Preface

Since the appearance of water on the Earth, aqua complex ions of metals must have existed. The subsequent appearance of life depended on, and may even have resulted from, interaction of metal ions with organic molecules. Attempts to use consciously and to understand the metal-binding properties of what are now recognized as electron-donating molecules or anions (ligands) date from the development of analytical procedures for metals by Berzelius and his contempories. Typically, by 1897, Ostwald could point out, in his 'Scientific Foundations of Analytical Chemistry', the high stability of cyanomercurate(II) species and that 'notwithstanding the extremely poisonous character of its constituents, it exerts no appreciable poison effect'. By the late 19th century there were numerous examples of the complexing of metal ions, and the synthesis of the great variety of metal complexes that could be isolated and crystallized was being rapidly developed by chemists such as S. M. Jørgensen in Copenhagen. Attempts to understand the 'residual affinity' of metal ions for other molecules and anions culminated in the theories of Alfred Werner, although it is salutary to remember that his views were by no means universally accepted until the mid 1920s. The progress in studies of metal complex chemistry was rapid, perhaps partly because of the utility and economic importance of metal chemistry, but also because of the intrinsic interest of many of the compounds and the intellectual challenge of the structural problems to be solved.

If we define a coordination compound as the product of association of a Brönsted base with a Lewis acid, then there is an infinite variety of complexing systems. In this treatise we have made an arbitrary distinction between coordination compounds and organometallic compounds that have metal–carbon bonds. This division roughly corresponds to the distinction — which most but not all chemists would acknowledge as a real one — between the cobalt(III) ions $[Co(NH_3)_6]^{3+}$ and $[Co(\eta^5\text{-}C_5H_5)_2]^+$. Any species where the number of metal–carbon bonds is at least half the coordination number of the metal is deemed to be 'organometallic' and is outside the scope of our coverage; such compounds have been treated in detail in the companion work, 'Comprehensive Organometallic Chemistry'. It is a measure of the arbitrariness and overlap between the two areas that several chapters in the present work are by authors who also contributed to the organometallic volumes.

We have attempted to give a contemporary overview of the whole field which we hope will provide not only a convenient source of information but also ideas for further advances on the solid research base that has come from so much dedicated effort in laboratories all over the world.

The first volume describes general aspects of the field from history, through nomenclature, to a discussion of the current position of mechanistic and related studies. The binding of ligands according to donor atoms is then considered (Volume 2) and the coordination chemistry of the elements is treated (Volumes 3, 4 and 5) in the common order based on the Periodic Table. The sequence of treatment of complexes of particular ligands for each metal follows the order given in the discussion of parent ligands. Volume 6 considers the applications and importance of coordination chemistry in several areas (from industrial catalysis to photography, from geochemistry to medicine). Volume 7 contains cumulative indexes which will render the mass of information in these volumes even more accessible to users.

The chapters have been written by industrial and academic research workers from many countries, all actively engaged in the relevant areas, and we are exceedingly grateful for the arduous efforts that have made this treatise possible. They have our most sincere thanks and appreciation.

We wish to pay tribute to the memories of Professor Martin Nelson and Dr Tony Stephenson who died after completion of their manuscripts, and we wish to convey our deepest sympathies to their families. We are grateful to their collaborators for finalizing their contributions for publication.

Because of ill health and other factors beyond the editors' control, the manuscripts for the chapters on Phosphorus Ligands and Technetium were not available in time for publication. However, it is anticipated that the material for these chapters will appear in the journal *Polyhedron* in due course as Polyhedron Reports.

We should also like to acknowledge the way in which the staff at the publisher, particularly

Dr Colin Drayton and his dedicated editorial team, have supported the editors and authors in our endeavour to produce a work which correctly portrays the relevance and achievements of modern coordination chemistry.

We hope that users of these volumes will find them as full of novel information and as great a stimulus to new work as we believe them to be.

41.1 INTRODUCTION

In preparing a review of the coordination chemistry complementary to that by Treichel[1] in the companion volumes on organometallic chemistry, we have been fortunate in the way in which manganese chemistry is so readily divided between the two. Probably as much as for any other metal, the organometallic chemistry of manganese, *i.e.* compounds with Mn—C bonds, is the chemistry of the lower oxidation states (I, 0 and −I); and the chemistry of manganese(II) and the higher oxidation states (III to VII) is that of classical coordination chemistry with the donor atoms nitrogen, oxygen and the halogens. Compounds with other Group V and Group VI donors have been prepared, but their known chemistry is not yet extensive. There are, of course, overlaps between the two areas, and the elegant work by Wilkinson and co-workers on the manganese(II), (III) and (IV) alkyls immediately comes to mind (see Section 41.3.2.2); similarly, many of the classical ligands of coordination chemistry, such as heterocyclic nitrogen ligands, and the phosphines and arsines, are widely used in organometallic chemistry. But this division into lower oxidation state/organometallic and higher oxidation state/coordination chemistry is as neat a division as one could hope for in chemistry.

Manganese has been a metal much neglected by the coordination chemist. Interest has recently been aroused, however, by the recognition of its biological role, especially in photosynthesis.[2]

This neglect is reflected in the treatment manganese has received, for example, in the Chemical Society's 'Annual Reports', and it is only within the last decade that significant volumes on the chemistry of manganese have appeared within the Gmelin system.[3] We often searched reviews on the chemistry of particular ligand systems in vain, or for just one or two references to manganese. In this regard it is pleasing to see the new series of annual reviews of the particular metals in *Coordination Chemistry Reviews*, which give adequate coverage to manganese.[4–6]

Available reviews are, of course, of diverse quality: they range from good comprehensive, critical reviews to simple compilations of published material, some of which do not even have the virtue of being comprehensive. But, since none of the recent reviews covers large areas, we note them in the sections for the various ligands.

Reasons for the neglect of manganese coordination chemistry undoubtedly relate to the dominance of the Mn^{II} state, its half-filled d^5 configuration, and all that follows from this, especially the lack of any reliable guide to the structure of the coordination polyhedron from anything other than X-ray methods. The great majority of Mn^{II} compounds are high spin, and, in the ^6S ground state, *d–d* transitions are forbidden by both the LaPorte and the spin state selection rules. Thus the *d–d* electronic spectra are of very low intensity and are of little use in determining metal stereochemistry; the compounds are colourless or very pale coloured. Thus in the period when transition metal coordination chemists believed in the *d–d* spectra as a reliable guide to structure, manganese could elicit but little interest.

Manganese(II) compounds are quite labile; the metal shows distinct class (a) character;[7] and its 'ionic radius' (defined by the M—H_2O distances in Table 1) is large compared with the other first row transition metals. These lead to distinct parallels with magnesium(II) rather than the latter, although there are also significant parallels with octahedral high spin nickel(II).

Many, but by no means all, manganese(II) compounds also are sensitive to oxidation by oxygen and their preparation is often complicated by the marked tendency for aqueous manganese solutions, under ambient conditions, to deposit the ubiquitous, highly insoluble manganese dioxide. Both add complications to manganese(II) chemistry and have undoubtedly made it less attractive to some workers. This sensitivity to oxygen and especially the products of the reactions are a major reason for the increasing interest in manganese chemistry. The last decade has seen significant developments: both manganese(III) and manganese(IV) have been properly characterized in a number of systems, and it appears that the +4 oxidation state is more accessible to manganese than, for example, iron. However, a great deal more needs to be done, and done properly, before we can pretend to have a reasonably balanced view of the relative accessibilities and stabilities of Mn^{III} and Mn^{IV}. Much has been, and is being, published on the reaction of manganese(II) species with O_2, the possibility of the existence of Mn—O_2 species and their structure and properties, and the nature of the final oxidized products. But there is very little light yet shed in this area.

The higher oxidation states V, VI and VII are all known, and are largely represented in the chemistry of the oxo ligand manganates. The highest oxidation state VII corresponds to the total number of 3*d* and 4*s* electrons—a feature of the earlier transition metals Sc to Cr. Manganese is, except for a few unstable oxoferrates, the last of this series, and although potassium permanganate is one of the best known manganese compounds, and is widely used, yet the chemistry of manganese and oxo ligands is by no means as extensive as that of chromium and vanadium.

In other aspects, especially in the dominance of the +2 oxidation state, manganese shows parallels with the later transition metals. It is the first transition metal for which +2 is the common oxidation state.

Table 1 M^{II}—OH_2 Bond Distances in the Hexaaquo Cations

Metal:	*Mg*	*Mn*	*Fe*	*Co*	*Ni*	*Cu*	*Zn*	*Cd*
M—OH_2 (Å)	[a] 2.09	2.19	2.17	2.11	2.09	2.22	2.13	2.30
	2.10	2.20	2.14	2.09	2.08	2.10	2.12	2.30
	2.05	2.15	2.10	2.08	2.04	1.96	2.08	2.24
	[b]	2.20	2.12	2.08	2.04	2.43	2.08	2.29
						1.94		

[a] In the Tutton salts there are three independent pairs of *trans* ligands: H. Montgomery, R. V. Chastain and E. C. Lingafelter, *Acta Crystallogr.*, 1966, **20**, 731; C. S. G. Phillips and R. J. P. Williams, 'Inorganic Chemistry', Oxford, 1966, vol. 2, p. 249.
[b] Aqueous solutions (X-ray data): H. Ohtaki, *Rev. Inorg. Chem.*, 1982, **4**, 103.

Thus, in its broad features, manganese chemistry reflects its position in the middle of the transition series.

As any scientific classification creates problems of definition, so our present classification based on oxidation state leads to difficulty in the placing of material. This is particularly, but not exclusively, true of *nitrosyls*.

It is common to classify M—NO moieties into compounds of: (a) the monoanion NO^-, characterized by lower energy NO stretching frequencies and a bent ($\sim 120°$) M—N—O bond; and (b) the nitronium cation NO^+, characterized by higher energy NO stretching frequencies and a short, linear M—N—O bond. Thus, for example, the compound $[Mn(NO)_3PPh_3]$, with three linear M—NO bonds, becomes a compound of Mn^{-III} and this we believe to be a chemical nonsense or at best a useless formalism. Further, we note also that a recent X-ray structural determination[8] of a compound of type (b) above shows significant bending in the M—N—O bond, and the authors suggest that such bonding may be more widespread in type (b) compounds.

Accordingly, we adopt the convention, in agreement with IUPAC nomenclature recommendations, that NO be regarded as a neutral ligand, and deal with the above trinitrosyl as a compound of manganese(0). This also means, for example, that the anions $[Mn(CN)_5NO]^{n-}$ ($n = 2, 3$) become here compounds of manganese(III) and (II), although they are often classified elsewhere under manganese(II) and (I), respectively.

The nature of the data: Since we have attempted to be critical in our assessment of the published data, it is as well that we note the bases used for much of this critical assessment.

Mixing any ligand (L), especially ligands containing one (or many) nitrogen or oxygen donor atom(s), with MnX_2 (X = a monoanion) in a suitable solvent system will lead to the separation of crystalline species (or a number of them) MnX_2L_n; deprotonation of the ligand, if possible, may give further compounds. Such information is, of itself, often of little interest, even though the products be 'new' compounds. Yet this is often the only established, meaningful fact in what may be quite long papers.

Sadly, many papers are published in which not even such a simple basic fact has been established. Despite published (in 1978) analytical figures, we find it hard to believe that a black residue, obtained by heating manganese(II) with an oxygen donor ligand in an aqueous alkaline solution in open vessels, is a manganese(II) compound; we think it more likely to have been MnO_2, perhaps admixed with some carbonaceous material. Powders, even of the expected colour, are suspect unless X-ray diffraction shows them to be a discrete crystalline species, or recrysallization can be achieved to give a product with say an IR spectrum identical with the original. Ideally all solids should generally be characterized by their X-ray diffraction patterns and IR spectra.

But having characterized a crystalline product, what then? What are the authors trying to achieve beyond preparing a new compound? If it is to show what compounds can form, then many papers fail to explore a proper range of reaction conditions; if it is to show how the ligand is bound to the metal, then there is currently but one reliable physical method for this job—X-ray diffraction. Sometimes this may simply mean demonstrating isomorphism with the compound of another metal of known structure (especially if supplemented with IR data). But practice shows that such isomorphism often does not happen, and then full X-ray analyses are the only reliable answer. It may be fun—perhaps quite absorbing fun—to play with the so-called 'sporting methods', such as vibrational spectra, electronic spectra and magnetism. But, especially in manganese chemistry where electronic spectra are of but little use for indicating structure, we have taken little note of structural assignments based on these 'sporting methods', although we may have noticed the work for other reasons, such as an intrinsic interest in the reported compounds.

Whilst *electronic spectra* do not have the structural use they have (with discretion) with nickel(II), it is at least possible to make some useful deduction from the colour of the products. We can, for example, conclude with some confidence that a black substance described as a manganese(II) compound with oxygen donors was not; that a white substance described as Mn^{IV} or Mn^{V} was not; and that a green compound, having the same intense colour as some related Mn^{III} species, was probably not manganese(II), despite the apparent stoichiometry (Section 41.3.3.2). Yet each of these has appeared in the recent literature.

It is arguable that the study of *magnetic moments* of coordination compounds has been as much a hindrance to the elucidation of stereochemistry as it has been of use. The earlier confidence that it would be possible to correlate 'stereochemistry of an atom with its effective magnetic moment'[9] has not been confirmed, although some impressive work has come out of magnetic studies. What is not arguable is that the chemistry of manganese would be no less further advanced if no paper had been wasted on arguments about structure of solid polymeric materials from magnetic moments.

Manganese with its great variety of oxidation states, each with varying numbers of unpaired 3*d* electrons, is magnetically interesting but not simple. The theoretical 'spin only' magnetic moments for oxidation states* +2, +3 and +4 are in Table 2, and for comparison some experimentally determined moments of some representative compounds are in Table 3.

Monomeric species, with no exchange interaction between adjacent metal atoms, typically exhibit moments close to the 'spin only' values. Most known compounds of manganese(II) and (III) are high spin, with the cyano compounds best known among the few low spin species. But these moments give no information about stereochemistry of the metal atom, and their purpose can be only to give information about the spin state and perhaps to help to confirm oxidation state.

In practice, measured moments range between 0 and 6.5 BM, and those differing significantly from 'spin only' values often are called 'anomalous', in the sense of a deviation from a norm. Such nomenclature, however, is probably in all cases fatuous—the deviation from the norm often itself being the norm.

Table 2 Theoretical Magnetic Moments (in BM) for Mn^{II}, Mn^{III} and Mn^{IV} Compounds (Based on 'Spin Only' Formula)

Oxidation State	*Spin State*			
	Spin Free	*Intermediate Spin*	*Spin Paired*	
			Oh Field	*Td Field*
Mn^{II}	5.92	3.87	1.73	1.73
Mn^{III}	4.90	—	2.83	0
Mn^{IV}	3.87	—	3.87*	1.73

* In an *Oh* field spin pairing will not occur.

Table 3 Experimental Room Temperature Magnetic Moments (in BM) of some Mn^{II}, Mn^{III} and Mn^{IV} Compounds

(a) Magnetically Dilute Species[a]

Oxidation State	*Compound*	*Spin State*	*Stereochemistry*	μ_{eff}
Mn^{II}	$[Mn(py)_6]Br_2$	Spin free	Oh	6.00
Mn^{II}	$(pyH)_2[MnCl_4]$	Spin free	Td	5.95
Mn^{II}	$K_4[Mn(CN)_6]$	Spin paired	Oh	1.80
Mn^{III}	$[Mn(acac)_3]$	Spin free	Oh	4.95
Mn^{III}	$K_3[Mn(CN)_6]$	Spin paired	Oh	3.18
Mn^{IV}	$K_2[MnF_6]$	Spin free	Oh	3.90
Mn^{IV}	$K_2[Mn(CN)_6]$	Spin free	Oh	3.94

(b) Magnetically Interactive Species

Oxidation State	*Compound*	*Stereochemistry*	μ_{eff}	*Ref.*
Mn^{II}	[Mn(salen)]	Five-coord. Dimeric?	5.24	[b]
Mn^{II}	[Mn(pc)]	Square planar	4.34	[c]
Mn^{III}	$[Mn_3O(OAc)_6(py)_3]py$	Trimeric	3.98	[d]
Mn^{III}	[(py)(pc)MnOMn(pc)(py)]	Octahedral O-bridged	2.07	[e]
Mn^{III}	[Mn(salen)(OAc)]	?	4.68	[f]
Mn^{IV}	[MnO(pc)]	?	3.75	[g]

Ligand abbreviations: acac = acetylacetone; OAc = acetate; pc = phthalocyanine; py = pyridine; salen = *N*,*N*′-ethylenebis(salicylaldimine)

* States lower than Mn^{II} are usually stabilized by strong field ligands giving rise to spin-paired systems; whereas the magnetic properties of Mn^{V}, Mn^{VI} and Mn^{VII} have not been widely studied.

Where magnetic moments are lower than the 'spin only' values, and full experimental evidence of antiferromagnetism is obtained, the results are often interpreted in terms of structures for which the best basis appears to be nothing more than the author's previous experience. The only proper procedure is to interpret the magnetic data *after* the structure is known and not *vice versa.*

The use of magnetic data as primary evidence for any structure is precluded by the variety of structural types—oligomeric and dimeric—which are known to give antiferromagnetism. In addition, manganese compounds exhibiting antiferromagnetism are now known to have metal atoms in different oxidation states and there is the further possibility of different spin states.

Yet another complication of which not sufficient heed is often taken is the presence of the ubiquitous, insoluble and paramagnetic MnO_2. It must be suspected as a by-product of the preparation of almost any compound of oxidation state greater than + 1, and so many products that are reported as dark powders, or even grey powders, probably possess appreciable amounts of MnO_2, thus invalidating the reported magnetic data, and possibly even the reported stoichiometry.

Although *nuclear magnetic resonance* studies have been of great use in elucidating the structures in solutions of the compounds of many of the metals, the paramagnetic nature of many manganese compounds, and in particular high spin Mn^{II}, has limited the applicability of this technique. Nevertheless, the very difficulty associated with obtaining Mn^{II} NMR spectra has been turned to advantage by using Mn^{II} as a magnetic relaxation probe in the study of biomechanisms and biomacromolecules.[10]

Although a drawback to NMR studies, the five unpaired electrons of high spin Mn^{II} compounds give rise to excellent *electron spin resonance* spectra. An early review[11] noted the effect upon ESR spectra of changing ligands about the Mn^{II} ion while retaining high symmetry, whereas a recent review summarizes the work that has been done upon compounds with a low-symmetry environment about the metal.[12] ESR studies have been applied in a most interesting manner to ligand speciation studies of manganese in aqueous environmental samples.[13] Although also paramagnetic, high spin d^4 Mn^{III} compounds appear to have short spin–lattice relaxation times and generally do not give good ESR spectra. Little work has been undertaken on the ESR of the higher oxidation states of manganese, although Mn^{IV} compounds are known to yield spectra.[11]

There is another basic lesson which many authors publishing in this area of chemistry have failed to heed; when labile compounds are dissolved in any solvent, information about the properties of the solution (*e.g.* a conductance measurement) gives no direct information about the solid compound. For some metal compounds, it may be possible to show (*e.g.* from electronic spectra) that the coordination sphere remains unchanged from the crystalline solid to the solution, but this appears not to be possible for manganese.

For these sorts of reasons we have found it necessary to neglect a significant portion of the published work, especially on ligand systems that offer the metal a choice of donor atoms.

The story of the coordination chemistry of manganese is very incomplete; it is only at an early stage of development compared with most of the other transition metals; and there is an obvious need for X-ray structural techniques to be used much more routinely in those studies of manganese chemistry that rely on the isolation and characterization of solid compounds for their purpose.

Finally a general point—we do not usually distinguish between 'binary compounds', 'salts' and 'complexes'. All give interesting examples of metal coordination polyhedra and the terms are arbitrary distinctions, derived from the history of chemistry as our understanding has developed. They have little meaning now beyond their use as jargon words by inorganic chemists. Whilst we (meaning coordination chemists) all understand what they mean and how to use them, they impose a barrier to communication with non-specialists and inhibit the learning process. Unfortunately, also, they are tendentious words, leading almost inevitably to the belief that the 'simple' chemistry of a metal ion can be understood by a study of only the binary compounds and salts, and that a study of the 'complexes' is a higher-order, more esoteric branch of knowledge. For these reasons, we have attempted to show in much of the following how the coordination chemistry of one metal can be described without the use of the tendentious word 'complex'.

41.2 MANGANESE(I) AND LOWER OXIDATION STATES

41.2.1 Introduction

This area of coordination chemistry gives the greatest overlap with the area generally classified as organometallic chemistry and reviewed by Treichel in the companion volume.

We attempt in Table 4 to give an overview of the range of oxidation states covered by the organometallic chemistry of manganese, and thus the bulk of the lower oxidation state chemistry

Table 4 The Oxidation States of the Organometallic Chemistry of Manganese

Oxidation State	*Examples*
Mn^{-I}	$Na[Mn(CO)_5]$
Mn^{0}	$[Mn_2(CO)_{10}]$, $[Mn_2(CO)_{10-n}L_n]$
Mn^{I}	$[Mn(CO)_5X]$, $[Mn_2(CO)_8X_2]$, $[Mn(CO)_{6-n}L_n]^+$, $[Mn(\eta\text{-}C_5Me_5)_2]^-$, $[Mn(\eta\text{-}C_5H_5)(\eta\text{-arene})]$, $[Mn(\eta\text{-arene})_2]^+$, $[Mn(\eta\text{-}C_5H_5)(CO)_3]$, $[Mn(CNR)_6]^+$
Mn^{II}	$(MnR_2)_n$, $[Mn(\eta\text{-}C_5R_5)_2]$, $[Mn(CNR)_6]^{2+}$
Mn^{III}	$[Mn(\eta\text{-}C_5Me_5)_2]^+$
Mn^{IV}	$[MnR_4P_2]$

See also the borane and carborane-manganese carbonyl compounds: R. N. Grimes, in 'Comprehensive Organometallic Chemistry', ed. G. Wilkinson, F. G. A. Stone and E. W. Abel, Pergamon, Oxford, 1982, vol. 1, p. 459.

of manganese. It is important to note, however, that in this area the oxidation state formalism is probably less clear cut and less useful than elsewhere.

Apart from the organometallic chemistry, there is but little manganese chemistry left for us to review and most of this is of the cyanides and nitrosyls, most of which could have reasonably been embraced within organometallic. Previous assignments of lower metal oxidation states to species such as [Mn(phthalocyanine)]$^-$ and [Mn(bipy)$_3$]^0 now are known to be incorrect and these species are treated under manganese(II). Furthermore, present indications are that [$Mn^{II}N_4$] macrocyclic systems, in general, cannot be reduced to Mn^I species, unlike those of the later transition metals, especially cobalt, nickel and copper. Although reduced species can and have been obtained, these, when properly studied, turn out to be not Mn^I or Mn^0 species, but rather Mn^{II} species of radical anion ligands (see Section 41.3.10).

As discussed previously, nitrosyls are classified according to oxidation state on the convention that NO is a neutral ligand.

41.2.2 Manganese(−I)

The only compound to be noted here is the recently described[14] cyano nitrosyl $K_3[Mn(CN)_2(NO)_2]$. This green compound has been made by the reduction of the dimeric species $K_4[Mn_2(CN)_4(NO)_4]$ with potassium in liquid ammonia. The IR spectrum suggests a tetrahedral structure similar to the isoelectronic $[Fe(CN)_2(NO)_2]^{2-}$.

41.2.3 Manganese(0)

The interpretation[15] of the observed paramagnetism of some yellow products of the reduction of $[Mn(CN)_6]^{4-}$ with K in liquid NH_3 as evidence for Mn^0 species is by no means unequivocal.

The only other Mn^0 species which come within our sphere of interest are nitrosyls, primarily derived from the carbonyl nitrosyls of Table 5. Of these, the two Mn^0 species have already been reviewed by Treichel,[1], as have the various series of currently known compounds of which these are respectively, the parents: series such as $[MnL(NO)_3]$, $[Mn(CO)_3L(NO)]$ and $[Mn(CO)_2L_2NO]$ *etc.*

Attempts[14] to prepare monocyano derivatives of $[Mn(CO)_4NO]$ and $[Mn(CO)(NO)_3]$ by treating with KCN in liquid NH_3 gave instead; for the former $K_2[Mn(CN)_3(CO)_3]$ and $K_3[Mn(CN)_4(CO)_2]$, and for the latter $K_4[Mn_2(CN)_4(NO)_4]$.

$K_4[Mn_2(CN)_4(NO)_4]$ has been isolated in *cis* and *trans* forms.[14] Evidence for a dimeric structure with Mn—Mn bonds derives from the diamagnetism of the compounds, the IR spectra and *cis–trans* conversions. Yellow crystals of the *cis* are obtained from the reaction in liquid

Table 5 The Primary Carbonyl Nitrosyls of Manganese

Compound	*Isoelectronic Series*	*Ref.*
$[Mn(CO)_4(NO)]$	$[Fe(CO)_5]$	1
$K[Mn(CO)_2(NO)_2]$	$[Fe(CO)_3NO]^-$, $[Co(CO)_4]^-$	a
$[Mn(CO)(NO)_3]$	$[Cr(NO)_4]$, $[Fe(CO)_2(NO)_2]$, $[Co(CO)_3(NO)]$, $[Ni(CO)_4]$	1

[a] R. E. Stevens, T. J. Yanta and W. L. Gladfelter, *J. Am. Chem. Soc.*, 1981, **103**, 4981.

NH_3 {ν_{NO} = 1664 and 1737 cm^{-1} (solid), and 1680, 1685 and 1731, 1734.5 cm^{-1} (ethanol solution)} and these can be converted to bluish needles of the *trans* by heating in ethanol in a sealed tube at 100 °C for several days {ν_{NO} = 1709, 1750 cm^{-1}}.

More recently Behrens and co-workers[16] were able to prepare the series of monocyano nitrosyl carbonyls by reactions such as equation (1). The Mn^0 compounds obtained in this work are listed in Table 6. $Na[Mn(CN)(CO)_3(NO)]$ dissolves readily in polar solvents such as water, ethanol, acetone or THF, but the solutions, even in the absence of light and air, are unstable. Crystalline salts, which are air stable, were obtained by adding such a solution to an excess of the appropriate cation. The related isonitrile species were prepared by alkylation of the cyano anions with R_3O^+.

$$[Mn(CO)(NO)_3] + NaN(SiMe_3)_2 \xrightarrow[20°C]{C_6H_6} Na[Mn(CN)(NO)_3] + O(SiMe_3)_2 \quad (1)$$

The compound $K_4[Mn(CN)_4NO]$ has recently been prepared[17] as a dark green, highly pyrophoric solid by the reduction of $K_3[Mn(CN)_5NO]$ with K in liquid NH_3. {ν_{NO} = 1370 cm^{-1}, *cf.* ν_{NO} for $K_3[Mn(CN)_5NO]$ = 1730 cm^{-1}}.

41.2.4 Manganese(I)

The white hexacyanomanganese(I) cation was first recognized by Manchot and Gall,[18] although a white crystalline solid, previously reported by Grube and Brause,[19], was undoubtedly the potassium salt. Manchot and Gall then reported[20] both the potassium and sodium salts, obtained by reduction of the appropriate Mn^{II} species in aqueous alkaline solution with Al powder, but a variety of other preparative methods now are available.[21,22]

Both $Na_5[Mn(CN)_6]$ and $K_5[Mn(CN)_6]$ are robust in dry air, but are soon oxidized in moist air, the more soluble Na^+ salt decomposing at the faster rate. They are also decomposed in a dry CO_2 atmosphere.

Aqueous solutions are yellow and are strongly reducing: the potential for the reaction $Mn^I \rightarrow Mn^{II} + e^-$ in aqueous 1.5 M NaOH is −1.06 V at 25 °C.

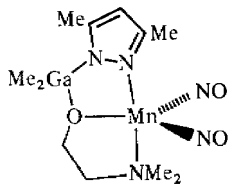
The Mn^I species are reoxidized by water at an appreciable rate, so that all studies of $[Mn(CN)_6]^{5-}$ in aqueous solutions (containing excess CN^-) refer to solutions also containing Mn^{II} species.

It has been shown polarographically[23] that the process $[Mn(CN)_6]^{5-} \rightleftarrows [Mn(CN)_6]^{4-}$ is reversible, and there is no evidence for disproportionation to Mn^{II} and Mn^0.

Decomposition of the yellow solutions in aqueous CN^- has been followed by monitoring[23] the fading of the intense single broad band at 365 nm. The data were interpreted as evidence for $[Mn(CN)_5OH]^{5-}$ and $[Mn_2(CN)_{10}O]^{10-}$ in these aqueous solutions, and the involvement of these species in the oxidation of Mn^I to Mn^{II}.

Closely related to the hexacyano species are the various isonitrile cations $[Mn(CNR)_6]^+$ and $[Mn(CNAr)_6]^+$, but these are covered in Treichel's review.[1]

Two manganese(I) cyanocarbonyls are known. *cis*-$K_3[Mn(CN)_4(CO)_2]$ has been prepared[14] from $Mn_2(CO)_{10}$ or $[Mn(CO)_4NO]$ with KCN in liquid NH_3. The *cis* configuration was assigned to the colourless crystalline compound on the basis of the IR spectrum. *fac*-$K_2[Mn(CN)_3(CO)_3]$ is also a product of the reaction of KCN in liquid NH_3 on $[Mn(CO)_4NO]$, but is best prepared from $[Mn(CO)_5Cl]$ and an ethanol solution of KCN at 120 °C under pressure. Again the isomeric structure is assigned[14] from the IR spectra.

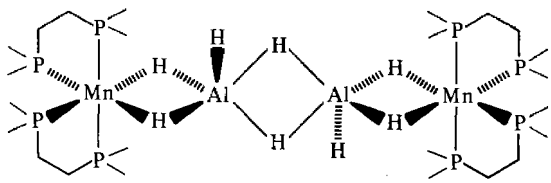


A range of dinitrosyl compounds of manganese(I) is known and most of them have been included in Treichel's review.[1] An interesting recent addition to the list is the compound (1), prepared[24] from

Table 6 Monocyano Nitrosyls[16]

Compound	*Physical form*	ν_{NO} (cm^{-1}) *(KBr disc)*
$Na[Mn(CN)(CO)_3NO]$	Red-brown, amorphous solid	1665
$[Ph_4As][Mn(CN)(CO)_3NO]$	Red needles	1687
[PPN][$Mn(CN)(CO)_3NO$][a]	Red needles	1675
$[Mn(CNMe)(CO)_3NO]$	Red, microcrystalline	1720
$[Mn(CNEt)(CO)_3NO]$	Red oil	1720
$Na[Mn(CN)(NO)_3]$	Grey-green, amorphous solid	1773, 1660
$[Mn(CNMe)(NO)_3]$	Green oil	1795, 1692
$[Mn(CNEt)(NO)_3]$	Green oil	1790, 1682

[a] PPN = bis(triphenylphosphine)immonium.



$[MnBr(NO)_2\{P(OMe)_3\}_2]$, $AgPF_6$ and Na^+L^- in THF. The dark red crystals had $\nu_{NO} = 1709$, 1643 cm^{-1} (cyclohexane).

(1)

Another class of compounds which formally comes within the guidelines for this review is the series of dicarbonyl cations $[Mn(CO)_2L_4]^+$, $[Mn(CO)_2L_2(L—L)]^+$ and $[Mn(CO)_2(L—L)_2]^+$ —both *cis* and *trans* isomers. But, since these have been reviewed by Treichel,[1] as have the monocarbonyl compounds, we simply note that several recent papers add significantly to the list of known compounds.[25–27]

An interesting new area of manganese(I) chemistry is opened up by the recent report[28] of the first transition metal compound of the tetrahydroalane(III) anion: $[Mn(AlH_4)(dmpe)_2]$ {where dmpe = 1,2-bis(dimethylphosphino)ethane}. This yellow, diamagnetic compound was prepared from $[MnBr_2(dmpe)_2]$ and excess $LiAlH_4$ in toluene. It appears to be monomeric in solution, with a bidentate AlH_4^- moiety, but an X-ray structure determination of the solid shows that two alane moieties bridge to form the dimer (**2**).

(2)

41.3 MANGANESE(II)

41.3.1 Introduction

This is the dominant oxidation state of manganese. It is the stable oxidation state of hexaaquomanganese, and of almost all of the manganese 'salts' that one finds in reagent bottles in the laboratory. Although many, but not all, manganese(II) species can be oxidized readily, and the chemistry of manganese(III) and manganese(IV) is receiving increasing attention, these oxidized species find use as oxidizing agents. On the other hand, reduction to manganese(I) is unusual, except for carbon ligands, and is apparently impossible for species with exclusively O,N or halogen donors, as evidenced by the scarcity of material in Section 41.2.

Manganese is the first transition metal for which +2 is the 'common' oxidation state—a feature of the remaining first row transition metals from iron to zinc. By comparison with its two neighbours to left and right—chromium and iron—manganese(II) is more stable than expected. This is commonly ascribed to the stable half-filled *d* electron shell of the high spin compounds.

The oxidation state diagrams in Figure 1 give a perspective on the relative stability of manganese(II) for OH_2, OH^- and O^{2-} ligands.

In many of its features, the chemistry of manganese(II) spans that of the alkaline earth metals {especially magnesium(II)} and that of the later first row transition metals. There are also parallels with cadmium(II) rather than zinc(II). These are all related to the more significantly ionic bonding for manganese and to the size of the metal 'ion'.

Manganese(II) is quite distinctly a *class (a) metal*.[7] This is manifest, for example, in the preference for O donor rather than N donor ligands, so that amino acid compounds become simply those of substituted carboxylates, and there is currently little evidence for the N bonding of peptides that leads to the interesting chemistry of the peptide compounds of the later transition metals. Of P and As ligands but little is known, although recent work suggests the possibility that this may become

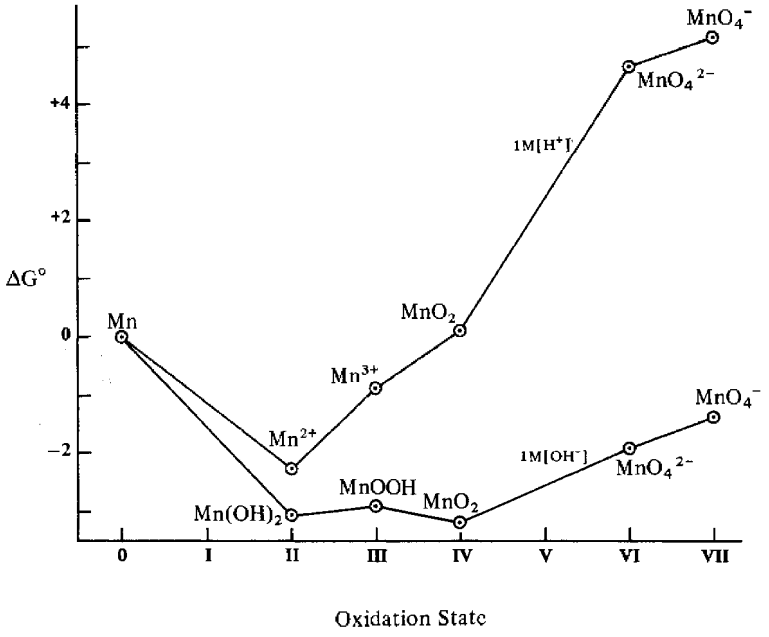


Figure 1 Oxidation state diagrams for manganese

one of the more important areas of Mn^{II} chemistry (see Section 41.3.4). Of S ligands, as well, there is yet little known (Section 41.3.6), although this does give an impression of difficulty in obtaining pure compounds because of lability and low stability. The state of manganese–sulfur chemistry is summed up in the statement that one recent paper adds enormously to this area.

The marked lability of manganese(II) species is undoubtedly one of the reasons for the neglect of manganese chemistry. This lability, often coupled with low stability of species (see Irving–Williams Series)[29] ensures that there is little correlation between solutions and solids, and adds an uncertainty to this area of chemistry that is largely absent from the chemistry of inert compounds.

The *spin state* of most manganese(II) compounds is high spin d^5 with a ^6S ground state—the few known exceptions are noted in the text (see also Table 7).

The *coordination geometries* are quite variable; and, in keeping with the lack of LFSE for the high spin d^5 configuration, ligand steric and electronic effects appear to play a major role in defining these geometries. We have already noted (Table 1) that manganese(II) is larger (whether defined by ionic or covalent radii, or more simply by comparative metal–ligand distances, as in Table 1) than other

Table 7 Coordination Polyhedra and Spin States for Manganese(II)

Coordination Number	*Donor Atoms*
(a) High Spin Polyhedra (μ_{eff} = 5.8–6.2 BM; $S = \frac{5}{2}$)	
8[a]	$[O_8][N_8][N_4O_4]$
7[a]	$[N_7][N_5O_2][N_2O_5]$
6 (Octahedral)	$[N_6][N_xO_{6-x}][O_6][P_4Cl_2][P_4Br_2][P_2I_4]$ $[S_6][S_4N_2][S_4Cl_2][F_6][Cl_6][Br_6][I_6]$ $[X_xO_{6-x}][X_xN_{6-x}]$ and [X, O, N] (X = Cl, Br)
6 (Trigonal Prismatic)	$[O_6][N_6]$
5[a]	$[C_3N_2][N_5][N_2O_3][O_5]$ $[N_4X][N_3X_2][N_2X_3][N_2OX_2]$ (X = Cl, Br)
4 (Tetrahedral)	$[C_4][N_4][C_3N][C_2N_2][C_3P][C_2P_2][S_4]$ $[N_2O_2][O_4][X_4][X_3N]$ (X = Cl, Br, I)
4 (Planar)	$[N_4][O_4]$
3 (Planar)	$[C_3][N_3][N_2O][O_3][X_3]$ (X = Cl, Br)
2 (Linear)	$[X_2][H_2]$ (X = Cl, Br)
(b) Intermediate Spin Polyhedra ($\mu_{eff} \sim 4$ BM; $S = \frac{3}{2}$)	
4 (Planar)	$[N_4]$
(c) Low Spin Polyhedra (μ_{eff} = 1.8–2.2 BM; $S = \frac{1}{2}$)	
6 (Octahedral)	$[C_6][C_5N][C_2P_4][Cl_2P_4][N_3O_3]$[b]

[a] We do not distinguish the various ideal polyhedra. Constraints within the molecules usually ensure that some 'intermediate' shape is adopted.
[b] The tris(ethylnitrosolato)manganese(II) anion (P. Gouzerh, Y. Jeannin, C. Rocchiccioli-Deltcheff and F. Valentini, *J. Coord. Chem.*, 1979, **6**, 221) has been described as a low spin species; but the details given are unique in manganese chemistry, and need further confirmation.

first row (+2) transition metals, and, in some ways, more akin to what are regarded as ionic metals, such as magnesium, calcium and cadmium. There are also indications that Mn^{II} is more plastic than the later transition metals. (This view derives from presently available X-ray structural data, although more comparative data are needed for confirmation.) By more plastic we mean that metal–ligand bond distances appear to be quite variable, and change more in response to ligand steric effects. We associate this 'plasticity' with the greater ionic component in the bonds.

Coordination number six appears, from the limited available data, the most common (Table 7). Lower coordination numbers are known but appear to be fairly rare: three is represented by some silylamides (Section 41.3.3.1) and in a dehydrated zeolite (Section 41.3.5.2.i); four-planar is known only for macrocyclic $[N_4]$ systems and as $[MnO_4]$ in a few unusual crystalline compounds; and four-tetrahedral is well characterized but still apparently less common than for Zn, Co and possibly even Ni. Coordination number five is also known, but few examples are yet characterized. On the other hand, higher coordination numbers seven and eight are less unusual here — hardly surprising in view of the larger size of Mn^{II}. Examples include seven coordinate $[Mn(edta)H_2O]^-$ (Section 41.3.9), $[Mn(py_3tren)]^{2+}$ (Section 41.3.3.6) and an $[MnO_7]$ species (Section 41.3.5.3.iii), and eight coordinate $[Mn(O_4)_2]^{2+}$ species (Section 41.3.5.4).

As noted in Section 41.1, the *electronic spectra* of Mn^{II} compounds have not been particularly useful in the elucidation of structure. Although there is some justification for the claim[30] that tetrahedral compounds are yellow to yellow-green in colour and have molar extinction coefficients of up to 100 times more intense than those for the pale pink or colourless octahedral compounds, yet these distinctions are not, in may cases, clear cut enough to lead to unambiguous stereochemical assignments.

It is true that tetrahedral[31] $[MnCl_4]^{2-}$, $[MnBr_4]^{2-}$ and $[MnI_4]^{2-}$ all have pale yellow or yellow-green colours, as do the isothiocyanato[32] and isocyanato[33] $[MnX_4]^{2-}$ species. It also appears to be true that these anionic species have *d–d* solution spectra (molecular structures appear to be unchanged in the solvents used, including CH_3CN) with molar extinction coefficients of the order of 1 to 15 — values which are indeed some 100 times more intense than those for the peaks in the spectrum[34] of the pale pink octahedral $[Mn(H_2O)_6]^{2+}$. Nevertheless, it does not follow that all pale yellow or green compounds of Mn^{II} are tetrahedral; the octahedral $[Mn(acac)_2(H_2O)_2]$ is yellow,[35] and the compounds $K_4[Mn(NCS)_6]\cdot 3H_2O$ and $Cs_4[Mn(NCS)_6]$ are described as red[36] and yellowish-green,[37] respectively. Furthermore [Mn(salen)] (salen = dianion of *N,N'*-bis(salicylaldehydo)ethylenediamine), which is yellow to orange (depending on crystal size),[38] is more likely to be planar than tetrahedral, although a five-coordinate dimer structure[39] is most likely for the solid; and in acetonitrile solution its *d–d* spectrum has molar extinction coefficients of between one and two.

Thus, whilst there may be some use for electronic spectra in confirming structure of Mn^{II} compounds,[40] it is not likely to be great. Many more spectra of known species will need to be accumulated for assessment, and a major difficulty with these labile systems will be to ensure that we know structure in solution first before we start trying to assign spectra.

41.3.2 Carbon Donor Ligands, Including Cyanides

41.3.2.1 Cyanides

Preparation of a pure binary cyanide $Mn(CN)_2$, which would of course involve bridging cyano groups in a polymeric structure, has not yet been achieved, nor has the preparation of any hydrates, but the crystalline solids $Mn(CN)_2\cdot L$ (L = DMSO, DMF and DMA) have been described recently.[41]

However, many mixed ligand species containing cyanide have been described, and the anionic hexacyano species $[Mn(CN)_6]^{4-}$ has been known[42] since at least 1869. It is a low spin species (Table 3); has been isolated in a range of salts $M^I_4[Mn(CN)_6]$ and $M^{II}_2[Mn(CN)_6]$ and their hydrates; yet it is not very robust in aqueous solution. As well as being subject to oxidation in the air, its aqueous solutions soon lose CN^-; unless such aqueous solutions contain an excess CN^- concentration of at least 1.5 M, green compounds of empirical formulae $M^IMn(CN)_3$ or $M^{II}Mn_2(CN)_6$ are precipitated. The half-life of exchange of labelled CN^- with $[Mn(CN)_6]^{4-}$ at pH 11.8 is only approximately five minutes.[43]

Recent work on aqueous cyanide solutions of $K_4[Mn(CN)_6]\cdot 3H_2O$ indicate that $[Mn(CN)_n(H_2O)_{6-n}]^{(n-2)-}$ with n = 1–5 and the binuclear species $[Mn(CN)_5—CN—Mn(CN)_5]^{7-}$ are present. On the addition of NaOH, the hydroxo species $[Mn(CN)_5OH]^{4-}$ is most likely formed, as are dimeric species with oxo or hydroxo ligands.[44]

$K_4[Mn(CN)_6]\cdot 3H_2O$ is usually a blue-violet material, although the more soluble $Na_4[Mn-$

$(CN)_6]\cdot 12H_2O$ has the expected yellow colour; both dissolve in aqueous cyanide to give yellow solutions. They are made[45] by treating manganese(II) acetate or carbonate with an excess of KCN or NaCN under rigorous exclusion of oxygen. The blue colour of the potassium salt suggests the presence of some Mn^{III} or Mn^{IV} in the solid and an interoxidation-state electron-transfer band.

An X-ray structural analysis[46] of $Na_4[Mn(CN)_6]\cdot 12H_2O$ shows the expected octahedral MnC_6 anion, with Mn—C = 1.95(3) Å.

The magnetic moment of the potassium salt at 300 K is 2.18 BM, corresponding to the presence of one unpaired electron with some orbital contribution.[47]

The acid species $H_4[Mn(CN)_6]$, or perhaps more properly $[Mn(CNH)_4(CN)_2]$, has been prepared[48] from $Pb_2[Mn(CN)_6]$ and H_2S.

The dark green insoluble products such as '$K\,Mn(CN)_3$' obtained from aqueous solutions of $K_4[Mn(CN)_6]$ (*q.v.*) are apparently more properly formulated as, *e.g.* $K_2Mn^{II}[Mn^{II}(CN)_6]$. The X-ray powder photograph can be indexed on a simple cubic cell of $a = 8.89$ Å; the IR spectrum shows a single 'bridging' ν_{CN} of 2062 cm^{-1}; and the magnetic moment of 4.53 BM all are consistent with a structure related to Prussian blue (see iron cyanides), consisting[49] essentially of equal numbers of low spin $[Mn^{II}C_6]$ and high spin $[Mn^{II}N_6]$ octahedra.

Another product formulated[50] as $K_{1.52}Mn(CN)_{3.72}$ has been made by fusing $K_3[Mn(CN)_6]$ and KCN at 650 °C. Available data suggest that it is merely an impure form of '$K\,Mn(CN)_3$'.

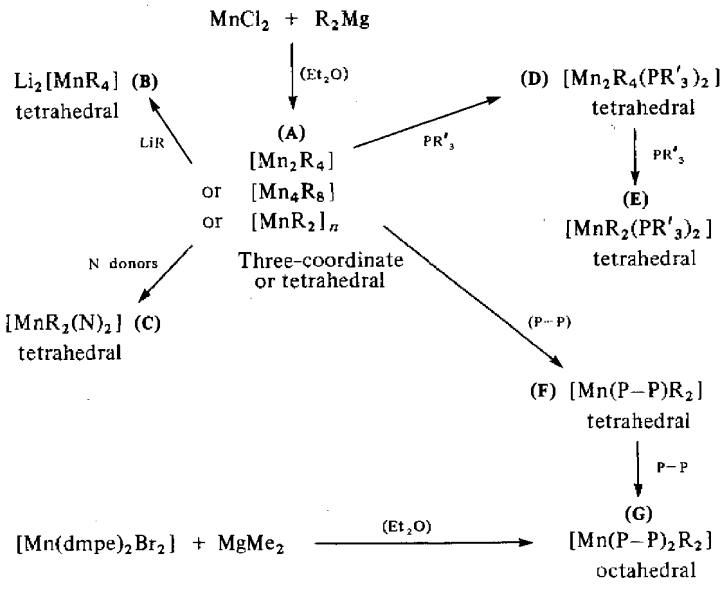
Interestingly, the action of NOCl on a suspension of green '$K\,Mn(CN)_3$' in sulfolane gives[51] a tan product of approximate composition $K_{0.5}Mn(CN)_3$. It appears to be identical with the product made by mixing[52] aqueous solutions of manganese(II) acetate and $K_3[Mn(CN)_6]$. Available physicochemical data on both products—$\nu_{CN} \approx 2150\,cm^{-1}$, $\mu_{eff} = 4.2$ BM per Mn, and a cubic unit cell of $a = 10.63$ Å—suggest again a Prussian blue type structure $KMn^{II}[Mn^{III}(CN)_6]$.

It is intriguing to note that the colours of green '$KMn(CN)_3$' and tan '$K_{0.5}Mn(CN)_3$' are the reverse of what one might expect from parallels in the iron Prussian blue system; '$KFe(CN)_3$' or $K_2Fe^{II}[Fe^{II}(CN)_6]$ is colourless, whereas '$K_{0.5}Fe(CN)_3$' or $KFe^{II}[Fe^{III}(CN)_6]$ is deep blue because of an interoxidation-state electron-transfer band. Clearly, further detailed study of these manganese systems is required, and the final explanation will probably need to take account of the availability of the Mn^{IV} state—note especially the tendency, under some conditions, for $[Mn^{III}(CN)_6]^{3-}$ to disproportionate to Mn^{II} and Mn^{IV}.

Species such as $Mn^{II}[M(CN)_6]\cdot 8H_2O$ (M = Fe, Ru, Os) and $Mn^{II}_3[M(CN)_6]\cdot nH_2O$ (M = Cr, Co) have been reviewed by Ludi and Gudel.[53] X-Ray structural analyses show that the former have *fac*-$[MnN_3O_3]$ octahedra from bridging cyanides and both terminal and bridging aquo groups, whereas the latter have[54] $[MnN_4O_2]$ octahedra.

A brown product, formulated[55] as $K_3Mn(CN)_5$, has been prepared by reducing $K_3[Mn(CN)_6]$ in hydrogen at 420 °C. The magnetic moment is 4.4 BM, and there appear to be bridging and terminal cyanides; but the exact formulation, including metal oxidation state, is not established from available data.

$[Mn(CN)_5NO]^{3-}$ is best prepared[56] as the purple, crystalline, diamagnetic potassium salt $K_3[Mn(CN)_5NO]\cdot 2H_2O$ by adding hydroxylamine to an aqueous solution of a manganese(II) 'salt' and an excess of KCN. Yields from the reaction[57] of NO with aqueous solutions of $[Mn(CN)_6]^{4-}$ are usually poor. Treatment of the potassium salt with a non-oxidizing acid gives[58] carmine-red $H_3[Mn(CN)_5NO]$.



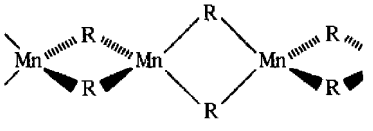
An X-ray structural analysis[59] of the potassium salt shows an almost linear Mn—NO with Mn—N = 1.66 Å and N—O = 1.21 Å. The vibrational spectrum[57] gives $\nu_{NO} = 1706\,cm^{-1}$; and the electronic spectrum shows three bands at 18 500, 28 600 and 45 900 cm^{-1} with molar extinction coefficients of 24, 114 and 16 000. Photolysis (UV) of anaerobic aqueous solutions leads[60] to $[Mn(CN)_6]^{4-}$ and NO, whereas, in the presence of oxygen, $[Mn(CN)_5(NO_2)]^{3-}$ is formed.[61]

Br_2 or HNO_3 oxidizes the nitrosyl anion to $[Mn(CN)_5NO]^{2-}$, and the standard reduction potential[56] for this reversible process is 0.6 V. Methylation[62] with methyl fluorosulfonate gives $[Mn(CNMe)_5NO](SO_3F)_2$.

41.3.2.2 Alkyls and aryls

Although normally classified within organometallic chemistry, the recently defined alkyls are a significant part of manganese(II) chemistry and we include them here.

The compounds described in four recent papers from Wilkinson's group[28,63–65] are summarized in Scheme 1. Comments on the various types of product follow the order of this scheme:



Scheme 1

(*A*) Only three binary alkyls MnR_2 have been isolated in pure form,[63] and are described as yellow to red crystals. X-Ray structural determinations of all three are known. They involved bridging alkyls and range from a dimer with pseudo three-coordinate Mn^{II} (**3**; R = CH_2CMe_2Ph); through a linear tetramer with two terminal three-coordinate metals and two central tetrahedra (R = CH_2CMe_3); to a long-chain polymer with mostly tetrahedral metals (**4**; R = CH_2SiMe_3). The low magnetic moments indicate antiferromagnetism.

(3)

(4)

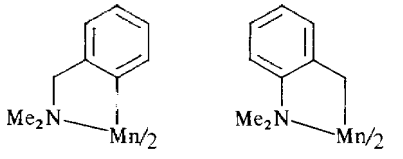
(*B*) Tetraalkylmanganate(II) species[63] are light sensitive. Colours range from yellow-orange to red. The known manganate with a bulky alkyl $Li_2[Mn(CH_2SiMe_3)_4]$ is orange-brown and behaves as a simple high spin tetrahedral $[MnR_4]^{2-}$ species, but the chemical and physical properties of the known tetramethylmanganates(II) are complicated by the small Li^+ cations.[63] Only when Li^+ is solvated, as in $[Li(TMEDA)_2][Mn(Me)_4]$ {TMEDA = 1,2-bis(dimethylamino)ethane}, do the solids appear to contain the simple high spin, tetrahedral $[MnR_4]^{2-}$ species.

(*C*) Solids isolated from the reaction with nitrogen donor ligands were $[MnR_2(N—N)]$ (where N—N is a chelating diamine: TMEDA or *N,N'*-dimethylpiperazine) and $[MnR_2py_2]$ (py = pyridine). All but one were described[63] as colourless solids and all apparently are high spin tetrahedral manganese(II) species. A related oxygen donor compound $[Mn(CH_2Ph)_2(dioxane)_2]$ also has been described.[66]

(*D*) Addition of unidentate phosphines to the alkyls gives a series of orange coloured dimers $[Mn_2R_4(PMe_3)_2]$. The X-ray structural determinations of three of them[64] show that they are dimers with essentially tetrahedral $[MnC_3P]$ polyhedra, although there is also an interesting close contact between one hydrogen atom on each of the bridging methylene groups and the manganese atom. The solid compounds are antiferromagnetic.

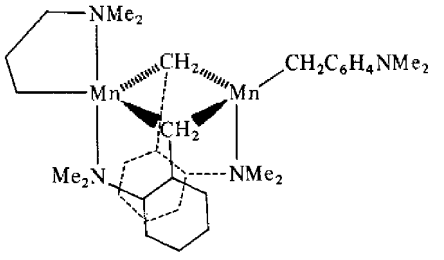
A related aryl compound $Mn(Ph)_2P(cyclo\text{-}C_6H_{11})_3$ has been described,[67] but its structure is unknown.

(*E*) When an excess of phosphine is added to solutions of the dimers, paler coloured bis-phosphine monomers are formed[65] (reaction 2). These tetrahedral monomers are high spin and are



thermally unstable. Indeed most of the solids isolated were found to lose phosphine readily, reverting to the dimers. However, $[Mn(CH_2CMe_2Ph)_2(PMe_3)_2]$ is indefinitely stable at room temperature in the absence of air, and the X-ray structure of the colourless crystals shows[65] the expected (distorted) tetrahedral geometry.

$$Mn_2R_4P_2 + 2P \rightleftharpoons 2[MnR_2P_2] \quad (2)$$



(*F*) With chelating phosphines, on the other hand, more robust $[MnC_2P_2]$ tetrahedra are obtained. Four solids $[MnR_2(dmpe)]$ were described[65] {dmpe = 1,2-bis(dimethylphosphine)ethane, and R = CH_2Ph, CH_2CMe_3, CH_2CMe_2Ph and CH_2SiMe_3} as yellow or colourless solids, containing high spin, tetrahedral monomers, which are thermally stable but air sensitive.

(*G*) Some of these alkyls can add two molecules of chelating phosphines to give red, low spin ($S = \frac{1}{2}$), octahedral $[MnC_2P_4]$ species. The first described[65] was the product of the chelating dialkyl *o*-xylyl—$[Mn\{o\text{-}C_6H_4(CH_2)_2\}(dmpe)_2]$—in which the M—C bonds (2.11 Å) are shorter than in the tetrahedral species (2.15 Å); the other is the dimethyl[28] species $[Mn(CH_3)_2(dmpe)_2]$.

The only other well-characterized alkyl or aryl compounds of manganese(II) appear to be two interesting isomeric species[68] (**5**) and (**6**). The aryl compound (**5**) has been isolated in a complex form $MnL_2 \cdot 2LiI \cdot 2THF$ (L = $C_6H_4CH_2NMe_2$) as pale-yellow air-sensitive crystals (μ_{eff} = 5.7 BM) of unknown molecular structure, and as the yellow-green $[MnL_2]$ (μ_{eff} = 5.5 BM) which is apparently a 'tetrahedral' monomer. On the other hand the bis-benzyl compound (**6**) parallels the alkyl-bridged dimers found for the above phosphines, and gives the only known example of a five-coordinate manganese(II) alkyl; its crystal structure shows a dimeric alkyl-bridged molecule (**7**) in which one metal atom is five-coordinate and the other four-coordinate. The expected antiferromagnetism is reflected in a room temperature magnetic moment of 2.6 BM.

(5) (6)

(7)

41.3.2.3 Fulminates and other carbon ligands

Several mixed ligand fulminates have been described. These include a poorly characterized ammine compound which was obtained[69] by reacting $Hg(CNO)_2$ with manganese amalgam in anhydrous methanol, which had been saturated with NH_3; and there are two reasonably robust yellow compounds $Mn(CNO)_2(N—N)_2$ (N—N = 2,2′-bipyridyl and 1,10-phenanthroline).[70] Various formulations have been suggested for these latter, but there appears to be no good evidence to suggest that they are not simply octahedral *cis*-$[Mn(CNO)_2(N—N)_2]$ species. On heating, they do not explode, but deflagrate vigorously.

An interesting acetylide is the rose-coloured $[Mn(C_2H)_2(NH_3)_4]$.[71] It dissolves in liquid NH_3 in the presence of KC_2H, apparently forming $K_2[Mn(C_2H)_4]$.

Also possibly involving Mn—C bonds is the compound[72] of the tricyanomethanide ion $Mn\{C(CN)_3\}_2\{(Me_2N)_3PO\}_2$. This colourless compound is not isomorphous with the octahedral Ni^{II} species, but also probably has an octahedral polymeric structure with bridging anions.

41.3.3 Nitrogen Ligands

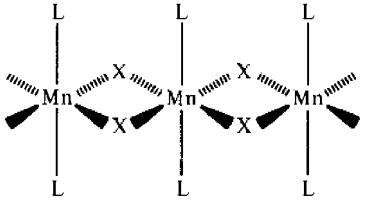
41.3.3.1 Unidentate ligands

(i) Ammonia and amido

Manganese(II) amines[73,74] are distinctly less stable and robust than those of the later transition metals.

In aqueous solutions, buffered with NH_4^+, the species $[Mn(NH_3)_n(OH_2)_{6-n}]^{2+}$, for $n = 1$–4, have been identified and the stability constants have been measured; for example, in 0.4 M NH_4Cl at 25 °C, $\log K_1 = 0.90$, $\log K_2 = 0.67$, $\log K_3 = -0.40$, and $\log K_4 = 0.30$. Apparently, only at high NH_3 concentrations, (> 2 M) is the hexaammine present in any significant concentration.

The known solid ammines are summarized in Table 8. Preparations with maximum n were generally made either by reacting solid MnX_2 with gaseous NH_3, or reacting MnX_2 or a hydrate with liquid NH_3. All lost NH_3 at rates depending on X, and the storage conditions. The species for n less than maximum value were characterized generally as steps in the thermal decomposition of the higher species.



Composition does not necessarily, of course, reflect coordinate number at the metal. This is especially so for the species for which $n > 6$; there is no evidence for $[MnN_7]$ or $[MnN_8]$ polyhedra except where special ligand steric effects promote higher coordinate numbers.

However, most of the species $MnX_2 \cdot 6NH_3$ are white powders, and probably contain the cation $[Mn(NH_3)_6]^{2+}$ (as do those for $n > 7$), and this is proved by X-ray powder diffraction for X = Cl, Br, I, ClO_4, SO_3F and BF_4, which have cubic crystal structures belonging to the CaF_2 type.

These compounds are sensitive to air, especially to moist air, generally turning brown, owing to oxidation and displacement of at least some of the NH_3. Sensitivity is anion dependent, with, for example, decreasing sensitivity from F^- to I^- amongst the halides.

The species $MnX_2 \cdot 4NH_3$ are surprisingly unusual: $MnCl_2 \cdot 4NH_3$ exists only under supercritical conditions, the thiocyanate needs further confirmation and the $[SiF_6]^{2-}$ species appears to be almost an exception; and in none of these cases are we certain of an $[MnX_2N_4]$ structure.

The diammines, on the other hand are well characterized and almost certainly have a linear polymeric structure as in (**8**) for (L = NH_3). The monoammines also are undoubtedly representatives of a well-characterized polymeric structural type, like the monopyridine compounds (*q.v.*).

(8)

Table 8 The Composition of Known Manganese(II) Ammines[73] $MnX_2(NH_3)_n$

X^-	$n NH_3$[a]									*Comments*
F										b
Cl	12	11	10	8	7	6	4	2	1	c
Br			10			6		2	1	
I						6		2

CN						6		2		d
NCS							4			
SO_3F						6				
$\frac{1}{2}SO_4$						6				
$\frac{1}{2}CrO_4$						6				
$\frac{1}{2}SiF_6$	12						4			e

[a] A few unusual species, listed in Gmelin,[73] but for which we think the evidence unsatisfactory, are omitted.
[b] At least two papers report the reaction of $MnF_2 + NH_3$, but products appear ill-defined and soon revert to MnF_2.
[c] Under normal conditions, the species for which $n = 6$, 2 and 1 only are observed. The other species (including $n = 4$) exist only under supercritical conditions.
[d] The species $Mn(CN)_2 \cdot 2NH_3$ seems suspect; colour was described as yellow-green and $\mu_{eff} = 6.3$ BM. In air it turns brown, losing HCN.
[e] Ref. 74.

Amido species of Mn^{II} are known. The binary compound $Mn(NH_2)_2$ is obtained[75] as an impure light yellow product from KNH_2 and $Mn(SCN)_2$ in liquid NH_3, but is stable only in the absence of air and water and below room temperature. The compounds $M_2[Mn(NH_2)_4]$ (M = Na, K, Rb, Cs), however, are relatively robust in the absence of water. The yellow crystalline compounds were obtained[76] by dissolving Mn in a liquid NH_3 solution of the alkali metal. An X-ray analysis of the K^+ salt confirms[77] the expected tetrahedral $[MnN_4]$ anion, with Mn—N = 2.12(4) Å.

(*ii*) *Aliphatic and aromatic amines and substituted amides*

Available data[78] on the products from the reaction of MnX_2 species with amines are both limited and often of poor quality. For the primary amines, data refer to the reaction of solid MnX_2 with gaseous RNH_2; but for most of the other amines, products were obtained from ethanol solutions. In the latter case, initial products often contained ethanol, $MnX_2 \cdot A_n \cdot (EtOH)_m$ (A = amine), but this was lost either on storage over $CaCl_2$ or on heating. It is not known whether the ethanol is bonded to the Mn or simply solvent of crystallization.

The poor quality of much of the data is evident both from the dark colours of many of the products, and from the lack of any meaningful structural data; of course, all pure species $MnX_2 \cdot A_n$ should be white or perhaps a very pale colour.

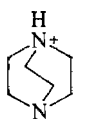
Most, but not quite all, of the high spin species $MnX_2 \cdot A_n$ are unstable to oxidation in the air and especially in moist air.

Observed stoichiometries for the compounds with the primary amines (Table 9) are for integral values of n in $(MnX_2 \cdot A_n)$ of 6, 4, 2 and 1 (the two non-integral values, assigned to nitrates, need further confirmation).

For $n = 6$, known compounds are confined to methylamine and ethylamine; these are probably $[MnA_6]X_2$ species. Tetrakis species are better defined here than for NH_3 and probably have $[MnX_2A_4]$ monomeric structures; but the most common stoichiometry is MnX_2A_2. These latter species probably have the linear polymer structure of (**8**).

Very little is known of compounds with the more sterically-demanding secondary amines. Two white aziridine (C_2H_5N) species $MnCl_2A_4$ and MnI_2A_5 have been described, but all other products (with piperidine, dialkylamines and substituted anilines) are described as 1:1 species $MnX_2 \cdot A$. (Unfortunately, all of the latter were described as brown or other dark colours and are therefore suspect.)

Tertiary amine compounds also are generally poorly defined. One attempt to obtain compounds of R_3N (R = Me, Et) from ethanol gave products which were not properly characterized, but which were formulated as containing R_3N and OR^- ligands. However, a white unstable solid $(MnCl_2 \cdot Et_3N)$ was obtained, which probably has a similar layer structure to $(MnCl_2 \cdot py)_n$. Trioctylamine can be used to extract Mn^{II} from aqueous acid solution into organic solvents, but the nature of the species involved is unknown.



The only available X-ray structural data refer to a compound of hexamethylenetetraamine $\{(CH_2)_6N_4\}$. A crystalline bis species has been shown[79] to have an all *trans*-$[MnCl_2N_2O_2]$ structure with long Mn—N bonds of 2.40 Å. The related cationic ligand (**9**) forms[80] the bis species $[MnX_3(LH)_2]X$ (X = Cl, Br); whereas ligand (**10**) does not bond to Mn; although Co, Ni and Cu form the species $[MnX_3(LH)]$ (X = Cl, Br, I), manganese forms[81] instead $(LH)_2[MnX_4]$.

Amido species of the secondary amine $NH(SiMe_3)_2$ have been studied in some depth.

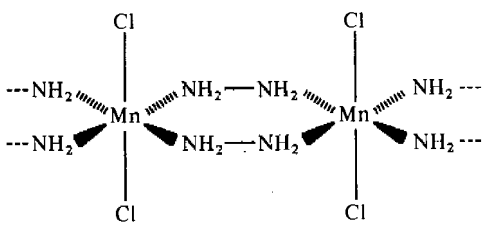
(9)

(10)

$Mn[N(SiMe_3)_2]_2$ was first made by Bürger and Wannagat[82] from MnI_2 and $NaN(SiMe_3)_2$ in THF, but Bradley and co-workers[83] have now shown that a reaction of $MnCl_2$ and the Li salt in THF gives pink $[Mn\{N(SiMe_3)_2\}_2(THF)]$, which is quite robust; it can be distilled without losing THF and is a paramagnetic (μ_{eff} = 5.91 BM) monomer.[84] At 120 °C, in a stream of argon, the THF is lost and recrystallization of the residue from pentane gives pink plates[83] of the dimer (**11**). An X-ray structure of this dimer shows Mn—N = 1.994 Å (terminal) and 2.184 Å (bridging), with a metal–metal distance of 2.841 Å. The magnetic moment of 3.34 BM (at 296 K) shows the expected antiferromagnetism.

(11)

More recently Horvath *et al.*[85] have improved the synthesis of $[Mn(NR_2)_2(THF)]$ and have shown that another series of yellow tetrahedral compounds $[Mn(NR_2)_2L_2]$ (where L = THF, py or Bu^t–CN) can be formed. All are thermally robust, but show exteme oxygen sensitivity. There is also an intriguing benzene species of unknown structure $[Mn\{N(SiMe_3)_2\}_2(C_6H_6)_2]$, and a series of mixed ligand species MnXY (where X = Cl, NO_3 and Bu; and Y = $N(SiMe_3)_2$ or OR).



Attempts to prepare compounds of NEt_2^- gave instead compounds of a reaction product of the amide (Section 41.3.3.2).

(*iii*) *Hydrazine and hydroxylamine*

Three types of compound of hydrazine and MnX_2 species have been characterized:[86] $MnX_2(N_2H_4)_n$ for n = 1, 2 and 3. Within these classes, they are of varying robustness—some are stable in air, others not.

The white n = 1 compounds are known only for MnF_2 and MnC_2O_4, and they are the stable species at ambient conditions for both. They can be prepared either by direct reaction or by loss of N_2H_4 from the bis species. The structure is unknown, but is undoubtedly polymeric and probably consists of both bridging hydrazine and anions. A similar compound has been described for 1,2-dimethylhydrazine, and with 4-nitrophenylhydrazine.

The bis compounds $MnX_2(N_2H_4)_2$ are the most common and have been characterized for X = F, Cl, Br, NCS, HCOO and OAc, and X_2 = oxalate and picramate. Crystalline hydrates of these also have been defined, as have hydrates for X = I and NO_3, but whether they have significantly different molecular structures from the anhydrous species is unknown. A full X-ray structural analysis of $MnCl_2(N_2H_4)_2$ characterizes the bis species as linear polymers based on double N_2H_4 bridges (**12**) (Mn—N = 2.27 Å and Mn—Cl = 2.57 Å). Bis compounds have also been described with phenylhydrazine and MnX_2 (for X = Cl, Br, I). Structures could be polymeric based either on bridging hydrazine as in (**12**), or on bridging halide as in (**8**).

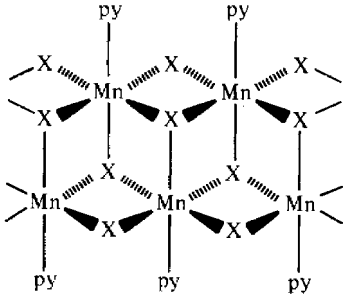
[b] X = $\frac{1}{2}SnBr_6$.
[c] X = $CF_3CO_2^-$, $CCl_3CO_2^-$, $SbCl_6$, $\frac{1}{2}HgCl_4$, $\frac{1}{2}Cr_2O_7$, ReO_4.
[d] At least ten others have been described.
[e] X = $Me_3CCO_2^-$, $\frac{1}{2}C_2O_4$.

A tetrakis compound of 4-nitrophenylhydrazine and $MnCl_2$ may be an example of a monomeric $[MnCl_2N_4]$ chromophore.

A few compounds of hydroxylamine and MnX_2 have been described,[87] but it is uncertain that any of them contain Mn—N bonds (see Section 41.3.9).

(*iv*) *Pyridines and quinolines*

Almost all of the known compounds[88] appear to be high spin six-coordinate species; they are generally colourless and sensitive to air, turning brown with loss of a nitrogen ligand.



The solid pyridine compounds are summarized in Table 10. Unlike the amines, tetrakis compounds are quite common, and hexakis species are less usual. This is probably related to the steric requirements of the α-hydrogens of pyridine. The room-temperature-stable combination of MnX_2 and py is usually a bis species.

In aqueous solution, potentiometric measurements have been interpreted in terms of only four species $[Mnpy_n(H_2O)_{(6-n)}]^{2+}$ ($n = 1$ to 4), with log K_n determined as 1.86, 1.59, 0.9 and 0.6, respectively. Perhaps the $n = 5$ and 6 species are formed at higher concentrations of pyridine, but, even in the solid state, there is yet no certainty that the compounds $MnX_2 \cdot 6py$ actually contain $[Mnpy_6]^{2+}$. It is virtually certain that the compound $Mn(ClO_4)_2 \cdot 8py$ is not eight-coordinate.

The *tetrakis* compounds, which are quite common here, probably all (because of the steric requirements of py) have a *trans*-$[MnX_2N_4]$ octahedral structure. X-Ray proof of this, however, is available only for $[Mn(NCS)_2py_4]$ and $MnSbCl_6 \cdot 4py$, and is obtained by comparison of the powder patterns with the octahedral Ni species.

Bis compounds are usually the final product of the other species when left at room temperature. They appear generally to have the polymeric structure (**8**) and show some antiferromagnetism, except where the bridging ligands, such as $[Ni(CN)_4]^{2-}$ and $[C_2O_4]^{2-}$, cause sufficient separation of metal centres. A full X-ray analysis of $MnCl_2py_2$ shows the polymeric structure with Mn—Cl = 2.56, 2.57 Å and Mn—N = 2.24 Å.

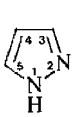
Monopyridine compounds result from thermal degradation of the bis species. They appear to have the polymeric structure (**13**) ($MnCl_2py$ is isomorphous with $NiBr_2py$). Further thermal degradation sometimes leads to a well-characterized phase $\{Mn_3X_6 \cdot 2py\}_n$.

(13)

Pentakispyridine compounds are known only in $Mn(ClO_4)_2 \cdot 5py \cdot 3H_2O$ which is of unknown structure, and there is an isoquinoline compound $MnCl_2 \cdot 5L$.

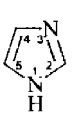
Tris compounds have been proposed only in $[py_2H][MnBr_3py_3]$ (which could be instead $[MnBr_2py_4] \cdot pyHBr$) and $[R_4N][MnBrCl_2py_3]$ (R = Me, Et) and a 4-picoline analogue, but even their formulation as discrete species needs X-ray confirmation.

Substituted pyridines (β or γ) generally give compounds of the same type as pyridine, although no hexakis compounds have yet been described. We especially notice, however, the compound $Mn(NCS)_2(3\text{-Br-py})_2$, which is 'freely soluble in the common organic solvents', unlike the other bis species. A tetrahedral $[MnN_4]$ has been proposed, although small oligomers, such as a five-coordinate dimer, are also possible.



2-Substituted pyridines, including quinoline, have more stringent steric requirements, and generally form only 1:2 and 1:1 species. Those so far described appear to be polymers, with structures such as (**8**) and (**13**), yet it is here especially that we might expect to encounter tetrahedral $[MnX_2L_2]$ species or five-coordinate dimers as in the biquinolyl compounds (Section 41.3.3.2).

A series of compounds formulated as $[RH]_2[MnCl_4py_4]$ are more likely to be six-coordinate, with free pyridine in the crystal lattice, if indeed they are discrete compounds and not mixtures.



(*v*) *Pyrazoles, imidazoles, triazoles, etc.*

The compounds of these ligands,[89] especially those of imidazole, have been more effectively studied than those of the more classical ligands, *i.e.* pyridine and ammonia. The biological role of imidazole moieties as donors has given impetus to these studies in the 1970s, and the compounds are generally more robust in the air and at ambient temperature, although some are still unstable, especially with respect to oxidation in moist air. Structural data are more complete; more full X-ray determinations are available, and nearly maximum use has been made of X-ray powder data, especially by Reedijk and co-workers,[90] for comparison with other species of known structure.

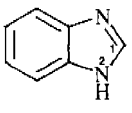


Table 11 gives the stoichiometries of the compounds $MnX_2 \cdot nL$. These were generally obtained as crystalline species from anhydrous ethanol, although a few of the species of lower *n* values were made by thermal decomposition. All are high spin, with some polymers showing antiferromagnetism, and most are, as expected, colourless; a few are pale pink, and there are some yellows, fawns and browns, but the detail is unimportant. A common feature seems to be bonding through the unsaturated nitrogen (=N–), and not through the NH nitrogen.

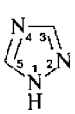


(14)

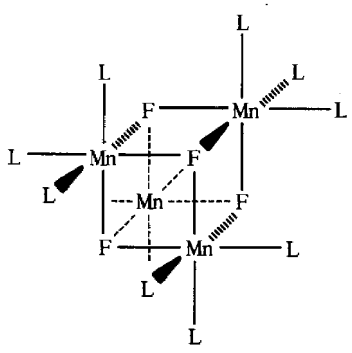
(15)

(16)

(17)

The compounds for $n = 6$ appear generally to contain $[MnN_6]^{2+}$ octahedra; proof comes from comparative X-ray data in some cases and in others reasonable evidence is available from ESR data. The one observed compound of higher *n*, that is $Mn(ClO_4)_2 \cdot 7(5\text{-Me-pyrazole})$, is isomorphous with an Ni species, known to be $[NiL_6](ClO_4)_2 \cdot L$, and thus belongs to this class. Where there are ring substituents adjacent to the bonding N, steric crowding destabilizes the $[MnN_6]^{2+}$ octahedra and species of lower *n* are obtained. In Table 11 there are two possible exceptions: $Mn(NCS)_2 \cdot 6(3,5\text{-diMe-pyrazole})$ and $Mn(NO_3)_2 \cdot 6(2\text{-Me-imidazole})$. The former appears from available data to have the structure $[Mn(NCS)_2L_4] \cdot 2L$, and there is only doubtful IR evidence that all the imidazoles are bonded in the latter. Note that in this latter case, both ClO_4 and BF_4 form only 1:4 species.

There are many $n = 4$ species here, most of which appear to have a *trans* octahedral $[MnX_2L_4]$ structure. Indications of this come from one available X-ray structure[91] {$[MnBr_2(5\text{-Me-pyrazole})_4]$, which has *trans* bromines at 2.73 Å and Mn—N of 2.25 Å}, from the ESR data and perhaps also from some of the IR data. Two crystalline forms of $Mn(NCS)_2(5\text{-Me-pyr})_4$, both of which are isomorphous with Ni species, have been interpreted as examples of *cis* and *trans* isomers, but the data do not absolutely require the acceptance of the view that one is a *cis* isomer.



The $n = 3$ species are of some interest in providing one of the few known examples of five-coordinate Mn^{II}. Fourteen of these species have been described (Table 11); some have been assigned (undefined) polymeric structures; but structure is known certainly only for $[MnCl_2(2\text{-Me-imid})_3]$. This is a five-coordinate monomer,[92] with 'intermediate' structure and bond distances Mn—Cl of 2.392 and 2.525 Å, and Mn—N of 2.19, 2.20 and 2.25 Å.

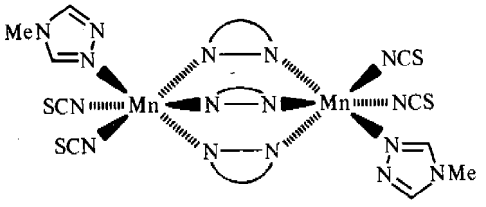
[a] Substituent positions are given in diagrams (**14**) to (**17**).
[b] Full X-ray structural analyses available—see text.
[c] Isomorphous with Fe, Co, Cu and Zn analogues.
[d] Isomorphous with Cu analogue.
[e] Tetrameric $[Mn_4F_4]$ species formed—see text.
[f] Isomorphous with Ni analogue (and usually others) thus identifying *Oh* or *D4h* symmetry.
[g] The structure is $[MnL_6](ClO_4) \cdot L$.
[h] Explosive above 200°C.
[i] See text for X-ray powder data.

Within this class are a series of compounds $MnF(BF_4) \cdot 3L$ (where L = 5-Me-pyrazole, 1-Et- and 1-Pr-imidazole). They resulted from attempts to prepare $Mn(BF_4)_2$ compounds, and all appear to have the tetrameric 'cubane' structure[93] of (**18**).

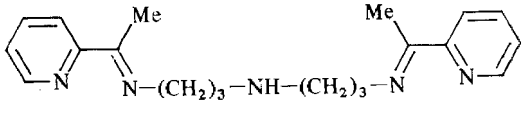


(**18**)

The $n = 2$ compounds appear to be generally antiferromagnetic polymers of structural type (**8**). One full X-ray study is available[94] on $MnCl_2(pyrazole)_2$, which gives Mn—Cl = 2.593 Å and Mn—N = 2.201 Å. There are, however, some interesting exceptions with the sterically hindered ligands. For 3,5-dimethylpyrazole, the F, Cl and NCS species are antiferromagnetic (especially the F), but the Br species which is not isomorphous with the Cl, is isomorphous with the Ni, Co and Zn species, and there are suggestions that it has a tetrahedral monomeric structure. Similarly, for $MnCl_2(1,2\text{-di-Me-imid})_2$, the magnetic moment is invariant between 100 and 300 K, and the compound also appears to be a tetrahedral monomer, whilst the alcohol solubility of the Me- and Bz-substituted benzimidazoles may point to tetrahedral monomers or five-coordinate dimers.

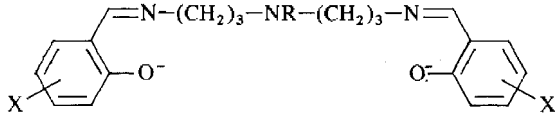
But few $n = 1$ compounds have been described. They probably have a polymeric chain structure like (**13**). There is also a series of tetrahedra $[R_4N][MnX_3L]$ (where X = Cl, Br and L = 1-Me, 1-Et, 1-Pr, 1-vinyl and 4-Me-imidazole).

The few known triazole (**17**) compounds are of different type. $MnSO_4$ forms a mono species under conditions where Ni forms a tris, and this has a monomeric structure[95] $[Mn(SO_4)(H_2O)L]$. On the other hand $Mn(NCS)_2$ forms a polymeric $Mn(NCS)_2 \cdot 2L$ species, in which the polymerization occurs through the triazole ligand (N-2 and N-4) bridging *trans* $Mn(NCS)_2$ units.[96] The other known triazole compound is $Mn_2(NCS)_4$(4-Me-triazole)$_5$ which has[97] the dimeric structure (**19**)



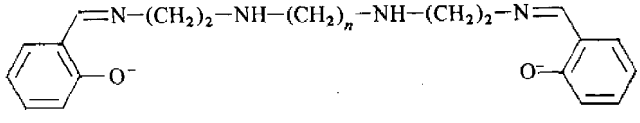
(19)

Another unusual species is the compound of Mn^{II} and the imidazoyl anion $[Mn_3(imid\text{-}H)_6 \cdot 2\,imid]$, made from manganese carbonyl. The colourless crystals are air sensitive, and have[98] a polymeric structure with alternating $[MnN_6]$ octrahedra and $[MnN_4]$ tetrahedra, bridged by the imidazole ligands. Each octahedral Mn is surrounded by four tetrahedral Mn's and each tetrahedron is surrounded by two other tetrahedra and two octahedra.



(*vi*) *Other neutral nitrogen ligands*

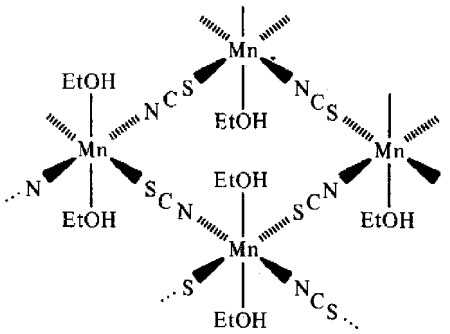
Very little work appears to have been done on manganese nitrile compounds, although several authors have described[99] $[Mn(RCN)_6]^{2+}$ and $[Mn(ArCN)_6]^{2+}$ species.



Nitrosyl compounds of manganese(II), in addition to the cyano nitrosyls (Section 41.3.2.2) and porphyrin species (Section 41.3.10.1), are represented by the compounds $[Mn(L)NO](ClO_4)_2$ (L = **20**) and [Mn(L′)NO] (L′ = **21**). The former was prepared by simply treating the compound with the pentaamine ligand with NO, and an X-ray structure analysis[100] shows an octahedral $[MnN_6]^{2+}$ species with Mn—N(O) of 1.58 Å and the other Mn—N distances ranging between 1.91 and 2.12 Å. The Mn^{II} compounds of the salicylaldiminate ligands (**21**) reacted reversibly[101] in solution with NO, many lost NO when attempts were made to isolate them, and even though crystalline, purple-red, diamagnetic solids were obtained, they were thermally unstable, reverting to yellow $[Mn^{II}(L')]$ and NO. The solutions, however, reacted with O_2 to give $[Mn^{III}(L')(NO_2)]$ species. Interestingly, the compounds of the sexadentate ligands (**22**) (n = 2, 3) also react[102] with NO to give red nitrosyl compounds in solution ($CHCl_3$) and these then react with O_2 to give green $[Mn^{III}(L'')(NO_2)]$, which *may* be seven-coordinate species.

(20)

(21)



(22)

Thiazyltrifluoride (NSF_3) is an interesting new ligand which forms colourless $[Mn(AsF_6)_2(NSF_3)_4]$. The X-ray analysis[103] shows Mn—N bonds of 2.19 Å and *trans* F atoms (from AsF_6^-) at 2.19 Å.

(*vii*) *Unidentate anions (including thiocyanate and azide)*

The *nitrite* anion appears to bond to Mn^{II} through its O atoms exclusively, and is treated in Section 41.3.5.

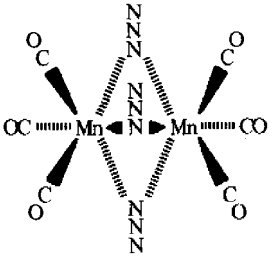
Thiocyanato, but not *cyanato* and *selenocyanato* species have been studied in some depth.[104] All three apparently prefer N-bonding to Mn^{II}, although there is at least one example of Mn—NCS—Mn bridging; polymeric $Mn(NCS)_2(EtOH)_2$ has[105] the layer structure represented in (**23**). In golden-yellow $HgMn(SCN)_4$, the bridging is Mn—NCS—Hg like the Fe, Co and Zn analogues. There is also some evidence for Mn—$\overset{|}{N}$—Mn bridging in some compounds of the substituted pyridines, but this needs X-ray confirmation.

(**23**)

The binary thiocyanate has been known[104] as the hydrate $Mn(NCS)_2 \cdot 3H_2O$ since 1842, and $Mn(NCS)_2$ can be obtained by heating this to 170 °C, or by heating the ethanol compound (**23**) to 110 °C. The selenocyanate has only been obtained as a THF or dioxane species, decomposing when attempts are made to remove these other ligands.

All three (NCO, NCS, NCSe) form a range of anionic species, and the known solids are summarized in Table 12. Some studies of solutions are available, but much remains to be learnt of the detailed structures adopted by Mn^{II} in these solutions. Both tetrahedral and octahedral species seem well characterized in the solid state, but it would be reassuring to have some X-ray confirma-

Table 12 Anionic Species with Cyanate, Thiocyanate and Selenocyanate



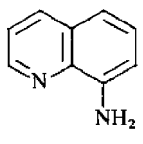
Anion	*Number of Salts*[a]	*Confirmed Structures*[b]	*First Reported*	*Ref.*
$[Mn(NCO)_4]^{2-}$	1	1	1964	33
$[Mn(NCS)_4]^{2-}$	10	—	1905	106
$[Mn(NCS)_4(AA)]^{2-}$[e]	2	—	1981	107
$Mn(NCS)_5^{3-}$[c]	2	—	1905	106
$[Mn(NCS)_6]^{4-}$	8	2[d]	1900	36, 37
$[Mn(NCSe)_4]^{2-}$	1	—	1965	108
$[Mn(NCSe)_6]^{4-}$	3	—	1965	108

[a] This refers to the numbers of solid compounds described with appropriate stoichiometry.
[b] The test adopted here is a demonstrated isomorphism with other metal compounds of known structure— through X-ray powder photography.
[c] These may be five-coordinate, but appear not to have been studied since the original work.
[d] $K_4[Mn(NCS)_6] \cdot 4H_2O$ is an isotype of the rhombohedral $K_4[Ni(NCS)_6] \cdot 4H_2O$ and $K_3[Cr(NCS)_6] \cdot 4H_2O$, and the quinolinium salt has been shown to be isomorphous with the Fe and Ni species.
[e] AA = bipy or phen.

tion of the tetrahedron. There are also two solids which may be examples of five-coordinate $[Mn(NCS)_5]^{3-}$ species. The recently reported yellow anions $[Mn(NCS)_4(AA)]^{2-}$ (where AA = bipy or phen) were prepared readily from aqueous ethanol. Related to these probably are the compounds[109] of the hexamethylenetetraamine monocation, $(C_6H_{13}N_4)_2Mn(NCS)_4$. The manganese compound is isomorphous with the Fe, Co and Ni analogues and the structure may well be an $[Mn(NCS)_4(N)_2]$ octahedron (*cf.* Section 41.3.3.1.2).

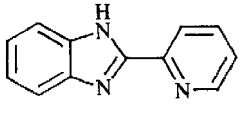
Both the binary *azide* $Mn(N_3)_2$, which, of course, detonates readily, and the tetrakis anion $[Mn(N_3)_4]^{2-}$ are known.[110] The latter has been isolated as the NEt_4^+ salt from various non-aqueous solvents and the *n*-cetyltrimethylammonium salt precipitates from aqueous solutions of the former. Products obtained have been described as light grey; the evidence for a monomeric tetrahedron is so far only IR; the compounds are light sensitive, turning brown. They are insensitive to shock, but do detonate in a flame.

Azido compounds with other ligands also have been studied. As with thiocyanate, so there is some evidence that azido can bridge through the one terminal N atom in at least some substituted pyridine compounds, a form of bridging that is well characterized[111] in the Mn^{II} tricarbonyl anion (**24**).



(24)

41.3.3.2 Bidentate ligands



With higher multidentates, but beginning with the bidentates, Mn^{II} compounds with nitrogen ligands become rather more robust. The 1,2-diaminoethane species $[Mnen_3]^{2+}$ is still quite sensitive to air; aqueous solutions are oxidized and the solids $[Mnen_3]X_2$ turn brown at varying rates; but $[Mnbipy_3]^{2+}$ and $[Mnphen_3]^{2+}$ are not at all easily oxidized.

Stability constants in water are generally quite low: log K_n's for $Mn(en)_n^{2+}$ are 2.8, 2.1 and 0.9, respectively (with log β_3 rising to 10.1 in DMSO); and for phen they are 4.0, 3.5 and 3.0.

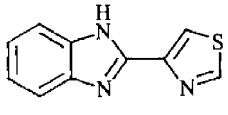


Table 13 lists the solid compounds $MnX_2 \cdot nL$, all of which are high spin. There are also significant reports of compounds with diamines, such as *m* and *p*-phenylenediamines, which are incapable of chelating. These compounds,[112] thus, can be treated simply as variations on the unidentate theme.

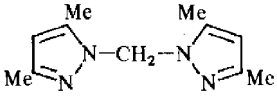
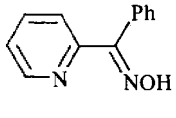
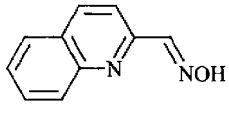


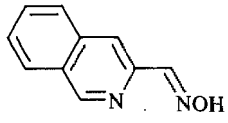
(25)



(26)



(27)



(28)

(29)

(30)

(31)

Except perhaps for the special case of the $n = 4$ species, the values of n seem invariably to define the number of bidentate ligands bonded to Mn: tris compounds are octahedral cations (one salt, the ethylxanthate, has been shown[123] to be isomorphous with the octahedral Fe, Co and Ni salts); bis

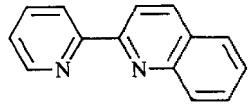
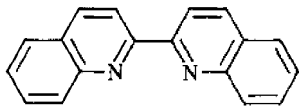
(**39**) R = Me			1		129

[a] The totals here include solvates and species known to be, for example, $[Mn(N{-}N)_2(H_2O)_2]X_2$.
[b] These products were described as brown and are suspect.

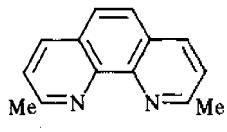


compounds are octahedral[130,131] $[MnX_2(N{-}N)_2]$ or $[Mn(N{-}N)_2(H_2O)_2]^{2+}$, *etc.* species; and, whilst the mono compounds in the solid state appear generally to be $\{MnX_2(N{-}N)\}_x$ polymers with bridging anions,[132] they dissolve to give $[Mn(N{-}N)(solvent)_4]^{2+}$ cations. Several anions $[MnX_4(N{-}N)]^{2-}$ also are known,[107] but have not been significantly explored.

The bis-chelate compounds of bipyridyl and phenanthroline appear to be invariably *cis* isomers[130,131,133] as a result of the steric effect of their α-hydrogens;[133] although, with the larger Mn—N distances, *trans* isomers may be available here.[133] Full X-ray structural analyses of $[Mn(NCX)_2bipy_2]$ (X = O, S) are available,[130,131] with the most reliable data giving[131] Mn—N(bipy) of 2.17–2.31 Å and Mn—N(CS) = 2.145 Å. The structure[124] of the closely related *cis*-$[Mn(NO_3)_2L_2]$ (where L = **32**) shows a significant feature of these Mn compounds: it is eight-coordinate, with both nitrates bidentate (Mn—O = 2.30–2.47 Å (average = 2.42) and Mn—N = 2.29–2.33 Å). Such eight-coordinate structures may be a common feature of the compounds with the oxyanions, including carboxylates.



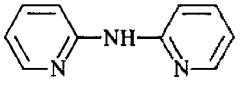
With substituents in the α-positions, the steric requirements of bipy and phen become more demanding, and ligands (**33**) and (**34**) give five-coordinate species.[125,126] The pyridyl-quinolyl ligand (**33**) gives a monomeric $[MnBr_2(H_2O)(N{-}N)]$, whilst the biquinolyl ligand (**34**) gives a dimeric $[(N{-}N)ClMn{-}Cl_2{-}MnCl(N{-}N)]$, no other compounds of these ligands appear to have been reported. With the bis-chelate compounds[113] of 2,9-dimethyl-1,10-phenanthroline (**35**), it will be interesting to see if the larger Mn^{II} will allow octahedral $[MnX_2(N{-}N)_2]$ species, or whether they will be five-coordinate $[MnX(N{-}N)_2]X$.



(32)

(33)

(34)



(35)

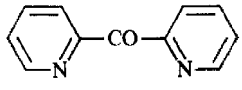


Table 14 Compounds with Bipyridyl Anions

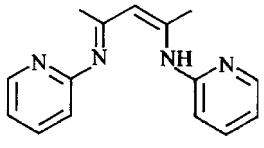
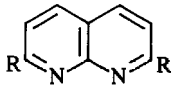
Compound	*Colour*	*Magnetic moment*(BM) *293* K	*80* K
$[Mnbipy_3]$	Black-brown needles	4.09	3.81
$[Mnbipy_3]\cdot 2THF$	Brown needles	4.1	3.8
$Li[Mnbipy_3]\cdot THF$	Deep red crystals	3.6	
$Na_4[Mnbipy_3]\cdot 3THF\cdot 5dioxane$	Black-violet crystals	5.99	



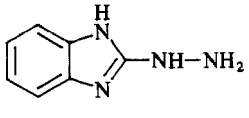
The $n = 4$ compounds (Table 13) have been known[113,134] for phenanthroline since 1933. Analogous Sr and Ba species, but which are not isomorphous with the Mn species, now are known[135] to be $[Mphen_2(H_2O)_4]^{2+}\cdot 2phen\cdot nH_2O$ species, and Drew *et al.*[136] have reported another example of a non-bonded phenanthroline. Attempts to obtain suitable crystals of Mn $phen_4X_2$ species for X-ray analysis have not been successful,[135] so the question of structure of the Mn species is still open. Eight-coordination is, however, established in the 1,8-naphthyridine (**39** for R = H) compound $[Mn(N{-}N)_4](ClO_4)_2$, which is isomorphous[129] with the Fe, Co, Ni, Cu and Pd species; it also occurs again in the $[Mn(NO_3)_2(N{-}N)_2]$ species; but, for the dimethyl ligand (**39** for R = Me), steric effects reduce the coordination number to six.



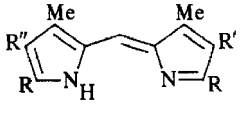
(36)

(37)

(38)

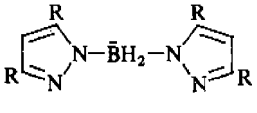


(39)

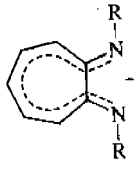


The $[Mnbipy_3]^{2+}$ cation undergoes at one-electron oxidation at ~ 1.4 V (*v* saturated calomel), and a number of reduction steps.[123,137]

Chemical reductions[123] in THF solutions have produced several crystalline reduced species (Table 14). The best available explanation of these species defines them as Mn^{II} compounds of radical anion ligands, either $bipy^-$ (for the first three) or $bipy^{2-}$ for the Na salt. The magnetism of the compounds containing $bipy^-$ is an interesting theoretical problem.



A range of other anionic bidentate ligand compounds also has been described (Table 15), including several $[Mn(N{-}N)_2]^0$ tetrahedra, but these are generally very sensitive to air and the studies so far have been of limited scope. We have real reservations about the dipyrromethane compound: there is little in the report, except stoichiometry, to distinguish it from the tris-Mn^{III} species.



(40)

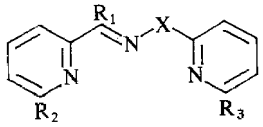
41.3.3.3 Terdentate ligands



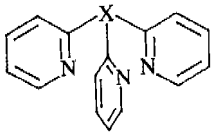
(*i*) *Linear ligands*

The study of the Mn^{II} compounds of the terdentate ligands has generally occurred as an addendum to the study of the compounds of the other metals, the one significant exception being a recent paper by Chiswell and Litster.[144]

Stability constants in aqueous solution are available for dien (bis(2-aminoethyl)amine),[145] bis(2-pyridylmethyl)amine[146] and terpy (2,2′2″-terpyridyl).[147] The determined log K_1's and log K_2's are, respectively: 4.0 and 2.8; 3.5 and 2.6; and 4.4 (K_2 not measured for terpy).

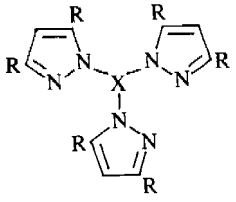
Both 2:1 and 1:1 solid $MnX_2 \cdot nL$ species have been well characterized. The 2:1 species are unexceptionable bis-ligand $[MnN_6]X_2$ octahedra: those with dien are white, and those with the unsaturated heterocyclic ligands related to terpy[144] are generally yellow. Electrochemical studies of the bis-terpy species, and analogues with related ligands,[147] have revealed a series of reduced species, which undoubtedly relate to the Mn^{II}-radical-anion species observed with bipyridyl (previous section).

Monoanions of the ligands (**46** for X = NH), formed by loss of the hydrazone proton, produce neutral molecules $[Mn(N_3)_2]^0$: four of these species have been described, and despite an earlier report to the contrary,[148] they are all high spin.[144]



(46)

In the 1:1 compounds $MnLX_2$, five-coordinate monomeric $[MnX_2N_3]$ structures appear to be dominant. Such structures were first seen concurrently in the compounds of pentamethyl-dien (X = Cl, Br),[149] terpy (X = Cl)[150] and paphy (**46** for X = NH, $R_1 = R_2 = R_3 = H$).[151] No full X-ray studies of Mn compounds are available, but powder patterns relate them to known Co and Zn species. Octahedral dimers $[Mn_2X_4L_2]$, and possibly polymers, probably exist also, as postulated by Madden and Nelson[152] for the chloro compound of bis(2-pyridylethyl)amine, but none are yet proven. The most complete study of the $[MnX_2L]$ species[144] produced 58 compounds with X = Cl, Br, I or NCS and L being one of 20 variations on the theme (**46**) or related ligands using quinolyl, benzthiazyl or oxime moieties. They had colours ranging from yellow, through orange, to brown; were all high spin; and X-ray powder patterns of fourteen of them (X = Cl or NCS) showed ten to be isomorphous with the almost certainly five-coordinate Co^{II} analogues, but not with the octahedral Ni^{II} dimers.



(ii) Tripod ligands

But few compounds of this class have been described. A high spin compound $[MnL_2](ClO_4)_2$ has been described[153] for L = (**47**, X = C—OH) and a compound $[MnCl_2L]$ has been described[154] for L = (**47**, X = N). The latter was thought to be tetrahedral, but seems more likely to be a five-coordinate monomer.

The other ligands studied have been the monoanions (**48**), where R = H or Me, X = GaMe,[155] BH or B-pyrazoyl.[140] These ligands form colourless, high spin $[MnN_6]^0$ octahedral species.

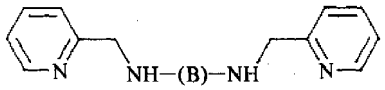
(47)

(48)

41.3.3.4 Quadridentate ligands

(i) Linear ligands

The classical linear tetraamine, triethylenetetraamine (trien), gives a 1:1 species in aqueous solution[156] with a log *K* of only ~5. Such aqueous solutions are very oxygen sensitive. The solid compounds prepared from this ligand and the other linear quadridentates are in Table 16.



The most common type $MnX_2 \cdot L$, which are yellow, orange or light green in colour, probably are largely octahedral $[MnX_2N_4]$ species. The sterically hindered 3,22,3-tet species[157] were isomorphous with their Fe^{II} analogues, but not with those of the later transition metals, for which five-coordinate [MX(3,22,3-tet)]X structures have been demonstrated: perhaps the larger Mn^{II} and Fe^{II} atoms allow $[MnX_2(3,22,3\text{-tet})]$ octahedral coordination. Also pertinent here is the compound of ligand (**56**): ring closure with formaldehyde to give macrocyclic species (Section 41.3.10) was achieved[162] for the other later transition metals but not for the (larger) Mn^{II}.

The cream or yellow $[Mn_2L_3]X_4$ species are of a type well characterized for such linear quadridentates: they probably have a structure in which each ligand acts as a bridging group between two metals, being bidentate to each, and thus giving two connected $[MnN_6]$ octahedra.

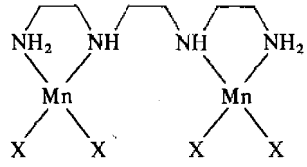


Table 16 Compounds Reported with the Linear Quadridentate Nitrogen Ligands

Ligand	*Compound—defined by X* $MnX_2 \cdot L$	$[Mn_2L_3]X_4$	MnX_2L_2	*Ref.*
trien	Br, ClO_4	Br, BPh_4	Br	156
3,22,3-tet[a]	Cl, Br			157
(**49**), B = $(CH_2)_2$	Cl, ClO_4	ClO_4		158
(**49**), B = $(CH_2)_3$[b,c]	Cl, Br, I, NO_2, NCS, ClO_4	BPh_4		158, 159

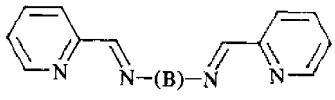
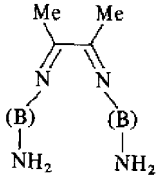
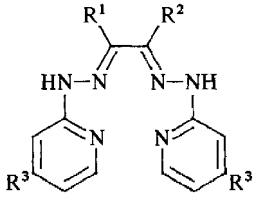
(**53**), $R^1 = R^3 = H$, $R^2 = Bu^t$	Cl			144
(**53**), $R^1 = R^2 = R^3$ = Me	Cl, Br, NCS			144
(**55**)	ClO_4			160
(**56**), R = H	Cl			161
(**56**), R = Me	Cl, NCS			161



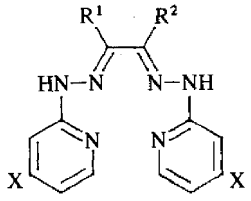
[a] 3,22,3-tet = bis-*N*,*N'*-(3-aminopropyl)piperazine.
[b] This ligand also forms a compound $Mn_2L(N_3)_4$ which is probably of structural type (**50**), but with further polymerization on the azide anion.
[c] A compound $MnLClPF_6$ also has been described.



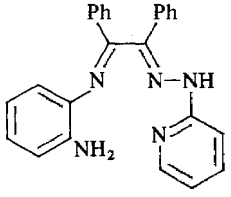
(49)



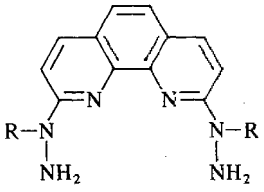
(50)



(51)

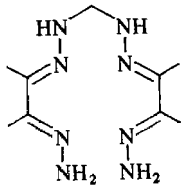


(52)



(53)

(54)



(55)

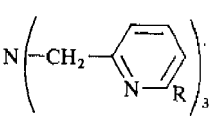
(56)

But of more interest are the species MnL_2X_2, which are possibly eight-coordinate. They tend to form with the more rigid, planar ligands (but *cf.* trien), and they are all ligands which show cumulative ring strain (C-strain),[163] especially when bound to the larger Mn^{II}. Thus, they are eminently suitable for two of them to fit comfortably, mutually perpendicular, around a manganese(II) atom. As with the tetrakis-bidentates (Section 41.3.3.2) X-ray studies await the collection of suitable crystals.

Ligands (**53**) to (**57**) are capable of losing two protons, to give $[Mn(quad\text{-}2H)]^0$ molecular species, and those of ligands (**53**) to (**55**) have been studied.[160,164] Attempts to prepare them by reaction (3), generally gave mostly MnO_2; but thirteen compounds of the dianions of ligands (**53**), (**54**) and (**55**) have been prepared by irradiating solutions of the ligand and $Mn_2(CO)_{10}$ in THF under N_2. They are generally deep violet to red in colour, the colours arising from ligand based charge transfer transitions, and generally appear to be monomers, rather than dimers with two N—C—N bridges as demonstrated for the Ni^{II} analogues.[165] A few examples of the dimers were found,[164] although, with the larger Mn,[II] they might have been expected to be more common. Perhaps the compound of ligand (**55**),[160] with magnetic moment between 4.8 and 5.4 BM, is a pure dimer of structural type related to the Ni dimer.[165]

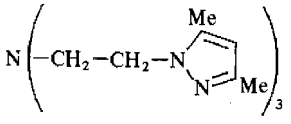
(57)

$$Mn(quad)X_2 + 2OR^- \longrightarrow [Mn(quad\text{-}2H)] + 2ROH \quad (3)$$



The monomeric Mn^{II} compounds derived from ligands (**53**) and (**54**) appear closely related to [Mn(phthalocyanine)] (Section 41.3.10.2) in their magnetic properties, and some, with temperature independent magnetic moments of near 4.0 BM, appear to be examples of pure $S = \frac{3}{2}$ species.

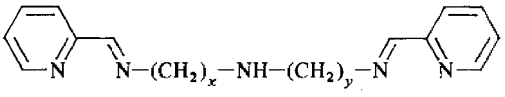
The reactions of these neutral species with O_2 in pyridine have been studied in depth (see Section 41.3.9.3 for a discussion of the oxygenation of Mn^{II} compounds of multidentate ligands).



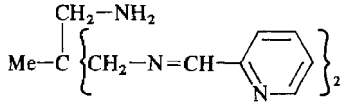
(*ii*) *Tripod ligands*

Me_6tren{tris(2-dimethylaminoethyl)amine} forms[166] five-coordinate species [MnX(Me_6tren)]X, which were among the first five-coordinate Mn^{II} species identified. More recent work has shown that the unsubstituted tren molecule also forms five-coordinate Mn^{II} species:[167] the solid compounds [MnX(tren)]BPh_4 were isolated for X = N_3, Cl, Br, CN, NCS and NCO; and the X-ray structures of the last two have shown a basically [$MnXN_4$]Y structure, although specific H bonding holds the cations in pairs in the solid state. Mn—N(H_2) distances were near 2.2 Å, Mn—N(apical), nearer 2.4 Å and Mn—N(CX) were near 2.1 Å.

Related ligands (**58**, R = H, Me)[146] and (**59**)[168] also have been studied. For the ligand (**58**, R = H), the data in aqueous solution have been interpreted as evidence for an $[MnN_4(H_2O)_3]^{2+}$ seven-coordinate structure.[146]



(58)

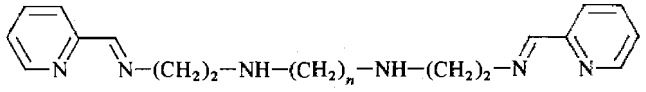


(59)

41.3.3.5 Quinquedentate ligands

The linear aliphatic ligand $(NH_2CH_2CH_2NHCH_2CH_2)_2NH$ forms[169] a 1:1 species in water with log K_1 of 7.0–7.5. Irreversible oxidation occurs in the air, but attempts to isolate Mn^{III} species or solid Mn^{II} species were unsuccessful. Except for several reports of single compounds, with no meaningful structural information, data on compounds of linear quinquedentates are restricted to a report from Coleman and Taylor.[170] They prepared nine compounds of the ligands (**60**) $MnX_2L \cdot nROH$ (X = Cl, Br, I or NCS; R = H, Me or Pr). All were high spin, with colours ranging from yellow to orange; the compounds were soluble in water, methanol, acetone and DMF; and all were said to show no observable reactivity with O_2 or NO, neither in the solid state nor in solution (DMF).

(60)

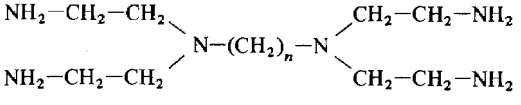


(61)

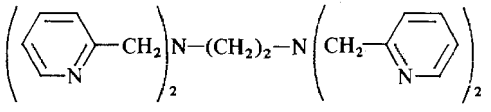
Early attempts[171] to prepare an Mn^{II} compound of the ligand (**61**) (see Section 41.3.3.6), gave instead white crystals of a compound $MnCl_2 \cdot L$, where L is a partially hydrolysed form (**61**), having lost one pyridylaldimine residue.

41.3.3.6 Sexadentate and septadentate ligands

(*i*) *Linear ligands*



The only report[102] of linear N_6 ligands gave three compounds [MnL]X_2 (X = NCS or I) of the ligands (**62**) (for n = 2 or 3). The bright yellow crystals of the high spin Mn^{II} compounds were stable in air for at least several weeks and do not react with O_2 or NO, neither in the solid nor in solution.



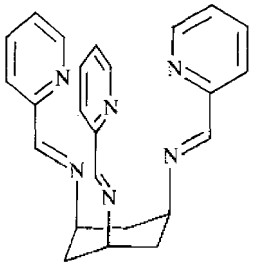
(62)

(ii) Bifurcated ligands

Data are available on the ligands (**63**) (for $n = 2$ or 3) and (**64**). Ligand (**63** for $n = 2$) forms a 1:1 species in water with log K_1 of 9.3 and the solution data have been interpreted[169] as evidence for a seven-coordinate polyhedron $[Mn(N_6)H_2O]^{2+}$, comparable with that proven for $[Mnedta(H_2O)]^{2-}$ (Section 41.3.9.5). Given the steric constraints of this amine ligand, it may be possible to obtain [MnLX]X species here.

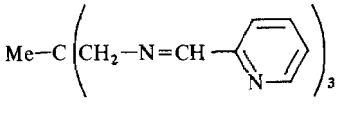
(63)

(64)



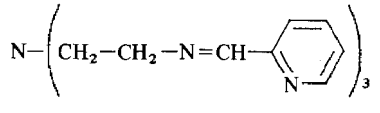
By contrast, the ligand (**63** for $n = 3$) has a log K_1 of only 5.3 and it readily forms binuclear species $Mn_2(N_6)^{4+}_{aq.}$ in water.

The pyridyl ligand (**64**), however, has a log K of 10.27 and the solid compound $[MnL](ClO_4)_2 \cdot H_2O$ has been isolated as yellowish needles.[146] Available data were interpreted as indicating an $[MnN_6]$ octahedral structure, with the water molecule not bonded to the metal.



(iii) Tripod ligands

The ligand $Et—C(CH_2NHCH_2CH_2NH_2)_3$ has a log K_1 of 8.2 in water: no solid derivatives have been reported.[169]



But the more interesting tripod ligands (**65**) to (**67**) are those which induce trigonal prismatic six-coordination and seven-coordination on Mn^{II}. Ligands (**65**) and (**66**) present their donor atoms at positions for trigonal prismatic rather than octahedral coordination, and, whereas the Mn^{II} d^5 high spin metal atom, in its yellow compounds, is largely content to accept the ligand's geometry, the later transition metals induce ligand distortions to approach octahedral geometry.[172]

(65)

(66)

(67)

The closely related ligand (**67**) is potentially septadentate, and although full details are not published, it seems that the Mn^{II} compound is indeed seven-coordinate, with an Mn—N (apical) distance of 2.79 Å.[173]

41.3.3.7 Uses of manganese nitrogen compounds

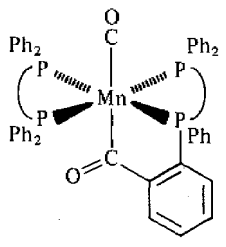
The following lists some of the more significant uses of the compounds noted in Section 41.3.3.

Manganese(II) nitrogen species, and especially $Mntrien^{2+}_{aq.}$, show strong catalytic activity towards the decomposition of H_2O_2 (only iron compounds seem more effective), and are used to accelerate the photopolymerization of vinyl monomers, in the presence of CCl_4.[156]

Some of the tetrakis compounds of substituted pyridines $[MnX_2L_4]$, especially where X = NCS, form clathrates with hydrocarbons, such as xylenes, cumenes, mesitylene, *etc.*; and specific compounds have been used to separate isomers of these hydrocarbons.[88]

Various nitrogen compounds have found use in corrosion inhibition, as fire-proofing agents for epoxy resins and flame retardants for polyurethane foams. For these and other uses, the reader is referred to the indices of *Chemical Abstracts*. One recent report[174] tells of the use of Mn^{II} chelates of phenanthroline and bipyridyl as contraceptive and antivenereal agents. The antibacterial and antifungal properties of these compounds have long been known.[175]

41.3.4 Phosphorus, Arsenic, Antimony and Bismuth Ligands



Although many tertiary phosphine, and to a lesser extent arsine, compounds of Mn^{I} have been known for many years, the corresponding complexes of Mn^{II} are relatively rare. The preference of Mn^{II} for oxygen, nitrogen and halogen donors has meant that few compounds with the heavier Group V donor atoms have been isolated. However, recent work demonstrates that, given anhydrous conditions, simple Mn^{II} salts will interact with tertiary phosphines to give compounds with a Mn^{II}—P bond.

Although the compounds $[Mn(PPh_3)_4]X_2$ (X = halogen), $[MnX_2(EPh_3)_2]$ (X = halogen; E = P or As),[176] and $[MnX_2(diars)_2]$ (X = halogen; diars = *o*-phenylenebisdimethylarsine)[177] were reported some years ago, work since then has indicated that in these original preparations, the actual ligands were phosphine or arsine oxides, *i.e.* that the Group V donor had oxidized in solution by reaction with oxygen.[178,179,180]

The lack of early success in obtaining tertiary phosphine and arsine compounds by direct interaction of the relevant ligands with Mn^{II} halides, led to the use of preparative methods incorporating oxidation of suitable Mn^{I} carbonyl compounds. Thus $[MnBr_2(CO)_2(diars)]$ was obtained by bromine oxidation of $[MnBr(CO)_3diars]$,[181] while $[Mn(CO)_2(dppe)_2]^{2+}$ (dppe = 1,2-diphenylphosphinoethane) was prepared by oxidation of $[Mn(CO)_2(dppe)_2]^{+}$ with nitric acid.[182] Such Mn^{II} carbonyl compounds were shown by infrared studies to possess *trans*-carbonyl structures and this fact was used to explain why the Mn^{I} compounds $[Mn(CO)_3TP]^{+}$ and $[Mn(CO)_2QP]^{+}$ {TP = bis(*o*-diphenylphosphinophenyl)phosphine; QP = tris(*o*-diphenylphosphinophenyl)phosphine}, in which the carbonyls must be in the *cis* configuration, could not be oxidized to give stable Mn^{II} compounds.[183]

A further example of the preparation of stable Mn^{II} phosphine and arsine compounds is shown by the oxidation with $NOPF_6$ in benzene of *trans*-$[MnBr(CO)_3L_2]$ (L = PMe_2Ph or $AsMe_2Ph$) and *cis*-$[MnBr(CO)_3L_2]$ (L_2 = dppe or L = $AsMe_2Ph$) to yield *fac*-$[MnBr(CO)_3L_2]^{+}$.[184]

Nevertheless, the complexity of the interaction of dppe with $Mn_2(CO)_{10}$ is a warning to those who postulate invariant ligand integrity in reactions. Although this reaction was originally claimed to yield three products, *viz.* $[Mn(CO)_2(dppe)_2][Mn(CO)_5]$, $Mn(CO)_3dppe$ and $Mn(CO)(dppe)_2$, an X-ray crystal study has shown that the last of these three compounds should be formulated as a Mn^{I} compound with a carbonyl-insertion reaction occurring between one of the phenyl rings on one of the phosphorus atoms and the manganese atom to yield a terdentate ligand (**68**).[185]

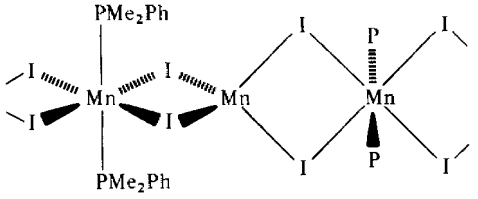
(68)

The early work on bidentate phosphine compounds of manganese was reviewed in 1972.[186] More recent preparations of the compounds $[MnX_2(diars)_2]$, and preparations of similar compounds with the ligand *o*-phenylene(dimethylarsine) (dimethylstibine), have indicated that if care is taken in

Table 17 Bond Lengths for $[MnCl_2(diphos)_2]^{n+}$ Compounds

Compound $[MnCl_2(diphos)_2]^{n+}$	*Bond Lengths* (Å) *Mn—Cl*	*Mn—P*
Mn^{II}, $n = 0$	2.502	2.625
Mn^{III}, $n = 1$	2.239	2.345
Mn^{IV}, $n = 2$	2.195	2.428

excluding water from the reactions, these compounds, and not the arsine oxides, can be prepared;[187] however, compounds of the two tertiary stibines, $Me_2Sb(CH_2)_3SbMe_2$ and $C_6H_4(SbMe_2\text{-}o)_2$ could not be obtained under similar conditions.



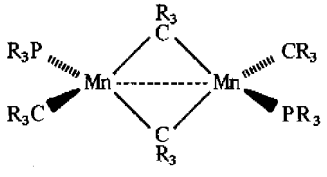
Other workers[180] have reported that the tertiary diphosphine, *o*-phenylenebis(dimethylphosphine) (diphos) reacts with anhydrous manganese(II) halides to yield yellow octahedral compounds of type $[MnX_2(diphos)_2]$ (X = Cl or Br), in which the halogens have a *trans* configuration. Unlike the corresponding diarsine compounds,[187] these diphosphine compounds are readily oxidized to octahedral orange Mn^{III} and then orange-brown Mn^{IV} species by the reactions: $[MnX_2(diphos)_2] + Ph_3CPF_6 \rightarrow [MnX_2(diphos)_2]^+$; $[MnCl_2(diphos)_2]^+ + HNO_3 \rightarrow [MnCl_2(diphos)_2]^{2+}$. The X-ray structures of all three chloro compounds have been reported[188] and are of particular interest as this work allows a rare direct comparison of changes in metal–ligand bond lengths with changes in metal oxidation state (Table 17). The reduction in Mn—Cl bond length with increase in positive charge on the metal is clearly observable, as is the decrease in Mn—P bond length in going from Mn^{II} to Mn^{III}. The unexpected increase in Mn—P bond length when Mn^{III} is oxidized to Mn^{IV} is found to be due to the closer chlorines in the latter compound 'pushing away' the phosphine methyl groups.

Trans-bromo structures are also found in the similar ditertiary phosphine bidentate complex $[MnBr_2(dmpe)_2]$ (dmpe = 1,2-bis(dimethylphosphino)ethane);[28] the Mn—P bond length in this compound (2.655 Å) being comparable with that found in $[MnCl_2(diphos)_2]$ (2.625 Å). The reaction of $[MnBr_2(dmpe)]$ with $LiAlH_4$ yields a Mn^I compound of stoichiometry $Mn(AlH_4)(dmpe)_2$ (Section 41.2.4).

The reactions of anhydrous manganese(II) halides with unidentate tertiary phosphines, R_3P, have been reinvestigated, and it has been shown that polymeric compounds, of formulation $MnX_2(PR_3)$ (X = halogen or thiocyanate), can be isolated from tetrahydrofuran solutions.[189] These compounds, isolated for a large range of phosphines, but excluding triphenylphosphine,[190] undergo reversible oxygenation in both the solid state and in solution yielding deep red, blue, purple or green compounds of type $MnX_2(PR_3)O_2$. A typical example is $MnBr_2(PBu^n_3)$ for which a dioxygen binding isotherm similar to that shown by myoglobin is claimed.[189] There appears to be no dioxygen bond breakage during these oxygenation reactions.[191]

Equilibrium data for the oxygen absorption have been deduced, and it is claimed that, for example, $[MnI_2(PBu^n_3)]$ will reversibly absorb and desorb completely one mole of dioxygen per mole of complex for more than 400 times, if the reaction is carried out in solution at −20 °C. In the solid state only the thiocyanato compounds of formulation $[Mn(NCS)_2(PR_3)]$ (where R = alkyl) reversibly bind oxygen.[192]

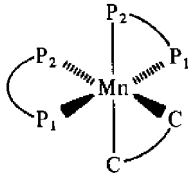
It has been shown[193] that the X-ray structure of the compound $MnI_2(PMe_2Ph)$ is polymeric with alternating octahedral and tetrahedral Mn^{II} entities (**69**). However, full details of the structure are as yet unknown. Binding of dioxygen in the solid state must be, one assumes, into the lattice structure of the crystalline compound. Thus crystal structures are most important in ascertaining how the gas molecules fit into the lattice.



(69)

These oxygenation reactions have been hailed as being of great importance[4] but the findings have been challenged by other workers,[194] who had not been able to isolate other than Mn^{II} tetrahydrofuran complexes from supposedly identical reaction procedures.[195]

Claims[192,196] with no details supplied yet, that many of the compounds of type $[MnX_2(PR_3)]$ reversibly bind not only dioxygen, but carbon monoxide, carbon dioxide, nitric oxide, sulfur dioxide and ethylene as well as dihydrogen, would appear to indicate that these polymeric complexes are a most versatile form of molecular sieve if the reactions proceed in the solid state. What may be the nature of binding of such a diverse group of molecules to the metal compounds is difficult to conceive. A further unresolved problem of the work lies in the results which indicate that reversible oxygenation occurs for many compounds both in solution as well as in the solid state. It is obvious that the mechanisms for oxygenation must be entirely different in these two situations even if in both cases each molecule of the compound can bind one dioxygen molecule.



The stabilization of Mn^{II}–alkyl and Mn^{II}–aryl bonds by use of tertiary phosphines has been shown by the ability of $[Ph_2MnP(cyclohexyl)_3]$ to undergo various insertion reactions, *e.g.* CO insertion to give $[(PhCOO)_2MnP(cyclohexyl)_3]$.[67] Further work[64] of great interest has shown that Mn^{II} dialkyls yield orange or yellow dimeric compounds of general type $[Mn_2R_4(PR_3)_2]$ (R = CH_2SiMe_3, CH_2CMe_3 and CH_2Ph) (**70**) when interacted with a number of unidentate tertiary phosphines. The X-ray structures of three compounds of this type have been shown to possess two asymmetrically bridging alkyl groups, with an additional terminal alkyl and one phosphine per manganese atom. In the presence of excess tertiary phosphine in light petroleum, the orange solutions of these dimeric compounds fade to a pale yellow colour. ESR spectra showed that monomers form due to a cleavage reaction (4).

(70)

$$[Mn_2(CH_2CMe_2Ph)_4(PMe_3)_2] + 2PMe_3 \rightleftharpoons 2[Mn(CH_2CMe_2Ph)_2(PMe_3)_2] \quad (4)$$

The X-ray crystal structure of this colourless monomer shows that it has a severely distorted tetrahedral geometry; the compound is high spin with a magnetic moment of 5.9 BM. Monomeric compounds of this type readily lose phosphine to re-form the dimer, but they can be stabilized by use of the bidentate phosphine, 1,2-bis(dimethylphosphino)ethane (dmpe) to replace the two unidentate phosphine moieties. On the other hand, if the two unidentate alkyl moieties are replaced by the bidentate ligand *o*-xylylene (o-$(CH_2)_2C_6H_4$), a low spin octahedral compound $Mn[o$-$(CH_2)_2C_6H_4](dmpe)_2$ (**71**) can be prepared. The metal–ligand bonds in this low spin compound are all noticeably shorter than those in the tetrahedral high spin monomer (Table 18).

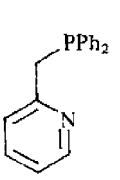
(71)

Table 18 Mn—Ligand Bond Lengths (Å) for High Spin $[Mn(CH_2CMe_2Ph)_2(PMe_3)_2]$ (A) and Low Spin $[Mn(o$-$\{CH_2\}_2C_6H_4)(dmpe)_2]$ (B)

Mn—L Bond	*Compound A*	*Compound B*
Mn—C	2.149	2.110 and 2.104
Mn—P	2.633	2.230 (Mn—P_1)*
		2.297 (Mn—P_2)

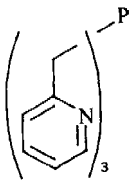
* see (71).

Other work[197] in the area of Mn^{II} alkyls has led to the disproportionation of Mn^{III} to yield Mn^{II} and Mn^{IV} species in the reaction (5).



$$[Mn(acac)_3] + dmpe + MeLi \xrightarrow[-78°C]{EtOEt} [MnMe_2(dmpe)_2] + [MnMe_4(dmpe)] \quad (5)$$

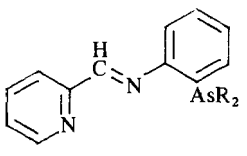
Phosphide compounds of manganese(II) have also been isolated. The tetra(diphenylphosphide)-manganate(II) ion has been prepared by the reaction sequence (6),[198] while in liquid ammonia at −75 °C '$[(Mn(NCS)_2(NH_3)_4]$' is claimed to react with $KPPh_2$ to yield either colourless $Mn(PH_2)_2 \cdot 3NH_3$ or $K_2[Mn(PH_2)_4] \cdot 2NH_3$.[199]



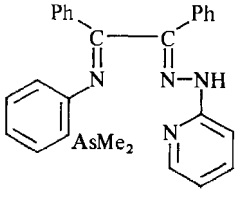
$$MnX_2 + KPPh_2 \cdot 2dioxane \xrightarrow{THF} KMn(PPh_2)_3 \xrightarrow{recryst.} K_2[Mn(PPh_2)_4] + Mn(PPh_2)_2 \quad (6)$$

(X = halide)

The Mn^{II} to phosphorus or arsenic bond can also be stabilized by use of hybrid multidentate ligands containing one or more nitrogen donors. Two early examples of compounds in which both nitrogen and phosphorus were bound to the Mn^{II} are:
(i) $[Mn(N—P)_3]Br_2$, (N—P = **72**);[200] (ii) the apparently five-coordinate $[Mn(N_3—P)Cl]Cl$, (N_3—P = **73**).[201]

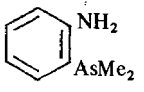


(72)



(73)

The linear terdentate hybrid ligands (**74**) with the donor set N—N—As, also yield compounds of the types $[MnX_2(N—N—As)]$ (X = Cl, Br or I), $[Mn(N—N—As)_2](ClO_4)_2$ and $[Mn(NCS)_2$-(N—N—As)], in which all three donor atoms appear to be bonded.[202] Similarly, all four donors of the quadridentate N—N—N—As ligand (**75**) appear to be coordinated in the compound [Mn-(N—N—N—As)], as in which both an imine proton and an arsenic methyl group are lost upon reaction of the ligand with $Mn_2(CO)_{10}$.[160]



R = Me or Et

(75)

(76)

The simple bidentate N—As ligand (**76**) yields the compounds $[MnBr_2(N—As)]$ and $[Mn$-$(N—As)_2](ClO_4)_2$ in which both donors are bound.[203]

41.3.5 Oxygen Ligands

Although the lowest limiting oxidation state for all oxygen ligands, Mn^{II} is also, on balance, the most stable. This comment is certainly true for neutral, and especially acid aqueous solutions, and, although alkaline solutions are oxidized by O_2, this is at least partially because of very low solubilities of the higher oxides, especially MnO_2.

Despite the importance of this area of Mn^{II} chemistry, we still have much to learn about basic structural preferences: the variety of polyhedra adopted; their relative importance, distortions of

them and the energy costs of such distortions. Available data, however, do suggest that non-directional, ionic bonding predominates in the Mn—L bond, even though covalency is not negligible.

A consequence of the predominantly ionic bonding is that effects on the ligands of Mn—L bonding, and therefore the energy profiles of the ligand vibrations, are not very different from the effects of H-bonding and 'non-bonded' interactions in crystalline solids. Thus attempts to define stereochemistries by vibrational methods are unreliable, a view that is strongly reinforced by the variety and complexity observed, for example, in the carboxylate compounds (Section 41.3.5.2.ii). We make no further apology for giving prominence in the following to the X-ray structural data.

41.3.5.1 Unidentate ligands

(*i*) *Water, hydroxide and oxide*

There is little doubt that the basic species formed when almost any compound MnX_2 is dissolved in water[204,205] is $[Mn(H_2O)_6]^{2+}$. It is seen in various crystalline solids, and the solution data give no real hint that we need to suspect the other coordination polyhedra, either higher or lower, are present in the aqueous solutions. So, $[Mn(H_2O)_6]^{2+}$ it is—mainly on the basis[205] of the optical spectra and correlation with the crystalline solids. In this respect, we note that XAFS studies on aqueous solutions derive an Mn—OH_2 distance of 2.18 Å, in good agreement with the observed distances in solids (Table 1).

The rate of exchange of bonded water with bulk solvent gives evidence that the process is *associative*, that is, it occurs through a seven-coordinate intermediate.[205] The two reported determinations give (averaged) kinetic parameters of: $k_1 = 2.15 \times 10^7\,s^{-1}$; $\Delta H^* = 7.8$ kcal mole^{-1}; $\Delta S^* = 1.2$ cal mole^{-1} K^{-1}; and $\Delta V^* = -5.4$ ml mole^{-1}. It is the negative ΔV^* which implies the associative mechanism. In the competition between a longer Mn—OH_2 bond favouring dissociation, and the greater space, made available by the longer bonds, favouring association, it appears that the latter wins. We can only notice the result and correlate it with the greater tendency shown by Mn^{II} to form seven-coordinate polyhedra.

All aqueous solutions of MnX_2 are, of course, further complicated by the formation of $[MnX_n(H_2O)_{6-n}]^{(2-n)+}$ species, and a perusal of the reported stability constants for these[206] indicates that they are formed to much the same extent as for the other first row transition metals. They are, however, less evident because of the lack of colour in the solutions. Such species also are encountered in X-ray structural analyses of Mn^{II} compounds. The species with $n > 2$ are formed in water in significant concentrations only in the presence of an excess of anion.

The 'hydrolysis' of Mn^{2+}_{aq} parallels that of its nearest neighbours Cr^{2+} and Fe^{2+}; at pH as low as 3.5, proton transfer to solvent, forming $[Mn(OH)(H_2O)_5]^+$ occurs, and the limiting value at low pH for K_h has been measured (25 °C) as 5×10^{-5} mole l^{-1}. At higher pH, polymerization (apparently dimerization) occurs,[207] leading eventually to the precipitation of solid, polymeric $Mn(OH)_2$.

$Mn(OH)_2$ is a well-characterized, stoichiometric, crystalline compound with the hexagonal $Mg(OH)_2$ structure. Although preparations of it require careful exclusion of O_2, the pure, isolated solid has good stability in the air; it occurs naturally (pyrochroite); and finds use as an industrial catalyst. It is weakly amphoteric, and can be recrystallized from hot, concentrated alkali solutions. This, of course, implies the formation of hydroxo and/or oxomanganates(II), and, indeed, solid, yellow $Na_2[Mn(OH)_4]$ has been desscribed,[208] as have $Ba_2Mn(OH)_6$ and $Sr_2Mn(OH)_6$.

Little is known of the 'basic salts':[209] Mn(OH)Cl has been decribed in two crystalline forms, which are said to have layer structures related to $Mg(OH)_2$; and the compounds $Mn_2(OH)_3X$ (X = Cl, Br, I) also are known, with the chloro compound again in two different crystalline forms, one of which occurs in the mineral kempite, isotypic with δ-$Cu_2(OH)_3Cl$. Crystalline phases containing both OH^- and oxyanion ligands are covered in Section 41.3.5.2.

Manganese(II) oxide exists in only one modification under normal conditions, and this has the simple rock salt cubic structure.[210,211] In addition, Mn^{II} occurs in some of the other binary oxides, and in a wide range of mixed oxides (Table 19). Most of these have been studied mainly for their magnetic and electrical properties, but we are here interested in any light they can shed on the structural preferences of Mn^{II}. Table 19 summarizes available data, referring largely to species for which three-dimensional refinements give bond length data, and confirm structures implied by symmetry and unit cell data. The area of interest shades imperceptibly into the compounds of the oxyanions, which we have separated into Tables 22–25.

The data show that Mn^{II}, unlike Mn^{IV} and some of the other metals, is not particularly fussy about

Table 19 Manganese(II) Coordination Polyhedra in Oxides and Hydroxides[a]

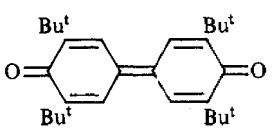
Phase	*Mn^{II} Polyhedra*		*Comments*
MnO	$[MnO_6]$ Octahedra	2.223 Å	Cubic, rock-salt structure
Mn_3O_4 α	$[MnO_4]$ Tetrahedra	2.07 Å	Hausmannite, $(MnO \cdot Mn_2O_3)$
Mn_5O_8	$[MnO_6]$ Trigonal Prism	3×2.13 Å 3×2.30 Å	$(2MnO \cdot 3MnO_2)$ $Cd_2Mn_3O_8$ type
MnM_2O_4	$[MnO_4]$ Tetrahedra	~2.03 Å [Cr]	Normal, cubic spinels M = Al, Ti, V, Cr
$MnMO_3$	$[MnO_6]$ Octahedra	2.10–2.26 Å	M = Ge, Sn, Ti
Mn_2MO_4 α-Ge	$[MnO_6]$ Octahedra	Two sites	Normal temperature and pressure, olivine type
β-Ge	$[MnO_6]$ Octahedra		High temperature and pressure, isotype with Co
δ-Ge	$[MnO_7]$	6(2.15–2.33) + 2.73 Å	High temperature and pressure
α-Ti	$[MnO_4]$ Tetrahedra	2×1.93; 2×1.95 Å	$Mn^{II}(Mn^{II}M^{IV})O_4$ spinel
	$[MnO_6]$ Octahedra	2.08–2.50 Å	
Sn	$[MnO_4]$ Tetrahedra		$Mn^{II}(Mn^{II}M^{IV})O_4$ spinel
	$[MnO_6]$ Octahedra		
$Mn_2V_2O_7$	$[MnO_6]$ Octahedra	2.13–2.30 Å	
$MnMO_4$	$[MnO_6]$ Octahedra	2.09–2.25 Å	M = Mo, W, U
MnM_2O_6	$[MnO_6]$ Octahedra	2.01–2.36 Å	M = Nb, Ta
$Mn_4Nb_2O_9$	$[MnO_6]$ Octahedra	1.99–2.23 Å	
$BaMn_2O_3$	$[MnO_5]$ Trigonal bipyramid	2.07–2.20 Å	
$Na_{14}(MnO_4)_2O$	$[MnO_4]$ Tetrahedra	2.09 Å	
$Mn_2Mo_3O_8$	$[MnO_4]$ Tetrahedra		Mg, Fe, Co, Ni, Zn and Cd isostructural
	$[MnO_6]$ Octahedra		
$Mn_2(Sb, Fe)O_3$	$[MnO_6]$ Octahedra	2.11–2.31 Å	
$Mn_8O_{10}Cl_3$	$[MnO_8]$ Cube	2.32 Å	Also $[Mn^{II}Cl_6]$ and Mn^{III} octahedra
$A_2Mn_3B_2O_2$	$[MnO_4]$ Planar	2.08–2.18 Å	(A = Sr, Ba; B = As, Sb, Bi)
Mn_2TaO_3	$[MnO_6]$ Trigonal prism	2.36 Å	Is this Ta^{II} or a lower (average) oxidation state for Mn?
$Mn_3A_2Ge_3O_{12}$	$[MnO_6]$ Octahedra		Garnet structure (A = Al, V)
	$[MnO_8]$ Dodecahedra		
$Mn(OH)_2$	$[MnO_6]$ Octahedra	2.207 Å	Isotype of $Ca(OH)_2$
$MnSn(OH)_6$	$[MnO_6]$ Octahedra	2.17 Å	
$Mn_2K(CrO_4)_2OH \cdot H_2O$	$[MnO_6]$ Octahedra		Isotype of $Cu_2Na(SO_4)_2 \cdot OH \cdot H_2O$

[a] Data for this table were obtained from the Gmelin volumes or from 'Structure Reports'.

its neighbours — neither their number, nor their arrangement. Certainly, $[MnO_6]$ octahedra are predominant, deriving from the occupation of the octahedral holes of close-packed oxygens. But often these octahedra are quite distorted, with Mn—O distances ranging from 1.99 to 2.50 Å and individual angular distortions of at least 15°. And four-planar, four-tetrahedral, five-, six- trigonal prismatic, seven- and eight- (both cubic and dodecahedral) coordinate polyhedra are observed; and most of these now have parallels in the more discrete coordination polyhedra upon which coordination chemists have largely concentrated to date.

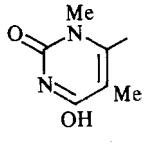
(*ii*) *Monohydric alcohols, alkoxides and phenoxides*

Solutions of MnX_2 in the alcohols give $[Mn(ROH)_6]^{2+}$ species,[212] and these cations have been isolated as crystalline solids for R = Me, Et. In more concentrated solutions, the species $[MnX_n(ROH)_{6-n}]^{(2-n)+}$ have been detected by EPR and ^1H NMR spectra. The alcohol ligands are easily replaced by water.



A number of other crystalline solids of type $MnX_2 \cdot n$ROH also have been isolated for primary alcohols, methyl to pentyl, (but not a secondary or tertiary alcohol) and $n = 1$ to 4, but not necessarily an integer. Many appear to be variations on MnX_2 polymeric systems, with ROH donors, as are the only two of known structure: $Mn_2Cl_4 \cdot 3EtOH$ consists of polymeric chains of alternating *cis*-$[MnCl_4(EtOH)_2]$ and $[MnCl_5(EtOH)]$ octahedra;[213] whilst $Mn_5Cl_{10} \cdot 14EtOH$ has three different Mn octahedra making up chains[214] of *trans*-$[MnCl_2(EtOH)_4]$, *cis*-$[MnCl_4(EtOH)_2]$ and *mer*-$[MnCl_3(EtOH)_3]$ (Mn—O distances range from 2.16 to 2.21 Å in the two structures).

Mn^{II} alkoxides and phenoxides have been studied only quite recently. Druce[215] reported two $Mn(OR)_2$ species in 1937, and the pale pink, insoluble $Mn(OMe)_2$ was described[216] in 1966, but the only reasonably complete study is that reported[217] by Horvath *et al.* in 1979. They prepared a total of eighteen solid alkoxides and six phenoxides by reaction (7). These ranged from amorphous polymers and gelatinous fibres to crystalline species. The pale coloured polymers were assigned octahedral $[MnO_6]$ structures, but some of the more crystalline species were more reactive, soluble in common organic solvents, and were thought to be monomers or 'loosely associated'. Wilkinson and co-workers, however, have shown[218] that $Mn(OBu^t)_2$ is trimeric in freezing benzene, and drew parallels with the three- and four-coordinate oligomeric alkyls (Section 41.3.2.2). It seems likely that few, if any, of these alkoxides or phenoxides will turn out to be two-coordinate monomers.[217] In a number of cases, Horvath *et al.* observed compounds $Mn(OR)_2 \cdot n$L (where L = py or THF) and characterized two yellow phenoxides $[Mn(OR)_2(THF)_2]$. All of these alkoxides were extremely air-sensitive, especially when wet, and, with traces of O_2, all the pale coloured products darken to brown or black materials. Several are pyrophoric, and the ethoxide reacts explosively with excess O_2. The solid 2,6-di-*t*-butylphenoxide reacts with controlled amounts of O_2 to give a green intermediate, which may be a compound of dioxygen, and recalls the interesting phosphine work of McAuliffe and co-workers (Section 41.3.4). Further reaction with O_2 gives a black material, from which the purple quinone (**77**) can be isolated in 76% yield.[217]



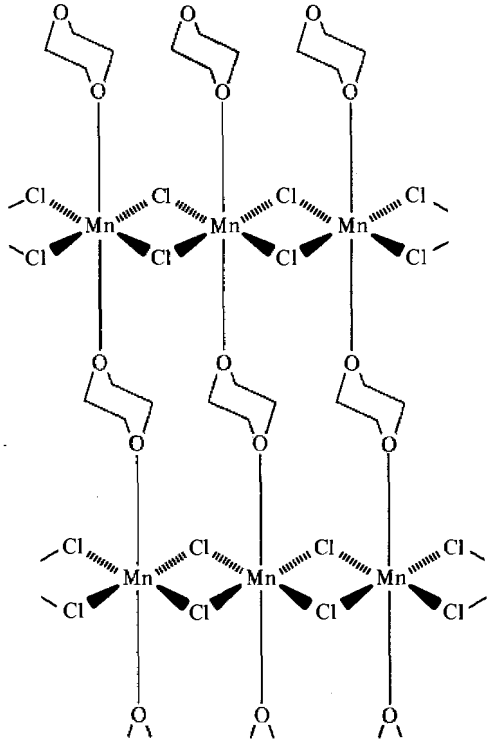
$Mn\{Al(OPr^i)_4\}_2$ is a light brown viscous liquid, which can be distilled *in vacuo* and is monomeric in boiling benzene.[219]

Within the phenoxide class, there is a compound with a four-coplanar $[MnO_4]$ polyhedron: in $[Mn\{Pt(NH_3)_2(L^-)_2\}_2]Cl_2 \cdot 10H_2O$ {where L^- is the anion of 1-Me-thymine (**78**)} the thymines are N-bonded to Pt and each Pt moiety is bidentate to a central Mn^{II}, so that the latter is bonded to four phenoxides in a planar array.[220]

$$Mn\{N(SiMe_3)_2\}_2 + ROH \longrightarrow Mn(OR)_2 + 2HN(SiMe_3)_2 \qquad (7)$$

(77)

(78)



(iii) Ethers

It is clear, from the behaviour of various MnX_2 species in diethyl ether,[221] that the ether molecules bind to the metal, although no significant crystalline solid compounds have been isolated and characterized, at least partially because of the volatility of the ether.

Two other commonly used solvent ethers (THF and dioxane), both of which have less significant steric problems, form somewhat more robust species.

For the solid compounds $MnX_2 \cdot 2THF$ (X = Cl, Br, I, NCS) the data,[221,222] at least for the halides, are consistent with an expected chain polymeric structure of type (**8**). The same proposed *trans*-$[MnX_4O_2]$ polyhedron is observed[223] in the crystal structure of $[Mn\{Ti^{III}(Cp)_2Cl_2\}_2(THF)_2]$, in which the *trans* THF oxygens are at 2.227(3) Å. The hexakis species $[Mn(THF)_6][SbCl_6]_2$ seems to be the only known compound with an all-ether $[MnO_6]^{2+}$ polyhedron.[224] A previously described perchlorate[221] is probably $[Mn(THF)_4(H_2O)_2](ClO_4)_2$.

Although capable of bidentate function to one metal, steric and conformational preferences generally seem to dictate that dioxane[221] acts either as a unidentate ligand or that it bridges two different metals, as in (**79**). The compound $MnCl_2 \cdot$ dioxane, for which (**79**) is the proposed structure, is not affected by six hours in vacuum at 100 °C! Other known $MnX_2 \cdot n$ dioxane species include those defined by $n = 1$, for X = ClO_4, NCS and NCSe, and $n = 2$ for X = Br and I, and some mixed aquo–ether compounds.[221]

(79)

(iv) Carbonyl ligands

The most commonly described class is that of the octahedral compounds $[ML_6]X_2$, which are summarized in Table 20. All appear to be simple octahedral cationic species, although only the pyrone and 4-butyllactam compounds have been shown to be isomorphous with a reliably octahedral Ni^{II} analogue. Robustness varies from the aldehydes, which rapidly turn brown, even if kept below 0 °C, to the lactam, which is 'stable to air and light, and moderately stable to heat'; but all are rapidly attacked by water.

In parallel with some of the nitrogen ligand compounds, a few of these carbonyl ligands give crystalline species $MnX_2 \cdot nL$, where $n > 6$. These include X = NCS, $n = 8$ and X = Br or I, $n = 10$ for urea;[225] and X = $SbCl_6$, $n = 7$ for 4-chlorobenzaldehyde.[226]

Table 20 Carbonyl Ligand Compounds $[MnL_6]X_2$

Ligand Class	*Specific Ligands*	X^-	*Ref.*
Aldehydes	Acet-, propion- and benz-aldehyde	$FeCl_4$, $InCl_4$	a
	2-Cl, 4-Cl and 4-Me-benzaldehyde	$SbCl_6$	226
Ketones	Acetone, chloroacetone, methylethylketone and acetophenone	$FeCl_4$, $InCl_4$	a
	2,6-Dimethyl-4-pyrone	ClO_4, BF_4	b
Esters	Methyl formate	$FeCl_4$, $InCl_4$	c
	Ethyl acetate	$SbCl_6$	c
Amides	Dimethylformamide, acrylamide	ClO_4	d, 231
Lactams	6-Capro and 4-butyl-lactam	ClO_4	e, f
Ureas	Urea, *t*-butyl-, dimethyl- and diethyl-urea	Br, I, ClO_4, NO_3	225, g, h

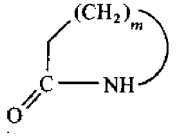
Compounds $MnX_2 \cdot 4L$ are described only for amides and ureas:



dimethylacetamide (X = NCS, ClO_4)[227,228] with the former being isomorphous with the Ni^{II} analogue and octahedral;

the lactams (**80**) (m = 5, 7 and 11; X = NCS)[229] — similar compounds are formed by Ni, Cu and Zn, but Co and Cd form $[ML_6][M(NCS)_4]$;

formamide (X = Cl),[230] and acrylamide ($X = NO_3$);[231]

urea (X = NCS, Cl, Br)[225,232] — an unrefined X-ray structure[233] proves the *trans*-octahedral structure for X = NCS;

dimethyl- and diethyl-ureas (X = NCS).[225]

(**80**)

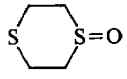
Only three $MnX_2 \cdot 3L$ compounds have been described[234–236]: $[MnBr_2(dimethylurea)_3]$ has a five-coordinate structure[234] with Mn—O at 2.04 and 2.18 Å; and $[MnCl_2(propionamide)_3]$ and $[MnCl_2(4\text{-butyllactam})_3]$ probably have a similar structure. A more exhaustive study of these ligand systems will probably produce more such five-coordinate species.

Well-defined crystalline compounds $MnX_2 \cdot nL$ for n = 2, 1 and < 1 also are described.[227,230,232,237] Most are apparently polymers of types (**8**) and (**13**), although tetrahedral $[MnX_2L_2]$ species may eventually be identified. A different polymer, with *cis* unidentate ethylacetates, at 2.17 and 2.24 Å, has been identified[238] in $[Mn(PO_2Cl_2)_2(ethylacetate)_2]$.

(*v*) *Ligands with NO, PO, AsO, SO and SeO groups*

With possible minor exceptions in the case of RNO_2, all of these ligands provide a single oxygen donor atom and all form similar compounds. The numbers of known compounds for the different ligand types are summarized in Table 21, both as an indication of areas of concentration of effort and an entry to the literature. Unfortunately, this contains very little basic structural data (Table 21) — only two full X-ray analyses and a few correlations of powder data.

After early problems in preparing some of these species, the use of special solvent systems, including ethyrlorthoformate as a dehydrating agent, and the $SbCl_6^-$ anion, has allowed significant extension of the class. The NO species are covered in a recent Gmelin volume[239] and the PO species were reviewed in 1971.[240]



The compounds $MnX_2 \cdot nL$, for n = 6, are found quite commonly in the pyridine-*N*-oxides and sulfoxides, but only one PO group compound is known. This is generally ascribed to steric (bulk

Table 21 The Numbers of Known Compounds $MnX_2 \cdot nL$ for the N, P, As, S and Se Oxide Ligands

Ligand Class	*Number[a] of Compounds for n =* 6	5	4	3	2	1	0.5	*Ref.*

or B-strain) effects and the argument probably is valid. But arguments, that 2,6-dimethylpyridine-oxide forms only a tetrakis compound for steric reasons, are confounded by the hexakis compound formed by the 2,4,6-trimethyl analogue. These hexakis compounds generally are pale yellow, are assumed to be $[MnL_6]X_2$ octahedra, and such a structure is proven for ligand (**81**).[241] They tend not to be very robust; the pyO species generally are sensitive to air, light and heat, apparently more so than the compounds for $n < 6$.

(81)

Whether steric bulk or crystal-packing effects are more important, many of the ligands, and especially the PO and AsO species, do form pentakis and tetrakis compounds several of which are hydrates.

The $n = 5$ compounds may be five-coordinate or may contain an anion in the sixth coordination site. The former is known[242] for $[Mn(Me_3AsO)_5](ClO_4)_2$. It absorbs H_2O in the air, forming octahedral $[Mn(Me_3AsO)_5H_2O](ClO_4)_2$.

In the $n = 4$ series, there are fixed points in the known structures[244,245] of the square pyramidal cations $[MnI(Ph_3PO)_4]^+$ and $[MnClO_4(Ph_2MeAsO)_4]^+$, and there has been a tendency to relate most of the other compounds to these. However, other compounds of the group may turn out to be tetrahedral $[MnO_4]X_2$ species*, and some, especially the hydrates, may be octahedral.

* Some of the correlations with Co and Ni structures, assigning tetrahedra, were made before the variety of five-coordinate structures was recognized, and must be considered doubtful.

The $n = 3$ species, on simplest interpretation, may be five-coordinate monomers $[MnX_2L_3]$ or ionic $[MnL_6][MnX_4]$ species. There has been a tendency to believe more in the latter than the former. There are also some hydrates, such as $Mn(ClO_4)_2 \cdot DMSO \cdot 4H_2O$, for which it is impossible to make even a reasonable guess about structures.

A wider variety of structural assignments is available for the $n = 2$ species: possible structures include tetrahedral monomers, five-coordinate anion-bridged dimers; other oligomers; and polymers, such as (**8**). Many tetrahedral monomers have been postulated, but none have yet been confirmed. The only fixed point in the sea of data is the structure of $[MnCl(NCS)(Ph_3PO)_2]$ which is a five-coordinate dimer,[246] with chlorine bridges.

The compounds for $n = 1$ or 0.5 undoubtedly have polymeric (layer) structures, of which (**13**) is an example. There is also an example of a 'cubane' tetramer like (**18**) in this class, $MnF(BF_4) \cdot$(2,6-diMepyO)$\cdot$MeOH, which resulted[239] from the reaction of 2,6-dimethylpyridine *N*-oxide with $Mn(BF_4)_2$.

(*vi*) *Dioxygen*

Reversibly formed Mn^{II} compounds with O_2 are persistent in the literature.[247] However, whilst it is clear that they do have a limited existence, no firm detail of the bonding in any of them is available through X-ray analyses. Attempts to obtain crystalline species have been thwarted by reactions of the $[MnO_2]$ moiety, giving other Mn^{III} and/or Mn^{IV} species.

Equally strong claims have been made for an $[Mn^{IV}—O_2^{2-}]\eta_2$ formulation in porphyrins, and an $[Mn^{III}—O_2^{-}]\eta_1$, superoxo formulation in phthalocyanines. Probably both can exist for the more electrovalently versatile manganese; but eventual hard proof, through X-ray work would seem at this stage to require some elegant chemical and physical experimentation, or perhaps just further exploration. (We think that the reversible combination of O_2 with the solid phosphine compounds (Section 41.3.4) is likely to have its final explanation given more in terms of clathrate formation, especially in view of the wide range of other gases reported to bind reversibly.)

It is somewhat surprising that Mn compounds with O_2 moieties appear to have such limited existence; 'peroxo' compounds of the higher oxidation states are an important feature of the earlier transition metals (and we shall notice a few, poorly characterized, examples for Mn in Section 41.5.3); and the metals which follow manganese — Fe and Co — have an extensive and important chemistry of reversible combination with the oxygen molecule. It is perhaps pertinent to recall that some Mn^{II} species are very efficient catalysts for the decomposition of hydrogen peroxide (Section 41.3.3.7).

41.3.5.2 Oxyanions

In this section we deal with the oxyanions of the non-metals, which usually have well-defined polyhedra, in contrast to the mixed oxides of Section 41.3.5.1(i). Such distinction is, of course, not always sharp.

(*i*) *Borates, carbonates and silicates*

A variety of crystalline borates of Mn^{II} has been characterized, and structural data are available for many[248] (Table 22). These show that the dominant Mn polyhedron is the octahedron, although two exceptions have been identified, derived from distortion of tetrahedra: in $LiMnBO_3$, the Mn atoms are displaced towards a fifth oxygen and are at the centres of $[MnO_5]$ polyhedra; and in MnB_4O_7, the MnO_4 tetrahedra have four other oxygens along normals to the faces, making an effectively $[MnO_8]$ polyhedron.

The octahedron also is adopted in the known carbonates[249] (Table 22). $MnCO_3$, although thermodynamically unstable in O_2 or air, decomposes only slowly, and the pink, almost white, compound occurs naturally as the mineral rhodochrosite. Only one crystalline form is known which has the calcite structure; and both $CaMn(CO_3)_2$ and $BaMn(CO_3)_2$ have the dolomite structure. The carbonate mineral sidorenkite ($Na_3MnCO_3PO_4$) has a bidentate carbonate group, which is somewhat unusual in inorganic structures.

However, there is distinctly more complexity in the range of known compounds, and in the observed coordination polyhedra, in the crystalline silicates.[250] There are only two basic silicates: Mn_2SiO_4, which occurs naturally (tephroite); and $MnSiO_3$ the metasilicate, which also occurs

Table 22 The Coordination Polyhedra of Crystalline Mn^{II} Borates and Carbonates

Compound	*Coordination Polyhedra with (av.) Bond Lengths* (Å)	*Comments*
MnB_4O_7	$[MnO_n]$ n = 4–8 (2.442–3.188)	Distorted tetrahedra with four other oxygens on normal to faces.
MnB_2O_4		Isomorphous with Fe and Mg.
MnB_2O_5	$[MnO_6]$	Isomorphous with known Co.
$Mn_3(BO_3)_2$	(i) $[MnO_6]$ (2.184) (ii) $[MnO_6]$ (2.214)	Jimboite.
$MnB_6O_{10}\cdot 8H_2O$		Isomorphous with Fe and Co.
$MnB_4O_7\cdot 9H_2O$	$[MnO_6]$ 2.15–2.22	
$MnB_2O_4\cdot 3H_2O$	$[MnO_6]$	Sussexite—chains of edge-linked octahedra.
$LiMnBO_3$	(i) $[MnO_5]$ 2.135 (ii) $[MnO_5]$ 2.156	H.c.p. oxygens; Mn in tetrahedral holes, but displaced towards fifth oxygen.
$Mn_3(OH)_2\{B(OH)_4\}PO_4$	(i) $[MnO_6]$ 2.204 (ii) $[MnO_6]$ 2.203	Very distorted, edge-sharing a bidentate BO_3 unit; Mn—O up to 2.41 Å (Seamanite).
Pinakiolites	$[MnO_6]$	A family of Mn^{II}/Mn^{III} borate minerals.
$CaMnB_2O_5\cdot H_2O$	(i)–(iii) $[MnO_6]$ 2.21	Roweite.
$MnCO_3$	$[MnO_6]$ 2.196	Calcite structure.
$CaMn(CO_3)_2$	$[MnO_6]$	Dolomite structure.
$Na_3MnCO_3PO_4$	$[MnO_6]$ 2.092–2.350	Sidorenkite—bidentate CO_3.

Table 23 Structural Data for Crystalline Mn^{II} Silicates

Compound	*Phase, Mineral*	*Mn Polyhedra and Bond Lengths (av. in* Å*)*
$MnSiO_3$	I (Rhodonite)	(i)–(iii) $[MnO_6]$ 2.219; 2.242; 2.223 (iv) $[MnO_7]$ 6 × ~2.2; 1 × 2.778 (v) $[MnO_7]$ 3 × 2.743; 4 × 2.139
	II (Pyroxmanganite)	(i)–(iv) $[MnO_6]$ 2.2 (v) $[MnO_7]$ 3 × 2.743; 4 × 2.141 (vi) $[MnO_7]$ 6 × 2.2; 1 × 2.796 (vii) $[MnO_7]$ 3 × 2.696; 4 × 2.144
	IV Garnet-type, tetragonal	(i) $[MnO_8]$ dodecahedral (ii) $[MnO_6]$
	β-form	$[MnO_6]$
Mn_2SiO_4	Tephroite	$[MnO_6]$
Mn^{II}/Mn^{IV} mineral	Långbanite	(i) $[MnO_6]$ 2 × 2.25; 4 × 2.34 (ii) $[MnO_5]$ TBP 2 × 2.23; 1.92; 1.96; 2.07 (iii) $[MnO_8]$ distorted rhombohedron 2 × 2.22; 6 × 2.46
Mn^{II}/Mn^{III} mineral	Braunite	(i) $[MnO_8]$ 2.33
$Mn_5(OH, F)_2(SiO_4)_2$	Allegheneyite	$[MnO_6]$(× 3) 2.221; 2.199; 2.215
$Mn_7(OH)_2(SiO_4)_3$	Leucophoenicite	$[MnO_6]$(× 4) 2.203; 2.258; 2.217; 2.206
$Na_2Mn_2Si_2O_7$		(i) $[MnO_4]$ 2.00–2.10 (ii) $[MnO_5]$ 2.03–2.42
$Na_2Mn(SiO_3)_2$		$[MnO_6]$ (× 2) 2.10; 2.33
$Na_5(Mn, Na)_3MnSi_6O_{18}$		$[(Mn_2Na)O_6]$ (× 3) 2.39; 2.27; 2.40[b] $[MnO_6]$ 1.96–2.24
$(Li, Na)Mn_4Si_5O_{14}OH$	Nambulite	$[MnO_6]$ (× 3) 2.233; 2.242; 2.188 $[MnO_7]$ 3 × 2.752; 4 × 2.145
$K_2Mn_5Si_{12}O_{30}\cdot H_2O$		$[MnO_6]$ (these polyhedra share an edge) $[MnO_4]$
$CaMnSi_2O_6$	Johannsenite	$[MnO_6]$ 2.17
$(Ca, Mn)_3Si_3O_9$	Bustamite	$[MnO_6]$ (× 2) 2.245; 2.203
$CaMn_4OH(Si_5O_{14}OH)\cdot H_2O$		$[MnO_6]$ (× 3) 2.204; 2.199; 2.205
$Ca_2Mn_7(OH)_2Si_{10}O_{28}\cdot 5H_2O$	Inesite	$[MnO_6]$ (× 4) $[MnO_6]$ 2.113–2.460; 2.133–2.513
$CaMn_2(BeSiO_4)_3$		
$Zn_2Mn(OH)_2SiO_4$	Hodgkinsonite	$[MnO_6]$ 2.222
$K_2Zn_4Mn_2(SiO_4)_2Si_2O_7$		$[MnO_5]$ (× 2) SP 1.91–2.22
$Na_2InOH\{SiO_3(OH)\}_2$		$[MnO_6]$ TP (× 2) 2.15–2.53
$PbMn(Si_2O_7)_3$		$[MnO_6]$ 2.26
$13MnO\cdot Sb_2O_5\cdot 2Al_2O_3\cdot 2SiO_2$	Catoptrite	$[MnO_6]$ (× 3) 2.22; 2.24; 2.19
$Mn_4(BeSiO_4)_3S$	Kelvite	$[MnO_3S]$ 2.082

[a] Unless otherwise stated $[MnO_6]$ polyhedra are octahedral, albeit often somewhat distorted; and $[MnO_4]$ polyhedra are tetrahedral. The more 'flexible' $[MnO_7]$ polyhedra are not defined, and the $[MnO_5]$ polyhedra only when they are very close to the extremes of trigonal bipyramid (TBP) or square pyramid (SP). TP = trigonal prism. Quoted bond lengths are usually averages, but hyphens, in some cases, indicate the range.

[b] Mn^{II} and Na^{I} share these sites, so the (averaged) distances observed experimentally probably overestimate the size of the hole in which the Mn^{II} is located.

naturally in several forms (Table 23). Both were described by Gorgeu in 1883. The former is known as a single phase, and is the end member of the olivine group of silicates. Its structure is simply based on hexagonal close packing of oxygens, with Mn^{II} in half the octahedral holes, and Si^{IV} in one-eighth of the tetrahedral holes. By contrast, the metasilicate has been characterised in five distinct phases, some of which are known only in minerals and appear to require the presence of small amounts of other metals for stability of the phase.

Available structural details for these silicates, and for the wide range of other known species containing Mn^{II} and silicate, are summarized in Table 23. Coordination numbers four (tetrahedral), five (both square pyramid and trigonal bipyramid and 'in-between' structures), six (mainly octahedral and distorted, but including one trigonal prism), seven (of various shapes) and eight (dodecahedra and distorted rhombohedra) all are defined; and there is evidence for three-coplanar in a zeolite: the hydrated form is five-coordinate (3×2.28 Å and 2×2.05 Å) but, on dehydration of this Mn-exchanged zeolite, the solid contains planar three-coordinate Mn^{II} with Mn—O = 2.11 Å.[251]

(*ii*) *Monocarboxylates*

(Monocarboxylates with other, different, functional groups, such as salicylate and picolinate, are discussed in other sections.)

This is one of the few areas of Mn^{II} chemistry for which a significant amount of structural data is available. Yet, the only pattern to emerge is one of variety of structure, mainly polymeric, and the absence of any hard evidence for a dimeric tetra-bridged species of the copper(II) acetate structure. There is a distinct impression, when first following through the literature, of encountering with almost each new structure some unexpected, novel feature, and the data certainly underline the sheer futility of attempting to define structure of crystalline solids by other than X-ray methods.

Two groups have been most prolific; Kennard's group[252] have been looking mainly at the structures of herbicide carboxylates, and Ciunik and Glowiak[253] the amino acid compounds, generally $MnX_2(AA)_2 \cdot nH_2O$. These latter all are bonded in zwitterion form, so that they are generally examples of substituted Mn^{II} carboxylate hydrates. The rest of the literature is accessible through the latest publications of these groups[252,253] and Gmelin.[254]

The majority of the Mn^{II} carboxylates and their hydrates are robust in the air, but some, for example $Mn(Bu^tCOO)_2$, react readily forming red-brown trinuclear Mn^{III} species. It is with the same carboxylate, that so-far-unsubstantiated claims have been made for dinuclear species,[255] such as $[Mn_2(Bu^tCOO)_4py_2] \cdot 2Bu^tCOOH$. Both formate and acetate have given compounds $M_2Mn(RCOO)_4 \cdot nH_2O$ (M = Na, K, NH_4).[254] Although structures are yet unknown, it is tempting to draw parallels with the tetrakis-nitrito and nitrato-manganate^{II} species (Section 41.3.5.2.iii).

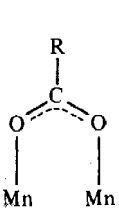

Table 24 contains data on approximately half the known structures, and a similar story emerges from the amino acid structures.[253] Monomers are known and there is the first example of a transition metal compound $[M(RCOO)(H_2O)_5]RCOO$; but most structures involve carboxylate bridging of three basic types (**82**)–(**84**), although one structure has *cis*-unidentate carboxylates and chooses to polymerize on a single bridging water molecule. The Mn polyhedron in the tetrahydrate for R = (**89**) is the only one to depart from the pattern of $[MnO_6]$ octahedra. It has *trans*-H_2O molecules at relatively normal distances of 2.28 and 2.31(2) Å, and in the plane normal to these are three

Table 24 Representative Structures of Carboxylate Compounds $Mn(RCO_2^-)_2 \cdot nH_2O$[252]

(*iii*) *Nitrites and nitrates*

Known details of the *nitrites* are largely confined to three papers.[256,257] Anhydrous $Mn(NO_2)_2$ is stable below 40 °C, and the pale yellow compounds $M_2[Mn(NO_2)_4]$, including the Cs salt and the yellow $Cs_3Mn(NO_2)_5$ require storage under mother liquor at 0 °C. The tetrakisnitrito species appears to have an $[MnO_8]$ polyhedron with all bidentate nitrites and is closely paralleled by other larger M^{II} species, *i.e.* those of Ca, Sr, Ba, Zn, Cd and Hg. A few mixed ligand compounds, with various neutral ligands, have been described but none give acceptable evidence for an N-bonded nitro.

Anhydrous manganese(II) *nitrate* is readily obtainable as pale red crystals, and like the hydrates, is hygroscopic.[258] Hydrated $Mn(NO_3)_2$, apparently largely as the tetrahydrate, is used commercially to colour porcelain and as an intermediate in the preparation of specific forms of MnO_2.

There are four well-characterized hydrates $Mn(NO_3)_2 \cdot nH_2O$ $n = 6$, 4, 2 and 1. The former appears to be another $[Mn(H_2O)_6]X_2$ species, but X-ray structural analyses of the others give examples of the modes of bonding of nitrate. $Mn(NO_3)_2 \cdot 4H_2O$, isostructural[259] with Zn and Ni, is a monomeric *cis*-$[Mn(NO_3)_2(H_2O)_4]$ octahedral species, with unidentate nitrates (Mn—O = 2.13–2.19 Å); the dihydrate is isostructural with Zn,[260] and has *trans*-$[MnO_4(H_2O)_2]$ octahedra (Mn—O = 2.05–2.14 Å), with nitrates bridging as in (**82**); and the monohydrate has both $[MnO_6]$ and $[MnO_8]$ polyhedra:[261] the former are *cis*-$[MnO_4(H_2O)_2]$ octahedra (Mn—O = 2.20 Å) and the latter are approximately dodecahedral, with four bidentate nitrates (Mn—O = 2.31–2.37 Å). The same eight-coordinate polyhedra are found in the compounds $M_2[Mn(NO_3)_4]$ (M = Na, K,

Ph_3MeAs and Ph_4As)[262]—the crystal structure of the latter showing two crystallographically distinct nitrates, one of which has Mn—O distances of 2.25 and 2.29 Å and the other 2.29 and 2.40 Å.

Nitrate groups also are found in various mixed ligand species with the other neutral ligands, and one of the few species to have been explored crystallographically is $[Mn(NO_3)_2(N{-}N)_2]$,[124] which also has bidentate nitrato groups (Section 41.3.3.2).

(*iv*) *Oxyanions of P and As*

The oxyanions of phosphorus and arsenic take up the major portion of a recent large volume of *Gmelin* (**C9**), which includes more than 100 compounds, hydrates and phases containing phosphate groups.[263] To pursue the detail of the latter is an exercise in phosphorus chemistry, so we concentrate on a survey of the available data on the Mn^{II} coordination polyhedra.

Mn^{II} phosphates find significant use in industry, including $MnHPO_4 \cdot 3H_2O$ for the preparation of luminescent materials, and $Mn(H_2PO_4)_2 \cdot 2.5H_2O$ in fertilizers and especially for manganese phosphate coatings on metals to improve wear resistance. The pyrophosphate $Mn_2P_2O_7$ is a useful calibrant for magnetic measurements.

There appears to be but one reference[179] to a *phosphinite* $Mn(Ph_2PO)_2$, although *phosphinates* are receiving attention: the compounds $Mn(R_2PO_2)_2$ (R = Bu^n, Bu^t, pentyl and octyl) are polymeric[264] and probably octahedral; and structural data are available on five compounds $Mn(R_2PO_2)_2 \cdot L$, showing close parallels with the carboxylates,[132,265] including zwitterion species.[266] PO_2 bridging like (**82**) and (**84**) occurs in these.

Only one *phosphonate*, the rather insoluble $MnHPO_3 \cdot H_2O$, appears to have been described, and there are six known polyphosphonates, ranging up to $Mn_2H_{17}P_7O_{21} \cdot 4H_2O$. A *fluorophosphate* $Mn(PO_3F) \cdot nH_2O$ and several *chlorophosphates* $Mn(Cl_2PO_2)_2 \cdot nL$ also are characterized.[238,267]

The remainder of the P oxyanion compounds, hydrates and phases are *phosphates* of various types, including pyro- and meta-phosphates, and polymers. Of the > 100 described species, including such mixed ligand species as Mn_2ClPO_4 and $Mn_5(OH)_4(PO_4)_2$, X-ray analyses are available on twenty-two and all but one $\{\beta'\text{-}Mn_3(PO_4)_2\}$ have $[MnO_6]$ octahedra with Mn—O generally averaging between 2.18 and 2.24 Å. This predominance of the octahedron probably derives in significant part from the general compatibility of Mn in octahedral holes and P in tetrahedral holes of close-packed oxygen. This 'compatibility', however, is seldom perfect for most of the polyhedra are distorted: in one case[268] bond length variations of 2.08–2.59 Å occur in the one octahedron and angular distortions of 10° are seen. Such distortion reaches a peak among known structures in $\beta'\text{-}Mn_3(PO_4)_2$, the nine independent atoms of which all have five nearest neighbours (range = 2.03–2.36 Å; average = 2.13–2.19 Å) and distinctly longer bonds to a sixth oxygen, that may be as close as 2.39 Å in the more regular octahedra to > 3.0 Å in the least.[269]

Table 25 Mn^{II} Arsenate Species with Non-octahedral Coordination Polyhedra

Compound Mineral	*Coordination Polyhedra*	*Bond Lengths* (Å) *Average*	*Range*
$Mn_2(OH)AsO_4$	$[MnO_5]$ (× 4)	2.129	2.065–2.223(6)
Sarkinite	$[MnO_6]$ Octahedron (× 4)	2.212	2.149–2.344
$Mn_2(OH)AsO_4$	$[MnO_5]$ (× 4)	2.12	
Eveite	$[MnO_6]$ Octahedron (× 4)	2.19	
$Mn^{II}Mn^0_2Sr_2As_2O_2^a$	$[MnO_4]$ Square plane	2.078	
$Mn^{II}Mn^0_2Ba_2As_2O_2$	$[MnO_4]$ Square plane	2.124	
$(Mn, Mg, Cu)_5(OH, Cl)(AsO_3)_3$	$[MnO_8]$ Cube	2.42	
Magnussonite (cubic)	$[MnO_6]$ Octahedron	2.19	
	$[MnO_6]$ Trigonal prism	2.24	
	$[MnO_4]$ Square plane	2.10	
$Mn_{26}[As_6(OH)_4O_{14}](As_6O_{18})_2CO_3$	$[MnO_6]$ Octahedron (× 4)	2.217	
Armagite	$[MnO_6]$ Trigonal prism	2.237	
$Mn_4[AsSi_3O_{12}(OH)]$	$[MnO_6]$ Octahedron (× 3)	2.222	2.099–2.366
Tiragalloite	$[MnO_{5+2}]$	2.198 (× 5), 2.625, 2.974	2.102–2.366
$Mn_{10}Sb_2As_2Si_2O_{24}$	$[MnO_8]$ Cube	2.42	
Parwelite	$[MnO_6]$ Octahedron	2.21	2.17–2.24
	$[MnO_5]$	2.09 and 2.12	
	$[MnO_4]$ Tetrahedron	2.07	

[a] Related Sb and Bi compounds have the same structure.

The arsenate polyhedra, on the other hand, show distinctly more variability; of the > 60 species described,[270] many of which are minerals, structural analyses are available for one-third and, of these, one-third appear to have non-octahedral Mn polyhedra (Table 25). (The proviso results from a report[268] that the earlier analysis, describing arsenoclasite as containing $[MnO_4]$, $[MnO_5]$ and $[MnO_6]$ polyhedra, was in error, and that there are only $[MnO_6]$ polyhedra—albeit distorted.)

One other interesting feature occurs in mixed Mn, Zn species: where there is a choice of octahedral and tetrahedral holes, Mn occupies the former and Zn the latter. Undoubtedly the size difference is the major, if not only, cause.

(*v*) *Oxyanions of S, Se and Te*

Robust manganese(II) *sulfinates* and *sulfonates* undoubtedly can exist, but there is very little detail on them in the literature. Lindner and co-workers[271] claimed evidence for both O,O- and S-bonded forms of $PhSO_2^-$, but the latter seems very unlikely.

The binary *sulfite* $MnSO_3$ and five distinct hydrates have been defined,[272-274] and the structures of the two different forms of the trihydrate are available. They show *fac*-$[MnO_3(H_2O)_3]$ and *cis*-$[MnO_4(H_2O)_2]$ octahedra. Various compounds $M_2Mn(SO_3)_2$, $K_2Mn_2(SO_3)_3$ and $Na_2Mn_4(SO_3)_5$ were described by Berklund in 1879 and Gorgeu in 1883.[272] They are unlikely to represent discrete $[Mn(SO_3)_2]^{2-}$ anions.

The *sulfate* $MnSO_4$ and its hydrates (7, 5, 4, 2 and 1) represent the stable oxidation state under ambient conditions. Compounds are colourless in finely-divided form and pale pink or rose coloured when crystalline. All appear to be examples of high spin octahedral Mn^{II}. Aqueous solutions have been much studied, to define the physical parameters, because of their importance in Mn production from its ores. Stability constants for 1:1, 1:2 and 1:3 species have been defined but detail (structurally) of the labile Mn polyhedra is unclear. Examples of unidentate and bridging sulfato are seen in the known crystal structures, but not bidentate or terdentate to the same metal atom. (However, bidentate function may occur in some of the mixed-ligand compounds described earlier.)

In all, some 80 compounds, phases and hydrates are listed in a 1976 volume of *Gmelin* (**C6**), including a few thiosulfates and polythionates. Of these, structural data are available only on *ca.* 10%, but they refer to at least one third of the types, and all show $[MnO_6]$ octahedra, often containing water molecules as well as oxygens of the sulfates. The octahedra $[MnO_x(H_2O)_{6-x}]$ are described for $x = 6$, 5, (*c*- and *t*-) 4 and 2, and the mineral mooreite $\{Mg_7Zn_4Mn_2(SO_4)_2(OH)_{26}\cdot 8H_2O\}$[275] has $[Mn(OH)_2(H_2O)_4]$ octahedra (and, incidentally, $[Zn(OH)_4]$ tetrahedra as well).

Species like $K_2Mn(SO_4)_2$ and $K_2Mn_2(SO_4)_3$ are known,[272] but they are unlikely to represent discrete 'complex' Mn anions. The 'complexity' of the solids will be defined primarily by close packing of the sulfates, with charge neutralization achieved by Mn^{2+} and other cations in appropriate 'holes'.

Of the 20 known *selenite* and *selenate* species,[272] structures are now available on more than one-third, and all show $[MnO_6]$ octahedra.[276] Manganese(II) selenite ($MnSeO_3$) has the perovskite ($CaTiO_3$) structure, with each $[MnO_6]$ octahedron provided by three SeO_3 groups (Mn—O = 2.235 Å); the monohydrate has $[MnO_5(H_2O)]$ octahedra (Mn—O = 2.14–2.31 Å); and the dihydrate has *cis*-$[MnO_4(H_2O)_2]$ octahedra (2.14–2.29 Å). This system also gives an example of an unexpected redox reaction: hot solutions of Mn^{II} and H_2SeO_3, and various other reaction routes, give orange-red crystals of $Mn(SeO_3)_2$, which is apparently another Mn^{IV}compound, like MnO_2, stabilized by its insolubility. There is an interesting structural parallel with the insoluble, white iodate $Mn(IO_3)_2$. $MnSe_2O_5$, $MnSeO_4$ and their hydrates also are known, as well as species like $Na_2Mn(SeO_4)_2$.

Fewer *tellurites* and *tellurates* are known:[272] $MnTeO_3$ is isostructural with the Se analogue, and tellurates are represented by species like Mn_3TeO_6—no $MnTeO_4$ species appear to have been described.

(*vi*) *Oxyanions of the halogens*

Very few binary compounds of this class have been described, but ClO_4^- is widely used as a counter ion for the preparation of many of the cationic species of the other neutral ligands, despite the instability that gives some risk of explosion! For many years, it was regarded as the standard for 'non-coordination'—especially in aqueous solution—and both the chlorate and perchlorate crystallized from aqueous solution as $[Mn(H_2O)_6]X_2$. However, the anhydrous $Mn(ClO_4)_2$ can be

prepared,[277] and both the di- and tetra-hydrates have been defined. Beginning with $Mn(ClO_4)_2$, other anhydrous metal perchlorates,[277] and some copper(II) and nickel(II) compounds,[278] perchlorato coordination has been increasingly recognized in the literature, and one of the first to be defined crystallographically was the arsine oxide species[245] $[MnClO_4(Ph_3AsO)_4]ClO_4$. Other perchlorato species have been noticed in the various sections on neutral ligands.

Two anhydrous iodates also are known[279] and both were first reported by Rammelsberg in the 19th century. The insoluble $Mn(IO_3)_2$ precipitates from aqueous mixture of Mn^{II} and IO_3^-. It is relatively robust in the short-term, but on long keeping releases I_2. The periodate $Mn_3(IO_5)_2$, however, is stable only below 15°C.

(*vii*) *Isopoly- and heteropolyanions of V, Nb, Mo and W*

Anions of this type containing Mn (II, III and IV) are listed in Table 26. Most of these have been isolated as crystalline solids.

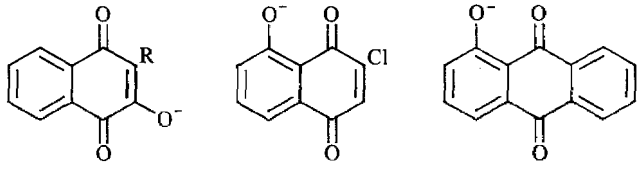
There is a tendency for stability of the higher oxidation states (III and IV), but a number of Mn^{II} species are defined,[280,281] the most robust of which appear to be the triheteropolyanion tungstomanganophosphates $[PMnW_{11}O_{39}(OH_2)]^{5-}$ and $[P_2MnW_{17}O_{61}(OH_2)]^{8-}$. Both are readily oxidized to Mn^{III}. The Mn atoms are high spin and magnetically dilute; and the anions are yellow-brown because of a metal–ligand charge-transfer band in the near UV. A cation exchange resin, in the H^+ form, completely removes Mn^{II}.

41.3.5.3 Bidentate ligands

(*i*) *Diethers, diols and diphenols*

The *ether* compounds have been little studied: only the 1,2-dimethoxyethane species $MnLX_2$ (X = Cl, Br), $[MnL_2(H_2O)_2](ClO_4)_2$ and $[MnL_3][SbCl_6]_2$ appear to have been described,[221] and all may contain ether chelates. Dioxane, on the other hand, acts as a bridging group in quite robust polymers (Section 41.3.5.1.iii).

Diol compounds are known, both of the neutral aliphatic ligands and in their deprotonated (alkoxide) form,[212] but generally have been studied for their reaction with O_2 and other oxidizing

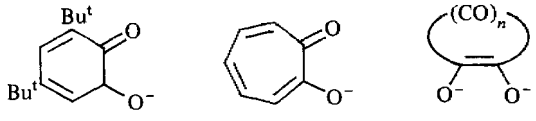


agents, to form Mn^{III} and Mn^{IV} species. Ethane-1,2-diol species $[MnX_2L_2]$ (X = Cl, Br, NO_3, $\frac{1}{2}SO_4$) are characterized by an X-ray analysis of the chloro compound, showing an $[MnCl_2O_4]$ octahedron. The alkoxide Mn(L-2H) was studied for its catalytic activity, but not characterized structurally. Various polyols, such as mannitol, inositol, *etc.*, appear also to act as diols, forming similar chelate compounds.[282] These have been studied mainly for their reaction with O_2 to give Mn^{III} and Mn^{IV} species, and little is known of the structures they adopt.

Catechol, with its more readily ionized protons (and other *o-diphenols*), in aqueous alkaline solution forms soluble, colourless anionic species. Stability constants for the 1:1 and 2:1 species have been measured ($\log K_1 = 7.5$, $\log K_2 = 5.7$) and the 3:1 species forms at pH > 11. In 0.3 M NaOH, the latter is readily oxidized by ferricyanide to Mn^{III}. Some crystalline species have been described, but need further characterization and most seem to be very air sensitive.[212,282] Again the interest in these compounds has been directed mainly towards their oxidation to Mn^{III} and Mn^{IV} species.

(*ii*) *Diketones and related ligands*

Significant data are available only on the α- and β-diketones and structurally related ligands.[283] A single tris-chelate cationic species of dimethylphthalate appears to be the sole representative of the γ-diketone type.



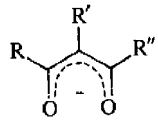
Neutral *α-diketones* are represented only in two crystalline quinone species $MnBr_2 \cdot L$ of unknown structure, but there is a litle more detail available on the anions of hydroxyquinones (**93**)–(**97**), the related tropolone (**98**) and the dianions of the cyclic carbonyls (**99**) for $n = 2$, 3 and 4. The latter give polymeric hydrates based on $[MnO_6]$ octahedra.[284] The hydroxyquinonate anions (**93**)–(**97**) have all given crystalline species $Mn(O, O)_2$, one of which (**97**) has been shown to be tetrameric.[285] This compound was prepared from $Mn_2(CO)_{10}$ and the hydroxyquinone in toluene; reaction in pyridine gave $[Mn(O,O)_2py_2] \cdot 2py$. The anion (**94**) has also been reported to give a solid $MnCl(O,O) \cdot 4EtOH$.

(**93**) R = H
(**94**) R = Me

(**95**)

(**96**)

(**97**)

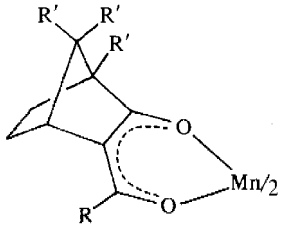


(**98**)

(**99**)

The tropolone compound $Mn(O,O)_2$, where (O,O) = (**98**), was prepared from the ligand and $Mn(OAc)_2$ in aqueous methanol, and, after drying, was sublimed. Undoubtedly, it is polymeric, but the details are unknown.

Acetylacetonate is usually considered the reference ligand for the *β-diketonates* and it has been comprehensively studied. Neutral ligand compounds are known: acacH acts as a unidentate ligand on an $(MnBr_2)_n$ linear polymer, like (**8**), and it chelates in $[Mn(acacH)_3][InCl_4]_2$.[286] A related ligand diamidomalonate has been proven to chelate in $[Mn(NO_3)_2L_2]$, which has bidentate amide and unidentate nitrates.[289]



But most of the chemistry of acetylacetone and related ligands concerns their behaviour as monoanions, bonding essentially in the keto-enol form (**100**). The types of ligands of this general

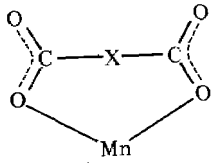
(105)

class, for which Mn^{II} compounds have been described, are summarized in Table 27, together with the structural types of the Mn compounds.

The binary compounds $Mn(O,O)_2$ are probably mostly, if not all, octahedral polymers[39] like the known Ni^{II} and Co^{II} species, but the detail is unknown beyond a report that $Mn(acac)_2$ is trimeric in benzene. However, for most of the other structural forms, X-ray analyses are available of proof of type: $[Mn(acac)_2(H_2O)_2]$, $[Mn(dbm)_2(THF)_2]\cdot 2THF$ {dbm = (**100**) for R = R″ = Ph; R′ = H},[288] $[Mn(acac)_2phen]$, $[Mn_2(acac)_4(allylNH_2)_2]$ and $NH_4[Mn(O,O)_3]$ {(O,O) = (**100**) for R = CF_3; R′ = H; R″ = furyl}.[289] All show Mn octahedra and there is no compelling evidence in any of the literature for alternative polyhedra in related compounds.

Most are pale-yellow crystalline products and are robust in the air. $Mn(acac)_2$ and its hydrate are sensitive to oxidation, as are many of the others, when wet (that is in equilibrium with a solution) but are reasonably robust when dried. Yet other compounds are distinctly less O_2 sensitive. The dihydrate $[Mn(acac)_2(H_2O)_2]$ readily loses water, and the anhydrous species can be sublimed at low pressures.[290] $Mn(acac)_2$ has been used as a catalyst for a variety of chemical reactions, including polymerizations.

(*iii*) *Dicarboxylates and hydroxycarboxylates*



The dicarboxylates have been separated from the compounds of Section 41.3.5.2(ii) because of the possibility of the formation of chelate rings (**106**). Such chelation, however, is by no means universal in these compounds. The 1:1, 1:2 and 1:3 species, which have been shown to exist in aqueous

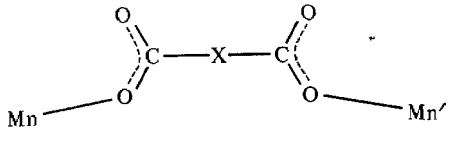
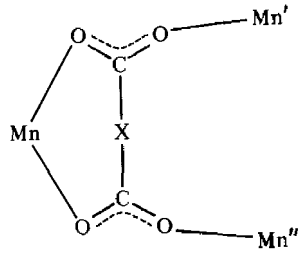
solutions and which, for oxalate, have log K's of approximately 4.5, 2 and 1.5 respectively, probably all have chelated ligands.[293] Certainly the 1:2 and 1:3 species can be oxidized to the chelated Mn^{III} species. However, most of the solid compounds (see Table 28 for the oxalate species, which have been most studied) are polymers, with the dicarboxylates currently known to bridge in the forms (**107**)–(**110**).



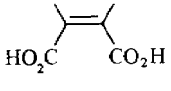
(**106**)



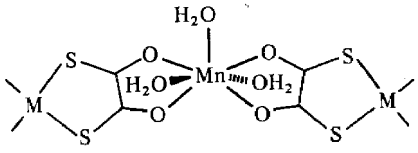
(**107**)

(**108**)

(**109**)



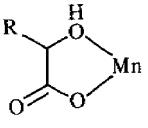
(**110**)



Malonate and the dianions of the other aliphatic dicarboxylic acids $HO_2C(CH_2)_nCO_2H$ (n = 1–8) have been isolated as crystalline hydrates, and some of these have been dehydrated.[293] X-Ray structural analyses have been reported for the malonate dihydrate,[294] which has *trans* H_2Os and bridging malonates of type (**110**), and for the succinate tetrahydrate and adipate dihydrate:[295] the succinate reputedly has a *trans*-$[MnO_2(H_2O)_4]$ polyhedron with bridging dicarboxylate, presumably as in (**109**). The monoanion of maleic acid (**111**) is only unidentate in crystalline $[Mn(H\text{-maleate})_2(H_2O)_4]$;[296] but the equivalent compound of phthalic acid is a bis-chelated octahedral $[Mn(O,O)_2(H_2O)_2]$ species.[297] Clearly other interactions in the solids, as well as the bonding interactions with Mn^{II}, define structure in the carboxylate compounds.

All of these species are relatively robust in the air, even in solution; but, especially when the pH is raised, they can be readily oxidized to Mn^{III}.

Another interesting structural variation has recently been reported[298] as occurring in some mixed metal compounds of dithiooxalate, *i.e.* $MMn(S_2C_2O_2)_2 \cdot 7.5\,H_2O$ (for M = Ni and Cu). These have the linear polymer structure (**112**), with seven-coordinate Mn^{II}.



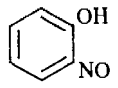
(111)

(112)

The *hydroxycarboxylates* are known in a range of crystalline binary Mn^{II} hydrates,[299–303] but the only ternary compounds are a $5NO_2$-salicylate, which is probably $Na_2[MnL_2(H_2O)_2]$, and the Na and K tartrates $M_2MnC_4H_2O_6 \cdot 6H_2O$.[299] Both the aliphatic and aromatic (only salicylates) hydroxycarboxylates form 1:1 and 1:2 species in aqueous solution, which are of relatively low stability, and much of the interest to date has been in their oxidations to Mn^{III} and Mn^{IV}—such oxidations being readily achieved in alkaline solutions, especially as the number of hydroxy groups on the ligand is increased.

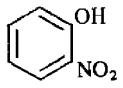
Table 29 contains the known structural details.[300–303] All are octahedral [MnO_6] species and a common feature is the chelate ring (**113**). Several of the compounds are *cis*-$[Mn(O,O)_2(H_2O)_2]$ monomers, but the more complex acids {(**113**) for R containing OH and/or CO_2H groups} form polymers. For example, citrate in $Mn_3(C_6H_5O_7)_2 \cdot 9H_2O$ acts as a terdentate ligand to one Mn and bridges to two others: there are $[Mn(H_2O)_6]^{2+}$ and $[MnO_5(H_2O)]$ polyhedra.

(113)



(*iv*) *Other ligands*

A range of bidentate O donor ligands, based on nitrogen oxides, have been reacted with Mn^{II}. Although several compounds of ligands (**114**) and (**115**) in their monoanion form have been described,[304] they are not fully characterized as Mn^{II} species, and the reported dark colours suggest the oxidation may have occurred during the preparations. Compounds of the other potentially anionic bidentates (**116**)–(**119**) are somewhat better characterized, although (**116**) appears to have been detected so far in only neutral unidentate function.[305] One compound of ligand (**117**) has been shown to be a *trans*-$[Mn(O,O)_2(H_2O)_2]$ octahedral species,[306] and the ligands (**118**) and (**119**) form rather insoluble $Mn(L—H)_2$ species, which are probably polymeric with [MnO_6] octahedra.[307,308]



The orange tris-chelated compounds of 2,2′-bipyridyl-*N*,*N*′-dioxide (**120**) are very sensitive to light and to oxygen: the most robust, the $[PtCl_4]^{2-}$ salt, has been described as being stable in the light for one hour. Like the $[Mn(terpyO_3)_2]^{2+}$ cations, they can be oxidized in CH_3CN to Mn^{III} and to Mn^{IV} (Section 41.3.5.4). Also described, have been $[Mn(bipyO_2)_2(NCS)_2]$ and $Mn(bipyO_2)Cl_2$, which appear to be somewhat more robust.[309]

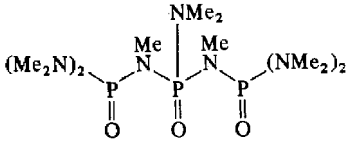
(119)

(120)



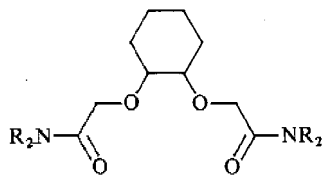
A few tris-bidentate di-sulfoxides also are known,[310] and a bidentate phosphate ester[311] and amide[312].

Two compounds of sulfoacetic acid ($HO_3SCH_2CO_2H$) were described by Hahn and Wolf in 1925, but there appears to have been no detailed study since on this ligand, or any other alkylsulfonic acid with Mn^{II}.

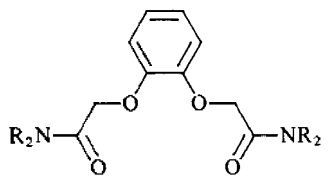
41.3.5.4 Multidentate ligands

For the cyclic, or crown, ethers, see Section 41.3.10.4. There appears to have been no systematic study of multidentate all-oxygen ligand compounds of Mn.

Two well-defined *neutral terdentates* terpyridyl-*N*,*N*′,*N*″-trioxide and the phosphoramide (**121**) both form MnX_2L and $[MnL_2]X_2$ species. For terpyridyltrioxide, the bright orange crystalline compounds $MnCl_2(terpyO_3)\cdot 3H_2O$ and $[Mn(terpyO_3)_2](ClO_4)_2\cdot 2H_2O$ are light sensitive, but the latter forms stable solutions in CH_3CN. Oxidation to both Mn^{III} and Mn^{IV} has been achieved electrochemically in reversible one-electron steps at half-wave potentials $E_{1/2} = 1.06$ and 1.77 V (versus SCE).[314] The phosphoramide (**121**) also forms 1:1 and 1:2 crystalline solids.[315]

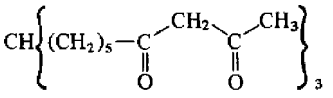


(121)



Anionic terdentates are certainly represented in a crystalline citrate (Section 41.3.5.3(iii)), and probably in some compounds of glycerol $\{CH_2(OH)CH(OH)CH_2OH\}$ and higher polyols which have been studied mainly for their oxidations to Mn^{III} and Mn^{IV} species.[316]

Quadridentate ligands appear to be represented solely by the ligands (**122**) and (**123**), which form eight-coordinate bis-chelate $[MnL_2]^{2+}$ cationic species.[317] The related $[Mn(N_4)_2]^{2+}$ compounds (Section 41.3.3.4(i)) have not yet been structurally characterized.



And there is a recent example of a *sexadentate* tris(β-diketone) ligand (**124**). Perhaps not surprisingly the trianion of this ligand gives a very robust Mn^{III} neutral molecule, which can be reduced to Mn^{II}; and this latter species also is kinetically stable to ligand exchange.[318]

(122)

(123)

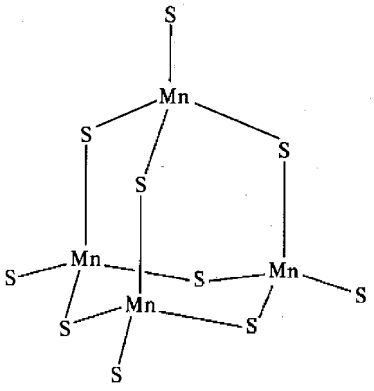
[a] Bond length data usually refer to the observed range. Where single values appear, these are averaged values. For phases without bond length data, inclusion in the table relies on X-ray powder data showing isomorphism with known species.

41.3.6 Sulfur Ligands

Manganese sulfur chemistry has been much neglected. Most detail is known of the simple solids, *i.e.* the bi-, ter- and quaternary sulfides, which so far have been generally neglected by the coordination chemist; something is understood of the 1,1-dithiolates, such as the dithiocarbamates, and of the 1,2-dithiolates or dithiolenes; but only now are results being reported of a systematic study of the thiol compounds. All Mn^{II} compounds are high spin d^5 species, with moments significantly below 5.9 BM being observed only where structures allow antiferromagnetism.

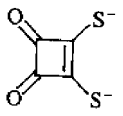
41.3.6.1 Sulfides and thiolates

Structural data are available (Table 30) for a range of binary, ternary and quaternary *sulfides* of manganese, almost invariably Mn^{II}, and these set the scene for the structures to be expected in the compounds with the more discrete polyhedra.[319] Indeed, the structural pattern is established in the simple binary compound MnS. Whereas, the stable modification of this (α-MnS) is green and has the cubic rock salt structure with $[MnS_6]$ octahedra, the well-known flesh-coloured precipitates of the qualitative analysis system are metastable β- and γ-modifications, which have $[MnS_4]$ tetrahedra with respectively the zinc blende or diamond (cubic) and wurtzite (hexagonal) structures. And so, in the rest of the known solids, there are almost equal numbers of four-coordinate tetrahedra and six-coordinate octahedra with no other polyhedra having been detected.



Although this same structural pattern is found in the discrete polyhedra formed by the *thiols*, there is a marked difference in redox properties; although there are no binary sulfides of higher oxidation state and very few ternary sulfides, yet many of the thiol species are very easily oxidized to stable Mn^{III} species. Hence, anaerobic conditions are usually required for the preparation of the Mn^{II} thiol species.[320]

The only monothiol studied, thiophenolate (PhS^-), forms pink tetrahedral $[Mn(SPh)_4]^{2-}$, isolated as $[NR_4]^+$ and $[PPh_4]^+$ salts,[320,321] and a red-orange, tetrameric anion $[Mn_4(SPh)_{10}]^{2-}$, which has the adamantane-like structure (**125**)[320] (which is, of course, a small fragment of the zinc blende or diamond structure of β-MnS). Each of these species has parallels in the other transition metals.



The anion $[Mn(SPh)_4]^{2-}$ was first prepared[321] from the manganese compound of dithiosquarate {dts (**126**)} and $[Mn(SPh)_2dts]^{2-}$ also was isolated. It probably represents another example of a tetrahedral $[MnS_4]$ species with a bidentate dithiol.

The original study[322] described the pink solids $K_2Mn(dts)_2 \cdot 2H_2O$, $[Ph_4P]_2Mn(dts)_2$ and $[Ph_4P]_2Mn(dts)_2 \cdot 2EtOH$. Perhaps they also are examples of bis-bidentate dithiolates, but the structural detail is unknown.

However, a dithiolate chelate compound has certainly been identified for 1,2-dithioethane[320] {$^-S(CH_2)_2S^- = edt$}: yellow-brown $[Me_4N]_2[Mn(edt)_2] \cdot CH_3CN$ and orange-yellow $[Ph_4P]_2[Mn(edt)_2]$ have been characterized; and an X-ray analysis of the former proves the bis-bidentate tetrahedral structure, with Mn—S = 2.43 Å (average) and an interchelate angle S—Mn—S of 91.5°. This anion is particularly sensitive to oxidation by O_2, giving green Mn^{III} species (Section 41.4.4).

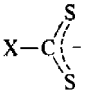
(125)

(126)

A related chelate compound—the first to be reported[323], and the most stable towards air (pink crystals were prepared by slow evaporation of solvent in the air)—is $[Mn\{SP(Ph)_2NP(Ph)_2S\}_2]$. This also is tetrahedral, with Mn—S distances of 2.426–2.457 Å and interchelate S—Mn—S angles of 106 and 112°.

41.3.6.2 Dithiolenes

Manganese(II) is but poorly represented in the chemistry of the dithiolenes.[324,325] Only one red-brown paramagnetic compound, $[PPh_4]_2[Mn(mnt)_2]$ {mnt = $(CN)_2C_2S_2^{2-}$}, appears to have been described. In addition, several unstable nitrosyls, such as $[NEt_4]_2[Mn(mnt)_2NO]$, are known.[326] They are described as being extremely unstable in air, decomposing rapidly in solution, but more slowly in the solid state.



41.3.6.3 Thiocarbonyls

This section appears to be represented so far by but one ligand and that by but one fully-characterized compound: *trans*-$[MnCl_2tu_4]$ (where tu = thiourea) is isomorphous with the Ni^{II} analogue.[327]

Dithio-β-diketonates have not yet been described for Mn. Under conditions which give $[M(SacSac)_2]$ species for M = Co, Ni, Cu, the only Mn^{II} products {and Fe^{II}} obtained[328] were the dithiolylium salts of $[MnCl_4]^{2-}$.

41.3.6.4 1,1-Dithiolates

Data are available on the dithiocarbamates {(**127**) for X = R_2N—abbreviated as R_2dtc}, xanthates {(**127**) for X = RO—abbreviated as Rxanth},[329,330] dithiophosphinates ($R_2PS_2^-$ for R = Me, Ph and CF_3)[331] and dithiocacodylate ($Me_2AsS_2^-$),[332] but mostly refer to the CS_2 ligands.

(127)

Generally, preparation of the Mn^{II} species requires anaerobic conditions—$Mn(Et_2dtc)_2$ is pyrophoric, although some of the other compounds are reasonably robust. On mixing aqueous solutions of $MnCl_2$ and the Na or K salt of the ligand, yellow MnL_2 compounds precipitate. The dithiocarbamates are rather insoluble, but the ethylxanthate has significant water solubility (0.1 $g\,l^{-1}$ at 25°C). One structural determination,[333] that of $Mn(Et_2dtc)_2$, shows a linear polymer with $[MnS_6]$ octahedra (Mn—S = 2.51–2.78 Å), no chelation but bridging of type (**84**). A recent study has explored the

antiferromagnetism of this compound.[334] A related compound (1,2-bis-dithiocarbamato-ethane) is the fungicide 'maneb'.

Through an electrochemical study of the Mn^{III} compounds, the anionic species $[Mn(R_2dtc)_3]^-$ have been characterized,[335] but not isolated. Reversible reduction to Mn^{II}, as in equation (8), is followed by dissociation (9) to MnL_2 and L^-; and reoxidation to Mn^{III} then is irreversible. Such tris aniono species, which appear to contain three chelating ligands, are apparently more stable in the xanthate series and $[MEt_4][Mn(Etxanth)_3]$ has been isolated as well as $[Mn(Etxanth)_2phen]$ and two forms of $[Mn(Etxanth)_2bipy]$. This difference has been ascribed to the insolubility of the bis-dithiocarbamates. However, the electrochemical study[335] shows that the dissociation (9) occurs in solution, and there is an alternative explanation: the small chelate ring for the RCS_2^- ligands confers significant instability on the larger Mn—S polyhedra of Mn^{II}, but this instability is reduced and the 'bite' of the chelate ring increased as Mn—S distances are reduced in Mn^{III} and Mn^{IV}.

$$[Mn^{II}(R_2NCS_2)_3]^- \underset{+e}{\overset{-e}{\rightleftharpoons}} [Mn^{III}(R_2NCS_2)_3]^0 \underset{+e}{\overset{-e}{\rightleftharpoons}} [Mn^{IV}(R_2NCS_2)_3]^+ \quad (8)$$

$$[Mn(R_2NCS_2)_3]^- \rightleftharpoons Mn(R_2NCS_2)_2 + R_2NCS_2^- \quad (9)$$

The enhanced stability of the tris-chelate species in the higher oxidation states is thus explained.

41.3.7 Halides

The artificiality of attempting to separate the compounds of the metals into 'salts' and 'complexes' becomes perhaps most apparent with the halides. As with the other transition metals, Mn^{II} forms, for example, at least the crystalline chlorides $MnCl_2$, M^IMnCl_3, $M^IMn_2Cl_5$, $M^IMn_4Cl_9$, $M^I_2MnCl_4$, $M^I_3MnCl_5$ and $M^I_4MnCl_6$ and other ternary and quaternary phases. As well, many of these, when crystallized from water, form hydrates; and, equally, there are 'solvates' formed from the other solvents including traditional 'ligands' like pyridine.

In almost all of the series of binary and ternary compounds known, there are examples of the dominant structural theme in the crystalline halide compounds—the $[MnCl_6]$ octahedron. These octahedra are derived, according to the point of view, from Mn^{2+} (and the other M^+) fitting into appropriate 'holes' in close-packed halide lattices, or from face-, edge- or corner-sharing of interconnected octahedra, forming polymers. In the hydrates and the other solvates, other octahedra, containing molecules of solvent, occur.

In the above list, there are also examples of discrete $[MnCl_4]^{2-}$ tetrahedra, especially in the $M^I_2MnCl_4$ and $M^I_3MnCl_5$ series, and especially when M^I is large. There are no known examples of tetrahedral fluoro species, but they are quite significant in the bromides and iodides. In describing such solids, it is perhaps not illogical to talk of Mn^{II} 'complexes'. However, the problem of definition of a 'complex' is well illustrated by the ternary hydrate $(NH_4)_2MnCl_4 \cdot 2H_2O$. Its structure is derived (Figure 2) from that of NH_4Cl, simply by replacing two adjacent NH_4^+ ions by a *trans*-$Mn(H_2O)_2$ unit; and a continuous series of solid solutions are known in the range $6NH_4Cl \cdot MnCl_2 \cdot 2H_2O$ to $2NH_4Cl \cdot MnCl_2 \cdot 2H_2O$. Which is the complex? Surely the ternary hydrate is at least as much a complex of NH_4Cl as it is a complex of manganese(II). Any attempt to separate, for example, $MnCl_2$ from ternary phases like $KMnCl_3$, by classifying one as a 'salt' and the other as a 'complex', is not only illogical but also denies their close relationship.

Accordingly we have tried a novel (to the coordination chemist) classification: taking firstly the solid compounds which contain linked octahedra; treating the tetrahedral $[MnX_4]^{2-}$ species as a separate problem; and then addressing the problem of the polyhedra formed in the fluid phases in another separate section. On current knowledge, these are the only coordination polyhedra to be considered for Mn^{II} halo compounds: four-planar is unknown, and five-coordinate species have been detected only in a few examples of $[MnX_2L_3]$ and $[Mn_2(\mu\text{-}X)_2X_2L_4]$, which have been discussed in the sections on the appropriate unidentate ligands.

The basic data are available in the Gmelin volumes **C4** and **C5**, with earlier reviews in Colton and Canterford's book,[336] and by Kemmitt;[210] and more recent data are in the annual reviews,[4–6] and from *Structure Reports*.

41.3.7.1 Crystalline halides with octahedral coordination

(*i*) *Fluorides*

All known crystalline Mn^{II} fluoro compounds have octahedral coordination for the metal. A feature of these fluorides is the lack of crystalline hydrates: only $MnF_2 \cdot 4H_2O$ (isostructural with Zn) appears to have been characterized.

The pink binary compound MnF_2, known since the time of Berzelius, is reasonably stable chemically and barely soluble in most common solvents. It is the most thoroughly studied of any manganese fluoro compound, being of interest for both its spectroscopic and magnetic properties: it was the compound in which the exciton and exciton–magnon structure of electronic transitions in antiferromagnetic insulators was first discovered and identified. The cubic perovskite $RbMnF_3$ also has been much studied because its magnetic behaviour is very close to that of the ideal isotropic Heissenberg antiferromagnet.

MnF_2, in its normal crystalline form (at least four others are known), has a tetragonally distorted rutile (TiO_2) structure, with Mn—F (average) = 2.11 Å. Similar bond lengths are found in the known structures of the ternary and quaternary phases (Table 31), many of which also can exist in different structural forms at different temperature and pressure. In only one known case, that of $Ba_2[MnF_6]$ at high pressure, is there evidence for a discrete $[MnF_6]^{4-}$ octahedron. (However, it may well be possible to define conditions for the separation from solution of compounds $[ML_6]^{4+}[MnF_6]^{4-}$, using suitably sized inert cations.) The normal form of Ba_2MnF_6 is best represented as $Ba_{2n}F_{2n}(MnF_4)_n$, with chains of corner sharing $[MnF_6]$ octahedra — a common feature of the M_2MnF_4 species.

Probably one of the major driving forces for the formation of such 'polymers', rather than discrete $[MnF_6]^{4-}$ anions, is the electroneutrality concept, which leads one to expect that highly charged ions will be unstable.

(*ii*) *Chlorides*

The structural variation observed here is greater than for the other halides; there is almost as much variety in the crystalline hydrates as in the (often hygroscopic) anhydrous compounds; and undoubtedly further variants will be found as the systems are further explored.

$MnCl_2$ is certainly the stable manganese chloride, as $MnCl_3$ is unstable above − 40°C, and claims for $MnCl_4$ have never been substantiated. Recent reports[85,189] describe reactive forms of the anhydrous material useful for preparing various compounds of $MnCl_2$ (and the other halides). However, in the normal form, crystalline $MnCl_2$ has the hexagonal layer-type structure defined first for $CdCl_2$. The pink solid is hygroscopic, very soluble in water and forms hydrates $MnCl_2 \cdot nH_2O$ (for n = 1, 2, 4 and 6). It also, of course, forms compounds $MnCl_2 \cdot nL$, often called complexes, with an enormous range of other ligands (L): those for unidentate ligands and n = 1 have structures like (**13**); the great majority of the n = 2 compounds appear to be chain polymers like (**8**); and $MnCl_2 \cdot 4H_2O$, like many other of the n = 4 species, is an octahedral monomer *cis*-$[MnCl_2(H_2O)_4]$. The hexahydrate, which is almost certainly $[Mn(H_2O)_6]Cl_2$, is stable only below − 2°C. For some

Phase	*Comment*
M^IMnF_3	Na, K, Rb, Cs, NH_4, Tl — usually cubic perovskites (Mn—F = 2.11–2.13 Å)
$MgMn_2F_6$ and Mg_2MnF_6	Both have MnF_2 structure
$M^IMn_3F_7$	Na only — no structural detail
$M^I_3Mn_2F_7$	M = K, Rb — tetragonal M_3 = NaCd or NaCa — cubic
$M^I_2MnF_4$	M = K, Rb, Cs — tetragonal (Mn—F = 2.09–2.11 Å) M_2 = Ba — orthorhombic, Mn—F = 2.037–2.151 Å (av. 2.098 Å)
$M^{III}MnF_5$	M = Al, Ga, Cr
Ba_2MnF_6	Normally $Ba_{2n}F_{2n}(MnF_4)_n$, but high pressure form has the $K_2[GeF_6]$ structure
$LiMn[GaF_6]$	Cation ordered version of $Na_2[SiF_6]$ (Mn—F = 2.121 Å)
$Na_2MnM^{III}F_7$	M = Fe, V (Mn—F = 2.08 Å)

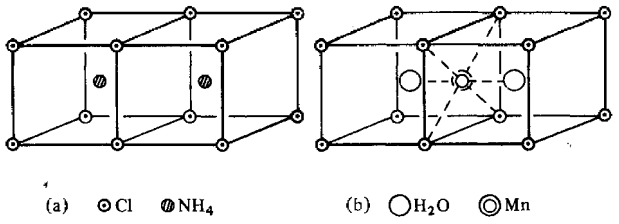

Figure 2 The relationship of $MnCl_2 \cdot 2NH_4Cl \cdot 2H_2O$ to the structure of NH_4Cl: (a) two adjacent cubic cells of NH_4Cl; (b) replacement of $2NH_4^+$ by $Mn(H_2O)_2^{2+}$

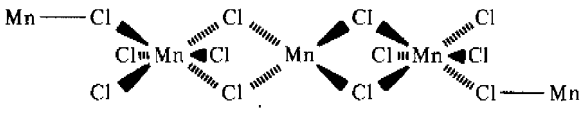

of the other unidentate ligands, we have also noticed compounds $MnCl_2 \cdot nL$ for $n < 1$. These have structures shading from the double chains of (**13**) into the fully layer structures of $MnCl_2$.

Mixing $MnCl_2$ and MCl (M = alkali metal cation, NH_4^+, *etc.*) in a melt of appropriate composition gives on cooling the ternary compounds $MMnCl_3$. Most of these pink or red solids are very hygroscopic and their preparation from water usually gives hydrates of them. At different stoichiometries, compounds of the series M_2MnCl_4 and sometimes also M_3MnCl_5 and M_4MnCl_6 can be

prepared, as well as hydrates of them, but especially of the former. In addition, a variety of more complex species, including the NH_4Cl complex of solid solutions (Figure 2), have been identified structurally (Table 32). The use of larger quaternary ammonium, phosphonium and arsonium cations to precipitate appropriate ternary compounds from organic solvents, like the alcohols and acetone, has further extended the range of known types.

(128)

(129)

In the great bulk of the known solids,[345] from $MnCl_2$ to $M_4\,MnCl_6$, and including M_2MnCl_4, the dominant coordination polyhedron for Mn is the octahedron: $[MnCl_6]$ units are formed by face-, corner- or edge-sharing of bridging chlorides in the anhydrous species (Table 32). Many of the compounds listed also undergo phase changes at different temperature and pressure, but the manganese retains octahedral coordination.

The only example of a discrete hexachloromanganese(II) anion appears to be in $K_4[MnCl_6]$, although others may be obtainable with appropriately sized 4+ cations, based, for example, on Pt^{IV}. The few examples of M_2MnCl_5 are examples of the only other structural theme, that of the tetrahedral $[MnCl_4]^{2-}$. Despite apparent stoichiometry, few of the known M_2MnCl_4 solid compounds contain this tetrahedral anion: although they give tetrahedra in melts,[346] most of the solids have layer type structures related to K_2NiF_4, containing corner-sharing $[MnCl_6]$ octahedra. Only one example of mixed coordination polyhedra for Mn^{II}–chloro species is known, the recently described $(Me_3NH)_3Mn_2Cl_7$, which contains both $[MnCl_6]$ in chains of face-sharing octahedra and discrete $[MnCl_4]^{2-}$ tetrahedra. As expected, the tetrahedra are most common in the compounds of the larger cations (Cs for the alkali metals). Measured bond lengths in the $MnCl_6$ octahedra range from 2.46 to 2.63 Å, but they are generally near 2.53–2.55 Å for bridging Cl and 2.50 Å for terminal Cl.

In the various 'hydrates', the water molecules usually are in the Mn coordination sphere. They make up the octahedra without the embarassment of high negative charges, and thus there are more examples here of monomers or small oligomers, like the dimers of (**129**). Other neutral ligands can replace the water, but very little work seems to have been attempted in this area for Mn. One recent report[347] postulated both $[MnCl_4L_2]^{2-}$ and $[MnCl_4L_4]^{2-}$ species for N donor ligands, but, whilst the former are quite acceptable, the latter are most unlikely to occur and cannot be accepted without full X-ray evidence.

Much of the interest in these compounds has been in their physical properties such as spectra, which have been reviewed recently in the Gmelin volumes,[348] and magnetism. Of particular interest for magnetic studies have been the compounds, such as $[NMe_4]MnCl_3$, which have one-dimensional magnetic coupling in the chains of face-sharing $MnCl_6$ octahedra.

(*iii*) *Bromides and iodides*

The bromo, and especially the iodo compounds of Mn^{II} are somewhat less robust than the chlorides, so that the variety of observed compounds and the structural patterns are less rich[349] (Tables 33 and 34).

Where compounds have been studied (and the structural data are less complete), there are close parallels between the chloro and bromo species, with one significant variation: there is a noticeable tendency for the bromides to form $[MnX_4]^{2-}$ tetrahedra more readily. Thus, $Rb_2[MnBr_4]$ is tetrahedral, whereas the chloro compound (Table 32) is known only as an octahedral polymer; and there is no octahedral polymer form of Cs_2MnBr_4 as there is for the chloro analogue. Similarly, in the various onium salts, discrete $[MnBr_4]^{2-}$ tetrahedra are more common. One intriguing compound in

Table 33 Structural Detail for the Mn^{II} Bromo Compounds

Compound	*Coordination Polyhedra*	*Comment*

(Ph_3MeAs)	$[MnBr_4]^{2-}$	Cubic. Discrete tetrahedra
Cs_3MnBr_5	$[MnBr_4]^{2-}$	Isomorphous with chloride
K_4MnBr_6	$[MnBr_6]$	

this series is $[Et_2OH]MnBr_3$, which is described as a light yellow solid. Perhaps it is an example of an $[Mn_2Br_6]$ dimer of tetrahedra. $K_4[MnBr_6]$ is an example of a discrete octahedron, and there is a recent report[351] of the preparation of $[Me_2NH_2]_4MnBr_6$.

Both $MnBr_2$ and MnI_2 have the CdI_2 layer structure, rather than the $CdCl_2$ variant of the chloride, but all form similar 'hydrates' of similar properties, with the tetrahydrates being the normally stable form. The compounds with the other neutral ligands appear generally to parallel the chloro species; but a recent report[193] of the structure of $MnI_2 \cdot PMe_2Ph$ raises an interesting structural variant: $[MnI_4P_2]$ octahedra alternate with MnI_4 tetrahedra, as in (**69**).

Ternary iodo compounds are formed only with large cations: the onium salts appear to be invariably examples of $[MnI_4]^{2-}$ tetrahedra, although both $CsMnI_3$ and $TlMnI_3$ give examples of $[MnI_6]$ polymers (Table 34).

41.3.7.2 Tetrahedral $[MnX_4]^{2-}$ and $[MnX_3L]^-$ species

Tetrahedral $[MnX_4]^{2-}$ species were identified by Nyholm and co-workers[352] in the first unequivocal demonstration of tetrahedra in transition metal compounds. More recent structural studies[317,328,343,345,349,350] have confirmed the existence and range of such tetrahedra some of which are listed in Tables 32–34. They are known for Cl, Br and I, but not for F. Cotton and Goodgame[31] first studied the electronic spectra, details of which have been summarized.[348]

There are also descriptions in the literature[349] of mixed ligand species $[MnBr_2Cl_2]^{2-}$, $[MnCl_2I_2]^{2-}$ and $[MnBr_2I_2]^{2-}$, but the data do not appear to prove the existence of such definite species rather than mixtures.

The conditions under which tetrahedra form are becoming clearer, although some of the identifications rely on spectra and a doubt must remain. (How different will be the spectra of $[MnCl_5]^{3-}$, if and when identified, from that of $[MnCl_4]^{2-}$?) The structural data (Tables 32–34) show that, of the binary and ternary compounds, few of the chloro species, more of the bromo species, and most of the iodo species have $[MnX_4]^{2-}$ tetrahedra in the solids. This progression needs no further explanation than size of halide (see especially the Cs and Rb species M_2MnX_4). In melts, however, M_2MnCl_4 compounds give tetrahedra.[345,346,349] Even in aqueous solution, and in other solvents (Section 41.3.7.3), in the presence of an excess of X^-, such tetrahedra have been detected, and it is assumed that $[MnX_3 \text{ solvent}]^-$ tetrahedra also are present. Such latter species are yet poorly

Table 34 Structural Detail for the Mn^{II} Iodo Compounds

Compound	*Coordination Polyhedra*	*Comment*
MnI_2	$[MnI_6]$	CdI_2 layer structure
$MMnI_3$ (Cs)	$[MnI_6]$	Hexagonal, related to $CsNiCl_3$, chains of face-sharing octahedra[5]
(Tl)	$[MnI_6]$	Edge-sharing double chains, like bromide
M_2MnI_4 (various)	$[MnI_4]^{2-}$	No X-ray data, but all known compounds appear to contain discrete tetrahedra
$MnI_2 \cdot PhMe_2P$	$[MnI_4]$ and $[MnI_4P_2]$	Octahedra and tetrahedra alternate in the chains[193]

characterized for Mn^{II}: among the few crystalline species are $[NR_4][MnX_3L]$ (R = alkyl; X = Cl, Br; and L = a unidentate imidazole N ligand).[39] In another pertinent example, whereas Co, Ni and Cu form compounds $[MnX_3L]$ {X = Cl, Br, I; and L = (**10**)}, Mn forms $L_2[MnX_4]$ species.[81]

41.3.7.3 Halo compounds of Mn^{II} in the fluid phases

In the gas phase, all MnX_2 compounds are linear symmetrical molecules with zero dipole moment.[346,353] In addition, dimers $[Mn_2(\mu\text{-}X_2)X_2]$ have been detected for at least the chloride and bromide.[353] Parallels with the alkyl (**3**) and amido (**11**) species are evident.

Liquid (melt) phases of the ternary compounds, or of MnX_2 in MX melts[346] give only octahedra for the fluorides, but tetrahedra for Cl, Br and I.

In water, all MnX_2 species dissolve to give $[Mn(H_2O)_6]^{2+}$, although at higher concentrations $[MnX_n(H_2O)_{6-n}]^{-(n-2)}$ species occur.[346,354] For F^-, K_1 is only of the order of five to ten. With excess halide, such species assume greater importance, and there is reasonable evidence for $[MnX_3H_2O]^-$ and $[MnX_4]^{2-}$ for X = Cl, Br. However, without the spin-allowed transitions found in the electronic spectra of the other transition metals, it is less easy to detect the various halo species for Mn^{II}.

In non-aqueous solutions, such as in $MeNO_2$ and CH_3CN, the tetrahedral anions $[MnX_4]^{2-}$ (X = Cl, Br, I) appear to maintain their integrity sufficiently, despite their lability, to allow meaningful measurement of some of the physical properties of these tetrahedra.

41.3.7.4 Fluoro anions of the nonmetals as ligands

Fluoro anions of the nonmetals, such as BF_4^-, PF_6^- and SiF_6^{2-} are usually used, instead of the explosive ClO_4^-, especially in non-aqueous solvents, when a counterion is required that does not compete too effectively for a place in the metal coordination sphere. However, since the acceptance of the reality of ClO_4^- coordination,[277,278] it has become to be recognized that these fluoro anions also can bond: BF_4^- is as good a ligand as ClO_4^-, although more subject to side reactions and therefore leading to unexpected products like the tetrameric species (**18**); PF_6^- is less good than ClO_4^-, and was originally used,[278] by contrast, to demonstrate perchlorate coordination; but direct bonding of AsF_6^- and SbF_6^- have now been demonstrated, both in the binary compounds MnX_2[335] and in the compound $[Mn(AsF_6)_2(NSF_3)_4]$.[103]

41.3.8 Hydrogen and Hydride Ligands

This is but a fringe area of Mn^{II} chemistry, although some detail of each class is known.

41.3.8.1 Hydrogen

The classification 'Mn hydrides' is persistent in the literature. The earlier view that H_2 'only dissolved' in metallic Mn, and formed no well-defined hydrides, was probably too simplistic, although Mn—H species are unlikely to be of great interest to the preparative chemist.

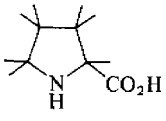
MnH_2 has been trapped in Ar or N matrices at 4 K, and spectroscopic measurements[356] suggest a bent molecule with H—Mn—H of $117 \pm 30°$; other authors[357] think that the results of some mathematical calculations in favour of a linear molecule should take precedence.

MnHI·1.5 THF has been described as resulting from the reaction of MnI_2 with $AlEt_3$ in THF, whereas related reactions usually produce binary MnAl derivatives.

The role of Mn^{II} hydrides in organometallic chemistry was reviewed[359] in 1973. But, most of the recent papers on Mn hydrides refer to the effect on the magnetism of intermetallic phases when H_2 is absorbed. In a few cases, stoichiometry has been determined—examples are Mn_2ErH_4, $Mn_2ErH_{4.6}$,[360] Mn_2ScH_4,[361] and Mn_2ZrH_3.[362] A neutron diffraction analysis of the latter shows 12 hydrogen (or deuterium) nearest neighbours for Mn, at 1.74–1.77 Å. Although no pattern is yet emergent, it seems not improbable that the oxidation state formalism will have but little use in this area of chemistry.

41.3.8.2 Hydride ligands

Both $Mn(BH_4)_2$ and $Mn(AlH_4)_2$ have been described,[363] but little is known of them and their reactions. Nöth[364] also described the species $Li_nMn(BH_4)_nX_2 \cdot mEt_2O$ ($n = 1, 2, 3$ and X = Cl, I) and $LiMn_2BH_4I_4$ as yellow or orange oils, obtained by reacting ether solutions of $LiBH_4$ and MnX_2 in various ratios and then evaporating to dryness.

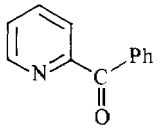


The Mn^{II} compounds of the boranes and carboranes were covered in the companion volume[365] and they include at least one example of a low spin Mn^{II} carborane.[366]

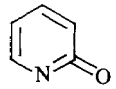
41.3.9 Mixed Donor Atom Ligands

Macrocyclic systems are discussed in Section 41.3.10.5.

41.3.9.1 'Ambiguous' N—O and bidentate N—O ligands



This is an area of chemistry in which most that has been attempted has been at a very superficial level. It is very easy in particular to synthesize Schiff base N—O donor set hybrid ligands and to make Mn^{II} compounds from them. It is not easy, unless one uses X-ray techniques, to unambiguously assign which ligand donor atoms are bound. Furthermore, the marked tendency of oxygen donors to form bridges, (such behaviour is very common for carboxylic acid residues, see Section 41.3.5.2.ii)often complicates the ligand binding pattern immensely. Thus in $[Mn(pro)(H_2O)_4]^{2+}$ {pro = D,L-proline (**130**)} one might simplistically expect a monomeric octahedral ion with both N and O donors of the proline coordinated. In fact X-ray analysis indicates that the N atoms do not bind to the Mn^{II}, but that the carboxylic acid groups bind both O atoms to adjacent Mn atoms to give a continuous polymer and an MnO_6 chromophore.[253]



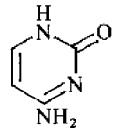
(130)

This section is constructed to deal firstly with the group of ligands which possess potential N and O donors which cannot both bind to the one Mn atom. The coverage will then extend, with increasing ligand denticity, to deal with ligands that can potentially bind more than one type of donor atom to the one Mn atom.

The major analytical technique that has been used to assign ligand binding atoms has been IR spectroscopy. Large numbers of workers have based their claims for or against the binding of specific donors on the change (or lack of change) of such 'parameters' as amine stretching frequencies, pyridine breathing modes or carbonyl stretching frequencies, upon binding of the free ligand to the metal. Thus 2-benzoylpyridine (**131**) in $[MnCl_2L_2(H_2O)_2]$ is postulated on IR data to be bound only by the pyridine nitrogen with the carbonyl group, whose IR stretching frequencies are virtually unchanged upon complexation, unbound.[367] On the other hand, $MnCl_2(tp)$ (tp = 2-pyridone, **132**) appears to be isomorphous with the corresponding Cu^{II} compound, which has been shown to possess a four-coordinate dichloro-bridged structure with unidentate oxygen bonding of tp. Again, in this case, the IR carbonyl stretching frequencies are unchanged upon complexation.[368]

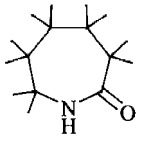
(131)

(132)



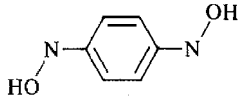
To demonstrate the difficulty of using IR evidence, Table 35 lists the CO stretching vibrations for cytosine {cy = (**133**)} and some cytosine compounds.[369] It is known that the structure of $CuCl_2(cy)_2$

Table 35 IR Carbonyl Stretching Vibrations for Cytosine and Some Cytosine Metal Compounds



Compound	*C=O stretching frequencies* (cm^{-1})
Cytosine (cy)	1703, 1662, 1615
$MnCl_2(cy)_2$	1676, 1658, 1601
$CuCl_2(cy)_2$	1676, 1656, 1621
$MnBr_2(cy)_2$	1676, 1656, 1621, 1593
$CuBr_2(cy)_2$	1683, 1660, 1630

is effectively planar with a $CuCl_2N_2$ chromophore, however the IR evidence would indicate that the carbonyl groups are bound in all cases.



Some ligands, which possess both potential N and O donors, but whose structure forbids chelation of both donors, are listed in Table 36 along with proposed bonding evidence. Although structures are in most cases unproven and may well be polymeric, many workers appear to favour the O-bonded system rather than the N-bonded. Such bonding is proposed for probably the simplest of these 'ambiguous' ligands, *viz.* hydroxylamine;[379] however the somewhat similar ligand, cyanoacetic acid is claimed to form N and O-bonded polymers with Mn^{II}.[380] The claim[381] that in $MnCl_2(biuret)_2$ the ligand (**148**) binds only O atoms to the metal would appear to support the contention that Mn^{II} prefers O donors. However, as this is the preferred method of binding of biuret to other transition metal ions, when the ligand is not acting as an anionic group, such support is questionable.

(145) R = Me

(146)

(147)

(148)

Possibly the clearest indication of the preference of Mn^{II} for O rather than N donors is seen in the compounds formed by the amino acids. The early work of Berezina and Pozigun[382] indicated that $MnX_2(aa)_n$, $MnSO_4(gly)_n$ and $Mn(NO_3)_2(gly)_n$ (where X = Cl or Br; aa = either glycine (gly) or α-alanine (α-ala); and n = 2, 4 or 6) could be prepared. IR evidence was used to show that the amino acids coordinated as zwitterions through only the O donor, except in the two cases, $MnCl_2(\alpha\text{-ala})_n$ and $Mn(NO_3)_2(gly)_n$, in which both the N and the O were bonded. A series of Polish papers[383] has shown that there is no X-ray evidence that, while the amino acid residue does not lose a proton, the N atom bonds. There are two types of amino acid compounds formed: (a) octahedral chain polymers in which the carboxylic acid group acts as a bridge between two adjacent Mn^{II} atoms, *e.g.*

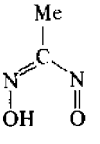
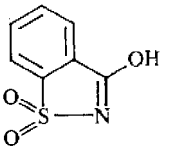
$[MnCl_2(gly)(H_2O)_2]_n$ and $[Mn(gly)_2(H_2O)_2]_nBr_2$, and (b) monomeric octahedral compounds in which the amino acids bind only through one of the O atoms, *e.g.* $[MnCl_2(gly)_2(H_2O)_2]$.



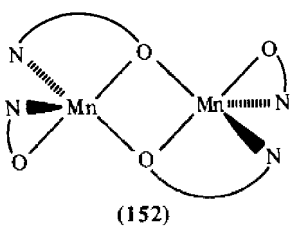
Stability constant measurements have been undertaken to show that in basic solution mixed amino acid ligands with two amino acid moieties present, *i.e.* NH_2—C(R)—C=N—C(R′)—COOH), yield complexes with log K values of the order of 6 to 7;[384] such compounds appear to bind the amine nitrogen.[385]

Berezina *et al.*[386] claim, using IR evidence, that the anionic glycine residues in $Mn(gly)_2 \cdot 2H_2O$ chelate as N—O bidentates. If this is the case, glycine is here paralleling what is believed to be the behaviour of the bidentate salicylaldimines (**149**), and the behaviour of the interesting low spin $[Mn^{II}L_3]^-$ ion {HL = ethylnitrosolic acid (**150**)}, which has been shown by X-ray work to be octahedral with binding of the N of the nitroso group and the oxime O atom.



However, there are always exceptions to any rule; in the compound $[MnL_2(H_2O)_2]$ {HL = (**151**)}, X-ray structural analysis[388] has shown the Mn atom to be bonded to the nitrogen atoms of two *trans* ligands.

(149)



(150)

(151)

The bis-bidentate salicylaldiminato compounds (**149**) of Mn^{II} have not been studied systematically.[173,389] Since Tsumaki[390] reported the red-gold benzyl compound (**149**) (R = $CH_2C_6H_5$ and X = H) in 1938, a number of yellow or orange solid compounds of empirical formula $MnL_2(H_2O)_x$ for various values of R and X in (**149**), have been prepared[39,391–393] (see Table 37). Many of these compounds appear to be polymeric[392] or at least dimeric,[39,393] but one of the few certain pieces of structural data is that reported on the orange compound (**149**) (R = Me, X = H), which has been shown to be isomorphous with its Zn analogue.[395] This Mn compound thus has the dimeric structure (**152**), with two five-coordinate Mn atoms. The compound does not exhibit antiferromagnetic coupling,[393] although other compounds of type (**149**) with different values for R and X appear to have low magnetic moments and their structures have been postulated as dimeric on the basis of temperature dependent magnetic studies.[39]

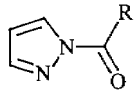
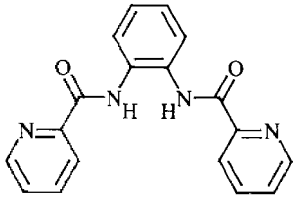
Undoubtedly, a whole series of Mn^{II} compounds of type (**149**) are readily obtainable, and should be of comparable air stability to the analogous Co^{II} species. One attempt to prepare the compound (**149**) for R = Pr^i and X = H, by mixing $Mn(NO_3)_2$ in water with salicylaldehyde and excess amine in ethanol, gave yellow crystals of formulation $[MnL_2]\cdot Pr^iNH_3NO_3$. Identical reactions for Co, Ni, Cu and Zn nitrates yielded only the corresponding compounds of type (**149**).[396] The stability constants of some of the bis-bidentate salicylaldiminato compounds of Mn^{II} have been found to be of the order expected in the Irving–Williams series.[394] Undoubtedly much more work is required in the area of synthesis and structural analysis before a clear picture of this system can be obtained and the relevance of magnetic data properly assessed.

The possible bidentate ligands with a chelating N—O donor set constitutes a virtually infinite set and a large number of this set has been thrust upon an unsuspecting Mn^{II} atom, often with very few conclusive results. Thus the Mn^{II} and Mn^{III} compounds of 8-hydroxyquinoline (**153**) and its substituted derivatives attract some 16 pages in Gmelin.[397] For Mn^{II} both deprotonated MnL_2 and protonated, *e.g.* $[MnCl_2(HL)_2]$, ligand compounds are described, but there are no X-ray structures. It appears likely that both the N and the O atoms are bound in the MnL_2 compound, as the structure of the Mn^{III} compound, $[MnL_3]$, has been published.[398]

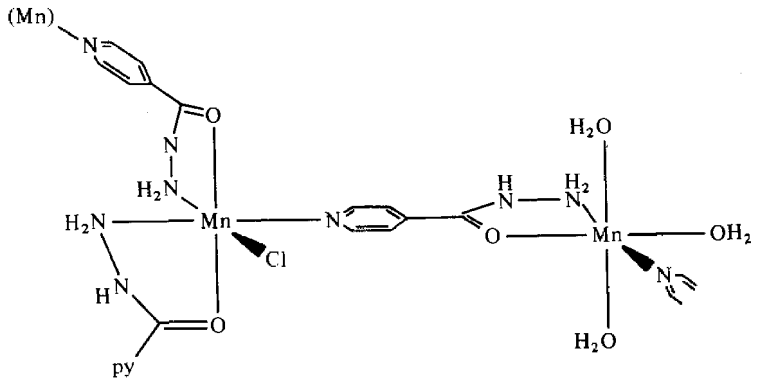


A number of N—O bidentate ligands developed from α-substituted pyridines (**154**) have been reacted with $MnCl_2$ to yield $MnCl_2L_2$ (see Table 38). It is claimed that these compounds bond *via* the pyridine N atom and the O atom. Other workers[403] have looked at similar ligands such as (**155**) and claimed, from IR studies, that both the N and the O atoms are bound in compounds of types of $MnCl_2L$ and $[MnL_2(H_2O)_2]_n$.

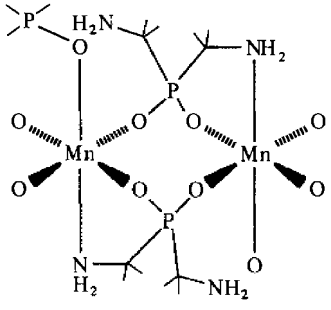
(**153**)



(**154**)



(**155**) R = NH_2 or Me



A development of the ligands derived from α-substituted pyridines is the potentially quadridentate ligand (**156**). It is suggested that the anhydrous cream-white $[MnCl_2L]$ compound is polymeric with each N—O pair of the ligand binding to a different Mn^{II} atom.[404] This tendency to polymerization is ably demonstrated in the X-ray structure (**157**) of the compound $[Mn_2ClL_3(H_2O)_3]Cl_3\cdot L_{0.5}$ (L = isonicotinyl hydrazide)[405], and in the possible structure[406] of di(bis[*N*-phenylaminomethyl]phosphinato)manganese(II) (**158**).

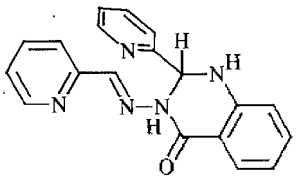
(**156**)

(157)

(158)

41.3.9.2 Mixed N—O donor atom terdentate ligands

Mn^{II} compounds of several types of terdentate Schiff base ligands are known.[173] Of interest for supposed biological reasons are ligands of donor set O—N—O derived from condensation of α-amino acids with salicylaldehyde,[407] pyruvic acid,[408] pyridoval[409] and substituted salicylaldehydes.[410] Although X-ray analysis[411] indicates that the compound $[Mn^{II}(pyridoxal\text{-}valine)_2]$ is octahedral, the structures of most of these compounds have not been fully elucidated. Claims of monomeric, dimeric and polymeric molecules are based mainly upon analytical results and upon room temperature magnetic susceptibility measurements. Nothing of special biological interest has come from this work.



The Mn^{II} compounds, derived from the terdentate O—N—O or S—N—O donor set Schiff base ligands obtained from the condensation of both substituted[412] and unsubstituted[412,413] *o*-hydroxyaniline, anthranilic acid[412] or *o*-aminobenzenethiol[413] with various salicylaldehyde residues, have the

stoichiometry MnL (where H_2L = the ligand). Temperature dependent magnetic data[412] support the polymeric nature of these compounds but their ready oxidation[412,414] suggests that such results may be due to the presence of higher oxidation state manganese.

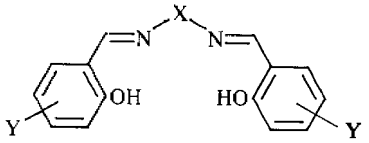
The preference of Mn^{II} for oxygen donor atoms is evidenced by the fact that with (**159**) Mn^{II} coordinates by a N—N—O donor set to yield the distorted trigonal bipyramidal compound $[MnCl_2L]$.[415] Comparison of the X-ray structure of this compound with the corresponding Cu^{II} compound shows that the latter compound uses an N—N—N donor set with both pyridine nitrogens coordinating.[416] Nevertheless, this preference is not always exhibited. In $[MnL_2](ClO_4)_2$, tris(2-pyridyl)methanol (**47**; X = COH) is claimed to possess an N—N—N donor set rather than the possible N—O—N set.[153] How the ligand would coordinate upon removal of the methanol proton is of interest; certainly the N—O—N donor set appears to be present in the white air-sensitive compound $[MnL_2]$ obtained when the sodium salt of (**160**) is reacted with $MnCl_2$.[24] Nevertheless, one must be impressed with the predilection of Mn^{II} for oxygen donors when one finds that the structure of $[MnL(H_2O)_2]$ (where L = iminodiacetic acid) is octahedral with an MnO_6 chromophore.[417]

(159)

(160)

41.3.9.3 Mixed N—O donor atom quadridentate ligands

The most comprehensively studied Mn^{II} Schiff base compounds are those of the quadridentate hybrid O—N—N—O donor set ligands of structure (**161**); the ligand salenH_2 {(**161**) where Y = H and X = $(CH_2)_2$} being the object of a number of different studies.[389,418] The orange-yellow, crystalline, air-stable compound [Mn(salen)(en)] was isolated in 1933 and shown to rapidly oxidize in solution.[419] The compound [Mn(salen)] has been prepared by the four main methods used to prepare metal compounds of ligands derived from the interaction of salicylaldehydes and primary amines,[420] these are:



(i) Preparation and isolation of the ligand and subsequent reaction with the metal salt (often the acetate);

(ii) Preparation and isolation of the bis(salicylaldehydato)metal(II) compound and subsequent reaction with the amine;

(iii) Reaction of the stoichiometric amounts of salicylaldehyde, amine and metal salt;

(iv) Interaction of a metal carbonyl with the prepared ligand in non-aqueous solvent under a nitrogen atmosphere (for cases in which the metal compound may be air sensitive).[421]

The magnetic properties of [Mn(salen)] have been the subject of a number of studies,[38,39,422] all of which have indicated the presence of antiferromagnetic interactions. As [Mn(salen)] has an X-ray powder pattern similar to $[Cu(salen)]_2$, a dimeric compound with mutual sharing of one of the oxygen atoms of each ligand,[423] its magnetism has been analysed in terms of such a structure.

(161)

The reaction of [Mn(salen)] with oxygen has been the subject of much study since the early claim that the product was $[Mn^{III}(salen)(OH)]$.[419] The topic has been reviewed,[424] but the nature of the product is still uncertain and the field badly requires definitive work, not least because the oxidation of Mn^{II} species is rapidly assuming great biological importance. Some results of oxygenation

Table 39 Oxygenation Reactions of [Mn(salen)]

Solvent and Temperature of Oxygenation	*Postulated Compounds Obtained*	μ_{eff} *per Mn atom*	*Ref.*
(i) Pyridine, 20°C	$[Mn^{III}(salen)O_{1/2}]_n$	1.92	39
(ii) DMF, 25°C	$[Mn^{III}(salen)]_2O \cdot H_2O$	1.97	39
(iii) DMSO, 25°C	$[Mn^{III}(salen)]_2O_2$	1.96	425
(iv) Pyridine, 25°C	$[Mn^{IV}(salen)O]_n$	1.99	425
(v) Pyridine, −15°C	[Mn(salen)(OH)]	2.01	426
(vi) Pyridine, 115°C	[Mn(salen)OH] + MnO_2		426

experiments of [Mn(salen)] are summarized in Table 39. Such reactions are not reversible. Oxygenation of Mn^{II} compounds of quadridentate N ligands has been noted in Section 41.3.3.4(i).

It is also claimed that nitric oxide reacts in DMSO with [Mn(salen)] to yield $[Mn^{III}(salen)O]_2O_2$.[427] This is surprising, as an ethanolic solution of manganese(II) acetate and salenH_2 is claimed to react with NO to yield $[Mn^{III}(salen)(OAc)]$.[38] On the other hand, it has been claimed that $[Mn^{III}(salen)CO]ClO_4$, a dimer with bridging carbonyls, can be isolated from the interaction of $[Mn(salen)(H_2O)_2]$ with oxygen in 50/50 MeOH/EtOH in the presence of ClO_4^- and NaOH.[428]

Much work has been published on the Mn^{II} compounds of (**161**) with X = $(CH_2)_2$ and Y = various substituents; a summary is provided in Table 40a. The remainder of Table 40 demonstrates the large number of compounds of general structure MnL (L = **161**) that have been prepared; structures of such components are not known, excepting that in which X = *meso*-2,3-butane, Y = H, which has been shown[426] to be isomorphous with the corresponding Co^{II} compound whose structure is square planar.[432]

The oxygenation reactions of many of these MnL compounds have been studied. $MnL \cdot H_2O$ (X = $(CH_2)_3$; Y = H) in refluxing pyridine reacts irreversibly with O_2 to yield a dimeric Mn^{III}

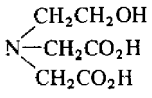
compound,[433] which can also be obtained by heating the Mn^{II} compound in the solid state in air at 80°C;[430] however in benzene at room temperature the oxygenation reaction yields $[MnL(O)\cdot\frac{1}{2}C_6H_6]$.[430] All the compounds of Table 40(c) react with O_2 in (i) boiling pyridine to yield [MnLOH] + MnO_2; (ii) pyridine at −15°C to yield [MnLOH]. These apparently Mn^{III} compounds do not reversibly lose oxygen.[426]

The preparation and oxygenation of a series of MnL compounds with L = (**161**) and X of varying aliphatic chain lengths from $(CH_2)_4$ up to $(CH_2)_{10}$ has been reported[431] {see Table 40(d)}. The compounds with X = $(CH_2)_5$ to $(CH_2)_{10}$ react with O_2 in DMSO to yield insoluble red-brown powdery materials of formulation [MnL(O)], excepting where X = $(CH_2)_8$ in which case $[MnL(O)_{1/2}]$ is obtained. The magnetic moments of the compounds [MnL(O)] fall in the range 3.2 to 3.7 BM, and it is claimed that Mn^{IV} μ-dioxo-bridging dimers are present. Oxygenation is not reversible. As noted above definitive (and hard) work is required in this area.



A 'double-sided' version of (**161**) has been produced in the ligand (**162**), which has shown to yield a Mn^{II} compound of formulation $Mn_2L\cdot H_2O$;[434] this compound being similar to the $Mn_2L\cdot 3H_2O$ compound obtained from (**163**).

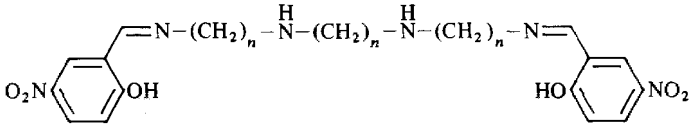
(168)

(169)

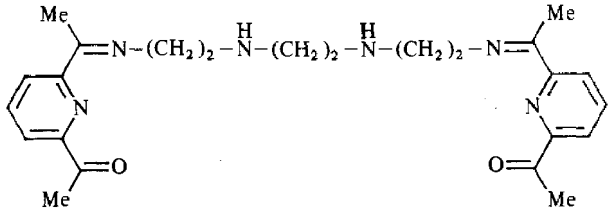
Quadridentate hybrid ligands of the tripod variety appear to favour polymerization, although such behaviour is not shown by the sexadentate edta. The ligand (**164**) loses two protons to yield the compound $[MnL(H_2O)]_n \cdot nH_2O$ (**165**),[435] while it is suggested that the ligand (**166**) dimerizes through the oxygen atoms in $[Mn_2L_2]^{2+}$.[436] However, the somewhat similar ligand (**167**) has been shown by X-ray analysis of the compound $[MnL(NCS)_2]$ to form a monomer with a distorted octahedral Mn^{II} atom.[437]

41.3.9.4 Mixed N—O donor atom quinquedentate ligands



Structure (**161**) can be expanded to yield quinquedentates by the inclusion of a donor atom in the X chain to yield for example $X = (CH_2)_n—Z—(CH_2)_n$ (where $n = 2$ and Z = NH or S; $n = 3$ and Z = O). Such ligands react with manganese(II) acetate to yield yellow $[MnL \cdot nH_2O]$ (where $n = 0.5$ or 1),[438] whose structures may well be polymeric as in the [CuL] compound (L = **161** in which $X = (CH_2)_2—NH—(CH_2)_2$ and Y = H).[439] These Mn^{II} compounds react with dioxygen irreversibly to yield probably Mn^{III} compounds. Various mechanisms of the interaction are fully discussed in a review.[424]

A most interesting quinquedentate is ligand (**168**) (R = 2′-pyridyl), which has been shown to yield the compounds $[Mn(LH_2)Cl_2] \cdot 5H_2O$ and $[MnL(H_2O)_2] \cdot 7H_2O$. In both compounds X-ray structural work proves that the ligand binds through two N and two O atoms of the ligand with the two pyridine residues at either end of the ligand chain non-bonding; the ligand forming a pentagonal plane about the metal with the two chlorine atoms in the former compound, and two water molecules in the latter, occupying positions six and seven of the coordination sphere above and below the ligand plane.[440] A similar seven-coordinate structure has been found in (**168**) in which $R = NH_2$.[441]



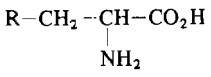
The preference of Mn^{II} for O donors (although it is very doubtful if both terminal pyridines could bind in a planar situation due to steric interaction), and the lack of preference of Mn^{II} for any particular stereochemical shape, are both clearly shown in these results. It is of interest that other workers believe that for the similar ligand (**169**), in the neutral compound $[MnL(H_2O)_2]$ the ligand binds *via* two N and two O atoms, with the octahedral coordination being completed by the two water molecules.[442]

41.3.9.5 Mixed N—O donor atom sexa- and octadentate ligands

Long-chain sexa- and octadentates are very often derived from Schiff base condensations. Some recent examples are shown in ligands (**170**)[443] and (**171**);[444] in both cases it is believed that the six and eight potential donor atoms respectively are bound in the Mn^{II} compounds.

(170)

(171)

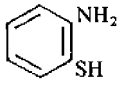


The edta compound of Mn^{II} has played on important role in expanding the coordination chemist's vision of the occurrence of higher coordination numbers. Hoard *et al.*[445] demonstrated that the large size of the Mn^{II} ion pushed back the sexadentate ligand and allowed a water molecule to coordinate, thereby producing a seven-coordinate ion, $[Mn(edta)H_2O)]^-$. On the other hand, the tetramethyl-

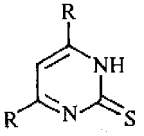
substituted 'edta' appears to be octahedral and possess at least some non-bonded oxygen donors in $[MnCl_2L]$.[446] Bi- and tri-nuclear edta compounds of Mn^{II} have been prepared. In the compound $Mn_2edta \cdot 9H_2O$ a seven-coordinate bridging structure is proposed,[447] whereas in $Mn_3(edta)_2 \cdot 10H_2O$ each of the edta residues retains a proton and adjacent seven-coordinate $[MnedtaH_2O]$ units are bridged by an $[Mn(H_2O)_4]$ unit bound to carboxyl oxygens of the edta residues.[448]

41.3.9.6 Mixed N—S donor atom ligands

As might be expected by reference to Section 41.3.6 on sulfur compounds of Mn^{II}, little work of real consequence has been done in this area.



A review[449] of the early 1970's details the manganese compounds of sulfur-containing amino acids, and quotes evidence that cysteine (**172**; R = SH) and penicillamine bind *via* both the N and S donor atoms at higher pH values; however, analysis of the papers quoted yielded little evidence for S binding. On the other hand, there is sound evidence that when the thiol group is methylated, as in *S*-methylcysteine and methionine (**172**; R = SMe and CH_2SMe respectively), the S does not coordinate, either in solution[450] or in the solid state.[451]



(172)

Work up to 1974 on N—S chelating agents is comprehensively covered by Ali and Livingstone;[452] although one has to delve deeply into this review to find the few references to Mn.

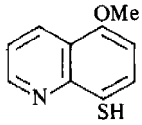


Table 41 lists some of the bidentate N—S ligands that are claimed to bind both donor atoms to Mn^{II}. Evidence for such binding is usually based upon doubtful IR interpretations coupled with compound stoichiometries; even the X-ray isomorphism of the compound of ligand (**174**) to a similar Co^{II} compound is somewhat doubtful.

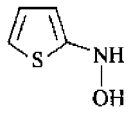
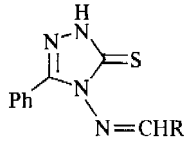


(173)



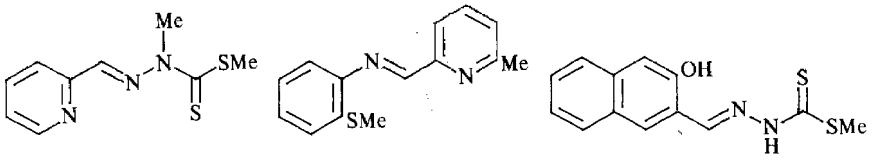
(174)

(175)

(176)

R = Ph or Furanyl

(177)



Long-chain terdentate ligands of donor sequence N—N—S (**178**), (**179**) and (**180**) have been shown to yield compounds of formulation $MnLX_2$ (X = halogen); such compounds have been claimed to be six-coordinate polymeric,[459] five-coordinate monomeric[460] and tetrahedral[461] respectively, with both N and S bonding. However, there is little evidence to justify any of these claims.

When the field is expanded to cover ligands of even higher denticity, the proof of binding of both N and S is indeed difficult. (**181**) is claimed to possess an N_4S chromophore in $[Mn(L)I]ClO_4$,[462] while (**182**) is proposed as a quinquedentate in $[Mn^{II}L]$, but not to form a compound with Mn^{III}.[463]

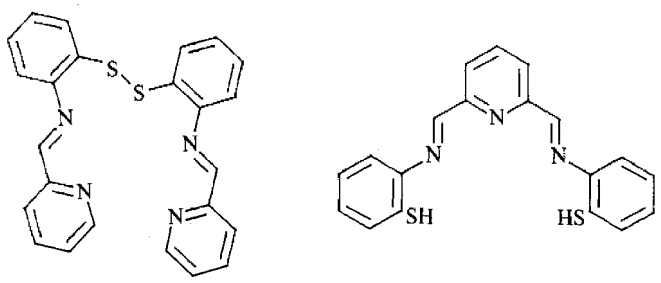


Table 41 Some Mn^{II} Compounds in which Bidentate N—S Ligands are Claimed to Bind both Donor Atoms

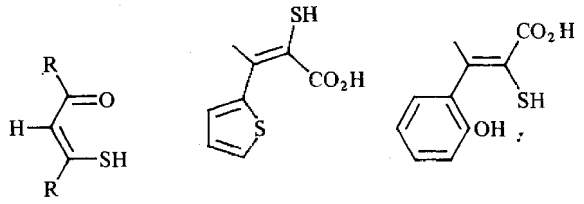
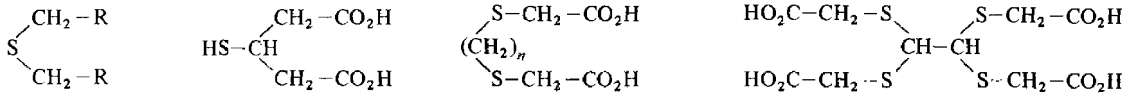
Ligand	*Compound Stoichiometry*	*N—S Binding Evidence*	*Ref.*
(**173**)	MnL_2	IR	453
(**174**) (R = H)	$Mn(HL)_2Cl_2$	X-Ray isomorphism	454
(**174**) (R = Me)	$Mn(HL)_2Cl_2$ (and Br_2)	IR and ESR	455
(**175**)	$MnL_2 \cdot 2HL$	IR	456
(**176**)	$Mn(HL)_2Cl_2$	IR	457
(**177**)	MnL_2Cl_2 (and Br_2)	IR	458

Note: Except for (**177**), HL = protonated and L = deprotonated form of the ligand.



(178) (179) (180)

(181) (182)



41.3.9.7 Mixed O—S donor atom ligands

There is sound evidence that bidentate O—S ligands can bind both donors to Mn^{II}. Ligand (**183**) has been shown to yield the compound $[Mn^{II}(L)_2(py)_2]$,[464] in which proton loss and both O and S binding appear certain. Ligands such as (**184**) may well bind both O and S to Mn^{II},[465] although it appears doubtful if (**185**) does.[466]

(183) (184) (185)

There is a small literature on multidentate O—S ligands possessing thioether sulfur atoms and carboxylic acid or hydroxy groups. Table 42 lists some of these compounds, together with their proposed stereochemistries and structures. In all compounds listed, binding of both all the sulfur atoms and all the carboxylic acid or hydroxy groups is proposed.

(186) (187) (188) (189)

Table 42 Some Mn^{II} Compounds of Multidentate O—S Ligands in Which Both O and S Donors are Bound

Ligand	*Compound Stoichiometry*	*Stereochemistry*	*Ref.*
(**186**) (R = CH_2OH)	$Mn(L)Cl_2$	Five-coordinate	467

41.3.10 Macrocyclic Ligands

41.3.10.1 Porphyrin ligands

Since the first report of a manganese porphyrin in 1904,[473] there has been a great deal of research involving such compounds largely because of their unusual properties and their possible relevance to biological systems such as green-plant photosynthesis.[474–477] For example, it is believed that a manganese porphyrin may function as the oxidant for the natural photosynthetic oxidation of water to molecular oxygen. This latter aspect has provided a motivation for a number of redox and photochemical studies.[478–481] The manganese porphyrins were reviewed in detail by Boucher in 1972.[482] Porphyrin complexes in the +2 to +5 oxidation states all exist although the +3 state is most stable.

Mn^{II} porphyrins may be obtained by direct reduction of the corresponding Mn^{III} porphyrin; for example, the tetraphenyl porphyrin (**190**), [Mn(TPP)], may be obtained by reduction of $[Mn^{III}Cl(TPP)]$ with $Cr(acac)_2$ in toluene[190] to yield the purple product [Mn(TPP)]·2(toluene).[483]

(190)

A number of other reductants have also been used to reduce Mn^{III} porphyrins in solution.[482] With dithionite,[480] the reaction is stoichiometric for a one-electron reduction above pH 8 but below this pH the $[Mn^{II}(TPP)]$ product undergoes demetallation. Related reduction can be induced by irradiation of a Mn^{III} porphyrin with visible light although, in the absence of an added electron donor, the quantum yields are low.[484]

Mn^{III} porphyrins may also be electrochemically reduced in a single electron step to yield the corresponding Mn^{II} porphyrin in both aqueous and non-aqueous media.[485] The potentials at which these reductions occur are sensitive to the nature of the solvent, counter ion present and pK_a of any bound ligands, as well as to the basicity of the porphyrin ring involved.[482–484] Similar factors also cause variation in the visible spectra of the respective compounds.[482]

In contrast to [Mn(phthalocyanine)] (see later) and [Fe(TPP)] which adopt intermediate-spin configurations, [Mn(TPP)] appears to be fully high-spin.[483] Treatment of this compound with a heterocyclic base such as 1-methylimidazole (1-MeImH), 2-methylimidazole (2-MeImH) or pyridine (py) leads only to 1:1 adducts being obtained; there appears to be no tendency for six-coordinate species to form even when the bases are present in large excess.[482–486] All the solid adducts have magnetic properties which correspond to high-spin d^5 configurations (with magnetic moments of 6.2–6.6 BM).

