PREFACE

THE Editorial Board of Comprehensive Inorganic Chemistry planned the treatise to fill a
gap in the literature. There was no work that provided more information than could be
found in single volumes but was not so large as to put it out of reach of all but a few central
libraries.

The Editorial Board drew up and incorporated in instructions to authors a scheme that
would make the best possible use of about five thousand pages. It was envisaged that the
treatise would be of service to a wide range of readers many of whom would not be pro-
fessional chemists. Convenience for all classes of reader was of paramount importance so
that if a conflict arose between brevity and ease of use, the latter was preferred. Nevertheless
the arrangement of the treatise is so systematic that such conflicts rarely occurred. The
convenience of the reader has been further ensured by the adoption of a consistent arrange-
ment of material within the chapters on the elements. The editors have been very gratified
to observe that authors have not found the imposed pattern unduly restrictive. It has
certainly helped to keep the accounts coherent and to preserve the intended balance between
the chapters. The editors are very sensible to the effort that authors have made to collaborate.

The section of the book devoted to the survey of topics, particularly those relating to
the transition elements, was a special interest of Sir Ronald Nyholm, whose death after
most chapters were in proof saddened many chemists. We hope that those chapters which
bear repeated evidence of his intellectual influence will be judged to be one of the many
worthy memorials that he left behind him.

16. GERMANIUM

E. G. ROCHOW

Harvard University

1. THE ELEMENT

1.1. DISCOVERY AND HISTORY. OCCURRENCE

Germanium was discovered by Clemens A. Winkler in 1886[1], following the accurate prediction of its existence by Mendeleef in 1871 as part of his formulation of the Periodic Law and his construction of the Periodic Table[2]. Much has been made in the past of the "complete agreement" of Winkler's findings with Mendeleef's predictions, but a more critical appraisal making use of modern constants for the element and its compounds[3] shows that the correspondence is not as close as once believed (see Table 1). The observation by Winkler that elemental germanium is not attacked by hydrochloric acid, but *is* attacked by concentrated solutions of NaOH, is but the first of a long series of observations pointing toward a less metallic behavior for germanium than had been expected. The element actually resembles arsenic in many respects, and Winkler first thought he had found eka-antimony rather than eka-silicon. When we consider that a water solution of GeO_2 is acidic, the point is emphasized.

Winkler obtained his germanium from the mineral argyrodite, which is Ag_8GeS_6. The element also occurs in canfieldite, $(Ag_8(SnGe)S_6)$, and in germanite, which is approximately $Cu_5(Cu,Fe)_6AsGeS_{12}$. Many other minerals (especially those of zinc, arsenic, tin, lead copper, and antimony) contain some germanium. Indeed, the element is extremely widespread in trace amounts: Papish demonstrated spectrographically that it is in almost all iron and zinc produced in the United States. The ionic potential (ratio of charge to radius) of germanium is so much like that of many other elements that germanium has very few distinctive minerals; it crystallizes with a dozen other elements in their pegmatite-type sulfide and arsenide minerals. Only the three special minerals mentioned above have enough Ge in them to have it appear in their formulas; some 16 other minerals contain 0.1% to 1% Ge, and 700 other minerals contain 0.0001% to 0.1% Ge[4]. Silicate rocks in general have the lowest Ge content. Coal ash from brown coal frequently contains Ge in the range 0.005% to 0.1%; the ash of some anthracites may run as high as 4% or even 7.5% Ge, thereby providing a possible source of the element[5]. Some spring waters from great depths in the earth contain Ge to the extent of 0.03 mg/l., but these are not practicable

sources. On the cosmic scale, germanium occurs as a trace element in iron meteorites, in stony meteorites, in the sun, and in the stars[5].

The abundance of Ge in the igneous rocks of the earth is usually given as 7 g per metric ton, or $7 \times 10^{-4}\%$[6], so it is somewhat more rare than Ga and Pb (15 and 16 ppm, respectively) but more abundant than As, Be, B, and Br. The hydrosphere contains very little: some 0.00005 mg/l. The cosmic abundance is 50 atoms per 10^6 atoms of silicon[7].

1.2. PRODUCTION AND INDUSTRIAL USE

Minerals of high Ge content, such as germanite, usually are roasted first to convert the sulfide to oxides, and then are put through an acid or alkaline extraction process (the advantage of the alkaline process is that gallium may be recovered at the same time). Special methods are used for the recovery of Ge from coal and from zinc ore concentrates. The processes will be treated briefly here; full details and references are available in the Gmelin supplementary volume[8].

By the acid method, germanite or other roasted ore is treated with fuming HNO_3 or a mixture of H_2SO_4 and fuming HNO_3 until only a greenish-white powder is left. The

HNO$_4$ is fumed off, concentrated HCl is added, and the mixture is heated in a distilling flask fitted with a fractionating column and an inlet tube for chlorine. The GeO$_2$ slowly converts to GeCl$_4$ and distils over, leaving non-volatile chlorides behind. The purpose of the chlorine is to keep arsenic in the pentavalent state, because AsCl$_5$ is less volatile than AsCl$_3$. The GeCl$_4$ can be rectified further, or hydrolysed to GeO$_2$ and then put through the HCl+Cl$_2$ treatment again to purify it.

By the alkaline method, the finely powdered ore is digested with an equal weight of 50% aq. NaOH, evaporated to dryness, and then stirred with hot water, filtered and washed. The filtrate contains sodium salts of Ge, Ga, As, and Mo oxyacids and thioacids. It is neutralized with H$_2$SO$_4$ and acidified with HNO$_3$, precipitating As$_2$S$_3$ and sulfur. The filtrate is neutralized and NH$_3$ is added, precipitating a hydrous GeO$_2$. This can be filtered off and converted to GeCl$_4$ by the HCl+Cl$_2$ treatment described above. Gallium usually is recovered from the alkaline filtrate by electrolysis.

An alternative dry method involves heating the powdered original ore in an *oxygen-free* stream of N$_2$ at 800° for 5 hr to drive off sulfur and As$_2$S$_3$. The residue is then heated to 825° in a stream of NH$_3$ for 12 hr, whereupon GeS$_2$ is reduced to GeS and sublimes. This can be oxidized to GeO$_2$ with fuming HNO$_3$ and treated as above.

Germanium-containing zinc oxide can be mixed with powdered charcoal and NaCl, and then heated to sintering temperature to drive off GeCl$_4$ and other chlorides. The condensate is taken up in water, treated with H$_2$SO$_4$ to precipitate PbSO$_4$, and the filtrate treated with zinc dust to precipitate the Cu, Ge, and As. Ignition of the precipitate gives oxides which can be heated with conc. HCl and Cl$_2$ as above.

Germanium in coal presents a special problem because during the usual procedure for burning the coal the Ge is converted to volatile GeO and is lost from the ash. For this reason the best starting material for recovery of Ge from the coal is not the ash but the flue dust. This can be treated as an "ore", or simply heated with 20% HCl to drive off all of the volatile chlorides. The oily layer of the distillate is then fractionated in a stream of chlorine to recover the GeCl$_4$, and the water layer is treated with H$_2$S to precipitate As$_2$O$_3$, GeS$_2$, and most other sulfides. The precipitate is extracted with conc. NaOH, and the extract either neutralized and heated with a large excess of HCl and Cl$_2$ to distil GeCl$_4$, or made 12 N with H$_2$SO$_4$ and treated with H$_2$S to precipitate GeS$_2$.

Elementary Ge is usually prepared from the pure white dioxide by reduction. This has to be done very slowly, below 540°, if hydrogen is used as the reducing agent, because too much volatile brown GeO is lost at higher temperatures. A simple and effective laboratory method, developed by Dennis[9], consists in reducing GeO$_2$ with sugar charcoal (as a source of very pure carbon free of Si and metals) in a graphite crucible. The GeO$_2$ is ground with an equal volume of sugar charcoal and then mixed with a similar quantity of finely pulverized NaCl. This mixture is put into the bottom of a graphite crucible and overlaid with a layer of NaCl, then a thick layer of sugar charcoal, and finally more NaCl. The crucible is then heated slowly, preferably over its entire surface (as in an induction furnace). The GeO$_2$ is reduced, any fumes of GeO are caught by the charcoal layer, the NaCl melts and acts as a flux, and the globules of Ge (m.p. 947°, vs. m.p. 801° for NaCl) coalesce at the bottom of the melt. The cooled crucible is broken open and the salt dissolved away from the regulus with warm water. Germanium does not form a carbide, and the element is not attacked by molten NaCl.

To obtain ultrapure elementary Ge for semiconductor use, the tetrachloride usually is

9 L. M. Dennis, *Zeit. anorg. allgem. Chem.* **174** (1928) 97; *J. Am. Chem. Soc.* **45** (1923) 2033.

purified extensively by distillation and then hydrolyzed to GeO_2. This is reduced slowly in H_2 (in graphite boats), melted to bars, and then purified by extensive zone-melting refining (see description under preparation of ultrapure silicon). The purity of the metalloid can be measured during the process by following its Hall-effect constant and its conductivity.

Nuclear Properties

The isotopes of Ge are listed in Table 2 (with nuclear masses given on the scale of $^{12}C = 12.00000$), and the nuclear behavior is summarized as of July 1966[10].

The natural mixture of isotopes has a cross-section of 2.23 barns for thermal neutrons; the cross-section becomes 5.13 barns for neutrons of 10.0 eV, and 4.47 barns for neutrons of 3800 eV energy. Neutron bombardment of the lighter isotopes of Ge results in the usual (n,γ) reaction to give the next heavier isotope, but ^{70}Ge undergoes an (n,p) reaction to give ^{70}Ga, and ^{72}Ge and ^{73}Ge react the same way. The ^{74}Ge isotope undergoes an (n,α) reaction to give ^{71}Zn. The isotopes of masses 74, 75, 76, 77 and 78 are fission products from the slow-neutron fission of ^{235}U.

Physical Properties

Germanium is a brittle metalloid which crystallizes in the cubic system, with a diamond lattice. There are no polymorphs. In the massive form its color is much like that of nickel; it is decidedly more yellowish than silicon. Since it is neither ductile nor malleable, its mechanical properties are difficult to measure with precision, but a list of selected physical properties is given in Table 3.

Because the classic investigations of Shockley and others on the properties of solid semiconductors (which led to the development of transistors, crystal diodes and many other electronic solid-state devices) were done with crystalline germanium, the electrical properties of the element have been studied more thoroughly than those of any other solid substance. The electrical conductivity and the Hall effect, in particular, have been investigated over an enormous range of compositions and of electrical and magnetic field strengths. Germanium of the very highest attainable purity is itself an intrinsic semiconductor; thermal promotion of electrons from a filled band to an empty conduction band is relatively easy (compared with that required in silicon or in diamond), and such promotion naturally increases the conductivity. Still easier access to conduction bands is provided by the deliberate introduction of new electron energy-level bands by adding controlled amounts of other elements. These impurities cause germanium to function also as an *extrinsic* semiconductor with just the right properties for the function in mind. The qualitative theory of such operation is easily understood: the introduction of B, Al, Ga and In causes substitution of some of the Ge atoms in the lattice with a Group III element, which can supply only three electrons to the binding network instead of four, and hence there is an electron deficiency (a "hole") in the structure. Migration of electrons from neighboring binding sites to the "holes" constitutes electrical conduction, and at the same time creates corresponding deficiencies elsewhere. Such introduction of Group III elements therefore makes an unfilled conduction band out of a previously filled one, and the resulting material is spoken of as *p*-type germanium because it contains "positive holes". Similarly, the introduction of P, As or Sb into the germanium crystal results in the replacement of some Ge atoms with Group V

elements having five electrons per atom instead of four, and the migration of these extra electrons under influence of an electric field constitutes the electrical conduction of *n*-type germanium. Junctions between *n*- and *p*-types of germanium function as rectifiers because they set up a barrier to conduction in one direction but not in the other: an a.c. field alternately sweeps out the carriers (when the situation is negative electrode/*p*-type/*n*-type/ positive electrode) and then pushes carriers across the junction (when the situation is positive

electrode/p-type/n-type/negative electrode). Such Ge diodes are cool, small, non-microphonic, rapid-operating devices which are very useful for radio demodulation and for switching circuits. The introduction of a *second* junction, either as a *pnp* or an *npn* arrangement, allows the center material to control much larger battery-induced currents between the two end materials, and so the arrangement (called a transistor) functions as an amplifier. Since the thickness of center material can be made very small (by diffusion techniques), the transit time for electrons can be correspondingly short, and the device will function at high

frequencies. Since it needs no cathode heater current, operates cold, and is small and mechanically nearly indestructible, the transistor has been welcomed into the electronics field and has been responsible for many of the new developments within that field.

Details of the effect on electrical conductivity brought about by controlled impurities in germanium, and of the dependence of conductivity on external factors, fill 330 pages of the supplementary volume of Gmelin (ref. 5, pp. 124–454) just in summary. Few of these facts are of interest to chemists, but the selected values for energy gaps (ionization energy in eV from nearest conductivity and valence bands) given in Table 4 may be useful.

1.3. CHEMICAL BEHAVIOR OF THE ELEMENT

Germanium does not absorb nitrogen, but adsorbs H_2, CO and CO_2, H_2O, alcohols, and oxygen- and halogen-containing compounds generally. When H_2O is adsorbed and the Ge subsequently is heated, H_2 is liberated and a film of oxide forms on the surface. Atomic hydrogen attacks Ge to form hydrides. Oxygen is adsorbed, but reaction with the underlying metalloid begins only at 575°; the rate of oxidation in terms of the quantity Q of O_2 taken up in time t follows the relation $Q = Q_\infty (1 - e^{-kt})$, where Q_∞ is the ultimate quantity

of O_2 consumed after a very long time, and the rate constant k has a value of 0.034 min^{-1} at 615° and 0.87 min^{-1} at 703° [11].

Methyl and ethyl chlorides and bromides (and undoubtedly many other alkyl and some aryl halides) in the vapor phase attack heated germanium to form the corresponding organo-germanium halides[12]. The powdered element burns in Cl_2 and Br_2 when warmed, forming the tetrahalide. Dry hydrogen chloride attacks the element at elevated temperatures to form $GeCl_4$ and impure $GeHCl_3$:

$$Ge + 4HCl = GeCl_4 + 2H_2$$
$$Ge + 3HCl = GeHCl_3 + H_2$$
(pure $GeHCl_3$ is best made by the union of $GeCl_2$ and HCl; see Dennis[9]). Sulfur reacts with Ge only at red heat, but H_2S reacts at 400° to form GeS_2.

Water slowly dissolves a thin evaporated film of Ge on Cu if oxygen is present, presumably because of the appreciable solubility of GeO_2. A 3% aq. solution of H_2O_2 dissolves massive Ge slowly at 20°, but quite rapidly at 90°–100°. Concentrated sulfuric acid at 90° has a slight action on massive Ge (1% loss of weight in 1 week), and concentrated nitric acid attacks it only superficially. Aqueous solutions of NaOH and KOH have little effect, but fused NaOH, KOH, Na_2CO_3, Na_2O_2 and $Na_2B_4O_7$ dissolve all forms of Ge quickly, forming alkali germanates. A solution of NaOCl also dissolves powdered Ge, forming GeO_2. Solutions of amides in liq. NH_3 do not attack it.

Germanium appears to form no carbide, but it alloys with many metals and metalloids. A complete tabulation of intermetallic compounds (as of 1968)[13] lists 152 compositions, from which the representative metal germanides of Table 5 have been abstracted. The relation of Ge with Si is unique: a continuous series of solid solutions is formed, and the two liquids also form ideal mixtures. About eighty ternary intermetallic compounds are known, and phase diagrams for many of the binary and ternary systems have been reported[13].

1.4. BIOLOGICAL ACTIVITY

Germanium is a ubiquitous component of living organisms, but it has no structural function (as silicon has in some exoskeletons), nor is it a proven required trace element for plants or animals[14]. Sax[15] reports that germanium has a low order of toxicity. Its compounds in general are much less poisonous than those of lead and tin, but GeH_4 has a hemolytic effect and is dangerous at levels above 100 ppm. Germanium halides hydrolyze to hydrohalogen acids, of course, and can be biologically unpleasant for this reason. The other product of hydrolysis, GeO_2, becomes toxic only at the level of 300 to 600 mg per kilo of body weight, and some tolerance to it can apparently be acquired by repeated sublethal doses[15, 16].

[15] N. I. Sax, *Dangerous Properties of Industrial Materials*, p. 736, Reinhold Publ. Corp., N.Y. (1962).

[16] See summary of biological activity given by F. Rijkens in *Organogermanium Compounds: A Survey of the Literature from Jan. 1950 to July 1960* (Institute for Organic Chemistry of the T.N.O., Utrecht, Holland, 1960), and the subsequent publications of the Germanium Research Committee through that Institute.

Although not markedly toxic, germanium is of some interest in two widely separated areas of biology and physiology: its erythropoietic effect, and the possible bacteriocidal or fungicidal effect of organogermanium compounds. Stimulation of the formation of red blood cells (erythrocytes) by injections of GeO_2 was first reported in 1922[17], and caused a flurry of activity aimed toward the treatment of anemias. The effect seems to vary among individuals and with the kind of anemia being treated, and the results sometimes are temporary. In all cases the effect is less pronounced than with repeated small doses of arsenic trioxide, but of course the danger of poisoning also is less. Acting on the view that the low solubility of GeO_2 in water might be the reason for the marginal and inconsistent results, much higher levels of germanium in the form of the highly soluble dimethyl-germanium oxide were adminstered to hamsters, and while these demonstrated the non-toxic behavior of $(CH_3)_2GeO$, the effect on erythrocyte levels was inconclusive[18].

The markedly poisonous nature of organolead compounds and the known bacteriocidal and fungicidal properties of some trialkyltin compounds have led to study of the effect of organogermanium compounds on microorganisms, but no utility has been found[16]. The marginal toxicity of most germanium compounds leads to the recurrent hope that some rather particular organogermanium structures will be found to be effective against invading microorganisms, or may restore balance to a pathogenic condition, without being dangerously toxic to a human host. So far, however, any such chemotherapeutic activity of germanium remains in the realm of hopeful speculation. On the average, each one of us ingests 1500 μg of germanium daily in our food[14], so we already have in our tissues an appreciable level of this element for which no function or decisive effect is known. Therefore any possible chemotherapeutic application would very likely require some specificity of structure (presumably in the direction of organogermanium chemistry), or some markedly higher local level of concentration of the element by methods as yet unknown.

1.5. ANALYTICAL DETERMINATION

Germanium can be detected by the blue line in its arc spectrum[19] at 4686 Å, by the band emission spectrum of its oxide in the visible range, and by the pale blue color of a flame into which a solution containing at least 10 mg of Ge per ml is sprayed. The decomposition of GeH_4 in a heated glass tube (as in the Marsh test for As) has also been used, but the GeH_4 must be generated by electrolysis of a dilute solution of NaOH containing the sample[20]. In solution, the presence of Ge can be determined by the precipitation of white GeS_2 from 12 N H_2SO_4 by addition of H_2S; the only other white sulfide is ZnS, and this precipitates only in alkaline solution. The presence of Ge in solution can also be recognized by the formation of a lemon-yellow Ge heteropolyacid when a 5% solution of ammonium molybdate is added in 0.15 to 0.34 N HNO_3. Various organic reagents (such as 9-phenyl-2,3,7-trioxy-6-fluoron) can also be used for the colorimetric estimation of Ge[21].

The quantitative determination of Ge can be accomplished gravimetrically by precipitation of GeS_2 from 6 N H_2SO_4, followed by thorough washing of the sulfide and then

oxidation to GeO_2 by repeated treatment with 30% H_2O_2 before ignition and weighing[22]. Magnesium germanate, barium germanium tartrate and various forms of complexed germanium molybdates may also be precipitated as weighable forms of Ge[22]. Titration of Ge complexes of polyhydric alcohols such as mannite and glucose with phenolphthalein indicator also is possible. Various colorimetric methods, based mostly on molybdate complexes, have been used[22]. In mineral and nonvolatile inorganic samples, determination of Ge is best accomplished by arc emission spectroscopy, making use of the lines at 3039.1, 2754.6, 2709.6, 2651.2 and 2592.6 Å. By use of internal standards and previous calibration, determination down to the level of 0.0005% Ge is possible[19, 23]. The polarographic determination of Ge^{4+} at a mercury cathode in alkaline solution (1 M $NH_4Cl + 0.5$ M NH_3; $E_c = -1.45$ and -1.70 V) or in acid solution (with the aid of NaH_2PO_2 as reducing agent) also is possible[24].

2. COMPOUNDS OF Ge(I)

2.1. MONOHYDRIDE, $(GeH)_x$

The action of moist air on alkali germanides, or better, the addition of NaGe to cold water[25], or the action of NH_4Br on NaGe in liq. NH_3[25], or the slow action of metallic Na on $GeHCl_3$ vapor at 60°[26], gives a brown amorphous solid of composition GeH which is insoluble in organic and inorganic solvents but is rapidly oxidized to GeO_2 by HNO_3 or H_2O_2. When dried in air it oxidizes with an explosive puff as soon as it is dry. In vacuum it evolves hydrogen slowly at 100° and decomposes explosively at 160° to form GeH_4 and finely divided Ge.

2.2. MONOHALIDES

Germanium monofluoride, GeF, is known only from the band emission spectrum from a discharge in GeF_4. The bond force constant of the molecule is calculated to be 3.92×10^5 dynes/cm[27].

Monomeric GeCl also is known from its band spectrum; the force constant is calculated to be 2.2×10^5 dynes/cm. A solid "subchloride", $(GeCl)_x$, is a high polymer of unknown structure made by passing $GeCl_4$ and H_2 through a hot tube at 1000°, or by reduction of an aq. solution of $GeCl_4$ with H_3PO_2. It is a dark brown solid which is stable up to 360° in vacuum but decomposes at 500° to give $GeCl_4$ and Ge; it is insoluble in common organic solvents, slightly soluble in H_2O (and slowly hydrolyzed), and oxidized rapidly by hot HNO_3. Boiling aq. KOH dissolves it very slowly:

$$2GeCl + 6KOH = 2K_2GeO_3 + 2KCl + 3H_2$$

The monobromide GeBr is known from its band spectrum, and the force constant is

2.0×10^5 dynes/cm. No GeI is known, even from a band spectrum, but the force constant for a hypothetical Ge–I bond is calculated to be 1.46×10^5 dynes/cm. No oxide, nitride or sulfide of Ge in the $+1$ oxidation state is known.

3. COMPOUNDS OF Ge(II)

3.1. DIHYDRIDE, GeH_2 ("POLYGERMENE")

The action of conc. HCl on a mixture of powdered NaCl and CaGe (with exclusion of oxygen) produces a yellow solid polymer of the composition $(GeH_2)_x$. Hydrolysis of Mg_2Ge in equal volumes of alcohol and conc. HCl gives a less pure product; small amounts can also be made by the thermal decomposition of Ge_2H_6. The substance is readily oxidized by bromine to $GeBr_4$, and by conc. HNO_3 or H_2O_2 (in alcohol plus aq. NH_3) to GeO_2. Conc. aq. alkalies convert it (by complex reactions) to GeH_4 and alkali germanites. At 200° (in the absence of air) it decomposes slowly to H_2 and Ge, and rapidly at 300°. A sharp blow on the dry solid can cause explosive decomposition to Ge, with burning of the liberated hydrogen. Treatment with hot aq. HCl yields H_2, Ge, GeH_4, Ge_2H_6 and Ge_3H_8.

3.2. GERMANIUM DIFLUORIDE, GeF_2

Germanium is much more easily reduced to the $+2$ state than silicon, and the tetrahalides GeX_4 react with elementary Ge to form dihalides GeX_2. The action of GeF_4 on powdered Ge produces a white solid for which no physical constants are available, but the chemical properties show it to be quite certainly GeF_2 (see section on GeF_4). Better examples are found among the higher dihalides.

3.3. GERMANIUM DICHLORIDE, $GeCl_2$

The slow passage of $GeCl_4$ vapor (at low pressure, *ca.* 0.1 torr) over powdered Ge at only 300° produces a light-yellow solid $GeCl_2$, which condenses in the cooler parts of the tube[28]. The same product is obtained from the thermal decomposition of $GeHCl_3$ (which, however. is usually made by the combination of $GeCl_2$ and HCl):

$$GeHCl_3 \underset{20°}{\overset{70°}{\rightleftharpoons}} GeCl_2 + HCl$$
Excess H_2 and $GeCl_4$ vapor passed through a hot silica tube at 800° also produce some $GeCl_2$.

At room temperature $GeCl_2$ is stable but easily oxidized. It adds Cl_2 and Br_2 to form tetrahalides (although I_2 is likely to form GeI_2), and it adds HCl readily to form $GeHCl_3$, but strangely it does not seem to add alkyl halides to form organogermanium halides. It hydrolyzes to form yellow $Ge(OH)_2$ (which dehydrates to brown GeO) and HCl (which may react with excess $GeCl_2$). It disproportionates in vacuum at 1000° or more to $GeCl_4$ and elementary germanium.

[28] L. M. Dennis and H. L. Hunter, *J. Am. Chem. Soc.* **51** (1929) 1151; F. M. Brewer, *ibid.* **31** (1927) 1817.

3.4. GERMANIUM DIBROMIDE, GeBr₂

The reduction of GeBr$_4$ and GeHBr$_3$ with zinc[28], or the action of a deficiency of HBr on Ge at 400°, produces GeBr$_2$, a yellow solid which melts at 122° and is slightly soluble in 5 N aq. HBr. Such a solution forms white crystalline coordination compounds with $(CH_3)_4NBr$, $(CH_3)_4AsBr$ and $(CH_3)_3C_2H_5AsBr$[29]. Pure GeBr$_2$ disproportionates to GeBr$_4$ and Ge at 150°, and hydrolyzes to Ge(OH)$_2$. It reacts readily with dry HBr at 40° to form GeHBr$_3$[28].

3.5. GERMANIUM DIIODIDE, GeI₂

Low-temperature methods are preferred for the preparation of GeI$_2$. Treatment of freshly precipitated Ge(OH)$_2$ with hot conc. HI, followed by reduction of the liberated iodine with H$_3$PO$_2$ and then cooling of the solution, causes precipitation of flaky crystals of GeI$_2$. Similarly, powdered GeS may be extracted with warm conc. HI, the excess GeS filtered off, the solution cooled and the crystals of GeI$_2$ recovered. However, the simplest preparative method consists in the reduction of GeI$_4$ with a slight excess of H$_3$PO$_2$: 20 g of GeI$_4$ is dissolved in 10 ml of 57% HI+20 ml H$_2$O and 7.6 ml of 50% H$_3$PO$_2$ added with stirring. The mixture is refluxed, the red crystals of GeI$_4$ slowly being converted to bright-yellow GeI$_2$. The mixture is cooled to 10°, the GeI$_2$ filtered and washed with dil. HI, and dried in vacuum (yield 75%)[30].

Pure sublimed GeI$_2$ is an orange solid which crystallizes in the hexagonal system: $a = 4.249$, $c = 6.833$ Å, Ge–I distance = 2.99 Å[31]. At 544° to 643° it disproportionates

$$2GeI_2(s) \rightleftharpoons Ge(s) + GeI_4(g)$$

with a heat of sublimation $\Delta H° = 30.1$ kcal/mole, a free energy change $\Delta G° = 17.9$ kcal/mole, and an entropy change $\Delta S° = 41.0$ cal/mole deg[31]. The crystals do not oxidize in dry air, but hydrolyze slowly in moisture. They dissolve in liq. NH$_3$ (with formation of GeNH) and in aq. HI. Iodine in aq. KI+HCl oxidizes GeI$_2$ to GeI$_4$:

$$GeI_2 + I_2 \xrightarrow{\text{HCl+KI}} GeI_4 \text{ (dissolved)} + 19.06 \text{ kcal}[31]$$

In the absence of HI, hydrolysis takes place during oxidation:

$$GeI_2 + I_3^- + 3H_2O = H_2GeO_3 + 4H^+ + 5I^- + 26.0 \text{ kcal}[31]$$

Many addition compounds of GeI$_2$ with amines and other nitrogenous bases are known[32].

3.6. GERMANIUM MONOXIDE, GeO

When GeO$_2$ is reduced to metal with carbon (q.v.) there is troublesome loss of volatile brown GeO, and the same can be said for any high-temperature reduction of Ge(IV) compounds with oxygen present. A mixture of Ge and GeO$_2$ powders heated to 1000° gives a yellow sublimate of amorphous GeO, and further heating at 650° gives dark-brown

crystalline GeO. Hydrolysis of germanium dihalides and GeS gives $Ge(OH)_2$, which dehydrates readily to GeO.

Crystalline GeO has a density of 1.83, a heat of formation (at 25°) of 6.0 kcal/mole, and a vapor pressure of 1.80 torr at 915°, 9.9 at 948° and 28.5 at 978°. The vapor-pressure equation is $4.57 \log p = -63,000/T + 57.9$[33], and the entropy content is $S_{298} = 56.1$ cal/mol deg. The molar magnetic susceptibility is -28.6×10^{-6}. Chemically, GeO disproportionates rapidly at 700° to $Ge + GeO_2$; the heat of this reaction is 54.8 kcal/mole and the entropy change is 42.0 cal/mol deg[33]. It is oxidized by a variety of reagents, among them silver perchlorate[33]:

$$GeO + 2AgClO_4 + 6HF = 2Ag + 2HClO_4 + H_2O + H_2GeF_6 + 66 \text{ kcal}$$
3.7. GERMANIUM(II) HYDROXIDE, $Ge(OH)_2$

Besides its derivation from other Ge(II) compounds, $Ge(OH)_2$ may also be prepared by the direct reduction of an acid solution of GeO_2. As done originally[34], GeO_2 is dissolved in aq. HCl (6 N) and reduced with H_3PO_2, whereupon yellow or red $Ge(OH)_2$ is precipitated by the addition of aq. NH_3. The product is washed with O_2-free water and dried. By a more recent procedure[31], 6 g of GeO_2 is dissolved in 30 ml of conc. NaOH, precipitated and redissolved by adding sufficient 6 N HCl, and then reduced with 45 ml of 50% H_3PO_2 at 100° over 5 to 6 hr. Neutralization of the cooled solution with NH_3 precipitates yellow $Ge(OH)_2$, which can be filtered under N_2. The color appears to be due to the presence of some GeO, because the material slowly dehydrates and darkens upon standing, and eventually becomes dark-brown GeO. The hydroxide is very easily oxidized to GeO_2; the standard potential for the reaction

$$Ge(OH)_2 + H_2O = GeO_2 + 2H^+ + 2e^-$$
is -0.118 V[31].

Because of the change in composition, the chemical properties of $Ge(OH)_2$ change with the age and color of the material. Freshly precipitated material dissolves readily in conc. HCl. The solubility of aged material in 4 N HCl is only 0.01 mole/l., but at high concentration of HCl the solubility increases markedly. Dilute aq. NaOH does not dissolve detectable amounts of $Ge(OH)_2$ if the base is less than 1 N, but 50% NaOH dissolves it by oxidizing it to sodium germanate, with evolution of hydrogen:

$$Ge(OH)_2 + 2NaOH = Na_2GeO_3 + H_2O + H_2$$
Latimer[35] gives the potential for the germanite–germanate oxidation in basic solution as -1.4 V.

3.8. GERMANIUM MONOSULFIDE, GeS

Although GeS was first made by reducing GeS_2 with Ge (Winkler) or with H_2 at 480° (Dennis), the simplest way to prepare it now is to precipitate GeS_2 (as by the action of H_2S

on a solution of $GeCl_4$ in 6 N HCl) and reduce the fresh precipitate with excess H_3PO_2 by stirring on a steam bath until a clear, colorless solution results. The cooled solution is then saturated with H_2S and neutralized with aq. NH_3, with H_2S still flowing. The resulting GeS is filtered under N_2 and dried in N_2 over P_2O_5[36]. The resulting amorphous red-brown powder may be crystallized by sublimation in vacuum at 600°; the crystals are orthorhombic bipyramidal, with $a = 4.29$, $b = 10.42$ and $c = 364$ Å (space group D_{2h}^{16}). Each Ge atom is surrounded by six S atoms in a deformed octahedral structure, with Ge–S distances of 2.47, 2.64, 2.91 and 3.00 Å. The closest S–S approach is 3.55 Å[37]. The calculated density is 4.24 g/cc, and the molar susceptibility is -4.9×10^{-6}. The crystals appear black, but transmitted light through thin sections is red, and reflected light steel gray[37]. The powdered substance hydrolyzes slowly in moist air and rapidly in liq. H_2O to form $Ge(OH)_2$ and then GeO. It dissolves slightly in aq. NaOH, but apparently only if some GeS_2 is present[36]. The solubility product in liq. NH_3 is 9×10^{-6}, and no ammonolysis takes place. An excess of Na in liq. NH_3 dissolves GeS to form a reddish solution of sodium polygermanide, and addition of NH_4Br to this causes evolution of GeH_4[37].

## 3.9. GERMANIUM(II) SELENIDE AND TELLURIDE

When H_2Se is passed into an aq. solution of $GeCl_2$, a dark-brown precipitate of GeSe forms. This substance is insoluble in 5% aq. HCl, alcohol and ether; it oxidizes readily in air, but is stable in CO_2 and can even be prepared from the elements in a CO_2 atmosphere at 500°. It crystallizes in the tetragonal system with $a = 8.83$ and $c = 9.76$ Å. The measured density is 5.30, the calculated 5.266 g/cc. The melting point is about 667°. It dissolves in a solution of Br_2 in HCl, and H_2O_2 in alkaline solution oxidizes it to GeO_2 and Se. Aq. HNO_3 oxidizes it to GeO_2 and H_2SeO_3[38].

The system Ge–Te shows a eutectic at 375° and an incongruent melting point for the compound GeTe at 725°. The bond force constant is 2.9×10^5 dynes/cm, and the bond distance is 2.85 Å (calcd. from at. radii, 2.39 Å). The crystal structure is cubic, with $a = 5.99$ at 460° and 5.98 at 390° (like Ge and Te structures). At room temperature the structure is more complicated and probably is non-stoichiometric. It is metallic in appearance, with density 6.20. It reacts with conc. HCl, H_2SO_4 and H_2O when heated, but aqua regia attacks it in the cold, as does a mixture of H_2O_2 and HCl[38].

3.10. GERMANIUM(II) IMIDE AND NITRIDE

In liquid NH_3, GeI_2 is completely ammonolyzed to the imide GeNH:

$$GeI_2 + 3NH_3 = GeNH + 2NH_4I$$
The NH_4I can be washed from the product by repeated extraction with liq. NH_3, leaving a canary-yellow powder[39] which oxidizes rapidly in air to GeO_2 and hydrolyzes in oxygen-free water to $Ge(OH)_2$ and NH_3. When heated to 300° in vacuum, the imide is converted to a dark-brown nitride:

$$3GeNH = Ge_3N_2 + NH_3$$

[36] L. S. Foster, *Inorganic Syntheses*, Vol. 2, p. 102, McGraw-Hill, N.Y. (1946); D. A. Everest and H. Terry, *J. Chem. Soc.* **1950**, 2282.

[37] Gmelin, *loc. cit.*, pp. 536–539.

[38] Gmelin, *loc. cit.*, pp. 541–544.

[39] L. S. Foster, *Inorganic Syntheses*, Vol. 3, p. 63, McGraw-Hill, N.Y. (1950).

This nitride decomposes into the elements at 500°, but when heated in H_2 at 500° to 600° it forms Ge and NH_3[40]. The α form of Ge_3N_4 is hexagonal close-packed, $a = 8.202$ and $c = 5.941$ Å; the β form has the phenacite structure[40], with $a = 8.038$ and $c = 3.074$ Å.

3.11. GERMANIUM(II) COMPOUNDS OF PHOSPHORUS AND ARSENIC

By melting Ge and white P_4 in an evacuated glass tube, impure GeP is obtained; the heat of formation is only 6 kcal/mole. At 540° the substance decomposes according to the equation

$$4GeP = 4Ge + P_4 - 37 \text{ kcal}$$
There also are some hypophosphite–halide double salts which can be obtained by evaporating solutions of Ge(II) salts containing excess H_3PO_2 left from the reduction procedures described above. In particular $Ge(H_2PO_2)_2 \cdot GeCl_2$, $3Ge(H_2PO_2)_2 \cdot GeBr_2$ (m.p. 129°) and $3Ge(H_2PO_2)_2 \cdot GeI_2$ (m.p. 120°) have been crystallized[41]. These compounds are stable in dry air at 20°, but hydrolyze to $Ge(OH)_2$. Warm conc. H_2SO_4 and HNO_3 oxidize them rapidly to GeO_2.

If the reduction of GeO_2 with limited H_3PO_2 is carried out in hot conc. H_3PO_3 solution, in the absence of halide ions, the cooled solution yields crystals of yellow-green $GeHPO_3$. This substance begins to decompose at 230° without melting, and becomes black at 300°. It is soluble in warm aq. HCl, HBr and H_3PO_4, but insoluble in cold dil. H_2SO_4, CH_3COOH, HCOOH and organic solvents. Conc. HNO_3 oxidizes it to GeO_2, and alkaline solutions convert it to hydrous GeO[41].

The phase diagram for the system Ge–As shows the compounds $GeAs_2$ (m.p. 732°) and GeAs (m.p. 737°)[42]. The α-phase is made up of mixed crystals of As and $GeAs_2$ and is hexagonal in structure with $a = 3.701$ Å, $c = 10.71$ Å and $c/a = 2.894$; pure As crystallizes in a foreshortened hexagonal structure, with $a = 3.754$ Å, $c = 10.52$ Å and $c/a = 2.802$. Both GeAs and $GeAs_2$ show an enhanced diamagnetism; the values for atomic susceptibility at 20° are: pure As -6×10^{-6}, $GeAs_2$ -19×10^{-6}, GeAs -16×10^{-6} and pure Ge -13×10^{-6}. The alloying of As with Ge renders the As more stable to the air, and the compounds mentioned above remained unaltered for months[42].

3.12. ORGANIC DERIVATIVES OF Ge(II)

The action of C_6H_5Li on GeI_2 in organic solvents gives an orange-brown solution from which polymers of the composition $(C_6H_5)_2Ge$ have been isolated[43]. Gilman and Gerow[44] studied the reaction in detail, and noted that a complex of the composition $(C_6H_5)_3GeLi$ is first obtained, and this dissociates to products which are difficult to characterize. Bromination of the product, for example, gives $(C_6H_5)_3GeBr$ instead of the expected $(C_6H_5)_2GeBr_2$. Preparation of germanium(II) alkyls and aryls by other routes is difficult because germanium

dihalides reduce mercury alkyls to metallic mercury, and organometallic reagents containing more active metals form complexes with the Ge(II) products[45].

4. COMPOUNDS OF Ge(III)

Germanium in an oxidation state of 3 is rare, but a few compounds of the type $R_2Ge-GeR_2$ (which some might consider compounds of divalent germanium, rather than trivalent) are known. The first of these is the supposed dimer $(GeH_2)_2$ which was obtained by the reaction of $NaGeH_3$ with bromobenzene in liquid ammonia[46]:

$$2NaGeH_3 + 2C_6H_5Br \xrightarrow{\text{liq. } NH_3} 2NaBr + 2C_6H_6 + (GeH_2)_2$$
The $(GeH_2)_2$ so obtained is not like the polygermene obtained by the action of conc. HCl on CaGe (*vide supra*), but is a white solid which disproportionates on warming to room temperature:

$$3(GeH_2)_2 = 2GeH_4 + 4GeH$$
The same white solid reacts with one equivalent of Na in liq. NH_3 to give a deep red solution supposedly of the composition $NaH_2Ge-GeH_2Na$ (like analogous tin compounds)[46].

A supposed Ge_2Cl_6 has also been obtained, by the thermal decomposition of GeCl at 210° at only 0.05 to 0.1 torr. The white crystalline product dissolves in $GeCl_4$ and C_6H_6, melts at 30°, is oxidized by air and by H_2O_2, and dissolves in warm aq. KOH with evolution of H_2[47]. No Ge_2Br_6 or Ge_2I_6 has been reported.

One possible interpretation of the term "Ge(III)" would include compounds of the type Ge_2H_6 and Ge_2Cl_6. These are definitely of the structure $X_3Ge-GeX_3$, and so are compounds of tetracovalent germanium. For this reason, Ge_2H_6 is described below along with GeH_4 and the other hydrides of Ge(IV), Ge_2Cl_6 is included with the chlorides, and so on.

5. COMPOUNDS OF Ge(IV)

5.1. GERMANIUM(IV) HYDRIDES

Monogermane, GeH_4

This formerly was made by the action of acids on an alloy of magnesium with germanium[48]. If aqueous acids are used, large quantities of hydrogen are produced and must be separated from the mixture of germanium hydrides; furthermore, the yield of hydrides based on Ge is disappointing. Ammonia-system acids are more satisfactory: the action of NH_4Br on powdered Mg–Ge alloy (3 parts Ge+2 parts Mg fused at 800°) suspended in liq. NH_3 converts 60% to 70% of the Ge to the various hydrides, which are separated by distillation in a vacuum chain. Some GeH_4 also is obtained from the thermal

decomposition of solid GeH, and also by the electrolysis of a solution of GeO_2 in H_2SO_4. More modern and practical methods consist in the reduction of $GeCl_4$ by $LiAlH_4$ in ether[49] (which requires only the simple separation of GeH_4 from ether vapor), and the still simpler and easier reduction of GeO_2 by $NaBH_4$ in water solution[50a, 50b]. By the last method, GeO_2 is dissolved in 1 M HBr and an excess of $NaBH_4$ solution (5 g in 100 ml H_2O) is added dropwise. The GeH_4 (with about 1% Ge_2H_6) is condensed from the stream of H_2 in a series of five traps cooled to $-196°$; the yield is 98%[50b].

Monogermane is a stable, colorless gas with physical properties listed in Table 6. It reacts with sodium dissolved in liq. NH_3 (with evolution of H_2) to form $NaGeH_3$, the same product obtained by splitting Ge_2H_6 with Na in the same medium. Treatment of the $NaGeH_3$ with NH_4Br in the same solvent then evolves pure GeH_4. Thermal decomposition (to $Ge+2H_2$) is very slow at 280°, but rapid at 375°; the deposited Ge is a catalyst for the further decomposition, so the rate is proportional to the 1/3 power of the pressure of GeH_4. Under appropriate conditions, the dissociation is a first-order reaction[51]. The photochemical decomposition (under Hg-arc irradiation, the GeH_4 being sensitized with Hg vapor) begins with stripping of one H atom and then a stepwise degradation of GeH_3 fragments[52].

In contrast to SiH_4 and SnH_4, GeH_4 does not ignite when it meets air. It can be mixed with pure oxygen, at low pressure, and the oxidation begins only slowly at 320°. In the range 230° to 330° the reaction produces H_2O and a white deposit of GeO_2, but at higher temperatures explosions may result, and brown Ge is deposited as the thermal dissociation of GeH_4 precedes the oxidation of its products.

In sharp distinction to SiH_4 (which is decomposed rapidly by even exceedingly dilute alkali solutions), GeH_4 is unaffected by 30% aq. NaOH, and of course is not hydrolyzed by the 1 M HBr in which it is made. It is a potent reducing agent; it reacts with aq. $AgNO_3$ to evolve hydrogen and precipitate a black mixture of Ag and Ge. Oxidizing agents convert it to GeO_2 and H_2O. It dissolves in liq. NH_3 to form a conducting solution believed to contain NH_4^+ and GeH_3^- ions, and the solution dissolves P_4 to form an ammonium phosphogermanide. Sodium and potassium in liq. NH_3 convert GeH_4 to $NaGeH_3$ and $KGeH_3$, white solids which are unstable at room temperature and decompose to the metal germanide and hydrogen. The substances $MGeH_3$ react in liq. NH_4 with CH_3Cl to form CH_3GeH_3, but the same substances react with CH_2Br_2 in a reductive way, not to yield $H_3GeCH_2GeH_3$[53]:

$$CH_2Br_2+2NaGeH_3+NH_3 \longrightarrow CH_3GeH_3+GeH_3NH_2+2NaBr$$
In the same solvent $NaGeH_3$ reduces aromatic halides to hydrocarbons, rather than forming $RGeH_2$[53]:

$$NaGeH_3+C_6H_5Br \longrightarrow C_6H_6+GeH_2+NaBr$$

Digermane, Ge_2H_6

This is obtained as a by-product in the preparation of GeH_4 as described above, and also by the circulation of GeH_4 through a silent electrical discharge at low pressures[54]. The physical properties, insofar as they are known, appear in Table 6.

Digermane decomposes at 200° in a manner that fits the scheme[55]

$$GeH_6 \longrightarrow 2GeH_3$$
$$GeH_3 + Ge_2H_6 \longrightarrow GeH_4 + Ge_2H_5$$
$$Ge_2H_5 \longrightarrow GeH_2 + GeH_3$$
$$GeH_2 \longrightarrow Ge + H_2$$
$$2GeH_2 \longrightarrow GeH_4 + Ge$$

The activation energy for such pyrolysis is 33.7 kcal[55]. Digermane oxidizes more easily than GeH_4, but less readily than Si_2H_6; oxidation proceeds at 100°:

$$2Ge_2H_6 + 7O_2 \longrightarrow 4GeO_2 + 6H_2O$$
In liq. NH_3, a solution of Ge_2H_6 has a conductivity of 0.97×10^{-3} recip. ohm-cm at $-60°$ (1.35×10^{-3} at 47°), which is 10,000 times as large as that of the pure solvent and indicates formation of a salt-like $(NH_4)_2Ge_2H_4$. The solution dissolves P_4 in much the same way as does a solution of GeH_4[56].

The *higher germanes* also ensue from circulation of GeH_4 through an electric discharge[54], more Ge_3H_8 being obtained than Ge_2H_6. Some Ge_3H_8 also was obtained by the classical method of Dennis, Corey and Moore[48], and most of the physical properties of the substance in Table 6 come from a sample prepared that way. When exposed to the air, Ge_3H_8 soon changes to a white solid, but does not ignite. It does not dissolve in water, but appears to be oxidized by air in the water. It is immiscible with 33% aq. NaOH, and does not react with it. Like Ge_2H_6, Ge_3H_8 dissolves in CCl_4 and reacts with it, apparently to form $GeCl_4$.

The formulas Ge_4H_{10} and Ge_5H_{12} in Table 6 refer to mixtures of isomers in unknown proportions. The Ge_4H_{10} decomposes slowly above 50° and rapidly above 100° to give GeH_4 and liquid products[53], and Ge_5H_{12} decomposes at 100° to GeH_4 and a solid residue. At 350° all the higher hydrides become Ge and H_2.

5.2. GERMANIUM(IV) HALIDES

Germanium Tetrafluoride, GeF_4

This probably is obtainable from the elements, but is much more easily obtained in pure form by the thermal decomposition of barium fluorogermanate, $BaGeF_6$. This salt is made by adding $BaCl_2$ to a solution of GeO_2 in aq. HF; the white granular solid is washed with cold water and dried at 120°. When heated in a silica tube (copper is unsatisfactory), copious evolution of GeF_4 begins at 600°. The gas does not attack dry glass at 25°, nor silica glass at 700°, but copper and other base metals reduce it at elevated temperatures. The gas itself does not decompose at 1000° and 100 mm. When passed over reduced Ge at temperatures above 100°, or over crystalline Ge at 350°, a white volatile solid GeF_2 is

[54] J. E. Drake and W. L. Jolly, *Proc. Chem. Soc.* **1961**, 379.
[55] H. J. Eméleus and H. H. G. Jellinek, *Trans. Faraday Soc.* **40** (1944) 93.
[56] P. Royen, *Z. anorg. Chem.* **235** (1938) 324.

formed. This solid dissolves in water, and the solution reduces $KMnO_4$ and I_2; when H_2S is added to it, GeS precipitates[57].

The physical properties of GeF_4 are given in Table 7. Chemically, GeF_4 reacts with limited water to precipitate gelatinous GeO_2 and form HF. In a large excess of water, the gas dissolves and heat is evolved; addition of KOH precipitates K_2GeF_6, showing that H_2GeF_6 is formed in the solution. Hydrolysis of small amounts of GeF_4 vapor in the throat and lungs produces hoarseness and extreme irritation. When the vapor of GeF_4 (at 1 atm) is passed over heated $AlCl_3$, $MgCl_2$ or $FeCl_3$, complete exchange of halogen occurs, giving only $GeCl_4$ and no mixed halides.

Besides the two fluorogermanate salts already mentioned, many others can be precipitated or crystallized from water solution. The easiest method of preparation is to dissolve dried precipitated GeO_2 in an excess of 40% aq. HF, and then add the base and cool the solution. Many organic bases form fluorogermanates this way, as well as hydrazine, ammonia and metallic hydroxides.

Germanium Tetrachloride, $GeCl_4$

This is the oldest and best-known covalent compound of germanium. It was prepared in 1886 by Clemens Winkler, who found that the germanium in a solution of GeO_2 in a large excess of hydrochloric acid could all be recovered as $GeCl_4$ just by heating the solution. Finely divided Ge ignites in chlorine, and massive Ge heated in a stream of Cl_2 soon reaches incandescence and produces $GeCl_4$. The tetrachloride may also be made from GeO_2 by heating the dioxide to $500°$ in a stream of CCl_4 vapor carried by N_2. The reductive chlorination also is possible with $COCl_2$ or a mixture of CO and Cl_2 at $600°$. Passing Cl_2 over a heated mixture of carbon and GeO_2 is not a satisfactory method; the best large-scale method is distillation from aq. HCl. Crude $GeCl_4$ can be freed from Cl_2 by blowing a stream of dry air through it (or by shaking it with Hg or with Hg_2Cl_2) and then purified by fractional distillation (see isolation of Ge from its ores, *supra*). The physical properties of pure $GeCl_4$ are given in Table 7. References 58–69 are a guide to the older literature.

Pure $GeCl_4$ is a colorless, refractive liquid with a sharp, penetrating odor. It fumes in moist air, and its vapor deposits a chalky coating of GeO_2 on glass surfaces which have not been dried in vacuum. The vapor is very stable (undecomposed at $950°$) but very reactive toward alkali metals (mixing the vapors of $GeCl_4$ and K gives a rapid reaction and a blue chemiluminescence). It undergoes halogen exchange if treated with PI_3 or SbF_3 or $SnBr_4$. Hydrogen reduces the vapor to Ge at $600°$, forming $GeCl_2$ as an intermediate product.

Liquid $GeCl_4$ reacts rather slowly with liquid water at the interface, depositing GeO_2. In liquid ammonia it forms the imide $Ge(NH)_2$, which decomposes on heating to form a nitride Ge_3N_4. The liquid is without action on H_2SO_4 or conc. aq. HCl, but reacts slowly with conc. aq. HNO_3 to become colored with oxides of nitrogen. In acetic anhydride $GeCl_4$ forms the tetra-acetate,

$$GeCl_4 + 4(CH_3CO)_2O = Ge(CH_3COO)_4 + 4CH_3COCl$$

but this cannot be isolated by distillation and is better prepared by a metathetic reaction with thallium monoacetate in acetic anhydride solution, precipitating TlCl. Primary and secondary amines react to form the amine hydrochloride and a substituted imide $Ge(NR)_2$, but tertiary amines such as $(C_2H_5)_3N$ form addition compounds, usually of the type

[57] L. M. Dennis and A. W. Laubengayer, *Zeit. f. Phys. Chem.* **130** (1927) 520; L. M. Dennis, *Z. anorg. Chem.* **174** (1928) 119.

$GeCl_4 \cdot 4R_3N$. Alcohols appear to react only very slowly with $GeCl_4$ to form esters; since the reaction with water

$$GeCl_4 + 2H_2O = GeO_2 + 4HCl$$
is definitely reversible at high concentrations of HCl (*vide supra*), the reaction with alcohols probably soon comes to equilibrium. Hence germanium alkoxides are best made by dissolving sodium in the alcohol and then adding $GeCl_4$:

$$GeCl_4 + 4C_2H_5ONa = Ge(OC_2H_5)_4 + 4NaCl$$
Germanium tetrachloride is readily purified and stored, and so is the favorite starting material for preparing a wide variety of *organogermanium* compounds through the agency of Grignard reagents, lithium alkyls and sodium condensations:

$$4C_2H_5MgBr \text{ (in } Et_2O) + GeCl_4 = (C_2H_5)_4Ge + 4MgBrCl$$

$$C_6H_5MgCl \text{ (in THF)} + GeCl_4 = C_6H_5GeCl_3 + MgCl_2$$

The subject of organogermanium chemistry is treated separately in a later section, but it may be said that ever since Clemens Winkler made the first organogermanium compound from it in 1887, $GeCl_4$ has been very important to the subject. It also is the common starting material for the preparation of addition compounds (with ethers and esp. cyclic and aromatic ethers, for example[69]) and of coordination compounds of the transition metals[70]. In this connection, it is interesting to note that although *silicon* forms very stable fluorosilicates containing the SiF_6^- ion, it forms no chlorosilicates M_2SiCl_6; *germanium*, on the other hand, not only forms fluorogermanates M_2GeF_6, but also chlorogermanates, such as Cs_2GeCl_6[71].

Germanium Tetrabromide, GeBr₄

This is readily prepared from the elements by conducting Br_2 vapor (diluted with N_2) over powdered Ge heated to 220° and collecting the products in an ice-cooled trap, or by refluxing finely powdered Ge with liquid Br_2 for 4 hr, evaporating the excess bromine at 25°, removing the last Br_2 with HgCl, and then distilling the tetrabromide. Pure $GeBr_4$ forms colorless ice-like crystals which turn yellow in ultraviolet light and hydrolyze rapidly in moist air. Active chlorides (such as $C_6H_5PCl_2$) convert it to chlorobromides, and eventually to $GeCl_4$. However, there is no halogen exchange with $SnCl_4$. Active metals such as Mg strip the bromine from $GeBr_4$ at 25° to 40°, leaving black dispersed Ge.

Germanium Tetraiodide, GeI₄

This may also be prepared from the elements, but its purification by distillation or sublimation is difficult because of decomposition. An easier way is to heat GeO_2 and aq. HI together, and then to extract the GeI_4 into CCl_4 or C_6H_6[72]. Thus GeO_2 is heated in a pressure flask with 20 equivalents of HI (sp. gr. 1.7) to 150° until the GeO_2 is dissolved, and then a stream of hot CO_2 is blown into the flask to vaporize any free iodine. Upon cooling,

orange crystals of GeI_4 deposit. These crystals slowly turn brown and disintegrate in moist air, becoming eventually a brown paste of GeO_2 in HI. Dry GeI_4 decomposes at 440°. Aq. NaOH converts it to Na_2GeO_3 and NaI, and liq. NH_3 converts it to $Ge(NH_2)_2$. Warming with $SnCl_4$, $ZnCl_2$, $CdCl_2$, $HgCl_2$, $PbCl_2$, $AsCl_3$, $SbCl_3$ or $SbCl_5$ converts it to $GeCl_4$. Passing NH_3 through a solution of GeI_4 in CCl_4 gives $GeI_4 \cdot 8NH_3$, and in the same solvent organic amines react with GeI_4 to give addition compounds containing 4, 5, 6 or 10 molecules of amine[73].

A few mixed halides, such as GeF_3Cl, GeF_2Cl_2, $GeFCl_3$, $GeClBr_3$, $GeCl_2Br_2$ and $GeCl_3Br$ are known[74], with properties intermediate between those of the tetrahalides. Those containing chlorine and bromine disproportionate readily.

Halogermanes, GeH_aX_{4-a}

Many volatile hydride–halides of germanium are known, some of which are characterized as given in Table 8. Of these, the most important are the "haloforms" $GeHCl_3$ and $GeHBr_3$. Mention has already been made of the ready reaction of $GeCl_2$ with anhydr. HCl to form $GeHCl_3$; variations of this preparative method include passing $GeCl_4$ vapor and H_2 through a silica tube at 900°, and heating Ge powder in a stream of HCl (diluted with N_2) at 500°. Parallel methods may be used for preparing $GeHBr_3$, or GeS may be dissolved in 40% aq. HBr. A more difficult route involves the preparation of GeH_4 and then the halogenation of this by reaction with limited HCl or HBr in contact with crystals of $AlCl_3$ or $AlBr_3$. Warming $GeHCl_3$ to 75° causes it to return to $GeCl_2$ and HCl. The hydride nature of the hydrogen in $GeHCl_3$ is shown by dissolving the $GeHCl_3$ in alcohols, whereupon H_2 slowly is evolved and $GeCl_4$ and $GeCl_2$ remain. The reactions of the hydride–halides follow in other respects the reactions of both halides and hydrides[75], including preferential hydrolysis of the halogen:

$$2GeH_3Cl + H_2O = (GeH_3)_2O + 2HCl$$
As in silicon chemistry, halogen exchange with chloroform and other carbon halides is noted:

$$GeHBr_3 + CHCl_3 = GeHClBr_2 + CHCl_2Br$$
Mixtures of $GeHCl_3$ and $GeHBr_3$ will also undergo halogen exchange to give $GeHClBr_2$ and $GeHCl_2Br$.

Some halogenated *digermanes* and *digermoxanes* are H_3GeGeH_2Cl (b.p. 88°), Ge_2Cl_6 (m.p. 41°), $Cl_3GeOGeCl_3$ (m.p. −60°, b.p. 70° at 13 mm, density 2.057 at 20°) and H_3GeGeH_3I (m.p. −17°).

5.3. GERMANIUM(IV) CHALCOGENIDES

Germanium Dioxide, GeO_2

This is the best-known solid compound of germanium. It is a stable, unreactive white powder which melts to a glass and can be used as a constituent of glasses which are more

[73] T. Karantassis and L. Capatos, *Compt. rend.* **193** (1931).

[75] F. G. A. Stone, *Hydrogen Compounds of the Group IV Elements*, pp. 63–76, Prentice-Hall, Englewood Cliffs, N.J. (1962).

refractive than the corresponding silicate glasses[76]. It is readily obtained by the hydrolysis of $GeCl_4$, yielding a microcrystalline form of the hexagonal modification of GeO_2 (with a structure much like that of low quartz)[77]. This is often called the "soluble" form, because it dissolves in cold water to the extent of 4 g/l. The same crystalline modification also is obtained by holding GeO_2 glass at 1080° until it devitrifies. The only other modification of GeO_2 is the "insoluble" or tetragonal form, which is obtained by hydrothermal conversion of the "soluble" form (by heating with water in a bomb at 355° for 100 hr). The "insoluble" form is stable up to 1033°, where it inverts slowly to the "soluble" form (which melts at 1116°). The physical properties of both forms are given in Table 9. The "soluble" form of

b At 14°.

GeO_2 is dissolved and converted to H_2GeF_6 by 25 N HF, and is attacked by 12 N HCl and 5 N NaOH, but the "insoluble" form resists these reagents; it dissolves only in 10 times its weight of fused NaOH at 550°, or in 5 times its weight of fused Na_2CO_3 at 900°[77]. The vitreous form of GeO_2 has the same structure as fused silica, and reacts with aq. HF and HCl like the hexagonal crystal modification. The electrical conductivity of GeO_2 is about 10 times that of SiO_2, at temperatures up to 1100°.

Germanium Disulfide, GeS_2

As indicated above, the common hexagonal form of GeO_2 is very soluble in moderately concentrated aqueous acids. When 6 N H_2SO_4 is saturated with GeO_2 and then H_2S is introduced, a precipitate of white GeS_2 forms (sometimes in pearly platelets). This may be filtered, then washed with H_2S-saturated water, H_2S-saturated alcohol, and finally ether. The GeS_2 must be dried in a desiccator, otherwise it will oxidize and hydrolyze. The

[76] L. M. Dennis and A. W. Laubengayer, *J. Am. Chem. Soc.* **47** (1925) 1945; *J. Phys. Chem.* **30** (1926) 1510.
[77] A. W. Laubengayer and D. S. Morton, *J. Am. Chem. Soc.* **54** (1932) 2303.

physical properties are listed in Table 9. Pure GeS_2 dissolves in 12 N HCl, evolving H_2S. When heated in air it turns brown and melts to a dark, vitreous mass, evolving SO_2. In water it hydrolyzes slowly, with a prominent odor of H_2S. It is slightly soluble in liq. NH_3, and in that medium reacts with dissolved sodium to give Na_2S and a dispersion of elementary Ge; addition of more sodium converts the latter to sodium germanide, which reacts with NH_4Br to produce GeH_4. In absolute alcohol GeS_2 reacts with H_2S to form a polymeric white solid, $H_2Ge_2S_5$.

Germanium Diselenide, GeSe₂

This is produced when H_2Se is introduced into a solution of GeO_2 in 6 N HCl. It is an orange solid which melts at 707° (with decomposition). The density is 4.56 at 25°, and the crystal form is orthorhombic, with $a = 12.96$, $b = 6.93$, $c = 22.09$ Å. The crystals oxidize when heated in air, with separation of the selenium. Aqueous acids have little effect on the substance in the absence of an oxidizing agent, but Br_2 in 12 N HCl dissolves it. Conc. HNO_3 oxidizes it to GeO_2 and H_2SeO_3.

Tellurium forms alloys with Ge, and the phase diagram shows evidence of a compound GeTe, but no $GeTe_2$. The GeTe is metallic in appearance, with a density of 6.20. Conc. HCl, and H_2SO_4 and H_2O_2 have no action on the solid, but conc. HNO_3 attacks it and forms GeO_2.

5.3. OXYACID SALTS OF Ge(IV)

Acetate

The addition of $TlC_2H_3O_2$ to a solution of $GeCl_4$ in acetic anhydride gives a precipitate of TlCl and a solution of $Ge(C_2H_3O_2)_4$, from which the latter can be isolated by concentrating the solution at low pressure and then cooling it. The $Ge(C_2H_3O_2)$ separates in white needles, m.p. 156°. It is soluble in benzene and acetone, and almost insoluble in CCl_4 and ether. It hydrolyzes readily in moist air to GeO_2 and $HC_2H_3O_2$.

Oxalate

When excess GeO_2 is heated with oxalic acid, a syrupy liquid of the composition $H_2[Ge(C_2O_4)_3]$ is obtained. The NaOH titer of this corresponds to only three-quarters of the original oxalic acid. No crystalline compound can be isolated, but the liquid forms stoichiometric complexes with quinine and with strychnine.

Sulfate

When $GeCl_4$ is heated with SO_3 in a bomb tube at 160° for 12 hr, $S_2O_5Cl_2$ and an unstable sulfate of Ge(IV) are formed[78].

$$GeCl_4 + 6SO_3 = Ge(SO_4)_2 + 2S_2O_5Cl_2$$

Organogermanium Oxyacid Salts

The preparation of oxyacid derivatives of Ge(IV) is facilitated by the presence of alkyl and aryl groups linked to Ge, so that formates, acetates, chloroacetates, perfluoroacetates,

[78] E. Hayek and K. Hinterauer, *Monatsh.* **82** (1951) 205.

propionates and benzoates become possible. For preparation and properties, see the extensive publications of H. H. Anderson[79].

Alkoxides Ge(OR)₄

The action of sodium alkoxides (and of other alkoxides of active metals[80]) on $GeCl_4$, Ge_2OCl_6, etc., gives colorless liquid germanium alkoxides of pleasant odor. The physical properties of some representative compounds are given in Table 10[81]. These substances

cannot be made in satisfactory yield directly from the alcohol and $GeCl_4$, probably because of reversibility of the alcoholysis. However, if a hydrohalogen acceptor such as NH_3 or pyridine is present, the alcoholysis proceeds satisfactorily. The germanium alkoxides are stable in dry air but are slowly hydrolyzed by moisture. Partial hydrolysis leads to polymeric alkoxygermanium oxides $(RO)_3GeOGe(RO)_3$, etc. The compound $Ge(OSiPh_3)_4$ is much more resistant to hydrolysis[82].

6. ORGANOGERMANIUM COMPOUNDS

6.1. GENERAL

Although germanium is a rather rare and little-known element, a large proportion of the research effort on it has been devoted to organogermanium chemistry. As a metalloid, germanium forms strong and durable bonds to carbon (bond dissociation energy $Ge-CH_3 = 59.1$ kcal/mole, $Ge-C_2H_5$ 56.7 kcal, $Ge-C_3H_7$ 56.8 kcal[83]), as well as to

hydrogen, oxygen and the halogens. Hence there are very many varieties of organo-germanium compounds, and the roster of individual compounds reached 2300 in 1967[84]. Obviously a complete account cannot be given here. All that can be done at present is to review the general methods of preparation, to list the physical properties of some representative compounds and to summarize the chemical behavior of these. For more detailed information, the reader is referred to several compilations and general textbooks of organometallic chemistry which have appeared[81, 84-87]. Current reviews appear in *Advances in Organometallic Chemistry* (Academic Press, N.Y., 1964-).

6.2. PREPARATIVE METHODS

1. *Alkylation of Ge halides, alkoxides, etc., by zinc alkyls and aryls:*

$$GeX_4 + 2R_2Zn = R_4Ge + 2ZnX_2$$
This reaction, first used by Winkler in 1886, is fairly satisfactory for tetra-alkyls (aside from the unpleasant making and handling of zinc alkyls), but it is difficult to control for the purpose of making organogermanium halides, and so is not much used any more. Mercury alkyls can be used instead of those of zinc.

2. *Alkylation of Ge halides by Grignard reagents:*

$$GeCl_4 + 2RMgCl = R_2GeCl_2, \text{ etc.}$$
This method is so versatile and so readily controlled that it is the favorite for making most compounds of the type $RGeX_3$, R_3GeX and R_4Ge. It also is used for preparing those dialkyldichlorogermanes which cannot be obtained readily by direct synthesis. Mixed alkyls of the type $RR'R''R'''Ge$ can also be made by successive alkylations with respective Grignard reagents, indicating the degree of flexibility which is possible. In the Grignard preparation of organogermanium halides, since halogen exchange between Ge and Mg is possible, it is important to use organomagnesium *bromides* with GeBr$_4$, and so on.

3. *Alkylation of Ge halides and pseudohalides by organolithium reagents:* It is principally a matter of choice whether organomagnesium or organolithium alkylating reagents be used, but sometimes there are advantages from the use of hydrocarbon solvents (possible with RLi), and sometimes no corresponding RMgX can be made (as was the case at one time when $CH_2\text{=}CHLi$ could be obtained but not $CH_2\text{=}CHMgX$).

4. *Sodium condensation reactions:* These are so difficult to control that they are seldom used.

5. *Direct synthesis:* This is principally a method for making dialkylgermanium dichlorides and dibromides, especially from the lower alkyl halides:

$$2CH_3Cl + Ge(+Cu \text{ catalyst at } 300°) = (CH_3)_2GeCl_2$$

The reaction always produces some $RGeCl_3$ (and a trace of R_3GeCl) as well as R_2GeCl_2, but the proportion of $RGeCl_3$ usually is less than that obtained in the corresponding silicon reaction. The method is simple and inexpensive, where it is applicable, and complexes with ethers are avoided entirely. Either powdered fused germanium or the black powder obtained by reducing GeO_2 with H_2 may be used, and 10% Cu powder is appropriate as catalyst[88].

6. *Addition of Ge–H compounds to alkenes and alkynes:* The addition of $GeHCl_3$ (so readily obtained; see above) to terminal olefins provides a good example of this convenient reaction[89]:

$$GeHCl_3 + CH_3(CH_2)_xCH = CH_2 = CH_3(CH_2)_xCH_2CH_2GeCl_3$$
The various additions are catalyzed by free-radical initiators, by ultraviolet light, by Pt on charcoal or by H_2PtCl_6, and by powdered Cu; each reaction has its own optimum conditions. In general, the additions are easier to conduct than those of the corresponding Si–H compounds, and $GeHCl_3$ is far more reactive than $SiHCl_3$ in such reactions. A tabulation of 109 organogermanium compounds prepared by such germane-to-olefin addition reactions, together with references and a discussion of the technique, is given in a 1966 review[90].

7. *Addition of alkali–metal derivatives of organogermanium compounds to unsaturated compounds:* This is a limited reaction, but a very handy one in some cases where a fourth organic group is to be added to germanium[91]:

$$(C_6H_5)_3GeLi + C_6H_{13}CH = CH_2 = (C_6H_5)_3GeCH_2CHLiC_6H_{13}$$
$$\downarrow H_2O$$
$$(C_6H_5)_3GeCH_2CH_2C_6H_{13}$$

$$(C_6H_5)_3GeK + HCHO = (C_6H_5)_3GeCH_2OK$$
$$\downarrow H_2O$$
$$(C_6H_5)_3GeCH_2OH$$

The reaction with carbonyl compounds does not always result in addition (as in the reaction with formaldehyde, above), but may result in decarbonylation:

$$2(C_6H_5)_3GeLi + CO(OC_2H_5)_2 = (C_6H_5)_3Ge-Ge(C_6H_5)_3 + CO + 2LiOC_2H_5$$
8. *Other methods:* Organodigermanes frequently are obtained by reductive coupling through the agency of Grignard reagents, and indeed the reaction of an excess of C_6H_5MgBr with $GeCl_4$ can produce a preponderance of either $(C_6H_5)_4Ge$ or $(C_6H_5)_3Ge-Ge(C_6H_5)_3$, depending on a slight change in the procedure[92]. These coupling reactions usually are explained by the formation of R_3GeMgX intermediates, although there is much controversy about whether germanium can form such Grignard-like compounds. Exchange reactions are quite common in germanium chemistry also, so that the interaction of $(C_6H_5)_3GeK$ and $(C_6H_5)_3SiCl$ gives not only $(C_6H_5)_3GeSi(C_6H_5)_3$, but also $(C_6H_5)_3GeGe(C_6H_5)_3$ and $(C_6H_5)_3SiSi(C_6H_5)_3$[93].

6.3. TETRA-ALKYLS AND TETRA-ARYLS, R_4Ge

The tetra-alkyls of germanium are somewhat more reactive than those of silicon, but are stable substances obtainable in great variety; hundreds of them (with similar and dissimilar R groups) are listed in the 1967 compendium prepared by Weiss[86]. The physical properties of a few are given in Table 11. The C–Ge bonds can be cleaved by bromine in CCl_4

$$(C_6H_5)_4Ge + Br_2 = (C_6H_5)_3GeBr + C_6H_5Br$$
or by hydrohalogen acids in the presence of aluminum halides (HF requires no AlF_3):

$$(CH_3)_4Ge + HBr(AlBr_3) = (CH_3)_3GeBr + CH_4$$
$$(C_2H_5)_4Ge + HF = (C_2H_5)_3GeF + C_2H_6$$
The R–Ge bond is moderately stable to aqueous acids, but HNO_3 in $(CH_3CO)_2O$ will cleave it, and so will $HClO_4$ in aq. C_2H_5OH. The relative rates of cleavage of $-C_6H_4OCH_3$ groups

[e] N.M.R. constants in Maddox, Stafford and Kaesz, compilation cited above.

from Si, Ge, Sn and Pb in the reaction of $(C_2H_5)_3MC_6H_4OCH_3$ with $HClO_4$ were $1:36:10^5:10^8$, as measured in aq. ethanol.[94] Transfer of alkyl groups to Ge of $GeCl_4$ and $GeBr_4$ occurs in the presence of $AlCl_3$ or $AlBr_3$, and to $SnCl_4$ without the aluminum halide. Metallic Li or Na–K alloy will cleave $(C_6H_5)_4Ge$, but not $(C_4H_9)_4Ge$.

Some interest attaches to the *unsaturated* tetra-alkyls of germanium and their possible polymerization. Vinyl and allyl compounds of the type $R_nGeR'_{4-n}$ (where R′ is methyl or ethyl) have been polymerized at 6000 atm and 120°, using peroxide initiators[95]. Mono-vinyl and monoallyl compounds gave oily liquids, while the polyfunctional compounds

[94] C. Eaborn and K. C. Pande, *J. Chem. Soc.* 1960, 1566.

[95] F. Rijkens, ref. 93, p. 29.

gave flexible or glassy solids. Readiness of polymerization of analogous .vinyl and allyl compounds of Group IV elements increases in the order Sn, Ge, C, Si[95]. Polymers may also be made by the addition of R_2MH_2 compounds (where M is a Group IV element) to unsaturated tetra-alkyls of the type $R_2MR'_2$, where R' is an alkyl group with terminal unsaturation[95]. References to many polymerization experiments with olefinic R_4Ge compounds are given by Weiss[86].

6.4. ORGANOGERMANIUM HYDRIDES

Many alkyl and aryl derivatives of GeH_4 are known, and the properties of a few representative compounds are given in Table 12. They show most of the reactions of the

[c] Observations on bond lengths in these compounds, together with some discussion of their chemical behavior, appear in F. G. A. Stone, *Hydrogen Compounds of the Group IV Elements*, chapter 3, Prentice-Hall, Englewood Cliffs, N.J. (1962).

[d] See also Monogermanes—their synthesis and properties, by J. E. Griffiths, *Inorg. Chem.* 2 (1963) 375. Vapor pressures for CH_3GeH_3, $(CH_3)_2GeH_2$ and $(CH_3)_3GeH$ are given there.

germanium hydrides themselves, moderated by the presence of R groups: hydrogen is replaced by halogen through the action of HX, reducing action is evident, hydrogen is expelled by $GeCl_4$ and SO_2Cl_2, etc., and addition to alkenes and alkynes occurs. It is interesting that lithium alkyls react in such a way as to metalate the germanium

$$(C_2H_5)_3GeH + RLi = (C_2H_5)_3GeLi + RH$$
whereas R_3SiH gives R_4Si and LiH.

6.5. ORGANOGERMANIUM HALIDES

Preparative methods 2, 3, 5, and 6 (see above) come into full play here, as well as halogen cleavage of tetra-alkyls and tetra-aryls. Hence very large numbers of compounds

R_3GeX, R_2GeX_2 and $RGeX_3$ are known, along with organogermanium halo-hydrides and organo-functional germanium halides. A full listing extends into the hundreds[86]; some constants for a few representative compounds are given in Table 13. Organogermanium halides hydrolyze *reversibly* (in sharp contrast to organosilicon halides) to give organo-germanium oxides and hydroxides, and reaction with ammonia gives primary, secondary,

$Cl_3GeCH_2CH_2GeCl_3$	56	131	12		

[a] See also J. E. Griffiths, *Inorg. Chem.* **2** (1963) 375.

and tertiary amines (depending on conditions and size of R group). Lithium in THF brings about coupling of R_3GeBr and $R_3'SiCl$ to give $GeSiR_3'$ compounds.

Organogermanium chlorides (and indeed $GeCl_4$ also) undergo an interesting and often useful reaction with diazomethane to replace chlorine ligands with chloromethyl groups, thereby establishing new Ge–C bonds[96]:

$$CH_3GeCl_3 + CH_2N_2 \longrightarrow CH_3(CH_2Cl)GeCl_2 + N_2$$

(yield 78%; b.p. 72° at 40 mm, $n_D^{25} = 1.4890$, $d_4^{25} = 1.642$).

This is an illustration of a general method for obtaining chloromethyl derivatives of

[96] D. Seyferth and E. G. Rochow, *J. Am. Chem. Soc.* **77** (1955) 907.

Ge and Si, in which a cold solution of CH_2N_2 in ether is added to the germanium chloride in the presence of a small amount of suspended copper powder. Nitrogen evolution takes place at $-60°$, and there are few by-products.

6.6. ORGANOGERMANIUM OXIDES

Considerable interest attaches to the possibility of making polymeric organogermanium oxides $(-R_2GeO-)_x$ analogous to the silicones $(-R_2SiO-)_x$, etc., so some attention has been given to the matter. When a mixture of $(CH_3)_2SiCl_2$ and $(CH_3)_2GeCl_2$ is hydrolyzed, the mixture of water-immiscible dimethylsiloxanes is found to contain no germanium; all of the germanium is found in the water layer. When $(CH_3)_2GeCl_2$ alone is added to water it dissolves, and evaporation of the solution in an oven at 105° leaves nothing behind. This indicates that the hydrolysis of $(CH_3)_2GeCl_2$ in pure water is reversible and incomplete, and that the partial hydrolysis products are water-soluble. A study of the hydrolytic dissociation[97] shows that a 0.6 M solution of $(CH_3)_2GeCl_2$ in water has a pH of 1.2, and that titration of this with 0.1 N NaOH produces a curve very much like that for the titration of HCl, with no precipitation of $(CH_3)_2GeO$ or $(CH_3)_2Ge(OH)_2$ even up to pH 12. The van't Hoff i factor is 5. This indicates that the hydrolytic dissociations

$$(CH_3)_2GeCl_2 \rightleftharpoons (CH_3)Ge^{++} + 2Cl^-$$
$$(CH_3)_2Ge^{++} + H_2O \rightleftharpoons (CH_3)_2GeOH^+ + H^+$$

and
$$(CH_3)_2GeOH^+ + H_2O \rightleftharpoons (CH_3)_2Ge(OH)_2(sol) + H^+$$

are taking place, and this was confirmed by precipitating sulfide, chromate, and thiocyanate salts of the $(CH_3)_2Ge^{++}$ ion[96]. Hence $(CH_3)_2GeCl_2$ behaves like a strong diprotic acid in water.

Extraction of a water solution of $(CH_3)_2GeCl_2$ with petroleum ether, followed by intensive drying of the ether layer before evaporation, leads to a cyclic tetramer $[(CH_3)_2GeO]_4$ which melts at 92°[98]. This dissolves readily in water (where it is present as monomeric units, probably $(CH_3)_2Ge(OH)_2$), and evaporation of the water solution yields a white polymer $[(CH_3)_2GeO]_x$ which melts at about 132° and appears fibrous but is revealed by electron microscopy[99] to consist of dendritic orthorhombic crystals. In the vapor phase at 200° and 100 mm, dimethylgermanium oxide exists as a trimer[98]; rapid quenching of the vapor produces unstable crystals which revert to the tetramer. The three forms of $(CH_3)_2GeO$ have different infrared spectra[98, 100], with Ge–C asymmetric stretching absorption at 598 cm^{-1}. The tetramer is non-toxic to hamsters, and causes little or no increase in the red blood cell count; both observations point toward no appreciable metabolism of the substance, and hence a biological stability[101].

*Diethyl*germanium oxide may also be made by hydrolyzing $(C_2H_5)_2GeCl_2$ prepared from Ge by the direct reaction of C_2H_5Cl[102]. The hydrolysis product is an oily mixture of polymers, less soluble in water than $(CH_3)_2GeO$ but decidedly soluble.

6.7. ORGANOFUNCTIONAL ORGANOGERMANIUM COMPOUNDS

Besides the simple alkyl and aryl germanium hydrides, halides, and related derivatives, there are many organogermanium compounds which have organofunctionality of one or more types:

(a) Unsaturation, as in vinyl, allyl, and other alkenyl and alkynyl compounds, obtained by dehydrochlorination or by Grignard or related techniques.

(b) Halogen substitution, as in CH_2Cl–Ge compounds from diazomethane reactions, or CF_3–Ge compounds (from addition of CF_3I to GeI_2, etc.).

(c) Cyano-, acetoxy-, and alkoxy-alkyl derivatives, often obtained from the corresponding haloalkyl compounds, or by such specialized procedures as addition of acrylonitrile to Ge–H bonds. Fifty such compounds are listed (with properties and references) in the Weiss compilation[86].

6.8. OTHER ORGANOGERMANIUM COMPOUNDS

A long series of organogermanium *pseudohalides* has been obtained by the action of AgCN, AgCNS, AgCNO, etc., on organogermanium halides[103]. The properties of some representative compounds are given in Table 14.

TABLE 14. ORGANOGERMANIUM PSEUDOHALIDES

Compound	M.p., °C	B.p., °C	At. pr., mm	n_D^{20}	d_{20}
$(CH_3)_3GeCN$	38.5	150	760	—

$(n-C_4H_9)_3GeNCS$		135	2	1.5039	1.071

Similarly, *organogermanium esters* of organic and inorganic acids may be made by reaction of silver or other heavy-metal salts of the acids with organogermanium halides, or by reaction of the latter with the acids themselves (or their anhydrides). Such esters act like organogermanium halides in their sensitivity to water and their solvolytic dissociations. Many are known (see ref. 86 for a listing); space permits only the physical constants for the trimethylgermanium esters and a few higher trialkylgermanium compounds in Table 15.

The *organogermanium oxides*[86] are best represented by the solid polymers of (CH$_3$)$_2$GeO (*vide supra*) and by the bis-trialkylgermanium oxides and their aryl counterparts (which are liquids prepared by hydrolysis of the chlorides R$_3$GeCl, or by oxidation of the hydrides, or by hydrolytic cleavage reactions). The physical properties of a few such germanoxanes are given in Table 16, together with those of (CH$_3$)$_2$GeO for comparison.

TABLE 16. ORGANOGERMANIUM OXIDES[86]

Besides the organogermanium oxides which invoke purely Ge–O–Ge structures, it is quite easy to make *mixed organometallic oxides* which involve Ge–O–Si and Ge–O–Sn linkages. These result from the interaction of compounds of the type R$_3$SiOLi with R$_3$GeCl, or from the reaction of R$_3$SiCl with R$_3$GeOLi, and so on. The properties of some of these mixed oxides appear in Table 17. The oxygen linkage is reactive to several kinds of cleavage agent: phenyl lithium converts (CH$_3$)$_3$GeOSi(CH$_3$)$_3$ to (CH$_3$)$_3$GeC$_6$H$_5$ and (CH$_3$)$_6$Si$_2$O[86], and AlCl$_3$ converts it to (CH$_3$)$_3$GeCl and (CH$_3$)$_3$SiOAlCl$_2$. Sulfur trioxide converts the same substance to the mixed sulfate (CH$_3$)$_3$GeOSO$_2$OSi(CH$_3$)$_3$[86]. The substance (CH$_3$)$_3$GeOSi(CH$_3$)$_3$ itself is said to be very toxic[86], which is surprising in that its fragments are not known to be.

TABLE 17. SOME ORGANOGERMANIUM MIXED OXIDES[86]

Closely related to the mixed oxides are the *organogermanium alkoxides*, which contain the linkage Ge–O–C and may be considered as alkoxide counterparts of the organogermanium halides. Indeed, they may readily be made from such halides by the action of sodium or lithium alkoxides, or by the action of the alcohols themselves if an HCl acceptor such as a tertiary amine also is used. Conversion reactions of organogermanium alkoxides with higher alcohols also are possible. The physical properties of some such alkoxides are given in Table 18.

TABLE 18. ORGANOGERMANIUM ALKOXIDES[86]

ᵃ At 20°C.

As expected, there also are many *organogermanium sulphides* and *mercaptides*. These are obtained by the reaction of organogermanium halides with sodium sulfide or mercaptide, or by reaction with H_2S in the presence of an HCl acceptor. Some compounds are listed in Table 19.

TABLE 19. ORGANOGERMANIUM SULFIDES AND MERCAPTIDES[86]

Compound	M.p., °C	B.p., °C	At. pr., mm	n_D^{20}	d_{20}

Similarly, *nitrogen derivatives* of organogermanium halides can be made by reaction with alkali–metal amides, or (in some cases) by reaction with ammonia or amines directly. Transamination is possible as a way of making one organogermanium amine from another, and even some organogermanium oxides can be converted to amines or amides by azeotropic distillation with an amine[86]. In general, organogermanium compounds of nitrogen and phosphorus and are sensitive to water, acids, and oxidizing agents. The properties of some representative compounds are given in Table 20. Related compounds containing the Ge–N–Sn and Ge–N–Pb linkages also are known[86], and can be prepared similarly.

TABLE 20. ORGANOGERMANIUM DERIVATIVES OF NITROGEN[86]

[a] At 22°C.

Lastly, there are *organodigermanes* and *polygermanes*, made by the condensation of organogermanium halides, using alkali–metal acceptors for the halogen atoms. Mixed compounds containing Ge–Si, Ge–Sn, and Ge–Pb bonds also may be made, usually by the reaction of R_3GeK or R_3GeLi with the appropriate organometallic halide (or vice versa, using R_3GeCl and R_3SiK, etc.). Intercondensations such as that of R_3GeBr with R_3SiCl (using sodium) also are possible. Cleavage reactions of such polymetalloidal compounds provide the basis for much speculation about relative electronegativities, but the relative bond energies usually provide a more reliable clue to what happens. The physical properties of some organogermanes and related compounds are given in Table 21.

TABLE 21. ORGANODIGERMANES, POLYGERMANES AND RELATED COMPOUNDS[86] [c]

[d] At 26°C.

7. COMPLEXES OF GERMANIUM(IV)

7.1. FLUOROGERMANATES AND CHLOROGERMANATES

As described in the section dealing with GeF_4, many fluorogermanate salts of organic and inorganic bases may be made by dissolving GeO_2 in 40% aq. HF and then adding the base[104]:

$$GeO_2 + 6HF = H_2GeF_6 + 2H_2O$$

$$H_2GeF_6 + 2C_6H_5NH_2 = (C_6H_5NH_3)_2GeF_6$$
Similarly, *chloro*germanates such as Cs_2GeCl_6 have been known many years[71]. Such halocomplexes of the form M_2GeX_6 constitute the simplest and earliest complexes of Ge(IV), and reveal much about germanium with a coordination number of six. The octahedral GeF_6 grouping is a dinegative ion, of course, but within the anion the bonding is much the same as that in the neutral SF_6 [105]. Alkali–metal fluorogermanates are soluble in water; the heavy-metal ones are not. The solubilities and densities of some nitrogen-base fluorogermanates[104] are given in Table 22.

TABLE 22. SOME NITROGEN-BASE FLUOROGERMANATES[104]

	d_{25}	H_2O	CH_3OH	C_2H_5OH

[a] With hydrolysis.

7.2. COMPLEXES OF TRANSITION METALS

The newer coordination chemistry of germanium deals largely with germane, chlorogermane, and organogermanium derivatives of π-complexes of the transition metals[106]. The presence of π acceptor ligands "conditions" the transition metal to form σ bonds to certain alkyl groups[107], and also to analogous groups containing other Group IV elements. A great many such compounds are known[106], some made by metathetical reactions involving a carbonyl metal anion:

$$(C_6H_5)_3GeCl + \pi\text{--}C_5H_5W(CO)_3^- = (C_6H_5)_3GeW(CO)_3\pi\text{--}C_5H_5 + Cl^-$$
[104] L. M. Dennis, B. J. Staneslow and W. D. Forgeng, *J. Am. Chem. Soc.* **55** (1933) 4392.
[105] W. Hückel, *Structural Chemistry of Inorganic Compounds*, Vol. 2, p. 689, Elsevier Publ. Co., Amsterdam (1951).
[106] F. G. A. Stone, *New Pathways in Inorganic Chemistry* (ed. Ebsworth, Maddock and Sharpe), chapter 12, pp. 283–302, Cambridge Univ. Press (1968).
[107] J. Chatt and B. L. Shaw, *J. Chem. Soc.* **1959**, 705; J. Chatt, *Rec. Chem. Prog.* **21** (1960) 147.

This method can be used to attach four metal atoms to Ge, starting with $GeCl_4$. Other compounds are made by elimination reactions, such as

$$HGeCl_3 + ClMn(CO)_5 = Cl_3GeMn(CO)_5 + HCl$$
Another general method consists in the insertion of germanium *dihalides* into metal–metal bonds, giving M–Ge–M configurations:

$$GeI_2 + Co_2(CO)_8 = (CO)_4Co(GeI_2)Co(CO)_4$$

Lithium derivatives of organogermanium compounds can also be used to react with halogen-bearing transition metals in suitable complexes:

$$2(C_6H_5)_3GeLi + [(C_2H_5)_3P]_2PtCl_2 = [(C_6H_5)_3Ge]_2Pt[P(C_2H_5)_3]_2 + 2LiCl$$
The structures of some transition metal–germanium compounds have been determined by X-ray crystallographic study, and these show the Ge atoms to be in distorted tetrahedral configuration, while the transition metals (here iron and manganese) show basically octahedral bonding[106]. In $(C_6H_5)_3GeMn(CO)_5$ the space group is P_1, and the Ge–Mn distance is 2.535 ± 0.02 Å[108]. In $Cl_2Ge[Fe(CO)_2\pi-C_5H_5]_2$ the space group is $C\,2/c$, and the Ge–Fe distance is 2.36 ± 0.01 Å[109].

The square-planar Pt–Ge complexes are said to be stable up to 150°, but the triphenyl-germanyl–palladium complex $[(C_2H_5)_3P]_2Pd[Ge(C_6H_5)_3]_2$ decomposes in solution at 20° [106]. The transition metal–germanium bonds are only moderately reactive: the compounds $(R_3P)_2Pt[Ge(C_6H_5)_3]_2$ are unaffected by air and water, but the Ge–Pt bonds are cleaved by I_2, HCl, and CCl_4. Reduction of Ge–Cl bonds with $NaBH_4$ is possible without destroying the Ge–Fe bond[106]:

$$Cl_2Ge[Fe(CO)_2\pi-C_5H_5]_2 \xrightarrow{\ \ NaBH_4\ \ } H_2Ge[Fe(CO)_2\pi-C_5H_5]_2$$

Related compounds containing organogermanium groups bonded to Cu, Ag, Au, Ti, Zr, Hf, Nb, Ta, Cr, W, and Mo have been collected by Weiss[86] from the patent literature (where they are of interest as catalytic agents), but the compositions and structures are not always clear. Some interest in such complexes as antiknock agents and as starting materials for thermal metal plating also is expressed.

17. TIN

E. W. ABEL

University of Exeter

1. THE ELEMENT

1.1. HISTORICAL

In the book of Numbers in the Bible's Old Testament, tin is mentioned as a metal of value under the name *bedil*. The ancient Indian author Veda refers to tin as *trapu*. Objects made of tin have been found in the tombs of ancient Egypt[1], and the tin–copper alloy bronze has been used from ancient times. Caesar, recording the presence of tin in Britain, referred to it as *plumbum album* as also did Pliny, to distinguish it from lead, which was *plumbum nigrum*.

Up to the 12th century A.D., the tin deposits of Cornwall were the only large European source of tin[2]. Subsequently the mines of Saxony and Bohemia became important. Nowadays, however, the Continent of Europe is almost entirely dependent upon imported ores.

1.2. OCCURRENCE AND DISTRIBUTION

Tin is found in nature almost exclusively as the tin(IV) oxide known as cassiterite or tinstone. Small quantities of stannite, $Cu_2S.FeS.SnS_2$, are known, and occasionally small amounts of tin metal are found in nature along with gold.

Cassiterite is found as primary deposits interspersed in other rocks particularly as "reef-tin" in granite, or alternatively in secondary deposits as "stream-tin", mixed with large quantities of clay and sand.

Principal suppliers of tin are Malaysia, Bolivia, Indonesia, Congo, Siam and Nigeria. Further important deposits are worked in China, Australia, Rhodesia, South Africa, Alaska, United States, Chile and the United Kingdom.

Tin is estimated to be present in the earth's crust as $4 \times 10^{-3}\%$ by weight, and to be in sea water at a concentration of 0·003 g/ton.

1.3. EXTRACTION

Despite the 78·6% of tin in pure SnO_2, the tin ores for extraction of the metal often contain only a few per cent of tin. Initial concentration is carried out by flotation removal of lighter rocks, such as silica, and magnetic removal of certain impurities such as tungsten minerals. Roasting volatilizes sulphur and arsenic and oxidizes many metals

---

[1] A. H. Church, *Chem. News*, **36** (1877) 168.
[2] T. R. Holmes, *Ancient Britain*, p. 483, Oxford (1907).

present, such as bismuth, zinc, iron and copper, into oxides which can be washed out by acid.

Cassiterite is reduced by carbon in a blast or reverberatory furnace. The crude molten tin is usually contaminated with iron, which is removed by oxidation. (This used to be carried out by "poling" the molten tin with a fresh green wood pole, which on charring released gas vigorously, and stirred the tin into contact with atmospheric oxygen.)

Tin is extensively recovered from tin plate scrap, either by electrolysis, whereby the scrap is made the anode in a caustic soda cell, or by detinning with chlorine to produce tin(IV) chloride. Iron unlike tin is not readily attacked by dry chlorine.

1.4. INDUSTRIAL AND COMMERCIAL UTILIZATION OF TIN

The primary tin consumption for the U.S.A., Japan, U.K., Germany and France for 1968 totalled over 120,000 tons. This was utilized as tinplate (47%), solder (21%), bronze (8%), babbitt (bearings) (6%) and tinning (5%). The remaining 13% was utilized for a wide miscellany of alloys and chemicals.

In addition to the extensive use of tin metal itself and its alloys, various compounds of tin are used in industry and commerce. Tin(IV) oxide is used as an opacifier for vitreous enamels, in ceramic glazes and as a polishing powder. Tin chlorides are used to weight natural silk, stabilize soap perfumes, silver glass mirrors and as chemical reducing agents. Tin(II) fluoride finds extensive use as an additive to dentifrices[3].

Monobutyltin compounds stabilize plastic films, and dibutyl and other organotins are present in up to 1% by weight of tin in polyvinylchloride, as a stabilizer[4].

Tributyltin compounds are used in industrial fungicides, insecticides, anti-fouling paints and disinfectants; and triphenyltin derivatives are now manufactured in hundreds of tons for agricultural pesticide purposes[5].

1.5. ALLOTROPES OF TIN

Tin has two crystalline forms. Above 18° the stable form is the so-called β or white tin, and below 18° the stable form is the so-called α or grey tin. An often described γ form of tin has no basis in fact.

In the grey α-tin each atom has four tetrahedral bonds resulting in three-dimensional covalent bonding throughout the crystal. In this α-form tin has an analogous structure to the diamond form of carbon.

In β-tin each atom has four nearest neighbours at 3·016 Å in the form of a very flattened tetrahedron, and two further neighbours at 3·175 Å. Thus instead of tetrahedral co-ordination as in α-tin, the white β-form of tin has each tin atom in a somewhat distorted octahedral environment as shown in Fig. 1.

Tin metal, as normally utilized, is the white β-form, and although the transition temperature for β-tin to α-tin is about 18°, the conversion of white to grey tin does not

---

take place except at much lower temperatures. An exception to this, however, is when grey tin is present and catalyses conversion of β-tin to α-tin below 18°.

Once started, the change from β-tin to α-tin proceeds quite rapidly, and due to the very

FIG. 1. (a) The tetrahedral environment of the tin atom in α-tin (cubic) and (b) the distorted octahedral environment of the tin atom in β-tin (tetragonal).

different crystalline forms and densities of the two allotropes, this conversion causes the tin to completely crumble and powder. The consequent destruction of tin objects caused this allotropic change to be known as tin disease, tin pest or tin plague.

1.6. ISOTOPES OF TIN

The isotopes of tin are listed in Table 1. None of the naturally occurring isotopes of tin is radioactive, and it is notable that no single isotope constitutes even one-third of natural tin.

TABLE 1. THE NATURAL AND ARTIFICIAL ISOTOPES OF TIN

Isotope	% abundance in natural tin	Half-life	Isotope	% abundance in natural tin	Half-life

^{118}Sn	24·01	—	^{126}Sn	—	3000 sec
			^{127}Sn	—	5400 sec

1.7. CHEMICAL PROPERTIES OF TIN METAL

Tin is virtually unattacked in air and water at ordinary temperatures, but at higher temperatures a film of oxide forms on the surface. Burning tin at white heat produces tin(II) oxide. Dilute acids only attack tin slowly to give tin(II) salts and hydrogen.

TABLE 2. PHYSICAL DATA FOR TIN
(Temperatures °C)

Melting point 232°; $\triangle H$ fusion 1·69 kcal/mole; $\triangle S$ fusion 3·35 cal/deg/mole

Concentrated nitric acid produces the hydrated tin(IV) oxide sometimes called metastannic acid. Tin evolves hydrogen with hot alkali solutions to form alkali stannates.

A number of dilute chemical solutions attack tin metal slowly, with consequent corrosion. Among these are aluminium chloride, aluminium potassium alum, ammonium sulphate, hydrochloric acid, hydrobromic acid, hydriodic acid, fluorine, chlorine, bromine, iodine, iron(III) chloride, potassium carbonate, potassium hydroxide, silver nitrate, zinc chloride, glycerol and maleic acid[6].

1.8. NUCLEAR MAGNETIC RESONANCE

The technique of nuclear magnetic resonance spectroscopy has been extensively utilized in tin chemistry.

There are three naturally occurring isotopes of tin which have non-zero nuclear magnetic moments—^{115}Sn (0·35% abundance), ^{117}Sn (7·67% abundance) and ^{119}Sn (8·68% abundance). In each of these isotopes the spin number (I) of the nucleus is one half; thus there are no quadrupole moments[7].

One of the most extensively studied effects of the presence of these three spin-active tin isotopes has been in organotin chemistry, where the presence of satellite bands on many

TABLE 4. CHEMICAL SHIFTS OF THE ^{119}Sn NUCLEAR
MAGNETIC RESONANCE IN VARIOUS COMPOUNDS FROM
THE ^{119}Sn RESONANCE IN $(CH_3)_4$Sn

Compound	Shift (δ) ppm
SnI$_4$ (CS$_2$ soln.)	1701
SnSO$_4$	909

SnCl$_3$(C$_4$H$_9$)	3
(CH$_3$)$_4$Sn	0
(CH$_3$)$_2$SnCl$_2$	−36
(C$_2$H$_5$)$_2$SnCl$_2$	−62
(C$_4$H$_9$)$_2$SnCl$_2$ (in acetone)	−71
(C$_4$H$_9$)$_2$SnCl$_2$ (in CS$_2$)	−114
(C$_2$H$_5$)$_3$SnCl	−151

† This figure is concentration dependent, and can be lowered by up to 200 ppm by the addition of hydrochloric acid, due presumably to the build up of SnCl$_3^-$ ion concentration.

of the proton magnetic resonances is due to the spin–spin interaction with tin isotopes of non-zero magnetic moments in about 17% of the molecules present. In common with many metal alkyls, the coupling constant for interacting nuclei separated by three bonds is usually greater than for nuclei separated by two bonds. Thus in tetraethyltin $J_{Sn-CH_2-CH_3}$ for the methyl protons is ± 71·2 c/s, and J_{Sn-CH_2} for the methylene protons is ± 32·2 c/s.

[6] Handbook of the Physicochemical Properties of the Elements, Ed. G. V. Samsonov, Oldbourne Press, London (1968).

[7] J. W. Emsley, J. Feeney and L. H. Sutcliffe, High Resolution Nuclear Magnetic Resonance Spectroscopy, Vol. 2, p. 1082, Pergamon Press (1966).

In proton magnetic resonance spectra the satellite bands due to [117]Sn and [119]Sn can usually be well resolved.

In observing the nuclear magnetic resonance of the tin isotope atoms, however, the [119]Sn isotope is both slightly more sensitive to detection, and is also the most abundant isotope. Thus it is usual to observe the [119]Sn spectra in nuclear magnetic resonance investigations on tin.

The most common reference material to date for tin resonance measurements is the [119]Sn line in tetramethyltin. This is usually used as a capillary external reference. Table 4 shows some [119]Sn chemical shifts from the [119]Sn resonance in $(CH_3)_4Sn$.

From the table it will be seen that there are not different regions of resonance for Sn^{II} compounds and Sn^{IV} compounds. Large solvent effects in both chemical shifts and coupling constants involving the [119]Sn nucleus are extensively reported, and are assumed to reflect the different coordination tendencies of tin towards many solvents, and to other species present in solution[8].

Many useful relationships enable [119]Sn chemical shift data to be extensively applied; thus for example when chlorine, bromine or iodine are attached to tin, each makes a fixed contribution to the overall [119]Sn shift regardless of the other groups attached to tin.

The very large range over which the [119]Sn chemical shifts extend suggests that the paramagnetic contribution to the shielding is the major factor controlling the shielding of the tin nucleus.

1.9. MÖSSBAUER SPECTROSCOPY

In addition to being a most powerful probe of the structure and nature of solid tin containing materials in the laboratory, the Mössbauer effect is rapidly gaining usage in the field of analysis of mineralogical tin-containing samples[9]. A portable Mössbauer spectrometer weighing less than 7 lb is now available for this purpose.

Isomer shift values seem to follow the electron density in the $5s$ subshell of tin, and hence it is possible to distinguish between the formal oxidation states of tin(II) and tin(IV). If the α (grey) form of tin is taken as a standard, then all tin(IV) compounds fall below this and all tin(II) compounds are above[10].

In many minerals of the type $MSnO_n$, the relative oxidation states of M and Sn were often assigned intuitively, and frequently erroneously. Mössbauer spectroscopy has now been utilized to assign definitively an oxidation state of tin, and hence of M in these materials. Similarly the so-called di-organotins R_2Sn were first shown by Mössbauer spectroscopy to be polymeric derivatives of tin(IV), rather than tin(II) compounds.

Most Mössbauer measurements of [119m]Sn spectra are taken at very low temperature, but it has been noted that six-coordination of tin is usually accompanied by the presence of a measurably large resonance at ordinary temperatures[11].

A useful feature of [119m]Sn Mössbauer spectra is the quadrupole splittings, which can be informative on the environmental symmetry of tin in a compound. A non-zero value of field gradient is expected in any molecule which does not possess cubic symmetry, with an accompanying quadrupole splitting of the Mössbauer resonance.

[8] J. J. Burke and P. C. Lauterbur, *J. Am. Chem. Soc.* **83** (1961) 326.

[9] J. J. Zuckermann, in *Mössbauer Effect Methodology*, **3** (1967) 15.

[10] V. S. Shpinel, V. A. Bryukhanov and N. N. Delyagin, *Soviet Physics J.E.T.P.* **14** (1962) 1256.

[11] V. I. Goldanski, E. F. Makarov, R. A. Stukan, T. N. Sumarokova, V. A. Trukhtanov and V. V. Khrapov, *Doklady Akad. Nauk. S.S.S.R.* **156** (1964) 474.

Very curiously, there is an absence of this quadrupole splitting in many tin compounds possessing obvious chemical asymmetry at the tin atom. Such asymmetric tin compounds have been classified into two sets. In the first set, where tin is directly bonded to atoms possessing lone pairs of electrons (F, Cl, Br, I, O, S, N, etc.), there is usually the expected measurable quadrupole splitting. In the second set of asymmetric Sn(IV) compounds, where tin is bonded directly to atoms bereft of lone pair electrons (H, Li, C, Ge, Sn, Pb, etc.), the predicted quadrupole splitting is not observed[12].

TABLE 5. THE MÖSSBAUER SHIFTS OF TIN AND SOME TIN COMPOUNDS RELATIVE TO α-TIN

Compound	Shift (δ) relative to α-tin, mm/sec
Tin(II) chloride	2·40
Tin(II) bromide	2·10
Tin(II) iodide	2·00
Tin(II) fluoride (monoclinic)	1·45
Pyridine tin(II) dichloride	1·30
Tin(II) sulphide	1·25
Tin(II) fluoride (orthorhombic)	1·20
Tin(II) telluride	1·20
Tin(II) orthophosphate	1·10
Tin(II) oxide ((tetragonal)	0·70
β-Tin	0·60
Tin(II) oxide (orthorhombic)	0·60
α-Tin	0
Tin(IV) iodide	−0·20
Organometallic tin(IV) compounds	−0·30 to −1·93
Tin(IV) sulphide	−0·80
Tin(IV) bromide	−1·00
Tin(IV) chloride	−1·90
Tin(IV) oxide	−2·26
Tin(IV) fluoride	−2·50

From Table 5 it is tempting to infer that in grey (α) tin there is tin(IV) interbonded, and in white (β) tin there is tin(II) interbonded The suggestion receives chemical support, in that the action of concentrated hydrochloric acid upon grey tin and white tin produces respectively $SnCl_4.5H_2O$ and $SnCl_2.2H_2O$.

2. COMPOUNDS

2.1. ALLOYS

Tin is one of the very important alloying metals, and the number of different alloys are too numerous to mention. Small changes in composition are made to suit specific purposes, and some representative compositions are given in Table 6.

About 20% of the world tin production goes to make solders of different types. It is the tin present that confers the ability of the solder to stick metals together.

True bronzes are copper based tin alloys with a good combination of chemical resistance, mechanical strength and ease of manufacture.

[12] N. N. Greenwood, quoted in ref. 9.

Tin-rich babbitt alloys find very extensive use as bearing metals in marine engines and automobile engines.

TABLE 6. REPRESENTATIVE COMPOSITIONS OF SOME TIN ALLOYS

Alloy	Sn %	Cu %	Pb %	Sb %	Bi %	Other %
Rhine metal	97	3				
Tinfoil	88	3	8	1		
Woods metal (m.p. 70°C)	12·5		25		50	Cd 12·5
Fusible alloy	15		32		53	
Pewter	85	7		2	6	
Soft solder	50				50	
Babbitt	90	4		6		
White metal	5	1	75	19		
Gun metal (bronze)	10	90				
Speculum (bronze)	33	67				
Medal (bronze)	8	90				Zn 2
Phosphor (bronze)	10	79·7		9·5		P 0·8

Tin is commonly a constituent of easily fusible alloys used in fire warning apparatus and other safety devices.

2.2. TIN(II) BONDING

With a ground state configuration for tin of $5s^2 5p^2$ it can form covalent tin(II) compounds with use of two unpaired p-electrons. Should the $5s^2$ electrons take no part in compound formation, the bond angle in such an SnX_2 molecule would be 90°. Normally,

FIG. 2. (a) $SnCl_2$ (gaseous), (b) $SnCl_3^-$, (c) M ← $SnCl_3$ complex, illustrating the directional lone pair of electrons in each case.

however, the s-electrons are incorporated into an sp^2 hybridized bond situation, and the resultant bond angle is about 120°. Thus, for example, tin(II) chloride in the gas phase has the structure illustrated in Fig. 2 (a), with two sp^2 orbitals forming covalent bonds to halogen and one directional lone pair of electrons. Figure 2 (b) shows the $SnCl_3^-$ ion in which tin(II) may be regarded as sp^3 hybridized, with the two tin chlorine bonds and the

directional lone pair of $SnCl_2$, but with the coordination of a chloride ion into the vacant sp^3 orbital. Figure 2 (c) shows how the directional lone pair of $SnCl_3^-$ behaves as a donor ligand to metals, etc. In this latter case it is possible for the tin atom to act simultaneously as a π-electron acceptor, thus increasing the overall strength of the tin–acceptor atom bond[13].

With a second ionization potential of 14·63 eV tin easily looses two $5p$ electrons to form a dipositive ion of $5s^2$ configuration. The separation of this ground state ($5s^2$) of Sn^{2+} ion from the first excited state ($5s^1p^1$) is only 6·64 eV. In such circumstances it is possible to gain extra crystal field stabilization by s–p mixing. Such extra stabilization energy can only be achieved, however, by an unsymmetrical distortion of the environment of the ion[14].

The large size of the Sn^{2+} ion gives it usually an octahedral environment in materials containing smaller ions such as fluoride and oxide; and maximum distortion is to be expected in such compounds of tin(II). The extra stabilization, and hence the extent of distortion, will, however, fall rapidly with increasing tin–anion distances.

2.3. TIN(IV) BONDING

Hybridization of the available $5s$ and $5p$ orbitals of tin produces a suitable situation for the formation of four tetrahedral covalent bonds   Many tin compounds such as the tin(IV) halides (except fluoride) and the organotins have this covalent mode of bonding.

Whereas tin(II) compounds do not appear to utilize the $5d$ orbitals except in the possible cases of π-bonding in donor–acceptor complexes, tin(IV) compounds make extensive use of $5d$ orbitals. Thus, for example, in complexes such as $(CH_3)_3SnCl.C_5H_5N$, the five-coordinate tin atom is sp^3d hybridized in a trigonal bipyramidal environment. Similarly in octahedral molecules or ions such as L_2SnCl_4 and $SnCl_6^{2-}$, the $5d$ orbitals of similar energy to the $5s$ and $5p$ orbitals are utilized to form sp^3d^2 hybrid orbitals for largely covalent bonds.

The Sn^{4+} ion (radius ~ 0.74 Å) may be regarded as present in the lattices of compounds like tin(IV) oxide and various stannates. The $5s^0p^0$ configuration of the Sn^{4+} ion should give regular octahedral coordination for tin in ionic lattices, but there are notable tendencies towards a distortion from octahedral environments to tetrahedral environments, due possibly to the partially covalent (and hence tending towards tetrahedral) character of the bonding in the lattice.

Whilst these descriptions of ionic and covalent bonding in Sn(II) and Sn(IV) represent considerable oversimplification, they do allow an effort at classification of tin compounds.

2.4. ORGANOMETALLIC COMPOUNDS

Compounds of tin(II) possessing a tin–carbon bond are extremely rare, and many compounds previously characterized as dialkyl- and diaryltins are now known to be telomeric derivatives of tin(IV) of the type $(R_2Sn)_n$. Exceptions are 10,11-dihydrodibenzostannoepin[15] and bis(cyclopentadienyl)tin[16]. The structure of the 10,11-dihydrodibenzostannoepin is very likely to be as in Fig. 3. The structure of $(C_5H_5)_2Sn$ in the gas phase is

an angular sandwich molecule[17], but this may be different in the crystal, and could be different in the gas, solution and solid phases.

The literature of organometallic tin chemistry is now one of the largest for any element, but is fortunately particularly well documented and reviewed[18-21]. In this section discussion is confined to the tetra-organotins, as the chemistries of the extensive ranges of R_3SnX,

FIG. 3. An example of an organometallic derivative of tin(II) 10,11-dihydrobenzostannoepin.

R_2SnX and $RSnX_3$ compounds are more appropriately covered in those sections dealing with the properties of the functional groups X when attached to tin (*vide infra*).

The tetra-alkyl- and tetra-aryltins are either colourless liquids or white crystalline solids, which are stable to air and water; many of them are now available in commercial quantities. In addition to the symmetrical compounds R_4Sn where four identical alkyl or aryl groups are attached to tin in a tetrahedral configuration, many unsymmetrical organotins of type

Formation of Tin–Carbon Bonds

The different methods now available for the formation of tin–carbon bonds are classified below.

Use of Organomercurys and Organozincs

These methods are largely of historical importance, and some of the very earliest organotins were prepared from them. These methods still find application in special circumstances.

$$SnCl_2 + R_2Hg \longrightarrow R_2SnCl_2 + Hg$$

$$2SnCl_2 + 2RHgCl \longrightarrow R_2SnCl_2 + 2Hg + SnCl_4$$

$$SnCl_4 + 2R_2Zn \longrightarrow R_4Sn + 2ZnCl_2$$

$$SnCl_2 + R_2Zn \longrightarrow [R_2Sn]_n + ZnCl_2$$

$$Sn + RZnCl \longrightarrow R_4Sn$$

Use of Sodium and Sodium–Tin Alloys

These methods are also of historical interest, but have continued to receive considerable attention, as the corresponding reaction for lead has proved such a convenient source of organoleads. A virtually quantitative yield of tetra-ethyltin is reported from ethyl bromide and a tin alloy containing 14% of sodium and about 15% of zinc. It is important to note, however, that quantitative in this context means a maximum of 25% based on tin due to the composition (NaSn) of the alloy.

$$4RX + 4NaSn \longrightarrow R_4Sn + 4NaX + (3Sn \downarrow)$$
The reaction is actually known to be considerably more complex than indicated by this overall equation; and trialkyltin halides, dialkyltins and hexa-alkylditins are formed as by-products. Of recent interest has been the Wurtz type of reaction between organic halides and tin tetrahalides in the presence of sodium:

$$4RCl + SnCl_4 + 4Na \longrightarrow SnR_4 + 4NaCl$$

Direct Interaction of Alkyl and Aryl Halides with Metallic Tin

The requirements of large amounts of organotin halides for industry makes this a particularly attractive route, and considerable efforts have been made to perfect a process comparable to the Rochow Process for the organosilicon halides[22, 23]. Whilst the "direct process" reaction between tin and ethyl iodide has been known for well over a century, only recently have the right conditions for the formation of good yields from alkyl halides been determined.

$$CH_3Cl + Sn \xrightarrow{175°} CH_3SnCl_3 + (CH_3)_2SnCl_2 + (CH_3)_3SnCl$$
$$\qquad\qquad\quad (6·6\%) \qquad (39\%) \qquad (4·6\%)$$
In this particular reaction small amounts of iodomethane and triethylamine were the catalysts.

