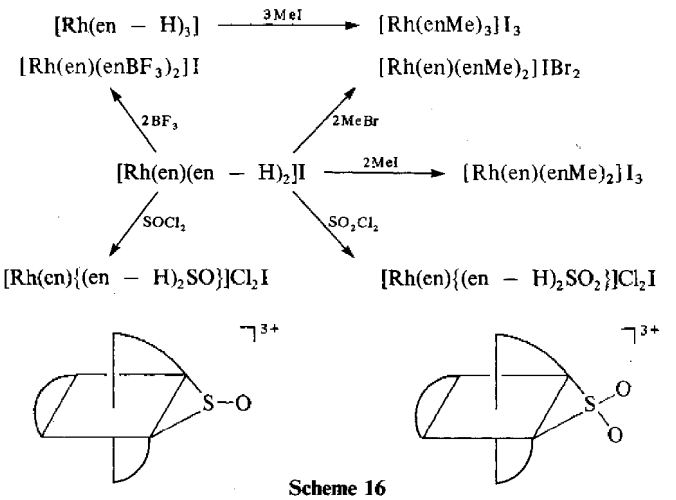
λλδ, λδλ, δλλ	B	92	55
λδδ, δλδ, ββλ	C	0	0
δδδ	D	0	0

rapid configurational changes occur between σ and λ forms, the four C–H groups in a given ethylenediamine ring are still inequivalent, leading to an AA′BB′ ^1H NMR pattern. The ^1H NMR spectra of $[Rh(en)_3]X_3$ (X = Cl^-, I^- or ClO_4^-) have virtually identical chemical shifts and band widths (for both the methylene and amine bands), and the spectra are virtually unchanged between 4 and 82°C, indicating rapid conformational averaging. As observed with $[Co(en)_3]^{3+}$,[613,614] ion pairing to multiply-charged oxyanions is directional, and conformational ordering effects can be observed for D_2O solutions of $[Rh(en)_3]^{3+}$ in the presence of phosphate, selenate and selenite ions.[613] These changes were interpreted to imply directional association favoring the (*lel*) ring configuration, an assignment supported by the similarity of the spectra of $[Co(en)_3]^{3+}$ and $[Rh(en)_3]^{3+}$ in the hydrogen-bonding solvent, trifluoroacetic acid.[613] A thorough conformational analysis of $[Rh(en)_3]Cl_3$ (D_2O solutions with a 220 MHz ^1H NMR) disputed this assignment, however,[615] as the expected AA′BB′ pattern was found to be slightly perturbed by the stronger coupling to the low field proton; spectra were interpreted in terms of a conformationally labile ethylenediamine system which gave an AA′BB′X spectrum. Analysis of the molecular conformation population is represented in Table 33. Theoretical considerations and analogy to $[Co(en)_3]^{3+}$ ion suggest that configurations A and B would have approximately equal populations, yet the B configuration (*lls*) dominates, and is presumed to be the lowest energy configuration for Δ-$[Rh(en)_3]^{3+}$. In the presence of phosphate ions, directional association favors the A configuration (*'lll'*), and at 0.3 M PO_4^{3-} the A and B configurations are almost equally populated.[615]

Petersen and co-workers used ^{13}C NMR to study configurational changes in $[Rh(en)_3]^{3+}$ and $[Rh(en)_2XY]^{n+}$ (*vide infra*), and observing only one ^{13}C resonance for $[Rh(en)_3]^{3+}$ (46.35 p.p.m. *vs.* TMS), also concluded that ring configurational changes are fast on the NMR time scale.[607]