X-Ray analyses of [Mn(TPP)] and the THF solvate of [Mn(TPP)(1-MeImH)] have been performed.[483,487,488] The X-ray data for the former compound suggests[487] that the Mn^{II} ion, with its relatively large radius, is positioned out of the N_4-plane of the macrocycle. This result is in accordance with earlier theoretical predictions.[489] The five-coordinate [Mn(TPP)(1-MeImH)] also has the Mn^{II} displaced from the porphyrin plane; in this case, the Mn^{II} lies 0.56 Å above the plane towards the 1-methylimidazole ligand. Calculations of the charge and spin distribution in the related Mn^{II} porphyrin containing a coordinated water in the axial position indicate that the Mn^{II} is strongly bound and that about 30% of the unpaired spin population ($S = 5/2$) is delocalized away from the Mn^{II} on to the attached ligands.[490]

The Mn^{II}(TPP) complexes of imidazole (ImH) and the imidazolate ion (Im) have also been isolated; both are high spin and five-coordinate.[491] The increased field strength of imidazolate over imidazole is insufficient to cause spin pairing (which was proposed to be a prerequisite for six-coordination to occur).

In part, because the Mn^{II} ion is not held in the donor plane of the porphyrin, demetallation of such complexes in acid becomes facile as shown in one study (where loss of metal was found to be

10^6 times faster than for the analogous Mn^{III} species).[492] Other studies involving the kinetics of exchange of zinc or cobalt for Mn^{II} in a porphyrin compound in ammoniacal medium have been reported.[493]

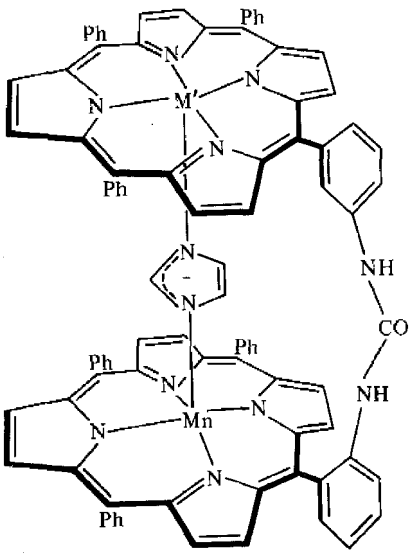
Mn^{II}-substituted haemoglobin undergoes irreversible oxidation to the corresponding Mn^{III} compound on exposure to oxygen[494] and the five-coordinate imidazole adducts mentioned previously also undergo similar oxidation in solution. For [Mn(TPP)], oxidation is very rapid although it is apparent that coordination of an axial base decreases the ease of oxidation. This effect is illustrated by the behaviour of the five-coordinate Mn^{II} species incorporating the 'picket fence' porphyrin[495] in the presence of a slight excess of the axial ligand. For this system the rate of oxidation to the Mn^{III} species is very slow (hours). At low temperatures (−78 to −90°C) a number of Mn^{II} porphyrins have been observed to react reversibly with oxygen in solvents such as toluene or toluene/THF.[483,484,496-498] Examples of such behaviour are illustrated by equations (10) and (11).

$$[Mn(TPP)] + O_2 \rightleftharpoons [Mn(TPP)O_2] \tag{10}$$

$$[Mn(TPP)py] + O_2 \rightleftharpoons [Mn(TPP)O_2] + py \tag{11}$$

A comparison of the affinities of the compounds of type [M(TPP)py] (M = Mn, Fe, Co) for molecular oxygen (under one atmosphere pressure) in toluene at −79°C gives $Co^{II} < Fe^{II} < Mn^{II}$. This order also corresponds to the ease of oxidation of the base-free metalloporphyrins from $M^{II} \rightarrow M^{III}$.[497,498]

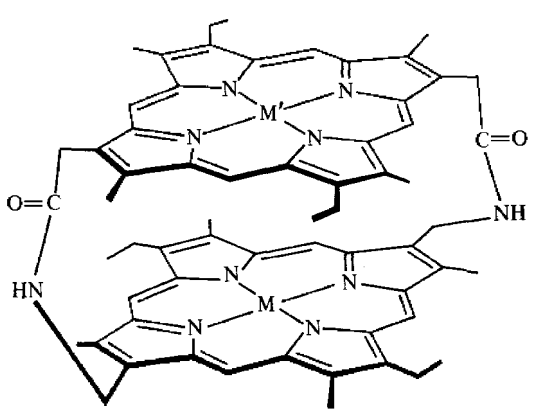
Optical and ESR measurements were initially used to study the reversible coordination of dioxygen by the above Mn^{II}(TPP) compound. The oxygenated product differs from the corresponding Co^{II} and Fe^{II} porphyrin adducts since it is of intermediate spin and contains three unpaired electrons ($S = 3/2$) rather than being low spin (as are the Fe^{II} and Co^{II} analogues). The ESR results suggested a bonding scheme in which the three unpaired electrons are localized on the manganese thus corresponding to a 'Mn^{IV}–peroxo' valency formalism. However subsequent IR studies suggest that the negative charge on the O_2 in [Mn(TPP)O_2] lies between those of the superoxo (O_2^-) and peroxo (O_2^{2-}) ions.[499] The studies[497,498] indicate that O_2 does not add to [Mn(TPP)py] but rather, adduct formation results in loss of the pyridine ligand to yield five-coordinate [Mn(TPP)O_2] as the product. The equilibrium constants for replacement of a metal-bound pyridine moiety by O_2 in [Mn(TPP)Py] and in the related compounds of a series of *p*-substituted tetraphenylporphyrins at −78°C are all less than unity.[496] Thus a high concentration of the coordinating base will not favour oxygen-adduct formation; this provides a rationale for the reported inability of Mn^{II} haemoglobin (with its high 'local' concentration of imidazole in the region of the metal ion) to reversibly bind molecular oxygen.[494]



The visible, ESR and IR studies mentioned previously are in accordance with the symmetric sideways coordination of dioxygen in [Mn(TPP)O_2] and such a coordination geometry is also consistent with the results of MO calculations.[500] The mode of bonding of the dioxygen thus appears to differ from that in the corresponding Fe^{II} and Co^{II} porphyrin adducts which contain the oxygen bound in an end-on fashion. Recent IR studies of the dioxygen adduct of octaethylporphyrinatomanganese(II), [Mn(OEP)O_2], prepared by matrix condensation techniques, indicate that the $\nu(O_2)$ stretch for this compound, as well as for the corresponding TPP and phthalocyanine complexes, all fall in the range 922–983 cm^{-1}.[501]

Deuterium NMR spectroscopy has been used to define the electronic structure of compounds generated by reaction of the superoxide ion with a Mn^{II} porphyrin.[502] The position of a deuterated-pyrrole signal together with a solution magnetic moment of 5.0 BM were interpreted as indicating the presence of a superoxomanganese(II) porphyrin system with spin coupling between the superoxide ligand and the manganese ion. This system has been proposed to be an excellent model for what has been postulated to be (formal) superoxide coupling to low-spin iron(III) in the oxyhaemoglobin molecule. Although the superoxide ion is not a usual substrate for haemoproteins, it is significant as an important resonance configuration for oxygenated haemoglobin and cytochrome P-450.

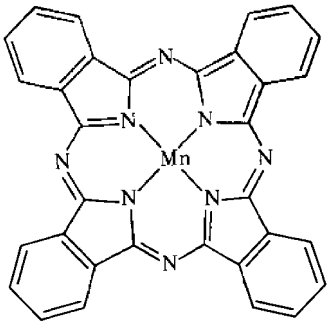
In contrast to its behaviour towards O_2, manganese-substituted haemoglobin binds NO reversibly at room temperature. Moreover, the Mn^{II} + NO system is isoelectronic with Fe^{II} + CO and has been argued to be a close model for the binding of CO to haemoglobin.[503] Examples of nitrosyl adduct formation by simple Mn porphyrins have also been reported.[504]



A number of dimetallic 'face to face' dimeric porphyrins containing Mn^{II} have been synthesized.[505] For example, urea-linked TPP dimers (**191**) have been obtained containing imidazolate ligands

bridging between Mn^{II}/Mn^{II} and Mn^{II}/Co^{II} centres. The study of such dimeric species is timely because of the growing number of bi- and tetra-nuclear metalloproteins (haemocyanin, copper oxidases, haemerythrin, superoxide dismutase and cytochrome oxidase) which have been found to exhibit interaction betwen heteronuclear metal sites. In particular, the imidazolate-bridged compound has been proposed to be a spin model for cytochrome oxidase even though it contains Mn^{II}/Co^{II} rather than Fe^{III}/Cu^{II} as occurs in the natural system. However, in each system there is an $S = 5/2$ metalloporphyrin interacting with an $S = 1/2$ centre. From the measured small value of $-J (= 5\,cm^{-1})$ for the antiferromagnetic coupling in the synthetic dimer it was concluded unlikely that histidine acts as a bridging ligand to Cu_B at the haem a_3 site of cytochrome oxidase.

(191)



A related series of mixed-metal 'face to face' porphyrin dimers (**192**) has been studied by Collman *et al.*[506] A motivation for obtaining these species has been their potential use as redox catalysts for such reactions as the four-electron reduction of O_2 to H_2O *via* H_2O_2. It was hoped that the orientation of two cofacial metalloporphyrins in a manner which permits the concerted interaction of both metals with dioxygen may promote the above redox reaction. Such a result was obtained for the Co^{II}/Co^{II} dimer which is an effective catalyst for the reduction of dioxygen electrochemically.[507] However for most of the mixed-metal dimers, including a Co^{II}/Mn^{II} species, the second metal was found to be catalytically inert with the redox behaviour of the dimer being similar to that of the monomeric cobalt porphyrin. However the nature of the second metal ion has some influence on the potential at which the cobalt centre is reduced.

(192)

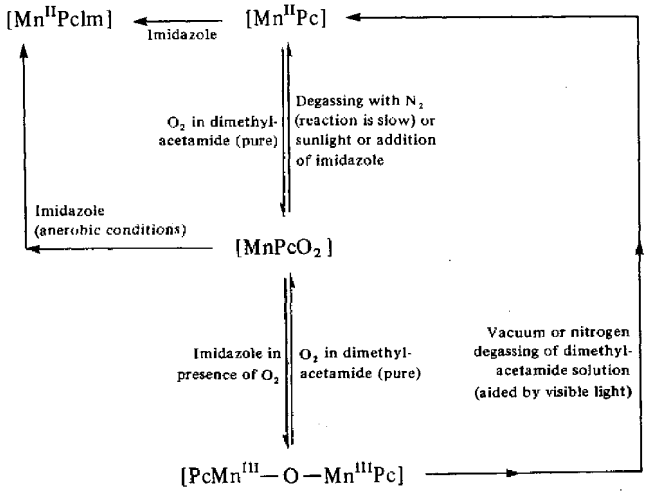
41.3.10.2 Phthalocyanine ligands

Much of the early interest in manganese porphyrins had its origins in prior work,[508,509] involving manganese phthalocyanine {**193**; [MnPc]}. Phthalocyanines (including those of manganese) were reviewed by Lever in 1962.[510] Since then, the general metal-ion chemistry of Pc and its derivatives has been discussed in numerous books and articles; two more recent reviews are by Boucher[511] and Berezin.[512]

(193)

Self condensation of phthalonitrile or *o*-cyanobenzamide in the presence of manganese metal gives a product which, on sublimation, yields pure [MnPc].[510] Alternatively this product may be obtained by the reaction of phthalonitrile with manganese acetate. Although similarities exist, the chemistry of manganese phthalocyanine species show many differences to that of the corresponding porphyrins.[6,510]

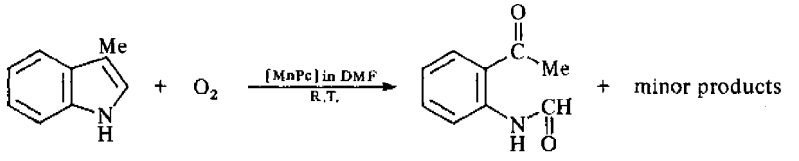
[MnPc] (β-polymorphic form) is unusual in that it provides an example of an intermediate spin state with $S = 3/2$ for the d^5 configuration. This compound also provides a rare example of a ferromagnetic molecular crystal ($J = +7.6\,cm^{-1}$). [MnPc] has been the subject of both X-ray[513,514] and neutron diffraction[515] studies. The coordination environment of the Mn ion is square planar and the overall molecule is isostructural with a range of other divalent phthalocyanines. Stacking of the planar [MnPc] molecules occurs in the lattice such that two pyrrole nitrogen atoms from each molecule lie exactly above or below the manganese belonging to adjacent molecules. The distance between manganese and the axial nitrogen atoms is 3.4 Å. The Mn^{II} atoms are aligned in linear arrays parallel to the *b* axis of the molecule such that [MnPc] may be considered to contain magnetic linear chains along the *b* axis of the crystal. The magnetic properties of [MnPc] are consistent with the presence of ferromagnetic intrachain exchange together with weak antiferromagnetic interchain interaction; the Curie temperature is 8.6 K.[516–518]



The X-ray and neutron diffraction data mentioned previously have been used in conjunction with the technique of polarized neutron diffraction (at 4.2 K) to deduce spin-density distributions in [MnPc].[519,520] In further investigations[514] it proved possible to determine individual 3*d* and 4*s* orbital populations on the manganese ion together with an estimate of 24% for the *d*-orbital electron density delocalized in the macrocyclic ring. From these studies it appears that the charge on the manganese is approximately +1; this charge appears to be achieved primarily by the loss of a 3*d* electron rather than a 4*s* electron.

Largely because of the possible involvement of manganese in the photosynthetic production of oxygen, the energetics of manganese phthalocyanine redox processes have been of considerable interest. Lever *et al.*[521] have used a number of electrochemical and other techniques to effect and characterize the oxidation of Mn^{II}(Pc) to Mn^{III}(Pc) species, ligand oxidation of Mn^{III}(Pc) and two successive one-electron reductions of Mn^{II}(Pc). The electrochemical studies were carried out using pyridine, dimethylsulfoxide or dimethylacetamide as solvent and perchlorate, chloride or bromide as the supporting electrolyte anion. Heterogeneous rate constants were obtained for several of these couples in the presence of perchlorate anion. Each of the couples showed near ideal behaviour with the exception of the chloride and bromide systems at higher scan rates. No evidence for the formation of Mn^{I} species was obtained.

[MnPc] reacts with a number of monodentate bases to yield low spin ($S = \frac{1}{2}$) adducts of type [$MnPcL_2$] (L = pyridine, imidazole, triethylamine *etc.*).[522,523] In the solid state [$MnPc(py)_2$] loses its two pyridines to yield [MnPc] on heating the adduct *in vacuo* at 100°C.[523]



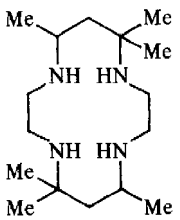
Despite earlier reports to the contrary [MnPc] does not react with oxygen in pyridine provided

the pyridine is rigorously dried and purified. If the latter condition is not met then reaction does occur with the end-product of the oxidation being a dinuclear Mn^{III} species of type $[(MnPcpy)_2O]$.[508,522–524] Nevertheless, reaction does occur in pure *N,N*-dimethylacetamide to yield a solution of the oxygen adduct. Reversal of the oxygenation occurs over many days on degassing the solution. The deoxygenation occurs more rapidly upon exposure to bright white light or upon addition of an electron donor to the solution in an evacuated flask. For the first reaction type the released molecular oxygen was detected using mass spectrometry. In contrast, when the adduct is reconverted to [MnPc] with electron donors such as imidazole, triethylamine, catechol *etc.*, no oxygen apears to be released. In this case the adduct seems to be mimicing oxidase activity of the type proposed by Uchida *et al.*[525] (see later). Further, addition of certain electron donors, such as imidazole, to the adduct in the presence of oxygen results in formation of a dinuclear species of type $[PcMn^{III}—O—Mn^{III}Pc]$; the latter may be reconverted to the oxygen adduct by reaction with oxygen in *N,N*-dimethylacetamide. The oxygen adduct has been isolated and has $S = \frac{1}{2}$. From the results of physical measurements,[522,526,527] the adduct was proposed to contain a bound superoxide and to be of type $[Mn^{III}PcO_2]$. The various reactions involving this compound are summarized in Scheme 2 (modified from reference 522 using, where appropriate, imidazole as the electron donor).

Scheme 2

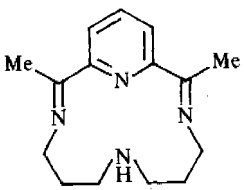
[MnPc] has been demonstrated to show high catalytic activity for the oxidation of 3-methylindole (equation 12) and thus mimics the action of tryptophan-2,3-dioxygenase.[525] The major product of the catalyzed oxygenation is 2-formamidoacetophenone, with 2-aminoacetophenone and the 2-isonitrile derivative as minor products. The model studies indicate that the substrate specificity for the oxygenation of indole derivatives is different to that of singlet oxygen or radical autoxidation. In other studies, the [MnPc] catalyzed autoxidation of phenols has been investigated[528] together with other catalytic redox reactions involving a number of different substrate types.[511]

(12)



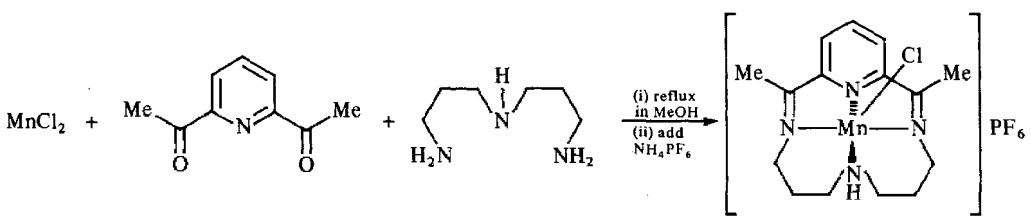
41.3.10.3 Other nitrogen donor macrocycles

In contrast to the large number of studies concerned with porphyrins and phthalocyanines, other macrocyclic ligand compounds of Mn^{II} have received somewhat less attention.[173,529,530] In part, this appears to reflect the fact that many compounds of this type tend to be of only moderate thermodynamic stability and in some instances are air and/or moisture sensitive. In addition, Mn^{II} has been shown to be ineffective as a template metal for certain cyclization reactions which occur in the presence of other ions.[159,162,531,532] This effect may be a consequence of the relatively large size of the Mn^{II} ion not enabling it to fit in the cavity of the target macrocycle. Alternatively, the often low affinity of Mn^{II} for the macrocycle precursors may contribute to the absence of a template effect for particular systems.



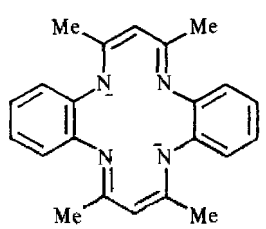
The *meso* form of the saturated tetradentate macrocycle (**194**) has been used to synthesize the

colourless compounds [MnX_2(**194**)] (X = CF_3SO_3, CH_3CO_2).[533] The synthetic procedure used to obtain these species is more demanding than often required for other first row transition metal complexes since these compounds are both oxygen and water sensitive. Further, the macrocycle appears to exhibit only low affinity for Mn^{II}. The compounds were obtained by reaction of (**194**) with $Mn(SO_3CF_3)_2 \cdot CH_3CN$ or $Mn(CH_3CO_2)_2$ in hot degassed acetonitrile under anhydrous conditions. Both compounds are high spin and the solid state ESR spectra indicate that the manganese ion is experiencing a relatively small tetragonal distortion in each case.

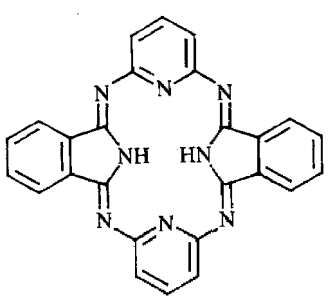


Using a template procedure involving condensation of 2,6-diacetylpyridine and the appropriate triamine in the presence of Mn^{II}, compounds of type [Mn(NCS)$_2$(**195**)] and [MnCl(**195**)]PF_6 have[534] been isolated. The synthesis of [MnCl(**195**)]PF_6 is illustrated by equation (13). Both compounds are high spin with magnetic moments of 5.94 BM; they appear to contain either five or six coordinated Mn^{II}. It is of interest that attempts to chemically oxidize these compounds to Mn^{III} species using $NOPF_6$ or H_2O_2 in acetonitrile in the presence of excess Cl^- ion were unsuccessful even though the Mn^{II} compounds of the fully-saturated (14-membered) macrocycle (**194**) readily oxidize under similar conditions. This difference in redox behaviour is undoubetedly related to the presence in (**195**) of a conjugated fragment containing three nitrogen donors. However it is inappropriate to speculate further about this since larger ring (N_5-donor) macrocycles incorporating this moiety do undergo oxidation to Mn^{III} species.

(194)



(195)

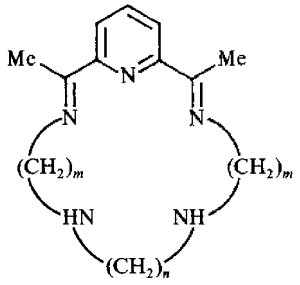


(13)

Mn^{II} compounds of the rigid dianionic macrocycle (**196**) of type [Mn(**196**)(amine)] (where amine = triethylamine or tri-*n*-propylamine) have been synthesized directly by reaction of the preformed macrocyle with $Mn(SO_3CF_3)_2$ in acetonitrile followed by addition of the amine.[535] These high spin compounds were assigned square pyramidal structures with the metal ion displaced from the plane of the macrocycle towards the axial ligand. Such a structure has been confirmed for [Mn(**196**)NEt_3] by X-ray diffraction.[536] This compound has the Mn^{II} ion 0.73 Å out of the N_4-macrocyclic plane. The hole size in (**196**) is smaller than in the porphyrins; the five-coordinate geometry appears to be a direct consequence of the Mn^{II} ion being too large to fit completely in the macrocyclic cavity. The coordinated macrocycle adopts a saddle shape reflecting steric interactions between the methyl groups and the aromatic rings.

A detailed resonance Raman study of these Mn^{II} species has been undertaken.[537,538] Relative to the spectrum of the free ligand, the vibrations observed to undergo large shifts on incorporation of the metal ion were those associated with the 'porphyrin-like' six-membered chelate rings.

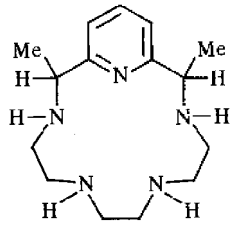
(196)



(197)

Descriptions of the synthesis of the tetraaza macrocycle (**197**) by a non-template procedure from *o*-phthalonitrile and 2,6-diaminopyridine as well as the synthesis of its Mn^{II} compound have been published.[539] The manganese species is very insoluble; it is high spin with a magnetic moment of 5.80 BM and obeys the Curie law between 85 and 300 K.

Manganese compounds of a number of N_5-donor macrocycles have been investigated. For example, following earlier work involving iron complexes of (**198**),[540,541] Alexander *et al.*[542] synthesized a range of high spin ($S = 5/2$) complexes of type $[MnX_2(\mathbf{198})]\cdot nH_2O$ (X = Cl, ClO_4, $n = 0$, 1 or 6). For example, orange $[MnCl_2(\mathbf{198})]\cdot 6H_2O$ was obtained by condensation of 2,6-diacetylpyridine with triethylenetetramine in methanol in the presence of manganese chloride. This product is isomorphous with the corresponding magnesium compound which was postulated to contain a $[Mg(\mathbf{198})(H_2O)_2]^{2+}$ moiety.[543] The single-crystal ESR spectrum of the Mn^{II} compound exhibits an unusual angular dependence of the ESR transitions.[544] This and the other compounds in the series were assigned seven-coordinate structures. For $[Mn(ClO_4)_2(\mathbf{198})]$, infrared evidence suggests that the perchlorate groups are coordinated in the solid.



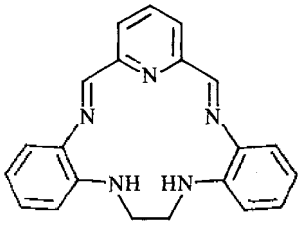
The macrocycle in $[MnCl_2(\mathbf{198})]\cdot H_2O$ can be reduced using a nickel–aluminium alloy under basic conditions.[545] Addition of cold concentrated nitric acid then leads to isolation of the reduced macrocycle (**201**) as its tetrahydrogennitrate salt.

(**198**) $n = m = 2$

(**199**) $m = 2$, $n = 3$

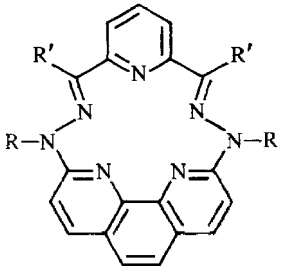
(**200**) $m = 3$, $n = 2$

(**201**)



Using a related *in situ* procedure to that just described, Drew *et al.*[546] showed that Mn^{II} acts as a template for the synthesis of compounds of all three macrocycles (**198**)–(**200**) containing 15-, 16- and 17-membered great rings respectively. The products are of type $M_nX_2L\cdot xH_2O$ and $MnXL(ClO_4)\cdot xH_2O$ (X = Cl, NCS or BPh_4; $x = 0$, 0.5, 2 or 6). As before, all the compounds are high spin with $S = 5/2$ ground states. The compounds of the 15- and 16-membered macrocycles have been assigned pentagonal bipyramid structures in which the macrocycle coordinates in the equatorial plane with the negatively charged monoanions or water molecules occupying the axial positions. These species are all mononuclear with the exception of those of type $[\{Mn(NCS)L\}_n][ClO_4]_n$ which were assigned NCS-bridged, polymeric structures in the solid state. The latter complexes exhibit Curie–Weiss behaviour with Weiss constants of -13 K in each case; this behaviour has been interpreted in terms of weak antiferromagnetic exchange. The 17-membered ring appears to yield metal compounds which have a somewhat different structure to those of (**198**) and (**199**). This was confirmed for $[Mn(NCS)_2(\mathbf{200})]$ by an X-ray diffraction study which shows that, while the coordination sphere is best considered as a distorted pentagonal bipyramid with the thiocyanate groups in axial sites, the macrocycle is distorted from planarity. The pyridine nitrogen is 0.92 Å out of the plane containing the other four ring nitrogens and the metal ion. The remaining compounds containing the 17-membered ring, $[MnCl(\mathbf{200})][ClO_4]$ and $[MnCl(\mathbf{200})]Cl\cdot 0.5H_2O$, appear to be six-coordinate and have been proposed to have pentagonal pyramidal structures with the vacant (axial) site being partially shielded by the folded macrocycle. In separate work, Dabrowiak *et al.*[534] also prepared manganese compounds of the 16- and 17-membered rings; these were used as precursors for the corresponding Mn^{III} compounds (see later).

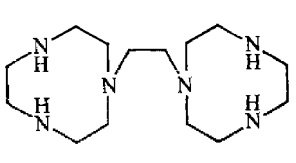
A crystal structure of the 1:1 adduct of 1,10-phenanthroline and the seven coordinate species, $[Mn(\mathbf{199})(H_2O)_2](ClO_4)_2$, indicates that the phenanthroline molecule is not coordinated to the manganese but is sandwiched between $[Mn(\mathbf{199})(H_2O)_2]^{2+}$ units in a lamellar structure.[136] The phenanthroline nitrogens are hydrogen bound to water molecules in adjacent complex ions; the structure also appears to be held together by π donor/π acceptor and dispersion forces.



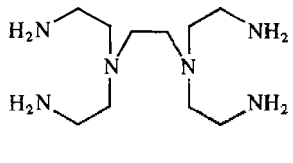
Compounds of type $[MX_2(\mathbf{202})]$ ($X = ClO_4$, NO_3) have also been reported.[547] Like the closely related dimethylated species, these compounds have been assigned distorted pentagonal bipyramidal structures and for the compound with $X = ClO_4$, an X-ray structure determination confirms this geometry.

Mn^{II} complexes of type $[MnClL]^+$ (where L = (**203**) with R = Me or $CH_2CH_2CH_2OH$; R′ = Me and R = Me; R = H) and $[MnX_2L]\cdot nH_2O$ (where L = (**203**) with R = Me, R′ = H or R = Me, R′ = Me) have been synthesized by Lewis and co-workers using a template procedure.[548–551] For example, to prepare the complex of (**203**; R = H, R′ = Me),[549] 2,6-diformylpyridine and 2,9-di(1-methylhydrazino)-1,10-phenanthroline monohydrochloride were condensed in a methanol/water mixture containing manganese chloride. X-Ray structure determinations of each of the species $[MnClL](BF_4)$ (L = (**203**) with R = CH_3 or CH_2CH_2OH),[549,550] indicate that they have similar coordination geometries: the Mn^{II} ion is six-coordinate (pentagonal pyramidal) and is bound by five macrocyclic nitrogens in a plane and by an axial chloro group. The metal ion is displaced from the N_5-plane towards the chloro ligand in each compound. For the metal compound containing the peripheral hydroxyethyl substituents, these groups are not coordinated. They lie on the same side of the macrocycle as the axial chloro ligand. The compounds of type $[MnX_2L]\cdot nH_2O$ have been assigned pentagonal bipyramidal coordination geometries.

The electrochemistry of a number of such six-coordinate compounds $[MnXL]^+$ and seven-coordinate compounds $[MX_2L]$ (with L = (**203**), R,R′ = Me and X = halide, water, triphenylphosphine oxide, imidazole, 1-methylimidazole or pyridine) has been investigated.[551] The redox behaviour of these compounds was of interest because it was considered that the potentially π-acceptor macrocycle (**203**; R = R′ = Me) may promote the formation of Mn^0 or Mn^I species or may yield a metal-stabilized ligand radical with the manganese remaining in its divalent state. For a number of macrocyclic ligand systems, it has been demonstrated that the redox behaviour can be quite dependent on axial ligation; it was also of interest to study whether this was the case for the present systems.



(202)

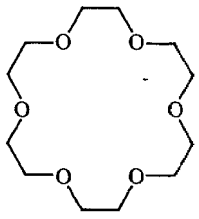


(203)

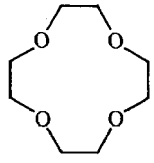
Cyclic voltammetry on the above compounds in acetonitrile gave a reversible one-electron reduction wave near −1.4 V (versus $Ag/AgNO_3$) in each case. Thus the reduction potential showed little variation with change of axial ligand. This suggests that the redox behaviour is confined to the coordinated macrocycle since, as just mentioned, axial ligand type would be expected to markedly influence redox behaviour directly involving the metal centre. Quantitative reduction using controlled potential electrolysis led to isolation of the corresponding one-electron reduction products. These were shown by ESR studies to be Mn^{II} ligand-radical species; it was postulated that the additional electron in these species resides in the diimine pyridine portion of the ligand. No evidence for metal-ion reduction was obtained even when π-acceptor axial ligands such as CO or phosphines were added to the solution in the electrochemical cell.

Few stability constants for manganese compounds of cyclic ligands have been reported. A log K value of 15.0 (I = 1.0 M, KNO_3; 25°C) for the 1:1 compound of the dicyclic ligand (**204**) and Mn^{II} has been reported.[552] The log value for the corresponding compound of the related non-cyclic ligand (**205**) is 9.3.[553] The large difference in these values illustrates well the operation of the 'macrocyclic effect'[544] in the bicyclic system.

(204)

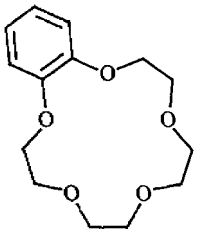


(205)



41.3.10.4 Oxygen donor macrocycles

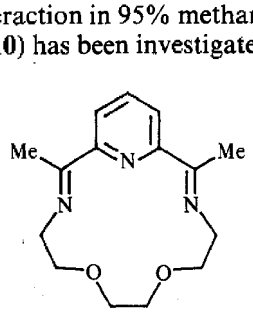
Mn^{II} compounds incorporating crown ether macrocycles have been reported. The coordination chemistry of crown ethers has been mainly concerned with the compounds of non-transition ions.[555] This is due, in part, to the generally weaker affinity of such ligands for transition metals. X-Ray studies indicate that a number of transition metal compounds containing crowns (which were isolated from aqueous solution) have the crowns H-bound to coordinated water molecules rather than being bound directly to the metal ion. Such an arrangement occurs in $[Mn(H_2O)_6](ClO_4)_2 \cdot L$,[556] $[Mn(NO_3)(H_2O)_5](NO_3) \cdot L \cdot H_2O$[557] and $[Mn_2Cl_2(H_2O)_8]Cl_2 \cdot L$ (where L = (**206**); 18-crown-6).[558] In contrast, it has proved possible to isolate yellow-orange $[MnL_2](Br_3)_2$ (L = (**207**); 12-crown-4) in which the macrocycles bind directly to the Mn^{II} ion; the synthesis was performed in methanol under anhydrous conditions.[559] The X-ray analysis of this compound indicates that the cation consists of two 12-crown-4 macrocycles bound in 'sandwich' fashion to the Mn^{II} ion. The Mn^{II} is located on a crystallographic mirror plane which requires that the O_4-donor set of each crown ligand be coplanar. The overall coordination geometry is square antiprismatic. It is evident from the mean length (2.31 Å) of the Mn—O bonds that the ether ligands are weakly bound.



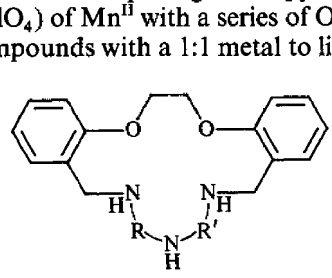
Other Mn^{II} compounds of polyethers have been reported. For example, a mono-crown species of composition $[MnL(MeNO_2)](SbCl_6)_2$ (where L = **206**) has been isolated after addition of 18-crown-6 in CH_2Cl_2 to $[Mn(MeNO_2)_6](SbCl_6)_2$ in $MeNO_2$.[508] The product rapidly decomposes in the presence of water. From infrared studies it was concluded that the $MeNO_2$ molecule is bound to the Mn^{II} and that at least one of the ether oxygens is not coordinated. Compounds of composition $(MnBr_2)_2L \cdot 3/2acetone \cdot H_2O$ (L = (**208**) benzo-15-crown-5) and $(MnX_2)_2L \cdot 8H_2O$ (L = **206**; X = Cl, Br) have also been isolated from non-aqueous reaction solutions.[561] Comparative infrared studies have also been used to investigate the nature of these species; however, it has not been possible to assign their structures with certainty.

(206)

(207)



(208)



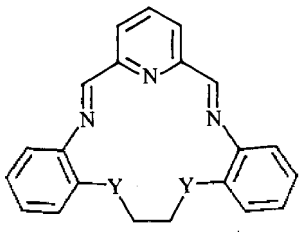
41.3.10.5 Mixed donor macrocycles

Studies in which 2,6-diacetylpyridine and 3,6-dioxaoctane-1,8-diamine were condensed in the presence of a stoichiometric amount of Mn^{II} led to isolation of orange $[Mn(NCS)_2(\mathbf{209})]$.[562] As found for the Mn^{II} compounds of the related N_5-ligand system, an X-ray study indicates that this high-spin species is seven-coordinate with the macrocycle occupying the pentagonal plane and the axial positions being filled by isothiocyanate groups. The five donor atoms of the macrocycle are almost coplanar although the structure is slightly distorted from true pentagonal bipyramidal geometry.

The interaction in 95% methanol (I = 0.1, Et_4NClO_4) of Mn^{II} with a series of O_2N_3-macrocycles of type (**210**) has been investigated.[563] In all cases compounds with a 1:1 metal to ligand stoichiome-

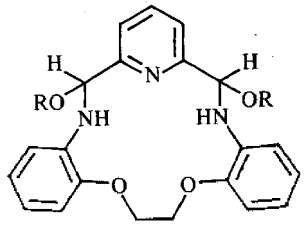
(209)

(210) R = $-(CH_2)_2-$, R′ = $-(CH_2)_2-$



R = $-(CH_2)_2-$, R′ = $-(CH_2)_3-$

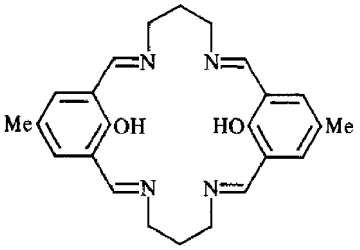
R = $-(CH_2)_3-$, R′ = $-(CH_2)_3-$



R = $-CH_2CH(CH_3)-$, R′ = $-CH_2CH(CH_3)-$

try were observed. As expected from the position of Mn^{II} in the Irving–Williams stability order, these compounds are all less stable (with log K values in the range 3.5–4.0) than the corresponding complexes of Co^{II}, Ni^{II}, Cu^{II} or Zn^{II}.

Pentagonal bipyramidal compounds of type $[MnX_2L]$ (where L = (**211**) with Y = O or S; X = ClO_4, NO_3) have been synthesized[547] using *in situ* procedures. In other studies it was observed that reaction of $MnCl_2$ with the appropriate ligand precursors in ethanol yielded initially a bright orange-yellow product of composition $MnCl_2L \cdot 2H_2O$ (L = (**211**) with Y = O.[564] If this product was removed from the reaction solution, needles of the free macrocycle (**212**) crystallized. In this product ethanol has added across each of the imine bonds of (**211**) with Y = O. Additions of this type have been documented in other imine-containing complexes,[565] a driving force for these reactions may be the relief of strain in the highly conjugated diimine precursor. If (**212**) is returned to the reaction filtrate and the solution warmed then red-brown $[MnCl_2(\mathbf{212})]$ crystallizes. In a further experiment the condensation was performed in the absence of the Mn^{II} and (**212**) was still isolated indicating that its formation is not controlled by a metal-template reaction.



(211) Y = O, S

(212)

Reaction of 5-methylisophthalaldehyde with 1,3-diaminopropane in the presence of manganese(II) chloride and manganese(II) acetate in methanol yields a dimetallic complex of type $Mn_2Cl_2L \cdot 2H_2O$ (where LH_2 = **213**)[566] in which the dianionic form of the macrocycle acts as a novel binucleating species. The proposed structure is one in which each metal ion is surrounded by an O_2N_2-donor set in an approximately planar arrangement with a chloro group occupying an axial position on each Mn^{II}; the coordination geometry of each Mn^{II} is approximately square pyramidal. A stereochemistry of this type has been confirmed for the analogous dicopper(II) species by X-ray diffraction.[567] The study of metal–metal interactions in the dimetallic compounds of (**213**) is simplified by the fact that both metal ions are in identical environments. However, in contrast to the compounds of this ligand with some other metal ions,[566,568,569] $Mn_2Cl_2L \cdot 2H_2O$ (where LH_2 = **213**) exhibits little evidence of antiferromagnetic interaction between adjacent Mn^{II} ions — the compound shows Curie–Weiss behaviour with a Weiss constant of $-7°$.[566] In other studies, the anhydrous compound Mn_2Cl_2L has been demonstrated to contain a slight ferromagnetic exchange interaction with $J = +0.2\,cm^{-1}$.[568]

(213)

Magnetic and electrochemical studies involving mixed metal compounds of deprotonated (**213**) have also been reported.[570,571] These compounds include Cu^{II}/Mn^{II} and Cu^{I}/Mn^{II} species.

For the $[Cu^{II}Cu^{II}L]^{2+}$ compound mentioned previously, two sequential reductions corresponding to conversion of this species to $[Cu^{II}Cu^{I}L]^{+}$ and then to $[Cu^{I}Cu^{I}L]$ were observed at -0.93 and $-1.32\,V$, respectively, relative to Fe/Fe^{+} in dimethylformamide. In contrast, for $[Cu^{II}Mn^{II}L]^{2+}$ the Cu^{II}/Cu^{I} wave occurs at $-1.0\,V$; a wave at $+0.150\,V$ corresponds to the Mn^{III}/Mn^{II} couple. It is

perhaps surprising that substitution of Fe^{II}, Co^{II}, Ni^{II} or Zn^{II} for the Mn^{II} in the above heteronuclear compound does not alter (within experimental error) the value of the Cu^{II}/Cu^{I} couple. This difference between the redox behaviour of the dicopper(II) species and $[Cu^{II}M^{II}L]^{2+}$ (M = Mn, Fe, Co, Ni or Zn) has been postulated to reflect the fact that only the $[Cu^{I}Cu^{II}L]^{+}$ species can exist to any extent as a resonance-stabilized delocalized ion.

The Cu^{I} in a series of $[Cu^{I}M^{II}L]^{+}$ compounds (including $[Cu^{I}Mn^{II}L]^{+}$) has been demonstrated[570] to have an axial affinity for some or all of the bases: carbon monoxide, ethylene, tris(*o*-methoxyphenyl)phosphine and 4-ethylpyridine. In all cases the binding constants for adduct formation are low; for example, for $[Cu^{I}Mn^{II}L]^{+}$ and CO or 4-ethylpyridine the values are $0.9\,M^{-1}$ and $22.5\,M^{-1}$, respectively. In contrast to the constant Cu^{II}/Cu^{I} reduction potentials mentioned above for the $[Cu^{II}M^{II}L]^{2+}$ species, the binding constants for the attachment of axial ligands to the Cu^{I} in the respective $[Cu^{I}M^{II}L]^{+}$ compounds show a slight dependence on the nature of M^{II}. Thus the binding studies indicate that communication occurs between adjacent metal ions. While the nature of these effects are as yet little understood, studies in this general area show potential for providing a fuller understanding of a number of metal-containing biological systems in which communication between adjacent metal ions has been demonstrated to occur.

41.4 MANGANESE(III)

Oxidation of Mn^{II} to Mn^{III} has long been known to occur, but details of the, sometimes complex, products are only now emerging. Whereas, in many systems, simple one-electron oxidation gives well-defined Mn^{III} species, yet in others the products may be mixtures of oxidation states, and there are examples of direct oxidation to Mn^{IV} without any detectable Mn^{III} intermediate (Section 41.5). Accordingly, many compounds which are called Mn^{III} in the literature, especially the various products of the 'oxygenation' of Mn^{II} salicylaldiminates (Section 41.3.9.3), must be assigned to the 'not proven' category at this stage.

There are few cationic compounds with neutral ligands: the known chemistry largely refers to compounds of the anionic ligands and generally the more electronegative donors O and F. However, there is an extensive chemistry with the macrocyclic $[N_4]$ ligands; $[Mn^{III}S_6]$ species are well characterized with the dithiolates, which can satisfy both charge and coordination shell requirements; and there is a recent report of $[MnI_3(PR_3)_2]$ (Section 41.4.2) which opens the possibility of new vistas. Compounds of the oxygen ligands have found good use as oxidizing agents in hydrocarbon chemistry, as has MnF_3 as a fluorinating agent.

Figure 1 indicates, and the observations for the various ligand systems (*q.v.*) add further detail, that Mn^{III} is often subject to disproportionation (14), a reaction which, in aqueous solutions, is often driven by precipitation of MnO_2 (equation 15).

$$2Mn^{III} \rightleftharpoons Mn^{II} + Mn^{IV} \tag{14}$$

$$Mn \rightleftharpoons MnO_2\downarrow + nH^{+} \tag{15}$$

Table 43 Coordination Polyhedra[a] and Spin States for Manganese(III)

Coordination Number	*Donor Atoms*
(a) High Spin Polyhedra (μ_{eff} = 4.8–5.3 BM)	
7	$[N_2O_5]$, $[N_5X_2]$[b]
6 (Octahedral)	$[N_6]$, $[N_xO_{6-x}]$, $[O_6]$
	$[S_6]$, $[S_4O_2]$
	$[F_6]$, $[F_4O_2]$
	$[Cl_6]$, $[Cl_3N_3]$, $[Cl_3O_3]$, $[Cl_2O_4]$, $[Br_3O_3]$
5	$[N_4X]$[b], $[O_5]$, $[S_5]$, $[Cl_5]$, $[I_3P_2]$[c]
4 (Tetrahedral)	$[O_4]$
(Planar)	$[O_4]$[d]
(b) Low Spin Polyhedra (μ_{eff} = 3.1–3.2 BM)	
6 (Octahedral)	$[C_6]$, $[N_6]$, $[C_5N][P_4Cl_2]$

[a] In most cases, the polyhedra are included only if X-ray proof of structure is available.
[b] Macrocyclic ligands.
[c] Spin state not yet reported.
[d] This refers to the basic chloride in Table 46.

Mn^{III} is formally d^4, and therefore the high spin configuration in an octahedral field is one of those, like the d^9 of Cu^{II}, which the Jahn–Teller theorem predicts should distort. Such distortions are indeed observed in the great majority of, but not all, known structures; and they often serve to identify the Mn^{III} polyhedra in mixed oxidation state compounds. There are few examples of other spin states (Table 43): $[Mn(CN)_6]^{3-}$ is an example of a low spin ($S = 1$) compound, and there are other examples in the macrocyclic compounds (Section 41.4.8).

Magnetic measurements, although useful for confirmation of spin state, have little diagnostic value, and ESR signals are usually not observed, reputedly because of fast spin relaxation.

Although again of little proven diagnostic value, except within limited classes like the solid halides,[348] the electronic spectra of these d^4 systems have spin allowed d–d transitions; and accordingly the compounds have more colour than those of Mn^{II}.

Except where specific ligand steric effects add kinetic stability, the compounds of Mn^{III}, including the low spin $[Mn(CN)_6]^{3-}$, are quite labile.

41.4.1 Carbon Ligands

The literature of Mn^{III} and Mn^{IV} *cyano* compounds[21,22,573] is somewhat confused by claims for non-existent species, which have since been disproved. Hence, we list in Table 44 only the known species for which acceptable proof has been published.

$K_3[Mn(CN)_6]$, which was one of the few examples of low spin Mn^{III}, was first prepared in 1837. Standard methods of preparation have been described; but, in some hands at least, these may lead to contamination of products with $[Mn_2O(CN)_{10}]^{6-}$. Hence, much of the early work on the physical properties of $[Mn(CN)_6]^{3-}$ is in doubt. There is but one form of the compound $K_3[Mn(CN)_6]$, —red, monoclinic crystals—in which measured Mn—C distances are 1.94, 1.99 and 2.00(×2) Å, giving the same average value of 1.98 Å as for the cubic $Cs_2Li[Mn(CN)_6]$. Magnetic measurements ($\mu_{eff} = 3.50$ BM at room temperature) indicate a low spin t_{2g}^4 configuration. The undiluted K^+ salt showed no ESR signal between 12 and 290 K.

Exchange of CN^- with $[Mn(CN)_6]^{3-}$ in water is very fast, and there are indications[22] of an 'associative' mechanism involving $[Mn(CN)_6H_2O]^{3-}$. Aqueous perchloric acid solutions often precipitate $Mn(CN)_3 \cdot nH_2O$,[574] which is another example of disproportionation of Mn^{III}, being formulated as $Mn^{II}[Mn^{IV}(CN)_6] \cdot nH_2O$ (Section 41.5.1).

A major contaminant of many of the earlier preparations of $K_3[Mn(CN)_6]$,[575] and often described as a different form of this, was a golden brown dimeric oxo-bridged species $[(CN)_5Mn—O—Mn(CN)_5]^{6-}$. It is also formed when $KMnO_4$ is reacted with KCN, and an X-ray analysis of the crystalline compound $K_7[Mn_2O(CN)_{10}] \cdot CN$ showed a linear Mn—O—Mn bridge, with Mn—O = 1.72 Å and Mn—CN = 1.97–2.06 Å. It is almost diamagnetic because of antiferromagnetism.

Various metal cations form precipitates with $[Mn(CN)_6]^{3-}$ in neutral or acid solution. One of them, $Fe_3[Mn(CN)_6]_2$ undergoes an interesting reaction: on heating, rearrangement occurs to $[Fe(CN)_6]^{4-}$.

With our formalism, accepting NO as a neutral ligand, $[Mn(CN)_5NO]^{2-}$ becomes an Mn^{III} compound, although it is not very comfortable here, especially when placed against $[Mn(CN)_5(NO_2)]^{3-}$, which it forms when irradiated (UV) in the presence of O_2. The nitrosyl is yellow, has a magnetic moment of 1.73 BM and a ν_{NO} of 1885 cm^{-1}.

Mn^{III} alkyls appear to be particularly prone to disproportionation.[197] Attempts to prepare them from $[Mn(acac)_3]$ and Li alkyls in the presence of phosphines give transient colour changes at low temperatures which appear to be the Mn^{III} species, but only Mn^{II} and Mn^{IV} alkyls (*q.v.*) have been isolated from the solutions. An interesting report,[576] which has not yet been confirmed, describes

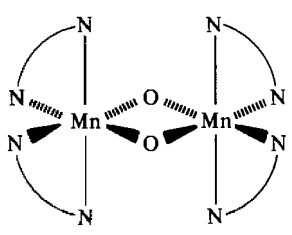
Table 44 The Mn^{III} and Mn^{IV} Cyano Compounds

Compound	*Oxidation State*	*Structure*	*Colour*
$M_3[Mn(CN)_6]$	III	$[Mn(CN)_6]^{3-}$ octahedral	Red
$Mn(CN)_3 \cdot nH_2O$	II/IV	$Mn^{II}[Mn^{IV}(CN)_6] \cdot nH_2O$	Green
$K_7Mn_2O(CN)_{11}$	III	$[(CN)_5MnOMn(CN)_5]^{6-}$	Golden-brown
$M_2[Mn(CN)_5NO]$	?	$[Mn(CN)_5NO]^{2-}$ octahedral	Yellow
$M_3[Mn(CN)_5NO_2]$	III		
$M_2[Mn(CN)_6]$	IV	$[Mn(CN)_6]^{2-}$ octahedral	Yellow

Mn^{III} monoalkyls $[MnR(N_2O_2)H_2O]$ {where (N_2O_2) is a Schiff base ligand (**161**)}, which is analogous to the well-characterized Co^{III} species. Six compounds were described, all with magnetic moments near 5.0 BM.

41.4.2 Nitrogen and Phosphorus Ligands

The known chemistry of Mn^{III} with nitrogen ligands, other than the macrocycles (Section 41.4.8), is still quite limited {but see also the mixed N, O ligands, Section 41.4.7}. Perhaps the tendency for Mn^{III} to disproportionate, in many ligand systems, is responsible for the failure to obtain $[Mn\{N(SiMe_3)_2\}_3]$, when these species have been obtained[84] for all other metals Sc^{III} to Fe^{III}.



Most of the data for this section come[78,210,572] from the reactions of $MnCl_3$ with uni-, bi- and ter-dentate ligands (Table 45). The green monopyridine compound (**214**) is not at all robust, but reacts further to give a more stable, brown tris compound $[MnCl_3py_3]$ (**215**). Compounds of the latter class generally are sensitive to moisture (although the NEt_3 compound is distinctly less so), but the py compound is stable up to 100°C under N_2. No physical measurements were reported, but the related terpy compound (**219**) is a typical, high spin, octahedral species.

The air stable red compounds (**215**) formed with the bidentate ligands, appear to be dimers, with magnetic moments reduced by antiferromagnetism; but the aquo species (**217**) are almost certainly $[MnCl_3(H_2O)(N_2)]$ octahedra. A structural analysis of the related, but more versatile, nitrato species $[Mn(NO_3)_3bipy]$ shows a seven-coordinate polyhedron with two bidentate nitrates and one bipy nitrogen almost co-planar (Mn—O = 2.11–2.40; Mn—N = 2.09 Å), and axial N (2.00 Å) and unidentate NO_3 (Mn—O = 1.90 Å). ESR spectra have been observed for the compounds (**215**), but they are very broad single lines (600 Øe).

Table 45 Solid $MnX_3 \cdot L_N$ Compounds for Nitrogen Ligands

Class		*Ligand and Comments*	μ_{eff} (BM)

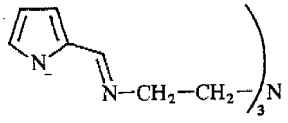
	($X = \frac{1}{2}SO_4^{2-}$)	py: chocolate-brown from hot py	
(**215**) MnX_3N_2	($X = Cl^-$)	bipy, phen: red or red-brown	3.9
(**216**)	($X = NO_3^-$)	bipy, phen: red crystals	5.0
(**217**) $[MnX_3N_2(H_2O)]$	($X = F^-$)	phen: orange-brown	4.9
	($X = Cl^-$)	bipy, phen: red-brown	5.0
(**218**) $[MnCl_3N_3]$		$N = NH_3$, RNH_2 (R = Me, Et, Pr, Bu): brown R_2NH (R = Me, Et): brown R_3N (R = Et, Bz): Et, brown; Bz, green py, quin: brown	
(**219**)		N_3 = terpy: brown	4.9
(**220**) $[(Mn^{III}O_2—Mn^{IV})(N_2)_4]X_3$		N_2 = bipy, phen ($X = ClO_4$, PF_6, $\frac{1}{2}S_2O_8^{2-}$): green	2.1–2.8
(**221**) $[Mn(N_2)_3](ClO_4)_3$		N_2 = en: green	4.9

Various reactions of excess phenanthroline or bipyridyl with Mn^{II} or Mn^{III} species in the air, or with $KMnO_4$ solutions, produce the compounds (**220**), which have the dimeric, dioxo-bridged, Mn^{III}/Mn^{IV} structure (**222**). These green compounds, isolated with various X^-, are stable in moist air at room temperature and in the daylight for several days, but decompose somewhat faster in solution. The Mn^{III} and the Mn^{IV} octahedra are well defined in the X-ray structural analysis of $[Mn_2O_2bipy_4](ClO_4)_3 \cdot 3H_2O$, with the Mn^{III} having the longer bond lengths and the expected tetragonal distortion.[577] Magnetic moments are low because of antiferromagnetism and ESR spectra showing hyperfine coupling to both Mn^{III} and Mn^{IV} have been obtained.



(**222**)

The green dimeric 3+ species can be oxidized to the 4+ Mn^{IV} species (Section 41.5.2), but, although there is good electrochemical evidence (in CH_3CN solution) for the quasi-reversible step (a) in reaction (16), the Mn^{III} dimer (2+) is unstable. Equally protonation of the dioxo-bridge atoms leads to increased instability; green solutions of the Mn^{III}/Mn^{IV} anion turn red on the addition of H^+; the process is immediately reversible; but reversibility decreases with time as the dimer decomposes to Mn^{II}.

$$[(N,N)_2Mn^{III}O_2Mn^{III}(N,N)_2]^{2+} \underset{(a)}{\rightleftharpoons} [(N,N)_2Mn^{III}O_2Mn^{IV}(N,N)_2]^{3+} \underset{(b)}{\rightleftharpoons} [(N,N)_2Mn^{IV}O_2Mn^{IV}(N,N)_2]^{4+} \quad (16)$$

Dihydroxy-bridged species with other N ligands have been postulated for some biguanide compounds, but the details here need to be confirmed by X-ray structural studies. However, both dihydroxy- and dimethoxy-bridged dimers are known for Mn^{III} compounds of salicylaldiminate ligands (Section 41.4.7).

The only reference to a tris-bidentate species is the compound (**221**), which is reported[578] to be a green crystalline compound with $\mu_{eff} = 4.85$ BM and $g = 2.08$. Many other $[MnN_6]$ compounds should therefore be accessible. One interesting recent example is the Mn^{III} compound of the ligand (**223**). This molecule lies on a crystallographic three-fold axis; is nearly octahedral $[MnN_6]$, but with a significant twist towards the eclipsed, trigonal prism, with Mn—N (pyrrole) 2.054 and (azomethine) 2.148(2) Å; and is the first example of Mn^{III} or any d^4 system, with a crossover from the high spin $S = 2$ state to the low spin $S = 1$ state at 40–50 K.[579]

(223)

The low spin configuration was earlier found in the deep-coloured, tris chelated amino-troponiminates $[Mn(L_N)_3]$ (for L_N = **43**). Black $[Mn(L_N)_3]$, prepared from $Mn_2(CO)_{10}$ and L_NH, had a magnetic moment of 3.12 BM; whereas the brown-black $[Mn(acac)_2(L_N)]$ and black $[Mn(acac)(L_N)_2]$ both were high spin species with $\mu_{eff} = 4.9$ BM (in $CHCl_3$).[141] An X-ray structural analysis of the latter showed a tetragonal distortion of the $[MnN_2O_4]$ octahedron.[580]

Phosphorus ligand compounds of Mn^{III}, except for alkyl and hydride species (Section 41.4.6), are confined to a report of $[MnCl_2(diphos)_2]Cl$ (see Section 41.3.4 and Table 17); and now the unexpected, dark-green, phosphine-iodo compound[581] $[MnI_3(PMe_3)_2]$, which has a trigonal bipyramidal five-coordinate structure, with axial phosphines (at Mn—P = 2.43–2.44 Å). Undoubtedly the latter compound is but the 'tip of the iceberg', and we can expect to see a considerable further development of this area of Mn^{III} chemistry; although it is pertinent to recall that the phosphine alkyls of Mn^{III} disproportionate.

41.4.3 Oxygen Ligands

Many compounds, with a range of ligands, have been isolated as crystalline solids. They are almost invariably good oxidizing agents; and, as such, are used in organic (hydrocarbon) chemistry, especially the acetate, but also now the sulfate and diphosphonate.[4–6]

41.4.3.1 Water, hydroxide and oxide

$[Mn(H_2O)_6]^{3+}$ is perfectly well characterized in the red crystalline alum $CsMn(SO_4)_2 \cdot 12H_2O$, but we have significant doubts about the current orthodoxy that it also is a significant component of green aqueous acid solutions.[572,582,583]

Mn^{III} in water was well reviewed[583] in 1968, and nothing published since appears to add significantly to the basic data. Interpretations were given in terms of $Mn^{3+}_{aq.}$, with hydrolysis to $MnOH^{2+}_{aq}$; which translates, not unreasonably to $[Mn(H_2O)_6]^{3+}$ and $[Mn(OH)(H_2O)_5]^{2+}$. The aqueous solutions are described as green and rather unstable. All data referring to $[Mn(H_2O)_6]^{3+}$ were obtained by extrapolating to some ideal, either of time or concentration. But, even so, the extinction coefficient obtained for the visible spectrum of this species is ten times that obtained for it in

$CsMn(SO_4)_2 \cdot 12H_2O$. Thus it seems not improbable that the solution data, even in concentrated acid solutions may refer instead to $[Mn(OH)(H_2O)_5]^{2+}$ or the dimer $[(H_2O)_4Mn(OH)_2Mn(H_2O)_4]^{4+}$; with the second species required by the analyses of the various kinetic data[583] being a further 'hydrolysed' (proton-transfer) species.

Complications which militate against the observance of pure $[Mn(H_2O)_6]^{3+}$ in aqueous solution are its oxidizing properties, the usual electroneutrality-driven 'hydrolysis' (or, more exactly, proton transfer to solvent) and the disproportionation reactions (14) and (15). The instability of the cation is shown in the behaviour of the alums $MMn(SO_4)_2 \cdot 12H_2O$ (M = K, Rb, Cs, NH_4): all four were isolated by Christensen in 1901, as red crystalline compounds, but only the Cs compound is stable at normal room temperatures and even this one begins to blacken and decompose at 33°C. No other solids containing the cation appear to have been described.

The aqueous solutions of Mn^{III} are stabilized by the presence of Mn^{II} and H^+. They become cloudy on standing, and at a rate which is accelerated by decreasing $[H^+]$ or $[Mn^{II}]$, or by increasing $[Mn^{III}]$. The cloudiness results, of course, from the formation of oxo/hydroxo polymers; but the detail of these and the kinetics of their formation are not understood, except by extrapolation from the behaviour of the other metal compounds.

At least for the solid state, we are on firmer ground, and the structural data[211] for most of the Mn^{III} oxo and hydroxo compounds are in Table 46. $Mn(OH)_3$ has not been detected, instead MnO(OH), in two major crystalline forms, is the species first formed when $Mn(OH)_2$ is oxidized in contact with alkaline solutions. Several other crystalline solids are known to contain OH^- (Table 46). However, we can only speculate that the green crystalline Na, Ba and Sr hydroxomanganates(III), described by Scholder and Kyri[584] in 1952, may contain the $[Mn(OH)_6]^{3-}$ anion, although the authors postulated $[Mn(OH)_5]^{2-}$ and $[Mn(OH)_7]^{4-}$ as well.

The coordination polyhedra are generally $[MnO_6]$ octahedra, with the sorts of distortion (Table 46) required by, but not certainly attributable to, the Jahn–Teller theorem. Such distortion is as often rhombic (2 + 2 + 2) as tetragonal (4 + 2). Bond distances average between 2.0 and 2.1 Å, and

Table 46 Structural Data for the Mn^{III} Oxo and Hydroxo Compounds

Compounds	*Polyhedra*	*Bond Distances* (Å)[a]
Mn_2O_3	$[MnO_6]$ (*i*)	1.963 (× 2); 1.996 (× 2); 2.050 (× 2) (2.00)

[e] Ref. 587.
[f] Ref. 588.
[g] The mineral bermanite—ref. 263.

thus are intermediate between those for Mn^{II} and Mn^{IV}. These distances, and the distortions, often serve to identify the +3 oxidation state in the solids. Similar octahedra are observed in silicate minerals,[250] such as braunite and henritermierite, and borate minerals,[248] such as the pinakiolites and gaudefroyite. One apparent exception to the rule of distortion is the $[Mn^{III}O_6]$ octahedron in $Mn_8O_{10}Cl_3$, which has bond lengths of 2.01 and 2.03 Å; but the $[MnCl_2O_4]$ octahedra, with Mn—Cl of 2.84 Å, are so distorted as to closely approach a planar $[MnO_4]$ geometry.

Five-coordinate and four-coordinate (tetrahedral) structures also are known. The five-coordinate polyhedra usually are square pyramidal with a distinctly longer axial bond; and, in one case, this is so long (2.94 Å) as again to suggest planar $[MnO_4]$ coordination.

The tetrahedron is known so far only in the dimeric oxoanion $[Mn_2O_6]^{6-}$, which was made by heating MnO and K_2O together at 610°C for ten days.[586]

41.4.3.2 Oxyanions

Nitrato compounds appear to be confined[258] to the thermally unstable $Mn(NO_3)_2$, $NO_2[Mn(NO_3)_4]$ and $[Mn(NO_3)_3L]$ (where L = bipy or phen). The latter are dichroic (red/green), and an X-ray analysis of the bipy compound[589] shows a (5 + 2) seven-coordinate structure, with axial (unidentate) nitrate (1.90 Å) and N (1.99 Å), and equatorial N (2.09 Å) and two bidentate nitrates (Mn—O = 2.11, 2.40 and 2.20, 2.24 Å).

Phosphato compounds,[590] however, are more significant: stable crystalline solids have been known since 1844 (Table 47); aqueous solutions of diphosphatomanganese(II) species have been used analytically; and $NH_4MnP_2O_7$ is a violet pigment ('manganese violet'). Even so, reported studies on the solids are quite limited—in many cases nothing has been reported since the original preparations, more than 60 years ago. X-Ray structural analyses of the red-violet compounds $MnH_3P_2O_6 \cdot 2H_2O$[590] and $Mn(PO_3)_3$[591] both show the expected, distorted $[MnO_6]$ octahedra.

The phosphate system is dominated by the insoluble green-grey $MnPO_4 \cdot H_2O$. However, violet solutions, which appear to contain mainly $[Mn(PO_4)_2]^{3-}$, can be obtained by dissolving Mn^{III} acetate in concentrated H_3PO_4. Phosphonato compounds have been studied in Ac_2O, and evidence reported for the 1:1, 2:3, 1:2 and 1:3 species with Mn^{III}; but only the 1:3 species could be detected in MeOH.

But the most intensively studied system, the most stable and that used as an oxidometric reagent, has been that of diphosphate ($P_2O_7^{4-}$) and Mn^{III} in aqueous solutions. The violet solutions, prepared by oxidizing Mn^{II} with $KMnO_4$ or HNO_3, are most robust at pH 4–6 and can be stored unchanged for at least one month. There is no agreement in the literature about the nature of the molecular anions present but at, and below, pH 4, $[Mn(H_2P_2O_7)_3]^{3-}$ appears to predominate; and, above pH 4, $HP_2O_7^{3-}$ species probably becomes more significant.

The *sulfate* $Mn_2(SO_4)_3$ can be prepared from Mn_2O_3 in hot, concentrated H_2SO_4 as dark-green needles, which are thermally stable but very hygroscopic.[592] From 70% H_2SO_4, red $[H^+(H_2O)_n]Mn(SO_4)_2$ can be obtained and the compounds $MMn(SO_4)_2$ (M = NH_4, K, Rb) have been described. (Unstable, hydrated 'alum' forms were noted in the previous section.) Sulfato compounds are formed in solution, are somewhat more robust than the aquo/oxo species, but details are still not clear. The blue colour described for $Al_4Mn_2(SO_4)_9$ by Étard in 1878/79 (and there are other compounds with other M^{III} sulfates)[592] suggest that it is worthy of further study.

Table 47 Crystalline Phosphato and Arsenato Compounds of Mn^{III}

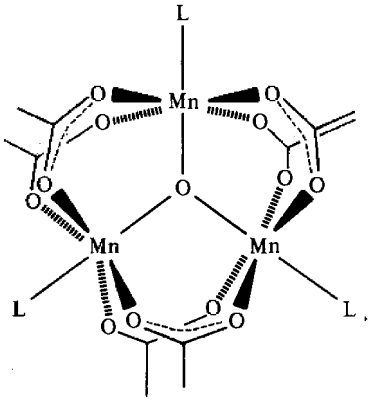
Compound	*Comments*
$MnH_3P_2O_6 \cdot 2H_2O$	Red-violet—$[MnO_4(H_2O)_2]$ octahedra[590]
$MMn(HPO_4)_2 \cdot nH_2O$	(M = Li, Na, K, NH_4) Red crystals—water soluble
$MnPO_4 \cdot H_2O$	Grey-green, insoluble
$Mn(PO_3)_3$	Red-violet—$[MnO_6]$ octahedra[591]
$NaMn(PO_3)_4$	From Mn_2O_3, HPO_3 and $NaPO_3$ at 1000°C
$Mn_4(P_2O_7)_3 \cdot nH_2O$	Violet
$MMnP_2O_7$	(M = K, NH_4) Red or violet
$MMnP_2O_7 \cdot nH_2O$	(M = Na, K, NH_4) Red or violet
$MnAsO_4 \cdot H_2O$	Brown-violet. X-Ray pattern related to PO_4 analogue
$Mn(H_2AsO_4)_3 \cdot 3H_2O$	Dark violet
$Mn^{II}_2Mn^{III}(OH)_4AsO_4$	The mineral Flinkite—$[MnO_6]$ octahedra

Selinites, on the other hand, have attracted recent interest: compounds $MMn(SeO_3)_2 \cdot nH_2O$ (M = H, NH_4, K, Rb, Cs) have been described[593] and X-ray analyses[594] of $Mn_2(SeO_3)_3 \cdot 3H_2O$ and $MnH(SeO_3)(Se_2O_5)$ reveal distorted $[MnO_6]$ octahedra.

Iodates of Mn^{III} are perhaps represented in the yellow to brown-yellow solids $M_2Mn(IO_3)_5$.

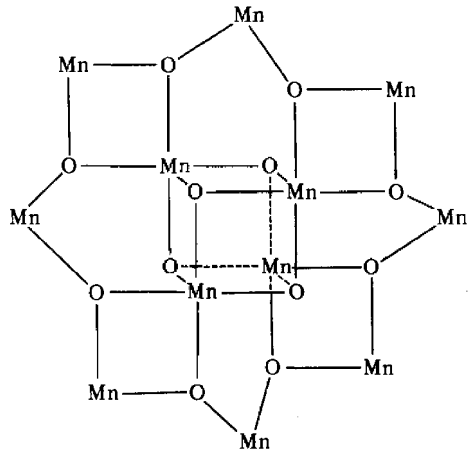
There is also a range of isopoly- and heteropoly-anion compounds which we have summarized in Table 26.

41.4.3.3 Carboxylates



There are two basic classes here: (a) the compounds of the monocarboxylates, such as acetate, which turn out to have a rather complex chemistry; and (b) the bidentate carboxylates, such as oxalate, malonate and salicylate which are straightforward bidentate anionic chelates.

Contrary to the assumptions in most of the literature,[254] it is now becoming clear that the monocarboxylates of Mn^{III} are 'basic' species, that is, they are compounds with oxo, as well as carboxylato, ligands. For acetate, neither the cinnamon brown 'dihydrate' first reported by Christensen in 1901, nor the 'anhydrous' species made from $Mn(NO_3)_2 \cdot 6H_2O$ and acetic anhydride by Späth in 1912, are examples of simple binary acetates. Rather, they are variants on a trinuclear structural theme $[Mn_3O(OOCR)_6L_3]^+$, with the planar structure (**224**), in which each Mn atom is bridged to its neighbours by two carboxylate bridges. This is proven for the product from acetic anhydride,[595] but is yet only an assumption for the 'dihydrate', for which the story may be more complex: similar reaction conditions to those used for its preparation, but with 50% more $KMnO_4$, produce a red-black mixed Mn^{III}/Mn^{IV} species,[596] described below.



Known variants of the structural theme (**224**) are: $[Mn_3O(OAc)_7HOAc]$ — the so-called anhydrous acetate[595] — in which L is an oxygen from an acetate which links the trimers into linear polymers, or, in one case, HOAc; $K_2\{Mn^{II}(H_2O)_2[Mn_3^{III}O(HCO_2)_9]_2\}$, in which L is an oxygen from a formate which links the Mn^{II} atoms to the trimer; and $[Mn_3O(OAc)_6L_3]\ ClO_4$ for L = py or β-pic[598] — the py compound is isomorphous with the Cr, Fe, Ru, Rh and Ir analogues.

A minor variation on this theme is seen in the neutral compounds $[Mn_3O(OAc)_6L_3]$ where L = py[599] or 3Cl-py.[600] In these, one of the Mn atoms is Mn^{II}, which is distinguished experimentally in the X-ray analysis of the 3Cl-py compound,[600] but not in that of the py compound.[599]

A further variation on this theme is seen in a mixed Mn^{III}/Mn^{IV} acetate, prepared[596] as red-black crystals as for '$Mn(OAc)_3 \cdot 2H_2O$', but using more $KMnO_4$. The compound is a dodecanuclear species $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4] \cdot 2HOAc \cdot 4H_2O$, in which the central $Mn_{12}O_{12}$ unit has the structure (**225**). There is a central cubane-like (Mn_4O_4) cluster of Mn^{IV} atoms, each linked *via* further triply-bridging oxides to two Mn^{III} atoms. The Mn atoms are then further linked by single or double acetate bridges of type (**82**) and water molecules complete the octahedra for half the Mn^{III} atoms. Bond lengths and distortions of the Mn^{III} polyhedra here, and in the other acetate compounds, serve to distinguish the different oxidation states.

(224)

(225)

Undoubtedly further variations will be identified as these carboxylates are further explored.

Oxalate forms red $[MnOx_3]^{3-}$ and green (*cis*) or yellow *trans*-$[MnOx_2(H_2O)_2]^-$, which have been known since 1936.[293,572] Usually, preparations of the bis species give the *cis* isomer, but it is the *trans* isomer which predominates in aqueous solution. The compounds are all rather unstable and are particularly sensitive to light. However, the malonates, known since 1922, are rather more robust and especially towards light. X-Ray structural analyses are available on tris[601] and *trans* bis[602] species, with all showing 2 + 2 + 2 distortions of the Mn^{III} octahedra.

Hydroxycarboxylate compounds of Mn^{III} are known for salicylates and various aliphatic acids.[299] Some crystalline solids have been isolated, including bis-chelate species of the salicylates $M[Mn(X\text{-}sal)_2L_2]$ ($L = H_2O$, py); but the only tris-chelate compound isolated is the black $Cs_3[Mn\{(CF_2)_2C(O)COO\}_3]$. Various red or green crystalline solids also are known with tartrate ligands and they are reasonably robust, but no structural data are available.

Much of the known detail on the hydroxycarboxylate ligands refers to the redox properties of aqueous alkaline solutions; and especially to electrochemical studies on the oxidation of the Mn^{II} species of glyceric, tartaric, gluconic, glucaric and citric acids to Mn^{III} and Mn^{IV}.[299,603] For each ligand, two Mn^{III} species were detected, and they appear to be a monomeric tris-chelate species and a dimeric oxo/hydroxo-bridged bis-chelate species.

41.4.3.4 Alcohol and phenol ligands

Orange-red Mn^{III} compounds of the polyhydroxy ligands, including the polyhydroxycarboxylates noted in the previous section, are formed either by bubbling air through the Mn^{II} compounds in aqueous alkaline solution or by dissolving 'manganese(III) acetate' in the liquid polyhydroxy alcohol.[212,603,604] Such solutions are relatively robust, but in acid solutions the Mn^{III} compounds appear only as intermediates in the oxidation of the alcohol to the ketone. Stability (robustness) of the Mn^{III} compounds increases with the number of alcohol groups, so that, for example, the sorbitol compounds[604] are more robust than those of glycerol.

Catechol and other diphenols have been known since 1926 to form Mn^{III} species, and they have recently been receiving closer attention.[282,603] In aqueous alkaline solution, tris-chelate species apparently are formed. However, these systems have the added complication of ligand oxidation to the semiquinone, which forms more (thermodynamically) stable species than the diphenol (see also Section 41.5.3.4): there is evidence for a tris-semiquinone Mn^{III} molecule, which is a four electron oxidizing agent according to equation (17).[603] Another semiquinone compound of Mn^{III} [Mn(salen)(DBSQ)] (DBSQ = 3,5-di-*tert*-butyl-*o*-benzosemiquinonate) has been described.[605]

$$[Mn^{III}(\text{semiquinone})_3] + 4e^- \rightleftharpoons [Mn^{II}(\text{diolate})_3]^{4-} \qquad (17)$$

41.4.3.5 Acetylacetonate and related ligands

A range of Mn^{III} compounds of acetylacetonate[283] is well established; they are used for preparing other Mn^{III} species; and have been studied as catalysts, especially for vinyl polymerizations.

Brown $[Mn(acac)_3]$, somewhat less robust than its Cr, Fe and Co analogues, has been prepared by a variety of routes, including the action of $KMnO_4$ on the ligand, reaction of the metal with the ligand in the presence of O_2, various oxidations of Mn^{II} species or reaction of the ligand with other Mn^{III} compounds. Details of a convenient preparation, from $KMnO_4$ and acacH, have appeared recently.[606]

The molecular species can be recrystallized from a variety of hydrocarbon and halocarbon solvents, and it has been identified in three crystalline forms, of which X-ray structural analyses are available on the β- and γ-forms.[607] Despite a misleading report in 1964, the $[MnO_6]$ octahedra are distorted: there is a 'compressed' (2 + 4) distortion for the β-form (Mn—O = 1.93–2.02 Å) and an 'elongated' (4 + 2) distortion for the γ-form {Mn—O = 1.94(×4) and 2.11(×2)}.

Similar green or brown tris-chelated compounds are described[283] for many of the usual range of available β-diketonates, the most stable compound being that formed with the sexadentate ligand (**124**).[318]

Solutions of $[Mn(acac)_3]$ react with HX to give brown $Mn(acac)_2X$ species (X = Cl, Br, I), and other compounds of this type (X = N_3, NCS, RCOO)[608] have been made by direct reactions. These compounds also are used for the preparation of other Mn^{III} compounds, especially of the por-

phyrins. X-Ray data on the azido and thiocyanato compounds show planar $Mn(acac)_2$ units (Mn—O = 1.91 Å) linked into linear polymers by bridging of the anion (for azide, Mn—N = 2.245 Å; and for thiocyanate, Mn—N = 2.189 and Mn—S = 2.880 Å).

In water, the cationic species $[Mn(acac)_2(H_2O)_2]^+$ form and several salts of this have been isolated, while with pyridine and other neutral unidentate ligands $[Mn(acac)_2XL]$ have been produced.[609]

Other mixed ligand systems studied include the troponeiminates (**43**) and 8-hydroxyquinoline; in both cases $[MnL_2L']$ and $[MnLL'_2]$ have been characterized. [Mn(acac)(salen)] represents a non-planar form of the salen ligand, related to the well-characterized Co^{III} compounds.[610]

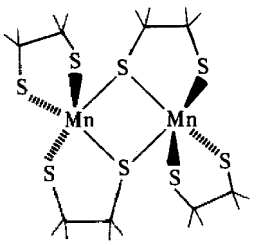
In the tris-tropolonato compound (L = **98**), the two independent molecules show either a 4 + 2 or a 2 + 2 + 2 distortion of the $[MnO_6]$ octahedra.[611]

41.4.3.6 Other oxygen ligands

Several *ether* compounds of $MnCl_3$ have been described,[221] but most are thermally unstable well below normal temperatures.

Of neutral *carbonyl* ligands, only purple $[Mn(urea)_6](ClO_4)_3$ appears to have been described. All Mn—O bond lengths are constrained to equality by the space group, but an analysis of the 'temperature factors' showed that there was scope for distortion of the octahedron and this was suggested to be dynamic.[612]

Related red $[MnL_6]X_3$ compounds with *pyridine* N-*oxides* have been reported,[613] but no structural data are yet available. These unidentate pyridine-*N*-oxides also form[613–615] red or green compounds $[MnCl_3L_3]$, which are probably octahedral, and green compounds $MnCl_3L_2$, which may well prove to be five-coordinate monomers. Blue $MnCl_3(Ph_3PO)_2$ and $MnCl_3(Ph_3AsO)_2$ also are known; and there is a bromo species $[MnBr_3(quinO)_3]$. Most of these tris- and bis-ligand compounds of MnX_3 are quite robust in dry air at normal temperatures, but are instantly decomposed by water and slowly decompose in moist air.



The tris-ligand cation of bipy-*N*-oxide (**120**),[613] and the bis-ligand cation of terpy-*N*-oxide[314] can be prepared by electrochemical oxidation of the Mn^{II} species in CH_3CN, and the robust dark-red crystalline perchlorates have been isolated.

41.4.4 Sulfur Ligands

No binary Mn^{III} *sulfide* is known and this oxidation state is known[319] only in several ternary sulfide phase: perhaps in cubic spinel species, such as $ZnMn_2S_4$, and probably (magnetic evidence) in several Nb and Ta ternary phases, formulated as $Mn_{0.33}NbS_2$, $Mn_{0.33}TaS_2$ and $Mn_{0.5}NbS_2$. Bond lengths for the first two are reported as 2.52 and 2.49 Å.

On the other hand, oxidation of the thiol compounds to Mn^{III} occurs so readily that Mn^{II} compounds have to be prepared anaerobically.

For simple *thiols*, only one species has been isolated and characterized to date. The dianion of 1,2-dithioethane (edt) in methanol solution with Mn^{II} forms $[Mn(edt)_2]^{2-}$ and reacts rapidly with O_2 to give green solutions, from which dark green crystalline $[Et_4N]_2[Mn_2(edt)_4]$ and the $[Ph_4P]$ salt were obtained.[320] X-Ray analysis of the former showed the dimeric structure (**226**) with asymmetric bridges Mn—S = 2.346 and 2.632(2) Å. The other three S atoms have shorter distances (2.316–2.323 Å), and the overall five-coordinate structure is reasonably close to the square pyramidal extreme with four short bonds and one long (axial) bond. The magnetic moment (3.96 BM) suggests some antiferromagnetic coupling.

(226)

[c] $CHCl_3$ solvate: R. J. Butcher and E. Sinn, *J. Am. Chem. Soc.*, 1976, **98**, 5159.

In solutions in donor solvents (DMF, DMSO and MeCN), dissociation equilibria occur, with the formation of presumably $[Mn(edt)_2(solvent)_2]^-$ monomers. Magnetic moments in these solutions (5.0–5.1 BM) are close to the spin-only value for high spin d^4, and the electronic spectra have been characterized.[320]

Dithiocarbamates of Mn^{III} have long been known because of the ease of oxidation from Mn^{II}: Marcel Delepine first described some of the dark violet $[Mn(R_2dtc)_3]$ compounds in 1907. They result[329,330,616] from the reaction, in open vessels, of aqueous Mn^{II} with the Na or K salt of the ligand; are reasonably robust under ambient conditions, but sensitive to light and moisture; and they have magnetic moments near 5 BM. The Se analogues also are known and have similar properties.[617]

Three X-ray analyses structurally characterize the compounds as tris-bidentate with four-membered chelate rings (Table 48); and show that the $[MnS_6]$ octahedra are distorted, not only trigonally by the chelate rings, but also by the (2 + 2 + 2) variation of the 'tetragonal' distortion observed in most Mn^{III} octahedra.

An electrochemical study has shown reversible reduction to Mn^{II} and oxidation to Mn^{IV} species; and a ^1H NMR study shows that isomerization, of the compounds of unsymmetrical ligands such as MePhdtc, is slow on the NMR time scale at $-60°C$ and occurs *via* a trigonal twist mechanism rather than a dissociative one.

Bis-dithiocarbamato compounds, such as $Mn(R_2dtc)_2Cl$, appear to be available, but not studied; and there is a recent report[618] of a nitrosyl $[Mn(R_2dtc)_2Cl(NO)]$.

41.4.5 Halides

The coordination chemistry of Mn^{III} with the halides[210,336,572] is distinctly more limited than that of Mn^{II}; the former are good halogenating agents for hydrocarbon compounds and the only binary compound able to exist at normal temperatures is MnF_3. Black solids, stable only below $-40°C$, probably represent $MnCl_3$, but the bromo and iodo compounds have never been observed.

There is more of a tendency here for the stoichiometry of the ternary compounds and their hydrates to reflect the coordination polyhedra. For example, there are a number of examples of $M_3[MnF_6]$ compounds, and those of formulae $MMnF_4 \cdot 2H_2O$ generally appear to be of structural type $M[MnF_4(H_2O)_2]$, with *trans* octahedra. However, the series M_2MnF_5, $M_2MnF_5 \cdot H_2O$, $MMnF_4$ and $MMnF_4 \cdot H_2O$ all are examples in which octahedra are formed by bridging of fluorides; although discrete $[MnCl_5]^{2-}$ five-coordinate polyhedra exist in the series M_2MnCl_5 and there are some unstable examples of $[MnCl_6]^{3-}$.

All of these coordination polyhedra are quite labile, and the structures of the Mn^{III} polyhedra in any solution depend only on the nature of the solvent and not the starting material. Stability constants K_1 to K_3, for aqueous fluoro species in perchlorate media, have recently been reported.[619]

MnF_3 is a red-purple crystalline solid which is readily soluble in water. It is antiferromagnetic only at low temperature. Also known are a mixed oxidation state fluoride, Mn_2F_5, and a hydrate which is said to be isostructural with $NiSnCl_6 \cdot 6H_2O$. Perhaps the latter represents an example of disproportionation, and may be $[Mn^{II}(H_2O)_6][Mn^{IV}F_6]$.

MnF_3 is structurally related to the other fluorides TiF_3 to CoF_3, but with the significant 2 + 2 + 2 distortion expected for the high spin d^4 configuration (Table 49). The $M_3[MnF_6]$ series of ternary compounds generally have tetragonally distorted fluoroperovskite structures, in which there are two sites for M, and hence mixed cation species such as $K_2Na[MnF_6]$ are readily prepared. Large tervalent cations, however, like $[M(NH_3)_6]^{3+}$ (M = Cr, Co, Rh) give cubic crystals which contain discrete $[MnF_6]^{3-}$ octahedra with experimentally equal Mn—F bonds, although the data can be interpreted in terms of a dynamic (or random) disorder.

Table 49 Bond Length Data for $[Mn^{III}F_6]$ Octahedra

Compound	*Bond Lengths* (Å)[a]				
MnF_3	1.79		1.91	2.09	(1.93)
K_2NaMnF_6		1.86[b]		2.06	(1.93)
$[Cr(NH_3)_6][MnF_6]$			1.922[c]		(1.92)
$[NH_4]_2MnF_5$		1.84[b]		2.09	(1.92)
$K_2MnF_5 \cdot H_2O$	1.821		1.842	2.072	(1.91)
$Rb_2MnF_5 \cdot H_2O$	1.835		1.860	2.089	(1.93)[d]
$Cs_2MnF_5 \cdot H_2O$	1.835		1.868	2.127	(1.94)[d]
$RbMnF_4 \cdot H_2O$	1.83		1.85	2.157	(1.94)[e]

[a] These are generally given in *trans* pairs, with averaged values in parentheses. Data are from Gmelin (C4) unless otherwise stated.
[b] Four equal bonds.
[c] All bonds equal in the cubic space group.
[d] Ref. 621.
[e] Ref. 622.

The violet M_2MnF_5 compounds and their monohydrates, for which a new, convenient method of preparation recently has been given,[620] all have chains of corner-sharing $[MnF_6]$ octahedra with *trans* bridging fluorides[621] (Table 49). The water molecules of the hydrates are accommodated between the chains.

$CsMnF_4$ has a layer structure with corner-sharing $[MnF_6]$ octahedra, and there are at least two different hydrates here: $RbMnF_4 \cdot H_2O$ has chains of alternating $[MnF_6]$ and *trans*-$[MnF_4(H_2O)_2]$ octahedra, whereas both Cs and $NMe_4[MnF_4(H_2O)_2]$ have discrete *trans*-diaquo octahedra.[622]

There is even less variety in the known chemistry of the chloro compounds because of their lower redox stability.[623] Although $MnCl_3$ is stable only below $-40°C$, apparently decomposing through a disproportionation reaction,[623] the oxidation state is stabilized with other ligands. Thus $MnCl_3$ is more robust in donor solvents, undoubtedly as species like $[MnCl_3L_3]$, and compounds of this type are well established for both N and O donors (Sections 41.4.2 and 41.4.3.6). There is also a series of pyridine-*N*-oxide compounds (Section 41.4.3.6) $MnCl_3L_2$ which may well be five-coordinate.

Certainly five-coordination is well established in the series of green compounds M_2MnCl_5 (M = alkyl ammonium, 2M = $bipyH_2$, $phenH_2$),[624] through an X-ray analysis of the bipyridylium salt.[625] Several purple or red-brown monohydrates (M = K, Rb and NH_4) also are known.[624] There is an interesting recent report[4] that Mn^{III} in a mixture of acetic acid and acetyl chloride, also containing MOAc, gives crystalline $M_2[MnCl_5]$ (M = Na, K, NH_4).

The brown hexachloro anion also is well established, but not very robust. It is isolated from solution[624,626] with large tervalent cations, such as $[Coen_3]^{3+}$, $[Copn_3]^{3+}$ and $[Rhpn_3]^{3+}$. The solids are instantly decomposed by water or on keeping at room temperature.

Of *bromo* compounds, there are yet only one or two compounds $[MnBr_3L_3]$ (Section 41.4.3.6), so the advent of a well-proven *iodo* compound $[MnI_3(PR_3)_2]$[581] was unexpected. It would be most surprising if the latter were to remain the sole representative of Mn^{III} iodo compounds: we can surely expect interesting further developments here.

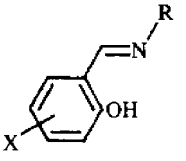
41.4.6 Hydrogen and Hydride Ligands



There is very little information available: MnH_3 has possibly been observed[356] in Ar and N_2 matrices at 4 K; $MnH_3(dmpe)_2$ appears to result from the reaction of H_2 with $MnH(C_2H_4)(dmpe)_2$ under pressure;[28,627] and there is a report of the preparation of $Mn(BH_4)_3$, but no confirmatory detail.[363]

41.4.7 Mixed Donor Atom Ligands

The chemistry in this section is almost exclusively that of Schiff base ligands; this reflects the predominance of the aldehyde/carbonyl condensation reaction with primary amines in the preparation of mixed donor atom ligands.

41.4.7.1 Mixed N—O donor atom bidentate ligands

Salicylaldehyde has been condensed with many primary amines to yield bidentate N—O ligands. Such ligands react with Mn^{III} acetate dihydrate to give compounds of stoichiometries $Mn(L)_3$ or $Mn(L)_2(X)$ (where HL = (**227**); X = Cl, Br, OH or OAc); examples are listed in Table 50.

(227)

Reliable structural information on most of these compounds is not available, although there is mass spectral evidence that the compounds listed against reference 629 are polymeric when X = OAc, but monomeric when X = Cl or Br. There has been an X-ray structural determination undertaken on the compound $Mn(L)_3$ for reference 632; bond lengths are listed in Table 51 (compound 1) and the structure has been shown to be a *trans* array of the three ligands around a pseudotetragonally distorted Mn atom.

Such distortion, which is predicted by the Jahn–Teller theorem, has also been found in the structures of the $Mn(L)_3$ compounds derived from non-Schiff base N—O bidentate ligands, such as the octahedral tris(8-hydroxyquinolato)manganese(III)·CH_3OH (or $0.5C_6H_{13}OH$) and the octahedral tris(α-picolinato)manganese(III) compounds (see compounds 2 and 3 respectively in Table 51).

41.4.7.2 Mixed N—O donor atom terdentate ligands

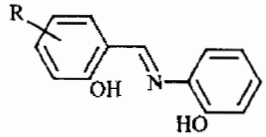
Once again the Schiff base ligand type predominates. The most common stoichiometry of compounds formed by the interaction of such ligands with Mn^{III} acetate, is that of Mn(L)(OAc) (L = dianionic Schiff base terdentate), obtained at higher pH values. Such compounds have been obtained from ligands (**228**) (n = 2 and X = H, 5-Br, 5-NO_2, 3-OMe or 3,5-diBr;[635] n = 3 and X = H),[636] (**229**) (R = Me and R′ = 2- or 4-pyridyl;[637] R = H, Me, Et or Pr and R′ = Ph[638]), and (**230**) (R = H, 5-Cl or 5-Br[639]). X-Ray structural analysis[636] of the compound Mn(L)(OAc) (where L = (**228**); X = H and n = 3) shows that it is a dimer with octahedral Mn^{III} atoms (**232**); bond

Table 51 Bond Lengths for $[Mn(N—O)_3]$ Compounds of Mn^{III}

	Bond Lengths (Å)			
	Axial Donors	*Equatorial Donors*		
N—O Ligand	*Mn—N*	*Mn—N*	*Mn—O*	*Ref.*
(**227**) R = Bz; X = H	2.251, 2.271	2.082	1.882, 1.896, 1.917	632
(**153**)	2.231, 2.265	2.056	1.912, 1.913, 1.920	633
(**154**) R = CO_2H	2.217, 2.254	2.059	1.891, 1.908, 1.942	634

lengths are, for the terdentate, Mn—O: 1.849 to 1.951 Å and Mn—N: 2.006 Å, and for the axial acetates, Mn—O: 2.2084 to 2.251 Å.

In the presence of anions other than acetate, compounds of similar stoichiometry, Mn(L)(X) (where X = Cl or Br;[638] OH[639] and OMe[640]) have been prepared. The compound in which X = OMe was obtained by hydrolysis of the potential quadridentate ligand (**231**) in an alkaline solution of $MnCl_2$, to yield (**233**) in which the terdentate ligand is (**229**) (where R = H and R′ = *o*-$NH_2C_6H_4$). Structure (**233**) indicates the marked tendency for these ligands to form polymers with Mn^{III} in the solid state.



Nevertheless, the monomeric Mn^{III} anionic compound $[Mn(L)_2]^{1-}$ (where L = *N*-salicylideneglycinato ligand) has been shown to exist in $[Mn^{II}(H_2O)_6][Mn^{III}(L)_2]\cdot 2H_2O$; the crystal structure[641] has a distorted octahedral Mn^{III} with two planar ligands with bond lengths: Mn—O 2.236 and 2.046, Mn—N, 2.065 Å for one ligand, and Mn—O, 1.934 and 1.861, Mn—N, 1.981 Å for the other ligand.

The compounds $[Mn(L)_2](NCS)$ (where L = (**234**); $n = 1$ or 2) are also claimed[642] not to be polymeric.

41.4.7.3 Mixed N—O donor atom quadridentate ligands

Once again Schiff base ligands predominate, and such work up to 1980 has been extensively reviewed by Connors *et al.*[173] Many of the compounds claimed to be Mn^{III} species have been

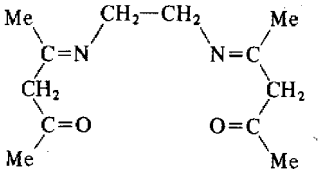
[b] These compounds analyse as monohydrates; they may well be alcoholates.



obtained by oxygenation reactions with Mn^{II} compounds of ligands of type (**161**). This is an area of research which has generated much information, but little definitive result. The literature has been extensively reviewed by Coleman and Taylor.[424]

Products of such oxygenation reactions are nearly always brown powders, and usually analyse as $Mn^{III}(L)(\frac{1}{2}X)$ or $Mn^{IV}(L)(X)$ (where L = (**161**) and X = O or OH).[425,643,426] Polymeric structures are suspected in most cases, and indeed black crystals of the compound Mn(saltn)OH·4py (where saltn = (**161**) with X = $(CH_2)_3$ and Y = H), obtained by the oxygenation of the corresponding Mn^{II} compound in pyridine solution, have been treated to X-ray structural analysis,[433] and the structure shown to be dimeric with two five-coordinate Mn^{III} atoms, each bridged by two hydroxy groups; the pyridine moieties are not bound directly to the metal.

Many compounds of formulation Mn(L)(Z) (where L = (**161**) and Z = a monoanion) have been prepared (see Table 52). Structural evidence upon such compounds is not abundant, but [Mn(salen)-(OAc)] has been shown[644] to possess approximately planar Mn(salen) units linked in a polymeric chain by singly bridging acetate ions. The very similar compound, in which the benzene rings of salen are replaced by naphthalene rings, also possesses the same polymeric structure.[645]

Other similar types of Mn^{III} compounds, in which Z is a non-charged ligand, *e.g.* $[Mn(L)H_2O]$ (see entry in Table 52 against reference 651), have been isolated, while compounds of type [Mn(salen)-(bident)] (where bident = acac or salicylaldehyde monoanions) and $[Mn(salen)(bident)]ClO_4$ (where bident = en or bipy), which were first reported[419] in 1933, have been studied more recently.[654]

Boucher *et al.*[655] have studied the Schiff base compounds of formulation [Mn(L)(X)] (where L = (**235**) and X = monoanionic ligand); X-ray structural analysis of the compound in which X = Cl shows that it has a distorted square pyramidal structure with a non-planar ligand arrangement.[656]

(235)

41.4.7.4 Mixed N—O donor atom quinque- and sexadentate ligands

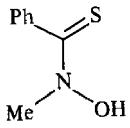
The Schiff base quinquedentate ligands (**161**), in which X = $(CH_2)_3$—NH—$(CH_2)_3$ and Y = 5-NO_2 or 3-MeO, form Mn^{III} compounds of the type Mn(L)(OH) when the corresponding Mn^{II} compound is oxygenated (see Section 41.3.9.4), whereas in similar compounds, in which Y is not an electron-withdrawing group, the ligand undergoes reaction when the Mn^{II} compound is oxygenated.[657]

An X-ray structural analysis of the compound [Mn(L)(NCS)] (where L = (**161**), X = $(CH_2)_3$—NH—$(CH_2)_3$ and Y is a fused C_6H_4 ring) shows an octahedral Mn^{III} atom, with the NCS group and the central N atom of the quinquedentate ligand occupying the apical positions.[658]

Coleman *et al.*[438] have described the preparation and cyclic voltammetry of a series of compounds [Mn(L)(NCS)] (where L = (**161**); X = $(CH_2)_n$—NH—$(CH_2)_m$ (n = 2 or 3 and m = 2, 3 or 4), $(CH_2)_2$—S—$(CH_2)_2$ and $(CH_2)_3$—O—$(CH_2)_3$; Y = H, 3-NO_2, 5-NO_2 and 5-OMe). Similar compounds, in which X = $(CH_2)_2$—P(Ph)—$(CH_2)_2$, have been described.[659]

In a series of interesting papers,[443] it has been shown that the Mn^{II} compounds from both quinque- and sexadentate ligands based on (**161**), in which X = $(CH_2)_n$—NH—$(CH_2)_m$ (n = 2 or 3, and m = 2 or 3) and $(CH_2)_n$—NH—$(CH_2)_m$—NH—$(CH_2)_p$, (n = 2 or 3, m = 2 or 3 and p = 2 or 3) respectively, will react with oxygen and nitric oxide. However, replacement of the salicylaldehyde group in (**161**) by a 2-pyridyl residue renders the Mn^{II} compounds inactive to such reactions.

The interesting potential septadentate tripod ligand, obtained by the condensation of 5-chlorosalicylaldehyde with tris(2-aminoethane)amine, has been shown to yield an almost undistorted octahedral Mn^{III} compound, MnN_3O_3, with the apical N atom of the ligand unbound.[660]



Early work on the dark red compound of Mn^{III} with edta suggested that its structure was $K[Mn(edta)H_2O]\cdot 1.5H_2O$.[661] However, X-ray work shows the compound to possess an octahedral structure with a sexadentate edta residue. Axial bond length distortion is observed, with two *trans* O atoms being 2.050 and 2.022 Å from the Mn atom, while the two equatorial Mn—O bonds are 1.907 and 1.889 Å and the two Mn—O bonds are 2.211 and 2.237 Å.[662] A very similar structural result was found in the case where edta was replaced by *trans*-1,2-diaminocyclohexane tetraacetic acid in $K[Mn(L)]\cdot H_2O$.[663]

Mechanisms of reduction by hydrazine, hydroxylamine and substituted benzene-1,2-diols of Mn^{III} compounds containing edta-type moieties have been studied.[664]

41.4.7.5 Mixed O—S and N—O—S donor atom ligands

A few interesting Mn^{III} compounds of O—S bidentates have been prepared. The interaction of Mn^{III} acetate with (**183**) (R = Ph) leads to ligand oxidation, but when R = Bu^t the tris-ligand Mn^{III} compound was obtained.[665]

A similar compound, $[Mn(L)_3]$ (HL = **236**), has been shown to possess an octahedral stereochemistry with marked tetragonal distortion; the bond lengths for the MnO_3S_3 chromophore are: Mn—$O_{(eq)}$ = 1.958 and 1.941; Mn—$O_{(ax)}$ = 2.132; Mn—$S_{(eq)}$ = 2.324 and 2.354; Mn—$S_{(ax)}$ = 2.584 Å.[666]

(236)

The sexadentate ligand (**161**) (where X = $(CH_2)_2$—S—$(CH_2)_2$—S—$(CH_2)_2$ and Y = H) has been claimed[463] to bind all three pairs of N, O and S atoms to yield a Mn^{III} compound; no Mn^{II} compound could be obtained (see Section 41.3.9.6).

41.4.8 Macrocyclic Ligands

41.4.8.1 Porphyrin ligands

Mn^{III} porphyrins have been extensively studied[482] with compounds containing the metal in this oxidation state being especially stable. Mn^{III} derivatives of partially reduced[482,667] porphyrins (such as the chlorins) have also been synthesized.

A number of physical studies have been performed on Mn^{III} porphyrins in an attempt to understand their electronic structure. The visible spectra of such compounds have been of particular interest. For most metal porphyrins the visible spectrum is insensitive to the nature of the coordinated metal and this has been interpreted as indicating little interaction between the metal and the porphyrin π-orbitals in such compounds. However this is not the case for Mn^{III} porphyrins which exhibit metal-dependent charge transfer absorptions. This dependence appears to reflect significant π orbital–Mn^{III} interaction. Resonance Raman and linear dichroism spectral studies are also consistent with this conclusion.[667]

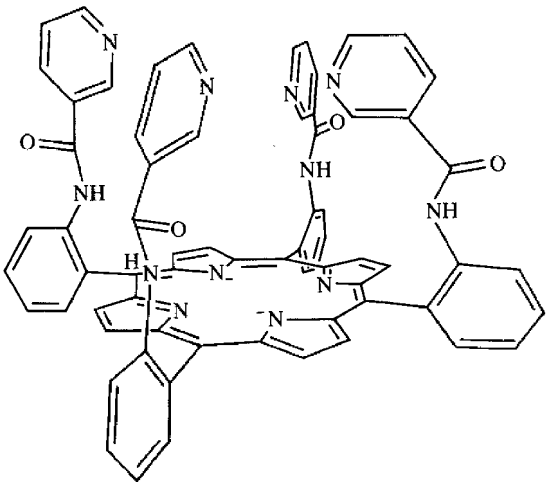
X-Ray structures of several Mn^{III} porphyrin compounds have been determined. Five-coordinate square pyramidal structures occur for [MnCl(TPP)],[668] $[MnN_3(TPP)]$[669] and [MnCN(TPP)][670] while *trans* pseudooctahedral geometries are found in $[MnN_3(TPP)(CH_3OH)]$,[668,671] and [MnCl(TPP)(py)].[672] For all these compounds the average inplane Mn—N bond lengths are near constant at 2.02 ± 0.1 Å. The manganese is displaced from the N_4-donor plane in each case with the displacement tending to be greatest for the five-coordinate species (0.23–0.27 Å). As expected from the smaller size of Mn^{III} the displacements in the latter compounds are less than that found in the related (high-spin) five-coordinate Mn^{II} compound, [Mn(TPP)(1-methylimidazole)]. In this case the Mn^{II} is positioned 0.56 Å above the donor plane.[483,488] Using spectrophotometric measurements the binding constant for formation of the latter 1:1 adduct with 1-methylimidazole was found to be 24.7 M^{-1} at 21°C.[673]

$[Mn(TPP)(CH_3OH)_2]^+$ as its perchlorate salt exists as two near identical independent ions in the solid state. The Mn^{III} is tetragonally coordinated with long Mn—O bonds in the axial positions.[673] The metal lies in the N_4-donor plane in each case.

The structure of the Mn^{III} compound $[Mn(TPP)imidazolate]_n$ consists of a linear polymer with imidazolate bridges between adjacent $[Mn^{III}(TPP)]^+$ moieties.[491] A curious feature of the structure is a short–short/long–long alternation of the Mn—N(Im) bond distances along the chain. This has been suggested to reflect alternating (predominantly) low- and high-spin Mn^{III} atoms in the chain. Before the synthesis of this compound all previously reported six-coordinated Mn^{III} porphyrins were high spin.[491] The unusual magnetic properties of the polymeric complex appear to reflect the enhanced ligand field strength of the deprotonated imidazole moiety. In accordance with this, the bis(imidazolate) compound $[Bu_4N][Mn(Im)_2(TPP)]$ is completely low spin.

Kinetic and equilibrium studies of the interaction of imidazole with a Mn^{III} porphyrin in aqueous solution have been reported.[675] Imidazole bonds to the Mn^{III} porphyrin in a step-wise fashion to yield initially an imidazole-bridged dimeric species followed by a monomeric bis(imidazole)–Mn^{III} porphyrin adduct.

Comparative variable-temperature magnetic susceptibility studies have been undertaken for [MnCl(TPP)] and [MnCl(TPP)(py)][676,677] and accurate estimates (-2.3 and $-3.0\ cm^{-1}$ respectively) of the zero-field splitting of the ground state of Mn^{III} in these compounds obtained. As expected the magnetic moments of both compounds at room temperature are close to the spin-only value for $S = 2$.



The reduction of Mn^{III} porphyrins [to Mn^{II} species] has been treated in Section 41.3.10.1.

Mn^{III} porphyrins may be electrochemically oxidized in non-aqueous media to yield Mn^{III} cation radicals and dications as the probable products.[485] The redox potentials depend on the nature of the solvent, counter ion present, pK_a of any axially-bound ligands as well as on the basicity of the porphyrin ring involved. Water-soluble Mn^{III} porphyrins are oxidized by a range of oxidants in aqueous alkaline solution to the corresponding Mn^{IV} porphyrins which appear to exist as μ-oxo dimers;[480] using hypochlorite as oxidant, a second oxidation step also occurs. In this case the product has been postulated to be a Mn^{V} oxo porphyrin. The Mn^{IV} and Mn^{V} porphyrins show only limited stability in water and revert to the stable Mn^{III} porphyrin upon standing in the dark for several

hours. Although in alkaline (or neutral) solution the initial oxidation product is a Mn^{IV} porphyrin, in acid the first electron may be removed from the π system of the porphyrin ring.

In other studies, reaction of [MnX(TPP)] ($X = N_3^-$ or OCN^-) with iodosylbenzene in hydrocarbon or halocarbon solvents yielded products formulated as μ-oxo dimers, $[Mn^{IV}X(TPP)]_2O$.[678] $[Mn^{IV}N_3(TPP)]_2O$ has been characterized by X-ray diffraction (see Section 41.5.7.1). Infrared evidence supports[678,679] the formulation of the dimers as being metal-centred oxidized products rather than containing porphyrin cation radicals; the possibility of ligand-centred *versus* metal-centred oxidation in higher-valent metallo porphyrins has been discussed by several authors.[680–682]

Meso-$\alpha,\alpha,\alpha,\alpha$-tetrakis(*o*-nicotinamidophenyl)porphyrin (**237**) is able to bind two metals in square planar environments which are orientated in planes coaxial with each other.[683] A number of studies using this ligand were instigated in attempts to obtain models for cytochrome *c* oxidase. However the coordination chemistry of this system is less straightforward than originally appeared, especially when involving substitution-labile metals such as Fe^{II}, Fe^{III} or Cu^{II}.[684] When an inert metal such as Ru^{II} is reacted with (**237**), coordination of the four pyridyl groups occurs to the ruthenium; ruthenium did not insert into the prophyrin under the conditions used. Once coordinated, the Ru^{II} appears to lock the nicotinic 'pickets' into place and hence inhibit the ligand isomerization reported to occur in the presence of more labile metal ions.[684] From this starting product, a mixed Ru^{II}/Mn^{III} product has been prepared. From cyclic voltammetric and spectrophotometric data, it was concluded that the proximity (~ 5 Å) of the two metal centres does not result in a major electronic perturbation of either metal in this case.

(237)

One motivation for the characterization of the above compounds has been to more fully understand the involvement of such higher valent manganese porphyrin complexes in model systems which imitate the catalytic activity of monooxygenase cytochrome P-450 and related enzymes. The catalytic cycle of cytochrome P-450 appears to involve the binding and reduction of molecular oxygen at a haem centre followed by the ultimate formation of a reactive iron oxo complex which is responsible for oxidation of the substrate. For example, cytochrome P-450 is able to catalyse alkane hydroxylation with great selectivity.

In model studies by Groves *et al.*,[685] an iron porphyrin was shown to catalyse the insertion of oxygen from iodosylbenzene into such hydrocarbons as cyclohexane; the enzyme can also cause the transfer of oxygen from iodosylbenzene.[686] It has been suggested[687] that the model reaction may proceed by oxygen atom transfer to yield an oxo–metal compound which then removes an aliphatic hydrogen atom followed by capture of the resulting carbon radical. Manganese porphyrin complexes, in the presence of a variety of reduced oxygen sources, have been demonstrated to act as a catalyst for the oxidation of alkanes, alkenes, alcohols, ethers, amines, phosphines and sulfides.[687–692] Equation (18) gives a typical reaction sequence.[692]

$$+ \text{PhIO} + [\text{MnX(TPP)}] \xrightarrow[25°C,\ N_2]{C_6H_6} \text{X} + \text{OH} + \text{other products} \qquad (18)$$

$$X = Cl, Br, I, N_3$$

In the majority of these reactions, higher valent (Mn^{IV} or Mn^{V}) compounds have been implicated in the respective reactions (*vide supra*). As mentioned previously, two μ-oxo Mn^{IV} porphyrin species have been characterized from the reaction of iodosylbenzene with Mn^{III} compounds of the type [MnX(TPP)].[678,690] These latter compounds are capable of oxidizing alkanes in good yield at room temperature, apparently *via* the intermediacy of alkyl free radicals.[693]

Within this general context, the formation of an acylperoxymanganese(III) species and its decomposition to an oxomanganese(V) species which undergoes oxygen atom transfer to alkenes has been investigated.[694]

Anchoring [MnOAc(TPP)] to a rigid polymer support considerably enhances the rate of cyclohexene epoxidation using sodium hypochlorite as the oxygen source.[695] This enhancement may be the result of site isolation restricting the formation of (less reactive) μ-oxo dimers during the formation of the higher-valent manganese species.

In the natural system, cytochrome P-450 catalyses reductive dioxygen activation to give the reactive iron oxo compound which is involved in the oxidation of the organic substrate. Such reductive dioxygen activation has been modelled by Tabushi *et al.*[696,697] using a $NaBH_4/Mn^{III}(TPP)/O_2$ redox system. In the presence of the reductant, $[Mn^{III}(TPP)]^+$ is converted to $[Mn^{II}(TPP)]$ which activates dioxygen to yield the strongly oxidizing species.

In a related reaction [MnCl(TPP)] has been reported to catalyse the specific oxidation of certain alkenes to ketones by molecular oxygen in the presence of $[NBu_4][BH_4]$;[688] the product ketones were then further reduced to alcohols under the conditions used. Related reactions involving $NaBH_4$ have been shown to convert ethylene to ethanol, propylene to acetone and *i*-propyl alcohol, and cholesterol to 3β,5α-dihydroxycholestane.[698] In these systems, molecular oxygen plus a reducing agent can be considered to be a substitute for the single oxygen donors such as iodosylbenzene. Colloidal platinum/H_2 will also effect the $[Mn^{III}(TPP)]^+$ to $[Mn^{II}(TPP)]$ reduction.[699] The relative reactivities of alkenes using the $H_2/[Mn^{III}(TPP)]^+/O_2$ system have been shown to closely resemble those for the $[Mn^{III}(TPP)]^+/C_6H_5IO$ system. A related biphasic system involving ascorbate as the reducing species has been reported.[700]

In an extension of the above studies involving oxygen atom transfer, Breslow and Gellman[701] have carried out a related amidation involving tosylamidation of cyclohexane to yield *N*-cyclohexyltoluene-*p*-sulfonamide in the presence of [MnCl(TPP)]; equation (19).

$$C_6H_{12} + PhI{=}NSO_2C_6H_4Me\text{-}p + [MnCl(TPP)] \xrightarrow[25°C,\ argon]{CH_2Cl_2} C_6H_{11}NHSO_2C_6H_5Me\text{-}p + \text{other products} \quad (19)$$

There appears to be considerable promise for other related metal-porphyrin catalysed nitrogen insertions for obtaining amides and amines. In this context, Groves and Takahashi[702] have reported the activation and transfer of nitrogen from a nitridomanganese(V) porphyrin complex, the reaction investigated being the aza analogue of epoxidation.

41.4.8.2 Phthalocyanine ligands

A number of Mn^{III} compounds of type [MnXPc] (where X is a singly charged monodentate ligand) have been prepared from [MnPc].[703,704] For example, reaction of [MnPc] with $SOCl_2$ or $SOBr_2$ yields [MnClPc] and [MnBrPc], respectively.[704] All these compounds exhibit high-spin d^4 magnetic moments of about 4.9 BM.

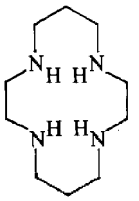
Reaction of [MnPc] with oxygen in pyridine which has not been rigorously purified yields the μ-oxo dimer, [pyPcMn^{III}—O—Mn^{III}Pcpy].[522–524] This purple compound has been studied by X-ray diffraction.[524] The structure contains two near flat and parallel MnPc systems joined by an oxygen atom which is midway between the manganese atoms. Each manganese has a pyridine bound opposite to the oxygen atom.

As discussed in Section 4.3.10.2, the dinuclear species reacts with oxygen in dimethylacetamide quantitatively to form the adduct $[MnPcO_2]$ which is formulated as containing Mn^{III} and a superoxo ion.[522] The dinuclear species is unstable in dimethylacetamide (or dimethylformamide) *in vacuo* to yield a mixture of mononuclear M^{II} and M^{III} compounds which in white light are cleanly photoreduced to [MnPc].[705]

The electrochemistry of the dinuclear compound has also been investigated; this compound undergoes a one-electron oxidation (+0.35 V *vs.* SCE) in pyridine to yield a species which is presumably mixed valent. It also undergoes a four-electron reduction (at −0.9 V) to yield two

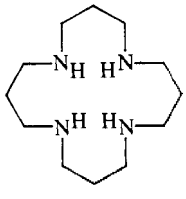
molecules of a species formulated as $Mn^{II}(Pc^{3-})$. An investigation of the reduction process indicates that an ECE mechanism takes place in this latter case. The presence of a Mn—O—Mn moiety in the dimeric species appears to shift the redox behaviour of the metal centres to potentials that are 700 mV more negative. As such, a Mn^{IV} state appears accessible for this system. The electrochemical generation of Mn^{III} phthalocyanine from [MnPc] under different conditions has already been discussed in Section 41.3.10.2. Related photochemically induced redox transitions have also been reported.[705] A study of the electrochemistry of mononuclear $[Mn^{III}OHPc]$ has also been performed.[706] This high-spin hydroxy species is readily prepared by treatment of the binuclear compound with water; the Mn—O—Mn bridge is quite susceptible to cleavage by nucleophiles. The voltametry of the hydroxy species is typical of $[Mn^{III}XPc]$ compounds with X being strongly bound. The cyclic voltammogram of the hydroxy compound in pyridine gives potentials for the Mn^{III}/Mn^{II} couple and for two successive one-electron reductions which are, as expected, virtually the same as those obtained for $Mn^{II}Pc$ species under related conditions.[521]

An artificial 'haemoglobin' has been synthesized in which Mn^{III} tetrasulfonated-phthalocyanine (TsPc) was used to replace the haem group.[707] On the basis of spectroscopic data, the product has been formulated as $[Mn^{IV}OPc]$·globin. Electrophoresis and molecular weight determinations indicate that the compound is dimeric. The compound does not reversibly bind oxygen and cannot act as a physiological carrier of oxygen. However, [MnOPc]·globin does have an affinity for additional ligands such as CN^-, CO, NO and imidazole.



In the solid, the dioxygen adduct of $[Mn^{II}(TsPc)]$ is best formulated as $[Mn^{III}(TsPc)O_2^-]$.[708] In solution, the ESR spectrum as a function of pH suggests that intramolecular electron transfer may occur between $[Mn^{II}(TsPc)O_2]$ and $[Mn^{III}(TsPc)O_2^-]$. The superoxide is only stable within the approximate pH range 11.5 to 13.5. Reaction of $[Mn(TsPc)O_2]$ with hydrazine hydrate has been reported to produce [Mn(TsPc)].[709]

41.4.8.3 Other nitrogen donor ligands



Largely because a manganese porphyrin containing the metal in a high oxidation state appears to be involved in the photosynthetic process,[710] a number of studies involving nitrogen donor synthetic macrocycles have been carried out in order to examine the oxidation states accessible to this ion as a function of macrocycle structure. Mn^{III} compounds of such macrocyclic ligands have been generated both chemically and electrochemically, and for a number of systems of this type, Mn^{III} appears to be the preferred oxidation state.

Mn^{III} species of cyclam (**238**) of type $[MnX_2(\mathbf{238})]^+$ (X = Cl, Br, NCS or N_3) have been prepared.[711] All compounds are high spin and appear stable indefinitely in the solid state. From spectral evidence the compounds were assigned *trans* octahedral structures. The species $[MnCl_2(\mathbf{238})]^+$ was obtained by reaction of (**238**) with manganese(II) chloride in methanol; oxidation was then effected by bubbling air through the solution for six hours. The product precipitated as its chloride salt on addition of concentrated hydrochloric acid to the reaction solution. The other compounds in the series were obtained from $[MnCl_2(\mathbf{238})]Cl$ by exchange reactions involving the chloro ligands.

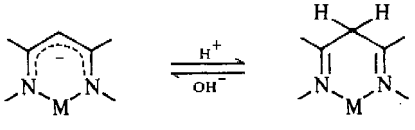
In other studies, Mn^{III} compounds of cyclam (**238**) and the related 15-membered ring (**239**) have been reported.[712] The compounds are of types $[MnX_2(\mathbf{238})]Y$ (X = Cl, Y = BF_4; X = Br, Y = Br_3, PF_6) and $[MnBr_2(\mathbf{239})]Y$ (Y = Br_3, PF_6) and were synthesized by reaction of anhydrous Mn^{II} chloride or bromide with the appropriate macrocycle in refluxing methanol (under nitrogen) following by oxidation to the Mn^{III} products using chlorine or bromine. The BF_4^- and PF_6^- salts were obtained by metathesis reactions involving the initial product from each preparation. Once again, the compounds have been assigned six-coordinate, high spin (d^4) structures in which the macrocycles coordinate to the Mn^{III} in a planar fashion.

(238)

(239)

Mn^{III} species of the *meso* form of the fully saturated N_4-macrocycle (**194**) may be prepared by oxidation, using a range of oxidants (such as chlorine, bromine, oxygen, nitrosonium salts and hydrogen peroxide), of the corresponding Mn^{II} species (see Section 41.3.10.3).[533] However the most efficient route involves oxidation of the product formed from Mn^{II} acetate and the macrocycle with $NOBF_4$ or $NOPF_6$ followed by addition of HX to give products of type $[MnX_2(\mathbf{194})]Y_2$ (where X = Cl, Br; Y = BF_4, PF_6^-). These Mn^{III} species display magnetic moments and electronic spectra which are consistent with high spin, tetragonally distorted d^4 systems. They are more stable to pH variation than are the Mn^{II} analogues. These Mn^{III} compounds are more readily reduced than a number of Mn^{III} porphyrins.

Corresponding complexes of the *racemic* form of (**194**) have also been obtained.[713] The *racemic* macrocycle was initially resolved as its nickel species and, after removal of the nickel, the optically-active macrocycle was used to prepare Mn^{III} compounds by a similar procedure to that given above for compounds of the *meso* ligand.

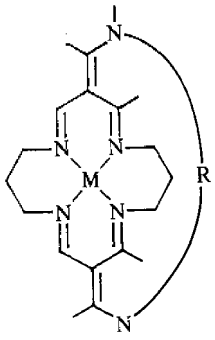


Two high spin Mn^{III} compounds of the pyridine-containing 15-membered macrocycle (**198**) of type $[MnX_2(\mathbf{198})]PF_6$ (X = Cl, Br) have been isolated after oxidation of the corresponding Mn^{II} complexes in acetonitrile with $NOPF_6$.[534] These compounds have been assigned pentagonal bipyramidal coordination geometries in which the macrocycle coordinates in a planar manner; reports of such a geometry for Mn^{III} are rare. Both compounds are high spin with magnetic moments of 4.94 BM. The analogous 16- and 17-membered N_5 ligands appear not to stabilize Mn^{III} and it has been suggested that these ligands may fold to yield octahedral Mn^{II} species in which the nitrogens of the macrocycle occupy one axial and four equatorial positions. The remaining axial position is filled by a halide ion. It is perhaps significant in this context that attempts to oxidize the octahedral Mn^{II} species of the N_4 macrocycle (**195**) to the corresponding Mn^{III} compounds were unsuccessful.

High spin Mn^{III} products of the dianionic N_4 macrocycle (**196**) of type [MnX(**196**)] where X is Cl, Br, SCN and N_3 have been prepared.[535] The chloro and bromo derivatives crystallize with a molecule of acetonitrile while the thiocyanate and azide derivatives were obtained unsolvated. In the former compounds, the acetonitrile may be weakly coordinated to the manganese ion. An X-ray structure determination of [MnNCS(**196**)] indicates that it has a square pyramidal coordination geometry with the NCS^- group N-bonded and coordinated in the axial position. As in other structures of this ring system, the macrocycle has a pronounced saddle shape. The Mn^{III} ion is displaced 0.356 Å from the N_4-donor plane.[714] The overall structure is similar to that of the Mn^{II} species, [Mn(**196**)NEt_3], discussed previously.[536]

The azide compound exhibits a slightly reduced magnetic moment (μ_{eff} = 4.78 BM);[535] this suggests the presence of antiferromagnetic coupled Mn^{III} ions (*via* an N_3^- bridge) in this compound.

Except for the azide derivative, the various Mn^{III} compounds gave similar electrochemical behaviour.[715] Each compound showed two one-electron oxidation steps, the first being reversible and the second somewhat irreversible. Evidence suggests that these oxidations essentially involve the coordinated macrocycle. Each compound exhibits a one-electron reduction wave which has been assigned to the conversion of Mn^{III} to Mn^{II}. It is evident that, relative to the saturated macrocycle (**194**),[533] the dianionic ligand (**196**) stabilizes Mn^{III} over Mn^{II}. No evidence for the generation of Mn^{IV} species was obtained during these studies.



All the above Mn^{III} compounds of (**196**) are stable as solids under dry nitrogen although they slowly decompose in air.[535] They also decompose in aqueous base but in acid undergo reversible protonation. The protonation site is probably the alkenic carbon of the β-diketone fragment; equation (20). Ni^{II} complexes of related macrocyclic ligands have been reported to undergo similar protonation reactions.[716,717]

(20)

In situ condensation of 2,6-diaminopyridine and acetylacetone has been proposed to yield compounds of type [MXL] (where LH_2 is the N_6-cyclic ligand formed by condensation of two molecules of each of the above precursors;[718] M = Cr, Mn, Fe or Co; and X is a range of mono anions). The structure of the Mn^{III} species (and, indeed of all of the compounds) was proposed to be square pyramidal; the pyridine nitrogens of the organic ligand were assumed not to bind to the Mn^{III}. However non-coordination of these donors would appear to induce considerable strain into the macrocyclic system and hence, in the absence of full X-ray structural data, the assigned structure should be considered tentative.

Reaction of tris(2,4-pentanedionato)manganese(III) with either of the macrobicyclic ligands of type (**240**) in acetonitrile leads to isolation of compounds of type $[MnClL](PF_6)_2$ in each case.[719] These compounds are five-coordinate and high spin. Both display slow but efficient catalase activity; both react smoothly with hydrogen peroxide in acetonitrile but the rate of oxygen evolution is much slower than for an effective catalase model compound based on Fe^{III} studied previously.[720] The manganese species gave no evidence that they exhibit peroxidase activity since, in the presence of phenolic substrates, no oxygenation activity was detected.[719]

(**240**) R = $(CH_2)_6$
R = *m*-xylylene

Electrochemical reduction of the Mn^{III} species leads to isolation of the corresponding high spin Mn^{II} compounds. The latter react irreversibly with dioxygen to regenerate the deprotonated forms of the respective Mn^{III} compounds.

41.5 MANGANESE(IV)

Manganese(IV) chemistry is dominated by the insoluble MnO_2, which forms so readily in aqueous solutions; and indeed the great bulk of Mn^{IV} chemistry involves compounds in which the metal's coordination partners are O-donor ligands. As well, in recent years, the range of known coordination partners for Mn^{IV} has been significantly extended: we now know of reasonably robust tetraalkyls $[MnC_4P_2]$, there are $[Mn^{IV}S_6]$, $[Mn^{IV}Cl_6]$ and $[Mn^{IV}F_6]$ compounds and some compounds with nitrogen ligands including porphyrins.

Except in the few cases where there is antiferromagnetic coupling between adjacent metal atoms, the compounds are high spin d^3 ($S = \frac{3}{2}$) species and the great majority of them are octahedral.

Some at least of the observable Mn^{IV} chemistry derives from the disproportionation of the Mn^{III} species, rather than from direct oxidation of the latter.

Many of the Mn^{IV} species are redox unstable and have significant existence because they react slowly. The ubiquitous MnO_2 is one example; and there is another in the insoluble $Mn(SeO_3)_2$, which precipitates from a solution of Mn^{II} and H_2SeO_3 in water.

One of the more interesting developments in Mn chemistry has been the recent demonstration of a thermal equilibrium between oxidation states II and IV in an $[MnO_4N_2]$ system, details of which may well offer the key to an understanding of the role of Mn in O_2 production in the photosynthetic system. Undoubtedly the continuing search for an understanding of this system will produce further advances in our understanding of Mn chemistry.

41.5.1 Carbon Ligands

Cyano compounds of Mn^{IV} are properly characterized only for the hexacyano anion $[Mn(CN)_6]^{2-}$: it has been isolated, as the yellow K^+ salt,[51] from the oxidation of the Mn^{III} anion in DMF with NOCl. It is immediately decomposed by deaerated water, with the separation of MnO_2. Magnetic measurements ($\mu_{eff} = 3.94$ BM) show it to be a high spin d^3 species. Perhaps surprising, in view of the reactivity of this anion, it has now been shown[574] that $Mn(CN)_3 \cdot nH_2O$, which precipitates from aqueous acid solutions of $[Mn(CN)_6]^{3-}$, has a cubic, Prussian blue type structure and should be formulated as $Mn^{II}[Mn^{IV}(CN)_6] \cdot nH_2O$. Impure samples of analogous compounds, in which Zn^{II} and Cd^{II} replace the Mn^{II}, also have been obtained.

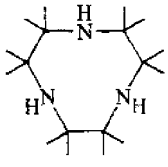
'$K_4Mn(CN)_8$' does not exist. It is one of those chimeras that seem to persist through acquiring textbook status before being debunked: products, which were described as such, were mixtures containing Mn^{III}—O—Mn^{III} species.

The relatively robust, tetrahedral, green, volatile MnR_4 (R = norbornyl) was reported in 1972 from the reaction of LiR and $MnCl_2$ in petroleum,[721] and the oxidation mechanism leading to the Mn^{IV} species in still apparently unexplained.[63] Related, but less thermally robust green compounds of 2-methyl-2-phenylpropyl and trimethylsilylmethyl were described by Wilkinson and co-workers[63] as arising when traces of O_2 were admitted to a solution of the Mn^{II} alkyl, and were identified particularly by their ESR spectra as $S = \frac{3}{2}$ species.

More recently octahedral [$MnMe_4$dmpe] has been isolated from a reaction that involves disproportionation of the Mn^{III} species.[576] The reaction of [$Mn(acac)_3$] with dmpe and MeLi in diethylether at −78°C gives a clear yellow solution, from which yellow crystals of the Mn^{IV} compound {and then the orange [$MnMe_2(dmpe)_2$]} were obtained. In another similar reaction [$MnMe_4(PMe_3)_2$] also was obtained. Such reactions would appear to offer a route to the exploration of an extensive chemistry of Mn^{IV} alkyls.

Yellow [$MnMe_4$dmpe] is a high spin compound (μ_{eff} = 3.87 BM in solution) and an X-ray analysis of its structure[576] shows Mn—P = 2.50 Å and Mn—C = 2.07 Å (*trans* to P) and 2.12 Å (*trans* to C).

41.5.2 Nitrogen and Phosphorus Ligands



Knowledge of nitrogen ligands, apart from the macrocyclic, and especially the porphyrin ligands, (Section 41.5.7) is confined to just a few compounds, which also have other ligands in their coordination sphere.[572]

Black [$MnCl_4$bipy] (with μ_{eff} = 3.82 BM) is one of the compounds formed in the reactions of $KMnO_4$ and bipy with concentrated aqueous HCl. It loses Cl_2 at room temperature.

Still reactive, but nonetheless well characterized are the μ-dioxo dimers noticed in Section 41.4.2. The reaction of bipy or phen and $KMnO_4$ in concentrated HCl produces green μ-dioxo species (**222**), which contain both Mn^{III} and Mn^{IV}. The latter has, of course, the shorter bond lengths (Mn—O = 1.784 and Mn—N = 2.02–2.08 Å, compared to 1.85 and 2.13–2.23 for Mn^{III}). Oxidation to the red, fully Mn^{IV} dimer, according to equation (16), occurs in CH_3CN at $E_{1/2}$ = 1.33 V (*vs.* SCE), for both bipy and phen; and the phenanthroline species has been isolated as [$Mn_2O_2(phen)_4$]-$(ClO_4)_4 \cdot H_2O$. Its magnetic moment is 1.86 BM at room temperature, reducing to 1.36 BM at 94 K. ESR data confirm the equivalency of the two Mn atoms and the absence of any significant electron pairing between them in solution (for bipy, g = 2.03 and A = 83 G).

Again, as for Mn^{III} (Section 41.4.2), there are some biguanide compounds,[722] which have been described as Mn^{IV} μ-dioxo species of similar type to the above; but there is a need for further characterization, especially, if possible, by X-ray techniques.

An even more interesting vista is opened up by a recent report of a tetranuclear [$Mn_4^{IV}O_6$] compound with the terdentate ligand (**241**).[723] The reaction of aqueous solutions of the amine and $MnCl_2$ in water with O_2 produces a black solution, and the addition of NaBr, and adjustment to pH 8, gives needle-like crystals of $[Mn_4O_6L_4]Br_{3.5}OH_{0.5} \cdot 6H_2O$.

(241)

An X-ray analysis shows the Mn_4O_6, adamantane-like nucleus (*cf.* the S analogue in Section 41.3.6.1) with each Mn atom also bonding to the terdentate amine ligand, giving [MnO_3N_3] octahedra {average bond lengths: Mn—O = 1.79 Å and Mn—N = 2.08(1) Å; and O—Mn—O = 128.7(8)°}. The magnetic moment of 3.96 BM per Mn suggests very little, if any, antiferromagnetism.

It would be surprising if this is not the first of many such cluster compounds to be detected, and they may form a class like the basically trinuclear carboxylates (Section 41.4.3.3).

Phosphine ligand compounds of Mn^{IV} are confined to the phosphine alkyls of Section 41.5.1, and $[MnCl_2(diphos)_2]Cl_2$ of Table 17 (Section 41.3.4). There are no authenicated arsine compounds.

41.5.3 Oxygen Ligands

41.5.3.1 Water, hydroxide and oxide

There is no evidence for the significant existence of an Mn^{IV} aquo species in water, nor for the binary hydroxide $Mn(OH)_4$, nor indeed for a definite oxide hydrate: the aqueous chemistry of Mn^{IV} is dominated by the insoluble MnO_2.[211,572]

Yet the $[Mn(OH)_6]^{2-}$ octahedron is found in the yellow-green to orange mineral jouravskite[724] $Ca_3Mn(OH)_6 \cdot CO_3 \cdot SO_4 \cdot 12H_2O$, in which the Mn—OH distance has been measured at 1.87 Å; and in despujolsite[725] $Ca_3Mn(SO_4)_2 \cdot (OH)_6 \cdot 3H_2O$ (Mn—O = 1.92 Å).

MnO_2 exists in an almost bewildering array of different structural types.[4–6,210,572,726] Most of them are non-stoichiometric, and contain more or less H_2O, OH^- and/or other metal atoms. It has been suggested that such phases, in the range of MnO_n (n = 1.7–2.0), whether synthetic or natural, should be designated by the German language name 'Braunstein'.[725] Of the known phases, only the β-modification (pyrolusite) corresponds in oxidation state and chemical purity to 'MnO_2'. The different modifications find widespread use in quite diverse areas of industry: from the Leclanché dry cells; through [O] sources in welding rods, safety matches, explosives and fireworks; as additives in glasses and cements; as ion-exchangers in water; to a wide range of applications as a catalyst, especially in oxidizing reactions.

Known forms of MnO_2 and the great bulk of other binary and ternary oxides[211] all contain octahedrally coordinated Mn^{IV}, with Mn—O distances averaging near 1.9 Å (Table 53), paralleling the situation in all known compounds of the chelating oxygen ligands.

However, there is at least one example of an $[MnO_4]^{4-}$ tetrahedron: Ba_3MnO_5 has the Cs_3CoCl_5 structure[572] and thus contains discrete tetrahedra. Such tetraoxomanganate tetrahedra dominate the chemistry of the higher oxidation states V to VII, and have been observed in the dimeric Mn^{III} compound $K_6[Mn_2O_6]$ (Section 41.4.3.1). It is not unlikely that, as the solid state structural chemistry of Mn^{IV} is further elucidated, more of these tetrahedra will be found and they may be significant in aqueous alkaline solutions. There are probably other examples in the solids reported by Scholder and co-workers.

Bridging oxide ligands are beginning to be detected in various oligomeric/cluster compounds: $[Mn_3O]$ (Section 41.4.3.3), $[Mn_2O_2]$ and $[Mn_4O_6]$ (Section 41.5.2) units are now known.

Table 53 Some of the Binary and Ternary Oxides of Mn^{IV}

Compound	*Comments*		*Bond Lengths* (Å) *Av.*	*Range*
MnO_2 (β-form)	Tetragonal rutile type	$[MnO_6]$	(1.88)	
Ramsdellite		$[MnO_6]$	(1.89)	1.86–1.92
Mn_3O_8	$(Mn^{II}_2Mn^{IV}_3O_8)$	$[MnO_6]$		1.85–1.92
$M^{II}_2Mn_3O_8$	M = Cu, Co, Cd	$[MnO_6]$		1.81–2.00
Li_2MnO_3 α	NaCl structure type	$[MnO_6]$		
β	$NaFeO_2$ superstructure of NaCl	$[MnO_6]$		
$BaMnO_3$	$CsNiF_3$ structure	$[MnO_6]$		1.88–1.91
$NiMnO_3$	Ilmenite structure	$[MnO_6]$		
Mg_2MnO_4	Cubic spinel			
M_2MnO_4	(M = Ca, Sr, Ba) Tetragonal K_2NiF_4 layer structure	$[MnO_6]$		
$CaMn_3O_7$				
$Ca_3Mn_2O_7$	$Sr_3Ti_2O_7$ type			
$Ca_4Mn_3O_{10}$	Isostructural with $Ca_4Ti_3O_{10}$	$[MnO_6]$		
$ZnMn_3O_7 \cdot 3H_2O$	Chalcophanite	$[MnO_6]$		
Mg_6MnO_8		$[MnO_6]$	(1.93)	
Sr_2CrMnO_6	Disordered perovskite	$[MnO_6]$	(1.94)	1.85–1.96
			(1.91)	
$CaCu_3Mn_4O_{12}$	Perovskite-like structure	$[MnO_6]$	(1.92)	
Ba_3MnO_5	Isotype of Cs_3CoCl_5—tetrahedral	$[MnO_4]^{4-}$		

41.5.3.2 Peroxo

There are arguments in the literature that the products of reversible oxygenation of Mn^{II} porphyrins should be regarded as Mn^{IV}–peroxo (η_2) species (Section 41.3.5.1.vi); and, although yet unproven, this does seem to fit with the emerging pattern of Mn chemistry.

Unlike its neighbour Cr, which also forms high oxidation state tetraoxo species, Mn does not form robust compounds containing peroxo ligands. The reaction of alkali tetraoxomanganate(VI) or Mn^{II} species with H_2O_2 in cooled, concentrated alkaline solutions gives slightly soluble red-brown to brown crystalline products, which are probably peroxomanganate(IV) species.

The product was dependent on concentration of alkali, and Scholder and Kolb[727] claimed the preparations of pure $M_2H_2[Mn(O_2)_3O]$ (M = Na, K), and of mixtures containing the compounds $M_3H[Mn(O_2)_4]$ (M = Na, K), $K_3H[Mn(O_2)_3O]$ and $K_4[Mn(O_2)_4]$. Undoubtedly, they were peroxo compounds, but confirmation of their structures must await X-ray data. They are unlikely to find much use: when dry they detonate above 0°C.

$K_2H_2[Mn(O_2)_3O]$ gives a red-brown aqueous solution, from which O_2 is slowly evolved, with precipitation of MnO_2.

41.5.3.3 Oxyanions

In these compounds the $[MnO_6]$ octahedron is clearly becoming unstable: the known compounds are not generally robust, but there are several interesting exceptions. There are yet no indications of any coordination polyhedron other than the octahedron.

Oxalate forms the only known carboxylato species—the green $K_4[Mn_2O_2(Ox)_4]\cdot nH_2O$ and apparently another orange coloured compound of unknown type.[572,728] The green dimer can be kept for *ca.* one week at −6°C, in the dark; but useful physical measurements have been made and its decomposition studied.[728]

Mn^{IV} phosphato species are formed[729] in solution only at very high $[H_3PO_4]$, by the reaction of $KMnO_4$. Such brown-red solutions, on standing or upon dilution, deposit the insoluble Mn^{III} species $MnPO_4\cdot H_2O$. Black plates, formulated as $[NH_4]_2Mn(PO_4)_2\cdot H_2O$, and the flesh-pink coloured solid obtained from concentrated aqueous H_3AsO_4 and formulated as $Mn(H_2AsO_4)_4$, may be examples of Mn^{IV} species; but further characterization is needed.

With the group VI oxyanions, sulfates and tellurates are probably represented in some of the reported data, but the major interest is in the insoluble selenite $Mn(SeO_3)_2$. $Mn(SO_4)_2$ may be represented[592] in the unstable black solid that can be prepared from $MnSO_4$ and $KMnO_4$ in 55% H_2SO_4. It dissolves in cold 40–70% H_2SO_4, forming a brown solution, which probably contains Mn^{IV} sulfato species. And some tellurates have been described as $Na_7H_7Mn(TeO_6)_3\cdot 3H_2O$ and $K_6H_8Mn(TeO_6)_3\cdot 5H_2O$, but not firmly characterized.

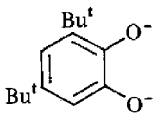
Thus the ready preparation of $Mn(SeO_3)_2$ stands in contrast: it can be made[730] as orange-red crystals in high yields by reacting aqueous Mn^{II} and H_2SeO_3 on the water bath; MnO_2 and SeO_2 in boiling water, or in a sealed flask at 250–300°C; Se and MnO_2 in aqueous H_2SO_4; or $KMnO_4$ and SeO_2 in water. The reaction (21) is reversible. Clearly, $Mn(SeO_3)_2$ represents a significant energy minimum for the Mn/Se/O system, and it is interesting to note that $Mn^{II}(IO_3)_2$ is an energy minimum in the Mn/I/O system.

$$MnSeO_4 + SeO_2 \underset{400°C}{\overset{200°C}{\rightleftharpoons}} Mn(SeO_3)_2 \qquad (21)$$

Iodato compounds of Mn^{IV} are known, having been first described by Berg in 1899; but do not appear to have been obtained free from Mn^{III} materials.[279] Amber or brown solutions can be obtained by dissolving MnO_2 in iodic acid and adding some periodate. Such solutions are robust in sealed quartz tubes, but in glass deposit red $K_2Mn(IO_3)_6$. A recent[731] study of the solid products has detected a range of solid solutions from $K_2Mn(IO_3)_6$ to $K_3H_2Mn(IO_3)_9$; and salts with other cations are known.

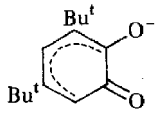
Periodate oxidizes Mn to $[MnO_4]^-$, but, with the proper choice of conditions, Mn^{IV} compounds (unstable now to oxidation rather than reduction) can be isolated. Red $Na_7H_4Mn(IO_6)_3\cdot 17H_2O$ and $K_7H_4(IO_6)_3\cdot 8H_2O$ have been described, and an X-ray analysis of the former showed a tris-bidentate $[Mn^{IV}O_6]$ species with Mn—O = 1.90 Å. The red, insoluble compounds $NaMnIO_6$ and $KMnIO_6$ are isostructural[732] with $NaNiIO_6$.

Another octahedral oxyanion $[Mn^{IV}O_6]$ species has been characterized[733] in one of the products



of evaporation of an aqueous solution of $HMnO_4$: violet $(H_3O)_2[Mn(MnO_4)_6]\cdot 5H_2O$ is unstable above $-4°C$.

And there is a range of heteropoly- and isopoly-anion compounds of Mn^{IV} with V, Nb, Ta, Mo and W (Table 26), most of which appear to be $[MnO_6]$ species.



41.5.3.4 Di- and polyhydroxy ligands, including catechol

A range of polyhydroxy and polyhydroxy-carboxylate manganese compounds has been shown to be oxidizable to Mn^{IV}, and one of them, the tris-chelate of the dianion of sorbitol, has been isolated[734] as a red-brown hygroscopic solid $(NMe_4)_2[Mn(C_6H_{12}O_6)_3\cdot 6H_2O$. Such compounds have been known[316] since Schottländer reported some yellow glycerate species $Na_2[MnL_3]$ and $Sr[MnL_3]$ in 1870; but they have only recently been studied in some detail.[734] Although X-ray data are not available, the sorbitolate compound appears to be another example, like the periodate (Section 41.5.3.3) of a tris-chelated Mn^{IV} anion, using two adjacent hydroxy groups of the sorbitol.

More detail is available on the chelated Mn^{IV} compounds of the anion of one of the catechols —3,5-di-*ter*-butylcatecholate (**242**). The Mn compounds of this dianion, in the presence of an excess of the ligand, can be oxidized to the Mn^{III} (Section 41.4.3.4) and Mn^{IV} species.[282] X-Ray analyses of the tris-chelated Mn^{IV} anion $[MnL_3]^{2-}$ give Mn—O bond lengths[735,736] between 1.89 and 1.92 Å. There are conflicting reports about the possibility of this anion supporting reversible binding of O_2.[282,737] The final explanation of the observed phenomena[282,737] will probably involve ligand oxidation to the semiquinone form (**243**).

(242)

(243)

The latter is almost certainly involved in an interesting thermal equilibrium (22), which has been observed in both pyridine and toluene solutions. When $[Mn_4^{II}L_8]$ (L = **243**) (Section 41.3.5.3.ii) was treated with py, purple crystals $[Mn^{IV}L_2py_2]\cdot 2py$ (L = **242**) were obtained. An X-ray analysis[738] proved the Mn^{IV}/catecholate formulation {Mn—O = 1.854(2) and Mn—N = 2.018(3) Å}, and a spectrophotometric study of the equilibrium (22) showed that the Mn^{IV} form prevails at low temperature in the solutions. There seems to be a real possibility that some such redox changes may offer an explanation of the role of Mn in biological photosynthetic water oxidation.

$$\underset{\text{Green}}{[Mn^{II}(\mathbf{243})_2py_2]} \rightleftharpoons \underset{\text{Purple}}{[Mn^{IV}(\mathbf{242})_2py_2]} \qquad (22)$$

41.5.3.5 Other ligands

Electrochemical studies[314,613] have shown that the $[Mn(bipyO_2)_3]^{2+}$ and $[Mn(terpyO_3)_2]^{2+}$ cations can be oxidized to the Mn^{IV} species in CH_3CN. The spectra of the Mn^{IV} cations were measured, but they are rather unstable and were not isolated.

There have also been some reports in the literature of Mn^{IV} compounds of acetylacetonate, but they have not yet been fully substantiated.

41.5.4 Sulfur Ligands

No binary or ternary phases containing Mn^{IV} sulfides appear to have been described; but well characterized, although reactive and somewhat difficult to handle, compounds are known with both 1,1- and 1,2-dithiolates.

As noticed in equation (8), the tris-*dialkyldithiocarbamato*-manganese(III) compounds $[Mn(R_2dtc)_3]$ are readily oxidized to the monocations[329,330] (oxidation potentials for the 16 compounds studied varied between 0.25 and 0.53 V). Such oxidations have been achieved chemically by

adding BF_3 to CH_2Cl_2 solutions of $[Mn(R_2dtc)_3]$ in the air, whence oxidized $[Mn(R_2dtc)_3]BF_4$ species were obtained; and, alternatively, by mixing benzene solutions of the Mn^{III} compound with acetone solutions of $[Mn(H_2O)_6]X_2$ ($X = ClO_4$, BF_4), whence either the ClO_4^- or BF_4^- salts were obtained. (The oxidizing agent in each case appears to have been O_2.)

The dark purple compounds $[Mn(R_2dtc)_3]X$ have magnetic moments typical of high spin d^3 systems (3.70–4.25 BM), and give EPR signals with isotropic g values and small hyperfine interaction. Confirmation of the $[Mn^{IV}S_6]$ structure of these compounds is given by an X-ray analysis of the piperidine compound $[Mn\{S_2CN(CH_2)_5\}_3]ClO_4 \cdot CHCl_3$: the tris bidentate species has Mn—S distances between 2.325 and 2.353 Å, averaging at 2.33 Å.

Tris-dithiolenemanganese compounds are known[324,325] only in the Mn^{IV} oxidation state, just as the bis compounds are only known as Mn^{II} (Section 41.3.6.2). Green crystals of $M_2[Mn(mnt)_3]$ ($M = PPh_4^+$ and $AsPh_4^+$) were prepared from $Mn(OAc)_3$, and black crystals of $[NR_4]_2[Mn(S_2C_6Cl_4)_3]$, giving magenta solutions, were prepared either from Mn^{II} in the air, or from $KMnO_4$. All have magnetic moments near 4 BM which is typical of high spin d^3 systems. Electrochemical studies have shown that they can be reduced in two one-electron steps and oxidized in two one-electron steps, but none of the reduced or oxidized species have been isolated. Identity of X-ray powder patterns with the Fe analogue suggests that $[AsPh_4]_2[Mn(mnt)_3]$ has the same octahedral structure defined for the Fe compound.

A recent report[739] describes several mixed ligand compounds $[Mn(R_2dtc)_2X_2]$ (X = Cl, Br).

41.5.5 Halides

The only binary halide known is the fluoride MnF_4; and, although ternary compounds are well established for both F^- and Cl^-, the latter are particularly unstable at normal temperatures and all are, to varying degrees, sensitive to water.[210,336,572]

MnF_4, known since 1928, has now been obtained in single crystals,[740] which have a trigonal unit cell, but the structure has not yet been reported. The ultramarine blue solid is very hygroscopic, loses F_2 slowly at normal temperatures and hydrolyses instantly in contact with water.

Three classes of ternary fluorides are known (Table 54). Red $O_2^+[Mn_2F_9]^-$ is the only representative of this class;[741] but all of the alkali metal species $MMnF_5$ are known. The former is polymeric, with double chains of linked $[MnF_6]$ octahedra, and, although structural analyses are not available, it seems certain that the brick-red $MMnF_5$ spp. also contain chains of $[MnF_6]$ octahedra. Magnetic moments, except for the O_2^+ species, are near 3.8 BM. They were first prepared by Hoppe and co-workers by fluorinating $MMnF_3$ at 450–510°C in a flow system, but details have now been given[742] of a wet method using 48% HF. This method also gave an interesting pyridine compound formulated as $MnF_4 \cdot py \cdot H_2O$, which is described as quite robust at normal temperatures, although having a faint odour of pyridine. Undoubtedly a wide range of N-donor compounds of similar type will be obtainable.

The third class of ternary fluorides is the simplest one—the compounds $M_2[MnF_6]$. All are yellow or orange-yellow with magnetic moments near 3.8 BM, as expected for octahedral Mn^{IV}. They crystallize in various forms: the alkali metal salts, being known in two hexagonal forms (one having the $Na_2[SiF_6]$ structure), a trigonal and a cubic form (the latter having the $K_2[PtCl_6]$ structure). The salts $M[MnF_6]$, for M = Mg, Ca, Cd, Hg have the $Li[SbF_6]$ structure; and, for M = Sr and Ba, the $Ba[GeF_6]$ structure. Mn—F bond lengths for six different measurements range between 1.72 and 1.75 Å, and average at 1.735 Å. These yellow, hygroscopic compounds are prepared by the action of F_2 on a mixture of MF and MnF_n or by reduction of $[MnO_4]^-$ in HF. Recently, $(NF_4)_2[MnF_6]$

Table 54 The Ternary Halide Compounds of Manganese(IV)

Compound Type	*Comments*	*Ref.*
$O_2^+Mn_2F_9^-$	Ruby-red needles or plates $\mu_{eff} = 5.63$ BM $[MnF_6]$ octahedra linked in double chains	741
$MMnF_5$	$M = O_2^+$. Red	740
	Li, Na, K, Rb, Cs. Brick-red $[MnF_6]$ octahedra, but details unknown	742
$M_2[MnF_6]$	M = Li–Cs, NO, NF_4; 2M = Mg–Ca Yellow or orange-yellow $[MnF_6]^{2-}$ octahedra	572, 743
$M_2[MnCl_6]$	M = K, Rb, Cs, NH_4, NR_4. Dark red, unstable solids. $K_2[PtCl_6]$ structure	623
$[MnCl_4bipy]$	Black crystals	572

has been proposed[743] as 'an outstanding solid oxidizer, with good thermal stability and a high active fluorine content'. It is, however, shock sensitive, especially in the presence of fuels, and reacts violently with water.

The chloro analogues are much less robust.[623] $MnCl_4$ is not known in crystalline form, although $[MnCl_4bipy]$ has been prepared (Section 41.5.2) and characterized. Like the hexachloromanganate(IV) species, however, it loses Cl_2 at normal temperatures. The very dark red, unstable solid $K_2[MnCl_6]$ was first prepared by the reduction of $Ca(MnO_4)_2$ with 40% HCl, followed by the addition of KCl; but it has also been made from 'Mn^{III} acetate' and potassium acetate in a large excess of acetyl chloride. Other salts of Rb, Cs, NH_4 and NMe_4 have been made, and all have face-centred cubic lattices of the K_2PtCl_6 type. The Mn—Cl distance in the potassium salt is 2.28 Å.

41.5.6 Mixed Donor Atom Ligands

Compounds of Mn^{IV} with the various multidentate ligands with different donor atoms have been postulated, especially as products of the 'oxygenation' of the Mn^{II} salicylaldiminato ligands (Section 41.3.9.3). But there is no unequivocal proof of this oxidation state in these compounds. It would be surprising if Mn^{IV} species do not form, even if they turn out to be oxidatively unstable. But we currently know nothing of consequence about the detail.

41.5.7 Macrocyclic Ligands

41.5.7.1 Porphyrin ligands

Higher-valent manganese porphyrins have been of interest since they have been shown to be important intermediates in the activation of hydrocarbons under mild conditions (Section 41.4.8). Their use as sensitizers for the photooxidation of water to oxygen has also provided a motivation,[479] although the involvement of a manganese porphyrin in the natural system has not been fully documented.

M^{IV} porphyrins may be generated by treatment of the corresponding Mn^{III} porphyrin with a strong oxidant, such as hypochlorite (Section 41.4.8.1). The local environment affects the ease of such oxidation and also the nature of the oxidation products.[480] In alkaline solution, such oxidation is facile and yields both Mn^{IV} and Mn^{V} porphyrins. The oxidation is similar, but less efficient, when it occurs in membranes or positively charged micelles. However, in both negatively charged micelles and microemulsions the oxidation is very inefficient: under these conditions no Mn^{V} was observed. In contrast to their redox behaviour, such changes in environment have little effect upon the spectroscopic and chemical properties of Mn^{III} porphyrin species.

Radiochemical (γ-irradiation) one-electron oxidation of [MnCl(TPP)] has also been demonstrated in tetrachloroethane at 77 K.[744] ESR and optical spectroscopy indicate that oxidation occurs at the metal centre to yield a Mn^{IV} compound.

The Mn^{IV} porphyrins tend to be of limited stability in water at neutral pH but are stable under strongly alkaline conditions.[479,482] In acid, rapid decomposition to Mn^{II} species occurs *via* a complex redox mechanism.[479] The reduction is catalyzed by redox catalysts, such as RuO_2 in acid, to yield O_2 in low yield as one product. This latter observation documents (in part) a route for the catalytic oxidation of water.

Hill and coworkers[745] have reported a range of Mn^{IV} porphyrin species, including the monomeric species $[Mn(OCH_3)_2(TPP)]$,[746] $[Mn\{PhI(OAc)O\}_2(TPP)]$[745] and $[MnX_2(TPP)]$ (X = N_3, NCO)[747] as well as the two types of dimeric species mentioned previously in Section 41.4.8.1, $[\{MnX(TPP)\}_2O]$[678] (X = N_3 and OCN) and $[\{MnX(OIPh)(TPP)\}_2O]$.[690] $[Mn(OCH_3)_2(TPP)]$ is obtained by oxidation of [Mn(OAc)(TPP)] in basic methanol using sodium hypochlorite or iodosylbenzene.[746] X-Ray diffraction indicates that this molecule is pseudooctahedral with the methoxy groups coordinated above and below the N_4-donor plane of the macrocycle. The compound has a high spin d^3 Mn^{IV} ground state with a magnetic moment of 3.9 BM. X-Ray studies of a number of the other monomeric species indicate related pseudooctahedral coordination geometries for these compounds. The X-ray structure of $[MnN_3(TPP)]_2O$ indicates an oxygen-bridged dimeric structure in which each manganese ion achieves a six-coordinate geometry.[678] The ground state of this compound is best described as containing two antiferromagnetically coupled Mn^{IV} (d^3) ions.

41.5.7.2 *Phthalocyanine ligands*

As noted in Section 41.4.8.2, there are suggestions in the literature of Mn^{IV} phthalocyanine species, such as [MnOPc]; but they appear much less accessible than for the porphyrins; and have yet to be fully characterized.

41.6 MANGANESE(V), (VI) AND (VII)

The coordination chemistry of these higher oxidation states is dominated by, but not completely confined to, the tetraoxomanganates.

41.6.1 Tetraoxomanganates

The tetraoxomanganate ion can be isolated, although it appears to be but of minor importance, for Mn^{IV} (in Ba_3MnO_5, Table 53), Mn^{III} (in $K_6[Mn_2O_6]$, Table 46) and even for Mn^{II} (in $Na_{14}(MnO_4)_2O$, Table 19); and it seems not unlikely that further examples will be found, especially for Mn^{IV}.

At the other end of the oxidation scale, purple tetraoxomanganate(VII) is, of course, the permanganate that one learns about so soon after the first introduction to chemistry; green MnO_4^{2-}, which is stable in alkaline solutions, has been 'known' since Glauber described a green melt obtained by heating pyrolusite (MnO_2) with saltpetre (KNO_3) in 1659; but MnO_4^{3-}, although noticed in the older literature as hypomanganate, was not recognized as such until the work of Lux in 1946.

Thus the tetrahedral $[MnO_4]^{n-}$ unit is remarkable in being the only coordination polyhedron that has been detected throughout the whole range of oxidation states Mn^{II} to Mn^{VII}.

It has not proven possible (at least not yet) to study the full range of these redox changes in any solution, but at least for the last three of the series (Mn^{V} to Mn^{VII}) there is considerable detail available on their relative stabilities.[211]

Tetraoxomanganate(V), first characterized by Lux, has been isolated in a range of solid compounds. Relatively pure salts $M_3[MnO_4]$, for M = Li, Na, K, Rb and Cs, have been described,[572,748,749] as well as $Ba_3[MnO_4]_2$, $Ba_5(MnO_4)_3OH$ and halo-apatite species such as Sr and $Ba_5(MnO_4)_3Cl$. Although a complete X-ray analysis is not available, there is no doubt about the existence of the $[MnO_4]^{3-}$ tetrahedron, through comparative powder data with $[VO_4]^{3-}$ and $[PO_4]^{3-}$ species; and mixed crystals $Li_3(PO_4/MnO_4)$ and $Sr_5(PO_4/MnO_4)_3Cl$ have been studied. Preparations rely on the reduction of $[MnO_4]^{-}$ in concentrated aqueous alkali, or oxidation of Mn^{II} or MnO_2 in an alkaline melt. The blue solids are very moisture sensitive; magnetic moments are near 2.8 BM, as expected for a d^2 system; and details of their spectra have been studied, especially in Li_3PO_4 and $Sr_5(PO_4)_3Cl$ matrices. The study involving the latter reports[750] a 'dynamic Jahn–Teller effect' in an excited state of $[MnO_4]^{3-}$.

The relative stabilities of Mn^{V} and Mn^{VI} in nitrite, nitrate, hydroxide, oxide and peroxide melts have recently been studied in some detail.[750] In $NaNO_2$ and $NaNO_2/Na_2O_2$ melts, $[MnO_4]^{3-}$ is favoured over $[MnO_4]^{2-}$, whereas in KNO_2 or KNO_3 melts it is the Mn^{VI} species which is favoured.[751] In aqueous alkaline solutions of blue Mn^{V}, the concentration of OH^- must be at least 8 M to prevent disproportionation to $[MnO_4]^{2-}$ and MnO_2.

Green tetraoxomanganate(VI), however, is robust in aqueous alkaline solutions only slightly above 1 M in $[OH^-]$: lower $[OH^-]$ leads to rapid disproportionation to MnO_2 and MnO_4^- (Figure 1). This anion has been isolated in a number of crystalline solids, especially the alkali metal salts $M_2[MnO_4]$ (M = Li → Cs), and an X-ray analysis of the K salt has proven the tetrahedral $[MnO_4]^{2-}$ unit, with Mn—O distances between 1.647 and 1.669 (average = 1.659 Å).

The green manganate(VI) ion is a d^1 system, and measured magnetic moments are near 1.8 BM.

Rapid exchange reactions between MnO_4^- and MnO_4^{2-} have been studied, and cation effects were interpreted in terms of an outer-sphere bridged activated complex.

Permanganate $[MnO_4]^-$ is relatively robust for a strong oxidizing agent. The potassium salt is widely used industrially for bleaching; as an antiseptic, preservative and astringent; as an oxidizer in water and air treatment; and for oxidizing hydrocarbon compounds: world production in the early 1970s was estimated at near 40 000 tonnes. It is as an oxidizing agent, rather than for its coordination chemistry, that it is best known chemically, being the source of a five electron oxidation in acid solution (reduced to Mn^{II}) or three electron oxidation in alkaline solution, where reduction stops at Mn^{IV} because of precipitation of MnO_2. Aqueous solutions are unstable, as any

student of its analytical applications will know; and indeed MnO_4^- is a good example of a kinetically stabilized compound.

A range of salts of the anion has been described and it is known as a ligand — one notable example being $(H_3O)_2[Mn^{IV}(MnO_4)_6]\cdot nH_2O$, which is one of the products of dehydration of $HMnO_4$ in water. An X-ray analysis of the potassium and calcium salts has given Mn—O at 1.63 Å — somewhat shorter, as expected, than in the manganate(VI) species.

One area of MnO_4^- oxidations that has not been greatly explored, and which may lead to new Mn compounds in lower oxidation states, is reaction in non-aqueous solvents. A recent description[752] of the salt of the $[(Ph_3P)_2N]^+$ cation, which is rather soluble in a number of dipolar aprotic solvents, gives at least one starting material for such work; and the use of crown ethers and cryptates, to 'solubilize' $MMnO_4$ species, gives another.

41.6.2 Other Oxo and Oxohalo Species

The compounds for which reasonable evidence is available of their existence are listed in Table 55. Other than the tetraoxomanganates, the compounds are rather unstable, are also very strong oxidizing agents and are liable to detonation, especially in contact with a fuel.

41.6.3 Porphyrin Ligands

Reactions of hypochlorite with Mn^{III} porphyrins (Section 41.4.8.1) under alkaline conditions appear to produce, as well as the Mn^{IV} species (Section 41.5.7.1), some Mn^V species, such as $[Mn(N_4)ClO]$; but these have a very limited existence.[687]

However, quite robust crystalline Mn^V nitrido compounds are produced when these oxidations are carried out in the presence of NH_3.[757]

These red compounds contain a Mn—N triple bond, are diamagnetic, five-coordinate and show considerable chemical stability. Thus while the isoelectronic oxochromium(IV) or oxomolybdenum(IV) porphyrins behave, respectively, as weak oxidants and reductants, the corresponding manganese(V)nitrido species exhibits enhanced redox stability. [MnN(TPP)] and related porphyrin species were also independently prepared by the reaction of iodosylbenzene with $[Mn^{III}X(porphyrin)]$ (X = Cl, Br, OAc) in dichloromethane in the presence of excess ammonia.[758]

Table 55 Compounds of Manganese(V), (VI) and (VII)

Compound	*Comments*
MnO_4^{3-}	Blue anion — characterized in crystalline compounds, in concentrated alkali solutions and in melts.
MnO_4^{2-}	Green anion — stable in aqueous solutions with $[OH^-] > 1M$; crystalline salts.
MnO_4^-	Purple anion — reasonably robust in water and in crystalline salts.
Mn_2O_7	Very unstable red/green liquid. Liable to detonation but IR and UV spectra recently obtained on matrix-isolated samples.[753]
$HMnO_4$	Permanganic acid or hydroxotrioxomanganate(VII). Also as a dihydrate. Both crystalline;[754] strong oxidizing agents, with parallels to $HClO_4$.
MnO_3F	Highly volatile (Wohler 1828).[572] Microwave data give *Td* with Mn—O = 1.586(5) and Mn—F = 1.724(5) Å. Dark green crystals at −78°C. Very moisture sensitive and decomposes explosively.
$MnOCl_3$	Green liquid from $KMnO_4$ reduced in HSO_3Cl.[755] Decomposes to $MnCl_3$ above 0°C and to $[MnO_4]^{3-}$ in aqueous alkali.
MnO_2Cl_2	Least stable of oxochlorides — decomposing at −30°C. Brown solutions in CCl_4.[755]
MnO_3Cl	Green in CCl_4 solution. Detonates in air above 0°C. Slowly hydrolysed to MnO_4^- and Cl^- in water.[755]
$MnO_3\cdot SO_3Cl(?)$	This species may exist in solution, but decomposes, during isolation attempts, to $MnO\cdot SO_3Cl$.[756]
Mn^V porphyrins	See Section 41.6.3

X-ray structural analyses[758,759] show square pyramidal structures with the metal 0.4 Å out of the $[N_4]$ donor atom plane and short, axial Mn≡N distances of 1.51 Å.

One of the structural analyses refers to a porphodimethene macrocycle,[759] which survived (12% yield) the reductive methylation of the analogous nitrido(octaethyl-porphyrin)manganese(V) species, illustrating the redox stability of such formally Mn^V compounds.

43.1 INTRODUCTION

The coordination chemistry of rhenium, the last of the stable elements to be discovered (in 1925), has in the last 25 years undergone a tremendous growth. This element now occupies an important place in contemporary inorganic chemistry. Entry into its chemistry is usually afforded by access to the commercially available (but relatively expensive) perrhenate salts NH_4ReO_4 and $KReO_4$, although rhenium metal is sometimes used as the starting material.

In surveying the coordination chemistry of rhenium we have been greatly assisted by the availability of the superb review entitled 'Recent Advances in the Chemistry of Rhenium' that was written by George Rouschias and published in 1974.[1] This comprehensive review covers all aspects of

rhenium chemistry and can usefully be consulted and used in conjunction with the present review. Other useful reference sources are an early review by Fergusson[2] on the coordination chemistry of rhenium dating from 1966, and two monographs on rhenium chemistry published around this same time.[3,4] Additionally, we have made use of the more recent editions of *Annual Reports (Section A)* and the *Specialist Periodical Reports*, published by the Royal Society of Chemistry, in surveying material for use in this review.*

Rhenium occupies a very important place in the development of the chemistry of complexes containing metal–metal double, triple and quadruple bonds. This chemistry involves coordination complexes that contain pairs or trinuclear clusters of rhenium atoms and has been surveyed in a recent monograph entitled 'Multiple Bonds Between Metal Atoms'.[5] This source, which covers the literature up to early 1981, has also been invaluable in preparing the present review and can be consulted for a more complete and detailed coverage of these classes of complexes.

Since the organometallic chemistry of rhenium is surveyed in the companion series *Comprehensive Organometallic Chemistry*,[6] every effort has been made to minimize overlap with these topics, although an occasional reference is made in the present review to certain alkyl, aryl, carbonyl and isocyanide complexes that may be covered more fully in the excellent review by Boag and Kaesz.[6]

Salts of the perrhenate anion (including perrhenic acid) are not only the single most important group of starting materials for the synthesis of other rhenium compounds but are also of importance in catalysis and other commercial processes. Although they are formally coordination complexes of Re^{VII} and they appear quite extensively in the chemical literature (*e.g.* see *Chemical Abstracts*), much of the interest in them is outside the confines of the topic of coordination chemistry as it is commonly accepted. Accordingly, an effort has been made here to keep the coverage of their chemistry to a minimum.

Oxidation states ranging from Re^{VII} to Re^{0} will be the subject of this review. Of these, Re^{VI}, Re^{I} and Re^{0} are rare, while Re^{II} is encountered mainly in triply bonded dirhenium complexes, *i.e.* those possessing the Re_2^{4+} core. Examples of mononuclear complexes that possess these oxidation states, together with their stereochemical properties, are presented in Table 1, while some properties of coordination complexes containing multiply bonded pairs or trinuclear clusters of rhenium atoms are given in Table 2. Several systematic studies have been carried out that correlate Re 4*f* binding energies (as measured by the ESCA technique) of complexes ranging from those of Re^{VII} to Re^{I} with metal oxidation state.[7–11] These results can be useful in helping to identify complexes of unknown structure.

Table 1 Oxidation States and Typical Stereochemistries of Mononuclear Coordination Complexes of Rhenium[a]

Oxidation state	*Coordination number*	*Geometry*	*Examples*
Re^{I}, d^6	6	Octahedron	$ReCl(N_2)(PMe_2Ph)_4$, $K_5Re(CN)_6$
		Trigonal bipyramid	$ReCl(dppe)_2$
Re^{II}, d^5	6	Octahedron	$[ReCl(N_2)(PMe_2Ph)_4]^+$
Re^{III}, d^4	7	Pentagonal bipyramid	$K_4Re(CN)_7 \cdot 2H_2O$
	6	Octahedron	*mer*-$ReCl_3(PMe_2Ph)_3$, $[Re(acac)_2Cl_2]^-$
	5	Trigonal bipyramid	$Re(SAr)_3(NCMe)(PPh_3)$
Re^{IV}, d^3	6	Octahedron	$ReCl_2(acac)_2$, K_2ReCl_6
	8	?	$ReH_5(PR_3)_3$
Re^{V}, d^2	6	Octahedron	$[ReF_6]^-$, $ReOCl_3(PEt_2Ph)_2$, $[ReO_2(en)_2]^+$
	5	Square pyramid	$[ReOBr_4]^-$, $[ReO(SPh)_4]^-$
Re^{VI}, d^1	8	Square antiprism?	$[ReF_8]^{2-}$
	7	Pentagonal bipyramid?	$[ReF_7]^-$
	6	Octahedron	$[ReN(NCS)_5]^{2-}$, $ReOCl_4(H_2O)$
		Trigonal prism	$Re(S_2C_2Ph_2)_3$
	5	Square pyramid	$[ReNCl_4]^-$
	4	Tetrahedron	$[ReO_4]^{2-}$
Re^{VII}, d^0	9	Tricapped trigonal prism	$[ReH_9]^{2-}$
	8	?	$[ReF_8]^-$
	7	?	$[ReOF_6]^-$
	6	Octahedron	$ReO_3Cl(bipy)$, $[ReO_3Cl_3]^{2-}$
		Trigonal prism	$[Re(NHSC_6H_4)_3]^+$
	5	Square pyramid	$Re(NPPh_3)(SPh)_4$
	4	Tetrahedron	$[ReO_4]^-$

[a] There are no well-documented mononuclear non-organometallic complexes of Re^{0} known as of this time.

* Several important papers (references 574–639) dealing with the coordination chemistry of rhenium were published after the submission of the original manuscript. The chapter has been updated by inclusion of paragraphs discussing these recent developments at appropriate points throughout the text.

Table 2 Some Properties of Multiply Bonded Dirhenium and Trirhenium Complexes Possessing the Re_2L_8 and Re_3L_{12} Units

Oxidation state	*Metal core*	*Electronic configuration*[a]	*Metal–metal bond order*	*Example*
Re^{II}	Re_2^{4+}	$\sigma^2\pi^4\delta^2\delta^{*2}$	3	$Re_2Cl_4(PR_3)_4$
	Re_3^{6+}		1.5?	$[Re_3Cl_6(py)_3]_n$
$Re^{II,III}$	Re_2^{5+}	$\sigma^2\pi^4\delta^2\delta^{*1}$	3.5	$Re_2Cl_5(PR_3)_3$
Re^{III}	Re_2^{6+}	$\sigma^2\pi^4\delta^2$	4	$[Re_2Cl_8]^{2-}$
	Re_2^{6+}	$\sigma^2\pi^2\delta^2\delta^{*2}$	2	$Re_2Cl_6(dppm)_2$
	Re_3^{9+}		2	$[Re_3Cl_{12}]^{3-}$
Re^{IV}	Re_2^{8+}	$\sigma^2\pi^4$	3	$[Re_2Cl_9]^-$

[a] Given for the dirhenium cores only. For a description of the Re—Re bonding in Re_3^{9+} and Re_3^{6+} see B. E. Bursten, F. A. Cotton, J. C. Green, E. A. Seddon and G. G. Stanley, *J. Am. Chem. Soc.*, 1980, **102**, 955 and references therein.

In the systematic treatment of the coordination chemistry of rhenium, we shall start with the lowest oxidation state and proceed, in order, to the next highest. Compounds will be considered, within each oxidation state, in order of increasing nuclearity (*i.e.* mono-, di- and tri-nuclear); we define nuclearity in terms of the number of metal atoms held together by metal–metal bonds. Some complexes where an ambiguity in assigning the metal oxidation state may exist (*e.g.* nitrosyls) are discussed in a separate section. In the case of hydrides we have arbitrarily given the hydride ligand a charge of -1 (*i.e.* H^-) and assign the metal oxidation state accordingly; for example, $Re_2H_6(PMe_2Ph)_5$ is treated as a hydride complex of rhenium(III).

43.2 RHENIUM(0) COMPLEXES

This is, as expected, the rarest oxidation state as far as non-organometallic complexes of rhenium are concerned. The dirhenium phosphite complex $Re_2[P(OMe)_3]_{10}$ has been prepared[12,13] in low yield by several methods, *viz.* the potassium–potassium iodide reduction of $ReOCl_3(py)_2$ or an $ReCl_4$–pyridine complex, followed by treatment with trimethyl phosphite. This yellow complex displays a $^{31}P\{^1H\}$ NMR spectrum that appears as a first order AB_4 pattern, and is isoelectronic with $Re_2(CO)_{10}$. It reacts with H_2 upon photolysis in THF solution to produce hydridorhenium(III) and other species.[13] The related triphenyl phosphite derivative $Re_2[P(OPh)_3]_{10}$ has been described[14] as a product of the reaction between $ReH_3(PPh_3)_4$ and $P(OPh)_3$.

A report describing the isolation of $K_6Re(CN)_6$ could not be substantiated in a later investigation of this system.[15]

43.3 RHENIUM(I) COMPLEXES

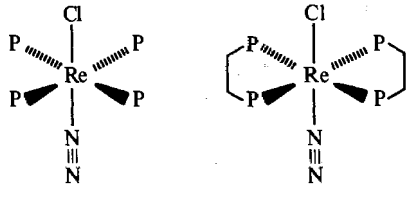
The most important complexes of rhenium(I) are those containing the dinitrogen ligand, in which the rhenium atom is also complexed by phosphine ligands.

43.3.1 Cyanide, Alkyl Isocyanide and Aryl Isocyanide Complexes

Through a careful reexamination of several literature reports, the existence of salts of the rhenium(I) $[Re(CN)_6]^{5-}$ anion has been confirmed.[15] It can be prepared by the reduction (using BH_4^- or K/Hg as reducing agents) of mixtures of $[ReCl_6]^{2-}$ and CN^-.[15–17] The potassium salt is isomorphous with its manganese and technetium analogues.[16] Other methods, including the reaction of Re_3Cl_9 with aqueous KCN solution and the reaction of K_2ReCl_6 with KCN under N_2(g), are also believed to give $K_5Re(CN)_6$.[15]

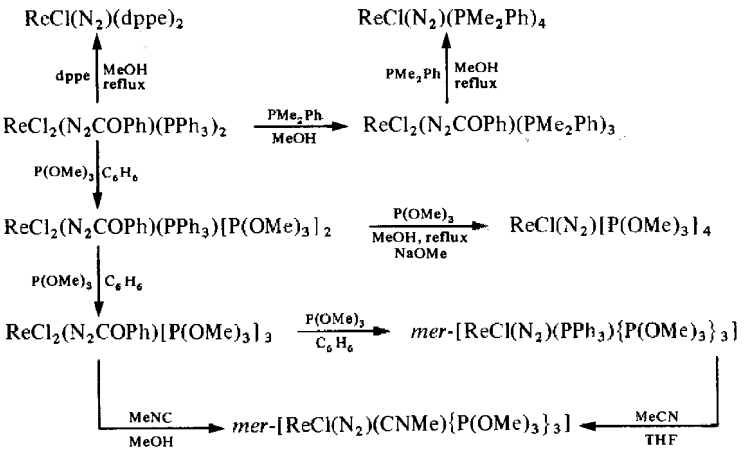
The pentacyanonitrosylrhenate(3−) ion, $[Re(CN)_5(NO)]^{3-}$, can be prepared by the reaction of hydroxylamine hydrochloride, $KReO_4$ and KCN in alkaline solution.[15] This preparative procedure had previously (and presumably incorrectly) been described as affording $K_3[Re(CN)_7(NO)]\cdot 4H_2O$.[18] The diamagnetic, red crystalline trihydrate $K_3[Re(CN)_5(NO)]\cdot 3H_2O$ is formally a derivative of rhenium(I), with coordination from NO^+. Its vibrational spectrum (Raman and IR), with ν(NO) at $\sim 1650\,cm^{-1}$, has been assigned in terms of C_{4v} symmetry.[15]

While non-carbonyl-containing isocyanide complexes of rhenium(I) are discussed elsewhere,[6] some recent developments are worthy of note here. The multiply bonded dirhenium(III) complexes $Re_2(O_2CMe)_4Cl_2$ and $(Bu^n_4N)_2Re_2Cl_8$ are reductively cleaved by alkyl and aryl isocyanides under reflux conditions to give salts of the homoleptic $[Re(CNR)_6]^+$ (R = CMe_3 or C_6H_{11}) and $[Re(CNAr)_6]^+$ (Ar = phenyl, *p*-tolyl, 2,6-dimethylphenyl or 2,4,6-trimethylphenyl) cations.[19–21] Similar forcing reaction conditions can also be used in the formation of the same cations by reaction of the isocyanides with K_2ReX_6 (X = Br or I) and Re_3X_9 (X = Cl, Br or I).[22] Milder conditions (reaction in acetone at room temperature) lead to the conversion of K_2ReI_6 to $Re(CNAr)_5I$ (Ar = phenyl or 2,6-dimethylphenyl), complexes that react reversibly with I_2 to give the rhenium(I) derivatives $Re(CNAr)_5I_3$ that contain coordinated triiodide.[22] While $[Re(CNR)_6]^+$ is inert to substitution by monodentate tertiary phosphines, routes to species of the type $[Re(CNR)_4(PR_3)_2]^+$ are provided by (a) the reductive cleavage of the triply bonded complexes $Re_2Cl_4(PR_3)_4$ (PR_3 = PEt_3 or PPr^n_3) by RNC ligands or (b) the reductive elimination of H_2 from the polyhydride complexes $ReH_7(PR_3)_2$ (PR_3 = PPh_3 or $PEtPh_2$) or $ReH_5(PPh_3)_2(NH_2C_6H_{11})$.[19] These rhenium(I) species exhibit electrochemically reversible one-electron oxidations ($E_{1/2}$ = +0.6 to +0.8 V *vs.* SCE for the RNC complexes and +1.05 to +1.20 V *vs.* SCE for the ArNC complexes),[19,21] and can be oxidized by the halogens to give $[Re(CNR)_6X]^{2+}$ and $[Re(CNAr)_6X]^{2+}$ (X = Cl or Br).[19,21]



The reduction of $ReCl_4(THF)_2$ by Na/Hg in the presence of *t*-butyl isocyanide is a high yield route to $ReCl(CNBu^t)_5$.[23] The trimethylphosphine derivatives of this, $ReCl(CNBu^t)_2(PMe_3)_3$ and $ReCl(CNBu^t)_3(PMe_3)_2$, are prepared by the reaction of Bu^tNC with $ReCl(PMe_3)_5$ (see Section 43.3.3). Both have been shown by X-ray crystallography to have octahedral structures and are protonated by fluoroboric acid to give $[ReCl(CNBu^t)(CNHBu^t)(PMe_3)_3]BF_4$ and $[ReCl(CNBu^t)_2(CNHBu^t)(PMe_3)_2]BF_4$, respectively, in which the $CNHBu^t$ ligands are believed to be *trans* to the Re—Cl bonds.

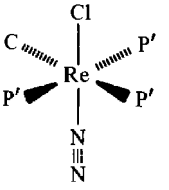
The X-ray crystal structure of *trans*-$ReCl(CNBu^t)(dppe)_2$ (dppe = $Ph_2PCH_2CH_2PPh_2$) as its tetrahydrofuran solvate has been reported,[574] and the Re—C≡N—C unit found to be close to linear. The preparation of *cis*- and *trans*-$[ReCl(CNMe)\{(p\text{-}CF_3C_6H_4)_2PCH_2CH_2P(C_6H_4\text{-}p\text{-}CF_3)_2\}_2]$ has also been described.[575] They are prepared by reacting $ReCl\{(p\text{-}CF_3C_6H_4)_2PCH_2CH_2P(C_6H_4\text{-}p\text{-}CF_3)_2\}_2$ with MeNC in THF at room temperature and reflux, respectively. The complexes *trans*-$[ReL_2(dppe)_2]BF_4$ (where L = CO or RNC, with R = Me, Bu^t, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, *p*-ClC_6H_4 or 2,6-$Cl_2C_6H_3$) have been prepared from the reaction of *trans*-$ReCl(N_2)(dppe)_2$ with L in THF in the presence of $TlBF_4$.[576]



43.3.2 Mixed Dinitrogen–Phosphine Ligand Complexes

43.3.2.1 Mononuclear derivatives

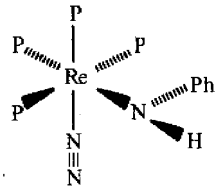
The chelated benzoyldiazenido complex of rhenium(V), $ReCl_2(N_2COPh)(PPh_3)_2$, is the key compound for the preparation of a series of rhenium(I)–dinitrogen complexes.[11,24–26] It reacts with monodentate and bidentate phosphine donors to form yellow complexes of the types $ReCl(N_2)(PR_3)_4$, (PR_3 = PMe_2Ph, $PMePh_2$, Me_2NPF_2 or $PHPh_2$) and $ReCl(N_2)[Ph_2P(CH_2)_2PPh_2]_2$. Of these, the complexes $ReCl(N_2)(PMe_2Ph)_4$ (**1**) and $ReCl(N_2)(dppe)_2$ (**2**; dppe = 1,2-bis(diphenylphosphino)ethane) are by far the most important, the structure of (**1**) having been established by X-ray crystallography which demonstrated the presence of a terminally bound dinitrogen ligand.[27] Analogous derivatives with arsine ligands such as arphos (1-diphenylphosphino-2-diphenylarsinoethane) and the mixed phosphine–phosphite species $ReCl(N_2)L_2(PPh_3)_2$ (L = PF_3, PH_2Ph or $P(OCH_2)_3OMe$) and the tetrakisphosphito derivatives $ReCl(N_2)[P(OMe)_3]_4$ and $ReCl(N_2)(dmope)_2$ (dmope = $(MeO)_2PCH_2CH_2P(OMe)_2$) have also been prepared by this same general procedure, or variations thereof (Scheme 1).[24,25,28,29]



(1) P = PMe_2Ph (2) P⌒P = dppe

Scheme 1 Routes to some dinitrogen complexes of rhenium(I)

If the benzoylazo complex $ReCl_2(N_2COPh)(PPh_3)_2$ is first converted into the related organodiazenido derivatives $ReCl_2(N_2COPh)(PMe_2Ph)_3$, $ReCl_2(N_2COPh)[P(OMe)_3]_3$ or $ReCl_2(N_2COPh)(PPh_3)[P(OEt)_3]_2$,[25,29,30] then the latter Re^{III} species can be used as precursors to the mixed phosphine–phosphite complex $ReCl(N_2)(PMe_2Ph)_2[P(OMe_3)_2]_2$ and the methyl isocyanide complexes *mer*-$[ReCl(N_2)(CNMe)\{P(OMe)_3\}_3]$ (**3**) and $ReCl(N_2)(CNMe)(PPh_3)[P(OEt_3)]_2$ (see Scheme 1). The structure of (**3**) shows it to be analogous to that of (**1**).[30] A listing of a selection of the more important dinitrogen complexes of rhenium(I) together with several of their of properties is given in Table 3. Other characterization studies have included ^{15}N NMR, X-ray photoelectron (ESCA) and low frequency vibrational spectroscopic measurements.[24,31–33]



(**3**) P′ = $P(OMe)_3$; C = CNMe

An alternative route to a dinitrogen complex of rhenium(I) involves the Na/Hg reduction of THF solutions of the phenylimido complexes of Re^V, $Re(NPh)Cl_3(PPh_3)_2$ or $Re(NPh)Cl_3(PMe_3)_2$, under a nitrogen atmosphere in the presence of excess PMe_3.[34] This gives $Re(NHPh)(N_2)(PMe_3)_4$ (**4**), which has been shown by X-ray crystallography to have a structure containing a *cis* disposition of N_2 and NHPh ligands. The Na/Hg reduction of $ReCl_4(THF)_2$ in THF solutions of PEt_2Ph under

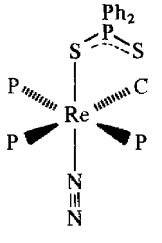
(4) P = PMe_3

an N_2(g) atmosphere gives a separable mixture of $ReH(N_2)(PEt_2Ph)_4$ and $ReCl(N_2)(PEt_2Ph)_4$.[35] The identity of the hydride derivative (for which ν(Re—H) = 1945 cm^{-1}) has been confirmed crystallographically (Table 3).



The hydrido species $ReH(N_2)(dppe)_2$ results from the reaction of $(Et_4N)_2ReH_9$ with dppe in propan-2-ol under an N_2 atmosphere.[36] An alternative preparation of this complex involves the reaction of N_2 with photogenerated coordinatively unsaturated $ReH(dppe)_2$.[37] This reaction can be reversed through the photo induced loss of N_2. Reaction of this complex with MeX (X = Br or I) gives $ReX(N_2)(dppe)_2$, while displacement of the N_2 ligand occurs upon its reaction with C_2H_4 and CO.[36] The properties of the hydride and phenylimido complexes resemble those of the other derivatives (Table 3).

An interesting and unusual route to a dinitrogen complex of rhenium(I) occurs upon reacting photogenerated $ReH_5(PMe_2Ph)_2$ and *t*-butylethylene in benzene under N_2. This yields the arene complex $(C_6H_6)Re(PMe_2Ph)(CH_2CH_2CMe_3)$ together with the *ortho*-metallated dinitrogen containing product *fac*-$Re(N_2)(PMe_2Ph)_3(PMe_2C_6H_4)$ (Table 3).[38]

Although the coordinated N_2 ligand in the Re^I derivatives has not yet been protonated or alkylated,[24] these complexes exhibit, nonetheless, an interesting reaction chemistry. The reactions of $ReCl(N_2)(PMe_2Ph)_4$ with pyridine ligands and bidentate monoanionic sulfur ligands proceed as shown in Scheme 2,[24–26] to give species in which the Re—N_2 unit is retained and which possess properties similar to those for the complexes listed in Table 3. Treatment of the dithiophosphinato complex $Re(\eta^2\text{-}S_2PPh_2)(N_2)(PMe_2Ph)_3$ with MeNC in THF under argon and tungsten filament light (Scheme 2) gave *mer*-$[Re(\eta^1\text{-}S_2PPh_2)(N_2)(CNMe)(PMe_2Ph)_3$ (**5**) as yellow crystals [ν(CN) = 2100 cm^{-1}, $\nu(N_2)$ = 1980 cm^{-1}].[39] Its crystal structure shows Re—N and N—N bond lengths [1.83(1) and 1.13(1) Å, respectively] somewhat shorter and longer, respectively, than those of (**3**), a result which is in accord with differences in the values of the $\nu(N_2)$ modes [2030 cm^{-1} for (**3**) *versus* 1980 cm^{-1} for (**5**)].

Scheme 2 Some reactions of dinitrogen complexes of rhenium(I)

(5) P = PMe_2Ph; C = CNMe

Cationic complexes may be obtained *via* abstraction of Cl^- from $ReCl(N_2)(dppe)_2$ by $TlBF_4$ (equation 1) in the presence of CH_3CN or PhCN.[29] An interesting by-product in the reaction with benzonitrile is the non-dinitrogen containing product $[Re(NCPh)_2(dppe)_2]BF_4$ which was isolated in low yield as orange plates. Hydrido complexes of Re^{III} result upon protonation of $ReH(N_2)(dppe)_2$[36] and $Re(S_2CNR)(N_2)(PMe_2Ph)_3$[26] with acids such as HBF_4, HCl and HBr in non-aqueous media (Scheme 2). When $Re(NHPh)(N_2)(PMe_3)_4$ is treated with HBF_4/THF, the BF_4^- salt of $[Re(N_2)(PMe_3)_5]^+$ can be isolated.[35] This cation has also been isolated as its chloride salt upon reacting $ReCl(PMe_3)_5$ with N_2 in methanol ($\nu(N_2) = 2030\,cm^{-1}$ (Nujol)).[35] The N_2 ligand in $Re(NHPh)(N_2)(PMe_3)_4$ is lost upon reaction of this complex with I_2/benzene and CO_2/toluene; the complexes $[Re(NHPh)I(PMe_3)_4]I$ and $Re(NHPh)(\eta^2\text{-}CO_2)(PMe_3)_3$ are formed, respectively.[35]

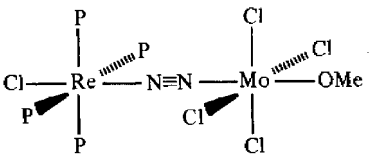
The lability of the N_2 ligand towards alkyl and aryl isocyanides has been demonstrated by equation (2) which occurs readily with both alkyl and aryl isocyanides.[40] The resulting complexes are 'electron rich', the alkyl isocyanide derivatives $ReCl(CNR)(dppe)_2$ (R = Me or Bu^t) undergoing electrophilic attack upon treatment with HBF_4 to form the carbyne complexes *trans*-$[ReCl(CNHR)(dppe)_2]BF_4$.[41] Other noteworthy features of the series of complexes $ReCl(CNR)(dppe)_2$ and $ReCl(CNAr)(dppe)_2$, are the low value of $\nu(CN)$, the presence of a 'bent' M—CNR coordination mode, and their ease of oxidation (as measured by cyclic voltammetry) to the corresponding rhenium(II) monocations.[40]

$$ReCl(N_2)(dppe)_2 + TlBF_4 \xrightarrow{RCN} [Re(N_2)(NCR)(dppe)_2]BF_4 + TlCl \quad (1)$$

$$trans\text{-}ReCl(N_2)(dppe)_2 + RNC \longrightarrow trans\text{-}ReCl(CNR)(dppe)_2 + N_2 \quad (2)$$

Many of the dinitrogen complexes of Re^I have been found to undergo a reversible one-electron oxidation to the corresponding 17-electron Re^{II} cations ($E_{1/2}$ between +0.05 and −0.26 V *vs.* SCE in CH_2Cl_2/MeOH solution with $(Bu^n_4N)BF_4$ as supporting electrolyte).[11,24] Such an oxidation can be accomplished chemically using $Cl_2/CHCl_3$ (Scheme 2) and other oxidants to give paramagnetic purple or green salts of $[ReCl(N_2)(PMe_2Ph)_4]^+$ or $[ReCl(N_2)(dppe)_2]^+$. Other important reactions that lead to the oxidation of the metal center involve the formation of rhenium(III) acyl- and aroyl-diazenido complexes $[ReCl_2(N_2COR)(PMe_2Ph)_3]$ (R = Me or Ph) by the treatment of $ReCl(N_2)(py)(PMe_2Ph)_3$ or $ReCl(N_2)(PMe_2Ph)_4$ with RCOCl (Scheme 2).[24,42] On the basis of ^{15}N NMR spectroscopy,[43] the diazenido ligands in these complexes are suggested to be 'singly-bent', *i.e.* $M{=}{=}{=}N{\equiv}{\equiv}{\equiv}N\diagdown R$. The formation of $ReCl_2(N_2COR)(PMe_2Ph)_3$ by this procedure is especially noteworthy since it represents essentially the reverse of the original preparation of the N_2 complexes starting with $ReCl_2(N_2COPh)(PMe_2Ph)_3$. Attempts to acylate or aroylate $ReCl(N_2)(dppe)_2$ have not yet been successful.[24]

A wider range or complexes of the type $ReCl(N_2)(R_2PCH_2CH_2PR_2)_2$ have now been prepared by the reaction of rhenium(V) complex $ReCl_2(N_2COPh)(PPh_3)_2$ with the appropriate diphosphine ligand (R = Et, C_6H_{11}, Ph, *p*-$MeOC_6H_4$, *p*-MeC_6H_4, *p*-ClC_6H_4 or *p*-$CF_3C_6H_4$).[575] The relationship between $E^{ox}_{1/2}$ (determined by cyclic voltammetry) and $\nu(N_2)$ for these complexes and others of this type has been examined.[575] The ^{15}N and ^{31}P NMR spectra of *trans*-$ReCl(N_2)(R_2PCH_2CH_2PR_2)_2$ (R = Ph or *m*-MeC_6H_4) and *trans*-$ReCl(N_2)(PMe_2Ph)_4$ are part of an extensive study of the NMR spectra of complexes that contain terminal dinitrogen ligands.[577] The treatment of *trans*-$ReCl(N_2)(dppe)_2$ with $PhC{\equiv}CCH_3$ in refluxing benzene or THF gives the η^2-phenylallene complex $ReCl(\eta^2\text{-}H_2C{-}C{=}CHPh)(dppe)_2$,[578] while terminal alkynes $HC{\equiv}CR$ (R = Et, Ph or CO_2Et) react to give the vinylidene complexes *trans*-$ReCl(C{=}CHR)(dppe)_2$.[579]



43.3.2.2 Mixed metal dinuclear and trinuclear derivatives

The complex $ReCl(N_2)(PMe_2Ph)_4$ (1) shows a remarkably strong tendency to react with other transition metal centers *via* its terminally bound dinitrogen ligand to give dinitrogen-bridged di- and tri-nuclear complexes.[24] A listing of these complexes, together with the preparative routes employed and certain of their properties, is given in Table 4. Two of these complexes, *viz.* (**6**) and (**7**) in Table 4, have been fully characterized structurally by X-ray crystallography, and shown to possess N—N bonds longer than those in the mononuclear complexes containing terminally bound dinitrogen (Table 3). Solution studies that have monitored the formation of adducts between $ReCl(N_2)(PMe_2Ph)_4$ and other Lewis bases (including several other Re^I—N_2 complexes) and the Lewis acids AlR_3 (R = Me, Ph or Cl), have demonstrated that this particular Re^I complex ranks high in

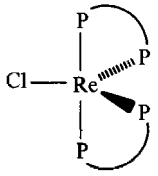
$$ReCl(N_2)(PMe_2Ph)_4 + ReOCl_2X(PPh_3)_2 \rightleftharpoons ReOCl_2X(PPh_3)[(N_2)ReCl(PMe_2Ph)_4] + PPh_3 \quad (3)$$

X = Cl or OMe

the order of base strength; 1:1 adducts of $AlMe_3$ with $ReCl(N_2)(PMe_2Ph)_4$, $ReCl(N_2)(dppe)_2$ and $ReCl(N_2)(py)(PMe_2Ph)_3$ have been isolated.[49] Apparently, the greater the transfer of electron density from the metal into the π^* dinitrogen orbitals (*i.e.* the lower $\nu(N_2)$ is) the more basic the terminal nitrogen atom is. In the case of the interaction of $ReCl(N_2)(PMe_2Ph)_4$ with $ReOCl_3(PPh_3)_2$ and $ReOCl_2(OMe)(PPh_3)_2$,[36] an equilibrium (equation 3) is established in $CHCl_3$ with K_{eq} values of 0.28 ± 0.03 and 0.004 ± 0.002, respectively, at 27°C.

Following the establishment of the structure of (**7**), a detailed study of the bonding in this molecule has been conducted through a combined electronic, IR, Raman and resonance Raman spectral investigation.[51] The Raman-active $\nu(N_2)$ mode is found close to 1800 cm^{-1}, while ν(Re—N) is at ~680 cm^{-1}. The bonding in this complex can approximately be described in terms of Re=N=N=Mo.[51]



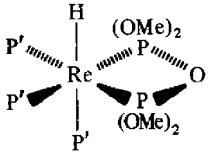
Dinitrogen-bridged complexes of *trans*-$ReCl(N_2)(PMe_2Ph)_4$ with $NbCl_5$ and $TaCl_5$ (1:1 adducts) and $ZrCl_4$ (2:1 adduct like $TiCl_4$) have been isolated.[579] The ^{15}N NMR spectra of these and other complexes of this type as well as dinitrogen complexes of rhenium(I) with the main group acceptor $AlMe_3$ have been studied.[580] Fenske–Hall MO calculations have been carried out on the molecule $[\{MoCl_4(OH)\}(\mu\text{-}N_2)\{ReCl(PH_3)_4\}]$.[581]

43.3.3 Other Phosphine Complexes

The sodium amalgam reduction under N_2 of $ReCl_4(THF)_2$ in THF containing an excess of PMe_3 affords the yellow chloride $ReCl(PMe_3)_5$ and the white hydride $ReH(PMe_3)_5$.[35] Both complexes are quite air stable and fairly reactive. The hydride can be hydrogenated to the trihydride $ReH_3(PMe_3)_4$, whereas the chloride $ReCl(PMe_3)_5$ can be methylated (using LiMe) to $ReMe(PMe_3)_5$. $ReCl(PMe_3)_5$ reacts directly with N_2 (in methanol) and CO (in diethyl ether) to form $[Re(N_2)(PMe_3)_5]Cl$ (see Section 43.3.2.1) and $ReCl(CO)_2(PMe_3)_3$, respectively.[35]

Although the Na/Hg reduction of $Re(NPh)Cl_3(PMe_3)_2$ in THF under N_2(g) in the presence of PMe_3 leads to $Re(NHPh)(N_2)(PMe_3)_4$ (see Section 43.3.2.1), a prolonged reaction time gives this complex as a minor product and the η^2-dimethylphosphinomethyl derivative $Re(\eta^2\text{-}CH_2PMe_2)(PMe_3)_4$ as the major one.

Irradiation of $ReH_3(dppe)_2$ with 366 nm light leads to the reductive elimination of H_2 and the formation of $HRe(dppe)_2$ or a solvated derivative thereof.[37] This photoproduct reacts with, among other things, N_2 and CO_2, to form the complexes $ReH(N_2)(dppe)_2$ (see Section 43.3.2.1) and the formate $Re(O_2CH)(dppe)_2$. The $ReH(dppe)_2$ intermediate can also be trapped by CO, C_2H_4 and C_2H_2, and can undergo reversible intramolecular insertion into the C—H bonds of the phenyl groups of the dppe ligands.[37] Related chemistry can also be developed from $ReCl(N_2)(dppe)_2$ (and to a certain extent also from $ReCl(N_2)(PMe_2Ph)_4$) which upon irradiation in methanol generates $ReCl(dppe)_2$ (**8**).[52] Under these conditions, the reactive photogenerated $ReCl(dppe)_2$ reacts with the solvent to yield $ReCl(CO)(dppe)_2$ and $ReClH_2(dppe)_2$. The X-ray crystal structure of (**8**) has recently been reported[53] and found to be that of a trigonal bipyramid.



(8) P—P = dppe

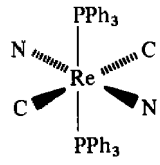
The complex $[ReCl\{p\text{-}CF_3C_6H_4)_2PCH_2CH_2P(C_6H_4\text{-}p\text{-}CF_3)_2\}_2]$ is obtained in moderate yield from the reaction of $ReCl(N_2)(PMe_2Ph)_4$ with the diphosphine in refluxing toluene.[575]

43.3.4 Phosphite Complexes

Using the same synthetic procedures that produce the Re^0 derivative $Re_2[P(OMe)_3]_{10}$ (Section 43.2),[12,13] the monohydrido complex $HRe[P(OMe)_3]_5$ is often formed in low yield and is also generated, along with other products, upon photolyzing $Re_2[P(OMe)_3]_{10}$ in the presence of H_2. It has been characterized by ^1H NMR spectroscopy (C_7D_8, $\delta - 9.5$ as a quintet of doublets with $J(P—H)_{trans} = 12$ Hz and $J(P—H)_{cis} = 24$ Hz) and mass spectroscopy, but has otherwise been little studied. When solutions of $ReCl_5$ in THF are reacted with trimethyl phosphite for one day, the resulting solution stripped to dryness, treated with fresh $P(OMe)_3$, and then reduced with K/Hg, the complex $[(MeO)_3P]_5Re—O—P(OMe)_2$ can be isolated in low yield.[13] It is formally a derivative of Re^I and may be formed by loss of a CH_3 radical from the putative 19-electron intermediate $Re[P(OMe)_3]_6$. It reacts with MeI to give $[Re\{P(OMe)_3\}_6]^+I^-$. An additional hydridorhenium(I) phosphite complex that has been isolated, albeit in low yield, from the K/Hg reduction of higher valent rhenium species in the presence of $P(OMe)_3$ ligand, is $HRe[P(OMe)_3]_3[(MeO)_2P—O—P(OMe)_2]$ (**9**) containing the novel tetramethyl diphosphite ligand. This stereochemically rigid molecule (^1H NMR spectrum in C_7D_8 shows the Re—H resonance as a multiplet at $\delta - 8.8$) is believed to contain a four-membered MPOP ring.

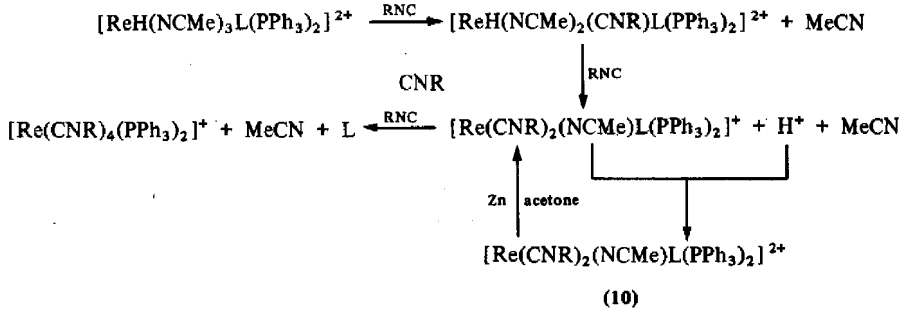
(9) P' = $P(OMe)_3$

The triphenyl phosphite complex $ReCl[P(OPh)_3]_5$ is obtained as white crystals in high yield by the reaction of $P(OPh)_3$ with $ReCl_2(N_2COPh)(PPh_3)_2$ in benzene.[29] This reaction clearly proceeds in a fashion different from that found with $P(OMe)_3$, *viz.* the formation of $ReCl(N_2)[P(OMe)_3]_4$.



43.4 RHENIUM(II) COMPLEXES

The most extensive group of complexes that are known to have this oxidation state are the mixed halide–phosphine derivatives of the triply bonded Re_2^{4+} core, a moiety that possesses the electron-rich $\sigma^2\pi^4\delta^2\delta^{*2}$ electronic configuration (Table 2).[5]



43.4.1 Mononuclear Complexes

43.4.1.1 Cyanide, alkyl isocyanides and aryl isocyanides

Early reports of cyano complexes of rhenium(II) of the types $[Re(CN)_6]^{4-}$ and $[Re(CN)_5]^{3-}$ could not be confirmed in a reinvestigation of the reactions that were said to lead to these products.[15] The only species definitively identified was the $[Re(CN)_7]^{4-}$ anion. Accordingly, the claim[54] that '$Ag_4[Re(CN)_6]$' can be methylated to give $[Re(CNMe)_6]^{2+}$ cannot now be supported. Indeed, solutions containing the authentic $[Re(CNR)_6]^{2+}$, $[Re(CNR)_4(PR_3)_2]^{2+}$ and $[Re(CNAr)_6]^{2+}$ cations (R = alkyl, Ar = aryl) can be generated electrochemically,[19,21] and do not appear to have properties that are in accord with those reported[54] for '$[Re(CNMe)_6]^{2+}$'. The rhenium(I) complexes $ReCl(CNR)(dppe)_2$ and $ReCl(CNAr)(dppe)_2$ also undergo a reversible electrochemical one-electron transfer to generate the corresponding monocations, but these latter species have not otherwise been characterized.[40] However, a series of quite stable, paramagnetic, mixed-ligand complexes of the type $[Re(CNR)_2(NCMe)L(PPh_3)_2](BF_4)_2$ (R = Pr^i or Bu^t, L = MeCN or py) have been prepared, and the crystal structure of $[Re(CNBu^t)_2(NCMe)_2(PPh_3)_2](BF_4)_2$ (**10**) has shown that it possesses the all-*trans* geometry.[55] Through an investigation of the reactions between RNC (R = Pr^i or Bu^t) and a range of monohydridorhenium(III) species $[ReH(NCMe)_3L(PPh_3)_2](BF_4)_2$ (L = MeCN, py, $C_6H_{11}NH_2$ or Bu^tNH_2), it was demonstrated that the sequence of reactions which involve the formation of (**10**) and other complexes of this type is as shown in Scheme 3. Note that these complexes are easily converted into their 18-electron rhenium(I) congeners, and are also formed

(10) C = CNR; N = NCMe

Scheme 3

from them upon treatment with acid and other mild oxidants.[55] Some properties of (**10**) and other mononuclear rhenium(II) species are given in Table 5.

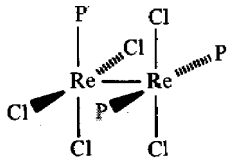
Recent attempts[22] to repeat the preparations of compounds that have been formulated[6] as the rhenium(II) derivatives $Re_3I_6(CNCy)_3$ and $Re_3I_6(CNCy)_6$ (Cy = cyclohexyl) were unsuccessful. The reactions of K_2ReI_6 and Re_3I_9 with cyclohexyl isocyanide and other isocyanides give well-defined complexes of Re^I and Re^{III} only. Also, the existence of *trans*-$ReBr_2(CNCy)_4$ has not yet been confirmed, despite attempts to do so.[22]

43.4.1.2 Phosphines and arsines

Such complexes occur exclusively as derivatives of the rhenium(II) halides. The neutral, presumably octahedral, complexes $ReX_2(diars)_2$ and $ReX_2(qas)$ (X = Cl, Br or I; diars = *o*-phenylene(bisdimethylarsine); qas = tris(*o*-diphenylarsinophenyl)arsine) are formed by reduction of the corresponding cationic rhenium(III) species.[2] The species $ReX_2(tas)$ (X = Cl, Br or I; tas = bis(*o*-diphenylarsinophenyl)phenylarsine) are prepared similarly but may be five-coordinate.[2] The complex $ReCl_2(PMe_2Ph)_4$ and some of its properties have been described (including its ESCA spectrum and electrochemical properties),[11] but details of its preparation have not.

The paramagnetic complexes *trans*-$[ReCl(N_2)(dppe)_2]X$ (X = Cl^-, Br_3^-, I_3^-, ClO_4^-, BF_4^-, PF_6^-, $FeCl_4^-$ or $CuCl_2^-$) and *trans*-$[ReCl(N_2)(PMe_2Ph)_4]FeCl_4$ are prepared by oxidation of the rhenium(I) analogues using oxidizing transition metal salts such as $AgNO_3$, $FeCl_3$ or $CuCl_2$ in ethanol or, alternatively, a stoichiometric amount of halogen in chloroform.[25] These complexes, which exist in green or purple forms, can be oxidized further with concomitant loss of N_2. Typical properties are given in Table 5, where it can be seen that these complexes resemble other isoelectronic rhenium(II) complexes, including the carbonyl derivatives *trans*-$ReCl_2(CO)_2(PR_3)_2$.[6,56]

43.4.2 Dinuclear Complexes Containing the Re_2^{4+} and Re_2^{5+} Cores



43.4.2.1 Monodentate phosphines

The most important complexes that possess these cores are those of stoichiometry $Re_2X_4(PR_3)_4$ (X = Cl, Br or I; PR_3 = PMe_3, PEt_3, PPr^n_3, PBu^n_3, PMe_2Ph or PEt_2Ph).[5,56] They are best prepared by the reaction between monodentate tertiary phosphines and the salts $(Bu^n_4N)_2Re_2X_8$ (X = Cl, Br or I).[57–61] These reactions proceed in a stepwise fashion, first to give the unreduced substitution product $Re_2X_6(PR_3)_2$, and then $Re_2X_5(PR_3)_3$ (**11**), followed by $Re_2Cl_4(PR_3)_4$ (**12**). While most reactions with phosphines have been found to terminate at the stage $Re_2Cl_4(PR_3)_4$, in the case of PPh_3 the reaction does not proceed beyond $Re_2Cl_6(PPh_3)_2$. This may be due in part to the insolubility of the resulting

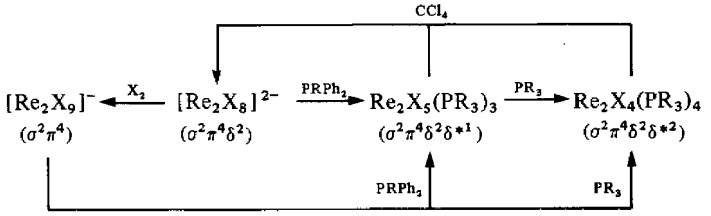
(11) P = PR_3



(12) P = PR_3

dirhenium(III) product in the reaction medium, although steric and/or electronic factors also dictate the course of this reaction.[56] The diphenylalkylphosphines $PRPh_2$, where R = Me or Et, give the 'mixed-valent' species $Re_2X_5(PRPh_2)_3$.[57] The extent of reduction (*i.e.* to Re_2^{5+} or Re_2^{4+}) is apparently dependent to a large extent upon the basicity of the phosphine. Thus, the addition of $NaBH_4$ to a reaction mixture containing $(Bu^n_4N)_2Re_2Cl_8$ and $PEtPh_2$ leads to further reduction to $Re_2Cl_4(PEtPh_2)_4$.[62]

While other methods have been used to form $Re_2X_4(PR_3)_4$ and $Re_2X_5(PR_3)_3$, (for example, the reductive cleavage by PR_3 of the Re_3X_9 clusters (X = Cl, Br or I) under reflux conditions[56]), these procedures are less convenient than the ones which utilize $(Bu^n_4N)_2Re_2X_8$. Those reactions between $(Bu^n_4N)_2Re_2X_8$ (X = Cl or Br) and phosphines that lead directly to the dirhenium(II) complexes $Re_2X_4(PR_3)_4$ are difficult to control so that they stop at the intermediate stage of reduction corresponding to $Re_2X_5(PR_3)_3$. However, quite simple methods exist for reoxidizing $Re_2X_4(PR_3)_4$ back to $Re_2X_5(PR_3)_3$.[56]

The X-ray crystal structures of two complexes of the type $Re_2Cl_4(PR_3)_4$ (**12**) (PR_3 = PEt_3 or PMe_2Ph), together with spectroscopic and magnetic studies on the paramagnetic $Re_2X_5(PR_3)_3$ (**11**) compound, have demonstrated that these two groups of complexes possess non-ligand bridged M_2L_8 eclipsed rotational geometries.

Relativistic Xα-SW calculations[5,63] on the hypothetical molecule $Re_2Cl_4(PH_3)_4$ and its monocation have shown that the two electrons in excess of those necessary to ensure a quadruple bond ($\sigma^2\pi^4\delta^2$ configuration) reside in the Re—Re δ^* orbital. The spectroscopic properties, redox behavior and general reaction chemistry of complexes of types (**11**) and (**12**) all serve to support this picture of the electronic structure.[5] Thus, they can be oxidized (both chemically and electrochemically) back to complexes of Re^{III} containing the Re_2^{6+} core. Refluxing CCl_4, oxidizes $Re_2Cl_4(PEt_3)_4$ to $[Et_3P\text{-}Cl]_2Re_2Cl_8$, while with the bromide analogue a mixture of $Re_2Cl_4Br_2(PEt_3)_2$ and $[Et_3PCl]_2Re_2Cl_4Br_4$ is produced.[57] Note that the salt $(Bu^n_4N)Re_2Cl_9$, which like other $[Re_2X_9]^-$-containing species can be formed by halogen (Cl_2 or Br_2) oxidation of $(Bu^n_4N)_2Re_2X_8$,[5] reacts with the phosphines PPh_3, $PEtPh_2$ and PEt_3 to give $Re_2Cl_6(PPh_3)_2$, $Re_2Cl_5(PEtPh_2)_3$ and $Re_2Cl_4(PEt_3)_4$, respectively.[64] The preceding redox results are summarized in Scheme 4.

Scheme 4 Chemical redox behavior of the Re_2^{n+} core

Although oxygen-free solutions of $Re_2X_4(PR_3)_4$ are quite stable, the presence of small amounts of oxygen can lead to the formation of species containing the Re_2^{5+} core.[63,65] In the case of the reaction between $Re_2Cl_4(PR_3)_4$ and O_2, it is believed that the $[Re_2Cl_4(PR_3)_4]^+$ cation is the dirhenium species that is formed initially, and that it is then converted into $Re_2Cl_5(PR_3)_3$ by scavenging chloride ion. This conclusion is supported by cyclic voltammetric studies[5,65] on solutions of $Re_2X_4(PR_3)_4$ (X = Cl, Br or I) in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2 which reveal that these complexes possess two one-electron oxidations that approach electrochemical reversibility. The first oxidation occurs at quite negative potentials (*e.g.* $E_{1/2} = -0.30$ V *vs.* SCE for $Re_2Cl_4(PMe_2Ph)_4$), thereby explaining the ease of oxidation to the monocation. In the presence of chloride ion, a series of coupled electrochemical–chemical reactions are possible for the chloro complexes as shown in Scheme 5. The difference between pathways *A* and *B* is the potential used for the oxidation of $Re_2Cl_4(PR_3)_4$ (*i.e.* +1.0 V in *A* and +0.5 V in *B*). It is also important to realize that either potential is sufficient to oxidize the first chemical product $Re_2Cl_5(PR_3)_3$ to its monocation $[Re_2Cl_5(PR_3)_3]^+$.

Note that both $Re_2Cl_5(PR_3)_3$ and $Re_2Cl_6(PR_3)_2$ have their own well-developed redox chemistry.[65] The former exhibits a one-electron oxidation in the neighborhood of +0.40 V *vs.* SCE and a one-electron reduction at $\simeq -0.7$ V *vs.* SCE. For the complexes $Re_2Cl_6(PR_3)_2$, a well-defined one-electron reduction to $[Re_2Cl_6(PR_3)_2]^-$ occurs very close to −0.05 V *vs.* SCE. In all instances, the species which may be generated electrochemically (*viz.* $[Re_2Cl_4(PR_3)_4]^+$, $[Re_2Cl_4(PR_3)_4]^{2+}$, $[Re_2Cl_5(PR_3)_3]^+$, $[Re_2Cl_5(PR_3)_3]^-$ or $[Re_2Cl_6(PR_3)_2]^-$) can be prepared chemically using $NO^+PF_6^-$ as the oxidant or cobaltocene as the reductant. By this mean the dirhenium cations can be isolated as their PF_6^- salts and the anions as their $[(\eta^5\text{-}C_5H_5)_2Co]^+$ salts.[65–67] These studies have included the isolation of the three complexes $Re_2Cl_4(PMe_2Ph)_4$, $[Re_2Cl_4(PMe_2Ph)_4]PF_6$ and $[Re_2Cl_4(PMe_2Ph)_4](PF_6)_2$, and their X-ray structural characterization.[66] This has provided a series of three complexes possessing M—M bonds of order 4, 3.5 and 3 with identical sets of monodentate ligands. The Re—Re bond lengths change from 2.241(1) to 2.218(1) to 2.215(2) Å as the bond order increases from 3 to 3.5 to 4. All three complexes have the same basic eclipsed structure that characterizes all compounds of the type $Re_2X_4(PR_3)_4$ (**12**). The expected shortening of the bond occurs on going from $Re_2Cl_4(PMe_2Ph)_4$ to $[Re_2Cl_4(PMe_2Ph)_4]^+$, but there is no change between $[Re_2Cl_4(PMe_2Ph)_4]^+$ and $[Re_2Cl_4(PMe_2Ph)_4]^{2+}$. Any decrease expected on the basis of an increase in Re—Re bond order (from 3.5 to 4) is nullified by a second effect which apparently results in a lessening of the σ and/or π bonding. The latter change results from orbital contraction effects which accompany the increase in charge (*i.e.* from Re_2^{5+} to Re_2^{6+}).

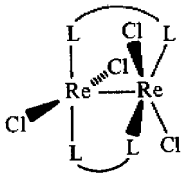
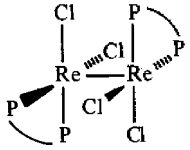
Scheme 5 Coupled electrochemical–chemical processes for Re_2^{n+} species



The use of cobaltocene has also been applied to the reduction of the dirhenium(III) carboxylates $Re_2(O_2CR)_4Cl_2$, where R = Pr, CMe_3 or Ph, to give the paramagnetc salts $[(\eta^5\text{-}C_5H_5)_2Co][Re_2(O_2CR)_4Cl_2]$ which are derivatives of the Re_2^{5+} core.[67] These same anions have also been generated electrochemically.[68]

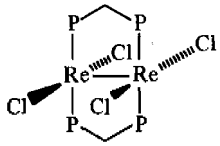


In addition to the rich redox chemistry that characterizes multiply bonded dirhenium complexes containing Re—Re bond orders of 4, 3.5 and 3, there are instances where facile Re—Re bond cleavage is encountered. Perhaps the best examples are those which involve reactions with π-acceptor ligands such as CO and RNC. Under such circumstances, the species $[Re_2Cl_4(PR_3)_4]^{n+}$, where $n = 0$, 1 or 2, react to form mononuclear complexes such as $ReCl_2(CO)_2(PR_3)_2$, $ReCl(CO)_3(PR_3)_2$ and $[Re(CNR)_4(PR_3)_2]^+$, the actual product isolated depending upon the starting material and choice of reaction conditions.[19,69] This is a reaction course that is encountered with many multiple bonded species containing M—M triple and quadruple bonds.[5]

43.4.2.2 Bidentate phosphines and arsines

Starting from $(Bu^n_4N)_2Re_2X_8$ (X = Cl, Br or I) or $Re_2X_4(PR_3)_4$, the dirhenium(II) complexes $Re_2X_4(LL)_2$ can be prepared[61,70] with the ligands LL = 1,2-bis(diphenylphosphino)ethane (dppe) or 1-diphenylphosphino-2-diphenylarsinoethane (arphos). The method that involves displacement of the PR_3 ligands from $Re_2Cl_4(PR_3)_4$ is the preferred synthetic procedure.[70] The spectroscopic properties of $Re_2X_4(LL)_2$ are in accord with these molecules possessing a structure in which the ligands

LL bridge the two metal centers. Because of the conformational demands of the resulting six-membered Re—Re—P—C—C—P and Re—Re—P—C—C—As rings, the rotational conformation about the Re—Re bond is expected to be staggered, a result which has been confirmed[71] by an X-ray crystal structure determination on the compound $Re_2Cl_4(dppe)_2$ (**13**). The mean torsional (rotational) angle is 39°, reflecting the absence of any inherent electronic barrier to rotation in a compound possessing the $\sigma^2\pi^4\delta^2\delta^{*2}$ configuration. An example of a triply bonded $Re_2X_4(LL)_2$ complex has been encountered in which the two ligands LL each chelate to a single metal atom and the conformation is eclipsed; this occurs for LL = $Ph_2P(CH_2)_3PPh$ (**14**).[72] This complex is prepared in modest yield upon refluxing an acetonitrile solution containing $(Bu^n_4N)_2Re_2Cl_8$ and the bidentate phosphine ligand.

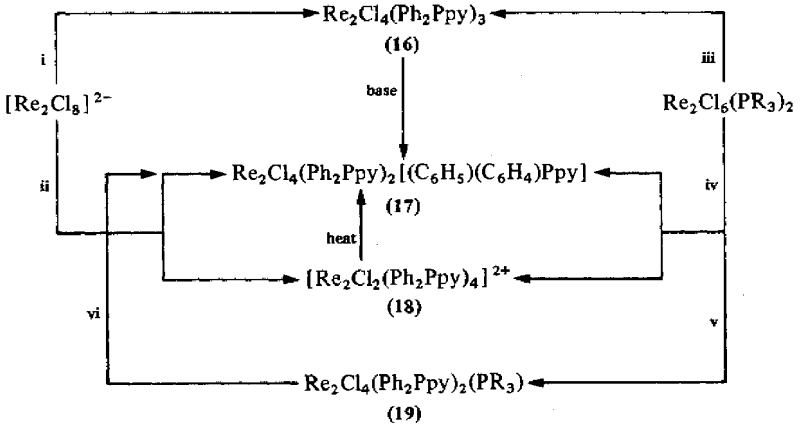


(13) L—L = dppe or arphos (14) P—P = $Ph_2P(CH_2)_3PPh_2$

Like the complexes $Re_2X_4(PR_3)_4$, the staggered species $Re_2X_4(LL)_2$, where LL = dppe or arphos and X = Cl, Br or I, exhibit two accessible one-electron oxidations.[73] These occur at $\simeq +0.25$ V and $\simeq +1.0$ V *vs.* SCE for solutions of these complexes in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2. The first process has been accomplished chemically using $NO^+PF_6^-$ as the oxidant to give paramagnetic, ESR-active $[Re_2Cl_4(LL)_2]PF_6$.

The chemistry of the dirhenium(II) complexes changes somewhat when the dppm ligand ($Ph_2PCH_2PPh_2$) is used. Although this bidentate phosphine can chelate, it shows a propensity for bridging two metal atoms. The complex $Re_2Cl_4(dppm)_2$ can be prepared by displacing the PPr^n_3 ligands in $Re_2Cl_4(PPr^n_3)_4$, although the use of $Re_2Cl_4(PEt_3)_4$ gives the mixed phosphine complex $Re_2Cl_4(PEt_3)_2(dppm)$.[70] Related procedures have been used to prepare $Re_2Cl_4(dppa)_2$ and $Re_2Cl_4(PMePh_2)_2(dppa)$ (dppa = bis(diphenylphosphino)amine).[74]

The bis-dppm complex can also be prepared, somewhat more conveniently, from the reaction between dppm and $Re_2Cl_6(PBu^n_3)_2$ in methanol, whereas the 'mixed-valent' species $Re_2Cl_5(dppm)_2$ results when diethyl ether is used as the reaction solvent.[74] While the structure of $Re_2Cl_4(dppm)_2$ (**15**) has not yet been determined crystallographically, there is little doubt that it contains two bridging dppm ligands in a *trans* disposition to each other. It exhibits, as expected, two one-electron oxidations ($E_{1/2} = +0.27$ V and $+0.80$ V *vs.* SCE).[74] When the electrolysis of dichloromethane solutions of $Re_2Cl_4(dppm)_2$ containing an excess of Cl^- is carried out at $+0.60$ V, the paramagnetic complex $Re_2Cl_5(dppm)_2$ is first formed, and this is in turn converted to $Re_2Cl_6(dppm)_2$, a complex that contains a Re—Re double bond (see Section 43.5.2.4). This conversion of $Re_2Cl_4(dppm)_2$ to higher oxidation state dirhenium species is represented in Scheme 6.



(15) P⌒P = dppm

$$Re_2Cl_4(dppm)_2 \xrightarrow{-e^-,\ +Cl^-} Re_2Cl_5(dppm)_2 \xrightarrow{-e^-,\ +Cl^-} Re_2Cl_6(dppm)_2$$

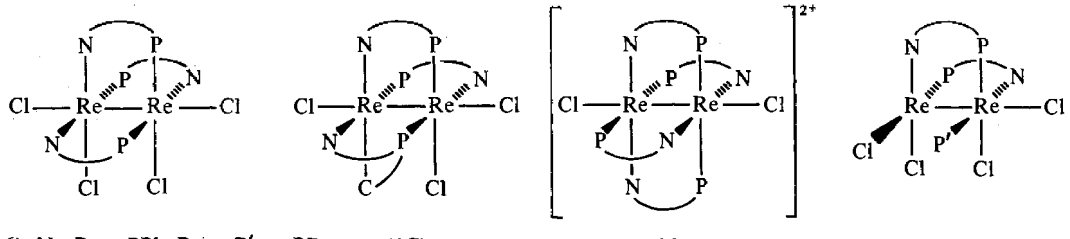
Scheme 6 Coupled electrochemical–chemical reactions involving $Re_2Cl_4(dppm)_2$



In the reactions between 2-(diphenylphosphino)pyridine (Ph_2Ppy) and the dirhenium(III) complexes $(Bu^n_4N)_2Re_2Cl_8$ and $Re_2Cl_6(PR_3)_2$ (R = Et or Bu^n), reduction takes place and several dark red-purple dirhenium(II) complexes can be isolated (Scheme 7).[75,76] The most noteworthy reaction is that between $(Bu^n_4N)_2Re_2Cl_8$ (or $Re_2Cl_6(PR_3)_2$) and Ph_2Ppy in methanol which first affords $Re_2Cl_4(Ph_2Ppy)_3$ (**16**); this complex in turn eliminates HCl in the presence of base to give the *ortho*-metallated complex $Re_2Cl_3(Ph_2Ppy)_2[Ph(C_6H_4)Ppy]$ (**17**). This complex has been subjected to an X-ray structure determination. Another product from this same reaction is the dirhenium(II) salt $[Re_2Cl_2(Ph_2Ppy)_4]Cl_2$, which contains four bridging Ph_2Ppy ligands. It can be metathesized with KPF_6 to give the salt $[Re_2Cl_2(Ph_2Ppy)_4](PF_6)_2$ (**18**), whose structure has been determned by X-ray crystallography. When acetone is used as the reaction solvent, $Re_2Cl_6(PR_3)_2$ reacts with Ph_2Ppy to give $Re_2Cl_4(Ph_2Ppy)_2(PR_3)$ (**19**) which can be converted into (**17**) upon reaction with one or two equivalents of Ph_2Ppy.[76]

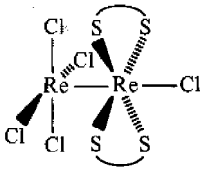
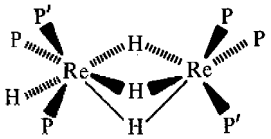
Scheme 7 Dirhenium(II) complexes of Ph_2Ppy



(16) N—P = PPh_2Ppy; P′ = PR_3 (17) (18) (19)

X-Ray crystal structures have now been carried out on the triply bonded complexes $Re_2Cl_4(dppm)_2$ (dppm = $Ph_2PCH_2PPh_2$) and α-$Re_2Cl_4(Me_2PCH_2CH_2PMe_2)_2$.[582] Studies have been made of the reactions between $Re_2Cl_4(dppm)_2$ and both CO and nitrile ligands; the metal–metal bonded complexes $Re_2(\mu\text{-Cl})(\mu\text{-dppm})_2Cl_3(CO)$,[583] $Re_2(\mu\text{-Cl})(\mu\text{-CO})(\mu\text{-dppm})_2Cl_3(CO)$[583] and $[Re_2(\mu\text{-dppm})_2Cl_3(NCR)_2]X$ (X = Cl^- or PF_6^-; R = Me, Et, Ph or 4-PhC_6H_4)[584] have been isolated and characterized. The Re—Re bond is also retained in the reactions of $Re_2Cl_4(dppm)_2$ with isocyanide ligands from which 1:1 and 1:2 complexes have been isolated, *viz.* $Re_2Cl_4(dppm)_2(CNR)$ (R = Me, Bu^t or xylyl) and $[Re_2Cl_3(dppm)_2(CNBu^t)_2]PF_6$.[585] As a by-product of the reaction between $Re_2Cl_4(dppm)_2$ and two equivalents of Bu^tNC, the novel paramagnetic μ-iminyl dirhenium(II,III) complex $[Re_2(\mu\text{-Cl})(\mu\text{-C=NHBu}^t)(\mu\text{-dppm})_2Cl_2(CNBu^t)_2]PF_6$ has been isolated.[586] The chemical oxidation of $[Re_2Cl_3(dppm)_2(NCR)_2]PF_6$ to $[Re_2Cl_3(dppm)_2(NCR)_2](PF_6)_2$ can be accomplished using $NOPF_6$,[587] and this same reagent converts $Re_2Cl_4(dppm)_2(CNR)$ to its monocation.[585] The complexes $[Re_2X_3(LL)_2L']^{n+}$ (n = 1 or 2; X = Cl or Br; LL = $Ph_2PCH_2CH_2PPh_2$ or $Ph_2PCH_2CH_2AsPh_2$; L′ = nitrile or isocyanide ligand) have also been prepared and characterized.[588]

43.4.2.3 Sulfur ligands



There are two compounds which fall into this category, *viz.* $Re_2Cl_5(DTH)_2$ and $[ReBr_2(DTH)]_n$ (DTH = 2,5-dithiahexane). Both are prepared by reaction of the appropriate $(Bu^n_4N)_2Re_2X_8$ salt with DTH in refluxing acetonitrile.[5] The structure of the bromide complex is unknown, although *n* is probably 2. In the case of $Re_2Cl_5(DTH)_2$ (**20**), this paramagnetic air-stable complex can be isolated as beautiful red-black dichroic crystals and its X-ray crystal structure shows that it possesses a staggered rotational conformation in which the two rhenium atoms are in quite dissimilar environments.[77] Formally, at least, it can be considered as the 'zwitterion' $Cl(DTH)_2Re^{II}Re^{III}Cl_4$.

(20) S—S = DTH

43.4.2.4 Hydrides

The reaction of two equivalents of the phosphite ligand $P(OCH_2)_3CEt$ (abbreviated P′) with the dirhenium(IV) hydride $Re_2H_8(PMe_2Ph)_4$ in benzene produces cleanly the complex $Re_2H_4(PMe_2Ph)_4P'_2$ (**21**), the unusual unsymmetric structure of which has been established by an X-ray crystal structure determination.[78] The two metal atoms have different coordination numbers and different formal oxidation states. Protonation of this complex with excess $HBF_4 \cdot Et_2O$ in benzene at room temperature gives the dirhenium(III) hydride $[Re_2H_5(PMe_2Ph)_4P'_2]BF_4$. Consistent with the fact that (**21**) has no symmetry, four Re—H resonances are seen in the ^1H NMR spectra at $-48°C$; by $+57°C$ these have coalesced to a single broad resonance implying that hydride migration to all four environments occurs.[79]

(21) P = PMe_2Ph; P′ = $P(OCH_2)_3CEt$

43.4.3 Trinuclear Complexes

The trinuclear rhenium(III) cluster halides Re_3X_9 (X = Cl or Br) react with many Lewis bases to form adducts of the type $Re_3X_9L_n$, where $n = 2$ or 3.[5] However, in the case of reactions with pyridine and related tertiary amines, reduction to the dark green-black trinuclear rhenium(II) complexes $[Re_3X_6L_3]_n$ occurs quite readily.[79,80] The three-electron reduction of the Re_3^{9+} cluster unit to give Re_3^{6+} is in accord with current ideas[81] concerning the electronic structures of these species. These reactions proceed *via* the unreduced adducts $Re_3X_9L_3$, but whether reduction does or does not occur depends upon the nature of X and L. The more basic amines (pK_a values > 4.9), *i.e.* pyridine, 3- and 4-methylpyridine, isoquinoline, 2-methylquinoline and benzimidazole, reduce Re_3Cl_9 to $[Re_3Cl_6L_3]_n$, while the relatively weak bases pyrazine, 2,6-dimethylpyrazine and 3-chloropyridine (pK_a values < 3) give the dark red-purple unreduced adducts $Re_3Cl_9L_3$. In the case of 2-methylpyridine, 2-vinylpyridine, 2,6-lutidine and quinoline, materials of 'intermediate' composition, approximating to $[Re_3Cl_7L_2]_n$, are produced. These phases correspond to a two-electron reduction of the Re_3^{9+} core.[5] A similar situation to that described above pertains to Re_3Br_9, but in this instance the more readily reducible bromide cluster is also reduced (to $[Re_3Br_6L_3]_n$) by the weak base 3-chloropyridine.[80] Based upon a consideration of the electronic absorption and ESCA spectral properties of the complexes $[Re_3X_6L_3]_n$, and their conversion to the rhenium(III) salts $(amineH)_2Re_3X_{11}$, it has been suggested[5] that they possess a halogen-bridged 'polymer of trimers' structure.

A variation in the nature of the reaction products that are formed by the amine reductions of Re_3Cl_9 is encountered in the case of acridine. The dark green salt $(AcrH)_2Re_3Cl_8$ is produced rather

than the adduct $[Re_3Cl_6(Acr)_3]_n$,[82] a noteworthy result since this complex contains the only known chloroanion of rhenium(II).

The reactions of Re_3X_9 (X = Cl or Br) with 2,2′-bipyridyl, 1,10-phenanthroline and 2,2′,2″-terpyridyl in acetone produce dark purple insoluble solids whose properties are in accord with the stoichiometry $(amineH)_xRe_3Cl_9(amine)_y$, in which the formal oxidation state of the rhenium is $+(3-x)$. The degree of reduction depends upon the reaction conditions that are used.[5]

43.5 RHENIUM(III) COMPLEXES

Most complexes of this oxidation state are derivatives of the rhenium(III) halides. They are classified according to the other ligands (if any) that are present. For example, $ReCl_3(PR_3)_3$ will be found under 'phosphine complexes' rather than 'halide complexes'. Mononuclear complexes of rhenium(III) are mostly of the types $[ReX_2L_4]^+$ and ReX_3L_3, but rarely $[ReX_4L_2]^-$. Additionally, two very important classes of complexes exist that are derivatives of the quadruply bonded dinuclear $[Re_2X_8]^{2-}$ and doubly bonded trinuclear $[Re_3X_{12}]^{3-}$ anions (X = Cl, Br or I).[1]

43.5.1 Mononuclear Complexes

43.5.1.1 Cyanide, alkyl isocyanides and aryl isocyanides

The best characterized cyanide complex of rhenium(III) is $K_4Re(CN)_7 \cdot 2H_2O$. It can be prepared as pale-yellow crystals through a variety of reactions between KCN and K_2ReX_6 (X = Cl or I), Re_3Cl_9 or $KReO_4$ in both aqueous and non-aqueous media.[15] The mixed salt $NaK_3Re(CN)_7 \cdot 3H_2O$ can be formed when NaCN is used in place of KCN. The $[Re(CN)_7]^{4-}$ anion is now known to be the product, often admixed with other well-defined higher oxidation state cyano rhenium species, in reactions that have previously been described as giving $[Re(CN)_6]^{4-}$, $[Re(CN)_5]^{3-}$, $[Re(CN)_6]^{3-}$, $[Re(CN)_6]^-$ and $[Re(CN)_8]^{3-}$. Indeed, there remains to be definitive structural proof that any of these latter anions have been isolated in a pure state, although there is no good reason to believe that such species cannot be prepared. For example, the X-ray powder pattern of the complex purported to be '$K_3Re(CN)_8 \cdot H_2O$'[83] resembles closely that of $K_4Re(CN)_7 \cdot 2H_2O$. The X-ray crystal structure of $K_4Re(CN)_7 \cdot 2H_2O$ shows[84] that this complex contains a pentagonal bipyramidal anion, with $r(Re—C_{ax}) = 2.077(3)$ Å and $r(Re—C_{eq}) = 2.095(5)$ Å, and is isostructural with $K_4V(CN)_7 \cdot 2H_2O$. This structural result confirms the conclusions based upon vibrational spectroscopic studies[15,85] that this geometry holds for $[Re(CN)_7]^{4-}$ in aqueous solution, as well as solid $K_4Re(CN)_7 \cdot 2H_2O$. The diamagnetism of this potassium salt is in accord with the presence of a low-spin d^4 configuration.

The following characterized isocyanide complexes of rhenium(III) are described elsewhere: $ReCl_3(CNMe)(PPh_3)_2$, $ReCl_3(CNMe)(dppe)$, $ReCl_3(CNMe)_3(PPh_3)$, $[ReCl_2(CNMe)_4(PPh_3)]^+$, $ReBr_3(CNMe)_4$ and $ReBr_3(CN\text{-}p\text{-}tol)_4$.[6] A recent attempt to isolate $ReBr_3(CN\text{-}p\text{-}tol)_3$, through the reaction of K_2ReBr_6 with *p*-tolNC in ethanol,[6] gave a material with the appropriate microanalytical data, color and IR spectroscopic properties, but it is by no means certain that this is the correct structural formulation.[22] The reaction between K_2ReI_6 and Bu^tNC in ethanol at room temperature gives golden-brown crystals of $[Re(CNBu^t)_5I_2]I_3$.[22] The related seven-coordinate chloride and bromide derivatives, $[Re(CNBu^t)_5X_2]PF_6$ (X = Cl or Br), are formed by the non-reductive cleavage of quadruply bonded $(Bu^n_4N)_2Re_2X_8$ upon their reaction with Bu^tNC in methanol.[19] The mixed isocyanide–halide–phosphine complexes of rhenium(III), $[Re(CNBu^t)_4(PEtPh_2)Cl_2]PF_6$ and $[Re(CNBu^t)_3(dppe)Cl_2]PF_6$, are likewise prepared by isocyanide cleavage of $Re_2Cl_6(PEtPh_2)_2$ or dimeric $Re_2Cl_6(dppe)_2$ (the latter containing $Re(\mu\text{-}Cl)_2Re$ bridges but no Re—Re bond).[19] These complexes show IR active $\nu(C{\equiv}N)$ modes (at $\sim 2200\,cm^{-1}$) that are in accord with them being derivatives of Re^{III}. The halogen (Cl_2, Br_2 or I_2) oxidation of $[Re(CNBu^t)_6]PF_6$ and $[Re(CNPh)_6]PF_6$ in chlorocarbon or acetone solvents in the presence of KPF_6, gives the salts $[Re(CNBu^t)_6X](PF_6)_2$ (X = Cl, Br or I) and $[Re(CNPh)_6X](PF_6)_2$ (X = Cl or Br).[19,21] Cyclic voltammetric studies have demonstrated that these complexes are quite easily reduced back to the parent rhenium(I) cations, the ease of reduction being I > Br > Cl and PhNC > Bu^tNC.[19,21]

When the reactions between various aryl isocyanides ArNC and $(Bu^n_4N)_2Re_2Cl_8$ are carrried out in methanol at room temperature, then rhenium(III)-containing complexes of the types $[Re(CNAr)_6]^+[ReCl_4(CNAr)_2]^-$ and $ReCl_3(CNAr)_3$ can be isolated.[21] These compounds display well-defined electrochemistry (cyclic voltammetry) in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2, the mononuclear Re^{III}

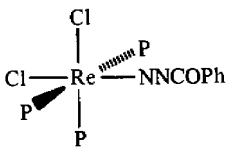
species displaying the redox processes

$$Re^{IV} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} Re^{III} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} Re^{II}$$

Characterization of the salts $[Re(CNAr)_6]^+[ReCl_4(CNAr)_2]^-$ has shown that freshly prepared samples contain the *trans* anion, but that CH_2Cl_2 solutions slowly isomerize to the corresponding *cis* isomer. The ^1H NMR spectra of these same salts reveal substantial Knight shifts associated with the paramagnetic d^4 $[ReCl_4(CNAr)_2]^-$ anions.[21] The properties of $[ReCl_4(CNAr)_2]^-$ resemble those for the nitrile analogues $[ReCl_4(NCR)_2]^-$ described in Section 43.5.1.5.

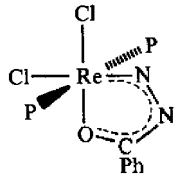
43.5.1.2 Amines, N-heterocycles and amido ligands

There are few simple complexes that contain two or more of these ligands bound to a single Re^{III} center. There are, on the other hand, a variety of mixed ligand complexes where one of these ligands is present.[1] Red-brown crystalline $ReCl_3(py)_3$ is prepared by the reaction between $ReCl_3$(benzil)(PPh_3) and pyridine, while with $ReCl_3(NCMe)(PPh_3)_2$ as the starting material, orange-brown $ReCl_3(py)_2(PPh_3)$ is produced.[86] A similar reaction between $ReCl_3(NCMe)(PPh_3)_2$ and 2,2′-bipyridyl in mixed dichloromethane–benzene solvent gives green crystalline $ReCl_3$-(bipy)(PPh_3).[86] The dark green complex $ReBr_3(NH_2$-*p*-tol$)_3$ is apparently the product from the reaction of *p*-toluidine with K_2ReBr_6.[22]



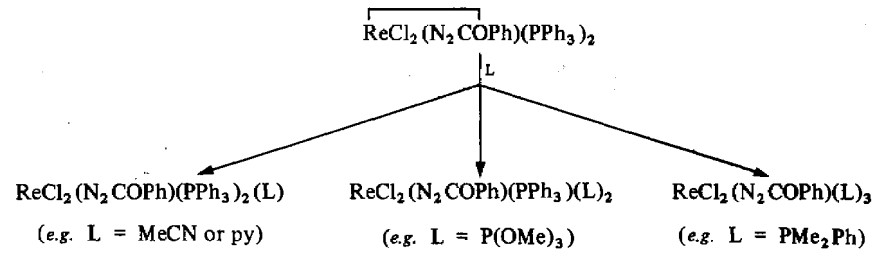
The rhenium(I) complex $Re(NHPh)(N_2)(PMe_3)_4$, which is prepared by the Na/Hg reduction of $Re(NPh)Cl_3(PMe_3)_2$ under an N_2(g) atmosphere,[34] reacts with I_2 to give $[Re(NHPh)I(PMe_3)_4]I$.[35] This constitutes a quite rare example of an amido complex of Re^{III} (see also Section 43.5.1.8).

Deprotonation of the rhenium(V) alkylimido (*i.e.* nitrene) complexes *trans*-$ReCl_3(NMe)(PRPh_2)_2$ and *trans*-$ReCl_3(NMe)(PMe_2Ph)_2$, using pyridine and PMe_2Ph/NEt_3 mixtures, respectively, gives the methyleneamido complexes of rhenium(III), $ReCl_2(N{=}CH_2)(py)(PRPh_2)_2$ (R = Me, Et or Ph) and $ReCl_2(N{=}CH_2)(PMe_2Ph)_3$.[1]



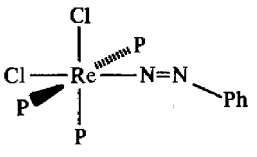
New methods for obtaining 2,2′-bipyridyl complexes of the types *fac*-$Re(bipy)(PR_3)Cl_3$ and *trans, cis*-$[Re(bipy)(PR_3)_2Cl_2]^+$ have been described.[589] The electrochemical and spectroscopic properties of these complexes have been measured.

43.5.1.3 Dinitrogen, diazenido and triazenido ligands

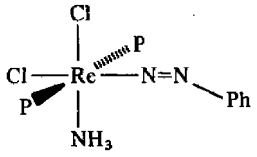


Dinitrogen complexes of rhenium(III) are rare while those of rhenium(I) are comparatively common (Section 43.3.2.1). The mixed hydride–dinitrogen complex $[ReH_2(N_2)(dppe)_2]BF_4$ is mentioned in Section 43.5.1.8. The reactions by which the rhenium(III) acyl- and aroyl-diazenido complexes $ReCl_2(N_2COR)(PMe_2Ph)_3$ (R = Me or Ph) can be formed by treatment of the rhenium(I) complexes $ReCl(N_2)(PMe_2Ph)_4$ and $ReCl(N_2)(py)(PMe_2Ph)_3$ with RCOCl have been described in Section 43.3.2.1 (see Scheme 2). These complexes display a ν(CO) mode at $\sim 1620\,cm^{-1}$ and ν(NN) at $1505\,cm^{-1}$.[42] The complex $ReCl_2(N_2COPh)(PMe_2Ph)_3$ (**22**) has also been prepared by reacting $ReCl_2(N_2COPh)(PPh_3)_2$ (**23**) with excess PMe_2Ph. This is one example of a more general type of reaction where (**23**) reacts with various ligands (MeCN, py, phosphites and other phosphines)[29,87] to give the products that are shown in Scheme 8. Further reaction with some of these same nucleophiles can give dinitrogen complexes of Re^I (see Section 43.3.2.1). An X-ray structure determination on complex (**22**) supports its formulation as a derivative of Re^{III}.[88] On the other hand, the green crystalline triphenylphosphine complex (**23**), which is prepared by the reaction of $ReOCl_3(PPh_3)_2$ with monobenzoylhydrazine and dibenzoylhydrazine in benzene–ethanol in the presence of hydrochloric acid, can be described formally as a derivative of Re^V or Re^{III}. The same is true for other complexes of this type that have been prepared by a similar procedure.[87] However,

(22) P = PMe_2Ph

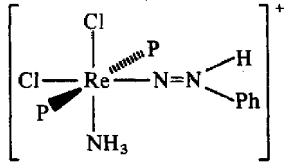


(23) P = PPh_3



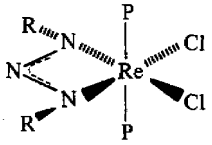
Scheme 8

while ν(CO) and ν(NN) modes have not been assigned in the IR spectra of these complexes, the ESCA spectrum of (**23**) has been interpreted in terms of its formulation as a derivative of Re^{III}.[89] In this event, the conversion of (**23**) to (**22**) constitutes a non-redox ligand substitution process.



When *mer*-$ReX_3(PMe_2Ph)_3$ (X = Cl, Br or I) is heated with phenylhydrazine in ethanol, a mixture of the phenyldiazenido complexes $ReX_2(N_2Ph)(PMe_2Ph)_3$ (**24**) and $ReCl_2(N_2Ph)(NH_3)(PMe_2Ph)_2$ (**25**) is produced.[88,90] The X-ray crystal structure of (**24**), when X = Cl, has confirmed its identity (r(Re—N) = 1.77(2) Å; r(N—N) = 1.23(2) Å),[91] and (**25**) is believed to have a very similar structure. The NH_3 ligand of (**25**) is easily displaced by CO, PMe_2Ph or PEt_2Ph, but not by MeCN, MeNC, py or PPh_3.[88,90] Reversible protonation of (**25**) can be achieved using HCl or HBr to give the salts $[ReCl_2(NNHPh)(NH_3)(PMe_2Ph)_2]X$. Structural studies on the bromide salt of (**26**) have shown that protonation occurs at the second nitrogen atom.[88,90]

(**24**) P = PMe_2Ph

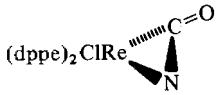


(**25**) P = PMe_2Ph

(**26**) P = PMe_2Ph

The compound $ReOCl_3(PPh_3)_2$ reacts, in the presence of PPh_3, with the lithium salts $Li(RN_3R)$ (R = Ph, *p*-MeC_6H_4, *p*-FC_6H_4 or *p*-ClC_6H_4) in boiling THF to yield the mononuclear, paramagnetic Re^{III} complexes $ReCl_2(RN_3R)(PPh_3)_2$. The reaction is believed to proceed as shown in equation (4).[92] The X-ray crystal structure of the derivative where R = *p*-MeC_6H_4 (**27**) shows the presence of chelating triazenido ligands. These complexes display the distinctive Knight-shifted ^1H NMR spectra that characterize paramagnetic mononuclear Re^{III} species.[92]

$$ReOCl_3(PPh_3)_2 + PPh_3 + Li(RN{=}{=}{=}N{=}{=}{=}NR) \longrightarrow ReCl_2(R_2N_3)(PPh_3)_2 + Ph_3PO + LiCl \quad (4)$$

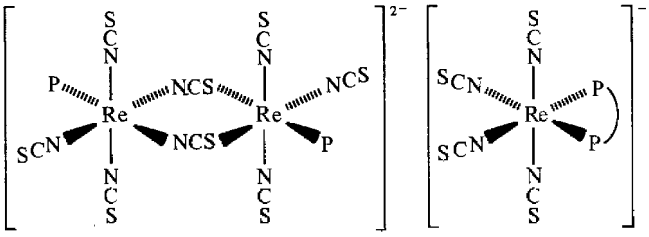


(**27**) P = PPh_3; R = *p*-tol

The syntheses and X-ray crystal structures of the diazenido complexes $Re(SCH_2CH_2SCH_2CH_2CH_2SCH_2CH_2S)(PPh_3)(N_2COPh)$[590] and $(Et_3NH)[Re_2(N_2Ph)_2(SPh)_7]$[591] have been published. The complex $ReCl(N_2Ph)_2(PPh_3)_2$ is formed by the reaction of $ReOCl_3(PPh_3)_2$ with excess phenylhydrazine in methanol,[591] or with Me_3SiN_2Ph in dichloromethane.[592] The bromo analogue can be made in an analogous fashion.[592] They react with excess HX in methanol to give the hydrazido(2−) ligand complex $ReX_2(NNHPh)(N_2)(PPh_3)_2$.[592]

43.5.1.4 Cyanate and thiocyanate

The isocyanate complex $ReCl(MeNCO)(dppe)_2$ (**28**), which has been formulated as a complex of Re^{III}, is prepared by a sequence of reactions that first involves the formation of the orange methyl



isocyanide complex $ReCl_3(CNMe)(PPh_3)_2$, from the reaction of a mixture of PPh_3 and $ReOCl_3(PPh_3)_2$ with MeNC, followed by its conversion, *via* a ligand-exchange reaction, to paramagnetic $ReCl_3(CNMe)(dppe)$ (μ_{eff} = 1.91 BM), and subsequent hydrolysis–deprotonation.

(28)

Electrochemical studies have shown that in non-aqueous media (MeCN or CH_2Cl_2), the $[Re(NCS)_6]^{2-}$ anion possesses a very accessible and quite reversible one-electron reduction ($E_{1/2}$ between −0.1 and −0.3 V depending upon solvent, *etc.*).[94,95] This result has led to the design of a procedure for the reduction of $(Bu^n_4N)_2Re(NCS)_6$ to pale yellow crystalline $(Bu^n_4N)_3Re(NCS)_6$ using $N_2H_4 \cdot H_2O$ as the reductant.[96] The resulting complex is extremely air sensitive in both the solid state and in solution, reverting to the stable $[Re(NCS)_6]^{2-}$ anion.

In contrast to the instability of $[Re(NCS)_6]^{3-}$, a variety of quite stable mixed ligand complexes are known.[94,97] The reactions of the quadruply bonded dirhenium(III) salt $(Bu^n_4N)_2Re_2(NCS)_8$ with monodentate and bidentate tertiary phosphines (PPr^n_3, PEt_2Ph, PPh_3, dppm and dppe) produce the green complexes $(Bu^n_4N)_2Re_2(NCS)_8L_2$ which contain dimeric thiocyanate-bridged anions (**29**) with magnetically dilute Re^{III} centers.[97] In the case of the dppm and dppe complexes, these phosphine ligands are believed to be bound in a monodentate fashion. These two complexes are unstable in acetonitrile solutions due to rapid intramolecular attack of the unbound 'dangling' tertiary phosphine groups upon the thiocyanate bridges. This leads to the formation of the yellow monomeric anions $[Re(NCS)_4(dppm)]^-$ and $[Re(NCS)_4(dppe)]^-$ (**30**). The orange-brown mononuclear complex $(Bu^n_4N)Re(NCS)_4(PEt_3)_2$ is formed by the reaction of $(Bu^n_4N)_2Re_2(NCS)_8$ with PEt_3, *via* the green intermediate $(Bu^n_4N)_2Re_2(NCS)_8(PEt_3)_2$.[97]

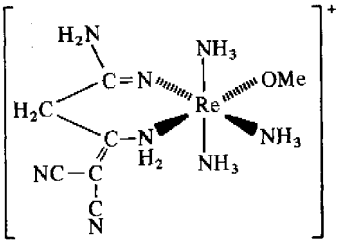
(29)

(30) P—P = dppm or dppe

Upon reacting $(Bu^n_4N)_2Re_2(NCS)_8(PEt_2Ph)_2$ (**29**; P = PEt_2Ph) with the bidentates dppe, bipy and phen, the paramagnetic mononuclear complexes $Re(NCS)_3(PEt_2Ph)$(bidentate) are formed.[97] These complexes display three electrochemically reversible one-electron waves in their cyclic voltammograms (recorded in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2) attributable to the processes

$$[Re]^+ \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Re]^0 \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Re]^- \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Re]^{2-}$$

([Re] represents the complex).[94] The X-ray crystal structure of the dppe derivative has confirmed that these compounds possess distorted octahedral structures.[94]



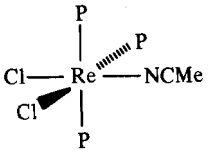
43.5.1.5 Nitriles and amidinates

The most important nitrile compound of Re^{III} is $ReCl_3(NCMe)(PPh_3)_2$, a complex which finds much use as a starting material for the synthesis of other Re^{III} complexes and some derivatives of Re^{IV}.[1] This complex and others of its kind are discussed in Section 43.5.1.6. Other complexes that contain a single nitrile ligand, *e.g.* $[ReOBr_4(NCMe)]^-$ and $[ReBr_4(NO)(NCMe)]^-$, are most conveniently considered in other sections, *i.e.* 'Rhenium(V) Complexes' (Section 43.7) and 'Nitrosyls' (Section 43.10), respectively, for the two examples cited here.

The reduction of $ReCl_4(NCMe)_2$ by NMe_3 in ethanol or by Cd/Hg in acetonitrile generates the paramagnetic $[ReCl_4(NCMe)_2]^-$ anion which can be isolated as its Cs^+, Cd^{2+} or Me_3NH^+ salts.[98]

These compounds, like $ReCl_3(NCMe)(PPh_3)_2$, do not display $\nu(C{\equiv}N)$ modes in their IR spectra (see Section 43.5.1.6). The *cis* stereochemistry of $[ReCl_4(NCMe)_2]^-$ has been confirmed by X-ray crystallography.[1] Reoxidation of the orange anion to *cis*-$ReCl_4(NCMe)_2$ can be accomplished using cold nitric acid, iodine or various oxidizing metal salts. The potential of the $[cis\text{-}ReCl_4(NCMe)_2]^{0,1-}$ couple is -0.33 V *vs.* SCE, as measured by cyclic voltammetry on 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2 solutions.[65] The salt $[Me_3NH]ReCl_4(NCMe)_2$ reacts with APh_3 (A = P, As or Sb) to give $ReCl_3(NCMe)(APh_3)_2$.[98] A novel route to the $[ReCl_4(NCMe)_2]^-$ anion involves the photochemical cleavage of the $[Re_2Cl_8]^{2-}$ anion. Ultraviolet irradiation of acetonitrile solutions of $(Bu^n_4N)_2Re_2Cl_8$ affords both tan-coloured $(Bu^n_4N)ReCl_4(NCMe)_2$ and orange $ReCl_3(NCMe)_3$.[99]

A most unusual reaction takes place between $ReOCl_3(PPh_3)_2$ and malononitrile in benzene to give a crystalline red product of stoichiometry $ReCl_3(C_6H_4N_4)(PPh_3)_2$. The yield of this product is increased in the presence of added PPh_3. It has been proposed[98] that this complex contains the 4-(dicyanomethylene)azetid-2-imine ligand $(NC)_2C{=}\overline{CNHC(NH)CH_2}$, formed by intramolecular nucleophilic addition of the enamine amino group to the non-conjugated nitrile group of the malononitrile dimer $(NC)_2C{=}C(NH_2)CH_2CN$ (abbreviated MND). When this complex is heated with pyridine, free MND is formed, while an orange crystalline complex, analyzing as 'Re(OMe)(MND)$(NH_3)_4$Cl', is produced when a methanol solution is treated with gaseous ammonia.[98] This compound is suspected of being the unusual amidine derivative (**31**); it can be isolated as its Cl^- or BPh_4^- salt.