[22] H. Tokunaga, Y. Murayama and I. Kijima, Japanese Patent (1964) 24958; *C.A.* **62** (1965) 14, 726.
[23] Nitto Chemicals, French Patent (1965) 1,393,779; *C.A.* **63** (1965) 9985.
Use of Grignard Reagents and Organolithiums

This is the most important laboratory method for the formation of the tin–carbon bond and is probably still the most extensively used industrial process.

$$SnX_4 + 4LiR \longrightarrow SnR_4 + 4LiX$$

$$SnX_4 + 4RMgX \longrightarrow SnR_4 + 4MgX_2$$
The reactions are of wide applicability for a great range of organic groups. Steric hindrance affects these reactions considerably, and yields from secondary or tertiary aliphatic groups is poor; and only two tertiary butyl groups may be attached to a tin atom. An excess of the organolithium or Grignard reagent is normally used to avoid, as far as possible, the formation of organotin halides as by-products. In many cases the Grignard reagent is generated *in situ*, and the synthesis consists of running the organic halide into a mixture of tin tetrahalide and magnesium metal, often in a hydrocarbon solvent, rather than ether.

Miscellaneous Methods

In addition to the methods classified above, a number of other routes to tin–carbon bonds have been reported, and some of these are indicated in equation form below.

$$4R_3Al + 3SnCl_4 \longrightarrow 3R_4Sn + 4AlCl_3$$

$$4CH_2N_2 + SnCl_4 \longrightarrow (ClCH_2)_4Sn + 4N_2$$

$$4C_6H_5C\vdots CNa + SnCl_4 \longrightarrow (C_6H_5C\vdots C)_4Sn + 4NaCl$$

$$CH_3Cl + SnCl_2 \longrightarrow CH_3SnCl_3$$

$$CH_3I + K_2SnO_2 \longrightarrow K[CH_3SnOO] + KI$$

$$C_6H_5N_2Cl + SnCl_2 \longrightarrow C_6H_5SnCl_3 + N_2$$

Additional to the wide range of symmetrical tetra-alkyls and tetra-aryls of tin(IV), numerous compounds of general formula R_3SnR', $R_2SnR'R''$, etc., are known where different alkyl and aryl groups are attached to a single tin atom.

A representative selection of organotins is listed in Table 8. A number of very comprehensive listings of such compounds are available.

The existence of tin–carbon bonds is not restricted to linear species, and many rings are known in which the tin–carbon bond is part of the heterocyclic bonding system. In the main these are made by metathetical reactions or intermolecular hydride additions.

$$(C_6H_5)_2SnCl_2 +$$
Physical Properties of Organotins

The physical properties of the tetra-organotins greatly resemble the hydrocarbons of similar constitution, but with higher density, refractivity, etc. Thus the lower members of the tetra-alkyltins are volatile liquids which become waxy solids at long chain length, and the tetra-aryls are all high melting point solids.

Electron diffraction, microwave spectroscopy and X-rays have shown the four organic

FIG. 4. Rapid movement of the trimethyltin group around the cyclopentadienyl ring in $C_5H_5Sn(CH_3)_3$.

groups in symmetrical organotins R_4Sn to be perfectly tetrahedral about the central tin atom.

The nuclear magnetic resonance spectra of organotins, in which a cyclopentadienyl group is attached to tin are of particular interest. They indicate that the σ-bond between tin and the carbon of the cyclopentadienyl group in, for example, $(CH_3)_3SnC_5H_5$ has a life-time of less than 10^{-4} sec at ordinary temperatures, and that the tin atom wanders around the C_5 ring[24, 25].

Chemical Properties of Organotins

Here discussion is limited to those reactions of organotins in which the tin–carbon bond is involved   Properties of the compounds of type R_3SnX, R_2SnX_2, etc., which are dependent upon the properties of the Sn–X bond rather than the organotin function of the molecule, are discussed under the various Sn–X sections below.

Organotins do not undergo hydrolysis or oxidation under ordinary conditions, but if ignited burn strongly with the emission of clouds of tin oxide.

Water and alcohol can sometimes bring about the fission of the tin–carbon bond in reactive organotins.

$$2C_6H_5 \vdots CSn(C_2H_5)_3 + H_2O \longrightarrow 2C_6H_5C \vdots CH + [(C_2H_5)_3Sn]_2O$$
$$NC_5H_4 . Sn(CH_3)_3 + ROH \longrightarrow C_5H_5N + (CH_3)_3SnOR$$

Mercaptans do not require especially active tin–carbon bonds to react with organotins, and under varying conditions virtually all types of tin–carbon bond can be converted to

[24] H. P. Fritz and C. G. Kreiter, *J. Organometallic Chem.* **1** (1964) 323.
[25] A. Davison and P. E. Rakita, *J. Am. Chem. Soc.* **90** (1968) 4479.

tin–sulphur bonds by thiols, and similarly for selenols. Elemental sulphur and selenium similarly break the tin–carbon bond
$$R_4Sn + R'SH \longrightarrow R_3SnSR' + RH$$
$$(C_6H_5)_4Sn + Se \longrightarrow (C_6H_5)_3SnSeC_6H_5$$
Under conditions of high temperature and pressure, hydrogen removes aryl groups from tin to deposit metal

$$(C_6H_5)_4Sn + H_2 \longrightarrow 4C_6H_6 + Sn$$
The organic groups attached to tin vary considerably in their ease of fission by halogen. In increasing ease of removal these groups are butyl, propyl, ethyl, methyl, vinyl, phenyl, benzyl, allyl, cyanomethyl and $-CH_2COOR$, an order which applies to many other tin–carbon fission reactions besides those of halogens.

Tin will often exchange organic groups cleanly, in good yield, with another metal or non-metal, providing a useful synthetic route to these materials.

$$(C_6H_5CH_2)_3SnCl + 4CH_3Li \longrightarrow 3C_6H_5CH_2Li + (CH_3)_4Sn + LiCl$$
$$(CH_2:CH)_4Sn + 4C_6H_5Li \longrightarrow 4CH_2:CHLi + (C_6H_5)_4Sn$$
$$(C_6H_5)_4Sn + BCl_3 \longrightarrow C_6H_5BCl_2 + (C_6H_5)_3SnCl$$

Among other reagents causing fission of tin–carbon bonds are hydrogen halides, mercury halides, bismuth halides, thallium chloride, arsenic halides, phosphorus halides, sulphuric acid, nitric acid, sulphur, sulphur dioxide, sulphuryl chloride and organic acids[18].

Organotins undergo proportionation reactions with tin tetrahalides to give the range of organotin halides, which are discussed in detail below.

$$nR_4Sn + (4 - n)SnX_4 \longrightarrow 4R_nSnX_{4-n}$$
$$(n = 1, 2 \text{ and } 3)$$
2.5. HYDRIDES

Binary Hydrides

The two binary hydrides of tin that are known to date are SnH_4 and Sn_2H_6[26].

SnH_4 was originally prepared in very low yield by the treatment of tin–magnesium alloy with dilute acids. The lithium aluminium hydride reduction of tin(IV) chloride has made SnH_4 easily available; in the presence of a trace of oxygen this reaction gives 80–90% yields. The oxygen is believed to inhibit the decomposition of stannane to tin and hydrogen[27, 28]. Tin(II) chloride is reduced by aqueous sodium borohydride to 84% yield of SnH_4 under optimum conditions[29].

In addition to a good yield of SnH_4, the potassium borohydride reduction of stannite ion in solution produced the hydride distannane Sn_2H_6. This hydride may be distilled in a vacuum system without decomposition provided relatively low pressures are used, but if a vessel containing Sn_2H_6 is allowed to warm to room temperature it is completely decomposed[27].

[27] W. L. Jolly, *Angew. Chem.* **72** (1960) 268; *J. Am. Chem. Soc.* **83** (1961) 335.
[28] H. J. Eméleus and S. F. A. Kettle, *J. Chem. Soc.* (1958) 2444.
[29] G. W. Schaeffer and M. Emilius, *J. Am. Chem. Soc.* **76** (1954) 1203.

From the infrared spectrum[30] of SnH_4, the estimated bond dissociation energy for Sn–H is 73·7 kcal/mole, which compares well with the value of 70·3 kcal/mole obtained as a mean dissociation energy for Sn–H from mass spectrometry measurements[31]. The thermochemical bond[32] energy of Sn–H has been obtained as 60·4 kcal/mole.

Analysis of the stretching vibrations[33] in $SnHD_3$ gives a value of the Sn–H distance as 1·701 ±0·001 Å, in good agreement with the Sn–H bond distance of 1·700+0·015 Å derived from the microwave spectrum[34] of CH_3SnH_3.

The nuclear magnetic resonance spectrum[35] shows a τ value of the protons in SnH_4 at 6·15, along with very large tin–proton coupling constants $^{119}Sn–H = 1931$ c/s and $^{117}Sn–H = 1846$ c/s.

All physical data on SnH_4 and SnD_4 are in full accord with a regular tetrahedral structure[36].

Stannane[37] melts at $-146°$ and has a normal boiling point of $-52·5°$.

Stannane undergoes appreciable decomposition to tin and hydrogen even at ordinary temperatures, but about 100°C it is very rapidly decomposed. The decomposition is first order with respect to stannane. Somewhat remarkably, oxygen inhibits decomposition at pressures above 1mm, and stannane may be stored mixed with oxygen at room temperature. At low pressures oxygen catalyses the decomposition of stannane[38, 39].

Stannane is toxic and is intermediate between silane and germane in its chemical properties; it is unattacked by dilute acids and alkalis, but is decomposed by concentrated acid or alkali. It is a powerful reducing agent, and is rapidly decomposed by solutions of transitional metal salts. Stannane and hydrogen chloride evolve hydrogen to form stannyl chloride, H_3SnCl, which is very unstable, undergoing noticeable decomposition, even at $-70°$. (Contrast H_3GeCl stable at 20°C and H_3SiCl stable at 200°C.)

Sodium in liquid ammonia may be titrated against SnH_4 to produce H_3SnNa and H_2SnNa_2. It would appear, however, that these two sodium derivatives are only stable as amines, as removal of ammonia, even at $-63·5°$, causes decomposition. H_3SnNa reacts with alkyl iodides in liquid ammonia to produce alkyl stannanes $RSnH_3$, and H_3SnNa with ammonium chloride regenerates SnH_4[28].

The SnH_3 radical may be trapped in an inert matrix at low temperature, and has been well characterized by its electron spin resonance spectrum[40].

Stannane reduces nitrobenzene in 94% yield and reduces benzaldehyde to benzyl alcohol virtually quantitatively. Only a 29% yield of isopropylamine was obtained from 2-nitropropane due to extensive decomposition of the stannane, catalysed by the amine[37].

Cobalt naphthenate di-tert-butyl peroxide, or palladium (10% on charcoal) or hexachloroplatinic acid are effective in catalysing the addition of stannane to olefins to form the corresponding tetra-alkyltins.

Stannane reacts with boron trifluoride to form tin(IV) fluoride quantitatively.

Organotin Hydrides

Any extensive study of the chemistry of the tin–hydrogen bond is extremely difficult in SnH_4 due to its inherent instability. In the case of the organotin hydrides, this difficulty is considerably allayed. The stability of the organotin hydrides increases with decreasing number of tin–hydrogen linkages in the molecule[19].

The organotin hydrides are almost invariably synthesized by the reduction of the corresponding organotin halide.

$$CH_3SnCl_3 + LiAlH_4 \longrightarrow CH_3SnH_3$$
$$(C_2H_5)_2SnCl_2 + LiAlH_4 \longrightarrow (C_2H_5)_2SnH_2$$
$$(C_6H_5)_3SnCl + LiAlH_4 \longrightarrow (C_6H_5)_3SnH$$
$$(CH_3)_3SnNa + NH_4Br \longrightarrow (CH_3)_3SnH$$
$$(C_4H_9)_3SnCl \xrightarrow{\text{Al/Hg} + H_2O} (C_4H_9)_3SnH$$

Examples of tin hydrides are known containing two or more tin atoms

$$(C_4H_9)_2Sn\text{—}Sn(C_4H_9)_2 + LiAlH_4$$
$$\underset{Cl\quad Cl}{\vert\quad\vert}$$

$$\longrightarrow (C_4H_9)_2Sn\text{—}Sn(C_4H_9)_2$$
$$\underset{H\quad H}{\vert\quad\vert}$$

$$[(C_4H_9)_2Sn]_n + (C_4H_9)_2SnH_2$$
$$6(C_6H_5)_2SnH_2 \longrightarrow H[(C_6H_5)_2Sn]_6H + 5H_2$$

Table 9 shows some examples of organotin hydrides together with boiling points where recorded.
TABLE 9. ORGANOTIN HYDRIDES

Hydride	B.p. °/mm	Hydride	B.p. °/mm
SnH_4	−52/760	$(C_4H_9)_2SnH_2$	75 – 76/12
CH_3SnH_3	0/760	$(C_4H_9)_3SnH$	76 – 78/0·7
$(CH_3)_2SnH_2$	35/760	$C_6H_5SnH_3$	57 – 64/105
$(CH_3)_3SnH$	59/760	$(C_6H_5)_2SnH_2$	89 – 93/0·3
$C_2H_5SnH_3$	35/760	$(C_6H_5)_3SnH$	168 – 172/0·5
$(C_2H_5)_2SnH_2$	99/760	$(C_4H_9)_2SnH(Cl)$	
$(C_2H_5)_3SnH$	52/20	$(C_4H_9)_2SnH(OOCCH_3)$	
$(C_3H_7)_3SnH$	76 – 82/12	$(C_4H_9)_2Sn–Sn(C_4H_9)_2$	
$C_4H_9SnH_3$	99 – 101/760	$\underset{H\quad H}{\vert\quad\vert}$	
		$H[(C_6H_5)_2Sn]_6H$	

In general, pure samples of tri-organotin hydrides are only slightly decomposed after several months at ordinary temperature; but on the other hand butyltin trihydride deposits an extensive yellow precipitate after only a few hours.

The tin–proton coupling constants in the methyltin hydrides, CH_3SnH_3 ($J_{119_{Sn-H}} = 1852$; $J_{117_{Sn-H}} = 1770$); $(CH_3)_2SnH_2$ ($J_{119_{Sn-H}} = 1758$; $J_{117_{Sn-H}} = 1682$); $(CH_3)_3SnH$ ($J_{117_{Sn-H}} = 1744$; $J_{117_{Sn-H}} = 1664$) c/sec, show a steady fall from SnH_4 ($J_{119_{Sn-H}} = 1931$; $J_{117_{Sn-H}} = 1846$), with increasing methyl content. The extra methyl groups are believed to cause a reduction in

the s character of the tin orbitals in the tin–hydrogen bond, and hence a reduction in the Sn–H coupling constant[41]. The dominant Fermi contact contribution to the coupling is proportional to the s character in the hybridized orbital used in the Sn–H bond

The reactions of the organotin hydrides are extremely diverse, and the organotin hydrides have found some use as specialist reducing agents in synthetic organic and inorganic chemistry. The following equations illustrate the diversity of organotin hydride reactions[42, 43].

$$(C_6H_5)_3SnH + CH_2{:}CHC_6H_5 \longrightarrow (C_6H_5)_3SnCH_2CH_2C_6H_5$$

$$(C_3H_7)_3SnH + CH{:}CC_6H_5 \longrightarrow (C_3H_7)_3SnCH{:}CHC_6H_5$$

$$(C_6H_5)_2SnH_2 + (C_6H_5)Si(CH{:}CH_2)_2 \longrightarrow (C_6H_5)_2Sn \underset{CH_2CH_2}{\overset{CH_2CH_2}{\diagup\diagdown}} Si(C_6H_5)_2$$

$$(C_6H_5)_2SnH_2 + CH_2{:}CHCOCH_3 \longrightarrow [(C_6H_5)_2Sn]_n + CH_2{:}CHCH(OH)CH_3$$

$$(C_6H_5)_3SnH + C_6H_5CHO \longrightarrow C_6H_5CH_2OH + (C_6H_5)_3SnSn(C_6H_5)_3$$

$$(C_4H_9)_3SnH + BrCH_2CHBrCH_3 \longrightarrow CH_2{:}CHCH_3 + H_2 + (C_4H_9)_3SnBr$$

$$CCl_4 + (C_4H_9)_3SnH \longrightarrow CHCl_3 + (C_4H_9)_3SnCl$$

$$(C_3H_7)_3SnH + RCH_2N_2 \longrightarrow (C_3H_7)_3SnCH_2R$$

$$(C_6H_5)_2PCl + (C_6H_5)_3SnH \longrightarrow (C_6H_5)_2PH + (C_6H_5)_3SnCl$$

$$(C_2H_5)_3SnH + RCHO \longrightarrow (C_2H_5)_3SnOCH_2R$$

$$(C_2H_5)_3SnH + C_6H_5N{:}CHC_6H_5 \longrightarrow (C_2H_5)_3SnN(C_6H_5)CH_2C_6H_5$$

$$(CH_3)_3SnH + (CF_3)_2CO \longrightarrow (CH_3)_3SnOCH(CF_3)_2$$

$$(C_2H_5)_3SnH + (C_2H_5)_2Zn \longrightarrow (C_2H_5)_3SnZnSn(C_2H_5)_3 + 2C_2H_6$$

$$(C_2H_5)_3SnH + [(C_2H_5)_3Ge]_3Sb \longrightarrow [(C_2H_5)_3Sn]_3Sb + (C_2H_5)_3GeH$$

2.6. COMPOUNDS OF NITROGEN, PHOSPHORUS, ARSENIC, ANTIMONY AND BISMUTH

Tin forms binary compounds with each of these Group V elements.

Tin nitride Sn_3N_4 is obtained by thermal decomposition of the product of reaction from liquid ammonia and tin(IV) chloride[44], and also by atomization of a tin cathode in an atmosphere of nitrogen[45]. Sn_3N_4 is reported stable to water, but to form tin(IV) chloride and ammonium chloride on attack by hydrochloric acid.

Tin and red phosphorus react in sealed evacuated silica tubes at about 500° to produce tin phosphides.

Many stoichiometries for tin phosphides are reported in the earlier literature, but more recent investigations show the phase Sn_4P_3 to predominate, though other phases with higher phosphorus content such as SnP are also formed. A single crystal of Sn_4P_3 has trigonal symmetry. This gives a structure where two non-equivalent phosphorus atoms are both surrounded octahedrally by six tin atoms with a mean tin phosphorus distance of 2·7 Å. One type of tin atom is octahedrally surrounded by six phosphorus atoms, but the other

[41] J. R. Holmes and H. D. Kaesz, *J. Am. Chem. Soc.* **83** (1961) 3903.

[44] R. Schwarz and A. Jeanmaire, *Chem. Ber.* **65** (1932) 1443.

[45] W. Janeff, *Z. Physik.* **142** (1955) 619.

type of tin atom is coordinated octahedrally by three phosphorus atoms and three tin atoms, with a tin–tin distance of above 3·25 Å[46].

A phase with this type of structure also crystallizes in the tin–arsenic system, but from phase analytical data the composition is near to Sn_3As_2. The substitutional solution of tin is believed to account for the deviation from the stoichiometric composition Sn_4As_3[47].

Tin becomes hard when alloyed with arsenic and there is a tendency for the alloys to crystallize. A full tin–arsenic phase diagram has been recorded[48].

The phases in the tin–antimony and tin–bismuth alloys have been investigated. Compounds of stoichiometry $SnSb$, Sn_4Sb_2, Sn_3Sb_2, $SnSb_2$ and Sn_3Bi have been claimed. The tin–antimony alloys form the basis of the so-called brittania metal and algiers metal.

Organotin Amines, Phosphines, Arsines, Stibines and Bismuthines

In addition to the binary compounds and alloys discussed above, there exist a large number of molecular compounds in which tin is bonded to the elements nitrogen, phos-

FIG. 5. Some reactions of the tin–nitrogen bond in organotin amines.

phorus, arsenic, antimony and bismuth. In these compounds it is possible to study the properties of discrete tin–Group V element single bonds.

Organotin nitrogen compounds are now very numerous[49], and tin derivatives of amines,

[46] O. Olofsson, *Acta Chem. Scand.* **21** (1967) 1659.

[49] J. G. A. Luijten, F. Rijkens and G. J. M. van der Kerk, *Advances in Organometallic Chemistry*, **3** (1965) 413.

hydrazine, formamide, urea, carbodi-imide and carbamic acids, etc., have been reported. Most intensive investigations have been carried out on the organotin amines, and all types are known from $(R_3Sn)_3N$, where nitrogen is coordinated by three tin atoms, to $(R_2N)_4Sn$, in which one tin is coordinated by four nitrogens, and cyclic amines of the type $(R_2SnNR^1)_3$. All these organotin amines are very water sensitive.

Some syntheses of the organotin amines are outlined in equation form below, and some of the extensive reactions[50] of this class are illustrated in Fig. 5. It is obvious from Fig. 5 that the organotin amines are available as powerful synthetic intermediates for a number of important reactions[51, 52, 53].

$$SnCl_4 + 4LiNR_2 \longrightarrow Sn(NR_2)_4$$

$$Li_3N + 3R_3SnCl \longrightarrow (R_3Sn)_3N$$

$$R_3SnNR_2 + R''_2NH \longrightarrow R_3SnNR_2$$

$$(CH_3)_3SnN(CH_3)_2 + RNH_2 \longrightarrow [(CH_3)_3Sn]_2NR$$

Organotin phosphines, arsines, stibines and bismuthines are known, and are exemplified, together with some of the commoner organotin amines in Table 10.

TABLE 10. SOME EXAMPLES OF ORGANOTIN AMINES, PHOSPHINES, ARSINES, STIBINES AND BISMUTHINES

Compound	B.p. °/mm [m.p.]	Compound	B.p. °/mm [m.p.]

2.7. OXIDES AND OXYGEN COMPOUNDS

Tin Oxides

Tin(II) oxide may be condensed from the vapour and trapped in an argon or nitrogen matrix at low temperature. In this form tin(II) oxide consists of Sn_2O_2 species which have a structure based on a planar (V_h) rhombus[55].

The common form of SnO is the black tetragonal orthorhombic modification (density 6·32). It is prepared by the hydrolysis of tin(II) salts to hydrated tin(II) oxide, with subsequent dehydration[56]. Special care has to be taken with reagents and with conditions to obtain pure samples[57]. This black oxide has a layer structure in which the tin atom lies at the apex of a square pyramid, the base of which is formed by the four nearest oxygen atoms (Sn–O = 2·21 Å). The Sn–Sn distance between the layers at 3·70 Å is so close to that of the Sn–Sn distance in tin metal, that some mode of tin–tin interaction cannot be ruled out[58].

A red orthorhombic modification of SnO is formed by heating suspensions of the white hydrous oxide. The red metastable form can be stabilized by the presence of about 1% phosphite, but if ammonia is used in the hydrolysis of the tin(II) chloride solutions, a red form of SnO is formed in the absence of stabilizing phosphite[59].

Tin(II) oxide undergoes rapid oxidation with incandescence to tin(IV) oxide upon heating around 300°. The action of heat upon tin(II) oxide in non-oxidizing conditions has yielded a very diverse range of reported results, and it is likely that different workers may have studied the oxide in differing states of purity[13]. On heating, tin(II) oxide disproportionates into tin(IV) oxide and tin. Whilst many intermediate oxides such as Sn_2O_3, Sn_3O_4 and Sn_5O_6 have been reported, it would appear that only Sn_3O_4 exists as a well-characterized discrete phase between SnO and SnO_2[60]. The formulation $Sn_2^{II}Sn^{IV}O_4$ for this intermediate oxide is not inconsistent with the Mössbauer spectrum.

Tin(II) oxide is amphoteric, dissolving in acids to give the tin(II) ion or anion complexes thereof; it dissolves in alkalis to form $Sn(OH)_3^-$ solutions.

Tin(IV) oxide occurs in nature as cassiterite, with a rutile type structure. It is also known in rhombic and hexagonal forms. Pure tin(IV) oxide is white and sublimes above 1800° without melting. It is not soluble in water, and is hardly attacked by acids or alkalis but dissolves easily on fusion with alkali hydroxides to form alkali stannates. SnO_2 is reduced to tin by heating with carbon or hydrogen, and forms tin(IV) chloride on heating in chlorine. Hydrous tin(IV) oxide is formed by hydrolysis of tin(IV) salt solutions. The so-called α-oxide (or α-stannic acid) formed by the slow, low temperature hydrolysis is readily soluble in acids and bases, showing the amphoteric nature of SnO_2. Rapid high temperature hydrolysis produces the so-called β-oxide (or β-stannic acid), which is exceedingly inert to solvents. Both α- and β-oxides have the rutile structure with absorbed water, and the somewhat considerable differences in their properties are believed due to differences in particle size and surface properties.

Hydroxy Compounds

Tin(II) hydroxide is not known. The hydrolysis[61] of tin(II) salt solutions under controlled conditions indicates the presence of the ions $SnOH^+$, $Sn_2(OH)_2^{2+}$ and $Sn_3(OH)_4^{2+}$, and it has been proposed that this has a ring structure as Fig. 6 (a).

Single crystals of the tin(II) oxide-hydroxide compound $3SnO.H_2O$ are obtained by the very slow hydrolysis of tin(II) perchlorate solution. In X-ray structural determination[62]

(a)

(b)

(c)

FIG. 6. Proposed structures of (a) $Sn_3(OH)_4^{2+}$, (b) $Sn(OH)_3^-$ and (c) $\{Sn_2O(OH)_4\}_2^-$.

this has been shown to contain Sn_6O_8 clusters, with six tin atoms at the corners of an octahedron, and an oxygen atom above each of the octahedron's eight faces, thus closely resembling the cluster structure of $Mo_6Cl_8^{4-}$. The formula is thus best written as $Sn_6O_8H_4$. This stoichiometry allows all of the oxygens in an infinite array of Sn_6O_8 clusters to be joined by hydrogen bonds.

It is interesting to note that the structure of the only well-characterized solid hydroxide phase, $Sn_6O_8H_4$, can be derived by the condensation and deprotonation of two of the cyclic ions $Sn_3(OH)_4^{2+}$, which are believed to predominate in solution.

Tin(II) oxide dissolves in alkalis to form the hydroxy-stannate(II) ion $Sn(OH)_3^-$, many salts of which have been isolated. The ion has the pyramidal structure illustrated in Fig. 6 (b). In addition to the $Sn(OH)_3^-$ ions the oxotetrahydroxyditin anions (Fig. 6 (c)) are known, and are partial dehydration products of the $Sn(OH)_3^-$ anions. Thus whereas $Ba\{Sn(OH)_3\}_2$ is the product of the interaction of barium hydroxide solution and $NaSn(OH)_3$ solution at 35°, at higher temperatures the salt $Ba\{Sn_2O(OH)_4\}$ of the dehydrated anion is formed[63].

[63] C. G. Davies and J. D. Donaldson, *J. Chem. Soc. (A)* (1968) 946.

Tin(IV) hydroxide is not known. Hydrolysis of tin(IV) salt solutions produces a white voluminous precipitate, which is not detectably crystalline, and may contain bonded water in a tin oxide gel. The freshly prepared material is called α-stannic acid, and is easily soluble in acid. Ageing produces β-stannic acid (or metastannic acid), which is more inert in acids, and has also developed an X-ray diffraction pattern characteristic of tin(IV) oxide. This metastannic acid may be obtained directly from tin and concentrated nitric acid. It remains open whether the differences between α- and β-stannic acids are solely due to differences in particle size.

The drying of tin(IV) oxide gel at 110° gives a reproducible product SnO_3H_2, which looses water stepwise between 110° and 600° to produce crystalline cassiterite[64].

Fusion of β-stannic acid with excess of alkaline hydroxide produces the crystalline salts

FIG. 7. Structure of the hexahydroxytin(IV) anion $Sn(OH)_6^{2-}$.

$M_2^I Sn(OH)_6$; and $Sn(OH)_6^{2-}$ ions are also well characterized in many other salts[65, 66]. The hexahydroxytin(IV) anions have the octahedral structure shown in Fig. 7, and the corresponding hexadeuteroxy compounds are known[67].

The hydrolysis of organotin halides gives rise to organotin hydroxides of different types, many of which, however, show a marked tendency to condense with loss of water[68, 69].

Trimethyltin hydroxide is an example of a well-characterized organotin hydroxide[70]. In the crystal it has the chain structure illustrated in Fig. 8 (a). In non-polar solvents a dimeric species $\{(CH_3)_3SnOH\}_2$ is present and is believed to have the dihydroxo-bridged structure of Fig. 8 (b).

Stannites and Stannates

The dehydration of trihydroxytin(II) anions to the oxotetrahydroxydistannites may be carried to completion on heating, to produce the stannites.

Many alkali and alkaline earth stannates have been reported and some have been well characterized. The action of heat upon the salt $K_2Sn(OH)6$ produces the hydrates $K_2SnO_3.H_2O$ and $3K_2SnO_3.2H_2O$ in addition to the anhydrous salt K_2SnO_3.

[70] N. Kasai, K. Yasuda and R. Okawara, *J. Organometallic Chem.* 3 (1965) 172.

Three distinct anhydrous salt phases may be produced by heating together the alkali oxides M_2^IO and SnO_2 in different ratios and under varying conditions[71]. K_2SnO_4 is triclinic; K_2SnO_3 is orthorhombic with each tin atom almost at the centre of a deformed octahedron, with chains of octahedra sharing faces; $K_2Sn_3O_7$ is orthorhombic[72]. Strong
(a)
(b)

FIG. 8. (a) Polymeric structure of $(CH_3)_3SnOH$ in the crystal, (b) dimeric structure of $(CH_3)_3SnOH$ in solution.

heating of K_4SnO_4 converts it successively to K_2SnO_3, $K_2Sn_3O_7$ and eventually SnO_2 by loss of K_2O.

In addition to the alkali stannates, other tin(IV) stannates such as $CdSnO_3$, Ca_2SnO_4 and Cd_2SnO_4 have been fully characterized.

The stannates are usually white crystalline substances sensitive to carbon dioxide; they react vigorously with water[73, 74].

Peroxides and Perstannates

Many hydroperoxides of tin and perstannates with such formulations as $H_2Sn_2O_7$, $HSnO_4.3H_2O$, $KSnO_4.2H_2O$ and $K_2Sn_2O_7.3H_2O$ have been reported from the action of hydrogen peroxide upon solutions of tin(II) and tin(IV). The exact nature of these compounds is unknown, and in many cases they may be only hydrogen peroxide adducts[75, 76, 77].

Stable organotin hydroperoxides are well characterized. Thus trimethyltin hydroperoxide is formed from $(CH_3)_3SnOH$ and hydrogen peroxide, and is quite stable when pure.

[77] S. Tanatar, Chem. Ber. 38 (1905) 1184.

$(CH_3)_3SnOOH$ decomposes on warming to $(CH_3)_2SnO$, CH_3OH and oxygen[78]. Similarly, H_2O_2 on $\{(C_2H_5)_3Sn\}_2O$ produces $(C_2H_5)_3SnOOH \cdot H_2O_2$ at $-60°$, and at room temperature forms the explosive compound $(C_2H_2)_2Sn(OH)OOH$[79].

Organotin alkylhydroperoxides [80, 81, 82] have been synthesized by a number of methods. Exemplary of these is the action of alkylhydroperoxides upon organotinhydrides.

$$(C_4H_9^n)_3SnH + C_4H_9^tOOH \longrightarrow (C_4H_9^n)_3SnOOC_4H_9^t$$
Examples of the compounds $R'_{4-n}Sn(OOR)_n$ can be made in solution for $n = 1-4$, but only the species where $n = 1$ and $n = 2$ are isolable as pure materials. But these latter compounds such as $(C_4H_9^n)_3\ SnOOC_4H_9$ and $(C_4H_9^n)_2Sn(OOC_4H_9^t)_2$ may be purified by vacuum distillation.

Dialkyltinoxyperoxides and bis(triaryl)tinperoxides $R_3SnOOSnR_3$ have been reported.

Organic Stannites and Stannates

Alkoxy compounds of both tin(II) and tin(IV) are known and may be regarded as the esters of the oxides SnO and SnO_2.

Tin(II) alkoxides have been prepared from either the action of tin(II) halides upon sodium alkoxides[83], or from the reaction between tin(II) halides and alcohols in the presence
(a)

(b)

Fig. 9. (a) 2,2'-Biphenylenedioxytin(II) and (b) o-Phenylenedioxytin(II).

of triethylamine[84]. Both tin(II) methoxide and tin(II) ethoxide are very reactive compounds. They are hydrolysed rapidly to tin(II) oxide, but with limited water the bis{alkoxytin(II)} oxide ROSnOSnOR is formed.

Another class of tin(II) organic oxygen derivatives are the tin(II) heterocycles formed by many dihydric phenols. Examples of this type of tin(II) oxygen ring system are 2,2'-biphenylenedioxytin(II) and o-phenylenedioxytin(II) illustrated in Fig. 9.

These tin(II) ring compounds are crystalline with remarkable thermal stability. They may be polymeric in the solid state with intermolecular tin–oxygen bridges, but in pyridine

solution they are monomeric and may utilize an empty p-orbital to complex donor solvents such as pyridine[85, 86].

Tin(IV) organic oxygen compounds are of many different types, and their chemistry has been extensively investigated.

Tin(IV) Alkoxides

Tin tetrachloride and sodium ethoxide produce the double alkoxide $NaSn_2(OC_2H_5)_9$, and not $Sn(OC_2H_5)_4$. The tetra-alkoxides of tin are best produced by an alcohol exchange reaction with the dimeric isopropyl alcoholate of tin tetra-isopropoxide[87, 88].

$$\{Sn(OC_3H_7^i)_4C_3H_7^iOH\}_2 + 8ROH \longrightarrow 2Sn(OR)_4 + 10C_3H_7^iOH$$
The tin alkoxides of primary alcohols are involatile and are presumably polymeric, with bridging alkoxy groups, but the monomeric tertiary alkoxides distil easily at reduced pressure, e.g. $(C_4H_9{}^tO)_4Sn$ b.p. $99°/4$ mm.

Organotin Oxides and Alkoxides

In addition to the tin(IV) alkoxides mentioned above, there have been synthesized many organotin compounds in which tin–oxygen bonds are present[18, 19]. The organostannoxanes are mostly obtained by the hydrolysis of the requisite halides, as exemplified below.
$$R_3SnX \xrightarrow{H_2O/OH^-} R_3SnOSnR_3$$

$$R_2SnX_2 \xrightarrow{H_2O/OH^-} R_2SnO$$

$$RSnX_3 \xrightarrow{H_2O/OH^-} RSn(O)OH$$

[88] D. C. Bradley, *Progress in Inorganic Chemistry*, **2** (1960) 303.

R₃SnOSnR₃ species are monomeric and structurally analogous to the organic ethers, though they are believed to be considerably more basic[89, 90]. The dialkyl- and diaryltin oxides R_2SnO are formally analogous to the silicones, but bear no resemblance in physical properties, being semi-crystalline powders. They are believed to contain polymeric chains, in which coordination takes place as shown in Fig. 10 (a) to render each tin atom five-coordinate. This would suggest that all tin atoms are present in four-membered Sn–O rings[69].

This ladder type of structure has recently been confirmed[91] for the dimeric species {(CH₃)₂SiO(CH₃)₂SnOSn(CH₃)₂OSi(CH₃)₃}₂ as shown in Fig. 10 (b).

Little structural information is available about the so-called alkyl/arylstannonic acids RSn(O)OH, but these may have a ring structure, and undergo dehydration to polymers as indicated below.
Organotin alkoxides have been synthesized in a variety of ways, as outlined below.

$$R_3SnOSnR_3 + R'OH \longrightarrow R_3SnOR'$$
$$R_2SnO + R'OH \longrightarrow R_2Sn(OR')_2$$
$$R_3SnCl + NaOR' \longrightarrow R_3SnOR'$$
$$R_3SnOR' + R''OH \longrightarrow R_3SnOR''$$
$$R_3SnNR_2 + R''OH \longrightarrow R_3SnOR''$$
$$R_3SnOR' + R''COOR''' \longrightarrow R_3SnOR''$$

Some diols produce[92] cyclic alkoxides as illustrated in Fig. 11.

Fig. 11. The cyclic organotin alkoxides formed from (C₄H₉)₂SnO and (a) 2,3-butanediol and (b) cyclohexanediol.

The tin–oxygen bonds of organotin oxygen compounds are often extremely reactive and undergo a wide variety of reactions as illustrated in Fig. 12.

Phenyltin trichloride and tropolone produce $C_6H_5Sn(tropolonato)_2Cl$, which is converted to $C_6H_5Sn(tropolonato)_3$ by reaction with sodium tropolonate. The complex $C_6H_5Sn(tropolonato)_3$ is monomeric, and is believed to contain hepta-coordinate tin[93].

FIG. 12. Some reactions of organotin alkoxides.

In contrast to the corresponding alkoxides of tin, the oxinates $R_2Sn(Ox)_2$ are stable to moisture. From spectroscopic data these tin oxinates are believed to be chelate compounds of hexa-coordinate tin. The corresponding R_3SnOx types are believed to be penta-coordinate[94].

Carboxylates

Tin(II) carboxylates such as tin(II) formate[95] and tin(II) acetate[96] are made by dissolving tin(II) oxide in the requisite carboxylic acid. Tin(II) acetate is stable, and can be stored for some months in air, but over longer periods of time it undergoes slow oxidation. It can be sublimed in vacuum to give very pure $(CH_3COO)_2Sn$ at about 150°, but at higher temperatures decomposes to tin(II) oxide, carbon dioxide and acetone. Tin(II) acetate hydrolyses slowly over several hours in water, but the adduct $(CH_3COO)_2Sn.2CH_3COOH$ formed by dissolving tin(II) acetate in glacial acetic acid is unhydrolysed, even in boiling water.

Tin(II) acetate is a useful reducing agent, and can act under certain conditions both as a reducing and acetylating agent, thus for example a 75% yield of 1,4-diacetoxynaphthalene is obtained from 1,4-naphthaquinone and tin(II) acetate in 20 min.

[93] E. L. Meutterties and C. M. Wright, *J. Am. Chem. Soc.* **86** (1964) 5132; *Quart. Revs. (London)* **21** (1967) 123.

[94] K. Ramaiah and D. F. Martin, *Chem. Comm.* (1965) 130.

[95] J. D. Donaldson and J. F. Knifton, *J. Chem. Soc.* (1964) 4801.

[96] J. D. Donaldson, W. Moser and W. B. Simpson, *J. Chem. Soc.* (1964) 5942.

With the exception of tin(II) formate, the tin(II) carboxylates are fibrous in nature, and of low solubility, suggesting a linear polymeric structure which can break down on sublimation, or upon solution in donor solvents. The Mössbauer and infrared spectra of tin(II) carboxylates are both in accord with the presence of long chains of pyramidally coordinated tin atoms containing bridging carboxylate groups[97].

In addition to the simple tin(II) carboxylates, evidence has been presented for many more carboxylate species of tin(II); thus CH_3COOSn^+, $(CH_3COO)_2Sn$, $(CH_3COO)_7Sn_3^-$, $(CH_3COO)_5Sn_2^-$ and $(CH_3COO)_3Sn^-$ have all been reported in tin(II)–acetate solutions[98].

The tri-acetatostannates have been well characterized and isolated as pure salts of the alkali metals and ammonia, and also as the alkaline earth salts.

The discrete $(RCOO)_3Sn^-$ ions in the tricarboxylatostannates have distorted pyramidal

(a)   (b)

(c)

FIG. 13. (a) Five-coordinate tin in R_3Sn-oxinate, (b) six-coordinate tin in $R_2Sn(oxinate)_2$ and (c) eight-coordinate tin in $Sn(oxinate)_4$.

coordination about each tin atom as shown in Fig. 14(b). The more complex anions such as $(CH_3COO)_7Sn_3^-$ and $(CH_3COO)_5Sn_2^-$ may be regarded as having chain structures analogous to the tin(II) carboxylate chain illustrated in Fig. 14 (a).

Tin(IV) tetracarboxylates may be synthesized from anhydrous acetic acid and tin(IV) chloride, or from thallium(I) carboxylate and tin(IV) iodide. They are in marked contrast to the tin(II) carboxylates, in that they are exceedingly sensitive to hydrolysis by traces of moisture, but are soluble in most organic solvents[99, 100].

Ditin hexa-acetate $(CH_3COO)_6Sn_2$ is formed by the action of acetic acid upon hexaphenylditin at 120°. It is quite a stable compound, and is believed to have the structure illustrated in Fig. 15, where two bridging acetate groups are present in addition to the

metal–metal bond. Hydrogen chloride at $-100°$ converts ditin hexa-acetate to ditin hexachloride[101].

The organotin(IV) carboxylates are of particular interest in that they appear to exist in more than one form. When trimethyltin hydroxide reacts with, for example, formic and acetic acids, the products are the very insoluble $(CH_3)_3SnOOCH$ and $(CH_3)_3SnOOCH_3$.

(a)

(b)
Fig. 14. Proposed structures of (a) tin(II) carboxylates and (b) the tricarboxylatotin anions.
Fig. 15. Ditin hexa-acetate.

These insoluble products are believed to be associated by bridging carboxylate groups, either as linear or ring polymers[69].

If, however, the polymeric forms of $(CH_3)_3SnOOCH$ and $(CH_3)_3SnOOCCH_3$ are heated in cyclohexane at $100°$ for several hours, they are both converted to new soluble forms. A remarkable point of interest is that the soluble and insoluble forms of these organotin carboxylates are sublimable in high vacuum without interconversion[102].

Tetra-ethylammonium trisoxalatostannate(IV) and tetra-ethylammonium trismalonato-stannate(IV) are made by the treatment of $\{(C_2H_5)_4N\}_2SnBr_6$ with silver oxalate and silver malonate respectively in acetone. These complex ions are not hydrolysed by water, and their infrared and Raman spectra have been measured and discussed[103].

2.8. TIN SALTS OF INORGANIC OXY-ACIDS

Numerous tin(II) and tin(IV) salts of inorganic oxy-acids, such as dithionates[106], carbonates, arsenates[104, 105], vanadates[104, 105], tungstates[104], borates[104], nitrates, sulphates, etc., have been reported in the literature. Very many of these, however, are ill characterized and of dubious stoichiometry. Some of the more authenticated compounds are discussed below.

Nitrates

A normal tin(II) nitrate is unknown, but dilute solutions of tin(II) nitrate are reasonably stable[107]. Such solutions may be made by nitrate metathesis from tin(II) chloride or sulphate, or alternatively by the dissolution of tin(II) oxide in dilute nitric acid. Efforts to evaporate such solutions to crystallization result in decomposition which may be violent. A number of explosions have been attributed to tin(II) nitrate systems, where the decomposition products are tin(IV) oxide and various nitrogen compounds such as hydroxylamine and nitrous oxide[108].

A basic tin(II) nitrate $Sn_3(OH)_4(NO_3)_2$ is made by the action of nitric acid upon a paste of hydrous tin(II) oxide. It is believed to be ionic and to contain the ion $Sn_3(OH)_4^{2+}$ illustrated in Fig. 6 (a). Basic tin nitrate is partly hydrolysed on dissolution in water. The presence of Sn(II) ions with NO_3^- makes thermal decomposition of the basic nitrate exceedingly violent, and $Sn_3(OH)_4(NO_3)_2$ may be classified as a high explosive[107].

Tin(IV) nitrate is formed by the action of N_2O_5, $ClNO_3$ or $BrNO_3$ upon tin(IV) chloride[109, 110]. The white volatile $Sn(NO_3)_4$ is believed to contain eight-coordinate tin, with each nitrate group behaving as a bidentate ligand. Tin(IV) nitrate reacts readily with aliphatic hydrocarbons with the formation of carboxylic acids, alkyl nitrates and nitro-alkanes; it reacts vigorously with diethyl ether. These reactions are attributed to the easy release of the very reactive NO_3 radicals.

$$Sn(NO_3)_4 \longrightarrow Sn(NO_3)_2 + 2NO_3$$
The compounds which release NO_3 radicals appear to be those in which the nitrate group is bonded in bidentate fashion. Thus the pyridine adduct $Sn(NO_3)_4(C_5H_5N)_2$, in which all of the nitrate groups are monodentate, is unreactive towards hydrocarbons and ether.

When $SnCl_4$ and N_2O_4 are mixed at $-10°$ in a stream of nitrogen, the compound

$SnCl_4.N_2O_4$ is formed as a pale yellow very hygroscopic powder. This is formulated as $NO^+[SnCl_4NO_3]^-$ in which a bidentate nitrate ligand produces an octahedral tin anion[111].

By a similar type of reaction between Cs_2SnCl_6 and liquid N_2O_5 the hexanitrate ion $Sn(NO_3)_6^{2-}$ was obtained as the caesium salt. The $Sn(NO_3)_6^{2-}$ may be presumed to be octahedral, with monodentate nitrate ligands[112].

A number of organotin nitrates such as $(CH_3)_3SnNO_3$ and $(CH_3)_2Sn(NO_3)_2$ are known[18, 113]. Structural information on these compounds to date is largely based upon spectroscopic data, and is conflicting. Organotin nitrates do however appear to contain metal coordinated nitrate groups, which may be mono- or bidentate, and in some cases bridging[69]. In the case of adducts such as $[(CH_3)_3Sn(NH_3)_2]^+NO_3^-$, however, there is non-coordinated nitrate ion present.

Triphenyltin nitrate has poor stability, and decomposes at quite low temperatures to nitrobenzene and diphenyltin oxide[114].

$$(C_6H_5)_3SnNO_3 \longrightarrow (C_6H_5)_2SnO + C_6H_5NO_2$$
Phosphates and Phosphites

The chemistry of tin phosphates is exceedingly complex, and very many stoichiometries have been reported[114, 115].

Tin(II) orthophosphate $Sn_3(PO_4)_2$ is reported from the interaction of sodium hydrogen phosphate upon tin(II) sulphate in sulphuric acid. Other tin(II) phosphates recorded are $SnHPO_4$, $Sn(H_2PO_4)_2$, $Sn_2P_2O_7$ and $Sn(PO_3)_2$.

Tin(IV) phosphates include $Sn_2O(PO_4)_210H_2O$, $Sn_2O(PO_4)_2$ and SnP_4O_7. Many complex phosphates such as $KSn(PO_4)_3$, $KSnOPO_4$ and $Na_2Sn(PO_4)_2$ are known[116].

The stoichiometry of the tin(II) and tin(IV) phosphates is controlled by the particular phosphate ion which is complexing to the tin(II) or the tin(IV) ion; thus a whole range of pyrophosphates and tripolyphosphates of tin have been detected, and there is a trend for tin(II) to complex long-chain polyphosphates, with average chain lengths up to fourteen[117].

Tin(IV) hypophosphite is remarkable in that it represents a class of compound containing tin(IV) and a strongly reducing anion. Considering the reduction potentials,

$$Sn^{4+} + 2e \longrightarrow Sn^{2+} \qquad (E = 0.15V)$$
$$H_3PO_3 + 2H^+ \longrightarrow H_3PO_2 + H_2O \qquad (E = -0.50V)$$
the very existence of $Sn(H_2PO_2)_4$ is surprising. The isolation of tin(IV) hypophosphite by bubbling oxygen through a solution of tin(II) oxide in hypophosphorous acid may be due to a combination of the low solubility of the product, and the often slow kinetics of hypophosphite reductions at ordinary temperatures[118].

In addition to the simple tin(IV) hypophosphite, a number of halogenohypophosphites

of tin(II) and tin(IV) such as $SnCl_4.Sn(H_2PO_2)_4$, $SnI_4.Sn(H_2PO_2)_4$, $SnBr_2.3Sn(H_2PO_2)_2$ and $SnI_2.3Sn(H_2PO_2)_2$ have been reported[119]

Perchlorates

The action of Cl_2O_3 upon tin(IV) chloride is reported to produce the tin(IV) perchlorates $Sn(ClO_4)_4.2Cl_2O_6$ and $Cl_2Sn(ClO_4)_2$, the structures of which are unknown, but which presumably must contain perchlorate groups coordinated to tin[120].

Organotin perchlorates such as $(CH_3)_3SnClO_4$ and $(CH_3)_2Sn(ClO_4)_2$ are better characterized, and are electrolytes in aqueous solution. Trimethyltin perchlorate (m.p. 128°) is volatile, and in the vapour the molecule is likely to have a bidentate perchlorate group attached to five-coordinate tin. In the crystal, however, the perchlorate group may have a bridging role in the structure[121].

Solutions of tin(II) perchlorate have been used in studies of tin complex formation, and one crystalline species has been isolated. Tin(II) perchlorate trihydrate is made by the action of tin(II) oxide upon 70% perchloric acid. $Sn(ClO_4)_2.3H_2O$ is very hygroscopic, melts at 240° and decomposes explosively at 250°. Mössbauer measurements suggest that one water molecule is bonded to tin, as in the tin(II) chloride dihydrate[122].

Sulphates

Tin(II) sulphate may be prepared by dissolving tin metal or a tin(II) salt in sulphuric acid. Pure tin(II) sulphate, however, is best made by the displacement of copper from a copper sulphate solution by metallic tin. Crystals of $SnSO_4$ are white and orthorhombic ($a = 8.81$; $b = 7.17$ and $c = 5.35$ Å). Tin(II) sulphate has an excellent shelf life, and is strongly recommended as a pure source of $Sn(II)$[123].

The thermal decomposition of $SnSO_4$ yields sulphur dioxide and tin(IV) oxide, and is an example of the numerous internal oxidation–reduction reactions which are undergone by oxygen containing tin(II) compounds.

The solubility of tin(II) sulphate in water decreases steadily with rise in temperature (35.2 g/100 ml of solution at 20°, 22.0 g/100 ml of solution at 100°). It is also quite soluble in concentrated sulphuric acid.

The basic tin(II) sulphate $Sn_3(OH)_2OSO_4$ is obtained as a well-defined crystalline material by the action of ammonia solution upon tin(II) sulphate. This basic tin sulphate looses water in one stage at 230° to leave the tin(II) oxysulphate $Sn_3O_2SO_4$.

Tin(IV) sulphate as the dihydrate $Sn(SO_4)_2.2H_2O$ is obtained from hydrous tin(IV) oxide in hot dilute sulphuric acid. The colourless crystals are exceptionally hygroscopic and best stored in sealed ampoules[124]. Tin(IV) sulphate hydrolyses completely in water, with precipitation of hydrous tin(IV) oxide, but is nevertheless freely soluble in dilute sulphuric acid to give a clear solution.

[124] M. Baudler, *Handbook of Preparative Inorganic Chemistry*, Ed. G. Brauer, Vol. I, 2nd ed., p. 744, Academic Press, New York.

Estimates of activity coefficients suggest that the dissolution of hydrous tin(IV) oxide in dilute sulphuric acid produces the $SnSO_4^{2+}$ ion in solution, with more concentrated sulphuric acid solutions causing further complexing to form $Sn(SO_4)_2$ and $H_2Sn(SO_4)_3$ in solution[125].

Tetramethyltin reacts with sulphuric acid to evolve methane and produce trimethyltin hydrogen sulphate $(CH_3)_3SnHSO_4$. The trialkyltin hydrogen sulphates and the dialkyltin dihydrogen sulphates behave as strong bases. It is most likely, however, that the cationic species present are protonated hydrogen sulphates, rather than stannonium ions[126].

Phenyltin compounds undergo cleavage in sulphuric acid to produce the hexa(hydrogen sulphate) stannic acid $H_2Sn(HSO_4)_6$ and its anions.

2.9. CHALCOGEN COMPOUNDS

Sulphides

The only three well-characterized sulphides of tin are SnS, Sn_2S_3 and SnS_2, though Sn_4S_5 has been claimed[127] by thermal decomposition of SnS_2. $SnOS$ is reported from the action of sulphur upon tin(II) oxide, and Sn_2S_3O, $Sn_5O_6S_4$ and $Sn_3O_7S_2$ have been reported as hydrated materials from various aqueous precipitations[128, 129].

Tin(II) sulphide may be made by the direct combination of the elements, but this product is usually non-stoichiometric; it is usually obtained by the sulphide precipitation of tin(II) salts, whence the initially hydrated form is easily dehydrated. Crystalline SnS, m.p. $1153°K$, b.p. $1500°K$, density ~ 5, has a very distorted NaCl structure[130] in which each tin atom has four different near neighbour sulphur distances of $2·62Å$, $2·68$ Å (2), $3·27$ Å (2) and $3·39$ Å. The analogous $PbSnS_2$ which occurs in Bolivian ores as the mineral theallite has the same distorted structure, in marked contrast to the perfect NaCl lattice of PbS.

SnS is reduced to tin by hydrogen, and converts to tin(IV) oxide on heating in the air. It is virtually insoluble in water (solubility product $\sim 10^{-27}$ at 25°C), but it can be recrystallized from tin(IV) chloride solutions as grey-blue metallic platelets.

Tin sesquisulphide has been reported as a constituent of Bolivian ores[131], and has been shown by X-ray work to be a distinct phase. The structure consists of infinite double rutile type strings of $Sn^{IV}S_6$ octahedra with Sn^{II} ions attached laterally[132].

Tin(IV) sulphide is prepared commercially as yellow platelets (density $4·51$) by the action of tin foil upon flowers of sulphur, and is used as mosaic gold and may be purified by sublimation. It is precipitated from mildly acid solutions of tin(IV) salts by sulphide ion.

SnS_2 crystallizes with a CdI_2 structure[133]. When formed by precipitation from aqueous solution the SnS_2 is easily redissolved in warm hydrochloric acid, but the product of the high temperature dry synthesis is very insoluble.

Thiostannates

The thiostannates may be made by a number of methods such as the action of alkali sulphide solutions upon tin(IV) sulphide or upon various stannate solutions. Well-crystallized species of definite stoichiometry are formed, which appear to be salts of the SnS_3^{2-} and SnS_4^{4-} ions. Invariably, however, the thiostannates crystallize highly hydrated, as for example in $Na_2SnS_3.8H_2O$ and $Na_4SnS_4.18H_2O$, and some water appears to be more strongly bound than the rest[134]. The structure of these compounds is unknown, but it has been suggested that the ions present may be either $[(HS)_3Sn(OH)_3]^{2-}$ or $[(H_2O)_3SnS_3]^{2-}$, and either $[(HS)_2Sn(OH)_2S_2]^{4-}$ or $[(H_2O)_2SnS_4]^{4-}$ rather than simply SnS_3^{2-} and SnS_4^{4-}.

In addition to the binary sulphides, other classes of compounds contain tin–sulphur bonds. Of these, the coordination complexes of thio-ethers with tin halides are discussed below in the chemistry of the tin halides.

Organotin Sulphides

The tin–sulphur covalent bond has been extensively studied, and a variety of synthetic methods[135] available for its formation are outlined below.

$$SnCl_4 + NaSR \longrightarrow (RS)_4Sn$$

$$(C_6H_5)_3SnCl + AgS \longrightarrow (C_6H_5)_3SnSSn(C_6H_5)_3$$

$$(CH_3)_3SnOH + RSH \longrightarrow (CH_3)_3SnSR$$

$$R_2SnO + R'SH \longrightarrow R_2Sn(SR')_2$$

$$(R_3Sn)_2O + H_2S \longrightarrow (R_3Sn)_2S$$

$$(C_6H_5)_4Sn + S \longrightarrow (C_6H_5)_2SnS$$

$$(CH_3)_3SnSn(CH_3)_3 + S \longrightarrow (CH_3)_3SnSSn(CH_3)_3$$

$$C_6H_5NCS + (C_2H_5)_3SnH \longrightarrow (C_2H_5)_3SnSCH:NC_6H_5$$

Some of the different types of organotin sulphur compounds are illustrated in Fig. 16. In all of these compounds, the tin(IV) atom is approximately tetrahedral, with the exception of Fig. 16 (f), which is polymeric[136], and in which tin is probably octahedral by inter-molecular coordination. This polymer may be broken down by ligands such as amines to produce complexes like Fig. 16 (g)[137].

The base strength measurements suggest that the organotin sulphides such as $(CH_3)_3SnSSn(CH_3)_3$ are stronger bases than the simple organic sulphides. This would be in accord with little or no back-bonding from sulphur to tin, and tin's lower electro-negativity[89,90].

Organotin sulphur compounds are fairly robust compounds, but undergo fission by halogens and halides. They are now manufactured on a large scale for industrial uses, especially as stabilizers for polyvinyl chloride and related plastics, where the $R_2Sn(SR')_2$ types are extensively used[4].

Selenides

In addition to SnSe and SnSe$_2$, the phase diagram[138] for tin–selenium shows the formation of Sn$_2$Se$_3$ by a peritectic reaction at 650°. Sn$_2$Se$_3$ has a tetragonal type of lattice $a = 6\cdot77$ Å, $c = 5\cdot86$ Å[139].
Fig. 16. Some examples of organotin–sulphur compounds.

SnSe is a grey blue solid, and may be synthesized by the direct interaction of the powdered elements, which starts at about 350°, and is extremely exothermic[140]. It melts at 861° and may be distilled without decomposition. Single crystals of considerable size

[138] F. Laves and Y. Baskin, Z. Krist. 107 (1959) 377.
[139] J. Willy, Compt. rend. 251 (1960) 1273.
[140] Y. Matakuta, T. Yamamoto and A. Osazaki, Mem. Fac. Sci. Kynsyu Univ. B1 (1953) 98.

are grown with some ease[141]. Crystal data on SnSe are contradictory, giving either a rhombic[140] structure $a = 4.33$ Å, $b = 3.98$ Å, $c = 11.18$ Å, or a cubic NaCl type of structure[142].

SnSe$_2$, m.p. 625°C, may be prepared by vacuum melting of stoichiometric quantities of the elements and as single crystals by the Bridgman method[143]. SnSe$_2$ has a CdI$_2$ structure $a = 3.811$ Å and $c = 6.137$ Å.

Both SnSe and SnSe$_2$ are semiconductors with specific resistances in the range 10^3 to 10^{-1} ohm cm, but electrical properties vary considerably with the history of heat treatment of the alloys. Impurities in SnSe behave somewhat unusually, and it is likely that antimony for example replaces tin atoms in the lattice up to 200°C, but above that replaces selenium in the lattice[144].

Both Sn$_2$Se$_3$ and SnSe$_2$ decompose on heating to SnSe and selenium. The molecules Sn$_2$Se$_2$ are detected by the mass spectrometer at high temperatures in the vapour, and these are believed to be tetrahedral clusters[145].

The selenothiostannates SnSe$_2$S^{2-} and the selenostannates SnSe$_3{}^{2-}$ are analogous to the thiostannates, and though well characterized, are of unknown structure[146].

Organic Selenides
A variety of molecular compounds exist in which there are discrete tin–selenium bonds.

The sodium, potassium and magnesium salts of selenols react with tin tetrahalides to afford complete halogen replacement[147], and organotin selenolates have been made in aqueous solution from the selenols[148].

$$\left.\begin{array}{l} RSeNa \\ RSeMgX \end{array}\right\} + SnX_4 \longrightarrow (RSe)_4Sn$$
$$R_3SnX + R'SeH \longrightarrow R_3SnSeR$$

The organoditin selenides are made by the action of the appropriate organotin halide upon sodium selenide[149, 150].

$$R_3SnCl + Na_2Se \longrightarrow R_3SnSeSnR_3$$
The organotin selenols R$_3$SnSeH have not been reported, but their lithium salts such as (C$_6$H$_5$)$_3$SnSeLi are known[151].

Some representative organotin–selenium compounds are listed[135] in Table 11.

Tellurides

The heating together of tin and tellurium causes the formation of SnTe with incandescence. SnTe can be sublimed to give large crystals and is stable at high temperatures.

SnTe is deposited from tin(II) solutions by the action of hydrogen telluride[152], and similarly SnTe$_2$ is supposedly formed from hydrogen telluride and tin(IV) solutions[153]. The linear SnTe$_2$ molecule is analogous to CO_2 and is detected at high temperatures.

Melting SnTe under high pressure gives two solid polymorphs[154], as well as liquid

TABLE 11. EXAMPLES OF MOLECULAR COMPOUNDS
CONTAINING TIN–SELENIUM BONDS

around 117°K. The normally NaCl structure of SnTe is converted by a pressure of 18,000 atm to an orthorhombic form with a 360% increase in electrical resistivity[155].

The organic tin–tellurium compounds have been little investigated, but the hexaphenyl-ditintelluride $[(C_6H_5)_3Sn]_2Te$ and its lithium salt have been reported[156]

2.10. HALOGENO COMPOUNDS

Tin(II) Halides

Tin(II) fluoride is obtained as colourless monoclinic crystals by the evaporation of a solution of tin(II) oxide in 40% hydrofluoric acid[157, 158]. From solutions of tin(II) fluorides with other fluorides an orthorhombic form of pure tin(II) fluoride has been isolated[159]. In this form tin is in an irregular trigonal pyramidal environment, with two Sn–F bonds of 2·15 Å, and one of 2·45 Å[160]. Three other fluorines at about 2·80 Å make up an overall distorted octahedral environment. From Mössbauer spectroscopy the tin–fluorine bonds in the orthorhombic form are believed to be more covalent than in the monoclinic form. Tin(II) fluoride is very soluble in water, and is extensively utilized.as a constituent of dentifrices[161–163]. The mixed halide SnFCl is obtained by action of hydrofluoric acid upon tin(II) chloride[164].

Tin(II) chloride is available commercially as the dihydrate, which is itself of interest. In crystalline $SnCl_2.2H_2O$ one molecule of water is lattice aquation[165], but the other is coordinated to the tin dichloride molecule, whereby the tin nominally attains an octet of electrons. Anhydrous tin(II) chloride is obtained from the dihydrate by the action of acetic

anhydride. Crystalline $SnCl_2$ has a layer structure in which there are Sn–Cl–Sn–Cl chains[166] The Sn–Cl bonds in the chain are 2·78 Å, and the pyramidal coordination of each metal is completed by a further chlorine at 2·67 Å. Considering the overall structure of $SnCl_2$ from layer to layer, tin may be regarded as nine-coordinate in this structure. Tin(II) bromide and tin(II) iodide are similar to $SnCl_2$ in the crystal, in that they do not contain
Fig. 17. Tin(II) chloride: (a) an angular discrete molecule in the gas phase; (b) the polymeric $(SnCl_2)_n$ chain present in crystalline $SnCl_2$; (c) coordination about tin in $SnCl_2 \cdot 2H_2O$, where only one water molecule is actually coordinated to tin.

discrete $SnBr_2$ and SnI_2 molecular units, but a polymeric layer structure; SnI_2 is conveniently made as brilliant red needles by heating iodine in 2N hydrochloric acid with tin[167].

In the gas phase $SnCl_2$, $SnBr_2$ and SnI_2 exist as discrete angular molecular species[168] (see Table 7).

The solubility of the tin(II) halides in water falls off markedly from $SnCl_2$ (84 g of $SnCl_2$ in 100 g of water at 0°C) to SnI_2 (0·96 g of SnI_2 in 100 g of water at 0°C).

Halogenotin(II) Anions

The halogenotin(II) acids H_2SnX_4 have been claimed both in solution and as crystalline solids in the older literature[169, 170]. Better characterized, however, are the many halogeno-

tin(II) salts such as $KSnF_3$, $Na_2Sn_2F_5$, $(NH_4)_4SnCl_6$, NH_4SnCl_3, K_4SnCl_6, $KSnBr_3$, K_2SnBr_4, K_4SnBr_6, $CsSn_2I_5$, $KSnI_3$, etc.[171-173].

Though the precise nature of many of these salts is unknown, information regarding the discrete ions present in some of these complexes show these materials to be lattice salts only.

Salts of the ions SnX_3 (where X=F, Cl, Br and I) have all been obtained from aqueous

solution. The SnX_3 ions are pyramidal, as shown in Fig. 18 (a), due to the presence of a sterically active non-bonding pair of electrons. This electron pair makes the trihalogenotin anions excellent ligands, resulting in a wide range of transitional metal complexes[174, 175]. In addition to being a σ-bonding donor group, the SnX_3 anion ligands are believed to be powerful π-acceptor ligands. Complexes which involve only the σ-donor characteristics are exemplified by the boron halide complex anions $[X_3B.SnCl_3]^-$, which are believed[176] to contain a boron–tin bond as shown in Fig. 18 (b). The formation and decomposition of some $SnCl_3$ complexes are exemplified in the following equations.

$$R_4AsSnCl_3 + BX_3 \longrightarrow R_4As^+[X_3B.SnCl_3]^-$$
$$PtCl_4^{2-} + 2SnCl_3^- \longrightarrow [Cl_2Pt(SnCl_3)_2]^{2-} + 2Cl^-$$
$$[Cl_2Pt(SnCl_3)_2]^{2-} + 2(C_6H_5)_3P \longrightarrow \{(C_6H_5)_3P\}_2PtCl_2 + 2SnCl_3^-$$
$$Pt(CO)_2Cl_2 + 2SnCl_3^- \longrightarrow [Cl_2Pt(SnCl_3)_2]^- + 2CO$$
[171] E. Rimbach and K. Fleck, Z. anorg. Chem. 94 (1916) 139.
[172] W. Pugh, J. Chem. Soc. (1953) 2491.
[173] V. Auger and T. Karantassis, Compt. rend. 181 (1925) 665.
[174] J. F. Young, R. D. Gillard and G. Wilkinson, J. Chem. Soc. (1964) 5176.
[175] R. D. Cramer, R. V. Lindsey, C. T. Prewitt and U. G. Stolberg, J. Am. Chem. Soc. 87 (1965) 658.
[176] M. P. Johnson, D. F. Shriver and S. A. Shriver, J. Am. Chem. Soc. 88 (1966) 1588.

Despite the existence of many well-characterized salts, $M_2SnCl_4.H_2O$, $M^{II}SnCl_4.nH_2O$ and $M^{III}SnBr_4.nH_2O$, it is unlikely that any contain a discrete SnX_4^{2-} ion. A structural investigation of the salt $K_2SnCl_4.H_2O$ showed it to be a lattice salt $KCl.KSnCl_3.H_2O$ with the tin atom present in a distorted pyramidal $SnCl_3^-$ ion, with three more distant chlorine atoms in the lattice completing a roughly octahedral environment about tin[177].

The ions $Sn_2X_5^-$ (X = F and Cl) are well defined[178], thus $Sn_2F_5^-$ is formed in concentrated tin(II) solutions containing insufficient fluoride ions to complete the formation of SnF_3^-. $Na_2Sn_2F_5$ contains discrete $Sn_2F_5^-$ ions as shown in Fig. 18 (c). Two SnF_2 groups are linked by fluorine, with bridging Sn–F distances of 2·22 Å and terminal Sn–F bond lengths of 2·07 Å[179].

$Sn_2F_5^-$ anions are also present in salt melts, and similar tin(II) chloride melts with the alkali metal chlorides provide evidence for the presence of $Sn_2Cl_5^-$ ions, and also $Sn_3Cl_7^-$ ions[180].

SnF_3^- is considerably the strongest of the halogenotin(II) complexes, as illustrated[181] by the dissociation constants SnF_3^- $1·1 \times 10^{-11}$, $SnCl_3^-$ 3×10^{-5}, $SnBr_3^-$ $4·5 \times 10^{-2}$.

Coordination Complexes of Tin(II) Halides

Tin(II) fluoride, chloride and bromide all have Lewis acid capability to form complexes with suitable bases. Complexes of oxygen and nitrogen species are numerous, and those

of sulphur somewhat rarer. Table 12 gives some examples of well-defined complexes of these three tin(II) halides[13].

With six outer shell electrons the tin(II) halides can be expected to be monofunctional acceptors to complete a valence shell. Whilst this accounts for the many 1:1 complexes in Table 12, it cannot be an explanation for other well-characterized stoichiometries. Whilst many of these other stoichiometries may be analogous to $SnCl_2.2H_2O$, in which one water molecule is coordinated and the other is only lattice water, it cannot be ruled out that in certain cases tin may use[13] vacant d orbitals to form these $SnCl_2.(base)_n$ complexes, where $n > 1$.

Tin(IV) Halides

Tin(IV) fluoride may be prepared by the action of anhydrous hydrogen fluoride upon tin(IV) chloride[182]. It is an extremely hygroscopic white crystalline solid which may be sublimed at about 700°. Although it is likely that gaseous SnF_4 has tetrahedral molecules with four-coordinate tin, solid SnF_4 differs markedly from the other three tin(IV) halides
FIG. 19. The layer structure of crystalline SnF_4.

in that each tin atom is six-coordinate. Crystalline tin(IV) fluoride has a layer structure[183] as illustrated in Fig. 19. Each tin atom is attached to four fluorine atoms in the plane of the layer with Sn–F = 2·08 Å, and also to two terminal fluorine atoms above and below the layer plane with Sn–F = 1·88 Å.

Tin(IV) chloride, bromide and iodide are all conveniently made by the direct action of the halogen upon metallic tin. Some of their physical properties are described in Table 13.

TABLE 13. PROPERTIES OF Sn(IV) CHLORIDE, BROMIDE AND IODIDE

Property	$SnCl_4$	$SnBr_4$	SnI_4

All three of these tetrahalides are volatile molecular species, in which discrete SnX_4 molecules are present in the gas, liquid and solid phases.

Tin(IV) chloride forms a number of hydrates, but that stable at ordinary temperature and pressure is $SnCl_4.5H_2O$. Tin(IV) tetrahalides are all hydrolysed by aqueous alkali.

[182] O. Ruff and W. Plato, *Chem. Ber.* **37** (1904) 673.
[183] R. Hoppe and W. Dahne, *Naturwiss.* **49** (1967) 254.

There is a rapid exchange of halogens in mixtures of tin(IV) chloride, bromide and iodide, and Raman spectra have shown the presence of all possible molecules of formula $SnBr_nI_mCl_{4-m-n}$ in such a mixture[184].

Hexahalogenotin(IV) Anions

The anions SnX_6^{2-} (X = F, Cl, Br and I) may be obtained from solutions of the tetra-halides containing an excess of halide ion. They have been isolated as salts with a wide variety of cations M^+ and M^{2+}. The salts contain discrete cations and the SnX_6^{2-} anions which are octahedral. A crystal structure determination[185] of Na_2SnF_6 showed tin to be in a distorted octahedral environment of fluorines, with Sn–F bonds of 1·83, 1·92 and 1·96 Å.

The well-characterized salt formulated as K_3HSnF_8 is better written as $K_2SnF_6.KHF_2$, and consists of a lattice of K^+, SnF_6^{2-} and linear FHF ions[186].

The parent acids of hexachlorostannates[187, 188] and hexabromostannates[189] may be precipitated as $H_2SnCl_6.6H_2O$ and $H_2SnBr_6.8H_2O$ by the action of hydrogen halide upon a concentrated solution of the appropriate tin(IV) halide.

$(NH_4)_2SnCl_6$ is the "pink salt" mordant of the dyeing industry.

In addition to the hexahalogenostannates a number of other complex halogenostannates are known, in which other ligands besides halogen are coordinated to tin. These may be prepared in a number of ways, and have been extensively studied[190]. Thus increasing addition of alkali to aqueous solution of SnF_6^{2-} causes initial formation of $SnF_5(OH)^{2-}$, and then $SnF_4(OH)_2^{2-}$, which is present in *cis* and *trans* forms; finally $SnF_3(OH)_3^{2-}$ as *cis* and *trans* isomers is obtained. Examples of other mixed di-anions of this type are SnF_5Cl^{2-}, $SnF_4Cl_2^{2-}$ (*cis* and *trans*), $SnCl_3F_3^{2-}$ (*cis* and *trans*), $SnCl_5F^{2-}$, $SnBrF_5^{2-}$, $SnBrClF_4^{2-}$, $SnIF_5^{2-}$, $Sn(NCO)F_5^{2-}$, $Sn(NCO)_2F_4^{2-}$ (*cis* and *trans*), $Sn(NCS)_3F_3^{2-}$, $Sn(CN)F_5^{2-}$ and $Sn(OOCCF_3)F_5^{2-}$.

In addition, octahedral mono-anions are known where one of the ligands is neutral, as, for example, in $Sn(H_2O)F_5^-$, $Sn\{(CH_3)_2SO\}ClF_4^-$, $SnNCS\{(CH_3)_2SO\}F_4^-$ and $Sn\{(CH_6H_5)_3P\}F_5^-$.

It is unlikely that the pentahalogenotin(IV) anions SnX_3 exist in solution, as they would pick up a solvent molecule to complete six-coordination. The SnX_3^- anions are, however, known in crystals, and $SnCl_5^-$ has been shown to be a trigonal bipyramidal species[191].

Coordination Complexes of Tin(IV) Halides

All four tetrahalides of tin form addition compounds with certain electron donors (L), such as amines, cyanides, ethers, sulphides, ketones, phosphines, arsines, etc.[192]. The most usual stoichiometry of these compounds is L_2SnX_4, but the presence of 1:1 adducts has been demonstrated in solution[193], and the occasional 1:1 adduct has been reported as a

solid. Some examples of tin(IV) halide complexes are given in Table 14, together with the stereochemistry, where known. In general, the stereochemistry of these octahedral complexes appears to be governed by steric factors, thus small ligands tend to give *cis* adducts, while larger sterically hindered ligands produce *trans* adducts.

The adducts of the more powerful donors give complexes such as (pyridine)$_2$SnCl$_4$ which are very insoluble[194], but with weaker ligands, complexes such as (tetrahydrofuran)$_2$SnCl$_4$ are soluble in solvents such as benzene, frequently with extensive dissociation[195].

Although crystalline adducts have not been isolated, there is evidence that 1:1 complexes are formed between tin(IV) chloride and aromatic hydrocarbons in solution[196].

Organotin Halides

The organotin halides are among the most widely investigated and used compounds of tin; and virtually the whole field of organotin chemistry is based upon the use of these materials as precursors[197]. The three basic types of organotin halide are R$_3$SnX, R$_2$SnX$_2$ and RSnX$_3$ and each class is known for a wide range of organic groups R, and all of the halogens with the sole exception of the type RSnF$_3$.

Many methods of synthesis are available, and all find their use for special cases[18]. The halogenation of tetra-organotins may be carried out by a number of reagents as outlined below, and possibly represents the most extensively used synthesis for the organotin halides.

$$R_4Sn + X_2 \longrightarrow R_3SnX + RX$$
$$R_3SnX + X_2 \longrightarrow R_2SnX_2 + RX$$
$$R_4Sn + HX \longrightarrow R_3SnX + RH$$
$$R_3SnX + HX \longrightarrow R_2SnX_2 + RH$$
$$(C_4H_9)_2Sn(CH = CH_2)_2 + AsBr_3 \longrightarrow (C_4H_9)_2SnBr_2 + (CH_2 = CH)_2AsBr$$
$$(C_6H_5)_4Sn + BF_3 \longrightarrow (C_6H_5)_3SnF + C_6H_5BF_2$$
$$R_4Sn + SO_2Cl_2 \longrightarrow R_2SnCl_2 + 2RCl + SO_2$$
Another very widely used synthesis of the organotin halides involves the proportionation reaction between tetra-organotins and tin(IV) halides[198]. In these reactions, illustrated below, it is to be noted that there is conservation of the whole organic content of the reaction as the required organotin halide, in contrast to the losses of organic groups in the above equations.

$$3R_4Sn + SnX_4 \longrightarrow 4R_3SnX$$
$$R_4Sn + SnX_4 \longrightarrow 2R_2SnX_2$$
$$R_4Sn + 3SnX_4 \longrightarrow 4RSnX_3$$
These reactions take place in decreasing order of ease Cl > Br > I, with fluoride little utilized[199].

[199] E. V. van den Berghe and G. P. van der Kelen, *J. Organometallic Chem.* **6** (1966) 522.

The tin–tin bonds in hexa-organoditins and the cyclic di-organotins undergo fission with halogen to form the corresponding halides[19, 200].

$$R_3Sn.SnR_3 + X_2 \longrightarrow 2R_3SnX$$
$$(R_2Sn)_n + nX_2 \longrightarrow nR_2SnX_2$$

The direct alkylation and arylation of tin halides with a variety of reagents is useful in certain cases, but usually leads to a mixture of products[197].

$$SnX_4 + nRMgX \longrightarrow R_nSnX_{4-n} + nMgX_2$$
$$SnX_4 + nRLi \longrightarrow R_nSnX_{4-n} + nLiX$$
$$SnX_2 + R_2Hg \longrightarrow R_2SnX_2 + Hg$$
There have been extensive investigations of the so-called "direct synthesis", from tin

metal and alkyl or aryl halides, and many organotin halides have been successfully synthesized in this way[201–204].

$$Sn + 3CH_3Br \longrightarrow CH_3SnBr_3 + SnBr_2$$
$$2Sn + 3C_6H_5CH_2Cl \longrightarrow (C_6H_5CH_2)_3SnCl + SnCl_2$$
$$Sn + 2RX \xrightarrow{\text{catalyst}} R_2SnX_2$$
In addition to the mononuclear organotin halides described above, there exist a very limited number of organoditin halides and organodistannoxane halides, as mentioned in Table 15.

With the exception of the fluorides, the organotin halides are liquids or low melting solids, and are mostly readily soluble in organic solvents, and are quite volatile.

upon the state of aggregation[205]. In general, however, organotin chlorides, bromides and iodides are unassociated in gas, liquid or crystal form.

In contrast, all of the organotin fluorides have strongly associated polymeric structures.
FIG. 20. (a) The chain structure of $(CH_3)_3SnF$ and (b) the sheet structure of $(CH_3)_2SnF_2$.

Thus, for example, trimethyltin fluoride has the chain structure shown in Fig. 20(a), in which each tin atom is five-coordinate[206].

Dimethyltin difluoride forms a layer structure as shown in Fig. 20 (b), wherein SnF_2 units form a two-dimensional infinite sheet, and the two methyl groups attached to each tin

[205] H. Kriegsmann and S. Pischtschan, *Z. anorg. Chem.* **308** (1961) 212.
[206] H. C. Clark, R. J. O'Brien and J. Trotter, *Proc. Chem. Soc.* (1963) 85; *J. Chem. Soc.* (1964) 2332.

are present above and below the sheet, giving each tin atom a resultant octahedral co-ordination[207]. Such a structure is analogous to SnF_4 in Fig. 19 when terminal fluorine atoms are present instead of methyl groups.

Organotin halides are chemically very reactive, and the halogen may be replaced by a wide variety of other atoms or groups.

Hydrogen replaces halogens, upon treatment with various hydrides[19, 208, 209].

$$4R_{4-n}SnX_n + nLiAlH_4 \longrightarrow 4R_{4-n}SnH_n + nLiX + nAlX_3$$
(R = alkyl and aryl; X = Cl, Br and I; n = 1, 2 and 3)
$$R_nSnCl_{4-n} + R_2AlH \longrightarrow R_nSnH_{4-n} + R_2AlCl$$
(n = 1, 2 and 3)

The halogen of organotin halides is replaceable by a wide variety of metals and metalloids[197, 210].

$$R_3SnCl + Li \longrightarrow R_3SnLi$$
$$(CH_3)_3SnCl + NaMn(CO)_5 \longrightarrow (CH_3)_3SnMn(CO)_5$$

$$(CH_3)_2SnBr_2 + Na \nearrow \underset{\underset{Na}{|}}{(CH_3)_2}Sn.\underset{\underset{Na}{|}}{Sn(CH_3)_2}$$
$$\searrow (CH_3)_2SnNa_2$$

$$(C_6H_5)_3SnCl + Ca \longrightarrow (C_6H_5)_3SnCaSn(C_6H_5)_3$$
$$(C_6H_5)_3SnCl + (C_6H_5)_3MK \longrightarrow (C_6H_5)_3SnM(C_6H_5)_3$$
(M = Si, Ge and Sn)

Similarly a range of non-metals replace halogen[211-213].

$$R_3SnCl + LiNR_2^1 \longrightarrow R_3SnNR_2^1$$
$$R_3SnCl + LiP(C_6H_5)_2 \longrightarrow R_3SnP(C_6H_5)_2$$
$$R_2SnX_2 + R'OH \longrightarrow R_2Sn(OR')_2$$

$$(CH_3)_2SnBr_2 + HSCH_2CH_2SH \longrightarrow \underset{CH_3}{\overset{CH_3}{>}}Sn\underset{S-CH_2}{\overset{S-CH_2}{<}}$$

$$(CH_3)_3SnCl + NaN_3 \longrightarrow (CH_3)_3SnN_3$$

In addition to these reactions involving displacement of halogen, many organotin halides behave as Lewis acids, like the tin(IV) halides themselves. Many different types of coordination complex are known[214].

Although the tetra-organotins are unable to form stable complexes, in which tin has a coordination number greater than four, the introduction of one halogen atom on tin is

[211] G. J. M. van der Kerk, J. G. A. Luijten and M. J. Janssen, *Chimia*. **16** (1962) 10.
[212] E. Wiberg and R. Rieger, German Patent 1,121,050 (1960).
[213] E. W. Abel and D. B. Brady, *J. Chem. Soc.* (1965) 1192.
[214] R. C. Poller, *J. Organometallic Chem.* **3** (1965) 321.

sufficient to produce Lewis acids which can complex with even relatively weak donor bases. Figure 21 (a) shows the stereochemistry of the complex (pyridine) $(CH_3)_3SnCl$[215, 216].

In addition to neutral ligands, the tri-organotin halides will take up halide ion[217] to form the complex ions $R_3SnX_2^-$; the trigonal bipyramidal structure of $(CH_3)_3SnBr_2^-$ is illustrated in Fig. 21 (b).

The Lewis acidity of the organotin halides increases considerably with higher halogen content, and the difference between their dipole moments in dioxane and hexane has been

FIG. 21. Structures of (a) pyridine$(CH_3)_3SnCl$, and (b) the $(CH_3)_3SnBr_2^-$ cation.

used as a measure of complex forming ability to obtain the following series of descending Lewis acidity, $SnCl_4 > C_6H_5SnCl_3 > (C_4H_9)_2SnCl_2 > (C_6H_5)_2SnCl_2 > (C_6H_5)_3SnCl > (C_4H_9)_3SnCl$[218]. Thus the halides R_2SnX_2 react with many bases to form very stable 2:1 complexes, which contain octahedral six-coordinate tin. Examples of this type of complex are (pyridine)$_2(C_2H_5)_2SnCl_2$; a,a'-dipyridyl $(CH_3)_2SnCl_2$ and 1,10-orthophenanthroline R_2SnX_2.

The di-organotin dihalides coordinate with one or two halide ions[219] to give respectively trigonal bipyramidal ions such as $(CH_3)_2SnF_3^-$ or octahedral di-anions[220] like $(C_2H_5)_2SnCl_2^-$ and $(CH_3)_2SnBr_4^{2-}$.

Tin(IV) Oxyhalides

A variety of tin oxyhalide stoichiometries have been reported by heating partly hydrolysed tin halides, but all of these materials are rather ill defined[221-223].

The compounds of formula $SnOX_2$ (X = F, Cl, Br and I), however, are analytically well characterized, though of unknown structure to date.

$SnOF_2$ is prepared as outlined in the scheme below, and is reported to be polymeric, and to contain six-coordinate tin[224].

$$SnCl_4 \xrightarrow{ClF} SnF_2Cl_2 \xrightarrow{ClONO_2} F_2Sn(ONO_2)_2 \xrightarrow{heat} F_2SnO$$

SnOCl$_2$ is made directly by the action of Cl$_2$O upon tin(IV) chloride.

$$Cl_2O + SnCl_4 \longrightarrow SnOCl_2 + 2Cl_2$$

It is an isomorphous white powder, and a cryoscopic molecular weight determination suggests the trimeric formulation (SnOCl$_2$)$_3$, possibly as a cyclic stannoxane[225].

The passage of Cl$_2$O or ozone into molten tin(IV) bromide produces SnOBr$_2$ as a solid amorphous to X-rays[226]. Similarly, the iodide SnOI$_2$ is made from tin(IV) iodide and ozone; and from spectroscopic evidence it is believed to consist of discrete SnOI$_2$ molecules[227].

The oxyhalides were originally reported to form co-ordination compounds such as SnOI$_2$ pyridine, with a variety of bases. A careful re-investigation of the pyridine.SnOCl$_2$ system, however, has revealed that the complexes formed are those of tin(IV) chloride, with a stoichiometric quantity of tin(IV) oxide present[228].

$$2SnOCl_2 + 2 \text{ pyridine} \overset{\times \longrightarrow 2 \text{ (SnOCl}_2\cdot\text{pyridine)}}{\underset{\longrightarrow \text{(pyridine)}_2SnCl_4 + SnO_2}{\Big\langle}}$$

It would appear therefore that the tin(IV) oxyhalides undergo disproportionation to tin(IV) halide and tin(IV) oxide in the presence of base.

2.11. PSEUDOHALOGEN COMPOUNDS

Few simple tin pseudohalides are known, but there is an extensive chemistry of organotin pseudohalides[229], in which the synthesis and properties of the tin–pseudohalogen bonds have been studied.

Cyanides

The only cyanides of tin are the organometallic cyanides of tin(IV), which have a number of available syntheses[229].

$$(C_6H_5)_3SnOH + HCN \longrightarrow (C_6H_5)_3SnCN$$
$$(C_2H_5)_3SnOSn(C_2H_5)_3 + HCN \longrightarrow (C_2H_5)_3SnCN$$
$$R_2Sn[N(C_2H_5)_2]_2 + HCN \longrightarrow R_2Sn(CN)_2$$
$$(CH_3)_3SnI + AgCN \longrightarrow (CH_3)_3SnCN$$
$$(C_4H_9)_3SnCl + KCN \longrightarrow (C_4H_9)_3SnCN$$
Trimethyltin cyanide has a remarkable structure in which disordered CN groups are symmetrically disposed on either side of planar (CH$_3$)$_3$Sn groups to produce polymeric chains containing trigonal bipyramidal five-coordinate tin.

Thus in the solid, the structure is intermediate between the cyanide and isocyanide forms, with Sn–C and Sn–N distances equal. The C–N bond is short (1·09 Å) indicating an

[225] K. Dehnicke, *Z. anorg. Chem.* **308** (1961) 72.
[226] K. Dehnicke, *Chem. Ber.* **98** (1965) 290.
[227] K. Dehnicke, *Z. anorg. Chem.* **338** (1965) 279.
[228] I. R. Beattie and V. Fawcett, *J. Chem. Soc.* (*A*) (1967) 1583.
[229] J. S. Thayer and R. West, *Advances in Organometallic Chemistry*, **5** (1967) 169.

essentially ionic group (cf. CN in NaCN = 1·05 Å), compared to the covalent cyanides where C–N is about 1·16 Å[230].

The melting or disolution of $(CH_3)_3SnCN$ breaks up the polymeric structure, but there is no firm evidence whether the tin–carbon bonds remain intact to form $(CH_3)_3SnCN$, or whether they break to form the isocyanide $(CH_3)_3SnNC$. The formation of $(C_4H_9)_3SnNCS$ from tributyltin cyanide is taken as evidence for the isocyanide formulation, but this is not conclusive. Also iron pentacarbonyl suffers the displacement of a carbon monoxide group by trimethyltin cyanide, to give the substituted carbonyl $(CH_3)_3SnNC.Fe(CO)_4$, which is believed to be the isocyanide complex[231].

Azides

Tin(IV) azide is unknown, but from the interaction of tin tetrachloride and sodium azide, the hexa-azidostannate may be isolated[232].

$$NaN_3 + SnCl_4 \longrightarrow Na_2Sn(N_3)_6$$

Organotin azides[229, 233] and an azidochlorotin[234] are also known.

$$R_3SnCl + NaN_3 \longrightarrow R_3SnN_3$$
$$(R = CH_3, C_4H_9 \text{ and } C_6H_5)$$
$$SnCl_4 + ClN_3 \longrightarrow Cl_3SnN_3$$

The organometallic azides largely lack any sensitivity to shock, and are surprisingly thermally stable; thus triphenyltin azide decomposes around 300°C, to tetraphenyltin and nitrogen[235].

The azide group in R_3SnN_3 behaves as a Lewis base to form such complexes as $(C_6H_5)_3SnN_3.BBr_3$ and $(C_6H_5)_3SnN_3.SnCl_4$ [236]. Such complexing is also believed to be
FIG. 22. Trimethyltin azide polymer.

present in the solid azides, R_3SnN_3, where the tin atom is in a bipyramidal five-coordinate environment with azide groups as bridges between planar R_3Sn units. If, however, the azide is severely hindered sterically, such as in the compound $\{C_6H_5C(CH_3)_2CH_2\}_3SnN_3$, it is unassociated[237].

Tributyltin azide and acetylene dicarboxylic acid evolve hydrazine and form

[237] J. S. Thayer, *Organometallic Revs.* **1** (1966) 157.

$(C_4H_9)_3SnOOCC:CCOOSn(C_4H_9)_3$; with the acetylenedicarboxylic ester, however, nitrogen is retained with the formation of triazoles[238].

$$R_3SnN_3 + C_2H_5OOCC:CCOOC_2H_5 \longrightarrow \begin{matrix} C_2H_5OOC=CCOOC_2H_5 \\ / \quad \backslash \\ R_3Sn-N \quad N \\ \backslash \quad // \\ N \end{matrix}$$

Isocyanates

$Si(NCO)_4$ and $Ge(NCO)_4$ are both known compounds[239], but there is no report to date of $Sn(NCO)_4$. There are, however, a number of covalent, volatile organotin(IV) isocyanates of the type R_3SnNCO and $R_2Sn(NCO)_2$[229, 233].

$$\left. \begin{matrix} R_3SnOH \\ R_3SnOSnR_3 \end{matrix} \right\} + CO(NH_2)_2 \longrightarrow R_3SnNCO$$

The infrared spectrum of $(CH_3)_3SnNCO$ has been recorded and fully assigned[240]. The tin isocyanates can be assigned this formulation rather than the cyanate alternative with some confidence from spectroscopic results. No cyanates have been reported, and are presumably unstable with respect to the isocyanates, as in the very unstable organic cyanates. It may, however, be possible to isolate tin cyanates at low temperatures.

The organotin isocyanates are very sensitive to hydrolysis, and many partially hydrolysed isocyanates such as $(C_6H_5)_4Sn_2(NCO)_2(OH)_2$ and $(C_4H_9)_8Sn_4(NCO)_4O_2$ have been isolated.

The triphenyltin fulminate $(C_6H_5)_3SnCNO$ rearranges at 146–148° to the isocyanate $(C_6H_5)_3SnNCO$.

The carbon–nitrogen double bond of these isocyanates undergoes insertion of ammonia, amines, alcohols, etc., in the manner of the organic isocyanates[229, 233].

$$(C_4H_9)_3SnNCO + NH_3 \longrightarrow (C_4H_9)_3SnNH.CO.NH_2$$

Isothiocyanates and Isoselenocyanates

Although $Sn(SCN)_4$ has been briefly mentioned in the literature[241], the known chemistry of isothiocyanatotin(IV) compounds is restricted to organometallic isothiocyanates and complexions. A wide range of syntheses have been used to obtain the organotin(IV) isothiocyanates[229, 233].

$$(C_4H_9)_3SnCl + AgNCS \longrightarrow (C_4H_9)_3SnNCS$$
$$(CH_3)_2SnCl_2 + NaCNS \longrightarrow (CH_3)_2Sn(NCS)_2$$
$$(C_2H_5)_3SnOSn(C_2H_5)_3 + HNCS \longrightarrow (C_2H_5)_3SnNCS$$
$$(CH_3)_3SnNC + S \longrightarrow (CH_3)_3SnNCS$$
$$(C_4H_9)_3SnOSn(C_4H_9)_3 + NH_2CSNH_2 \longrightarrow (C_4H_9)_3SnNCS$$
These compounds are very stable thermally; thus $(C_4H_9)_3SnNCS$ withstands prolonged heating in vacuum at 180° without change.

238 J. G. A. Luijten and G. J. M. van der Kerk, *Rec. Trav. Chim.* **83** (1964) 295.
239 F. A. Miller and G. L. Carson, *Spectrochim. Acta* **17** (1961) 977.
240 J. S. Thayer and D. P. Strommer, *J. Organometallic Chem.* **5** (1966) 383.
241 R. Bock, *Z. anal. Chem.* **133** (1951) 110.

Spectroscopic data points to the isothiocyanate Sn—N=C=S structure[242], despite the very strong tendency for tin to bond to sulphur, and the normally weak tin–nitrogen bond. Similarly, the corresponding selenocyanates are believed to have the SnNCSe sequence of bonding[229].

Certain of the organotin isothiocyanates are sufficiently strong Lewis acids to form complexes, as do the tin(IV) halides. Thus in $(CH_3)_2Sn(NCS)_2(bipy)$, the central tin atom becomes octahedral upon coordination of the 2,2'-bipyridyl. In the same way, the thio-
FIG. 23. Some isothiocyanato anions of tin(IV).

cyanate ion may behave as the Lewis base[243], and complex ions such as $[(CH_3)_3Sn(NCS)]_2{}^-$, $[(CH_3)_2Sn(NCS)_4]^{2-}$ and $[CH_3Sn(NCS)_5]^{2-}$ are known (Fig. 23).

The complex isothiocyanato-fluoride ions $F_{6-n}Sn(NCS)_n$ ($n = 1$, 2 and 3) have been characterized in solution, and cis and trans isomers recognized from ^{19}F nuclear magnetic resonance studies[190], where $n = 2$ and 3 (Fig. 23).

Tin(II) isothiocyanate is best made by controlled crystallization from a solution of tin(II) sulphate and sodium thiocyanate[244]. The white crystalline product is believed to contain predominantly N-bonded isothiocyanate groups, but extensive thiocyanato bridging is also suggested by infrared spectroscopy.

Thermal decomposition of $Sn(NCS)_2$ gives predominantly SnS at about 150°, a mixture, of SnS and SnS_2 at about 200°, and above this temperature predominantly SnS_2[244].

$Sn(NCS)_2$ is hydrolysed by water, and forms weak complexes with dialkyl ethers.

[242] R. A. Cummins and P. Dunn, *Australian J. Chem.* **17** (1964) 411.

[244] B. R. Chamberlain and W. Moser, *J. Chem. Soc.* (*A*) (1969) 354.

From potentiometric studies, the species $Sn(NCS)^+$, $Sn(NCS)_2$ and $Sn(NCS)_3^-$ are shown to be present in aqueous solution[245], and the salts $K_2Sn(NCS)_4.MeOH$, $KSn(SO_4)NCS$, $CsSn(NCS)_3$, $(CH_3)_4NSn(NCS)_3$ and $(C_2H_5)_4NSn(NCS)_3$ have been isolated, but no structural data is available for these compounds[244].

2.12. METAL–METAL BONDS INVOLVING TIN

Alkali Metal Derivatives

These compounds have proved very powerful intermediates in the preparation of a wide range of organotin compounds, and several methods have been investigated for their synthesis. Many of the syntheses are carried out in liquid ammonia[246–248].

$$R_3SnX + 2Na \longrightarrow R_3SnNa + NaX$$
$$R_2SnX_2 + 4Na \longrightarrow R_2SnNa_2 + 2NaX$$
$$R_3SnSnR_3 + 2Na \longrightarrow 2R_3SnNa$$

Organotin alkali derivatives can, however, be prepared in solvents other than liquid ammonia, probably with greatest success in the case of lithium; thus $(C_6H_5)_3SnLi$ and $(CH_3)_3SnLi$ are obtained in about 80% yield from the corresponding halide and lithium in tetrahydrofuran[249]. In addition, the organotin lithiums can be prepared from the diphenyltins[250], or from tin(II) chloride[251].

$$\{(C_6H_5)_2Sn\}_n + C_6H_5Li \longrightarrow (C_6H_5)_3SnLi$$
$$3RLi + SnCl_2 \longrightarrow R_3SnLi + 2LiCl_2$$
Conductivity measurements show triphenyltin sodium and trimethyltin sodium to be strong electrolytes in liquid ammonia[252, 253], but no solid structural information is available. It is possible that these materials have an electron deficient type of bonding in the crystals, similar to the alkali metal alkyls.

The organotin alkali metal compounds are air sensitive, converting to the oxides R_3SnONa, which hydrolyse to the hydroxide R_3SnOH or the oxide $(R_3Sn)_2O$.

The ionization of these compounds in solution may be formulated as $M^+SnR_3^-$, with the R_3Sn^- ion exactly analogous to the organic carbonion. Thus these powerfully nucleophilic ions complement the R_3Sn^+ cations present in solutions of the organotin halides, and where a synthesis is not possible with one, it can normally be accomplished by the other.

One specially interesting synthesis of organotin substituted alcohols involves the insertion of epoxides and other cyclic esters into the tin–alkali bond, and subsequent hydrolysis of the sodium alkoxide formed[254].

$$R_3SnNa + \overline{O.CH_2.CHR} \longrightarrow R_3SnCH_2CH(R)ONa$$

Tin Bonded to Other Non-Transitional Metals

The organotin equivalents of Grignard reagents and the organotin equivalents of magnesium dialkyls are made according to the equations below[255].

$$C_2H_5MgBr + (C_6H_5)_3SnH \longrightarrow (C_6H_5)_3SnMgBr + C_2H_6$$

$$2(C_6H_5)_3SnCl + 2Mg \xrightarrow{\ C_2H_5Br\ } \{(C_6H_5)_3Sn\}Mg$$

A similar displacement of hydrocarbon from complexed alkyls of cadmium and zinc produce metal–metal bonded species of these metals as shown in Fig. 24 (a) and (b)[256].

Tin–boron bonds have been formed by the metathesis of triethyltin lithium with the respective dimethylaminoboron chlorides to give species containing either one or two boron–tin bonds, as illustrated in Fig. 24 (c) and (d)[257].

The chemistry of the compounds containing tin bonded to another Group IV element, other than carbon or tin itself, is extensive. The two most useful synthetic methods have been the elimination of alkali halide, and the displacement of amine[258, 259].

$$R_3SnN(C_2H_5)_2 + (C_6H_5)_3GeH \longrightarrow R_3SnGe(C_6H_5)_3$$

$$(C_6H_5)_3SnLi + (C_6H_5)_3SiCl \longrightarrow (C_6H_5)_3SnSi(C_6H_5)_3$$

Of particular interest are the compounds $\{(C_6H_5)_3M\}_4M'$ such as $\{(C_6H_5)_3Pb\}_4Sn$ and $\{(C_2H_5)_3Sn\}_4Ge$, for which almost all combinations of the Group IV elements are known for carbon to lead[260].

Tin–Tin Bonds

In addition to the tin–tin bonds present in the metallic tins, there exists a good range of molecular species which contain tin–tin bonds. A number of general methods have become apparent for the formation of the tin–tin bonds[261].

The tin equivalent of a Wurtz reaction between organotins and sodium yields the tin–tin bond[262].

$$2R_3SnCl + 2Na \longrightarrow R_3Sn–SnR_3$$

The weak bonds between tin and oxygen and tin and nitrogen gives the opportunity for the displacement of amines[263] and alcohols[264] and even water[265] by tin hydrides, with a concomitant metal–metal bond formation.

$$R_3SnNR_2 + HSnR_3'' \longrightarrow R_3SnSnR_3'' + R_2'NH$$

$$R_3SnOR' + HSnR_3'' \longrightarrow R_3SnSnR_3'' + R'OH$$

$$(R_3Sn)_2O + 2HSnR_3 \longrightarrow 2R_3SnSnR_3 + H_2O$$

Tin hydrides lose hydrogen easily to form tin–tin bonds.

$$2R_3SnH \longrightarrow R_3SnSnR_3 + H_2$$
In addition, the metathetical elimination of alkali halides has proved useful for the non-symmetrical compounds.

$$R_3SnNa + ClSnR_3' \longrightarrow R_3SnSnR_3'$$
By these methods molecules containing up to nine sequential tin–tin bonds have been synthesized[19].

(a)   (b)

(c)   (d)
FIG. 24. Some examples of metal–metal bonded species containing (a) cadmium–tin bonds, (b) zinc–tin bonds, (c) and (d) tin–boron bonds.

Linear and Branched Polytins

Virtually all of the known compounds of this class are organotin derivatives, though a very few examples containing tin–halogen, tin–hydrogen and tin–oxygen bonds are known.

Ditins

A very large number of ditins are known, and have usually been made by one of the general reactions outlined above. The robustness of the tin–tin bond is very dependent upon the other substituent groups, thus hexamethylditin and hexa-ethylditin are both unstable in the presence of air, but hexaphenylditin is unaffected by oxygen in benzene solution[261]. The air oxidation of hexa-ethylditin is proposed to occur through a peroxide $(C_2H_5)_3SnOOSn(C_2H_5)_3$ to the oxide $(C_2H_5)_3SnOSn(C_2H_5)_3$ [266].

266 Yu A. Alexandrov and N. N. Vyshinki, *Tr. Khim. i Khim. Tekhnol.* 4 (1962) 656.

The tin–tin bonds in hexa-arylditins do not undergo dissociation to give free radicals, as do the corresponding hexa-aryls of carbon.

The Raman spectrum of hexamethylditin has been analysed[267] to give a tin–tin stretching force constant of $1 \cdot 0 \pm 0 \cdot 1 \times 10^{-5}$ dynes/cm. Nuclear magnetic resonance spectra of di- and poly-tins have been interpreted to indicate an increasing percentage of s character in the tin–tin bond with increasing chain length of tin atoms[268]. Some of the strong ultraviolet absorptions in the hexa-organoditins are believed to be characteristic of the tin–tin bond[269].

The metal–metal bond in ditins undergoes a range of reactions which can be regarded as either fissions or insertions. In the latter type of reaction the two tin moieties remain in the same molecule.

Organotin halides are the products from the reaction of ditins with both halogen and hydrogen halide[18, 270].

$$R_3SnSnR_3 + X_2 \longrightarrow 2R_3SnX$$
$$R_3SnSnR_3 + 2HX \longrightarrow 2R_3SnX + H_2$$
In both cases reaction quantities and conditions must be carefully controlled in order to avoid fission of the tin–carbon bonds present.

Organic halides cause a number of different types of reaction; thus, for example, trifluoromethyliodide behaves as a halogen[271].

$$(CH_3)_3SnSn(CH_3)_3 + CF_3I \longrightarrow (CH_3)_3SnI + (CH_3)_3SnCF_3$$
Trityl chloride has an analogous behaviour to the reaction of hydrogen chloride above[272].

$$(C_2H_5)_3SnSn(C_2H_5)_3 + 2(C_6H_5)_3CCl \longrightarrow 2(C_2H_5)_3SnCl + (C_6H_5)_3C.C(C_6H_5)_3$$
These dehalogenations at carbon are extended in the action of hexa-ethylditin upon ethylene dibromide, where intramolecular removal of the halogen takes place[273].

$$(C_2H_5)_3SnSn(C_2H_5)_3 + BrCH_2CH_2Br \longrightarrow CH_2:CH_2 + 2(C_2H_5)_3SnBr$$
It is possible that such a dehalogenation reaction may have extensive usage in organic chemistry.

Hexa-organoditins take up sulphur to produce the bis(trialkyl/aryltin) sulphides $R_3SnSSnR_3$.

Organic peroxides[274], peranhydrides[275] and peroxy esters[276] cause the fission of tin–tin bonds to give the corresponding tin–oxygen compounds.

$$R_3SnSnR_3 + (tert\text{-}C_4H_9O)_2 \longrightarrow R_3SnO\text{-}t\text{-}C_4H_9$$
$$R_3SnSnR_3 + (C_6H_5COO)_2 \longrightarrow R_3SnOCOC_6H_5$$
$$R_3SnSnR_3 + C_6H_5COO\text{-}t\text{-}C_4H_9 \longrightarrow R_3SnOCOC_6H_5 + R_3SnO\text{-}t\text{-}C_4H_9$$

Under special circumstances olefins[277] and acetylenes[278] will undergo an insertion type of reaction to the multiple bond by the addition of the two halves of a ditin.

$$CF_2:CF_2 + (CH_3)_3SnSn(CH_3)_3 \longrightarrow (CH_3)_3Sn.CF_2CF_2.Sn(CH_3)_3$$

$$CF_3C \vdots CCF_3 + (CH_3)_3SnSn(CH_3)_3 \longrightarrow$$

Hexachloroditin contains a tin–tin bond, but disproportionates below 0°C to tin(II) and tin(IV) chlorides[101].

Tri-, Tetra-, Penta- and Hexa-Tins

Whilst tin–tin bonds appear to be incapable of existing in the very long chains of the lighter Group IV elements, the ability to catenate is still considerable, and up to six adjacent tin–tin bonds are known, with even more in the cyclic species[19, 261]. The increasing number of tin–tin bonds lowers considerably the stability of many of these compounds, and renders them unstable in the atmosphere. Additional to the linear polytins are some branched species exemplified by {(C6H5)3Sn}4Sn and C6H5Sn{Sn(C2H5)3}3 [279, 280].

$$(C_6H_5)_3SnLi \xrightarrow{SnCl_2} \{(C_6H_5)_3Sn\}Li \xrightarrow{(C_6H_5)_3SnCl} \{(C_6H_5)_3Sn\}_4Sn$$

$$C_6H_5SnH_3 \xrightarrow{3(C_2H_5)_3SnNR_2} C_6H_5Sn\{Sn(C_2H_5)_3\}_3 + 3R_2NH$$
Cyclic Polytins

Four-,[281] five-,[282] six-[282, 283] and nine-membered[284] rings are well characterized in this class.
The synthetic methods[19] for formation of the tin–tin bonds, and the fission reactions of the tin rings largely parallel those for the linear polytins.

$$(C_2H_5)_2SnH_2 + (C_2H_5)_2SnCl_2 \xrightarrow{\text{pyridine}} \{(C_2H_5)Sn_2\}_9$$

(a)   (b)
FIG. 25. (a) Tetra(triphenyltin)tin and (b) phenyltri-(triphenyltin)tin.

Tin–Transitional Metal Bonds

Many transitional metals have now been incorporated into compounds containing tin–transitional metal bonds[210, 285]. The syntheses can be roughly divided into four main classes.

(a) Insertion Reactions
(b) Alkali Halide Metathesis

$$(C_6H_5)_3SnLi + \{(C_6H_5)_3P\}PtCl_2 \longrightarrow (C_6H_5)_3SnPt(Cl)\{P(C_6H_5)_3\}_2$$

(c) Elimination Reactions

$$SnCl_2 + \pi\text{-}C_5H_5Fe(CO)_2HgCl \longrightarrow \pi\text{-}C_5H_5Fe(SnCl_3)(CO)_2 + Hg$$

$$Zr\{N(C_2H_5)_2\}_4 + 4(C_6H_5)_3SnH \longrightarrow Zr\{Sn(C_6H_5)_3\}_4 + 4(C_2H_5)_2NH$$
(d) Oxidative Addition Reactions

$$SnCl_4 + \{(C_6H_5)_3P\}_2Ir(CO)Cl \longrightarrow \{(C_6H_5)_3P\}_2PIr(SnCl_3)(CO)Cl_2$$

$$(C_6H_5)_3SnCl + \{(C_6H_5)_3P\}_4Pt \longrightarrow (C_6H_5)_3SnPtCl\{(C_6H_5)_3P\}_2$$
The number of individual compounds that possess one or more tin–transitional metal bonds is very large, and the table only includes some representative examples.

Covalent metal–metal bonding in these compounds can be inferred from the synthetic

285 N. S. Vyazankin, G. A. Razuvaev and O. A. Kruglaya, *Organometallic Revs.* (*A*), 3 (1968) 323.

methods and from chemical composition. Moreover, X-ray crystallographic studies of a number of compounds have shown directly the presence of the tin–metal bond[286-289].
FIG. 26. Some examples of metal sequences and metal clusters containing tin–transitional metal bonds.

Figure 26 illustrates some of the many metal sequences and metal clusters known to contain tin–transitional metal bonds.

A number of reagents cause fission of the tin–transitional metal bond[290, 291].

$$(CH_3)_3SnCo(CO)_4 + I_2 \longrightarrow (CH_3)_3SnI + Co(CO)_4I$$

$$(CH_3)_3SnMn(CO)_5 + (C_6H_5)_2PCl \longrightarrow (CH_3)_3SnCl + [(C_6H_5)_2PMn(CO)_4]_2 + CO$$

$$(CH_3)_3SnMn(CO)_5 + C_2F_4 \longrightarrow (CH_3)_3SnCF_2CF_2Mn(CO)_4$$

TABLE 16. COMPLEXES CONTAINING DISCRETE TIN–TRANSITIONAL METAL BONDS ARRANGED BY GROUPS

V	Cr	Mn	Fe	Co	
		$(C_6H_5)_3SnMn(CO)_5$ $(C_6H_5)_2Sn\{Mn(CO)_5\}_2$	$\{C_5H_5Fe(CO)_2\}_4Sn$ $(CH_3)_4Sn_3Fe_4(CO)_{16}$	$(C_4H_9)_3SnCo(CO)_4$ $BrSn\{Co(CO)_4\}_3$	$[C_5H_5(CC$
Nb	Mo	Tc	Ru	Rh	
	$(CO)_5MnSn(CH_3)_2Mo(CO)_3C_5H_5$		$(CO)_4Ru\{Sn(C_6H_5)_3\}_2$ $[Ru(SnCl_3)_2(CO)_2Cl_2]^{2-}$	$\{(C_6H_5)_3P\}_2(CO)_2RhSn(CH_3)_3$ $[Rh(SnCl_3)_2(CO)Cl]^{2-}$	
Ta	W	Re	Os	Ir	
	$C_5H_5(CO)_3WSn(CH_3)_3$	$(CH_3)_2Sn\{Re(CO)_5\}_2$ $[\{(CO)_5Re\}_3Sn]_2$		$(C_6H_5)_3P(CO)_3IrSn(C_6H_5)_3$ $[Ir_2Cl_6(SnCl_3)_4]^{4-}$	$\{(C_6H_5)_3P$ $[Pt(SnCl_3)$

In contrast, however, many reactions may be carried out on such molecules, whilst the metal–metal bond remains intact[292, 293].

$$(C_6H_5)_3SnMn(CO)_5 + Cl_2 \longrightarrow Cl_3SnMn(CO)_5 + C_6H_5Cl$$
$$Cl_2Sn\{Co(CO)_4\}_2 + RMgX \longrightarrow R_2Sn\{Co(CO)_4\}_2$$
Some complexes containing platinum–tin bonds function as hydrogenation catalysts[294], and although complexes in which the $SnCl_3^-$ ligand is attached to platinum can be isolated crystalline, in solution some dissociation takes place leaving vacant sites for coordination of olefins and hydrogen. Thus a highly reactive intermediate is produced, reverting to the original complex after hydrogen transfer to the olefin (or acetylene) has occurred. It is believed that the very high *trans*-activating ability of the $SnCl_3^-$ group is important here, and this *trans* effect is thought to originate mainly in the π-acceptor ability of the ligand These same platinum–tin complexes catalyse double bond migration in olefins.

18. LEAD

E. W. ABEL

University of Exeter

1. THE ELEMENT

1.1 HISTORICAL

The very easy extraction of lead from its ores made it one of the few metals used extensively from earliest times[1]. One of the earliest-dated specimens is a lead statue found in the Dardanelles on the site of the ancient city of Abydos. This is believed to date from 3000 B.C.