Little chemistry of $[Rh(en)_3]^{3+}$ has been presented, as it is thermally inert, although Watt and co-workers have reported on the products formed upon deprotonation of $[Rh(en)_3]^{3+}$ by KNH_2.[603,616–618] Deprotonation occurs as represented in equation (122), and all three products (x = 1, 2 or 3) have been characterized by IR analysis.[603] Reaction of $[Rh(en)_3]^{3+}$ with five equivalents of KNH_2 (25°C, 5 days) reportedly leads to dark green crystals of a paramagnetic (μ_{eff} = 1.5 ± 0.1 BM) solid identified as K[Rh(en − 2H)(en − H)$_2$].[616] Reaction of this material with water regenerates $[Rh(en)_3]^{3+}$, and quantitative reduction to Rh metal and the IR spectrum show that K[Rh(en − 2H)(en − H)$_2$] is a Rh^{III} complex without a Rh—H linkage. Watt concludes that the 'origin of paramagnetism remains obscure'.[616] Deprotonation of $[Rh(dien)_2]$ with amide ion has also been shown to lead to the doubly deprotonated [Rh(dien − H)$_2$]I, a diamagnetic H_2O-sensitive solid.[617] Further deprotonation leads to a pyrophoric solid (presumed to be [Rh(dien − H)-(dien − 2H)]), and an ill-characterized species assumed to be the hexadeprotonated $[Rh(dien - 3H)_2]^{3-}$.[617]



$$[Rh(en)_3]I_3 + xKNH_2 \longrightarrow [Rh(en - H)_x(en)_{3-x}]I_{(3-x)} + xNH_3 + xKI \quad (122)$$

$$x = 1, 2 \text{ or } 3$$

The deprotonated tris(ethylenediamine) complexes are, not unexpectedly, nucleophilic. The pale yellow doubly deprotonated complex [Rh(en − H)$_2$(en)]I acts as a nucleophile toward MeI, MeBr, $SOCl_2$, SO_2Cl_2, and triply deprotonated [Rh(en − H)$_3$] is electrophilically attacked by MeI (Scheme 16).[618] The methylated species are air and H_2O stable, but while air stable, the BF_3 and SO_2Cl_2 adducts hydrolyze rapidly. The low S—O stretching frequencies observed led to the suggested bonding configurations shown in Scheme 16, with the sulfur atoms bonded to two amine nitrogens.[618]

(*ii*) *$[Rh(en)_2XY]^{n+}$ complexes*

Basolo and Johnson opened the now extensive field of bis(ethylenediamine)Rh^{III} chemistry with a major study[619] of complexes of the form $[Rh(A)_4ClX]^{n+}$ (A_4 = $(NH_3)_4$, $(en)_2$, (*meso*-bn)$_2$, (±-bn)$_2$,

Scheme 16

(C,C,C',C'-tetramethylen)$_2$, tren or trien). The general synthetic route requires reaction of $RhCl_3 \cdot 3H_2O$ with a stoichiometric amount of the hydrochloride salt of the appropriate amine, followed by the gradual addition of a stoichiometric amount of NaOH to the refluxing solution. As part of this study, *cis* and *trans* isomers of $[Rh(en)_2X_2]^+$ (X = Cl, Br, I, NO_2 or N_3) as well as $[Rh(en)_2ClY]^{n+}$ (Y = SCN^-, NO_2^- or NH_3) were prepared and characterized by UV/visible and IR spectroscopy, with geometric assignments made on the basis of optical resolution (for the *cis* form), absorption spectra, and base-catalyzed hydrolysis of the *cis* complexes.[619] Reaction of *trans*-$[Rh(en)_2X_2]^+$ with BH_4^- was shown to lead to the monohydride (with retention of the *trans* geometry),[620] and the large *trans* effect of the H^- ion led to *trans*-$[Rh(en)_2H_2]^+$. Vibrational IR and Raman spectra for a variety of $[Rh(en)_2XY]^{n+}$ complexes showed that the Rh—N stretch occurs at 555–575 cm^{-1}, with N—Rh—N deformations at about 250 cm^{-1} and the Rh—X stretch (X = Cl, Br or I) between 150 and 350 cm^{-1}.[621] Conductivities (in DMSO solution) of *cis*- and *trans*-$[Rh(en)_2Cl_2]Cl$, as well as some *cis* dichlorobis(substituted diamine) complexes are similar to those for the Cr^{III} and Co^{III} analogs, and are characteristic of 1:1 salts.[622] The $[Rh(en)_2(H_2O)_2]^{3+}$ ions are weak diprotic acids, with the *trans* isomer an order of magnitude more acidic than the *cis* form (Table 34).