(31)

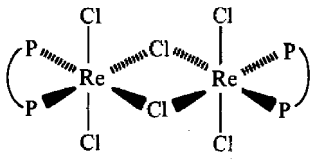
43.5.1.6 Phosphines, phosphites, arsines and stibines

The most extensive and important group of complexes are those with phosphine ligands. They are usually encountered as derivatives of mononuclear rhenium(III) halides. Compounds of the type ReX_3L_3, where L represents a trialkyl-, dialkylphenyl- or alkyldiphenyl-phosphine, or -arsine, constitute an extensive class of mononuclear rhenium(III) complexes; examples are $ReCl_3(PEt_3)_3$, $ReBr_3(PMePh_2)_3$ and $ReCl_3(AsEt_2Ph)_3$.[1,100] These complexes, which range in color from yellow to dark brown, are paramagnetic, exhibit Knight-shifted ^1H NMR spectra and invariably possess the *mer* octahedral configuration. The X-ray crystal structure of *mer*-$ReCl_3(PMe_2Ph)_3$ has been determined.[101] They are most conveniently prepared by reacting $ReOCl_3(PPh_3)_2$ or $ReCl_3(NCMe)(PPh_3)_2$ with the appropriate phosphine in boiling benzene,[1,100,102] the reaction of *trans*-$ReCl_4(PR_3)_2$ with excess PR_3 in boiling ethanol[1] or, in the case of *mer*-$ReX_3(PMe_2Ph)_3$ (X = Cl or Br), by heating $KReO_4$ in concentrated hydrohalic acid with PMe_2Ph in ethanol.[103] By reacting $ReOCl_3(dppe)$ with PEt_2Ph in boiling benzene, the mixed phosphine complex $ReCl_3(dppe)(PEt_2Ph)$ can be produced.[100] In the reactions involving the reduction of higher valent oxo–rhenium species, the phosphine ligand serves as the reducing agent by facilitating oxygen transfer from the metal through formation of the appropriate phosphine oxide. Spectroscopic studies (*e.g.* electronic absorption, IR and NMR) have been carried out on many of these complexes.[1,100]

When $ReOCl_3(PPh_3)_2$ is reacted with an excess of PPh_3 in refluxing acetonitrile, reduction to Re^{III} again occurs, but in this instance the product is $ReCl_3(NCMe)(PPh_3)_2$ (**32**).[86] This same complex has also been prepared as a relatively minor product in the reaction between β-$ReCl_4$ and PPh_3 in acetonitrile.[104] The mechanism of its formation from $ReOCl_3(PPh_3)_2$ has been looked at in some detail.[86] This complex is a very important starting material for synthesis of many rhenium(III) species,[1,86] including some of the $ReCl_3(PR_3)_3$ complexes described above. Several complexes of the type $ReX_3(NCR)(PPh_3)_2$ have been prepared using other nitrile solvents (R = Pr^n, Bu^t, n-C_7H_{15} or Ph) and $ReOX_3(PPh_3)_2$ (X = Cl or Br) as the starting material.[86] The reactions of $ReX_3(NCMe)(PPh_3)_2$ with the phosphines $PEtPh_2$, PPr^nPh_2 and PBu^nPh_2 result in displacement of the PPh_3 ligands and the formation of $ReBr_3(NCMe)(PEtPh_2)_2$ and $ReX_3(NCMe)(PRPh_2)_2$ (X = Cl or Br;

R = Pr^n or Bu^n) rather than $ReX_3(PRPh_2)_3$.[100] The $AsPh_3$ and $SbPh_3$ analogues $ReCl_3(NCMe)(APh_3)_2$ (A = As or Sb) are prepared by the reaction of $[Me_3NH]ReCl_4(NCMe)_2$ with $AsPh_3$ or $SbPh_3$.[98]

(32) P = PPh_3



Although complexes of the type $ReX_3(NCR)(PPh_3)_2$ do not exhibit an identifiable $\nu(C{\equiv}N)$ mode in the IR mull spectra, the X-ray crystal structure of $ReCl_3(NCMe)(PPh_3)_2$ (**32**) confirms the presence of normal N-bound acetonitrile, with Re—Cl distances of 2.35 Å (*trans* to Cl) and 2.40 Å (*trans* to MeCN).[105] These complexes exhibit the expected paramagnetism for d^4 Re^{III} complexes.[86] The complex $ReCl_3(NCMe)(PPh_3)_2$ and its analogues are readily oxidized by halocarbons to give Re^{IV} complexes. When solutions of $ReCl_3(NCMe)(PPh_3)_2$ are allowed to undergo oxidation in air, the pale green crystalline complex $ReOCl_3(OPPh_3)(PPh_3)$ is formed; the latter complex in turn reacts with PPh_3 to give $ReOCl_3(PPh_3)_2$ and Ph_3PO.[86]

Studies of the electrochemical behavior of *mer*-$ReCl_3(PMe_2Ph)_3$ in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2 show that it possesses both a reversible one-electron oxidation ($E_{1/2} = +0.67$ V *vs.* SCE) and a one-electron reduction.[65] A later investigation of this system showed that the electrochemical oxidation of $ReCl_3(PMe_2Ph)_3$ in acetonitrile at +0.9 V with $NaClO_4$ as supporting electrolyte could be used to prepare the violet colored rhenium(IV) complex $[ReCl_3(PMe_2Ph)_3]ClO_4$. In the presence of $(Et_4N)Cl$, this electrolysis produced *trans*-$ReCl_4(PMe_2Ph)_2$.[106] When $ReCl_3(PMe_2Ph)_3$ is reduced in acetonitrile, it is believed that the resulting monoanion reacts rapidly with solvent to produce $ReCl_2(PMe_2Ph)_3(NCMe)$, although a pure sample of the latter compound has not been isolated. However, its Re^{III} analogue, *viz.* $[ReCl_2(PMe_2Ph)_3(NCMe)]ClO_4$, is apparently formed upon reacting *mer*-$ReCl_3(PMe_2Ph)_3$ with $AgClO_4$ in acetonitrile.[106]

Complexes of the type *trans*-$ReCl_4(PR_3)_2$ (PR_3 = PEt_3, PPr^n_3, PBu^n_3, $PMePh_2$ or PPh_3) exhibit a very accessible one-electron reduction in the potential range −0.1 to −0.5 V *vs.* SCE (in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2).[65] Solutions containing the yellow Re^{III} monoanions have been generated but pure salts have not yet been isolated.[106]

A variety of well-characterized paramagnetic salts of the cationic species $[ReX_2(diars)_2]^+$ and $[ReX_2(dppe)_2]^+$ (X = Cl, Br or I) have been known for many years.[2] They are believed to possess a *trans* configuration. Their preparations have involved the reaction of $KReO_4$ with dppe in ethanolic hydrochloric acid, or $ReOX_3(dppe)$ with dppe in boiling EtOH, and the reaction of $HReO_4$ with diars in hot EtOH in the presence of hypophosphorous acid and the appropriate HX.[1,2,107] These two general synthetic methods (or variations thereof) are probably the best ones, although these complexes have been prepared by several other less direct routes.[1] More recent developments have included the synthesis of $[ReCl_2(Ph_2P(CH_2)_3PPh_2)_2]Cl$ and $[ReCl_2(Ph_2PCH{=}CHPPh_2)_2]Cl$ by the usual method starting from $KReO_4$,[100] and the preparation of $[ReCl_2(dppa)_2]X$ (X = Cl or PF_6; dppa = bis(diphenylphosphino)amine) from the cleavage of $(Bu^n_4N)_2Re_2Cl_8$.[74] Salts containing the diamagnetic $[ReCl(dppe)_2]^{2+}$ dication can apparently be produced by oxidizing $ReCl(N_2)(dppe)_2$ beyond the stage $[ReCl(N_2)(dppe)_2]^+$, using $AgNO_3$ or $AgClO_4$ as oxidants.[25] Another class of well-defined complexes that contain bidentate phosphines and arsines are the halide-bridged species $Re_2(\mu\text{-}X)_2X_4(LL)_2$ (X = Cl or Br; LL = dppe or arphos). These magnetically dilute compounds are the major products formed when $(Bu^n_4N)_2Re_2X_8$ (X = Cl or Br) is reacted with dppe or arphos in acetonitrile at room temperature.[70,108] An earlier report[2] describing the existence of diamagnetic, 'five-coordinate' $ReCl_3(diars)$ is worth reinvestigating in view of these more recent findings. The X-ray crystal structure of the magenta colored acetonitrile solvate $Re_2(\mu\text{-}Cl)_2Cl_4(dppe)_2 \cdot 2MeCN$ (**33**) has shown that the Re—Re distance is very long (~3.81 Å).[109] When complex (**33**) is refluxed in acetonitrile, the orange-brown monomer $ReCl_3(NCMe)(dppe)$ is formed through cleavage of the Re—Cl—Re bridging bonds.[70] When this reaction is carried out in the presence of an excess of dppe, a yellow insoluble complex of stoichiometry $[ReCl_3(dppe)_{1.5}]_n$ is produced.[70] It is unclear at present whether it is a dppe-bridged polymer, or ionic $[ReCl_2(dppe)_2][ReCl_4(dppe)]$.

Complexes with polydentate phosphine and arsine ligands are known but in most instances their structures are in doubt and they remain inadequately characterized.[2] The reaction between $ReCl_3(NCMe)(PPh_3)_2$ and $(Ph_2PCH_2)_3CMe$ (abbreviated P_3) gives paramagnetic (μ_{eff} = 1.8 BM), green-

(33) P—P = dppe

yellow crystalline *fac*-$ReCl_3(P_3)$.[100] A complex of this same stoichiometry had previously been prepared by the reduction of $ReOCl_3(P_3)$ in aqueous acetone using sodium dithionite.[110] This buff colored complex could be converted to the bromide by reaction with LiBr. Both the chloride and bromide are paramagnetic ($\mu_{eff} \sim 1.7$ BM) and exhibit sharp ^1H NMR spectra. However, the two different samples of $ReCl_3(P_3)$ have quite different melting points (154–6°C[110] *versus* 225–227°C[100]) thereby implying that they are not one and the same. Other less well-defined species are mentioned briefly in Section 43.5.3.3 (see Table 7).

There are a few reports which describe phosphite complexes of rhenium(III) that bear a close analogy to the phosphine derivatives $ReX_3(PR_3)_3$. Thus, the sythesis of *fac*-$ReCl_3[P(OEt)_3]_3$ has been accomplished through the reaction of $ReOCl_3(PPh_3)_2$ with an excess of $P(OEt)_3$. This structural formulation is based upon IR and NMR spectra characterization.[111] A more extensive study has led to the isolation of paramagnetic *mer*-$ReX_3[P(OR)_3]_3$ (X = Cl, Br or I; $P(OR)_3 = P(OEt)_3$ or $P(OCH_2)_3CMe$).[112] The triaryl phosphite complexes $ReI_3[P(OPh)_3]_3$, $ReI_3[P(O\text{-}p\text{-}tol)_3]_3$ and $ReX_3(PPh_3)_2[P(OPh)_3]$ are also known,[1,2] and the suggestion has been made that $ReI_3[P(OPh)_3]_3$ exists in the *mer* configuration.[113]

Phosphido complexes are not at present an important facet of rhenium(III) chemistry. The reaction between $ReOCl_3(PPh_3)_2$ and $PHPh_2$ in hot benzene gives $ReCl_2(PPh_2)(PHPh_2)_3$, but, surprisingly, this complex is said to be diamagnetic.[1] Preliminary details of the isolation of the diamagnetic homoleptic dicyclohexylphosphide complex [Li(DME)]$Re(PCy_2)_4$ have been reported.[114] The $[Re(PCy_2)_4]^-$ anion may be four-coordinate but in good donor solvents (*e.g.* THF or DME) it is believed to equilibrate with a purple paramagnetic adduct.

The complex *trans*-$[ReCl_2(Me_2PCH_2CH_2PMe_2)_2]PF_6$ has been synthesized and its X-ray crystal structure determined.[593] The related ^{186}Re-labeled complex has been made from $[^{186}ReO_4]^-$.[593]

43.5.1.7 Oxygen and sulfur donors

β-Diketone complexes of rhenium(III) are the most extensive and best characterized of those that contain oxygen and sulfur ligands. The tris-acetylacetonate (pentane-2,4-dionate, acac) of rhenium(III), $Re(acac)_3$, was first reported in 1960 as being a product of the reaction of ReO_2 with acetylacetone.[115] Twelve years later more convenient synthetic procedures were reported that involved the reaction between $Re(acac)_2Cl_2$ or $ReCl_2(acac)(PPh_3)_2$ and Na(acac).[116] Other synthetic methods involve the Zn or Zn/Hg reduction of $Re(acac)_2Cl_2$.[117] The complex $Re(hfac)_3$ (hfac = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate) has been prepared by reacting $ReCl_2(hfac)(PPh_3)_2$ with Na(hfac).[116] Dark red crystalline $Re(acac)_3$ and $Re(hfac)_3$ are volatile and exhibit well-defined mass spectra.[116] They are paramagnetic ($\mu_{eff} = 1.7$–1.8 BM at 290 K) and exhibit temperature independent paramagnetism. A consideration of the X-ray powder data for these two complexes indicates that they possess the typical tris(β-diketonate)metal structure. $Re(acac)_3$ is extremely susceptible to oxidation thereby making its handling quite difficult.[116] A rhenium(III) complex of salicylaldehyde, $ReCl_3(salH)(PPh_3)_2$, is also known (Section 43.5.1.9).

When the rhenium(V) complexes $ReOX_2(OEt)(PPh_3)_2$ (X = Cl, Br or I) are reacted with acacH in hot benzene, the species $ReOX_2(acac)(PPh_3)_2$ are formed first, and then react further to give paramagnetic, orange-red $ReX_2(acac)(PPh_3)_2$.[118] In the related reactions between $ReOCl_2(OEt)(PEt_2Ph)_2$ and acacH, and of $ReOCl_2(OEt)(PPh_3)_2$ with hfacH and tfacH (tfac = 1,1,1-trifluoropentane-2,4-dionate), the complexes $ReCl_2(acac)(PEt_2Ph)_2$, $ReCl_2(hfac)(PPh_3)_2$ and $ReCl_2(tfac)(PPh_3)_2$, respectively, can be produced.[118] When $ReOCl_2(OEt)(PPh_3)_2$ is refluxed with acacH in the absence of the benzene solvent, it appears that further substitution occurs to give $ReCl(acac)_2(PPh_3)$ (after 16 hours), and that this is followed by oxidation to the Re^{IV} complex $Re(acac)_2Cl_2$ as the reflux time is increased (to 50 hours).[118] An X-ray structure determination on a crystal of $ReCl_2(acac)_2(PPh_3)_2$ has shown[119] that it is the isomer that possesses a *trans* arrangement of phosphine ligands and *cis* disposition of Re—Cl bonds.[119]

The one-electron reduction of *cis*- or *trans*-$Re(acac)_2Cl_2$ to [*trans*-$Re(acac)_2Cl_2]^-$ can be accom-

plished through the reaction of these Re^{IV} complexes with Tl(acac) in ether, Na/MeCN or K/MeCN.[117] The bromide complex $K[Re(acac)_2Br_2]$ has also been prepared using the potassium reduction method. Cation exchange between $K[Re(acac)_2Cl_2]$ and $(Ph_4As)Cl$ in aqueous solution affords blue-green crystals of $(Ph_4As)[Re(acac)_2Cl_2]$,[117] the X-ray crystal structure of which has shown that the anion possesses a *trans* octahedral structure.[120] The major difference between the structure of the anion and *trans*-$Re(acac)_2Cl_2$ is the lengthening of the Re—Cl bond lengths of the former.[120]

When $ReCl_3(NCMe)(PPh_3)_2$ is heated with benzil (PhCOCOPh) in benzene, dark purple $ReCl_3(PhCOCOPh)(PPh_3)$ is formed along with *trans*-$ReCl_4(PPh_3)_2$. The analogous reaction with 9,10-phenanthraquinone (phenquin) gives the blue complex $ReCl_3(phenquin)(PPh_3)$.[86] The benzil complex is paramagnetic ($\mu_{eff} = 1.85$ BM) and reacts with pyridine to give $ReCl_3(py)_3$ and benzil, an important reaction since this is the only route to the tris-pyridine complex (see Section 43.5.1.2).

Coordination complexes of rhenium(III) that contain sulfur ligands are relatively uncommon, although a couple of derivatives with the diethyldicarbamato ligand resemble the related acac complexes. The reaction of $ReCl_3(NCMe)(PPh_3)_2$ with $NaS_2CNEt_2 \cdot 3H_2O$ in acetone leads to the formation of red-brown $Re(S_2CNEt)_3$. The related reaction with $NaS_2CNPh_2 \cdot 2H_2O$ gave dark purple crystalline $Re(S_2CNPh_2)_3(PPh_3)$ in which one of the diphenyldithiocarbamate ligands is believed to be monodentate.[121] The complex $ReCl_2(S_2CNEt_2)(PPh_3)_2$ is best prepared by the reaction of $ReOCl_2(S_2CNEt_2)(PPh_3)_2$ with PPh_3 by prolonged refluxing in ethanol.[121] The seven-coordinate carbonyl-containing rhenium(III) complex $Re(S_2CNEt_2)_3CO$ is produced by the reaction of $ReCl(CO)_5$ with $(Et_2NCS)_2$ and has been structurally characterized by X-ray crystallography.[6] Mixed hydrido–dithiocarbamate complexes of Re^{III} of the types $ReH(S_2CNR_2)X(PMe_2Ph)_3$ and $ReH(S_2CNR_2)_2(PMe_2Ph)_2$ are also known (see Section 43.5.1.8).

Thiourea reacts with $(Bu^n_4N)_2Re_2X_8$ (X = Cl or Br) with the resulting cleavage of the Re—Re quadruple bond and the formation of insoluble complexes formulated as $ReX_3(tu)_3$.[1] Similar products are formed upon reacting thiourea with ReO_4^- in 2 M hydrochloric acid, but all these products remain incompletely characterized.[1] The reactions of K_2ReX_6 (X = Cl, Br or I) with cysteine ($cystH_2$) have been investigated and preliminary details reported describing the isolation of the crystalline, non-ionic, diamagnetic compounds of formula $Re(cystH)_2X$ (X = Cl, Br or I).[122] A well-characterized set of thiol derivatives are the five-coordinate complexes $Re(SAr)_3(NCMe)(PPh_3)$ (Ar = Ph, *p*-tol, C_6F_5 or C_6Cl_5) that are formed by the reaction of $[ReO(SAr)_4]^-$ with excess PPh_3 in refluxing MeCN. The X-ray crystal structure of the derivative where Ar = Ph has shown that the geometry is trigonal bipyramidal.[204]

43.5.1.8 Mononuclear and dinuclear hydrides

Hydride complexes of rhenium, including those of Re^{III}, were the subject of an excellent review by Kaesz and Saillant that covered the literature up to 1971.[123] Included in this, and also in the slightly later review by Rouschias,[1] was coverage of the important complexes $ReH_3(PPh_3)_4$, $ReH_3(dppe)_2$ and $ReH_3(PPh_3)_2(dppe)$, together with $ReH_2X(dppe)_2$ (X = Cl, Br or I) which is formed by the halogenation of $ReH_3(dppe)_2$, plus the acac-containing complexes $ReH_2(acac)(PPh_3)_3$ and $ReHX(acac)(PPh_3)_3$ (X = Cl, Br or I). The complexes $ReH_3(dppe)_2$ and $ReH_3(PPh_3)_2(dppe)$ are prepared by reacting $ReH_5(PPh_3)_3$ with dppe,[124] while $ReH_3(PPh_3)_4$ is formed upon treating $ReO(OEt)I_2(PPh_3)_2$ with $NaBH_4$ in the presence of an excess of PPh_3.[127] The synthesis of the analogous PMe_2Ph derivative $ReH_3(PMe_2Ph)_4$ has been accomplished by the $LiAlH_4$ reduction of a THF solution of *mer*-$ReCl_3(PMe_2Ph)_3$ and PMe_2Ph.[125] An attempt to prepare the tri-*p*-tolylphosphine analogue of $ReH_3(PPh_3)_4$ by a related procedure gave a red product that was formulated as $[ReH_3(P\text{-}p\text{-}tol_3)_2]_2$.[126] This compound, which purportedly has a PPh_3 analogue of this same stoichiometry,[127] is most likely $Re_2H_8(P\text{-}p\text{-}tol_3)_4$, or some closely allied dirhenium polyhydride, and therefore possesses a formal oxidation state higher than Re^{III}. The white PMe_3 complex $ReH_3(PMe_3)_4$ can be prepared by treating $ReH(PMe_3)_5$ or $Re(\eta^2\text{-}CH_2PMe_2)(PMe_3)_4$ with H_2.[35]

The spectroscopic properties of $ReH_3(PR_3)_4$ (PR_3 = PPh_3, PMe_2Ph or PMe_3) and $ReH_3(dppe)_2$ (see Table 6) show that in solution they are fluxional, as evidenced by a high field quintet for the Re—H resonance in the ^1H NMR spectra. The temperature dependence of the ^1H NMR spectra of $ReH_3(dppe)_2$, $ReH_3(dpae)_2$, $ReH_3(PPh_3)_2(dppe)$ and $ReH_3(PPh_3)_2(dpae)$ (dpae = $Ph_2AsCH_2CH_2AsPh_2$) have been studied down to -90°C or so.[136] For $ReH_3(dppe)_2$ and $ReH_3(dpae)_2$, two of the three hydride ligands were equivalent at ~ -50°C, the decoupled spectrum appearing as an AB_2 pattern with $J_{H_A-H_B} \approx 9.5$ Hz. The ^1H NMR spectrum of $ReH_3(PPh_3)_2(dppe)$ consists of a triplet of triplets, as expected for three equivalent protons coupled to two non-equivalent pairs of phosphorus atoms.[136] While the solid-state structures of the complexes with monodentate phos-

[a] Measured in C_6D_6 or C_7D_8 at room temperature or thereabouts. Abbreviations are as follows: q = quintet, qd = quintet of doublets, t = triplet, dt = doublets of triplets, br = broad.
[b] Measured as KBr pellet or Nujol mull (NM).
[c] Not reported.
[d] Resonances due to different isomers.
[e] $J_{H—H} = 2.4$ Hz.
[f] Not observed.

phines, $ReH_3(PR_3)_4$, have not been determined by X-ray crystallography, those of $ReH_3(dppe)_2$ and $ReH_3(PPh_3)_2(dppe)$ have and, in both instances, the geometry has been described as a distorted pentagonal bipyramid.[128]

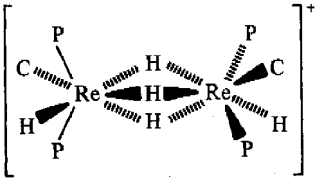
The reaction chemistries of $ReH_3(PR_3)_4$ (PR_3 = PPh_3 or PMe_2Ph) and $ReH_3(dppe)_2$ have to date been explored more thoroughly than those of any other hydrido complexes of rhenium(III). While $ReH_3(PPh_3)_4$ reacts with an excess of HX (X = Cl or Br) in benzene to give the rhenium(IV) salts $(Ph_3PH)ReX_5(PPh_3)$,[129] $ReH_3(dppe)_2$ and $ReH_3(PMe_3)_4$ can be protonated to give the tetrahydrido cationic complexes,[35,124] as shown in equation (5) for $ReH_3(PMe_3)_4$. Upon treatment of $ReH_3(PPh_3)_4$ with $P(OPh)_3$, substitution of up to three of the PPh_3 ligands can occur to give $ReH_3(PPh_3)_2[P(OPh)_3]_2$ and $ReH_3(PPh_3)[P(OPh)_3]_3$.[130] Few other mixed hydride–phosphite complexes of rhenium(III) are known at present. A mixture of $[ReH_2[P(OMe)_3]_5]^+$ and $ReH_2[P(OMe)_3]_3(O_2CCF_3)$ is believed to be produced upon protonating $Re_2[P(OMe)_3]_{10}$ with trifluoroacetic acid, while $ReH_3[P(OMe)_3]_4$ has been characterized by ^1H NMR spectroscopy (Table 6) as one of the products from photolyzing H_2–$Re_2[P(OMe)_3]_{10}$ mixtures in THF.[13]

$$ReH_3(PMe_3)_4 + HBF_4 \xrightarrow[-78°C]{THF} [ReH_4(PMe_3)_4]BF_4 \quad (5)$$

A very important reactivity difference between $ReH_3(dppe)_2$ and $ReH_3(PR_3)_4$ lies in their photochemical properties. While the initial photoproduct of the 366 nm irradiation of $ReH_3(dppe)_2$ is the highly reactive species $ReH(dppe)_2$ (see Section 43.3.3), in the case of $ReH_3(PMe_2Ph)_4$ phosphine loss rather than the elimination of H_2 occurs.[125] Under an H_2 atmosphere the 16-electron species $ReH_3(PMe_2Ph)_3$ smoothly converts to $ReH_7(PMe_2Ph)_2$ *via* the intermediacy of $ReH_5(PMe_2Ph)_3$ (equation 6). The putative 14-electron intermediates $ReH_3(PAr_3)_2$ (Ar = aryl) are other examples of coordinatively and electronically unsaturated hydrido species. They are believed to be formed in reactions of $ReH_7(PAr_3)_2$ that result in the dehydrogenation of alkanes.[131]

$$ReH_3(PMe_2Ph)_4 \xrightarrow[H_2]{h\nu} PMe_2Ph + ReH_5(PMe_2Ph)_3 \xrightarrow[H_2]{h\nu} PMe_2Ph + ReH_7(PMe_2Ph)_2 \quad (6)$$

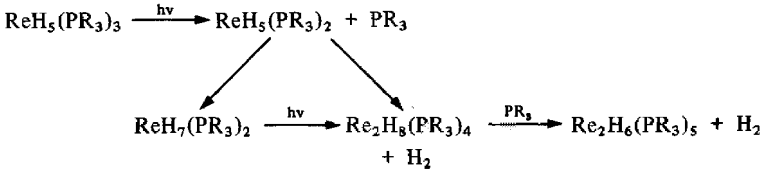
Protonation of $ReH(N_2)(dppe)_2$ with HBF_4 in benzene gives the cream colored salt $[ReH_2(N_2)(dppe)_2]BF_4$. When HCl is used in place of HBF_4 then $ReHCl_2(dppe)_2$ is formed, presumably *via* the intermediacy of $[ReH_2(N_2(dppe)_2]Cl$.[36] In a similar fashion, treatment of the rhenium(I) complex $ReCl(PMe_3)_5$ with one equivalent of aq. 48% HBF_4 produces the yellow monohydride $[ReHCl(PMe_3)_5]BF_4$ (Table 6).[35] Other dinitrogen complexes of rhenium(I) provide a route, *via* protonation, to hydrido–rhenium(III) species. The complexes *mer*-$Re(S_2CNR_2)(N_2)(PMe_2Ph)_3$ (R = Me or Et) react with an excess of HX (X = Cl or Br) in THF to give $[ReH_2(S_2CNR_2)X(PMe_2Ph)_3]X$, which on treatment with NEt_3 or pyridine give $ReH(S_2CNR_2)X(PMe_2Ph)_3$. The latter species are converted to $ReH(S_2CNR_2)_2(PMe_2Ph)_2$ when reacted with $Na(S_2CNR_2)$ in acetone solution.[26] Spectroscopic properties of representative complexes of these types are given in Table 6.



When slurries in acetonitrile of the heptahydride complex $ReH_7(PPh_3)_2$ and the pentahydrides $ReH_5(PPh_3)_2L$ (L = py or $C_6H_{11}NH_2$) are treated with HBF_4, then H_2 is evolved and quantitive yields of the yellow colored salts $[ReH(NCMe)_3(PPh_3)_2L](BF_4)_2$ (L = MeCN, py or $C_6H_{11}NH_2$) are obtained.[132] This constitutes an alternative and quite simple strategy for the preparation of monohydrido–rhenium(III) complexes. These complexes exhibit a reversible one-electron oxidation at ~ 1.0 V *vs.* SCE, as measured by the cyclic voltammetric technique. Bulk electrolysis of CH_2Cl_2 solutions of $[ReH(NCMe_3)_3(PPh_3)_2L]^{2+}$ affords purple $[ReH(NCMe)_3(PPh_3)_2L]^{3+}$, a rare example of a mononuclear hydrido–rhenium(IV) species.[132]

A more complete account is now available[594] describing the protonation reactions of the complexes $ReH_7(PPh_3)_2$, $ReH_5(PPh_3)_2L$ (L = py, $C_6H_{11}NH_2$ or Bu^tNH_2) and $ReH_4I(PPh_3)_3$ with $HBF_4 \cdot Et_2O$ in acetonitrile or propionitrile (for a preliminary report see ref. 132). This procedure affords the seven-coordinate monohydrido complexes $[ReH(NCR)_3(PPh_3)_2L](BF_4)_2$ in good yield.

The very air-sensitive complex $ReH_2(NHPh)(PMe_3)_4$ can be obtained by the Na/Hg reduction of $Re(NPh)Cl_3(PMe_3)_2$ in the presence of excess PMe_3 under an H_2 atmosphere or by the oxidative addition of hydrogen to $Re(NHPh)(N_2)(PMe_3)_4$. This reaction (equation 7) is reversible at room temperature. The ^1H NMR spectrum of this complex has been interpreted in terms of the presence of two isomers (Table 6).[34] When the reduction of $Re(NPh)Cl_3(PMe_3)_2$ is carried out under argon in the presence of excess PMe_3 then the yellow crystalline monohydride $ReH(NHPh)(\eta^1\text{-}CH_2PMe_2)(PMe_3)_4$ is believed to be the reaction product.[34]



$$Re(NHPh)(N_2)(PMe_3)_4 + H_2 \rightleftharpoons ReH_2(NHPh)(PMe_3)_4 + N_2 \quad (7)$$

The tetrahydrido–dirhenium(II) complex $Re_2H_4(PMe_2Ph)_4P'_2$ (**21**) (P′ = $P(OCH_2)_3CEt$) (see Section 43.4.2.4) can be protonated using $HBF_4 \cdot Et_2O$ in benzene solution to give the dirhenium(III) complex $[Re_2H_5(PMe_2Ph)_4P'_2]BF_4$.[78] An X-ray structure determination (carried out at −160°C) shows it to have the symmetric structure $(Me_2PhP)_2(P')HRe(\mu\text{-}H)_3ReH(P')(PMe_2Ph)_2$ with an Re—Re distance (2.605(2) Å) very similar to that in $Re_2H_4(PMe_2Ph)_4P'_2$ (2.597(1) Å).[78] At −60°C this complex exhibits (in CD_2Cl_2) three hydride resonances in its ^1H NMR spectrum, two of which are due to inequivalent bridging hydride environments (ratio 2:1), and one ^{31}P ABX pattern consistent with the solid-state symmetry. By +16°C the $^{31}P\{^1H\}$ spectrum appears as an A_2X pattern, and the two types of bridging hydride ^1H NMR resonances coalesce but remain distinct from the terminal hydride triplet. The latter triplet pattern arises from coupling of each of the equivalent terminal hydride ligands to the two 'local' PMe_2Ph ligands.[78] The characteristics of the ^1H NMR spectrum of $[Re_2H_5(PMe_2Ph)_4P'_2]^+$ at +16°C are also seen in the related spectrum of $[Re_2H_5(PPh_3)_4(CNBu^t)_2]PF_6$ (**34**) over the temperature range +35 to −70°C. This complex is prepared through the reaction of $[Re_2H_8(PPh_3)_4]PF_6$ with Bu^tNC in dichloromethane,[132,133] and an X-ray crystal structure determination has shown that it possesses a structure very similar to that of the mixed phosphine–phosphite derivative with an Re—Re distance of 2.604(1) Å.[133] The maroon complex (**34**) can be oxidized by $(NO)PF_6$ in acetone to afford the paramagnetic, ESR-active, dark blue compound $[Re_2H_5(PPh_3)_4(CNBu^t)_2](PF_6)_2$.[132,134] In contrast to the lack of reaction between (**34**) and Bu^tNC, its oxidized congener reacts rapidly to give $[Re(CNBu^t)_4(PPh_3)_2]PF_6$ and gaseous H_2, along with significant quantities of (**34**) that are formed by back reduction of the dication without concomitant isocyanide coordination.

(34) P = PPh_3; C = $CNBu^t$

Photolysis of benzene or isooctane solutions of $ReH_5(PR_3)_3$ (PR_3 = PMe_2Ph, $PMePh_2$ or PPh_3) results in the photoextrusion of a PR_3 ligand rather than H_2.[125,135] This leads (as shown in Scheme 9) to the formation of several products, including $Re_2H_6(PR_3)_5$ in the case of PR_3 = PMe_2Ph or $PMePh_2$ (but not PPh_3). A further product obtained in the case of the photolysis of $ReH_5(PPh_3)_3$ is the trihydride $ReH_3(PPh_3)_4$.[125] The structural characterization of $Re_2H_6(PMe_2Ph)_5$ has included an X-ray structure determination, but not all the metal-bound hydrogens have been located.[135] The metal–metal separation is 2.538(4) Å. ^1H NMR spectral evidence is consistent with the structure $(Me_2PhP)_3HRe(\mu\text{-}H)_3ReH_2(PMe_2Ph)_2$, so that this complex could be viewed as a mixed oxidation state species.[135]

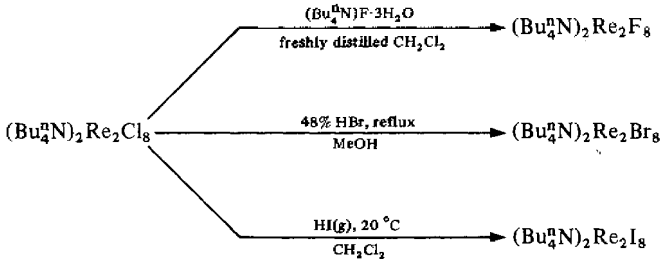
Scheme 9 Photochemistry of $ReH_5(PR_3)_3$ (ref. 135)

43.5.1.9 Mixed donor atom ligands

An important recent development has been the isolation of several mixed N—O ligand complexes of Re^{III}. The complex $ReCl_3(NCMe)(PPh_3)_2$ reacts in boiling salicylaldehyde (salH) to produce green $ReCl_3(salH)(PPh_3)_2$ in low yield.[205] In this paramagnetic complex the salH ligand is believed to be bound through its carbonyl oxygen, at least on the basis of its IR spectral properties. The Schiff base rhenium(V) complexes $ReOX_2L(PPh_3)$ [X = Cl or Br; L = *N*-methylsalicylideneiminate, *N*-phenylsalicylideneiminate, ½*N*,*N*′-ethylenebis(salicylideneiminate)] react with an excess of PMe_2Ph to give the red rhenium(III) complexes $ReX_2L(PMe_2Ph)_2$ *via* the intermediacy of $ReOX_2L$-

(PMe_2Ph).[206] These paramagnetic complexes exhibit well-defined Knight-shifted ^1H NMR spectra and are believed to have a *trans* disposition of PMe_2Ph ligands and a *cis* arrangement of Re—X bonds. The complex $ReCl_2$(Ph-sal)$(PMe_2Ph)_2$ is said to isomerize when heated under argon in toluene to give the isomer with the phosphine and halide ligands mutually *cis* to one another.[207] The Schiff base complex $ReCl_2$(Ph-sal)$(PMe_2Ph)_2$ reported previously,[206] has now been structurally characterized by X-ray crystallography.[595] The complex $ReCl_2$(Me-sal)$(PPh_3)_2$ has been prepared by the reaction of *trans*-$ReCl_4(PPh_3)_2$ with the lithium salt of the ligand in refluxing benzene.[207]

The pyrazolylborate complex $ReCl_2(PPh_3)[HB(pz)_3]$ can be prepared in high yield by the reaction of $ReOCl_2[HB(pz)_3]$ with PPh_3 in hot toluene.[572]



43.5.2 Dinuclear Complexes Containing the Re_2^{6+} Core

Section 43.4.2 dealt with the chemistry of coordination complexes that are derivatives of the triply bonded Re_2^{4+} core, possessing the $\sigma^2\pi^4\delta^2\delta^{*2}$ electronic configuration. The removal of two electrons from this configuration gives rise to complexes that contain the quadruply bonded Re_2^{6+} core. The literature covering the period between the discovery of this class of complexes in 1964 and the latter part of 1981 is surveyed in the text 'Multiple Bonds Between Metal Atoms' by F. A. Cotton and R. A. Walton that was published in 1982.[5] This source (Chapters 2 and 8 in particular) should be consulted for an exhaustive survey of this field. Accordingly, we shall in the present section restrict our coverage to a relatively brief consideration of the literature for the period 1964–81 and a more thorough treatment of the work that has been published since that time. Since salts of the octahalodirhenate(III) anion serve as the most convenient starting point for the synthesis of almost all dirhenium(III) complexes, they will be considered first.

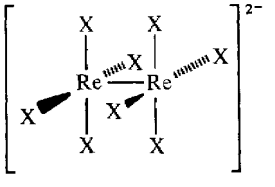
The quadruply bonded dirhenium(III) acetate complex $Re_2Cl_4(O_2CCH_3)_2 \cdot 2H_2O$ reacts with PPh_3 in refluxing ROH (R = Me, Et or Pr^n) to give the red crystalline complexes $Re_2Cl_4(OR)_2(PPh_3)_2$ which have proved to be the $Re^{IV}Re^{II}$ mixed valent species $(RO)_2Cl_2ReReCl_2(PPh_3)_2$.[596] The one-electron oxidation and one-electron reduction of the complex $Re_2(\mu\text{-}Cl)_2(\mu\text{-dppm})_2Cl_4$[74] can be accomplished using $NOPF_6$ and cobaltocene as the oxidant and reductant, respectively, to give paramagnetic ions that possess Re—Re bond orders of 1.5.[587,597]

43.5.2.1 Halides

The tetra-*n*-butylammonium salt $(Bu_4^nN)_2Re_2Cl_8$, because of its relative ease of preparation and favourable solubility properties in many organic solvents, has been the most commonly used starting material in dirhenium(III) chemistry. This blue crystalline material was for many years most conveniently prepared by the hypophosphorous acid reduction of $[ReO_4]^-$ in aqueous hydrochloric acid.[137] However, because of the relatively low yield in which this salt was prepared (40% or less), another more convenient method has been sought and, very recently, discovered.[138,139] The reaction between $(Bu_4N)ReO_4$ and refluxing benzoyl chloride affords a solution which upon the addition of an HCl(g) saturated solution of $(Bu_4^nN)Br$ dissolved in ethanol gives $(Bu_4^nN)_2Re_2Cl_8$ in 90% yield. Both $[ReCl_6]^{2-}$ and $Re_2(O_2CPh)_2Cl_4$ have been isolated as intermediates in this reaction.[138] An alternative starting material for the synthesis of $(Bu_4^nN)_2Re_2Cl_8$ with PhCOCl is $ReOCl_3(PPh_3)_2$, which is itself prepared from perrhenate. This reaction proceeds *via* red *trans*-$ReCl_4(PPh_3)_2$ which can be isolated.[138] Cation exchange reactions can be used to obtain other salts of this anion,[5] while halide exchange reactions can be used to prepare the related fluoride, bromide and iodide anions as shown in Scheme 10.[5,140,141] An alternative route to $(Bu_4^nN)_2Re_2X_8$ (X = Cl, Br or I) involves the treatment of solutions of the benzoate complex $Re_2(O_2CPh)_4Cl_2$ with HX(g) in the presence of $(Bu_4^nN)X$ (equation 8).[61] A variety of other less convenient procedures exist for the preparation of salts of the $[Re_2X_8]^{2-}$ anions (X = Cl or Br) that contain the cesium cation or various organic cations.[5] Of these, the conversion of the trinuclear cluster Re_3Cl_9 to $[Re_2Cl_8]^{2-}$ by reaction with molten $Et_2NH_2^+Cl^-$ is of special note since it proceeds in quite high yield.[142] However, it suffers from one big disadvantage, in that it requires a ready source of Re_3Cl_9, a compound that is itself best prepared from $[Re_2Cl_8]^{2-}$ *via* the quadruply bonded acetate complex $Re_2(O_2CMe)_4Cl_2$.[143] Another recent noteworthy study[144] showed that the dirhenium octahydride complex $Re_2H_8(PPh_3)_4$ (see Section 43.6.1.10), reacts with allyl chloride or bromide to give $(Ph_3PC_3H_5)_2Re_2X_8$ in 70–80% yield (equation 9). When $Re_2H_8(PPh_3)_4$ is treated with HCl(g) in MeOH the mixed salt $(Ph_3PH)_2Re_2Cl_8 \cdot 5(Ph_3PH)ReCl_5(PPh_3)$ is formed.[144]

Scheme 10

$$Re_2(O_2CPh)_4Cl_2 + 8HX + 4(Bu^n_4N)^+ \xrightarrow[\text{reflux}]{ROH} (Bu^n_4N)_2Re_2X_8 + 4Ph_2CO_2H + 4H^+ \quad (8)$$



(X = Cl, Br or I)

$$Re_2H_8(PPh_3)_4 + \text{excess } C_3H_5X \xrightarrow{THF} (Ph_3PC_3H_5)_2Re_2X_8 + C_3H_6 + H_2 \quad (9)$$

(X = Cl or Br)

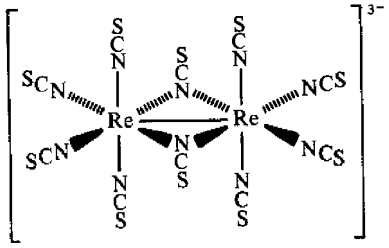
With the exception of $Cs_2Re_2Cl_8 \cdot H_2O$ and $Cs_2Re_2Br_8$, other salts possessing alkali metal cations (K^+ or Rb^+) and the NH_4^+ cation have generally been prepared (admixed with the corresponding salts of $[ReCl_6]^{2-}$) *via* the high pressure reduction of $[ReO_4]^-$ by molecular hydrogen in concentrated hydrochloric acid.[5] These compounds, while being structurally similar to $(Bu^n_4N)_2Re_2X_8$ and possessing the same electronic structure, have such low solubilities in non-aqueous organic solvents that their chemical reactivities have not been explored in any great detail.

Several X-ray crystal structures have been determined for salts containing the $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$ anions, all of which were published before 1982.[5,145] The only recent structure determination is that of $[(DMA)_2H]_2Re_2Br_8$ (DMA = dimethylacetamide).[146] While the crystal structures of the fluoride and iodide salts $(Bu^n_4N)_2Re_2X_8$ have not yet been determined, there can be no doubt that they possess the typical $[Re_2X_8]^{2-}$ (**35**) structure, which is characterized by an eclipsed rotational conformation and a very short Re—Re distance (2.22–2.25 Å).[5] Following the isolation of the complex $Re_4I_8(CO)_6$ by the I_2 oxidation of $Re_2I_2(CO)_6(THF)_2$ in heptane, an X-ray crystal structure determination showed that this tetrarhenium complex could be viewed formally as a complex between two $Re(CO)_3^+$ fragments and $[Re_2I_8]^{2-}$, the association occurring *via* bent Re—I—Re bridges that involve six of the iodine atoms of $[Re_2I_8]^{2-}$. However, as a consequence of this structure, the rotational conformation within the central Re_2I_8 unit is staggered rather than eclipsed and, as a result, the Re—Re bond length increases to 2.279(1) Å.[147] In accord with the bonding scheme for such a species,[5] as the conformation shifts from eclipsed to staggered, the δ bonding diminishes (*i.e.* d_{xy}–d'_{xy} overlap) and the metal–metal bond order decreases from four to three.

(35)

The electronic structures of the $[Re_2X_8]^{2-}$ anions have been the subject of much interest. Molecular orbital calculations have established the correctness of the bonding model that pictures the Re—Re bond as being one of order four with the $\sigma^2\pi^4\delta^2$ ground state electronic configuration.[5,148] This has further been supported by electronic absorption spectral studies, including the definitive assignment of the $\delta \rightarrow \delta^*$ transition,[5,148,149] and vibrational spectral measurements (including resonance Raman spectra).[149] The latter have led to the assignment of the ν(Re—Re) frequencies both in the ground and excited states.[5,149]

An appreciation of the bonding in these molecules has led to studies of the emission spectra of $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$,[5] including an investigation of the electron transfer chemistry of the luminescent excited state of the octachlorodirhenate(III) anion, *i.e.* $\{[Re_2Cl_8]^{2-}\}^*$. These experiments have revealed that $\{[Re_2Cl_8]^{2-}\}^*$ functions as a strong oxidant as well as a moderately good reductant in non-aqueous media.[150] In particular, the reaction of the $\delta\delta^*$ singlet $\{[Re_2Cl_8]^{2-}\}^*$ with



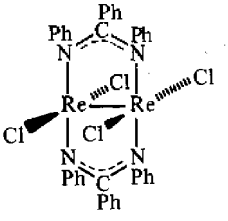
electron acceptors such as TCNE provides a facile route to the powerful inorganic oxidant $[Re_2Cl_8]^-$.[150] In this context it should be noted that the $[Re_2Cl_8]^{2-}$ anion has a quite well-defined electrochemistry. A one-electron reduction occurs close to -0.85 V *vs.* SCE in acetonitrile, but approaches electrochemical reversibility only at high sweep rates.[5] This reduction is chemically irreversible. Cyclic voltammetric measurements have shown[21,150] that the $[Re_2Cl_8]^{2-}/[Re_2Cl_8]^-$ couple occurs at $+1.24$ V *vs.* SCE in MeCN and at $+1.20$ V *vs.* SCE in CH_2Cl_2. The electrochemical properties of $(Bu^n_4N)_2Re_2Br_8$ have not been as extensively studied, although acetonitrile solutions of this complex have been shown by cyclic voltammetry to possess irreversible reductions at -0.70 V and -1.32 V *vs.* SCE.[5] Chemical oxidations and reductions of the $[Re_2X_8]^{2-}$ anions and their derivatives which give rise to dirhenium complexes possessing formal charges either greater or less than $+6$[5] are discussed in those sections that survey the appropriate oxidation states, *i.e.* $[Re_2Cl_9]^-$ is discussed with other Re^{IV} compounds while the complexes $Re_2Cl_4(PR_3)_4$ (and $Re_2Cl_5(PR_3)_3$, *etc.*) are included with Re^{II} species.

Few methods have yet been developed for preparing mixed octahalo anions, although the reaction of $(Bu^n_4N)_2Re_2Cl_8$ with calculated quantities of 48% hydrobromic acid has been used to prepare $[Re_2Cl_6Br_2]^{2-}$, $[Re_2Cl_3Br_5]^{2-}$ and $[Re_2Cl_2Br_6]^{2-}$.[151] Also, the CCl_4 oxidation of $Re_2Br_4(PEt_3)_4$ produces the salt $(Et_3PCl)_2Re_2Cl_4Br_4$, along with a quantity of $Re_2Cl_4Br_2(PEt_3)_2$[57] (see Section 43.4.2.1). The analogous reaction of $Re_2Cl_4(PEt_3)_4$ with CCl_4 gives $(Et_3PCl)_2Re_2Cl_8$,[57] an illustration of the relative ease with which complexes possessing the Re_2^{4+} and Re_2^{5+} cores can be oxidized back to Re_2^{6+}.[5]

43.5.2.2 Thiocyanate and selenocyanate

The reactions of $(Bu^n_4N)_2Re_2Cl_8$ with NaSCN and KSeCN in non-aqueous media give dark red $(Bu^n_4N)_2Re_2(NCS)_8$ and purple $(Bu^n_4N)_2Re_2(NCSe)_8$, respectively.[5] The spectroscopic characterizations of these two complexes accord with them possessing the type of structure depicted by (**35**) with N-bound NCS and NCSe ligands.[5] In the case of $[Re_2(NCS)_8]^{2-}$, cation exchange reactions can be used to give other salts. Polarographic and cyclic voltammetric measurements, in MeCN and CH_2Cl_2 respectively, have shown that $(Bu^n_4N)_2Re_2(NCS)_8$ possesses two accessible one-electron reductions close to -0.1 V and -0.75 V *vs.* SCE.[5,94]

In the reaction between $(Bu^n_4N)_2Re_2Cl_8$ and NaSCN, acidified MeOH is the solvent which is used in the preparation of the aforementioned $(Bu^n_4N)_2Re_2(NCS)_8$, whereas the use of acetone produces red-brown $(Bu^n_4N)_2Re(NCS)_6$ and dark green $(Bu^n_4N)_3Re_2(NCS)_{10}$ (**36**), both of which are oxidation products of $(Bu^n_4N)_2Re_2(NCS)_8$.[152,153] The X-ray crystal structure of paramagnetic (**36**) shows that this symmetric dirhenium complex possesses an edge-shared bioctahedral structure with an Re—Re bond (2.613(1)Å). The structural details imply that the oxidation state description is $(+3.5, +3.5)$ rather than $(+4, +3)$. Note that in the reaction of $(Bu^n_4N)_2Re_2(NCS)_8$ with phosphines, the Re—Re bond is cleaved to a similar bioctahedral structure $[Re_2(\mu\text{-}NCS)_2(NCS)_6(PR_3)_2]^{2-}$ (see Section 43.5.1.4) which, however, does not possess an Re—Re bond, *i.e.* the latter complexes are magnetically dilute $(+3, +3)$ species.

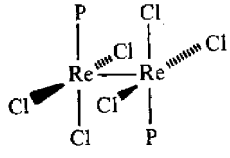


(36)

43.5.2.3 N-Heterocycles and amidine ligands

A poorly characterized, insoluble, gray-black 2,2′-bipyridine complex formulated as $[ReCl_3(bipy)\cdot 3/2H_2O]_n$ (the value of n is unknown) has been obtained from the reaction of $(Bu^n_4N)_2Re_2Cl_8$ with bipy in *n*-butanol. It is paramagnetic ($\mu_{eff} = 1.36$ BM), but its spectral properties give few clues as to its structure.[108]

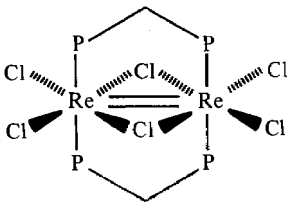
The reactions of $(Bu^n_4N)_2Re_2Cl_8$ with *N,N′*-diphenylbenzamidine ($PhC(NPh)_2H$), *N,N′*-di-



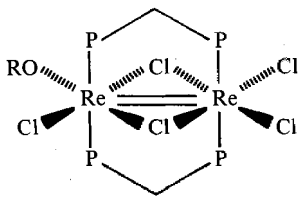
methylbenzamidine ($PhC(NMe)_2H$) and *N,N'*-diphenylacetamidine ($MeC(NPh)_2H$) have been found to produce the amidinato-bridged species $Re_2[(PhN)_2CPh]_2Cl_4$, $Re_2[(PhN)_2CPh]_2Cl_4 \cdot THF$, $Re_2[(PhN)_2CMe]_2Cl_4$ and $Re_2[(MeN)_2CPh]_4Cl_2 \cdot CCl_4$, all of which have been characterized by X-ray crystallography. The first three complexes have a *trans* disposition of amidinate ligands as shown in the case of $Re_2[(PhN)_2CPh]_2Cl_4$ (**37**), whereas $Re_2[(MeN)_2CPh]_4Cl_2 \cdot CCl_4$ has the closely related tetracarboxylato-type structure (*i.e.* $Re_2(O_2CR)_4Cl_2$, see Section 43.5.2.5) with two weakly bound axial chloride ligands. The THF solvate is of special interest since the THF molecule occupies one of the empty coordination sites colinear with the Re—Re bond and the rotational conformation is twisted 6° from the perfect eclipsed one found in the parent.[5] The Re—Re distances in these complexes fall in the narrow range 2.18 to 2.21 Å.[154,155]

(37)

43.5.2.4 Phosphines and arsines



The reaction of the $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$ anions with monodentate tertiary phosphines (*e.g.* PEt_3, PPr^n_3, PBu^n_3, PEt_2Ph, $PEtPh_2$ and PPh_3) in methanol gives the green substitution products $Re_2X_6(PR_3)_2$. The X-ray crystal structure of $Re_2Cl_6(PEt_3)_2$ (**38**) has confirmed the close structural relationship of these complexes to the parent anions.[57,156,157] The related reaction of $[Re_2X_8]^{2-}$ with $AsPh_3$ gives $Re_2X_6(AsPh_3)_2$. The phosphine complexes have been found to undergo one-electron reductions to give the monoanions $[Re_2X_6(PR_3)_2]^-$ possessing Re—Re bonds of order 3.5 (see Section 43.4.2.1). The oxidation of the triply bonded dirhenium(II) complex $Re_2Cl_4(PMe_2Ph)_4$ using $(NO)PF_6$ has been shown to give the salts $[Re_2Cl_4(PMe_2Ph)_4]PF_6$ and $[Re_2Cl_4(PMe_2Ph)_4](PF_6)_2$ (Section 43.4.2.1).[66] The latter diamagnetic quadruply bonded dicationic complex is isoelectronic with the neutral derivatives $Re_2X_6(PR_3)_2$. It reacts with Cl^- to give $Re_2Cl_6(PMe_2Ph)_2$ and can be cleaved by CO to give the mononuclear rhenium(I) carbonyl complex $ReCl(CO)_3(PMe_2Ph)_2$.[65,69]

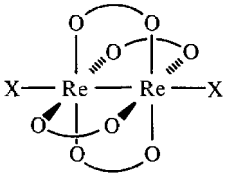


(38) P = PEt_3

While the reactions of $[Re_2X_8]^{2-}$ (X = Cl, Br or I) with dppe or arphos give either the triply bonded dirhenium(II) complexes $Re_2X_4(LL)_2$ (LL = dppe or arphos) (see Section 43.4.2.2) or the dimeric halogen-bridged magnetically dilute rhenium(III) complexes $Re_2(\mu\text{-}X)_2X_4(LL)_2$ (see Section 43.5.1.6), the complex $Re_2Cl_6(dppm)_2$ (**39**) can be prepared by the reaction of $(Bu^n_4N)_2Re_2Cl_8$ with bis(diphenylphosphino)methane in acetonitrile or dichloromethane.[70,74] It can also be generated by the electrochemical oxidation of $Re_2Cl_4(dppm)_2$ or $Re_2Cl_5(dppm)_2$ in the presence of chloride ion (see Section 43.4.2.2). The X-ray crystal structure of purple crystalline (**39**) confirms the structure proposed previously on the basis of ESCA data.[70,74] Furthermore, the structural details, including the Re—Re bond distance of 2.616(1) Å,[74] are in accord with the structure that had been predicted on the basis of this compound possessing a rhenium–rhenium double bond ($\sigma^2\pi^2\delta^2\delta^{*2}$ configuration).[158] The properties of (**39**) are very similar to those of the complexes $Re_2Cl_6(Ph_2Ppy)_2$[76] and $Re_2Cl_6(dppa)_2$ (dppa = bis(diphenylphosphino)amine)[74] that have been prepared by the reactions of $Re_2Cl_6(PBu^n_3)_2$ and $(Bu^n_4N)_2Re_2Cl_8$ with Ph_2Ppy and dppa, respectively. Accordingly, these three complexes are believed to have similar structures and to be members of the class of complexes that contain Re—Re double bonds. Other such derivatives are the alkoxide complexes $Re_2Cl_5(OR)(dppm)_2$ (**40**) (R = Me, Et, Pr^n or Bu^n) that are formed preferentially over

$Re_2Cl_6(dppm)_2$ when $(Bu^n_4N)_2Re_2Cl_8$ is reacted with dppm in the appropriate refluxing ROH solvent.[74]

(39) P⌒P = dppm



(40)

Electrochemical studies on solutions of (**39**) and (**40**) in 0.2 M $(Bu_4N)PF_6$–CH_2Cl_2 show that these complexes exhibit a well-defined and rich redox behavior. In the case of (**39**) four couples are observed in the potential range + 1.8 to − 1.4 V *vs.* SCE; two correspond to one-electron oxidations and two to one-electron reductions.[74]

43.5.2.5 Sulfates and alkyl and aryl carboxylates

The sulfato-bridged complex $Na_2Re_2(SO_4)_4 \cdot 8H_2O$ has been prepared by the reaction of $(Bu^n_4N)_2Re_2Cl_8$ with sulfate anion and may be reconverted to the chloro anion by reaction with refluxing hydrochloric acid in the presence of $(Bu^n_4N)Cl$. The structure shows the presence of weakly coordinated axial water molecules (r(Re—Re) = 2.214(1) Å, $r(Re—O)_{H_2O}$ = 2.28 Å).[159]

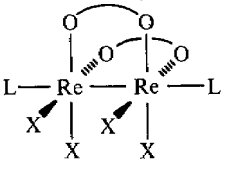
(41) O⌒O = O_2CR; X = Cl, Br, or I

Dirhenium(III) carboxylates of the type $Re_2(O_2CR)_{4-x}X_{2+x}$ (x = 0, 1 or 2) are known for a variety of carboxylate ligands and for X = Cl, Br or I. They constitute derivatives of $[Re_2X_8]^{2-}$ that are formed by the stepwise replacement of up to three pairs of *syn* halide ligands by bridging carboxylate ligands. They possess electronic structures that are closely related to those of the $[Re_2X_8]^{2-}$ anions. Their syntheses, structures and chemical reactivities have been fairly extensively reviewed for the period up to late 1981.[5,154] An example is shown in (**41**).

The conversion of the $[Re_2X_8]^{2-}$ anions (X = Cl, Br or I) into the orange-brown alkyl carboxylate complexes of the type $Re_2(O_2CR)_4X_2$ is most conveniently accomplished by reaction with refluxing mixtures of the appropriate acid and anhydride (if available).[61,142] In the reactions between $[Re_2X_8]^{2-}$ and XCH_2CO_2H (X = Cl or Br) both carboxylate coordination and halide exchange can occur, *e.g.* $[Re_2Cl_8]^{2-} + CH_2BrCO_2H \rightarrow Re_2(O_2CCH_2Br)_4Br_2$.[160] Rather than starting with salts of the $[Re_2Br_8]^{2-}$ and $[Re_2I_8]^{2-}$ anions, it is actually more convenient to react the chloro complexes $Re_2(O_2CR)_4Cl_2$ with liquid HBr or HI (equation 10).[68] In the presence of an excess of HX and the appropriate $(Bu^n_4N)X$ salt, this latter reaction may be used to regenerate $(Bu^n_4N)_2Re_2X_8$.[61] The corresponding aryl carboxylate complexes $Re_2(O_2CAr)_4X_2$ are best prepared from the acetates through exchange reactions (equation 11). While several other procedures have been used to prepare $Re_2(O_2CR)_4X_2$ complexes (X = Cl or Br) (*e.g.* using Re_3Cl_9 or *trans*-$ReOX_3(PPh_3)_2$[5]), none are as convenient or as generally applicable as the methods that employ $[Re_2X_8]^{2-}$.

$$Re_2(O_2CR)_4Cl_2 + 2HX \longrightarrow Re_2(O_2CR)_4X_2 + 2HCl \quad (10)$$

(X = Br or I)

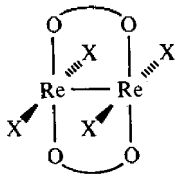


$$Re_2(O_2CCH_3)_4X_2 + 4ArCO_2H \longrightarrow Re_2(O_2CAr)_4X_2 + 4CH_3CO_2H \quad (11)$$

X-Ray structural studies on several complexes of the type $Re_2(O_2CR)_4X_2$ (**41**) (R = alkyl or aryl; X = Cl or Br) have established the now familiar multiply bonded carboxylate-bridged structure containing a very short Re—Re distance (~2.24 Å).[5,145] This structural unit is also present in $[Re_2(O_2CR)_4](ReO_4)_2$,[161] a 'mixed-valent' complex that contains weakly coordinated axial perrhenate anions and which is formed, along with $Re_2(O_2CR)_4Cl_2$ and $[Re_2(O_2CR)_3Cl_2](ReO_4)$ (*vide infra*), from the reaction of Re_3Cl_9 with refluxing carboxylic acids;[162] the perrhenate-containing species arise when oxygen is present. The existence and stability of $[Re_2(O_2CR)_4](ReO_4)_2$ (the derivative with R = Pr^n has been characterized by X-ray crystallography)[161] point out the lability of the axial halide ligands of $Re_2(O_2CR)_4X_2$, a result that accords with the formation of $Re_2(O_2CR)_4(NCS)_2$ and $[Re_2(O_2CR)_4(H_2O)_2]SO_4$ upon the reaction of $Re_2(O_2CR)_4Cl_2$ (R = Pr^n) with AgSCN and Ag_2SO_4, respectively.[5]

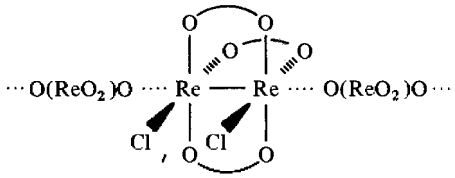
Electrochemical measurements of $Re_2(O_2CR)_4X_2$ (R = an alkyl or aryl group and X = Cl, Br or I) have revealed that CH_2Cl_2 solutions of these complexes are fairly easily reduced to the corresponding monoanions $[Re_2(O_2CR)_4X_2]^-$. The voltammetric half-wave potentials fall in the range −0.13 to −0.42 V *vs.* SCE, and show a dependence upon the nature of the halogen (becoming more negative in the order I < Br < Cl) and upon the Taft σ^* parameter for R.[68] The reduced anions can be prepared chemically using cobaltocene as the reducing agent to give $[(\eta^5\text{-}C_5H_5)_2Co]$-$[Re_2(O_2CR)_4X_2]$.[67] ESR spectral measurements and other characterization studies show that these species possess the $\sigma^2\pi^4\delta^2\delta^{*1}$ electronic configuration and, therefore, an Re—Re bond order of 3.5.

An especially important set of reactions of $Re_2(O_2CMe)_4Cl_2$ occurs with gaseous HX (X = Cl, Br or I). When run at temperatures between 300 and 350°C, these reactions afford the trinuclear rhenium(III) halides Re_3X_9 in close to quantitative yield. This is the one procedure that can conveniently be used to prepare all three halides.[143]



Complexes of stoichiometry $Re_2(O_2CR)_2X_4$ and $Re_2(O_2CR)_3X_3$ represent intermediate degrees of substitution between $[Re_2X_8]^{2-}$ and $Re_2(O_2CR)_4X_2$. Of these two sets of derivatives, the former are the more commonly encountered, the dark blue hydrated acetates $Re_2(O_2CMe)_2X_4\cdot 2H_2O$ (X = Cl or Br) being prepared either from $[Re_2X_8]^{2-}$ or by the high pressure hydrogen reduction of $KReO_4$ or K_2ReX_6 in a mixture of HX and acetic acid.[5,163,164] These hydrated species react with ligands (L) such as py, DMF, DMSO, dimethylacetamide and Ph_3PO to form other adducts of the type $Re_2(O_2CMe)_2X_4L_2$.[5,165] In those instances where the X-ray crystal structures of such molecules have been determined,[5,145] there is a *cis* arrangement of bridging acetate groups (**42**). This is also the case for the formate complex $(NH_4)_2[Re_2(O_2CH)_2Cl_6]$ and its diphenylformamide (DPF) derivative $Re_2(O_2CH)_2Cl_4(DPF)_2$ where a *cisoid* arrangement of carboxylate groups is present.[5] A close similarity in the spectral properties (IR and electronic absorption) of this group of acetate complexes[165] supports the notion that they are structurally very similar. Several mixed halide derivatives of the type $Re_2(O_2CMe)_2Cl_{4-x}Br_xL_2$ (L = DMF, DMSO or dimethylacetamide) were obtained as by-products during the autoclave synthesis of *cis*-$Re_2(O_2CMe)_2Br_4L_2$. Apparently, the presence of chloride in these products arose from impurities adsorbed on the wall of the autoclave from preceding experiments that involved an HCl-containing reaction mixture.[166]

(42) $O\overset{\frown}{O}$ = O_2CR; X = Cl, Br, or I



While thermal studies show that the axial ligands L of $Re_2(O_2CMe)_2X_4L_2$ can be lost upon heating, it is clear that this can be a complex process, although in the case of L = H_2O, this gives rise to the anhydrous form of the acetates $Re_2(O_2CMe)_2X_4$.[164,167] These same anhydrous compounds have also been formed through the thermal decomposition of $Re_2(O_2CMe)_4X_2$,[164] and the decomposition of the pivalate complex $Re_2(O_2CCMe_3)_4Cl_2$ *in vacuo* gives green crystalline $Re_2(O_2CCMe_3)_2Cl_4$ or pink $Re_2(O_2CCMe_3)_3Cl_3$ (*vide infra*) depending upon the temperature.[168] X-Ray structural studies on anhydrous $Re_2(O_2CMe)_2X_4$ (X = Cl or Br), $Re_2(O_2CCMe_3)_2Cl_4$ and $Re_2(O_2CPh)_2I_4$ have shown that a *trans* arrangement of carboxylate groups is present (**43**),[5,168,169] thereby demonstrating that a loss of axial ligands is accompanied by a *cis* → *trans* isomerization.

A few examples of the 3:3 carboxylate:halide complexes $Re_2(O_2CR)_3X_3$ have been obtained. One such example is $Re_2(O_2CCMe_3)_3Cl_3$ which is formed during the thermal decomposition of

(43)

$Re_2(O_2CCMe_3)_4Cl_2$ *in vacuo* at 240°C.[168] Violet $Re_2(O_2CMe)_3Cl_3$ has been prepared by dissolving $Re_2(O_2CMe)_2Cl_4$ in cold glacial acetic acid, while the analogous bromide is formed upon treating a chloroform solution of $Re_2(O_2CMe)_2Br_4$ with the stoichiometric quantity of acetic acid.[5,164] The structure of $Re_2(O_2CCMe_3)_3Cl_3$ represents a situation intermediate between that of (**41**) and (**43**), with $[Re_2(O_2CCMe_3)_3Cl_2]^+$ units linked by bridging Cl^- ligands into chains. A similar structure exists for $Re_2(O_2CH)_3Cl_3$, while in the case of $[Re_2(O_2CR)_3Cl_2]ReO_4$, a complex formed upon refluxing Re_3Cl_9 with carboxylic acids in the presence of oxygen,[162,170] perrhenate substitutes for an axial halide as shown by an X-ray crystal structure for the derivative where R = Pr^i (**44**).

(44) $O\overset{\frown}{O} = O_2CR$

A variety of dirhenium(III) carboxylates of the types $Re_2(O_2CMe)_4Br_2$, *trans*-$Re_2(O_2CMe)_2X_4$ (X = Cl or Br), *cis*-$Re_2(O_2CMe)_2X_4L_2$ (L = py, DMSO, *etc.*), $Re_2(O_2CH)_2Cl_4L_2$ (L = DMF or DMSO) and $(NH_4)_2[Re_2(O_2CH)_2Cl_6]$ have been studied by ^{35}Cl or ^{81}Br NQR spectroscopy and the results compared with data for salts of the $[Re_2Cl_8]^{2-}$ and $[Re_2Br_8]^{2-}$ anions.[171] Also of interest are some screening studies that were carried out on the use of $[Re_2(O_2CEt)_4]SO_4$ and several derivatives of the type $Re_2(O_2CR)_2X_4 \cdot 2H_2O$ as antitumour agents.[172]

Mixed alkyl–carboxylato complexes of dirhenium(III) have been prepared starting from either $Re_2(O_2CMe)_4Cl_2$ or $[Re_2Me_8]^{2-}$. The chemistry of these multiply bonded complexes (*e.g.* $Re_2(O_2CMe)_2R_4$ and $Re_2(O_2CMe)_4Me_2$) is discussed elsewhere (see refs. 5 and 6).

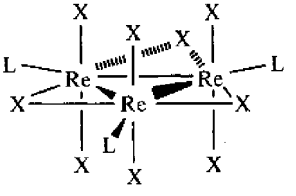
43.5.2.6 Sulfur ligands

The complexes $Re_2X_6(tmtu)_2$ and $Re_2X_6(DTH)_2$ (X = Cl or Br; tmtu = tetramethylthiourea; DTH = 2,5-dithiahexane) are formed upon reacting $(Bu^n_4N)_2Re_2X_8$ with these ligands under mild reaction conditions. These complexes are believed, on the basis of spectroscopic data, to possess structures akin to that of $Re_2Cl_6(PEt_3)_2$ (**38**), although in the case of the DTH derivatives this means that this potentially bidentate ligand may be bonding in a monodentate fashion.[5]

43.5.2.7 Mixed donor atom ligands

Only two such complexes will concern us here. One of them, the doubly bonded dirhenium(II) complex $Re_2Cl_6(Ph_2Ppy)_2$ which contains the mixed P—N bidentate 2-(diphenylphosphino)pyridine ligand, has been described in Section 43.5.2.4. The other complex is $Re_2(hp)_4Cl_2$ (Hhp = 2-hydroxypyridine), which is prepared by the reaction of $(Bu^n_4N)_2Re_2Cl_8$ with the molten ligand and has a structure very similar to that of $Re_2(O_2CR)_4X_2$ (**41**), but with an even shorter Re—Re bond distance (2.206(2) Å *versus* 2.24 Å).[173]

43.5.3 Trinuclear Complexes Containing the Re_3^{9+} Core



The trinuclear rhenium(III) halides Re_3X_9 (X = Cl, Br or I), and the mixed halides $Re_3X_{9-n}Y_n$ (*e.g.* $Re_3Cl_3Br_6$), contain Re—Re double bonds[174] and are the precursors to an extensive class of coordination complexes that are formed by the addition of up to three ligands to the available

coordination sites on these cluster halides, *i.e.* $Re_3X_9L_n$, where $n = 1$, 2 or 3 (**45**).[5] Many such complexes exist for X = Cl or Br,[5] but for Re_3I_9, only complexes with L = alkyl or aryl isocyanide ligand are known. Note that the reaction of Re_3I_9 with ligands such as tertiary amines or tertiary phosphines leads to the decomposition of the cluster.[175]

The synthetic and structural chemistry of Re_3X_9 has been reviewed and this source[5] can be usefully consulted for coverage of the literature up to late 1981. Note that in addition to the ability of Re_3X_9 to form coordination complexes involving minimum perturbation of the cluster structure, other reactions of note are the reductive cleavage of Re_3X_9 (X = Cl, Br or I) by isocyanide ligands to give $[Re(CNR)_6]^+$ (see Section 43.3.1)[22] and by phosphine ligands to give $Re_2X_4(PR_3)_4$ and $Re_2X_5(PR_3)_3$ (see Section 43.4.2.1).[56] Also, heterocyclic tertiary amines (L) can reduce Re_3X_9 (X = Cl or Br) to give trinuclear clusters of the type $[Re_3X_6L_3]_n$ (Section 43.4.3). The coordination chemistry that has been developed for trirhenium(III) cluster species containing Re—C (alkyl) bonds (*i.e.* $—CH_3$ and $—CH_2SiMe_3$) is discussed elsewhere (see refs. 5 and 6).

43.5.3.1 Cyanide, alkyl isocyanides and aryl isocyanides

The only cyanide-containing complexes known are $(Et_4N)_3[Re_3Cl_9(CN)_3]$ and $(Et_4N)_3[Re_3Cl_3(CN)_9]$ which can be isolated by the reaction between $(Et_4N)CN$ and Re_3Cl_9. In these reactions, no more than six of the Re—Cl bonds of the parent Re_3Cl_9 cluster can be replaced by cyanide.[176] The Re—Cl bonds that remain intact involve the Re—Cl—Re bridging units of (**45**).

(**45**) X = Cl or Br

While the earlier literature on isocyanide ligands has been reviewed recently,[6] subsequent studies have demonstrated the generality of the reactions that occur at room temperature between Re_3X_9 (X = Cl, Br or I) and alkyl or aryl isocyanides that lead to $Re_3X_9(CNR)_3$ (R = Me, $CHMe_2$, CMe_3, C_6H_{11} or *p*-tolyl).[22] The spectroscopic properties of these complexes show that the Re_3X_9 unit is intact. The electrochemical properties of solutions of the chloride and bromide complexes in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2 show a well-behaved one-electron oxidation close to +1.6 V *vs.* SCE and an irreversible reduction at ~ −0.15 V.[22] Note that when the reactions between Re_3X_9 and RNC are carried out in refluxing acetone and alcohol solvents, reductive cleavage of these clusters occurs to give $[Re(CNR)_6]^+$ (Section 43.3.1).

43.5.3.2 Nitrogen ligands

The reactions between Re_3X_9 (X = Cl or Br) and the more basic heterocyclic tertiary amines (L) that result in the reduction of the cluster and the formation of $[Re_3X_9L_3]_n$ (Section 43.4.3) are known to proceed *via* the intermediacy of $Re_3X_9L_3$, since purple $Re_3Cl_9py_3$ can first be isolated by careful control of the reaction conditions.[79] The less basic amines such as pyrazine, 2,6-dimethylpyrazine and 3-chloropyridine give unreduced $Re_3X_9L_3$. Similar 1:3 adducts have also been prepared by the reactions of Re_3Cl_9 with acetonitrile and benzonitrile.[5]

A careful study of the Re_3Cl_9–NH_3(l) system has shown[177] that ammonolysis occurs, and that the purple material that remains upon evaporation of the resulting reaction solution is a mixture of $Re_3Cl_6(NH_2)_3(NH_3)_3$ and NH_4Cl. This work has permitted a meaningful reassessment of earlier studies dealing with the reaction of Re_3X_9 with ammonia, and with primary and secondary amines, and their reinterpretation in terms of solvolysis of the Re—X bonds.[5]

Azide and thiocyanate react with Re_3Cl_9 in a similar fashion to that described for cyanide (Section 43.5.3.1) to give salts of the $[Re_3Cl_9X_3]^{3-}$, $[Re_3Cl_6X_6]^{3-}$, $[Re_3Cl_3X_9]^{3-}$ and $[Re_3Cl_3X_8]^{2-}$ anions (X = N_3 or NCS).[176,178] There is also evidence that $[Re_3(NCS)_{12}]^{3-}$ can be formed from Re_3X_9 (X = Cl or Br) under forcing reaction conditions, further reflecting the fact that the order of Re—Cl bond lability is $Cl_t \gg Cl_b$.[178]

43.5.3.3 Phosphines and arsines

The preparation and structural characterization of $Re_3Cl_9(PEt_2Ph)_3$ was an important early advance in the development of the chemistry of the halides Re_3X_9.[5] An X-ray crystal structure determination established that it possessed structure (**45**) (L = PEt_2Ph) with short Re—Re bonds (2.49 Å) but long Re—P distances (2.70 Å), the latter arising from steric crowding.[179] Other monodentate phosphines ($PMePh_2$, $PEtPh_2$ and PPh_3) and $AsPh_3$ from crystalline purple-red tris adducts with Re_3Cl_9 and Re_3Br_9 that bear a close structural relationship to $Re_3Cl_9(PEt_2Ph)_3$.[5] When the reactions between phosphines PR_3, PR_2Ph or $PRPh_2$ (R = alkyl) and Re_3X_9 (X = Cl, Br or I) are carried out in refluxing acetone or alcohol solvents, the lower valent dirhenium complexes $Re_2X_4(PR_3)_4$, $Re_2X_4(PR_2Ph)_4$ and $Re_2X_5(PRPh_2)_3$ are produced.[57,80,175] The coordination of several phosphole ligands to Re_3Cl_9 has also been investigated. Ethanol solutions of 3-methyl-1-phenylphosphole (mPP) and 3,4-dimethyl-1-phenylphosphole (dPP) react immediately to form diamagnetic $Re_3Cl_9L_3$ (L = mPP and dPP). With bulky phospholes like 1,2,5-triphenylphosphole (TPP), complex formation requires reflux conditions and gives the less stable solvated complexes $Re_3Cl_9L_2 \cdot CH_2Cl_2$.[180]

In contrast to the well-defined adducts with monodentate phosphines and arsines, the reactions of Re_3Cl_9 and Re_3Br_9 with polydentate ligands give products that with few exceptions are not well characterized. An exception is $Re_3Cl_9(dppe)_{1.5}$ which is formed upon mixing acetone or THF solutions of Re_3Cl_9 and dppe. Spectroscopic evidence favors it being an authentic Re_3Cl_9 derivative, containing intermolecular dppe bridges.[181] There is also evidence that small quantities of mononuclear $[ReCl_2(dppe)_2]Cl$ are formed in this reaction.[182] The corresponding reaction between Re_3Cl_9 and *o*-phenylenebisdimethylarsine (diars) in acidified (HCl) ethanol gives red insoluble $Re_3Cl_9(diars)_2$ together with small quantities of $[ReCl_2(diars)_2]Cl$.[182] In the case of tri-, tetra- and hexadentate and phosphine and arsine ligands, the true nature of the resulting products is poorly understood.[5,183] A summary of the reactions that have been carried out together with the proposed stoichiometries of the products is given in Table 7.

43.5.3.4 Oxygen ligands

Most complexes containing oxygen donors are of the type $Re_3X_9L_3$ (X = Cl or Br).[5] These have been prepared with Ph_3PO, Ph_3AsO, DMF, HMPA and sulfoxide ligands and they possess properties that clearly demonstrate their close structural relationship to $Re_3Cl_9(PEt_2Ph)_3$ (**45**).[5] The ligand 1,2,5-triphenylphosphole oxide reacts with Re_3Cl_9 in refluxing dichloromethane to give the solvate $Re_3Cl_9L_2 \cdot CH_2Cl_2$.[186] With the bidentate ligand acetylacetone (acacH), both in-plane coordination and solvolysis of one of the out-of-plane terminal Re—X bonds per rhenium atom occurs to give $Re_3Cl_6(acac)_3$.[178] The rather novel cluster complex $Re_3Br_3(AsO_4)_2(DMSO)_3$ is apparently formed upon reacting an acetone solution of Re_3Br_9 with silver arsenate, followed by extraction of the resulting solid into dimethyl sulfoxide.[184] The structure, on the basis of spectroscopic measurements, has been suggested to involve the capping of the faces of the Re_3 triangle by two tridentate arsenate ligands. This is a further illustration of the lability of the terminal Re—X bonds in the Re_3X_9 clusters.

A recent and quite original approach to the synthesis of Re_3X_9 cluster complexes involves the cocondensation of rhenium atoms, generated from a positive hearth electron-gun furnace, and reactive halocarbons such as 1,2-dibromo- (or dichloro-) ethane. Extraction of the reaction matrix at room temperature with THF gives $Re_3X_9(THF)_3$ (X = Cl or Br) in yields of ~90%.[185] This strategy will likely see further developments in the future.

Table 7 Products from the Reactions of Re_3Cl_9 with Tri-, Tetra- and Hexa-dentate Phosphine and Arsine Ligands

Ligand (abbreviation)	*Product(s)*	*Comments*	*Ref.*
$(Ph_2PCH_2)_3CMe$ (P_3)	$Re_3Cl_9(P_3)$	Red crystals; THF as solvent	5
$(Ph_2PCH_2CH_2)_2PPh$ (Pf—Pf—Pf)	$Re_3Cl_9[(Pf)_3]_2$	Reaction solvent dependent	5
$(Ph_2AsCH_2CH_2)_2PPh$ (Asf—Pf—Asf)	$Re_3Cl_9(Asf—Pf—Asf)_2$	Brown solid; MeCN as solvent	183
$(Ph_2PCH_2CH_2)_3P$ ($P(Pf)_3$)	$Re_3Cl_9[P(Pf)_3]_2$, $\{ReCl_3[P(Pf)_3]\}_n$[a]	Reaction solvent dependent	5
$Ph_2P(CH_2)_2P(Ph)(CH_2)_2P(Ph)(CH_2)_2PPh_2$ (Pf—Pf—Pf—Pf)	$\{ReCl_3[(Pf)_4]\}_n$[a]	Reaction solvent dependent	5
$(Ph_2PCH_2CH_2)_2PCH_2CH_2P(CH_2CH_2PPh_2)_2$ ($P_2(Pf)_4$)	$ReCl_2[P_2(Pf)_4]^+$[a]	2-Methoxyethanol as solvent	5

[a] Product is believed to be a mononuclear rhenium(III) derivative.

The nitrate-containing salt $Cs_3Re_3Cl_9(NO_3)_3$ has been prepared by the addition of $CsNO_3$ to a solution of Re_3Cl_9 in ice-cold nitric acid. This reaction is accompanied by the oxidation of some of the rhenium and the formation of Cs_2ReCl_6.[187]

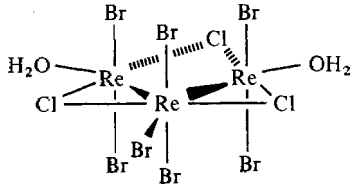
There also exist several stable derivatives of Re_3X_9 that contain coordinated water molecules. This situation arises with certain complex halides of Re_3X_9 (Section 43.5.3.6) and in the case of the diethyl sulfide complex $Re_3Cl_9(Et_2S)_2(H_2O)$ (Section 43.5.3.5). The aforementioned sections should be consulted for further reference to these complexes.

43.5.3.5 Sulfur and selenium ligands

Few such complexes are known and once again they are of the type $Re_3X_9L_3$ (**45**). The complexes with 1,4-thioxane, $Re_3Cl_9(C_4H_8OS)_3$, and diethyl sulfide, $Re_3Cl_9(Et_2S)_2(H_2O)$, have been described, the former possessing S-bound 1,4-thioxane.[181,182] In acetone solution Re_3Cl_9 reacts with 2,5-dithiahexane (DTH) to give polymeric $Re_3Cl_9(DTH)_{1.5}$, possessing, it is believed, bridging DTH ligands that are in the *trans* rotational conformation.[181] Under more forcing reaction conditions, the polymer structure breaks down and up to three monodentate DTH ligands may coordinate to the Re_3Cl_9 cluster. Both the chloride and bromide clusters Re_3X_9 react with sodium diethyldithiocarbamate (Nadtc) to form $Re_3X_6(dtc)_3$, species that are very similar to the corresponding acac derivative $Re_3Cl_6(acac)_3$ (Section 43.5.3.4). The remaining terminal Re—Cl bonds of the chloride complex $Re_3Cl_6(dtc)_3$ can be replaced upon reaction with silver thiocyanate to yield $Re_3Cl_3(NCS)_3(dtc)_3$.[178]

The only derivative of Re_3X_9 that contains a selenium ligand is one of stoichiometry $Re_3Cl_9L_2 \cdot CH_2Cl_2$ that is formed by the reaction of Re_3Cl_9 with 1,2,5-triphenylphosphole selenide in refluxing dichloromethane.[186]

43.5.3.6 Halides



Salts containing the complex halides $[Re_3X_{9+n}]^{n-}$ (X = Cl or Br; n = 1, 2 or 3) constitute the most important group of coordination complexes of the trinuclear halides of rhenium(III). The key example is $Cs_3Re_3Cl_{12}$, because its structural characterization by X-ray crystallography first demonstrated the trinuclear structure of Re_3X_9 and its derivatives (see structure **45**), and its identification played a decisive role in opening up the field of multiple metal–metal bond chemistry.[5] The cesium salt is prepared by mixing Re_3Cl_9 with CsCl in concentrated hydrochloric acid.[188] This simple synthetic procedure can be effectively used to prepare nearly all such complex halides of Re_3Cl_9 and Re_3Br_9.[5] Salts have been prepared with both alkali metal cations and various organic cations (*e.g.* pyH^+ and Ph_4As^+).[5] The success relies in large part upon the quite remarkable stability of such solutions to oxidation to mononuclear rhenium(IV) species. The $[Re_3Cl_{12}]^{3-}$ anion and species like it bear a close structural relationship to Re_3Cl_9; each of the intermolecular Re—Cl bridges of Re_3Cl_9 are cleaved and replaced by a terminally bound chloride ligand.[189,190] The Re—Re distance in $Cs_3Re_3Cl_{12}$ is 2.477(3) Å.

The specific salt of an $[Re_3X_{9+n}]^{n-}$ anion that can be isolated depends primarily upon the choice of cation and of X, although in a few instances crystals have been grown under conditions sufficiently different that different anions can be stabilized by the same cation, *e.g.* $Cs_3Re_3Br_{12}$ and $Cs_2Re_3Br_{11}$.[5,178] Crystal structure determinations on the salts $(Ph_4As)_2Re_3Cl_{11}(H_2O)$, $Cs_3Re_3Br_{12}$ and $Cs_2Re_3Br_{11}$ have confirmed their identity, the first complex containing a coordinated water molecule.[5] These studies have further demonstrated that in cases where one of the rhenium atoms is deficient (*i.e.* $Cs_2Re_3Br_{11}$), the structure distorts in such a way that the two Re—Re bond lengths that are associated with the deficient Re atom are shorter (2.43 Å) than the remaining Re—Re bond (2.49 Å).[191]

An important radiochemical exchange experiment using $H^{36}Cl$ has shown that for $[Re_3Cl_{12}]^{3-}$, the order of substitutional lability is Cl_t (in-plane) > Cl_t(out-of-plane) ≫ Cl_b, a conclusion that is further supported by chloride–pseudohalide exchange reactions using N_3^-, CN^- and NCS^- (see Sections 43.5.3.1 and 43.5.3.2). In addition to these lability studies, there are other reactions that have revealed that the Re_3X_9 clusters are susceptible to oxidative disruption under certain conditions. Thus it has been found that while the quinolinium salt $(quinH)_2Re_3Br_{11}$ can be isolated upon treating a saturated solution of Re_3Br_9 in 48% hydrobromic acid with an excess of quinoline, the salt $(quinH)_2Re_4Br_{14}$ can also be isolated from this reaction medium.[192] Use of pyridine or Et_4N^+ in place of quinoline gives the pyH^+ or Et_4N^+ salts of $[Re_4Br_{14}]^{2-}$. An X-ray crystal structure determination of $(quinH)_2Re_4Br_{14}$ shows that it should be formulated as $(quinH)_2[ReBr_6]$-

$[Re_3Br_9(H_2O)_3]$.[193] The closely related green-brown complex $(Bu^tPCl_3)_2[ReCl_6][Re_3Cl_9]$ has been prepared by a different route, namely, the reaction between $ReCl_5$, PCl_3 and Bu^tCl in CS_2. Its structural formulation is based upon IR, electronic absorption and mass spectral studies.[194]

When solutions of Re_3Br_9 in hydrobromic acid are subject to air oxidation, salts of $[ReBr_6]^{2-}$ and $[ReOBr_4]^-$ can be isolated upon addition of the appropriate cation.[195] In a similar vein, the addition of a hydrobromic acid solution of Re_3Cl_9 to an aqueous solution of CsBr can lead to crystals of Cs_2ReCl_6, Cs_2ReBr_6, $Cs_5Re_4Cl_6Br_{12}$ (believed to be $Cs_2ReBr_6 \cdot Cs_3Re_3Cl_6Br_6$) and $CsRe_3Cl_3Br_7(H_2O)_2$ (**46**) provided one is patient in the work-up procedure.[187] The X-ray crystal structure of complex (**46**) has revealed that the $[Re_3Cl_3]^{6+}$ core is intact and that water molecules occupy two of the three in-plane terminal coordination sites.[196] These oxidations of the Re_3Cl_9 and Re_3Br_9 units in hydrohalic acids presumably arise, at least in part, from oxygen. However, another important reaction that can lead to Re^{IV} is the well-documented disproportionation of Re_3X_9 (equation 12) in the solid state at elevated temperatures or in molten halide media.[31,197]

(46)

$$4Re_3X_9 \longrightarrow 3Re^0 + 9[ReX_6]^{2-} \qquad (12)$$

43.5.4 Hexanuclear Clusters of Rhenium(III)

The ternary sulfide phases $M^I_4[Re_6S_8]S_{4/2}(S_2)_{2/2}$ (M^I = Na or K) have been prepared by the reaction of Re, $KReO_4$ or ReS_2 with a large excess of Na_2CO_3 or K_2CO_3 and sulfur (alternatively a stream of H_2S can be used) at a temperature of 750–800°C.[198,199] X-Ray crystal structure determinations have confirmed the presence of the $[Re_6S_8]$ core in these Re^{III} complexes (Re—Re distance 2.59–2.63 Å) and the presence of intra- and inter-cluster sulfide bridges and bridging disulfide units. These red crystalline complexes have been found to transform to black crystals upon standing in air or various solutions with little loss of crystal integrity but with a change from insulating to semiconducting behavior.[198]

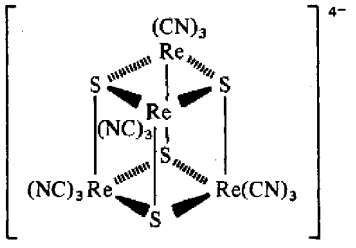
The preparation of similar ternary sulfide phases using barium or strontium carbonates in place of sodium and potassium has led to the isolation of $Ba_2Re_6S_{11}$ and $Sr_2Re_6S_{11}$ when the preparations are carried out at $\approx$ 1400°C in a stream of H_2S.[200] These rhenium(III) complexes are, like their alkali metal analogues, diamagnetic and have a structure containing the $\{[Re_6S_8]S_{6/2}\}^{4-}$ framework, thereby differing from $M^I_4[Re_6Cl_8]S_{4/2}(S_2)_{2/2}$ in the absence of bridging disulfide units.

One of the stimuli for studying these complexes is their close relationship to the well-known Chevrel phases MMo_6Y_8 (Y = S, Se or Te). Accordingly, a noteworthy recent development is the discovery of octahedral rhenium–selenide clusters. The phase $Re_6Se_8Cl_2$ has been prepared by the high temperature reaction ($\sim$ 1300 K) of $ReCl_5$ with mixtures of Re and Se.[201] An X-ray crystal structure has shown the presence of the $[Re_6Se_8]$ core possessing Re—Re distances of 2.63–2.67 Å. The presence of two terminal Re—Cl bonds (*trans* to one another) inhibits interlayer linkages.[201]

The semiconductor-like rhenium telluride phase Re_2Te_5 has been characterized by X-ray crystallography and shown to possess the usual octahedral Re_6 core (r(Re—Re) = 2.67–2.72 Å) within the structure $\{[Re_6Te_8]Te_6\}Te$, in which the $[Re_6Te_8]$ clusters are linked *via* butterfly-like [Te{Te—Te—Te}$_2$] units.[202]

Mixed-metal clusters that contain rhenium, *e.g.* the phase $Mo_{1.5}Re_{4.5}Se_8$, can also be prepared by direct reaction of the elements. They contain the octahedral $(Mo,Re)_6$ cluster.[203]

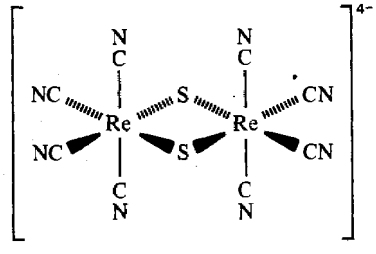
Preliminary X-ray structural data have been reported[598] for $Re_6(\mu_3\text{-}Se)_4(\mu_3\text{-}Cl)_4Cl_6$. The phases $Re_6X_4X'_{10}$ (X = Se or Te; X′ = Cl or Br) react with various ligands L in DMSO to give materials of stoichiometry $[Re_3X_2X'_5 \cdot L \cdot DMSO]_n$ (L = Et_3N, $Me_2NCH_2CH_2NMe_2$ or bipy).[599] The clusters $M^I_4[Re_6S_8]S_{2/2}(S_2)_{4/2}$ (M^I_4 = Rb_4 or K_2Rb_2) have been synthesized by the reaction of alkali metal carbonates with Re in a stream of H_2S at 800°C. The analogous selenides $M^I_4Re_6Se_{13}$ have also been obtained.[600]



43.6 RHENIUM(IV) COMPLEXES

The most numerous complexes of this oxidation state are halide species of the types ReX_4L_2, $[ReX_5L]^-$ and $[ReX_6]^{2-}$.[1] Also, in contrast to the lower oxidation states, Re^{IV} begins to display the tendency for oxo–rhenium bonding (in this instance in Re—O—Re bridges) that becomes so dominant in the chemistry of the higher oxidation states Re^V, Re^{VI} and Re^{VII}. At the same time, the propensity of rhenium to form multiple metal–metal bonds that was apparent in the chemistry of Re^{II} and Re^{III} begins to diminish in the case of Re^{IV}. One final general point concerns the fact that the Re^{IV} oxidation state, like that of Re^V, is apparently present in many of the complexes that contain multidentate mixed donor ligands which have been used for the spectrophotometric determination of rhenium. These complexes, which are usually generated by the $SnCl_2$ reduction of Re^{VII} in hydrochloric acid, are for the most part of ill-defined structure and often of uncertain oxidation state, although the Re:ligand stoichiometry is usually known. Such poorly characterized systems, recent examples of which include rhenium complexes of *N*-(4-methoxyphenyl)-α-thiopicolinamide and various thiohydrazones,[208,209] will not be discussed further.

43.6.1 Mononuclear Complexes



43.6.1.1 Cyanides and alkyl isocyanides

Salts of the $[Re(CN)_{6+n}]^{(n+2)-}$ anions are unknown, and a report that $K_4[ReO_2(CN)_4]$ can be prepared by the reaction of K_2ReCl_6 with an excess of aqueous KCN at room temperature gave, in other hands, a mixture of $K_3[ReO_2(CN)_4]$, $K_5[Re(CN)_6]$ and $K_5[Re_2(CN)_9(OH)_3]\cdot 2H_2O$.[15] The reactions of K_2ReCl_6 with KSCN/KCN or KSeCN/KCN melts at 250 and 320°C respectively give the diamagnetic, red-brown, cubane-like clusters $[Re_4(\mu_3\text{-}S)_4(CN)_{12}]^{4-}$ and $[Re_4(\mu_3\text{-}Se)_4(CN)_{12}]^{4-}$. When KOCN is used in place of KSCN then ReO_2 is formed.[15,210] The sulfide and selenide species have been isolated as their K^+, Cs^+, $(Ph_4P)^+$ and $(Ph_4As)^+$ salts, and the X-ray crystal structures of $(Ph_4P)_4[Re_4L_4(CN)_{12}]\cdot 3H_2O$ (L = S or Se) (**47**) determined.[210] These results contradict an earlier report that $[Re(CN)_6]^-$ can be prepared using this procedure. The IR and Raman spectra of the crystalline salts and their solutions accord quite nicely with the crystal structure data.[15]

(47)

The reaction between $NaReO_4$ and H_2S in an excess of aqueous NaCN solution yields salts of the diamagnetic $[Re_2(\mu_2\text{-}S)_2(CN)_8]^{4-}$ ion.[15] The blue-green Cs^+, $(Ph_4P)^+$ and $(Ph_4As)^+$ salts have been isolated and the X-ray crystal structure of $(Ph_4P)_4[Re_2(\mu_2\text{-}S)_2(CN)_8]\cdot 6H_2O$ (**48**) shows it to be an edge-shared bioctahedron with Re—S—Re bridges.[211] The Re—Re distance of 2.60 Å is substantially shorter than the comparable distance(s) (2.755 Å) present in tetranuclear (**47**), but the extent of Re—Re bonding in these complexes remains unknown.

(48)

The methyl isocyanide complex $(Bu^n_4N)[ReCl_5(CNMe)]$ is prepared in rather low yield in the reaction between $(Bu^n_4N)_2Re_2Cl_8$ and MeNC in ethanol.[212] It is a member of a relatively extensive class of complexes of the type $[ReX_5L]^-$ (X = halide) (Section 43.6.1.9).

43.6.1.2 *Ammonia and* N-*heterocycles*

Complexes of Re^{IV} with ammonia and aliphatic amines are not well defined and the chemistry has been little explored. $ReCl_5$ reacts with NH_4Cl at 195°C to give a material formulated as $[ReCl_4(NH_3)]$ which at higher temperature (250°C and above) decomposes first to $[ReCl_3(NH_2)]$ and then to ReNCl and Re_2NCl.[213]

The pyridine complex *cis*-$ReCl_4(py)_2$ has been obtained by dissolving β-$ReCl_4$ in dry pyridine, a reaction which also gives $(pyH)_2Re_2Cl_8$.[104] It has also been obtained, as has its bromide analogue, by the more traditional method of pyrolyzing $(pyH)_2ReX_6$,[1,2] a procedure that has been used for the synthesis of other compounds of the type $ReCl_4L_2$. The complexes $ReX_4(bipy)$ and $ReX_4(phen)$ (L = Cl or Br) can be prepared by the pyrolysis of $(LH)_2ReX_6$(L = bipy or phen), the reaction of $ReCl_5$ or K_2ReBr_6 with molten bipy, or the reaction of $ReBr(CO)_3(bipy)$ with refluxing dry Br_2.[1,214] A variation of the last of these procedures to include the reaction between $ReCl(CO)_3(bipy)$ and Br_2 gives the mixed halide derivative $ReClBr_3(bipy)$.[214]

The brown or red py, bipy and phen complexes have electronic absorption spectra and magnetic properties that accord with their being magnetically dilute t_{2g}^3 species, and low frequency IR spectra that show ν(Re—X) patterns consistent with *cis* octahedral geometries. This contrasts with the properties of a black complex purported to be $Re(OH)Cl_3(phen)$ that was prepared by the reaction of an aqueous solution of K_2ReCl_6 with an ethanol solution of phen.[215] A magnetic moment of 2.1 BM is not consistent with its formulation as a normal magnetically dilute Re^{IV} complex. However, the presence of a low-spin configuration is a possibility. Previous reports of the isolation of $ReI_4(py)_2$ from the interaction of ReI_4 with pyridine in acetone[2] could not be confirmed in a later reinvestigation of this system.[216] Also, since $ReI_4(bipy)$ and $ReI_4(phen)$ are not formed in the analogous reactions involving 2,2-bipyridyl or 1,10-phenanthroline,[216] a report describing the preparation of $ReI_4(phen)$ by such a procedure[2] is at this time still open to question. However, the treatment of $[ReO_2(py)_4]I \cdot H_2O$ with freshly distilled HI has been reported to give $ReI_4(py)_2$. The magnetic moment of this complex (μ_{eff} = 3.59 BM) supports it being a Re^{IV} derivative.[258]

The mixed phosphine–pyridine complex $ReCl_4(py)(PPh_3)$ is formed as orange crystals by the reaction of *trans*-$ReCl_4(PPh_3)_2$ with boiling pyridine for ten minutes.[217] Salts of the $[ReCl_5(py)]^-$ and pyrazine-bridged $[(ReCl_5)_2pyz]^{2-}$ anions are also known and are discussed in Section 43.6.1.9.

43.6.1.3 *Diazenido and imido ligands*

While rhenium(III) complexes containing diazenido ligands are quite numerous and well characterized (Section 43.5.1.3), those of rhenium(IV) are rare. The benzoyldiazenido complex $ReCl_2(N_2COPh)(PPh_3)_2$ (**23**) reacts with Cl_2 in CCl_4 in two steps. The brown, crystalline, air stable Re^{IV} complex $ReCl_3(N{=}NCOPh)(PPh_3)_2$ is formed first, and this on further treatment with Cl_2 is converted to *trans*-$ReCl_4(PPh_3)_2$ according to equations (13) and (14).[87] This Re^{IV} complex exhibits a ν(N=N) mode at 1580 cm^{-1} in its IR spectrum and has a magnetic moment of 2.85 BM.

$$ReCl_2(N_2COPh)(PPh_3)_2 + \tfrac{1}{2}Cl_2 \longrightarrow ReCl_3(N_2COPh)(PPh_3)_2 \quad (13)$$

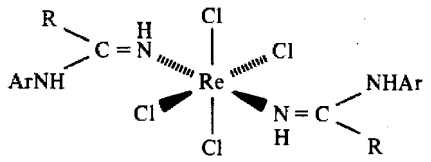
$$ReCl_3(N_2COPh)(PPh_3)_2 + Cl_2 \longrightarrow ReCl_4(PPh_3)_2 + PhCOCl + N_2 \quad (14)$$

The one example of an imido complex of rhenium(IV) is $Re(NPh)Cl_2(PMe_3)_3$ which has been prepared by the reduction of $Re(NPh)Cl_3(PMe_3)_2$ in THF using one equivalent of Na/Hg in the presence of an excess of trimethylphosphine. This air sensitive, dark red crystalline complex is paramagnetic with a magnetic moment of 1.66 BM at room temperature, and is further characterized by a broad ESR signal centered at g = 1.74 for a frozen benzene solution.[34] These observations have been interpreted in terms of a low-spin Re^{IV} species with a ligand field of low symmetry.

43.6.1.4 *Cyanate and thiocyanate*

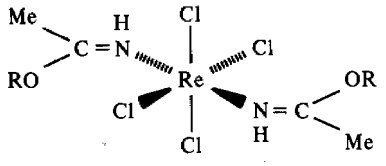
The brown hexacyanato complex $(Ph_4As)_2[Re(CNO)_6]$ has been reported to be the product of reaction K_2ReCl_6 with KOCN in molten dimethylsulfone followed by dissolution of the residue in

water and its rapid precipitation by the addition of $(Ph_4As)Cl$.[218] Its magnetic moment (4.1 BM) is significantly higher than that found for other species of the type $[ReX_6]^{2-}$ (*e.g.* X = thiocyanate) and is not readily explained. The interpretation of the IR spectrum of this salt, based upon a consideration of the ν(CN), ν(CO) and ν(NCO) modes,[218] in terms of O-bound cyanate ligands should be treated with caution in the absence of definitive X-ray structure data. Also, the ease with which $[Re_4(\mu\text{-}S_3)_4(CN)_{12}]^{4-}$ is formed in a K_2ReCl_6/KSCN/KCN melt system by sulfide abstraction from the KSCN (Section 43.6.1.1), raises the question as to whether an analogous reaction course (*i.e.* O abstraction) might occur to some extent in a KOCN/dimethylsulfone melt system. Indeed, the reaction of a KCNO/KCN melt with K_2ReCl_6 is known to give ReO_2.



The well-characterized and stable hexakis(isothiocyanato)rhenate(IV) anion is a key species (along with $[ReO(NCS)_5]^{2-}$) in the spectrophotometric determination of rhenium in solutions generated by the reduction of $[ReO_4]^-$ with thiocyanate and tin(II) ion in hydrochloric acid.[219,220] The dark red-brown salts $Cs_2Re(NCS)_6$ and $(Bu^n_4N)_2Re(NCS)_6$ are best prepared by the reaction of K_2ReCl_6 with molten KSCN, followed by cation exchange in aqueous CsCl, and of $(Bu^n_4N)_2Re_2Cl_8$ with NaSCN in acetone, respectively.[152,221] The addition of thallous acetate to an aqueous solution of $Cs_2Re(NCS)_6$,[221] and the mixing of a methanol solution of $(Ph_4As)Cl$ with a THF solution containing $[Re(NCS)_6]^{2-}$,[152] have been used to prepare $Tl_2Re(NCS)_6$ and $(Ph_4As)_2Re(NCS)_6$, respectively. The Sn^{II} reduction of $[ReO_4]^-$ and SCN^- in hydrochloric acid produces red solutions from which the salts $(Ph_4As)_2Re(NCS)_6$ and $(Ph_4As)_2ReO(NCS)_5$ have both been isolated.[220,222] These results throw into doubt the recent notion that $[ReO(SCN)_4]^{2-}$ is present in such solutions.[223] The $[Re(NCS)_6]^{2-}$ anion has been thoroughly characterized spectroscopically,[152,220] and magnetic moment determinations on the Cs^+, Tl^+, $(Bu^n_4N)^+$ and $(Ph_4As)^+$ salts show them to be well-behaved octahedral Re^{IV} species; the room temperature magnetic moments are 3.66, 3.36, 3.50 and 3.38 BM, respectively.[152,221] Electrochemical measurements have shown that the $[Re(NCS)_6]^{2-}$ anion exhibits an irreversible one-electron oxidation above +1.0 V *vs.* SCE (+1.23 V in MeCN and +1.03 V in CH_2Cl_2) and a reversible reduction at ~ −0.2 V *vs.* SCE (−0.11 V in MeCN and −0.28 V in CH_2Cl_2).[94,95] The one-electron reduction is both electrochemically and chemically reversible as demonstrated by the isolation of $(Bu^n_4N)_3Re(NCS)_6$ upon using $N_2H_4 \cdot H_2O$ as reducing agent (Section 43.5.1.4).[96]

A report[2] describing the isolation of the complex $ReO(SCN)_2(py)_3$ through the addition of pyridine to the solution generated by the $SnCl_2$ reduction of $KReO_4$ has not been confirmed. Such a complex would be most unusual for it would contain the hitherto unknown terminal $[Re{=}O]^{2+}$ moiety.



43.6.1.5 Nitriles and amidates

Like other higher valent halides of the transition metals, $ReCl_5$ is reduced by acetonitrile to give the rhenium(IV) complex $ReCl_4(NCMe)_2$.[98] Other nitrile complexes $ReCl_4(NCR)_2$ (R = Pr^n or Ph) can be prepared by this same route or by ligand exchange from $ReCl_4(NCMe)_2$. Later work has shown[224] that this synthetic procedure for $ReCl_4(NCMe)_2$ gives predominantly the crystalline green *cis* isomer together with a small amount of the brown-green *trans* form. A detailed comparison has been made of the spectroscopic properties (IR, electronic absorption and ESCA) of *cis*- and *trans*-$ReCl_4(NCMe)_2$.[224] This complex can also be prepared by the dissolution of β-$ReCl_4$ in boiling acetonitrile.[104] The oxidation of acetonitrile solutions of *fac*-$Re(CO)_3X(NCMe)_2$ (X = Cl or Br) with Cl_2 or Br_2 gives pale green *cis*-$ReCl_4(NCMe)_2$ and brown *cis*-$ReBr_4(NCMe)_2$, respectively in yields exceeding 50%.[225] This method provides a convenient alternative and, furthermore, is applicable to the bromide complex. The acetonitrile complex $[Et_4N][ReCl_5(NCMe)]$ is also known (Section 43.6.1.9).

The reactivity of *cis*-$ReCl_4(NCR)_2$ has been studied in considerable detail.[98] Reduction to $[ReCl_4(NCMe)_2]^-$ takes place quite readily (Section 43.5.1.5), while displacement of the MeCN ligands can be accomplished using APh_3 (A = P, As or Sb) (Section 43.6.1.6). The complexes $ReCl_4(NCR)_2$ react rapidly in the cold with primary aromatic amines ($ArNH_2$) to give the stable, orange amidato complexes $ReCl_4[NH{=}C(R)(NHAr)]_2$ (Ar = *p*-tol, *m*-C_6H_4F and *p*-$C_6H_4(CO_2Et)$ for R = Me; Ar = *p*-$C_6H_4(OMe)$ for R = Ph). These behave as typical Re^{IV} species (*e.g.* μ_{eff} = 3.5 BM) and are believed to possess a *trans* octahedral structure (**49**). The corresponding reactions of $ReCl_4(NCMe)_2$ with methanol and ethanol give the green crystalline complexes $ReCl_4[NH{=}C(Me)OR]_2$ (M = Me or Et) (**50**); in the case of the methanol reaction, $Cs_2[Re(OMe)Cl_5]$ (Section 43.6.1.9) can be isolated from the reaction filtrate upon addition of CsCl.

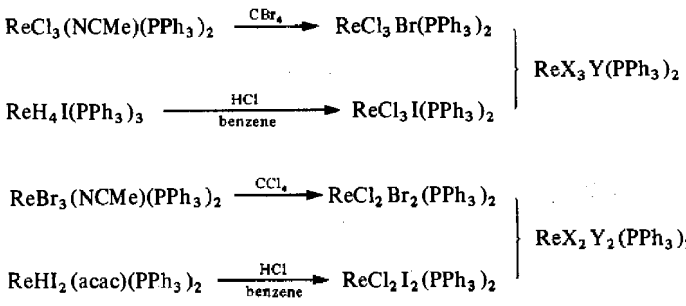
(50) R = Me or Et



43.6.1.6 Phosphines, arsines and stibines

The complexes *trans*-$ReCl_4L_2$ that are formed with monodentate phosphine, arsine and stibine ligands constitute a very stable and easily prepared class of compounds. This is especially true in the case of *trans*-$ReCl_4(PPh_3)_2$ which can be obtained by what seems to be a myriad of procedures. This is illustrated in Table 8 wherein are listed a selection of the more important methods that are known to produce complexes of the type *trans*-$ReX_4(AR_3)_2$ (X = Cl, Br or I; A = P, As or Sb). Note that in the reaction between *cis*-$ReCl_4(NCMe)_2$ and PPh_3, a short reaction time followed by a rapid quenching of the reaction gives *cis*-$ReCl_4(NCMe)(PPh_3)$.[233] There are numerous other examples where such complexes, especially the dark red-scarlet phosphine derivatives, are formed as reaction by-products; *e.g.* the formation of *trans*-$ReCl_4(PR_3)_2$ in the carbonylation of $Re_2Cl_4(PR_3)_4$ (PR_3 = PPr^n_3 or PMe_2Ph).[69,234] Several mixed halide complexes of the types $ReX_3Y(PPh_3)_2$ and $ReX_2Y_2(PPh_3)_2$ are known, and can be prepared either by the reactions of hydrido–rhenium species with HX[227,235] or the halocarbon oxidation of $ReX_3(NCMe)(PPh_3)_2$ (Scheme 11).[86] Salts of the $[ReX_5(PR_3)]^-$ anions are also known (Section 43.6.1.9).

The vibrational spectrum (a single IR active ν(Re—X) mode),[1] magnetic properties (μ_{eff} = 3.4–3.7 BM),[102] and an X-ray crystal structure determination on *trans*-$ReCl_4(PMe_2Ph)_2$,[101] all

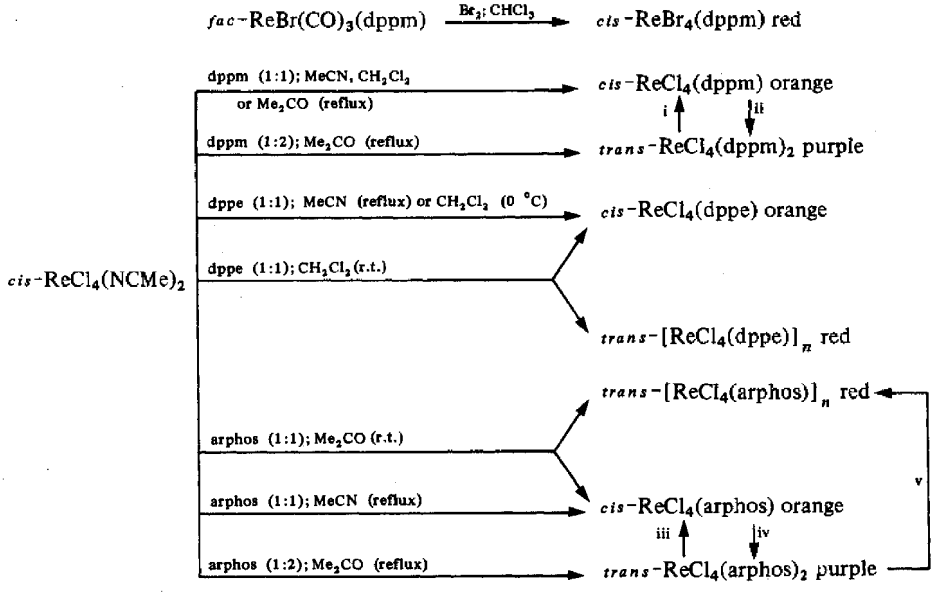
Cl	APh_3	$ReCl_3(NCMe)(APh_3)_2$ + CCl_4	A = As or Sb	98



Scheme 11 Mixed halide complexes of the types $ReX_3Y(PPh_3)_2$ and $ReX_2Y_2(PPh_3)_2$

serve to confirm the magnetically dilute *trans*-octahedral structure of this class of complexes. Electrochemical measurements on acetonitrile and dichloromethane solutions of several *trans*-$ReCl_4(PR_3)_2$ complexes show that a reversible one-electron reduction to the monoanion $[trans\text{-}ReCl_4(PR_3)_2]^-$ is very accessible ($E_{1/2}$ in the range -0.1 to -0.5 V *vs.* SCE).[65,106]

A suggestion some years ago that the reaction of $[ReO_4]^-$ with PEt_2Ph and hydrochloric acid in boiling ethanol yields the well-characterized *cis* and *trans* isomers of $ReOCl_3(PEt_2Ph)_2$ together with the violet rhenium(IV) complex *trans*-$Re(OH)Cl_3(PEt_2Ph)_2$,[107] has apparently been confirmed by an X-ray structure determination of the latter complex.[236] The observed Re—O bond length of 1.795(4) Å and the observation of an IR-active ν(O—H) band at 2920 cm^{-1} support this contention.[236] Some degree of double bond character in the Re—O(H) bond may explain the low magnetic moment (1.92 BM),[107] since this could impart a low-spin configuration (one unpaired electron) to this system.

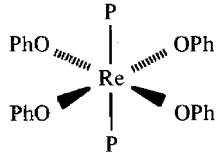
Complexes of the type $ReX_4(LL)$ containing bidentate phosphine and arsine ligands have been prepared by two general methods. The halocarbon oxidation of the rhenium(III) complexes $Re_2(\mu\text{-}X)_2X_4(dppe)_2$ (X = Cl or Br) (Section 43.5.1.6) leads to the halocarbon solvates of *cis*-$ReX_4(dppe)$.[108] The X-ray crystal structure of *cis*-$ReCl_4(dppe)\cdot 3/4\ CCl_4$ has confirmed the nature of these products.[237] Orange-red crystalline *cis*-$ReX_4(dppe)$ can also be prepared upon heating $Re_2(\mu\text{-}X)_2X_4(dppe)_2$ with acetic acid–acetic anhydride mixtures but, depending upon the reaction conditions, contamination by $Re_2(O_2CMe)_4X_2$ or $ReOCl_3(dppeO_2)$ can ensue.[108] Orange *cis*-$ReCl_4(dppe)$ has also been prepared by the Cl_2 oxidation of $ReH_3(dppe)(PPh_3)_2$ in benzene solution.[124]

A second general approach involves the reaction of *cis*-$ReCl_4(NCMe)_2$ with bis(diphenylphosphino)methane (dppm), bis(1,2-diphenylphosphino)ethane (dppe) and 1-diphenylphosphino-2-diphenylarsinoethane (arphos)[233] but, surprisingly, the reaction products are very dependent upon the reaction conditions. These results[233] are summarized in Scheme 12, together with details of the route to *cis*-$ReBr_4(dppm)_2$ *via* the Br_2 oxidation of $ReBr(CO)_3(dppm)$.[214] Complexes of the types *cis*-$ReCl_4(LL)$, *trans*-$ReCl_4(LL)_2$ or polymeric *trans*-$ReCl_4(LL)$ with LL in a *trans*, bridging conformation, can be isolated depending upon the nature of LL, the reaction stoichiometry and the reaction conditions (solvent and temperature).[233] These complexes have been thoroughly characterized on the basis of their far IR, electronic absorption and ESCA spectra, and also their magnetic properties.[214,233] Cyclic voltammetric measurements on CH_2Cl_2 solutions of *cis*-$ReCl_4(LL)$ reveal the existence of a reversible one-electron reduction at ~ -0.05 V *vs.* SCE.[65] The differences in behavior observed with the dppm, dppe and arphos ligands can be rationalized in terms of *trans*-$ReCl_4(LL)_2$

i, refluxing CH_2Cl_2; ii, excess dppm, refluxing acetone; iii, refluxing $CHCl_3$ or DMF; iv, excess arphos, refluxing acetone; v, *cis*-$ReCl_4(NCMe)_2$, refluxing acetone.

Scheme 12

being the thermodynamically favored product for LL = dppm or arphos but not dppe. In the case of *cis*-$ReCl_4$(dppm), the strained chelate ring is unstable in the presence of excess dppm. Although a more stable five-membered ring is present in *cis*-$ReCl_4$(arphos), the formation of a second Re—P bond provides the driving force for its conversion to *trans*-$ReCl_4$(arphos)$_2$. On the other hand, when CH_2Cl_2, $CHCl_3$ or DMF solutions of *trans*-$ReCl_4(LL)_2$ are kept at room temperature for many hours or heated for short periods, the orange complexes *cis*-$ReCl_4$(LL) can be regenerated, provided that excess ligand is not present. The course of these reactions is clearly favored by an increase in entropy upon loss of one of the bidentate ligands.



While attempts to prepare the complex $ReCl_4$(dpae) (dpae = 1,2-bis(diphenylarsino)ethane) were unsuccessful,[233] complexes with other bidentate arsines have been isolated. ReX_4(diars) {X = Cl or Br; diars = *o*-phenylenebis(dimethylarsine)} has been prepared by the halogen oxidation of $ReX(CO)_3$(diars),[1] while the complexes $ReCl_4$(dtcb) and $ReCl_4$(dhcp) (dtcb = 1,2-bis(dimethylarsino)-3,3,4,4-tetrafluorocyclobut-1-ene and dhcp = 1,2-bis(dimethylarsino)-3,3,4,4,5,5-hexafluorocyclopentene) are formed as green solids from the reaction of $ReCl_5$ with dtcb and dhcp in carbon tetrachloride.[238,239] The dtcb complex is also isolable, admixed with yellow $[ReCl_2(dtcb)_2]ClO_4$, from the reaction of dtcb with solutions generated by the H_3PO_2 reduction of the $KReO_4$/HCl/EtOH/H_2O system.[238] The room temperature magnetic moments of $ReCl_4$(dtcb) and $ReCl_4$(dhcp) are 2.97 and 2.55 BM, respectively, and are lower than normally found ($\sim$3.4 BM) for Re^{IV} complexes.[239] Nonetheless, these are authentic mononuclear Re^{IV} species containing *cis* chelating arsine ligands as demonstrated by an X-ray crystal structure determination of $ReCl_4$(dtcb).[238]

43.6.1.7 Oxygen and sulfur ligands

The chemistry of Re^{IV} with oxygen ligands is not especially well developed. The simple aqua anions $[ReCl_5(H_2O)]^-$ are known (Section 43.6.1.9), as are the hydroxo species $[ReX_5(OH)]^{2-}$ and the methoxide $[ReCl_5(OMe)]^{2-}$ (Section 43.6.1.9). Rhenium(IV) is also believed to be incorporated into certain heteropolyacids upon treating $[SiW_{11}O_{39}]^{8-}$ and $[P_2W_{17}O_{61}]^{10-}$ with $[ReCl_6]^{2-}$ under nitrogen.[1]

The $[ReX_5(OH)]^{2-}$ anions exist in equilibrium with the μ-oxo-bridged dirhenium(IV) species $[Re_2OX_{10}]^{4-}$ (Section 43.6.1.8). The latter constitute examples of a class of complex that possess a linear Re^{IV}—O—Re^{IV} unit, and which may contain additional oxygen or sulfur ligands. These complexes include $Re_2OX_6(SEt_2)_4$ and $Re_2OX_6(EtSCH_2CH_2SEt)_2$ (X = Cl or Br),[240] $K_2[Re_2OL_2Cl_6]$ (HL = a dipeptide or tripeptide ligand such as glycylalanine, glycylleucine or glyclglycylglycine),[241] $K_2H_2[Re_2OL_2(SO_4)_4]$ (HL = picolinic acid, nicotinic acid or isonicotinic acid), $K_2[Re_2OL_2(SO_4)_4]$ (L = picolinamide, nicotinamide or isonicotinamide),[242] as well as an assortment of μ-oxo species containing OH^- ligands, *e.g.* $[Re_2O(OH)_6(LL)_2]^{4-}$ (LL = oxalate, citrate, tartrate or gallate)[1] and $K_2[Re_2OL_2(OH)_2(SO_4)_2]$ (HL = picolinic acid or isonicotinic acid),[243] and Re^{IV} complexes that purportedly contain the $[Re_2O_3]$ moiety, *e.g.* $H_2[Re_2O_3L_4]$ (HL = penicillamine).[244] The identities of these complexes require confirmation since they are based mostly upon conductance, spectroscopic and magnetic data. In no instance has an X-ray crystal structure been carried in order to support the formulations of any of these systems.

The complex *trans*-$Re(OPh)_4(PMe_3)_2$ (**51**) is one of the two well-characterized alkoxides of Re^{IV}. It is prepared in low yield by the reaction of $ReOCl_4$ with NaOPh in diethyl ether/THF followed by the addition of PMe_3.[245] The red crystalline complex (**51**) has been shown by X-ray crystallography to possess the *trans* structure that usually characterizes ReX_4L_2 type complexes. The other complex is $Cs_2[ReCl_5(OMe)]$ that is discussed in Section 43.6.1.9.

(51) P = PMe_3

An earlier report that the reaction of $ReOCl_2(OEt)(PPh_3)_2$ with hot acetylacetonate produces dimeric $Re_2Cl_4(acac)_4$, *via* the intermediacy of $ReCl(acac)_2PPh_3$ (Section 43.5.1.7), was later shown to be incorrect; orange $Re_2Cl_4(acac)_4$ is in reality *trans*-$ReCl_2(acac)_2$.[246] This conclusion has been confirmed by an X-ray crystal structure determination.[247] Alternative methods have been developed

to prepare *trans*-$ReCl_2(acac)_2$, *viz.* refluxing $ReOCl_2(acac)(PPh_3)$ in acacH under N_2, or refluxing solutions of $ReCl_2(acac)(PPh_3)_2$ {or $ReCl_2(acac)(PPh_3)(OPPh_3)$} in acacH in air overnight. By work-up of the reaction filtrates, small amounts of red-brown *cis*-$ReCl_2(acac)_2$ can be isolated.[246] The reactions between $ReOX_2(OMe)(PPh_3)_2$ (X = Cl, Br or I) and the β-diketones acacH or dbmH (dbmH = dibenzoylmethane) have been used to prepare $ReX_2(acac)_2$ (X = Br or I) and *cis*-$ReCl_2(dbm)_2$. The acac complexes display characteristic mass spectra, exhibiting an abundant parent ion peak, and they have room temperature magnetic moments of 3.1–3.3 BM. Their IR spectra, dipole moments (in benzene) and X-ray powder patterns support the notion that the bromide complex consists primarily of the *cis* isomer (with a small amount of *trans*), while the iodide is the *trans* isomer.[246]

In an extraction–photometric method for the determination of rhenium, a sulfito complex $[(Me_2CHCH_2CH_2)_2NH_2]_2ReO(SO_3)Cl_2$ is supposedly formed when Re^{IV} is extracted from 3.2 M hydrochloric acid containing SO_3^{2-} with diisoamylamine in ethyl acetate or CCl_4.[248] This formulation should be treated with some scepticism until it can be confirmed. Complexes of Re^{IV} with organic acids have been prepared by the reaction of K_2ReCl_6 with the appropriate acid in a 1:3 or 1:2 molar ratio.[249] These products were claimed to contain the $[Re(C_2O_4)_3]^{2-}$ or $[ReCl_2L_2]^{2-}$ (LH_2 = phthalic, glutaric or aspartic acid) anions but have not been characterized in much detail, although upon hydrolysis they apparently give ReO_2.

There is a report describing the isolation of the violet 1:1 nitromethane complex $ReCl_4(MeNO_2)$ following the dissolution of $ReCl_5$ in $MeNO_2$,[250] but this complex remains otherwise uncharacterized and its existence unsubstantiated. By a similar procedure, namely reaction with $ReCl_5$, the solvents THF, dioxane and 1,4-oxathiane reduce this halide to give *trans*-$ReCl_4L_2$ (L = THF, dioxane or oxathiane), the complex *trans*-$ReCl_4(C_4H_8OS)_2$ containing S-bound thioxane.[251] The related bromide complex *trans*-$ReBr_4(C_4H_8OS)_2$ can be prepared by reacting K_2ReBr_6 with 1,4-oxathiane in HBr.[251] Upon heating *trans*-$ReCl_4(PPh_3)_2$ in air to 200°C, the corresponding triphenylphosphine oxide complex is obtained. This shows a characteristic ν(P=O) mode (at ~1150 cm^{-1}) in its IR spectrum.[229] This behavior contrasts to some extent with the related thermal transformations of *trans*-$ReCl_4(PEtPh_2)_2$ and *trans*-$ReCl_4(PEt_2Ph)_2$ which give $ReCl_4[OP(OEt)Ph_2]_2$ (*via* $ReCl_4(OPEtPh_2)_2$) and $ReCl_4[OPEt_{2-n}(OEt)_nPh]_2$ (n = 0, 1 or 2), respectively.[230,231] The course of these reactions can be followed by IR spectroscopy through monitoring of the ν(P=O) and ν(P—O—Et) vibrations.

The salts $(Et_4N)[ReCl_5L]$ (L = DMSO and DMF) are known, as is the thiourea (tu) derivative $(Et_4N)[ReCl_5(tu)]$ (see Section 43.6.1.9). Thioether (Et_2S, $EtSCH_2CH_2SEt$ and 1,4-oxathiane) and thiol (penicillamine) sulfur ligand complexes of Re^{IV} have already been mentioned in this section, and constitute, along with some dithiocarbamate derivatives, the majority of the complexes of Re^{IV} that are known to contain Re—S bonds. The reaction of $ReCl(CO)_5$ with tetraethylthiuram disulfide gives several products of which two contain Re^{IV}.[252] Both brown $[Re(S_2CNEt_2)_4][ReCl_4(S_2CNEt_2)]$ and red crystalline $ReCl_2(S_2CNEt_2)_2$ can be isolated from a benzene solution of the reactants. These complexes have room temperature magnetic moments of 3.7 and 2.9 BM, respectively. IR spectral measurements on $ReCl_2(S_2CNEt_2)_2$ show two ν(Re—Cl) modes (305s and 278 m cm^{-1}) in accord with a *cis* octahedral stereochemistry. This complex can also be prepared through the reaction of *trans*-$ReCl_4(PPh_3)_2$ with this same thiuram disulfide in benzene, while the related dibenzyl dithiocarbamate analogue $ReCl_2[S_2CN(CH_2Ph)_2]_2$ is obtained by the interaction of $ReCl(CO)_5$ with tetrabenzylthiuram disulfide.[252] The mixed sulfide–cyanide and selenide–cyanide species $[Re_4(\mu_3\text{-}X)_4(CN)_{12}]^{4-}$ (X = S or Se) and $[Re_2(\mu\text{-}S)_2(CN)_8]^{4-}$ are described in Section 43.6.1.1.

43.6.1.8 The mixed oxide–halide anions $[Re_2(\mu\text{-}O)X_{10}]^{n-}$

Salts of these anions (n = 4 or 3) constitute the best characterized of the Re^{IV} complexes that contain a linear Re—O—Re unit.[1,2] Prepared by the reduction of $KReO_4$,[253] the nearly diamagnetic red-brown salt $K_4[Re_2OCl_{10}]$ was shown by X-ray crystallography to possess a structure with a linear Re—O—Re unit (Re—O distances = 1.865(2) Å) which joins to two $[ReOCl_5]$ octahedra.[254] The question as to the nature of the blood-red product that is formed upon treating $[Re_2OCl_{10}]^{4-}$ in dilute hydrochloric acid with H_2O_2 or other oxidants[1,253] has apparently been answered by an X-ray crystal structure determination on a product, $Cs_3Re_2OCl_{10}$, isolated from one such solution.[255] Formally, this mixed-valent complex is derived by a one-electron oxidation of $[Re_2OCl_{10}]^{4-}$ but in view of its symmetrical structure with r(Re—O) = 1.832(3) Å, it must be considered an Re (+3.5, +3.5) species.[255] There is no explanation for the earlier reported magnetic moment of 3.57 BM for this complex, the implication being that this value is probably in error.[253,255] These

complexes contain the type of linear Re—O—Re unit that is believed to be present in the 'parent' oxide–chloride $[ReOCl_2]_n$.[256] Furthermore, these results provide the structural base from which to consider the nature of other derivatives that supposedly contain the Re^{IV}—O—Re^{IV} unit (Section 43.6.1.7).

A report describing the preparation of oxyfluoro species purported to be $M_4Re_2OF_{10}$ (M = K or Cs) has been published.[601] They have been characterized on the basis of spectroscopic, magnetic and conductivity measurements.

43.6.1.9 Complex halides $[ReX_6]^{2-}$, $[ReX_5(OH)]^{2-}$, $[ReCl_5L]^-$ and related species

Stable and easily prepared hexahalorhenate(IV) species $[ReX_6]^{2-}$ are known for X = F, Cl, Br and I. The preferred method for making $[ReX_6]^{2-}$ (X = Cl, Br or I) is by the reduction of $[ReO_4]^-$ in concentrated HX in the presence of a reducing agent such as I^-, Sn^{II} or hypophosphorous acid (which gives yields greater than 90%).[1] $[ReF_6]^{2-}$ can be prepared by reducing ReF_6 with alkali metal iodides in liquid SO_2 or by reacting molten KHF_2 with either a $KReO_4/KI$ mixture or K_2ReBr_6.[257]

The remarkable stability of the $[ReX_6]^{2-}$ anions is demonstrated by their formation as by-products in numerous reactions. For example, treatment of $[ReO_2(py)_4]Br \cdot 2H_2O$ with hot concentrated HBr produces $ReOBr_3(py)_2$ along with $(pyH)_2ReBr_6$.[258] Reaction of $(Bu^n_4N)_2Re_2Cl_8$ with CO(g) in MeCN gives $ReCl(CO)_5$ as the major product, but $[Re(NCMe)_4(CO)_2]_2[ReCl_6]$ is also formed.[259] When $ReH_7(PPh_3)_2$ is reacted with allyl halide (C_3H_5X; X = Cl, Br or I) in an ether solvent the salt $(Ph_3PC_3H_5)_2ReX_6$ is formed in quite good yield.[144] The addition of PCl_3 and Bu^tCl to a solution of rhenium(V) chloride in carbon disulfide, results in a product containing both Re_3Cl_9 and $[ReCl_6]^{2-}$, $(Bu^tPCl_3)_2[Re_3Cl_9]$ $[ReCl_6]$.[194] K_2ReCl_6 is also formed as an 'intermediate' in the preparation of $(Bu^n_4N)_2Re_2Cl_8$ in the method involving the reaction of PhCOCl with $KReO_4$. K_2ReCl_6 does not react further due to its insolubility in the reaction solvent (PhCOCl), and reduces the yield of the desired product, however, use of $(Bu^n_4N)ReO_4$ in place of $KReO_4$ allows the production of the $[Re_2Cl_8]^{2-}$ to proceed with yields up to 95%.[138] A final example is from a spectroscopic study done on the products of the H_2 reduction of $KReO_4$ in HCl solution. These products were determined to be $[ReCl_6]^{2-}$ and $[Re_2Cl_8]^{2-}$, both of which could be precipitated from the solution by addition of NH_4Cl.[260]

The mixed ligand species of the type $[ReX_nX'_{6-n}]^{2-}$ (n = 1–5; X = Cl; X' = Br or I) can be prepared by heating a mixture of K_2ReX_6 and $K_2ReX'_6$ in a quartz tube at high temperature, and then separating the products by ion column chromatography. Apparently the *cis* and *trans* isomers for n = 2, 3 and 4 of the mixed Re—I—Cl complexes cannot be separated.[261–264] Mixed Re—Br—Cl complexes have also been obtained by pouring concentrated solutions of K_2ReCl_6 and K_2ReBr_6 dropwise into ethanol.[265] The mixed ligand complexes have been studied by electronic absorption[261,262,264] and far IR spectroscopy,[263] as well as by X-ray diffraction.[261,263]

The structure of $[ReX_6]^{2-}$ is expected from simple ligand field considerations to be a regular octahedron. Crystals of K_2ReF_6 have been studied[266] by X-ray diffraction and found to be of the K_2GeF_6 type. The Re—F distance is 1.953 Å, and the $[ReF_6]^{2-}$ octahedron is slightly compressed. K_2ReCl_6 and K_2ReBr_6 have regular octahedral structures of the K_2PtCl_6 type; all Cl and Br atoms are crystallographically equivalent. K_2ReI_6, however, is less symmetrical and has three different iodine environments.[1] Structural studies done on $[ReX_6]^{2-}$ salts with cations other than K include recent neutron diffraction measurements on $(NH_4)_2ReCl_6$.[267]

The spectroscopic and magnetic properties of $[ReX_6]^{2-}$ anions have been thoroughly studied; the reviews by Rouschias[1] and Fergusson[2] should be consulted for a detailed discussion of these studies through 1972. Subsequent work in this area has expanded or refined previous measurements, and in many cases has been confirmatory or complimentary. Sharp-line absorbance, luminescence and Raman spectra have been measured for $[ReF_6]^{2-}$ in pure and host crystal environments.[268] $[ReCl_6]^{2-}$ and $[ReBr_6]^{2-}$ have been studied by high resolution IR[269] and sharp-line luminescence spectroscopy[270] and the far IR region of $M^I_2ReCl_6$ (M^I = K, Rb, Cs, Tl, NH_4, *etc.*) has been examined at very high pressures (up to 20 kbar).[271] Accurate values of the Raman-active fundamentals ν_1 (a_{1g}), ν_2 (e_g) and ν_5 (t_{2g}) of $[ReCl_6]^{2-}$ have been reported along with calculations of the parallel and perpendicular bond polarizability derivatives.[272] These results have been discussed in terms of the pre-resonance Raman effect. The resonance Raman spectrum of $(Et_4N)_2ReI_6$ has been measured at 80 K; the a_{1g} vibrational mode was found to be coupled to the electronic transition Γ_8 ($^4A_{2g}$) → Γ_8 ($^2T_{1g}$).[273]

The hexahalorhenate(IV) anions have been the subjects of extensive electronic absorption spectra studies. Their spectra have been recorded in aqueous and non-aqueous solvents, in halide melts, in the solid state and doped into other crystal hosts (*e.g.* K_2PtCl_6 or Cs_2ZrCl_6). The energy level

diagram for Re^{IV} in an octahedral crystal field has been assigned and crystal field parameters have been measured.[1] More recently, the low temperature single crystal absorption spectra of $[ReX_6]^{2-}$ (X = F, Cl or Br) in a variety of Sn host crystals with trigonal symmetry have been recorded using polarized light.[274,275] Ligand field calculations were used to rationalize the type and degree of trigonal field splitting. The electronic transitions of $[ReF_6]^{2-}$ in single crystals of Cs_2ReF_6 and doped into Cs_2GeF_6 have been measured at liquid He temperatures.[276] Crystal field parameters and spin–orbit coupling information have been derived and the vibrational structure has been interpreted on the basis of $K \neq O$ lattice effects and a small distortion in the pure Cs_2ReF_6 crystal. K_2ReCl_6 single crystals have also been studied at liquid He temperatures.[277] The magnetic circular dichroism and absorption spectra of $[ReCl_6]^{2-}$ and $[ReBr_6]^{2-}$ in cubic hosts at liquid He temperatures have been measured and most of the bands have been assigned to allowed or parity forbidden charge transfer transitions.[278] Earlier work had favored a *d–d* interpretation of these bands. Another study has analyzed the charge transfer (ligand-to-metal) spectra of a series of octahedral transition metal complexes including $[ReX_6]^{2-}$ (X = Cl, Br or I) using a simple crystal field model.[279]

Most of the recent investigations of the magnetic properties of $[ReX_6]^{2-}$ have involved ammonium or substituted ammonium salts. K_2ReCl_6 and K_2ReBr_6 are ordered antiferromagnetics at 4.2 K.[1] Antiferromagnetic behavior is also found for the $(MeNH_3)^+$ and $(Me_2NH_2)^+$ salts of $[ReX_6]^{2-}$ (X = Cl or Br).[280,281] Additionally, the synthesis and properties of $(NH_4)_2ReCl_6$ have been the subjects of a recent study,[282] as have those of $(RH)_2ReCl_6$ (R = cyclohexylamine, $PhNEt_2$, $PhNMe_2$ or 2,5-lutidine).[283]

There have been several polarographic studies done on $[ReCl_6]^{2-}$ and $[ReBr_6]^{2-}$ in which a one-electron reduction has been observed.[284,285] The cathodic one-electron reduction of $[ReX_6]^{2-}$ (X = Cl, Br or I) to give $[ReX_6]^{3-}$ is complicated by a secondary process involving the reduction of $[ReX_5(H_2O)]^-$ (*viz.* $[ReX_5(H_2O)]^- + e^- \rightarrow ReX_5(OH)^{3-} + H^+$) which is formed in solution by the hydrolysis of $[ReX_6]^{2-}$.[286,287] Cyclic voltammetric measurements on acetonitrile solutions of $(Bu^n_4N)_2ReX_6$ (X = Cl or Br) have shown that in addition to the one-electron reduction ($E_{1/2} = -1.18$ and -0.90 V *vs.* SCE for X = Cl and Br, respectively), a reversible one-electron oxidation is also observed.[95]

In general, the $[ReX_6]^{2-}$ anions are quite inert to substitution. Aquation of $[ReCl_6]^{2-}$ is especially slow, but is catalyzed by Hg^{II}, Tl^{III}, Cd^{II} and In^{III}.[288] For $[ReBr_6]^{2-}$, aquation is somewhat easier, but is also catalyzed by Tl^{III}. $[ReF_6]^{2-}$ is stable to hydrolysis and can be recrystallized from aqueous solutions.[257] The hydrolysis and the kinetics of metal-ion-catalyzed aquation have been investigated for both $[ReCl_6]^{2-}$ and $[ReBr_6]^{2-}$.[288,289]

The aqua anion $[ReCl_5(H_2O)]^-$, which can undergo hydrolysis to $[ReCl_5(OH)]^{2-}$, has been structurally characterized by X-ray crystallography in the bis(dithiobisformamidinium) salt $[(NH_2)_2CSSC(NH_2)_2]_2[ReCl_5(H_2O)]Cl_3 \cdot 2H_2O$.[290] This green crystalline substance was obtained as one of several products in a study of the $[ReO_4]^-$/thiourea/HCl system. The Re—O distance in the pseudooctahedral anion is quite short (2.076(10) Å).[290] An alternative means of preparing $[ReCl_5(H_2O)]^-$ is through the reaction of the salt $[(Pr^n_4N)ReCl_5]_n$, which contains the polymeric chlorine-bridged $[(ReCl_5)^-]_n$ anion, with a moist atmosphere.[291] Salts of $[(ReCl_5)^-]_n$ can be prepared by reacting $ReCl_5$ with an equimolar amount of $(R_4N)Cl$ (R = Et or Pr^n) in boiling CH_2Cl_2 for several days. If $ReCl_5$ is reacted with Et_4NCl in a 1:3 mole ratio, then $(Et_4N)_2ReCl_6$ is formed in almost quantitative yield. The air-stable mustard-colored salts $[(R_4N)ReCl_5]_n$ react with many donors (MeCN, DMF, py, DMSO, PPh_3, tu or H_2O) to form the salts $(R_4N)ReCl_5(L)$. Reaction with the bridging ligand pyrazine (pyz) gives $[(R_4N)ReCl_5]_2pyz$.[291] This is the most general synthetic route for salts of $[ReCl_5L]^-$, although other methods are known, such as the treatment of $ReH_3(PPh_3)_4$ with HX to give $(Ph_3PH)[ReX_5(PPh_3)]$ (X = Cl or Br),[129] and the reaction of $(pyH)_2ReX_6$ with pyridine at 190°C which gives $(pyH)[ReX_5(py)]$ (X = Cl or Br).[292] These complexes possess spectroscopic (far IR and electronic absorption) and magnetic properties that are typical of magnetically dilute Re^{IV} species.[291]

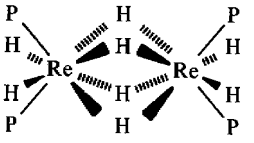
Salts of the $[ReX_5(OH)]^{2-}$ anions (X = Cl, Br or I), which are related to $[ReX_5(H_2O)]^-$ through the hydrolysis reaction given in equation (15), have been isolated in a few instances[1,2] and appear to have properties in accord with the expected pseudooctahedral structure. These anions are in equilibrium with the μ-oxo dirhenium(IV) species $[Re_2OX_{10}]^{4-}$ (Section 43.6.1.8). The cream-yellow colored methoxide derivative $Cs_2[ReCl_5(OMe)]$ has been prepared from the reaction of *cis*-$ReCl_4(NCMe)_2$ with hot MeOH saturated with gaseous HCl.[98]

$$[ReX_5(H_2O)]^- \rightleftharpoons [ReX_5(OH)]^{2-} + H^+ \qquad (15)$$

The complexes $[ReCl_4(PhC_2Ph)]_2$ and $ReCl_5(PhC_2Ph)$ have been prepared by the reaction of $ReCl_5$ with diphenylacetylene, and the former converted into the salt $Ph_4P[ReCl_5(PhC_2Ph)]$.[602]

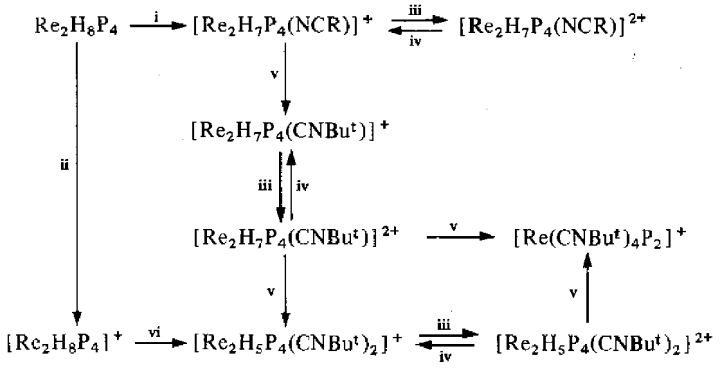
Some interesting radical cation salts of dibenzotetrathiafulvalene (DBTTF) and tetramethyltetrathiafulvalene (TMTTF) with inorganic anions, including $[ReCl_6]^{2-}$, have been prepared which possess metallic conductivity. These compounds, having the general formula $(DBTTF)_8(MCl_6)_3$ (M = Sn, Pt, Re or Te), have identical electrical properties, with their metal–insulator transition occurring in the range 120–150 K.[293,294]

43.6.1.10 Hydrides



Mononuclear hydride compelxes of Re^{IV} are very rare. The only class of such complexes that has been isolated in the solid state is $ReHX_2(acac)(PPh_3)_2$ (X = Cl, Br or I).[227] The iodide complex is apparently prepared by the reaction of $ReH_2(acac)(PPh_3)_3$ with I_2, whereas the chloride and bromide are formed upon dissolving this same complex in CHX_3. Although the chloride and iodide were shown by magnetic susceptibility measurements to be paramagnetic, their moments are quite different. All three complexes display weak ν(Re—H) modes in their IR spectra.[227] The electrochemical oxidation of the yellow monohydride of rhenium(III) $[ReH(NCMe)_3(PPh_3)_2(py)](BF_4)_2$ generates solutions that contain the violet colored tricationic species $[ReH(NCMe)_3(PPh_3)_2(py)]^{3+}$. Similar behavior characterizes the systems $[ReH(NCMe)_3(PPh_3)_2(NH_2C_6H_{11})](BF_4)_2$ and $[ReH(NCMe)_4(PPh_3)_2](BF_4)_2$, but in none of these cases have salts of the rhenium(IV) trications been isolated.[132]

The most thoroughly studied hydrido complexes of rhenium(IV) are those of the type $Re_2(\mu\text{-}H)_4H_4(PR_3)_4$ (PR_3 = PPh_3, $PEtPh_2$, $PMePh_2$, PEt_2Ph or PMe_2Ph) which can be prepared by thermolysis of $ReH_7(PR_3)_2$,[232] the photolysis of $ReH_7(PR_3)_2$ or $ReH_5(PR_3)_3$[125,135] and/or the reaction of mixtures of phosphine and $(Bu^n_4N)_2Re_2Cl_8$ with $NaBH_4$ in methanol or ethanol.[62,144] The triphenylarsine analogue $Re_2H_8(AsPh_3)_4$ has been prepared in low yield (12%) by reacting $ReOCl_3(AsPh_3)_2$ with $LiAlH_4$ in THF at 0°C.[134] The chemistry of these complexes, which had originally been reported as 'agnohydrides' because of the uncertainty as to the number of hydride ligands present,[232] was not explored in any detail until their structure was established through a neutron diffraction analysis of $Re_2H_8(PEt_2Ph)_4$ (**52**).[295] The short Re—Re distance (2.538(4) Å) may indicate some degree of multiple Re—Re bonding in these complexes but this is by no means certain. The terminal H_2P_2 units and the bridging H_4 unit are in a mutually staggered arrangement.[295] In the high field ^{1}H NMR spectra of these complexes, the resonance due to the hydride ligands is seen as a symmetric quintet in the region δ − 5.0 to − 8.1, with J(P—H) ~ 8–9.5 Hz.[125,232,295,296] For the arsine complex $Re_2H_8(AsPh_3)_4$, the ^{1}H NMR spectrum shows a hydride singlet at δ − 6.66.[134] These observations are in keeping with this class of molecules being fluxional at room temperature; details of variable temperature studies have not yet been reported, with the exception of a limited ^{1}H NMR spectral study of $Re_2H_8(PEt_2Ph)_4$ which did not yield a frozen-out spectrum at low temperatures.[295]



These structural studies have been followed by a consideration of the bonding and the conformational preferences in molecules of the type represented by (**52**).[297] Also, it has been shown that the dinuclear core of $Re_2H_8(PPh_3)_4$ is preserved upon the reactions of this complex with allyl chloride and bromide which give a mixture of $(Ph_3PC_3H_5)_2Re_2X_8$ (X = Cl or Br), H_2 and propene. However, this dimetal unit is disrupted when reacted with allyl iodide since, in this instance, the mononuclear rhenium(IV) complex $(Ph_3PC_3H_5)_2ReI_6$ is formed.[144] Electrochemical measurements by the cyclic voltammetric technique have shown that solutions of $Re_2H_8(PEt_nPh_{3-n})_4$ (n = 0, 1 or 2) and $Re_2H_8(AsPh_3)_4$ in 0.2 M $(Bu^n_4N)PF_6$–CH_2Cl_2 possess two one-electron oxidations, the first of which ($E_{1/2}$ = − 0.16 to − 0.40 *vs.* SCE) is reversible. Solutions of the paramagnetic ESR-active cations $[Re_2H_8L_4]^+$ (L = PEt_nPh_{3-n} or $AsPh_3$) can be generated by controlled potential electrolysis and, in the case of the PPh_3 derivative, the salt $[Re_2H_8(PPh_3)_4]PF_6$ can be prepared using $Ph_3C^+PF_6^-$ (or $C_7H_7^+PF_6^-$) as the oxidant in CH_2Cl_2.[134,296] Interestingly, when a nitrile solvent RCN (R = Me, Et or Ph) is used in place of CH_2Cl_2 in this reaction, hydride abstraction rather than oxidation takes place to give $[Re_2H_7(PPh_3)_4(NCR)]PF_6$. In these complexes the RCN ligands are easily substituted by Bu^{t}NC to give $[Re_2H_7(PPh_3)_4(CNBu^t)]PF_6$, and this complex like its nitrile precursors can be oxidized reversibly in two one-electron steps. The most accessible one-electron oxidation ($E_{1/2}$ = − 0.03 to + 0.19 V *vs.* SCE) can be accomplished chemically using $NOPF_6$.[134]

The paramagnetic, monocationic species $[Re_2H_8(PPh_3)_4]^+$ displays a tremendous enhancement in reactivity compared to its neutral parent $Re_2H_8(PPh_3)_4$, as does $[Re_2H_7(PPh_3)_4(CNBu^t)]^{2+}$ compared to $[Re_2H_7(PPh_3)_4(CNBu^t)]^+$. This aspect of the chemistry of these complexes is shown in Scheme 13, wherein the redox chemistry and substitution chemistry of the dirhenium polyhydrides towards Bu^{t}NC are summarized.[134] Another means of activating the complexes $Re_2H_8(PR_3)_4$ (PR_3 = $PMePh_2$ or PMe_2Ph) involves their interaction with $[Cu(NCMe)_4]PF_6$ according to equation

(16).[307] These novel hexanuclear species display an unprecedented planar rhomboidal metal array consisting of two intact Re_2 units and two Cu^+ cations. These clusters can be considered as 'raft-like' aggregates and therefore represent a geometric analogue of a metal surface.[307]

43.6.1.11 Mixed donor atom ligands

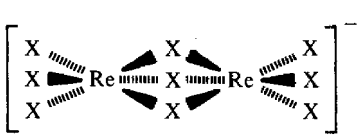
Certain of these complexes have been described in Section 43.6.1.7, *viz.* those with peptide ligands, pyridinecarboxylic acids and derivatives, and penicillamine. The most extensive studies have been carried out on Schiff base complexes in which the Schiff base ligands are either tetradentate and dianionic, or bidentate and monoanionic. The complexes of the former type, *trans*-$ReCl_2(N_2O_2)$, where N_2O_2 represents the dianionic Schiff base ligands derived from sal_2enH_2 = *N,N′*-ethylenebis(salicylideneimine), sal_2propH_2 = *N,N′*-trimethylenebis(salicylideneimine), sal_2phenH_2 = *N,N′-o*-phenylenebis(salicylideneimine) and $acac_2enH_2$ = *N,N′*-ethylenebis(acetylacetimine), are formed by refluxing *trans*-$ReCl_4(PPh_3)_2$ with one equivalent of the Schiff base and two equivalents of NEt_3 in dry toluene under nitrogen.[298] These complexes are paramagnetic and show a single ν(Re—Cl) mode in the IR spectra in accord with the *trans* geometry (**53**). In the absence of NEt_3, the preceding reactions of $ReCl_4(PPh_3)_2$ with sal_2enH_2 and sal_2propH_2, when carried out in dry THF, give $ReCl_4(sal_2enH_2)$ and $ReCl_4(sal_2propH_2)$. The complexes are believed to contain the neutral Schiff base ligand bound only through its N-donor atoms.[298]

(53)

The complex *trans*-$ReCl_4(PPh_3)_2$ is also the starting material for the synthesis of several complexes derived from the bidentate Schiff bases Me-salH = *N*-methylsalicylideneimine and Ph-salH = *N*-phenylsalicylideneimine.[207] In benzene or toluene solvents the Schiff base (LH) or its lithium salt reacts to give $ReCl_4(LH)(PPh_3)$, $ReCl_4(LH)_2$, $ReCl_3(L)(PPh_3)$ or $ReCl_2(L)_2$. The related PMe_2Ph derivatives $ReCl_3(L)(PMe_2Ph)$ can be obtained by refluxing *cis*-$ReCl_2(L)(PMe_2Ph)_2$ in CCl_4 or by heating it in toluene under a stream of CO for a long time. The detailed stereochemistries of these complexes have not been established, although $ReCl_2(L)_2$ probably has a *trans* arrangement of Re—Cl bonds on the basis of a single ν(Re—Cl) mode in the IR spectra.[207] The analogous 8-hydroxyquinoline (oxineH) complexes $ReCl_3(oxine)(PPh_3)$ and $ReCl_2(oxine)_2$ were prepared by procedures similar to those used for their Schiff base analogues.[207] Also, paramagnetic complexes of the type $Re(OH)Cl(L)_2$ (LH = 2- or 8-hydroxyquinoline) have been described but they remain inadequately characterized. They are said to be formed when the appropriate $(LH_2)_2ReCl_6$ salts are heated with excess of LH in acetic acid.[215]

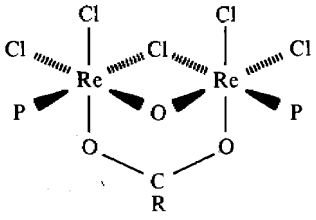
There is a report that describes the isolation of several complexes of Re^{IV} (and of Re^{V}) with thiosemicarbazide and its derivatives. These are obtained by the reactions of $[ReCl_6]^{2-}$, and the so-called α-$ReCl_4$, with thiosemicarbazide and the thiosemicarbazones of acetone, quinolinealdehyde and 5-chlorosalicylaldehyde.[299] While the thiosemicarbazide complex is paramagnetic, in accord with its being an Re^{IV} species, the structural formulation proposed for this complex (and for others of its kind) is based primarily upon IR spectroscopic data and should therefore be regarded as highly speculative.

Neutral complexes $ReX_2(L)_2$, where X = Cl or Br, and LH = 8-quinolinol or 8-quinolinethiol, are formed in the dehydrohalogenation of the corresponding $(LH_2)_2ReX_6$ salts.[603] Several complexes of rhenium(IV) with pyridinecarboxylic acids have also been described.[604] These include $ReCl_2(CO_2\text{-}2\text{-}py)_2$, $ReCl_4(3\text{-}pyCO_2H)_2$ and $ReCl_4(4\text{-}pyCO_2H)_2$.



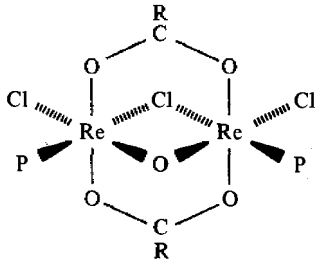
43.6.2 Dinuclear Complexes Containing a Rhenium–Rhenium Bond and Oxide and/or Halide Bridges

The nonahalodirhenate(IV) anions $[Re_2X_9]^-$ (X = Cl or Br) (**54**) possess Re—Re triple bonds ($\sigma^2\pi^4$ configuration) and can be prepared by halogen oxidation of $(Bu^n_4N)_2Re_2X_8$.[300] The salts $(Bu^n_4N)Re_2Cl_9$ (dark green) and $(Bu^n_4N)Re_2Br_9$ (dark red) have been isolated and while they are quite stable in the solid state their solutions are easily reduced to produce either $(Bu^n_4N)_2Re_2X_9$ (an Re (+3.5, +3.5) derivative) or $(Bu^n_4N)_2Re_2X_8$.[300] The paramagnetic, violet $[Re_2Cl_9]^{2-}$ anion has also been prepared by the reactions of β-$ReCl_4$ with $(Ph_4As)Cl$ in MeOH–conc. HCl and with PPh_3 in anhydrous acetone.[5,104] These reactions lead to the salts $(Ph_4As)_2Re_2Cl_9$ and $(DOTP)_2Re_2Cl_9$, respectively, where DOTP represents the 1,1-dimethyl-3-oxobutyltriphenylphosphonium cation which is formed by the acid-catalyzed condensation of acetone followed by a Michael addition of triphenylphosphine. Various salts of $[Re_2Cl_9]^{2-}$ (with $(DOTP)^+$, $(Ph_3PH)^+$, $[(Ph_3PO)_2H]^+$, $(Ph_4As)^+$ and $(Et_4N)^+$) have also been prepared starting from $ReCl_5$, but in several of these instances the yields are rather low.[5,226,301]



An X-ray crystal structure determination has been carried out on (**54**) for X = Cl. The ESCA spectrum of the complex $(Bu^n_4N)Re_2Cl_9$ shows that the bridging Cl atoms have higher Cl 2*p* binding energies (by ~1.3 eV) than those in the terminal Re—Cl bonds.[302] The complexes $(Bu^n_4N)Re_2Cl_9$ and $(Bu^n_4N)_2Re_2Cl_8$ display identical reactivities towards tertiary phosphines, reactions with PPh_3, $PEtPh_2$ and PEt_3 giving $Re_2Cl_6(PPh_3)_2$, $Re_2Cl_5(PEtPh_2)_3$ and $Re_2Cl_4(PEt_3)_4$, respectively.[64]

Amongst the products that can be isolated when *trans*-$ReOX_3(PPh_3)_2$ (X = Cl or Br) are reacted with carboxylic acids in boiling toluene are dark green $Re_2OX_5(O_2CR)(PPh_3)_2$ (X = Cl or Br) and purple $Re_2OCl_3(O_2CR)_2(PPh_3)_2$.[217] X-Ray crystal structure studies on $Re_2OCl_5(O_2CEt)(PPh_3)_2$ (**55**) and $Re_2OCl_3(O_2CEt)_2(PPh_3)_2$ (**56**) have shown that these complexes possess short Re—Re bonds (2.51–2.52 Å) although it is unclear what these values reflect in terms of actual Re—Re bond orders.[303,304] Complexes of the types (**55**) and (**56**) represent intermediate stages of reduction (Re(+4) and Re(+3.5), respectively) in the conversion of $ReOCl_3(PPh_3)_2$ to $Re_2(O_2CR)_4Cl_2$, the final product of these reactions.



There is one example of a structurally characterized μ-dioxo complex of rhenium(IV). Dissolution of ReO_2 in an oxalic acid–potassium oxalate mixture ($Re:H_2C_2O_4:K_2C_2O_4$ = 1:3:1) gave, amongst other things, three groups of crystals (dark-red, red and green-red).[305] Yields of these products were not reported but an X-ray structure determination on the green-red material showed it to be $K_4[Re_2O_2(C_2O_4)_4]\cdot 3H_2O$, containing an $Re(\mu\text{-}O)_2Re$ unit and an Re—Re distance (2.362(1) Å) which is shorter than that in (**55**) and (**56**) and presumably reflects a considerable degree of Re

(54) X = Cl or Br

(55) P = PPh_3

(56) P = PPh_3

—Re multiple bond character. This result raises the important question as to whether some of the rhenium(IV) complexes that are believed to contain a linear Re—O—Re unit (Section 43.6.1.7) might not in reality have structures related to this oxalate derivative. The suggestion that the Re^{IV} complex with 5,6-diphenyl-2,3-dihydro(asym)triazine-3-thione (HL), that has been used for the spectrophotometric determination of rhenium, might be $Re_2(\mu\text{-}O)_2L_4$, containing bidentate (N and S) coordination from L, is not without precedent. This complex is prepared by the usual $SnCl_2$ reduction of $[ReO_4]^-$ in HCl in the presence of HL.[306]

Other oxide ligand complexes that can be mentioned here are the ternary rare earth rhenates. These include a few phases that contain dirhenium(IV) centers, of which $La_4Re_2O_{10}$ and $La_6Re_4O_{18}$ are of special note since the eclipsed $[Re^{IV}{}_2O_8]$ units that are present can be considered to contain Re—Re bonds of order three.[5,308] The phase $NH_4ReO_{1.5}F_3 \cdot H_2O$ has been shown to possess a structure that contains isolated $[Re_8O_{12}F_{24}]$ units. This material is paramagnetic and is an insulator.[309]

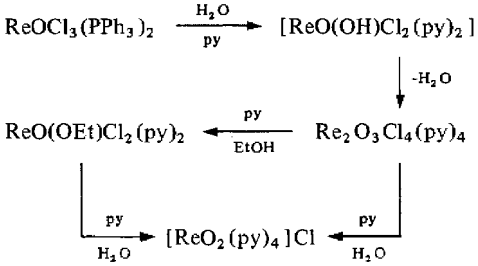
43.7 RHENIUM(V) COMPLEXES

The most prevalent complexes of this oxidation state are those which contain the $[ReO]^{3+}$, $[ReO_2]^+$ and $[Re_2O_3]^{4+}$ moieties, a reflection of the increasing stability of the rhenium–oxygen bond as the oxidation state increases. The tendency of Re^V to form multiple bonds (as in $[Re{=}O]^{3+}$ and $[O{=}Re{=}O]^+$) is also seen in its behavior toward nitrogen, *viz.* the stabilization of the $[Re{\equiv}N]^{2+}$ (nitrido) and $[Re{\equiv}NR]^{3+}$ (nitrene) moieties. With few exceptions, complexes of Re^V have been found to be essentially diamagnetic, *i.e.* to contain a spin-paired d^2 configuration. Because of the dominance of the $[ReO]^{3+}$, $[ReO_2]^+$ and $[Re_2O_3]^{4+}$ units in the chemistry of Re^V, such complexes will be considered first in the chemistry of this oxidation state.

43.7.1 Mononuclear Complexes Containing the $[ReO]^{3+}$ Moiety

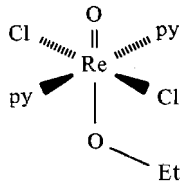
43.7.1.1 Cyanides and aryl isocyanides

The species $[ReO(OH)(CN)_4]^{2-}$ is formed upon protonation of $K_3ReO_2(CN_4)$ and then eliminates water to give $[Re_2O_3(CN)_8]^{4-}$.[310] While other methods have been described for generating $[ReO(OH)(CN)_4]^{2-}$, cyano derivatives containing the $[ReO]^{3+}$ unit are rarely encountered. However, another example is the monoanionic species $[ReO(H_2O)(CN)_3F]^-$, which is believed to be formed upon the treatment of $[ReO_2(CN)_4]^{3-}$ with hot, 40% HF.[311] The reaction of *p*-tolyl isocyanide (*p*-tolNC) with $ReO(OEt)I_2(PPh_3)_2$ is reported to give $[ReO(OEt)I(PPh_3)_2(CN\text{-}p\text{-}tol)]I$ or $ReO(OEt)I_2(PPh_3)(CN\text{-}p\text{-}tol)$ depending upon whether hot ethanol or acetone is used as the reaction solvent.[312]



43.7.1.2 Amines and N-heterocycles

There are several reports in the older literature that describe the isolation of $ReOCl_3(py)_2$, $ReOCl_3(en)$ and $ReOX_3(bipy)$ (X = Cl or Br), often *via* the protonation of the corresponding dioxo–rhenium(V) species.[1,2] In more recent years interest in these particular molecules, none of which has been characterized crystallographically, has continued. The thermal decomposition of $(NH_4)_2ReOCl_5$ is said to lead to $(NH_4)[ReOCl_4(NH_3)]$ and $ReOCl_3(NH_3)_2$, whereas the reaction of



$(NH_4)_2ReOCl_5$ with various nitrogen donors is described as giving $ReOCl_3(L)_2$ (L = py, Et_2NH, 1/2bipy or 1/2phen), $(NH_4)[ReOCl_4(Et_2NH)]$ and $ReOCl_3(DMF)$.[313] Green $ReOCl_3(py)_2$ is formed upon reacting $ReOCl_4$ or $ReOCl_4(POCl_3)$ with pyridine.[314] $ReOCl_3(bipy)$ has been prepared by the reaction of bipy with $ReOCl_4$,[314] and as a brown solid through a similar reaction involving $ReOCl_3(PPh_3)(OPPh_3)$,[86] while green and violet isomers have also been described.[315] The former is isolated both by the H_3PO_2 reduction of a mixture of $HReO_4$ and bipy in HCl/EtOH, and upon heating $(bipyH)_2ReCl_6$ in 6 M hydrochloric acid in a current of air; dark green $ReOBr_3(bipy)$ is prepared by a similar procedure. The violet form is produced, along with $[ReO(OH)(bipy)_2]^{2+}$, when the latter reaction is carried out in more dilute hydrochloric acid (0.4 M). The violet form converts to green $ReOCl_3(bipy)$ when heated in 6 M HCl and has a much higher magnetic moment (2.1 *vs.* 0.4 BM).[315] This high magnetic moment raises the question as to whether Re^{IV} is present, perhaps as an impurity.

The protonation of the ethylenediamine complex $[ReO_2(en)_2]^+$, using the hydrohalic acids, has been described as a means of forming complexes that have been formulated $ReO(OH)X_2(en)$ (green), $[ReO(OH)(en)_2]X_2$ (purple) (X = Cl, Br or I) and $[Re(OH)_2Cl_2(en)]Cl$ (green).[316] These structural formulations are based largely upon the spectroscopic and magnetic properties of the products. In no instance has the result of an X-ray structure determination been reported, although a brief mention was made (in 1978) of the forthcoming publication of the structural details of $[ReO(OH)(en)_2](ClO_4)_2$, for which the Re=O and Re=OH distances are 1.72 and 1.83 Å, respectively.[317] Crystallographic measurements may be necessary in order to distinguish the $ReO(OH)X_2(en)$ formulation from the alternative one of $Re_2O_3X_4(en)_2$. These reactions are also complicated by the fact that in boiling concentrated HX, the complexes Cs_2ReOCl_5, $(enH_2)ReBr_6$ and $ReI_4(en)$ are also formed.[316] While the protonation of $[ReO_2(py)_4]^+$ in cold moderately concentrated HBr and HI is said to give $ReO(OH)X_2(py)_2$ {X = Br (green) or I (light brown)}, complexes which are analogous to $ReO(OH)X_2(en)$, more concentrated hot acid produces $ReOBr_3(py)_2$ and $(pyH)_2ReBr_6$ and $ReI_4(py)_2$, respectively.[258]

The complex $[ReO_2(py)_4]Cl$ is the final product in the reaction of $ReOCl_3(PPh_3)_2$ (or $ReCl_5$) with wet pyridine. Its formation has been postulated to occur *via* the intermediacy of the three complexes shown in Scheme 14.[318] While the hydroxy species has not been structurally characterized, its ethoxide analogue $ReO(OEt)Cl_2(py)_2$ has been shown by X-ray crystallography to have a structure (**57**) with the EtO ligand *trans* to the terminal Re—O bond.[319] Of special note is the shortness of the Re—O bonds (1.896(6) and 1.684(7) Å, an observation that has led to the suggestion that the Re—O bond orders lie somewhere between two and three for Re—O_t, and between one and two for Re—OEt.[319] The reaction of $ReOCl_3(py)_2$ with ethanol has been found to be a route to this same ethoxide complex.[314]

Scheme 14

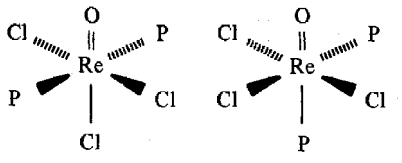
43.7.1.3 Thiocyanate and other nitrogen donors

The most important thiocyanate complex of rhenium(V) is the oxopentakis(isothiocyanate) species $[ReO(NCS)_5]^{2-}$. It has been implicated as one of the species that is present (along with $[Re(NCS)_6]^{2-}$) when $[ReO_4]^-$ is reduced with tin(II) ion in acidic thiocyanate solutions.[220] Several well-characterized salts (Et_4N^+, $Bu^n_4N^+$, Ph_4P^+ and Ph_4As^+) have been prepared by ligand exchange reactions involving salts of the $[ReOBr_4(NCMe)]^-$, $[ReOCl_5]^{2-}$ or $[ReOCl_5]^-$ anions.[220,320] The salt $(Ph_4As)_2ReO(NCS)_5$ has also been prepared by the tin(II) chloride reduction of $NaReO_4$ in an acidic NH_4NCS solution.[220] It has been suggested that the samples of the salts $M^I_2ReO(NCS)_5$ ($M^I = Cs^+$, Tl^+ or Me_4N^+), that can be prepared by the reaction of Cs_2ReOCl_5 with KSCN in hot water,[321] are contaminated with $[Re(NCS)_6]^{2-}$ salts and possibly with other complexes as well.[220] The $[ReO(NCS)_5]^{2-}$ salts display characteristic IR and electronic absorption spectral properties, *e.g.* a ν(ReO) mode close to 960 cm^{-1} in their IR spectra, but variations in the magnetic properties reported for the salt $(Ph_4As)_2ReO(NCS)_5$ need to be clarified.[220,320] Other thiocyanate complexes that have been reported include those formulated as being of the types $ReO(SCN)_3(PR_3)_2$ (PR_3 = PPh_3 or PEt_2Ph), $ReOCl(NCS)_2(PPh_3)_2$ and $ReO(OH)(NCS)_2(PPh_3)_2$, some of which remain inadequately characterized especially with regard to the mode of thiocyanate binding.[1,2] Also, a brown solid analyzing as $(Et_4N)_2ReOCl_2(NCS)_3$ has been isolated from the reaction mixture that is obtained upon reacting KSCN with a compound purported to be $ReCl_3(OEt)_2$.[322]

The acetonitrile-containing anion $[ReOBr_4(NCMe)]^-$ is described in Section 43.7.1.6. The only known dialkylamido compound is red, diamagnetic, crystalline $ReO[N(SiMe_3)_2]_3$ (ν(Re=O) at 978 cm^{-1}), It is a unique four-coordinate compound of rhenium(V), that can be prepared by the interaction of $ReOCl_4$ with $LiNMe_2$.[245]

43.7.1.4 Phosphines, phosphites, arsines and stibines

Monodentate tertiary phosphines and arsines form a very large number of six-coordinate complexes of the types $ReOX_3(L)_2$, $ReOX_3(L)(L')$ and $ReO(OR)X_2(L)_2$, where X = halide or NCS; L = a tertiary phosphine, arsine or stibine ligand; L′ = DMSO, Ph_3PO or a phosphite ligand; and R = alkyl group.[1,2] Of these, $ReOCl_3(PPh_3)_2$ is by far the most important compound since it is commonly used as a starting material for the synthesis of many other rhenium complexes. The preparations of $ReOX_3(L)_2$ and $ReO(OR)X_2L_2$ can be quite varied but usually utilize solutions of $[ReO_4]^-$ in alcohol in the presence of an excess of the appropriate hydrohalic acid.[1,2] Alternative procedures include reactions of $[ReOX_5]^{2-}$ (X = Cl or Br) with phosphines,[323] phosphine exchange reactions using $ReOX_3(PPh_3)_2$ (X = Cl or Br)[323], the thermal decomposition of $(Ph_3PH)_2ReOCl_5$ which gives $ReOCl_3(PPh_3)_2$ *via* the intermediacy of $(Ph_3PH)[ReOCl_4(PPh_3)]$,[324] and thiocyanate or halide exchange reactions of $ReOX_3(PR_3)_2$.[107,325] Complexes of the type $ReOX_3(L)_2$ have been prepared for X = Cl, Br, I or NCS, and phosphine and arsine ligands (L) such as PPh_3, PEt_2Ph, PEt_3, $AsPh_3$, $AsMe_2Ph$ and the stibine Ph_3Sb.[1,2] The mixed halide complex $ReOCl_2I(PPh_3)_2$ has also been described; its preparation involves the reaction of $[ReOI_2(PPh_3)_2]^+$ with HCl.[1] In the case of the complexes $ReO(OR)X_2(L)_2$, both alkyl and aryl alkoxy derivatives have been prepared.[1] Further details of these and other synthetic procedures are described by Rouchias.[1] However, note should be taken of the remarkable ease with which rhenium halides partake in 'oxygen abstraction' reactions to afford oxorhenium(V) species; the formation of $ReOCl_3(PPh_3)_2$ in the reaction between PPh_3 and $ReCl_5$ or β-$ReCl_4$ in acetone is an illustration of this tendency.[104,226]



Assignment of the structures of the $ReOX_3L_2$ complexes [*trans* (one form) or *cis* (two forms)] has until recently rested largely upon spectroscopic data (IR, NMR and electronic absorption) and dipole moment measurements.[107,323,325,326] Of special note is the very characteristic ν(ReO) mode that occurs as a sharp intense band in the vicinity of 970 cm^{-1}.[107,326] Thus, $ReOCl_3(PEt_2Ph)_2$ has been shown to exist in *cis* and *trans* forms (blue and green respectively);[107] a third 'isomeric' violet form has been shown to be in actuality the rhenium(IV) complex *trans*-$Re(OH)Cl_3(PEt_2Ph)_2$.[236] The X-ray crystal structure of *trans*-$ReOCl_3(PEt_2Ph)_2$ (**58**) has confirmed this structural assignment, as is also the case for *cis*-$ReOCl_3(PEt_2Ph)_2$ (**59**), although in this particular instance the structure determination is not yet complete.[327,328] Some structural details of these complexes and related species are given in Table 9.

The structural characterization of the alkoxide derivatives *trans*-$ReO(OEt)Cl_2(PPh_3)_2$ and *trans*-$ReO(OR)I_2(PPh_3)_2$ (R = Me or Et) show that these complexes resemble closely the structure of the pyridine complex *trans*-$ReO(OEt)Cl_2(py)_2$ (**57**) (Section 43.7.1.2), with a *trans* O=Re—OR unit

Table 9 Structural Details for Phosphine and Arsine Complexes of the Type $ReOX_3L_2$

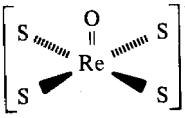
and a *trans* arrangement of Re—P bonds.[327,329] This is, in turn, similar to (**58**) but with OR replacing the *trans* chloride ligand. There is some evidence that complexes of the type $ReO(OR)X_2(PPh_3)_2$ isomerize quite rapidly in certain organic solvents.[118]

Cationic species of the type $[ReOX_2(PPh_3)_2]ReO_4$ (X = Cl, Br or I) have been described as being produced when $ReO_2I(PPh_3)_2$ is reacted with oxygen or $ReO(OEt)X_2(PPh_3)_2$ is treated with perrhenic acid in acetone, but their identity requires confirmation. Several well-characterized mixed ligand complexes of the type $ReOX_3(L)(L')$ are also known, where L represents a phosphine ligand and L′ is DMSO, DMF, Ph_3PO, $PhEt_2PO$ or one of several phosphite ligands. The mixed phosphine–phosphine oxide complex $ReOCl_3(PPh_3)(OPPh_3)$ is formed when a current of air is passed through a suspension of $ReCl_3(NCMe)(PPh_3)_2$ in boiling benzene,[86] and probably has a structure similar to that of $ReOX_3(PEt_2Ph)(OPEt_2Ph)$ (X = Cl or Br) (Table 9) in which the phosphine oxide ligand is *trans* to the terminal Re=O bond.[327] The DMSO analogue $ReOX_3(PPh_3)(DMSO)$ (X = Cl or Br) is formed by the interaction of DMSO with $ReOX_3(PPh_3)_2$ or $ReO(OEt)Cl_2(PPh_3)_2$ and concentrated hydrohalic acid.[331] The DMF-containing complex $ReOCl_3(PPh_3)(DMF)$ has also been prepared and possesses a structure where the O-bound DMF ligand is *trans* to the terminal Re =O unit.[327] When *trans*-$ReOX_3(PPh_3)_2$ is treated with $P(OMe)_3$ and phosphites of the type $P[(OCH_2)_3CR]$ (R = Me or Et), the mixed phosphine–phosphite complexes $ReOX_3(PPh_3)$(phosphite) are formed.[112] In the case of the $P(OMe)_3$ complex $ReOCl_3(PPh_3)[P(OMe)_3]$, two isomers can be isolated (blue and green); these are best distinguished on the basis of differences in their low frequency IR spectra (ν(Re—Cl) modes).

Another type of mixed ligand complex is that which contains an anionic ligand, as exemplified by the acetylacetonate derivative $ReOCl_2(acac)(PPh_3)$. This green complex, as well as its bromide and iodide analogues, can be prepared by the reaction of $ReOX_2(OEt)(PPh_3)_2$ with acacH using very short reaction times.[118] $ReOCl_2(acac)(PPh_3)$ can also be prepared by the interaction of $ReOCl_3(PPh_3)(OPPh_3)$ with acacH.[86] The related PEt_2Ph complex $ReOCl_2(acac)(PEt_2Ph)$ has also been prepared.[118] These diamagnetic complexes are characterized by a ν(Re=O) band at $\sim 980\,cm^{-1}$ in their IR spectra, and a structure in which one of the oxygen atoms of the chelating acac ligand is *trans* to the terminal Re=O unit (Table 9).[332]

Several complexes of $[ReO]^{3+}$ that contain bidentate and tridentate phosphine/arsine ligands have been prepared and characterized. Some of these, *viz.* $ReOCl_3$(dppe), $ReOCl_3(Et_2PCH_2CH_2PEt_2)$, $ReOCl_3$(diars) and $ReOX_3$(tas) (X = Cl or Br; tas = bis(*o*-diphenylarsinophenyl)phenylarsine) are described in the older literature which has been summarized by Fergusson.[2] $ReOCl_3$(dppe) and $ReOCl_3(Et_2PCH_2CH_2PEt_2)$ can be prepared by the reaction of the phosphine with $NaReO_4$ in a boiling alcohol–conc. HCl solution.[107] More recent preparations of $ReOX_3$(dppe) (X = Cl, Br or I) have involved the reactions of $[ReO_2(dppe)_2]X$ with HX in ethanol (X = Cl or Br) and of $ReO_2I(PPh_3)$(dppe) with HI.[330,333] The X-ray crystal structures of $ReOX_3$(dppe) (X = Cl or Br) have been determined (Table 9).[327] The pale green dppm complex $ReOCl_3$(dppm) has been obtained by the reaction of *cis*-$ReCl_4(NCMe)_2$ with dppm in hot acetone for a period of 48 hours. This complex apparently forms by oxygen abstraction from the acetookwzwne solvent.[233] The reaction between $KReO_4$, $(Ph_2PCH_2)_3CMe$ (abbreviated P_3) and H_3PO_2 in ethanol–conc. HCl gives blue $ReOCl_3(P_3)$ and upon prolonged reflux (24 hours) a small quantity of a green isomer. Although both complexes possess a ν(Re=O) mode at $\sim 985\,cm^{-1}$, it has been suggested that the green isomer is a seven-coordinate complex containing tridentate P_3 while the blue form is six-coordinate with bidentate coordination from the P_3 ligand.[110] The reaction of either the green or blue form with ethanol gives $ReO(OEt)Cl_2(P_3)$, in which one of the phosphine groups is uncoordinated.[110]



43.7.1.5 Oxygen and sulfur ligands

Mixed phosphine–oxygen donor complexes of $[ReO]^{3+}$ that contain DMSO, DMF, acac, Ph_3PO and $PhEt_2PO$ are described in Section 43.7.1.4. Complexes of the type $ReOX_3(OPR_3)_2$ (X = Cl or

Br; R_3PO = Ph_3PO, Ph_2EtPO, Ph_2HPO, $Ph_2P(O)CH_2CH_2P(O)Ph_2$ or $Ph_2P(O)CH{=}CHP(O)Ph_2$) can be prepared by reaction of the ligand with solutions of K_2ReOX_5 (X = Cl or Br) in acidified (HCl or HBr) acetone.[323] Alternatively, the thermal oxidation of the phosphine derivatives $ReOX_3(PR_3)_2$ in air at temperatures up to 200°C can give these same phosphine oxide species.[323,324]

The reaction between $ReOCl_3(AsPh_3)_2$ and dioxane or 1,4-oxathiane leads to displacement of $AsPh_3$ by the latter ligands; the oxathiane complex presumably contains S-bound ligands.[251] In fact, a range of sulfur donors are capable of stabilizing the Re^V oxidation state containing the $[ReO]^{3+}$ moiety. 1,2-Bis(ethylthio)ethane ($EtSCH_2CH_2SEt$) reacts with K_2ReOCl_5 in hydrochloric acid to give a mixture of diamagnetic blue needles and green plates (ν(Re=O) at 980 and 970 cm^{-1}, respectively) that are believed to be $ReOCl_3(EtSCH_2CH_2SEt)$ and $ReO(OH)Cl_2(EtSCH_2CH_2SEt)$, respectively.[334] Several complexes of Re^V with thiourea (tu) and *N,N'*-ethylenethiourea (entu) have been reported, but the structural formulations are based largely upon microanalytical data and IR spectroscopic and conductiometric measurements, *e.g.* $ReOCl_3(L)_2 \cdot nH_2O$, $[ReOCl(L)_4]Cl \cdot 2H_2O$, $K[ReOCl_4(L)] \cdot 2H_2O$ (L = tu or entu). The formation of these complexes has been investigated by spectrophotometric and potentiometric methods through monitoring the reaction between $[ReOCl_5]^{2-}$ and tu or entu in 6 M HCl.[336,337] While none of the complexes isolated in these studies have been subjected to X-ray crystal structure analyses, closely related species have been prepared by reacting $KReO_4$, with tu in concentrated hydrochloric acid. The structures of two of the resulting complexes, one obtained as blue crystals, the other being green, have been determined.[338,339] These complexes, $[ReOCl_2(tu)_2(H_2O)]Cl$ and $ReOCl_3(tu)(H_2O)$, both possess octahedral structures in which the water molecule is bound *trans* to the oxo O atom. The terminal Re—O distances are 1.654(10) and 1.713(19) Å, respectively, in the cationic and neutral complex, while the corresponding Re—OH_2 distances are 2.231(10) and 2.291(20) Å. These results are of additional significance in view of the application of the Re^{VII}–HCl—Sn^{II}–thiourea system in the analytical chemistry of rhenium. However, while Re^V and Re^{IV} thiourea complexes are said to be formed depending on the $SnCl_2$ concentration, attempts at the structural characterization of any tin-containing species have so far been frustrated.[340,341]

Synthetic procedures for complexes of oxorhenium(V) containing thiol ligands are now well established and several of these derivatives are well characterized structurally. The reaction between $(Ph_4As)ReOBr_4$ and PhSH in acetonitrile in the presence of the base NEt_3 has proved to be a convenient means of preparing $(Ph_4As)ReO(SPh)_4$ (**60**). The crystal structure of this complex as its acetonitrile solvate has shown that the anion possesses a square pyramidal geometry with an Re—O distance of 1.686(9) Å.[342] An alternative route to this anion and others of the type $[ReO(SAr)_4]^-$ (Ar = Ph, *p*-tol, C_6F_5 or C_6Cl_5) involves the reaction of $ReOCl_3(PPh_3)_2$ with excess aryl thiolate anion in refluxing methanol.[204] These species, which have been isolated as their Ph_4P^+ salts, show an intense ν(Re=O) band in the range 990–950 cm^{-1} in their IR spectra.[204] The selenol analogue $(Ph_4As)ReO(SePh)_4$ has also been prepared and characterized.[342]

(60) S = SPh

The analogous ethanedithiol derivative $(Ph_4As)ReO(SCH_2CH_2S)_2$ can be prepared by one of two procedures, namely, the reaction of $NaReO_4$ with ethanedithiol and $NaBH_4$ in THF, or the reaction of $(Bu^n_4N)ReOBr_4$ with a solution of the ethanedithiolate in THF.[343] Similar procedures have been developed for the synthesis of $A_2[ReO(dtox)_2]$ (A = Bu^n_4N or Ph_3MeAs; dtox = 1,2-dithiooxalate), $(Ph_4As)ReO(mnt)_2$(mnt = maleonitriledithiolate) and $(Bu^n_4N)ReO(tdt)_2$ (tdt = 3,4-dimercaptotoluene) using the appropriate $[ReOBr_4]^-$ salt as the synthetic starting material.[343] The mnt derivative has also been prepared by the reaction of $[ReCl_6]^{2-}$ with Na_2mnt and I_2.[344] These orange-brown crystalline compounds exhibit the usual ν(Re=O) modes in the range 990–950 cm^{-1}, and possess low magnetic moments which are field strength dependent.[343] In all instances, they most likely possess a mononuclear square pyramidal geometry. This has been confirmed in the case of the Cs^+ salt of $[ReO(dtox)_2]^-$ by an X-ray crystal structure determination.[345] A rhenium(V) complex containing dithiooxamide (dto) of stoichiometry $ReOCl_3(dto)_2$ is formed upon reacting dto with a solution containing $[ReOCl_5]^{2-}$ in acetic acid–HCl.[346]

The voltammetric behavior of $[ReO(L{-}L)_2]^-$ (L–L = SCH_2CH_2S, tma, dtox, mnt or tdt) has been

examined at Hg and Pt electrodes. A reduction occurs at potentials more negative than −0.9 V (*vs.* SCE) but oxidatively there appears to be little tendency to form Re^{VI} complexes.[343]

An especially interesting complex is the one derived from mercaptothioacetic acid ($HSCH_2COSH$, tmaH), *viz.* $(Bu^n_4N)ReO(tma)_2$. This has been prepared by the reaction of (Bu^n_4N)-$ReOBr_4$ with commercial samples of thioglycolic acid in MeOH following adjustment of the pH to 7.5 with 10 M NaOH. The formation of $[ReO(tma)_2]^-$ reflects the presence of sizeable concentrations of mercaptothioacetic acid in the thioglycolic acid.[343] These observations are important since several studies have been made of the complexation of Re^V (and Re^{VII}) by thioglycolic acid in acidic media, although the resulting complexes are poorly defined.[347,348]

The dialkyl dithiocarbamate complexes $ReOCl_2(Et_2dtc)(PPh_3)$ and $ReOX(R_2dtc)_2$ (X = Cl or Br; R = Me, Et or $\frac{1}{2}(CH_2)_5$) are best prepared by the reaction of $ReOX_3(PPh_3)_2$ in dry acetone with the appropriate tetraalkylthiuram disulfide, or, in the case of the Et_2dtc derivatives, by treatment with thallium diethyldithiocarbamate.[121] The methoxide-containing complex $ReO(OMe)(Et_2dtc)_2$ is formed by the reaction of $Re_2O_3(Et_2dtc)_4$ with dry methanol. Like the other R_2dtc complexes it displays a characteristic $\nu(Re{=}O)$ mode (940 cm^{-1}) in its IR spectrum.[349]

Salts of the $[ReO(SAr)_4]^-$ anions (Ar = mesityl, 2,6-diisopropylphenyl or 2,4,6-triisopropylphenyl) have been isolated as their Et_3PH^+ and Ph_4P^+ salts.[605] Attempts to recrystallize $Re(SC_6H_3(Pr^i)_2)_3(MeCN)(PPh_3)_2$ from CH_2Cl_2–EtOH gave the salt $[Ph_3PSC_6H_3(Pr^i)_2]^+[ReO(SC_6H_3(Pr^i)_2)_4]^-$. The X-ray crystal structure of this complex and $(Ph_4P)[ReO(SC_6H_2Me_3)_4]$ have been determined.[605]

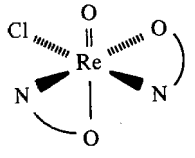
43.7.1.6 Halides

The oxo species that will be considered here are those of the types $[ReOX_5]^{2-}$, $[ReOX_4]^-$ and $[ReOX_4L]^-$, where L represents a monodentate donor and X = Cl, Br and/or I.[1,2] Salts containing the pseudooctahedral $[ReOX_5]^{2-}$ anions (X = Cl or Br) are often easily prepared but can be contaminated with paramagnetic $[ReCl_6]^{2-}$ and diamagnetic $[ReO_4]^-$ due to the disproportionation of Re^V to Re^{VII} and Re^{IV} that can occur in aqueous media (equation 17).[1,350] The $[ReOCl_5]^{2-}$ anion may be obtained by reducing $[ReO_4]^-$ with iodide in concentrated hydrochloric acid, or by dissolving $ReOCl_4$ or $ReCl_5$ in concentrated hydrochloric acid and adding a large cation.[1,331,351] The bromide analogue $[ReOBr_5]^{2-}$ is probably best prepared as its Cs^+ salt by the dissolution of $ReCl_5$ in 48% hydrobromic acid followed by the addition of CsBr, but can also be prepared from the reduction of $ReOBr_4$ in hydrobromic acid.[352,353] Cation exchange can also be used to prepare other salts.[324,354] Only a very brief mention has been made of the $[ReOI_5]^{2-}$ anion and it is not well characterized.[1]

$$3Re^V \longrightarrow 2Re^{IV} + Re^{VII} \qquad (17)$$

Magnetic studies on pure samples of $M^I_2ReOX_5$ salts have shown that these complexes are essentially diamagnetic, so that claims[354] of significant residual paramagnetism can most likely be attributable to $[ReX_6]^{2-}$ contaminants.[351] Potassium, rubidium and cesium salts of $[ReOX_5]^{2-}$ (X = Cl or Br) are seemingly isostructural with those of other closely related transition metal species of the type $[MOX_5]^{2-}$ (M = Cr, Mo, W, Tc).[355,356] A careful study has been made of the electronic absorption spectral properties and vibrational spectra (IR and Raman) of Cs_2ReOX_5 (X = Cl or Br), the latter dealing with the assignment of the Re=O and Re—X stretching and deformation modes.[351,355]

Studies of the equilibria existing in solutions of $[ReOCl_5]^{2-}$ in hydrochloric acid reveal that the Re—Cl bond *trans* to Re=O is labile and that substitution by water can occur to give $[ReOCl_4$-$(H_2O)]^-$,[357,358] which is a derivative of the $[ReOCl_4]^-$ anion. The best procedure for the preparation of salts of $[ReOX_4]^-$ (X = Cl, Br or I) involves the reduction of $[ReO_4]^-$ with zinc in concentrated sulfuric acid with HX present.[359] Reactions of $[ReOX_4]^-$ with monodentate ligands can be used to prepare the six-coordinate anions $[ReOX_4(L)]^-$ (L = H_2O or MeCN).[359,360] The triphenylphosphine derivative $(Ph_3PH)[ReOCl_4(PPh_3)]$ can be obtained by the treatment of $ReOCl_3(PPh_3)_2$ with hydrogen chloride and through the thermolysis of $(Ph_3PH)_2ReOCl_5$,[324,331] while the treatment of $(NH_4)_2ReOCl_5$ with Et_2NH, MeCN and EtOH is said to give complexes of stoichiometry $(NH_4)[ReOCl_4(L)]$.[313] X-Ray structural data have confirmed the octahedral structures of several $[ReOX_4(L)]^-$ salts in which L is weakly bonded *trans* to the Re=O bond. Such data were first reported for $(Ph_4As)[ReOBr_4(NCMe)]$[361] and $(Et_4N)[ReOBr_4(H_2O)]$,[360] and later supplemented by crystallographic data for $(Ph_4As)[ReOCl_4(H_2O)]$[362,573] and the salt $[(NH_2)_2CSSC(NH_2)_2][ReOCl_4$-



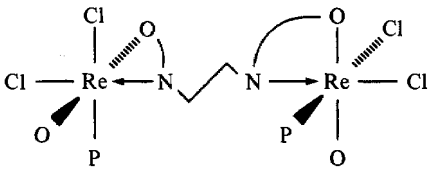
H_2O)]Cl·H_2O.[363] All revealed a very short Re—O distance (1.63–1.73 Å) that accord with its multiple bond character. The crystals of $[(NH_2)_2CSSC(NH_2)_2][ReOCl_4(H_2O)]Cl \cdot H_2O$ were obtained (together with $[ReOCl_2(tu)_2(H_2O)]Cl$ and $ReOCl_3(tu)(H_2O)$ — see Section 43.7.1.5) in a complicated reaction involving the reduction by thiourea (tu) of $KReO_4$ in concentrated HCl. The dithiobisformamidinium cation is an oxidation product of the thiourea.[363]

The complex $(Ph_4P)_2ReOCl_5$ which can be obtained as its bis-CH_2Cl_2 solvate from the reaction of $ReCl_5$ with Ph_4PCl in the presence of water has been characterized by X-ray crystallography.[606]

43.7.1.7 Mixed donor atom ligands and macrocycles

Complexes of $[ReO]^{3+}$ containing Schiff bases constitute the most extensive group of complexes derived from mixed donor atom ligands. Salicylaldehyde (salH), which serves as a precursor to most of the Schiff bases, also forms several well-defined complexes. The compound $ReOCl_2(sal)(PPh_3)_2$ can be prepared by reacting salH (or its lithium salt) with $ReOCl_3(PPh_3)_2$, or with a mixture of $KReO_4$, PPh_3 and excess hydrochloric acid in boiling EtOH.[205] Treatment of this complex with PMe_2Ph leads to the formation of $ReOCl_2(CHOsal)(PMe_2Ph)_2$ through the opening of the chelate ring and the conversion of the monoanionic bidentate sal ligand to a monodentate donor, bound through its phenolic oxygen (in which form it is abbreviated CHOsal). The reaction of salH with $(Ph_4As)ReOCl_4$ in refluxing ethanol gives $(Ph_4As)[ReOCl_3(sal)]$. These three diamagnetic complexes each possess a ν(Re=O) mode in the range 975–960 cm^{-1}, and probably have structures in which the phenolic oxygen in bound *trans* to the terminal Re=O unit.[205] The salt $(Ph_4P)[ReOCl_3(sal)]$ has also been reported and is synthesized by heating neat salicyaldehyde with $(Ph_4P)_2ReCl_6$ or a solution in ethanol with $(Ph_4P)ReOCl_4$.[364]

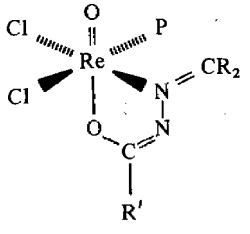
The bidentate monoanionic Schiff bases *N*-methylsalicylideneiminate (Me-sal) and *N*-phenylsalicylideneiminate (Ph-sal) react with $ReOX_3(PPh_3)_2$ or $ReOX_2(OEt)(PPh_3)_2$ (X = Cl or Br) to afford the six-coordinate species $ReOX_2(L)(PPh_3)$ or $ReOX(L)_2$ (L = Me-sal or Ph-sal), depending upon the reaction stoichiometry.[365] A similar procedure can be used to obtain the analogous complexes derived from 8-hydroxyquinoline (oxineH), *viz.* $ReOX_2(oxine)(PPh_3)$ and $ReOX(oxine)_2$,[365] while the reaction of $(Ph_4As)ReOCl_4$ with a two-fold stoichiometric amount of Schiff base in hot ethanol can be used to prepare $ReOCl(L)_2$ (L = Me-sal, Ph-sal or oxine).[366] The reaction of $ReOX_2(L)(PPh_3)$ with PMe_2Ph has proven to be a simple means of preparing $ReOX_2(L)(PMe_2Ph)$.[206] An X-ray crystal structure determination on $ReOCl(Me\text{-}sal)_2$ (**61**) has shown that the phenolic oxygen of one of the Me-sal ligands is, as expected, *trans* to the short multiply bonded Re=O unit (1.680(4) Å).[367] In the case of $ReOX_2(L)(PPh_3)$, some systems have been isolated as *cis* and *trans* isomers, and the pale green 'intermediate' $ReOCl_3(Me\text{-}salH)(PPh_3)$ has been prepared by the reaction of $ReOCl_3(PPh_3)_2$ with Me-salH in benzene at room temperature.[368]



(**61**) $\overset{\frown}{N\ O}$ = Me—sal

When a stoichiometric quantity of the Schiff base Me-salH or Ph-salH, or the bidentate oxineH, is reacted with $(Ph_4As)ReOCl_4$ in anhydrous THF, the salts $(Ph_4As)[ReOCl_4(LH)]$ are produced, whereas these same reactions when carried out in boiling ethanol give $(Ph_4As)[ReOCl_3(L)]$.[366]

Studies involving the tetradentate, dianionic Schiff base ligands derived from sal_2enH_2 = *N*,*N*′-ethylenebis(salicylideneimine), sal_2propH_2 = *N*,*N*′-trimethylenebis(salicylidenamine), sal_2phenH_2 = *N*,*N*′-*o*-phenylenebis(salicylideneimine) and $acac_2enH_2$ = *N*,*N*′-ethylenebis(acetylacetimine) have shown that analogous procedures to those described above can be used to prepare the Schiff-base-bridged species $[ReOX_2(PPh_3)]_2(sal_2en)$ (X = Cl or Br), $[ReOCl_3(PPh_3)]_2(acac_2enH_2)$, $\{[ReOCl_3]_2(sal_2en)\}^{2-}$ and $\{[ReOCl_4]_2(sal_2enH_2\}^{2-}$, as well as the mononuclear complexes $ReOCl(L)$ (L = sal_2en, sal_2prop, sal_2phen or $acac_2en$).[298,365,366,368] The latter mononuclear species have been proposed to contain a structure with the Re—Cl bond *trans* to Re=O,[298] although such a stereochemistry is not found in the case of the X-ray crystal structure of green crystalline $[ReOCl_2(PPh_3)]_2(sal_2en)$ (**62**).[369] In this complex (r(Re=O) = 1.68(1) Å and ν(Re=O) = 969 cm^{-1}) a phenolic oxygen is *trans* to the terminal Re=O bond. The mustard-yellow complex $ReOCl_3$(a-



cac_2enH_2) can be isolated upon reacting $ReOCl_3(PPh_3)_2$ with $acac_2enH_2$ in refluxing THF. ^1H NMR spectral data for this complex have been interpreted in terms of a bidentate chelating N-bound $acac_2enH_2$ ligand in the enolized form.[298]

(62)

Several complexes derived from the tridentate Schiff base *N*-(2-hydroxyphenyl)salicylideneimine (HOPh-salH) have been synthesized and the X-ray crystal structures of *trans*-ReOCl(L)(OPh-sal) (L = H_2O or MeOH) and *cis*-ReOCl(PMe_2Ph)(OPh-sal) determined.[607] The structures of the previously prepared Schiff base complexes *trans*-$ReOBr_2$(Ph-sal)(PPh_3),[608] and *cis*- and *trans*-$ReOCl_2$(Me-sal)(PPh_3)[609] have been reported.

Rhenium(V) complexes of vinyl amides RCOCH=C(R′)NH_2 of the type $ReOCl_2$[C(O^-)=CHC(R′)=NH](PPh_3) have been prepared by reacting the amides with $ReOCl_3(PPh_3)_2$ in anhydrous benzene or THF. These complexes, for which R′ = $CH_2CH_2CO_2H$ when R = Ph or C_6H_{13}, or R′ = Me or $CH_2CH_2CO_2Me$ when R = Ph, probably possess the usual octahedral structure with the ligand oxygen donor *trans* to Re=O.[370] When mixtures of ketones and $ReOCl_3(PPh_3)_2$ are treated with acyl- or aryl-hydrazine hydrohalides in refluxing benzene, derivatives of the ketone hydrazone are formed. The reaction of $ReOBr_3(PPh_3)_2$ with benzoylhydrazine hydrobromide and acetone gives an analogous bromide complex.[87] An X-ray crystal structure on the derivative [acetone benzoylhydrazonido(1)-*N*′,*O*]dichlorooxo(triphenylphosphine)rhenium(V) shows that these species have the structure depicted in (**63**).[371]

(63) P = PPh_3

An assortment of other mixed donor ligand complexes of oxo–rhenium(V) are also known but these are not particularly well characterized and, generally speaking, their structures are uncertain. These data include the complexation of Re^V by such ligands as 2-aminobenzenethiol,[372] thiosemicarbazides,[373] 1-methyl-2-mercaptoimidazole[374] and 2-mercaptobenzothiazole.[345] Recently, the pyrazolylborate complex $ReOCl_2[HB(pz)_3]$ has been prepared.[572]

Macrocylic complexes of rhenium are rare. The complex [ReO(OPh)L], where H_2L = octaethylporphine, has been prepared starting from the oxide Re_2O_7 in refluxing phenol. Its spectral properties have been described, including the assignment of ν(Re=O) at 946 cm^{-1}.[375]

43.7.2 Mononuclear Complexes Containing the $[ReO_2]^+$ Moiety

43.7.2.1 Cyanide and aryl isocyanides

One of the most stable and best characterized cyano complexes of rhenium is the $[ReO_2(CN)_4]^{3-}$ anion. It is prepared quite conveniently by the reduction of $[ReO_4]^-$ using hydrazine hydrate in the presence of CN^-.[2] The structure of the potassium salt $K_3ReO_2(CN)_4$ has been determined by both X-ray[376] and neutron diffraction[377] and shown to contain a *trans* dioxo arrangement of Re=O bonds, with r(Re—O) ≃ 1.78 Å. The protonation of $[ReO_2(CN)_4]^{3-}$ leads first to $[ReO(OH)(CN)_4]^{2-}$, which then eliminates water to give $[Re_2O_3(CN)_8]^{4-}$.[310,378] Rates of oxygen exchange between *trans*-$[ReO_2(CN)_4]^{3-}$ and water have been determined in both acidic and basic

media. In acid, a mechanism involving exchange of an oxo ligand that is facilitated by protonation is believed to occur. On the other hand, in basic media exchange occurs only after replacement of an equatorial cyano ligand by a solvent water molecule or hydroxide ion.[379]

An MO treatment of the bonding in diamagnetic $[ReO_2(CN)_4]^{3-}$ has been used to interpret the electronic absorption spectrum of this species,[380] while a detailed analysis of the vibrational spectra of $K_3ReO_2(CN)_4$, $K_3ReO_2(^{13}CN)_4$ and $K_3Re^{18}O^{16}O(CN)_4$ is available.[381] The $\nu(^{16}O{=}Re{=}^{16}O)$ modes are at 775 (IR) and 879 (Raman) cm^{-1}. The electronic absorption and emission spectra of $[ReO_2(CN)_4]^{3-}$ (and the ethylenediamine and pyridine complexes $[ReO_2(en)_2]^+$ and $[ReO_2(py)_4]^+$ — see Section 43.7.2.2) have been investigated.[610]

A *p*-tolyl isocyanide complex of stoichiometry $[ReO_2(PPh_3)_2(CNR)_2]I$ has been reported[312] but remains incompletely characterized. Other isocyanide-containing derivatives are unknown.

43.7.2.2 Amines and N-heterocycles

Diamagnetic species of the types $[ReO_2L_4]^+$ (L = py, picolines, NH_3 or primary amines) and $[ReO_2(LL)_2]^+$ (LL = ethylenediamine (en) and other bidentate primary amines, or bipy) constitute an extensive series of complexes whose preparations and reactivities, including the protonation of the dioxorhenium unit, are thoroughly reported in earlier reviews.[1,2] These species are usually encountered in salts with the following anions: Cl^-, Br^-, I^-, ClO_4^- and ReO_4^-. The most extensively studied systems are the yellow-orange species $[ReO_2(py)_4]^+$ and $[ReO_2(en)_2]^+$, both of which display characteristic $\nu(O{=}Re{=}O)$ vibrations at $\sim 820\,cm^{-1}$ in their IR spectra.[326]

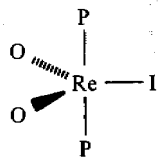
Their syntheses can be accomplished using starting materials like K_2ReCl_6 and $KReO_4$,[382,383] but they can also be formed easily from compounds such as β-$ReCl_4$ and $Re_2O_3Cl_4(py)_4$ (and many others) when oxygen and water are present.[318,384]

The X-ray crystal structure of *trans*-$[ReO_2(en)_2]Cl$ has been the subject of three separate studies, the most recent determination giving $r(Re{-}O) = 1.765(7)$ Å.[317] The results of X-ray structural studies are also available for *trans*-$[ReO_2(en)_2]NO_3$[385] and *trans*-$[ReO_2(py)_4]Cl \cdot 2H_2O$,[317] for which the Re=O bond distances are reported as 1.764(9) Å and 1.764(13) Å, respectively.

Several complexes are also known where more than one type of ligand (including an amine or *N*-heterocycle) is present in the $[ReO_2]^+$ coordination sphere; examples include $[ReO_2(py)_3(PPh_3)]^+$ and $[ReO_2(py)_2(PPh_3)_2]^+$ (see Section 43.7.2.3), and some mixed aqua–fluoride–pyridine derivatives, *e.g.* $[ReO_2py_3]F$, $[ReO_2(py)_2(H_2O)F]$ and $[ReO_2(py)_2(H_2O)_2]F$, that have been described as being formed starting from $[ReO_2(py)_4]F$.[386]

The electronic absorption spectra of various dioxorhenium(V) *trans*-$[ReO_2L_4]^+$ species have been investigated (L = py, 4-Mepy or 4-Bu^{t}py), and these species have been shown to exhibit luminescence in the solid state and in aprotic solvents but not in water.[387]

In addition to spectroscopic studies on $[ReO_2(en)_2]^+$ and $[ReO_2(py)_4]^+$,[610] the reduction of the en complex and its 1,3-diaminopropane analogue with the aquated electron has been found to generate transient d^3 Re^{IV} complexes.[611] Re_2O_7 is reduced by PEt_3 in the presence of pyridine, 4-methylpyridine or 4-phenylpyridine, to give $[ReO_2L_4]ReO_4$ in good yield. The X-ray crystal structure of *trans*-$[ReO_2(4\text{-}Mepy)_4]ReO_4$ has been determined.[612]



The incorporation of rhenium into zeolites *via* $[ReO_2(en)_2]Cl$ has been found to lead to lower catalytic activity (in the hydrogenation of benzene) than is the case for catalysts obtained by impregnating zeolite NaY with NH_4ReO_4 solution.[388]

43.7.2.3 Phosphines

The six-coordinate complexes $ReO_2I(PEt_2Ph)_3$ and $ReO_2I(dppe)(PPh_3)$ are formed when five-coordinate $ReO_2I(PPh_3)_2$ is reacted with PEt_2Ph or one equivalent of dppe.[330] In a similar fashion, the reaction of $ReO_2I(PPh_3)_2$ with an excess of py can be used to prepare $[ReO_2(py)_3(PPh_3)]X$ (X = I or ClO_4), which in turn reacts with PPh_3 to give $[ReO_2(py)_2(PPh_3)_2]^+$.[330] The treatment of $ReO_2I(PPh_3)_2$ with an excess of dppe gives $[ReO_2(dppe)_2]^+$, which can also be generated directly from ReO_4^- by reaction with HX in ethanol.[330,333]

The complex used to prepare the preceding complexes, *viz.* $ReO_2I(PPh_3)_2$ (**64**), is itself most easily obtained as violet crystals by stirring a suspension of $ReOI_2(OR)(PPh_3)_2$ (R = Me or Et) in wet acetone.[329,330] This reaction is believed to occur as shown in equation (18), and an X-ray crystal structure determination has shown that (**64**) possesses a geometry somewhat intermediate between that of a trigonal bipyramid and a square pyramid, although it resembles the former more closely. This structure is characterized by a *trans* disposition of phosphine ligands, an O—Re—O angle of

139° and Re=O distances of 1.742(11) Å.[329] This is the only structure known to date in which the two oxide ligands in an $[ReO_2]^+$ moiety are not *trans* to one another.

(64) P = PPh_3

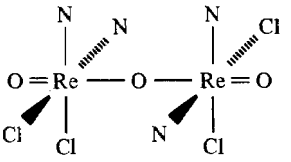
$$ReOI_2(OR)(PPh_3)_2 + H_2O \xrightarrow{\text{acetone}} ReO_2I(PPh_3)_2 + ROH + HI \quad (18)$$

The complexes $ReO_2I(PPh_3)_2$ and $ReOI_3(AsPh_3)_2$ are useful synthetic starting materials for the preparation of the 2-butyne complex $ReOI(MeC{\equiv}CMe)_2$.[613] Dirhenium heptaoxide Re_2O_7 reacts with PMe_3 to give *trans*-$[ReO_2(PMe_3)_4]ReO_4$,[614] while when the reduction is carried out using PEt_3 in the presence of pyridine, 4-methylpyridine or 4-phenylpyridine, the mixed valent salts $[ReO_2L_4]$-ReO_4 are obtained.[612]

43.7.2.4 Other ligands

Complexes in which both fluoride and water have been incorporated into the inner coordination sphere are described in Section 43.7.2.2. A DMSO derivative $ReO_2I(DMSO)_2$ has been reported to exist but remains inadequately characterized,[331] as are the thiocyanate-containing species formulated as $[ReO_2(CNS)_4]^{3-}$, for which evidence of solid compounds is doubtful,[2] and $[ReO_2(NCS)_2(PPh_3)_2]^-$, the latter having been isolated as its Na^+, NH_4^+ and Ph_4As^+ salts through the reaction between $ReO(OH)(NCS)_2(PPh_3)_2$ and OH^- in the presence of an excess of SCN^-.[389] The existence of the thiourea-containing cation $[ReO_2(tu)_4]^+$ has been described in the literature before 1963, but its identity remains questionable.[2]

43.7.3 Complexes Containing the μ-Oxo-bridged $[Re_2O_3]^{4+}$ Moiety



43.7.3.1 Cyanide

The acidification of solutions containing $[ReO_2(CN)_4]^{3-}$ leads to $[Re_2O_3(CN)_8]^{4-}$, a species which has been isolated as its $[Pt(NH_3)_4]_2Re_2O_3(CN)_8$ salt and structurally identified by X-ray crystallography.[310,390] The linear O=Re—O—Re=O unit is characterized by Re—O distances of 1.698(7) and 1.915(1) Å. A detailed analysis has been made of the vibrational spectrum of $[Re_2O_3(CN)_8]^{4-}$ and the ν(Re=O) and ν(Re—O—Re) modes assigned, *viz.* ν(Re=O) (Raman), 1017 cm^{-1}, ν(Re=O) (IR), 1008 cm^{-1}, ν(Re—O—Re) (IR), 720 cm^{-1} and ν(Re—O—Re) (Raman), 205 cm^{-1}.[381] The rates of oxygen exchange of the anion have been determined, the mechanism by which the exchange of terminal oxo ligands occurs being facilitated by association with H^+.[379] The diamagnetic, mixed alkali metal salt $K_3Na[Re_2O_3(CN)_8]\cdot 2H_2O$ has also been prepared and spectroscopically characterized by IR and electronic absorption spectroscopy. Its IR-active ν(Re=O) and ν(Re—O—Re) modes have been assigned to bands at 995 and 725 cm^{-1}, respectively.[378] An MO analysis of the electronic structure of $[Re_2O_3(CN)_8]^{4-}$ is available.[391]

43.7.3.2 Ethylenediamine and N-heterocycles

The neutral ethylenediamine complex $Re_2O_3Cl_4(en)_2$ is formed upon allowing a solution of $[ReO(OH)(en)_2]^{2+}$ in 2 M HCl to stand.[331] The green crystalline material that results has a structure very closely related to that of $[Re_2O_3(CN)_8]^{4-}$ as established by X-ray crystallography.[392] The related pyridine and 2,2′-bipyridyl complexes have been prepared by reacting $ReCl_4$ or $ReCl_5$ with py or bipy in wet acetone, by the reaction of $ReOCl_4$ with bipy in absolute ethanol, and by the reactions of $ReOX_3(PPh_3)_2$ or $ReO(OEt)Cl_2(PPh_3)_2$ with py in wet benzene.[314,318,384] The reaction scheme by which $ReOCl_3(PPh_3)_2$ is converted into $Re_2O_3Cl_4(py)_4$ is shown in Scheme 14. The pattern of Re—O stretching modes of the py complex (**65**) is similar to that of the analogous CN^- and en complexes. However, this complex differs from the CN^- and en derivatives in havings its two sets of equatorial ligands in a staggered arrangement one to the other (in this molecule the twist angle

is 113°).[393] The Re—O distances are as follows: Re=O_t, 1.715(16), 1.764(16); Re—O_b, 1.943(16), 1.903(16) Å.[393]

(65) N = py

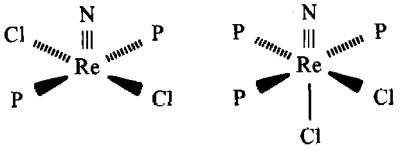
43.7.3.3 Dialkyldithiocarbamates

The dialkyldithiocarbamate complexes $Re_2O_3(R_2dtc)_4$ (R = Me, Et or Ph) are best prepared by reacting $ReOCl_3(PPh_3)_2$ or $Re_2O_3Cl_4(py)_4$ with $Na^+R_2dtc^-$ in acetone.[121,349] The best characterized complex is the diethyldithiocarbamate derivative $Re_2O_3(Et_2dtc)_4$, whose X-ray crystal structure has been determined.[394,395] The complex has a structure which closely resembles that of (**65**), but with an angle of twist of 40° away from the fully eclipsed conformation. Its vibrational spectrum exhibits the following characteristic Re—O stretching modes: ν(Re=O) (Raman), 961 cm^{-1}, ν(Re=O) (IR), 955 cm^{-1}, ν(Re—O—Re) (IR), 670 cm^{-1} and ν(Re—O—Re) (Raman), 191 cm^{-1}.[381] An interesting reaction of $Re_2O_3(Et_2dtc)_4$ is its conversion to $ReO(OMe)(Et_2dtc)_2$ when treated with dry methanol. This reaction can be reversed in the presence of trace amounts of water through the formation of $ReO(OH)(Et_2dtc)_2$ which subsequently dimerizes.[349]

The related nitrene(imido)–oxo complex $[Re(NPh)(Et_2dtc)_2]_2O$ is known (Section 43.7.4), and can be prepared by the action of aniline on $Re_2O_3(Et_2dtc)_4$ in refluxing benzene.[121] The oxo–sulfido derivative $Re_2O_2S[(PhCH_2)_2dtc]_2$ can be isolated as brown needles in low yield as one of the products from the reaction between $ReCl(CO)_5$ and tetrabenzylthiuram disulfide in benzene. The IR spectral characteristics of this complex include ν(Re=O) at 895 cm^{-1} and ν(Re—S—Re) at 448 and 435 cm^{-1}.[252]

43.7.3.4 Other ligands

Several oxo-bridged mixed fluoro–hydroxo–oxalato complexes of rhenium(V) that are prepared by boiling freshly precipitated ReO_2 with oxalic acid and 40% HF may actually be derivatives of the $[Re_2O_3]^{4+}$ moiety. They have been formulated as containing the $[Re_2O(C_2O_4)(OH)_6F_2]^{2-}$ anion but remain inadequately characterized.[396]



The tin(II) chloride reduction of $[ReO_4]^-$ and 2-aminobenzenethiol (N—S) in hydrochloric acid gives a red-brown complex $ReO(OH)(N—S)_2$ which is air sensitive and converts to green $Re_2O_3(N—S)_4$.[372] The macrocyclic complex $Re_2O_3(L)_2$ (LH_2 = octaethylporphine) has been the subject of a preliminary report but few details are available.[375]

The reaction of $ReOCl_3(PPh_3)_2$ with the tetradentate Schiff base ligands LH_2 (sal_2enH_2, sal_2propH_2, sal_2phenH_2 or $acac_2enH_2$) in the presence of two equivalents of NEt_3 without precautions to exclude air gives $Re_2O_3(L)_2$.[298] These brown or green complexes have IR spectral properties {ν(Re=O) and ν(Re—O—Re)} fully in accord with this formulation and exhibit the parent molecular ion in their mass spectra. When the complex $ReOCl(acac_2en)$ is exposed to O_2 in dichloromethane–benzene solution, the novel compound $[Re_3O_4(acac_2en)_3]ReO_4$ is formed.[397] An X-ray crystal structure shows that the O=Re—O—Re—O—Re=O backbone contains three different Re—O bond lengths. The terminal Re—O bonds are shortest (1.683(5) Å), and *trans* to these are two long bonds (2.076(12) Å), while the two remaining Re—O bonds on either side of the central rhenium atom are intermediate in length (1.785(7) Å).[397]

43.7.4 Nitrides and Imides (Nitrenes)

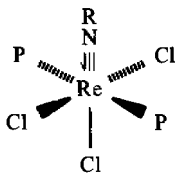
The stable nitrido complexes $ReNX_2(PR_3)_n$(X = Cl, Br or I; n = 2 or 3) are easily prepared by the reaction of species containing the $[ReO]^{3+}$ moiety with hydrazine hydrochloride in ethanol.[87,398–400] The mechanism of these reactions has been investigated.[399] The X-ray crystal structures of the representative five- and six-coordinate species $ReNCl_2(PPh_3)_2$(**66**) and $ReNCl_2(PEt_2Ph)_3$ (**67**)

have been determined and the Re—N bonds, which are formally of order three, found to be very short (1.603(9) and 1.788(11) Å, respectively).[401,402] A similar structure has also been established for $ReNCl_2(PMe_2Ph)_3$, but the Re—N distance is shorter that in the case of the PEt_2Ph analogue, *viz.* 1.660(8) Å.[403]

(66) P = PPh_3 (67) P = PR_2Ph

The diphosphine analogues $[ReNX(LL)_2]Y$ (X = Cl, Br or I; LL = dppm, dppe or $Ph_2P(CH_2)_3PPh_2$; Y = Cl, Br, I, I_3, ClO_4 or BPh_4) are prepared either by reacting $ReNX_2(PPh_3)_2$ with LL in a suitable solvent or, in the case of $[ReNCl_2(dppe)_2]Cl$, the reaction of $ReOCl_3(dppe)$ with hydrazine hydrochloride in ethanol.[404,405] Another important derivative is the square pyramidal complex $ReN(Et_2dtc)_2$ which can be isolated as lemon-yellow crystals by the interaction of $ReNCl_2(PPh_3)_2$ with $NaEt_2dtc \cdot 3H_2O$ in acetone.[121,406] The cyano species $K_3ReN(CN)_5$ and $K_2ReN(CN)_4 \cdot H_2O$ are also known and are believed to contain six-coordinate rhenium.[407,408]

A fairly detailed study has been made of the ^1H NMR, far IR and electronic absorption spectral properties of the complexes $ReNX_2(PEt_2Ph)_3$ (X = Cl, Br or I).[325] The characteristic $\nu(Re{\equiv}N)$ modes occur close to 1000 cm^{-1} in the IR spectra of these and other nitrido–rhenium(V) complexes.[399,404]



The terminal nitrido ligand is sufficiently basic so as to coordinate to Lewis acids, as in the reaction of $ReNCl_2(PMe_2Ph)_3$ with $MoCl_4(NCMe)_2$ to give the bridged nitrido complex $(PhMe_2P)_3Cl_2ReNMoCl_4(NCMe)$.[1,409] Another illustration of the basicity of $[Re{\equiv}N]^{2+}$ is seen in the reactions of $ReN(R_2dtc)_2(PMe_2Ph)_n$ (R = Me or Et; $n = 0,1$) with the electrophilic reagents $Ph_3C^+BF_4^-$, $[Me_3O]^+BF_4^-$ and 2,4-$(NO_2)_2C_6H_3SCl$ to give the salts $[Re(NR')(R_2dtc)_2(PMe_2Ph)_n]BF_4$ (R′ = Ph_3C or Me) and $Re(NSAr)Cl(Et_2dtc)_2$ (Ar = 2,4-$(NO_2)_2C_6H_3$).[410] These complexes are imido derivatives, other examples of which will be considered below. Substitutional lability of the other ligands bound to the $[Re{\equiv}N]^{2+}$ moiety are another characteristic of these complexes. Thus the phosphine ligands of $ReNX_2(PPh_3)_2$ (X = Cl or Br) can be replaced, completely or partially, by the N-heterocycles py, bipy and phen.[411,412]

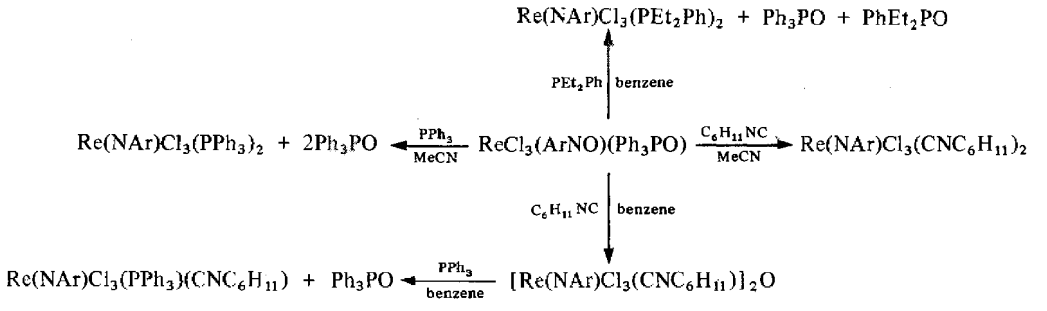
A large number of octahedral organoimido (nitrene) complexes of the form $Re(NR)X_3L_2$ (X = halide; R = alkyl, aryl or aroyl) are known which formally contain a rhenium–nitrogen double bond.[1] These complexes are usually prepared by routes which involve the reaction of $ReOCl_3(PR_3)_2$ with aromatic amines (equation 19), 1,2-disubstituted hydrazines, phosphinimines ($Ph_3P{=}NR$), phenyl isocyanate and sulfynilamines (ArNSO) (equation 20), some of the procedures being quite general while others are rather specific.[1,413,417] Interestingly, when $ReOCl_3(PPh_3)_2$ is reacted with mono- or di-aroylhydrazine hydrochlorides in benzene–ethanol, the diazenido species $ReCl_2(N_2COAr)(PPh_3)_2$ is formed. This can be considered either as a derivative of Re^V or Re^{III} (see Section 43.5.1.3 for further details). In the presence of a ketone, the hydrochlorides of both aryl- and aroyl-hydrazines ($R'CONHNH_2$) give oxo–rhenium(V) complexes of the corresponding ketone hydrazine ligands rather than imido complexes (see Section 43.7.1.7).

$$ReOCl_3(PR_3)_2 + ArNH_2 \longrightarrow Re(NAr)Cl_3(PR_3)_2 + H_2O \quad (19)$$

$$ReOCl_3(PPh_3)_2 + ArNSO \longrightarrow Re(NAr)Cl_3(PPh_3)_2 + SO_2 \quad (20)$$

The X-ray crystal structures of the isostructural set of complexes $Re(NR)Cl_3(PEtPh_2)_2$ (R = Me, C_6H_4-*p*-OMe or C_6H_4-*p*-Ac) (**68**) show that the Re—N—C moiety is very close to being linear (*i.e.*

(68) P = PEt_2Ph

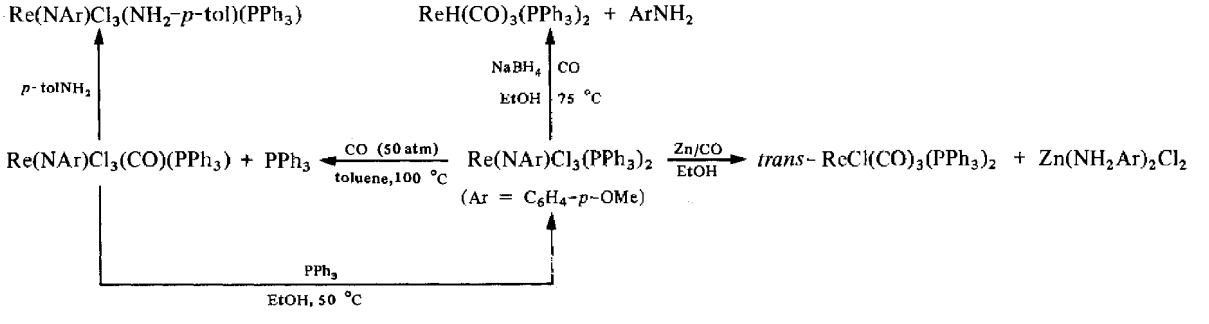


sp hybridization at N) and that the Re—N bond lengths are so similar to those of the corresponding nitrido complexes that the Re—N bonds can be considered as being of order three.[414,415] The structurally characterized complex *trans*-$[Re(NMe)(NH_2Me)_4Cl](ClO_4)_2$ (r(Re—N) = 1.694(11) Å) has been obtained from the reaction between K_2ReCl_6, $MeNH_2$, water and oxygen.[416]

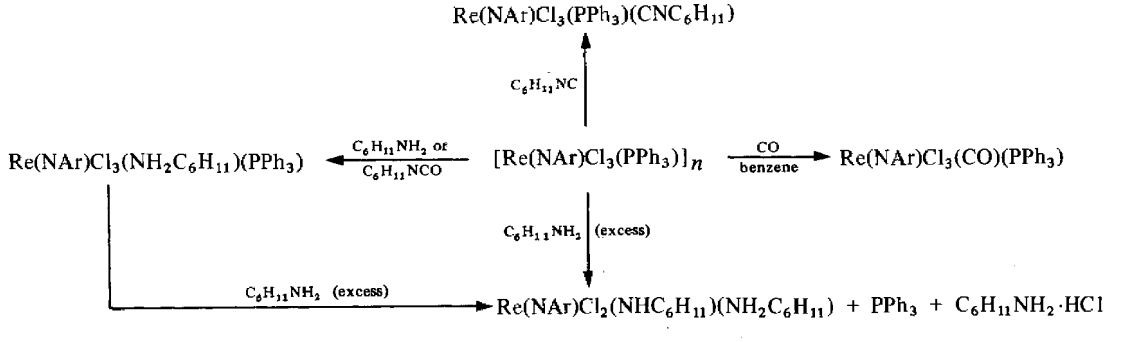
Mixed phosphine–phosphite complexes $Re(NPh)X_3(PPh_3)[P(OMe)_3]$ can be obtained by the reaction of $ReOX_3(PPh_3)[P(OMe)_3]$ with aniline in refluxing benzene,[112] while the mixed pyridine–phosphine species $[Re(NR)Cl_2(PR_3)_2(py)]^+$ are also isolable as is $[Re(NMe)Cl_2(PMe_2Ph)_3]^+Cl^-$.[419] The diethyldithiocarbamate species $Re(NPh)Cl(Et_2dtc)_2$ and $[Re(NPh)(Et_2dtc)_2]_2O$ are formed by the action of tetraethylthiuram disulfide upon $Re(NPh)Cl_3(PPh_3)_2$, and the reaction of aniline on $Re_2O_3(Et_2dtc)_4$ in refluxing benzene, respectively.[121] The μ-oxo bridged complex can also be prepared by the reaction of an acetone solution of sodium diethyldithiocarbamate trihydrate with $Re(NPh)Cl_3(PPh_3)_2$, and is formed from $Re(NPh)Cl(Et_2dtc)_2$ in wet acetone in the presence of Na_2CO_3. This complex exhibits a ν(Re—O—Re) mode at 660 cm^{-1} in its IR spectrum.[121] A detailed study of the imino–dithiocarbamate system has shown that the complexes $Re(NR)(R'_2dtc)_3$ and $Re(NR)(R'_2dtc)_2(OR'')$ (R = Me, Ph or *p*-tol; R′ = Me or Et; R″ = Me or Et) can be prepared by the action of $Tl(R'_2dtc)$, $Me_3SiS_2CNR'_2$ or $NaOR''$ upon $Re(NR)Cl(R'_2dtc)_2$.[417] While IR and ^1H NMR spectral evidence suggests that one of the R'_2dtc ligands is monodentate in $Re(NR)(R'_2dtc)_3$, an X-ray crystal structure determination of *trans*-Re(*N*-*p*-tol)$(Me_2dtc)_2(OEt)$ reveals a bent nitrene unit (Re—N—C ≃ 156°) with an abnormally long Re—N bond (1.745(5) Å). The ethoxy ligand is also bent at the O atom. These observations reflect the 'electron rich' nature of the Re atom in these complexes, and as a consequence the Re—N bond order approaches two.[417]

A compound which is believed to be the arylimido–hydrido complex Re(*N*-*p*-tol)$HCl_2(PPh_3)_2$ is formed upon reacting Re(*N*-*p*-tol)$Cl_3(PPh_3)_2$ with sodium isopropoxide in isopropanol.[418] This compound, as well as its *p*-methoxyphenylimido analogues, can also be obtained by using ZnO/EtOH in place of $NaOPr^i/Pr^iOH$. However, the reaction between Re(*N*-*p*-tol)$Cl_3(PPh_3)_2$ and ZnO (or triethylamine) in EtOH proceeds further in a second step to give Re(*N*-*p*-tol)$HCl(OEt)(PPh_3)_2$, and when C_2D_5OH is used in place of C_2H_5OH, the deuterated species Re(*N*-*p*-tol)$DCl(OC_2D_5)(PPh_3)_2$ is formed. The methoxide derivative Re(*N*-*p*-tol)$HCl(OCH_3)(PPh_3)_2$ and the non-hydrido complex Re(*N*-*p*-tol)$Cl_2(OCH_3)(PPh_3)_2$ have also been prepared by similar procedures to those described above.[418] The conversion of Re(*N*-*p*-tol)$HCl(OEt)(PPh_3)_2$ back to Re(*N*-*p*-tol)$HCl_2(PPh_3)_2$ is achieved by reaction with gaseous HCl in diethyl ether, and when the latter product is in turn treated with gaseous Cl_2 in this same solvent, the starting arylimido complex Re(*N*-*p*-tol)$Cl_3(PPh_3)_2$ is regenerated.[418] An unusual feature of the ^1H NMR spectra of the $Re(NAr)HCl_2(PPh_3)_2$ complexes is the assignment given to the resonance due to the hydridic hydrogens; this is purported to occur as a triplet at around δ3.5 (J(P—H) = 15 Hz). The ν(Re—H) modes in the IR of the hydrido complexes are located at ~2000 cm^{-1}.[418]

Alkyl and arylimido complexes of rhenium(V) undergo a variety of interesting reactions. These include the conversion of the alkylimido complexes $Re(NR)Cl_3(PR_3)_2$ to methyleneamido–rhenium(III) species containing the Re(N=CHR′) moiety upon reaction with bases such as pyridine. The complexes isolated by this method are $Re(N{=}CH_2)Cl_2(PR_3)_2(py)$ (PR_3 = PPh_3, $PEtPh_2$ or $PMePh_2$), $Re(N{=}CH_2)Cl_2(PMe_2Ph)_3$ and Re(N=CHR)$Cl_2(PPh_3)_2$(py) (R = Me or Et).[419] Another instance where reaction occurs at the imido ligand is that between $Re(NAr)Cl_3(PPh_3)_2$ and O_2 in refluxing toluene. In the case of Ar = Ph, *p*-tol or C_6H_4-*p*-OMe, the diamagnetic N-bound arylnitroso complexes $ReCl_3(ArNO)(Ph_3PO)$ are formed.[413,420] Although they are not yet fully characterized structurally, these nitroso complexes have an IR absorption band at ~1350 cm^{-1} which has been assigned to ν(NO) of the N-bound ArNO ligand.[413] The arylnitroso ligand ArNO in these complexes is easily deoxygenated as shown by the reactions given in Scheme 15 for the case where Ar = *p*-tol.[420] In all instances, reaction with phosphines or $C_6H_{11}NC$ gives arylimido species. This includes the formation of a compound that is believed to be a μ-oxo-rhenium(VI) derivative in the case of reaction with $C_6H_{11}NC$ in benzene.



The substitutional lability of $Re(NAr)Cl_3(PPh_3)_2$ has been demonstrated through reactions with CO under various conditions (Scheme 16).[413] However, enhanced reactivity is encountered if $Re(NAr)Cl_3(PPh_3)_2$ (Ar = *p*-tol) is first reacted with elemental sulfur to remove one PPh_3 ligand as Ph_3PS and generate $[Re(NAr)Cl_3(PPh_3)]_n$ (n is probably 2).[420] This latter complex reacts with *p*-nitrotoluene (at 80–90°C) to give the nitroso complex $ReCl_3(ArNO)(Ph_3PO)$ with *p*-toluidine as the by-product, while in benzene or CCl_4 solvents, O_2 reacts with $[Re(NAr)Cl_3(PPh_3)]_n$ to give $ReCl_3(ArNO)(Ph_3PO)$ together with the rhenium(VI) species $Re(NAr)Cl_4(Ph_3PO)$ (see Section 43.8.1).[420] The reactions of $[Re(NAr)Cl_3(PPh_3)]_n$ with various neutral ligands are summarized in Scheme 17. Of special note is the complex $Re(NAr)Cl_2(NHC_6H_{11})(NH_2C_6H_{11})$ which contains



Scheme 15

amine, amido and arylimido ligands. The carbonyl-containing complex $Re(NAr)Cl_3(CO)(PPh_3)$ resembles the related *p*-methoxyphenylimido derivative in Scheme 16. It is of further significance in that it contains a CO ligand bound to a very high oxidation state metal center; the high value of the $\nu(CO)$ mode (at $2040\,cm^{-1}$) reflects this.

The reactions of $Re(NR)Cl_3(PPh_3)_2$ and related complexes with salicylaldehyde[615] and Schiff base ligands[616] produce various complexes in which the organoimido ligand is retained. The X-ray crystal structures of six-coordinate $Re(NC_6H_4\text{-}p\text{-}Me)Cl_2(sal)(PPh_3)$[615] and $Re(NC_6H_4\text{-}p\text{-}Me)Cl_2(R\text{-}sal)(PPh_3)$ (R = Me or Ph)[616] have been reported. The preparation of $Re(NR)Cl_3(PPh_3)_2$ complexes has been accomplished by heating $ReOCl_3(PPh_3)_2$ with the formamidine ligands RNHCHNR (R = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4 or *p*-FC_6H_4) in THF under reflux and, in the case of R = *p*-MeC_6H_4, by heating the triazenido complex $ReCl_2(RN_3R)(PPh_3)_2$ in CCl_4 under reflux.[617] The X-ray crystal structure of $Re(NPh)Cl_3(PPh_3)_2$ as its CH_2Cl_2 solvate has been published,[618] as have details of the preparation and structure of the Lewis acid–base complex $Re(NBCl_3)Cl_2(PMe_2Ph)_3$ which contains a nitrido bridge.[619] Treatment of $ReCl_2(N_2COPh)(PPh_3)_2$ (**23**) with excess benzoylhydrazine in methanol gives $ReCl_2(PPh_3)_2(NNHCOPh)(NHNHCOPh)$ which has been characterized by X-ray crystallography; the latter complex exhibits both linear hydrazido(2−) and end-on hydrazido(1−) ligation.[620] There is a report on a rhenium(V) nitrido complex of phthalocyanine.[621]

Scheme 16

Scheme 17

43.7.5 Other Complexes

43.7.5.1 Oxygen and sulfur ligands

One of the best characterized molecules is $ReCl_5(OPCl_3)$ which is obtained in crystalline form by cooling a saturated solution of $ReCl_5$ in $POCl_3$. Its structure has been solved by X-ray crystallography (r(Re—O) = 2.15(1) Å), and details of its IR spectrum are available.[421] The incorporation of Re^V into heteropolymolybdate and heteropolytungstate anions has been accomplished (*e.g.* $[PRe^VW_{11}O_{40}]^{4-}$),[422] and this oxidation state is also encountered in certain oxo anions, including the phases $Ln_4Re_2O_{11}$ and $Ln_6Re_4O_{18}$ (Ln = lanthanide) which contain edge-sharing $[Re_2O_{10}]$ units. The latter phases are reviewed elsewhere.[1,308]

Several well-characterized sulfur ligand complexes are known including the anionic species $[ReS(SCH_2CH_2S)_2]^-$ which contains a terminal sulfido ligand. It is a close structural analogue of $[ReO(SCH_2CH_2S]_2]^-$ (Section 43.7.1.5) and is prepared by reacting K_2ReCl_6 with an excess of 1,2-ethanedithiol in refluxing methanol in the presence of Et_3N, or in the reactions between $ReCl_4(PPh_3)_2$ or $ReNCl_2(PPh_3)_2$ and ethanedithiol. Cation exchange can be used to prepare the Me_4N^+ and Ph_4P^+ salts, the X-ray crystal structure of the former showing the presence of a square pyramidal anion (r(Re=S) = 2.104(2) Å and r(Re—S) ≃ 2.30 Å).[243] A similar synthetic strategy to that described above, but using the trithiol $MeC(CH_2SH)_3$ in place of $HSCH_2CH_2SH$, gives $[Re\{SCH_2)_3CMe\}_2]^-$. This trigonal prismatic anion has been structurally characterized as its Ph_4P^+ salt. The average Re—S distance is 2.331(5) Å, and the average eclipsed inter-ligand S···S distance is 2.83 Å, indicative of a significant sulfur–sulfur interaction contributing towards the stabilization of this trigonal prismatic geometry.[424]

The Re^{VI} complexes derived from the ligands 2-aminobenzenethiol and 4-chloro-2-aminobenzenethiol $Re(NHSC_6H_4)_3$ and $Re(NHSC_6H_3Cl)_3$ (abbreviated as $Re(abt)_3$ and $Re(abtCl)_3$, respectively), can be reduced by hydrazine to give the deep blue Re^V anions which may be isolated as the salts $Ph_4As[Re(abt)_3]$ and $Ph_4As[Re(abtCl)_3]$ upon the addition of Ph_4AsCl.[425] A similar situation holds in the case of dithiolates of the type $A[Re_2(S_2C_2R_2)_3]$ (A = Et_4N or Ph_4As; R = Ph or H).[2]

Various salts that contain the $[Re(Et_2dt)_4]^+$ cation can be prepared by several routes starting from $ReCl(CO)_5$. These compounds are diamagnetic and the cation evidently possesses an eight-coordinate geometry.[252]

43.7.5.2 Halides

Hexafluororhenates(V) can be formed by reacting ReF_6 with alkali metal iodides in SO_2 or IF_5 solution. ReF_6 is also reduced by NO to give $NOReF_6$ and in HF solution by $N_2H_6F_2$ to $N_2H_6(ReF_6)_2$.[257] A study of the reaction of ReF_6 with $Re_2(CO)_{10}$ in liquid HF has shown that the complexes $Re(CO)_5F\cdot ReF_5$ and $[Re(CO)_6]^+[Re_2F_{11}]^-$ are formed.[426] The metals Cd, Cu and Tl reduce ReF_6 in acetonitrile to yield the acetonitrile solvates $Cd(ReF_6)_2\cdot 5MeCN$, $CuReF_6\cdot 4MeCN$ and $TlReF_6\cdot 2MeCN$.[257] The IR, Raman and electronic spectra of the salts of $[ReF_6]^-$ accord with the octahedral symmetry of the anion,[257,427] while the magnetic properties of some hexafluororhenate(V) salts can be attributed to antiferromagnetic interactions.[257]

Crystals of $CsReF_6$ were grown from a solution containing ReF_5 and CsF dissolved in anhydrous hydrogen fluoride, and an X-ray structure determination carried out.[622]

The reaction of $ReCl_5$ with PCl_5 at 300°C gives the hexachlororhenate(V) salt $[PCl_4]^+[ReCl_6]^-$.[428]

43.7.5.3 Hydrides

Hydrido complexes of rhenium(V) are well known and are in many instances easily prepared and very stable.[123,429] The pentahydrido complexes are usually prepared by treating $ReCl_3(PR_3)_3$ or $ReOCl_3(PR_3)_2$ with $LiAlH_4$ or $NaBH_4$ in tetrahydrofuran, or by reacting the heptahydride $ReH_7(PR_3)_2$ with excess PR_3. The complexes so prepared include $ReH_5(PR_3)_3$ (PR_3 = $P(p\text{-tol})_3$, PPh_3, $PEtPh_2$, $PMePh_2$, PEt_2Ph or PMe_2Ph), $ReH_5(AsEtPh_2)_3$, $ReH_5(PPh_3)(dppe)$ and $ReH_5(dppe)_2$, in which one of the two bidentate phosphines is monodentate.[125,126,232,430,431] The mixed-ligand complexes $ReH_5(PPh_3)_2L$ (L = PEt_2Ph, $AsPh_3$, $C_3H_5NH_2$, $C_3H_5NH_2$, $C_6H_{11}NH_2$, py or $C_5H_{10}NH$) are obtained upon heating $ReH_7(PPh_3)_2$ with excess L in boiling tetrahydrofuran.[144,232] The room temperature ^1H and ^{31}P NMR spectra of the complexes show that on the NMR time scale all five Re—H protons are equivalent as are the phosphorus nuclei; the proton resonance appears as a quartet in the spectrum of the $ReH_5(PR_3)_3$ complexes and as a triplet in the mixed ligand

complexes $ReH_5(PR_3)_2L$.[232] The temperature dependence of the $^1H\{^{31}P\}$ NMR spectrum of $ReH_5(PEtPh_2)_3$ and the ^1H NMR spectrum of $ReH_5(AsEtPh_2)_3$ shows that at low temperature three of the five hydride protons are magnetically inequivalent, the observed intensity ratio being 1:2:1:1.[432] This study, coupled with a partial crystal structure determination of $ReH_5(PPh_3)_3$ (the hydride ligands were not located), has led to the suggestion that the structures of these species approximate to either a dodecahedron, a truncated octahedron or bicapped octahedron.[432]

The complexes $ReH_5(PAr_3)_3$ (Ar = Ph or *p*-tol) react with halogens ($X_2 = Br_2$ or I_2) to give the mixed hydride–halide species $ReH_4X(PAr_3)_3$, while reaction with $SnCl_2$ gives $ReH_4(SnCl_3)(PAr_3)_3$.[235] When $ReH_4I(PPh_3)_3$ is treated with additional I_2 in air, oxidation to $ReO_2I(PPh_3)_2$ occurs.[235] The mixed hydride–halide complexes $ReH_2X_3(PMe_2Ph)_3$ (X = Cl or Br) have been isolated as light yellow solids by reacting $ReX(N_2)(py)(PMe_2Ph)_3$ with HX(g) in THF solution at 0°C.[42] Protonation of the rhenium(III) hydrides $ReH_3(dppe)_2$ and $ReH_3(PPh_3)_2(dppe)_2$ by the addition of various acids gives colorless salts of the $[ReH_4(dppe)_2]^+$ and $[ReH_4(PPh_3)_2(dppe)]^+$ cations.[124] In a similar fashion, the addition of HBF_4 to $ReH_3(PMe_3)_4$ in THF at −78°C gives white, air-stable $[ReH_4(PMe_3)_4]BF_4$. The ^1H NMR spectrum of this complex is temperature dependent showing a quintet ($\delta - 5.40$) at 60°C.[35] The reaction of excess of HX (X = Cl or Br) with *mer*-$Re(S_2CNR_2)(N_2)(PMe_2Ph)_3$ in THF at 20°C gives the salts $[ReH_2X(S_2CNR_2)(PMe_2Ph)_3]X$ according to equation (21). These complexes (R = Me or Et) have ^1H NMR spectra that for the Re—H units display a doublet of triplets ($\delta ca. -4.2$) which reflect the equivalence of the two hydride ligands with splitting arising from one unique and two equivalent phosphorus atoms.[26]

$$mer\text{-}Re(S_2CNR_2)(N_2)(PMe_2Ph)_3 + 2HX \longrightarrow [ReH_2X(S_2CNR_2)(PMe_2Ph)_3X + N_2 \quad (21)$$

The pentahydrido complexes $ReH_5(PR_3)_3$ and $ReH_5(PR_3)_2L$ are quite stable kinetically to further reaction with σ donors, such as phosphines, and π acceptors, such as CO and RNC, since vigorous reaction conditions are necessary to induce further reaction.[296] However, these complexes can be activated by electrochemical oxidation in the potential range +0.10 to +0.40 V *vs.* SCE; an irreversible oxidation is observed within this range, the value of which correlates with the basicity of L ($E_{p,a}$ decreases in the sequence PPh_3 (+0.37 V) > PEt_2Ph (+0.29 V) > py (+0.17 V) > $C_6H_{11}NH_2$ (+0.16 V) > $C_5H_{10}NH$ (+0.11 V). Oxidation is easiest with the complex where the build-up of electron density at the metal is greatest.[296] Interestingly, the reaction of the mild oxidant $[Cu(NCMe)_4]PF_6$ with $ReH_5(PR_3)_3$ (PR_3 = $PMePh_2$ or PMe_2Ph) in THF does not result in a redox reaction but rather in the formation of the novel complex $[(R_3P)_3H_2Re(\mu\text{-}H)_3Cu(\mu\text{-}H)_3ReH_2(PR_3)_3]PF_6$ according to the stoichiometry given in equation (22). The structural formulation is based upon an X-ray structure determination together with ^1H NMR spectral measurements.[307] A redox reaction occurs between $ReH_5(PPh_3)_2L$ (L = $C_6H_{11}NH_2$ or $C_5H_{10}NH$) and allyl chloride leading to expulsion of H_2 and the formation of $(Ph_3PC_3H_5)_2ReCl_6$ and some propene.[144]

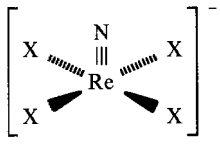
$$2ReH_5(PR_3)_3 + [Cu(NCMe)_4]PF_6 \longrightarrow [(ReH_5(PR_3)_3)_2Cu]PR_6 + 4MeCN \quad (22)$$

(PR_3 = $PMePh_2$ or PMe_2Ph)

Photolysis of benzene or isooctane solutions of $ReH_5(PR_3)_3$ (PR_3 = PPh_3, $PMePh_2$ or PMe_2Ph) results in the formation of the reactive 16-electron species $ReH_5(PR_3)_2$ as a result of the photoextrusion of a PR_3 ligand. Several hydrido–phosphine products can be produced following the formation of $ReH_5(PR_3)_2$ as shown in Scheme 9.[125,135] These include $ReH_7(PR_3)_2$ which is formed if the photolysis is carried out under an H_2 atmosphere.[125] The photochemistry of $ReH_5(PMe_2Ph)_3$ has also been investigated by laser and conventional flash photolysis.[433] While the species $ReH_5(PMe_2Ph)_2$ is observed in saturated hydrocarbon solvents, photolysis in benzene gives $(\eta^2\text{-}C_6H_6)ReH_5(PMe_2Ph)_2$. Also, dimerization to give $Re_2H_8(PMe_2Ph)_4$ (see Scheme 9 and refs. 125 and 135) proceeds by the thermal reaction of a phototransient with the ground state saturated species $ReH_5(PMe_2Ph)_3$. The phototransient species $ReH_5(PR_3)_2$ exhibits some interesting organometallic chemistry as demonstrated by its reaction with saturated and unsaturated organics, the former in the presence of a hydrogen acceptor.[38]

43.7.5.4 Miscellaneous ligands

The hexacyanate anion $[Re(OCN)_6]^-$ has been claimed to be the species that is formed upon reacting $ReCl_5$ with KCNO in dimethyl sulfone,[218] while the ammonolysis of $ReCl_5$ in liquid ammonia gives $ReCl_3(NH_2)_2 \cdot 2NH_3$.[352] Halogens oxidize the $[ReX_2(diars)_2]^+$ cations to eight-coordinate $[ReX_4(diars)_2]^+$ (X = Cl or Br).[2]



Rhenium pentachloride reacts with diisopropylcarbodiimide in CCl_4 to form the monomeric six-coordinate amidino complex $ReCl_4[Pr^iNC(Cl)NPr^i]$.[623]

43.8 RHENIUM(VI) COMPOUNDS

43.8.1 Nitrides, Imides (Nitrenes) and Amides

The reaction between anhydrous liquid ammonia and $ReOCl_4$ at $-33°C$ affords brown insoluble $[ReO(NH_2)_4]_2$ together with an ammonia-soluble species formulated (tentatively) as $NH_4[ReO(NH_2)_4Cl]$. The IR spectrum of $[ReO(NH_2)_4]_2$ displays a ν(Re—O—Re) mode at 830 cm^{-1}, thereby supporting the presence of a polymeric [—O—Re—O—Re—] chain system.[434]

The nitrido complexes $A[ReNCl_4]$ ($A = Me_4N^+$ or Ph_4As^+) are formed upon reacting $ReNCl_4$ with ACl in $POCl_3$.[435] The Ph_4As^+ salt has also been formed by reacting Ph_4AsCl with the chlorothionitrene complex $Re(NSCl)Cl_4(POCl_3)$ in CH_2Cl_2 solution.[436] The analogous bromide $Ph_4As[ReNBr_4]$ is formed by the thermal decomposition *in vacuo* at 210°C of dark violet crystalline $Ph_4As[Re(NBBr_3)Br_4]$ which is itself prepared by reacting $Ph_4As[ReNCl_4]$ with excess BBr_3.[437] The salts of the $[ReNX_4]^-$ anions possess IR-active ν(ReN) modes between 1085 and 1100 cm^{-1}, as does the salt $Ph_4As[Re(NBBr_3)Br_4]$.[435,437] The X-ray crystal structures of the salts $Ph_4As[ReNX_4]$ (X = Cl or Br) have been determined and show that the $[ReNX_4]^-$ anions possess a distorted square pyramidal geometry (**69**) with very short Re—N distances of 1.62 Å and the Re atom located above the plane of the four X groups.[435,437] The ESR spectrum of $[ReNCl_4]^-$ doped into the $Ph_4As[ReNCl_5]$ host has been reported, and the spectrum of $[ReNCl_4]^-$ in frozen MeCN solution is indicative of the presence of $[ReNCl_4(NCMe)]^-$.[438]

(69) X = Cl or Br

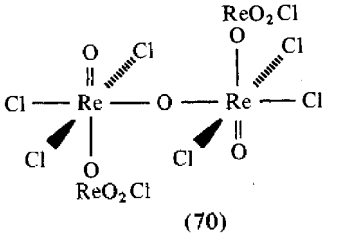
The reaction of $ReNCl_3$ with py, bipy and PPh_3 gives $ReNCl_3(py)_3$, $ReNCl_3(bipy)$ and $ReNCl_3(PPh_3)_2$, respectively, whereas when $Ph_4As[ReNCl_4]$ is treated with py or PPh_3, $Ph_4As[ReNCl_4(L)]$ (L = py or PPh_3) is formed.[439] The admixing of KNCS and $Ph_4As[ReNCl_4]$ in refluxing methanol in the presence of an excess of Ph_4AsNCS gives the salt $(Ph_4As)_2[ReN(NCS)_5]$, which possesses the expected octahedral structure with a short Re—N (nitrido) distance of 1.66 Å.[440] Other nitrido–rhenium(V) complexes include $[ReNCl_3(POCl_3)]_4 \cdot 2POCl_3$, which forms eight membered Re_4N_4 rings with alternating Re≡N· · · ·Re units (r(Re≡N) = 1.68(2) Å) and is prepared upon treating $ReNCl_4$ with excess $POCl_3$.[441] Another example is a compound formulated as $(Ph_4As)_2[Re_2FN_2Cl_7]$, which is proposed to be a μ-fluoro complex with terminal nitrido ligands.[442] It is formally a derivative of Re^{VI} and is prepared by mixing $ReNCl_4$ and Ph_4AsF in acetonitrile. Its structure has not yet been determined by X-ray crystallography, but magnetic susceptibility measurements (over the range 4.8–280 K) indicate that the complex is magnetically dilute (μ_{eff} = 1.66 BM per Re atom), behavior that is similar to that found for $Ph_4P[ReNCl_4]$ (μ_{eff} = 1.67 BM per Re atom).[442]

The *p*-tolylimido complex Re(*N*-*p*-tol)$Cl_4(Ph_3PO)$ is believed to be formed as one of the products in the oxygenation of $[Re(N\text{-}p\text{-tol})Cl_3(PPh_3)]_n$ in CCl_4 or benzene.[420] Its magnetic moment (μ = 1.61 BM) supports this formulation.[420] The *N*-chloroalkylated derivatives $Re(NR)Cl_4(POCl_3)$ (R = CCl_3 or C_2Cl_5) are formed upon reacting $ReCl_5$, dissolved in $POCl_3$, with cyanogen chloride or CCl_3CN in the presence of Cl_2. An X-ray crystal structure determination has shown that for the complex $Re(NC_2Cl_5)Cl_4(POCl_3)$, the Re—N distance is 1.69(1) Å and the Re—N—C angle approaches linearity (169°).[443] When cyanogen is used in place of cyanogen chloride and CCl_3CN in the above reactions, the bis-nitrido complex $(Cl_3PO)Cl_4M(NCCl_2CCl_2N)MCl_4(POCl_3)$ is formed.[444] The treatment of $Re(NR)Cl_4(POCl_3)$ (R = CCl_3 or C_2Cl_5) with Ph_4AsCl gives the salts $Ph_4As[Re(NR)Cl_5]$.[445]

A novel reaction occurs when $ReCl_5$ reacts in $POCl_3$ solution with $(NSCl)_3$ to give the formally rhenium(VI) chlorothionitrene complex $Re(NSCl)Cl_4(POCl_3)$, together with the rhenium(VII) derivative $Re(NSCl)_2Cl_3(POCl_3)$.[436] The chlorothionitrene ligand is related to the arylthionitrene moiety as found in $Re(NSAr)Cl(Et_2dtc)_2$ (Ar = 2,4-$(NO_2)_2C_6H_3$) (Section 43.7.4).