Lead was in common usage in Ancient Egypt for ornamental objects and solder, and lead salts were used to glaze pottery. The Hanging Gardens of Babylon were floored with sheet lead as a moisture retainer, and the Babylonians and other ancients used lead for caulking and for the fastening of iron bolts and hooks in bridges, houses and other stone buildings.

The most extensive use of lead by the ancients was for the manufacture of water pipes. The Romans produced lead pipes in standard diameters and regular 10-ft lengths. Many such pieces of pipe work have been recovered perfectly preserved in modern times from ruins in Rome and many other Roman sites throughout Europe. Over four centuries, it is estimated, the Roman Empire extracted and used six to eight million tons of lead, with a peak annual production of around sixty thousand tons[2].

1.2. OCCURRENCE AND DISTRIBUTION

The most important ore of lead is galena or lead glance PbS, which is widely distributed throughout the world[1]. Other ore minerals of lead are anglesite ($PbSO_4$), cerussite ($PbCO_3$), pyromorphite ($PbCl_2 . 3Pb_3(PO_4)_2$) and mimetesite ($PbCl_2 . 3Pb_3(AsO_4)_2$). Other lesser minerals are crocoite (or kallochrome, or red-lead ore) ($PbCrO_4$), wulfenite (or molybdenum lead spar, or yellow lead ore) ($PbMoO_4$) and stolzite ($PbWO_4$).

The main sources of lead ores currently worked are in the U.S.A., Australia, Mexico, Canada and the U.S.S.R., but substantial quantities are mined in Peru, Morocco, Yugoslavia, Germany, Spain, South Africa, Italy and Bolivia.

1.3. EXTRACTION

Lead ores are initially crushed and concentrated by flotation, when lighter impurities such as zinc sulphide are removed. At this stage ore concentrates in general contain about

---

[1] *Lead in Modern Industry*, p. 1, Lead Industries Association, New York (1952).
[2] *Nouveau traité de chimie minérale*, Vol. VIII, Part 3, p. 469, ed. P. Pascal, Masson et Cie, Paris (1963).

40% of lead by weight. The ore is roasted in air to convert the sulphide to oxide and sulphate, in which process extensive evolution of sulphur dioxide takes place.

After mixing with limestone and coke the roasted ore is smelted in blast furnaces to yield crude lead. Major impurities are gold, silver, copper, antimony, arsenic and bismuth. At this stage the lead is hard, due to the arsenic and antimony present. The lead is now melted and kept molten at a temperature below the melting point of copper, whereby the copper present crystallizes and can be skimmed out. If air is now blown into the molten lead, arsenic and antimony float out as oxides, and after this process the lead is referred to as soft lead[1].

Gold and silver may be removed from soft lead by the Parkes process. This involves the preferential extraction of silver and gold into added molten zinc, which then rises to the surface of the lead and after solidification can be skimmed off. The final impurity of a little zinc can be removed either by air oxidation, or more recently by evaporation.

This series of processes renders lead one of the purest of commercial metals, and the chemical specification for the purest commercial grade available in bulk requires 99·94% lead with no single impurity greater than 0·0025%, with the exception of bismuth which may be up to 0·05%.

Lead may be further refined electrolytically up to 99·995%, and finally zone refining produces lead better than 99·9999% pure[3].

In the earth's crust lead is estimated to be present as $1·6 \times 10^{-3}$% by weight, and to be in sea water at a concentration of 0·004 g/ton.

1.4. LEAD METAL

Lead has no allotropic modifications, and crystallizes with face-centred cubic structure ($a = 4·9489$ Å), with nearest neighbour lead–lead distance as 3·49 Å[4].

Lead, together with iridium and thallium, forms a group of close-packed metals isolated from the other close-packed metals, in that the interatom distances in iridium, thallium and lead are very large compared with those of neighbouring elements[5].

The outstanding physical properties of pure lead are its high density, softness, malleability, flexibility, low melting point, low strength and low elastic limit. These characteristics, together with its high corrosion resistance, are the basis of most applications of lead metal.

1.5. ISOTOPES

Table 1 illustrates the range of lead isotopes. Only four isotopes occur in nature and these are non-radioactive. Lead isotope analyses form an important tool in the calculation of geological ages in minerals in the region 1–6000 million years, and convenient tables have been prepared for this purpose. Only [204]Pb is known to be completely non-radiogenic. [206]Pb, [207]Pb and [208]Pb can be present (though not necessarily so) in minerals from radioactive decay[6].

1.6. NUCLEAR MAGNETIC RESONANCE

About one-fifth of the atoms in naturally occuring lead are present as ^{207}Pb, which has nuclear spin (I) of $\frac{1}{2}$, which enables nuclear magnetic resonance measurements to be carried out on lead and its compounds. Extremely large chemical shifts up to 16,000 ppm are encountered, which indicate a large paramagnetic contribution to shielding at the lead nucleus. The calculated values for paramagnetic shielding of ^{207}Pb nuclei are in good agreement with those observed experimentally[7]. Some ^{207}Pb chemical shifts are recorded in Table 2.

High resolution proton magnetic resonance spectra have been reported for organoleads and organolead hydrides[8]. In $(CH_3)_3PbH$ the τ value of the hydridic proton is 2·32, and the coupling constant for ^{207}Pb and the hydric proton is large, at 2379 cycles/sec. The τ vaiue of the methyl protons in $(CH_3)_3PbH$ and $(CH_3)_4Pb$ are respectively 9·15 and 9·27.

In tetraethyl lead the observed coupling constant from ^{207}Pb to the methyl protons (125 cycles/sec) is larger than the coupling constant from ^{207}Pb to the methylene protons (41·0 cycles/sec), though notably the two constants are of opposite sign[9].

1.7. ALLOYS

Lead is alloyed with many other metals, and some compositions of these alloys are represented in Table 3.

TABLE 3. REPRESENTATIVE COMPOSITIONS OF SOME LEAD ALLOYS†

Alloy	Pb %	Sn %	Sb %	As %	Cd %	Other %
Battery plate	94		6			
Magnolia metal	90		10			
Type metal	70	10	18			Cu 2
Aluminium solder (U.S.P. 1,333,666)	92				8	
Lead foil	87	12	1			
Marine babbitt	72	21	7			
Solder (plumber's)	67	33				
Solder (soft)	50	50				

† Most of these alloys are reported with considerable variations on these compositions.

1.8. CHEMICAL PROPERTIES OF METALLIC LEAD

Pure lead is bluish-white in colour and has a bright lustre. With air and water vapour the metal forms a thin surface film of oxycarbonate which protects the underlying metal. This film can easily be observed forming when freshly cut metal rapidly loses its lustre. Whilst bulk metal is only superficially oxidized, finely divided lead takes fire if dropped through the air.

The attack of lead by oxygenated water produces lead hydroxy compounds, which can result in lead poisoning by consumption of water carried in lead pipes. If the water contains small amounts of carbonate or silicate, however, attack of pipes becomes negligible.

Ionic radii Pb^{2+} 1·21 Å; Pb^{4+} 0·84 Å

Both in the vapour and in solution in mercury, lead is monatomic.

With a potential of +0·130 V relative to the normal hydrogen electrode, it would be thought that lead should, in general, dissolve in dilute acids. The discharge of hydrogen upon lead does, however, have a very high overpotential. This, together with, in some cases the formation of insoluble coatings, affects profoundly the action of acids upon lead.

Sulphuric acid (unless perfectly anhydrous) does not dissolve lead, due to the insoluble lead sulphate coating. Lead is widely used for handling sulphuric acid, and is unattacked even by concentrated acid below 200°C.

Hydrochloric acid dissolves lead very slowly, but nitric acid dissolves lead rapidly with evolution of oxides of nitrogen and formation of lead nitrate.

Acetic acid rapidly attacks lead in the presence of oxygen.

The solubility of lead in pure water is low[12], and equilibration of lead with air-free water at 24° indicated a solubility of 311×10^{-6} g/litre.

Bulk metal lead in contact with acidic solutions is a fairly good reducing agent, and with alkali it is quite a powerful reductor. A technique similar to that of the familiar Jones reductor with amalgamated zinc is also possible using lead in place of zinc. Although the reducing power of the lead reductor is less than the Jones zinc reductor, there are certain advantages in the selectivity of ions reduced[13].

1.9. INDUSTRIAL AND COMMERCIAL UTILIZATION[1]

World production of lead is about two million tons a year, but because lead is easily refined, and does not normally become contaminated in service, lead and lead-alloy scrap constitute an important factor in the lead market. It is estimated that over 80% of the lead

TABLE 6. STANDARD REDUCTION POTENTIALS OF LEAD HALF REACTIONS
AT 25°, REFERRED TO THE NORMAL HYDROGEN ELECTRODE[14]

Reduction		$E°$ in volts
$Pb^{2+} + 2e^-$	$= Pb$	-0.126
$HPbO_2^- + 2e^- + H_2O$	$= Pb + 3OH^-$	-0.54
$PbCl_2(S) + 2e^-$	$= Pb + 2Cl^-$	-0.268
$PbBr_2(S) + 2e^-$	$= Pb + 2Br^-$	-0.280
$PbI_2(S) + 2e^-$	$= Pb + 2I^-$	-0.365
$PbS(S) + 2e^-$	$= Pb + S^{2-}$	-0.98
$PbSO_4(S) + 2e^-$	$= Pb + SO_4^{2-}$	-0.3563
$Pb^{4+} + 2e^-$	$= Pb^{2+}$	$\sim +1.7$
$PbO_2(S) + 2e^- + 4H^+$	$= Pb^{2+} + 2H_2O$	$+1.455$
$PbO_2(S) + 2e^- + 4H^+ + SO_4^{2-}$	$= PbSO_4(S) + 2H_2O$	$+1.685$
$PbO_2(S) + 2e^- + H_2O$	$= PbO(S, red) + 2OH^-$	$+0.248$

The $PbSO_4$–Pb couple is a common reference electrode whose potential has been determined as a function of temperature from 0° to 60°C. Similarly, data of the other half reactions that are involved in the lead acid storage battery are known accurately over a 0°–60°C temperature range[15].

used to manufacture batteries re-enters the market. The following list gives an approximate indication of some of the major consumers of lead: storage batteries ($\sim 35\%$), tetraethyl lead ($\sim 10\%$), cable covering ($\sim 10\%$), solder ($\sim 10\%$), red lead and litharge ($\sim 5\%$), building lead ($\sim 5\%$), caulking ($\sim 5\%$). Other lead uses are white lead, bearing metal, ammunition, type metal and radiation shields.

1.10. ANALYSIS

No truly specific reagent or test for lead exists. Thus unless the nature of the sample is known in advance, preliminary separations of lead are made. Useful separation procedures are well documented[16].

A number of the persistent lines of lead are suitable for spectrographic analysis by arc or spark spectra[17].

No single gravimetric method, of the great variety used in the determination of lead, is clearly the most satisfactory. The thermal stabilities of a number of the weighed precipitates used have been recorded, and such considerations are clearly important[18].

Among the best-known gravimetric precipitants for lead are sulphate, chromate, molybdate, phosphate, oxalate, anthranilate, oxinate, mercaptobenzothiazolate and phthalate.

[18] C. Duval, *Inorganic Thermogravimetric Analysis*, Elsevier, Amsterdam (1953).

Volumetric methods of lead estimation involving titration with molybdate, chromate, phosphoric acid, ferrocyanide, fluoride and iodide are all available, in addition to the complexometric titrations with reagents such as EDTA.

For the estimation of lead at extremely low concentrations polarographic methods are best utilized. Anodic dissolution polarography can estimate the lead content of 10^{-8} molar lead solutions to a precision of about 5 % [19].

Very small traces of lead in water can be effectively collected by co-precipitation with mercury sulphide. After treatment with peroxide, the collected HgS is ignited and the mercury vaporized away. The residual lead can be tested with sodium rhodizonate. Lead at concentrations of 10^{-8} are detected easily by this method[20]. The method is also applicable to the analysis of reagents for traces of lead contaminant.

The presence of tetra-organolead compounds in fuels is detected by first decolorizing the fuel from added dye with activated charcoal. A drop of fuel is placed on a filter paper and irradiated under an ultraviolet lamp, hence evaporating fuel and decomposing the organo-lead. Lead is then detected by adding a drop of freshly prepared 0·1 % solution of dithizone in chloroform. A deep red spot of lead dithizonate indicates presence of lead, and retention of the green dithizone colour indicates absence of the metal[16].

1.11. TOXICITY

All compounds of lead are toxic, and lead poisoning has been long known and exhaustively studied[21]. Nevertheless, lead poisoning still constitutes one of the most important industrial hazards[22].

Minute quantities of lead are ingested regularly by humans from contaminated food and drink, but such quantities are easily eliminated by normal body processes. Causes of harmful accumulations in this way are now very rare.

Serious lead intoxication is now most frequently encountered by inhalation of vapours or dusts of lead and lead compounds. Thus the processes of spraying or sanding lead paints are extremely hazardous without proper protection. The specified maximum allowable atmospheric pollution is 0·15 mg of lead per cubic metre of air.

Lead poisoning can be cured and recovery is usually 100 %. The most common treatment now is the intravenous injection of the sodium calcium salt of ethylenediaminetetra-acetic acid, which results in an immediate ten- to thirty-fold increase in the urinary excretion of lead. The clinical symptoms of lead poisoning are relieved in this way in a short time.

2. COMPOUNDS

2.1. ORGANOLEAD COMPOUNDS

Tetraethyl-lead, together with tetramethyl-lead and the mixed ethylmethyl-leads, is made on a larger scale commercially than all other organometallic compounds together.

This renders it a fairly cheap chemical at about $0·35 per pound. A quarter of a million tons is used annually in the U.S.A. alone as an antiknock agent in motor fuels[23-26].

Industrially, the tetra-alkyl-leads are normally made by the action of alkylchloride upon sodium–lead alloy[26], or by the electrolysis of alkylmagnesium halides using a sacrificial lead anode, where the anode is attacked by alkyl radicals or anions. On a laboratory scale, however, the action of a Grignard reagent upon lead(II) halide remains the favoured synthesis, especially of the alkyl compounds R_4Pb[27]. In the case of aryl compounds, R_6Pb_2 is formed and has to be treated with halogen to produce R_3PbX, which is then further treated with Grignard to give R_4Pb[24]. Some other methods utilized to form lead(IV)–carbon bonds are outlined below[24].

$$Pb + Li + C_6H_5Br \rightarrow (C_6H_5)_4Pb$$
$$(C_2H_5)_2Zn + PbCl_2 \rightarrow (C_2H_5)_4Pb$$
$$RLi + PbX_2 \rightarrow R_4Pb$$
$$R_3Al + PbX_2 \rightarrow R_4Pb$$

The lead(IV) alkyls and aryls are stable at ordinary temperatures, but release organic free radicals on heating. Subsequent reactions are complex and among the pyrolysis products of tetramethyl-lead are 2-methyl-2-propene, propylene, ethylene, hydrogen, methane and ethane.

The fission of the lead–carbon bond is caused by a number of reagents as outlined below[24].

$$R_4Pb + Na \xrightarrow{NH_3} R_3PbNa$$
$$(CH_3)_4Pb + AgNO_3 \longrightarrow (CH_3)_3PbNO_3$$
$$(C_2H_5)_4Pb + PCl_3 \longrightarrow C_2H_5PCl_2 + (C_2H_5)_2PCl$$
$$R_4Pb + SOCl_2 \longrightarrow R_2PbCl_2 + R_3PbCl$$
TABLE 8. SOME ORGANOLEAD(IV) COMPOUNDS

[27] M. Baudler, in *Handbook of Preparative Inorganic Chemistry*, 2nd ed., Vol. 1, p. 763, ed. G. Brauer, Academic Press, New York.

From various studies the following series of relative ease of cleavage by halogen or halides has been established for organic groups attached to lead: α-naphthyl, p-xylyl, p-tolyl, phenyl, methyl, ethyl, n-propyl, isobutyl, isoamyl, cyclohexyl (least easily cleaved)[24].

The only well-defined examples of lead(II) organometallic compounds are bis(cyclopentadienyl)lead(II) and its ring methyl derivative[28]. In the gas phase[29] this has a bent sandwich structure as shown in Fig. 1 (a). Such a structure is also proposed[30] to account for the solution spectra of $(C_5H_5)_2Pb$, where the two rings are believed bonded to two sp^2 lead hybrid orbitals, and a further sp^2 orbital contains a non-bonding pair of electrons. Such a bonding situation is in accord with the crystal structure of the orthorhombic form shown in Fig. 1 (b).
FIG. 1. The structure of $(C_5H_5)Pb$: (a) in the gas and solution and (b) in the orthorhombic crystal form.

Here each lead atom is attached to two bridging cyclopentadienyl groups and one terminal cyclopentadienyl group[31]. The lead to ring bonds are all at approximately 120°, and the polymer may be considered to arise by the lone pair of electrons on each monomer interacting with a cyclopentadienyl ring of another monomer.

A monoclinic form of $(C_5H_5)_2Pb$ is of unknown structure[31].

2.2. HYDRIDES

Lead hydride is the least well characterized of the Group IVB hydrides. It is formed along with hydrogen, on the electrolysis of dilute sulphuric acid with lead electrodes, and by the dissolution of lead–magnesium alloy in dilute acid[32]. The hydride of lead formed in small quantities is assumed to be PbH_4 (b.p. $\sim -13°C$)[33].

In alkali or weakly acid solutions, lead cathodes disintegrate at high current densities. This is believed due to the formation of the unstable hydride PbH_2 at the cathode, and at

current densities over 10–50 mA/cm² the formation of PbH_2 was believed to be quantitative[34].

A lead hydride has been reported from the bombardment of lead films by hydrogen atoms[35].

Organolead Hydrides

The organohydrides of lead(IV) are not as robust as the corresponding compounds of tin, germanium and silicon, but are nevertheless sufficiently stable for an extensive study of the lead–hydrogen bond to be made.

Trialkyl-lead hydrides and dialkyl-lead dihydrides were made by reducing the corresponding chlorides with lithium aluminium hydride at low temperature ($-78°$)[36, 37, 38].

The exchange reaction between organotin hydrides and organolead salts has also proved a useful synthesis for organolead hydrides[39].

$$(n\text{-}C_4H_9)_3PbX + (C_6H_5)_3SnH \rightarrow (n\text{-}C_4H_9)_3PbH + (C_6H_5)_3SnX$$
Trimethyl-lead hydride (m.p. $\sim -106°$) and triethyl-lead hydride (m.p. $\sim -145°$) were found to decompose to the corresponding tetra-alkyl-lead, lead metal and hydrogen.
FIG. 2. Some reactions of the lead–hydrogen bond in trialkyl-lead hydrides.

[39] H. M. J. C. Creemers, A. J. Leusink, J. G. Noltes and G. J. M. van der Kerk, *Tetrahedron Letters* (1966) 3167.

Evolution of hydrogen begins on warming to about $-30°$ to $-20°$, but even at $0°$ the hydrides are not completely decomposed for several hours.

Some of the reactions of trialkyl-lead hydrides are outlined[40] in Fig. 2.

Very unstable trialkyl-lead borohydrides have been made from organolead alkoxides and diborane at $-78°$.

$$4R_3PbOCH_3 + 3(BH_3)_2 \rightarrow 4R_3PbBH_4 + 2HB(OCH_3)_2$$
These trialkyl-lead borohydrides react with methanol to release trialkyl-lead hydrides, and decompose at about $-30°$ to hexa-alkyldileads[41].

2.3. COMPOUNDS OF NITROGEN, PHOSPHORUS ARSENIC, ANTIMONY AND BISMUTH

Binary Compounds

Lead(II) azide is discussed with the pseudohalides, and lead nitrides are not known.

The phosphides of lead are not well characterized and appear to interconvert easily[42]. PbP_5 was obtained from a liquid ammonia solution of rubidium phosphide and lead nitrate. PbP_5 is spontaneously inflammable in air, and dissociates on heating with loss of phosphorus[43].

The action of phosphine upon alcoholic lead acetate solution produces Pb_3P_2 [44].

Arsine and lead(II) acetate form the very unstable arsenide Pb_3As_2[45].

In addition to these few binary compounds of lead with the Group VB elements, there is a considerable range of mineral compounds which contain lead, and either arsenic, antimony or bismuth, but these are ternary and quaternary materials such as sartorite $PbAs_2S_4$, dufrenoysite $Pb_2As_2S_5$, sperrylite $Pb_4As_2S_7$, sakharovite $PbBiSbS_4$ and semseyite $Pb_9Sb_8S_2$.

Organolead Amines, Phosphines, Arsines and Stibines

In addition to the binary compounds discussed above, there are a few examples of discrete lead–nitrogen[46], lead–phosphorus, lead–arsenic and lead–antimony bonds in various compounds, but they are considerably more rare than the corresponding compounds of tin, germanium and silicon.

Coordination compounds such as the di-ammine of diphenyl-lead dibromide contain discrete lead–nitrogen bonds, but such complexes are very unstable[47]. In the case of the diaryl-lead oxinates, however, the coordinate nitrogen–lead bond is quite stable[48].

The first organolead amine reported[49] was sec-$C_4H_9.NH.Pb(C_2H_5)_3$, prepared from triethyl-lead chloride and sodium sec-butylamide. Other amines of lead include $(CH_3)_3PbN(CH_3)Ge(CH_3)_3$ [50] and $(CH_3)_3PbN[Si(CH_3)_3]_2$ [51].

In addition to these ammines, many organolead sulphonamides, phthalimides and sulphimides contain lead–nitrogen bonds[52,53,54]. The sulphimides, phthalimides and sulphonamides are not hydrolysed by water, in marked contrast to the organolead amines.

The mono-, bi- and tri-lead phosphines exemplified by $(C_6H_5)_3PbP(C_6H_5)_2$ [55], $[(C_6H_5)_3P]_2PC_6H_5$ [56] and $[(C_6H_5)_3Pb]_3P$[57] are all crystalline solids which decompose readily upon warming. They are synthesized by the reaction of organolead halides with the requisite phosphine. The same method, along with the metathetical removal of sodium chloride from the organolead halide and the requisite sodium arsenide or stibnide, is used to prepare the organolead arsines and stibines in Table 9.

2.4. OXYGEN COMPOUNDS

Oxides of Lead

Lead(II) oxide (litharge) is the oxide of lead formed when lead is heated in the air. The industrial preparation involves blowing air into molten lead.

Two crystal forms of lead(II) oxide are known: the yellow orthorhombic form is the stable form above 488°C, and the red tetragonal form is stable at ordinary temperatures[58].

Ultrapure PbO is made by precipitation from lead acetate solution by ammonium hydroxide in polyethylene vessels. In such wet preparations of lead(II) oxide, the yellow orthorhombic form is first produced which undergoes transformation to the red tetragonal PbO. This transformation is particularly sensitive to impurities, and the presence of elements such as silicon, germanium, phosphorus, arsenic, antimony, selenium, tellurium, molybdenum and tungsten in concentrations as low as 10 ppm prevents the transformation. The use of polythene vessels for the preparation of ultrapure red lead(II) oxide is emphasized, because sufficient silica is released from glass vessels to prevent the yellow to red conversion[58, 59].

The so-called "black" lead(II) oxide is merely yellow or red PbO with a thin surface film of elemental lead.

In tetragonal lead(II) oxide[60], each lead atom has four oxygen near neighbours, all lying to one side, and all of the oxygen atoms lie between every other pair of lead layers as in Fig. 3.

The oxygen atoms in rhombohedral PbO have proved impossible to locate by X-ray intensity measurements[61], but their positions were determined by neutron diffraction[62]. The structure consists of a chain in which lead has two nearest oxygen neighbours (Pb–O = 2·21 Å). These chains are loosely bonded into layers by two Pb–O bonds (Pb–O = 2·49 Å).

The layer in rhombohedral PbO is a slightly puckered version of that in tetragonal PbO, where four equal Pb–O bonds (2·30 Å) replace the two short (2·21 Å) and two long (2·49 Å)

Pb–O bonds. This close similarity of structures presumably allows small impurities to stabilize the yellow rhombic form at ordinary temperatures. The two crystal forms can be obtained simultaneously by heating lead carbonate at 400° in a melt of potassium and sodium nitrates, when over a period of one day red prisms of tetragonal PbO and yellow plates of rhombic PbO are formed along with orange needles of Pb_3O_4.
FIG. 3. Tetragonal lead(II) oxide.

Lead(IV) oxide can be obtained in a very pure form by the hydrolysis of lead tetra-acetate[63,64]. In this form it is particularly reactive and useful as an oxidizing agent in organic chemistry. More usually lead(IV) oxide is made by the hypochlorite oxidation of lead(II) acetate solutions[65], or by the action of nitric acid upon Pb_3O_4.

Formed in this way PbO_2 has the rutile structure[65], but another orthorhombic form of PbO_2 is known[66]. This is prepared by the anodic deposition during electrolysis of lead acetate, lead nitrate or sodium plumbite solutions under specific conditions. This so-called α-form of PbO_2 has the niobite (columbite) type of structure, which consists essentially of a hexagonal close-packed assemblage of oxygen atoms in which one-half of the octahedral holes are occupied by Pb^{4+} ions. This gives the Pb^{4+} ion six oxygen nearest neighbours, two at 2·16 Å, two at 2·17 Å and two at 2·22 Å[66].

Lead(IV) oxide is formed in nature as the somewhat rare mineral plattnerite, which is isomorphous with rutile and many other dioxides like SnO_2, MnO_2, ZrO_2 and ThO_2.

Lead (IV) oxide is difficult to obtain in a perfectly anhydrous state, as the temperature for complete drying initiates release of oxygen to form PbO and Pb_3O_4. If carefully heated in a stream of oxygen, however, completely anhydrous lead(IV) oxide can be made.

The action of heat decomposes lead(IV) oxide to oxygen (partial pressure of O_2 reaches one atmosphere at 344°C with a coarse-grained PbO_2) and to Pb and Pb_3O_4. Lead(IV) oxide is a powerful reducing agent but is not a peroxide. Rapid grinding with sulphur or red phosphorus produces inflammation, explaining the use of lead(IV) oxide in matches.

Lead(IV) oxide is an essential constituent of the lead–acid accumulator. A single cell of the battery consists of one electrode of lead sponge and the other of a mesh of lead which is impregnated with lead(IV) oxide. The electrolyte is strong sulphuric acid.

The two electrode reactions are:

$$PbSO_4 + 2e^- \rightarrow Pb + SO_4^{2-} \qquad E_0 = -0.356 \text{ V}$$
$$PbO_2 + SO_4^{2-} + 4H^+ + 2e^- \rightarrow PbSO_4 + H_2O \qquad E_0 = 1.685 \text{ V}$$

Acting in opposition the electrode reactions provide an overall potential of 2.041 V, but the potential delivered by the cell will depend upon temperature, the acid concentration and current flow.
FIG. 4. Structure of Pb_3O_4.

Pb_3O_4 has a structure[67, 68, 69] which consists of chains of $Pb^{IV}O_6$ octahedra joined by opposite edges; the chains are linked by Pb(II) ions coordinated by three oxygen atoms pyramidally as in Fig. 4. Thus Pb_3O_4 can be looked upon as lead(II) plumbate, and nitric acid attacks Pb_3O_4 to, in effect, remove $2PbO$ and leave PbO_2.

The finely divided Pb_3O_4 (minium or red lead) used as a preservative and in paints is usually made by the action of heat upon PbO or $PbCO_3$ in a current of air. A macrocrystalline form is obtained by the slow crystallization of Pb_3O_4 from a mixed solution of $K_2Pb(OH)_4$ and $K_2Pb(OH)_6$ [70], or alternatively from PbO_2 and sodium hydroxide in the presence of water in a steel bomb at about 375° [71].

Pb_3O_4 evolves oxygen on heating, and the oxygen reaches a pressure of about 0.2 atm at about 550°. If, however, dissociation into oxygen and lead(II) oxide is prevented by raising the oxygen pressure over Pb_3O_4, it melts at about 830°.

[71] G. L. Clark, N. C. Schieltz and T. T. Quirke, J. Am. Chem. Soc. 59 (1937) 2305.

Much has been written of oxides of lead, other than Pb_3O_4, which lie between the compositions of PbO and PbO_2.

The differential thermal analysis of the decomposition of PbO_2, together with X-ray analysis, has shown two further oxide phases as illustrated below[72].

$$PbO_2 \xrightarrow[\text{about } 375°]{\text{about } 280°} \alpha\text{-}PbO_x \quad (x \sim 1\cdot66)$$

$$\alpha\text{-}PbO_x \xrightarrow[\text{above } 375°]{} \beta\text{-}PbO_y \quad (y \sim 1\cdot5)$$

$$\beta\text{-}PbO_y \longrightarrow Pb_3O_4$$
A monoclinic structure is proposed for $\alpha\text{-}PbO_{1\cdot66}$, which is probably the Pb_7O_{11} and Pb_5O_8 of earlier workers. $\beta\text{-}PbO_{1\cdot5}$ has an orthorhombic structure, with composition Pb_2O_3.

Hydroxy Compounds

There appears to be only one crystalline lead oxide–hydroxide, which has been formulated as $3PbO \cdot H_2O$ [73]. Comparisons of the X-ray data with the corresponding tin compound suggest that this compound is better written as $Pb_6O_8H_4$, with a structure illustrated in Fig. 5, in which an octahedral Pb_6 cluster is contained in a cube of oxygen atoms, with hydrogen bonds between all oxygen atoms[74].
FIG. 5. Proposed cluster structure of the Pb_6O_8 units in lead oxide–hydroxide. ▨ = Pb; ◎ = O.

$Pb_6O_8H_4$ is obtained either by hydrolysis of lead(II) acetate solutions[75], or from reduced pressure evaporation of solutions of tetragonal PbO in large volumes of carbon dioxide free water[76]. Such a preparation and the proposed structure are in line with the hydroxy-lead(II)

anions $Pb_3(OH)_4^{2+}$ and $Pb_6(OH)_6^{4+}$ which are reported in partially hydrolysed solutions of lead(II) salts. Such ions are likely to contain metal clusters.

When aqueous sodium hydroxide is added to a solution of lead nitrate, two basic nitrates are precipitated with stoichiometries $Pb(NO_3)_2.Pb(OH)_2$ and $Pb(NO_3)_2.5Pb(OH)_2$. Even at pH = 12 (which is considerably past the equivalence point), there is no indication of precipitation of $Pb(OH)_2$ as such[77].

Many other alkali precipitations from solutions of lead(II) salts have various basic salt formulations, and are often well-characterized crystalline materials.

If a current of air is passed through a solution of lead(II) acetate during the addition of sodium hydroxide solution, the carbon dioxide content of the air is sufficient to precipitate all of the lead as hexagonal platelets with the formulation $3PbCO_3.2Pb(OH)_2$[78]. Another better-known basic carbonate of lead $2PbCO_3.Pb(OH)_2$ is formed when lead sulphate or lead chloride is boiled with sodium carbonate solution.

The commercial product "white-lead" is of variable composition, but is essentially the $2PbCO_3.Pb(OH)_2$ mentioned above. It is made by a number of processes, which give different physical characteristics such as particle size, which affect its use as a white paint pigment.

In the Dutch and German "dry" processes lead sheet is exposed to acetic acid vapour and carbon dioxide. Lead acetate, basic lead acetate and finally basic lead carbonate (white lead) appear to be formed sequentially. The so-called French, English and Hebrew "wet" processes involve the formation of a suspension or dough of basic lead acetate by dissolving lead(II) oxide in boiling lead acetate solution. The subsequent passage of carbon dioxide produces the basic lead carbonate. The formation of black lead sulphide in sulphur-containing atmospheres is a drawback in the use of $2PbCO_3.Pb(OH)_2$ as a white pigment.

$2PbCO_3.Pb(OH)_2$ is found as a mineral hydrocerussite (or plumbonacrite) in many parts of the world, and has also been obtained as a corrosion product of lead roofing[79].

The complex formation between Pb^{2+} and OH^- has been studied in perchlorate solutions and the following complex ions are noted[80, 81] to be present in solution before precipitation commences, $Pb(OH)_3^-$, $Pb_4(OH)_4^{4+}$, Pb_2OH^{3+}, $Pb_3(OH)_4^{2+}$, $PbOH^+$, $Pb_6(OH)_8^{4+}$, together with dissolved $Pb(OH)_2$.

The predominant ion present is $Pb_4(OH)_4^{4+}$, which is likely to have a cyclic bridged structure similar to that of $Sn_4(OH)_4^{4+}$.

The so-called metaplumbates $M_2^IPbO_3.3H_2O$ are made by fusing lead(IV) oxide with an excess of potassium hydroxide[82, 83]. These compounds are actually the alkali metal salts of the hexahydroxylead(IV) anion $Pb(OH)_6^{2-}$. The salts contain discrete $Pb(OH)_6^{2-}$ ions analogous to the corresponding $Sn(OH)_6^{2-}$ of tin(IV)[84, 85]. $Na_2Pb(OH)_6$ has also been made by the electrolytic oxidation of alkali hydroxide solutions of Pb(II), and also by the controlled alkali hydrolysis of lead(IV) acetate[86].

Plumbites and Plumbates

As already mentioned in the hydroxide section above, alkaline solutions of lead contain a complex set of lead hydroxo cations; but at low lead concentrations the anion $Pb(OH)_3^-$ is present. This trihydroxyplumbite is also believed present when precipitated amphoteric lead "hydroxide" is dissolved in alkali. No evidence for the $Pb(OH)_4^{2-}$ anion has been found, though solutions of lead "hydroxide" in strong potassium hydroxide solution are often written as $K_2Pb(OH)_4$.

In addition to the hexahydroxyplumbates referred to above in the hydroxide section, there are two other types of plumbate. The alkali metal plumbates have the formulation $M_2^I PbO_3$. These are made by the carefully controlled dehydration of the $M_2^I Pb(OH)_6$ salts of the alkali metals[86, 87]. If the dehydration is not carefully controlled below 110°, however, the $M_2^I Pb(OH)_6$ decomposes with evolution of oxygen as well as water. Alternatively K_2PbO_3 along with $K_2Pb_3O_7$ can be made in a melt of KOH and PbO_2, and they are both isostructural with the corresponding stannates[88].

The metaplumbates of strontium and barium $M^{II}PbO_3$ are made by fusion of strontium or barium nitrates with lead(II) oxides[89]. The oxides of nitrogen released convert the lead(II) to lead(IV). Calcium orthoplumbate Ca_2PbO_4 is formed when calcium nitrate and lead(II) oxide are fused in the stoichiometry $Ca(NO_3)_2 . PbO$. The barium and strontium orthoplumbates are prepared by heating barium or strontium carbonates with lead(II) oxide in the stoichiometry $[MCO_3]_2 . PbO$; the necessary oxidation is caused by the atmosphere[90].

$BaPbO_3$ (density 8·30) has the ideal perovskite structure and $SrPbO_3$ (density 7·79) has a somewhat deformed orthorhombic perovskite structure[91].

Ba_2PbO_4 (density 7·34) is tetragonal with Pb–O distances 2·15 and 2·07 Å and BaO distances 2·66 and 2·88 Å [89].

Neither the metaplumbates nor the orthoplumbates can be regarded as containing discrete PbO_3^{2-} and PbO_4^{4-} ions respectively[90].

Oxy and Hydroxy Halides

The lead oxyhalides Pb_2OCl_2, $Pb_3O_2Cl_2$ and Pb_3OCl_4 occur in nature respectively as matlockite ($PbCl_2 . PbO$), mendipite ($PbCl_2 . 2PbO$) and penfieldite ($2PbCl_2 . PbO$).

Lead oxyfluorides of unknown composition are reported from the passage of fluorine over PbO_2, or steam over PbF_2. An oxyfluoride Pb_2OF_2 is reported to be tetragonal[92].

In addition to the oxychlorides occurring as minerals, the two compounds Pb_2OCl_2 and $Pb_3O_2Cl_2$ can be made in a number of ways, including the action of the requisite amount of alkali upon lead chloride solutions. $Pb_3O_2Cl_2$ melts without decomposition at 693°C, and the heat of formation from $PbCl_2$ and 2PbO is 9·24 kcal/mole[93].

The compositions Pb_2OBr_2, $Pb_3O_2Br_2$ and $Pb_5O_4Br_2$ have been reported for the lead oxybromides, but only Pb_2OI_2 for the oxyiodides[93].

The chlorite, chlorate and perchlorate together with the corresponding bromine and iodine compounds are known with various formulae $Pb_xO_yX_z$, but these are discussed below as oxy-salts, and should not be confused with the lead oxyhalides.

The lead(II) hydroxychloride Pb(OH)Cl occurs as the mineral laurionite, whose structure is closely related to that of lead(II) chloride. In Pb(OH)Cl, lead exhibits nine coordination, with five chlorine atoms (Pb–Cl = 3·23 Å) and one hydroxide group (Pb–OH = 2·67 Å) at the apices of a trigonal prism, and three further hydroxide groups in the equatorial plane beyond the centres of the prism faces[94].

An iodo-laurionite Pb(OH)I is made from a solution of lead acetate and warm lead iodide solution.

The lead(IV) oxychloride $PbOCl_2$ is prepared by the action of Cl_2O on a solution of lead(IV) chloride in carbon tetrachloride. $PbOCl_2$ (d. 5·04 g/cc) is pale violet when completely dry, and appears to be amorphous. It decomposes at 95° to lead(II) chloride and oxygen, and is very hygroscopic, undergoing hydrolysis to lead(IV) oxide and hydrogen chloride[95].

Organolead Oxides, Hydroxides and Alkoxides

The organolead hydroxides $R_2Pb(OH)_2$ and R_3PbOH are prepared by the alkaline hydrolysis of the corresponding halides. The corresponding oxides $R_3PbOPbR_3$ and $(R_2PbO)_n$ are prepared by the action of sodium upon the hydroxides. The oxides are extremely sensitive to water, undergoing rehydrolysis to the corresponding hydroxides[96, 97, 98].

The trialkyl-lead hydroxides and oxides are not easy to obtain completely pure, due to a marked tendency to decompose at room temperature. The triaryl-lead hydroxides, however, are much more stable[99].

The solvated $(CH_3)_2Pb^{2+}$ ion has been studied in aqueous solution, and it is concluded that in the $[(CH_3)_2Pb(H_2O)_n]^{2+}$ complex, the CH_3–Pb–CH_3 skeleton is linear. The equilibria outlined below are for the hydrated $(CH_3)_2Pb^{2+}$ cation under various conditions of acidity[100].

$$(CH_3)_2Pb^{2+} \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} \left[(CH_3)_2Pb \underset{OH}{\overset{OH}{<>}} Pb(CH_3)_2 \right]^{2+}$$

pH < 5   pH 5–8

$$OH^- \downarrow \uparrow H^+$$

$$[(CH_3)_2Pb(OH)_3]^- \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} (CH_3)_2Pb(OH)_2$$

pH > 10   pH 8–10

The ozonization of tetra-ethyl-lead at $-68°$ gives an unidentified product which decomposes at room temperature to produce $(C_2H_5)_3PbOH$, $[(C_2H_5)_2PbO]_n$, $(C_2H_5)_3PbOC_2H_5$ together with acetaldehyde and ethanol[101]. Good yields of the oxides $R_3PbOPbR_3$ are obtained by the action of ozone upon the hexa-organodileads R_3PbPbR_3.

With alcohols some alkyl-leads undergo fission.

$$R_4Pb + R'OH \rightarrow R_3PbOR' + RH$$
The alcohol reactivity falls off steadily from $R'OH = CH_3OH$ to $R'OH = C_4H_9OH$, which is unreactive[102].

The best preparation of organolead alkoxides involves the metathesis between sodium alkoxides and the organolead halides[103].

Trimethyl-lead methoxide $(CH_3)_3PbOCH_3$ is polymeric[104], as shown in Fig. 6. The properties of the lead–oxygen bond in the organolead alkoxides and the organolead oxides
FIG. 6. Polymeric structure of $(CH_3)_3PbOCH_3$ in the crystal.

have been investigated and many reactions of the "insertion" type are known, as illustrated by the equations below.

$$(C_6H_5)_3PbOCH_3 + CS_2 \rightarrow (C_6H_5)_3Pb\text{-}S\text{-}C\text{-}OCH_3$$
$$\overset{\|}{S}$$

$$(C_4H_9)_3PbOCH_3 + Cl_3CCHO \rightarrow (C_4H_9)_3PbO\text{-}CH\text{-}OCH_3$$
$$\overset{|}{CCl_3}$$

$$(C_6H_5)_3PbOPb(C_6H_5)_3 + Cl_3CCHO \rightarrow (C_6H_5)_3PbOCHOPb(C_6H_5)_3$$
$$\overset{|}{CCl_3}$$

$$(C_6H_5)_3PbOCH_3 + C_6H_5NCS \rightarrow (C_6H_5)_3Pb\text{-}S\text{-}C\text{-}O\text{-}CH_3$$
$$\overset{\|}{N\text{-}C_6H_5}$$

$$(C_6H_5)_3PbOCH_3 + (CCl_3)_2CO \rightarrow (C_6H_5)_3PbOCOCH_3 \quad \overset{CCl_3|}{}$$
$$\overset{|}{CCl_3}$$
Many of the complexes of lead such as lead(II) oxinate which are used in lead analyses presumably contain a lead–phenoxide type of linkage, but no structural data are available.

Triphenyl-lead 8-oxyquinolinate is reported to have lead four-coordinate in ethanol but five-coordinate in benzene solution (see Fig. 7 (a) and (b))[105]. In monophenyl-lead

tris(8-oxyquinolinate) only one of the nitrogen atoms can be quaternized by methyl iodide, suggesting the structure in Fig. 7 (c) in which lead is six-coordinate[106].
FIG. 7. (a) Triphenyl-lead 8-oxyquinolinate in ethanol solution. (b) Triphenyl-lead 8-oxyquino-linate in benzene solution. (c) Monophenyltris(8-oxyquinolinate). (ON represents the oxygen and nitrogen coordination points in 8-oxyquinolinate.)

Carboxylates

The best-known carboxylate of lead(II) is lead(II) acetate, $(CH_3COO)_2Pb.3H_2O$ (sugar of lead), made by dissolving lead(II) oxide in acetic acid. The salt is very soluble in water (1 g dissolves in about 1·6 ml of cold water or 0·5 ml of boiling water). Solutions are only partly ionized[107], which accounts for the strong solvent effect of acetates upon lead compounds. (Aqueous solutions of lead(II) acetate freely dissolve lead(II) oxide.)

$$Pb^{2+} + CH_3COO^- \rightarrow CH_3COOPb^+ \qquad K_1 = 145$$
$$Pb^{2+} + 2CH_3COO^- \rightarrow (CH_3COO)_2Pb \qquad K_2 = 810$$
$$Pb^{2+} + 3CH_3COO^- \rightarrow (CH_3COO)_3Pb^- \qquad K_3 = 2950$$
Lead acetate solutions absorb carbon dioxide from the air and precipitate insoluble carbonates.

Many other lead(II) carboxylates are known such as formate, propionate, butyrate, stearate, oxalate, tartrate, etc., many of which find industrial uses as lubricant additives, varnish driers, silk weighing, etc.[108].

[108] The Merck Index, 8th ed., Merck Sharpe and Dohm, Rahaway, New Jersey.

Lead(IV) acetate is best made by the action of glacial acetic acid upon Pb_3O_4. The colourless crystals are very sensitive to moisture, hydrolysing to lead(IV) oxide and acetic acid[109, 110].

It is very extensively used as a selective oxidizing agent in organic chemistry.

Other lead(IV) carboxylates such as propionate, butyrate and stearate are known.

Organolead(IV) carboxylates of general formulae R_3PbO_2CR', $R_2Pb(O_2CR')_2$ and $RPb(O_2CR')_3$ are known. The equations below indicate some of the syntheses available[111-115].

$$R_4Pb + R'COOH \rightarrow R_3PbO_2CR'$$
$$(C_2H_5)_4Pb + (CH_3COO)_4Pb \rightarrow (C_2H_5)_3PbO_2CCH_3$$
$$(C_2H_5)_6Pb_2 + (C_6H_5COO)_2 \rightarrow (C_2H_5)_3PbO_2CC_6H_5$$
$$R_3PbX + R'COOAg \rightarrow R_3PbO_2CR'$$
$$R_3PbOH + R'COOH \rightarrow R_3PbO_2CR'$$
$$R_2PbO + R'COOH \rightarrow R_2Pb(O_2CR')_2$$
$$R_2PbX_2 + R'COOAg \rightarrow R_2Pb(O_2CR')_2$$
$$R_2Pb(O_2CR')_2 + Hg(O_2CR')_2 \rightarrow RPb(O_2CR')_3$$
$$(CH_3COO)_4Pb + R_2Hg \rightarrow RPb(O_2CCH_3)_3$$
$$RPbO_2H + R'COOH \rightarrow RPb(O_2CR')_3$$
Very many organolead carboxylates have been investigated for potential commercial uses. Little structural information is available for these compounds, but the trimethyl-lead carboxylates are believed to be coordination polymers[116, 117] in which planar trimethyl-lead ions are joined by carboxylate groups as in Fig. 8, producing five-coordinate lead.
FIG. 8. Polymeric trimethyl-lead carboxylates.

Organolead peroxides of type R_3PbOOR and $R_3PbOOPbR_3$ exist and are reasonably stable[118, 119], but the peroxycarboxylates R_3PbO_3CR are very unstable and are not well characterized[120].

2.5. LEAD SALTS OF INORGANIC ACIDS

Sulphates, Selenates, Fluorosulphonates and Chlorosulphonates

Lead(II) sulphate is precipitated from lead(II) solutions by sulphate ions, and is one of the popular gravimetric precipitates for lead. Its increased solubility in concentrated sulphuric acid suggests formation of sulphato or bisulphato complexes of lead(II). Lead selenate is precipitated similarly from Pb^{++} and SeO_4^{--} mixing.

Lead(IV) sulphate may be prepared by a number of methods. Concentrated sulphuric acid on either lead(IV) fluoride[121] or lead(IV) acetate[122] produces $Pb(SO_4)_2$; and electrolysis of strong sulphuric acid with lead electrodes gives $Pb(SO_4)_2$ under carefully controlled conditions[123]. $Pb(SO_4)_2$ is stable in dry air, but is hydrolysed to PbO_2 by moisture[123]

If an acid solution of $Pb(SO_4)_2$ is treated with alkali sulphate, salts such as $K_2Pb(SO_4)_3$ are obtained. No structural data are available for these salts, but they are likely to contain the $[Pb^{IV}(SO_4)_3]^{2-}$ anion [124].

Lead(IV) acetate dissolves in concentrated sulphuric acid[125] to form hexa(hydrogen-sulphato)plumbic acid $H_2Pb(HSO_4)_6$, and the ions $[HPb(HSO_4)_6]^-$ and $[Pb(HSO_4)_6]^{2-}$. Lead(IV) acetate is also soluble in selenic, fluorosulphuric and chlorosulphuric acids, giving yellow solutions which may contain $H_2Pb(HSeO_4)_6$, $H_2Pb(FSO_3)_6$ and $H_2Pb(ClSO_3)_6$ respectively.

The organometallic sulphates of lead(IV) are stable crystalline compounds made by the action of sulphuric acid upon the requisite organometallic oxide or hydroxide.

Nitrates

Lead(II) nitrate is normally made by the action of nitric acid upon lead metal or lead(II) oxide. It is freely soluble in water, but contrary to the behaviour of most nitrates, it is incompletely dissociated in solution[126, 127]. The $PbNO_3^+$ cation has a formation constant of 15·1 at infinite dilution at 25°C.

$$Pb^{2+} + NO_3^- \rightarrow PbNO_3^+ \qquad (K = 15\cdot1)$$

The formation constant of the reaction at ionic strength 2·0 is approximately 2·6.

A number of basic nitrates of lead are known, and are discussed in the hydroxy section above.

Efforts to prepare lead(IV) nitrate or hexanitrato complexes of lead(IV) have, to date, been unsuccessful[128]. The organometallic nitrates of lead(IV) are, however, well known and crystalline specimens of such nitrates as $(C_2H_5)_3PbNO_3$, $(CH_3)_3PbNO_3$, $(C_6H_5)_3PbNO_3$, $(C_2H_5)_2Pb(NO_3)_2$, $(C_6H_5)_2Pb(NO_3)_2.2H_2O$ and $(p\text{-}CH_3.C_6H_4)_2Pb(NO_3)_2.3H_2O$ can be prepared by a variety of reactions.

$$(C_6H_5)_4Pb + HNO_3 \rightarrow (C_6H_5)_2Pb(NO_3)_2.2H_2O$$
$$(C_2H_5)_4Pb + HNO_3 \rightarrow (C_2H_5)_2Pb(NO_3)_2$$
$$(C_{12}H_{25})_3PbCl + AgNO_3 \rightarrow (C_{12}H_{25})_3PbNO_3$$
$$(C_6H_5)_4Pb + Cu(NO_3)_2 \rightarrow (C_6H_5)_3PbNO_3$$

[128] K. W. Bagnall, D. Brown and J. G. H. Du Preez, J. Chem. Soc. (1964) 5523.

The Raman spectrum of an aqueous solution of dimethyl-lead dinitrate suggests that the dimethyl-lead cation has undissociated nitrate ion as well as water in its coordination sphere[129].

The action of N_2O_4 on lead tetra-alkyls produces the compounds formulated as $[R_4Pb(NO)_2](NO_3)_2$, in which the octahedral complex ion $[R_4Pb(NO)_2]^{2+}$ is believed present. Although the stoichiometry of this series of compounds is well established, the structural formulation seems very dubious[130].

Oxyhalogen Salts

Lead(II) chlorite, chlorate, bromate, iodate and perchlorate are the known oxyhalogen salts of lead. $Pb(ClO_2)_2$ is made by the action of $Ba(ClO_2)_2$ solution upon lead nitrate solution[131]. The yellow crystals have a pseudotetragonal cell ($a = 4 \cdot 14$ Å, $c/a = 1 \cdot 51$)[132].

Lead(II) chlorite decomposes upon heating to a mixture of lead(II) chloride and lead(II) perchlorate, or alternatively to oxygen and lead(II) chloride depending upon the rate and intensity of heating.

Lead(II) chlorate is obtained as the hydrate $Pb(ClO_3)_2 \cdot H_2O$ from the dissolution of lead carbonate in aqueous chloric acid. The anhydrous chlorate is got by careful heating of the hydrate at 110–150°, but at higher temperatures decomposition to lead(II) chloride, lead(IV) oxide, chlorine and oxygen occurs, and the breakdown can be explosive.

Solutions of lead acetate and potassium bromate precipitate the less soluble lead bromate. It is possible for the double salt $Pb(BrO_3)_2 \cdot Pb(OCOCH_3)_2$ to be formed in this preparation, and this double salt explodes violently at about 165°, or even at room temperature upon percussion. Two fatal accidents have occurred by explosions of $Pb(BrO_3)_2$ due to the double salt impurity present, and lead(II) bromate prepared in this way should be treated with extreme care[133]. An alternative synthesis involves treatment of lead carbonate with bromic acid to form $Pb(BrO_3)_2 \cdot H_2O$ [134].

Lead iodate precipitates as the anhydrous salt from lead(II) solutions and alkali iodate solutions. It is thermally more stable than the chlorate or bromate, and only decomposes at 250–300°.

The variation of the aqueous solubilities of lead(II) chlorate, bromate and iodate are remarkable. 1 ml of water at 18°C will dissolve 4·4 g of $Pb(ClO_3)_2$, $1 \cdot 3 \times 10^{-2}$ g of $Pb(BrO_3)_2$ and $1 \cdot 9 \times 10^{-5}$ g of $Pb(IO_3)_2$.

$Pb(ClO_4)_2 \cdot 3H_2O$ (m.p. 84°) is made by the dissolution of lead carbonate in aqueous perchloric acid[135]. The monohydrate m.p. 153–155° is also known.

Phosphites and Phosphates

The phosphate of lead(IV) formulated as $Pb(H_2PO_4)_4$ was synthesized electrolytically from lead electrodes and strong phosphoric acid[136]. It is formed as white crystals which are stable in the air, and it behaves as a slow but fairly strong oxidizing agent, releasing iodine from potassium iodide.

[135] H. F. Roscoe, *Ann. Chem. Liebigs*, **121** (1862) 356.
[136] K. Elbs and R. Nubling, *Z. Electrochem.* **9** (1903) 776.

The corresponding monoacid phosphate of lead(IV), $Pb(HPO_4)_2$, was made by the action of phosphoric acid upon lead(IV) acetate[137].

Lead(II) hypophosphite $Pb(H_2PO_2)_2$ was prepared by dissolution of lead(II) oxide[138] or lead carbonate[139] in hypophosphorous acid, or alternatively by metathesis between lead(II) nitrate and calcium hypophosphate[140]. It is slightly soluble in cold water to give a feebly acidic solution, but is much more soluble in hot water. On treatment of $Pb(H_2PO_2)_2$ with a strong solution of lead nitrate, it forms the nitrohypophosphite $Pb(H_2PO_2)NO_3$, which behaves as a detonant[140].

The neutral hypophosphite $Pb_2P_2O_6$ has been characterized by its infrared spectrum[141] over the region 4000–650 cm^{-1}.

The phosphite $PbHPO_3$ may be obtained by the metathesis of lead nitrate or lead acetate with alkalic phosphite[142], or alternatively by the partial neutralization of phosphorous acid solution with lead carbonate[143]. When $PbHPO_3$ is dissolved in a warm concentrated solution of phosphorous acid the acid phosphite $Pb(H_2PO_3)_2$ is obtained, and can be isolated as large transparent crystals[142].

Certain basic phosphites formulated as $2PbHPO_3.2PbO.H_2O$, $PbHPO_3.2PbO.\frac{1}{2}H_2O$ and $PbHPO_3.PbO.\frac{1}{2}H_2O$ have also been reported[139, 143, 144], though the stoichiometries may be dubious. In addition, halogenophosphites and nitratophosphite $PbPO_3F$ [145], $PbHPO_3.PbCl_2.H_2O$, $PbHPO_3.2PbBr_2.H_2O$ [146] and $PbHPO_3.Pb(NO_3)_2$ are claimed[142].

Melts of phosphorus(V) oxide and lead(II) oxide containing less than about 65% molar of lead(II) oxide form glasses, and are not discussed with the discrete phosphates of lead outlined below.

Lead(II) metaphosphates formulated as dimetaphosphate $Pb(PO_3)_2$, trimetaphosphate $\frac{1}{2}[Pb_3(PO_3)_6.3H_2O]$, tetrametaphosphate $Pb_2(PO_3)_4$ and hexametaphosphate $Pb_3(PO_3)_6$ have been claimed. Preparations usually involve the action of alkali metaphosphate upon soluble lead(II) salts, but conditions appear to be critical for obtaining the right product[147, 148, 149]. Fusion methods involving lead nitrate and phosphorus(V) oxide have also been used[150].

The three orthophosphates of lead are well characterized, and have been extensively studied.

$PbHPO_4$ exists in nature as the mineral monetite (density 5·66 g/cc), which is monoclinic $(a = 4·66 Å, b = 6·64 Å, c = 5·77 Å, \beta = 83°)$, the unit cell containing two $PbHPO_4$ units[151].

PbHPO$_4$ is only slightly soluble in water, and disproportionates to the phosphate Pb$_3$(PO$_4$)$_2$ and phosphoric acid on boiling in water. PbHPO$_4$ is transformed to the pyrophosphate Pb$_2$P$_2$O$_7$ on heating. The decomposition starts at about 195° and probably proceeds via the tetrametaphosphate of lead.

PbHPO$_4$ may be synthesized from lead nitrate and phosphoric acid in the right conditions[152].

Phosphoric acid dissolves PbHPO$_4$ to form Pb(H$_2$PO$_4$)$_2$ [152]. This lead diacid phosphate is stable in the air but decomposed by water. A number of compounds of the type Pb(HRPO$_4$)$_2$, where R is CH$_3$, C$_2$H$_5$, C$_3$H$_7$, etc., are also known[153].

Lead orthophosphate Pb$_3$(PO$_4$)$_2$ may be prepared in a number of ways. Pb$_3$(PO$_4$)$_2$ is the product of the neutralization of PbHPO$_4$ with ammonia[154], and lead(II) chloride and Na$_2$HPO$_4$ give Pb$_3$(PO$_4$)$_2$ [155]. The solubility of lead orthophosphate in water is 1.35×10^{-4} g/l. at 20°. Pb$_3$(PO$_4$)$_2$ is dimorphic[156] with a transition point at 782°, and it melts at 1104°.

Various apatites of lead are known[156-160] with the general stoichiometry 3[Pb$_3$(PO$_4$)$_2$].PbX$_2$ where X = F, Cl, Br, I and OH. These apatites of lead form a homogeneous crystallographic group in the same way as the better-known apatites of calcium. The chloroapatite 3[Pb$_3$(PO$_4$)$_2$].PbCl$_2$ occurs in nature as the mineral pyromorphite (density 7.01 g/cc, dielectric constant 47.5 at $\lambda = 75$ cm).

A mixed hydroxyapatite of calcium and lead Ca$_5$PB$_5$(PO$_4$)$_6$(OH)$_2$ (density 5.39 g/cc) is hexagonal with $a = 9.62$ Å and $c = 7.08$ Å[161].

Many arsenites and arsenates comparable to the above phosphites and phosphates have been characterized[162].

Carbonates

Lead carbonate PbCO$_3$ occurs in nature as the mineral cerusite. It may be prepared by the action of alkali carbonate upon a solution of lead acetate or nitrate, but the preparation must be kept cold in order to avoid formation of the basic carbonate. Another method of preparation of the neutral carbonate involves shaking a cold solution of sodium carbonate with a suspension of a salt of lead which has a low solubility, but which is not as insoluble as lead carbonate itself[163]. Chloride, bromide and sulphate have been utilized in this context.

PbCO$_3$ as cerusite is orthorhombic and is isomorphous with aragonite CaCO$_3$, strontianite SrCO$_3$ and witherite BaCO$_3$. PbCO$_3$ has a density 6.58 g/cc and a unit cell $a = 5.195$ Å, $b = 8.436$ Å and $c = 6.152$ Å[164].

Lead carbonate appears to undergo slight decomposition on exposure to strong light and is decomposed to carbon dioxide and lead(II) oxide on heating; thus at 184°, for example, it

has a dissociation pressure of 10 mm of mercury[165]. Decomposition starts at about 130° and is complete at about 470° [166].

$PbCO_3$ has a solubility product in pure water of $3 \cdot 3 \times 10^{-14}$, but the solubility is much increased by the presence of carbon dioxide in the water, even in quite small amounts[167].

The halogenocarbonates $PbCl_2 . PbCO_3$ and $PbBr_2 . PbCO_3$ are isomorphous[168, 169], but the corresponding iodide could not be made. The chlorocarbonate $PbCl_2 . PbCO_3$ is present in nature as the mineral phosgenite, and can be made by the action of phosgene upon lead hydroxide or by the action of carbon dioxide upon a solution of lead chloride. Natural and synthetic phosgenite have been shown to have identical crystal structures.

In the thermal decomposition of lead carbonate it is believed that the basic carbonates $PbO . PbCO_3$, $2PbO . PbCO_3$ and $3PbO . 5PbCO_3$ are formed as intermediates[166, 170], but the very well-characterized basic carbonate is the hydroxycarbonate $Pb(OH)_2 . 2PbCO_3$, the mineral hydrocerusite. The basic carbonate $Pb(OH)_2 . 2PbCO_3$ can be made by the action of urea and water upon basic lead acetate. In a sealed tube at 130° the urea is converted to ammonium carbonate, which precipitates $Pb(OH)_2 . 2PbCO_3$ as fine hexagonal crystals[171]. The hydroxycarbonate $3PbCO_3 . 2Pb(OH)_2$ has been characterized by X-ray crystallography, and is made by passing air into an alkaline solution of lead acetate[172].

2.6. CHALCOGEN COMPOUNDS

Sulphides

Lead(II) sulphide crystallizes in a perfect NaCl structure[173] with Pb–S distance 2·97 Å, and is the only binary sulphide of lead. It is found in nature as large regular crystals of galena. It has a grey-blue metallic character and density about 7·6. It is best synthesized in a crystalline form by the action of thiourea upon sodium plumbite solution[174].

PbS is a p-type semiconductor when sulphur rich and an n-type semiconductor when lead rich. A conductivity of $1 \cdot 3 \times 10^{-4} \Omega^{-1}$ cm^{-1} is found for stoichiometric PbS [175]. Crystalline PbS is a remarkable radio detector, and was widely used in early crystal radio receivers.

Lead sulphide sublimes unchanged[176] and has a vapour pressure of about 20 mm of mercury at 1000°C, and boils at about 1200°C. It is exceedingly insoluble in water (solubility product about 8×10^{-28} at 25°C)[177], but it is attacked by strong acids.

Very many organolead compounds containing covalent lead–sulphur bonds are known

with general formulae R_3PbSR', $R_2Pb(SR')_2$, $R_3PbSPbR_3$, etc., in which lead(IV) is present. Some synthetic routes to these types are outlined below[178].

$$(C_2H_5)_3PbOH + (NH_2)_2CS \rightarrow (C_2H_5)_3PbSPb(C_2H_5)_3$$
$$R_3PbOH + R'SH \rightarrow R_3PbSR'$$
$$(C_2H_5)_4Pb + S \rightarrow (C_2H_5)_3PbSPb(C_2H_5)_3$$
$$(C_6H_5)_3PbSLi + (C_6H_5)_3SnCl \rightarrow (C_6H_5)_3PbSSn(C_6H_5)_3$$
In addition to these linear compounds, the heterocyclic ring $(C_6H_5)_2\overline{PbSCH_2CH_2S}$ contains lead–sulphur bonds.

All these sulphur derivatives of lead(IV) are considerably less stable than the corresponding compounds of tin, germanium and silicon[178].

Lead, however, is unique in Group IVB in forming stable lead(II) thiolates. These are formed instantly as yellow crystalline precipitates by the direct action of thiols upon solutions of lead(II) salts. These lead mercaptides form yellow crystals with sharp melting points which are soluble in many organic solvents[179]. Whilst no structural data are available, these compounds appear to be covalent thiolates of lead(II).

Lead(II) mercaptides have been widely used as intermediates.

$$(CH_3S)_2Pb + CH_3COCl \rightarrow CH_3COSCH_3$$
$$(RS)_2Pb + BrCH_2CH_2COONa \rightarrow RSCH_2CH_2COONa$$

They are oxidized in the air or by iodine to produce the corresponding disulphides, but nitric acid produces the corresponding sulphonic acid.

$$(RS)_2Pb + O \rightarrow R_2S_2 + PbO$$
$$(RS)_2Pb + I_2 \rightarrow R_2S_2 + PbI_2$$
At about 200° the lead(II) mercaptides disproportionate to the organic sulphide and lead sulphide[179].

$$(RS)_2Pb \rightarrow R_2S + PbS$$
Selenides

Thermal and X-ray analysis, and other physical methods have shown that PbSe is the only compound formed in the lead–selenium system[180]. PbSe is a lead-grey compound, m.p. 1065°, with a cubic NaCl lattice ($a = 6.12$ to 6.15 Å from various determinations). PbSe occurs in nature as the mineral clausthalite, which is isomorphous with galena. Lead selenide is synthesized by the interaction of stoichiometric quantities of the elements at 1200–1250°, with subsequent annealing in argon at 800° [181]. It can also be made by the action of hydrogen selenide upon lead salts, but some free selenium is liberated during the reaction. Lead selenide is precipitated from a solution of lead acetate and selenourea in the presence of hydrazine. Purification of PbSe can be carried out by vacuum distillation at 10^{-6} mm Hg, or alternatively by zone refining. When PbSe crystals are grown from a melt containing a small excess of selenium or lead, the semiconductor (5×10^{-2} to 5×10^{-3} ohm cm) single crystals will have respectively hole or electron conductivity[180].

Films of lead selenide up to 1000 Å thick are completely oxidized to $PbSeO_3$ in air at 350° after 10 min; bulk samples oxidize more slowly. The photoconductivity of lead selenide is sensitive to the content of oxygen and other elements in the deposited film[180]. Photosensitivity is in the range 3–10 μ, and increases with reduction of temperature[182].

Few organic lead–selenium compounds are known, but organolead selenolates such as $(CH_3)_3PbSeR$ are known, as also are examples of the hexa-aryldilead selenides $(R_3Pb)_2Se$ [178]. The lithium salts $(C_6H_5)_3PbSeLi$ are formed in an interesting manner by the direct attack of selenium upon the lithium triaryl-lead.

$$(C_6H_5)_3PbLi + Se \rightarrow (C_6H_5)_3PbSeLi$$
Tellurides

PbTe is the sole telluride of lead and occurs in nature as the mineral altaite. It may be synthesized by high-temperature reaction of stoichiometric quantities of the elements, or by the action of tellurium powder on a boiling solution of lead salt.

PbTe melts at 860°. It behaves as a semiconductor of the n- and p-types depending upon which component is present in slight excess. PbTe displays photoconductivity at low temperatures[183].

The mixed telluride $Pb_xSn_{1-x}Te$ shows potential as a tuneable long-wavelength laser under variable temperature and pressure[184].

Organolead tellurides are very rare and appear to be currently restricted to $[(C_6H_5)_3Pb]_2Te$ (m.p. 129°) and its lithium salt $(C_6H_5)_3PbTeLi$ [178].

2.7. HALOGENO COMPOUNDS

Lead(II) Halides

Lead(II) fluoride is obtained as a white crystalline powder by dissolving lead carbonate in hydrofluoric acid and decomposing the hydrofluoride formed by rapid melting. Alternatively it is prepared from lead metal and anhydrous hydrofluoric acid at 160° under autogenous pressure.

Lead(II) fluoride is dimorphic, the low-temperature rhombic PbF_2 form having the $PbCl_2$ structure and the high-temperature (above 316°C) form having the cubic fluorite structure[185].

Lead(II) chloride, bromide and iodide are all prepared by addition of the requisite halide to solutions of lead(II) ion. Lead(II) chloride and bromide are white like the fluoride, and lead(II) iodide forms bright yellow very characteristic hexagonal plates. The solubilities of the lead(II) halides in water increase markedly on heating.

In crystalline $PbCl_2$ and $PbBr_2$ each lead atom is coordinated by nine halide ions, six of which lie at the apices of a trigonal prism, with the remaining three beyond the centres of the three prism faces. PbI_2 has the CdI_2 layer structure[186].

Electron diffraction measurements of the vapours of $PbCl_2$, $PbBr_2$ and PbI_2 show them as angular molecules, with bond lengths shown in Table 7. Some doubt, however, has been cast upon the existence of PbX_2 molecules in the vapour state[187].

Freezing point curves and conductimetric studies of mixtures of lead(II) halides show the existence of a variety of mixed halides such as PbFCl, PbFBr, PbFI, $PbCl_2.4PbF_2$ and $PbBr_2.4PbF_2$.

Lead(II) chlorofluoride is sparingly soluble in water, and is the precipitate deposited when a lead salt is added to a solution containing both fluoride and chloride ions. This precipitation of PbFCl is the basis of an important analytical method for the determination of fluoride. PbBrF is also only very sparingly soluble in water.

PbFCl and PbFBr have a tetragonal complex layer structure.

Lead(IV) Halides

Only lead(IV) fluoride and chloride are known. The non-existence of lead(IV) bromide and iodide can be put down to the reducing power of Br^- and I^- or, stated alternatively, the inability of bromine and iodine to oxidize lead(II).

Lead(IV) fluoride is obtained by the direct fluorination of lead(II) fluoride at about 300° [188]. It is formed as white needles which are very sensitive to moisture, immediately decolorizing due to the formation of brown PbO_2. PbF_4 has a tetragonal cell ($a = 4\cdot24$ Å and $c = 8\cdot03$ Å).

Lead(IV) chloride is a clear yellow highly refracting liquid which fumes in moist air, and under certain circumstances decomposes explosively to lead(II) chloride and chlorine. It is best prepared by the action of concentrated sulphuric acid upon pyridinium hexachloroplumbate, and stored under pure concentrated sulphuric acid at $-80°$ in the dark[189].

Coordination Complexes of Lead Halides

An early report indicates[190] the following coordination complexes of lead(IV) chloride: $PbCl_4(NH_3)_2$; $PbCl_4(NH_3)_4$; $PbCl_4(CH_3NH_2)_4$; $PbCl_4(C_2H_5NH_2)_4$; $PbCl_4(C_3H_7NH_2)_4$; $PbCl_4(C_6H_5NH_2)_3$; $PbCl_4(C_5H_5N)_2$.

No structural information is available upon these complexes, but the L_2PbCl_4 types are likely to contain six-coordinate octahedral lead, and the L_4PbCl_4 types may contain eight-coordinate lead[191].

The complex bis(thiourea) $PbCl_2$ is of some interest as a coordination complex of lead(II) chloride. Each lead atom is in a distorted trigonal prism environment of four sulphur atoms (Pb–S = $3\cdot02$ Å) and two chlorine atoms (Pb–Cl = $2\cdot75$ Å). Lead may, however, be regarded as seven-coordinate rather than six-coordinate, as each lead atom also has a chlorine near the centre of a lateral face of the trigonal prism (Pb–Cl = $3\cdot22$ Å)[192].

Halogenolead(II) Ions

Solutions of lead(II) halides contain the PbX^+ ion in addition to the Pb^{2+} and X^- ions. The thermodynamics of these ion dissociations have been investigated by conductimetric methods[193].

$$Pb^{2+} + X^- \rightarrow PbX^+$$
X	ΔG at 25° kcal/mole	ΔH kcal/mole	ΔS cal/deg/mole
Cl	$-2\cdot18$	$4\cdot38$	$22\cdot0$
Br	$-2\cdot02$	$2\cdot88$	$18\cdot4$

193 G. H. Nancollas, *J. Chem. Soc.* (1955) 1458.

Alkali fluorides and lead(II) fluoride form alkali fluoroplumbites. In the case of potassium the compound formed is K_4PbF_6, but in the cases of rubidium and caesium the compounds have stoichiometry $MPbF_3$ with perowskite structures[194].

The solubilities of lead(II) chloride, bromide and iodide decrease at first in the presence of halide ion, due to the common ion effect, but with further halide ions the solubility rapidly increases with the formations of complex ions.

From aqueous crystallizations and phase studies on mixed salt systems, a quite remarkable number of solid state stoichiometries have been obtained for the halogenoplumbites. Representative of these are KPb_2Cl_5, K_2PbCl_4, $CsPbCl_3$, $RbPbCl_3$, $KPbBr_3$, $KPbI_3$, Cs_4PbCl_6, K_4PbF_6, K_4PbCl_6 and K_4PbBr_6.

Spectroscopic measurements on $PbCl_2$–Cl^- solutions do not permit positive identification of $PbCl_3^-$ and $PbCl_4^{2-}$, but the limiting spectrum of $PbCl_2$ in 11 M hydrochloric acid is believed due to $PbCl_6^{4-}$ in solution[195].

It is likely that the PbX_3^- ions are pyramidal like the corresponding SnX_3^- ions. The pale yellow $KPbI_3.2H_2O$ is particularly well known, and is formed when warm aqueous solutions of lead nitrate and potassium iodide are mixed. The complex is somewhat weak, and renewed heating causes dissociation to potassium iodide and lead(II) iodide. Anhydrous white $KPbI_3$ is formed by storing the dihydrate over concentrated sulphuric acid, or by dissolving $KPbI_3.2H_2O$ in acetone (in which it is quite soluble), and precipitating with ether.

Anhydrous $KPbI_3$ is curious, in that when reattacked by water it immediately forms bright yellow lead(II) iodide rather than $KPbI_3.2H_2O$. This reaction is used for the detection of traces of water in gases or organic solvents. The stabilities of the halide complexes of lead[193,196] are in the order $I^- > Br^- > Cl^- \gg F^-$; no fluoride complexes are detectable in solution. It is believed that chlorine, bromine and iodine utilize d-orbitals for partial double bonding to lead in these complex ions[197].

In the salt $NH_4Pb_2Br_5$ the lead atom has two nearest bromine neighbours at 2·98 Å, two bromines at 3·16 Å and four bromines at 3·35 Å. It would appear to consist of discrete NH_4^+ and Br^- ions along with $PbBr_2$ molecules. The Br–Pb–Br angle in the $PbBr_2$ units is ~85·5°, and the Pb–Br bond length at 2·98 Å is about half-way between covalent and ionic distances for Pb–Br[198].

The salts K_4PbF_6, K_4PbCl_6 and K_4PbBr_6 are remarkable in having PbX_6^{4-} octahedral anions[199].

Halogenolead(IV) Ions

The hexafluoroplumbates M_2PbF_6 are prepared either by dissolution of alkali plumbate in hydrofluoric acid, or by neutralizing an alkali metal carbonate with a solution of PbF_4 in hydrofluoric acid.

The salt K_3HPbF_8 has been prepared in a number of ways, such as adding lead tetraacetate to a solution of potassium fluoride in hydrofluoric acid, or by dissolving a fusion of lead(IV) oxide and alkali in hydrofluoric acid. The well-defined crystals are made up of K^+, HF_2^- and PbF_6^- ions[200].

200 M. F. A. Dove, J. Chem. Soc. (1959) 3722.

The alkaline earth salts $MPbF_6$ present an interesting series of structural changes. $CaPbF_6$ contains no discrete complex ions, but consists of a superstructure of the ReO_3 type[201]. $SrPbF_6$ contains linear polymeric complex ions of the type $(PbF_5)_n^{n-1}$ along with F^- ions, and $BaPbF_6$ has discrete PbF_6^{2-} ions. The alkaline earth fluoroplumbates were made by the direct fluorination of the plumbates $MPbO_3$.

The hexachloroplumbate salts M_2PbCl_6 represent a convenient and stable source of lead(IV). A solution of H_2PbCl_6 is easily produced by the action of chlorine upon a fine suspension of lead(II) chloride in concentrated hydrochloric acid. Subsequent addition of solutions of either ammonium or potassium chloride produces the corresponding M_2PbCl_6 salt as lemon yellow crystals. The alkali hexachloroplumbates are isomorphous with the hexachlorostannates.

Organolead Halides

Compared with the other Group IVB organometallic halides, knowledge of organolead halides is somewhat sparse[24, 25, 26, 202]. The types R_3PbX and R_2PbX_2 are well characterized, but compounds of formula $RPbX_3$ are practically unknown.

The usual method for the preparation of organolead halides is by the action of hydrogen halides upon tetra-organoleads. Initial reaction involves fission of one carbon–lead bond, with loss of a further alkyl/aryl group under more vigorous conditions.

$$R_4Pb + HX \rightarrow R_3PbX + RH$$
$$R_3PbX + HX \rightarrow R_2PbX_2 + RH$$
The trialkyl- and triaryl-lead halides R_3PbX in which X is chlorine, bromine, or iodine have all been prepared in this way at low temperature in a solvent. At higher temperatures the principal product is the di-alkyl- or di-aryl-lead halide.

Halogenation by metal and other halides, and by the halogens themselves, has proved to be useful synthetic routes from the tetra-organoleads to the organolead halides in various special cases[203, 204].

$$(C_6H_5)_4Pb + 2AlCl_3 \rightarrow (C_6H_5)_2PbCl_2 + 2C_6H_5AlCl_2$$
$$R_4Pb + SOCl_2 \rightarrow R_3PbCl + RSOCl \qquad (R = alkyl)$$
$$Ar_4Pb + SOCl_2 \rightarrow Ar_2PbCl_2 + Ar_2SO$$
Although at first appearing an unattractive route, the fission by halogens of the lead–lead bond in hexa-alkyl-dileads is in fact an economic route to the trialkyl-lead halides[202]. This is a result of the formation of the hexa-alkyl dileads as cheap by-products of the commercial synthesis of the antiknock tetra-alkyl-leads.

$$R_3Pb.PbR_3 + X_2 \rightarrow 2R_3PbX \qquad (R = alkyl, X = Cl, Br and I)$$

The attractive proportionation reaction between tetra-organotins and tin(IV) tetrahalides for the preparation of organotin halides is of little use in organolead chemistry, as the low thermal stability of organolead halides and the lead(IV) halides does not allow the temperature range of these proportionations to be reached, except in a few special cases[205].

[201] R. Hoppe and K. Blinne, *Z. anorg. Chem.* **293** (1958) 251.
[202] I. Ruidisch, H. Schmidbauer and H. Schumann, *Halogen Chemistry*, Vol. 2, p. 269, ed. V. Gutmann, Academic Press (1967).
[203] M. Geilen, J. Nasielski, J. E. Dubois and P. Fresnet, *Bull. Soc. Chim. Belg.* **73** (1964) 293.
[204] R. Gelius, *Z. anorg. Chem.* **334** (1964) 72.
[205] P. R. Austin, *J. Am. Chem. Soc.* **54** (1932) 3287.

One of the more important synthetic methods for the preparation of the organometallic halides of silicon, germanium, and tin is the "direct" reaction between organic halide and metal. All efforts to use this approach for the preparation of the organolead halides have been entirely unsuccessful.

Table 10 contains examples of some representative organolead halides. The fluorides are best prepared by the action of alkali fluorides upon organolead halides, or hydrogen fluoride upon alkyl-lead hydroxides[206].

$$(C_6H_5)_3PbBr + KF \rightarrow (C_6H_5)_3PbF + KBr$$
$$(CH_3)_3PbOH + HF \rightarrow (CH_3)_3PbF + H_2O$$
The sole examples of the halides $RPbX_3$ reported to date are obtained by partial alkylation of $CsPbCl_3$ with alkyl halide[207].

TABLE 10. SOME REPRESENTATIVE ORGANOLEAD HALIDES

Compound	M.p., °C	Compound	M.p., °C
$(CH_3)_3PbF$	305 decomp.	$(CH_3)_2PbCl_2$	155
$(CH_3)_3PbCl$	190 decomp.	$(C_6H_5)_2PbBr_2$	—
$(CH_3)_3PbBr$	133 decomp.	$(C_6H_5)_2PbI_2$	103
$(C_2H_5)_3PbI$	20	$(C_6H_5)_2(C_2H_5)PbCl$	147
$(CH_2=CH)_3PbCl$	119	$(C_6H_5)_2(CH_3)PbBr$	118

Definitive structural information on the organolead halides is extremely sparse, and structural determinations would be desirable. Most organolead halides have low solubilities in non-polar organic solvents, but dissolve more readily in strongly polar solvating solvents. The fluorides behave as ionic salts, but early suggestions that other organolead halides are also largely ionic have not been borne out. Thus trimethyl-lead chloride and tri-ethyl-lead chloride are non-conducting in tetramethylene sulphoxide[208].

Infrared data on the halides $(CH_3)_3PbX$ suggest a chain-like constitution involving halogen bridges between lead atoms[209].

An X-ray crystal structure determination of diphenyl-lead dichloride showed it to have a linear polymeric structure as shown in Fig. 9. There is an octahedral coordination about each lead atom, and all the chlorine atoms are bridging in character[210].
FIG. 9. Structure of $(C_6H_5)_2PbCl_2$ in the crystal.

[210] V. Busetti, M. Mammi and A. Del Pra, Int. Union of Cryst., 6th Int. Cong. Rome, 1963, Abstract A.73.

The monohalides R_3PbX have an unpleasant smell, and the lower trialkyl-lead halides are extremely sternutatory, and should be handled with care.

The organometallic halides are the starting point of most organometallic syntheses involving lead, and the halogen atom or atoms may be replaced by a great variety of other atoms and groups.

Borohydrides[211] and aluminohydrides[212] react with organolead halides to form the hydrides R_3PbH and R_2PbH_2, but due to the very low thermal stability of the products, such reactions must be carried out at very low temperatures.

$$(CH_3)_3PbBr + KBH_4 \rightarrow (CH_3)_3PbH$$

$$(CH_3)_2PbCl_2 + LiAlH_4 \rightarrow (CH_3)_2PbH_2$$

Metallation of the organolead halides by lithium, sodium or potassium yields the synthetically useful metal tri-organoleads, whose exact nature is presently not fully understood.

Under suitable conditions the action of sodium upon the organometallic lead halides produces a Wurtz type of reaction and the formation of the hexa-organodileads. The tri-organolead chlorides are reduced to the hexa-organodileads by aluminium in dilute potassium hydroxide solution[213].

In addition to the reactions involving the fission of the lead–halogen bond, the organolead halides undergo coordination reactions in which they remain intact, but undergo changes of stereochemistry due to the incoming ligand. $(CH_3)_3PbCl$ and $(C_2H_5)_3PbCl$ both form 1:1 complexes with tetramethylene sulphoxide, dimethylacetamide and dimethylformamide, in which the oxygen atoms bond to lead to give a trigonal bipyramidal structure with a planar tri-alkyl lead unit[208].

Diphenyl-lead dichloride complexes with such ligands as pyridine (1·2), dimethylsulphoxide (1:2), 1,1'-dipyridyl (1:1), and ortho-phenanthroline (1:1) to produce octahedral complexes[214] as illustrated in Fig. 10.
FIG. 10. Six-coordinate lead in organolead complexes. (a) $(C_6H_5)_2PbCl_2$.dipy. and (b) $[(C_2H_5)_2PbCl_4]^{2-}$.

Both tri-organolead halides and di-organolead dihalides complex with halide ions to produce trigonal bipyramidal and octahedral complex anions such as $[(C_6H_5)_3PbCl_2]^-$, $[(C_2H_5)_3PbCl_3]^{2-}$, $[(C_2H_5)_3PbCl_2]^-$ and $[(C_2H_5)_2PbCl_4]^{2-}$.

2.8. PSEUDOHALIDES

Thiocyanates and Selenocyanates

Lead(II) thiocyanate is precipitated from lead(II) solutions by potassium thiocyanate solution; a very pure form is obtained from lead nitrate. It is light-sensitive, and it decomposes at about 190°C[215].

Lead(II) thiocyanate has a structure of particular interest. Each lead atom is eight-coordinate with two pairs of sulphur atoms (at 3·05 and 3·14 Å) and two pairs of nitrogen atoms (at 2·70 and 2·72 Å), all from different thiocyanate ions. Further, all thiocyanate ions are bridging, and each thiocyanate ion makes contact with four lead(II) ions—two at each end. The thiocyanate ion is effectively linear with S–C 1·53 Å and C–N 1·26 Å[216].

Lead(IV) isothiocyanate has been reported from the action of the acid upon lead tetra-acetate. $Pb(NCS)_4$ undergoes very ready disproportionation to thiocyanogen and lead(II) isothiocyanate, and has consequently been little investigated[217].

The corresponding organometallic derivatives of lead(IV), R_3PbNCS and $R_2Pb(NCS)_2$, are, however, much more stable and more extensively studied[218, 219]. The isothiocyanato linkage Pb–N=C=S is believed present in these complexes from spectroscopic evidence, and a full assignment of the infrared spectrum of $(CH_3)_3PbNCS$ has been made. In contrast, however, the selenocyanate $(C_6H_5)_3PbSeCN$ is believed to have the normal Pb–Se–C≡N attachment rather than the iso alternative[220].

Isocyanates

Only organometallic isocyanates of lead(IV) R_3PbNCO (R = CH_3 and C_2H_5) are known[218, 219].

$$(C_2H_5)_3PbCl + KOCN \rightarrow (C_2H_5)_3PbNCO$$

These are believed to contain metal–nitrogen rather than metal–oxygen bonds[218].

The triphenyl-lead fulminate $(C_6H_5)_3PbCNO$ is reported to rearrange to the isocyanate $(C_6H_5)_3PbNCO$ at 174° [221].

Cyanides

Lead(II) cyanide has been little studied[222, 223], and although a compound has been formulated as $Pb(CN)_2$, there is considerable doubt about its true nature. The action of hydrocyanic acid upon lead(II) salts has been variously reported as producing $Pb(CN)_2$ and $Pb(CN)_2PbO$.

Organometallic cyanides of lead(IV), however, are well known[112, 224, 225].

$$R_3PbCl + KCN \rightarrow R_3PbCN$$
$$R_3PbOH + HCN \rightarrow R_3PbCN$$
$$R_3PbOH + NaCN \rightarrow R_3PbCN$$
$(C_6H_5)_3PbCN$ is reported stable up to 250°C.

Azides

Azides of lead are known for both Pb(II) and Pb(IV) states.

Lead(IV) azide was made by the action of hydrazoic acid upon Pb_3O_4. The red solution of $Pb(N_3)_4$ fades rapidly and the product was not isolated, though nitrogen was evolved and $Pb(N_3)_2$ was deposited.

Highly explosive red crystals were deposited by the action of $(NH_4)_2PbCl_6$ upon sodium azide solution and, though not analysed, a lead(IV) complex azide was believed present[226].

The organometallic azides of lead(IV) are more stable and have been widely studied The types R_3PbN_3 and $R_2Pb(N_3)_2$ are obtained by the action of hydrazoic acid upon R_3PbOH or R_2PbO.

Triphenyl-lead azide melts without decomposition at 180°, and is the least thermally stable of the Group IV triphenylmetal azides; the products of decomposition are $(C_6H_5)_4Pb$ and nitrogen[218].

Lead(II) azide is dimorphic. The slow diffusion of lead nitrate and sodium azide produces a monoclinic (β) form ($a = 5.09$ Å, $b = 8.84$ Å and $c = 17.51$ Å), whilst the α-form is precipitated on mixing solutions of alkaline azides and lead(II) salts, and is orthorhombic ($a = 6.63$ Å, $b = 11.31$ Å and $c = 16.24$ Å). The β-form is converted to the α-form by the action of light, but may be preserved for years in the dark.

Both α- and β-forms of lead(II) azide are very sensitive to shock and to thermal decomposition, but the activation energy for decomposition of the β-form is considerably lower than that of the α-form, and at about 260°C the violence of detonation of the β-form is about twenty times greater than that of the α-form[227].

Lead(II) azide has a very low solubility (solubility product at 20°C $= 2.58 \times 10^{-9}$), but is decomposed by dilute nitric and dilute hydrofluoric acid.

Lead(II) azide is an extraordinarily treacherous compound, and should be handled with great respect. Explosive decomposition is catalysed by small quantities of impurities.

Various basic azides such as $PbN_6 \cdot PbO$ and $(PbN_6)_3(PbO)_5$ have been characterized by X-rays from suspensions of lead azides and oxides[228].

2.9. METAL–METAL BONDS CONTAINING LEAD

Alkali Metal Derivatives

Alkali metal derivatives of the type R_3PbM are most stable for R = aryl and M = lithium, though many others are used *in situ* in reactions without being isolated[24, 26].

$$R_3Pb \cdot PbR_3 + Na \xrightarrow{NH_3} R_3PbNa$$
$$(C_6H_5)_2PbBr_2 + Li \xrightarrow{NH_3} (C_6H_5)_2PbLi_2$$
$$PbCl_2 + LiR \longrightarrow R_3PbLi$$
$$R_4Pb + Na \xrightarrow{NH_3} R_3PbNa$$
No structural information is available for these compounds, but they are likely to have some ionic character $R_3Pb^{-\delta}\text{-}M^{+\delta}$.

226 H. Moller, *Z. anorg. Chem.* **260** (1949) 249.
227 C. S. Garner and A. S. Gomm, *J. Chem. Soc.* (1931) 2123.
228 W. Feitknecht and M. Sahli, *Helv. Chim. Acta*, **37** (1954) 1423 and 1431.

The alkali metal tri-organoleads have been widely utilized as synthetic intermediates and their reactions are exemplified in the lithium organoleads.

$(C_6H_5)_3PbLi$ is completely hydrolysed by water to Pb, LiOH and C_6H_6.

Displacement of the alkali metal by reactions with halides have proved very extensive.

$$(C_6H_5)_3PbLi + H_{4-n}CCl_n \rightarrow \{(C_6H_5)_3Pb\}_nCH_{4-n} \qquad n = 1, 2, 3 \text{ and } 4$$

$$(C_6H_5)_nPbLi_{4-n} + RX \rightarrow (C_6H_5)_nPbR_{4-n} \qquad n = 2 \text{ and } 3$$

$$(C_6H_5)_3PbLi + C_2Cl_6 \rightarrow (C_6H_5)_3PbCl + LiC_2Cl_5$$
Insertion reactions into the lithium–lead bond has realized a useful source of organolead functional derivatives[229].

$$(C_6H_5)_3PbLi + \overline{CH_2CH_2CH_2O} \rightarrow C_6H_5PbCH_2CH_2CH_2OLi$$

$$(C_6H_5)_3PbLi + \overline{CH_2CH_2S} \rightarrow (C_6H_5)_3PbCH_2CH_2SLi$$

$$(C_6H_5)_3PbLi + \overline{CH_2CH_2NCOR} \rightarrow (C_6H_5)_3PbCH_2CH_2N(Li)COR$$

$$(C_6H_5)_3PbLi + X \rightarrow (C_6H_5)_3PbXLi \qquad X = S, Se \text{ and } Te$$
Compounds with Lead–Lead Bonds

In addition to the lead–lead bonded compounds discussed in detail below, there are many compounds known in which lead and another Group IV metal are bonded together[230].

$$(C_6H_5)_3GeLi + PbCl_2 \rightarrow [(C_6H_5)_3Ge]_4Pb$$

$$(C_6H_5)_3PbLi + GeCl_4 \rightarrow [(C_6H_5)_3Pb]_4Ge$$
As the least extensively catenating member of the Group IVB elements, the longest sequence of lead is a chain of three atoms.

The hexa-alkyl and hexa-aryl dileads are very numerous and many synthetic approaches are available[231].

$$(CH_3)_3PbCl + NH_4Pb(CH_3)_3 \rightarrow (CH_3)_3Pb \cdot Pb(CH_3)_3$$

$$(C_6H_5)_3PbCl + Na \rightarrow (C_6H_5)_3Pb \cdot Pb(C_6H_5)_3$$

$$(CH_3)_3PbH \xrightarrow{\Delta} (CH_3)_3Pb \cdot Pb(CH_3)_3 + H_2$$

$$(CH_3)_2CO + NaPb + H_2SO_4 \rightarrow \{(CH_3)_2CH\}_3Pb \cdot Pb\{CH(CH_3)_2\}_3$$

$$(C_6H_5)_3PbLi + (C_6H_5)_3PbCl \rightarrow (C_6H_5)_3Pb \cdot Pb(C_6H_5)_3$$

$$(C_6H_{11})_3PbNa + Hg \rightarrow (C_6H_{11})_3Pb \cdot Pb(C_6H_{11})_3$$

$$C_6H_5MgBr + PbX_2 \rightarrow (C_6H_5)_3Pb \cdot Pb(C_6H_5)_3$$
The reaction of Grignard reagents upon lead(II) halides is believed to involve initially the formation of unstable lead(II) diaryls which polymerize and subsequently decompose to hexa-aryldileads and lead metal.
[229] L. C. Willemsens and G. J. M. van der Kerk, *J. Organometallic Chem.* 4 (1965) 34.
[230] L. C. Willemsens and G. J. M. van der Kerk, *J. Organometallic Chem.* 2 (1960) 260 et seq.
[231] H. Gilman, W. H. Atwell and F. K. Cartledge, *Adv. Organometallic Chem.* 1 (1964) 90.

In addition to the compounds containing just one lead–lead bond, there exists $[(C_6H_5)_3Pb]_4Pb$, which contains four lead–lead bonds and six different lead–lead–lead sequences (Fig. 11). It is best made by the simultaneous hydrolysis and oxidation of triphenylphembyl lithium at low temperature[230].

The bright red product may be recrystallized from chloroform, but decomposes over a few days to hexaphenyldilead and lead.
FIG. 11. Tetrakis (triphenyl-lead) lead.

All of the lead–lead bonds in $[(C_6H_5)_3Pb]_4Pb$ are broken by iodine to form $(C_6H_5)_3PbI$ and PbI_2.

Despite early statements to the contrary, the hexa-aryldileads do not dissociate in solution to radicals as do the hexa-arylethanes. An electron diffraction study of $(CH_3)_3Pb.Pb(CH_3)_3$ indicates a normal covalent structure, with Pb–Pb bond length 2·88 Å[232].

Lead–lead bonds undergo fission by a variety of agents, and some of the reactions are believed to have complex mechanisms. Some of the overall reactions are represented below.

$$R_6Pb_2 + HX \rightarrow R_3PbX + PbX_2 + RH$$
$$R_6Pb_2 + X_2 \rightarrow R_3PX + R_2PbX_2 + PbX_2$$
$$R_6Pb_2 + AlCl_3 \rightarrow R_4Pb + PbX_2 + RAlX_2$$
$$R_6Pb_2 + AgNO_3 \rightarrow R_3PbNO_3 + Ag$$
$$R_6Pb_2 + KMnO_4 \rightarrow R_3PbOPbR_3$$
$$R_6Pb_2 + C_2H_5ONa \rightarrow R_3PbOC_2H_5 + Pb(OC_2H_5)_2$$
$$R_6Pb_2 + RSSR \rightarrow R_3PbSR$$
Hexaphenyldilead disproportionates upon heating to tetraphenyl-lead and lead metal.

The well-characterized ions Pb_4^{4-} and Pb_9^{4-} may be regarded as containing lead–lead bonds. The structure of Pb_4^{4-} is tetrahedral and may be regarded as analogous to the P_4 moiety[233]. It is suggested that the Pb_9^{4-} ion takes the shape of a tricapped trigonal prism, with each lead atom virtually equidistant from the centre of the ion cluster[234].

Lead–Transitional Metal Bonds

Whilst lead–transitional metal bonds have not been investigated to the same extent as the corresponding bonds of silicon, germanium and tin, there is a significant range of examples[235].

Organolead halides undergo metatheses with metal carbonyl anions.

$$(C_2H_5)_3PbCl + Fe(CO)_4^{2-} \rightarrow [(C_2H_5)_3Pb]_2Fe(CO)_4$$
$$(C_6H_5)_2PbCl_2 + Co(CO)_4^- \rightarrow (C_6H_5)_2Pb[Co(CO)_4]_2$$
$$(C_6H_5)_3PbCl + \pi\text{-}C_5H_5Cr(CO)_3^- \rightarrow (C_6H_5)_3PbCr(CO)_3(\pi\text{-}C_5H_5)$$
The lead–transitional metal bonds and sequences in these compounds are best illustrated in Fig. 12.

The lead–transitional metal bonds undergo rapid fission with halogens.
FIG. 12. Some compounds containing lead–transitional metal bonds.

19. NITROGEN

K. JONES

The University of Manchester Institute of Science and Technology

1. GENERAL INTRODUCTION

1.1. HISTORY

The history of nitrogen and its compounds dates back to early geological times and to the controversy of whether the earth's atmosphere then contained ammonia or nitrogen. Arabic alchemists are said to have known of salts of ammonia and nitric acid; however, it was not until 1772 that nitrogen was discovered and 1774 that free ammonia was prepared[1]. The preparation of urea from ammonium cyanate by Wöhler in 1828 played its part in helping to break down the "organic" theory[2]. Although this undoubtedly removed the barrier between organic and inorganic chemistry, in some respects the distinction has never been so rigid as today.

The importance of nitrogen compounds in the soil was only realized after about 1862, and it was 1886 before it was shown that nitrogen from the atmosphere was "fixed" by organisms inhabited in the nodules of roots on certain plants[3]. The sources of nitrogen fertilizers in use then were plant and animal wastes, Chile saltpetre, and ammonium sulphate—a byproduct of the coke and coal-gas industry.

The first synthetic processes involving nitrogen compounds were also important methods of nitrogen fixation. The Frank–Caro process (1895) for the production of calcium cyanamide is still operated in a modified form for a very small rapidly diminishing market, but the Birkeland–Eyde (1900) arc oxidation of nitrogen to nitric oxide and hence nitric acid is now obsolete. However, the first decade of this century saw the major developments in the industrial production of nitrogen compounds including the Raschig hypochlorite oxidation of ammonia to hydrazine (1907), the Ostwald catalytic oxidation of ammonia to nitric oxide for nitric acid production (1908) and the Haber catalytic synthesis of ammonia (1909), all of which are still operated today[4, 5]. Indeed, it is only recently that any alternative to the high-pressure catalytic synthesis of ammonia has seemed feasible, but with the recent preparation of stable molecular nitrogen complexes of certain transition metals, and the reported conversion of nitrogen to ammonia at room temperature and atmospheric pressure

[5] C. Matasa and E. Matasa, *L'Industrie Moderne des Produits Azotes*, Dunod, Paris (1968) (in French).

in the presence of homogeneous molecular catalysts[6], a significant development in nitrogen fixation would seem to be imminent.

Finally, an historical section would not be complete without a mention of the considerable literature that is already available on the inorganic chemistry of nitrogen. Comprehensive texts include Mellor first published in 1928 [7] and with two supplements as recent as 1964 [8] and 1967 [9], and *Gmelins Handbuch*[10] of 1936. A new series edited by Colburn[11] provides authoritative reviews of major areas of nitrogen chemistry up to the mid-sixties, and a bimonthly trade journal[12] indicates trends, supplies and prices of commercial materials. Most of us owe our introduction to nitrogen chemistry to one of the many inorganic texts[13-18], but especially to Yost and Russell's book[19] of 1944, and more recently the shorter monograph by Jolly[20] in 1964.

1.2. OCCURRENCE AND DISTRIBUTION

Nitrogen constitutes 78% by volume of the earth's atmosphere and occurs in considerable quantities in natural gas. The atmosphere also contains small amounts of ammonia, ammonium salts, nitrates and oxides of nitrogen produced by lightning discharge during thunderstorms as well as increased concentrations over cities due largely to automobile exhaust pollution. All soils contain up to 1% combined nitrogen, but the major natural deposits are as nitre (KNO_3) in India, and saltpetre ($NaNO_3$) in Chile and other desert regions of South America. Smaller amounts of combined-nitrogen are associated with coal and oil. A considerable amount is found *in vivo*, living organisms having an average combined-nitrogen content of about 16%.

As nitrogen is not very soluble in water, the oceans are not potential sources of combined nitrogen, although there is clearly sufficient to meet the demand of all marine life. Marine algae must obtain their nitrogen from that dissolved in ocean water, and this may be as low as 0.03 g/ton, of which only about 5% is in the form of nitrate[21].

At a time when the analysis of moon samples is awaited, it is appropriate to mention the extra-terrestrial sources of nitrogen compounds. Spectra of N_2, NH, NO and CN have been observed in giant superstars and comets, and recently ammonia spectra from interstellar dust clouds have been reported[22]. The atmosphere of Mars contains nitrogen, while that of Jupiter and probably Saturn contain ammonia[23].

1.3. PRODUCTION AND INDUSTRIAL USE

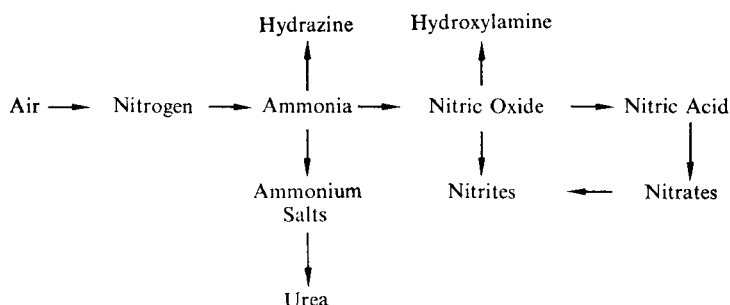
The need to develop industrial methods capable of even greater production capacity of "fixed" nitrogen containing materials for use as fertilizers has run parallel to the ever-increasing demand for food. Saltpetre can be used directly as a fertilizer, and in 1913 accounted for more than half of the world production of fixed nitrogen. Today, however, most of the total world production of nitrogen-containing compounds comes from synthetic routes starting with atmospheric nitrogen. Figure 1 summarizes the present-day route by which the principal nitrogen compounds are produced.


FIG. 1. Industrial routes to nitrogen compounds.

Although the manufacture of ammonia is the most important single use of elemental nitrogen, both gaseous and liquid nitrogen have found increasing application as an inert atmosphere and a cryogenic material. The demand for nitrogen is not expanding more rapidly than in the food industry where the gas is used during processing and in packaging to prevent oxidative deterioration, and liquid nitrogen is used for food freezing both in storage and during transport[24].

The principal methods of nitrogen manufacture are by liquefaction of air or removal of oxygen from air by combustion. The latter source is that normally used in the Haber process for the synthesis of ammonia[25]. This is the only nitrogen fixation process of major importance now in world-wide use, and involves the reaction of nitrogen and hydrogen at high temperatures and pressures in the presence of a catalyst according to the equation

$$N_2 + 3H_2 \overset{\text{catalyst}}{\rightleftharpoons} 2NH_3$$
[22] A. C. Cheung, D. M. Rank, C. H. Townes and W. J. Welch, *Nature*, **221** (1969) 917.
[23] F. H. Day, *The Chemical Elements in Nature*, Harrap, London (1963).
[24] M. Sittig, *Nitrogen in Industry*, Van Nostrand, New York (1965).
[25] R. Noyes, *Ammonia and Synthesis Gas*, Noyes Development Corporation, New Jersey (1967).

Hydrogen for the Haber process is commonly produced by the thermal decomposition, reforming or oxidation of hydrocarbons, and frequently in conjunction with the nitrogen purification process. Other sources of hydrogen, such as the electrolysis of water, etc., are equally acceptable, but depend on resources local to the production site.

A large quantity of ammonia is converted into a variety of ammonium salts by simple neutralization reactions, principally for use as fertilizers[26]. Both anhydrous and aqueous ammonia are also used directly as fertilizers by soil injection and spray techniques. Increasing amounts of ammonia are being converted into urea via ammonium carbamates:

$$2NH_3 + CO_2 \rightarrow NH_2CO_2NH_4 \rightarrow NH_2CONH_2 + H_2O$$

Urea contains a higher percentage of nitrogen than any other solid fertilizer, and also finds application in urea–formaldehyde resins as well as in melamine production.

The production of hydrazine by the Raschig process[27] only accounts for a modest amount of ammonia:

$$2NH_3 + OCl^- \rightarrow N_2H_4 + H_2O + Cl^-$$

Because of the high heat of combustion, one of the major uses of hydrazine and its derivatives, and potentially the largest, is as a component of rocket propellants. The rocket motor of the service module used during the recent successful moon landings was powered by such a fuel.

Large amounts of ammonia are oxidized via nitric oxide to nitric acid by the following reactions:

$$12NH_3 + 15O_2 \rightarrow 12NO + 18H_2O$$
$$12NO + 6O_2 \rightarrow 12NO_2$$
$$12NO_2 + 4H_2O \rightarrow 8HNO_3 + 4NO$$
Nitric acid is used principally for the production of nitrates as fertilizers, nitro-compounds as explosives and to a lesser extent for a multitude of purposes in the chemical industry[26]. Thus from these principal compounds it is possible to synthesize all nitrogen derivatives, the nature of which are to be described in subsequent sections.

It is probably apparent even from such a brief outline of the major industrial processes producing nitrogen compounds that they are related to such an extent with each other and also with the natural resources of a particular country that many factors enter into the planning of a viable production unit. As an indication of the current trend[28], one of the most modern sites is operated by Esso Chemie at Europoort in The Netherlands, and includes plants for the production of ammonia, nitric acid, urea and calcium ammonium nitrate. The ammonia plant is equal to the world's largest, producing 1500 short tons of liquid ammonia per day in a single production line. The synthesis gas is obtained by reforming natural gas from the nearby North Sea gasfields. The carbon dioxide produced in the shift conversion is removed and regenerated as feedstock for the urea plant. Ammonia is oxidized via nitric oxide to nitric acid from which ammonium nitrate is formed by neutralization. Coagulation of ammonium nitrate solution with limestone gives calcium ammonium nitrate, another useful fertilizer. The plant is operated with a high degree of automation, and is located conveniently for shipping.

1.4. NUCLEAR PROPERTIES

1.4.1. Isotopes and Radioisotopes

Seven isotopes of nitrogen are known of which ^{14}N and ^{15}N are stable and occur in natural nitrogen-containing substances in the ratio 272:1. Natural abundances of stable isotopes vary slightly depending on the source of the element; the percentage abundances 99.635 and 0.365 for atmospheric nitrogen correspond to an atomic weight of 14.0067 based on the IUPAC scale $^{12}C = 12.000000$ atomic mass units. The remaining five isotopes ^{12}N, ^{13}N, ^{16}N, ^{17}N and ^{18}N are radioactive, the longest lived being ^{13}N with a half-life of nearly 10 min, and since it is neutron deficient, charged particle accelerators are necessary to produce it in reasonable amounts. Even so, experiments can be performed near such equipment[29]. ^{13}N as $^{13}NH_3$ can be obtained by dissolving the target foils used in the radio-chemical synthesis $^{12}C(d, n)^{13}N$, but a recent report[30] indicates that the product reacts as atomic nitrogen-13 (see section 2.12). The properties of nitrogen isotopes are listed in Table 1.

Thus as the half-lives of the radioisotopes are inconveniently short for most chemical experiments, tracer and isotope-effect studies are generally conducted using the stable ^{15}N isotope. Clearly, the scope and success of such investigations depend on the availability of efficient methods of separation and enrichment, the variety of labelled compounds which can be prepared and the analytical techniques to determine and monitor ^{15}N concentration.

1.4.2. Separation of ^{15}N from ^{14}N

(a) By Chemical Exchange[31]

If A' and B' are two molecules containing ^{14}N, and A'' and B'' are similar molecules containing ^{15}N, then the equilibrium constant for the reaction

$$A'_{(a)} + B''_{(b)} \rightleftharpoons A''_{(a)} + B'_{(b)}$$
can be expressed by

$$K = \frac{[Q_{A''}/Q_{A'}]_{(a)}}{[Q_{B''}/Q_{B'}]_{(b)}}$$

where $Q_{A''}$, etc., refer to the partition functions for the reaction between A'' and A', etc. The $Q_{\cdot}/Q_{\cdot\cdot}$ ratios can be calculated, and values greater than unity indicate that enrichment is possible. To obtain appreciable enrichment, a countercurrent system is desirable, and this is most effective if one phase is liquid and the other gaseous.

Thus for the exchange of gaseous ammonia with aqueous solutions of ammonium salts described by the equation

$$^{15}NH_3(g) + {}^{14}NH_4^+(aq) \rightleftharpoons {}^{14}NH_3(g) + {}^{15}NH_4^+(aq)$$
separations of up to 75% ^{15}N have been achieved, and with columns in series 99.9% enriched material can be obtained[32, 33]. The procedure is to pass ammonium nitrate solution down a packed column to a flask containing aqueous sodium hydroxide. In the flask,

[b] C. J. L. Lock, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. VIII, Supplement II, Longmans, London, 1967, Section XXXV, p. 526.

ammonia gas is liberated and rises up the column and exchanges with the ammonium ions in the descending solution. As a result, ^{15}N tends to concentrate in the liquid phase while the gaseous ammonia contains relatively more of the unwanted lighter isotope. A counter-current system may take 2–3 weeks to reach equilibrium after which time the aqueous solution can be continuously bled off at such a rate so as not to disturb the equilibrium.

Similarly, 99% enrichment can be obtained from the process based on the exchange reaction

$$^{15}NO(g) + {}^{14}NO_3^-(aq) \rightleftharpoons {}^{14}NO(g) + {}^{15}NO_3^-(aq)$$
and this method is now used commercially. Nitric oxide is produced from nitric acid at the bottom of the column and converted back at the top according to the equations[34]

$$2HNO_3 + 3SO_2 + 2H_2O = 2NO + 3H_2SO_4$$
$$2NO + 1.5O_2 + H_2O = 2HNO_3$$
Isotope separations based on chemical exchange are not restricted to gas–liquid counter-current methods. For example, high purity ^{15}N has been obtained by exchange between NH_4^+ adsorbed on Dowex X-12 resin and NH_4^+ in equilibrium with unionized NH_4OH in solution[35]. Since two chemically different species are involved, the isotope exchange factor is relatively large for the equilibrium

$$NH_4^+ + OH^- \rightleftharpoons NH_4OH$$
(b) *By Thermal Diffusion*[32]

Although $^{15}N_2$ can be separated by thermal diffusion, the quantity of separated isotope is relatively small. The separation in a thermal diffusion column containing a mixture of nitric oxide and nitrogen dioxide is assisted by the gas-phase equilibrium

$$^{14}NO_2(g) + {}^{15}NO(g) \rightleftharpoons {}^{15}NO_2(g) + {}^{14}NO(g)$$
(c) *Other Methods*

Many other methods of preparation have been reported for specific applications; even simple fractional distillation of nitric oxide provides an efficient method[36] for the simultaneous concentration of the rarer isotopes of both nitrogen and oxygen in the form $^{15}N^{18}O$. Methods applicable to specific nitrogen compounds will be mentioned in the appropriate section of this chapter dealing with such compounds.

1.4.3. Synthesis of Compounds Containing ^{15}N

The preparative route to a particular labelled compound is to some extent governed by the enriched starting materials that can be obtained directly from separation methods. Fortunately, many key nitrogen compounds are now available from commercial sources[37,38] including N_2, NO, NO_2, NH_3, HNO_3, ammonium salts and nitrates, as 5% 30%, or 95% ^{15}N enriched materials. The degree of enrichment is likely to be dictated by the application for which the product is required.

[37] Office Nationale Industriel de l'Azote (ONIA), 40 avenue Hoche, Paris (VIIIᵉ), France.

[38] Isomet Corporation, Palisades Park, New Jersey, USA.

The preparation of choice should preferably involve only one or two stages, and provide for quantitative conversion of all the ^{15}N in the enriched starting material into labelled product, which in turn should be easily separated in high yield from unreacted starting materials and byproducts. Clearly, methods requiring a gross excess of an enriched material should be avoided if possible, and to overcome these and other problems, syntheses which would not normally be used may be applicable. It is safe practice to carry out the preparation under identical conditions of scale and apparatus using unlabelled materials prior to the synthesis using enriched compound to establish the procedure for optimum yield. It is also necessary to consider ^{15}N recovery procedures should anything go wrong during the synthesis and also from the final product. Manipulative technique is simplified, however, by the fact that all ^{15}N enriched compounds prepared so far undergo negligible exchange with atmospheric nitrogen under normal conditions, in marked contrast to labelled hydrogen, carbon and oxygen compounds, where contact with atmospheric moisture and carbon dioxide must be avoided.

1.4.4. [15]N Analysis[32]

The mass spectrometer has proved to be the most useful instrument for isotopic analysis, and in general ^{15}N abundance ratios can be determined to a precision of $\pm 0.1\%$. Nitrogen gas is the most satisfactory material for mass spectrometric isotope analysis, as even mixtures of [14]N_2, [14]N[15]N and [15]N_2 do not exchange at ordinary temperatures. Thus in most experiments involving ^{15}N, it is necessary to convert the combined nitrogen of the material to be analysed into elemental nitrogen. Inorganic compounds can either be reduced to ammonia directly, or oxidized to nitrate and then converted into ammonia by Devarda's alloy. Ammonia is readily oxidized to nitrogen by alkaline hypobromite. Procedures for converting organic nitrogen compounds into nitrogen are based on the methods of Dumas or Kjeldahl followed by oxidation, taking considerable precautions to avoid contamination by atmospheric nitrogen (see section 1.8).

Nitrous oxide can be used for mass-spectrometric ^{15}N analysis instead of nitrogen, and is useful when the labelling position is of particular interest. This arises because the thermal decomposition of labelled ammonium nitrate produces two different isotopic isomers of nitrous oxide, depending on where the ^{15}N originated, which can be distinguished by the mass spectrometer.

$$[15]NH_4[14]NO_3 \xrightarrow[\text{decomposition}]{\text{Thermal}} [15]N[14]NO + 2H_2O$$
$$[14]NH_4[15]NO_3 \xrightarrow[\text{decomposition}]{\text{Thermal}} [14]N[15]NO + 2H_2O$$
Caution should be exercised in the choice of reference standards for isotopic analysis as some compounds (salts produced as byproducts of nitric acid, for example) contain significantly lower than the normal natural abundance level of ^{15}N as a result of isotopic fractionation during the manufacturing process.