Direct synthesis of the *trans* form of $[Rh(en)_2XY]^{n+}$ is generally easier than that of the *cis* isomer, but the *cis* configuration can be ensured by bonding a bidentate to the two non-ethylenediamine coordination sites. The $[Rh(en)_2ox]NO_3$ salt was prepared by refluxing an aqueous solution of *cis*-$[Rh(en)_2Cl_2]NO_3$ with Na_2ox for 2.5 h.[629] In the presence of trace amounts of BH_4^- (at pH 4.7), a refluxing solution of either *cis*- or *trans*-$[Rh(en)_2Cl_2]^+$ reacts with ox^{2-} within seconds to form $[Rh(en)_2ox]^+$.[630,631] This BH_4^- catalyzed substitution (with *trans* to *cis* isomerization) was shown to be a general route to $[Rh(en)_2AA]^{n+}$ complexes (for AA = en, ox^{2-}, gly^-, ala^-, $malonate^{2-}$).[630–635] Reaction of the $[Rh(en)_2ox]^+$ with various anions in strongly acidic solution was then developed as a convenient route to *cis*-$[Rh(en)_2X_2]^+$ ions (X = Cl, Br, NO_2).[632] The electronic spectra of a rich variety of $[Rh(en)_2XY]^{n+}$ ions are recorded in Table 35, and depending upon the position of the charge-transfer bands, generally consist of two spin-allowed *d–d* transitions (descended from $^1A_1 \rightarrow {}^1T_1(O_h)$ and the higher energy $^1A_1 \rightarrow {}^1T_2$ transitions). The spin-forbidden $^1A_1 \rightarrow {}^3T_1$ transition has been observed in *trans*-$[Rh(en)_2Cl_2]ClO_4$ at −189°C as a very weak shoulder at 469 nm.[644]

Resolution of *cis*-$[Rh(en)_2XY]^{n+}$ has been effected by numerous workers; Basolo isolated $(-)_{535}$-$[Rh(en)_2Cl_2]^+$ as the bromocamphor-π-sulfonate (BCS) salt.[619] Gillard separated $(+)_{589}$-$[Rh(en)_2(C_2O_4)]^+$ ion (initially as the (+)-$[Co(EDTA)]^-$ salt), and found it to be isomorphous with

$(-)_{589}$-$[Co(en)_2(ox)][(+)[Co(EDTA)]$, implying the L (now called the Δ) configuration for $(+)_{589}$-$[Rh(en)_2ox]^+$.[636] The $(+)_{589}$-$[Rh(en)_2(NO_2)_2]^+$ ion was also separated by the same technique. Spontaneous resolution can be observed if a solution containing $(+)$-$[Rh(en)_2ox]^+$ is added to a saturated solution of racemic $[Rh(en)_2ox]Cl$, as $(+)_{589}$-$[Rh(en)_2ox]Cl$ precipitates; a solution of $(-)_{589}$-$[Co(en)_2ox]^+$ can also be used to initiate the precipitation of $(+)_{589}$-$[Rh(en)_2ox]Cl$.[636] Bailar[633] also generated $(-)_{589}$-$[Rh(en)_2Cl_2]^+$ as the BCS salt, and showed that ammoniations (in liquid and aqueous ammonia) also occur with retention of configuration. Such substitution studies (summarized in Scheme 17), and a comparison of the electronic and CD spectra with their Co analogs has allowed the assignment of absolute configuration for a variety of *cis*-$[Rh(en)_2XY]^{n+}$ ions (Table 36).