43.8.2 Halides and Oxide Halides

The only complex halides of Re^{VI} that do not contain a terminal Re=O moiety are the fluororhenate(VI) anions $[ReF_7]^-$ and $[ReF_8]^{2-}$ which are prepared by the reaction of ReF_6 with alkali metal fluorides. The action of ReF_6 on $M^I_2ReF_8$ is also a route to M^IReF_7 (M^I = K, Rb or Cs).[257] While $[ReF_8]^{2-}$ has a square antiprismatic geometry, the vibrational spectra of $[ReF_7]^-$ salts is in accord with pentagonal bipyramidal structure (D_{5h} symmetry). The magnetic moments of $M^I_2ReF_8$ salts are apparently higher (1.6–1.7 BM) than those reported for M^IReF_7 (0.6–0.7 BM).[257]



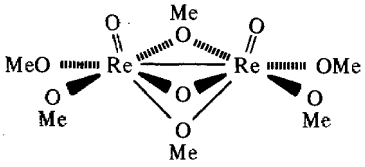
The controlled hydrolysis of M^IReF_7 (M^I = Rb or Cs) in wet acetonitrile is a suitable method for preparing the light green oxidefluorides M^IReOF_5.[446] The $[ReOF_5]^-$ anion has also been generated by the partial hydrolysis of ReF_6 in aqueous HF and characterized by ESR spectroscopy at 77 K.[447] The vibrational spectrum of M^IReOF_5 (M^I = Rb or Cs) has been assigned in terms of C_{4v} symmetry for the anion.[448] The parent oxidefluoride $ReOF_4$ forms a pale blue 1:1 adduct with SbF_5 which has a dimeric structure in which two Re atoms and two Sb atoms are linked through fluorine bridges into distorted eight-membered rings.[449]

The oxidechloride $ReOCl_4$ reacts with stoichiometric amounts of water, MeCN and $POCl_3$, to form the adducts $ReOCl_4(L)$, in which L is *trans* to the Re=O group.[314,434,450] These complexes are paramagnetic ($\mu_{eff} \approx 1.7$ BM) and possess ν(Re=O) modes close to 1020 cm^{-1}.[314,434] The ESR spectra at low temperature of the MeCN and $POCl_3$ adducts have been recorded and analyzed in considerable detail,[451] and comparable spectral data are also available for anhydrous toluene and CCl_4 solutions of $ReOCl_4$ in the presence of Ph_3PO, urea, MECN, acetone, Et_2O, DMG and dioxane.[452] The X-ray crystal structure of the bright red, volatile hydrate $ReOCl_4(H_2O)$ confirms that the strongly bonded oxo group (Re—O = 1.63(2) Å) is *trans* to a weakly bonded H_2O ligand (Re—O = 2.27(2) Å).[450] A gas-phase electron diffraction study has been made of $ReOCl_4$.[625]

The reaction between $ReOX_4$ (X = Cl or Br) and A^+X^- (A = Et_4N, Ph_4P or Ph_4As) in anhydrous $CHCl_3$ or CH_2Cl_2 is a convenient method for preparing $A[ReOX_5]$.[434,453] The action of gaseous HCl upon suspensions of $[ReO_4]^-$ in various aqueous and non-aqueous media has also been used to prepare the salts $(Ph_4As)ReOCl_5$ and $(Ph_4P)ReOCl_5$.[362,454] The $[ReOCl_5]^-$ anion is also generated in the $[ReOCl_5]^{2-}$–H_2SO_4–HCl and $[ReOCl_5]^{2-}$–$H_4P_2O_7$–HCl systems where it has been characterized by ESR and electronic absorption spectroscopy.[455,456] In the pyrophosphoric acid system, the existence of $[ReOCl_4(H_3P_2O_7)]^-$ has also been proposed. A study of the electronic absorption spectrum of the $[ReOBr_5]^{2-}$–H_2SO_4–HBr system indicates that $ReOBr_4$ and $[ReOBr_5]^-$ are formed,[457] a result that has led to the development of a good synthetic procedure for $ReOBr_4$ through the reaction of NH_4ReO_4 with an excess of NaBr in concentrated sulfuric acid.[458] In the case of the analogous $[ReOF_5]^{2-}$–H_2SO_4–HF system, it is believed that $[ReOF_5]^-$ is generated.[457]

The results of various studies on the ESR spectrum of $[ReOCl_5]^-$ are available,[451,455,459] and the magnetic properties and IR and electronic absorption spectra of the paramagnetic salts $A[ReOCl_5]$ (A = Et_4N, Ph_4P or Ph_4As) have been reported.[434,453] The partial hydrolysis of the $[ReOCl_5]^-$ ion gives mauve $[Re_2O_3Cl_8]^{2-}$ which can be isolated as its Et_4N^+ and Ph_4As^+ salts.[453] These complexes, which display ν(Re=O) and ν(Re—O—Re) modes at ~970 and ~740 cm^{-1}, respectively, are essentially diamagnetic, but other than the presence of an O=Re—O—Re=O moiety, it remains unclear as to which of several possible isomers has been isolated.[453] The use of a different method to generate the $[Re_2O_3Cl_8]^{2-}$ anion was reported subsequently, namely, the reaction of $[ReO_4]^-$ with acetyl chloride in acetic acid–HCl.[460] However, the salts that were isolated (tetraphenylphosphonium and 2,3,5-triphenyltetrazolium) did not have the same properties as those that had been prepared *via* $[ReOCl_5]^-$. For example, they are described as possessing a magnetic moment of 1.5 BM and their ν(Re—O—Re) mode is purportedly close to 910 cm^{-1}.[460]

An interesting 'derivative' of $[Re_2O_3Cl_8]^{2-}$ is the complex oxidehalide $Re_2O_3Cl_6(ReO_3Cl)_2$ (**70**) which is formed in the reaction between ReO_3 and $ReCl_5$, and by the UV irradiation of a mixture of $ReOCl_4$, $ReOCl_4(H_2O)$ and ReO_3Cl.[461] The X-ray crystal structure of (**70**) shows that each of the two perrhenyl chloride fragments are weakly bound to the $Re_2O_3Cl_6$ unit *via* an oxygen atom. The short Re=O terminal bonds (Re—O) = 1.69(2) Å) are *cis* to the bridging Re—O—Re unit (Re—O = 1.847(1) Å).[461]



(70)

43.8.3 Oxoanions and Alkoxides

There exist quite a large number of ordered perovskites A_2BReO_6 (A = Ca, Sr or Ba; B = Ca, Sr, Ba, Mg, Mn, Fe, Co *etc.*) and other mixed oxides that contain Re^{VI},[1] but these are not considered to be coordination complexes and, accordingly, they will not be considered here. The interesting violet colored salt $(Me_4N)_2ReO_4$, which contains the paramagnetic $[ReO_4]^{2-}$ anion, can be prepared by the controlled potential one-electron reduction of $[ReO_4]^-$ in acetonitrile (-2.30 V *vs.* SCE).[462,463] In water, the first electron transfer is believed to be followed by the disproportionation of Re^{VI} to Re^{VII} and Re^{IV}, thereby leading to an overall three-electron process at the electrode.[463] In weakly acidic solutions, oxalate and citrate increase the ease of reduction of the $[ReO_4]^-$ anion through the reversible formation of 1:1 complexes.[464] A study has been made of the reaction of $[ReO_4]^-$ with the equated electron in neutral aqueous solution to give $[ReO_4]^{2-}$.[624] The salt $(Me_4N)_2ReO_4$ crystallizes in an antifluorite-like cubic face-centered lattice. The magnetic and spectroscopic properties of this complex have been reported.[462]

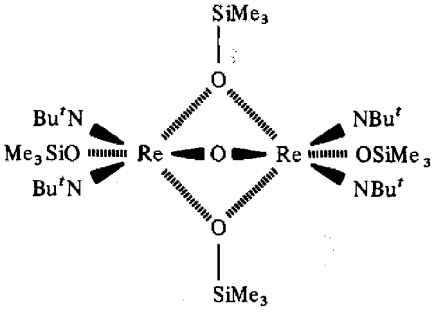
The simplest alkoxide of Re^{VI} is $Re(OMe)_6$ which can be prepared by reacting ReF_6 with $Si(OMe)_4$. It is volatile in high vacuum at room temperature and displays the parent ion in its mass spectrum.[465] The alkoxide $ReO(OBu^t)_4$ is formed when $ReOCl_4$ is treated with $LiOBu^t$ in diethylether. This paramagnetic blue crystalline solid is thermally unstable above 0°C, but has been characterized by IR spectroscopy (ν(Re=O) at 992 cm^{-1}).[245] The analogous reaction of $LiOPr^i$ with $ReOCl_4$ can lead to the isolation of green crystalline $\{Li[ReO(OPr^i)_5]\cdot LiCl(THF)\}_2$. This ESR-active complex possesses a ν(Re=O) mode at 987 cm^{-1} in its IR spectrum and a complicated dimeric structure in the crystalline state in which octahedral $[ReO(OPr^i)_5]^-$ anions are present and some of the alkoxide groups are involved in forming bridges to the Li^+ ions in the lattice.[247] When $ReOCl_4$ is dissolved in methanol in the presence of a tertiary amine, orange air-sensitive crystals of the complex $(MeO)_2ORe(\mu\text{-}O)(\mu\text{-}OMe)_2ReO(OMe)_2$ (**71**) are formed. This diamagnetic complex has Re—O stretching frequencies at 982 and 968 cm^{-1} assignable to ν(Re=O) and at 756 cm^{-1} to ν(Re—O—Re).[245] Its X-ray crystal structure shows the presence of a short Re—Re contact (2.559 Å) and Re=O and Re—O—Re distances of ~1.70 and ~1.91 Å, respectively.[245]

(71)

43.8.4 Sulfur and Mixed Sulfur–Nitrogen Ligands

The trigonal prismatic complexes $Re(S_2C_2Ph_2)_3$ and $Re(tdt)_3$, where $S_2C_2Ph_2$ and tdt are the *cis*-1,2-diphenylethene-1,2-dithiolato and toluene-3,4-dithiolato ligands, respectively, can be prepared from the reactions of the appropriate ligands with $ReCl_5$.[2] The X-ray crystal structure of $Re(S_2C_2Ph_2)_3$ reveals it to be a near perfect trigonal prism.[2] Detailed studies have been made of the ESR and electronic spectra and redox properties of these complexes.[2,466,467] Similar complexes to those obtained with these 1,2-dithiolate ligands (1,2-dithiolenes)[468] can be prepared using 2-aminobenzenethiol and 4-chloro-2-aminobenzenethiol. The blue-green complexes $Re(NHSC_6H_4)_3$ and $Re(NHSC_6H_3Cl)_3$ (abbreviated $Re(abt)_3$ and $Re(abtCl)_3$, respectively) were prepared by dissolving the Re^{VII} complexes $Re(NSC_6H_4)(NHSC_6H_4)_2$ and $Re(NSC_6H_3Cl)(NHSC_6H_3Cl)_2$ in aqueous acetone.[425] Both complexes are paramagnetic ($\mu_{eff} \simeq 1.46$ BM) and are found to undergo reversible one-electron oxidation and reduction processes. Thus, this series of complexes resembles the corresponding tri(dithiolene) set in attaining formal oxidation states of V, VI and VII. These complexes are believed to have a trigonal prismatic geometry.[425] An ESR study of trigonal prismatic $Re(abt)_3$ (where $abtH_2$ = 2-aminobenzenethiol) has been carried out to study the effects of concentration and solvent composition on the extent of molecular aggregation.[626]

43.9 RHENIUM(VII) COMPLEXES



43.9.1 Nitrides, Imides (Nitrenes) and Amides

The only simple nitrido complex is the salt K_2ReO_3N, which is formed in the reaction between Re_2O_7 and KNH_2 in liquid ammonia.[1] The reaction of PPh_3 with $ReNCl_4$ gives the phosphinimato

complex $Re(NPPh_3)Cl_4(PPh_3)$,[439] which is analogous to the compound $Re(NPPh_3)(SPh)_4$. This latter molecule can be isolated, in low yield, following air oxidation of the solution that is generated by the interaction of $ReNCl_2(PPh_3)_2$ with excess phenylthiolate anion in hot acetonitrile.[204] The role of oxygen in this reaction may involve the oxidation of a $[ReN(SPh)_4]^{2-}$ intermediate to the Re^{VII} nitride $ReN(SPh)_4$. The X-ray crystal structure of square pyramidal $Re(NPPh_3)(SPh)_4$ shows that the Re—N—P angle is ~163° and that the Re—N and N—P distances of 1.743(7) and 1.634(9) Å are in accord with considerable Re—N and P—N multiple bonding. The formation of these phosphinimato complexes of Re^{VII} presumably reflects the considerable electrophilic character of the Re^{VII}–nitride moiety.

The tris(*tert*-butylimido) complex $(Me_3SiO)Re(NBu^t)_3$ can be prepared by the reaction of trimethylsilylperrhenate with *tert*-butyl(trimethylsilyl)amine in hexane (equation 23).[469] When a deficiency of amine is used in this reaction, the yellow crystalline complex (**72**) is formed.[470] It can be viewed as the product of the silylation of $[(Me_3SiO)Re(NBu^t)_2O]_2$ by $Me_3SiOReO_3$. The addition of four equivalents of HCl to $Me_3SiORe(NBu^t)_3$ in CH_2Cl_2 produces $Re(NBu^t)_2Cl_3$ in high yield. This monomeric complex is believed to possess a trigonal bipyramidal geometry with the two imido ligands in equatorial positions.[471] The analogous bromide complex is best prepared by reacting $Re(NBu^t)_2Cl_3$ with Me_3SiBr in toluene, and various alkyl, alkylidene and alkylidyne complexes can be generated by addition of the appropriate alkylating agent.[471]

$$Me_3SiOReO_3 + 3Bu^tNH(SiMe_3) \longrightarrow Me_3SiORe(NBu^t)_3 + 3Me_3SiOH \qquad (23)$$

(72)

While the treatment of ReO_3Cl with diisopropylamine gives the volatile, moisture sensitive dialkylamine compound $(Pr^i)_2NReO_3$, the related reaction with $(Me_3Si)_2NLi$ in diethylether produces the red, air-stable, crystalline complex $(Me_3SiO)_2Re[N(SiMe_3)_2](NSiMe_3)_2$, which is believed to be five-coordinate with trimethylsilyl-amide, -imide and -oxide groups.[472] Another imido complex is the bis-chlorothionitrene derivative $Ph_4As[ReCl_4(NSCl)_2]$ which is formed upon reacting $Re(NSCl)_2Cl_3(POCl_3)$ with Ph_4AsCl in CH_2Cl_2.[436] An X-ray crystal structure determination reveals that the two NSCl ligands have a *cis* arrangement with nearly linear Re=N=S units.[436]

Other nitrene-containing compounds are the pair of molecules $ReF_5(NCl)$ and $ReF_5(NF)$ which are formed upon reacting ReF_6 with Me_3SiN_3 at low temperature in the presence of ClF_3. The resulting complex reaction mixture also gives rise to small and variable quantities of $ReNF_4$.[473] X-Ray crystal structure determinations on $ReF_5(NX)$ (X = Cl or F) show that the Re—N bond is short (~1.73 Å), a result which accords with the high frequency of the IR active ν(Re—N) mode (1205 cm^{-1}).[473] The nitride—chloride $ReNCl_4$ has been prepared by the reaction of $ReCl_5$ with NCl_3, and it has been structurally characterized by X-ray crystallography; it possesses a structure similar to that of $WOCl_4$.[474]

The direct fluorination of $ReNCl_4$ between 80°C and 130°C gives the moisture-sensitive material $ReNF_4 \cdot ReF_5(NCl)$, an *N*-chloronitrene adduct,[627] in which the $ReNF_4$ and $ReF_5(NCl)$ molecules are linked by a linear asymmetric fluorine bridge. The black crystalline salt $(Ph_3PCl)[ReCl_4(N_2S_2)]$ is obtained by the reaction of $Re(NSCl)_2Cl_3(POCl_3)$ with PPh_3. An X-ray crystal structure determination reveals the presence of an ReN_2S_2 five-membered ring.[628]

43.9.2 Oxo Species

43.9.2.1 Perrhenates and related species

The aqueous chemistry of rhenium(VII) is dominated by the great stability of the $[ReO_4]^-$ ion.[1] Dirhenium heptoxide (Re_2O_7) is a yellow volatile crystalline compound which dissolves in water to

form a colorless, strongly acidic solution of perrhenic acid. The anhydrous acid can be obtained as pale yellow hygroscopic needles, the crystal structure of which shows the presence of $O_3Re—O—ReO_3(H_2O)_2$ molecules possessing a linear Re—O—Re bridge.[475] In more dilute solutions the acid is completely dissociated to the $[ReO_4]^-$ anion.[1]

A study has been made of the oxygen exchange between $[ReO_4]^-$ and water under acid catalysis,[476] and while molecular $ReO_3(OH)$ has not been isolated, several esters of perrhenic acid have been prepared. These include R_3MOReO_3 (M = Si, Ge or Sn; R = Me, Et or Ph), which can be prepared by the reaction of $AgReO_4$ with R_3MCl, and $Bu^t_3SiOReO_3$, which is formed by treating Re_2O_7 with tri-*t*-butylsilanol.[477–479] The alkoxides $ROReO_3$ (R = Me or Bu^t) are formed through the interaction of ReO_3Cl or $Me_3SiOReO_3$ with the silyl ethers Me_3SiOR in hydrocarbon solvents.[472] An X-ray crystal structure on $Me_3SiOReO_3$ has confirmed its monomeric tetrahedral structure,[480] while the properties of $MeOReO_3$ suggest that it has a polymeric structure with methoxide bridges.[472] NQR studies (Re-185 and Re-187) have been carried out on Me_3MOReO_3.[481] A variety of other derivatives of the type ReO_3X exist, including the cases where X = halide, NO_3 or $N(Pr^i)_2$.[1,472] These compounds react with various ligands to form coordination complexes that are described in Sections 43.9.2.3 and 43.9.2.4.

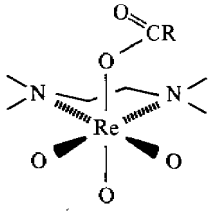
Perrhenic acid can be extracted into non-aqueous organic solvents by aliphatic amines, tributyl phosphate, phosphine oxides, arsine oxides and amine *N*-oxides.[1,482,483] Most metal cations form very stable perrhenates. This is especially true of the main group elements, the first transition series and the rare earths.[1,308] The X-ray crystal structure of some of the simplest salts have been determined, *e.g.* NH_4ReO_4 and $KReO_4$.[1,484,485] Rhodium(III) perrhenate $Rh(ReO_4)_3 \cdot nH_2O$ has also been described,[486] and is apparently the first of the platinum metal derivatives to be isolated. While the $[ReO_4]^-$ ion is strictly tetrahedral in solution, lower symmetries may be encountered in crystalline salts as monitored by IR and Raman spectroscopy.[1] The electronic structure of the $[ReO_4]^-$ ion has been studied experimentally and theoretically,[1] including a study of the valence level electron structure by X-ray photoelectron spectroscopy.[487]

There is a quite extensive chemistry associated with the so-called mesoperrhenates and orthoperrhenates, which are derivatives of the $[ReO_5]^{3-}$ and $[ReO_6]^{5-}$ anions, and various mixed metal oxides. These phases have been surveyed in some detail in the review by Rouschias.[1] More recent developments have included studies on rhenium–apatites containing the square pyramidal $[ReO_5]^{3-}$ unit,[488–490] hexagonal perovskites with cation vacancies that contain $[ReO_6]^{5-}$,[491] and the double oxides $M_3Re_2O_{10}$ (M = Sr or Ba) and $M_5Re_2O_{12}$ (M = Ca or Sr).[492]

The $[ReO_4]^-$ ion is known to be a weak ligand.[1] Recent examples of this are encountered in the case of [Cu(HL)($OReO_3$)], where H_2L = 2,2′-(1,3-propanediyldiiminobis(2-methyl-3-butanone)dioxine), which has been structurally characterized by X-ray crystallography,[493] the cation $[Co(NH_3)_5(OReO_3)]^{2+}$,[494] and the structurally characterized species $[Re_2(O_2CR)_4](ReO_4)_2$ and $[Re_2(O_2CR)_3Cl_2]ReO_4$ (see Section 43.5.2.5).

The perrhenate anion is present in the organic superconductor materials $(TMTSF)_2ReO_4$, where TMTSF = tetramethyltetraselenafulvalene, and $(BEDT\text{-}TTF)_4(ReO_4)_2$, where BEDT-TTF = bis(ethylenedithiolo)tetrafulvalene,[495,496] and is also an important precursor to Re—Pt reforming catalysts and metathesis catalysts. The latter role has led to studies of the thermal decomposition,[497,498] the laser Raman spectra[499] and the X-ray photoelectron spectra[497,499,500] of catalytically important perrhenates, especially NH_4ReO_4 and $Al(ReO_4)_3$.

43.9.2.2 Other oxygen ligands



In addition to the structurally characterized species $Re_2O_7(H_2O)_2$ (Section 43.9.2.1), the complex $Re_2O_7(H_2O)_2(dioxane)_2$ can be isolated from solutions of Re_2O_7 in H_2O–dioxane.[1] In the presence of small amounts of water, the compound $Re_2O_6(OH)_2 \cdot 3dioxane$ has been obtained.[501] The crystals contain dimeric centrosymmetric $[O_3Re(\mu\text{-}OH)_2ReO_3]$ units with the octahedral coordination sphere around each rhenium being completed by bridging 1,4-dioxane molecules (one O donor per Re), the latter linking the dimeric units into endless chains. The remaining dioxane molecules are hydrogen bonded to the μ-OH groups.[501]

Evidence has been presented that in 1–10 M H_2SO_4 rhenium(VII) forms 1:1 and 1:2 complexes, the latter being formulated as $[ReO_2(SO_4)_2]^-$.[502,503] The complexation of $[ReO_4]^-$ in concentrated alkali with polyhydroxyl compounds (*e.g.* D-gluconolactone and D-mannitol) is said to occur,[504] while edta (H_4L), when treated with an aqueous Re^{VII} solution, precipitates a complex formulated as $Ba[ReO_3(HL)] \cdot Ba_2L \cdot 4H_2O$ upon the addition of $BaCO_3$.[505]

The addition of $B(OTeF_5)_3$ to ReF_7 produces the complex $ReO_2(OTeF_5)_3$,[506] while $ReCl_5$ reacts

with Cl_2O, in the presence of $POCl_3$, to give dimeric $[ReO_3(O_2PCl_2)(POCl_3)]_2$ in which bridging O_2PCl_2 groups are believed to be present.[507]

Several carboxylate complexes of the type $RCO_2ReO_3(L)$ {R = Me, CF_3, CMe_3 or Ph; L = THF, py or tetramethylethylenediamine(tmed)} have been prepared and characterized.[472] The treatment of Re_2O_7 with the acid anhydrides in THF allows the isolation of colorless crystalline $RCO_2ReO_3(THF)$ (R = Me, CF_3 or CMe_3). The benzoate complex can be prepared by carboxylate exchange in diethyl ether. The complexes with py and tmed are formed by ligand exchange involving the displacement of the THF ligand of $RCO_2ReO_3(THF)$. All these complexes are believed, on the basis of IR and NMR spectroscopic studies, to be six-coordinate. In the case of the tmed complexes (**73**), monodentate RCO_2 groups are present.[472] The same is apparently true in the case of an analogous complex that contains the chelating 2-hydroxypyridine ligand, $MeCO_2ReO_3(Hhp)$, and which is prepared by reacting $MeCO_2ReO_3(THF)$ with Hhp in ether or chlorocarbon solvents.[472]

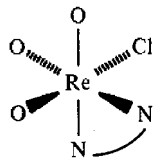
(73)

Complexes that contain dimethylformamide, *viz.* $ReO_3X(DMF)_2$ (X = F or Cl) and $Et_4N[ReO_3Cl_2(DMF)]$, and other oxygen donors are described in Section 43.9.2.4.

43.9.2.3 Amines and N-heterocycles

The complexes $RCO_2ReO_3(L)$, where L = py, tmed or Hhp, have been described in Section 43.9.2.2. The analogous alkoxide derivatives $ROReO_3(tmed)$ (R = Me or Bu^t) have also been prepared and so have the stable, crystalline diisopropylamido species $(Pr^i)_2NReO_3(py)$ and $[(Pr^i)_2NReO_3]_2tmed$.[472] Reference to the complexes $ReO_3Cl(L)_2$ (L = py, 1/2bipy or 1/2phen) is found in Section 43.9.2.4 along with other halide containing species.

The thermal decomposition of $[ReO_2(py)_4]X\cdot nH_2O$ (X = Br or I) at temperates of 135°C (X = I) or 155°C (X = Br) gives a pale brown solid formulated as $Re_2O_7(py)_2$. This product is described as having ν(Re—O) bands at 970, 910 and 880 cm^{-1}. The material obtained by the pyrolysis of $[ReO_2py_4]Cl\cdot 2H_2O$ is, however, violet and its structural relationship to the pale brown material described above is uncertain at present.[258]



The X-ray crystal structure of the complex $Re_2O_7py_3$[612] has been reported. It is composed of two inequivalent Re atoms, linked by a single μ-O bridge, which exhibit coordination numbers of five and six.[629]

43.9.2.4 Halides

A variety of neutral adducts of the halides ReO_3F and ReO_3Cl are known. Both form 1:2 complexes with DMF, the fluoride being formed by the reaction of Re_2O_7 with HF in DMF,[508] while the solvolysis of $[ReO_3Cl_3]^{2-}$ in DMF first gives $Et_4N[ReO_3Cl_2(DMF)]$, followed by the formation of $ReO_3Cl(DMF)_2$.[509] Other complexes of the type $ReO_3Cl(L)_2$ (L = DMSO, $MeCONMe_2$, $(Me_2N)_2CO$ and $(Me_2N)_3PO$) have also been prepared but are rather unstable.[1] Complexes of ReO_3Cl with 8-hydroxyquinoline (oxineH) have been prepared and have been formulated as $ReO_3Cl(oxineH)_2$ and $ReO_3Cl(oxineH)\cdot noxineH$, in which oxineH is believed to be bound in a monodentate and bidentate fashion, respectively. In DMF solution the complex $ReO_3(oxine)(DMF)$ is formed.[510]

The py and bipy complexes $ReO_3Cl(py)_2$ and $ReO_3Cl(bipy)$ can be obtained quite easily from the direct reaction of ReO_3Cl with the corresponding ligand in CCl_4 solution.[314] An alternative method that has been used for the bipy complex, which is also applicable to its phen analogue, $ReO_3Cl(phen)$, involves the reaction of $HReO_4$ with bipy (or phen) in the presence of concentrated

hydrochloric acid.[9] The IR spectral properties of the py, bipy and phen complex (the ν(Re—O) modes)[9,314] are in accord with the complexes possessing similar structures. The X-ray crystal structure derivative ReO_3Cl(bipy) (**74**) has shown that it has a *fac*-stereochemistry, with Re—O distances of 1.708(9) Å (*trans* to N) and 1.718(15) Å (*trans* to Cl).[511] ReO_3Cl(phen) is believed to be isostructural with this. However, when attempts were made to grow crystals by dissolving it in concentrated hydrochloric acid and allowing the solution to stand in a desiccator over P_2O_5, a resulting yellow crystalline complex was identified as $(phenH_2)[ReO_3Cl_2(H_2O)]Cl$ by X-ray crystallography.[512] The structure solution is not of high precision because of a disorder problem, but the anion clearly possesses a *fac* octahedral geometry.[512]

(74) N—N = bipy

Complex oxide fluorides of Re^{VII}, which can be regarded as derivatives of $ReOF_5$, ReO_2F_3 and ReO_3F, are all known. The only salts that contain $[ReOF_6]^-$ are $NO[ReOF_6]$ and $NO_2[ReOF_6]$ which are produced by the reaction of NOF and NO_2F with $ReOF_5$.[257] The reaction between ReO_2F_3 and MF (M = Na, K, Rb or Cs) in a sealed quartz tube at 200°C has been used to prepare $MReO_2F_4$.[513] On the other hand, two procedures can be used to prepare salts of the $[ReO_3F_3]^{2-}$ anion. The action of IF_5 upon a mixture of $KReO_4$ and KF gives $K_2ReO_3F_3$, a white solid that is hydrolyzed by moist air,[446] while $(Me_4N)_2ReO_3F_3$ is formed by reacting $ReO_3F(DMF)_2$ with Me_4NF in ethanol.[508] The vibrational spectra of $KReO_2F_4$ and $K_2ReO_3F_3$ have been studied and assigned assuming C_{2v} symmetry for each.[448] Studies of the $[ReO_4]^-$—HF—H_2O system have led to suggestions that the $[ReO_4F]^{2-}$, $[ReO_3(OH)F_2]^{2-}$ and $[ReO_2(OH)(HF_2)_3]^-$ ions exist under certain conditions, but none have been isolated.[257]

While the isolation of $CsReO_2Cl_4 \cdot CsCl$ has been reported and its thermal stability investigated,[514] the best known oxide chloride anion of Re^{VII} is $[ReO_3Cl_3]^{2-}$. Various salts have been prepared by the reaction of ReO_3Cl with the chlorides ACl (A = Me_4N^+, Et_4N^+, pyH^+, Me_3NH^+ and $Mepy^+$) in inert solvents,[515] and the important cesium salt $Cs_2ReO_3Cl_3$ by the dissolution of $[ReO_4]^-$ in concentrated hydrochloric acid saturated with hydrogen chloride.[516] The X-ray crystal structure of $Cs_2ReO_3Cl_3$ has confirmed the *fac* octahedral geometry of the anion (similar to that in **74**), with an average Re—O bond length of 1.70(2) Å.[517] This geometry is the same as that deduced on the basis of IR spectral measurements.[515]

A somewhat different mode of coordination is encountered in the complexes $ReO_3Cl \cdot AlCl_3$, $ReO_3Cl \cdot NbCl_5$ and $ReO_3Cl \cdot SbCl_5$, which are believed (from IR spectral evidence) to contain Re =O—M (M = Al, Nb or Sb) bridges, and thereby do not involve any increase in the coordination number about rhenium.[518,519]

The fluoride ion donor properties of $ReOF_5$ have been demonstrated by the preparation of $[ReOF_4]AsF_6$ and $[Re_2O_2F_9]Sb_2F_{11}$ which have been characterized by vibrational spectroscopy and mass spectrometry. The X-ray crystal structure of $[Re_2O_2F_9]Sb_2F_{11}$ consists of discrete monofluorine-bridged dimeric anions and cations.[630] The ^{19}F NMR spectra of solutions obtained by dissolving Re_2O_7 in 60% HF in ethanol have been interpreted in terms of the presence of ReO_3F, $[ReO_2F_4]^-$, $[ReO_2(OEt)F_3]^-$ and $ReO(OEt)F_4$.[631] The five-coordinate anion $[ReO_3Cl_2]^{2-}$ has been isolated as its Ph_4P^+ salt from the reaction of ReO_3Cl with Ph_4PCl in dichloromethane.[632]

43.9.2.5 Thioperrhenates

When H_2S is passed into an aqueous solution of $[ReO_4]^-$, the electronic absorption spectrum changes, signaling the formation of the species $[MO_{4-n}S_n]^-$ (n = 1–4).[1,520] Of the four possible species only $[ReO_3S]^-$ and $[ReS_4]^-$ have been completely characterized structurally in the crystalline state.[1,520] The electronic absorption spectra of all four species have been reported,[520] and a detailed study has been made of the resonance Raman spectrum of $[ReS_4]^-$ as part of a more general investigation of the vibrational spectra of some of these species.[1,520] In this case, particularly informative spectra were obtained for $(Ph_4P)ReS_4$ where the overtones of the ν_1 mode were seen out

to $10\nu_1$.[520] The laser-excited emission spectrum of this same salt reveals a mixture of relaxed and partially relaxed luminescence thought to originate from the vibronic levels of the $^1T_2$ excited state.[521]

Further studies of the resonance Raman spectra of $(Ph_4P)ReS_4$ have been reported.[633]

43.9.3 Thiolate Ligands

Oxidation of the Re^{VI} complexes $Re(NHSC_6H_4)_3$ and $Re(NHSC_6H_3Cl)_3$ (abbreviated $Re(abt)_3$ and $Re(abtCl)_3$, respectively) in THF in the presence of an excess of *p*-toluenesulfonic acid can be accomplished using O_2 and H_2O_2, respectively.[425] This gives the diamagnetic salts $[Re(abt)_3]^+(C_7H_7SO_3)^-$ and $[Re(abtCl)_3]^+(C_7H_7SO_3)^-$. These complexes resemble the corresponding tris(dithiolene) derivatives $Re(S_2C_2R_2)_3$ in attaining a formal oxidation number of VII upon undergoing a one-electron oxidation.[522] When $KReO_4$ is reacted with *o*-aminobenzenethiol, the brown complex $Re(NSC_6H_4)(NHSC_6H_4)_2$, *i.e.* Re(abt-H)$(abt)_2$, containing one doubly deprotonated and two singly deprotonated coordinated amines, is formed. The analogous complex derived from 4-chloro-2-aminobenzenethiol is made by a related procedure.[425] These two complexes can be converted to the Re^{VI} species $Re(abt)_3$ and $Re(abtCl)_3$ (see Section 43.8.4) upon prolonged treatment with acetone.[425]

43.9.4 Halides

Rhenium heptafluoride reacts with nitryl and nitrosyl fluorides to form NO_2ReF_8 and $NOReF_8$.[257] The Raman spectra of the solids and ^{19}F NMR spectra of their HF solutions have been interpreted in terms of D_{4d} symmetry for the $[ReF_8]^-$ anion. The cationic species $[ReF_6]^+$ can be formed by heating ReF_7 with SbF_5 by which means $[ReF_6]^+[SbF_6]^-$ and $[ReF_6]^+[Sb_2F_{11}]^-$ can be formed.[257]

More extensive studies of the ReF_7–SbF_5 system (see ref. 257) have led to the isolation of $[ReF_6]^+[Sb_2F_{11}]^-$ and $[ReF_6]^+[Sb_3F_{16}]^-$ which have been characterized by vibrational spectroscopy.[630]

43.9.5 Hydrides

Hydrido complexes of the types $[ReH_9]^{2-}$, $[ReH_8(L)]^-$ and $ReH_7(L)_2$ (L = a phosphine or arsine ligand) constitute one of the more important groups of polyhydride complex of the transition elements.[123,429] Of these, $[ReH_9]^{2-}$ is historically of most importance since it was the first polyhydride complex to be prepared. It can be isolated as its sodium and potassium salts which can be prepared by the reduction of $[ReO_4]^-$ using Na or K metal.[523,524] The reaction of $[ReH_9]^{2-}$ in 2-propanol with the phosphines PPh_3, PBu^n_3 or PEt_3, and with $AsPh_3$ gives the substitution products $[ReH_8(L)]^-$,[431] while the reactions of $ReCl_4(L)_2$, $ReOCl_3(L)_2$ or $ReO(OR)Cl_2L_2$ with $LiAlH_4$ provide convenient routes to $ReH_7(L)_2$ (L = P-*p*-tol$_3$, PPh_3, $PEtPh_2$, PEt_2Ph, $AsEt_2Ph$ or 1/2dppe).[126,232]

A neutron diffraction study of K_2ReH_9 has shown that the anion possesses a tricapped trigonal prismatic geometry with an average Re—H distance of 1.68(5) Å.[525] The ^1H NMR spectrum of $[ReH_9]^{2-}$ in aqueous solution reveals a single proton signal, and detailed studies have been made of the vibrational spectrum of this anion, including measurements on single crystals of K_2ReH_9.[1,526] On the other hand, structural data on $[ReH_8(L)]^-$ and $ReH_7(L)_2$ are incomplete. The monoanions are characterized by ν(Re—H) modes at 1980, ~1930 and ~1850 cm^{-1} in their IR spectra, and a doublet for the Re—H resonance is found at $\delta \approx -8$ (J(P—H) ≈ 18 Hz) in the NMR spectra denoting dynamic isomerization.[431] SCF-Xα-SW calculations have been carried out on $[ReH_9]^{2-}$ and $[ReH_8(PH_3)]^-$ assuming a close structural relationship between these two species, with the PH_3 ligand in an equatorial position. Fluxionality is also found for solutions of $ReH_7(L)_2$ as studied by ^1H NMR spectroscopy; a triplet is observed in the region between $\delta - 4$ and $\delta - 6$ for phosphine derivatives (J(P—H) ≈ 13–20 Hz) and a singlet at $\delta - 6.0$ for $ReH_7(AsEt_2Ph)_2$.[126,232] The ν(Re—H) modes of these complexes have been located between 1980 and 1870 cm^{-1} in their IR spectra.[126,232] X-Ray crystal structure determinations have located the R_3P—Re—PR_3 unit of $ReH_7(PPh_3)_2$, $ReH_7(PMe_2Ph)_2$ and $ReH_7[P(Pr^i)_2Ph]_2$, the P—Re—P angles being in the range 139 to 147°. However, whether this is in accord with the expected distorted tricapped trigonal prismatic geometry is unclear.[528,529]

The deuterides $ReD_7(PPh_3)_2$, $ReD_7(PEt_2Ph)_2$, and ReD_7(dppe) are easily prepared and undergo acid-catalyzed H–D exchange with ethanol but the mechanism of this exchange is unknown.[232]

Exchange also occurs between $ReH_7(PEt_2Ph)_2$ and deuterobenzene at 100°C, and $ReD_7(PPh_3)_2$ is slowly converted to the hydride by hydrogen gas under ambient conditions.[232] $ReH_7(PPh_3)_2$ also serves as a key starting material for some important organic transformations.[131]

The interaction of $LiAlH_4$ with $Re(NPh)Cl_3(PMe_3)_2$ followed by methanol hydrolysis at low temperatures gives $ReH_6(NHPh)(PMe_3)_2$. The ^1H NMR spectrum of this complex in the hydride region shows a triplet at $\delta -5.73$ with $J(P—H) = 21$ Hz, while the $^{31}P\{^1H\}$ spectrum possesses a singlet at $\delta -30.9$. Accordingly, this complex, like other nine-coordinate rhenium hydrido species, is fluxional.[530]

43.10 NITROSYL COMPLEXES AND OTHERS WHERE AN AMBIGUITY IN OXIDATION STATE ASSIGNMENT MAY EXIST

While this section deals primarily with nitrosyl complexes of rhenium, there are other systems where ambiguity in assigning oxidation states can arise. These include rhenium complexes derived from the 2-aminobenzenethiol ligands, *viz.* $[Re(NHC_6H_3X)_3]^{+,0,-}$ (X = H or Cl), and the dithiolates $[Re(S_2C_2R_2)_3]^{+,0,-}$, species which are described in the appropriate sections dealing with Re^V, Re^{VI} and Re^{VII} oxidation states (see Sections 43.7.5.1, 43.8.4 and 43.9.3). Other examples are the tris(2,2′-bipyridine) and tris(1,10-phenanthroline) complexes $Re(bipy)_3$ and $Re(phen)_3$, which can be prepared by the Na/Hg reduction of $ReCl_4(THF)_2$ in THF in the presence of bipy or phen. These air-sensitive, purple solids have magnetic moments of 4.1 and 4. BM, respectively.[531]

In the case of the nitrosyl derivatives, a quite extensive chemistry has been developed. For convenience, we consider these complexes as a single group to avoid any confusion in the assigning of formal oxidation states. $[Re(NO)X_5]^{2-}$ salts are known for X = F, Cl, Br and I. General methods for preparation of the F,[532] Cl[533] and Br[534] derivatives include the addition of NO gas to hydrated ReO_2 in either aqueous or ethanolic HX solutions and the reaction between so-called $Re(NO)(OH)_3$ and aqueous HX. The iodide salt has been made by the latter method: Cs_2CO_3 or Rb_2CO_3 dissolved in aqueous HI is added to a solution of $Re(NO)(OH)_3$ in warm aqueous HI to produce black crystalline $M^I_2[Re(NO)I_5]$ (M^I = Cs or Rb).[535]

Neutral $Re(NO)X_3(L—L)$ and cationic $[Re(NO)X(L—L)_2]PtCl_6$ (L—L = bipy or phen) can be prepared from $[Re(NO)X_5]^{2-}$ (X = F, Cl, Br or I).[532–535] Reactions of $(Et_4N)_2[Re(NO)X_5]$ with a variety of polar solvents produce $(Et_4N)[Re(NO)X_4L]$ (L = MeOH, EtOH, MeCN, DMSO, *etc.*) which upon heating yield $(Et_4N)[Re(NO)X_4]$.[536] Crystal structures of $(Et_4N)[Re(NO)Cl_4(py)]$[537] and $(Et_4N)[Re(NO)Br_4L]$[538] (L = EtOH or MeCN) have been performed showing the molecules to have a distorted octahedral geometry with the solvent molecules situated *trans* to linear Re—NO units. The reaction of $(Et_4N)_2[Re(NO)X_5]$ with N-donor ligands in EtOH or MeCN also gives salts with the formulation $(Et_4N)[Re(NO)X_4L]$, where L = pyridine, aniline or $PhCH_2NH_2$, while refluxing $[Re(NO)X_5]^{2-}$ in diglyme produces the trisubstituted complexes $Re(NO)X_2L_3$, where L = pyridine or 4-picoline.[539] The reactions of $H_2[Re(NO)X_5]$ (X = Cl or Br) have been studied and include the addition of L = bipy or phen to concentrated HX solutions of $H_2[Re(NO)X_5]$ to give $LH_2[Re(NO)X_5]$,[540] which gives $Re(NO)X_3L$ on heating, and the reaction of $H_2[Re(NO)X_5]$ with pyHX in HX solution which yields $(pyH)_2[Re(NO)X_5]$.[541] Heating the latter complex to 250°C in a CO_2 atmosphere produces $(pyH)[Re(NO)X_4(py)]$; heating to 400°C under CO_2 gives $[Re(NO)X_3(py)_2]$.

Another reaction producing $[Re(NO)X_5]^{2-}$ (X = Cl or Br) as a variety of R_4N^+ salts (R = Me, Et, Bu or Ph) is that of $ReO(OEt)(PPh_3)_2X$ with NO gas in refluxing EtOH in the presence of R_4NX.[542] $Re(NO)X_3(PPh_3)_2$ is also produced in this reaction.

The electronic absorption spectra and far IR spectra of tertiary phosphine complexes of the types $Re(NO)X_3(PR_3)_2$ and $Re(NO)X_2(PR_3)_3$ have been compared,[325] and an IR spectral study made of $[Re(^{14}NO)X_5]^{2-}$ and $[Re(^{15}NO)X_5]^{2-}$.[543] Several polarographic studies[544–546] have been carried out on the $[Re(NO)X_5]^{2-}$ anions and their related substitution products. One study[545] compared $[Re(NO)X_5]^{2-}$ with $[ReX_6]^{2-}$, finding the two species electrochemically similar and implying that Re is 'quadrivalent' in the nitrosyl complex. X-Ray photoelectron spectroscopic (XPS) evidence, in conjunction with electrochemical and dipole moment measurements,[11] also indicates that NO is present in a neutral or negatively charged state in a variety of Re—NO complexes with formal oxidation states ranging from +1 to +4 even though the Re—NO interaction is essentially linear, and thus can be considered formally as a three-electron donor, NO^+. Whether the nitric oxide is present as NO^+ with Re^{II}, or as NO^- with Re^{IV}, or as some intermediate situation has not been determined. In another study focusing on the charge distribution in these complexes, it was concluded, on the basis of electrochemical measurements, that the electron transfer was from the Re, with NO making little contribution to the redox orbital.[547]

A more recent XPS study of $[Re(NO)X_5]^{2-}$ and some related complexes reports evidence for a linear to bent transformation in the bonding mode of coordinated NO when the samples are exposed to X-rays.[548]

$ReH_2(NO)(PPh_3)_3$ has been prepared by refluxing $[Re(NO)X_5]^{2-}$ (X = Cl or Br) and PPh_3 in ethanol followed by slow addition of $NaBH_4$. This hydride complex reacts with X_2 to give $Re(NO)X_3(PPh_3)_2$ (X = Cl, Br or I) and either $ReH_2(NO)(PPh_3)_3$ or $[Re(NO)X_5]^{2-}$ reacts with CO gas to give $Re(NO)(CO)_2(PPh_3)_2$.[549] The crystal structure of $ReH_2(NO)(PPh_3)_3$[550] shows it to have distorted octahedral geometry with two PPh_3 ligands in axial positions and the other PPh_3, the two hydrides, and the NO in equatorial positions. The NO is linked linearly as NO^+.

In the reaction of hydrated ReO_2 with gaseous NO in the absence of HX, the complex $Re(NO)(OH)_3 \cdot H_2O$ is said to be formed.[533] Both this reaction and that of ReO_2 and NO in the presence of HX have $[ReO_4]^-$ as a by-product. $Re(NO)(OH)_3 \cdot H_2O$ and the related $Re(NO)Cl_3 \cdot xH_2O$ have been the subjects of a number of investigations with regard to their synthesis, interconversion and hydrolysis reactions.[551–553] The acid $H[Re(NO)(C_2O_4)(OH)_2(H_2O)]$ is purported to be formed from the reaction of $Re(NO)(OH)_3 \cdot H_2O$ with oxalic acid in aqueous medium, and the K^+, NH_4^+ and Pb^{2+} salts of the acid have been described.[554] The anion of this acid reacts with organic diimines to produce the mixed ligand complexes, $Re(NO)L(C_2O_4)X$ (L = bipy or phen; X = OH or Cl). $Re(NO)(OH)_3 \cdot H_2O$ does not react directly with acetic acid, but when refluxed in a mixture of acetic acid and acetic anhydride, a product proposed to be $[Re_4(NO)_4(O_2CCH_3)_6O(OH)_4]$ has been reported.[555]

Most rhenium nitrosyl complexes have been prepared using NO, NOX or HNO_3 as the nitrosylating agent. Recently, the reductive nitrosylation of $[ReO_4]^-$ with $NH_2OH \cdot HCl$ in the presence of NCS^- or N_3^- in an alkaline medium has been accomplished.[556] The complexes formed in this way include $[Re(NO)X_3(H_2O)]^-$ (X = NCS or N_3) and $[Re(NO)X_2(L)(H_2O)]$ (L = bipy or phen), containing the $[ReNO]^{2+}$ moiety and existing in several isomeric forms.

Another method of introducing a nitrosyl group is by the use of *N*-nitrosoamides. An ethanol solution of $ReCl_4(PPh_3)_2$, *N*-methyl-*N*-nitrosotoluene-*p*-sulfonamide, PPh_3 and $NaBH_4$ gives $ReH(NO)_2(PPh_3)_2$. Addition of the same *N*-nitrosoamide to $ReH(CO)_2(PPh_3)_3$ in refluxing benzene yields $Re(NO)(CO)_2(PPh_3)_2$.[557] The reactions of these complexes with X_2 (X = Cl, Br or I) and RX (X = halide; R = H, Me, MeCO and PhCO) have been investigated.

A phase that is said to possess the stoichiometry $Re(NO)Cl_5$ has been prepared by passing NO gas through a CCl_4 solution of $ReCl_5$. Using benzene instead of CCl_4 yields $Re(NO)Cl_4 \cdot C_6H_6$.[558] So-called $Re(NO)Cl_5$ has been reacted with a variety of donor ligands to produce materials analyzing as $Re(NO)Cl_4(NCMe)$, $Re(NO)Cl_4(py)_2$, $Re(NO)Cl(Ph_3PO)(NCMe)$ and $Re(NO)Cl_4(phen)_2$.[558] The X-ray crystal structure of $Re(NO)Cl_4(NCMe)$ shows the molecules to have an octahedral geometry with a *cis* arrangement of the NO and MeCN ligands.[559]

A complex which was first reported to be $[Re(NO)Cl_2(PPh_3)_2]$,[560] made by passing NO gas through a suspension of $[ReCl_2(N_2COPh)(PPh_3)_2]$ in benzene–methanol (1:1), has been reformulated as $[Re(NO)Cl_2(OMe)(PPh_3)_2]$.[561] Reactions of this complex with L (L = CO, NH_3, SO_2, MeCN, PhCN, py, $MeNHNH_2$, $NH_2CH_2CH_2OMe$ or TCNE) result in the substituted products $[Re(NO)Cl_2(PPh_3)_2L]$, while reactions with tertiary phosphines tend to give products in which the PPh_3 ligands are displaced, such as $[Re(NO)Cl_2(PR_3)_3]$. The reaction with PMe_2Ph yields $[Re(NO)Cl_2(PMe_2Ph)_2(PPh_3)]$.[560]

$[Re(NO)Cl_2(OMe)(PPh_3)_2]$ also reacts with $NaBH_4$ and PPh_3 to give a high yield of $ReH_2(NO)(PPh_3)_3$, which in turn is a useful starting material for a variety of rhenium nitrosyl complexes.[561] $ReH_2(NO)(PPh_3)_3$ reacts with HCl in ethanol to form $Re(NO)Cl_2(PPh_3)_3$, while the addition of the latter complex to a CH_2Cl_2 solution saturated with CO gas results in $Re(NO)Cl_2(CO)(PPh_3)_2$. $Re(NO)Cl_2(PPh_3)_3$ also reacts with *p*-tolyl isocyanide in refluxing benzene to yield $Re(NO)Cl_2(CN\text{-}p\text{-}tol)_2(PPh_3)$. The fluoro cation $[Re(NO)F(CO)(PPh_3)_3]^+$ can be prepared by the reaction of $ReH_2(NO)(PPh_3)_3$ with HBF_4 or HPF_6 in the presence of CO. This cation reacts with $X^- = H^-$, OCH_3^- or F^- to give the neutral species $Re(NO)XF(PPh_3)_3$. The crystal structure of the perchlorate salt of this fluoro cation has been determined; the PPh_3 ligands are meridonal and the fluoride is *trans* to the linear Re–NO group.

A thiolato–nitrosyl complex $[Re_2(NO)_2(SPh)_7]^-$ has been made in low yield by reacting $[Re(NO)Cl_2(PPh_3)_2]$ (later reformulated as $[Re(NO)Cl_2(OMe)(PPh_3)_2]$)[560,561] with thiophenol in refluxing methanol in the presence of triethylamine. The crystal structure performed on the $[Ph_4P]^+$ salt of the *p*-tolylthiol derivative shows the complex to consist of two pseudooctahedral rhenium units linked by three bridging thiolato ligands. The Re—Re distance of 2.783(1) Å indicates significant metal–metal interaction.[562]

Thionitrosyl complexes of rhenium have been prepared either by the addition of S_2Cl_2 or SCl_2 to nitride-containing rhenium species or by introduction of NS *via* $NS^+SbF_6^-$. Thus, $ReNCl_2(PRPh_2)_2$ (R = Ph or Pr^n) and S_2Cl_2 give $Re(NS)Cl_3(PRPh_2)_2$; $ReNX_2(PR_3)_3$ (PR_3 = PMe_2Ph, PEt_2Ph or

$PMePh_2$; X = Cl or Br) and half an equivalent of S_2Cl_2 yield $Re(NS)ClX(PR_3)_3$; an excess of either S_2Cl_2 or SCl_2 added to $ReNCl_2(PR_3)_3$ gives $Re(NS)Cl_3(PR_3)_2$; and $[ReNCl(dppe)_2]Cl$ with S_2Cl_2 forms $[Re(NS)Cl(dppe)_2]Cl$.[563] The reaction between $Re(CO)_5Br$ and $NS^+SbF_6^-$ leads to formation of $[Re(CO)_5NS]^{2+}$, a cation which can also be prepared by elimination of F^- from $[Re(CO)_5(NSF)]^+$ using AsF_5.[564,565]

There are very few monomeric rhenium complexes with two nitrosyl ligands. The earliest examples also contained PPh_3, such as $Re(NO)_2X(PPh_3)_2$ (X = Cl, Br or I)[542,566] and $Re(NO)_2X_2(PPh_3)_2$ (X = Cl or Br).[566] More recently, $Re(NO)_2X_3$ (X = Cl or Br) and several related dinitrosyl complexes have been prepared. $Re(NO)_2Cl_3$ is associated by Cl bridges and can be obtained in quantitative yield from the reaction between $ReCl_5$ and CCl_3NO_2.[567] The bromo derivative cannot be made directly from $ReBr_5$, but addition of excess BBr_3 to $Ph_4P[Re(NO)_2Cl_4]$ yields $Ph_4P[Re(NO)_2Br_4]$ which can then be reacted with $AlBr_3$ in CH_2Br_2 to produce $Re(NO)_2Br_3$.[568] The NO ligands are in a *cis* arrangement; $Re(NO)_2Br_3$ is dimeric with Br bridges.

$Re(NO)_2Cl_3$ adds an MeCN molecule when dissolved in this solvent giving $Re(NO)_2Cl_3(NCMe)$. Addition of Ph_4AsCl to the MeCN product in CH_2Cl_2 produces the salt $Ph_4As[Re(NO)_2Cl_4]$.[567] The X-ray crystal structures of the MeCN adduct and the Ph_4As^+ salt have been solved; the NO groups are *cis* to one another in both cases. The reaction of $Ph_4As[Re(NO)_2Cl_4]$ in CH_2Cl_2 in the presence of MeCN and H_2O gives $Ph_4As[Re(NO)Cl_4(OC(NH_2)CH_3)]$.[569]

Other reactions of $Re(NO)_2Cl_3$ include the addition of PPh_3 in CH_2Cl_2 to form the phosphene-iminato complex $[Re(NO)Cl_3(NPPh_3)(OPPh_3)]$[570] and the addition of excess $SbPh_3$ in CH_2Cl_2 to produce $[Re(NO)_2Cl_2(SbPh_3)_2]$.[571]

Further examples of rhenium nitrosyls have been reported. The reactions of $Re(NO)Cl_2(OCH_3)(PPh_3)_2$ with thiophenols which contain methyl or isopropyl groups in their *ortho* positions gives trigonal bipyramidal complexes of the type $ReNO(SR)_4$. The X-ray crystal structure of the complex where R = 2,6-diisopropylphenyl has been determined.[634,635] Thiophenols without ortho substituents give dinuclear $[Re_2(NO)_2(SR)_7]^-$ which contain a triple thiolate bridge.[634,635] The reductive nitrosylation of $[ReO_4]^-$ using an excess of CN^-, OH^- and $NH_4OH \cdot HCl$ has been used to prepare $K_3[Re(NO)(CN)_5] \cdot 2H_2O$.[636] A similar procedure using NCS^- in place of CN^-, followed by acidification and treatment with NO_2^-, is said to provide a route to the dinitrosyls $A[Re(NO)_2(NCS)_3]$ (A = Me_4N, Et_4N, Ph_4P or Ph_4As) and $Re(NO)_2(NCS)_2(LL)$ (LL = bipy or phen).[637] Another interesting example of a thionitrosyl complex has been described. $[Ph_4As]_2[Re(NS)(NSCl)Cl_4]$ has been synthesized from the reaction between S_4N_4, $ReNCl_4$ and Ph_4AsCl in CH_2Cl_2. Its X-ray crystal structure has been solved.[638] The analogous reaction of S_4N_4 with $ReCl_5$ gives $[Ph_4As]Re(NS)Cl_5$.[638]

43.11 MISCELLANEOUS COMPLEXES

A series of polyoxotungstate anions which contain high valent rhenium, *e.g.* $[SiW_{10}Re_2O_{40}]^{2-/3-/4-}$, have been synthesized in the form of $Bu^n_4N^+$ salts.[639] The anions contain rhenium in oxidation states VII, VI and V. Cyclic voltammograms, ESR and electronic absorption spectra have been used to characterize these complexes.

Because of factors beyond the editors' control, the submission of the manuscript for this chapter was delayed. In order to minimize any delay in publishing 'Comprehensive Coordination Chemistry' as a whole, the coverage of iron(II) and lower states appears at the end of this volume, commencing on page 1179.

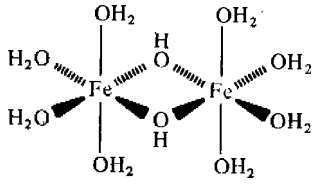
44.2.1 INTRODUCTION

The common oxidation states of iron are +2 and +3. The relative stability of the two oxidation states in acid aqueous solution is defined by the standard electrode potential of +0.77 V for the Fe^{3+}/Fe^{2+} couple.[1a] This potential is such that the hydrated Fe^{II} cation is thermodynamically unstable with respect to atmospheric oxidation (equation 1). The oxidation is even more favourable in basic solution (equation 2). It is apparent, therefore, that the chemistry of iron, including its



importance in biology, is closely associated with the ready interconversion of these two oxidation states and with the dependence of the redox potential on the ligand environment.

$$2Fe^{2+} + \tfrac{1}{2}O_2 + 2H^+ \longrightarrow 2Fe^{3+} + H_2O \qquad E^0 = 0.46\,V \tag{1}$$

$$Fe(OH)_2(s) + OH^- \longrightarrow \tfrac{1}{2}Fe_2O_3 \cdot 3H_2O + e^- \qquad E^0 = -0.56\,V \tag{2}$$

The small size (Goldschmidt radius 0.53 Å) and relatively high charge of the Fe^{3+} ion are responsible for its strong tendency to hydrolyze in aqueous solution. Thus, the hexaaqua ion is a Brönsted acid of moderate strength ($pK_a = 3.05$) existing in the undissociated form only below pH ~ 2 (equation 3). At higher pH further proton dissociations lead to the formation of hydroxo- and oxo-bridged di- and poly-nuclear species such as (1) and eventually to precipitation of hydrated iron(III) oxide.[1b] The high charge density of Fe^{3+} is also responsible for its strong affinity for 'hard' or 'class a' donors such as oxygen and F^-. It is for this reason that Fe^{3+}, unlike Fe^{2+}, forms few stable complexes with ligands such as ammonia or simple amines which are also good Brönsted bases in aqueous solution.

$$[Fe(H_2O)_6]^{3+} \rightleftharpoons [Fe(H_2O)_5(OH)]^{2+} + H^+ \tag{3}$$

(1)

The Fe^{III} ion has a d^5 electron configuration. While it is high spin ($S = \frac{5}{2}$) in most of its complexes there is the possibility of the stabilization of low-spin ($S = \frac{1}{2}$) ground states in strong octahedral fields such as generated by CN^- and many bi- or poly-dentate ligands containing unsaturated nitrogen (Figures 1 and 2). In addition, intermediate spin ($S = \frac{3}{2}$) states may be produced in fields of lower symmetry.

Magnetic susceptibility measurements and ESR and Mössbauer spectra provide convenient means for distinguishing between different possible spin states in most cases. For the common case of high-spin octahedral iron(III) which has an orbitally non-degenerate $^6A_1$ ground state the magnetic moment is given by the high-spin-only value of 5.92 BM which should be temperature independent. Where deviations from this value occur either an antiferromagnetic or, less commonly, a ferromagnetic interaction between adjacent paramagnetic centres of a thermally controlled equilibrium between different spin states is usually indicated. Spin-doublet and spin-quartet ground states are associated with magnetic moments, at ambient temperature, close to 4.0 BM and 2.2 BM, respectively, corresponding to the presence of one and three unpaired electrons (Figure 1).

Because of the orbital singlet nature of high-spin Fe^{III} there are no excited states of the same spin multiplicity and all '*d–d*' transitions are therefore spin forbidden as well as Laporte forbidden. The free-ion ground state ^6S becomes $^6A_1$ in a cubic field while the first excited state ^4G splits into two T states, $^4T_1$ and $^4T_2$, and into a degenerate pair, $^4A_1$ and ^4E (Figure 2). The first four ligand field

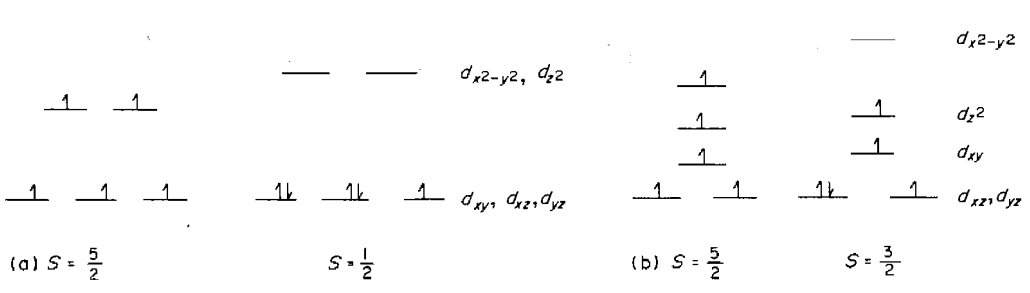


Figure 1 The occupation of the 3*d* orbitals in weak and strong field (a) octahedral and (b) square pyramidal Fe^{III} complexes

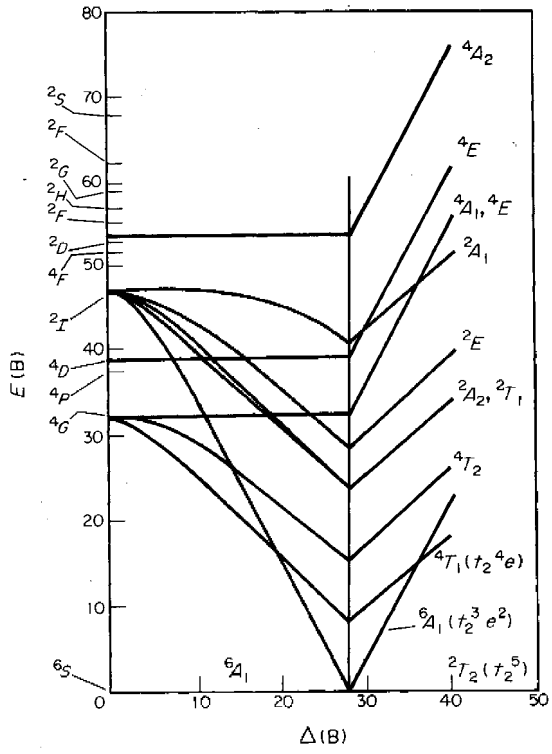

Figure 2 A semiquantitative energy level diagram (Tanabe–Sugano diagram) for the d^5 configuration[2]

transitions for the high-spin d^5 ion are therefore those indicated in equation (4). Since these sextet–quartet transitions are both spin and parity forbidden, intensities seldom exceed $\sim 0.01\ dm^3 mol^{-1} cm^{-1}$; in tetrahedral symmetry a measure of *d–p* mixing occurs and somewhat higher intensities are usually observed. In strong octahedral fields the $^2T_2$ component of the ^2I free-ion excited state becomes sufficiently lowered in energy to become the ground state (Figure 2) corresponding to the spin-paired t_{2g}^5 *d* orbital electron occupation shown in Figure 1.

$$\begin{aligned} {}^6A_1 &\longrightarrow {}^4T_1 \\ {}^6A_1 &\longrightarrow {}^4T_2(G) \\ {}^6A_1 &\longrightarrow {}^4T_1, {}^4E \\ {}^6A_1 &\longrightarrow {}^4T_2(D) \end{aligned} \tag{4}$$

As a result of the spin- and parity-forbidden nature of the ligand field transitions of the high-spin d^5 ion many simple salts and complexes of iron(III) have little or no colour. The hexaaqua ion, for example, has a very pale violet colour while $[FeF_6]^{3-}$ is virtually colourless. Where strong colour in high-spin iron(III) compounds does occur this can usually be assigned to ligand-to-metal charge transfer absorption (or to internal transitions of the coordinated ligand) as in the yellow and red-brown $[FeCl_4]^-$ and $[FeBr_4]^-$ complexes. The analytical applications of the blood red colour of Fe^{3+}/NCS^- complexes are well known.

The commonest coordination number of Fe^{III} is six but a range of other coordination numbers — three, four, five, seven and eight — are also well established. Examples of all of these will be given in the following pages along with discussion of the structural and electronic factors which determine them.

The treatment of the coordination chemistry of iron(III), and higher states, adopted in this review is, as elsewhere in this volume, by means of ligand type. We begin with Main Group IV ligands and follow with ligands of Groups V, VI, VII, mixed donor atom ligands and macrocyclic ligands. Naturally occurring ligands are not considered separately as in other chapters but, instead, are treated together with synthetic ligands of the same donor atom class. Some overlap between sections is inevitable. Iron(III) complexes are considered first followed by complexes of higher oxidation

states. Because of the comparable stabilities of iron(II) and iron(III) no discussion of the coordination chemistry of iron(III) can ignore that of iron(II). However, it is hoped that the unavoidable reference to iron(II), the subject of the preceding chapter, will be illuminating rather than merely repetitive. In preparing this review emphasis has naturally been placed on recent rather than early work while at the same time hopefully giving due place to the latter. The coverage is far from comprehensive since limitations of space dictated ruthless selection of material. Such selection is necessarily subjective and, in this chapter, probably reflects as much on the author's preferences and prejudices as on his good judgement. Valuable early accounts of various aspects of iron(III), (IV) and (VI) chemistry may be found in refs. 3–9. For more recent general treatments see refs. 10–15.

44.2.2 CARBON LIGANDS

Organometallic compounds of iron have been comprehensively covered in the companion work, 'Comprehensive Organometallic Chemistry'.[16] The present review is therefore restricted to Fe^{III} complexes of cyanide.

44.2.2.1 Cyanide Complexes

A comprehensive monograph[17] on cyano complexes of the transition metals, including Fe^{III}, is available. Cyanides and fulminates as ligands are also the subject of Chapter 12 of Volume 1 of this series.[18] The ambidentate nature of the CN^- ion has also been reviewed.[19]

The short C—N distance of 1.16 Å in CN^- is in accordance with the existence of a C≡N triple bond. The highest occupied σ orbital is localized on the carbon atom (Figure 3) and this dictates that the carbon end of the ion is more basic than the nitrogen end.[20] It is thus expected, and observed, that when acting as a monodentate ligand CN^- coordinates *via* the carbon atom, with a linear, or near linear, M—C≡N bond system. CN^- can, of course, act as a bridging ligand between neighbouring metal ions, using both carbon and nitrogen atoms.

The most important cyano complex of Fe^{III} is the red hexacyanoferrate(III) anion, $[Fe(CN)_6]^{3-}$. This is usually prepared, as the potassium salt, by the oxidation of hexacyanoferrate(II), $[Fe(CN)_6]^{4-}$, with chlorine. $[Fe(CN)_6]^{3-}$ has a magnetic moment of 2.25 BM at 300 K in accordance with the presence of one unpaired electron as required for a $^2T_2$ ground state (Figure 1) with appreciable orbital contribution.[21]

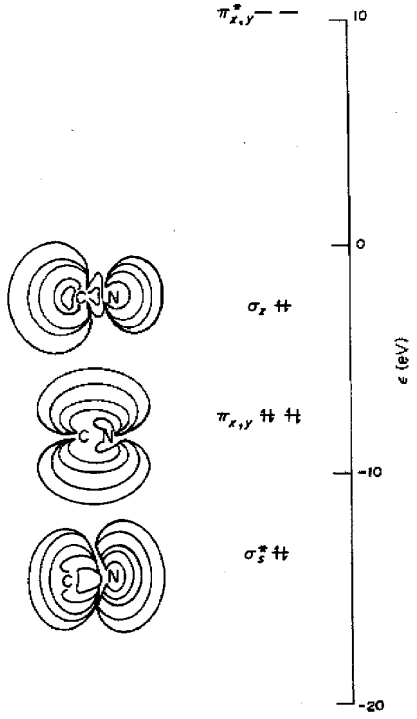

Figure 3 Molecular orbitals of the cyanide ion. Orbital energies calculated by a semiempirical SCF–MO procedure[19]

$K_3[Fe(CN)_6]$ is dimorphic, existing in monoclinic and orthorhombic forms, depending on how the ordered layers are stacked in the crystal lattice. The complex anion has near octahedral symmetry with Fe—C and C—N distances close to 1.95 and 1.14 Å, respectively.[22] Interestingly, the Fe—C bond in $[Fe(CN)_6]^{3-}$ is longer than in $[Fe(CN)_6]^{4-}$ (1.92 Å) despite the smaller size of the Fe^{3+} ion. This is attributed to the π-accepting capacity of the CN^- ion, the π bonding being more pronounced in the lower valence state complex[15,17]. However, the Fe^{III} complex is nonetheless thermodynamically more stable (by about 10^7) than the Fe^{II} complex. This apparent anomaly has been attributed to a very negative entropy of hydration of the highly charged $[Fe(CN)_6]^{4-}$ anion. The same considerations account, of course, for the less positive standard electrode potential ($E^\circ = +0.36$ V) for $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ than observed for the hydrated ions ($E^\circ = +0.77$ V).[17] $[Fe(CN)_6]^{3-}$ is therefore a moderately effective oxidizing agent. In contrast to $[Fe(CN)_6]^{4-}$ the corresponding Fe^{III} complex is poisonous and is generally more reactive in regard to ligand substitution. Several substitution products of the type $[Fe^{III}(CN)_5L]^{n-}$ are known where L = *e.g.* H_2O, NH_3, N_3^-, SCN^-, heterocyclic amine.[23–26] Like the parent $[Fe(CN)_6]^{3-}$ ion, all have magnetic properties and Mössbauer spectra[27] characteristic of low-spin Fe^{III}. In the IR spectra the ν(CN) stretching vibrations occur in the range 2090–2150 cm^{-1}. Further details may be found in Sharpe's monograph[17] and references therein. In the pentacyano complexes a new band in the electronic spectra has been assigned as L → Fe charge transfer in origin with the aid of magnetic circular dichroism measurements.[28]

The bridging capacity of the CN^- ion has been mentioned, this arising from the presence of a non-bonded electron pair on the nitrogen as well as the carbon atom. Many polymeric transition metal cyanides are known, the structures of which may involve chains, sheets or three-dimensional networks. For the case of iron the best known are the Prussian blues and the Turnbull's blues.[29,17,19] The former are obtained by treating a solution of Fe^{III} with $[Fe(CN)_6]^{4-}$ and the latter by treating a solution of Fe^{II} with $[Fe(CN)_6]^{3-}$. IR,[30] magnetic[31] and Mössbauer[32] data have shown that the two substances are essentially the same although variations in composition accompany variations in preparative conditions (Figure 4). These materials are now formulated as iron(III) hexacyanoferrate(II) complexes regardless of the combination of starting materials, the iron(III) component being high-spin. The intense colour is attributed to electron transfer between Fe^{II} and Fe^{III}. Significantly, $K_2Fe[Fe(CN)_6]$, which contains only Fe^{II}, is white. A single crystal X-ray study of $Fe_4[Fe(CN)_6]_3 \cdot xH_2O$ (x = 14–16) has revealed[33] that the average distances are Fe^{II}—C = 1.92 Å, C—N = 1.13 Å and Fe^{III}—N = 2.03 Å. A neutron diffraction study has also been carried out.[34] The complexes $Fe[Fe(CN)_5X] \cdot xH_2O$ (X = H_2O, NH_3 or CO) have been prepared.[35] These also contain high-spin Fe^{III}—N and low-spin Fe^{II}—C centres. The structure of the $[PPh_4]^+$ salt of the binuclear complex anion $[Fe_2(CN)_{10}(NH_3)]^{4-}$ formed by reaction of $[Fe(CN)_6]^{3-}$ with $[Fe(CN)_5(NH_3)]^{2-}$ has been described.[36] The polynuclear complex formed by reaction of $[Fe(CN)_6]^{3-}$ with $[Cu(dien)]^{2+}$ contains both linear and non-linear Fe—C≡N—Cu linkages.[37]

The bifunctional capability of the CN^- ion also means that, as well as acting as a bridge between adjacent metal centres, the nitrogen end may act as a base towards H^+ and various Lewis acids. The acid $H_3Fe(CN)_6$ is somewhat unstable and difficult to obtain pure; it is said to be a strong acid in aqueous solution. Not surprisingly, when charge effects are considered, the coordinated CN^- group has poorer basic character in Fe^{III} complexes than in corresponding Fe^{II} complexes.[38] A number of adducts with Lewis acids such as BF_3 have been reported.[20]

An interesting series of dinuclear iron–cyano complexes $[(NC)_5Fe—L—Fe(CN)_5]^{4-,5-,6-}$ in which the metal centres are bridged *via* bifunctional heterocyclic amines such as pyrazine, 4,4′-bipy-

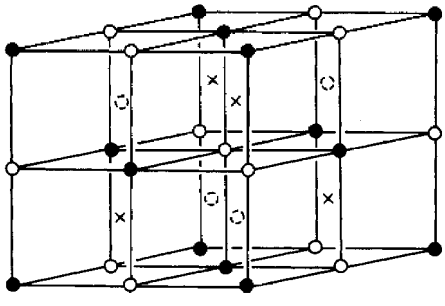

Figure 4 The structure of Prussian blue and related compounds. If none of the cube centre sites are occupied, the structure is that of ferric ferricyanide (both black and white Fe positions occupied by Fe^{III}); if every second cube centre site (marked with a dotted circle) is occupied by K^+, the structure is that of soluble Prussian blue (black = Fe^{II}, white = Fe^{III}); if all the centre sites are occupied by K^+ (crosses as well as dotted circles) the structure is that of dipotassium ferrous ferrocyanide (black and white sites = Fe^{II})

ridine and *trans*-1,2-bis(4-pyridyl)ethylene have been described.[36] Mixed valence species $[Fe^{II}—L—Fe^{III}]^{5-}$ are generated as intermediates in the two-electron redox process (equation 5). However, conproportionation constants for the [II.II] + [III.III] $\rightleftharpoons$ 2[II.III] equilibria corresponded fairly closely to a statistical distribution of the three species, rendering unlikely the isolation of the pure mixed valence complex. An intervalence transfer transition for solutions of the mixed valence species was observed in the near IR at $\sim 8000\,cm^{-1}$, the energy depending only slightly on the nature of the bridging ligand. The intensity of the intervalence band indicated only a small degree ($\sim 1\%$) of electron delocalization. These systems therefore appear to belong to Class II of the Robin–Day classification[40] for which there is only a weak coupling between the metal centres.

$$[Fe^{III}—L—Fe^{III}]^{4-} + 2e^- \rightleftharpoons [Fe^{II}—L—Fe^{II}]^{6-} \quad (5)$$

Other cyano complexes of Fe^{III}, containing only one or two cyano groups, will be considered in later sections which focus principally on the coordination chemistry of the associated ligands.

44.2.3 NITROGEN LIGANDS

The affinity of iron(III) for nitrogen is relatively low except where stability is enhanced by chelation, particularly with multidentate ligands containing anionic oxygen, or in macrocyclic ligands, or where stability is enhanced *via* ligand field stabilization effects accompanying spin pairing.

44.2.3.1 Monodentate Ligands

Addition of ammonia or simple amines to aqueous solutions merely precipitates the hydrous oxide, $Fe_2O_3 \cdot nH_2O$, though under anhydrous conditions the poorly stable hexaammines $[Fe(NH_3)_6]X_3$ (X = *e.g.* Cl, Br) are said to be formed.[41] These of course, are readily decomposed by water. $[Fe(NH_3)_5(NO)]Cl_2$ has been formulated[42] as a complex of Fe^{III} with NO^- rather than of Fe^I with NO^+.

A number of Fe^{III} compounds containing pyridine have been reported. Some of these[43] have salt structures containing the pyridinium cation, $[pyH]^+$, however, together with *e.g.* $[FeCl_4]^-$. Some genuine complexes do appear to exist, however. Reaction of $FeCl_3$ with anhydrous pyridine gives a red complex formulated as *fac*-$Fepy_3Cl_3 \cdot py$ on the basis of IR and ESR spectra.[44] An analogous thiocyanate complex, $Fepy_3(NCS)_3$, has also been prepared from ethanolic solution.[45] Use of pyrazine or pyrimidine in place of pyridine afforded complexes believed to be dimeric or polymeric containing pyrazine or pyrimidine bridges.[43] The green complex $[FeL_2Cl_3]$ (L = 4-cyanopyridine), prepared by reaction of anhydrous $FeCl_3$ with 4-cyanopyridine in trichloromethane, has a trigonal bipyramidal structure in which the three chlorine atoms occupy the equatorial positions and the pyridine nitrogen atoms the axial positions.[46] The magnetic properties (μ_{eff} = 5.56 BM at 296 K, 4.77 BM at 9 K) suggest a measure of intermolecular antiferromagnetic interaction.

The Fe^{III} atom in the complex salt $[Ph_4As]_2[Fe(N_3)_5]$[47] also has a trigonal bipyramidal geometry with the equatorial Fe—N distances slightly shorter than the axial distances.[48] The complex is high-spin with the magnetic moment (6.0 BM) close to the spin-only value. In contrast to the five-coordination found for the azido complex the cyanato and thiocyanato complexes, $[Ph_4As][Fe(NCO)_4]$ and $[Me_4N]_3[Fe(NCS)_6]$, isolated from non-aqueous media, are, respectively, tetrahedral and octahedral.[49,50] IR and electronic spectral data indicate that the bonding atom of the pseudohalide ion is nitrogen in both cases.[49,50]

Among the relatively few examples of three-coordinate transition metal compounds is the Fe^{III} complex of bis(trimethylsilyl)amine, $[Fe\{N(SiMe_3)_2\}_3]$.[51] The structure has been determined.[52] The 'FeN_3' and '$FeNSi_2$' units are planar, the latter making an angle of 49° with each other. The magnetic moment is 5.91 BM at 298 K and the susceptibility obeys the Curie–Weiss law with $\theta = -10°$. A very large quadrupole splitting ($5.12\,mm\,s^{-1}$) was observed in the Mössbauer spectrum.[53]

44.2.3.2 Bidentate Ligands

$[Fe(en)_3]Cl_3$ has been prepared by the slow addition of 1,2-diaminoethane (en) to anhydrous $FeCl_3$ in absolute ethanol. The complex is low-spin having a magnetic moment of 2.45 BM at room

temperature, falling to 2.17 BM at 80 K. The data are in accord with those predicted assuming a spin–orbit coupling constant of $-400\,cm^{-1}$, a delocalization constant of 1.0 and little or no axial distortion. Mössbauer data also indicate low distortion, the quadrupole splitting being much smaller ($1.09\,mm\,s^{-1}$ at 290 K) than observed for $[Fe(phen)_3]^{3+}$ ($1.67\,mm\,s^{-1}$) or $[Fe(terpy)_2]^{3+}$ ($3.09\,mm\,s^{-1}$).[54] The absence of low energy charge transfer absorption allowed a determination of and tentative assignment of the ligand field spectrum in the solid state and evaluation of the ligand field parameters Dq, B and C as 1950, 500 and $2000\,cm^{-1}$, respectively; the value of B corresponds to ~ 50% reduction from the free ion value. Corresponding values of Dq and B for $[Fe(CN)_6]^{3-}$ have been reported as 3500 and $720\,cm^{-1}$, respectively.[55]

Oxidation of the tris complexes of Fe^{II} with the α-diimine ligands such as 2,2′-bipyridyl (bipy) and 1,10-phenanthroline (phen)[56] affords the corresponding Fe^{III} complexes $[Fe(bipy)_3]^{3+}$ and $[Fe(phen)_3]^{3+}$. These blue complexes have low-spin ($S = \frac{1}{2}$) ground states, as conclusively shown by magnetic,[57,58,61] Mössbauer[59] and ESR[60] measurements. The crystal structure of $[Fe(phen)_3][ClO_4]_3 \cdot H_2O$ has been determined.[60] The Fe^{III} ion is octahedrally coordinated by three symmetrically bidentate phen ligands, the Fe—N distance being 1.973(8) Å. The ESR spectrum determined at ~ 85 K showed the principal g values to be along the molecular pseudo C_3 axis ($g_1 = 1.459$) and in plane normal to it ($g_2 = 2.615$, $g_3 = 2.727$). The ESR measurements together with the temperature dependent magnetic susceptibility data were interpreted to yield a splitting of the orbital degeneracy of the $^2T_{2g}$ ground term such that the $^2A_{1g}$ orbital singlet lies lowest, some $800\,cm^{-1}$ below ^2E_g.

Unlike the CN^- ion, replacement of H_2O in the coordination sphere of the hexaaqua Fe^{2+} or Fe^{3+} by bipy or phen raises the standard redox potential (from 0.77 V to 1.12 V in the case of phen). This stabilization of the lower oxidation state is attributed to extensive back-coordination of the t_{2g}^6 electrons into the vacant p_π^* orbitals of the α-diimine ligands. The intense red colour of the Fe^{II} complexes is likewise due to this metal-to-ligand charge transfer. The reversibility of the redox reaction and the easily detectable colour change make these complexes very useful redox indicators.[61,62]

The dicyano complexes $[Fe(bipy)_2(CN)_2]X$ and $[Fe(phen)_2(CN)_2]X$ (X = ClO_4, NO_3) are also low-spin with magnetic properties[63] and Mössbauer spectra[59] (Table 1) comparable with those of the tris complexes. Little or no t_{2g} electron delocalization was apparent in the magnetic results. The stereochemistry of these mixed ligand complexes is presumably *cis*.

Table 1 Mössbauer Parameters for Some Iron(III) Complexes with Nitrogen Donor Ligands

Complex	*T (K)*	*Isomer shift (δ)*[a] ($mm\,s^{-1}$)	*Quadrupole splitting (ΔE_Q)* ($mm\,s^{-1}$)
$[Fe(en)_3]Cl_3$	r.t	0.14	1.09
$[Fe(bipy)_3][ClO_4]_3 \cdot 3H_2O$	300	0.03	1.69
	80	0.06	1.80
$[Fe(phen)_3][ClO_4]_3 \cdot H_2O$	300	0.05	1.62

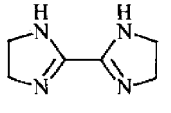
	77	0.07	3.43

[a] Relative to iron foil.

Treatment of Fe^{III} salts in aqueous media with phen gives not the blue tris complex $[Fe(phen)_3]^{3+}$ but brown dinuclear complexes of composition $Fe_2O(phen)_2X_2 \cdot nH_2O$ (X = ClO_4^-, NO_3^-, Cl^-, $\frac{1}{2}SO_4^{2-}$).[64] These binuclear complexes have temperature dependent paramagnetic susceptibilities corresponding to *ca.* 1.9 BM per Fe atom at room temperature and decreasing with decrease in temperature. The results are best interpreted[65] in terms of antiferromagnetic superexchange interaction[81] between high-spin ($S = \frac{5}{2}$) paramagnetic centres linked *via* an oxo bridge as in structure (**2**). Analysis of the magnetic data gave values of the exchange coupling constant J of *ca.* $-100\,cm^{-1}$. In support of the presence of a μ-oxo bridge was the observation of a strong band in the IR at 840–860 cm^{-1} assigned to the Fe—O—Fe stretching vibration, this being a commonly observed feature of such compounds. Mössbauer isomer shifts confirm the assignment of $S = \frac{5}{2}$ spin states to the interacting Fe^{III} ions.[59]

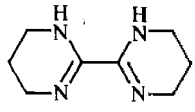
$$[Cl(phen)_2Fe{-}O{-}Fe(phen)_2Cl]^{2+}$$

(2)



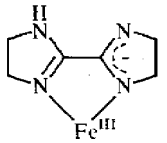
A number of studies of the complex of empirical formula $Fe(phen)Cl_3$ have been made. First prepared by Simon *et al.*[65] it has been formulated as $[Fe(phen)_2Cl_2][FeCl_4]$ on the basis of magnetic,

spectrophotometric, conductimetric and IR data and of the isolation of a perchlorate salt $[Fe(phen)_2Cl_2]ClO_4$.[65–67] On the other hand two modifications prepared by Fitzsimmons and co-workers[59] in glacial acetic acid and in aqueous HCl have been assigned a chloride-bridged structure since neither form displayed the Mössbauer resonance expected for the $[FeCl_4]^-$ anion. More recently, a single crystal X-ray structure determination[68] on the product of reaction of $FeCl_3$ with phen in acetone has revealed the $[Fe(phen)_2Cl_2][FeCl_4]$ structure. The six-coordinate cation has the expected *cis* configuration. The complex is high-spin, the magnetism conforming fairly closely to the Curie law. The high-spin nature of this complex shows that, as with Fe^{II}, coordination of only two phen molecules does not affect spin pairing. Not unexpectedly, the Fe—N distances are significantly longer than in the low-spin complex $[Fe(phen)_3][ClO_4]_3$.[60]

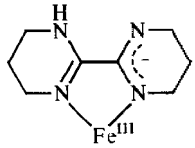


The red complexes $[Fe(phen)_2ox]\cdot 5H_2O$ and $[Fe(phen)_2mal]\cdot 7H_2O$ (ox = oxalate, mal = malonate), as well as related complexes containing 4,7-dimethyl-1,10-phenanthroline and 2,2′-bipyridyl as ligands, originally formulated[69] as containing Fe^{II} in the rare spin-triplet ($S = 1$) ground state, have been reexamined.[70] It was found that when the complexes were prepared under the rigorous exclusion of oxygen the products were violet in colour and showed different magnetic properties, typical of Fe^{II} complexes exhibiting a $^5T_2 \rightleftharpoons {}^1A_1$ spin equilibrium (the oxalate) or having a $^5T_2$ ground state (the malonate). The originally prepared red species are now believed to be $[Fe^{II}(diimine)_3]_2[Fe^{III}(dianion)_3]$ $(dianion)_3 \cdot nH_2O$ by analogy with the properties of complexes such as $[Fe^{II}(diimine)_3]_3[Fe^{III}(dianion)_3]_2 \cdot nH_2O$ obtained directly by reacting solutions of $[Fe^{II}(diimine)_3]^{2+}$ and $[Fe^{III}(dianion)_3]^{3-}$. These mixed valence salts contain low-spin ($S = 0$) cations and high-spin ($S = \frac{5}{2}$) anions thus displaying average magnetic moments per Fe atom of close to 4.0 BM, *i.e.* in the range expected for spin-triplet Fe^{II} systems. A reinvestigation[71] of the complex first thought to be an O_2 adduct of $[Fe(bt)_2(NCS)_2]$ (bt = 2,2′-bi-2-thiazoline) with a spin-triplet ground state[72] has similarly led to its reformulation as $[Fe^{II}(bt)_3]_2[Fe^{III}(NCS)_6](ClO_4)$. Spin-quartet ground states ($S = \frac{3}{2}$) have been proposed[73] for some Fe^{III} complexes of biguanides on the evidence of their magnetic properties ($\mu_{eff} = ca.$ 4.0 BM) and Mössbauer spectra. The structures of the complexes are unknown, however.

Whereas the complexes $[Fe(bipy)_3]^{3+}$ and $[Fe(phen)_3]^{3+}$ are low spin the tris ligand complexes of other α-diimine ligands with Fe^{III} may not be. Thus, $[Fe(bi)_3][ClO_4]_3$ [bi = 2,2′-bi-2-imidazoline (**3**)] is high spin ($S = \frac{5}{2}$) while $[Fe(bhp)_3][ClO_4]_3$ [bhp = 2,2′-bi-1,2,3,4-tetrahydropyrimidine (**4**)] has a $^2T_2$ ground state but with a thermally accessible $^6A_1$ excited state in the 80–300 K temperature range.[74] The corresponding Fe^{II} complexes of (**3**) and (**4**) also show thermally controlled spin transitions in this temperature range; (**4**) is therefore an example of a ligand which generates spin-cross-over conditions in both iron(II) and iron(III) complexes.[74]

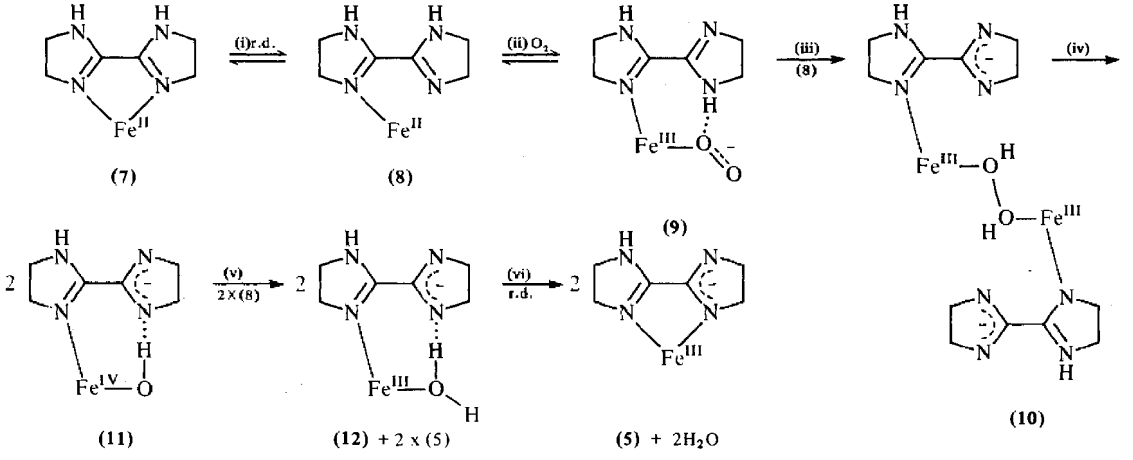


The orange tris ligand complexes of (**3**) and (**4**) with Fe^{III} can be reversibly deprotonated using NaOMe, but not weaker bases such as pyridine, to afford the dark green complexes $[Fe(bi)_2(biH)]^{2+}$ (**5**) and $[Fe(bhp)_2(bhpH)]^{2+}$ (**6**) in which one of the three ligands is monodeprotonated. The latter complex (**6**) has $\mu_{eff} = 1.87$ BM at 93 K rising to 3.70 BM at 353 K indicative of a $^2T_2 \rightleftharpoons {}^6A_1$ spin equilibrium in this complex also, a conclusion supported by Mössbauer spectra. In contrast, the complex $[Fe(bi)_2(biH)][ClO_4]_2$ (**5**) is fully in the high-spin form ($\mu_{eff} = 5.91$ BM) at 293 K though there are indications of the beginnings of a transition to $^2T_2$ below 100 K.[74]



(3)

(4)



(5)

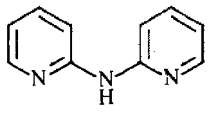
(6) Only monodeprotonated ligand shown

The green Fe^{III} complex $[Fe(bi)_2(biH)]^{2+}$ (**5**) containing one monodeprotonated ligand can also be prepared by aerial oxidation of the red Fe^{II} complex $[Fe(bi)_3]^{2+}$ (**7**) in dry acetonitrile solution. The stoichiometry of the oxidation (equation 6) was established by measurement of the O_2 consumed (pressure change at constant volume) and of the water produced (GLC) and the kinetics of

the reaction were monitored spectrophotometrically.[75] The reaction occurs in two stages, each essentially first order in complex and independent of $[O_2]$ except where $[O_2]$ is low. An unusual feature of the reaction is that while all the O_2 is consumed in the initial (fast) reaction ($t_{1/2}$ *ca.* 6 m at 30°C in MeCN) only half of the Fe^{III} product is formed during this stage. It follows that the second reaction ($t_{1/2}$ *ca.* 60 m) involves the (slow) decay of some oxygen-containing intermediate to the remainder of the product. The mechanism outlined in Scheme 1 has been proposed.[75] While no direct evidence for the intermediacy of the iron(IV) species (**11**) was found the scheme is consistent with the dissociative kinetics observed during the initial rapid uptake and associated formation of half of the Fe^{III} product (**5**) [steps (i)–(v)], followed by the formation of the remainder to (**5**) *via* the slow step (vi). It is considered that the ligand-to-metal proton transfer does not occur until after the two-electron transfer step (iii) and that the initially formed adduct (**9**) may be stabilized *via* a hydrogen bonding interaction involving the coordinated O_2 and the acidic hydrogen of the ligand. 2-(2′-Pyridyl)imidazole (pyim) forms low-spin tris complexes both of the neutral ligand and of the monodeprotonated anionic ligand.[76]

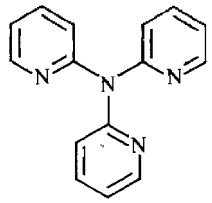
Scheme 1 r.d. = rate determining step. Only one of three ligands is shown

$$4[Fe^{II}(bi)_3]^{2+} + O_2 \longrightarrow 4[Fe^{III}(bi)_2(biH)]^{2+} + 2H_2O \quad (6)$$



44.2.3.3 Ter- and Poly-dentate Ligands

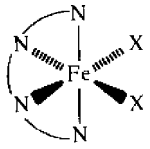
Rather few well-defined complexes of Fe^{III} with ter- and poly-dentate nitrogen ligands are known other than those of macrocyclic ligands, synthetic and naturally occurring, which are considered in later sections.



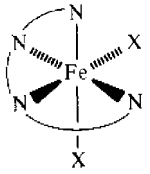
Direct addition of 2,2′,2″-terpyridyl to Fe^{III} salts leads to reduction and formation of the $[Fe^{II}(terpy)_2]^{2+}$ cation. However, oxidation of the Fe^{II} complex gives Fe^{III} complexes the nature of which depends on the particular anion present. For the case of X = halide or NCS the product have the formula $Fe(terpy)X_3$ and may have a high-spin five-coordinate (distorted square pyramidal) structure.[77] For $X = ClO_4$ the low-spin $[Fe(terpy)_2][ClO_4]_3$ is obtained while for $X = NO_3$ the product appears to have a μ-oxo binuclear structure with strong antiferromagnetic coupling[78] similar to the situation in analogous complexes of bipy and phen.

In di-2-pyridylamine (**13**) and tri-2-pyridylamine (**14**) the central aliphatic nitrogen atom is unfavourably positioned for participation in a chelating coordination mode and usually only bidentate (**13**) or tridentate (**14**) behaviour is observed. Three classes of complex with Fe^{III} have been identified.[79] One class comprises salt structures such as $[dipyamH]_2[Cl_3Fe{-}O{-}FeCl_3]$ containing protonated ligand cations and binuclear μ-oxo anions. These complexes show the expected ν(NH) vibration in the IR along with a strong ν(Fe—O—Fe) vibration at 860–890 cm^{-1}. The crystal and molecular structure of the related complex $[pyH]_2[Cl_3Fe{-}O{-}FeCl_3]\cdot py$ containing the pyridinium cation has been determined.[80] Tripyam also forms a series of apparently mononuclear complexes $[Fe(tripyam)X_3]$ (X = halide) while for dipyam a third class of complex, *e.g.* $Fe_2Cl_4O(dipyam)_3\cdot 5H_2O$ of uncertain structure has been obtained.[79]

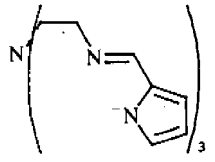
The tetradentate ligands *N*,*N*′-bis(2-pyridylmethyl)ethylenediamine (pmen) and 2,2′:6′,2″:6″,2‴-tetrapyridyl (tetpy) form μ-oxo binuclear Fe^{III} complexes in which the pairs of $S = \frac{5}{2}$ ions are



(13)



(14)



antiferromagnetically coupled with $J = -89\,cm^{-1}$ for $[Fe_2(pmen)_2(H_2O)_2O][SO_4]_2 \cdot H_2O$ and $-83\,cm^{-1}$ for $[Fe_2(tetpy)_2(H_2O)_2O][SO_4]_2 \cdot 5H_2O$.[82,83] The former complex is assigned a *cis* configuration while the latter complex of the less flexible tetpy ligand has the *trans* configuration. Both complexes largely retain the binuclear structure in aqueous solution but differ in stability as pH is increased. This stability difference is attributed to the different stereochemistry of the two quadridentate ligands, *cis*-α for pmen and *trans* for tetpy. The corresponding mononuclear complexes of pmen, *viz.* high-spin $[Fe(pmen)Cl_2]Cl$ and low-spin $[Fe(pmen)(OH_2)(OH)][ClO_4]_2$, have been prepared.[84] An interesting spin-state change ($S = \frac{1}{2}$ to $X = \frac{5}{2}$) accompanies a structural rearrangement from *cis*-α (**15**) to *cis*-β (**16**) geometry when the conjugate dihydroxo base of both salts is formed.

(15) *cis*-α

(16) *cis*-β

(17)

Although the Schiff base {(pyrol)$_3$tren} (**17**) formed by condensation of pyrrole-2-carboxaldehyde with 2,2′,2″-tris(ethylamino)amine is potentially heptadentate the neutral low-spin complex [Fe{(pyrol)$_3$tren}] has a six-coordinate (trigonally distorted octahedral) structure, the distance between the metal atom and the central tertiary aliphatic nitrogen being greater than the van der Waals contact distance.[85]

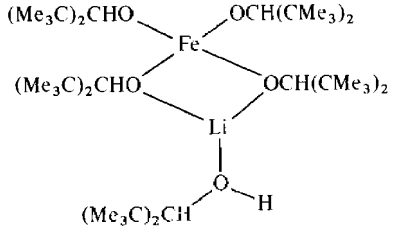
44.2.4 PHOSPHORUS AND ARSENIC LIGANDS

Unlike the lower oxidation states of iron the affinity of Fe^{III} for phosphorus, arsenic and antimony donor atoms is relatively low. Simple adducts $Fe(PPh_3)Cl_3$ and $Fe(AsPh_3)Cl_3$, presumably of distorted tetrahedral structure, have been prepared by reaction of $Fe_3(CO)_{12}$ with PPh_3 or $AsPh_3$ in $CHCl_3$[86,87] while direct reaction of Fe^{III} salts with the tertiary phosphines and arsines in diethyl ether afforded bis complexes of the type $Fe(PPh_3)_2X_2$ (X = Cl, NCS, NO_3). These were non-electrolytes in nitrobenzene and high-spin with magnetic moments close to 5.9 BM but in the absence of further information the structures must remain uncertain.[88–90]

Complexes with bidentate ligands are better defined.[97] Common reaction products of $FeCl_3$ and, to a lesser extent $FeBr_3$, with bidentate P- and As-containing bidentate ligands, are salt structures of the type *trans*-$[Fe(E—E')Cl_2][FeCl_4]$ containing low-spin cations (E,E′ = P or As).[91–96] Many of these complexes have been studied by Mössbauer spectroscopy[98–100] as well as by more conventional techniques. The complex anion $[FeCl_4]^-$ may be replaced by *e.g.* halide, ClO_4^-, BF_4^- and PF_6^- in many cases.[95,96] Examples of complexes containing tri- and tetra-dentate ligands are the neutral complex [Fe(TAS)(NCS)$_3$] (TAS = methylbis(3-propanedimethylarsine)arsine)[101] and the complex salt $[Fe(TTA)Cl_2][FeCl_4]$ (TTA = tris(3-dimethylarsinopropyl)arsine)[102] in both of which the complexes Fe^{III} ions are low-spin.

Consideration of the $[Fe^{IV}]$ oxidation products of diarsine Fe^{III} complexes is deferred.

44.2.5 OXYGEN-CONTAINING LIGANDS



44.2.5.1 Complexes of Neutral Monodentate Ligands

Most simple hydrated Fe^{III} salts of oxyacids such as nitrate and perchlorate are presumed to contain the hexaaqua ion $[Fe(H_2O)_6]^{3+}$ though few crystallographic studies are available.[103,104] The

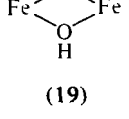
structure of $Fe(NO_3)_3 \cdot 9H_2O$ comprises two crystallographically distinct $[Fe(H_2O)_6]^{3+}$ octahedra, each possessing crystallographic ($\bar{1}$) symmetry, connected by a complex hydrogen-bonded network involving the nitrate anions and lattice water molecules.[103] The mean Fe^{III}—O distance (1.986(7) Å) is 0.14 Å shorter than the Fe^{II}—O distance in $[Fe(H_2O)_6]^{2+}$ and is, in fact, the shortest Fe^{III}—O distance yet determined for coordinated water molecules. The introduction of other ligands into the coordination sphere results in a lengthening of the Fe^{III}—O distances of the remaining water molecules. Salts of other anions including sulfate and chloride usually contain one or more coordinated anions.[103–107] Thus, for example, $FeCl_3 \cdot 6H_2O$ contains the *trans*-$[Fe(H_2O)_4Cl_2]^+$ cation[105] while $[NH_4]_2FeCl_5 \cdot H_2O$ contains $[Fe(H_2O)_5Cl]^{2+}$.[106] The strong yellow colour of these salts contrasts with the pale violet colour of this hexaaqua cation and is, of course, due to chloride-to-Fe^{III} charge transfer absorption. ESR spectra of $FeCl_3 \cdot 6H_2O$ in $AlCl_3 \cdot 6H_2O$ are consistent with the presence of *trans*-$[Fe(H_2O)_4Cl_2]^+$ ions.[44] $FeCl_3 \cdot 2.5\,H_2O$, however, is made up of a *cis*-$[Fe(H_2O)_4Cl_2]^+$ cation, a $[FeCl_4]^-$ anion and a water of crystallization.[107] X-Ray diffraction studies of concentrated aqueous solutions of $FeCl_3$, $FeCl_3 \cdot 6H_2O$ and $Fe_2(SO_4)_3$ have revealed the presence of a range of species, mononuclear and polynuclear, depending on concentration and pH.[108,109] $[FeCl_4]^-$ may be extracted into ether from hydrochloric acid solutions.

Iron(III) chloride, and other simple salts, react with a range of organic ligands such as alcohols, ethers, aldehydes, ketones, amides, sulfoxides, amine and phosphine oxides, *etc.* The structures of many of these complexes are unknown; some appear to be simple addition compounds while others have salt structures.

The alcoholates $FeCl_3 \cdot 2ROH$ (R = Me, Et, *etc.*) have been isolated from solutions of $FeCl_3$ in benzene containing the appropriate alcohol.[109] When base is present the corresponding alkoxides may be obtained.[110] These have trimeric $[Fe_3(OR)_9]$ structures containing a triangular core of three antiferromagnetically coupled Fe^{III} ions linked by oxo bridges.[111] In contrast, reaction of $FeCl_3$ with $Li[OCH(CMe_3)_2]$ gave the binuclear complex (**18**).[112]

(18)

Ethers generally have poor coordinating capacity for transition metals except where the ether function forms part of a multidentate chelating ligand. They appear to interact best with metal ions having few *d* electrons, and complexes of cyclic ethers appear to be more stable than those of open-chain ethers. A four-coordinate, presumably distorted tetrahedral, high-spin complex $[FeCl_3(THF)]$ (THF = tetrahydrofuran) has been prepared by direct reaction under anhydrous conditions.[113] Molecular weight and other measurements indicate some concentration-dependent association in benzene and 1,2-dichloroethane. A distorted octahedral structure has been assigned to the perchlorate salt of the cationic complex $[Fe(THF)_4(H_2O)_2]^{3+}$, however.[114]



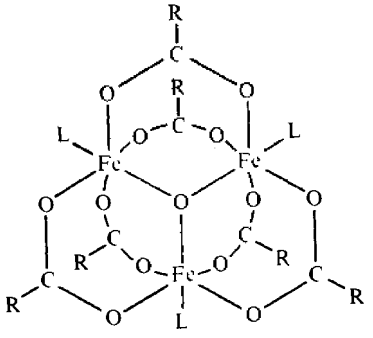
Although amides and sulfoxides have a potential ambidentate character, complexes with first row transition metal ions appear, invariably, to be oxygen bonded. Many six-coordinate Fe^{III} complexes $[FeL_6]X_2$ (L = *e.g.* DMF, DMA, urea, HMPA, DMSO; X = ClO_4^-, NO_3^-, Cl^-) have been prepared and their physical properties (IR, UV/vis, ESR and magnetic) reported in many cases.[115] Complexes of other stoichiometries such as $FeCl_3 \cdot 2DMSO$ and $FeCl_3 \cdot 4DMSO$ have also been reported,[116] the latter having the familiar salt structure $[Fe(DMSO)_4Cl_2][FeCl_4]$. Analogous complexes of the cyclic amides ethyleneurea and propyleneurea may have the same structure.[117] Treatment of metallic iron with DMSO and CCl_4 at above 100°C is said to give a mixture of *cis*- and *trans*-$[Fe(DMSO)_4Cl_2] \cdot X$ (X = Cl^- or $FeCl_4^-$).[118]

A number of hexakis(pyridine *N*-oxide) complexes $[FeL_6]X_3 \cdot nH_2O$ (L = pyridine *N*-oxide or ring-substituted derivative, X = ClO_4^-, NO_3^-) have been prepared.[119–121] As expected for an octahedral field of O-donor ligands the complexes are all high-spin ($\mu_{eff} \simeq 6.0$ BM). The ν(Fe—O) stretching vibration has been observed in the 320–400 cm^{-1} range. ESR measurements suggest considerable distortion from octahedral symmetry in at least some of these complexes.[120] Use of Fe^{III} chloride or bromide led to complexes of the type $[FeL_2Cl_2][FeCl_4]$[120,121] or $[FeL_3Cl_3]$[120] as found also for complexes with other O-donor ligands.

In contrast to the complexes of pyridine *N*-oxides, it appears that not more than four phosphine *N*-oxides can coordinate to one Fe^{III} ion, presumably for steric reasons. With Ph_3PO and Ph_3AsO and analogous ligands, complexes of stoichiometry $FeL_4(ClO_4)_3$ and FeL_2X_3 (X = Cl, Br, NCS, NO_3) are common.[122,123] ESR and vibrational spectra imply that the perchlorate complexes contain planar $[FeL_4]^{3+}$ ions, the arsine oxide exercising the larger ligand field, that the halide complexes have the salt structure *trans*-$[FeL_4X][FeX_4]$, and that the thiocyanate and nitrate are five-coordinate monomers.[123] Perchlorate ion coordination may be involved in some complexes of *n*-alkylphosphine oxides reflecting lower steric effects than in corresponding aromatic phosphine oxides.[124] Bidentate bitertiary phosphine oxides (L—L) in which the phosphorus atoms are linked *via* methylene, ethylene, tetramethylene and hexamethylene groups react with Fe^{III} chloride and nitrate in organic solvents to yield complexes of the types $[Fe(L—L)_2Cl_2][FeCl_4]\cdot nH_2O$, $[Fe(L—L)(ONO_2)_3]$, $[Fe(L—L)(ONO_2)_2][NO_3]$ or $[Fe_2(L—L)_3(ONO_2)_4][NO_3]_2\cdot 2H_2O$. Analytical, spectroscopic (IR, UV/vis, ESR, Mössbauer), magnetic and conductance measurements have been used to assign probable structures, these being five- or six-coordinate depending on the nature of the bis-phosphine.[125]

44.2.5.2 Complexes of Carboxylates and Related Anionic Ligands

An important aspect of the chemistry of iron(III), briefly referred to in the introduction, is the tendency of Fe^{III} to undergo hydrolytic polymerization in aqueous media, leading to di- and poly-nuclear complexes in which the metallic centres are linked by oxygen bridges.[126] Perhaps the simplest of these species is the dihydroxo-bridged dimer di-μ-hydroxo-octaaquadiiron(III) $[(H_2O)_4Fe(OH)_2Fe(H_2O)_4]^{4+}$ postulated to be the dominant species present at low pH on the basis of spectral, magnetic and other physical properties.[127] More recently, confirmation of the nature of this dimer has been obtained from EXAFS studies.[128] The results show that each Fe^{III} is octahedrally coordinated to two bridging OH^- ligands and to four H_2O molecules. The planar ring **(19)** comprises Fe—O(H)—Fe and O—Fe—O angles of 101° and 79°, the Fe—(OH), Fe—(OH_2) and Fe···Fe distances being 1.89, 2.03 and 2.91 Å, respectively. These parameters compare well with those found for the same structural unit occurring in di-μ-hydroxo-bis[2,6-pyridinedicarboxylatoaquairon(III)] and derivatives.[129] All of these doubly bridged di-Fe^{III} systems show magnetic moments below the spin-only value of 5.92 BM expected for high-spin Fe^{III} which further decrease with decrease in temperature. Generally, the susceptibility *vs.* temperature data can be fitted to the spin–spin interaction model based on the exchange Hamiltonian $H = -2J\bar{S}_1\bar{S}_2$ with $\bar{S}_1 = \bar{S}_2 = \frac{5}{2}$, for which the variation of molar susceptibility with temperature is given by equation (7), where $x = \exp(J/kT)$, J = coupling constant and $N\alpha$ is the temperature-independent-paramagnetism term.[130–132] For the doubly bridged dimers the antiferromagnetic coupling is usually relatively weak ($J < -20\,cm^{-1}$) whereas for the single bridged μ-oxo dimers (*vide infra*) J is commonly of the order of -90 to $-100\,cm^{-1}$.



(19)

$$X_A = \frac{N\beta^2 g^2}{kT}\left[\frac{55 + 30x^{10} + 14x^{18} + 5x^{24} + x^{28}}{11 + 9x^{10} + 7x^{18} + 5x^{24} + 3x^{28} + x^{30}}\right] + Na \qquad (7)$$

Fe^{III} forms a number of basic carboxylates of general formula $[Fe_3O(O_2CR)_6L_3]X$ where R = Me, CMe_3, amino acid residue, *etc.*, L = *e.g.* H_2O, MeOH, py, DMF and X = anion.[133–136] X-Ray diffraction studies have shown that these complexes are trinuclear (see structure **20**) containing an O-centred triangular cluster of Fe^{III} atoms, the Fe_3O core being planar[133] or nearly so.[134] These complexes also show weak antiferromagnetic interactions. A variety of models have been considered.[136] The most appropriate appears to be that, consistent with the known structures, based on an equilateral triangular arrangement of Fe^{III} atoms with a small degree of *inter*trimer antiferromagnetic exchange in addition to the (larger, *i.e.* $J \approx -30\,cm^{-1}$) *intra*molecular interaction. The mixed valence complexes $[Fe^{II}Fe^{III}_2O(O_2CMe)_6L_3]$ (L = H_2O or py)[137,138] have been studied by Mössbauer, IR and optical spectroscopy and magnetic susceptibility methods.[139a] Variable-temperature magnetic susceptibility data for the aqua complex are interpreted in terms of a Heisenberg–Dirac–Van Vleck $S_2 = 2$, $S_1 = S_3 = \frac{5}{2}$ spin-exchange model with $J_{12} = J_{23} = -50.0\,cm^{-1}$ and $J_{13} = -14.5\,cm^{-1}$.

An intervalence electron–transfer band, not present in the 'Fe_3^{III}' analogue, was observed in the room temperature electronic spectrum at 13 800 cm^{-1}. Mössbauer spectra indicated distinct Fe^{II} and Fe^{III} sites at 17 K while at 300 K a single absorption was observed. The thermal barrier to electron transfer in the trimer was estimated as about 470 cm^{-1}. Triiron clusters of this type, in the presence of zinc powder, acetic acid, aqueous pyridine and oxygen, are reported[140] to effect the oxidation of saturated hydrocarbons. The exchange interactions in the series of complexes $[Fe_2^{III}M^{II}O(O_2CMe)_6py_3]\cdot py$ (M = Mg, Mn, Co, Ni or Zn) which, M = Ni excepted, are isomorphous with the mixed valence complex referred to above have been measured.[139b]

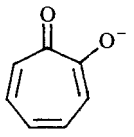
(20)

Tetranuclear and pentanuclear Fe^{III} clusters can also be prepared.[134,141] The Fe_5 complex is antiferromagnetic while the Fe_4 complex is ferromagnetic with a very asymmetric Mössbauer spectrum.[134]

The complex $K_5[Fe_3O(SO_4)_6(H_2O)_3]$, like the corresponding acetate, also contains a planar Fe_3O core, with, in this case, each pair of Fe atoms additionally bridged by two SO_4^{2-} groups.[142] The magnetic behaviour likewise conforms to that predicted by the triangular cluster model ($H = -2JS_1\cdot S_2 + S_1\cdot S_3 + S_2\cdot S_3$) with $J = -26.0\,cm^{-1}$, $g = 2.00$ and $N\alpha = 0$. The generally similar behaviour to that of the structurally related carboxylates indicates that magnetic exchange originates predominantly from interaction of different Fe^{III} ions *via* their mutual overlap with appropriate filled valence orbitals of the central oxygen atom; superexchange *via* the bridging sulfate ions is considered to be small or negligible.[143]

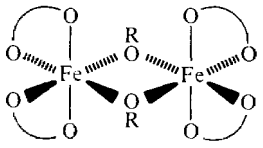
In addition to the polynuclear carboxylate complexes considered above, a number of mononuclear complexes are also known. Among these are the tris(oxalato) complexes. $K_3[Fe(ox)_3]\cdot 3H_2O$ is readily prepared by H_2O_2 oxidation of the Fe^{II} oxalate in the presence of oxalic acid and excess oxalate ion.[144] The green crystals are photosensitive, the oxalate ligand being oxidized to CO_2 with concomitant reduction of the metal to Fe^{II}. The structure has been determined;[145] the FeO_6 coordination sphere has approximate octahedral symmetry with some trigonal distortion. As expected for a magnetically dilute mononuclear Fe^{III} complex the magnetic moment at 300°C (5.96 BM) is close to the spin-only value.[146]

The tetranitratoferrate anion $[Fe(NO_3)_4]^-$, like the corresponding anionic complexes of Mn^{II}, Co^{II} and Zn^{II}, contains eight-coordinate metal ion involving four almost symmetrical bidentate nitrate groups.[147] The anion has essentially dodecahedral (D_{2d}) symmetry.



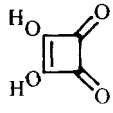
44.2.5.3 Complexes of Diketones and Related Ligands

Fe^{III} readily forms a range of stable, highly coloured complexes with the anions of β-diketones, such as acetylacetone (acacH).[148] The best known of these is the neutral tris complex $[Fe(acac)_3]$ for which a convenient new high yield synthesis has recently been described.[149] A single crystal X-ray structure determination[150] has confirmed the expected near-octahedral arrangement of the six oxygen donor atoms. Considerable distortion from octahedral symmetry is found in the corresponding tris complex of the tropolone anion (**21**), largely because of the smaller bite of the chelating group.[151] These complexes are, of course, high-spin; some magnetic anisotropy of the $^6A_{1g}$ ground state has been detected and interpreted in terms of zero-field splitting.[146] A simple one-electron MO scheme has been used to treat the UV/vis spectra of $[Fe(acac)_3]$ and derivatives containing Me, CF_3 and Ph substituents.[152] The three main absorption bands at 30 000–37 000 cm^{-1}, 24 000–29 000 cm^{-1}



and 20 000–23 000 cm^{-1} were assigned to $\pi \rightarrow \pi^*$, $t_{2g} \rightarrow \pi^*$ and $\pi \rightarrow e_g$ transitions, respectively. [Fe(acac)$_3$] has been reported to have catalytic activity for stereoselective β-epoxidation of cholesterol and analogues with H_2O_2.[153]

The complex [Fe(acac)$_2$Cl] is mononuclear and five-coordinate. The Fe^{III} atom is located slightly above (0.51 Å) the plane of the four acac oxygen atoms (Fe—O, 1.95 Å) with the Cl atom occupying the apical position (Fe—Cl, 2.22 Å) of an overall square pyramid.[154] Magnetic properties and Mössbauer spectra have been measured.[155]



A series of dimeric Fe^{III} complexes [L_2Fe(OR)]$_2$ (where L = acac or the enolate of dipivaloylmethane, R = Me, Et or Pr^i) have been prepared and characterized.[130] These contain the dialkoxy-bridged structures (**22**) as judged by molecular weight, IR and magnetic susceptibility measurements. Values of J in $H = 2J\vec{S}_1 \cdot \vec{S}_2$ ($S_1 = S_2 = \frac{5}{2}$) were determined to be *ca.* $-10\,cm^{-1}$. A similar structural framework occurs in the dinuclear complex formed from Fe^{III} and the dianion of 3,4-dihydroxy-3-cyclobutene, better known as squaric acid (**23**).[156] In this complex the bridging groups are hydroxide rather than alkoxide groups and the superexchange coupling in somewhat smaller ($J = -7.0\,cm^{-1}$).

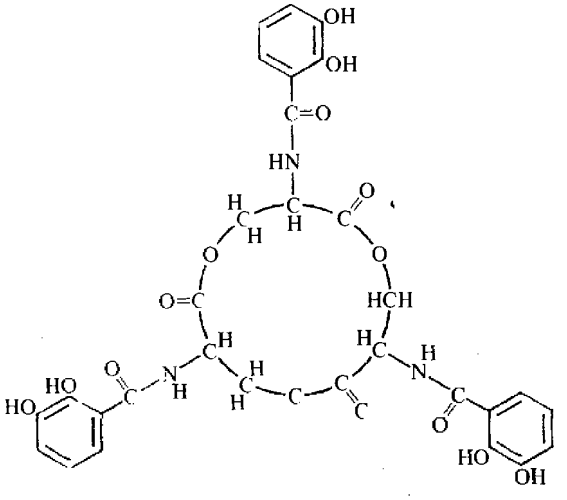
(22)

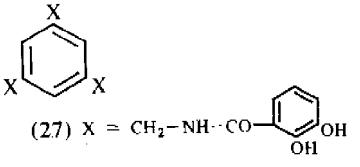
(23)

44.2.5.4 Complexes of Phenols, Catechols, Quinones and Related Systems



Much of the recent interest in iron complexes of hydroxybenzenes derives from the importance of such compounds in controlled iron transport within bacteria. Since, at physiological pH, iron is largely present as insoluble hydrated iron(III) oxide ($K_{sp} \sim 2 \times 10^{-39}$) it is not readily available. Nature has therefore developed mechanisms for the controlled solubilization, transport and release of the iron as needed by the organism.[157] This mechanism utilizes chelating agents called siderophores.[158] Nearly all the siderophores employ negatively charged oxygen-donor chelating functional groups. The two prinicpal classes are the catecholates and the hydroxamates. (Hydroxamate complexes are considered in the following section.) Fe^{III}–phenolate groups also occur in catechol dioxygenases.[159]

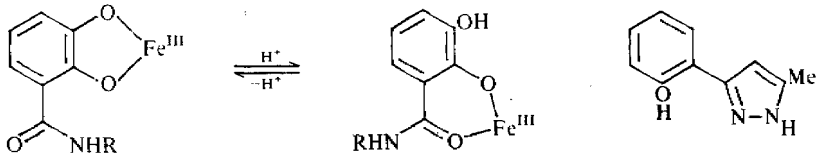
Despite the large amount of recent work devoted to iron(III)–catecholate derivatives rather less is known of the coordination chemistry of Fe^{III} with monophenols. The colour reaction of Fe^{III} with the phenolic group has been employed analytically for a long time but only very recently has a complex of monodentate phenoxide been structurally defined.[160] The red-orange compounds [Et_4N][$Fe(OC_{10}H_{13})_4$] (**24**) and [Ph_4P][$Fe(OC_6H_2Cl_3)_4$] (**25**) of 2,3,5,6-tetramethylphenolate and 2,4,6-trichlorophenolate were obtained from reactions of $FeCl_3$ with the appropriate lithium phenolate in the presence of the quaternary ammonium (or phosphonium) cation in anhydrous ethanol. Both complexes have somewhat distorted FeO_4 coordination geometry, the distortion being most marked in (**25**) where the O—Fe—O bond angles range from 99.3° to 122.9°. The Fe—O distances in both complexes are, at 1.847 Å in (**24**) and 1.866 Å in (**25**), significantly shorter than the average Fe—O distance (2.02 Å) observed in the FeO_6 core of [Fe(catecholate)$_3$]$^{3-}$ complexes. Both (**24**) and (**25**) undergo a reversible one-electron reduction at -1.32 and -0.45 V, respectively (*vs.* SCE in MeCN), reflecting, in the case of the tetramethylphenolato complex particularly, strong stabilization of the +3 oxidation state. Electronic spectra are dominated by three intense charge transfer transitions, the two low energy bands allowing a determination of the tetrahedral ligand-field splitting parameter, Δ_t, of 8000 cm^{-1} (**24**) and 7400 cm^{-1} (**25**), *i.e.* about twice as large as for $[FeCl_4]^-$.



Catechol is a very weak acid and at low pH is a poor ligand forming only a transient complex which undergoes a redox reaction to give Fe^{II} and *o*-quinone as products. At higher pH, however, very stable iron(III) tris(catecholate) complexes are formed which are indefinitely stable in the absence of air.[161] The structure of K_3[Fe(cat)$_3$]·1.5 H_2O has been determined by single crystal X-ray diffraction,[161] in order to probe the coordination occurring in the Fe^{III} complex of the microbial iron transport compound enterobactin (**26**) (the cyclic triester of 2,3-dihydroxy-*N*-benzoyl-l-serine) which is itself a tricatechol.[162,163] The complex anion has approximate D_3 symmetry, the primary distortion being a bending of the catechol rings away from planarity with the O—M—O planes. The

average Fe—O bond lengths are 2.015 Å, somewhat longer than the Cr—O bonds (1.986 Å) in the isostructural Cr^{III} complex.

The high-spin Fe^{III}–enterobactin complex is exceptionally stable thermodynamically having the largest formation constant (*ca.* 10^{52}) known for any Fe^{III} complex.[164] A number of synthetic analogues for enterobactin which contain 1,2-dihydroxyphenyl chelating groups have been investigated.[162,165] One of these, hexadentate 1,3,5-tris(2,3-dihydroxybenzoylaminomethyl)benzene (**27**) has been shown[165] to form a 1:1 $[FeL]^{3-}$ complex with a formation constant of $10^{45.8}$.

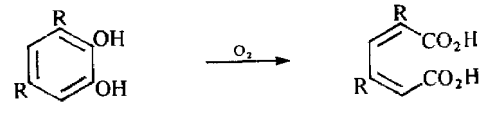


(26)

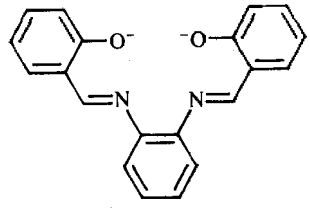
(27) X = CH_2–NH–CO–

An important biological requirement of iron–enterobactin systems is the release of iron from the highly stable $[Fe(ent)]^{3-}$ complex once inside the cell. The redox potential for $[Fe(ent)_3]^{3-}$ (estimated as *ca.* −750 mV at pH 7) is probably too negative to allow reduction to Fe^{II} by known biological reductants at physiological pH.[168] At lower pH the redox potential may shift towards positive values, however. In one mechanism for the release of iron from enterobactin at low pH it is proposed[166,169] that an internal redox reaction occurs between Fe^{3+} and catechol to generate a blue Fe^{II}–semiquinone species.[167] However, this mechanism in aqueous solution has been challenged by Raymond and co-workers[170] who, using Mössbauer and ESR techniques, found no evidence for reduction to Fe^{II} in the pH range 2–10, though some indication of a quasireversible redox reduction at low pH in methanol was apparent. An earlier mechanism[171] for iron release involves cleavage of the central triester ring of enterobactin by a specific esterase which would raise the redox potential. However, it has since been shown that catechoylamides which lack the triester ring retain the very negative redox couples. An alternative mechanism involves three protonation steps with a concomitant change from a 'catecholate' (**28**) to a 'salicylate' (**29**) mode of bonding which has the effect of dramatically raising the redox potential and bringing it within the range of physiological reductants.[164,170]

In an attempt to model the specific iron-binding site of the human milk protein, lactoferrin, believed to involve two or three tyrosyl residues per iron atom, a range of Fe^{III} phenolate complexes have been prepared.[172] These exemplify the donor sets FeO_6 to $FeO_2N_2O'_2$ where O represents a phenolate oxygen, N an aliphatic or aromatic nitrogen and O′ a carboxylate or methanol oxygen. Electronic and ESR spectra have been reported along with the results of an X-ray structure determination of one member of the series, $[FeL_2(MeOH)_2]NO_3 \cdot MeOH$ where LH is 2-(5-methylpyrazol-3-yl)phenol (**30**). The high-spin six-coordinate complex has an all-*trans* configuration, the Fe—O (phenolate) bond being 1.888 Å.

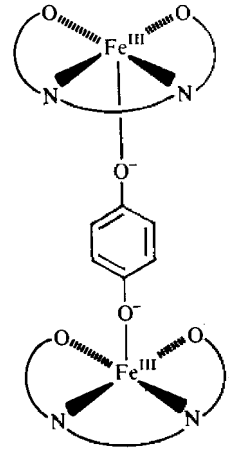


(28) (29) (30)



The non-heme iron enzymes catechol 1,2-dioxygenase and protocatechuate 3,4-dioxygenase catalyze the dioxygenation of catechols to *cis,cis*-muconic acids (**31**).[159] Spectroscopic studies suggest the active site to contain a mononuclear high-spin Fe^{III} centre coordinated to at least two tyrosines, this being responsible for the LMCT absorption resulting in the red colour of the enzymes. Substrate binding alters the colour but does not replace the bound tyrosine.[173,174] Kinetic and resonance Raman (RR) studies[175] further suggest that the cathechol substrate may be bound in a monodentate fashion. This coordination mode has recently been confirmed in the model compound [Fe(saloph)(catH)] (saloph = *N,N'*-(1,2-phenylene)bis(salicylidinimato); (**32**).[176] In this mononuclear high-spin complex the metal ion has a square pyramidal geometry in which it is raised 0.55 Å above the mean basal plane and with a rather short (1.828 Å) apical Fe—O (cat) bond. The analogous complex [Fe(salen)(catH)] has also been prepared. This can be deprotonated with strong base to give the anionic complex $[Fe(salen)(cat)]^-$ having markedly different properties[177] and in which the catecholate is chelated in a six-coordinate structure in which the tetradentate salen ligand has rearranged from an equatorial to a *cis-β* configuration in order to accommodate the bidentate catecholate dianion. An interesting observation is that the monodentate catecholate complex reacts readily with O_2 to form the chelated semiquinone while the chelated catecholate is unreactive.[178] While these results may imply a monodentate catecholate interaction between substrate and enzyme it should be noted that other workers found that chelated 3,5-di-*tert*-butylcatechol in [Fe(NTA)-(cat)] (NTA = nitrilotriacetate) does undergo the catechol ring cleavage.[179]

Fe^{III} complexes of semiquinones may also be prepared by reaction of Fe^{II}–Schiff base complexes such as [Fe(salen)] with *o*-quinones.[180,181] The product complexes $[Fe^{III}(salen)(SQ)]$ have Mössbauer spectra characteristic of high-spin Fe^{III} and magnetic moments near 4.86 BM at room temperature and are therefore formulated as high-spin Fe^{III} complexes in which the unpaired electron of the coordinated *o*-semiquinone is antiferromagnetically coupled to the Fe^{III} ion ($-J > 600\,cm^{-1}$) to give complexes with $S = 2$ ground states.[181] The crystal structure of the complex in which SQ = phenanthrenesemiquinone (phenSQ) has been determined.[178] This complex has a similar distorted octahedral geometry to that of $[Fe(salen)(cat)]^-$. The complex $[Fe(phenSQ)_3]\cdot phenQ$ (phenQ = the quinone form of phenSQ) reacts with bipy or phen to give complexes of formulation [Fe(phenSQ)(phenCAT)(bidentate nitrogen base)], which, on the basis of magnetic properties and Mössbauer spectra, are considered to be high-spin Fe^{III} complexes.[182] The mixed valence character of the complexes is indicated by the observation of an intervalence transfer band at 1100 nm in the solid state and in solvents of low dielectric constant. The non-appearance of the intervalence band in high dielectric constant solvents may be due to an intramolecular electron transfer to a $[Fe^{II}(phenSQ)(nitrogen\ base)]$ species.



Reaction of $[Fe^{II}salen]$ with *p*-quinones gives, in contrast, the binuclear complexes $[Fe_2(salen)_2Q]$.[180] It was shown by a variety of properties (magnetic measurements and IR, ESR and Mössbauer spectra) that the compounds consist of high-spin Fe^{III} ions bridged by the dianion Q (structure **33**) of the hydroquinone which transmits weak ($-J < 6\,cm^{-1}$) antiferromagnetic interaction.[183] This structure has been confirmed, for the case of Q = the dianion of hydroquinone, by a single crystal structure determination.[176]

(31)

(32)

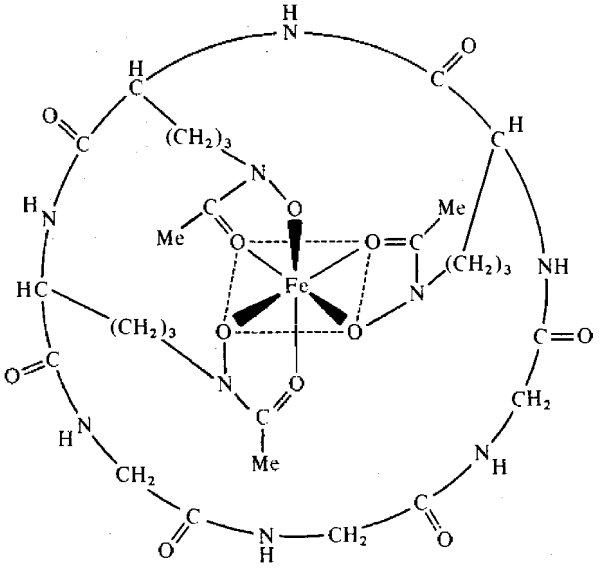
(33)

The electrochemistry of 8-quinolinol and 2-methyl-8-quinolinol complexes of iron in DMSO has been studied with a view to probing the redox chemistry of iron proteins containing histidine and tyrosine functional groups. Four reversible Fe^{II}/Fe^{III} redox couples occur between $+0.25$ V and -0.30 V (*vs.* SCE) as a function of solution acidity.[184] The methyl-substituted ligand also forms a μ-oxo bridged binuclear complex comprising high-spin five-coordinate Fe^{III} with $J = -80\,cm^{-1}$.[185]

44.2.5.5 Complexes of Hydroxamic Acid, Thiohydroxamic Acid and Derivatives

The second main class of Fe^{III}–specific sequestering agents (siderophores) responsible for the acquisition and assimilation of iron employ hydroxamate ligating groups (**34**).[157,158,186] Two important subclasses are the ferrioxamines and the ferrichromes (Figure 5). Examples are ferrioxamine B, a linear trihydroxamic acid and ferrichrome A, a cyclic hexapeptide carrying three hydroxamate-containing side chains.

(34)



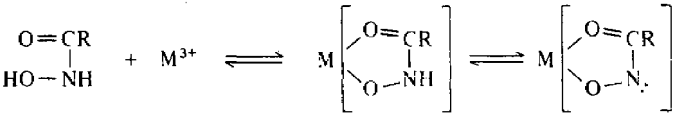


Figure 5 The structure of ferrichrome

The hydroxamic acids (**35**) are rather weak acids ($pK_a \sim 9$) which in acid solution form deeply coloured 1:1 complexes with Fe^{III}, a reaction which has long had analytical application for the hydroxamate functional group. Complexes of hydroxamic acids with a range of metal ions, including Fe^{III}, have been reviewed.[187] Mössbauer spectra are typical of high-spin Fe^{III} complexes.[188] In neutral solution a high-spin, octahedral tris(hydroxamato)iron(III) complex (**36**) is formed, the hydroxamate anion acting as a bidentate ligand. Such complexes are very stable with formation constants (β_3) approaching 10^{30}. In sharp contrast, the stabilities of corresponding Fe^{II} complexes are much lower (β_2 for the bis complex with acetohydroxamic acid $= 3 \times 10^8$) so that reduction of the Fe^{III} provides a mechanism for the release of the iron in the natural situation. The neutral tris complexes of Fe^{III} (**36**) can be further deprotonated in strongly basic media to generate the trianionic hydroximato complex $[FeL_3]^{3-}$ (**37**).

(35) Hydroxamic acid (36) Hydroxamato complex (37) Hydroximato complex

The asymmetry of the hydroxamate ligand leads to the possibility of the isolation of geometrical (and optical) isomers in the tris complexes. However, for high-spin Fe^{III}, expected to be kinetically labile, all structures so far determined have the *cis* configuration. Thus, for example, the most stable crystalline form of tris(benzohydroxamato)iron(III) has the *cis* configuration,[189] as have also ferrichrome A,[190,191] and ferric *N,N',N''*-triacetylfusarinine.[192] However, for the inert Cr^{III} complexes, on the other hand, both the *cis* and *trans* geometrical isomers have been separated and characterized in solution;[193] in addition, the *trans* isomer of tris(benzohydroxamato)chromium(III) has been structurally defined by X-ray diffraction.[194] More recently, the structures of both *cis* and *trans* isomers of the tris(benzohydroximato)chromate(III) anions have been determined.[195] Interestingly, the *cis* and *trans* isomers were obtained by deprotonation of the neutral hydroxamato complexes of opposite geometry.

In view of the kinetic lability of high-spin Fe^{III} it might be expected that the metal ion undergoes ready exchange in hydroxamate complexes. However, as shown by Raymond and co-workers, this is not always the case. For example, tris(hydroxamato)iron(III) complexes have been resolved into their component optical isomers and have been found to be very stable in various non-aqueous solvents.[196] Even slower substitution kinetics may be expected for natural siderophores comprising a single hexadentate ligand. Experiments on the kinetics of iron exchange and iron removal from complexes of ferrioxamine and ferrichrome A using ^{55}Fe and UV/vis spectrophotometric techniques have in fact shown that exchange is extremely slow; half-lives for exchange are > 200 h under certain conditions.[197]

The stabilities of Fe^{II} complexes of hydroxamates are much lower than those of Fe^{III} (β_2 for the bis Fe^{II} complex of acetohydroxamic acid = 3×10^8). It is thought, therefore, that the mechanism of release of iron from hydroxamate siderophores may occur *via* reduction of Fe^{III} to the much more weakly bound Fe^{II} state,[157] as also proposed for the tris(catecholato) siderophores. Cyclic voltammetry has shown that the Fe^{III} hydroxamate complexes undergo reversible or quasi-reversible one-electron reductions under suitable conditions. The observed formal potential E_f is pH dependent, decreasing from -0.388 mV (*vs.* SCE) at pH 7 by 60 mV per pH unit, for the case of tris(acetohydroxamato)iron(III), consistent with progressive deprotonations of the coordinated ligand. Thus, deprotonation stabilizes the Fe^{III} *vs.* the Fe^{II} state.[198,199]

Recently, a potentially new class of siderochrome has been isolated from bacteria such as *Pseudomonas fluorescens* containing thiohydroxamic acids which form very stable Fe^{III} complexes.[200] Both the parent acids and their chelates show antibiotic properties and may be involved in bacterial iron transport. The thiohydroxamate chelates, like their hydroxamate analogues, display high-spin $S = \frac{5}{2}$ properties, though some evidence for a high-spin $\rightleftharpoons$ low-spin equilibrium in one case has been reported.[201] The structure of tris(*N*-methylthioformohydroxamato)iron(III) has been determined.[202] The crystals examined contained a Λ-*cis* arrangement of ligands though the related complex, tris(benzothiohydroxamato)iron(III), could be resolved into the Λ and Δ isomers.[203] Electrochemical studies[199,204] have shown that replacing the carbonyl oxygen (in hydroxamates) by sulfur (as in thiohydroxamates) increases the reduction potential which would make the biological release of iron by reduction easier.

The bis(thiohydroxamate) complex $[FeL_2Cl]$ (L = *N*-methylbenzothiohydroxamate anion) has a five-coordinate (pseudo square pyramidal) structure comprising two *trans* bidentate 'SO' donor groups and a Cl atom.[205,206] It has been shown[205] (by magnetic, Mössbauer and ESR properties) to be high-spin indicating that the overall ligand field is smaller than that occurring in intermediate-spin dithiocarbamate systems ('S_4Cl' donor set).

44.2.6 SULFUR LIGANDS

44.2.6.1 Sulfido and Thiolato Complexes

Few areas of coordination chemistry can have undergone such rapid advances in the last decade as the chemistry of iron–sulfur cluster compounds. The stimulus for the rapid growth in this field has been the goal of modelling the active sites in the non-heme iron proteins involved in photosynthesis, mitochondrial respiration and nitrogen fixation. Following the recognition of the occurrence of the 'FeS_4' coordination unit in mono-, di- and tetra-nuclear proteins which mediate rapid and reversible electron transfer reactions, inorganic chemists have accepted the challenge to prepare synthetic analogues having the same distinctive physical and chemical properties. A remarkable degree of success has been achieved. Many excellent reviews[207] are available and these should be consulted as sources to the detail contained in primary publications.

There are at least five structural types of iron–sulfide–thiolate complex. The best known are

mononuclear tetrahedral $[Fe(SR)_4]^{2-,1-}$, binuclear $[Fe_2S_2(SR)_4]^{3-,2-}$ containing the planar $[Fe_2(\mu_2\text{-}S)_2]$ core, and tetranuclear $[Fe_4S_4(SR)_4]^{3-,2-}$ containing the cubane $[Fe_4(\mu_3\text{-}S)_4]$ core (Figure 6). Recently, two other classes of cluster containing three and six iron atoms have been discovered.[208,209]

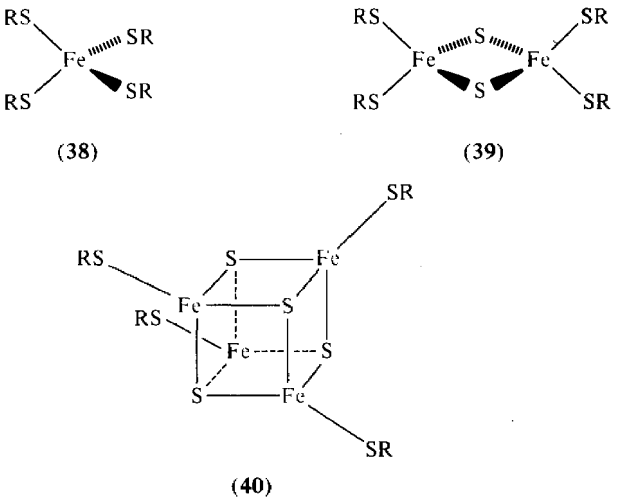

Figure 6 Structural units occurring in iron–thiolate complexes

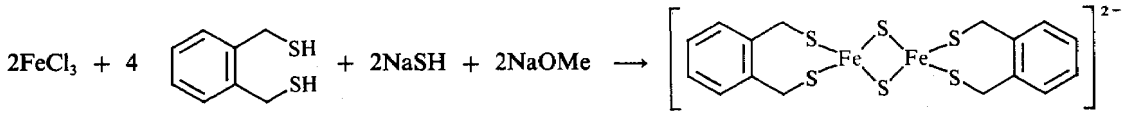
44.2.6.1.1 Mononuclear 'FeS_4' systems



This structural unit occurs in the one-iron proteins, rubredoxins (Rd), obtained from bacteria, in which the active site is $[Fe(S\text{-}Cys)_4]$, where S-Cys is a cysteinyl residue of the protein chain [structure (**38**) of Figure 6]. These proteins have molecular weights typically about 6000. The variety of physical investigations (magnetic susceptibility,[210] ESR,[211] Mössbauer,[212] optical absorption,[207,213] MCD[214]) have demonstrated that the two redox states, Rd_{ox} and Re_{red}, coupled by one-electron transfer at $E^0 \sim -0.4$ to -0.6 V, contain Fe^{III} and Fe^{II}, respectively.[215] The X-ray structure[216] of *Clostridium pasteurianum* Rd_{ox} at 1.2 Å resolution has indicated a distorted tetrahedral 'FeS_4' active site; the Fe—S distances range from 2.24 to 2.33 Å and the S—Fe—S angles from 104° to 114°. Rather few well-characterized synthetic compounds containing the 'FeS_4' coordination unit are known;[217] most contain Fe^{II} and are not oxidizible to Fe^{III}, often because of the tendency of the Fe^{III} complexes to undergo autoredox reactions to Fe^{II} and RSSR. A notable exception is the complex $[NEt_4][Fe(S_2\text{-}o\text{-}xyl)_2]$ (S_2-*o*-xyl = *o*-xylyl-α,α′-dithiolate) prepared by reaction of the dithiol with $[FeCl_4]^{2-}$ followed by aerobic oxidation.[218] Comparison of the structures of the Fe^{III} and Fe^{II} complexes has shown that in both cases the metal atom is in a slightly distorted tetrahedral environment. There is some lengthening (~ 0.09 Å) of the mean Fe—S bond distance on reduction. Both complexes are high-spin ($S = \frac{5}{2}$, $S = 2$). In the 77 K Mössbauer spectra the isomer shifts (δ, *cf.* natural iron) and quadrupole splittings (ΔE_Q) are 0.13 and 0.57 mm s^{-1} (Fe^{III}) and 0.61 and 3.28 mm s^{-1} (Fe^{II}). Cyclic voltammetric measurements in DMF confirmed that the two complexes are related by a quasi-reversible one-electron process at ~ 1.0 V, a somewhat more negative potential than would be expected for the proteins in the same medium.

More recently three other mononuclear $[Fe(SR)_4]^-$ complexes containing monodentate thiolate have been structurally defined. In these SR$^-$ = SPh^-,[219] SEt^-[219] and 2,3,5,6-tetramethylbenzenethiolate.[220] Sterically hindered thiolate ligands appear to stabilize the $[Fe(SR)_4]$ coordination unit and thus provide a means for the preparation by ligand exchange of the previously elusive (non-hindered) monodentate tetrathiolato iron(III) complexes.

44.2.6.1.2 Dinuclear 'Fe–S' systems

A wide variety of synthetic binuclear iron complexes (**39**) bridged by sulfide, disulfide and/or thiolate groups are known. They have proven to be good models for the two-iron ferredoxin proteins, as demonstrated by comparisons of structure and properties. Early attempts to isolate two-iron complexes by direct reaction of a monothiol with $FeCl_3$, NaSH and NaOMe afforded only four-iron products suggesting that a particularly high stability is associated with the tetrameric

cubane structure (**40**) relative to other possible Fe—S reaction products.[221] It was argued that use of a chelating dithiol which is unable to span the ~7 Å distance between thiolate coordination sites in the tetramer might lead to the desired two-iron product. This strategy proved successful for the case where RSH is *o*-xylydithiol (**41**) (equation 8), a crystalline product (**42**) being isolated by the use of a quaternary cation. It was further discovered that related complexes of non-chelating aryl thiols could be readily prepared by ligand exchange. The structures of the *o*-xylyl dimer (**42**) and of the corresponding complex containing *o*-tolylthiol ligands have been determined.[221] Both are centrosymmetric sulfide-bridged dimers containing a planar Fe_2S_2 core with each Fe^{III} atom in an approximately tetrahedral environment. The short Fe···Fe separation suggests some direct metal–metal interaction. Subsequently, improved syntheses for the two-iron complexes were developed.[222] These involved reaction of $FeCl_3$, elemental sulfur and thiolate in the presence of tetraalkylammonium ions in MeOH solution at ambient temperature; in the absence of $[NR_4]^+$ the final reaction products were the four-iron tetranuclear clusters. Analogous selenium compounds were obtained by the use of elemental selenium in place of sulfur.

(41) (42)

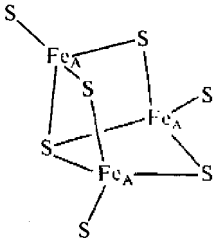
A remarkable similarity in properties between the synthetic two-iron complexes and the oxidized forms of the two-iron ferrodoxins has been observed and subsequently placed on a firm structural basis by the X-ray structure determination of Fd_{ox} of *Spirulina platensis*.[223] Optical spectra of $[Fe_2S_2(S\text{-}o\text{-}xyl)_2]^{2-}$ (**42**) and Fd_{ox} are closely similar.[224] Both the synthetic and natural systems have magnetic susceptibilities well below those expected for isolated Fe^{III} ions and which approach zero at low temperature, indicative of strong intramolecular antiferromagnetism. The data lead to coupling constants $J = -148\,cm^{-1}$ for (**42**)[225] which compares with $J = -143$ to $-185\,cm^{-1}$ for various Fd_{ox}.[226] Mössbauer parameters are also in good agreement. The isomer shifts for spinach Fd_{ox} is $0.22\,mm\,s^{-1}$[227] while for the synthetic analogues values of $0.17\,mm\,s^{-1}$ have been observed.[225] The smaller quadrupole splitting ($\sim 0.35\,mm\,s^{-1}$) in the synthetic systems[225] compared to spinach Fd_{ox} ($0.65\,mm\,s^{-1}$)[228] may reflect a lower site symmetry in the latter.

Electrochemical investigation[221] of the synthetic dimers in DMF has revealed two quasi-reversible one-electron reduction waves at -1.25 V and -1.49 V (*vs.* SCE), for the *o*-xylyl system, attributable to the three-member electron transfer series given in equation (9). Since two-iron Fd_{ox} proteins undergo a single one-electron reduction (to give Fd_{red}) it is concluded that Fd_{red} contains the total oxidative level (formally $Fe^{II} + Fe^{III}$) as the synthetic trianion. No protein oxidation level corresponding to the tetraanion (Fe^{II}, Fe^{II}) has yet been detected. The antiferromagnetic coupling present in Fd_{ox} proteins in retained on reduction to Fd_{red} ($J \approx -100\,cm^{-1}$) leading to a spin doublet ground state.[226] Spectroscopic studies[226] (ESR, NMR, optical, Mössbauer) have revealed the occurrence of two (spectroscopically) distinct metal sites having the properties of high-spin tetrahedral Fe^{III} and Fe^{II}, thus characterizing Fd_{red} as a class II mixed valence species, *i.e.* one having a localized Fe^{III}, Fe^{II} oxidation state configuration. Similar properties were found for the one-electron reduction product (generated in solution) of $[FeS_2(S_2o\text{-}xyl)_2]^{2-}$ (**42**) leading to the conclusion that the localized mixed-valence behaviour is not a consequence of the protein structure but is an intrinsic property of any $[Fe_2S_2(SR)_4]^{3-}$ species and, indeed, of any species containing the $[Fe_2S_2]$ core.[229]

$$\underset{[Fe^{II}, Fe^{II}]}{[Fe_2S_2(SR)_4]^{4-}} \rightleftharpoons \underset{[Fe^{II}, Fe^{III}]}{[Fe_2S_2(SR)_4]^{3-}} \rightleftharpoons \underset{[Fe^{III}, Fe^{III}]}{[Fe_2S_2(SR)_4]^{2-}} \quad (9)$$

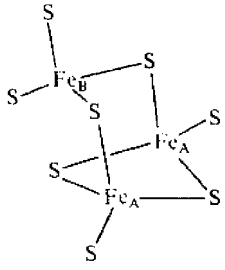
The exchange of *o*-xylyl dithiolate by aryl thiolate has already been noted. Such exchange (equation 10) is fairly general for one-iron and four-iron systems as well as two-iron and is the basis of the core extrusion method for the identification of active sites in iron–sulfur proteins. This type of reaction can be extended to the replacement of coordinated thiolate by other nucleophiles. For example, reaction of the complexes $[Fe_2S_2(SR)_4]^{2-}$ (and also the four-iron clusters) with benzoyl chloride afford $[Fe_2S_2Cl_4]^{2-}$ (or $[Fe_4S_4Cl_4]^{2-}$).[230] Comparison of the crystal structure of $[NEt_4]_2$-$[Fe_2S_2Cl_4]$ with those of the previously investigated *o*-xylyl dithiolate and *p*-tolyl thiolate complexes demonstrates that the replacement occurs virtually without structural change and reinforces the view that the Fe_2S_2 core in two-iron systems (and the Fe_4S_4 core in four-iron systems) is an integral

substructural unit which can be transferred intact from one ligand environment to another, including those in proteins. Both the two-iron and four-iron dimers and tetramers are also reactive with respect to substitution of core S by Se as demonstrated by ^{1}H NMR spectroscopy in MeCN solution.[231]



$$[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-} + 4RSH \longrightarrow [Fe_2S_2(SR)_4]^{2-} + 2o\text{-xylSH} \quad (10)$$

44.2.6.1.3 Trinuclear 'Fe–S' systems



Three-iron clusters have been detected only very recently. An $Fe_3(\mu\text{-}S)_3$ unit from *Azotobacter vinelandii* ferrodoxin I has been identified crystallographically.[208] This protein also contains a [4Fe–3S] cluster. The [3Fe–3S] unit has a near planar cyclic structure (**43**). Each tetrahedral Fe atom has two terminal ligands of which five are cysteinyl side chains while the sixth appears to be an oxygen atom from H_2O or OH^-. The Fe···Fe distances, unlike those in two-iron and four-iron clusters, are long at 4.1 Å. On the other hand, EXAFS measurements on two other proteins, ferrodoxin II from *Desulfovibrio gigas*[232] and beef heart aconitase,[233] both containing isolated three-centre Fe cores, have indicated Fe···Fe distances of ~2.7Å. This closer metal···metal separation is incompatible with a planar [3Fe–3S] ring. Moreover, it has been shown that aconitase contains four labile S atoms, not three.[233] The situation is further confounded by the resonance Raman results of Spiro and collaborators[234] on ferredoxins from *A. vinelandii*. The observed spectra are not compatible with the planar [3Fe–3S] structure obtained in the crystallographic study. Instead, they strongly indicate a [3Fe–4S] structure of type (**44**) or (**45**) derived from the [4Fe–4S] cubane core. Since there is no reason to question the validity of the crystallographic results[208] it must be concluded that the two groups of investigators examined different chemical species. Since the [3Fe–4S] structure appears to occur in all other three-iron proteins so far examined it has been speculated[234] that one S atom was lost during the isolation procedure for the planar [3Fe–3S] specimen, with accompanying structural rearrangement.

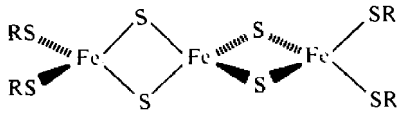
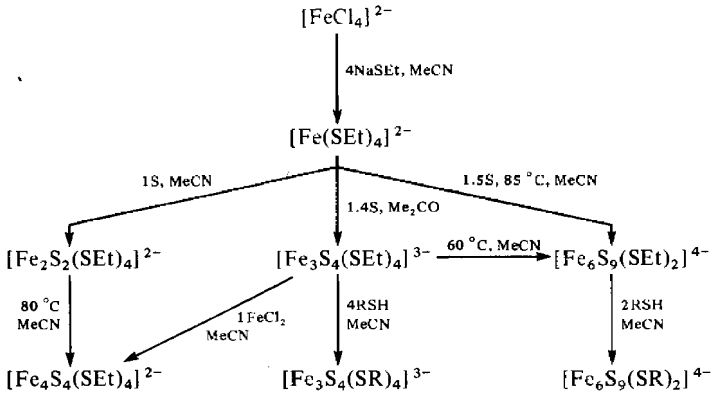
(44)



(45)

Structural diversity in trinuclear iron sulfide complexes has been extended by the isolation of a number of synthetic systems having a pyramidal $[Fe_3(\mu_3\text{-}S)]$ central unit (**46**)[235] or a linear arrangement $[FeS_2FeS_2Fe]$ (**47**).[236] The former structure (**46**) occurs in Fe^{II} and Co^{II} complexes of stoichiometry $[M_3S(S_2\text{-}o\text{-xyl})_3\}^{2-}$ and comprises an apical μ_3-S atom bonded to three M atoms arranged in a nearly equilateral triangle.[235] Each M atom is coordinated to one terminal and one bridging sulfur atom of a dithiolate ligand, affording distorted tetrahedral $M^{II}S_4$ units in structures that closely approach overall C_3 symmetry. The reduced, somewhat temperature dependent, magnetic moments (2.28 BM per metal ion at 301 K for M = Fe) and other properties are consistent with the occurrence of magnetic coupling. The Fe^{II} complex shows a quasi-reversible oxidation (at −0.59 V *vs.* SCE).[235]

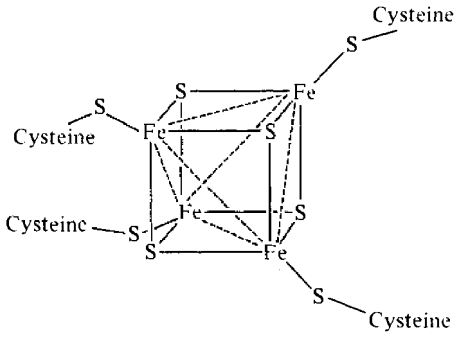


(46)

(47)

The complexes $[Fe_3S_4(SR)_4]^{3-}$ (R = Et or Ph), isolated as the $[NEt_4]^+$ salts, were prepared by reaction of the strongly reducing $[Fe^{II}(SEt)_4]^{2-}$ complex with 1.4 equivalents of sulfur in acetone. The corresponding benzenethiolate was then obtained by ligand exchange. Indeed, the $[Fe(SEt)_4]^{2-}$ complex was found to be a very versatile precursor to a range of Fe—S—SR compounds, affording direct entry to bi-, tri-, tetra- and hexa-nuclear clusters, as outlined in Scheme 2 which also indicates conversion pathways between [3Fe–4S] and higher order clusters.[236]

Scheme 2 Preparation routes to two-, three-, four- and six-iron sulfur–thiolate clusters



The anion of $[NEt_4]_3[Fe_3S_4(SPh)_4]$ consists of two tetrahedral FeS_4 units linked by a central Fe atom also in tetrahedral sites; the two outer Fe atoms are each coordinated by two thiolate groups (structure **47**). The Fe···Fe separation is 2.714 Å, *i.e.* similar to that deduced from EXAFS experiments for *D. gigas* ferredoxin II. Despite this, the structures of the three-iron cores in the natural and synthetic systems are considered to be quite different as judged by their different ESR spectra ($g \approx 2.01$ in the oxidized form of the protein, $g \approx 4.2$ in $[Fe_3S_4(SEt)_4]^{3-}$) and other properties.

44.2.6.1.4 Tetranuclear 'Fe—S' systems

The four-iron clusters are the most thoroughly studied group of iron–sulfur cluster compounds.[207,237] In nature they occur in the four-iron and eight-iron ferredoxins (Fd) and the so-called high-potential (HP) proteins and many synthetic analogues have been studied. Their structures and properties are naturally rather more complex than those of the systems considered above. The physiological function of the ferredoxins is to transfer electrons and a major challenge of the inorganic chemist has been to develop simpler synthetic systems which reproduce, as far as possible, the distinctive electrochemical and other properties of the active sites of the proteins. As in the case of the one-iron, two-iron and three-iron sulfur compounds already considered, our present understanding of the chemistry of the ferredoxins owes much to the elegant synthetic analogue approach of Holm and co-workers whose publications should be consulted for fuller detail.

The ferredoxin and high-potential proteins contain one or two $[Fe_4S_4(S\text{-}Cys)_4]$ clusters (**48**) each of which acts as a one-electron transfer agent. The same structural unit occurs in many synthetic systems in which a thiolate ion takes the place of the cysteinyl residue of the proteins. The close similarity in the structures of the $[Fe_4S_4(SR)_4]$ units between proteins and synthetic analogues has been demonstrated by X-ray structure determinations[238–244] on members of both classes, as can be seen from an inspection of the structural parameters collected in Table 2. Clearly, the synthetic compounds can be regarded as accurate structural models for the proteins. The basic geometry of this common structural unit is that of a tetrahedron of four iron atoms interpenetrating a second (larger) tetrahedron of four S atoms. Each S^{2-} ion (designated S*) is bonded to three Fe atoms and each Fe atom bears a terminal SR group, cysteinyl residues in the case of the proteins. In all cases the central 'cube' is compressed towards D_{2d} symmetry. An important feature of results of HP_{red} and HP_{ox} is that the structural parameters appear very insensitive to the overall oxidation level. Moreover, there is no evidence for localized Fe^{II}, Fe^{III} states in any of these mixed valence structures. This is in accord with the findings of spectroscopic investigations[245] capable of detecting localized Fe^{II}, Fe^{III} states with lifetimes of 10^{-4} to 10^{-16} seconds. Physical properties have shown that the Fe–S clusters in $[Fe_4S_4(SR)_4]^{2-}$ are isoelectronic with those occurring in the Fd_{ox} and HP_{red} proteins thus

establishing that these forms of the proteins contain, formally, two Fe^{III} and two Fe^{II} ions. Since the magnetic moments of the dianions are well below the values for high- and low-spin Fe^{III} and high-spin Fe^{II}, and since they are further reduced on cooling, it follows that the metal centres are antiferromagnetically coupled giving a resultant singlet ground state.[246]

(48)

Table 2 Average Dimensions (Å or °) in Some $[Fe_4S_4^*(SR)_4]$ Units[a]

	*Fe—S**	*Fe—S*	*Fe···Fe*	*S—Fe—S**	*S*—Fe—S**	*Fe—S*—Fe*

[a] Data from ref. 207 and 238–244 in which original sources may be found.

Electrochemical studies[247] have shown that $[Fe_4S_4(SR)_4]^{2-}$ complexes undergo both one-electron reductions and one-electron oxidations (equation 11). Property comparisons with the proteins have allowed the equivalence, in overall oxidation state level, between $[Fe_4S_4(SR)_4]^{3-}$ and Fe_{red} and between $[Fe_4S_4(SR)_4]^{-}$ and HP_{ox}, to be established. The 'super-reduced' species HP_{s-red} and the 'super-oxidized' species do not appear to be active in the natural protein metabolism. However, the $[Fe_4S_4(SR)_4]^{3-}$ complex ($S = \frac{1}{2}$) has been isolated and shown to have similar optical ESR and Mössbauer spectra to those of Fd_{red} proteins.[248] In contrast to the [4Fe-4S] core of the Fd_{red} analogue, $[Fe_4S_4(SPh)_4]^{3-}$, which is distorted from cubic to elongated D_{2d} symmetry, the core of the $[Fe_4S_4(SCH_2Ph)_4]^{3-}$ anion consists six short and six long Fe—S bonds in C_{2v} symmetry.[249] This kind of distortion appears to be exceptional, however, the usual structural effect accompanying $[Fe_4S_4(SR_4)]^{2-}$ to $[Fe_4S_4(SR)_4]^{3-}$ being compressed $D_{2d} \rightarrow$ elongated D_{2d}.

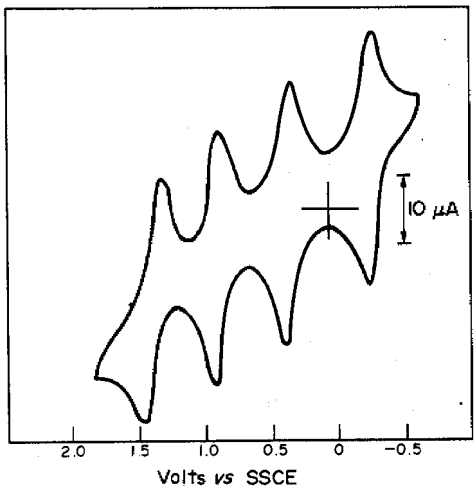
$$\begin{array}{ccccc} [Fe_4S_4(SR)_4]^{3-} & \rightleftharpoons & [Fe_4S_4(SR)_4]^{2-} & \rightleftharpoons & [Fe_4S_4(SR)_4]^{-} \\ Fd_{red} & & Fd_{ox} & & Fd_{s\text{-}ox} \\ HP_{s\text{-}red} & & HP_{red} & & HP_{ox} \end{array} \qquad (11)$$

A point of difference between the natural and synthetic Fe—S compounds lies in the potential values at which oxidation/reduction occurs, these generally being more negative for the analogues ($E_{1/2} \sim -1.05$ to -0.75 V). Discrepancies originally ascribed to effects due to the influence of the polypeptide structure can now be attributed, in part, to differences in solvent medium.[247] However, the polypeptide must still have an attenuating effect on redox potentials, possibly by protecting the active site from solvent. A ^1H NMR study[250] of the redox equilibria of $[Fe_4X_4(SR)_4]^{2-,3-}$ (X = S, R = CH_2Ph or *p*-C_6H_4Me; X = Se, R = CH_2Ph) showed rates *ca.* 10^4 greater than for Fd or HP proteins, the differences being attributed to the steric influence of protein structure.

Preparative methods and reaction sequences leading to $[Fe_2S_4(SR)_4]^{2-}$ complexes, and pathways for interconversion to related clusters have been described and discussed.[236,251,252] The series of complexes $[Fe_4S_4(SC_6H_4\text{-}o\text{-}X)_4]^{2-}$ (X = NH_2, OMe, OH or SMe) have been prepared by ligand substitution from $[Fe_4S_4(SBu^t)_4]^{2-}$ and the structure of the complex in which X = OH has been

solved by X-ray crystallography. This cluster contains three conventional tetrahedral FeS_4 sites and one distorted trigonal bipyramidal FeS_4O site achieved by chelation of one *o*-SC_6H_4OH ligand. The Fe—S bond to the chelated ligand is only 0.035 Å longer than the other three though the Fe—O(H) distance (2.318 Å) reflects a weaker, secondary interaction. Mössbauer spectra displayed separate quadrupole-split doublets for the case of X = OH and SMe but only a single doublet for X = NH_2 suggestive of no secondary bonding in this case.[253] An interesting feature of the Mössbauer results is the high isomer shifts ($\delta > 0.5$ mm s^{-1} at 4.2 K relative to natural Fe) very close to the values found for the P clusters of nitrogenase.[254]

Several other tetranuclear iron–sulfur cluster compounds of general formula $[Fe_4S_4X_4]^{n+,n-}$, in which X is a non-thiolate terminal ligand, have been studied in some detail. These include systems in which X = Cl, η^5-C_5H_5, NO and dithiolene. The structure of the dianion $[Fe_4S_4Cl_4]^{2-}$ has been determined; it exhibits the same cubane-like stereochemistry, distorted from T_d to D_{2d}, found in the corresponding thiolate tetramer dianion, showing that the core structure is rather insensitive to the nature of the terminal ligands.[230] Similar considerations apply to the case of complexes containing the X = η^5-C_5H_5[255,256] or X = $[S_2C_2(CF_3)_2]$[257] terminal ligands. Variations in core dimensions occur, however, according to the overall charge of the core. Thus, the geometry of the parent neutral diamagnetic $[Fe_4S_4(\eta\text{-}C_5H_5)_4]$ complex distorts from tetragonal D_{2d} to orthorhombic D_2 on oxidation (*via* Ag^I, I_2 or Br_2) to the monocation, while, on further oxidation to the dication[258] there is a further distortion of the cube towards a flattened iron tetrahedral structure with four short and two long Fe···Fe distances; this contrasts with the four long and two short bonds in the neutral compounds.[256] Nonetheless, the basic structural features of the core framework remain intact as is nicely illustrated[258,259] by the occurrence of four electrochemically reversible one-electron waves in the cyclic voltammogram (Figure 7) of $[Fe_4S_4(\eta^5\text{-}C_5H_5)_4]^n$ in MeCN corresponding to the couples 3+/2+ through to 0/−1 (equation 12).



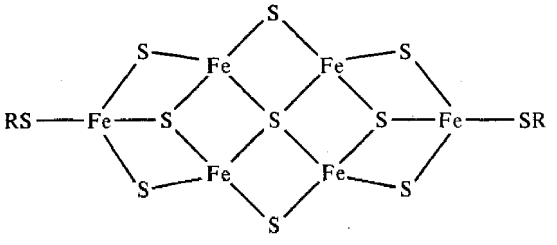


Figure 7 Cyclic voltammogram of $[Fe_4(\eta^5\text{-}C_5H_5)_4(\mu_3\text{-}S)_4]^{2+}$ in acetonitrile at a platinum bead electrode with a scan rate of 1 V s^{-1}

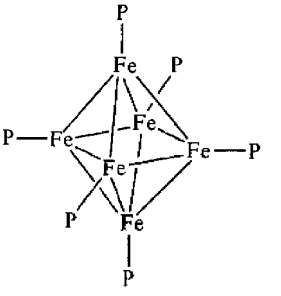
$$+3 \overset{1.41\,V}{\rightleftharpoons} +2 \overset{0.88\,V}{\rightleftharpoons} +1 \overset{0.33\,V}{\rightleftharpoons} 0 \overset{-0.33\,V}{\rightleftharpoons} -1 \qquad (12)$$



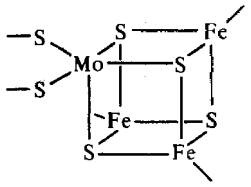
The nitrosyl complex $[Fe_4S_4(NO)_4]$ reveals two reversible 0/−1 and −1/−2 couples in CH_2Cl_2 solution. A structural comparison of the monoanion with the neutral parent again reveals core deformation ($T_d \rightarrow D_{2d}$) on reduction involving changes in Fe···Fe distance within the core. The architectural variations have been rationalized in terms of a cluster bonding model in which the unpaired electron in the monoanion occupies a t_1 level of largely antibonding character.[260] Analogous complexes $[Fe_4S_2(\mu_3\text{-}NCMe_3)_2(NO)_4]^{0,-1}$ in which two of the bridging sulfide ions of the core have been replaced by the electronically equivalent triply bridging *N-tert*-butyl anion, have been described.[261] A different core structure is found in the black Roussin salt $[AsPh_4][Fe_4S_3(NO)_7]$. Here, the anion comprises a trigonal pyramid of four Fe atoms with triply bridging S^{2-} ions and Fe—Fe bonds linking the apical Fe(NO) fragment to each of the three basal $Fe(NO)_2$ moieties.[262]

44.2.6.1.5 Hexanuclear 'Fe–S' systems

The most recent additions to the family of polynuclear iron–sulfur cluster compounds are those having a hexanuclear six-iron core. Two types have been isolated, exemplified by $[Fe_6S_9(SR)_2]^{4-}$ (**49**) (R = Et, Bu^t or SCH_2Ph)[263,256,264] and $[Fe_6S_8(PEt_3)_6]^{2+}$ (**50**).[265] The complexes (**49**) have a delocalized ($4Fe^{III}$, $2Fe^{II}$) mixed valence formulation while paramagnetic (**50**) contains all six metals, formally, in the Fe^{III} oxidation state. Complexes (**49**) were prepared by methods outline in Scheme 2 while (**50**) was prepared by reaction of $Fe(BF_4)_2 \cdot 6H_2O$ and PEt_3 (molar ratio *ca.* 1:3) with H_2S in O_2-free acetone–ethanol at room temperature, followed by a period of air exposure, and, finally, precipitation as the $[BPh_4]^-$ salt.[265] The two complexes have quite different structures. The dication (**50**) is built up of an octahedron of iron atoms with the sulfur atoms triply bridging all octahedral faces; each square pyramidal Fe atom is additionally coordinated by a PEt_3 molecule.[265] The core structure in (**49**) on the other hand contains three different types of bridging sulfur atom, six μ_2-S, two μ_3-S and one μ_4-S. The structure can be regarded as derived from two incomplete $[Fe_4S_4]$ units, each lacking one Fe atom, linked by the common μ_4-S atom.[236,264]

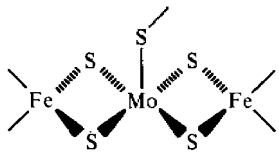
(**49**) The structure of the hexanuclear $[Fe_6S_9(SR)_2]^{3-}$ cluster

(**50**) Each of the eight sulfur atoms triply bridges an octahedral



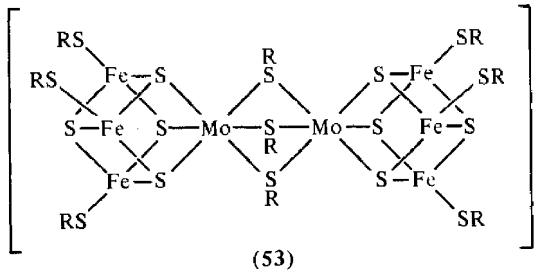
44.2.6.1.6 'Mo–Fe–S' complexes

The isolation by Shah and Brill[266] from nitrogenase enzyme of an iron–molybdenum cofactor (FeMo-co) containing Fe, acid labile S and Mo in the approximate ratio (6–8)Fe:(4–6)S:Mo, believed to be the catalytic site (in a reduced oxidation level) for the reduction of dinitrogen to ammonia, has greatly stimulated attempts to prepare and characterize synthetic compounds containing Mo and Fe together in the same cluster. This goal was given added significance by the recognition from X-ray absorption spectra (XAS) and EXAFS studies[267] of several Fe—Mo proteins that the coordination unit might contain structures such as (**51**) or (**52**), *i.e.* types of cluster very similar to those already well established for Fe—S compounds, and for which synthetic procedures *via* 'spontaneous self-assembly' were available. Application of these synthetic methods, involving the use of $[MoS_4]^{2-}$, known to act as a ligand,[268] as a soluble source of Mo led to the isolation of a series of heteropolynuclear products *via* reactions such as given in equations (13) and (14).[269] Structure determinations[270,271] of crystalline salts of anions (**53**) and (**54**) have confirmed the occurrence in both of the cubane-like $MoFe_3S_4$ unit, one of the proposed structural models for FeMo-co. The two cubane $MoFe_3S_4$ subclusters are linked by different types of bridging unit to afford the so-called 'double cubane' cluster. Other smaller, Fe—Mo—S complexes such as (**55**) and (**56**) have also been prepared.[272,273] The structural similarity of (**52**) to the other proposed model for FeMo-co is obvious. The tungsten analogues of many of these complexes have also been prepared.[274] A significant observation is the occurrence of a spin-quartet ($S = \frac{3}{2}$) type of ESR spectrum in some of the synthetic clusters[273] as also observed in FeMo-co.[275] For a detailed description of the structures, physical properties and reactions of these complexes the review article by Holm,[276] and the references therein, should be consulted.

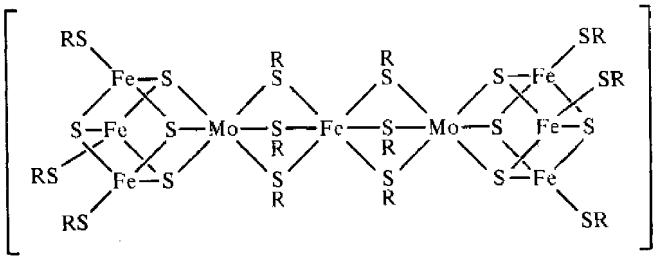


$$2MoS_4^{2-} + 6FeCl_3 + 17RS^- \longrightarrow \underset{(53)}{[Mo_2Fe_6S_8(SR)_9]^{3-}} + 4RSSR + 18Cl^- \quad (13)$$

$$2MoS_4^{2-} + 7FeCl_3 + 20RS^- \longrightarrow \underset{(54)}{[Mo_2Fe_7S_8(SR)_{12}]^{3-}} + 4RSSR + 21Cl^- \quad (14)$$



More recently, the preparation of the trianion $[MoFe_4S_4(SEt)_3(cat)_3]^{3-}$ (**57**) (cat = catecholate), which contains a single cubane type $[MoFe_3S_4]$ core, by a cleavage of the Fe^{III}-bridged double cubane $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$ (**54**) has been described. The EXAFS spectrum of (**57**) is in qualitative



(51)

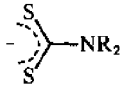
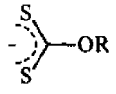
(54)

(55)

(56)

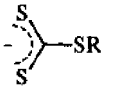


(57)

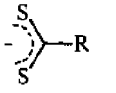


agreement with that of FeMo-co.[277] The electronic properties of single and double $[MoFe_3S_4]$ cubane-type clusters have been compared and contrasted. Oxidized $[MoFe_3S_4]^{3+}$ single cubanes consist of electronically delocalized spin-coupled clusters with $S = \frac{3}{2}$ ground states. In one case, at least, the reduced $[MoFe_3S_4]^{2+}$ cluster has an $S = 2$ ground state. The double cubanes having two Mo—(SR)—Fe bridges exhibit subcluster spin coupling resulting in a singlet ground state while triply bridged double cubanes show weaker subcluster interaction giving an $S = 2$ ground state for each subcluster.[278]

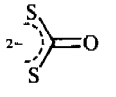
44.2.6.2 Complexes of Dithiocarbamates and Related Ligands



There are a number of negatively charged ligands capable of coordinating *via* two sulfur atoms (or one sulfur and one oxygen atom) to a metal ion with formation of four-, five- or six-membered chelate rings (see structures **58** to **68**). Other modes of coordination, *i.e.* unidentate or bridging, are also known for the same group of ligands. Several reviews are available.[279–286]

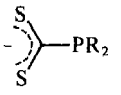


(58) Dithiocarbamate

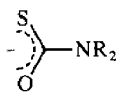


(59) Xanthate

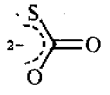
(60) Thioxanthate



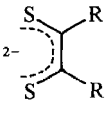
(61) Dithiocarboxylate



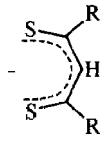
(62) Dithiocarbonate



(63) Trithiocarbamate



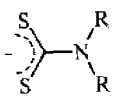
(64) Dithiophosphinate



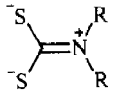
(65) Monothiocarbamate

(66) Monothiocarbonate

(67) Dithiolate



(68) Dithio-β-diketonate



The iron(III) dithiocarbamates are the most extensively studied, largely because of their interesting magnetic properties. Cambi and co-workers[287] first showed that tris(dialkyldithiocarbamato)-iron(III) displayed spin cross-over phenomena between high-spin and low-spin states. As indicated earlier (Figure 1) Fe^{III} in a weak octahedral field has a $^6A_{1g}$ ($t_{2g}^3e_g^2$) ground term and gives rise, in the absence of magnetic interactions with other paramagnetic centres, to magnetic moments close to the spin-only value of 5.92 BM ($S = \frac{5}{2}$). In a strong field, on the other hand, the term $^2T_{2g}$ (t_{2g}^5) lies lowest and in this case room temperature moments are commonly close to about 2.0 BM corresponding to the presence of one unpaired electron in the t_{2g} orbital set, *i.e.* $S = \frac{1}{2}$. The difference between the observed moment and the spin-only value of 1.73 BM arises from small contributions from the non-zero value of the orbital contribution of the angular momentum in the t_{2g}^5 configuration. In practice, deviations from standard high- or low-spin behaviour in magnetically dilute systems can arise whenever the ligand field is comparable in strength with the mean electron-pairing energy appropriate to the Fe^{III} d^5 configuration. In cases where the energy of the high-spin state lies only slightly (from *ca.* 50 to *ca.* 400 cm^{-1}) above that of the low-spin state there will be a thermally controlled population of the two states which will be manifested by a temperature dependent magnetic moment between the limiting values of 5.9 BM at high temperatures and 2.0 BM at low temperatures.

Temperature dependent magnetic susceptibility measurements of several tris-*N*,*N*-dialkyldithiocarbamate complexes have been successfully interpreted in these terms.[288–291] However, only in the case of solutions can a simple Boltzmann distribution between high- and low-spin states be expected.[292] This is because of complicating secondary solid state effects such as vibrations in crystal packing, solvation and, in certain cases, the existence of the complex in more than one crystal modification leading to phase changes on temperature variation. Mössbauer effect studies[293] show only one, averaged, temperature dependent quadrupole-split doublet. The failure to observe separate signals due to the two spin states has been attributed to high-spin $\rightleftharpoons$ low-spin cross-over periods shorter than the Mössbauer timescale (1.5×10^{-7} s). The same applies to NMR shifts. Also, Hall and Hendrickson[294] demonstrated, from ESR measurements, that the spin-flipping rate is of the order of 10^{10} s^{-1}. It should be noted, however, that separate signals for the two spin isomers could be detected in the Mössbauer spectra of some tris(monothio-β-diketonato)iron(III) complexes, indicating slower exchange in the case of this unsymmetrical chelating ligand.[295]

It has been observed that the position of the $^6A_1 \rightleftharpoons {}^2T_2$ equilibrium in dithiocarbamate complexes $[Fe(S_2CNR_2)_3]$ is quite sensitive to the nature of the NR_2 substituent.[290] As is apparent from the collected data in Table 3 the room temperature magnetic moments shift in favour of the $^2T_2$ state as the NR_2 groups change from the cyclic pyrrolidyl group of *N*,*N*-di-*n*-alkyl, to *N*-alkyl, *N*-aryl, to *N*,*N*-di-*sec*-alkyl. It has been suggested that this trend may have a steric origin since the RNR angle is expected to increase in the same order leading in turn, to an increased contribution of resonance form (**70**), compared to (**69**), this having the stronger ligand field. However, other workers[296] have argued that limiting structure (**70**) will have the lower field and that its importance will increase with increase in electron releasing ability of the NR_2 group. In agreement with this argument an increase in μ_{eff} with increase in pK_a of the secondary amine was observed, except for those amino groups having a secondary carbon atom. The exceptional position of these systems in the correlation was explained in terms of non-coplanarity of the CS_2 and NR_2 planes. It was further observed[290] that xanthates $[Fe(S_2COR)_3]$ are almost completely in the low-spin form while dithiophosphinates $[Fe(S_2CPR_2)_3]$ (R = OMe, OEt, OPr^n, OPr^i) are almost completely high-spin in the 90–300 K temperature range. The magnetic properties of diselenocarbamato complexes are very similar to those of corresponding thio compounds but with the position of the spin equilibrium shifted towards the low-spin state in most examples.[297] The thioxanthates, in contrast to xanthates, also appear to be examples of spin equilbrium systems.[298]

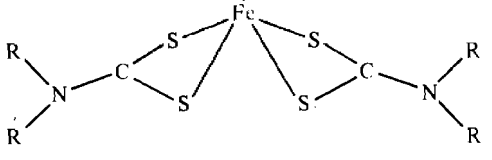
Since it can be predicted that depopulation of the (high-spin) sextet level in favour of the (low-spin) doublet level should be accompanied by a contraction of the $[FeS_6]$ core in spin transition systems, it is to be expected that the position of the spin equilibrium K will depend on pressure. This has been experimentally verified for several tris(dithiocarbamato)iron(III) complexes in chloroform solution at pressures up to 5000 atmospheres at room temperature. On the assumption that the molecular volume contraction ΔV arises entirely as a result of the spin change, equation (15) can be applied to the calculation of the volume change. Values of ΔV of the order of $5\,cm^3\,mol^{-1}$ were obtained for systems with a wide variety of N substituents.[289,290] The values correspond to a contraction of the Fe—S bond length of about 0.1 Å, during the ${}^5A \rightarrow {}^2T$ transition.

$$\Delta V = -RT\left(\frac{\delta \ln K}{\delta P}\right)_T \tag{15}$$



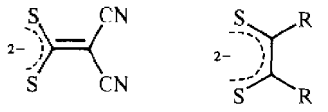
Crystallographic confirmation of this effect has been obtained, first by Hoskins and Kelly[299] and subsequently by Healy and White.[300] In the complex $[Fe(S_2CNBu^n_2)_3]$ which is largely in the high-spin form at room temperature ($\mu_{eff} = 5.32$ BM) the mean Fe—S bond length is 2.42 Å whereas in the xanthate complex $[Fe(S_2COEt)_3]$, largely in the low-spin form ($\mu_{eff} = 2.72$ BM at 296 K), the mean Fe—S distance is 2.32 Å. The same difference of 0.1 Å in mean Fe—S distance was observed between the high-spin ($\mu_{eff} = 5.9$ BM at 300 K) tris(*N*-pyrrolidyldithiocarbamate) and the mainly low-spin ($\mu_{eff} = 3.0$ BM at 300 K) *N*-methyl-*N*-phenyl derivative. In addition, there are certain alterations in the overall symmetry of the coordination polyhedron as a consequence of the spin change. Thus, the high-spin dithiocarbamate with Bu^n as substituent has a structure intermediate between trigonal prismatic and octahedral, whereas in the low-spin xanthate the structure is closer to octahedral.[299] In $[Fe(S_2CNEt_2)_3]$ the Fe—S distance changes from 2.357 Å at 297 K ($\mu_{eff} = 4.3$ BM) to 2.306 Å at 79 K ($\mu = 2.2$ BM) but in this case crystal packing is also different at these two temperatures.[301]

The contraction in Fe—S bond length accompanying the ${}^6A \rightarrow {}^2T$ spin change is also reflected in a change in the Fe—S stretching frequencies. With the aid of ^{54}Fe and ^{57}Fe isotopic substitution the assignment of ν(Fe—S) vibrations in the regions 210–240 cm^{-1} and 300–340 cm^{-1} for high- and low-spin forms, respectively, has been made.[302]

The ${}^6A_1 \rightleftharpoons {}^2T_2$ spin transition in dithiocarbamatoiron(III) complexes is sensitive not only to temperature, pressure and chemical modification but also to the number and nature of solvent

molecules included in the lattice structure.[290,303] With solvents such as benzene and nitrobenzene the equilibrium is shifted towards a low-spin ground state while in solvents such as H_2O, $CHCl_3$ and CH_2Cl_2 capable of hydrogen bonding the equilibrium is shifted towards the high-spin state. Although the symmetry of six-coordinate tris(dithiocarbamato)iron(III) complexes is that of a trigonally distorted octahedron rather than pure octahedral, the distortion would seem to be too small for a component, $^4A_2$ to ^4E, of the split $^4T_1$ ($t_{2g}^4 e_g$) level to become the ground state. However, it was speculated[303] that this might occur in the case of the CH_2Cl_2 solvate of tris(morphoinyldithiocarbamate)iron(III) whose magnetic moment appeared not to fall below values (~4 BM) appropriate to a spin quartet ground state even at very low temperatures. However, a subsequent detailed Mössbauer examination of this system by the same group,[304] and by others,[305] has shown conclusively that only sextet and double states are involved.

Treatment of the tris(dialkyldithiocarbamato)iron(III) complexes in benzene with a controlled amount of concentrated hydrohalic acid affords the black bis(ligand) complexes $[FeX(S_2CNR_2)_2]$ (X = Cl, Br or I).[306] For X = Cl the complexes may also be prepared by irradiation of the tris(ligand) complex in a halogenated solvent. This free radical reaction is believed to proceed *via* excited-state labilization of one ligand followed by attack of solvent.[307] Analogous complexes of pseudohalide ions (X = NCO^-, NCS^- or $NCSe^-$) have been obtained from reaction of the parent tris complex with the appropriate Ag^+ salt.[380] Representative complexes of this class have been shown by X-ray diffraction methods to have square pyramidal structures (**71**) in which the sulfur atoms of the two bidentate ligands comprise the basal plane (Fe—S ~ 2.228–2.30 Å) with the halide ion in the apical position (Fe—Cl ~ 2.26–2.28 Å).[309,310] In the cases examined the metal atom sits ~0.6 Å out of the mean S_4 plane in the direction of the apical halide ion.

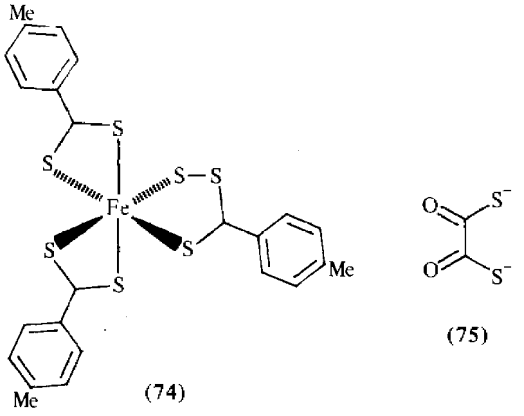


(71)

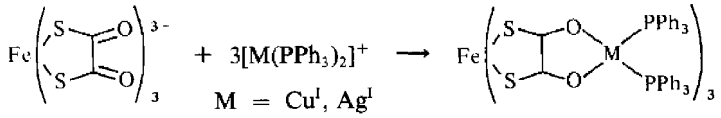
While for the tris(dithiocarbamate) complexes the symmetry is not sufficiently distorted from cubic to generate a spin-quartet ground state ($S = \frac{3}{2}$), this is no longer true for the square pyramidal bis(complexes) and these exhibit nearly temperature independent magnetic moments close to 3.9 BM corresponding to three unpaired electrons (Figure 1). ESR and magnetic anisotropy data are consistent with a $^4A_2$ ground state.[306,310] Large quadrupole splittings ($\Delta E \approx 2.7\ mm\ s^{-1}$) are consistent with the large electric field gradient at the iron nucleus expected for the C_{2v} point symmetry.[311]

Fe^{III} dithiocarbamates $[Fe(dtc)_3]$ undergo reversible or nearly reversible one-electron oxidations and one-electron reductions in polar organic solvents to generate Fe^{IV} and Fe^{II} species, respectively (equation 16). The bright yellow air-sensitive Fe^{II} complexes appear to be high spin while the Fe^{IV} systems (*vide infra*) have low-spin d^4 configurations.[282b]

$$[Fe^{IV}(dtc)_3]^+ \rightleftharpoons [Fe^{III}(dtc)_3] \rightleftharpoons [Fe^{II}(dtc)_3]^- \qquad (16)$$



1,1-Dicyanoethylene-2,2-dithiolate (**72**), which like the dithiocarbamates forms four-membered chelate rings, gives tris complexes with Fe^{III} which are high spin ($S = \frac{5}{2}$) with, presumably, six-coordinate structures.[312] The geometrical isomer 1,2-dicyanoethylene-1,2-dithiolate (**73**; R = CN) and related dithiolenes give five-membered chelate rings and form Fe^{III} complexes with a variety of structures and properties. The $[PPh_4]^+$ salt of $[Fe\{S_2C_2(CN)_2\}_3]^{3-}$ is low spin.[313] The bis complexes $[Fe\{S_2C_2(CN)_2\}_2]_2^n$ are dimeric in the solid state and constitute an electron transfer series with $n = 0$, -1 and -2. The structure of $[NBu_4]_2[Fe\{S_2C_2(CN)_2\}_2]_2$ has been determined. Each Fe atom has a square pyramidal geometry in which the basal plane contains four sulfur atoms (of two bidentate dithiolene anions) the apical position being occupied by a bridging sulfur atom of a second monomer unit. The magnetic properties are consistent with antiferromagnetically coupled $S = \frac{1}{2}$ spins.[314] The dimeric bis(dithiolene) complexes are cleaved by various monodentate bases to afford complexes of the type $[Fe(S_2C_2R_2)_2B]^-$. Those complexes in which B is a 'soft' ligand such as PPh_3, $AsPh_3$ RNC or CN^- have doublet ground states, while those where B is *e.g.* amine, phosphine oxide, halide or N_3^-, exhibit quartet ground states.[315]



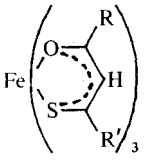
(72) (73)

The low-spin complex [Fe(*p*-tol CS_2)$_2$ (*p*-tol CS_3)] contains two four-membered chelate rings and one five-membered chelate ring (**74**) involving the metal–disulfide linkage. Fe—S distances in the five-membered chelate ring are slightly smaller than in the four-membered ring, while the S···S 'bite' distance is distinctly larger, as in dithiolene complexes.[316]

The dithiooxalate ion (**75**) binds to metal ions *via* the sulfur atoms, and the tris complexes with Fe^{III} may be low- or high-spin depending on the charge distribution within the ligand. Thus when the low-spin (μ_{eff} = 2.30 BM at 300 K) complex $[Ph_4As]_3[Fe(dto)_3]\cdot 3MeNO_2$ (**76**) was treated with the cations $[M(PPh_3)_2]^+$ M = Cu^I or Ag^I (reaction 17), the crystalline high-spin complexes (**77**) were obtained ($\mu_{eff} \simeq$ 5.9 BM).[317] Although the dithiooxalates show some electrochemical activity they are not subject to the same extensive electron delocalization which is a prominent feature of the dithiolenes; they are thus closer in properties to the thioxanthates in this respect.

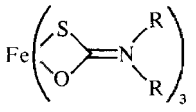
(74) (75)

(76) (77) (17)



Six-membered chelate rings are found in complexes of dithioacetylacetonate (SacSac). [Fe(Sacac)$_3$] may be obtained in crystalline form by reaction of Fe^{II} salts with acetylacetone and H_2S in acidified alcohol. The 'FeS_6' unit is a slightly distorted octahedron, two of three ligands being related by a two-fold symmetry axis with the third inequivalent ligand subtending a larger S—Fe—S angle. The mean Fe—S distance is 2.25 Å in good agreement with values found in other low-spin dithio chelates, and, as before, the metal–chelate rings are essentially planar. The low-spin nature of this complex inferred from magnetic susceptibility measurements (μ_{eff} = 2.00 BM at 293 K, 1.75 BM at 100 K) is confirmed by the large values of the quadrupole spitting (1.96 mm s^{-1} at 4.2 K) in the Mössbauer spectrum. A rhombic character is apparent from the observation of three g values in the ESR spectrum of the powder (g_1 = 2.14, g_2 = 2.09, g_3 = 2.01).[318]

The spin-pairing effect of sulfur as a donor atom is nicely illustrated by a comparison of the magnetic properties of the series of complexes [Fe(acac)$_3$], [Fe(Sacac)$_3$] and [Fe(SacSac)$_3$]. Thus, while the first has a high-spin ground state and the last is essentially fully low-spin, the asymmetrical 'O,S' ligand Sacac forms both high- and low-spin complexes (**78, 79**) depending on the nature of the ligand substituents. Thus, for R = R^1 = Ph the room temperature moment is 5.50 BM, while for R = CF_3, R^1 = Ph, it is 2.31 BM. A trigonal antiprismatic rather than trigonal prismatic arrangement of the *fac*-O_3S_3 donor set is seen in the values of the twist angles ϕ(52° in **78**, 60° in **79**) of the two parallel triangles defined by the three oxygen and the three sulfur donor atoms.[319]



There is a marked difference, for systems of comparable spin state, between the Fe—S bond lengths of four-membered chelate rings and those of six-membered chelate rings. The values of

~2.41 and ~2.32 Å found for high- and low-spin dithiocarbamates and xanthates are significantly larger than the values of 2.36 and 2.25 Å observed for (**78**) and (**79**).[319]

Complexes of the monothiocarbamate anion (R_2mtc) promise to have a coordination chemistry as rich as that of the dithiocarbamates and are the subject of a recent review.[284] The tris bidentate arrangement of ligands found in the six-coordinate dithiocarbamates is also found in the monothiocarbamates. In the complex [Fe(mtcMe$_2$)$_3$] the twist angle ϕ between the triangle formed by the three sulfur atoms and the parallel triangle formed by the three oxygen atoms was found to be 33.2°, *i.e.* intermediate between that ($\phi = 0°$) for a trigonal prismatic arrangement and that ($\phi = 60°$) for an trigonal antiprismatic (pseudooctahedral) arrangement, similar to the situation found in most analogous dithiocarbamato iron(III) complexes.[320] The two complexes (**80**) and (**81**) are also $^6A \rightleftharpoons {}^2T$ spin-equilibrium systems between 6 and 300 K although the former can also be obtained in a crystalline modification that remains high-spin down to 10 K. Mössbauer spectra at low temperatures indicate that the $^6A \rightleftharpoons {}^2T$ interconversion rates are $> \sim 10^7 s^{-1}$. A single ESR signal at $g = 4.3$ probably arises from rhombically distorted high-spin Fe^{III} isomers.[321]

(78) R = R′ = Ph
(79) R = CF_3, R′ = Ph

(80) R = Me
(81) R = Et

44.2.7 HALIDE COMPLEXES

In keeping with the 'hard' or 'class a' nature of the Fe^{3+} ion the most stable complexes are formed with the small non-polarizable F^- ion.[322] Consecutive formation constants for some fluoro and chloro complexes in aqueous solution may be found in ref. 322. Bromo complexes are even less stable than chloro complexes while with the easily oxidizable I^- ion no stable simple iodides have been prepared although a very few complexes containing Fe^{III}—I bonds are known in combination with other ligands. Consistent with the stability order $F^- > Cl^- > Br^-$ is the occurrence of higher coordination number Fe^{III} complexes with F^- than with Br^-. Thus, while F^- readily forms hexacoordinate $[FeF_6]^{3-}$ complex ions and no tetrafluoro complex ions, Cl^- forms both $[FeCl_6]^{3-}$ and $[FeCl_4]^-$ while Br^- apparently does not form a stable hexabromo complex $[FeBr_6]^{3-}$.

The anhydrous binary halides FeX_3 (X = F, Cl or Br) have near regular octahedral coordination as reflected in the absence of resolved splitting in the Mössbauer spectra (isomer shifts 0.49–0.55 mm s^{-1}). The hexahydrate, $FeCl_3 \cdot 6H_2O$, however, has a *trans* octahedral arrangement $[Fe(H_2O)_4Cl_2]Cl \cdot 2H_2O$ and exhibits pronounced quadrupole splitting.[27,323] The dihydrate and heptahydrate of pentafluorodiiron, $Fe_2F_5 \cdot 2H_2O$ and $Fe_2F_5 \cdot 7H_2O$ are Fe^{II}, Fe^{III} mixed valence systems. The structure of the red dihydrate has been determined.[324] It consists of a three-dimensional network with distinct Fe^{II} and Fe^{III} sites. The formally Fe^{III} ions occupy vertex-sharing 'FeF_6' octahedra while the Fe^{II} sites in '$Fe(H_2O)_2F_4$' share the vertex positions of the fluoride equatorial plane. The Fe^{III}—F and Fe^{II}—F distances are 1.941 and 2.060 Å, respectively. The structure is ferromagnetically ordered below 48 K but above this temperature distinct quadrupole-split absorptions for the two sites are apparent showing that this is a class II[40] mixed-valence compound.[325] The yellow heptahydrate, on the other hand, is formulated as $[Fe^{II}(H_2O)_6][Fe^{III}F_5(H_2O)]$ and therefore as a class I mixed-valence system.

A number of tetra-, penta- and hexa-fluoride anions are known, the last mentioned being the most important.[326] The tetra- and penta-fluorides have reduced magnetic moments and are probably polymers with fluoride bridges;[327] the hexafluorides containing the discrete $[FeF_6]^{3-}$ have magnetic moments close to 5.90 BM at room temperature.[328] The complex $K_2[FeF_5(H_2O)]$ also consists of discrete six-coordinate anions with one F^- ion replaced by a water molecule, although the anions are linked into chains by strong hydrogen bonds (O···F, 2.54 Å).[329]

A large number of complexes containing the tetrahedral $[FeCl_4]^-$ anion have been prepared; some have already been mentioned. Several single crystal X-ray structure determinations are available. Among the most accurate are those of $[AsPh_4][FeCl_4]$,[330] $[PCl_4][FeCl_4]$[311] and $[Fe(NCMe)_6][FeCl_4]_2$.[332] Fe—Cl distances (2.182–2.187 Å) agree well among the different structures although there are small departures in Cl—Fe—Cl angle from the tetrahedral value in some cases.

The complex of stoichiometry $(NMeH_3)_2FeBr_5$ should be formulated as $[NMeH_3]_2[FeBr_4]Br$ since it contains the tetrahedral $[FeBr_4]^-$ complex anion; mean Fe—Br distances are 2.32Å while the Br—Fe—Br angles vary up to 4° from the true tetrahedral value.[333] It has also been shown[334] that the complex of formula $(pyH)_3Fe_2Cl_9$ contains only the $[FeCl_4]^-$ ion and not the triply chloride-bridged dinuclear $[Fe_2Cl_9]^{3-}$ anion as first supposed; the complex should thus be formulated as the mixed salt $[pyH]_2[FeCl_4]_2 \cdot [pyH]Cl$.

The complete series of complexes $[NEt_4][FeX_{n-4}Y_n]^-$ (X = Cl, Y = Br, n = 0–4) has been synthesized and the far IR and Mössbauer spectra reported. The vibrational spectra are consistent with the lowering of the molecular symmetry from T_d to C_{3v} and from T_d to C_{2v} (Table 4). The reduction in symmetry is not reflected in the Mössbauer spectra, however, since a narrow unbroadened single peak was observed in all the spectra.[335]

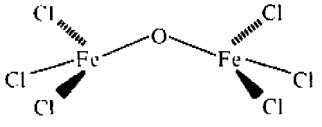


Table 4 IR and Mössbauer data[a] for $[Fe^{III}X_{(4-n)}Y_n]^-$ anions

Anion	*ν(Fe—X)* (cm^{-1})	*δ(X—Fe—X)* (cm^{-1})	*Isomer Shift at 77 K* ($mm\,s^{-1}$)
$[FeCl_4]^-$	388	137	0.282
$[FeCl_3Br]^-$	391, 350, 296	135, 117	0.285
$[FeCl_2Br_2]^-$	385, 348, 296, 266	126, 225, 74	0.321
$[FeClBr_3]^-$	384, 295, 270	120, 73	0.333
$[FeBr_4]^-$	294	98	0.350

[a] Data from ref. 335.
[b] Relative to natural iron.

The hexachloroferrate(III) anion $[FeCl_6]^{3-}$ may be stabilized in the solid state by the use of large cations such as $[Co(NH_3)_6]^{3+}$, $[Co(pn)_3]^{3+}$ (pn = 1,3-diaminopropane) and $[NMeH_3]^+$. Magnetic moments lie in the accepted range for high-spin ($S = \frac{5}{2}$) octahedral configurations as do the Mössbauer spectra also which consist of a single absorption at *ca.* $+0.5\,mm\,s^{-1}$ (*vs.* natural iron).[336] The vibrational spectra[337] and optical spectra[336] have been assigned.

Slow evaporation of aqueous solutions of $FeCl_3 \cdot 6H_2O$ and *e.g.* NH_4Cl or KCl affords salts of the six-coordinate $[FeCl_5(H_2O)]^{2-}$ anion. Single crystal Raman studies have been reported for this ion.[338] Several other complexes, in which one or more of the chlorides of $[FeCl_4]^-$ or $[FeCl_6]^{3-}$ have been replaced by other ligands, have been described and structurally characterized. The μ-oxo dinuclear complex $[pyH]_2[Cl_3Fe—O—FeCl_3] \cdot py$ (**82**) contains distorted tetrahedral '$FeOCl_3$' units bridged by the oxygen atom *via* short Fe—O bonds (1.755 Å), the Fe—O—Fe angle being 155.6°. The Cl—Fe—Cl and Cl—Fe—O angles are in the range 108–111° and the Fe—Cl distances (2.208–2.219 Å) are somewhat lengthened with respect to those in $[FeCl_4]^-$. As expected for the local C_{3v} symmetry about each Fe^{III} atom two IR active Fe—Cl stretching vibrations, *e* and a_1, are observed, at $360\,cm^{-1}$ and $311\,cm^{-1}$. Strong absorption at $860\,cm^{-1}$ is assigned to the Fe—O—Fe antisymmetric stretch. Strong antiferromagnetic coupling occurs between the $S = \frac{5}{2}$ spins. The coupling constant ($J = -92\,cm^{-1}$) is not appreciably different from values reported for other binuclear μ-oxo complexes in which the Fe^{III} ions are in a square pyramidal or octahedral environment. This is the first example of a binuclear Fe^{III} complex containing, apart from the bridge, only monodentate ligands, and the first example of a μ-oxo Fe^{III} complex having tetrahedral coordination.[339]

(82)

The complex $[Fe(4\text{-}CN\text{-}py)_2Cl_3]$ (4-CN-py = 4-cyanopyridine) is a trigonal bipyramid with the three Cl atoms occupying the equatorial sites and the pyridine ring nitrogens the axial positions.[340] This is one of a very few structurally defined trigonal pyramidal Fe^{III} complexes. An earlier example, $[Fe(N_3)_5]^{2-}$, has already been mentioned;[48] the complex $FeCl_3$(diox) (diox = dioxane) may have a similar geometry.[341]

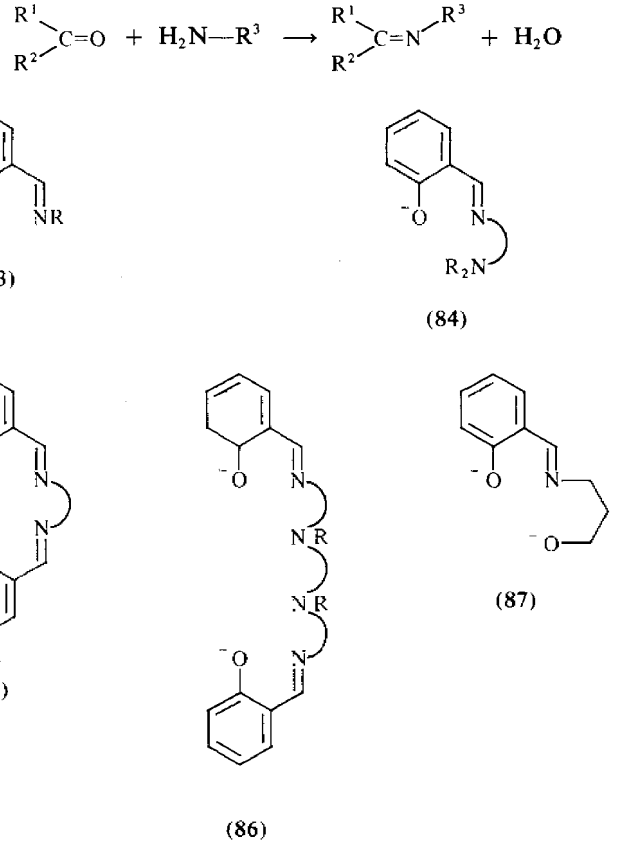
The molecular structure of the dimeric species $[Fe_2Cl_6]$ has been investigated by vapour phase electron diffraction. The two tetrahedral Fe^{III} atoms are bridged by two Cl atoms in a puckered Fe_2Cl_2 ring. As for related dimeric molecules such as $[Al_2Cl_6]$ the terminal Fe—Cl bonds (2.127 Å) are significantly stronger than the bridging Fe—Cl bonds (2.326 Å).[342]

44.2.8 COMPLEXES OF MIXED DONOR ATOM LIGANDS

44.2.8.1 Complexes of Schiff Base Ligands

In this section complexes of acyclic Schiff base ligands only are considered, macrocyclic Schiff base complexes are included in a later section.

Condensation reactions (equation 18) between carbonyl compounds and primary amines have provided one of the most important and widely studied classes of chelating ligand. A particularly important carbonyl precursor for the synthesis of Schiff base ligands is salicyaldehyde first used by Pfeiffer and Tsumaki.[343] A wide variety of ligand types may be obtained *via* the Schiff base condensation reaction which vary in denticity, flexibility, nature of donor atoms (in addition to nitrogen and oxygen) and in electronic properties. Some of the more important classes of ligand derived from salicyaldehyde are shown, in the anionic (deprotonated) form, in Figure 8. Within each class subtle alterations in coordinating characteristics can be achieved by variation in the nature of the R substituents and in the nature and position of the phenyl ring substituents. A wide diversity of coordination geometries and magnetic behaviour has been found.



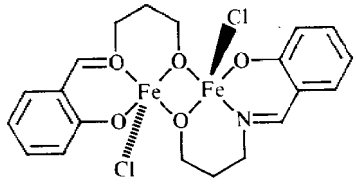


Figure 8 Some important classes of Schiff base ligands derived from salicylaldehyde

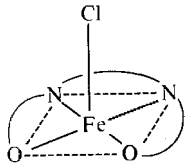
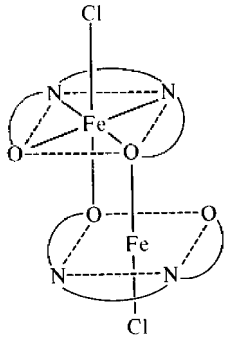
The bidentate *N*-substituted salicyaldimines (**83**) form complexes of stoichiometry $[Fe(salNR)_2X]$ (X = Cl or Br) which have high-spin ($S = \frac{5}{2}$) monomeric five-coordinate structures.[344] An X-ray investigation of the R = *n*-propyl, X = Cl derivative indicated a stereochemistry intermediate between trigonal bipyramidal and square pyramidal.[345] The derivative with R = 2-phenylethyl, X = Cl apparently exists in two crystalline modifications, one having a monomeric trigonal bipyramidal structure,[346] the other having a distorted structure intermediate between a trigonal bipyramid and a square pyramid which allows a loose association between adjacent monomer units.[347] This weak association leading to a phase change to a six-coordinate modification is suggested to be responsible for the reduction in magnetic moment, from the normal high-spin value, at temperatures below 140 K.



The complex $[Fe(salpa)Cl_2]_2$, where salpa is the tridentate dianionic ligand of type (**87**) formed from the reaction of salicyaldehyde with 3-aminopropanol, also contains five-coordinate Fe^{III} but, this time, in a genuinely dimeric structure (**88**). The iron atoms of the dimer are bridged by the

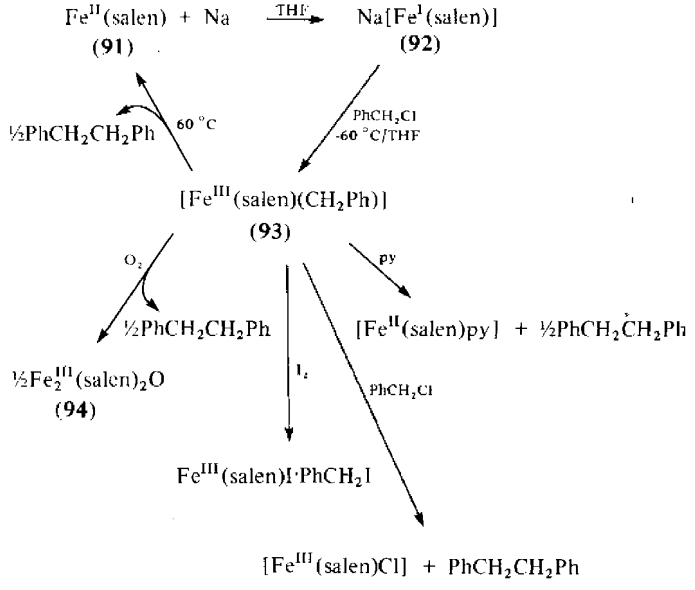
alkoxide oxygens to form a four-membered ring with Fe—O distances of 1.983 and 1.934 Å and angles of 75.9° and 104.1° at iron and oxygen, respectively. Considering the geometry as (distorted) square pyramidal the basal plane is made up of the donors of the tridentate ligand and the bridging alkoxide oxygen with the chlorine atom in the apical position. The magnetic behaviour accords with the occurrence of antiferromagnetic superexchange interaction mediated by the dialkoxy bridge, μ_{eff} having the reduced value of 4.52 BM at room temperature and falling further to 2.37 BM at liquid nitrogen temperature.



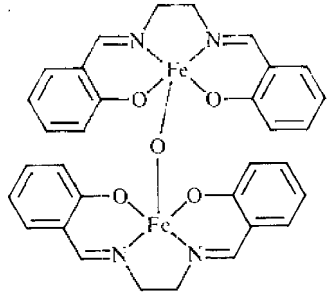
Reaction of $[Fe(salpa)Cl]_2$ with Na_2O_2 afforded the red crystalline complex $[Fe_2(salpa)(salpaH)_2]$·toluene in which salpaH is the monomeric form of the tridentate ligand.[348] In this dinuclear complex each Fe^{III} atom is six-coordinate and linked to the other *via* bridging propoxide groups in, once again, an almost planar four-membered Fe_2O_2 ring. Despite having nearly identical distorted octahedral geometries (with *trans* nitrogen atoms) the iron atoms are nevertheless non-equivalent. One iron atom is coordinated by two doubly deprotonated tridentate salpa ligands, the two propoxide groups which are in *cis* positions providing the bridging atoms for the dimeric unit. The second iron atom is coordinated by the two monodeprotonated salpaH ligands each acting in a bidentate fashion with uncoordinated OH groups. As in the dimeric five-coordinate complex described, the Fe^{III} centres are antiferromagnetically coupled with the coupling constant being in the range -5 to $-10\,cm^{-1}$.

(88)

(89)



(90)



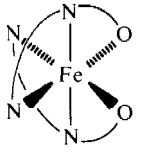
Condensation of two equivalents of salicyaldehyde with a diprimary amine, commonly 1,2-diaminoethane (en), provides a convenient route to tetradentate Schiff base ligands of type (**85**). For the case where the amine is en the product ligand is abbreviated as salen. Different modifications of the complex of formula Fe(salen)Cl may be obtained according to the method of preparation or isolation, one monomeric and one dimeric.[349] The monomeric form (**89**), obtained by recrystallization of the dimeric form from nitromethane and containing a molecule of solvent in the lattice, has a square pyramidal structure with the metal atom sitting ~0.46 Å above the best plane defined by the 'N_4O_2' donor set of the tetradentate ligand, in the direction of the apical Cl atom.[350] In the dimer (**90**), isolated from acetone solution, two molecules of monomer each share one oxygen atom from each salen ligand to give an overall octahedral coordination for each metal ion.[351] The bridging Fe—O bond, *trans* to the Fe—Cl bond, in the dimer is 0.24 Å longer than the mean of the Fe—O bonds in the N_4O_2 planes and may reflect the tendency for the dimer to dissociate into monomers in chloroform solution. The monomeric and dimeric Fe(salen)X (X = Cl or Br) complexes, and various ring substituted derivatives are readily distinguished on the basis of their magnetic properties.[349] The monomers have magnetic moments at room temperature close to the spin-only value of 5.92 BM and obey the Curie–Weiss law with small Weiss constant. The dimers, on the other hand, have subnormal room temperature moments which are further reduced on decrease in temperature. In these cases the magnetic data have been successfully fitted to the theoretical equation describing antiferromagnetic superexchange between pairs of interacting $S = \frac{5}{2}$ spins, yielding coupling constants J of between -6.5 and $-8.0\,cm^{-1}$ in different cases. IR and Mössbauer spectra also provide useful criteria for the recognition of monomeric and dimeric forms of Fe(salen)X complexes. Those compounds known or suspected to be dimeric displayed up to three bands between 800 and 900 cm^{-1}, while in compounds believed to be mononuclear a single band was observed in this region. Similarly Mössbauer isomer shifts and quadrupole splittings both tended to be smaller for the five-coordinate (mononuclear) complexes than for the six-coordinate (dinuclear) complexes.[352]

The preparation and properties of some unusual organometallic Fe^{III} complexes of salen have been described by Floriani and Calderazzo.[353] It was found that the iron(II) complex (**91**) can be reduced to the corresponding monoanion (**92**) by sodium in THF. The extremely air-sensitive

monoanion, believed to be a high-spin Fe^{I} d^7 species, behaves as a strong nucleophile and reacts at $-60°$ with benzyl chloride to give (**93**) (see Scheme 3), a rare example of a compound containing an Fe^{III}—carbon σ bond. This complex has a high-spin ($S = \frac{5}{2}$) configuration as evidenced by the magnetic moment of 5.87 BM at room temperature and presumably has a mononuclear square pyramidal structure similar to that of the mononuclear form of Fe(salen)Cl. The complex (**93**) is both thermally unstable and O_2 sensitive (Scheme 3) leading to reduction to Fe(salen) and oxidation to the μ-oxo complex (**94**), respectively, along with dibenzyl. The Fe—C bond is also cleaved by Lewis bases such as pyridine and cyclohexyl isocyanide and by reaction with benzyl chloride and I_2 (Scheme 3).

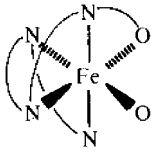
Scheme 3 Preparation and reactions of organometallic iron(III) complexes

(**94**)



A second series of dinuclear Fe^{III}–salen complexes [Fe(salen)O_2] (**94**) has been extensively investigated[354–357] following Pfeiffer and Tsumaki's first report.[343] These complexes have five-coordinate structures, in contrast to the six-coordinate [Fe(salen)Cl]$_2$ dimers, in which the two approximately square 'FeN_2O_2' moieties are linked by a single oxygen bridge. In two solvate modifications the Fe—O—Fe bridge angle has been shown[354,355] to be 139° and 142°. A much larger antiferromagnetic coupling occurs in the singly-bridged μ-oxo compounds than in the doubly oxygen-bridged [Fe(salen)Cl]$_2$ dimers already discussed, J having values in the range of -87 to $-100\,cm^{-1}$ for various members of the former class. Various possible reasons for the different exchange interactions can be considered. Firstly the Fe—O distances (1.97–1.98 Å) are appreciably shorter in the μ-oxo complex than those (1.92–2.18 Å) in [Fe(salen)Cl]$_2$. This would suggest a measure of multiple bonding in the former, possibly allowing transmission of exchange coupling *via* π as well as σ pathways. There is also a large difference in Fe—O—Fe angle in the two systems. Since a ferromagnetic interaction is predicted when the bridge angle is close to 90° it may be that the relatively small net antiferromagnetism in [Fe(salen)Cl]$_2$ is a result of the small Fe—O—Fe angles ($\sim 95°$) in this case. The products of reaction of [Fe_2(salen)$_2$O] with trichloroacetic, trifluoroacetic, salicylic and

picric acids are dimers of composition $[Fe(salen)X]_2$, where X is the conjugate base of the acid HX, with magnetic properties very similar to those of $[Fe(salen)Cl]_2$. A monomeric compound is formed on reaction with picolinic acid, however.



The reduced form of salen, salen-H, in which the two imino groups have been hydrogenated, also forms a dimeric complex $[Fe(salen\text{-}H)Cl]\cdot 2H_2O$ believed[358] to have a similar phenoxy-bridged six-coordinate structure to that of the parent Schiff base complex $[Fe(salen)Cl]_2$. However, this ligand gives a di-μ-hydroxo dimer $[Fe(salen\text{-}H)(OH)]_2\cdot 2H_2O\cdot 2py$ rather than a μ-oxo dimer and, as expected for a 'FeO_2Fe' bridging unit in which the bridge angles are relatively small (102.8° in this case), the superexchange coupling ($J = -10.4\,cm^{-1}$) is relatively weak.[359]

44.2.8.1.1 Spin-crossover iron(III)–Schiff base complexes

Several examples of high-spin ($S = \frac{5}{2}$) $\rightleftharpoons$ low-spin ($S = \frac{1}{2}$) systems have already been encountered in the section dealing with dithiocarbamato and related ligands. Iron(III) complexes of the tridentate and hexadentate Schiff base ligands of types (**84**) and (**86**) constitute new families providing many examples of spin crossover.[360–366] The bis(tridentate) and mono(hexadentate) ligand complexes both contain the metal ion in a distorted octahedral geometry, FeN_4O_2 core, in which the two terminal oxygen atoms occupy *cis* positions and the remaining four nitrogens (two *cis* amines and two *trans* imines) complete the coordination sphere structures (**95**) and (**96**). These complexes may be high-spin or low-spin depending on the nature and position of substituents, counterions, lattice solvent and even geometrical isomerism. In addition, the position of the spin equilbrium and the nature of the transition is significantly influenced by pressure and often by grinding[366] of the solid. Structures of several complexes of this class, in both spin states, are now available.[361–363] It is of particular interest to examine the effects of the spin change on bond lengths and other structural parameters. It has been observed, for example, that the average Fe–ligand bond length is longer by about 0.12 Å in the high-spin complex ($\mu_{eff} = 5.75$ BM at room temperature) $[Fe(X\text{-}salmeen)_2]PF_6$ (X = 5-OMe, salmeen = *N*-methylethylenediaminesalicylaldiminato anion, *i.e.* R = Me in structure **84**) than in the predominantly low-spin complexes where X = 3-OMe ($\mu_{eff} = 3.20$ BM) or X = 5-NO_2 ($\mu_{eff} = 2.58$ BM). However, the bond length difference is not uniform, the Fe—N bonds varying much more (~0.16 Å) than the Fe—O bonds (~0.02 Å).[363] Closely similar effects are also observed for complexes of the hexadentate ligands (**86**).[361] The $^2T \rightleftharpoons {}^6A$ spin equilibria are dependent on the nature of ring substituent X and, for solids, on the nature of the counterion. NO_2 as substituent favours the low-spin form while OMe as substituent favours the high-spin form relative to the parent unsubstituted complex. In solution the position of the spin equilibrium is solvent dependent. The effect of solvent is interpreted largely as arising from a specific hydrogen-bonding interaction of the solvent with the N—H groups of the trien backbone.[360] The $[Fe(X\text{-}sal)_2\ trien]^+$ complexes exhibit a reversible one-electron electrochemical reduction. From the temperature dependence of the half-wave potentials for the reduction it has been possible to determine the electron-transfer entropy change (ΔS_{et}) and to compare with this the entropy change (ΔS_{sc}) associated with the spin equilibrium. It was found that while ΔS_{sc} is almost constant for different systems, ΔS_{et} shows a considerable dependence on the high- and low-spin isomer populations, becoming larger as the low-spin fraction increases.[364] The question as to whether spin crossover occurs before (equation 19) or after (equation 20) electron transfer was approached by measurement of heterogeneous electron transfer rates. Results obtained strongly point to an overall electron transfer mechanism that involves spin conversion of Fe^{III}, prior to electron transfer, *i.e.* equation (19) and not equation (20).[365]

$$[Fe^{III}{}_{ls}(t_{2g}{}^5)] \overset{e^-}{\rightleftharpoons} [Fe^{II}{}_{ls}(t_{2g}{}^6)] \overset{SC}{\rightleftharpoons} [Fe^{II}{}_{hs}(t_{2g}{}^4 e_g{}^2)] \quad (20)$$

Both ultrasonic and laser Raman temperature jump techniques have been applied to the measurement of the spin state interconversions (equation 21) in solution.[361–369] On the basis of measurements on a range of complexes it was concluded that intersystem crossing rates are faster in solution than in the solid state, as judged from Mössbauer spectra, and faster for the bis complexes of the tridentate ligands than for those of the hexadentate ligands. Data pertaining to some differently substituted $[Fe(X\text{-salmeen})_2]^+$ complexes are in Table 5.[367]

[a] Data from ref. 367. [b] K_{eq} = [hs]/[ls] at temperature T in °C in parenthesis.

A limited number of Fe^{III} complexes with sulfur-containing Schiff base ligands derived from thiosalicylaldehyde have been prepared. Among these is the complex $[\{Fe(tsalen)\}_2O]\cdot py$ obtained from reactions of the Fe^{II} complex Fe(tsalen) with O_2 (tsalen is the sulfur analogue of the tetradentate ligand salen). Like the salen complex the sulfur analogue also contains a μ-oxo linkage and a square pyramidal arrangement for each Fe(tsalen)O unit. The Fe—O—Fe bond angle is 159°, *i.e.* somewhat larger than in corresponding salen complexes but within the range of bond angles found in Fe^{III}—O—Fe^{III} complexes generally. A point of difference between $[\{Fe(salen)\}_2O]$ and $[\{Fe(t\text{-}salen)\}_2O]$ is that while the metal ions in the 'oxygen' ligand complex are in the $S = \frac{5}{2}$ state and strongly coupled, in the 'sulfur' complex the Fe^{III} ions are $S = \frac{1}{2}$ and weakly coupled. Low-spin Fe^{III} also occurs in the bis complexes of the tridentate ligand (tsaleten), the sulfur analogues of ligand type **(84)**.[368–370]

44.2.8.2 Complexes of Aminocarboxylates, Amino Acids and Related Ligands

The polydentate anions of the polyamine-polycarboxylic acids are well known to form stable high coordination number complexes with a wide range of metal ions. Edta is, of course, the best known. In the complexes $Li[Fe(edta)(H_2O)]\cdot 2H_2O$ and $Rb[Fe(edta)(H_2O)]\cdot H_2O$ the hexadentate edta tetraanion and one H_2O molecule provide the seven donor atoms for a pentagonal bipyramidal coordination shell for each Fe^{III} ion.[371] In $[Fe(edtaH)(H_2O)]$ the coordination number of the metal ion is six since one carboxylic acid group of the ligand is protonated and uncoordinated.[372] The complex $Ca[Fe(DCTA)(H_2O)]_2$ contains seven-coordinate Fe^{III} (DCTA = *trans*-1,2-diaminocyclohexane-*N*,*N*′-tetraacetate).[373] The coordination numbers of the central Fe^{III} atom in the chelates of diethylenetriaminepentaacetic acid H_5DTPA and several of its salts are variable, six in the complex of the parent acid, seven in the mono $[NH_4]^+$ salt and eight in the dialkali metal salts.[374]

The dimeric complex $[Fe_2(edta)_2O]^{4-}$ is formed by base hydrolysis of the mononuclear complexes.[375] The X-ray structure of the related complex $[enH_2][Fe_2(Hedta)_2O]\cdot 6H_2O$ has been determined (Hedta = *N*-hydroxyethylenediaminetriacetate). Each Hedta ligand is pentadentate and the two Fe(Hedta) moieties are linked by a near linear (165°) Fe—O—Fe bridge.[376] As found for other μ-oxo bridged di-Fe^{III} complexes already mentioned, these complexes are also antiferromagnetically coupled with $J \approx -95\,cm^{-1}$. The complexes also exhibit a series of ligand field bands of enhanced intensity in the visible region and a number of higher energy absorptions which have been assigned to simultaneous pair electronic excitations arising from coupled LF transitions.[375]

44.2.8.2.1 Hemerythrin and model compounds

An important group of naturally occurring amino acids complexes of iron are the hemerythrins —the oxygen-carrying proteins in a variety of marine worms. Most hemerythrins have molecular

weights of about 108 000 and consist of eight subunits each of which contains a binuclear iron active site. As a result of the application of modern physical methods such as EXAFS, resonance Raman and Mössbauer spectroscopy, as well as crystallographic studies, together with conventional chemical and biochemical studies, a very useful picture of the nature of the active site in hemerythrin has now emerged.[377]

The oxidation states present in the different forms of hemerythrin are indicated in Figure 9. The colourless deoxy form reversibly binds O_2 in the ratio of $2Fe:O_2$ to give the burgundy coloured oxy form. In addition, an oxidized met form containing only Fe^{III} but no O_2 may be obtained as well as a mixed valence semi-met form [Fe^{III}, Fe^{II}]. Assignment of oxidation states originally based on chemical reactions[378] has been amply confirmed by spectroscopic[379–382] measurements. Moreover, the presence of a μ-oxo bridge between the metal centres in the oxy and met forms of the protein became apparent from magnetic studies and from Mössabuer,[380] optical and vibrational spectra. The exchange coupling constants J of $-134\,cm^{-1}$ for met hemerythrin and of $-77\,cm^{-1}$ for oxyhemerythrin[383] are not too different from the range of values of -90 to $-130\,cm^{-1}$ found in synthetic compounds containing μ-oxo linkages. These structural conclusions have been confirmed by various crystallographic studies[384,385] of the met and azidomet forms, the latest of these being carried out at 2.0 Å resolution. In the met form one of the two iron atoms is octahedrally coordinated while the second iron atom is in a highly distorted trigonal bipyramidal environment. In addition to the μ-oxo bridge the metal centres are also linked by the carboxylate groups of glutamate and aspartate groups. Remaining coordination sites are taken by nitrogen atoms from histidine residues of the amino acid side chains (Figure 10). Addition of azide converts the five-coordinate centre in met hemerythrin to octahedral with accompanying minor changes in bond lengths and angles and conformational changes in the protein. Although there is some disagreement between X-ray and EXAFS studies in relation to bond angles and distances, the main geometrical features of the oxy and met forms of the protein appear well established.

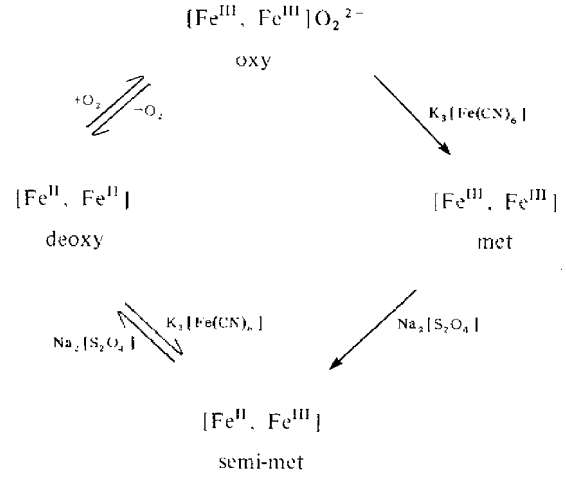

Figure 9 Interconversion of different forms of hemerythrin

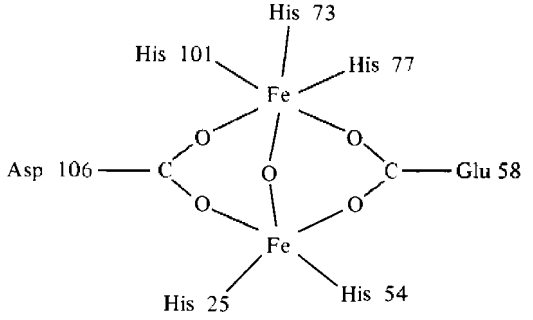

Figure 10 The coordination of the two Fe^{III} ions in met hemerythrin

A (μ-oxo)bis(μ-carboxylato)diiron(III) core in a model for met hemerythrin has been prepared by spontaneous 'self-assembly' in aqueous solutions of iron(III) perchlorate, sodium acetate and sodium tri-1-pyrazolylborate.[386] The resulting binuclear complex was shown to be very similar in structure and properties to that of met hemerythrin. Thus, the two Fe^{III} atoms are linked *via* a μ-oxo

bridge (Fe—O—Fe = 123.5°) and two μ-acetato bridges, the remaining coordination sites being filled by the tridentate pyrazolylborate ligands. Antiferromagnetic behaviour with $J = -122\,cm^{-1}$ compared well with that ($J = -134\,cm^{-1}$) for metaquo hemerythrin.[386]

EXAFS spectra[387] of the deoxy[Fe^{II}, Fe^{II}] form of hemerythrin suggest the absence of the μ-oxo bridge, in agreement with the lack of antiferromagnetic coupling. Analysis of the data suggests that on conversion of oxy- to deoxy-hemerythrin (equation 22) the bound O_2 is replaced by OH^- and the short bond to the bridging oxygen atom is broken, leaving it bound to one iron. Thus, one iron becomes five-coordinate while the other remains six-coordinate.

$$[Fe^{III}—O—Fe^{III}—O_2] + H_2O \rightleftharpoons [Fe^{II}—OH, Fe^{II}—OH] + O_2 \quad (22)$$

Of central interest in the chemistry of hemerythrin is the mode of interaction of O_2 with the binuclear Fe^{III} active site. Several structural models (**97–101** in Figure 11) have been considered, all incorporating a peroxido diiron(III) formalism, as required by the resonance Raman identification of ν(O—O) at 844 cm^{-1}, and its displacement to 796 cm^{-1} on $^{18}O_2$ isotopic substitution.[388] The use of unsymmetrically labelled dioxygen, $^{16}O^{18}O$, has been of service in discriminating between the symmetrically bound O_2 adducts (**97**), (**98**) and (**101**) and the asymmetric models (**9**) and (**100**). For the former a single symmetric O—O stretch would be expected whereas ν(O—O) should be a doublet if either of the unsymmetrical structures (**99**) or (**100**) is the correct one. The RR results obtained strongly favour the unsymmetrical structure (**99**) or (**100**).[389] In fact, structure (**100**) in which the peroxo group is terminally bound to one Fe^{III} centre, taking the place of the azide ligand in metazido hemerythrin, is the preferred structural candidate on present knowledge.

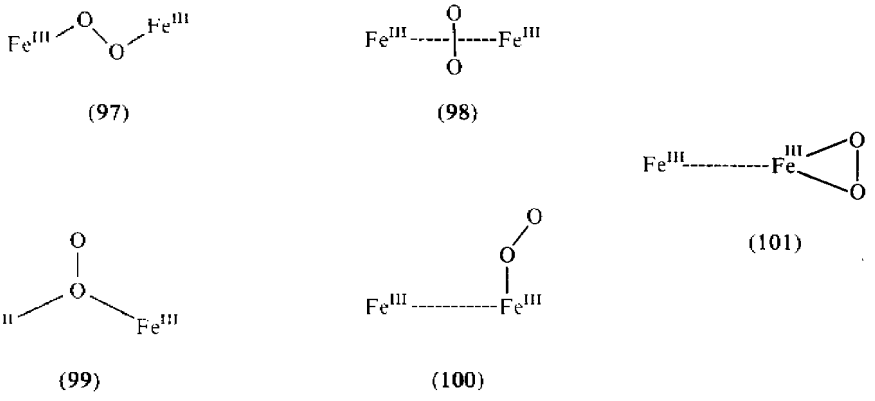

Figure 11 Idealized structural representations for the $Fe_2 \cdot O_2$ active site in hemerythrin

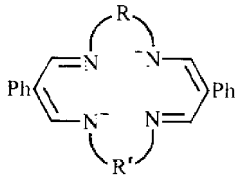
44.2.9 MACROCYCLIC LIGANDS

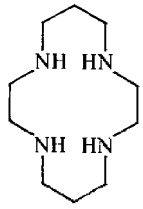
Complexes of large ring compounds containing a set of suitably positioned donor atoms—macrocyclic ligands—have engaged the attention of chemists for a long time but particularly over the last two decades. A major stimulus for the study of macrocyclic compounds has been the desire to mimic and probe the function of certain metal ions in natural systems where they are known to be ligated to macrocyclic molecules. These include, of course, the well-known porphyrin and corrin rings containing a planar array of four nitrogen atoms. Iron(III) complexes of porphyrins will be considered in a later section. We first consider some iron(III) complexes of synthetic macrocylic ligands.

44.2.9.1 Synthetic Macrocyclic Ligands



Nearly all iron complexes of synthetic macrocyclic ligands contain nitrogen either as the only ligand atom or as the major donor present. Moreover, most macrocyclic ligands are tetradentate usually presenting a roughly planar 'N_4' donor set to the centrally complexed metal ion. The comprehensive review by Melson[390] of the coordination chemistry of macrocyclic compounds should be consulted for work published up until 1978.

Iron(III) complexes of tetradentate 'N_4' macrocyclic ligands may be five-coordinate (square pyramidal) or six-coordinate (approximately octahedral), and high-spin ($S = \frac{5}{2}$), intermediate spin



($S = \frac{3}{2}$) or low-spin ($S = \frac{1}{2}$), depending on the nature of the macrocyclic ligand, *i.e.* its size and degree of unsaturation, and on the number of the axial ligands.

Examples of iron(III) complexes displaying all three ground states within the same family of macrocycles are found among complexes of the 14-, 15- and 16-membered ligands (**102**), (**103**) and (**104**).[391] The five-coordinate complexes $[Fe^{III}N_4X]$ have the intermediate ($S = \frac{3}{2}$) spin ground state when the macrocycle is 14- or 15-membered and where X = halide or carboxylate, whereas analogous compounds of the 16-membered macrocycle (**104**) are high spin ($S = \frac{5}{2}$). For the case of X = thiolate, all three spin states were found: *viz.* [14]-SPh, $S = \frac{1}{2}$; [15, 16]-SPh, $S = \frac{3}{2}$; [16]-SCH_2Ph, $S = \frac{5}{2}$. The results demonstrate the effects of ring size and axial ligand on spin state (Table 6).

The spin state of the six-coordinate complexes $[Fe(cyclam)X_2]^+$ [cyclam = 1,4,8,11-tetraazacyclotetradecane (**105**)] is governed by the geometrical configuration of the 14-membered macrocycle, being high-spin for the *cis* complexes and low-spin for the *trans* complexes. However, *trans*-$[Fe(cyclam)Br_2][ClO_4]$ with $\mu_{eff} = 3.90$ BM at 295 K may exist in a high-spin $\rightleftharpoons$ low-spin equilibrium.[392]

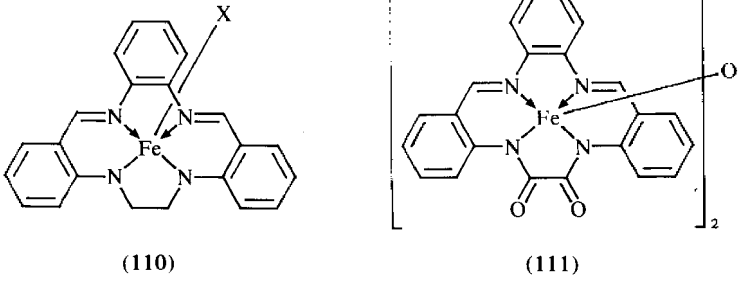
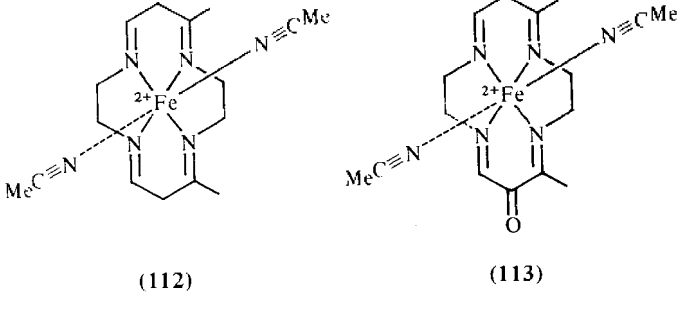
[a] From ref. 391. [b] Relative to iron metal.

Iron has been found to be very effective in promoting the oxidative dehydrogenation of secondary amine groups bound to the metal as part of a macrocyclic ligand generating new macrocyclic complexes having higher degrees of unsaturation.[393–395] One example is the preparation of, successively, the triimine complex (**108**) and the tetraimine complex (**109**) from the diimine complex (**106**) (see Scheme 4). Atmospheric oxygen readily performs the oxidation under the influence of Fe^{III}, while stronger oxidizing agents are generally required in the case of nickel or copper complexes. Although reactant and product complexes contain the metal ion in the +2 oxidation state there seems little doubt that a first step in the oxidative dehydrogenation is an oxidation of Fe^{II} to Fe^{III}, this being followed by an electron transfer, with accompanying deprotonation, from the coordinated secondary amine group to Fe^{III}. Oxidation of the radical so formed then generates the new imine centre (Scheme 5).[393] The intermediate iron(III) complex [Fe([14]4,11-diene-N_4)$(MeCN)_2$][ClO_4]$_3$ (**107**) has been isolated. This, and other derivatives containing coordinated Cl^- or NCS^- in place of MeCN, are low-spin ($\mu_{eff} = 2.15$–2.30 BM).[394]

(**106**) (**107**) (**108**) (**109**)



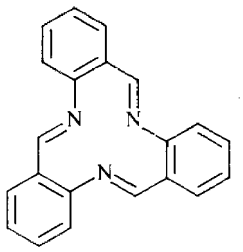
Scheme 4 Proposed pathway for the generation of triimine and tetraimine complexes *via* oxidative dehydrogenation



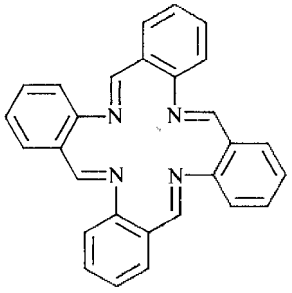
Scheme 5 Proposed radical mechanism for the iron-promoted oxidative dehydrogenation of a coordinated secondary amine group[393]

An interesting Fe^{III}-mediated macrocyclic ligand *oxygenation* has been observed.[396] When the Fe^{III} complex (**110**; X = $MeCO_2$) in DMF was heated for 6 h at 80°C black needles were slowly deposited. X-Ray analysis revealed that the product is the μ-oxo dimer (**111**) in which the —N—CH_2—CH_2—N— bridge of the reactant macrocyclic has been oxidized to the oxamido ligand. It was suggested that this oxidation also proceeds *via* a radical mechanism in which the initial step is elimination of acetic acid and generation of an Fe^{II} radical species.

Ligand oxygenation (**112** → **113**) of Fe^{II} complexes of bis(β-diimine) macrocycles by molecular oxygen has also been observed. Again, an Fe^{III}-mediated radical mechanism has been suggested for this oxidation.[397]

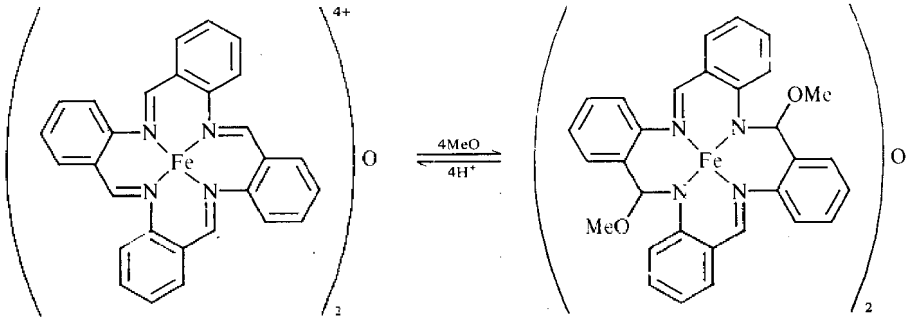


(**110**) (**111**)

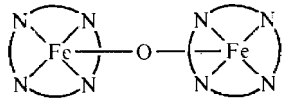


(**112**) (**113**)

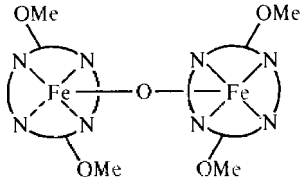
Many of the synthetic macrocyclic ligands have been synthesized by metal ion template methods. One of the best examples is provided by the self-condensation reactions of *o*-aminobenzaldehyde.[390,398] In the absence of metal ions, *o*-aminobenzaldehyde gives a variety of polycyclic structures. In the presence of certain metal ions complexes of the tridentate macrocycle (**114**) and/or of the tetradentate macrocycle (TAAB) (**115**) may be obtained. Among those in the latter category are the dinuclear Fe^{III} complexes $[Fe_2(TAAB)_2O]X_4 \cdot 4H_2O$ (X = ClO_4 or NO_3) (**116**) and the mononuclear complexes $[Fe(TAAB)F]X_2 \cdot 2H_2O$. Magnetic and other properties have established μ-oxo structures for the binuclear complexes, with the expected strong antiferromagnetic coupling ($J = -65$ to $-111\ cm^{-1}$). The μ-oxo bridge is cleaved, with difficulty, by acid fluoride to generate the low-spin mononuclear species. An interesting reaction of the μ-oxo dimers is that with methoxide ion giving complexes (**117**) of the new dianionic ligand formed by nucleophilic addition of the OMe^- to two imine bonds.[398]



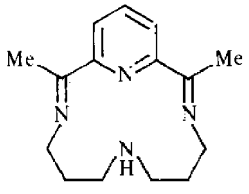
An early demonstration of the template effect in the synthesis of macrocyclic ligands was the metal-ion-controlled cyclic condensation of 2,6-diacetylpyridine with 3,3′-diaminodipropylamine to give complexes of the 14-membered 'N_4' ring (**118**), usually abbreviated (Me_2pyo[14]triene N_4).[399] Effective template ions include Ni^{II}, Co^{II} and Cu^{II}. Well-characterized iron complexes have not been



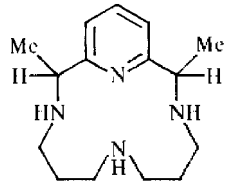
(114)



(115)



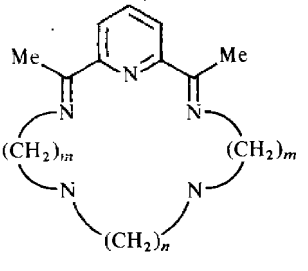
(116)



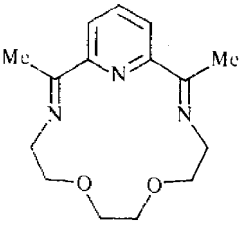
(117)

obtained. However, the two C=N bonds of (**118**) may be hydrogenated to afford the macrocycle (**119**), Me_2pyo[14]ene N_4, which can exist in *meso* and racemic forms. Fe^{III} derivatives of the *meso* ligand have been prepared. These have the formula $[Fe(Me_2pyo[14]ene N_4)X_2]Y$ (X = Cl or Br; Y = ClO_4 or BF_4) and, on the evidence of the magnetic properties and Mössbauer spectra, are assigned low-spin six-coordinate structures. They show excellent catalytic activity for the decomposition of H_2O_2 in aqueous acid solution.[400]

(118)

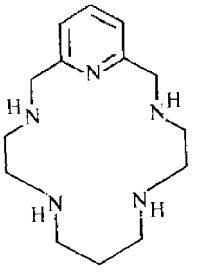


(119)



Extension of the metal ion template method to condensations between 2,6-diacetylpyridine with other linear polyamines has proven successful in many cases. Thus, for example, Fe^{III} salts are effective templates for the synthesis of the pentadentate macrocycles (**120**), (**121**) and (**123**) denoted (222-N_5), (232-N_5) and (222-N_3O_2), respectively, but not for the (323-N_5) macrocycle (**122**).[401–403] The template action of the metal ion was evidenced by the fact that in its absence the products of reaction were oils or gums, indicative of an oligomeric or polymeric constitution. Such materials showed IR in bands at $\sim 1700\,cm^{-1}$ and/or $\sim 3300\,cm^{-1}$ indicating the presence of unreacted keto and/or primary amine groups. In contrast, in the presence of an equimolar quantity of Fe^{III} salt, crystalline high-spin complexes of stoichiometry $[Fe(mac)X_2]Y$ (X = *e.g.* Cl, Br, I or NCS; Y = ClO_4, NO_3, BF_4, BPh_4 or PF_6) were obtained from acid solutions. In basic media antiferromagnetically coupled

dinuclear complexes containing μ-oxo bridges are obtained. In both series of complexes, mononuclear or binuclear, the pentadentate macrocyclic ligand maintains an approximately planar array of donor atoms around the central metal ion. Two monodentate ligands above and below this pentagonal plane complete the pentagonal bipyramidal geometry of the complexes. Single crystal structure determinations of $[Fe(222\text{-}N_5)(NCS)_2][ClO_4]$[402,404], $[Fe(232\text{-}N_5)(NCS)_2][ClO_4]$[402] and $[Fe_2(222\text{-}N_5)_2(ClO_4)_2O][ClO_4]_2\cdot H_2O$[404] have been carried out. Cyclic voltammetry has shown that the mononuclear Fe^{III} complexes undergo two one-electron processes in acetonitrile solution. The more positive (reversible) process can be ascribed to the Fe^{III}/Fe^{II} couple, and the more negative reduction (reversible at fast scan speeds) corresponds to the formation of a ligand radical anion, *i.e.* addition of an electron to the lowest antibonding orbital of the conjugated pyridyl–diimino system. The Fe^{III}/Fe^{II} couple occurs in the range $+0.3$ to -0.4 V *vs.* SCE depending somewhat on the nature of the axial ligands as well as on the particular macrocyclic ligand. The values of the couples suggested that the Fe^{II} complexes should have reasonable stability to oxidation. In agreement with this prediction crystalline Fe^{II} complexes of all three macrocycles could be prepared by dithionite reduction.[405] Structural studies and various physical properties have established the retention of the basic pentagonal bipyramidal structure on reduction. Despite the differences in size of Fe^{3+} and Fe^{2+} there is little change in the average Fe—N(macrocycle) bond length on change of oxidation state. What does occur, however, is a movement of the metal closer to the unsaturated (trimethine) segment of the macrocycle on reduction.[406] This is attributed to a measure of metal-to-macrocycle back coordination in the lower oxidation state. The apparent instability of the Fe^{III} complex of the 17-membered 'N_5' macrocycle (**122**) is presumably a consequence of a mismatch in size between metal ion and macrocycle cavity in this case. Mössbauer spectra of several of the high-spin seven-coordinate complexes $[Fe(222\text{-}N_5)X_2]ClO_4$ have been measured over a range of temperatures. The temperature dependent spectra were interpreted in terms of paramagnetic relaxation effects; a correlation between the electric field gradient and the zero-field splitting was demonstrated and shown to change sign as the field strength of the axial ligand X was varied.[407] The complexes are photochemically active[408,409] to a degree dependent on the nature of the axial ligands, leading to reduction of the metal centre and oxidation of the axially coordinated ligand.[409]



Reaction of the Fe^{II} complexes of $222\text{-}N_5$ and $232\text{-}N_5$ with O_2 leads to formation of the μ-oxo dimers. It is conceivable that an intermediate in the formation of the μ-oxo dimer is a μ-peroxo–di-iron(III) species as proposed for reactions of other Fe^{II} complexes with O_2. Evidence for the stabilization of the μ-peroxo species in aqueous solution has been adduced by Kimura *et al.*[410] for the case of the Fe^{II} complex of the related saturated macrocycle (**124**). This yellow Fe^{II} complex absorbs O_2, non-reversibly, in aqueous solution in the ratio of one O_2 per two Fe, forming a red purple solution stable for up to 3 h at ambient temperature.[410]

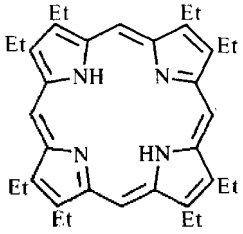
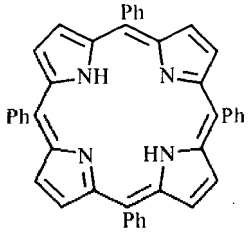
(124)



44.2.9.2 Porphyrins and Related Ligands

Iron porphyrins serve as the prosthetic group for the biologically important class of proteins known as the hemoproteins. These include the oxygen transport and storage proteins, hemoglobin and myoglobin, the electron carrier cytochromes, as well as various oxidase and oxygenase enzymes. As a result, the hemoproteins and synthetic iron porphyrin complexes have received much attention. A vast literature has now accumulated, particularly over the past few years, and it is therefore quite impossible to do other than indicate the principal classes of iron(III) porphyrin complex known to occur, together with a brief description of the structures and properties of some representative examples. Many comprehensive reviews are available.[411–416]



The parent ligand porphine has the planar conjugated tetrapyrrole ring structure (**125**) containing a 16-membered inner larger ring. In the naturally occurring metalloporphyrins all eight pyrrole carbon atoms are completely substituted. Commonly used synthetic porphyrins are octaethylporphyrin (H_2OEP) (**126**) and *meso*-tetraphenylporphyrin (H_2TPP) (**127**).

(125)

(126)

(127)

In the metal complexes the two pyrrole hydrogens are usually replaced by the metal ion so that porphyrin is coordinating as the dianion. Because of the conjugated nature of the dianionic porphyrin ring the hole size is fairly well fixed (some variability *via* ring puckering is permitted) at about 2.01 ± 0.08 Å. Thus, while some metal ions may sit in the hole in the same plane as the ring, others, being too large, may be forced to sit out-of-plane. Usually, though not always, the metal ion will be bound to all four nitrogen donors of the porphyrin ring. The metal ion can then acquire five- or six-coordination by binding one or two monodentate ligands in axial positions. Indeed, higher coordination numbers are found in several cases but for iron porphyrin complexes coordination numbers are restricted to four, five and six, and to five and six only for the case of Fe^{III} complexes.

The properties of a particular iron porphyrin are controlled in several different ways—by variation in the nature and position of porphyrin ring substituents, the number and nature of axial ligands, and the spin state and oxidation state of the metal ion. Not least, the protein itself in the natural systems plays a major role in the tailoring of the properties of the prosthetic group for the particular biological function it is to perform.

Most six-coordinate Fe^{III}–porphinato complexes, $[Fe(por)L_2]^+$, have low-spin ($S = \frac{1}{2}$) configurations.[413,417–420] In such cases, the equatorial Fe—N distances are close to 1.99 Å and Fe—N(axial) distances usually less than 2.0 Å. Displacements of the Fe atom out of the porphyrin 'N_4' plane are usually small. However, a number of complexes in which the axially ligating group is relatively weak field display high-spin ($S = \frac{5}{2}$) ⇌ low-spin ($S = \frac{1}{2}$) spin equilibria at accessible temperatures[421,422] or are actually fully high-spin as in the case of $[Fe(TPP)F_2]^-$ and $[Fe(TPP)(EtOH)_2]^+$.[423,424] The distinctive differences in magnetic properties and in Mössbauer and ESR spectra of the two classes are clearly reflected in the structural parameters as may be seen from an inspection of the data in Table 7. Thus, for the low-spin complexes the average Fe^{III}–N(porphyrin) distance in the low-spin complexes (vacant $d_{x^2-y^2}$ orbital) is < 2.00 Å whereas in the high-spin complexes (occupied $d_{x^2-y^2}$ orbital) this bond length is an excess of 2.00 Å.

Five-coordinate (square pyramidal) Fe^{III} complexes[425–427] containing a single axial ligand are generally high-spin ($S = \frac{5}{2}$) with the metal atom displaced from the porphyrin 'N_4' plane in the direction of the apical ligand.[413] Structural data for some representative examples are in Table 8.

However, more recently, a number of intermediate spin ($S = \frac{3}{2}$) iron(III) complexes have been prepared.[429–434] Stabilization of this spin state can be expected, in either square pyramidal or tetragonal symmetry, whenever the axial ligand field is very weak compared to the equatorial ligand field, such that $d_{x^2-y^2}$ lies well above d_{z^2} in energy and remains unoccupied. Examples of $S = \frac{3}{2}$ complexes are $[Fe(OEP)(ClO_4)]$[429] $[Fe(OEP)(EtOH)_2][ClO_4]$,[429,434] $[Fe(TPP)(ClO_4)]$[430] and $[Fe(TPP)(H_2O)_2][ClO_4]$[430] in which the axial ligands are the weakly bonding ClO_4^- ion or EtOH and H_2O molecules. Several of the complexes of thic class have effective magnetic moments at room temperature in the range 4.5–5.5 BM, significantly larger than expected for an $S = \frac{3}{2}$ state. Since Mössbauer spectra and other properties exclude the existence of a thermal equilibrium between magnetically distinct spin states, it has been postulated[435] that there is a quantum admixture of $S = \frac{3}{2}$ and $S = \frac{5}{2}$ states. Quantum mechanical admixing, presumed to occur *via* spin–orbit coupling when the energy separation between the pure states is small, may be recognized also on the basis of unusual $g \approx 4$ ESR signals as well as by a drop in magnetic moment at low temperatures.

A common product of the autoxidation of iron(II) porphyrins is the μ-oxo dimer[436,439] (equation 23), a reaction of importance in relation to O_2 transport and utilization in nature. These μ-oxo dimers contain two high-spin ($S = \frac{5}{2}$) Fe^{III} ions which are antiferromagnetically coupled through the oxo bridge,[437,438] as noted above for several other classes of μ-oxo Fe^{III} complex. An alternative route to the μ-oxo dimers is reaction of mononuclear [Fe(por)X] (X = *e.g.* Cl) with OH^-. The geometry[439] of the coordination sphere in the five-coordinate μ-oxo dimers approximates very closely to that found in the uncoupled five-coordinate monomers (see Table 8). In $[Fe_2(TPP)_2O]$ the bridge is near linear with Fe—O—Fe = 174.5°. It is interesting to compare the μ-oxo complex $[Fe_2(TPP)_2O]$[439] with the μ-nitrido complex $[Fe_2(TPP)_2N]$.[440] Structural parameters, specifically the short Fe—N(por) distance (1.99 Å) and the relatively small out-of-plane displacement (0.32 Å) of the Fe^{III} atom from the porphyrin ring are suggestive of a low-spin ($S = \frac{1}{2}$) ground state (compare with data in Table 8). Similar conclusions were reached on the basis of X-ray photoelectron studies.[441] On the other hand Mössbauer spectra[442] appear to favour a high-spin description with a formal oxidation state of Fe^{III}, Fe^{III} or rapidly exchanging Fe^{III}, Fe^{IV}, while a resonance Raman study[443] likewise favours the high-spin Fe^{III} formulation.

$$4Fe^{II} + O_2 \longrightarrow 2Fe^{III}—O—Fe^{III} \qquad (23)$$

The mechanism of the autoxidation of Fe^{II} porphyrins has been studied in detail by visible and ^1H NMR spectroscopy.[444] This is an important reaction and its understanding, and circumvention, have formed the basis of the strategies for the design of synthetic iron(II) complexes capable of the reversible binding of O_2. As mentioned above the usual ultimate product of Fe^{II} porphyrin autoxidation is the μ-oxo dimer. La Mar and Balch and co-workers[444] have shown that addition of O_2 to toluene solutions of $Fe^{II}P$ (**128**) (P = a porphyrin dianion) leads to the formation of an intermediate (**130**) which may be detected at -80°C by visible and ^1H NMR spectra. This intermediate has been formulated as a peroxo-bridged diiron(III) species on the basis of its antiferromagnetism in solution and the stoichiometry of its formation. Upon warming, this μ-peroxo complex decomposes quantitatively to the μ-oxo species (**132**) together with O_2. This reaction has been shown to be first order in (**130**). The overall mechanism for the autoxidation is summarized in equations (24)–(30). The formation of the Fe^{IV} species (**131**) is consistent with other information on this oxidation state of iron (*vide infra*). Evidence for a different kind of Fe^{III} porphyrin–peroxo complex in solution has been presented. This mononuclear species formulated as $[Fe^{III}(por)(O_2)]^-$ (por = TPP or OEP) appears to be produced *via* a redox reaction between Fe^{II} porphyrin and O_2^-. Visible, IR, resonance Raman and ESR spectra support a formulation of the complexes in which the peroxide is bidentately coordinated to Fe^{III} in the 'sideways-on' (Griffiths) fashion (structure **133**).[445]

The low temperature spectroscopic observation of the Fe^{IV} ferryl complex (**134**) [P = TPP, B = py, pip or *N*-Me-im] formed *via* reaction (31) has been followed by the demonstration by the same group of its role in oxygen atom transfer reactions. Thus, it was found[446] that PFe^{II} catalyzes

$$Fe^{II}P + O_2 \longrightarrow O_2Fe^{II}P \quad (24)$$
(128) (129)

$$PFe^{II}O_2 + Fe^{II}P \longrightarrow PFe^{III}—O_2—Fe^{III}P \quad (25)$$

the oxidation of triphenylphosphine in toluene to triphenylphosphine oxide. It is considered[446] that $PFe^{IV}O$ is the active oxidant and that the catalytic cycle in Scheme 6 applies. Fe^{III} species such as [FePCl], $[FePB_2]^+$ and [PFe—O—FeP] were inactive, though the μ-oxo dimer of phthalocyanatoiron(III) [PcFe—O—FePc] can apparently perform the same oxidation in the presence of pyridine under mild conditions.[447]

$$PFe^{III}—O—O—Fe^{III}P + 2B \longrightarrow 2BPFe^{IV} \quad (31)$$

44.2.9.2.1 The heme proteins

In the heme proteins the prosthetic group consists of iron coordinated to a substituted porphyrin. The versatility of the heme proteins is apparent in the range of different functions they perform, mediate or catalyze. These functions are associated with, for example, dioxygen transport (hemog-

lobin), dioxygen storage (myoglobin), electron transfer (cytochromes), catalysis of oxygenation reactions such as hydroxylation (cytochrome P_{450}), and of oxidation involving hydrogen peroxide (peroxidases and catalases). The adaptation of the heme protein to a particular function is controlled by a variety of structural and other factors, often in intriguing and subtle ways. These include alteration of the substitution pattern of the porphyrin ring (affecting *e.g.* the redox potential of the metal centre), the nature of the axial ligation at the iron centre (affecting spin state, reactivity and redox potential), and the conformational/structural/interactive relationships of the prosthetic group with the amino acid chain of the protein. In all of these metalloproteins the redox activity of the coordinated metal ion is central to the biological function, all involving changes in oxidation state during an operational cycle. Usually the cycling in oxidation state is between +2 and +3 but higher oxidation states may also be involved.

The dioxygen-carrying proteins, hemoglobin and myoglobin, as well as the many synthetic model systems that have been developed recently,[448] will not be considered here in this chapter since their chemistry is mainly that of iron in the +2 oxidation state. The present chapter is therefore restricted to a brief description of the structure and reactivity of some cytochrome and peroxidase proteins.

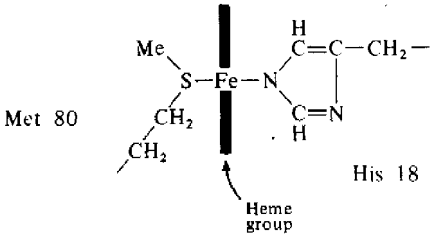
44.2.9.2.2 Electron transport heme proteins

The cytochromes are the electron carrier heme proteins occurring in the mitochondrial respiratory chain.[449] There are five cytochromes linking coenzymes Q (ubiquinone) and O_2 in this electron transport chain (Scheme 7). Cytochromes are also involved in energy transfer in photosynthesis. The iron atom in cytochromes cycles between the Fe^{II} and Fe^{III} states, *i.e.* they are one-electron carriers, in contrast to CoQ and the NADH flavins they act upon which are two-electron carriers. Thus, one molecule of reduced CoQ transfer its two high potential electrons to two molecules of cytochrome b, the next member of the electron transport chain.

$$\text{CoQ} \rightarrow \text{cyt b} \rightarrow \text{cyt } c_1 \rightarrow \text{cyt c} \rightarrow \text{cyt}(a + a_3) \rightarrow O_2$$

Scheme 7 The electron transport chain linking coenzyme Q and O_2

The five cytochromes between CoQ and O_2 (Scheme 7) increase incrementally in redox potential, spanning an overall potential of about one volt. The various cytochromes differ in structure and properties. In cyt b, cyt c_1 and cyt c the prosthetic group is heme itself, iron–protoporphyrin-IX, as in hemoglobin and myoglobin. Cytochrome c is structurally well defined in both the Fe^{II} and Fe^{III} states.[450] It consists of a polypeptide chain of 104 amino acid residues and a covalently attached heme group. One axial site of the iron atom is occupied by the nitrogen from a histidine residue and the other axial site by a sulfur atom from a methionine residue of the protein chain (Figure 12). Thus, unlike myoglobin and hemoglobin, cytochrome c functions without change in axial ligation. Indeed, as reinforced by studies on model compounds of low-spin Fe^{II} and Fe^{III} porphyrins containing axial thioether ligands, there is little alteration in Fe—S bond length as change of oxidation state of the metal.[451]



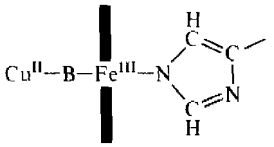


Figure 12 The heme group in cytochrome c showing the axial ligation to methionine and histidine residues of the protein chain

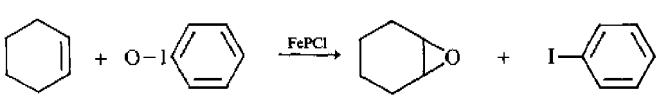
An interesting feature of cytochrome c, which is present in all organisms that contain a mitochondrial respiratory chain, is that it has remained virtually unchanged since it evolved more than 1.5×10^9 years ago.