1.4.5. Uses of [15]N

Highly enriched [15]N_2 may have nuclear reactor applications because of the low thermal neutron absorption cross-section compared to ordinary nitrogen[29], but the major use of ^{15}N has been in tracer work. Of particular mention is its use in mechanistic studies of chemical, biochemical and nitrogen-fixation processes.

1.4.6. Nuclear Magnetic Resonance[39, 40]

Although both of the stable isotopes of nitrogen have non-zero spin numbers, neither isotope is particularly favourable for n.m.r. investigation (Table 2). ^{14}N has a spin number $I = 1$ with consequent electric quadrupole moment, and very low n.m.r. sensitivity.

TABLE 2. DATA PERTINENT TO NUCLEAR MAGNETIC RESONANCE STUDIES WITH NITROGEN ISOTOPES[a, b]

	^{13}N	^{14}N	^{15}N
Natural abundance (%)		99.635	0.365

In compounds where the nitrogen atom is in an asymmetric electronic environment, the spectra are affected by quadrupole broadening to such an extent that fine structure cannot be resolved. However, ^{14}N chemical shifts can be measured using broad-line equipment. Indeed, the discovery of chemical shift is associated with the work of Proctor and Yu[41], who found that the frequency of the ^{14}N resonance depended on the chemical compound chosen, and for NH_4NO_3 solution they detected two resonances separated by 1.0 kHz in a field of 10,500 gauss (*ca.* 300 ppm). ^{14}N gives rise to chemical shifts extending over a range of some 900 ppm (Table 3), and values can be correlated with the electronic environment at the nitrogen atom. Note that the symmetric ammonium ion has the highest chemical shift whereas structures of lower electronic symmetry at nitrogen such as the nitrite appear at lower chemical shift. The ammonium, nitrate and nitrite ions in aqueous solution are all used as reference standards for reporting chemical shifts.

In order to interpret observed chemical shift data, it is necessary to separate the dia-magnetic and paramagnetic components. This has been carried out for NOX

compounds[42, 43], and the graph illustrated in Fig. 2 shows that $-\sigma_p$ is inversely proportional to the energy of the $n \rightarrow \pi$ band in the ultraviolet-visible spectrum as predicted by Pople theory[39].

Although the principal causes of chemical shift differences are understood, the applications of ^{14}N chemical shifts have been mainly empirical. As an example, the characterization of metal–pseudohalide complexes raises the problem of which atom is bonded to the metal. For thiocyanates, where the point of attachment has been reliably determined by X-ray crystallography, it was found that sulphur-bonded complexes gave ^{14}N chemical shifts

[42] J. Mason and W. Van Bronswijk, *Chem. Communs.* (1969) 357.
[43] J. Mason, unpublished results.

0–20 ppm to low field for the free NCS⁻ resonance, whereas nitrogen-bonded complexes appear at 50–130 ppm to high field of NCS⁻. Thus it is possible to predict whether related complexes contain metal–nitrogen or metal–sulphur bonds[44].
FIG. 2. Plot of the paramagnetic component of the observed shift versus the wavelength of the $n \to \pi$ band for NOX compounds.

The problem of ^{14}N quadrupole broadening and lack of fine structure can be overcome by using the ^{15}N isotope which has a spin number $I = \frac{1}{2}$. However, the very low n.m.r. sensitivity and the low natural abundance (0.365 %) make ^{15}N isotope enrichment essential. It is for this reason that the technique is likely to be limited to specialized applications. For example, the structure of $S_4N_3^+$ illustrated in Fig. 3 is consistent with the spectrum obtained from a sample enriched to 97.2 % ^{15}N [45].

in 70% HNO_3 relative to $^{15}NH_4$
FIG. 3. The ^{15}N n.m.r. spectrum and structure of $S_4^{15}N_3^+$.

1.4.7. Nuclear Quadrupole Resonance[46, 47]

As a consequence of its spin number $I = 1$, the ^{14}N nucleus has an electric quadrupole moment. The coupling of this nuclear quadrupole moment with the field produced by electrons from neighbouring atoms causes a torque to be exerted on the molecule that in turn gives rise to hyperfine structure in the rotational spectrum. The magnitude of the quadrupole coupling constant eQq can be determined either from pure quadrupole spectra or from microwave spectra and related to the asymmetry of the electron charge cloud

surrounding the nitrogen nucleus. Quadrupole coupling constants for some nitrogen compounds are listed in Table 4. For nitrous oxide, the central nitrogen atom is in a more symmetric electron environment than the terminal nitrogen atom corresponding to its lower coupling constant.

1.5. PHYSICAL PROPERTIES OF THE NITROGEN ATOM

It is usual when discussing the factors which contribute to the overall chemistry of an element to consider the fundamental atomic properties. Such properties fall broadly into two groups: (1) properties of the free nitrogen atom itself which can be measured or calculated directly, e.g., atomic weight or ionization energy, and (2) properties associated with concepts used to rationalize the behaviour of the nitrogen atom in chemically combined states, such as electro-negativity and electron affinity. Properties associated with the nitrogen nucleus have already been listed in Tables 1 and 2, where properties like nuclear spin can be classified as (1), while nitrogen chemical shift data presented in Table 3 would come under group (2). Other atomic nitrogen properties are presented in Table 5 and are concerned mainly with atomic dimensions and thermodynamic functions.

TABLE 5. PHYSICAL PROPERTIES OF THE NITROGEN ATOM

Property	Temperature (K)	Value

D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Bailey and R. H. Schumm, *Selected Values of Chemical Thermodynamic Properties*, NBS Technical Note 270-3, Washington (1968).

Parameters from nitrogen atomic spectra which are listed include the ground-state terms for nitrogen atoms and ions together with their corresponding ionization energies in Table 6 and the low-lying atomic energy terms in Table 7. In the nitrogen ^4S ground state,

all three $2p$ electrons have parallel spins, while in the ^2D and ^2P states two of the $2p$ electrons are paired. These nitrogen atoms are produced during the dissociation processes and their correct assignment was important in determining the value of the dissociation energy of molecular nitrogen. In Table 6 one must note that N I refers to the ground state and N II to the singly ionized species. The ionization energies were calculated from the limiting wave numbers obtained from spectral terms.

TABLE 6. ELECTRONIC DESCRIPTION OF THE GROUND STATES OF FREE NITROGEN ATOM AND IONS TOGETHER WITH THE CORRESPONDING IONIZATION ENERGIES IN VARIOUS UNITS

N	Ground state	Spectroscopic state	Ionization energy		
			Wave numbers (cm^{-1})	Volts	kcal/g atom
I	$1s^22s^22p^3$	$^4S_{3/2}$	117 345	14.545	335
II	$1s^22s^22p^2$	$^3P_0$	238 846.7	29.605	683
III	$1s^22s^22p$	$^2P_0$	382 625.5	47.426	1 097
IV	$1s^22s^2$	$^1S_0$	624 851	77.450	1 784
V	$1s^22s$	$^2S_{1/2}$	789 532.9	97.863	2 256
VI	$1s^2$	$^1S_0$	4 452 800	551.93	12 730
VII	$1s$	$^2S_{1/2}$	5 379 860	663.82	15 300

C. E. Moore, *Atomic Energy Levels as derived from the Analyses of Optical Spectra*, Natl. Bur. Std. US Circ., 467, Vol. 1 (1949).

From another spectroscopic point of view, when materials are subjected to X-radiation, electrons from the innermost shells of an atom can be emitted and subsequently detected by high resolution magnetic or electric analysis. Thus electron spectroscopy for chemical analysis (ESCA)[48] is capable of determining the electronic levels of nitrogen in a molecule

TABLE 7. LOW-LYING ATOMIC ENERGY TERMS FOR NITROGEN

Spectroscopic state	Wave numbers (cm^{-1})	Electron volts	kcal/g atom
Ground state $^4S_{3/2}$	0	0	0
$^2D_{5/2}$	19 223	2.383	54.95
$^2D_{3/2}$	19 231	2.385	54.98
$^2P_{1/2,3/2}$	28 840	3.574	82.45

Lindberg, *ESCA Atomic, Molecular and Solid State Structure Studied by Means of Electron Spectroscopy*, Nova Acta Regiae Societatis Scientiarum Upsaliensis, Ser. IV, Vol. 20, Uppsala (1967), p. 108.

to the precision set by the widths of the atomic levels themselves. Of particular use to the chemist is the comparison of values measured for the nitrogen $1s$ level in various compounds. For example, sodium azide $[Na^+(\overset{-}{N}=\overset{+}{N}=\overset{-}{N})]$, the central nitrogen atom of the azide ion, has a calculated charge of $+0.64$ while the other two nitrogen atoms have a charge of -0.72. The electron spectrum accordingly shows two nitrogen $1s$ lines of which the one of higher kinetic energy is twice the intensity of the other.

1.6. NITROGEN CHEMISTRY

Under the heading of General Introduction (section 1), this section attempts to indicate the scope of inorganic nitrogen chemistry and to outline the general trends and principles on which the subject can be rationalized. For this it will be convenient to list those concepts and fundamental properties associated with chemical combination and to define and illustrate such terms with examples from nitrogen chemistry for reference in the detailed discussion of each type of nitrogen compound in later sections.

Nitrogen will form bonds to most elements, perhaps the only exceptions being the noble gases; however, there is spectroscopic evidence for a diatomic xenon–nitrogen molecule of low stability[49]. Thus although nitrogen compounds of almost 100 elements need to be considered, the information is not evenly distributed over the Periodic Table. As so many of the most important nitrogen compounds contain only the light elements of the first short period, it is not surprising that nitrogen chemistry has centred around substances containing the elements hydrogen, carbon, nitrogen and oxygen, which include the organic compounds containing nitrogen[50], together with the hydrides, oxides and their related derivatives. Naturally these latter compounds will figure prominently in subsequent sections of this chapter. Apart from the halogen derivatives (see section 9), the nitrogen chemistry of the remaining elements will be considered individually in the chapter appropriate to the element concerned. However, as the majority of elements are metals, the nitrogen chemistry of metals as a group will be considered with reference to their complexes of nitrogen ligands of the inorganic or organic variety, and their salts of nitrogen anions such as amides, azides and nitrides. Mention will also be made to the considerable chemistry involving metal-nitrogen covalent bonds, which has largely emerged from developments in the organometallic chemistry of both transition and non-transition elements[51]. It is in such areas that the formal boundaries between organic, organometallic and inorganic chemistry become sufficiently blurred as to allow discussion of related compounds without embarrassment or apology to the purists. In fact, a survey of the known types of organic compounds containing nitrogen can suggest related structures containing other elements. Subsequent experiments based on such comparative exercises have led to the synthesis of novel compounds to which a great deal of recent experience in preparative inorganic chemistry bears witness. And perhaps this practical approach is no more appropriate than in nitrogen chemistry when one considers all that has been written, e.g., about the low chemical reactivity of molecular nitrogen, and this is equated with the facile reactions which have recently been

[51] See *J. Organometal. Chem.*, 1963–date; *Organometal. Chem. Rev.*, 1966–date; *Annual Survey of Organometallic Chemistry*, 1964–date (eds. D. Seyferth and R. B. King), Elsevier, Amsterdam.

reported for the formation of nitrogen complexes in certain transition metal derivatives (see section 2.11).

The traditional exercise of vertical relationships between nitrogen and the other elements of Group V is probably not very meaningful except to emphasize their great differences. So few nitrogen compounds have isostructural phosphorus analogues that only isolated comparisons can be made[52]. It is more profitable to relate the chemistry of nitrogen to that of its neighbouring elements in the first short period, carbon and oxygen, the so-called horizontal relationship. For example, nitrogen is strongly electro-negative, forms hydrogen bonds and multiple bonds, is capable of catenation to a minor extent (the longest nitrogen chain so far reported[53] being N_8 in the organic derivative PhN=N—NPh—N=N—NPh—N=NPh), and is limited to a maximum covalency of four, all properties which would correctly position nitrogen between carbon and oxygen in the first row of the Periodic Table.

1.6.1. Bonding

The electronic structures of nitrogen compounds are generally rationalized on the basis of a completed octet of electrons around each atom in the molecules. From the electronic configuration $1s^22s^22p^3$, nitrogen has five electrons in the valence shell; hence the octet can be achieved by accepting or sharing three extra electrons from atoms or groups bonded to nitrogen. As nitrogen only accepts electrons from the most electro-positive elements,

TABLE 8. HOW NITROGEN CAN ACHIEVE AN OCTET OF ELECTRONS

Type	Example		
Electron gain	N^{---}	Li_3N	lithium nitride
Electron gain and sharing	HN^{--}	AgNH	silver imide
	H_2N^-	KNH_2	potassium amide
Electron sharing single bond	:N≤	NH_3	ammonia
Electron sharing double bond	⁄N=C<	$R_2C=NR$	imines
	⁄N=N′	RN=NR	diazenes
	⁄N=O	NOCl	nitrosyl chloride
Electron sharing triple bond	:N≡N:	N_2	nitrogen
	N≡C—C≡N	C_2N_2	cyanogen
	(C≡N)⁻	KCN	potassium cyanide
Electron loss and sharing	NH_4^+	NH_4Cl	ammonium chloride
	NR_4^+		quaternary salts
	$N_2H_5^+$	$R_4NXN_2H_5Cl$	hydrazinium hydrochloride

bonding occurs predominantly by the formation of covalent bonds of the single or multiple variety, which may lead to ionic species by subsequent gain or loss of an electron. Examples of each type are included in Table 8. Ions formed by electron loss show nitrogen at its maximum coordination number of four, corresponding to the number of orbitals available in first short period elements.

[52] W. E. Dasent, *Nonexistent Compounds*, Edward Arnold, London (1965).
[53] P. A. S. Smith, *Open-chain Nitrogen Compounds*, Vol. 1, Benjamin, New York (1965), p. 10.
There also exist stable compounds such as nitric oxide and nitrogen dioxide in which there is an odd number of electrons and hence no possibility of achieving completed octets around all the atoms in the molecules. In such circumstances paramagnetism due to un-paired electrons can be detected, and bonding descriptions are usually rationalized in terms of molecular orbital theory. Thus, although electron counts for molecules are still noted, bonding is thought of in terms of the overlapping of atomic or hybrid orbitals, the effectiveness of such overlap being controlled by both symmetry and energy considerations. The usual way of obtaining molecular orbitals is by the linear combinations of atomic orbitals, the LCAO/MO method. Molecular orbitals formed by overlap of atomic orbitals along the molecular axis give rise to σ-bonds while those formed by overlap of atomic orbitals perpendicular to the molecular axis produce π-bonds. Nitrogen, like its neighbour-ing elements of the first short period, is capable of forming such π-bonds predominantly to itself, carbon, and oxygen of the $p_\pi-p_\pi$ type as indicated in Table 8. While the majority of examples involving π-bonding will be of this type, mention will of course be made to $p_\pi-d_\pi$ bonding (e.g. in Si–N compounds) which can occur with elements of the second and subsequent periods. Satisfactory explanations of the bonding in nitrogen compounds are provided either by the valence bond approach or molecular orbital theory, so both descrip-tions will be discussed for particular compounds in their appropriate sections[54].

Information about chemical bonds comes principally from two parameters, bond length as determined by diffraction or spectroscopic techniques[55], and bond strength from quantitative energy measurements during a bond-making or more frequently a bond-breaking process[56]. Theoretically one would expect to find a simple relationship between these two parameters, and undoubtedly short bonds are stronger than long bonds between the same elements. However, the nature of a particular bond will be dependent on the electronic configuration of the elements involved, the kind of orbital available and factors contributing to the bond polarity such as electro-negativity.

On the other hand, there is the problem of what is meant by bond strength. It is only with diatomic molecules that the bond dissociation energy can be defined unambiguously as the energy required to split the molecule into its component atoms. The bond dissociation energies of some nitrogen diatomic species are given in Table 9. For polyatomic molecules however, it is necessary to distinguish between two situations. The energy required to atomize a molecule can be determined, and by dividing this value by the number of bonds broken, the average bond energy $E(N—X)$ results. Alternatively, bond strength could refer to the energy required to break one specific bond in the molecule in which case it is termed the bond dissociation energy $D(NX_2—X)$. For example, consider the atomization of ammonia:

$$NH_3(g) = N(g) + 3H(g); \qquad \Delta H_{298} = +280.3 \text{ kcal/mol}$$

As three N–H bonds are broken, $E(N—H) = 280.3/3 = 93.4$ kcal/mol. However, this value is different from that for the removal of a single hydrogen atom from ammonia:

$$NH_3(g) = NH_2(g) + H(g); \qquad D(NH_2—H) = 104 \text{ kcal/mol}$$
$$NH_2(g) = NH(g) + H(g); \qquad D(NH—H) = 95 \text{ kcal/mol}$$
$$NH(g) = N(g) + H(g); \qquad D(N—H) = 81 \text{ kcal/mol}$$

[54] M. Green, in *Developments in Inorganic Nitrogen Chemistry*, Vol. 1 (ed. C. B. Colburn), Elsevier, Amsterdam (1966), p. 1.

[55] *Tables of Interatomic Distances and Configuration in Molecules and Ions* (ed. L. E. Sutton), Chemical Society Special Publications 11 and 18, London (1958 and 1965).

[56] L. Pauling, *The Nature of the Chemical Bond*, 3rd edn., Cornell University Press, Ithaca, New York (1960).

The sum of the bond dissociation energies is, of course, equal to the energy of atomization, but the regular decrease in dissociation energy is attributed to decreasing s character of the bonding orbitals.

TABLE 9. BOND DISSOCIATION ENERGIES IN SOME DIATOMIC SPECIES OF NITROGEN

Species	Bond dissociation energy	
	eV	kcal/mol
NH	3.21 ± 0.16	74
NH$^+$	3.7 ± 0.4	85
BN	4.0 ± 0.5	92
CN	7.75 ± 0.2	178
CN$^+$	4.7 ± 0.4	108
N$_2$	$9.760 + 0.005$	225.1
N$_2^+$	8.73 ± 0.01	201.4
NO	6.5 ± 0.01	149.9
NO$^+$	10.86 ± 0.04	250.4
NF	4 ± 1	92
MgN	1.5 ± 0.5	35 ± 10
AlN	3 ± 1	70
SiN	4.5 ± 0.4	104
PN	7.1 ± 0.05	164
NS	5.0 ± 0.7	115
NCl	4 ± 0.5	92
NSe	4.5 ± 1	104
NBr	2.8 ± 0.2	65
SbN	3.1 ± 0.5	71

A. G. Gaydon, *Dissociation Energies and Spectra of Diatomic Molecules*, 3rd edn., Chapman & Hall, London (1968), pp. 257-88.

Such information can be used to estimate other bond energies. For the atomization of hydrazine,

$$N_2H_4(g) = 2H(g) + 4H(g); \qquad \triangle H = 411.6 \text{ kcal/mol}$$
If we assume that the bond energy of the N–H bonds is the same as in ammonia, then the bond energy of the N–N bond $E(NH_2—NH_2) = 411.6 - (4 \times 93.4) = 38.0$ kcal/mol. The bond dissociation energy for the reaction

$$N_2H_4(g) = 2NH_2(g) \text{ gives } D(NH_2—NH_2) = 60 \text{ kcal/mol}$$
Clearly these values are significantly different, but by using the sum of the two appropriate dissociation energies $D(NH—H)$ and $D(N—H)$, a closer estimate to $D(NH_2—NH_2)$ can be obtained.

$$D(NH_2—NH_2) = 411.6 - [2 \times (95 + 81)] = 59.6 \text{ kcal/mol}$$
Thus bond energies calculated from thermochemical data and bond lengths determined by diffraction techniques for some common nitrogen bonds are listed in Table 10 together with the bond order for the particular bond in a specific compound. The bond order is

defined as the number of electron pairs involved in bonding two atoms in a molecule, and represents the bond multiplicity. The data in Table 10 is reasonably consistent (compounds with anomalous values have been intentionally omitted) in that bond energy and bond order increase as bond length decrease, and can be used to estimate values of unrecorded bond energies or bond lengths.

TABLE 10. BOND ENERGIES AND BOND LENGTHS FOR SOME NITROGEN BONDS

Bond	Typical molecule	Bond order	Bond length[a] (Å)	Bond energy[b] (kcal/mol at 298 K)
N—H	NH	1	1.084	85
	NH_3	1	1.031	93.4
	NH_4^+	1	1.034	86
	HN_3	1	1.012	85
N—C	$MeNH_2$	1	1.47	69.7
N=C	$(MeC=NOH)_2$	2	1.29	147

1.6.2. Oxidation States

Nitrogen is capable of exhibiting all formal integral oxidation states from $+5$ to -3. By convention, the oxidation state of nitrogen in a particular molecule or ion containing fluorine, oxygen or hydrogen, is defined as the formal charge per atom of nitrogen if every fluorine, oxygen and hydrogen present carries a charge of -1, -2 and $+1$ respectively[57].

[57] C. K. Jorgensen, *Oxidation Numbers and Oxidation States*, Springer-Verlag, New York (1969).

Some examples are listed in Table 11. This definition relates nitrogen to fluorine—the most electro-negative element, and to oxygen and hydrogen—the constituent elements of water, the solvent for which most information is available. It is not in any way meant to restrict the application of the formal oxidation number concept to compounds only containing the elements mentioned. Since only oxygen and fluorine are more electro-negative than nitrogen,

TABLE 11. OXIDATION STATES OF NITROGEN COMPOUNDS

Oxidation state	Example
5	N_2O_5, HNO_3, NO_3^-
4	NO_2, N_2O_4
3	HNO_2, NO_2^-, NOF, NF_3
2	NO, N_2F_4
1	N_2O, $H_2N_2O_2$, $N_2O_2^{2-}$, HNF_2
0	N_2
−1	NH_2OH, H_2NF
−2	N_2H_4, $N_2H_5^+$
−3	NH_3, NH_4^+

it is with these elements that nitrogen can exhibit positive oxidation states although it should be realized that nitrogen in its positive states is not to be regarded as cationic nor in its negative states necessarily as an anion. Thus the concept of oxidation number to describe the oxidation state of an element is most useful in balancing equations, calculating the stoichiometry of reactions, and especially in conjunction with oxidation-reduction

TABLE 12. STANDARD REDOX POTENTIALS (pH = 0) FOR SOME NITROGEN COUPLES[a]

Electrode reaction	Equation	Couple	$E°$ (volts)
$N^{-II} + e = N^{-III}$	$N_2H_5^+ + 3H^+ + 2e = 2NH_4^+$	$N_2H_5^+/NH_4^+$	+1.275
$N^{-I} + e = N^{-II}$	$2NH_3OH^+ + H^+ + 2e = N_2H_5^+ + 2H_2O$	$NH_3OH^+/N_2H_5^+$	+1.42
$N^0 + 2e = N^{-II}$	$N_2 + 5H^+ + 4e = N_2H_5^+$	$N_2/N_2H_5^+$	−0.23
$N^0 + e = N^{-I}$	$N_2 + 2H_2O + 4H^+ + 2e = 2NH_3OH^+$	N_2/NH_3OH^+	−1.87
$N^I + e = N^0$	$H_2N_2O_2 + 2H^+ + 2e = N_2 + 2H_2O$	$H_2N_2O_2/N_2$	+2.65

$N^{III} + e = N^{II}$	$HNO_2 + H^+ + e = NO + H_2O$	HNO_2/NO	+1.00
$N^{IV} + e = N^{III}$	$N_2O_4 + 2H^+ + 2e = 2HNO_2$	N_2O_4/HNO_2	+1.07
$N^V + 2e = N^{III}$	$HNO_3 + 2H^+ + 2e = HNO_2 + H_2O$	HNO_3/HNO_2	+0.94
$N^V + N^{II} + e = 2N^{III}$	$HNO_3 + NO + H^+ + e = 2NO_2^- + 2H^+$	$HNO_3:NO/HNO_2$	+0.49
$N^V + e = N^{IV}$	$2HNO_3 + 2H^+ + 2e = N_2O_4 + 2H_2O$	HNO_3/N_2O_4	+0.79
$3N^0 + e = 3N^{I/3}$	$3N_2 + 2H^+ + 2e = 2HN_3$	N_2/HN_3	−3.1

[a] G. Charlot, D. Bézier and J. Courtot, *Selected Constants. Oxidation-reduction Potentials*, Pergamon, London (1958).

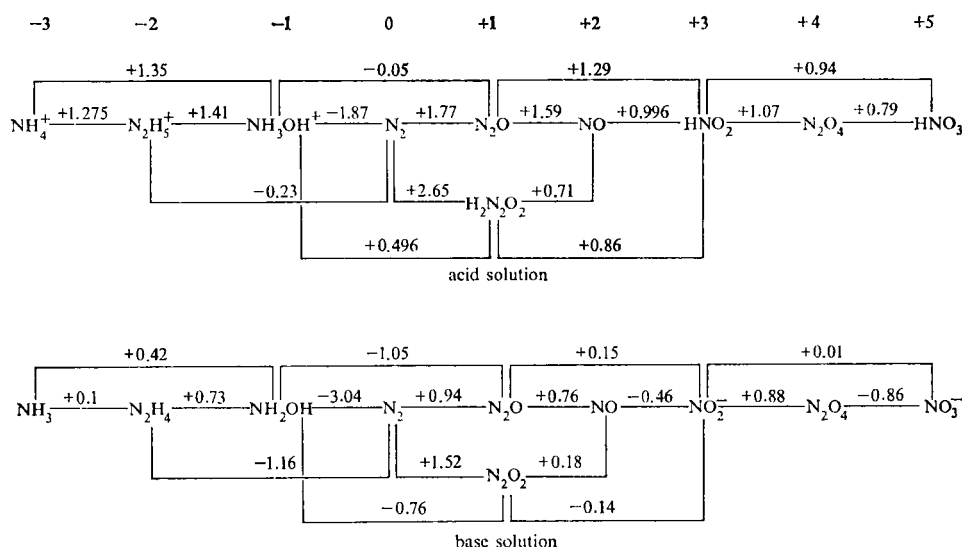
processes[58]. Redox reactions can be defined in terms of changing oxidation states, and if the values of the oxidation-reduction potentials are known, a clear picture of the redox solution chemistry of the element can be obtained. Apart from normal tabulations (Table 12), Latimer diagrams[59] as in Fig. 4 summarize the relationships between the various states, but these methods of presentation have largely been superseded by a graphical


FIG. 4. Latimer diagrams for nitrogen species in aqueous solution.

method first suggested by Frost[60] and Ebsworth[61], and referred to as oxidation state diagrams (Fig. 5) by Phillips and Williams. These latter authors emphasize the use of such diagrams in their textbook, and take nitrogen as the example to illustrate the general principles of their application[62]. It will be shown that oxidation state diagrams for nitrogen can convey a good deal more information than can be conveniently presented by other methods.

The oxidation state diagram illustrated in Fig. 5 consists of a plot of the oxidation state versus the volt equivalent for various nitrogen species (molecules and ions containing the elements nitrogen, oxygen and hydrogen only) in aqueous acid solution. By definition, the volt equivalent of any nitrogen species, say HNO_3, is the product of its oxidation number and its redox potential measured relative to elemental nitrogen at 25°C.

$$E° \ HNO_3/N_2 = +1.246 \ V$$
$$N^V + 5e = N^0$$
$$VE = 5 \times 1.246 = +6.23 \ V$$

[58] A. G. Sharpe, The Principles of Oxidation and Reduction, Royal Institute of Chemistry Monographs for Teachers Series, No. 2, London (1959).
[59] W. E. Latimer, Oxidation Potentials, Prentice-Hall, Englewood Cliffs, New Jersey (1952).
[60] A. A. Frost, J. Am. Chem. Soc. 73 (1951) 2680.
[61] E. A. V. Ebsworth, Education in Chemistry 1 (1964) 123.
[62] C. S. G. Phillips and R. J. P. Williams, Inorganic Chemistry, Oxford (1965), p. 314.

VE represents a reversible electrode potential corresponding to the free energy change (volts × 23.03 = kcal/mol) of the two nitrogen species involved according to the equation

$$HNO_3 + 2.5H_2 \rightarrow 0.5N_2 + 3H_2O$$
$$VE = (6.23 \times 23.06) = 144 \text{ kcal/mol}$$
Thus in Fig. 5, the values of *VE* in volts and their corresponding free energy values in kcal/mol are indicated for each nitrogen species, and hence the redox potential of any couple is simply the slope of the line joining the points corresponding to the two species involved.
Fig. 5. The oxidation state diagram for nitrogen in acid solution.

The greater the slope, the stronger oxidizing or reducing the couple depending on whether the slope is positive or negative. So it follows that by comparing slopes of lines one can compare oxidizing and reducing properties not only within the nitrogen series but with other elements, and it is for this reason that a group of different sloped lines representing other redox couples are included near the upper left hand corner of the figure. For example, the N_2–$N_2H_5^+$ couple will be a thermodynamically stronger reducing agent than H^+–H_2, and likewise N_2–NH_3OH^+ will be stronger than Zn^{++}–Zn. A vertical downward movement on the diagram corresponds to an increase in stability and occurs with a decomposition

reaction, e.g. $H_2N_2O_2$ decomposes readily into N_2O and H_2O. A similar situation arises in considering ammonium nitrate as the line joining NH_4^+ and nitric acid is bisected to give the position of ammonium nitrate at a point just above N_2O. The fact that N_2O can be conveniently prepared by heating ammonium nitrate is at least consistent with this observation. Thus when more than two species lie on the same line, an equilibrium is likely to result, whereas any species occurring at a convex point on the diagram should be thermodynamically unstable with respect to disproportionation into the neighbouring species.
FIG. 6. The oxidation state diagram for nitrogen in acid and alkaline solution.

Reactions in alkaline solution can also be considered, and an oxidation state diagram constructed in a similar way. Figure 6 shows the oxidation state diagram for nitrogen in both acid and alkaline solutions, and includes the volt equivalents VE and $VE(OH)$ together with corresponding free energy values for individual nitrogen species. VE and $VE(OH)$ values differ for charged species due to the reaction

$$2H_2O + 2e \rightarrow H_2 + 2OH^-$$

having a standard potential of 0.828 V on the standard hydrogen scale. This means that for fully ionized acids, the value of $VE(OH)$ will be lower than VE by 0.828 V corresponding to a decrease of 19.1 kcal/mol. For example, $HNO_3 = 6.23 - 0.828 = 5.4$ V or

$144 - 19.1 = 125$ kcal/mol, the lower value being due to the neutralization reaction which occurs when nitric acid is formed in alkaline solution:

$$HNO_3 + OH^- \rightarrow NO_3^- + H_2O$$
For weak acids, some energy is used to ionize the acid, and hence the $VE(OH)$ value will be higher than $VE - 0.828$ to the extent of $(RT/F) \ln K_a$, where K_a is the dissociation constant for a monobasic acid, i.e.

$$VE(OH) = VE - [0.828 + (RT/F) \ln K_a]$$

TABLE 13. THERMODYNAMIC FUNCTIONS AT 25°C FOR SELECTED NITROGEN SPECIES

Species	State	Formula weight	$\triangle H_f^\circ$ (kcal/mol)	$\triangle G_f^\circ$ (kcal/mol)	S° (cal/deg mol)

D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Bailey and R. H. Schumm, *Selected Values of Chemical Thermodynamic Properties*, NBS Technical Note 270-3, Washington (1968).

Bases in alkaline solution lie at slightly higher than the VE value, the increase being related to the acid dissociation constant of the conjugate acid of the base:

$$VE(OH) = VE + (RT/F) \ln K_a$$

The free energies corresponding to the $VE(OH)$ values for hydrides such as NH_3 or N_2H_4 are simply the standard free energies of formation from the elements. Clearly, neutral species such as N_2, N_2O, NO and N_2O_4 will be unaffected:

$$VE(OH) = VE$$

Thus thermodynamic data for a large number of reactions can be calculated using the oxidation state diagram in Fig. 6 together with the heats of formation, free energies of formation and entropies of selected nitrogen species listed in Table 13. However, one should not forget the limitations of thermodynamic considerations which only sort out reactions into possible or impossible and does not take into account kinetic factors, i.e. the rate at which a possible reaction occurs or how they will affect the choice between two alternative reactions.

1.6.3. Stereochemistry

In common with other neighbouring first-row elements, the maximum coordination number for nitrogen is four, and thus the only regular stereochemical arrangements that it can exhibit are tetrahedral, pyramidal, planar, angular and linear. The shapes of most nitrogen molecules can be predicted using the Sidgwick–Powell[63] approach by allowing each pair of electrons on the central atom to take up the stereochemical position of maximum repulsion irrespective of whether the electrons are involved in bonding or not. The extension of this approach by Gillespie and Nyholm[64] is also appropriate for considering distortions produced by the electrostatic interactions between lone pairs and bonds. As the electrons of a lone pair lie closer to the atomic nucleus than those in a bond, electrostatic repulsion between electron pairs will be greatest in the sequence

loan pair:loan pair > loan pair:bond pair > bond pair:bond pair

For example, the lone pair:bond pair repulsion reduces the HNH bond angle in NH_3 to $108°$ from what is initially regarded as sp^3 hybrid orbitals with tetrahedral bond angles of $109° 28'$.

Substituted ammonias of the type R_3N are in general also pyramidal. Thus molecules of the type $RR'R''N$ should have non-superposable mirror images and hence exhibit optical activity. No such optical isomers have yet been isolated because inversion can readily take place, i.e. where one isomer reverts to the other by an umbrella type of movement and the nitrogen atom crosses over from one side of the plane N' to the other N'' accompanied by the potential energy change illustrated in Fig. 7. For ammonia this potential energy barrier to inversion is only about 6 kcal/mol, and similar values would be expected for R_3N type molecules, whereas a barrier of the order of 20 kcal/mol would be necessary in order to make the rate of interconversion sufficiently slow for isolation of optical isomers to be possible[65].

[64] R. J. Gillespie and R. S. Nyholm, in *Progress in Stereochemistry*, Vol. 2 (ed. W. Klyne and P. B. D. de la Mare), Butterworths, London (1968), p. 261.

[65] R. E. Weston, *J. Am. Chem. Soc.* **76** (1954) 2645.

On the basis of this argument, one might expect all compounds containing nitrogen bonded to three groups to be pyramidal. However, in circumstances where the lone pair on nitrogen can participate in partial double bonding (π-bonding) with the neighbouring atom, even planar structures have been reported. For example, trisylylamine $(H_3Si)_3N$ is coplanar with Si–N bond lengths considerably shorter than a single bond (see section 4)[66]. Nitrogen is coplanar both in urea NH_2CONH_2 and in formamide $HCONH_2$ where the C–N bond lengths also suggest appreciable double bond character[67].
FIG. 7. Inversion of R_3N compounds.

1.7. BIOLOGICAL PROPERTIES OF NITROGEN

1.7.1. The Nitrogen Cycle

Nitrogen is found in many compounds which are vital to all forms of life including proteins, nucleic acids, co-enzymes, vitamins and hormones. Animals synthesize these complex molecules from organic intermediates available in food, while plants are able to utilize simple inorganic compounds which arise in the soil[23]. The concentration of nitrogen compounds in the soil, however, is low, and would quickly become depleted in the absence of some replenishing process involving the abundant source of the element available from the atmosphere[68]. This process whereby micro-organisms convert atmospheric nitrogen into simple nitrogen compounds on which the majority of plants can thrive is known as nitrogen fixation. The initial product of fixation is ammonia, from which further transformations can be easily rationalized.

The routes by which nitrogen pass between environment and living organisms is usually illustrated as the nitrogen cycle[69] in Fig. 8. Organisms thus play a critical role in the nitrogen cycle which maintains in the soil an adequate supply of nitrogen compounds essential to plant life. The extra addition of nitrogen compounds to the soil usually leads to both increased yields and better quality of many crops, but because nitrogen uptake is related to plant assimilation of other elements, commercial fertilizers are often compounded in definite ratios of available nitrogen, phosphorus and potassium. The choice of nitrogen compounds for use as fertilizer is quite wide, and includes ammonia, ammonium salts, nitrates, urea,

[69] J. J. W. Baker a   G. E. Allen, *The Study of Biology*, Addison-Wesley, Reading, Mass. (1967).

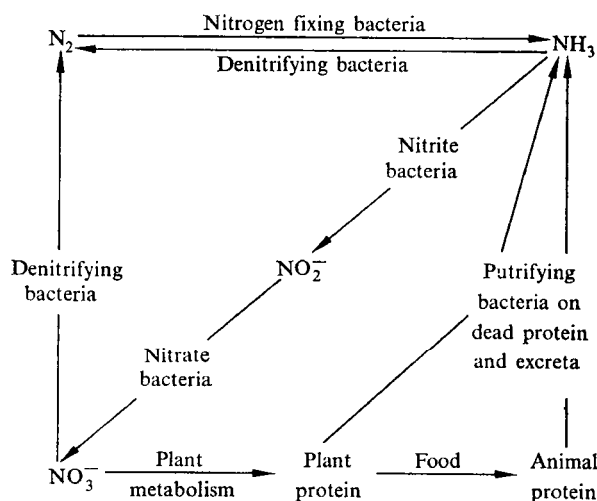
ureaform and calcium cyanamide, in a variety of physical forms as powders, crystals, pellets, prills and liquid. The actual physical form of a fertilizer is important from the view of storage and the mode of application[26].


FIG. 8. The nitrogen cycle.

With regard to nitrogen uptake, fertilization by foliar sprays is now carried out on an increasing scale, but nitrogen is usually assimilated by plants in the form of ammonium or nitrate ions through the root system. Ammonia is rather immobile in the ground being held in the soil structure as the ammonium cation and tending to be released over a prolonged period. Nitrate, on the other hand, can move freely in the soil moisture and is taken up quickly by plants, although losses by leaching can be considerable. Calcium cyanamide is hydrolysed to give ammonia as also is urea, while guanyl urea and the urea–formaldehyde condensation product known as ureaform are slow-release fertilizers. Indiscriminate use of fertilizers can deplete the soil of other essential growth factors or accumulate undesirable byproducts, which emphasizes the need to select fertilizers to meet the specific needs of the particular soil and crop combination. The currently used methods of conserving land fertility by alternating grain with legumes or combining crop rotation with livestock farming will be substituted by balanced nitrogen fertilizers to ensure continuous utilization of all arable land.

1.7.2. Nitrogen Fixation

Micro-organisms from the genera *Clostridium*, *Azobacter* and *Azotobacter*, which are normally found in the soil, are capable of performing the complete process of nitrogen fixation quite independently, as also are certain species of aerobic, anaerobic and photosynthetic bacteria, actinomyces, yeasts and blue–green algae. The only plants which can take part in nitrogen fixation are those which bear root nodules (notably the legume family) inhabited by bacteria of the genus *Rhizobium*. This association between plant and bacteria

is termed symbiosis, which means that in the presence of a fixed nitrogen source both can exist separately, but when fixed nitrogen is not available, neither can grow or fix nitrogen independently[3].

Research has been aimed at isolating the nitrogen-fixing enzyme system as cell-free extracts in a pure state[70]. It is known that the reduction of elemental nitrogen by the enzyme system nitrogenase occurs in conjunction with the related system hydrogenase to give ammonia as the product. No intermediate reduced nitrogen species have yet been isolated. The enzyme system required for nitrogen reduction involves at least two protein components which contain the elements iron and molybdenum[71], and is capable of other remarkable reductions. For example, azide can be reduced to ammonia, cyanide to methane and ammonia, and even acetylene has been reduced to ethylene. The proposed mechanisms of fixation have recently been reviewed[6] but are likely to be modified in the light of recent experience with the chemistry of nitrogen complexes (see section 2.11.3).

1.8. ANALYTICAL CHEMISTRY OF NITROGEN

The methods used in the identification, characterization and analysis of specific nitrogen compounds and ions will be discussed in each following section, and general reference will be made to the problems associated with their detection and determination in a variety of raw materials, processes and products. Thus in this section, only general principles behind the analytical chemistry of nitrogen will be indicated together with the routine methods of nitrogen determination currently used in analytical laboratories[72].

Nitrogen, and ultimately all nitrogen compounds are capable of being converted into molecular nitrogen, can be identified by its emission spectrum with a quartz spectrograph, and its purity determined by mass spectrometry. For detecting the presence of nitrogen compounds without regard to specific identification, oxidation to nitrate or reduction to ammonia followed by some suitable spot test[73] is usually adequate. Nitrogen in organic compounds is usually detected by Lassaigne fusion with sodium where the resulting cyanide is confirmed by the Prussian-blue test.

In general, the quantitative determination of nitrogen in unknown materials is also based essentially on simple conversions to nitrate, ammonia or nitrogen, which can be estimated by a range of conventional chemical analytical techniques including titrimetric[74, 75], colorimetric[76, 77], gravimetric[75] and gasometric methods[78]. However, the need to develop rapid methods for the analysis of compounds and mixtures associated with

industrial processes has required the application of physical methods based on chromato-graphy, thermal conductivity, mass spectrometry and absorption spectroscopy, the tendency being for continuous on-line analysis where possible.

The routine determination of nitrogen in organic materials is also as the element or ammonia, and the methods briefly outlined below are clearly applicable to the analysis of many nitrogen complexes of metals, organometallic derivatives, as well as some purely inorganic compounds.

The Dumas method[79] dating from 1831 is based simply on the thermal decomposition of organic material with a metal oxide in an atmosphere of carbon dioxide. The liberated nitrogen is then measured volumetrically over potassium hydroxide solution which absorbs the other combustion products and carbon dioxide carrier gas. The method is applicable with a wide range of samples, even inorganic compounds by adding some organic material such as benzoic acid, and has reached an advanced state of sophistication with the availa-bility of an automatic commercial instrument[80]. For these reasons it is generally the method of choice.

The Kjeldahl method[79, 81], although not applicable to all organic nitrogen compounds, is still widely used in fertilizer and food analysis. The method involves digestion of organic nitrogen-containing material with sulphuric acid and potassium sulphate in the presence of a catalyst (HgO) at about 350°C. The nitrogen is converted to ammonia, and remains in the acid solution as ammonium sulphate. The acid digest is diluted and then made sufficiently basic to permit quantitative distillation of the ammonia. The ammonia is absorbed in standard acid and then back titrated with standard base. Developments have also been made in automating the method using the Technicon AutoAnalyzer[82].

In the ter Meulen method[79], organic nitrogen-containing material is pyrolysed in an atmosphere of hydrogen, and the vaporized products passed over Ni–Mg catalyst at 320°C to give ammonia which can be determined titrimetrically or colorimetrically depending on the amount of nitrogen present. This method is particularly good for determining traces of nitrogen and has found application in petroleum analysis.

The chemical composition of a substance, however, is often only an initial step to characterizing a new or known compound. The way in which the investigation will subse-quently proceed depends largely on the equipment available and to some extent on the techniques in vogue at the time. Many nitrogen compounds which are stable in the gaseous or liquid phase can be identified, characterized and even analysed by the modern spectro-scopic techniques applicable in organic chemistry of infrared, ultraviolet, n.m.r., mass spectrometry and gas–liquid chromatography. Detailed structural parameters of volatile materials can also be obtained from electron diffraction and other spectroscopic techniques. The investigation of solid materials, traditionally an inorganic activity, usually relies on finding suitable solvents in which to carry out spectroscopic examinations. However, although the results of such "sporting" techniques are adequate in identifying known substances and predicting structures for new compounds, the chemist is ultimately only satisfied when he can rationalize the chemistry of the material with structural parameters from X-ray crystallography.

2. ELEMENTAL NITROGEN

2.1. DISCOVERY AND HISTORY

Although it is difficult to say who first isolated nitrogen and clearly recognized it as a definite substance, Rutherford in Scotland is generally credited with the discovery[83], although Scheele in Sweden made similar independent observations about the same time. In 1772, oxygen from air was removed by combustion, then the soluble products were dissolved out, and the remaining gas was reported to extinguish flames and destroy life. This asphyxiating gas (German *Stickstoff*), which Scheele called "foul air", was later recognized to be an element by Lavoisier who called it *azote*, meaning without life; the prefix *az* still being used in chemical nomenclature as an indication of combined nitrogen in many of its compounds, e.g. azide, hydrazine, etc.

2.2. OCCURRENCE AND DISTRIBUTION

Nitrogen constitutes 78% by volume of the earth's atmosphere. The concentration of nitrogen gas decreases with increase in distance from the surface of the earth, and it has been claimed that perceptible fractionation of the two stable isotopes occurs due to gravitation[84]. Considerable quantities of nitrogen occur in natural gas and thermal springs, and it has even been detected in the atmosphere of the planet Mars.

2.3. PRODUCTION OF NITROGEN

The three principal methods of manufacturing nitrogen[85] are the low-temperature separation of air, the chemical deoxygenation of air and the dissociation of ammonia. The preparation of synthesis gas for the production of ammonia will be discussed in section 3.3.

2.3.1. Low-temperature Separation from Air

Gaseous and liquid nitrogen are produced by air separation plants based on the low-temperature fractional distillation of liquid air[86]. Modern gas liquefaction plants are based largely on the Linde process which revolutionized the industry in the early years of this century by applying the Joule–Thompson effect.

The main stages of the process involve (i) compression of air, (ii) purification of compressed air, (iii) cooling of compressed air, (iv) liquefaction by expansion and cooling, and (v) fractional distillation.

In the diagram illustrated in Fig. 9, filtered air enters the compressor cylinder *A* and the pressure is raised to 200 atm. After carbon dioxide and water have been removed in *B*, the heat produced by rapid compression is absorbed as it passes through the heat exchanger *C*. The compressed air is then allowed to expand suddenly at the orifice *D*, where it cools rapidly due to the Joule–Thompson expansion (an isenthalpic process). This cooled air

[86] M. Sittig, *Nitrogen in Industry*, Van Nostrand, New Jersey (1965).

still at slight positive pressure enters the outer tube E surrounding the inner tube leading to D, and cools it further, producing such a low temperature that the incoming gases liquefy at D and collect in F. The cooled air leaving E can then be circulated back via the heat exchanger or direct to the cylinder, thus completing a partial cycle. The compressed air can also be liquefied in an expanding engine by an isentropic process. The liquid air is fractionated in various columns depending on whether gaseous or liquid products are required.
FIG. 9. The liquefaction of air.

Modern air separation plants operate very efficiently with a high degree of automation and are capable of producing several tons of liquid nitrogen per hour[87]. Laboratory units producing high purity liquid nitrogen at up to 4 litres per hour are also available[88].

2.3.2. Chemical Deoxygenation of Air

The obvious chemical method of removing oxygen from air is by combustion[89]. Usually the oxidizable substance is a carbonaceous material such as a hydrocarbon or coal. Quantities are calculated so that all the oxygen is converted to carbon dioxide which can be removed by scrubbing the gas under pressure with water or monoethanolamine. Residual water is removed by condensation or by passing through driers containing silica gel or activated alumina. Substantially pure nitrogen is thus obtained and used as inert atmosphere for steel- and metal-working.

2.3.3. Dissociation of Ammonia

For ammonia to be decomposed into nitrogen, the principal use of which is to prepare ammonia, must sound rather peculiar logic. However, ammonia is readily available in a pure state and reasonably cheap, and can be "cracked" directly simply by reversing the conditions required for its synthesis (see section 3.3). Ammonia at 600°C and pressures of 1–15 atm in the presence of a catalyst (usually a metal of the platinum group) is almost completely dissociated into nitrogen and hydrogen. The hydrogen can be partially or

[90] Anon., *Nitrogen*, No. 5 (1960) 38.

totally removed by combustion with air, and this can occur concurrently with the dissociation reaction to maintain the temperature. After further treatment, nitrogen can be obtained pure if required, but the process is particularly useful when a reducing atmosphere is required.

2.3.4. Other Methods

One way of physically separating air into its components without resorting to low-temperature distillation is by molecular sieve[91]. The critical diameters of the atmosphere gases nitrogen, oxygen and argon are 3.0, 2.8 and 3.8 Å respectively. As natural and synthetic zeolites can be obtained with pore channels of specific dimensions, one with a cut-off at just below 3 Å would be suitable. The method has been shown to be capable of producing nitrogen 99.25% pure, but optimum conditions gave a product containing about 10% oxygen.

Other methods which have been suggested include separation by selectively permeable films, adsorption and diffusion. All these other methods could also be applied more directly to nitrogen–hydrogen mixtures from ammonia dissociation.

2.3.5. Storage and Handling of Nitrogen[86]

Although cylinders of compressed nitrogen are convenient for small-scale and intermittent use, the trend in recent years has been more towards the handling of large quantities as liquid. Small amounts of liquid can be stored in Dewar vessels of glass or copper insulated by a vacuum. Larger quantities are contained in Horton spheres which are made up of a stainless steel inner sphere surrounded by insulation and supported in a protective carbon steel shell. Twelve ton loads of liquid nitrogen can be transported by road and delivered as either gas or liquid.

The main precautions to be observed when handling liquid nitrogen and equipment that has been in contact with it are with regard to frostbite. Care should be taken to avoid being splashed especially when immersing an object at room temperature. Precautions should also be taken to avoid large areas of liquid nitrogen to be exposed to the atmosphere since it can condense oxygen in concentrations which can become hazardous in the presence of organic material. Adequate ventilation should be ensured when large amounts of evaporating liquid nitrogen are confined to enclosed places, as oxygen content of the air can be reduced with the danger of asphyxiation.

2.4. INDUSTRIAL USES OF NITROGEN

2.4.1. Chemical Applications

The manufacture of ammonia is the most important single use of elemental nitrogen[92]. In the Haber process, nitrogen and hydrogen react at high temperatures and pressures in the presence of a catalyst according to the equilibrium

$$N_2(g) + 3H_2(g) \underset{}{\overset{\text{catalyst}}{\rightleftharpoons}} 2NH_3(g)$$
The process will be discussed in detail in section 3.3.

[91] Anon., *Chem. Week.* **92** (1963) 37.

[92] A. J. Harding, *Ammonia Manufacture and Uses*, Oxford University Press, Oxford (1959).

Important quantities of nitrogen have been used in calcium cyanamide production[93] which can be used as a fertilizer and was formerly an important route to ammonia. The Frank–Caro process involves burning limestone to produce lime which reacts with coke in an electric furnace giving calcium carbide as the main product. The finely ground carbide then reacts with pure nitrogen at 1100°C to give calcium cyanamide.

$$CaCO_3 \rightarrow CaO + CO_2$$
$$CaO + 3C \rightarrow CaC_2 + CO$$
$$CaC_2 + N_2 \rightarrow CaCN_2 + C$$

Related to this reaction is the Bucher process first described by Castner and which was formerly used for the manufacture of sodium cyanide by the reaction of nitrogen with red-hot charcoal and sodium.

$$Na_2CO_3 + 2C \rightarrow 2Na + 3CO$$
$$2Na + 2C \rightarrow Na_2C_2$$
$$Na_2C_2 + N_2 \rightarrow 2NaCN$$

The Birkeland–Eyde electric arc oxidation of atmospheric nitrogen to nitric oxide for nitric acid production was developed in Norway using low-cost hydroelectric power. At the present time, however, all such arc processes are uneconomical and obsolete. A large demonstration plant was built and operated during 1953 in an attempt to develop a direct nitrogen-fixation route to nitric oxide by the high-temperature combination of the elements in the "pebble-bed" or Wisconsin process[94], but this too proved uneconomic.

The use of nitrogen in metal nitride synthesis will be considered in section 4.2.

2.4.2. Cryogenic Applications[86, 87]

Liquid nitrogen is used in the laboratory as a convenient medium for cooling apparatus, condensing gaseous materials in vacuum apparatus, and for preparing "slush baths" by cooling a liquid to its melting point to provide a constant-temperature bath. Liquid air is no longer used in cryogenic work because of the potential inflammable and explosive hazards which can occur in the event of contamination by organic materials.

Many materials which are tough or pliable at ambient temperatures become brittle at liquid nitrogen temperatures and less likely to overheat or deteriorate during grinding operations. Other mechanical uses include shrink fitting where a slightly oversize component contracts sufficiently on cooling to −196°C to slide into position and be held firmly on expansion as it attains ambient temperature.

Liquid nitrogen is also finding increasing use in food-freezing processes and as a refrigerant for frozen and perishable foods during transit. Other modern applications are to be found in cryobiology and cryosurgery, while the largest single consumer of liquid nitrogen in the United States is the aerospace industry.

2.4.3. Inert Atmosphere Applications[86]

In the laboratory, dry nitrogen is a satisfactory substitute for argon in most of its applications as an inert atmosphere in dry boxes and glove bags. The food industry use nitrogen during preparation, packing and canning of a wide variety of food products to prevent spoilage by atmospheric oxygen. Nitrogen acts as a protective atmosphere for the

---

[93] Anon., *Nitrogen*, No. 22 (1963) 32.
[94] E. D. Ermenc, *Chem. Engng. Prog.* **52** (1956) 149.

bright hardening and annealing of steel, chilling in aluminium foundries and during arc welding. The molten tin bath used in the manufacture of float glass is also protected by nitrogen.

Chemical industries use nitrogen atmosphere either to avoid reaction with oxygen or to prevent the formation of dangerous explosive mixtures. Some examples of its application include the manufacture of reactive organic chemicals, acrylonitrile, polyamides, polyesters, lubricants and waxes. It is also used in the petroleum industry during fuel storage, polymerization processes and plastics fabrication.

Based on its properties as a non-reactive gas, nitrogen finds application as a fluidizing gas in powder technology, a propellant gas in aerosols, an inert pressure medium for liquids which are reactive with air and for the agitation of liquids.

2.5. LABORATORY PREPARATION OF NITROGEN

For most laboratory applications, nitrogen from cylinders can be used directly or after purification. However, laboratory methods of preparation may be appropriate if small quantities of high-purity nitrogen are required or when the conversion of a nitrogen compound to the element is required during an analytical procedure. Nitrogen prepared by chemical methods is free from inert gas impurities, which makes it particularly useful for spectroscopic purposes. Such methods include the following[95]:

(1) The reaction of ammonium ion and nitrite ion:

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$$
In practice, saturated sodium nitrite solution is added dropwise to hot saturated ammonium chloride solution, or saturated ammonium nitrite solution can be warmed directly.

(2) The reaction of ammonia and bromine:

$$8NH_3 + 3Br_2 \rightarrow N_2 + 6NH_4Br$$
The oxidation of ammonia is a general procedure, other oxidizing agents being dichromate (as in (3)), ozone, fluorine and manganese dioxide. Ammonia can also be thermally decomposed to nitrogen and hydrogen in the presence of a platinum catalyst.

(3) The decomposition of ammonium dichromate:

$$K_2Cr_2O_7 + (NH_4)_2SO_4 \rightarrow N_2 + Cr_2O_3 + K_2SO_4 + 4H_2O$$
The thermal decomposition of ammonium dichromate is an explosive reaction which can be controlled by the presence of sulphate, presumably as a result of slow diffusion in the solid state.

(4) The thermal decomposition of metal azides[96]:

$$2NaN_3 \xrightarrow{300°} 2Na + 3N_2$$
Sodium or barium azide can be purified by recrystallization and careful drying, and if the forerun of nitrogen produced is discarded, then spectroscopically pure nitrogen can be obtained.

2.6. PURIFICATION OF NITROGEN

Nitrogen prepared by laboratory methods from aqueous solutions may be purified by passing the gas through gas-washing bottles containing dilute sulphuric acid to remove ammonia, iron(II) sulphate solution to remove nitric oxide, chromium(II) or vanadium(II) solutions to remove oxygen, and, finally, concentrated sulphuric acid to remove water. The use of gas-washing bottles, however, tends to saturate the gas with water vapour, necessitating very efficient drying.

As most commercial sources of nitrogen are produced by the liquefaction of air, cylinders of compressed nitrogen usually contain inert gases (mainly argon), oil vapour, carbon dioxide, water and oxygen as impurities totaling not more than 0.5% depending on grade. In general, the low oxygen–low moisture grade nitrogen requires little or no purification. For most applications, the presence of inert gases is not important, but the complete removal of oxygen and water is often necessary. Water and carbon dioxide can be removed by passing the gas through Linde molecular sieve grade 4A followed by passage through a column of manganese(II) oxide supported on fireclay at 100°C to remove oxygen[97]. Oxygen can also be removed by passing the gas over copper at 400°C or preferably an active form[14] at 170°C, over a tungsten filament at 2300°C, or with hydrogen over a platinum catalyst. Any water present can be removed either by passing the gas through a trap cooled in liquid nitrogen at −196°C or through a desiccant train containing phosphorus pentoxide or anhydrous magnesium perchlorate. Small amounts of oxygen and water can be removed in one operation by bubbling the gas through a trap containing 25:75 sodium–potassium liquid alloy[95].

For spectroscopic purposes, nitrogen once purified should only be contained in closed systems previously baked out under high vacuum.

2.7. NUCLEAR ISOTOPES $^{14}N_2$, $^{14}N^{15}N$, $^{15}N_2$

Atmospheric nitrogen contains 0.365% of the heavier isotope ^{15}N, and the remaining 99.635% being the only other naturally occurring isotope ^{14}N. Thermal diffusion columns can be used to produce highly concentrated ^{15}N from nitrogen gas, but quantities produced in this way are small[98]. However, as previously mentioned (section 1.4.4), gaseous nitrogen is the form to which compounds are converted for mass-spectrometric isotope analysis, and hence the enriched material can be recovered as the element. Both $^{15}N_2$ and $^{15}N^{14}N$ are available commercially in at least 95% enriched material[99].

The mass spectrometry of N_2 has naturally received detailed attention[100], particularly in respect of calculating ^{15}N concentration from direct measurement of the ratio of masses 28:29 ($^{14}N_2^+$–$^{14}N^{15}N^+$) or 30:29 ($^{15}N_2^+$–$^{15}N^{14}N^+$). This is only possible with any accuracy because mixtures of $^{14}N_2$, $^{14}N^{15}N$, $^{15}N_2$ do not exchange isotopes at ordinary temperatures. Indeed, no evidence could be obtained for isotope exchange between $^{14}N_2$ and $^{15}N_2$ over

[97] C. C. Addison and B. M. Davies, *J. Chem. Soc.* A (1969) 1822.

[100] W. Spindel, in *Inorganic Isotopic Syntheses* (ed. R. H. Herber), Benjamin, New York (1962), pp. 81–118.

the temperature range 30–1000°C, and it was concluded that the lower limit activation energy for the exchange reaction

$$^{15}N + {}^{14}N^{14}N \rightarrow {}^{14}N + {}^{15}N^{14}N$$
must be between 14 and 31 kcal/mole[101].

The reaction of active nitrogen (see section 2.12) with labelled nitric oxide either at room temperature and 380°C yields $^{14}N^{15}N$ exclusively in amounts equivalent to the active nitrogen concentration[101]

$$^{14}N + {}^{15}NO \rightarrow {}^{14}N^{15}N + O$$
2.8. STRUCTURE AND BONDING

Solid nitrogen exists in two enantiotropic forms at atmospheric pressure with a transition point of 35.6 K [102]. At 20 K, the α form is cubic with a molecular lattice containing four molecules (internuclear distance 1.065 Å) per unit cell, whereas at 39 K β-nitrogen crystallizes in a hexagonal form. Recently, however, a third high-pressure modification γ-nitrogen has been reported to be tetragonal at 20.5 K and 4015 atm pressure[103]. Neutron diffraction indicates single neighbour distances of 1.1 Å for liquid nitrogen while gaseous nitrogen exists as a diatomic molecule with an internuclear distance of 1.097 Å as determined by microwave spectroscopy.

As the diatomic molecular structure is present in all three phases, the simplest description of the bonding in nitrogen is as three electron-pair bonds giving an octet of electrons on each atom[104]. Thus with six electrons involved in a triple bond, this leaves a lone pair at each end of the molecule ($:N \equiv N:$).

Molecular orbital theory can also supply a satisfactory description of the bonding in nitrogen which is consistent with most of its properties[105]. Molecular orbitals in their simplest form are considered to be linear combinations of atomic orbitals. This approximation is valid for valence orbitals which interact by the LCAO/MO method only if the orbitals involved have similar energies and the same symmetry, while the symmetry of the molecule requires that each molecular orbital be made up of equal contributions from the two atoms. Assuming the molecule to be lying on the z axis, the s orbitals of each nitrogen can overlap to form a σ-bonding and σ-antibonding molecular orbitals, and the p_z orbitals can do the same. The p_x orbitals of each nitrogen being perpendicular to the z axis overlap to form π-bonding and π-antibonding molecular orbitals parallel to the molecular axis. The p_y orbitals interact similarly. As each orbital is capable of containing two electrons, the electrons of nitrogen will fill the lowest energy orbitals first. Figure 10 shows the energy diagram for nitrogen, and can be summarized as

$$2[N(1s^2 2s^2 2p_x 2p_y 2p_z)] \rightarrow N_2(1s\sigma^b)^2(1s\sigma^*)^2(2s\sigma^b)^2(2s\sigma^*)^2(2p\sigma^b)^2(2p\pi^b)^4$$
The strikingly similar physical properties of the isoelectronic molecules, nitrogen and carbon monoxide, invites comparison of the bonding in view of their differing reactivity.

[105] C. J. Ballhausen and H. B. Gray, *Molecular Orbital Theory*, Benjamin, New York (1965).
FIG. 10. Molecular orbital energy diagram for nitrogen.

A point that was not mentioned in the simple molecular orbital description above was that because the s and p_z atomic orbitals belong to the same symmetry species, they can be hybridized[106]. Hybridization will give rise to two new levels, σ_1 predominantly an s orbital with some p_z character, and σ_2 predominantly p_z with some s character, whose energies indicate that the major effect of hybridization is to increase the bonding power of σ_2. The energy level diagrams are illustrated in Fig. 11.

For carbon monoxide, however, the atomic orbitals of the two atoms which form the σ-bond are not equivalent. Figure 11 shows that the σ_1 of carbon interacts with σ_2 of oxygen to form the σ bond. Consequently the lone pair of carbon in :C≡O: will be in a σ_2 orbital and have largely p_z character, while the lone pair of the oxygen atom will be in σ_1 and have largely s character.

The bond order, calculated by subtracting the number of antibonding electrons from the number of bonding electrons and dividing by two, is three for the nitrogen molecule in agreement with the triple bond obtained by the simple octet rule. This is the maximum value as either the removal of one electron from a bonding orbital to form N_2^+ or the addition of an electron to an antibonding orbital to form N_2^- gives a decrease in the bond order

[106] H. H. Jaffé and M. Orchin, *Tetrahedron* **10** (1960) 212.

from 3 to $2\frac{1}{2}$ accompanied by appropriate increases in the bond length and decreases in bond dissociation energy.

FIG. 11. Molecular orbital energy diagrams for nitrogen and carbon monoxide.

2.9. MOLECULAR CONSTANTS

Molecular constants for the nitrogen crystal modifications are tabulated in Table 14 and have been mentioned in section 2.8 in connection with bonding.

The principle source of molecular data is from spectroscopy[107]. Although the selection rule requires a change in dipole moment for infrared and microwave spectra to be observed,

[107] R. F. Barrow and A. J. Merer, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part 2, Longmans, London (1967), p. 454.

TABLE 14. MOLECULAR CONSTANTS OF THE NITROGEN MOLECULE[102,103]

Crystal modification	α-nitrogen	β-nitrogen[a]	γ-nitrogen
Range of stability	< 35.6 K	> 35.6 K	> 3500 atm
Temperature and pressure of X-ray structure determination	21 K/1 atm	50 K/1 atm	20.5 K/4015 atm
System	Cubic	Hexagonal	Tetragonal
Space group	$P2, 3$	$P6_3/mmc$	$P4_2/mnm$
Symmetry	T^4	D_{6h}^4	D_{4h}^4
Lattice constants: a	5.667	3.93	3.957
c		6.50	5.109
c/a		1.654	1.29
Internuclear distance	1.065 Å		

[a] W. E. Streib, T. H. Jordan and W. N. Lipscomb, *J. Chem. Phys.* **37** (1962) 2962.
FIG. 12. Some N_2 band systems.

homonuclear molecules can always be suitably perturbed under pressure or in condensed phases. These absorptions agree with the value of the strongest Raman line at 2331 cm⁻¹ and its overtones[108]. As regards electronic spectra, however, there is no shortage of data as more band systems are known for nitrogen than for any other molecule[107,109,110], and some of these are indicated in Fig. 12.

Electronic spectra arise from the promotion of an electron from one state to another and are observed when the electron returns to the original state. Thus for each excited state, an electronic configuration can be assigned and various parameters like the equilibrium bond length can be computed.

Values for the constants of the ground state of the nitrogen molecule, for spectroscopic purposes written

$$KK(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(3\sigma_g)^2 X^1\Sigma_g^+,$$

result from the rotational analysis of the Lyman–Birge–Hopfield system and rotational and vibrational Raman spectral data:

$$G_v = 2358.07(v+\tfrac{1}{2}) - 14.188(v+\tfrac{1}{2})^2 - 0.0124(v+\tfrac{1}{2})^3$$
$$B_v = 1.9987 - 0.01781(v+\tfrac{1}{2})$$
$$r_e = 1.0976 \text{ Å}$$

The dissociation energy of N_2 has been the subject of considerable debate[109], but the value of 9.760 ± 0.005 eV, 225.1 kcal/mol is now well established.

Three Rydberg series are known[107], the band heads being represented by the following equations.

The Worley–Jenkins series converging on $X^2\Sigma^+$ of N_2^+.

$$X\text{–}X: KK(\sigma_g)^2(\sigma_u)^2(\pi_u)^4(\sigma_g)(np\sigma_u), \ ^1\Sigma_u^+$$
$$v_m = 125\,666 - R[m + 0.3450 - 0.1000/m - 0.100/m^2]^2 \qquad m = 2, 3, \ldots, 26$$

Worley's third series, converging on $v = 1$ of $A^2\Pi_{\frac{1}{2}}$.

$$A\text{–}X: KK(\sigma_g)^2(\sigma_u)^2(\pi_u)^3(\sigma_g)(ns\sigma_g)^2, \ ^1\Pi_u$$
$$v_m = 136\,607 - R/[m - 0.0441 - 0.018/m]^2 \qquad m = 2, 3, \ldots, 6$$

The Hopfield series, which converges on $B^2\Sigma^+$.

$$B\text{–}X: KK(\sigma_g)^2(\sigma_u)(\pi_u)^4(\sigma_g)^2(ns\sigma_g), \ ^1\Sigma_u^+$$
$$v_m = 151\,240 - R/[m - 0.092]^2 \qquad m = 3, 4, \ldots, 10, \quad R = 109\,735 \text{ cm}^{-1}$$

Five electronic states of the nitrogen molecule ion N_2^+ are known, $X^2\Sigma_g^+$, $A^2\Pi_u$, $B^2\Sigma_u^+$ $D(^2\Pi_g)$ and $C^2\Sigma_u^+$, and all the allowed transitions between these states have been observed[107].

[108] B. P. Stoicheff, *Adv. Spectrosc.* **1** (1959) 91.

[109] A. G. Gaydon, *Dissociation Energies and Spectra of Diatomic Molecules*, 3rd edn., Chapman & Hall, London (1968), p. 184.

The dissociation energy of N_2^+ ($X^2\Sigma_g^+$) has been calculated from the ionization potential of nitrogen and is related to the dissociation energy of N_2 by the equation

$$D_0(N_2^+) = D_0(N_2) + IP(N) - IP(N_2)$$
$$D_0(N_2^+) = 9.760 + 14.545 - 15.58$$
$$D_0(N_2^+) = 8.73 \pm 0.01 \text{ eV, } 201.4 \text{ kcal/mol}$$
$$r_e(N_2^+) = 1.118 \text{ Å}$$

2.10. PHYSICAL PROPERTIES

Physical constants for molecular nitrogen are given in Table 15 together with some specific values for temperature variable parameters while properties which are described by equations are listed in Table 16.

The adsorption of nitrogen[102] is being mentioned under physical properties although this is not intended to presume what mode of interaction between nitrogen and the adsorbent might be. Indeed, the terms physisorption and chemisorption were intended to indicate the ease or difficulty of removal of an adsorbate from an adsorbent surface, and are only adequate in describing extreme situations. Originally, the adsorption of nitrogen by various substances was a means of determining surface properties of the adsorbent, and useful in characterizing high surface-area materials. A variety of materials have been studied in this context, including silica gels, glass, carbon, minerals, salts, metal oxides and metals. In physisorption and surface area studies, nitrogen has given way to monatomic argon, but it is the sorption of nitrogen on metals that commands the interest from a catalytic viewpoint. The infrared absorption of nitrogen chemisorbed on a nickel surface[111] at 2202 cm⁻¹ is only ca. 100 cm⁻¹ lower than the Raman active band of nitrogen itself, and suggests that only one end of the nitrogen molecule is bonded to the adsorbent. Field emission microscopy has been used to study nitrogen adsorption on metal tips[112]. For iron, the nitrogen molecules are aligned with their axes perpendicular to the 111 face, and at 400–500°C it has been estimated that the heat of chemisorption to iron approximates to the heat of formation of iron nitride[113].

2.11. CHEMISTRY AND CHEMICAL PROPERTIES

2.11.1. Reactions of Nitrogen with the Elements

It is appropriate that the reaction of nitrogen with the first element of the Periodic Table, hydrogen, is the basis of nearly all nitrogen chemistry. Suffice it to mention here that the reaction to produce ammonia only proceeds at an appreciable rate at elevated temperatures and pressures in the presence of a catalyst (see section 3.3.1). Lithium is one of the few elements to enter into reaction with nitrogen at room temperature, but the formation of lithium nitride proceeds smoothly at elevated temperatures[114]:

$$6Li + N_2 \rightarrow 2Li_3N$$

[114] C. C. Addison and B. M. Davies, *J. Chem. Soc.* A (1969) 1822.

Although the other alkali metals also form nitrides, no reaction occurs between nitrogen and the element. Beryllium and the alkaline earth metals all react with nitrogen at elevated temperatures forming nitrides. Boron, aluminium, silicon and germanium also react with

nitrogen at high temperature to give nitrides, whereas cyanogen[115] ($N \equiv C — C \equiv N$) is formed when nitrogen reacts with incandescent coke. Of the transition metals, scandium, yttrium, the lanthanide elements, zirconium, hafnium, vanadium, chromium, molybdenum, tungsten, manganese, thorium, uranium and plutonium all react with nitrogen at elevated temperatures to form nitrides of the general formula MN [116, 117].

Reactions also occur between nitrogen and mixtures of elements. For example, hydrogen, carbon and nitrogen react slowly at temperatures above 1900 K to give hydrogen cyanide:

$$C(s) + \tfrac{1}{2}H_2(g) + \tfrac{1}{2}N_2(g) \rightarrow HCN(g)$$

This reaction is thought to have been associated with basic life processes[84] in connection with the equilibrium

$$NH_3(g) + C(s) \rightleftharpoons HCN(g) + H_2(g)$$
Many metal nitrides are also formed when metals react with ammonia[117] under conditions of temperature and pressure at which ammonia is at least partially dissociated.

2.11.2. Reactions of Nitrogen with Compounds

One might have expected the scope of reactions between nitrogen and compounds to be somewhat wider in view of the selection of reagents available, but until recently this was not

[115] T. K. Brotherton and J. W. Lynn, Chem. Rev. 59 (1959) 841.
[116] Handbook of Physicochemical Properties of the Elements (ed. G. V. Samsonov), Oldbourne, London (1968).
[117] R. T. Sanderson, Chemical Periodicity, Reinhold, New York (1960), p. 201.

so. One of the earliest reactions of nitrogen to be put to commercial use was the reaction with calcium carbide[118]:

$$CaC_2 + N_2 = CaCN_2 + C; \qquad \Delta H(298 \text{ K}) = -72.7 \text{ kcal/mol}$$

After heating to 700°C to initiate, the reaction is self-sustaining at 1100°C. Similarly, another feasible route to ammonia after hydrolysis of the product was the alkali cyanide process[119]

$$Na_2CO_3 + 4C + N_2 \xrightleftharpoons{\text{Fe catalyst}} 2NaCN + 3CO; \qquad \Delta H(298 \text{ K}) = 138.5 \text{ kcal/mol}$$
There are also a few organic reactions in which nitrogen is involved; for example, a nitrogen-containing product is obtained when the benzene–sulphenium cation is generated in the presence of nitrogen[120]:

$$C_6H_5S^+ + N_2 \rightarrow [C_6H_5SN_2^+]$$
The exchange of labelled nitrogen with diazomethane has also been reported[121]:

$$CH_2N_2 + {}^{15}N_2 \rightarrow CH_2{}^{15}N_2 + N_2$$
Reactions of nitrogen with organometallic species were first reported[122,123] in 1964, and their investigation has continued with a view to establishing a basis for the catalytic fixation of nitrogen. In the Volpin reaction, nitrogen reacts at room temperature and modest pressures (< 150 atm) with a two-component system consisting of a transition metal halide (i.e. $TiCl_4$, $CrCl_3$, WCl_6) and an organometallic reagent (RLi, RMgX, R_3Al, etc.) in an organic solvent. In general, the reaction product is not isolated, but hydrolysed to ammonia in yields approaching 2 mole/mole of transition metal. Various mechanisms have been proposed[123], but all refer to the organometallic reagent as the reducing agent responsible for producing the transition metal in a low oxidation state.

Van Tamelen has reported 10–15% yields of ammonia without recourse to hydrolysis[124]. Titanium tetrachloride was added to potassium *tertiary* butoxide in diglyme under nitrogen to give bis(*tertiary*-butoxy)titanium dichloride.

$$TiCl_4 + 2Bu^tOK \xrightarrow{N_2} TiCl_2(OBu^t)_2$$
Addition of two moles of potassium resulted in the reduction of titanium(IV) to titanium(II) together with the slow evolution of ammonia over a period of several weeks. Recently, however, the fixation and reduction of nitrogen was achieved at room temperature and atmospheric pressure in an overall catalytic fashion[125].

Thus the overall process is expressed by the equation

$$N_2 + 6e^- + 6ROH \rightarrow 2NH_3 + 6OR^-$$
2.11.3. Molecular Nitrogen Adducts

(a) Synthesis

Undoubtedly the most exciting area of nitrogen chemistry at present is the work on nitrogen complexes of transition metals. It is well known that both iron(II) and molybdenum(V) are involved in the enzyme system responsible for natural nitrogen fixation (see section 1.7), and although it has been assumed by some that an initial stage in the fixation process might involve complex formation of the nitrogen molecule with the transition metal[123], until quite recently no such model compounds were known. In contrast to the forcing conditions required for combination with most elements, it is remarkable that molecular nitrogen can react with suitable substrates at ambient temperature and pressure to form stable adducts analogous to the complexes of the isoelectronic ligand carbon monoxide.

As with so many new discoveries, however, the first and several subsequent nitrogen complexes were obtained while pursuing other aims and were clearly not anticipated in those experiments where nitrogen was intended as an inert atmosphere. In 1965 Allen and Senoff were attempting to devise simple methods for the preparation of ruthenium amines when they found that hydrazine hydrate with potassium pentachloroaquaruthenite(III) or commercial ruthenium trichloride gave salts of yellow nitrogenpentamineruthenium(II)[126].

$$K_2[Ru^{III}Cl_5(H_2O)] + N_2H_4 \cdot H_2O \rightarrow [Ru^{II}(NH_3)_5N_2]X_2 \quad X = Cl, Br, I, BF_4, PF_6$$
or   RuCl_3
The general formula of these complexes was proposed after taking into account their magnetic, conductivity, spectroscopic, analytical and chemical properties[127]. Of particular importance was the assignment of a very sharp infrared band in the region 2100–2170 cm^{-1} to the nitrogen–nitrogen stretching frequency, and this band appears to be characteristic for such complexes.

The following year, Collman and Kang reported[128] the preparation of chloronitrogenobis(triphenylphosphine)iridium(I)[129] from the reaction of Vaska's iridium compound and an acyl azide:

129 Available from Strem Chemicals Inc., 150 Andover St., Danvers, Mass. 01923, USA.

The first cobalt derivative was prepared by reacting cobalt acetylacetonate with diethyl-aluminium ethoxide in an atmosphere of nitrogen[130]:

$$Co(acac)_3 + 3Et_2AlOEt + 3Ph_3P + N_2 \rightarrow CoH(N_2)(PPh_3)_3$$
As no metal–hydrogen stretching frequency could be detected in the infrared spectrum, the product was initially formulated incorrectly as the nitride complex. An independent investigation using triisobutylaluminium reported a mixture of the nitride and the hydride/nitride complex[131]. The presence of hydride was confirmed by proton n.m.r.[131], and also when Sacco and Rossi discovered the equilibrium which can be quantitatively displaced in either direction under the conditions of room temperature and atmospheric pressure simply by changing the atmosphere[132].

$$CoH_3L_3 + N_2 \rightleftharpoons CoH(N_2)L_3 + H_2 \qquad L = PPh_3, PEtPh_2$$
More recently, the reaction of π-cyclo-octenyl-π-cyclo-octa-1,5-diene cobalt with tertiary phosphines under hydrogen and subsequently with nitrogen gives the complexes via the following equilibria[133]:

$$Co(C_8H_{13})(C_8H_{12}) + 2L \rightleftharpoons Co(C_8H_{13})L_2 + C_8H_{12}$$
$$Co(C_8H_{13})L_2 + L \rightleftharpoons [Co(C_8H_{13})L_3] \rightleftharpoons CoHL_3 + C_8H_{12}$$
$$CoHL_3 + N_2 \rightleftharpoons CoHN_2L_3$$
$$L = PPh_3, PMePh_2, PEtPh_2, PBuPh_2, PEt_2Ph, PBu_2Ph, PBu_3$$

Harrison and Taube investigated the behaviour of reduced solutions of ruthenium(III) in an atmosphere of nitrogen and characterized a binuclear ion[134]:

$$[Ru(NH_3)_5Cl]^{2+} \xrightarrow[\text{0.1 M } H_2SO_4]{\text{Zn/Hg}} [Ru(NH_3)_5H_2O]^{2+}$$

with vertical pathway labeled N_2, 10^{-3} M soln., Zn removed, leading to:

$$[Ru(NH_3)_5N_2]^{2+} \xleftarrow{\text{NH}_4\text{OH}} \tfrac{1}{2}[(NH_3)_5RuN_2Ru(NH_3)_5]^{4+}$$

The binuclear complex shows no absorption in the region of the infrared spectrum associated with the $N \equiv N$ stretching frequency but does exhibit a strong band in the Raman spectrum at 2100 cm^{-1} which shifts to 2030 cm^{-1} in the $^{15}N_2$ analogue[135], and is consistent with the predicted symmetrical structure[134]. A similar isotopic shift from 2145 to 2080 cm^{-1} has also been observed for the $^{14}N_2$ and $^{15}N_2$ complexes of $[Ru(NH_3)_5N_2][BF_4]_2$ [136].

Nitrogen complexes of osmium have now been prepared by hydrazine hydrate[137] and zinc amalgam[138] reduction methods, while iron compounds are formed via hydride

L = PMePh$_2$, PMe$_2$Ph, Ph$_2$PCH$_2$PPh$_2$, Ph$_2$PCH=CHPPh$_2$, $\frac{1}{2}$(Ph$_2$PCH$_2$CH$_2$PPh$_2$)

$$ReCl_2(PMe_2Ph)_4 \xrightarrow[\text{N}_2/\text{THF}]{\text{Zn/Hg}} trans\text{-}[ReCl(N_2)(PMe_2Ph)_4]$$

The first dinitrogen complex cis-[Ru en$_2$(N$_2$)$_2$][BPh$_4$]$_2$ was prepared by hydrazine reduction[142], and more recently infrared evidence has been presented[143] for the existence of [Ru(NH$_3$)$_4$(N$_2$)$_2$]Br$_2$.

(b) *Structure and Bonding*

The first molecular nitrogen complex to be prepared, [Ru(NH$_3$)$_5$(N$_2$)]Cl$_2$, has a disordered crystal, which means that the N$_2$ ligand randomly occupies any of the six octahedral positions around ruthenium in the unit cell[144]. Thus the X-ray structure determination showed ruthenium apparently surrounded by six ligands, each comprising five-sixths

NH_3 and one-sixth N_2 as illustrated in Fig. 13. Nitrogen is collinear with the metal within the error imposed by disorder, but no accurate bond lengths could be measured.

Fortunately, an X-ray structure determination has been completed on $CoH(N_2)(PPh_3)_3$ (Fig. 14)[145]. The structure is a trigonal bipyramid with the vacant site (due to low diffracting power of hydrogen) *trans* to the N_2 group.

The parameters for two independent molecules were reported although the differences were not regarded as significant. Co—N—N is linear, while Co—N is comparable with Co—C for cobalt carbonyl compounds but significantly shorter than a typical Co—N bond distance of 1.96 Å in various cobalt amines. The N—N distance of 1.11 Å is comparable to 1.0976 Å in gaseous N_2 and 1.118 Å in N_2^+.

Prior to the formation of nitrogen complexes, attention was often drawn to the similarities in the physical properties of nitrogen and carbon monoxide, and in general the differences in the molecular orbital description of the bonding in the two molecules were regarded as significant in accounting for the marked variation in chemical reactivity[106]. Now that nitrogen complexes have been shown to have structural similarities with metal carbonyl derivatives, the simplest description of the bonding between nitrogen and the metal is exactly analogous to the situation in metal carbonyls, viz. the formation of a σ bond by donation of the lone-pair of electrons on one of the nitrogen atoms to a vacant orbital on the metal together with a π bond formed by the back donation of electrons from d orbitals on the metal to an empty antibonding π orbital on the nitrogen molecule. In carbon monoxide, the highest filled orbital contains the lone pair on the carbon atom which has predominantly p character and able to form a directional bond to metals. In nitrogen, however, the lone-pairs lie in σ orbitals of low energy similar to that of the oxygen atom in carbon monoxide, and are concentrated largely between the atoms[106]. Thus with the σbonding of nitrogen to the metal so ineffective, clearly the major contribution to the stability of nitrogen complexes must therefore be due to back-bonding from the metal into the lowest empty antibonding π orbital.

Consistent with this description of the bonding is the infrared spectral data. All mononuclear nitrogen complexes so far prepared have a strong sharp absorption band in the region 1919–2220 cm^{-1}, assigned to the nitrogen–nitrogen stretching frequency[123]. The absorption is sometimes split in solid phase spectra, but appears as a singlet for solutions. This range of values is lower than the Raman stretching frequency of 2330 cm^{-1} for molecular nitrogen, and suggests a slightly lower bond order in the complexes. Further lowering of the stretching frequency is observed for the binuclear complex $[(NH_3)_5RuN_2Ru(NH_3)_5]^{4+}$ consistent with increased π-bonding of the type Ru$\rightarrow$N$\equiv$N$\leftarrow$Ru, and an increase for the dinitrogen complex cis-$[Ru(en)_2(N_2)_2]^{2+}$ at 2220 and 2190 cm^{-1} over the mononitrogen complex at 2130 cm^{-1} suggests that these systems have to share the π-bonding ability of the metal.

(c) *Properties*

The properties so far examined have been mainly concerned with the characterization of these compounds as molecular nitrogen complexes. However, the incentive to find a simple transition metal complex to catalyse the reaction of atmospheric nitrogen with some hydrogen source (preferably water) to produce ammonia (comparable perhaps to the alchemist's search for philosophers stone) has restricted somewhat the field of investigation to reactions with reducing agents.

Although there have been several reports of molecular nitrogen complexes being reduced to ammonia, these have been shown by careful re-investigation to be due to the presence of impurities[146]. The reducing agents investigated to date (1969) have failed to reduce the

146 J. Chatt, R. L. Richards, J. R. Saunders and J. E. Fergusson, *Nature* **221** (1969) 551.

nitrogen molecule ligand in currently known complexes to ammonia, although perhaps even when it is achieved there may be some reluctance to rush into print.

The principal reactions that have been encountered so far lead to removal of the nitrogen ligand as molecular nitrogen or ligand exchange reactions[123,127], but no doubt a considerable chemistry awaits investigation.

2.12. ACTIVE NITROGEN

The glowing gas produced when an electric discharge is passed through molecular nitrogen at low pressure (0.1–2 mm) is commonly known as active nitrogen[102,147,148]. The name arises as a consequence of its high chemical reactivity when compared with ordinary nitrogen which may be attributed to the presence of ground state $N(^4S)$ atoms. These atoms have a relatively long lifetime as recombination involves a three-body collision:

$$N(^4S) + N(^4S) + M \xrightarrow{k} N_2 + M$$
If M is a surface, k is the first order rate constant for heterogeneous recombination, and this mechanism may predominate at nitrogen pressures below 3 torr in systems of low atom concentration. Where M represents atomic or molecular nitrogen, a termolecular homogeneous association reaction, second order in active species, largely describes the rate of decay of active nitrogen above 3 torr. Both reactions are partially responsible for producing excited molecular states, and it is these excited molecules returning to the ground state that give rise to the emission of the first positive band system of the molecular nitrogen spectrum in the Lewis–Rayleigh afterglow:

$$N_2(B^3\Pi_g) \rightarrow N_2(A^3\Sigma_u^+) + h\nu$$

The nitrogen atom content of active nitrogen may be estimated from its reaction with nitric óxide by following visually the colour changes in a sequence of chemiluminescent association reactions which are known collectively as the "NO titration". With no added nitric oxide, activε nitrogen in a flow system emits the characteristic yellow afterglow downstream from the discharge.

$$N(^4S) + N(^4S) \xrightarrow{M} N_2^* \rightarrow N_2 + h\nu \quad \text{(yellow emission)} \tag{1}$$

Addition of NO at flow rates less than the available concentration of $N(^4S)$ atoms in the active nitrogen stream results in the very fast reaction

$$N(^4S) + NO \rightarrow N_2 + O(^3P) \tag{2}$$
The oxygen atoms so formed may react with excess atomic nitrogen to produce excited nitric oxide molecules which emit the blue-coloured β and γ bands of NO:

$$N(^4S) + O(^3P) \rightarrow NO^* \rightarrow NO + h\nu \quad \text{(blue emission)} \tag{3}$$

With relatively small amounts of NO, reaction (3) occurs simultaneously with reaction (1), and the gas stream appears purple. When the flow rate of NO exceeds that of $N(^4S)$, reaction (2) being the fastest, eliminates all nitrogen atoms, hence reactions (1) and (3) are

[147] A. N. Wright and C. A. Winkler, *Active Nitrogen*, Academic Press, New York (1968).
[148] K. R. Jennings and J. W. Linnett, *Quart. Rev.* 12 (1958) 116.

no longer possible. Instead, excited nitrogen dioxide is formed which emits the greenish-yellow NO_2 bands associated with the "airglow":

$$NO + O(^3P) \rightarrow NO_2^* \rightarrow NO_2 + h\nu \quad \text{(greenish-yellow)} \tag{4}$$

When NO is added at a flow rate equivalent to that of atomic nitrogen, both NO and $N(^4S)$ atoms are destroyed, and the slow light-producing association reactions (1), (3) and (4) cannot occur; hence no light is emitted. Thus, as the flow rate of NO is slowly increased, the colours change progressively through yellow, purple, blue, darkness and greenish yellow. Hence the flow rate of NO at the dark "end point" gives a measure of the concentration of $N(^4S)$ in the active nitrogen. The results of this relatively simple method agree well with estimations by other techniques[147].

The reactions of active nitrogen, however, not only involve nitrogen atoms. Indeed, metastable nitrogen molecules formed by three-body recombination reactions are capable of dissociating gases which are stable to direct attack by nitrogen atoms[149]:

$$N_2(A^3\Sigma_u^+) + CO_2(^1\Sigma_g^+) = N_2(X^1\Sigma_g^+) + CO(^1\Sigma_g^+) + O(^3P)$$
$$N_2(A^3\Sigma_u^+) + H_2O(^1A_1) = N_2(X^1\Sigma_g^+) + OH(^2\Pi) + H(^2S)$$

Although a number of chemical reactions of active nitrogen with other elements have been reported, the majority tend to result in the formation of nitrides. Even the reactions with hydrocarbons and organometallics are uneventful, and metal carbonyls generally only give rise to the emission spectra of the metal atoms. Recently, however, aqueous active nitrogen has been prepared, and its versatility as a reagent demonstrated[150] by the transformations $Fe^{II} \rightarrow Fe^{III}$ and $Fe^{III} \rightarrow Fe^{II}$ in 0.05 M H_2SO_4, $I^- \rightarrow I_3^-$ in neutral solution and $Ce^{IV} \rightarrow Ce^{III}$ in 0.5 M H_2SO_4.

Active nitrogen has also been encountered in other ways. Atomic ^{13}N was produced by the $^{12}C(d, n)^{13}N$ reaction using a 7 MeV deuteron beam on a carbon dioxide source[151]. The nitrogen produced was allowed to react with CO_2–N_2 mixtures at atmospheric pressure and the products analysed by radio-g.l.c. The product spectrum was explained by the following reaction scheme:

$$^{13}N^* + CO_2 \rightarrow {}^{13}NO + CO$$
$$^{13}N^* + N_2 \rightarrow {}^{13}NN^* + N$$
$$^{13}NN^* + CO_2 \rightarrow {}^{13}NNO + CO$$
$$^{13}NN^* + M \rightarrow {}^{13}NN + M^*$$

2.13. BIOLOGICAL PROPERTIES[152]

Although nitrogen is a vital element to all life, it cannot be assimilated by the higher animals nor by the majority of plants from its most abundant source as molecular nitrogen (see section 1.7). To mammals, atmospheric nitrogen is just a convenient inert carrier gas for respiratory oxygen and expiratory carbon dioxide. However, exposure to high-pressure air causes some nitrogen to dissolve in the blood and other body fluids. At very high pressures, nitrogen has a narcotic effect, apparently due to removal of oxygen from the nervous tissues. If the pressure is suddenly lowered, the dissolved nitrogen forms bubbles

[152] F. Call, in ref. 85, pp. 567–615.

which are released in the body, and can cause pains in the muscles and joints, partial paralysis, fainting and eventually death. Much attention has been paid to the problem of "diver's bends", and slow decompression is always practised by underwater swimmers.

Nitrogen, unlike isoelectronic carbon monoxide, is not toxic, but in high concentrations it is an asphyxiant. It is the principal constituent of "blackdamp" (87% N_2, 13% CO_2), a well-known hazard in coal-mines, but similar situations can be encountered in enclosed spaces where liquid nitrogen has been allowed to evaporate.

## 2.14. ANALYTICAL CHEMISTRY OF MOLECULAR NITROGEN[153, 154]

Nitrogen can generally be detected in any gaseous mixture with a quartz spectrograph without preliminary separation. This technique is also applicable for the determination of nitrogen in solids and in solutions by sparking under reduced pressure. The presence of larger amounts of nitrogen can be indicated by heating with magnesium:

$$3Mg + N_2 \rightarrow Mg_3N_2$$
Magnesium nitride is greenish yellow in colour, and is readily decomposed by water to give ammonia which can be identified by its odour or by a chemical test:

$$Mg_3N_2 + 6H_2O \rightarrow 2NH_3 + 3Mg(OH)_2$$
The determination of molecular nitrogen is most often encountered in connection with furnace or dry-box atmospheres and only occasionally as a product of reaction. In mixtures of gases, nitrogen is usually determined by difference after the other gases have been absorbed. The presence of inert gases would lead to high results; however, in such cases one would need to resort to absorbing nitrogen. One such method is the quantitative absorption by calcium carbide to form calcium cyanamide at 800°C.

$$CaC_2 + N_2 \xrightarrow{800°C} CaCN_2 + C$$
Small amounts of nitrogen in the presence of other gases have been estimated by mass spectrometry, which is also used to detect and determine the impurities in cylinder nitrogen. Nitrogen dissolved in metals can be released by vacuum fusion techniques and, after removal of impurities, measured volumetrically.

3. AMMONIA

3.1. HISTORY OF AMMONIA

The penetrating odour of ammonia was known even in prehistoric times and was originally encountered in connection with ammonium chloride from urine and other animal wastes. Later, ammonia solutions were the only well-known soluble base, and were used in the fulling and dyeing of wool[155]. Notable dates in the history of ammonia were: 1661

[153] A. J. Clear and M. Roth, in *Treatise on Analytical Chemistry*, Part II, Section A, Vol. 5 (eds. I. M. Kolthoff and P. J. Elving), Interscience, New York (1961), p. 217.

[154] K. I. Vasu, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part 2, Longmans, London (1967), pp. 563–673.

[155] J. W. Mellor, *Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, *Nitrogen*, Longmans, London (1928), Section 14.

when Boyle realized that ammonium chloride was composed of ammonia and hydrogen chloride; 1774 when Priestley distilled ammonium chloride with lime and collected ammonia over mercury; and 1785 when Berthollet decomposed ammonia by electric spark into its constituent elements and determined its stoichiometric composition. The early nineteenth century saw the production of ammonia liquor as a byproduct of the coal-gas industry[156] followed by development of synthetic routes to ammonia in the beginning of the twentieth century[157].

3.2. OCCURRENCE OF AMMONIA

Ammonia was believed to be present in the atmosphere during the early stages of the earth's evolution, but it is now thought that nitrogen and carbon dioxide predominated[156]. Ammonia can be detected in air, rain, snow, etc., originating from the immense quantities of ammonia which are constantly formed in nature by putrefaction of the protein from dead plants, animals and micro-organisms. Rivers and sea water may also contain appreciable amounts, particularly near the sea-bed as ammonium salts are found in the deposits obtained after evaporation of sea water[158]. The nitrogen-containing compounds in coal and oil are thought to originate from similar sources.

3.3. PRODUCTION OF AMMONIA

3.3.1. Synthetic Production from the Elements[159-162]

Virtually all ammonia is produced industrially by the reversible reaction between hydrogen and nitrogen at elevated temperatures and pressures in the presence of a catalyst according to the equation

$$N_2(g) + 3H_2(g) \xrightleftharpoons{\text{catalyst}} 2NH_3(g); \qquad \Delta H(298 \text{ K}) = -22.08 \text{ kcal/mol}$$
Although Nernst and Yost[163] were the first to measure the improvement in the equilibrium yield under pressure, this process was developed by Haber[164] between the years 1905 and 1913, and illustrates how the application of thermodynamic principles can result in a major industrial process. Consider Le Chatelier's principle as applied to this equilibrium; the formation of ammonia will be favoured by high pressures (a consequence of the decrease in volume accompanying the formation of product from reactants) and low temperatures (a result of the exothermic nature of the reaction). However, when the temperature is lowered the rate at which the corresponding equilibrium mixture is attained also decreases.

Haber realized that the way to maintain an acceptable rate of equilibrium while keeping the temperature low enough to produce reasonable equilibrium concentrations of ammonia was to employ a catalyst. Finely divided iron containing one or more "promoters" was eventually found to be a most effective catalyst[165].

Many ammonia production plants have been built over the years throughout the world[166]. Probably no two plants are identical, but they are all in principle similar to the original Haber–Bosch process. What has changed dramatically, however, is the scale of operation, with the largest plants at present on stream being capable of producing 1500 tons of ammonia per day[167]. Such advancement represents major developments in the scale-up of high-pressure reactions and solution of the accompanying chemical engineering problems. For the purpose of considering the chemical basis of the main stages in ammonia production, the overall process can be described quite generally as in Fig. 15.

Production of hydrogen and nitrogen

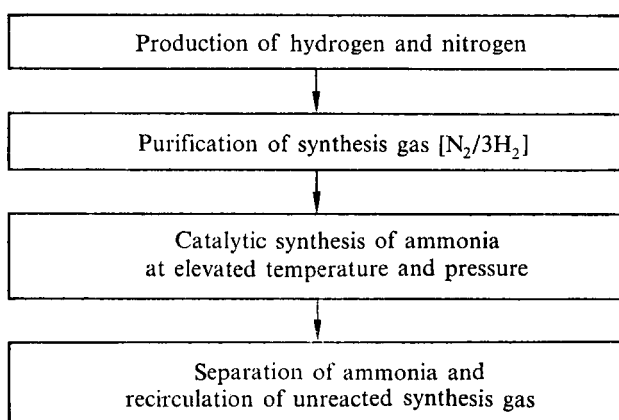

FIG. 15. General scheme for the production of ammonia.

(a) *Sources of Nitrogen and Hydrogen and Purification*

The mixture of hydrogen and nitrogen used as feedstock in the Haber process is appropriately known as synthesis gas, and for the successful operation of the process it is necessary that the mixture be of high purity. The only source of nitrogen is the atmosphere, from which it is obtained in a pure form either from the fractionation of liquid air[168] or the chemical deoxygenation of air[160]. Hydrogen may be available as a byproduct of some other process (such as catalytic cracking of petroleum naphtha in the production of petrol[160]) or from the electrolysis of water where electricity is cheap[167]; but when it is required specifically for ammonia synthesis, it is usually produced from hydrocarbon and carbonaceous fuels.

168 M. Sittig, *Nitrogen in Industry*, Van Nostrand, New Jersey (1965).

The incomplete combustion of a fuel such as coal, coke or charcoal gives "producer gas", the approximate composition of which is 25% CO, 70% N_2, 4% CO_2 together with smaller amounts of hydrogen, methane and oxygen. "Water gas" is prepared by blowing steam over coke or anthracite at bright red heat:

$$C + H_2O \rightleftharpoons CO + H_2; \qquad \triangle H(298) = +31.38 \text{ kcal/mol}$$

The carbon monoxide from both these processes can react with steam in the "shift reaction" to give more hydrogen:

$$CO + H_2O \xrightleftharpoons{\text{catalyst}} CO_2 + H_2; \qquad \triangle H(298) = -9.84 \text{ kcal/mol}$$

Saturated hydrocarbons as found in natural gas, refinery gas and light naphtha readily decompose at high temperatures to methane which can undergo the process of steam reforming and subsequent shift reaction[159]:

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2; \qquad \triangle H(298) = +49.27 \text{ kcal/mol}$$
$$CO + H_2O \rightleftharpoons CO_2 + H_2; \qquad \triangle H(298) = -9.84 \text{ kcal/mol}$$

The heat for the endothermic steam-reforming reaction is produced by the introduction of a controlled amount of air causing partial oxidation of some of the gas stream, while at the same time providing nitrogen for the synthesis gas mixture[159]:

$$CH_4 + \tfrac{1}{2}O_2 \rightleftharpoons CO + 2H_2; \qquad \triangle H(298) = -8.50 \text{ kcal/mol}$$
$$CO + \tfrac{1}{2}O_2 \rightleftharpoons CO_2; \qquad \triangle H(298) = -63.64 \text{ kcal/mol}$$
$$H_2 + \tfrac{1}{2}O_2 \rightleftharpoons H_2O; \qquad \triangle H(298) = -57.80 \text{ kcal/mol}$$

Thus, in effect, an equilibrium mixture is created between H_2, O_2, H_2O, CO, CO_2 and CH_4, nitrogen acting only as a diluent, and conditions of temperature, pressure, catalysts, residence times, etc., are chosen so that synthesis gas contaminated only by carbon dioxide is the predominant product[160].

(b) Purification of Synthesis Gas[159, 160]

Primarily, the purification of the synthesis gas stream is in order to maintain the life of the catalyst which would be "poisoned" by the presence of sulphur compounds, water, oxygen and oxides of carbon. Thus the oxidation of carbon monoxide in the shift reaction as well as being a further source of hydrogen is a necessary part of purification. However, sulphur compounds are removed with zinc oxide even prior to carbon monoxide conversion, as they would also poison the catalysts used in the shift reaction. Ammoniacal copper(I) solution is used to scrub out traces of carbon monoxide while active charcoal has been used for subsequent absorption of organic sulphur compounds. Carbon dioxide is removed under pressure by scrubbing with water, ethanolamine or hot potassium carbonate solution.

Final traces of impurities are sometimes removed by condensation at liquid nitrogen temperature and atmospheric or higher pressure. Indeed, in a process using a feedstock rich in hydrogen (>75%), there are advantages in using a low-temperature fractionation to separate the hydrogen[160]. In plants where cryogenic purification is omitted, inert gases accompanying nitrogen from air tend to concentrate in the synthesis reactor and in effect lower the rate of reaction. This necessitates periodic venting, although this vented gas provides an excellent enriched source for the separation of inert gases.

(c) *Reaction Conditions*[159]

The principle variable distinguishing the different processes is the operating pressure, of which a few are compared in Table 17.

TABLE 17. COMPARISON OF AMMONIA SYNTHESIS PROCESSES

Process	Pressure (atm)	Temperature (°C)	Catalyst	Ammonia (%)
Haber–Bosch	300–325	530–560	Double promoted iron	13–15
Fauser–Montecatini	280–300	520–550	Promoted iron	12–14
Mont Cenis	100–160	440–480	Iron cyanide	8–10
Kellogg	150–200	500–520	Promoted iron	11–12
Casale	500–900	500	Promoted iron	18–20
Claude	1000	495–600	Promoted iron	28–30

In general, pressures of about 300 atm have been preferred, but with the largest plants it has been necessary to operate at 200 atm due to compressor limitations[160]. For a particular pressure the choice of temperature has to be within the range in which the catalyst gives high activity, usually about 500°C. This is a convenient compromise between the low temperatures desirable for a high equilibrium concentration and the higher temperatures necessary for increased reaction rate.

A third variable is the space velocity[160]. Clearly, at a constant temperature, an increase in space velocity decreases the percentage of ammonia in the exit gas, but results in a substantial increase in the amount of ammonia produced per volume of catalyst. This leads to a fourth variable because at the space velocities normally used in ammonia synthesis, the maximum amount of ammonia in the exit gas occurs at the hydrogen–nitrogen ratio of 2.5:1.0 rather than the stoichiometric ratio of 3:1.

Ammonia is condensed from the exit gas as the liquid by water cooling and/or refrigeration, and the unreacted elements are compressed and recirculated.

(d) *Catalyst Systems*[169–171]

The iron catalyst first developed by Mittasch in 1910 is still the basis of catalyst systems in current use[172]. These are prepared when iron oxide, generally in the form of magnetite (Fe_3O_4) is sintered or fused with small amounts of one or more oxides Al_2O_3, K_2O, CaO and MgO, called "promoters". The mixture is then reduced either in the converter of an ammonia plant by slow heating with synthesis gas until the plant operating temperature is reached, or pre-reduced with pure hydrogen and the resultant catalyst stabilized to render it non-pyrophoric. Both methods reduce the oxide to iron metal in a suitably divided and activated state ready for use as the active catalyst. Thus "double promotion", i.e. the

[169] *Catalyst Handbook*, ICI, Wolfe Scientific Books, London (1970).

[170] W. G. Frankenburg, in *Catalysis*, Vol. 3 (ed. P. H. Emmett), Reinhold, New York (1955), pp. 171–263.

[171] C. Bokhoven, C. Van Heerden, R. Westrik and P. Zweitering, in *Catalysis*, Vol. 3 (ed. P. H. Emmett), Reinhold, New York (1955), pp. 265–348.

[172] A. Mittasch, *Z. Elektrochem.* **36** (1930) 569.

addition to iron oxide of both an acidic or amphoteric oxide such as Al_2O_3, and an alkaline oxide such as potassium oxide, increases the activity of the resultant catalyst over that for singly promoted catalysts. It is thought that in such systems the Al_2O_3 contributes to the generation and stabilization of porosity and of large surface, whereas K_2O promotes catalytic action even though its presence may reduce the free iron surface[167].

Decrease in the activity of a catalyst is always observed over a period of time, and in order to maintain efficiency and to prolong the life of such large amounts of catalyst as are involved with a synthesis plant, the pressure, temperature, residence time, etc., are systematically varied to maintain optimum economy. However, the catalyst can deteriorate more rapidly under severe operating conditions resulting in disintegration, while permanent poisoning, e.g. with sulphur compounds, can also necessitate total replacement.

The reaction at the catalyst site is exothermic as demonstrated by the rise in temperature of the gas stream as it proceeds through the reactor. Thus it is important to dissipate the heat produced particularly by the initial reaction of synthesis gas at the catalyst bed localized near the inlet port, while towards the end of the converter where the feedstock will be somewhat diluted with product and at slightly lower pressure, the catalyst will not be used to maximum efficiency. Synthesis converters are thus designed to give even reaction conditions throughout, and any excess heat produced is recovered to pre-heat the entering synthesis gas to the operating temperature of the converter.

(e) *Reaction Kinetics*

In the reversible reaction

$$N_2 + 3H_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2NH_3; \qquad \triangle H(298) = -22.08 \text{ kcal/mol}$$
the net rate of reaction is the difference between the ammonia synthesis reaction rate k_1 and the ammonia decomposition reaction rate k_2. Equilibrium occurs when the net rate of reaction is zero, that is when $k_1 = k_2$. An increase in temperature will increase k_2 considerably and k_1 to a lesser extent because it is exothermic, while an increase in pressure will favour k_1. The effect of temperature and pressure on equilibrium volume of ammonia[173] can be seen in Table 18, related to $K_p = p_{NH_3}^2/p_{N_2} \cdot p_{H_2}^3$.

TABLE 18. VOLUME PERCENTAGE OF AMMONIA IN $N_2/3H_2$ EQUILIBRIUM MIXTURES

Pressure (atm)	Temperature (°C)					
	200	300	400	500	600	700
10	50.66	14.73	3.85	1.21	0.49	0.23
50	74.38	39.41	15.27	5.56	2.26	1.05
100	81.54	52.04	25.12	10.61	4.52	2.18
300	89.94	70.96	47.00	26.44	13.77	7.28
600	95.37	84.21	65.20	42.15	23.10	12.60
1000	98.29	92.55	79.82	57.47	31.43	12.87

173 A. T. Larsen, *J. Am. Chem. Soc.* **46** (1924) 367.

However, because these are not ideal gases, K_p does not remain constant for a given temperature and pressure above 50 atm, and the increase in the value of K_p at higher pressures indicates that the conversion is even more favourable under such conditions than would be predicted assuming perfect gases.

Emmett and Brunauer[174] first suggested that the rate-determining step in the synthesis reaction is the chemisorption of nitrogen on the surface of the catalyst. Although this step requires a considerable activation energy, the subsequent steps of hydrogenation on the surface of the catalyst and desorption of the ammonia require only small amounts of activation energy and thus occur at a fast rate. Similarly, in the decomposition of ammonia, the rapid adsorption and dehydrogenation of NH_3 on the surface of the catalyst is followed by slow desorption of nitrogen molecules from the surface of the catalyst. This hypothesis was used by Temkin and Pyzhev[175] to develop the rate equation

$$\frac{dP}{dt} NH_3 = k_1 p_{N2} \left(\frac{p_{H_2}^3}{p_{NH_3}^2} \right) - k_2 \left(\frac{p_{NH_3}^2}{p_{H_2}^3} \right)$$

The nitrogen adsorbed on the surface is in equilibrium with hydrogen and ammonia in the gas phase, and it is assumed that nitrogen adsorption is unaffected by the pressure of varying amounts of hydrogen and ammonia. The above equation was formulated with concentrations represented by partial pressures, but was later revised for use at high pressures by the introduction of fugacities and an additional correction factor[176]:

$$\frac{dP}{dt} NH_3 = k_1 f_{N_2} \left[\frac{f_{H_2}^3}{f_{NH_3}^2} \right]^\alpha - k_2 \left[\frac{f_{NH_3}^2}{f_{H_2}^3} \right]^{1-\alpha} \frac{\exp (\overline{V}_s - \overline{V}_a)P}{RT}$$

The exponent α is < 1 and is frequently taken as 0.5. $\overline{V}_s$ and $\overline{V}_a$ are the partial molar volumes of adsorbed nitrogen and of the transition state for adsorption respectively, and P is the total pressure; k_1 and k_2 are related to the fugacity equilibrium constant for the reaction by

$$k_1 = k_2 K$$

and if the exponential factor is donated by ψ, then the equation can be rearranged to give

$$r = k_2 \left[\left(\frac{K_f f_{N_2} f_{H_2}^3}{f_{NH_3}^2} - 1 \right) \left(\frac{f_{NH_3}^2}{f_{H_2}^3} \right)^{1-\alpha} \right] \psi$$

Recent evidence has confirmed that the chemisorption of nitrogen is the rate-determining step[177], that the rate of adsorption is equal to the rate of ammonia synthesis[178] and that the modified Temkin–Pyzhev equation correlates with the most recent P and T equilibrium data[179].

3.3.2. Small-scale Production of Ammonia

Compared to the scale on which the Haber process is operated, all other methods for the commercial production of ammonia are small scale. Prior to the Haber process, the principal synthetic route to ammonia was by the hydrolysis of cyanamides or cyanides.

[178] J. J. F. Scholten, J. A. Konvalinka and P. Zweitering, *Trans. Faraday Soc.* **56** (1960) 262.
[179] A. Nielsen, J. Kjaer and B. Hansen, *J. Catalysis* **3** (1964) 68.

Calcium cyanamide produced by the Frank–Caro process[168] can be hydrolysed with dilute sodium hydroxide solution in an autoclave above 100°C:

$$CaCN_2 + 3H_2O \rightarrow 2NH_3 + CaCO_3$$
Hydrolysis at 400–500°C of sodium cyanide, prepared by the Bucher process from coal, alkali and nitrogen, was considered as a potential route to ammonia even after the Haber process had become well established:

$$NaCN + 2H_2O \rightarrow HCO_2Na + NH_3$$
However, these methods are now of historic interest only.

Ammonia can be regenerated from ammonium salts simply by heating with a base. Alkaline earth metal oxides and hydroxides have been used with the naturally occurring ammonium chloride[156].

Ammonia can be released from a variety of organic waste materials. Such methods generally involve the residues of organic reactions where oxidation and hydrolysis of proteins release ammonia[156]. However, the principal source of non-synthetic ammonia is obtained when fuels such as coal, oil and peat are processed by distillation, gasification or hydrogenation[156]. Prior to the development of the Haber process, ammonia and ammonium sulphate were produced from coal as a byproduct of coke and coal-gas manufacture. Ammonia liquor collected from condensers and washers is steam distilled in the presence of lime, and the ammonia evolved is absorbed in sulphuric acid. Alternative methods of recovering ammonia simultaneously with sulphur, or as ammonium bicarbonate and phosphate, have been investigated in order to produce lower cost products[156]. Only part of the nitrogen in coal is recovered as ammonia and yields generally amount to less than 10 lb of ammonia per ton of coal. Thus with the low price of synthetic ammonia, the sale of byproduct ammonium sulphate only partially off-sets the cost of recovery.

3.3.3. Handling, Storage and Corrosion

Bulk ammonia is usually stored as cold liquid in insulated Horton spheres[161]. As the gas slowly volatilizes it can be refrigerated and returned to the tank or used directly in some ammonia-consuming process. It is transported as the liquid in cylinders or tank-wagons capable of withstanding the vapour pressure at ambient temperatures.

Although ammonia itself presents few corrosion problems, the conditions under which ammonia is prepared have required the development of special alloys for the construction synthesis reactors[162]. Liquid and gaseous ammonia can be stored or handled in equipment made from cast iron, steel, aluminium, polythene and natural or synthetic rubber. However, copper and its alloys, nickel or polyvinyl chloride should not be allowed into contact with either gaseous or liquid ammonia. Laboratory cylinder pipework and valves are best made from stainless steel.

From a safety consideration, it is not always realized that ammonia is flammable in certain concentrations in air, but since the high concentrations are seldom encountered, the relative explosion or fire hazard is small. Mercury may also react with ammonia to form explosive compounds; hence the use of mercury thermometers should be avoided. However, the greatest potential danger arises from accidental spillage or escape of ammonia leading to high concentrations which can cause severe irritation. Respirators should always be at hand in places where ammonia is handled.

3.4. USES OF AMMONIA

As the nitrogen fertilizer industry is based almost entirely on ammonia[180], its principal uses are in the production of ammonium salts (see section 5.2), and the oxidation of ammonia in the route to nitric acid and its many derivatives[181] (see section 18.3). Ammonium nitrate is related to both the fertilizer and explosive industries. Similarly, the production of urea, not only for fertilizer use but also for conversion to cyanuric acid and melamine, are new major ammonia users[159, 181].

Ammonia is used in the Solvay ammonia–soda process, where its properties as an alkaline material capable of easy regeneration finds application. Anhydrous ammonia is also used in the petroleum industry to neutralize acid constituents of oil, thus protecting the plant from corrosion without the formation of aqueous solutions or emulsions. A weak aqueous solution is also used as a household cleanser[182].

Since anhydrous ammonia can be transported as the liquid, it can be regarded as a portable source of nitrogen and hydrogen by ready dissociation, under conditions exactly the reverse to its formation.

The food and beverage industries use ammonia as nutriment in fermentation processes. The rubber industry use ammonia atmospheres for the vulcanization of certain hard rubber products, while natural and synthetic latex is stabilized during transportation and storage by ammonia[182]. The textile industry use ammonia in connection with the production of synthetic fibres such as cuprammonium rayon, and in the preparation of hexamethylene-diamine for nylon-6,6 and caprolactam for nylon-6 [181]. The applications of ammonia cannot be concluded without reference to its considerable use in what organic chemists term ammonolysis reactions, leading to cyanides, amides, amines, nitriles, dye intermediates and urea[181, 183].

3.5. LABORATORY PREPARATION AND PURIFICATION OF AMMONIA

The laboratory preparation of ammonia from ammonium salts in strongly basic solution is usually only required for analytical purposes as pure synthetic NH_3 is commercially available in steel cylinders[184]. Passage of the gas through regenerated activated charcoal is sufficient to remove minor impurities such as oil vapour and carbon monoxide. The gas is then dried by passing over soda-lime, potassium hydroxide, sodium wire, and, finally, phosphorus pentoxide. The lack of reaction with P_2O_5 can be used as the indication of successful pre-drying. The gas that boils off the blue solution of liquid ammonia containing a little sodium is also perfectly dry[185]. Gaseous ammonia can be condensed to liquid by passing through traps cooled in liquid nitrogen. Alternatively, liquid ammonia can be withdrawn from an inverted cylinder into Dewar vessels in an efficient fume cupboard.

[185] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, Vol. I (ed. G. Brauer), Academic Press, New York (1963), p. 460.
To prepare a pure carbonate-free aqueous ammonia solution, cylinder ammonia is purified through activated charcoal and soda-lime and bubbled through well-boiled water in a container protected from the atmosphere by a soda-lime tube[185].
3.6. NUCLEAR ISOTOPES $^{15}NH_3$, $^{14}ND_3$, $^{15}ND_3$

Pure dry $^{15}NH_3$ is most conveniently prepared by treating a solution of an enriched ammonium salt with excess alkali (see section 1.4.3) and drying the final product over metallic sodium[186]:

$$^{15}NH_4^+ + KOH \rightarrow {}^{15}NH_3 + H_2O + K^+$$
As most nitrogen-containing compounds can be oxidized to nitrate or nitrite, the reduction to ammonia with Devarda's alloy (50% Cu, 45% Al, 5% Zn) in alkaline solution[187] provides a general method to recover enriched nitrogen as a useful starting material $^{15}NH_3$. As an alternative, the conversion of $^{15}N_2$ into $^{15}NH_3$ can be achieved by the formation of an ionic metal nitride and subsequent hydrolysis[188]:

$$3Ca + {}^{15}N_2 \rightarrow Ca_3{}^{15}N_2 \xrightarrow{6H_2O} 2{}^{15}NH_3 + 3Ca(OH)_2$$

Similarly, ammonia-d$_3$ can be prepared by the deuterolysis of an ionic metal nitride[157]:

$$Li_3N + 3D_2O \rightarrow ND_3 + 3LiOD$$
$$Mg_3N_2 + 6D_2O \rightarrow 2ND_3 + 3Mg(OD)_2$$

The method is also convenient for preparing the doubly labelled compound[190]:

$$Ca_2{}^{15}N_3 + 6D_2O \rightarrow 2{}^{15}ND_3 + 3Ca(OD)_2$$
$^{15}NH_3$, $^{14}ND_3$ and enriched ammonium salts are all available commercially[191].

3.7. STRUCTURE AND BONDING

The Sidgwick–Powell approach[192] to molecular shape predicts ammonia to be pyramidal. This result is arrived at by considering each of the three bonding pairs of electrons between nitrogen and the hydrogens together with the lone pair residual on nitrogen as occupying positions of mutual repulsion in a tetrahedral arrangement. The Nyholm–Gillespie extension to this approach[193] further suggests that the H–N–H angle is slightly smaller than the tetrahedral angle due to the greater repulsion between the lone pair on nitrogen and the bond-pairs than between the bond pairs themselves. These predictions are borne out by the structural parameters for gaseous ammonia as obtained from spectroscopic and electron

diffraction data listed in Table 19. X-ray and neutron diffraction studies on crystalline ammonia also indicate a similar shape, but with significantly longer N–H bond lengths. Each nitrogen in the ammonia lattice has six equidistant nearest neighbour nitrogen atoms which by their position and distance indicate that the structure is further stabilized by hydrogen bonding[194].

[a] Refs. 194, 195, 198, 199.

Thus although the bond angles in ammonia are a fine balance between electrostatic repulsive forces and hybridization energies, in fact the energy difference between the pyramidal and planar arrangement is small enough (5.9 kcal/mol) for the molecule to invert[195]. Figure 16 illustrates the resultant potential energy curve with two minima corresponding to the two equivalent nitrogen positions of equilibrium either side of the hydrogen atom plane. The dotted lines represent the potential energy of non-inverting molecules. The vibrational states are split into symmetric and antisymmetric levels, the effects of which can be detected in infrared and microwave spectra.

195 C. H. Townes and A. L. Schawlow, *Microwave Spectroscopy*, McGraw-Hill, New York (1955).

Self-consistent molecular orbital calculations[196,197] on the NH_3 molecule indicate that a small transfer of electrons leaves the hydrogen more positive, and there is clearly some hybridization of the nitrogen bonding orbitals.

FIG. 16. The potential energy of ammonia as a function of the displacement of the nitrogen atom from the plane of the hydrogen atoms.

3.8. MOLECULAR CONSTANTS

Various molecular constants[198] of ammonia and deuteroammonia are listed in Table 19. The electronic spectrum of ammonia consists of five transitions and ionization continua in the far ultraviolet[199]. The infrared spectrum of ammonia is complicated by the large number of vibration–rotation interactions as well as by the inversion doubling previously mentioned[199]. The Raman spectrum is complex and the microwave spectrum contains some very intense lines also arising from transitions between the component levels of the inversion-doubled ground state[199]. The inversion frequency can be calculated from an equation of the type

$$v = v_0 - a[J(J+1) - K^2] + bK^2 + \text{higher powers of } J \text{ and } K,$$

the origin of the system being at 23785.88 mHz. Such transitions have been used in the ammonia beam maser (microwave amplification by stimulated emission of radiation).

3.9. PHYSICAL PROPERTIES OF AMMONIA

Physical constants[200, 201] for ammonia are listed in Table 20 together with some specific values for those which vary with temperature, while properties which can be described by equations are listed in Table 21. Values which have been reported for physical properties of isotope isomers of ammonia (ND_3, $^{15}NH_3$) follow expected trends.

Perhaps the most significant effect on the physical properties of ammonia is that of hydrogen bonding which occurs in the condensed phases. The normal melting and boiling points (195.4 and 239.7 K) are much higher than would be expected for an unassociated hydride of a first short period element, and have been estimated to be 108 and 143 K respectively if hydrogen bonding were absent[202]. The breakdown of hydrogen bonding occurs to the extent of 26% on melting, 7% between the melting and boiling points and 67% on boiling. For the same reason, the thermodynamic properties are affected in that Trouton's constant is consistent with an associated solvent, and the enthalpy and entropy of vaporization are abnormally high. Properties associated with the excellent solvent properties of ammonia (see section 3.10.4) are a consequence of the high dipole moment and the dielectric constant.

The adsorption of gaseous ammonia on solids has been extensively studied[198]. Efficient adsorbents such as charcoal impregnated with various acidic materials are used in ammonia gas masks. The adsorption characteristics of ammonia at metal surfaces are also important in its synthesis and other catalytic reactions[198].

3.10. CHEMISTRY AND CHEMICAL PROPERTIES OF AMMONIA

3.10.1. Decomposition

The photochemical decomposition of ammonia has been studied with a view to establishing the mechanism including the following:

$$NH_3 + h\nu \rightarrow NH_2 + H$$
$$NH_3 + H + M \rightleftharpoons NH_4 + M$$
$$NH_4 + NH_2 \rightarrow 2NH_3 \text{ or } NH_3 + NH + H_2$$
$$2NH \rightarrow N_2 + H_2$$

Hydrazine is produced by both photochemical and by the glow discharge of ammonia, and decompositions in the presence of other substances have also been studied[203].

The decomposition of ammonia by electric discharge is not wholly attributable to ionization, and the detection of the NH radical in emission spectra when ammonia flows through a discharge tube is evidence for the mechanism:

$$NH_3 + e^- \rightarrow NH_3^* + e^-$$
$$NH_3 \rightarrow NH + H_2$$
$$NH + NH_3 \rightarrow N_2 + 3H_2$$
The presence of other materials with ammonia in glow or silent discharge can catalyse the decomposition to the elements or react to produce compounds which further interact.

The decomposition of ammonia to its elements at a solid surface has been widely investigated[203]. In particular the decomposition on iron and promoted iron catalysts has been mentioned in connection with ammonia synthesis (section 3.3) and nitrogen production (section 2.3.3). The platinum group metals are usually chosen as catalysts for the decomposition process, while other transition metals react with the nitrogen produced to form nitrides.

### 3.10.2. Oxidation of Ammonia[202]

The explosive limits of ammonia with air or oxygen depend not only on the temperature and pressure of the mixture but also on the means of ignition, size of open or closed vessel, etc. Explosive mixtures of ammonia in dry air at atmospheric temperature and pressure contain 16–27% by volume while the limits for ammonia with oxygen are 25–75%. These limits widen as the pressure is increased.

Stable ammonia–air flames cannot be produced by gas mixtures at room temperature, but with 19.4% NH_3 in air pre-heated to 150°C, a flame temperature of 1600°C can be obtained. Spectroscopic examination of such flames show bands due to NH_3, NH_2, NH, OH and O_2, while the combustion products contain traces of NH_3 and NO. Combustion of liquid ammonia with liquid oxygen in a rocket motor gives a temperature of 3060 K and an exhaust velocity of 1770 m/s. Liquid ammonia reacts with liquid oxygen at temperatures near the critical temperature (132.4°C) to form ammonium nitrate, ammonium nitrite and nitrogen.

The catalytic oxidation of ammonia to nitric oxide is important as the major step in the manufacture of nitric acid[159, 203]. For this process, it is the aim to promote the reaction:

$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O; \qquad \triangle H(298) = -216.55 \text{ kcal/mol}$$

and suppress possible alternative reactions, some of which are:

$$4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O; \qquad \triangle H(298) = -302.95 \text{ kcal/mol}$$
$$4NH_3 + 4O_2 \rightarrow 2N_2O + 6H_2O; \qquad \triangle H(298) = -263.85 \text{ kcal/mol}$$
$$4NH_3 + 7O_2 \rightarrow 4NO_2 + 6H_2O; \qquad \triangle H(298) = -271.15 \text{ kcal/mol}$$
$$4NH_3 + 6NO \rightarrow 5N_2 + 6H_2O; \qquad \triangle H(298) = -432.55 \text{ kcal/mol}$$
$$2NO \rightarrow N_2 + O_2; \qquad \triangle H(298) = -43.04 \text{ kcal/mol}$$
$$2NH_3 \rightarrow N_2 + 3H_2; \qquad \triangle H(298) = -22.04 \text{ kcal/mol}$$

Thus although the formation of nitric oxide is thermodynamically unfavourable with respect to nitrogen, by passing pre-heated ammonia–air mixture over a platinum catalyst at
203 F. D. Miles, *Nitric Acid Manufacture and Uses*, ICI Ltd., Oxford University Press, London (1961).

temperatures above 650°C for a very short contact time, the formation of nitric oxide is favoured. Unfortunately, platinum has an appreciable vapour pressure at the reaction temperature, and although the less-volatile rhodium–platinum alloys are employed, the catalyst losses constitute a significant running cost which can only be partly offset by recovery from flue dust. All surfaces, in fact, catalyse the oxidation of ammonia, but most materials tend to produce nitrogen to such an extent as to make them unsuitable for this process.

It is now generally agreed that the oxidation occurs through collision of ammonia with a platinum surface almost completely covered with adsorbed oxygen. However, a large number of reaction intermediates have been isolated and there has been difference of opinion as to the initial nitrogen oxidation species. Mechanisms have been postulated based on the initial formation of three alternative species—imide, nitroxyl and hydroxylamine. The imide mechanism was first suggested by Raschig and developed by Zawadzki[204].
Reactions to give NO:

$$NH_3 + O \rightarrow NH + H_2O$$
$$NH + O_2 \rightarrow HNO_2 \rightarrow NO + OH$$
$$2HNO_2 \rightarrow NO + NO_2 + H_2O$$
$$HNO_2 + O_2 \rightarrow HNO_4 \rightarrow NO + O_2 + OH$$

Other side reactions:

$$NH + O \rightarrow HNO \rightarrow \tfrac{1}{2}N_2O + \tfrac{1}{2}H_2O$$
$$NH + NH_3 \rightarrow N_2H_4$$
$$2NH \rightarrow N_2 + H_2$$
$$NH_3 + HNO_2 \rightarrow N_2 + 2H_2O$$
$$2NO \rightarrow N_2 + O_2$$
$$2OH \rightarrow H_2O + O$$

The nitroxyl theory of Andrussov[205] in which ammonia reacts initially with molecular oxygen is at variance with the generally accepted view that adsorbed oxygen is in the atomic form, but in fact, most of the reactions also appear in the other two mechanisms.
Reactions to give NO:

$$NH_3 + O_2 \rightarrow HNO + H_2O$$
$$HNO + O_2 \rightarrow HNO_3$$
$$4HNO_3 \rightarrow 4NO + 2H_2O + H_2$$

Other side reactions:

$$HNO + NH_3 \rightarrow N_2 + H_2O + H_2$$
$$H_2 + \tfrac{1}{2}O_2 \rightarrow H_2O$$

Hydroxylamine was proposed as the primary reaction product after it had been isolated from an ammonia oxidation reaction[206].
Reactions to give NO:

$$NH_3 + O \rightarrow NH_2OH$$
$$NH_2OH + O_2 \rightarrow HNO_2 + H_2O$$
$$HNO_2 + O_2 \rightarrow HNO_4 \rightarrow NO + O_2 + OH$$
$$4HNO_2 \rightarrow 4NO + O_2 + 2H_2O$$

[204] J. Zawadzki, *Discuss. Farday Soc.* (1950) 140.
[205] L. Andrussow, *Angew. Chem.* **63** (1951) 21.
[206] M. Bodenstein, *Z. Elektrochem.* **47** (1941) 501.

Other side reactions:

$$NH_2OH + O \rightarrow HNO + H_2O$$
$$2HNO \rightarrow N_2O + H_2O$$
$$HNO_2 + NH_3 \rightarrow N_2 + 2H_2O$$
$$HNO + NH_2OH \rightarrow N_2 + 2H_2O$$
$$2OH \rightarrow H_2O + O$$

The way in which the three primary products may be formed can be visualized as in Fig. 17. In this scheme, the ammonia becomes co-ordinated to an oxygen atom adsorbed on the catalyst via the nitrogen lone pair. Hydrogen of the ammonia may then hydrogen bond to the attached or other oxygen atoms adsorbed on the catalyst surface with resultant isomerization to hydroxylamine or dehydrogenation to nitroxyl, imine or even nitric oxide.
FIG. 17. Mechanism for the oxidation of ammonia.

3.10.3. Reactions of Ammonia with Elements and their Compounds[207]

The exchange reaction of ammonia with hydrogen or deuterium does not proceed at any appreciable rate unless catalysed by a metal such as platinum. Both the thermal and mercury photosensitized exchange reaction proceed by the chain mechanism via the initial monodeuterated product:

$$D_2 \rightleftharpoons 2D$$
$$NH_3 + D \rightleftharpoons NH_2D + H$$
$$H + D_2 \rightleftharpoons HD + D$$
The reactions of ammonia with alkali and alkaline–earth metals will be discussed in section 3.10.4. Calcium, strontium and barium carbonates react with ammonia to form the

207 J. D. F. Marsh, in ref. 156, Section VII(a), pp. 328–41.

corresponding cyanamide, whereas magnesium, zinc and lead carbonates are reduced to the metals:

$$CaCO_3 + 2NH_3 \rightarrow CaCN_2 + 3H_2O$$
$$3ZnCO_3 + 2NH_3 \rightarrow 3Zn + 3H_2O + 3CO_2 + N_2$$
Many metal salts form adducts with ammonia (see section 3.10.6) which are often precursors of the corresponding amides, imides and nitrides (see section 4).

Boron hydrides and halides with ammonia form an extensive co-ordination and derivative chemistry as do the organo- and halo-derivatives of the other Group III elements.

Ammonia and carbon monoxide react under pressure at elevated temperature in the presence of catalysts to give formamide or hydrogen cyanide:

$$NH_3 + CO \rightarrow HCONH_2$$
$$NH_3 + CO \rightarrow HCN + H_2O$$
Hydrogen cyanide can also be formed by catalytic action of ammonia and air on hydrocarbons[162]:

$$2NH_3 + 2CH_4 + 3O_2 \rightarrow 2HCN + 6H_2O$$
The reactions of ammonia with sulphur compounds give rise to an extensive N–S chemistry[208], and similarly phosphorus compounds give P–N derivatives[209]. Reactions of the halogens and interhalogen compounds with ammonia will be discussed in section 9.

3.10.4. Reactions of Liquid Ammonia

Liquid ammonia is probably the best-known non-aqueous solvent[200, 201, 210, 211]. Inevitably, its solution chemistry has been rationalized by analogy with aqueous chemistry. In

the same way that oxygen compounds are considered as being derived from water, so ammonia can be regarded as the parent solvent of the nitrogen system of compounds[212]. Thus the class of ammono compounds have direct analogues in the aquo series as indicated in Table 22. Comparisons of this type have found most successful application in preparative chemistry as structurally related compounds often react in similar ways.

Before discussing detailed properties and reactions involving liquid ammonia, it is useful to indicate the solvent properties of ammonia by comparison with the more familiar properties of water. The lower boiling point of ammonia ($-33°C$) compared to water ($100°C$) is indicative of the reduced amount of hydrogen bonding in liquid ammonia, but its influence is still seen by the fact that compounds capable of forming hydrogen bonds such as amines, alcohols and phenols, are miscible with ammonia in all proportions. The significant dielectric constant of ammonia ($\varepsilon = 23$ at $-33°C$), which although lower than water ($\varepsilon = 82$ at $25°C$), means that ammonia is not only capable of dissolving a wide range of ionic materials (Table 23), but is superior to water in its solvent action towards organic compounds such as hexane, carbon tetrachloride, benzene, etc.[183].

The heats of solution of electrolytes in liquid ammonia are frequently more negative than in water as indicated in Table 24, consistent with ammonia being highly basic. Such

[a] Ref. 200.

basic solvent properties are particularly suitable for the study of reduction reactions[200]. Other solutes include the alkali metals which can dissolve in liquid ammonia reversibly, in contrast to the familiar violent reactions with water. Ammonia is also a stronger donor solvent than water as evidenced by the ease of formation of ammonia complexes with transition metal ions in aqueous solution. However, the self-ionization of water is considerably more extensive than for ammonia due to the fact that the O–H bond is more readily broken than the N–H bond. For this reason, hydrolysis reactions tend to be both more common throughout chemistry and more capable of reacting to completion than corresponding solvolysis reactions involving ammonia (ammonolysis).

212 E. C. Franklin, *The Nitrogen System of Compounds*, Reinhold, New York (1935).

(a) *Acid–Base Properties of Liquid Ammonia*[200, 201]

The acid–base properties of ammonia result largely from the self-ionization reaction

$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^-; \qquad K_{-33°} = [NH_4^+][NH_2^-] = \sim 10^{-30}$$
Thus although the conductivity of liquid ammonia is quite small, ammonia is a strong proton acceptor enabling most potential proton donors to act as an acid. Thus weak acids by aqueous standards such as acetic acid are almost completely dissociated in liquid ammonia similar to mineral acids in aqueous solution:

$$CH_3COOH + NH_3 \rightarrow NH_4^+ + CH_3COO^-$$
Likewise, conventionally very weak acids such as water or arsine can also form salts in liquid ammonia:

$$K^+ + NH_2^- + H_2O \xrightarrow{\text{liq. NH}_3} NH_3 + KOH$$

$$K^+ + NH_2^- + AsH_3 \xrightarrow{\text{liq. NH}_3} NH_3 + KAsH_2$$
This enhanced ionization is not meant to imply that weak acids become stronger, but because acid strength is relative to the solvent in which it is measured, it merely emphasizes the fact that the NH_4^+ ion, being symmetric and non-polar, is a weaker acid in liquid ammonia than is the asymmetric and polar H_3O^+ ion in water.
Alkali metal hydrides and oxides are stronger bases than the amide ion and hence are capable of removing protons from an ammonia molecule:

$$LiH + NH_3 \rightarrow LiNH_2 + H_2$$

$$Na_2O + NH_3 \rightarrow NaNH_2 + NaOH$$
(b) *Reactions in Liquid Ammonia*[200, 211]

By choosing salts of suitable solubility from Table 23, a large number of metathetical reactions can be carried out in liquid ammonia which would not be possible in water. Some examples are:

$$Ba(NO_3)_2 + 2AgCl \xrightarrow{\text{liq. NH}_3} BaCl_2 + 2AgNO_3$$

$$AgNO_3 + KNH_2 \xrightarrow{\text{liq. NH}_3} AgNH_2 + KNO_3$$

$$(NH_4)_2S + Ca(NO_3)_2 \xrightarrow{\text{liq. NH}_3} CaS + 2NH_4NO_3$$

Liquid ammonia has also long been used as a medium for coupling reactions, particularly in organometallic and metal carbonyl chemistry:

$$Ph_3GeNa + Me_3SnBr \xrightarrow{\text{liq. NH}_3} Ph_3GeSnMe_3 + NaBr$$

$$[Co(NH_3)_4][SCN]_2 + 2LiC_5H_5 \xrightarrow{\text{liq. NH}_3} [Co(NH_3)_4][C_5H_5]_2 + 2LiSCN$$

$$2Cr(CO)_6 + 2NaBH_4 \xrightarrow{\text{liq. NH}_3} Na_2[Cr_2(CO)_{10}]$$

Ammonia complexes of metal halides, $MX_n \cdot xNH_3$, often termed ammoniates, can be formed conveniently by dissolving the halide in liquid ammonia and evaporating off the excess solvent:

$$MX \xrightarrow{\text{liq. } NH_3} MX_n \cdot xNH_3$$
However, the interaction between metal halides and ammonia is often complicated by a further reaction involving the ammonolysis of one or more of the metal–halogen bonds:

$$MX \xrightarrow{\text{liq. } NH_3} MNH_2 + NH_4X$$

This reaction is one of the principal methods of preparing metal–nitrogen compounds.

(c) Metal–Ammonia Solutions[198,200,201,211,213]

Liquid ammonia is capable of dissolving the alkali metals, the alkaline–earth metals (except beryllium) and some of the lanthanide elements (particularly europium and ytterbium giving ions in the $+2$ oxidation state). All these elements are among the most electropositive, and it would appear that the factors responsible for a metal having a high oxidation potential (high solvation energy, low sublimation energy and low ionization energy) are the same as those responsible for solubility in ammonia. Some solubilities of alkali metals are listed in Table 25.

TABLE 25. SOLUBILITIES OF METALS IN LIQUID AMMONIA [a]

Metal	Temperature (°C)	g metal per 100 g NH₃	g atom metal per 100 g NH₃	mol NH₃/g atom metal

[a] Ref. 200.

Of their physical properties, dilute metal–ammonia solutions are characterized by their blue colour, while more concentrated solutions generally have a metallic or bronze appearance. The blue colour results from a very intense broad band that occurs around 15,000 Å, which for the alkali metals is similar in position, shape and extinction coefficient irrespective of which metal is studied. Dilute solutions are paramagnetic, but this decreases as solutions become more concentrated. As dilute metal–ammonia solutions become more

[213] W. L. Jolly, in *Progress in Inorganic Chemistry*, Vol. I (ed. F. A. Cotton), Interscience, New York (1959), p. 235.

concentrated, the conductivity decreases to a minimum then rises sharply to values approaching those of pure metals for solutions near saturation. When alkali metals dissolve in liquid ammonia, there is a considerable increase in the volume of solution, and vapour pressure measurements suggest considerable polymerization of the species in solution.

The physical properties of metal–ammonia solutions have been explained by regarding the process of dissolution as a dissociation giving solvated metal ions and solvated electrons, which in dilute solutions exist essentially independently. Thus although solvated metal ions are easy enough to visualize, solvated electrons are currently described in terms of the "cavity" model, which considers that the electron creates a large cavity for itself in the solvent while nearby solvent molecules orient themselves so as to position the hydrogen atoms nearest to the electron. An alternative description of solvated electrons is the "expanded metal" model which assumes that on dissolution the metal ion is separated from the electron by only a single layer of ammonia molecules. Both models are consistent with the anomalous density as a result of the space which the electron occupies, but the equivalent conductance values, and in particular the absorption spectra, are more consistent with a model involving solvated electrons essentially independent of the metal ions.

In concentrated metal–ammonia solutions, there are insufficient solvent molecules to co-ordinate both the metal ions and the electrons, so these solutions consist of solvated metal ions in an electron pool, similar to a metal with its electrons in a conductor band.

(d) *Reactions of Metal–Ammonia Solutions*[200,211,213]

Metal–ammonia solutions are stable over long periods, but decomposition to hydrogen and metal amide occurs slowly if impurities are present but rapidly with suitable catalysts such as transition metal salts:

$$2M + 2NH_3 \xrightarrow{\text{liq. NH}_3} 2MNH_2 + H_2$$
In view of the powerful reducing properties of metal–ammonia solutions, they are often regarded as convenient electron producing reagents:

$$M \xrightarrow{\text{liq. NH}_3} M^+ + e^- \quad \text{(M, for example = alkali metal)}$$
Thus in the same way that partial ionic equations in aqueous chemistry are often used to describe individual reaction steps in an overall process, so the reactions of metal–ammonia solutions can be described as electron addition reactions which may also involve bond cleavage.
Electron addition without bond cleavage can be represented as

$$e^- + A \xrightarrow{\text{liq. NH}_3} A^- \quad \text{or} \quad M + A \xrightarrow{\text{liq. NH}_3} MA$$
For example, peroxides and superoxides can be prepared by bubbling oxygen through metal–ammonia solutions:

$$O_2 + K \xrightarrow{\text{liq. NH}_3} KO_2$$
Similarly, the reduction of nitric oxide with sodium in liquid ammonia is thought to give the nitroside ion:

$$NO + Na \xrightarrow{\text{liq. NH}_3} NaNO$$

Other examples illustrate methods of preparing complexes and ions of metals in low oxidation states:

$$KMnO_4 + K \xrightarrow{\text{liq. NH}_3} K_2MnO_4$$

$$Mn_2(CO)_{10} + 2Na \xrightarrow{\text{liq. NH}_3} 2NaMn(CO)_5$$

$$K_2Ni(CN)_4 + 2K \xrightarrow{\text{liq. NH}_3} K_4Ni(CN)_4$$

$$[Pt(en)_2]I_2 + 2K \xrightarrow{\text{liq. NH}_3} [Pt(en)_2] + 2KI$$

$$[Ir(NH_3)_5Br]Br + 3K \xrightarrow{\text{liq. NH}_3} [Ir(NH_3)_5Br] + 3KBr$$

$$[Pd\{o\text{-}C_6H_4(PEt_2)_2\}_2]Br_2 + 2Na \xrightarrow{\text{liq. NH}_3} [Pd\{o\text{-}C_6H_4(PEt_2)_2\}_2] + 2NaBr$$

Electron addition accompanied by bond cleavage is described by the equations:

$$e^- + A - B \xrightarrow{\text{liq. NH}_3} A\cdot + B^-$$

$$2e^- + A - B \xrightarrow{\text{liq. NH}_3} A^- + B^-$$
Some examples of this type of reaction include:

$$2NH_4Cl + 2K \xrightarrow{\text{liq. NH}_3} 2NH_3 + H_2 + 2KCl$$

$$2RC \equiv CH + 2Na \xrightarrow{\text{liq. NH}_3} 2RC \equiv CNa + H_2$$

$$Fe(CO)_5 + 2Na \xrightarrow{\text{liq. NH}_3} Na_2[Fe(CO)_4] + CO$$

$$Ge_2H_6 + 2K \xrightarrow{\text{liq. NH}_3} 2KGeH_3$$
Unlike the above reactions in which the radical formed initially dimerizes, the triethyltin radical is stable in liquid ammonia:

$$Et_3SnCl + K \xrightarrow{\text{liq. NH}_3} Et_3Sn\cdot + KCl$$
In a few instances, the anions formed in such reactions undergo ammonolysis:

$$N_2O + NH_3 + 2K \xrightarrow{\text{liq. NH}_3} N_2 + KOH + KNH_2$$

$$KNCO + NH_3 + 2K \xrightarrow{\text{liq. NH}_3} KCN + KOH + KNH_2.$$
3.10.5. Ammonia Hydrates and Aqueous Chemistry of Ammonia[198]

The extent to which ammonia in aqueous solution exists as ammonium hydroxide has long been discussed. Ammonia is very soluble in water in which it is involved in the equilibrium

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-; \qquad K = \frac{[NH_4^+][OH^-]}{[NH_3]} = 1.81 \times 10^{-5} \,(pK_b = 4.75)$$
This data suggests that the formation of ammonium hydroxide is improbable. The phase diagram of the ammonia–water system shows three eutectics and two compounds corresponding to the formulae $NH_3 \cdot H_2O$, and $2NH_3 \cdot H_2O$. Crystal structures confirm that neither substance contains NH_4^+, OH^- nor discrete NH_4OH molecules. The monohydrate has chains of H_2O linked by hydrogen bonds (2.76 Å), and cross-linked by NH_3 into a three-dimensional lattice by OH $\cdots$ N (2.78 Å) and O $\cdots$ H—N (3.21–3.29 Å). Aqueous ammonia

[a] Ref. 200.

is probably hydrated in a similar way. The name "ammonium hydroxide" therefore is a misnomer since at present there is no evidence to suggest that undissociated NH_4OH exists in aqueous solution.

Some physical parameters of ammonia hydrates and aqueous ammonia solutions are listed in Tables 26 and 27. Vapour pressures and vapour pressure compositions have been determined for 0–100% aqueous ammonia over the range -50 to $+210°C$ at pressures of 0.1–20 atm, and partial pressures can also be calculated from the empirical formula

$$\log_{10} p = \frac{7.6468t}{t+230} - \frac{0.7486t + 236.68}{t+230} \times \log_{10} \frac{1000}{C} - 1.6$$

where p = partial pressure in mm, t = temperature in °C and c = concentration of ammonia in g NH_3 per 100 g solution.

3.10.6. Addition Compounds

The addition compounds of ammonia have been mentioned in connection with their formation during reactions in liquid ammonia (section 3.10.4.b). In ammoniates of the type $MX_n \cdot xNH_3$, the ammonia and halogen each occupy co-ordination positions round the metal in a molecular complex, and should be distinguished from metal amines in which ammonia molecules are co-ordinated round a metal ion. In this section we are primarily concerned with the former type. However, the interaction of metal halides with ammonia has been extensively studied[211] and formation of $MX_n \cdot xNH_3$ is frequently accompanied by ammonolysis which involves replacement of some or all of the halogen atoms by amino groups. Some metal halides are ammonolysed immediately, and in such cases ammoniates may only be considered to exist as transient intermediates. The course of such reactions has usually been considered to proceed through the sequence, metal halide (usually in solution) leading to ammoniated metal halide followed by stepwise base-catalysed elimination of hydrogen halide. The system is aided by solvents which can extract the ammonium halide as it forms, forcing the equilibrium reaction to completion.

Organic substituted ammonia (amines) can be employed to reduce or limit solvolysis reactions. Fully substituted (tertiary) amines, of course, prevent any further reaction after complex formation although primary and secondary amines can also have the same effect in certain stereochemical situations. A wide variety of organic-nitrogen mono-, di- and multi-dentate ligands including amines, diamines (ethylene-diamine) and heterocyclic bases (pyridine) to name a few, have found application[214], but it is only recently that amino derivatives of other elements (see section 4) have been considered as potential Lewis bases.

3.11. BIOLOGICAL PROPERTIES OF AMMONIA

As mentioned in section 1.7, ammonia is a key substance in the natural nitrogen fixation process. Formerly, most nitrogen fertilizers were based on ammonium salts, but more recently anhydrous ammonia and ammonia solutions have been applied directly. As regards the human metabolism of nitrogen compounds, ammonia occurs in all body fluids but is

[214] W. P. Griffith, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), p. 241.

difficult to differentiate from urea. Ammonia is excreted through the urine and together with urea accounts for the removal of waste nitrogen products[215].

Exposure to small concentrations of gaseous ammonia causes attack to the mucous membrane, and although it only acts as an irritant to the eyes and throat, exposure to high concentrations can induce oedema, haemorrhage and empyema. Some safety limits are indicated in Table 28.

TABLE 28. PHYSIOLOGICAL RESPONSE TO CONCENTRATIONS (IN ppm) OF AMMONIA IN AIR

Least detectable odour	53
Least amount causing immediate irritation to eyes	698
Least amount causing immediate irritation to throat	408
Least amount causing immediate coughing	1720
Maximum concentration allowable for prolonged exposure	100
Maximum concentration allowable for short exposure $\frac{1}{2}$–1 hour	300–500
Dangerous concentration even for short exposure $\frac{1}{4}$ hour	2500–4500

3.12. ANALYTICAL CHEMISTRY OF AMMONIA[216]

The following methods are applicable to the estimation of free ammonia to be distinguished from ammonium ion. Ammonia in sufficient quantity can easily be detected and identified by its odour, but the most common spot test is that with Nessler reagent. Other sensitive colorimetric methods of estimation are based on the blue colour formed by its reaction with phenol and hypochlorites, also the purple colour produced when ammonia solution is treated with chloramine-T followed by pyridine-pyrazolone reagent[217]. The latter method is particularly sensitive and applicable to coloured samples as the purple colour can be extracted into carbon tetrachloride and remains stable and reproducible.

A simple method for determining free ammonia in solution is by direct titration with an acid using methyl red as indicator[218]. Ammonia can also be oxidized by sodium hypobromite to nitrogen which can be measured volumetrically[219].

$$2NH_3 + 3NaOBr \rightarrow 3NaBr + H_2O + N_2$$
The principal impurities in cylinder ammonia are non-condensable gases, nitrogen, argon and neon together with moisture and traces of oil. An estimate of the impurity level in the atmosphere above liquid ammonia can be obtained by treating a sample in a gas burette with sulphuric acid and measuring the volume directly.

4. AMIDES, IMIDES, AND NITRIDES

4.1. CLASSIFICATION OF COMPOUNDS

Although metal–nitrogen compounds will be discussed with the chemistry of each particular element, it is appropriate here to indicate the range and variety of such derivatives and to attempt a comparative study of these compounds. Thus, with the exception of hydrogen, nitrogen, oxygen and halogen compounds of nitrogen (discussion of which accounts for virtually the remainder of this chapter), the chemistry of compounds in which nitrogen is bonded to one or more of the remaining elements is outlined in this section. All of these elements, comprising essentially the metals and metalloids, have an electronegativity lower than nitrogen, which might imply an electronic displacement towards nitrogen and be useful in predicting possible reaction courses. Thus as oxides and hydroxides are regarded as being derived from the parent molecule water, so in the same way amides, imides and nitrides are related to ammonia[220]. In principle, these classes of compounds can be thought of as being formed by replacing one or more hydrogen atoms of ammonia by other elements. Clearly, any remaining hydrogen attached to nitrogen of the amide or imide produced could be substituted by some other element or group, as also could other valency positions on the element bonded to nitrogen. It is in this context that organo groups have played an important rôle in facilitating the synthesis of derivatives containing only one element–nitrogen bond[221], thus simplifying their chemical investigation without the complications of multi-functional reactants.

Simple metal amides $M(NH_2)_x$ of the alkali and alkaline–earth metals are quite stable, but amides of heavier elements such as silver can be explosive[222]. Very few imides are known, however, and lithium imide is probably the best characterized compound of its type. Analogous compounds derived from organic amines and imines are now known for many transition and non-transition metals and metalloids, but these, in general, are of quite different character to related conventional inorganic derivatives.

Metal nitrides can be conveniently divided into four classes[223]—salt-like, metallic, diamond-like and covalent. The salt-like ionic nitrides, which include compounds of lithium, alkaline–earth metals, together with some electropositive Group IIIA metals, are characterized by the presence of N^{3-} ions in the crystal lattice. The metallic nitrides, so named because of their physical similarity to refractory hard metals, are often called interstitial nitrides. They include compounds of transition metals, and are also related to borides, carbides, silicides and phosphides of such elements[223, 224]. Their structures are expanded metal lattices in which nitrogen atoms occupy interstitial positions which indicates why these compounds tend to exhibit non-stoichiometry and variable composition. The diamond-like nitrides of Group III elements boron, aluminium, gallium and indium have graphite- or wurtzite-type structures. The covalent nitrides, such as $(CN)_2$, PN, AsN, S_4N_4, are reasonably volatile materials and parent compounds to a large number of derivatives.

[223] B. R. Brown, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. I, *Nitrogen*, Part I, Longmans, London (1964), Section III, pp. 150–239.

[224] P. Schwarzkopf and R. Kieffer, *Refractory Hard Metals*, Macmillan, New York (1953), pp. 223–60.

Organometallic derivatives of the type $(Me_3Sn)_3N$ and $[(Me_3Si)_2N]_2Cd$ would also be included in this group.

Thus, in review, the nitrogen chemistry of the elements can be summarized as follows. The alkali metals are capable of forming each class of nitrogen mentioned above, with lithium and sodium derivatives being important in organic chemistry. Alkaline–earth metals form amides and nitrides, but only magnesium and beryllium form derivatives of organic amines. The transition elements are predominantly useful as nitrides[223], but the synthesis and properties of amino derivatives of the elements titanium[225], zirconium[226], hafnium[226], vanadium[225], niobium[226], tantalum[226], chromium[227], molybdenum[228], tungsten[229], manganese[230], iron[231], cobalt[232], nickel[233], palladium[234], platinum[235], copper[236], silver[237], uranium[238] and thorium[226], have at least begun to be investigated. Zinc, cadmium and mercury form amides and unstable nitrides, and only a few organic derivatives have been reported[221]. The elements of Group III form covalent nitrides and organo-derivatives, and in particular the chemistry of boron nitrogen compounds[239,240] has received particular attention because of their relationship to organic systems, B–N being isoelectronic with C–C. From the Group IV elements, organic chemistry of nitrogen is a subject in itself[241], and organosilicon–nitrogen chemistry is advanced with many cyclic derivatives[242]. Germanium–nitrogen[243] closely resembles silicon, while organotin–nitrogen[244] compounds have turned up some unexpected properties which have led to the discovery of analogous situations in the chemistry of other elements. Phosphorus–nitrogen chemistry[245,246] is quite extensive in connection with phosphonitrilic halides and other condensed systems[247], but the nitrogen chemistry of arsenic and antimony have not received much attention[248],

In Group VI, sulphur–nitrogen chemistry is a flourishing field of research[249].

Finally, attention must be drawn to the problem of nomenclature. In organic chemistry, "amide" is the class name for compounds containing the group —$CONH_2$, whereas in inorganic parlance it refers to metal derivatives of ammonia, e.g. sodium amide is $NaNH_2$ and not $NaCONH_2$. On the other hand, metal amides can easily be thought of as amino derivatives of metals, and for this reason they are often referred to by this "organic" nomenclature, especially when naming cyclic derivatives. Some examples are given in Table 29.

TABLE 29. NAMES OF NITROGEN COMPOUNDS FO THE ELEMENTS

Formula	Name and alternatives
$NaNH_2$	Sodium amide
Ag_2NH	Silver imide
Li_3N	Lithium nitride
$Bu^n_3SiNH_2$	Tri-n-butylsilylamine, tri-n-butylsilylamide
$(Me_3Si)_2NH$	Bis(trimethylsilyl)amine, hexamethyldisilylamide
$(H_3Si)_3N$	Trisilylamine
$(HBNH)_3$	Borazine, borazole
$Ti(NMe_2)_4$	Tetrakis(dimethylamino)titanium, titanium tetradimethylamide
Me_3SnNEt_2	Diethylaminotrimethylstannane, trimethyltin diethylamide

4.2. METHODS OF PREPARATION

Solutions of alkali and alkaline–earth metals in liquid ammonia with a trace of catalyst (usually a simple transition-metal salt) produce the corresponding metal amide (1)[222]:

$$2Na + 2NH_3 \xrightarrow[FeSO_4]{race} 2NaNH_2 + H_2 \tag{1}$$
Another general method in liquid ammonia involves the precipitation of metal amides by adding potassium amide to liquid ammonia solutions of soluble salts of these metals as in (2)[222]:

$$CdCl_2 + 2KNH_2 \xrightarrow{liq.\ NH_3} Cd(NH_2)_2 + 2KCl \tag{2}$$
Similar amides can also be prepared by reaction of the corresponding metal-alkyl or metal-aryl with ammonia (3, 4)[222, 250]:

$$PhNa + NH_3 \rightarrow NaNH_2 + C_6H_6 \tag{3}$$

$$Et_2Zn + 2NH_3 \rightarrow Zn(NH_2)_2 + 2C_2H_6 \tag{4}$$
[249] H. G. Heal, in *Inorganic Sulphur Chemistry* (ed. G. Nickless), Elsevier, Amsterdam (1968), pp. 459–508; M. Becke-Goehring and E. Fluck, in *Developments in Inorganic Nitrogen Chemistry*, Vol. 1 (ed. C. B. Colburn), Elsevier, Amsterdam (1966), pp. 150–240.
[250] O. Schmitz-DuMont, *Rec. Chem. Progr.* **29** (1968) 13.

Metal amides containing organic substituents on the metal are not very common but have been prepared by method (5) comparable to (2), while metal amides derived from organic amines are obtained in ways (6–8)[243, 251] similar to (2) and (3):
$$Ph_3GeCl + KNH_2 \xrightarrow{\text{liq. NH}_3} Ph_3GeNH_2 + KCl \tag{5}$$

$$C_4H_9Li + Me_2NH \rightarrow LiNMe_2 + C_4H_{10} \tag{6}$$

$$TiCl_4 + 4LiNMe_2 \rightarrow Ti(NMe_2)_4 + 4LiCl \tag{7}$$

$$Me_3SnCl + LiNMe_2 \rightarrow Me_3SnNMe_2 + LiCl \tag{8}$$
There are also particular instances when organometallic halides or oxides can react with simple amines to give the amino-metal derivative directly (9, 10):

$$Me_3SiCl + 2Et_2NH \rightarrow Me_3SiNEt_2 + Et_2NH \cdot HCl \tag{9}$$

$$BCl_3 + 6Me_2NH \rightarrow B(NMe_2)_3 + 3Me_2NH \cdot HCl \tag{10}$$

The organic groups attached to nitrogen can be varied by transamination reactions (11, 12)[251]:

$$Nb(NMe_2)_5 + 2Et_2NH \rightarrow (Me_2N)_3Nb(NEt_2)_2 + 2Me_2NH \tag{11}$$

$$Ti(NMe_2)_4 + 3Pr_2^iNH \rightarrow Me_2NTi(NPr_2^i)_3 + 3Me_2NH \tag{12}$$

Lithium imide is prepared by heating the amide (13), whereas organometallic imides are formed by exchange reactions (14):

$$2LiNH_2 \xrightarrow[\text{in vacuo}]{360°} Li_2NH + NH_3 \tag{13}$$

$$(Me_3Si)_2SO_4 + 3NH_3 \rightarrow (Me_3Si)_2NH + (NH_4)_2SO_4 \tag{14}$$

Imides have also been prepared by the thermal decomposition of dialkylamino-derivatives of niobium and tantalum (15)[252], and by reaction of amines with oxo-compounds of rhenium (16)[253].

$$Ta(NEt_2)_5 \rightarrow (Et_2N)_3Ta:NEt + Et_2NH + C_2H_4 \tag{15}$$

$$Cl_3Re(O)(EtPh_2P)_2 + MeNH_2 \rightarrow Cl_3Re(:NMe)(EtPh_2P)_2 + H_2O \tag{16}$$

The two main methods of forming binary compounds of nitrogen are from the elements[254, 255] (17)[256], and from the corresponding metal amide (18)[223]:

$$6Li + N_2 \rightarrow 2Li_3N \tag{17}$$

$$3Zn(NH_2)_2 \rightarrow Zn_3N_2 + 4NH_3 \tag{18}$$

Common modifications to these methods include the reduction of a metal oxide or halide in the presence of nitrogen (19–21), or the formation of a metal amide as an intermediate in the reaction between a metal and ammonia (22)[223]:

$$Al_2O_3 + 3C + N_2 \rightarrow 2AlN + 3CO \tag{19}$$

$$2TiO_2 + 4TiC + 3N_2 \rightarrow 6TiN + 4CO \tag{20}$$

$$2ZrCl_4 + N_2 + 4H_2 \rightarrow 2ZrN + 8HCl \tag{21}$$

$$3Ca + 6NH_3 \rightarrow [3Ca(NH_2)_2] \rightarrow Ca_3N_2 + 4NH_3 \tag{22}$$

[256] C. C. Addison and B. M. Davies, *J. Chem. Soc.* A (1969) 1822.

Most of these reactions are carried out at elevated temperatures and in some cases under pressure, and contrast with the facile formation of corresponding organometallic[257] (23) and metal complex nitride[258] (24) derivatives:

$$3Me_3SnCl + Li_3N \rightarrow (Me_3Sn)_3N + 3LiCl \qquad (23)$$
$$Cl_3Re(O)(EtPh_2P)_2 + 2NH_3 \rightarrow Cl_2Re(:N)(EtPh_2P)_2 + H_2O + NH_4Cl \qquad (24)$$

4.3. NUCLEAR ISOTOPES[259]

Labelled sodium amide has been prepared by heating sodium metal with enriched ammonia:

$$2Na + 2^{15}NH_3 \rightarrow 2Na^{15}NH_2 + H_2$$
A similar method can also be used to prepare $Ca(^{15}NH_2)_2$.

Calcium or magnesium react with nitrogen at elevated temperatures to give the nitride which can conveniently liberate ammonia by hydrolysis.

$$3Ca + {}^{15}N_2 \rightarrow Ca_3{}^{15}N_2$$
$$Ca_3{}^{15}N_2 + 6H_2O \rightarrow 3Ca(OH)_2 + 2^{15}NH_3$$
Labelled ammonia was used for the preparation of labelled trisilylamine in order to record the ^{15}N coupling in the nuclear magnetic resonance spectrum[260]:

$$3H_3SiCl + {}^{15}NH_3 + Et_3N \rightarrow (H_3Si)_3{}^{15}N + 3Et_3N \cdot HCl$$

4.4. USES[223, 261]

The applications of metal nitrides are based essentially on their physical properties of high melting points, extreme hardness, metallic conductivity and high chemical inertness. Aluminium nitride and silicon nitride, pure or in combination with the corresponding oxides or carbides, are used as refractory materials for crucibles, boats, thermocouple protecting tubes, crucible coatings and linings. Sintered parts containing these materials can be prefabricated in metal powder followed by nitriding in a nitrogen gas stream at high temperatures. Several metal nitrides have been used as heterogeneous catalysts in a variety of processes, one of the best known being iron nitride in the Fischer–Tropsch method of hydriding carbonyls. Boron nitride in the form with the zincblende structure, sometimes known as borazon, is about as hard as diamond, and silicon nitride bonded silicon carbide has also been used as an abrasive. Some III–V metal nitrides, AlN, GaN and InN, have applications as semiconductors. UN and ThN have been proposed as fuels and breeders in high-temperature nuclear reactors.

Metal amides are used as reducing agents while amino derivatives of some elements are useful intermediates in organic and organometallic syntheses.

4.5. STRUCTURE AND BONDING

Descriptions of the bonding in metal–nitrogen compounds are based almost entirely on parameters obtained from structure determinations by X-ray diffraction techniques. The salt-like ionic nitrides all contain N^{3-} ions (~ 1.4 Å radius) in their crystal lattices. For example, lithium nitride Li_3N has a hexagonal structure, while many Group II nitrides are

TABLE 30. PHYSICAL PROPERTIES OF IONIC AND COVALENT METAL NITRIDES[a]

[a] Ref. 223.

anti-isostructural with the oxides of these elements, i.e. the metal atoms occupy the positions of the oxygen atoms and the nitrogen those of the metal atoms in M_2O_3. Similarly, other nitrides with formulae corresponding to the usual valency of the metal in combination with nitrogen(III) can also be thought of as containing some ionic character. In Ge_3N_4

the metal has four tetrahedral nitrogen neighbours and nitrogen forms coplanar bonds to three metal atoms. Some lanthanide element nitrides of general formula MN which crystallize in the NaCl-type structure have magnetic moments which suggest M(III). Thus the metallic character shown by these nitrides is probably due to small deviations from stoichiometry such as vacancies among the N^{3-} anions[262]. UN_2 crystallizes as the fluorite structure and also seems to contain uranium(VI) and N^{3-} ions. Structural data on these and similar compounds are summarized in Table 30.

In metallic nitrides of general formulae MN, M_2N and M_4N, the nitrogen atoms occupy some or all of the interstices of cubic- or hexagonal-close-packed metallic lattices. These compounds are often referred to as hard metals with properties characteristic of alloys. But in spite of their metallic appearance and high conductivity, they are usually harder and melt at higher temperatures than metals[223]. Structural data on metallic nitrides are listed in Table 31.

[262] C. K. Jorgenson, *Oxidation Numbers and Oxidation States*, Springer-Verlag, New York (1969).

The nitrides of Group III elements, MN, have properties which tend towards covalency. Boron nitride can be prepared in two forms: one is related to graphite, being a lattice of hexagonal layers, and this form can be converted into material with the zincblende structure like that of diamond, with which it is both isoelectronic and isostructural. Relevant structural data is also listed in Table 30.

The structures of metal amides and imides have also been investigated (Table 32), but it is the organo-substituted derivatives which are of current interest and which reveal unique structural and bonding situations. Organoboron–nitrogen compounds show $(p \rightarrow p)\pi$-interaction in the B–N bonds of monomeric aminoboranes, and a consequence of this multiplicity is that free rotation about these bonds is hindered. This has been

demonstrated by [1]H n.m.r. studies on $Ph(Cl)BNMe_2$ and $vinyl(Br)BNMe_2$ which show non-equivalent methyl groups on nitrogen[263]. A wide selection of cyclic and condensed ring boron–nitrogen derivatives have also been prepared and characterized[221]. Fewer aluminium–nitrogen compounds are known[221, 264] but, none the less, $(PhAlNPh)_4$ has a unique structure based on a Al_4N_4 cube[265]. The dimethylamino derivative Me_2AlNMe_2 and its gallium and indium analogues are dimeric both in solution and in the vapour phase, but undergo transition to a glass at 50–80°C. These crystal-glass transitions are reversible,

and the glasses are thought to consist of mixtures of cyclic oligomers and short-chain polymers[266].

The organic chemistry of nitrogen provides the ultimate in variety of compounds against which nitrogen derivatives of other elements can be compared[241]. Some parameters of organic nitrogen compounds are included in Table 33. Organosilicon–nitrogen compounds have attracted considerable attention[242], particularly since the molecular structure of tri-silylamine $(H_3Si)_3N$, as determined by electron diffraction, was planar at nitrogen[267]. This result has been confirmed, and other related derivatives such as $(H_3Si)_2NN(SiH_3)_2$, $(H_3Si)_2NH$, $(H_3Si)_2NMe$, $(H_3Si)_2NBF_2$, $[(Me_3Si)_2N]_3Al$, all show similar stereochemistry at nitrogen[268]. With analogous carbon compounds being pyramidal, the most popular explanation for planarity at nitrogen is $(p \rightarrow d)\pi$-bonding interaction between nitrogen and silicon. The evidence for such interactions in silicon systems has recently been reviewed[269]. A similar explanation has been proposed for planar $(H_3Ge)_3N$ [268].

Little structural information is available on organotin–nitrogen compounds but $(p \rightarrow d)\pi$-interactions are not thought to be important. The chemistry of amino-tin deriva-tives can be rationalized on the basis of a weak polar Sn–N bond[244]. A wide variety of phosphorus–nitrogen compounds are known including cyclic derivatives[246], and like other second-row elements, the involvement of d orbitals in the P–N bond has been proposed.

Tetrasulphur tetranitride, the simplest nitride of sulphur, has an eight-membered cage structure in which the four sulphur atoms form a bisphenoid while the four nitrogen atoms are coplanar and occupy the corners of a square. A large number of other cyclic S–N systems are also known[249]. Structural parameters for covalent nitrides and their related organo derivatives are included in Table 33.

4.6. PHYSICAL PROPERTIES

Some physical properties of metal amides, metal nitrides and a selection of representative amino derivatives of the elements are listed in Tables 30–33, together with structural parameters which have been commented on in section 4.5.

4.7. CHEMISTRY AND CHEMICAL PROPERTIES

The chemistry of metal nitrides is not very well developed. This is due to the fact that some nitrides are chemically quite inert, and those that do react tend to give hydrolysis or decomposition products:
$$2AlN + 3H_2O \rightarrow Al_2O_3 + 2NH_3$$
$$2VN + 3H_2SO_4 \rightarrow V_2(SO_4)_3 + 3H_2 + N_2$$
Many ternary metal nitrides, $MM'N_2$, etc., do not appear to have been investigated as to chemical reactivity and may well prove to be of interest.

Metal amides and imides are readily hydrolysed[222]:

$$NaNH_2 + H_2O \rightarrow NaOH + NH_3$$
$$Li_2NH + 2H_2O \rightarrow 2LiOH + NH_3$$
The metal amides can also be deamminated to the corresponding imide and nitride by heating, but in some instances further decomposition takes place:

$$Mg(NH_2)_2 \rightarrow Mg_3N_2 + 4NH_3$$
$$2LiNH_2 \rightarrow Li_2NH + NH_3$$
$$2NaNH_2 \rightarrow 2NaH + N_2 + H_2$$
$$2NaNH_2 \rightarrow 2Na + N_2 + 2H_2$$

Sodium amide can also be reduced with carbon at red heat:

$$NaNH_2 + C \rightarrow NaCN + H_2$$
The chemistry of alkali metal amides and a few substituted amino derivatives of metals and metalloids (predominantly main group elements) has been investigated sufficiently for some of the main lines of development to emerge. Tin is an element whose organometallic chemistry has received considerable recent attention[270] and although organotin–nitrogen compounds are among the more reactive, some of their reactions have since proved to be quite general and applicable to similar derivatives of other elements[244]. These reactions can be divided into the two types: substitution and addition:

$$\geqslant Sn-N< + XY \rightarrow \geqslant Sn-X + YN<$$
$$\geqslant Sn-N< + Z \rightarrow \geqslant Sn-Z-N<$$
Specific examples of these general reactions illustrate the variety of products that can be obtained and include the replacement of acidic, neutral and basic hydrogen, halogen

[270] W. P. Neumann, *Die Organische Chemie des Zinns*, Ferdinand Enke Verlag, Stuttgart (1967).

metathesis, transmetalation, dehydrohalogenation and insertion reactions (R and R' can be any non-reacting organic group, usually Me, Et, Ph, etc.)[244]:

$$R_3SnNR_2 + EtOH \rightarrow R_3SnOEt + R_2NH$$
$$R_3SnNR_2 + PhC \equiv CH \rightarrow R_3SnC \equiv CPh + R_2NH$$
$$R_3SnNR_2 + R_3'SnH \rightarrow R_3SnSnR_3' + R_2NH$$
$$R_3SnNR_2 + HMn(CO)_5 \rightarrow R_3SnMn(CO)_5 + R_2NH$$
$$R_3SnNR_2 + CF_2{=}CFCl \rightarrow R_3SnF + CFNR_2{=}CFCl$$
$$R_3SnNR_2 + Me_3SiCl \rightarrow R_3SnCl + Me_3SiNR_2$$
$$R_3SnNR_2 + (Ph_3P)_3IrHCl \rightarrow R_3SnCl \cdot R_2NH + (Ph_3P)_3IrH$$
$$R_3SnNR_2 + CS_2 \rightarrow R_3SnSCSNR_2$$
$$R_3SnNR_2 + PhNCO \rightarrow R_3SnNPhCONR_2$$
Similar reactions also occur with amino derivatives of transition metals of which titanium, zirconium, niobium and tantalum amides have been investigated most[225]. Clearly, a large area of metal nitrogen chemistry remains to be explored.

4.8. ANALYTICAL CHEMISTRY OF AMIDES, IMIDES AND NITRIDES[271]

Hydrolysis of simple amides gives ammonia and the metal hydroxide, both of which can be determined separately by titration with acid:

$$NaNH_2 + H_2O \rightarrow NaOH + NH_3$$
Similarly, imides and hydrolysable nitrides can also be dissolved in acid, and after making the solution strongly basic the ammonia can be distilled into standard acid and back-titrated with standard base.

Amino derivatives of metals and metalloids yield free amine on hydrolysis which can also by analysed by acid–base titrimetry. Alternatively, the conventional methods, used for determining organic nitrogen, of Dumas or Kjeldahl, are usually appropriate for amides derived from organic amines.

Metal nitrides which are soluble in acids present no problem in nitrogen analysis as the compound dissolves to give metal and ammonium salts. However, for metal nitrides which are resistant to chemical attack by wet methods, fusion or vacuum fusion in the presence of sodium peroxide may be necessary in order to obtain an estimate of nitrogen content.

5. AMMONIUM SALTS

5.1. OCCURRENCE[272, 273]

As ammonium salts are quite soluble in water, major terrestrial deposits which may have formed have long since been leached away. However, ammonium chloride is still found in places where natural combustion processes have been at work on nitrogen-containing

[271] K. I. Vasu, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part II, Longmans, London (1967), Section XXXVII, p. 563.

[272] J. W. Mellor, *Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, *Nitrogen*, Longmans, London (1928).

[273] *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. I, *Nitrogen*, Part I, Longmans, London (1964).

materials in the absence of water, e.g. in crevices in the vicinity of volcanoes, undoubtedly as a sublimation product. Ammonium sulphate has also been found in volcanic craters. Natural steam vents in Italy have been harnessed to yield considerable amounts of ammonium carbonate by the controlled interaction of carbon dioxide and ammonia present in the steam and water. Ammonium iodide can be sublimed from burning seaweed, and ammonium chloride was obtained from the combustion of animal waste also by sublimation. Apart from the byproduct ammonium salts from the coal-gas industry, all ammonium salts are now produced from synthetic ammonia.

5.2. PRODUCTION[274]

Ammonium fluoride is produced by neutralizing strong hydrofluoric acid with liquid ammonia until just alkaline and then filtering off the product[275]:

$$HF + NH_3 \rightarrow NH_4F$$
For the production of ammonium chloride, however, direct neutralization is only economical if chlorine or hydrochloric acid is available at an adjacent plant, in order to offset the costs due to corrosion problems. Thus the common method of producing fertilizer grade ammonium chloride is by dual-salt process[276]. Such a situation is present in the Solvay ammonia–soda process for producing sodium carbonate which can be described by the following reaction scheme (1)–(5):

$$CaCO_3 \xrightarrow{-CO_2} CaO \xrightarrow{+H_2O} Ca(OH)_2 \tag{1}$$

$$NH_3 + H_2O + CO_2 \rightarrow NH_4HCO_3 \tag{2}$$

$$NH_4HCO_3 + NaCl \rightarrow NaHCO_3 + NH_4Cl \tag{3}$$

$$2NaHCO_3 \rightarrow Na_2CO_3 + CO_2 + H_2O \tag{4}$$

$$2NH_4Cl + Ca(OH)_2 \rightarrow 2NH_3 + CaCl_2 + H_2O \tag{5}$$
Modification of this process to produce ammonium chloride of suitable purity would also dispense with reactions (1) and (5) associated with ammonia recovery. After separation of the sodium bicarbonate in (3), more ammonia is added to the mother liquor, then salted out with sodium chloride and cooled to below 15°C at which temperature ammonium chloride crystallizes out. The product is centrifuged, washed and dried. Higher grade material can be produced by double decomposition[276]:

$$(NH_4)_2SO_4 + 2NaCl \rightarrow Na_2SO_4 + 2NH_4Cl$$
The ammonia–carbon dioxide–water system gives rise to a number of products which are often referred to collectively as ammonium carbonate[277] but which include, amongst others, the individual species $(NH_4)_2CO_3$, ammonium bicarbonate NH_4HCO_3 and ammonium carbamate $NH_2CO_2NH_4$. Ammonium bicarbonate free of these other compounds can be crystallized when an aqueous solution saturated with ammonia and carbon dioxide at 60°C is allowed to cool under a pressure of carbon dioxide. Ammonium carbonate

[274] C. J. Pratt and R. Noyes, *Nitrogen Fertilizer Chemical Processes*, Noyes Development Corporation, New Jersey (1965).
[275] D. M. McC. Steele, in ref. 273, Section VIII, pp. 370–7.
[276] N. L. Ross Kane, in ref. 273, Section IX, pp. 378–432.
[277] K. W. Allen, in ref. 273, Section XII, pp. 459–68.

can be formed when gaseous ammonia and carbon dioxide react in a humid atmosphere. At higher temperatures and pressures, ammonia and carbon dioxide form ammonium carbamate which is also in equilibrium with its dehydration product urea:

$$CO_2 + 2NH_3 \rightleftharpoons NH_2CO_2NH_4$$
$$NH_2CO_2NH_4 \rightleftharpoons NH_2CONH_2 + H_2O$$
Conditions favourable for the formation of commercially desirable urea hinge on the fact that the reaction velocity of the dehydration process proceeds at a reasonable rate only when the temperature is raised which likewise increases the decomposition pressure of the carbamate. Hence a higher pressure must also be used, and modern urea production units operate at 175–210°C and 170–400 atm [274].

Ammonium sulphate is produced principally from direct neutralization, but the gypsum process in which ammonium carbonate reacts with a suspension of calcium sulphate in water is still operated in countries having sources of calcium sulphate but no sulphur:

$$(NH_4)_2CO_3 + CaSO_4 \rightarrow CaCO_3 + (NH_4)_2SO_4$$
Direct neutralization is the only major commercial process for the production of ammonium nitrate either in solution or in the molten state[279]. Processes based on Chilean nitrate are nowadays much less important:

$$(NH_4)_2SO_4 + 2NaNO_3 \rightarrow 2NH_4NO_3 + Na_2SO_4$$
Crystalline diammonium hydrogen phosphate is produced from liquid ammonia and orthophosphoric acid[280]:

$$2NH_3 + H_3PO_4 \rightarrow (NH_4)_2HPO_4$$
5.3. APPLICATIONS AND USES[274, 281]

The principal use of ammonium salts is as fertilizers and as with all fertilizer salts, special attention must be paid not only to the chemical purity of the product, but also the physical characteristics of the material. Both pure compounds and mixtures (physical and chemical) are produced and applied as aqueous solutions or solids in the form of crystals, granules or prills, appropriate to the particular material. With solids, fairly even sized particles are desirable for it is the presence of "fines" that can lead to caking. This happens particularly with hygroscopic substances and can be troublesome from an application point of view, but in the case of ammonium nitrate could in certain circumstances constitute an explosion hazard[282]. For this reason, solid ammonium salt fertilizers are often coated with an inert material such as fine limestone or Kieselguhr, and water is eliminated as far as possible both before packing and during storage[283]. The factors influencing the choice of fertilizer for a particular application are varied and complex, but the nitrogen content of such materials is clearly favourably considered at the present time in view of the increased

demand for fertilizers of high nitrogen content such as ammonium nitrate (35%), urea (46%) and the controlled-release fertilizer ureaform (38%).

Regarding the other uses of ammonium salts, all the halides are employed as catalysts[276, 284, 285], the fluoride being involved in isomerization, alkylation and cracking of hydrocarbons. The fluoride is also used for cleaning metal surfaces, as a solder flux, and for etching glass[275]. The main uses of ammonium chloride are in the manufacture of dry cell batteries and in galvanizing where the molten zinc bath is protected from atmospheric oxidation by a layer of ammonium chloride through which steel sheet and articles pass to ensure that they are free of surface oxide. Ammonium chloride is also a mordant in the dyeing industry[276].

Ammonium carbonate and related compounds when heated produce gaseous products leaving no residue, and such materials find application as blowing agents for sponge rubber and plastics formation, smelling salts and baking powder[277]. Urea, the dehydration product of ammonium carbamate, is used in urea–formaldehyde resins and in the production of melamine[274].

Ammonium sulphate like the chloride and the phosphate can be used as a fire-retardant and are constituents in aqueous fire-proofing solutions for cottons and cellulose fabrics. On the other hand, ammonium nitrate is an explosive which although not entirely satisfactory, because of its relatively cheap cost is widely used particularly for blasting purposes[279]. Being hygroscopic during storage, ammonium nitrate is somewhat unpredictable, and for this reason is often compounded with other recognized explosives. High purity ammonium nitrate is required in the preparation of nitrous oxide (see section 10) for use as an anaesthetic, and ammonium perchlorate is a solid rocket fuel[286].

5.4. LABORATORY PREPARATION

Ammonium halides are prepared by the straightforward neutralization of halogen acid and ammonia:

$$HX + NH_3 \rightarrow NH_4X$$
Ammonium fluoride can be sublimed from a mixture of ammonium chloride and excess sodium fluoride:

$$NH_4Cl + NaF \rightarrow NH_4F + NaCl$$
On further heating the product loses ammonia to leave ammonium hydrogen fluoride:

$$2NH_4F \rightarrow NH_4HF_2 + NH_3$$

Ammonium chloride is prepared by a number of methods all of which rely on sublimation for final purification[276]. The direct action of ammonia on bromine under water may be used to produce ammonium bromide, but care must be taken to ensure that an alkaline solution is maintained to avoid the formation of explosive nitrogen tribromide[284]:

$$8NH_3 + 3Br_2 \rightarrow 6NH_4Br + N_2$$
[284] J. D. Richards, in ref. 273, Section X, pp. 433–47.
[285] J. D. Richards, in ref. 273, Section XI, pp. 448–58.
[286] P. W. M. Jacobs and H. M. Whitehead, *Chem. Rev.* **69** (1969) 551.

Similarly, the iodide can also be formed by reacting the element with ammonium sulphide or ammonia and hydrogen peroxide[285]:

$$(NH_4)_2S + I_2 \rightarrow 2NH_4I + S$$
$$2NH_3 + H_2O_2 + I_2 \rightarrow 2NH_4I + O_2$$
Halogen oxyacid salts are usually prepared by neutralization methods, but as with the ammonium salts of all oxidizing anions, decomposition can occur unexpectedly, e.g. ammonium chlorate is unstable and has a tendency to explode without apparent cause:

$$HClO_3 + NH_3 \rightarrow NH_4ClO_3$$
$$HClO_4 + NH_3 \rightarrow NH_4ClO_4$$
Ammonium carbonate is prepared by bringing ammonia and carbon dioxide together in aqueous solution, but the product is invariably contaminated by ammonium bicarbonate and ammonium carbamate[277]. Urea, the dehydration product of ammonium carbamate, was originally prepared by Wöhler from ammonium cyanate which can also be related to the ammonia–carbon dioxide–water system[277]:
Ammonium carbonate is sometimes a convenient starting material for the preparation of other ammonium salts:

$$(NH_4)_2CO_3 + CaSO_4 \rightarrow (NH_4)_2SO_4 + CaCO_3$$
$$(NH_4)_2CO_3 + Ca_3(PO_4)_2 + 3SO_2 + 3O_2 + 2H_2O \rightarrow 2NH_4H_2PO_4 + 3CaSO_4 + CO_2$$
Ammonium hexafluorophosphate can be prepared either by the reaction of ammonium fluoride and phosphorus pentachloride or by the degradation of phosphonitrilic chloride with hydrogen fluoride[287]:

$$PCl_5 + 6NH_4F \rightarrow NH_4PF_6 + 5NH_4Cl$$
$$(PNCl_2)_n + 6nHF \rightarrow nNH_4PF_6 + 2nHCl$$
5.5. NUCLEAR ISOTOPES $^{15}NH_4$ AND ND_4

A number of ^{15}N ammonium salts are available commercially[288] and most could be readily prepared from ^{15}N ammonia. Singly labelled ^{15}N-urea can be prepared by Wöhler's reaction of $^{15}NH_4CNO$, but the most satisfactory method for fully labelled urea is by the

[287] W. Kwasnik, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. I (ed. G. Brauer), Academic Press, New York (1963), Section 4, pp. 150–271.

[288] Office Nationale Industriel de l'Azote (ONIA), 40 avenue Hoche, Paris (VIII°), France; Isomet Corporation, Palisades Park, New Jersey, USA.

ammonolysis of diphenyl carbonate[289]. Deutero-ammonium salts are readily prepared by D₂O exchange reactions or directly by deuterolysis of metal nitrides[290]:

$$Mg_3N_2 + 8D_2O \rightarrow 2ND_4OD + 3Mg(OD)_2$$

Magnesium ammonium orthophosphate is essentially insoluble (~ 0.5 g/l), and is used for the quantitative determination of radiophosphorus-32[291]. This salt can be precipitated from an orthophosphate solution by adding a slight excess of magnesia mixture (slightly acidic solution of magnesium and ammonium chlorides) followed by a large excess of concentrated ammonia:

$$^{32}PO_4^{3-} + Mg^{2+} + NH_4^+ \xrightarrow{H_2O} MgNH_4{}^{32}PO_4 \cdot 6H_2O$$
5.6. STRUCTURE AND BONDING

The ammonium ion is tetrahedral with an overall radius of about 1.43 Å which compares with values of 1.33 and 1.48 Å for potassium and rubidium ions respectively[292], and indicates why many compounds of these ions are isostructural. However, where differences do occur, they are often attributed to hydrogen bonding[293]. For example, the structures of KHF_2 and NH_4HF_2 are of the CsCl type, but the HF_2^- ions are differently oriented with the NH_4^+ ion having four near F^- neighbouring ions in a tetrahedral arrangement with which it can form N–H–F bonds, whereas K^+ has all eight F^- neighbours equidistant[275]. Structural data on ammonium salts are listed in Table 34. In ammonium fluoride, where the strongest hydrogen bonds would be expected, the structure shows a completely ordered hexagonal arrangement of fluoride and ammonium ions. Each ammonium ion is surrounded tetrahedrally by four ammonium ions with each fluoride ion acting as hydrogen bond acceptor for four hydrogen bonds at the corners of the tetrahedra[294]. The remaining ammonium halides each have a high-temperature phase with the NaCl structure and lower temperature modifications with CsCl and tetragonal structures[292]. Explanations for the stability of these various phases have been discussed in terms of order–disorder phenomena. The lower transition temperatures are often referred to as lambda points, and are believed to correspond to transitions in which the restricted rotation of the ammonium ions become free. In ammonium perchlorate the ammonium group is apparently free to rotate[286], while ammonium hexafluorosilicate provides an example of dimorphism and disorder[294].

Ammonium sulphate undergoes a ferroelectric transition at $-49.7°C$, which has structurally been shown to involve the displacement of two independent ammonium ions in the structure which results in stronger hydrogen bonds in the ferroelectric phase (one in which there can occur a spontaneous polarization capable of reversal by the application of an electric field without causing dielectric breakdown of the material)[294].

Ammonium nitrate has a tendency to cake on storage which is due not only to its hygroscopic nature but also to breakdown of the particles as a direct result of changes in

5.8. PHYSICAL PROPERTIES

A few general physical properties of some ammonium salts are listed in Table 36. Selected values of the thermodynamic properties[296] for ammonium salts in the crystalline state (c), and for molar aqueous solutions (aq) are given in Table 37.

TABLE 37. THERMODYNAMIC PROPERTIES OF AMMONIUM SALTS[a]

Salt	State	ΔH°_{f0}	ΔH°_{f}	ΔG°_{f}	$H^{\circ}_{298}-H^{\circ}_{0}$	S°	C°_{p}

5.9. CHEMISTRY AND CHEMICAL PROPERTIES

Ammonium salts undergo slight hydrolysis in aqueous solution, but this does not usually restrict the solution chemistry:

$$NH_4^+ + H_2O \rightleftharpoons NH_3 + H_3O^+; \qquad K_{298} = 5.5 \times 10^{-10}$$
Likewise, although most ammonium salts dissociate at elevated temperatures to give ammonia and the protonated anion, the process need not be regarded as a decomposition reaction, for subsequent recombination in the vapour phase is often a convenient method of purification[276]:

$$NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g); \qquad \triangle H = 42.3 \text{ kcal/mol}; K_{298} = 10^{-16}$$

However, it would appear that salts containing small or highly charged anions polarize the ammonium cation so that dissociation occurs more readily than with salts containing large uninegative anions. In contrast, salts with oxidizing anions tend to decompose irreversibly. For example, in the same way that the ammonium ion can be oxidized to nitrogen and nitrogen oxides by nitric–hydrochloric acid mixture, so the violent high-temperature decomposition of ammonium nitrate is similar[279]:

$$2NH_4NO_3 \xrightarrow{\ 300°C\ } 2N_2 + O_2 + 4H_2O$$
The slow controlled decomposition of ammonium nitrate, however, provides the route to nitrous oxide (see section 10), and the thermal decomposition of ammonium perchlorate is also temperature dependent[286]:

$$NH_4NO_3 \xrightarrow{\ 200\text{–}260°C\ } N_2O + 2H_2O$$

$$4NH_4ClO_4 \xrightarrow{\ <300°C\ } 2Cl_2 + 2N_2O + 3O_2 + 8H_2O$$

$$2NH_4ClO_4 \xrightarrow{\ >300°C\ } Cl_2 + 2NO_2 + O_2 + 4H_2O$$
Ammonium chloride sublimes without melting and the vapour is completely dissociated into hydrogen chloride and ammonia. In its action on metals, however, ammonium chloride at, say, 250°C is considerably more reactive than the corresponding concentration of free hydrogen chloride. Also aqueous solutions of ammonium chloride react very much like dilute hydrochloric acid, properties which demonstrate the corrosive nature of the substance. An explanation for this is based on the theory that "onium" salts in the fused, solid or solution states, being acids in the Brönsted sense of the term, give rise to cations with a tendency to split off a proton:

$$NH_4Cl \rightleftharpoons Cl^- + NH_4^+ \rightleftharpoons NH_3 + H^+$$
Ammonium chloride can be oxidized to nitrosyl chloride and chlorine with strong oxidizing agents like nitric acid, and in a similar reaction potassium perchlorate is quantitatively reduced:

$$8HNO_3 + 6NH_4Cl \rightarrow 2NOCl + 2Cl_2 + 6N_2 + 3O_2 + 16H_2O$$
$$KClO_4 + 2NH_4Cl \rightarrow KCl + Cl_2 + N_2 + 4H_2O$$
From a synthetic point of view, the reaction of ammonium chloride and boron trichloride or one of its complexes gives B-trichloroborazine[276]:

$$3BCl_3 + 3NH_4Cl \rightarrow (ClBNH)_3 + 9HCl$$
Most reactions of ammonium fluoride and ammonium bifluoride are ones in which they act as fluorinating agents[275]:

$$NH_4F + SO_3 \longrightarrow NH_4SO_3F$$
$$NH_4F + P_2O_5 \longrightarrow NH_4PO_2F_2$$
$$3NH_4F + AsCl_3 \longrightarrow AsF_3 + 3NH_4Cl$$
$$6NH_4F + 3SiCl_4 \longrightarrow 2SiCl_3F + SiF_4 + 6NH_4Cl$$
$$NH_4F + BrF_3 \longrightarrow NH_4BrF_4$$
$$2NH_4HF_2 + MnF_2 \xrightarrow{\text{electrolyse}} (NH_4)_2MnF_6 + H_2$$
Ammonium iodide is somewhat similar in its reactions[285].

$$4NH_4I + SnO_2 \rightarrow SnI_4 + 4NH_3 + 2H_2O$$

Ammonium salts are important components in fused salt chemistry. For example, molten ammonium nitrate rapidly oxidizes and dissolves metals[279]. Ammonium sulphate and ammonium nitrate also form a large number of complex and double salts of interest in phase rule studies, ammonium salt purification processes and fertilizer compounding.

In the same way that alkali metals can be obtained in the free state by electrolysis of their salts, various attempts have been made to produce free "ammonium" by the reduction of ammonium salts. Electrolysis of a cold ammonium salt solution using a mercury cathode or treatment of this solution with an alkali–metal amalgam gives a product of ammonium in mercury known as ammonium amalgams:

$$NH_4^+ + NaHg_x \rightarrow (NH_4)Hg_x + Na^+$$
The amalgam is a stable solid at $-85°C$ which becomes a pasty material as it attains room temperature with accompanying decomposition to mercury, ammonia and hydrogen:

$$2(NH_4)Hg_x \rightarrow 2xHg + 2NH_3 + H_2$$
Amalgams of substituted ammonias can also be prepared by analogous methods[298].

Conventional electrolysis of aqueous ammonium halides can be represented by the following general equations:

$$2NH_4^+ + 2e^- \rightarrow 2NH_3 + H_2$$
$$2X^- \rightarrow 2X + 2e^-$$
$$2X + NH_4X \rightarrow NH_2X + 2HX$$
$$4NH_2X \rightarrow 2NH_4X + N_2 + X_2$$
$$2OH^- \rightarrow H_2O + O + 2e^-$$
Thus the final products are aqueous ammonia and hydrogen at the cathode, together with halogen, hydrogen halide, nitrogen and a little oxygen, are liberated at the anode[276, 284, 285].

[298] W. L. Jolly, *Inorganic Chemistry of Nitrogen*, Benjamin, New York (1964), p. 43.

5.10. BIOLOGICAL PROPERTIES[299]

The principal rôle of ammonium salts is as fertilizers, and the various physical and chemical characteristics of such materials are major factors taken into consideration in choosing a fertilizer for a particular application. Ammonium salts also play an important part in nitrogen metabolism, but this is not easy to define or analyse because of ammonia–ammonium salt–urea equilibria.

5.11. ANALYSIS OF AMMONIUM SALTS[300]

In the Formol titration, ammonium salts and organic amino acids react with formaldehyde to release acid which can be titrated with standard base:

$$4NH_4^+ + 6HCHO \rightarrow (CH_2)_6N_4 + 6H_2O + 4H^+$$
However, ammonium salts are generally detected and analysed as ammonia which can be released simply by making the solution alkaline. Ammonia can then be distilled into saturated boric acid, and the borate formed determined by titration with standard hydrochloric acid using bromocresol green–methyl red indicator.

Probably the most widely and commonly used method of estimating ammonium and ammonia in aqueous solution is by the colorimetric method using alkaline potassium mercuri–iodide commonly known as Nessler reagent. The reaction can be represented by the following equation, although the composition of the brown precipitate has also been given as $NHg_2I \cdot H_2O$:

$$2K_2HgI_4 + 2NH_3 \rightarrow NH_2Hg_2I_3 + 4KI + NH_4I$$

It is, of course, not necessary to know the exact stoichiometry of the reaction or even the species involved so long as Beer's law is obeyed for a known range of ammonia concentrations. An alternative colorimetric method of analysis is based on the reaction of ammonia with phenol and hypochlorites.

6. HYDRAZINE

6.1. PRODUCTION

The principal commercial method for producing hydrazine is the Raschig synthesis[301-4] of 1907 based on the partial oxidation of ammonia by hypochlorite in aqueous alkali (1):

$$2NH_3 + NaOCl \rightarrow N_2H_4 + NaCl + H_2O \tag{1}$$
[299] F. Call, in ref. 273, Section XVII, pp. 567–615.
[300] K. I. Vasu, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part II, Longmans, London (1967), pp. 563–673.
[301] G. H. Hudson, R. C. H. Spencer and J. P. Stern, in ref. 300, pp. 69–114.
[302] L. F. Andrieth and B. A. Ogg, *The Chemistry of Hydrazine*, Wiley, New York (1951).
[303] F. Raschig, *Schwefel- und Stickstoffstudien*, Verlag Chemie, GmbH, Leipzig–Berlin (1924).
[304] C. Matasa and E. Matasa, *L'Industrie Moderne des Produits Azotes*, Dunod, Paris (1968).

The overall process is stepwise and dependent on the rapid initial formation of chloramine which proceeds to completion even in the cold (2):

$$NH_3 + OCl^- \rightarrow NH_2Cl + OH^- \qquad (2)$$

The reactions of chloramine that follow have since been shown[305] to produce hydrazine either by nucleophilic attack of ammonia (3) and subsequent neutralization (4), or by preliminary formation of the chloramide ion (5) followed by nucleophilic attack of ammonia (6):

$$NH_3 + NH_2Cl \rightarrow N_2H_5^+ + Cl^- \quad slow \qquad (3)$$

$$N_2H_5^+ + OH^- \rightarrow N_2H_4 + H_2O \quad fast \qquad (4)$$

$$NH_2Cl + OH^- \rightarrow NHCl^- + H_2O \quad fast \qquad (5)$$

$$NHCl^- + NH_3 \rightarrow N_2H_4 + Cl^- \quad slow \qquad (6)$$
However, a further reaction can occur between chloramine and the product hydrazine as in (7):

$$2NH_2Cl + N_2H_4 \rightarrow 2NH_4Cl + N_2 \quad fast \qquad (7)$$
Clearly, reaction (7) is undesirable, particularly as it proceeds at a faster rate than the hydrazine producing reactions (3) and (4), or (5) and (6). It is now known that reaction (7) is catalysed by traces of metal ions, notably copper(II), even in concentrations of a few ppm. This can be inferred from the fact that reaction (7) does not occur when very pure reagents are used nor in the presence of complexing agents which inactivate metal ions in solution. Since the former method is somewhat impractical on an industrial scale, the addition of a glue-like material or gelatine to the reaction mixture as discovered by Raschig[303] is still used and serves to inhibit and suppress reaction (7) while in some way assisting the hydrazine-forming reactions.

The Raschig process as it operates industrially is continuous, and involves mixing an ammonia–hypochlorite (30:1) solution with a gelatine solution in the cold followed by rapid heating through a reactor at 150°C under pressure to avoid loss of ammonia. After a residence time in the reactor of only 1 second, the liquid contains about 0.5% by weight of hydrazine corresponding to about 60% conversion based on hypochlorite. Ammonia and steam are then stripped off in stages, concentrating the hydrazine solution through 2%, 10% and final distillation to give pure hydrazine hydrate $N_2H_4 \cdot H_2O$ (64% hydrazine) in overall yields of up to 70% [301, 304]. Urea can also be used as a source of ammonia, otherwise the process is very similar requiring the presence of an inhibitor and rapid heating to give good yields[302]:

$$NH_2CONH_2 + NaOCl + 2NaOH \rightarrow N_2H_4 \cdot H_2O + NaCl + Na_2CO_3$$
New modifications of the Raschig process include the reaction of ammonia and chlorine in a ketone solvent[304, 306] to give a diazacyclopropane, presumably via chloramine and

[305] G. Yagil and M. Anbar, *J. Am. Chem. Soc.* **84** (1962) 1797.
[306] *Chem. Engng. News* (1965), 5 July, p. 38.

ketimine, which can take up another mole of ketone under acid conditions giving a ketazine capable of acid hydrolysis under pressure to produce hydrazine sulphate:

$$2NH_3 + Cl_2 \rightarrow NH_4Cl + NH_2Cl$$

$$NH_3 + R_2CO \rightarrow R_2C{=}NH + H_2O$$

$$NH_4Cl + R_2C{=}NH + NH_3 \rightarrow NH_4Cl + R_2C \overset{\displaystyle NH}{\underset{\displaystyle NH}{\Big\langle}}$$

$$R_2CO$$

$$2R_2CO + N_2H_6SO_4 \xleftarrow[H_2SO_4]{2H_2O} R_2C{=}N{-}N{=}CR_2 + H_2O$$
Aqueous hydrazine and hydrazine hydrate can be concentrated to about 85% by further distillation. However, anhydrous hydrazine can only be obtained from aqueous media by dehydration with solid caustic soda or potash followed by distillation. Alternatively, hydrazine sulphate can be precipitated from dilute hydrazine solutions by treatment with dilute sulphuric acid, and after filtration and drying, reaction with liquid ammonia precipitates ammonium sulphate leaving anhydrous hydrazine after the ammonia has evaporated off the filtrate:

$$N_2H_4 + H_2SO_4 \xrightarrow{H_2O} N_2H_6SO_4$$

$$N_2H_6SO_4 + 2NH_3 \xrightarrow{\text{liq. } NH_3} N_2H_4 + (NH_4)_2SO_4$$
Other methods by which hydrazine is formed include the decomposition of ammonia and related derivatives by irradiation either in the presence or absence of inert gases krypton or xenon into amide radicals (NH_2^-) which can dimerize[307]:

$$NH_3 \xrightarrow{h\nu} NH_3^+ + e^-$$

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2$$

$$NH_4^+ + e^- \rightarrow NH_2 + H_2$$

$$NH_3 \xrightarrow{h\nu} NH_2^+ + H^{\cdot} + e^-$$

$$N_2H_4 + H^{\cdot} \rightarrow N_2H_3^- + H_2$$

$$N_2H_4 + H^{\cdot} \rightarrow NH_2^- + NH_3$$
Similarly, in the direct oxidation of ammonia with molecular oxygen, hydrazine can be detected when the gas mixture is passed over the alkaline surface of activated metal oxides.

The majority of other reactions in which hydrazine is a major product are based on the reduction of compounds already containing N–N bonds including nitramide, nitroso-hydroxylamine, nitrosoamines, nitrosoketones and organic azo compounds[301,302,308]. It has also been claimed that hydrazine is formed when carbonyl-forming metals such as nickel react with urea at 60–70°C [301]:

$$NH_2CONH_2 \xrightarrow{Ni} CO + N_2H_4$$
[307] N. J. Friswell and B. G. Gowenlock, in *Advances in Free-Radical Chemistry*, Vol. 2 (ed. G. H. Williams), Logos Press, Academic Press, London (1967), pp. 1–45.

[308] L. A. Raphaelson, in *Kirk–Othmer Encyclopedia of Chemical Technology*, 2nd edn., Vol. II, Interscience, New York (1966), pp. 164–96.

6.2. APPLICATIONS AND USES OF HYDRAZINE

Hydrazine is surprisingly stable in view of its endothermic nature:

$$N_2(g) + 2H_2(g) \rightarrow N_2H_4(l); \qquad \triangle H_f^\circ = 12 \text{ kcal/mol}$$
It will burn in air or any other oxygen source with a considerable evolution of heat and conversion to low molecular weight products[302]:

$$N_2H_4(l) + O_2(g) \rightarrow N_2(g) + 2H_2O(l); \qquad \triangle H = 148.6 \text{ kcal/mol}$$
Hence a major use of hydrazine and its derivatives is as a fuel for guided missiles and rockets[302]. When combined with an appropriate oxidizing agent such as liquid oxygen, hydrogen peroxide, nitric acid or fluorine, it gives high exhaust velocities and hence high specific impulse at relatively low combination temperatures. Its stability and good storage properties make it suitable for immediate use, and it can be rapidly ignited catalytically to give high exhaust velocities and hence high specific impulse at relatively low combination temperatures. The disadvantage of the relatively high melting point of hydrazine (2°C) is that at temperatures which prevail in the upper atmosphere it can solidify, and for this reason derivatives such as *NN*-dimethylhydrazine are used, either pure or as mixtures with hydrazine[301, 308].

Hydrazine salts of strongly oxidizing anions may also find application as explosives, e.g. solid hydrazine nitrate explodes more readily than ammonium nitrate[309]. Its affinity for oxygen has also been used to remove oxygen from high-pressure boiler systems, and similarly hydrazine prevents discoloration of amines, stabilizes lubrication oils and inhibits peroxide formation in glycol ethers, presumably by suppressing oxidative deterioration[301].

Hydrazine is attractive as a reducing agent because of its high available hydrogen content and because its oxidation product is nitrogen. Hydrazine will reduce a number of important metal salts to the element including silver, the traditional way of producing mirrors and metal coatings. Metals important as catalysts such as nickel can also be reduced in a finely divided form or coated on plastics[301, 308]. Hydrazine and its salts are also used as a reducing agent in organic syntheses[301] and in analytical chemistry[302]. The reducing properties also make hydrazine hydrohalides useful as fluxes for welding and soldering metals, particularly copper and its alloys, as no residue remains to initiate corrosion at the join[301]. A further use relying on reducing properties is as a fuel in the hydrazine–oxygen fuel cell[310] in which the overall reaction is:

$$N_2H_4 + O_2 \rightarrow N_2 + 2H_2O; \qquad E^\circ = 1.56 \text{ V}$$
where the anode reaction is

$$N_2H_4 + 4OH^- \rightarrow N_2 + 4H_2O + 4e^-; \qquad E^\circ = 1.16 \text{ V}$$
and the cathode reaction is

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-; \qquad E^\circ = 0.40 \text{ V}$$
High current densities can be obtained as the concentration polarization is preserved due to the high solubility of hydrazine in the electrolyte. A significant cost reduction in producing fuel cells would see their widespread application[308].

[309] T. Urbanski, *Chemistry and Technology of Explosives*, Vol. II, Pergamon Press, London (1965).

[310] S. S. Tomter and A. P. Anthony, *The Hydrazine Fuel Cell System in Fuel Cells*, Amer. Inst. of Chem. Engineers, New York (1963), pp. 22–31.

Applications arising from the difunctional nature of hydrazine include reactions with dibasic acids such as sebacic acid, to give polymeric amides that can be drawn into fibres, and it is also incorporated in some polymeric materials as a cross-linking agent[308]. The formation of free radicals can to some extent arise as a result of homolytic fission of the symmetrical diamine[307]. Free radicals formed during the decomposition or oxidation of hydrazine have been used as initiators to several polymerization processes, particularly in emulsion polymerization where hydrazine can also act as a blowing agent in the production of plastic foams[301]. Hydrazine derivatives find wide use as chemotherapeutic agents, particularly in the treatment of leprosy and tuberculosis[301].

6.3. LABORATORY PREPARATION OF HYDRAZINIUM SULPHATE, HYDRAZINE HYDRATE AND ANHYDROUS HYDRAZINE

Hydrazine sulphate is prepared by a small-scale Raschig process using either lime water or sodium ethylenediaminetetra-acetate to complex the traces of heavy metal present which catalyse the decomposition of the product[311]:

$$2NH_3 + NaOCl + H_2SO_4 \rightarrow N_2H_6SO_4 + NaCl + H_2O$$
The product is only slightly soluble in cold dilute acid and so can be filtered off and recrystallized from hot aqueous solution if necessary.

Hydrazine hydrate can be obtained by distillation of hydrazine sulphate in alkaline solution, and collecting the fraction with the boiling range 117–119°C at atmospheric pressure.

$$N_2H_6SO_4 + 2KOH \rightarrow N_2H_4 \cdot H_2O + K_2SO_4$$
Anhydrous hydrazine can be distilled in a stream of nitrogen after dehydrating hydrazine hydrate with solid sodium hydroxide or barium oxide. Alternatively, hydrazine salts can be cleaved with ammonia and the hydrazine separated by vacuum distillation.

$$N_2H_5Cl + NH_3 \rightarrow N_2H_4 + NH_4Cl$$
The insolubility of ammonium sulphate in liquid ammonia also forms the basis of a separation to give hydrazine of high purity:

$$N_2H_6SO_4 + 2NH_3 \xrightarrow[\text{ammonia}]{\text{liquid}} N_2H_4 + (NH_4)_2SO_4$$
6.4. NUCLEAR ISOTOPES $^{15}N_2H_4$

Because such a large excess of $^{15}NH_3$ is necessary to avoid side reactions; the Raschig synthesis is a particularly unfavourable process to carry out using enriched materials. However, by taking advanced precautions to ensure recovery of all ^{15}N byproducts, $^{15}N_2H_4$ can be obtained from the overall process[312]:

$$2^{15}NH_3 + OCl^- \rightarrow {}^{15}N_2H_4 + H_2O + Cl^-$$
[311] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. I (ed. G. Brauer), Academic Press, New York (1963), pp. 468–72.
[312] J. W. Cahn and R. E. Powell, *J. Am. Chem. Soc.* **76** (1954) 2568.

Alternatively, the singly labelled compound can be prepared by adding excess $^{14}NH_3$ to the enriched ammonia–hypochlorite solution prior to heating[313]:

$$^{15}NH_3 + OCl^- \rightarrow {}^{15}NH_2Cl + OH^-$$

$$^{15}NH_2Cl + {}^{14}NH_3 + OH^- \rightarrow {}^{15}NH_2{}^{14}NH_2 + H_2O + Cl^-$$
The enriched hydrazine is distilled off with excess ammonia into dilute sulphuric acid and recrystallized as the sulphate. Anhydrous hydrazine can be obtained by shaking the labelled hydrazine sulphate with liquid ammonia at $-45°C$, filtering off the ammonium sulphate and then evaporating the ammonia solvent from the filtrate. N_2D_4 and related compounds have been used for spectroscopic purposes[314].

6.5. STRUCTURE AND BONDING

One of the significant comparisons between the ammono- and aquo- series of compounds is the structural and chemical comparison of hydrazine with hydrogen peroxide. As indicated by the high values for the melting point, boiling point and Trouton's constant, hydrazine is extensively associated through hydrogen bonding in the condensed phases, but monomeric in the gas phase[315]. Electron diffraction data[316] give the N–N–H angle as 112° and the N–N bond length as 1.45 Å, suggesting sp^3 hybridization at the nitrogen atoms. Thus it is reasonable to assume that the two nitrogen atoms are joined by a σ bond, rotation around which can give rise to one or other of the conformational isomers illustrated in Fig. 18.
FIG. 18. Conformations of hydrazine.

Clearly the large dipole moment of 1.85 Debye units eliminates the *trans* (C_{2h}) conformation, and the *gauche* form is usually considered to be the equilibrium conformation as both the eclipsed and semi-eclipsed conformations would involve coplanar repulsions[317]. *Ab*

initio calculations of the barriers to internal rotation give values of 11.88 and 3.70 kcal/mol[318], and the fundamental frequencies, infrared and Raman bands have been assigned based on C_2 symmetry[314, 319].

Hydrazine being dibasic can give rise to two series of salts $N_2H_4 \cdot HA$ and $N_2H_4 \cdot 2HA$ which contain the $N_2H_5^+$ and $N_2H_6^{2+}$ ions respectively[301]. However, some confusion has arisen with salts of di- and poly-basic acids in part due to nomenclature. For example,

TABLE 38. CRYSTAL STRUCTURES OF HYDRAZINE AND SOME OF ITS SALTS[a]

Compound	Crystal system	Lattice parameters (Å)	Interatomic distances (Å)
N_2H_4	Monoclinic	$a = 3.56, b = 5.78$ $c = 4.53, \beta = 109.5°$	N–N = 1.46

$N_2H_6SO_4$, commonly known as hydrazine sulphate, contains the $N_2H_6^{2+}$ and SO_4^{2-} ions[320] and would be more precisely named as hydrazinium($+2$) or hydrazonium sulphate, whereas $N_2H_6C_2O_4$ has been reported[321] to be hydrazinium monoxalate $N_2H_5^+ HC_2O_4^-$. In hydrazinium difluoride $N_2H_6F_2$, the $N_2H_6^{2+}$ ions have the fully staggered conformation when viewed along the N–N axes, and are linked to the fluoride ions entirely by hydrogen bonding[322]. As hydrogen bonding is not possible with the other halides, the dichloride

$N_2H_6Cl_2$ has a somewhat distorted fluorite structure[323]. The crystal structures of some simple hydrazine salts are given in Table 38. The name for hydrazine hydrate, however, would appear to be accurate, for in the crystal each water molecule is linked by six hydrogen bonds to discrete hydrazine molecules[324], and there is no evidence for structures based on $N_2H_5^+$ OH^- or $N_2H_6^{2+}$ O^{2-}.

Although in comparisons the similarities between hydrazinium and ammonium salts are frequently emphasized, there are often important structural differences. For example, $(NH_4)_2Zn(SO_4)_2 \cdot 6H_2O$ contains water of crystallization, some of which is co-ordinated to the metal, whereas $(N_2H_5)_2Zn(SO_4)_2$ is anhydrous implying that the hydrazinium groups may also be co-ordinated. X-ray structure determination indicates that this is so with the hydrazinium groups co-ordinated *trans* to octahedral zinc and participating in hydrogen bonding with bridging sulphate groups[325].

A large number of hydrazine complexes of general formula $M^{II}(N_2H_4)X_2$ in which the ligand acts as a bidentate chelate bridging between two metal atoms have been reported[326]. Very little structural information is available, but infrared studies indicate that the complex $[Hg(N_2H_4)Cl_2]_n$ has an extended chain structure. $Hg(N_2H_4)_2Cl_2$ is also known and may contain terminal hydrazine groups of C_2 local symmetry, bonded at one end only[327], but the formula can also be written $HgCl_2 \cdot 2N_2H_4$ suggesting the presence of hydrazine of crystallization. Other derivatives of hydrazine include the hydrazide ions $N_2H_3^-$ and $N_2H_2^{2-}$, for which infrared data on $[Zn(N_2H_3)_2]_n$ is consistent with a polymer chain of six-membered ring repeat units[328], while $[Hg_2(N_2H_2)]Cl_2$ has a layer lattice structure[327].

6.6. MOLECULAR CONSTANTS

Several infrared and Raman spectroscopic investigations have been carried out on hydrazine[314], and assignments are consistent with C_2 symmetry as indicated in Table 39. A variety of other spectroscopic data is also known for hydrazine including ultraviolet[301], microwave[329], nuclear magnetic resonance[330] and mass spectra[331]. Infrared spectra have been recorded on hydrazine complexes and salts[332], and the values for the band assigned to the N–N stretching frequency correlates well with the corresponding N–N bond length. In a series of related compounds, v(N–N) can be used to assign the structure type[333] as the value is lower for unidentate N_2H_4 than for bridged N_2H_4, and $N_2H_5^+$ is lower than $N_2H_6^{2+}$, a trend which probably reflects the state of repulsion between the lone pairs.

and its derivatives are given in Table 42. Other thermodynamic data which are pertinent to the chemistry of hydrazine are the standard heats of formation of the amino NH_2^- and hydrazino $N_2H_3^-$ radicals at 44 ± 2 and 46 ± 5 kcal/mol respectively[334]. These values are conditional on the bond dissociation energies $D(NH_2-NH_2) = 60 \pm 4$ kcal/mol and $D(N_2H_3-H) = 76 \pm 7$ kcal/mol. From the heat of atomization of hydrazine of 411.6 kcal/mol, and assuming that the average N–H bond energy in hydrazine is the same as the average N–H bond energy in ammonia, the bond energy $E(N-N)$ is 38 kcal/mol[307,335].

6.8. CHEMISTRY AND CHEMICAL PROPERTIES

6.8.1. Decomposition

Although hydrazine is kinetically stable at room temperature and even at temperatures approaching its critical temperature (380°C), the positive free energy of formation, however,

[a] In ref. 334.

is indicative of potential instability. As the only stable products of hydrazine decomposition are ammonia, nitrogen and hydrogen, the varying amounts of each can often be expressed[302] in the form of a general equation (1):

$$3N_2H_4 \rightarrow 4(1-x)NH_3 + (1+2x)N_2 + 6xH_2 \tag{1}$$
Thus the products of decomposition can be specified for a particular set of conditions simply by indicating the value of x. The overall general equation, however, represents the extent to which the individual reactions (2–4) occur.

$$3N_2H_4(g) \rightarrow 4NH_3(g) + N_2(g); \qquad \Delta H = -37.4 \text{ kcal/mol} \tag{2}$$

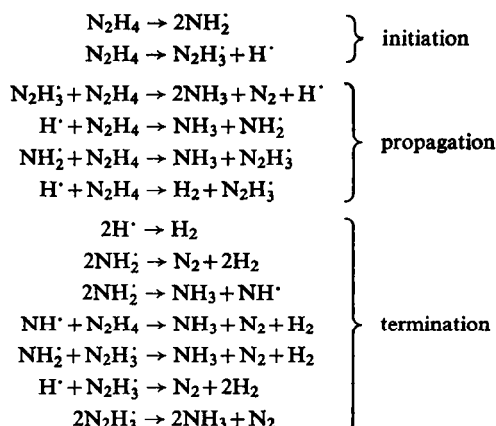
$$N_2H_4(g) \rightarrow N_2(g) + 2H_2(g); \qquad \Delta H = -22.8 \text{ kcal/mol} \tag{3}$$

$$N_2H_4(g) + H_2(g) \rightarrow 2NH_3(g); \qquad \Delta H = -44.8 \text{ kcal/mol} \tag{4}$$
As reactions which produce ammonia must be thermodynamically favoured under conditions where ammonia is stable, the presence of hydrogen would be expected to increase the stability of hydrazine as in (4). For example, when gaseous hydrazine is decomposed thermally at 250–310°C on silica, the products correspond to equation (2) ($x = 0$), whereas decomposition on platinum wire gives $x = 0.25$ [302].

Considerable evidence has accumulated to indicate that the gaseous decomposition of hydrazine involves free radicals[307]. Several mechanisms have been proposed[302] which can be separated into initiation, propagation and termination steps involving atomic hydrogen, imide, amide and hydrazyl radicals as intermediates in reactions of the type described below:

$$N_2H_4 \rightarrow 2NH_2^{\cdot}$$
$$N_2H_4 \rightarrow N_2H_3^{\cdot} + H^{\cdot}$$
$\left.\right\}$ initiation

$$N_2H_3^{\cdot} + N_2H_4 \rightarrow 2NH_3 + N_2 + H^{\cdot}$$
$$H^{\cdot} + N_2H_4 \rightarrow NH_3 + NH_2^{\cdot}$$
$$NH_2^{\cdot} + N_2H_4 \rightarrow NH_3 + N_2H_3^{\cdot}$$
$$H^{\cdot} + N_2H_4 \rightarrow H_2 + N_2H_3^{\cdot}$$
$\left.\right\}$ propagation

$$2H^{\cdot} \rightarrow H_2$$
$$2NH_2^{\cdot} \rightarrow N_2 + 2H_2$$
$$2NH_2^{\cdot} \rightarrow NH_3 + NH^{\cdot}$$
$$NH^{\cdot} + N_2H_4 \rightarrow NH_3 + N_2 + H_2$$
$$NH_2^{\cdot} + N_2H_3^{\cdot} \rightarrow NH_3 + N_2 + H_2$$
$$H^{\cdot} + N_2H_3^{\cdot} \rightarrow N_2 + 2H_2$$
$$2N_2H_3^{\cdot} \rightarrow 2NH_3 + N_2$$
$\left.\right\}$ termination


Such decompositions are often used as sources of these radicals for further study. The amino radical $NH_2^{\cdot}$ can also be produced in reactions of HN_3, NH_2OH and Me_2NNH_2, whereas hydrazine is the principal source of the hydrazyl radical $N_2H_3^{\cdot}$. Reactions of $N_2H_3^{\cdot}$ in the above scheme reflect the tendency of the N–N bonded radical to produce N–N by the observations that dimerization to tetrazane has only been mentioned as a possibility at $-178\,°C$, and even thermodynamically favoured disproportionation is not suggested in favour of nitrogen and ammonia formation[302].

$$2N_2H_3^{\cdot} \longrightarrow NH_2NHNHNH_2$$

$$2N_2H_3^{\cdot} \longrightarrow N_2H_2 + N_2H_4$$

$$\longrightarrow 2NH_3 + N_2$$
6.8.2. Oxidation

Hydrazine–air mixture can be ignited above 130°C in a metal burner, whereas it is reported[302] that hydrazine–oxygen mixture with a platinum catalyst can ignite at only 30°C.

$$N_2H_4(l) + O_2(g) \rightarrow N_2(g) + 2H_2O(l); \qquad \Delta H = -148.6 \text{ kcal/mol}$$
However, most oxidation reactions of hydrazine yield a mixture of ammonia and nitrogen, some give hydrazoic acid and a few nitrogen only. Such complex situations can only be rationalized for a number of idealized reactions in aqueous solution for which redox potentials can be compared as in equations (5)–(10) and in the oxidation state diagram illustrated in Fig. 19.

$$N_2H_5^+ \rightarrow NH_4^+ + \tfrac{1}{2}N_2 + H^+ + e^-; \qquad E^\circ = -1.74 \text{ V} \qquad (5)$$

$$N_2H_5^+ \rightarrow \tfrac{1}{2}NH_3 + \tfrac{1}{2}NH_4^+ + H^+ + 2e^-; \qquad E^\circ = +0.11 \text{ V} \qquad (6)$$

$$N_2H_5^+ \rightarrow N_2 + 5H^+ + 4e^-; \qquad E^\circ = -0.23 \text{ V} \qquad (7)$$

$$N_2H_4 + OH^- \rightarrow NH_3 + \tfrac{1}{2}N_2 + H_2O + e^-; \qquad E^\circ = -1.16 \text{ V} \qquad (8)$$

$$N_2H_4 + OH^- \rightarrow \tfrac{1}{2}N_3^- + \tfrac{1}{2}NH_3 + H_2O + 2e^-; \qquad E^\circ = -0.92 \text{ V} \qquad (9)$$

$$N_2H_4 + 4OH^- \rightarrow N_2 + 4H_2O + 4e^-; \qquad E^\circ = -1.16 \text{ V} \qquad (10)$$
Fig. 19. Oxidation state diagram for hydrazine and related nitrogen species.

The shape of the graph in Fig. 19 suggests that disproportionation type reactions are possible. Several attempts have been made to classify oxidizing agents according to the equations (5)–(10), but invariably overall reactions are described by a combination of more than one equation. Experiments using $^{14}NH_2^{15}NH_2$ have been necessary to establish that $^{14}N^{15}N$ is formed by (7) and (10), but in (5) and (8) half of the nitrogen formed has a random distribution of the ^{15}N isotope[336]. Mechanisms consistent with this, and supported by other evidence, are generally free radical type involving the generation of diimide and hydrazyl radicals[302, 307]:

$$N_2H_4 \rightarrow N_2H_3^{\cdot} + H^{\cdot}$$

$$2N_2H_3^{\cdot} \rightarrow \underset{\text{Tetrazane}}{N_4H_6} \rightarrow N_2 + 2NH_3$$

$$N_2H_4 \rightarrow \underset{\text{Diimide}}{HN{=}NH} \rightarrow \underset{\text{Imide}}{2NH^{\cdot}}$$

$$2N_2H_2 \rightarrow \underset{\text{Tetrazene}}{N_4H_4} \rightarrow N_2 + N_2H_4$$

$$N_2H_2 + NH^{\cdot} \rightarrow \underset{\text{Triazene}}{H_3N_3} \rightarrow N_2 + NH_3$$

$$2N_2H_2 \rightarrow \underset{\text{Isotetrazene}}{NH{=}NNHNH_2} \rightarrow HN_3 + NH_3$$
6.8.3. Reactions of Anhydrous Hydrazine

The high dielectric constant of anhydrous liquid hydrazine suggests that it should be a reasonable solvent for many ionic compounds. These include alkali-metal halides, tetra-alkylammonium halides and many carboxylic acids which are completely dissociated in it, but a number of oxides, sulphates and carbonates are practically insoluble[337]. Complexes and solvates have been formed by dissolving metal halides, etc., in liquid hydrazine to give $M^{II}X_2 \cdot 2N_2H_4$ as well as hydrazinium double salts $(N_2H_5)_2M^{II}(SO_4)_2$ [326]. However, as a solvent for acid–base reactions, there is no advantage over the more readily available and safer liquid ammonia as their proton affinities are so similar.

The self-ionization reaction of pure liquid hydrazine is

$$2N_2H_4 \rightleftharpoons N_2H_5^+ + N_2H_3^-$$
Thus although many compounds are known to behave as strong acids, a few substances including the alkali metal hydrazides behave as bases. Sodium hydrazide NaN_2H_3 explodes violently in the presence of O_2 or when heated above 100°C. It was formerly prepared by dissolving sodium in liquid hydrazine in the absence of air, but even that method was unpredictably hazardous. Sodium hydrazide is now made from sodium amide or sodium hydride and used as a suspension in an ether solvent:

$$NaR + N_2H_4 \rightarrow NaN_2H_3 + RH \qquad (R = H, NH_2)$$
The reactions of sodium hydrazide with a number of organic compounds has been investigated[337], but apart from the neutralization reaction, the inorganic chemistry of metal hydrazides has not received much attention[336]:

$$NaN_2H_3 + N_2H_5Cl \rightarrow 2N_2H_4 + NaCl$$

[336] W. L. Jolly, *The Inorganic Chemistry of Nitrogen*, Benjamin, New York (1964).
[337] V. Gutmann, *Coordination Chemistry in Non-Aqueous Solutions*, Springer-Verlag, New York (1968), pp. 48–49.

More recently, however, organometallic derivatives of hydrazine have been prepared by methods appropriate to the formation of metal amides[339].

$$4Me_3SnNMe_2 + N_2H_4 \rightarrow (Me_3Sn)_2NN(SnMe_3)_2 + 4Me_2NH$$

There seems no reason why such derivatives should not be formed by elements other than boron[340], silicon[341] and tin[339].

6.9. BIOLOGICAL PROPERTIES[302]

In the nitrogen fixation process, no intermediates between nitrogen and ammonia have been isolated, and although a reductive pathway via diimine and hydrazine would seem to be preferred, there is little supporting evidence[342]. However, if either of these species are formed during fixation, it is likely that they remain closely associated with the enzyme until reduction to ammonia is complete.

Hydrazine is a dangerous though non-cumulative poison as it can inhibit certain enzyme systems causing reduced body metabolism. Skin contact with anhydrous hydrazine leads to caustic-like burns, and dissolves hair, while the vapour produces severe irritation of eyes and mucous membrane. However, some hydrazine salts and derivatives are used as chemotherapeutic agents[301].