Reduced cytochrome c passes its electron on to the next member of the respiratory chain, cytochrome $(a + a_3)$. These two cytochromes, together known as cytochrome c oxidase, comprise two iron–porphyrin prosthetic groups and two copper centres. Electrons are transferred to cytochrome a and then to a_3 which contains Cu which cycles between the +1 and +2 oxidation states. The net function performed by this terminal member of the electron transport chain is the four-elec-

tron reduction of O_2 to H_2O with release of energy which is stored in the ADP–ATP cycle, and the reoxidation of reduced cyt c to the oxidized form (equation 32).[452,453] Various spectroscopic (ESR,[454] MCD[455]) and magnetic studies[455] have shown that the enzyme contains one isolated heme unit (cytochrome a) which is low-spin in both the oxidized and reduced forms and one isolated copper centre which is ESR active. The second heme unit (cytochrome a_3), believed to be the O_2 binding site, is associated with the second copper atom which is EPR undetectable. Variable temperature magnetic susceptibility measurements have shown that the iron atom of the fully oxidized (resting) form of the enzyme is in the $S = \frac{5}{2}$ spin state and strongly antiferromagnetically coupled to the EPR non-detectable copper atom in the $S = \frac{1}{2}$ spin state.[456] The data indicate a coupling constant $-J$ of $\geqslant 200\,cm^{-1}$, leading to a resultant $S = 2$ ground state, for the spin-coupled [Fe—B—Cu] dimer. One axial position of the coordination sphere of the iron atom in cyt a_3 is believed to be an imidazole group[457] while the other is occupied by a bridging ligand B responsible for the superexchange interaction with the Cu^{II} ion (structure **135**). The nature of the bridging ligand B remains uncertain. Several candidates have been proposed on the basis of the properties of various model binuclear complexes containing coupled Fe^{III}–Cu^{II} pairs. These include the imidazolate ion (from a histidine residue of the protein),[454,456,458] an oxo (or hydroxo) bridge (derived from O_2 itself)[459,460] and a thiolate group (from a cystein residue).[461]

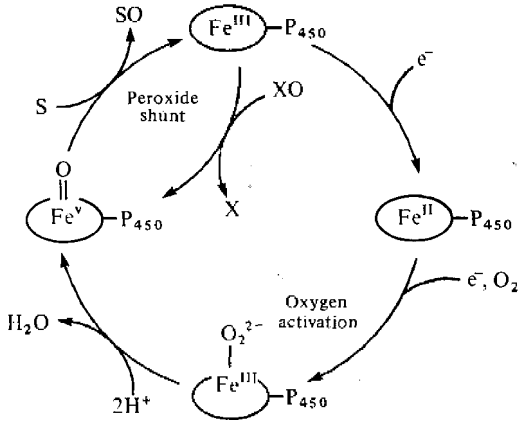
$$4\text{cyt c}^{II} + O_2 + 4H^+ \longrightarrow 4\text{cyt c}^{III} + 2H_2O \qquad (32)$$

(135)



44.2.9.2.3 Cytochrome P_{450}, peroxidase and catalase enzymes

Cytochrome P_{450}, named after the wavelength (in nm) of the absorption maximum of the carbon monoxide complex of the reduced form, is not an electron transport protein but actually a monoxygenase enzyme which catalyzes the incorporation of one atom of O_2 into an organic substrate while the second atom is reduced to H_2O. A common activity is the catalytic hydroxylation of substrates (equation 33) which include hydrocarbons and steroids. Other oxidations mediated by P_{450} enzymes are epoxidation, oxidative group transfer involving involving a 1,2-carbon shift with concomitant incorporation of oxygen as a carbonyl group at the C-1 position, and heteroatom oxygenation.[462–464] The active site of P_{450} comprises an iron protoporphyrin IX moiety in a hydrophobic cleft in the surface of the apoprotein. The metal ion is always five- or six-coordinate. One axial ligand is believed to be the thiolate anion from a cysteine residue of the polypeptide chain. The second axial position is the site for O_2 binding. The mechanism of hydroxylation of substrates by cyt P_{450} was first proposed to be an oxenoid process in which an oxene species inserted into a carbon–hydrogen bond in a manner analogous to carbenes. Subsequently, Groves and co-workers[463,465] demonstrated that alkane hydroxylation proceeded by a stepwise process involving the formation of a carbon-centred free radical *via* hydrogen abstraction by a perferryl (Fe^V=O) intermediate (equation 34). A significant discovery was that exogenous oxygen donors such as iodosylbenzene and alkyl hydroperoxides are effective oxygen sources for the enzyme in the absence of dioxygen and a reducing agent. This suggested that dioxygen is bound and reduced to metal-bound peroxide at the active site. The epoxidation of alkenes by iodosylbenzene (equation 35) was also found to be catalyzed by synthetic iron porphyrins. The mechanism[466] for the epoxidation using either O_2 or PhIO is summarized in Scheme 8.



Peroxidase and catalase enzymes catalyze oxidations by hydrogen peroxide and the disproportionation of hydrogen peroxide into dioxygen and water (equations 36 and 37). The two classes of

$$RH + O_2 + 2H^+ + 2e^- \longrightarrow ROH + H_2O \qquad (33)$$

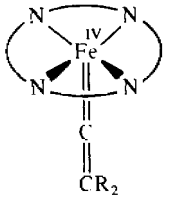
$$[Fe^V{=}O] \xrightarrow{RH} [Fe(OH) + R\cdot] \longrightarrow Fe^{III} + ROH \qquad (34)$$

(35)

Scheme 8 A catalytic cycle for oxygen activation and transfer by cytochrome P_{450} (S = substrate, *e.g.* alkene; X = *e.g.* iodosylbenzene)[466]

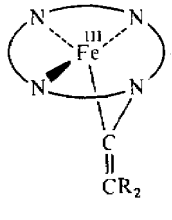
enzyme have strong similarities, not only in function but also in structure and mechanism of action.[467,468] These heme proteins have attracted much attention in recent years because, like cytochrome P_{450}, they appear to involve novel high oxidation state species of iron as intermediates in the redox cycles and because the oxo–iron species, in synthetic compounds, may have practical value as catalysts in the functionalization of organic molecules. The best characterized enzyme of this class is horseradish peroxidase (**HRP**). This contains protoporphyrin IX and in the resting state the iron is in the +3 oxidation state, probably coordinated to an imidazole nitrogen atom (from a histidine residue) in one axial position with, possibly, an exchangeable aquo group in the sixth position.[468,469] There is evidence for both high- and low-spin forms of the Fe^{III} ion. Upon reaction with H_2O_2 or organic peroxides the iron(III) prosthetic group undergoes a two-electron oxidation to generate a green compound HRP-I which then may undergo a one-electron reduction to give the red species HRP-II. The collective evidence of a variety of spectroscopic and other studies strongly favours a low-spin ($S = 1$) Fe^{IV} formulation for both HRP-I and HRP-II, with the porphyrin ring forming a π-cation radical in the case of HRP-I (equations 38 and 39).[470–473] Similar considerations probably apply to the catalase family of enzymes.[474]

$$H_2O_2 + SH_2 \xrightarrow{\text{peroxidase}} 2H_2O + S \quad (36)$$



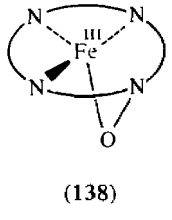
$$H_2O_2 + H_2O_2 \xrightarrow{\text{catalase}} 2H_2O + O_2 \quad (37)$$

$$[PFe^{III}] + H_2O_2 \longrightarrow \underset{\text{[HRP-I]}}{[\cdot PFe^{IV}{=}O]} + H_2O \quad (38)$$



$$[\cdot PFe^{IV}{=}O] + R \longrightarrow \underset{\text{[HRP-II]}}{[PFe^{IV}{=}O]} + \cdot R \quad (39)$$

Oxidation products of Fe^{III} porphyrin complexes may not always involve Fe^{IV}, however. Thus, magnetic, Mössbauer and structural studies on [Fe(TPP)Cl][$SbCl_6$] allow assignment as an Fe^{III} ($S = \frac{5}{2}$) complex of a radical porphyrin cation.[475]



Recently synthesized iron porphyrin–carbene complexes (**136**) may be considered as carbon analogues of the oxo–iron(IV) porphyrin (HRP-II and CAT-II) species.[476] The one-electron oxidation of [Fe(TPP)(C=CR_2)] (R = aryl) by $CuCl_2$ affords the stable complex [Fe(TPP)(C=CR_2)] Cl (TPP = *meso*-tetra-*p*-tolyl porphyrin and R = *p*-ClC_6H_4) which has a visible spectrum very similar to that of CAT-I. X-Ray analysis of this complex has revealed a structure (**137**) in which the vinylidene moiety has inserted between the iron atom and one pyrrole ring of the porphyrin and it is suggested that this may constitute a model, *i.e.* structure (**138**), for the active site of CAT-I as an alternative to the Fe^{IV} cation radical model.[477]

(136)

(137)

(138)

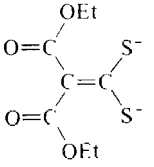
44.2.10 IRON(IV), IRON(V) AND IRON(VI)

Usually, high oxidation states of metals are stabilized most effectively when in combination with the most electronegative atoms, fluorine and oxygen. Rather surprisingly, no Fe^{IV} or higher oxidation state compounds with fluorine are known. Indeed rather few stable or well-defined higher oxidation state iron compounds are known. Despite this, there can be no doubt about the importance of such compounds. We have already encountered the Fe^{IV} and Fe^{V} states in reactive intermediates in the reactions of several metalloproteins and of several synthetic porphyrin complexes.

The Sr^{2+} and Ba^{2+} salts of the ferrates(IV), Sr_2FeO_4 and Ba_2FeO_4, may be prepared by oxidation of a mixture of hydrated iron(III) oxide with the alkaline earth metal oxide or hydroxide with oxygen at 800–900°C (equation 40).[478] These black compounds do not contain discrete $[FeO_4]^{4-}$ ions and are really mixed metal oxides. They are readily decomposed by mineral acids to Fe^{III} and O_2. Vibrational spectra of some of these systems have been recorded.[479]

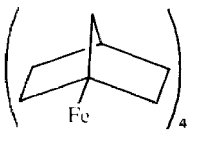
$$Sr_3[Fe(OH)_6]_2 + Sr(OH)_2 + \tfrac{1}{2}O_2 \longrightarrow 2Sr[FeO_4] + 7H_2O \qquad (40)$$

The oxidation of the iron(III) complexes $[Fe(DAS)_2X_2][FeX_4]$ (DAS = *o*-phenylenebisdimethylarsine, X = Cl, Br) with concentrated nitric acid followed by addition of the appropriate anion led to the isolation of black $[Fe(DAS)_2X_2]Y_2$ ($Y = BF_4^-$, ClO_4^-, ReO_4^-).[480] The magnetic properties indicate two unpaired electrons consistent with a low-spin t_{2g}^4 configuration in a tetragonal (*trans* halide) structure. Mössbauer quadrupole splittings are large ($\sim 3.2\,mm\,s^{-1}$) and temperature independent.[481]



The most stable iron(IV) complexes are those containing dithiocarbamate and related ligands. Reaction of tris(dithiocarbamato)iron(III) complexes $[Fe^{III}(S_2CNR_2)_3]$ (R = Me, Et, Pr^i, cyclohexyl) with BF_3 in the presence of air yields the complexes $[Fe^{IV}(S_2CNR_2)_3]BF_4$. Salts containing other counterions such as PF_6^- and ClO_4^- may be obtained by variations in the preparative methods.[482,483] I_2 may be used as oxidant in certain cases.[483] These intensely coloured complexes have magnetic moments at room temperature in the range 3.2–3.4 BM, measured in chloroform solution. These values are consistent with low-spin ($S = 1$) ground states when allowance is made for some distortion from cubic symmetry. Mössbauer isomer shifts in the range 0.1–0.2 mm s^{-1} relative to iron metal are lower than those characteristic of Fe^{III} compounds consistent with the removal of one *d* electron from Fe^{III} (d^5) to give Fe^{IV} (d^4). Quadrupole splittings are in the range 2.0–2.5 mm s^{-1}, *i.e.* somewhat smaller than observed for the tetragonal $[Fe(DAS)X_2]^{2+}$ complexes mentioned above, but still much larger than the splitting usually observed for Fe^{III} complexes.[482,284] The structure of the cation in $[Fe(S_2CNR_2)_3]ClO_4$ [$R_2 = (CH_2)_4$] is very similar to that of the corresponding Fe^{III} complex. There is, however, a significant shortening (0.11 Å) in the average Fe—S distance as expected for a depopulation of the antibonding e_g orbital, as well as for the higher formal charge on the metal.[485] As found for many Fe^{III} complexes of 'sulfur' ligands, the 'FeS_6' core in the Fe^{IV} complex conforms neither to the ideal octahedral nor trigonal prismatic arrangements, the angle of twist between the triangular faces being 38°.

Despite the ambiguity regarding the assignment of formal oxidation states to metal and ligand in many dithiolate complexes, the structure and properties of the benzyltriphenylphosphonium salt of tris(1,1-dicarboethoxyethylene-2,2-dithiolato)ferrate $[BzPh_3P]_2[Fe(DED)_3]$ (DED = structure **139**) are considered[486] to be best described in terms of an Fe^{IV} complex. The structure is close in important details to that of the dithiocarbamate complex described above.[485]



Mixed valence Fe^{III}, Fe^{IV} oxo-bridged dimers $[Fe_2L_2O]X$ (L = TPP or salen; X = PF_6, BF_4, ClO_4 or I_3) have been prepared by oxidation of the μ-oxo diiron(III) complexes.[487,488] Antiferromagnetic exchange interaction was indicated by the variable temperature magnetic susceptibility data which could be fitted to the theoretical equations for an isotropic exchange ($H = -2J\,S_1 \cdot S_2$) in an $S_1 = \frac{5}{2}$, $S_2 = 2$ dimer. The exchange parameter J was found to fall in the range -7.5 to $-17.6\,cm^{-1}$ for $[Fe_2(salen)_2O]X$ and in the range -82.5 to $-119\,cm^{-1}$ for $[Fe_2(TPP)_2O]X$. Mössbauer spectra of both series of complexes, recorded at 4.2 and 77 K, consisted of a single quadrupole-split doublet, showing that the rate of electron transfer between the metal centres is faster than $\sim 10^7\,s^{-1}$. The ESR spectra of the salen complexes were reported to consist of a single isotropic signal at $g \simeq 2.0$, this being somewhat temperature dependent in line width. This behaviour is consistent with a thermal intervalence electron transfer rate of the order of $10^{10}\,s^{-1}$. For the $[Fe_2(TPP)_2O]X$ complexes either a high-spin Fe^{III} ESR signal or no ESR signal was observed suggesting that thermal electron transfer rates are less than $10^{10}\,s^{-1}$ in these cases.[488] $[Fe_2(TPP)_2O]$ can also be oxidized electrochemically to $[Fe_2(TPP)_2O]^{2+}$ which may be formulated either as $[Fe^{IV}—O—Fe^{IV}]$ or $[Fe^{IV}—O—Fe^{III}(por^+)]$.[489]

An organometallic compound containing iron formally in the +4 oxidation state is the purple

tetralkyl $[Fe(nor)_4]$ (**140**) (nor = 1-norbornyl) formed by reaction of $FeCl_3 \cdot OEt$ with 1-norbornyllithium. The stability of this complex and of those of other transition metal ions is probably associated with the bulky nature of the alkyl ligand which serves to protect the metal from attack by reagents.[490]

(139)

(140)

The + 5 oxidation state of iron is very rare and has been firmly established only for the ferrate(V) oxyanion $[FeO_4]^{3-}$. The K^+ salt has been prepared by heating K_2FeO_4 with KOH in O_2 at 700–800°C or from KO_x and Fe_2O_3 in O_2 at similar temperatures.[491,492] An impure form of Na_3FeO_4 has been obtained on heating Na_3FeO_3 in O_2 at high pressure. X-Ray investigations indicate a tetrahedral structure for the $[FeO_4]^{3-}$ anion.

Iron(V) has been suggested to occur as intermediates in the reactions of various biological systems, *e.g.* in HRP-I. However, as noted above, this species is probably best regarded as an Fe^{IV} complex of the porphyrin radical cation.

The chemistry of iron(VI) is confined to that of the ferrate(VI) $[FeO_4]^{2-}$ ion. $K_2[FeO_4]$ may be prepared by the oxidation of hydrated Fe_2O_3 in concentrated aqueous alkali with KClO or KBrO (equation 41)[491,493]. Electrolysis of concentrated alkali solutions with an iron anode has also been employed as a method for the preparation of $[FeO_4]^{2-}$.[494,495] Pure materials appear to be limited to the salts with alkali metal ions and Ba^{2+}. The purple salts contain discrete tetrahedral $[FeO_4]^{2-}$ anions and the alkali metal salts have the orthorhombic β-K_2SO_4 structure.[493,496] The magnetic moments are in the range 2.8–3.2 BM consistent with the presence of two unpaired electrons.[493,497] Electronic,[498] ESR[499] and Mössbauer[500] spectra have been reported.

The ferrate(VI) ion is moderately stable in concentrated alkali solution but decomposes rapidly in neutral or acidic solutions according to equation (42). The strong oxidizing power of $[FeO_4]^{2-}$ is reflected in the redox couple of ~ 2.0 V for the half reaction (equation 43). The ferrate(VI) ion is a stronger oxidizing agent than permanganate and has found application in the oxidation of alcohols and other organic compounds.[501–503]

$$Fe_2O_3 \cdot 3H_2O + 4OH^- + 3ClO^- \longrightarrow 2[FeO_4]^{2-} + 3Cl^- + 5H_2O \quad (41)$$

$$2[FeO_4]^{2-} + 10H^+ \longrightarrow 2Fe^{3+} + 5H_2O + \tfrac{3}{2}O_2 \quad (42)$$

$$[FeO_4]^{2-} + 8H^+ + 3e^- \rightleftharpoons Fe^{3+} + 4H_2O \quad (43)$$

Ruthenium

MARTIN SCHRÖDER and T. ANTHONY STEPHENSON
University of Edinburgh, UK

45.1 INTRODUCTION 279
45.2 MERCURY-CONTAINING LIGANDS 280
45.3 GROUP IV LIGANDS 281
45.3.1 Cyanides and Fulminates 281
45.3.1.1 Ruthenium(I) cyanides 281
45.3.1.2 Ruthenium(II) cyanides 281
45.3.1.3 Ruthenium(III) cyanides 283
45.3.1.4 Ruthenium(IV), (V) and (VII) cyano complexes 284
45.3.2 Silicon-containing Ligands 284
45.3.2.1 Carbonyl complexes 284
45.3.2.2 Carbonyl complexes containing group IV, V or VI donor ligands 285
45.3.2.3 Tertiary phosphine and arsine complexes 287
45.3.3 Germanium-containing Ligands 287
45.3.4 Tin-containing Ligands 287
45.3.4.1 Ruthenium(II) halide complexes 287
45.3.4.2 Ruthenium(II) carbonyl and carbonyl halide complexes 288
45.3.4.3 Ruthenium(II) complexes containing group IV, V or VI donor ligands 288
45.3.5 Lead-containing Ligands 289
45.4 NITROGEN LIGANDS 289
45.4.1 Ammines 289
45.4.1.1 Mononuclear complexes $[Ru(NH_3)_6]^{x+}$ 289
45.4.1.2 Mononuclear complexes $[RuL_n(NH_3)_{6-n}]^{x+}$ 291
45.4.1.3 Binuclear complexes 311
45.4.1.4 Tri- and poly-nuclear complexes 320
45.4.2 Amines 321
45.4.2.1 Mononuclear complexes $[RuL_6]^{2+}$ 321
45.4.2.2 Mononuclear complexes $[RuL_3]^{2+/3+}$ 321
45.4.2.3 Mononuclear complexes with nitrogen donor ligands 322
45.4.2.4 Mononuclear complexes with oxygen donor ligands 323
45.4.2.5 Mononuclear complexes with halide ligands 324
45.4.2.6 Binuclear complexes 325
45.4.3 Heterocycles 325
45.4.3.1 Mononuclear complexes 325
45.4.3.2 Binuclear and polynuclear complexes 357
45.4.4 Nitrosyls 361
45.4.4.1 Nitrogen donor complexes 361
45.4.4.2 Oxygen donor complexes 362
45.4.4.3 Sulfur donor complexes 362
45.4.4.4 Halide complexes 362
45.4.5 Hydrazines, Diimines and Related Ligands 363
45.4.6 Nitrides 364
45.4.7 Thiocyanates 365
45.4.8 Nitriles 365
45.5 PHOSPHORUS, ARSENIC AND ANTIMONY LIGANDS 366
45.5.1 Mononuclear Ruthenium(0) Complexes 366
45.5.1.1 RuL_5, $RuL_nL'_{5-n}$, $RuL_nL'_{4-n}$ *complexes (L = P donor; L' = P donor, MeCN, alkene)* 366
45.5.1.2 Nitrosyl complexes 367
45.5.1.3 Carbonyl and/or isocyanide complexes 370
45.5.2 Bi-, Tri- and Tetra-nuclear Ruthenium(0) Complexes 372
45.5.2.1 Nitrosyl complexes 372
45.5.2.2 Carbonyl complexes 373
45.5.3 Ruthenium(I) Complexes 374
45.5.3.1 Mononuclear complexes 374
45.5.3.2 Bi- and tetra-nuclear complexes 374

45.5.4 Mononuclear Ruthenium(II) Complexes 376
45.5.4.1 $[RuL_6]^{2+}$, $[RuXL_n]^{+}$ (n = 4,5), $[RuX(L—L)_2]^{+}$, $[RuL']^{2+}$ cations (X = halide, alkyl etc.) 376
45.5.4.2 $[RuXYL_n]$ complexes (n = 2,3,4; X,Y = halide) 377
45.5.4.3 $[RuXY(L\text{-}L)_n]$ complexes (n = 2,3; X,Y = halide) 379
45.5.4.4 Polydentate P, As or Sb donor ligand halide complexes 380
45.5.4.5 Carbon donor ligand complexes 380
45.5.4.6 Nitrogen donor ligand complexes 391
45.5.4.7 Oxygen donor ligand complexes 399
45.5.4.8 Sulfur donor ligand complexes 404
45.5.4.9 Mixed donor atom (P–N, P–O, P–S) ligands 408
45.5.5 Bi-, Tri-, Tetra- and Poly-nuclear Ruthenium(II) Complexes 410
45.5.5.1 Triple halide-bridged complexes (and related species) 410
45.5.5.2 Double halide-bridged complexes (and related species) 413
45.5.5.3 Binuclear complexes with polydentate phosphine bridges 414
45.5.5.4 Miscellaneous 415
45.5.6 Mixed Valence Ruthenium(II)/Ruthenium(III) Complexes 415
45.5.7 Mononuclear Ruthenium(III) Complexes 416
45.5.7.1 Monodentate P, As and Sb donor ligand complexes 416
45.5.7.2 Bi- and poly-dentate P and As donor ligand complexes 417
45.5.8 Bi- and Tri-nuclear Ruthenium(III) Complexes 418
45.5.9 Ruthenium(IV) and Higher Oxidation State Complexes 419
45.5.10 Useful Books and Reviews 420

45.6 OXYGEN LIGANDS 420
45.6.1 Aqua Complexes 420
45.6.2 Hydroxy Complexes 421
45.6.3 Oxo Complexes 421
45.6.4 Ketoenolate Complexes 423
45.6.5 Carboxylate Complexes 425
45.6.5.1 Monocarboxylates 425
45.6.5.2 Dicarboxylates 429
45.6.6 Miscellaneous 429

45.7 SULFUR LIGANDS 430
45.7.1 Sulfido, Thiolato and Thiazole Complexes 430
45.7.2 Thioethers 432
45.7.3 Metallothioanions as Ligands 433
45.7.4 Dithiocarbamato and Related Complexes 433
45.7.5 Dithio-phosphinato and -phosphato Complexes 436
45.7.6 Dithiolene, Dithiocarboxylate and Related Complexes 436
45.7.7 Dithio- and Monothio-β-diketonate Complexes 436
45.7.8 Thiourea Complexes 437
45.7.9 Sulfoxide Complexes 437

45.8 SELENIUM AND TELLURIUM LIGANDS 439
45.9 HALOGEN LIGANDS 440
45.9.1 Ruthenium(I) Halides 440
44.9.2 Ruthenium(I) Carbonyl Halides 440
45.9.3 Ruthenium(II) Halides 441
45.9.4 Ruthenium(II) Aquahalide Complexes 442
45.9.5 Ruthenium(II) Carbonyl Halides 442
45.9.5.1 Carbonyl fluorides 442
45.9.5.2 Neutral carbonyl chlorides, bromides and iodides 442
45.9.5.3 Anionic carbonyl halides 443
45.9.6 Ruthenium(III) Halides 443
45.9.6.1 Pure neutral halides 443
45.9.6.2 Pure anionic halides 444
45.9.6.3 Aqua- and hydroxo-halide complexes 445
45.9.6.4 Carbonyl halides 446
45.9.7 Ruthenium(IV) Halides 446
45.9.7.1 Pure neutral halides 446
45.9.7.2 Pure anionic halides and related species 447
45.9.7.3 Oxo-, hydroxo- and aqua-halide complexes 447
45.9.8 Ruthenium(V) Halides 448
45.9.9 Ruthenium(VI) Halides 449
45.9.10 Ruthenium(VIII) Halides 450

45.10 HYDROGEN AND HYDRIDE LIGANDS 450
45.10.1 Ruthenium(0) Complexes 450
45.10.2 Ruthenium(I) Complexes 450
45.10.3 Mononuclear Ruthenium(II) Complexes 450
45.10.3.1 Dihydrido complexes 450
45.10.3.2 Monohydrido complexes 452

45.10.3.3 Anionic complexes 460
45.10.4 Bi-, Tri-, Tetra- and Poly-nuclear Ruthenium(II) Complexes 461
45.10.5 Higher Oxidation State Hydrido Complexes 462
45.10.6 References to Catalytic Reactions of Ruthenium Hydrido and Related Complexes 463

45.11 MIXED DONOR ATOM LIGANDS 463
45.11.1 N–O Ligands 463
45.11.1.1 Schiff base complexes 463
45.11.1.2 Oxime complexes 464
45.11.1.3 Amino acid, 8-hydroxyquinoline, dipicolinic acid and related complexes 465
45.11.1.4 6-Methyl-2-pyridinolate and acetamide complexes 466
45.11.1.5 Edta and related complexes 466

45.1 INTRODUCTION

Ruthenium was discovered by Karl Karlovitch Klaus in 1844 in Tartu, Estonia (Ruthenia is latin for Russia). It is a rare metal with a natural abundance in the earth's crust of *ca.* 10^{-3} p.p.m. The main sources are laurite, the native alloys osmiridium and iridiosmium and other platinum metal concentrates.

Ruthenium has an atomic number of 44, electronic configuration $[Kr]4d^7 5s^1$ and an atomic weight of 101.07. It possesses seven stable isotopes ^{96}Ru ($I = 0$, 5.5%), ^{98}Ru ($I = 0$, 1.87%), ^{99}Ru ($I = \frac{3}{2}$, 12.72%), ^{100}Ru ($I = 0$, 12.62%), ^{101}Ru ($I = \frac{5}{2}$, 17.07%), ^{102}Ru ($I = 0$, 31.61%), ^{104}Ru ($I = 0$, 18.58%), and exists in four allotropes, the stable α-phase being grey–white in colour. The metal is insoluble in all acids including *aqua regia* and is resistant to oxygen up to 600°C whereupon it forms RuO_2. The metal dissolves in fused KOH to give $K_2[RuO_4]$.

Ruthenium exhibits a wide range of oxidation states from VIII to −II, the most common being III and II for 'classical-type' ligands. The least common oxidation states are VII, V, I and −I. The higher oxidation states are stabilized by small π donor ligands such as F^-, O^{2-}, N^{3-} (*e.g.* $[Ru^{VI}F_6]$, $[Ru^{VIII}O_4]$, $[Ru^{VI}NCl_4]^-$); conversely π acceptor ligands such as CO, PR_3 stabilize the lower oxidation states (*e.g.* $[Ru^{-II}(CO)_4]^{2-}$, $[Ru^0(CO)_5]$, $[Ru^0(CO)_3(PPh_3)_2]$). Ligands which are good σ donors but show no substantial π acceptor or donor properties (*e.g.* H_2O, NH_3) are usually associated with Ru^{III} and Ru^{II}. Table 1 summarizes the oxidation states and coordination numbers for complexes of ruthenium.

Ruthenium(0), d^8: The chemistry is primarily one of mononuclear, polynuclear carbonyls and tertiary phosphine complexes; a range of Ru^0 nitrosyls are known.

Ruthenium(I), d^7: Very few monomeric complexes are known with dimerization and polymerization reactions *via* Ru—Ru metal bond formation being prevalent.

Ruthenium(II), d^6: A wide range of Ru^{II} complexes incorporating carbonyl, phosphine, ammine and heterocyclic ligands are known. Virtually all Ru^{II} complexes are octahedral and diamagnetic with a t_{2g}^6 configuration (unless steric constraints are present). Catalytic processes utilizing Ru^{II} phosphine complexes, kinetic studies on substitution reactions of $[Ru(NH_3)_5L]^{2+}$ and the photophysics and photochemistry of $[Ru(bipy)_3]^{2+}$ and related systems have been areas of major advance in recent years.

Ruthenium(III), d^5: Ru^{III} is often associated with 'classical-type' ligands, *e.g.* ammine, water, halides. They are octahedral low spin t_{2g}^5 species with one unpaired electron and generally substitutionally inert. The electronic structure of polynuclear carboxylates and mixed valence $Ru_2^{II/III}$ complexes of the type $[Ru(NH_3)_5]_2L^{5+}$ has been the subject of much interest particularly with respect to the degree of unpaired electron delocalization within these molecules.

Ruthenium(IV), d^4: These complexes are often octahedral or distorted octahedral with a t_{2g}^4 low

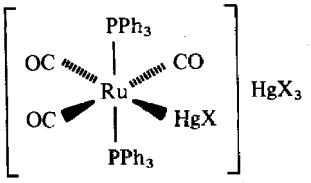
Table 1

Oxidation state	*Coordination number*	*Complex*
Ru^{-II}	4	$[Ru(PF_3)_4]^{2-}$, $[Ru(CO)_4]^{2-}$
Ru^{0}	4	$[RuCl(NO)(PPh_3)_2]$
	5	$[Ru(CO)_3(PPh_3)_2]$, $[Ru(PF_3)_5]$, $[Ru(CO)(dmpe)_2]$, $[RuH(NO)(PR_3)_3]$
	6	$[Ru(dad)_3]$
Ru^{I}	6	$[Ru(\mu\text{-}I)(CO)_2PPh_3]_2$, $[Ru_2(\mu\text{-}H)(\mu\text{-}OH)(PMe_3)_6]$
Ru^{II}	5	$[RuCl_2(PPh_3)_3]$, $[RuHCl(PPh_3)_3]$
	6	$[Ru(NH_3)_6]^{2+}$, $[Ru(NH_3)_5py]^{2+}$, $[Ru(bipy)_3]^{2+}$, $[RuCl_5NO]^{2-}$, $[Ru(TPP)(CO)EtOH]$, $[Ru(OH_2)_6]^{2+}$, $[RuH_2(PPh_3)_4]$, $[Ru(CN)_6]^{4-}$, $[RuCl_3NO(PR_3)_2]$
Ru^{III}	6	$[Ru(NH_3)_6]^{3+}$, $[RuCl(NH_3)_5]^{2+}$, $[Ru(oxal)_3]^{3-}$, $[Ru(acac)_3]$, $[Ru(OH_2)_6]^{3+}$, *mer*-$[RuCl_3(PR_3)_3]$, $[RuCl_3(AsPh_3)_2MeOH]$, $[\{Ru(NH_3)_5\}_2O]^{4+}$
Ru^{IV}	4	$[RuF_4]$
	6	$[RuCl_6]^{2-}$, $[Ru_2Cl_8N(OH_2)_2]^{3-}$, $[Ru_2OCl_{10}]^{4-}$
	7	$[RuH_3(SiR_3)(PPh_3)_3]$, $[RuH_4(PPh_3)_3]$
Ru^{V}	6	$[RuF_5]_4$, $[RuF_6]^{-}$
Ru^{VI}	5	$[RuO_3(OH)_2]^{2-}$, $[RuNCl_4]^{-}$
	6	RuF_6, $[RuO_2Cl_4]^{-}$
Ru^{VII}	4	$[RuO_4]^{-}$
Ru^{VIII}	4	$[RuO_4]$

spin configuration giving μ_{eff} = 2.7–2.9 BM which decreases with decreasing temperature. Oxo- and nitrido-bridged polynuclear complexes of Ru^{IV} are of particular interest, while more recently organometallic and hydrido Ru^{IV} species have been synthesized.

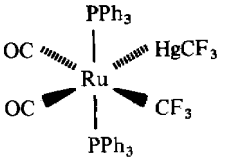
Ruthenium(V), (VI), (VII), (VIII) (d^3, d^2, d^1, d^0): These complexes are restricted to halo, oxo and nitrido species such as $[RuNCl_4]^{-}$, $[RuNCl_5]^{2-}$ and $[RuO_4]^{2-/1-/0}$. Oxo complexes of ruthenium have been used as oxidation catalysts.

This article reviews the coordination chemistry of ruthenium up to mid-1984 with particular emphasis on work published since 1967. The organometallic chemistry of ruthenium has been reviewed[1] and is not covered herein. Previous reviews of the coordination chemistry of ruthenium have been published by Griffith,[2] Seddon[3–5] and Gmelin,[6] with a more general review by Cotton and Wilkinson.[7] Since ruthenium complexes often show multi-electron redox behaviour, the ordering of the contents within the review has been taken according to the ligands bound to the metal, with subdivisions where applicable, for metal oxidation states. The main reason for this approach is to facilitate data retrieval and cross referencing.



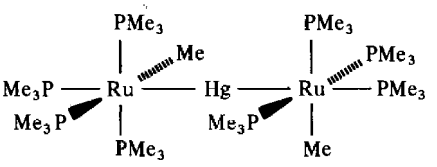
45.2 MERCURY-CONTAINING LIGANDS

Very few papers have been published on compounds containing direct ruthenium–mercury bonds and of these, several are strictly outwith the scope of this review since the other ligands present are either carbocyclic rings or other carbon-bonded groups, *e.g.* $[(Ru(\eta\text{-}C_5H_5)_2)_2Hg_2Br_4]$,[8] $[Ru_3(CO)_9(HgBr)(C_2Bu^t)]_2$[9] and $[RuCl_2(CNEt)_4(HgCl_2)]$.[10]



The first examples of compounds containing Ru—Hg bonds were $[Ru(HgX)(CO)_3(PPh_3)_2]HgX_3$ (**1**) (X = Cl, Br, I) prepared by the reaction of mercury(II) halides with $[Ru(CO)_3(PPh_3)_2]$.[11] Similar reactions, however, with $[RuI(CO)_2(PPh_3)_2]I$ and HgI_2 (1:1 molar ratio) give $[RuI(CO)_3(PPh_3)_2]HgI_3$ and $[\{RuI(CO)_3(PPh_3)_2\}_2]HgI_4$ (2:1 molar ratio).[12] Oxidation of $[Ru(CO)_3(\eta^4\text{-}C_8H_8)]$ with HgX_2 affords $[Ru(X)(HgX)(CO)_3]_2$ (X = Cl, Br or SCN), in which the halogen bridge can be cleaved with pyridine to give $[RuX(HgX)(CO)_3py]$ (X = Cl, Br).[13]

Reaction of $[Ru(CO)_3(PPh_3)_2]$ or $[Ru(CO)_2(PPh_3)_3]$ with $Hg(CF_3)_2$ has been shown by X-ray analysis to give $[Ru(HgCF_3)(CF_3)(CO)_2(PPh_3)_2]$ (**2**).[14] The average C—F distance in the Ru-bound CF_3 group is 0.1 Å longer than in the Hg-bound CF_3 group and the Ru—Hg bond length is 2.628(1)Å. The compound reacts with aqueous $HClO_4$ to convert the CF_3 group to a CO group with retention of the Ru—Hg linkage, *viz.* $[Ru(HgCF_3)(CO)_3(PPh_3)_2]ClO_4$. Treatment of $RuCl_3$ in acetone with $HgCl_2$ followed by EPh_3 is claimed to give $[RuCl_2(HgCl_2)(EPh_3)_2]$ (E = P, As, Sb) (ν_{RuHg} 178–172 cm^{-1}).[15] Interaction of *cis*-$[RuClMe(PMe_3)_4]$ with 1% sodium amalgam over a period of three days at ambient temperature yields the trimetallic complex (**3**) in which the methyl groups are orientated *ca.* 90° from one another.[16a] Reaction of $[Ru_3(NO)(CO)_{10}]$ with $HgCl_2$ gives $[Ru_3(NO)(CO)_{10}]_2Hg$.[16b] Finally, the Hg^{2+}-catalysed aquation of the $[RuCl(NH_3)_5]^{2+}$ cation has been studied in both aqueous solution and in a variety of mixed water–organic solvents.[17] Kinetic



data in aqueous solution are consistent with preequilibrium formation of a chloro-bridged intermediate $[(NH_3)_5Ru—Cl—Hg]^{4+}$ followed by dissociation to release $[HgCl]^+$ and the rapid addition of water to give $[Ru(NH_3)_5(OH_2)]^{3+}$.

45.3 GROUP IV LIGANDS

45.3.1 Cyanides and Fulminates

45.3.1.1 Ruthenium(I) cyanides

Gamma-ray irradiation at 77 K and X-ray irradiation at room temperature of single crystals of the diamagnetic $K_4[Ru(CN)_6]\cdot 3H_2O$ produce paramagnetic low spin Ru^I species.[18] At room temperature, the ESR spectra were interpreted in terms of the species $[Ru(CN)_5(NC)]^{5-}$ whereas at liquid nitrogen temperature $[Ru(CN)_4(NC)_2]^{5-}$ is observed. However, parallel studies by Symons and Wilkinson on $K_4[Ru(CN)_6]$ in various host lattices suggest that γ irradiation produces such species as $[Ru(CN)_4(CN')H_2O]^{4-}$, $[Ru(CN)_4(CN')_2]^{5-}$, $[Ru(CN)_4(CN')X]^{5-}$ and $[Ru(CN)_4X_2]^{5-}$ (X = Cl, Br), where CN′ indicates a cyanide ligand tilted off the z axis.[19]

45.3.1.2 Ruthenium(II) cyanides

(i) $Ru(CN)_2$ and the $[Ru(CN)_6]^{4-}$ ion

$Ru(CN)_2$ was prepared in 1920 by addition of KCN to the blue 'ruthenium dichloride' solution.[20] No structural information is available on the material. $K_4[Ru(CN)_6]$ was first made in 1896 either by the action of KCN on $K_2[RuO_4]$ or by boiling a solution of $RuCl_3$ with an excess of KCN until the solution loses its colour.[21] As described elsewhere,[2] various other metal salts of this anion have been prepared together with the anhydrous free acid $H_4[Ru(CN)_6]$ and in several earlier studies, the electronic, IR and Raman spectra[22] have been recorded and assignments proposed. The IR spectra of solid $Y_4[Ru(CN)_6]$ (Y = H, D) have been measured and interpreted as showing unsymmetrical (N—Y···N) bonds.[23] The ^{99}Ru NMR spectrum of $K_4[Ru(CN)_6]$ has been recorded.[24]

The X-ray structure of $Mn_2[Ru(CN)_6]\cdot 8H_2O$ confirms that the ruthenium ion is coordinated by six cyanide ions in a slightly distorted octahedron (average Ru—C and C—N distances are 2.028(6) and 1.160(8) Å respectively) and all the CN groups are bonded through nitrogen to manganese.[25]

A detailed investigation of the surface-enhanced Raman scattering from adsorbed $K_4[Ru(CN)_6]$ clearly demonstrates that the molecule interacts with the metal surface *via* a CN bridge. The strength of this interaction is dependent upon the metal surface (Ag or Cu) and the applied potential. Furthermore, the spectra from both metals show vibrational modes which are only IR active in bulk phase, indicating a symmetry lowering on adsorption.[26] Mössbauer parameters for $K_4[Ru(CN)_6]$ and other ruthenium–cyano compounds such as $K_4[Ru(CN)_5NO_2]\cdot 2H_2O$ and $K_2[Ru(CN)_5NO]\cdot 2H_2O$ have been reported and discussed.[27]

A method for the preparation of thin films of $Fe_4[Ru(CN)_6]_3$ ('ruthenium purple') involving electrochemical reduction of $K_3[Ru(CN)_6]$ in a solution of $Fe_2(SO_4)_3$ has been developed.[28] This 'ruthenium purple' modified electrode is claimed to be one of the best catalysts for evolution of oxygen and chlorine. Electrochemical studies on polyammonium macrocyclic complexes of $[Ru(CN)_6]^{4-}$ indicate a 1:1 stoichiometry with a monoelectronic, reversible, oxidation for these complexes; this illustrates the control of redox potential of anions by complexation with appropriate receptor molecules.[29] The kinetics of oxidation of $[Ru(CN)_6]^{4-}$ by $[MnO_4]^-$ in $HClO_4$ have been investigated by stopped-flow techniques. It is found that $[Ru(CN)_6]^{4-}$ is quantitatively oxidized to $[Ru(CN)_6]^{3-}$ in accordance with equation (1) and that two protonated intermediates $[RuH(CN)_6]^{3-}$ and $[RuH_2(CN)_6]^{2-}$ are involved in the oxidation process.[30]

$$MnO_4^- + 5Ru^{II} + 8H^+ \longrightarrow Mn^{2+} + 5Ru^{III} + 4H_2O \quad (1)$$

Finally, reaction of $[Ru(CN)_6]^{4-}$ with alkylating agents such as dimethyl sulfate[31] or triethyloxonium tetrafluoroborate in acetone[32] gives high yields of the isocyanide cations $[Ru(CNMe)_6]^{2+}$ and $[Ru(C{\equiv}N{-}C(Me)_2CH_2(CO)Me)_6]^{2+}$ respectively. Treatment of the former with simple amines leads to various carbene complexes such as $[Ru(CNMe)_4(C(NHMe)_2)_2]^{2+}$.[31]

(*ii*) *Monomeric Ru^{II} cyanides containing N donor ligands*

$K_2[Ru(CN)_5(NO)]$, the only fully established nitrosyl cyanide ruthenium complex, is prepared by reaction of $K_4[Ru(CN)_6]$ with HNO_3.[33] Its Mössbauer spectrum,[27b] which shows a more positive isomer shift than $K_4[Ru(CN)_6]$, is ascribed to the greater π acceptor ability of NO^+ compared to CN^-. For $K_4[Ru(CN)_5(NO_2)]$, prepared by reaction of $K_2[Ru(CN)_5NO]$ with OH^-,[34a] a decrease in isomer shift[27b] is attributed to the poor π acceptor ability of NO_2^-. The X-ray structure of $Na_2[Ru(CN)_5NO]\cdot 2H_2O$, prepared from '$RuCl_3\cdot xH_2O$' and NaCN by oxidation with HNO_3 has been reported. Some reactions of this anion with various nucleophiles are discussed.[34b] Interestingly, a recent paper claims that the final product of the $[Ru(CN)_6]^{4-}/HNO_3$ reaction is $[Ru(CN)_3(NO)(H_2O)_2]$.[35]

Reaction of $[Ru(NH_3)_5OH_2]^{2+}$ and $Na[BH_3CN]$ under argon leads to the formation of $[Ru(BH_3CN)(NH_3)_5]^+$ which on exposure to air gives the ruthenium(III) dication $[Ru(BH_3CN)(NH_3)_5]^{2+}$. Dissolution of the former in 3 M HCl produces the hydrogen cyanide complex $[Ru(NCH)(NH_3)_5]^+$ coordinated at the nitrile nitrogen.[36] More recent studies by Isied and Taube[37] have shown that this HCN complex can be prepared by direct reaction of HCN with $[Ru(NH_3)_5OH_2]^{2+}$ and that its instability is due to intramolecular rearrangement of N- to C-bound ligand, followed by labilization of the *trans* ammonia group and subsequent polymerization to $[RuCN(NH_3)_4]_n^{n+}$. Similarly reaction of $[RuCN(NH_3)_5OH_2]^{2+}$ with equimolar amounts of NaCN gave $[RuCN(NH_3)_5]^+$. Reaction of either the latter or $[Ru(NCH)(NH_3)_5]^{2+}$ with isonicotinamide (isn) gave *trans*-$[Ru(CN)(NH_3)_4(isn)]^+$.

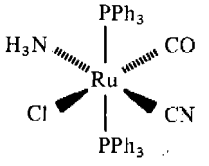
The synthesis of $[Ru(CN)_5pz]^{3-}$ (pz = pyrazine) has been described (equations 2 and 3); the *N*-methylated derivative is similarly prepared. The effective pK_a of $[Ru(CN)_5pzH]^{2-}$ (0.4 ± 0.1) has been measured by spectrophotometric titration and its value contrasted with that of $[Fe(CN)_5pzH]^{2-}$ (0.065 ± 0.06) and $[Ru(NH_3)_5(pzH)]^{3+}$ (2.85 ± 0.1).[38] The electronic spectra[39a] and voltammetric behaviour[39b] of a series of $[Ru(CN)_5L]^{3-}$ anions (L = various aromatic nitrogen heterocycles) have been reported and fully discussed.

$$[Ru(CN)_6]^{4-} + Br_2 \xrightarrow{H_2O} [Ru(CN)_5OH_2]^{3-} + BrCN + Br^- \quad (2)$$

$$[Ru(CN)_5OH_2]^{3-} + \text{N}\!\!\diagup\!\!\diagdown\!\!\text{N} \longrightarrow \left[Ru(CN)_5\text{N}\!\!\diagup\!\!\diagdown\!\!\text{N}\right]^{3-} + H_2O \quad (3)$$

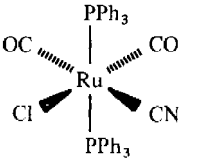
A substantial amount of work has been published on *cis*-$[Ru(CN)_2(bipy)_2]$ and the corresponding $[Ru(CN)_2(phen)_2]$. Much of this is concerned with their interesting photochemical and photophysical properties and these are fully discussed, together with those of the well-known and exhaustively studied $[Ru(bipy)_3]^{2+}$ in Sections 45.4.3.1.viii.a and 45.4.3.1.vi.b respectively.

The compound *cis*-$[Ru(CN)_2(bipy)_2]\cdot 3H_2O$ was first prepared from NaCN, 2,2′-bipyridyl and $K_2[RuCl_5(OH_2)]$ followed by reduction with bisulfite ion. It is protonated on the cyanide nitrogen atoms by perchloric acid in acetic acid[40] and its IR spectrum has been recorded and discussed.[41] An alternative synthesis from reaction of $[Ru(C_2O_4)(bipy)_2]\cdot 4H_2O$ with NaCN is available.[42]



(*iii*) *Monomeric Ru^{II} cyanides containing other ligands*

A few cyano phosphine and arsine complexes of ruthenium(II) have been reported. These include *trans*-$[RuH(CN)(dmpe)_2]$ (dmpe = $Me_2P(CH_2)_2PMe_2$) obtained from the corresponding chloro complex and aqueous KCN[43] or more recently by treatment of $[RuH(2\text{-np})(dmpe)_2]$ (2-np = 2-naphthyl) with HCN. The latter gives a 85% *cis*, 15% *trans* isomer mixture (^1H NMR evidence).[44]



The complex *trans*-$[Ru(CN)_2(eda)_2]$ {eda = ethylene-1,2-bis(diphenylarsine)}[45] and quadridentate tertiary phosphine and arsine complexes such as $\{Ru(CN)_2[E(o\text{-}C_6H_4EPh_2)_3]\}$ (E = P, As) are

prepared by reaction of the corresponding chloro compounds with NaCN.[46] Reaction of $[Ru(\eta^2\text{-}CS_2Me)(CO)_2(PPh_3)_2]ClO_4$ with CN^- gives $[RuCN(\eta^1\text{-}CS_2Me)(CO)_2(PPh_3)_2]$ which then loses CO to generate $[Ru(CN)(\eta^2\text{-}CS_2Me)CO(PPh_3)_2]$.[47]

Two carbonyl complexes $K_2[Ru(CN)_2I_2(CO)_2]$ (from ruthenium carbonyl iodide and KCN)[48] and $[RuCl(CN)(NH_3)(CO)(PPh_3)_2]$ (**4**) (from treatment of $[RuCl_2(CCl_2)(CO)(PPh_3)_2]$ with ammonia) are known. Reaction of the latter with CO gives $[RuCl(CN)(CO)_2(PPh_3)_2]$ (**5**).[49]

(4)

(5)

(iv) Binuclear Ru^{II} cyanides

Most of these complexes are formed *via* reaction of $[Ru(CN)_6]^{4-}$ with other transition metal compounds and involve bridging cyano groups. For example, DMF solutions of *cis*-$[Ru(CN)_2(bipy)_2]$ and either $K[PtCl_3(C_2H_4)]$ or *cis*- or *trans*-$[PtCl_2LL']$ (L = C_2H_4, Me_2S, L' = 4-methylpyridine) react to give 1:1 and 1:2 adducts. Spectroscopic studies indicate that adduct formation results in appreciably enhanced emission lifetimes. The compound $\{Ru(CN)_2(bipy)_2[PtCl_2(C_2H_4)]_2\}$ can be isolated but no structural information is available as yet.[50] Similarly aqueous solutions of $[Ru(CN)_6]^{4-}$ and bis(histidinato)cobalt(III) develop an orange–red colour when exposed to visible light and the formation of the single cyano-bridged complex anion $[(L\text{-hist})_2Co(NC)Ru(CN)_5]^{3-}$ is proposed.[51] The closely related species $[(en)_2NH_3Co(NC)Ru(CN)_5]^-$ has been synthesized[52a] and many other references to cyano-bridged Ru^{II}/metal complexes are to be found in references 52b and 53 with the latter describing the synthesis, photophysical properties and excited state redox behaviour of $[CN(bipy)_2RuCNPtdien]^{2+}$ and $[dienPtNC[Ru(bipy)_2]CNPtdien]^{4+}$. Polymeric cations made up of $Ru(bipy)_2$ units linked by cyanide bridges can be prepared by reacting $[Ru(CN)_2(bipy)_2]$ with $[Ru(C_2O_4)(bipy)_2]$.[54]

The mechanism of formation of these species probably involves initial formation of an outer sphere complex and then reorganization to form a cyano-bridged compound. For example, mixing of $[RuCl(NH_3)_5]^{2+}$ and $[Ru(CN)_6]^{4-}$ solutions produces a new absorption maximum at 510 nm ($\varepsilon = 20$) assigned to an outer sphere intervalence transfer transition from Ru^{II} to Ru^{III}. Irradiation of this band leads to the formation of $[(NH_3)_5Ru(NC)Ru(CN)_5]^-$ as a stable photoproduct whereas intervalence excitation of the starting ion pair yields its redox isomer $[Ru^{II}Cl(NH_3)_5]^+/[Ru^{III}(CN)_6]^{3-}$ which can diffuse apart.[55] Similarly, saturated DMSO solutions of $[Co(NH_3)_6]^{3+}/[Ru(CN)_6]^{4-}$ exhibit an absorption band at 360 nm ($\varepsilon = 580$) assigned to the intervalence transfer from a reducing Ru^{II} to an oxidizing Co^{III} centre,[56] and in a very thorough study, Curtis and Meyer have examined outer sphere charge transfer (OSCT) transitions for a series of mixed metal ion pairs $[M(CN)_6, Ru(NH_3)_5L]^-$ (M = Fe, Ru, Os; L = pyridine or substituted pyridine). From a detailed analysis of these OSCT bands, a number of proposals regarding the 'structure' and the extent of electronic coupling in these species are made.[57,58a] Related studies on the binuclear $[(NH_3)_5RuNC\text{-}Ru(bipy)_2CN]^{3+}$ and trinuclear $[(NH_3)_5RuNCRu(bipy)_2CNRu(NH_3)_5]^{6+}$ have been published.[58b]

Finally, the action of H_2SO_4 on $K_4[Ru(CN)_6]$ is reported to give the formally mixed valence $[Ru_2(CN)_5OH_2]$ as a blue powder, which reacts with ammonia to produce $NH_4[Ru_2(CN)_5(NH_3)_4]$.[59] However this is old work and more evidence is required to substantiate these claims.

45.3.1.3 Ruthenium(III) cyanides

Treatment of a solution of $K_4[Ru(CN)_6]$ with Cl_2 results in several colour changes and warming with H_2SO_4 then precipitates a green–black product of composition $Ru(CN)_3 \cdot 5H_2O$; with concentrated ammonia this gives $Ru(CN)_3 \cdot 2NH_3 \cdot H_2O$ which is also insoluble.[59] Much more recently, because coordinated methylamine ligands are more susceptible to oxidation than the free base, it has been found that exposure of $[Ru(NH_2Me)_6]^{2+}$ cations to oxygen under ambient conditions produces $Ru(CN)_3 \cdot 3H_2O$.[60]

Earlier studies reveal that a yellow solution is obtained by reaction of $[Ru(CN)_6]^{4-}$ with H_2O_2,

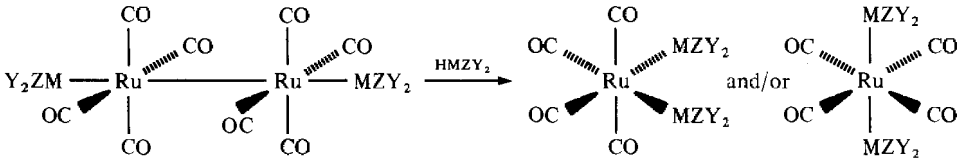
Ce^{IV} or bismuthate in acid conditions, or with ozone in neutral. This solution presumably contains the $[Ru(CN)_6]^{3-}$ ion {*cf.* more recent work involving $[MnO_4]^-$ oxidation—equation (1), Section 45.3.1.2.i}. The potential of the $[Ru(CN)_6]^{3-}/[Ru(CN)_6]^{4-}$ couple is $+0.86 \pm 0.05$ V *vs.* SCE.[61] Hydroxyl radicals produced by pulse radiolysis also converts $[Ru(CN)_6]^{4-}$ into $[Ru(CN)_6]^{3-}$.[62] Studies on the decomposition of aqueous solutions of $[Ru(CN)_6]^{3-}$ reveal that reactions such as aquation (to $[Ru(CN)_5OH_2]^{2-}$), dimerization and ligand oxidation to form $[Ru(CN)_5(CNO)]^{4-}$ are involved.[63]

Finally, Gillard *et al.* report that the $[Ru(CN)_2(bipy)_2]^+$ cation (obtained by oxidation of $[Ru(CN)_2(bipy)_2]$ with Cl_2 or cerium(IV) nitrate) reacts with water to give the $[Ru(bipy)_2(H_2O)_2]^{3+}$ cation. Reduction of this solution in the presence of SCN^- gives $[Ru(SCN)_2(bipy)_2]\cdot 4H_2O$.[64]

45.3.1.4 Ruthenium(IV), (V) and (VII) cyano complexes

Treatment of $K_3[Ru_2NCl_8(OH_2)_2]$ with KCN gives the very stable species $K_5[Ru_2N(CN)_{10}]\cdot 3H_2O$. On the basis of IR and Raman studies, an eclipsed (D_{4h}) structure with a linear RuNRu unit is proposed, although of course, these indirect methods cannot distinguish between this and the staggered (D_{4d}) configuration. Cyano complexes of Ru^{IV} are unusual and it is suggested that in this compound the strong π donor effects of the nitrido ligand force the ruthenium to behave as a Ru^{III} or even Ru^{II} centre.

Reaction of RuO_4 with ice cold solutions of NaCN in the presence of caesium ion did not yield the expected $Cs_2[Ru(CN)_4(O)_2]$ anion (*cf.* $Cs_2[RuCl_4(O)_2]$, Section 45.9.9). Instead a green paramagnetic salt formulated as $Cs_3[Ru^V(CN)_4(CNO)_2(O)]$ is formed. The reaction of $K_2[RuO_4]$ with NaCN in the presence of Cs^+ give a yellow paramagnetic material $Cs_5[Ru_2(CN)_9(O)_5]$ (containing formally Ru^{VII}?).[65]



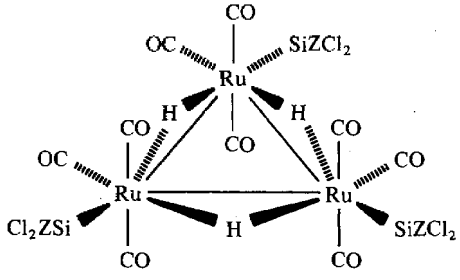
45.3.2 Silicon-containing Ligands

45.3.2.1 Carbonyl complexes

Many of the complexes with silicon-containing ligands and carbonyl groups are outwith the scope of this review in that they are octahedral with four CO groups per ruthenium. Nevertheless, since these compounds are often the precursors for species with three or less CO groups per ruthenium, a brief outline of their syntheses and characterization is given in this section.

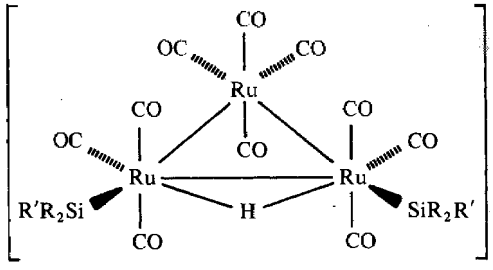
$$[Ru_3(CO)_{12}] \xrightarrow[\text{or } h\nu]{\Delta} [Ru(CO)_4] \xrightarrow{HMZY_2} [RuH(MZY_2)(CO)_4] \xrightarrow[-H_2]{\Delta}$$

(6)



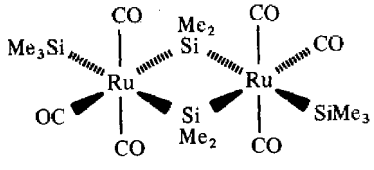
(7) (8)

Scheme 1

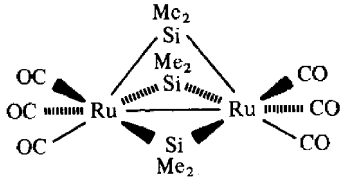


As discussed in detail elsewhere,[1] most of these silicon-containing tetracarbonyl complexes are made *via* either photochemical or thermal reaction of $[Ru_3(CO)_{12}]$ with a silicon hydride (Scheme 1; M = Si). This yields an intermediate $[RuH(SiZY_2)(CO)_4]$ (**6**) which may decompose to $[Ru(SiZY_2)(CO)_4]_2$ (**7**) by loss of H_2 or may react with more $HSiZY_2$ to give *cis*- and/or *trans*-$[Ru(SiZY_2)_2(CO)_4]$ (**8**) [Z = Y = Me, Et, Pr,[66] Cl;[66,67] Z = Me, Y = Cl;[66,68,69] Z = Cl, Y = Me[69] (not all combinations of products formed)]. The latter can also be formed by direct reaction of $[Ru(SiZY_2)(CO)_4]_2$ with $HSiZY_2$. The stereochemically non-rigid behaviour of (**8**) (M = Si, Ge, Sn) has been investigated by $^{13}C\text{-}\{^1H\}$ NMR spectroscopy.[69] Related tetracarbonyl complexes with chelating disilanyl ligands have been formed directly from $[Ru_3(CO)_{12}]$ and an extensive range of mixed Group IVB ligand complexes have been made from $[Ru(SiMe_3)(CO)_4]^-$. (See reference 1, p. 909 for details.)

It has been reported that reaction of $[Ru_3(CO)_{12}]$ with $HSiZCl_2$ (Z = Me, Cl) at elevated temperature gives the trinuclear clusters $[Ru_3(\mu\text{-}H)_3(CO)_9(SiZCl_2)_3]$ (**9**) in addition to $[Ru(SiZCl_2)_2(CO)_4]$. A mechanism of formation of these species is tentatively proposed[70] although attempts to synthesize the corresponding $SiMe_2Cl$ and $SiMe_3$ trinuclear clusters were unsuccessful. A related cluster anion $Na[Ru_3H(CO)_{10}(SiR_2R')_2]$ can be synthesized from $Na[Ru_3H(CO)_{11}]$ and $HSiR_2R'$. On the basis of NMR evidence, structure (**10**) is proposed.[71]

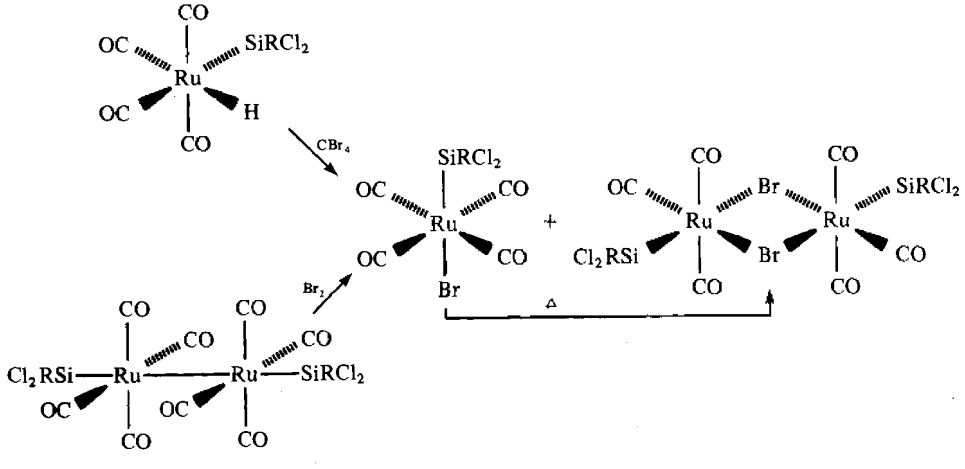


Pentamethyldisilane reacts with $[Ru_3(CO)_{12}]$ to form $[Ru(\mu\text{-}SiMe_2)(SiMe_3)(CO)_3]_2$ (**11**), also obtained from HSi_2Me_5 and $[Ru(MMe_3)(CO)_4]_2$ (M = Si or Ge);[72] the structure of (**11**) has been verified by X-ray analysis (Ru···Ru, 2.96 Å).[73] In contrast, 1,1,2,2-tetramethyldisilane reacts with $[Ru(MMe_3)(CO)_4]_2$ to give $[Ru_2(CO)_6(\mu\text{-}SiMe_2)_3]$ (**12**).[72]



(9)

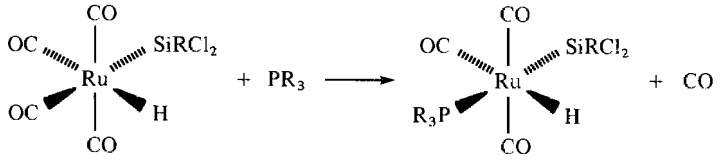
(10)



(11)

(12)

Reaction of $[Ru(SiMe_3)(CO)_4]_2$ with bromine or iodine gives *trans*-$[RuX(SiMe_3)(CO)_4]$ and pyrolysis of these materials produces the halide-bridged species $[RuX(SiMe_3)(CO)_3]_2$ as an isomeric mixture.[74] However, as shown in Scheme 2, treatment of *cis*-$[RuH(SiRCl_2)(CO)_4]$ with CBr_4 results in the formation of $[RuBr(SiRCl_2)(CO)_3]_2$ (single isomeric form) together with *trans*-$[RuBr(SiRCl_2)(CO)_4]$. Similar products are obtained when the Ru—Ru bond in $[Ru(SiRCl_2)(CO)_4]_2$ is cleaved with Br_2.[68] Reaction of $[Os(CO)_5]$ with *trans*-$[RuBr(SiCl_3)(CO)_4]$ at 0°C gives $[(CO)_5Os\text{-}RuBr(SiCl_3)(CO)_3]$ which on standing in solution isomerized to $[Br(CO)_4OsRu(SiCl_3)(CO)_4]$.[75]



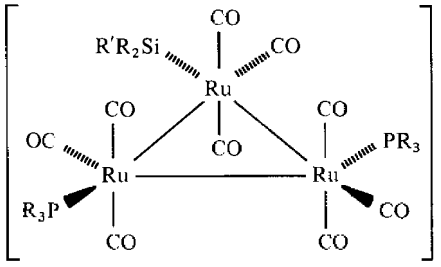
Scheme 2

45.3.2.2 Carbonyl complexes containing group IV, V or VI donor ligands

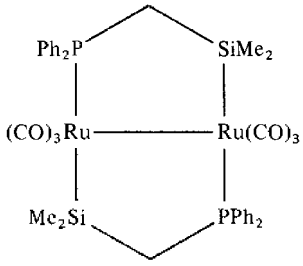
In *cis*-$[Ru(SiCl_3)_2(CO)_4]$ only the CO groups *trans* to silicon exchange with ^{13}CO.[76] Substitution by PPh_3 to giver *mer*-$[Ru(SiCl_3)_2(CO)_3PPh_3]$ has a similar rate and a wide range of other *mer*-

$[Ru(SiCl_3)_2(CO)_3L]$ (L = PF_3, $P(OPh)_3$, $AsPh_3$, $SbPh_3$, $CNC(Me)_3$ *etc.*) are readily prepared.[67] Similar results are obtained with *cis*-$[Ru(SiMeCl_2)_2(CO)_4]$, and likewise with $[RuH(SiRCl_2)(CO)_4]$, P donor ligands displace the CO group *trans* to $-SiRCl_2$ (equation **4**).[68] Synthesis of the related $[RuX(SiZY_2)(CO)_3L]$ (L = $P(OMe)_3$, PPh_3 *etc.*, X = Cl, Br, I, $ZY_2 = Me_3$; Cl_3; Z = Me, Y = Cl) are readily achieved by cleavage of $[RuX(SiZY_2)(CO)_3]_2$ with L.[68,74]

Further substitution in *mer*-$[Ru(SiCl_3)_2(CO)_3L]$ could only be accomplished when L had a small cone angle. Thus, the second CO group is not replaced by PPh_3 even at 80°C whereas $P(OMe)_3$ reacts at room temperature to give $[Ru(SiCl_3)_2(CO)_2PPh_3\{P(OMe)_3\}]$ and $[Ru(SiCl_3)_2(CO)_2L_2]$ (L = PF_3, $PPhMe_2$ *etc.*) are also formed under mild conditions.[67] Kinetic studies on CO substitution reactions of $[Ru(SiCl_3)_2(CO)_3L]$ complexes indicate a dissociative mechanism and a *cis* effect of L which is almost entirely steric in origin.[77] The dicarbonyl complex $[Ru(SiMe_3)_2(CO)_2(PPh_3)_2]$ can however by synthesized by reaction of $[Ru(SiMe_3)(CO)_4]_2$ (**7**) with PPh_3 (equation 5) or by oxidative addition of $HSiMe_3$ to $[Ru(CO)_3(PPh_3)_2]$ under UV irradiation.[66] Reaction of $[RuH_2(CO)_2(PEt_3)_2]$ with $SiClMe_3$ also gives $[Ru(SiMe_3)_2(CO)_2(PEt_3)_2]$.[78a] A study of the photochemistry of $[RuH(SiEt_3)(CO_3)PPh_3]$ indicates that both facile loss of CO and reductive elimination of Et_3SiH can occur.[78b]

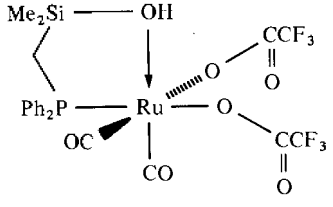


(4)



$$[Ru(SiMe_3)(CO)_4]_2 + PPh_3 \longrightarrow Ru(SiMe_3)_2(CO)_2(PPh_3)_2 + Ru(CO)_3(PPh_3)_2 \quad (5)$$

Substitution of the equatorial groups in *cis*-$[Ru(SiCl_3)_2(CO)_4]$ by a variety of bidentate ligands (L–L) gives $[Ru(SiCl_3)_2(CO)_2(L–L)]$ *via* monodentate intermediate $[Ru(SiCl_3)_2(CO)_3(L–L)]$ complexes (L–L = diene, $MeS(CH_2)_2SMe$, $Ph_2P(CH_2)_2PPh_2$, *o*-$C_6H_4[AsMe_2]_2$ *etc.*). With $Ph_2E(CH_2)_2EPh_2$ (E = P, As), it is also possible to isolate the binuclear complexes $\{[Ru(SiCl_3)_2(CO)_3]_2(L–L)\}$.[79]



The trinuclear cluster anions $[Ru_3(SiR_2R')(CO)_9(PR_3)_2]^-$ are prepared from $Na[Ru_3H(CO)_{10}(SiR_2R')_2]$ and isolated as the $[N(PPh_3)_2]^+$ salts. Structure (**13**) is proposed on the basis of NMR data.[80] Finally, reaction of $[Ru_3(CO)_{12}]$ with $Ph_2PCH_2SiMe_2H$ affords the symmetrically bridged diruthenium compound (**14**) (Ru—Ru 3.056(1) Å). Treatment of (**14**) with CF_3CO_2H gives the mononuclear phosphinomethyl–dimethylsilanol complex $[Ru(PPh_2CH_2SiMe_2OH)(CO)_2(CO_2CF_3)_2Et_2O]$ (**15**) in which the Et_2O molecule is hydrogen-bonded to the silanol-O with O···O 2.64 Å.

(13)

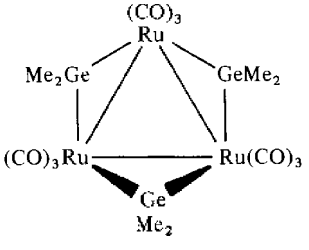
(14)

(15)

45.3.2.3 Tertiary phosphine and arsine complexes

Silyl–ruthenium(IV) complexes $[RuH_3(SiR_3)L_n]$ (R_3 = various combinations of H, F, Cl, Me, Ph, OMe, OEt; L = PPh_3, $AsPh_3$, $P(C_6H_4Me\text{-}p)_3$; n = 2, 3) are formed by reaction of an excess of $HSiR_3$ with $[RuH_2L_4]$, $[RuHClL_3]$, $[RuCl_2L_3]$ or $[RuCl_3(AsPh_3)_3]$. Complexes of the type $[RuH_2X(SiR_3)L_3]$ (X = Cl, I) are obtained by reaction of the chlororuthenium(II) complexes with $HSiCl_3$ or of $[RuH_3(Si(OEt)_3)(PPh_3)_3]$ with $CDCl_3$ or I_2. These dihydrides are unstable in solution in the absence of an excess of silane and revert to $[RuHX(PPh_3)_3]$. In some cases, $[Ru(SiR_3)_2(PPh_3)_3]$ are formed.[82,83,84]

These silyl–ruthenium complexes are very reactive. For example, incomplete H–D exchange occurs between $[RuH_3(SiR_3)L_3]$ and D_2 at room temperature. Treatment with excess HCl gives the free silane and $[RuCl_2(PPh_3)_3]$, whereas with CO, $[RuH_2CO(PPh_3)_3]$ is formed. Exchange of silyl groups occurs on reaction of $[RuH_3(SiR_3)(PPh_3)_3]$ (R_3 = $(OEt)_3$, Cl_2Me) with $HSiF_3$ whereas iodine gives $[RuH_2I(Si(OEt)_3)(PPh_3)_3]$ and H_2.



Finally, extensive investigations of the ability of $[RuCl_2(PPh_3)_3]$ to catalyse the hydrosilation of a range of organic substrates have been made. (See references 1 and 85 for full details.)

For details of other silyl–ruthenium compounds containing polyalkenes, azulenes and arenes, see reference 1, pp. 915–919.

45.3.3 Germanium-containing Ligands

Although in comparison to Si much less work has been published on the reactions of germyl hydrides with $[Ru_3(CO)_{12}]$, reaction with $HGeMe_3$ gives compounds $[Ru(GeMe_3)(CO)_4]_2$ (**7**), $[Ru(GeMe_3)_2(CO)_4]$ (**8**) and $[Ru(\mu\text{-}GeMe_2)(GeMe_3)(CO)_3]_2$ (*cf.* **11**) (Scheme 1, M = Ge). In addition, pyrolysis of $[Ru(GeMe_3)_2(CO)_4]$ (**8**) at 140°C gave $[Ru(\mu\text{-}GeMe_2)(CO)_3]_3$ (**16**) and a small amount of $[Ru_2(\mu\text{-}GeMe_2)_3(CO)_6]$ (*cf.* **12**).[86] A number of tetracarbonyl complexes containing different Group IVB ligands can be made from the $[Ru(GeMe_3)(CO)_4]^-$ anion which is obtained by reduction of $[Ru(GeMe_3)(CO)_4]_2$ with Na/Hg (see reference 1, p. 912 for details). X-Ray structural analysis of the *cis* and *trans* isomers of $[Ru(GeCl_3)_2(CO)_4]$ reveals a short Ru—Ge distance (2.48 Å) indicative of the high π-bonding ability of the $GeCl_3^-$ anion.[87]

The compound $[Ru(GeMe_3)_2(CO)_2(PPh_3)_2]$ (isomeric mixture) is formed from $[Ru(GeMe_3)_2(CO)_4]$ and PPh_3.[86] No germyl–ruthenium(IV) compounds of type $[RuH_3(GeR_3)L_n]$ have been reported although in one instance hydrogermylation of 1-hexene catalysed by $[RuCl_2(PPh_3)_3]$ is observed (equation 6).[88] Treatment of $RuCl_3$ with $GeCl_2Et_2$ followed by EPh_3 is reported to give $[RuCl_2(GeEt_2Cl)(EPh_3)_3]$ (E = P, As, Sb). Other germyl–ruthenium compounds containing hydrocarbon moieties are discussed in reference 1, p. 915.

(16)

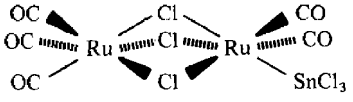
45.3.4 Tin-containing Ligands

45.3.4.1 Ruthenium(II) halide complexes

It has long been known that interaction of tin(II) chloride with solutions of platinum metal salts gives coloured species which have been utilized analytically but until recently, the nature of the

species present in solution was uncertain. Reactions of $SnCl_2$ with hydrated $RuCl_3$ or RuO_4 in dilute hydrochloric acid give yellow or orange salts containing the $[RuCl(SnCl_3)_5]^{4-}$ anion,[89] previously described as $[RuCl_2(SnCl_3)_2]^{2-}$.[90] The structure has been confirmed by X-ray analysis and the first example of ^{119}Sn–^{99}Ru coupling has been observed in the ^{119}Sn FT NMR spectrum of this anion.[91] The ^{119}Sn Mössbauer spectrum of '$[RuCl_2(SnCl_3)_2]^-$' is reported.[92] Reaction of $[RuCl(SnCl_3)_5]^{4-}$ with L (L = thiourea or its substituted derivatives) is claimed to give $Me_4N[Ru(SnCl_3)_3L_3]$, $[Ru(SnCl_3)_2L_4]$ and $[RuL_6](SnCl_3)_2$.[93]



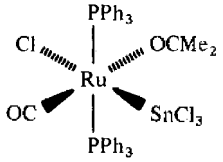
Another route to the $[RuCl(SnCl_3)_5]^{4-}$ anion is from reactions between $SnCl_2$ and $[RuCl_5NO]^{2-}$ in HCl solution; intermediates such as orange $[RuCl_3(SnCl_3)_2NO]^{2-}$ and brownish-black $[Ru_2Cl_6(SnCl_3)_2(NO)_2]^{4-}$ were characterized.[94] The $[RuCl_2(SnCl_3)_4]^{4-}$ ion is reported in a Japanese patent[95] and further work has substantiated this claim.[96]

Reaction of '$RuCl_3 \cdot xH_2O$' with SnF_2 in aqueous HF followed by addition of MF (M = Na, K or NH_4) gives $M_4[Ru(SnF_3)_6]$ which on treatment with HX in the presence of $[Me_4N]^+$ gives $[Me_4N]_4[RuX(SnF_3)_5]$ (X = Cl, Br).[97] The $[Ru(SnF_3)_6]^{4-}$ anion is also formed by treatment of $H_4[RuCl(Sn(OH)_3)_5]$ with $SnCl_2$ in HF.[98] The ^{119}Sn NMR spectrum of the corresponding $[Ru(SnCl_3)_6]^{4-}$ (made *in situ* by reaction of '$RuCl_3 \cdot xH_2O$' with a ten-fold excess of $SnCl_2 \cdot 2H_2O$ in 3 M HCl) has been published.[96,99]

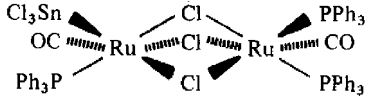
45.3.4.2 Ruthenium(II) carbonyl and carbonyl halide complexes

As for silicon and germanium, reaction of $[Ru_3(CO)_{12}]$ with $HSnR_3$ gives good yields of $[Ru(SnR_3)_2(CO)_4]$; for R = Me, a small amount of $[Ru(\mu\text{-}SnMe_2)(SnMe_3)(CO)_3]_2$ (*cf.* **11**) is also produced;[100] the structure of the latter has been confirmed by X-ray analysis.[101] Other ways of forming the $[Ru(SnR_3)_2(CO)_4]$ complexes are by treatment of $[RuH_2(CO)_4]$ with $HSnMe_3$ or $SnPh_3Cl$, reaction of $[Ru(MMe_3)_2(CO)_4]$ (M = Si,Ge)[66,86] with $HSnMe_3$, or by reaction of $Me_3SnCH_2NMe_2$ with $[Ru_3(CO)_{12}]$.[102] Reaction of the $[Ru(MMe_3)(CO)_4]^-$ anions (M = Si,Ge) with SnR_3Cl gives the mixed group IVB ligand complex $[Ru(MMe_3)(SnR_3)(CO)_4]$ and treatment of these with SnR'_3Cl gives $[Ru(SnR'_3)(SnR_3)(CO)_4]$. With $SnCl_2Me_2$, the anion $[Ru(SiMe_3)(CO)_4]^-$ yields $[Ru(\mu\text{-}SnMe_2)(CO)_4]_2$.[66] The X-ray structure of $[Ru(SnMe_3)(CO)_4]_2$ shows the linear Sn—Ru—Ru—Sn unit and eclipsed configuration of the CO groups (*cf.* **7**; Scheme 1).[103]

The reaction of $SnCl_4$ with $[Ru_3(CO)_{12}]$ (xylene, 135°C) gives $[Ru_2Cl_3(SnCl_3)(CO)_5]$ (**17**); a trinuclear derivative $[Ru_3(CO)_{12}SnCl_4]$ is formed at room temperature and is thought to contain a linear Ru_3 sequence. On heating this may form $[RuCl(SnCl_3)(CO)_4]$ which can dimerize with loss of $SnCl_2$ to form (**17**). Under CO (70 atm) the product is *trans*-$[Ru(SnCl_3)_2(CO)_4]$ which does not isomerize to the *cis* form in solution.[104,105]



(17)



The 'RuCOX' (X = Cl or Br) solutions react with SnX_2 to form lemon-yellow $[RuCl_2(SnX_3)_2(CO)_2]^{2-}$; the chloro complex is also formed from $[RuCl_2(CO)_2]_n$ and $SnCl_2$ in HCl solution.[106,107,108] The related $[RuCl(SnMe_3)(CO)_4]$ is prepared by cleavage of one of the Ru—Sn bonds in $[Ru(SnMe_3)_2(CO)_4]$, using I_2 at −5°C.[74]

45.3.4.3 Ruthenium(II) complexes containing group IV, V or VI donor ligands

Treatment of the 'RuCOCl' solutions with PPh_3 and $SnCl_2$ in acetone gives lemon-yellow crystals initially formulated as $[Ru_2Cl_3(SnCl_3)(CO)_2(PPh_3)_3(Me_2CO)_2]$[106] but shown by X-ray analysis to be the monomer (**18**). This is converted to the bridged derivative (**19**) by warming in benzene; both complexes readily eliminate $SnCl_2$, the latter giving $[Ru_2Cl_4(CO)_2(PPh_3)_3]$[109] (see Section 45.5.5.1).

(18)

(19)

White *trans*-$[Ru(SnCl_3)_2(CNEt)_4]$ and *cis*-$[RuCl(SnCl_3)(CNEt)_2(EPh_3)_2]$ are formed by insertion of $SnCl_2$ into $[RuCl_2(CNEt)_4]$ or *cis*-$[RuCl_2(CNEt)_2(EPh_3)_2]$ (E = P, As, Sb) respectively.[10,110] Similarly reaction of $RuCl_3$ with $SnCl_2$ followed by EPh_3 gives $[RuCl(SnCl_3)(EPh_3)_3]$[15] and treatment of *trans*-$[RuHX(PHPh_2)_4]$ or $[RuCl_2(DMSO)_4]$ with $SnCl_2$ gives *trans*-$[RuH(SnCl_3)(PHPh_2)_4]$[111] and $[Ru(SnCl_3)_2(DMSO)_4]$[112] respectively.

Reaction of the $[RuCl_2(SnX_3)_2(CO)_2]^{2-}$ anions with pyridine (X = Cl, Br) gives $[Ru(SnX_3)_2(CO)_2(py)_2]$; with SEt_2, the cationic complex $[Ru(SnCl_3)(CO)_2(SEt_2)_3]^+$ is formed.[108]

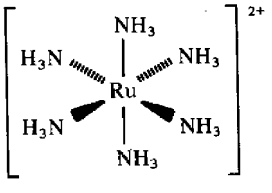
Finally, reaction of $[RuI(CO)_3(PPh_3)_2]I$ with SnI_2 (1:1 mole ratio) gives $[RuI(CO)_3(PPh_3)_2]SnI_3$. The same compound is formed by oxidation of $[Ru(CO)_3(PPh_3)_2]$ with SnI_4; in C_6H_6 under reflux the latter reaction produces *cis*-$[RuI_2(CO)_2(PPh_3)_2]$ and SnI_2.[12]

45.3.5 Lead-containing Ligands

The only reference to ruthenium–lead complexes is the preparation of *cis*-$[Ru(PbMe_3)_2(CO)_4]$ from reaction of $[Ru(CO)_4]^{2-}$ with $PbClMe_3$ (reference 1, p. 912).

45.4 NITROGEN LIGANDS

45.4.1 Ammines



45.4.1.1 Mononuclear complexes $[Ru(NH_3)_6]^{x+}$

Ruthenium(II): $[Ru(NH_3)_6]^{2+}$ (**20**) is a diamagnetic orange complex which can be prepared by reaction of $RuCl_3$ with NH_4OH in the presence of zinc dust (equations 7 and 8),[113–115] by treatment of $RuCl_3$, $[RuCl_5H_2O]^{2-}$, $[RuCl(NH_3)_5]^{2+}$ or $[RuCl_6]^{2-}$ with hydrazine and NH_4Cl,[116,117] by refluxing $[Ru(NH_3)_5N_2]^{2+}$ with concentrated NH_3 solution[117] or by reduction of $[Ru(NH_3)_6]^{3+}$ (see below). The single crystal X-ray structures of $[Ru(NH_3)_6]X_2$ (X = I^-, Cl^-) (**20**) have been reported[118,119] and show octahedral geometry around ruthenium(II) with Ru—N = 2.144 Å for the I^- salt.[118] The UV visible spectrum of (**20**) shows an absorption at 267 nm,[116] while its Mössbauer spectrum has also been reported.[120] The IR spectrum of $[Ru(NH_3)_6]^{2+}$ has been analysed,[117,121–123] and on the basis of deuteration shifts using highly concentrated nujol mulls the band predominantly due to the T_{1u} (Ru—N) stretching vibration, $\nu_{Ru\ N}$, has been reassigned to the absorption at 430 cm^{-1}.[123]

$$2RuCl_3 + Zn + 16NH_3 \longrightarrow 2[Ru(NH_3)_6]Cl_2 + [Zn(NH_3)_4]Cl_2 \quad (7)$$

(**20**)

$$[Ru(NH_3)_6]Cl_2 + [Zn(NH_3)_4]Cl_2 + 4HCl \longrightarrow [Ru(NH_3)_6][ZnCl_4] + 4NH_4Cl \quad (8)$$

(20)

$[Ru(NH_3)_6]^{2+}$ is a good reducing agent ($E^\circ = -0.214$ V *vs.* SHE for $[Ru(NH_3)_6]^{2+/3+}$ couple),[124] and has been studied in relation to outer-sphere electron transfer reactions.[118,124–126] The self exchange between $[Ru(NH_3)_6]^{2+}$ and $[Ru(NH_3)_6]^{3+}$ (equation 9) has a rate constant $k = 3.2 \times 10^3\ M^{-1}s^{-1}$ in CF_3SO_3H,[127] with $\Delta H^{\neq} = 43.1 \pm 1.0$ kJ mol^{-1} and $\Delta S^{\neq} = -11 \pm 3$ J K^{-1} mol^{-1}.[128] Reductive quenching[128] of excited state $[Ru(bipy)_3]^{2+*}$ by $[Ru(NH_3)_6]^{2+}$ *via* an outer-sphere mechanism has been reported[129] (see Section 45.4.3.1). Oxidation of $[Ru(NH_3)_6]^{2+}$ by $[Ru(NH_3)_5py]^{3+}$ occurs with a rate constant, $k = 7.2 \times 10^5\ M^{-1}s^{-1}$.[130] Electron transfer reactions between $[Ru(NH_3)_6]^{2+}$ and a series of cobalt(III) complexes have been studied.[131–134] The one electron reduction of $[Co(L)(OH_2)_2]^{5+}$ (L = tetra-4-*N*-methylpyridyl porphine) (equation 10) occurs at a rate ($k_{12} = 1.2 \times 10^5\ M^{-1}s^{-1}$ at 15.5°C; $K_{equil} = 8.9 \times 10^5$) higher than that observed for the reduction of $[Co(NH_3)_5(OH_2)]^{3+}$ and $[Co(NH_3)_6]^{3+}$.[135,136] This is consistent with the $E_{1/2}$ values for the Co^{III}/Co^{II} couples, with the rate of reaction decreasing with increasing pH.[137] The reduction of

$[CoX(NH_3)_5]^{2+}$ (X = NCS^-, SCN, N_3^-, F^-, Cl^-, Br, I^-, OAc^-, RCO_2^-)[124,126,131,133,138–141] $[CoX(NH_3)_5]^{3+}$ (X = H_2O,[142] nitrile,[143] glycine, alanine[144]) and $[Co(en)_2(L–L)]^{n+}$ (L–L = thiolate, thioether, alkoxy, carboxylate)[145] by $[Ru(NH_3)_6]^{2+}$ has been studied kinetically, the specific rates for reduction of the nitrile complexes being increased due to electron withdrawal by the C≡N moiety.[143] For the glycine and alanine complexes, no pH dependence was observed,[144] the electron transfer being thought not to occur *via* coordination of carboxylate to ruthenium.[144,145] Kinetic studies have also been carried out on the reduction of $[Fe(L)(OH_2)_2]^{5+}$ (L = tetra-4-*N*-methylpyridyl porphine),[146] $[Fe(edta)]^-$,[147] cytochrome aa_3,[148] cytochrome c(III),[149] platinum(IV)[150] and copper(II)/(III)[124,151] complexes and perchlorate salts.[124] The reduction of Fe^{III} is found to be faster than that of $[FeOH]^{2+}$.[128] The importance of non-adiabaticity in the above outer-space mechanisms has been discussed.[129,152]

$$[Ru(NH_3)_6]^{2+} + [Ru(NH_3)_6]^{3+} \longrightarrow [Ru(NH_3)_6]^{3+} + [Ru(NH_3)_6]^{2+} \quad (9)$$

$$[Ru(NH_3)_6]^{2+} + [Co^{III}(L)(OH_2)_2]^{5+} \rightleftharpoons [Ru(NH_3)_6]^{3+} + [Co^{II}(L)(OH_2)_2]^{4+} \quad (10)$$

Under protic conditions $[Ru(NH_3)_6]^{2+}$ is oxidized by O_2 to give $[Ru(NH_3)_6]^{3+}$ and H_2O_2 (equation 11),[153] the reduction of O_2 being 10^4 faster than the corresponding reduction of H_2O_2.[153] The reduction of H_2O_2 to H_2O by $[Ru(NH_3)_6]^{2+}$ shows first order dependence on $[Ru^{II}]$ and saturation dependence on $[H_2O_2]$.[154] A mechanism involving addition of H_2O_2 to a distorted, activated six-coordinate complex $*[Ru(NH_3)_6]^{2+}$ to give a seven-coordinate intermediate (**21**) (equation 12) has been postulated.[154] The photooxidation of $[Ru(NH_3)_6]^{2+}$ at a ferrocene derivatized photoanode has been reported.[155] The aquation of $[Ru(NH_3)_6]^{2+}$ is found to be $[H^+]$ catalysed with rate constant $k = 1.24 \times 10^{-3}\,M^{-1}s^{-1}$ at 25°C,[156] an interaction of H^+ and Ru^{II} π–d electron density being proposed to labilize the Ru—N bond.[157a] The hydroformylation of ethylene is catalysed by $[Ru(NH_3)_6]^{2+}$ on zeolites; the active species is thought to be $[Ru(OH)(NH_3)_5]^{2+}$.[157b]

$$\frac{-d[O_2]}{dt} = k[[Ru^{II}(NH_3)_6]^{2+}][O_2] \qquad k = 1.26 \times 10^2\ M^{-1}s^{-1} \text{ at } 25°C,\ \mu = 1 \quad (11)$$

$$[Ru(NH_3)_6]^{2+} \rightleftharpoons *[Ru(NH_3)_6]^{2+} \xrightarrow{H_2O_2} [Ru(NH_3)_6(H_2O_2)]^{2+} \xrightarrow[2H^+]{[Ru(NH_3)_6]^{2+}}$$

(21)

$$2[Ru(NH_3)_6]^{3+} + 2H_2O \quad (12)$$

Ruthenium(III): $[Ru(NH_3)_6]^{3+}$ (**22**) is colourless and is prepared usually by the oxidation of $[Ru(NH_3)_6]^{2+}$.[115] Oxidizing agents that have been used include hydrazine hydrochloride,[116] $Na_2[PtCl_6]$,[115] $Na[AuCl_4]$,[115] acidified NO_2^- salts,[158] Br_2 in the presence of NaBr[113] and Br_2 vapour.[159] Heating of $[RuCl(NH_3)_5]Cl_2$ with hydrazine hydrochloride,[160] or treatment of $[Ru(NH_3)_5(OH_2)]^{2+}$ with hydrazoic acid[161] also gives $[Ru(NH_3)_6]^{3+}$. The latter reaction is proposed to occur *via* a nitrene intermediate (**23**) (equations 13–15).[161] $[Ru(NH_3)_6]^{3+}$ shows an absorption band at 276 nm,[116,162] while X → Ru charge transfer bands for $[Ru(NH_3)_6]X_3$ (X = Cl^-, Br^-, I^-) have also been assigned;[156] for X = I^- and Br^-, two maxima are observed due to $^2P_{3/2}$–$^2P_{1/2}$ doublet splitting of the halide ion.[156] The Ru—N stretching vibration ν_{Ru-N} for the complexes $[Ru(NH_3)_6]X_3$ (X = Cl^-, Br^-, I^-, BF_4^-) occurs in the IR in the region 485–424 cm^{-1}.[117] The single crystal X-ray structures of $[Ru(NH_3)_6]X_3$ (X = BF_4^-,[118] Cl^-[119]) confirm an octahedral geometry for ruthenium(III) with Ru—N = 2.104 Å for the BF_4^- salt.[118] Magnetic susceptibility measurements in the range 80–300 K show $[Ru(NH_3)_6]X_3$ to have a low spin d^5 configuration with μ_{eff} = 1.90 BM (87 K), 2.17 BM (292 K) for the Br^- salt.[163] Aqueous solutions of $[Ru(NH_3)_6]^{3+}$ turn yellow on addition of NaOH with a new absorption at 400 nm due to the formation of $[Ru(NH_2)(NH_3)_5]^{2+}$ (**24**) (equation 16).[164] $[Ru(NH_2)(NH_3)_5]^{2+}$ is believed to play an important role in the base catalysed proton exchange reactions of $[Ru(NH_3)_6]^{3+}$ in H_2O.[164] When $[Ru(NH_3)_6]^{3+}$ is dissolved in HPO_4^{2-}/NaOH buffer (pH 12), however, no yellow solution is obtained; in addition absorptions for $[Ru(NH_2)(NH_3)_5]^{2+}$ were found to show marked dependence on anions.[165] Subsequently the optical spectra of basic solutions of $[Ru(NH_3)_6]^{3+}$ were analysed assuming the presence of a hydroxide ion pair and $[Ru(NH_2)(NH_3)_5]^{2+}$, the formation constants of which were 5.4 M^{-1} and 1.8 M^{-1} respectively.[166] The aquation of $[Ru(NH_3)_6]^{3+}$ proceeds *via* two parallel reaction pathways: (a) pH independent, (b) base catalysed, pK_a of $[Ru(NH_3)_6]^{3+}$ = 13.1.[166]

$[Ru(NH_3)_6]^{3+}$, like $[Ru(NH_3)_6]^{2+}$, participates in outer-sphere electron transfer reactions, a range of such reactions involving the reduction of $[Ru(NH_3)_6]^{3+}$ having been reported. $[Ru(NH_3)_6]^{3+}$ quenches the excited state $[Ru(bipy)_3]^{2+*}$ and has been suggested as a possible oxidant in related redox systems.[167] The reduction of $[Ru(NH_3)_6]^{3+}$ by Cr^{2+},[125] $[V(bipy)_3]^{2+}$,[168] $[V(H_2O)_6]^{2+}$ ($\Delta H^{\neq}$ = 2.5 kJ mol^{-1}, $\Delta S^{\neq} = -42$ J K^{-1} mol^{-1} at 298 K[169] and U^{III} ($\Delta H^{\neq}$ = 1.0 kJ mol^{-1},

$$[Ru(NH_3)_5(OH_2)]^{2+} \xrightarrow{N_3H} [Ru(NH_3)_5(N_3H)]^{2+} \longrightarrow [(H_3N)_5Ru^{IV}{-}\ddot{N}H]^{2+} + N_2 \quad (13)$$

(23)

$$[(H_3N)_5Ru^{IV}{-}\ddot{N}H]^{2+} \xrightarrow{H^+} [(H_3N)_5Ru^{IV}{-}NH_2]^{3+} \quad (14)$$

$$[(H_3N)_5Ru^{IV}{-}NH_2]^{3+} + [Ru(NH_3)_5(OH_2)]^{2+} \xrightarrow{H^+} [Ru(NH_3)_6]^{3+} + [Ru(NH_3)_5(OH_2)]^{3+} \quad (15)$$

(22)

$$[Ru(NH_3)_6]^{3+} + {}^-OH \rightleftharpoons [Ru(NH_2)(NH_3)_5]^{2+} + H_2O \quad (16)$$

(22) (24)

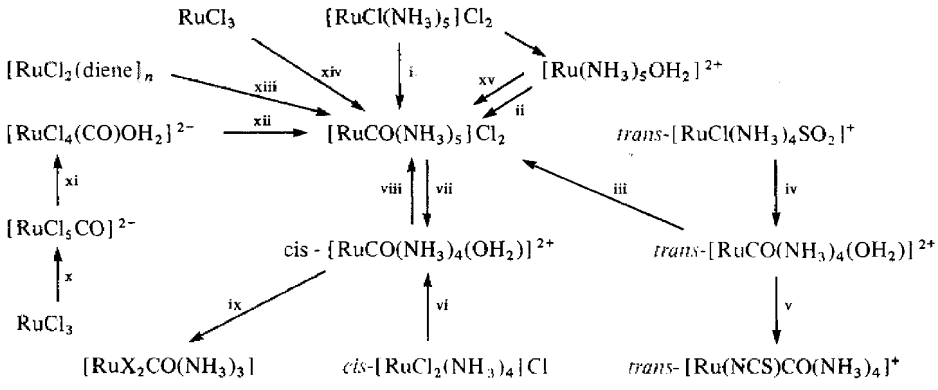
$\Delta S^{\neq} = -39\,J\,K^{-1}\,mol^{-1}$)[170,171] has been studied. No acid dependence was observed in the oxidation of Np^{III} by $[Ru(NH_3)_6]^{3+}$,[172] while the second order reduction by Ti^{III} was found to be inversely proportional to $[H^+]$, suggesting that $Ti(OH)^{2+}$ was the active reductant.[173] $[Ru(NH_3)_6]^{3+}$ forms a range of mixed valent salts with $[Ru(CN)_6]^{4-}$, $[Fe(CN)_6]^{4-}$[58,174] and $[Fe(CN)_5L]^{3-}$ (L = CO, DMSO, pz, py, imid)[174] which show outer-sphere intervalence charge transfer bands in the visible-near IR region. A plot of optical electron transfer energy *versus* difference in redox potential of the complexes increases linearly; these results have been discussed[58,174] in terms of Hush theory.[175,176] Photolysis of $[Ru(NH_3)_6]^{3+}$ at 185 nm leads to substantial photoreduction in the presence of 2-propanol, methanol or ethanol which act as radical scavengers of the excited state $[Ru(NH_3)_6]^{3+*}$.[177] $[Ru(NH_3)_6]^{3+}$ has been reduced by $e^-_{(aq)}$[178] and by organic radicals *via* outer-sphere mechanisms, the order of reactivity being $\dot{C}H_2OH < CH_3\dot{C}HOH < (CH_3)_2\dot{C}OH < CH_3\dot{C}OH\text{-}CO_2^- < CH_3CO\dot{C}(O^-)CH_3$;[178,179] in general $R\dot{C}(OH)CO_2H$ was found to be less reactive than $R\dot{C}(OH)CO_2^-$.[180] The low yield UV photoaquation of $[Ru(NH_3)_6]^{3+}$ has been reported.[181] The adsorption–desorption of $[Ru(NH_3)_6]^{3+}$ on pyrolytic graphite electrodes coated with Nafion 125 and on clay-modified electrodes has been described.[182,183]

Ruthenium(IV) and (V): Oxidation of $[Ru(NH_3)_6]^{3+}$ by $\dot{O}H$ gives $[Ru(NH_3)_6]^{4+}$ which rapidly decays to $[Ru(NH_3)_6]^{5+}$ and $[Ru(NH_3)_6]^{3+}$ with a rate constant $k = 4.5 \times 10^9\,M^{-1}\,s^{-1}$.[178]

45.4.1.2 Mononuclear complexes $[RuL_n(NH_3)_{6-n}]^{x+}$

Ruthenium ammine–phosphine and –selenium complexes are discussed in Sections 45.5.4.6 and 45.8 respectively.

(*i*) *Carbon donor ligand complexes*

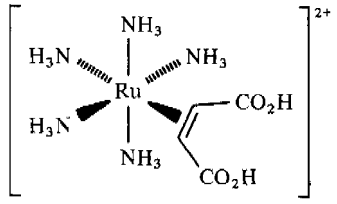


(a) Cyanides and related ligands

Cyano–ammine complexes are also discussed in Section 45.3.1.2.ii $[Ru(NH_3)_5OH_2]^{2+}$ reacts with isocyanide L in ethanol to give $[Ru(L)(NH_3)_5]^{2+}$, and on further reaction, the bis adduct *trans*-$[Ru(L)_2(NH_3)_4]^{2+}$ (L = benzyl isocyanide, cyclohexyl isocyanide).[184a] Aquation of *trans*-$[Ru(CNC_7H_7)_2(NH_3)_4]^{2+}$ yields *trans*-$[Ru(CNC_7H_7)(NH_3)_4(OH_2)]^{2+}$.[184a] Measurements on the rate of aquation of $[Ru(CNC_7H_7)(NH_3)_5]^{2+}$ to *trans*-$[Ru(CNC_7H_7)(NH_3)_4(OH_2)]^{2+}$ indicate that isocyanide labilizes the *trans* NH_3 by a factor of forty compared with the aquation of $[Ru(NH_3)_6]^{2+}$.[184a] Likewise the rate of aquation of *trans*-$[Ru(CNC_7H_7)(NH_3)_4(isn)]^{2+}$ is also enhanced by isocyanide, a low affinity of ruthenium(II) for isn being observed in these systems.[184a] $E_{1/2}$ values for the above complexes have been measured, the electrolysis of $[Ru(CNC_7H_7)(NH_3)_5]^{2+}$ at 0.79 V *vs.* NHE yielding the ruthenium(III) species $[Ru(CNC_7H_7)(NH_3)_5]^{3+}$.[184a] The solid state thermal reactions of $[Ru(NH_3)_5L]^{2+}$ (L = MeNC, CO) have been analysed and compared with the reactivity of analogous complexes of N_2, NCMe and NO.[184b]

(b) Carbonyls and alkenes

Carbonyl and alkene complexes of ruthenium have been previously reviewed.[1] The syntheses of $[Ru(CO)(NH_3)_5]^{2+}$ are summarized in Scheme 3. The dependence of $\nu_{C\equiv O}$ upon counterion and upon solvent has been discussed.[188] The Mössbauer spectrum of $[Ru(CO)(NH_3)_5]^{2+}$ has been reported.[27c,120] The replacement of H_2O by isn in *trans*-$[Ru(L)(NH_3)_4(OH_2)]^{2+}$ has been assessed, the lability increasing in the order L = CO = N_2 < isn < py < imid (N bound) ≃ NH_3 < OH^- < CN^- < SO_3^{2-} < imid (C bound).[189] For π acid ligands good correlation between specific rate and $E_{1/2}$ values for the ruthenium(II)/(III) couple was observed.[189]



Treatment of $[RuCl(NH_3)_5]^{2+}$ with Ag^+ followed by reduction by zinc amalgam in aqueous

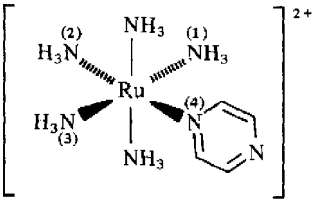
solution and addition of L yields $[Ru(L)(NH_3)_5]^{2+}$ (L = fumaric acid, ethylene, isobutene, 1,4-cyclohexadiene, acetylene, phenylacetylene, 3-hexyne).[190] The complex of 3-hexyne has also been prepared by addition to $[Ru(NH_3)_5(acetone)]^{2+}$.[191] The complexes show $d \rightarrow \pi^*$ charge transfer bands in the range 200–300 nm while the C=C and C≡C stretching vibrations $\nu_{C=C}$, $\nu_{C\equiv C}$ are lowered in energy by 100–200 cm^{-1} on complexation. The single crystal X-ray structure of the fumaric acid adduct (**25**) shows the alkene to be carbon η^2 bound to the metal centre, C=C = 1.413 Å, Ru—C = 2.172 Å, Ru—N = 2.143–2.154 Å, with the axial NH_3 ligands bending away from the equatorially bound alkene.[190] The stabilization of ruthenium(II) in these systems ($E_{1/2}$ = 0.54 V *vs.* NHE for $[Ru^{II}(3\text{-hexyne})(NH_3)_5]^{2+}$) is ascribed to back-bonding from metal to alkene.[190]

(25)

Carbon bonded imidazole derivatives are discussed in Section 45.4.1.2.ii.b.

(*ii*) *Nitrogen donor ligand complexes*

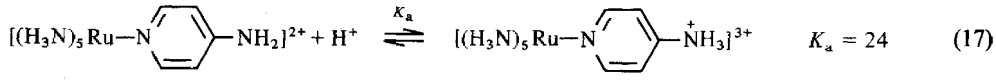


(a) Amines

Treatment of $[RuCl(NH_3)_5]^{2+}$ with $Ag(O_2CCF_3)$, followed by zinc amalgam reduction and addition of amine yields $[Ru(L)(NH_3)_5]^{2+}$ (L = cyclohexylamine, benzylamine, methylamine).[192] Oxidation of these complexes with Br_2 produces the corresponding ruthenium(III) species $[Ru(L)(NH_3)_5]^{3+}$.[192] Subsequent oxidation of the amine ligand can readily occur to give imine and nitrile products, explaining the relatively few complexes of this type that have been isolated (see Section 45.4.2).

(b) Monodentate heterocycles

Ruthenium(II): A range of complexes of the type $[Ru(L)(NH_3)_5]^{2+}$ (*e.g.* L = pyridine,[193–196] pyridazine,[193] pyrazine,[193,195,197] pyrimidine,[193] triazine,[193] 2-cyanopyridine, 3-cyanopyridine, 4-cyanopyridine,[198] 2-, 3- and 4-RC(O)-substituted pyridines (R = $CHMe_2$, CH_2Et, CH_2Pr^i,[199] OMe, NH_2, OH,[194] H,[193] Ph[195]), *N*-methylpyrazine,[197] 4,4′-bipyridine,[195] 1,2-bis(4′-pyridyl)ethylene,[195] hypoxanthine,[200] guanine,[201] xanthine,[202] 4-dimethylaminopyridine[196]) have been prepared by reaction of $[RuCl(NH_3)_5]Cl_2$ with a Ag^+ salt (AgO_2CCF_3 is often used) followed by zinc amalgam reduction



and addition of ligand L. Alternatively L may be added directly to $[Ru(NH_3)_5(OH_2)]^{2+}$. Reduction of $[RuL(NH_3)_5]^{3+}$ chemically by H_2S[203] or electrochemically[204] has been used to generate $[RuL(NH_3)_5]^{2+}$ (L = pyridine, 4-aminopyridine). The single crystal X-ray structure of $[Ru(NH_3)_5pz]^{2+}$ (**26**) shows octahedral ruthenium(II) with Ru—N(NH_3) = 2.15–2.17 Å, and a shortened Ru—N(pz) = 2.006 Å due to $d\pi(Ru) \rightarrow {}^*\pi(pz)$ back-bonding.[205] The plane of the pyrazine ring intersects the equatorial plane containing N-1, N-2, N-3 and N-4 at 45° thus minimizing steric effects.

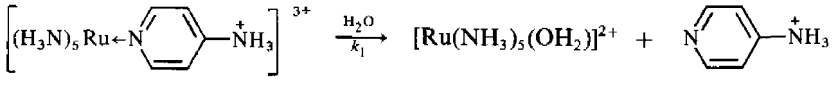
(26)

The electronic spectra of these complexes show solvent dependent $Ru^{II} \rightarrow L$ charge transfer bands[193,196] which have been used to assess the degree of metal → ligand back-bonding.[206] The Ru^{II}/Ru^{III} redox couples for the complexes have been correlated with the energies of the $Ru^{II} \rightarrow L$ charge transfer bands,[193] *e.g.* for L = py, $\lambda = 407$ nm ($\varepsilon = 7700\,M^{-1}cm^{-1}$), $E_{1/2} = +0.38$ V *vs.* SSCE.[191] Mössbauer studies of $[Ru(NH_3)_5L]^{2+}$ (L = pyridine, pyrazine) have been reported.[120] The degree of back-donation from the ruthenium(II) centre has been probed by ^1H and ^{13}C NMR for the complexes $[Ru(L)(NH_3)_5]^{2+}$ (L = pyridine, 4-methyl pyridine, 4-benzoyl pyridine, pyrazine, methyl pyrazine).[38,207] The shifts in the ^{13}C NMR spectra for the 3- and 4-positions were found to be consistent with back-bonding to the ligand from the metal centre.[207] In addition, the C≡N stretching vibration $\nu_{C\equiv N}$ for 4-cyanopyridine shifts to low energy on coordination to the $[Ru(NH_3)_5]^{2+}$ moiety.[198] $[Ru(NH_3)_5L]^{2+}$ (**27**) (L = 4-aminopyridine) shows a Ru → L charge-transfer band at 360 nm. At low pH this absorption decreases in intensity due to protonation of the free amine (equation 17),[204] suggesting that the lone pair on the uncoordinated NH_2 influences the M → L charge transfer process. On protonation of (**27**), LH^+ becomes a better π acceptor shifting λ_{max} to longer wavelength.[204] On coordination of pyrazine, 4,4′-bipyridine and 1,2-bis(4′-pyridyl)-ethylene to $[Ru(NH_3)_5]^{2+}$, the basicity of the free N site is increased (pK_a for complexes = 2.6, 4.4, 5.0 respectively).[195] This effect has been discussed in relation to stronger metal → ligand back-donation in the protonated complexes[193] and in terms of the degree of delocalization of the protonated species.[195] The enthalpy of protonation of $[Ru(NH_3)_5pz]^{2+}$ is found to be $-20.5\,kJ\,mol^{-1}$.[208] This work has been further extended by the synthesis of complexes $[Ru(NH_3)_5LH]^{3+}$ incorporating potentially bidentate ligands (L = *e.g.*, 1,1′-bis(4′-pyridyl)amine).[209] The rate of reduction of pyrazine *N*-oxide was found not to be increased on coordination to the $[Ru(NH_3)_5]^{2+}$ moiety in spite of the N—O stretching vibration ν_{N-O} decreasing from 1313 cm^{-1} in the free oxide to 1258 cm^{-1} in the complex.[210] The synthesis,[196] electronic, IR and resonance Raman spectra of $[Ru(L)(NH_3)_5]^{3+}$ (L = 1-methyl-4,4′-bipyridine) have been published.[211]

The pseudoexchange rate for the $[Ru(NH_3)_5py]^{2+/3+}$ couple has been determined as $k = 4.7 \times 10^5\,M^{-1}s^{-1}$ at 25°C.[212] The reduction of cytochrome c,[213,214] myoglobin,[215–217] Co^{III} and $Cu^{II/III}$ complexes by $[Ru(L)(NH_3)_5]^{2+}$ (L = histidine, pyridine, pyrazine, 4,4′-bipyridine) has been reported.[151,218,219] The reduction of O_2 by $[Ru(NH_3)_5(isn)]^{2+}$, and *cis*- and *trans*-$[Ru(NH_3)_4(isn)(OH_2)]^{2+}$ occurs *via* outer-sphere formation of O_2^- with rate constants $k = 1.08 \times 10^{-1}$, 1.38×10^{-1} and $3.03 \times 10^{-2}\,M^{-1}s^{-1}$ respectively (equation 18).[220] Ruthenium(III) and decreasing acidity were found to inhibit the reduction due to competition between the reaction of O_2^- and Ru^{III} and protonation of O_2^- followed by reaction of Ru^{II} (equations 19–22).[220] $[Ru(NH_3)_5(isn)]^{2+}$ is oxidized by HO_2 with a rate constant $k = 9.07 \times 10^6\,M^{-1}s^{-1}$ *via* an outer-sphere mechanism that shows anomalous behaviour with regard to Marcus theory.[221] The mechanism and kinetics of the reduction of O_2 in the presence of Cl^- has been discussed.[220] Reduction of H_2O_2 by $[RuL(NH_3)_5]^{2+}$ (L = 1-methylimidazole) is first order in $[Ru^{II}]$.[154]

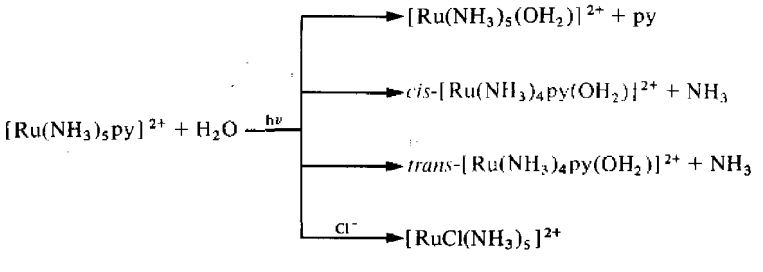
(27)

$$\frac{-d[Ru^{II}]}{dt} = 2k[Ru^{II}][O_2] \quad (18)$$



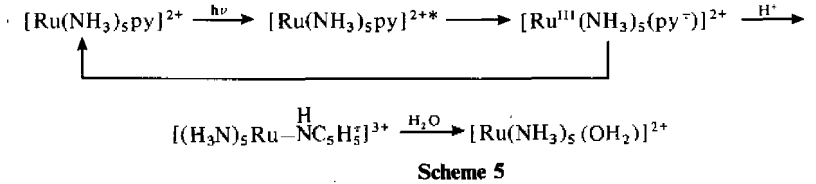
$$Ru^{II} + O_2 \rightleftharpoons Ru^{III} + O_2^- \quad (19)$$

$$O_2^- + H^+ \rightleftharpoons HO_2 \quad (20)$$

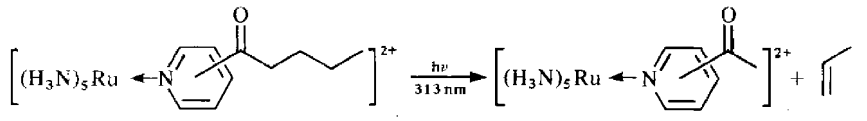


$$Ru^{II} + HO_2 \longrightarrow Ru^{III} + HO_2^- \quad (21)$$

$$H^+ + Ru^{II} + HO_2 \longrightarrow Ru^{III} + H_2O_2 \quad (22)$$



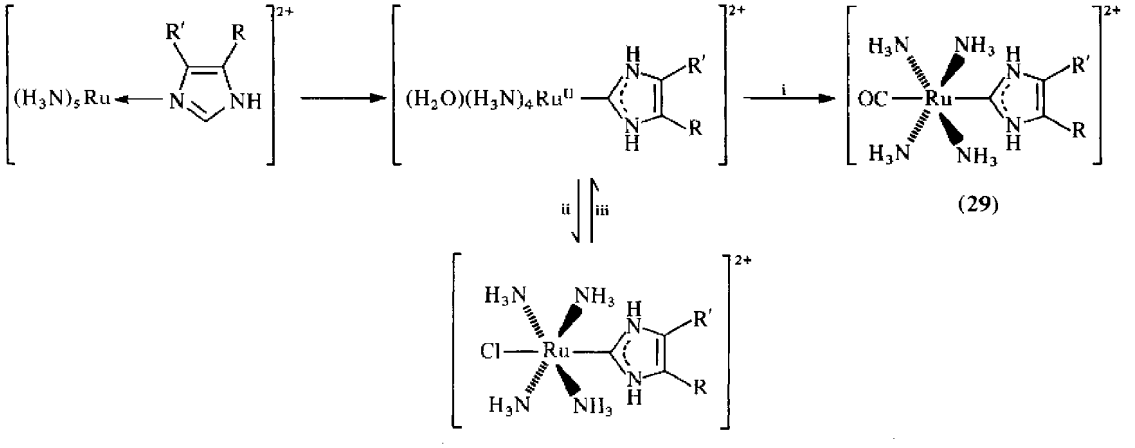
$[Ru(NH_3)_5py]^{2+}$ aquates at a slower rate than $[Ru(NH_3)_6]^{2+}$, while electron withdrawing groups on coordinated pyridine slow the aquation still further.[157,222] The kinetics of aquation of protonated (**27**) have been studied to give a rate law (equation 23) with rate constant $k_1 = 4.4 \times 10^{-2}\,s^{-1}$.[204] The photoactivation of the relatively non-labile $[Ru(NH_3)_5py]^{2+}$ has been reported. Photosubstitution of $[Ru(NH_3)_5py]^{2+}$ is found to be wavelength dependent and often leads to the formation of several products[223,224] (Scheme 4) (*cf.* the photochemistry of $Ru(bipy)_3^{2+}$ which shows photoluminescence and is relatively photosubstitution inert,[225,226] see Section 45.4.3.1.vi). The quantum yield for the aquation of $[Ru(NH_3)_5py]^{2+}$ on irradiation at the Ru → L charge transfer band was found to be pH dependent suggesting competitive acid-catalysed and acid independent reaction pathways.[227] A proposed mechanism for photoaquation of $[Ru(NH_3)_5py]^{2+}$ is given in Scheme 5.[225] Studies on charge transfer excited species $[RuL(NH_3)_5]^{2+*}$ showed evidence for ligand field excited states, and indicated that the metal → ligand charge transfer excited state (MLCT) was in fact substitutionally unreactive;[226] the excited state responsible for photosubstitution in $[Ru(NH_3)_5py]^{2+}$ is therefore believed to be ligand field (LF) in character.[228] Thus, if the LF state is of lower energy relative to the MLCT state, photolability and substitution would be expected to readily occur, whereas for systems where the MLCT state is of lowest energy, photostability would be prevalent.[228] The role of solvent in the relative ordering of these levels has been intimated.[228] Flash photolysis experiments on a series of complexes $[RuL(NH_3)_5]^{2+}$ (L = substituted pyridines, aromatic heterocycles) show the formation of long-lived transients for those complexes that are photosubstitution inert.[229] These intermediates have been proposed to involve a pyridine ligand π-bonded to Ru^{II} with an uncoordinated N which can be reversibly protonated with aquation of the complex.[229] UV irradiation of $[Ru(NH_3)_5py]^{2+}$ in aqueous NaCl solution yields initially $[Ru(NH_3)_5(OH_2)]^{2+}$ which is oxidized to $[RuCl(NH_3)_5]^{2+}$.[230] The photolysis of the pyridyl complex (**28**) at 313 nm leads to a novel carbon–carbon bond cleavage reaction on the ligand site (equation 24).[199]



$$-\frac{d[Ru^{II}L]}{dt} = \frac{k_1 K_a[H^+][Ru^{II}L]}{1 + K_a[H^+]} \quad (23)$$

Scheme 4

Scheme 5



(28)

(24)

The rate of aquation of $[Ru(NH_3)_5(imid)]^{2+}$ was found to be 500 times faster than for the pyridyl derivative. A series of substituted imidazole adducts was therefore prepared and studied by ^1H NMR. This clearly showed an intramolecular arrangement of N-bound to C-bound imidazole (Scheme 6).[231–234] The single crystal X-ray structure of (**29**) confirms[232] the formation of a Ru—C bond (2.218 Å), with CO *trans* to imidazole ($R^1 = R = Me$). In general, the N-bound imidazole complexes are unstable below pH 2 due to facile aquation *via* highly labilizing[189] C-bound intermediates.[232] The electrochemistry and reactions with H_2O_2 and O_2 of N- and C-bound imidazole complexes have been reported.[235] C-bound xanthine derivatives have also been prepared.[202,236] The binding of $[Ru(NH_3)_5]^{2+}$ to double helical and single stranded DNA has been reported to occur at N-7 of guanine.[201,237] $[Ru(NH_3)_5]^{2+}$ has been anchored to graphite electrodes using polyvinylpyridine and polyacrylonitrile.[238]

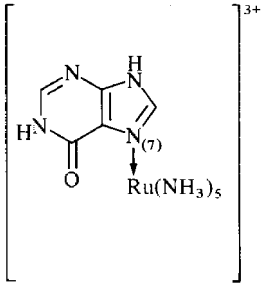
The rates of substitution of H_2O in *cis*- and *trans*-$[RuL(NH_3)_4(OH_2)]^{2+}$ have been measured, and the effect of L on the lability of H_2O assessed[189] (see Section 45.4.1.2.i.b). Equilibrium constants for equation (25) have been measured[239] for a range of ligands L (Table 4).

(29)

i, CO; ii, O_2, Cl^-; iii, Zn/Hg, H_2O

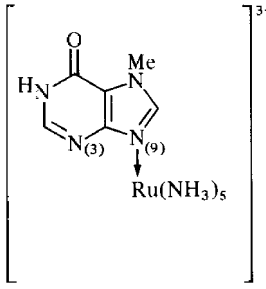
Scheme 6

$$trans\text{-}[Ru(SO_3)(NH_3)_4(OH_2)] + L \underset{}{\overset{K_{equil}}{\rightleftharpoons}} [Ru(SO_3)(NH_3)_4L] + H_2O \qquad (25)$$



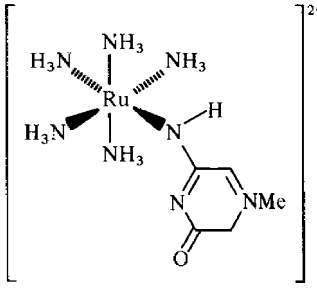
Complexes of the type *trans*-$[RuL_2(NH_3)_4]^{2+}$ can be prepared by treatment of $[RuCl_2(NH_3)_4]^+$ with $Ag(O_2CCF_3)$, reduction by zinc amalgam and addition of L (L = pyridine, pyrazine, 3- and 4-RCO pyridine; R = OMe, NH_2, OH).[194,240] Reaction of *cis*- or *trans*-$[RuCl_2(NH_3)_4]^+$ with pyHCl and zinc amalgam gives *cis*- or *trans*-$[Ru(NH_3)_4py_2]^{2+}$,[241] while reduction of $[Ru(NH_3)_4py_2]^{3+}$ by H_2S also yields $[Ru(NH_3)_4py_2]^{2+}$.[203] A series of mixed ligand complexes of type *trans*-$[RuLL'(NH_3)_4]^{2+}$ (L = pyridine, L′ = pyrazine, pyrazine H^+, 4-acyl pyridine; L = pyrazine, L′ = pyrazine, pyrazine H^+;[240,242] L = pyridine, 3-chloropyridine, 3,5-dichloropyridine, L′ = 4-cyano-*N*-methyl pyridinium, *N*-methyl-4,4′-bipyridine[196]) have been prepared by treatment of *trans*-$[Ru(SO_4)L(NH_3)_4]^+$ with zinc amalgam and L′. The basicity of these complexes was found to decrease in the order $[Ru(NH_3)_5pz]^{2+}$ > *trans*-$[Ru(NH_3)_4(py)(pz)]^{2+}$ > *trans*-$[Ru(NH_3)_4(pz)_2]^{2+}$ > pz > *trans*-$[Ru(pzH)(NH_3)_4pz]^{3+}$ > $[Ru(NH_3)_5pz]^{3+}$.[240] The visible spectrum of some of the mixed ligand complexes shows two metal → ligand charge transfer absorption bands,[240] these being found to be highly solvent dependent.[196] The single crystal X-ray structure of *cis*-$[Ru(NH_3)_4(isn)_2]^{2+}$ shows a net decrease in the Ru^{II}–N(isn) distance relative to Ru^{III}–N(isn) in *cis*-$[Ru(NH_3)_4(isn)_2]^{3+}$;[243] this is attributed to metal → isn $d \rightarrow \pi^*$ back-bonding in the ruthenium(II) complex.[243] Reaction of $[Ru(NH_3)_5N_2]^{2+}$ with py yields $[Ru(NH_3)_4py_2]^{2+}$ and $[Ru(NH_3)_2py_4]^{2+}$,[244]

while photolysis of *trans*-$[RuLL'(NH_3)_4]^{2+}$ in the visible region leads to photoaquation of NH_3.[240,245] The redox couples for a series of complexes $[RuL(NH_3)_5]^{2+/3+}$ and $[Ru(L)_2(NH_3)_4]^{2+/3+}$ have been measured and correlated with the electronic properties of L.[246]



Ruthenium(III): $[RuL(NH_3)_5]^{3+}$ and $[Ru(L)_2(NH_3)_4]^{3+}$ (L = pyridine,[194] *N*-methylpyrazine$^+$,[197] 3- and 4-RCO pyridine; R = OMe, NH_2, OH[194]) have been prepared by Ag^I or Ce^{IV} oxidation of the corresponding ruthenium(II) complexes. The preparation of $[RuL(NH_3)_5]^{3+}$ by air oxidation of $[RuL(NH_3)_5]^{2+}$ (L = imidazole, 1-methylimidazole, 4-methylimidazole, 3,5-dimethylimidazole, benzimidazole) has also been achieved,[231,232] with the formation of $[RuCl(NH_3)_4(imid)]^{2+}$ as a side product.[231] Reaction of *cis*-$[Ru(NH_3)_4(OH_2)_2]^{2+}$ with isn in HCl yields $[RuCl(NH_3)_4isn]^{2+}$,[222] while *cis*- or *trans*-$[RuCl(NH_3)_4SO_2]^+$ with L in aqueous solution gives *cis*- or *trans*-$[Ru(SO_4)(L)(NH_3)_4]^+$ (L = pyridine, isonicotinamide,[222] 3-chloropyridine, 3,5-dichloropyridine,[196] substituted imidazole[239,247]) which reacts with HX to form $[RuX(L)(NH_3)_4]^{2+}$ (X = Cl^-, Br^-, I^-).[222,239] The $E_{1/2}$ values for the $Ru^{III/II}$ couples in these complexes are influenced by X rather than L, while the energy of the $Ru^{III} \rightarrow L$ charge transfer is also markedly dependent on X.[222] The electronic and vibrational spectra of $[RuL(NH_3)_5]Cl_3$ (L = 4-dimethylaminopyridine) have been analysed;[211] For L = 4-aminopyridine protonation of the complex leads to loss of the $L \rightarrow M$ charge transfer band at 505 nm indicating lone pair involvement in the CT process.[204]

The single crystal X-ray structure of $[Ru(NH_3)_5pz]^{3+}$, prepared by PbO_2 oxidation of $[Ru(NH_3)_5pz]^{2+}$,[197] shows a longer Ru^{III}–N(pz) distance (2.076 Å) and slightly shorter Ru^{III}–$N(NH_3)$ bonds (2.10–2.13 Å) as compared with the ruthenium(II) analogue which has bond lengths of 2.006 Å and 2.15–2.17 Å for those linkages.[205] Similar lengthening of the Ru^{III}–N(isn) distances is also observed for *cis*-$[Ru(NH_3)_4(isn)_2]^{3+}$.[243] $[Ru(NH_3)_5pz]^{3+}$ is less basic than the ruthenium(II) analogue,[240] a similar decrease in pK_a being observed[235,248] for $[RuL(NH_3)_5]^{3+}$ (L = C-bound, N-bound imidazole, pK_a for coordinated imidazole = 11.00, 7.06 respectively) compared with free imidazole (pK_a = 14.2). The synthesis of the protonated complex $[Ru(LH)(NH_3)_5]^{4+}$ (L = 1,1′-bis(4-pyridyl)amine) by Cl_2 oxidation of $[Ru(LH)(NH_3)_5]^{3+}$ in HCl has been achieved.[209]



The interaction of ruthenium(III) with biologically active ligands has been studied in complexes $[RuL(NH_3)_5]^{3+}$ (L = guanine,[201,249] xanthine derivatives,[202] hypoxanthine,[200] cytidine, adenosine tubercidin,[249] histidine,[236] histidine of ribonuclease A[250]). These products show low energy $L \rightarrow M$ charge transfer bands, the cytidine and adenosine adducts dissociating or isomerizing on reduction to ruthenium(II).[249] The single crystal X-ray structures of $[RuL(NH_3)_5]Cl_3$ (L = hypoxanthine, 7-methylhypoxanthine) have been determined.[257] Hypoxanthine is bound through N-7 (Ru—N-7 = 2.087 Å) (**30**), while for 7-methylhypoxanthine, N-3 to N-9 linkage isomerization can occur,[200,251] the crystal structure of (**31**) showing Ru^{III} bound to N-9 (Ru—N-9 = 2.094 Å).[251] The X-ray structure of $[Ru^{III}L(NH_3)_5]^{2+}$ (L = 1-methylcytosine$^-$) (**32**) shows a short Ru—N(cytosine) bond (1.983 Å), with hydrogen bonding between a ring N atom of cytosine and two NH_3 ligands.[252]

(30)

(31)

(32)

The outer-sphere reduction of $[Ru(NH_3)_5py]^{3+}$ with $[Fe(CN)_6]^{4-}$ and $[Ru(NH_3)_6]^{2+}$ (k = 4.3 × 10^6, 7.2 × 10^5 $M^{-1}s^{-1}$ respectively) has been studied.[130] $[RuL(NH_3)_5]^{3+}$ (L = pyridine, substituted pyridine) forms ion pairs with $[M^{II}(CN)_6]^{4-}$ (M = Fe, Ru, Os) which show in concentrated solutions outer-sphere charge transfer bands in the near IR (λ = 915 nm for $[Ru(NH_3)_5py]_4[Fe(CN)_6]_3$), interactions between $[M(CN)_6]^{4-}$ and an ammine face or with the pyridine ligand being postulated.[57,130,215] The reduction of $[Ru(NH_3)_5isn]^{3+}$ by Cr^{II} has been noted to be 2 × 10^4 faster than Cr^{II} reduction of Co^{III};[194] the formation of a binuclear Ru^{III}–Cr^{II} intermediate with Cr^{II} bound to the amide or carbonyl of isonicotinamide was proposed[194] (see Section 45.4.1.3). Kinetic studies on the reduction of $[Ru(NH_3)_5py]^{3+}$ by Cr^{II},[253] V^{II},[253] Ti^{III}[254] and $[Co(edta)]^{2-}$[219] (k = 3.4 × 10^{-3}, 1.2 × 10^5, 4.2 × 10^3, 32 $M^{-1}s^{-1}$ respectively), $[Ru(NH_3)_5pz]^{3+}$ and *cis*-$[Ru(NH_3)_4(isn)_2]^{3+}$ by Ti^{III} (k = 1.5 × 10^5, 1 × 10^6 $M^{-1}s^{-1}$ respectively)[254] and $[RuL(NH_3)_5]^{3+}$ (L = pz, 4,4′-bipy) by $[Co(edta)]^{2-}$ (k = 77 $M^{-1}s^{-1}$ for 4,4′-bipy complex)[219,255] have been reported

and the mechanisms discussed. The oxidation of horseheart ferrocytochrome and related species by $[Ru(NH_3)_5L]^{3+}$ at low pH has been studied.[215–217,256,257] O_2^- reduces $[Ru(NH_3)_5isn]^{3+}$ with a rate constant $k = 2.18 \times 10^8\,M^{-1}s^{-1}$.[221] The efficient hydrolysis of *p*-nitrophenylacetate in the presence of $[Ru(imid^-)(NH_3)_5]^{2+}$,[258] and the reduction of $[RuL(NH_3)_5]^{3+}$ (L = py, isn) and $[Ru(NH_3)_4(isn)_2]^{3+}$ by Cu^I have been reported.[259] Outer-sphere ligand to metal charge transfer absorption bands have been observed in the electronic spectra of $[Ru(NH_3)_5py]^{3+}$ with halide ions.[260]

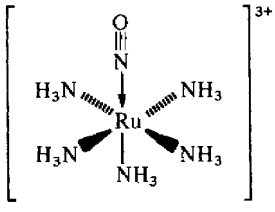
Ruthenium(IV): $[Ru(NH_3)_5py]^{3+}$ disproportionates at high pH to give $[Ru(NH_3)_5py]^{2+}$ and $[Ru(NH_3)_5py]^{4+}$.[261] Formation of Ru^{II} is second order in $[Ru^{III}]$, with $[Ru(NH_3)_5py]^{3+}$ being reformed from $[Ru(NH_3)_5py]^{4+}$ at pH 8–8.5.[261]

(c) Bidentate heterocycles

Ruthenium(II): (See also Section 45.4.3.1.ix). Reaction of $[Ru(NH_3)_4(OH_2)_2]^{2+}$, $[Ru(NH_3)_5(OH_2)]^{2+}$ or $[Ru(NH_3)_5(acetone)]^{2+}$ with L–L gives complexes $[Ru(L–L)(NH_3)_4]^{2+}$, while $[Ru(L–L)_2(NH_3)_2]^{2+}$ may be prepared by treatment of $[Ru(L–L)_2Cl_2]$, or preferably $[Ru(L–L)_2(OH_2)_2]^{2+}$ with NH_3 (L–L = 2,2′-bipyridine, 1,10-phenanthroline, 2,2′-bipyrimidine, or related heterocycles.[196,203,262–267] The ruthenium(II) complexes show intense metal → ligand charge transfer bands (not present in ruthenium(III) products)[267] and a related one electron $Ru^{II/III}$ redox couple. The electrochemistry of $[Ru(bipy)_2(NH_3)_2]^{2+}$ ($E_{1/2} = +1.27$ V *vs.* SCE) has been reported,[196,268a] and a spatially isolated redox orbital model proposed for this and related systems.[268b] Aerial oxidation of $[Ru(L–L)(NH_3)_4]^{2+}$ (L–L = 2-aminomethylpyridine) yields the corresponding 2-pyridinalimine adduct.[263] ^1H NMR of $[Ru(L–L)_2(NH_3)_2]^{2+}$ (L–L = 4,4′-dimethyl-2,2′-bipyridine) indicates that the complex is in the sterically preferred *cis* configuration.[269] Exchange rates have been measured[127] for $[Ru(bipy)(NH_3)_4]^{3+/2+}$ ($k = 7.7 \times 10^5$ in CF_3SO_3H, $2.2 \times 10^6\,M^{-1}s^{-1}$ in $HClO_4$, $\Delta H^{\neq} = 16.7\,kJ\,mol^{-1}$, $\Delta S^{\neq} = -100\,J\,K^{-1}\,mol^{-1}$), and for $[Ru(bipy)_2(NH_3)_2]^{3+/2+}$ ($k = 8.4 \times 10^7\,M^{-1}s^{-1}$ in $HClO_4$). Reduction of O_2 by $[Ru(phen)(NH_3)_4]^{2+}$ occurs with a rate constant $k = 7.73 \times 10^{-3}\,M^{-1}s^{-1}$,[220] while exchange reactions with $[Co(OH_2)_6]^{3+}$ have also been reported.[270]

Ruthenium(III): $[Ru(L–L)_2(NH_3)_2]^{3+}$ and $[Ru(L–L)(NH_3)_4]^{3+}$ may be prepared by chemical or electrochemical oxidation of ruthenium(II) analogues and are found to be strong oxidizing agents. Reduction of $[Ru(terpy)(bipy)(NH_3)]^{3+}$, $[Ru(bipy)_2(NH_3)_2]^{3+}$, $[Ru(terpy)(NH_3)_3]^{3+}$ and $[Ru(bipy)(NH_3)_4]^{3+}$ with $[Fe(OH_2)_6]^{2+}$ has been reported and related to Marcus theory.[271] Oxidation of $[(NH_3)_4Ru]_2bipym^{4+}$ at +1.02 V *vs.* NHE leads to binuclear cleavage and the formation of $[Ru(bipym)(NH_3)_4]^{3+}$ and $[Ru(NH_3)_4(OH_2)_2]^{3+}$.[262] The reduction of $[Ru(bipy)(NH_3)_4]^{3+}$ with Cu^I has been reported.[272]

(d) Nitrosyls

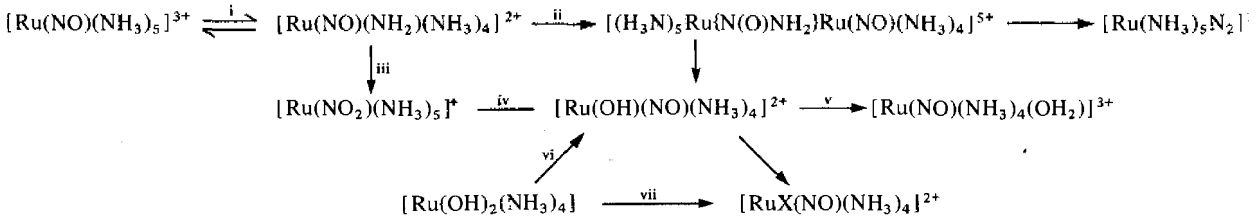


Transition metal nitrosyl complexes have been the subject of several reviews.[273–277]

Ruthenium(II): $[Ru(NO)(NH_3)_5]^{3+}$ was originally synthesized by treatment of $[Ru(NH_3)_6]^{3+}$ with NO_2^- in HCl.[158,278] It can also be prepared by aerial oxidation of $[Ru(NH_3)_6]^{3+}$ at pH 13 with NaOH[279] (equation 26), by reaction of $[Ru(NH_3)_6]^{3+}$ with NO under acidic conditions[280–282] (equation 27) or by direct substitution of H_2O in $[Ru(NH_3)_5(OH_2)]^{3+}$ by NO.[158] The N—O stretching vibration ν_{NO} for $[Ru(NO)(NH_3)_5]^{3+}$ occurs at 1908 cm^{-1};[279] the single crystal X-ray structure[283–285] of (**33**) shows Ru—N(NO) = 1.770, N—O = 1.172, Ru—N(NH_3) = 2.017–2.133 Å with a near linear nitrosyl ligand.[283] Thus the binding of NO in $[Ru(NO)(NH_3)_5]^{3+}$ should be regarded as $[Ru^{II}—NO^+]$ rather than $[Ru^{III}—NO]$, consistent with the diamagnetism of the complex. Analysis of the electronic absorption spectra of related complexes rules out a magnetically coupled $[Ru^{III}–NO]$ model.[286] Mössbauer studies of $[RuNO(NH_3)_5]^{3+}$ have been reported.[27c,120]

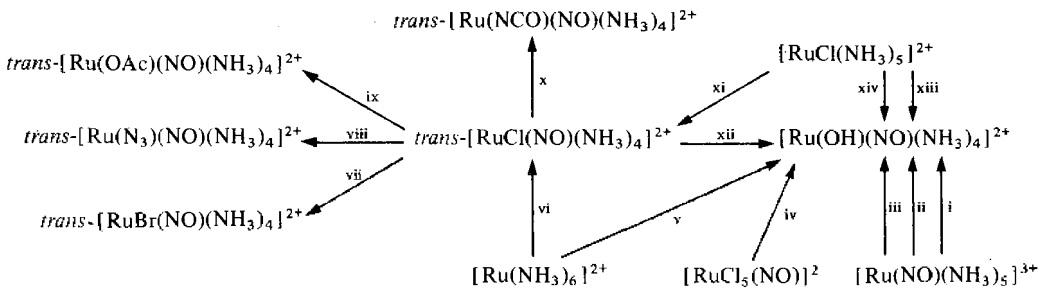
$$[Ru(NH_3)_6]^{3+} \xrightarrow[O_2]{pH\ 13} [Ru(NO)(NH_3)_5]^{3+} \qquad (26)$$

$$[Ru(NH_3)_6]^{2+} \xrightarrow[NO]{H^+} [Ru(NO)(NH_3)_5]^{3+} \qquad (27)$$



(33)

(33)



Whereas the aquation of $[Ru(NH_3)_6]^{3+}$ is very slow (several days), the reaction of $[Ru(NH_3)_6]X_3$ with NO is relatively fast with rate constants $k = 2.0 \times 10^{-1}$ for $X = Cl^-$, $1.9 \times 10^{-1} M^{-1} s^{-1}$ for $X = Br^-$ with first order dependence on [NO] and $[\{Ru(NH_3)_6\}^{3+}]$.[158] The dependence of the kinetics on pH has been discussed.[287] Reaction of $[RuBr(NH_3)_5]^{2+}$ with NO gives $[Ru(NO)(NH_3)_5]^{3+}$ and $[RuBr(NO)(NH_3)_4]^{2+}$.[158] The ^1H NMR of $[Ru(NO)(NH_3)_5]^{3+}$ shows increased H^+ exchange at the *trans* NH_3 group relative to $[Ru(NH_3)_5CO]^{2+}$. Schemes 7 and 8 summarize the reactivity of ruthenium ammine–nitrosyl complexes.

The single crystal X-ray structures of $[RuCl(NO)(NH_3)_4][Ru(NO_2)_4(OH)(NO)]$ and $[Ru(OH)(NO)(NH_3)_4][Os(NO_2)_4(OH)NO]\cdot 0.5H_2O$ have been reported.[296b]

Scheme 8

For *trans*-$[Ru^{II}X(NO)(NH_3)_4]^{x+}$, the N—O stretching vibration ν_{N-O} has been found to be a good indicator of *trans* effects of X; ν_{N-O} decreases in the order $NH_3 > NCO^- > N_3^- > -OAc > Cl^- > Br^-$.[268] ^1H NMR studies of *cis*- and *trans*-$[Ru(NO)(NH_3)_4(OH_2)]^{3+}$ in concentrated H_2SO_4 show the complexes to be stable for approximately fifteen minutes.[297] IR[298] and X-ray structural analyses[283] of *trans*-$[Ru(OH)(NO)(NH_3)_4]Cl_2$ have been reported and indicate binding of NO^+ to Ru^{II} (< RuNO = 173.8°).

For $[Ru(NO)(NH_3)_5]^{3+}$, $E° = -0.12$ V *vs.* SCE at 23°C.[299] Radiolysis of $[Ru(NO)(NH_3)_5]^{3+}$ yields a one-electron reduction product $[Ru(\dot{N}O)(NH_3)_5]^{2+}$ (**34**) which rapidly adds organic radicals (equations 28 and 29).[299] Reduction of $[Ru(NO)(NH_3)_5]^{3+}$ in the presence of a range of alcohols, amines and carboxylic acids RH yields products $[Ru(N(O)R)(NH_3)_5]^{2+}$.[300,301] $[Ru(\dot{N}O)(NH_3)_5]^{2+}$ is proposed as an intermediate in the redox catalysed aquation of $[Ru(NO)(NH_3)_5]^{3+}$ to *trans*-$[Ru(OH)(NO)(NH_3)_4]^{2+}$ which occurs with rate constants $k = 3.1 \times 10^9$, $5.5 \times 10^8 M^{-1} s^{-1}$ for $\dot{C}O_2$ and $CH_3\dot{C}OH$ respectively.[302] The rates of reaction are independent of $[\{Ru(NO)(NH_3)_5\}^{3+}]$ but depend linearly upon $[\{Ru(\dot{N}O)(NH_3)_5\}^{2+}]$ produced during the radical reaction. $[Ru(\dot{N}O)(NH_3)_5]^{2+}$ is scavenged by O_2 with a rate constant $k = 7.6 \times 10^6 M^{-1} s^{-1}$.[299]

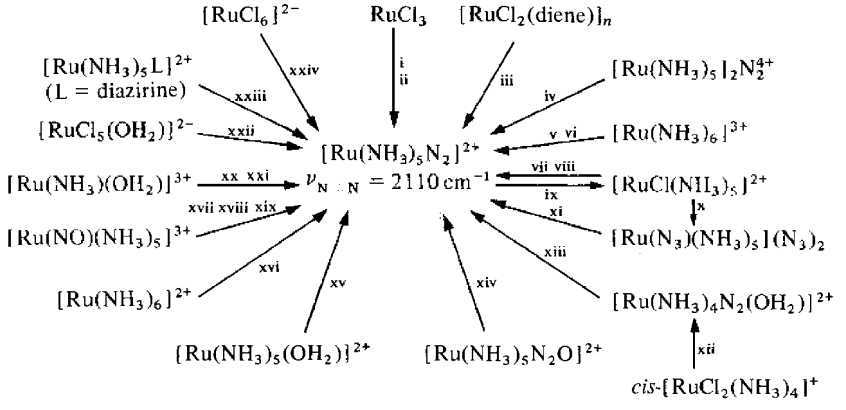
Nitrosyl ammine intermediates have been detected when $[Ru(NH_3)_6]^{3+}$ is treated with O_2 in

$$[Ru(NO)(NH_3)_5]^{3+} + e^-_{(aq)} \longrightarrow [Ru(\dot{N}O)(NH_3)_5]^{2+} \quad (28)$$

(34)

$$[Ru(\dot{N}O)(NH_3)_5]^{2+} + R\cdot \longrightarrow [Ru\{N(O)R\}(NH_3)_5]^{2+} \quad (29)$$

(34)

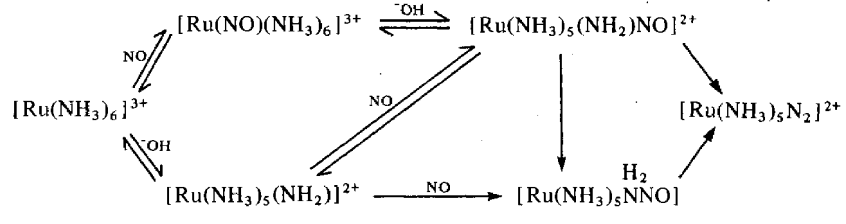


zeolites at 450 K[303] while reaction of $[Ru(NO)(NH_3)_5]^{3+}$ with $[Cr(OH_2)_6]^{2+}$ affords a dimeric species $[(NH_3)_4(OH_2)Ru—NH—Cr(OH_2)_5]^{5+}$.[282]

(e) Dinitrogen

The activation of N_2 by transition metal complexes has been reviewed.[304–308]

Ruthenium(I): Pulse radiolysis of $[Ru(NH_3)_5N_2]^{2+}$ yields $[Ru^I(NH_3)_5N_2]^+$ with a rate constant $k = 4.2 \times 10^9\,M^{-1}s^{-1}$. The product dismutes to $[Ru(NH_3)_5N_2]^{2+}$ and $[Ru(NH_3)_5N_2]^0$ ($2k = 2.7 \times 10^9\,M^{-1}s^{-1}$) with subsequent deposition of Ru metal.[309]



Ruthenium(II): The synthesis of $[Ru(NH_3)_5N_2]^{2+}$ was first prepared in 1965 by refluxing $RuCl_3$ in aqueous hydrazine.[310] Since then a range of methods have been developed for the synthesis of this complex. Scheme 9 summarizes the main routes to $[Ru(NH_3)_5N_2]^{2+}$.

Scheme 9

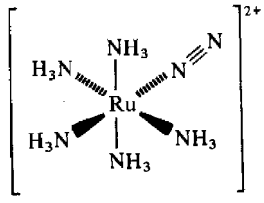
High yields of $[Ru(NH_3)_5N_2]^{3+}$ can be obtained from the reaction of $[Ru(NH_3)_6]^{2+}$ with NO at pH 8.45,[280,314] the yield dropping with lowering of pH and falling to zero at pH 6.[280] The proposed mechanism for the formation of $[Ru(NH_3)_5N_2]^{2+}$ from $[Ru(NH_3)_6]^{3+}$ is illustrated in Scheme 10.[158,280,287] Labelling experiments confirm that N_2 formation in the complex arises from combination of NO and coordinated NH_3 (equation 30),[314] whereas in the reduction of $[Ru(NH_3)_5N_2O]^{2+}$ by Cr^{II}, N_2 arises solely from coordinated N_2O (equation 31).[314,318] The mechanism of formation of $[Ru(NH_3)_5N_2]^{2+}$ from $[Ru(NH_3)_6]^{3+}$ and N_2H_4 involves oxidation of coordinated N_2H_4 to N_2 (equation 32).[116] The kinetics of formation of $[Ru(NH_3)_5N_2]^{2+}$ from $[Ru(NH_3)_5OH_2]^{2+}$ and N_2 has been reported (equation 33); $k_1 = 7.3 \times 10^{-2}$, $k_{-1} = 2.03 \times 10^{-6}\,s^{-1}$, $K_{equil} = 3.3 \times 10^4$.[324,325]

$$-\frac{d[[Ru(NH_3)_6]^{3+}]}{dt} = k_H[Ru^{III}][NO] + k_{OH}[Ru^{III}][NO][^-OH]$$

Scheme 10

$$[Ru(NH_3)_6]^{3+} + {}^{15}NO \longrightarrow [Ru(NH_3)_5{}^{29}N_2]^{2+} \quad (30)$$

$$[Ru(NH_3)_5{}^{15}N{}^{15}NO]^{2+} \xrightarrow{Cr^{II}} [Ru(NH_3)_5{}^{30}N_2]^{2+} \quad (31)$$



$$\underset{\lambda = 276\,nm}{[Ru(NH_3)_6]^{3+}} \xrightarrow{N_2H_4} \underset{\lambda = 380\,nm}{[Ru(NH_3)_5N_2H_4]^{3+}} \longrightarrow \underset{\lambda = 510\,nm}{[Ru(NH_3)_5(NH{=}NH)]^{2+}} \xrightarrow{O_2} \underset{\lambda = 221\,nm}{[Ru(NH_3)_5N_2]^{2+}} \quad (32)$$

(35)

$$[Ru(NH_3)_5(OH_2)]^{2+} + N_2(aq) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Ru(NH_3)_5N_2]^{2+} + H_2O \quad (33)$$

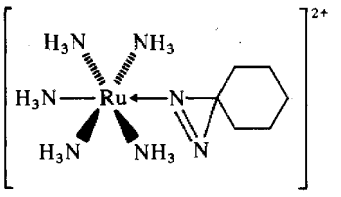
The single crystal X-ray structure of $[Ru(NH_3)_5N_2]^{2+}$ (**35**) confirms the linear linkage of N_2 (Ru—N = 2.11 Å, N≡N = 1.12 Å).[326]

Ab initio SCF–MO calculations[327] and Hartree–Fock–Slater studies[328] predict that the polarization of coordinated N_2 will be $Ru—\overset{\delta-}{N}—\overset{\delta+}{N}$. Bands in the vibrational spectrum have been assigned[329,330] to the N≡N and Ru—N(N_2) stretching modes. The frequency and intensity of $\nu_{N\equiv N}$ are found to be dependent upon counterion and solvent, due to electrostatic interactions in solution.[188,331] Mössbauer and ^{15}N NMR studies on $[Ru(NH_3)_5N_2]^{2+}$ have been reported.[27c,120,332,333] Linkage isomerism of coordinated N_2 has been detected in the solid state ($t_{1/2} = 2 \pm 1$ days at 22°C in the dark) and solution ($t_{1/2} = 2$ h at 25°C),[318] a weak π-bonded intermediate being postulated[318] (equation 34).

(35)

$$Ru \leftarrow {}^{15}N{\equiv}{}^{14}N \rightleftharpoons Ru \leftarrow \overset{{}^{15}N}{\overset{\|}{{}^{14}N}} \rightleftharpoons Ru \leftarrow {}^{14}N{\equiv}{}^{15}N \quad (34)$$

For $[Ru(NH_3)_5N_2]^{2+}$, $E_{1/2} = +0.72$ V *vs.* SCE.[334] *Cis*-$[Ru(NH_3)_4(OH_2)_2]^{2+}$ takes up one equivalent of N_2 to afford $[Ru(NH_3)_4(N_2)(OH_2)]^{2+}$,[320] while treatment of $[RuCl(NH_3)_5]^{2+}$ or *cis*-$[RuCl_2(NH_3)_4]^+$ with N_2H_4 at −23°C for 1 h and 10 min respectively is reported to yield $[Ru(NH_3)_4(N_2)_2]^{2+}$ ($\nu_{N\equiv N}$ = 2220, 2185 cm^{-1}).[335]



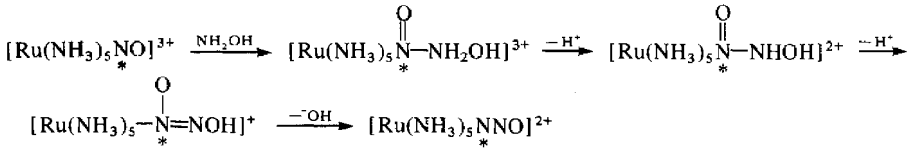
The N_2 ligand in $[Ru(NH_3)_5N_2]^{2+}$ may be displaced by other ligands; thus, with pyridine $[Ru(NH_3)_5py]^{2+}$ and $[Ru(NH_3)_4py_2]^{2+}$ are formed.[244] The photochemistry of $[Ru(NH_3)_5N_2]^{2+}$ has been studied in terms of oxidation of Ru^{II} to Ru^{III}, and of ligand substitution reactions *via* ligand field excited states.[336–338] For the N_2 complex, the principal photoreaction is redox in character[337] (equations 35–37). Thermolysis of solid $[Ru(NH_3)_5N_2]X_2$ (X = Cl^-, Br^-, I^-) at 165–213°C liberates NH_3 yielding initially $[RuX(NH_3)_4N_2]X$, with the rate increasing in the order $Cl^- < Br^- < I^-$. The Cl^- reaction is proposed to occur *via* an S_N1 mechanism, while for Br^- and I^-, S_N2 mechanism predominates.[339] Above 243°C N_2 is liberated.[339] The reactivity of $[Ru(NH_3)_5N_2]^{2+}$ in zeolites has been reported,[340–342] air oxidation yielding zeolite-bound ruthenium red.[342]

$$\underset{\lambda = 221\,nm}{[Ru(NH_3)_5N_2]^{2+}} \xrightarrow[HCl]{h\nu} \underset{\lambda = 330\,nm}{[RuCl(NH_3)_5]^{2+}} \quad (35)$$

$$[Ru(NH_3)_5N_2]^{2+} \xrightarrow[NH_3]{h\nu} \underset{\lambda = 276\,nm}{[Ru(NH_3)_6]^{3+}} \quad (36)$$

$$[Ru(NH_3)_5N_2]^{2+} \xrightarrow[H_2O]{h\nu} \underset{\lambda = 290\,nm}{[Ru(OH)(NH_3)_5]^{2+}} \quad (37)$$

Reaction of diazirine L with $[Ru(NH_3)_5OH_2]^{2+}$ yields $[Ru(NH_3)_5L]^{2+}$ (**36**) which is oxidized in air or by H_2O_2 to $[Ru(NH_3)_5N_2]^{2+}$ and cyclohexanone.[323] The single crystal X-ray structure of (**36**) indicates strong $d \rightarrow p\pi^*$ (N=N) back-bonding with Ru—N(N_2) = 1.911 Å, Ru—N(*trans* NH_3) = 2.147 Å, N=N = 1.28 Å, < RuNN = 141.6°.[323]



(36)

Ruthenium(III): Reaction of $[Ru(NH_3)_5N_2]^{2+}$ with $\dot{O}H$ yields $[Ru^{III}(NH_3)_5N_2]^{3+}$ which rapidly aquates to $[Ru(OH)(NH_3)_5]^{2+}$.[309] For $[Ru(NH_3)_5N_2]^{3+}$ the specific rate of aquation $k = 70\,s^{-1}$.[315]

(f) Nitrous oxide

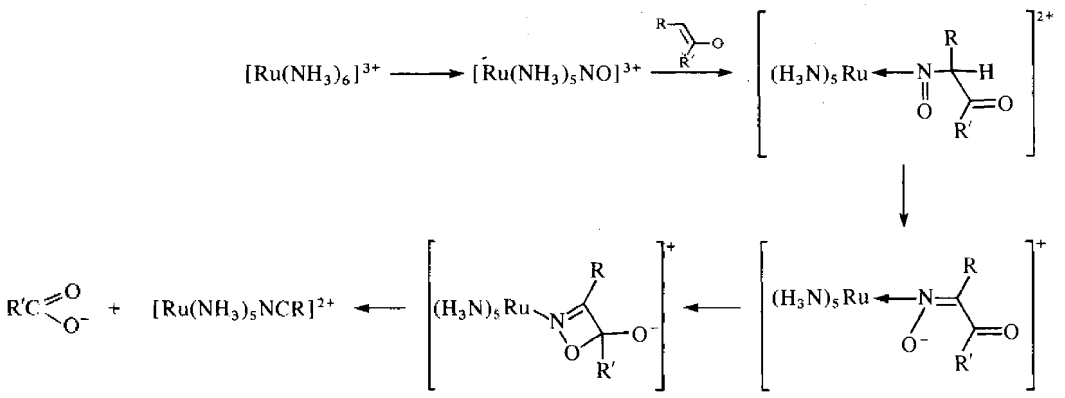
Ruthenium(II): Reaction of $[Ru(NH_3)_5(OH_2)]^{2+}$ with oxygen free N_2O at 30–40 atm yields the adduct $[Ru(NH_3)_5N_2O]^{2+}$ (equation 38).[314,343,344] At lower pressures, $[Ru(NH_3)_5N_2]^{2+}$ and $\{[Ru(NH_3)_5]_2N_2\}^{4+}$ are formed. $[Ru(NH_3)_5N_2O]^{2+}$ may also be prepared by reaction of $[Ru(NO)(NH_3)_5]^{3+}$ with NH_2OH under basic conditions.[281,292,322] Scheme 11 gives the proposed mechanism for this reaction, with the N of NO remaining bound to the Ru centre.[322,345] $[Ru(NH_3)_5N_2O]^{2+}$ can be isolated as a by-product in the reaction of $[Ru(NO)(NH_3)_5]^{3+}$ with N_2H_4.[322] X-Ray powder results and the electronic and vibrational spectra of $[Ru(NH_3)_5N_2O]^{2+}$ are consistent with linear bound N_2O, $RuN{\equiv}NO$,[345] with characteristic IR bands at 1160 cm^{-1} and 2250 cm^{-1}.[322]

$$[Ru(NH_3)_5(OH_2)]^{2+} + {}^{15}N^{15}NO \longrightarrow [Ru(NH_3)_5{}^{15}N^{15}NO]^{2+} + H_2O \qquad (38)$$

Scheme 11

The reduction of complexed N_2O by Cr^{II} and V^{II} is increased by facts of 10^8 and 10^7 respectively over reduction of free N_2O.[346,347] The kinetics of these reactions have been discussed.[346,347]

(g) Cyanates and thiocyanates



The complexes $[Ru(L)(NH_3)_5]^{2+}$ (L = $^-$NCO, $^-$NCS, $^-$NCSe) can be prepared by reaction of $[RuCl(NH_3)_5]^{2+}$ with L in refluxing aqueous solution, or by treatment of $[RuCl(NH_3)_5]^{2+}$ with Ag^+ followed by reduction with zinc amalgam and addition of L.[348,349] With excess NCS, further reaction leads to the formation of a range of amine–thiocyanate complexes including $[Ru(NCS)_2(NH_3)_4]^+$[350–352] and the proposed $[Ru(NCS)_2(SCN)_2(NH_3)_2]^-$.[352,353] A low energy charge transfer band is observed for $[Ru(NCO)(NH_3)_5]^{2+}$ and is assigned to $e(\pi L) \rightarrow t_2(4dRu)$ transition.[354] On the basis of the energy of *d–d* transitions in $[Ru(L)(NH_3)_5]^{2+}$, a spectrochemical series of L (NH_3 > $^-$NCO > $^-$OAc > $^-$NCS > $^-$NCSe) was proposed.[349] Reaction of the dimer $[(NH_3)_5RuSSRu(NH_3)_5]^{4+}$ with CN^- gives S-bound $[Ru(SCN)(NH_3)_5]^+$ which rearranges to the N-bound $[Ru(NCS)(NH_3)_5]^{2+}$.[355,356] An alternative preparation of $[Ru(SCN)(NH_3)_5]^{2+}$ has been reported.[352] The hydrolysis of $[Ru(NCO)(NH_3)_5]^{2+}$ is acid catalysed with the proposed formation of $[Ru(NH_2CO_2H)(NH_3)_5]^{3+}$ as a reactive intermediate.[348]

The reduction of $[Ru(NCS)(NH_3)_5]^{2+}$ by Ti^{III} and Ti(Hedta) shows second order kinetics with rate constants k = 840 and $2.8 \times 10^4\,M^{-1}\,s^{-1}$,[357] inner-sphere electron transfer *via* $^-$NCS bridges being proposed for both systems.[357]

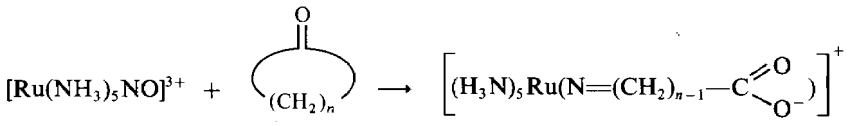
(h) Nitriles

Ruthenium(II): Treatment of $[Ru(NH_3)_5(OH_2)]^{2+}$ or $[Ru(NH_3)_5(acetone)]^{2+}$ with L or $[RuCl(NH_3)_5]^{2+}$ with zinc amalgam in the presence of L yields $[RuL(NH_3)_5]^{2+}$ (L = acetonitrile, benzonitrile,[358] substituted benzonitrile,[196,358,359] acrylonitrile,[360] hydrogen cyanide,[36,37] ethyl cyanoformate,[361] dicyanamide, malononitrile, substituted malononitrile, tricyanomethanide,[362] 4-cyano-1-methylpyridinium[196]). Reaction of a hundred-fold excess of RCHO (R = Ph, Me) with $[Ru(NH_3)_6]^{2+}$ under alkaline conditions yields $[Ru(NH_3)_5NCR]^{2+}$.[363–365] The likely mechanism of this reaction is given in Scheme 12. An alternative route to nitrile complexes is by reaction of $[Ru(NH_3)_5OH_2]^{2+}$ with aldoximes, *e.g.* RMeC=NOH, to afford $[Ru(NH_3)_5(NCMe)]^{2+}$ and

ROH.[366,367] A wide range of alkoximes have been surveyed for this reactivity, the reaction proceeding *via* deaquation and elimination of ROH with no net redox change occurring at the metal centre.[366–368]

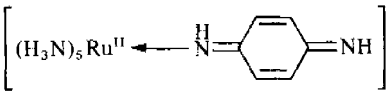
Scheme 12

Complexation of RCN to ruthenium(II) centres leads to shifts of the C≡N stretching vibration $\nu_{C\equiv N}$ to lower frequencies as compared with $\nu_{C\equiv N}$ for the free ligand.[369] This is due to strong $d\pi \rightarrow \pi^*$ back-bonding from Ru^{II} to the nitrile ligand,[358,360] and is consistent with the remarkable unreactivity of these d^6 complexes compared with the corresponding d^5 Ru^{III} species[370,371] (see below). The binding of acrylonitrile to the $[Ru(NH_3)_5]^{2+}$ moiety has been studied by ^1H NMR and confirms terminal N binding rather than π bonding through C≡N or C=C.[360] ^1H NMR has also been used to probe the degree of back-bonding from Ru^{II} to coordinated nitrile, the observed shielding of geminal protons for coordinated acrylonitrile and 1-methylacrylonitrile, and of the 3- and 4-protons of benzonitrile being consistent with an extensive back-bonding model.[372] The electronic and resonance Raman spectra of $[RuL(NH_3)_5]^{3+}$ (L = 4-cyano-1-methylpyridinium$^+$)[211] and Mössbauer studies on $[RuL(NH_3)_5]^{2+}$ (L = benzonitrile, acetonitrile)[120] have been published. The photolysis of $[Ru(NH_3)_5(NCMe)]^{2+}$ in aqueous conditions in the presence of Cl^- gives $[RuCl(NH_3)_5]^{2+}$ and $[Ru(NH_3)_5(OH_2)]^{2+}$.[224,337]



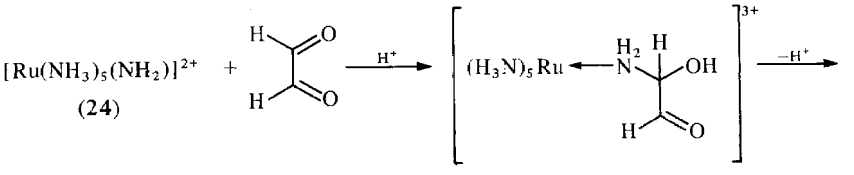
Ruthenium(III): Ruthenium(III) nitrile complexes $[RuL(NH_3)_5]^{3+}$ may be synthesized by reaction of L with $[Ru(NH_3)_5OH_2]^{3+}$,[196] oxidation of $[Ru(L)(NH_3)_5]^{2+}$ with Ce^{IV} or Ag^I,[359] by direct treatment of $[RuCl(NH_3)_5]^{2+}$ with L under reflux[358,360] or by aerial oxidation of coordinated amines.[192] The IR spectrum of these complexes shows the C≡N stretching vibration $\nu_{C\equiv N}$ to occur at higher frequencies than in the free ligand,[358,360] indicating net π back-donation from π^* (L) $\rightarrow d\pi$ (Ru^{III}). This is also reflected in the reactivity of nitrile ligands coordinated to Ru^{III}.

The specific rates of base hydrolysis of $[Ru(NH_3)_5NCR]^{3+}$ are 2.2×10^2 (R = Me) and $2 \times 10^3\ M^{-1}\ s^{-1}$ (R = Ph) which is 10^6 times more reactive than the corresponding Ru^{II} complex, and 10^8 times more reactive than the free ligand.[370,371,373] General base catalysis is observed in these reactions suggesting ^-OH attack on coordinated nitrile as an initial step leading to amido complexes $[Ru(NHC(O)R)(NH_3)_5]^{2+}$.[370,371] On coordination of *tert*-butylmalononitrile to $[Ru(NH_3)_5]^{3+}$ the pK_a of the ligand decreases from 13.1 to 3.85,[362] the enhanced acidity of *tert*-butylmalononitrile on coordination to Ru^{III} being attributed to the relative net π acceptor ability of the metal centre; *cf.* the increase in basicity and decrease in basicity of pyrazine on coordination to $[Ru(NH_3)_5]^{2+}$ and $[Ru(NH_3)_5]^{3+}$ respectively.[240] The acid hydrolysis of $[Ru(NH_3)_5NCR]^{3+}$ has been reported to occur with specific rates $k = 1.2 \times 10^{-5}$ (R = Me), $3.4 \times 10^{-5}\ M^{-1}\ s^{-1}$ (R = Ph).[373]

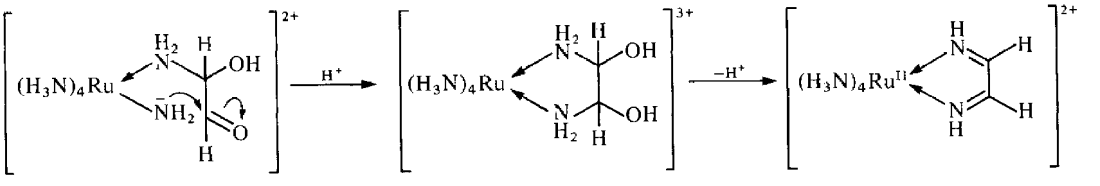


(i) Imines, amides and related ligands

Imine complexes have been involved as intermediates in the condensation of aldehydes with $[Ru(NO)(NH_3)_5]^{3+}$ under basic conditions to form nitrile complexes;[364,365] in certain cases the imine species have been isolated (equation 39).[364] Reaction of $[RuCl(NH_3)_5]^{2+}$ with $Ag(O_2CCF_3)$ followed by addition of ligands L (L = quinone diimine derivatives of 1,4-diaminobenzene, 1-amino-4-dimethylaminobenzene, 1,4-diaminonaphthalene, 4-aminophenol) gives complexes $[RuL(NH_3)_5]^{2+}$, *e.g.* (**37**).[374] These products show intense metal to ligand charge transfer bands near 550 nm ($\varepsilon = 3 \times 10^4\ M^{-1}\ cm^{-1}$), the basicity of the diimine ligand being increased on coordination to ruthenium(II). A reversible couple between Ru^{II}(diimine) and Ru^{II}(diamine) is observed.[374] Reaction of $[Ru(NH_3)_6]^{3+}$ with diketones such as biacetyl yields under basic conditions the corresponding bidentate diimine complexes (**38**).[375,376] The kinetics of the reaction have been elucidated and

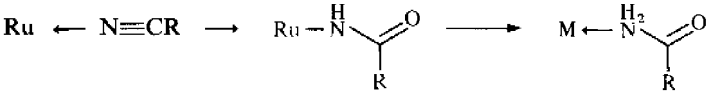


shown to proceed with [$^-$OH] dependence *via* the intermediate $[Ru(NH_2)(NH_3)_5]^{2+}$ (**24**) (Scheme 13). The diimine complex (**38**) shows a reversible oxidation couple at +0.56 V *vs.* SCE, controlled potential electrolysis of chemical oxidation with Br_2 yielding the ruthenium(III) analogue.[375,376]

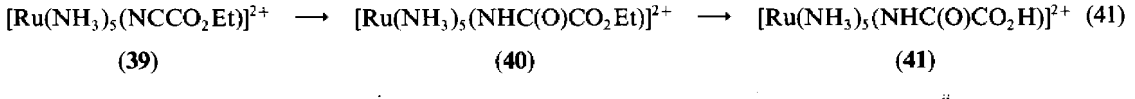


(39)

(37)

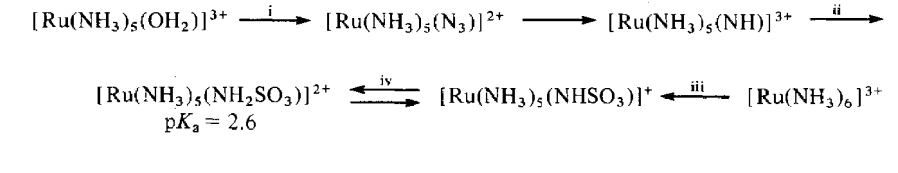


(38)



$$\frac{d[Ru^{II}]}{dt} = k[Ru^{III}][\text{biacetyl}][^-OH]$$

Scheme 13



The base hydrolysis of Ru^{III} nitrile complexes to amido products has been reported (equation 40).[370] Reaction of $[Ru^{II}(NH_3)_5(NCCO_2Et)]^{2+}$ (**39**) with AgO yields $[Ru^{III}(NHC(O)CO_2Et)(NH_3)_5]^{2+}$ (**40**) which in mild alkali gives the oxamic acid derivative (**41**) (equation 41).[361] The hydrolysis of $[Ru(NCO)(NH_3)_5]^{2+}$ gives $[Ru(NH_2CO_2H)(NH_3)_5]^{3+}$.[348] Amide derivatives of $[Ru(NH_3)_5]^{3-}$ may also be prepared directly from the reaction of $[Ru(NH_3)_5OH_2]^{2+}$ with $RCONH_2$ (R = Me, Ph),[371] while sulfamide complexes have been synthesized by reaction of SO_3^{2-} on azide complexes[377] or by attack of $S_2O_3^{2-}$ on coordinated NH_3 (Scheme 14).[378]

Scheme 14

(iii) Oxygen donor ligand complexes

(a) Aqua and hydroxy ligands

Ruthenium(II): $[Ru(NH_3)_5OH_2]^{2+}$ can be most efficiently prepared by zinc amalgam reduction of $[RuCl(NH_3)_5]Cl_2$ in aqueous solution.[208,319,325] More recently, an alternative route avoiding Zn^{2+} and Cl^- ion has been developed based on the aquation of electrochemically reduced $[Ru(O_3SCF_3)(NH_3)_5]^{2+}$.[208] Alternative routes include the photolysis[379] and acid-catalysed hydrolysis[380] of $[Ru(NH_3)_6]^{2+}$ and the reduction of $[Ru(NH_3)_5(OH_2)]^{3+}$.[203] The lability of the aqua ligand in these systems makes $[Ru(NH_3)_5OH_2]^{2+}$ an excellent starting material for the synthesis of substituted pentaammine complexes, and for the study of their kinetics of formation.

Tables 2 and 3 give data on the substitution reactions of $[Ru(NH_3)_5OH_2]^{2+}$ with a range of ligands L.[381-383] The kinetics of substitution on $[Ru(NH_3)_5OH_2]^{2+}$ are first order in $[[Ru(NH_3)_5(OH_2)]^{2+}]$ and [L] with rate constant in the range $k = 0.048 \rightarrow 0.32\ M^{-1}s^{-1}$ at 25°C for L = pyridine, 3- and 4-cyanopyridine, acetonitrile, benzonitrile, perfluorobenzonitrile.[384,385] Electron-donating groups on L were found to enhance the rate of substitution, while electron-withdrawing groups decreased the rate. An S_N1 mechanism was suggested, with pyridines reacting relatively slowly due to steric factors.[384] The enthalpies for substitution of $[Ru(NH_3)_5OH_2]^{2+}$ by acetonitrile, imidazole, pyridine, thiodiethanol, $[Ru(NH_3)_5pz]^{2+}$, isonicotinamide, pyrazine, *N*-methylpyrazinium$^+$, dimethyl sulfoxide and CO have been found to be -38.4, -38.9, -53.1, -57.3, -57.7, -64.0, -70.3, -75.3, -80.3 and $-160.3\ kJ\ mol^{-1}$ respectively.[208]

Methylamine	3.5×10^3	3.5×10^3
Methyl sarcosinate	50 ± 10	2.0

The kinetics of substitution of L on *trans*-$[Ru(SO_3)(NH_3)_4(OH_2)]$ have been reported (Table 4) and indicate that replacement of NH_3 by SO_3^{2-} lowers the affinity for the incoming ligand approximately ten-fold, but increases the rate of substitution approximately 100-fold, a much greater lowering of affinity being observed with methionine methyl ester.[386] Reaction of $[Ru(NH_3)_5(OH_2)]^{2+}$ with $P(OEt)_3$ in acetone gives $[Ru(NH_3)_4(P(OEt)_3)_2]^{2+}$ from which the derivatives *trans*-$[RuL(NH_3)_4(P(OEt)_3)]^{2+}$ could be prepared;[387] for aquation (L = H_2O) of the diphosphite complex the rate constant $k = 1.12 \times 10^{-5}\ s^{-1}$. Substitution reactions of *trans*-$[Ru(NH_3)_4(OH_2)[P(OEt)_3]^{2+}$ were studied and an order for the affinity of the complex for the entering ligand was found to be $P(OEt)_3 > SO_3^{2-} >$ imid(N bound) > isn > pz > $Mepz^+$.[387] For SO_3^{2-} and N-bound imid, bond making was proposed to be substantial in the activated complex, whereas for isn, pz and $Mepz^+$, noticeable outer-sphere complex formation was indicated.[387] Reaction of *trans*-$[Ru(SO_4)(NH_3)_4isn]^+$ with CF_3SO_3H and zinc amalgam gives *trans*-$[Ru(NH_3)_4isn(OH_2)]^{2+}$.[388] The labilizing effect of L in *trans*-$[RuL(NH_3)_4(OH_2)]^{2+}$ was probed by kinetic measurements and the labilizing

effect of L was found to increase in the order L = N_2 < CO < isn < pz < imid(N bound) < $-NH_3$ < ^-OH < $P(OEt)_3$ < ^-CN < SO_3^{2-} < imid(C bound).[387] The kinetics of substitution of *cis*- and *trans*-$[Ru(NH_3)_4(OH_2)_2]^{2+}$ to $[RuL(NH_3)_4(OH_2)]^{2+}$ and then to $[RuL_2(NH_3)_4]^{2+}$ have been studied;[385] for L = pyridine, the second order rate constants $k_1 = 9 \pm 1$ (*cis* isomer) and $0.74\ M^{-1}s^{-1}$ (*trans* isomer) for initial substitution, and $k_2 = 1.2 \pm 0.5$ (*cis* isomer) and $0.5 \pm 0.5\ M^{-1}s^{-1}$ (*trans* isomer) for the second substitution reaction.[385] Photolysis of $[Ru(NH_3)_5(OH_2)]^{2+}$ in the presence of Cl^- affords $[RuCl(NH_3)_5]^{2+}$.[379]

Table 4 Selected Kinetic and Equilibrium Data for Reactions[239,386]

Electron transfer between $[Ru(NH_3)_5(OH_2)]^{2+}$ and $[RuCl(NH_3)_5]^{2+}$ ($k = 1.0 \times 10^3\ M^{-1}s^{-1}$) yields $[Ru(NH_3)_5OH_2]^{3+}$ and $[RuCl(NH_3)_5]^+$.[178] The rate of electron transfer is reported to be independent of $[H^+]$, and decreases in the order $I^- > Br^- > Cl$, the reaction proceeding *via* an outer-sphere type mechanism.[389] Subsequent aquation of $[RuCl(NH_3)_5]^+$ occurs to give $[Ru(NH_3)_5OH_2]^{2+}$ ($k = 4.7\ s^{-1}$) thus rendering the overall aquation of $[RuCl(NH_3)_5]^{2+}$ catalysed by reducing agent.[125,178] The kinetics of reduction of $[CoX(NH_3)_5]^{2+}$ (X = F^-, Cl^-, Br^-, I^-, ^-NCS, ^-SCN, N_3^-) and $[Co(ox)(NH_3)_4]^-$ by $[Ru(NH_3)_5OH_2]^{2+}$ have been reported and discussed in terms of inner- and outer-sphere electron transfer mechanisms.[133,139,390] $[Ru(NH_3)_5(OH_2)]^{2+}$ with VO^{2+} yields green binuclear complexes $[(NH_3)_5Ru^{II}OV^{IV}(L)_n]^{4+}$ (L = H_2O,[380] edta derivatives[391]) which show M → L charge transfer bands near 600 nm. The ESR spectra and electron transfer processes in these systems have been reported.[391] Reduction of H_2O_2 and cytochrome c by $[Ru(NH_3)_5OH_2]^{2+}$ has been studied,[154,392] while $[Ru(NH_3)_5OH_2]^{2+}$ has been bound to polyvinyl pyridine coated electrodes.[393]

Ruthenium(III): $[Ru(NH_3)_5OH_2]^{3+}$ has been prepared by reaction of $[RuCl(NH_3)_5]Cl_2$ with dilute NH_3 and acidification to pH 3,[394] by reaction of $[Ru(O_3SCF_3)(NH_3)_5)](O_3SCF_3)_2$ with H_2O,[208] by protonation of $[Ru(OH)(NH_3)_5]^{2+}$ with 3 M CF_3SO_3H[362] or by treatment of $[Ru(NH_3)_6]Cl_2$ with HCl.[395] $[Ru(OH)(NH_3)_5]^{2+}$[278,396] can be isolated from the reduction of $[RuCl(NH_3)_5]Cl_2$ with zinc amalgam followed by air oxidation of the product, from the reaction of $[RuCl(NH_3)_5]Cl_2$ with NH_3,[290,397] and from the aquation of $[Ru(NH_3)_6]^{3+}$ under basic conditions.[164] The latter reaction proceeds *via* two independent pathways: (a) pH independent, and (b) base-catalysed aquation *via* $[Ru(NH_2)(NH_3)_5]^{2+}$ intermediate;[166] for $[Ru(NH_3)_5OH_2]^{3+}$ $pK_a = 4.2$.[235,398]

Substitution reactions of $[Ru(NH_3)_5OH_2]^{3+}$ have been reported (Table 3).[383] Thermolysis of $[Ru(NH_3)_5OH_2]X_3$ in the solid state takes place *via* a two step process to give initially $[RuX(NH_3)_5OH_2]^{2+}$ in a rate-determining step, with subsequent formation of $[RuX(NH_3)_5]^{2+}$ (X = Cl^-, Br^-, I^-, NO_3^-);[399a] the activation energies and entropies for these reactions have been assessed.[399a,399b] In solution, anation of $[Ru(NH_3)_5OH_2)]^{3+}$ shows second order kinetics.[124,399c,400] The photolysis of $[Ru(NH_3)_5(OH_2)]^{3+}$ has been reported.[177]

Electron transfer reactions of $[Ru(NH_3)_5OH_2]^{3+}$ with Sm^{II},[401,402] Yb^{II},[401,402] Eu^{II},[401,402] Fe^{III},[128] $[Fe^{III}OH]^{2+}$,[128] U^{III},[170] Cr^{II},[125,402] V^{II}[402] and $[Ti^{III}(OH)]^{2+}$[254] have been studied. $[Ru(NH_3)_6]^{3+}$ on zeolites can be converted to a complex of the type $[Ru(NH_3)_x(OH)_y(CO)_z]^{n+}$ which is an active catalyst for the water gas shift reaction.[403]

$[Ru(NH_3)_4(OH_2)_2]^{3+}$ is prepared *via* addition of CF_3SO_3H to $[Ru(ox)(NH_3)_4]^+$;[404a] the affinity of *trans*-$[Ru^{III}L(NH_3)_4OH_2]^{3+}$ (L = C-bound imidazole) for imidazole, py, isn, Cl^-, Br^-, I^- is very low ($K_{assoc} = 1.2$ for isn) except for NCS^- ($K_{assoc} = 3.3 \times 10^4\ M^{-1}$); a large kinetic labilization by C-bound imidazole is implied.[235]

Electrochemical evidence for the interconversion of $[Ru^{IV}(O)(NH_3)_5]^{2+}$, $[Ru^{III}(OH)(NH_3)_5]^{2+}$ and $[Ru^{III}(NH_3)_5(OH_2)]^{3+}$ has been obtained using activated glassy carbon electrodes.[404b]

$[Ru(O)_2(NH_3)_4]^{2+}$ and related ruthenium(VI) complexes incorporating the *trans* dioxo moiety have been reported.[65]

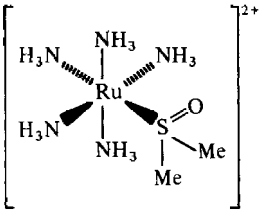
(b). Carboxylates

Ruthenium(II): The polarographic reduction of $[Ru^{III}L(NH_3)_5]^{2+}$ (L = formate, acetate, propionate, butyrate, glycolate, glycinate) shows a reversible one electron transfer to give Ru^{II} at a DME in aqueous solution.[405,406] $E_{1/2}$ values for this couple were found to become more positive with increasing $[H^+]$.[406] The reversible uptake of CO_2 by $[Ru(NH_3)_5(OH_2)]^{2+}$ has been described.[187b]

Ruthenium(III): Reaction of $[Ru(OH)(NH_3)_5]Cl_2$ with acetic anhydride followed by acid hydrolysis and treatment with Ag^+ gives $[Ru(OAc)(NH_3)_5]^{2+}$.[397] Oxalic acid with $[Ru(OH)(NH_3)_5]^{2+}$[290] or $[RuCl(NH_3)_5]^{2+}$[404a] affords *cis*-$[Ru(ox)(NH_3)_4]^+$. Carboxylato complexes can be prepared generally by treatment of $[RuCl(NH_3)_5]^{2+}$ with $Ag(O_2CCF_3)$ followed by addition of carboxylate buffer in DMF.[402] Charge transfer bands for the complexes $[Ru(O_2CR)(NH_3)_5]^{2+}$ are observed near 300 nm, and are related to the $E_{1/2}$ values for reduction of the complexes.[405]

Aquation of $[Ru(O_2CR)(NH_3)_5]^{2+}$ proceeds *via* two pathways: (a) an acid-catalysed S_N1 process, and (b) an acid independent S_N2 process for R = CH_2F, CH_2Cl, CH_2Br, CH_2I.[407] For R = $CHCl_2$, CCl_3 the aquation reaction is not catalysed by H^+ due to the high acidity of the coordinated ligand.[407–409] Data for the aquation of non-halo carboxylate complexes are given in Table 5; the mechanisms of the reactions have been discussed.[410–412] Anation of $[Ru(O_2CCH_2Cl)(NH_3)_5]^{2+}$ is reported to proceed *via* predominantly an S_N1 mechanism.[409]

Table 5 Kinetic Data for Aquation of $[Ru(O_2CR)(NH_3)_5]^{2+}$[410] for which Aquation Rate Law is Rate = [complex]($k_{H_2O} + k_H[H^+]$)



RCO_2^-	$k_{H_2O}(s^{-1})$	$k_H(M^{-1}s^{-1})$
Formate	5.37×10^{-5}	3.3×10^{-3}

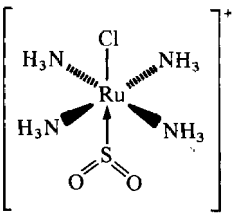
Propionate	14×10^{-5}	2.5×10^{-3}
Isobutyrate	13.7×10^{-5}	1.7×10^{-3}
Glycolate	5.7×10^{-5}	0.75×10^{-3}
Glycinate	6.75×10^{-5}	3.1×10^{-3}

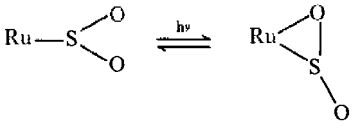
The reduction of *cis*-$[Ru(ox)(NH_3)_4]^+$, $[Ru(oxH)(NH_3)_5]^{2+}$ and $[Ru(OAc)(NH_3)_5]^{2+}$ by $[Ru(NH_3)_6]^{2+}$ and $[Ru(NH_3)_5OH_2]^{2+}$ has been studied;[413] the rates of reduction are acid dependent and increase with increasing $[H^+]$ with outer-sphere mechanisms being proposed.[413] Inner-sphere reductions of $[Ru(O_2CR)(NH_3)_5]^{2+}$ have been reported with Cr^{II}[402] and Ti^{III}.[414,415] Acid dependent second order kinetics were observed for Ti^{III} reactions which occur *via* electron transfer in a deprotonated binuclear intermediate, the rate constant for reduction being identified as the rate constant for substitution on Ti^{III}.[414] For the salicylato complex, no acid dependence was observed;[415] cross-bridging between Ru^{III} and Ti^{III} through the π-system of carboxylate was proposed.[415] Reaction of $[Ru(NH_3)_6]^{3+}$, $[RuCl(NH_3)_5]^{2+}$ or *cis*-$[RuCl_2(NH_3)_4]^+$ with LH_2 (LH_2 = catechol, 2,3-dihydroxynaphthalene) yields *cis*-$[RuL(NH_3)_4]^+$, while reaction with LH_3 (LH_3 = 3,4-dihydroxybenzoic acid, 3-(3,4-dihydroxyphenyl)propanoic acid) yields $[RuL(NH_3)_4]$;[416] the properties of these complexes have been discussed.[416]



(c) Sulfoxides and related ligands

Ruthenium(II): Refluxing $[Ru(NH_3)_5N_2]^{2+}$ in aqueous DMSO yields $[Ru(NH_3)_5DMSO]^{2+}$ (**42**).[417] ^1H NMR and IR spectral data for $[Ru(NH_3)_5\{S(O)(Me)_2\}]^{2+}$, $[Ru(ND_3)_5\{S(O)(Me)_2\}]^{2+}$, $[Ru(ND_3)_5\{S(O)(CD_3)_2\}]^{2+}$ and $[Ru(NH_3)_5\{S(O)(CD_3)_2\}]^{2+}$ indicate that the DMSO ligand is S-bonded.[417] This is confirmed by the single crystal X-ray structure of $[Ru(NH_3)_5DMSO]^{2+}$ (**42**) which shows Ru—S = 2.188 and S—O = 1.527 Å with lengthening of Ru—N distance *trans* to S to 2.209 Å.[418]

A range of SO_2, HSO_3^- and SO_3^{2-} complexes of $[Ru(NH_3)_5]^{2+}$ and $[Ru(NH_3)_4]^{2+}$ have been prepared.[2,419,420] Reaction of $[RuCl(NH_3)_4SO_2]^+$ with NH_3 yields $[Ru(SO_3)(NH_3)_5]$ which on acidification gives $[Ru(NH_3)_5SO_2]^{2+}$,[419,420] the Mössbauer of which has been reported.[120] Treatment of $[RuCl(NH_3)_5]^{2+}$ with HSO_3^-/SO_2 yields *trans*-$[Ru(HSO_3)_2(NH_3)_4]$ which can be converted to *trans*-$[RuX(NH_3)_4SO_2]^+$ with HX (X = Cl^-, Br^-).[196,419–421] The single crystal X-ray structure of *trans*-$[RuCl(NH_3)_4SO_2]Cl$ (**43**) shows[421] the SO_2 ligand to be S bonded with Ru—S = 2.072 Å, S—O = 1.462, 1.394 Å Ru—Cl = 2.415 Å with a planar $RuSO_2$ moiety. *Trans*-$[RuL(NH_3)_4SO_2]^{2+}$ may be prepared by reaction of *trans*-$[RuCl(NH_3)_4SO_2]^+$ with L (L = pz, isn, imid).[239,422] Photolysis of *trans*-$[RuCl(NH_3)_4SO_2]^+$ leads to linkage isomerism of the SO_2 ligand, from S-bonded SO_2 (ν_{SO} = 1255, 1110 cm^{-1}) to η^2-bonded SO_2 (ν_{SO} = 1165, 940 cm^{-1}) (equations 42 and 43).[423]



(42)

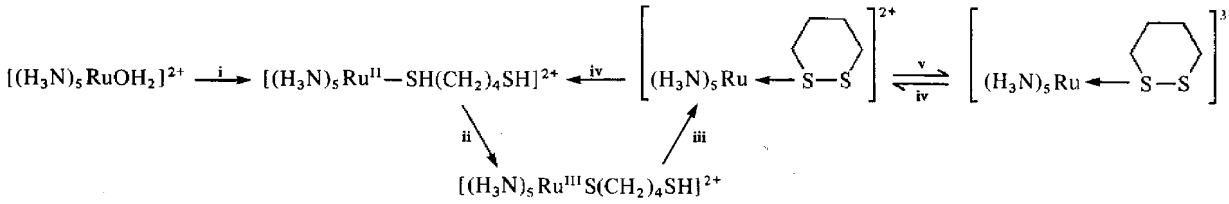
(43)

$$[RuCl(NH_3)_4SO_2]^+ \underset{h\nu\ 365\,nm\ 195\,K}{\overset{h\nu\ 365\,nm\ 25\,K}{\rightleftharpoons}} [RuCl(NH_3)_4(\eta^2\text{-}SO_2)]^+ \quad (42)$$

(43)

$[Ru(NH_3)_4(OH_2)(SO_2)]^{2+}$ may be prepared by reaction of *cis*-$[RuCl_2(NH_3)_4]Cl$ with zinc amalgam, HSO_3^- followed by acidification.[239,422] In solution, the SO_2 complex is in equilibrium with HSO_3^- and SO_3^{2-} derivatives (equations 44 and 45).[422] The rates of substitution of pyrazine into the SO_2 (**44**), HSO_3^- (**45**) and SO_3^{2-} (**46**) complexes have been measured; rate constants $k = 0.033$, 0.2, 13.5 $M^{-1}s^{-1}$ at 25°C respectively.[422] The rate of substitution for *cis*-$[Ru(SO_3)(NH_3)_4OH_2]$ is independent of [pz], the rate-determining step being release of NH_3 *trans* to SO_3^{2-}.[422]

$$\underset{\textbf{(44)}}{\textit{trans}\text{-}[Ru(NH_3)_4(OH_2)SO_2]^{2+}} + H_2O \rightleftharpoons \underset{\textbf{(45)}\ pK_a = 2.15}{\textit{trans}\text{-}[Ru(HSO_3)(NH_3)_4(OH_2)]^+} + H^+ \quad (44)$$



$$\underset{\textbf{(45)}}{\textit{trans}\text{-}[Ru(HSO_3)(NH_3)_4(OH_2)]^+} \rightleftharpoons \underset{\textbf{(46)}\ pK_a = 5.05}{\textit{trans}\text{-}[Ru(SO_3)(NH_3)_4(OH_2)]} + H^+ \quad (45)$$

Ruthenium(III): Oxidation of $[Ru(NH_3)_5\{S(O)(Me)_2\}]^{2+}$ (**42**) to the Ru^{III} complex leads to S → O isomerization at a specific rate $k = 7.0 \times 10^{-2}\,s^{-1}$; reduction back to Ru^{II} reverses the isomerization ($k = 30\,s^{-1}$) reforming (**42**).[424] Aquation is associated with both reactions. The 3+/2+ couples are 1.0 V and 0.01 V *vs.* SCE for the S- and O-bonded complexes respectively.[424] The electrochemistry of $[Ru(NH_3)_5SO_2]^{2+}$ has been studied;[425] oxidation at +0.5 V *vs.* SCE leads to the formation of the Ru^{III} complex with hydrolysis of coordinated SO_2 at a rate constant $k = 2.4 \times 10^{-2}\,s^{-1}$.[425] Treatment of $[RuCl(NH_3)_5]Cl_2$ with CF_3SO_3H leads to a high yield of labile $[Ru^{III}(OSO_2CF_3)(NH_3)_5]^{2+}$,[426,427] which readily undergoes substitution reactions to $[RuL(NH_3)_5]^{3+}$.[208,426,427] Reaction of $[Ru(NH_3)_5OH_2]^{3+}$ with $S_2O_3^{2-}$ yields $[Ru(S_2O_3)(NH_3)_5]^+$[378] while *trans*-$[Ru(SO_4)(L)(NH_3)_4]^+$ can be prepared by reaction of *trans*-$[RuCl(NH_3)_4SO_2]^+$ with L (L = pyridine, 3-chloropyridine, 3,5-dichloropyridine) in aqueous solution.[196] Oxidation of $[RuCl(NH_3)_4SO_2]^+$ with H_2O_2 in the presence of Na_2CO_3 and py gives $[Ru(SO_4)(NH_3)_4py]^+$.[428]

(*iv*) *Sulfur donor ligand complexes*

(See also Section 45.7). Reaction of $[Ru(NH_3)_5OH_2]^{2+}$ with an excess of L gives products $[RuL(NH_3)_5]^{2+}$ (L = 2,6-dithiaspiro[3.3]heptane,[429,430] $MeS(CH_2)_3SMe$,[429] H_2S,[431] $HS(CH_2)_4SH$,[432] Me_2S,[433] $S(C_2H_4)_2S$,[434] $S(C_3H_6)_2S$[434]). For $[Ru(NH_3)_5(SH_2)]^{2+}$ and $[Ru(NH_3)_5(SH_2)]^{3+}$, $pK_a = 4.0$ and −10 respectively, while for $[Ru(NH_3)_5(SHEt)]^{2+}$ and $[Ru(NH_3)_5(SHEt)]^{3+}$ $pK_a = 9$ and −7 respectively.[431] For the formation of $[Ru(NH_3)_5(SH_2)]^{2+}$ (equation 46), $K_{equil} = 1.5 \times 10^3\,M^{-1}$,[431] thioethers having generally a greater affinity for Ru^{II} than for Ru^{III}.[431] Reduction of $[RuL(NH_3)_5]^{3+}$ (L = $S(CH_2)_4S$) with zinc amalgam gives $[RuL(NH_3)_5]^{2+}$, which on further reduction yields $[Ru(NH_3)_5HS(CH_2)_4SH]^{2+}$;[432] reoxidation to $[RuL(NH_3)_5]^{3+}$ has been shown to occur with O_2 or Ce^{IV} (Scheme 15).[432] The aquation of $[Ru(NH_3)_5X(Me)_2]^{2+}$ to $[Ru(NH_3)_4(OH_2)X(Me)_2]^{2+}$ occurs with rate constants $k = 4.2 \times 10^{-6}$ (X = S), 1.0×10^{-5} (X = Se), 1.2×10^{-4} (X = Te) reflecting an increasing labilization order of $(Me)_2S < (Me)_2Se < (Me)_2Te$.[433]

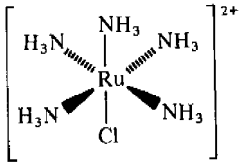
$$[Ru(NH_3)_5(OH_2)]^{2+} + H_2S \overset{K_{equil}}{\rightleftharpoons} [Ru(NH_3)_5(SH_2)]^{2+} + H_2O \quad (46)$$

i, $HS(CH_2)_4SH$; ii, O_2 or Ce^{IV}; iii, [O]; iv, Zn/Hg; v, Ce^{IV}

Scheme 15

Oxidation of $[Ru^{II}(LH)(NH_3)_5]^{2+}$ with O_2 or Ce^{IV} gives $[Ru^{III}L(NH_3)_5]^{2+}$ (L = $\bar{S}CH_2Me$, $\bar{S}(CH_2)_3SH$, $\bar{S}(CH_2)_4SH$, $\bar{S}Ph$, $\bar{S}(Me)_2$),[432,433] while treatment of $[Ru(NH_3)_5OH_2]^{2+}$ with $[(Me)_3S]PF_6$ yields $[Ru^{II}(NH_3)_5S(Me)_3]^{3+}$.[435] The Ru^{III} complexes show strong ligand → metal charge transfer bands *e.g.* for $[Ru(NH_3)_5S(Me)_2]^{3+}$ $\lambda = 453$ nm ($\varepsilon = 3 \times 10^2\,M^{-1}\,cm^{-1}$).[434,435] The lability and reactivity of thioethers bound to Ru^{II} and Ru^{III} have been fully discussed in relation to the electronic and redox properties of these systems.[383,396,429–436]

(*v*) *Halide complexes*



Ruthenium(II): $[RuCl(NH_3)_5]^+$ can be prepared by reduction of $[RuCl(NH_3)_5]^{2+}$ with Ti^{III} [173] or Ru^{II},[173] photolysis of $[Ru(NH_3)_5OH_2]^{2+}$ in the presence of Cl^- [379] or by radiolysis of $[RuCl(NH_3)_5]^{2+}$.[178] For $[RuCl(NH_3)_5]^{2+}$, *cis*- and *trans*-$[RuCl_2(NH_3)_4]^+$, $E_{1/2}$ for Ru^{II}/Ru^{III} couple = −0.282 V, −0.328 V and −0.412 V *vs.* SCE respectively.[334,425] $[RuCl(NH_5)_5]^+$ aquates rapidly to give $[Ru(NH_3)_5OH_2]^{2+}$ together with $[RuCl(NH_3)_5]^{2+}$ (equation 47).[379,425,437] The oxidation of $[RuCl(NH_3)_5]^+$ by CoL_3^{3+} (L = en, cyclohexanediamine) follows first order dependence on $[Co^{III}]$ and $[Ru^{II}]$ *via* an outer-sphere electron transfer with rate constant $k = 3.8 \times 10^{-3}$ and $6.2 \times 10^{-3}\,M^{-1}\,s^{-1}$ respectively.[438]

$$[RuX(NH_3)_5]^+ + H_2O \rightleftharpoons [Ru(NH_3)_5(OH_2)]^{2+} + X^- \qquad (47)$$

$X = Cl^-$, $K_{equil} = 0.7\,M$, $\Delta H^{\neq} = 50\,kJ\,mol^{-1}$, $\Delta S^{\ddagger} = -67\,J\,K^{-1}mol^{-1}$, $k = 6.3\,s^{-1}$

$X = Br^-$, $K_{equil} = 0.92\,M$, $\Delta H^{\neq} = 59\,kJ\,mol^{-1}$, $\Delta S^{\ddagger} = -42\,J\,K^{-1}mol^{-1}$, $k = 5.4\,s^{-1}$

Ruthenium(III): $[RuX(NH_3)_5]X_2$ can be prepared by treatment of $RuCl_3$ or $[RuCl_5(OH_2)]^{2-}$ with hydrazine followed by HCl,[117,325,439] by refluxing $[Ru(NH_3)_6]^{3+}$ in HX[113,114,193,394,421,440–442] or by solid state thermal substitution of $[Ru(NH_3)_6]X_3$ (X = Cl^-, Br^-, I^-).[443,444] The single crystal X-ray structure of $[RuCl(NH_3)_5]Cl_2$ (**47**) shows Ru—N = 2.07–2.11 Å, Ru—Cl = 2.34 Å.[439] Reaction of *cis*-$[Ru(ox)(NH_3)_4]^+$ or $[RuX(NH_3)_4SO_2]^+$ with refluxing HX (X = Cl^-, Br^-, I^-)[290,445–447] or thermolysis of $[RuCl(NH_3)_5]Cl_2$[444] yields $[RuX_2(NH_3)_4]^+$. $RuCl_3(NH_3)_3$ has been prepared by action of O_2 on blue solution of $[Ru(NH_3)_6]^{2+}$ in HCl,[442,448] by reaction of HCl with *cis*-$[RuCl_2(NH_3)_4]^+$[197] and by thermolysis of $[RuCl_2(NH_3)_4]Cl$.[444] The single crystal X-ray structure of *fac*-$[RuCl_3(NH_3)_3]$ shows Ru—N = 2.105–2.467 Å, Ru—Cl = 2.323–2.529 Å.[449]

(47)

Halo–ammine complexes show halide → Ru^{III} charge transfer bands[450] which have been characterized by circular dichroism studies.[354] Calculations predict that the Ru—N bond strength increases in the order *cis*-$[RuX_2(NH_3)_4]^+$ < $[RuX(NH_3)_5]^{2+}$ < $[Ru(NH_3)_5OH_2]^{3+}$ < $[Ru(NH_3)_6]^{3+}$, with Ru—NH_3 *trans* to X weaker than when *cis* to X.[451] The magnetic and ESR properties of $[RuCl(NH_3)_5]Cl_2$ have been reported.[163,452,453]

Anation of *trans*-$[Ru(NH_3)_4(isn)(OH_2)]^{3+}$ by Cl^- and Br^- proceeds *via* first order kinetics;[388] with I^- however, more complex kinetics are observed with the rate law being given by equation (48).[388] The k_a term can be accounted for by equations (49) to (51), with the k_b term suggesting a possible

electron transfer from I^- to Ru^{III} not involving free I_2.[388] The role of halide in the reduction of O_2 by *trans*-$[Ru(NH_3)_4(isn)(OH_2)]^{2+}$ has been discussed. *Trans*-$[RuI(NH_3)_4(isn)]I_2$ can also be prepared by treatment of *trans*-$[Ru(SO_4)(NH_3)_4(isn)]^+$ with NaI.[388]

$$\frac{-d[Ru^{III}(OH_2)]}{dt} = k_a[I^-]^{\frac{1}{2}}[I_3^-]^{-\frac{1}{2}} + k_b[I^-]^2 \quad (48)$$

$$2[Ru^{III}(OH_2)] + 3I^- \longrightarrow 2[Ru^{II}(OH_2)] + I_3^- \quad (49)$$

$$[Ru^{II}(OH_2)] + I^- \longrightarrow [Ru^{II}(I)] + H_2O \quad (50)$$

$$2[Ru^{II}(I)] + I_3^- \longrightarrow 2[Ru^{III}(I)] + 3I^- \quad (51)$$

The ligand exchange reactions of $[RuX(NH_3)_5]^{2+}$ ($X = Cl^-$, Br^-, I^-) (equation 52) have been studied and are proposed to take place *via* a two step process with the rate-determining step being the formation of $[Ru(NH_3)_5OH_2]^{3+}$ (equations 53 and 54).[454] The mechanisms for Br^- exchange for $[RuBr_2(NH_3)_4]^+$ in aqueous and mixed solvent systems have been discussed.[455] The aquation of $[RuX(NH_3)_5]^{2+}$ ($X = Cl^-$, Br^-, I^-) has been reported to occur *via* an associative S_N2 mechanism,[456,457] with base hydrolysis being substantially faster than the corresponding acid hydrolysis.[398,458] Scheme 16 illustrates the proposed S_N2cb and S_N2 processes for the base hydrolysis of $[RuX(NH_3)_5]^{2+}$ ($X = Cl^-$, Br^-, I^-) for $[^-OH] = 0.03$–0.2 M,[459a,459b] although an S_N1cb mechanism has been attributed to the reaction at lower ^-OH concentrations of 3.78×10^{-4}–2.65×10^{-3} M.[398] The aquation of $[RuCl(NH_3)_5]^{2+}$ is catalysed by Hg^{2+}[17] and $[Ru(NH_3)_5(OH_2)]^{2+}$,[125] the former reaction occurring *via* the formation of a chloro-bridged intermediate.[17] Acid hydrolysis of *cis*-$[RuCl_2(NH_3)_4]^+$ takes place with retention of configuration.[457] The UV photoaquation of $[RuCl(NH_3)_5]^{2+}$ has been reported in very low yield,[181] while photoaquation of *cis*-$[RuX_2(NH_3)_4]^+$ ($X = Br^-$, I^-) gives *cis*-$[RuX(NH_3)_4(OH_2)]^{2+}$.[460,461] No photoaquation is observed for $X = Cl^-$.[461] $[RuCl(OH)(NH_3)_4]^+$ has been prepared by treatment of $RuCl_3$ with NH_3 in aqueous ethanol.[462]

$$[RuX(NH_3)_5]^{2+} + X^{-*} \xrightarrow{k_1} [RuX^*(NH_3)_5]^{2+} + X^- \quad (52)$$

$$k_1 = 3.15 \times 10^{-4}\,s^{-1},\ X^- = Cl^-$$

$$k_1 = 3.63 \times 10^{-4}\,s^{-1},\ X^- = Br^-$$

$$k_1 = 1.1 \times 10^{-4}\,s^{-1},\ X^- = I^-$$

$$[RuX]^{2+} \xrightarrow[H_2O]{RDS} [RuOH_2]^{3+} + X^- \quad (53)$$

$$[RuOH_2]^{3+} \xrightarrow{X^{-*}} [RuX^*]^{2+} + H_2O \quad (54)$$

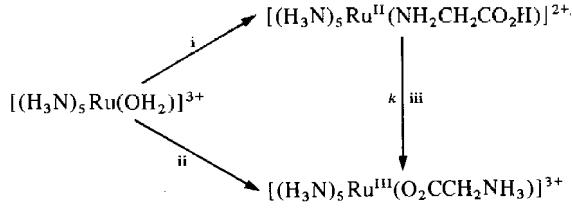
$$[RuX(NH_3)_5]^{2+} + {}^-OH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RuX(NH_2)(NH_3)_4]^+ + H_2O$$

$$\downarrow k_3 \qquad\qquad \downarrow k_2$$

$$[Ru(OH)(NH_3)_5]^{2+} \qquad [Ru(OH)(NH_3)_5]^{2+}$$

For $X = Cl^-$, $[^-OH] = 0.03 - 0.2$ M; $k_1 = 9.29 \times 10^{-2}$, $k_{-1} = 2.65 \times 10^{-2}$, $k_2 = 6.78 \times 10^{-1}$, $k_3 = 1.13 \times 10^{-1}\,M^{-1}s^{-1}$

Scheme 16



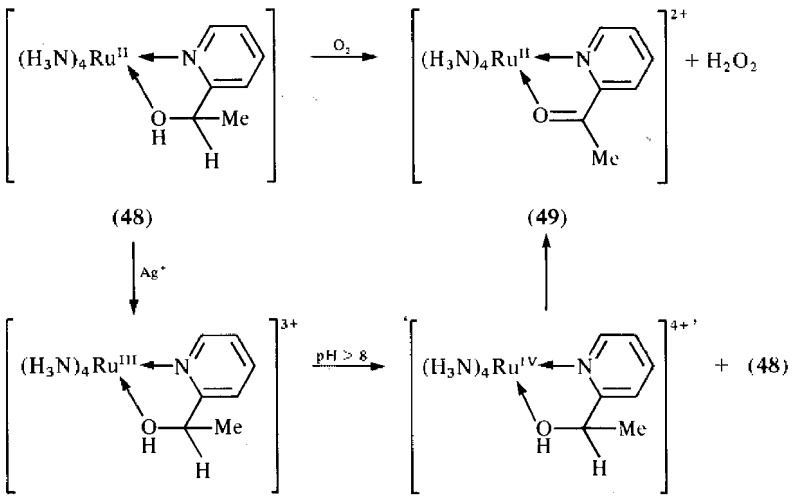
The solid state thermal deamination–anation of $[RuX(NH_3)_5]Y_2$ (s) to $[RuXY(NH_3)_4]Y$ (s) ($X = Cl^-$, Br^-; $Y = Cl^-$, Br^-, I^-, NO_3^-) has been investigated and the mechanism of the reactions discussed.[463] Thermal degradation of $[RuX(NH_3)_5]X_2$ occurs *via* the reduction of Ru^{III} by halide or by ammonia[444,464,465] with the initial formation of $[RuX_3(NH_3)_3]$ ($X = Cl^-$, Br^-). The thermal stability of $[RuX(NH_3)_5]^{2+}$ was found to decrease in the order $Cl^- > Br^- > I^-$.[443]

The reduction of $[RuX(NH_3)_5]^{2+}$ by Ti^{III} shows second order kinetics, with the rate of reaction being inversely proportional to $[H^+]$ indicating that $TiOH^{2+}$ and not Ti^{3+} is the reductant; rate constant $k = 12$, 56.0, 112.0 $M^{-1}s^{-1}$ for $X = Cl^-$, Br^-, I^- respectively.[173,466] The reduction of $[RuCl(NH_3)_5]^{2+}$, *cis*-$[RuCl_2(NH_3)_4]^+$ and *cis*-$[RuCl(NH_3)_4(OH_2)]^{2+}$ by Cr^{II} follows pseudo first order kinetics at higher $[Cr^{II}]$ with rate constant $k = 460$, 117 and 154 s^{-1} respectively.[402,467,468] For *trans*-$[RuCl_2(NH_3)_4]^+$ second order kinetics is observed.[468] Reductions with Cr^{II} occur *via* an

inner-sphere mechanism with the formation of binuclear chloro-bridged intermediates [Ru^{III}—Cl—Cr^{II}] followed by electron transfer to give [Ru^{II}—Cl—Cr^{III}] and dissociation to Ru^{II} and Cr^{III} products.[125,402,467,468] Reduction of $[RuX(NH_3)_5]^{2+}$ (X = Cl^-, Br^-, I^-) by U^{III} probably proceeds *via* an inner-sphere mechanism,[171] whereas for reduction by V^{II} an outer-sphere mechanism predominates;[402,468] by contrast, reduction of $[Ru(NH_3)_5OH_2]^{3+}$ by U^{III} is thought to occur *via* an outer-sphere process.[171] The reaction of $[RuX(NH_3)_5]^{2+}$ with organic radicals has been reported,[180] while I^-/I_2 coupling experiments using electrodes chemically modified with $[RuCl(NH_3)_5]Cl_2$ exhibited electrocatalysis.[469] An intervalence charge transfer band at $\lambda = 510$ nm has been observed on mixing $[RuCl(NH_3)_5]^{2+}$ with $[Ru(CN)_6]^{4-}$.[55,470]

(*vi*) *Amino acids, esters and mixed donor complexes*

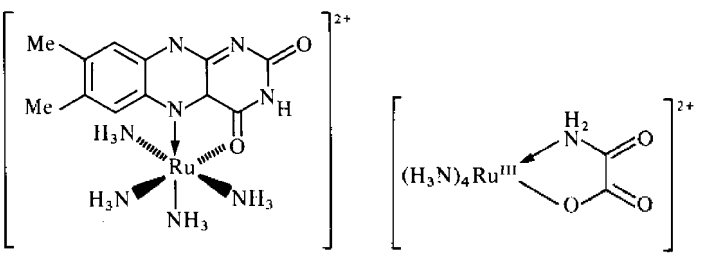
Addition of L to $[Ru(NH_3)_5OH_2]^{2+}$ under basic conditions yields the complexes $[RuL(NH_3)_5]^{2+}$ (L = glycine,[471] ethyl glycine,[383] methyl sarcosine,[383] glycinamide,[472] *N*-ethyl glycinamide,[472] glycylglycine,[472] glycylglycinamide,[472] ethyl glycylglycine[472]). Oxidation of the glycine complex $[Ru^{II}(NH_3)_5(NH_2CH_2CO_2H)]^{2+}$ leads to N → O isomerization to give $[Ru^{III}(NH_3)_5(O_2CCH_2NH_3)]^{3+}$ (Scheme 17).[471] For the ethyl glycine complex $[Ru^{II}(NH_3)_5(NH_2CH_2CO_2Et)]^{3+}$, N → O rearrangement occurs within the Ru^{III} oxidation state to yield $[Ru^{III}(NH_3)_5OC(OEt)CH_2NH_3]^{3+}$ under acidic conditions.[473] $[H^+]$ inhibits reversion to the N-bonded complex, with the hydrolysis of the ethyl glycinate ligand being found to be much faster for this system than for the $[Co(NH_3)_5]^{3+}$ analogue.[473] Under acidic conditions (pH = 3) $[RuL(NH_3)_5]^{3+}$ (L = glycinamide, *N*-ethyl glycinamide, glycylglycine, glycylglycinamide, ethyl glycylglycine) reacts to form $[RuL(NH_3)_4]^{3+}$ in which the ligand L is N,O bonded.[472] At higher acidities aquation to $[Ru(NH_3)_5OH_2]^{3+}$ is a competing reaction, with the rate law being $k = k' + k''[H^+]$ where k' corresponds to chelate formation and k'' to aquation.[472] Treatment of *cis*-$[Ru(NH_3)_4(OH_2)_2]^{3+}$ at pH 1 with L gives $[Ru(L)(NH_3)_4]^{3+}$ (L = glycylglycine, glycinamide, *N'*-ethyl glycinamide) with the ligand L being *N,N'* bonded.[404a] Rearrangement to the N,O-bound isomer is slow, but can be achieved more readily by reduction to the Ru^{II} species in acidic solution and reoxidizing.[404a] It is interesting to note here that the N-bonded complex $[RuL(NH_3)_5]^{3+}$ (L = acetamide) does not rearrange to the O-bonded isomer. However, for L = formamide, reduction does lead to N → O isomerization to form the O-bonded Ru^{II} species which on reoxidation, decays with a specific rate $k = 1\,s^{-1}$ to the N-bonded starting material.[474] The above linkage isomerization reactions and relative stabilities of the products have been fully discussed.[404a,471–474] Radiolabelled Ru^{III}–ammine complexes of amino acids have been reported.[475]



$$k = k_1 + \frac{k_2}{[H^+]},\quad k_1 = 2 \times 10^{-3}\,s^{-1},\quad k_2 = 1.25 \times 10^{-4}\,M^{-1}s^{-1}.$$

i, (a) Zn/Hg, (b) sodium glycinate; ii, glycine, 3 h; iii, [O]

Scheme 17

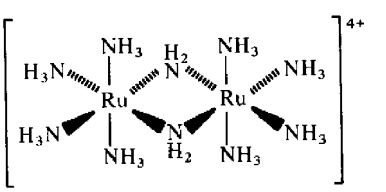


Reaction of $[Ru(NH_3)_4(OH_2)_2]^{2+}$ with L (L = 2-pyridine carboxaldehyde,[263] 2-pyridine alcohol[476a]) yields the complexes $[Ru^{II}L(NH_3)_4]^{2+}$. These products can be interconverted by oxidation of the pyridine alcohol derivative (**48**) to the acetyl pyridine complex (**49**) (Scheme 18).[476a] The complexes $[Ru(NH_3)_nL]^+$ (*n* = 4,5; LH = pyrazinecarboxylic acid) have been generated in which L can be mono- or bi-dentate.[476b]

Metalloflavin complexes of type $[RuL(NH_3)_4]^{2+}$ have been synthesized by reaction of $[Ru(NH_3)_5OH_2]^{2+}$ and *cis*-$[Ru(NH_3)_4(OH_2)_2]^{2+/3+}$ with flavin ligand, L.[477–479] The single crystal X-ray

Scheme 18

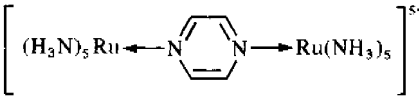
structure of the 10-methylisoalloxazine complex (**50**) has been reported and confirms a bidentate N,O chelate with Ru—O = 2.088 Å, Ru—N(flavin) = 1.980 Å, Ru—N(NH_3) = 2.12 Å, the short Ru—N(flavin) distance being consistent with back-bonding from Ru^{II}.[477,479] (**50**) shows two, one electron reductions.[478,480] More recently, resonance Raman studies on flavin derivatives of $[Ru(NH_3)_4]^{2+}$ have been published.[481] Condensation of $[Ru(NH_3)_6]^{3+}$ with oxalic acid is reported to yield (**51**).[375]



45.4.1.3 Binuclear complexes

Ruthenium ammine–phosphine and –selenium complexes are discussed in Sections 45.5 and 45.8 respectively.

(*i*) *Nitrogen donor bridged complexes*



(a) Amines

Refluxing $RuCl_3$ for two hours in ethanol followed by treatment with NH_3 at 90°C for two to three hours yields a black product $[(NH_3)_4Ru(NH_2)_2Ru(NH_3)_4]Cl_4 \cdot 4H_2O$ (**52**).[482] The single crystal X-ray structure of (**52**) confirms the presence of two bridging NH_2 ligands with Ru—$N(NH_2)$ = 2.011, 2.029 Å, Ru—$N(NH_3)$ = 2.130–2.146 Å.[482]

(b) Heterocycles and nitriles

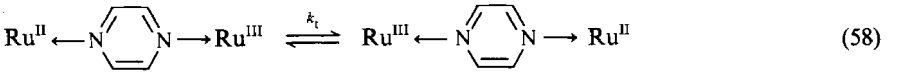
Several reviews on binuclear pentaammine ruthenium complexes have been published.[483–488] Since the initial report by Creutz and Taube in 1969 on the synthesis of the mixed valence dimer $[Ru(NH_3)_5]_2pz^{5+}$ (**53**),[489] a wide range of binuclear ruthenium ammine complexes have been prepared and characterized. The basis for this work was to study the extent of metal–metal interaction across the bridging ligand, and in particular to assess the charge distribution in the mixed valence complexes $[Ru(NH_3)_5]_2L^{5+}$. These complexes can be described as either (a) charge localized systems with no interaction between Ru^{II}/Ru^{III} centres (Class I), (b) having only partial metal–metal coupling (Class II) or (c) fully delocalized with $Ru^{II\frac{1}{2}}/Ru^{III\frac{1}{2}}$ centres (Class III).[175,490] Hush theory predicts[175,176] that a moderately coupled Class II mixed valence system will show an intervalence charge transfer band for the light-induced transition (equation 55). The analysis of intervalence bands, particularly their solvent dependence, has been the subject of much discussion.[484,491] More recently, the vibronic coupling model[492–494] has been applied to the analysis of intervalence charge transfer bands and good agreement has been observed for localized systems while discrepancies have occurred for supposed delocalized ones.[495] A full discussion of the theoretical basis for these models is outside the scope of this review, and is summarized in Creutz's review.[484] The measurement of comproportionation constant K_c for equation (56) has also been used to assess the stabilization due to delocalization of $[Ru(NH_3)_5]_2L^{5+}$ relative to $[Ru(NH_3)_5]_2L^{4+}$ and $[Ru(NH_3)_5]_2L^{6+}$.[491] The properties of intervalence charge transfer bands and evaluation of K_c have been commonly used parameters for the assignment of Class II or Class III behaviour to these types of mixed valence complexes.

(53)

$$[Ru^{II}, Ru^{III}]^{5+} \xrightarrow{h\nu} [Ru^{III}, Ru^{II}]^{5+} \quad (55)$$

$$[2,2]^{4+} + [3,3]^{6+} \overset{K_c}{\rightleftharpoons} 2[2,3]^{5+} \quad (56)$$

Reaction of $[Ru(NH_3)_5OH_2]^{2+}$ (generally prepared by treatment of $[RuCl(NH_3)_5]^{2+}$ with $Ag(O_2CCF_3)$ at 80°C, removal of precipitated AgCl, acidification with $NaHCO_3$ in aqueous solution to pH 2–3 and reduction by zinc amalgam) with half an equivalent of L yields the binuclear complex $[Ru(NH_3)_5]_2L^{4+}$ (L = for example, pyrazine,[195,197] pyrimidine,[496] 4,4′-bipyridine,[195,209,497] 1,2-bis(4-pyridyl)ethylene,[195] 1,1′-bis(4-pyridyl)methane,[209] 1,1′-bis(4-pyridyl)amine,[209] 1,2-bis(4-pyridyl)-acetylene,[209] 3,3′-dimethyl-4,4′-bipyridine,[209] dicyanobenzenes,[496] dicyanonaphthalenes,[496] cyanogen[498]). Dithionite has been used as a counterion for the isolation of the complexes in the solid state.[499] The [2,2] species $[Ru(NH_3)_5]L^{4+}$ can be oxidized to the $[2,3]^{5+}$ and $[3,3]^{6+}$ ions electrochemically or chemically.[209,500] Thus, the Creutz–Taube complex $[Ru(NH_3)_5]_2pz^{5+}$ may be prepared by oxidation of the $[2,2]^{4+}$ ion with Ag^+, while further oxidation with Ce^{4+} yields the $[3,3]^{6+}$ ion (equation 57).[197]



$$\underset{[2,2]^{4+}}{[Ru(NH_3)_5]_2pz^{4+}} \xrightarrow{Ag^+} \underset{[2,3]^{5+}}{[Ru(NH_3)_5]_2pz^{5+}} \xrightarrow{Ce^{4+}} \underset{[3,3]^{6+}}{[Ru(NH_3)_5]_2pz^{6+}} \quad (57)$$

$$\lambda = 547\,nm\ (Ru^{II} \rightarrow L) \qquad \lambda = 565\,nm\ (Ru^{II} \rightarrow L) \qquad no\ Ru^{II} \rightarrow L$$

$$no\ IVCT \qquad \lambda = 1562\,nm\ (IVCT) \qquad no\ IVCT$$

The single crystal X-ray structure of $[Ru(NH_3)_5]_2pz^{5+}$ (**53**) has been reported;[501,502a] this shows Ru—N(pz) = 2.002 Å, Ru—N(NH_3 *trans* to pz) = 2.135 Å, Ru—N(NH_3 *cis* to pz) = 2.110 Å.[502a] A full crystallographic study of the series $[(H_3N)_5Ru(pz)Ru(NH_3)_5]^{n+}$ (n = 4,5,6) has been published.[502b] The $[2,3]^{5+}$ complex shows an intervalence charge transfer band in the near IR at 1562 nm ($\varepsilon = 5 \times 10^3\,M^{-1}\,cm^{-1}$),[503] in addition to a $Ru^{II} \rightarrow$ ligand charge transfer band at 565 nm ($\varepsilon = 2.1 \times 10^4\,M^{-1}\,cm^{-1}$)[197,489] while the $[2,2]^{4+}$ complex shows an analogous charge transfer band at 547 nm ($\varepsilon = 3 \times 10^4\,M^{-1}\,cm^{-1}$).[489] Neither the $[2,2]^{4+}$ nor $[3,3]^{6+}$ ions show an intervalence charge transfer band at 1562 nm; the $[3,3]^{6+}$ ion shows no absorbance at 565 nm.[197] Although the observation[197,489] of an intervalence band for the mixed valent species $[Ru(NH_3)_5]_2pz^{5+}$ was consistent with Hush theory,[176] the solvent dependence of the absorption suggested that a more delocalized formalism for the complex should be invoked.[486] In addition, the comproportionation constant K_c of 4×10^6 indicated a relative stabilization of the $[2,3]^{5+}$ ion.[197] The question of whether the Creutz–Taube ion should be regarded as a Class II or Class III system is still the topic of much debate.

Highly contradictory reports on the degree of delocalization in the complex have been published, with many techniques being used in an attempt to distinguish between the two possible classifications. Conflicting IR,[197,486,489,502,504–506] photoelectron spectroscopy,[505,507–511] ^{99}Ru Mössbauer,[502,512] resonance Raman,[502,513] ^{1}H NMR,[506,514] powder ESR (8–50 K),[506] single crystal ESR,[502a,515,516] magnetic susceptibility,[506] electrochemical[197,486] and kinetic[486] studies have been published. The contradictory results obtained for the $[2,3]^{5+}$ complex may be partially reconciled however by regarding the rate of intramolecular electron transfer k_t in (**53**) as being rapid (equation 58). In principle, experiments with a faster resolution time than k_t could detect Class II behaviour, while techniques with a slower resolution time would suggest Class III characteristics for (**53**). A value for k_t of $10^{13}\,s^{-1} > k_t > 10^{11}\,s^{-1}$ has been proposed,[484,486] suggesting a substantial degree of delocalization in the molecule. The Creutz–Taube complex appears to be at the frontier of Class II/Class III behaviour, and as such, a description of delocalization within the molecule in terms of k_t would seem most appropriate.[484]

(58)

The complex $[Ru(NH_3)_5]_2$4,4-bipy^{4+} (4,4′-bipy = 4,4′-bipyridine) shows one, two electron oxidation,[517] the $[3,3]^{6+}$ ion being formed on addition of Br_2 or Cl_2 (Scheme 19).[497] $[Ru(NH_3)_5]_2$ 4,4-bipy^{5+} can not be prepared directly from the $[2,2]^{4+}$ ion, but is generated by addition of Ru^{II} to the $[3,3]^{6+}$ ion.[497,500] The mixed valence $[2,3]^{5+}$ ion shows an intervalence charge transfer band at 1030 nm ($\varepsilon = 880\,M^{-1}\,cm^{-1}$),[500] and has a comproportionation constant $K_c = 20$ near to a statistical value,[209,497] suggesting no special stability for this mixed valence complex. Solvent dependence of the intervalence charge transfer absorption agrees well with the Hush model,[518,519] and the rate of intramolecular electron transfer for $[Ru(NH_3)_5]_2$4,4-bipy^{5+} has been estimated as $k_t < 10^8\,s^{-1}$ [484] indicating weakly coupled Class II behaviour.

$$[(H_3N)_5Ru(OH_2)]^{2+} \xrightarrow{4,4'\text{-bipy}} [Ru(NH_3)_5]_2\text{4,4′-bipy}^{4+} \xrightarrow{Br_2 \text{ or } Cl_2} [Ru(NH_3)_5]_2\text{4,4′-bipy}^{6+} \xrightarrow{[Ru(NH_3)_5OH_2]^{2+}} [Ru(NH_3)_5]_2\text{4,4′-bipy}^{5+}$$

Scheme 19

A good example of a Class III binuclear complex is the cyanogen adduct $[Ru(NH_3)_5]_2NCCN^{5+}$; K_c is estimated as $> 10^{13}$ [498] with an intervalence charge transfer band at 1429 nm ($\varepsilon = 4.1 \times 10^2\,M^{-1}\,cm^{-1}$).[503] The IR spectrum of the $[2,3]^{5+}$ ion shows $\nu_{C\equiv N}$ at 2210 cm^{-1}, intermediate between the values of 1960 cm^{-1} and 2330 cm^{-1} for the $[2,2]^{4+}$ and $[3,3]^{6+}$ species respectively. Thus for $[Ru(NH_3)_5]_2NCCN^{5+}$, the rate of electron transfer k_t between metal centres has been estimated as $k_t > 10^{13}\,s^{-1}$.[484,486,498] A theoretical molecular orbital analysis of the mixed valence complexes $[Ru(NH_3)_5]_2L^{5+}$ has proposed[520] that for L = pz, the electron is in an orbital coupled over both metal centres. For L = non-conjugated dinitrile or 4,4′-bipyridine, non-equivalent metal centres were suggested, while for L = cyanogen, a highly coupled, symmetric ground state was found.[520]

Table 6 lists data for binuclear mixed valence pentaammine ruthenium complexes.

The bridging of dinitrile ligands in binuclear pentaammine ruthenium complexes can be accompanied by deprotonation of the nitrile. Thus, on oxidation of $[Ru(NH_3)_5]_2L^{4+}$ (L = malononitrile, *tert*-butylmalononitrile) to the mixed valence $[2,3]^{5+}$ species, deprotonation of the bridging ligand occurs to yield $[Ru(NH_3)_5]_2(L^-)^{4+}$ (equation 59).[362,428,526,527] The enormous enhancement of pK_a for the nitrile ligands on binding to Ru^{III} can be illustrated in the $[Ru^{II}—L—Ru^{III}]^{5+}$ and $[Ru^{III}—L—Ru^{III}]^{6+}$ complexes where $pK_a = -0.7$ and -4.8 for L = malonitrile, $pK_a = 1.6$, -3.0 for L = *tert*-butylmalononitrile respectively.[362] Similar pK_a enhancement has been observed for mononuclear systems.[362]

$$[(H_3N)_5Ru^{II}(L)Ru^{II}(NH_3)_5]^{4+} \longrightarrow [(H_3N)_5Ru^{II}(L^-)Ru^{III}(NH_3)_5]^{4+} \quad (59)$$
$$[2,L,2]^{4+} \qquad\qquad [2,L^-,3]^{4+}$$

$[Ru(NH_3)_4]_2$bipym^{4+} (bipym = 2,2′-bipyrimidine) has been prepared by treatment of $[Ru(NH_3)_5OH_2]^{3+}$ with bipym in the presence of zinc amalgam.[262] The complex shows two oxidations at +0.830 V and +1.02 V *vs.* NHE, the second oxidation leading to cleavage of the bimetallic unit. Photolysis of the $[Ru(NH_3)_4]_2$bipym^{4+} causes only slight decomposition of the complex.[262]

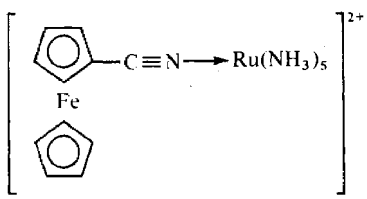
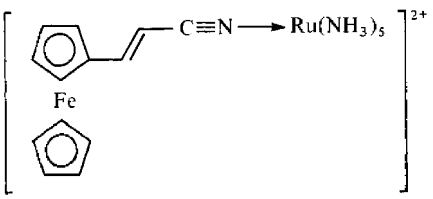
[a] For $[(H_3N)_5Ru^{III}(L^-)Ru^{III}(NH_3)_5]^{5+}$. [b] For $[(H_3N)_5Ru^{II}(L^-)Ru^{III}(NH_3)_5]^{4+}$.

Reaction of *trans*-$[RuCl(NH_3)_4SO_2]Cl$ with $NaHCO_3$, pz and then H_2O_2 yields the binuclear complex $[(SO_4)(H_3N)_4Ru^{III}pzRu^{III}(NH_3)_4SO_4]^{2+}$ which can be converted to $[Hpz(H_3N)_4Ru^{II}pzRu^{II}(NH_3)_4pzH]^{6+}$ by treatment with zinc amalgam, pyrazine and acid.[242] This latter species is a useful intermediate in the synthesis of tri- and tetra-nuclear complexes. A range of complexes of type *trans*-$[L'(NH_3)_4Ru(imid)Ru(NH_3)_4L]^{n+}$ ($L' = SO_2$, SO_4^{2-}, H_2O; imid = imidazole derivatives; $L = SO_4^{2-}$, NH_3) have been synthesized by reaction of $[Ru(SO_3)(NH_3)_4OH_2]$ and the corresponding mononuclear fragment.[247,528a] These complexes have been studied electrochemically and intervalence charge transfer bands observed for mixed valence species.[247,528a] Irradiation of the $[RuCl(NH_3)_5]^{2+}/[Ru(CN)_6]^{4-}$ ion pair leads to the formation of $[(H_3N)_5Ru^{III}NCRu^{II}(CN)_5]^-$.[55] The binuclear species $[(H_3N)_5Ru(pz)Ru(CN)_5]^{-/0}$ have been prepared and their electronic properties compared with related symmetric and asymmetric complexes.[528b] Reaction of $[Ru(NH_3)_5pz]^{2+}$ with $[Ru^{III}(Hedta)OH_2]$ produces a trapped valence complex $[(H_3N)_5Ru^{II}pzRu^{III}(edta)]^+$ (**54**). Photolysis of (**54**) leads to an activated $[Ru^{III}—pz^{\cdot-}—Ru^{III}]$ dimer (**55**) which decays back to (**54**).[529]



$k_1 = 0.8 \times 10^{10}\,s^{-1}$ $k_2 > 10^{11}\,s^{-1}$



Binuclear complexes $[(H_3N)_5Ru(L)RuX(bipy)_2]^{3+}$ ($X = Cl^-$, L = pz, 4,4′-bipy, 1,2-bis(4-pyridyl)ethylene, 1,2-bis(4-pyridyl)ethane; $X = NO_2^-$, L = pz) have been synthesized by reaction of $[Ru(NH_3)_5OH_2]^{2+}$ with $[RuX(L)(bipy)_2]^+$.[530] The [2,3]$^{4+}$ and [3,3]$^{5+}$ complexes have been generated, and the intervalence charge transfer bands for the mixed valence species analysed.[531–533] For $X = Cl^-$, L = pz, 4,4′-bipy, 1,2-bis(4-pyridyl)ethylene, absorptions were observed at 960 nm ($\varepsilon = 530$), 695 nm ($\varepsilon > 300$) and 680 nm ($\varepsilon > 300\,M^{-1}cm^{-1}$) respectively.[530] No such band was observed for the 1,2-bis(4-pyridyl)ethane analogue.[530] The metal–metal coupling in $[(H_3N)_5Ru^{II}pzRu^{III}Cl(bipy)_2]^{4+}$ has been estimated to be three times lower than for the Creutz–Taube ion.[531,532] The preparation of $[(H_3N)_5RupzRu(NCCH_3)(bipy)_2]^{5+}$ has been reported.[530]

The interactions of the $[Ru(NH_3)_5]^{2+}$ moiety and its derivatives with other metal centres in ligand-bridged heterobimetallic complexes of the type $[(NH_3)_5Ru—L—M]$ have been investigated. Systems that have been studied include M = Cr^{III}, L = 4-amidopyridine;[534,535] M = Ni^{II}, L = pz;[536] M = Cu^{II}, L = pz;[536–538] M = Cu^{I}, L = 4-vinyl pyridine;[539,540a] M = Co^{III},[540b] L = 3-O_2Cpy,[541] 4-O_2Cpy,[541] 3-O_2CCH_2py,[541] 4-O_2CCH_2py,[541] 4-NCpy,[542] pz,[542] 4,4′-bipy,[522,542] 3,3′-bipy,[523] 1,1′-bis(4-pyridyl)methane,[523] 1,2-bis(4-pyridyl)ethane,[522] 1,2-bis(4-pyridyl)ethylene,[522] 1,1′-bis(4-pyridyl)-methanol,[523] 3,3′-dimethyl-4,4′-bipyridine,[522] bis-(4-pyridyl)sulfide,[522] 1,4-dicyanobicyclo[2.2.2]octane;[543] M = Rh^{III}, L = 4-NCpy,[542,544] pz,[542] 4,4′-bipy;[542] M = Fe^{II}, L = pz,[545] Cp derivatives.[546,547] Ni^{II}, Cu^{II} and Zn^{II} bind to $[Ru(NH_3)_5pz]^{2+}$ (equation 60) with association quotients K = 17, 32 and 3.1 M^{-1} respectively.[536] Photolysis of the Ru^{II}—pz—Cu^{II} complex leads to bleaching of the charge transfer band with the formation of a Ru^{III}—pz—Cu^{I} dimer.[537] Binding of Cu^{I} to $[RuL(NH_3)_5]^{3+}$ (L = 4-vinyl pyridine) *via* the alkene (K_{equil} = 8.4 × 10^3) has been reported, with subsequent electron transfer from Cu^{I} to Ru^{III} at a rate constant k = 9.7 $M^{-1}s^{-1}$.[539] The complex $[(NC)_5Fe^{II}pz-Ru^{II}(NH_3)_5]^{1-}$, prepared by reaction of $[Ru(NH_3)_5pz]^{2+}$ with $[Fe(CN)_5OH_2]^{3-}$, shows two, one electron oxidations at +0.45 V and +0.72 V *vs.* NHE for oxidation of Ru^{II} and Fe^{II} respectively.[545] The neutral species has been formulated as a trapped valence Class II system, with an intervalence charge transfer band at 1330 nm.[545] The first order specific rate constants for electron transfer from Ru^{II} to Co^{III} in $[(H_3N)_5Co^{III}L\ Ru^{II}(NH_3)_4OH_2]^{n+}$ (L = substituted pyridines, 4,4′-bipyridyl derivatives) are in the range $k = 1 \times 10^{-4}$ to $44 \times 10^{-3}\ s^{-1}$.[522,548] More recently, a range of Co–Ru dimers with polypeptide bridges have been prepared, and electron transfer reactions within the binuclear system investigated.[549–551] Ferrocene–ruthenium heterobinuclear complexes (**56**) and (**57**) have been synthesized and compared with polynuclear ferrocene derivatives.[546,547] The Fe^{II}, Ru^{II} dimers show one electron oxidations at +0.44 V and +0.85 V for (**56**) and +0.44 V and +0.66 V *vs.* SCE for (**57**) with intervalence charge transfer bands in the near IR being observed for the Fe^{II}, Ru^{III} species.[546]

$$[(H_3N)_5Ru\ pz]^{2+} + M^{II} \rightleftharpoons [(H_3N)_5Ru \leftarrow N \bigcirc N \rightarrow M^{II}]^{4+} \qquad (60)$$

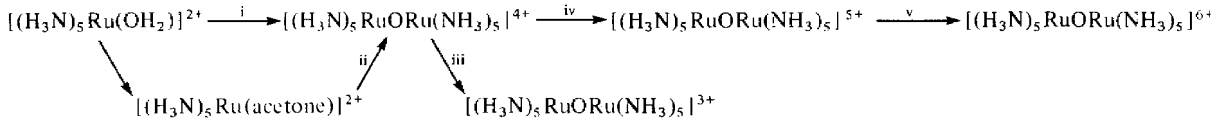
(**58**)



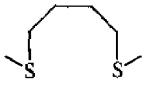
(58)

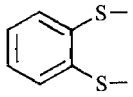
$[(Ru(NH_3)_5)_2N_2]^{4+}$ shows two, one electron oxidations at +0.73 V and +1.2 V *vs.* SCE.[315,334] The mixed valence $[2,3]^{5+}$ ion can be generated by oxidation of the $[2,2]^{4+}$ complex with Br_2 or Ce^{4+},[315,557] and shows an intervalence charge transfer band at 1020 nm, and a comproportionation constant $K_c = 10^8$ (see Table 6) indicating Class III delocalized behaviour.[315,484] $[(Ru(NH_3)_5)_2N_2]^{5+}$ decomposes (rate constant $k = 0.1\,s^{-1}$) to $[Ru(NH_3)_5N_2]^{2+}$ and $[RuX(NH_3)_5]^{n+}$ ($X = SO_4^{2-}$, $n = 1$; $X = HSO_4^-$, $n = 2$) in SO_4^{2-} electrolyte.[557] For the $[2,3]^{5+}$ complex, the specific rate of aquation $k = 2.4 \times 10^{-2}\,s^{-1}$.[315] Oxidation of $[(Ru(NH_3)_5)_2N_2]^{5+}$ at +1.2 V yields $[(Ru(NH_3)_5)_2N_2]^{6+}$, the specific rate of aquation of which has been estimated as greater than $10^3\,s^{-1}$.[315] This contrasts with the stability of $[(Os(NH_3)_5)_2N_2]^{5+}$ which is indefinitely stable in H_2O.[315]

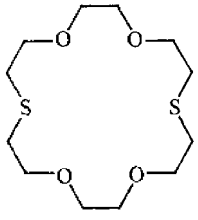
The preparation of $[(RuX(NO)(NH_3)_4)_2N_2]^{4+}$ ($X = Cl^-$, Br^-) has been reported.[558] Reaction of *cis*-$[Ru(NH_3)_4(OH_2)_2]^{2+}$ with $[Os(NH_3)_5N_2]^{2+}$ yields $[(H_2O)(H_3N)_4Ru^{II}N_2Os^{II}(NH_3)_5]^{4+}$ *via* second order kinetics.[559] The heteronuclear dimer can be oxidized at +0.1 V *vs.* SSCE in H_2SO_4/K_2SO_4 at pH 3.3 to give the mixed valence Ru^{III}—Os^{II} product which shows an intervalence charge band at 755 nm.[559] There has been a report of an N_2O dimer $[(Ru(NH_3)_5)_2N_2O]^{4+}$.[560]

(*ii*) *Oxygen donor bridged complexes*

Oxidation of $[Ru(NH_3)_5acetone]^{2+}$ with O_2 or oxidation of $[Ru(NH_3)_5OH_2]^{2+}$ with $LiClO_4$ in acetone yields the Ru^{III}—Ru^{III} dimer $[Ru(NH_3)_5]_2O^{4+}$ (Scheme 20).[561] The complex shows oxidations at +0.32 V and +1.67 V and a reduction at −1.98 V *vs.* SSCE.[561] The mixed-valence Ru^{IV}—Ru^{III} complex can be generated by oxidation with Br_2. A molecular orbital description of the Ru—O—Ru moiety has been given. Electronic, vibrational, redox, photoelectron and magnetic data for these complexes have been described, with the 5+ ion being assigned as a delocalized system.[561] The complexes $[(Ru(NH_3)_4)_2L]^{2+/3+/4+}$ and $[(H_3N)_4RuLRu(bipy)_2]^{3+/4+}$ (L = pyrazine-2,5-dicarboxylate) have been synthesized, and their spectroscopic features discussed.[562] The formation of a linear CO_2 bridge in $[(Ru(NH_3)_5)_2CO_2]^{4+}$, prepared by reaction of $[Ru(NH_3)_5N_2]^{2+}$ with CO_2 at high pressure or by treatment of $[Ru(NH_3)_5(OH_2)]^{2+}$ with N_2O/Zn amalgam and CO_2, has been proposed.[187b]







i, acetone, $LiClO_4$; ii, O_2; iii, −1.98 V; iv, +0.32 V; v, +1.67 V *vs.* SSCE[561]

Scheme 20

(*iii*) *Sulfur donor bridged complexes*

This area has been reviewed.[484,563] Reaction of $[RuL(NH_3)_5]^{2+}$ with $[Ru(NH_3)_5OH_2]^{2+}$ yields the dimeric complexes $[(Ru(NH_3)_5)_2L]^{4+}$ (L = thioether).[429,434] Table 7 summarizes intervalence charge transfer and K_c data for the complexes $[(Ru(NH_3)_5)_2L]^{5+}$. Treatment of $[Ru(NH_3)_5OH_2]^{2+}$ with C_2H_4S and COS, with H_2S followed by oxidation, or reduction of $[Ru(NH_3)_5SO_2]^{2+}$ with zinc amalgam gives $[(H_3N)_5RuSSRu(NH_3)_5]^{4+}$ (**59**), which reacts with HSO_3^- and CN^- to produce $[Ru(SSO_3)(NH_3)_5]^+$ and $[Ru(SCN)(NH_3)_5]^+$ respectively with the latter species isomerizing to $[Ru(NCS)(NH_3)_5]^{2+}$.[356] The single crystal X-ray structure of (**59**) shows Ru—S = 2.191, 2.195 Å.[565] The bridging unit has been proposed to have predominantly a Ru^{III}—S⋯S—Ru^{II} formulation,[565] although resonance Raman studies have preferred a Ru^{III}—S—S—Ru^{III} configuration.[566] Reaction

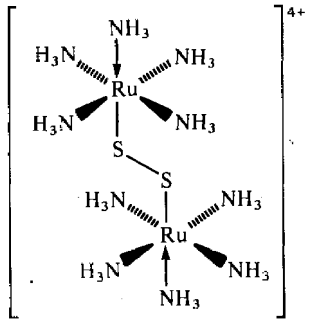


Table 7 Comproportionation Constants (K_c) and Intervalence Charge Transfer (IVCT) Bands for Mixed Valence Complexes $[Ru(NH_3)_5]_2L^{5+}$

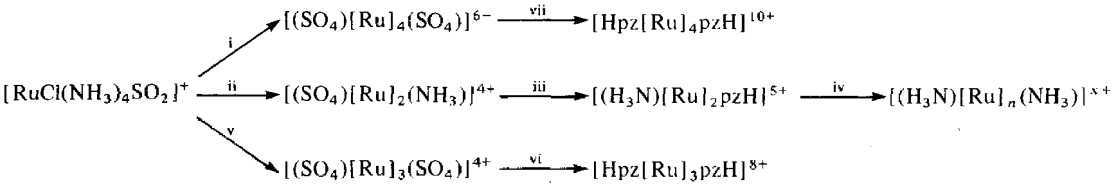
of *trans*-$[Ru(SO_4)(NH_3)_4isn]^+$ with zinc amalgam and L yields $[(Ru(NH_3)_4isn)_2L]^{4+}$ (L = $MeS(CH_2)_3SMe$, 2,6-dithiaspiro[3.3]heptane).[429]

(*iv*) *Halide-bridged complexes*

Blue chloro–ammine complexes can be prepared by treating $[Ru(NH_3)_6]Cl_2$ with HCl at 0 °C.[442,448] Oxidation of the blue Ru^{II}—Ru^{III} dimer $[Ru_2Cl_3(NH_3)_6]^{2+}$ with Ce^{IV} yields the corresponding yellow Ru^{III}–Ru^{III} complex.[448] The exact nature of these species is unknown, although a trichloro-



(59)

bridged structure has been proposed on the basis of one ν_{Ru-Cl} stretching vibration being observed in the IR at 270 cm^{-1}.[448]

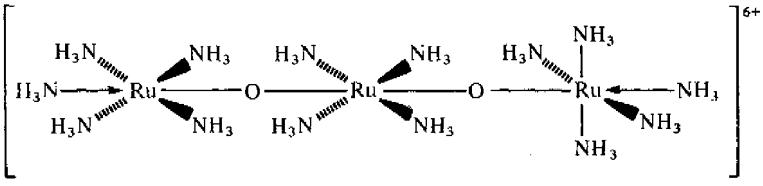
45.4.1.4 Tri- and poly-nuclear complexes

(*i*) *Nitrogen donor bridged complexes*

A series of tri-, tetra-, penta- and hexa-nuclear pyrazine-bridged complexes have been prepared by Taube and co-workers (Scheme 21).[242,486] The mixed valence complexes show intervalence charge transfer absorptions in the near IR. The metal → ligand charge transfer band moves to lower energy as the chain length increases. On oxidation, this absorption decreases in intensity and moves to higher energy until, in the fully oxidized complexes, the band disappears.[242] The extent of end to end interactions in the mixed valence complexes has been discussed.[242,486,547]

i, $NaHCO_3$, $[Hpz[Ru]_2pzH]^{5+}$, H_2O; ii, $NaHCO_3$, $[Ru(NH_3)_5pzH]^{3+}$, HBF_4, H_2O; iii, Zn/Hg, pz; iv, $[RuCl(NH_3)_5]^{2+}$, Zn/Hg; v, $NaHCO_3$, $[Ru(NH_3)_4(pzH)_2]^{4+}$; vi, Zn/Hg, pz, H^+; vii, Zn/Hg, pz.

Scheme 21[242]



Reaction of $[Ru(L)_2(bipy)_2]^{2+}$ with $[Ru(NH_3)_5OH_2]^{2+}$ in the dark in acetone yields the [2,2,2]$^{6+}$ trimer $[(H_3N)_5Ru^{II}LRu^{II}(bipy)_2LRu^{II}(NH_3)_5]^{6+}$ (L = pz, 4,4′-bipy, 1,2-bis(4-pyridyl)ethylene, 1,2-bis(4-pyridyl)ethane);[567] oxidation with Br_2 to give the [2,2,3]$^{7+}$ and [3,2,3]$^{8+}$ systems was achieved. The sites of oxidation appear to be localized, with no long range interaction between remote pentaammine moieties.[567]

The tetranuclear complex $[(Ru(NH_3)_5)_4TCNE]^{8+}$ shows four, one electron oxidations and a one electron reduction.[527] The 10+ is more stable than the 9+ and 11+ species, with a strong coupling between metal centres being proposed.[527] A heteronuclear ferrocene–ruthenium complex $[(Ru(NH_3)_5)_2Fc(CN)_2]^{4+}$ ($Fc(CN)_2$ = 1,1′-dicyanoferrocene) has been prepared. No evidence was observed for an end to end interaction in the corresponding 5+ ion.[547]

(*ii*) *Oxygen donor bridged complexes*

Reaction of $RuCl_3$ in ethanol with ascorbic acid at 85°C for 3 h, reduction of volume and treatment with NH_3 for 1 h at 90°C in the air yields a brown [3,4,3]$^{6+}$ complex $[Ru_3O_2(NH_3)_{14}]^{6+}$ (**60**) commonly known as ruthenium red.[568–571] The single crystal X-ray structure of $[Ru_3O_2(NH_3)_{14}]^{6+}$ shows[572] a linear Ru—O—Ru—O—Ru backbone with Ru—O

= 1.857–1.845 Å, < RuORu = 171.5°. For the central and one end Ru atom, the Ru—N (equatorial) bonds are eclipsed, with the other end Ru—N (equatorial) bonds twisted by 31° to give a non-centrosymmetric ion. Reaction of $[Ru_3O_2(NH_3)_{14}]^{6+}$ with en yields $[Ru_3O_2(NH_3)_{10}(en)_2]^{6+}$,[568] the single crystal X-ray structure of which shows a linear backbone with the en ligands bound to the central Ru.[573] The central Ru—N bonds are eclipsed with respect to the Ru—N (equatorial) bonds of both end groups, which are themselves eclipsed relative to one another.[573] Ruthenium red is also identified as the product when $[Ru(NH_3)_5N_2]^{2+}$ is oxidized in air on Y-type zeolite.[342]

(60)

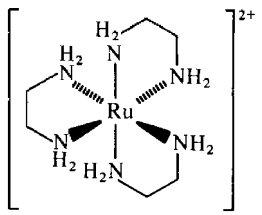
Oxidation of $[Ru_3O_2(NH_3)_{14}]^{6+}$ or $[Ru_3O_2(NH_3)_{10}(en)_2]^{6+}$ with HCl in air, or by Cl_2 water gives the $[4,3,4]^{7+}$ analogue ruthenium brown.[568] Mössbauer studies on the 6+ and 7+ ions are in agreement with linear structures for these complexes.[574] The resonance Raman spectra of ruthenium red and brown and of their en analogues have been reported.[575] Ruthenium brown is reduced by ^-OH in a second order reaction with rate constant $k = 1.9 \times 10^4\,s^{-1}\,mol^{-1}$, $\Delta H^{\neq} = 79.5\,kJ\,mol^{-1}$, reduction of the en derivative being faster.[568,576,577] The mechanism of the reaction was initially thought to proceed *via* formation of a peroxy-bridged Ru—O—O—Ru species,[578] but recent evidence suggests possible attack on coordinated NH_3 to give nitrosyl intermediates.[579]

The use of ruthenium red as a staining reagent for electron microscopy has been reviewed.[580] The complex is active for the staining of cell walls;[570,580] its possible binding modes to DNA[581] and interference with Ca^{2+} transport[582,583] have been discussed.[584]

45.4.2 Amines

45.4.2.1 Mononuclear complexes $[RuL_6]^{2+}$

Ruthenium(II) amine complexes have been reviewed.[585] The complexes $[Ru(NH_2R)_6]^{2+}$ (R = Me, Pr^n, Bu^i, Bu^n) can be prepared by treatment of $RuCl_3$ with the corresponding amine in the presence of zinc under argon (equation 63).[60,586] If the reaction is carried out under N_2, formation of $[Ru(NH_3)_5N_2]^{2+}$ is detected. The products $[Ru(NH_2R)_6]^{2+}$ are air sensitive and are readily oxidized by dioxygen to cyano complexes,[60,587] coordinated amine being more susceptible to oxidation than the free base. Reaction of $[RuX_4L_2]$ with L yields $[RuL_6]^{2+}$ (L = substituted anilines).[588] The value of $10\,Dq$ for the complexes $[RuL_6]^{2+}$ places aniline between en and H_2O in the spectrochemical series.[586]



$$RuCl_3 + 6RNH_2 \xrightarrow[Ar]{Zn} [Ru(NH_2R)_6]^{2+} \qquad (63)$$

45.4.2.2 Mononuclear complexes $[RuL_3]^{2+/3+}$

Ruthenium(II): Reaction of $RuCl_3$ with en in the presence of Zn at pH 1–2 yields $[Ru(en)_3]^{2+}[ZnCl_4]^{2-}$ which can be converted to the canary yellow dichloro salt $[Ru(en)_3]Cl_2$ by treatment with lithium anthranilate (equations 64 and 65).[589–591] Reduction of (−)-$[Ru(en)_3]^{3+}$ with Zn gives (−)-$[Ru(en)_3]^{2+}$.[592] The single crystal X-ray structure of *rac*-$[Ru(en)_3]^{2+}[ZnCl_4]^{2-}$ (**61**) shows O_h geometry around the ruthenium with Ru—N = 2.132 Å (*cf.* with Ru—N = 2.11 Å for $[Ru(en)_3]^{3+}$) and average < NRuN = 81.6°.[593] The absolute configuration and axial rotational strength of $[Ru(en)_3](NO_3)_2$ have been resolved[594] and the conformational stability of $[RuL_3]^{2+}$ (L = en, 1,2-diaminopropane) probed by ^1H NMR studies.[595,596] IR,[590] electron absorption optical rotatory dispersion, circular dichroism[592] and Mössbauer[120] data for $[Ru(en)_3]^{2+}$ have been reported.

$$RuCl_3 + 3en \xrightarrow{Zn} [Ru(en)_3][ZnCl_4] \qquad (64)$$

$$[Ru(en)_3][ZnCl_4] \xrightarrow{2Li(an)} [Ru(en)_3]Cl_2 + Zn(an)_2 + 2LiCl \qquad (65)$$

(61)

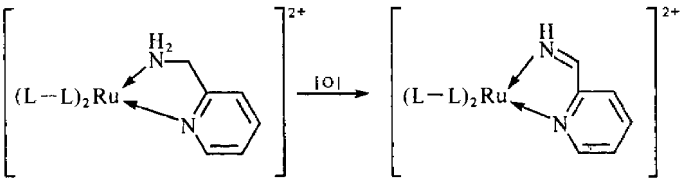
Like $[Ru(NH_3)_6]^{2+}$, $[Ru(en)_3]^{2+}$ is a good outer-sphere oxidizing agent; redox reactions with Fe^{3+}, $FeOH^{2+}$,[128] O_2[153] and $[CoX(NH_3)_5]^{2+}$ (X = F^-, Cl^-, Br^-, I^-)[139] have been studied. For the reaction with $[CoF(NH_3)_5]^{2+}$, $\Delta H = 29.4\,kJ\,mol^{-1}$, $\Delta S = -120\,J\,K^{-1}\,mol^{-1}$.[139] The self-exchange between $[Ru(en)_3]^{2+/3+}$ is slower than for $[Ru(NH_3)_6]^{2+/3+}$.[128] Treatment of $[Ru(en)_3]^{2+}$ with I_2 in NaI solution gives an intense yellow colouration with an absorption band at 448 nm. The product of the reaction was initially formulated as a Ru^{VI} complex,[597] however oxidative dehydrogenation of an en ligand to a diimine species has been shown to occur.[598]

Reaction of $RuCl_3$ with *o*-phenylenediamine in the presence of Zn yields the tris(diimine) complex of *o*-benzoquinone diimine.[599]

Ruthenium(III): Oxidation of $[Ru(en)_3][ZnCl_4]$ by silver anthranilate or with $[enH_2](NO_3)_2$ gives the pale yellow complex $[Ru(en)_3]Cl_3$.[600–602] The single crystal X-ray structure of *rac*-$[Ru(en)_3]^{3+}$ shows the en rings to have *lcl* conformation with significant puckering, Ru—N = 2.11 Å.[603] The ESR spectrum of $[Ru(en)_3]^{3+}$ has been measured at 4 K diluted in single crystals of $[Rh(en)_3Cl_3]_2 \cdot NaCl \cdot 6H_2O$ and as a powder with $[Co(en)_3]Br_3 \cdot H_2O$ at K and X band respectively.[604,605] $[Ru(en)_3]I_3$ has $\mu_{eff} = 2.2$ BM consistent with low spin d^5 Ru^{III}.[600] Electronic absorption,[600,605] optical rotatory dispersion and circular dichroism data[592] for $[Ru(en)_3]^{3+}$ have been reported. The enantiomers of $[Ru(en)_3]I_3$ have been resolved by fractional precipitation with optically active $[Rh(ox)_3]$.[592]

$[Ru(en)_3]^{3+}$ undergoes outer-sphere electron transfer with Cu^{I}[606] and Ti^{III}.[607] An outer-sphere charge transfer band from anion to complex cation has been observed near 450 nm for concentrated solutions of $[Ru(en)_3]I_3$.[608] The oxidation of Np^{3+} by $[Ru(en)_3]^{3+}$ (equation 66) in trifluoromethane sulfonate has been studied; rate constant $k = 8.96\,M^{-1}\,s^{-1}$, $\Delta H^{\neq} = -52.7\,kJ\,mol^{-1}$, $\Delta S^{\neq} = -173.6\,J\,K^{-1}\,mol^{-1}$.[609] E_f for the $[Ru(en)_3]^{3+/2+}$ couple was assessed as 0.172 V *vs.* Ag/Ag^+.[128,609] Oxidation of U^{3+} in trifluoromethane sulfonate occurs with a rate constant $k = 1.62 \times 10^5\,M^{-1}\,s^{-1}$, $\Delta H^{\neq} = -1.3\,kJ\,mol^{-1}$, $\Delta S^{\neq} = -163\,J\,K^{-1}\,mol^{-1}$.[170]

$$[Ru(en)_3]^{3+} + Np^{3+} \xrightarrow{k} [Ru(en)_3]^{2+} + Np^{4+} \qquad (66)$$



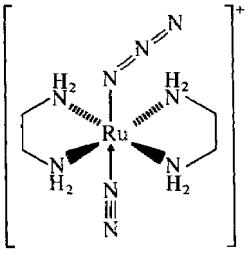
45.4.2.3 Mononuclear complexes with nitrogen donor ligands

Reaction of $[RuCl_2L_2]$ with en in refluxing aqueous ethanol yields $[RuL_2en]^{2+}$ (L = bipy,[264] phen,[610] 2-(phenylazo)pyridine[611]). The complexes $[RuL(en)_2]^{2+}$ may be prepared by reduction of $[RuCl_2(en)_2]^+$ with zinc amalgam in acetic acid followed by addition of L.[610] The electrochemistry of $[Ru(bipy)_2en]^{2+}$ has been reported.[268] The reduction of $[Ru(bipy)(tmed)_2]^{3+}$ to the Ru^{II} species has been achieved with H_2S,[203] while treatment of $[Ru(bipy)py_4]^{2+}$ with en gives $[Ru(bipy)(en)py_2]^{2+}$.[612]

Oxidation of amine complexes tends to occur at the coordinated amine to give imine and nitrile products.[587,610,613,614a] The aromatization of piperazine and piperidine (L) has been achieved by oxidation of $[Ru(NH_3)_5L]^{2+}$.[614b] Reaction of $[Ru(phen)_2en]I_2$ with Ag^+ and NaOCl gives $[Ru(phen)_2diim]^{2+}$,[610] while treatment of $[Ru(en)_3]^{2+}$ with NaOH, $AgNO_3$ and HI yields $[Ru(en)_2diim]^{2+}$ (**62**) (equation 67).[597,598,610] The four electron oxidation of $[Ru(bipy)_2L]^{2+}$ (L = en, *trans*-1,2-diaminocyclohexane) to the corresponding diimine species has been achieved chemically and electrochemically,[614a] while the two electron oxidation for L = 2-aminomethylpyridine and 1,2-diamino-2-methylpropane forms monoimine products (equations 68).[614a] The reactions are thought to proceed *via* Ru^{III} intermediates, a correlation between oxidative dehydrogenation and the $Ru^{II/III}$ couple for the complexes being noted.[610] The back-bonding from Ru^{II} to the diimine ligand has been discussed.[614a]

$$[Ru(en)_3]^{2+} \xrightarrow{[O]} \left[(en)_2Ru\right]^{2+} \qquad (67)$$

(61) (62)



(68)

An amine ligand in $[Ru(NH_2R)_6]^{2+}$ can be replaced by an organic nitrile, *e.g.* PhCN, in the presence of Zn to give $[Ru(NH_2R)_5NCPh]^{2+}$.[60] Alternatively nitrile complexes can be prepared by oxidation of coordinated amines. Thus, oxidation of $[Ru(bipy)_2(NH_2CH_2R)_2]^{2+}$ (prepared by treatment of $RuCl_2(bipy)_2$ with RCH_2NH_2 in methanol) at 1.1 V, 0.8 V and 1.1 V *vs.* SSCE for RCH_2NH_2 = allylamine, benzylamine, *n*-butylamine respectively yields $[Ru(bipy)_2(NCR)_2]^{2+}$ *via* Ru^{III} and imine intermediates.[613] The same products may be prepared directly from the reaction of $[Ru(CO_3)(bipy)_2]$ with the corresponding nitrile.[613]

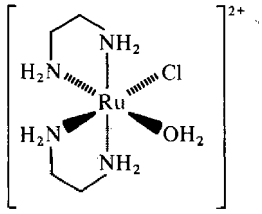
Cis-$[RuL_2(OH_2)_2]^{3+}$ reacts with NaN_3 to give *cis*-$[Ru(N_3)_2L_2]^+$ (L = en, ½trien);[317,615] *cis*-$[Ru(N_3)_2trien]^+$ can also be prepared by reaction of *cis*-$[RuCl_2trien]Cl$ with NaN_3.[394] On heating at 65°C for 25 min, *cis*-$[Ru(N_3)_2(en)_2]^+$ decomposes to *cis*-$[Ru(N_3)(N_2)(en)_2]^+$ with ν_{NN} at 2130 cm^{-1} and ν_{NNN} at 2050 cm^{-1}.[317,615,616] The trien analogue is formed on heating at 45°C for 3 h.[394]

Treatment of *cis*-$[Ru(N_3)(N_2)(en)_2]^+$ with cold HNO_2 affords a mixture of *cis*-$[Ru(N_2)_2(en)_2]^{2+}$ (ν_{NN} = 2220, 2190 cm^{-1}) and its aquation product *cis*-$[Ru(N_2)(en)_2OH_2]^{2+}$ (ν_{NN} = 2130 cm^{-1}).[317,616] These products can further aquate to $[Ru(en)_2(OH_2)_2]^{2+}$.[320] Reaction of *trans*-$[RuCl_2(en)_2]^+$ with Ag^+ followed by NaN_3 gives *trans*-$[Ru(N_3)(N_2)(en)_2]^+$ (**63**) the single crystal X-ray structure of which confirms a distorted O_h geometry around Ru^{II} with Ru—$N(N_2)$ = 1.894 Å, Ru—$N(N_3^-)$ = 2.191 Å, Ru—N(en) = 2.108–2.144 Å, < $RuNN(N_3^-)$ = 116.7°, < $RuNN(N_2)$ = 179.3°.[617]

(63)

The formation of *cis*-$[RuL_2(N_2)(OH_2)]^{2+}$ has been reported from the reaction of *cis*-$[RuL_2(OH_2)_2]^{2+}$ with N_2 with rate constants $k = 4.98 \times 10^5$, 8.55×10^5 s^{-1} for L = en and ½trien respectively.[320] Unlike $[Ru(NH_3)_5OH_2]^{2+}$, *cis*-$[Ru(N_2)(en)_2OH_2]^{2+}$ does not appear to react with N_2.[616] The trien complex $[Ru(N_2)(trien)OH_2]^{2+}$ can be prepared by solvolysis of $[RuX(trien)]_2N_2^{2+}$ (X = I^-, Br^-) under basic conditions.[618] Reaction of thiourea with *cis*-$[Ru(N_3)_2(en)_2]^+$ gives $[Ru\{NSC(NH_2)_2\}(en)_2OH_2]^{3+}$.[317] $[RuCl_3(NO)]$ reacts with amines NR_3 in EtOH to yield $[RuCl_3(NO)(NR_3)_2]$.[123,619]

45.4.2.4 Mononuclear complexes with oxygen donor ligands



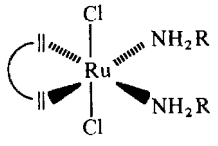
Photolysis of $[Ru(en)_3]^{2+}$ in aqueous acidic conditions yields $[Ru^{II}(enH)(en)_2OH_2]^{3+}$.[379]

Reaction of *cis*-$[RuCl_2(en)_2]^+$ with Ag^+ in H_2O yields *cis*-$[Ru(en)_2(OH_2)_2]^{3+}$.[462,615,616,620] The kinetics of anation of *cis*-$[Ru(en)_2(OH_2)_2]^{3+}$ and *cis*-$[RuX(en)_2OH_2]^{2+}$ (X = Cl^-, Br^-) have been reported to be first order with respect to [halide] and [complex].[400] The ligand field photolysis of *cis*- and *trans*-$[RuCl_2(en)_2]^+$ has been studied (equations 69 and 70) with *cis* and *trans* products $[RuCl(en)_2OH_2]^{2+}$ interconverting.[621,622] The single crystal X-ray structure of *cis*-$[RuCl(en)_2OH_2]^{2+}$ (**64**), prepared by reaction of $[RuCl_2(en)_2]^+$ with CF_3SO_3H followed by H_2O,[457,623] shows six-coordinate Ru^{III} with Ru—N = 2.10 Å, Ru—Cl = 2.323 Å, Ru—O = 2.093 Å.[623] The complex hydrolyses with retention of configuration in aqueous acid.[623] Treatment of $[Ru(NH_2Me)_6]^{2+}$ with O_2 in aqueous conditions yields $[Ru(OH)(NH_2Me)_5]^{2+}$ *via* a Ru^{III} aqua species;[587] the complex readily decomposes to cyano products.[587]

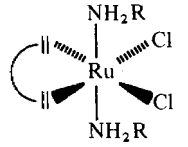
$$cis\text{-}[RuCl_2(en)_2]^+ \xrightarrow[H_2O/H^+]{h\nu} \underset{84\%}{cis\text{-}[RuCl(en)_2(OH_2)]^{2+}} + \underset{16\%}{trans\text{-}[RuCl(en)_2(OH_2)]^{2+}} \quad (69)$$

$$trans\text{-}[RuCl_2(en)_2]^+ \xrightarrow[H_2O/H^+]{h\nu} trans\text{-}[RuCl(en)_2(OH_2)]^{2+} + cis\text{-}[RuCl(en)_2(OH_2)]^{2+} \quad (70)$$

34% 66%

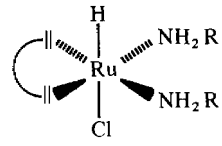


(64)



Reaction of $[Ru(ox)_3]^{3-}$ with L yields *trans*-$[Ru(ox)_2L_2]^-$ (L = aniline derivatives), which reacts with HX to produce $[RuX_4L_2]^-$ (X = Cl^-, Br^-).[586,588] The analogous reactions with en lead to the formation of the double salts $[Ru(ox)(en)_2]^+[Ru(ox)_2en]^-$ and $[RuX(en)_2]^+[RuX_4(en)]^-$ respectively.[620,624] Prolonged treatment with HX produces *cis*-$[RuX_2(en)_2]X$.[620] $[Ru(ox)L_2]^+$ (L = en, ½trien) can be isolated from the reaction of $[RuCl_2L_2]^+$ with Ag^+ and oxalate.[620]

45.4.2.5 Mononuclear complexes with halide ligands



Ruthenium(II): The synthesis of $[RuX_2L_4]$ (X = halide, L = aniline derivative) has been mentioned.[586] Reaction of $[Ru(enH)(en)_2OH_2]^{3+}$ with Cl^- yields $[RuCl(enH)(en)_2]^{2+}$.[379] Red solutions produced by refluxing $RuCl_3$ under CO react with $C_6H_5NH_2$ in ethanol to give $[RuCl_2(CO)_2(NH_2C_6H_5)_2]$,[108] the electrochemistry of which has been reported.[625] Refluxing amines L with $[RuCl_2(diene)]_n$ yields two isomers of the complex $[RuCl_2L_2(diene)]$.[626a,626b] The single crystal X-ray structures of $[RuCl_2L_2diene]$ (L = piperidine, diene = norbornadiene (**65**),[626a] L = aniline, diene = norbornadiene (**66**),[627] L = 1-hexylamine, diene = 1,5-cyclooctadiene (**67**))[626a] have been carried out. For (**65**) Ru—N = 2.237, 2.248 Å;[626a] for (**67**) Ru—N = 2.174 Å, Ru—Cl = 2.458 Å;[626a] for (**66**) Ru—N = 2.213 Å, Ru—Cl = 2.415, 2.407 Å.[627] The ^1H and ^{13}C NMR spectra of these isomers have been discussed.[626a] Another product isolated from the reaction of $[RuCl_2(diene)]_n$ with amine was $[Ru(Cl)(H)(L)_2(diene)]$ (**68**),[626b] the single crystal X-ray structure of which shows Ru—H = 1.57 Å, Ru—Cl = 2.555 Å, Ru—N = 2.240 Å, with ν_{RuH} at 2040 cm^{-1} in the IR spectrum.[628] Reaction of $[RuCl(CO)_3]_2$ with RNH_2 yields $[RuCl(CONHR)(NH_2R)_2(CO)_2]$ which on acidification gives $[RuCl(NH_2R)_2(CO)_3]^+$.[629a] Treatment of $[RuCl_2(arene)]_2$ with en produces $[RuCl(en)(arene)]^+$ with the formation of small amounts of $[Ru(en)_3]^{2+}$.[629b]

(65) $[RuCl_2(nbd)(pip)_2]$
(66) $[RuCl_2(nbd)(anil)_2]$

(67) $[RuCl_2(cod)(hex)_2]$

(68)

Ruthenium(III): Reaction of $[Ru(ox)_3]^{3-}$ with amine L followed by HX yields *cis*-$[RuX_2L_2]^+$ (L = en, 1,2-diaminopropane, ½trien);[457,618,620] $[RuX_4(en)]^-$ has been isolated from these reactions.[620] The absolute configuration of (−)-*cis*-$[RuCl_2(en)_2]^+$ has been determined,[630] and can be converted to the *trans* isomer by heating for 1 min at 60°C with ethylene glycol.[631] *Trans*-$[RuX_2L]^+$ may be alternatively prepared by treatment of $[RuCl_5(OH_2)]^{2-}$ with L (L = $(en)_2$, $(1,2\text{-diaminopropane})_2$, $(1,2\text{-diamino-}N,N'\text{-dimethylethane})_2$, 1,9-diamino-3,7-diazanonane, 1,10-diamino-4,7-diazadecane, 1,11-diamino-4,8-diazaundecane).[632–634] Oxidation of $[RuCl(enH)(en)_2]^{2+}$ with $[Ru(en)_3]^{3+}$ gives $[RuCl(enH)(en)_2]^{3+}$[379] while solvation effects in *cis*-$[RuBr_2(en)_2]^+$, *trans*-$[RuX_2(en)_2]^+$ (X = Cl^-, Br^-, I^-, NCS^-) and *trans*-$[RuX_2L]^+$ (X = Cl^-, Br^-; L = 1,9-diamino-3,7-diazanonane) have been probed by ESR spectroscopy.[635]

The acid and base hydrolysis of *cis*- and *trans*-$[RuCl_2L]^+$ (L = $(NH_3)_4$, $(en)_2$, $(1,2\text{-diaminopropane})_2$, trien, 1,9-diamino-3,7-diazanonane) have been studied;[457,631,634,636–638] the role of increased chelation in the observed rates of hydrolysis has been assessed[457,634,637] and related to the $E_{1/2}$ values

for the $Ru^{III/II}$ redox couples.[636,639] *Trans*-$[RuCl_2(en)_2]^+$ hydrolyses more slowly than the *cis* isomer, the aquation of *cis*-$[RuCl_2(en)_2]^+$ being Hg^{2+} catalysed (equation 71).[640] An S_N1 mechanism *via* a square pyramidal intermediate has been proposed,[634,636,637,640] hydrolysis occurring with retention of configuration.[457,458,634,637] Base hydrolysis occurs *via* a conjugate base mechanism, with a second order rate law (equation 72).[458] The ligand field (LF) and ligand–metal charge transfer (LMCT) excited state photochemical aquation of *trans*-$[RuX_2(en)_2]X$ has been studied.[641–643] For $X = I^-$, LF excitation led to aquation with greater than 85% stereochemical change, whereas for LMCT excitation retention of configuration was observed. For $X = Cl^-$, Br^-, the LF and LMCT bands overlap and stereochemical mixing was found in the products.[641]

The reduction of *trans*-$[RuXL]^+$ ($X = 2Cl^-$, $2Br^-$, $2I^-$, $BrCl^{2-}$; $L = (en)_2$, 1,9-diamino-3,7-diazanonane) by Cr^{II} and V^{II} has been reported.[644,645] Reduction by Cr^{II} follows a rate expression (equation 73) consistent with an inner-sphere mechanism involving bridging chloro species;[644,645] an outer-sphere mechanism has been suggested for reductions with V^{II}.[644]

$$cis\text{-}[RuCl_2(en)_2]^+ \xrightarrow{Hg^{2+}} cis\text{-}[RuCl(en)_2(OH_2)]^{2+} \longrightarrow cis\text{-}[Ru(en)_2(OH_2)_2]^{3+} \quad (71)$$

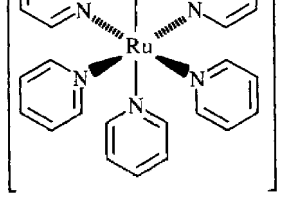
(HCl)

$$\frac{-d[\text{complex}]}{dt} = k[^-OH][\text{complex}] \quad (72)$$

$$k_{obs} = (k_1 + k_x[X^-])[Cr^{II}] \quad (73)$$

Thermolysis of $(LH)_2[RuCl_6]$ ($L = Et_2NH$) has been proposed to yield $[RuCl_4L_2]$ ($L = Et_2NH$).[646]

45.4.2.6 Binuclear complexes

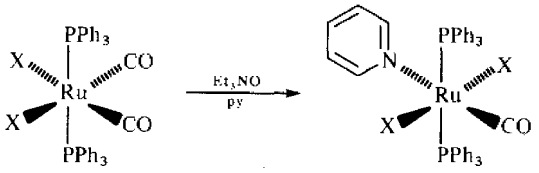


Treatment of $[RuL_2(N_2)(OH_2)]^{2+}$ with $[RuL_2(OH_2)_2]^{2+}$ (L = en, ½trien) yields the dimer $[RuL_2(OH_2)]_2N_2^{4+}$.[320] On reduction with zinc amalgam *cis*-$[RuBr_2(trien)]$ reacts with N_2 in the presence of KX to give $[(trien)XRu^{II}(N_2)Ru^{II}X(trien)]X_2$ ($X = Br^-$, I^-).[618] $[(en)_2ClRu(OH)RuCl(en)_2]^{3+}$ is reported to be the product of photolysis of *cis*-$[RuCl(en)_2OH_2]^{2+}$.[621] The nitrido-bridged complex $[Ru_2N(en)_5]^{5+}$[647] is discussed in Section 45.4.6.

45.4.3 Heterocycles

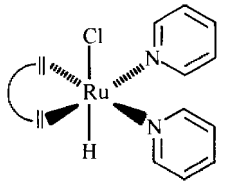
45.4.3.1 Mononuclear complexes

(*i*) *Monodentate heterocyclic complexes* $[RuL_6]^{2+/3+}$



Reaction of $[Ru(OH_2)_6]^{2+}$ with excess of L (L = pyridine, pyrazine, pyridazine) yields $[RuL_6]^{2+}$.[648] Analogous products have also been prepared by extended reflux of pyridine with $[RuH(HOMe)_3(PPh_3)_2]^+$ or $[RuH(OH_2)_3(PPh_3)_2]^+$,[649] or by reaction of $[Ru(cod)(N_2H_4)_4]^{2+}$ with 2-methylpyridine.[650] The single crystal X-ray structure of $[Rupy_6]^{2+}$ (**69**) shows Ru—N = 2.10–2.14 Å with octahedral Ru^{II}. (**69**) shows a metal to ligand charge transfer band at 341 nm, with a larger Ru—N force constant compared with data for the Ru—NH_3 bond.[649] For the $[Rupy_6]^{3+/2+}$ couple $E^\circ = +1.29$ V *vs.* NHE.[649]

(**69**)

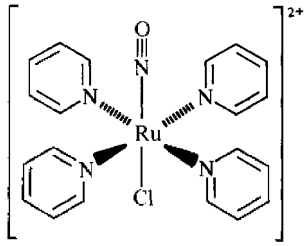


(ii) Monodentate heterocyclic complexes with carbon donor ligands

Treatment of $[RuCl_2(CO)_3]_2$ with py in THF yields $[RuCl_2(CO)_3py]$[651] which reacts further to give $[RuCl_2(CO)_2py_2]$.[651-653] Reaction of $[RuX_2(CO)_4]$ (X = Br^-, I^-) with L at room temperature leads to the formation of $[RuX_2(CO)_3L]$ (L = py, 3-methylpyridine, 3,4-dimethylpyridine).[654] The complexes $[RuCl_2(CO)L_3]$ (L = py, 3-methylpyridine) have been isolated from the reactions of $[RuCl_2(CO)diene]_2$ (diene = 1,5-cod, nbd) with L;[655] for L = quinoline, the complex $[RuCl_2(CO)_2L_2]$ was obtained.[655] Replacement of Cl^- in $[RuCl_2(CO)_2py_2]$ has been achieved by treatment with Ag^+ to yield $[Ru(OAc)_2(CO)_2py_2]$ in the presence of ^-OAc, or $[Ru(CO)_2(NCMe)_2py_2]^{2+}$ in acetonitrile.[656] The decarbonylation of $[RuCl_2(CO)_2L_2]$ with bidentate ligands has been reported.[657] Decarbonylation of $[RuX_2(PPh_3)_2(CO)_2]$ (X = Cl^-, Br^-) with Et_3NO in pyridine gives $[RuX_2(PPh_3)_2(CO)py]$ (equation 74) with inversion of stereochemistry.[658]

(74)

Reaction of $[RuCl_3(CO)nbd]^-$ with py yields $[RuCl_3(CO)py_2]^-$ and $[RuCl_2(CO)(nbd)py]$[659] while refluxing $[Ru(cod)(N_2H_4)_4]^{2+}$ with excess of L affords $[Ru(cod)L_4]^{2+}$ (L = py, 4-methylpyridine);[650] the catalytic reduction of nitroalkenes and *N*-oxides by CO and H_2O has been achieved using $[Ru(cod)py_4]^{2+}$.[660] The complex $[Ru(NCS)_2(CO)_2py_2]$ has been prepared by reaction of $[Ru(NCS)_2(CO)_2]_n$ with pyridine.[661] Amine exchange reactions of $[RuClH(cod)L_2]$ (L = amine) with pyridine, 4-methylpyridine and 4-dimethylaminopyridine have been studied; the single crystal X-ray structure of $[RuClH(cod)py_2]$ (**70**) shows[662] Ru—N = 2.167, 2.153 Å, Ru—Cl = 2.584 Å, Ru—H = 1.60 Å.



(70)

The pK_a of $[Ru(CN)_5(pzH)]^{2-}$ is 0.4 compared with 2.85 for $[Ru(pzH)(NH_3)_5]^{2+}$.[38] Ruthenium–cyano complexes are discussed in Section 45.3.1

(iii) Monodentate heterocyclic complexes with nitrogen donor ligands

Treatment of $[Ru(NO_2)_2py_4]$ with HX yields $[RuX(NO)py_4]^{2+}$ (X = Cl^-, Br^-); with X = ClO_4^-, $[Ru(OH)(NO)py_4]^{2+}$ is obtained.[663] The single crystal X-ray structure of *trans*-$[RuCl(NO)py_4]^{2+}$ (**71**) shows a linear RuNO unit with < RuNO = 174.8°, Ru—NO = 1.760 Å, N—O = 1.132 Å, Ru—Cl = 2.314 Å shortened due to the *trans* effect of nitrosyl, Ru—N(py) = 2.111 Å.[664] The nitrosyl in $[RuX(NO)py_4]^{2+}$ behaves as an electrophile, reaction with ^-OH leading to the reversible formation of $[RuX(NO_2)py_4]$.[663] The ClO_4^- salt of (**71**) reacts with N_3^- to give a mixture of $[RuCl(N_3)py_4]$ and $[Ru(Cl)py_4(OH_2)]^+$, while the PF_6^- salt of (**71**) yields $[RuCl(N_2)py_4]^+$ which rapidly loses N_2 in solution.[663] The one electron electrochemical reduction of (**71**) generates $[Ru(NO)py_4(OH_2)]^{2+}$; further reduction either electrochemically or with zinc amalgam produces $[RuCl(NH_3)py_4]^+$.[663] $[RuCl\{N(O)SO_3\}py_4]$ can be prepared by treatment of (**71**) with SO_3^{2-},[665] while reaction of $[RuI_2(NO)]$ with py is proposed to give a dimeric species of stoichiometry $[RuI_2(NO)py_2]_2$.[666]

(71)

Thermolysis of $(LH)_2[RuCl_5(NO)]$ (L = benzimidazole, imidazole, 5-nitrobenzimidazole, benzotriazole, py) leads to the initial formation of $[RuCl_4(NO)L]^-$ with subsequent reaction to afford $[RuCl_3(NO)L_2]$.[646] When solutions of $RuCl_3$ with NaNCS in pyridine are refluxed for three days, a product formulated as $[Ru(NCS)_2py_4]$ can be isolated.[667] Nitrosyl and thionitrosyl complexes containing heterocycles with arsine or phosphine ligands have been reported.[668]

(*iv*) *Monodentate heterocyclic complexes with oxygen donor ligands*

The complexes $[RuL(OH_2)_5]^{3+}$ (L = *N*-methylpyrazinium$^+$), $[RuL_2(OH_2)_4]^{2+}$ (L = py, pz) and $[Rupy_4(OH_2)_2]^{2+}$ can be isolated from the reaction of L with $[Ru(OH_2)_6]^{2+}$.[648] Reaction of $K_3[Ru(ox)_3]$ with py under reflux for 1 h followed by reduction with zinc amalgam yields $[Ru(ox)py_4]$.[669] Treatment of $[RuCl_2py_4]$ with NO_2^- produces $[Ru(NO_2)_2py_4]$.[663] The ruthenium(VI) complex $[RuO_2Cl_2py_2]$ with a *trans*-dioxo O=Ru=O moiety can be prepared by reaction of RuO_4 with py in the presence of HCl.[65] A product of stoichiometry RuO_4py_2 has been isolated from the reaction of RuO_4 with pyridine; the exact nature of this complex is unknown but is likely to involve Ru^{III} and/or Ru^{IV}.[670–674a] *Trans*-$[Ru^{IV}(O)Cl(py)_4]^+$ can be prepared by oxidation of *trans*-$[RuCl(NO)(py)_4]^{2+}$; the single crystal X-ray structure of the Ru^{IV}–oxo product shows an unusually long Ru—O distance of 1.862 Å.[674b]

(*v*) *Monodentate heterocyclic complexes with halide ligands*

Treatment of $[RuCl_6]^{2-}$ with L under reflux conditions yields $[RuCl_2L_4]$ (L = py, 2-, 3- and 4-methylpyridine.[675,676] $[Ru(ox)py_4]$ reacts with HCl to give *cis*-$[RuCl_2py_4]$. Recrystallization of *cis*-$[RuCl_2py_4]$ from pyridine leads to the isolation of the more stable *trans* isomer.[669] Extended reflux of $[RuCl_2(PPh_3)_3]$ or $[RuCl_2(AsPh_3)_2]_2$ with L yields $[RuCl_2L_4]$ (L = quinoline, 2-methylpyridine, 2-aminopyridine) together with mixed phosphine– and arsine–amine complexes.[677] The IR spectra of complexes of type $[RuCl_2L_4]$ have been reported.[669,675]

The complexes $[RuCl_3L_3]$ can be prepared by reaction of $[RuCl_2L_4]$ with HCl (L = py, 2-, 3- and 4-methylpyridine),[675] by reflux of $RuCl_3$ with L (L = imidazole, substituted imidazoles)[678] or by fusion of RuX_3 (X = Cl^-, Br^-, I^-) with molten L (L = thiazolidine-2-thione).[679] $[RuCl_3py_3]$ and $[RuCl_3pyL_2]$ (L = 2-methylbenzonitrile) show a reversible $Ru^{II/III}$ couple near 0.0 V *vs.* SCE, and a reversible $Ru^{III/IV}$ couple.[680] The differences between *fac* and *mer* isomers towards redox reactions have been discussed.[680] Treatment of $[RuCl_4(NCR)_2]^-$ with pyridine gives $[RuCl_4py_2]^-$.[681] The IR and magnetic properties of complexes $[RuCl_3L_3]$ have been reported.[675] Halo complexes of 3-methyl rhodanine, adenosine and xanthosine have been prepared by reflux of $RuCl_3$ with ligand in alcoholic solvents.[682,683]

Thermolysis of $(LH)_2[RuCl_6]$ yields $[RuCl_4L_2]$ (L = imidazole, 5-nitrobenzimidazole, benzimidazole, pyridine, benzotriazole, Et_2NH);[646,684] for L = pyridine thermolysis at higher temperatures gives $[RuCl_3py_2]_2$.[684]

(*vi*) *Bidentate heterocylic complexes* $[RuL_3]^{n\pm}$

(*a*) $[RuL_3]^+$

$[Ru(bipy)_3]^+$ can be generated by reductive quenching of excited state $[Ru(bipy)_3]^{2+}$* (see below) or by controlled potential electrolysis of $[Ru(bipy)_3]^{2+}$ at -1.42 V.[685,686] $[Ru(bipy)_3]^{1+/0/1-}$ have been generated electrochemically and their absorption spectra are consistent with the formation of charge localized ruthenium(II)–bipy radical species.[687,688] Comparison of the electronic spectra for $[Ru(bipy)_3]^{2+/1+/0/1-}$ shows the progressive growth of a band near 340 nm which is observed also for free ($bipy^-$) radical anion, and the concomitant collapse of the ($bipy^0$) $\pi \rightarrow \pi^*$ transition near 290 nm.[687–690] Bands assigned to intervalence charge transfer transition between coordinated ($bipy^0$) and ($bipy^-$) occur at 4500 cm^{-1} (ε = 210, 345 M^{-1} cm^{-1}) for $[Ru(bipy)_3]^{1+/0}$ respectively;[691] no such absorptions are observed for $[Ru(bipy)_3]^{2+/1-}$.[691] $[Ru(bipy)_3]^+$ shows a metal to ligand charge transfer band at 495–510 nm.[685,688,689,692–695] The ESR spectra of $[Ru(bipy)_3]^{1+/0}$ indicate interligand electron hopping with line broadening of the isotropic signal near g = 2,[696,697] no such line broadening being observed for $[Ru(bipy)_3]^{1-}$.[697] The charge localized assignment for $[Ru(bipy)_3]^{+/0}$ is further confirmed by resonance Raman data[698] which show bands assigned to both ($bipy^0$) and ($bipy^-$) in

the complexes. The redox orbital localization in $[Ru^{II}(bipy^{-})(bipy)_2]^{+}$ has been compared to the electron distribution in charge transfer excited state $[Ru(bipy)_3]^{2+*}$[687,688,691,697–700] (see below). Spectro–electrochemical studies on reduced complexes of $[RuL_3]^{2+}$ (L = 3,3′-biquinoline,[701] 5,5′-bis(ethoxycarbonyl)-2,2′-bipyridine,[687] 4,4′-bis(ethoxycarbonyl)-2,2′-bipyridine,[687,702] 4,4′-dimethyl-2,2′-bipyridine,[687] 4,4′-bis(diethylcarbamyl)-2,2′-bipyridine[687]) have been published. Voltammetry of $[RuL_3]^{2+}$ (L = bipy, 4,4′-bis(ethoxycarbonyl)-2,2′-bipyridine) at low temperatures indicates spatially isolated, localized orbitals for these complexes.[703–705a]

$[Ru(bipy)_3]^{+}$ is oxidized to $[Ru(bipy)_3]^{2+}$ by O_2, $[Co(bipy)_3]^{3+}$ and $[NiCN_4]^{2-}$ at pH 11 with rate constants $k = 7.4 \times 10^9$, 1.6×10^9 and $4.1 \times 10^7\ M^{-1}\ s^{-1}$ respectively.[685,689,692] $[Ru(bipy)_3]^{0}$ obtained by controlled potential electrolysis of $[Ru(bipy)_3]^{2+}$ at -1.65 V generates H_2 on reaction with H_2O;[686] no evolution of H_2 is observed on treatment of $[Ru(bipy)_3]^{+}$ with H_2O.[686]

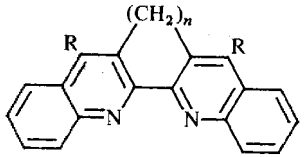
(b) $[RuL_3]^{2+}$

Over the past fifteen years a vast literature has built up around tris(diimino) complexes of Ru^{II}, particularly $[Ru(bipy)_3]^{2+}$. This has been based upon the photochemical behaviour of $[Ru(bipy)_3]^{2+}$ and the nature of its excited state $[Ru(bipy)_3]^{2+*}$ in relation to the use of such complexes as potential solar energy converters. $[Ru(bipy)_3]^{2+}$ is stable up to 300°C irrespective of the nature of the anion, the decomposition product being metallic Ru or RuO_2.[705b] Early preparations of $[Ru(bipy)_3]^{2+}$ and $[Ru(phen)_3]^{2+}$ were achieved by fusion of $RuCl_3$ with molten ligand at 250°C[706,707] or by refluxing $[RuCl_5(OH_2)]^{2-}$ with ligand in the presence of tartrate[708,709] or hypophosphite.[707,710,711] The preparation of $[Ru(bipy)_3]^{2+}$ by reduction of $RuCl_3$ with H_2 over Pt black followed by treatment with bipy in MeOH has been recommended.[712] By addition of optically active tartrate salt, Λ-$[Ru(bipy)_3]^{2+}$ has been isolated[708,709,713] and ion association measurements for $[Ru(phen)_3]^{2+}$[714,715] and the optical activity of $[Ru(bipy)_3]^{2+}$ and $[Ru(phen)_3]^{2+}$[716] have been studied. Λ-$[Ru(phen)_3]^{2+}$ has been used in clay column chromatography for the optical resolution of metal complexes.[717,718] The intercalation of $[Ru(phen)_3]^{2+}$ into DNA has been reported.[719] NMR studies of bipy complexes of Ru^{II} have been published.[267,269] Table 8 summarizes selected data on the synthesis, electronic spectra and redox properties of complexes of type $[RuL_3]^{2+}$. A comprehensive account of the photochemistry, photophysics and theoretical models derived from absorption and luminescent data for $[Ru(bipy)_3]^{2+}$ is beyond the scope of this review. Several excellent reviews of this area have appeared in the literature,[3–5,487b,727,731,767–784] the accounts by Seddon and Seddon,[3–5] and Kalyanasundaram[768] being particularly detailed.

The electronic absorption spectrum of $[Ru(bipy)_3]^{2+}$ shows bands at 185 nm, 208 nm and 285 nm assigned to bipy $\pi \rightarrow \pi^*$ transitions, and *d–d* transitions at 323 nm, 345 nm, 238 nm, 250 nm.[727,731] The intense absorption at 454 nm ($\varepsilon = 14600\ M^{-1}\ cm^{-1}$)[724] is assigned to a metal to ligand charge transfer;[267,785–790] this latter transition shows a long tail absorption above 500 nm which has been assigned to a spin-forbidden metal to ligand charge transfer.[711,790] The luminescence of $[Ru(bipy)_3]^{2+}$ was first reported by Paris and Brandt in 1959 as an emission near 600 nm and was assigned as charge transfer in nature.[791] Later this was reassigned to a singlet *d–d* transition[792,793] and then to a spin-forbidden triplet–singlet charge transfer from $(t_{2g})^5(\pi^*)^1$ to $(t_{2g})^6$ (equation 75).[790,794,795] The orbital nature of the MLCT absorption and emission spectra of $[Ru(bipy)_3]^{2+}$, and hence the electronic structure of the excited state $[Ru(bipy)_3]^{2+*}$, has been the subject of much controversy.

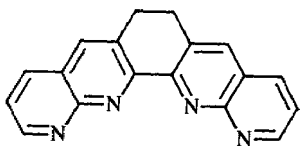
$$\underset{(t_{2g})^6}{[Ru(bipy)_3]^{2+}} \xrightarrow{h\nu} \underset{(t_{2g})^5(\pi^*)^1}{[Ru(bipy)_3]^{2+*}} \xrightarrow{h\nu'} \underset{(t_{2g})^6}{[Ru(bipy)_3]^{2+}} \qquad (75)$$

To rationalize the luminescence characteristics of $[Ru(bipy)_3]^{2+*}$ Crosby and co-workers have developed in a series of papers[727,736,787,793,802–807] an electron-ion parent (EIP) coupling model[804,805] to describe the orbital symmetries of the excited states. In this model, the electronic structure of $[Ru(bipy)_3]^{2+*}$ could not be simply described as singlet or triplet; since the luminescence is charge transfer *d–π** in character, spin-orbit coupling would be expected to occur thus mixing the emitting states and thus the emission was described as occurring from a 'manifold' of spin-orbit states ${}^3CT \rightarrow {}^1A_{1g}$,[790,803–805,808] with three emitting levels of A_1, E and A_2 symmetries. $[Ru(bipy)_3]^{2+*}$ was therefore described as a d^5 Ru^{III} centre with one electron delocalized over three bipy ligands[685,787] and the temperature dependence and polarization of the luminescence predicted.[3–5,768]



More recently, however, the EIP model has been modified and alternative models that generate the requisite manifold of emitting levels have gained favour. Photoselection data for the emission of $[Ru(bipy)_3]^{2+*}$ were found to be inconsistent with the EIP model[789,809,810] with a far greater degree of polarization than would be expected for an ion of D_3 symmetry.[811–813] Since the single crystal X-ray structure of $[Ru(bipy)_3]^{2+}$ shows[814] the complex to have D_3 symmetry with short Ru—N = 2.056 Å

Table 8 Synthesis, Absorption Spectra and Redox Properties of Complexes $[RuL_3]^{2+}$



Ligand (L)	*Synthesis*	*λ (ε) (nm × 10^{-4} $M^{-1}cm^{-1}$)*	$E_{1/2}$ (V)	*Reference electrode (solvent)*

distances (consistent with strong $Ru^{II} \rightarrow$ bipy back-donation), more recent proposals have led to the thesis that the excited state in $[Ru(bipy)_3]^{2+*}$ is of lower symmetry than D_3; *e.g.* with a localized bipy radical such as $[Ru^{III}(bipy^-)(bipy)_2]^{2+}$. Direct experimental evidence for localized charge distribution in $[Ru(bipy)_3]^{2+*}$ has come from absorption[699,700,815–817] and resonance Raman spectral studies[818–823] on the excited state species. The absorption spectrum of $[Ru(bipy)_3]^{2+*}$ shows a band near 360 nm assignable to coordinated ($bipy^-$) radical anion,[699,700,815–817] while frequency shifts between $[Ru(bipy)_3]^{2+}$ and $[Ru(bipy)_3]^{2+*}$ have been found to be analogous to those observed in the IR spectra for ($bipy^0$) and ($bipy^-$).[818–822] This has led to the conclusion that on the vibrational time scale, the electron is localized on only one bipy ligand, rather than delocalized over all three. Voltammetric data suggest[703–705a] a localized formalism for the redox orbitals of $[Ru(bipy)_3]^{2+}$ and this is confirmed by spectroscopic studies on $[Ru(bipy)_3]^{+}$. Polarized single crystal emission,[824] absorption data,[720,825,826] and resonance Raman studies[827,828] on $[Ru(bipy)_3]^{2+}$ have been published. Analysis of the charge transfer absorption spectrum of $[Ru(bipy)_3]^{2+}$ by CD[786,825,826,829,830] and by molecular orbital X_α and Hückel calculations[789,831,832] has led to a model[789] which involves only weak coupling ($\sim 600\,cm^{-1}$) between bipy ligands. This is consistent with spectral studies for $[Ru(bipy)_3]^{2+*}$ and $[Ru(bipy)_3]^{+}$. More recently an electronic structural model[833] based on the absorption spectrum of $[Ru(bipy)_3]^{2+}$ has indicated that the luminescent excited state can be regarded as a triplet with less than 10% singlet character. The exact nature of the excited state species $[Ru(bipy)_3]^{2+*}$ is still the subject of much discussion and is likely to remain so in the near future.

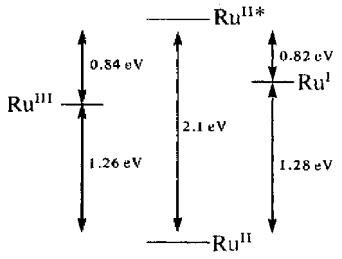
$[Ru(bipy)_3]^{2+*}$ can not only be generated by photolysis of $[Ru(bipy)_3]^{2+}$, but also *via* electron transfer reactions in the dark to give chemiluminescent activity. This has been achieved by the reduction of $[Ru(bipy)_3]^{3+}$ with ^-OH,[834] N_2H_4, $NaBH_4$, edta,[834,835] e^-_{aq},[836] H_2SO_4,[837] oxalate[838] or $[Ru(bipy)_3]^{+}$[729] (Scheme 22). The chemiluminescent spectrum obtained from the reduction of $[Ru(bipy)_3]^{3+}$ was found to be identical to that of the photoluminescent spectrum of $[Ru(bipy)_3]^{2+}$.[836] Chemiluminescence has been extended to electrogenerated chemiluminescence (ECL) in which reduced and oxidized forms of $[Ru(bipy)_3]^{2+}$ are cogenerated by rapid cycling between E_{ox} of the $Ru^{II/III}$ couple and E_{red} of the first reduction potential followed by annihilation of $[Ru(bipy)_3]^{3+}$ with $[Ru(bipy)_3]^{+}$ (equation 76).[725,729,838,839] Electron transfer during ECL experiments occurs *via* an outer-sphere mechanism conforming to Marcus theory.[840,841] The efficiency obtained from ECL and pulse radiolysis[836] experiments is generally higher than that for photoluminescence[842–845] and more recently ECL studies have been carried out at electrodes modified by polymer surface films.[846,847] The photoinduced disproportionation of $[Ru(bipy)_3]^{2+}$ on photolysis in a glass matrix to yield $[Ru-(bipy)_3]^{+}$ and $[Ru(bipy)_3]^{3+}$ has been reported (equation 77 and 78).[848]

Scheme 22

$$[Ru(bipy)_3]^{3+} + [Ru(bipy)_3]^{+} \longrightarrow [Ru(bipy)_3]^{2+*} + [Ru(bipy)_3]^{2+} \quad (76)$$

$$[Ru(bipy)_3]^{2+*} \longrightarrow [Ru(bipy)_3]^{3+} + e^-_{glass} \quad (77)$$

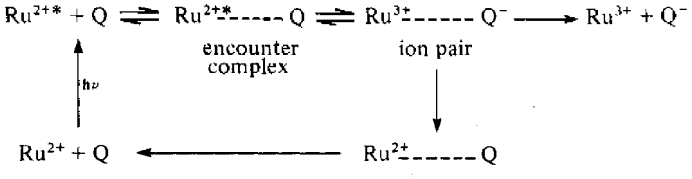
$$[Ru(bipy)_3]^{2+} + e^-_{glass} \longrightarrow [Ru(bipy)_3]^{+} \quad (78)$$



Quenching of the luminescence of $[Ru(bipy)_3]^{2+*}$ by a quencher Q can occur *via* energy transfer to give $[Ru(bipy)_3]^{2+}$, by reductive quenching to $[Ru(bipy)_3]^{+}$ or by oxidative quenching to yield $[Ru(bipy)_3]^{3+}$ (equations 79–81).[849] The parallels between quenching mechanisms and photodiode behaviour at a molecular level have been made.[850] The relative $E_{1/2}$ values for $[Ru(bipy)_3]^{3+/2+/1+}$ and $Q^{1-/0/1+}$ play an important role as to which mechanism is observed.[849] The oxidation potential of $[Ru(bipy)_3]^{2+*}$ has been estimated at -0.84 V *vs.* NHE[686,851] making it a stronger reducing agent by approximately 2.1 V compared with $[Ru(bipy)_3]^{2+}$.[694] $[Ru(bipy)_3]^{2+*}$ is more reactive towards both reduction and oxidation than the ground state molecule[695] (Scheme 23)[767,775] consistent with its

formalism as $[Ru^{III}(bipy^{-})(bipy)_2]^{2+}$. A range of inorganic and organic reagents have been used to quench the excited state $[Ru(bipy)_3]^{2+*}$ species.[852,853] Oxidative quenching of $[Ru(bipy)_3]^{2+*}$ and related excited state complexes has been reported with $S_2O_8^{2-}$,[695,808,839,854–856] O_2,[769,857–863] $[Co(NH_3)_6]^{3+}$,[864] $[CoX(NH_3)_5]^{2+}$ (X = Cl^-, Br^-, I^-),[851,864] $[CoL(NH_3)_5]^{3+}$,[865,866] $[Co(ox)_3]^{3-}$,[867,868] $[Co(acac)_3]$,[869] Co^{III} macrocyclic complexes,[870,871] $[CoCl(Hedta)]^-$,[864] $[Co(phen)_3]^{3+}$,[863] binuclear Co^{III} species,[872,873] $[Fe(CN)_6]^{3-}$,[863,874] $[Fe(ox)_3]^{3-}$,[864,867] Fe^{3+},[129,728,863,875–880] $[Cr(ox)_3]^{3-}$,[867,868] Tl^{III},[878] $[Os(bipy)_3]^{3+}$,[863] $[Ru(NH_3)_6]^{3+}$,[863,880] Hg^{II},[881–883] bipy derivatives[865,879,880,884–890] and nitrobenzene.[884,891] Reductive quenching has been studied with $[Fe(CN)_5L]^{3-}$,[849] $[Mo(CN)_6]^{4-}$,[874,892] Eu^{II},[694,695,892,893] $[Os(CN)_6]^{4-}$,[695,873,874] amines,[884,894–897] dopamine,[898] adrenaline,[898] L-dopa,[898] dtc^-,[899] methoxybenzenes,[895] aromatic ethers,[894] hydroquinone[894] and water,[894] while energy transfer mechanism has been observed for Cr^{III},[728,868,874,900–904] Ti^{III} [905] and O_2.[906] Quenching reactions with Fe^{II},[129,878] Ru^{II},[851] Ru^{III},[907] Cu^{II},[908,909] Ag^{I},[910,911] Eu^{III},[129,695] $[PtCl_4]^{2-}$,[868] $[Ni(CN)_4]^{2-}$,[874] Os^{II},[907] Os^{III}, Os^{IV}, Os^{VI} [912] and *N*,*N*′-dimethylaniline,[888,913,914] have also been reported. Quenching of $[Ru(bipy)_3]^{2+*}$ does not occur with $[Co(CN)_6]^{3-}$, $[Pt(CN)_4]^{2-}$ or $[Pd(CN)_4]^{2-}$.[874] Energy transfer quenching is thought to be favoured when absorption and emission spectra of the reacting species overlap.[905,915]

Energy transfer quenching $[Ru(bipy)_3]^{2+*} + Q \longrightarrow [Ru(bipy)_3]^{2+} + Q^*$ (79)

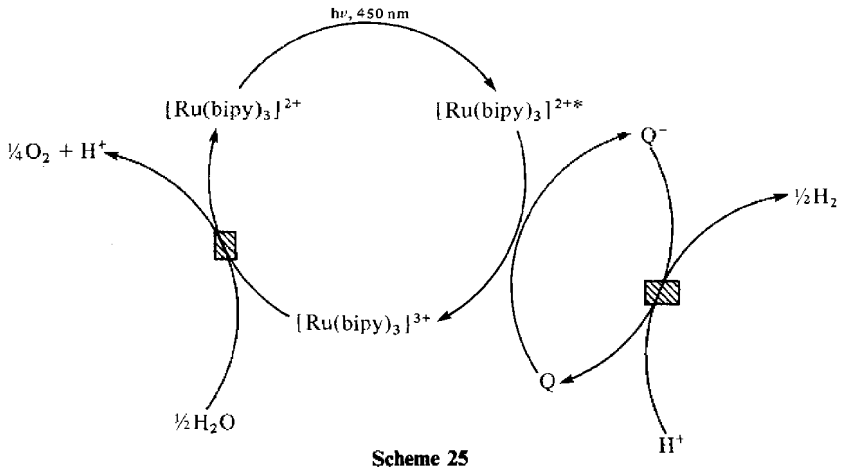


Reductive quenching $[Ru(bipy)_3]^{2+*} + Q \longrightarrow [Ru(bipy)_3]^{+} + Q^{+}$ (80)

Oxidative quenching $[Ru(bipy)_3]^{2+*} + Q \longrightarrow [Ru(bipy)_3]^{3+} + Q^{-}$ (81)

Scheme 23

The use of electron transfer quenching of $[Ru(bipy)_3]^{2+*}$ (equations 80 and 81) for the conversion of photolysis energy to generate radical species has been developed. Bipyridinium salts such as *N*,*N*′-dimethyl-4,4′-bipyridinium^{2+} (MV^{2+}) and *N*-methyl-4,4′-bipyridinium^{+} have been used successfully as electron acceptors.[865] Flash photolysis studies indicate that the formation of free radicals occurs *via* one electron transfer from $[Ru(bipy)_3]^{2+*}$,[865] while the quenching of $[Ru(bipy)_3]^{2+*}$ by nitrobenzene has been described in terms of encounter complex and ion pair formation (Scheme 24).[891] Quenching by binuclear superoxy Co^{III} species has been formulated as being due to 90% electron transfer and 10% energy transfer.[873] The relaxation processes of excited state polypyridyl complexes[916] and electron transfer kinetics in these systems[768] have been discussed. The oxidation of Ph_3N to Ph_3N^+ has been achieved using photosensitized $[Ru(bipy)_3]^{2+}$ and MV^{2+} (equations 82–84).[917]

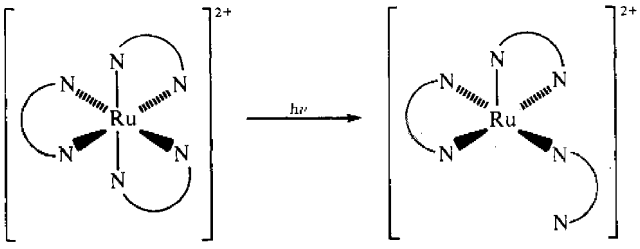


Scheme 24

$Ru^{2+} \longrightarrow Ru^{2+*}$ (82)

$Ru^{2+*} + MV^{2+} \longrightarrow Ru^{3+} + MV^{+}$ (83)

$Ru^{3+} + NPh_3 \longrightarrow Ru^{2+} + {}^{+}NPh_3$ (84)



With the ability of photolytically sensitizing $[Ru(bipy)_3]^{2+}$ to $[Ru(bipy)_3]^{2+}*$ and transferring an electron to a quencher Q to generate a strong oxidant $[Ru(bipy)_3]^{3+}$ and reductant Q^- simultaneously, much attention has been focused on the possible utilization of $[Ru(bipy)_3]^{2+}$ as a photocatalyst for the photochemical splitting of water to H_2 and O_2. Although $[Ru(bipy)_3]^{2+}*$ does not cleave water itself, a series of papers have appeared in the literature describing the decomposition of H_2O to H_2 and/or O_2 and related redox processes using $[Ru(bipy)_3]^{2+}$ or a derivative as a photosensitizer in conjunction with a range of radical carriers and homogeneous and heterogeneous catalysts.[854,894,918–949] Scheme 25 illustrates a typical cycle utilizing the oxidative quenching of $[Ru(bipy)_3]^{2+}*$.[918] The photochemical splitting of H_2O by tris(diimino) Ru^{II} complexes is discussed in Chapter 62.5. $[Ru(bipy)_3]^{2+}$ mediates the photoreduction of alkenes with 1-benzyl-1,4-dihydronicotinamide[950] and the photooxidation of phenols.[951] More recently, electron transfer reactions of $[Ru(bipy)_3]^{2+}$ derivatives (particularly those incorporating vinyl substituents) have been studied in polymeric films at electrode surfaces,[183,846,952–977] with colloids,[978] at ion exchange surfaces,[979] in zirconium phosphate lattices,[897] and zeolites[980] in order to investigate the formation of photocurrents; surfactant bipy derivatives have also been studied in micellar solutions.[854,888,963,964,981–987a] Work has been directed also to the development of new photosensitizers of type $[RuL_3]^{2+}$.[987b] The cation $[Ru(bpz)_3]^{2+}$ (bpz = 2,2′-bipyrazine) is a superior photosensitizer to $[Ru(bipy)_3]^{2+}$ and shows emission at 603 nm with a half-life of the excited state $t_{1/2} = 1.04\,\mu s$,[750–752] compared with a $t_{1/2} = 6.0\,\mu s$ for $[Ru(bipy)_3]^{2+}*$.[711,753] Whereas $[Ru(bipy)_3]^{2+}*$ is oxidatively quenched by triethanolamine to $[Ru(bipy)_3]^{3+}$, $[Ru(bpz)_3]^{2+}*$ is reductively quenched to $[Ru(bpz)_3]^{+}$ which undergoes electron transfer with MV^{2+} to yield MV^{+}.[750] This is consistent with the redox properties of $[Ru(bpz)_3]^{2+}$ which is oxidized and reduced at potentials ~0.5 V more positive than $[Ru(bipy)_3]^{2+}$.[752] Protonation equilibria for $[Ru(bpz)_3]^{2+}*$ have been measured[988] and ECL has been generated by reaction of $[Ru(bpz)_3]^{+}$ with $[Ru(bpz)_3]^{3+}$.[752] The single crystal X-ray structure of $[RuL_3]^{2+}$ (L = 4,7-dimethyl-2,3,8,9-dibenzo-5,6-dihydrophenanthroline) has been reported.[989] Photochemical studies on $[RuL_3]^{2+}$ (L = 2,2′-bithiazoline) indicate that aromatized cyclic ligands are not essential for charge-transfer emission,[990] while $[RuL_3]^{-}*$ (LH = 2,2′-dipyridyl amine) has been reported to show spatially isolated single ring emission.[766] The luminescence of complexes containing nitro and phosphonium bipy ligands has been studied.[991a] More recently, covalently linked photosensitizer (bipy) and electron acceptor (MV^{2+}) complexes have been synthesized.[991b]

Scheme 25

The photochemical stability of $[Ru(bipy)_3]^{2+}$ towards ligand substitution reactions has been the mainstay of its use as a photosensitizer.[992,993] More recently however photosubstitution reactions have been reported.[767,768,994] The EIP model has been modified by Houten and Watts[995,996] to take into account high temperature substitution reactions by introducing a higher set of non-luminescent levels.[997,998] Substitution photochemistry of $[Ru(bipy)_3]^{2+}$ by Br^- is quenched by ferrocene three times as strongly as luminescence suggesting that the photoreactive LF state is not in thermal equilibrium with the luminescent excited state.[999] Photolysis of $[Ru(bipy)_3]^{2+}$ with X^- yields $[RuX_2(bipy)_2]$ ($X^- = Cl^-$,[1000] Br^-,[1001] I^-,[1002] ^-NCS,[1003] ^-NCO,[1004] ^-NCSe,[1004] NO_2^-,[1002] N_3^-,[1002] malonate,[1002] ^-CN[1002]). Solvolysis may also occur to give the complexes $[Ru(bipy)_2(NCMe)_2]^{2+}$,[757,1005] $[RuCl(bipy)_2S]$ (S = MeCN, $MeNO_2$)[1006] and $[RuX(bipy)_2DMF]^+$ (X = Br^-,[1001] ^-NCS[1003]); the role of chlorinated solvents in these photoreactions has been discussed.[1000] Association of H^+ in ground

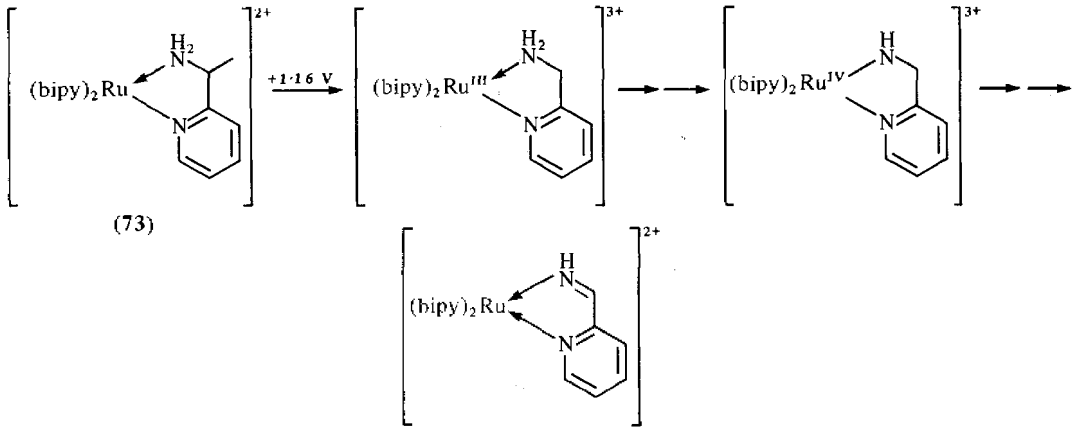
state and excited state $[Ru(bipy)_3]^{2+}$ has been suggested[225,1007] leading to decomposition *via* loss of bipy ligands.[994,1008,1009] Monodentate bipy intermediates have been proposed in these reactions[767,994,1010,1011] which is consistent with data for the photoracemization of $[Ru(bipy)_3]^{2+}$ *via* rotation of five-coordinate intermediate species (**72**) (equation 85).[1012] The photoanation of $[Ru(bpz)_3]^{2+}$ in MeCN by Cl^- yields *cis*-$[RuCl(bpz)_2(NCMe)]^+$ and *cis*-$[RuCl_2(bpz)_2]$.[751]

(85)

(72)

There have been several reports of covalent hydration and pseudo-base formation in the reactions of $[RuL_3]^{2+}$ (L = bipy,[64,709] phen, 5-nitro-1,10-phenanthroline,[743,1013–1022] 2,2′-bipyrimidine[1023]) with a range of nucleophiles. These reactions are proposed to involve nucleophilic attack on the coordinated heterocyclic ligand to give in the case of CN^- attack on phen and 5-nitro-1,10-phenanthroline complexes, 2-, 6- or 9-cyano derivatives.[1014] The proposals for pseudo-base formation have come under severe criticism[1024–1029] although the yields of these products in solution are likely to be low.[1023,1030,1031] For $[RuL_3]^{2+}$ (L = 2,2′-bipyrimidine) ring cleavage is reported to occur in the presence of ^-OH to yield $[Ru(OH)(bipym)_2(pym)]^+$.[1023] The acidity of the 3,3′-protons in $[Ru(bipy)_3]^{2+}$ has been noted although covalent hydration was not observed directly.[1029,1032]

(c) $[RuL_3]^{3+}$

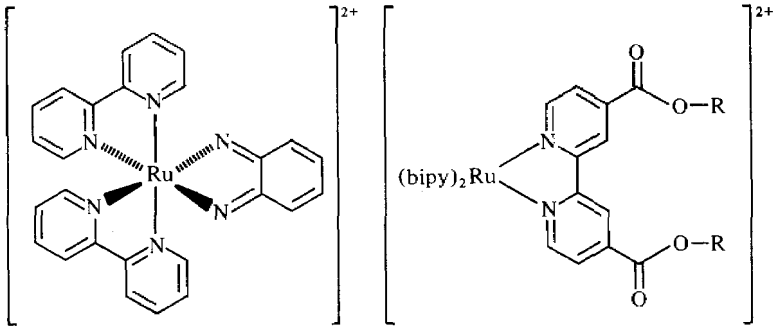


Complexes of type $[RuL_3]^{3+}$ can be prepared by chemical or electrochemical oxidation of $[RuL_3]^{2+}$ (Table 8) or as a product in the oxidative quenching of excited state $[RuL_3]^{2+}*$ (see above). The oxidation of $[Ru(bipy)_3]^{2+}$ by PbO,[837] Tl^{III},[1033] Cl_2,[722] and Ce^{IV}[1034] has been reported. $[Ru(bipy)_3]^{3+}$ shows a band near 680 nm ($\varepsilon = 407\,M^{-1}\,cm^{-1}$)[267,723] with no MLCT band near 454 nm as observed for $[Ru(bipy)_3]^{2+}$.[724] The ESR spectrum of $[Ru(bipy)_3]^{3+}$ is consistent with a Ru^{III} d^5 configuration.[604] $[RuL_3]^{3+}$ (L = bipy, phen) have been reported not to racemize or dissociate in water, but react to give covalently hydrated species.[64] The electrochemical formation and spectroscopy of $[Ru(bipy)_3]^{3+}$ in $AlCl_3$/*N*-(1-butyl)pyridinium chloride melts have been described.[1035]

$[Ru(bipy)_3]^{3+}$ undergoes outer-sphere electron transfer with reducing agents such as alkyl radicals,[1036] BH_4^-,[1037] cyclohexanone,[1038] ^-OH,[1039] $[Ru(bipy)_3]^{2+}$,[152,1040] Co^{II},[1040–1043] Co^{III},[1044] $[Cr(bipy)_3]^{3+}*$,[1045] $[Fe(OH_2)_6]^{2+}$,[271,1046–1048] $[Fe(CN)_6]^{4-}$,[1047] $[Mo(CN)_6]^{2-}$,[1047] $SbCl_3$[860] and Hg^I.[722] For the oxidation of $[Fe(OH_2)_6]^{2+}$ by $[Ru(phen)_3]^{3+}$ and $[Ru(bipy)_3]^{3+}$, $\Delta H^{\neq} = -5.65, -1.26\,kJ\,mol^{-1}$; $\Delta S^{\neq} = -151, -138\,J\,K^{-1}\,mol^{-1}$ respectively.[1043] The reaction of $[Ru(phen)_3]^{3+}$ with $[Ru(bipy)_3]^{2+}$ proceeds with a rate constant $k = 1.2 \times 10^9\,M^{-1}\,s^{-1}$ and $\Delta H^{\neq} = 32.2\,kJ\,mol^{-1}$, $\Delta S^{\neq} = -27.6\,J\,K^{-1}\,mol^{-1}$.[1046] The oxidation of H_2O to O_2 has been achieved using Co^{II} in the presence of $[Ru(bipy)_3]^{3+}$.[1049]

The electrochemistry of $[RuL_3]^{2+}$ (L = bipy, phen) has been extended by the measurement of the $[RuL_3]^{4+/3+}$ redox couples in liquid SO_2 at +2.78 V and +2.60 V *vs.* SCE respectively.[723,726]

(vii) Bidentate heterocyclic complexes $[RuL_2L']^{n+}$, $[RuLL'L'']^{n+}$



A range of mixed ligand complexes $[RuL_2L']^{2+}$ have been prepared and their spectroscopic, luminescent and redox properties studied (Table 9). The absorption and CD spectra of $[Ru(phen)_2(bipy)]^{2+}$ and $[Ru(bipy)_2(phen)]^{2+}$ have been discussed.[1052] $[Ru(bipy)_2L]^{2+}$ [L = 2-(aminomethyl)pyridine, 2-(1-aminoethyl)pyridine (**73**)] undergoes oxidative dehydrogenation on oxidation at +1.16 V *vs.* SCE (Scheme 26).[1068,1074] The rate-determining step of reaction is deprotonation at the α carbon atom with concomitant two electron transfer from ligand to metal.[1074] The single crystal X-ray structure of (**73**) shows[1074] Ru—N(py) = 2.062 Å, Ru—$N(NH_2)$ = 2.121 Å, Ru—N(bipy) = 2.064, 2.046, 2.044, 2.057 Å. The single crystal X-ray structure of the related complex $[Ru(bipy)_2(NH)_2C_6H_4]^{2+}$ (**74**) has been reported and shows short Ru—$N(NH)_2C_6H_4$ distances of 2.038, 1.996 Å suggesting strong back-bonding from Ru^{II} to the diimino ligand.[1069]

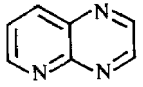
(73)

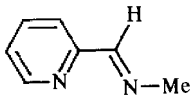
Scheme 26

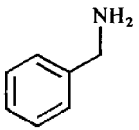
The luminescent properties of the excited state species $[RuL_2L']^{2+}$* have been investigated with the aim of developing more efficient photosensitizers than $[Ru(bipy)_3]^{2+}$.[733] Mixed ligand Ru^{II} complexes incorporating surfactant long chain ester derivatives of bipy have been synthesized, for example (**75**) and (**76**),[888,1055,1061–1063,1075–1083] and their luminescence investigated in micellar solutions.[1061–1063,1079,1081] These surfactant complexes are generally found to be inactive for the photochemical cleavage of water,[986,1059,1060,1084,1085] hydrolysis of the ester moieties and destruction of assemblies being a particular problem with these systems.[986] Irradiation of $[Ru(bipy)_2L]^{2+}$ (L = 2,2′-bipyridine-4,4′-dicarboxylic acid) in the presence of edta, MV^{2+} and Pt catalyst produces H_2 at one tenth of the rate as observed for $[Ru(bipy)_3]^{2+}$.[1086] This is ascribed to the electron withdrawing effect of the carboxyl or ester functions to bimolecular quenching of the excited state by water;[1086] H^+ transfer in the excited state species has been studied and the luminescence measured as a function of pH.[1087] The deprotonated complex was found to be a stronger base in the excited state than in the ground state,[1087] while for complexes of 4,7-dihydroxy-1,10-phenanthroline, an increase in acidity has been observed in the excited state.[1053] The linking of complexes $[RuL_2L']^{2+}$ to polystyrene supports,[1088] and the preparations of vinyl polymers[953,1056,1089] and chemically modified electrodes[1090,1091] have been reported.

(74)

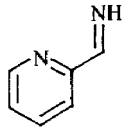
(75) R =







(76) R = $C_{18}H_{37}$



The lifetimes of excited state $[Ru(bipy)_2L]^{2+}$* vary according to L; for example, the half-life for $[RuL_3]^{2+}$* (L = 2,2′-bibenzimidazole) $t_{1/2} = 1.00\,\mu s$, for $[Ru(bipy)_2L]^{2+}$* $t_{1/2} = 3.00\,\mu s$ as compared with $t_{1/2} = 6.0\,\mu s$ for $[Ru(bipy)_3]^{2+}$*.[711,753] This has led to the study of excited state species for mixed ligand systems particularly with regard to localized and delocalized formalisms for $[RuL_2L']^{2+}$*. Using the EIP model, Crosby has proposed ligand–ligand coupling in the excited and ground state of $[Ru(bipy)_2L]^{2+}$ (L = 4,4′-dimethyl-2,2′-bipyridine, 4,4′-diphenyl-2,2′-bipyridine, 5,6-dimethyl-1,10-phenanthroline, 4,7-dimethyl-1,10-phenanthroline, 4,7-diphenyl-1,10-phenanthroline),[806]

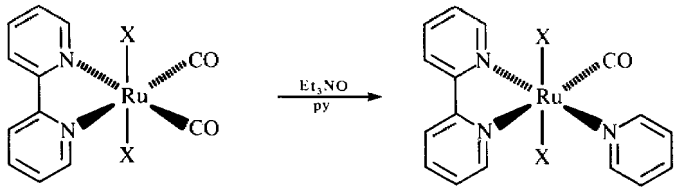
$[Ru(bipy)_2phen)]^{2+}$ and $[Ru(bipy)(phen)_2]^{2+}$.[806,1050,1092,1093] More recently, the absorption spectra of $[Ru(bipy)_x(phen)_{3-x}]^{2+}$ have been interpreted as superpositions of the tris chelate $[Ru(bipy)_3]^{2+}$ and $[Ru(phen)_3]^{2+}$ end points,[1051] suggesting localized, weakly coupled excited states. For the complexes $[Ru(bipy)_2L]^{2+}$ (L = 2-(2′-pyridyl)quinoline,[754,1065,1094] 2,2′-biquinoline,[1065,1094,1095] 3,3′-biquinoline,[1094] 2,2′-bipyridine-4,4′-dicarboxylic acid,[1057] 2,2′-bipyridine-4,4′-diethyl carboxylate,[1057] 4,4′-dinitro-2,2′-bipyridine[1094]), $[Ru(bipy)L_2]^{2+}$ (L = 3,3′-biquinoline)[1094] and $[Ru(phen)_2L]^{2+}$ (L = 2-(2′-pyridyl)quinoline,[1094] bipy,[1096] 2,2′-biquinoline,[1094] dmch[1094]) no clear dual emission has been observed, emission occurring from the lowest energy charge transfer excited state localized on the ligand which is easiest to reduce.[754,1094,1097] A degree of energy transfer from phen to 2-(2-pyridyl)quinoline (L) has been suggested however for $[Ru(phen)_xL_{3-x}]^{2+}$.[740] The electrochemistry of $[RuL_2L']^{2+}$ (L = 2,2′-bipyrimidine, L′ = bipy, 4,4′-dimethyl-2,2′-bipyridine, 5,5′-dimethyl-2,2′-bipyridine) indicates that for the primary reduction product, the electron is localized on a single 2,2′-bipyrimidine ligand.[734] Kinetic and emission data for a range of mixed ligand complexes $[Ru(bipy)_{3-x}L_x]^{2+}$ (L = 2,2′-bipyrazine, 2,2′-bipyrimidine), $[RuL_{3-x}L'_x]^{2+}$ (L = 2,2′-bipyrimidine, L′ = 2,2′-bipyrazine) and $[RuLL'L'']^{2+}$ (L = bipy, L′ = 2,2′-bipyrimidine, L″ = 2,2′-bipyrazine) have been reported.[1098a] For synthetic and electrochemical work in this area see references 1098a–d. Spectro–electrochemical studies on $[Ru(bipy)_2L]^{1+/0/1-}$ (L = 2,2′-biquinoline, phen, dmch) have been carried out and the results related to a localized redox orbital model.[701]

$[Ru(bipy)_2L]^{2+}$ (L = 4,4′-dichloro-2,2′-bipyridine) is susceptible to attack by nucleophiles at the 4,4′ positions of the substituted bipy, reactivity being higher for the coordinated than for the free ligand.[1099]

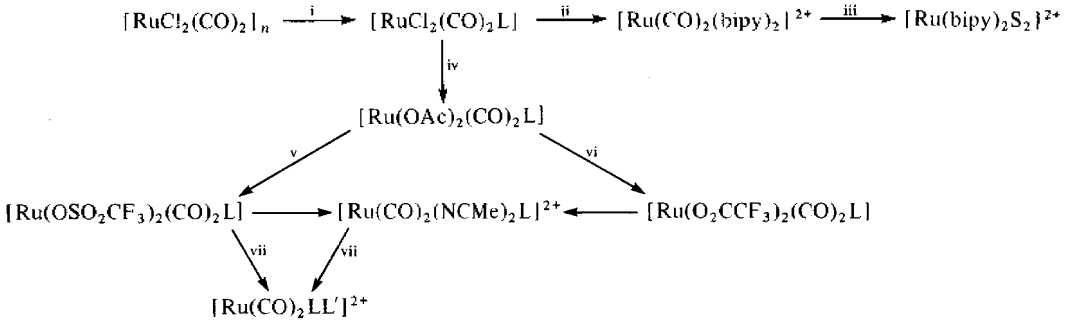
(*viii*) *Bidentate heterocyclic complexes with carbon donor ligands*

A wide range of complexes of type $[RuL_2XY]^{2+/1+/0}$ (L = bidentate heterocycle) have been prepared and their chemical and photochemical properties investigated.[264–267,611,785,1100]



(a) Cyanides (see Section 45.3.1)

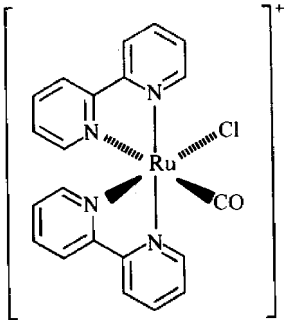
Cis-$[Ru(CN)_2(bipy)_2]$ can be isolated by treatment of $[Ru(ox)(bipy)_2]$ with NaCN in aqueous MeOH and chromatography on silica or alumina,[40,41,55,266] by photolysis of $[Ru(bipy)_3](CN)_2$[1002] or by reaction of $RuCl_3$ with L (L = bipy, phen or heterocyclic derivatives) followed by NaCN to yield $[Ru(CN)_2(L)_2]$.[1055,1082] The interaction of $[Ru(CN)_2(bipy)_2]$ with Ag^+,[1101] $[Pt(dien)]^{2+}$ (dien = diethylenetriamine),[1102] $[PtCl_3(C_2H_4)]^-$ and *cis*- and *trans*-$[PtCl_2(L)(L')]$ (L = C_2H_4, Me_2S; L′ = 4-methylpyridine)[50,1103] yields CN bridged 1:1 and 1:2 adducts and the luminescence properties of these complexes have been described. The excited state chemistry[1100] and electron transfer quenching reactions of $[Ru(CN)_2(L)_2]$* with pyridinium salts,[1104] O_2,[857] Cu^{2+},[1105] Fe^{3+},[879] paraquat[879] and aqueous acid[1106,1107] have been reported. The electrochemistry of $[Ru(CN)_2(bipy)_2]$ has been reported.[268b]



Hydrolysis of $[Ru^{III}(CN)_2(bipy)_2]^+$ yields $[Ru(bipy)_2(OH_2)_2]^{3+}$.[64]

(b) Carbonyls and related ligands

Reaction of the red solution obtained from refluxing RuX_3 with CO in EtOH with L yields $[RuX_2(CO)_2L]$ (X = Cl^-, Br^-; L = bipy, phen,[48,108,652,1108–1111] diphos[652,653]). Treatment of $[RuX_2(CO)_2L]$ with HX′ gives $[RuX'_2(CO)_2L]$ (X′ = $CF_3CO_2^-$, $MeCO_2^-$, $CF_3SO_3^-$) from which $[Ru(CO)_2(NCMe)_2L]^{2+}$ can be generated.[1108] The electrochemistry of $[RuCl_2(CO)_2L]$ (L = bipy, phen) has been reported.[625] The decarbonylation of $[RuX_2(CO)_2L]$ (**77**) (L = bipy, X = Cl^-, $CF_3CO_2^-$; L = phen, X = Cl^-, Br^-) with Et_3NO in pyridine yields $[RuX_2(CO)L(py)]$ (**78**) with retention of stereochemistry (equation 86),[658] while treatment of $[RuCl_2(CO)_2L]$, $[RuCl_2(CO)py(phen)]$ or $[Ru(CO)_2(phen)_2]^{2+}$ with Me_3NO in 2-methoxyethanol in the presence of L′ gives $[RuL(L')_2]^{2+}$ (L = phen, bipy, L′ = bipy, phen, 3,4,7,8-tetramethyl-1,10-phenanthroline).[657] $[RuCl_3(C_7H_8)CO]^-$ reacts with L to produce $[RuCl_2(CO)L]_n$ and $[RuCl_3(CO)L]^-$ (L = bipy, phen).[659] Treatment of $[Ru(O_3SCF_3)_2(CO)_2phen]$ with L (L = bipy, phen, 3,4,7,8-tetramethyl-1,10-phenanthroline,[1108] 4,4′-dimethyl-2,2′-bipyridine,[1112a] 4,4′-diisopropyl-2,2′-bipyridine[1112a]) yields the complexes $[Ru(CO)_2(phen)L]^{2+}$; likewise reaction of $[Ru(CO)_2(NCMe)_2L]^{2+}$ with L gives *cis*-$[Ru(CO)_2L_2]^{2+}$.[1108,1112a] $[Ru(CO)_2(bipy)_2](PF_6)_2$ catalyses the reduction of CO_2 to formic acid and CO under alkaline conditions, and to CO only under acidic conditions.[1112b] The formation of $[Ru(CO)_2py_2L]^{2+}$ (L = bipy, phen) has been achieved by treatment of $[Ru(CO)_2(NCMe)_2py_2]^{2+}$ with L.[656] Reaction of $[RuCl_2(CO)_2L]$ with L′H (L′H = acetylacetone, benzoylacetone, dibenzoylmethane, 2-hydroxyacetophenone, 2-hydroxbenzophenone, 3-hydroxy-4-methoxy-benzophenone, 8-hydroxyquinoline, salicylaldehyde, L = phen, bipy) yields $[Ru(CO)_2LL'_2]$.[1113] Scheme 27 illustrates the synthesis of some heterocyclic complexes of ruthenium carbonyls.



(77) (78) (86)

i, L (L = phen, bipy);[1108,1112,1114] ii, bipy, H_2O, EtOH, Δ;[1114] iii, hν, S (S = MeOH, H_2O, MeCN);[1114]
iv, HOAc or AgO_2CR;[656] v, CF_3SO_3H (L = phen);[656] vi, AgO_2CCF_3;[656]
vii, L′ (L′ = phen, bipy, 3,4,7,8-tetramethyl-1,10-phenanthroline)[656,1108,1112]

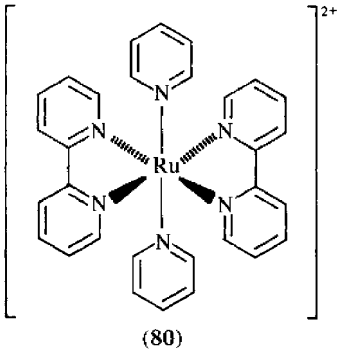
Scheme 27

Reaction of $RuCl_3$ with two equivalents of bipy in DMF yields $[RuCl_2(bipy)_2]$ together with *cis*-$[RuCl(CO)(bipy)_2]^+$ (**79**) in 30–50% yield.[1115–1117] *Cis*-$[RuCl(CO)L_2]^+$ (L = bipy, phen) can also be prepared by carbonylation of $[RuCl_2L_2]$[1116,1118] or by reaction of *cis*-$[RuCl(bipy)_2OH_2]^+$ with Ph-C≡CH in water at 100°C.[1119] Extended carbonylation of $[RuCl_2(bipy)_2]$ in the presence of Ag^+ yields $[Ru(CO)_2(bipy)_2]^{2+}$.[1116,1118] The single crystal X-ray structure of *cis*-$[RuCl(CO)(bipy)_2]^+$ (**79**) shows a six-coordinate Ru^{II} centre with Ru—C = 1.861, Ru—Cl = 2.396, Ru—N = 2.097, 2.066, 2.177, 2.104 Å.[1115] (**79**) catalyses the photochemical water-gas shift reaction.[1117,1120] $[RuCl(CO)(bipy)_2]^+$ reacts with N donor ligands L′ under reflux to give *cis*-$[Ru(CO)(bipy)_2L']^{2+}$, whereas the photochemical reaction yields *cis*-$[RuCl(bipy)_2L']^+$.[1115] The relevance of this reactivity to the possible synthesis of $[RuCl(bipy)_2(\eta^1\text{-bipy})]^+$ has been discussed.[1115] *Cis*-$[RuH(CO)L_2]^+$ can be prepared by treatment of $[RuCl(CO)L_2]^+$ (L = bipy, 4,4′-dimethyl-2,2′-bipyridine) with BH_4^-, and reacts with aqueous acid to give $[Ru(CO)(bipy)_2OH_2]^{2+}$ and H_2 (equation 87).[1121] Reaction of $[Ru(CO_3)(bipy)_2]$ with HCO_2H for 1 h affords $[Ru(O_2CH)(bipy)_2CO]^+$ which loses CO_2 in refluxing 2-methoxyethanol to yield *cis*-$[RuH(bipy)_2CO]^+$.[1121] The role of $[RuH(CO)(bipy)_2]^+$ as a possible intermediate in the photochemical generation of H_2 from H_2O by $[Ru(bipy)_2]^{2+}$ has been intimated.[1121]

(79)

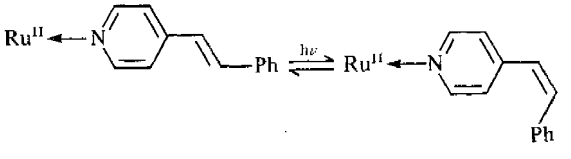
$$[Ru(H)(CO)(bipy)_2]^+ + H_3O^+ \longrightarrow [Ru(CO)(bipy)_2(OH_2)]^{2+} + H_2 \quad (87)$$

Reaction of *cis*-$[Ru(bipy)_2(OH_2)_2]^{2+}$ with PhC≡CH yields *cis*-$[Ru(CO)(\eta^1\text{-}CH_2Ph)(bipy)_2]$,[1119] while treatment of *cis*-$[Ru(bipy)_2(acetone)_2]^{2+}$ with nbd gives $[Ru(C_7H_8)(bipy)_2]^{2+}$ ($\lambda = 421$ nm, $\varepsilon = 6780\,M^{-1}cm^{-1}$, $E_{1/2} = +1.70$ V *vs.* SSCE, in MeCN.[191] *Trans*-$[RuCl_2(C_7H_8)(bipy)]$ ($\lambda = 390$ nm, $\varepsilon = 1460\,M^{-1}cm^{-1}$, $E_{1/2} = +1.04$ V *vs.* SSCE in MeCN) has been prepared by reaction of $[RuCl_2(C_7H_8)]_n$ with bipy in acetone.[191]



The single crystal X-ray structure of *trans*-$[Ru(bipy)_2(PPh_3)_2]^{2+}$[1122,1123] and the synthesis of related bis(phosphine) complexes[1005] have been reported. Reaction of $[RuCl_2L_2]$ (L = bipy,[1124], 2-(arylazo)pyridine[1066]) with phosphine, arsine and stibine ligands (L′) affords the complexes $[RuCl(L)_2L']^+$ while with bidentate ligands L′ $[Ru(bipy)_2L']^{2+}$ can be isolated.[1124] (See Section 45.5).

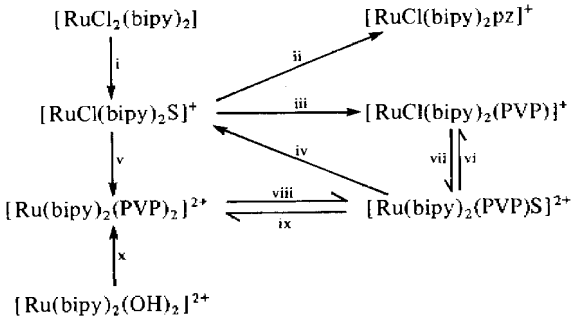
(*ix*) *Bidentate heterocyclic complexes with nitrogen donor ligands*



(a) Tertiary amines

A range of complexes of type *cis*-$[RuL_2L'_2]^{2+}$ and $[RuLL'_4]^{2+}$ (L = bidentate heterocycle; L′ = tertiary amine) has been synthesized and their electronic spectra analysed.[267,785] The synthesis of $[Ru^{II}L_2L'_2]^{n+}$ (L = bipy, phen, L′ = py,[264–266] pz,[1125] pyrazole,[1126] *cis*- and *trans*-4-stilbazole,[1127,1128] ^-NCS[64,266] substituted triazoles,[1129] MeCN,[266,757,1126] N_3^-,[266,1130] 3- and 4-nicotinic acid,[1058] 3- and 4-aminopyridine,[745] 4,4′-bipyridine;[850,1091] L = 4,4′-dimethyl-2,2′-bipyridine, L′ = py[1122,1123]) can be typically achieved by refluxing $[RuCl_2L_2]$ with L′,[611,1126,1127,1131] treatment of $[RuCl_2L_2]$ with Ag^+ followed by L′[1126,1132] or by reaction of L′ with $[RuL_2(OH_2)_2]^{2+}$.[1125,1133] The absolute configuration of *cis*-$[Ru(phen)_2py_2]^{2+}$ has been assigned *via* absorption and CD spectra.[266,1134] Reaction of *trans*-$[RuL_2(OH_2)_2]^{2+}$ with L′ (L = bipy, phen, L′ = py, MeCN, pyrazole) yields the complexes *trans*-$[RuL_2L'_2]^{2+}$.[612,1005,1122,1131,1133] The single crystal X-ray structure of *trans*-$[Ru(phen)_2py_2]^{2+}$ (**80**) shows Ru—N(py) = 2.097, Ru—N(phen) = 2.096, 2.100 Å[1122,1133] with unfavourable α-H interactions being proposed between heterocyclic rings;[1005] structural analysis of *trans*-$[RuL_2py_2]^{2+}$ (L = 4,4′-dimethyl-2,2′-bipyridine) confirms distorted bipyridyl ligands.[619,1123] Photolysis of *trans*-$[Ru(phen)_2py_2]^{2+}$ yields the *cis* isomer in good yield.[1133] Photolysis of $[Ru(bipy)_3]^{2+}$ or $[Ru(bpz)_3]^{2+}$ yields substituted products *via* loss of one bipy or bpz ligand.[751,757,1002,1004,1005] The electrochemistry of *cis*- and *trans*-$[Ru(bipy)_2py_2]^{2+}$ has been reported[268a,268b,691]; *cis*- and *trans*-$[Ru(bipy)_2py_2]^+$ have been electrogenerated and show intervalence charge transfer bands at 4350 cm^{-1} ($\varepsilon = 121\,M^{-1}cm^{-1}$) and 4090 cm^{-1} ($\varepsilon = 100\,M^{-1}cm^{-1}$) respectively.[691] Deprotonation reactions of $[Ru(bipy)_2L_2]^{2+}$ (L = pyrazole) have been studied,[1126] while photochemical isomerization reactions of $[Ru(bipy)_2L_2]^{2+}$ (L = *trans*- and *cis*-stilbazole) and $[Ru(bipy)_2LX]^+$ have been reported to occur in butyronitrile *via* CT excited state to give ligand radical anions (equation 88).[1127,1128] The formation of pseudo-base adducts between nucleophiles and $[Ru(bipy)_2py_2]^{2+}$ has been reported,[1135] but later refuted by other workers as a simple substitution reaction with pyridine loss.[1029]

Reaction of $[RuCl_3(bipy)]$ with py in refluxing EtOH for 24 h gives $[Ru(bipy)py_4]^{2+}$;[612,1131] further reaction with L (L = en, 2-methylaminopyridine, 2-ethylaminopyridine, phen, bipy) yields $[Ru(bipy)(L)py_2]^{2+}$.[612]



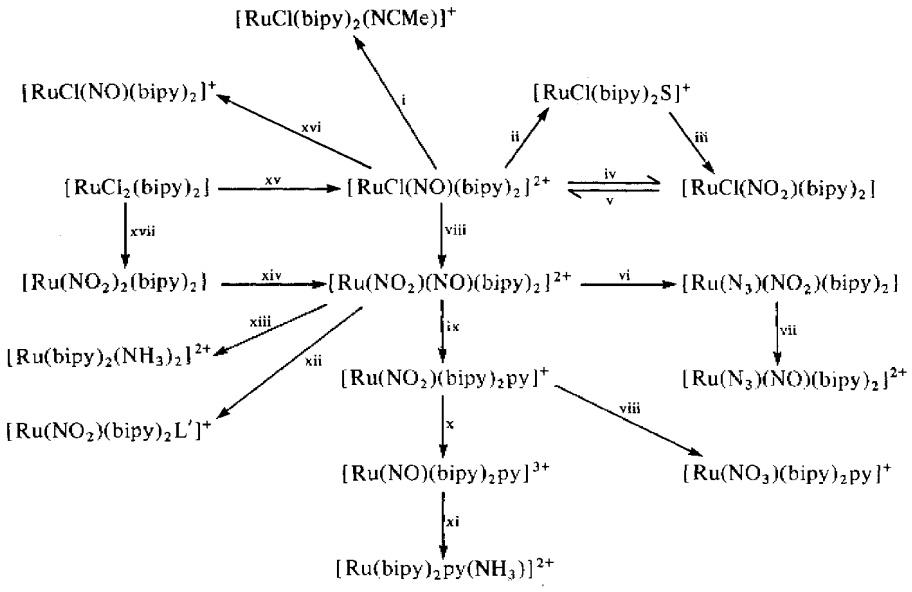
(80)

(88)

$[RuCl(bipy)_2py]^+$ can be prepared by treatment of $[RuCl_2(bipy)_2]$ with py followed by NaCl;[1136] substitution reactions of *cis*-$[Ru(phen)_2py_2]^{2+}$ with a range of anions proceed with retention of configuration.[1130] Photolysis of $[Ru(bipy)_2py_2]^{2+}$ and $[Ru(bipy)_2(NCMe)_2]^{2+}$ in CH_2Cl_2 with X^- yields $[RuX(bipy)_2py]^+$, $[RuX(bipy)_2(NCMe)]^+$ and $[RuX_2(bipy)_2]$ ($X = ClO_4^-$, NO_3^-, ^-NCS, Br^-, Cl^-, NO_2^-) *via* a dissociative mechanism.[1137]

A range of vinyl and carboxypyridyl derivatives of $[Ru(bipy)_2]^{2+}$ have been prepared and electron transfer reactions and the photochemical activity of these complexes as polymer films at electrode surfaces studied.[745,861,953,1058,1138–1148] Some chemical transformations involving polyvinyl pyridine (PVP) are illustrated in Scheme 28.[1138,1142–1144,1149] The charge transfer luminescence spectra of *cis*- and *trans*-$[Ru(bipy)_2py_2]^{2+}$,[1096,1150] *cis*-$[Ru(bipy)_2L_2]^{4+}$ (L = 2-methyl-4,4′-bipyridinium$^+$),[1151] *cis*- and *trans*-$[Ru(bipy)(phen)py_2]^{2+}$, $[Ru(bipy)py_2(L)]^{2+}$ (L = en, $(NH_3)_2$, 2-methylaminopyridine, 2-ethylaminopyridine) and $[RuCl(bipy)py_3]^+$ have been measured.[1096]

i, solvent S; ii, pz; iii, PVP, Δ; iv, Cl^-; v, PVP, Δ; vi, Cl^-, Δ; vii, hν, solvent S; viii, hν, solvent S, ix, PVP, Δ; x, PVP



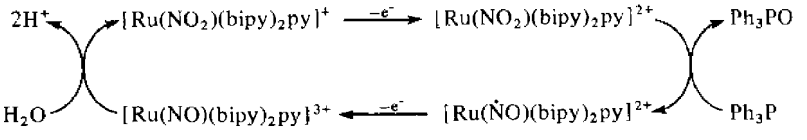
Scheme 28

For electron transfer reaction between $[Ru(bipy)_2py_2]^{3+}$ and $[Fe(OH_2)_6]^{2+}$, $\Delta H^{\neq} = +1.26\,kJ\,mol^{-1}$ and $\Delta S^{\neq} = -130\,J\,K^{-1}\,mol^{-1}$.[1043]

(b) Nitrosyls and related ligands

Reaction of $[RuX_2L_2]$ ($X = Cl^-$, Br^-; L = bipy, phen) with NO_2^- yields $[Ru(NO_2)_2L_2]$; acidification with HCl forms $[RuCl(NO)L_2]^{2+}$ while with HPF_6 $[Ru(NO_2)(NO)L_2]^{2+}$ is produced.[1152–1154] The thermal decomposition of $(phenH)_2[RuCl_5(NO)]$ gives $[RuCl(NO)phen]^{2+}$,[646] while reaction of $[RuCl_3(NO)]_n$[619,1155,1156] or $[RuCl_5(NO)]^{2-}$[1157] with L yields $[RuCl_3(NO)L]$. Treatment of *trans*-$[Ru(bipy)_2(OH_2)_2]^{2+}$ with $NaNO_2$ followed by acidification gives *trans*-$[Ru(NO)(OH)(bipy)_2]^{2+}$.[1005] Scheme 29 summarizes work on the interconversion of NO^+, NO_2^- and NO_3^- complexes.[1158] The reduction of $[Ru(NO)(bipy)_2L]^{3+}$ (L = NH_3, py, MeCN) and $[RuX(NO)(bipy)_2]^{2+}$ ($X = N_3^-$, Cl^-, NO_2^-) electrochemically or by I^- yields $[Ru(NO)(bipy)_2L]^{2+}$ and $[RuX(NO)(bipy)_2]^+$ respectively.[1159,1165,1166] There was found to be a linear correlation between ν_{NO} and $E_{1/2}$ for the reversible one electron reduction of these complexes. The site of reduction is essentially π^* (NO) in character and thus can be regarded as reduction of coordinated NO^+ to NO with a lowering in frequency of the N—O stretching vibration ν_{NO} from 1940 and 1970 cm^{-1} for $[RuCl(NO)(bipy)_2]^{2+}$ and $[Ru(NO)(bipy)_2NCMe]^{3+}$ to 1650 and 1610 cm^{-1} for $[RuCl(NO)(bipy)_2]^+$ and $[Ru(NO)(bipy)_2NCMe]^{2+}$ respectively.[1159,1165,1166] $[RuCl_2(bipy)_2]$ reacts with $[Ru(NO)(bipy)_2NCMe]^{3+}$ (rate constant $k > 10^6\,M^{-1}\,s^{-1}$) to give $[RuCl_2(bipy)_2]^+$ and $[Ru(NO)(bipy)_2NCMe]^{2+}$.[1159,1166] The oxidation of $[RuCl(NO)(bipy)_2]^+$ at chemically modified electrodes has been reported.[1145] *Cis*-$[RuCl(NO_2)(bipy)_2]$ can be oxidized to give a transient Ru^{III} complex $[RuCl(NO_2)(bipy)_2]^+$ which decomposes *via* O transfer to yield $[RuCl(NO)(bipy)_2]^{2+}$ (**81**) and $[RuCl(NO_3)(bipy)_2]^+$ (**82**) (equation 89).[1167,1168] This observation has led to the use of $[RuCl(NO_2)(bipy)_2]$ and $[Ru(NO_2)(bipy)_2py]^+$ for the electrocatalytic oxidation of PPh_3 under alkaline conditions whereby the NO_2^- complex can be regenerated from the NO^+ species by reaction with base ($\bar{O}H$ or lutidine) (Scheme 30).[1167] This electrocatalytic cycle has been extended by immobilization of $[Ru(NO_2)(isn)(bipy)_2]^+$ on alkyl amine silanized modified PtO electrodes, thus enabling the catalytic oxidation of PPh_3 at a modified electrode surface.[1169,1170]

A series of electrophilic reactions of coordinated nitrosyl group has been reported. $[RuCl(NO)(bipy)_2]^{2+}$ reacts with aryl amines $ArNH_2$ to give $[RuCl(N_2Ar)(bipy)]^{2+}$ which shows a degree of diazonium ion character with $\nu_{N\equiv N}$ in the range 1980–2100 cm^{-1}.[1171,1172] Cleavage of these complexes occurs with KI in aqueous solution at 60°C to yield $[RuI_2(bipy)_2]$, N_2 and iodoaryl

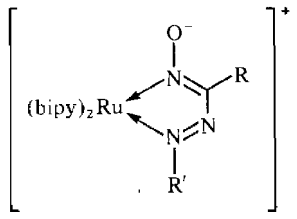


i, hν, MeCN;[1159] ii, N_3^-; S (S = H_2O, MeCN, MeOH, acetone);[1149, 1160–1162] iii, NO_2^-;[1161] iv, ^-OH;[1154, 1163] v, H^+, $SnCl_4$ or BF_3;[1163] vi, N_3^-;[1159] vii, HPF_6;[1159] viii, Ce^{IV};[1153] ix, (a) KN_3 (b) py (NH_3, MeCN, H_2O);[1153, 1159, 1161] x, H^+;[1153, 1159] xi, $+6e^-$; $+5H^+$;[1164] xii, L' (L' = MeCN, NH_3, PPh_3, pz);[1153] xiii, $+12e^-$, $+12H^+$;[1164] xiv MeCN, HPF_6;[1153] xv, (a) NO_2^- (b) HCl;[1152] xvi, I^-;[1159] xvii, NO_2^- [1152]

Scheme 29

$$2[RuCl(NO_2)(bipy)_2] \xrightarrow{-3e^-} [RuCl(NO)(bipy)_2]^{2+} + [RuCl(NO_3)(bipy)_2]^+ \quad (89)$$

(81) **(82)**



Scheme 30

products.[1171] $[RuCl(p\text{-}N_2C_6H_4Me)(bipy)_2]^{2+}$ shows an irreversible one electron reduction to give a coordinated N_2Ar radical product which decomposes in MeCN to $[RuCl(bipy)_2NCMe]^+$.[1165] Reaction of $[RuX(NO)(bipy)_2]^{2+}$ with C_6H_5NRR' yields $[RuX\{N(O)C_6H_4NRR'\}(bipy)_2]^+$ (X = Cl^-, R = R' = Me, R = H, R' = Me; X = NO_2^-, R = R' = Me, R = H, R' = Me).[1173] ^{15}N labelling experiments indicate that the N of nitrosyl remains bound to the metal centre.[1174] The same complexes can be prepared by reaction of $[RuCl(bipy)_2(acetone)]^+$ with $4\text{-}N(O)C_6H_4NMe_2$ and show $d\pi \rightarrow \pi^*$ (nitrosoarene) charge transfer bands near 600 nm in addition to bands assigned to $d\pi \rightarrow \pi^*$ (bipy) transitions.[1173] $[RuCl\{N(O)C_6H_4NRR'\}(bipy)_2]^+$ shows a $Ru^{II/III}$ couple and a one electron reduction on the nitrosoarene ligand.[1175] Further reaction with a second mole of arylamine can occur to yield $[Ru\{N(O)C_6H_4NMe_2\}_2(bipy)_2]^{2+}$ (**83** in equation 90).[1173,1174] Addition of arylhydrazones RCH=NNHR' (R = Me, Ph, $p\text{-}MeC_6H_4$, R' = Ph, $p\text{-}MeC_6H_4$) to $[RuCl(NO)(bipy)_2]^{2+}$ gives the products $[Ru(bipy)_2L]^+$ (**84**) in $MeOH/MeO^-$.[1176] (**84**) can also be synthesized by direct reaction of NaL with $[RuCl_2(bipy)_2]$. Protonation raises the $Ru^{III/II}$ couple from +0.8 V for (**84**) to +1.0 V *vs.* SCE for $[Ru(LH)(bipy)_2]^{2+}$.[1176] Treatment of $[RuCl(NO)(bipy)_2]^{2+}$ with phenol yields $[RuCl\{N(O)C_6H_4OH\}(bipy)_2]^+$.[1174]

Reactions of $[RuCl(NO)(bipy)_2]^{2+}$ and $[Ru(NO)(bipy)_2py]^{3+}$ with RO^- (R = Me, Et, Pr^i) yield the products $[RuCl\{N(O)OR\}(bipy)_2]^+$ and $[Ru\{N(O)OR\}(bipy)_2py]^{2+}$ respectively;[1177]

$$[Ru(NO_2)(bipy)_2\{N(O)C_6H_4NMe_2\}]^+ \underset{-OH}{\overset{H^+}{\rightleftharpoons}} [Ru(NO)(bipy)_2\{N(O)C_6H_4NMe_2\}]^{3+} \xrightarrow{C_6H_5NMe_2} [Ru(bipy)_2\{N(O)C_6H_4NMe_2\}_2]^{2+} \quad (90)$$

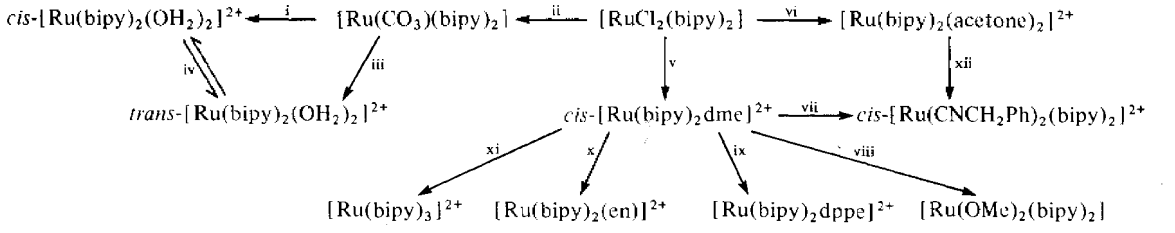
(83)

(84)

$d\pi Ru^{II} \rightarrow \pi^*$ (N(O)OR) back-bonding is significant in these species, the N(O)OR ligand being a better π acceptor than NO, py or MeCN.[1177] The photo induced addition of ^-OH to $[RuCl(NO)(bipy)_2]^{2+}$ gives the metastable product $[RuCl(NO_2H)(bipy)_2]^+$ which regenerates the starting material in the dark.[1178] SO_3^{2-} reversibly adds to $[RuX(NO)(bipy)_2]^+$ (X = Cl^-, Br^-) to give $[RuX\{N(O)SO_3\}(bipy)_2]$.[665] The single crystal X-ray structure of the chloro complex shows a distorted octahedral environment around Ru^{II} with Ru—N(N(O)SO_3) = 1.90 Å and a long N—S bond length of 1.82 Å.[665] Addition of Hacac to $[RuCl(NO)(bipy)_2]^{2+}$ gives N-bound MeCOC(NO)COMe.[1179]

(c) Other nitrogen donors

Thermal substitution reactions of $[RuCl_2(bipy)_2]$ with diazadienes (dad) yield $[Ru(bipy)_2dad]^{2+}$ species.[1180] The N-bound thiocyanate complex $[Ru(NCS)_2(bipy)_2]$[355] can be prepared by treatment of $RuCl_3$ with bipy in refluxing EtOH for 48 h followed by NaNCS for 24 h,[667,1181] or by photolysis of $[Ru(bipy)_3](NCS)_2$.[355,1003] The latter method also yields $[Ru(NCS)(bipy)_2DMF]^+$ as a side product.[1003] $[Ru(N_3)_2(bipy)_2]$ and $[Ru(N_3)(bipy)_2L]^+$ (L = py, MeCN) can be electrochemically or chemically oxidized with Br_2 or Ce^{IV} to the corresponding Ru^{III} species which undergo thermal and photo induced decomposition in MeCN *via* electron transfer from N_3^- to Ru^{III} (equation 91).[1182] Treatment of $[Ru(nbd)(NCMe)_4]^{2+}$ with L (L = bipy, phen, 5-methyl-1,10-phenanthroline) yields $[Ru(L)(NCMe)_4]^{2+}$.[1183] Oxidation of $[Ru(bipy)_2(NH_2CH_2R)_2]^{2+}$ by eight electrons leads to the formation of the dinitrile complex $[Ru(bipy)_2(NCR)_2]^{2+}$.[1184]

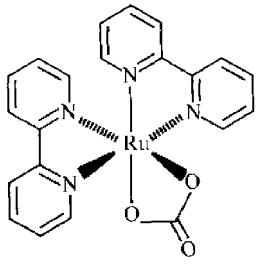


$$[Ru(N_3)_2(bipy)_2] \xrightarrow[MeCN]{h\nu} [Ru(N_3)(bipy)_2(NCMe)] + \tfrac{3}{2}N_2 \quad (91)$$

(x) Bidentate heterocyclic complexes with oxygen donor ligands

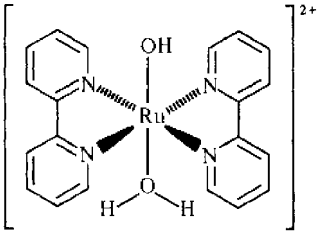
Ruthenium(II): Acidification of $[Ru(CO_3)L_2]$ (L = phen, bipy, bpz) in aqueous solution yields *cis*-$[Ru(bipy)_2(OH_2)_2]^{2+}$[1119,1133,1185–1187] which on photolysis gives the *trans* isomer *via* a five-coordinate intermediate.[1005,1133,1187] $[RuCl_2L_2]$ (L = 2-(phenylazo)pyridine, 2-(3-tolylazo)pyridine) undergoes stereoretentive displacement of Cl^- in the presence of Ag^+ to yield $[RuL_2(OH_2)_2]^{2+}$ which can be deprotonated to $[Ru(OH)L_2(OH_2)]^+$ and $[Ru(OH)_2L_2]$.[1186,1188] The diaqua complexes are useful starting materials for the synthesis of products of type $[Ru(bipy)_2XZ]^{n+}$ (X, Z = *e.g.* py, pz, MeCN, NO_2^-, NO^+, halides, PR_3).[611,1005,1133,1161,1181,1185,1188] Scheme 31 shows some substitution chemistry of the $[Ru(bipy)_2]^{2+}$ moiety. The second order rate constants for substitution on $[Ru(bipy)_2(OH_2)_2]^{2+}$ decrease in the order $N_3^- > NO_2^- > SCN^- >$ py.[1158,1181] The catalytic photooxidation of water using *trans*-$[Ru(bipy)_2(OH_2)_2]$ on hectorite has been reported, the active complex being thought to be $[Ru(bipy)_2(OH_2)]_2O^{4+}$.[1190]

Treatment of $[RuX(NO)(bipy)_2]^{2+}$ with KN_3 in solvent S yields $[RuX(bipy)_2S]^+$ (X = Cl^-, NO_2^-; S = acetone, methanol, H_2O).[1161,1162] Likewise $[Ru(bipy)_2py(OH_2)]^{2+}$ can be prepared by reaction of $[Ru(NO)(bipy)_2py]^{3+}$ with KN_3 in water or by treatment of $[RuCl(bipy)_2py]^+$ with Ag^+ in water.[1136]



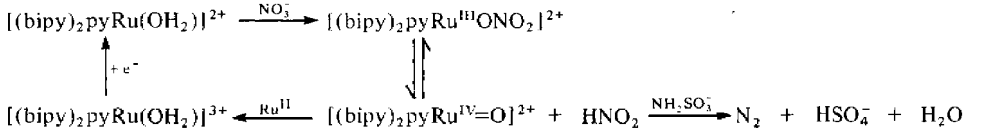
Cis-$[RuCl_2(bipy)_2]$ in refluxing DMSO yields *cis*-$[RuCl(bipy)_2DMSO]^+$,[1191] while $[RuCl_2(DMSO)_4]$ with 8-aminoquinoline (L) gives $[RuCl_2(L)(DMSO)_2]$.[1192] The single crystal X-ray structure of $[Ru(CO_3)(bipy)_2]$ (**85**), prepared by reaction of $[RuCl_2(bipy)_2]$ with $NaHCO_3$,[1160,1193] shows bidentate CO_3^{2-} with Ru—O = 2.087, Ru—N(*cis* to O) = 2.042, Ru—N (*trans* to O) = 2.013 Å.[1194] Treatment of $[RuCl_2L_2]$ (L = bipy and phen derivatives) with carboxylates (L′) gives products of type $[RuL'L_2]^{n+}$ (L′ = 2,5-pyrazine dicarboxylate,[562] oxalate,[264,369,1195] acac[268a,269]). Reaction of

i, HPF_6, H_2O;[1186,1187] ii, $NaHCO_3$;[1160] iii, $h\nu$, $HClO_4$;[1187] iv, $h\nu$;[1187] v, $AgPF_6$, DME;[1189] vi, Ag^+, acetone;[1189] vii, $CNCH_2Ph$;[1189] viii, MeO^-;[1189] ix, dppe;[1189] x, en;[1189] xi, bipy;[1189] xii, $CNCH_2Ph$[1189]



Scheme 31

$[Ru(CO_3)(bipy)_2]$ with hydroxamates (H_2L) yields the complexes $[Ru^{II}(HL)(bipy)_2]^+$ and $[Ru^{II}(L)(bipy)_2]$, which show $Ru^{II/III}$ and $Ru^{III/IV}$ couples in MeCN.[1196] A series of partially characterized complexes involving hydroquinone have been reported.[1195]



(85)

Ruthenium(III): $[Ru(bipy)_2(OH_2)_2]^{3+}$ has been proposed as an intermediate in the reaction of $RuCl_3$ with bipy in aqueous conditions at pH 2.[1197] In the presence of ClO_4^{2-}, $[Ru(bipy)_2(OH_2)_2]^{2+}$ is oxidized to $[Ru(OH)(bipy)_2OH_2]^{2+}$. The single crystal X-ray structure of *trans*-$[Ru(OH)(bipy)_2OH_2]^{2+}$ (**86**) shows Ru—N = 2.090, 2.099 and Ru—O = 2.007 Å with intermolecular hydrogen bridges between coordinated OH_2 and OH ligands.[1187] Oxidation of $[Ru(bipy)_2py(OH_2)]^{2+}$ at +0.8 V *vs.* SCE yields $[Ru^{III}(OH)(bipy)_2py]^{2+}$,[1136] while oxidation by NO_3^- gives in acidic conditions $[Ru^{III}(bipy)_2py(OH_2)]^{3+}$ *via* a Ru^{IV} intermediate (Scheme 32).[1198] In the presence of $NH_2SO_3^-$, the HNO_2 produced is reduced to N_2 and on electrochemical regeneration of the Ru^{II} starting material, the system becomes catalytic for the reduction of NO_3^- to N_2.[1198] The oxidation of H_2O_2 by $[Ru(OH)(bipy)_2py]^{2+}$ has been studied.[1199] $[Ru(bipy)_2py(OH_2)]^{3+}$ has a $pK_a = 0.85$ compared to its Ru^{II} analogue which has a pK_a of 10.79.[1136] The formation of $[Ru(OH)(bipy)_2py]^{2+}$ from $[Ru(bipy)_2py(OH_2)]^{2+}$ and $[Ru(O)(bipy)_2py]^{2+}$ is first order in $[Ru^{II}]$ and $[Ru^{IV}]$.[1200] Oxidation of hydroxamate complexes $[Ru^{II}(LH)(bipy)_2]^+$ and $[Ru(L)(bipy)_2]$ with Ce^{IV} yields the corresponding Ru^{III} species.[1196]

(86)

Scheme 32

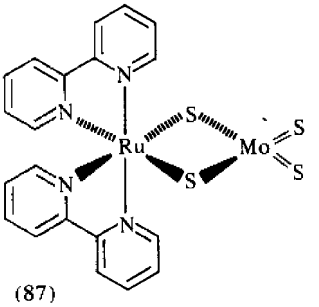
Ruthenium(IV): $[Ru(bipy)_2py(OH_2)]^{2+}$ can be oxidized by Ce^{IV} or by controlled potential electrolysis to $[Ru(O)(bipy)_2py]^{2+}$ (ν_{Ru-O} at 792 cm^{-1}) which oxidizes PPh_3 to $OPPh_3$ (Scheme 33).[1136,1201–1204] ^{18}O labelling shows that O transfer from Ru=O to PPh_3 occurs *via* first order kinetics with rate constant $k = 1.75 \times 10^5\ M^{-1}\ s^{-1}$.[1202] $[Ru(O)(bipy)_2py]^{2+}$ has been used electrocatalytically for the oxidation of alkenes, alcohols, aldehydes, aromatics[1204] and chloride to chlorine.[1205] The H–D kinetic isotope effects for the oxidation of H_2O_2 by Ru^{III} and Ru^{IV} have been measured as 16 and 22 respectively.[1199] The oxidation of 2-propanol by $[Ru(O)(bipy)_2py]^{2+}$ occurs *via* a two electron hydride transfer from the α-carbon to Ru=O; no transfer of coordinated O was observed, while a slower oxidation of substrate by Ru^{III} *via* a one electron transfer was detected.[1203] Electrode supported oxidation catalysts based on Ru^{IV} have been achieved by deposition of films containing $[Ru(bipy)_2(OH_2)]^{2+}$ bound to poly-4-vinylpyridine.[1186] $[Ru(O)L_2py]^{2+}$ (L = 2-(phenylazo)pyridine), prepared by Ce^{4+} oxidation of $[RuL_2py(OH_2)]^{2+}$ ($E^\circ = +1.20$ V), catalyses the oxidation of H_2O to O_2.[1206]

$$[Ru(bipy)_2py(OH_2)]^{2+} \xrightarrow{+0.53\ V} [Ru(bipy)_2py(OH)]^{2+} \xrightarrow{+0.42\ V} [Ru(bipy)_2py(O)]^{2+} \xrightarrow{PPh_3}$$

$$[Ru(bipy)_2py(OPPh_3)]^{2+} \xrightarrow{MeCN} [Ru(bipy)_2py(MeCN)]^{2+} + OPPh_3$$

Scheme 33

Ruthenium(V), (VI), (VII), (VIII): Electrochemical studies on *cis*-$[Ru(bipy)_2(OH_2)_2]^{2+}$ show a series of one electron couples to $Ru^{III/IV/V/VI}$ (Scheme 34),[1207,1208] the Ru^{VI} species being thought to be the active complex in the oxidation of Cl^-.[1205] Reaction of RuO_4 with bipy and phen yield products of stoichiometry RuO_4bipy and $Ru_2O_7phen_2$ which have been assigned as Ru^{VIII} and Ru^{VII} complexes respectively;[1209] from their spectroscopic and chemical properties however they appear to be lower valent species. A series of partially characterized products have been synthesized by reaction of these complexes with bipy in MeOH.[674a,1195,1210] A genuine Ru^{VI} complex $[Ru(O)_2Cl_2(bipy)]$ has been prepared from the reaction of RuO_4 with HCl and bipy.[65,1211]



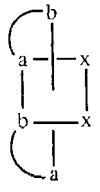
$$cis\text{-}[Ru(bipy)_2(OH_2)_2]^{2+} \xrightarrow{+0.53\ V} [Ru(bipy)_2(OH)(OH_2)]^{2+} \xrightarrow{+0.76\ V} [Ru(bipy)_2(O)(OH_2)]^{2+} \xrightarrow{+0.94\ V}$$

$$[Ru(bipy)_2(O)(OH)]^{2+} \xrightarrow{+1.07\ V} [Ru(bipy)_2(O)_2]^{2+}$$

Scheme 34

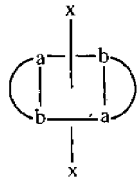
(*xi*) *Bidentate heterocyclic complexes with sulfur donor ligands*

The synthesis and catalytic behaviour of $[Ru(S_2MoS_2)(bipy)_2]$ (**87**) have been described.[1212a]



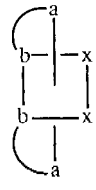
(87)

(*xii*) *Bidentate heterocyclic complexes with halide ligands*



Ruthenium(II): A range of complexes of type $[RuCl_2L_2]$ have been prepared by a variety of routes.[264–266,738] *Cis*-$[RuCl_2(bipy)_2]$ can be prepared by reaction of $RuCl_3$ with bipy in refluxing DMF for 8 h in the presence of LiCl,[1115,1124] by substitution of py in *cis*-$[Ru(bipy)_2py_2]^{2+}$ by Cl^-,[1131] or by activation of $RuCl_3$ in refluxing H_2O/EtOH, followed by evaporation and dissolution in aqueous HCl and addition of bipy in H_2O/acetone.[1212b] *Trans*-$[RuCl_2(bipy)_2]$ has been synthesized by

addition of LiCl to *trans*-$[Ru(bipy)_2(OH_2)_2]^{2+}$ or by photolysis of $[Ru(CO_3)(bipy)_2]$ in HCl.[1005] Refluxing solutions of $[Ru(bipy)py_4]^{2+}$ with bipy in EtOH followed by addition of HCl yield mixtures of *cis*- and *trans*-$[RuCl_2(bipy)_2]$.[1131] The *cis* isomer can be prepared by repeated treatment of the *cis*/*trans* mixture with py to give $[Ru(bipy)_2py_2]^{2+}$ followed by conversion to the dichloro complex with HCl.[1131] Other routes to $[RuCl_2(bipy)_2]$ include reaction of $[RuCl_3(Hdma)]$ (dma = dimethylacetamide) with bipy,[1213] $[RuCl_5(OH)]^{2-}$ with bipy and X^- ($X^- = Cl^-$, Br^-, I^-),[369,708,1214] photolysis of $[Ru(bipy)_2py_2]X_2$[1137] or $[Ru(bipy)_3]Cl_2$ in acetone,[1006] heating $[RuCl(bipy)_2(NCMe)]Cl$ in CH_2Cl_2,[1006] vacuum pyrolysis of $[Ru(bipy)_3]Cl_2$ at 290°C for 2 h[369] or treatment of $[Ru(ox)(bipy)_2]$ with HCl.[369] The electronic spectra of $[RuX_2(bipy)_2]$ ($X = Cl^-$, Br^-, I^-) have been reported.[267,738,785,1214] Thermolysis of $(phenH)[RuCl_4phen]$[266,1112] or reaction of $[Ru(phen)_2py_2]^{2+}$ with X^-[1130] yields $[RuX_2(phen)_2]$ while 2,2′-bipyrazine[1185,1215] and 2,2′-biquinoline[1065] derivatives of $[RuCl_2L_2]$ have also been reported. Treatment of (Hpq)$[RuCl_4(pq)]$ with HCl, Hg and KCl yields $[RuCl_2(pq)_2]$ (pq = 2-(2′-pyridyl)quinoline).[1065] Refluxing $RuCl_3$ with 2-(phenylazo)pyridine (L) in EtOH gives blue β-$[RuCl_2L_2]$ (**88**).[1216] Reaction of L with $[RuCl_2(DMSO)_4]$ in acetone for 17 h[1216] or refluxing $RuCl_3$ with L in MeOH for 8 h[1066] leads to the formation of green γ-$[RuCl_2L_2]$ (**89**) which can be converted to the blue α isomer $[RuCl_2L_2]$ (**90**) by reflux in xylene for 3 h.[1216] Substitution reactions of $[RuCl_2L_2]$ have been reported.[611,1066]



(88)

β

(89)

γ

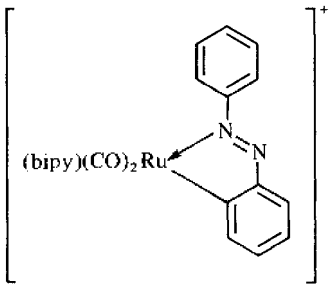
(90)

α

$[RuCl_2(bipy)_2]$ undergoes solvolysis in H_2O,[1181] DMSO[1191] and MeCN.[1006] $[RuCl(bipy)_2OH_2]^+$ has been partially resolved by (+)-tartrate.[1217] Reduction of $[RuCl_4(bipy)]^-$ by Ti^{2+} yields $[RuCl_4(bipy)]^{2-}$ which catalyses the hydrogenation of maleic acid to succinnic acid *via* a $[RuCl_3(H)bipy]^{2-}$ intermediate.[1218] The reductive electrochemistry of $[RuCl_2(bipy)_2]$ and related $[Ru(bipy)_2]^{2+}$ species has been interpreted in terms of a spatially isolated redox orbital model with π^* electron density localized on individual bipy ligands.[268a]

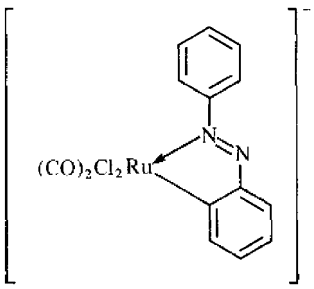
Ruthenium(III): For $[RuCl_2(bipy)_2]$, $E_{1/2}(Ru^{II/III}) = +0.35$ V *vs.* SCE, with electron withdrawing groups on bipy increasing $E_{1/2}$.[268a,738] $[RuCl_2(bipy)_2]^+$ can be prepared by oxidation of $[RuCl_2(bipy)_2]$,[369,675,1197] by Cl^- substitution on $[RuCl(p\text{-}N_2C_6H_4Me)(bipy)_2]^{2+}$[1145] or by Cl_2 oxidation of $[Ru(ox)(bipy)_2]$ in the presence of Cl^-.[369] $[RuCl_2(bipy)_2]^+$ undergoes rapid solvolysis in H_2O to yield $[RuCl(bipy)_2OH_2]^{2+}$; both $[RuCl_2(bipy)_2]^+$ and $[RuCl(bipy)_2OH_2]^{2+}$ have been resolved with (+)-tartrate.[1197,1217,1219]

$[RuCl_3(bipy)OH_2]$ can be prepared by reduction of $[RuCl_4(bipy)]$ in H_2O and EtOH[265] or by refluxing $RuCl_3$ with aqueous HCl and bipy for several days.[612,712,1131] The complex is often used for the preparation of tris chelate species $[Ru(bipy)L_2]^{2+}$ (Table 9).[612,712,745,1131] Refluxing $[RuCl_5OH]^{2-}$ with L in the presence of Cl^-,[264,265] or treatment of $RuCl_3$ with H_2 in MeOH followed by aerial reflux of the resulting green solution with L and KCl has been reported to give $[RuCl_4L]^-$ (L = bipy, phen).[1220] The magnetic properties of $[RuCl_4bipy]^-$ have been studied.[163]

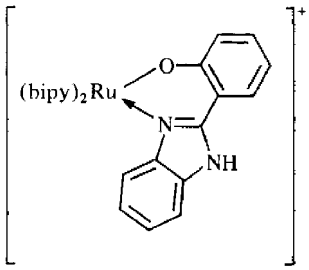


Ruthenium(IV): $[RuCl_4L]$ has been reported to be the product of the oxidation of $LH[RuCl_4L]$ with Cl_2 or Ce^{IV} in HNO_3,[264,265] while thermolysis of $(phenH_2)[RuCl_6]$ yields $[RuCl_4phen]$.[684] The magnetic properties of these complexes have been reported.[1221]

(*xiii*) *Bidentate heterocyclic complexes with mixed donor ligands*

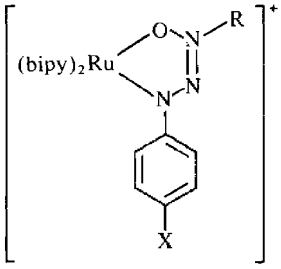


Reaction of $[Ru(azb)Cl(CO)_2]_2$ (azb = 2-(phenylazo)phenyl) with bipy gives $[Ru(azb)(CO)_2bipy]^+$ $[Ru(azb)Cl_2(CO)_2]^-$ (**91**) with the azb ligand binding through N and C.[1222]

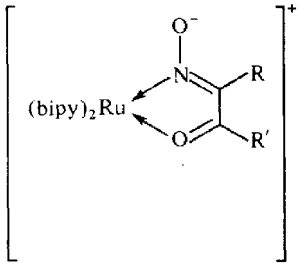


Treatment of $[RuCl_2(bipy)_2]$ with L^- yields $[RuL(bipy)_2]^+$ (**92**) which shows redox activity at $E_{1/2} = +0.39$, -1.67 and -2.00 V *vs.* SCE.[1070,1071] Complexes (**93**) have been prepared by reaction of L with $[Ru(CO_3)(bipy)_2]$ or $[Ru(bipy)_2(EtOH)_2]^{2+}$;[1223] oxidation of (**93**) to $[Ru^{III}L(bipy)_2]^{2+}$ can be achieved chemically or electrochemically, the energy of the L → metal charge transfer band in the Ru^{III} complexes correlating with the values for the $Ru^{II/III}$ redox couple.[1223] The complexes [Ru-

$(bipy)_2L]^+$ (L = azophenols, azonaphthols) have been reported.[1224] Reaction of $[RuCl_2(bipy)_2]$ with isonitrosoketonates yields complexes of type $[RuL(bipy)_2]^+$ (**94**).[1225,1226] As for the complexes (**93**), (**94**) show correlation between $E_{1/2}$ for the $Ru^{II/III}$ couple and the energy of L → metal charge transfer bands in the Ru^{III} species; protonation of (**94**) raises the $Ru^{II/III}$ redox potential.[1226] An alternative route to (**94**) is by the reaction of *cis*-$[RuCl(NO)(bipy)_2]^{2+}$ with propiophenone in $MeOH/MeO^-$.[1227]

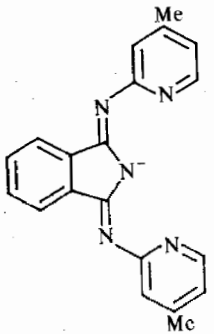


(91)



(92)

(93)



(94)

Chiral complexes of amino acids and related ligands of type Δ and Λ $[RuL(bipy)_2]^+$ (L = (−)-serine,[1228] (−)-tryptophane,[1229] 5-hydroxytryptophane,[1230] phenylalanine,[1230] (−)-alanine[1231,1232]) and $[RuL(bipy)_2]$ (L = (−)-aspartate,[1233] (−)-glutamate[1234a]) have been reported. Inversion of the Δ and Λ isomers has been studied and equilibrium constants for the isomerization reactions determined[1228,1229,1233,1240a]. More recently, chiral complexes Δ, Λ-$[Ru(L)_2L']^+$ (L = bipy, phen; L'H = *S*-threonine, *S*-allothreonine) have been prepared and studied crystallographically.[1234b] Reaction of $[RuCl_2(bipy)_2]$ with 8-mercaptoquinoline (L) under basic conditions yields the N,S complex $[RuL(bipy)_2]^+$; alkylation of the coordinated ligand at S has been achieved with MeI.[1235]

(*xiv*) *Tridentate heterocyclic complexes* $[RuL_2]^{n+}$

$[Ru(terpy)_2]^{2+}$ can be prepared by fusion of $RuCl_3$ with the ligand at 250–260°C,[1236] reduction of $RuCl_3$ with H_2 over Pt black followed by reaction with terpy in MeOH[807] or by reaction of $[RuCl_5(OH_2)]^{2-}$ with terpy in the presence of H_3PO_2.[728] The synthesis, electronic spectra and redox properties of related bis chelate complexes $[RuL_2]^{2+}$ are summarized in Table 10. The electrochemistry of $[Ru(terpy)_2]^{2+}$ has been studied;[723,725,1241,1242] cyclic voltammetry shows a one electron oxidation at + 1.264 V, *vs.* SSCE in DMF.[697] ESR studies on the reduced products indicate that the first two reductions are ligand based with the redox orbitals being located on single chelate rings.[1242] The charge transfer luminescence of $[RuL_2]^{2+}$ (L = terpy, 4′-phenyl-2,2′,6′,2″-terpyridine, 4,4′,4″-triphenyl-2,2′,6′,2″-terpyridine) has been interpreted on the basis of a delocalized excited state,[1243] but more recently, also interpreted using a charge-trapped model[1244] (see Section 45.4.3.1.vi). The half-life of $[Ru(terpy)_2]^{2+*}$ is estimated as approximately 1.2 ns and undergoes electron transfer quenching with $[Fe(OH_2)_6]^{3+}$ to give $[Ru(terpy)_2]^{3+}$ and $[Fe(OH_2)_6]^{2+}$.[1245] The reduction of $[Ru(terpy)_2]^{3+}$ by $[Fe(OH_2)_6]^{2+}$ is first order in $[Ru^{III}]$ and $[Fe^{II}]$ with $\Delta H^{\neq} = -11.72\,kJ\,mol^{-1}$, $\Delta S^{\neq} = -172\,J\,K^{-1}\,mol^{-1}$.[1043] The luminescence of $[RuL_2]^{2+}$ (L = 2.6-di(2′-quinolyl)pyridine) has been studied and assigned as charge transfer in nature.[1238] $[RuL_2]^{2+}$ (L = 2,4,6-tri(2′-pyridyl)-1,3,5-triazine) is reported to undergo pseudo-base formation by attack of ^-OH on the triazine ring.[1246,1247a] More recently, the complex $[Ru(L)_2]^{2+}$ (L = 5,5″-diphenyl-2,2′,2″-terpyridine) has been synthesized.[1247b]

Table 10 Synthesis, Absorption Spectra and Redox Properties of Complexes $[RuL_2]^{2+}$

(xv) Tridentate heterocyclic complexes with carbon donor ligands

Reaction of $RuCl_3$ with terpy in refluxing DMF gives *trans*-$[RuCl_2(CO)terpy]$[1116,1248] the single crystal X-ray structure of which shows Ru—N = 2.070, 2.013, 2.084 Å, Ru—Cl = 2.400, 2.403 Å, Ru—C = 1.865 Å.[1248] The single crystal X-ray structure of *cis*-$[RuCl_2(CO)terpy]$, prepared by decarbonylation of $[RuCl_2(CO)_2terpy]$ with Me_3NO in CH_2Cl_2, shows Ru—N = 2.080, 1.969, 2.081 Å, Ru—Cl = 2.420, 2.438 Å, Ru—C = 1.886 Å.[1248] $[RuX_2(CO)_2]_n$ (X = Cl^-, Br^-) reacts with terpy to give $[RuX_2(CO)_2terpy]$; the single crystal X-ray structure of two forms of $[RuBr_2(CO)_2terpy]$ shows bidentate terpy ligand which can be protonated to yield $[RuX_2(CO)_2(H\text{-}terpy)]^+$.[1248] $[RuCl_3terpy]$ reacts with L (L = PPh_3, $PTol_3$) to give *trans*-$[RuCl_2(terpy)L]$ which can be converted to the *cis* isomer in refluxing 1,2-dichloroethane.[1249] The *cis* isomer can also be isolated from the reaction of $[RuCl_2(PPh_3)_3]$ with terpy; carbonylation of *cis*- or *trans*-$[RuCl_2(terpy)(PPh_3)]$ gives *cis*- or *trans*-$[RuCl_2(CO)(terpy)]$. *Cis*-$[Ru(terpy)(OH_2)_2PPh_3]^{2+}$ with PhC≡CH yields $[Ru(\eta^1\text{-}CH_2Ph)(CO)(terpy)(PPh_3)]^+$ and PhMe.[1119] The preparation of *trans*-$[RuCl(terpy)(PPh_3)_2]^+$ has been reported.[1249]

Reaction of $[Ru_3(CO)_{12}]$ with $KHB(pz)_3$ yields $[RuX(CO)_2L]$ (X = Cl^-, Br^-, I^-; L = tris(pyrazolyl)borate).[1250] Treatment of $[RuCl_2(C_6H_6)]_2$ with $B(pz)_4^-$ (tetrakis(1-pyrazolyl)borate) in MeCN gives $[Ru(B(pz)_4)(C_6H_6)]^+$, the single crystal X-ray structure of which shows octahedral Ru^{II} with Ru—N = 2.105, Ru—C = 2.20 Å.[1251]

(xvi) Tridentate heterocycles with nitrogen donor ligands

Reaction of $[Ru(terpy)(bipy)(OH_2)]^{2+}$ or $[Ru(terpy)(bipy)Cl]^+$ with L (L = NH_3,[1184] py,[1252] 4-vinylpyridine,[1252] cyclohexylamine,[259] (α-methylbenzyl)amine,[259] isopropylamine,[1253] 4-chlorostilbazole,[1254] 1,2-bis(4′-pyridyl)ethylene,[1254] benzonitrile[259]) yields the complexes $[Ru(terpy)(bipy)L]^{2+}$. The 4,4′-dimethyl-2,2′-pyridyl species have been prepared.[259] Oxidation of $[Ru(terpy)(bipy)(NH_2CHMe_2)]^{2+}$ and related amine complexes by four electrons gives the Ru^{IV} product $[Ru(NCMe_2)(terpy)(bipy)]^{3+}$ *via* a two electron oxidation intermediate $[Ru(terpy)(bipy)(NH{=}C\text{-}Me_2)]^{2+}$.[259,1253] The single crystal X-ray structure of $[Ru(NCMe_2)(terpy)(bipy)]^{3+}$ shows a linear Ru—N—C moiety with a short Ru—N($NCMe_2$) bond of 1.831 Å suggesting multiple bonding between Ru—N.[259] The oxidation of coordinated NH_3 in $[Ru(terpy)(bipy)NH_3]^{2+}$ to NO_3^- in $[Ru(NO_3)(terpy)(bipy)]^{2+}$ has been achieved by controlled potential electrolysis at +0.8 V *vs.* SCE in water.[1164,1184] The reaction occurs *via* $[Ru(NO)(terpy)(bipy)]^{3+}$ and $[Ru(NO_2)(terpy)(bipy)]^+$ intermediates. The reverse process, reduction of NO_2^- to NH_3, has also been observed (Scheme 35).[1164,1184] Comparisons between this redox system and its osmium analogue have been made in relation to $E_{1/2}$ values and the differences between Ru—NO and Os—NO mixing.[1255] Quenching of the excited state $[Ru(terpy)(bipy)NH_3]^{2+}$* using Fe^{3+}(aq) and paraquat has been reported.[879]

i, EtOH, Δ, 3 h;[259] ii, bipy, EtOH, H_2O, Δ, 3 h;[259] iii, NO_2^-, H_2O, Δ, 3 h;[259] iv, HPF_6, MeOH;[259] v, $-6e^-$, $+H_2O$, $-5H^+$[1164,1184]

Scheme 35

Reaction of $[RuCl_3(terpy)]$ with L yields the *mer* isomers of $[Ru(terpy)L_3]$ (L = 4-vinylpyridine, *trans*-stilbazole, 4-chlorostilbazole, 1,2-bis(4-pyridyl)ethylene); $[RuCl(terpy)(stilbazole)_2]^+$ was also

isolated from the reaction.[1254] Likewise, treatment of the tripyrazolylmethane complex $[RuCl_3\{HC(pz)_3\}]$ with 4-vinylpyridine gives $[RuCl_3\{HC(pz)_3\}(vpy)_3]^{2+}$.[1254]

$[RuCl_2(NO)terpy]^+$ is the product from the reaction of $[RuCl_5(NO)]$ with terpy.[1157] [RuCl(NO)(tetrapy)] has been reported.[1157]

(*xvii*) *Tridentate heterocyclic complexes with oxygen and sulfur donor ligands*

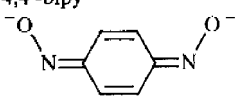
$[Ru(terpy)(bipy)OH_2]^{2+}$ can be prepared by treatment of $[RuCl(terpy)(bipy)]^+$ with Ag^+ in water,[265,1068,1252] or by aquation of $[Ru(O_3SCF_3)(terpy)(bipy)]^+$.[1256] A range of substitution products of $[Ru(terpy)(bipy)OH_2]^{2+}$ has been prepared.[1158] Oxidation to $[Ru^{III}(OH)(terpy)(bipy)]^{2+}$ and $[Ru^{IV}(O)(terpy)(bipy)]^{2+}$ has been achieved electrochemically in solution and on surface film (equation 92).[1186,1203,1204,1257a,1257b] This system has been used for the catalytic oxidation of 2-propanol, *p*-toluic acid and xylenes.[1186,1203,1204,1258] The kinetics and mechanism of the oxidation of aromatic hydrocarbons[1258] and 2-propanol[1203] by $[Ru(O)(terpy)(bipy)]^{2+}$ have been discussed.[1203,1258] A slower reaction of $[Ru^{III}(OH)(terpy)(bipy)]^{2+}$ occurs *via* a one electron outer-sphere transfer.[1203]

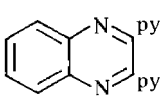
$$[Ru(terpy)(bipy)(OH_2)]^{2+} \xrightarrow{0.49\,V} [Ru(terpy)(bipy)OH]^{2+} \xrightarrow{0.62\,V} [Ru(terpy)(bipy)(O)]^{2+} \quad (92)$$

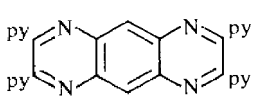
Treatment of $[RuCl(terpy)(bipy)]^+$ with CF_3SO_3H under N_2 gives $[Ru(O_3SCF_3)(terpy)(bipy)]^+$, which when treated with dry air at 110°C for 5 h yields the Ru^{III} analogue $[Ru(O_3SCF_3)(terpy)(bipy)]^{2+}$.[1256] Aquation of $[Ru(O_3SCF_3)(terpy)(bipy)]^{2+}$ occurs readily to give $[Ru(terpy)(bipy)OH_2]^{3+}$.[1203,1204,1256] The luminescence and redox chemistry of $[Ru(terpy)(bipy)L]^{2+}$ (L = OH_2, phenothiazine, *N*-methylphenothiazine, thianthrene) have been reported.[1259]

(*xviii*) *Tridentate heterocyclic complexes with halide ligands*

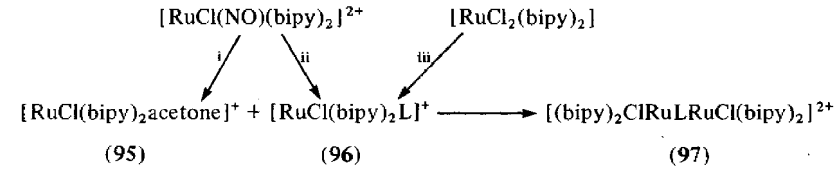
$[RuCl_3(terpy)]$ can be prepared by reaction of $RuCl_3$ with terpy in refluxing EtOH for 3 h.[259,1249,1252] The corresponding complex of 1,3-bis(4-methyl-2-pyridylimino)isoindoline (L) $[RuCl_3L]$ can be prepared by the same method[1240,1260] and has been used for the catalytic oxidation of alcohols.[1260]







The preparation of $[RuCl(terpy)(bipy)]^+$ has been achieved by reaction of $[RuCl_4(bipy)]$ or $[RuCl_4bipy]^-$ with terpy,[264,265,1181] by treatment of $[RuCl_3terpy]$ with bipy[259,1252] and by decarbonylation of $[RuCl_2(CO)_2(bipy)_2]$ with Me_3NO in the presence of terpy in 2-methoxyethanol.[657] A range of substitution products of $[RuCl(terpy)(bipy)]^+$[1068,1181] and related complexes have been reported.[264,265]



45.4.3.2 Binuclear and polynuclear complexes

(*i*) *Nitrogen donor bridged complexes*

This area has been reviewed.[484] A range of binuclear [2,2], [2,3] and [3,3] complexes of type $[RuCl(bipy)_2]_2L^{n+}$, $[Rupy(bipy)_2]_2L^{n+}$ and $[Ru(bipy)_2]L^{n+}$ and related systems have been prepared (Table 11). Dimerization reactions have been carried out using a general strategy involving labile solvent coordinated mononuclear substrates. For example, $[RuCl(NO)(bipy)_2]^{2+}$ can be activated by N_3^- in acetone to give $[RuCl(bipy)_2(acetone)]^+$ (**95**) which readily adds $[RuCl(bipy)_2L]^+$ (**96**) to produce the binuclear complexes $[RuCl(bipy)_2]_2L^{2+}$ (**97**) (L = pz,[1125,1149,1261,1263,1265] 4,4′-bipyridine,[1149,1265] 1,2-bis(4′-pyridyl)ethylene[1149,1265] 1,2-bis(4′-pyridyl)ethane,[1265] pyrimidine[1266,1265]) (Scheme 36). $[Ru(bipy)_2py]_2$ (4,4′-bipy)$^{4+}$ can be prepared by an analogous route.[1269] The purification of these binuclear complexes has been discussed.[1271] Oxidation of the [2,2] complexes to the [3,3] species can be carried out electrochemically or chemically, while the mixed valence [2,3] species may be generated directly from the [2,2] species, or by reaction of [2,2] with [3,3] in 1:1 molar ratios.[1132,1149,1263,1265,1266] The degree of delocalization in the mixed valence [2,3] complexes has been assessed. Magnetic properties of the complexes $[RuCl(bipy)_2]_2L^{5+}$ (L = pz, pyrimidine, 4,4′-bipyridine, 1,2-bis(4′-pyridyl)ethylene, 1,2-bis(4′-pyridyl)ethane) suggest very little interaction between the metal centres;[1272] this, together with electrochemical, K_c and intervalence charge transfer absorption data (Table 11), indicates trapped valence Class II behaviour for these complexes.[484,530,1261,1263,1265–1267] Electron transfer in these systems has been likened to the outer-sphere electron transfer between $[RuCl(bipy)_2py]^{2+}$ and $[RuCl(bipy)_2py]^+$.[1261,1263,1265,1267] No dramatic dif-

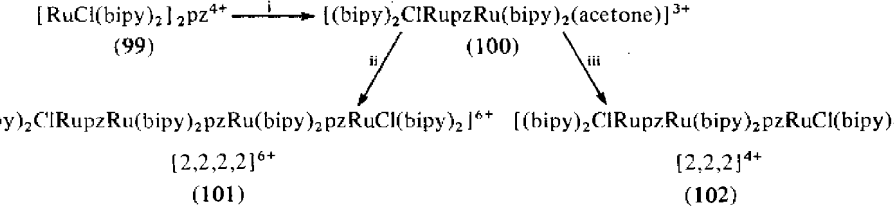
Scheme 36

ference was observed in metal–metal interactions in $[RuCl(phen)_2]_2L^{3+}$ compared with $[RuCl(bipy)_2]_2L^{3+}$.[1132]



A range of tetradentate ligands have been used to bridge $[Ru(bipy)_2]^{2+}$ moieties (Table 11).[746,762,1054,1064,1067,1072,1073,1240,1260,1273] Reaction of $[RuCl_2(bipy)_2]$ with L under refluxing conditions gives $[Ru(bipy)_2]_2L^{4+}$ (L = 2,2′-bipyrimidine),[746,762,1064] while for L = 2,3-dipyridylquinoxaline, $[RuCl_2(bipy)_2]$ was treated with Ag^+ in acetone followed by addition of L.[1064] Binuclear complexes incorporating pyrazole and benzimidazole anion bridging ligands have been developed (Scheme 37).[1072,1126] Oxidation of the pyrazole $[2,2]^{2+}$ species (**98**) to the $[3,2]^{3+}$ product leads to the formation of a very strong Ru^{III}–pyrazole bond with concomitant bridge cleavage.[1126] $[Ru(bipy)_2]_2L^{4+}$ (L = 2,3-bis(2′-pyridyl)pyrazine) has been prepared from $[RuCl_2(bipy)_2]$; the $[3,2]^{5+}$ ion decomposes in solution.[1067] The synthesis and electrochemistry of bi-, tri- and tetra-nuclear species incorporating a 2,2′,3,3′-tetra-2-pyridyl-6,6′-biquinoxaline bridge have been described,[1073] while binuclear complexes of isoindoline derivatives and the binding of Cu and Pd salts to related monomeric complexes have also been reported.[1240,1260] The characteristics of intervalence transfer in mixed metal Ru/Os dimers have been fully discussed.[1273b] Hetero-binuclear species based on $[Ru(CN)_2(bipy)_2]$ are discussed in Section 45.4.3.1.viii.

i, Ag^+, acetone; ii, pyrazH; iii, KOH

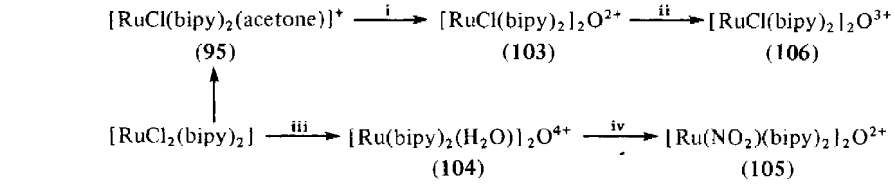
Scheme 37[1126]

A series of trinuclear,[1054,1149] tetranuclear[746,1149] and higher polynuclear[1125] products have been prepared. Treatment of $[RuL_3]^{2+}$ (L = 2,2′-bipyrimidine) with three equivalents of $[RuCl_2(bipy)_2]$ in refluxing water yields the tetranuclear species $[Ru(bipy)_2(bipym)]_3Ru^{8+}$.[746] The $[2,2]^{2+}$ species $[RuCl(bipy)_2]_2pz^{2+}$ (**99**) reacts with N_3^- in acetone to give the dimer $[(bipy)_2ClRuL-Ru(bipy)_2(acetone)]^{3+}$ (**100**); reaction with half an equivalent of pz, or one equivalent of $[RuCl(bipy)_2pz]^+$ leads to the formation of the tetramer $[2,2,2,2]^{6+}$ (**101**) and trimer $[2,2,2]^{4+}$ (**102**) respectively (Scheme 38).[1149] The electrochemistry of (**101**) and (**102**) has been investigated (equations 93 and 94) and metal–metal interactions in the mixed valence products discussed.[1149,1272] The trinuclear complex $[N\{CH_2CH_2OphenRu(bipy)_2\}_3]^{6+}$ has been prepared.[1054]

i, KN_3, acetone; ii, ½pz; iii, $[RuCl(bipy)_2pz]^+$

Scheme 38[1149]

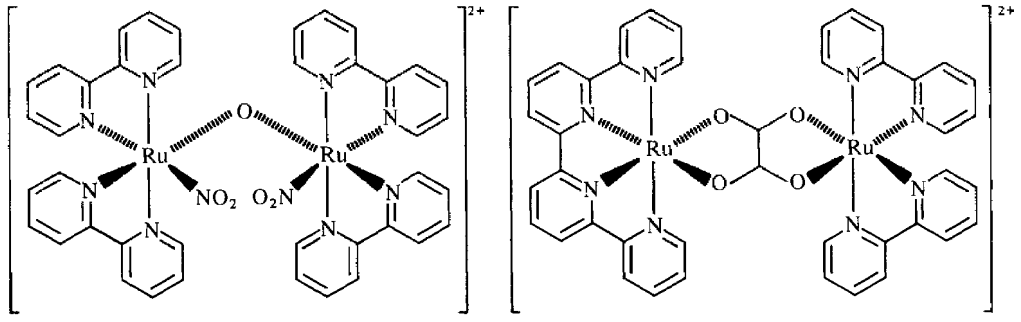
$$[2,2,2]^{4+} \xrightarrow{-2e^-} [3,2,3]^{6+} \xrightarrow{-e^-} [3,3,3]^{7+} \quad (93)$$



$$[2,2,2,2]^{6+} \xrightarrow{-2e^-} [3,2,2,3]^{8+} \xrightarrow{-e^-} [3,3,2,3]^{9+} \xrightarrow{-e^-} [3,3,3,3]^{10+} \quad (94)$$

(*ii*) *Oxygen donor complexes*

Reaction of $[RuCl(L)_2 \text{ acetone}]^+$ (**95**), prepared from $[RuCl(NO)(L)_2]^{2+}$ with N_3^- in acetone, with O_2 for 72 h yields the oxo-bridged dimer $[RuCl(L)_2]_2O^{2+}$ (**103**) (L = bipy, phen).[1274] Treatment of $[RuCl_2(bipy)_2]$ with Ag^+ for 8 h in refluxing water gives $[Ru(bipy)_2(OH_2)]_2O^{4+}$ (**104**) which can be readily converted to the nitro derivative $[Ru(NO_2)(bipy)_2]_2O^{2+}$ (**105**) on reaction with $NaNO_2$ (Scheme 39).[1207,1212b,1274] The redox properties of $[RuCl(bipy)_2]_2O^{2+}$ have been investigated and the oxidized $[3,4]^{3+}$ (**106**), $[4,4]^{4+}$ and reduced $[2,3]^{1+}$ ions generated.[1274] PES studies on the mixed valence $[3,4]^{3+}$ ion indicate strong coupling between equivalent Ru atoms.[1274] The single crystal X-ray structure of $[Ru(NO_2)(bipy)_2]_2O^{2+}$ (**105**) shows < RuORu = 157.2° with Ru—O = 1.876, 1.890 Å, with a Ru to Ru distance of 3.692 Å.[1275]

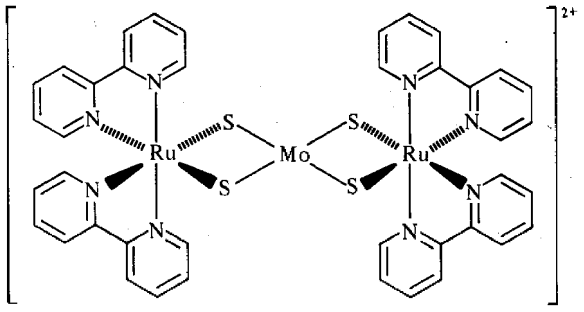


The oxo-bridged dimers $[Ru(L)_2OH_2]_2O^{2+}$ (L = bipy, phen) catalytically oxidize H_2O to O_2[1207] and $2Cl^-$ to Cl_2[1205,1207] in the presence of excess of Ce^{IV}. The mechanism of H_2O oxidation is believed to occur *via* the four electron oxidation species $[5,5]^{4+}$ (equation 95).[1207] The use of these binuclear complexes on chemically modified electrodes has been reported,[1205] and their involvement in the photooxidation of H_2O at the surface of hectorite mentioned.[1190]

Reaction of $[RuCl_2(bipy)_2]$ with L^{2-} (L^{2-} = pyrazine-2,5-dicarboxylate) gives $[Ru(LH)(bipy)_2]^+$ and a green binuclear species $[Ru(bipy)_2]_2L^{2+}$.[562] No intervalence charge transfer absorption was observed for the mixed valence $[2,3]^{3+}$ ion in contrast to the complexes $[Ru(NH_3)_4]_2L^{3+}$ and $[(NH_3)_5Ru(L)Ru(bipy)_2]^{4+}$.[562] The single crystal X-ray structure of $[Rupy_4]_2(ox)^{2+}$ (**107**) shows a centrosymmetric planar oxalate bridging Ru^{II} ions with Ru—O = 2.096, 2.133 Å.[1276]

i, O_2, 72 h; ii, Cl_2; iii, $AgNO_3$, H_2O, Δ, 8 h; iv, $NaNO_2$

Scheme 39[1274]



$$[(bipy)_2Ru^{V}(=O)-O-(O=)Ru^{V}(bipy)_2]^{4+} + 2H_2O \longrightarrow [(bipy)_2Ru^{III}(OH_2)-O-(H_2O)Ru^{III}(bipy)_2]^{4+} + O_2 \quad (95)$$

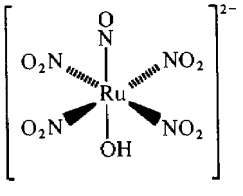
Reaction of RuO_4 with phen in CCl_4 yields a supposed oxy-bridged Ru^{VII} dimer $[Ru_2O_7(phen)_2]$.[1209] (see Section 45.4.3.1.x).

(*iii*) *Sulfur donor complexes*

The binuclear complex (**108**) has been synthesized and its use as a catalyst for the electrochemical reduction of acetylene in MeOH/DMF discussed.[1212a]

(108)

(*iv*) *Halide complexes*



Reaction of $[RuCl_2(AsPh_3)_2]_2$ with bipy is reported to yield a dimer of stoichiometry $[Ru_2Cl_4(bipy)_3]$.[677] Reaction of $[Ru(CO_3)(bipy)_2]$ with *cis*-$[RuCl_2(bipy)_2]$ under acidic conditions gives $[RuCl(bipy)_2]_2^{2+}$; the complex can be oxidized to a $[3,2]^{3+}$ ion which decomposes in MeCN to $[RuCl_2(bipy)_2]^+$ and $[Ru(bipy)_2(NCMe)_2]^{2+}$.[1160] The weakness of the Cl^- bridge in the mixed valence compound is assigned to the high strength of the Ru^{III}—Cl bond leading to bridge cleavage.[1126,1160]

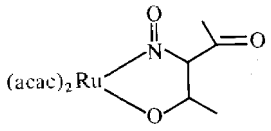
45.4.4 Nitrosyls

Ruthenium shows a wide nitrosyl chemistry and several reviews of the area have been published.[273–277] ^{15}N NMR studies on nitrosyl complexes show that N is deshielded by up to 450 p.p.m. in bent as compared with linear NO ligands.[1277] PES studies of core binding energies for nitrosyl complexes have been reported and comparisons between coordinated NO^+ and ^+N_2R assessed.[1278,1279] ^{99}Ru Mössbauer spectra of $[RuX_5(NO)]^{n+}$ (X = ^-CN, NH_3, ^-NCS, Cl^-, Br^-) have been measured at 4.2 K, and the chemical isomer shift found to decrease as ligand field strength of X decreases;[27c,1280] the changes in quadrupolar splitting have been discussed in terms of σ donor and π acceptor abilities of coordinated ligands.[1280]

45.4.4.1 Nitrogen donor complexes

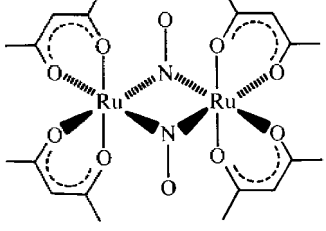
Nitrosyl ammine, amine, heterocyclic and phosphine complexes are discussed in Sections 45.4.1, 45.4.2, 45.4.3 and 45.5 respectively. A range of nitrosyl complexes incorporating NO_2^- and NO_3^- ligands have been reported. Treatment of $RuCl_3$ with $NaNO_2$ yields $[Ru(OH)(NO_2)_4(NO)]^{2-}$ (**109**),[1281–1283] the single crystal X-ray structure of which shows a linear Ru—N—O(nitrosyl) with ^-OH and NO^+ mutually *trans*; Ru—N(NO_2) = 2.079 Å, Ru—N(NO) = 1.748 Å.[1284] The IR spectrum of $[Ru(OH)(NO_2)_4(NO)]^{2-}$ has been assigned by ^{14}NO and ^{15}NO labelling experiments.[298] Reaction of ruthenium(II) nitrosyls with HNO_3 gives a wide range of products of general type $[Ru(NO_2)_x(NO_3)_y(NO)_2]^{n+}$; the separation of some of the products has been achieved,[2,1285–1292a] *e.g.* $[Ru(NO_3)_3(NO)(OH_2)_2]$, $[Ru(NO_2)(NO_3)(NO)(OH_2)_3]^+$, $[Ru(NO_2)(NO_3)_2(NO)(OH_2)_2]$. In the presence of tributyl phosphate (tbp), $[Ru(NO_3)_3(NO)(OH_2)_2]$ gives an equilibrium mixture of $[Ru(NO_3)_3(NO)(tbp)_2]$, which can be extracted into dodecane.[1286]

(109)



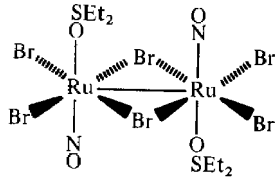
Treatment of $[RuCl_5(NO)]^{2-}$ with KNCS yields $[Ru(NCS)_5(NO)]^{2-}$[1292b] the Mössbauer spectrum of which has been reported.[27c] The reaction between $[Ru(CN)_6]^{4-}$ and HNO_3 yields $[Ru(CN)_5NO]^{2-}$[1281,1283,1293] (see Section 45.3.1).

45.4.4.2 Oxygen donor complexes



$[Ru(NO)(OH_2)_5]^{3+}$ can be prepared by reaction of $[Ru(OH_2)_6]^{2+}$ with NO,[282] or by protonation with HNO_3 of $[Ru(OH)_3NO]_n$ formed by alkaline hydrolysis of $[RuCl_3(NO)]_n$.[1294–1296] Reaction of $[Ru(NO)(OH_2)_5]^{3+}$ with $[Cr(OH_2)_6]^{2+}$ yields the dimeric product $[(H_2O)_5Ru—NH—Cr(OH_2)_5]^{5+}$, the rate of formation of which is first order in $[Cr^{II}]$ and $[Ru^{II}]$.[282]

$[RuCl_3(NO)(OH_2)_2]$ reacts with diketones, *e.g.* acacH, to give the halo-bridged dimer $[RuCl_2(acac)(NO)]_2$.[619] At pH 3 *cis*-$[RuCl(acac)_2(NO)]$ is formed while a tetramer $[Ru(acac)_2(NO)]_4$ has also been proposed;[1297] at pH 6 $[RuCl_3(NO)(OH_2)_2]$ with Hacac yields $[Ru(acac)_2(hia)]$ (**110**) which can also be prepared directly from *cis*-$[RuCl(acac)_2(NO)]$.[1297] The single crystal X-ray structure of the dimer $[Ru(acac)_2(NO)]_2$ (**111**) shows Ru—O = 2.031 Å, Ru—N = 1.918 Å with a planar $Ru(\mu\text{-}NO)_2Ru$ unit.[1298] The structure of $[RuL_2(NO_2)(NO)]^{2-}$ (L = 2,4,5,6-(1*H*,3*H*)pyrimidinetetrone-5-oximate) has been reported, chelation of L being through O of oximate and the 6-carbonyl moiety with *cis* NO and NO_2.[1299] Reaction of $[RuCl_3(NO)(OH_2)_2]$ with glycinate gives $[Ru(OH)_3(gly)(NO)]^-$.[1300]

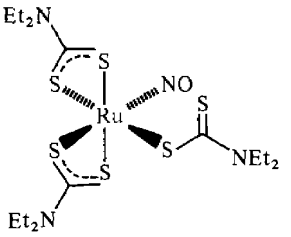


Oxidation of $[RuBr_3(SEt_2)_2(NO)]$ produces $[RuBr_3(NO)(OSEt_2)]_2$ (**112**), the X-ray structure of which shows a Br^--bridged dimer with sulfoxide *trans* to NO; Ru—N = 1.71 Å, Ru—O = 2.058 Å.[1301]

(110)

(111)

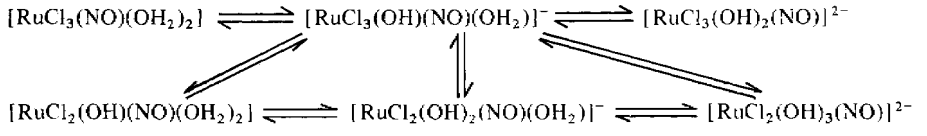
(112)



45.4.4.3 Sulfur donor complexes

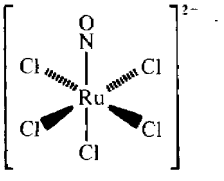
Reaction of $[RuCl_3(NO)]$ with thioethers (L) in EtOH gives complexes $[RuCl_3(NO)L_2]$ (L = SEt_2, SEtPh, SPr_2 $S(CH_2Ph)_2$, SPrPh, SMePh, $SeEt_2$, SePhEt) with L being mutually *trans*;[619,1302,1303] the synthesis of $[RuBr_3(NO)(SEt_2)_2]$ has been reported.[1301] The ^1H and ^{13}C NMR and IR spectra of these complexes have been analysed.[1302,1303] The complexes $[RuX_3(NO)L_2]$ (X = Cl^-, Br^-; L = PPh_3, $AsPh_3$) react with elemental sulfur to give the sulfide dimers $[RuX_2(NO)L_2]_2S$ which can be oxidized with perbenzoic acid to the sulfoxy-bridged species $[RuX_2(NO)L_2]_2SO$.[1304]

Reaction of $[RuCl_3(NO)]$ with dithioacetylacetonate ($sacsac^-$) in water yields *trans*-$[Ru(sacsac)_2Cl(NO)]$.[1305] Polarography of this product shows two reversible reductions at −0.27 V and −1.43 V *vs.* Ag/AgCl, compared with $[Ru(sacsac)_3]$ which shows only one redox couple at +0.04 V *vs.* Ag/AgCl corresponding to the $Ru^{III/II}$ couple.[1305–1307] More recently dithiocarbamate derivatives *cis*- and *trans*-$[RuX(S_2CNRR')_2(NO)]$ (X = Cl^-, Br^-, I^-, Fe^-, NO_2^-, ^-OH, ^-NCO, N_3^-, SCN^-; R = R′ = Me, Et; R = Me, R′ = Et; R = Me, R′ = Ph) have been prepared from $[RuCl_3(NO)]$ and $Na^+(^-S_2CNRR')$ in MeOH followed by acidification and treatment with X^-.[1308] *Cis*-$[Ru(S_2CNMe_2)_2(^{15}NO_2)(NO)]$ undergoes exchange between NO and NO_2 ligands.[1308] *Cis*-$[Ru(S_2CNRR')_3(NO)]$ can also be isolated from the above reactions[1308] or prepared directly from $[Ru(S_2CNRR')_3]$ with NO.[1309] The ^1H NMR spectrum of the complex with R = R′ = Me differentiates between unidentate and bidentate dtc ligands;[1308] this is confirmed by the single crystal X-ray structure of $[Ru(S_2CNEt_2)_3(NO)]$ (**113**) which shows two bidentate dtc ligands with Ru—S = 2.415 Å and one monodentate dtc with Ru—S = 2.398 Å *cis* to NO, Ru—N = 1.72 Å.[1310]



45.4.4.4 Halide complexes

Reaction of $RuCl_3$ with NO in EtOH yields $[RuCl_3(NO)]$[1292,1300,1302] while $[RuX_3(NO)]_n$ (X = Cl^-, Br^-, I^-) can be prepared by treatment of RuO_4 with HX and HNO_3.[1311,1312] In aqueous solution,



(113)

these complexes may be regarded as $[RuX_3(NO)(OH_2)_2]$[1313] and are highly useful starting materials for the synthesis of ruthenium nitrosyls. The kinetics of hydrolysis of $[RuCl_3(NO)(OH_2)_2]$ show displacement of three Cl^- ligands at decreasing rates with no loss of NO^+, pK_1 and pK_2 for $[RuCl_3(NO)(OH_2)_2]$ being 4.9 and 7.5 respectively (Scheme 40).[1313] The interaction of $[RuCl_3(NO)(OH_2)_2]$ with glycine and alanine has been reported.[1314]

Scheme 40[1313]

Anation of $[RuX_3(NO)]$ with halide,[1311,1312,1315] reaction of $RuCl_3$ with HCl and NO for 48 h followed by NH_4Cl[1315] or treatment of $RuCl_3$ with NOCl in EtOH[282,1316] yield $[RuCl_5(NO)]^{2-}$. $[RuCl_5(NO)]^{2-}$ with X^- gives $[RuX_5(NO)]^{2-}$ ($X = Br^-$, I^-).[1316] The single crystal X-ray structure of $[RuCl_5(NO)]^{2-}$ (**114**) shows octahedral Ru^{II} with Ru—Cl(equatorial) = 2.373–2.379, Ru—Cl(*trans* to NO) = 2.357, Ru—N = 1.738, N—O = 1.131 Å, < RuNO = 176.7°,[1317a] with $[RuF_5(NO)]^{2-}$ being found to be isostructural.[1317b] The IR spectrum of $[RuCl_5(NO)]^{2-}$ has been assigned,[298,1318–1324] with $\nu_{^{14}NO}$ = 1876, 1850, 1844 cm^{-1} for X = Cl^-, Br^-, I^- respectively.[1318] The ^{19}F NMR spectrum[1325] and Mössbauer data[27] for $[RuX_5(NO)]^{2-}$ have been reported. The rate of hydrolysis of $[RuCl_5(NO)]^{2-}$ is more rapid under basic conditions although hydrolysis of $[RuCl_4(OH)(NO)]^{2-}$ is pH independent at pH < 2.5 and pH = 7.5–9.5.[1315,1326] The crystal structure of $[RuCl_4(OH)(NO)]^{2-}$ (Ru—N = 2.04 Å) has been reported.[1327]

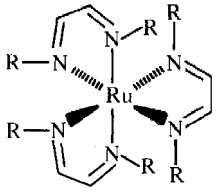
(114)

$[RuCl_5(NO)]^{2-}$ shows a reversible one electron oxidation, the electrogenerated product being assigned on the basis of IR, ESR and magnetic data to low spin $[Ru^{III}Cl_5(NO)]^-$.[1328,1329a]

Reaction of $RuCl_3$ with $S_3N_3Cl_3$ gives a brown product '$[RuCl_3(NS)]$' which, on treatment with Ph_4PCl in aqueous solution, yields $PPh_4[RuCl_4(NS)(OH_2)]$, the single crystal X-ray structure of which shows octahedral geometry with H_2O *trans* to NS and < RuNS = 170.9° and N—S = 1.504 Å.[1329b]

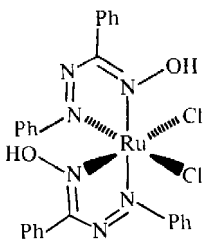
45.4.5 Hydrazines, Diimines and Related Ligands

Refluxing solutions of $[RuCl_2(cod)]_n$ with hydrazines yield complexes of type $[Ru(cod)(NH_2NRR')_4]^{2+}$ and $[Ru(H)(cod)(NH_2NRR')_3]^+$.[650] These products are converted to $[Ru(NH_2NCRR')_2(PR_3)_4]^{2+}$ (R = R' = Me) on reaction with PR_3, while with LiX, $[Ru(H)(X)(cod)]_2NH_2NMe_2$ ($X = Cl^-$, Br^-) is isolated.[650] PES studies indicate that aryldiazo and aryldiimine



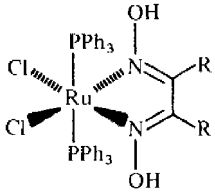
ligands possess low overall charge and are less polar than coordinated N_2.[1279] $[Ru(cod)(NH_2NH_2)_4]^{2+}$ reacts with isocyanides CNR in refluxing acetone to give *trans*-$[Ru(CNR)_4(NH_2NMe_2)_2]^{2+}$;[1330] in ethanol reaction of $[Ru(cod)(NH_2NH_2)_4]^{2+}$ and $CNCMe_3$ yields *mer*-$[Ru(CNCMe_3)_3(NH_2NH_2)_3]^{2+}$, which in cold acetone is converted to *trans*-$[Ru(CNCMe_3)_4(NH_2NH_2)_2]^{2+}$ and under refluxing conditions to *mer*-$[Ru(CNCMe_3)_3(NH_2NMe_2)_3]^{2+}$.[1330] $[Ru(cod)(NH_2NHMe)_4]^{2+}$ with CNR yields *trans*-$[Ru(CNR)_4(NH_2NHMe)_2]^{2+}$.[1330] Interaction of $[RuCl_2(PPh_3)_3]$ with hydroxylamine under basic conditions gives $[RuCl(NH_2O)(NH_2OH)(PPh_3)_2]$ which has been postulated as having an η^2-NH_2O^- ligand.[1331]

The syntheses of $[Ru(N_2C_6H_4\text{-}4\text{-}R)(CO)_2L_2]^+$ (R = NO_2, F, H, OMe, NMe_2, L = PPh_3; R = OMe, L = $PPh_2(4\text{-}MeC_6H_4)$ and $[Ru(N_2C_6H_3\text{-}2,6\text{-}R'_2)(CO)_2(PPh_3)_2]^+$ (R = Me, Cl) from $[Ru(CO)_3L_2]$ have been reported.[1332] Protonation with HX yields $[Ru(N_2HC_6H_4\text{-}4\text{-}R)(CO)_2L_2]^{2+}$ reversibly together with $[Ru(I)(N_2HC_6H_4\text{-}4\text{-}F)(CO)_2(PPh_3)_2]^+$ and $[RuCl_2(N_2HC_6H_4\text{-}4\text{-}R)(CO)(PPh_3)_2]$ as isolable products.[1332] Ruthenium blue solutions with PhN_2Ph give the postulated dimeric product $[Ru_2Cl_4(C_6H_4N_2Ph)(PhN_2Ph)]$ with an *ortho*-metallated PhN_2Ph ligand.[676]



Reaction of $[RuH_2(PPh_3)_4]$ or $[Ru(H)(C_6H_4PPh_2)(PPh_3)(C_2H_4)]$ with dad (dad = (4-$MeOC_6H_4N{=}CH)_2$) yields a dark product $[Ru(dad)_3]$ (**115**), the single crystal X-ray structure of which confirms a tris-chelate configuration, formally Ru^0 with Ru—N(average) = 2.06 Å;[1333,1334] the diamagnetic solid is rapidly oxidized in air to $[Ru(dad)_3]^{2+}$.[1333,1334] Treatment of $RuCl_3$ in THF with Zn powder followed by dad gives *cis*-$[RuCl_2(dad)_2]$.[1335] A range of organometallic derivatives of dad ligands, *e.g.* $[Ru_3(CO)_8(dad)]$, $[Ru(CO)_3(dad)]$, $[Ru_2(CO)_6(dad)]$, $[Ru_4(CO)_8(dad)_2]$, have been synthesized and their reactivity and rearrangement chemistry investigated.[1,1336–1346]

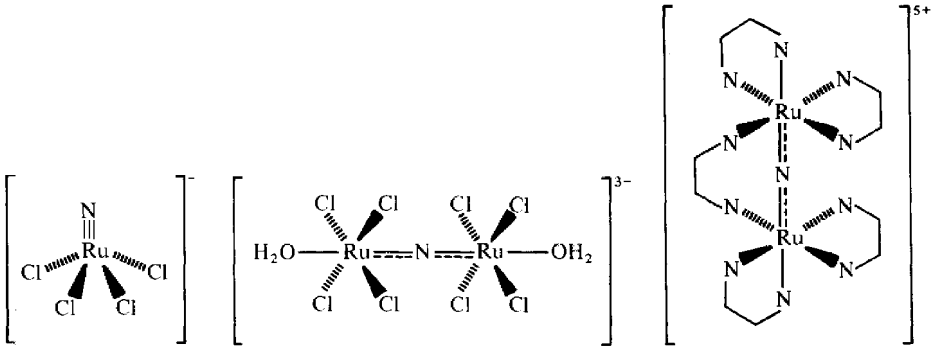
RuX_3 reacts with a range of arylazooximes to give *cis*- and *trans*-$[RuCl_2(HL)_2]$ (HL = RN=NC(=NOH)R').[1347,1348] The X-ray structure of the *cis* isomer for R = R' = Ph (**116**) shows Ru—N = 1.986 Å indicating strong back-bonding.[1348] $[RuCl_2(HL)_2]$ with PR_3 in the presence of NEt_3 produces $[RuL_2(PR_3)_2]$ (PR_3 = PPh_3, ½diphos).[1347] Reaction of $RuCl_3$ or $[RuCl_2(HL)_2]$ with HL in the presence of NEt_3 however gives the Ru^{III} tris chelate product $[RuL_3]$ (HL = PhN=NC(=NOH)Me).[1347] The Ru^{III} complexes $[RuCl_2(L)(HL)]$ and $[RuCl_2L_2]^-$ have also been generated and show ligand to metal charge transfer bands near 580 and 1000 nm; the corresponding Ru^{II} species show metal to ligand charge transfer bands near 680 nm.[1349]



$[RuCl_2(PPh_3)_3]$ reacts with oximes L to give complexes of type $[RuCl_2(PPh_3)_2L]$ (**117**) which have been characterized by IR and ^1H and ^{31}P NMR spectroscopy.[1331]

(115)

(116)



(117)

45.4.6 Nitrides

The chemistry of transition metal nitrido[1350] and organoimido[1351] complexes has been reviewed. Few mononuclear nitrido complexes are known. Reaction of *trans*-$[Ru(O)_2X_4]^{2-}$ with N_3^- and HX yields $Cs_2[RuNX_5]$ (X = Cl^-, Br^-) on addition of CsX while with larger cations (Ph_4As^+, Bu_4N^+) $[RuNX_4]^-$ was isolated.[65] The single crystal X-ray structure of $[RuNCl_4]^-$ (**118**) shows square pyramidal Ru^{VI} with Ru—N = 1.570 Å, Ru—Cl = 2.310 Å.[1352] Addition of L (L = py, pyridine *N*-oxide, isoquinoline, DMSO) or L' (L' = hexamethylenetetramine, pz or dioxane) to $[RuNCl_4]^-$ gives adducts $[RuNCl_4(L)]^-$ and $[RuNCl_4]_2L'^{2-}$.[1353]

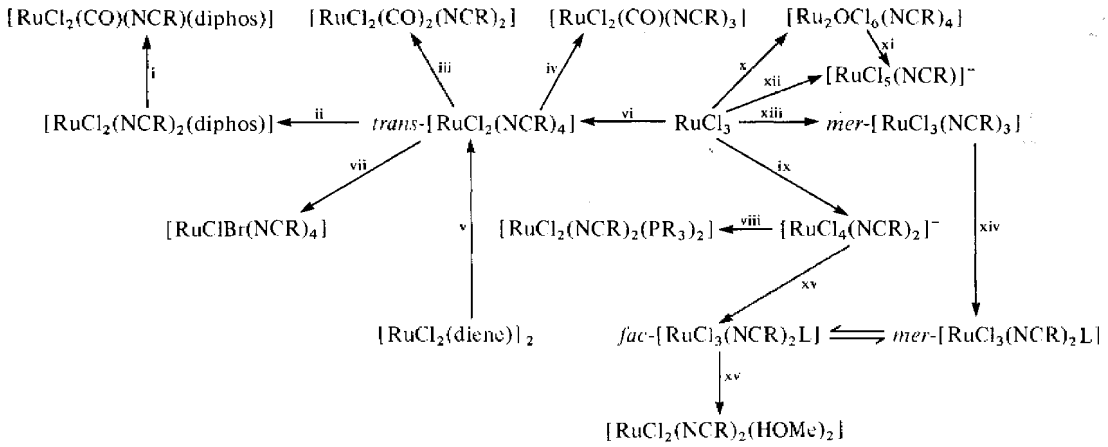
Reaction of $[RuCl_5(NO)]^{2-}$ with $SnCl_2$ or HCHO yields the centrosymmetric binuclear nitrido complex $[Ru_2NCl_8(OH_2)_2]^{3-}$.[94,1354,1355] The single crystal X-ray structures of $K_3[Ru_2NCl_8(OH_2)_2]$[1356,1357] and $(NH_3)_3[Ru_2NCl_8(OH_2)_2]$ (**119**)[1358] show Ru—N = 1.718 Å Ru—O = 1.80 Å, < ORuN = 179.7°.[1356] A range of other substituted nitrido dimers have been prepared, *e.g.* $[Ru_2NX_8(OH_2)_2]^{3-}$ (X = Br^-, NCS^-), $[Ru_2N(NO_2)_6(OH)_2(OH_2)_2]^{3-}$, $[Ru_2NX_2(NH_3)_8]^{3+}$ (X = Cl^-, Br^-, NO_3^-), $[Ru_2NX_3(NH_3)_6(OH_2)]^{2+}$ (X = Cl^-, NCS^-, N_3^-),[1355] $[Ru_2NCl_8(CO)_2]^{3-}$,

$[Ru_2N(CN)_{10}]^{5-}$.[65] Vibrational spectra of these complexes are consistent with linear Ru—N—Ru units with $\nu_{Ru_2N} = 1083\,cm^{-1}$ for $[Ru_2NCl_8(OH_2)_2]^{3-}$.[65,1355] The resonance Raman[1359] and Mössbauer spectra[1360] of binuclear nitrides have been reported. Prolonged treatment of $[Ru_2NCl_8(OH_2)_2]^{3-}$ with en yields $[Ru_2N(en)_5]^{5+}$ (**120**) the single crystal X-ray structure of which shows a bridging en ligand and Ru—N(nitride) = 1.742 Å with < RuNRu = 174.6°; $\nu_{Ru_2N} = 1048\,cm^{-1}$.[647]

(118) (119) (120)

In the original preparation of ruthenium red $[Ru_3O_2(NH_3)_{14}]^{6+}$, an impurity 'ruthenium violet' was isolated.[570] This compound has been proposed to be a trinuclear species $[Ru_3N_2(NH_3)_8(OH)(OH_2)_5]^{5+}$ with a linear Ru_3N_2 backbone; a closely related osmium system has been synthesized.[1361]

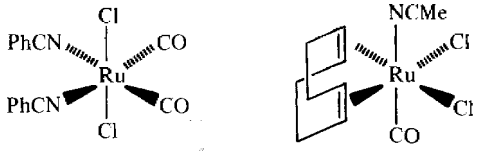
45.4.7 Thiocyanates



Ruthenium(II): $[Ru(SCN)_6]^{4-}$ is reported to be formed on treatment of $[Ru(NCS)_6]^{3-}$ with molten thiocyanate.[355,1362] $RuCl_3$ with CO in EtOH reacts with NH_4NCS to give proposed dimers $[Ru_2(NCS)_6(CO)_4]^{2-}$ and the monomer $[Ru(NCS)_4(CO)_2]^{2-}$.[1363]

Ruthenium(III): Reaction of $RuCl_3$ or $RuCl_6^{3-}$ with NCS^- yields $[Ru(NCS)_6]^{3-}$.[1362,1364–1366] Using high voltage electrophoresis, this product has been shown to be a mixture of four isomers of the type $[Ru(NCS)_n(SCN)_{6-n}]^{3-}$[1367,1368] with mixed N- and S-bound NCS^-. The far IR spectra of these complexes confirm mixed S and N bonding.[353] Heating solid Bu_4N^+ salts of the above mixture yields $[Ru(NCS)_5(SCN)]^{3-}$, while the PPN^+ salt rearranges to $[Ru(NCS)_6]^{3-}$ above 160°C.[1368] $[Ru(NCS)_6]^{3-}$ may also be prepared by treating $(Bu_4N)_3[Ru(NCS)_5SCN]$ with a one-hundred-fold excess of $Bu_4N^+Br^-$ in EtOH.[1368]

45.4.8 Nitriles



Ruthenium(II): Transition metal complexes of organonitriles have been reviewed.[1369] $[Ru(\pi\text{-allyl})_2(nbd)]$ reacts in MeCN to give $[Ru(nbd)(NCMe)_4]^{2+}$ with further reflux yielding $[Ru(NCMe)_6]^{2+}$.[1183] Refluxing solutions of $[Ru(cod)(N_2H_4)_4]^{2+}$ and $[Ru(H)(cod)(NH_2NRR')_3]^+$ in MeCN yield $[Ru(cod)(NCMe)_4]^{4+}$ and $[RuH(cod)(NCMe)_3]^+$ respectively.[650] $[RuCl_2(cod)]_n$ in MeCN gives $[RuCl(cod)(NCMe)_3]^+$ which is converted to $[Ru(cod)(NCMe)_4]^{2+}$ and $[Ru(cod)(NCMe)_3(MeOH)]^{2+}$ on treatment with $AgPF_6$ in MeCN and MeOH respectively.[1370] Treatment of $[Ru(cod)(NCMe)_4]^{2+}$ with L yields $[Ru(cod)(NCMe)_2L_2]^{2+}$ (L = py, propylamine, 4-picoline) and $[Ru(cod)(NCMe)_3L]^{2+}$ (L = Et_2S).[1370] Ruthenium blue solution with PhCN produces $[RuCl_2(NCPh)_3]_2$ which reacts with L to give $[RuCl_2(NCPh)_2L_2]$ (L = $PhNH_2$, $\frac{1}{2}$bipy).[676] Scheme 41 summarizes the reactivity of halo–nitrile complexes.

Trans-$[RuCl_2(NCR)_4]$ can be prepared by reaction of $[RuCl_2(diene)]_2$ with nitrile,[1372] or by reduction of $RuCl_3$ with H_2 over Adams catalyst and treatment with RCN;[676,1371] $[RuCl_2(NCMe)_4]$ catalytically oxidizes decylmethyl sulfide under O_2 at 100 PSI ($7 \times 10^{-5}\,kg\,m^{-2}$) at 100°C to the sulfoxide.[1375] Carbonylation of *trans*-$[RuCl_2(NCR)_4]$ yields $[RuCl_2(CO)_2(NCR)_2]$ (R = Me, Et, Pr, Pr^i, Ph, $PhCH_2$);[1371] the single crystal structure of $[RuCl_2(CO)_2(NCPh)_2]$ (**121**) has been reported.[1376] $[RuX_2(CO)_3]_2$ (X = Cl^-, Br^-) with RCN produces $[RuX_2(CO)_3(NCR)]$[651] while $[RuCl_2(CO)(cod)]_2$ with RCN gives $[RuCl_2(CO)(cod)(NCR)]$; the structure of the MeCN adduct (**122**) has been published.[1377]

i, CO;[1371] ii, diphos;[1371] iii, CO, acetone, Δ;[1371] iv, CO, MeOH, Δ;[1371] v, RCN;[1372] vi, Pt, H_2, RCN;[676, 1371] vii, LiBr;[1371] viii, PR_3;[681] ix, MeOH, RCN;[681] x, RCN, 45–70 °C, 2 h;[1373, 1374] xi, CH_2Cl_2, Et_4NCl;[681] xii, RCN, 4 h, Δ;[681] xiii, RCN, MeOH, 70 °C, 1–3 h;[1373, 1374] xiv, L (L = py, PhSMe, R'CN);[1373, 1374] xv, MeOH, 48 h;[681]

Scheme 41

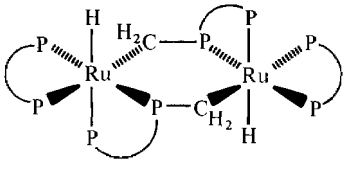
(121) (122)

Ruthenium(III): $RuCl_3$ with RCN in refluxing MeOH gives $[RuCl_3(NCR)_3]$ together with the novel side product $[RuCl(NCR)_5][RuCl_4(NCR)_2]$ which reacts with L to yield $[RuCl_2(NCR)_2L_2]$ (L = py, PPh_2Me).[1373,1374] The electrochemistry of $[RuCl_3L_3]$ (L = 2- and 3-methylbenzonitrile) and $[RuCl_3L_2L']$ (L = 2-methylbenzonitrile, L' = MeCN, py) shows $Ru^{II/III}$ and $Ru^{III/IV}$ redox couples, the *fac* isomers being more difficult to reduce than the corresponding *mer* isomers.[680]

45.5 PHOSPHORUS, ARSENIC AND ANTIMONY LIGANDS

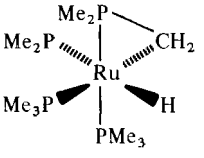
45.5.1 Mononuclear Ruthenium(0) Complexes

45.5.1.1 $[RuL_5]$, $[RuL_nL'_{5-n}]$, $[RuL_nL'_{4-n}]$ complexes (L = P donor; L' = donor, MeCN, alkene)



$[Ru\{P(OMe)_3\}_5]$ can be prepared either by Na/Hg reduction in THF of $[RuCl_2\{P(OMe)_3\}_4]$ in the presence of excess $P(OMe)_3$[1378,1379] or by photolysis of $[Ru_3(CO)_{12}]/P(OMe)_3$ mixtures.[1380] At low temperatures (−125°C), its $^{31}P-\{^1H\}$ NMR spectrum consists of a limiting A_2B_3 pattern but variable temperature studies suggest that facile intramolecular scrambling of $P(OMe)_3$ ligands occurs at higher temperatures.[1378] Heating $[Ru\{P(OMe)_3\}_5]$ to 120°C in *n*-hexane results in a novel rearrangement to form *cis*-$[Ru(Me)(P\{OMe\}_3)_4P(O)(OMe)_2]$ and both these compounds will react with MeI to give $[Ru(Me)(P\{OMe\}_3)_5]I$.[1380]

The related $[Ru(PF_3)_5]$ compound was first prepared by reaction of $RuCl_3$ and PF_3 (500 atm/250°C) in the presence of copper,[1381,1382] and more recently by treatment of $[Ru_3(CO)_{12}]$ with PF_3 at high pressure (500 atm/160°C/12 h).[1383] This extremely volatile white solid which is fluxional even at −160°C[1384] sublimes at room temperature and decomposes to an unidentified red polynuclear compound at 155°C. It also reacts with K/Hg to give the colourless liquid $K_2[Ru(PF_3)_4]$.[1381,1382]



$[Ru(PF_2NMe_2)_5]$ can be directly synthesized by cocondensation of ruthenium vapour and PF_2NMe_2[1385] or by reductive elimination of acetic acid from $[RuH(OCOMe)(PPh_3)_3]$ on treatment with PF_2NMe_2 at elevated temperatures.[1386] Under milder conditions, hydrido/acetato/phosphine

compounds are formed (see Section 45.10.3.2). The compounds $[Ru(PF_2NC_4H_8)_5]$, $[Ru(PF_3)_3(PPh_3)_2]$ and $[Ru(PF_3)_4PPh_3]$ can be prepared by the same route. The latter complex is also formed if $[Ru(PPh_3)(\eta^4\text{-}C_4H_6)_2]$ is treated with an excess of PF_3, whereas with other L ($P(OMe)_3$, $P(OCH_2)_3CMe$, PF_2NMe_2), only one butadiene molecule is displaced and $[Ru(PPh_3)L_2(C_4H_6)]$ is formed.[1387] High resolution NMR studies establish fluxional behaviour for all these complexes.

Treatment of $[RuH(2\text{-np})(dmpe)_2]$ (2-np = 2-naphthyl) with L (L = CO, C_2H_4, $P(OMe)_3$) gives the five-coordinate zerovalent complexes $[Ru(dmpe)_2L]$,[1388] whereas pyrolysis of the hydride results in loss of naphthalene and formation of a compound of empirical formula $[Ru(dmpe)_2]$. However its IR spectrum contains a ν(RuH) band at *ca.* 1800 cm^{-1}[1389] and an X-ray analysis shows its solid state structure to be the novel dimeric Ru^{II} complex (**123**) which results from intermolecular oxidative addition of methyl groups to ruthenium.[1390] Similarly reaction of *trans*-$[RuCl_2(PMe_3)_4]$ with Na/Hg in C_6H_6 gives '$Ru(PMe_3)_4$', shown by NMR studies to be $[RuH(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ (**124**).[1391a,1391b] However, reduction of $[RuCl_2(PMe_3)_2\{P(OMe)_3\}_2]$ with Na/Hg in the presence of $P(OMe)_3$ gives $[Ru(PMe_3)_2\{P(OMe)_3\}_3]$.[1391c]

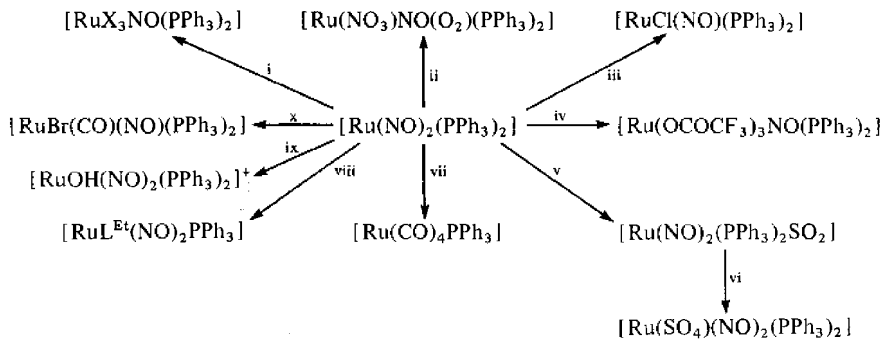
(123)

(124)

The genuine Ru^0 complex $[Ru(dppe)_2L]$ (L = $P(OMe)_3$, CO) can be prepared by reaction of $[Ru(dppe)_2$ styrene] (synthesized from $[Ru(PPh_3)_2(styrene)_2]$ and dppe) with L;[1392] $[Ru(PMe_3)_4C_2H_4]$ has been synthesized both by reaction of $[Ru(PMe_3)(\eta\text{-}C_6H_6)(C_2H_4)]$ with PMe[1391a] and by the interaction of *trans*-$[RuCl_2(PMe_3)_4]$ with $MgEt_2$. NMR data for the latter suggest that the C_2H_4 group is bound in the η^2 or metallacyclopropane form and this is confirmed by X-ray analysis.[1393]

Although strictly outside the scope of this review, other genuine Ru^0 alkene (or arene) phosphine complexes include $[Ru(PPh_3)_2(styrene)_2]$,[1394] $[Ru(PPh_3)_2(C_2H_4)_2(styrene)]$,[1394] $[Ru(dppm)_2$-styrene],[1392] $[Ru(P\{OCH_2\}_3CEt)_3nbd]$,[1395] $[Ru(PR_3)(\eta^4\text{-}C_4H_6)_2]$,[1394,1396] $[Ru(PPh_3)_3(\eta^4\text{-}C_4H_6)]$,[1394] $[Ru(PR_3)_2(C_6H_6)]$,[1397] $[Ru(PMe_3)(cod)(cot)]$,[1398] $[Ru(dppm)_2(cod)]$,[1399] $[Ru(PR_3)_3$-$(CH_2C_6H_4CH_2)]$,[1400] $[Ru(CO)(PPh_3)_2(\eta^4\text{-}C_5H_6)]$ and $[Ru(L)(\eta^4\text{-}C_5H_6)]$ (L = $MeC(CH_2PPh_2)_3$, $PhP(CH_2CH_2PPh_2)_2$).[1401] However, many have been reformulated as *ortho*-metallated Ru^{II} compounds[1402] (see also reference 1 and Section 45.5.4.5.v for more information).

Finally, electrochemical reduction of $[RuCl_2(PPh_3)_4]$ in MeCN gives a complex formulated as $[Ru(\eta^2\text{-}MeCN)(PPh_3)_4]\cdot MeCN$.[1403] However, chemical reduction of $[RuCl_2(PPh_3)_n]$ (n = 3 or 4) with Na/Hg or Mg/Hg in MeCN/THF gives the isomeric *ortho*-metallated $[RuH(C_6H_4PPh_2)(MeCN)(PPh_3)_2]$.[1404] It is claimed that these products are identical[1404] but this has been refuted.[1405] Labile intermediates such as $[Ru(MeCN)_2(PPh_3)_2]$ (paramagnetic and presumably tetrahedral), $[RuMeCN(PPh_3)_3]$ and $[Ru(MeCN)_3PPh_3]$ are also observed on chemical reduction of $[RuCl_2(PPh_3)_4]$.[1404]

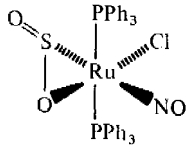


45.5.1.2 Nitrosyl complexes

Ruthenium forms more nitrosyl complexes than any other element. The dinitrosyl complex $[Ru(NO)_2(PPh_3)_2]$ was first prepared from $[RuCl_2(CO)_2(PPh_3)_2]$ and $Na[NO_2]$ in DMF; $[Ru(ONO)_2(CO)_2(PPh_3)_2]$ is formed initially but this isomerizes to $[Ru(NO_2)_2(CO)_2(PPh_3)_2]$ which decomposes to the $[Ru(NO)_2(PPh_3)_2]$ complex,[1406] probably *via* $[Ru(ONO)(CO)(NO)(PPh_3)_2]$.[1407]

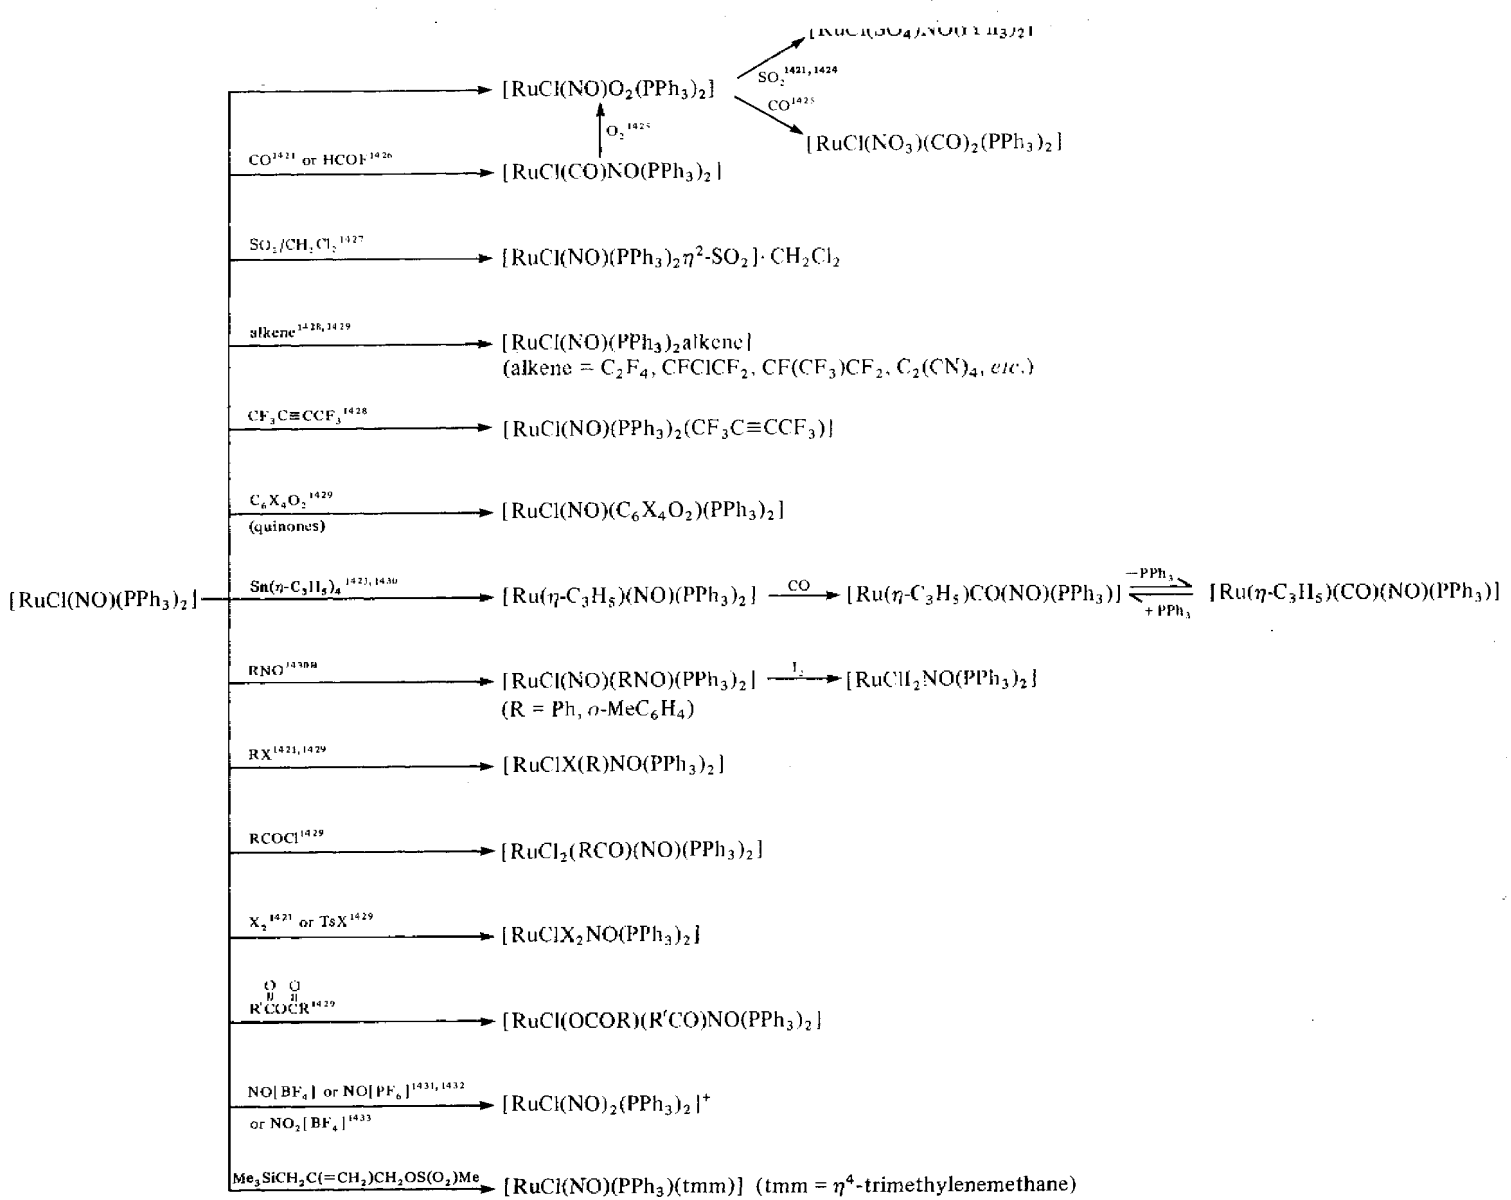
Other synthetic routes to this useful compound are by reaction of $[RuH_4(PPh_3)_3]$ with NO,[1408] by treatment of $[RuHCl(PPh_3)_3]$, $[RuH(NO)(PPh_3)_3]$ or $[RuCl(NO)(PPh_3)_2]$ with $[Co(NO)(DMG)_2]$[1409] or by reaction of $RuCl_3/PPh_3$ (1:2 mole ratio) with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide in the presence of Et_3N.[1410a] Direct reaction of $[RuCl_2(PPh_3)_3]$ with NO in acetone or C_6H_6 gives both $[Ru(NO)_2(PPh_3)_2]$ and $[RuCl_3NO(PPh_3)_2]$ (see Section 45.5.4.6.iii); in $CHCl_3$ only $[RuCl_3$-$(NO)(PPh_3)_2]$ is formed.[1411]

The X-ray crystal structures of $[Ru(NO)_2(PPh_3)_2]\cdot nC_6H_6$ (n = 0,[1412] 0.5[1413]) reveal that the compound is pseudotetrahedral with linear NO groups and is thus best described as a formally Ru^{-II}, NO^+ complex. Physical measurements performed on this compound include ^{15}N NMR spectro-



scopy (which supports the presence of linear RuNO groups in the solid state and in solution),[1414] XPS studies[1278] and electrochemical studies in MeCN which reveal an irreversible two electron oxidation process. In the presence of excess chloride ion, it gives a stable product (possibly $[RuCl_2(NO)_2(PPh_3)_2]$) from which $[Ru(NO)_2(PPh_3)_2]$ can be electrochemically regenerated.[1415] Some reactions of $[Ru(NO)_2(PPh_3)_2]$ are shown in Scheme 42.

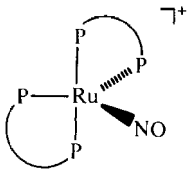
i, X_2;[1413] $PhCH_2Br/\Delta$;[1416] ii, O_2;[1406, 1413] iii, $[RuCl_2(PPh_3)_3]/Zn$;[1413] iv, CF_3CO_2H;[1417] v, SO_2;[1418] vi, air;[1418] vii, CO/100 atm/24 h;[1418, 1419] viii, L_2^{Et} = (EtNCH$_2$CH$_2$NEtC=)$_2$;[1420] ix, air;[1406] x, CO, $PhCH_2Br$, toluene/Δ[1416]



Scheme 42

The ruthenium analogue of Vaska's compound, $[RuCl(NO)(PPh_3)_2]$, can be prepared by reaction of $[RuCl_3NO(PPh_3)_2]$ with Zn dust or Zn/Cu in boiling C_6H_6.[1421–1423] Some of the reactions exhibited by this useful starting material, namely addition of neutral molecules such as alkene, CO, SO_2 *etc.*, chloride displacement by allyl anion or oxidative addition to form Ru^{II} nitrosyls are shown in Scheme 43. Similar studies have been made on $[RuCl(NO)(AsPh_3)_2]$[1434] and the related complexes [RuCl(NO)(L–L)], [RuCl(CO)(NO)(L–L)], [RuCl(NO)(P(OCH$_2$)$_3$CEt)(L–L)] and $[RuCl(CO)(NO)(PPh_2CH_2Ph)_2]$ (L—L = *trans*-spanning 2,11-bis(diphenylphosphinomethyl)benzo[*c*]-phenanthrene) are known.[1435] X-Ray structural analysis on $[Ru(NO)(PPh_3)_2(\eta\text{-}C_3H_5)]$ reveals a distorted tetrahedral structure with an almost linear RuNO group[1423] whereas $[RuCl(NO)_2(PPh_3)_2PF_6$[1432] has a square based pyridimidal structure containing one bent apical and one linear equatorial nitrosyl group (ν_{NO} 1687, 1845 cm^{-1}); recent solid state ^{15}N NMR studies support this conclusion.[1414b] However, ^{15}N NMR studies suggest that in solution an equilibrium mixture of isomeric structures is present,[1277] and that the linear and bent NO ligands undergo rapid intramolecular interconversion.[1436] The sulfate complex $[RuCl(SO_4)NO(PPh_3)_2]$ contains pseudooctahedral ruthenium with *trans* phosphines and a bidentate sulfato group (see Section 45.5.4.6.iii);[1424] $[RuCl(NO)(PPh_3)_2\eta\text{-}SO_2]\cdot CH_2Cl_2$ (**125**)[1427] has a very similar geometry except the η^2-SO_2 is S/O bonded. Another Ru^0 sulfur dioxide complex briefly mentioned in the literature is $[Ru(SO_2)_2(PPh_3)_2]$ (from $[RuH_4(PPh_3)_3]$ and SO_2).[1408,1437]

(125)



A high yield route to the preparation of $[RuCl(CO)(NO)(PPh_3)_2]$ is *via* treatment of [RuHCl(CO)(PPh$_3$)$_3$] with *N*-nitroso-*N*-methyltoluene-*p*-sulfonamide.[1438] The low frequency of the ν(RuCl) bond in the IR spectrum (266 cm^{-1}) indicates a weak Ru—Cl bond and indeed the chloride group is readily replaced by a range of anionic ligands to give $[RuX(CO)NO(PPh_3)_2]$ (X = OH, Br, I, N_3, NCO, NCS, HCO_2).[1438] The iodide has a trigonal bipyramidal geometry[1439] but the other members of the series may be closer to tetragonal pyramidal and may have a bent nitrosyl group.[1438] The dioxygen adducts $[RuX(NO)(O_2)(PPh_3)_2]$ (X = Cl, OH, CN, NCS) can be prepared by treatment of $[RuX(CO)(NO)(PPh_3)_2]$ with O_2.[1440] Reaction of $[RuCl(CO)(NO)L_2]$ (L = PPh_3, PCy_3) with

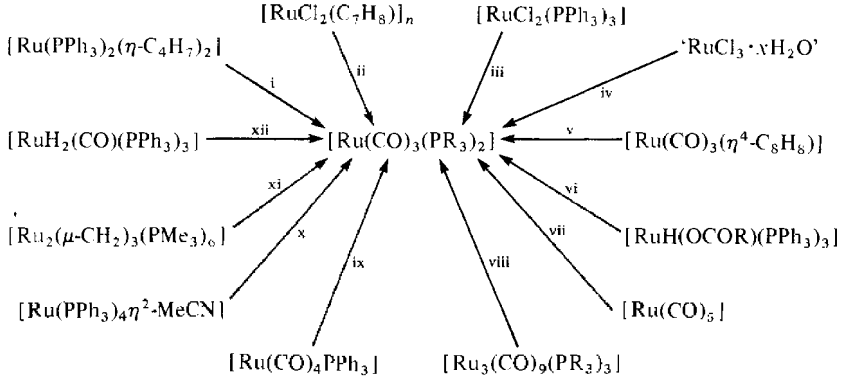
CO in CH_2Cl_2 in the presence of large anions gives $[Ru(CO)_2(NO)L_2]Y$ ($Y = BPh_4$, PF_6). These cations can also be prepared by reaction of $[Ru_3(CO)_9(PPh_3)_3]$ with $NO[PF_6]$ in MeOH. Unlike the isoelectronic $[Ru(CO)_3(PR_3)_2]$, these nitrosyl cations undergo further substitution with PPh_3 to yield $[Ru(CO)NO(PPh_3)_3]^+$. Complete CO replacement is not possible with monodentate phosphines but dppe gives both $[Ru(CO)(NO)PPh_3(dppe)]^+$ and $[Ru(NO)(dppe)_2]^+$. A more convenient route to all these cations is by addition of ligands to the highly reactive solvated species obtained *in situ* by treatment of $[RuCl(CO)(NO)(PPh_3)_2]$ with $Ag[PF_6]$ in acetone. The $[Ru(CO)_2(NO)L_2]^+$ cations react with halide ion (X^-) to regenerate the neutral complexes $[RuX(CO)(NO)L_2]$.[1441]

Crystallographic studies on the $[RuNO(dppe)_2]^+$ and $[RuNO(dppp)_2]^+$ cations[1442] (dppp = $Ph_2P(CH_2)_3PPh_2$) confirm the expected trigonal bipyramidal structure (**126**) with basal almost linear NO groups. Variable temperature ^{31}P NMR studies indicate that these compounds undergo facile intramolecular rearrangement probably *via* a Berry pseudorotation process.[1443]



(126)

The related sterochemically non-rigid hydrido complexes $[RuH(NO)(PR_3)_3]$ can be prepared by refluxing $[RuCl_3(NO)(PR_3)_2]$ with ethanolic KOH in the presence of excess PR_3 (R_3 = Ph_3, Ph_2Me, Ph_2Pr^i, Ph_2Cy).[1444] The $[RuH(NO)(PPh_3)_3]$ complex has a slightly distorted trigonal bipyramidal structure with equatorial PPh_3 groups and a linear NO group.[1442a,1445] The ESCA spectrum of this compound is available.[1446]

45.5.1.3 Carbonyl and/or isocyanide complexes

$[Ru(CO)_3(PPh_3)_2]$ was first prepared by reduction of $[RuCl_2(CO)_2(PPh_3)_2]$ with Zn dust in DMF under four atmospheres pressure of CO.[1447] A number of alternative syntheses have since been developed (Scheme 44) and X-ray analysis has just confirmed its trigonal bipyramidal[1457] structure. $[Ru(CO)_3dppe]$ can be prepared from either $[Ru_3(CO)_{12}]$[1458] or $[Ru(CO)_3(\eta^4\text{-}C_8H_8)]$, the mechanism of the latter involving bimolecular attack of the tertiary phosphine on the substrate.[1450] A high yield synthesis of $[Ru(CO)_3(Ph_2Ppy)_2]$ from $[Ru_3(CO)_{12}]$ is also available.[1459]

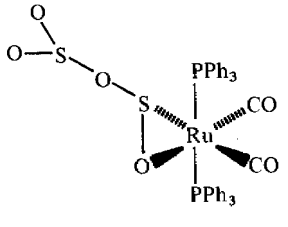
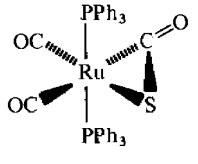


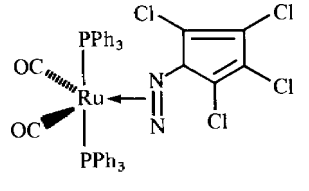
Scheme 44

Treatment of $[Ru(CO)_5]$ with PPh_3 under UV irradiation gives $[Ru(CO)_4PPh_3]$,[1452] also formed by heating $[Ru_3(CO)_9(PPh_3)_3]$ with CO under pressure[1453,1460] or more conveniently (along with $[Ru(CO)_3(PPh_3)_2]$) by photolysis of $[Ru_3(CO)_{12}]$ and PPh_3 in hexane. The latter route can be extended to PBu^n_3 and $PMePh_2$ derivatives.[1461a] An almost quantitative yield of $[Ru(CO)_4PPh_3]$ is obtained from the carbonylation under pressure of $[Ru(CO)_3(PPh_3)_2]$[1461b] or $[Ru(NO)_2(PPh_3)_2]$.[1418,1419] The reaction of $[Ru_3(CO)_{12}]$ with PBu^t_3 is solvent dependent; in boiling *n*-butanol $[Ru(CO)_4(PBu^t_3)]$ is isolated, whereas in MeOH, the sole product is $[Ru(CO)_3(PBu^t_3)_2]$.[1462] X-Ray analyses of $[Ru(CO)_4\{P(OMe)_3\}]$[1463] and $[Ru(CO)_4(AsPh_3)]$[1464] reveal a trigonal bipyramidal structure with an axial non-carbonyl ligand. In contrast, $[Ru(CO)_4(SbPh_3)]$ (from $[Ru_3(CO)_{12}]$ and $SbPh_3$ irradiated in *n*-hexane) has a trigonal bipyramidal structure with an equatorial $SbPh_3$ group.[1465] The corresponding $[Ru(CNBu^t)_4PPh_3]$ (trigonal bipyramidal structure with an equatorial PPh_3 group) is also known.[1466] IR studies however indicate that both axial and equatorial isomers are present in solution for $[Ru(CO)_4(EPh_3)]$ (E = As, Sb) and it is believed that the σ donor properties of EPh_3 are an important factor in determining the site preference.[1464]



Under high pressures (35 atm/160°C/12 h) of PF_3, $[Ru_3(CO)_{12}]$ reacts to give mononuclear $[Ru(CO)_{5-n}(PF_3)_n]$ (n = 3,4 and 5) with only traces of n = 1 or 2. Increasing the CO content only increases the amounts of complexes with n = 3 and 4; in the absence of added CO, $[Ru(PF_3)_5]$ (see Section 45.5.1.1) is formed, in 95% yield. All these mononuclear species are fluxional (^{19}F NMR evidence) and their IR spectra show that a mixture of all possible isomers is obtained.[1383]

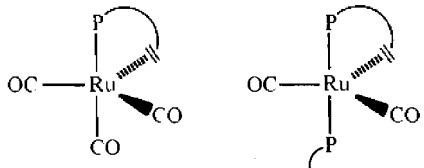
Similar stepwise displacement of CO from $[Ru_3(CO)_{12}]$ with $P(OMe)_3$ (under UV irradiation) can be monitored by ^{31}P NMR spectroscopy. This shows evidence for $[Ru(CO)_{5-n}\{P(OMe)_3\}_n]$ (n = 1–5) intermediates. The stable $[Ru(P(OMe)_3)_5]$ is ultimately isolated (see Section 45.5.1.1).[1380]



The very reactive compound $[Ru(CO)_2(PPh_3)_3]$ is synthesized either by deprotonation of $[RuH(CO)_2(PPh_3)_3]^+$,[1467] reaction of $Li[OEt]$ with $[Ru(N_2C_6H_4R)(CO)_2(PPh_3)_2]^+$[1468] or by reaction of $[Ru(\eta^2\text{-MeCN})(PPh_3)_4]$ with a deficiency of CO.[1403] It is probably trigonal bipyramidal with axial CO groups and readily adds hydrogen to give *cis*-$[RuH_2(CO)_2(PPh_3)_2]$;[1467] the hydrogen is displaced by π acceptor ligands to give $[Ru(CO)_2(PPh_3)_2L]$ (L = O_2, CO, C_2H_4, CH_2=CHCN).[1467,1469] A wide range of other ruthenium complexes of type $[Ru(CO)_2(PR_3)_2L]$, (*e.g.* L = CS_2,[1470] CSe_2,[1470] S_2,[1471] R'NCO,[1472] NHCOR,[1472] R'NCONR',[1472] $CF_3CHFCF_2N_3$,[1473] SO_2,[1474] C_2F_4,[1475] $(CN)_2C(CF_3)_2$,[1475] $(CF_3)_2C$=O,[1475] RNCS[1476]), are readily synthesized from either $[Ru(CO)_2(PPh_3)_3]$ or $[Ru(CO)_3(PR_3)_2]$. Low temperature crystallography[1477] on the SO_2 compound (**127**) shows the presence of a second molecule of SO_2 coordinated to the terminal oxygen of the η^2-SO_2 group. Reaction of $[Ru(CO)_3(PPh_3)_2]$ with COS first gives $[Ru(CO)_2(PPh_3)_2(\eta^2\text{-COS})]$ (**128**) which with additional COS produces $[Ru(S_2CO)(CO)_2(PPh_3)_2]$; reaction of (**128**) with PPh_3 gives $[Ru(CO)_3(PPh_3)_2]$ and $SPPh_3$.[1478] The complexes $[Ru(CO)_2(PPh_3)_2N_2R]$ (**129**) shown by X-ray analysis (for R = C_5Cl_4) to have η^2-coordination of the diazo group are prepared from $[Ru(CO)_2(PPh_3)_2(C_2H_4)]$ and the appropriate diazo derivative.[1479] Other diazenido complexes are discussed in Section 45.5.4.6.iv.

(127)

(128)



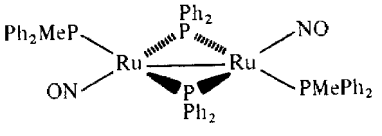
(129)

The zerovalent isocyanide complexes $[Ru(CO)_2(CNp\text{-Tol})(PPh_3)_2]$ and $[Ru(CO)(CNp\text{-Tol})(PPh_3)_3]$ can be prepared by deprotonation of the cationic hydride complexes $[RuH(CO)_2(CNp\text{-Tol})(PPh_3)_2]^+$ and $[RuH(CO)(CNp\text{-Tol})(PPh_3)_3]^+$ respectively. The latter reacts with O_2 to give $[Ru(CO)(CNp\text{-Tol})(O_2)(PPh_3)_2]$ whereas in the former, one of the CO ligands is oxidized to give the ruthenium carbonate $[Ru(CO_3)(CO)(CNp\text{-Tol})(PPh_3)_2]$.[1480] Reaction of $[Ru(CO)(CNR)(PPh_3)_3]$ (R = *p*-Tol, *p*-$MeOC_6H_4$) or $[Ru(CO)_2(PPh_3)_3]$ with electrophilic alkenes such as fumaronitrile, maleonitrile *etc.* gives $[Ru(CO)Y(PPh_3)_2(alkene)]$ (Y = CO, CNR). The dicarbonyl compounds exist as two geometric isomers in solution and interchange by a combined alkene rotation–Berry mechanism.[1481] $[RuCO(CNp\text{-Tol})(PPh_3)_3]$ is also obtained by dehydrochlorination of $[RuHClCO(CNp\text{-Tol})(PPh_3)_2]$ with 1,8-diazabicyclo[5.4.0]undec-7-ene in the presence of PPh_3; similar treatment of $[RuHCl(CO)(PPh_3)_3]$ in a CO atmosphere gives $[Ru(CO)_3(PPh_3)_2]$.[1482] Further reactions of $[Ru(CO)_3(PPh_3)_2]$ and $[Ru(CO)_2(PPh_3)_3]$ which involve oxidation to Ru^{II} are discussed

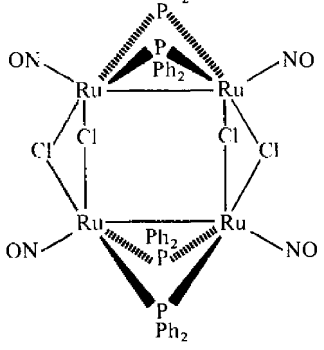
in Section 45.5.4 and monomeric Ru^0 carbonyl phosphine complexes containing NO groups, *e.g.* $[RuX(CO)NO(PPh_3)_2]$, $[Ru(CO)_2NO(PPh_3)_2]^+$, are covered elsewhere (Section 45.5.1.2). Reference 1 p.932 contains a review on the catalytic properties of $[Ru(CO)_3(PPh_3)_2]$.

Related species with bi- and multi-dentate P and As donor ligands include $[Ru(CO)_3f_6fos]$ {$f_6fos = (CF_2)_3C(PPh_2)=C(PPh_2)$},[1483] $[Ru(CO)_3L—L]$ (L—L = dppe[1450,1458] and *trans*-spanning 2,11-bis(diphenylphosphinomethyl)benzo[*c*]phenanthrene),[1484] $[Ru(CO)_2MeC(CH_2PPh_2)_3]$,[1485] $[Ru(CO)_2PhE(o\text{-}C_6H_4EPh_2)_2]$ (E = P, As) and $[Ru(CO)\ E(o\text{-}C_6H_4EPh_2)_3]$ (E = P, As).[46] All these compounds are obtained by treatment of $[Ru_3(CO)_{12}]$, (or sometimes $[Ru(CO)_3(PPh_3)_2]$), with the appropriate ligand and are believed to have trigonal bipyramidal structures. $[Ru(CO)_2ttp]$ and $[Ru(CO)_2(Cyttp)]$ [tpp = $PhP\{(CH_2)_3PPh_2\}_2$; Cytpp = $PhP\{(CH_2)_3PCy_2\}_2$] have been synthesized both from $[Ru_3(CO)_{12}]$ and by Na/Hg reduction of $[RuCl_2(ttp)]$, $[RuCl_2(Cyttp)]$, $[Ru(CO)_2(ttp)](BF_4)_2$ or $[RuH(CO)_2(tpp)]BF_4$.[1486] The very air sensitive $[Ru(CO)(dppe)_2]$ can be prepared by decarboxylation of $[Ru(O_2CH)Me(CO)(PPh_3)_2]$ in the presence of dppe,[1487] whereas the analogous $[Ru(CO)(dmpe)_2]$ is obtained by carbonylation of $[RuH(2\text{-}np)(dmpe)_2]$.[1388] Reaction of $[Ru(\eta^2\text{-}MeCN)(PPh_3)_4]$ with a deficiency of CO is also claimed to give $[Ru(CO)(PPh_3)_4]$.[1403] Treatment of $[Ru(dppm)_2(cod)]$ with CO gives $[Ru(CO)(dppm)(cod)]$ and $[Ru(CO)_2(dppm)(cod)]$.[1399]

Reaction of $o\text{-}CH_2{=}CHC_6H_4PPh_2$ (SP) with $[Ru_3(CO)_{12}]$ gives $[Ru(CO)_3SP]$ (**130**) and $[Ru(CO)_2(SP)_2]$ (**131**), the proportions of which depend on the ratio of reactants. An excess of SP reacts with $[Ru_3(CO)_{12}]$ to give $[Ru(CO)(SP)_2]$ which has a trigonal bipyramidal structure with the vinyl groups and CO coordinated in the equatorial plane.[1488] Reaction of $o\text{-}Ph_2PC_6H_4CH{=}CHCHMeC_6H_4PPh_2$ (1-BDPB) with $[Ru_3(CO)_{12}]$ gives $[Ru(CO)_2(1\text{-}BDPB)]$ in which the P atoms are believed to span the axial position of a trigonal bipyramid.[1489]



(130) (131)



45.5.2 Bi-, Tri- and Tetra-nuclear Ruthenium(0) Complexes

45.5.2.1 Nitrosyl complexes

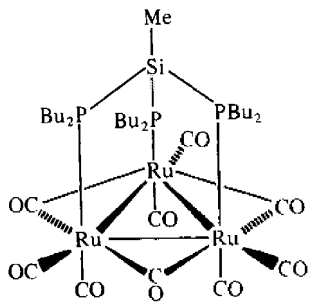
The reaction of $[RuCl_3(NO)(PMePh_2)_2]$ with Ph_2PH and a Zn/Cu couple yields the binuclear phosphido-bridged complex $[Ru(NO)(\mu\text{-}PPh_2)(PMePh_2)]_2$ (**132**); the tetranuclear species (**133**) (formally a mixed Ru^0/Ru^{II} complex) is also obtained in poor yield. Compound (**132**) can also be obtained from $[RuH(NO)(PMePh_2)_3]$,[1490,1491] and the PPh_3 analogue is known.[1491,1492]

(132)

(133)

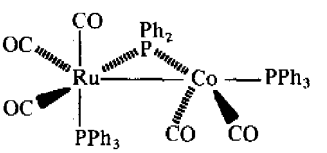
Kinetic studies on the reaction of $[Ru_3(CO)_{10}(NO)_2]$ with PPh_3 suggest a dissociative process involving stepwise displacement of CO to give first $[Ru_3(CO)_9(NO)_2PPh_3]$ and then $[Ru_3(CO)_8(NO)_2(PPh_3)_2]$.[1493] The ^{13}C NMR spectrum of the latter shows that it is the equatorial CO groups in $[Ru_3(CO)_{10}(NO)_2]$ which are replaced.[1494] $[(Ph_3P)_2N][Ru_3(CO)_{10}NO]$ has been synthesized in high yield by reaction of $[(Ph_3P)_2N]NO_2$ with $[Ru_3(CO)_{12}]$.[1495]

45.5.2.2 Carbonyl complexes



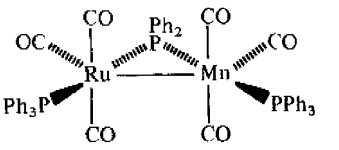
A substantial amount of work has been published on the reactions of $[Ru_3(CO)_{12}]$ particularly with P donor ligands and this is very thoroughly reviewed in references 1 and 3–5. The usual products from thermal reaction of $[Ru_3(CO)_{12}]$ with PR_3 are $[Ru_3(CO)_9(PR_3)_3]$, the mono- and di-substituted derivatives normally not being isolated unless bulky phosphines such as PCy_3 are used. With phosphines with small substituents *e.g.* PH_3, PMe_3 it is also possible to isolate $[Ru_3(CO)_8(PR_3)_4]$. Likewise reaction of $[Ru_3(CO)_{12}]$ with PF_3/CO mixtures gives in addition to $[Ru(CO)_{5-n}(PF_3)_n]$ (Section 45.5.1.3) a less volatile residue of red crystals identified by mass spectrometry as a mixture of $[Ru_3(CO)_{12-n}(PF_3)_n]$ (n = 1–6).[1383] Similar results are obtained with AsR_3 although fewer data are available. For SbR_3, only a cursory mention of $[Ru_3(CO)_9(SbPh_3)_3]$ appears in the literature.[1496]

However, it has been shown that an excellent route to many $[Ru_3(CO)_{12-n}L_n]$ (n = 1–4) species is *via* the radical anion $[Ru_3(CO)_{12}]^-$, generated by addition of sodium diphenylketyl. An extensive list of products obtained by this novel method is given in ref. 1497a and X-ray structures of $[Ru_3(CO)_{11}PCy_3]$, $[Ru_3(CO)_{10}\{P(OMe)_3\}_2]$, $[Ru_3(CO)_9(PMe_3)_3]$[1498] and $[Ru_3(CO)_{10}Ph_2PCH_2PPh_2]$[1499a] are now available. These reactions also provide routes to mixed ligand derivatives such as $[Ru_3(CO)_9(PMe_3)(PPh_3)P(OMe)_3]$ and $[Ru_3(CO)_9(PMe_3)(dppe)]$. Studies have shown that irradiation of $[Ru_3(CO)_{12}]$ and PMe_2Ph in THF containing $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ gives $[Ru_3(CO)_{11}PMe_2Ph]$.[1499b] Detailed electrochemical studies on $[Ru_3(CO)_{12}]$ are also reported.[1499c]



As discussed elsewhere (references 1, 3–5 and Section 45.5.1.3), reactions between $[Ru_3(CO)_9(PR_3)_3]$ and CO or PR_3 result in break-up of the cluster with formation of $[Ru(CO)_4PR_3]$ and $[Ru(CO)_3(PR_3)_2]$ respectively. The extensive kinetic studies on these substitution and dissociative reactions are reviewed in reference 1, p. 878. There is a paper which details the characterization and photochemistry of SiO_2-modified $LRu(CO)_4$ and $L_3Ru_3(CO)_9$ (L = $PPh_2(CH_2)_2Si(OEt)_3$), prepared from $[Ru(CO)_4L]$ and $[Ru_3(CO)_9L_3]$ respectively with a hydrocarbon suspension of SiO_2.[1500]

Related trinuclear carbonyl complexes $[Ru_3(CO)_{10}(L\text{–}L)]$ can be synthesized from thermal reactions of $[Ru_3(CO)_{12}]$ and L–L (*e.g.* L–L = dppm,[1501] dppe[1502]) and with $MeSi(PBu_2)_3$[1503] the 'capped' $[Ru_3(CO)_9\{(Bu_2P)_3SiMe\}]$ (**134**) is formed. Again, the radical ion-initiated route provides a better method to the above and also $[Ru_3(CO)_8(L\text{–}L)_2]$ (dppm, dpam) and the dppm bridged $[Ru_3(CO)_{11}]_2$dppm.[1497a] Reaction of $[Ru_3(CO)_{12}]$ with an equimolar amount of $(RO)_2PNR'P(OR)_2$ gives $[Ru_3(CO)_{10}\{\mu\text{-}(RO)_2PNR'P(OR)_2\}]$ which reacts further with excess ligand under UV irradiation to give $[Ru_2(\mu\text{-}CO)(CO)_4\{\mu\text{-}(RO)_2PN(R')P(OR)_2\}_2]$.[1497b] Treatment of $[Ru_3(CO)_8(dppm)_2]$ with $Ag(OCOCF_3)$ gives the adduct $[Ru_3(CO)_8(dppm)_2][\mu\text{-}Ag(O_2CCF_3)]$.[1497c] With the fluorocarbon tertiary phosphine or arsine ligands (ffos, ffars or $f_6$fos), thermal reaction with $[Ru_3(CO)_{12}]$ under mild conditions gives $[Ru_3(CO)_{12-2n}(L\text{–}L)_n]$ (n = 1 and 2); refluxing in toluene for several hours produces $[Ru_2(CO)_6(L\text{–}L)]$ and on irradiation $[Ru(CO)_3L\text{–}L]$ is formed.[1483]



A number of interesting heterobimetallic carbonyl complexes containing phosphido bridges have been synthesized. These include $[RuCo(\mu\text{-}PPh_2)(CO)_5(PPh_3)_2]$ (**135**) made by reaction of $[RuHCl(CO)(PPh_3)_3]$ with $Na[Co(CO)_4]$. The Ru—Co bond length of 2.05 Å implies a single bond between the atoms. Stepwise displacement from (**135**) of PPh_3 by CO gives $[RuCo(\mu\text{-}PPh_2)(CO)_6PPh_3]$ and $[RuCo(\mu\text{-}PPh_2)(CO)_7]$ respectively whereas with HCl two isomers of $[RuCoHCl(\mu\text{-}PPh_2)(CO)_4]$ are formed.[1504] Treatment of $[RuCl_2(PPh_2Cl)(p\text{-cymene})]$ with $[Co_2(CO)_8]$ provides an alternative route to $[RuCo(\mu\text{-}PPh_2)(CO)_7]$.[1505a] Reaction of $[RuCo(\mu\text{-}PPh_2)(CO)_7]$ with $NaBH_4$ gives $[RuCoH(\mu\text{-}PPh_2)(CO)_6]^-$ shown by X-ray analysis to have a terminal Ru—H linkage *cis* to the μ-PPh_2 group.[1505b] Preliminary results on the related binuclear Ru—Mn complexes $[RuMn(\mu\text{-}PPh_2)(CO)_6(PPh_3)_2]$ (**136**) and $[RuMnCl(\mu\text{-dppm})_2(\mu\text{-}CO)_2(CO)_3]$ (**137**), isolated from reaction of $Na[Mn(CO)_5]$ with $[RuCl_2(PPh_3)_3]$ and *cis*-$[RuCl_2(dppm)_2]$ respectively have been published.[1506] Reaction of $[Ru(dppm)_2cod]$ with $[RuCl(CO)_2]_2$[1507a] in the presence of excess CO at 70°C produces the binuclear $[RuRhCl(\mu\text{-}CO)(dppm)_2]$ (**138**), whereas $[RuH_2(dppm)_2]$ and $Mo(CO)_6$ give $[RuMo(\mu\text{-dppm})_2(CO)_6]$ which has an interesting chemistry.[1507b]

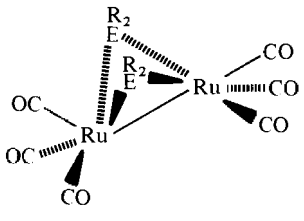
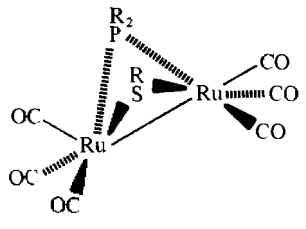
45.5.3 Ruthenium(I) Complexes

45.5.3.1 Mononuclear complexes



There are very few monomeric Ru^I complexes containing P or As donor ligands; dimerization with formation of a metal–metal bond is preferred in most instances. Brief references are made to $[RuCl_2(NO)(PPh_3)_2]$ obtained as a minor side-product in the preparation of $[RuCl_3NO(PPh_3)_2]$[1508] and also by reaction of $[RuCl_2NO(PPh_3)]_2$ with PPh_3.[1329] This product shows an ESR spectrum indicative of a paramagnetic $Ru^I(d^7)$ complex. However, reaction of $[RuI_2(NO)]_n$ with $AsMePh_2$ gives a compound of empirical formula '$[RuI_2NO(AsMePh_2)_2]$' which is essentially diamagnetic and is therefore tentatively formulated as the metal–metal bonded dimer $[RuI_2(NO)(AsMePh_2)_2]_2$.[1509]

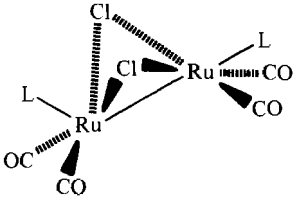
Electroreduction of $[RuCl(dppp)_2]PF_6$ leads to the Ru^I species $[RuCl(dppp)_2]$ and then the Ru^0 anion $[RuCl(dppp)_2]^-$ although only the *ortho*-metallated product $[\overline{RuH(C_6H_4PPh(CH_2)_3PPh_2)}\text{-}(dppp)]$ was isolated;[1509a] $[Ru(NO)(dppp)_2]^+$ also undergoes two reversible reductions.[1510]



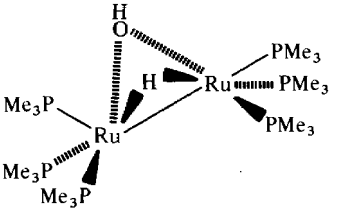
A series of compounds such as $[RuCl_2(NO)(AsMePh_2)_3]$, $[RuCl_2NO(DMSO)L_2]$, (L = $AsPh_3$, $SbPh_3$, $AsMePh_2$, $AsMe_2Ph$) and $[RuCl_2NO(L\text{–}L)_2]$ (L–L = dppm, dpae) have been reported. These have been formulated as Ru^{II} species but have ν_{NO} bands characteristic of NO^+ (!!).[1511] A further critical examination of these complexes is very desirable.

45.5.3.2 Bi- and tetra-nuclear complexes

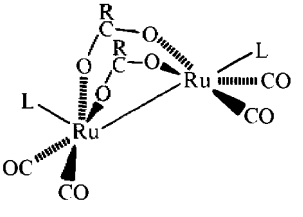
In contrast to Ru^0, Ru^{III} and especially Ru^{II}, relatively few Ru^I complexes containing P or As donor ligands are reported. Reaction between $[Ru_3(CO)_{12}]$ and E_2R_4 in C_6H_6 gives $[Ru(\mu\text{-}ER_2)(CO)_3]_2$ (**139**) (E = P, As; R = Me, C_6F_5).[1512–1514] Reduction of (**139**; $ER_2 = PMe_2$) produces the Ru^0 diamagnetic dianion; a paramagnetic radical anion (formally $Ru_2^{I,0}$ is formed on mixing (**139**) with its dianion and analysis of the NMR spectra of the latter and the ESR spectrum of the radical anion indicates that the general geometry, including the Ru—Ru bond, is preserved in all three complexes. Iodine cleaves the Ru—Ru bond of (**139**; $ER_2 = PMe_2$) to give the Ru^{II} dimer $[RuI(\mu\text{-}PMe_2)(CO)_3]_2$.[1515] The complex (**139**) ($ER_2 = PPh_2$) has been synthesized, together with various trinuclear hydrido complexes, by irradiation (> 300 nm) of $[Ru_3(CO)_9(PPh_2H)_3]$.[1516] The mixed P- and S-bridged complex $[Ru_2(\mu\text{-}PPh_2)(\mu\text{-}SPh)(CO)_6]$ (**140**) is obtained from $[Ru_3(CO)_{12}]$ and Ph_2PSPh by cleavage of the P—S bond.[1517]



(139)

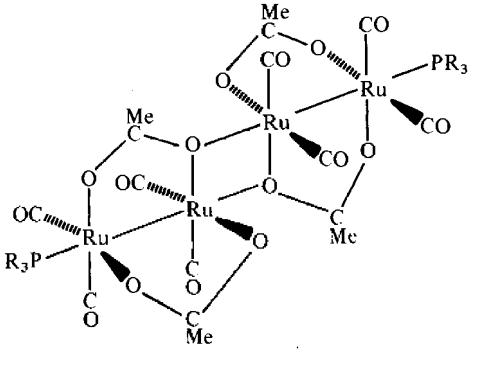


(140)

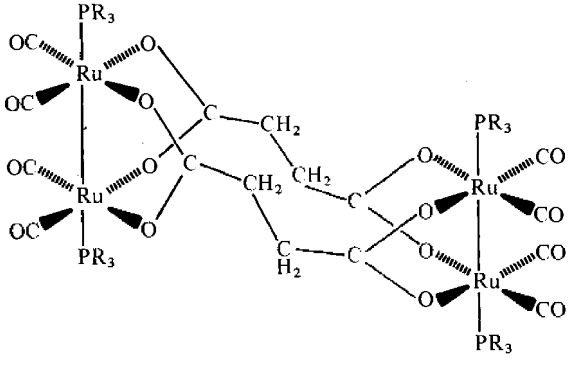


Closely related binuclear Ru^{I} complexes $[Ru(\mu\text{-}Cl)(CO)_2(PBu^t{}_2R)]_2$ (**141**) are generated by reaction of the 'Ru(CO)Cl' solution with the bulky phosphines $PBu^t{}_2R$ (R = Bu^t, Ph or *p*-Tol).[1518,1520] With smaller substituents, $[RuCl_2(CO)_2(PR_3)_2]$ are formed (see Section 45.5.4.5.i). Compounds (**141**) undergo facile PR_3 exchange to yield $[Ru_2(\mu\text{-}Cl)_2(CO)_4(PR_3)(PR'_3)]$ and metathetical reactions with heavier halides give the bromo and iodo analogues; $[Ru(\mu\text{-}I)(CO)_2(PPh_3)]_2$ is also formed by reaction of $[Ru_2(\mu\text{-}Cl)_2(\mu\text{-}Fe(CO)_4)(CO)_4(PPh_3)_2]$ (Section 45.5.5) with KI[1519a] whereas interaction of $[Ru_2(CH_2)_3(PMe_3)_6]$ (Section 45.5.8) with water gives $[Ru_2(\mu\text{-}H)(\mu\text{-}OH)(PMe_3)_6]$ (**142**).[1521] [Ag(OCOMe)] and (**141**) produce $[Ru(\mu\text{-}OCOMe)(CO)_2(PBu^t{}_2R)]_2$ (**143**), and other routes to these carboxylate compounds are by reaction between $[Ru_3(CO)_{12}]$ and RCO_2H in the presence of $PBu^t{}_3$,[1522] treatment of $[Ru_3(CO)_9(PPh_3)_3]$ with $MeCO_2H$[1523] or reaction of $[Ru(OCOR)(CO)_2]_n$ with equimolar amounts of L (L = PBu_3, PPh_3, $P(p\text{-}C_6H_4F)_3$, $AsPh_3$; R = H, Me, Et — not all combinations).[1524] The corresponding $[Ru(\mu\text{-}OMe)(CO)_2(PBu^t{}_3)]_2$ is readily obtained from reaction of $[Ru(CO)_3(PBu^t{}_3)_2]$ with MeOH.[1522a,1520]

(141)

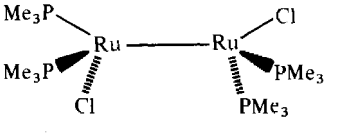


(142)



(143)

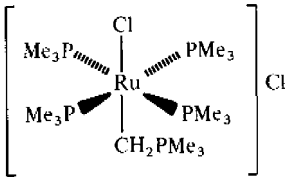
Reaction of $[Ru(OCOMe)(CO)_2]_n$ with PBu_3 (2:1 mole ratio of Ru:P) at 150°C in C_6H_6 has yielded the tetrameric $[Ru_4(OCOMe)_4(CO)_8(PBu_3)_2]$ (**144**) together with a minor amount of (**143**). Compound (**144**) can also be prepared by reacting $[Ru(OCOMe)(CO)_2]_n$ with (**143**) in C_6H_6 at 150°C. Treatment of the tetramer (**144**) with the stoichiometric amounts of PBu_3 then gives (**143**). Similarly $[Ru_3(CO)_{12}]$ and glutaric acid in boiling toluene give $[Ru_2(OCO(CH_2)_3OCO)(CO)_4]_n$ which on treatment with PBu_3 (1:1 mole ratio of Ru:P) yields $[Ru_4(OCO(CH_2)_3OCO)_2(CO)_8(PBu_3)_4]$ (**145**). X-Ray analyses of (**144**) and (**145**) reveal that the structures consist of couples of dimers linked by carboxylate groups.[1525,1526] The corresponding $[Ru_4(OCO(CH_2)_nOCO)_2(PBu_3)_4]$ (n = 0–2) are also known.[1527]



Another Ru^{I}/PR_3 complex is $[RuCl(PMe_3)_2]_2$ obtained in low yield from the reaction of $[Ru_2(OCOMe)_4Cl]$ and $[Mg(MeOC_6H_4)_2]$ in the presence of excess PMe_3[1528] and formulated as the dimer (**146**) on the basis of its diamagnetism, ^{31}P NMR and far IR spectra.[1529] The binuclear Ru^{I} nitrosyls $[RuI_2NO(AsMePh_2)_2]_2$ and $[RuCl_2NO(PPh_3)]_2$ are covered in Section 45.5.3.1.

(144)

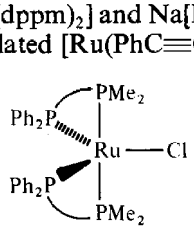
(145)



(146)

For completion, although carbocyclic ring complexes are not the province of this review, $[Ru_2(CO)_3PR_3(\eta\text{-}C_5H_5)_2]$, made by treatment of $[Ru(CO)_2(\eta\text{-}C_5H_5)]_2$ with PR_3, are other formally Ru^I binuclear complexes.[1530]

45.5.4 Mononuclear Ruthenium(II) Complexes



45.5.4.1 $[RuL_6]^{2+}$, $[RuXL_n]^+$ (n = 4,5), $[RuX(L\text{–}L)_2]^+$, $[RuL']^{2+}$ cations (X = halide, alkyl etc.)

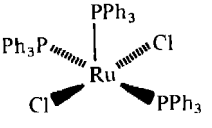
To date the only routes to the fully substituted cations $[RuL_6]^{2+}$ are by reaction in MeOH of $[RuX_2(nbd)]_n$[1531,1532] (X = Cl, Br) or $[RuCl_2(PPh_3)_3]$[1533] with an excess of $P(OMe)_3$ or $P(OMe)_2Ph$. For L = $P(OMe)_3$, some $[RuCl\{P(OMe)_3\}_5]^+$ is also isolated from the mother liquor. If less $P(OMe)_2Ph$ is used, the binuclear cations $[Ru_2X_3(P(OMe)_2Ph)_6]^+$ are formed, (see Section 45.5.5.1), and these are the only products isolated on reaction of $[RuX_2(nbd)]_n$ with bulkier PR_3 groups such as $P(OEt)_3$, $P(OEt)_2Ph$, $P(OR)Ph_2$ (R = Me, Et).[1531,1532] Reaction of $[Ru\{P(OMe)_3\}_5]$ or $[RuMe\{P(O)(OMe)_2\}\{P(OMe)_3\}_4]$ with MeI gives $[RuMe\{P(OMe)_3\}_5]I$,[1380] and one of the products from the reaction of *trans*-$[RuCl_2(PMe_3)_4]$ with the lithiated ylide $Li[Me_2P(CH_2)_2]$ is $[RuCl(PMe_3)_4(CH_2\text{-}PMe_3)]Cl$ (**147**).[1380,1534]

(147)

Treatment with $Ph_3C[BF_4]$ of the reaction mixture from $[Ru_2(OCOMe)_4Cl]$, $[Hg(MeOC_6H_4)_2]$ and PMe_3 gives $[RuCl(PMe_3)_4]BF_4$ ($^{31}P\text{-}\{^1H\}$ NMR spectrum is a sharp singlet), formulated as a fluxional five-coordinate monomer. A compound of empirical formula $[RuCl(PMe_3)_4]Cl$ is also obtained from *trans*-$[RuCl_2(PMe_3)_4]$ left in C_6H_6 for several weeks. However its $^{31}P\text{-}\{^1H\}$ NMR spectrum consists of an A_2X_2 pattern at ambient temperature which suggests that it is the binuclear dication $[RuCl(PMe_3)_4]_2Cl_2$.[1529] The analogous cations $[RuCl(P(OMe)Ph_2)_4]^+$ and $[RuCl(P(OEt)Ph_2)_4]_2^{2+}$ can be synthesized by reaction of $[RuCl_2(PPh_3)_3]$ or $[RuCl_2(P(OR)Ph_2)_3]$ with an excess of $P(OR)Ph_2$ in EtOH. These undergo further rearrangement to form $[Ru_2Cl_3(P(OMe)Ph_2)_6]^+$ and $[Ru_3Cl_5(P(OEt)Ph_2)_9]^+$ respectively (see Section 45.5.5.1).[1533] The deeply coloured pentacoordinate cations $[RuX(L\text{—}L)_2](PF_6)$ (L—L = dppp, 2-(diphenylphosphinoethyl)pyridine; X = Cl, Br) are formed by treatment of *trans*-$[RuX_2(L\text{—}L)_2]$ with ethanolic solutions of $NH_4[PF_6]$, and these take up small neutral ligands to give *trans*-$[RuXL'(L\text{–}L)_2]PF_6$ (L′ = CO, MeCN).[1535] Five-coordinate cations are not obtained by this route with the less bulky dppm or dppe ligands,[1535] but they have been prepared for the unsymmetrical diphosphine ligands $Ph_2P(CH_2)_3PMe_2$ and $Ph_2P(CH_2)_3PMePh$. Non-fluxional trigonal bipyramidal structures (**148**) are proposed on the basis of ^{31}P NMR spectral studies.[1536a] However, there is evidence for square pyramidal geometry (when L = PMe_2Ph).[1536b] Preliminary studies have also indicated that one of the products from reaction of *cis*-$[RuCl_2(dppm)_2]$ and $Na[Mn(CO)_5]$ in THF is the very air-sensitive $[RuCl(dppm)_2THF]Mn(CO)_5$.[1506] The related $[Ru(PhC{\equiv}C)(PMe_2Ph)_5]PF_6$ is known.[1537]

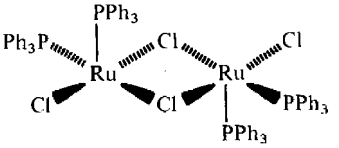
(148)

A number of Ru^{II} cations containing polydentate P or As donor ligands have been reported. For example, prolonged reflux of $[RuCl_2(PPh_3)_3]$ in C_6H_6 with the hexatertiary phosphine *P,P,P′,P′*-tetrakis(2-diphenylphosphinoethyl)-α,α′-diphospha-*p*-xylene (TDDX) gives as the main product the binuclear $[Ru_2Cl_4(PPh_3)_2(TDDX)]$ (see Section 45.5.5.3), but treatment of the filtrate



with $NH_4[PF_6]$ precipitates some $[Ru(TDDX)](PF_6)_2$ in which pentadentate coordination of the ligand is tentatively suggested.[1538] The corresponding ligand *As,As,As',As'*-tetrakis(2-diphenylarsinoethyl)α,α'-diphospha-*p*-xylene (TDADX) gives the chocolate brown [RuCl(TDADX)]Cl under the same conditions. In this case TDADX acts as a tetradentate ligand which may be coordinated to a single Ru^{II} atom either through one P and three As or through all four As atoms. Carbonylation yields [RuCl(CO)(TDADX)]Cl.[1539] The five-coordinate cation [RuCl(tet-1)]Cl (tet-1 = $Ph_2P(CH_2)_2PPh(CH_2)_2P(Ph)(CH_2)_2PPh_2$) is also obtained by reaction of $[RuCl_2(PPh_3)_3]$ with tet-1 in dry C_6H_6, and again carbonylation affords [RuCl(CO)(tet-1)]Cl. In contrast, direct reaction of $[RuCl_2(DMSO)_4]$ with either tet-1 or tet-2 $\{P[(CH_2)_2PPh_2]_3\}$ in C_6H_6/MeOH gives the S-bonded DMSO cations [RuCl(DMSO)tet]Cl.[1540]

45.5.4.2 [RuXYL$_n$] complexes (n = 2,3,4; X,Y = halide)



(i) L = monodentate P donor ligand

The products of reaction of tertiary phosphines with '$RuCl_3 \cdot xH_2O$' are very dependent upon the nature of PR_3 and the reaction conditions. Thus with an excess of PPh_3 in MeOH,[106,1541] EtOH[1542] or isopropanol[1542] at reflux for several hours, red-brown $[RuCl_2(PPh_3)_3]$ is formed whereas shaking the reaction mixture at room temperature yields $[RuCl_2(PPh_3)_4]$[106] (shown by $^{31}P\text{-}\{^1H\}$ NMR studies[1543,1544] to be best formulated as $[RuCl_2(PPh_3)_3 \cdot PPh_3]$ with one PPh_3 group trapped in the lattice). Prolonged reaction at room temperature in MeOH using a 1:2 molar ratio of Ru to PPh_3 gives green $[RuCl_3(PPh_3)_2MeOH]$[106] (see Section 45.5.7.1), whereas these reactants in isobutanol or cyclohexanol yield black, polymeric $[RuCl_2(PPh_3)_2]_n$[1542] (which can also be made by heating $[RuCl_2(PPh_3)_3]$ under reflux in methyl ethyl ketone,[1545] or by reduction of $[RuCl_3(PPh_3)_2MeOH]$ with hydrogen).[1546,1547] Solvents such as 2-methoxyethanol and benzyl alcohol take part in the reaction producing $[RuHCl(CO)(PPh_3)_3]$ (see Section 45.10.3.2.iii)[1542,1548] and $[RuCl_2(CO)(PPh_3)_3]$ (Section 45.5.4.5.i)[1542] respectively.

Other routes to $[RuCl_2(PPh_3)_3]$ include the treatment of $[RuH_2(N_2)(PPh_3)_3]$ or $[RuH_2(PPh_3)_4]$ with HCl[1549] or reaction of $Cs[Ru(\eta\text{-}C_6H_6)Cl_3]$[1550] (or the reduced 'ruthenium blue' solution)[676] with PPh_3. An X-ray structural analysis confirms the five-coordinate structure (**149**); a distorted square pyramidal structure with one of the phenyl *ortho* hydrogens blocking the sixth coordination position.[1551] Osmometric molecular weight studies in acetone on $[RuCl_2(PPh_3)_n]$ ($n = 3,4$)[106] suggest extensive dissociation in solution and spectrophotometric measurements in deoxygenated C_6H_6 supported these conclusions (equations 96 and 97).[1552] However, variable temperature ^{31}P NMR studies indicate that the dissociation product $[RuCl_2(PPh_3)_2]_n$ is a five-coordinate dimer (**150**) ($n = 2$) rather than a four-coordinate monomer ($n = 1$) and equation (98) rather than (97) is a better representation of the species present in non-polar media.[1543,1544] Note that the different ^{31}P NMR spectrum of '$RuCl_2(PPh_3)_2$' reported later by Vrieze *et al.*[1553] is in fact a spectrum of $[RuCl_2(PPh_3)_2(2\text{-}MeCOC_5H_4N)]$.[1554] The ^{31}P NMR spectra also reveal the fluxional nature of all the ruthenium complexes shown in equation (98) and quantitative kinetic and thermodynamic data are available.[1543]

(149)

(150)

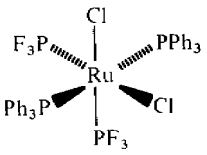
$$[RuCl_2(PPh_3)_4] \rightleftharpoons [RuCl_2(PPh_3)_3] + PPh_3 \quad (96)$$

$$[RuCl_2(PPh_3)_3] \rightleftharpoons [RuCl_2(PPh_3)_2] + PPh_3 \quad (97)$$

$$2[RuCl_2(PPh_3)_3] \rightleftharpoons [RuCl_2(PPh_3)_2]_2 + 2PPh_3 \quad (98)$$

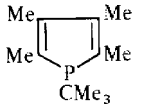
In more polar media, conductometric,[106] spectrophotometric[1552] and ^{31}P NMR spectroscopic studies[1544] reveal the presence of an alternative dissociation pathway for $[RuCl_2(PPh_3)_3]$, namely loss of Cl^- to produce Ru^{II} cations (equations 99 and 100) although unpublished work indicates that the triply-bridged chloride dimer $[Ru_2Cl_4(DMA)(PPh_3)_4]$ is present.[1555] Synthesis of pure $[RuBr_2(PPh_3)_3]$ by reaction of methanolic '$RuCl_3 \cdot xH_2O$'/LiBr solutions with PPh_3 has also been

claimed,[106] but subsequent ^{31}P NMR studies revealed that a mixture of $[RuCl_xBr_{2-x}(PPh_3)_3]$ ($x = 0$–2) is formed.[1543] However, pure $[RuBr_2(PPh_3)_3]$ can be synthesized by reaction of $[Ph_3(PhCH_2)P]_3[Ru_2Br_9]$ with PPh_3 in MeOH. This has very similar properties to $[RuCl_2(PPh_3)_3]$.[1556]



$$[RuCl_2(PPh_3)_3] \rightleftharpoons [RuCl(PPh_3)_3]^+ + Cl^- \quad (99)$$

$$[RuCl(PPh_3)_3]Cl \rightleftharpoons [RuCl(PPh_3)_2]Cl + PPh_3 \quad (100)$$



A number of other complexes of type $[RuCl_2L_n]$ (L = P donor ligand, $n = 2,3$ or 4) can be made by either direct reaction of '$RuCl_3 \cdot xH_2O$' or the reduced 'ruthenium blue' solution with L. These include L = P(*p*-Tol)$_3$ ($n = 3,4$),[1557,1558] P(*p*-MeOC$_6$H$_4$)$_3$ ($n = 3$),[1559] $PMe_2(CH_2Ph)$ ($n = 4$),[1560] PMe_2(1-*np*) ($n = 3$),[1561] $P(OMe)_3$ ($n = 4$, *trans*),[1562] $PPh_2(C_6H_4SO_3H)$ ($n = 2$),[1563] $PHPh_2$ ($n = 4$, *trans*),[1564,1565] $PHEt_2$ ($n = 4$),[1564] various substituted phospholes ($n = 3,4$),[1566,1567] and 3,3′,4,4′-tetraMe-1,1′-diphosphaferrocene ($n = 4$, *trans*).[1568] The *trans* isomer of $[RuCl_2(PHMe_2)_4]$ is also prepared from '$RuCl_3 \cdot xH_2O$' and Me_2PPMe_2 in H_2O or EtOH, the hydrogen being abstracted from the solvent,[1569] whereas treatment of $[Ru_2Cl_3(PMe_2Ph)_6]Cl$ with $PHPh_2$ gives the *cis* isomer.[1565] For the preparation of $[RuCl_2\{P(OEt)_3\}_4]$, '$RuCl_3 \cdot xH_2O$' and $P(OEt)_3$ are reacted in the presence of $Na[BH_4]$.[1570] Treatment of $[RuH(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ (**124**) with HX (X = Cl, Br) leads to *cis*-$[RuX_2(PMe_3)_4]$ whereas with CH_2X_2 (X = Cl, Br, I) or MeI, a mixture of $[RuX_2(PMe_3)_4]$ and $[RuX(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ is produced.[1391b]

However, most P donor ligands react with '$RuCl_3 \cdot xH_2O$' in aqueous EtOH or 2-methoxyethanol to give the triple chloride-bridged complexes $[Ru_2Cl_3L_6]Cl$, (see Section 45.5.5.1), which do *not* generally react with an excess of L to give $[RuCl_2L_4]$. A better route to the latter is therefore *via* reaction of L with $[RuCl_2(PPh_3)_{3\text{ or }4}]$, usually in non-polar media to minimize formation of ionic species. This method affords both $[RuCl_2L_3]$ (L = $PEtPh_2$,[1544] P(OR)Ph_2 (R = Me, Et),[1533] $PRPh_2$ (R = Me, $MeCH_2CH(Ph)CH_2$),[1571] $PMe(Ph)(PhCH_2)$,[1572] *etc.*) and $[RuCl_2L_4]$ (L = $P(OPh)_3$[1573] PMe_2Ph (*cis*;[1544] *trans*[1400]), $P(OMe)_2Ph$,[1533] $P(OMe)_3$,[1533] PEt_3,[1400] $PMePh_2$,[1400] PMe_3,[1529,1574] $PRPh_2$ (R = Me, $MeCH_2CH(Ph)CH_2$)[1571] and various 1-substituted 3,4-dimethylphospholes[1575] *etc.*). For $n = 4$, both *cis* and *trans* isomers are found and these undergo thermal and photochemical isomerization in solution (see references 1533 and 1575 for details). Reaction of $[RuH(C_6H_4PPh_2)(PMe_3)_3]$ with HCl gives $[RuCl_2(PMe_3)_3]$.[1391c] Many of these monomeric complexes also undergo facile rearrangement in solution to form various bi- and sometimes tri-nuclear species as discussed in Section 45.5.5.1.

A number of mixed P donor ligand complexes $[RuX_2L_xL'_y]$ are also known. Most of the compounds in this category involve a combination of PPh_3 and fluorophosphines. For example, treatment of *cis*-$[RuH_2(PF_3)_2(PPh_3)_2]$ with gaseous HX gave *cis*-$[RuX_2(PF_3)_2(PPh_3)_2]$ (X = Cl, Br)[1576] whose structure (**151**) was verified by X-ray analysis for X = Cl.[1577] Other routes to (**151**) include reaction of $[RuCl_2(PPh_3)_3]$ or $[RuHCl(CO)(DMA)(PPh_3)_2]$ with two moles of PF_3[1578] and of $[RuCl_2(C_{10}H_{16})(PF_2NMe_2)]$ ($C_{10}H_{16}$ = 2,7-dimethylocta-2,6-diene-1,8-diyl) with PF_3 and then PPh_3.[1579] Compound (**151**) is also formed *via* binuclear, triple chloride-bridged intermediates (Section 45.5.5.1), on treatment of $[RuCl_2(PPh_3)_3]$ with equimolar amounts of PF_3.[1580] Reaction of $[RuCl_2(PPh_3)_3]$ with allyl difluorophosphite gives $[RuCl_2(PF_2CH_2CH{=}CH_2)_2(PPh_3)_2]_n$[1581] whereas the sterically bulky phosphole 1-Me_3CDMP (**152**) gives the stereochemically rigid, pentacoordinate $[RuCl_2(PPh_3)(Me_3CDMP)_2]$ (*cf.* other 1-substituted 3,4-dimethylphospholes (RDMP) which afford $[RuCl_2(RDMP)_4]$ (R = Me, Bu, Ph, $PhCH_2$)].[1575] It has been shown that *trans*-$[RuCl_2(PMe_3)_4]$ reacts with $P(OMe)_3$ to give *trans, mer*-$[RuCl_2(PMe_3)_3P(OMe)_3]$ and *all trans*-$[RuCl_2(PMe_3)_2\{P(OMe)_3\}_2]$ whereas *trans*-$[RuCl_2\{P(OMe)_3\}]$ and PMe_3 gives *trans,cis,cis*-$[RuCl_2(PMe_3)_2\{P(OMe)_3\}_2]$.[1391c]

(151)

(152)

These monomeric $[RuCl_2L_n]$ complexes (particularly L = PPh_3) are very useful precursors for the synthesis of a wide range of Ru^{II} compounds of type $[RuCl_2Y_{4-x}L_x]$ ($x = 1$–3; Y = C, N, O or S donor ligands). Complete displacement of the chloride groups with other anionic ligands is also

readily achieved to give the six-coordinate complexes $[Ru(X–X)_2L_2]$ (X–X = $^-S_2CNR_2$, ^-SOCPh, ^-OCOR, ^-acac, *etc.*). For detailed examples see reference 85 and Sections 45.5.4.5 to 45.5.4.9. References to the widespread catalytic properties of $[RuCl_2(PPh_3)_3]$ are given in Section 45.10.6, together with those for the closely related $[RuHCl(PPh_3)_3]$ and other catalytically active species.