6.10. ANALYSIS OF HYDRAZINE[301, 302]

Since hydrazine is a powerful reducing agent, tests with a wide range of oxidizing agents are only specific if other reducing agents like hydroxylamine are absent. The reaction of hydrazine with organic aldehydes to form coloured organic azines is often used as a spot test and is specific even in the presence of hydroxylamine and other nitrogen compounds. For example, the reaction with p-dimethylaminobenzaldehyde gives the corresponding azine which rearranges in the presence of strong acids to a quinoid structure which forms the basis of a colorimetric method of analysis:
As hydrazine is a weak base ($K_B = 8.5 \times 10^{-7}$ at 25°C), it can be determined together with its major impurity ammonia by titration with acid. Hydrazine alone can then be titrated in 3–5 M HCl with standard potassium iodate solution with chloroform to help

detect the end point at which iodine is discharged. Although the overall reaction is described by the equation

$$N_2H_4 + KIO_3 + 2HCl \rightarrow KCl + ICl + N_2 + 3H_2O$$
the process involves reduction of the iodate by hydrazine to iodine which is subsequently oxidized by additional iodate to iodine monochloride. This is known as the direct iodate method, the indirect method being based on the fact that both hydrazine and iodide ions reduce iodate to iodine which can be titrated with thiosulphate. Potassium bromate can also be used in place of iodate.

Volatile impurities in hydrazine are generally detected and determined by physical techniques, particularly by infrared spectroscopy on liquid or gaseous samples.

7. HYDROXYLAMINE

7.1. PRODUCTION AND INDUSTRIAL USE

In the conventional Raschig synthesis of hydroxylamine[343-6], nitrite is reduced with bisulphite and sulphur dioxide at 0°C to give hydroxylamido-N,N-disulphate which can be hydrolysed stepwise to hydroxylammonium sulphate. The nitrite solution is prepared by burning ammonia–air mixture over a platinum–rhodium catalyst grid to give NO and NO_2, and the gases absorbed in ammonium carbonate solution:

$$NO + NO_2 + 2(NH_4)_2CO_3 + H_2O \rightarrow 2NH_4NO_2 + 2NH_4HCO_3$$
$$NH_4NO_2 + 2SO_2 + NH_3 + H_2O \rightarrow HON(SO_3NH_4)_2$$
$$HON(SO_3NH_4)_2 + H_2O \rightarrow HONHSO_3NH_4 + NH_4HSO_4$$
$$2HONHSO_3NH_4 + 2H_2O \rightarrow (HONH_3)_2SO_4 + (NH_4)_2SO_4$$
Thus using ammonium salts, the process also yields a large amount of ammonium sulphate as saleable byproduct. In an effort to find a process giving much less or no byproducts, the catalytic reduction of nitric oxide has been suggested[343, 347]. For this process, nitric oxide is manufactured by passing ammonia–oxygen mixture and steam as diluent over platinum–rhodium catalyst at about 600°C:

$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O$$

Surprisingly, conditions can be controlled to give nitric oxide of greater than 99% purity in spite of the variety of other reactions which are thermodynamically favourable (see section 11). The reduction of nitric oxide is again platinum catalysed at low pH with $NO:H_2$ ratios greater than theoretical 1:1.5:

$$2NO + 3H_2 + H_2SO_4 \rightarrow (HONH_3)_2SO_4$$
An alternative reduction process is the electrolytic reduction of nitric acid usually in mixed sulphuric–hydrochloric acid using amalgamated lead electrodes[343, 345, 346]. The

[347] *Nitrogen*, No. 50 (1967) 27.

product is recovered by passing dry hydrogen chloride through the electrolysed solution and filtering off the precipitated hydroxylammonium chloride:

$$HNO_3 + 6H^+ + 6e^- \rightarrow HONH_2 + 2H_2O$$
$$\downarrow HCl$$
$$(HONH_3)Cl$$
The hydrolysis of aliphatic nitro compounds during reflux with strong mineral acids offers economic routes to hydroxylamine derivatives and carboxylic acids as useful by-products[343]:

$$2RCH_2NO_2 + H_2SO_4 + 2H_2O \rightarrow 2RCOOH + (HONH_3)_2SO_4$$
Such starting materials are readily obtained by vapour phase nitration of aliphatic hydrocarbons, e.g. 1,2-dinitroethane can be prepared from ethylene and dinitrogen tetroxide, and subsequent hydrolysis gives hydroxylammonium sulphate as the sole product in acid solution[343]:

$$CH_2{=}CH_2 + N_2O_4 \rightarrow O_2NCH_2CH_2NO_2 \xrightarrow[H_2O]{H_2SO_4} CO_2 + CO + (HONH_3)_2SO_4$$
Aqueous solutions of hydroxylamine are obtained from hydroxylammonium salts by ion exchange, while free hydroxylamine can be prepared by ammonolysis of hydroxylammonium sulphate with liquid ammonia. Insoluble ammonium sulphate can be filtered off and the solvent evaporated under reduced pressure to leave unstable solid hydroxylamine[343].

As part of its extensive organic chemistry[348], a major use of hydroxylamine or its salts is the preparation of cyclohexanone oxime in the manufacture of caprolactam which is an intermediate in the production of polyamides for synthetic fibres:
Hydroxylamine and its salts in their rôle as reducing agents act as anti-oxidants in photographic developers, stabilizers of monomers and for reducing copper(II) to copper(I) in the dyeing of acrylic fibres. Hydroxylamine is an effective adsorbent for removing nitrous gases, but nitric oxide must first be oxidized to nitrogen dioxide. Hydroxylammonium sulphate on a silica-gel carrier is capable of performing both operations, and for this reason is used as an absorbent in combustion analysis[343].

7.2. LABORATORY PREPARATION OF HYDROXYLAMINE AND RELATED COMPOUNDS[349]

Hydroxylammonium phosphate is prepared in high yield and purity from the chloride and trisodium orthophosphate:

$$3(HONH_3)Cl + H_3PO_4 + 3NaOH \rightarrow (HONH_3)_3PO_4 + 3NaCl + 3H_2O$$
[348] N. V. Sidgwick, *The Organic Chemistry of Nitrogen*, 3rd edn., revised and rewritten by I. T. Millar and H. D. Springall, Oxford University Press, Oxford (1966).

[349] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. I (ed. G. Brauer), Academic Press, New York (1963), pp. 500–11.

Free hydroxylamine can then be conveniently prepared by the thermal decomposition of tertiary hydroxylammonium phosphate under reduced pressure:

$$(HONH_3)_3PO_4 \rightarrow H_3PO_4 + 3NH_2OH$$
While the bulk of material distils over at 135–137°C/13 mm, the temperature and pressure must be monitored continually and not allowed to rise above 150°C or 30 mm for fear of explosion. The product which still contains water can be recrystallized from absolute alcohol at −18°C, rapidly suction-filtered and dried briefly in a vacuum desiccator over sulphuric acid. Hydroxylamine can also be prepared from hydroxylammonium chloride after reaction with sodium alkoxide in alcohol and separating free hydroxylamine by crystallization from the alcohol solution after filtering off the sodium chloride:

$$(HONH_3)Cl + NaOR \xrightarrow{ROH} NH_2OH + NaCl + ROH$$
Potassium hydroxylamine disulphonate can be prepared by the reaction of potassium nitrite and potassium metabisulphite:

$$KNO_2 + 2KHSO_3 \rightarrow HON(SO_3K)_2 + KOH$$
Hydrolysis of the product gives potassium sulphate and hydroxylammonium bisulphate which can be separated and recrystallized[349]:

$$HON(SO_3K)_2 + 2H_2O \rightarrow (HONH_3)HSO_4 + K_2SO_4$$
7.3. NUCLEAR ISOTOPES ND₂OD [350]

Attempts to prepare deuterohydroxylamine by successive exchanges of hydroxylamine with deuterium oxide were unsuccessful. However, deuterium oxide exchanges with tertiary hydroxylammonium phosphate to give the fully deuterated compound which can be thermally decomposed at 130°C/13 mm to give hydroxylamine-d₃.

$$2D_2O + (HONH_3)_3PO_4 \rightarrow 2H_2O + (DOND_3)_3PO_4 \xrightarrow{\Delta} D_3PO_4 + 3ND_2OD$$
7.4. STRUCTURE AND BONDING

Hydroxylamine can exist as two configurational isomers, usually termed *cis* and *trans*, together with numerous *gauche* conformations resulting from varying degrees of rotation of the OH group around the N–O bond, as illustrated in Fig. 20. An X-ray study of crystalline hydroxylamine detailed in Table 43 gave the N–O bond distance as 1.47 Å and other intermolecular hydrogen bonded N · · · O distances at 2.74, 3.07, 3.11 and 3.18 Å. Of these, the 2.74 Å bond corresponds to O–H · · · N and the 3.07 Å bond to O · · · H–N by analogy to the situation in oximes, while the third hydrogen atom of hydroxylamine remains uninvolved in hydrogen bonding which is taken as evidence consistent with the molecule having the *trans* configuration in the solid state[351]. Infrared spectra have also been fully assigned as in Table 44 based on hydroxylamine having C_s symmetry, and the presence of double bands indicates that the vapour phase probably contains a mixture of *cis* and *trans* isomers although the possibility of the *gauche* configuration being present cannot be excluded[352]. Using the molecular parameters computed from this spectroscopic data, N–O 1.46 Å, O–H 0.96 Å, N–H 1.01 Å, and angles HON 103°, HNO 105°, HNH 107°,

[b] In ref. 356.

ab initio calculations of the barriers to internal rotation gave values of 1.16 and 11.95 kcal/mol corresponding to the *cis* and *trans* conformations[353].

The N–O bond length in hydroxylammonium halides as determined by X-ray diffraction[354] and spectroscopic techniques[355] is 1.45 Å, and 1.41 Å for hydroxylammonium perchlorate[356]. These values are in agreement with the N–O single covalent bond length

calculated[357] by correcting the sum of the covalent radii of nitrogen and oxygen for dif-
ferences in electro-negativities of the atoms, i.e.

$$(0.735 + 0.735) - [-0.08(\chi_N - \chi_O)] = 1.47 - 0.04 = 1.43 \pm 0.02 \text{ Å}.$$

However, the neutron diffraction study[358] of hydroxylammonium chloride gave an N–O
bond length of 1.383 Å which is much shorter than the X-ray value of 1.47. The N–H,
1.044 Å, and O–H, 0.996 Å, bond lengths are unremarkable although hydrogen bonding to
each chlorine is indicated, and the dihedral angle between the NOH plane and the ONH
plane is 53.6°.

Only a few hydroxylamine complexes are known for which the bonding arrangements
are illustrated in Fig. 21. Comparison of infrared spectra indicate a similarity between
hydroxylamine complexes of cobalt(III) and platinum(II) with analogous amine com-
plexes[359]. Thus it seems likely that the metal is bonded to nitrogen rather than oxygen.

7.5. MOLECULAR CONSTANTS

The structural parameters of hydroxylamine and hydroxylammonium salts are given in Table 43. The infrared spectrum of hydroxylamine together with the principal bands assigned to the hydroxylammonium ion are listed in Table 44. Raman and infrared spectra have been recorded for hydroxylammonium halides and assigned[355] by considering the local symmetry of the molecule as $C_{3v}(H_3NO)$ and $C_s(OH)$.

7.6. PHYSICAL PROPERTIES

The values of some physical properties of hydroxylamine are listed in Table 45.

Such information is rather sparse on account of the fact that pure hydroxylamine is unstable, particularly in the liquid phase. Alkali metal halides and similar salts dissolve in liquid hydroxylamine which resembles water in its solvent properties. It is hygroscopic, forming reasonably stable solutions with water and with the lower alcohols, but has relatively low solubility in most other common organic solvents. Hydroxylamine can be regarded as water in which one of the hydrogens has been replaced by the more electro-negative amide group, or as ammonia with a hydrogen replaced by the more electron-attracting hydroxyl group. Thus aqueous hydroxylamine solutions are less basic than either ammonia or hydrazine:

$$NH_2OH + H_2O \rightarrow HONH_3^+ + OH^-; \quad K_b = 6.6 \times 10^{-9}$$
Aqueous solutions of hydroxylammonium salts are therefore less stable than corresponding ammonium salts, and undergo considerable hydrolysis in aqueous solutions to yield acidic solutions. The physical properties of a few hydroxylammonium salts are listed in Table 46.

Hydroxylamine, either anhydrous or in strong alkali, can undergo acidic ionization even

TABLE 45. PHYSICAL PROPERTIES OF HYDROXYLAMINE[a, b]

Property	Temperature (K)	Value

though with a dissociation constant approaching 10^{-14} at an ionic strength of 0.72 it is a weaker acid than water itself:

$$2NH_2OH \rightarrow HONH_3^+ + NH_2O^-$$

$$NH_2OH + OH^- \rightarrow NH_2O^- + H_2O$$
Such properties are demonstrated by the formation of the unstable calcium salts $Ca(ONH_2)_2$ and $Ca(OH)(ONH_2)$ [345].

7.7. CHEMISTRY AND CHEMICAL REACTIONS

Anhydrous hydroxylamine is usually kept at $0\,^\circ$C as decomposition by internal oxidation-reduction to ammonia and nitrogen or nitrous oxide occurs even at room temperature. Hydroxylammonium salts derived from strong acids are more stable than the free base; nevertheless they do decompose near their melting point or above $200\,^\circ$C, often violently even when unconfined:

$$4HONH_3^+ \rightarrow N_2O + 2NH_4^+ + 3H_2O + 2H^+$$
Hydroxylammonium phosphate at lower temperatures splits off hydroxylamine which distils and can be separated.

The reaction of nitrous acid with the hydroxylammonium ion is thought to give nitroxyl which can decompose to nitrous oxide or dimerize to give hyponitrous acid[360]:

$$HONH_3^+ + HNO_2 \rightarrow 2HNO + H_3O^+$$

$$2HNO \rightarrow H_2O + N_2O$$

$$2HNO \rightarrow H_2N_2O_2$$
However, the main decomposition reaction in alkaline solution is

$$3NH_2OH \rightarrow NH_3 + N_2 + 3H_2O$$

while the reaction in acid solution gives mainly nitrous oxide:

$$4NH_2OH \rightarrow N_2O + 2NH_3 + 3H_2O$$
Thus a large number of reactions of hydroxylamine involve oxidation-reduction processes. Such properties seem appropriate when hydroxylamine is considered as the intermediate compound in relation to hydrogen peroxide and hydrazine. This comparison is even more clearly expressed in terms of the redox potentials associated with the following equations[361] and by the redox diagram illustrated in Fig. 22.

In acid solution:

$$2H_2O \rightarrow H_2O_2 + 2H^+ + 2e^-; \qquad E^\circ = 1.77 \text{ V}$$

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-; \qquad E^\circ = 0.68 \text{ V}$$

$$N_2H_5^+ + 2H_2O \rightarrow 2HONH_3^+ + H^+ + 2e^-; \qquad E^\circ = 1.42 \text{ V}$$

$$NH_4^+ + H_2O \rightarrow HONH_3^+ + 2H^+ + 2e^-; \qquad E^\circ = 1.35 \text{ V}$$

$$HONH_3^+ \rightarrow \tfrac{1}{2}N_2 + 2H^+ + H_2O + e^-; \qquad E^\circ = -1.87 \text{ V}$$

$$2HONH_3^+ \rightarrow N_2O + 6H^+ + H_2O + 4e^-; \qquad E^\circ = -0.05 \text{ V}$$

$$2HONH_3^+ \rightarrow H_2N_2O_2 + 6H^+ + 4e^-; \qquad E^\circ = -0.44 \text{ V}$$
[360] R. Nast and I. Föppl, *Z. anorg. Chem.* **263** (1950) 310.
[361] W. E. Latimer, *Oxidation Potentials*, Prentice-Hall, Englewood Cliffs, New Jersey (1952).

In basic solution:

$$3OH^- \rightarrow HO_2^- + H_2O + 2e^-; \qquad E^\circ = 0.87 \text{ V}$$
$$N_2H_4 + 2OH^- \rightarrow 2NH_2OH + 2e^-; \qquad E^\circ = 0.74 \text{ V}$$
$$N_2H_4 + 4OH^- \rightarrow N_2 + 4H_2O + 4e^-; \qquad E^\circ = -1.16 \text{ V}$$
$$2NH_2OH + 2OH^- \rightarrow N_2 + 4H_2O + 2e^-; \qquad E^\circ = -3.04 \text{ V}$$
$$2NH_2OH + 4OH^- \rightarrow N_2O + 5H_2O + 4e^-; \qquad E^\circ = -1.05 \text{ V}$$
$$2NH_2OH + 6OH^- \rightarrow N_2O_2^{2-} + 6H_2O + 4e^-; \qquad E^\circ = -0.73 \text{ V}$$
FIG. 22. Redox diagram for hydroxylamine and related species.

Thus, in general, hydrogen peroxide, hydroxylamine and hydrazine act as reducing agents in acidic solutions and as oxidizing agents in neutral or alkaline media. However, by varying the conditions even within this classification, different products predominate. For example, the reaction of silver bromide and hydroxylamine gives nitrogen and nitrous oxide, whereas mercurous nitrate gives mainly nitrous oxide:

$$2NH_2OH + 2AgBr \rightarrow 2Ag + N_2 + 2HBr + 2H_2O$$
$$2NH_2OH + 4AgBr \rightarrow 4Ag + N_2O + 4HBr + H_2O$$
$$2NH_2OH + 2Hg_2(NO_3)_2 \rightarrow 4Hg + N_2O + 4HNO_3 + H_2O$$
The investigation of the reduction of hydroxylamine with aqueous chromium(II) gave 1:2 stoichiometry and first-order reaction with the rate-determining step leading to the formation of $HONH_3^+$ [362].

$$2H^+ + 2Cr(H_2O)_6^{2+} + HONH_3^+ \rightarrow NH_4^+ + 2Cr(H_2O)_6^{3+} + H_2O$$
The participation of free-radicals (NH_2^-) in such reactions is indicated by polymerization occurring when titanium(III) reacts with hydroxylamine in the presence of vinyl monomer[343].

A number of hydroxylamine complexes of transition metals have been prepared, particularly among the platinum metals, but the area is lacking in structural studies. The non-transition element derivatives of hydroxylamine are also mainly restricted to one area— that of the sulphuric acid derivatives[343, 363]. These include both N- and O-derivatives commonly described as derivatives of sulphuric (IUPAC) or sulphonic acids:

Hydroxylamine

Hydroxylamido-
N-sulphuric acid (I)

Hydroxylamido-
O-sulphuric acid (II)

Hydroxylamido-N,N-
disulphuric acid (III)

Hydroxylamido-N,O-
disulphuric acid (IV)

Hydroxylamido-N,N,O-
trisulphuric acid (V)
A number of nitrosyl and nitroso derivatives can also be thought of as being derived from hydroxylamine. The compounds (I)–(V) above can be prepared conveniently by methods[363] outlined in equations below:

A considerable organic chemistry of hydroxylamine centres around oxime formation, the Beckmann, rearrangement, and its use in organic synthesis as a reducing agent[334, 348]. Organometallic hydroxylamine derivatives have not received much attention, but triorganosilyl chlorides react with hydroxylamine to give the silylamine oxide as evidenced by the characterization of the product from subsequent reaction with phenyl isocyanate[364]:

$$Me_3SiCl + NH_2OH \rightarrow [Me_3Si\overset{+}{N}-\overset{-}{O}H_2] \xrightarrow{2PhNCO} Me_3SiN \begin{array}{c} \diagup CONHPh \\ \\ \diagdown CO_2NHPh \end{array}$$
7.8. BIOLOGICAL PROPERTIES

Hydroxylamine and its salts are moderately toxic substances which may cause both reversible and irreversible changes in the body associated with methaemoglobinemia[345]. Free hydroxylamine is known to be present in stagnant water due to bacteriological reduction of nitrite. For a long time its rôle in the nitrogen fixation process was considered to be important, but it is now thought to be the key intermediate[343].

7.9. ANALYSIS OF HYDROXYLAMINE[343, 365]

A very sensitive spot test for hydroxylamine is provided by the green colour produced by its reaction with 8-hydroxyquinoline, and it only fails in the presence of large amounts of hydrazine. Paper chromatography has also been used to separate various nitrogen containing compounds including hydroxylamine.

The fact that hydroxylamine is reduced by alkaline iron(II) sulphate, whereas hydrazine is not affected has been developed into a method for its determination by estimating the amount of ammonia evolved. Hydroxylamine hydrochloride can be determined readily by oxidation with iron(III) ammonium sulphate and the iron(II) produced titrated with

[364] U. Wannagat and J. Pump, *Monatsh. Chem.* **94** (1963) 141.

[365] A. J. Clear and M. Roth, in *Treatise on Analytical Chemistry*, Part II, Vol. 5 (eds. I. M. Kolthoff and P. J. Elving), Interscience, New York (1961), pp. 288–90.

permanganate, or by oxidation with excess potassium bromate in the presence of hydrochloric acid, and after the addition of potassium iodide, the iodine liberated by excess bromate titrated with thiosulphate. Appropriate reducing agents are titanium(III) chloride in excess followed by back-titration with iron(III) using thiocyanate as indicator.

8. HYDROGEN AZIDE AND AZIDES

8.1. PRODUCTION AND INDUSTRIAL USE

Sodium azide is a reasonably stable material which is produced on a commercial scale, and is the principal starting material for the preparation of all other azides[366-9]. It is obtained by passing nitrous oxide into fused sodamide. The melt acts as a vigorous reducing agent while the water formed is removed by immediate reaction with the excess sodium amide giving recoverable ammonia:

$$NaNH_2 + N_2O \rightarrow NaN_3 + H_2O$$
$$NaNH_2 + H_2O \rightarrow NaOH + NH_3$$
Nitrous oxide, ammonia and sodium in liquid ammonia can react directly under pressure without prior isolation of the sodamide, and although the reaction is faster, the overall yield is lower due to the formation of elemental nitrogen[367]:

$$4Na + 3N_2O + NH_3 \rightarrow NaN_3 + 3NaOH + 2N_2$$
An alternative preparative route is the addition of powdered sodium nitrate to sodium amide at 175°C to give sodium azide in yields up to 65%:

$$3NaNH_2 + NaNO_3 \rightarrow NaN_3 + 3NaOH + NH_3$$

As sodamide is difficult to produce industrially, a more convenient starting material is sodium oxide[370].

$$2Na_2O + N_2O + NH_3 \xrightarrow{110-190°} NaN_3 + 3NaOH$$
In each process the products can be dissolved in water and sodium azide recrystallized from solution. Other methods of forming azides are from reactions of hydrazine with nitrous acid, nitrogen trichloride, or in low yields from a variety of oxidizing agents[369]:

$$N_2H_5^+ + HNO_2 \rightarrow HN_3 + H^+ + 2H_2O$$
$$N_2H_5OH + NCl_3 + 4OH^- \rightarrow N_3^- + 3Cl^- + 5H_2O$$
The major use of inorganic azide depends on the explosive nature of heavy metal azides, particularly lead azide. Lead azide can be precipitated from a mixture of aqueous azide and soluble lead salt solutions.

$$Pb(NO_3)_2 + 2NaN_3 \rightarrow Pn(N_3)_2 + 2NaNO_3$$
[366] K. G. Mason, in ref. 300, pp. 1–15.

[367] K. G. Mason, in ref. 300, pp. 16–68.

[368] D. M. Yost and H. Russell, Jr., *Systematic Inorganic Chemistry*, Prentice-Hall, New York (1944), pp. 122–31.

[369] H. M. Sisler, in *Comprehensive Inorganic Chemistry*, Vol. 5 (eds. M. C. Sneed and R. C. Brasted), Van Nostrand, New York (1956), pp. 41–52.

[370] C. Matasa and E. Matasa, *L'Industrie Moderne des Produits Azotes*, Dunod, Paris (1968), p. 557. Van Nostrand, New York (1956), pp. 41–52.

However, although precipitation methods appear to be attractive preparative routes from a separation point of view, the products are usually contaminated with trapped ions present in the solution. These trapped ions are thought to be a major contributing factor responsible for spontaneous detonation. This kind of contamination can clearly occur with all double decomposition reactions, while the neutralization of lead oxide with hydrazoic acid suffers the disadvantage of forming insoluble lead azide only on the surface of the lead oxide particles, in addition to the hazards of handling strong hydrazoic acid solutions. To overcome both of these problems the reaction of pure aqueous lead nitrite solution with an alcoholic solution of hydrogen azide has been proposed. The azide destroys the nitrite anion to give gaseous products while simultaneously forming insoluble lead azide as the only species remaining suspended in the solvent:

$$Pb(NO_2)_2 + 4HN_3 \rightarrow Pb(N_3)_2 + 2N_2 + 2N_2O + 2H_2O$$
Minor applications of azides include their incorporation of barium and strontium azides as getters in electric discharge tubes, alkali-metal azides in anti-corrosion solutions and the thermal decomposition of electro-positive metal azides in the production of foam rubber[367].

The wide use of lead azide for detonators in preference to other explosive materials such as mercury fulminate is based on reliability under a variety of adverse, in particular damp conditions rather than superior detonation characteristics.

8.2. LABORATORY PREPARATION OF HYDROGEN AZIDE AND AZIDES

Pure hydrogen azide is an extremely explosive material, but it can be formed by the action of molten stearic acid on sodium azide[366, 372], although its preparation should only be attempted in conjunction with extreme safety precautions. Because of the high incidence of explosions with pure hydrogen azide, it is expedient to work only with dilute solutions where possible. Aqueous solutions can be prepared in comparative safety by acidifying alkaline sodium azide solution with 40% sulphuric acid during the distillation of water to give a solution containing about 3% HN_3. Anhydrous ether solutions of HN_3 can also be prepared by dropwise addition of concentrated sulphuric acid to a mixture of ether and aqueous sodium azide during which time the bulk of the ether and HN_3 distils off. The ether solution can be dried over calcium chloride and redistilled if necessary.

Sodium azide is prepared in the laboratory by reacting dried nitrous oxide with sodium amide at 170–190°C:

$$2NaNH_2 + N_2O \rightarrow NaN_3 + NaOH + NH_3$$

Alternatively, hydrazine hydrate in ether reacts with nitrous acid formed by the breakdown of ethyl nitrite in the presence of sodium methoxide:

$$N_2H_4 \cdot H_2O + EtONO + NaOMe \rightarrow NaN_3 + EtOH + MeOH + 2H_2O$$
Ammonium azide can be prepared[367] from ammonia and nitrous oxide over $Ni–Al_2O_3$:

$$2NH_3 + N_2O \xrightarrow{Ni/Al_2O_3} NH_4N_3 + H_2O$$
[371] P. Gray, *Quart. Rev.* **17** (1963) 441.

[372] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, Vol. I (ed. G. Brauer), Academic Press, New York (1963), p. 472.

Potassium, rubidium or caesium azides can be prepared from metal carbonates[372] or hydroxides[373] and hydrogen azide produced *in situ* by acidifying sodium azide:

$$M_2CO_3 + 2HN_3 \rightarrow 2MN_3 + H_2O + CO_2$$
Metal azides[367] and complex azides are also generally prepared from hydrogen azide or its sodium salt by various exchange reactions as illustrated below:

$$Ba(OH)_2 + 2HN_3 \longrightarrow Ba(N_3)_2 + 2H_2O$$
$$AlH_3 + 3HN_3 \longrightarrow Al(N_3)_3 + 3H_2$$
$$Me_2Be + 2HN_3 \longrightarrow Be(N_3)_2 + 2MeH$$
$$(C_2H_5)_2Mg + 2HN_3 \longrightarrow Mg(N_3)_2 + 2C_2H_6$$
$$LiBH_4 + 4HN_3 \longrightarrow LiB(N_3)_4 + 4H_2$$
$$B(N_3)_3 + NaN_3 \longrightarrow NaB(N_3)_4$$
$$SnCl_4 + 6NaN_3 \longrightarrow Na_2Sn(N_3)_6 + 4NaCl$$
$$2Ph_4AsCl + CoSO_4 + 4NaN_3 \longrightarrow (Ph_4As)_2Co(N_3)_4 + 2NaCl + Na_2SO_4$$
$$3Ph_4AsCl + CrCl_3 + 6NaN_3 \longrightarrow (Ph_4As)_3Cr(N_3)_6 + 6NaCl$$
$$4Ph_4AsCl + CuSO_4 + 6NaN_3 \longrightarrow (Ph_4As)_4Cu(N_3)_6 + 4NaCl + Na_2SO_4$$
$$2Ph_4AsCl + K_2(PtCl_4) + 4NaN_3 \xrightarrow{H_2O} (Ph_4As)_2Pt(N_3)_4 \cdot H_2O + NaCl + 2KCl$$
$$2Ph_4AsCl + H_2PtCl_6 + 6NaN_3 \longrightarrow (Ph_4As)_2Pt(N_3)_6 + 6NaCl + 2HCl$$
$$Ph_4AsCl + K(AuCl_4) + 4NaN_3 \longrightarrow (Ph_4As)Au(N_3)_4 + 4NaCl + KCl$$
$$Ph_4PCl + 2CdSO_4 + 5NaN_3 \xrightarrow{H_2O} Ph_4P[Cd_2(N_3)_5] \cdot H_2O + 2Na_2SO_4 + NaCl$$

In a similar way, organometallic azides have also been synthesized[375]:

$$Ph_2BCl + NaN_3 \rightarrow Ph_2BN_3 + NaCl$$
$$Me_6Al_2 + 4HN_3 \rightarrow 2MeAl(N_3)_2 + 4CH_4$$
$$Et_2AlCl + NaN_3 \rightarrow Et_2AlN_3 + NaCl$$
$$(Me_3Si)_2NH + 3HN_3 \rightarrow 2Me_3SiN_3 + NH_4N_3$$
$$Bu_3^nSnCl + NaN_3 \rightarrow Bu_3^nSnN_3 + NaCl$$
$$Ph_3PbOH + HN_3 \rightarrow Ph_3PbN_3 + H_2O$$
Covalent azides are well-characterized derivatives[376]. Fluorine reacts with hydrazoic acid in a stream of nitrogen to give unstable fluorine azide:

$$2F_2 + 4HN_3 \rightarrow FN_3 + N_2 + NH_4F$$

Chlorine azide is also spontaneously explosive in both the condensed and solid phases, but can be prepared in carbon tetrachloride solution by mixing aqueous sodium azide with sodium hypochlorite over the organic solvent in a separating funnel, followed by acidification with acetic acid with vigorous mixing. After separating the organic layer, the safest way to obtain gaseous chlorine azide is to bubble nitrogen through the solution, and collect the nitrogen–chlorine azide mixture under reduced pressure:

$$NaOCl + NaN_3 + 2HOAc \rightarrow ClN_3 + 2NaOAc + H_2O$$
[373] A. D. Yoffe, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), pp. 72–149.
[374] W. Beck, E. Schuierer and K. Fedl, *Angew. Chem. Int. Edn. Engl.* 5 (1966) 249.
[375] J. S. Thayer, *Organometal. Chem. Rev.* 1 (1966) 157.
[376] K. Dehnicke, *Angew. Chem. Int. Edn. Engl.* 6 (1967) 240.

Analogous bromine and iodine compounds are also known, but are stable only at sub-zero temperatures[376].

From Group VI the reaction of sulphuryl chloride with sodium azide leads to unstable sulphuryl azide:

$$SO_2Cl_2 + 2NaN_3 \rightarrow SO_2(N_3)_2 + 2NaCl$$
Explosive azidosulphates are obtained readily by the reaction of hydrazinosulphuric acid with potassium nitrite:

$$H_2NHNSO_3H + KNO_2 \rightarrow N_3SO_3K + 2H_2O$$
Hydrazoic acid and salts react with carbon disulphide to produce azidothiocarbonic acid derivatives from which free azidocarbonium disulphide can be formed[369]:

$$HN_3 + CS_2 \rightarrow N_3CSSH$$
$$NaN_3 + CS_2 \rightarrow N_3CSSNa$$
$$2N_3CSSNa + I_2 \rightarrow (N_3CSS)_2 + 2NaI$$
Phosphorus azides such as phosphonitrilic azide and a variety of organophosphorus azides are well known, while azides of nitrogen include unstable nitrosyl azide, N-azido-dimethylamine and related N-azidohexamethyldisilazane[367]:

$$(PNCl_2)_3 + 6NaN_3 \rightarrow [PN(N_3)_2]_3 + 6NaCl$$
$$(CF_3)_2PCl + LiN_3 \rightarrow (CF_3)_2PN_3 + LiCl$$
$$NO \cdot HSO_4 + NaN_3 \rightarrow NON_3 + NaHSO_4$$
$$Me_2NCl + NaN_3 \rightarrow Me_2NN_3 + NaCl$$
$$(Me_3Si)_2NCl + LiN_3 \rightarrow (Me_3Si)_2NN_3 + LiCl$$
The nitrogen pseudohalogen derivatives N_3–N_3 and $N(N_3)_3$, which correspond to the chlorine analogues Cl_2 and NCl_3, are not known.

With regard to compounds containing carbon–azide bonds, a considerable organic chemistry has been investigated[377], and a few essentially inorganic compounds like carbonyl azide are also known[369]:
$$CO(NHNH_2)_2 + 2HNO_2 \rightarrow CO(N_3)_2 + 4H_2O$$

Dicyandiazide is obtained by the action of cyanogen bromide on sodium azide, and is one of a number of pseudohalogen type compounds[369]:

$$2CNBr + 2NaN_3 \rightarrow (CNN_3)_2 + 2NaBr$$
8.3. NUCLEAR ISOTOPES OF HN$_3$ AND AZIDES

As no exchange occurs between the central and terminal nitrogen atoms of the azide ion, synthesis of compounds labelled in either or both positions is possible. Potassium

[377] N. V. Sidgwick, *The Organic Chemistry of Nitrogen*, 3rd edn., revised and rewritten by I. T. Millar and H. D. Springall, Oxford University Press, Oxford (1966), pp. 488–502.

azide containing labelled terminal nitrogen atoms is prepared by the reaction of hydrazine
hydrate and labelled ethyl nitrite in the presence of potassium methoxide[378]:

$$Na^{15}NO_2 + EtOH + HCl \rightarrow Et^{15}NO_2 + NaCl + H_2O$$

$$N_2H_4 \cdot H_2O \quad + \quad MeOK \quad + \quad Et^{15}NO_2 \longrightarrow K^{15}NN^{15}N$$

Azide with only the central nitrogen atom labelled is most conveniently prepared from labelled nitrous oxide and calcium amide:

$$Ca(NH_2)_2 + {}^{15}NNO \xrightarrow{\text{dil. } H_2SO_4} HN^{15}NN \xrightarrow{\text{KOH}} KN^{15}NN$$
Alternatively, centrally labelled sodium azide can be synthesized by an organic route[367]:
8.4. STRUCTURE AND BONDING

The structure of hydrogen azide as determined by electron diffraction methods shows that the three nitrogen atoms are collinear and the HNN bond angle is 112°. The two N–N distances differ considerably, $HN–N_2$ being 1.24 Å and $HN_2–N$ is 1.13 Å, and these values are comparable to those reported for organic azides[373]. Examination of metal azides by X-ray and neutron diffraction methods, some results of which are given in Table 47, reveal that discrete azide ions are also linear, but with both the N–N distances the same length of 1.16 Å.

Thus on the basis of bond lengths, a distinction can be made between ionic and covalent azides, and approximate bond orders can be estimated by comparison with the bond lengths in isoelectronic and other nitrogen species listed in Table 48. Also the higher symmetry

TABLE 48. BOND LENGTHS AND ANGLES IN NITROGEN AND RELATED

[a] Refs. 367, 371, 373, 379.

associated with the azide ion means that both terminal nitrogen atoms are identical, whereas in covalent azides each of the three nitrogen atoms has a different electronic environment.

The bonding in hydrogen azide can be described by the valence bond approach and visualized in terms of resonance between the canonical structure illustrated in Fig. 23. The HNN bond angle and distances calculated on the basis of equal resonance between conventional electron pair structures (i) and (ii) agree well with reported values, while the non-pairing structure (iii) is an alternative approximation[379] predicting bond orders of about the correct magnitude and a bond angle consistent with the state of hybridization at nitrogen (bonded to hydrogen) being something between sp^2 and sp^3.

On the basis of molecular orbital theory, the sixteen valence electrons of hydrogen azide are distributed four into two lone pairs, six into three σ bonds, four into two π bonds,

(a) Valence bond structures:

(b) Molecular orbitals description:

lone pairs and σ bonds

non-bonding π-molecular orbital

Fig. 23. Valence bond and molecular orbital descriptions of the bonding in hydrogen azide.

[379] M. Green, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), pp. 1–71.

and two into non-bonding orbitals as illustrated in Fig. 23. With the azide group of hydrogen azide being asymmetrical, the itr ogen atom bonded to hydrogen requires approximately sp^2 hybridization to account for the HNN bond angle, while the other two nitrogen atoms are sp hybridized.

The azide ion, however, is a symmetrical linear molecule, and as it contains sixteen electrons it is both isostructural and isoelectronic with the cynamide ion NCN^{2-}, the cyanate ion NCO^-, the fulminate ion CNO^-, the nitronium ion NO_2^+ and carbon dioxide. The valence bond canonical structures are illustrated in Fig. 24. However, the postulation

Fig. 24. Valence bond and molecular orbital descriptions of the bonding in the azide ion.

of structures (ii) and (iii) with localized formal charges of -2 is somewhat extreme, and the description of the azide ion is perhaps better represented by non-pairing structures (iv)–(vi)[379].

The molecular orbital description of the azide ion also illustrated in Fig. 24 can be derived from first principles by considering the interactions of the available atomic orbitals of related symmetry. The symmetry of the orbitals of the central nitrogen atom can be simply assigned on the basis of the transformations which result from carrying out the symmetry operations of the point group to which the molecule belongs, namely $D_{\infty h}$. Likewise, linear combinations of related atomic orbitals on the terminal nitrogen atoms can also be assigned, and molecular orbitals are formed by combining orbitals of all three nitrogen atoms which transform alike, as indicated below:
Thus in the $^1\Sigma_g^+$ ground state, the sixteen valence electrons occupy the lowest molecular orbitals of the energy level diagram illustrated in Fig. 25, giving the configuration $(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(1\pi_g)^4$, with the highest energy electrons in non-bonding orbitals.

The azide radical N_3 is known in flash photolysis and molecular beam studies, but little has been deduced about its structure. Hence the linear structure and bonding description which has been proposed is based on the assumption that the removal of a further electron from the non-bonding orbital of the azide ion causes only slight alterations to internuclear distances and other bond parameters[371].

Finally, azides can act as bridging groups and although their structures have usually been assumed to be of the M—N—N—N—M′ type, there is, in principle no reason why structures of the type
should not also be considered[380].

[380] M. Straumanis and A. Cirulis, Z. anorg. Chem. 252 (1943) 9.

8.5. MOLECULAR CONSTANTS

The infrared and Raman spectra of hydrogen azide have been thoroughly investi-gated[381] and the assignment of five in-plane (A') vibrations and one out-of-plane (A'') vibration as listed in Table 49, is consistent with a planar molecule.

TABLE 49. FUNDAMENTAL FREQUENCIES IN HN_3 AND DN_3[a]

Vibration	Approximate description	Frequency (cm^{-1})			
		HN_3		DN_3	
		Gas	Solid	Gas	Solid
$\nu_1\ (A')$	H–N stretching	3336	3090	2480	2308
$\nu_2\ (A')$	N–N–N asym. stretching	2140	2162	2141	2155
$\nu_3\ (A')$	N–N–N sym. stretching	1274	1299	1183	1230
$\nu_4\ (A')$	H–N–H bending	1150	1180	955	977
$\nu_5\ (A')$	N–N–N bending	522	—	498	—
$\nu_6\ (A'')$	N–N–N bending	672	—	638	—

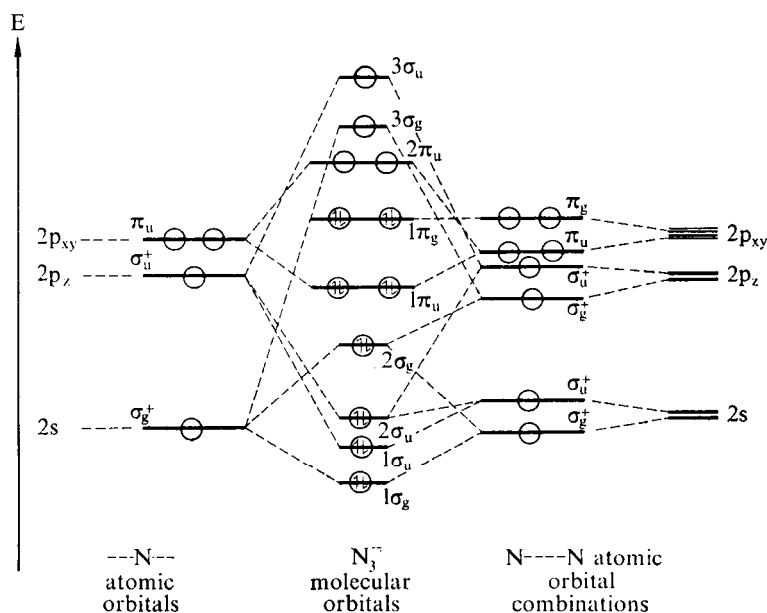

FIG. 25. The molecular orbital energy level diagram for the azide ion N_3^-.

[381] K. Nakamoto, *Infrared Spectra of Inorganic and Coordination Compounds*, Wiley, New York (1963), pp. 76, 176.

As the azide ion is a linear symmetrical triatomic group of $D_{\infty h}$ symmetry, the symmetric stretching frequency ν_1 is Raman active and infrared inactive while both the bending vibration ν_2 and the asymmetric stretching frequency ν_3 are infrared active and Raman inactive. However, values for all three modes can be derived from infrared spectra due to the presence of combination bands such as $\nu_3 - \nu_1$ or $\nu_1 + \nu_2$. Spectra of heavy metal and ionic azides which have been recorded are given in Table 50.

Although solid-phase infrared spectra often give rise to splitting due to the packing of the ions in the lattice, new bands related to ν_3 have been observed when alkali-metal azides were irradiated by ultraviolet light at low temperatures. The presence of transitory excited azide ions or charge transfer effects have been suggested as possible explanations[382].

Infrared spectra have also been most useful in the characterization of covalent azides in particular organometallic derivatives where the asymmetric stretching frequency is invariably characteristic[375], but the presence of the symmetric stretching frequency although theoretically active, is not always observed.

TABLE 50. INFRARED FREQUENCIES AND FORCE CONSTANTS OF THE AZIDE ION N_3^- IN METAL AZIDES[a]

8.6. PHYSICAL PROPERTIES

Some related thermochemical properties of the azide radical and ions listed[371] in Table 51 can be used particularly in calculations predicting the course of decomposition reactions (see section 8.7.1). The electro-negativity calculated for the azide ion using this data lies close to that of the bromide ion.

TABLE 51. THERMOCHEMICAL PROPERTIES OF THE AZIDE RADICAL AND IONS

Property	Temperature (K)	Value
Enthalpy of formation		
$\triangle H_f$ (N_3^-, g)	298	34.8 ± 0.1 kcal/mol
$\triangle H_f$ (N_3^-, g)	298	105 ± 3 kcal/mol
$\triangle H_f$ (N_3^+, g)	298	388 ± 5 kcal/mol
E (electron affinity) (N_3^-)		70 ± 5 kcal/mol
I (ionization energy) (N_3^-)		283 ± 6 kcal/mol
Electro-negativity $(E+I)/(130 \text{ kcal})$		2.71

The list of reasonably reliable values for the physical properties of hydrogen azide in Table 52 is somewhat incomplete due partly to the hazards and accompanying problems of

TABLE 52. PHYSICAL PROPERTIES OF HYDROGEN AZIDE[a]

[a] Refs. 366, 371.

maintaining hydrogen azide in a pure state during their determination. For similar reasons, some properties are only discussed qualitatively. For example, the dielectric constant has not been measured, but as a number of salts dissolve in hydrogen azide to yield electrically conducting solutions, it must be fairly large.

Some physical properties of selected metal azides have been compiled in Table 53.

8.7. CHEMISTRY AND CHEMICAL PROPERTIES

8.7.1. Decomposition

Although the vast majority of azides undergo explosive decomposition, the slow decomposition of azides can also be brought about in a variety of ways. For example, hydrogen azide can be decomposed by thermal, photochemical, photolytic and by electric discharge methods[371]. Unlike explosive decomposition which results in the formation of the elements, slow decomposition can give rise to a variety of other compounds. For hydrogen azide these have been explained on the basis of the initial step in the decomposition being fission of the longest (consequently the weakest) N–N bond (HN–N₂) to give elemental nitrogen and the imine radical[373], probably in an excited state as dissociation into ground state products is forbidden by the correlation (spin conservation) rules and alternative modes of dissociation are thermodynamically less favourable:

$$\text{Allowed:} \quad HN_3(^1A') \rightarrow NH(^1\Delta) + N_2(^1\Sigma_g^+); \qquad \Delta H = 33 \pm 2 \text{ kcal/mol}$$

$$\text{Forbidden:} \quad HN_3(^1A') \rightarrow NH(^3\Sigma^-) + N_2(^1\Sigma_g^+); \qquad \Delta H = 5 \pm 2 \text{ kcal/mol}$$

$$\text{Allowed:} \quad HN_3(^1A') \rightarrow H(^2S_g) + N(^2\Pi_g); \qquad \Delta H = 85 \pm 3 \text{ kcal/mol}$$
Further reaction of the imine radical can lead to the formation of diimine or ammonia, and hydroxylamine or nitrous acid if water or oxygen are present. Diimine has been detected in mass spectrometric examination of the products after hydrogen azide was subjected to electric discharge[383], and is believed to be the active intermediate in the oxidation of hydrazine:

$$:NH + HN_3 \rightarrow HN{=}NH + N_2$$

$$:NH + 2HN_3 \rightarrow NH_3 + 3N_2$$

$$:NH + H_2O \rightarrow NH_2OH$$

$$:NH + O_2 \rightarrow HONO$$
If the products of thermal decomposition of hydrogen azide at 1000°C under low-pressure conditions are collected on a surface cooled with liquid nitrogen, the stoichiometry of the process is

$$6HN_3 \rightarrow 7N_2 + H_2 + (NH)_4$$

[a] Refs. 367, 371, 373.

At $-196°C$ the blue paramagnetic substance $(NH)_4$ is unreactive and gives no X-ray diffraction pattern, but when it is allowed to attain a temperature between -150 and $-125°C$, it is transformed into colourless ammonium azide[384].

The decomposition reactions of metal azides are usually only explosive if the overall process is exothermic; however, since the elements are the products, the heat of decomposition corresponds to the standard enthalpy of formation of the salt (see Table 53). For example, the alkali metal azides are not explosive and decompose smoothly:

$$2NaN_3(s) \rightarrow 2Na(s) + 3N_2(g)$$
However, in some cases the nitride is formed:

$$3LiN_3 \rightarrow Li_3N + 4N_2$$

It is not clear whether the formation of nitride occurs by subsequent reaction between nitrogen and the metal or as a result of initial $MN-N_2$ bond fission as in covalent azide decompositions. This latter situation has been proposed for the photochemical decomposition of mercury(I) azide[385], and from this point of view such compounds are termed covalent solids.

The decomposition of heavy metal azides can be described in terms of excitation of the azide ion with subsequent promotion of an electron to the conduction band leaving the azide radical. The dissociation of the ground state azide radical $(^2\Pi_g)$ into ground state products N and N_2 is forbidden by the correlation rules, while the allowed dissociation into excited states requires 62 kcal/mol and is therefore not important at normal temperatures. However, the interaction of two azide radicals is also allowed, and being an exothermic process, it is considered to be the important step in the decomposition of solid ionic azides:

$$N_3^- + h\nu \rightarrow N_3^{-*}$$

$$N_3^{-*} \rightarrow N_3 + e^-$$

$$N_3(^2\Pi_g) \rightarrow N(^4S_g) + N_2(^1\Sigma_g^+); \qquad \triangle H = \quad 7.5 \pm 3 \text{ kcal/mol}$$

$$N_3(^2\Pi_g) \rightarrow N(^2D) + N_2(^1\Sigma_g^+); \qquad \triangle H = \quad 62 \pm 3 \text{ kcal/mol}$$

$$2N_3(^2\Pi_g) \rightarrow 3N_2(^1\Sigma_g^+); \qquad \triangle H = -210 \pm 6 \text{ kcal/mol}$$
The rapid exothermic decomposition of azide leading to explosive ignition or detonation has often been experienced but is less-well understood[371]. Apart from uniform or localized heating, the effects of electric current, impact, friction, ultrasonic and shock waves, exposure to intense light or ionizing radiation, can all cause azide to explode. The simplest interpretation which provides a relationship between each of these methods of initiation is on the basis of conversion to thermal energy. However, the various methods of initiation are now known to occur in more than one way and also to depend on other factors such as the variation in sensitivity of different azides, the presence of ionic and metallic impurities,

and even the nature of the surface and physical size of the material itself. Nevertheless, the propagation of a "critical" condition is perhaps most easily visualized as proceeding by a self-heating mechanism in which the energy of decomposition brings about the decomposition of further material at an accelerating rate.

8.7.2. Reactions of Azides

Hydrogen azide dissolves in water to give a weakly acidic solution. From the measured dissociation constant, hydrazoic acid is about as strong as acetic acid:

$$HN_3(aq) \rightleftharpoons H^+(aq) + N_3^-(aq); \quad \cdot \ K = 1.8 \times 10^{-5}$$
$$pK_a = 4.77 \text{ at } 298 \text{ K}$$

$$\triangle H^\circ_{298} = 3.60 \text{ kcal/mol}$$

However, although the acid dissociates only slightly in aqueous solution, metals dissolve in it accompanied by the evolution of ammonia and nitrogen analogous on the ammonia-aquo basis to the action of nitric acid on metals.

$$Zn + 3HN_3 \rightarrow Zn(N_3)_2 + NH_3 + N_2$$
The basic dissociation constant of $H_2N_3^+$ has also been estimated from experiments involving the equilibration of hydrogen azide between chloroform and pure sulphuric acid.

$$HN_3 + H_2O \rightleftharpoons H_2N_3^+ + OH^-; \quad pK_a = -6.21$$
The oxidizing and reducing properties of azides in acidic and basic aqueous solutions can be summarized by the following couples:

In acid solution:

$$3NH_4^+ \rightleftharpoons HN_3 + 11H^+ + 8e^-; \quad E^\circ_{298} + 0.66 \text{ V}$$

$$NH_4^+ + N_2 \rightleftharpoons HN_3 + 3H^+ + 2e^-; \quad E^\circ_{298} + 1.82 \text{ V}$$

$$HN_3 \rightleftharpoons 3/2N_2 + H^+ + e^-; \quad E^\circ_{298} - 2.8 \text{ V}$$

In basic solution:

$$NH_3 + N_2H_4 + 7OH^- \rightleftharpoons N_3^- + 7H_2O + 6e^-; \quad E^\circ_{298} - 0.62 \text{ V}$$

$$N_3^- \rightleftharpoons 3/2N_2 + e^-; \quad E^\circ_{298} - 3.1 \text{ V}$$
However, the fractional oxidation numbers encountered with individual nitrogen atoms in azides can be confusing, and for this reason comparisons with other redox systems are more conveniently illustrated by oxidation state diagrams as discussed in section 1.6.2.

The principal inorganic reactions of hydrogen azide all involve breakdown of the N–N–N grouping and lead to the formation of simpler nitrogen species, often the element.

For example, the reduction of hydrogen azide can give various products but does not provide any useful preparative routes:

$$HN_3 + 6[H] \xrightarrow[\text{Pd}]{\text{colloidal}} NH_3 + N_2H_4$$

$$HN_3 + H_2 \xrightarrow[\text{black}]{\text{Pt}} NH_3 + N_2$$

$$2HN_3 + [O] \xrightarrow[\text{black}]{\text{Pt}} 3N_2 + H_2O$$

$$3HN_3 \xrightarrow[\text{Ni}]{\text{Raney}} NH_3 + 4N_2$$

$$HN_3 + 3[H] \xrightarrow{\text{SnCl}_2/\text{HCl}} NH_4^+ + N_2$$

$$2HN_3 + 10[H] \xrightarrow{\text{Al/NaOH}} 3N_2H_4$$
Hydrogen azide and nitrous acid react quantitatively according to the equation:

$$HNO_2 + HN_3 \rightarrow N_2O + N_2 + H_2O$$
The course of this reaction has been determined by ^{15}N labelling experiments in which the nitrous acid nitrogen appeared quantitatively as the central atom in nitrous oxide while the central nitrogen of the azide group always resulted as elemental nitrogen. The reaction of hydrogen azide with strong nitric acid gives nitrogen as the chief product with varying amounts of N_2O, NO, N_2O_3 and NO_2 presumably formed from further reactions of nitric oxide with excess nitric acid[366].

$$HN_3 + HNO_3 \rightarrow N_2 + 2NO + H_2O$$
The action of sulphuric acid on hydrogen azide gives some hydroxylamine, while hydrogen chloride gives ammonium chloride:

$$HN_3 + H_2O \xrightarrow{\text{sulphuric acid}} N_2 + NH_2OH$$

$$3HN_3 + HCl \rightarrow NH_4Cl + 4N_2$$
In general, the azide ion (N_3^-) in metallic azides behaves like a halide ion, and being both isoelectronic and isostructural with cyanate (CNO^-) and isocyanate (NCO^-), it is regarded as a true pseudohalide. The azide ion has a cylindrical shape[371] about 5.1 Å long overall with a diameter of 3.5 Å and its position in the spectrochemical series has been estimated to lie between water and fluoride[386]. These favourable steric properties and greater ligand strength over chloride, whose ionic diameter is 3.62 Å and ligand strength less than fluoride, makes azide a most useful competitive ligand in reactions of transition metal complexes[387].

Some typical reactions of metallic azides are illustrated by the following equations:

$$NaN_3 + H_2 \xrightarrow{\text{colloidal Pd}} NaNH_2 + N_2$$

$$2N_3^- + 3H_2 \xrightarrow{\text{Al-Hg}} 2NH_3 + 2N_2$$

$$2NaN_3 + 2ICl \xrightarrow{0°} 2NaCl + I_2 + 3N_2$$

$$NaN_3 + NOCl \rightarrow NaCl + N_2O + N_2$$
[386] P. J. Staples and M. Tobe, *J. Chem. Soc.* (1960) 4812.

[387] W. P. Griffith, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), pp. 241–306.

Another general reaction of the azide ion which has been extensively investigated is the oxidation of azide by iodine in acid solution in the presence of a catalyst such as sodium thiosulphate:

$$2N_3^- + 2H^+ + I_2 \rightarrow 2HI + 3N_2$$
Reactions which are less easy to formulate include the ability of azide to inhibit catalase activity in the catalase–iron redox system, while from a preparative point of view, $Na^{14}CN$ can be obtained in good yields when sodium azide and barium $[^{14}C]$ carbonate are carefully heated in an atmosphere of nitrogen.

In contrast, halogen azides are hydrolysed in basic solution, and this provides the basis of a convenient method for their analysis by oxidation of arsenite:

$$XN_3 + 2OH^- \rightarrow N_3^- + OX^- + H_2O; \quad X = \text{halogen}$$

$$AsO_3^{3-} + XN_3 + 2OH^- \rightarrow AsO_4^{3-} + N_3^- + X^- + H_2O$$
Finally, mention should also be made concerning the rôle of azides as reagents in organic chemistry in which the group can take part in a wide variety of substitution and addition reactions as well as the cyclization and acidic reactions of hydrogen azide[366, 367].

8.8. BIOLOGICAL PROPERTIES[388]

Hydrogen azide has an unbearably pungent odour, inhalation of which causes dizziness, headache and strong irritation of the mucous membranes. It is classed as a deadly non-cumulative poison, and concentrations in air of even less than 1 ppm are considered very dangerous. Sodium azide can cause cardiac irregularities and lowering of blood pressure, although non-lethal doses can confer some protection against the action of body X-irradiàtion.

8.9. ANALYSIS OF AZIDES[367]

Silver azide precipitated from neutral or weak nitric acid solutions resembles silver chloride except that it is a sensitive explosive but stable to light. Azide solutions give a blood-red colour with ferric salts which is used as a colorimetric method for its determination. Azides react with cerium(IV) in acid solution:

$$2Ce^{4+} + 2N_3^- \rightarrow 3N_2 + 2Ce^{3+}$$
The nitrogen liberated can be measured volumetrically or excess cerium(IV) can be added and back titrated with standard ferrous ammonium sulphate. Another method for the determination of lead azide is based on the conversion to hydrogen azide with dilute sulphuric acid which can then be distilled into excess cerium(IV) solution which is then titrated with standard sodium oxalate. Excess permanganate in the presence of manganese(II) will also oxidize azide in acid media to nitrogen and can be back titrated iodometrically.

[388] F. Call, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. I, *Nitrogen*, Part I, Longmans, London (1964), Section XVII, p. 568.

9. NITROGEN–HALOGEN COMPOUNDS

9.1. CLASSES OF NITROGEN–HALOGEN COMPOUNDS

In this section, only molecules containing a nitrogen–halogen bond will be considered[389]. Unfortunately, the formulae of compounds containing nitrogen, halogen and other elements are not always explicit in describing which atoms are bonded together. For example, nitrosyl chloride is usually formulated NOCl, whereas the constituent atoms are bonded O=N—Cl, while NSF thiazyl fluoride is not a sulphur analogue of the nitrosyl halides as the halogen is attached to sulphur N≡S—F. Further confusion results from the poor systematization of the nomenclature of such derivatives, particularly those containing nitrogen, fluorine and oxygen. For example, there is no systematic name for the class of compounds F—N=N(O)—R, and of the various trivial and reasonable names which have been used to describe F—N=N(O)—Me, perhaps methyl N'-fluorodiimide N-oxide is least ambiguous.

Attention is drawn to these problems of formulation and chemical nomenclature in this field because of the current attention being given to such materials as high-energy oxidizing agents[390]. Indeed, it is in this context of investigating the properties of such compounds as potential ingredients of advances chemical propellants that so much new information has become available. Clearly the fluorine derivatives have received most attention[391–3] because of the position of —NF_2 when substituent oxidizer groups are arranged in decreasing order of oxidizing power:

$$-F, \ -OF, \ -NF_2, \ -ClF_4, \ -O, \ -ClF_2, \ -NO_3, \ -ClO_4, \ -NO_2$$
Apart from the binary nitrogen–halogen series of compounds, the other classes of compounds which will be considered are the haloamines[394] HNX_2 and H_2NX, the oxohalides[395–7] including nitrosyl halides[398,399] XNO, nitryl halides XNO_2, trifluoramine oxide[390] ONF_3, related ions NF_2O^-, NFO_2^-, $HNFO_2^-$, $NF_2O_2^-$ and a few sulphur derivatives[400] of NF_2 such as NF_2SF_5. Numerous organic N–X derivatives are also well known[391,401]. The binary nitrogen–halogen compounds can be further subdivided on the basis of the number of nitrogen atoms per molecule. This is primarily relevant to fluorine–nitrogen derivatives which include the mononuclear NF_4^+ ion, NF_3, NF_2X and possibly

9.2. PREPARATION

9.2.1. Nitrogen–Halogen Compounds

Nitrogen trifluoride was first prepared[403] in 1928 by the electrolysis of molten ammonium hydrogen fluoride, and this is the basis even of the present-day commercial production. Direct fluorination methods have also been investigated[390] and the reaction with ammonia can be controlled in the presence of copper to give NF$_3$ in yields up to 60%:

$$2NH_3 + 3F_2 \rightarrow 6HF + N_2$$

$$4NH_3 + 3F_2 \xrightarrow{Cu} NF_3 + 3NH_4F$$
Nitrous oxide can be fluorinated or electrolysed in anhydrous hydrogen fluoride solution, but both reactions give rise to oxyfluoride byproducts:

$$N_2O + 2F_2 \xrightarrow{400-700°} NF_3 + NOF$$
Nitrogen trifluoride is often a product in the reactions of other nitrogen–fluorine derivatives, e.g.

$$2N_3F + 2OF_2 \xrightarrow{UV} 2NF_3 + 2N_2 + O_2$$
and also of the fluorination of nitrogen-containing materials, but direct combination of the elements has only been observed under glow discharge conditions:

$$N_2 + F_2 \xrightarrow[10\ mm,\ -196°]{5\ kV,\ 10\ mA} NF_3$$
Nitrogen trichloride is formed almost quantitatively by the action of excess chlorine or hypochlorous acid with ammonium ion in acid solution:

$$NH_4Cl + 3Cl_2 \rightarrow NCl_3 + 4HCl$$
The reaction can be carried out in chloroform to give solutions which are stable for several days. The handling of dilute solutions containing less than 18% NCl$_3$ is not dangerous, but above this concentration it is an exceedingly explosive substance. Thus in order to avoid the build up of dangerous concentrations or the handling of bulk quantities when NCl$_3$ is used on a large scale in the bleaching and sterilizing of flour, it is prepared by electrolysing an acid solution of ammonium chloride at pH 4. The gaseous product is swept out of the cell diluted with air for immediate use and its production simply controlled electrically as required[389].

An equilibrium is thought to exist[404] when bromine reacts in liquid ammonia at $-78°$, as a pale reddish-yellow colour is observed with solutions of low concentration while a

[404] J. Jander, *Chemistry in Anhydrous Liquid Ammonia*, Vol. 1, Part I, of *Chemistry in Nonaqueous Ionizing Solvents* (eds. G. Jander, H. Spandau and C. C. Addison), Interscience, New York (1966), p. 374.

reddish-violet solid of composition $NBr_3 \cdot 6NH_3$ together with ammonium bromide remains when the solvent is evaporated at $-78°$:

$$3NH_2Br + 4NH_3 \rightleftharpoons NBr_3 \cdot 6NH_3$$
Decomposition of this material is slow at $-70°$, rapid at $-50°$ and explosive when warmed to room temperature.

The compound commonly known as nitrogen triiodide is also an ammonia complex formed when iodine, potassium triiodide or potassium dibromiodide is added to ammonia[405]:

$$3I_2 + 5NH_3 \rightarrow NI_3 \cdot NH_3 + 3NH_4I$$

$$3KIBr_2 + 5NH_3 \rightarrow NI_3 \cdot NH_3 + 3NH_4Br + 3KBr$$
The use of finely divided iodine, formed by precipitation when alcoholic iodine solution is poured into water, can give a product containing less ammonia than indicated by the above formula[406]. All forms of the material are extremely dangerous, the brown–black powder explodes at the slightest touch and sometimes even under water. Thus detonation is so unpredictable that storage of the material is impossible.

Of the mixed halogen–nitrogen compounds, chlorodifluoramine has been most thoroughly investigated as an intermediate for the synthesis of potential high energy NF_2 compounds. It was first characterized[407] in 1959 as a product of decomposition when difluoramine–boron trichloride complex was allowed to warm to room temperature:

$$HNF_2 + BCl_3 \xrightarrow{-130°} HNF_2 \cdot BCl_3 \xrightarrow{-80 \text{ to } 25°} ClNF_2 + HCl + Cl_2 + BF_3 + BCl_3$$
$$(50\%)$$
$ClNF_2$ is now prepared by the hypochlorite method[390] in which aqueous NaOCl (5–10% NaOH saturated with chlorine) reacts at pH 6 with difluoramine, N,N-difluoroureas or N,N-difluorosulphonamide (prepared by aqueous fluorination of sulphamide):

$$HNF_2 + NaOCl \xrightarrow{0°} ClNF_2 + NaOH$$

$$NH_2CONF_2 + NaOCl \rightarrow ClNF_2$$

$$NH_2SO_2NF_2 + NaOCl \xrightarrow{5°C} ClNF_2 \quad (70\%)$$
Quantitative yields can be obtained by using HgO instead of NaOH to displace the Cl_2/H_2O equilibrium:

$$HNF_2 + HOCl \xrightarrow[\text{HgO}]{0°} ClNF_2 + H_2O$$
Other methods of preparing $ClNF_2$ include:

$$HNF_2 + Bu^tOCl \rightarrow ClNF_2 \quad (100\%)$$

$$4NaCl + NaN_3 + F_2 \xrightarrow{0°} ClNF_2$$

$$N_3F + Cl_2 \xrightarrow{50°-80°} ClNF_2$$

Bromodifluoramine, which is less stable than the chlorine analogue, was prepared in 1960 by the hypohalite method[390]:

$$HNF_2 + Br_2(aq) \xrightarrow{HgO} BrNF_2 + HBr$$
Dichlorofluoramine is explosive in the liquid state and was prepared in 1960 by the reaction[408]:

$$ClF + NaN_3 \xrightarrow[\text{Ni tube}]{-10° \text{ to } 0°} Cl_2NF$$
The reaction of BrF with NaN_3 gave an unidentified product, but did not appear to be Br_2NF. No mixed halides containing iodine have as yet been characterized[390].

Tetrafluorohydrazine was first identified[390, 409] in 1957 among the thermal decomposition products of nitrogen trifluoride, and its preparation is based on the thermal reduction of NF_3 by copper, arsenic, antimony or bismuth:

$$2NF_3 + 2M \rightarrow N_2F_4 + 2MF$$
NF_3 can also be reduced through hot fluidized carbon[410], and although the yields of N_2F_4 can be high, there is a separation problem from fluorocarbon contaminants:

$$4NF_3 + C \xrightarrow{440°} 2N_2F_4 + CF_4$$
Mixtures of nitrogen trifluoride and nitric oxide also react when passed through a heated nickel tube for short residence times giving moderate yields of N_2F_4:

$$2NF_3 + 2NO \xrightarrow[600°]{\text{Ni tube}} N_2F_4 + 2NOF$$
The other major production route to N_2F_4 is from difluoramine generated by the urea method[390]. HNF_2 can be oxidized quantitatively with hypochlorite at pH 12, or reversibly with aqueous acidic ferric chloride solution, N_2F_4 being the only gaseous product evolved from the aqueous phase:

$$2HNF_2 + NaOCl \xrightarrow{pH\ 12} N_2F_4 + NaCl + H_2O$$

$$2HNF_2 \underset{Fe^{2+}/H_2SO_4}{\overset{Fe^{3+}/HCl}{\rightleftharpoons}} N_2F_4$$
It should of course be pointed out that the formation of tetrafluorohydrazine implies the presence of the stable difluoroamine free radical ($\cdot NF_2$) with which there is ready equilibrium[411]:

$$N_2F_4 \rightleftharpoons 2\cdot NF_2$$
Difluorodiazine N_2F_2 was first identified[412] in 1942 as a thermal decomposition product of N_3F, but it is now most conveniently prepared[413] in almost quantitative yields by the thermal decomposition of the $KF \cdot HNF_2$ complex:

$$KF + HNF_2 \xrightarrow{-80°} KF \cdot HNF_2 \xrightarrow{20°} N_2F_2 + KHF_2$$

[413] E. A. Lawton, D. Pilipovich and R. D. Wilson, *Inorg. Chem.* **4** (1965) 118.

Small quantities of N_2F_2 can be prepared in good yield by the fluorination of sodium azide, and it is also an isolatable product of the following reactions:
$$NH_4F \cdot HF \xrightarrow{\text{electrolysis}} N_2F_2 \quad (5-10\%)$$

$$NF_3 + NH_3 \xrightarrow{\text{Cu reactor}} N_2F_2 \quad (5\%)$$

$$NF_3 + Hg(g) \xrightarrow[\text{discharge}]{\text{electric}} N_2F_2 \quad (15\%)$$

$$HNF_2 + KF(aq) \xrightarrow{pH\ 8.6} N_2F_2 \quad (75\%)$$
These methods give mixtures of both the *cis*- and *trans*-isomers, but in the following methods only the *trans*-isomer is found[390]:

$$N_2F_4 + AlCl_3 \xrightarrow{-80° \text{ to } -112°} N_2F_2 \quad (48\%)$$

$$N_2F_4 + MCl_2 \rightarrow N_2F_2 \quad (M=Sn, Co, Fe, Mn, Ni)$$

$$N_2F_4 \cdot SbF_5 + NOCl \rightarrow N_2F_2 \quad (90\%)$$
The two isomers are thermally interconvertible and *trans*-N_2F_2 isomerizes[390] into the *cis*-form in >90% yields with a trace of fluorine in a stainless steel reactor at 75°.

The preparation of halogen azides FN_3, ClN_3 and BrN_3 has been described[402] in section 8 under azides, but mention is included here in view of their similarity to other nitrogen–halogen compounds.

Considerable effort has been spent in searching for and investigating binary fluorine–nitrogen ions[390]. Salts of the tetrafluoroammonium cation NF_4^+ have been synthesized by the following methods and their presence demonstrated by ^{19}F n.m.r.:

$$NF_3 + F_2 + AsF_5 \xrightarrow[\text{discharge}]{\text{electric glow}} NF_4^+ AsF_6^-$$

$$NF_3 + F_2 + SbF_5 \xrightarrow{200°/100 \text{ atm}} NF_4^+ SbF_6^-$$

$$N_2F_3^+ AsF_6^- + F_2 \rightarrow NF_4^+ AsF_6^-$$

Although the NF_2^+ ion is observed as the most intense peak in the NF_3 mass spectrum, no stable salts have yet been prepared.

Fluorodiazonium N_2F^+ salts have been made[390] by abstraction of a fluoride ion from *cis*-difluorodiazine with BF_3 or AsF_5:

$$cis\text{-}N_2F_2 + BF_3 \xrightarrow[50°]{150 \text{ atm}} N_2F^+ BF_4^-$$

$$cis\text{-}N_2F_2 + AsF_5 \xrightarrow{-196 \text{ to } 25°} N_2F^+ AsF_6^-$$
An $N_2F_3^+$ salt is believed to be formed[390] when N_2F_4 reacts with the $AsF_3 \cdot SbF_5$ complex[414]. The product is stable and has the composition NF_2SbF_5, which may be formulated $N_2F_4 \cdot 2SbF_5$ or $N_2F_3^+ SbF_6^- \cdot SbF_5$, in which the SbF_5 group is either complexed to $N_2F_3^+$ or in a bridged arrangement as $Sb_2F_{11}^-$. Similarly, 1:1 and 1:2 complexes of N_2F_4 with AsF_5 are known[390] and appear to be $N_2F_3^+ \cdot AsF_6^-$ and $N_2F_3^+ \cdot As_2F_{11}^-$.

[414] J. K. Ruff, *J. Am. Chem. Soc.* **87** (1965) 1140.

9.2.2. Haloamines

Difluoramine HNF_2 is an unstable explosive material[415] which was first reported[416] in 1931 as a product from the electrolysis of ammonium bifluoride. It can be made in 40% yield by the reaction of N_2F_4 with thiophenol or butyl mercaptan[417]:

$$N_2F_4 + 2PhSH \xrightarrow[\text{4 hr}]{50^\circ} 2HNF_2 + PhSSPh$$
However, it is most conveniently prepared[390] by the hydrolysis of N,N-difluorourea obtained from the aqueous fluorination of urea:

$$NH_2CONH_2(aq) \xrightarrow{F_2/N_2} \underset{(70\%)}{NF_2CONH_2} \xrightarrow{c.\ H_2SO_4} \underset{(100\%)}{HNF_2}$$
Monofluoramine H_2NF was also claimed to be a minor product of the electrolysis of ammonium bifluoride, but this does not seem to have been confirmed[390].

Dichloramine $HNCl_2$ has not been isolated pure but it can be formed in solution by the reaction of aqueous ammonia with hypochlorite in acid solution at about pH 5:

$$NH_3 + 2OCl^- + H^+ \rightarrow HNCl_2 + H_2O + OH^-$$
If the reaction is carried out at pH 8.5, the product is monochloramine H_2NCl:

$$NH_3 + OCl^- \xrightarrow{pH\ 8.5} H_2NCl + OH^-$$
Monochloramine can be isolated by distillation at high vacuum followed by drying and condensation or by fractional distillation from the reaction of chlorine with excess gaseous ammonia[406]:

$$Cl_2 + 2NH_3 \rightarrow H_2NCl + NH_4Cl$$

Ethereal solutions of monobromamine H_2NBr and dibromamine $HNBr_2$ can be prepared by the reaction of bromine and ammonia in ether at low temperatures[404]. Iodamine has also been postulated as an intermediate in the iodine–ammonia reaction[405].

Several attempts have been made without success[390] to prepare compounds containing fluorammonium ions NH_3F^+, or $NH_2F_2^+$. However, low temperature 1:1 complexes of HNF_2 with KF or RbF may contain the bifluoramide ion $FHNF_2^-$:

$$HNF_2 + KF \rightarrow KF \cdot HNF_2 \rightarrow K^+[HFNF_2]^-$$

9.2.3. Oxohalides

The nitrosyl halides[406] FNO, ClNO and BrNO, are all usually prepared by direct halogenation of nitric oxide:

$$2NO + X_2 \rightarrow 2XNO$$
The preparations have each been the subject of much study. The mechanism of the FNO synthesis is thought to be

$$F_2 + NO \rightarrow FNO + F$$

$$F + NO \rightarrow FNO^* \xrightarrow{(M)} FNO$$
$$\downarrow$$
$$FNO + h\nu$$
[415] E. A. Lawton and J. Q. Weber, *J. Am. Chem. Soc.* **85** (1963) 3595.
[416] O. Ruff and L. Staub, *Z. anorg. allgem. Chem.* **198** (1931) 32.
[417] J. P. Freeman, A. Kennedy and C. B. Colburn, *J. Am. Chem. Soc.* **82** (1960) 5304.

FNO can also be prepared by fluorination of NO with a metal fluoride such as AgF_2:

$$NO + AgF_2 \rightarrow FNO + AgF$$

The NO–Cl$_2$ reaction is kinetically third order[418], one mechanism for which assumes the formation of the NO dimer as an intermediate:

Fast equilibrium: $2NO \rightleftharpoons (NO)_2$

Rate-determining step: $(NO)_2 + Cl_2 \rightarrow 2ClNO$

$$\frac{d[ClNO]}{dt} = k[NO]^2[Cl_2]$$
The NO–Br$_2$ reaction is also third order and perhaps better represented as an equilibrium in that BrNO cannot be obtained pure as it decomposed reversibly to NO and Br$_2$:

$$2NO + Br_2 \rightleftharpoons 2BrNO$$
Nitryl fluoride FNO$_2$ is prepared[397] by fluorination of NO$_2$ or sodium nitrate with elemental fluorine or a metal fluoride such as CoF$_3$:

$$2NO_2 + F_2 \rightarrow 2FNO_2$$

$$NaNO_2 + F_2 \rightarrow FNO_2 + NaF$$

$$NO_2 + CoF_3 \xrightarrow{300°} FNO_2 + CoF_2$$

The NO$_2$–F$_2$ reaction is believed to proceed:

Rate-determining step: $NO_2 + F_2 \rightarrow FNO_2 + F$

Fast reaction: $F + NO_2 + M \rightarrow FNO_2 + M$

Nitryl chloride ClNO$_2$ can be produced[406] by the interaction of chlorosulphonic acid and anhydrous nitric acid:

$$ClSO_3H + HNO_3 \rightarrow ClNO_2 + H_2SO_4$$
Similarly, any reactions generating NO_2^+ from nitric acid under anhydrous conditions in the presence of chlorine will produce ClNO$_2$:

$$HNO_3 + 2H_2SO_4 \rightarrow NO_2^+ + H_3O^+ + 2HSO_4^-$$

$$\downarrow HCl$$

$$ClNO_2 + H_2O + 2H_2SO_4$$

$$N_2O_5 + PCl_5 \rightarrow 2ClNO_2 + POCl_3$$
Nitryl bromide BrNO$_2$ is reported[404] to exist in equilibrium with bromine and NO$_2$–N$_2$O$_4$ in a mixture of these reagents.

Trifluoramine oxide ONF$_3$ was reported[419] in 1966 but had previously been synthesized in 1961. It was obtained[390] by electric discharge of NF$_3$–O$_2$–OF$_2$ mixtures at $-196°$, flame

[418] I. C. Hisatsune and L. Zaforte, *J. Phys. Chem.* **73** (1969) 2980.
[419] N. Bartlett and S. P. Beaton, *Chem. Communs.* (1966) 167.

fluorination of NO or photochemical fluorination of NOF at 25°. ONF_3 is now made in stoichiometric yields by fluorination of NOF with iridium hexafluoride[420] whereas OsF_6 or PtF_6 give only trace amounts:

$$3NOF + 2IrF_6 \xrightarrow{20°} ONF_3 + 2NO^+IrF_6^-$$
Attempts have been made to prepare salts of the ions NOF_2^-, $NO_2F^=$, HNO_2F^- and $NO_2F_2^-$, but no conclusive evidence is available[390].

The majority of compounds containing sulphur, nitrogen and halogen do not contain an N–X bond[400, 421]. However, a number of NF_2, NF and NCl derivatives are known and their preparations are exemplified by the following equations:

$$N_2F_4 + S_2F_{10} \xrightarrow{140°} 2SF_5NF_2 \ (60\%)$$

$$N_2F_2 + N_2F_4 + SF_4 \xrightarrow[17\ hr]{100°} SF_5NF_2 \ (100\%)$$

$$N_2F_4 + CF_3SF_3 \xrightarrow{UV} trans\text{-}CF_3SF_4NF_2 \ (7\%)$$

$$N_2F_2 + N_2F_4 + SO_2 \xrightarrow[21\ hr]{100°} FSO_2NF_2 \ (83\%)$$

$$(FSO_2)_2NH + F_2/He \xrightarrow{25°} (FSO_2)_2NF$$

$$NSF + Cl_2 \xrightarrow{CsF} ClN{=}SF_2$$
Finally, the compound nitrosodifluoramine NF_2NO has been identified[422] as the intense dark blue material which collects on a liquid nitrogen cold finger when the gaseous products formed by heating 10:1 mixtures of NO and N_2F_4 to 300° are condensed. The compound dissociates on vaporization to give NO and N_2F_4 in a 2:1 ratio.

9.3. STRUCTURE AND BONDING

Structures which have been determined for nitrogen–halogen and oxygen–nitrogen–halogen compounds are detailed in Tables 54 and 55 respectively.

In general, their shapes are as would be predicted on the basis of the Sidgwick–Powell approach. The NF_3 molecule has similar symmetry to ammonia[423] and its bonding is readily described in terms of molecular orbitals. The decrease in FNF bond angle as compared to HNH, although usual, is surprising when one considers that fluorine is much larger than hydrogen. N_2F_4 has a skew configuration[424] similar to hydrazine, due presumably to the repulsion between the nitrogen lone-pairs in an sp^3 environment. Dissociation results in the ·NF_2 free radical whose nineteen electrons can be contained in the resonance structures illustrated in Fig. 26. On a molecular orbital description, the unpaired electron probably lies in a $2b_1$ antibonding orbital[423], also illustrated in Fig. 26.

Both the isomers of difluorodiazine N_2F_2 have N–F bond lengths longer[425] than those of NF_3 and an N–N distance shorter than in MeN=NMe. It has been in situations like this that the Linnett approach to the theory of chemical bonding has been most useful[426]. The basis of this approach is the assignment of electrons into spin sets rather than electron pairs. For structures containing one or more atoms capable of catenation, a number of combinations would be possible. On this basis N_2F_2 would have four satisfactory electronic structures as illustrated in Fig. 27. The structural parameters clearly demonstrate the importance of the mirror image resonance structures. Furthermore, its dissociation product, the NF molecule, would by this description have a formal charge of $+1$ on the fluorine atom which may indicate why it dimerizes so readily.

$2b_1$ antibonding orbital

[425] R. K. Bohn and S. H. Bauer, Inorg. Chem. 6 (1967) 309.
[426] J. W. Linnett, The Electronic Structure of Molecules, Wiley, New York (1964).
FIG. 27. Linnett structures of N_2F_2.

The nitrosyl halides contain a long nitrogen–halogen bond while the N–O bond length is about the same as in nitric oxide. FNO with eighteen electrons is best described in terms of a Linnett non-pairing structure illustrated in Fig. 28 rather than the formal F—N=O. A similar situation is present in ClNO.
FIG. 28. Linnett structure of FNO.

The nitryl halides FNO_2 and $ClNO_2$, which contain twenty-four electrons, are isoelectronic and isostructural with the nitrate ion and, as indicated in Table 55, the NO_2 groups are similar in shape and size to the nitrite ion. In FNO_2 the N–F bond length is similar to that in NF_3, which implies a full two-electron bond. Assignment of three electrons to each N–O bond satisfies the electron count and places formal charges of $+1$ on nitrogen and $-\frac{1}{2}$ on each oxygen as illustrated in Fig. 29, but the N–Cl distance in $ClNO_2$ is lengthened slightly suggesting a greater contribution from the alternative structure.

FIG. 29. Linnett structures of FNO_2 and $ClNO_2$.

9.4. MOLECULAR CONSTANTS

As the majority of nitrogen–halogen compounds are covalent, much of the available data for calculating molecular constants arises from information given by methods applicable in organic chemistry, in particular the spectroscopic techniques of infrared, n.m.r. and mass spectrometry. Infrared spectra of N–X species have been widely used as a means of indicating the presence of either a particular structural feature or a particular compound[390]. Full assignments of the bands in some nitrogen–fluorine derivatives have led to the calculation of structural parameters. With regards to n.m.r. data, [14]N n.m.r. can theoretically be recorded for all N–X compounds but in fact experimental difficulties have prevented this until quite recently[427,428]. [15]N n.m.r. can only be considered when circumstances warrant the expense incurred by the synthesis of such compounds with highly enriched ^{15}N materials. However, much information has been obtained through [19]F n.m.r.

of fluorine–nitrogen species[429], the spectra of which are relatively easy to obtain, frequently simple and can often establish unequivocal structures. Some ^{19}F and ^{14}N chemical shifts of nitrogen–fluorine species relative to $CFCl_3$ and the saturated aqueous nitrite ion respectively are given in Table 56.

The interpretation of fragmentation patterns in mass spectra has also led to useful predictions concerning the chemistry of nitrogen–fluorine compounds[409], but the generally low intensities of such species[391] due to the reluctance of fluorine to lose an electron and form a positive ion is a major limitation[392].

Dipole moments[430] have been measured for a number of N–X compounds which are listed in Table 57. In comparing the values of NF_3 and NH_3, 0.234 and 1.47 D respectively, the large difference is explained on the basis that in NF_3 the N–F bond moments are so oriented as to almost cancel the lone-pair–nitrogen moment, whereas the bond and lone-pair–nitrogen moments of NH_3 are additive. Likewise the strength of N–F bonds in terms of bond energies have been discussed, and again the distribution in NF_3 is believed to be different to that in ammonia[390]. Some other values are also included in Table 57 for comparison.

9.5. PHYSICAL PROPERTIES

The physical properties of nitrogen–halogen compounds which are easy to prepare and handle have been well investigated, but the unstable and explosive materials are less well documented. Values for these properties are presented in groups of related compounds in Tables 58–64.

9.6. CHEMISTRY AND CHEMICAL PROPERTIES

9.6.1. Nitrogen–Halogen Compounds

Nitrogen trifluoride is a remarkably unreactive material whose properties are more like those of inert CF_4 than of its other immediate neighbour highly reactive OF_2. This may to some extent be attributed to its thermal stability with respect to the elements; however, at elevated temperatures, NF_3 acts as a fluorinating agent towards a variety of metals and metalloids and this provides a method of preparing tetrafluorohydrazine[390]:

$$2NF_3 + 2M \rightarrow N_2F_4 + 2MF$$
NF_3 is slowly hydrolysed by aqueous base at 100° or aqueous HCl at 133°, but is resistant to strong acids and neutral aqueous solutions. It reacts with aqueous iodide, conventional reducing agents such as $LiAlH_4$, and sparking with reducing agents such as H_2, NH_3, CH_4, CO, H_2S or H_2O can lead to violent explosions[389]:

$$4NF_3 + 3LiAlH_4 \rightarrow 4NH_3 + 3LiAlF_4$$

$$2NF_3 + 3H_2O \xrightarrow{\text{spark}} 6HF + NO + NO_2$$
Although weak associations have been reported[431] between NF_3 and BF_3 at $-125°$ and for NF_3 and BCl_3 at $-100°$, it is clear that the unshared electron pair of NF_3 does not contribute much Lewis base character.

Nitrogen trichloride undergoes photochemical decomposition to the elements particularly in the presence of chlorine, while detonation can be initiated in several ways including thermal and mechanical shock[389]. The reactions of NCl_3 with nitrogen oxides are complex, but the main reaction with NO at $-80°$ is thought to be

$$NCl_3 + 2NO \rightarrow N_2O + NOCl + Cl_2$$

[b] W. B Fox, J. S. McKenzie, E. R. McCarthy, J. R. Holmes, F. R. Stahl and R. Juurik, Inorg. Chem. 7 (1968) 2064.

NCl_3 is readily hydrolysed but its reaction with chlorite even in aqueous solution can be used for the preparation of chlorine dioxide[389]:

$$NCl_3 + 3H_2O \rightarrow NH_3 + 3HOCl$$
$$NCl_3 + 3H_2O + 6NaClO_2 \rightarrow 6ClO_2 + 3NaCl + 3NaOH + NH_3$$
$$2NCl_3 + 6NaClO_2 \rightarrow 6ClO_2 + 6NaCl + N_2$$

With the uncertainty as to the nature of nitrogen tribromide, little is known of its chemistry[389]. Nitrogen triiodide–ammonia complex has maximum stability to hydrolysis at pH 10, but it readily reacts with acids, base or aqueous sulphite[389]:

$$NI_3 \cdot NH_3 + HCl \rightarrow [NI_3 + NH_4Cl] \xrightarrow{4HCl} 3ICl + 2NH_4Cl$$
$$NI_3 \cdot NH_3 + 4NaOH \rightarrow 2NaI + NaNO_2 + NH_3 + 2H_2O$$
$$NI_3 \cdot NH_3 + 3Na_2SO_3 + 3H_2O \rightarrow 3Na_2SO_4 + 3HI + 2NH_3$$

[a] Ref. 394.

The reactions of chlorodifluoramine that have been studied as part of the advanced oxidizer research programme have recently been summarized[390]. Many reactions give quite complex mixtures, some of which are more easily achieved by analogous reactions of N_2F_4–Cl_2 mixture. Photolytic reactions of $ClNF_2$ or their reactions with nucleophiles frequently give N_2F_4 as the only product while its reaction with n-alkyl mercury compounds leads to the formation of difluoraminoalkanes[391]:

$$3ClNF_2 + R_2Hg \rightarrow RNF_2 + 2RHgCl + RCl + N_2F_4$$
Reactions of other mixed halogen–nitrogen compounds only lead to decomposition products.

There have been several attempts to classify the numerous reactions of tetrafluoro-hydrazine[391, 392]. Many reactions involve $\cdot NF_2$ radicals formed by dissociation at elevated temperatures.

Examples[390] include additions to unsaturated systems, reactions with other radicals or processes involving hydrogen abstraction:
$$N_2F_4 \rightleftharpoons 2 \cdot NF_2 \xrightarrow{R_f CF=CF_2} R_f CF(NF_2)CF_2NF_2$$

$$N_2F_4 \rightleftharpoons 2 \cdot NF_2 \xrightarrow{2NO} 2NONF_2$$

$$N_2F_4 \rightleftharpoons 2 \cdot NF_2 \xrightarrow[50° \, 4 \, hr]{2PhSH} 2HNF_2 + PhSSPh$$

[a] Ref. 398.

N_2F_4 can act as a strong fluorinating agent under a wide range of conditions and hence unlikely to occur by way of a common mechanism[390]:

$$N_2F_4 + SiH_4 \xrightarrow{25°} SiF_4 + N_2 + H_2$$

$$N_2F_4 + Li \xrightarrow{-80 \text{ to } 250°} LiF + Li_3N$$

$$N_2F_4 + S \xrightarrow{110 \text{ to } 140°} SF_4 + SF_5NF_2$$
The hydrolysis of N_2F_4 under various conditions leads to the formation of HF together with NO at 60°, N_2 and NO_3^- at 133°, and N_2O and NO_2^- at 133° in basic solution. Furthermore, N_2F_4 can behave as a reducing agent in its reaction with oxygen difluoride:

$$2N_2F_4 + OF_2 \rightarrow 3NF_3 + NOF$$
Finally, reactions in which a fluoride ion is abstracted from N_2F_4 lead to stable salts[414] which are thought to be the $N_2F_3^+$ ion:

$$N_2F_4 + AsF_5 \rightarrow N_2F_3^+ AsF_6^-$$
Attempts to carry out addition reactions across the nitrogen–nitrogen double bond of cis- and trans-difluorodiazine have so far been unsuccessful. All that can be said is that the

[b] Ref. 395.

cis-form exhibits greater reactivity than the *trans*-isomer as evidenced[432] by its reaction over a period of 2 weeks with glass to form SiF_4 and N_2O.

Reactions of binary fluorine–nitrogen ions[390] include those of the fluorodiazonium ion as the hexafluoroarsenate $N_2F^+AsF_6^-$ in HF solution:

$$N_2F^+AsF_6^- + NaF \xrightarrow{HF} NaAsF_6 + cis\text{-}N_2F_2$$

$$N_2F^+AsF_6^- + H_2O \longrightarrow N_2O + HAsF_6 + HF$$

$$2N_2F^+AsF_6^- + 2NO \xrightarrow{25^\circ} 2NOAsF_6 + N_2 + cis\text{-}N_2F_2$$

$$2N_2F^+AsF_6^- + 2O_2 \longrightarrow 2O_2AsF_6 + 2N_2 + F_2$$
Reactions of the ionic species thought to be $N_2F_3^+$ with reducing agents have been carried out in liquid SO_2 or AsF_3 and lead to the formation of *trans*-N_2F_2:

$$N_2F_3^+SbF_6^- \cdot SbF_5 + 2(C_5H_5)_2Fe \rightarrow N_2F_2 + 2(C_5H_5)_2FeSbF_6$$

$$N_2F_3^+SbF_6^- \cdot SbF_5 + 2NOCl \rightarrow N_2F_2 + 2NOSbF_6 + Cl_2$$

$$N_2F_3^+SbF_6^- \cdot SbF_5 + I_2 \rightarrow N_2F_2 + [2I^+] + 2SbF_6^-$$
9.6.2. Haloamines

Difluoramine forms weak complexes with both Lewis acids such as boron halides, and Lewis bases like ethers, and can thus be described as amphoteric. These complexes are not usually very stable and either decompose or dissociate[433]:

$$HNF_2 + BCl_3 \xrightarrow{-80^\circ} BCl_3 \cdot HNF_2 \xrightarrow[\text{to } 25^\circ]{\text{warming}} ClNF_2 + BCl_3 + BF_3 + HCl + Cl_2 + \text{white solid}$$

$$HNF_2 + BF_3 \underset{-56 \text{ to } -23^\circ}{\rightleftharpoons} BF_3 \cdot HNF_2$$
The relative base strengths of difluoramines[431] decrease in the order

$$EtNF_2 > MeNF_2 \sim CD_3NF_2 > HNF_2 > ClNF_2 > N_2F_4 \sim CF_3NF_2 \sim NF_3$$
Complexes of difluoramine with basic alkali metal fluorides[434], $MF \cdot HNF_2$, are thought to be hydrogen-bonded complexes of the type $M^+F^- \cdot HNF_2$, although some evidence suggests $M^+ \cdot FH\text{-}NF_2^-$. Thermal decomposition of such complexes gives *cis*- and *trans*-isomers of difluorodiazine in good yield:

$$2MF \cdot HNF_2 \rightarrow FN{=}NF + 2MF \cdot HF$$

The redox reaction of HNF_2 with base is described by the following equations and any additional fluoride ion which is formed over the stoichiometric amount probably results from the hydrolysis of N_2F_2 or N_2F_4:

$$2HNF_2 + 2NaOH \rightarrow N_2F_2 + 2NaF + 2H_2O$$

$$4HNF_2 + 4NaOH \rightarrow N_2F_4 + N_2 + 4NaF + 4H_2O$$
[432] C. B. Colburn, F. A. Johnson, A. Kennedy, K. McCallum, L. C. Metzger and C. O. Parker, *J. Am. Chem. Soc.* **81** (1959) 6397.

[433] R. C. Petry, *J. Am. Chem. Soc.* **82** (1960) 2400.

[434] H. E. Dubb, R. C. Greenough and E. C. Curtis, *Inorg. Chem.* **4** (1965) 648.

HNF_2 is reduced rapidly and quantitatively with aqueous hydrogen iodide[435] while its oxidation with aqueous ferric solution to give tetrafluorohydrazine is thought to proceed via NF_2^-:

$$HNF_2 + 4HI \longrightarrow NH_4F + 2I_2 + HF$$

$$2HNF_2 + 2Fe^{3+} \xrightarrow{H_2O} N_2F_4 + 2Fe^{2+} + 2H^+$$
However, it would appear that more than one of these three reaction types complex formation, redox and ionic, can occur simultaneously[390].

Monochloramine is an important intermediate in the Raschig synthesis of hydrazine from the reaction of ammonia with hypochlorite (see section 6.1). In alkaline solution, H_2NCl decomposes to nitrogen and ammonia by way of hydroxylamine intermediate. Presumably the initial step is NH_2OH formation by nucleophilic substitution followed by rapid decomposition[436]:

$$H_2NCl + OH^- \rightarrow NH_2OH + Cl^-$$

$$H_2NCl + 2NH_2OH + OH^- \rightarrow N_2 + NH_3 + 3H_2O + Cl^-$$
Reaction of monochloramine with tertiary amines and phosphines provides convenient routes to substituted hydrazonium chlorides and aminophosphonium chlorides[437]:

$$H_2NCl + R_3N \rightarrow (R_3NNH_2)Cl$$

$$H_2NCl + R_3P \rightarrow (R_3PNH_2)Cl$$
9.6.3. Oxohalides

Nitrosyl fluoride FNO readily reacts with many elements forming metal fluorides and with a variety of metal fluorides to form nitrosyl salts[396, 397]:

$$FNO + M \rightarrow MF + NO$$

$$FNO + AsF_5 \rightarrow NOAsF_6$$
The reaction of FNO with iridium hexafluoride also leads to the formation of trifluoramine oxide[420]:

$$3FNO + 2IrF_6 \rightarrow 2NOIrF_6 + ONF_3$$
Like the other nitrosyl halides, FNO reacts with hydroxylic compounds to give nitrites:

$$XNO + ROH \rightarrow RONO + HX$$
In the reaction with water, however, the nitrous acid formed initially reacts further to give nitric acid and nitric oxide:

$$XNO + H_2O \rightarrow HNO_2 + HX$$

$$3HNO_2 \rightarrow HNO_3 + 2NO + H_2O$$
Thus the overall mixture is a potent solvent for metals, being similar in composition to aqua regia (HNO_3–HCl):

$$4XNO + 3H_2O \rightarrow HNO_3 + HNO_2 + 2NO + 4HX$$
[435] E. A. Lawton and J. Q. Weber, *J. Am. Chem. Soc.* **81** (1959) 4755.
[436] M. Anbar and G. Yagil, *J. Am. Chem. Soc.* **84** (1962) 1790.
[437] W. Jolly, *Inorganic Chemistry of Nitrogen*, Benjamin, New York (1964).

The reaction of nitrosyl halides in basic solutions is also similar[389]:

$$4XNO + 6NaOH \rightarrow NaNO_3 + NaNO_2 + 4NaX + 2NO + 3H_2O$$

FNO reacts with SO_2 to give nitrososulphuryl fluoride[438] which can be stored at $-78°$ and acts as stabilized FNO by decomposing into its constituent compounds on warming to $19°$:

$$FNO + SO_2 \rightleftharpoons FSO_2NO$$
Equilibrium constants for the thermal decomposition of nitrosyl chloride have been determined:

$$2ClNO \rightleftharpoons 2NO + Cl_2$$
At elevated temperatures, however, the rate of decomposition is faster than would be expected due to the formation of chlorine atoms by the reaction

$$NO + Cl_2 \rightleftharpoons ClNO + Cl$$
which can then cause further decomposition of ClNO by the reverse process. ClNO also reacts rapidly and reversibly with other halogens[389]:

$$2ClNO + I_2 \rightleftharpoons 2NO + 2ICl$$
The oxidation of ClNO leads to decomposition into nitrogen dioxide and chlorine:

$$ClNO + \tfrac{1}{2}O_2 \rightarrow NO_2 + \tfrac{1}{2}Cl_2$$
Liquid nitrosyl chloride is a useful ionizing solvent[439] for other nitrosyl salts (see section 11.7), and can act as a medium for preparing nitrosyl derivatives of metal halide anions:

$$ClNO \rightleftharpoons NO^+ + Cl^-$$

$$ClNO + FeCl_3 \xrightarrow[\text{ClNO}]{\text{liq.}} NO^+FeCl_4^-$$
Nitrosyl bromide like ClNO also decomposes reversibly even at room temperature ($\sim 7\%$ at 1 atm pressure of BrNO), and a rapid reversible reaction occurs when chlorine is present[389]:

$$2BrNO \rightleftharpoons 2NO + Br_2$$
Nitryl fluoride FNO_2 reacts with most metals to form both the metal fluoride and oxide, whereas some Group VI metals form the oxyfluoride, while almost all non-metals give nitryl salts[397]:

$$\left. \begin{array}{l} 2FNO_2 + Zn \rightarrow ZnF_2 + 2NO_2 \\ NO_2 + Zn \rightarrow ZnO + NO \end{array} \right\}$$

$$2FNO_2 + Cr \rightarrow CrO_2F_2 + 2NO$$

$$\left. \begin{array}{l} 3FNO_2 + B \rightarrow BF_3 + 3NO_2 \\ FNO_2 + BF_3 \rightarrow NO_2BF_4 \end{array} \right\}$$
Nitryl chloride $ClNO_2$ decomposes at about $120°$ according to the following equations:

$$ClNO_2 \rightarrow NO_2 + Cl$$
$$Cl + ClNO_2 \rightarrow NO_2 + Cl_2$$

---
[438] W. Kwasnik, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. I (ed. G. Brauer), Academic Press, New York (1963), Section 4, pp. 150–271.

[439] V. Gutmann, in *Halogen Chemistry*, Vol. 2 (ed. V. Gutmann), Academic Press, London (1967), p. 399; V. Gutmann, *Coordination Chemistry in Non-aqueous Solutions*, Springer-Verlag, New York (1968).

The reaction of $ClNO_2$ with NO leads to two other nitrogen species:

$$ClNO_2 + NO \rightarrow NO_2 + ClNO$$
Hydrolysis of nitryl chloride gives nitric and hydrochloric acids as final products formed when the initial products nitrous and hypochlorous acids interact, whereas ammonolysis in liquid ammonia yields chloramine and ammonium nitrite:

$$ClNO_2 + H_2O \rightarrow [HOCl + HNO_2] \rightarrow HNO_3 + HCl$$
$$ClNO_2 + 2NH_3 \rightarrow H_2NCl + NH_4NO_2$$
Other nitryl salts are formed by the reaction of $ClNO_2$ with metal chlorides in liquid chlorine as solvent[389]:

$$ClNO_2 + SbCl_5 \xrightarrow{\text{liq. } Cl_2} NO_2^+ SbCl_6^-$$
9.7. BIOLOGICAL PROPERTIES

Nitrogen trifluoride is a toxic, colourless gas with little odour at concentrations of 500 ppm in air but has a pungent odour at higher concentrations. Tetrafluorohydrazine also causes considerable respiratory distress and is highly toxic[390]. Thus, because so few details have been reported, it is expedient to regard all nitrogen–halogen compounds as toxic and to be handled out of contact in closed systems.

9.8. ANALYSIS

The majority of nitrogen–halogen compounds are characterized by normal research laboratory procedures of micro-analysis of one or more of the elements present together, with an investigation of some spectroscopic[440] and other physical properties. The techniques used to handle volatile nitrogen–halogen compounds are similar to those used for other reactive halogen compounds[441].

10. NITROUS OXIDE

10.1. PRODUCTION AND INDUSTRIAL USE

The industrial manufacture of nitrous oxide is essentially a scale-up of the well-known laboratory method involving the thermal decomposition of ammonium nitrate[442]:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$
As has been mentioned previously (section 5.3), ammonium nitrate is a high explosive and, consequently, various precautions are taken to reduce or preferably eliminate the possibility of detonation during the decomposition process. For this purpose, catalysts can be employed, but the process can be controlled by leading a concentrated aqueous ammonium nitrate solution into a reactor at 275°C.

[440] R. F. Barrow and A. J. Merer, in ref. 389, Section XXXIV, pp. 454–525.
[441] R. D. Peacock, in *Advances in Fluorine Chemistry*, Vol. 4 (eds. M. Stacey, J. C. Tatlow and A. G. Sharpe), Butterworths, London (1965), p. 31.
[442] I. R. Beattie, in ref. 389, p. 158.

Alternative methods have been suggested including the reaction of hydroxylamine and aqueous nitrite, but the oxidation of ammonia by oxygen in the presence of a catalyst yields such a variety of products in various amounts depending on the experimental conditions that it might be possible to optimize on nitrous oxide as the principal product. The mechanism is complex, but N_2O can be envisaged as being formed by one or other of the following routes:

$$NH_3 + O \rightarrow NH_3O$$
$$NH_3O + O \rightarrow HNO + H_2O$$
$$2HNO \rightarrow N_2O + H_2O$$

$$NH_3 + O \rightarrow NH_3O$$
$$NH_3O + O_2 \rightarrow HNO_2 + H_2O$$
$$NH_3O + HNO_2 \rightarrow N_2O + 2H_2O$$

$$NH_3 + O \rightarrow NH + H_2O$$
$$NH + O \rightarrow HNO$$
$$2HNO \rightarrow N_2O + H_2O$$
Added to these are many reactions producing NO, N_2 and other byproducts. However, in spite of the obvious complexity, up to 88 % nitrous oxide can be obtained from ammonia oxidation using manganese catalysts containing iron or bismuth at 200–300°C, and 71 % nitrous oxide from MnO–BiO catalysts at 200°C.

A small concentration of nitrous oxide is also found in the atmosphere which is thought to originate either from the decomposition of fixed nitrogen compounds in the soil, bacterial metabolism, or by the interaction of nitrogen and oxygen atoms produced by photochemical decomposition of ozone[443].

The principal use of nitrous oxide is as an anaesthetic for which it is available in a high state of purity in cylinders. It also has a high solubility in cream, and hence can be used as the propellant gas in forming whipped-cream products[443].

10.2. LABORATORY PREPARATION AND PURIFICATION OF NITROUS OXIDE

Potassium dinitrososulphite, which can be prepared by passing a fast stream of nitric oxide through potassium sulphite solution, decomposes in weakly acid solution to give nitrous oxide[444]:

$$K_2SO_3 + 2NO \rightarrow K_2SO_3(NO)_2 \rightarrow K_2SO_4 + N_2O$$
Alternatively, ammonium nitrate decomposes exothermically at 170°C to give nitrous oxide:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$
Since the reaction can be explosive, care must be taken to ensure that the temperature does not rise above 250°C during the reaction, and also to prevent condensed water returning into the molten salt[444].

[443] I. R. Beattie, in ref. 389, p. 189.

[444] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. 1 (ed. G. Brauer), Academic Press, London (1963), p. 484.
The gas can be purified by passing through 4M potassium hydroxide solution followed by liquefaction and fractional distillation at low temperature. Pure nitrous oxide in steel cylinders can be used directly or after further purification by low temperature distillation.

Nitrous oxide is also formed when nitramide or hyponitrites decompose, during the reduction of nitrites and nitrates, and in the reaction of nitrite with hydroxylamine or hydrazoic acid[443]:

$$NH_2NO_2 \xrightarrow{\Delta} N_2O + H_2O$$

$$Na_2N_2O_2 + H_2O \xrightarrow{\Delta} N_2O + 2NaOH$$

$$2HNO_2 + SO_2 \rightarrow N_2O + H_2O + SO_3$$

$$HNO_2 + NH_2OH \rightarrow N_2O + 2H_2O$$

$$HNO_2 + HN_3 \rightarrow N_2O + N_2 + H_2O$$
10.3. NUCLEAR ISOTOPES OF N_2O

The various labelled isotope isomers $^{15}N^{14}NO$, $^{14}N^{15}NO$, and $^{15}N_2O$ may all be conveniently synthesized by the thermal decomposition of the appropriately labelled form of ammonium nitrate[445]:

$$^{15}NH_4NO_3 \rightarrow {}^{15}NNO + 2H_2O$$

$$NH_4{}^{15}NO_3 \rightarrow N^{15}NO + 2H_2O$$

$$^{15}NH_4{}^{15}NO_3 \rightarrow {}^{15}N_2O + 2H_2O$$

The temperature of decomposition should be maintained at $200 \pm 20°C$ as appreciable amounts of nitrogen and other oxides are formed at higher temperature or explosions can occur.

Nitrous oxide enriched in ^{18}O has been prepared by adding a solution of sodium azide in ^{18}O-enriched water to a solution of nitrite–^{18}O also in ^{18}O-enriched water at pH 2.5, then purified by storing first over solid NaOH then concentrated sulphuric acid[446]:

$$HN_3(aq) + HN^{18}O_2(aq) \rightarrow N_2{}^{18}O + N_2 + H_2O$$
Alternatively, the reaction of hydroxylamine hydrochloride and nitrous acid[446] formed by bubbling dry hydrogen chloride through sodium nitrite in ^{18}O-enriched water yields nitrous oxide–^{18}O:

$$NH_2OH(aq) + HN^{18}O_2(aq) \rightarrow N_2{}^{18}O + 2H_2O$$
10.4. STRUCTURE AND BONDING

The crystal structure of N_2O and CO_2 are so similar that their shapes were erroneously considered to be the same. Early diffraction data clearly indicated that N_2O was linear, but the atoms could not be individually located because the scattering power of nitrogen and oxygen are so similar[443]. Furthermore, now that the asymmetrical NNO structure has been confirmed by a variety of spectroscopic methods, the X-ray and neutron diffraction studies

[445] W. Spindel, in *Inorganic Isotopic Syntheses* (ed. R. H. Herber), Benjamin, New York (1962), p. 87.
[446] I. Dostrovsky and D. Samuel, in *Inorganic Isotopic Syntheses* (ed. R. H. Herber), Benjamin, New York (1962), p. 133.

are consistent with a disordered structure in that N_2O molecules are randomly oriented NNO and ONN. Further evidence for this disorder is given by the extrapolated entropy of N_2O at 0 K being 1.14 e.u. close to the calculated value $R \ln 2 = 1.38$ for random orientation rather than zero for a perfectly ordered crystal[447].

The NO and NN distances[448] indicate bond orders of roughly 1.5 and 2.5 respectively; electronic structures can be rationalized by postulating approximately equal contributions from each of the two resonance structures:

$$:N \equiv \overset{+1}{N} - \overset{-1}{\underset{..}{O}}: \qquad :\overset{-1}{N} = \overset{+1}{N} = \overset{.}{\underset{..}{O}}:$$
However, the bonding situation in N_2O is most simply represented by the Linnett non-pairing structure[449]:

$$:\overset{-\frac{1}{2}}{N} = \overset{+1}{\underset{.}{N}} - \overset{-\frac{1}{2}}{\underset{..}{O}}:$$
A similar description can be deduced from molecular orbital theory in which all the bonding and non-bonding orbitals are filled while the anti-bonding levels are empty. Such a situation seems to confer extra stability and arises with sixteen-electron triatomic systems of which N_2O is an example together with other isoelectronic species NO_2^+, CO_2, N_3^-, NCO^-, CN_2^{2-}, etc.

10.5. MOLECULAR CONSTANTS

Molecular constants for nitrous oxide are listed in Table 65. The electronic spectrum consists of a number of diffuse bands and several Rydburg series, the two lowest giving ionization potentials in agreement with the photo-ionization value[450]. One ultraviolet

band-system of the gaseous N_2O^+ ion is also known, and e.s.r. investigation of the γ-irradiation of solid nitrous oxide at 77K indicates[451] the presence of at least three radicals one of which is N_2O^+. The infrared spectra of the various nitrogen and oxygen isotope isomers of nitrous oxide have also been fully investigated[450,452], while the presence of two strong Raman lines corresponding to the fundamental frequencies v_1 and v_3 indicates that nitrous oxide cannot have a centre of symmetry[450].

10.6. PHYSICAL PROPERTIES

Physical constants for nitrous oxide are listed in Table 66.

TABLE 66. PHYSICAL PROPERTIES OF NITROUS OXIDE[443]

Property	Temperature (K)	Value
Melting point	182.29	$-90.86°C$
Boiling point	184.67	$-88.48°C$

[452] K. Nakamoto, *Infrared Spectra of Inorganic and Coordination Compounds*, Wiley, New York (1963), p. 80.

The adsorption of nitrous oxide on various solids has been investigated as well as solubility studies in water and organic solvents[443]. The hydrate $N_2O \cdot 6H_2O$ has a clathrate structure, but no oxygen exchange was detected using $H_2{}^{18}O$ over a wide pH range[453].

10.7. CHEMISTRY AND CHEMICAL PROPERTIES

10.7.1. Decomposition[443]

The thermal decomposition of nitrous oxide results in the formation of the elements at an appreciable rate in the temperature range 585–850°C by a unimolecular process involving the fission of the weaker bond:

$$N_2O \rightarrow N_2 + \tfrac{1}{2}O_2$$

As the activation energy for the process is 59 kcal/mol, the energetics contravene the spin conservation rule requiring zero change in total electron spin in elementary processes:

$$N_2O \rightarrow N_2 + O[^1D]; \qquad \triangle H° = 85.1 \text{ kcal/mol}$$
$$N_2O \rightarrow N_2 + O[^3P]; \qquad \triangle H° = 39.7 \text{ kcal/mol}$$
The presence of other molecules either act as catalysts or inhibitors, while photochemical decomposition also requires consideration of nitric oxide formation in spite of both its contradiction of the spin conservation rule and unfavourable energy requirements.

$$N_2O \rightarrow NO + \tfrac{1}{2}N_2; \qquad \triangle H° = 115.1 \text{ kcal/mol}$$

10.7.2. Reactions

Compared to other oxides of nitrogen, nitrous oxide is relatively unreactive and inert towards halogens and alkali metals at room temperature. With hydrogen however, the main reaction is:

$$N_2O + H_2 \rightarrow N_2 + H_2O; \qquad \triangle H° = 75 \text{ kcal/mol}$$
The ignition temperature for H_2–N_2O gas mixtures is lower than that for hydrogen in air or oxygen, and it is more exothermic than the H_2–O_2 reaction due to the lower energy requirement to dissociate nitrous oxide (45 kcal/mol) as opposed to molecular oxygen (60 kcal/mol). Hence the process is not simply dependent on the dissociation of nitrous oxide and the following scheme has been suggested[454]:

$$
\begin{aligned}
&2N_2O \rightarrow N_2O^* + N_2O \\
&N_2O + H_2 \rightarrow N_2O^* + H_2 \\
&N_2O \rightarrow N_2 + O \\
&O + H_2 \rightarrow OH + H
\end{aligned}
\quad \Bigg\} \text{ Initiation}
$$

$$
\begin{aligned}
&H + N_2O \rightarrow OH + N_2 \\
&OH + H_2 \rightarrow H_2O + H
\end{aligned}
\quad \Bigg\} \text{ Propagation}
$$

$$2H + M \rightarrow H_2 + M \qquad \text{Termination}$$
[453] R. Bonner and J. Bigeleisen, *J. Am. Chem. Soc.* 74 (1952) 4944.
[454] H. W. Melville, *Proc. Roy. Soc.* A, 146 (1934) 737.

Explosion limits are extremely wide, and even nitrous oxide diluted with up to 79% nitrogen can form explosive mixtures with hydrogen. Also the H_2–O_2 reaction is sensitized by nitrous oxide, e.g. when oxygen is added to N_2O–H_2 mixtures, instantaneous ignition or an autocatalytic reaction resulting in an explosion occurs.

Nitrous oxide is only slowly reduced by $TiCl_3$ to ammonia and by $CrCl_2$ to nitrogen. Sodium borohydride, however, does not react with nitrous oxide by itself, but a number of transition metal complexes, particularly cobalt(I) derivatives, can act as catalysts for the reduction to nitrogen[455].

$$N_2O + 2H \rightarrow N_2 + H_2O$$
A further recent development in this area has been the reduction of N_2O with nitrogentris-(triphenylphosphine)cobalt hydride and tris(triphenylphosphine)cobalt trihydride in the presence of excess triphenylphosphine[456]. Results have been interpreted in terms of oxidation of triphenylphosphine to triphenylphosphine oxide and the evolution of hydrogen and nitrogen as well as formation of nitrogen complexes in solution suggesting the following reaction:

$$H_3Co(PPh_3)_3 + Ph_3P + N_2O \rightarrow H(N_2)Co(PPh_3)_3 + Ph_3PO + H_2$$
When carbon, phosphorus, sulphur or metals whose oxides have high heats of formation are heated in nitrous oxide, they ignite and often burn more vigorously than in air, forming the oxide and nitrogen:

$$M + N_2O \rightarrow MO + N_2$$
Similarly, with atomic chlorine, the intermediate oxide decomposes to give the elements as final products[443]:

$$Cl + N_2O \rightarrow [ClO] + N_2$$
$$2[ClO] \rightarrow Cl_2 + O_2$$
Thus the reactions of nitrous oxide in its rôle as an oxidizing agent involve large free energy changes but have higher activation energies than the corresponding reactions involving molecular oxygen.

Probably the most remarkable reaction of nitrous oxide is with molten sodium or potassium amide at about 200°C to yield azides (see section 8.1):

$$2KNH_2 + N_2O \rightarrow KN_3 + KOH + NH_3$$

10.8. BIOLOGICAL PROPERTIES

Inhaled in small amounts, nitrous oxide induces intoxication and hysterical excitement often accompanied by convulsive laughter ("laughing gas"), whereas in larger amounts it acts as a narcotic. As it is not capable of supporting respiration, in anaesthesia it is administered as a mixture with oxygen and is particularly used in dentistry and gynaecology. With lower concentrations of nitrous oxide in oxygen, it can be used as an analgesic. Prolonged anaesthesia may lead to undesirable side-effects[457].

The rôle of nitrous oxide in natural nitrogen fixation processes is not understood, but it is a product and substrate of bacterial metabolism[458].

10.9. ANALYSIS OF NITROUS OXIDE[459]

Thermal decomposition of nitrous oxide in the presence of platinum or palladium catalyst will liberate oxygen which can be detected with alkaline pyrogallol reagent, but is not specific to this particular oxide. The mass spectrometer is probably the most reliable technique for detecting small quantities of gas. However, infrared absorption spectroscopy is a more accessible technique, and depending on other gases present, the intensity of one of the infrared bands at 590, 1285 and 2224 cm^{-1} can be used to estimate the nitrous oxide content of gas mixture. In connection with the use of nitrous oxide as an anaesthetic, its estimation in admixture with oxygen and ether can be carried out by the acoustic gas analyser which, as its name implies, is based on the variation of the velocity of sound according to the density of the gas. Hence by pre-calibrating for various mixtures, nitrous oxide content can be continuously monitored. If nitrogen is also present, oxygen has to be determined separately by means of an oxygen analyser for the four components to be estimated.

Combustion methods include reduction over a palladium catalyst followed by volumetric determination of the nitrogen:

$$N_2O + H_2 \rightarrow N_2 + H_2O$$
Alternatively, nitrous oxide can be reduced over heated copper gauze:

$$N_2O + Cu \rightarrow CuO + N_2$$
or as another variation to eliminate interference from carbon dioxide:

$$N_2O + CO \rightarrow N_2 + CO_2$$
11. NITRIC OXIDE

11.1. PRODUCTION AND INDUSTRIAL USE

From an industrial point of view, nitric oxide is probably the most important oxide of nitrogen[460]. It is produced by the catalytic oxidation of ammonia[461, 462] at 800–960°C:

$$4NH_3 + 5O_2 \xrightarrow{\text{Pt-Rh}} 4NO + 6H_2O; \qquad \Delta H(298) = -216.55 \text{ kcal/mol}$$
This, and the alternative reactions which are possible in ammonia oxidation, have been considered in more detail in section 3.10.2

The direct reaction of nitrogen and oxygen requires high temperatures before equilibrium conditions are such as to bring any appreciable yields of nitric oxide. The Birkeland–Eyde electric arc oxidation of atmospheric nitrogen was developed during the 1920's in countries where hydroelectric power was cheap, but the process is now obsolete[460]. More recently the combustion of air–natural gas mixtures in the "pebble-bed" or Wisconsin process can produce temperatures of over 2000°C, and although the process is feasible, it is not at present economic[463]. The equilibrium concentrations of NO for each process

[463] E. D. Ermenc, *Chem. Engng. Progress* **52** (1956) 149.

are 4% and 2% respectively, and the gas mixture has even to be cooled rapidly to prevent any further loss by decomposition (see section 11.7.1).

Clearly, the fate of most nitric oxide is oxidation to nitrogen dioxide almost as soon as it is formed, and the principal industrial application of both oxides is as intermediate oxidation products in the manufacture of nitric acid[464]. The presence of nitric oxide in the atmosphere can obviously occur through lightning discharge and it is also present in automobile exhausts[465], hence subsequent oxidation and dissolution produces nitric acid in very low concentration in rain water. However, although this could be considered as providing a beneficial source of fixed nitrogen, the build-up of concentrations of nitrous fumes in city atmospheres is likely to be a considerable health hazard. Nitric oxide is also present in the upper atmosphere, and important in photochemical reactions arising from solar radiation[466].

11.2. LABORATORY PREPARATION AND PURIFICATION OF NITRIC OXIDE[467]

Nitric oxide may be prepared from aqueous solution by the reaction between nitrous acid and iodine or ferrocyanide:

$$2KNO_2 + 2KI + 2H_2SO_4 \rightarrow 2NO + 2K_2SO_4 + I_2 + 2H_2O$$
$$KNO_2 + K_4Fe(CN)_6 + 2CH_3COOH \rightarrow NO + K_3Fe(CN)_6 + 2CH_3COOK + H_2O$$

When dilute sulphuric acid is added dropwise on to sodium nitrite, the nitrous acid formed initially decomposes to give a steady stream of nitric oxide:

$$6NaNO_2 + 3H_2SO_4 \rightarrow 4NO + 2H_2O + 3Na_2SO_4 + 2HNO_3$$
The gas is purified by passing through 90% sulphuric acid followed by 50% potassium hydroxide then dried by passing through a trap cooled in solid CO_2–ether mixture, and condensed over phosphorus pentoxide cooled with liquid nitrogen. On fractional distillation, the middle cut is collected and redistilled to give pure NO.

Dry nitric oxide can be obtained directly simply by heating the solid mixture of chromium(III) oxide with nitrate and nitrite, preferably in the presence of calcined iron(III) oxide[468]:

$$3KNO_2 + KNO_3 + Cr_2O_3 \rightarrow 4NO + 2K_2CrO_4$$
Nitric oxide is also formed in conjunction with other gases during the reduction[461] of nitric acid, nitrates and nitrites, or nitrosyl derivatives:

$$8HNO_3 + 3Cu \longrightarrow 2NO + 3Cu(NO_3)_2 + 4H_2O$$
$$2Ba(NO_2)_2 + I_2 \xrightarrow{225°C} 2NO + Ba(NO_3)_2 + BaI_2$$
$$2NOCl + 2I^- \longrightarrow 2NO + I_2 + 2X^-$$

[466] J. Heicklen and N. Cohen, in *Advances in Photochemistry*, Vol. 5 (eds. W. A. Noyes, Jr., G. S. Hammond and J. N. Pitts), Interscience, New York (1968), pp. 157–328.

[467] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, Vol. I (ed. G. Brauer), Academic Press, New York (1963), p. 460.

[468] R. A. Ogg, Jr. and J. D. Ray, *J. Am. Chem. Soc.* **78** (1956) 7993.

Nitrosonium salts react with hydroxylic solvents:

$$NO^+ + OH^- \rightleftharpoons HNO_2 \rightleftharpoons NO_2^- + H^+$$

Thus the equilibrium is only displaced to the left in strongly acidic media. Nitrosonium hydrogen sulphate is formed therefore by dissolution of nitrites or dinitrogen trioxide in sulphuric acid[469]:

$$N_2O_3 + H_2SO_4 \rightarrow 2NO^+ + 3HSO_4^- + H_3O^+$$

although hydrolysis occurs in solutions containing less than 80% H_2SO_4.

11.3. NUCLEAR ISOTOPES OF NITRIC OXIDE[470]

^{15}NO is commercially available or can be prepared by the reduction of nitrogen dioxide, nitrites or nitrates with mercury and sulphuric acid:

$$6^{15}NO_2 + 4Hg + 2H_2SO_4 \rightarrow 4^{15}NO + Hg_2(NO_3)_2 + 2HgSO_4 + 2H_2O$$

Conversion of ammonia into nitric oxide can be achieved most conveniently without proceeding via nitrogen by direct oxidation with permanganate in an autoclave for 7–8 hr at 170–180°C to nitrate which can be reduced to nitric oxide as before. By passing a mixture of oxygen and nitrogen through a high-tension electric arc, a mixture of N_2O_3 and N_2O_4 is formed which can also be reduced to NO as above. This method has been used in the preparation of ^{15}NO and $N^{18}O$ by using the appropriate enriched elements[471].

11.4. STRUCTURE AND BONDING

X-ray crystallography[472] shows that solid nitric oxide consists of a loosely bound dimeric $(NO)_2$ species which may have a rectangular shape. The residual entropy and other physical properties[461] also suggest that complete randomization of the two orientations occurs, and although the mean distance between the two NO units is about 2.4 Å, it is not possible to tell whether they are oriented in the same direction or head to tail as illustrated in the structure:

$$
\begin{array}{c}
N \ldots\ldots O \\
| \qquad\quad | \quad 1.10\ \text{Å} \\
O \ldots\ldots N \\
2.38\ \text{Å}
\end{array}
$$
The blue-coloured liquid phase is also asssociated and infrared studies[473] provide some evidence for N–N bonds implying a *cis*-configuration with the structure:

$$
\begin{array}{c}
\cdot N\!-\!N\cdot \\
\| \quad \| \\
O \quad O
\end{array}
$$

However, nitric oxide is normally encountered as a gas, in which phase it is colourless and monomeric with little tendency to associate via electron pairing.

[471] I. Dostrovsky and D. Sammuel, in *Inorganic Isotopic Synthesis*, (ed. R. H. Herber), Benjamin, New York (1962).

[472] W. J. Dulmange, E. A. Meyers and W. N. Lipscomb, *Acta Cryst.* **6** (1953) 760.

[473] W. G. Fateley, H. A. Bent and B. Crawford, *J. Chem. Phys.* **31** (1959) 204.

Using molecular orbital theory, the electronic structure of nitric oxide in the ground state is usually written[474]

$$NO \ ^2\Pi \ (1\sigma^+)^2(2\sigma^+)^2(3\sigma^+)^2(1\pi)^4(4\sigma^+)^2(5\sigma^+)^2(2\pi)^1$$
Molecular orbital calculations suggest[475] that the 3σ, 4σ and 5σ orbitals are bonding, non-bonding and anti-bonding respectively, with the last electron entering into an antibonding π orbital and accounting for the paramagnetism. Furthermore this theory predicts the bond order to be 2.5, and that it should not be too difficult to remove an electron to form the NO$^+$ ion with a shorter and stronger bond than NO itself. In fact, each of these predictions is correct, the bond length of NO (1.14 Å) lies between that of a double (1.18 Å) and a triple bond (1.06 Å), the ionization potential of 9.25 eV is appreciably lower than for similar molecules (N_2, O_2 and CO are 15.6, 12.1 and 14.0 eV respectively) and the stretching frequency of the NO$^+$ ion in nitrosyl salts (2150–2400 cm^{-1}) is higher than nitric oxide itself (1888 cm^{-1}). In fact, salts of the nitrosyl cation, or the nitrosonium ion as it is alternatively named, such as the perchlorate, bisulphate and tetrafluoroborate, are well-characterized crystalline solids which are isomorphous with corresponding hydroxonium and ammonium salts[469]. The NO$^+$ species is also isoelectronic with N_2, CO and CN$^-$, each of which can be considered by molecular orbital theory as having an electronic structure containing no antibonding π electrons and a bond order of 3. Thus it is not surprising that a wide range and variety of NO complexes of transition metals (see Chapter 46) analogous to metal carbonyls are known. In most cases, NO transfers an electron to the metal, and the NO$^+$ so formed further donates a lone pair of electrons from nitrogen to the metal to give compounds like $Fe(NO)_2(CO)_2$ and $Co(NO)(CO)_3$ which are stable and isoelectronic with $Ni(CO)_4$.

The valence bond approach is also worthy of mention, for although NO is often represented by the resonance forms

$$\overset{+}{\cdot N}{-}\overset{-}{O} \ \leftrightarrow \ \cdot N{=}O \ \leftrightarrow \ \overset{-}{N}{=}\overset{+}{O}\cdot \ \leftrightarrow \ N{\equiv}O\cdot$$
it is adequately described by the Linnett non-pairing structure[474]:

$$:\overset{\cdot\cdot}{N}\overset{\cdot}{=}O:$$

while the cation NO$^+$ is

$$[:N{\equiv}O:]^+$$

Similarly, the anion NO$^-$ would on the same basis have the structure

$$[:N{=}O:]^-$$
however, most compounds in which these ions were thought to be present are now known to contain the anion $N_2O_2^{2-}$ [476].

11.5. MOLECULAR CONSTANTS

Various molecular constants of nitric oxide are listed in Table 67.

The electronic absorption spectrum of NO extends from just below 2300 Å to the vacuum ultraviolet region. Transitions between the ground electronic state and the $A^2\Sigma^+$, $B^2\Pi_r$, $C^2\Pi$ and $D^2\Sigma^+$ states are usually referred to as γ, β, δ and ε bands respectively and have been extensively investigated[466, 477]. Infrared and Raman spectra of various isotope isomers of nitric oxide as gas, liquid, solid and matrix trapped molecule samples also indicate the presence of *cis* or *trans* dimer (ONNO) forms[477]. However, the fundamental bands are also split due to an interaction between the angular and spin momentum vectors ($L = 1$, $S = \frac{1}{2}$) which may couple $L+S$ or $L-S$ dividing the $^2\Pi$ ground state into

TABLE 67. MOLECULAR CONSTANTS OF NITRIC OXIDE[a]

Property	Value
X-ray diffraction data[b]	
System	Monoclinic
Space group	$P2_1/a$
Lattice constants	$a = 6.68$, $b = 3.96$,
	$c = 6.55$, $\alpha = 127.9°$
N–O bond length	1.10 Å
N $\cdots$ O intermolecular distance	2.38 Å
Electron diffraction data[c]	
N–O bond length	1.15 Å
Fundamental vibration frequency	1876 cm^{-1}
Force constant	1.59×10^6 dynes/cm
Moment of inertia	16.47×10^{-40} g/cm^2
Dipole moment	0.15 D
Bond dissociation energy	6.50 eV, 149.9 kcal
First ionization potential	9.25 eV
Magnetic susceptibility (293 K)	1.46×10^{-3} c.g.s. units
Magnetic moment (296 K)	1.837 BM

an upper paramagnetic state $^2\Pi_{3/2}$ and a lower diamagnetic state $^2\Pi_{\frac{1}{2}}$. Interaction with the rotational motion of the molecule also causes the upper state to split into four sub-levels giving rise to three absorption lines with the usual selection rule $m_s = \pm 1$, and in fact they are each observed to be further split into three components due to the interaction of the spin of the nitrogen nucleus[461]. The energy difference between the paramagnetic and diamagnetic $^2\Pi$ states is only about 350 cal/mol and as kt is considerably greater than this value at room temperature and comparable down to even quite low temperatures, it is this

[477] R. F. Barrow and A. J. Merer, in ref. 459, p. 507.

phenomenon that gives rise to the temperature dependence of the magnetic moment. The hyperfine splitting of the electron spin resonance spectrum of NO is also explained on the basis of a strong interaction between the moment of the unpaired electron and the rotation of the molecule, and also leads to the conclusion that about 60% of the spin density is concentrated on the nitrogen atom[478]. Microwave spectral data have been used to obtain values for magnetic hyperfine structure constants, the nuclear quadrupole resonance moment and the dipole moment[477].

The various dissociative ionization processes have also been studied in great detail and their corresponding appearance potentials are consistent with the value of 6.50 ± 0.01 eV for the dissociation energy of nitric oxide. Photo-ionization and electron impact studies are in agreement that the ionization potential for the formation of NO^+ is 9.25 ± 0.02 eV[20].

11.6. PHYSICAL PROPERTIES

Physical constants for nitric oxide are listed in Table 68.

11.7. CHEMISTRY AND CHEMICAL PROPERTIES

11.7.1. Decomposition of Nitric Oxide

As the free energy change in the formation of nitric oxide from the elements is large and positive:

$$N_2 + O_2 \rightarrow 2NO; \qquad \triangle G = +20 \text{ kcal/mol}$$

the isolation of a reasonable yield of product requires not only a high temperature but also a rapid rate of cooling of the equilibrium mixture.

The equilibrium constant of the reaction $K = [NO]^2/[N_2][O_2]$, which at 298 K is 5.27×10^{-31}, has been calculated for a wide range of conditions, but their experimental confirmation has been difficult.

Although many products have been reported for the thermal decomposition of nitric oxide, the principal reaction to be considered is that reverting to the elements:

$$2NO \rightarrow N_2 + O_2$$
The results of several investigations indicate that at 1130–1330°C the decomposition is described by a second-order homogeneous reaction, whilst at higher temperatures reactions involving atomic nitrogen and nitrogen dioxide become important[461]. Heterogeneous decomposition of nitric oxide on platinum and platinum–rhodium wire above 1000°C is bimolecular with respect to NO and is retarded proportionally to the oxygen concentration. Photochemical decomposition of nitric oxide has also been widely investigated, and the products vary to some extent with the state of excitation from which the nitric oxide is decomposed[466].

11.7.2. Oxidation

Undoubtedly the most important reaction of nitric oxide is its oxidation to nitrogen dioxide[460]:

$$2NO + O_2 \rightarrow 2NO_2$$

Work on this classical termolecular reaction was first carried out by Bodenstein[480] in 1918, and extensive investigations which have been reported since that date confirm that it follows a simple third-order rate law over a wide range of experimental conditions:

$$-d(NO)/dt = k[NO]^2[O_2]$$

However, a further unusual feature of this reaction is that the rate constant decreases with increasing temperature. This can be accounted for in the mechanism which postulates the initial formation of dimer:

$$2NO \rightleftharpoons N_2O_2$$

$$N_2O_2 + O_2 \xrightarrow{k''} 2NO_2$$
Since the equilibrium constant K for the dimerization step should decrease with increasing temperature, the process can now be described by the rate law:

$$-d[NO]/dt = k'K[NO]^2[O_2]$$

where K is the equilibrium constant for the dimerization and $k'K$ is synonymous with k. Thus the negative temperature coefficient is explained on the basis that since K should be expected to decrease with temperature, it is not unreasonable to expect $k'K$ to do the same, particularly with a very low energy of activation.

An alternative mechanism[481] involves the species NO_3, together with the possibility of the pernitrite–nitric oxide complex. Like nitrogen trioxide, dinitrogen pentoxide has also been detected by infrared spectroscopy[482] during nitric oxide–oxygen reactions which may lend support for the scheme:

$$NO + O_2 \rightleftharpoons NO_3$$
$$NO_3 + NO \rightarrow 2NO_2$$
$$NO_3 + NO_2 \rightarrow N_2O_5$$
$$N_2O_5 + NO \rightarrow 3NO_2$$
11.7.3. Reactions of Nitric Oxide

Being the simplest stable molecule with an odd number of electrons, nitric oxide has been well investigated with regard to its reactivity towards atoms, free radicals and other paramagnetic species. Many of these reactions have provided unique systems for study by gas kinetics[466, 483] and the results of which have led to an understanding of their mechanisms.

The use of nitric oxide in the monitoring of atomic nitrogen has already been mentioned in section 2.12, while chemiluminescence due to the reaction

$$NO + O \rightarrow NO_2 + h\nu$$
has likewise been used for both the qualitative and quantitative estimation of atomic oxygen[484]. The termolecular reaction

$$NO + O + M \rightarrow NO_2 + M$$
is also well known and first order in each reactant.

[484] F. Kaufman, in *Progress in Reaction Kinetics*, Vol. I (ed. G. Porter), Pergamon, Oxford (1961), p. 1.

Of similar major importance is the reaction of NO with hydrogen atoms produced by electric discharge[485] to give nitroxyl HNO, which has also been prepared by the flash photolysis of nitroalkanes or isoamyl nitrite. Nitroxyl has also been postulated as an intermediate in several industrial processes (see section 3.10.2), and its infrared spectrum in an argon matrix at 20°C has been recorded[486], as well as the value of 48.6 kcal/mol for the bond strength[487] $D(\text{H-NO})$.

In the reactions of NO with the halogens, both atomic and molecular species need to be considered and their mechanisms are among those generalized as follows:

$$NO + X_2 \rightarrow X_2NO$$
$$NO + X_2NO \rightarrow 2XNO$$
$$NO + X_2 \rightarrow XNO + X$$
$$NO + X \rightarrow XNO^*$$
$$XNO^* \rightarrow XNO + h\nu$$
$$XNO^* + M \rightarrow XNO + M$$
Although the NO-F_2 reaction gives FNO predominantly, some ONF$_3$ can be obtained by photochemical fluorination of NO even at room temperature[488]. The nitric oxide–chlorine system has been most thoroughly investigated as both radical and molecular halogen reactions are important contributing factors in the overall mechanism[466, 489]. Less is known about the NO-Br_2 reaction, but with iodine the mechanism is thought[466] to be

$$NO + I \rightleftharpoons INO$$
$$INO + I \rightarrow NO + I_2$$
Likewise, the reaction of NO with HI

$$NO + 6HI \rightarrow NH_4I + H_2O + 5/2I_2$$

is thought to involve the following steps[490]:

$$NO + HI \rightarrow HNO + I$$
$$HNO + HI \rightarrow H_2 + INO$$
$$HNO + I_2 \rightarrow HI + INO$$
$$INO + I \rightarrow NO + I_2$$
Reactions with other halogen compounds are equally complex. Nitryl chloride reacts rapidly with NO[491], but it is uncertain whether this reaction involves oxygen or chlorine transfer.

$$NO + ClNO_2 \rightarrow NO_2 + ClNO$$

[490] J. L. Holmes and E. V. Sundaram, *Trans. Faraday Soc.* **62** (1966) 910.
[491] E. C. Freiling, H. S. Johnston and R. A. Ogg, *J. Chem. Phys.* **20** (1952) 327.

Nitric oxide and hydrogen chloride condense to a deep blue liquid which may contain the complex NOHCl. With xenon fluorides, the reactions with NO have been followed by mass spectrometry which indicates[492] stepwise removal of fluorine:
$$XeF_4 + NO \rightarrow XeF_3 + FNO$$
$$XeF_2 + NO \rightarrow XeF + FNO$$
Nitric oxide can, however, be oxidized with iodine pentoxide[461]:

$$10NO + 2I_2O_5 \rightarrow 2I_2 + 5N_2O_4$$
$$10NO + 3I_2O_5 \rightarrow 3I_2 + 5N_2O_5$$
Halogenated methyl radicals add to NO to form nitroso compounds[466] of which, perhaps, the best known[493] is the blue gas trifluoronitrosomethane CF_3NO:

$$CF_3 + NO \rightarrow CF_3NO$$
$$CFCl_2 + NO \rightarrow CFCl_2NO$$
$$CF_2H + NO \rightarrow CF_2HNO \rightarrow CF_2{=}NOH$$
However, with diboron tetrahalides breakdown of the unstable adducts occurs[494, 495]:

$$3B_2Cl_4 + 3NO \xrightarrow{-40°C} 3B_2Cl_4 \cdot NO \rightarrow B_2(NO)_3 \cdot BCl_3 + BCl_3$$
$$\downarrow$$
$$B_2(NO)_3 + BCl_3$$
$$3B_2F_4 + 6NO \longrightarrow 4BF_3 + 3N_2O + B_2O_3$$
$$6B_2F_4 + 6NO \longrightarrow 8BF_3 + 3N_2 + 2B_2O_3$$

The primary step in the reaction of nitric oxide with ozone is a bimolecular second-order reaction[466]:

$$NO + O_3 \rightleftharpoons NO_2 + O_2; \qquad \triangle H(298) = -47.8 \text{ kcal/mol}$$

with possible secondary reactions:

$$2NO_2 + O_3 \rightarrow N_2O_5 + O_2$$
$$2NO + O_2 \rightarrow 2NO_2$$
Similarly, the gas phase oxidation of NO with HNO_3 also gives nitrogen dioxide[496]:

$$NO + 2HNO_3 \rightarrow 3NO_2 + H_2O$$
The reactions of NO with the oxides of sulphur have been investigated in view of their relevance to the chamber process for the manufacture of sulphuric acid[497], and losses occur when nitrous oxide is produced:

$$2NO + SO_2 \rightarrow N_2O + SO_3$$
$$NO + 2SO_3 \rightarrow (SO_3)_2NO$$
$$2NO + 2SO_2 + 2H_2O \rightarrow 2H_2SO_3NO \rightarrow H_2SO_3(NO)_2 \rightarrow N_2O + H_2SO_4$$
$$+$$
$$H_2SO_3$$

[494] A. K. Holliday and A. G. Massey, *J. Inorg. Nucl. Chem.* **18** (1961) 108.
[495] A. K. Holliday and F. B. Taylor, *J. Chem. Soc.* (1962) 2767.
[496] J. H. Smith, *J. Am. Chem. Soc.* **69** (1947) 1741.
[497] T. J. P. Pearce, in *Inorganic Sulphur Chemistry* (ed. G. Nickless), Elsevier, Amsterdam (1968), p. 543.

The intermediate dinitrososulphites can be prepared as follows[467]:

$$2NO + K_2SO_3 \rightarrow K_2SO_3(NO)_2$$

$$6NO + Na_2S_2O_4 + 2NaOH \rightarrow 2N_2O + Na_2SO_3 \cdot N_2O_2 + Na_2SO_4 + H_2O$$
Nitrogen compounds which react with NO include ammonia as in the side-reactions during NO production by ammonia oxidation[464]:

$$2NH_3 + 3NO \rightarrow 5/2N_2 + 3H_2O$$
NO at 20 atm pressure is also taken up by solutions of nitrosonium salts forming the deep blue $N_2O_2^+$ cation: which is thought to be responsible for the colour during the chamber process for the production of sulphuric acid[498]:

$$NO^+HSO_4^- + NO \rightarrow N_2O_2^+HSO_4^-$$

Nitrogen trichloride reacts with nitric oxide[499] and at $-150°C$ the overall reaction is

$$NCl_3 + 3NO \rightarrow 2NOCl + N_2O + Cl$$
but at $-80°C$ the main reaction is represented by

$$NCl_3 + 2NO \rightarrow N_2O + NOCl + Cl_2$$
Reaction of nitric oxide with carbon compounds, in particular organic-free radicals, have been reviewed[466]. The explosive reaction with carbon disulphide has received much attention[461] because of the associated light emission. The reaction of sodium oxide with NO gives sodium hydronitrite initially which then decomposes[500]:

$$4Na_2O + 4NO \xrightarrow{100°C} 4Na_2NO_2 \rightarrow 2Na_2O + 2NaNO_2 + Na_2N_2O_2$$
With alkali metal hydroxides, both N_2O and N_2 are formed[501]:

$$4NO + 2MOH \rightarrow N_2O + 2MNO_2 + H_2O$$

$$6NO + 4MOH \rightarrow N_2 + 4MNO_2 + 2H_2O$$
Sodium reacts with NO directly or in liquid ammonia to give $(NaNO)_x$[502]; which on the evidence of its X-ray diffraction pattern is thought to be different to ordinary sodium hyponitrite and possibly may be cis-$Na_2N_2O_2$. Infrared spectra of the product of reaction of lithium with NO in an argon matrix suggests LiON rather than LiNO[503]. A solution of hyponitrous acid is obtained when a stream of NO is passed through an ether solution of lithium aluminium hydride[504].

The reaction of nitric oxide with transition metal compounds[505] is an important route to nitrosyl complexes which will be discussed in Chapter 46. Classes of compounds containing the nitrosyl group including metal nitrosyls $[Ru(NO)_4]$, nitrosyl carbonyls $[Co(NO)(CO)_3]$, nitrosyl halides $[Fe(NO)_2I]$, nitrosyl pseudohalides $[Fe(NO)(CO)_5]^{2-}$ and organometallic (principally cyclopentadienyl) nitrosyl derivatives[506]
$$[(\pi\text{-}C_5H_5)_2Mn_2(NO)_3]$$
have been extensively investigated.

11.8. ANALYSIS OF NITRIC OXIDE

The classic qualitative test for NO is the brown ring test which is demonstrated by the interaction of NO with aqueous iron(II) solution to give $[Fe(NO)]^{2+}$. A standard quantitative estimation is based on the assumption that nitric and nitrous acid solutions produce pure NO when shaken with concentrated sulphuric acid which can be measured volumetrically in a Lunge nitrometer. Combustion methods based on the reaction of NO with carbon monoxide lead to the volumetric measurement of nitrogen after absorbing other residual gases[507].

$$2NO + 2CO \rightarrow 2CO_2 + N_2$$
Of the other chemical methods, NO can be absorbed directly in an excess of acid permanganate solution and the residual permanganate reduced with excess iron(II) solution which is then back-titrated with standard permanganate.

$$10NO + 6KMnO_4 + 9H_2SO_4 \rightarrow 3K_2SO_4 + 6MnSO_4 + 10HNO_3 + 4H_2O$$

Most other methods depend on the conversion of NO to nitrites:

$$4NO + O_2 + 4KOH \rightarrow 4KNO_2 + 2H_2O$$

$$2NO + HNO_3 + 3H_2SO_4 \rightarrow 3NOHSO_4 \xrightarrow{3H_2O} 3HNO_2 + 3H_2SO_4$$
and subsequent determination either by titration with permanganate:

$$5HNO_2 + 2KMnO_4 + 3H_2SO_4 \rightarrow K_2SO_4 + 2MnSO_4 + 5HNO_3 + 3H_2O$$
or colorimetrically[508] by a diazo coupling reaction such as Griess reagent (sulphanilic acid and α-naphthylamine).

Of the physical techniques, infrared spectroscopy is applicable and the bands at 1850 and 1925 cm^{-1} useful to estimate the concentration of NO in the gas phase. However, mass spectrometry is probably the best method of determining NO content, and a good example of its potential is its ability to monitor NO concentrations in the exhausts of internal combustion engines[509].

12. DINITROGEN TRIOXIDE

12.1. PREPARATION

The history of dinitrogen trioxide has been traced back[510, 511] even to before 1816 when Gay-Lussac proposed its existence. However, pure N_2O_3 can only be obtained as a pale-blue solid or as an intense blue liquid just above its freezing point ($-100.1\,°C$). At higher temperatures dissociation becomes important:

$$N_2O_3 \rightleftharpoons NO + NO_2$$
Blue   Colourless Brown

$$2NO_2 \rightleftharpoons N_2O_4$$
Brown   Colourless
Thus as the temperature of the liquid N_2O_3 rises towards $0\,°C$, it becomes tinged green due presumably to the colour combination of blue N_2O_3 with the pale-yellow colour of liquid N_2O_4 containing a trace of NO_2. This explanation is consistent with the fact that the dissociation of N_2O_4 (like N_2O_3) only occurs at temperatures above its melting point ($-11\,°C$). In the gas phase, N_2O_3 is largely dissociated as evidenced by the brown colour of NO_2 particularly above the boiling point of N_2O_4 ($21.3\,°C$).

Dinitrogen trioxide is usually prepared by condensing equimolar amounts of nitric oxide and nitrogen dioxide (in equilibrium with dinitrogen tetroxide) at about $-20\,°C$.

$$2NO + N_2O_4 \rightarrow 2N_2O_3$$
The nitrogen dioxide can of course be prepared *in situ* simply by introducing the calculated quantity of oxygen to bring about the controlled oxidation of half of the nitric oxide:

$$4NO + O_2 \rightarrow 2N_2O_3$$
It can also be readily prepared[512] by adding 1:1 nitric acid dropwise onto arsenic(III) oxide warmed to about $70\,°C$:

$$2HNO_3 + 2H_2O + As_2O_3 \rightarrow N_2O_3 + 2H_3AsO_4$$
Alternatively, passing sulphur dioxide into fuming nitric acid gives a solution of nitrosyl hydrogen sulphate from which N_2O_3 can be obtained simply by hydrolysis[512]:

$$SO_2 + HNO_3 \rightarrow NOHSO_4$$

$$2NOHSO_4 + H_2O \rightarrow N_2O_3 + H_2SO_4$$
There is, however, a problem when it comes to drying the product, for although phosphorus pentoxide is capable of dehydrating N_2O_3, it can also react with its dissociation products[513]:

$$P_2O_5 + N_2O_4 \rightarrow P_2O_5 \cdot 2NO + O_2$$

12.2. STRUCTURE AND BONDING

X-ray data on single crystals of dinitrogen trioxide at $-115°C$ suggest that the structure is disordered[514], and this may have to do with the phase transition that occurs at $-125°C$. Matrix trapped molecules of N_2O_3 do not simplify the structural situation either, for both the nitrito and nitroso-nitro isomeric forms have been identified spectroscopically[515]:

More recently, electron diffraction data indicate that the molecule is planar with non-equivalent nitrogen atoms (Fig. 30) in agreement with the nitroso-nitro structure previously proposed on the basis of microwave results[517].
Fig. 30. The nitroso-nitro structure of dinitrogen trioxide.

Some molecular constants are given in Table 69.

The N–N bond length in N_2O_3 (1.86 Å) is unusually long when compared with the conventional N–N single bond length as in hydrazine (1.45 Å), although such a situation is not unique in nitrogen chemistry. In this connection, the bonding in N_2O_3 is thought to be closely related to the situation in N_2O_4 (see section 13) where calculations[518] involving 8π and 10σ electrons lead to a bond order of 0.76 consistent with the observed bond length. Other electronic structures which have been proposed to represent the bonding in N_2O_3 range from the Linnett non-pairing structures also illustrated in Fig. 30, to the π-only descriptions which are supposed to involve overlap only between the lone pairs on each nitrogen[519].

Mention should also be made to the fact that molecular orbital calculations together with X-ray photoelectron spectroscopy show that the anion in Angeli's salt ($Na_2N_2O_3$) has the structure[520]:

$$O=N-N\begin{array}{c} O^- \\ \diagup \\[-0.5em] \diagdown \\ O^- \end{array}$$
TABLE 69. MOLECULAR CONSTANTS OF DINITROGEN TRIOXIDE[a]

Property	Value
X-ray diffraction data	
System	Tetragonal
Space group	$D_4^{10}\ I4_12$
Lattice constant	$a = 16.4$ Å, $c = 8.86$ Å
Unit cell	32 molecules
Electron diffraction data[b]	
N–N bond length	1.864 Å
Microwave spectra[c]	
N–N bond length	1.85 ± 0.03 Å
Infrared spectra	
N–N bond length	2.08 Å
N–O bond length	1.12 Å

12.3. PHYSICAL PROPERTIES

Gas-phase equilibrium constants and related thermodynamic functions have been determined[521] for the dissociation reaction

$$N_2O_3(g) \rightleftharpoons NO(g) + NO_2(g)$$

Thus because of this reaction many physical constants cannot be measured, while the values for some among the brief list in Table 70 are only approximate.

At temperatures around its freezing point, however, it is likely that N_2O_3 behaves as a pure compound, but even here other complications occur. It has a tendency to supercool,

[520] D. N. Hendrickson, J. M. Hollander and W. L. Jolly, Inorg. Chem. **8** (1969) 2642.
[521] I. C. Hisatsune, J. Phys. Chem. **65** (1961) 2249.

and some confusion has arisen between the freezing point ($-100.7°C$) and the nearby eutectic (33.7 wt. % NO in NO_2) temperature[522] at $-106.2°C$. At the other end of the liquid phase, dissociation clearly makes it impossible to record a true boiling point[523], for as liquid N_2O_3 warms up, NO is evolved together with the N_2O_3 vapour pressure leaving a mixture of NO_2 and N_2O_3 in the liquid phase. Values which have been quoted for the boiling point usually refer to the temperature at which the total vapour pressure over the mixture is equal to one atmosphere. Vapour pressure changes for liquid mixtures of nitric oxide and dinitrogen tetroxide vary considerably with composition in the region $NO_{1.5}$ as the vapour above such mixtures is almost pure nitric oxide which has such a low solubility.

TABLE 70. PHYSICAL PROPERTIES OF DINITROGEN TRIOXIDE[a]

Property	Temperature (K)	Value
Melting point	172.45	$-100.7°C$
Boiling point		between $-40°C$ and $+3°C$
Transition temperature	148	$-125°C$

near ultraviolet spectra have also received attention[519]. The blue colour due to a band at 5400–5900 λ is usually assigned to an $n \to \pi^*$ electronic transition between a lone-pair electron on the nitroso-nitrogen and an antibonding π^* orbital, while the band in the near ultraviolet at $\sim 6500\,\lambda$ is associated with a π–π^* transition involving the N–N bond. The ^{14}N n.m.r. spectrum also offers a direct demonstration[526] of the structure with a resonance at $+165$ ppm (relative to saturated aqueous nitrite ion at room temperature) due to the nitro-nitrogen, and the nitroso-nitrogen gives a line at -70 ppm. The low field position of this latter resonance is explained on the premiss that the mixing of the readily accessible $n_N \to \pi^*$ excited states with the ground state by the magnetic field de-shields the ^{14}N nucleus.

12.4. REACTIONS

One of the main problems in studying the reactions of a substance like N_2O_3 is one of carrying out adequate ancillary experiments to determine the effects of its dissociation products on the reaction under investigation. This is further complicated by their participation in exchange processes:

$$^{14}NO + {}^{15}NO_2 \rightleftharpoons {}^{15}NO + {}^{14}NO_2; \quad K_{298} = 0.96 \pm 0.02$$
Exchange even between NO and solid N_2O_3 at $-118°C$ is known to occur[527], although gas–liquid and vapour phase equilibria are of interest in ^{15}N isotope concentration[528].

The reactions involving water support the idea of N_2O_3 being the formal anhydride of nitrous acid:

$$2HNO_2 \to N_2O_3 + H_2O$$

Indeed, the reaction of N_2O_3 or an equimolar mixture of NO and NO_2 in aqueous alkaline solution result in conversion to nitrite:

$$N_2O_3 + 2OH^- \to 2NO_2^- + H_2O$$
$$(NO + NO_2)$$
Gas phase reactions lead to rather more complex equilibria which are involved in nitric acid formation[529]:

$$N_2O_3 \rightleftharpoons NO + NO_2$$
$$NO + NO_2 + H_2O \rightleftharpoons 2HNO_2$$
$$3HNO_2 \to HNO_3 + 2NO + H_2O$$
The reactions of N_2O_3 with concentrated acids such as sulphuric, selenic, perchloric and tetrafluoroboric, provide preparative routes to the corresponding nitrosyl salts, $NO^+HSO_4^-$, $NO^+HSeO_4^-$, $NO^+ClO_4^-$, $NO^+BF_4^-$:

$$N_2O_3 + 3H_2SO_4 \to 2NO^+ + H_3O^+ + 3HSO_4^-$$

Reference should also be made to the solubility of N_2O_3 in other non-aqueous solvents particularly organic solvents such as benzene, toluene, carbon tetrachloride and chloroform, as well as its rôle in liquid N_2O_4 reactions[530] which produce nitric oxide (see section 13).

12.5. ANALYSIS

Dinitrogen trioxide can be detected and determined even in the presence of its dissociation products NO and NO_2, by infrared and ultraviolet spectroscopic methods[510]. Frequently, however, only an estimate of the total nitrogen oxide content is required, and methods based on their absorption as nitrite or nitrate followed by colorimetric analysis are employed[531]. Such methods are commonly used for analysis of "nitrous fumes"[532] which usually refers to mixtures of NO and NO_2 and other oxides that exist in equilibrium with them (principally N_2O_3 and N_2O_4). However, the full analysis of such mixtures often requires a combination of techniques including physical equipment such as gas chromatographs using helium carrier gas and thermal conductivity detectors, or mass spectrometers[531].

13. NITROGEN DIOXIDE AND DINITROGEN TETROXIDE

13.1. PRODUCTION AND INDUSTRIAL USE

Nitrogen dioxide and dinitrogen tetroxide are discussed together because under ordinary conditions of temperature and pressure both species occur in the presence of each other in a state of equilibrium[533-5]:

$$2NO_2 \rightleftharpoons N_2O_4$$
Thus N_2O_4 having the higher molecular weight is the low-temperature form, and NO_2 the dissociation product at higher temperatures. Their equilibrium concentrations at various temperatures are indicated in Table 71.

Like other molecules with an odd number of electrons (free radicals), the monomer NO_2 is coloured, whereas the dimeric form N_2O_4 is colourless, hence the intensity of the red–brown colour in the gas phase can be used to monitor the monomer concentration[535].

TABLE 71. EQUILIBRIUM CONCENTRATIONS OF NO_2 AND
N_2O_4 AT ORDINARY TEMPERATURES

Temperature (°C)	Phase	Equilibrium concentration	
		NO_2	N_2O_4

535 P. Gray and A. D. Yoffe, *Chem. Rev.* **55** (1955) 1069.

On an industrial scale, NO_2–N_2O_4 is produced by the oxidation of nitric oxide during the manufacture of nitric acid[536]:

$$2NO(g) + O_2(g) \rightarrow 2NO_2(g)$$
Thus the principal use of NO_2–N_2O_4 in forming nitric acid[536, 537] is described by its reaction with water according to the overall equation

$$3NO_2(g) + H_2O(l) \rightleftharpoons 2HNO_3(aq) + NO(g)$$
13.2. PREPARATION OF NO₂/N₂O₄

The equilibrium mixture NO_2–N_2O_4 is usually prepared on a laboratory scale either by reduction or decomposition of nitric acid, or more conveniently by the thermal decomposition of a heavy metal nitrate. Rigorously dried lead nitrate can be heated in a steel bomb[533] or a tube furnace[538] under a slow stream of oxygen which helps prevent contamination by N_2O_3:

$$2Pb(NO_3)_2 \rightarrow 4NO_2 + 2PbO + O_2$$

The evolved gases are passed through a condenser to remove traces of nitric acids then over phosphorus pentoxide to complete the drying process. The gas is condensed at $-78\,°C$ and can be further purified by fractional distillation, rejecting the first fraction and collecting the remainder in individual ampoules which are then sealed. Pure dinitrogen tetroxide freezes as a colourless solid, whereas a pale-green solid results if traces of moisture are present, colour being a sensitive test of purity[533].
Other methods which have been used to prepare nitrogen dioxide include the oxidation of nitric oxide:

$$2NO + O_2 \rightarrow 2NO_2$$
the reaction of dinitrogen trioxide and dinitrogen pentoxide:

$$N_2O_3 + N_2O_5 \rightarrow 4NO_2$$
the reaction of nitric acid with sulphur dioxide:

$$2HNO_3 + SO_2 \rightarrow 2NO_2 + H_2SO_4$$

the reaction of nitric acid and phosphorus pentoxide:

$$4HNO_3 + 2P_2O_5 \rightarrow 4NO_2 + O_2 + 4HPO_3$$

the reaction of nitric acid and copper:

$$Cu + 4HNO_3 \rightarrow 2NO_2 + Cu(NO_3)_2 + 2H_2O$$
the reaction of nitrosyl chloride with silver nitrate:

$$NOCl + AgNO_3 \rightarrow 2NO_2 + AgCl$$
the reaction of nitrosonium hydrogen sulphate and potassium nitrate:

$$NOHSO_4 + KNO_3 \rightarrow 2NO_2 + KHSO_4$$
[536] I. R. Beattie, in ref. 459, Section XXII, pp. 158–72.

[537] C. Matasa and E. Matasa, *L'Industrie Moderne des Produits Azotes*, Dunod, Paris (1968), p. 460.

[538] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, 2nd edn., Vol. I (ed. G. Brauer), Academic Press, New York (1963), p. 488.

Such methods may be convenient and adequate for some purposes, but the presence of other non-metal compounds generally leads to impurities in the product.

13.3. NUCLEAR ISOTOPES OF NITROGEN DIOXIDE[539]

The oxidation of enriched nitric oxide with excess molecular oxygen is rapid and complete at room temperature:

$$^{15}NO + \tfrac{1}{2}O_2 \rightarrow {}^{15}NO_2$$
Similarly, $N^{18}O^{16}O$ and $N^{18}O_2$ can be prepared by treating $N^{18}O$ with normal and ^{18}O-enriched oxygen respectively.

Based on the thermal decomposition of heavy metal nitrates, $^{15}NO_2$ has been prepared by heating $K^{15}NO_3$ with PbO_2, or dissolving $K^{15}NO_3$ in 85% phosphoric acid and adding copper metal:

$$M(^{15}NO_3)_2 \rightarrow 4{}^{15}NO_2 + 2MO + O_2$$
Nitrogen dioxide enriched in ^{18}O can also be prepared[540] by heating the lead nitrate that is formed from lead chloride and $KN^{18}O_3$. The nitrogen oxides collected at $-196°C$ are vaporized and allowed to react with oxygen to ensure complete oxidation of the nitric oxide to the nitrogen dioxide. NO_2 is then re-condensed at $-78°C$, and the excess oxygen and nitrogen pumped off.

13.4. STRUCTURE AND BONDING

The solid phase consists entirely of N_2O_4 molecules and shows two modifications known as the monoclinic form[541] which is unstable with respect to the cubic form[542]. The structures of the molecules in both phases which have been determined by X-ray diffraction are similar and are in agreement with a planar structure with a centre of symmetry:
although infrared evidence suggests that non-planar O_2N–NO_2 and even $ONONO_2$ structures are present at $-196°C$ and $-269°C$ respectively[543]. Indeed, nitrosonium nitrate $NO^+NO_3^-$ has been prepared by oxidation of NO at $-196°C$ and it has been suggested[544] that the stabilities of the N_2O_4 isomers decrease in the order

$$O_2NNO_2 > NO^+NO_3^- > ONONO_2.$$
Structural evidence for N_2O_4 in the liquid phase is less direct, but it is thought that more than one form exists and in particular one through which the formation of ion pairs $[NO^+][NO]_3^-$ can be accounted[533]. Electron diffraction study of the vapour at $-20°C$

[542] J. S. Broadley and J. M. Robertson, *Nature* 164 (1949) 915.
[543] I. C. Hisatsune and J. P. Devlin, *J. Chem. Phys.* 31 (1959) 1130.
[544] L. Parts and J. Y. Miller, Jr., *J. Chem. Phys.* 43 (1965) 136.

supports the planar structure[545] although there seems to be no obvious reason why there should not be free rotation of the NO$_2$ groups about the long N–N bond.

The V-shaped structure of nitrogen dioxide in the gas phase has been confirmed by a variety of spectroscopic methods and by electron diffraction[546] giving the N–O bond length of 1.19 Å and the ONO bond angle of 134°. Using Linnett-type valence bond structures, electronic configurations which maintain a complete octet of electrons round each atom are possible for the seventeen-electron NO$_2$ molecule[547] as shown in Fig. 31.

FIG. 31. Valence bond structures of NO$_2$.

The bonding can also be described in terms of molecular orbital theory, and NO$_2$ provides a good example to illustrate the procedure by which molecular orbitals can be constructed for simple molecules[548]. Since NO$_2$ is angular, the orbitals of the molecule must be characterized according to the operations of the point group which describes the molecular shape C_{2v} for which the character table is:

C_{2v}	E	$C_2(z)$	$\sigma_v(xz)$	$\sigma_v(yz)$
A$_1$	1	1	1	1
A$_2$	1	1	-1	-1
B$_1$	1	-1	1	-1
B$_2$	1	-1	-1	1

The NO$_2$ molecule is fixed in the co-ordinate system so as to be situated say in the xz plane as illustrated in Fig. 32.

By carrying out the operations of the point group $C_{2v}[C_2(z)$, $\sigma_v(xz)$ etc.] on each atomic orbital of nitrogen ($2s$, $2p_z$, etc.) and then on linear combinations of the orbitals on the oxygen atoms [$(s+s)$, $(s-s)$, (p_z+p_z), etc.], the transformation properties of each orbital can be calculated and assigned to an irreducible representation (a_1, a_2, etc., corresponding

[545] R. G. Snyder and I. C. Hisatsune, *J. Chem. Phys.* **26** (1957) 960.

[546] G. R. Bird, *J. Chem. Phys.* **25** (1956) 1040.

[547] M. Green, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), pp. 1–71.

[548] C. J. Ballhausen and H. B. Gray, *Molecular Orbital Theory*, Benjamin, New York (1965), p. 76.
FIG. 32. The NO$_2$ molecule.

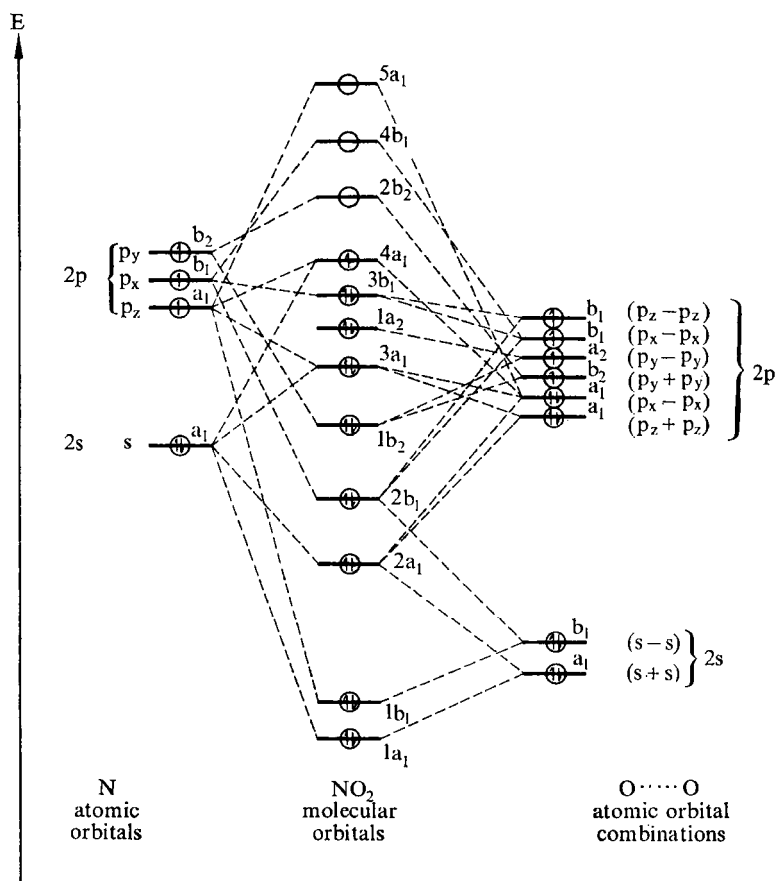
to A$_1$, A$_2$ in the character table). Thus having assigned the available atomic orbitals to the appropriate symmetry type, the molecular orbitals for NO$_2$ can be constructed simply by combining those atomic orbitals with the same symmetry. These molecular orbitals can then be presented in the form of an energy-level diagram as in Fig. 33 into which electrons


FIG. 33. Molecular orbital diagram for NO$_2$.

are allocated to the lowest molecular orbitals to give the ground state configuration of the molecule:

$$^2A_1 \quad (1a_1)^2(1b_1)^2(2a_1)^2(2b_1)^2(1b_2)^2(3a_1)^2(1a_2)^2(3b_1)^2(4a_1)^1$$

Thus although the $1a_2$, $3b_1$ and $4a_1$ levels are all fairly close together, the unpaired electron is assigned to the $4a_1$ orbital if one considers the large splitting that is observed in the e.s.r. spectrum. This is produced by an unpaired s electron interacting with the spin of the ^{14}N nucleus, and both $1a_2$ and $3b_1$ are made up of p functions, whereas the $4a_1$ level is composed partly of nitrogen and oxygen $2s$ orbitals. The first excited state has the configuration:

$$^2B_1 \quad (1a_1)^2(1b_1)^2(2a_1)^2(2b_1)^2(1b_2)^2(3a_1)^2(1a_2)^2(3b_1)^1(4a_1)^2$$
FIG. 34. Ozone, nitrogen dioxide and carbon dioxide correlation diagrams.

and the absorption band in the NO_2 spectrum at 23,000 cm^{-1} is usually assigned to the $^2A_1 \rightarrow {}^2B_1$ transition[547, 548].

A diagram similar to that in Fig. 33 can be arrived at by correlating the molecular orbital diagrams of structurally related compounds. From this point of view, NO_2 can be considered as the compromise situation between ozone, a C_{2v} molecule with smaller angle and longer bonds, and carbon dioxide, a linear molecule with point group $D_{\infty h}$ and shorter bonds. The correlation diagram in Fig. 34 indicates the approximate energies of NO_2 molecular orbitals simply by joining the appropriate corresponding orbitals of O_3 and CO_2 (note that the different notation for CO_2 is due to it having a centre of symmetry). These

correlation diagrams can also be used to estimate the bond angles of low-lying excited states while the bond length can be inferred by considering to what extent antibonding orbitals are involved[549].

With regard to the description of the bonding in N_2O_4, this would appear to be less straightforward[533]. There is general agreement that the molecule is planar, has a long N–N bond and all the N–O bonds are of equal length. Planarity in this situation implies a restriction to rotation about the N–N bond which normally would be expected to result from steric restraint or multiple bonding. However, there would not appear to be any steric hindrance, particularly in the gas phase, and a bond length longer than that of a normal N–N single bond (N–N in hydrazine is 1.47 Å) is not consistent with multiple bonding either. Thus this unusual situation has led to the proposal of various novel descriptions of the bonding. The usual structure is a resonance hybrid of the canonical forms illustrated in Fig. 35.

FIG. 35. Valence bond structures for N_2O_4.

FIG. 36. Linnett non-pairing structures for N_2O_4.

549 A. D. Walsh, J. Chem. Soc. (1953) 2266.

Here the long N–N bond is explained on the basis of repulsion due to formal positive charges lying on adjacent atoms, but it does not offer a satisfactory explanation for planarity. Similarly, resonance between the Linnett non-pairing structures in Fig. 36 also provides a simple picture of N_2O_4 which nicely explains the long one-electron N–N bond but fails to account for the planarity[547].

More recently it was suggested that the central bond is a π bond with little or no σ character[550]. However, this is not now thought to be correct, and calculations[551] suggest

that although the main part of the N–N bond is σ in character, there is a fairly large π contribution from orbitals which lie in the plane of the molecule (similar to combinations of the $3b_2$ orbitals of NO_2) and not from the more usual orbitals perpendicular to the plane.

13.5. MOLECULAR CONSTANTS

Some molecular constants for N_2O_4 are listed in Table 72, while values for NO_2 and NO_2^+ are compared in Table 73 together with some relevant spectroscopic[552] and thermodynamic data[553]. Electron spin resonance spectra have been recorded for NO_2 in various matrices[554].

13.6. PHYSICAL PROPERTIES

Some physical data for NO_2 have already been mentioned in Table 73, but so few experimentally determined values are known because of their need to be measured at temperatures above 200°C to ensure complete dissociation of N_2O_4. Values of physical constants for N_2O_4 are listed in Table 74.

[552] R. F. Barrow and A. J. Merer, in ref. 459, p. 515.

[553] D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Bailey and R. H. Schumm, *Selected Values of Chemical Thermodynamic Properties*, NBS Technical Note 270-3, Washington (1968).

[554] P. W. Atkins and M. C. R. Symons, *The Structure of Inorganic Radicals*, Elsevier, Amsterdam (1967), p. 127.

However, only the solid phase consists of pure N_2O_4, and values for properties of the liquid refer to material containing the equilibrium quantity of NO_2. This probably makes no difference just above the melting point but is likely to be significant towards the boiling point, accompanying the colour change from very pale yellow to deep red–brown over the same temperature range. The solvent properties of liquid N_2O_4 will be discussed further in section 13.7.2.

13.7. CHEMISTRY AND CHEMICAL PROPERTIES

13.7.1. Reactions of NO_2

It is unlikely that perfectly pure NO_2 can be formed at atmospheric pressure, for the temperature required to dissociate N_2O_4 also coincides with the onset of thermal decomposition of NO_2 which becomes significant above 150°C and complete[536] at about 600°C:

$$N_2O_4 \rightleftharpoons 2NO_2 \rightleftharpoons 2NO + O_2$$
At low partial pressures, photochemical decomposition occurs and can be studied under conditions where the recombination of nitric oxide and oxygen is so slow as to be negligible. The proposed mechanism[555] is:

$$NO_2 + h\nu \rightarrow NO_2^*$$
$$NO_2^* + NO_2 \rightarrow 2NO + O_2$$
Low concentrations of NO_2 in hydrogen and oxygen–air mixtures depress considerably the ignition temperatures and effect the explosion limits[556]. The overall reaction between NO_2 and hydrogen is given as

$$NO_2 + H_2 \rightarrow NO + H_2O$$
for which the following mechanism has been proposed[557]:

$$H_2 + NO_2 \rightarrow H + HNO_2$$
$$H + NO_2 \rightarrow NO + OH$$
$$OH + H_2 \rightarrow H_2O + H$$
$$OH + NO_2 + M \rightarrow HNO_3 + M$$
$$OH + NO + M \rightarrow HNO_2 + M$$

[555] R. G. W. Norrish, *J. Chem. Soc.* (1929) 1158.
[556] A. C. Egerton and J. Powling, *Proc. Roy. Soc.* A, **193** (1948) 172.
[557] P. G. Ashmore and B. P. Levitt, *Trans. Faraday Soc.* **53** (1957) 945.

Such reactions are also thought to be involved in the reactions between water and NO_2 in the production of nitric acid[536]:

$$2NO_2 + H_2O \rightarrow HNO_3 + HNO_2$$
$$3HNO_2 \rightarrow HNO_3 + 2NO + H_2O$$

It is not surprising therefore that NO_2 in the presence of those compounds with which it is in equilibrium is strongly corrosive towards metals.
Other oxidations involving nitrogen dioxide[558] include the reactions with halogen compounds:

$$NO_2 + 2HCl \rightarrow NOCl + H_2O + \tfrac{1}{2}Cl_2$$

At higher temperatures the nitrosyl halide decomposes:

$$NO_2 + 2HCl \rightarrow NO + H_2O + Cl_2$$
$$NO_2 + 2HBr \rightarrow NO + H_2O + Br_2$$

Likewise, a variety of bimolecular gas phase reactions involving NO_2 have been studied[559]:

$$NO_2 + NH_3 \rightarrow HNO_2 + NH_2$$
$$NO_2 + F_2 \rightarrow NO_2F + F$$
$$NO_2 + Cl_2O \rightarrow NO_2Cl + OCl$$
$$NO_2 + ClO_2 \rightarrow NO_3 + OCl$$
$$NO_2 + CO \rightarrow NO + CO_2$$

Thus the description of nitrogen dioxide as a fairly reactive free radical is well illustrated by dimerization, combination with other free radicals[560], addition, and abstraction reactions, with inorganic and organic molecules[561].

### 13.7.2. Reactions of Liquid Dinitrogen Tetroxide[533]

Homolytic dissociation of N_2O_4 always occurs to a small extent in the liquid phase:

$$N_2O_4(l) \rightleftharpoons 2NO_2(l); \qquad \Delta H_{diss} = 19.5 \text{ kcal/mol}$$

but of the various alternative heterolytic dissociation processes, it is perhaps surprising that the nitronium and nitrite ions have never been recognized as free ions in liquid N_2O_4. In fact the chemistry of the N_2O_4 solvent system is rationalized on the basis of self-ionization to give nitrosyl and nitrate ions according to the equation

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^-$$

analogous to the ionization of water or liquid ammonia:

$$2H_2O \rightleftharpoons H_3O^+ + OH^-$$
$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$
[558] J. H. Thomas, in *Oxidation and Combustion Reviews*, Vol. I (ed. C. F. H. Tipper), Elsevier, Amsterdam (1965), p. 137.

[559] A. F. Trotman-Dickenson and G. S. Milne, *Tables of Bimolecular Gas Reactions*, NBS-9, Washington (1969).

[560] Y. Rees and G. H. Williams, in *Advances in Free-radical Chemistry*, Vol. 3 (ed. G. H. Williams), Logos Press, London (1969), p. 199.

[561] A. V. Topchiev (translated by C. Matthews), *Nitration of Hydrocarbons and other Organic Compounds*, Pergamon, London (1959).

Thus although the free ions in liquid N_2O_4 cannot be detected by methods such as infrared or Raman spectroscopy due to their low concentration, the large difference between the molar polarization and molar refraction is attributed[562] to the presence of polar constituents in the liquid phase which are not present in either solid or gaseous states. These polar constituents are likely to be ion pairs rather than free ions because of the low dielectric constant of the solvent, and although ionic reactions will still occur, they do so as a result of collisions between ion pairs rather than free ions. Consequently, simple metal salts are insoluble in pure liquid N_2O_4, but do dissolve in mixtures of N_2O_4 diluted with solvents of higher dielectric constant[533]. Thus the addition of nitromethane ($\varepsilon = 37$) produces conducting solutions in which the self-ionization of N_2O_4 is enhanced to such an extent that dissociation is complete in solvents like perchloric or sulphuric acids:

$$N_2O_4 + 3H_2SO_4 \rightarrow NO^+HSO_4^- + HNO_3 + SO_3 + H_3O^+HSO_4^-$$
Likewise a similar situation can be achieved by the addition of a donor solvent (such as ethyl acetate, diethyl ether, diethylnitrosamine, etc.). This arises from the electron-deficient nature of N_2O_4 and its tendency to form molecular addition compounds with donor molecules[533], in particular oxygen and nitrogen bases bonded to the nitrogen(s) of N_2O_4:

$$nD + N_2O_4 \rightleftharpoons D_n \cdot N_2O_4 \rightleftharpoons (D_nNO)^+NO_3^-$$
The wide variety of reactions in which liquid N_2O_4 can participate are summarized briefly below, although it should not be assumed that all such reactions are necessarily unique to the liquid phase. Acid–base reactions are described by the neutralization equation

$$NO^+ + NO_3^- \rightleftharpoons N_2O_4$$
Thus in liquid N_2O_4, nitrosyl chloride reacts with silver nitrate[563]:

$$NOCl + AgNO_3 \xrightarrow{N_2O_4} AgCl + N_2O_4$$
comparable with the corresponding reactions in water or liquid ammonia:

$$HCl + KOH \xrightarrow{H_2O} KCl + H_2O$$
$$NH_4Cl + NaNH_2 \xrightarrow{NH_3} NaCl + 2NH_3$$
Similarly, compounds that produce "basic" solutions in liquid N_2O_4 are typified by alkylammonium nitrates which introduce excess nitrate into the system. Thus the reaction of zinc in these solutions illustrates the amphoteric behaviour of zinc compounds[564] in N_2O_4:

$$Zn + 2EtNH_3 \cdot NO_3 + 2N_2O_4 \rightarrow [EtNH_3]_2[Zn(NO_3)_4] + 2NO$$
again directly analogous to reactions in water and liquid ammonia:

$$Zn + 2NaOH + 2H_2O \rightarrow Na_2[Zn(OH)_4] + H_2$$
$$Zn + 2NaNH_2 + 2NH_3 \rightarrow Na_2[Zn(NH_2)_4] + H_2$$
[562] C. C. Addison, H. C. Bolton and J. Lewis, *J. Chem. Soc.* (1951) 1294.
[563] C. C. Addison and R. Thompson, *J. Chem. Soc.* (1949) S211.
[564] C. C. Addison and N. Hodge, *J. Chem. Soc.* (1954) 1138.

In contrast, the nitrosonium compounds are the "solvo-acids" and increase the concentration[533] of the NO^+ ion in liquid N_2O_4. Thus using tin as example,

$$Sn + 2NOCl \xrightarrow{N_2O_4} SnCl_2 + 2NO$$

again analogous to the corresponding reactions in water and liquid ammonia:

$$Sn + 2HCl \xrightarrow{H_2O} SnCl_2 + H_2$$
$$Sn + 2NH_4Cl \xrightarrow{NH_3} SnCl_2 + 2NH_3 + H_2$$

Silver, zinc, mercury and the alkali metals react quite readily when brought into contact with liquid N_2O_4. For example, sodium requires continual stirring to expose clean metal surface if the reaction is to proceed to completion:
$$Na + N_2O_4 \rightarrow NaNO_3 + NO$$

At room temperature nitric oxide is evolved, but at lower temperatures or under pressure the formation of blue–green N_2O_3 is apparent[533]. The reaction is again directly analogous to those in water and liquid ammonia:

$$2Na + 2H_2O \rightarrow 2NaOH + H_2$$
$$2Na + 2NH_3 \rightarrow 2NaNH_2 + H_2$$
However, a number of other metals (Cd, Mn, Co, Cu, In, U) are only soluble if the liquid N_2O_4 is diluted with a solvent of higher dielectric constant such as nitromethane. The mixture becomes more reactive by enhancement of the self-ionization process of N_2O_4:

$$Cu + 3N_2O_4 \xrightarrow{MeNO_2} Cu(NO_3)_2 \cdot N_2O_4 + 2NO$$
Similarly, the presence of donor solvents like ethyl acetate, diethyl ether, dimethyl sulphoxide, etc., in liquid N_2O_4 form the basis of excellent solvent systems for metals giving a variety of products including some stable solvate compounds containing dinitrogen tetroxide of crystallization[533]:

$$Ca + 2N_2O_4 \xrightarrow{EtOAc} Ca(NO_3)_2 + 2NO$$
$$Mg + 3N_2O_4 \xrightarrow{EtOAc} Mg(NO_3)_2 \cdot N_2O_4 + 2NO$$
$$Bi + 3N_2O_4 \xrightarrow{Me_2SO} Bi(NO_3)_3 \cdot 3Me_2SO + 3NO$$
$$Cu + N_2O_4 \xrightarrow{AcOH} Cu(OAc)_2$$
$$Cu + 5N_2O_4 \xrightarrow{5-30\% \; PhCN} Cu(NO_3) \cdot 2PhCN \cdot 4N_2O_4 + NO$$

Solvolysis reactions in liquid N_2O_4 are reactions of a salt MX with the solvent in which the anion X is totally or partially replaced by the nitrate ion, being the anion characteristic of the medium:

$$MX + N_2O_4 \rightarrow MNO_3 + NOX$$
Many such reactions have been reported including the following selection[533]:

$$R_4NCl + N_2O_4 \rightleftharpoons R_4N \cdot NO_3 + NOCl$$
$$ZnCl_2 + N_2O_4 \rightleftharpoons Zn(NO_3)_2 + 2NOCl$$
$$CaO + 2N_2O_4 \rightarrow Ca(NO_3)_2 + N_2O_3$$
$$Na_2O_2 + N_2O_4 \rightarrow 2NaNO_3$$
$$NaOH + N_2O_4 \rightarrow NaNO_3 + HNO_2$$
This reaction provides an excellent route to anhydrous metal nitrates from the corresponding halides, particularly where X = Br or I as NOX decomposes preventing the possible formation of nitrosyl compounds[533]:

$$TiI_4 + 4N_2O_4 \rightleftharpoons Ti(NO_3)_4 + 4NO + 2I_2$$
The oxidation properties of N_2O_4 towards inorganic compounds generally involve the donation of oxygen atoms rather than the removal of electrons from metal ions. This is well illustrated by the unusual salts that have been prepared by the oxidation of sodium hyponitrite[565] with N_2O_4:

$$Na_2N_2O_2 \xrightarrow{rapid} \beta\text{-}Na_2N_2O_3 \xrightarrow{slow} Na_2N_2O_5 \xrightarrow[100°]{slow} Na_2N_2O_6$$

$$\left.\begin{array}{l} NH_2OH \\ EtNO_3 \\ NaOEt \end{array}\right\} \rightarrow \alpha\text{-}Na_2N_2O_3 \xrightarrow{rapid} Na_2N_2O_4 \xrightarrow{slow} Na_2N_2O_6$$
Accordingly, the reaction of N_2O_4 with cobalt forms cobalt(II) rather than cobalt(III) compounds, and its selective oxidizing properties in organic chemistry[566] are unique, particularly its ability to restrict oxidation to a single stage when further oxidation would appear to be possible.

Dinitrogen tetroxide reacts readily with water according to the overall equation

$$3N_2O_4 + 2H_2O \rightarrow 4HNO_3 + 2NO$$

Several mechanisms, more than one of which may be applicable, have been proposed to account for the absorption stage in nitric acid production[536] (see section 18.3) including the following:
$$N_2O_4(g) \rightarrow N_2O_4(l)$$

$$N_2O_4(l) + H_2O(l) \rightarrow HNO_3(l) + HNO_2(l)$$

$$2HNO_2(l) \rightarrow HNO_3(l) + NO(l)$$

$$N_2O_4 \rightarrow NO^+ + NO_3^-$$

$$N_2O_4 + H_2O \rightarrow H^+ + NO_3^- + HNO_2$$

$$2HNO_2 \rightarrow H_2O + NO + NO_2$$
However, in spite of this ready reaction, simple hydrated salts do not dehydrate completely when immersed in liquid N_2O_4 (e.g. $MgSO_4 \cdot 7H_2O \rightarrow MgSO_4 \cdot 2H_2O$), and the selective reactivity may be related to possible differences in the bonding of the water[567].

Metal carbonyls react with N_2O_4 under mild conditions and provide simple preparative routes to metal nitrates and their N_2O_4 solvates[533]:

$$Co_2(CO)_8 + 8N_2O_4 \rightarrow 2Co(NO_3)_2 \cdot 2N_2O_4 + 8CO + 4NO$$

$$Fe(CO)_5 + 4N_2O_4 \rightarrow Fe(NO_3)_3 \cdot N_2O_4 + 5CO + 3NO$$

$$Mn_2(CO)_{10} + N_2O_4 \rightarrow Mn(CO)_5NO_3 + [Mn(CO)_x(NO)_y]$$
[565] C. C. Addison, G. A. Gamlen and R. Thompson, *J. Chem. Soc.* (1952) 338.
[566] B. O. Field and J. Grundy, *J. Chem. Soc.* (1955) 1110.
[567] C. C. Addison and D. J. Chapman, *J. Chem. Soc.* (1965) 819.

The reaction of N$_2$O$_4$ with organometallic compounds like tetramethyltin is explosively violent even at $-80°$ and the reagents require dilution with an inert solvent[566]:

$$Me_4Sn + 2N_2O_4 \xrightarrow{\text{EtOAc}} Me_2Sn(NO_3)_2$$

Finally, the reaction of N$_2$O$_4$ with the electron acceptor molecule boron trifluoride has received much attention. The reagents react both in 1:1 and 1:2 ratio to give stoichiometric solid products which have been formulated as containing the nitronium ion[567]:

$$N_2O_4 \xrightarrow{\text{BF}_3} NO_2^+[BF_3 \cdot NO_2]^- \xrightarrow{\text{BF}_3} NO_2^+[F_3BONOBF_3]^-$$

Thus the overall scheme for N$_2$O$_4$ dissociation can be considered as in the following scheme[533]:

$$2NO_2 \rightleftharpoons N_2O_4 \rightleftharpoons [NO_2^+ + NO_2^-] \xrightarrow[\text{transfer}]{\text{O atom}} NO^+ + NO_3^-$$

$$\downarrow BF_3 \qquad\qquad\qquad \downarrow \text{donor solvents}$$

$$NO_2^+[BF_3 \cdot NO_2]^- \qquad D_n \cdot N_2O_4 \quad (D_n \cdot NO)^+ NO_3^-$$

13.8. BIOLOGICAL PROPERTIES[570]

The toxic properties of nitrogen dioxide are well known, but the presence of dangerous concentrations in everyday situations is not widely appreciated. NO$_2$ is the most dangerous component of "nitrous fumes", the name given to mixtures of oxides of nitrogen of variable composition. These mixtures can arise as a result of many industrial processes involving combustion but particularly electric-arc processes, electric-arc welding and oxy-acetylene welding. Hazards occur when such operations are carried out in confined, unventilated spaces. It is not considered safe to work for prolonged periods in an atmosphere containing >5 ppm NO$_2$, and short periods at higher concentrations can lead to symptoms such as inflammation of the lower respiratory tract and a marked elevation in the blood platelet count. Continued inhalation of concentrations >100 ppm has led to death.

13.9. ANALYSIS OF NO$_2$–N$_2$O$_4$[571]

In large enough amounts, nitrogen dioxide is readily recognized by its characteristic red–brown colour. It can also be identified in equilibrium with its dimer by spectroscopic methods[552]; NO$_2$ gives infrared absorption at 1626 cm^{-1}. Ultraviolet spectroscopy can also be used because dinitrogen tetroxide absorbs up to about 390 mμ, and nitrogen dioxide in the 390–500 mμ region. Nitrogen dioxide gives a positive test with Griess reagent due

to the presence of nitrite in solution, which can also form the basis of a colorimetric method of analysis[572]. The application of titrimetric methods is somewhat similar to those described for nitric oxide. Nitrogen dioxide can be oxidized with excess cerium (IV) which is back-titrated with sodium oxalate:

$$NO_2 + Ce^{4+} + H_2O \rightarrow NO^- + Ce^{3+} + 2H^+$$
Reference should also be made, however, to the analysis of nitrous fumes. This usually refers to mixtures of nitric oxide, nitrogen dioxide and other oxides that exist in equilibrium with them (principally N_2O_3 and N_2O_4). Their toxicity has directed considerable attention to the detection and estimation of small amounts of such materials[573]. Thus in this connection, and frequently in other situations, only the total nitrogen oxide content is required, and this can be obtained by oxidation with alkaline hydrogen peroxide to nitrate which can be determined colorimetrically by the phenoldisulphonic acid method. This can be preceded by absorption in Griess–Ilosvay reagent to obtain a separate estimation of NO_2 content if required. For full analysis of such nitrogen oxide mixtures, mass spectrometry provides the quickest most reliable method. However, more recently, gas chromatographic techniques have been developed which are capable of separating mixtures containing oxides of both nitrogen and carbon as well as elemental nitrogen using helium as carrier gas and thermal conductivity cell detectors[574].
14. DINITROGEN PENTOXIDE

14.1. PREPARATION

Dinitrogen pentoxide is usually prepared in the laboratory by the dehydration of concentrated nitric acid with phosphorus pentoxide[575, 576]:

$$2HNO_3 + P_2O_5 \rightarrow N_2O_5 + 2HPO_3$$

Considerable care must be exercised during this reaction, as the procedure[577] involves either the dropwise addition of concentrated HNO_3 (d $1.525\,g/cm^3$) onto a large excess of P_2O_5 at $-10°C$ followed by slow distillation at about $35°C$, or by adding P_2O_5 in one portion to nitric acid previously cooled to $-78°C$ then allowing the mixture to attain room temperature slowly[578]. The principal alternative method is by the oxidation of nitrogen dioxide with ozone:

$$2NO_2 + O_3 \rightarrow N_2O_5 + O_2$$
[573] *Methods for the Detection of Toxic Substances in Air*, Booklet No. 5, *Nitrous Fumes*, Ministry of Employment and Productivity, HM Factory Inspectorate, HMSO, London (1969).

[577] N. S. Gruenhut, M. Goldfrank, M. L. Cushing and G. V. Caesar, *Inorganic Syntheses*, Vol. III (ed. L. F. Andrieth), McGraw-Hill, New York (1950), p. 78.

[578] G. V. Caesar and M. Goldfrank, *J. Am. Chem. Soc.* **68** (1962) 372.

The difficulties encountered when attempting to dry NO_2 make it preferable[579] to oxidize dry NO with dry O_2 first, and when this reaction is complete then passing O_2–O_3 through. Another variation is bubbling ozonized oxygen through liquid N_2O_4.

N_2O_5 is also formed in the Birkland–Eyde arc process for the fixation of nitrogen and also when chlorine, phosphoric oxychloride or nitryl chloride reacts with silver nitrate[575]:

$$NO_2Cl + AgNO_3 \rightarrow N_2O_5 + AgCl$$

The electrolysis of N_2O_4 dissolved in nitric acid also affords oxidation[575] to N_2O_5:

$$2NO_3^- + N_2O_4 \rightarrow 2N_2O_5 + 2e^-$$
14.2. STRUCTURE AND BONDING

Dinitrogen pentoxide is a colourless crystalline solid which is stable in diffuse light below 8°C, but decomposes on exposure to sunlight or on warming even to room temperature. Above ~ -78°C, the crystal structure of N_2O_5 as determined by X-ray diffraction is consistent with the fully ionic nitronium nitrate $NO_2^+ NO_3^-$ lattice in which the nitronium ion is linear and symmetrical with NO bond lengths (1.154Å) comparable to isoelectronic and isostructural carbon dioxide (C–O = 1.163 Å), while the nitrate group is both symmetrical and planar (N–O = 1.24 Å) as usual. Raman and infrared spectra[581] also indicate the presence of nitronium and nitrate ions. At lower temperatures, however, a molecular structure, O_2N—O—NO_2, similar to that found by electron diffraction for the gaseous phase[582] is present. The central NON bond angle is close to 180° and the bonding can be described by a Linnett non-pairing structure in Fig. 37.
FIG. 37. Non-pairing valence bond configuration for molecular N_2O_5.

Valence bond structures for the NO_2^+ ion (also isoelectronic and isostructural with N_3^- and CN_2^{2-} ions) together with Linnett non-pairing structures[583] are illustrated in Fig. 38. Alternatively, in terms of molecular orbital theory, the ground state configuration is

$$(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(1\pi_g)^4$$

in which the sixteen electrons are contained in filled bonding and non-bonding orbitals while the anti-bonding levels remain empty[583].

14.5. REACTIONS

Although N_2O_5 is colourless, absorption occurs at ~ 3800 Å in the ultraviolet region, and this has been assigned to photodecomposition according to the equation[581]

$$N_2O_5 \rightleftharpoons N_2O_4 + O(^3P)$$

The thermal decomposition of N_2O_5 has played an important rôle in the theory of reaction rates[575]:

$$2N_2O_5 \rightarrow 2N_2O_4 + O_2$$
The decomposition rate is first order:

$$-d[N_2O_5]/dt = k[N_2O_5]$$

and the overall reaction has been described by the following scheme[585]:

$$N_2O_5 \rightleftharpoons NO_2 + NO_3$$
$$NO_2 + NO_3 \rightarrow NO_2 + O_2 + NO$$
$$NO + N_2O_5 \rightarrow 3NO_2$$
[585] R. A. Ogg, Jr., *J. Chem. Phys.* **15** (1947) 337.

Labelled NO_2 undergoes rapid exchange[586] with N_2O_5:

$$^{14}N_2O_5 + {}^{15}NO_2 \rightleftharpoons {}^{15}N_2O_5 + {}^{14}NO_2$$
and many gas phase reactions of N_2O_5 depend on initial dissociation to NO_2 and NO_3 with the latter then further acting as an oxidizing agent.

Dinitrogen pentoxide is the formal anhydride of nitric acid and being deliquescent it is very readily hydrated:

$$N_2O_5 + H_2O \rightarrow 2HNO_3$$
With hydrogen peroxide, pernitric acid is also formed[587]:

$$N_2O_5 + H_2O_2 \rightarrow HNO_3 + HNO_4$$
In anhydrous solvents like nitric, perchloric, sulphuric and phosphoric acids, N_2O_5 dissociates providing a convenient source of nitronium ions and a suitable preparative route to nitronium salts[588]:

$$N_2O_5 + 3H_2SO_4 \rightarrow 2NO_2^+ + H_3O^+ + 3HSO_4^-$$

$$N_2O_5 + 3HClO_4 \rightarrow 2NO_2^+ + H_3O^+ + 3ClO_4^-$$

$$2N_2O_5 + H_3O^+ClO_4^- \rightarrow NO_2^+ClO_4^- + 3HNO_3$$

$$N_2O_5 + 2SO_3 \rightarrow [NO_2^+]_2S_2O_7^{2-}$$

$$N_2O_5 + FSO_3H \rightarrow NO_2^+FSO_3^- + HNO_3$$
The strong oxidizing action of N_2O_5 can cause violent reactions with reducing agents including metals and organic substances to give nitrates and/or oxides[575]:

$$N_2O_5 + Na \rightarrow NaNO_3 + NO_2$$

$$N_2O_5 + NaF \rightarrow NaNO_3 + FNO_2$$

$$N_2O_5 + I_2 \rightarrow I_2O_5 + N_2$$
15. NITROGEN TRIOXIDE

The existence of the nitrogen trioxide radical NO_3 has for long been assumed judging by its frequent postulation in nitrogen oxide reaction mechanisms. For example, dinitrogen pentoxide undergoes thermal decomposition by a homogeneous first-order gas-phase reaction (see section 14). However, the reaction is not unimolecular as was initially thought, and one mechanism which is consistent with the data involves the preliminary equilibrium[589]

$$N_2O_5 \rightleftharpoons NO_2 + NO_3$$

followed by

$$NO_3 + NO_2 \rightarrow NO_2 + O_2 + NO$$

$$NO_3 + NO \rightleftharpoons 2NO_2$$
[586] A. R. Amell and F. Daniels, *J. Am. Chem. Soc.* **74** (1952) 6209.
[587] R. Schwartz, *Z. anorg. allgem. Chem.* **256** (1947) 3.
[588] D. R. Goddard, E. D. Hughes and C. K. Ingold, *J. Chem. Soc.* (1950) 2559.
[589] R. A. Ogg, Jr., *J. Chem. Phys.* **5** (1937) 873.

Similarly, NO_3 is involved in the rate-determining step to account for the products of the NO_2-methane reaction[590]:

$$2NO_2 \rightleftharpoons NO + NO_3$$

$$NO_3 + CH_4 \rightarrow HNO_3 + CH_3$$

$$CH_3 + NO_2 \rightarrow CH_3NO_2$$
However, in the N_2O_5 catalysed decomposition of ozone, the steady state of NO_3 can be high enough for its spectrum to be recorded as an extremely intense banded absorption in the region 5000–7100 Å[591]. Indeed its presence in ozone can be detected by a colour change from the violet–blue of ozone to a more intense pure bright blue. Thus the mechanism for the N_2O_5–O_3 reaction involves the equilibria which are important in N_2O_5 formation[592]:

$$N_2O_5 \rightleftharpoons NO_2 + NO_3$$

$$NO_2 + O_3 \rightarrow NO_3 + O_2$$

$$NO_3 + NO_3 \rightarrow 2NO_2 + O_2$$
Nitrogen trioxide has also been identified by e.s.r. in electron irradiated $NaNO_3$ crystals[593]. It is usually assumed to have a planar symmetrical structure in the ground state, and its electronic structure can be described by Linnett non-pairing structures[594] as illustrated in Fig. 39.
FIG. 39. Linnett non-pairing structure of NO_3.

A molecular orbital description suggests that the unpaired electron lies in an energy state composed only of orbitals from oxygen[595].

An isomeric form with the asymmetric pernitrite OONO structure has also been detected in the reaction of nitric oxide and oxygen at low pressure[596]:

$$O_2 + NO \rightleftharpoons OONO$$

16. HYPONITROUS ACID AND HYPONITRITES

16.1. PREPARATION

Hyponitrous acid crystallizes as white deliquescent plates[597] which are explosively unstable, detonating even when rubbed with a glass rod. It can be prepared reasonably pure by treating silver hyponitrite with anhydrous hydrogen chloride in ether, and after the silver chloride has been filtered off, the ether can be evaporated off from the filtrate[598].

$$Ag_2N_2O_2 + 2HCl \xrightarrow{\text{ether}} H_2N_2O_2 + 2AgCl$$
The metal salts are generally prepared in variable yield by reduction methods, sodium amalgam being a favourite reducing agent:

$$2NaNO_3 + 8Na/Hg + 4H_2O \rightarrow Na_2N_2O_2 + 8NaOH + 8Hg$$
$$2AgNO_3 + 2NaNO_2 + 4Na/Hg + 2H_2O \rightarrow Ag_2N_2O_2 + 2NaNO_3 + 4NaOH + 4Hg$$
15N isotopically labelled hyponitrites have also been synthesized by this method. Similarly, if bulk sodium metal is allowed to disintegrate in pyridine under a hydrogen atmosphere, the sodium–pyridine adduct can act as a reducing agent towards nitric oxide:

$$2Na + 2NO \xrightarrow[\text{benzene}]{\text{pyridine}} Na_2N_2O_2$$
The hyponitrites of the alkaline earth metals have each been obtained by reducing the corresponding nitrate with magnesium amalgam[599]:

$$Ca(NO_3)_2 + 4Mg/Hg + 4H_2O \rightarrow CaN_2O_2 + 4Mg(OH)_2 + 4Hg$$
Other methods of preparation include the condensation of hydroxylamine (prepared from the hydrochloride and sodium alkoxide), alkyl nitrite and sodium alkoxide[597]:

$$NH_2OH + RO—N{=}O \rightarrow H_2N_2O_2 + ROH$$
$$H_2N_2O_2 + 2NaOR \rightarrow Na_2N_2O_2 + 2ROH$$
The silver salt has also been prepared by way of hydroxylamine disulphonate and sodium hydroxylamine monosulphonate[598]:

$$NaNO_2 + NaHSO_3 \rightarrow HONHSO_3Na + NaOH$$
$$2HONHSO_3Na + 2KOH + 2AgNO_3 \rightarrow Ag_2N_2O_2 + 2NaHSO_3 + 2KNO_3 + 2H_2O$$
Mention should also be made to the isomer nitramide NH_2NO_2 which is formed by acid hydrolysis of the nitrocarbamate ion followed by ether extraction[598]:

$$EtOCONH_2 + EtONO_2 \rightarrow EtOCONHNO_2 + EtOH$$
$$\downarrow 2KOH$$
$$K_2(OCONNO_2) + EtOH + H_2O$$
$$K_2(OCONNO_2) + H_2SO_4 \rightarrow NH_2NO_2 + CO_2 + K_2SO_4$$
[597] M. N. Hughes, *Quart. Rev.* **22** (1968) 1.
[598] P. W. Schenk, in *Handbook of Preparative Inorganic Chemistry*, Vol. I (ed. G. Brauer), Academic Press, New York (1963), pp. 492–8.
[599] H. Block, in ref. 571, pp. 407–8.

16.2. STRUCTURE AND BONDING

The presence of an N=N double bond is suggested by both chemical and physical properties of hyponitrites, and hence the question of *cis–trans*-isomerism arises[597]:
It is now known that the *trans*-isomer is usually isolated from normal preparative methods. Evidence for this includes the assignment of three fundamental vibrations which are both infrared and Raman active consistent with a structure belonging to the C_{2h} point group[600]. Infrared and n.m.r. studies also suggest that the free acid has a symmetrical structure[597].

There is some infrared evidence that the so-called alkali metal "nitrosyls" (formed by the action of NO on alkali metals or in liquid ammonia) are dimeric and have the *cis*-hyponitrite configuration[601].

The red nitrosopentammines of cobalt(III), formerly regarded as monomeric $[Co(NH_3)_5NO]^{2+}$, have been shown to be dimeric with bridging hyponitrito groups in a *cis* planar configuration[602]

$$[(NH_3)_5Co—NNO—Co(NH_3)_5]^{4+}$$
$$\mid$$
$$O$$
Their infrared spectra also show $v(NO)$ to be in the region 1040–1195 cm^{-1} similar to the spectra of other complexes where bridging $N_2O_2^{2-}$ groups are suspected[603], e.g., $K_6[(CN)_5Co(N_2O_2)Co(CN)_5]$ and iron and ruthenium nitrosyls $[(NO)_3M(N_2O_2)M(NO)_3]$.

In the absence of structural parameters, a full discussion of the bonding in hyponitrites is not possible. However, the strong absorption in the ultraviolet region at 248 mμ ($\varepsilon = 3980$) is characteristic of compounds containing a N=N bond[604], which suggests that the bonding in the hyponitrite ion is adequately described by the structure
Crystalline nitramide, however, is quite different[605]:

[605] C. A. Beevers and A. F. Trotman-Dickenson, *Acta Cryst.* **10** (1957) 34.

16.3. PHYSICAL PROPERTIES

Due, no doubt, to the instability of hyponitrous acid, few of its physical constants have been recorded[597]. Perhaps the most important fact is that it reacts as a weak dibasic acid, and the values for the ionization constants are $K_1 = 9 \times 10^{-8}$ and $K_2 = 1 \times 10^{-11}$:

$$H_2N_2O_2 \overset{K_1}{\rightleftharpoons} H^+ + HN_2O_2^- \overset{K_2}{\rightleftharpoons} 2H^+ + N_2O_2^-$$
From the temperature variation of the dissociation constants the first and second enthalpies of ionization for hyponitrous acid have been estimated[606] to be 3.7 and 6.1 kcal/mol. This compares with the calorimetric value (11.1 kcal/mol) for the sum of the two[607]. The enthalpy of formation of aqueous $HN_2O_2^-$ and $H_2N_2O_2$ is -12.4 and -15.4 kcal/mol respectively[608].

It is not usual to regard nitrous oxide as the anhydride of hyponitrous acid because the equilibrium

$$N_2O(g) + H_2O(l) \rightleftharpoons H_2N_2O_2(aq)$$
lies completely to the left. Indeed, it has been calculated that an equilibrium pressure of 10^{27} atm of N_2O would be necessary in order to obtain a 0.001 M aqueous solution of hyponitrous acid[609]. Organic solvents are particularly useful in $H_2N_2O_2$ chemistry and the partition coefficients between aqueous solution and benzene, diethyl ether and di-n-butyl ether, $K = [H_2N_2O_2]_{solvent}/[H_2N_2O_2]_{aqueous}$, are 3.6×10^{-4}, 1.14 and 7.7×10^{-2} respectively[597].

16.4. CHEMICAL PROPERTIES

The decomposition of hyponitrous acid in aqueous solution leads principally to nitrous oxide and water. At pH 4–14 the predominant unstable species in hyponitrous acid decompositions is the hydrogen hyponitrite ion

$$HN_2O_2^- \rightarrow N_2O + OH^-$$
However, at pH 1–3 and 25°C, $H_2N_2O_2$ has a half-life of about 16 days which decreases to orders of minutes if the temperature or acidity is increased. Under such conditions the following mechanism is thought to be relevant:
However, the fact that decomposing hyponitrous acid solutions cause polymerization of added acetonitrile suggests the presence of free radical intermediates. The OH and NO_2 radicals are likely to be involved because nitrophenols are formed when benzene is added,

[606] M. N. Hughes and G. Stedman, *J. Chem. Soc.* (1963) 1239.

[607] W. M. Lattimer and H. W. Zimmerman, *J. Am. Chem. Soc.* **61** (1939) 1550.

[608] D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Bailey and R. H. Schumm, *Selected Values of Chemical Thermodynamic Properties*, NBS Technical Note 270-3, Washington (1968).

[609] D. M. Yost and H. Russell, Jr., *Systematic Inorganic Chemistry*, Prentice-Hall, New York (1944), pp. 52–57.

and in fact, the process is initiated by OH radicals in the presence of oxidation transfer agents M according to the scheme[597]:

$$M + OH \rightarrow M^+ + OH^-$$
$$M^+ + H_2N_2O_2 \rightarrow M + HONNO + H^+$$
$$HONNO \rightarrow N_2O + OH$$
$$HONNO + H_2N_2O_2 \rightarrow 2NO + N_2 + H_2O + OH$$
$$NO + H_2N_2O_2 \rightarrow HNO_2 + N_2 + OH$$
$$HNO_2 + H_2N_2O_2 \rightarrow [ONON{=}NOH] \rightarrow NO_2 + N_2 + OH$$
$$NO_2 + H_2N_2O_2 \rightarrow H^+ + NO_3^- + N_2 + OH$$
$$OH + HNO_2 \rightarrow H_2O + NO_2$$
$$OH + NO_2 \rightarrow H^+ + NO_3^-$$
The reaction of nitrous acid with hyponitrous acid in dilute solution has also been studied separately[610] and is essentially described by the equation

$$HNO_2 + H_2N_2O_2 \rightarrow HNO_3 + N_2 + H_2O$$
although at higher concentrations some N_2O is formed.

Hyponitrites are relatively stable towards reduction, as witnessed by their formation in the presence of strong reducing agents like sodium amalgam, whereas oxidation to nitrite or nitrate occurs readily. For example, the oxidation with iodine provides the basis of a convenient analytical method[611]:

$$H_2N_2O_2 + 3I_2 + 3H_2O \rightarrow HNO_3 + HNO_2 + 6HI$$
The oxidation of $Na_2N_2O_2$ with liquid N_2O_4 to form $Na_2N_2O_x$ (where $x = 3, 4, 5, 6$) has been considered[604] in section 13. However, in the presence of an inert solvent of high dielectric constant such as nitromethane, the reaction goes to completion rapidly:

$$2N_2O_4 + N_2O_2^{2-} \rightarrow ONON{=}NONO + 2NO_3^-$$
$$\downarrow$$
$$N_2 + 2NO_2$$
The mechanism based on electrophilic attack by NO^+ on the oxygen atoms of the hyponitrite anion is further supported by the similar reaction of nitrosonium perchlorate with hyponitrite in nitromethane suspension[612]:

$$2NO^+ClO_4^- + N_2O_2^{2-} \rightarrow ONON{=}NONO + 2ClO_4^-$$
$$\downarrow$$
$$N_2 + 2NO_2$$
Perhaps, however, the most important aspect of hyponitrite redox chemistry is the possibility that it is an intermediate in the nitrogen cycle[597]. In particular, it is the ammonia-nitrite oxidation step that is thought to proceed via hydroxylamine and hyponitrous acid although the latter could result from dimerization of nitroxyl NOH.

Sodium hyponitrite decomposes on heating to 260°C *in vacuo* or 335°C at atmospheric pressure to give sodium oxide, nitrite and nitrate together with nitrogen. It is partially

[610] M. N. Hughes and G. Stedman, *J. Chem. Soc.* (1963) 2824.
[611] G. Ferrani, *Ann. Chim. (Italy)* **48** (1958) 322.
[612] M. N. Hughes and H. G. Nicklin, *Chem. Communs.* (1969) 80.

hydrolysed in water or dilute acids to N_2O, NO_4 and N_2, but oxidized by permanganate. Alkali-metal hyponitrites also decompose thermally[613]:

$$MNO_2 \rightarrow MO + N_2O$$
$$3MNO_2 \rightarrow 2MO + M(NO_2)_2 + 2N_2$$
in an analogous manner to the silver salt:

$$Ag_2N_2O_2 \rightarrow Ag_2O + N_2O$$
$$3Ag_2N_2O_2 \rightarrow 2Ag_2O + 2AgNO_2 + 2N_2$$
Finally, nitramide like isomeric hyponitrous acid is also a weak acid in aqueous solution:

$$NH_2NO_2 \rightleftharpoons H^+ + NHNO_2^-; \qquad K = 2.6 \times 10^{-7}$$

and decomposes by a base-catalysed reaction to nitrous oxide and water:

$$NH_2NO_2 + B \xrightarrow{slow} NHNO_2^- + BH^+$$
$$NHNO_2^- \xrightarrow{fast} N_2O + OH^-$$
17. NITROUS ACID AND NITRITES

17.1. PRODUCTION AND INDUSTRIAL USE

Nitrous acid is an important intermediate in the N_2O_4–H_2O reaction during the production of nitric acid (see section 18.3), but it cannot be isolated during this process[614].

$$N_2O_4 + H_2O \rightleftharpoons HNO_2 + HNO_3$$
For although the salts and esters of nitrous acid are fairly stable, the free acid is usually used and prepared *in situ* by acidification of aqueous nitrite solutions below room temperature due to its instability with respect to[614, 615]:

$$3HNO_2 \rightleftharpoons H_3O^+ + NO_3^- + 2NO$$
However, it is the reverse of such equilibria that are operative in industrial processes whereby metal nitrites are obtained from the absorption of nitrous fumes in basic solutions of metal hydroxides, carbonates, sulphides, etc.:

$$NO + NO_2 + 2NaOH \rightarrow 2NaNO_2 + H_2O$$

For sodium nitrite, industrially the most important nitrite, although the purity of the raw product from this process is often less than 60%, better than 99% purity can be obtained simply by four recrystallizations. Alkali-metal nitrites can also be obtained by the thermal decomposition of readily available nitrates:

$$2NaNO_3 \xrightarrow{\Delta} 2NaNO_2 + O_2$$
[613] T. M. Oza and V. T. Oza, *J. Phys. Chem.* **60** (1956) 192.
[614] H. Block, in ref. 571, Section XXXII, pp. 353–407.
[615] D. M. Yost and H. Russell, Jr., *Systematic Inorganic Chemistry*, Prentice-Hall, New York (1944), pp. 58–70.

However, the process can be carried out at lower temperatures and with better yields by the addition of a reducing agent such as coke or iron, etc.:

$$2NaNO_3 + C \rightarrow 2NaNO_2 + CO_2$$
Sodium nitrite is used industrially[614, 616] for the synthesis of hydroxylamine and its derivatives, organic nitrites and nitro-compounds, and particularly in diazotization reactions leading to azo dyes and pharmaceuticals. Inorganic nitrites are also components of textile bleaching agents, heat transfer media, corrosion inhibitors, blowing agents, monomer stabilizers and commercial explosives.

17.2. LABORATORY PREPARATION

Nitrous acid is prepared simply by the acidification of a nitrite with any moderately strong or mineral acid at below room temperature. An aqueous solution free of any dissolved salts is conveniently obtained using an exchange reaction which produces an insoluble salt[614]:

$$Ba(NO_2)_2 + H_2SO_4 \rightarrow 2HNO_2 + BaSO_4$$
$$AgNO_2 + HCl \rightarrow HNO_2 + AgCl$$
Pure nitrous acid has also been prepared by low-temperature ion exchange of sodium nitrite in aqueous glycol dimethylether[617]. Where the presence of salts is of no consequence, sodium nitrite is acidified with hydrochloric acid cooled in a salt-ice bath[614].

Commercial sodium nitrite can be easily purified by recrystallization or prepared by one of the following methods:

$$2NaNO_3 \xrightarrow{\Delta} 2NaNO_2 + O_2$$
$$NaNO_3 + Na_2Fe_2O_4 + 2NO \rightarrow 3NaNO_2 + Fe_2O_3$$
$$2NaOH + N_2O_3 \rightarrow 2NaNO_2 + H_2O$$
Similarly, silver nitrite, the other convenient starting reagent for introducing the nitrite group by halide replacement reactions, is best obtained as the sparingly soluble salt from the exchange reaction[614]:

$$AgNO_3 + NaNO_2 \rightarrow AgNO_2 + NaNO_3$$
Also, dinitrogen trioxide in alkaline solutions, as indicated above for sodium nitrite, gives practically pure nitrite solutions. Thus these reagents provide convenient laboratory methods of synthesis for most nitrites as illustrated by the following examples:

$$Li_2O + N_2O_3 \rightarrow 2LiNO_2$$
$$KCl + AgNO_2 \rightarrow KNO_2 + AgCl$$
$$2NH_3 + H_2O + N_2O_3 \rightarrow 2NH_4NO_2$$
$$Ba(OH)_2 + NO + NO_2 \rightarrow Ba(NO_2)_2 + H_2O$$
Such methods are also applicable to the formation of transition metal complexes:

$$[Co(NH_3)_5H_2O]^{3+} + HNO_2 \rightarrow [Co(NH_3)_5ONO]^{2+} + H^+ + H_2O$$
[616] C. Matasa and E. Matasa, *L'Industrie Moderne des Produits Azotes*, Dunod, Paris (1968), p. 567.
[617] C. S. Scanley, *J. Am. Chem. Soc.* **85** (1963) 3888.

17.3. NUCLEAR ISOTOPES OF NITROUS ACID AND NITRITES

The availability of $Na^{15}NO_2$ free of nitrate contamination is a vital reagent for introducing ^{15}N into a very large number of organic compounds. Nitrogen-15 can be oxidized in a high voltage electric arc to give a mixture of nitrogen oxides, of which the higher oxides can be reduced to nitric oxide with mercury and sulphuric acid. The oxidation by permanganate in an autoclave at 180–190°C gives nitrate which can be similarly reduced. If the subsequent oxidation of ^{15}NO over sodium hydroxide solution is controlled by slow addition of oxygen, the enriched nitrogen dioxide reacts with the excess nitric oxide as it is formed producing dinitrogen trioxide $^{15}N_2O_3$ which dissolves in the caustic soda to give labelled nitrite:

$$^{15}NO + \tfrac{1}{2}O_2 \rightarrow {}^{15}NO_2$$
$$^{15}NO + {}^{15}NO_2 \rightarrow {}^{15}N_2O_3$$
$$^{15}N_2O_3 + 2NaOH \rightarrow 2Na^{15}NO_2 + H_2O$$
Free sodium nitrite–^{15}N can be obtained by crystallization after concentration by evaporation in a platinum dish[618].

Alkali metal nitrites can also be prepared by heating a nitrate with metallic lead, but the product is usually contaminated with nitrate:

$$Na^{15}NO_3 + Pb \rightarrow Na^{15}NO_2 + PbO$$
Oxygen-18-enriched nitrites can be prepared by simple exchange reactions between the normal nitrite and ^{18}O-enriched water. For example sodium nitrite–^{18}O can be prepared simply by dissolving dry unlabelled sodium nitrite in ^{18}O-enriched water acidified with perchloric acid to pH 4.9. Silver nitrite–^{18}O can then be precipitated out when silver perchlorate, also in ^{18}O-enriched water, is added to the enriched nitrite solution[619]:

$$NaNO_2 + 2H_2{}^{18}O \rightarrow NaN^{18}O_2 + 2H_2O$$
$$AgClO_4 + NaN^{18}O_2 \rightarrow AgN^{18}O_2 + NaClO_4$$
17.4. STRUCTURE AND BONDING

Three structures can be envisaged for nitrous acid, two of which would be related as *cis* and *trans* isomers as illustrated in Fig. 40.
Fig. 40. Possible structures for nitrous acid.

That hydrogen is bonded to oxygen rather than nitrogen is indicated by magnetic susceptibility measurements[614], while infrared spectra[620] show absorptions which are assigned to both *cis* and *trans* configurations, and which also suggest that the *trans* isomer is more

stable than *cis* by about 500 cal/mol [621]. The probable structural parameters for nitrous acid [614] are shown in Fig. 41.
FIG. 41. Structures for nitrous acid and the nitrite ion.

Crystal data on some ionic metal nitrites [614] are listed in Table 77, and in all cases the nitrite ion has an angular shape with N–O distances reported between 1.13 to 1.23 Å and the ONO bond angle between 116° and 132°.

TABLE 77. CRYSTAL STRUCTURES OF IONIC NITRITES[a]

Compound	Crystal system	Lattice parameters (Å)
$LiNO_2 \cdot H_2O$	Monoclinic	$a = 3.31, b = 14.10, c = 6.36,$ $\beta = 105°$
$NaNO_2$	Orthorhombic	$a = 3.55, b = 5.56, c = 5.37$
KNO_2	Monoclinic (distorted $NaNO_2$-type)	$a = 4.45, b = 4.99, c = 7.31,$ $\beta = 114° 50'$
$CsNO_2$	Monometric	$a = 4.34$
$AgNO_2$	Orthorhombic	$a = 3.505, b = 6.14, c = 5.16$
$NaAg(NO_2)_2$	Orthorhombic	$a = 7.89, b = 10.62, c = 10.83$
$Ba(NO_2)_2$	Hexagonal	$a = 7.05, b = 17.66$
$2Ba(NO_2)_2 \cdot TlNO_2$	Rhombic	$a = 13.48, b = 17.94, c = 4.958$

[a] Ref. 614.

The electronic structure of nitrous acid is more or less as would be expected, and the N–O bond lengths indicated in Fig. 41 are consistent with bond orders of 1 and 2. The nitrite ion, however, contains eighteen electrons for which two resonance forms seem likely as well as the alternative non-pairing structure [622] illustrated in Fig. 42.
FIG. 42. Electronic structures of NO_2^-.

The ONO bond angle is consistent with sp^2 hybridization at the nitrogen atom, but the N–O bond lengths are closer to a bond order of 2 than 1.5.

[621] A. P. Altshuller, *J. Phys. Chem.* **61** (1957) 251.

[622] M. Green, in *Developments in Inorganic Nitrogen Chemistry*, Vol. I (ed. C. B. Colburn), Elsevier, Amsterdam (1966), p. 42.

The molecular orbital description of the NO_2^- ion is

$$(1a_1)^2(1b_2)^2(2a_1)^2(1b_1)^2(3a_1)^2(2b_2)^2(1a_2)^2(3b_1)^2(4a_1)^2$$

Four of these orbitals are bonding and five non-bonding suggesting individual N–O bond orders of 2. However, both these descriptions are approximations and overlook the fact that overlap can vary considerably and also the slight anti-bonding character of some levels.

Nitrite is also capable of bonding to metal atoms in other ways[623] as indicated in Fig. 43.
FIG. 43. Bonding of the nitrite group to metals.

The formation of nitro (i) and nitrito (ii) complexes such as $[Co(NH_3)_5NO_2]^{2+}$ and $[Co(NH_3)_5ONO]^{2+}$ is well established. Evidence for such structures is largely spectroscopic because differences in the bond orders and symmetries of the nitrite group in such configurations are reflected in their infrared spectra[624]. In general, nitrito complexes are less stable than the corresponding nitro complexes, and isomerization usually occurs quite readily. The rate of isomerization from nitrito to the nitro form is faster in solution than in the solid state although the absence of exchange between the —ONO group and the solvent or added nitrite ion implies that the group does not leave the co-ordination sphere of the metal during isomerization[625]:
Of the bridging structures (iii)–(v) illustrated in Fig. 43, structure (iii) has been confirmed for the compound $[Nien_2(ONO)]BF_4$ which forms poymer chains of Ni—ON(O)Ni units[626].

[a] Ref. 627.

17.5. MOLECULAR PROPERTIES

The infrared and Raman spectra of nitrous acid have been recorded in solution. Infrared and ultraviolet absorption spectroscopy have been important in demonstrating that the nitrous acid molecule exists in equilibrium in the gas phase[627]

$$NO(g) + NO_2(g) + H_2O(g) \rightleftharpoons 2HNO_2(g); \qquad K(298) = 1.74$$
Spectra of *cis* and *trans* HNO_2 and DNO_2 have been recorded. The non-linear structure of the nitrite ion has also been confirmed by the appearance of fundamental frequencies v_1, v_2 and v_3 in both infrared and Raman spectra at 1335, 830 and 1250 cm^{-1} respectively[624].

17.6. PHYSICAL PROPERTIES

Nitrous acid is unknown as a pure substance in condensed phases, but in the gas phase it can be detected in the absence of dissociation products when equilibrium is rapidly established[614]. Solutions of nitrous acid have a limited useful life due to the decomposition

$$3HNO_2 \rightarrow H_3O^+ + NO_3^- + 2NO$$
Consequently few physical constants for HNO_2 have been measured. Some thermodynamic data[627] are given in Table 78.

In aqueous solution, HNO_2 is a weak monobasic acid [$pK_a(291) = 3.3$] which forms reasonably stable salts with electro-positive elements. Ionic nitrites have high solubility in water[615], and the properties of aqueous solutions such as densities, viscosities and vapour pressures have been investigated[614]. Phase diagrams for metal nitrite–water systems in the presence of related substances have also been recorded together with thermodynamic data on fused salt mixtures containing sodium nitrite. Some physical properties of ionic nitrites are given in Table 79.

TABLE 79. PHYSICAL PROPERTIES OF IONIC NITRITES[a]

Property	NH_4NO_2	$LiNO_2$	$NaNO_2$	KNO_2	$AgNO_2$
Melting point (°C)	s 32–3		282–4	441	
Decomposition point (°C)	60–70		320		
Transition temperature (°C)			160–2	47	
Density d_0^{20} (g/cm³)			2.144		
Heat of solution (kcal/mol)		2.38	−3.57	−3.40	10.07
Heat of formation (kcal/mol)		94.16	85.06	87.66	

[a] Ref. 614.

17.7. CHEMISTRY AND CHEMICAL PROPERTIES

In aqueous solutions, HNO_2 is best regarded[628] as hydroxylated NO^+ implying that OH^- can be replaced by other bases to give NOX. Highly acidic solutions favour the

[627] D. D. Wagman, W. H. Evans, V. B. Parker, I. Halow, S. M. Bailey and R. H. Schumm, *Selected Values of Chemical Thermodynamic Properties*, NBS Technical Note 270-3, Washington (1968).
[628] T. A. Turney and G. A. Wright, *Chem. Rev.* **59** (1959) 497.

formation of NO$^+$ or its hydrated equivalent (H$_2$NO$_2^+$), while in dilute acid the unionized species HONO is present.

$$HONO + H^+ \rightleftharpoons NO^+ + H_2O; \qquad K(293) = 2 \times 10^{-7}$$

This sort of equilibrium has been demonstrated by the exchange reaction

$$H_2^{18}O + HONO \rightleftharpoons H^{18}ONO + H_2O$$
However, aqueous solutions of nitrous acid are also unstable and decompose rapidly when heated. The following mechanism has been suggested:

$$4HNO_2 \rightleftharpoons N_2O_4 + 2NO + 2H_2O; \qquad \text{rapid}$$
$$N_2O_4 \rightarrow NO^+ + NO_3^-; \qquad\qquad \text{rate determining}$$
$$NO^+ + H_2O \rightleftharpoons HNO_2 + H^+$$
The decomposition of ammonium nitrite solution can also be regarded as similar to that of nitrous acid and ammonia in aqueous solution:

$$NH_4NO_2 \rightarrow NH_4^+ + NO_2^-$$
$$NH_4^+ \rightarrow NH_3 + H^+$$
$$2H^+ + NO_2^- \rightarrow H_2O + NO^+$$
$$NO^+ + NH_3 \rightarrow NH_3NO^+ \rightarrow N_2 + H^+ + H_2O$$
Explosive decomposition occurs[629] with solid NH$_4$NO$_2$:

$$NH_4NO_2 \rightarrow N_2 + 2H_2O$$
Silver nitrite is also susceptible to disproportionation during thermal decomposition[614, 615]:

$$AgNO_2 \rightleftharpoons Ag + NO_2$$
$$AgNO_2 + NO_2 \rightleftharpoons AgNO_3 + NO$$
The redox aqueous solution chemistry of nitrites is best described[630] by the following equations:

In acid solution:

$$HNO_2 + H_2O \rightleftharpoons NO_3^- + 3H^+ + e^-; \qquad E° -0.94 \text{ V}$$
$$NO + H_2O \rightleftharpoons HNO_2 + H^+ + e^-; \qquad E° -0.99 \text{ V}$$
$$N_2O + 3H_2O \rightleftharpoons 2HNO_2 + 4H^+ + 4e^-; \qquad E° -1.29 \text{ V}$$

In alkaline solution:

$$NO_2^- + 2OH^- \rightleftharpoons NO_3^- + H_2O + 2e^-; \qquad E° -0.01 \text{ V}$$
$$NO + 2OH^- \rightleftharpoons NO_2^- + H_2O + e^-: \qquad E° +0.46 \text{ V}$$
$$N_2O + 6OH^- \rightleftharpoons 2NO_2^- + 3H_2O + 4e^-; \qquad E° -0.15 \text{ V}$$
Oxidation of nitrous acid by atmospheric oxygen proceeds by oxidation of nitric oxide formed by decomposition of the acid, and the resulting dinitrogen tetroxide reacting with water:

$$4HNO_2 \rightarrow N_2O_4 + 2NO + 2H_2O$$
$$2NO + O_2 \rightarrow N_2O_4$$
$$N_2O_4 + H_2O \rightarrow HNO_2 + HNO_3$$

---
[629] T. Urbański, *Chemistry and Technology of Explosives*, Vol. II, Pergamon, Oxford (1965), p. 491.
[630] P. Gray and A. D. Yoffe, *Chem. Rev.* **55** (1955) 1069.