(*ii*) *L = monodentate As donor ligand*

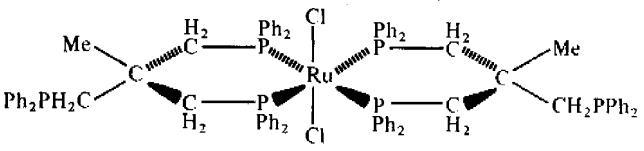
In contrast to the large amount of work on $[RuCl_2(PR_3)_n]$ compounds, relatively little has been published on the corresponding tertiary arsine complexes. Attempts to synthesize $[RuCl_2(AsR_3)_3]$ *via* '$RuCl_3 \cdot xH_2O$' and AsR_3 in MeOH gave $[Ru^{III}Cl_3(AsR_3)_2MeOH]$ (R = Ph,[106] *p*-Tol[625,1582]); the bromo derivatives are also available. The above reaction in EtOH gives a mixture of $[RuCl_3(AsPh_3)_3]$ and $[RuCl_3(AsPh_3)_2EtOH]$[1547] and not $[RuCl_2(AsPh_3)_3]$ as previously claimed.[1583] However extended reflux (17 h) of '$RuCl_3 \cdot xH_2O$' and $AsMe_2Ph$ in MeOH gives *cis*- and *trans*-$[RuCl_2(AsMe_2Ph)_4]$ whereas shorter reflux times (1 h) in 2-methoxyethanol yield $[RuCl_3(AsMe_2Ph)_3]$.[1584] Similar extended reflux in EtOH produces $[RuCl_2L_4]$ [L = $AsRPh_2$ (R = Me, Et, Pr, Bu);[1585] $AsMe_2(PhCH_2)$[1560]]. Another route to these compounds is *via* ligand exchange in non-polar solvents with either $[RuCl_2(PPh_3)_3]$ or $[RuCl_3(AsPh_3)_2MeOH]$ in the presence of Zn/Hg.[1586] Treatment of the reduced 'ruthenium blue' solution with $AsMe_2Ph$ and $AsMePh_2$ in alcohol is reported to give the five-coordinate $[RuCl_2(AsR_3)_3]$ complexes.[1511]

Earlier claims[1587] that reaction of '$RuCl_3 \cdot xH_2O$' and an excess of $AsPh_3$ in boiling 2-butanol gives the brown solid $[RuCl_2(AsPh_3)_2]_n$ are incorrect. On the basis of magnetic, ESR and electrochemical evidence, this has been reformulated as the mixed valence $[Ru_2Cl_5(AsPh_3)_4]$ (see Section 45.5.6).[1588] It is likely that $[Ru_2Cl_5(AsPh_3)_4]$ and not $[RuCl_2(AsPh_3)_2]_n$ is also formed on treatment of $[RuCl_3(AsPh_3)_2MeOH]$ with $AsPh_3$ in propanol.[1586] The insoluble mixed ligand polymer $[RuCl_2(AsPh_3)(PPh_3)]_n$ is claimed[1586] but this may also be a mixed valence species. However, it appears that genuine $[RuCl_2(AsPh_3)_2]_n$ can be prepared by treatment of $[RuCl_3(AsPh_3)_2MeOH]$ with 1 atm H_2 in DMA at 25°C.[1546,1547]

(*iii*) *L = monodentate Sb donor ligand*

The only complexes of this type are with $SbPh_3$. Reaction of '$RuCl_3 \cdot xH_2O$' and $SbPh_3$ in MeOH at ambient temperature gives the very insoluble deep red $[RuCl_2(SbPh_3)_3]_n$; the same compound is obtained under reflux in MeOH or 2-methoxyethanol.[106] A more soluble pink form (presumably monomeric) has been prepared by reaction of alcoholic solutions of the reduced 'ruthenium blue' solution with $SbPh_3$.[1511] An earlier report on the preparation of $[RuCl_2(SbPh_3)_4]$ from $K_2[RuCl_6]$ and $SbPh_3$ is available[1589] and the corresponding $[RuBr_2(SbPh_3)_4]$ is known.[1590]

45.5.4.3 [RuXY(L–L)$_n$] complexes (n = 2,3; X,Y = halide)



Earlier work by Chatt *et al.* on reactions of '$RuCl_3 \cdot xH_2O$' with various diphosphines $R_2P(CH_2)_2PR_2$ (R = Me, Et or Ph) and Nyholm *et al.* with *o*-$C_6H_4(AsMe_2)_2$(diars) led to the preparation of *cis*- and *trans*-$[RuCl_2(R_2P(CH_2)_2PR_2)_2]$[43,1591] and *trans*-$[RuCl_2(diars)_2]$[1592] respectively. Replacement of chloride with Br^-, I^-, ^-OCOMe, SCN^- was achieved. More recently, a wider range of the *trans* compounds $[RuCl_2(L–L)_2]$ have been obtained by treatment of either $[RuCl_2(PPh_3)_3]$, $[RuCl_2(py)_4]$, $K_2[RuCl_5(OH_2)]$ or '$RuCl_3 \cdot xH_2O$' with L–L in alcoholic solution (L–L = dppm,[1593–1595] dppe,[1571,1594,1595] dppp,[1535a,1536a,1594] 2-(diphenylphosphinoethyl)pyridine,[1535b] $Ph_2As(CH{=}CH)AsPh_2$ (eda),[45,1593] diars,[1596] *o*-$C_6H_4(PMePh)_2$,[1597] *o*-$C_6H_4(AsMePh)_2$,[1597] $Ph_2P(CH_2)_3PMe_2$,[1536a] $Ph_2P(CH_2)_3PMePh$,[1536a] *etc.*), or with excess dppm, eda and $Ph_2As(CH_2)_2AsPh_2$, by displacement of all the CO from 'RuCOCl' solutions.[1593] Some *trans*-$[RuCl_2(dmpe)_2]$ is also formed by treating $[RuH(2\text{-np})(dmpe)_2]$ with $CDCl_3$.[44] Metathesis of *trans*-$[RuCl_2(eda)_2]$ with NaX (X = NCS, I, N_3, CN) yields *trans*-$[RuX_2(eda)_2]$ but with NaBr, $[RuClBr(eda)_2]$ is formed.[45]

The complexes *cis*- and *trans*-$[RuCl_2(dppm)_2]$ undergo isomerization reactions induced by light, heat or oxidation to Ru^{III}. The conversion *trans* → *cis* occurs thermally while *cis* → *trans* occurs photochemically apparently by irradiation of the lowest lying *d–d* transition.[1598] In water/alcohol mixtures photolysis of *cis*- or *trans*-$[RuCl_2(dmpe)_2]$ gives *trans*-$[RuCl(OH_2)(dmpe)_2]^+$, while *trans*-$[RuCl(DMSO)(dmpe)_2]^+$ is always observed in DMSO. These results are consistent with the

formation of a five-coordinate excited-state fragment as the primary photochemical process and the thermodynamic preference for $[RuCl(dmpe)_2^+]^*$ to rearrange to the isomer with Cl^- in the apical position.[1599]

A detailed investigation of the stereochemistry of *cis*- and *trans*-$[RuCl_2(L\text{–}L)_2]$ (L–L = *o*-$C_6H_4(EMePh)_2$; E = As, P) has been undertaken. The optically active, racemic, *meso*, *syn*, and *anti* forms of the *trans* compound were isolated for both ligands; each of these subsequently isomerized to the corresponding *cis* complex by reaction with $AlEt_3$ and the various diastereoisomers of the latter separated and characterized. Whereas the *trans* isomers are relatively inert, the *cis* complexes readily undergo stereospecific halogen substitution by I^- and CO.[1597] A minor product obtained from the reaction of '$RuCl_3 \cdot H_2O$' with $\pm$*o*-$C_6H_4(PMePh)$, in the presence of formaldehyde is *trans*-$[RuCl_2\{(\pm)\text{-}o\text{-}C_6H_4(PMePh)_2\}\{(\pm)\text{-}o\text{-}C_6H_4(PMePh)P(O)MePh]$ containing P,P′ and O,P′ bidentate ligands respectively.[1600a]

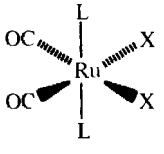
Reaction of $[Ru(OH_2)_6](tos)_2$ with dppe gives $[Ru(dppe)_2(tos)_2]$ (tos = *p*-toluenesulfonate).[1600b] Reaction of $[RuCl_2(PPh_3)_3]$ with $MeC(CH_2PPh_2)_3$ (triphos) affords the white compound $[RuCl_2(triphos)_2]$ shown by ^{31}P NMR spectroscopy to have structures (**153**) with non-coordinated P atoms,[1594] whereas $Ph_2AsCH_2AsPh_2$ (dpam) forms $[RuCl_2(dpam)_3]$ which contains one bi- and two mono-dentate dpam ligands.[1593] The reinvestigation of the reaction of $[RuCl_2(PPh_3)_3]$ with equimolar amounts of $Ph_2P(CH_2)_nPPh_2$ (n = 1–4) has been reported. Only for n = 4 is the complex $[RuCl_2(PPh_3)(chelate)]$ isolatable. ^{31}P NMR evidence is also presented for binuclear species such as $[Ru_2Cl_4(L\text{–}L)_2(PPh_3)_2]$[1601] (see Section 45.5.5).

(153)

Various $[RuCl_2(L\text{–}L)_2]$ have been prepared starting from either $[RuCl_2(DMSO)_4]$[1511] or reduced solutions of $[Ru_2OCl_{10}]^{4-}$ and X-ray structures of *cis*- and *trans*-$[RuCl_2(dppm)_2]$ are reported.[1602a] Reaction of $[RuCl_2(PPh_3)_3]$ with $Ph_2P(CH_2)_nPPhCH_2CH_2CpH$ (LH) (n = 3,4) has been shown to give neutral [RuLCl] complexes containing a coordinated Cp group.[1602b]

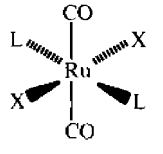
45.5.4.4 Polydentate P, As or Sb donor ligand halide complexes

Although reaction of $MeC(CH_2PPh_2)_3$ (triphos) with $[RuCl_2(PPh_3)_3]$ gives compound (**153**) where triphos acts as a bidentate ligand,[1594] the analogous reaction with $PhP\{(CH_2)_2PPh_2\}_2$ gives the five-coordinate monomer $[RuCl_2PhP\{(CH_2)_2PPh_2\}_2]$.[1540] In contrast, reaction of this tritertiarz phosphine with '$RuCl_3 \cdot xH_2O$' in boiling EtOH gives a binuclear chloride-bridged complex (see Section 45.5.5.2). Likewise, reaction of '$RuCl_3 \cdot xH_2O$' with $PhP\{(CH_2)_3PPh_2\}_2$ (ttp) and $PhP\{(CH_2)_3PCy_2\}_2$ (Cyttp) affords $[RuCl_2(ttp)]_x$ and $[RuCl_2(Cyttp)]$ respectively. The former is polymeric and the latter monomeric, presumably due to steric effects of the larger cyclohexyl groups.[1486] Incomplete displacement of PPh_3 from $[RuCl_2(PPh_3)_3]$ occurs on treatment with $P[(CH_2)_2PPh_2]_3$ (tet-2) to produce $[RuCl_2(PPh_3)(tet\text{-}2)]$, in which tet-2 acts as a terdentate ligand.[1540] Interestingly, the same reaction with $Ph_2P(CH_2)_2PPh(CH_2)_2PPh_2$ (tet-1) gives the five-coordinate cation [RuCl(tet-1)]Cl,[1540] although the product from reaction of tet-1 with $[RuCl_2py_4]$ is formulated elsewhere as $[RuCl_2(tet\text{-}1)]$, and $[RuCl_2N\{(CH_2)_2PPh_2\}_3]$ is also reported.[1595]



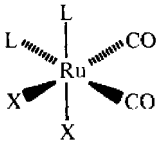
A series of six-coordinate complexes $[RuCl_2(ligand)]$ containing the quadridentate ligands (*o*-$Ph_2L \cdot C_6H_4)_3L'$, (L = P or As; L′ = P, As or Sb but not all combinations), have been prepared by reaction of '$RuCl_3 \cdot xH_2O$' or $[RuCl_2(PPh_3)_3]$ with the appropriate ligand. Metathesis with NaX gives the corresponding $[RuX_2(ligand)]$ (X = Br, I, NCS, CN but not all combinations).[46] An X-ray analysis of $[RuBr_2\{As(o\text{-}C_6H_4AsPh_2)_3\}]$ confirms the distorted octahedral structure.[1603a] Reaction of $[RuCl_2py_4]$ with $Ph_2P(CH_2)_2P(Ph)(CH_2)_2P(Ph)(CH_2)_2PPh_2$ (L) gives *trans*-$[RuCl_2L]$.[1603b]

45.5.4.5 Carbon donor ligand complexes

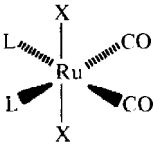


(*i*) *Carbonyl halides*

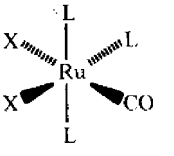
A very large number of compounds of general formula $[RuX_2(CO)_xL_{4-x}]$ (X = Cl, Br, I; L = PR_3, AsR_3, $SbPh_3$; x = 1–3) have been synthesized in the last 25 years. Since this is the subject



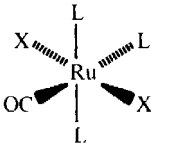
of detailed reviews,[1,3,4,5,1604,1605] only a brief account is presented here. For $x = 3$, the best route is *via* reaction of the cluster compounds $[Ru_3(CO)_9L_3]$ with halogens or hydrocarbon solvents[1560] (*e.g.* L = PPh_3, $PMe_2(CH_2Ph)$, $AsMe_2(CH_2Ph)$; x = Cl, Br, I).[1560,1606] For $x = 2$ and 1, several methods are available and these lead to the various geometrical isomers (**154–157**; $x = 2$) and (**158, 159**; $x = 1$) which can also interconvert under thermal or photochemical stimulation (see references 1607–1610). For example, reaction of $[RuI_2(CO)_2]_n$ with L gives $[RuI_2(CO)_2L_2]$ (**154**) whereas $[RuI_2(CO)_2(p\text{-}MeC_6H_4NH_2)_2]$ and L under mild conditions gives products of stereochemistry (**155**) which isomerize thermally to (**154**). These iodo compounds are converted into the corresponding chloro or bromo compounds by treatment with the appropriate halogen, usually with preservation of the original stereochemistry.[1611] The dicarbonyl species can also be obtained by direct reaction of $[RuX_2(CO)_3]_2$ (X = Cl, Br), $[RuCl_2(CO)_2]_n$, $[RuCl_2(CO)_3THF]$[1612] or $[RuCl_4(CO)_2]^{2-}$[1613] with L or by treatment of carbonylated, alcoholic solutions of $RuCl_3$ with L.[106,1584,1614a] As detailed in Table 1, reference 1, p. 693, the latter route also leads to $[RuCl_2COL_3]$ in some instances. Bromo and iodo analogues of $[RuCl_2COL_3]$ can be obtained by metathesis, the ease of replacement of Cl dependent upon the *trans* ligand; Cl *trans* to PR_3 is substituted more rapidly than Cl *trans* to Cl or CO which allows the isolation of some intermediate $[RuClY(CO)(PR_3)_3]$ complexes (X = Br, I, SCN).[1614a] The same intermediates can be obtained by treatment of $[RuHCl(CO)(PR_3)_3]$ with HX (X = Br, I), together with some $[RuX_2(CO)(PR_3)_3]$ (**158**).[1614b]



(154)



(155)

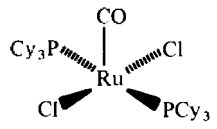


(156)

(157)

(158)

(159)



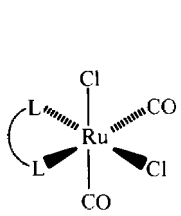
An alternative method is by carbonylation of complexes of Ru^{II} or Ru^{III} containing P, As or Sb donor ligands, *e.g.* $[RuCl_2(PPh_3)_3]$ reacts with CO to give $[RuCl_2(CO)_2(PPh_3)_2]$ (the isomer formed depending on conditions),[106,1607] whereas $[RuCl_2(P(OMe)Ph_2)_3]$ produces $[RuCl_2(CO)(P(OMe)Ph_2)_3]$ (isomer **158**),[1615] and $[RuCl_2(PMe_3)_4]$ forms $[RuCl_2CO(PMe_3)_3]$ (isomer **159**).[1391c] More examples are given in Table 2, reference 1, p.695. Solvento complexes $[RuCl_2(CO)(PR_3)_2(solvent)]$ (solvent = DMA, DMF, DMSO, MeOH) have also been isolated from these reactions.[1558,1607,1616]

In some instances, decarbonylation of the solvent provides the source of CO, *e.g.* reaction of '$RuCl_3 \cdot xH_2O$' and PPh_3 in benzyl alcohol gives $[RuCl_2(CO)(PPh_3)_3]$;[1542] $[Ru_2Cl_3(PEt_2Ph)_6]Cl$ decarbonylates saturated aldehydes RCHO to give $[RuCl_2CO(PEt_2Ph)_3]$[1617] and reaction of '$RuCl_3 \cdot xH_2O$', PPh_3, KOH, 2-methoxyethanol and aqueous HCHO, followed by CCl_4 produces $[RuCl_2(CO)_2(PPh_3)_2]$;[1410b] a similar recipe yields $[RuX_2CO(AsRPh_2)_3]$ (R = Me, Et, Pr).[1618] Other routes to $[RuCl_2COL_3]$ are by reaction of $[RuCl_2(PPh_3)_3]$ with CO_2[1619] and cocondensation of Ru with $(COCl)_2$, followed by addition of PMe_3.[1620] Reaction of $[Ru(CO)_3(PPh_3)_2]$ with $(NSCl)_3$ gives $[RuCl_2(CO)_2(PPh_3)_2]$,[1621] and X-ray structures of some of these mono- and di-carbonyl complexes have been published.[1575,1610,1622]

Detailed studies of the thermally and photochemically induced interconversions of the various isomers of $[RuX_2(CO)_2L_2]$ reveal that the key step is dissociation of CO to form five-coordinate intermediates.[1608,1610] A similar study on $[RuCl_2CO(PMe_2Ph)_2L]$ (L = $P(OMe)_3$, $P(OMe)_2Ph$) suggests that the isomerization mechanisms involve phosphorus ligand dissociation.[1609] An electrochemical study of $[RuCl_2(CO)(PMe_2Ph)_3]$ reveals that the compound undergoes a reversible one-electron oxidation.[625]

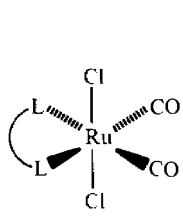
Treatment of carbonylated, 2-methoxyethanol solutions of $RuCl_3$ with bulkier phosphines such as PCy_3 gives the five-coordinate $[RuCl_2CO(PCy_3)_2]$[1623a,1623b] shown by X-ray analysis to have the distorted square pyramidal structure (**160**);[1624] a cyclohexyl hydrogen atom blocks the sixth coordination position (Ru···H = 2.31 Å). Reaction of (**160**) with L′ (CO, fumaronitrile, $CH_2{=}CHCN$) gives $[RuCl_2(CO)L'(PCy_3)_2]$.[1623a,1625] Even bulkier phosphines such as $PBu^t{}_2Ph$ and $PBu^t{}_2(p\text{-Tol})$ react with the 'RuCOCl' solution to give dimeric ruthenium(I) complexes $[Ru(\mu\text{-Cl})(CO)_2PR_3]_2$ (see Section 45.5.3.2). These probably form because the $PBu^t{}_2Ph$ groups are too bulky to permit six coordination. As discussed elsewhere, related compounds containing $SnCl_3^-$, {*e.g.* $[RuCl(SnCl_3)CO(Me_2CO)(PPh_3)_2]$},[109] $SiMe_3$ {*e.g.* $[RuCl(SiMe_3)(CO)_3PPh_3]$},[68,74] and $SiCl_3$ {*e.g.* $[Ru(SiCl_3)_2(CO)_2PPh_3(P(OMe)_3)]$}[67] (Section 45.3.2) are available.

There are relatively few examples of cationic and anionic carbonyl halides containing monodentate P, As or Sb donor ligands. Reaction of $[Ru(CO)_3(PPh_3)_2]$ with I_2 or SnI_4 gives



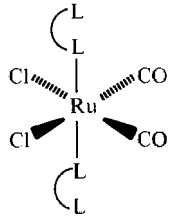
(160)

$[RuI(CO)_3(PPh_3)_2]Z$ (Z = I,[1626] SnI_3[12]); on heating, these form $[RuI_2(CO)_2(PPh_3)_2]$. Similar cations $[RuX(CO)_3(PR_3)_2]^+$ are obtained by reaction of phosphine-substituted carbonyl halides with Lewis acids ($AlCl_3$, $AlBr_3$, $FeCl_3$) in benzene under CO (X = Cl, Br; R = Cy, Et, Ph).[1627] In some systems, Lewis acid adducts can be isolated. Thus treatment of $[RuCl_2(CO)_2(PMe_3)_2]$ with $FeCl_3$ in CH_2Cl_2 at 25°C gives $[RuCl(Cl \rightarrow FeCl_3)(CO)_2(PMe_3)_2]$. Addition of more $FeCl_3$ affords $[Ru(Cl \rightarrow FeCl_3)_2(CO)_2(PMe_3)_2]$.[1628] The related cations $[RuCl(CO)_2(CS)(L–L)]BPh_4$ are known (see Section 45.5.4.5.ii).[1629a] Dissolving $[RuCl_2CO(P(OMe)Ph_2)_3]$ in MeOH and adding $Na[BPh_4]$ gives the five-coordinate cation $[RuCl(CO)(P(OMe)Ph_2)_3]^+$; with $[RuCl_2CO(P(OEt)Ph_2)_3]$, the binuclear $[RuCl(CO)(P(OEt)Ph_2)_3]_2$ $(BPh_4)_2$ is formed[1615] (*cf.* $[RuCl(P(OMe)Ph_2)_4]^+$ and $[RuCl(P(OEt)Ph_2)_4]_2^{2+}$ (Section 45.5.4.1).[1533] The chiral octahedral cations $[RuR(CO)_2L^*(PMe_3)_2]^+$ (L* = PhPMeR′ *etc.*) have been prepared and $^2J_{PP}$ between the diastereotopic PMe_3 groups determined.[1629b]

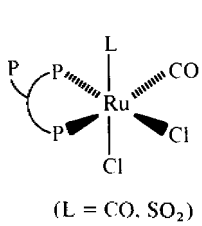


Reaction of $[Ru(CO)_3(PPh_3)_2]$ or $[RuI_2(CO)_2(PPh_3)_2]$ with MeI gives $MePh_3P[RuI_3(CO)_2PPh_3]$.[1630] Closely related carbonyl anions $[RuCl_3COL_2]^-$ (L = $AsPh_3$, $SbPh_3$) are prepared by treatment of $Ph_3(PhCH_2)P[RuCl_3CO(nbd)]$ with stoichiometric amounts of L; some $[RuCl_2COL(nbd)]$ (Section 45.5.4.5.vi) is also formed. With excess $SbPh_3$, $[RuCl_2CO(SbPh_3)_3]$ (**158**) is the main product.[659] Treatment of $[RuCl_2CO(MeOH)(PPh_3)_2]$ with $[AsPh_4]Cl \cdot HCl$ in acetone gives $AsPh_4[RuCl_3CO(PPh_3)_2]$.[1616]

Relatively little work has been published on carbonyl halide complexes of polydentate phosphines and arsines. Thus reaction of $[RuX_2(CO)_2]_n$ (X = Cl, Br, I) with dppe, eda and $Ph_2E(CH_2)_4EPh_2$ (E = P, As) gives $[RuX_2(CO)_2(L–L)]$ (**161**; X = Cl),[1631] whereas treatment of the ethanolic 'RuCOCl' solution with dppm or eda gives isomer (**162**). With dpam, $[RuCl_2(CO)_2(dpam)_2]$ (**163**) with unidentate dpam coordination is formed.[1593] Detailed studies on the analogous dicarbonyl complexes *cis*- and *trans*-$[RuCl_2(CO)_2(L–L)]$ (L–L = *o*-$C_6H_4(EMePh)_2$; E = As, P) have appeared. The *trans* isomers were prepared from $[RuCl_2(CO)_2]_n$ and L–L in boiling EtOH or 2-methoxyethanol whereas treatment of $[RuCl_2(CO)_3]_2$ with L–L in EtOH at room temperature affords the less stable *cis* isomers. For L–L = *o*-$C_6H_4(PMePh)_2$, the tricarbonyl cations $[RuCl(CO)_3L–L]Cl$ can be prepared and the dicarbonyls undergo reversible decarbonylation to give the chloro-bridged dimers $[RuCl_2(CO)(L–L)]_2$. Reaction of these dimers or the netural dicarbonyls with DMSO gives exclusively *cis*-$[RuCl_2(CO)(DMSO)(L–L)]$ (with S-bonded DMSO).[1632,1633] Carbonylation of $[RuCl_2(ttp)]_x$ gives *cis*- and *trans*-$[RuCl_2(CO)ttp]$ whereas only *trans*-$[RuCl_2(CO)Cyttp]$ is formed with $[RuCl_2(Cyttp)]$.[1486] The cations $[RuX(CO)_2(Cyttp)]X'$ (XX′ = HCl, HBr, HBF_4, Cl_2, Br_2) are prepared by oxidative addition of halogens and acids to $[Ru(CO)_2(Cyttp)]$ whereas treatment of $[RuCl_2(tpp)]_x$ with CO and $Tl[BF_4]$ gives $[Ru(CO)_2(tpp)](BF_4)_2$.[1486]



Halogenation of $[Ru(CO)_2triphos]$ (triphos = $MeC(CH_2PPh_2)_3$) gives initially the salts $[RuX(CO)_2triphos]X$ (X = Cl, Br) which lose CO reversibly to give $[RuX_2(CO)(triphos)]$. The neutral chloro complex contains a labile Ru—P bond since it also reacts reversibly with SO_2 to give $[RuCl_2CO(SO_2)(triphos)]$ (**164**).[1485] Treatment of these and related $[RuX(CO)_2(triphos)]X'$ cations with a variety of neutral ligands L (L = Bu^tNC, $P(OMe)_3$, PMe_2Ph *etc.*) in the presence of trimethylamine *N*-oxide yields chiral complexes of the type $[RuX(CO)L(triphos)]X'$. The compound $[RuMe(CO)(CNBu^t)(triphos)]PF_6$ has been resolved, and the absolute configuration of the (+)-enantiomer has been determined.[1634]



(161)

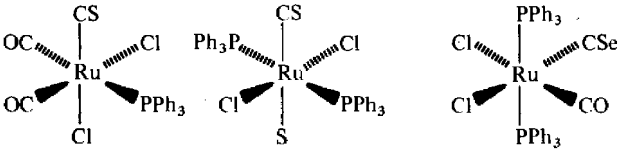
(162)

(163)

(L = CO, SO_2)

(164)

Reactions of $[RuCl_2(L\text{–}L)_2]$ (L–L = dppm or dppe) with CO and silver salts of non-coordinating anions produce $[Ru(CO)_2(L\text{–}L)_2]^{2+}$ (both *cis* and *trans* isomers). A series of compounds of general formula $[Ru(CO)_2(dppm)_2AgY]X_2$ may also be isolated (Y = O_2PF_2, Cl, ClO_4, $BF(OH)_3$; X = BF_4, AsF_6, ClO_4), which are proposed to contain a dppm ligand bridging Ru and Ag, the bond between which is reversibly cleaved by $MeNO_2$ on the NMR time scale.[1635] Treatment of the dicarbonyl cations $[Ru(CO)_2(L\text{–}L)_2]^{2+}$ with $Na\{HB(OEt)_3\}$ produces the formyl species $[Ru(CHO)(CO)(L\text{–}L)_2]^+$ as confirmed by the X-ray analysis of *trans*-$[Ru(CDO)(CO)(dppe)_2]SbF_6 \cdot CH_2Cl_2$.[1636] Studies have revealed that *trans*-$[Ru(CHO)(CO)(dppe)_2]SbF_6$ decomposes in CH_2Cl_2 to give *cis*-$[RuH(CO)(dppe)_2]SbF_6$ which subsequently isomerizes to the *trans* isomer. However, *cis*-$[Ru(CHO)(CO)(dppm)_2]SbF_6$ gives $[RuH(CO)_2(dppm)_2]SbF_6$ with a monodentate dppm ligand but chelation occurs on photolysis in CH_2Cl_2 to give *trans*-$[RuCl(CO)(dppm)_2]SbF_6$ *via* *trans*-$[RuH(CO)(dppm)_2]SbF_6$.[1637a] It has been shown that *trans*-$[Ru(CHO)(CO)(dp)_2]SbF_6$ [dp = 1,2-bis(diphenylphosphine)benzene] decomposes to *trans*-$[RuH(CO)(dp)_2]SbF_6$ *via* a free radical mechanism.[1637b] Monocarbonyl cations of type $[RuCl(CO)(L\text{–}L)_2]^+$ are also prepared by direct reaction of *trans*-$[RuCl_2(dppm)_2]$ with CO[1593] or by reaction of the five-coordinate cations $[RuCl(L\text{–}L)_2]^+$ (L–L = dppp, 2-diphenylphosphinoethylpyridine) with CO.[1535]



Hydridocarbonyls and carbonyl complexes containing C, N, O or S donor ligands are covered in later sections of this review.

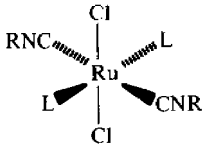
(*ii*) *CS and CSe complexes*

Reaction of $[RuCl_2(CS)(CO)_3]$ (made from $[Ru_3(CO)_{12}]$ and $CSCl_2$) with PPh_3 gives $[RuCl_2(CO)_2CS(PPh_3)]$ (**165**). With bidentate ligands L–L (L–L = $Ph_2E(CH_2)_2EPh_2$; E = P, As) a mixture of species is obtained and only $[RuCl(CO)_2CS(L\text{—}L)]BPh_4$ could be isolated in pure form.[1629a] Bridge cleavage of $[RuCl_2(CS)(PPh_3)_2]_2$ (Section 45.5.5.2) with CO gives $[RuCl_2CO(CS)(PPh_3)_2]$, the isomer formed depending on the reaction conditions,[1638] whereas with MCl/HCl, $M[RuCl_3(CS)(PPh_3)_2]$ (M = Ph_4As, Et_4N, $Ph_3(PhCH_2)P$) is obtained.[1639] Treatment of the double chloride-bridged dimer with DMF gives $[RuCl_2(CO)DMF(PPh_3)_2]$ which on recrystallization from $MeOH/CH_2Cl_2$ produces $[RuCl_2(CS)MeOH(PPh_3)_2]$ (**166**);[1616] the aqua analogue $[RuCl_2(OH_2)(CS)(PPh_3)_2]$ is formed by reaction of $[RuCl_2(PPh_3)_3]$ with CS_2 in xylene.[1640] Reaction of $[RuCl_2(PPh_3)_3]$ with neat CS_2 gives the binuclear complexes $[RuCl_2(CS)(PPh_3)_2]_2$ and $[Ru_2Cl_4(CS)(PPh_3)_4]$[1639,1641] (see Section 45.5.5.1) and the monomeric $[RuCl_2CO(CS)(PPh_3)]$ (?) is claimed.[1642]

The alkoxyphenylphosphine complexes $[RuCl_2(CS)L_3]$ [L = $P(OR)Ph_2$ (R = Me, Et), $P(OMe)_2Ph$] are prepared by reaction of either $[Ru_2Cl_4(CS)(PPh_3)_4]$ or $[RuCl_2CS(PPh_3)_2]_2$ with an excess of L in C_6H_6. Addition of $Na[BPh_4]$ to alcoholic solutions of these $P(OR)Ph_2$ complexes then gives $[RuCl(CS)(P(OMe)Ph_2)_3]BPh_4$ and $[RuCl(CS)(P(OEt)Ph)_3]_2(BPh_4)_2$. No cationic complexes are generated under these conditions for $[RuCl_2(CS)\{P(OMe)_2Ph\}_3]$.[1615]

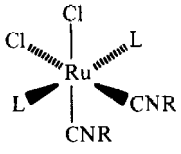
The Ru^0 complex $[Ru(CO)_2(PPh_3)_3]$ reacts readily with CY_2 (Y = S, Se) to form $[Ru(CY_2)(CO)_2(PPh_3)_2]$.[1470] These compounds are readily methylated with MeI to give $[Ru(CY_2Me)(CO)_2(PPh_3)_2]^+$. Displacement of CO with X^- affords neutral $[RuX(CY_2Me)(CO)(PPh_3)_2]$ and treatment of these dithio- or diseleno-methyl ester complexes with HX produces the mixed thio- or seleno-carbonyl complexes $[RuX_2(CO)(CY)(PPh_3)_2]$ (X = Cl, Br).[1643] These compounds are also formed on treatment of $[RuCl_2(CCl_2)(CO)(PPh_3)_2]$ with H_2Y.[49] An X-ray structure determination shows $[RuCl_2CO(CSe)(PPh_3)_2]$ to have structure (**167**). The long Ru—Cl bond (2.477 Å) *trans* to CSe compared to 2.428 Å (Ru—Cl *trans* to CO) demonstrates the strong *trans* influence of the CSe ligand.[1643,1644] Chromatography of $[RuI_2(CO)(CSe)(PPh_3)_2]$ on alumina affords $[RuI(OH)(CO)(CSe)(PPh_3)_2]$ (with OH *trans* to CSe).[1643] A report on the preparation of hydride complexes such as $[RuHCl(CS)(PPh_3)_3]$, and $[RuH(\eta^2\text{-}OCOR)CS(PPh_3)_2]$ (R = H, Me) has appeared (see Section 45.10.3.2.iii). The corresponding $[RuCl(\eta^2\text{-}OCOH)CS(PPh_3)_2]$ is also synthesized from $[RuCl_2(OH_2)(CS)(PPh_3)_2]$ and $Na[OCOH]$.[1645] Some CNR complexes containing CS and CSe are described in the next section.

(**165**) (S = DMF, MeOH) (**167**)



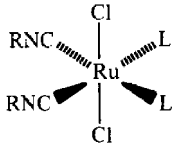
(**166**)

(iii) CNR, CNHR and related carbene complexes



Reaction of $[RuX_3(AsRPh_2)_3]$ (X = Br, Cl; R = Et, Me, Ph) with *p*-tolyl isocyanide in acetone or alcohol gives $[RuX_2(AsRPh_2)_2(CN\text{-}p\text{-}Tol)_2]$.[1646] A more detailed study on $[RuCl_3L_3]$ (L = PMe_2Ph, $PPr^n{}_2Ph$, $PBu^n{}_2Ph$) shows that the ruthenium(III) cations $[RuCl_2(CNR)L_3]^+$ are first formed and these undergo reduction to various isomers (**168–170**) of $[RuCl_2(CNR)_2L_2]$.[1647] Other routes to $[RuX_2(CNR)_2(ER_3)_2]$ involve direct reaction of $[RuCl_2(PPh_3)_3]$, $[RuX_3(AsPh_3)_2MeOH]$ or $[RuX_2(SbPh_3)_n]$ (X = Cl, *n* = 3; X = Br, *n* = 4) with CNR;[1411,1590,1648] the ^{13}C NMR spectrum of $[RuCl_2(CNPh)_2(PPh_3)_2]$ (**170**) is reported.[1649] These isomers undergo facile interconversion in solution on thermal or photochemical excitation, and the mechanism of isomerization is proposed to occur *via* the photoelimination of PPh_3.[1590,1650] The analogous $[Ru(OCOMe)_2(CNMe)_2(PPh_3)_2]$ are prepared from the action of CNMe on $[Ru(OCOMe)_2(PPh_3)_2]$[1651] and treatment of *cis*-$[RuCl_2(CNEt)_2(EPh_3)_2]$ (**169**) with $SnCl_2$ in 2-methoxyethanol gives *cis*-$[RuCl(SnCl_3)(CNEt)_2(EPh_3)_2]$ (E = P, As, Sb).[110]

Direct reaction of $[RuX_2CO(AsRPh_2)_3]$ (X = Cl, Br; R = Me, Et, Pr) with *p*-tolyl isocyanide gives $[RuX_2(CO)(CN\text{-}p\text{-}Tol)(AsRPh_2)_2]$[1652] and the X-ray structures of $[RuCl_2(CO)(CN\text{-}p\text{-}ClPh)(PPh_3)_2]$[1653] (**171**) and $[RuCl(Ph)CO(CNCMe_3)(PMe_2Ph)_2]$ (**172**)[1654] have been reported. Treatment of the five-coordinate $[RuCl(R')(CO)(PPh_3)_2]$ with CNR affords $[RuCl(R')(CO)(CNR)(PPh_3)_2]$ (R = R′ = *p*-Tol). Heating this in boiling CH_2Cl_2 gives an orange material, shown by X-ray analysis to be the iminoacyl complex (**173**). Protonation of (**173**) with HCl gives the aminocarbene complex $[RuCl_2[C(NHR)R'](CO)(PPh_3)_2]$.[1655] Reaction of O_2 with the zerovalent $[Ru(CO)_2(CN\text{-}p\text{-}Tol)(PPh_3)_2]$ (Section 45.5.1.3) gives the carbonate (**174**).[1480]



The product of reaction between $[RuCl_2(PPh_3)_3]$ and CS_2 in boiling xylene reacts with CNR to give the yellow *trans* isomer of $[RuCl_2(CNR)(CS)(PPh_3)_2]$. Isomerization to a colourless *cis* isomer occurs in toluene under reflux and this reacts with $Ag[ClO_4]$ to give $[RuCl(OClO_3)(CNR)(CS)(PPh_3)_2]$ which in turn gives $[RuCl(CNR)(CO)(CS)(PPh_3)_2]ClO_4$ on carbonylation. This cation reacts with SeH^- to give (**175**) which on methylation with MeI affords $[Ru(\eta^2\text{-}Se{=}CSMe)(CNR)(CO)(PPh_3)_2]^+$ (**176**). Treatment of (**176**) with aqueous HCl in toluene/EtOH solution under reflux liberates MeSH and produces $[RuCl_2(CNR)(CSe)(PPh_3)_2]$ in high yield.[1640,1645] The dicarbonyl complexes $[RuCl_2(CNR)(CO)_2PPh_3]$ can be made by reaction of $[RuCl_2(CO)_2(CS)PPh_3]$ with NH_2R; this reaction goes *via* a labile amino(mercapto)carbene complex which eliminates H_2S.[1629a] Other, isocyanide complexes containing hydride ligands are covered in Section 45.10.

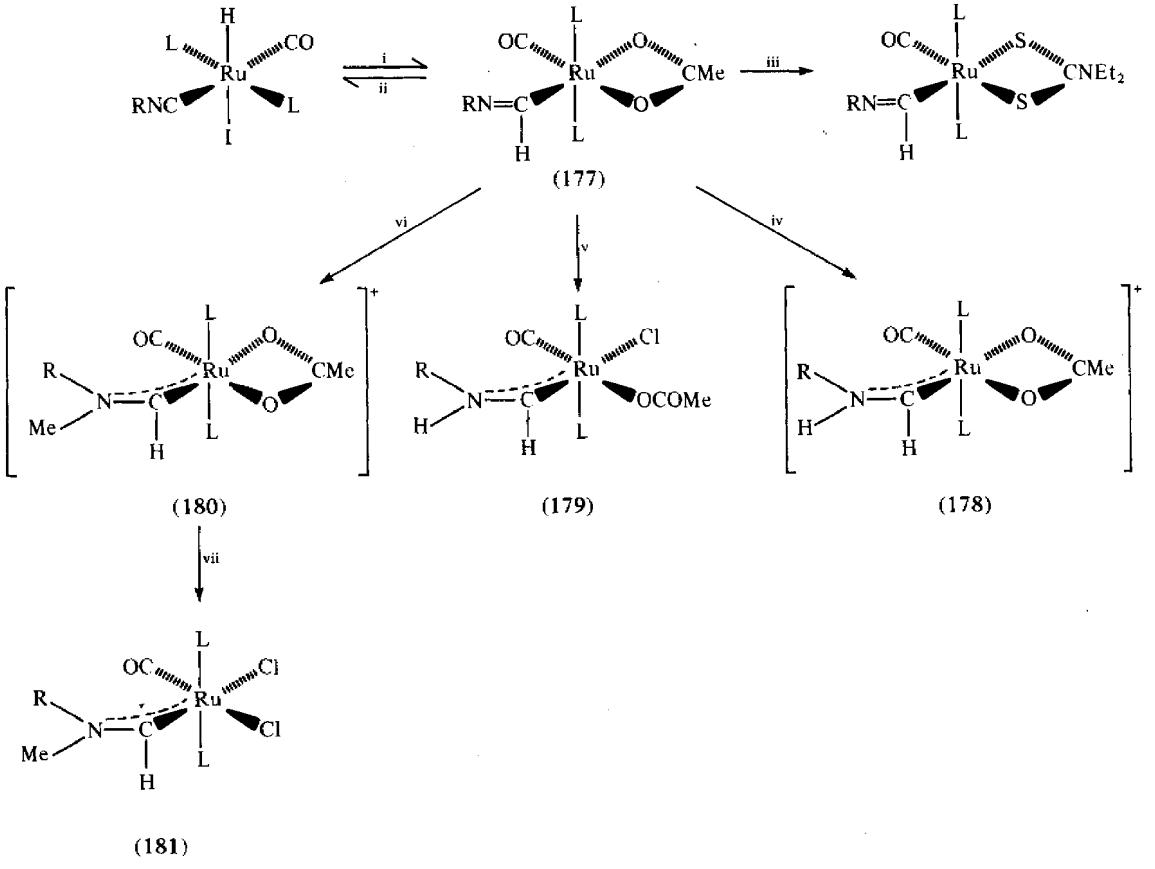
(173)

(174)



(175) L_4 = (CO)(CNR)$(PPh_3)_2$

(176)

Roper and co-workers[1656] have reported the synthesis of a number of formimidoyl (CNHR) complexes. For example reaction of $[RuHI(CN\text{-}p\text{-}Tol)(CO)(PPh_3)_2]$ with acetate ion promotes hydrogen migration from ruthenium to isocyanide to give the formimidoyl complex (**177**) (L–L = OCOMe). Treatment with $^-S_2CNEt_2$ gives (**177**) (L–L = S_2CNEt_2). The nitrogen atom of the CNHR group is attacked by electrophiles to generate a range of secondary carbene complexes such as (**178**) (with $HClO_4$) and (**179**) (with HCl) (Scheme 45). With dimethylsulfate, methylation of (**177**) (L–L = OCOMe) leads to the cationic *N*-*p*-tolylmethylaminocarbene complex (**180**). The bidentate acetato group is then removed by addition of LiCl to give the neutral carbene (**181**). Other examples of P donor ligand compounds containing these C-bonded ligands are to be found in the above references.

i, ^-OCOMe; ii, HI; iii, $^-S_2CNEt_2$; iv, $HClO_4$; v, HCl; vi, Me_2SO_4; vii, LiCl

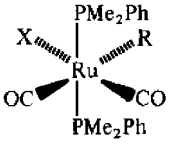
Scheme 45

Reaction of $[RuCl_2(PPh_3)_3]$ with electron-rich alkenes $(R\overline{NCH_2CH_2NRC}=)_2$ ($L^R{}_2$, R = Me, Et, CH_2Ph) affords *trans*-$[RuCl_2(L^R)_4]$ which for R = Me react with PF_3 and $P(OMe)_3$ to give *trans*-$[RuCl(L^{Me})_4(PF_3)]Cl$ and *trans*-$[RuCl(L^{Me})_2\{P(OMe)_3\}_3]Cl$ respectively. More complicated reactions occur with aryl-substituted electron-rich alkenes. Thus, reaction of $L^{R'}{}_2$ (R′ = Ph, *p*-Tol or *p*-$MeOC_6H_4$) with $[RuCl_2(PPh_3)_3]$ in refluxing xylene gives the cyclometallated product (**182**). Further reactions undergone by this stereochemically rigid five-coordinate complex include displacement of both PPh_3 groups by other PR_3 to give $[\overline{RuCl(L^{R'})}(PR_3)_2]$ or of one PPh_3 group by $L^{Et}{}_2$ to give $[\overline{RuCl(L^{R'})}(L^{Et})PPh_3]$. The latter compound is also formed by treatment of $[\overline{RuCl_2(L^{R'})}(NO)PPh_3]$ (made from $[RuCl_3NO(PPh_3)_2]$ and $L^{R'}{}_2$) with $L^{Et}{}_2$. Small ligands L′ add to (**182**) and $[\overline{RuCl(L^{R'})}(PR_3)_2]$ to give the six-coordinate $[\overline{RuCl(L^{R'})}(PR_3)_2L']$ (L′ = CO, PF_3, $P(OMe)_3$, N_2, MeCN).[1420,1657,1658a] The compound $[RuCl_2(L^{Me})_4]$ is a good hydrosilylation catalyst.[1658b]

(182) X = H, Me or OMe; L = PPh_3

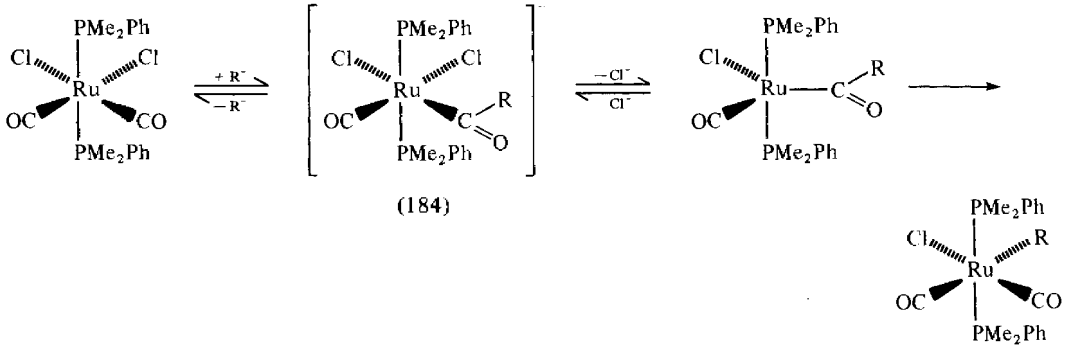
(iv) Alkyl, aryl and acyl complexes

Most of the early work in this area[1659] was concerned with reactions between *cis*- and *trans*-$[RuX_2(L–L)_2]$ (X = halide; L–L = dmpe, dppe or dppm) and various alkylating and arylating reagents. Thus, *cis*-$[RuCl_2(L–L)_2]$ and LiR (R = Me, Ph) give the corresponding dimethyl and diphenyl complexes, *cis*-$[RuR_2(L–L)_2]$ respectively. *Cis*-$[RuEt_2(dmpe)_2]$ has been prepared from *trans*-$[RuCl_2(dmpe)_2]$ and $MgEt_2$ whereas with *trans*-$[Ru(OCOMe)_2(dmpe)_2]$, the *trans* diethyl isomer is formed.[16a] Use of the less reactive AlR_3 compounds affords only the monoalkyl derivatives $[RuClR(L–L)_2]$ (alkyl = Me, Et, Pr^n) from both the *cis* and *trans* dichloro complexes; the monoaryl analogues (R = Ph, *p*-MeC_6H_4) are also available. Further reaction of *cis*-$[RuClMe(L–L)_2]$ with LiMe gives *cis*-$[RuMe_2(L–L)_2]$ whereas treatment with Br^-, I^- or SCN^- produces $[RuXR(L–L)_2]$. The latter are also formed by reaction of $[RuHR(L–L)_2]$ (see Section 45.10.3.2.i) with hydrogen halides. The compound *cis*-[Ru(2-np)(Cl)(dmpe)$_2$] is also the major product together with *ca.* 20% $[RuCl_2(dmpe)_2]$ on treatment of *cis*-[Ru(2-np)H(dmpe)$_2$] with $CDCl_3$,[44] and $[RuClMe(diars)_2]$ is obtained from $[RuCl_2(diars)_2]$ and LiMe.[1659] Detailed NMR studies are reported on many of these alkyl and aryl complexes.[1659,1660]



The corresponding dialkyl and diaryl complexes *cis*-$[RuR_2(PMe_3)_4]$ (R = Me,[1661] Ph[1528]) are best prepared by treatment of $[Ru_2(OCOMe)_4Cl]$ with MgR_2 and PMe_3 in THF. The dimethyl derivative has also been synthesized by reaction of *trans*-$[RuCl_2(PMe_3)_4]$ and LiMe in ether.[1380a,1534] Studies[16] have shown that treatment of this di-Me compound with one equivalent of HCl at −78°C gives *cis*-$[RuCl(Me)(PMe_3)_4]$ whereas with $MeCO_2H$, *cis*-$[Ru(\eta^1\text{-}OCOMe)Me(PMe_3)_4]$ is formed; more HCl produces $[RuCl(PMe_3)_4]_2Cl_2$. The mono-Me complex also reacts with 1% Na/Hg to give *cis*-$[RuMe(PMe_3)_4]_2Hg$ (see Section 45.2). The five-coordinate PPh_3 complex $[RuCl(Me)(PPh_3)_3]$ results from the reaction of $[RuCl_2(PPh_3)_3]$ with $AlMe_3$ in C_6H_6.[1662] Related mono-Me complexes include *cis*-$[RuMe\{P(O)(OMe)_2\}\{P(OMe)_3\}_4]$ generated by heating $[Ru\{P(OMe)_3\}_5]$ in *n*-hexane in a sealed tube and $[RuMe\{P(OMe)_3\}_5]I$, obtained by reaction of MeI with either of these isomers.[1380] The ylide complex $[RuCl(CH_2PMe_3)(PMe_3)_4]Cl$ (Section 45.5.4.1) results from reaction of *trans*-$[RuCl_2(PMe_3)_4]$ with $Li[Me_2P(CH_2)_2]$.[1534]

Trifluoroiodomethane oxidatively adds to *trans*-$[Ru(CO)_3\{P(OCH_2)_3CEt\}_2]$ in C_6H_6 to give $[RuI(CF_3)(CO)_2L_2]$[1663] whereas the photochemical reaction of chlorotrifluoroethylene with *trans*-$[Ru(CO)_3(PMe_2Ph)_2]$ affords an isomeric mixture of $[RuCl(\eta^1\text{-}CF{=}CF_2)(CO)_2(PMe_2Ph)_2]$.[1664a] Various compounds containing a Ru—CF_3 bond, *e.g.* $[Ru(CF_3)(HgCF_3)(CO)_2(PPh_3)_2]$ (Section 45.2) and $[RuCl(CF_3)(CO)_2(PPh_3)_2]$, are also reported and conversions to difluorocarbene species discussed.[14] Reaction of $[RuCl_2(CF_2)CO(PPh_3)_2]$ with $HOCH_2CMe_3$ gives $[RuCl_2(CFOCH_2CMe_3)CO(PPh_3)_2]$.[1664b] A preliminary communication on reactions of $[RuCl_2(CCl_2)CO(PPh_3)_2]$ is available.[49]



In an interesting insertion reaction, $[RuHCl(CO)(PPh_3)_3]$ and RCH=CHR′ dimethyl fumarate, methyl sorbate, methyl acrylate, *N,N*′-dimethylacrylamide or CH_2=CH-2-py) give $[RuCl(CO)(RCH{-}CH_2R')(PPh_3)_2]$ in which the alkyl residue is bidentate, coordinated through the σ-alkyl bond and also *via* R′. With CH_2=CHCN, however, the halide-bridged $[RuCl\{CHMe(CN)\}CO(PPh_3)_2]_2$ with a more normal monodentate alkyl group is formed.[1665a,b] Alkyl acrylates insert into $[RuHClCO(PPh_3)_3]$ under mild conditions to give Ru—C σ-bonded compounds $[RuCl(CH_2CH_2CO_2R)CO(PPh_3)_2]$.[1665c]

Reaction of *trans*-$[RuCl_2(CO)_2(PMe_2Ph)_2]$ with HgR_2 (R = Me, Ph) provides a convenient route to $[RuCl(R)(CO)_2(PMe_2Ph)_2]$ since even when HgR_2 is added in large excess, there is no replacement of the remaining chloride ligand.[1666] The methyl derivative $[RuCl(Me)(CO)_2(PMe_3)_2]$ is also obtained by photolysis of $[RuCl_2(CO)_2(PMe_3)_2]$ and dimethyltitanocene.[1667] Treatment however of either the *cis* or *trans* isomer with LiR leads to $[RuR_2(CO)_2(PMe_2Ph)_2]$ (R = Me, Ph, 3- and 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 4-FC_6H_4), and the mixed $[RuRR'(CO)_2(PMe_2Ph)_2]$ are readily synthesized from $[RuCl(R)(CO)_2(PMe_2Ph)_2]$ and LiR′.[1668] Spectroscopic (IR, NMR) studies reveal that all these compounds have configuration (**183**) irrespective of the stereochemistry of the starting material.[1666,1668] The proposed mechanism of formation of the monoalkyl or aryl complexes involves loss of CO and formation of intermediate Hg adducts. However, for reactions with LiR (Scheme 46) it is suggested that the mechanism involves nucleophilic attack by R^- on the carbon atom of a CO ligand to yield the acyl intermediate (**184**). In support of this proposal, reaction of $[RuMe_2(CO)_2(PMe_2Ph)_2]$ with CO gives first $[RuMe(COMe)(CO)_2(PMe_2Ph)_2]$ and then $[Ru(COMe)_2(CO)_2(PMe_2Ph)_2]$. Similarly, $[RuClMe(CO)_2(PMe_2Ph)_2]$ and $[RuMePh(CO)_2(PMe_2Ph)_2]$ afford $[RuCl(COMe)(CO)_2(PMe_2Ph)_2]$ and $[RuPh(COMe)(CO)_2(PMe_2Ph)_2]$ respectively on carbonylation and with L′ (L′ = PR_3, $P(OR)_3$, $AsMe_2Ph$), $[RuX(COMe)(CO)(PMe_2Ph)_2L']$ (X = Cl, Ph) are formed.[1668,1669] However no evidence is found for benzoyl complexes when $[RuX(Ph)(CO)_2(P-$

$Me_2Ph)_2$] (X = Cl, Br, I, Me, COMe, Ph) are treated with CO at atmospheric pressure or with PMe_2Ph. This is in contrast to studies on related complexes [Ru(C_6H_4Me-4)X$(CO)_2(PPh_3)_2$] (X = Cl, Br, I) (for preparation, see Scheme 47) which are in equilibrium in solution with acyl species [RuX(COC_6H_4Me-4)$(CO)(PPh_3)_2$].[1670] The low value of ν_{CO} (1550 cm^{-1}) suggests the acyl group is dihapto rather than monohapto and this is confirmed by crystal structure analyses of [RuI(η^2-COC_6H_4Me-4)$(CO)(PPh_3)_2$] and of the related [RuI(η^2-COMe)$(CO)(PPh_3)_2$] (**185**; X = I; R = Me) which is prepared from [Ru$(CO)_2(PPh_3)_3$] and MeHgI in benzene.[1671] Interestingly, it has been suggested that the corresponding [RuCl(COEt)$(CO)(PPh_3)_2$] contains an η^1-acyl group and that it does not isomerize to [RuCl(Et)$(CO)_2(PPh_3)_2$] in solution.[1672] Complexes of formula [RuCl(COEt)$CO(PPh_3)_2$Solvent] (Solvent = C_6H_6, CH_2Cl_2, THF) can be obtained by reaction of PPh_3 with [RuCl(COEt)$(CO)_2]_2$ (prepared by treating [RuCl$(CO)_3(\eta$-$C_3H_5)$] with C_2H_4 under pressure).[1673] Reaction of [RuHCl$(PPh_3)_3$] and [RuHCl$(CO)(PPh_3)_3$] with aldehydes has also been claimed to give [RuCl(COR)$(CO)(PPh_3)_2$] (R = Me, Et).[1674] However, it has been pointed out[1670] that the IR and NMR spectra of these compounds are identical with those of [RuCl(OCOR)$(CO)(PPh_3)_2$], and since it is known that [$RuCl_2(PPh_3)_3$] and PhCHO give [RuCl(OCOPh)$CO(PPh_3)_2$][1675a] (see Section 45.5.4.7.vi), the acyl formulation seems unlikely here. The binuclear complex [$Ru_2(CO)_5PPh_3(\mu$-$PPh_2)(\mu$-O=CPh)] containing bridging phosphido and acyl groups is obtained by pyrolysis of [$Ru_3(CO)_9(PPh_3)_3$].[1675b] The double acyl-bridged compound [$Ru_2(\mu$-O=$CEt)_2(CO)_6$] undergoes facile substitution of a CO by PPh_3 *etc.*[1675c]

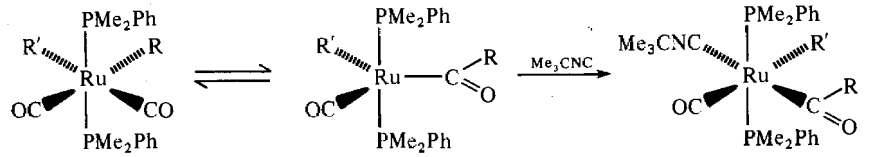
(**184**)

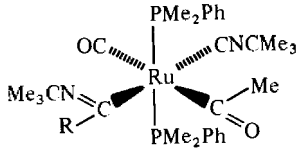
Scheme 46



i, [Hg(p-Tol)$_2$] or [Hg(p-Tol)Cl]/toluene/Δ; ii, CO; iii, CH_2Cl_2

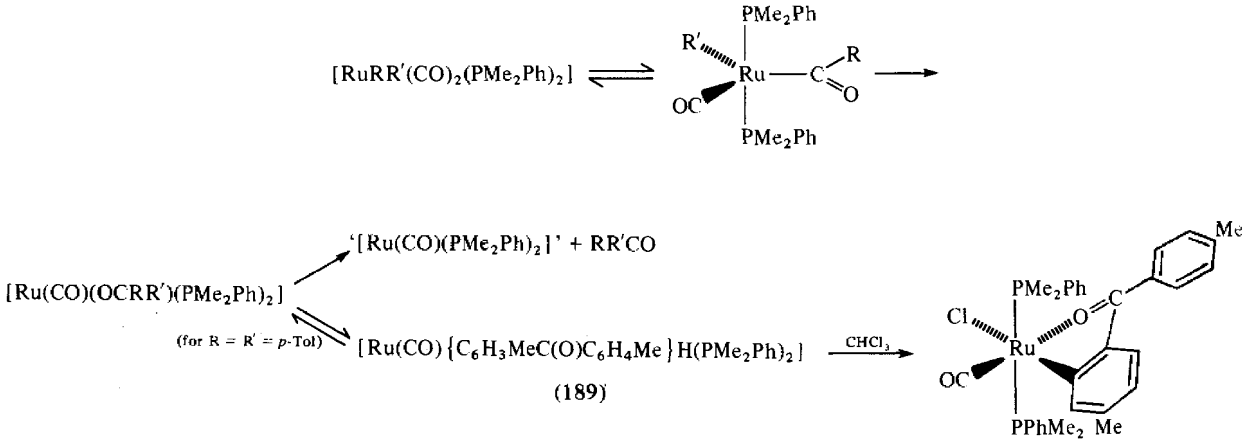
(**185**)

Scheme 47



It has been revealed[1676] that the diaryl complexes [RuRR′$(CO)_2(PMe_2Ph)_2$] will react with Me_3CNC to give [RuR′(COR)$(CO)(CNCMe_3)(PMe_2Ph)_2$] shown by X-ray analysis (for R = R′ = Ph) to have structure (**186**).[1677] Kinetic studies indicate that the rate-determining step is combination of the aryl and CO ligands followed by rapid attack of the isonitrile *trans* to the acyl ligand (Scheme 48). In unsymmetrical diaryl compounds, the aryl ligand bearing the more electron-releasing substituent becomes incorporated in the acyl ligand. Similar complexes [RuR(COMe)$(CO)(CNCMe_3)(PMe_2Ph)_2$] are formed from [RuMeR$(CO)_2(PMe_2Ph)_2$] (R = Ph, COMe, Me) and Me_3CNC. In this instance [RuMe(COMe)$CO(CNCMe_3)(PMe_2Ph)_2$] (**186**) reacts with more Me_3CNC to form (**187**); in the absence of added Me_3CNC, complex (**186**) (R = R′ = Me)

slowly disproportionates into $[RuMe_2(CO)_2(PMe_2Ph)_2]$ and (**187**).[1678a] Treatment of $[RuH(CO)_3]_n$ with PPh_3, followed by elution from a silica gel column with EtOH gives $[Ru(OH)(OCEt)(CO)_2PPh_3]$.[1678b]



(186)

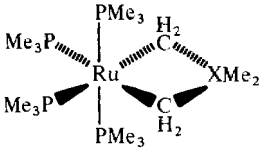
Scheme 48

(187)

The complexes $[RuRR'(CO)_2(PMe_2Ph)_2]$ also decompose intramolecularly in $CHCl_3$ at 298 K to yield ketones RR'CO. A proposed mechanism (Scheme 49) involves reductive elimination by C—C bond formation. For R = R' = *p*-Tol, the unusual product (**188**) is isolated and it is suggested that this arises from oxidative addition of the ketone in the proposed Ru^0 intermediate to form (**189**) and subsequent reaction with $CHCl_3$ replaces hydride by chloride.[1679a] There is a report of the crystal structure of (**188**) and further examples of the synthesis of *ortho*-metallated ketone complexes.[1679b]

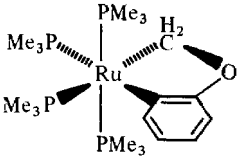
Scheme 49

(188)



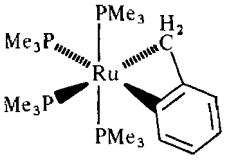
Alkyl, aryl and acyl nitrosyl phosphines and hydridophosphine complexes of Ru^{II} are covered in Sections 45.5.4.6.iii and 45.10 respectively.

(*v*) *Cyclometallated complexes*



Cyclometallation is a reaction in which a chelate metal alkyl or aryl is generated by cleavage of a C—H bond in a coordinated ligand, a new metal–carbon σ bond being formed at the point of cleavage (*e.g.* compound (**182**) in Section 45.5.4.5.iii). Since most of the work on these types of complex is contained in another review (reference 1, p.734), only a brief survey is included here.

Reaction of $[Ru_2(OCOMe)_4Cl]$ with $[Mg(Me_3SiCH_2)_2]$ and PMe_3 in THF gives the metallacycle (**190**; X = Si). On reaction with $[Mg(CH_2Bu^t)_2]$ the neopentyl compound (**190**; X = C) is formed,[1661] whereas $[Mg(2\text{-}MeOC_6H_4)_2]$ produces (**191**).[1528] Compound (**190**; X = C) is also obtained by reaction of *cis*-$[RuClMe(PMe_3)_4]$ or $[Ru_2Cl_3(PMe_3)_6]BF_4$ with $[MgCl(CH_2Bu^t)]$; reaction of *cis*-



$[RuCl(Me)(PMe_3)_4]$, *trans*-$[RuCl_2(PMe_3)_4]$ or $[RuCl(PMe_3)_4]_2Cl_2$ with $[MgCl(CH_2Ph)]$ gives (**192**).[16] Treatment of *trans*-$[RuCl_2(PMe_3)_4]$ with the lithiated ylide $Li[Me_2P(CH_2)_2]$ gives complex (**193**) containing both a three- and four-membered metallacycle together with the cation $[RuCl(PMe_3)_4(CH_2PMe_3)]Cl$ (**147**) (Section 45.5.4.1).[1380,1534] Another example of a three-membered metallacycle is $[RuI(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ obtained by reaction of $[RuH(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ with MeI; some *trans*-$[RuI_2(PMe_3)_4]$ is also formed.[1391] The metallacycle $[RuCl(CH_2PMe_2)(PMe_3)_3]$ and spirocycle $[Ru(CH_2PMe_2)_2(PMe_3)_2]$ have been prepared by reaction of *cis*-$[Ru(OCOMe)Cl(PMe_3)_4]$ and *cis*-$[Ru(OCOMe)_2(PMe_3)_4]$ respectively with $Li[N(SiMe_3)_2]$.[1680] Reaction of $[RuHCl(CO)(PPh_3)_3]$ with alkenes such as dimethyl fumarate and 2-vinylpyridine give the metallacycles (**194**) and (**195**) respectively,[1665] and with 2-formylpyridines, insertion into the Ru—H bond gives *cis*-$[RuCl(OCH_2C_5H_4N)(CO)(PPh_3)_2]$.[1681] The related complex (**196**) is prepared by reaction of $[RuCl(OCOMe)(CO)(PPh_3)_2]$ with acetophenone at elevated temperatures[1682] [*cf.* compound (**188**) in Section 45.5.4.5.iv].

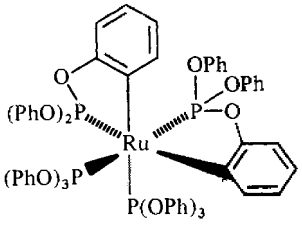
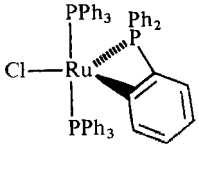
(195)

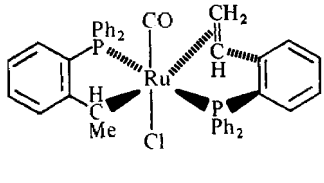


(196)

A number of complexes containing one or more *ortho*-metallated tertiary phosphite or phosphine ligands are known. For example, reaction of $[RuHCl(PPh_3)_3]$ and $P(OPh)_3$ in C_6H_6 at room temperature gives hydrogen and the *ortho*-bonded complex (**197**); on treatment with H_2 (or D_2), $[RuX\{(2,6\text{-}X_2C_6H_3O)_3P\}_4]$ (X = H, D) is readily formed,[1683] while CO in boiling benzene affords $[RuCl\{(C_6H_4O)P(OPh)_2\}CO\{P(OPh)_3\}_2]$.[1684] Reaction of $[RuHCl(CO)(PPh_3)_3]$ with $P(OPh)_3$ in boiling xylene leads to displacement of PPh_3 to give low yields of $[RuCl(CO)P(OPh_3)_2(P—C)]$ (P—C = $C_6H_4OP(OPh)_2$) whereas with $[RuH_2(PPh_3)_4]$, the dimetallated product (**198**) is obtained.[1685] Sodium amalgam reduction of $[RuCl_2(P(OPh)_3)_4]$ also gives (**198**),[1686a] (as does reaction of (**197**) with sodium phenoxide)[1686b] and the analogous dimetallated phosphite species *cis*-$[Ru(P—C)_2(cod)]$[1687] and *cis*-$[Ru(P—C)_2(CO)_2]$[1688] are reported.



Most of the cyclometallated tertiary phosphine complexes also contain Ru—H bonds (see Section 45.10.3.2.ii). However, the yellow cyclometallated PPh_3 complex $[RuCl(C_6H_4PPh_2)(PPh_3)]_2$ has been identified as the product of stoichiometric hydrogenation of alkenes such as maleic acid with $[RuHCl(PPh_3)_3]$. It reacts with CO in solution to give $[RuCl(C_6H_4PPh_2)(CO)(PPh_3)]$.[1689] Reaction of $[RuHCl(PPh_3)_3]$ with an excess of Li, Zn or Mg methyls gives some $[RuMe(C_6H_4PPh_2)(PPh_3)_2]Et_2O$ together with various hydridomethyl complexes (Section 45.10.3.2.i).[1690] The chloride analogue $[RuCl(C_6H_4PPh_2)(PPh_3)_2]$ (**199**) is prepared by reaction of $[RuCl_2(PPh_3)_3]$ with $[Zr(\eta\text{-}C_5H_5)_2Me_2]$,[1691] and thermal decomposition of $[RuH(C_6H_4PPh_2)L(PPh_3)_2]$ (L = MeCN, py) gives a mixture of products including the bis-*ortho*-metallated complex $[Ru(C_6H_4PPh_2)_2L(PPh_3)]$.[1404]

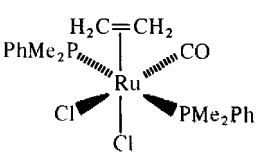


(197)

(198)

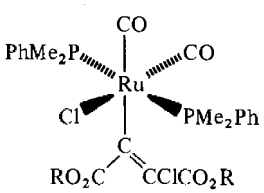
(199)

(200)



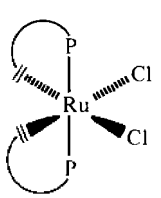
Finally, as detailed in reference 1, p.739 various *ortho*-metallated complexes have been generated from the ligand *o*-CH_2=$CHC_6H_4PPh_2$ (SP); *e.g.* reaction of $[RuCl_2(CO)_2(SP)_2]$ with boiling 2-methoxyethanol gives, as the major product $[Ru(o\text{-}CHMeC_6H_4PPh_2)Cl(CO)(SP)]$ (**200**). Other more complex products from this reaction are discussed in reference 1489. See Section 45.5.4.6.v for an example of a cyclometallated formazan derivative.

(*vi*) *Alkene complexes*

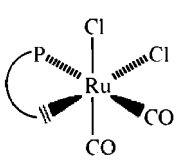


Reaction of all-*trans*$[RuCl_2(CO)_2(PMe_2Ph)_2]$ with C_2H_4 in $CHCl_3$ gives $[RuCl_2(CO)(PMe_2Ph)_2\text{-}C_2H_4]$, shown by X-ray analysis to have structure (**201**). The ^1H and ^{13}C NMR data are consistent with retention of this structure in solution, and show free rotation of the C_2H_4 group about the Ru—C_2H_4 axis down to $-40°C$.[1692] The alkenyl complexes $[RuCl(CO)_2(EMe_2Ph)_2\{CCO_2R)$=$C(CO_2R)Cl\}]$ (**202**) (E = P, As; R = Me, Et) have been synthesized by reaction of *trans*-$[RuCl_2\text{-}(CO)_2(EMe_2Ph)_2]$ with the alkynes $RO_2CC{\equiv}CCO_2R$. The proposed mechanism of formation of (**202**) involves initial formation of the alkyne complexes $[RuCl_2(CO)(EMe_2Ph)_2(RO_2CC{\equiv}CCO_2R)]$ which then undergo intramolecular nucleophilic attack by a chloride ligand. Further reaction of (**202**; R = Me) with EMe_2Ph gives $[RuCl(CO)(EMe_2Ph)_3\{C(CO_2Me)$=$C(CO_2Me)Cl\}]$.[1693] Treatment of the dimer $[RuCl(\eta^1\text{-}C_3H_5)(CO)_2(\eta^2\text{-}CH_2{=}CHCN)]_2$ with PPh_3 gives $[RuCl(\eta^1\text{-}C_3H_5)(CO)_2(PPh_3)(\eta^2\text{-}CH_2{=}CHCN)]$.[1694] Other monoalkene complexes include $[RuCl_2CO(PCy_3)_2L']$ (L′ = fumaronitrile, CH_2=$CHCN$), $[\{RuCl_2CO(PCy_3)_2\}_2TCNE]$ (with a bridging TCNE ligand)[1625] and $[RuCl(NO)(PPh_3)_2$alkene] (see Section 45.5.1.2).

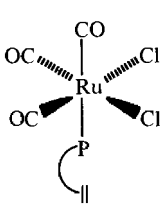
Treatment of '$RuCl_3{\cdot}xH_2O$' with *o*-CH_2=$CHC_6H_4EPh_2$ (E = P, As) gives $[RuX_2(L\text{–}L)_2]$ (X = Cl, Br). The compound $[RuCl_2(SP)_2]$ (E = P) exists in three isomeric forms all with both vinyl groups coordinated, two with *trans* chlorides and hence *cis* and *trans* phosphines, the most stable isomer having structure (**203**). The bromo phosphine and the arsine complexes exist only in form (**203**).[1695] Treatment of $[RuCl_2(SP)_2]$ in refluxing 2-methoxyethanol with CO results in displacement of the vinyl groups to form $[RuCl_2(CO)_2(SP)_2]$ whereas direct reaction of '$RuCl_3{\cdot}xH_2O$', SP and CO in 2-methoxyethanol yields $[RuCl_2(CO)_2SP]$ (**204**), which decomposes to $[RuCl_2(CO)SP]_2$ on further heating. On reaction of $[RuCl_2(CO)_3]_2$ and SP, $[RuCl_2(CO)_3SP]$ (**205**) is initially produced.[1695] The X-ray structural analysis of $[RuCl_2CO(BDPH)]$ (BDPH = 1,6-bis(diphenylphosphino)-*trans*-3-hexene), in which the BDPH moiety is bound *via* the alkenic group and two P atoms occupying mutually *trans* positions, has been reported.[1696]



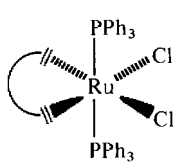
Reaction of $[RuCl_2(PPh_3)_n]$ (n = 3,4) or $[RuX_3(EPh_3)_2MeOH]$ with norbornadiene gives the very insoluble $[RuX_2(EPh_3)_2(nbd)]$ (E = P, As; X = Cl, Br),[106,655,1697] shown by X-ray analysis (for E = P) to have structure (**206**).[1698a] A more soluble analogue $[RuX_2(PMe_2Ph)_2(nbd)]$ is prepared from $Ph_3(PhCH_2)P[RuX_3CO(nbd)]$ and PMe_2Ph. With $[RuCl_3CO(nbd)]^-$ and $PMePh_2$ (1:2 molar ratio), a mixture of $[RuCl_2(PMePh_2)_2(nbd)]$ and $[RuCl_2CO(PMePh_2)_3]$ is formed. Reaction of the nbd anion with EPh_3 in 1:2 molar ratio gives $[RuCl_2CO(EPh_3)nbd]$ and some $[RuCl_3CO(EPh_3)_2]^-$ anion (E = As, Sb).[659]



(201)



(202)



(203)

(204)

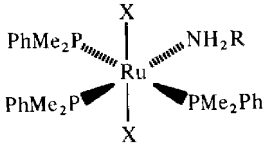
(205)

(206)

The insoluble cycloheptatriene complex $[RuCl_2(chpt)]_n$ undergoes bridge cleavage reactions to give $[RuCl_2L(chpt)]$ (L = $AsPh_3$, PBu_3, PPh_3, $P(OPh)_3$). These Lewis base derivatives react with thallium β-diketonates to give the cyclohexadienyl complexes $[Ru(dike)L(C_7H_8\text{-}dike)]$ resulting from attack of diketone on the coordinated hydrocarbon as well as on the metal.[1372]

Ru^{II} hydride alkene complexes are covered in Section 45.10, but other Ru^{II} P, As or Sb donor

ligand complexes containing delocalized π-electron ligands such as η^3-allyl, η^5-cyclopentadienyl, η^5-cyclohexadienyl, η^5-carborane and η^6-arene are outside the scope of this review (see references 1, 3 and 1698b for further information).



Binuclear compounds containing tertiary phosphines and ethene are discussed in Sections 45.5.5.1 and 45.5.5.2.

45.5.4.6 Nitrogen donor ligand complexes

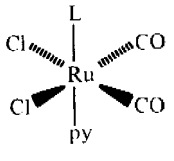
(*i*) *Ammine, amine, hydrazine and carbamoyl complexes*

Surprisingly few ammine or amine complexes containing P or As donor ligands are known. The cations *trans*-$[Ru(NH_3)_4\{P(OR)_3\}_2]^{2+}$ (R = Me, Et, Bu, Pr^i) can be prepared by treatment of $[Ru(NH_3)_5OH_2]^{n+}$ (n = 2,3) or *trans*-$[Ru(NH_3)_4(OH_2)(SO_2)]^{2+}$ cations with $P(OR)_3$ in acetone. In aqueous CF_3SO_3H, hydrolysis to *trans*-$[Ru(NH_3)_4(OH_2)\{P(OEt)_3\}]$ occurs and reaction of this with $P(OR)_3$ gives *trans*-$[Ru(NH_3)_4P(OR)_3\{P(OEt)_3\}]$ (R = Me, Bu, Pr^i). Displacement of water by pyrazine affords *trans*-$[Ru(NH_3)_4P(OEt)_3pz]^{2+}$.[1699,1700a] The binuclear complex μ-TEPP-*trans*-$[Ru(NH_3)_4P(OEt)_3]_2(PF_6)_4$ has been prepared. This readily hydrolyses to form *trans*-$[Ru(NH_3)_4(OH_2)(P(OEt)_3)]^{2+}$.[1700b] Reaction of *trans*-$[RuCl(N_3)(diars)_2]$ with dry HCl gas, followed by addition of BPh_4^-, gives first *trans*-$[RuCl(N_2)(diars)_2]BPh_4$ and then *trans*-$[RuCl(NH_3)(diars)_2]BPh_4$.[1701]

The neutral $[RuX_2(NH_2R)(PMe_2Ph)_3]$ (**207**) (X = Cl, Br; R = H, Me, Bu) arise from reaction of *mer*-$[RuX_3(PMe_2Ph)_3]$ with NH_2R in anhydrous ethanol. Hydrazines also yield $[RuCl_2(NH_2NHR)(PMe_2Ph)_3]$ (R = H, Ph) and the binuclear $[RuCl_2(N_2H_4)(PMe_2Ph)_2]_2$ but secondary and tertiary amines give only $[RuX_2(EtOH)(PMe_2Ph)_3]$. However, when small amounts of water are present, dealkylation of secondary amines occurs to produce the corresponding $[RuX_2(NH_2R)(PMe_2Ph)_3]$.[1702] Similar monosubstituted compounds are obtained by reaction of $[RuCl_2(PPh_3)_2]_n$ with aniline, *o*-chloroaniline and *o*-toluidine.[1703] However NH_3, most hydrazines and amines react with $[RuCl_2(PPh_3)_2]_n$ or $[RuCl_2(PPh_3)_3]$ to form the disubstituted $[RuCl_2L_2(PPh_3)_2]$ (L = NH_2R; R = H, $PhCH_2$, *p*-$MeOC_6H_4$, $Me(CH_2)_4$, $(PhCH_2)HNNH_2$, $NHEt_2$, NEt_3; L_2 = en, 1,2-$(H_2N)_2C_6H_3Me$-*p*, *etc.*);[677,1545,1703] $[RuCl_2(NH_2CH_2Ph)_2(PPh_3)_2]$ catalyses the oxidation of NH_2CH_2Ph to PhCN.[1703] The $AsPh_3$ analogues $[RuCl_2L_2(AsPh_3)_2]$ (L = $NHEt_2$, NEt_3, N_2H_4, NH_3, $MeNH_2$, *etc.*) are also known.[677,1704] Treatment of $[Ru(N_2H_4)_4cod](BPh_4)_2$ with various PR_3 in acetone gives the hydrazone complexes *trans*-$[Ru(NH_2NCMe_2)_2L_4](BPh_4)_2$ (L = $P(OMe)_3$, $P(OEt)_3$, $P(OMe)_2Ph$, $P(OCH_2)_3CR$; R = Me and Et) whereas $[Ru(NH_2NHMe)_4(cod)](PF_6)_2$ and $P(OMe)_2Ph$ produces $[Ru(NH_2NHMe)_2(P(OMe)_2Ph)_4](PF_6)_2$.[650,1705] Reaction of $[RuH_2(PPh_3)_4]$ and *o*-phenylenediamine gives the diimine complex $[Ru\{o\text{-}C_6H_4(NH)_2\}(PPh_3)_3]$.[1706]

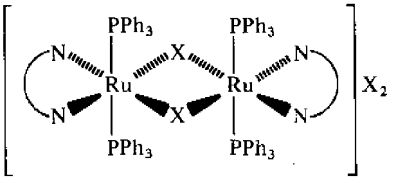
(207)

Other ammine, amine and hydrazine complexes include $[RuCl_2L(CO)(PPh_3)_2]$ (L = NH_2p-Tol, NH_2-*p*-$OMeC_6H_4$, $PhHNNH_2$) from $[RuCl_2(PPh_3)_3]$, L and CO;[629a] $[RuCl(CN)NH_3(CO)(PPh_3)_2]$ from reaction of $[RuCl_2(CCl_2)CO(PPh_3)_2]$ with NH_3,[49] $[Ru(SOCPh)_2L_2(PR_3)_2]$ (L = NH_3, NH_2Et; L_2 = $HNC(Me)CH_2CMe_2NH_2$, en) (see Section 45.5.4.8.v),[1707,1708] and $[Ru(dttd)(N_2H_4)PPh_3]$ (see Section 45.5.4.8.iii).[1709]



The carbamoyl complexes $[RuCl(CO)_2(CONHp\text{-}Tol)(PPh_3)_2]$ are generated by displacement of NH_2R from $[RuCl(CO)_2(NH_2R)_2(CONHp\text{-}Tol)]$[629a] whereas $[Ru(CO)_2(CONHR)(PPh_3)_2]BF_4$, (prepared from $[Ru(CO)_2(PPh_3)_2(RNCO)]$ and HBF_4), gives $[RuCl(CO)(CONHR)(PPh_3)_2]_n$ (R = COPh) on addition of LiCl.[1472]

(*ii*) *Mono-, bi- and tri-dentate N-heterocyclic complexes*

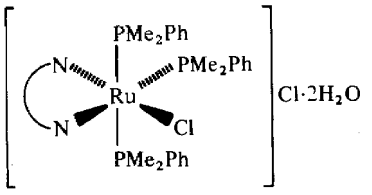


Treatment of $[RuCl_2(PPh_3)_2]_2$ or $[RuX_2(PPh_3)_3]$ (X = Cl, Br) with pyridine leads to stepwise replacement of PPh_3 groups giving $[RuCl_2(py)_2(PPh_3)_2]$, $[RuX_2(py)_3PPh_3]$ and *trans*-

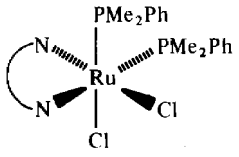
$[RuX_2(py)_4]$;[1545,1587,1697] 4-acetylpyridine affords $[RuCl_2(4\text{-}MeCOC_5H_4N)_2(PPh_3)_2]$[1553] whereas 2-methyl- and 2,6-dimethyl-pyridine are apparently too sterically congested to react.[1545] $[RuCl_2(PPh_3)_3]$ with Li[PhNpy] in toluene (PhNpy = anion of 2-(*N*-anilino)-pyridine) gives two isomers of $[Ru(PhNpy)_2(PPh_3)_2]$. In one isomer the coordinating atoms *N*-py, *N*-Ph and PPh_3 are all in a *cis* arrangement; in the other, the py rings are *trans* to each other. Both isomers display two quasi-reversible oxidation waves assignable to Ru^{III}/Ru^{II} and Ru^{IV}/Ru^{III} couples.[1710] Similarly, $[Ru(NCS)_2(PPh_3)_2]_n$ and pyridine affords $[Ru(NCS)_2(py)_3(PPh_3)]$.[1711] Cleavage of the chloro-bridged species $[RuCl_2(CO)_2L]_2$ (L = $PBu^t{}_2Ph$, $PBu^t{}_2p$-Tol) and $[RuCl_2(CS)(PPh_3)_2]_2$ with pyridine gives $[RuCl_2(CO)_2pyL]$ (**208**)[1519] and $[RuCl_2(CS)py(PPh_3)_2]$[1638] respectively, whereas $[RuHCl(CO)(PBu^t{}_2Me)_2]$ (after treatment with HCl) reacts with pyridine to form $[RuCl_2CO(py)_2(PBu^t{}_2Me)]$.[1712]

The nature of the product from reaction of $[RuCl_2(CS)(PPh_3)_2]_2$ and 2,2′-bipyridyl (or 1,10-phenanthroline) is reported to be solvent dependent. Thus in CS_2, work-up gives $[RuCl_2(CS)(N\text{–}N)PPh_3]$ whereas in MeOH, $[RuCl(bipy)(PPh_3)_2]_2Cl_2$ (**209**) (or $[RuCl_2(phen)(PPh_3)_2]$) are isolated.[1638] However since the major species from $[RuCl_2(PPh_3)_3]$ and CS_2 is the triple chloride-bridged $[(PPh_3)_2CSRuCl_3RuCl(PPh_3)_2]$ rather than $[RuCl_2CS(PPh_3)_2]_2$ (see Section 45.5.5.1),[1639,1641] it is likely that these products arise from bridge cleavage of the asymmetric binuclear complex. Direct reaction of $[RuX_2(PPh_3)_3]$ (X = Cl, Br) with these heterocycles in CH_2Cl_2 provides a high yield route to (**209**). However reaction of $[RuCl_2(PPh_3)_3]$ or $[RuCl_3(PPh_3)_2(MeOH)]$ with an excess of N–N in MeOH gives red solutions from which the monomeric cations $[RuCl(N\text{–}N)_2PPh_3]Cl$ are isolated. The corresponding $[RuCl(bipy)_2AsPh_3]^+$ cation is obtained as its BPh_4^- salt from reaction of $[RuCl_3(bipy)AsPh_3]$ (Section 45.5.7.1), bipy and $Na[BPh_4]$ in MeOH.[1697,1713] An alternative route to a wider range of $[RuCl(bipy)_2L]^+$ cations (L = PPh_3, $P(p\text{-Tol})_3$, $PMePh_2$, $PBu^n{}_3$, $Ph_2P(CH_2)_nPPh_2$ (n = 1,3), $Ph_2PC{\equiv}CPPh_2$, $Ph_2As(CH_2)AsPh_2$, $AsPh_3$, $SbPh_3$) is *via* treatment of $[RuCl(bipy)_2S]^+$ (S = H_2O, acetone) with the appropriate L.[1124] In some instances the dications $[Ru(bipy)_2L_2]^{2+}$, (L = $P(p\text{-Tol})_3$, $PMePh_2$, $Ph_2P(CH_2)_nPPh_2$ (n = 1,2,3), *cis*-$Ph_2PCH{=}CHPPh_2$), can be isolated as their PF_6^- salts.[1124,1189] The electronic spectra and redox properties of all these cations are discussed[1124] and the X-ray crystal structure of $[Ru(bipy)_2(PPh_3)_2](PF_6)_2$ reveals a *trans* arrangement of PPh_3 groups.[1122,1123] The related $[Ru(NO_2)(bipy)_2PPh_3]^+$ cation has also been reported.[1153]

(208)

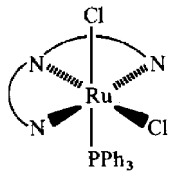


(209) N–N = bipy, phen



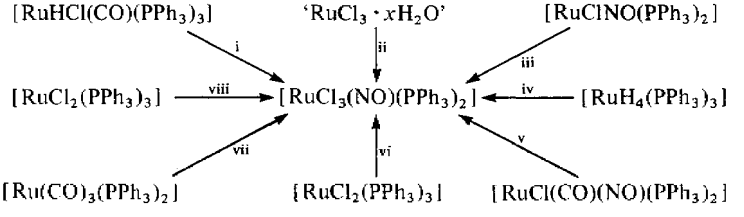
Reaction of *mer*-$[RuCl_3(PMe_2Ph)_3]$ and an excess of bipy in MeOH followed by recrystallization from acetone–light petroleum gives $[RuCl(bipy)(PMe_2Ph)_3]Cl\cdot 2H_2O$ (**210**) and $[RuCl(bipy)(PMe_2Ph)_2(OCMe_2)]Cl$, whereas in CH_2Cl_2 $[RuCl_2(bipy)(PMe_2Ph)_2]$ (**211**) and a small amount of $bipyH[RuCl_3(bipy)(PMe_2Ph)]$ are formed. With phen in CH_2Cl_2, $[RuCl_2(phen)(PMe_2Ph)_2]$ is produced but in MeOH followed by recrystallization from CH_2Cl_2–light petroleum, the main product is $[RuCl(phen)(PMe_2Ph)_2(CH_2Cl_2)]Cl$, together with small amounts of $phenH[RuCl_3(phen)PMe_2Ph]\cdot H_2O$. Treatment of *mer*-$[RuCl_3(PMe_2Ph)_3]$ with 3,4,7,8-tetramethyl-1,10-phenanthroline (Me_4phen) in MeOH gives $[RuCl(Me_4phen)(PMe_2Ph)_3]Cl$. In contrast, with 2,9-dimethyl-1,10-phenanthroline (Me_2phen) only $[Ru_2Cl_2(Me_2phen)_4]Cl_2$ and $[Ru_2Cl_3(PMe_2Ph)_6]Cl$ are isolated.[1713]

Other bipy and phen compounds include $[Ru(SC_6F_5)bipy(PPh_3)_2]_2Cl_2$ (from reaction of (**209**); N–N = bipy, X = Cl) with $[Pb(SC_6F_5)_2]$)[1714] and the two isomers of $[Ru(SOCPh)_2(N\text{–}N)(PMe_2Ph)_2]$ (see Section 45.5.4.8.v).[1708]



The reaction of $[Ru(terpy)Cl_3]$ with an excess of L (L = PPh_3, $P(p\text{-Tol})_3$) in the presence of Et_3N yields violet *trans*-$[RuCl_2L(terpy)]$ (terpy = 2,2′,2″-terpyridyl). This complex can be converted into *cis*-$[RuCl_2L(terpy)]$ (**212**) by boiling in 1,2-dichloroethane and the *cis* isomer can also be prepared by treatment of $[RuCl_2(PPh_3)_3]$ with terpy in boiling C_6H_6. The chloride in the *cis* isomer is significantly more labile than that in the *trans* isomer and addition of PPh_3 gives the *trans*-$[RuCl(PPh_3)_2(terpy)]^+$ cation. With CO, the *cis* and *trans* isomers give *cis*- and *trans*-$[RuCl_2CO(terpy)]$ respectively.[1249] Reaction of *cis*-$[Ru(OH_2)_2(PPh_3)(terpy)]^{2+}$ with PhC≡CH gives the alkyl complex $[Ru(\eta\text{-}CH_2Ph)CO(PPh_3)(terpy)]^+$.[1119]

(210)



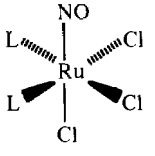
(211)

(212)

(iii) Nitrosyl, thionitrosyl, azido and dinitrogen complexes

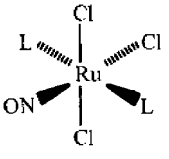
The ruthenium(II) nitrosyl complexes $[RuCl_3(NO)L_2]$ (L = PR_3, AsR_3, SbR_3) were first prepared by the reaction of $[RuCl_3NO(OH_2)_n]$ with L in ethanol; treatment with NaBr or LiI gave the corresponding $[RuX_3NOL_2]$ (X = Br, I).[123,1715,1716] Alternative routes to $[RuCl_3NO(PPh_3)_2]$ are shown in Scheme 50. Compounds of this type are also generated by the method shown in equations (101)–(104). A reinvestigation of the original synthetic route by Townsend and Coskran[1720] revealed that for L = PMe_2Ph, $AsMe_2Ph$, the kinetically favoured isomer (**213**) could be isolated which readily converts on heating to the thermodynamically favoured isomer (**214**). For other L, only isomer (**214**) is observed. X-Ray analyses of $[RuCl_3(NO)L_2]$ (L = PPh_3,[1718] $PMePh_2$[1721]) confirm this observation and reveal a linear RuNO group; multinuclear NMR studies are also reported.[1722] Studies have indicated that irradiation (at 365 nm) of both (**213**) and (**214**) (for L = PMe_2Ph) induces isomerization to (**215**); reconversion to (**214**) requires thermal energy. For L = PPh_3, the photochemical reaction is reversible at ambient temperature and in the presence of $SbPh_3$, $[RuCl_3NO(PPh_3)(SbPh_3)]$ is produced.[1723]

i, N_2O;[1717] ii, PPh_3/*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide;[1410a, 1508] iii, TsCl;[1430] iv, NOCl;[1408] v, Cl_2;[1438] vi, NO_2/LiCl;[1718] vii, NOCl;[1719] viii, NO/$CHCl_3$[1411]



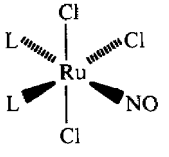
Scheme 50

$$[Ru(CO)_2(NO)(PPh_3)_2]^+ + Cl_2 \longrightarrow [RuCl_3NO(PPh_3)_2] + \textit{cis}\text{-}[RuCl_2(CO)_2(PPh_3)_2]^{1441} \quad (101)$$



$$[RuCl_2(PPh_3)_3] + NO \xrightarrow[\text{or benzene}]{\text{acetone}} [RuCl_3NO(PPh_3)_2] + [Ru(NO)_2(PPh_3)_2]^{1411} \quad (102)$$

$$[RuCl_2(PPh_3)_4] + [CoNO(DMG)_2] \longrightarrow [RuCl_3NO(PPh_3)_2] + [RuCl(NO)O_2(PPh_3)_2]^{1409} \quad (103)$$

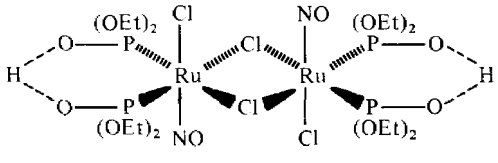


$$[Ru(NO)_2(PPh_3)_2] + PhCH_2Br \xrightarrow[\Delta]{\text{toluene}} [RuBr_3NO(PPh_3)_2] + [RuBr_2(NCPh)_2(PPh_3)_2]^{1416} \quad (104)$$

(213)

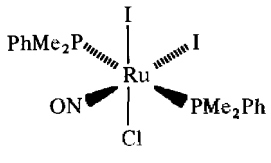
(214)

(215)



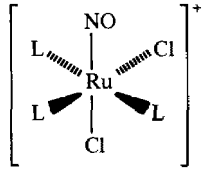
Reaction of $[RuCl_3NO(EPh_3)_2]$ (E = As, Sb) with various $P(OR)_3$ and dppe gives $[RuCl_3(NO)L_2]$ [L = $P(OR)_3$ (R = Me, Et, Bu), $\frac{1}{2}$dppe] and kinetic studies indicate that ligand dissociation to generate a five-coordinate $[RuCl_3NO(EPh_3)]$ intermediate is an important step.[1724]

Other complexes $[RuCl_3NO(L—L)]$ (L—L = dppm, *cis*-$Ph_2AsCH{=}CHAsPh_2$, $Ph_2PCH_2OCH_2PPh_2$) are formed from $[RuCl_3NO]$ but again dpam is anomalous forming $[RuCl_3$-

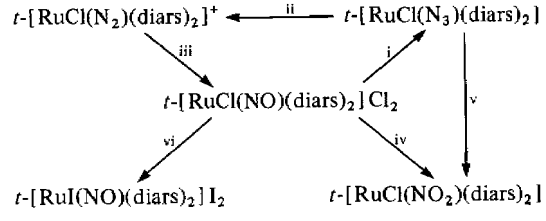


$NO(dpam)_2]$.[1593] Some studies on anchoring of $[RuCl_3NO(SbPh_3)_2]$ to polymer-bound phosphinic ligands are reported,[1725] and the mixed ligand complex $[RuCl_3NO(AsPh_3)OAsPh_3]$ is known.[1726] Treatment of '$RuCl_3 \cdot xH_2O$' and $P(OPh)_3$ with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide in dry *tert*-butanol gives green $[RuCl_3NO\{P(OPh)_3\}_2]$. However, the same reaction in EtOH affords the unusual yellow dimer (**216**), shown by X-ray analysis to contain unsymmetrical RuPOHOP moieties.[1727] Other binuclear nitrosyl complexes are the unusual $[RuX_2NO(EPh_3)]_2Y$ (X = Cl, Br; E = P, As; Y = S, SO).[1304]

As detailed in Scheme 43 (Section 45.5.1.2), $[RuCl(NO)(PPh_3)_2]$ undergoes oxidative addition reactions with various halogens, alkyl, aryl and acyl halides to give the corresponding Ru^{II} NO complexes.[1421,1429] Similar studies are reported for $[RuCl(NO)(AsPh_3)_2]$.[1434] With $[RuCl(NO)(PMePh_2)_2]$ and I_2, *trans* halide addition is followed by facile isomerization in solution to give (**217**).[1428] Mixed halide derivatives are also prepared by treatment of $[RuX(CO)(NO)(PPh_3)_2]$ with halogens Y_2 giving $[RuXY_2NO(PPh_3)_2]$ (with *trans* PPh_3 groups).[1438] The corresponding sulfato complex $[RuCl(SO_4)(NO)(PPh_3)_2]$ is obtained by reaction of $[RuCl(NO)(PPh_3)_2]$ or $[RuH(NO)(PPh_3)_3]$ with SO_2,[1424] whereas $[Ru(NO)_2(PPh_3)_2]$ or $[RuH(NO)(PPh_3)_3]$ and R_FCO_2H afford $[Ru(OCOR_F)_3NO(PPh_3)_2]$ (R = CF_3, C_2F_5)[1417,1728a,1728b] and $[RuCl(NO)(PPh_3)_2]$ gives $[RuCl(NO)(C_6X_4O_2)(PPh_3)_2]$ (X = Cl, Br) on treatment with quinones.[1429]



In reactions of $[RuCl_3NO]$ with L in ethanol, the cations $[RuCl_2(NO)L_3]^+$ (L = PMe_2Ph, $AsMe_2Ph$) can be isolated from the filtrate as either BPh_4^- or Cl^- (for L = PMe_2Ph) salts. NMR evidence suggests configuration (**218**).[1720] The cations *trans*-$[RuCl(NO)(diars)_2]^{2+}$ can be similarly prepared from $[RuCl_3(NO)]$ and diars.[1729] As shown in Scheme 51, this cation exhibits a rich chemistry producing azido, dinitrogen, ammine and nitro complexes.[1701,1730] Reaction of *cis*-$[RuCl_2(diars)_2]$ with NaN_3 in boiling 2-methoxyethanol gives *cis*-$[Ru(N_3)_2(diars)_2]$[1701] and similarly, *trans*-$[Ru(N_3)_2(eda)_2]$ is formed from *trans*-$[RuCl_2(eda)_2]$[45] and $[Ru(N_3)_2\{N(CH_2CH_2PPh_2)_3\}]$ from $[RuCl_2\{N(CH_2CH_2PPh_2)_3\}]$.[1595] *Cis*-$[Ru(N_3)_2(PMe_3)_4]$ has been synthesized from *cis*-$[RuMe_2(PMe_3)_4]$ and Me_3SiN_3.[1731] Addition of N_2 to the electron rich carbene complex (**182**) gives $[RuCl(L^{R'})(PR_3)_2N_2]$ (see Section 45.5.4.5.iii).

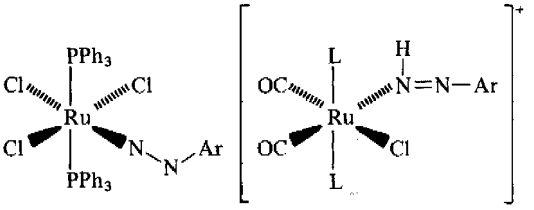


(216)

(217)

(218)

i, NaN_3 or N_2H_4; ii, $[NO_2][SbF_6]$, or $[NO][PF_6]$ or HCl;
iii, $[NO][PF_6]$; iv, NaOH; v, $h\nu/O_2$; vi, excess LiI



Scheme 51

Finally, reaction of various ruthenium(II) and (III) compounds with $[NSCl]_3$ in THF gives thionitrosyl complexes. Examples include $[RuCl_3(NS)(EPh_3)_2]$ (partial X-ray analysis has been reported for E = P),[1732] $[RuBr_2Cl(NS)(EPh_3)_2]$ (E = P, As) and $[RuCl_3(NS)(AsPh_3)(EPh_3)]$ (E = P, Sb).[668]

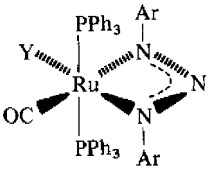
(*iv*) *Diazenido (NNR) and diazene (RN=NR) complexes*

Reaction of $[RuCl_2(PPh_3)_3]$ with various aryl diazonium tetrafluoroborates in the presence of LiCl gives the diazenido complexes $[RuCl_3(NNAr)(PPh_3)_2]$ (Ar = *p*-Tol, *p*-$MeOC_6H_4$, *p*-ClC_6H_4,

p-$O_2NC_6H_4$). X-Ray analysis for the tolyl complex[1718] and its acetone solvate[1733] confirms structure (**219**) with a bent diazenido ligand (formally ArN_2^+). A ^{15}N NMR method to distinguish between the different geometries exhibited by diazenido ligands is also available.[1734] In the absence of LiCl, reaction of $[RuCl_2(PPh_3)_3]$ with $[p\text{-}MeOC_6H_4N_2]PF_6$ in acetone gives a mixture of the cations $[RuCl_2(NNAr)(PPh_3)_2]_n^{n+}$ and $[Ru_2Cl_3(NNAr)_2(PPh_3)_3]^+$ whereas in MeCN, $[Ru_2Cl_2(MeCN)_3(NNAr)_2(PPh_3)_4]^{2+}$ is isolated.[1717]

(219) (220)

In contrast, treatment of $[RuHCl(PPh_3)_3]$ with $[ArN_2]X$ affords $[RuCl(NNAr)_2(PPh_3)_2]X$ (X = BF_4, PF_6) which undergoes chlorination to produce $[RuCl_3(NNAr)(PPh_3)_2]$ (**219**).[1717] The five-coordinate compound $[RuHCl(CO)_2PBu^tPr^n_2)]$ reacts with $[PhN_2]BF_4$ to give a phenyldiazene complex $[RuCl(NH{=}NPh)(CO)_2(PBu^tPr^n_2)]BF_4$ for which spectroscopic data suggest structure (**220**; L = $PBu^tPr^n_2$),[1519] whereas $[RuHCl(CO)(PPh_3)_3]$ and $[ArN_2]BF_4$ give '$[RuCl(FBF_3)(NH{=}NAr)CO(PPh_3)_2]$' which has a weakly coordinated BF_4^- ligand. Acetone solutions of the latter yield $[RuCl(NH{=}NAr)(CO)_2(PPh_3)_2]BF_4$ (**220**; L = PPh_3) with CO and $[RuCl_2(NH{=}NAr)(CO)(PPh_3)_2]$ with LiCl. The complex $[RuH(NH{=}NAr)(CO)(PPh_3)_3]BF_4$ (from $[RuH_2CO(PPh_3)_3] + [ArN_2]BF_4$[1735]) reacts with LiCl to give the same dichloro compound.[1736]



Addition of $[ArN_2]^+$ to $[Ru(CO)_3(PPh_3)_2]$ affords $[Ru(NNAr)(CO)_2(PPh_3)_2]^+$.[1735,1737] This gives $[RuX(NNAr)(CO)_2(PPh_3)_2]$ (X = Cl, F, Br, I) on treatment with X^- which then protonate readily to form the phenyldiazene salts (**220**) as confirmed by a structural analysis on $[RuCl(NH{=}NPh)(CO)_2(PPh_3)_2]ClO_4 \cdot CH_2Cl_2$.[1738] The preparations of analogous hydrido diazenide and diazene complexes such as $[RuH(NH{=}NPh)(CO)_2(PPh_3)_2]^+$, $[RuH(NNPh)(CO)_2(PPh_3)_2]$ and $[RuH(NNPh)(CO)(PPh_3)_2]$ are discussed in reference 1735.

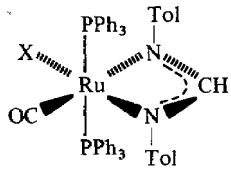
Finally, *trans*-$[RuX_2L_2]$ (X = Cl, Br, I; L = 2-(arylazo)pyridine) reacts with various PR_3 and $Ph_2P(CH_2)_nPPh_2$ ($n = 2,3$) to give the cations $[RuX(PR_3)L_2]^+$, $[Ru(PR_3)_2L_2]^{2+}$ and $[Ru(Ph_2P(CH_2)_nPPh_2)L_2]^{2+}$ respectively. A correlation between the Ru^{III}/Ru^{II} electrode potential and the visible spectra of these compounds is demonstrated.[1739]

(*v*) *Triazenido (RNNNR), formamidinato (RNC̄(H)NR), formazan (RNNC(R)NNR), formamido (RNC̄(H)O), thioformamido (RNC̄(H)S) and ureylene (RNCONR^{2-}) complexes*

Bidentate 1,3-diaryltriazenido complexes can be synthesized by reaction of 1,3-diaryltriazenes, (ArNNNHAr), with either Ru^0 or Ru^{II} hydride complexes. For example, $[RuHXCO(PPh_3)_3]$ (X = H, Cl) and $[Ru(CO)_3(PPh_3)_2]$ give $[RuH(ArNNNAr)(CO)(PPh_3)_2]$ in boiling C_6H_6 or EtOH, whereas $[RuHCl(CO)(PPh_3)_3]$ affords $[RuCl(ArNNNAr)(CO)(PPh_3)_2]$ in C_6H_6 at room temperature. An X-ray analysis on $[RuH(p\text{-}TolN_3Tol\text{-}p)(CO)(PPh_3)_2]$ confirms configuration (**221**).[1740,1741] Alternative routes to triazene complexes involve displacement of halide ion from halo–ruthenium complexes with triazenido anions (*e.g.* equations 105 and 106).[1742,1743]

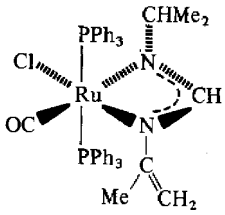
Diarylcarbodiimides (ArN=C=NR) insert into Ru—H bonds to give the corresponding formamidinato (ArN===C̄H===NAr) complexes (equation 107). Configuration (**222**) assigned on the basis of NMR evidence has been confirmed for X = H by X-ray analysis.[1744] Compound (**222**; X = H) is also prepared from $[RuH_2(PPh_3)_4]$ and *p*-TolNCO.[1745] In boiling C_6H_6, Pr^iNCNPr^i inserts into the Ru—H bond of $[RuHCl(CO)(PPh_3)_3]$ but concomitant dehydrogenation of a Pr^i group gives $[RuCl\{CH_2{=}C(Me)NCHNCHMe_2\}CO(PPh_3)_2]$ (**223**) as confirmed by X-ray analysis.[1746]

(221) Y = H, Cl



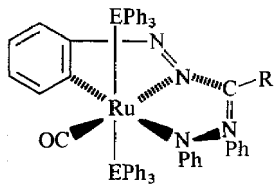
$$[RuHCl(PPh_3)_3] + Li[N_3Ph_2] \longrightarrow [RuH(PhN_3Ph)(PPh_3)_3] + LiCl \quad (105)$$

$$[RuCl_2(PPh_3)_n] + Li[N_3Ph_2] \longrightarrow [Ru(PhN_3Ph)_2(PPh_3)_2] + 2Cl^- \quad (106)$$



(or $HN_3Ph_2 + Et_3N$)

$$[RuHX(CO)(PPh_3)_3] + TolNCNTol \longrightarrow \quad (107)$$

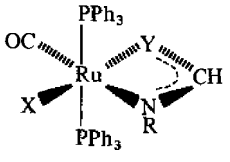


(X = H, Cl, Bv, $OCOCF_3$)

(222)

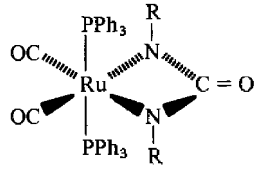
(223)

(224)



Reaction of $[RuH_2(CO)(EPh_3)_3]$ (E = P, As) or $[RuHCl(CO)(PPh_3)_3]$ with 1,5-diphenylformazans (PhN=NC(R)=NNHPh) in boiling 2-methoxyethanol or DMF affords the deep green cyclometallated formazan derivatives $[Ru\{(O—C_6H_4)N=NC(R)=NNPh\}CO(EPh_3)_2]$, (**224**) (as established by X-ray analysis for R = Ph, E = P). Isomeric hydrido intermediates of form $(RuH(PhN=NCH=NNPh)CO(PPh_3)_2]$ have been isolated as pink (with *cis*-PPh_3) or purple (with *trans*-PPh_3) complexes and convert to the green cyclometallated compound on further heating.[1747]

Alkyl and aryl isothiocyanates, RNCS, undergo insertion reactions into Ru—H bonds to give thioformamido, (RN=CH=S), complexes (equations 108 and 109)[1748] whereas aryl isocyanates, RNCO, and $[RuHX(CO)(PPh_3)_3]$ (X = H, Cl, Br) afford the analogous formamido complexes (**225**; Y = O). Under more forcing conditions, reaction of the dihydride with *p*-TolNCO results in cleavage of a molecule of isocyanate and formation of the ureylene complex $[Ru(TolNCONTol)(CO)_2(PPh_3)_2]$ (**226**).[1745] Compound (**226**; R = *p*-$TolSO_2$) is also obtained by reaction of $[Ru(CO)_3(PPh_3)_2]$ with toluene-*p*-sulfonyl isocyanate at room temperature in C_6H_6.[1472]

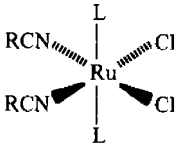


$$[RuHX(CO)(PPh_3)_3] + RNCS \longrightarrow [RuX(RNCHS)(CO)(PPh_3)_2] \quad (108)$$

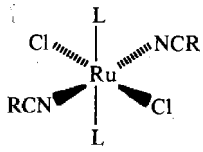
(X = H, Cl, Br, $OCOCF_3$) (R = Me, Et, Ph, *p*-Tol)

$$[RuH_2(PPh_3)_4] + RNCS \longrightarrow [Ru(RNCHS)_2(PPh_3)_2] \quad (109)$$

(225) Y = O, S



(226) R = *p*-Tol, *p*-$TolSO_2$



(*vi*) *Nitriles and N bonded thiocyanates and selenocyanates*

Reaction of $[RuCl_2(PPh_3)_3]$ and various alkyl or aryl nitriles RCN gives $[RuCl_2(RCN)_2(PPh_3)_2]$ (R = Me, Pr^n, Pr^i, Ph, $PhCH_2$, CH_2=CH *etc.*); in boiling acetone the *cis* isomer (**277**) is obtained whereas toluene yields the *trans* isomer (**228**). Recrystallization of (**228**) from acetone gives (**227**). With dinitriles, $[RuCl_2L_2(PPh_3)_2]$ is formed (L = $NC(CH_2)_nCN$ (*n* = 1–4), phthalonitrile).[1545] Recrystallization of the bis(MeCN) complex from C_6H_6 affords the binuclear $[RuCl_2(MeCN)(PPh_3)_2]_2$.[1404] The corresponding $[RuCl_2(RCN)_2(AsPh_3)_2]$ (R = Me, Pr, CH_2=CH)

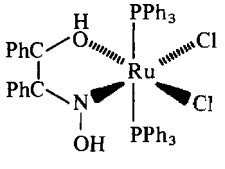
are known,[677,1749] and also the ethyl(diphenylphosphino)acetate analogue (equation 110).[1750] An alternative route to (**228**) (L′ = various PR_3) is *via* bridge cleavage of $[RuCl_2(PhCN)_3]_2$ while treatment of $Et_4N[RuCl_4(RCN)_2]$ with $PMePh_2$ yields $[RuCl_2(RCN)_2(PMePh_2)_2]$.[681] Treatment of the polymeric $[Ru(NCS)_2(PPh_3)_2]_n$, (made from $[RuCl_2(PPh_3)_3]$ and SCN^-), with MeCN gives $[Ru(NCS)_2(MeCN)_2(PPh_3)_2]$,[1711] and the closely related $[Ru(NCE)_2(CO)_2(PPh_3)_2]$ (E = S, Se) are prepared from $[Ru(CO)_3(PPh_3)_2]$ and $(ECN)_2$.[661,1626]

(227)

(228)

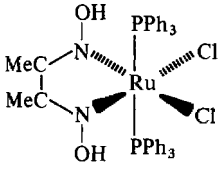
$$[RuCl_3(o\text{-}MeC_6H_4CN)_3] + PPh_2CH_2C(O)OEt \longrightarrow [RuCl_2(o\text{-}MeC_6H_4CN)_2(PPh_2CH_2C(O)OEt)_2] \quad (110)$$

(228)



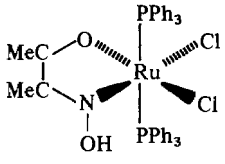
The cations *fac*-$[Ru(RCN)_3L_3]^{2+}$ are generated either by treatment of $[Ru_2Cl_3L_6]Cl$ (L = PMe_2Ph, $PMePh_2$) with $Ag[BF_4]$ and RCN (R = Me, Et, Pr, Ph, $MeOC(O)CH_2^-$),[1752] by protonation of $[Ru_2(OH)_3(PMe_2Ph)_6]^+$ with HPF_6 in MeCN[1753] or by reaction of $[Ru(MeCN)_4(cod)]^{2+}$ with $P(OMe)_2Ph$ or $P(OMe)_3$ in nitromethane.[1370] The *fac* isomer isomerizes to the *mer* form on recrystallization.[1753] In MeCN, $[Ru(MeCN)_4cod]^{2+}$ and L give $[Ru(MeCN)_4L_2]^{2+}$ (L = PPh_3, $PMePh_2$, PMe_2Ph, $P(OMe)_2Ph$ and $P(OMe)_3$). The monocations $[RuCl(MeCN)_3L_2]^+$ (L = PPh_3, $PMePh_2$, PMe_2Ph) can be synthesized from $[RuCl(MeCN)_3(cod)]PF_6$ and L in refluxing MeCN,[1370] and treatment of $[RuX(L\text{–}L)_2]PF_6$ (L–L = dppe, $Ph_2P(CH_2)_2NC_5H_4$) with MeCN gives the six-coordinate *trans*-$[RuX(MeCN)(L\text{–}L)_2]PF_6$.[1535] Treatment of $[Ru(OCOMe)(OH_2)(PPh_3)_3]BF_4$ with MeCN gives $[Ru(OCOMe)(MeCN)(PPh_3)_3]^+$ which reacts with aqueous HBF_4 to produce the $[Ru(OH_2)(MeCN)_2(PPh_3)_2]^{2+}$ dication.[1754]

Nitrile complexes containing Ru—H bonds are covered in Section 45.10.

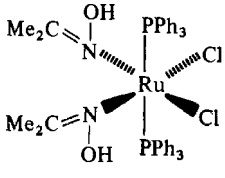


(*vii*) *Oxime and Schiff base complexes*

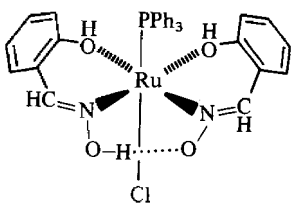
In the absence of alkali, hydroxyoximes, α-dioximes and α-carbonyloximes displace PPh_3 from $[RuCl_2(PPh_3)_3]$ and form complexes of type (**229**), (**230**) and (**231**) respectively. Small simple oximes give the six-coordinate bis(oxime) compounds (**232**) whereas with more bulky substituents the pentacoordinate $[RuCl_2\{N(OH)C(Me)(Bu^t)\}(PPh_3)_2]$ is formed. In MeOH, reductive decarboxylation of solvent occurs with formation of $[RuHCl(CO)(LH)(PPh_3)_2]\cdot MeOH$ (L—H = cyclohexanone oxime, acetophenone oxime and *n*-butylphenylketone oxime). In the presence of base, chloride displacement occurs and both α-dioximes and α-carbonyloximes give *trans*-$[Ru(oxime)_2(PPh_3)_2]$. Similar products are formed with pyrinaldoxime but with salicyaldoxime, stepwise replacement of chloride produces first (**233**) and then (**234**).[1755]



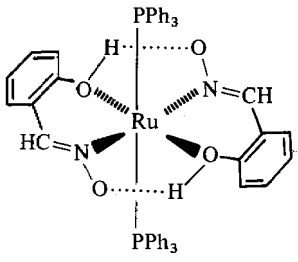
Treatment of $[RuCl_2(PPh_3)_3]$ with the sodium salts of Schiff bases also leads to chloride displacement. For example, *N*-benzylsalicylideneimine gives (**235**) whereas *N,N′*-ethylenebis(pentane-2,4-dione-monoimine) yields (**236**).[1756,1757a,1757b] The air sensitive compound (**237**) has been reported.[1758a] Redox reactions of the compound $[RuC_2H_4(N{=}CHC_6H_4O\text{-}o)_2(PPh_3)_2]$ with I_2, $FeCl_3$ and O_2 have been reported.[1758b] Reaction of $[RuCl_2(PPh_3)_3]$ with the sodium salt of *N,N′*-bis(salicylaldehydo)ethylenediamine (salenH_2) gives $[Ru(salen)(PPh_3)_2]$ whereas with the free ligand in methanol, the ruthenium(III) complex $[RuCl(salen)PPh_3]$ is formed.[1756,1758c]



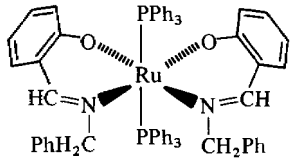
(229)



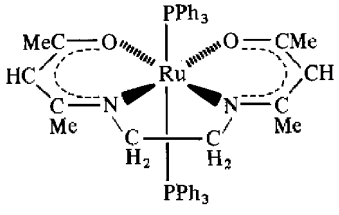
(230)



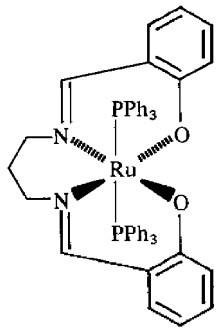
(231)



(232)

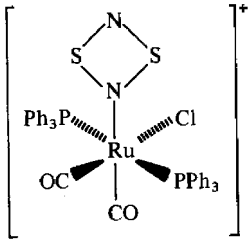


(233)

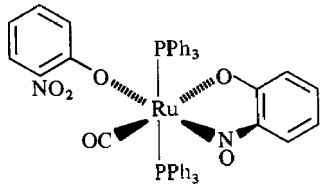


(234)

(235)



(236)



(237)

(*viii*) *Miscellaneous*

Reaction of $[RuCl_2(CO)(PPh_3)_2]$ and $S_2N_2 \cdot 2AlCl_3$ in CH_2Cl_2 gives $[RuCl(S_2N_2)(CO)_2(PPh_3)_2]$-$AlCl_4$, (**238**), the first example in which the S_2N_2 group acts as a monodentate ligand through nitrogen.[1759]

(238)

(239)

Aminoacid complexes $[RuClL(PPh_3)_2]$ (LH = glycine, L-serine, L-hydroxyproline and L-allohydroxyproline) can be prepared by reaction of $[RuCl_2(PPh_3)_3]$ with the appropriate amino acid in the presence of $Na[HCO_3]$. Glycerin is oxidatively dehydrogenated in the presence of $[RuClL(PPh_3)_2]$ and *N*-methylmorpholine-*N*-oxide.[1760] On heating $[RuH_2(PPh_3)_4]$ with 2-hydroxypyridine and 8-hydroxyquinoline, $[RuX_2(PPh_3)_2]$ (X = 2-OC_5H_4N, 8-OC_9H_6N) is formed whereas 2-mercaptopyridine, 2-aminothiophenol and 2-aminophenol form $[Ru(chelate)_2(PPh_3)_2]$ even at room temperature.[1706] Reaction with *N*-sulfinylaniline (NSA) gives $[RuCl_2(EPh_3)_2(NSA)_2]$ (E = P, As) *via* *N*-coordination.[1761]

Reaction of $[Ru(CO)_3(PPh_3)_2]$ with 2-nitrophenol in boiling C_6H_6 gives the unusual Ru^{II} complex (**239**) in which on nitrophenol ligand has undergone reduction to a nitrosophenolate anion and another coordinates *via* only the phenolate group.[1762]

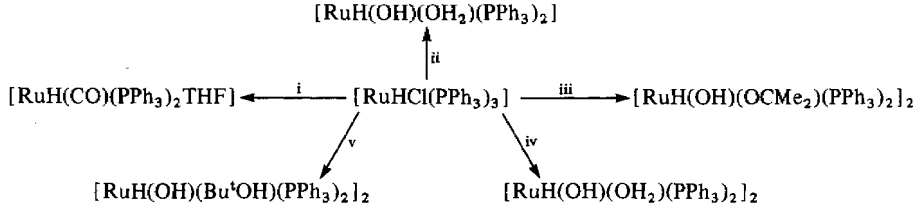
45.5.4.7 Oxygen donor ligand complexes

(i) Water, alcohol, acetone, dimethylformamide, dimethylacetamide and tetrahydrofuran complexes

A number of O donor solvento complexes containing P donor ligands have been reported. Treatment of $[RuCl_2(CS)(PPh_3)_2]_2$ with DMF gives $[RuCl_2(CS)(PPh_3)_2DMF]$ which on recrystallization from $MeOH/CH_2Cl_2$ produces $[RuCl_2(CS)MeOH(PPh_3)_2]$.[1616] Similarly $[RuCl_2(CO)DMF(PPh_3)_2]$, (from $[RuCl_2(PPh_3)_3]$ and CO in DMF), forms $[RuCl_2(CO)MeOH(PPh_3)_2]$[659,1616] and not the five-coordinate $[RuCl_2(CO)(PPh_3)_2]$ as originally suggested.[1607] The aqua analogues are obtained as shown in equations (111) and (112), and carbonylation of $[RuCl_2(PPh_3)_3]$ in DMA gives $[RuCl_2(CO)DMA(PPh_3)_2]$.[1607]

$$\text{'}RuCl_3\cdot xH_2O\text{'} + HCO_2H \longrightarrow \text{'}RuCl_2(OH_2)(CO)\text{'} \xrightarrow{PPh_3} [RuCl_2(OH_2)(CO)(PPh_3)_2]^{1763} \quad (111)$$

$$[RuCl_2(PPh_3)_3] + CS_2 \xrightarrow[\Delta]{\text{xylene}} [RuCl_2(OH_2)CS(PPh_3)_2]^{1640} \quad (112)$$

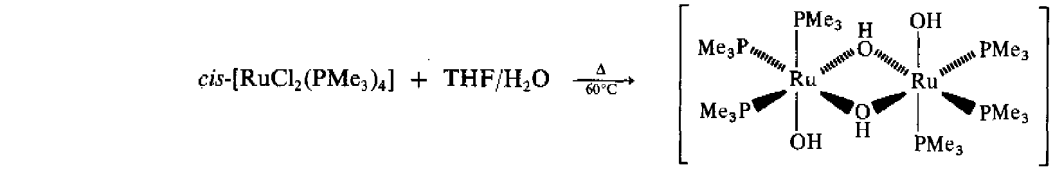


On heating $[RuCl_2(PPh_3)_3]$ in acetone, red $[RuCl_2Me_2CO(PPh_3)_2]_n$ precipitates whilst with higher ketones, black $[RuCl_2(PPh_3)_2]_n$ is produced.[1545] Secondary and tertiary amines react with *mer*-$[RuX_3(PMe_2Ph)_3]$ in anhydrous EtOH to give $[RuX_2(EtOH)(PMe_2Ph)_3]$ (X = Cl, Br)[1702] and treatment of $[RuH_2(PPh_3)_4]$ with SO_2 in wet toluene gives the aqua intermediate $[RuSO_4(OH_2)(SO_2)(PPh_3)_2]$.[1764] Complexes of formula $[RuCl(COEt)CO(PPh_3)_2Solvent]$ (Solvent = C_6H_6, THF, CH_2Cl_2) arise from reaction of PPh_3 with $[RuCl(COEt)(CO)_2]_2$.[1673] Direct reaction of $[Ru(OH_2)_6](tos)_2$ with PPh_3 gives $[Ru(tos)_2(OH_2)_2(PPh_3)_2]$ (tos = *p*-toluenesulfonate).[1600b]

The aqua cation $[RuCl(OH_2)(CNR)(CS)(PPh_3)_2]ClO_4$ has been synthesized by reaction of *cis*-$[RuCl_2(CNR)(CS)(PPh_3)_2]$ with $Ag[ClO_4]$ in $EtOH/CH_2Cl_2$[1645] and protonation of $[RuH(OCOMe)(PPh_3)_3]$ with aqueous HBF_4 in acetone gives $[Ru(OCOMe)(OH_2)(PPh_3)_3]BF_4$ as the end product. Intermediate hydrido cations such as $[RuH(Solvent)(PPh_3)_3]^+$ are produced in this reaction (see Section 45.10.3.2.v).[1754] Other solvated hydrido complexes include $[RuH(OH_2)(CO)_n(PPh_3)_{4-n}]BF_4$ (n = 1,2),[1765] $[RuH(MeOH)(PMe_2Ph)_4]PF_6$, $[RuH(EtOH)(dppe)_2]PF_6$,[1766] $[RuH(OH_2)(CO)_2(PPh_3)_2]^+$, $[RuH(OH_2)_2(MeOH)(PPh_3)_2]^+$[1754] (Section 45.10.3.2.v) and various hydroxo species containing H_2O, THF, acetone and *tert*-butanol (Section 45.5.4.7.ii).

The reactive intermediate $[Ru(Me_2CO)_3(PMe_2Ph)_3]^{2+}$ is generated by treatment of $[Ru_2(OH)_3(PMe_2Ph)_6]^+$ with HPF_6 in acetone.[1753] $[RuCl(SnCl_3)(Me_2CO)CO(PPh_3)_2]$[109] and $[RuCl(dppm)_2THF]Mn(CO)_5$[1506] are discussed in Sections 45.2 and 45.5.4.1 respectively.

(ii) Hydroxo complexes



Reaction of $[RuCl_2(PPh_3)_3]$ with NaOH in THF containing 10% water gives $[RuCl(OH)(OH_2)(PPh_3)_2]_2$ but on prolonged heating this is converted to $[RuH(OH)(PPh_3)_2(THF)]_2$. As shown in Scheme 52,[1767] these and other hydrido–hydroxo dimers, together with their monomeric analogues $[RuH(OH)(PPh_3)_2Solvent]$ (Solvent = H_2O, THF), are obtained by treatment of $[RuHCl(PPh_3)_3]$ with aqueous carbonate-free NaOH or KOH in THF or acetone. Another route to $[RuH(OH)(OH_2)(PPh_3)_2]$ is by reaction of $[RuH(C_6H_4PPh_2)Et_2O(PPh_3)_2]$ (Section 45.10.3.2.ii) with water in THF.[1402] Further complications arise because of subsequent transformation of some of these products into tetranuclear complexes containing terminal carbonyls and bridging OH, H and PPh_2 ligands, *e.g.* $[Ru_4H_4(OH)_2(PPh_2)_2(CO)_2(Me_2CO)_2(PPh_3)_6]$.[1767]

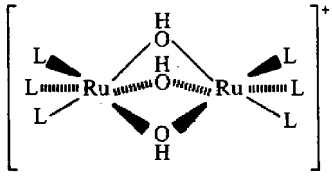

Scheme 52

Other binuclear hydroxo species are $[Ru(OH)_2(PMe_3)_3]_2$ (**240**)[1521] (equation 113), $[Ru_2(OH)_3L_6]^+$ (**241**) (L = PMe_2Ph, $PMePh_2$, $P(OMe)Ph_2$, PMe_3) and $[Ru_2(OH)_2(PPh_3)_4(BF_4)_2]$ (**242**). The PMe_3 cation is best prepared by reaction of $[Ru_2(CH_2)_3(PMe_3)_6]$ with $[Ph_3C]BF_4$ in THF[1768] whereas treatment of $[RuH(NH_2NMe_2)_3(cod)]^+$ with PR_3 in acetone/MeOH followed by addition of water provides a high yield route to the others.[1753] Compound (**242**) arises from reaction of [RuH(OCOMe)$(PPh_3)_3$] with HBF_4 in MeOH. The low conductivity in $MeNO_2$ suggests anion coordination or ion-pairing.[1769] The related hydroxo-bridged complex (**243**) is produced by reaction of $[RuHCl(Pr^iNCHCHNPr^i)(PPh_3)_2]$ with water in toluene.[1770]

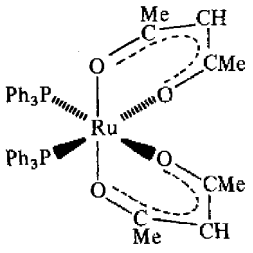
(240)

(241)

(242)

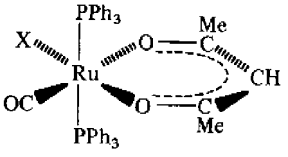
(243)

Trimetallic hydroxo-bridged complexes such as $[Ru_2(\mu\text{-}OH)_2\{\mu\text{-}Fe(CO)_4\}(CO)_4L_2]$ (L = PPh_3, PMe_3, $AsPh_3$) and $[Ru_2(\mu\text{-}OH)(\mu\text{-}H)\{\mu\text{-}Fe(CO)_4\}(CO)_4(PPh_3)_2]$ are covered in Section 45.5.5.



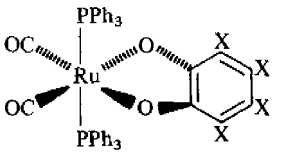
(*iii*) *Ketoenolate (dike) and quinone complexes*

Reaction of $[RuH_2(PPh_3)_4]$ with acetylacetone in boiling 2-methoxyethanol in the presence of Et_3N gives orange crystals of $[Ru(acac)_2(PPh_3)_2]$ shown by ^1H NMR spectroscopy to have the *cis* configuration (**244**). Similar compounds are obtained using trifluoroacetylacetone and hexafluoroacetylacetone.[1771] The rate of inversion between the optical isomers of (**244**) is slow at ambient temperature and hence the enantiomers can be resolved.[1772] $[Ru(acac)_2(PPh_3)_2]$ can also be prepared from $[RuCl_2(PPh_3)_3]$, acacH and Et_3N in boiling C_6H_6 and on recrystallization from MeOH and C_6H_6 gives orange and green forms respectively. These products have identical NMR and electronic spectral properties and it is suggested that they may differ in the solid either in the orientation of the phenyl groups or because of the existence of a *trans* isomer.[1545] In the absence of base, compounds such as $[RuCl(acac)(PPh_3)_2]_2$, which are formulated as chloride-bridged dimers are isolated; the corresponding $AsPh_3$ compounds are also known.[1704]



Treatment of $[RuHCl(CO)(PPh_3)_3]$ with acacH in boiling 2-methoxyethanol gives $[RuCl(acac)(CO)(PPh_3)_2]$ (**245**) whereas in the presence of Et_3N, the hydrido complex $[RuH(acac)CO(PPh_3)_2]$ (**245**) is produced. The latter also arises from direct reaction of $[RuH_2(CO)(PPh_3)_3]$, $[RuH(NO_3)CO(PPh_3)_2]$ or $[Ru(CO)_3(PPh_3)_2]$ with acacH,[1771,1773] or $[Ru(OCOCF_3)_2(CO)(PPh_3)_2]$ with acacH/KOH.[1774] Complexes of similar stoichiometry result from reaction of $[RuHX(CO)(PPh_3)_3]$ (X = H, Cl) with acacH in C_6H_6.[1775] The fluorinated β-diketonates $[Ru(dike)_2(PPh_3)_2]$ and $[RuX(dikete)CO(PPh_3)_2]$ (X = H, Cl) are also known.[1771,1776] Interestingly, reaction of $[RuH_2(CO)(PPh_3)_3]$ with $[Pd(facfac)_2]$ in boiling C_6H_6 gives a mixture of [RuH(facfac)$(CO)(PPh_3)_2$] and *cis*-[Ru$(facfac)_2CO(PPh_3)$] which can be separated by chromatography.[1776] Treatment of $[Ru(NO_3)_2CO(PPh_3)_2]$ (Section 45.5.4.7.v) with acetylacetone gives $[Ru(NO_3)(acac)CO(PPh_3)_2]$ containing a monodentate NO_3^- ligand,[1773] and likewise $[Ru(OCOCF_3)_2(CO)(PPh_3)_2]$ gives [Ru(OCOCF$_3$)(dike)$(CO)(PPh_3)_2$] (dike = acac, facfac).[1774]

Tetrachloro- and tetrabromo-1,2-benzoquinone react with $[Ru(CO)_3(PPh_3)_2]$ to give the orange complexes (**246**). The same compounds are obtained using tetrachloropyrocatechol and base. Cyclic voltammetry indicates that compounds (**246**) undergo reversible one-electron transfer reactions and these oxidation products can be chemically generated.[1777a] Treatment of $[RuCl(NO)(PPh_3)_2]$ with various quinones yields $[RuCl(NO)(C_6X_4O_2)(PPh_3)_2]$[1430] whereas $[RuCl_2(PPh_3)_3]$ affords the ruthenium(IV) complexes $[RuCl_2(C_6X_4O_2)(PPh_3)_2]$ (X = Cl, Br).[1777a] The catecholate-bridged dimer

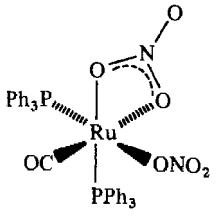


$[Ru(CO)_2(PPh_3)(\mu\text{-}o\text{-}O_2C_6Cl_4)]_2$ undergoes bridge cleavage with Group V donors and halide ions to give $[Ru(CO)_2(PPh_3)L(o\text{-}O_2C_6Cl_4)]$ (L = PPh_3, $AsPh_3$ *etc.*) and $[RuX(CO)_2(PPh_3)(o\text{-}O_2C_6Cl_4)]^-$ (X = Cl, Br, I) respectively. Chemical oxidation of these monomers gives semiquinone complexes.[1777b] Direct reaction of $[RuCl_2(CO)_n(PPh_3)_{3-n}]$ (n = 0–3) with *o*-semiquinolates of Na, Tl or Cu gives $[RuClL(CO)_n(PPh_3)_{3-n}]$ (HL = 3,6-di-*tert*-butyl-1,2-semiquinone *etc.*).[1777c]

(244)

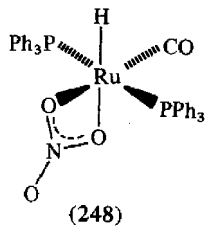
(245) X = H, Cl

(246) X = Cl, Br



(*iv*) *Dioxygen complexes*

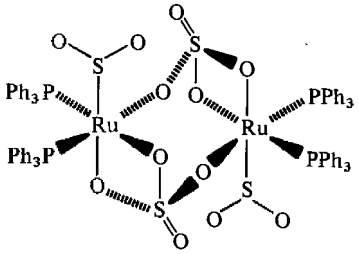
Apart from the formally Ru^0 compounds $[RuX(NO)O_2(PPh_3)_2]$ and $[Ru(CO)(CNR)O_2(PPh_3)_2]$,[1480] the only claims for $Ru^{II}O_2$ species are concerned with O_2 absorption by $[RuCl_2(PPh_3)_3]$ and '$RuCl_2(AsPh_3)_3$'. However, the green material obtained by exposure of solutions of $[RuCl_2(PPh_3)_3]$ to air is attributed to formation of unspecified triphenylphosphine oxide complexes[1411,1544,1547] and the compound $[RuCl_2(AsPh_3)_3O_2]$ has been reformulated as the binuclear μ-peroxo complex $[(AsPh_3)_3Cl_2RuO_2RuCl_2(AsPh_3)_3]Cl_2$.[1778] Note however that earlier workers[1547] suggested that Ru^{III} arsine oxide complexes may be present here.



(*v*) *Nitrato, sulfato, carbonato and perchlorato complexes*

Reaction of $[RuHCl(CO)(PMe_2Ph)_3]$ with aqueous HNO_3 gives $[RuCl(NO_3)(CO)(PMe_2Ph)_3]$ containing a monodentate NO_3^- ligand.[1614c] Similarly, treatment of $[RuH_2CO(PPh_3)_3]$ with HNO_3 gives $[Ru(NO_3)_2CO(PPh_3)_2]$ (**247**) which exhibits facile intramolecular exchange of its uni- and bi-dentate NO_3^- groups. A preliminary communication reports the preparation of $[Ru(NO_3)_2(PMe_2Ph)_3]$ from reaction of $[Ru_2X_3(PMe_2Ph)_6]^+$ (X = OH, H) with HNO_3; $[RuH(PMe_2Ph)_5]^+$ and HNO_3 give $[Ru(NO_3)(PMe_2Ph)_5]^+$.[1753] The dicarbonyl complex $[Ru(NO_3)_2(CO)_2(PPh_3)_2]$ (with unidentate NO_3^- ligands) is prepared either by reaction of (**247**) with CO or treatment of $[Ru(CO)_3(PPh_3)_2]$ with HNO_3. Reaction of (**247**) with EtOH or propanol gives the hydrido complex $[RuH(NO_3)(CO)(PPh_3)_2]$ (**248**) and with $PMePh_2$, $[Ru(NO_3)_2CO(PMePh_2)_3]$ is formed. Facile cleavage of one or more Ru—O bonds in (**247**) or (**248**) with ligands such as acacH (Section 45.5.4.7.iii), $^-$OCOMe (Section 45.5.4.7.vi) and dithioacid anions (Section 45.5.4.8.ii) can also occur. Compound (**247**) is a good catalyst for dehydrogenating primary and secondary alcohols.[1773,1779]

Treatment of $[Ru(CO)_3(PR_3)_2]$ (PR_3 = PPh_3, $PPh_2(p\text{-Tol})$] with SO_2 in C_6H_6 gives the air sensitive compounds $[Ru(CO)_2(PR_3)_2(SO_2)]$ (see (**127**) in Section 45.5.1.3) which on exposure to air affords $[Ru(SO_4)(CO)_2(PR_3)_2]$.[1474] Other routes to this compound are shown in equation (114).[1474,1477] An X-ray structure analysis confirms the presence of bidentate sulfate.[1780] The related complex $[RuCl(SO_4)(NO)(PPh_3)_2]$ (Section 45.5.4.6.iii) is well characterized.[1424] An unusual reaction occurs between $[RuH_2(PPh_3)_4]$ and SO_2 in toluene. The first product is the yellow aqua complex $[RuSO_4(OH_2)(SO_2)(PPh_3)_2]$ which slowly rearranges in solution to the binuclear toluene solvate (**249**). X-Ray analysis reveals that this contains unidentate SO_2 and bridging SO_4^{2-} groups.[1764]



(247)

(248)

$$[Ru(CO)_3(PPh_3)_2] + \text{concentrated } H_2SO_4 \xrightarrow{THF} [Ru(SO_4)(CO)_2(PPh_3)_2] \quad (114)$$

$$[Ru(CO)_2(PPh_3)_2SO_2] + SO_2 \text{ (or } PPh_3) \longrightarrow [Ru(SO_4)(CO)_2(PPh_3)_2]$$

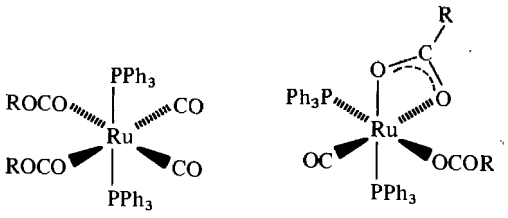
(249)

Aerial oxidation of the $[RuH(CO)_2(PPh_3)_2(CN\text{-}p\text{-}Tol)]^+$ cation gives the carbonate complex $[Ru(CO_3)(CO)(PPh_3)_2(CN\text{-}p\text{-}Tol)]$[1480] and a rare example of an O-bound perchlorate compound is $[RuCl(OClO_3)(CNR)(CS)(PPh_3)_2]$ obtained by reaction of $[RuCl_2(CNR)(CS)(PPh_3)_2]$ with $Ag[ClO_4]$.[1640]

(*vi*) *Carboxylato complexes*

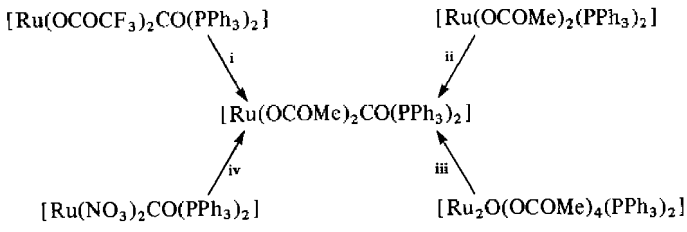
A considerable amount of work has been published on Ru^{II} carboxylate complexes containing P donor ligands. Thus reaction of $[RuCl_2(PPh_3)_3]$ with sodium acetate in boiling *tert*-butanol gives $[Ru(\eta^2\text{-}OCOMe)_2(PPh_3)_2]$.[1769] A range of analogous carboxylates are formed using the appropriate RCO_2H in acetone (R = Et, Ph, Bu^t) in the presence of $Na[HCO_3]$.[1545] As described elsewhere (Section 45.10.3.2.i) reactions in lower boiling point alcohols lead to $[RuH(OCOR)(PPh_3)_3]$.[1451] Treatment of $[RuH_2(PF_2NMe_2)_2(PPh_3)_2]$ with CF_3CO_2H gives the mixed phosphine complex $[Ru(\eta^2\text{-}OCOCF_3)_2(PF_2NMe_2)(PPh_3)]$ whereas with $[RuH_2L(PPh_3)_3]$, $[Ru(OCOF_3)_2L(PPh_3)_2]$ (L = PF_3, PF_2NMe_2) with bi- and uni-dentate $OCOCF_3$ ligands is formed.[1576] The corresponding $[Ru(OCOR)_2(PMe_2Ph)_3]$ are also reported (equations 115 and 116) and $[Ru\{C_6H_4OP(OPh)_2\}_2(P(OPh)_3)_2]$ (**198**) gives $[Ru(\eta^1\text{-}OCOR_F)_2\{P(OPh)_3\}_4]R_FCO_2H$ (R_F = CF_3, C_2F_5), with only unidentate $^-OCOR_F$ groups, on treatment with the appropriate carboxylic acid.[1685] The preparations of *cis*-$[Ru(\eta^1\text{-}OCOMe)Me(PMe_3)_4]$ from *cis*-$[RuMe_2(PMe_3)_4]$ and $MeCO_2H$,[16a] and $[Ru(\eta^2\text{-}OCOMe)Cl(PPh_3)_3]$ and $[Ru(\eta^2\text{-}OCOMe)Cl(PMe_3)_4]$[1680] have been reported.[1680]

$$[Ru_2X_3(PMe_2Ph)_6]PF_6 + CF_3CO_2H \longrightarrow [Ru(OCOCF_3)_2(PMe_2Ph)_3]^{1753} \quad (115)$$



(X = H, OH)

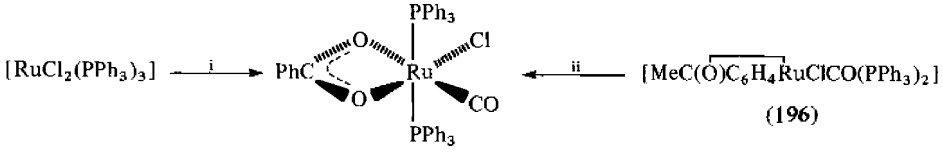
$$mer\text{-}[RuH(BH_4)(PMe_2Ph)_3] + RCO_2H \longrightarrow [Ru(OCOR)_2(PMe_2Ph)_3]^{1752} \quad (116)$$



(R = Me, Bu^t)

A wide range of PR_3, carbonyl carboxylates have been prepared. For example $[Ru(CO)_3(PPh_3)_2]$ and RCO_2H in boiling C_6H_6 or 2-methoxyethanol give $[Ru(\eta^1\text{-}OCOR)_2(CO)_2(PPh_3)_2]$ (**250**) (R = H, Me, Et, CF_3 *etc.*).[1447,1523,1728a,1781,1782] This method has been employed to synthesize the open chain polyether carboxylate complexes $[Ru(\eta^1\text{-}L)_2(CO)_2(PPh_3)_2]$ (L = 1-(*o*-carboxymethoxyphenoxy)-2-(*o*-hydroxyphenoxy)ethanato(1−)].[1783] The monocarbonyls $[Ru(OCOR)_2(CO)(PPh_3)_2]$ (**251**), (with mono- and bi-dentate ^-OCOR groups which undergo facile intramolecular exchange), are obtained from $[RuH_2(CO)(PPh_3)_3]$ and RCO_2H (R = CF_3, C_2F_5, C_6F_5, *p*-C_6H_4Cl, *p*-$C_6H_4NO_2$], whereas weaker RCO_2H give the hydrido complexes $[RuH(\eta^2\text{-}OCOR)(CO)(PPh_3)_2]$.[1728a,1781,1782,1784] The acetate analogue $[Ru(OCOMe)_2(CO)(PPh_3)_2]$ can be prepared by several routes (Scheme 53) and the related compounds $[Ru(OCOCF_3)_2CO(PPh_3)_m(L\text{–}L)]$ (L–L = $C_6H_4(PPh_2)_2$, m = 0, 1; $Ph_2P(CH_2)_2AsPh_2$, m = 1 and $Ph_2P(CH_2)_nPPh_2$, n = 3,4; m = 0) have been synthesized by reaction of $[RuH_2(CO)(PPh_3)(L\text{–}L)]$ with CF_3CO_2H.[1786]

Reaction of $[RuHCl(CO)(PMe_2Ph)_3]$ with RCO_2H under mild conditions affords $[RuCl(\eta^1\text{-}OCOR)(CO)(PMe_2Ph)_3]$ (R = Me, Et, Ph) with a unidentate ^-OCOR group[1614c] but under more vigorous conditions, $[RuHCl(CO)(PPh_3)_3]$ gives the chelate derivatives $[RuCl(\eta^2\text{-}OCOR)CO(PPh_3)_2]$.[1728a,1781,1782] Other routes to the benzoate complex (**252**) are shown in Scheme 54. The thiocarbonyl analogue $[RuCl(\eta^2\text{-}OCOH)CS(PPh_3)_2]$ has been prepared by reaction of $[RuCl_2(OH_2)CS(PPh_3)_2]$ with $Na[OOCH]$[1645] and treatment of $[RuCl(p\text{-}Tol)CO(PPh_3)_2]$ with for-



(250) (251)

Scheme 53

mate ion gives the aryl carbonyl derivative [Ru(η^2-OCOH)(*p*-Tol)CO(PPh_3)$_2$]. Thermal decarboxylation of the latter yields [Ru(CO)(PPh_3)$_3$] (see Section 45.10.3.2.ii) which on reaction with HCHO affords [Ru(η^2-OCOH)(Me)CO(PPh_3)$_2$].[1487] The nitrosyl complexes [RuCl(OCOR)(COR)(NO)(PPh_3)$_2$] are known (Section 45.5.4.6.iii).[1429] Reactions of these CO compounds with other O-donor ligands such as NO_3^- and β-diketonates are discussed elsewhere and many of these neutral complexes catalyse the dehydrogenation of alcohols and the hydrogenation of ketones and alkenes.[1786,1787,1788]

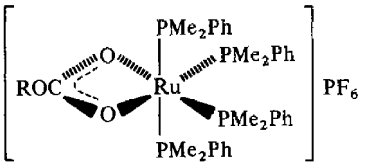
(252)

i, PhCHO/Δ;[1675] ii, $PhCO_2H$[1682]

Scheme 54

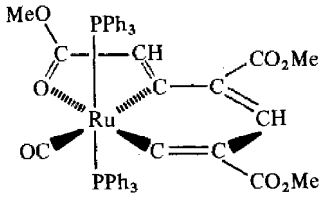
A number of cationic tertiary phosphine complexes containing carboxylate ligands have been synthesized. Examples include [Ru(η^1-$OCOCF_3$)(PMe_2Ph)$_5$]$^+$ (from [RuH(PMe_2Ph)$_5$]$^+$ and CF_3CO_2H), [Ru(η^2-OCOR)(PMe_2Ph)$_4$]PF_6[1753] (confirmed by X-ray analysis[1789] for R = Me) and [Ru(η^2-OCOMe)(OH_2)(PPh_3)$_3$]BF_4[1754] obtained as the end product by protonation of [RuH(η^2-OCOMe)(PPh_3)$_3$] with aqueous HBF_4 in acetone. The various hydrido intermediates are discussed in Section 45.10.3.2.v. Other carboxylate cations described in reference 1754 are [Ru(η^2-OCOMe)L(PPh_3)$_3$]BF_4 (L = MeCN, CO) from reaction of the aqua cation with L. An X-ray analysis of the [Ru(η^2-OCOMe)CO($PMePh_2$)$_3$]PF_6 analogue has been published.[1790]

Other references to carboxylato complexes containing P donor ligands are to be found in Sections 45.3.2, 45.5.4.5.iii, 45.5.8, 45.6.5 and 45.10.



(*vii*) *Carbonate ester and carbamato complexes*

Treatment of [RuH(PMe_2Ph)$_5$]PF_6 with CO_2 in MeOH or EtOH gives the bidentate monoalkylcarbonate esters (**253**). Recrystallization of [Ru(η^2-OCOH)(PMe_2Ph)$_4$]PF_6 from ROH/acetone also gives (**253**). The hydrido complex [RuH(O_2COR)(PPh_3)$_3$] is obtained from [$RuH_2(PPh_3)_4$], CO_2 and

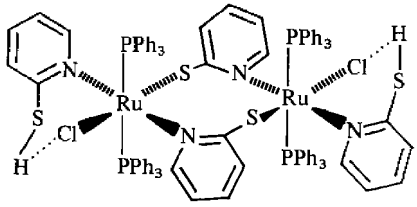


ROH[1791] and similar reactions (equations 117 and 118) yield the corresponding dimethylcarbamato complexes;[1792] X-ray analysis[1793] confirms the structure of $[Ru(O_2CNMe_2)(PMe_2Ph)_4]BF_4$. Structural analysis also reveals that the product from reaction of $[RuH_2(CO)(PPh_3)_3]$ with methyl propiolate is the novel metallocycle (**254**).[1794]

$$[RuH(PMe_2Ph)_5]BF_4 + CO_2 \xrightarrow{NMe_2H/EtOH} [Ru(O_2CNMe_2)(PMe_2Ph)_4]BF_4 \quad (117)$$

$$[RuH_2(PPh_3)_4] + CO_2 \xrightarrow{NMe_2H/EtOH} [RuH(O_2CNMe_2)(PPh_3)_3] \quad (118)$$

(253)



(254)

45.5.4.8 Sulfur donor ligand complexes

(*i*) *Thiolato and sulfido complexes*

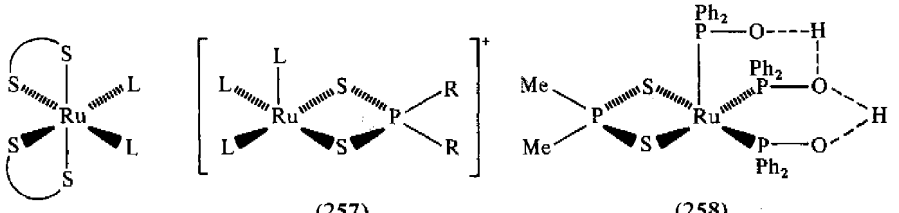
Very few complexes containing SH^- or SR^- and P donor ligands have been reported. Rare monomeric complexes are $[RuH(SR)(PPh_3)_3]$ (R = H, Ph, $PhCH_2$) obtained by treatment of $[RuH_2(PPh_3)_4]$ or $[RuH_4(PPh_3)_3]$ with RSH (or S_8 for R = H); the corresponding SMe derivative is obtained from $[RuH_2(PPh_3)_4]$ and dimethyldisulfide.[1795a,1795b] Aniline-2-thiol in the presence of base displaces both chloro ligands from $[RuCl_2(PPh_3)_3]$ to give the chelate complex $[Ru(2\text{-}H_2NC_6H_4S)_2(PPh_3)_2]$ whereas pyridine-2-thiol produces a dimeric species (**255**) with pyridine-2-thiolato bridges.[1545] Several other binuclear complexes containing these ligands are known (equations 119–121). Reaction of $[Ru(CO)_3(PPh_3)_2]$ with 2,2′-dipyridyldisulfide (RSSR) gives $[Ru(SR)_2(CO)_2PPh_3]$ (with mono- and bi-dentate SR groups) which on standing for several days converts to $[Ru(SR)_2(CO)PPh_3]$ (with bidentate SR groups).[1796b] The preparation of $[Ru(tddtH)_2(CO)(PPh_3)_2]$ by reaction of $[Ru(CO)_3(PPh_3)_2]$ with 1,3,4-thiadiazole-2,5-dithiol($tddtH_2$) has been reported. The mono- and bi-dentate ligands display dynamic interchange.[1796c]

(255)

$$[RuCl(bipy)(PPh_3)_2]_2Cl_2 \xrightarrow[acetone]{Pb(SC_6F_5)_2} [Ru(SC_6F_5)(bipy)(PPh_3)_2]_2Cl_2^{1714} \quad (119)$$

$$[RuH(cod)(NH_2NMe_2)_3]^+ \xrightarrow[ii.\ YSH\ (Y = Me, H)]{i.\ PR_3\ acetone/MeOH} [(PR_3)_3Ru(SY)_3Ru(PR_3)_3]^{+\,1753} \quad (120)$$

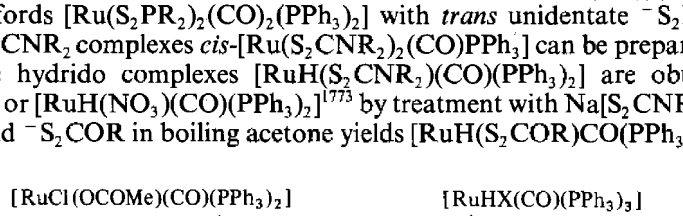
$$[RuI(\eta^2\text{-}CS_2Me)(CO)(PPh_3)_2] \xrightarrow[C_6H_6/\Delta]{RNH_2} [RuI(SH)(CO)(CNR)PPh_3]_2^{1796} \quad (121)$$



(R = Me, Bu^n, Bu^i, Pr^i, Pr^n, $PhCH_2$)

Examples of bridging sulfido complexes are $[RuX_2NO(EPh_3)]_2S$ (X = Cl, Br, E = P, As) made by reaction of $[RuX_3NO(EPh_3)_2]$ with sulfur; oxidation with perbenzoic acid gives $[RuX_2NO(EPh_3)]_2SO$.[1304] A polymeric complex of empirical formula '$[Ru_3Cl_3S_2(PPh_3)_3]$' is purported to be the product from $[RuCl_2(PPh_3)_3]$ and sulfur[1449] and species such as $[Ru(CO)_2(PPh_3)S]_2$ and $[Ru(CO)_2(SPPh_3)_2S]CH_2Cl_2$ also appear in the literature.[1642] Treatment of $[RuH(PMe_3)_3(CH_2PMe_2)]$ with S_8 in C_6H_6 has given $[Ru(PMe_3)_3S_6]$ which on dissolution in acetone gave $[Ru(PMe_3)_3S_7]$. The S_7^{2-} is tridentate, forming two five-membered rings.[1796d]

(*ii*) *Dithio-phosphinato, -phosphato, -carbamato, -carbonato, -ester and -carbonimidato complexes*

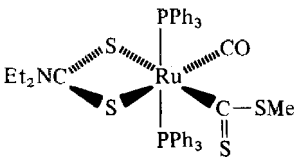


Complexes of general formula $[Ru(S–S)_2L_2]$ (S–S = S_2PR_2 (R = Me, Et, Ph), S_2CNR_2 (R = Me, Et), S_2COR (R = Me, Et); L = PPh_3, PMe_2Ph, $PMePh_2$, $PEtPh_2$, $P(OPh)_3$, $P(OMe)Ph_2$, $P(OEt)Ph_2$, $P(OMe)_2Ph$) can be synthesized by the prolonged reaction of compounds such as $[RuCl_2L_3]$, (L = PPh_3, $PEtPh_2$, $P(OR)Ph_2$), $[RuCl_2L_4]$ (L = PMe_2Ph, $PMePh_2$, $P(OMe)_2Ph$, $P(OPh)_3$) and *mer*-$[RuCl_3(PMe_2Ph)_3]$ with the appropriate Na[S–S].[1797–1799] Reaction of $[RuCl_2(diene)]_n$ with $Na[S_2PMe_2]\cdot 2H_2O$ gives $[Ru(S_2PMe_2)_2diene]$ (diene = cod, nbd) and the labile diene moiety is readily replaced by other bidentate ligands to give $[Ru(S_2PMe_2)_2(L–L)]$ (L–L = dppm, dppe, diars); for diars, *trans*-$[Ru(S_2PMe_2)_2(diars)_2]$ is also formed.[1800] Tetramethylthiuram disulfide and $[RuH_2(PPh_3)_4]$ also gives $[Ru(S_2CNMe_2)_2(PPh_3)_2]$.[1801] In most instances, NMR spectroscopic studies indicate the *cis* configuration (**256**), verified by X-ray analysis for $[Ru(S_2PEt_2)_2(PMe_2Ph)_2]$,[1802] and also reveal facile interconversion at ambient temperature of optical isomers (for the $^-S_2PR_2$ compounds) and restricted rotation about the C—N bond (for the $^-S_2CNR_2$ compounds). Rate constants and associated activation parameters for these processes have been determined by line shape analysis of their ^1H NMR spectra and a mechanism of optical inversion involving Ru—S bond cleavage proposed.[1798,1799,1803]

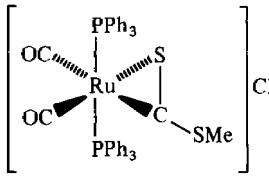
Under mild conditions of reaction, several intermediates can be isolated from treatment of $[RuCl_2L_n]$ with $S–S^-$ anions. These include the six-coordinate $[RuCl(S_2PR_2)L_3]$ which rearrange in alcoholic media to the red five-coordinate cations $[Ru(S_2PR_2)L_3]^+$ (**257**) and $[Ru(S_2COMe)_2L_3]$ (with uni- and bi-dentate $^-S_2COMe$ groups) which on heating give $[Ru(S_2COMe)_2L_2]$ [L = PMe_2Ph, $P(OR)Ph_2$ (R = Me, Et)]. Reaction of $[RuCl_2(PMe_2Ph)_4]$ with $Na[S_2CNR_2]$ in EtOH gives the $[Ru(S_2CNR_2)(PMe_2Ph)_4]^+$ cations whereas in C_6H_6 $[Ru(S_2CNR_2)_2(PMe_2Ph)_3]$ are formed.[1799] The tetrakisphosphine cation is also prepared from reaction of $[RuH(PMe_2Ph)_5]^+$ with CS_2 in a $NHMe_2$/EtOH mixture.[1792] Treatment of some of these $[Ru(S—S)_2L_2]$ complexes with ligands (L′) of greater basicity gives either $[Ru(S–S)_2LL']$ (L = PPh_3, PMe_2Ph; L′ = $P(OPh)_3$) and/or $[Ru(S–S)_2L'_2]$ [L′ = $P(OPh)_3$, PMe_2Ph, $PHPh_2$, $P(OMe)_2OH$, $PCl_{3-n}Ph_n$ (n = 0–2)] whereas with $PClPh_2$ in a H_2O/MeOH mixture, the unusual product (**258**) is isolated *via* the intermediate $[Ru(S_2PMe_2)PPh_3\{(Ph_2PO)_2H\}]$.[1798,1804] ^{31}P NMR spin-lattice relaxation times are reported for some of these $^-S_2PMe_2$ complexes.[1805]

(256) (257) (258)

The yellow monocarbonyls *cis*-$[Ru(S_2PR_2)_2(CO)L]$ are obtained by carbonylation of $[Ru(S_2PR_2)_2L_2]$. For L = PMe_2Ph, two isomers of formula $[Ru(S_2PMe_2)_2CO(PMe_2Ph)_2]$ (with uni- and bi-dentate $^-S_2PMe_2$ groups) are also formed.[1798] Reaction of $[Ru(CO)_3(PPh_3)_2]$ with R_2PS_2H (R = Ph, OPh) affords $[Ru(S_2PR_2)_2(CO)_2(PPh_3)_2]$ with *trans* unidentate $^-S_2PR_2$ groups.[1806] The corresponding $^-S_2CNR_2$ complexes *cis*-$[Ru(S_2CNR_2)_2(CO)PPh_3]$ can be prepared by several routes (Scheme 55). The hydrido complexes $[RuH(S_2CNR_2)(CO)(PPh_3)_2]$ are obtained from $[RuHCl(CO)(PPh_3)_3]$[1801] or $[RuH(NO_3)(CO)(PPh_3)_2]$[1773] by treatment with $Na[S_2CNR_2]$. Likewise, $[RuHCl(CO)(PPh_3)_3]$ and ^-S_2COR in boiling acetone yields $[RuH(S_2COR)CO(PPh_3)_2]$ (R = Me, Et).[1801]

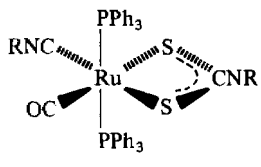


i, $Na[S_2CNR_2]$ (R = Me, Et);[1801] ii, $[Me_2NCS_2]_2$, C_6H_6, Δ;[1801]
iii, $Na[S_2CNR_2]$/MeOH;[1773] iv, $[Me_2NCS_2]_2$, C_6H_6, Δ[1801]



Scheme 55

Other examples of complexes containing $^{-}S_2CNR_2$ groups are $[Ru(S_2CNEt_2)(CNH\textit{p}\text{-Tol})(CO)(PPh_3)_2]$ (**177**) (Section 45.5.4.5.iii) and $[Ru(S_2CNEt_2)(CO)(CS)(PPh_3)_2]^+$, obtained by protonation of $[Ru(S_2CNEt_2)(\eta^1\text{-}CS_2Me)CO(PPh_3)_2]$ (**259**).[47] In compound (**259**), the dithioester group, CS_2Me, is bound through carbon only but examples of complexes containing chelated CS_2Me ligands are $[Ru(\eta^2\text{-}CS_2Me)(CO)_2(PPh_3)_2]ClO_4$ (**260**)[1470,1807] and $[RuCN(\eta^2\text{-}CS_2Me)\text{-}CO(PPh_3)_2]$.[47]



Addition of an excess of aryl or alkyl isothiocyanates to $[Ru(CO)_2(PPh_3)_3]$ gives the dithiocarbonimidato complexes $[Ru(S_2CNR)(CNR)(CO)(PPh_3)_2]$ (R = Me, Et, Ph) (**260a**).[1476] The related $[Ru(S_2CO)(CO)_2PPh_3]$ is made by addition of COS to the Ru^0 complex $[Ru(CO)_2(PPh_3)_2(\eta^2\text{-COS})]$ (**128**) (Section 45.5.1.3).[1478] Reaction of *fac*-$[RuH(\eta^2\text{-}C_6H_4PPh_2)(PMe_3)_3]$ with CS_2 and COS gives *fac*-$[Ru(SCHS)(\eta^2\text{-}C_6H_4PPh_2)(PMe_3)_3]$ and *fac*-$[Ru(S_2CO)CO(PMe_3)_3]$ respectively.[1391c]

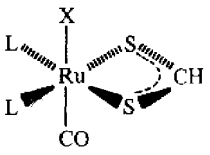
(259)

(260)

(260a)

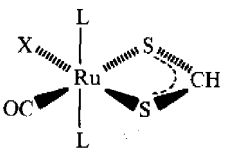
(*iii*) *Dithiolene complexes*

Bis(perfluoromethyl)dithiolene, $S_2C_2(CF_3)_2$, reacts with $[Ru_3(CO)_{12}]$ in boiling *n*-heptane to give an orange product which on treatment with PPh_3 affords $[Ru\{S_2C_2(CF_3)_2\}CO(PPh_3)_2]$ as a mixture of orange and violet crystals. These two complexes are structural isomers which interconvert in solution, the orange form being the more stable.[1808] X-Ray structural analyses reveal both isomers to be square pyramidal, with the axial group being CO in the orange form and PPh_3 in the violet form.[1809] Reaction of the orange product with $AsPh_3$ gives $[Ru\{S_2C_2(CF_3)_2\}CO(AsPh_3)_2]$ but with $P(OMe)Ph_2$ and $P(OMe)_3$, $[Ru\{S_2C_2(CF_3)_2\}L_3]$ are formed.



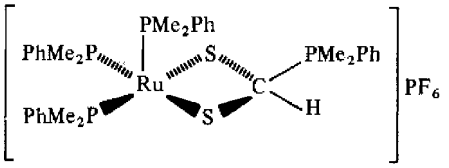
In boiling *n*-decane, $S_2C_2(CF_3)_2$ and $[Ru_3(CO)_{12}]$ give a green material which reacts with an excess of EPh_3 to produce $[Ru\{S_2C_2(CF_3)_2\}_2(EPh_3)_2]$ (E = P, As, Sb); with less EPh_3, $[Ru\{S_2C_2\text{-}(CF_3)_2\}_2EPh_3]$ (E = P, As) are isolated and if the latter (for E = P) is treated with hydrazine hydrate and then $Ph_4AsCl\cdot HCl$, $Ph_4As[Ru\{S_2C_2(CF_3)_2\}_2PPh_3]$ (μ_{eff} = 1.79 BM) is generated. Electronic spectral studies reveal that in solution, $[Ru\{S_2C_2(CF_3)_2\}_2(EPh_3)_2]$ is extensively dissociated into the monoadducts.[1808]

Reaction of $[RuCl_2(PMe_3)_4]$ with $Li_2[dttd]$ and $[RuCl_2(PPh_3)_3]$ with H_2dttd gives $[Ru(dttd)L_2]$ (H_2dttd = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane). The PMe_3 ligands are inert but one PPh_3 ligand is readily substituted by CO or N_2H_4 to yield $[Ru(dttd)(CO)PPh_3]$ and $[Ru(dttd)(N_2H_4)PPh_3]$ respectively. However, refluxing $[Ru(C_6H_4S_2)_2(CO)_2]^{2-}$ (see Section 45.7.6) in EtOH in the presence of excess PMe_3 and subsequent alkylation with $1,2\text{-}C_2H_4Br_2$ provides a route to $[Ru(dttd)\text{-}(CO)PMe_3]$.[1709]

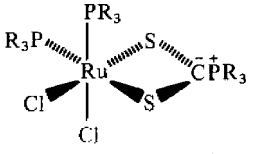


(*iv*) *Dithiocarboxylato complexes*

The best synthetic route to dithioformate complexes is by insertion of CS_2 into ruthenium–hydride bonds. Thus $[Ru(S_2CH)_2(PPh_3)_2]$ can be prepared by reaction of CS_2 with $[RuH_2(PPh_3)_4]$,[1437] $[RuH_4(PPh_3)_3]$,[1408,1810] $[RuH_3(SiR_3)(PPh_3)_2]$[83] or $[RuH(OCOH)(PPh_3)_3]$.[1811] X-Ray analysis confirms a *cis* configuration.[1812] Carbonyl complexes $[RuX(S_2CH)(CO)L_2]$ (**261**) (L = PCy_3, PPh_3) are obtained from treatment of $[RuHCl(CO)((PCy_3)_2]$[1623,1813] or of $[RuHX(CO)(PPh_3)_3]$ (X = Cl, Br, O_2CCF_3,[1810] NO_3[1773]) with CS_2. These isomerize to (**262**) on heating in C_6H_6 or toluene. The orange cation $[Ru(S_2CH)(PMe_2Ph)_4]^+$ (X-ray structure of PF_6^- salt available)[1814] results from reaction of CS_2 on $[RuH(PMe_2Ph)_5]^+$.[1792] In boiling MeOH this isomerizes to the purple five-coordinate $[Ru\{S_2C(H)PMe_2Ph\}(PMe_2Ph)_3]PF_6$ (**263**) which reacts with excess $P(OMe)_3$ to give the yellow octahedral complex $[Ru(S_2CH)(PMe_2Ph)_2\{P(OMe)_3\}_2]PF_6$ whereas with the larger $P(OMe)Ph_2$, the purple $[Ru\{S_2C(H)(PMe_2Ph\}(P(OMe)Ph_2)_3]PF_6$ is formed.[1815] Equimolar amounts of $P(OMe)_3$ and (**263**) give the intermediate $[Ru(S_2CH)(PMe_2Ph)_3P(OMe)_3]PF_6$, and a study of the kinetics and mechanism of this substitution reaction is available.[1816]



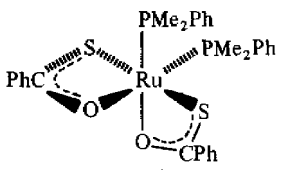
Reaction of $[RuCl_2(PPh_3)_3]$ with CS_2 gives several binuclear products (Section 45.5.5.1) and also a product initially formulated as $[RuCl(\eta^2\text{-}CS_2)(PPh_3)_3]Cl$.[1638] Further studies on the more soluble $PEtPh_2$ analogue suggest it should be reformulated as the phosphoniodithiocarboxylate complex (**264**). Dissolving (**264**) in MeOH and adding BPh_4^- gives $[RuCl(MeOH)(S_2CPEtPh_2)(PEtPh_2)_2]$-$BPh_4$.[1558] The cation $[RuH(S_2CPCy_3)CO(PCy_3)_2]^+$ is prepared in similar fashion from $[RuHCl(CO)(PCy_3)_2]$ and CS_2 and the closely related $[RuCl(S_2CPCy_3)CO(PCy_3)_2]^+$ arises from treatment of $[RuCl_2CO(PCy_3)_2]$ with the zwitterion ligand $S_2\bar{C}\overset{+}{P}Cy_3$.[1817]



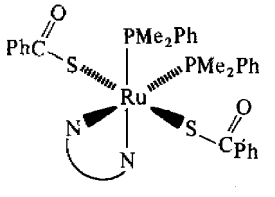
(261)

(262)

(263)

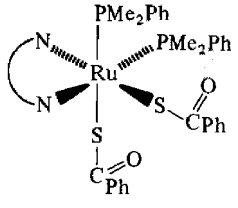


(264)



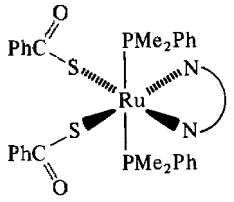
(*v*) *Monothio-carboxylato, -carbamato and -carbonato complexes*

$[RuCl_2(PPh_3)_3]$ reacts with excess sodium or ammonium monothiobenzoate in boiling MeOH or acetone to give $[Ru(SOCPh)_2(PPh_3)_2]$ while *mer*-$[RuCl_3(PMe_2Ph)_3]$ with Na[SOCPh] in acetone yields $[Ru(SOCPh)_2(PMe_2Ph)_2]$ (**265**). These complexes which have *trans* and *cis* phosphine ligands respectively and contain bidentate $[SOCPh]^-$ react with monodentate Lewis bases to give $[Ru(SOCPh)_2L_2(PR_3)_2]$ (L = CO, NH_3, NH_2Et) which contain monodentate *trans* S-bonded $[SOCPh]^-$.[1707] Reaction of (**265**) with bidentate nitrogen donors gives $[Ru(SOCPh)_2$-$(N\text{–}N)(PMe_2Ph)_2]$ but various isomers are formed, namely (**266**; N–N = en; **267** [major] and **268** [minor]; N–N = bipy and phen).[1708] The unusual compound (**266**; N–N = $HNC(Me)CH_2C$-Me_2NH_2) is isolated by reaction of *mer*-$[RuCl_3(PMe_2Ph)_3]$ with $[NH_4][SOCPh]$ in acetone.[1707]

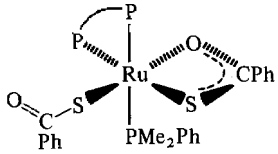


Treatment of (**265**) with dppe gives the two isomers (**269**) and (**270**) (NMR evidence) and the structure of (**269**) has been verified by X-ray analysis. An isomeric mixture of *mer*-$[Ru(SOCPh)_2$-$(PMe_2Ph)_3]$ (with uni- and bi-dentate $[SOCPh]^-$) arises from addition of PMe_2Ph to (**265**) whereas shaking *cis*-$[RuCl_2(PMe_2Ph)_4]$ in MeOH for short periods with $NH_4[SOCPh]$ gives the *facial* isomer; prolonged interaction gives the $[Ru(SOCPh)(PMe_2Ph)_4]^+$ cation.[1818] Thioacetic acid reacts with $[Ru(NO_3)_2CO(PPh_3)_2]$ in MeOH to give $[Ru(SOCMe)_2CO(PPh_3)_2]$ (with bi- and uni-dentate $[SOCMe]^-$). Two isomers are formed depending on reaction conditions.[1773] The thioformate complex $[Ru(SOCH)_2(CO)_2(PPh_3)_2]$ is claimed.[1642]

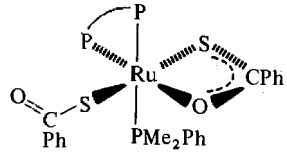
(265)



(266)



(267)



The monothiocarbonate and monothiocarbamate cations $[Ru(SOCY)(PMe_2Ph)_4]PF_6$ (Y = OEt, NMe_2) can be prepared by treating $[RuH(PMe_2Ph)_5]PF_6$ with COS in EtOH or EtOH/$NHMe_2$ respectively.[1792]

(268)

(269)

(270)

(*vi*) *Sulfur dioxide and dimethyl sulfoxide complexes*

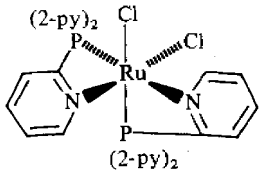
Few ruthenium(II) sulfur dioxide complexes are reported. These include the monomeric $[RuSO_4(OH_2)(PPh_3)_2SO_2]$ (from $[RuH_2(PPh_3)_4]$ and SO_2) which slowly rearranges to the binuclear $[RuSO_4(PPh_3)_2SO_2]_2$ [see Section 45.5.4.7.v and (**249**)][1764] and the poorly characterized $[RuXCl(PPh_3)_2SO_2]$ (X = Cl, H) from reaction of SO_2 with $[RuCl_2(PPh_3)_3]$ and $[RuHCl(PPh_3)_3]$ respectively. Prolonged reaction of the hydride complex with SO_2 gives rise to $[Ru_3Cl_3(PPh_3)_4(SO_2)_2]$(?)[1411,1449] while treatment of $[RuHX(CO)(PCy_3)_2]$ with SO_2 in C_6H_6 for 4 h yields $[RuHX(CO)(PCy_3)_2SO_2]$ (X = Cl, Br);[1813] $[RuCl_2(CO)(triphos)SO_2]$ (**164**) is discussed in Section 45.5.4.5.i.

Reaction of $[RuCl_2(DMSO)_4]$ with PPh_3 affords $[RuCl_2(DMSO)_2PPh_3]$ whereas $P(OPh)_3$ leads to $[RuCl_2(DMSO)\{P(OPh)_3\}_3]$; IR and NMR studies indicate S-bonded DMSO groups.[112] Related complexes include $[RuCl_2(DMSO)_2(triphos)]$, [RuCl(DMSO)L]Cl (L = tet-1 or tet-2),[1540] $[RuCl_2(DMSO)L_3]$ (L = $AsMePh_2$, $AsMe_2Ph$, $SbPh_3$), $[RuCl_2(DMSO)_2(AsPh_3)_2]$[1511] and references to the preparation of other Ru^{II} DMSO compounds such as $[RuCl_2CO(DMSO)(PPh_3)_2]$, *cis*-$[RuCl_2(CO)(DMSO)(L–L)]$ (Section 45.5.4.5.i) and *trans*-$[RuCl(DMSO)(dmpe)_2]^+$ (Section 45.5.4.3) are given elsewhere.

(*vii*) *Miscellaneous*

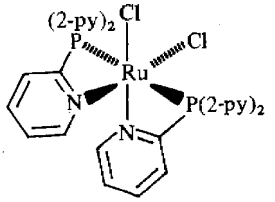
Reaction of $[RuCl_2(PPh_3)_3]$ with *N*-phenylcarbamoylpyrrole-2-thiocarboxamide (PTH) gives $[RuCl_2(PTH)_2PPh_3]$ which contains a strong ruthenium–sulfur bond.[1819] With an excess of 1-arylte-traazole-5-thiones in boiling C_6H_6, S-coordinated $[RuCl_2\{ArN_4H(CS)\}_3PPh_3]$ (Ar = Ph, *o*-Tol, *p*-ClC_6H_4, *p*-$MeOC_6H_4$) are formed;[1820] reaction of $[RuCl_2(PPh_3)_3]$ with COS gives $[RuCl_2(SPPh_3)PPh_3]_2$ and $OPPh_3$. In the presence of PPh_3, the black dimeric carbonyl complex $[RuCl_2(SPPh_3)CO]_2$ is isolated; the corresponding Ph_3AsS complex has also been reported.[1642]

45.5.4.9 Mixed donor atom (P—N, P—O, P—S) ligands



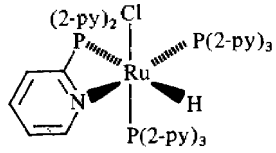
(*i*) *P–N ligand complexes*

Reaction of $[RuCl_2(PPh_3)_3]$ with tris(2-pyridyl)phosphine in C_6H_6 at room temperature produces the two isomers (**271**) and (**272**) whereas with $[RuHCl(PPh_3)_3]$, compound (**273**) with only one bidentate P(2-py)$_3$ ligand is formed.[1821] Treatment of '$RuCl_3 \cdot xH_2O$' with $PPh_2(C_6H_4NMe_2)$ (PN) gives $[RuCl_2(PN)_2]$;[1822] $[RuCl_5(OH_2)]^{2-}$ or $[RuCl_2(PPh_3)_3]$ with 2-(diphenylphosphinoethyl)pyridine in boiling aqueous EtOH affords *trans*-$[RuCl_2\{Ph_2P(CH_2)_2(py)\}_2]$. Treatment of the latter with ethanolic solutions of $NH_4[PF_6]$ gives the five-coordinate cation $[RuCl\{Ph_2P(CH_2)_2(py)\}_2]PF_6$ which readily reacts with CO or MeCN (L′) to give *trans*-$[RuClL'\{Ph_2P(CH_2)_2(py)\}_2]PF_6$.[1535b] The neutral dicarbonyl (**274**) is obtained by chlorination of $[Ru_3(CO)_9(PPh_2py)_3]$ and this reacts with more 2-(diphenylphosphino)pyridine to give $[RuCl_2(CO)_2(PPh_2py)_2]$ (with *trans* P-bound $PPh_2(py)$ and *cis* CO, *cis* Cl groups).[1459,1823]

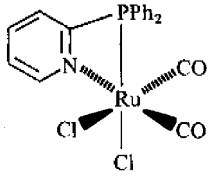


The binuclear complexes (**275**) and (**276**), which interconvert on heating in solution, have been synthesized either by reaction of $[RuCl_2(CO)_2(PPh_2py)_2]$ with $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone) or from $[Ru(CO)_3(PPh_2py)_2]$ and $[PdCl_2(cod)]$.[1459]

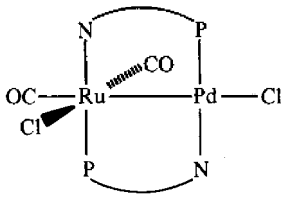
(*ii*) *P–O ligand complexes*



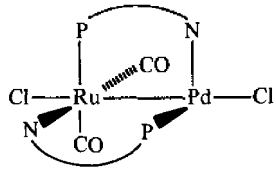
The octahedral chelate complex *trans*-$[RuCl_2(PO)_2]$, formed by reaction of '$RuCl_3 \cdot xH_2O$' with 2-(diphenylphosphino)anisole, $PPh_2(2\text{-}MeOC_6H_4)$, in boiling EtOH, reacts with CO at room temperature, the weak Ru—O bonds being broken stepwise, to give first $[RuCl_2(CO)(PO)_2]$ (**277**) and



(271)

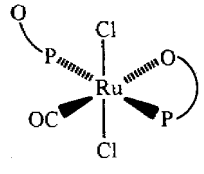


(272)

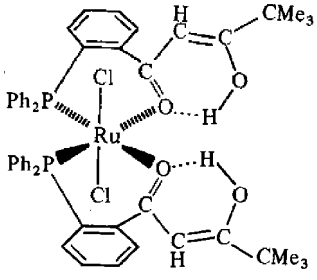


(273)

(274)

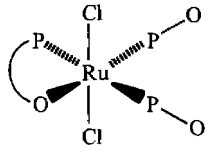


(275)



(276)

then $[RuCl_2(CO)_2(PO)_2]$ (all *trans* isomer). At higher temperatures in alkane solvents, the *cis* Cl, *cis* CO isomer of the latter is obtained. Similar complexes are produced with *tert*-butyl isocyanide.[1822,1824] The related complex $[RuCl_2\{PPh_2(2\text{-}OCC_6H_4)\}_2]$ (from '$RuCl_3 \cdot xH_2O$' and $PPh_2(2\text{-}OHCC_6H_4)$] undergoes decarbonylation on heating to give *cis*, *cis*, *trans*-$[RuCl_2(CO)_2(PPh_3)_2]$.[1825] Phosphine exchange of $PPh_2(2\text{-}C_6H_4COCH_2COBu^t)$ with $[RuCl_2(PPh_3)_3]$ affords (**278**) which further reacts with copper acetate to form a bimetallic complex in which copper is bound to the four oxygen atoms.[1826]



In contrast, reaction of '$RuCl_3 \cdot xH_2O$' with $PPh_2(CH_2C(O)OEt)$ in hot EtOH gives $[RuCl_2\{PPh_2(CH_2C(O)OEt)\}_3]$ shown by X-ray analysis to have structure (**279**). This compound exhibits facile intramolecular exchange of the bi- and one of the uni-dentate PO ligands and reacts readily with CO to give both mono- and di-carbonyl derivatives $[RuCl_2(CO)_n\{PPh_2(CH_2C(O)OEt)\}_2]$. The corresponding $[RuCl_2\{o\text{-}MeC_6H_4CN\}_2\{PPh_2CH_2C(O)OEt\}_2]$ (**228**) is known (see equation 110 and Section 45.5.4.6.vi).[1750]

(277)

(278)

(279)

In common with all these P—O ligand complexes which contain long Ru—O bonds, X-ray structural analysis of $[RuCl(Me)(cod)P(2\text{-}MeOC_6H_4)_3] \cdot CH_2Cl_2$, (prepared from $[RuCl(Me)(cod)\text{-}MeCN]_2$ and $P(2\text{-}MeOC_6H_4)_3$), reveals a distorted octahedral configuration with a 2-methoxyphenyl oxygen atom occupying the sixth coordination site [Ru—O = 2.58 Å).[1827] An analogous structure is found for $[RuCl(Me)(cod)\{PPh_2(2\text{-}MeOC_6H_4)\}]$.[1828] The complex *trans*-$[RuCl_2\{(\pm)\text{-}o\text{-}C_6H_4(PMePh)_2\}$ $(\pm)\text{-}o\text{-}C_6H_4(PMePh)(O)MePh)]$ containing P,P′ and O,P′ bidentate ligands respectively is covered in Section 45.5.4.3.

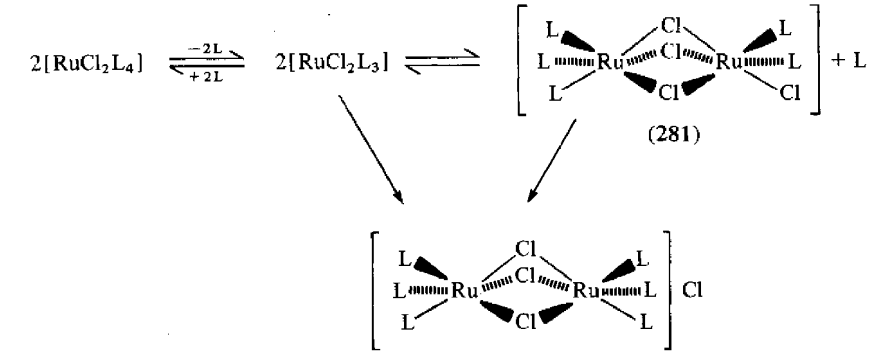
(*iii*) *P–S ligand complexes*

The only reference found to complexes of this type is a paper by Sanger and Day on reactions of $Ph_2P(CH_2)_2SPh$ (PS) with $[RuCl_2(CO)_3]_2$ which gives P-bonded $[RuCl_2(CO)_3PS]$ and then $[RuCl_2(CO)_2(PS)_2]$. However, when an ethanolic solution of '$RuCl_3 \cdot xH_2O$' and excess $Ph_2P(CH_2)_2SPh$ are refluxed for a prolonged period, an insoluble pink solid $[RuCl_2(PS)_2]_x$ which

probably contains bidentate $Ph_2P(CH_2)_2SPh$ is precipitated. Reaction of '$RuCl_3 \cdot xH_2O$' with $Ph_2P(CH_2)_2SPh$ under an atmosphere of CO gives first $[RuCl_2(CO)(PS)_2]$ and then some $[RuCl_2(CO)_2(PS)_2]$.[1829] The complexes $[RuCl_2(4\text{-}R_2PDBT)_2]$ (R = Ph, *p*-Tol; DBT = dibenzothiophene) were prepared in high yield from $[RuCl_2(PPh_3)_3]$ and $4\text{-}R_2PDBT$. X-Ray diffraction studies reveal that for R = *p*-Tol, an all *cis* geometry is adopted.[1830]

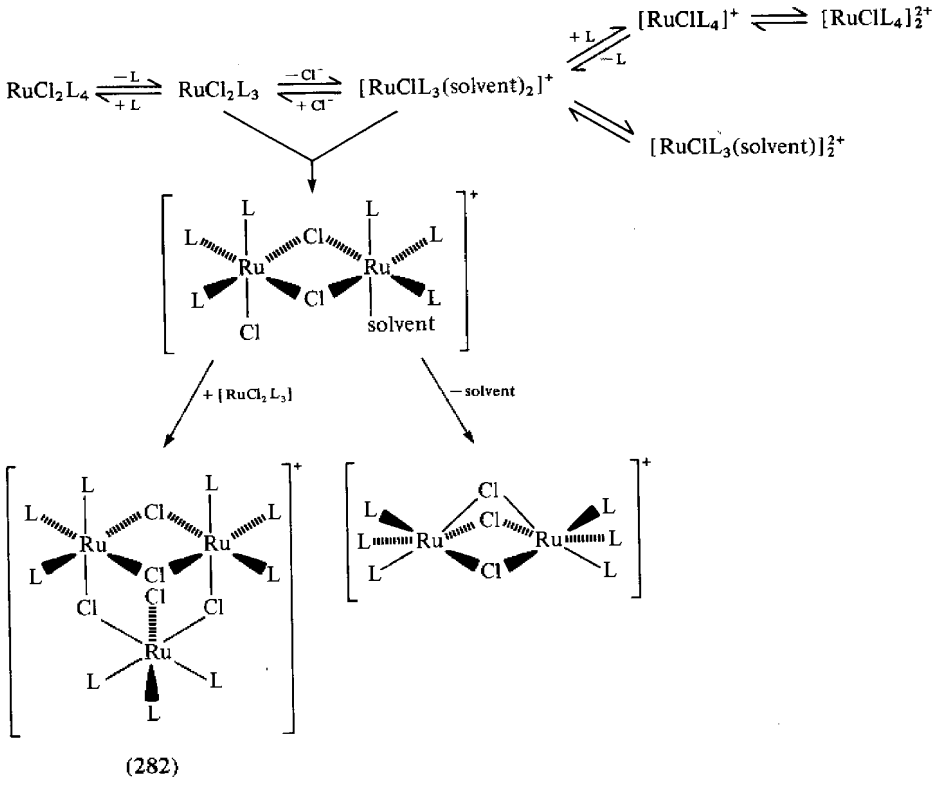
A range of P—C ligand complexes are known and these are fully discussed under the headings cyclometallated (Sections 45.5.4.5.v and 45.10.3.2.iii) and alkene complexes (Section 45.5.4.5.vi).

Macrocycle complexes containing P, As or Sb donor ligands are covered in Section 45.12.



45.5.5 Bi-, Tri-, Tetra- and Poly-nuclear Ruthenium(II) Complexes

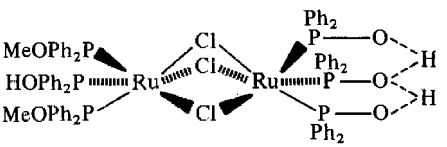
45.5.5.1 Triple halide-bridged complexes (and related species)



Compounds of the type $[L_3RuCl_3RuL_3]Y$ (L = various alkyl and aryl substituted PR_3; Y = Cl, ClO_4, SCN, BPh_4) were first prepared in 1961 by reaction of '$RuCl_3 \cdot xH_2O$' with L in aqueous MeOH or EtOH.[1591a] A wider range of these cations (L = $P(OR)Ph_2$, $P(OR)_2Ph$, $P(OR)_3$ (R = Me, Et), $AsRPh_2$, AsR_2Ph *etc.*) are now available, usually from reaction of '$RuCl_3 \cdot xH_2O$', $[RuCl_2(nbd)]_n$, $[RuCl_2(PPh_3)_n]$, Ru–arenes or the reduced 'ruthenium blue' solution with L in polar media.[629b,676,1531,1532,1533,1544,1550,1561,1585,1614b] The confacial bioctahedral geometry (**280**) has been verified by X-ray structural analyses for L = PEt_2Ph (Y = *mer*-$[RuCl_3(PEt_2Ph)_3]^-$),[1831] PMe_2Ph (Y = PF_6)[1832] and PMe_3 (Y = BF_4).[16a]

The related cations $[L_3RuX_3RuL_3]^+$ (X = OH^-, L = PMe_2Ph, $PMePh_2$, $P(OMe)Ph_2$; X = F, I, SH, SR; L = PMe_2Ph, $PMePh_2$) are synthesized by treatment of $[RuH(NH_2NMe_2)_3(cod)]^+$ with L in acetone/MeOH followed by addition of HX.[1753] The $[Ru_2(OH)_3(PMe_3)_6]^+$ cation is obtained from $[Ru_2(CH_2)_3(PMe_3)_6]$ and $[Ph_3C]BF_4$ in THF[1768] and crystal structures for this and the PMe_2Ph analogue are published. The $[Ru_2H_3L_6]^+$ cations [L = PMe_2Ph, PMe_3) are discussed in Section 45.10.4. Treatment of these hydroxo complexes with HX in $MeNO_2$ provides a high yield route to the pure $[Ru_2X_3L_6]^+$ cations (L = PMe_2Ph; X = Cl, Br, I).[1556] The iodo and bromo derivatives can also be prepared from $[Ru_2Cl_3L_6]^+$ and NaI or '$RuCl_3 \cdot xH_2O$', LiBr and L respectively[1614b] but ^{31}P NMR evidence indicates that these are a mixture of $[Ru_2Cl_nX_{3-n}L_6]^+$ cations.[1556]

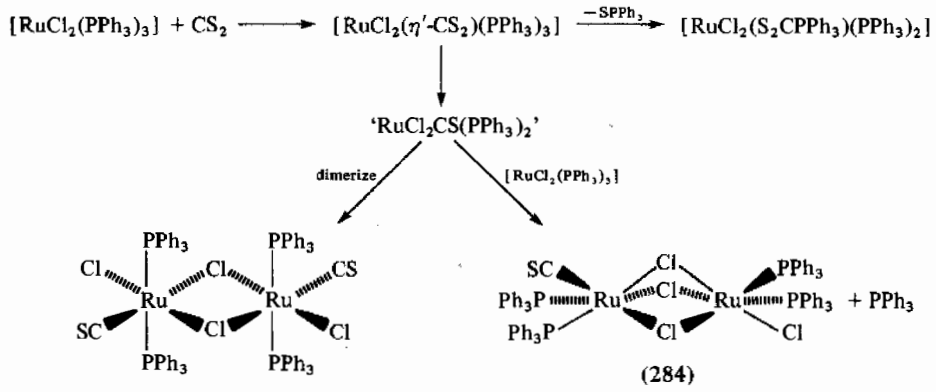
Pyrolysis of $[Ru_2Cl_3(PEt_2Ph)_6]Cl$ in methyl acetate or *n*-propyl propionate gives $[Ru_2Cl_3(PEt_2Ph)_6][RuCl_3(PEt_2Ph)_3]$ and/or the neutral binuclear complexes $[(PEt_2Ph)_3RuCl_3RuCl(PEt_2Ph)_2]$ (**281**) (X-ray analyses available).[1617,1831,1833] An alternative route to the latter is by reaction of $[RuCl_2(PPh_3)_3]$ with L in non-polar solvents such as hexane or petroleum ether. Monomeric $[RuCl_2L_{3\text{ or }4})$ are first produced (see Section 45.5.4.2.i) and in solution these rearrange to $[Ru_2Cl_4L_5]$ and/or $[Ru_2Cl_3L_6]Cl$ depending on the nature of L and of the solvent (Scheme 56). High yields of $[Ru_2Cl_4L_5]$ (L = $PClPh_2$, $PEtPh_2$, PEt_2Ph) can be prepared by this intermolecular coupling method.[1544] For L = $P(OR)_2Ph$, $P(OR)Ph_2$ no neutral $[Ru_2Cl_4L_5]$ are observed and this is attributed to the high nucleophilicity of the Ru—P bonds. Instead, various ionic species such as $[Ru_2Cl_3L_6]^+$, $[RuCl\{P(OMe)Ph_2\}_4]^+$, $[RuCl\{P(OEt)Ph_2\}_4]_2^{2+}$ and $[Ru_3Cl_5\{P(OEt)Ph_2\}_9]^+$ (**282**) are isolated (Scheme 57).[1533] Reaction of $[Ru_2Cl_5(PEtPh_2)_4]$ with equimolar amounts of AgCl gives the fluxional heterotrimetallic complex $[Ru_2Cl_5(PEtPh_2)_4AgPEtPh_2]$ in which a Ag^I ion is linked to one terminal and two bridging-chloride ligands.[1832a] The double chloride-bridged $[RuCl(PMe_3)_4]_2Cl_2$ can be synthesized by leaving *trans*-$[RuCl_2(PMe_3)_4]$ in C_6H_6 for several weeks.[1529] Pyrolysis of $[Ru_2Cl_3\{P(OMe)Ph_2\}_6]Cl$ produces the unusual compound (**283**) in which all the Ru—P bonds are



Scheme 56

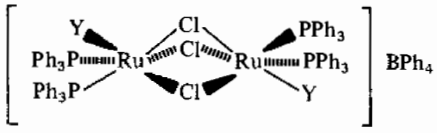
(282)

Scheme 57



(283)

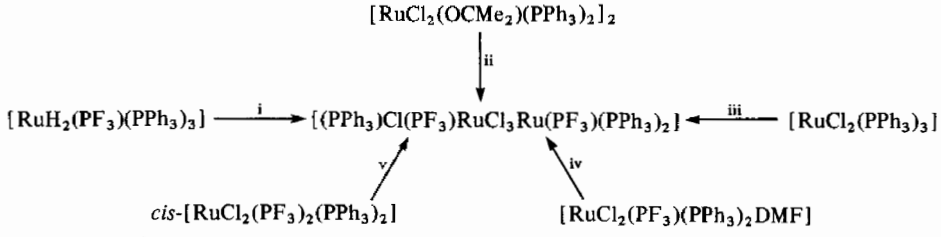
retained but some cleavage and partial hydrolysis of O—Me bonds has occurred[1834] (*cf.* (**258**) in Section 45.5.4.8.ii).



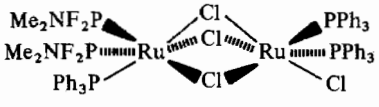
The neutral, binuclear complex $[(PPh_3)_2(CS)RuCl_3RuCl(PPh_3)_2]$ (**284**) (X-ray analysis available)[1835] together with some $[RuCl_2(CS)(PPh_3)_2]_2$ and $[RuCl_2(S_2CPPh_3)(PPh_3)_2]$ are obtained by reaction of $[RuCl_2(PPh_3)_3]$ with CS_2.[1639,1641] Possible reaction pathways are shown in Scheme 58 and these suggestions are supported by the high yield synthesis of $[Ru_2Cl_4Y(PR_3)_4]$ (Y = CO, CS; PR_3 = PPh_3, P(*p*-Tol)$_3$) from $[RuCl_2(PR_3)_3]$ and $[RuCl_2Y(PR_3)_2DMF]$ (equation 122).[1558,1616] Extension of this intermolecular coupling method to prepare $[(PPh_3)_2(CO)RuCl_3RuCl\{P(p\text{-}Tol)_3\}_2]$[1558] and $[(PPh_3)_2CORuCl_3OsCl(PPh_3)_2]$[1836a] is possible. Furthermore, heating $[RuCl_2Y(PPh_3)_2MeOH]$ in CH_2Cl_2 gives an isomeric mixture of $[PPh_3Cl(Y)RuCl_3Ru(Y)(PPh_3)_2]$ and reaction of these with PPh_3 and $Na[BPh_4]$ then affords the cations $[(PPh_3)_2YRuCl_3RuY(PPh_3)_2]BPh_4$ (**285**) (Y = CO, CS).[1616] Other routes to $[Ru_2Cl_4(CO)_2(PPh_3)_3]$ are by reaction of $[RuCl_3CO(nbd)]^-$ with an excess of PPh_3 in CH_2Cl_2,[1616] treatment of $[RuHX(CO)(PPh_3)_3]$ (X = H,[1580] Cl[1717]) with HCl in C_6H_6 or elimination of $SnCl_2$ from $[Ru_2Cl_3(SnCl_3)(CO)_2(PPh_3)_3]$ (**19** and Section 45.3.4.3).[109] Some NMR evidence for compounds of formulation '$[Ru_2Cl_4(L\text{–}L)_2(PPh_3)_2]$' (L–L = dppe, dppp) has been published[1601] and unpublished work[1555] suggests that the anionic $[Ru_2Cl_5(PPh_3)_4]^-$ is formed by addition of Cl^- to $[Ru_2Cl_4(DMA)(PPh_3)_4]$. A high yield method of incorporating ligands such as N_2, alkenes, alkynes *etc.* into the terminal positions of $[L_{3-x}Cl_xRuCl_3RuCl_yL_{3-y}]$ by displacement of terminal chloride using $Tl[BF_4]$ has been published.[1836b]

$$[RuCl_2Y(PR_3)_2DMF] + [RuCl_2(PR_3)_3] \xrightarrow[\Delta]{\text{acetone}} [(PR_3)_2YRuCl_3RuCl(PR_3)_2] + PR_3 + DMF \quad (122)$$

An isomeric mixture of the analogous PF_3 complex $[Ru_2Cl_4(PF_3)_2(PPh_3)_3]$ can be generated by reaction of $[RuH_2(PF_3)(PPh_3)_3]$ with HCl. Other methods of preparation of this compound are shown in Scheme 59. Methods (iii) and (iv) also afford $[(PPh_3)Cl(PF_2NMe_2)RuCl_3Ru(PF_2\text{-}NMe_2)(PPh_3)_2]$ whereas reaction of *cis*-$[RuCl_2(PF_2NMe_2)_2(PPh_3)_2]$ with equimolar amounts of



Scheme 58



(285) Y = CO, CS

$[RuCl_2(PPh_3)_3]$ gives the isomers (**286**) and (**287**). The mono-PF_3 complex $[Ru_2Cl_4(PF_3)(PPh_3)_4]$ is obtained from reaction of $[RuCl_2(PPh_3)_3]$ with PF_3 in 2:1 molar ratio and the mixed PF_3/CO complex $[Ru_2Cl_4(CO)PF_3(PPh_3)_3]$ from $[Ru_2Cl_4CO(PPh_3)_4]$ and PF_3 (1:1 mole ratios).[1580] The heterobimetallic complexes (**288**) can be synthesized by intermolecular coupling of equimolar amounts of $[RuCl_2(PPh_3)_3]$ and *mer*-$[RhCl_3L_3]$ (L = PMe_2Ph, PEt_2Ph, PBu_3, PBu_2Ph, PPh_3).[1837]

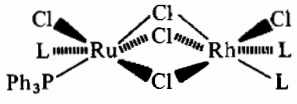
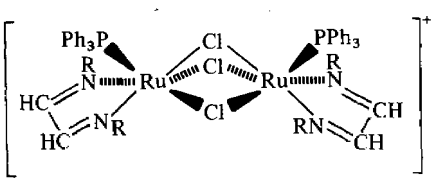
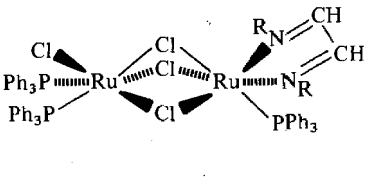


Scheme 59

(286)



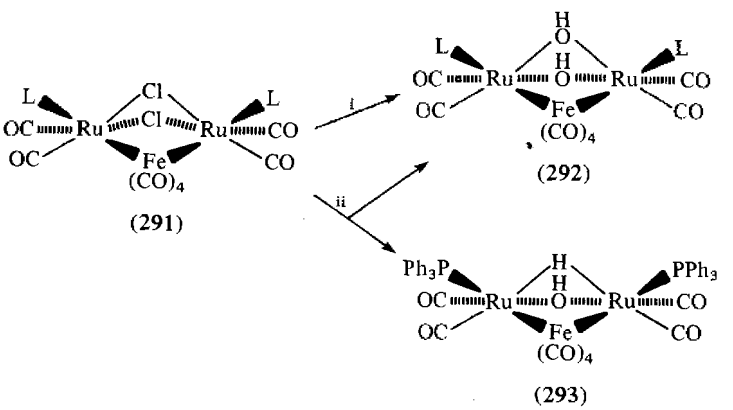
(287)



(288)

Another example of a neutral triple halide-bridged complex of this type is $[(PPh_3)_2ClRuCl_3RuN_2(PPh_3)_2]$ formed by treating $[RuCl_2(PPh_3)_4]$ in THF, in a reverse osmosis cell with nitrogen under pressure. This compound reacts with $N_2B_{10}H_8SMe_2$ to give $[(PPh_3)_2ClRuCl_3$-$Ru(N_2B_{10}H_8SMe_2)(PPh_3)_2]$.[1838] The interesting diazadiene complexes (**289**) and (**290**) have been prepared by reaction of $[RuCl_2(PPh_3)_3]$ with diazadiene in 1:2 and 2:1 molar ratios respectively. The unusual hydroxo-bridged complex $[(PPh_3)(Pr^iNCHCHNPr^i)RuCl(OH)_2RuH(PPh_3)_2]$ (**243**) (Sec-

tion 45.5.4.7.ii) is produced by the reaction of $[RuHCl(Pr^iNCHCHNPr^i)(PPh_3)_2]$ with water in toluene.[1770] A similar reaction between $[RuCl_2(PPh_3)_3]$ and a 1.5-fold molar excess of the electron-rich alkene $(MeNCH_2CH_2NMeC{=})_2$ $(L^{Me})_2$ affords $[Ru_2Cl_4(L^{Me})_3(PPh_3)_2]$.[1657a]



(289)

(290)

Some examples of electrogenerated triple halide-bridged ruthenium(II) anions are given in Section 45.5.6.

Finally, a series of related trimetallic halide- and hydroxo-bridged complexes have been reported. Thus reaction of $[Ru(arene)Cl_2L]$ with $[Fe_2(CO)_9]$ gives the novel complex $[Ru_2(\mu\text{-}Cl)_2\{\mu\text{-}Fe(CO)_4\}(CO)_4L_2]$ (**291**) which undergoes further reaction with aqueous Na_2CO_3 in acetone to give (**292**) and in isopropanol to give (**293**) and (**292**) (Scheme 60).[1519a] A report on the preparation of $[Ru_2(\mu\text{-}Cl)_2\{\mu\text{-}Fe(CO)_4\}(CO)_4Ph_2P(CH_2)_2PPh_2]$ is available.[1499]

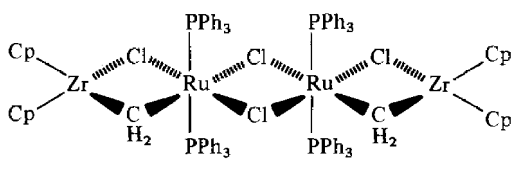
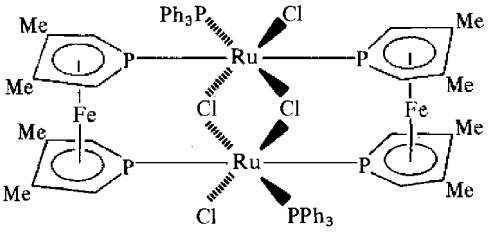
45.5.5.2 Double halide-bridged complexes (and related species)



Reaction of $[Ru(CO)_4PPh_3]$ with halogens in boiling acetone or with chlorinated solvents at room temperature gives the dimeric species $[RuX_2(CO)_2PPh_3]_2$ (X = Cl, Br, I).[1454] The same compounds are formed by heating $[RuX_2(CO)_3PPh_3]$ in C_6H_6.[1606c] Related complexes $[RuX_2(CO)_2L]_2$ (X = Cl, Br; L = $PBu^t{}_2Ph$, $PBu^t{}_2(p\text{-Tol})$, $PBu^t{}_3$) are obtained by treatment of the ruthenium(I) dimers $[RuCl(CO)_2L]_2$ with halogens.[1519,1520b] or (for X = I) by reaction of $[RuI_2(CO)_3]_2$ with $PBu^t{}_3$ for short periods in 2-methoxyethanol;[1839] $[RuCl_2(CO)_2L_3]_2$ (L = PMe_3, PEt_3) are also known.[1840] All these compounds have terminal CO groups and bridging and terminal halides. Reaction of '$RuCl_3 \cdot xH_2O$' with ethylene-1,2-bis(diphenylarsine) (eda) in boiling 2-methoxyethanol gives $[RuCl_2CO(eda)]_2$.[45] Analogous compounds $[RuCl_2CO(L)_2]_2$ with PR_3 and AsR_3 ligands are obtained by treatment of $[RuCl_3CO(nbd)]^-$ with PPh_3,[659] heating $[RuCl_2CO(AsPh_3)_3]$ in toluene[1841a] or by leaving all *trans*-$[RuCl_2(CO)_2(PMe_2Ph)_2]$ to stand in acetone for several days.[1608] The thiocarbonyl complexes $[RuCl_2(CS)(L)_2]_2$ (L = PPh_3,[1638,1639,1641] $P(p\text{-Tol})_3$[1558]) are also available *via* $[RuCl_2L_3]$ and CS_2. Reaction of '$RuCl_3 \cdot xH_2O$', PMe_3 and CO gave $[RuCl_2(CO)_2(PMe_3)]_2$ which catalysed the alcoholysis of Et_3SiH.[1841b]

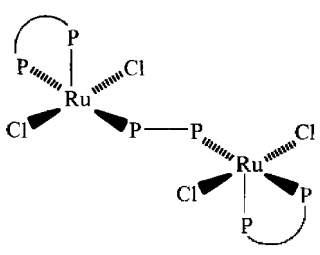
Other CO and CS double halide-bridged species include the cations $[RuClY\{P(OEt)Ph_2\}_3]_2(BPh_4)_2$ (Y = CO, CS) obtained by dissolution of $[RuCl_2Y\{P(OEt)Ph_2\}_3]$ in EtOH containing $Na[BPh_4]$,[1615] and the novel anionic complex (**294**) from reaction of '$RuCl_3 \cdot x$-



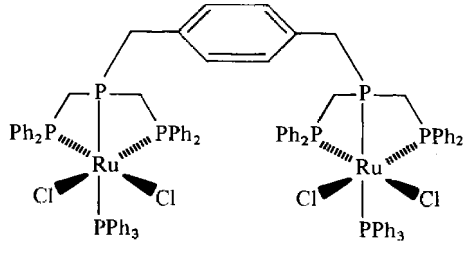
H_2O', NaI, PBu^t_3 with CO in refluxing 2-methoxyethanol.[1839] As discussed elsewhere (Scheme 57, Section 45.5.5.1) the $[RuCl\{P(OEt)Ph_2\}_4]^{2+}_2$ cation can be prepared from $[RuCl_2(PPh_3)_3]$ or $[RuCl_2(P(OEt)Ph_2)_3]$ treated with $P(OEt)Ph_2$ in EtOH[1535] and $[RuCl(PMe_3)_4]^{2+}_2$ is also known.[1529] Under UV irradiation, reaction of $[RuCl_2(PPh_3)_3]$ and $[ZrCp_2MeCl]$ affords the interesting zirconium–ruthenium complex (**295**)[1691] and direct reaction of '$RuCl_3 \cdot xH_2O$' tritertiary phosphine $PhP\{(CH_2)_2PPh_2\}_2$ (L) in boiling EtOH gives the binuclear chloride-bridged $[RuCl_2L]_2$.[1842] Treatment of $[RuCl_2(PPh_3)_3]$ with 3,3',4,4'-tetraMe-1,1'-diphosphaferrocene (DPF) gives the unusual binuclear complex $[RuCl_2(DPF)PPh_3]_2$ whose structure (**296**) was confirmed by X-ray analysis.[1568] Reduction of $[Ru_2Cl_5(PEt_2Ph)_4]$ with $Na[BH_4]$ in the presence of C_2H_4 or PhC≡CH(L') leads to the double halide-bridged complexes $[(PEt_2Ph)_3ClRu(\mu\text{-}Cl)_2RuL'_2Cl(PEt_2Ph)]$.[1836b]

(294)

(295)



(296)



The following double halide-bridged compounds are discussed elsewhere: $[RuCl_2(PPh_3)_2]_n$ (Section 45.5.4.2.i), $[RuCl_2(AsPh_3)_2]_n$ (?) (Section 45.5.4.2.ii), $[RuCl_2(CO)L\text{–}L]_2$ (L–L = *o*-$C_6H_4(EMePh)_2$; E = P, As) (Section 45.5.4.5.i), $[RuCl_2CO(SP)]_2$ (Section 45.5.4.5.vi), $[RuCl(CO)(CONHR)(PPh_3)_2]_n$ (Section 45.5.4.6.i), $[RuCl(N\text{–}N)(PPh_3)_2]_2Cl_2$ (N–N = bipy, phen) (Section 45.5.4.6.ii), $[RuCl\{CHMe(CN)\}CO(PPh_3)_2]_2$ (Section 45.5.4.5.iv), $[RuCl_2NO(\{P(OEt)_2O\}_2H)]_2$ (Section 45.5.4.6.iii), $[RuCl_2(NNAr)(PPh_3)_2]^{n+}_n$, $[Ru_2Cl_2(MeCN)_3(NNAr)_2(PPh_3)_4]^{2+}$ (Section 45.5.4.6.iv), $[RuCl_2(MeCN)(PPh_3)_2]_2$ (Section 45.5.4.6.vi), $[RuCl_2(PPh_3)_2Me_2CO]_n$ (Section 45.5.4.7.i), $[RuCl(acac)(EPh_3)_2]_2$ (Section 45.5.4.7.iii), $[RuCl_2(SPPh_3)PPh_3]_2$ and $[RuCl_2(SPPh_3)CO]_2$ (Section 45.5.4.8.vii).

45.5.5.3 Binuclear complexes with polydentate phosphine bridges

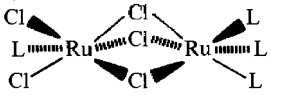
The chiral ditertiary phosphine, diop, displaces all three PPh_3 groups from $[RuCl_2(PPh_3)_3]$ to give the green binuclear complex $[Ru_2Cl_4(diop)_3]$ (**297**),[1571,1843] which is a good catalyst for asymmetric transfer hydrogenation of prochiral unsaturated acids or esters by alcohols.[1571,1844,1845] The analogous compound $[Ru_2Cl_4(dppb)_3]$ is obtained either by reaction of dppb with $[RuCl_2(PPh_3)_3]$ or $K_2[RuCl_5(OH_2)]$[1535] or by decomposition of $[RuHCl(dppb)_2]$.[1846a] Reaction of $[RuCl_2(cod)]_n$ with 2,2'-bis-(diphenylphosphine)-1,1'-binaphthyl (BINAP) gives the chiral $[Ru_2Cl_4(BINAP)_2NEt_3]$ which is an

(297)

(298)

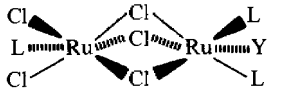
excellent catalyst for asymmetric hydrogenation of alkenes and some cyclic anhydrides.[1846b] Prolonged reaction of $[RuCl_2(PPh_3)_3]$ in hot C_6H_6 with the hexadentate ligand TDDX gives the bridged complex (**298**),[1538] and the related complexes $[RuCl_2(CO)_2]_2L$ (L = $Ph_2P(CH_2)_2P(Ph)(CH_2)_2$-$P(Ph)(CH_2)_2PPh_2$ (tet-1) and $P[(CH_2)_2PPh_2]_3$ (tet-2) are also known.[1540] The cation $[(bipy)_2ClRu(\mu$-dppm$)RuCl(bipy)_2]^{2+}$ can be prepared by treatment of $[RuCl_2(bipy)_2]$ with dppm in EtOH.[1267]

45.5.5.4 Miscellaneous



Other bi-, tri-, tetra- or poly-nuclear Ru^{II} complexes mentioned in earlier sections are $[(RuCl_2$-$CO(PCy_3)_2)_2TCNE]$ (Section 45.5.4.5.vi), $[RuCl_2(N_2H_4)(PMe_2Ph)_2]_2$ (Section 45.5.4.6.i), $[Ru(NCS)_2(PPh_3)_2]_n$ (Section 45.5.4.6.ii), various bi- and tetra-nuclear hydrido and halo/hydroxo compounds (Section 45.5.4.7.ii), $[RuX_2NO(EPh_3)_2]_2Y$ (Y = S, SO) (Section 45.5.4.8.1), $[Ru(SC_6$-$F_5)(bipy)(PPh_3)_2]_2$, $[RuI(SH)(CO)(CNR)PPh_3]_2$, $[RuCl(2\text{-}HSC_5H_4N)(2\text{-}SC_5H_4N)PPh_3]_2$, $[Ru_3Cl_3S_2(PPh_3)_3]$ (Section 45.5.4.8.i), $[RuSO_4(SO_2)(PPh_3)_2]_2$ (Section 45.5.4.7.v), $[Ru_3Cl_3$-$(SO_2)_3(PPh_3)_4]$ (Section 45.5.4.8.vi) and $[RuPdCl_2(CO)(PPh_2py)_2]$ (Section 45.5.4.9.i).

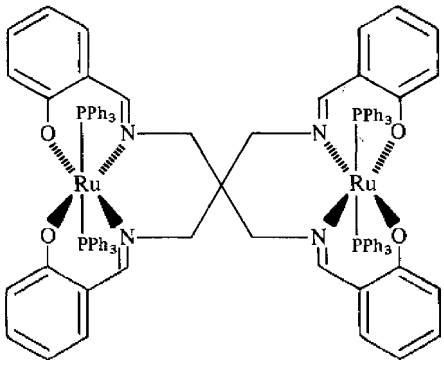
45.5.6 Mixed Valence Ruthenium(II)/Ruthenium(III) Complexes



The first formally mixed valence $Ru_2^{II/III}$ complexes, namely $[Ru_2Cl_5L_4]$ (L = PBu^n_3, $P(pent)^n_3$) were synthesized in 1967 by the prolonged interaction of excess L on '$RuCl_3 \cdot xH_2O$' in EtOH[1847] and the 'symmetric' structure (**299**) was later confirmed by X-ray analysis for L = PBu^n_3.[1848] More recently, the corresponding red-brown $As(p\text{-}Tol)_3$ and $AsPh_3$ complexes have been prepared by reaction of '$RuCl_3 \cdot xH_2O$' with excess AsR_3 in EtOH and butan-2-ol respectively.[1588] The latter was previously reported as the Ru^{II} polymer $[RuCl_2(AsPh_3)_2]_n$.[1587] However, reaction of '$RuCl_3 \cdot xH_2O$' with $As(p\text{-}Tol)_3$ in butan-2-ol or with $As(p\text{-}C_6H_4Cl)_3$ in MeOH gives the yellow-green isomer (**300**). Evidence for these formulations comes from detailed ESR, magnetic and electrochemical studies and is supported by the single crystal X-ray structure of $[(PEt_2Ph)Cl_2RuCl_3Ru(PEt_2Ph)_3]$ (**300**), synthesized by aerial oxidation of $[(PEt_2Ph)_2ClRuCl_3Ru(PEt_2Ph)_3]$ (Section 45.5.5.1) in HCl/$MeNO_2$ solution.[1588] The related complexes $[(PR_3)_2YRuCl_3RuCl_2PR_3]$ (Y = CO, CS; R = Ph, *p*-Tol) are produced by aerial oxidation of $[(PR_3)_2YRuCl_3RuCl(PR_3)_2]$ (Section 45.5.5.1) and are believed to have structure (**301**).[1556,1639,1836a,1849] The mixed valence complexes $[Ru_2Cl_5(mppl)_4]$[1567] (mppl = 3-methyl-1-phenylphosphole) and $[Ru_2Cl_5(dpae)_2]$[1588] are also known.

(299)

(300)



(301)

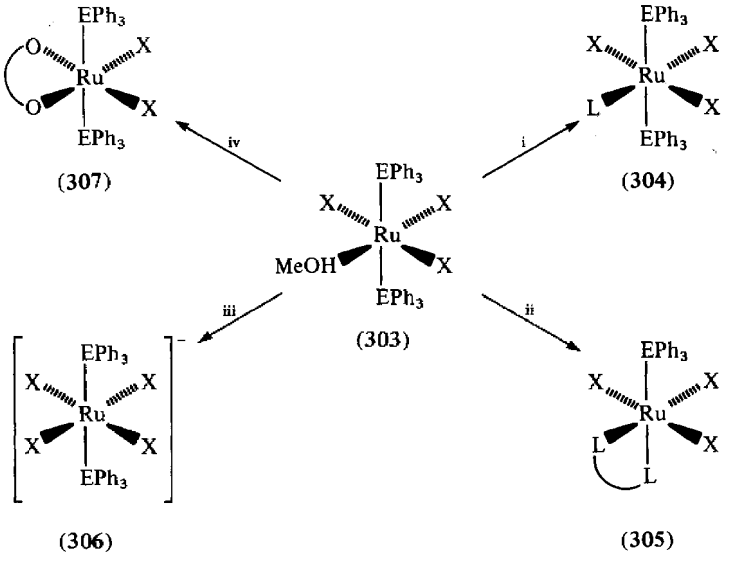
Other mixed valence triple halide-bridged $Ru_2^{II,III}$ complexes can be generated electrochemically from stable $Ru_2^{II,II}$ or $Ru_2^{III,III}$ compounds and characterized by *in situ* spectroscopic measurements. Examples include $[Ru_2Cl_3(PEt_2Ph)_6]^{2+}$ $[Ru_2Cl_4(PEt_2Ph)_5]^+$, $[Ru_2Cl_4Y(PPh_3)_4]^+$ (Y = CO, CS), and $[Ru_2Cl_6\{As(p\text{-}Tol)_3\}_3]^-$. An examination of the intervalence charge transfer bands in the optical spectra of these complexes reveals that the degree of metal–metal interaction decreases as the molecular asymmetry increases. Bulk electrogeneration, followed by *in situ* characterization, of $Ru_2^{II,II}$ anions such as $[(PEt_2Ph)Cl_2RuCl_3Ru(PEt_2Ph)_3]^-$ and $[As(p\text{-}Tol)_3Cl_2RuCl_3RuCl\{As(p$-$Tol)_3\}_2]^{2-}$ is also possible.[1556,1850]

The mixed valence $[(bipy)_2ClRu(\mu$-dppm$)RuCl(bipy)_2]^{3+}$ cation, which is a valence-trapped species with an intervalence charge transfer band at 8020 cm^{-1}, is synthesized by stoichiometric oxidation of $[(bipy)_2ClRu(\mu$-dppm$)RuCl(bipy)_2]^{2+}$ with $[Fe(bipy)_3]^{3+}$.[1267] Compound (**302**) has been prepared and in the semioxidized $Ru^{III} \cdots Ru^{II}$ complex derived from (**302**), some interaction between Ru atoms is proposed although no intervalence charge transfer band is detected.[1758a]

The synthesis and reactivity of complexes such as $[Ru_3O(OCOMe)_6(PPh_3)_3]$ in which the ruthenium has a mean oxidation state of $+2\frac{2}{3}$ are covered in Section 45.6.5.

(302)

45.5.7 Mononuclear Ruthenium(III) Complexes



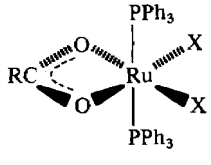
45.5.7.1 Monodentate P, As and Sb donor ligand complexes

An extensive series of paramagnetic Ru^{III} complexes $[RuCl_3L_3]$ ($L = PR_3$ or AsR_3) can be synthesized from '$RuCl_3 \cdot xH_2O$' concentrated HCl and L in EtOH, using much shorter reaction times than those required to give $[Ru_2Cl_3L_6]Cl$ or $[RuCl_2L_4]$.[1584,1585,1851] The bromo compounds are also available and IR and ESR studies suggest meridional structures.[1722,1852,1853] The phosphole complex $[RuCl_3(dmppl)_3]$ (dmppl = 3,4-dimethyl-1-phenylphosphole) is also reported.[1567] However, for $L = AsPh_3$[106] and $As(p\text{-}Tol)_3$[625,1582] reaction with '$RuCl_3 \cdot xH_2O$' in boiling MeOH gives the green methanolates $[RuCl_3(AsR_3)_2MeOH]$ (**303**) and the PPh_3 analogue is obtained in low yield by shaking MeOH solutions of PPh_3 with '$RuCl_3 \cdot xH_2O$' (2:1 molar ratio).[106] The bromo compounds are known and the preparation of $[RuCl_3(AsPh_3)_3]$ (two isomers?) and $[RuCl_3(AsPh_3)_2OAsPh_3]$[1726] (previously formulated as $[RuCl_3(AsPh_3)(OAsPh_3)_2]$)[1854] is also published. Note however that the compound reported as $[RuCl_2(AsPh_3)_3O_2]$[1583] has been reformulated as the binuclear μ-peroxo complex $[(AsPh_3)_3Cl_2RuO_2RuCl_2(AsPh_3)_3]Cl_2$[1778] although earlier workers[1547] suggested that all the physicochemical properties could be ascribed to Ru^{III} arsine oxide complexes. Further work to resolve these differences is now required.

As shown in Scheme 61, these $[RuX_3(EPh_3)_2MeOH]$ complexes are excellent precursors for the synthesis of a wide range of low spin Ru^{III} compounds containing O, N or S donor ligands.[106,1697,1855,1856] The same types of compound can be prepared from $[RuX_3\{As(p\text{-}Tol)_3\}_2MeOH]$,[625,1582] $[RuCl_3(AsPh_3)_3]$ or '$[RuCl_3(AsPh_3)_2OAsPh_3]$'.[1726,1749] Thus the labile MeOH group can be replaced by a variety of donor ligands L to give $[RuX_3(EPh_3)_2L]$ (**304**). For L = pyridine, the monopyridine complex could be isolated only by adding a large excess of light petroleum to quench the reaction immediately after addition of pyridine.[1855] The related *mer,trans*-$[RuCl_3(NH_3)\{P(OMe)_3\}_2]$ is obtained as a by-product from reaction of '$RuCl_3 \cdot xH_2O$' (containing nitrogen impurity) with $P(OMe)_3$ in refluxing MeOH.[1562] Ligands such as pyridine, Me_2S, isocyanides and the bidentate bipy and phen also displace one of the EPh_3 groups from (**303**) to give $[RuX_3(EPh_3)L_2]$ (**305**). The mixed $[RuCl_3(PPh_3)py(CNR)]$ is prepared by treatment of the reactive $[RuCl_3(PPh_3)_2py]$ with CNR.[1855] Spectroscopic and dipole moment measurements support the proposed structures. Treatment with halide ion in the presence of a large cation gives the Ru^{III} anions (**306**). For E = P, the same compound is produced by reaction of $[RuCl_2(PPh_3)_3]$ with MCl/HCl ($M = AsPh_4^+$, Me_4N^+) or $Ph_4As[Ru(N)Cl_4]$ with PPh_3 in cold acetone.[1857] Other anions can be prepared either by direct exchange with $[RuCl_4(EPh_3)_2]^-$ (*e.g.* $L = P(OPh)_3$, PEt_3, PMe_2Ph) or, as their phosphonium salts, by reaction of the 'RuCOCl' solution with excess L ($L = PEt_3$, PEt_2Ph, PMe_2Ph).[1749,1858] The *trans* structure is established by ESR and IR spectroscopy[1852,1858,1859] and their magnetic circular dichroism and optical spectra have been analysed.[1860] Under more forcing conditions, reduction of (**303**) to Ru^{II} complexes generally occurs (see Section 45.5.4 for examples). However, rather surprisingly, *mer*-$[RuCl_3L_3]$ ($L = PPh_3$, $PMePh_2$, PMe_2Ph, $PEtPh_2$) have been synthesized by reaction of $[RuCl_3(AsPh_3)_2MeOH]$ with an excess of L in boiling C_6H_6.[1586]

An electrochemical survey of many of these compounds has been reported. Most of the neutral compounds show a reversible one-electron reduction and an irreversible one-electron oxidation whereas the anions (**306**) exhibit irreversible reduction and quasi-reversible oxidation behaviour.[625]

Reaction of (**303**) or $[RuCl_3(EPh_3)_3]$ with β-diketones leads to partial replacement of halide and



(X = Cl, Br; E = P, As – not all possible combinations)

i, L = Me_2CO, THF, $MeNO_2$, DMF, DMSO, RCHO, NH_3, $MeNH_2$, Et_2S, CS, py, RCN (R = Me, Pr, Ph, $PhCH_2$, CH_2=CH) *etc.*; ii, L = ½ bipy, ½ phen, Me_2S, py, 2-MeC_5H_4N, pyrazine, 4,4′-bipy, 1,4-dithian, CNR; iii, X = Cl^-; Br^-; iv, various β-diketones

Scheme 61

formation of $[RuX_2(dike)(EPh_3)_2]$ (**307**);[1861,1862] $[RuCl_2(acac)(dppe)]$ is also known.[1863] The bromotropolonate complexes $[RuCl_2L(EPh_3)_2]$ (L = bromotropolonate, E = P, As) are given by reaction of L with $[RuCl_3(EPh_3)_3]$,[1864] whereas $[RuCl_3(PPh_3)_3]$ and *N*-phenylcarbamoylpyrrole-2-thiocarboxamide (PTH) afford S-bonded $[RuCl_3(PTH)_2(PPh_3)]$.[1819] Treatment of $[RuX_2(PPh_3)_3]$ with RCO_2H in aerated solvents affords $[RuX_2(OCOR)(PPh_3)_2]$ (R = Me, Et, Ph, *p*-Tol *etc.*) whose structure (**308**) is established by X-ray analysis (for X = Cl; R = Ph).[1865] This compound is also prepared by reaction of $[RuCl_2(PPh_3)_3]$ with dibenzoyl peroxide.[1866] A route to $[RuCl_2(OCOR)(AsPh_3)_2]$ (R = Me, Et) is published although it was suggested these are dimeric with chloride bridges and unidentate ^-OCOR ligands.[1704]

(308)

A number of cationic Ru^{III} compounds containing P or As donor ligands are known. Examples include $[RuCl_2(CNR)(PR_3)_3]^+$ (from reaction of *mer*-$[RuCl_3(PR_3)_3]$ and CNR, see Section 45.5.4.5.iii),[1647] $[RuCl_2bipy(PPh_3)_2]BPh_4$ (from $[RuCl_3(PPh_3)_2(MeNO_2)]$, bipy and $Na[BPh_4]$ heated in MeOH) and $[RuCl_2(PhCN)(bipy)(PPh_3)]Cl\cdot H_2O$ (from $[RuCl_3(bipy)PPh_3]$ in MeOH treated with an excess of PhCN).[1713] Studies have revealed that oxidation of $[RuCl_2(PMe_3)_4]$ with $AgPF_6$ gives $[RuCl_2(PMe_3)_4]PF_6$.[1391c]

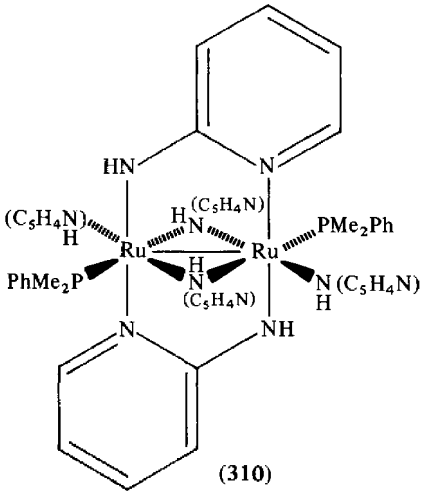
45.5.7.2 Bi- and poly-dentate P and As donor ligand complexes

The ruthenium(III) cations *cis*- or *trans*-$[RuCl_2(L–L)_2]ClO_4$ (L–L = dmpe, depe) are readily prepared by treatment of the corresponding *cis*- or *trans*-$[RuCl_2(L–L)_2]$ with $HClO_4$; their ESR spectra are reported.[1591a,1852] Oxidation of *trans*-$[RuCl_2(dppm)_2]$ with $NO[BF_4]$ affords *trans*-$[RuCl_2(dppm)_2]BF_4$ although this must be isolated rapidly to avoid conversion to nitrosyl complexes.[1593] Chemical or electrochemical oxidation of *cis*-$[RuCl_2(dppm)_2]$ also gives *trans*-

$[RuCl_2(dppm)_2]^+$.[1598] Oxidation of $[RuCl_2(diars)_2]$ with Cl_2 in the presence of X^- produces *trans*-$[RuX_2(diars)_2]X$ (X = Cl, Br, I)[1592] and other Ru^{III} cations generated by oxidation of their neutral Ru^{II} precursors include $[Ru(1,2\text{-}O_2C_6X_4)(CO)_2(PPh_3)_2]^+$ (X = Cl, Br)[1777a] and $[RuCl_2\{PPh_2(2\text{-}MeOC_6H_4)\}_2]^+$.[1824] Direct reaction of '$RuCl_3 \cdot xH_2O$' with the neopentyldi(tertiary phosphine), $(Me_3CCH_2)_2P(CH_2)_2P(CH_2CMe_3)_2$, gives $[RuCl_2(L\text{–}L)_2]^+$[1867] whereas with $Ph_2P(CH_2)_2SPh$ (SP), $[RuCl_3SP]$ is first produced.[1829]

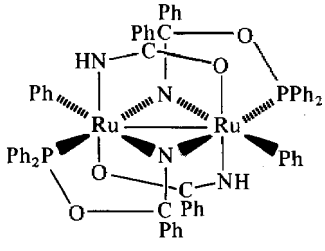
Few Ru^{III} complexes containing polydentate P or As donor ligands are known. Thus, reaction of '$RuCl_3 \cdot xH_2O$' with the hexatertiary phosphine $[Ph_2PCH_2CH_2]_2P(CH_2)_2P[CH_2CH_2PPh_2]_2$ (L) in boiling EtOH gives the brown Ru^{III} cation $[RuCl_2L]^+$ isolatable as its PF_6^- salt (μ_{eff} = 1.7 BM); tetradentate coordination of the ligand is proposed.[1868] In contrast, reaction of the closely related TDDX ligand (see Section 45.5.4.1) with '$RuCl_3 \cdot xH_2O$' gives the binuclear Ru^{III} cation $[Ru_2Cl_4(TDDX)](PF_6)_2$ (*cf.* $[Ru_2Cl_4(PPh_3)_2TDDX]$ (**298**), Section 45.5.5.3).[1538] Chlorine oxidation of $[RuCl_2\{N(CH_2CH_2PPh_2)_3\}]$ affords the corresponding Ru^{III} cation.[1595]

45.5.8 Bi- and Tri-nuclear Ruthenium(III) Complexes



Heating the methanolates $[RuX_3(AsR_3)_2MeOH]$ (**303**) (X = Cl, Br; R = Ph, *p*-Tol) in non-coordinating solvents such as C_6H_6 or CH_2Cl_2 provides a high yield route to the paramagnetic triple halide-bridged complexes $[(AsR_3)X_2RuX_3RuX(AsR_3)_2]$ (**309**). These undergo stepwise, one-electron reductions to form the $[Ru_2X_6(AsR_3)_3]^{n-}$ anions (n = 1,2).[1850] Under milder conditions, loss of MeOH from (**303**) in the above solvents gives brown compounds of empirical formula $[RuX_3(AsR_3)_2]$. Monomeric trigonal bipyramidal structures were initially proposed for these species[1582,1697,1859] but on the basis of electrochemical evidence (two reversible one-electron reductions), they were reformulated as the double halide-bridged $[(AsR_3)_2X_2RuX_2RuX_2(AsR_3)_2]$.[625] However a comparison of electrochemical, magnetic, ESR and optical spectral properties strongly indicates that the latter are also the triple halide-bridged $[Ru_2X_6(AsR_3)_3]$ (**309**) containing one molecule of clathrated AsR_3.[1869] (*cf.* $[RuCl_2(PPh_3)_3] \cdot PPh_3$).[1543,1544]

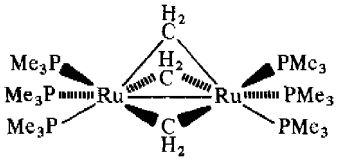
Related binuclear complexes $[Ru(NCS)_3(EPh_3)_2]_2$ (E = As, Sb) can be prepared by reaction of $[RuCl_3(EPh_3)_3]$ with $NH_4[NCS]$.[1704,1711] These are formulated as double bridged species but they might be $[Ru_2(NCS)_6(EPh_3)_3]EPh_3$. There are two brief references to $[RuX_3(PPh_3)_2]_n$ complexes; $[RuI_3(PPh_3)_2]_2$ from reaction of $[RuH_2(PPh_3)_4]$ with I_2[1870] and $[RuCl_3(PR_3)_2]_2$ (R = Bu, Pr, Pent) from '$RuCl_3 \cdot xH_2O$' and PR_3 in EtOH.[1847] The latter is formulated as a double chloride-bridged species but more definitive evidence is now required. The interesting complex $[RuCl_3(mppl)]$ (mppl = 3-methyl-1-phenylphosphole) is also known.[1567] Electrogeneration and *in situ* spectroscopic characterization of triply halide-bridged binuclear $Ru_2^{III,III}$ cations such as $[Ru_2Cl_5(PEt_2Ph)_4]^+$, $[Ru_2Cl_3(PEt_2Ph)_6]^{3+}$ and $[Ru_2Cl_4(PEt_2Ph)_5]^{2+}$ have been accomplished;[1850] oxygenation of $[RuCl_3(AsPh_3)_3]$ is claimed to give the binuclear μ-peroxo complex $[(AsPh_3)_3Cl_2RuO_2RuCl_2(AsPh_3)_3]Cl_2$ rather than $[RuCl_3(AsPh_3)_2(OAsPh_3)]$ (see Section 45.5.7.1).[1778]



Reaction of $[Ru_2(OCOMe)_4Cl]$ with $Li[C_5NH_4NH]$ in THF followed by addition of PMe_2Ph gives dark red crystals of $[Ru_2(C_5NH_4NH)_6(PMe_2Ph)_2]$, shown by X-ray analysis to have structure (**310**), in which the anionic ligand exhibits three modes of coordination. This is the first edge-sharing

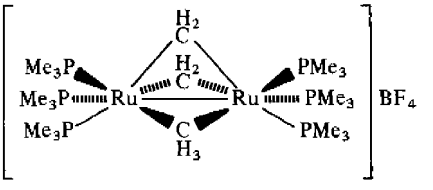
(309)

(310)



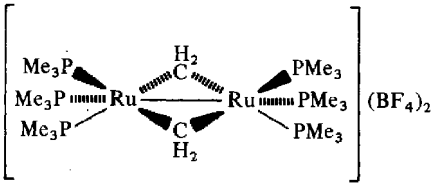
(311)

biooctahedral molecule having a bond between two d^5 metal atoms and also the first in which the (μ_2, η^1) bridging atoms are imido nitrogen atoms.[1817a]

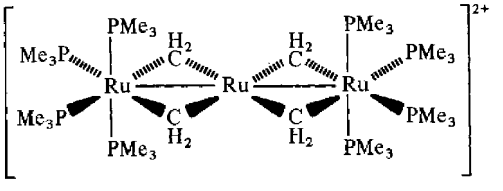


Treatment of $[Ru_2(OCOMe)_4Cl]$ with excess molten benzamide ($PhCONH_2$) affords $[Ru_2(PhCONH)_4Cl]$ which reacts with PPh_3 in DMSO/MeOH to generate the novel complex $[Ru_2(Ph)_2(PhCONH)_2(\mu\text{-}NC(Ph)OPPh_2)_2]$ (**311**). This consists of two equivalent Ru^{III} atoms surrounded by a distorted octahedron of ligand atoms. The $Ph_2POC(Ph)N^-$ ligand coordinates through its P and N atoms to form a five-membered chelate ring and the nitrogen atom also serves as a bridge to the other Ru atom. This chelating ligand is (at least formally) the product of attack of a $PhCONH^-$ oxygen atom on Ph_3P with concomitant shift of a phenyl group to Ru and loss of H.[1871b]

The reaction between $[Ru_3O(OCOMe)_6(OH_2)_3]OCOMe$ and $MgMe_2$ in the presence of PMe_3 yields the diamagnetic tri-μ-methylene complex (**312**). The short Ru^{III}—Ru^{III} distance of 2.650(1) Å probably indicates the presence of a metal–metal bond and hence accounts for the observed diamagnetism. Compound (**312**) reacts with one equivalent of HBF_4 or $[Ph_3C]BF_4$ to give $[(Me_3P)_3Ru(\mu\text{-}CH_2)_2(\mu\text{-}CH_3)Ru(PMe_3)_3]BF_4$ (**313**) and with an excess of HBF_4 or CF_3SO_3H to eliminate methane and produce $[(Me_3P)_3Ru(\mu\text{-}CH_2)_2Ru(PMe_3)_3](BF_4)_2$ (**314**). The above protonation can be readily reversed by addition of alkyllithiums.[1521,1768,1872]

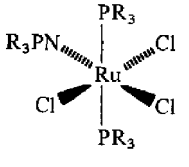


The remarkable trinuclear cation (**315**) is isolated by protonation with HBF_4 of the red oil which is also obtained from the $[Ru_3O(OCOMe)_6(OH_2)_3]OCOMe$, $MgMe_2$, PMe_3 reaction mixture. This formally contains two Ru^{III} and a central, tetrahedrally coordinated Ru^{IV} ion.[1521,1768,1872]



(312)

(313)



(314)

(315)

45.5.9 Ruthenium(IV) and Higher Oxidation State Complexes

There are few Ru^{IV} complexes containing soft P, As or Sb donor ligands. Treatment of $Bu^n{}_4N[RuNCl_4]$ with EPh_3 in boiling acetone gives the diamagnetic $[Ru^{VI}Cl_3N(EPh_3)_2]$ (E = Sb, As). Further reaction of the $AsPh_3$ compound with various PR_3 in cold acetone produces the novel phosphineimidato complexes $[RuCl_3(NPR_3)(PR_3)_2]$ (PR_3 = PPh_3, $PEtPh_2$, PEt_2Ph, $PMePh_2$, PEt_3); with PMe_2Ph, the intermediate $[RuCl_3(NPMe_2Ph)(AsPh_3)_2]$ is isolated.[1857] Magnetic moments typical of Ru^{IV} (μ_{eff} *ca.* 2.8 BM at room temperature) are observed and the structure (**316**) is confirmed by X-ray analysis of the $[RuCl_3(NPEt_2Ph)(PEt_2Ph)_2]$ complex.[1873]

(316)

Other Ru^{IV} complexes discussed elsewhere include $[RuCl_2(C_6X_4O_2)(PPh_3)_2]$ (X = Cl, Br) (Section 45.5.4.7.iii), $[RuH_3(SiR_3)(PPh_3)_3]$ (Section 45.3.2.3), $[RuH_4(PPh_3)_3]$, $[RuH_4(PPh_3)_2]_2$, $[RuH_3(PR_3)_4]^+$ (Section 45.10.5), $[RuF_4(PF_3)]_n$ and $RuF_4 \cdot AsF_5$ (Section 45.9.7.2).

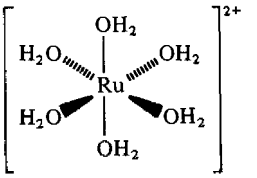
Higher oxidation state complexes are confined to $[RuO_4PF_3]$ and $[RuO_4(PF_3)_2]$ (from RuO_4 and PF_3). Similar reactions with PCl_3 or PBr_3 reduce the tetroxide to RuO_2PX_3 (X = Cl, Br).[1874] Preliminary communications on the hexahydrides $[RuH_6(PR_3)_2]$ (R = Ph, Cy) have recently appeared (see Section 45.10.5).

45.5.10 Useful Books and Reviews

For more detailed information about P, As, and Sb donor ligand complexes, the following books and reviews are recommended. 'Transition Metal Complexes of Phosphorus, Arsenic and Antimony Ligands' edited by C. A. McAuliffe, McMillan, 1973; 'Phosphine, Arsine and Stibine Complexes of the Transition Elements' by C. A. McAuliffe and W. Levason, Elsevier, 1979; 'Comprehensive Organometallic Chemistry' edited by Sir Geoffrey Wilkinson, F. G. A. Stone and E. W. Abel, Pergamon Press, 1982, Volume 4, Sections 32.1 to 32.9, 'The Chemical and Catalytic Reactions of Dichlorotris(triphenylphosphine)ruthenium(II) and its Major Derivatives' by F. H. Jardine in *Progress in Inorganic Chemistry*, 1984, volume 31, pp. 265–370, 'The Chemistry of Ruthenium' by E. A. Seddon and K. R. Seddon, Elsevier, 1984, chapters 7–14, and volume 7 (Comprehensive Review Index) of this series.

45.6 OXYGEN LIGANDS

Ruthenium complexes of oxygen donor ligands incorporating other donor ligands are discussed in the corresponding section for the other ligand. Ternary and related compounds are outside the scope of this review.



45.6.1 Aqua Complexes

The chemistry of ruthenium aqua complexes has been compared to the corresponding ammine species.[1875]

Ruthenium(II): $[Ru(OH_2)_6]^{2+}$ can be prepared by reduction of RuO_4 with metallic Pb[648,1876] or Sn[1877] or by electrochemical[1878] or chemical reduction of $[RuCl_5(OH_2)]^{2-}$ using Pt/H_2.[282,1879] Purification of the pink product as its ditosylate salt by ion exchange column chromatography has been described.[1876,1879] The single crystal X-ray structure of $[Ru(OH_2)_6](tos)_2$ (**317**) shows an average Ru—O distance of 2.122 Å.[1876] EXAFS,[1880] IR, Raman[1881] and electronic[601] spectral data for $[Ru(OH_2)_6]^{2+}$ have been reported, Dq and B being evaluated as 2100 cm^{-1} and 423 cm^{-1} respectively.[1878] The force constant for the symmetric Ru—OH_2 stretching vibration has been calculated as 1.91 mdyn $Å^{-1}$.[1881]

For the redox couple $[Ru(OH_2)_6]^{3+/2+}$, $E_{\frac{1}{2}} = +0.205$ V *vs.* NHE.[648,1882] The rate of self exchange between $[Ru(OH_2)_6]^{3+/2+}$ (equation 123) has been determined as $\sim 50\,M^{-1}s^{-1}$ by ^{17}O, ^{99}Ru NMR,[1883] IR force constant[1881] and kinetic (Marcus Theory) measurements.[1884] $[Ru(OH_2)_6]^{2+}$ is readily oxidized to $[Ru(OH_2)_6]^{3+}$ by O_2,[282] ClO_4^-,[1885] $[RuL(NH_3)_5]^{3+}$ (L = py, isn),[1884] $[Ru(bipy)_3]^{3+}$, $[Os(bipy)_3]^{3+}$, $[Co(phen)_3]^{3+}$ and $[Fe(OH_2)_6]^{3+}$.[1884] The oxidation of $[Ru(OH_2)_6]^{2+}$ by ClO_4^- in the presence of halides follows kinetics given by equation (124), where $k_1 = 3.2 \times 10^{-3}\,M^{-1}s^{-1}$, $K = 1.2\,M^{-1}$, the rate being limited by slow substitution on Ru^{II}.[1885,1886] The same rate-determining step has been invoked in the $[Ru(OH_2)_6]^{2+}$ catalysed substitution reactions of $[Ru(OH_2)_6]^{3+}$ by halide ion X^- with second order rate constant $k = 8.5 \times 10^{-3}$, 10.2×10^{-3}, $9.8\,M^{-1}s^{-1}$ for $X = Cl^-$, Br^-, I^- respectively.[1877] The rate of water exchange on $[Ru(OH_2)_6]^{2+}$ has been measured as $1.44 \times 10^{-2}\,s^{-1}$ at 24.5°C by ^{17}O NMR studies.[1883]

$[Ru(OH_2)_6]^{2+}$ is a good starting material for the synthesis of substituted aqua complexes, *e.g.* $[Ru(NO)(OH_2)_5]^{3+}$,[282] $[Ru(py)_x(OH_2)_{6-x}]^{2+}$ ($x = 4,2,0$);[648] reaction of $[Ru(OH_2)_6]^{2+}$ with N_2 at

(317)

5 atm for 72 h yields the N_2-bridged dimer $[Ru(OH)_5]_2N_2^{4+}$.[1879] Addition of N_2 to $[Ru(OH_2)_6]^{2+}$ to give $[Ru(N_2)(OH_2)_5]^{2+}$ was found to proceed approximately 35 times more slower than the addition of N_2 to $[Ru(NH_3)_5OH_2]^{2+}$.[1879]

$$[Ru(OH_2)_6]^{2+} + [Ru(OH_2)_6]^{3+} \overset{k}{\rightleftharpoons} [Ru(OH_2)_6]^{3+} + [Rh(OH_2)_6]^{2+} \quad (123)$$

$$\frac{d[[Ru(OH_2)_6]^{3+}]}{dt} = 2k_1[ClO_4^-][Ru^{II}](1 + K[Cl^-])^{-1} \quad (124)$$

Ruthenium(III): $[Ru(OH_2)_6]^{3+}$ is readily prepared by oxidation of $[Ru(OH_2)_6]^{2+}$.[1876,1887] The single crystal X-ray structure of $[Ru(OH_2)_6](tos)_3$ shows an average Ru—O distance of 2.029 Å.[1876] The temperature independent magnetic moment of $[Ru(OH)_6]^{3+}$ has been measured as 1.92 BM[1888] with powder and single crystal ESR spectra in $CsGa(SO_4)_2 \cdot 12H_2O$ giving $g_\parallel = 1.494$, $g_\perp = 2.517$, $A_\parallel = 2.2 \times 10^{-3}\,cm^{-1}$ and $A_\perp = 1 \times 10^{-4}\,cm^{-1}$.[1888] IR and Raman[1881] spectra of $[Ru(OH_2)_6]^{3+}$ have been reported, the force constant for the symmetrical Ru—OH_2 stretching vibration being estimated as 2.98 mdyn $Å^{-1}$;[1881] molecular orbital calculations,[1890] EXAFS[1880] and NMR[1889] data have also been published. Absorption spectra for $[Ru(OH_2)_6]^{3+}$ give values for Dq and B of 3000 cm^{-1} and 600 cm^{-1} respectively.[1881,1891] For the formation of $[Ru(OH)(OH_2)_5]^{2+}$, $pk = 2.4$ at 20°C.[1891] The reduction of $[Ru(OH_2)_6]^{3+}$ by $[Ru(NH_3)_6]^{2+}$, $[RuCl(OH_2)_5]^{2+}$ and $[V(OH_2)_6]^{2+}$ has been reported.[1884] The preparation of $[Ru(OH_2)_6]^{4+}$ in solution has been claimed.[1892]

45.6.2 Hydroxy Complexes

The chemistry of hydroxy and high valence aqua complexes of ruthenium is generally very ill-defined; for a full discussion see reference 3.

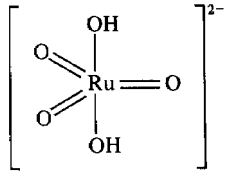
The most important hydroxy complex is the red/brown Ru^{IV} product formulated as $[Ru_4(OH)_{12}]^{4+}$ prepared by oxidation of Ru^{III} nitrosyls and nitrates with HNO_3,[1893] by electrolytic[1894] or chemical[1895–1898] reduction of RuO_4 or in potentiometric studies of Ru^{IV} in methylsulfonic and nitric acid at pH 1.5–4.[1899] $[Ru_4(OH)_{12}]^{4+}$ shows multi-redox behaviour, the generation of intermediates formulated as $[Ru_4(OH)_{10}]^{5+}$, $[Ru_4(OH)_8]^{6+}$, $[Ru_4(OH)_6]^{7+}$ and $[Ru_4(OH)_4]^{8+}$ being available.[1893,1895,1897,1899,1900] The direct formation of $[Ru_4(OH)_4]^{8+}$ by electrolysis of $[Ru_4(OH)_{12}]^{4+}$ at a Pt electrode has been reported, the Ru^{III} complex decomposing to a binuclear species of type $[Ru_2(OH)_5]^{4+}$ *via* first and zero dependence in $[Ru^{III}]$ and $[H^+]$ respectively.[1901] Ruthenium hydroxy species are active hydrogenation catalysts.[1902]

45.6.3 Oxo Complexes

Oxo (M=O) complexes of ruthenium,[1903] associated high valence chemistry[1904] and the properties of ruthenium(II) and (III) oxides[3–5] have been reviewed.

Ruthenium(IV): RuO_2 can be prepared by high temperature oxidation of Ru metal[1905,1906] or $RuCl_3$,[1907–1910] by dehydration of hydrated RuO_2,[1911,1912] or reduction of RuO_4, $[RuO_4]^-$ or $[RuO_4]^{2-}$ by $NaBH_4$.[1913,1914] The compound has a rutile structure in crystalline form with octahedral Ru with Ru—O = 1.984 Å for four connectivities and Ru—O = 1.942 Å for the other two;[1915–1918] no direct Ru—Ru bonding occurs within the structure.[1919] PES,[1920] Mössbauer[27a,1921,1922] and magnetic susceptibility[1908,1923] data for RuO_2 have been published with $\chi = 1.10 \times 10^{-6}$ and 1.76×10^{-6} EMU g^{-1} at 1.3 and 1033 K respectively. In recent years RuO_2 and related oxides have found uses in catalytic systems, particularly in the generation of O_2 from H_2O[1924–1929] (see Section 45.4.3.1.vi) and the water-gas shift reaction.[1930]

The chemistry of ruthenates $MRuO_3$ has been reviewed (see reference 3, pp. 116–135).



Ruthenium(V): Several reports on the preparation of hydrated ruthenium(V) oxide have appeared.[1910,1913–1936] These products are not well characterized and require further detailed analysis. Cluster species of type $[Ru_4O_{16}]^{2-}$ have been proposed to exist in Na_3RuO_4.[1937]

Ruthenium(VI): $[RuO_4]^{2-}$ is stable in aqueous alkaline conditions and can be generated by fusion of $RuCl_3$ or RuO_2 with KNO_3 and KOH,[1938–1942] reduction of RuO_4 with aqueous KOH (equations 125 and 126),[1943a] oxidation of RuO_2 by Na_2O[1943b] or $NaBiO_3$[1944,1945] and by the oxidation of $RuCl_3$ with alkaline $K_2S_2O_8$[1211,1946,1947] or hypochlorite.[1948] Problems with overoxidation to Ru^{VII} and Ru^{VIII} exist with reactions using Na_2O[1943b] and hypochlorite.[1948,1949] $[RuO_4]^{2-}$ can be isolated most con-

veniently in the solid state as its relatively insoluble barium salt, the single crystal X-ray structure of which shows the complex to be $Ba[Ru(O)_2(OH)_3]$ (**318**) with trigonal bipyramidal Ru^{VI} and *trans* hydroxides, Ru=O = 1.755 Å, Ru—OH = 2.02 Å.[1950–1952] The IR and Raman spectra of the solid are consistent with this structure,[1211,1953,1954] although solution studies suggest that the major species is $[RuO_4]^{2-}$, deuteration experiments indicating the absence of hydroxy species.[1953–1956] $[RuO_4]^{2-}$ shows absorptions near 480 and 380 nm[1949,1957–1962] and an isotropic ESR signal at $g = 2.0$, with a magnetic moment $\mu_{eff} = 2.75$ BM.[1963] The Mössbauer spectrum of $[RuO_4]^{2-}$ has been reported.[1964]

$$4RuO_4 + 4OH^- \longrightarrow 4[RuO_4]^- + 2H_2O + O_2 \quad (125)$$

$$4[RuO_4]^- + 4OH^- \longrightarrow 4[RuO_4]^{2-} + 2H_2O + O_2 \quad (126)$$

(318)

$K_2[RuO_4]$ and $Na_2[RuO_4]$ are stable in aqueous alkali giving a bright orange solution, disproportionation to Ru^{VII} and Ru^{IV} occurring in acidic and neutral conditions.[1936,1949] The electrochemistry of $[RuO_4]^{2-}$ has been reported.[1965] $[RuO_4]^{2-}$ acts as a two electron oxidant for the stoichiometric and catalytic oxidation of alcohols, aldehydes and amines to carboxylic acids and ketones.[1211,1944–1947,1966–1974] The reagent is less reactive towards carbon–carbon double bonds than RuO_4, $[RuO_4]^-$ or OsO_4 and has been used for the oxidation of unsaturated alcohols.[1211,1969] The use of $Ba[Ru(O)_2(OH)_3]$, $[Ru(O)_2Cl_3]^-$ and $[Ru(O)_2Cl_2(bipy)]$ for the oxidation of alcohols to aldehydes and ketones has been described.[1211]

Ruthenium(VI) complexes of periodate[1948] and sulfate[1953,1975,1976] have been reported. RuO_3 can be generated in the vapour phase at 1200°C[1905,1977–1980] and has been proposed to be an intermediate in the oxidation of substrates by RuO_4.[1966,1981,1982]

Ruthenium(VII): $[RuO_4]^-$ may be most readily prepared by reaction of $[RuO_4]^{2-}$ with Cl_2 or NaOCl.[1948,1957,1960] Alternative preparations include fusion of $RuCl_3$ with KNO_3 and KOH[1983] or reduction of RuO_4 with KOH at 0°C (equation 125).[1960,1969] $K[RuO_4]$ is less soluble than $K_2[RuO_4]$ forming very dark green almost black crystals. The single crystal X-ray structure of $[RuO_4]^-$ shows a distorted tetrahedral Ru centre with Ru—O = 1.79 Å and ⟨ORuO = 106°[1984] (*cf.* with $Ba[Ru(O)_2(OH)_3]$). IR and Raman spectra for $[RuO_4]^-$ have been reported.[1954–1956,1984] The electronic spectrum of $[RuO_4]^-$ shows absorptions near 390 and 320 nm; the assignment of these transitions and their relationship to absorption bands observed for RuO_4 and $[RuO_4]^{2-}$ have been the subject of much debate.[1948,1949,1957–1961,1985,1986] The Mössbauer spectrum of $[RuO_4]^-$ has been reported.[1964]

$[RuO_4]^-$ is reduced under alkaline conditions to $[RuO_4]^{2-}$ (equation 126) *via* a rate law given in equation (127); the proposed mechanism of reaction is given in equations (128)–(132).[1935,1987] Electron exchange between $[RuO_4]^-$ and $[RuO_4]^{2-}$ occurs with second order kinetics, rate constant $k > 3 \times 10^4\,M^{-1}s^{-1}$ at 0°C; with $[MnO_4]^{2-}$ the specific rate constant for electron transfer $k = 5.7 \times 10^2\,M^{-1}s^{-1}$ at 20°C with $\Delta H^\circ = 17\,kJ\,mol^{-1}$, $\Delta S = -46\,J\,K^{-1}mol^{-1}$, $\Delta H^{\neq} = 29\,KJ\,mol^{-1}$, $\Delta S^{\neq} = -46\,J\,K^{-1}\,mol^{-1}$.[1988a]

$$\text{Rate} = k[[RuO_4]^-]^2[OH^-]^3 \quad (127)$$

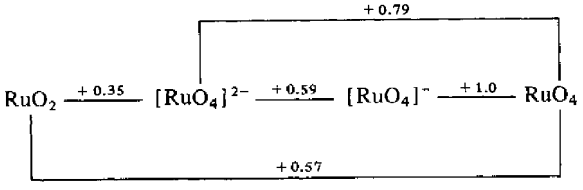
$$[RuO_4]^- + 2[OH^-] \rightleftharpoons [RuO_4(OH)_2]^{3-} \quad (128)$$

$$[RuO_4(OH)_2]^{3-} + [RuO_4]^- \rightleftharpoons [RuO_4(OH)_2]^{2-} + [RuO_4]^{2-} \quad (129)$$

$$[RuO_4(OH)_2]^{2-} \rightleftharpoons [RuO_4]^{2-} + H_2O_2 \quad (130)$$

$$H_2O_2 + OH^- \rightleftharpoons H_2O + HO_2^- \quad (131)$$

$$HO_2^- + OH^- \longrightarrow H_2O + O_2 \quad (132)$$



$[RuO_4]^-$ oxidizes alcohols and aldehydes to ketones and carboxylic acids, and readily cleaves carbon–carbon double bonds.[1211,1968,1969] The use of $Bu_4N[RuO_4]$, prepared by the fusion of $RuCl_3$ with KNO_3 and KOH and subsequent reaction with Cl_2 and addition of Bu_4NOH, for the oxidation of alcohols to aldehydes and ketones in acetone or CH_2Cl_2 has been described.[1988b]

Ruthenium(VIII): The chemistry of RuO_4 has been reviewed (reference 3, pp.45–55).

RuO_4 is a toxic, highly volatile yellow product (m.p. 25.4°C, b.p. 40°C) which tends to explode in the solid state. It can be prepared by oxidation of $RuCl_3$, RuO_2 or $[RuCl_6]^{2-}$ with Ce^{IV},[1989,1990] $NaIO_4$,[1943a,1991] NaOCl,[1992,1993] ClO_4^-,[1994] $Cr_2O_7^{2-}$,[1995] BiO_3^-[1957] or BrO_3^-,[1996,1997] oxidation of $[RuO_4]^{2-}$ with Cl_2[1998] or $K[MnO_4]$,[1999] or by hydrolysis of $RuOF_4$, RuF_5 or RuF_4 followed by oxidation with F_2.[2000] The most convenient method of preparation is by oxidation of RuO_2 by aqueous $NaIO_4$ at 0°C followed by extraction of RuO_4 into CCl_4;[1943a,1981,1991,2001] RuO_4 can be stored as a yellow solution in CCl_4 over $NaIO_4$.

Electron diffraction studies on RuO_4 in the gaseous phase show the Ru—O distance to be 1.705 Å, with no deviation from tetrahedral geometry being observed.[2002] The photoelectron spectrum of RuO_4 has been reassigned to give an orbital ionization sequence $2t_2 < 2a_1 < 1e < 3t_2 < 1t_1$,[2003,2004] previously studied samples being contaminated with CO_2[2005] or N_2.[2006] Theoretical calculations based on SCF-Xα,[2007] extended Hückel[2008] and Hartree–Fock–Slater Discrete Variation MO[1958,1986] methods have been used to predict the energy level sequence and have inverted the energies of the $1e$ and $2a_1$ levels. The electronic absorption spectrum of RuO_4 has been reported,[2008–2013] a CD study showing that the absorption near 390 nm is due to a $1t_1 \rightarrow 2e$ transition.[2001,2014] Mössbauer,[1964] and IR and Raman[1954,2015–2019] spectra for RuO_4 in the gaseous, liquid and solid states have been published, RuO_4 retaining its T_d symmetry in CCl_4. ^{99}Ru, ^{101}Ru and ^{17}O NMR studies on RuO_4 show the coupling constant $J_{^{17}O-^{99}Ru} = 23.4$ Hz.[24,2020]

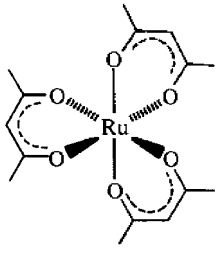
The redox chemistry of RuO_4 has been investigated, Scheme 62 illustrating the potentials for the interconversion of the oxy anions of ruthenium.[1949,2021,2022] Electrochemical reduction of RuO_4 in the presence of a series of anions yields partially characterized nitrato and hydroxy complexes of Ru^{II} and Ru^{III}.[2023] Reaction of RuO_4 with two electron donors L (L = NH_3, PF_3) yields adducts $RuO_4 \cdot L$.[1874] In the case of L = PF_3, an apparent binuclear complex $[RuO_4]_2PF_3$ was formed at −100°C.[1874]

Scheme 62

RuO_4 is an extremely powerful oxidizing agent that has found important uses in the stoichiometric and catalytic[1991,2024] oxidation of organic substrates.[1982,2025] The reactivity of RuO_4 towards organic substrates has been reviewed,[3,1982,2025] and compared with corresponding reactivity of OsO_4.[2026] The oxidations of alcohols,[1957,1966,1981,1997,2027–2030] aldehydes,[1977] alkenes,[1993,1997,2031,2032] alkynes,[2033,2034] ethers,[1997,2035–2038] lactones,[2039] amines,[2040,2041] amides,[1997] aromatics,[2024,2035,2042–2050] sulfides,[2048] oxalic acid,[2051] and Se^{IV}[1989] by RuO_4 have been reported, with reaction occurring *via* two successive, two electron transfers.[1966] The oxidation of 2-propanol in 1–6.5 M $HClO_4$ solution occurs *via* a pathway where hydride abstraction is rate determining, while at high pH, the rate-determining step is carbonium ion formation.[1981,2036]

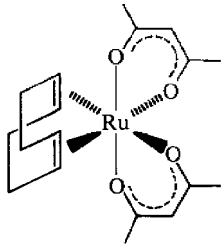
45.6.4 Ketoenolate Complexes

A range of ketoenolate complexes $[Ru^{III}L_3]$ (HL = $RC(O)CH_2C(O)R^1$, R = R^1 = Me,[163,2052] CF_3,[2052–2056] Ph,[2052,2057,2058] 4-NO_2Ph,[2058,2059] Bu^t;[2052,2055,2060] R = CF_3, R′ = Ph,[2055,2061] Bu^t,[2061] Me;[2054,2056,2057,2061,2062] R = Me, R′ = Ph;[2062] HL = $RC(O)CHR'C(O)R''$, R = R″ = Ph, Me, CF_3, Bu^t, R′ = Ph)[2052] have been prepared by reaction of blue ruthenium(III) chloride with the corresponding diketone under basic conditions or by ligand exchange with [Ru(acac)$_3$]. The tris chelate complexes of (+)-3-acetylcamphor[2063] and (+)-3-trifluoroacetylcamphor[2064] $[RuL_3]$, for example, have been prepared by ligand exchange reaction with [Ru(acac)$_3$] in ethyl benzoate at 160°C; the diastereomers have been separated by tlc on silica and assigned by ^1H NMR studies.[2063] For tris complexes of



asymmetric ligands (L = A–B), *mer* and *fac* isomers of $[Ru(A–B)_3]$ can be isolated.[2054,2057,2062] The formation of ^{103}Ru labelled $[Ru(acac)_3]$ has been described.[2060] $[Ru(acac)_3]$ has been resolved by chromatography on montmorillonite containing Δ-$[Ni(phen)_3]^{2+}$,[2065,2066] by complex formation with (2*R*,3*R*)-(−)-dibenzoyl tartaric acid[2067] and partially resolved by chromatography on D-(+)-lactone.[2068]

The single crystal X-ray structure of $[Ru(acac)_3]$ (**319**) shows octahedral Ru^{III} with average Ru—O distance of 2.0 Å.[2069] The magnetic properties of $[Ru(acac)_3]$ are consistent with low spin d^5 Ru^{III} with $\mu_{eff} = 1.91$ and 1.75 BM at 298 K and 85.2 K respectively,[163,2057,2070] while the ESR spectrum of $[Ru(acac)_3]$ in $[Al(acac)_3]$ shows a three line signal with $g_x = 1.28$, $g_y = 1.74$, $g_z = 2.82$[2071] suggesting a dynamic Jahn–Teller effect in the complex.[2072] IR[2073] and NMR[2062,2074,2075] spectra for $[Ru(acac)_3]$ have been reported. $[Ru(acac)_3]$ shows absorptions at 476 nm ($\varepsilon = 1.68 \times 10^3$), 324 ($\varepsilon = 1.7 \times 10^3$) and 265 nm ($\varepsilon = 2.7 \times 10^4\,M^{-1}\,cm^{-1}$) in methanol[2057,2070] with Dq being estimated as 1540 cm^{-1}.[2076] Kinetic studies on ligand exchange in $[Ru(acac)_3]$ in acetyl acetone have been carried out; the first order rate constant $k = 9.5 \times 10^{-5}\,s^{-1}$ at 158°C with exchange occurring without decomposition. The rate-determining step was proposed to be formation of complex involving unidentate acac.[2077,2078]



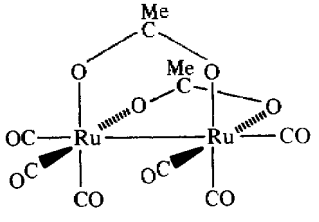
Mass spectral data for $[RuL_3]$ (HL = $RC(O)CH_2C(O)R'$, R = R′ = Me, CF_3; R = Me, R′ = CF_3) suggest relatively little tendency for internal redox reactions in these complexes.[2056] Several studies on the electrochemistry of tris ketoenolate complexes have been published.[2052,2055,2062,2064,2079] $[Ru(acac)_3]$ shows a one electron redox couple to $[Ru(acac)_3]^-$ at $E_{\frac{1}{2}} = -0.72$ V and −0.51 V *vs.* SCE in MeCN and H_2O respectively.[2079] The effect of substitution on acac on the $Ru^{III/II}$ redox couples for the corresponding complexes has been assessed and related to the redox couples $[Ru(NH_3)_6]^{2+/3+}$, $[Ru(en)_3]^{2+/3+}$ and $[Ru(CN)_6]^{3-/4-}$.[2055] A linear relationship was observed between $E_{\frac{1}{2}}$ values for the $Ru^{IV/III/II}$ couples and the sum of the Hammett constants for the functionalities on the coordinated ketoenolate.[2052] Association between $[RuL_3]^-$ and alkali metal ions has been noted;[2052] the rate of aquation of $[Ru(acac)_3]^-$ was found to be relatively slow, with a rate constant $k < 1 \times 10^2\,M^{-1}\,s^{-1}$.[2078] $H[Ru(acac)_3]$ is observed to be a relatively strong acid with $pK_a < 3.5$.[2078]

The complex $[RuL_3]$ (LH = (+)-3-acetylcamphor) can be reduced by treatment with Na/Hg for 40 h, or oxidized by controlled potential electrolysis to the corresponding Ru^{II} and Ru^{IV} species respectively with retention of configuration.[2064] The Ru^{III} diastereomers are found to isomerize at 170°C.[2064] Electron transfer and reduction of derivatives of $[Ru(acac)_3]$ by Ti^{III} have been investigated,[2080,2082] the electron transfer in the ketoenolato bridged Ru—L—Ti binuclear intermediate occurring with a rate constant $k = 21\,s^{-1}$.[2081] $[Ru(acac)_3]$ has been found to be an active catalyst in carbonylation and homologation reactions.[2083–2088]

$[Ru(acac)_2(CO)_2]$ has been synthesized by reduction of $[Ru(acac)_3]$ in THF at 160°C with H_2 and CO at high pressure,[2089] in benzene with CO at 150°C,[2090] by treatment of $[Ru(acac)_2(NCMe)_2]$ with CO at 110°C[2091] or reaction of $Ru_3(CO)_{12}$ with Hacac at 150°C in THF.[2089] $[Ru(acac)_2(cod)]$ (**320**) can be prepared by treatment of $RuCl_3$ with cod and oxalic acid in refluxing ethanol for 2 h, followed by treatment with acetic acid, Hacac and K_2CO_3.[2053,2092,2093] A similar route yields $[Ru(acac)_2(nbd)]$.[2094] $[Ru(acac)Cl_2(OH_2)_2]$ has been synthesized by reaction of $RuCl_3$ with acac in aqueous HCl.[1863] A highly unusual pentanuclear $RuFe_4$ complex linked by ketoenolate and Cp^- functions has been reported; the complex is capable of undergoing an eight electron change, four at the Ru atom and one each at the Fe atoms.[2095d]

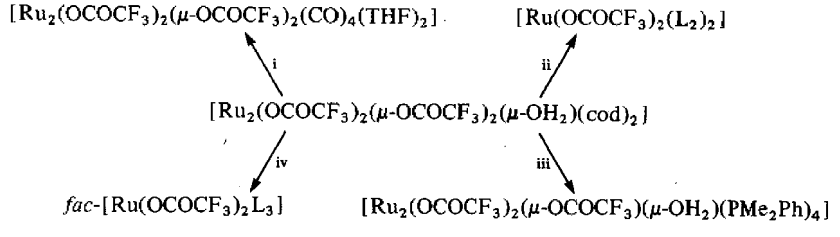
(319)

(320)



The complexes $[RuL_3]$ (LH = tropolone, α-isopropenyltropolone) have been prepared by reaction of $RuCl_3$ with LH in the presence of $NaHCO_3$; the NMR spectra of these products show them to have predominantly the *mer* configuration.[2095a] Ketoenolate complexes incorporating phosphine, ammine and amine ligands are discussed in Sections 45.5, 45.4.1 and 45.4.2 respectively.

45.6.5 Carboxylate Complexes

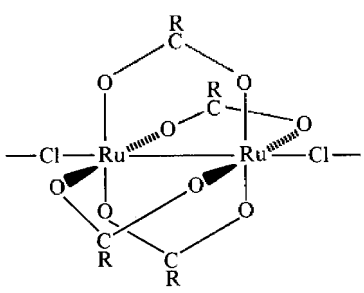


45.6.5.1 Monocarboxylates

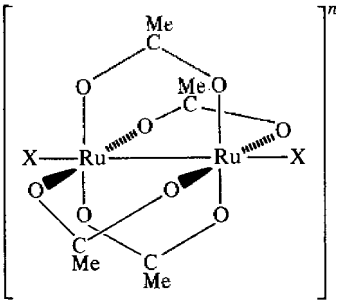
Treatment of $[Ru_3(CO)_{12}]$ with carboxylic acids at reflux gives, as the major product, the insoluble polymeric species $[Ru(OCOR)(CO)_2]_n$ (R = Me, Et, C_9H_{19}).[1524] For R = Me, this is also formed by carbonylation (1 atm) of '$RuCl_3 \cdot xH_2O$' and Na[OCOMe] in $MeCO_2H$/acetone at 80°C.[2096] Interestingly, reaction of $[Ru_3(CO)_{12}]$ with 4-fluorobenzoic acid (HL) gives $[Ru_2L_2(CO)_5OH_2]$, shown by X-ray analysis to have bridging carboxylate groups and a terminal aqua ligand.[2095b] The reaction of $[Ru_3(CO)_{12}]$ with C_2H_4 and H_2O under pressure also gives a propionato complex containing the $[Ru(CO)_2(\mu\text{-}O_2CEt)]_2$ unit.[2095c] Reaction of $[Ru(\mu\text{-}OCOMe)(CO)_2]_n$ with CO (50 atm; 80°C) in hexane[1524] or carbonylation (1 atm) of '$RuCl_3 \cdot xH_2O$' and Na[OCOMe] in aqueous $MeCO_2H$ at 80°C[2096] affords $[Ru_2(OCOMe)_2(CO)_6]$ of probable structure (**321**). Both $[Ru(OCOR)(CO)_2]_n$ and $[Ru_2(OCOMe)_2(CO)_6]$ react with a wide range of ligands to yield the complexes $[Ru(\mu\text{-}OCOMe)(CO)_2L]_2$ (L = MeCN, $AsPh_3$, py, piperidine and various PR_3) (**143**; Section 45.5.3.2).[1519,1524,2097,2098] Tetrameric $[Ru_4(OCOMe)_4(CO)_8(PBu_3)_2]$ (**144**; Section 45.5.3.2) can also be prepared from $[Ru(OCOMe)(CO)_2]_n$.[1525,1526] The complexes $[Ru(OCOMe)(CO)_2]_n$ and $[Ru_2(\mu\text{-}OCOMe)(CO)_2(pip)]_2$ have been shown to be active catalysts for the selective homogeneous carbonylation of a variety of cyclic secondary amines;[2098,2099] $[Ru(OCOMe)(CO)_2]_2$ also catalyses the isomerization of alkenes.[2100]

The binuclear Ru^{II} carboxylates $[Ru_2(OCOR)_2(\mu\text{-}OCOR)_2(\mu\text{-}OH_2)(cod)_2]$ (R = CF_3, CCl_3, CH_2Cl) have been synthesized *via* protonation of $[Ru(\eta^3\text{-}C_3H_4R)_2(cod)]$ with haloacetic acids. Some reactions of these complexes (R = CF_3) are shown in Scheme 63.[2101]

(321)

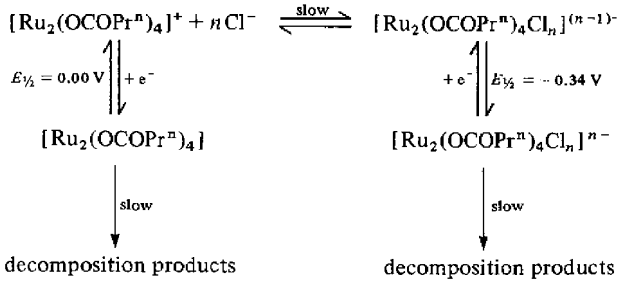


i, CO(1 atm), THF/50 °C; ii, L_2 = dppm or dppe (4 equiv), Et_2O, 25 °C;
iii, PMe_2Ph (4 equiv), THF/25 °C; iv, L = PMe_2Ph, $PMePh_2$, PPh_3 (6 equiv), Et_2O, 25 °C



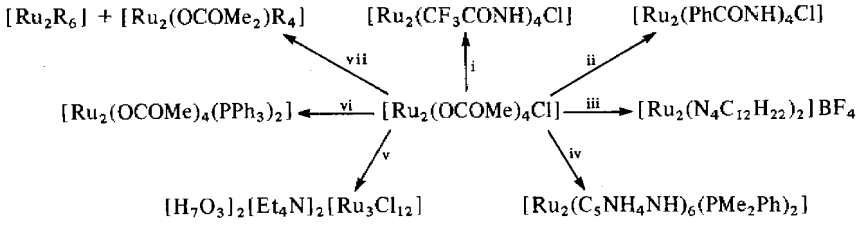
Scheme 63

Reaction of '$RuCl_3 \cdot xH_2O$' with acetic acid/acetic anhydride mixtures gives the brown solid $[Ru_2(OCOMe)_4Cl]$ (**322**) and a green solution (see below).[2102] Higher yields of (**322**) are obtained if the reaction is performed in the presence of an excess of LiCl.[1769] A range of complexes of type $[Ru_2(OCOR)_4X]$ (R = Me; X = Cl, Br, I, SCN, NO_3, OCOMe; R = Ph, H; X = Cl, Br; R = Et, Pr^n, CH_2Cl; X = Cl) can be prepared either from '$RuCl_3 \cdot xH_2O$' or by carboxylate or anion exchange reactions on (**322**).[2102–2104] X-Ray structural analyses on the butyrate,[2105] propionate,[2106] acetate[2106–2108] (X = Cl) and formate[2109] (X = Br) reveal $[Ru_2(OCOR)_4]^+$ units linked into infinite chains by axially bridging halide groups (Ru····Ru ≈ 2.28 Å). Variable temperature magnetic susceptibility studies on all these compounds show $\mu_{eff} \approx 4$ BM per molecule at 300 K (Curie–Weiss constant $\theta = 20$ K for R = Pr^n), which indicates the presence of three unpaired electrons (quartet ground state).[2102–2104,2110] This information together with extensive spectroscopic evidence (ESR,[2110] electronic,[2102,2105,2108,2111–2114] resonance-Raman,[2111,2114] IR, Raman,[2111,2115] and SCF–Xα–SW calculations[2112] suggest the ground state electronic configuration $\sigma^2p^4\delta^2\pi^{*2}\delta^{*1}$. The ESR spectrum[2110]



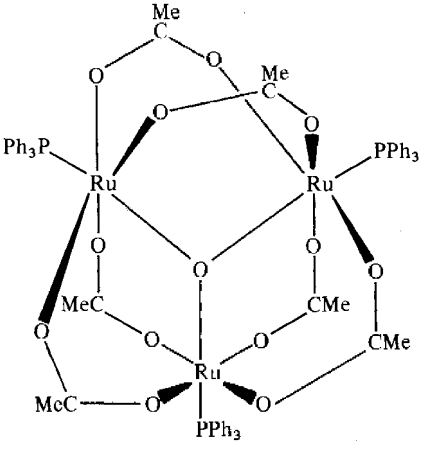
indicates that the three unpaired electrons are fully delocalized. Cyclic voltammetric studies (*vs.* SCE) on $[Ru_2(OCOPr^n)_4Cl]$ in CH_2Cl_2 reveal two reduction waves, one of which disappears on addition of an excess of Cl^- ion.[2110,2113] The proposed reduction process is shown in Scheme 64 and the electronic spectra of the reduced species have been published.[2116] Rate constants for the reduction of $[Ru_2(OCOMe)_4]^+$ by Ti^{3+} are available.[2080] $[Ru_2(OCOMe)_4(THF)_2]$ has been successfully isolated by reaction of $[Ru_2(OCOMe)_4Cl]$ with one equivalent of Me_3SiCH_2MgCl and its structure confirmed by X-ray analysis. Magnetic measurements ($\mu_{eff} \approx 3.1$ BM per molecule at 305 K) suggest a $\sigma^2\pi^4\delta^2\delta^{*1}\pi^{*3}$ electronic configuration.[2117]

(322)



(323) X = Cl ($n = -1$); OH_2 ($n = +1$)

Scheme 64

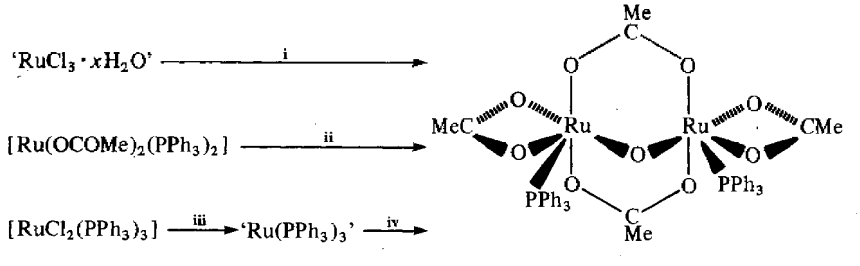


Hydrolysis of (**322**) affords $[Ru_2(OCOMe)_4(OH_2)_2]^+$ whereas treatment with CsCl gives $Cs[Ru_2(OCOMe)_4Cl_2]$; these have the discrete dimeric structure (**323**).[2106] With pyridine, (**322**) gives $[Ru(OCOMe)_2py_4]$ and $[Ru(OCOMe)_2py_2]$, with uni- and bi-dentate OCOMe coordination respectively,[2102] whereas Bu^tNC produces *trans*-$[Ru(OCOMe)_2(Bu^tNC)_4]$.[2118] The corresponding $[Ru(OCOH)_2py_n]$ ($n = 2,4$) can be prepared from reaction of $[Ru_3O(O_2CH)_6(OH_2)_3]O_2CH$ with pyridine.[2119] Related complexes include $Na[Ru(OCOH)_3(OH_2)]$ (from '$RuCl_3 \cdot xH_2O$' and Na[OCOH])[2119] and $[Ru(OCOMe)(azb)(CO)_2]$ (from $[RuCl(azb)(CO)_2]_2$ and Ag[OCOMe]).[1222] Some other reactions of $[Ru_2(OCOMe)_4Cl]$ are shown in Scheme 65 and further discussed in the appropriate section. Calorimetric measurements of the enthalpies of adduct formation to $[Ru_2(OCOPr^n)_4Cl]$ by various Lewis bases are now available.[2121c] Reaction of (**322**) with HBF_4 in MeOH, followed by addition of PPh_3 gives a solution which contains a very active alkene and alkyne hydrogenation catalyst.[2122] Other monocarboxylate complexes containing P or As donor ligands are discussed in Sections 45.5.4.7.vi and 45.10.

i, CF_3CONH_2/Δ;[2116] ii, molten $PhCONH_2$;[1871b] iii, $C_{22}H_{22}N_4^{2-}$, $Na[BF_4]$, EtOH;[2120] iv, $Li(C_5NH_4NH)$; PMe_2Ph;[1871a] v, 12 M HCl, $[Et_4N]Cl$;[2121] vi, PPh_3/MeOH;[1769] vii, RMgCl ($R = Me_3SiCH_2$, Me_3CCH_2)[2218,2219]

Scheme 65

The main component of the green solution, formed by reaction of '$RuCl_3 \cdot xH_2O$' with acetic acid/acetic anhydride, was believed to contain a binuclear ruthenium acetato complex,[2102] but an X-ray structure determination on its PPh_3 adduct, $[Ru_3O(OCOMe)_6(PPh_3)_3]$ (**324**), (mean oxidation state $+2\frac{2}{3}$), suggested it should be reformulated as an oxotriruthenium species.[2123] Later, more detailed investigations[2124] of the reaction of '$RuCl_3 \cdot xH_2O$' with Na[OCOMe], $MeCO_2H$ in EtOH showed the product to be the dark green $[Ru_3O(OCOMe)_6(OH_2)_3]OCOMe$ (**325**) (μ_{eff} at 298 K is 1.77 BM/molecule). In aqueous solution the hydrolytic equilibrium shown in equation (133) is established with the cation favoured at pH < 2 and the anion at pH > 9. Compound (**325**) is an active catalyst for the conversion of unsaturated carbinols to saturated ketones,[2125] and some oxidative transfer dehydrogenation reactions.[2126] Detailed vibrational spectral studies on (**325**) and related species are available.[2127]



(324)

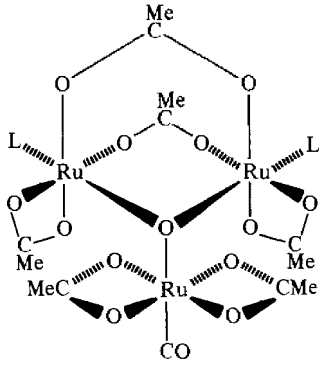
$$[Ru_3O(OCOMe)_6(OH_2)_3]^+ \underset{}{\overset{-H^+}{\rightleftharpoons}} [Ru_3O(OCOMe)_6OH(OH_2)_2] \overset{-H^+}{\rightleftharpoons} [Ru_3O(OCOMe)_6(OH)_2(OH_2)]^- \quad (133)$$

(**325**)

Reduction of (**325**) with H_2 in aqueous media gives the light green, diamagnetic intermediate $[Ru_3O(OCOMe)_6(OH_2)_3]$ which undergoes a further two electron reduction to yield yellow $[Ru_3(OCOMe)_6(OH_2)_3]$ (μ_{eff} at 298 K is 0.4 BM/molecule). The latter is very oxygen sensitive and rapidly reinserts oxygen to regenerate $[Ru_3O(OCOMe)_6(OH_2)_3]$. Reaction of (**325**) with pyridine affords the corresponding blue $[Ru_3O(OCOMe)_6py_3]^+$ cation which is readily reduced by H_2 to $[Ru_3O(OCOMe)_6py_3]$ and then $[Ru_3(OCOMe)_6py_3]$.[2124]

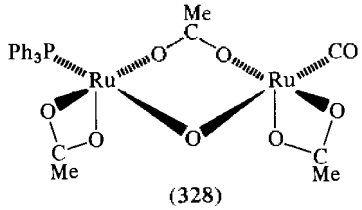
The diamagnetic $[Ru_3O(OCOMe)_6(PPh_3)_3]$ (**324**), formed by reaction between PPh_3 and $[Ru_3O(OCOMe)_6(OH_2)_3]^{n+}$ ($n = 1,0$), is not reduced by H_2 at ambient temperature although it does form an extremely air-sensitive, reduced yellow solution (formulated as '$Ru(OCOMe)_2PPh_3$') under more forcing conditions. Reoxidation of this does not regenerate (**324**) but instead the purple, diamagnetic $[Ru_2O(OCOMe)_4(PPh_3)_2]$ (**326**). Some other routes to (**326**) are shown in Scheme 66.[1769,2124] Related complexes are known for other carboxylates (OCOH,[2119] OCOEt,[2124] OCOPr,[2124] $OCOCH_nCl_{3-n}$ ($n = 0$–2)[2128] *etc.*).

(326)



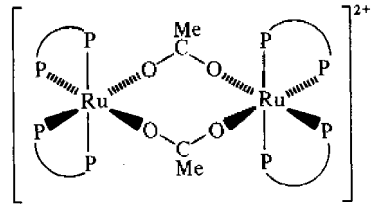
i, PPh_3, Na[OCOMe], MeOH; ii, O_2/MeOH; iii, Ag^+; iv, O_2/Na[OCOMe]

Scheme 66



If $[Ru_3O(OCOMe)_6(OH_2)_3]OCOMe$ is treated with H_2 at 80°C in DMF, the monohydride $[Ru_3(H)O(OCOMe)_5(DMF)_3](OCOMe)$ is first formed which undergoes a subsequent intramolecular reduction to produce $[Ru_3O(OCOMe)_4(DMF)_n][OCOMe]$. Further reduction with H_2 yields dimeric ruthenium(I) species such as $[Ru_2(OCOMe)_2(HO_2CMe)MeOH]$ together with $[Ru(OCOMe)(CO)L]_2$ (L = PPh_3, $SbPh_3$, py *etc.*), isolated by addition of L to the DMF solution. The final products are a mixture of $[Ru(OCOMe)(CO)_2L]_2$ and $[RuH(CO)_3]_n$.[2129] Further studies indicate that $[Ru_3(H)O(OCOMe)_5(DMF)_3](OCOMe)$ catalyses the hydrogenation and isomerization of alkenes. Interestingly, only one ruthenium centre is involved in the catalytic process.[2130]

Carbon monoxide reacts slowly with $[Ru_3O(OCOMe)_6(MeOH)_3]^+$ in MeOH but the reduced forms, $[Ru_3O(OCOMe)_6(MeOH)_3]$ and $[Ru_3(OCOMe)_6(MeOH)_3]$ rapidly give purple, paramagnetic $[Ru_3O(OCOMe)_6(CO)(MeOH)_2]$ (**327a**); with pyridine (**327a**) gives $[Ru_3O(OCOMe)_6(CO)py_2]$ (**327b**) which is also prepared from $[Ru_3O(OCOMe)_6py_3]^+$ and CO. Reaction of (**327a**) with PPh_3 yields turquoise $[Ru_2O(OCOMe)_3CO(PPh_3)]$ (**328**) also formed from $[Ru_3O(OCOMe)_6(PPh_3)_3]$ and CO.[1651] Note, however that other workers suggest that $[Ru_3O(OCOMe)_6(CO)py_2]$ has a symmetric structure of type (**324**).[2131]

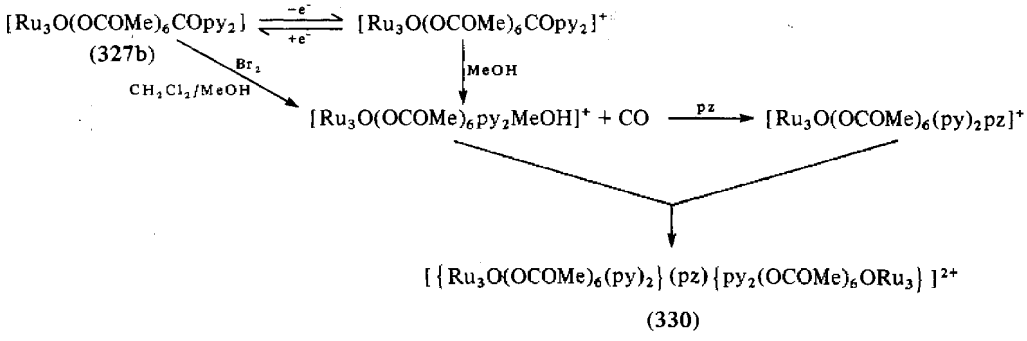


Treatment of $[Ru_3O(OCOMe)_6(MeOH)_3]^+$ with dppm or dppe gives the binuclear cations (**329**) whereas dppm and $[Ru_3O(OCOMe)_6(MeOH)_3]$ affords two isomers of $[Ru_2(OCOMe)_4(dppm)_2]$; some $[Ru(OCOMe)_2(dppm)_2]$ is also produced. With dppe and $[Ru_3O(OCOMe)_6(MeOH)_3]$, the product analyses for $[Ru_6O_2(OCOMe)_{12}(dppe)_3]$ and this is tentatively formulated as two $[Ru_3O(OCOMe)_6]$ units linked by three bridging dppe groups.[2119]

(327) (a) L = MeOH; (b) L = py

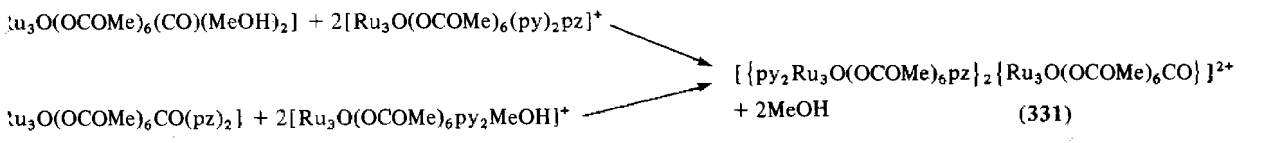
(328)

(329)



Reactions of $[Ru_3(OCOMe)_6(MeOH)_3]$ with MeNC, NO, SO_2 are fully discussed in reference 1651. For example MeNC gives $[Ru_3O(OCOMe)_6(NCMe)_2MeOH]$ and NO followed by PPh_3 affords $[Ru_3O(OCOMe)_6(NO)(PPh_3)_2]$.

Electrochemical studies on $[Ru_3O(OCOMe)_6py_2L]^+$ (L = pyrazine, *etc.*) (see Scheme 67 for synthesis) reveal the existence of a series of redox states $[Ru_3O(OCOMe)_6py_2L]^n$ ($n = +3$ to -2). The electronic properties have been interpreted *via* a MO scheme which assumes strong Ru—Ru interaction *via* the central oxygen atom and also direct metal–metal bonding.[2131,2132] Rates of electron self-exchange between $[Ru_3O(OCOMe)_6(py)_3]^+$ and $[Ru_3O(OCOMe)_6(py)_3]$ have been determined by ^1H NMR line broadening experiments.[2133]



The pyrazine-bridged dimer (**330**) is prepared as shown in Scheme 67. Detailed cyclic voltammetric studies on this and related N-heterocyclic ligand bridged dimers indicate a weak cluster–cluster interaction across the bridge at anodic potentials but significant interactions at cathodic potentials as the electron content of the clusters increases. Electronic spectral measurements support this conclusion.[2132,2134]

The ligand bridged trimeric cluster (**331**) (PF_6^- salt) has been prepared as shown in Scheme 68. This complex shows spectacular electron-transfer behaviour with a total of ten one- or two-electron waves between +2.2 and −1.7 V (in MeCN *vs.* SSCE). Again, these electrochemical studies suggest that when the total electron content is low, interelectronic cluster interactions are weak but as the

electron content increases, electronic coupling between the cluster sites is enhanced. In fact at negative potentials, a series of closely spaced, one electron waves suggests the beginning of band-like behaviour in this discrete molecular system.[2135]

Scheme 67

Scheme 68

Reaction of $[NH_4]_2[RuCl_6]$ with 10% HCO_2H gives $[NH_4]_2[RuCl_4(OCOH)(OH_2)]$ whereas with Na[OCOH], $[NH_4]_3[RuCl_5(OCOH)]\cdot 2H_2O$ is produced.[2136]

45.6.5.2 Dicarboxylates

The ruthenium(III) trisoxalato anion $[Ru(C_2O_4)_3]^{3-}$ was first prepared by Charonnat as its potassium salt by reaction between $K_2[RuCl_5(OH_2)]$ and $K_2[C_2O_4]$.[2137] Later workers[2138] found that this method led to KCl contamination and prepared $K_3[Ru(C_2O_4)_3]\cdot 3H_2O$ by reaction of $K_4[Ru_2OBr_{10}]$ with $H_2[C_2O_4]$ and HCHO, followed by neutralization with $K[HCO_3]$. Treatment of $RuO_2\cdot xH_2O$ with an excess of ammonium hydrogen oxalate gives $[NH_4]_3[Ru(C_2O_4)_3]\cdot 1.5H_2O$.[588] The magnetic properties,[588,2139] electronic[2139,2140] and ESR spectra[604] and electrochemical behaviour[2141] of this anion are fully documented.

The $[Ru(C_2O_4)(OH_2)_4]^+$ ion has been reported to exist in aqueous solution and the $[Ru(C_2O_4)_2(OH_2)_2]^-$ anion has been isolated as its sodium salt by treatment of $[Ru_2(OCOMe)_4Cl]$ with aqueous $Na_2[C_2O_4]$ under an oxygen atmosphere. This anion undergoes a facile one-electron reduction by Ti^{III} *via* an inner-sphere mechanism.[2143] Other $[Ru(C_2O_4)_2L_2]^-$ anions (L = N donor ligands) are discussed in Section 45.4. Reaction of $K_3[Ru(C_2O_4)_3]$ with $[enH_2][C_2O_4]$ gives the *cis*-$[Ru(C_2O_4)(en)_2]^+$ cation.[620]

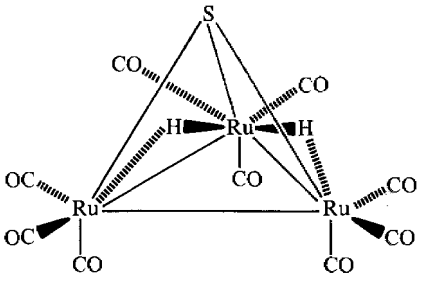
Other oxalato complexes include various nitrosyl species such as $K_2[RuCl_3(C_2O_4)NO]$, $K_2[RuCl(C_2O_4)_2NO]$, $K[Ru(C_2O_4)_2NO(py)]$, $[RuCl(C_2O_4)NO(py)_2]$,[2144] the black $K_2[Ru(C_2O_4)_3]$[2145] from oxidation of $K_3[Ru(C_2O_4)_3]$ with H_2O_2 and $Cs_2[RuO_2(C_2O_4)_2]$,[65] obtained by treatment of RuO_4 with ice cold solutions of $Cs_2[C_2O_4]$ and oxalic acid. The latter contains a *trans* RuO_2 unit. The mixed valence anion $[Ru_2(OCOMe)_2(C_2O_4)_2(OH_2)_2]^-$ has been synthesized by reaction of $[Ru_2(OCOMe)_4Cl]$ with oxalic acid. Reduction with Ti^{III} gives $[Ru_2(OCOMe)_2(C_2O_4)_2]^{2-}$ *via* an intermediate containing two ruthenium atoms and one titanium atom.[2146]

Aqueous solution studies between Ru^{III} or Ru^{IV} with citric acid indicate that 1:3 and 1:2 complexes respectively are formed.[2147]

45.6.6 Miscellaneous

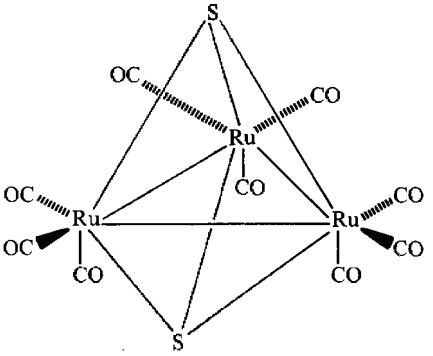
Ruthenium complexes incorporating only nitrate, sulfate[2148] or related oxy-anion ligands are generally ill-defined.[3] The chemistry of heavy metal nitrates,[2149] nitrites[2150] and dioxygen[2151a] com-

plexes has been reviewed. The fluorosulfate complexes $[Ru(SO_3F)_3]$, $[Ru(SO_3F)_4]^-$, $[Ru(SO_3F)_5]^-$ and $[Ru(SO_3F)_6]^{2-}$ have been reported.[2151b]



Reaction of $[RuBr_2(CO)_4]$ with L (L = pyridine *N*-oxide, $OPPh_3$) in $CHCl_3$ yields the complexes $[RuBr_2(CO)_3L)$.[2152] The products $[RuCl_3L_3]$ (L = 2,6-lutidine *N*-oxide,[2153] phosphole *N*-oxide derivatives,[2154] 8-hydroxyquinoline-*N*-oxide[2155,2156]) and O bonded $[RuCl_3L_2]$ (L = thiomorpholin-3-one)[679] have been prepared.

45.7 SULFUR LIGANDS

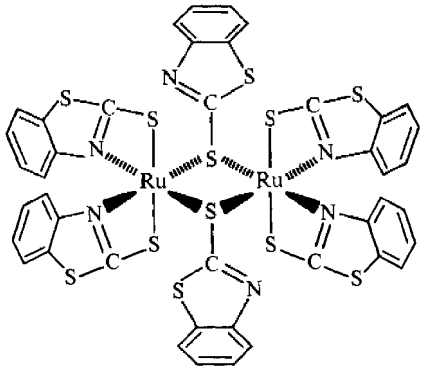


45.7.1 Sulfido, Thiolato and Thiazole Complexes

No simple sulfides of Ru in formal oxidation states less than four are apparently known; thus 'Ru_9S_8' has been shown to be a mixture of RuS_2 and Ru.[2157] Earlier work[2] reveals that the Ru^{IV} complex RuS_2 can be made from the elements at high temperatures and that it has the pyrite structures.[2158] More recently, poorly crystallized samples of diamagnetic RuS_2 were prepared by reaction of the anhydrous $[NH_4]_2[RuCl_6]$ with H_2S at 180°C for 4 h. These amorphous products were annealed under various conditions and the resulting degree of crystallinity was determined.[2159,2160] The high temperature enthalpy and decomposition pressure of RuS_2 (to form Ru(s) and $S_2(g)$)[2161] and IR data and normal coordinate calculations[2162] are available. Synthesis of members of the $Co_{1-x}Ru_xS_2$ ($0 \leqslant x \leqslant 1$) and $Rh_{1-x}Ru_xS_2$ ($0.5 \leqslant x \leqslant 1$) systems has been accomplished by the sulfurization of mixtures of $[NH_4]_2[RuCl_6]$ with either $[Co(NH_3)_5Cl]Cl_2$ or $[NH_4]_3[RhCl_6]$ and variable temperature magnetic susceptibility measurements recorded.[2163] The polysulfides RuS_3 and RuS_6 can also be prepared by reaction of $K_2[RuCl_6]$ and H_2S; RuS_6 is oxidized by air to a pyrosulfite $[Ru(S_2O_5)_2]$ and a 'thiometallate', possibly $[Ru(SH)_6]^{3-}$, can be obtained from polysulfides and $[RuCl_6]^{2-}$.[2] However, this is old work and further studies in this area are desirable.

Reaction of RuO_4 with SCl_2 in CCl_4 gives the brown, moisture sensitive $[RuCl_4S]_x$. A binuclear structure with a RuS_2Ru bridge is proposed.[2164] Another sulfido-bridged complex is $[Ru_3H_2(\mu_3\text{-}S)(CO)_9]$ (**332**) from reaction of $[Ru_3(CO)_{12}]$ with $Na_2[SO_3]$ and alcoholic KOH.[2165] A higher yield route to (**332**) is by reaction of $[Ru_3(CO)_{12}]$ with sulfur under a CO/H_2 atmosphere in refluxing octane; some $[Ru_3S_2(CO)_9]$ (**333**) is also formed.[2166] Compound (**332**) is also generated by addition of water to the trihydrido cation $[Ru_3H_3(\mu\text{-}S)(CO)_9]^+$.[2167,2168] Variable temperature ^{13}C NMR studies on (**332**) reveal both H and CO scrambling processes.[2169] With $[Ru_3(CO)_{12}]$ and cyclohexene sulfide, a yellow solid of composition $[RuS(CO)_3(C_6H_{10})]_n$ has been isolated.[2165]

(332)

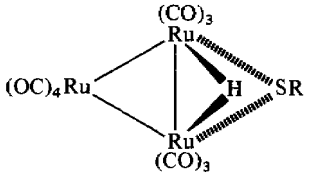


(333)

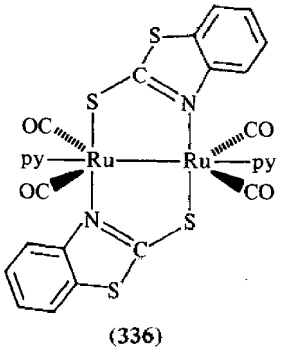
Sulfido complexes containing P or As donor ligands, *e.g.* $[RuX_2NO(EPh_3)]_2S$ (X = Cl, Br; E = P, As), $[Ru_3Cl_3S_2(PPh_3)_3]$, $[Ru(CO)_2(PPh_3)S]_2$ *etc.*, are discussed in Section 45.5.4.8.i.

Reaction of $NEt_4[RuCl_4(MeCN)_2]$ with 4 equivalents of the Li salt of either 2,3,5,6-tetramethylbenzenethiol or 2,4,6-triisopropylbenzenethiol (LH) and 0.5 equivalents of the corresponding sulfide in MeOH/MeCN solutions give high yields of $[RuL_4(MeCN)]$, shown by X-ray analyses to have trigonal bipyramidal structures with axial MeCN groups. Electrochemical studies reveal that both $[RuL_4MeCN]^+$ and $[RuL_4MeCN]^-$ can be generated.[2170a] Reaction of $[RuL_4MeCN]$ with CO at room temperature gives $[RuL_4CO]$, a rare example of a Ru^{IV} carbonyl complex.[2170b] A series of six-coordinate octaethylporphyrin complexes [Ru(SR)(OEP)(CO)] can be synthesized by treatment of [Ru(OEP)CO] with SR^- (R = CMe_3, Et, $CH_2CH_2CO_2Me$).[2171]

Reaction of the reduced 'ruthenium blue' solution with thiols such as 2-aminobenzenethiol and 4-toluenethiol (LH) gives highly insoluble compounds of stoichiometry $[Ru(L)_2]_n$ which are prob-

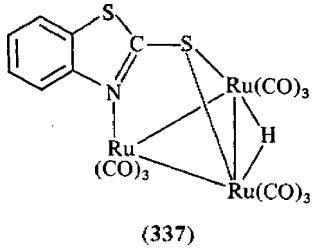


ably polymeric with sulfur bridges. Attempts to cleave these bridges with PPh_3 and *p*-toluidine were unsuccessful. The benzothiazole-2-thiol (LH) complex of stoichiometry $[RuL_3]$ is weakly paramagnetic, dimeric in $CHCl_3$ and structure (**334**) is proposed. Reaction of the reduced 'ruthenium blue' solution with pyridine-2-thiol gives the highly insoluble and polymeric $[RuCl_2(pySH)_2]_n$ which reacts with PPh_3 to yield $[Ru(pyS)_2(PPh_3)_2]$.[676] A Ru^{III} complex of 3,4,5-pyridazinetrithiol has also been reported.[2172a] Also reaction of $[Ru(acac)_3]$ with HSPh has been shown to give polymeric $[Ru(SPh)_3]_n$.[2172b]

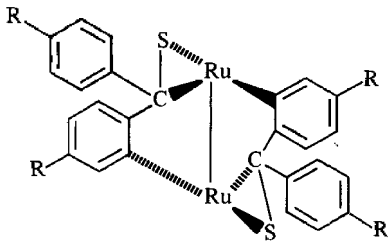


(334)

Treatment of the 'RuCOCl' solution with thiophenol produces the light brown $[Ru(SPh)_2(CO)_2]_3$, formulated as a trimer on the basis of an osmometric molecular weight determination. Similar reactions with dithiols gave yellow complexes of uncertain composition[107] but with 2-aminothiophenol, the orange brown $[Ru(SC_6H_4NH_2)_2(CO)_2]$ was isolated.[108] Reaction of $[Ru_3(CO)_{12}]$ with thiols (including thiophenol) affords the binuclear $[Ru(SR)_2(CO)_3]_2$ and the polymeric $[Ru(SR)_2(CO)_2]_n$ (R = Me, Et, Bu^n, Ph); the formation of $[Ru(SPh)_3]$ is also mentioned.[2173] Similar products are formed with organic disulfides. For example, Ph_2S_2 and $[Ru_3(CO)_{12}]$ produces $[RuSPh(CO)_3]_2$, $[RuSPh(CO)_3]_n$, $[Ru(SPh)_2(CO)_3]_n$ and two forms of $[Ru(SPh)_2(CO)_2]_n$; Et_2S_2 gives $[RuSEt(CO)_3]_2$ and $[Ru(SEt)_2(CO)_2]_n$[2174] whereas Me_2S_2 generates $[Ru(SMe)_2(CO)_2]_n$ ($n = 242$) which on bromination gives $[RuBr(SMe)_2(CO)_2]_2$.[2175] The mixed P- and S-bridged complex $[Ru_2(\mu\text{-}PPh_2)(\mu\text{-}SPh)(CO)_6]$ [(**140**); Section 45.5.3.2] is obtained from $[Ru_3(CO)_{12}]$ and Ph_2PSPh.[1517] Under milder conditions, $[Ru_3(CO)_{12}]$ and RSH afford the trinuclear hydrido complexes $[Ru_3H(\mu\text{-}SR)(CO)_{10}]$ (**335**) (R = Et, Br^n)[2176] which for R = Et undergo protonation in 98% H_2SO_4 to generate the $[Ru_3H_2(\mu\text{-}SEt)(CO)_{10}]^+$ cation.[2167,2168]



Treatment of $[Ru(azb)Cl(CO)_2]_2$ (azb = 2-phenylazophenyl) with sodium benzenedithiolate gives $[Ru(azb)(SPh)(CO)_2]_2$, a compound containing bridging SPh groups whereas sodium 2-aminobenzenethiolate (abt) yields the monomeric $[Ru(azb)(abt)(CO)_2]$ with a chelating abt ligand.[1222] Reaction of mercaptobenzothiazole (mbtH) with $[Ru_3(CO)_{12}]$ in MeOH gives a mixture of products but addition of pyridine and recrystallization affords $[Ru(mbt)_2(py)_2(CO)_2]$, (with *cis* CO, *cis* py and mutually *trans* mbt ligands coordinated in the thiolate form *via* the exocyclic sulfur atom), and $[Ru(mbt)py(CO)_2]_2$ (**336**), probably *via* initial formation of $[Ru_2(mbt)_2(CO)_6]$. In the latter, the Ru—Ru bond is bridged by the thiazole ligand.[2177,2178] Under mild conditions (toluene, 50°C/1 h), $[Ru_3(CO)_{12}]$ and mbtH generate $[Ru_3H(C_7H_4NS_2)(CO)_9]$ (**337**) in which the heterocyclic ligand is attached to the cluster *via* a bridging thiolato group and a third ruthenium by nitrogen. Under the same mild conditions, mercaptoethanoic acid and $[Ru_3(CO)_{12}]$ afford $[Ru_3H(\mu\text{-}SCH_2CO_2H)(CO)_{10}]$ with a structure similar to that of other $[Ru_3H(\mu\text{-}SR)(CO)_{10}]$ (**335**) complexes.[2179] Reaction of $[Ru_3(CO)_{12}]$ with thiobenzophenones produces the novel *ortho*-metallated complex (**338**) in high yield.[2180]



(335)

(336)

(337)

(338) R = OMe, Me

Other examples of carbonyl clusters containing sulfido or thiolato ligands include the hydrocarbon complexes $[Ru_2(\mu\text{-}SBu^t)(CO)_4(\mu_2\text{-}\eta^7\text{-}C_7H_7)]$, $[Ru_3(\mu_3\text{-}S)(CO)_6(\mu_3\text{-}\eta^8\text{-}C_8H_8)]$[2181] and also $[Ru_6H_2(SEt)_2(CO)_{15}]$ and $[Ru_6HC(SEt)_3(CO)_{15}]$.[2182]

Cations such as $[Ru(SR)(NH_3)_5]^{2+}$, $[(NH_3)_5RuS_2Ru(NH_3)_5]^{4+}$, are discussed in Sections 45.4.1.2.iv and 45.4.1.3.iii respectively and thiolato complexes containing P donor ligands in Section 45.5.4.8.i. References to the preparation of other ruthenium-thiol and -thione complexes are given in reference 3. Reaction of $[Ru(edta)(OH_2)]$ with RSH gives $[Ru(edta)SR]^{2-}$ (see Section 45.11.1.5).

Finally, although outside the scope of this review, various $\eta\text{-}C_5H_5$ and $\eta\text{-}C_6H_6$ complexes containing thiolato groups are known. Examples include $[Ru(SR)(CO)_2(\eta\text{-}C_5H_5)]$, $[Ru(\mu\text{-}SR)(CO)(\eta\text{-}C_5H_5)]_2$, $[Ru_3(\mu\text{-}SR)_3(CO)_2(\eta\text{-}C_5H_5)_3]$ (reference 1, p.781) and $[Ru_2(\mu\text{-}SEt)_3(\eta\text{-}C_6H_6)_2]BPh_4\cdot MeOH$.[2183]

45.7.2 Thioethers

The Ru^{III} monomers $[RuCl_3(SRR')_3]$ (R = Ph; R′ = Me, Et, Pr^n, Bu^n; R = R′ = Me, Et) are generally prepared by heating under reflux an ethanolic solution of '$RuCl_3\cdot xH_2O$' with an excess of RR′S.[2184–2186] The corresponding bromides are prepared by shaking the chlorides with LiBr in acetone. With Me_2S and Et_2S, the red $[RuCl_3(SR_2)_3]$ was contaminated with black $[RuCl_3(SR_2)_2]_2$ which can be separated by fractional crystallization. Under milder conditions of reaction, small amounts of yellow $[RuCl_2(SMe_2)_4]$ are also formed.[2185] The low μ_{eff} of the binuclear species (*ca.* 1.0 BM/Ru at 293 K) suggests some Ru—Ru interaction probably *via* chloro bridges. Initially, $[RuCl_3(SEt_2)_3]$ was assigned a *fac* configuration on the basis of its IR spectrum and the similarity of its X-ray powder pattern to *fac*-$[IrCl_3(SEt_2)_3]$.[2184,2187] However, further ^1H NMR studies on the latter indicate it has a *mer* configuration which suggests that all the $[RuX_3L_3]$ have a *mer* structure;[2188] their ESR spectra are consistent with this conclusion.[1852,2185]

Interestingly, reaction of '$RuCl_3\cdot xH_2O$' with $PhPr^iS$ in boiling MeOH gives $[RuCl_3(SPhPr^i)_2MeOH]$ (*cf.* $[RuCl_3(EPh_3)_2MeOH]$ (E = P, As); Section 45.5.7.1). Treatment of this with MeCN gives first $[RuCl_3(SPhPr^i)_2MeCN]$ and then $[RuCl_3(MeCN)_3]\cdot MeCN$. Facile SR_2 displacement is a general feature of the $[RuCl_3(SPhR)_3]$ complexes (see equation 134).[2185]

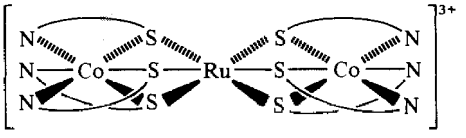
$$[RuCl_3(SPhR)_3] + L \xrightarrow{C_6H_6} [RuCl_3L_3]\cdot 0.5C_6H_6 \quad (L = PhNH_2, py) \qquad (134)$$

Other dialkyl sulfide complexes include the unusual cation $[Ru(SnCl_3)(CO)_2(SEt_2)_3]^+$, obtained by treating $[RuCl_2(SnCl_3)_2(CO)_2]^{2-}$ with three moles of Et_2S,[108] $[Ru(MeCN)_3(SEt_2)(cod)]^{2+}$ (from $[Ru(MeCN)_4cod]^{2+}$ and Et_2S),[1370] various $[RuCl_3NO(SRR')_2]$ (see Section 45.4.4.3),[123,1301,1302,1303] $[RuCl_3(PPh_3)(SMe_2)_2]$ (see Section 45.5.7.1), $[RuCl_3CO(SMe_2)_2]^-$ (from reaction of $[RuCl_3CO(nbd)]^-$ and Me_2S),[659] and ammine complexes such as $[Ru(NH_3)_5SMe_2]^{2+}$, $[Ru(NH_3)_4(OH_2)SMe_2]^{2+}$, $[Ru(NH_3)_4L_2]^{2+}$ (L = $MeS(CH_2)_2CH(NH_2)CO_2Me$), and $[(NH_3)_5RuL\text{-}Ru(NH_3)_5]^{n+}$ (L = 1,4-dithiane, 1,5-dithiocane; n = 4,5) *etc.* (see Sections 45.4.1.2.iv and 45.4.1.3.iii).

The reaction of '$RuCl_3\cdot xH_2O$' with various disulfides in boiling EtOH affords $[RuCl_3(RS(CH_2)_2SR)_{1.5}]_n$ (R = Et, Pr^n, Ph). For R = Et, reaction with pyridine gives $[RuCl_3(ES(CH_2)_2SEt)py]$ suggesting that one sulfide molecule is bridging and the other chelating in the parent molecule.[2185] Parallel work by Rice *et al.*[2189] reports the synthesis of other examples of $[RuCl_3L_{1.5}]_n$ [L = 1,4-dithiane, $RS(CH_2)_2SR$ (R = Me, Et)] and also $[RuCl_3(RS(CH_2)_2SR)]_n$ (R = Me, Ph; n = probably 2) and $[RuCl_3(PhS(CH_2)_2SPh)_2]_n$ (n = probably 2).

In boiling 2-methoxyethanol, reduction occurs to give $[RuX_2(RS(CH_2)_2SR)_2]$ (X = Cl, Br) (see reference 2190 for variable temperature ^1H NMR studies on $[RuX_2(MeS(CH_2)_2SMe)_2]$) and for

R = Et, chemical oxidation with $HClO_4$ or Br_2 then generates the Ru^{III} cations $[RuX_2(EtS(CH_2)_2SEt)_2]^+$. For R = Ph, carbonylation in boiling 2-methoxyethanol gives $[RuX_2(CO)_2(PhS(CH_2)_2SPh)$ (with *cis*-CO and *trans* X groups).[2185] Compounds of this type are also formed as shown in equation (135). Similarly, $[RuX_2(CO)_2(SR_2)_2]$ (various isomers) and in some instances $[RuX_2(CO)(SR_2)_3]$ can be prepared.[1611,2191,2192] Interestingly, reaction of ethane-1,2-dithiol with $[RuI_2(CO)_2]_n$ gives the unstable $[RuI_2(CO)_2(HS(CH_2)_2SH)_2]$ in which the sulfur ligands may be monodentate.[1611]



$$[RuI_2(CO)_2]_n + RS(CH_2)_2SR \longrightarrow [RuI_2(CO)_2(RS(CH_2)_2SR)] \quad (R = Et, Ph)^{1611,2191} \quad (135)$$

The Ru^{III} anion $[RuCl_4(MeS(CH_2)_2SMe)]^-$ is obtained as its $AsPh_4^+$ and NMe_4^+ salts from '$RuCl_3 \cdot xH_2O$', 2,5-dithiahexane and $[AsPh_4]HCl_2$ in acetone or $[NMe_4]Cl$ in absolute alcohol.[2193]

Treatment of '$RuCl_3 \cdot xH_2O$' with the trisulfide 1,1,1-tris(ethylthiomethyl)ethane in boiling 2-methoxyethanol gives $[RuCl_3\{MeC(CH_2SEt)_3\}]$ which on further heating with DMF affords $[RuCl_2(CO)\{MeC(CH_2SEt)_3\}]$. This is a rare example of a solvent decarbonylation reaction with a sulfide complex. Carbonylation in 2-methoxyethanol also yields $[RuCl_2(CO)_2\{MeC(CH_2SEt)_3\}]$ formulated as a seven-coordinate Ru^{II} compound.[2185] The corresponding $[RuCl_3\{S(CH_2CH_2CH_2SMe)_2\}]$ is obtained by reaction of '$RuCl_3 \cdot xH_2O$' with the trithioether in EtOH.[2194]

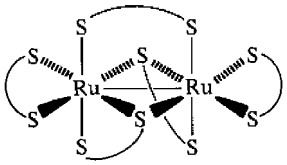
45.7.3 Metallothioanions as Ligands

The complexes $[Ru(CoL_3)_2]X_3 \cdot nH_2O$ (**339**) (X = Cl, I, BPh_4) (μ_{eff} = 1.8 BM at 303 K) are prepared by reaction of $RuCl_3$ with a large excess of CoL_3 (L = $NH_2CH_2CH_2S^-$), followed by addition of NaI or $Na[BPh_4]$. A study of the ESR spectra of this and the corresponding Fe^{III} complex suggests severe distortion from octahedral geometry. Hyperfine structure from the two equivalent cobalt nuclei indicates that the unpaired electron is delocalized over all three metal ions.[2195]

(339)

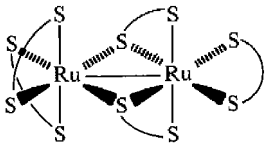
Treatment of $[RuCl_2(bipy)_2] \cdot 2H_2O$ with equimolar amounts of $[NH_4]_2[MoS_4]$ in aqueous EtOH for 18 h at room temperature produces the bimetallic complex (**87**). Reaction of (**87**) with more $[RuCl_2(bipy)_2] \cdot H_2O$ then affords the trimetallic cation (**108**), isolated as its PF_6^- salt. Electrochemical reduction of these species at −1.7 V in the presence of acetylene produces some ethylene and ethane[1212] (see Sections 45.4.3.1.xi and 45.4.3.2.iii respectively).

45.7.4 Dithiocarbamato and Related Complexes



Several reviews which cover the chemistry of ruthenium dialkyldithiocarbamates have appeared in the last fifteen years.[2196–2199] Cambi and Malatesta[2200] and later Malatesta[1309] reported the low spin, monomeric $[Ru(S_2CNR_2)_3]$ (R = Me, Et, Bu^n) which they prepared by reacting $K_2[RuCl_6]$ with aqueous $Na[S_2CNR_2]$. More recently, compounds of this type have been prepared by the reaction of $Na[S_2CNR_2]$ with solutions of '$RuCl_3 \cdot xH_2O$'.[2201,2202] A crystal structure determination for R = Et shows the RuS_6 core to have approximate D_3 symmetry and a twist towards trigonal prismatic geometry.[2203,2204] Essentially the same RuS_6 core geometry is found for $[Ru(S_2CN(CH_2)_4O)_3] \cdot 2.5CHCl_3$ with the hydrogen atom of each $CHCl_3$ hydrogen-bonded to the sulfur atoms of various ligands.[2202] The temperature-dependent ^1H NMR spectra of various $[Ru(S_2CNRR')_3]$ reveal both intramolecular metal-centred inversion and ligand-centred geometric isomerization which are attributed to a trigonal twist mechanism and S_2C—N bond rotation respectively. The distortion of the RuS_6 core towards trigonal prismatic coordination may be the reason for ease of metal-centred inversion which involves a trigonal twist pathway.[2201] Mass spectral[2205] and ESR data[604] on several $[Ru(S_2CNR_2)_3]$ are available.

Several studies[2206–2210] have been published on the redox behaviour of $[Ru(S_2CNR_2)_3]$. A one electron reversible reduction to $[Ru(S_2CNR_2)_3]^-$ is observed but the one electron oxidation is

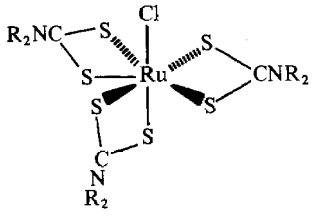


quasi-reversible and the product $[Ru(S_2CNR_2)_3]^+$ is unstable towards further reaction or decomposition. For example, in MeCN, the electrochemical oxidation product of $[Ru(S_2CNEt_2)_3]$ is the diamagnetic $[Ru(S_2CNEt_2)_3MeCN]^+$ cation.[2210] Earlier studies[2206,2207] had indicated that $[Ru(S_2CNEt_2)_3]^+$ was synthetically accessible and aerial oxidation in the presence of BF_3 was reported to yield $[Ru(S_2CNEt_2)_3]BF_4$.[2207] However, X-ray analysis revealed the product to be the binuclear $Ru_2^{III,III}$ cation $[Ru_2(S_2CNEt_2)_5]BF_4$ (**340**) (β-isomer). Electrochemical studies on (**340**) in MeCN showed a four member series (equation 136) and the one electron reduction product $[Ru_2^{II,III}(S_2CNEt_2)_5]$ was isolated.[2208]

Independent studies involving chromatographic separation of the reaction products of '$RuCl_3 \cdot xH_2O$' and $Na[S_2CNPr^i_2]$ led to the isolation of some $[Ru_2(S_2CNPr^i_2)_5]X$ ($X = Cl^-$, $Ru_2Cl_6^{2-}$), shown by X-ray analysis to have structure (**341**) (α-isomer).[2211] The α-$[Ru_2(S_2CNMe_2)_5]^+$ cation is converted to the β-isomer by heating in $CHCl_3$ and the interconversion can be monitored by ^1H NMR spectroscopy. Reduction of the α-isomers is more facile than the β-isomers but the β-$[Ru_2(S_2CNR_2)_5]^-$ rapidly isomerizes to give the α-$[Ru_2(S_2CNR_2)_5]^-$ anion which is the reverse of the situation for the cations.[2209] A detailed reexamination[2210] of the preparation of compounds (**340**) and (**341**) reveals that chemical oxidation of $[Ru(S_2CNR_2)_3]$ using BF_3 gas in the absence of oxygen yields the α-isomer; in the presence of oxygen, only the β-isomer is formed. The ^1H NMR spectra of α- and β-$[Ru_2(S_2CNMe_2)_5]^+$ have been assigned by variable temperature and ligand-exchange studies and an isomerization reaction mechanism proposed.

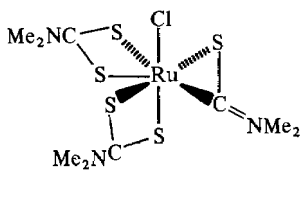
$$Ru_2(S_2CNR_2)_5]^{2+} \longleftarrow [Ru_2(S_2CNR_2)_5]^+ \rightleftharpoons [Ru_2(S_2CNR_2)_5] \rightleftharpoons [Ru_2(S_2CNR_2)_5]^- \quad (136)$$

(340)



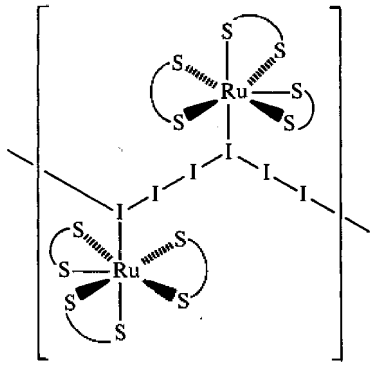
(341)

The α- and β-isomers of $[Ru_2(S_2CNR_2)_5]^+$ can be reduced to the paramagnetic α- and β-$[Ru_2(S_2CNR_2)_5]$ respectively by reaction with $Na[BH_4]$ in ethanol. For R = Et, the green α-isomer converts in toluene to the purple β-isomer with a first-order rate constant of $8 \times 10^{-4} s^{-1}$ at 30°C. Photolysis in $CHCl_3$ yields the oxidized cations with chloride counterions and retained α and β stereochemistry.[2210]



Seven-coordinate, diamagnetic Ru^{IV} complexes $[RuCl(S_2CNR_2)_3]$ (R = Me, Et) are obtained by photolysis of $[Ru(S_2CNR_2)_3]$ in $CHCl_3$ or CH_2Cl_2 or by reaction with gaseous HCl in C_6H_6. X-Ray analysis reveals a distorted pentagonal bipyrimidal structure (**342**) although the compound is non-rigid in CD_2Cl_2 solution even at −95°C.[2212] More detailed photochemical studies on $[Ru(S_2CNR_2)_3]$ at λ = 265–366 nm in various chlorinated solvents show that in addition to (**342**), some α-$[Ru_2(S_2CNR_2)_5]Cl$ is formed; a reaction pathway involving the formation of an excited Ru^{II} species $[Ru(S_2CNR_2)_2(S_2^+CNR_2)]^*$ is proposed to explain these results.[2213] Interestingly, photolysis at 366 nm in the presence of a large excess of benzophenone gives the unusual product $[RuCl(S_2CNMe_2)_2(\eta^2\text{-}SCNMe_2)]$ (**343**) in greater than 90% yield. Variable temperature ^1H NMR studies on this non-rigid, pentagonal bipyramidal molecule are reported.[2214] In donor-type solvents S such as MeCN and DMSO, compound (**342**) forms $[Ru(S_2CNEt_2)_3S]Cl$; further reaction with PPh_3 gives $[Ru(S_2CNEt_2)_3PPh_3]Cl$ and all these seven-coordinate Ru^{IV} complexes are stereochemically non-rigid. In propylene carbonate, $[Ru(S_2CNEt_2)_3Cl]$ is undissociated and exhibits a one electron oxidation and a two electron reduction step to form $[Ru(S_2CNEt_2)_3]^-$.[2210]

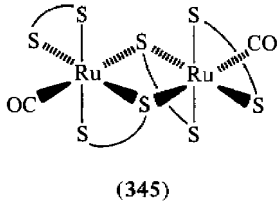
Addition of iodine to $[Ru(S_2CNRR')_3]$ in $CHCl_3$ affords the diamagnetic Ru^{IV} complexes $[Ru(S_2CNRR')_3I_3]$ (**344**) (R = R′ = Me, Et, Ph, $PhCH_2$; R = Me; R′ = Ph). X-Ray analysis (for R = R′ = Me) shows the molecule to be seven-coordinate with one iodide ion coordinated in an axial position while an I_2 molecule strongly solvates the iodide atom. Again all the R groups are magnetically equivalent on the ^1H NMR timescale even at −90°C.[2210,2215] Addition of $Ag[BF_4]$ in acetone to these $[Ru(S_2CNR_2)_3X]$ compounds gives ultimately $[Ru_2(S_2CNR_2)_5]BF_4$ and with $Na[S_2CNR_2]$, $[Ru(S_2CNR_2)_3]$ is formed. Both these reactions illustrate the lability of the Ru—X bond.[2210,2212,2215]



Interestingly, $[Ru(S_2CNEt_2)_3NO]$ is six-coordinate with one of the $^-S_2CNEt_2$ groups monodentate. This is not too surprising since the complex contains a Ru^{II} d^6 ion which has a marked preference for an octahedral t_{2g}^6 configuration.[2203] Hydrogen-1 and ^{13}C NMR studies of $[Ru(S_2C-$

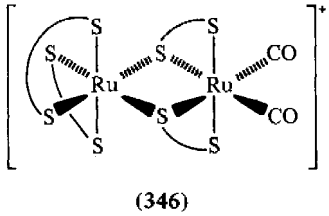
(342)

(343)



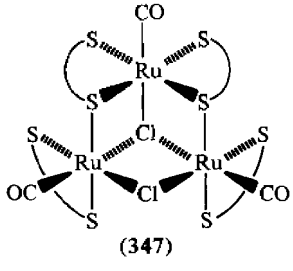
(344)

$NR_2)_3NO]$ (R = Me, Et) (made by passing NO through $CHCl_3$ solutions of $[Ru(S_2CNR_2)_3]$), show hindered rotation about the C=N bond in the two bidentate sulfur ligands but free rotation at ambient temperature in the monodentate ligand; there is no exchange between mono- and bi-dentate ligands at room temperature.[1308,2216]



The complexes *trans*-$[RuCl(S_2CNR_2)_2NO]$ (R_2 = Me, Et, MePh, MeEt) are prepared by reaction of $[RuCl_3NO]$ with two equivalents of $Na[S_2CNR_2]$. A series of *cis*-$[RuX(S_2CNR_2)_2NO]$ (X = Cl, Br, I, NO_2, SCN, N_3, NCO, F) can be synthesized by treatment of the *trans* chloro compound with either HX or AgX. Heating some of these *cis* isomers to 160–210°C results in quantitative conversion to the *trans* isomer. Several cationic solvates *trans*-$[Ru(S_2CNR_2)_2NO(S)]^+$ (S = H_2O, MeOH) were also isolated and ^1H and ^{13}C NMR studies on all these compounds indicate stereochemical rigidity at ambient temperature.[1308]

The binuclear $[Ru_2N(S_2CNEt_2)_4]Cl$ has been prepared by reaction of $K_3[Ru_2NCl_8(OH_2)_2]$ with $Na[S_2CNEt_2]$. It is a non-electrolyte in acetone solution and may be polymeric in the solid state with ---Ru—Cl—Ru—N—Ru—Cl--- chains.[65]



The yellow crystalline '$Ru(S_2CNR_2)_2CO$' (R = Me, Et) and $[Ru(S_2CNR_2)_2(CO)_2]$ (R = Me, $PhCH_2$) were prepared by reaction of ethanolic 'RuCOCl' solutions with $Na[S_2CNR_2]$ or tetrasubstituted thiuramdisulfide.[107] The latter (R = Me) is also prepared by treating $[Ru_3(CO)_{12}]$ with tetramethylthiuramdisulfide or by the prolonged reaction of $[RuCl_2(CO)_2(PPh_3)_2]$ with $Na[S_2CNMe_2]$.[1798] The related thioxanthate complex $[Ru(S_2CSMe)_2(CO)_2]$ is formed by addition of CS_2 to THF solutions of $Na_2[Ru(CO)_4]$, followed by reaction with methyl iodide.[2217] Prior ageing of the 'RuCOCl' solution and treatment with tetrabenzylthiuramdisulfide gives $[Ru\{S_2CN(CH_2Ph)_2\}_2(CO)_2]Cl$ (μ_{eff} = 1.8 BM).[107] However, X-ray analyses by Raston and White[2218] reveal that '$Ru(S_2CNEt_2)_2CO$' has the dimeric structure (**345**) in the solid state. Compound (**345**) is also formed, together with some *cis*-$[Ru(S_2CNEt_2)_2(CO)_2]$ by reaction of β-$[Ru_2(S_2CNEt_2)_5]$ with CO under UV irradiation.[2210] Slow electrochemical oxidation of (**345**) affords the mixed valence $Ru_2^{II,III}$ cation, $[Ru_2(S_2CNEt_2)_4(CO)_2]^+$ (**346**), isolated in high yield as its BF_4^- salt. The most important feature of this structure is that the CO groups are now both coordinated to the same Ru atom, which indicates that the oxidation reaction has resulted in an unusual CO rearrangement. The Ru—Ru distance of 3.614(1) Å indicates no significant Ru—Ru bonding.[2219] Another interesting Ru^{II} trinuclear complex (**347**) was isolated in minute quantities by prolonged reaction of methanolic solutions of 'RuCOCl' with the ester $MeSC(S)NEt_2$.[2220]

(345)

(346)

(347)

Treatment of (**345**) (R_2 = Me_2, Et_2 or MePh) with bis(perfluoromethyl)-1,2-dithietene in boiling THF gives violet, diamagnetic crystals of $[Ru(S_2CNR_2)_2(S_2C_2(CF_3)_2)]$ which were characterized by ^1H NMR and IR spectroscopy.[2221] Some $[Ru(S_2CNMe_2)_2diene]$ (diene = nbd, cod) have been prepared by reaction of $[RuX_2diene]_n$ with $Na[S_2CNMe_2]$.[2222] For the preparation of pentamethylenedithiocarbamate and related ligands, see references 2223–2225.

A range of complexes containing dithiocarbamate or dithiocarbonate groups and P donor ligands are described in Section 45.5.4.8.ii.

45.7.5 Dithio-phosphinato and -phosphato Complexes

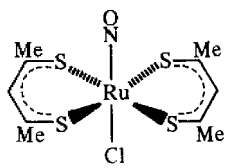
The violet complex $[Ru(S_2PPh_2)_3]$ can be prepared by the reaction of $[RuCl_3(AsPh_3)_2MeOH]$ (or '$RuCl_3 \cdot xH_2O$') with $Na[S_2PPh_2]$ in acetone.[1697] Its NMR[1697] and ESR spectra[604] have been reported. The black compound $[Ru(S_2PEt_2)_3]$ ($\mu_{eff} = 1.93$ BM) is mentioned but no preparative details are given.[2226] The analogous $[Ru\{S_2P(4\text{-}ClC_6H_4)_2\}_3]$ ($\mu_{eff} = 1.7$ BM), (from '$RuCl_3 \cdot xH_2O$' and $Na[S_2PR_2]$ in water)[2227] and $[Ru\{S_2P(OEt)_2\}_3]$ (from $K_2[RuCl_5(OH_2)]$ and $NH_4[S_2P(OEt)_2]$),[2228] are also known. The reaction between $[Ru_3(CO)_{12}]$ and Ph_2PS_2H gives *cis*-$[Ru(S_2PPh_2)_2(CO)_2]$.[1798]

Various Ru^{II} complexes containing P or As donor ligands as well as $[Ru(S_2PMe_2)_2(diene)]$ (diene = cod, nbd)[1800] are described in Section 45.5.4.8.ii.

45.7.6 Dithiolene, Dithiocarboxylate and Related Complexes

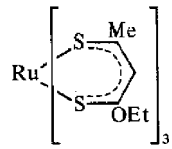
Apart from early reports of the preparation of $[Ru(S_2C_2Ph_2)_3]$ (originally formulated as $[Ru(S_2C_2Ph_2)_2]$),[2229] and the synthesis[2229] and ESR spectrum of the $[Ru(mnt)_3]^{3-}$ anion,[604] the chemistry of ruthenium dithiolenes is relatively unexplored. Other examples of dithiolenes and related complexes include $(AsPh_4)_3[Ru\{S_2C{=}C(CN)_2\}_3]$ (from $[RuCl_6]^{2-}$ and $[S_2C{=}C(CN)_2]^{2-}$ in water),[230] $[RuL_3]$ (L = S_2CCH_2Ph,[2231] S_2CPh,[2232] $S_2CC_6H_4$-4Me,[2232] 2-hydroxybenzenedithiocarboxylate,[2233] 8-quinolinedithiocarboxylate),[2234] $(Ph_4As)_3[Ru(dto)_3]$ (dto = dithiooxalate)[604] and various Ru^{II} and Ru^{III} quinazoline-2,4(1*H*,3*H*)-dithione (QH) complexes such as $[RuCl_2(Q)(QH)py_2]$, $[RuCl_2(Q)(QH)(OH_2)_2]$, $[Ru(Q)_2(py)_2]$.[2235] The ESR spectra of several of these compounds are analysed in detail.[604,2230] Ruthenium(III) complexes with the following ligands have also been reported: piperazinedithiocarboxylate, piperazinebis(dithiocarboxylate),[2236] 1,2,4-triazoline-5-thione derivatives.[2237]

As discussed elsewhere (Section 45.5.4.8.iii), reaction of $[Ru_3(CO)_{12}]$ with $S_2C_2(CF_3)_2$ in boiling *n*-heptane gives an impure orange coloured carbonyl adduct which reacts with various P and As donor ligands to give clean products. In boiling *n*-decane, $[Ru_3(CO)_{12}]$ and $S_2C_2(CF_3)_2$ produces an impure green material, believed to be $[Ru\{S_2C_2(CF_3)_2\}_2]_2$ which also reacts with P and As donor ligands.[1808] Reaction of the reduced 'ruthenium blue' solution with toluene-3,4-dithiol ($L'H_2$) gives dark brown, polymeric $[Ru_2L'_3]$ ($\mu_{eff} = 0.6$ BM).[676]



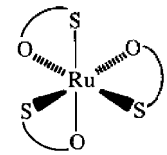
Reaction of $[RuCl_2(CO)_3THF]$ with $Li(SC_6H_4SMe\text{-}o)$ yields *cis*-$[Ru(MeSC_6H_4S)_2(CO)_2]$; with Li[1,2-$S_2C_6H_4$], *cis*-$[Ru(C_6H_4S_2)(CO)_2]^{2-}$ is obtained and isolated as its NMe_4^+ salt. Treatment of the latter with 1,2-$C_2H_4Br_2$ gives *cis*-$[Ru(dttd)(CO)_2]$ (H_2dttd = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane).[1709] Further reactions of these compounds with PR_3 ligands are discussed in Section 45.5.4.8.iii. Dithiocarboxylate complexes containing P donor ligands are covered in Section 45.5.4.8.iv.

45.7.7 Dithio- and Monothio-β-diketonate Complexes



There is a review on transition metal dithio-β-diketonate complexes[2238] but very little work has been published on those of ruthenium. Treatment of $[RuCl_3NO(OH_2)]$ and acetylacetone with H_2S in a saturated HCl/EtOH solution affords the red-brown $[RuCl(sacsac)_2NO]$ for which a *trans* structure (**348**) was proposed on the basis of ^1H NMR spectroscopy. Polarographic studies in acetone/$Et_4N[ClO_4]$ reveal two reversible one electron reductions at -0.27 V and -1.44 V,[1305] whereas $[Ru(sacsac)_3]$, (made as above starting from '$RuCl_3 \cdot xH_2O$'), undergoes a one electron reduction at $+0.04$ V (relative to Ag/AgCl). The magnitude and reversible nature of these reduction potentials suggest that the isolation of sacsac compounds in unusually low formal oxidation states should be possible.[1306,1307,2055] The ESR spectrum of $[Ru(sacsac)_3]$ is consistent with low spin Ru^{III} (t_{2g}^5) with a large low symmetry distortion[604,2239] and its μ_{eff} of 1.72 BM at 290 K supports this conclusion. Detailed electronic spectra (35 000–10 000 cm^{-1}) are reported and some tentative assignments proposed.[2239]

The related *O*-ethylthioacetothioacetate ruthenium(III) complex $[Ru(EtOsacsac)_3]$ (**349**) is prepared by direct reaction of '$RuCl_3 \cdot xH_2O$', EtOsacsacH and Na[OCOMe] in EtOH. The dark green solid is thermally unstable above 60°C.[2240]



A series of papers[2241–2244] have appeared on the preparation and physicochemical properties of the monothio-β-diketonates $[Ru(RC(S)=CHCOCF_3)_3]$ (R = Ph, *p*-MeC_6H_4, *m*-MeC_6H_4, 2-thienyl, β-naphthyl, Pr^i, *m*-ClC_6H_4, *m*-BrC_6H_4) and $[Ru(RC(S)XC(O)Ph)_3]$ (X = CH, R = Ph, NHPh, NBu_2; X = N, R = piperidino, NBu_2).[1751a] Information given includes mass spectra (molecular ion peak observed), dipole moments (which suggest a facial octahedral configuration (**350**) in which all S atoms are mutually *cis*), and magnetic data over the temperature range 83–293 K. The compounds are all low spin Ru^{III} with magnetic moments in the range 1.68–1.84 BM (at 293 K). They obey the Curie–Weiss Law with large negative values for the Weiss constant. Brown, diamagnetic $[Ru(PhC(S)CHC(O)Ph)]_4$ was reported as the product from the reaction between $K_2[RuCl_6]$ and PhC(S)CHC(O)Ph but it was very poorly characterized.[1751b]

(348)

(349)

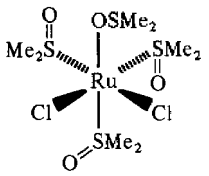
(350)

Some monothio-carboxylate, -carbonate and -carbamate complexes have also been synthesized but these all contain P donor ligands (see Section 45.5.4.8.v).

45.7.8 Thiourea Complexes

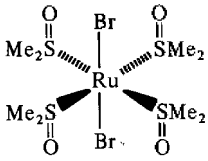
The reaction of thiourea with Ru^{III} ions is of analytical importance and much work has been done towards developing a reliable method of analysis.[2245] Although earlier studies[2246] suggested that only two thiourea complexes were present in $HClO_4$ solution, namely $[Ru(tu)]^{2+}$ and $[Ru(tu)_3]$, Youmans has shown that reaction of aqueous HCl solutions of '$RuCl_3 \cdot xH_2O$' with an excess of thiourea at 100°C gives $[Ru(tu)_6]^{3+}$ isolated as its $[HgI_4]^{2-}$ salt. Magnetic measurements (μ_{eff} = 2.0 BM at 300 K) support the Ru^{III} formulation and IR studies indicate Ru—S bonding.[2247]

More recently,[2248] $[RuCl(tu)_5]Cl_2$ has been isolated as have a number of complexes containing substituted thioureas such as diphenylthiourea, allylthiourea, naphthylthiourea *etc.* For other (mainly Russian) references to studies of the interaction of thiourea and substituted thioureas with ruthenium(III), see reference 3, p. 212.



For ammine complexes containing SO_2, *e.g.* $[Ru(NH_3)_4(SO_2)(OH_2)]^{2+}$, $[RuCl(NH_3)_4SO_2]Cl$ *etc.*, see Section 45.4.1.2.iii.c.

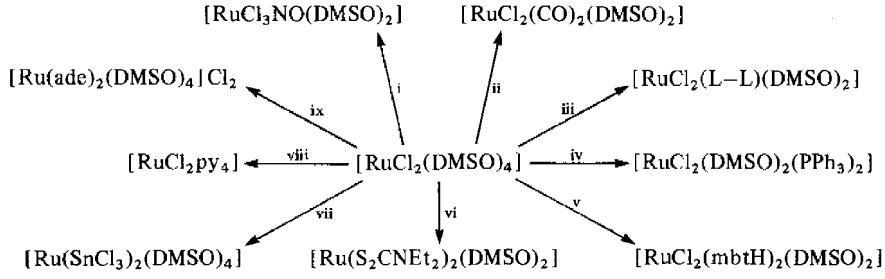
45.7.9 Sulfoxide Complexes



These are covered in this section because most ruthenium sulfoxide complexes contain predominantly S-bonded groups. Two reviews on transition metal sulfoxides have been published.[2249,2250] Yellow $[RuX_2(DMSO)_4]$ (X = Cl, Br) were first prepared by the reduction of '$RuCl_3 \cdot xH_2O$' (or $RuBr_3$) in DMSO at 80°C with H_2.[2251] Later studies revealed that the same compounds are formed in quantitative yield by heating the halides for a few minutes with DMSO under reflux.[112] The bromo compound is also formed by prolonged shaking of $[RuBr_3(AsPh_3)_2MeOH]$ with DMSO.[1697] The deuterated products $[RuX_2(d^6\text{-DMSO})_4]$ are obtained in analogous fashion.

The IR,[112,2251] ^1H[112,2252] and ^{13}C[2253] NMR spectra of yellow $[RuCl_2(DMSO)_4]$ suggest the presence of both S- and O-bonded DMSO groups and X-ray analysis[2254] confirms structure (**351**) with a facial arrangement of S-bonded ligands. A less stable, red isomer of $[RuCl_2(DMSO)_4]$ has also been described and it was concluded on the basis of IR evidence that it should be formulated as $[Ru(OSMe_2)_n(SOMe_2)_{4-n}Cl_2]$ ($n \geq 2$).[2186]

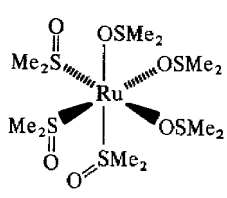
For $[RuBr_2(DMSO)_4]$ however, spectroscopic evidence indicates exclusively S-bonded groups[1697,2252] and an X-ray study[2255] confirms structure (**352**), with a *trans* arrangement. IR measurements suggest that $[RuI_2(DMSO)_4]$ has a similar structure.[2252] This difference in structure between the chloro and bromo complexes helps to rationalize the fact that the latter is a much more active sulfide oxidation catalyst.[2256,2257] Compounds of tetramethylene sulfoxide of type $[RuX_2(TMSO)_4]$ (X = Cl, Br, I) with only S-bonded groups are known,[2258,2259] and the thermal decomposition of $[RuCl_2(DMSO)_4]$ has been studied by tga and dta techniques.[2186] Hydrolysis of $[RuCl_2(DMSO)_4]$ can be monitored by ^1H NMR spectroscopy and various aqua complexes detected.[2252,2260a]



(351)

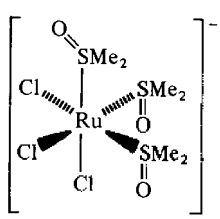
(352)

Some reactions of $[RuCl_2(DMSO)_4]$ in which either the chloride or some or all of the DMSO groups are replaced are shown in Scheme 69.[112] Similar studies have been reported using *trans*-$[RuBr_2(DMSO)_4]$.[2260b] Note that in the absence of DMSO, adenine and cytosine are claimed to react with $[RuCl_2(DMSO)_4]$ to give the binuclear species $[Ru_2Cl_4(ade)_3(DMSO)_4]$ and $[Ru_2Cl_4(cyt)_4(DMSO)_2(MeOH)_4]$ respectively.[2261] A paper has revealed that reaction of $[RuCl_2(DMSO)_4]$ with various anionic bidentate ligands such as *o*-$HO_2CC_6H_4NHCOMe$ (AABH) *etc.* provides a convenient route to $[Ru(AAB)_2(DMSO)_2]$. With uninegative terdentate ligands, (L), complexes of formula $[Ru(L)_2]$ are formed.[2262]



i, NO; ii, CO; iii, L–L = 2,2′-bipy, 1,10-phen or 2-aminopyridine; iv, PPh_3; v, 2-mercaptobenzothiazole (mbtH); vi, $Na[S_2CNEt_2]$; vii, $SnCl_2$; viii, py; ix, adenine/DMSO[2260]

Scheme 69

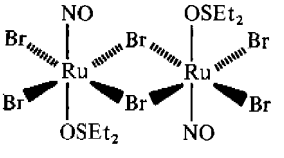


In the presence of Ag^+ in D_2O, $[RuCl_2(DMSO)_4]$ gives *fac*-$[Ru(DMSO)_4(OD_2)_2]^{2+}$ and in DMSO, this provides a route to the $[Ru(DMSO)_6]^{2+}$ cation, with counterion ClO_4^-[112] or BF_4^-.[2263] Equation (137) shows another route to this cation. The diene/DMSO cation is made by reaction of $[Ru(N_2H_4)_4cod](BPh_4)_2$ with DMSO in acetone. IR,[650,2263] ^1H[650,2252,2263] and ^{13}C[2253] NMR studies on this hexakis cation suggest both S- and O-bonded DMSO groups which is confirmed by crystallographic evidence (structure **353**).[2263] Hydrolysis of (**353**) leads to stepwise displacement of O-bonded DMSO to form $[Ru(DMSO)_{6-n}(OD_2)_n]^{2+}$ (n = 1–3) respectively.[2252,2260a,2263] Reaction of (**353**) (BF_4^- salt) with adenine in DMSO gives $[Ru(ade)_2(DMSO)_4](BF_4)_2$.[2260a] Treatment of $[RuCl_2(DMSO)_4]$ with stoichiometric amounts of $Ag[BF_4]$ in DMSO generates $[RuCl(OSMe_2)_2(SOMe_2)_3]^+$.[2252]

Reduction of '$RuCl_3 \cdot xH_2O$' with H_2 at 80°C in the presence of a stoichiometric amount of DMSO in DMA solution affords yellow $NMe_2H_2[RuCl_3(DMSO)_3]$, the cation being a reduction product of the solvent. The deuterated analogue is readily prepared and X-ray analysis shows the *fac* S-bonded structure (**354**).[2264] In water loss of chloride produces some $[RuCl_2(DMSO)_3(OH_2)]$ and treatment with Ag^+/D_2O forms $[Ru(DMSO)_3(OD_2)_3]^{2+}$.[2252,2263] With adenine in DMSO, $[RuCl_2(ade)(DMSO)_3]$ is produced.[2260a]

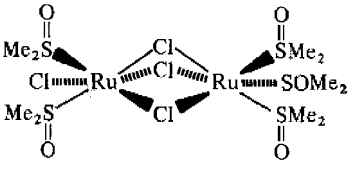
$$[Ru(DMSO)_4cod](BPh_4)_2 \xrightarrow{DMSO} [Ru(DMSO)_6](BPh_4)_2^{650} \qquad (137)$$

(353)



(354)

Complexes (**351**), (**353**) and (**354**) will catalyse the hydrogenation (DMA, 60°C, 1 atm) of acrylamide to 1-aminopropane[2263,2264] but are inactive for the hydrogenation of alkenes.[2263] Compounds (**351**) and (**354**) catalyse the hydrogenation of methyl vinyl ketone to methyl ethyl ketone and the reduction of unsaturated carboxylic acids.[2265]



Neutral, monomeric ruthenium(II) complexes containing chiral sulfoxide ligands have been prepared by sulfoxide exchange reactions with $[RuCl_2(DMSO)_4]$, and these show some catalytic activity for the hydrogenation of prochiral unsaturated carboxylic acid substrates.[2266] With bulkier sulfoxide ligands (L), trimeric complexes $[RuCl_2L_2]_3$ are formed and racemic methyl phenyl sulfoxide (mpso) affords polymeric $[RuCl_2(mpso)_2]_n$.[2265,1843]

Other monomeric Ru^{II} complexes containing DMSO ligands include S-bonded $[Ru(NH_3)_5(DMSO)]^{2+}$ (from $[Ru(NH_3)_5N_2]^{2+}$ and DMSO),[244,418] $[RuCl_3NO(DMSO)_2]$ (from '$RuCl_3 \cdot xH_2O$', DMSO and NO),[112] $[RuClX(DMSO)(\eta\text{-}C_6H_6)]$ (X = Cl, H).[2250] References to the preparation of DMSO compounds containing P or As donor ligands are given in Section 45.5.4.8.vi.

The binuclear O-bonded $[RuBr_3NO(OSEt_2)]_2$ (**355**) is formed by photochemically-induced aerial oxidation of $[RuBr_3NO(Et_2S)_2]$ in $CHCl_3$,[1301] whereas heating moist toluene solutions of $[RuCl_2(DMSO)_4]$ affords $[Ru_2Cl_4(DMSO)_5]$.[1192] Detailed IR and NMR (^1H and ^{13}C) studies establish the triple chloride-bridged structure (**356**) containing exclusively S-bonded DMSO groups. In contrast to $[RuCl_2(DMSO)_4]$, (**356**) undergoes a reversible one electron oxidation to generate *in situ* the mixed valence cation $[Ru_2Cl_4(DMSO)_5]^+$.[2253]

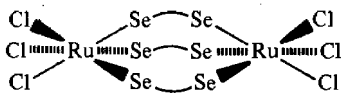
(355)

(356)

Relatively little evidence exists for monomeric Ru^{III} sulfoxide complexes. Thus $[RuCl_3(DMSO)_3]$ was prepared by the reaction between DMSO and the reduced 'ruthenium blue' solutions[676] but later reports[112] indicate that it is unrepeatable. However, direct reaction of '$RuX_3 \cdot xH_2O$' with di-*n*-propyl or di-*n*-butyl sulfoxide (L) is claimed to give $[RuX_3L_3]$ (X = Cl, Br) and IR data suggest the presence of both O- and S-bonded ligands.[2258] Other Ru^{III} sulfoxides include $[Ru(DMSO)_6]X_3$ (X = Cl, ClO_4), $[Ru(DMSO)_5Cl]Cl_2$ and $M[RuCl_4(DMSO)_2]$ (M = Bu_4N^+, Na^+). The first two contain both O- and S-bonded DMSO but the latter only S-bonded.[2186,2267] Reaction of $[RuBr_3(AsPh_3)_2MeOH]$ with $DMSO/H_2O$ (1:1 v/v) gives O-bonded $[RuBr_3(AsPh_3)_2DMSO]$; in neat DMSO, $[RuBr_2(DMSO)_4]$ is formed.[1697]

45.8 SELENIUM AND TELLURIUM LIGANDS

In contrast to sulfur (Section 45.7), relatively little has been published on ruthenium complexes containing selenium and tellurium ligands.



$RuSe_2$ and $RuTe_2$ are normally prepared from the elements at high temperature or by heating $RuCl_3$ with Se or Te.[2] These have the pyrite structure.[2158,2268] Other measurements on these compounds include IR spectra, force constant and normal coordinate calculations,[2162] a ^{125}Te Mössbauer spectrum[2269] and the determination of the high temperature enthalpy and decomposition pressure of $RuSe_2$.[2270] A low temperature modification of $RuTe_2$ of the marcasite type has been prepared. At 620°C, this transforms monotropically into the pyrite type form.[2271] $Rh_{1-x}Ru_xSe_2$ ($x < 0.45$) is known and exhibits superconductivity.[2272]

Reaction of $[Ru_3(CO)_{12}]$ with selenium or tellurium under a CO/H_2 atmosphere in refluxing octane gives $[Ru_3H_2(\mu_3\text{-}E)(CO)_9]$ (E = Se, Te) (see (**332**) Section 45.7.1) and $[Ru_3Se_2(CO)_9]$ (see (**333**), Section 45.7.1).[2166] Low yields of (**332**) are also obtained from reaction of $[Ru_3(CO)_{12}]$ with EO_2 and alcoholic KOH.[2165] The interesting binuclear complex $[(NH_3)_5RuSe_2Ru(NH_3)_5]Cl_4$ has recently been synthesized.[2273]

The yellow binuclear compounds $[Ru(EPh)(CO)_3]_2$ (E = Se, Te) are minor products from reactions between $[Ru_3(CO)_{12}]$ and Ph_2E_2. These react further with Ph_2E_2 to give two forms of orange, polymeric $[Ru(EPh)_2(CO)_2]_n$ (n = 6–7 and 12–14) as major products. The seleno compound $[Ru(SePh)(CO)_3]_2$ may exist as two isomers, but only one, probably with the *anti* conformation was isolated.[2274] Irradiation of $[Ru(CO)_2(\eta\text{-}C_5H_5)]_2$ with Ph_2Se_2 gives $[Ru(SePh)(CO)_2(\eta\text{-}C_5H_5)]$ and

$[Ru(\mu\text{-SePh})(CO)(\eta\text{-}C_5H_5)]_2$ (reference 1, p. 781). $[RuL_4(MeCN)]$ and $[RuL_4(CO)]$ (LH = 2,3,5,6-$(CH_3)_4C_6HSeH$ or 2,4,6-$(Pr^i)_3C_6H_2SeH$) have been prepared.[2170b]

A number of seleno- and telluro- ether complexes are known. For example, treatment of $[RuI_2(CO)_2]_n$ with various selenides or tellurides affords $[RuI_2(CO)_2L_2]$ and/or $[RuI_2(CO)L_3]$ [L = Et_2Se, Ph_2Se, Bu_2Te, Ph_2Te]. Isomeric mixtures are frequently formed and separated by fractional crystallization. The chloro and bromo analogues can be prepared by treatment of the iodo complex with Cl_2 or Br_2 respectively.[1611,2191] Similarly, Ph_3PSe gives $[RuI_2(CO)_2(SePPh_3)_2]$ which decomposes in DMF to produce $[Ru_2I_4(CO)(SePPh_3)_2DMF]$. $[RuI_2(CO)_2PhSe(CH_2)_2SePh]$ is formed unexpectedly from $[RuI_2(CO)_2]_n$, Ph_2Se_2, EtOH and C_6H_6 at 150°C. The ethano bridge is presumably generated by catalytic dehydration of EtOH.[1611] On the basis of ^1H NMR and molecular weight measurements, the complex of empirical formula $[RuCl_3(Pr^iSe(CH_2)_2SePr^i)]_{1.5}$ is proposed to have the dimeric structure (**357**).[2275]

(357)

Complexes of type $[RuX_3NOL_2]$ (L = Et_2Se, EtPhSe) are readily prepared[1302] and exhibit facile inversion at selenium.[1303] Ammine cations such as $[Ru(NH_3)_5EMe_2]^{2+}$, $[Ru(NH_3)_4(OH_2)(EMe_2)]^{2+}$ (E = Se, Te),[433] $[Ru(SePh)(NH_3)_5]^{2+}$[432] are also known (*cf.* SR_2 analogues in Section 45.4.1.2.iv).

The only diselenocarbamates of ruthenium mentioned in the literature are $[Ru(Se_2CNEt_2)_3]$ (from Et_2NCSe_2H and $Na_2[RuCl_6]$),[2276] and $[Ru(Se_2CNMe_2)_3NO]$.[2216] Selenourea is reported to form a blue-green complex with Ru^{IV} solutions in 6 M HCl[2277] and interactions between selenourea and Ru^{III} have been investigated.[2278]

Other selenium-containing complexes include the benzeneseleninato compounds $[Ru(RC_6H_4SeO_2)_3]$ and $[Ru(RC_6H_4SeO_2)_2X]$, (R = H; *p*- and *m*-Cl, Br; *p*-Me; X = Cl, Br), whose IR spectra indicate *O,O'*-seleninato coordination. The tris-complexes are octahedral and the bis are polymeric, octahedral with bridging halides.[2279,2280] Reaction of $[Ru(CO)_3(PPh_3)_2]$ with $(SeCN)_2$ affords $[Ru(NCSe)_2(CO)_2(PPh_3)_2]$.[2281]

Selenocarbonyl complexes and related species are discussed in Sections 45.5.4.5.ii and 45.5.4.5.iii.

45.9 HALOGEN LIGANDS

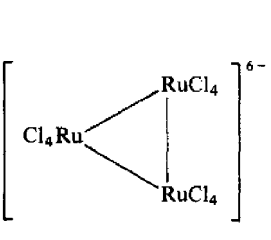
This section covers the chemistry of pure halides, aqua-, hydroxo-, oxo- and carbonyl halides. For nitrido and nitrosyl halides see Sections 45.4.6 and 45.4.4.4 respectively. Unlike most other sections of this article, much of the published work on ruthenium halides is pre-1970 and excellent, detailed reviews[2,3] have appeared in the literature. Therefore in order to conserve space and avoid undue repetition, only a relatively brief account containing earlier key references and more recent data is presented here.

45.9.1 Ruthenium(I) Halides

Although reactions of hypophosphorous acid with aqueous solutions of RuX_3 (X = Cl, Br, I) are claimed to give RuX *in situ*,[2282] further work in this area is now required. More recently, Ru^I chloro compounds of possible formula $H[Ru_2Cl_3(DMA)_2]$ have been isolated from reaction of '$RuCl_3 \cdot xH_2O$' with H_2 in DMA; these species are effective catalysts for hydrogenation of alkenes and unsaturated carboxylic acids.[2283]

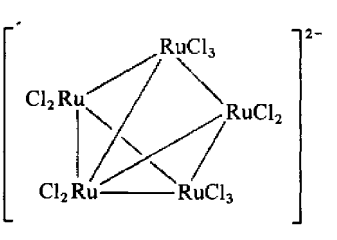
45.9.2 Ruthenium(I) Carbonyl Halides

Brief reports on the preparation and properties of colourless $[RuBr(CO)]_n$, (from $RuBr_3$ and CO at 350 atm and 180°C),[2284] and orange $[RuI(CO)_x]_n$, (from $RuCl_3$ or $[RuI_2(CO)_2]_n$ with CO or $[Ru(CO_5)]$ and I_2),[1110] have appeared in the literature. A reinvestigation of these compounds would be of considerable interest.



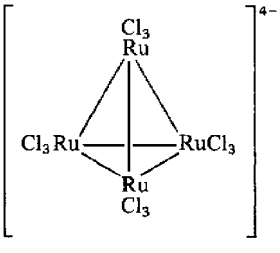
45.9.3 Ruthenium(II) Halides

Although there are a number of reports of the preparation of $RuCl_2$ in the early literature, it appears that this species has never been prepared in a pure state. In fact the reported method of preparation is similar to that established for β-$RuCl_3$ (see Section 45.9.6.1)[2285] and incomplete chlorination with consequent contamination of $RuCl_3$ by ruthenium metal was probably responsible for the erroneous claims. However, residues with Ru:Cl ratios of *ca.* 1:2 have been isolated from the reduced 'ruthenium blue' solution (see below); a black solid with a Ru:Br ratio of *ca.* 1:2 is obtained from the corresponding violet–blue Ru^{II} bromide solution.[2286,2287] No RuX_2 (X = F, I) are known.

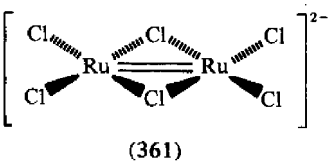


Chemical or electrochemical reduction of aqueous or alcoholic solutions of '$RuCl_3 \cdot xH_2O$', $K_2[RuCl_6]$ or $K_4[Ru_2OCl_{10}]$ produce the well-known reduced 'ruthenium blue' solutions which are both useful synthetic precursors for many ruthenium(II) and (III) complexes[676] and active catalysts for alkene hydrogenation and isomerization.[2283] However in spite of 180 years of effort the composition of these blue solutions still remains uncertain. For an excellent and detailed account of this fascinating but extremely complicated topic, see reference 3, p. 342. In brief, a survey of the experimental data clearly reveals that there are several species present in solution, in an equilibrium whose position depends on the pH and chloride ion concentration of the solution. Earlier workers suggested that an important component of these solutions was $[RuCl_4]^{2-}$ and various solids purporting to contain this anion were isolated by addition of cations such as Cs^+, pyH^+, enH_2^{2+} *etc.* Later workers[2288] have proposed a trimeric structure (**358**) for this anion.

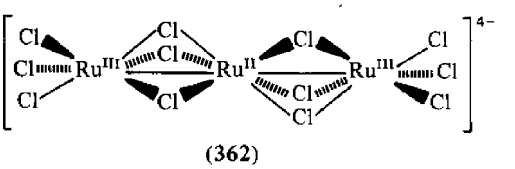
Rose and Wilkinson,[2288] by treatment of the methanolic blue solutions with various cations, have trapped out stable solids of composition $M[Ru_5Cl_{12}]$ ($M = Fe(bipy)_3^{2+}$, $Ru(bipy)_3^{2+}$, $[C_6H_4(CH_2PPh_3)_2]^{2+}$ and proposed structure (**359**). The ESR spectra of these materials are essentially identical to those of the blue solutions in various solvents, so it is reasonable to assume that the ion present in the solids is also present in the blue solutions. However, the ESR spectrum and magnetic properties of (**359**) (μ_{eff} = 1.3 BM per five ruthenium atoms) are not consistent with what might be expected to be a diamagnetic cluster. Furthermore, the blue solutions obtained by electrolytic reduction of $K_2[RuCl_5(OH_2)]$ in 0.01 M HCl and which can be separated into the binuclear blue components $[Ru_2Cl_3]^{2+}$, $[Ru_2Cl_4]^+$, $[Ru_2Cl_5]$, (and unidentified anionic species), by ion exchange techniques at 0°C have the same ESR spectra as (**359**).[2289] It has been suggested that these $Ru_2^{II,III}$ mixed valence complexes are isostructural with the ammines $[(NH_3)_3Ru(\mu\text{-}Cl)_3Ru(NH_3)_3]^{2+}$ (see Section 45.4.1.3.iv), *e.g.* $[(H_2O)_3RuCl_3Ru(H_2O)_3]^{2+}$ *etc.* Clearly more work is now required to resolve these differences of structural formulation.



Upon saturation with HCl gas, the blue methanolic solutions turn green and addition of a cation gives green solids of empirical formula $M[RuCl_3]$ ($M = pyH^+$, Et_4N^+) for which the tetrameric structure (**360**) has been proposed.[2288] Interestingly, reaction between '$RuCl_3 \cdot xH_2O$' and $Na[S_2CNPr^i_2]$ gives as one of the minor products, $[Ru_2(S_2CNPr^i_2)_5]_2[Ru_2Cl_6] \cdot 2CHCl_3$, which contains the only crystallographically characterized chloro complex (**361**) of Ru^{II}.[2211] Clearly this dimeric formulation must be considered as a possibility for Rose and Wilkinson's green complexes $M_n[RuCl_3]_n$.[2290] The claim of brown trimeric anions $[Ru_3Cl_9]^{3-}$ (from reaction of aqueous solutions of '$RuCl_3 \cdot xH_2O$' with H_2O_2)[2290] has been withdrawn; they are now reformulated as the binuclear Ru^{IV} anions $[Ru_2OCl_9(OH_2)]^{3-}$ (reference 5, p. 97).



(358)



(359)

(360)

(361)

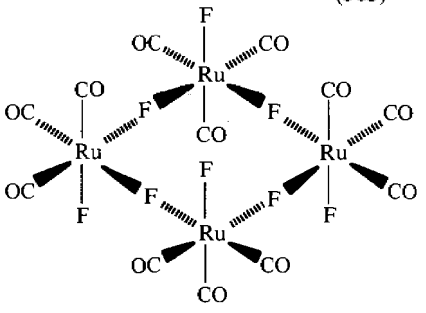
(362)

Dissolution of $[Ru_2(OCOMe)_4Cl]$ in 12 M HCl also gives a deep blue solution and addition of $[Et_4N]Cl$ and solvent evaporation leads to the slow precipitation of the deep green, mixed valence $[H_7O_3]_2[Et_4N]_2[Ru_3Cl_{12}]$ (**362**) which has been characterized crystallographically.[2121a] It is believed that this complex is derived from the components of the ruthenium blue solution by trace amounts of aerial oxidation. The ground state electronic structure and electronic spectra of (**362**) have been calculated by the SCF–Xα–SW method.[2291]

Violet-blue solutions are obtained from chemical reduction of $RuBr_3$ in ethanolic or HBr/H_2O media.[2287,2292] These give similar electronic[2292] and ESR spectra[2288] to their chloride analogues. Blue solutions are also generated by reduction of green ethanolic solutions of RuI_3.[2287]

45.9.4 Ruthenium(II) Aquahalide Complexes

Polarographic half-wave potentials for the reduction of various monomeric aquachlororuthenium(III) complexes $[RuCl_n(OH_2)_{6-n}]^{(3-n)+}$ $(0 \leqslant n \leqslant 3)$ have been reported. The various Ru^{II} products then undergo rapid aquation to give $[Ru(H_2O)_6]^{2+}$ (see Section 45.6.1). A cyclic voltammetric study on $[RuCl(OH_2)_5]^+$ reveals that at high sweep rates, only the oxidation wave due to $[RuCl(OH_2)_5]^+$ is observed; at lower rates, a wave due to $[Ru(H_2O)_6]^{2+}$ grows in. The $[RuCl_3(OH_2)_3]^-$ anion aquates too rapidly to be studied by cyclic voltammetry but the rates of aquation of *cis*- and *trans*-$[RuCl_2(OH_2)_4]$ were calculated as 0.13 and 0.14 s^{-1} respectively.[2293]



45.9.5 Ruthenium(II) Carbonyl Halides

45.9.5.1 Carbonyl fluorides

Reaction of $[RuF_2(CO)_3 \cdot RuF_5]_2$ (see Section 45.9.8) with CO (100 atm/200°C) gives pale yellow $[RuF_2(CO)_3]_4$ of structure (**363**). Compound (**363**) is also formed as shown in equation (138). The mass spectrum of (**363**) has been analysed in terms of an initial fragmentation to yield $[Ru_2F_3(CO)_6]^+$ and $[Ru_2F_4(CO)_5]^+$. It reacts with HCl to give $[RuCl_2(CO)_3]_2$ and with an excess of XeF_2 to form *fac*-$[RuF_3(CO)_3]$.[2294,2295]

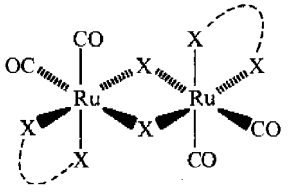
$$[Ru_3(CO)_{12}] + XeF_2 \xrightarrow[\text{or HF}]{CFCl_2CF_2Cl} [RuF_2(CO)_3]_4 \qquad (138)$$

(**363**)

(**363**)

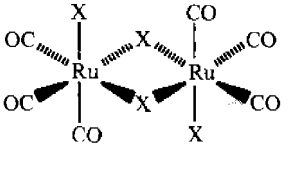
45.9.5.2 Neutral carbonyl chlorides, bromides and iodides

For detailed references, see the excellent accounts of this area in references 1 and 3. The first report of ruthenium(II) carbonyl halides was in 1924 when polymeric $[RuX_2(CO)_2]_2$ were prepared by passing CO over RuX_3 (X = Cl, Br, I) at *ca.* 270°C.[2296] Other routes to these compounds include reaction of $[Ru_3(CO)_{12}]$ and halogens in inert solvents above 140°C,[2297] evaporation of aqueous HX solutions containing $[RuX_4(CO)_2]^{2-}$,[1613,2298] thermal decomposition of $[RuX_2(CO)_4]$ (or $[Ru_2X_4(CO)_6]$) at 200°C *in vacuo*,[2297] or carbonylation of $[RuCl_2(cht)]_2$.[1372] IR data show two ν_{CO} bands, indicating a *cis*-$(CO)_2$ arrangement in a 'kinked' structure (**364**).[2299]



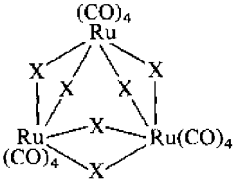
Other neutral Ru^{II} carbonyl halides are of the type *cis*-$[RuX_2(CO)_4]$, $[RuX_2(CO)_3]_2$ and $[Ru_3X_6(CO)_{12}]$. The best route to *cis*-$[RuI_2(CO)_4]$ is shown in equation (139).[2300] Treatment of

$[RuBr_2(CO)_3]_2$ with CO (80–90 atm/20–120°C) gives pure *cis*-$[RuBr_2(CO)_4]$; the chloride reacts similarly but rapidly reforms $[RuCl_2(CO)_3]_2$ in the absence of CO.[651] For other preparations see reference 1, p. 672. X-Ray (for X = I),[2301] IR, ^{13}C NMR and mass spectral data are available.[2300,2302]



$$[Ru_3(CO)_{12}] + I_2 \xrightarrow[100°C/40\,atm/13\,h]{CO/C_6H_6} \underset{(90\%)}{cis\text{-}[RuI_2(CO)_4]} \qquad (139)$$

Carbonylation of '$RuCl_3 \cdot xH_2O$' in methanol (60°C/10 atm/24 h) and subsequent evaporation of solvents is the best route to $[RuCl_2(CO)_3]_2$.[2303] Treatment of $[Ru_3(CO)_{12}]$ with CHX_3 in the presence of ethanol also affords $[RuX_2(CO)_3]_2$ (X = Cl, Br)[653] and oxidation of $[Ru(CO)_3(\eta^4\text{-}C_8H_8)]$ with I_2 gives $[RuI_2(CO)_3]_2$.[2304] Other routes include thermal decomposition of *cis*-$[RuX_2(CO)_4]$[654] and carbonylation of $[RuCl_2(nbd)]_n$ or $[RuCl_2(C_6H_6)]_2$ in alcohols.[187a] Detailed mass spectral data have been recorded.[2302] The structure (**365**) of $[RuX_2(CO)_3]_2$ (X = Cl, Br)[2305] is consistent with the IR data obtained in pure $CHCl_3$. Discrepancies between authors in the earlier IR solution spectral results in $CHCl_3$ are ascribed to the presence of ethanol stabilizer producing solvated monomers such as $[RuCl_2(CO)_3(EtOH)]$.[651] Reactions with Lewis bases to give $[RuX_2(CO)_3L]$ and $[RuX_2(CO)_2L_2]$ are covered in other sections. Reaction with $SbCl_5$ and HCl in CH_2Cl_2 gives $[RuCl_2(CO)_3]_2SbCl_3$.[2306]



At room temperature $[RuX_2(CO)_4]$ rapidly trimerize to form $[Ru_3X_6(CO)_{12}]$ which are proposed to have structure (**366**). The chloride is most conveniently prepared by direct chlorination of $[Ru_3(CO)_{12}]$ in refluxing $CHCl_3$. In solution, they readily lose CO to give $[RuX_2(CO)_3]_2$.[2297,2307]

(364)

(365)

(366)

45.9.5.3 Anionic carbonyl halides

Reaction of '$RuCl_3 \cdot xH_2O$' with HCl/HCO_2H (1:1 mixtures), under reflux produces a series of striking colour changes (deep red to green to orange to yellow), over a period of 30 h.[2298,2308] Treatment of the solution at the appropriate time with CsCl led to isolation of red $Cs_2[RuCl_5CO]$, green $Cs_2[trans\text{-}RuCl_4CO(OH_2)]$ (confirmed by X-ray analysis),[2309] orange $Cs_2[cis\text{-}RuCl_4(CO)_2]$ and yellow $Cs[fac\text{-}RuCl_3(CO)_3]$ salts respectively. Evaporation of the final solution gave $[RuCl_2(CO)_2]_n$. Less convenient routes to these anions include carbonylation and subsequent reduction by H_2 of '$RuCl_3 \cdot xH_2O$'/H_2O/HCl solutions, carbonylation of reduced 'ruthenium blue' solutions and addition of chloride to $[RuCl_2(CO)_2]_n$ and $[RuCl_2(CO)_3]_2$, (giving $[RuCl_4(CO)_2]^{2-}$ and $[RuCl_3(CO)_3]^-$ respectively).[1613,2310]

Analogous bromo and iodo anions are formed by reaction of '$RuX_3 \cdot xH_2O$' with HX/HCO_2H[2298,2308] or, for $Cs_2[RuX_4(CO)_2]$, by treatment of $Cs_2[RuCl_4(CO)_2]$ with HX. The red 'RuCOCl' solution exchanges with iodide to give a red-brown solution from which dark brown $[Et_4N]_2[Ru_2I_6(CO)_4]$ (with *cis* $Ru(CO)_2$ groups) is obtained by addition of $[Et_4N]Cl$.[2311] For schemes and further details see reference 1, p. 670. For reactions with Lewis bases see Sections 45.4.3.1.ii and 45.5.4.5.i.

45.9.6 Ruthenium(III) Halides

45.9.6.1 Pure neutral halides

Ruthenium(III) fluoride can be prepared by the reduction of ruthenium(V) fluoride with either iodine or sulfur at elevated temperatures[2312] or in an impure form by reduction of $[RuF_5]_4$ with ruthenium metal.[2313] It is a dark brown powder shown by X-ray powder diffraction studies to consist of RuF_6 corner shared octahedra, (with Ru----Ru separations of 3.37 Å).[2314] Neutron diffraction studies reveal no evidence of magnetic ordering even at 4.2 K.[2315]

After considerable confusion and effort (see reference 3, p. 156 for a comprehensive review of the earlier literature), it was shown by Fletcher and co-workers[2316] that two modifications of water

insoluble $RuCl_3$ (namely α and β) could be prepared in a pure state. The dark brown β-form is best obtained by heating ruthenium sponge at 330–340°C in a 1:3 mixture of CO and Cl_2 and the black α-form by heating the β-form in a current of chlorine to 700°C. The $\beta \rightarrow \alpha$ transition occurs at 450°C and is irreversible.[3] The α-form is isostructural with violet $CrCl_3$ and α-$TiCl_3$ and has a strongly defect-ordered layer structure with Ru----Ru = 3.46 Å. The β-form has a distorted octahedral environment of chloride ions, with a Ru----Ru distance of 2.83 Å. Detailed magnetic measurements reveal that β-$RuCl_3$ is antiferromagnetic below 600 K and shows extremely low values of χ_m, whereas α-$RuCl_3$ has much higher magnetic susceptibilities, *e.g.* μ_{eff} = 2.14 BM at room temperture, and only becomes antiferromagnetic below 13 K.[2317] The optical properties of the latter have been studied in IR, visible and UV regions by reflectance spectroscopy.[2318] Information on other physicochemical properties is to be found in reference 3.

Water soluble hydrated or commercial $RuCl_3$ (*i.e.* '$RuCl_3 \cdot xH_2O$') is usually prepared by the evaporation of a solution of $[RuO_4]$ in hydrochloric acid. However, it is important to note that it is a heterogeneous, ill-defined mixture of variable oxidation-state, oxochloro and hydroxochloro monomeric and polymeric ruthenium complexes. Nevertheless, it is by far the most common starting material for the preparation of ruthenium complexes. Note that evaporation of aqueous solutions of '$RuCl_3 \cdot xH_2O$' (pH *ca.* 1.5) several times on a waterbath removes most of the HCl contaminant and this purified '$RuCl_3 \cdot xH_2O$' is much more reactive towards, for example, various organic ligands such as 1,3-cyclohexadienes.[2319]

Commercial '$RuCl_3 \cdot xH_2O$' is widely used as a catalyst (see references 3 and 2320 for details of earlier studies). Examples include the oxidation of amines and alcohols,[2321] the production of glycol esters from synthesis gas,[2322] and the generation of 1,3-diol derivatives from reaction of dienes and alkenes with aldehydes and carboxylic acids.[2323]

Pure samples of water insoluble, black-brown $RuBr_3$ can be prepared by prolonged reaction between ruthenium and bromine at 450–500°C and 20 atm.[2324] X-Ray analysis reveals that the structure is based upon chains of $(Ru_2Br_3)Br_{\frac{3}{2}}$ groups with the metal in approximately octahedral coordination with a Ru----Ru separation of 2.73 Å.[2325,2326] It exhibits only a very weak temperature-independent paramagnetism, indicative of strong metal–metal interactions.[2326] A water soluble version of '$RuBr_3 \cdot xH_2O$' prepared from $[RuO_4]$ (or ruthenium(III) hydroxide) and HBr is also known.[2327]

RuI_3 can be synthesized either by the metathetical reaction between '$RuCl_3 \cdot xH_2O$' and KI in aqueous solution, by the action of hydriodic acid on $[RuO_4]$,[2327,2328] or by thermal decomposition of $[RuI(NH_3)_5]I_2$ or *cis*-$[RuI_2(NH_3)_4]I$.[464,465] The black powder is sparingly soluble in water with a similar structure to $RuBr_3$.[2325] For other properties see reference 3, p. 161.

45.9.6.2 Pure anionic halides

$K_3[RuF_6]$ can be prepared by fusing RuX_3 (X = Cl, I) with $K[HF_2]$ in the absence of oxygen. It is a brownish-grey powder, isomorphous with $K_3[RhF_6]$, with μ_{eff} = 1.25 BM at room temperature. Its electronic and IR spectra are available.[2329,2330]

Virtually all the methods of preparing $[RuCl_6]^{3-}$ are a variation on a method developed by Charonnat which involves recrystallizing salts of $[RuCl_5(OH_2)]^{2-}$ from 12 M hydrochloric acid.[2331] A convenient synthesis of $K_3[RuCl_6]$ is to add the correct molar ratio of KCl to the methanolic 'ruthenium blue' solution, heat under reflux in air and then recrystallize the product from 12 M HCl.[1220] Reduction of $[RuCl_6]^{2-}$ by H_2[2332] and by $H\cdot$[2333] (generated by pulse radiolysis) has been studied. Extensive physicochemical studies on this anion with a variety of cations include X-ray analysis (for $[Al(H_2O)_6]^{3+}$[2331] and $[PhNH_3]^+$ cations[2334]), electronic and IR spectra,[3,2333,2335,2336a,2336b] magnetic circular dichroism,[2337] magnetic measurements (*ca.* 2 BM at 300 K),[2338] ESR,[2339] WHMO[2340] and SCF–Xα–SW calculations on the ground state electronic structure[2291] and measurement of the kinetics of isotope exchange for the reaction shown in equation (140).[2341]

$$[RuCl_6]^{3-} + {}^{36}Cl^- \rightleftharpoons [RuCl_5{}^{36}Cl]^{3-} + Cl^- \qquad (140)$$

$[RuCl_6]^{3-}$ in aqueous HCl solution will activate H_2 homogeneously and hence catalyse its reduction of Ru^{IV} and Fe^{III}.[2342] It will also catalyse the isotopic exchange between H_2O and D_2[2343] and the hydration of alkynes, although the active species in the latter process are probably the aquachloro species $[RuCl_5(OH_2)]^{2-}$ and $[RuCl_4(OH_2)_2]^-$.[1613] The preparation and properties of these and related aquahalide Ru^{III} complexes are discussed in the next section.

There are many reports in the early literature of complexes of the general formula $A_4[RuCl_7]$

which are probably the crystal aggregates $A_3[RuCl_6]ACl$.[2] Thus, $[N(CH_2CH_2NH_3)_3]H[RuCl_7]\cdot 2H_2O$ has spectroscopic properties identical to $K_3[RuCl_6]$ and is formulated as $[N(CH_2CH_2NH_3)_3][RuCl_6]HCl\cdot 2H_2O$,[2338] and $[PhNH_3]_6[RuCl_9]$ is isomorphous with its bromide analogue, whose crystal structure reveals the formulation $[PhNH_3]_6[RuBr_6]Br_3$.[2334] Compounds of formula $A_2[RuCl_5]$ are also known but attempts to repeat many of these preparations have resulted only in the isolation of $A_4[Ru_2OCl_{10}]$[2334] (see Section 45.9.7.3). Nevertheless dehydration of $K_2[RuCl_5(OH_2)]$ or heating $K_2[RuCl_6]$ in HCl at 600°C gives $K_2[RuCl_5]$. Magnetic susceptibility measurements on this material (μ_{eff} = 1.64 BM at 350 K; 1.14 BM at 80 K) are significantly lower than for the $[RuCl_6]^{3-}$ ions (*ca.* 2 BM at 300 K),[2338] which might suggest it should be formulated as a $[Ru_2Cl_{10}]^{4-}$ ion.[2344] Thermal stability studies on this anion and other chlororuthenates such as α-$RuCl_3$ and $K_3[RuCl_6]$ have been reported.[2345]

Earlier Russian work[2346] on the preparation of the $[Ru_2Cl_9]^{3-}$ anion has been verified. $Cs_3[Ru_2Cl_9]$ can be prepared by solid state reaction at 700°C between stoichiometric proportions of CsCl and $RuCl_3$.[2347] Its X-ray structure (Ru—Ru = 2.725(3) Å), magnetic susceptibility (μ_{eff} = 0.51 BM per Ru at 300 K),[2347] redox properties (see equation 141 for $[NBu_4]^+$ salt in CH_2Cl_2; $E_{\frac{1}{2}}$ values *vs.* Ag/AgCl reference electrode)[2348] and electronic spectra[2291,2346] have been reported and SCF–Xα–SW calculations performed which establish a '$a_1'^2e'^4e''^4$' ground state electronic structure.[2291] The analogous $K_3[Ru_2Br_9]$ is readily prepared by reaction of '$RuCl_3\cdot xH_2O$' with a concentrated HBr/ethanol mixture followed by addition of KBr. The magnetic, redox and electronic spectral properties and Ru—Ru internuclear distance (2.86 Å) of this anion are very similar to those of $[Ru_2Cl_9]^{3-}$.[2335,2348]

$$\underset{35e^-}{[Ru_2^{II,III}Cl_9]^{4-}} \overset{-0.57\,V}{\rightleftharpoons} \underset{34e^-}{[Ru_2^{III,III}Cl_9]^{3-}} \overset{+0.92\,V}{\rightleftharpoons} \underset{33e^-}{[Ru_2^{III,IV}Cl_9]^{2}} \overset{+1.58\,V}{\rightleftharpoons} \underset{32e^-}{[Ru_2^{IV,IV}Cl_9]^{-}} \quad (141)$$

Salts of the $[RuBr_6]^{3-}$ anion (with counterions such as $[PhNH_3]^+$[2334] and $[N(CH_2CH_2NH_3)_3]^{3+}$[2338]) have been prepared by analogous routes to those of the chloride derivatives and fully characterized by structural and spectroscopic techniques.[3] Compounds of formulation $A_4[RuBr_7]$ (probably $A_3[RuBr_6]ABr$) and $A_2[RuBr_5]$ (probably $A_4[Ru_2OBr_{10}]$) are also reported.[3]

45.9.6.3 Aqua- and hydroxo-halide complexes

Ion exchange techniques have been used to separate the species present in aqueous solutions of ruthenium trichloride. The species present are $[RuCl_n(OH_2)_{6-n}]^{(3-n)+}$ ($0 \leqslant n \leqslant 6$) and their electronic spectra are available.[1887,2349–2351]

A number of these aquachloro complexes have been isolated and characterized by X-ray analysis. Thus, red $M_2[RuCl_5(OH_2)]$ can be prepared by ethanolic reduction of $[RuO_4]$ in HCl in the presence of MCl (M = K, Rb, Cs, NH_4),[2352] by reduction of $K_4[Ru_2OCl_{10}]$,[2335] or by reaction between $K_3[Ru(C_2O_4)_3]$ and HCl.[2353] The bromo derivatives $M_2[RuBr_5(OH_2)]$ are made by exactly analogous routes.[2354] The X-ray structure of the potassium[2355] and caesium chloro salts[2356] confirm the octahedral structure with Ru—Cl = 2.311 (*trans* to H_2O), 2.353 Å (*cis* to H_2O). Detailed magnetic (μ_{eff} *ca.* 2 BM at 300 K)[2357] and IR studies[2358] have been reported. Oxidation in $HCl/HClO_4$ solutions give dimeric oxo-bridged Ru^{IV} species[2359] whereas in 2 M HCl, $[RuCl_6]^{2-}$ is formed reversibly.[2360,2361]

The red *cis*-$[RuCl_4(OH_2)_2]^-$ anion is prepared (as the H^+ salt) by evaporation of a solution of $[RuO_4]$, HCl and ethanol,[2362] or, as its NH_4^+, Rb^+ or Cs^+ salts, by reduction of ammonium ruthenate with $SnCl_2$ and HCl in the presence of the appropriate cation.[2363] The latter type of route also gives $M[RuBr_4(OH_2)_2]$.[2364] Interconversion between H[*cis*-$RuCl_4(OH_2)_2$] and the green *trans* isomer is possible (equation 142).[2362] Solutions of *trans*-$[RuCl_4(OH_2)_2]^-$ are also obtained by aerial oxidation of the reduced methanolic blue solutions and addition of $[AsPh_4]Cl$ then precipitates green $AsPh_4$[*trans*-$RuCl_4(OH_2)_2$] (ν(Ru—Cl) 336 cm^{-1}).[2288] The X-ray structure of the red $AsPh_4$[*cis*-$RuCl_4(OH_2)_2$] complex has been reported with Ru—Cl = 2.325 (*trans* to H_2O), 2.355 Å (*cis* to Cl).[2365]

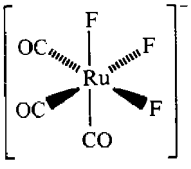
$$cis\text{-}H[RuCl_4(OH_2)_2] \underset{\Delta(HCl)}{\overset{\Delta(EtOH)}{\rightleftharpoons}} trans\text{-}H[RuCl_4(OH_2)_2] \quad (142)$$

Orange *mer*- and *fac*-$[RuCl_3(OH_2)_3]$ can be separated by elution at low temperature of aged ruthenium(III) chloride[2350] (or $K_2[RuCl_5(OH_2)]$)[2366] solutions through successive cation and anion exchange columns, which removes any charged species. Studies on these solution species include

dipole moment,[2366] IR[2367] and electronic[2350] spectral measurements. The kinetics of interconversion of the two isomers have been determined and it is found that the *mer* isomer is more labile than the *fac* isomers towards aquation, producing *cis*-$[RuCl_2(OH_2)_4]^+$.[2351]

Both *cis*- and *trans*-$[RuCl_2(OH_2)_4]^+$ cations can be successfully separated from aged solutions of '$RuCl_3 \cdot xH_2O$' in 0.3 M HCl by elution from a cation exchange column.[2349] The *trans* isomer, which is also made by heating blue hydrochloric acid solutions of Ru^{II} under N_2, has an ESR spectrum consistent with axial symmetry.[2288] For the interconversion $cis \rightleftharpoons trans$, $K = 1$.[2351]

The pentaaqua cation $[RuCl(OH_2)_5]^{2+}$ can be isolated in solution using cation exchange techniques.[1887] It electronic spectrum[1887] and rate of aquation ($t_{\frac{1}{2}} > 1$ year) have been measured (*cf.* for $[RuCl_6]^{3-}$, aquation to $[RuCl_5(OH_2)]^{2-}$ takes only a few seconds). Thus, cationic and neutral aquachlororuthenium(III) species are relatively substitutionally inert, compared to anionic species.[2351]



As mentioned earlier (Section 45.9.6.2) aqueous solutions of '$RuCl_3 \cdot xH_2O$' catalyse the hydration of alkynes. Detailed mechanistic studies indicate that the catalytic activity is dependent upon the combined concentrations of $[RuCl_4(OH_2)_2]^-$ and $[RuCl_5(OH_2)]^{2-}$.[1613]

The binuclear mixed valence chloro species $[Ru_2Cl_{n+3}]^{(2-n)+}$ $(0 \leqslant n \leqslant 2)$ are discussed in Sections 45.9.3.

Finally, there are some earlier reports of ill-defined hydroxo- and oxo-halide species such as $[Ru_2Cl_2(OH)_2]$, $[Ru_2OCl_4]$, $[RuCl_2(OH)(H_2O)]$ and $[en_2H_2]_5[RuCl_5OH]$ *etc.* (see reference 2, p. 135).

45.9.6.4 Carbonyl halides

Reaction between $[Ru_3(CO)_{12}]$ and an excess of XeF_2 in either $CFCl_2CF_2Cl$ or anhydrous HF at room temperature affords the air sensitive, paramagnetic, ($\mu_{eff} = 1.92$ BM), solid $[RuF_3(CO)_3]$. It is also formed by reaction of $[RuF_2(CO)_3]_4$ with an excess of XeF_2. The ESR spectrum in HF solution at 77 K confirms the monomeric, facial structure (**367**).[2295]

(367)

As discussed in Section 45.9.5.3, reaction of '$RuX_3 \cdot xH_2O$' with HX/HCO_2H (1:1 mixtures) under reflux produces initial deep red solutions containing the $[RuX_5CO]^{2-}$ anions (X = Cl, Br) which can be precipitated (for X = Cl) as its caesium salt.[2298,2308] For X = Cl, the same anion is formed by carbonylation of aqueous HCl solutions of '$RuCl_3 \cdot xH_2O$',[186,1613,2310] or treatment of $[RuCl_2CO(nbd)]_2$ with $[Ph_3(PhCH_2)P]Cl/HCl$ in acetone.[2368,2369] X-Ray structures of the $M_2[RuCl_5CO]$ salt ($M = Cs^+$,[2309] $Ph_3(PhCH_2)P^+$ [2368,2369]) are available. Evaporation of these red solutions yields an impure form of 'RuX_3CO' (possibly contaminated with RuX_3). No Ru^{III} iodocarbonyl complex has been isolated owing to its facile reduction but some IR evidence for its existence in solution is reported.[2298]

45.9.7 Ruthenium(IV) Halides

45.9.7.1 Pure neutral halides

Yellow crystals of RuF_4 can be synthesized by reaction of $[RuF_5]_4$ with iodine and iodine pentafluoride. It has a room temperature magnetic moment of 3.04 BM which drops to 2.51 BM at 88 K.[2370] Reaction with water gives RuO_2.[2000,2370]

Ruthenium(IV) chloride has been detected in the vapour phase on heating $RuCl_3$ and Cl_2 between 400–800°C.[2371] It is the principal vapour phase species up to 853°C[2372] and it is reported that solid $RuCl_4$ can be isolated by cooling the above vapour to liquid air temperatures. Above −30°C, it decomposes to $RuCl_3$ and Cl_2.[2373,2374] Note however that Fletcher and co-workers[2285] suggest that the above observations are compatible with oxochlorides such as $[Ru_2OCl_6]$ and are not, *per se*, evidence for the existence of $RuCl_4$.

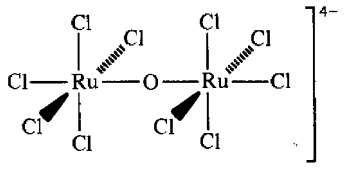
All attempts to prepare RuX_4 (X = Br, I) have given only the trihalides (see Section 45.9.6.1).

45.9.7.2 Pure anionic halides and related species

$K_2[RuF_6]$ can be prepared by the action of water on $K[RuF_6]$[2375] and has a trigonal structure.[2376] An alternative preparation, which gives a cubic structure, is to fuse $K_2[Ru(NO_2)_4OH(NO)]$ (or $RuCl_3$) with $K[HF_2]$ at 250°C.[2376,2377] Other alkali metal salts (Na^+, Rb^+, Cs^+) are available,[2378] and also rhombohedral $Ba[RuF_6]$ (from $RuCl_3$, $BaCl_2$, F_2 at 350°C)[2379] and $[NO]_2[RuF_6]$ (by prolonged reaction between $[NO][RuF_6]$ and an excess of NOF at 150°C).[2380] Magnetic data,[2381] IR[2382] and electronic spectral studies[2330,2383] have been published. The enthalpy of solution of $K_2[RuF_6]$ in water at 298 K has been measured and the single ion hydration enthalpy of gaseous $[RuF_6]^{2-}$ determined.[2384] Reaction of $[RuF_6]$ with PF_3 in anhydrous hydrogen fluoride gave polymeric $[RuF_4(PF_3)]_n$. The low magnetic susceptibility values (μ_{eff} = 1.81 BM per Ru at 293 K) probably arise from strong magnetic exchange in the solid state. Treatment of RuF_6 with AsF_3 gives the adduct $RuF_4 \cdot AsF_5$ formulated on the basis of IR evidence as $(RuF_3)_n^{n+}$ $(AsF_6)_n^{n-}$.[2385]

Earlier methods of preparation of $K_2[RuCl_6]$ include the oxidation of $K_2[RuCl_5(OH_2)]$ with Cl_2, reaction of $K_2[RuO_4]$ with cold dilute HCl, recrystallization of $K_4[Ru_2OCl_{10}]$ from concentrated HCl and the reduction of $[RuO_4]$ with concentrated HCl in the presence of KCl.[3] Unfortunately most of these methods produce some $K_4[Ru_2OCl_{10}]$ contaminant and, therefore, more elaborate preparations to obtain purer samples have been devised.[2360,2386] For example, reduction of $K_4[Ru_2OCl_{10}]$ to $K_2[RuCl_5(OH_2)]$ with ethanol and then oxidation by Cl_2 to $K_2[RuCl_6]$. Other alkali metal and organic cation salts are available. For example, '$RuCl_3 \cdot xH_2O$' and $[Et_4N]Cl$ in thionyl chloride gives $[Et_4N]_2[RuCl_6]$.[2387]

The potassium salt forms black crystals which have a cubic lattice and a Ru—Cl distance of 2.29(4) Å.[2388,2389a] Extensive magnetic measurements (μ_{eff} *ca.* 2.8 BM at room temperature), IR, Raman and electronic spectral studies have been published on the $[RuCl_6]^{2-}$ anion (see reference 3, p. 94 and references 2336b and 2389b for details), although much of the earlier work is suspect because of contamination by diamagnetic $K_4[Ru_2OCl_{10}]$. The results are consistent with a model in which both the spin-orbit coupling constants and the interelectronic coupling factors are close to their free-ion values, although the possibility of contributions from higher excited states cannot be ruled out.[2390] Similar results are obtained for the $[RuBr_6]^{2-}$ anion, prepared as its potassium salt, either by oxidation of concentrated aqueous solutions of $K_2[RuBr_5(OH_2)]$ with Br_2[2391] or by passing Br_2 through solutions of $K_2[RuCl_6]$, $K_3[RuCl_6]$, $K_2[RuCl_5(OH_2)]$, $K_4[Ru_2OCl_{10}]$ or $RuCl_3$ in hydrobromic acid.[2335]



The NQR spectrum of $K_2[RuCl_6]$ shows a single resonance frequency over the temperature range 77–298 K[2386] but on standing its aqueous solutions are slowly reduced and polarographic studies show this involves irreversible reduction to $[RuCl_5(OH_2)]^{2-}$ probably *via* $[RuCl_6]^{3-}$.[2360] The latter is formed directly by reaction of $[RuCl_6]^{2-}$ with H_2,[2332,2392] H·[2333] or Br^-[2393] and the kinetics of this process have been measured. Heating $K_2[RuCl_6]$ *in vacuo* gives $K_3[RuCl_6]$, α-$RuCl_3$ and Cl_2,[2394] and treatment of $Et_4N[RuCl_5(RCN)]$ with DMF affords the $[RuCl_5(DMF)]^-$ anion.[681]

The binuclear mixed valence anions $[Ru_2^{III,IV}X_9]^{2-}$ (X = Cl, Br) have been electrogenerated from $[Ru_2X_9]^{3-}$. Variable temperature magnetic measurements on analyte solutions of these 33 valence electron anions (μ_{eff} = 4.40 BM per molecule at 273 K for X = Br), indicate three unpaired electrons per molecule suggesting a spin quartet electronic ground state. Electrogeneration of the $[Ru_2^{IV,IV}X_9]^-$ anions is possible but compound instability makes quantitative magnetic measurements impossible.[2348] Observation of the intervalence charge transfer transition in the near IR spectrum of $[Ru_2Cl_9]^{2-}$ [but not $[Ru_2Cl_9]^{n-}$ (n = 3,1)] supports a spin-trapped description of the bonding.[1869]

No hexaiodoruthenates(IV) have been prepared

45.9.7.3 Oxo-, hydroxo- and aqua-halide complexes

$K_4[Ru_2OCl_{10}]$, originally formulated as $K_2[RuCl_5(OH)]$, can be made by the reaction of $[RuO_4]$, $K_2[RuO_4]$ or $RuO_2 \cdot xH_2O$ with potassium chloride dissolved in 5 M HCl. The rubidium and caesium salts are made by similar methods.[2395] Its formulation as a binuclear complex followed the observation that the complex was diamagnetic, and structure (**368**) with a linear Ru—O—Ru skeleton was subsequently confirmed by X-ray analysis.[2389a] A molecular orbital description of the bonding in (**368**) has been given, which accounts for both the diamagnetism and the short Ru—O bond lengths.[2396] Extensive electronic, resonance Raman and IR spectral measurements have been reported for this anion and various detailed assignments proposed.[2397,2398] Polarographic reduction of (**368**) leads to irreversible formation of $[RuCl_5(OH_2)]^{2-}$.[2399]

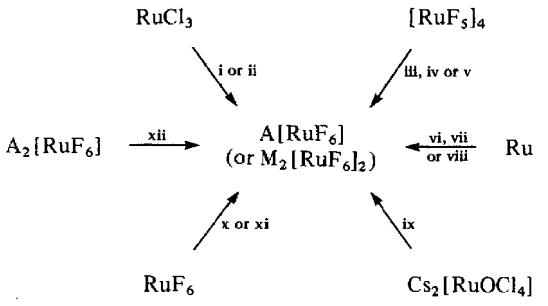
(368)

Black crystals of $K_4[Ru_2OBr_{10}]$ can be prepared from $[RuO_4]$, HBr and KBr and measurements of its IR, electronic and resonance Raman spectra suggest it is isostructural with $[Ru_2OCl_{10}]^{4-}$.[3] Hydrolysis of $[RuF_6]^{2-}$ in neutral or acid solution is reported to form the corresponding $[Ru_2OF_{10}]^{4-}$ anion. This will react with Cl^- to give $[Ru_2OCl_{10}]^{4-}$ which polymerizes to $[Ru_2Cl_2(OH)_2]_n$.[2400] Reaction of '$RuCl_3 \cdot xH_2O$' with Cl_2 is claimed to give $[Ru_2OCl_6]$ and $[Ru_2OCl_5]$[2285] (see Section 45.9.7.1).

Other studies on the Raman spectra of aqueous solutions of $K_4[Ru_2OCl_{10}]$ or $K_2[RuCl_6]$ indicate the presence of a range of aqua- or hydroxo-chloride species. These include $[Ru_2OCl_9(OH_2)]^{3-}$ (isolated by Crisp and Seddon[5]), $[Ru_2OCl_8(OH_2)_2]^{2-}$ and $[RuCl_4(OH)_2]^{2-}$ anions.[2401] In aqueous methanol solutions containing Ru^{IV} chlorides, $[Ru_2Cl_6(MeOH)(OH_2)(OH)_2]$ is claimed to be present.[2402] The preparation and properties of $[Ru_2OCl_6(NCR)_4]$ are discussed in references 1373 and 1374.

A number of publications have appeared on the effect of adding halide ions to solutions of Ru^{IV} in $HClO_4$. Although there is now general agreement as to the colour and electronic spectra of the various species formed, there has as yet been no hard identification of any of the chromophores. A range of formulations have been suggested which include monomers such as $[RuCl_4(OH)_2]^{2-}$, $[RuOCl_4]^{2-}$, $[RuCl_2(OH)_2(OH_2)_2]$, binuclear $[Ru_2OCl_9(OH_2)]^{3-}$, $[Ru_2OCl_8(OH_2)_2]^{2-}$, $[Ru_2O_2Cl_6(OH_2)_3]^{2-}$ and a variety of polynuclear species. For detailed references to this complicated area see reference 3, p. 108.

Finally, treatment of aged '$RuCl_3 \cdot xH_2O$' in 12 M HCl with $[Et_4N]Cl$ in the presence of a few drops of Hg produces a complex described as '$[Et_4N]_2[Ru_2Cl_7(OH)_3]$'. This may contain a Ru—O—Ru linkage.[681]



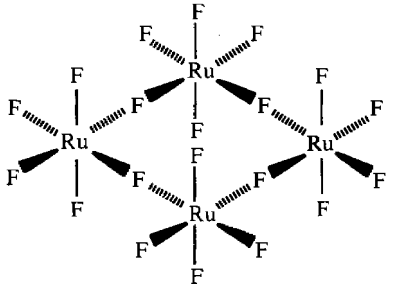
45.9.8 Ruthenium(V) Halides

The only ruthenium(V) halides reported are those containing fluoride. Green ruthenium(V) fluoride can be prepared by direct fluorination of the metal at 300°C,[2403] by reduction of $[RuF_6]$ with B_2O_3,[2404] BiF_3, SbF_3, Ru or H_2[2385] or by reaction of the metal and BrF_3. The latter method first generates $[BrF_2][RuF_6]$ which decomposes at 120°C *in vacuo* to give $[RuF_5]_4$ and BrF_3.[2375] The tetrameric structure (**369**) has been confirmed by X-ray analysis,[2405] but its mass spectrum[2403] indicates that the vapour consists of an equilibrium between monomer, dimer, trimer and tetramer units. Magnetic measurements reveal the presence of significant interactions between adjacent metal ions.[2406,2407] Mössbauer[2408] and IR[2409] spectral measurements are also available. Some of the reactions of $[RuF_5]_4$ are discussed below but further details are to be found in reference 3, p. 79.

The hexafluororuthenate(V) anion $[RuF_6]^-$ is readily prepared with a variety of cations such as alkali metals, alkaline earths, Ag^+, Tl^+, $[XeF]^+$, $[Xe_2F_3]^+$, $[O_2]^+$, $[NO]^+$, $[SF_3]^+$, $[BrF_2]^+$. Some of the synthetic routes are shown in Scheme 70. Measurements on this anion include various X-ray structural analyses, magnetic data (*ca.* 3.60 BM at room temperature), IR, Raman and diffuse reflectance spectra.[3] Interestingly, $XeF[RuF_6]$ can be oxidized by F_2 at 350°C to give $[XeF_5][RuF_6]$. X-Ray structures of both species have been determined and reveal significant interaction between the $[XeF_n]^+$ cation and $[RuF_6]^-$ anion, producing substantial distortion (particularly for $n = 1$), of the latter from regular octahedral geometry.[2418] All the $[RuF_6]^-$ metal salts are stable in dry air but in water dissolve to produce $[RuF_6]^{2-}$, O_2 and RuO_4. This is believed to be due to two competing reactions, a reduction and a disproportionation (equations 143 and 144).[2375]

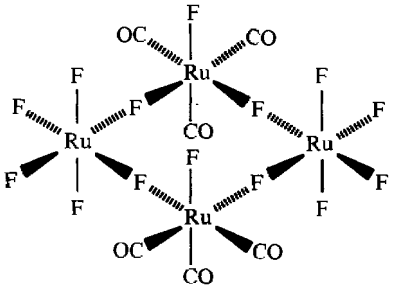
Reaction of XeF_2 and $[RuF_5]_4$ in 1:2 molar ratio yields $[XeF][Ru_2F_{11}]$.[2411,2412] The same binuclear anion is produced upon prolonged storage at room temperature of $O_2[RuF_6]$;[2419] $[KrF][Ru_2F_{11}]$ is also known.[2420]

The mixed Ru^{II}–Ru^{V} complex $[RuF_2(CO)_3 \cdot RuF_5]_2$ can be prepared by reaction of $[RuF_5]_4$ with CO in a flow system at 200°C or by heating $[Ru_3(CO)_{12}]$ with a large excess of XeF_2 at 100°C in $CFCl_2CF_2Cl$. A tetrameric structure (**370**) has been proposed on the basis of IR and magnetic



i, ACl, BrF_3 (A = Li, Na);[2410] ii, ACl, F_2 (A = K, Rb, Cs);[2379] iii, TlF, SeF_4 (A = Tl);[2375] iv, XeF_2, BrF_5 (A = XeF^+ or $Xe_2F_3^+$ depending on mole ratio of $[RuF_5]_4$ to XeF_2)[2411] or XeF_2(fuse) (A = XeF^+);[2412] v, SF_4, 108 °C (A = SF_3^+);[2413] vi, BrF_3, AX (AX = KBr, CsBr, AgBr) or $M[BrO_3]_2$ (M = Ca, Sr, Ba);[2375, 2379] vii, F_2/O_2, Δ, 300 °C (A = O_2^+);[2414] viii, KF, anhydrous HF (A = K);[2385] ix, F_2, 150 °C (A = Cs); x, H_2O (A = H_3O^+);[2415] xi, NO or NOF (A = NO^+);[2416] xii, F_2, 200–300 °C (A = Na, K, Rb, Cs)[2417]

Scheme 70



measurements. Further reaction of (**370**) with CO (100 atm/200 °C) gives the pale yellow $[RuF_2(CO)_3]_4$ (**363** and Section 45.9.5.1).[2294,2295]

$$4[RuF_6]^- + 6H_2O \longrightarrow 4[RuF_6]^{2-} + 4H_3O^+ + O_2 \quad (143)$$

$$4Ru^V \longrightarrow Ru^{VIII} + 3Ru^{IV} \quad (144)$$

(369)

(370)

45.9.9 Ruthenium(VI) Halides

Dark brown $[RuF_6]$ can be made by direct fluorination of the metal at elevated temperatures, the product being distilled rapidly out of the reaction zone or condensed at low temperature.[2385] $[RuF_5]_4$ which is much less volatile is also formed during the reaction. X-Ray powder patterns show the molecule to be isostructural with other platinum metal hexafluorides[2421,2422] and, together with the IR spectrum,[2423] suggest an octahedral structure. The solid is volatile at room temperature decomposing rapidly at 200 °C to give $[RuF_5]_4$ and F_2. It is also highly reactive and will attack Pyrex glass at room temperature.[2421] A recent paper describes the redox reactions of RuF_6 to produce species such as $[RuF_4(PF_3)]_n$ (with PF_3) $RuF_4 \cdot AsF_5$ (with AsF_3), $RuF_5 \cdot ClF_3$ (with ClF_3) and RuF_5 (using various reagents — see Section 45.9.8).[2385]

The compound originally formulated as $K_2[RuF_8]$[2312] has now been shown to be a mixture of $K[RuF_6]$ and $K[HF_2]$.[2375]

Ruthenium(VI) oxide tetrafluoride, $[RuOF_4]$, is reported to have been prepared by the action of a mixture of BrF_3 and Br_2 on ruthenium. The enthalpy and entropy of vaporization, X-ray powder pattern and magnetic properties (μ_{eff} = 2.91 BM at room temperature) have been measured.[2406] However more recently other workers also claim to have prepared $[RuOF_4]$ (by the fluorination of RuO_2 at 400–500 °C), but it shows different properties to the earlier product. Evidence for its formulation is based on mass spectroscopy (which shows the molecular ion $[RuOF_4]^+$), elemental analysis and IR spectrum (ν(Ru=O) = 1040 cm^{-1}). The solid is unstable, even at room temperature, decomposing to $[RuF_4]$ and O_2.[2000] A report on the physical and chemical properties of RuF_6 and $RuOF_4$ is available.[2424]

The diamagnetic, tetrachlorodioxoruthenate(VI) salts $A_2[RuO_2Cl_4]$ (A = Cs, Rb) can be prepared by treating $[RuO_4]$ with an excess of ACl in dilute HCl. Likewise, CsBr/HBr affords $Cs_2[RuO_2Br_4]$. Their IR spectra suggest they contain a *trans* RuO_2 unit.[65] $Cs_2[RuO_2Cl_4]$ reacts with F_2 at 150°C to give $Cs[RuF_6]$, with boiling 10 M HCl to give $Cs_2[RuCl_6]$, and with water to produce $[RuO_4]$ and RuO_2.[2455]

45.9.10 Ruthenium(VIII) Halides

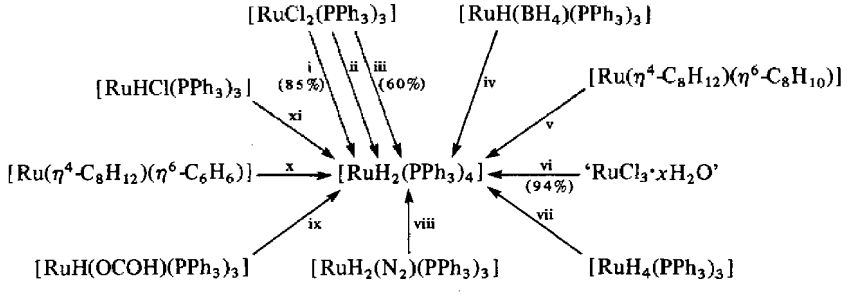
Several claims for the formation of $[RuF_8]$ by fluorination of Ru or RuO_2, have been published. It is a highly reactive yellow solid which exists only at low temperatures (or in the presence of an excess of fluorine), and is far more volatile than $[RuF_5]_4$.[2426]

45.10 HYDROGEN AND HYDRIDE LIGANDS

45.10.1 Ruthenium(0) Complexes

Apart from hydridoruthenium carbonyl cluster compounds (see Sections 45.10.3.3 and 45.10.4) the only Ru^0 hydride complexes are the deep brown $[RuH(NO)(PR_3)_3]$ (R_3 = Ph_3, Ph_2Me, Ph_2Pr^i, Ph_2Cy) which are fully discussed in Section 45.5.1.2.

45.10.2 Ruthenium(I) Complexes



The only hydrido complex containing a formally Ru^I centre is the diamagnetic, air-sensitive $[Ru_2H(OH)(PMe_3)_6]$, obtained by heating $[Ru_2(\mu\text{-}CH_2)_3(PMe_3)_6]$ at 60°C in light petroleum or THF with an excess of water. On the basis of ^{31}P, ^{13}C and ^1H NMR spectra, structure (**142**) (see Section 45.5.3.2) is proposed.[1521]

45.10.3 Mononuclear Ruthenium(II) Complexes

45.10.3.1 Dihydrido complexes

(i) $[RuH_2L_xL'_{4-x}]$ (L = L' = P donor ligand, x = 4,3,2), $[RuH_2(L—L)_2]$ and related species

The yellow compound $[RuH_2(PPh_3)_4]$ was first prepared in 24% yield by the reduction of $RuCl_3$ or $[Ru(acac)_3]$ with $AlEt_3$ in the presence of PPh_3.[1870] Some higher yield routes to this complex are shown in Scheme 71. An X-ray analysis shows a distorted octahedral configuration with essentially *cis* hydride ligands,[2434] and in solution facile dissociation occurs to give free PPh_3 and $[RuH_2(PPh_3)_3]$.[1838,1870] A compound of the latter formula can be isolated by successive addition of '$RuCl_3 \cdot xH_2O$' and $Na[BH_4]$ to hot ethanolic PPh_3 (three moles/mole Ru).[2427] As discussed elsewhere (Section 45.10.3.1.ii), these $[RuH_2(PPh_3)_n]$ complexes exhibit a range of interesting reactions.

i, $Na[BH_4]$, PPh_3, H_2, $MeOH/C_6H_6$;[1408] ii, $Na[BH_4]$, PPh_3, $MeOH/C_6H_6$;[1408, 2427–2429] iii, $Li[NMe_2]$ (2 equiv.);[2430] iv, PPh_3, $EtOH/\Delta$;[2431] v, PPh_3, H_2, THF;[2432] vi, $Na[BH_4]$, PPh_3, $EtOH/\Delta$;[1402, 2427] vii, PPh_3;[1549, 2429, 2433] viii, PPh_3;[2428, 2429, 2433] ix, PPh_3;[1811, 2433] x, $PPh_3/h\nu$;[2434] xi, KOH/Bu^tOH[1767]

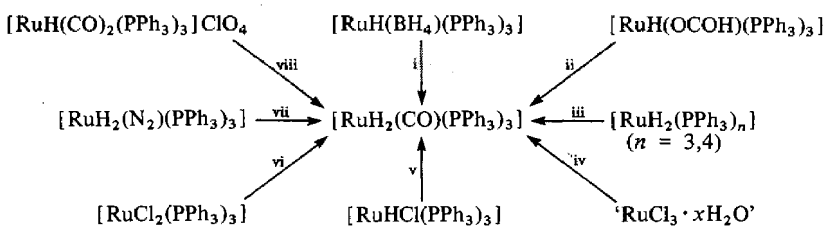
Scheme 71

Similar routes to those shown in Scheme 71 can be used to prepare other $[RuH_2L_4]$ complexes. For example, method (v) works well for L = $PMePh_2$, PMe_2Ph and $P(OMe)_3$,[2432] and method (vi) is excellent for the preparation of various tertiary phosphine and phosphite complexes.[1570,2435] The reaction of $[Ru_2Cl_3(PMePh_2)_6]Cl$ with hydrazine, $PMePh_2$ and H_2 under pressure[2436] or with KOH in isopropanol[1752] affords $[RuH_2(PMePh_2)_4]$ which is also produced by treatment of $[RuH(PMePh_2)_4(MeOH)]PF_6$ with H_2.[1766] $[RuH_2(PMe_3)_4]$ can be prepared by reduction of either $[Ru_2(OCOMe)_4Cl]$ or $[Ru_3O(OCOMe)_6(H_2O)_3]OCOMe$ with Na/Hg in THF under H_2 (3 atm) in the presence of PMe_3,[1521] or from *cis*-$[RuClMe(PMe_3)_4]$ and $LiAlH_4$ or NaOMe,[16a] whereas $[RuH_2(PHPh_2)_4]$ is prepared by reaction of *cis*- or *trans*-$[RuCl_2(PHPh_2)_4]$ with an excess of LiOMe in boiling MeOH.[111]

The majority of these $[RuH_2L_4]$ complexes adopt the *cis* configuration in the solid state, although *cis–trans* mixtures are sometimes observed in solution,[2437,2438] and crystals of *trans*-$[RuCl_2(P(OEt)_2Ph)_4]$ can be grown.[2439] Some of these compounds (but not for PMe_3) are stereochemically non-rigid in solution, undergoing intramolecular ligand exchange which can be monitored by ^1H and ^{31}P NMR spectroscopy.[2436,2437] The tertiary phosphines (except for PMe_3), unlike the phosphite complexes, readily lose a PR_3 group on heating and hence provide a ready synthesis of $[RuH_2YL_3]$ compounds (*e.g.* L = $PMePh_2$, Y = CO, PhCN;[2435,2436] see Section 45.10.3.1.ii for more examples).

The PF_3 complex *cis*-$[RuH_2(PF_3)_4]$ is obtained in high yield from the reaction of PF_3 (400 atm) and H_2 (120 atm) with anhydrous $RuCl_3$ and Cu powder at 250°C for 20 h. Reaction with Et_3N generates the monoanion $[RuH(PF_3)_4]^-$, which is stereochemically non-rigid,[1384] and with K/Hg, $K_2[Ru(PF_3)_4]$ is formed.[1381b] The mixed fluorophosphine/PPh_3 complexes $[RuH_2L(PPh_3)_3]$, $[RuH_2L_2(PPh_3)_2]$ {L = PF_3, $PF_2(NMe_2)$} and $[RuH_2(PF_3)(PF_3NMe_2)(PPh_3)_2]$ are also reported.[2440] Reaction of $[RuH_2(PPh_3)_4]$ with dppm gives $[RuH_2(dppm)(PPh_3)_2]$.[1399]

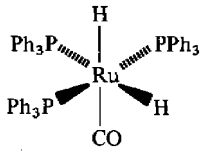
Reduction of *trans*-$[RuHCl(L–L)_2]$ (see Section 45.10.3.2.i) with an excess of $LiAlH_4$ gives $[RuH_2(L–L)_2]$ (L–L = depe, *o*-$C_6H_4(PEt_2)_2$) which were initially formulated as *trans* isomers.[1591c] However, the ^1H NMR spectrum for the depe compound indicates a *cis* configuration[2437] and this is supported by the X-ray analysis of *cis*-$[RuH_2(dppe)_2]$,[2432] made by method (v), Scheme 71. Other routes to these types of compound are by displacement of 2-naphthyl by H_2 (or D_2) from *cis*-$[RuH(2\text{-np})(dmpe)_2]$,[1388] treatment of $[RuH(L–L)_2]^+$ (L–L = dppe, dppp, dppb) with H_2, deprotonation of $[RuH_3(dppp)_2]PF_6$ with Et_3N,[1766] or reaction of [Ru(cod)(cot)] with dppe or dppm under H_2.[1398,1399]



Finally rare examples of polydentate P donor ligand complexes containing two hydrido groups are *cis*-$[RuH_2\{P(OMe)_3\}(ttp)]$ and *trans*-$[RuH_2(PPh_3)(ttp)]$ (ttp = $PhP(CH_2CH_2CH_2PPh_2)_2$), prepared by reaction of $[RuH(BH_4)(ttp)]$ (Section 45.10.3.2.i) with the appropriate P donor ligand and Et_3N in THF.[1486,2441]

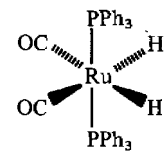
(ii) *$[RuH_2Y_xL_{4-x}]$ (L = P donor ligand, Y = C, N or O donor ligand; x = 1,2,3,4)*

Reaction of $[RuHCl(PPh_3)_3]$ with $AlEt_3$ in ether in a N_2 atmosphere,[1549,2428,2442] reverse osmosis of $[RuH_2(PPh_3)_4]$ under N_2 pressure[1838] or treatment of $[RuH(OCOH)(PPh_3)_3]$ with N_2[1811,2433] affords the dinitrogen compound $[RuH_2(N_2)(PPh_3)_3]$ as an air-sensitive white solid (ν_{NN} = 2147 cm^{-1}). The $P(p\text{-Tol})_3$ analogue is obtained by borohydride reduction of $[RuCl_2\{P(p\text{-Tol})_3\}_3]$ under N_2.[1599,2428] The N_2 group is readily displaced by various Lewis bases to give $[RuH_2Y(PPh_3)_3]$ (Y = PPh_3, CO, PhCN, NH_3, $N_2B_{10}H_8SMe_2$) and by H_2 to form $[RuH_4(PPh_3)_3]$[2428] (see Section 45.10.5); treatment of the latter with N_2 regenerates $[RuH_2N_2(PPh_3)_3]$ and with CO, and RCN, $[RuH_2CO(PPh_3)_3]$ and $[RuH_2(RCN)(PPh_3)_3]$ (R = Me, Ph) respectively are formed.[1408] Interestingly, IR and NMR evidence indicates that N_2 has a much greater affinity than 2-pentene for $[RuH_2(PPh_3)_3]$.[2443] X-Ray analysis reveals that $[RuH_2(N_2B_{10}H_8SMe_2)(PPh_3)_3]\cdot 3C_6H_6$ has a linear RuNNR linkage with *cis* hydrides, *trans* PPh_3 groups.[2444] Some other routes to the white $[RuH_2CO(PPh_3)_3]$ (**371**) are shown in Scheme 72. Similarly $[RuH_2CO(PMePh_2)_3]$ is obtained by reaction of $[RuH_2(PMePh_2)_4]$ with CO,[2435,2436] treatment of $[RuH(\eta^2\text{-}BH_4)(PMePh_2)_3]$ with CO in the presence of Et_3N or heating $[Ru_2Cl_3(PMePh_2)_6]Cl$ with ethanolic KOH.[1752] Reaction of the 'RuCOCl' solution with $PEtPh_2$ and a large excess of $Na[BH_4]$ or $Na[BH_3CN]$ affords $[RuH_2CO(PEtPh_2)_3]$.[2431]



Other compounds of type $[RuH_2YL_3]$ are $[RuH_2(CO)(PPh_3)(L–L)]$ (L–L = $Ph_2P(CH_2)_nPPh_2$ (*n* = 1–4), $Ph_2P(CH_2)_2AsPh_2$, 1,2-$(Ph_2P)_2C_6H_4$),[1786] $[RuH_2CO(ttp)]$,[2441] $[RuH_2(PPh_3)_3(\eta^2\text{-}C_5H_{10})]$,[2446] $[RuH_2(PPh_3)_3THF]$ (from $[RuCl_2(PPh_3)_3]$ and Na/Hg or Mg/Hg in THF),[1404] and $[RuH_2(RNCHCHNR)(PPh_3)_n]$ (*n* = 2,3; R = Ph, $CHMe_2$, CMe_3, 4-MeO-Ph) which are believed to contain monodentate diazadiene ligands in some instances.[2447]

The dicarbonyl complexes $[RuH_2(CO)_2(PPh_3)_2]$ (**372**) can be synthesized by treatment of [Ru-



i, EtOH/Δ;[2431] ii, CO;[1811,2433] iii, HCHO;[1767,2427] iv, PPh_3, HCHO/KOH(Δ);[1410a] v, NaOMe/MeOH;[1767] vi, H_2, Et_3N, ROH;[2445] vii, EtOH;[2445] viii, ^-OEt[1467]

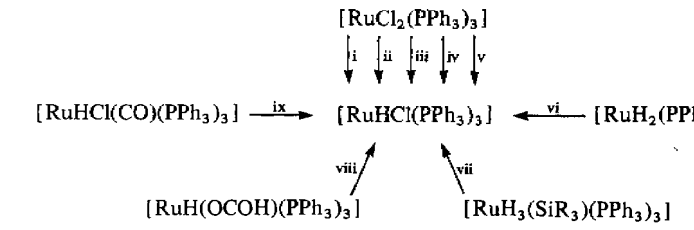
Scheme 72

(371)

(372)

$(CO)_3(PPh_3)_2$] with H_2 under pressure[1452] or [$Ru(CO)_2(PPh_3)_3$] with H_2 (1 atm).[1469] Other methods involve the reaction of the thermally unstable [$RuH_2(CO)_4$] with L (either PEt_3 or PPh_3) and treatment of [$RuCl_2(CO)_2L_2$] with $LiAlH_4$.[78a] The latter method can also be used to prepare [$RuH_2(CO)_2$(dppe)] and reaction of the 'RuCOCl' solution with 5-phenyl-5*H*-dibenzophosphole (DBP) and $Na[BH_4]$ yields [$RuH_2(CO)_2(DBP)_2$].[2431] Evidence for the existence of a hydrido–tricarbonyl complex has been presented; at high pressures [$RuH_2(CO)_3PPh_3$] is in reversible equilibrium with [$Ru(CO)_4(PPh_3$] and H_2.[2448]

Other [$RuH_2Y_2L_2$] complexes are [RuH_2(bipy)$(PPh_3)_2$] (from [$RuH_2(PPh_3)_4$] and bipy), [$RuH_2\{C_6H_4(CN)_2\}(PPh_3)_3$],[1706] [$RuH_2(CNBu^t)_2(PMe_3)_2$] (from [$RuMe_2(PMe_3)_4$] and $CNBu^t$ in THF),[2444] and [RuH_2(MeCN)$(PPh_3)_3$].[1404]



Finally, information on the preparation, Raman, IR, ^1H, ^{13}C NMR spectra and reactions of [$RuH_2(CO)_4$] is given in references 78a, 2448 and 2450 and references to dihydridoruthenium carbonyl cluster compounds are cited in Sections 45.10.3.3 and 45.10.4.

45.10.3.2 Monohydrido complexes

(i) [RuHXL$_n$], [RuHX(L–L)$_2$] (n = 3,4; L = P, As donor ligand; X = halide, alkyl, aryl, BH$_4$, OCOR) and related species

Treatment of [$RuCl_2(PPh_3)_3$] in C_6H_6/EtOH with H_2 for several days gives violet–black crystals of [$RuHCl(PPh_3)_3$]. This compound is also formed if the reaction is carried out under H_2 pressure (100 atm; 12 h) or in pure C_6H_6 in the presence of an organic base.[2445,2451] Other routes to this reactive material are shown in Scheme 73. In method (viii), use of HX or MeI gives the corresponding [$RuHX(PPh_3)_3$] (X = Br, I)[1437,1811,2433] and [$RuH_2(PPh_3)_4$] with EtBr and I_2 respectively also affords these complexes.[1870] A single crystal X-ray analysis of [$RuHCl(PPh_3)_3$]·C_6H_6 reveals a highly distorted trigonal bipyramid with the two axial PPh_3 groups being bent away from the perpendicular position to accommodate the equatorial PPh_3 group.[2454] Another compound of empirical formula 'RuHCl$(PPh_3)_3$' results from treatment of [$RuH_2(PPh_3)_4$] in C_6H_6 with 1,4-$Cl_2Si_4Ph_8$ in the presence of excess Et_3N. However, this is a red dimeric compound with different physical and spectroscopic properties from purple [$RuHCl(PPh_3)_3$]·C_6H_6.[2455] Other monomeric [$RuHClL_3$] complexes [L = $AsPh_3$,[2431] $AsMePh_2$,[1511] $PPh_2(C_6H_4SO_3H)$,[1563,2456] P(2-py)$_3$,[1821] dmppl;[1566,1567] L_3 = triphos, tet-1[1539,1540]) are available.

Several compounds of type [$RuHXL_4$] are known. For example, *trans*-[$RuHX(PHPh_2)_4$] (X = Cl, Br, I, SCN) are made by reaction of *cis*-[$RuH_2(PHPh_2)_4$] with NaX. The chloro compound is also prepared as shown in equation (145); it reacts with $SnCl_2$ to give *trans*-[$RuH(SnCl_3)(PHPh_2)_4$].[111] Low yield routes to *cis*-[$RuHCl(PMe_3)_4$] are shown in equation (146), but high yield routes have been reported, namely by dropwise addition of one equivalent of HCl to an etherial solution of

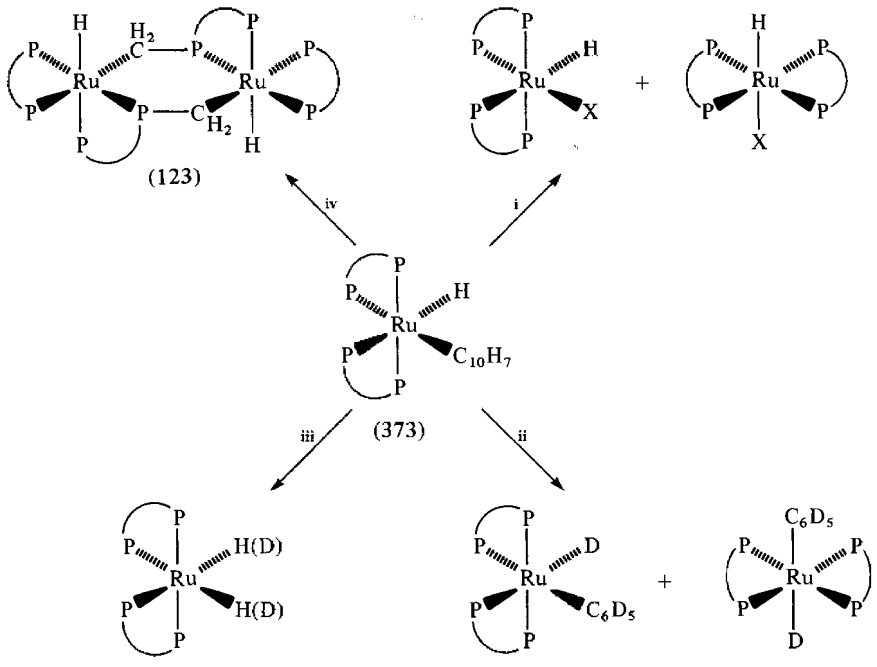
i, $Na[BH_4]$, C_6H_6/H_2O (Δ);[2445] ii, R_3SiH (R = Me, Et);[82] iii, $Li[NMe_2]$ (1:1 mole ratio)/THF;[2430] iv, Et_3SiH, PPh_3, Et_3N in C_6H_6;[83] v, RCH_2OH;[2452,2453] vi, $CHCl_3$;[2430] vii, $CDCl_3$;[84] viii, HCl;[1811,2433] ix, $h\nu$ (366 nm)[1456]

Scheme 73

cis-$[RuH_2(PMe_3)_4]$ at $-78°C$ or by reaction of *cis*-$[RuClMe(PMe_3)_4]$ with one equivalent of either $Li[BH_4]$ or $LiAlH(OMe)_3$.[16a]

Bidentate P and As donor ligand monohydrido complexes *trans*-$[RuHCl(L–L)_2]$ were first prepared by reduction of *cis*-$[RuCl_2(L–L)_2]$ with an excess of $Li[AlH_4]$ in THF (L–L = diars, dmpe, depe, dppm, *o*-$C_6H_4(PEt_2)_2$).[1591] More recently, *trans*-$[RuHCl(Ph_2P(CH_2)_nPPh_2)_2]$ (n = 2–4) and $[RuHCl(diop)_2]$ were synthesized by exchange of the appropriate L–L with $[RuHCl(PPh_3)_3]$. Reaction of $[RuHCl(PPh_3)_3]$ with $Ph_2As(CH_2)_2AsPh_2$ gives $[RuHCl(Ph_2As(CH_2)_2AsPh_2)_2]$ but $Ph_2As(CH_2)AsPh_2$ yields $[RuHCl(PPh_3)_2(Ph_2As(CH_2)AsPh_2)]$.[1846] Equation (147) shows another route to this type of complex. Although both ^1H and ^{31}P NMR studies on $[RuHCl(diop)_2]$ show inequivalent P atoms characteristic of a *cis* configuration, X-ray analysis reveals a distorted octahedron with H *trans* to Cl.[2457] This compound is also an active alkene hydrogenation catalyst.[2458] Treatment of $[Ru(dppe)_2(styrene)]$ with $P(OPh)_3$ (or $P(OMe)_3$ at higher temperatures) gives $[RuH\{P(O)(OR)_2\}(dppe)_2]$ (R = Me, Ph).[1392]

$$\text{*cis*- or *trans*-}[RuCl_2(PHPh_2)_4] \xrightarrow{LiOMe} \text{*trans*-}[RuHCl(PHPh_2)_4] \quad (145)$$
$$\text{*cis*-}[RuCl_2(PHPh_2)_4] \xrightarrow{H_2/Et_3N}$$



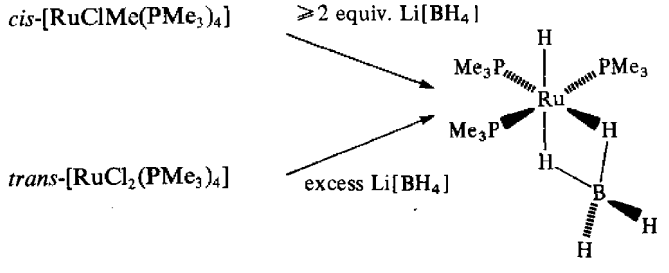
$$\text{*trans*-}[RuCl_2(PMe_3)_4] \xrightarrow[THF]{Na/Hg} \text{*cis*-}[RuHCl(PMe_3)_4]^{1529} \quad (146)$$
$$[Ru_2(OCOMe)_4Cl] \xrightarrow[\text{excess } PMe_3]{MgEt_2}$$

$$[RuCl_2(PPh_3)_3] + L–L \xrightarrow[\text{2-methoxyethanol}]{Et_3N,\ H_2} [RuHCl(L–L)_2] \quad (147)$$
$$(L–L = dppp,\ Ph_2P\{CH_2\}_3PMePh,\ Ph_2P\{CH_2\}_3PMe_2)^{1536}$$

$$\text{*cis*-}[RuH(2\text{-}C_{10}H_7)(dmpe)_2] \rightleftharpoons [Ru(C_{10}H_8)(dmpe)_2] \quad (148)$$

The corresponding hydrido/alkyl (and aryl) complexes *cis*-$[RuHR(L–L)_2]$ (L–L = dppe, dppm, dmpe; R = Me, Et, Ph) are readily prepared from *cis*-$[RuClR(L–L)_2]$ and $Li[AlH_4]$[1659] whereas treatment of *cis*- or *trans*-$[RuCl_2(dmpe)_2]$ with arene radical anions affords *cis*-$[RuH(\eta^1\text{-aryl})(dmpe)_2]$ (aryl = phenyl, 2-naphthyl, anthryl, phenanthryl).[1389] In solution, these compounds are in tautomeric equilibria with significant concentrations of Ru^0 complexes (*e.g.* equation 148) although X-ray analysis for aryl = 2-naphthyl confirms the presence of the six-coordinate Ru^{II} species (**373**) in the solid state.[2459] Some reactions of (**373**) with various substrates to produce other hydrido complexes are shown in Scheme 74.[44,2460a] Note that the compound of empirical formula ['$Ru(dmpe)_2$'] obtained by pyrolysis of $[RuH(2\text{-np})(dmpe)_2]$ (reaction (iv); Scheme 74) is a binuclear Ru^{II} hydrido complex, resulting from intermolecular oxidative addition of methyl groups to ruthenium.[1390]

Reaction of *cis*-$[RuClMe(PMe_3)_4]$ with excess NaOMe in THF affords *cis*-$[RuHMe(PMe_3)_4]$ which is also obtained by methylation of *cis*-$[RuHCl(PMe_3)_4]$ with MeMgCl.[16a] Higher homologues such as *cis*-$[RuHR(PMe_3)_4]$ (R = Et, Pr^n) can be prepared from *trans*-$[RuCl_2(PMe_3)_4]$ and excess MgR_2 in THF.[1393] The reaction of $[RuHCl(PPh_3)_3]$ with LiMe in diethyl ether also affords alkyl derivatives but the product is dependent on the Li:Ru ratio used. Thus, with a small excess of LiMe,

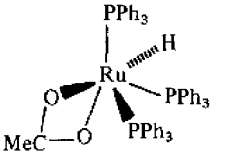


i, HX (X = CN, CH_2CN, CH_2OMe, C_6H_4CN); ii, C_6D_6, 60 °C; iii, $H_2(D_2)$; iv, Δ

Scheme 74

yellow $[RuHMe(PPh_3)_2(Et_2O)_2]$ contaminated with some LiCl is formed; a large excess of LiMe gives $[RuHMe(PPh_3)_2(LiMeOEt_2)_2]$. These complexes are extremely reactive *e.g.* dissolution in THF and warming gives methane and $[RuH(C_6H_4PPh_2)(PPh_3)(THF)_2]$.[1689]

The preparation of hydrido complexes by means of $[BH_4]^-$ may involve Ru—BH_4 intermediates and in some cases these can be isolated. Thus reaction of '$RuCl_3 \cdot xH_2O$', $[RuCl_2(PPh_3)_3]$ or the 'reduced ruthenium blue' with $Na[BH_4]$ in the presence of a large excess of PPh_3 gives $[RuH(BH_4)(PPh_3)_3]$.[2431] Treatment of $[RuCl_2(ttp)]_x$ with excess $Na[BH_4]$ in boiling THF gives $[RuH(\eta^2\text{-}BH_4)ttp]$ which at ambient temperature shows discrete ^1H NMR signals for the Ru—H, each of the two bridging protons and the two terminal BH's. Variable temperature studies indicate scrambling of the BH_4^- protons at two different temperatures which is interpreted as a two-step process. The latter compound in the presence of Et_3N catalyses the hydrogenation of 1-octene to octane at rates comparable to that with $[RhCl(PPh_3)_3]$.[2441] The active hydrogenation catalyst $[RuH(\eta^2\text{-}BH_4)(PMePh_2)_2]$ is synthesized from *fac*-$[Ru(MeCN)_3(PMePh_2)_3](BF_4)_2$ and $Na[BH_4]$[1752] and $[RuH(\eta^2\text{-}BH_4)(PMe_3)_3]$ is also known (equation 149). X-Ray analysis of the latter confirms the *mer* octahedral configuration (**374**).[16a] The analogous *mer*-$[RuH(\eta^2\text{-}BH_4)(PMe_2Ph)_3]$ has been prepared by treatment of *mer*-$[RuCl_3(PMe_2Ph)_3]$ with $NaBH_4$ in EtOH at 25°C.[2460b]



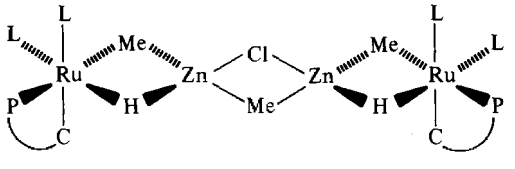
(149)

(374)

A suspension of $[RuCl_2(PPh_3)_3]$ in boiling MeOH containing the sodium salt of a carboxylic acid is reduced by H_2 or sodium hypophosphite to give the yellow $[RuH(OCOR)(PPh_3)_3]$ (R = Me, CH_2Cl, CF_3, Et, Pr, Pr^i, Ph *etc.*),[1451,2461] shown by X-ray analysis (R = Me)[2462] to have the distorted octahedral structure (**375**) which is retained in solution.[2463] A more rapid preparation of these active

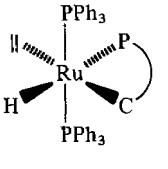
homogeneous catalysts for hydrogenation of 1-alkenes is by treatment of $[RuH_2(PPh_3)_4]$ with the appropriate RCO_2H in boiling 2-methoxyethanol or by rapid successive addition of '$RuCl_3 \cdot xH_2O$', RCO_2H and KOH to a solution of PPh_3 in boiling EtOH;[1781] the latter method can be used to give $[RuH(OCOMe)(Ph_2PPhSO_3H\text{-}m)_3]$.[1563] Carbon dioxide reacts readily with $[RuH_2(PPh_3)_4]$, $[RuH_4(PPh_3)_3]$ or $[RuH_2(N_2)(PPh_3)_3]$ in aromatic solvents to give the formato complex $[RuH(OCOH)(PPh_3)_3]$[1437,1811,2433] whereas $[RuH_2(PPh_3)_4]$ and CO_2 in ROH produce $[RuH(O_2COR)(PPh_3)_3]$[1791] and in $NHMe_2$/EtOH, the carbamato complex $[RuH(O_2CNMe_2)(PPh_3)_3]$ is formed.[1792]

(375)



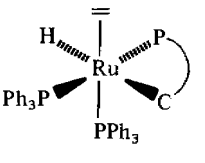
Reaction of $[RuH_2(PPh_3)_4]$ and dicarboxylic or α-hydroxy acids in boiling isopropanol yields $[RuH(OCOCH_2OCOH)(PPh_3)_3]$, $[RuH(OCOH(OH)R)(PPh_3)_3]$ and the dimeric complexes $[\{RuH(PPh_3)_3\}_2(OCO(CH_2)_nOCO)]$ ($n = 2$–4);[2464] with five-membered cyclic dicarboxylic anhydrides such as phthalic anhydride, C—O bond cleavage occurs to give $[RuH(o\text{-}OCOC_6H_4CHO)(PPh_3)_3]$.[2465]

Displacement of PPh_3 groups from $[RuH(OCOR)(PPh_3)_3]$ is also possible. Thus $[RuH(OCOMe)(PPh_3)_nL_{3-n}]$ ($n = 0$–3; L = $P(OMe)_3$, $P(OCH_2)_3CMe$, PF_2NMe_2, Bu^tNC, ½dppe — not all combinations) are reported[1386] and $[RuH(OCOMe)(Ph_2P(CH_2)_nPPh_2)_2]$ ($n = 2,3$) is mentioned.[1594] The complex $[RuH(OCOCF_3)(PF_3)_2(PPh_3)_2]$ can be prepared by reaction of $[RuH_2(PF_3)_2(PPh_3)_2]$ with CF_3CO_2H.[1576]

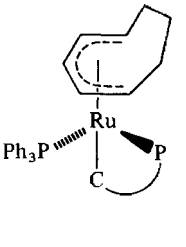


(*ii*) *Cyclometallated complexes*

Cyclometallation is defined in Section 45.5.4.5.v where some examples of complexes which do not contain Ru—H bonds are given. The majority of *ortho*-metallated ruthenium tertiary phosphine complexes are also monohydrides. For example reaction of $[RuHCl(PPh_3)_3]$ with LiR (R = Me, Me_3SiCH_2) in ethers at ambient temperature produces $[RuH(C_6H_4PPh_2)(PPh_3)_2S]$ (S = Et_2O, THF) which are formed by loss of CH_4 or $SiMe_4$ from $[RuHR(PPh_3)_2S_2]$. By use of an excess of LiMe, $ZnMe_2$ or $MgMe_2$ in Et_2O, yellow crystalline compounds containing Li, Mg or Zn as well as *ortho*-metallated PPh_3 ligands are obtained *e.g.* (**376**).[1690]



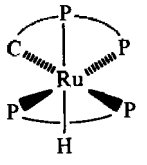
Treatment of $[RuH(C_6H_4PPh_2)(PPh_3)_2Et_2O]$, $[RuH_2(PPh_3)_4]$ or $[RuH_4(PPh_3)_3]$ with C_2H_4 gives a white solid of empirical formula $[Ru(PPh_3)_3C_2H_4]$ which converts to a pale orange isomer on heating. Initially these were formulated as Ru^0 complexes[2466] but further studies reveal that they are the Ru^{II} *ortho*-metallated species (**377**) and (**378**) respectively. An analogous reaction with cod gives (**379**) and a mechanism of formation involving Ru^{II} hydrido intermediates is proposed.[1402] Reduction of $[RuCl_2(PPh_3)_n]$ ($n = 3$ or **4**) with Na/Hg or Mg/Hg in MeCN/THF gives $[RuH(C_6H_4PPh_2)(MeCN)(PPh_3)_2]$ whereas reduction in THF/py affords a mixture of two isomers of the corresponding $[RuH(C_6H_4PPh_2)(py)(PPh_3)_2]$; in the presence of 2,2′-bipy, the dark red $[RuH(C_6H_4PPh_2)(bipy)(PPh_3)]$ is produced.[1404]



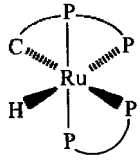
(376) L = PPh_3

(377)

(378)

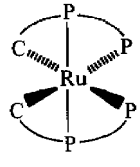


(379)

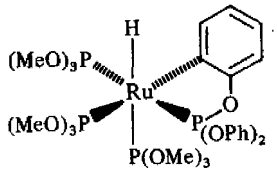


Electrochemical reduction of $[RuCl(dppp)_2]PF_6$ affords unstable anionic complexes which rapidly internally metallate to give $[RuH(C_6H_4P(Ph)(CH_2)_3PPh_2)(dppp)]$.[1509a] Direct synthesis of this complex is achieved by reaction of $[Ru(styrene)_2(PPh_3)_2]$ with dppp and $[RuH(C_6H_4P(Ph)(CH_2)_2PPh_2)(dppe)]$ (two isomers) is formed by treating $[Ru(styrene)(dppe)_2]$ with toluene. Hot toluene gives (**380**) whereas at room temperature isomer (**381**) is isolated. On standing for three days at room temperature, the dimetallated complex (**382**) can be isolated.[1392]

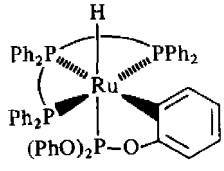
Other cyclometallated tertiary phosphine complexes include $K[RuH_2(C_6H_4PPh_2)(PPh_3)_2]\cdot C_{10}H_8\cdot Et_2O$ (formed by reaction of $[RuHCl(PPh_3)_3]$ with potassium naphthalide in THF at $-80°C$),[2467] $[RuH(C_6H_4PPh_2)(CO)(PPh_3)_2]$ (from thermal decarboxylation of $[Ru(o\text{-}Tol)(OCOH)CO(PPh_3)_2]$,[1487] $[RuH(\eta^2\text{-}Me_2PCH_2)(PMe_3)_3]$ (see Section 45.5.1.1) and 'Ru(dmpe)$_2$' (see reaction (iv), Scheme 74 in Section 45.10.3.2.i). Reaction of *trans*-$[RuCl_2(PMe_3)_4]$ with Na/Hg in the presence of PPh_3 gives *fac*-$[RuH(C_6H_4PPh_2)(PMe_3)_3]$ which reacts with MeI and CS_2 to give *mer*-$[RuI(C_6H_4PPh_2)(PMe_3)_3]$ and *fac*-$[Ru(SCHS)(C_6H_4PPh_2)(PMe_3)_3]$ respectively.[1391c] Several *ortho*-metallated tertiary phosphite ruthenium hydrides have been characterized. For example treatment of $[Ru(CO)_2\{P(OMe)_3\}_3]$ with $P(OPh)_3$ produces (**383**)[1380] and likewise reaction of $[RuH(\eta^2\text{-}BH_4)ttp]$ with $P(OPh)_3$ yields the *ortho* metallated complex (**384**) even at room temperature.[2441] In boiling C_6H_6, $[RuH_2(CO)(PPh_3)_3]$ and $P(OPh)_3$ affords $[RuH\{(C_6H_4O)P(OPh)_2\}CO(PPh_3)P(OPh)_3]$ whereas more forcing conditions also produce some $[RuH\{(C_6H_4O)P(OPh)_2\}CO\{P(OPh)_3\}_2]$.[1685]



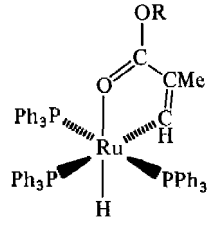
The compound $[RuH_2(PPh_3)_4]$ will cleave the vinyl CH bonds of neat alkylmethacrylates to give the five-membered metallacyclic complex (**385**), confirmed by an X-ray analysis of the *n*-butyl derivative.[2468]



(380)



(381)



(382)

(383)

(384)

(385)

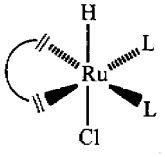
(iii) [RuHXY$_x$L$_{4-x}$] (L = P or As donor ligand, X = halide, OCOR, NO$_3$, dike, BF$_4$, dithioacid; Y = CO and/or CNR; x = 1,2)

Many hydrido–carbonyl complexes of ruthenium are obtained by decarbonylation of oxygen containing solvents (commonly alcohols). Thus Ru^{III} halides react with EPh_3 in high boiling point alcohols such as 2-methoxyethanol or ethylene glycol to give $[RuHX(CO)(EPh_3)_3]$ (E = P, As; X = Cl, Br).[2469] Later papers reporting the preparation of these complexes include HCHO in the recipe.[1410b,1841a] Ruthenium tertiary phosphine halide compounds also react with alcohols, particularly in the presence of base to give stable hydrido–carbonyl complexes (equation 150).[1584,1614b] The strong *trans* labilizing effect of the hydride ligand in $[RuHCl(CO)(PR_3)_3]$ can then be used to effect substitution with various P and As donor ligands (L) to form $[RuHCl(CO)(PR_3)_2L]$ (often in equilibrium with starting material).[1581,1685,2470,2471] The corresponding $[RuHCl(CS)(PPh_3)_3]$ is prepared by reaction of $[RuCl(OCOH)CS(PPh_3)_2]$ (Section 45.5.4.7.vi) with PPh_3.[1645]

$$[Ru_2Cl_3(PR_3)_6]Cl \xrightarrow[\Delta]{KOH/EtOH} [RuHCl(CO)(PR_3)_3] \qquad (150)$$

Decarbonylation of 2-methoxyethanol provides the CO ligands for formation of the five-coordinate bulky phosphine complexes $[RuHCl(CO)L_2]$ (L = PCy_3,[2472] PBu^t_2R (R = Me, Et)[1712]). These compounds readily take up CO to give $[RuHCl(CO)_2L_2]$ (L = PCy_3,[1813] PBu^t_2R[1712]) with *trans* L and

cis CO ligands. Treatment of *cis*-$[RuCl_2(CO)_2(PBu^tPr^n_2)_2]$ with 2-methoxyethanol/KOH yields $[RuHCl(CO)_2(PBu^tPr^n_2)_2]$[1519] and $[RuHCl(PPh_3)_3]$ and CO affords $[RuHCl(CO)_2(PPh_3)_2]$.[1449] The latter is also produced from $[RuCl_2(PPh_3)_3]$ in DMA treated with a H_2/CO mixture.[1607]



The five-coordinate $[RuHCl(CO)(PBu^t_2Et)_2]$ also reacts with MeNC to give $[RuHCl(CO)(CNMe)(PBu^t_2Et)_2]$[1712] and other neutral isocyanide monohydrido complexes include $[RuHX(CO)(CNR)(PPh_3)_2]$ (X = Cl, Br, I).[1480,1652,1656a,1717] Pyridine and SO_2 add to $[RuHCl(CO)(PCy_3)_2]$ to give $[RuHCl(CO)py(PCy_3)_2]$[2472] and $[RuHCl(CO)(SO_2)(PCy_3)_2]$[1813] respectively. With acetylene or phenylacetylene (L), $[RuHCl(CO)L(PCy_3)_2]$ is formed.[1623b]

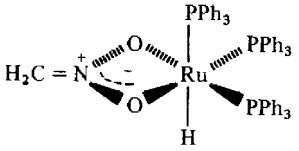
Reaction of a six-fold excess of PPh_3 with 'Ru(CO)Cl' in EtOH in the presence of $Na[BH_4]$ affords a mixture of isomers of $[RuH(BH_4)(CO)(PPh_3)_3]$ which both contain a monodentate BH_4 ligand. The bulky PCy_3 generates $[RuH(BH_4)(CO)(PCy_3)_2]$ and with DBP and $Na[BH_3CN]$, $[RuH(BH_3CN)(CO)_2(DBP)_2]$ is formed.[2431]

Other carbonyl complexes of type $[RuHX(CO)_xL_2]$ ($x = 1,2$) include $[RuH(OCOR)(CO)_x(PPh_3)_2]$ (from $[RuH_2(CO)(PPh_3)_3]$ and RCO_2H),[1728a,1774] $[RuH(NO_3)(CO)_x(PPh_3)_2]$ (Section 45.5.4.7.v), $[RuH(dike)CO(PPh_3)_2]$ (Section 45.5.4.7.iii) and $[RuH(S–S)CO(PPh_3)_2]$ (S–S = $^-S_2CNR_2$, ^-S_2COR) (Section 45.5.4.8.ii).

(*iv*) *Other neutral monohydrido complexes containing C, N, O or S donor ligands*

Norbornadiene reacts with $[RuHCl(PPh_3)_3]$ in C_6H_6 to give $[RuHCl(PPh_3)_2(nbd)]$,[2445] shown[2473] to exist in solution as a single isomer. The analogous complexes $[RuHClL_2(cod)]$ (L = piperidine, $C_6H_{11}NH_2$, $NHMe_2$) are formed by reaction of $[RuCl_2(cod)]_n$ with amines at high temperature; X-ray analysis for L = piperidine establishes structure (**386**).[628] Reaction of the unusual dimer $[\{RuHX(cod)\}_2(NH_2NMe_2)]$ (X = Cl, Br) with Lewis bases in boiling acetone or MeOH generates a range of $[RuHX(cod)L_2]$ (L = $PMePh_2$, $SbPh_3$, $AsPh_3$, py). These are stable in the solid state but decompose in solution; spectroscopic (NMR, IR) data suggest structure (**386**).[2474]

(386)



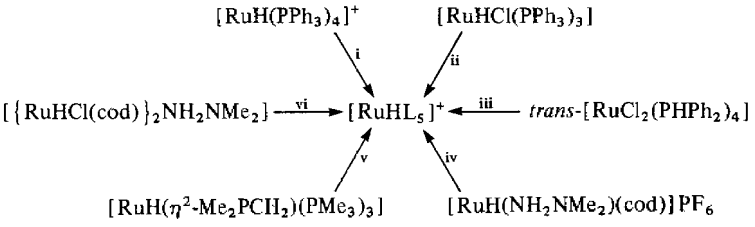
Propene oxidatively adds to $[\overline{RuH(C_6H_4PPh_2)}MeCN(PPh_3)_2]$ (or to the isomeric $[Ru(\eta\text{-}MeCN)(PPh_3)_4]MeCN$ to give $[RuH(\eta\text{-}C_3H_5)(MeCN)(PPh_3)_2]$[1404,2475] which then reacts with an excess of isobutene to give the 2-methylallyl complex $[RuH(\eta^3\text{-}C_4H_7)(MeCN)(PPh_3)_2]$, whereas treatment with $PHPh_2$ affords $[RuH(\eta\text{-}C_3H_5)(PMePh_2)_3]$.[2475] A similar hydrido-η^3-1-phenylallyl complex $[RuH(\eta^3\text{-}C_3H_4Ph)(MeCN)(PPh_3)_2]$ is isolated in high yield from reaction of $[Ru(\eta\text{-}MeCN)(PPh_3)_4]MeCN$ with allylbenzene in MeCN.[1405] A series of η-1-3 and η-1-5 cyclohexadienyl Ru^{II} hydrides such as $[RuH(PPh_3)_2(\eta\text{-}C_6H_7)]$ can be obtained by reaction of $[Ru(PPh_3)_2(styrene)_2]$ with cyclohexane,[2476] whereas 1-hexene gives a mixture of *syn*- and *anti*-$[RuH(PPh_3)_2(styrene)(1\text{-}3\text{-}\eta\text{-}C_6H_{11})]$.[1394] Other C donor ligand complexes include $[RuH(PPh_3)_2(\eta\text{-}C_5H_5)]$, $[RuHCl(PPh_3)(\eta\text{-}C_6Me_6)]$, and a range of carborane complexes (reference 1, p. 806).

The diamagnetic red complex $[RuH\{N(SiMe_3)_2\}(PPh_3)_2]$ can be isolated from reaction of $[RuHCl(PPh_3)_3]$ with $Li[N(SiMe_3)_2]$. It is a rare example of a d^6 14-electron species and is proposed to have a distorted tetrahedral geometry.[2477] With diazadienes, $[RuHCl(PPh_3)_3]$ yields $[RuHCl(dad)(PPh_3)_2]$ which disproportionates in polar media to give $[RuH_2(dad)(PPh_3)_2]$, $[RuH_2(CO)(PPh_3)_3]$ and $[Ru_2Cl_3(dad)_2(PPh_3)_2]Cl$.[1770] Treatment of $[RuH_2(PPh_3)_4]$ with cyclic imides such as (+)-camphorimide, phthalimide, succinimide gives $[RuH(imido)(PPh_3)_3]$ in which the imide acts as a bidentate ligand coordinating *via* its N and O atoms.[2478] The potentially bidentate ligands 2-hydroxypyridine and 8-hydroxyquinoline react with $[RuH_2(PPh_3)_4]$ at room temperature to give $[RuHX(PPh_3)_3]$ (X = 2-OC_5H_4N, 8-OC_9H_6N) and 2-aminopyridine yields $[RuH(HNC_5H_4N)(PPh_3)_3]$. With pyrocatechol and resorcinol, the yellow crystalline complexes $[RuH(OC_6H_4OH)(PPh_3)_2]\cdot n[(OH)_2C_6H_4]$ ($n = 2$ and 0 respectively) are isolated and ^1H NMR studies indicate that the phenolic rings are π-bonded.[1706]

In contrast, $[RuHCl(PPh_3)_3]$ and 2,2′-bipyridyl give a poorly soluble red-brown material which may be $[RuHCl(bipy)(PPh_3)_2]_2$ although it could not be purified.[2445] There is also a brief mention in the literature of the reaction of $[RuH(PhN_3Ph)(PPh_3)_3]$ (see Section 45.5.4.6.v) with N_2 in a reverse osmosis cell to give $[RuH(N_2)(PhN_3Ph)(PPh_3)_2]$.[1838]

As noted elsewhere, various monohydrido complexes containing diazenido, diazene (Section 45.5.4.6.iv), triazenido, formazan and thioformamido (Section 45.5.4.6.v) ligands are available.

The yellow compound $[RuH(CH_2NO_2)(PPh_3)_3]$, obtained from the reaction of $MeNO_2$ with $[RuH_2(PPh_3)_4]$ or $[RuH(C_6H_4PPh_2)(PPh_3)_2Et_2O]$ is thought to contain bidentate O bonded $CH_2NO_2^-$ as in (**387**).[1402] Reaction of $[RuCl_2(PMe_3)_2\{P(OMe)_3\}_2]$ with Na/Hg in benzene gives the aryl hydrido complex *cis*-$[RuH(C_6H_5)(PMe_3)_2\{P(OMe)_3\}_2]$.[1391c]

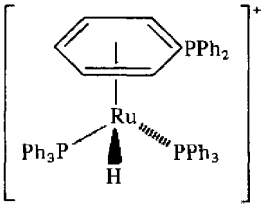


(387)

A range of Ru hydrido/hydroxo complexes are known, *e.g.* $[RuH(OH)(PPh_3)_2solvent]$ (solvent = H_2O, THF) (see Section 45.5.4.7.ii for details) and the related $[RuH(SR)(PPh_3)_3]$ (R = H, Me, Ph, $PhCH_2$) have been prepared (see Section 45.5.4.8.i). The sulfoxide complexes $[RuHCl(DMSO)_2(triphos)]$, $[RuHCl(DMSO)(tet\text{-}1)]$,[1540] $[RuHCl(DMSO)_2(AsPh_3)_2]$, $[RuHCl(DMSO)(AsMePh_2)_3]$ and $[RuHCl(DMSO)(AsMe_2Ph)_3]$[1511] are also reported.

(*v*) *Cationic monohydride complexes*

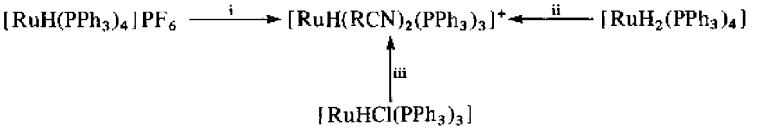
Triphenylmethyl hexafluorophosphate abstracts one hydride ion from $[RuH_2(PPh_3)_4]$ to give $[RuH(PPh_3)_4]PF_6$.[2479] The formation of a five-coordinate sixteen electron cation in preference to the eighteen electron species $[RuH(PPh_3)_5]^+$ is attributed to the steric bulk of the PPh_3 ligands since smaller ligands such as $P(OR)_2Ph$, $P(OR)_3$ (R = Me, Et), $PHPh_2$, PMe_2Ph, PMe_3 do form $[RuHL_5]^+$ cations. Some methods of synthesizing the latter are shown in Scheme 75. In method (iv), treatment with only four equivalents of PMe_2Ph in MeOH gives $[RuH(MeOH)(PMe_2Ph)_4]^+$[1766] and the mixed cations $[RuH(PF_3)_2(PPh_3)_2]BF_4$ are generated from $[RuH_2(PF_3)_2(PPh_3)_2]$ and HBF_4.[1576] Interestingly, $[Ru(CNBu^t)_5]$ deprotonates *nido*-2,3-Me_2-2,3-$C_2B_4H_6$ to give the related $[RuH(CNBu^t)_5]^+$ cation stabilized by a carborane anion.[2482]



i, L = $P(OR)_2Ph$ (R = Me, Et) or $PHPh_2$;[2479] ii, $P(OMe)_3$ or $P(OMe)_2Ph$, or $PHPh_2$; PF_6^-;[111, 1531, 1532] iii, $PHPh_2$/MeOH; PF_6^-;[1565] iv, excess L ($P(OEt)_3$ or $P(OMe)_2Ph$ or PMe_2Ph), MeOH/Δ;[1766, 2480] v, PMe_3; PF_6^-,[1391] vi, $P(OMe)_3$ or $P(OMe)_2Ph$[2474, 2481]

Scheme 75

The $[RuH(PMe_2Ph)_5]^+$ cation has a distorted octahedral structure[2480] which shows evidence of the strain caused by non-bonded repulsions between the substituents on phosphorus and is consequently very reactive. For example, reaction with CO_2 in ROH gives the monoalkylcarbonate esters $[Ru(O_2COR)(PMe_2Ph)_4]^+$ (**253**; Section 45.5.4.7.vii) and with CS_2, $[Ru(S_2CH)(PMe_2Ph)_4]^+$ is formed (Section 45.5.4.8.iv).

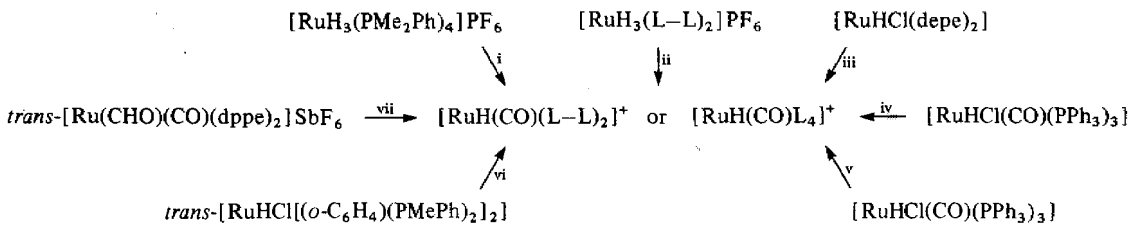


The red solution of $[RuH(PPh_3)_4]PF_6$ turns yellow on standing and a pale yellow solid of empirical formula $[RuH(PPh_3)_3]PF_6$ can be isolated. Spectroscopic data are consistent with struc-

ture (**388**) in which one of the PPh_3 ligands in η-bonded to Ru *via* one of the phenyl rings,[1754,2479] and this has been confirmed by X-ray analysis. Compound (**388**) is also formed in good yield by reaction of $[RuH_2(PPh_3)_4]$, $[RuH_4(PPh_3)_3]$ or $[RuH(OCOMe)(PPh_3)_3]$ with HBF_4/MeOH in the presence of excess PPh_3.[1754]

(388)

In the absence of an excess of PPh_3, the initial red species on protonation of [RuH(OCOMe)$(PPh_3)_3$] with HBF_4 is $[RuH(solvent)(PPh_3)_3]^+$ (solvent = MeOH, acetone) which in MeOH forms the yellow $[RuH(H_2O)_2(MeOH)(PPh_3)_2]^+$ cation. This cation is also obtained by treatment of $[Ru(OCOMe)(H_2O)(PPh_3)_3]BF_4$ with aqueous HBF_4 under hydrogen. Treatment of [RuH(OCOMe)$(PPh_3)_3$] in MeOH or acetone containing MeCN with aqueous HBF_4 gives the $[RuH(MeCN)_2(PPh_3)_3]^+$ cation.[1754] Cations of this type are also prepared as shown in Scheme 76 and assigned an octahedral structure with RCN *trans* to hydride.[2479]

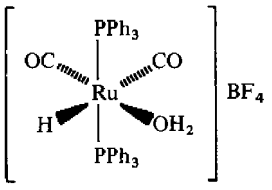


i, MeCN/MeOH, Δ; ii, $Ph_3C[BF_4]$, CH_2Cl_2, MeCN; iii, RCN, MeOH, KPF_6
(R = Me, Pr, Pr^i, Ph, *p*-Tol, $MeOC_6H_4$, ClC_6H_4)

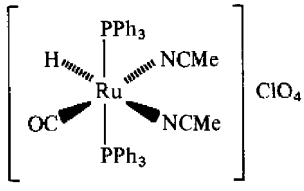
Scheme 76

Reaction of $[RuH(NH_2NMe_2)cod]PF_6$ (see later) with the ditertiary phosphines dppp and dppb gives the five-coordinate $[RuH(L–L)_2]PF_6$ whereas dppe in EtOH yields the six-coordinate $[RuH(EtOH)(dppe)_2]PF_6$.[1766b] Protonation of $[RuH_2(dppm)_2]$ with HBF_4 in aqueous MeOH gives *trans*-$[RuH(OH_2)(dppm)_2]BF_4$.[1399] The corresponding $[RuH(Me_2P(CH_2)_3PPh_2)_2]BPh_4$ has been synthesized from *trans*-$[RuHCl(Me_2P(CH_2)_3PPh_2)_2]$ stirred with ethanolic solutions of $Na[BPh_4]$. It is not fluxional at room temperature and a trigonal bipyramidal structure is proposed.[1536a] More recent work suggests these compounds are square pyramidal in structure.[1536b]

Several routes to the monocarbonyl hydrido cations $[RuH(CO)(L–L)_2]^+$ and $[RuH(CO)L_4]^+$ are available (Scheme 77). Method (iii) with $CNBu^t$ in place of CO gives *trans*-[RuH(CNBu^t)$(depe)_2]^+$.[2484] Other monocarbonyl cations include $[RuH(S_2CPCy_3)(CO)(PCy_3)_2]^+$ (from CS_2 and $[RuHCl(CO)(PCy_3)_2]$),[1817] *cis*-$[RuH(CO)(bipy)_2]^+$ (prepared by heating *cis*-$[Ru(\eta^1$-OCOH)$CO(bipy)_2]^+$ in 2-methoxyethanol[1121a,b] or by treatment of *cis*-$[RuCl(CO)(bipy)_2]^+$ with $NaBH_4$)[1121c] and $[RuH(H_2O)(CO)(PPh_3)_3]BF_4$ (from treatment of $[RuH_2(CO)(PPh_3)_3]$ with aqueous HBF_4). Further reaction of the latter with CO gives $[RuH(H_2O)(CO)_2(PPh_3)_2]BF_4 \cdot EtOH$ (**389**) whose X-ray analysis reveals an extensive hydrogen-bonding network between the BF_4^- ion, the coordinated water molecule and the EtOH of crystallization.[1765] Compound (**389**) is also prepared by carbonylation of $[RuH(acetone)(PPh_3)_3]BF_4$.[1754] Treatment of $[RuHCl(CO)(PPh_3)_3]$ with $Ag[ClO_4]$ in MeCN gives $[RuH(CO)(MeCN)_2(PPh_3)_2]ClO_4$ (**390**) and since the MeCN groups are of different lability (*trans* to H and CO), a range of complexes are accessible by stepwise replacement. For example, treatment with CO, followed by PPh_3 gives $[RuH(CO)_2(PPh_3)_3]^+$ with *trans* CO groups.[1467] The tricarbonyl hydrido cation $[RuH(CO)_3(PPh_3)_2]^+$ is obtained by treatment of $[Ru(CO)_3(PPh_3)_2]$ with $NO[BF_4]$ or $NO[PF_6]$[2486a] and a preparative route to the cations $[RuH(N_2)(DMSO)_2(AsPh_3)_2]Cl$ and $[RuH(N_2)(DMSO)(AsMePh_2)_3]Cl$ has appeared.[1511]

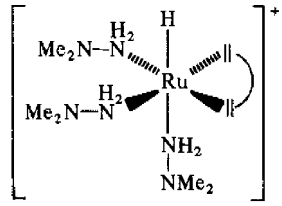


A series of monohydrido cations containing the tridentate ligands ttp and Cyttp have been reported. For example, reaction of $[RuH(\eta^2\text{-}BH_4)(ttp)]$ with HBF_4 and the appropriate ligand gives $[RuHL_2(ttp)]BF_4$ (L = $P(OMe)_3$, MeCN, CO). For L = $P(OMe)_3$, three different isomers (*i.e. trans, cis- syn* and *cis- anti*) are obtained depending on such factors as solvent used, reaction conditions



i, CO;[1766] ii, CO (L–L = dppe or dppp);[1766] iii, CO/acetone;[2484] iv, $Me_2P(CH_2)_3PPh_2$, $Li[ClO_4]$, EtOH;[1536] v, $PHPh_2$;[1565] vi, CO, PF_6^-;[2485] vii, CH_2Cl_2[1637]

Scheme 77



and sequence of addition of reagents. Some mixed ligand complexes such as $[RuH(MeCN)(PF_3)(ttp)]BF_4$ and $[RuH(CO)(P(OMe)_3)(ttp)]BF_4$ are also reported. Oxidative addition of acids to $[Ru(CO)_2(Cyttp)]$ affords the $[RuH(CO)_2(Cyttp)]^+$ cation[1486a,2441] whereas $[RuH(CO)_2triphos]Cl$ is formed from $[Ru(CO)_2triphos]$ and acetyl chloride.[2486b]

(389)

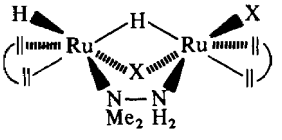
(390)

(391)

Treatment of a suspension of $[RuCl_2(cod)]_n$ in MeOH with *N,N*-dimethylhydrazine gives $[RuH(NH_2NMe)_2cod]^+$ isolated as its BPh_4^- or PF_6^- salts[650] and shown by X-ray analysis[2487] to have structure (**391**) with coordination *via* the less basic but more sterically favoured NH_2 nitrogen atoms. The NH_2NMe_2 groups are readily replaced by other N and P donor ligands to give $[RuHL_3(cod)]^+$ (L = N_2H_4, MeNHNH$_2$, py, 4-Mepy, $P(OMe)_3$, $P(OCH_2)_3CMe$, PPh_2OMe, PMe_2Ph, $PMePh_2$).[650,2488] Reaction of the dimer $[\{RuHX(cod)\}_2NH_2NMe_2]$ (X = Cl, Br) with 4-methylpyridine in EtOH or with $AgNO_3$ in MeCN also produces $[RuHL_3cod]^+$ (L = 4-Mepy, MeCN) respectively,[2474] and the coordinated cod in $[RuH(PMe_2Ph)_3(cod)]PF_6$ is readily replaced by 1,3-dienes to give $[RuH(PMe_2Ph)_3(diene)]PF_6$ (diene = buta-1,3-diene, hexa-1,3-diene).[2489]

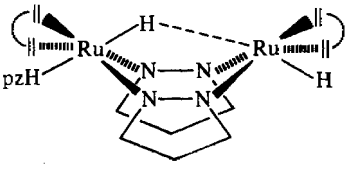
45.10.3.3 Anionic complexes

There are relatively few examples of anionic ruthenium hydrido complexes. Thus, several papers have discussed the preparation of the $[RuH_6]^{4-}$ ion from Ru, H_2 and various lanthanide dihydrides at 800°C.[2490,2491] The ^{99}Ru Mössbauer spectra at 4.2 K for various $M_2[RuH_6]$ (M = Ca, Sr, Eu, Y) are consistent with diamagnetic Ru^{II} centres.[2492]



An unusual anionic dihydrido ruthenium complex is formed by reduction of $[RuHCl(PPh_3)_2]_2$ with potassium naphthalide at low temperature in THF, followed by recrystallization from toluene containing a small amount of diglyme. The physicochemical evidence is consistent with its formulation as the binuclear $[\{Kdiglyme\}^+\{RuH_2(PPh_2)(PPh_3)\}^-]_2$. Note that reduction of $[RuHCl(PPh_3)_3]$ with potassium naphthalide gives the *ortho*-metallated complex $K[RuH_2(C_6H_4PPh_2)(PPh_3)_2]C_{10}H_8 \cdot Et_2O$.[2467,2493]

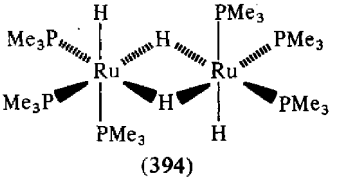
A number of new anionic ruthenium hydrides have been synthesized by Halpern *et al.* These include *fac*-$[RuH_3(PPh_3)_3]^-$, isolated as its K^+ salt by reaction of $K[RuH_2(C_6H_4PPh_2)(PPh_3)_2]$ with H_2 (1 atm) in THF at 25°C, and $K[RuH(PPh_3)_2(anthracene)]$. Treatment of the latter with H_2 gives $K[RuH_5(PPh_3)_2]$ whose spectral data are consistent with a fluxional pentagonal bipyramidal structure. This pentahydride complex exhibits a rich chemistry, reacting with 1-hexene to produce the coordinatively unsaturated $[RuH_3(PPh_3)_2]^-$ anion and with cyclohexadiene to give $[RuH(PPh_3)_2cyclohexadiene]^-$. Anthracene regenerates $[RuH(PPh_3)_2anthracene]^-$ whereas ethylene affords the *ortho*-metallated $[Ru(C_6H_4PPh_2)(PPh_3)(C_2H_4)]^-$. Several of these complexes are good catalysts for the hydrogenation of anthracene to 1,2,3,4-tetrahydroanthracene.[2494]



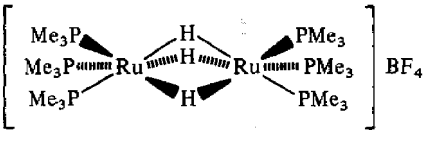
Other anionic ruthenium hydrides include the stereochemically non-rigid $[RuH(PF_3)_4]^-$ (from reaction of *cis*-$[RuH_2(PF_3)_4]$ with Et_3N),[1384] the protonated intermediates $[RuH(CN)_6]^{3-}$ and $[RuH_2(CN)_6]^{2-}$ (see Section 45.3.1.2.i) and an extensive range of tri-, tetra- and hexa-nuclear ruthenium hydride carbonyls, such as $[Ru_3H(CO)_{11}]^-$, $[Ru_4H(CO)_{13}]^-$, $[Ru_4H_3(CO)_{12}]^-$ and $[Ru_6H(CO)_{18}]^-$ (see reference 1, pp. 889–906).

45.10.4 Bi-, Tri-, Tetra- and Poly-nuclear Ruthenium(II) Complexes

The unusual hydrido-bridged complex $[\{RuHX(cod)\}_2NH_2NMe_2]$ (X = Cl, Br) is prepared by addition of either LiCl or LiBr to a boiling acetone/MeOH solution of $[RuH(NH_2NMe_2)_3(cod)]Y$ (Y = PF_6 or BPh_4).[2474] An X-ray analysis[2495] (for X = Cl) shows that its structure (**392**) consists of two Ru atoms linked by three different bridging ligands. Some reactions of this compound involving bridge cleavage and substitution are discussed in earlier sections. The X-ray structure of $[\{RuH(pz)cod\}_2pzH]$ has shown structure (**393**) with a semi-bridging hydride ligand.[2496]



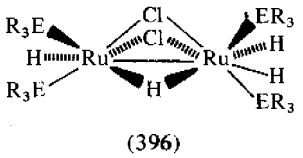
(392)



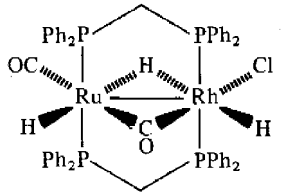
(393)

Treatment of $[Ru_2(\mu\text{-}CH_2)_3(PMe_3)_6]$ with H_2 (3 atm) in light petroleum affords the red crystalline diamagnetic $[Ru_2H_4(PMe_3)_6]$ shown by X-ray analysis to have structure (**394**). This double bridged species is quantitatively converted to $[Ru_2H_3(PMe_3)_6]BF_4$ (**395**) by reaction with aqueous HBF_4 in THF. It can also be obtained by reaction of H_2 (3 atm) with either $[Ru_2(\mu\text{-}CH_2)_2(\mu\text{-}CH_3)(PMe_3)_6]BF_4$ or $[Ru_2(\mu\text{-}CH_2)_2(PMe_3)_6][BF_4]_2$ in MeOH. The Ru—Ru distance in (**395**) is 2.540(1) Å.[1521] A complex analysing for $[Ru_2H_3(PMe_2Ph)_6]PF_6$ is produced by refluxing $[Ru(OCOH)(PMe_2Ph)_4]PF_6$ in MeOH in air.[1753] The related hydroxo-bridged complex $[PPh_3(Pr^iNCHCHNPr^i)Ru(\mu\text{-}OH)_2(\mu\text{-}Cl)RuH(PPh_3)_2]$ (**243** and Section 45.5.4.7.ii) is produced by the reaction of $[RuHCl(Pr^iNCHCHNPr^i)(PPh_3)_2]$ with water in toluene.[1770] The novel compound $[Ru_2H_4N_2(PPh_3)_4]$ with three bridging hydrides and a multiple metal–metal bond is known.[2497a] In the ruthenium catalysed conversion of methanol to methyl formate, $[RuCl_2(PPh_3)_3]$ is converted to the dinuclear cation $[(PPh_3)_2(CO)Ru(\mu\text{-}H)(\mu\text{-}Cl)_2Ru(CO)(PPh_3)_2]^+$, isolated as its PF_6^- salt.[2497c]

(394)



(395)



As discussed elsewhere (Section 45.10.3.2.i) reaction of $[RuH_2(PPh_3)_4]$ with 1,4-dichlorooctaphenyltetrasilane in the presence of Et_3N gives the dimeric $[RuHCl(PPh_3)_3]_2$, tentatively formulated on the basis of ^1H, ^{31}P NMR and IR spectroscopy as a bis-μ-chloro complex with terminal hydrido ligands.[2455] Reaction of H_2 with $[RuX_3(EPh_3)_2MeOH]$ in toluene or DMA in the presence of bases such as 'proton sponge' is reported to yield five-coordinate halide-bridged dimers $[RuHX(EPh_3)_2]_2$ (X = Cl, Br; E = P, As). Some evidence was also found for the existence of $[Ru^{III}HBr_2(AsPh_3)_2]$.[1546] However, unpublished work[1555] indicates that the above reactions also produce the Ru^{III} dimers $[RuH_2X(ER_3)_2]_2$ with possible structure (**396**) and these are in equilibrium with $[RuHX(ER_3)_2]_2$. Reduction of anhydrous $RuCl_3$ with sodium sand in neat Me_3P gives $[\{RuH(PMe_3)_3\}(\mu\text{-}Me_2PCH_2)_2]$.[2497d]

In a communication, reaction of the Ru^0 complex [Ru(cod)(cot)] with two equivalents of dppm in the presence of H_2 gives a compound of empirical formula $[RuH_2(dppm)_2]$. On the basis of ^{31}P and ^1H NMR evidence, this was tentatively formulated as a trinuclear complex,[1398] but further studies indicate that a mixture of monomeric *cis*- and *trans*-$[RuH_2(dppm)_2]$ is formed.[1399] A similar reaction with dppe gives $[RuH_2(dppe)_2]$,[1398] also formed by reaction of $[Ru(tos)_2(dppe)_2]$[1600a] with $NaAlH_4$. Pyrolysis of [RuH(2-np)(dmpe)$_2$] gives a compound of empirical formula '$[Ru(dmpe)_2]$' which is shown by structural analysis to be the dimeric Ru^{II} hydride (**123**; Section 45.5.1.1).

Treatment of $[RuH_2(PPh_3)_4]$ with an excess of hydroquinone in THF gives a highly insoluble compound tentatively formulated as the binuclear complex $[Ru_2H_2(O_2C_6H_4)_3(PPh_3)_4]$ (with a bridging hydroquinone ligand)[1706] whereas $[RuH_2(dppm)_2]$ and $[RhCl(CO)_2]_2$ affords the unusual $[RuRhH_2Cl(\mu\text{-}CO)CO(dppm)_2]$ (**397**).[1507a] Reaction of $[RuH_2(dppm)_2]$ with $[RhCl(cod)]_2$ produces $[RuRhH_2Cl(cod)(dppm)_2]$ (containing one bridging Cl, H and dppm group).[2497b] Treatment with $Na[BH_4]$ gives the coordinatively unsaturated $[RuRhH_3(dppm)_2]$.[2497c] Reactions with CO, $P(OMe)_3$ and LiMe are also reported. Reaction of $[MoRu(CO)_5(dppm)_2]$ with H_2 gives the dihydrogen-bridged complex $[MoRuH_2(CO)_5(dppm)_2]$.[1507b]

(396)

(397)

Examples of trinuclear hydrido complexes containing ruthenium include $[Ru_2(\mu\text{-}H)(\mu\text{-}OH)\{\mu\text{-}Fe(CO)_4\}(CO)_4(PPh_3)_2]$ (**293** and Section 45.5.5.1), $[Ru_3(\mu\text{-}H)_2(\mu\text{-}P, \eta^2\text{-}CH_2{=}CHC_6H_4PPh_2)(CO)_8]$ (from pyrolysis of $[Ru_3(CO)_{10}SP]$ at 80°C; SP = *o*-$CH_2{=}CHC_6H_4PPh_2$),[2498a] $[Ru_3(\mu\text{-}H)_3(CO)_9(SiZCl_2)_3]$ (**9** and Section 45.3.2.1) $[RuRh_3H(CO)_{12}]$, $[RuCo_3H(CO)_{10}(PPh_3)_2]$[2498b] and a series of phosphido-bridged clusters derived from photolysis of $[Ru_3(CO)_9(PHPh_2)_3]$ or reaction of $[Ru_3(CO)_{12}]$ with $PHPh_2$ *e.g.* $[Ru_3(\mu\text{-}H)_2(\mu\text{-}PPh_2)_2(CO)_8]$, $[Ru_3(\mu\text{-}H)_2\{\mu\text{-}PPh_2\}_2(CO)_7(PHPh_2)]$ *etc.*[1516] Many other hydrido carbonyl clusters containing three to six ruthenium atoms are known but these are outside the scope of this review {see reference 1, p. 889 for further details and reference 2499 for the X-ray structural analysis of the chiral cluster $[Ru_4H_4(CO)_9(PMe_2Ph)[P(OC_6H_4Me\text{-}p)_3][P(OCH_2)_3CEt]$}.

45.10.5 Higher Oxidation State Hydrido Complexes

In the presence of proton sponge, the complexes $[RuCl_2(PPh_3)_2]_2$, $[RuHCl(PPh_3)_2(nbd)]$ or $[RuX_2YL_2]$, (X = Y = Cl, Br, or X = Cl, Br; Y = O_2CR; L = PPh_3, $P(p\text{-Tol})_3$ or $AsPh_3$), react with H_2 in DMA or toluene to give the compounds $[RuH_2XL_2]_2$ (X = Cl, Br). The Ru^{III} product $[RuH_2Cl\{P(p\text{-Tol})_3\}_2]_2$ has been characterized by analytical, molecular weight, ^1H and ^{31}P NMR methods and chemical reactions and the data suggest the asymmetric structure (**396**). A reinvestigation of the reaction between $[RuCl_2(PPh_3)_3]$ and H_2 in DMA to form $[RuHCl(PPh_3)_3]$ also indicates that in the presence of excess Cl^-, a long lived intermediate, tentatively formulated as $[Ru_2H_3Cl_3(PPh_3)_4]$, is formed.[1555] In earlier work, reaction of $[RuBr_3(AsPh_3)_2]$ with H_2 in DMA at 25°C was claimed to give $[RuHBr_2(AsPh_3)_2]$.[1546]

The tetrahydrido complex $[RuH_4(PPh_3)_3]$ is readily obtained as very air sensitive white crystals by reaction of $[RuCl_2(PPh_3)_3]$ with $NaBH_4$ in C_6H_6/MeOH; in the presence of excess PPh_3, $[RuH_2(PPh_3)_4]$ is produced and this can be converted to the tetrahydride by passing a stream of H_2 through a C_6H_6 solution of the compound.[1408,1549,2427,2428] The tetrahydride is also generated from $[RuH_2(N_2)(PPh_3)_3]$ and H_2, a conversion which is readily reversed on exposure to nitrogen. Other routes are shown in equation (151).[1811,2433,2442] Solid $[RuH_4(PPh_3)_3]$ reacts with various other substrates (CO, NO, SO_2, NOCl, RCN) with displacement of H_2 to give compounds containing these ligands.[1408] Thus it might be effectively considered as a Ru^{II} complex containing neutral dihydrogen. The corresponding $[RuH_4(DBP)_3]$ (DBP = 5-phenyl-5*H*-dibenzophosphole) can be synthesized from $[RuCl_3(DBP)_3]$ and $NaBH_4$[2431] and it has been shown that $[RuH_4(PR_3)_3]$ (R = Pr^i, Cy, NEt_2) can be prepared by treatment of $[Ru(cod)(cot)]$ with three equivalents of PR_3 under H_2. These complexes in deuterated aromatic solvents exhibit H–D exchange between the solvent and the coordinated phosphines.[2500] $[RuH_4\{P(p\text{-}FC_6H_4)_3\}]$ is also known and has been shown to dehydrogenate cyclooctane at 150°C in the presence of a hydrogen acceptor.[2501]

$$\begin{matrix}[RuHCl(PPh_3)_3] \\ [RuH(OCOH)(PPh_3)_3]\end{matrix} \xrightarrow[H_2]{H_2/Et_3Al} [RuH_4(PPh_3)_3] \qquad (151)$$

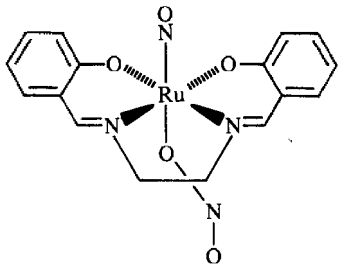
The cationic Ru^{II} monohydrides $[RuH(MeOH)(PMe_2Ph)_4]PF_6$, $[RuH(EtOH)(dppe)_2]PF_6$ and $[RuH(dppp)_2]PF_6$ oxidatively add H_2 under ambient conditions to form the Ru^{IV} trihydrido cations $[RuH_3(PMe_2Ph)_4]PF_6$ and $[RuH_3(L\text{–}L)_2]PF_6$ (L–L = dppe, dppp), a process which can be reversed

on heating. Addition of HPF_6 to $[RuH_2(PMePh_2)_4]$ and $[RuH_2(dppb)_2]$ also gave very unstable trihydrido cations which revert to the dihydride on recrystallization.[1766] The corresponding $[RuH_3(PPh_3)_4]^+$ has been obtained, together with the dimer $[RuHCl(PPh_3)_3]_2$, by treatment of $[RuH_2(PPh_3)_4]$ with 1,4-$Cl_2Si_4Ph_8$ in the presence of Et_3N.[2502] A related 16 electron species $[RuH_3(PPh_3)_3]^+$ is tentatively claimed[1754] but no NMR data were reported because of rapid H_2 evolution in solution. The novel compound $[Ru_2H_6N_2(PPh_3)_4]$ can be prepared by recrystallization under nitrogen of the hydrogenation product of $[Ru(PPh_3)_2(styrene)_2]$. An X-ray analysis reveals structure (**398**) with four bridging hydrides and a short Ru—Ru distance (2.556(3) Å), consistent with a Ru—Ru double bond (although it is possible that this compound might be $[Ru_2H_4N_2(PPh_3)_4]$).[2497a] ^1H and ^{31}P NMR spectra indicate that the crude hydrogenation product is a mixture of $[RuH_6(PPh_3)_2]$ and $[Ru_2H_8(PPh_3)_4]$.[2503] Similar diamagnetic binuclear complexes $[Ru_2H_8L_4]$ (L = PPr^i_3, PBu^t_3), are produced by reaction of [Ru(cod)(cot)] with L at 40°C (although further work suggests these should be reformulated as $[Ru_2H_6L_4]$ species),[2497a] whereas with PCy_3, $[RuH_6(PCy_3)_2]$ is isolated.[1398] The latter loses H_2 thermally, photochemically or *in vacuo* to give $[Ru_2H_6(PCy_3)_4]$. Protonation of $[RuH_6(PCy_3)_2]$ with HBF_4/H_2O leads to $[Ru(OH_2)_5(PCy_3)]BF_4$ whereas reaction with ethylene produces the metallated complex $[RuH\{C_6H_{10}P(C_6H_{11})_2\}(PCy_3)(C_2H_4)_2]$.[2497a]

(398)

The silyl–ruthenium(IV) complexes $[RuH_3(SiR_3)L_n]$ (n = 2,3; L = PPh_3, $AsPh_3$, P(p-Tol)$_3$) and $[RuH_2X(SiR_3)L_3]$ (X = Cl, I) are discussed in Section 45.3.2.3.

45.10.6 References to Catalytic Reactions of Ruthenium Hydrido and Related Complexes



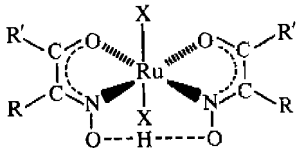
A number of the compounds discussed in this section *e.g.* $[RuHCl(PPh_3)_3]$, $[RuH(OCOR)(PPh_3)_3]$, $[RuH_2(PPh_3)_4]$, $[RuHCl(CO)(PPh_3)_3]$, *etc.* and some from other sections *e.g.* $[Ru(CO)_3(PPh_3)_2]$, $[RuCl_2(PPh_3)_3]$, $[RuCl_3(EPh_3)_2MeOH]$ (Section 45.5) $[RuCl_2(DMSO)_4]$ (Section 45.7.9), '$RuCl_3 \cdot xH_2O$' (Section 45.9) are excellent homogeneous catalysts (or catalyst precursors) for such reactions as hydrogenation, isomerization, hydroformylation, polymerization, oxidation *etc.* of various organic substrates. Further references to these catalytic reactions are to be found in Chapters 61.1–61.5 and 67 of the present work and also in the following books and reviews. 'Comprehensive Organometallic Chemistry' edited by Sir Geoffrey Wilkinson, F. G. A. Stone and E. W. Abel, Volume 4 Section 32.9, Volume 8 and Volume 9 (Table 9 of Review Index), Pergamon Press, 1982. 'The Chemical and Catalytic Reactions of Dichlorotris(triphenylphosphine)ruthenium(II) and its Major Derivatives' by F. H. Jardine in 'Progress in Inorganic Chemistry', 1984, Volume 31, pp. 265–370. 'The Chemistry of Ruthenium' by E. A. Seddon and K. R. Seddon, Elsevier, 1984.

45.11 MIXED DONOR ATOM LIGANDS

45.11.1 N–O Ligands

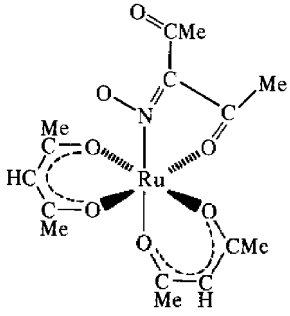
45.11.1.1 Schiff base complexes

Treatment of $[Ru_3(CO)_{12}]$ with *N*,*N*′-bis(salicylaldehydo)ethylenediamine (salenH_2) in either DMF[2089] or toluene[2504] gives the dimeric yellow complex $[Ru(salen)CO]_2$; this compound is also formed by carbonylation of *trans*-$[Ru(salen)(PPh_3)_2]$[1756] (see Section 45.5.4.6.vii). Reaction with pyridine forms [Ru(salen)COpy] which undergoes facile oxidation with $[PhN_2]BF_4$, $[p\text{-}NO_2C_6H_4N_2]BF_4$ or $[Et_3O]BF_4$ to generate $[Ru(salen)COpy]BF_4$.[2504] Interaction of $[RuCl_2(CO)_2]_n$ or $[RuCl_2(CO)_3]_2$ with Na_2[salen] yields *cis*-$[Ru(salen)(CO)_2]$ and with $[RuCl_2(nbd)]_n$, [Ru(salen)(nbd)] is obtained.[1756] Nitrosation of $[Ru(salen)(PPh_3)_2]$ in THF at 60°C affords *trans*-[Ru(ONO)(salen)NO] (**399**) with an O-bonded nitrito group.[2505] Reaction of $[Ru(acac)_3]$ with *N*-benzylethylsalicylideneimine (LH) in ethyl benzoate gives the chiral tris complex $[RuL_3]$ which can be separated by TLC into its enantiomers.[2506]



(399)

For Schiff base complexes containing tertiary phosphines, see Section 45.5.4.6.vii.

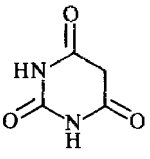


45.11.1.2 Oxime complexes

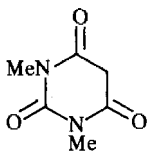
(i) Isonitrosoketones

Reaction of '$RuX_3 \cdot xH_2O$' with α-benziloxime [PhC(=O)C(=NOH)Ph] (HB) gives products formulated on the basis of IR, ESR, magnetic and electrochemical data as *trans*-$[Ru^{III}X_2(HB)B]$ (**400**) (X = Cl, Br).[1347,2507] A wider range of isonitrosoketone (hydroxyiminoketone) complexes of type (**400**) are now available, (R = R′ = Me; R′ = Ph, R = H, Me; R′ = Me, R = Ph), and these undergo both chemical and electrochemical reduction to generate the blue $[RuX_2(HB)B]^-$ anions. Addition of Et_3N deprotonates (**400**) to give $[RuX_2B_2]^-$ and reprotonation occurs on treatment with $HClO_4$.[2508] Similar reactions occur with arylazooximes [RC(=NOH)N=NAr] to give $[RuX_2(HL)L]$ (see Section 45.4.5),[1347,1349] and some ruthenium isonitrosoketonates containing 2,2′-bipyridyl ligands are described in Section 45.4.3.1.xiii.

(400)

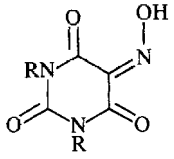


(401)

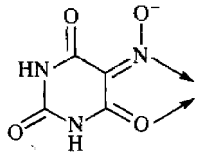


An unusual hydroxyiminoketone complex is (**401**) obtained by reaction of '$Ru(OH)_3NO$' with acacH at pH 6.5. At lower pH values either *cis*-$[Ru(acac)_2(Cl)NO]$ or $[Ru(acac)_2NO]_4$ is formed.[1297]

(ii) Ketoximes

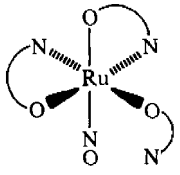


Treatment of $Na_2[RuOH(NO_2)_4NO]$ with an excess of the barbituric acids (**402**) yields the violurato anions $[Ru^{II}(VR_2)_3]^-$ (R = H, Me) which have been isolated with a variety of cations.[2509] These anions can also be prepared by either reaction of '$RuCl_3 \cdot xH_2O$' with violuric acid (VR_2H; **403**) in EtOH or $K_2[RuCl_5(OH_2)]$ and $Na[VR_2]$ in aqueous media.[2510] X-Ray analyses on $H_3O[Ru(VH_2)_3] \cdot 3H_2O$[2511] and $Ba[Ru(VH_2)_3]_2 \cdot 9H_2O$[2512] reveal an octahedral geometry with the violurato ligand coordinated as shown in (**404**). Retention of this geometry in solution is confirmed by ^1H NMR spectroscopy,[2509,2513] and the ^{13}C and ^{15}N NMR spectra of these $[Ru(VR_2)_3]^-$ are available.[2514] The analogous $H[Ru(dmho)_3]$ (dmho = 5,5-dimethylcyclohexane-1,2,3-trione-2-oxime) can be prepared by treatment of aqueous solutions of $Na[RuOH(NO_2)_4NO]$ with dmh (5,5-dimethylcyclohexane-1,3-dione).[2515] Further studies on the reaction of $Na_2[RuOH(NO_2)_4NO]$ with stoichiometric amounts of barbituric acid have led to the isolation of the intermediates $Na[RuOH(NO_2)_2(VH_2)NO]$ and *cis*-$[RuOH(VH_2)_2NO]$ and a detailed reaction mechanism is proposed.[2516]

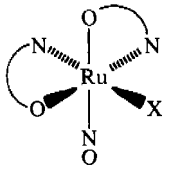


and

(402)



(403)

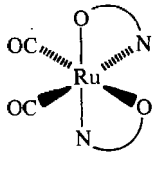


(404)

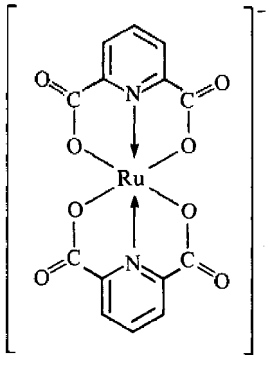
A number of reactions of these $[Ru(VR_2)_3]^-$ anions have been examined. Thus, deprotonation of aqueous solutions of $K[Ru(VH_2)_3]$ with KOH gives $K_4[Ru(VH)_3]$, whereas $Na[Ru(VH_2)_3]$ and NaOH followed by addition of $BaCl_2$ affords the dark blue $Ba_{2.5}[Ru(VH)_2(V)]$.[2513] Heating $[Ru(VR_2)_3]^-$ in dilute aqueous HCl produces the $[RuCl_2(VR_2)_2]^-$ anions.[2510] Reaction with $Na[NO_2]$ in $HClO_4$ gives $[Ru(VR_2)_3NO]$ (**405**), whereas treatment with $Na[NO_2]$ in hydrohalic media yields $[RuX(VR_2)_2NO]$ (**406**) (R = H, Me; X = Cl, Br). The rate determining step in the latter reaction involves breaking of the ring chelate.[2509,2517] Further complexes of type $[RuX(VR_2)_2NO]$ (X = Cl, OH, NO_3) and $[Ru(VR_2)_2Y(NO)]ClO_4$ (Y = H_2O, py, DMSO *etc.*) can be prepared by substituting the labile MeCN group of $[Ru(VR_2)_2(MeCN)NO]ClO_4$ (synthesized by refluxing $[Ru(NO_3)(VR_2)_2NO]$ with MeCN and $HClO_4$) with the appropriate ligand.[2510] A detailed study on the reactions of $[RuX(VR_2)_2NO]$ with β-diketones is also available.[2518]

Finally, treatment of $K_2[RuCl_5NO]$ with barbituric acid gives the $[Ru(barb)Cl_3NO]^{2-}$ and $[Ru(barb)_5NO]^{2-}$ anions which can undergo further deprotonation.[2519]

(405)



(406)



For oxime complexes containing tertiary phosphines, see Section 45.5.4.6.vii.

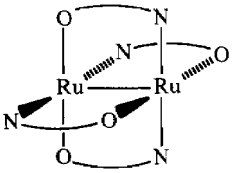
45.11.1.3 Amino acid, 8-hydroxyquinoline, dipicolinic acid and related complexes

Treatment of $[RuCl_2(diene)]_n$ (diene = nbd, 1,5-cod) with aqueous glycine (GlyH) at reflux yields two isomers of $[Ru(Gly\text{-}O)_2(diene)]\cdot H_2O$ which were successfully separated.[2520] The corresponding 8-hydroxyquinoline complex can be prepared by reaction of $[RuCl_2(1,5\text{-cod})]_n$ with 8-hydroxyquinoline and $Na_2[CO_3]$ in hot DMF.[2222] The dicarbonyl complex (**407**) is obtained in 6% yield together with $[Ru_3(CO)_8(8\text{-hq})_2]$ (76%), from reaction of $[Ru_3(CO)_{12}]$ with 8-hydroxyquinoline. On heating to 170°C, (**407**) isomerizes to a species with *cis* CO groups and equivalent 8-hydroxyquinoline ligands.[2521a] Treatment of $[RuHCl(CO)(PPh_3)_3]$ with 8-hydroxyquinoline (HL) gives $[RuCl(CO)(PPh_3)_2L]$.[2521b]

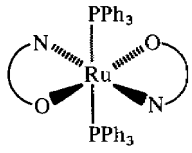
(407)

(408)

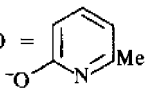
The nitrosyl complexes K[Ru(Gly-O)(OH)$_3$NO] and K[Ru(Ala)(OH)$_3$NO] arise from reaction of aqueous [RuCl$_3$(OH$_2$)$_2$NO] with glycine[1300] and L-α-alanine[2522] respectively, followed by anion exchange with 2 M KCl; [RuCl$_2$(Ala)$_4$] has also been claimed.[2523] Brief reports have been published on the reaction of '$RuCl_3 \cdot xH_2O$' with tris(hydroxymethyl)aminomethane (thamH) which gives [RuCl(tham)]$_2$Cl$_2$[2524] and [RuCl$_2$(DMSO)$_4$] and *N*-glycylglycine (Gly-Gly), which forms [Ru(Gly-Gly)(DMSO)$_3$].[112]



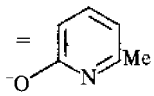
The [Ru^{III}(dipic)$_2$]$^-$ anion (**408**) has been synthesized starting from K$_2$[RuCl$_5$(OH$_2$)][2525] or '$RuCl_3 \cdot xH_2O$'.[2526] Compound (**408**) undergoes facile reduction with zinc or ascorbic acid to give burgundy coloured solutions of [Ru^{II}(dipic)$_2$]$^{2-}$ and the kinetics of electron transfer with the latter have been studied.[2525] Reaction of '$RuCl_3 \cdot xH_2O$' with equimolar amounts of dipicolinic acid and various mixed donor ligands such as glycine, nicotinic acid, isonicotinic acid, *o*-aminobenzoic acid *etc.* (N–O) gives the polymeric [Ru^{III}(dipic)(N–O)]$_n \cdot$H$_2$O.[2526] Some complexes of isonicotinic acid hydrazide (L) of type [Ru^{III}Cl$_2$L$_2$]Cl are known.[2527]



References to ammine, 2,2′-bipyridyl and tertiary phosphine complexes containing these ligands are to be found in Sections 45.4.1.2.vi, 45.4.3.1.xiii and 45.5.4.6.viii, 45.10.3.2.iv.



45.11.1.4 6-Methyl-2-pyridinolate and acetamide complexes



Reaction of [Ru$_2$(OCOMe)$_4$Cl] with sodium 6-methyl-2-pyridinolate [Na(mph)] at ambient temperature gives an 8% yield of [Ru$_2$(mhp)$_4$]$\cdot$CH$_2$Cl$_2$ (**409**) (r(Ru----Ru) = 2.238(1) Å). Magnetic (μ_{eff} = 2.9 BM/molecule) and PE spectral measurements suggest a $\sigma^2\pi^4\delta^2\delta^{*1}\pi^{*3}$ ground state electronic configuration.[2528] A detailed comparison of the structure of (**409**) with other [M$_2$(mhp)$_4$] complexes (M = Mo, Rh, Pd) has appeared.[2529]

In contrast, reaction of '[Ru$_2$(OCOMe)$_4$(PPh$_3$)$_2$]' with Na(mhp) in MeOH under reflux affords the monomeric species (**410**), the first example reported in which mhp acts as a chelating ligand.[2530]

(**409**) N–O = 

(**410**) N–O = 

The mixed valence Ru$_2^{II,III}$ complexes [Ru$_2$(RCONH)$_4$Cl] (R = CF$_3$,[2116] Me,[2531a] Ph[1871b]) have been prepared by reaction of [Ru$_2$(OCOMe)$_4$Cl] with RCONH$_2$. Like the corresponding carboxylato complexes, these molecules contain three unpaired electrons and detailed spectroelectrochemical studies indicate that the corresponding Ru$_2^{III,III}$ (for R = Me only), Ru$_2^{II,II}$ and possibly Ru$_2^{II,I}$ species can be generated in solution. However, the redox behaviour is very sensitive to the nature of the solvent and the amount of chloride ion present. The mixed valence Ru$_2^{II,III}$ complexes [Ru$_2$L$_4$Cl] (L = 2-hydroxypyridine, 2-anilinopyridine, 6-chloro-2-hydroxypyridine) were prepared from [Ru$_2$(OCOMe)$_4$Cl]. All these complexes exhibit a polar arrangement of the bonding ligands.[2531b]

The reaction of [Ru$_2$(PhCONH)$_4$Cl] with PPh$_3$ to give the novel [Ru$_2$Ph$_2$(PhCONH)$_2$(μ-NC(Ph)OPPh$_2$)$_2$] (**311**) is described in Section 45.5.8. For tertiary phosphine complexes of related ligands, see Sections 45.5.4.5.v and 45.5.4.6.v.

45.11.1.5 Edta and related complexes

Reaction between '$RuCl_3 \cdot xH_2O$' and Na$_2$[H$_2$edta] gives the yellow paramagnetic [Ru^{III}(Hedta)(OH$_2$)]$\cdot$4H$_2$O and [RuCl(H$_2$edta)(OH$_2$)]$\cdot$3.5H$_2$O.[2532] In water, stepwise hydrolysis of the former occurs to give [Ru(edta)(OH$_2$)]$^-$ and [Ru(OH)(edta)]$^{2-}$ respectively. Electrochemical studies reveal that electron transfer is rapid and reversible for the [Ru(edta)(OH$_2$)]$^{-/2-}$ couple and that [Ru^{II}(edta)(OH$_2$)]$^{2-}$ is oxidized by perchlorate ion.[2533] Reaction of the latter with formate ion affords the carbonyl complex [Ru(edta)(CO)]$^{2-}$.[2534]

Matsubara and Creutz[2535] have investigated the kinetics of substitution on $[Ru^{III}(edta)(OH_2)]^-$ and $[Ru(edta)(OH_2)]^{2-}$ anions and found rate constants higher than those of corresponding ruthenium compounds with oxygen and nitrogen donor ligands, especially for Ru^{III} in which substitution is faster by as much as ten orders of magnitude. Thus they generated an extensive series of $[Ru(edta)L]^{-/2-}$ anions (L varying from water to aromatic N-heterocycles), and measured their electronic spectra and redox potentials.

Ruthenium(III) edta complexes can be attached to a graphite electrode surface *via* the uncoordinated carboxylate function and some redox couples for several $[Ru(edta)L]^{-/2-}$ complexes are reported.[238]

In a subsequent paper, Diamantis *et al.*[2536] have reported the synthesis of compounds of type $[Ru(H_nedta)L_n]$ [L = CO, NO *etc.* (n = 1) and L = RCN (n = 2)] by reaction of $[Ru(Hedta)OH_2]^-$ with the appropriate ligand in the presence of H_2/Pt. The compounds were characterized by a range of spectroscopic techniques which indicate that the ligands L are accommodated in equatorial positions. For L = N_2, the anions $[Ru(edta)N_2]^{2-}$ and $[\{Ru(edta)\}_2N_2]^{4-}$ were isolated. The corresponding $Na_2[Ru(pdta)N_2]\cdot 2H_2O$ (H_4pdta = propylenediaminetetraacetic acid) has been prepared from $[Ru(Hptda)(OH_2)]\cdot H_2O$ and NaN_3,[2537]

The complexes $[Ru^{II}(H_2edta)L_2]$ (L = py, 4-MeC_5H_4N, ½bipy, ½phen, ½dppe, *etc.*) and $[Ru^{III}(H_2edta)L'_2]$ (L′ = HSCN, ½acac, ½DMG, ½S_2CNEt_2 *etc.*) have been prepared from $[Ru(Hedta)(OH_2)]^-$ and $[Ru(Hedta)(OH_2)]$ respectively. These have been fully characterized and also further reactions of the carboxylic acid functions in the free glycinate arms investigated (with CH_2N_2 and *p*-toluidine).[2538] Reaction of $[Ru(edta)OH_2]$ with RSH gives $[Ru(edta)SR]^{2-}$.[2539]