The reaction with hydrogen peroxide also produces nitrate, but the mechanism probably involves the formation of peroxynitrous acid HOONO, isomeric with nitric acid, as an intermediate:

$$HNO_2 + H^+ \rightleftharpoons NO^+ + H_2O$$

$$H_2O_2 + NO^+ \rightarrow HOONO + H^+ \rightarrow NO_3^- + 2H^+$$
As such mixtures act as initiators of polymerization reactions, it is thought that peroxynitrous acid can decompose by way of free radicals[631]:

$$HOONO \rightarrow \cdot OH + NO_2^\cdot$$
Nitrous acid and nitrites are readily reduced[615] to a variety of nitrogen species, even to hyponitrous acid with tin(II) and to ammonia with H_2S, but more commonly to NO and N_2O:

$$SO_2 + 2HNO_2 \rightarrow 2NO + H_2SO_4$$

$$H_2O + 2SO_2 + 2HNO_2 \rightarrow N_2O + 2H_2SO_4$$
Hydrazine salts lead to the formation of azides which also react with HNO_2 to give nitrous oxide[632]:

$$N_2O_5^+ + HNO_2 \rightarrow HN_3 + 2H_2O + H^+$$

$$HN_3 + HNO_2 \rightarrow N_2O + N_2 + H_2O$$
The mechanism of this latter reaction has been investigated using ^{15}N substituted azides, and the route of each nitrogen atom traced[633]:

$$\underset{* \quad \dagger}{NNN^-} + NO^+ \rightleftharpoons \underset{* \quad \dagger}{NNNNO} \rightarrow \underset{* \quad \dagger}{NN + NNO}$$

With hydroxylamine, nitrous oxide is also obtained but the route is different[615] under acid and neutral conditions[634]:
Other reactions of nitrites include[614]:

$$NaNO_2 + NH_2CONH_2 \longrightarrow NaCNO + N_2 + 2H_2O$$

$$NaNO_2 + NO_2 \xrightarrow{450°C} NaNO_3 + NO$$

$$NaNO_2 + Na_2O \longrightarrow Na_3NO_3$$

$$2NaNO_2 + 2Na \xrightarrow{liq.\ NH_3} Na_4N_2O_4\ (Na_2NO_2)$$

$$2Ba(NO_2)_2 + I_2 \rightleftharpoons Ba(NO_3)_2 + 2KI + 2NO$$

$$2HNO_2 + 2HI \longrightarrow I_2 + 2NO + 2H_2O$$

$$HNO_2 + H_2O + I_2 \longrightarrow HI + HNO_3$$

17.8. BIOLOGICAL PROPERTIES[635]

Nitrite is a principal intermediate in the nitrogen cycle and important in both nitrification and denitrification processes. In the former, nitrite is regarded as the precursor to nitrate, while the latter can occur by reduction of nitrite to a volatile material or by its reaction with amino groups giving elemental nitrogen.

Nitrites are dangerously poisonous materials and show symptoms which resemble those of cyanide poisoning. Fatal accidents have occurred through the use of sodium nitrite in place of sodium chloride to season food.

17.9. ANALYSIS OF NITROUS ACID AND NITRITES[636]

Nitrous acid is never encountered in the pure state and is stable only in cold aqueous solutions:

$$3HNO_2 \rightleftharpoons H_3O^+ + NO_3^- + 2NO$$
However, all nitrites react in acid solution, by intermediate formation of nitrous acid, with primary aromatic amines to form diazonium compounds which are capable of coupling with amino or hydroxy derivatives to form azo dyes. For example, α-naphthylamine can be diazotized and coupled with sulphanilic acid to give the red azo dye α-naphthylamine-p-azobenzene-p-sulphonic acid.

Titrimetric procedures involve oxidation with permanganate according to the equation

$$5NO_2^- + 2MnO_4^- + 6H^+ \rightarrow 5NO_3^- + 2Mn^{2+} + 3H_2O$$
although it is recommended that the nitrite solution be mixed with excess permanganate prior to acidification, and the permanganate back-titrated iodometrically to avoid any losses due to nitrous acid decomposition.

Small amounts of nitrite in the presence of nitrate can be determined by reaction with sulphamic acid by measuring the volume of nitrogen evolved:

$$NaNO_2 + HSO_3NH_2 \rightarrow NaHSO_4 + N_2 + H_2O$$
18. NITRIC ACID AND NITRATES

18.1. DISCOVERY AND HISTORY

Nitric acid was certainly known by the alchemists of the thirteenth century who prepared it by heating a mixture of copper sulphate, alum and saltpetre for use in refining precious metals. In 1776 Lavoisier proved that nitric acid contained oxygen, and in 1783 Cavendish showed that the dew produced by the electric sparking of humid air contained nitric acid and also demonstrated that it contained nitrogen and oxygen. The complete chemical composition was established in 1816 by Gay-Lussac and Berthollet[637].

[635] F. Call, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. I, *Nitrogen*, Part I, Longmans, London (1964), Section XVII, pp. 567–615.

[636] K. I. Vasu, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part II, Longmans, London (1967), p. 643.

[637] F. D. Miles, *Nitric Acid Manufacture and Uses*, ICI Ltd., Oxford University Press, London (1961).

From 1825 for almost a century, the saltpetre beds of Chile provided the world demand for nitrate. As the nineteenth century relied on natural resources, so the twentieth century has seen the necessity of synthetic routes from readily available starting materials. The investigations of Ostwald into the catalytic oxidation of ammonia at about the time the Haber process for the synthetic production of ammonia was being developed have provided the basis of the nitric acid industry today[637, 638].

18.2. OCCURRENCE OF NITRIC ACID AND NITRATES

A very large amount of nitric acid is produced by lightning and other electric discharges in the atmosphere and washed down on to the land by rain. It has been suggested that apart from providing land with combined nitrogen, that some may have led to the formation of alkali metal nitrate, deposits, particularly in dry climates. The extensive deposits in the caliche beds of the desert region of Chile have been exploited since the early nineteenth century. Chile saltpetre is sodium nitrate containing some potassium nitrate and sodium iodate. The caliche layer is usually 2–4 m thick just below the surface and can contain up to 70% $NaNO_3$ although much of the ore now mined contains less than 10% nitrates[639]. The chemical composition also suggests that the origin of the deposits may have been sea-weed washed up from the sea followed by the action of nitrifying bacteria in a dry climate[637].

18.3. PRODUCTION AND INDUSTRIAL USE OF NITRIC ACID AND NITRATES

Nitric acid was formerly made[637, 638, 640] from the reaction of sodium nitrate recrystallized from Chile saltpetre with concentrated sulphuric acid:

$$2NaNO_3 + H_2SO_4 \rightarrow Na_2SO_4 + 2HNO_3$$
The nitric acid was distilled from the mixture after rejecting the forerun containing hydrochloric acid and nitrosyl chloride resulting from chloride impurity. Excess sulphuric acid was added forming some bisulphate to maintain a fluid melt, but this also produced frothing due to the water vapour released during pyrosulphate formation:

$$NaNO_3 + H_2SO_4 \rightarrow NaHSO_4 + HNO_3$$
$$2NaHSO_4 \rightarrow Na_2S_2O_7 + H_2O$$
Nowadays, the principal route to nitric acid is based on the oxidation of nitric oxide to nitrogen dioxide and subsequent absorption in water[637, 639, 641, 642]:

$$2NO + O_2 \rightarrow 2NO_2$$
$$3NO_2 + H_2O \rightarrow 2HNO_3 + NO$$

Nitric oxide can be produced directly by the oxidation of atmospheric nitrogen but neither the Birkeland–Eyde arc oxidation[637] nor the Wisconsin thermal process[643] are economical at the present time. Thus, the catalytic oxidation of ammonia (see section 3.10.2) is the only method currently used[639]. Under suitable conditions platinum–rhodium catalyst[644] has a high specificity in promoting the oxidation to nitric oxide rather than the thermodynamically more favourable reaction to nitrogen:

$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O; \qquad \triangle H = -229.4 \text{ kcal/mol}$$
$$4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O; \qquad \triangle H = -312.1 \text{ kcal/mol}$$
This reaction can be carried out at atmospheric or higher pressures using air or pure oxygen. The oxidation of NO to NO_2 (see section 11.7.2) is also favoured by high pressures as well as low temperatures, with the conversion time being proportional to the square of the pressure. Higher pressures also improve the absorption of nitrogen dioxide in water giving stronger nitric acid[639]. Some of the reactions involved include the following:

$$2NO_2 + H_2O \rightarrow HNO_3 + HNO_2$$
$$2HNO_2 \rightarrow H_2O + NO_2 + NO$$
$$3NO_2 + H_2O \rightarrow 2HNO_3 + NO$$
The exothermic NO_2–H_2O reaction is carried out in towers by counter-current absorption giving dilute acid from which the excess NO_2 is bleached out with air. The gases leaving the towers usually contain low concentrations of nitrogen oxides which may require further treatment before being allowed to enter the atmosphere[639]. Most of the energy requirements of a modern HNO_3 unit can be supplied by steam generated by the plant.

Nitric acid of 50–70% strength is produced by commercial processes operating at atmospheric and higher pressures. However, because of azeotrope formation between nitric acid and water, simple distillation at atmospheric pressure does not increase the strength of weak acid above 68.5%. The usual method of concentrating nitric acid is by counter-current dehydration using 95% sulphuric acid giving 96–98% nitric acid and 65% sulphuric acid which can be concentrated by evaporation.[637] An alternative and cheaper method is that in which concentrated magnesium nitrate solution and weak nitric acid together with 80–90% nitric acid are fed into a stripping column[639]. The nitric acid vapours evolved are further fractionated, condensed and part of the product returned to the stripping column. The weak magnesium nitrate solution can be concentrated by thermal and vacuum evaporation. The use of chemical dehydration agents can be avoided if liquid N_2O_4 is used in the absorption step. 98–99% HNO_3 is obtained when liquid N_2O_4 is heated to 70°C at 50 atm for about 4 hr with theoretical quantities of air and dilute nitric acid[639].

The production of nitrates is probably the principal use of nitric acid[642]. Ammonium nitrate is manufactured in large quantities by the neutralization reaction for use as fertilizer and explosive[645] (see section 5). Sodium nitrate can also be readily obtained from weak nitric acid and soda ash[639]:

$$2HNO_3 + Na_2CO_3 \rightarrow 2NaNO_3 + CO_2 + H_2O$$
or from sodium chloride[646]:

$$4HNO_3 + 3NaCl \rightarrow 3NaNO_3 + H_2O + Cl_2 + NOCl$$
$$3NOCl + 2Na_2CO_3 \rightarrow NaNO_3 + 3NaCl + 2NO_2 + 2CO_2$$

[645] K. F. J. Thatcher, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. I, *Nitrogen*, Part I, Longmans, London (1964), pp. 506–62.

[646] E. D. Crittenden, in *Fertilizer Nitrogen* (ed. G. Sauchelli), Reinhold, New York (1964), pp. 331–43.

Chile saltpetre is still mined, and the sodium nitrate is extracted from the caliche by leaching the crushed ore at 40°C with water. The solution is cooled to 15°C in heat exchangers then to 5°C by liquid ammonia, and the sodium nitrate slurry separated in centrifuges. Solar evaporation plants are also used to recover nitrate from residues[639].

Potassium nitrate is made by the double decomposition reaction

$$KCl + NaNO_3 \rightarrow KNO_3 + NaCl$$
Alkaline earth metal nitrates and some compound fertilizers are also produced by similar methods. For example, nitric acid can replace sulphuric acid in the treatment of phosphate rock to give nitrophosphates according to the generalized equation[639]

$$Ca_{10}(PO_4)_6F_2 + 14HNO_3 \rightarrow 3Ca(H_2PO_4)_2 + 7Ca(NO_3)_2 + 2HF$$

Large quantities of nitric acid are used for the nitration of organic compounds in the production of commercial explosives (nitroglycerine, nitrocellulose, trinitrotoluene, cyclotrimethylenetrinitramine) and numerous organic intermediates[639, 647]. The oxidizing properties of HNO_3 are manifest in its application as a rocket propellant[642] and in many organic[647] and inorganic[642] oxidation reactions. Most metals can be made to dissolve in nitric acid, and even the noble metals are attacked in the presence of hydrochloric acid (aqua regia). Stainless steel, silicon iron and aluminium resist high-strength acid, but alloy steels are necessary for dilute solutions. Stainless steel is often used for modern plant construction and fluorocarbon resins are inert to all strengths of acid and being flexible can be used for gaskets, seals and linings[639]. Nitrates are also incorporated in explosives (KNO_3 in gunpowder) and have many minor applications, but their principal use is as fertilizers[639, 648].

18.4. LABORATORY PREPARATION AND PURIFICATION

Nitric acid is usually available from commercial sources and so laboratory preparations are not often required, but because of its continual decomposition in the presence of light or heat it is necessary to purify it for certain purposes. Technical grade nitric acid can be rendered halogen-free by distilling over a small amount of silver nitrate and using the middle-cut[649]. Anhydrous nitric acid can be obtained by distilling acid of the highest concentration available over P_2O_5 or with pure H_2SO_4, in an all-glass vacuum distillation apparatus (no grease) in the absence of light. The product distills over at 36–38°C/20 mm pressure as a colourless liquid which can be redistilled from pure H_2SO_4 with a stream of ozonized oxygen passing through the liquid and stored below its freezing point[650].

The preparative methods appropriate to the nitrates of individual elements will be discussed in their respective chapters, but mention will be made here to four reagents from which most nitrates can be prepared[651, 652]. Aqueous nitric acid reacts with most metals

[652] C. C. Addison and N. Logan, in *Preparative Inorganic Reactions*, Vol. I (ed. W. L. Jolly), Interscience, New York (1964), p. 141.

and their oxides or carbonates to form metal nitrate hydrates. Liquid N_2O_4 (see section 13.7.2), particularly in the presence of solvents of higher dielectric constant, dissolve a number of metals to give anhydrous metal nitrates[653]:

$$Ca + 2N_2O_4 \xrightarrow{MeNO_2} Ca(NO_3)_2 + 2NO$$
Liquid N_2O_5 also reacts with metal oxides and chlorides to give addition compounds which can be thermally decomposed *in vacuo* to anhydrous metal nitrates[651]:

$$TiCl_4 + 4N_2O_5 \rightarrow Ti(NO_3)_4 + 2N_2O_4 + 2Cl_2$$

One of the most powerful nitrating agents is $ClONO_2$ nitrosyl hypochlorite (often referred to as chlorine nitrate $ClNO_3$), which reacts with most metals[654] or metal chlorides explosively at room temperature but can be controlled at temperatures between -40 and $-70°C$:

$$SnCl_4 + 4ClONO_2 \rightarrow Sn(NO_3)_4 + 4Cl_2$$
Perhaps the least familiar nitrate compounds are those of the halogens, and these have been prepared by the following methods[651, 655]:

$$F_2 + NaNO_3 \longrightarrow FONO_2 + NaF$$

$$2ClO_2 + 2N_2O_5 \longrightarrow 2ClONO_2 + N_2O_4 + 4O_2$$

$$BrF_3 + 3N_2O_5 \xrightarrow[-30 \text{ to } -50°]{CCl_3F} Br(NO_3)_3 + 3FNO_2$$

$$ICl_3 + 3ClONO_2 \xrightarrow{-70°} I(NO_3)_3 + 3Cl_2$$
18.5. NUCLEAR ISOTOPES OF NITRIC ACID AND NITRATES

Nitrogen can be oxidized in a high-voltage discharge to nitrogen dioxide which is then dissolved in a slight deficiency of dilute potassium hydroxide solution:

$$2^{15}NO_2 + 2KOH \rightarrow K^{15}NO_3 + K^{15}NO_2 + H_2O$$
Over a period of a few hours, the resulting acid solution causes the nitrite present to disproportionate:

$$3H^{15}NO_2 \rightarrow H^{15}NO_3 + 2^{15}NO + H_2O$$

The presence of excess oxygen at $50°C$ converts the oxides of nitrogen completely into nitrate within a few hours, from which $K^{15}NO_3$ can be crystallized out, or alternatively concentrated sulphuric acid is added and $H^{15}NO_3$ obtained by distillation[656].

$^{15}NH_3$ can be oxidized directly to nitrate with aqueous permanganate in an autoclave at $170–180°C$ for $7–8$ hr. The enriched product is separated from permanganate decomposition products, and after addition of sulphuric acid, $H^{15}NO_3$ distilled off. The labelled nitric acid can be converted into any of its salts by simple neutralization reactions[656].

[656] W. Spindel, in *Inorganic Isotopic Syntheses* (ed. R. H. Herber), Benjamin, New York (1962), p. 99.

Nitric acid-d is prepared by the reaction of nitrogen dioxide with ozone in deuterated water[657]:

$$2NO_2 + O_3 \rightarrow N_2O_5 + O_2$$
$$N_2O_5 + D_2O \rightarrow 2DNO_3$$
Oxygen-18-enriched nitric acid is prepared by exchange between nitric acid and ^{18}O-enriched water[658]. The potassium salt can then be obtained by neutralizing the acid with a solution of potassium hydroxide also in ^{18}O-enriched water. After crystallization, the product can be further enriched by heating with more enriched water and fuming nitric acid in a sealed tube at 70°C for 38 hr. After the removal of the volatiles by vacuum distillation, the potassium nitrate remaining contains up to 84% ^{18}O.

18.6. STRUCTURE AND BONDING

In general the nitrate ion is planar (D_{3h} symmetry) with all N–O bond distances close to 1.22 Å. This can be represented in valence bond terms by resonance structures based on those illustrated in Fig. 44.

FIG. 44. Valence bond and non-pairing structures for NO₃⁻.

Molecular orbitals can also be constructed for the nitrate ion on the basis of three σ bonds using sp^2 hybrid orbitals and the p_z orbitals of nitrogen and the three oxygens combining to form a π orbital containing two electrons. Thus twenty-four electrons are contained in bonding and non-bonding orbitals only which is a stable configuration for a tetratomic species, similar to sixteen-electron triatomic and ten-electron diatomic molecules[659].

In nitric acid, however, the hydrogen is covalently bonded to one of the oxygen atoms of the nitrate group. Structural parameters[660, 661] for HNO₃ and FNO₃ are illustrated in Fig. 45.

FIG. 45. The structure of HNO₃ and FNO₃.

From these data, the electronic configuration is probably best represented by the non-pairing structures in Fig. 46 analogous to nitryl halides.
FIG. 46. Linnett non-pairing structures for covalent $XONO_2$ molecules.

Covalent metal nitrates[662, 663] present the opportunity for the nitrate group to demonstrate the different ways it can bond to metals as illustrated in Fig. 47.
FIG. 47. Bonding possibilities in covalent metal nitrates.

For example, the nitrate groups act as unidentate ligands[653] in $(CO)_5MnONO_2$, bidentate ligands in uranyl nitrate[664] and bridging groups in basic beryllium nitrate[665], the symmetry in each case being at best C_{2v}. An example of a compound with the terdentate C_{3v} structure is not known, but each of the oxygen atoms in half the nitrate groups of the α-form of copper(II) nitrate are involved in bonding to a copper atom[666].

Thus covalent bonding can be easily recognized by infrared spectroscopy[667] due to the lowering of the symmetry of the nitrate group. The greater stability of covalent metal nitrates over non-metal nitrates may be due to back donation of electrons from the metal to empty orbitals of the nitrate group.

18.7. MOLECULAR CONSTANTS

Pure anhydrous nitric acid exists only in the solid phase, and X-ray analysis of single crystals indicates[660] that the unit cell is monoclinic. In contrast, the hydrates $HNO_3 \cdot H_2O$ and $HNO_3 \cdot H_2O$ are orthorhombic[668]. Electron diffraction[669] and microwave data[670] for

The spectroscopic properties of nitric acid have received much attention[671] in particular as a means of establishing what species are present in nitric acid solutions[672, 673]. Satisfactory assignments of the fundamental frequencies were made[671] for the HNO_3 molecule by treating the OH group as of C_s symmetry and the NO_2 group as of C_{2v}. For the nitrate ion,

electronic and infrared spectra have been studied in molten alkali nitrates and solids, and the allowed fundamentals have also been observed in Raman solution spectra. Values of bands recorded for alkali metal nitrates are in close agreement with calculated[650] figures listed in Table 80.

18.8. PHYSICAL PROPERTIES

The values of physical properties listed in Table 81 refer predominantly to liquid nitric acid in which self-dissociation occurs to a greater extent than any other pure liquid[672]. The

presence of ionic species is supported by the high electrical conductivity[673] and also by the appearance of weak lines at 1050 cm^{-1} and 1400 cm^{-1} when the Raman spectrum is recorded on pure nitric acid just after melting[671]. Further spectroscopic studies[671, 674] have established that such species result from self-ionization:

$$2HNO_3 \rightleftharpoons H_2O + N_2O_5 \rightleftharpoons H_2O + NO_2^+ + NO_3^-$$
followed by further ionization of H_2O in HNO_3:

$$H_2O + HNO_3 \rightleftharpoons H_3O^+ + NO_3^-$$
The single ^{15}N n.m.r. peak which appears at the average position of NO_2^+, NO_3^- and HNO_3 suggests that rapid exchange occurs between such species[675]. Thermodynamic properties are also listed[676] in Table 81.

The concentration of water formed during the dissociation equilibrium of nitric acid is low[677]; however, HNO_3 is miscible with water in all proportions and can be extracted from 6–16 M aqueous solutions into benzene or toluene as the hemi-hydrate $2HNO_3 \cdot H_2O$. Some properties of the two crystalline hydrates, HNO_3H_2O (Raman spectra of which show that it exists as hydroxonium nitrate[678] $H_3O^+NO_3^-$) and $HNO_3 \cdot 3H_2O$ are given in Table 82, and the existence of a dimer hydrate $2HNO_3 \cdot 3H_2O$ has also been confirmed[679]. A few acid salts such as $NH_4NO_3 \cdot 2HNO_3$ and $KNO_3 \cdot HNO_3$ which may be thought of either as

containing HNO_3 of crystallization or solvated anions are known[680]. However, the evolution of heat which occurs when nitrates are dissolved in HNO_3 is probably due to the formation of such species. Thus although nitric acid is a good ionizing solvent for electrolytes in general, salts are only sparingly soluble unless they produce NO_2^+ or NO_3^- ions.

Physical properties of nitrates of the elements allow a rather arbitrary division into ionic and covalent compounds. In this context the term nitrate is applied to compounds containing nitrate ions, whereas the prefix nitrato refers to materials in which the group is covalently bonded through oxygen[651]. Ionic metal nitrates form hydrated compounds, have high solubility in water and give rise to an extensive aqueous solution chemistry. However, the relatively low melting points of the anhydrous alkali and alkaline–earth metal nitrates and their eutectic mixtures, together with their ease of handling, have made such materials ideal for study as molten salts[681].

18.9. CHEMISTRY AND CHEMICAL PROPERTIES

The decomposition of nitric acid occurs in both the liquid and the gas phase according to the general equation[672]

$$2HNO_3 \rightleftharpoons 2NO_2 + H_2O + \tfrac{1}{2}O_2$$

Like so many decomposition reactions of compounds containing nitrogen and oxygen, the various steps in the proposed mechanisms are further complicated by the possibility of setting up other equilibria. One mechanism is based on the dehydration of nitric acid[682]:

$$2HNO_3 \rightarrow N_2O_5 + H_2O$$

followed by the normal first order decomposition of dinitrogen pentoxide[683]:

$$N_2O_5 \rightarrow NO_2 + NO_3$$

$$NO_2 + NO_3 \rightarrow NO_2 + O_2 + NO$$

$$NO + N_2O_5 \rightarrow 3NO_2$$
An alternative mechanism involves OH radicals[684]:

$$HNO_3 \rightarrow NO_2 + OH$$

$$OH + HNO_3 \rightarrow NO_3 + H_2O$$

$$NO_3 + NO_2 \rightarrow NO_2 + O_2 + NO$$

$$NO + NO_3 \rightarrow 2NO_2$$
A similar mechanism was also proposed for the decomposition of nitric acid under flash photolysis conditions in which the NO_3 radical was identified as an intermediate[685].

[684] H. S. Johnson, L. Foering and R. J. Thompson, *J, Phys. Chem.* **57** (1953) 390.

[685] D. Husain and R. G. W. Norrish, *Proc. Roy. Soc. (London)* A, **273** (1953) 165.

The decomposition of liquid nitric acid is much faster than gas-phase reactions at corresponding temperatures, and considerable effort has been directed to finding additives which may act as inhibitors during storage. However, although the addition of 1% lead dioxide to colourless concentrated nitric acid prevents decomposition to the extent that it remains colourless for some time, water has the greatest inhibiting effect, which suggests that dehydration mechanisms are important[686].

The thermal decomposition of metal nitrates by heating provides a method of preparing nitrites of the more electropositive elements (see section 17.1):

$$2NaNO_3 \rightarrow 2NaNO_2 + O_2$$
The temperature at which decomposition commences varies for different compounds[651, 687] and further decomposition can proceed simultaneously:

$$2KNO_3 \rightarrow K_2O + N_2 + 5/2O_2$$

Heavy metal nitrates decompose directly to the oxide presumably because the corresponding nitrites are thermally so much less stable:

$$2Pb(NO_3)_2 \rightarrow 2PbO + 4NO_2 + O_2$$

Silver nitrate decomposes directly to the metal:

$$2AgNO_3 \rightarrow 2Ag + 2NO_2 + O_2$$

The thermal and explosive decomposition of ammonium nitrate has been discussed elsewhere[645, 688] (see section 5). Covalent halogen nitrates (XO—NO_2) are thermally unstable even at room temperature[655, 689].

In the presence of suitable reducing agents, the oxygen released during solid state nitrate decompositions can give rise to explosive oxidations (e.g.: gunpowder). Thus nitrates in the solid and molten states are strong oxidizing agents, whereas neutral or alkaline aqueous solutions of the nitrate ion are weaker oxidizing agents than nitric acid. The redox properties of nitrate in aqueous acidic and basic solutions are summarized in the Ebsworth diagrams in section 1.6.2, and by which the course of reaction between nitrate and other nitrogen species can be predicted. Some other redox reactions of nitric acid are illustrated by the following equations[690]:

$$2HNO_3 + 3SO_2 \rightarrow 2NO + 2SO_3 + H_2SO_4$$

$$HNO_3 + 3HCl \rightarrow NOCl + Cl_2 + 2H_2O$$

$$2HNO_3 + 3H_2AsO_3 \rightarrow 2NO + 3H_3AsO_4 + H_2O$$

Nitric acid in general behaves as a typical strong acid, and its reactions with metals, oxides, carbonates and other anions constitute important methods of producing nitrates[642, 648, 690]. Metals are usually attacked more rapidly by dilute rather than concentrated nitric acid from which oxides of nitrogen are normally liberated but seldom according to stoichiometry[690]. Pure nitric acid, however, is considered as an acceptor solvent on the basis of its reactions with donor compounds and its inability to solvate metal ions[680]. However, in concentrated sulphuric acid, the solution chemistry of HNO_3 is dominated by the presence of the nitronium ion[672]:

$$HNO_3 + H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2HSO_4^-$$
Such solutions are of importance in aromatic nitration reactions[672, 688, 691], on which a considerable part of the chemical industry is based[637, 642, 647]. Crystalline nitronium salts have been prepared[692], isolated and fully characterized[672].

18.10. BIOLOGICAL PROPERTIES[693]

Nitrates are the most important group of fertilizers and a source of fixed nitrogen which can be taken up by plants rapidly. This may be related to the high solubility of nitrates in water, and also to the requirement of cations such as potassium in the soil. However, nitrate can be lost by reduction to free nitrogen by soil bacteria in denitrification processes, although other organisms are involved in replacing it by nitrification of ammonia.

Liquid nitric acid is dangerous to the body as it penetrates and destroys tissue, the extent of the damage being proportional to the contact time. Nitric acid vapours, or as an aerosol, are particularly toxic, giving symptoms similar to those of nitrous fumes which may only occur after the time of exposure. Contact even to low concentrations for short periods of time should be avoided.

18.11. ANALYSIS OF NITRIC ACID AND NITRATES[694]

A very sensitive spot test for nitrate is the yellow colour produced when it reacts with diphenylamine under short ultraviolet radiation. Nitrates can also be reduced with Devarda's alloy in alkaline solution to ammonia which can be detected or determined by a variety of methods as previously described in section 3.12. A gasometric method for the determination of either organic or inorganic nitrates is available, based on the reduction of nitrate to nitric oxide by mercury in concentrated sulphuric acid:

$$2KNO_3 + 4H_2SO_4 + 3Hg \rightarrow 2NO + K_2SO_4 + 3HgSO_4 + 4H_2O$$

Even a gravimetric method is known using "nitron" (1,4-diphenyl-3,5-endanilo-4,5-dihydro-1,2,4-triazole); but many ions are known to interfere.

[694] K. I. Vasu, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. II, *Nitrogen*, Part II, Longmans, London (1967), pp. 563–673.

Of the numerous colorimetric methods available for the determination of nitrate, the majority seem to be based on nitration of phenols, reactions with amines, or reduction to nitrite followed by a diazotization and coupling reaction.

The analysis of nitric acid poses several problems of its own, which arise mainly from its volatility, reversible decomposition on exposure to light or heat, and high reactivity. Mixtures with sulphuric acid are also encountered through nitrating mixtures and in the manufacture of sulphuric acid.

20. PHOSPHORUS

ARTHUR D. F. TOY

Stauffer Chemical Company, New York

1. ELEMENTAL PHOSPHORUS

1.1. DISCOVERY

Bones, guano, excrement, and fish have been used as fertilizer since antiquity. The major element in these substances responsible for the increase in crop yield was not discovered until 1669. This discovery has been credited to Hennig Brandt, an impoverished German merchant who sought to become rich by converting base metal to gold. According to the account by G. W. von Leibniz[1], Brandt made the discovery while carrying out alchemical experiments with urine. The substance he obtained glowed in the dark and burst into flame when exposed to air; it was subsequently named phosphorus, a term derived from φῶς, light, φορέω, I bear.

The presence of phosphorus in the vegetable kingdom was first detected by B. Albino in 1688, as recorded in his Dissertato de Phosphoro Liquido et Solido[1]. Almost a hundred years later, in 1769–70, phosphorus as an essential ingredient in the bones of both men and animals[1] was recognized by J. G. Gahn and C. W. Scheele. The first discovery of phosphorus in a mineral (pyromorphite, a lead phosphate) was made by Gahn in 1779[2]. Subsequently, T. Bergman and J. L. Proust found phosphorus also in the mineral apatite. The elucidation of the elemental nature of phosphorus and the composition of phosphoric anhydride however was credited to L. Lavoisier[1, 3].

1.2. OCCURRENCE AND DISTRIBUTION

For a century after its discovery, the only source of phosphorus was urine. As the demand for phosphorus and phosphates increased, guano and bones became the main source. In fact, the need for bones in England was so great in the early 1800s that battlefields of Europe were turned to as the source of supply[2]. Bone ash from South America was also a source of phosphate. Bone contains approximately 23% mineral matter of which calcium phosphate calculated as $Ca_3(PO_4)_2$ is 87%, and calcium carbonate 12%[4]. Most of the bones were converted to phosphate fertilizers by treatment with sulfuric acid.

The use of minerals as sources of phosphate began in England in the early 1840s.

[4] Ref. 2, pp. 30–32.

Since only low grade coprolite was available, explorations were undertaken in other countries for richer sources. Phosphatic minerals are quite abundant on the earth. According to Clarke and Washington[5], phosphorus is more abundant than carbon and less than chlorine in the ten mile crust of the earth, hydrosphere and atmosphere. They estimated that phosphorus is twelfth in the list of elements which make up 99.6% of the crust of the earth, or 0.142%. Phosphorus is even found in meteorites of extraterrestrial origin in the form of iron and nickel phosphides.

In *Dana's System of Mineralogy*[6] many naturally occurring crystalline phosphate minerals are listed along with their accepted names. However, only the apatite family of minerals is of industrial importance. Apatites have hexagonal crystalline structure and include fluorapatite, $Ca_5(PO_4)_3F$, chlorapatite, $Ca_5(PO_4)_3Cl$, and hydroxylapatite, $Ca_5(PO_4)_3(OH)$. There is also the carbonate–apatite, $Ca_{10}(PO_4)_6(CO_3) \cdot H_2O$ which is not a true apatite. Apatite deposits are found in many parts of the world. The largest deposit which is actively mined is in the Kola Peninsula, near Kirovsk[7], in the Soviet Arctic part of Scandinavia.

The world's largest source of phosphate, however, is the amorphous phosphate rock or phosphorite, of which the largest known deposits are found in the United States in the states of Florida, Tennessee, Utah, Idaho, Wyoming, Montana, North and South Carolina, Kentucky, Virginia and Arkansas. Important deposits are also found in the countries of Algeria, Tunisia, Egypt and Morocco. Lesser deposits are in the islands in the Indian and Pacific oceans, which include those of the Ocean, Christmas and Nauru Islands and the islands of the Marshall, Pellew, and Society group. Less important deposits which are actively mined are located in Australia, Japan, New Zealand, Belgium, France and England[8].

Origin and Nature of Phosphorite Deposits

The large deposits of phosphorites over the world are believed to have originated from the small quantity of phosphate normally present in granite rocks in the earth's surface. Through weathering and leaching, it found its way into the soil, spring water, and eventually to the sea where it was absorbed and concentrated in the shells, bones, and tissue of marine organisms. Remains of these organisms accumulated in the bottom of the sea along with calcium carbonate, and the latter, due to its higher solubility, gradually leached away. The phosphate which remained formed into compact phosphatic nodules. Over the years, due to the uplift of the ocean floor and other geological changes, some of the phosphatic sediments became deposits in dry land[1].

All of the phosphorites found in the mineral deposits have approximately the same $CaO : P_2O_5 : F$ ratio as the mineral fluorapatite: a typical analysis for F is between 2 to 4%. Their physical character varies from hard and flint-like to soft and plastic. Nearly all contain iron and aluminum oxides, carbonates, silicates, and organic matters. The phosphate content, expressed as $Ca_3(PO_4)_2$ (or BPL, bone phosphate of lime), varies from about 65% in Florida pebbles to about 75% in the high-grade deposits of Morocco, Algeria and Tunisia. Brown rocks of Tennessee and oolitic phosphatic material of Western

[8] Ref. 2, p. 37.

States also have phosphate analysis falling within this range. The crystalline apatite of Kola Peninsula, upon concentration by flotation, yields material up to 88% BPL. Apatite, in spite of its high analysis, is not always competitive with phosphorite on an equal basis for conversion to superphosphate fertilizers by treatment with sulfuric acid. Crystalline apatite in its reaction with sulfuric acid requires about three times as long for completion than the porous phosphorite[9]. This factor is not significant when the material is used for the electric furnace production of phosphorus.

The world production of phosphate rock in 1967 is estimated to be 100 million short tons. In the United States the production is about 39 million short tons with Florida accounting for about 78%, the Western States for 14%, and Tennessee and North Carolina the remainder[10].

1.3. PRODUCTION

Methods

The original process for the production of elemental phosphorus, as described by Robert Boyle in 1680, was based on the method of Brandt[1]. It involved the distillation of a large quantity of partly digested urine to the consistency of a thick syrup. Fine white sand was added and the mixture heated in a retort first gently to remove the volatiles, and then very intensely to produce phosphorus which distilled over and collected under water. When bone ash was used as phosphatic raw material, the process consisted of treatment with sulfuric acid to produce phosphoric acid which was then concentrated and heated with coke in a retort to produce phosphorus.

Production of phosphorus by heating a mixture of silica, coke and phosphate rock was first proposed by Auberton and Boblique in 1867 and the use of the electric furnace for heating such a mixture was proposed by J. B. Readman in 1890[11]. The basic method for producing elemental phosphorus today, except for engineering improvements, is essentially that of the method originated by Readman. Lower grade phosphate sand contaminated with clay is concentrated by washing to an average P_2O_5 content of 28 to 30%. Higher grade sand of 26–28% P_2O_5 content is used directly in combination with washed sand. These fine phosphatic grains are compacted or "nodulized," and then sintered into fused agglomerates having an average diameter of $\frac{1}{2}$ to $1\frac{1}{2}$ in. The nodules, which are mechanically very strong and resist abrasion even at high temperature, are then mixed with silica and coke particles of similar size. Such a mixture is called "furnace burden". A typical furnace burden has a SiO_2/CaO ratio of 0.8 to 1.2 and a P_2O_5/C ratio of 2.3 to 2.6.

The electric furnace for the reaction is lined on the bottom and sides with thick carbon blocks while the top is lined with refractory bricks. In a 65–70 MW furnace the three carbon electrodes which supply power for the reaction weigh about 25 tons each. They go through an almost air-tight seal in the furnace roof into the reaction zone and are supported in a manner which enables them to move vertically automatically depending on the power requirements of the fluctuating furnace conditions. The temperature in the reaction zone is 1400–1500°. The phosphorus produced vaporizes and rises with carbon monoxide and entrained dust through the space between the furnace burden

---

[9] Ref. 2, p. 122.

[10] R. W. Lewis, *U.S. Dept. of Interior, Bureau of Mines, Mineral Industry Survey*, Dec. 1967.

[11] Ref. 2, p. 132.

particles, and the mixture then passes next through a Cottrell electrostatic precipitator where most of the dust is removed. The phosphorus vapor is then cooled, condensed, and collected under water. The CO gas is recovered for use as fuel in the sintering operation. By-product calcium silicate is drawn off from the bottom of the furnace as a molten liquid. The iron phosphide or "ferrophos" formed from the iron impurities present in the phosphate ore is also drawn off as a melt.

Many proposals have been made for modifying the phosphorus production process. They have varied from the use of intimately mixed powdered carbon, phosphate rock and silica for promoting easier reaction to the use of a fluid bed as the reactor[12-15]. All of the proposals are chemically feasible, but thus far none has been able to overcome the consequent engineering problems well enough to replace the electric furnace process.

Chemistry

The mechanism of phosphate reduction is quite complex and there is no complete agreement among investigators on the exact path of each step in the reaction sequence. The overall reaction is generally represented by the following simplified equation:

$$Ca_3(PO_4)_2 + 3SiO_2 + 5C \longrightarrow 3CaSiO_3 + 5CO + P_2$$
Some proposed mechanisms for the reaction are listed below:

Phosphide mechanism[16]:

$$5Ca_3(PO_4)_2 + 40C \longrightarrow 5Ca_3P_2 + 40CO$$
$$3Ca_3(PO_4)_2 + 5Ca_3P_2 \longrightarrow 24CaO + 8P_2$$

Acid displacement mechanism:

$$2Ca_3(PO_4)_2 + 6SiO_2 \longrightarrow 6CaSiO_3 + P_4O_{10}$$
$$P_4O_{10} + 10C \longrightarrow 2P_2 + 10CO$$

CO reduction mechanism:

$$Ca_3(PO_4)_2 + 5CO \longrightarrow 3CaO + 5CO_2 + P_2$$
$$5CO_2 + 5C \longrightarrow 10CO$$
The phosphide theory is generally regarded for thermodynamic reasons as unlikely. A recent study by Dorn[17] on the equilibrium of the system CaO, $Ca_4P_2O_9$, $Ca_3P_2O_8$, Ca_3P_2, CaC_2, CO and P_2, showed that calcium phosphate is reduced by carbon directly to Ca_3P_2 only at a P_2 pressure of greater than 10^4 atm. At lower pressures only CaO is formed.

The acid displacement mechanism has considerable experimental support. According to this mechanism, fused silica behaves as an acid at high temperatures and it displaces P_4O_{10} from $Ca_3(PO_4)_2$. Molten $CaSiO_3$ [18] is formed as a by-product. The expelled P_4O_{10} is reduced by carbon to give elemental phosphorus along with carbon monoxide. These combined reactions are achieved in the temperature range 1250-1500°. In the absence

of silica, thermal decomposition of $Ca_3(PO_4)_2$ to P_4O_{10} and CaO occurs at above $1800°$. Ross, Mehring and Jones[19] found that when pure tricalcium phosphate mixed with one-fifth of its weight of carbon is heated in a reducing atmosphere, 96% of the phosphorus content is volatilized at $1400°$ and 100% at $1550°$.

The decomposition reaction is shown as follows:

$$Ca_3(PO_4)_2 + 5C \longrightarrow 3CaO + P_2 + 5CO$$
requires 418,900 cal with a decomposition temperature of $1385°$. For the same reaction in the presence of silica, as shown in the following equation, the decomposition temperature is reduced to $1190°$ and the heat requirement is 365,350 cal.

$$Ca_3(PO_4)_2 + 3SiO_2 + 5C \longrightarrow 3CaSiO_3 + P_2 + 5CO$$

The formation of calcium silicate flux reduces the fusion temperature of the reaction mixture and changes the environment of the reaction. The molten slag also serves as a fluid medium in which the overall reaction proceeds more readily than is possible with the solid system.

In proposing the CO reduction mechanism, Dorn[17] questioned the validity of the acid displacement theory. From published thermochemical data, he calculated that the P_4O_{10} pressure over $Ca_3P_2O_8 + 3SiO_2$ melt is only 10^{-18} atm. His own experiments have shown that in the reaction of calcium phosphate with carbon in the presence of CO, the tricalcium phosphate is reduced by the CO. The P_2 formed volatilizes off with the by-product CO_2, leaving behind solid CaO. The CO_2 is subsequently reduced by C to CO to continue the reaction. In this process CO gas diffuses into the phosphate particle and the P_2 and CO_2 diffuse out of the particle. One support for the theory is that the reduction also goes, though at a reduced rate, even when the carbon is not in direct contact with the phosphate particle. The heat requirement for the described overall reaction was calculated as 398,000 cal/mole P_2. The observations made by Ross, Mehring and Jones[19] on the direct reduction of phosphate by carbon at $1400–1500°$ may be interpreted as support for the CO reduction mechanism.

Dorn has also studied the reduction of the $CaO–P_2O_5–SiO_2$ melt system. It was shown that a graphite rod partially immersed in the melt has a higher consumption just *above* the melt surface rather than beneath the melt surface. This observation supports the fact that the reduction of calcium phosphate/calcium silicate melt occurs predominately at the melt–vapor boundary via the CO reduction mechanism.

Ershov[20] believes that calcium phosphate is not reduced in an electric furnace until melted. This is based on the analysis of samples of furnace burden taken at different heights from a furnace during overhaul. He found that the P_2O_5 content of the phosphorite decreased from that of the original phosphorite only after it was melted. From his data, he proposed the following mechanism: At the high temperature zone, the phosphorite begins to melt and dissolves some SiO_2. The liquid phase flows down and wets and dissolves solid lumps of phosphorite. The dissolved calcium phosphates then react with the coke which decreases the P_2O_5 content of the melt. The phosphorus produced is vaporized.

In an industrial electric furnace, the yield of elemental phosphorus based on the phosphorus content in the burden is approximately 88–92%. Some of the phosphorus is

[20] V. A. Ershov, *Khim. Prom.* **42** (4) (1966) 283–4.

lost in the calcium silica slag. More of the phosphorus is lost as "ferrophos". Power consumption averages 13,200 kWh or 11,357,557 kcal per ton of phosphorus.

1.4. ALLOTROPES OF PHOSPHORUS AND P_2 VAPOR

White Phosphorus

The most common form of phosphorus is white phosphorus, a solid obtained by the condensation of phosphorus vapor under water. Impurities such as arsenic and hydrocarbons are usually present. For industrial purposes, many methods of purification are used. One method proposed involves the extraction of molten phosphorous with polyphosphoric acid followed by decantation and washing with water. After filtering through a column of activated charcoal and Fuller's earth, the final product contains only 0.005% inorganic and 0.009% organic impurities[21]. Phosphorus may also be purified by redistillation in the presence of an absorbent such as activated carbon[22]. Purified phosphorus is white or colorless depending on the size of the crystals, and has a waxy appearance not unlike that of paraffin. Since it ignites in air with the self-ignition temperature of 34°, it is usually transported under water. Ordinary white phosphorus is the a or high temperature variety with a specific gravity of 1.8232. It is insoluble in water, but very soluble in CS_2 (89.8 g/100 g sat. soln. at 10°)[23], PCl_3, $POCl_3$, liquid SO_2, and liquid NH_3, slightly soluble in alcohol, ether, benzene, xylene, methyl iodide, glycerine, and acetic acid. It crystallizes from CS_2 in rhombic dodecahedral[24]. X-ray diffraction shows that it is cubic with large unit cells containing 56 molecules of P_4 and a lattice constant of 7.17 Å. It is a non-conductor. It has a melting point of 44.1° and a boiling point of 287°.

Beta-phosphorus is obtained by the conversion of the a form at $-76.9°$ under atmospheric pressure; or at 64.4° under 11,600 atm[25]. It consists of hexagonal crystals with a specific gravity of 1.88. Its other properties are similar to those of the a form. The heat of transformation of the a to the β forms is equal to -3.8 ± 0.2 kcal/mole P_4 at $-76.9°$ [26].

P_2 is formed to an appreciable amount when P_4 is heated to 800°. The P_2 in turn dissociates to P and the equilibrium of this latter dissociation has been studied in the vapor phase over $UP-UO_2$. The dissociation energy of P_2 is calculated as to have a most probable experimental value of 114 ± 6 kcal/mole[27]. The heat capacity of P_2 vapor at 25° is 7.63 cal/°C mole; that for P_4 vapor is 16.0 cal/°C mole[28].

Red Phosphorus

Commercial red phosphorus is prepared by heating white phosphorus at about 400° for several hours. Iodine, sulfur or sodium may be used as a catalyst. The residual white phosphorus is removed by wet grinding and boiling with sodium carbonate solution. Red phosphorus under normal temperature and humidity conditions reacts very slowly with

water vapor and O_2 in air. This reaction, catalyzed by metal impurities such as Fe and Cu, results in the formation of phosphine and oxyacids of phosphorus and may be stabilized with 1% by weight of magnesium oxide or sodium aluminate.

Many forms of red phosphorus have been reported[29]. Pauling and Simonetta[30] have suggested that the structure of red phosphorus may be the result of cleavage of one of the P_4 tetrahedron bonds followed by polymerization into the following molecular chain:
The conditions of formation, chain structures of variable length and different terminal groups (such as the catalyst used, or O and OH groups from stray oxygen or water and other impurities) probably account for some of the forms reported in the literature[31].

Red phosphorus as produced by commercial processes is almost entirely amorphous (average density = 2.16 g/cm³). Amorphous red phosphorus may also be produced by ultraviolet radiation of white phosphorus. The latter reaction is responsible for the nodules of red phosphorus seen on the surface of solid sticks of white phosphorus after long storage and exposure to light or the precipitation of red phosphorus from a solution of phosphorus in PCl_3. Photochemical production of red phosphorus is believed to be through the dissociation of P_4 to P_2 molecules which recombine to form polymeric red phosphorus.

Rubenstein and Ryan[32] have studied the preparation of red phosphorus from 300–610° X-ray diffraction data, diffuse reflection spectra, and fluorescence emission data showed only two allotropic forms of red phosphorus. Phosphorus when heated at 420° and lower is deep red and often metallic, while heating higher than 436° gives forms varying in color from deep maroon to orange-red. The two allotropic forms observed were prepared by heating at 570° for 16 hr and 170 hr, respectively. They correspond most to forms IV and V of Roth, DeWitt, and Smith[29].

The most well-characterized red or violet phosphorus is the so-called Hittorf's phosphorus[33]. It was prepared originally by heating phosphorus in contact with lead at a temperature range of 500–600°. The phosphorus which dissolved in the lead while hot separated out on cooling as small dark reddish-violet crystals. Various literature references report Hittorf's phosphorus as form V of red phosphorus and with a crystal structure which is rhombohedral or triclinic and density of 2.34 g/cm³. Thurn and Krebs[34] reported that Hittorf's phosphorus crystallizes in monoclinic form with space group $P2/c$ ($a = 9.21$, $b = 9.15$, $c = 22.59$ Å, and $\beta = 106.1°$); $Z = 84$. The structure is based on two units: a P_8 group and a P_9 group. The units are linked, each through two further P atoms, to form infinite, tube-like structures of pentagonal cross-sections. The tubes are packed parallel to one another to form layers. A double layer consists of two interlocking systems held together by van der Waals' forces.

The enthalpies of transition at 25° were reported by O'Hare and Hubbard[35] for the following processes:

Black Phosphorus

There are four forms of black phosphorus reported in the literature. The crystalline orthorhombic form was originally prepared by Bridgman[25, 36] by heating white phosphorus to 200° under a pressure of 12,000 atm. It has a density of 2.69 g/cm³ and melts at about 610°. Under very high pressure, this orthorhombic form is reported to undergo reversible transition to successively denser rhombohedral and cubic forms[37]. The amorphous form[38] with a density of 2.25 g/cm³ transforms to the orthorhombic form at higher temperature and pressure (see Fig. 1).

In the conversion of white phosphorus to black phosphorus by heat and pressure, soluble impurities present in industrial grade yellow phosphorus inhibit the polymorphous

(Reprinted by permission of John Wiley & Sons Inc.)

transformation. Studies with purified white phosphorus showed that the m.p. of black phosphorus rises smoothly with increase in pressure, and is about 1000° at 18,000 kg/cm² [39]. No new modification is formed up to 20,000 kg/cm² and 1000° [40].

Patz[41, 42] reported that the transformation of colorless phosphorus into black modification at a pressure of 13,868 kg/cm² starts at 201°, 20,802 kg/cm² at 183°, 27,736 kg/cm² at 164°, and 34,670 kg/cm² at 145°. At a pressure of 41,600 kg/cm² only a few minutes were necessary.

Orthorhombic black phosphorus may be made under atmospheric pressure using mercury as catalyst. Purified white phosphorus is distilled into an ampule and heated in the presence of mercury and seed crystals of black phosphorus: 3 days at 280° increase over 1 day to 380°, and hold at 380° for 3 days. The mercury is removed by amalgamation with lead[43].

The black modification of phosphorus can also be prepared in the highly crystalline orthorhombic form from a solution of phosphorus in liquid bismuth[44]. The crystals obtained after dissolving the bismuth matrix with 1 : 1 nitric acid are generally needle
FIG. 2. A part of an infinite puckered layer of phosphorus atoms parallel with the (010) plane in the structure of black phosphorus[44].

shape with the needle axis coincident with the crystallographic a-axis. A complete single-crystal study by Brown and Rundqvist verified the earlier work of Hultgren et al.[45] The cell dimensions are $a = 3.3136\pm0.0005$, $b = 10.478\pm0.001$ and $c = 4.3763\pm0.0005$ Å. Space group is $Cmca$; $Z = 8$. The main atomic arrangement of orthorhombic black

In the lattice of the orthorhombic black phosphorus, up to 74% of the atoms can be substituted by arsenic[46]. The material exhibits a flakiness somewhat similar to that of mica and graphite. It is a semiconductor of electricity with an electrical resistivity of 0.711 ohm cm^{-3} at 0°[47]. From 300 to 700°K, resistivity can be fitted by the expression $\rho_{av} = 4.6 \times 10^{-3}$ exp $(0.35/2kT)$ ohm-cm[48]. At high temperature, it is an intrinsic semiconductor with a gap width of 0.33 eV[46].

Black orthorhombic phosphorus is the least reactive form of the elemental phosphorus;
FIG. 4. Vapor pressure of liquid phosphorus. Liquid does not exist in the region represented by the broken portion of the line due to rapid red phosphorus formation[52]. (Reprinted by permission of John Wiley & Sons Inc.)

completely stable in air. It can be ignited with a match only with difficulty. It sublimes in a nitrogen atmosphere at 490° [25]. The heat of sublimation is 38.7±0.2 kcal/mole P_4 at 25° [26].

By means of the curves C_p vs. T and C_p vs. ln$T$, respectively, the enthalpy change of crystalline orthorhombic black phosphorus between 0 and 298.15°K, $H = 882.6 \pm 1.5$ cal/mole, and the absolute entropy at 298.15°K, $S = 5.457 \pm 0.010$ cal/deg/mole were calculated. At 20–37°K, the heat capacity of phosphorus is proportional to $T^{2.3}$ and at 13–20°K to $T^{2.7}$, where T is the absolute temperature[49].

The rhombohedral form of black phosphorus is detected by high-pressure X-ray

diffraction technique when orthorhombic black phosphorus is subjected to a pressure of 83–102 kb. It is of the A7 (arsenic) type of structure with $a = 3.377$ Å, $c = 8.806$ Å.

The cubic form of black phosphorus, $a = 2.377$ Å, shows up in the X-ray pattern when the pressure is increased to around 124 kb. The transition of the cubic and the rhombohedral forms is reversible at 111 ± 9 kb. When the pressure is returned to atmospheric pressure, only the orthorhombic form is shown[50].

Liquid Phosphorus

The same liquid is obtained no matter whether white, red or black phosphorus is melted or the vapor is condensed[51]. On rapid cooling, white phosphorus is obtained. The vapor pressure curve of liquid phosphorus is shown in Fig. 4[51]. X-ray diffraction studies[53] of liquid phosphorus indicate that the phosphorus atoms are presented in the form of symmetrical P₄ tetrahedral with a P–P distance of 2.25 Å. The density ($d = $ g/cm³) and viscosity (η in centipoises) of pure liquid phosphorus are given by the following equation[49].

$$d = 1.7862 - (9.195 \times 10^{-4})t \text{ for } 280° > t > 10°$$

$$\log \eta = -1.3879 = 514.4/(273.2 + t) \text{ for } 140° > t > 20°$$

Water dissolves to the extent of 3.6 mg H₂O/g P₄ in the temperature range of 25–45°: mercury dissolves 0.29 mg per g P₄ at 25°[52].

The physical properties and physical constants of α-white phosphorus are summarized in Table 1.

TABLE 1. PHYSICAL PROPERTIES AND PHYSICAL CONSTANTS OF α-WHITE PHOSPHORUS[51, 54–57]

Atomic weight	30.9738
Crystal structure	Cubic system lattice constant 7.17 Å
Molecular unit	P₄
Dielectric constant at 20° and 1 atm	4.1 cgse
Electrical resistivity	1×10^{11} ohm-cm at 11°
Density	1.828 g/cm³
Atomic volume of solid	16.9 cm³
Melting point	44.1°
Heat of fusion	$\Delta H_{317.26} = 600 \pm 3$ cal/mole P₄
Boiling point	280.5°
Critical temperature	695°
Critical pressure	82.2 atm
Surface tension (liquid)	43.09 dynes/cm at 78.3°
	35.56 dynes/cm at 132.1°
Index of refraction	1.8244 for D line at 29.2°

Levine and Stull[61] had calculated the thermodynamic functions of gaseous P_4 between 0° and 1000°K with the use of known spectroscopic data. The values for 298.15°K were $S° = 66.893$, $C_p = 16.051$ and $-(G° - H°_{298.15})/T = 66.893$ cal/deg/mole.

1.5. CHEMISTRY AND CHEMICAL PROPERTIES

Atomic Structure

The electronic structure of phosphorus consists of 15 electrons in the ground state distributed as $1s^2\, 2s^2\, 2p^6\, 3s^2\, 3p_x\, 3p_y\, 3p_z$. The atomic energy levels for phosphorus are shown as follows[62]:

[58] Ref. 55, p. 569.

3d   ~2eV

3p   9eV

3s   7.5eV
The gaseous P_4 molecule shows four phosphorus atoms arranged in a regular tetra-hedron with a P–P distance of 2.21 ± 0.02 Å and a moment of inertia about any of its three major axes of 2.51×10^{-40} g/cm² [63]. The nuclear spin of $_{15}P^{31}$ is $\frac{1}{2}(h/2\pi)$, with zero electric quadrupole moment, and therefore suited for interpretation of the electronic structure of its molecules or molecule ions by nuclear magnetic resonance data. In a 10 kG field $_{15}P^{31}$ resonates at 17.24 Mc/s[64].

Pauling and Simonetta calculated that the bonding atomic orbitals in P_4 are 98% $3p$, with only 2% of $3s$ and $3d$ character. Consequently the bonds in P_4 are bent. The P_4 molecule has P–P–P bond angles of 60°, and since an unstrained P–P–P bond angle should
FIG. 5. A sketch demonstrating the manner in which the valence-shell electron density is distributed in three dimensions[66].

be 90° this represents a strain energy of 22.8 kcal/mole of P_4, and accounts for its high reactivity.

Hart, Robin and Kuebler[66], though their study of the electronic spectrum of P_4, have calculated that strong pi bonds are present in the molecule and that their presence leads to a resonance which vitiates the concept of "bend bonds" and "strain energy" in P_4. Based on their calculations, an electron density map shows that regions of highest density are situated symmetrically above each of the triangular faces of the tetrahedral P_4 molecules

with each of the high density regions connected to the other three by lower density streamers, as shown in Fig. 5.

General Types of Phosphorus Compounds and Their Molecular Structures

A phosphorus atom forms many types of compounds. Some of the general types with the orbitals used in the formation of the bonds and their geometry are shown in Table 2 [56, 62, 67].

TABLE 2

Number of bonds or valency	Orbital or hybrid	Directional properties and geometry		Example
3	p		pyramidal	PH_3
	(lone pair present)			
4	sp^3		tetrahedral	PH_4^+ $OP(OH)_3$, $POCl_3$
	(in compounds with PO and PS bond d orbitals of phosphorus may be used in $d\pi-p\pi$ bonding)			
5	sp^3d		trigonal bipyramid	PCl_5, PF_5
6	sp^3d^2		octahedral	PF_6^-

Phosphorus has empty d orbitals of fairly low energy, so if the atom to which phosphorus donates electrons has the same symmetry as the empty d orbitals in the phosphorus, this usually results in back donation. An over-all multiple bond character may result from this phenomenon.

1.6. BIOLOGICAL PROPERTIES

White phosphorus is very poisonous, with a lethal dose of approximately 0.1 g[68], and the maximum allowable concentration of white phosphorus is 0.1 mg/m³ of air[69]. It is absorbed in the liver and in the blood. The chronic disease contracted by workers in factories where yellow phosphorus is carelessly handled is known as necrosis of the bones, especially of the teeth and jaw. It is known also by the common name of "phossy-jaw" disease. With the advent of strict safety and hygienic control in phosphorus factories

[67] H. R. Allcock, *Heteroatom Ring Systems and Polymers*, p. 21, Academic Press, New York (1967).
[68] Ref. 2, p. 5.
[69] M. B. Jacobs, *The Analytical Toxicology of Industrial Inorganic Poisons*, p. 576, Interscience Publishers Inc., New York (1967).

this disease is no longer common. Since one entry of phosphorus to the body is via decayed teeth, periodic dental check-ups are required for all workers and no open cavities are permitted.

The first aid treatment for white phosphorus taken internally consists of emptying the stomach by induced vomiting or stomach pump, or by drinking a glass of water containing $\frac{1}{4}$ g of cupric sulfate. The cupric sulfate is effective because it coats the phosphorus[70] with a layer of copper phosphide.

Phosphorus must never be permitted to come in contact with skin or clothing and prolonged exposure to phosphorus vapor should be avoided. Phosphorus removal after accidental contact is facilitated by application of a dilute cupric sulfate solution which converts finely divided phosphorus particles to black copper phosphide and coats the larger particles with copper phosphide and renders it non-igniting.

1.7. NUCLEAR PROPERTIES

Phosphorus has only one stable isotope, P^{31}. The data on the six radioactive isotopes of phosphorus are summarized in Table 3[71, 72].

TABLE 3

Isotope	Half-life	Type of decay	Major radiations: Approximate energies (MeV) and intensities	Principal means of production	Decay product
$_{15}P^{28}$	0.28 sec	β^+, no α	β^+ 11.0 max. γ 0.511 (200%, $\gamma^{\pm}$), 1.780 (75%), 2.6, 4.44 (10%), 4.9, 6.1, 6.7, 7.0, 7.6 (5%)	$Si^{28}(p, n)$	$_{14}Si^{28}$
$_{15}P^{29}$	4.45 sec	β^+	β^+ 3.95 max. γ 0.511 (200%, $\gamma^{\pm}$), 1.28 (0.8%), 2.43 (0.2%)	Si^{28} (d, n)	$_{14}Si^{29}$
P^{30}	2.50 min	β^+	β^+ 3.24 max. γ 0.511 (200%, $\gamma^{\pm}$), 2.23 (0.5%)	Al^{27} (α, n) S^{32} (d, α) Si^{29} (p, γ)	$_{14}Si^{30}$
P^{32}	14.28 days	β^-	β^- 1.710 max. average β energy: 0.69 colorimetric 0.70 ion ch	P^{31} (n, γ) S^{34} (d, α) S^{32} (n, p)	$_{16}S^{32}$
P^{33}	24.4 days	β^-	β^- 0.248 max. γ no γ	S^{33} (n, p) Cl^{37} (γ, α)	$_{16}S^{33}$

The isotopes P^{28}, P^{29} and P^{34} have half-lives too short to be of interest in isotopic synthesis. Isotopes P^{32} and P^{33} are useful for labelling purposes[73]. Of the two, P^{32} is

[73] R. H. Herber, *Inorganic Isotopic Synthesis*, p. 143, W. A. Benjamin Inc., New York (1962).

commercially available. It is produced by nuclear reactor irradiation with either (1) $P^{31}(n, \gamma)P^{32}$ or (2) $S^{32}(n, p)P^{32}$. Reaction (1) is carried out by the action of thermal neutrons on red phosphorus as the target. No further chemical treatment is required if one allows possible interfering activities such as Si^{31}, Al^{28} with short-lived periods to decay. One disadvantage of this process is the relatively low specific activity that can be obtained. The highest specific activity of P^{32} available as red phosphorus is reported to be 550 mc/g = 0.55 $\mu c/\mu g$.

The production of P^{32} by method (2) uses the very high fast-neutron flux near the core of the reactor. It gives an essentially carrier-free product with specific activities as high as 1 to 5 mc/μg. After a short cooling period only S^{35} remains which may then be removed by distillation at 500°. If the sulfur is purified prior to irradiation other purification steps are seldom necessary[73]. The P^{32} residue may be recovered by dissolution in 0.05 N HCl and radiometrically[74] the yield of the separation approaches 99%.

Red phosphorus, P^{32} and $KH_2P^{32}O_4$ are the two unprocessed forms of radioisotopic phosphorus available commercially.

1.8. USES

Most of the phosphorus produced is converted to phosphoric acids and their various salts. Their chemistry and application will be covered in their respective sections.

Elemental white phosphorus because of its ease of self-ignition in air was originally used for starting a fire. In the late 1780s the "ethereal match" consisted of a slip of paper tipped with white phosphorus sealed in a glass tube. When a fire was needed, the glass tube was broken to admit air to oxidize the phosphorus which ignited the paper. Later developments led to the use of wooden splints with a tip of white phosphorus, chalk or diatomaceous earth, glue and sulfur or paraffin. Potassium chlorate was subsequently also introduced into the formulation. When such a match is struck, frictional heat causes phosphorus to ignite by air. Friction also causes the rapid oxidation of phosphorus and organic binder by potassium chlorate. The combined heat of these exothermic reactions rapidly ignites the sulfur which then transmits the flame to the wooden splint. The inert diatomaceous filler serves the purpose of regulating and moderating the combustion reactions.

Due to the high toxicity of white phosphorus, which exacted a fearful toll of lives among the early matchmakers, its use for matches was banned. This use started in Finland in 1872, and was taxed out of existence in the United States in 1913. White phosphorus was replaced by the much less toxic red phosphorus. This change led to the development of the "safety match" as represented by the book matches. In such matches, a head contains approximately 50% potassium chlorate, 10% animal glue binder, 5% sulfur and the remainder being mostly ground glass on a tip of a paper splint previously dipped in paraffin. A separate friction striking surface has as basic ingredients approximately 50% red phosphorus as the igniting agent, 15% glue as the binder, 30% glass powder as friction agent and 5% zinc oxide or calcium carbonate as stabilizer for the red phosphorus[75].

White phosphorus is used extensively as a chemical warfare agent. When oxidized in an excess of air, it forms phosphorus oxide which appears as a dense white smoke with

very high obscuring power. It is used also in incendiary bombs and shells as a self-igniting agent. Phosphorus-containing munition shells when exploded have the additional property of raining small particles of burning phosphorus which stick tenaciously to the clothing and skin of the enemy.

The sensitivity of phosphorus to ignition is also utilized for amusement purposes, e.g. in caps for cap pistols. These caps have one section of potassium chlorate and the other of red phosphorus, sulfur and calcium carbonate. When the two sections are struck together in a cap pistol, a small explosion results.

Other uses for elemental phosphorus are as poisons in baits for rodents and as ingredients for incendiaries.

2. PHOSPHIDES

Phosphorus reacts with most of the metallic elements at elevated temperature to form phosphides. Each element forms one or more crystalline phosphides of a specific metal-to-phosphorus ratio. Some ratios correspond to the classical valency rule and some do not. Literature references on phosphides are rather numerous. With the introduction of modern phase-analytical methods, many members of this class of compounds are well characterized. The properties of some metallic phosphides were summarized by Farr[76] in 1950. Van Wazer[77] reviewed the subject in 1958 and more recently (1965) Aronsson, Lundström and Rundqvist[78] critically reviewed the preparation, properties and crystal chemistry of various phosphides. The structural chemistry of the phosphides was reviewed by Corbridge[79]. In Table 4 are listed the compositions of well-characterized phosphides compiled by Aronsson, Lundström and Rundqvist[78]. Readers are referred to the above references for detailed information and additional references.

2.1. METHODS OF PREPARATION

1. By the direct reaction of the elements heated in vacuum or in an inert atmosphere: For elements which form several stable phosphides of different metal-to-phosphorus ratio, the correct ratio of the elements must be used. For elements which form only one phosphide, an excess of phosphorus, either red or white, may be used and the excess phosphorus then removed by distillation. Other sources of phosphorus are the phosphorus-rich phosphides which when heated decompose to the lower phosphides with the liberation of phosphorus.

2. By the reduction of metal phosphate with carbon at high temperature: An example of this method is the preparation of calcium phosphide, Ca_3P_2, by the reduction of calcium phosphate with carbon.

3. By the heating of the metal or metal halide, or metal sulfide, with phosphorus

halide or phosphorus hydride: This method may be illustrated by the preparation of boron phosphide by the heating of B_2S_3 with PH_3 at 1200° to 1400°.

4. By the high temperature electrolysis of molten salt baths containing the metal oxide and an alkali phosphate: This was reported to be the only successful method for the preparation of W_3P.

2.2. CLASSES, PROPERTIES AND CRYSTAL STRUCTURES

Phosphides may be divided into two general classes:

(1) Those which are reactive and easily undergo hydrolysis.

(2) Those which are metallic in nature and do not undergo hydrolysis easily.

The alkali and alkaline earth phosphides, as well as the phosphides of the lanthanides

and other electropositive metals, are in general very reactive and hydrolyze in water to give phosphines.

The phosphides of the transition metals constitute the largest and the most studied class of phosphides. These phosphides and the phosphides of the more noble metals are characterized by hardness, high melting point, high thermal and electric conductivity, metallic luster and resistance to attack by dilute alkaline or acids[79]. Some of this class of phosphides, however, will react with hot nitric acid.

The properties of the phosphides are intimately associated with the electronic structure of the metal component. However, minute impurities also produce drastic changes in the properties, especially the electrical properties. Differences in homogeneity and porosity (high melting materials are made by sintering) account for further discrepancies[78].

Phosphides can also be classified as either "phosphorus rich" or "metal rich". The structure of the phosphorus-rich phosphides is that of polymerized phosphorus atoms around the metal atoms. The metal-rich phosphides may be described in terms of coordination polyhedra of metal atoms enclosing phosphorus atoms. The immediate coordination sphere of the metal atoms contains both metal and phosphorus atoms[79].

In Table 5 are listed some examples of phosphides; their method of preparation, crystal structure, molecular data and some physical and chemical properties.

Of the metal–phosphorus systems studied, one of the more important ones is that of iron–phosphorus. Since the iron-phosphides "ferrophos" are produced as by-products in the commercial production of elemental phosphorus, they represent the largest volume of metal phosphides produced. A phase diagram[77] for this system is shown in Fig. 6.

2.3. APPLICATIONS

"Ferrophos" until recently was added to the iron smelting process used to manufacture high-grade steel. In this process, phosphorus in the "ferrophos", along with the phosphorus impurity present originally in the iron, is oxidized and reacted with the calcium and magnesium oxides in the lining of the furnace to form slag. Such phosphate-containing slag is useful as fertilizer. The phosphorus and iron values in ferrophos are thus recovered.

Phosphorus in the concentration of 0.1 to 0.3% as an alloying element in iron greatly increases its strength and corrosion-resistance. Another interesting application for phosphorus in steel is the preventing of sticking of steel sheets together when several sheets are pack rolled[80].

Phosphorus has a marked effect in improving the hot and cold roll characteristics, softening, recrystallization, and grain growth of copper. Alloys of copper with 2–6% phosphorus can be hot-rolled at 450–650° down to 0.021 in. in thickness. This rolling is carried out with light passes which favors the breaking of the copper–copper phosphide eutectic[80].

One application for reactive phosphides depends on their property of releasing the highly toxic phosphines when reacted with moisture. Thus aluminum phosphide is used in formulations for fumigants[81]. Zinc phosphide has been used as the poison ingredient

[80] J. R. van Wazer, *Phosphorus and Its Compounds*, Vol. II, pp. 1823–55, Interscience Publishers Inc., New York (1961).

[81] L. Hüter, U.S. 2,826,486, March 11, 1958, to Deutsche Gold und Silber Scheideanstalt vormals Roessler.

in baits for rodents[82]. Zinc phosphide was reported to have a toxicity (mg/kg) to hens of 10–11, to ducks and geese of 8–10, and to pigs of 10–12[83]. For comparison, the toxicity (mg/kg) of HCN to birds is 0.1 and to rabbits 4.

Calcium phosphide, when reacted with water, releases spontaneously flammable phosphines. This property makes it an important ingredient in certain types of navy sea flares.

Phosphides of tantalum, tungsten, and niobium are resistant to oxidation at high temperature. It has been suggested that nose cones of space vehicles made of these metals be coated with layers of the respective phosphides to protect against too rapid oxidation upon re-entry and passage through the atmosphere[84].

Many phosphides are semiconductors. The energy gap E in eV for BP = 4.5, AlP = 2.5, GaP = 2.25, InP = 1.25[78]. Thus some of these phosphides are proposed as ingredients for transistors.

3. PHOSPHORUS HYDRIDES AND PHOSPHONIUM COMPOUNDS

Investigations on phosphorus hydrides began in the latter part of the eighteenth century. The best known members of this class of compound are phosphine, PH_3, and biphosphine, P_2H_4. The compound PH has been characterized only by spectroscopic means. Some of the higher phosphines have been isolated, but not fully characterized.

3.1. THE PH MOLECULE

The PH molecule does not exist at room temperature. It is formed by the reaction of phosphorus vapor with hydrogen and detected by the prominent spectral band at 3400 Å. This corresponds to the $^3\Pi \rightarrow {}^3\Sigma$ transition with a ground state of $^3\Sigma^-$ The PH distance has been found to be 1.43 Å or a single bond[85]. Peyton[86] in his spectroscopic study of the green chemiluminescence from an atomic reaction between H atom and P vapor, postulated that besides the $^3\Sigma^-$ ground state, there is also a new electronic $^1\Sigma^+$ state. Spectra of PH molecules are also observed in the shock wave decomposition of argon-diluted PH_3 [87].

3.2. PHOSPHINE

Preparation

There are many methods for the preparation of phosphine. Convenient preparative methods for the laboratory are:

1. By the hydrolysis of a metal phosphide such as aluminum phosphide or calcium phosphide. An example of this method is that described by Baudler, Ständeke and Dobbers[88] for the preparation of several hundred grams quantity of phosphine at one time. It involves the hydrolysis of calcium phosphide, and the by-products P_2H_4 and higher phosphines

are simultaneously decomposed thermally into more phosphine along with phosphorus and hydrogen.

2. By the pyrolysis of lower acids of phosphorus[89] such as phosphorous acid at 205–210°; this process is described in ref. 89.

3. By the action of a KOH solution on PH_4I[87]. This method produces very pure phosphine.

For the industrial production of phosphine, white phosphorus is hydrolyzed in the presence of sodium hydroxide; sodium hypophosphite is obtained as a co-product. It is also produced by the electrolytic reduction of white phosphorus. This process with its many variations has been reported in the patent literature[90].

Phosphine may also be formed by the direct combination of gaseous hydrogen and phosphorus. The yield increases with an increase in pressure and a decrease in temperature. This reaction proceeds too slowly to be of practical use[91]. The preparation of phosphine by the reduction of phosphorus trichloride with lithium hydride[92] or lithium aluminum hydride[93] has also been reported.

Structure and Physical Properties of Phosphine

Phosphine has a pyramidal structure with a H–P–H bond angle of 93° 5'—close to the theoretical value for p-bonding. The unshared pair of electrons is thus predominantly s character. It has a P–H ristance of 1.419 Å and a dipole moment of $0.55D$. The average bond energies $E_{P-H} = 76.4$ kcal/mole.

In the mass spectrometer, the most abundant ions and their appearance potentials are:

PH^+ ($m/e = 32$) at 13.1 ± 0.2 eV, PH_3^+ ($m/e = 74$) at 10.4 ± 3 eV,

PH_2^+ ($m/e = 33$) at 14.0 ± 0.2 eV and P^+ ($m/e = 1$) at 16.0 ± 31 eV[94].

In the solid state, phosphine has four modifications[95]. The temperature (°C) and $\Delta H°$ (cal/mole) for various phase changes are as follows:

Temp.	−242.81		−223.67		−185.00		−133.75		−89.72	
$PH_{3(sy)}$	⇄	$PH_{3(s\alpha)}$	⇄	$PH_{3(s\beta)}$	⇄	$PH_{3(s\delta)}$	⇄	$PH_{3(l)}$	⇄	$PH_{3(g)}$
$\Delta H°$	19.6		185.7		115.8		270.4		3,489	
At −170°, phosphine is a face centered cubic with $a = 6.31$ Å[96].

Chemical Properties and Toxicity

A solution of phosphine in water (solubility 26 cc in 100 cc H_2O at 17°) is neither basic nor acidic by pH measurements. The acid constant is about 10^{-29} and the base constant about 10^{-25} [97]. Phosphine undergoes gradual decomposition in water, forming

phosphorus, hydrogen and a solid of the approximate composition of P_2H. A hydrate, $PH_3 \cdot 5.9H_2O$, has been reported[85].

Phosphine burns readily in air (lower explosive limit is 1.79 vol. % in air)[98]. However, in the gas phase oxidation with oxygen, there are upper and lower critical pressures with an intermediate range of explosive oxidation. This has been shown to be a branch chain reaction and is affected by presence of impurities. The product of the oxidation is various oxy-acids of phosphorus and water[94]. Phosphine is stable at room temperature or below, but does undergo thermal decomposition to elemental phosphorus (red) and hydrogen. Phosphine also photodissociates. With flash photolysis at above 1950 Å, PH and PH_2 radicals are detected spectroscopically[99]. Red phosphorus and hydrogen are also obtained in this decomposition reaction[100].

One of the hydrogens in phosphine may be replaced by an alkali metal. Thus $NaPH_2$ may be prepared by the reaction of phosphine with triphenylmethyl sodium, $(C_6H_5)_3CNa$, in an ether solution. From the industrial standpoint, the most important reaction of phosphine is that with formaldehyde in an aqueous hydrochloric acid solution:

$$PH_3 + 4CH_2OH + HCl \longrightarrow (HOCH_2)_4PCl$$
The product, tetrakis (hydroxymethyl) phosphonium chloride[101], is the major ingredient in the formulation with urea–formaldehyde or melamine–formaldehyde resins for the permanent flameproofing of cotton cloth[°°2].

Phosphine is extremely poisonous. The recommended maximum concentration in the atmosphere for 8 hr of exposure is 0.3 ppm by volume. Short exposure tolerance is 50–100 ppm for 1 hr and the immediately fatal concentration is 400 ppm. The garlic odor threshold is about 2 ppm by volume[98]. Symptoms of phosphine poisoning are anorexia, abdominal pain, headache, nausea, running nose, cough and depression. Because of its toxicity, phosphine has been used as a grain fumigant (27,000 lb used in 1964)[98]. Phosphine generated *in situ* from AlP is also used for this purpose (see section on phosphides). For protection against phosphine, gas mask canisters containing specially impregnated activated charcoal are used. Impregnating agents such as $K_2Cr_2O_7$ and Ag_2CrO_4 are described in the patent literature[103].

Phosphine in air may be determined by metering a known volume of air through a tube packed with silica gel impregnated with $AgNO_3$. The quantity (at the ppb level) of phosphine is determined by the length of black color formed in the tube as compared to a known standard[104]. Phosphine may also be indicated (in the 0.1 to 4 parts/liter gas range) by the reduction of a gold salt to produce a blue-violet color of colloidal gold[105].

3.3. PHOSPHONIUM HALIDES

Phosphine reacts with hydrogen halides to form the corresponding phosphonium halides of which the best known is phosphonium iodide, a beautiful colorless tetragonal

crystalline compound. Phosphonium iodide is also prepared by the reaction of phosphorus with iodine in carbon disulfide solution. The carbon disulfide is then evaporated and the residue of P_2I_4 and phosphorus obtained upon treatment with water under CO_2 atmosphere forms the phosphonium iodide[106]. The compound has a vapor pressure of 50 mm at 20° and 760 mm at 62.5°. The melting point is 18.5° (under its own vapor pressure) and the heat of fusion is 12,680 cal/mole. It is easily purified by sublimation. The space group and unit cell data are: space group P_4/nmm, $z = 2$, $a = 6.34$ Å and $c = 4.62$ Å. NMR data showed a P–H distance of 1.42 Å[96]. The calculated total lattice energy is 14.2 ± 5 kcal/mole[107].

TABLE 6. PHYSICAL PROPERTIES OF PH_3

Density $PH_3(g)$ (air = 1) = 1.1829; 1.529 g/liter at 0° and 1 atm
Sp.gr. (D) of $PH_3(l)$ at T (°K) = $D = 0.744 + 0.0005952 (186.8 - T)$[a]
Surface tension of liquid at $-105.9° = 22.783$ dynes/cm[a]
Vapor pressure equation of liquid phosphine =
$$\log p \text{ cm} = 9.73075 - 1.7853 \times 10^{-2}T + 2.9135 \times 10^{-5}T^2 - 1.0273 \times 10^3 T^{-1} \text{ [b]}$$
Vapor pressure PH_3 at m.p. of CS_2 = 171 mm[c]
Colorless gas at r.t. and normal pressure[b]
B.p. = $-87.8°$ [b]
M.p. = $-133.8°$ [b]
Heat of vaporization (kcal) = 3.49
Heat of fusion (kcal)[b] = 0.27
Critical temperature = $+51°$ [b]
Critical pressure = 64 atm[b]
Solubility, water: 26 cc in 100 cc at 17°[d]; cyclohexanol: 286 cc in 100 cc at 25° [b]
Autoignition temperature = 104° to 122°F[e]
Heat of formation (kcal) = 2.29[b]
Entropy $S°_{298}$ = 50.35 cal/deg[a]
Electron affinity = 0.5 eV[f]
Far u.v. adsorption: intense absorption bands of $PH_3(g)$ at 1910 Å[g]
NMR chemical shift from H_3PO_4 = 238 ppm[h]

its heat of fusion is 12,680 cal/mole. Its sublimation point is $-28°$, critical temperature 48.8–50.1° and critical pressure 74.2–75.0 atm[91].

Other phosphonium compounds such as PH_4BF_3Cl, PH_4BCl_4, PH_4BBr_4 and PH_4SO_3Cl have also been reported in the literature[109, 110].

3.4. DIPHOSPHINE AND HIGHER PHOSPHINES

Diphosphine, P_2H_4, formed as a minor co-product in the generation of phosphine by the hydrolysis of calcium phosphide, is separated from phosphine by freezing. It is a liquid which boils at 56° (vapor pressure at 25° $= 200$ mm[93]) and freezes at $-99°$. The specific gravity is 1.02 at 12°. It is quite unstable and decomposes to give PH_3 and polymeric liquid and solid phosphorus hydrides of variable composition[96]. The calculated value for $D(H_2P–PH_2) = 74.1$ kcal/mole[111].

A new phosphorus hydride, P_2H_2, has been reported by Fehlner[112]. It is identified by mass spectrometry from the products of the pyrolytic decomposition of P_2H_4. The triphosphine P_3H_5 is isolated as a white solid also by the decomposition of diphosphine. Baudler and her co-workers[113] have identified a series of higher chain and cyclic phosphines by mass spectrometry from the higher boiling fraction of the product from the hydrolysis of Ca_3P_2 or by the disproportionation of P_2H_4.

4. PHOSPHORUS HALIDES AND PHOSPHORUS PSEUDOHALIDES

Phosphorus combines with halogens in various ratios to form phosphorus halides. Phosphorus monohalides PCl, PBr, and PI are unstable under normal conditions and are detected only in spectral bands. Phosphorus dihalides, PX_2, which are actually X_2PPX_2, are represented by the known compounds P_2F_4, P_2Cl_4 and P_2I_4. The best known of phosphorus halides, the trihalides, are PF_3, PCl_3, PBr_3 and PI_3. Phosphorus pentahalides with the exception of the pentaiodide are all known. There exist also certain phosphorus polyhalides containing more than five halogens per phosphorus atom. Various pseudohalides as well as mixed halides have also been prepared and characterized.

4.1. PHOSPHORUS DIHALIDES (TETRAHALODIPHOSPHINES[114])

Tetrafluorodiphosphine

Phosphorus difluoride or tetrafluorodiphosphine is the newest member of the tetrahalodiphosphine family to be discovered. Parry et al.[115] prepared it in high yield by coupling

two PF_2 groups together under reduced pressure according to the following equation:

$$2PF_2I + 2Hg \longrightarrow P_2F_4 + Hg_2I_2$$
Available data indicated that the compound undergoes hydrolysis reaction as shown in the following equation:

$$2P_2F_4 + H_2O \longrightarrow 2PHF_2 + F_2POPF_2$$
Tetrachlorodiphosphine

Tetrachlorodiphosphine, Cl_2PPCl_2, may be obtained (in low yield) by an electric discharge passing through a mixture of PCl_3 and hydrogen under reduced pressure[114] or by a microwave discharge on PCl_3 at 1–5 mm pressure.

The heat of formation of Cl_2PPCl_2 as estimated from mass spectral data is $\Delta H_f = -106$ kcal/mole, and the P–P bond energy is 58 kcal/mole. NMR spectra, using a frequency of 24,288 Mc/s, give a single peak with a chemical shift of -155 ppm relative to 85% H_3PO_4[116].

Tetrachlorodiphosphine is a colorless liquid with a m.p. of $-28°$. It decomposes on standing at room temperature to PCl_3 and a nonvolatile solid. Hydrolysis of P_2Cl_4 in basic solution has been studied by anion exchange chromatography. This reaction gives 50% P_2H_4 and 50% $P_2(OH)_4$. The latter product then reacts with water to give H_3PO_2 and H_3PO_3[117].

The presence of a lone pair of electrons on each phosphorus atom in P_2Cl_4 permits it to act either as a mono- or difunctional Lewis base. It reacts with nickel carbonyl to form a series of complexes. In the presence of a large excess of $Ni(CO)_4$ at 0° under CO pressure, a yellow white solid $P_2Cl_4 \cdot 2Ni(CO)_4$ is formed which decomposes when the CO pressure is released[118].

Tetraiododiphosphine

Many methods are reported in the literature for the preparation of tetraiododiphosphine: (1) by heating a mixture of iodine with red phosphorus at 180–190°; (2) by heating phosphorus(III) iodide with red phosphorus in n-butyl iodide[114]; (3) by the reaction of iodine with white phosphorus dissolved in carbon disulfide solutions. Evaporation of this last solution produces orange crystalline solid in high yield.

The heat of formation of P_2I_4, $\Delta H_{f298.16}$, is -19.76 kcal/mole $P_2I_4(s)$[119]. The compound has a m.p. of $125.5°$[120]. It is very soluble in carbon disulfide, slightly soluble in benzene, ethyl ether and liquid sulfur dioxide, and may be conveniently recrystallized from chlorobenzene. The crystal structure is triclinic with a P–P distance of 2.21 Å, P–I bond length of 2.475 Å. The dipole moment in carbon disulfide is 0.45 D.

Tetraiododiphosphine in CS_2 solution reacts with oxygen to form phosphorus(III) iodide and an unstable yellow polymer of variable composition of phosphorus iodide and oxygen. Its reaction with sulfur in CS_2 gives $P_2I_4S_2$. Most of the reaction of P_2I_4, however, results in the cleavage of the P–P bond[121]. Thus, hydrolysis in water gives a mixture of oxyacids of phosphorus [including $(HO)_2(O)PP(O)(OH)_2$] along with phosphines. Reaction with bromine splits the P–P bond to produce $PBrI_2$ in about 90% yield[122].

4.2. PHOSPHORUS TRIHALIDES AND PHOSPHORUS TRIPSEUDOHALIDES

Phosphorus Trifluoride

Phosphorus trifluoride (trifluorophosphine) is prepared by the fluorination of phosphorus trichloride with AsF_3, ZnF_2 or CaF_2. The method described in ref. 123 involved the use of zinc fluoride as the fluorinating agent. Other fluorinating agents such as benzoyl fluoride may also be used[124]. The preparation of PF_3 by the reaction of red phosphorus with liquid HF in a closed system has also been reported[125].

The heat of reaction between CaF_2 and PCl_3 obtained at 356.6° in a fluid bed reactor and corrected to 25° was found to be $\Delta H = -2.361$ kcal/mole PCl_3[126]. The standard values of formation at 0° for PF_3 are $\Delta H_0 = -226.03$ kcal/mole, $\Delta F_0 = -242.36$ kcal/mole, $S_0 = 54.78$ e.u. and P-F bond energy is 119.4 kcal/mole[147].

Phosphorus trifluoride is a colorless gas. It forms complexes with transition metals similar to those formed by CO. Like CO it is also very poisonous due to the formation of a complex with blood hemoglobin. It hydrolyzes slowly in moist air, more rapidly in water and very rapidly in alkaline solution.

Pace and Petrella[128] observed two solid transitions, one at 83.75°K with a heat of transition of 59.9 cal/mole and the other at 110.56°K with a heat of transition of 552.3 cal/mole. The heat of fusion at the triple point temperature of 121.85°K was reported to be 223.9 cal/mole. The heat of vaporization at b.p. (171.77°K) is 3.485 kcal/mole compared to the value of 3.94 kcal/mole reported in the earlier literature. The vapor pressure of the liquid is given by the equation:

$$\log P_{mm} = -606.1714/T + 2.98575 \log T - 0.26322$$

The density of the liquid is given as:

$$d = 2.332 - 0.004407\ T$$

The entropy of the gas in the standard state at b.p. is calculated to be 58.48 cal/mole from calorimetric data.

Phosphorus Trichloride

Phosphorus trichloride is industrially the most important of phosphorus halides. It is prepared on a large scale by the chlorination of an excess of white phosphorus dissolved in a refluxing phosphorus trichloride solution. In the laboratory preparation, it is more convenient to replace white phosphorus with red phosphorus[129]. Other methods of preparation are only of academic interest.

The standard heats of information are $\Delta H^{\circ}_{f(l)} = -73.3$ kcal/mole and $\Delta H^{\circ}_{f(g)} = -65.5$ kcal/mole[114]. The vapor pressure is expressed as:

$$\log P_{mm} = 7.472 - 1600/T \text{ (10 mm at 22°, } -50 \text{ mm at 6°, 100 mm at 21°)}$$

The mean bond-dissociation energy $D(P-Cl)$ is 76.2 kcal/mole[130].

The predominant reaction of phosphorus trichloride in a mass spectrometer is the formation of the positive ion PCl_2^+ at 12.5 eV. Other ions formed are PCl_3^+ at 12.2 eV, PCl^+ at 17.5 eV and P^+ at 22.1 eV[131].

Phosphorus trichloride molecule has a pyramidal structure of C_{3v} symmetry. The dipole moment measured in carbon tetrachloride is 0.8 ± 0.1 D[114]. Sobhanadri[132] calculated the dipole moment from molecular orbitals and concluded that the lone pair of electrons contributes to the dipole moment and that the calculations indicate about 8% hybridization for PCl_3. The critical density and critical temperature are 0.520 and 290.0°, respectively[133]. Various other physical properties are listed in Table 7.

Phosphorus trichloride is soluble in ether, benzene, chloroform, carbon disulfide, carbon tetrachloride and sulfur dioxide. The P–Cl bond is highly polar and the phosphorus atom is quite susceptible to nucleophilic attack. It hydrolyzes violently in water, forming HCl and phosphorous acid. When the hydrolysis is carried out under controlled conditions, especially in ice-cold sodium carbonate solution, various mixtures of lower oxoacids of phosphorus are formed.

Reaction of phosphorus trichloride with a stoichiometric quantity of phenol gives triphenyl phosphite:

$$PCl_3 + 3C_6H_5OH \longrightarrow P(OC_6H_5)_3 + 3HCl$$
The direct reaction of phosphorus trichloride with aliphatic alcohols gives dialkyl phosphonate:

$$PCl_3 + 3ROH \longrightarrow (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}H + RCl + 2HCl$$
When the reaction with alcohol is carried out in the presence of a tertiary amine as HCl acceptor, trialklyl phosphite results.

$$PCl_3 + 3ROH + 3R'_3N \longrightarrow (RO)_3P + 3R'_3N \cdot HCl$$

Phosphorus trichloride is an important intermediate for the formation of organic phosphorus compounds containing the carbon to phosphorus bond, e.g.:

$$PCl_3 + RCl + AlCl_3 \longrightarrow [RPCl_3]^+[AlCl_4]^- \xrightarrow{H_2O} RPOCl_2[134]$$

$$2PCl_3 + RH + O_2 \longrightarrow RP(O)Cl_2 + POCl_3 + HCl[135]$$

$$PCl_3 + 3RMgBr \longrightarrow R_3P + 3MgBrCl[136]$$

$$PCl_3 + 3C_6H_5Na \longrightarrow (C_6H_5)_3P + 3NaCl$$

$$PCl_3 + C_6H_6 \xrightarrow{\Delta} C_6H_5PCl_2 + HCl[137]$$

$$PCl_3 + CH_4 \xrightarrow[O_2 \text{ catalyst}]{\Delta} CH_3PCl_2 + HCl[138]$$
The phosphorus atom in phosphorus trichloride is a good electron donor and forms purely

σ-bonded complexes with boron halides. An example of such a complex is $PCl_3 \cdot BBr_3$, a solid of m.p. $42°$[114]. This compound undergoes a halogen exchange reaction on standing to form phosphorus tribromide and boron trichloride.

Phosphorus trichloride is quite toxic and the danger limit is above 4 mg per cubic meter of air. It attacks the respiratory tract and causes a sensation of suffocation and inflammation of the lungs with frothy bloodstained expectoration. A concentration of 600 ppm is lethal in a few minutes. Concentrations of 50–80 ppm are harmful after exposure of 30–60 min and a concentration of 0.7 ppm is the maximum that can be tolerated for exposure of several hours. The maximum allowable concentration is considered to be 0.5 ppm[134]. Accidental contact with skin calls for thorough washing with water.

The important uses for phosphorus trichlorides are as indicated above: (1) as an intermediate for phosphite esters, such as triphenyl phosphite, trimethyl phosphite, tris-

betachloroethyl phosphite and diethyl phosphonate $\left[\begin{array}{c} O \\ \| \\ (C_2H_5O)_2PH \end{array} \right]$, which are all com-

pounds of industrial importance; (2) as a chlorinating agent for converting alkyl alcohols to alkyl chlorides, and organic acids to organic acid chlorides; (3) as intermediate for organophosphorus compounds containing the carbon to phosphorus bonds; (4) as an intermediate for phosphorous acid and metal phosphites; (5) as an intermediate for the preparation of PCl_5, $POCl_3$, $PSCl_3$ and the phosphorus pseudohalogens.

Phosphorus Tribromide

Phosphorus tribromide is prepared by the bromination of an excess of phosphorus in phosphorus bromide as the solvent. Other inert solvents such as benzene or carbon tetrachloride may also be used. Their use, however, necessitates fractionation of the final reaction mixture[140].

Phosphorus tribromide is a colorless liquid. Its vapor pressure is represented by the equation:

$$\log p_{mm} = 7.53 - \frac{2076}{T} \quad (10 \text{ mm at } 48°; 100 \text{ mm at } 84°)$$

The standard heats, free energies, and equilibrium constants of formation at $25°$[119] are as follows:

$$\Delta H_f°(l) = -47.5 \text{ kcal/mole}, \Delta H_f°(g) = -35.9 \text{ kcal/mole};$$
$$\Delta F_f°(g) = 41.2 \text{ kcal/mole}, \log K_f = 30.19$$

Other miscellaneous properties include:

$$C_p(g) = 18,154 + 2.045 \times 10^{-3}T - 0.153 \times 10^5 T^{-2}$$

where T is 298–800°K, and entropy of vaporization, $\Delta S_{446.4} = 20.79$ e.u[119]. The mean bond-dissociation energy D(P–Br) is 61.7 kcal/mole[130]. Other physical constants are shown in Table 7.

Based on electron diffraction or microwave spectroscopy data, the molecule of phosphorus tribromide is pyramidal with a Br–P–Br angle close to $100°$. This structure has been confirmed also by Raman spectral studies[114].

[139] M. B. Jacobs, *The Analytical Toxicology of Industrial Inorganic Poisons*, pp. 576–89, Interscience Publishers Inc., New York (1967).

[140] J. F. Gay and R. N. Maxson, *Inorganic Synthesis*, Vol. II, pp. 147–51, Ed. W. C. Fernelius, McGraw-Hill Book Co., New York (1946).

The chemical properties of phosphorus tribromide follow closely those of phosphorus trichloride except for the difference in reactivity due to the difference in the degree of polarity of the phosphorus halogen bonds. This applies to the action of nucleophilic reagents on the phosphorus atom as well as to the hydrolysis reaction. (Hydrolysis under controlled conditions yields polyacids of complex structures.) The hydrolysis of phosphorus tribromide in acid solution to give HBr and H_3PO_3 involves an energy change of $-67.2\pm$ 0.6 kcal/mole[114]. The oxidation reaction with gaseous oxygen is not so easily controlled as in the case of PCl_3 and results in an explosive reaction with the formation of phosphorus pentoxide and bromine.

Phosphorus Triiodide

Phosphorus triiodide, a hexagonal red crystalline material, is prepared by the direct action of iodine on white phosphorus in carbon disulfide. The heat of formation is reported to be $\Delta H^{\circ}_{f298.16} = -10.9$ kcal/mole[119]. Alternative methods of synthesis involve the action of HI or metal iodide on phosphorus trichloride.

The molecule of phosphorus triiodide is pyramidal in shape with very low polarity of the phosphorus–iodine bond. This is consistent with the observed zero dipole moment of the compound in CS_2 solution. The chemical properties of phosphorus iodide are not as well studied as those of the chloride or the bromide. In general, the products of hydrolysis are quite similar to those from the chloride and the bromide, the major difference being that a greater percentage of phosphine is formed from PI_3 as are compounds with a P–P linkage[114].

4.3. PHOSPHORUS TRI-MIXED HALIDES

Phosphorus tri-mixed halides are formed by the rearrangement of a mixture of the pure trihalides:

$$PBr_3 + PCl_3 \rightleftharpoons PClBr_2 + PCl_2Br$$

The reaction reaches equilibrium in about 1 to 1.5 hr[141]. Existence of the specific compounds is detected by NMR data as well as by Raman and infrared studies. The fluorine containing halides are sufficiently stable for isolation. The chloride-bromides or chloride-iodides have not been definitely isolated as pure compounds[114].

The phosphorus difluoride halides, PF_2Cl, PF_2Br and PF_2I, are prepared by the reaction shown in the following equation[142]:

$$(CH_3)_2NPF_2 + 2HX \longrightarrow PF_2X + (CH_3)_2NH \cdot HX$$

All of these compounds undergo decomposition reaction fairly rapidly and may be stored only at $-196°$. The physical properties of some phosphorus mixed fluoride halides are listed in Table 7.

4.4. PHOSPHORUS TRIPSEUDOHALIDES AND TRI-MIXED HALIDE PSEUDOHALIDES

Phosphorus tripseudohalides are in general prepared by exchange reaction between phosphorus trichloride and the metal pseudohalides.

141 M. L. Delwaulle and M. Bridoux, *Compt. Rend.* **248** (1959) 1342–4.

142 J. G. Morse, K. Cohn, R. W. Rudolph and R. W. Parry, *Inorganic Synthesis*, Vol. X, pp. 153–6, Ed. E. L. Muetterties, McGraw-Hill Book Co., New York (1967).

Phosphorus Tricyanide

This compound is prepared by the action of phosphorus trichloride on silver cyanide in the presence of solvents such as chloroform, carbon tetrachloride or benzene[143]:

$$PCl_3 + 3AgCN \longrightarrow P(CN)_3 + 3AgCl$$

To avoid possible explosion in this reaction, silver cyanide precipitated from slightly acidic silver nitrate solution and stored in a dark bottle is recommended[144].

Pure phosphorus tricyanide is a white needle-like crystalline compound which sublimes at 160–180° and melts close to 200°. It is quite sensitive to water, forming hydrogen cyanide, phosphorous acid and a yellow phosphorus compound. It is, however, stable at room temperature to dry oxygen, air or ozone[145].

The crystals of phosphorus tricyanide are tetragonal with $z = 16$, $a = 14.00$ and $c = 10.81$ Å. The molecules are pyramidal and exhibit C_{3v} symmetry[146].

Phosphorus Triisocyanate

The compound $[P(NCO)_3]$ may be prepared by the action of a suspension of lithium isocyanate $[LiNCO$ from $CO(NH_2)_2$ and $LiCO_3]$ in benzene or phosphorus trichloride[147]. It may also be prepared by treating $NaOCN$ with PCl_3 in liquid SO_2 solvent. It is soluble in acetone, benzene and chloroform. Colton and St. Cyr reported that the structure is iso (P–NCO) and not normal (POCN)[148].

The isocyanate groups react with alcohols to form the corresponding carbamates

$$\begin{array}{cc} \text{H} & \text{O} \\ | & || \\ \end{array}$$

> P–N–C–OR and with ammonia or amines to form the phosphorus containing ureas

$$\begin{array}{ccc} \text{H} & \text{O} & \text{H} \\ | & || & | \\ \end{array}$$

> P–N–C–N–R. The latter type of compounds have been reported to be useful for imparting flame resistance to cotton[149]. The pure compound polymerizes on standing.

Phosphorus Triisothiocyanate, P(NCS)₃

This compound is prepared by the action of ammonium or potassium thiocyanate on phosphorus trichloride in CH_3CN or liquid SO_2 as solvents. The isostructure is indicated by the infrared spectra and molar refraction[150]. It has a m.p. $< -20°$ and b.p. 265°. When heated, it forms a polymer which is stable[151].

Phosphorus Tri-mixed Halide Pseudohalides

Phosphorus triisocyanate and triisothiocyanate also form phosphorus tri-mixed halide-isocyanates and halide-isothiocyanates. The mixed chloride-isocyanates and chloride-isothiocyanates, $PCl_2(NCO)_2$, $PCl(NCO)_2$, $PCl_2(NCS)$ are prepared by the reaction of

the silver isocyanate or thioisocyanate with an excess of phosphorus trichloride. The fluoride-isocyanates and fluoride-isothiocyanates $PF_2(NCO)$, $PF(NCO)_2$, $PF_2(NCS)$ are prepared by the fluorination of the $P(NCO)_3$ or $P(NCS)_3$ with antimony trifluoride[151].

4.5. PHOSPHORUS PENTAHALIDES

The known phosphorus pentahalides are PF_5, PCl_5 and PBr_5.

Phosphorus Pentafluoride

Phosphorus pentafluoride is prepared in a high yield by the reaction of PCl_5 with CaF_2 at $300–400°$ [152]. The heat of formation as determined by fluorination of α-white phosphorus is $\Delta H^{\circ}_{f298}(g) = -381.4 \pm 0.8$ kcal/mole. The average energy of the P–F bonds was calculated as $\Delta E = -109.7$ kcal per bond[153].

Electron diffraction studies showed that PF_5 is a trigonal bipyramid with a significant difference between the lengths of the axial and equatorial bonds: P–F(eq) $= 1.534 \pm 0.004$ Å and P–F(ax) $= 1.577 \pm 0.005$ Å and an average P–F of 1.551 ± 0.001 Å. Calculations by Cotton[154] predict that the axial bonds are weaker than the equatorial ones.

At room temperature, PF_5 is a colorless gas hydrolyzed immediately by water. It is stable in dry glass at $250°$ and can be liquefied under 46 atm pressure at $16°$ [155].

Phosphorus pentafluoride strongly complexes with amines, ethers, nitrates, sulfoxides and organic bases. It is a strong catalyst in ionic polymerization reactions such as the polymerization of tetrahydrofuran to form elastomers[152].

Phosphorus Pentachloride

Chlorination of phosphorus trichloride under controlled conditions results in the formation of phosphorus pentachloride[156]. It is a greenish-white tetragonal crystal, soluble in carbon disulfude and benzoyl chloride. It may be recrystallized from carbon tetrachloride solution.

Electron diffraction studies showed that in the vapor state, the molecule is in the form of a trigonal bipyramid with the phosphorus atom approximating sp^3d hybridization. In the solid state, the crystals have an ionic structure corresponding to $(PCl_4)^+$ $(PCl_6)^-$ with sp^3-hybridization and sp^3d^2-hybridization for the cation phosphorus and anion phosphorus respectively[157]. In the tetrahedral cation, the P–Cl bond is 1.97 Å while in the octahedral anion the planar P–Cl bond is 2.04 Å and the apical P–Cl bond is 2.08 Å. In the gaseous state, the apical P–Cl bond distance is also greater than the distance of the equatorial bonds[158].

[156] R. N. Maxson, *Inorganic Synthesis*, Ed. H. S. Booth, Vol. I, pp. 99–100, McGraw-Hill Book Co., New York (1939).

[157] J. R. van Wazer, *Phosphorus and its Compounds*, Vol. I, pp. 184–261, Interscience Publishers Inc., New York (1958).

[158] D. E. Corbridge, *Topics in Phosphorus Chemistry*, 3 (1966) 57–396.

Phosphorus pentachloride dissociates in the vapor state:

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2$$

and follows the equation:

$$\log K_{mm} = -20,000/(457T) + 1.75 \log T + 6.66.$$

At 160°, the vapor of PCl_5 is 13.5% dissociated. In the exchange of the chlorine atoms of phosphorus pentachloride with radioactive chlorine in carbon tetrachloride solution, it was shown that three equatorial chlorine atoms undergo rapid exchange and the two apical chlorines exchange more slowly[157].

The reaction of phosphorus pentachloride with water is very violent, forming hydrogen chloride and phosphoric acid. However, with a controlled quantity of water, phosphorus oxychloride is formed:

$$PCl_5 + H_2O \longrightarrow POCl_3 + 2HCl$$
Phosphorus pentachloride has been used as a chlorinating agent in organic chemistry:

$$ROH + PCl_5 \longrightarrow POCl_3 + RCl + HCl$$
One interesting reaction is that with ammonium chloride to form various polymeric forms of phosphonitrilic chloride (see section on phosphonitrilic chloride):

$$PCl_5 + NH_4Cl \longrightarrow (PNCl_2)_3\text{-to higher polymers} + 3HCl$$
Phosphorus pentachloride also forms additional compounds with certain metal halides Examples of such compounds are $PCl_5 . BCl_3$, $2PCl_5 . GaCl_3$ and $PCl_5 . AlCl_3$. This reaction results in the transfer of a chloride ion to the acceptor molecule: e.g., $[PCl_4]^+ [AlCl_4]^-$.

Phosphorus Pentabromide

Pure phosphorus pentabromide is obtained by the reaction of phosphorus tribromide with an excess of bromine in carbon disulfide solution. It may be recrystallized from nitrobenzene solution.

Phosphorus pentabromide decomposes completely in the vapor phase to $PBr_3 + Br_2$. In the solid state, it has the structure of $[PBr_4]^+ Br^-$. In CH_3CN solution, phosphorus pentabromide is a conductor with species PBr_4^+ and PBr_6^-. The anion is stabilized by solvation while the cation is relatively stable[158]. The force constants according to the Urey–Bradley field method are $k_1 = 2.19 \times 10^5$ dynes/cm, $k_2 = 0.18 \times 10^5$ dynes/cm, $\gamma_3 = 0.028 \times 10^5$ dynes/cm[159]. It acts as a brominating agent for converting organic acids to acyl bromides. It also forms addition compounds with some metal bromides, e.g., $AuBr_3PBr_5$ or $[PBr_4]^+ [AuBr_4]^-$, $[PBr_4]^+ [BBr_4]^-$, $[PBr_4]^+ [SnBr_5]^-$ [114].

4.6. PHOSPHORUS MIXED PENTAHALIDES

Phosphorus mixed pentahalides are prepared by the addition of one halogen to the phosphorus trihalide of a second halogen. The best known compounds are the mixed fluoride-halides and fluoride-bromides, e.g., PF_4Cl, PF_3Cl_2, PF_2Cl_3, $PFCl_4$, PF_3Br_2, PF_2Br_3, $PFBr_4$ [125].

The compounds PF_3Cl_2, PF_2Cl_3, $PFCl_4$ all appear to have a basic trigonal bipyramid structure. The spectrum of $PFCl_4$ shows the F atom occupying the axial site; the F atoms

[159] H. Gerding and P. C. Nobel, *Rec. trav. chim.* **77** (1958) 472–8.

in PF_2Cl_3 also assume axial positions, while in PF_3Cl_2 the structure is C_{2v}, in which there are one equatorial and two axial F atoms[160]. Hückel-type molecular orbital calculations by van der Voorn and Drago showed that the equatorial p orbitals are more electronegative than the axial orbitals; this is because the phosphorus orbital is concentrated in the equatorial orbitals. This gives rise to stronger equatorial than axial bonds[161]. The vapor-state electric dipole moment was found to be 0.68 ± 0.02 D for PF_3Cl_2, 0 for PF_2Cl_3 and 0.21 D for $PFCl_4$. The differences are attributed to the differences in bonding between equatorial and axial positions of the trigonal bipyramid[162].

In the phosphorus fluorochloride series, the last member to be prepared was PF_4Cl. This was accomplished by the low temperature controlled fluorination of the molecular form of PF_3Cl_2 by SbF_3 [163] (b.p. $= -43.4°$, m.p. $= -132 \pm 3°$, heat of vaporization $= 5.16$ kcal/mole). It decomposes on storage at room temperature slowly to PF_3 and PCl_2F_3.

The mixed phosphorus fluoride–bromide PF_3Br_2 is a solid with a m.p. $-20°$ and a b.p. $ca.$ $106°$, and is prepared by the addition of Br_2 to PF_3. The compound $PFBr_4$ is prepared by passing a bromine–nitrogen mixture into liquid PBr_2F or its CCl_4 solution at $-75°$. The compound is ionic $[[PBr_4]^+F^-]$ at room temperature, m.p. $87°$ (decomp.)[164].

4.7. PHOSPHORUS POLYHALIDES

Phosphorus chlorides of P : Cl ratio greater than 1 : 5 have not been well characterized. Phosphorus polybromides PBr_7 (red crystals), PBr_9 and PBr_{17} (m.p. $14.5°$) have been reported. Crystalline phosphorus poly mixed halides of seven or more halogen atoms per phosphorus have also been reported in the literature. Examples of such compounds are PCl_6I, PCl_5BrI, PCl_3Br_4, $PClBr_5I$, PBr_6I[157]. The crystal structure of PCl_6I as determined by X-ray diffraction shows a mixture of symmetrical tetrahedral $[PCl_4^+]$ cations and linear $[ClICl]^-$ anion. Many of the phosphorus poly mixed halides have not as yet been well characterized.

5. PHOSPHORYL HALIDES, PHOSPHORYL PSEUDOHALIDES, PHOSPHORYL HALIDE-PSEUDOHALIDES, PYROPHOSPHORYL HALIDES AND POLYPHOSPHORYL HALIDES

5.1. PHOSPHORYL HALIDES

Preparation

The most important member of this class of compound is phosphoryl chloride which is prepared commercially by the two methods shown in the following equations:

$$2PCl_3 + O_2 \longrightarrow 2POCl_3$$
$$P_4O_{10} + 6PCl_5 \longrightarrow 10POCl_3$$
Pure oxygen reacts rapidly with PCl_3 at $20–50°$; air is not so effective as an oxidation agent

[160] J. E. Griffiths, R. P. Carter, Jr. and R. R. Holmes, *J. Chem. Phys.* **41**(3) (1964) 863–76.
[161] P. C. van der Voorn and R. S. Drago, *J. Am. Chem. Soc.* **88**(14) (1966) 3255–60.
[162] R. R. Holmes and R. P. Carter, *J. Chem. Phys.* **43**(5) (1965) 1645–9.
[163] R. P. Carter, Jr. and R. R. Holmes, *Inorg. Chem.* **4**(5) (1965) 738–9.
[164] L. Kolditz and K. Bauer, *Z. anorg. u. allgem. Chem.* **302** (1959) 230–6.

The reaction of PCl_5 with P_4O_{10} is generally carried out by chlorinating a slurry of P_4O_{10} in PCl_3. In this manner the handling of two reactive solids is avoided. The PCl_5 formed *in situ* reacts instantaneously with P_4O_{10}, first in the excess PCl_3 and then in the $POCl_3$ product as solvent for the reaction. The standard heat, free energy and equilibrium constants of formation for $POCl_3$ at 25° are:

$$-\Delta H_f°(vapor) = 141.5 \text{ kcal/mole}, \quad -\Delta H_f°(liquid) = 151.0 \text{ kcal/mole}$$
$$-\Delta F_f°(vapor) = 130.3 \text{ kcal/mole}, \quad \log K_f(vapor) = 95.508[165].$$

Phosphoryl bromide can be prepared by methods analogous to those for $POCl_3$. An alternative method reported in the patent literature[166] consists of bubbling gaseous HBr through a mixture of $POCl_3$ in the presence of $AlCl_3$ catalyst at about 80°. When a deficiency of HBr is used, $POCl_2Br$ may be isolated from the reaction mixture. The method described in ref. 167 is that of the reaction between P_4O_{10} and PBr_5.

Phosorhyl fluoride is generally prepared by the fluorination of $POCl_3$ with metallic fluorides such as lead, zinc, silver, or sodium fluoride. When sodium fluoride is used, the reaction can be carried out in such nonaqueous solvents as CH_3CN by heating under atmospheric pressure[168]. When benzoyl fluoride is used as the fluorinating agent, $POCl_2F$ and $POClF_2$, in addition to POF_3, are also obtained[169]. Phosphoryl fluoride may also be prepared directly by the action of MgF_2 on $Mg_2P_2O_7$ at above 750° [170]. The phosphoryl mixed fluoride–chloride and mixed fluoride–bromide may also be prepared by the fluorination of $POCl_3$ or $POBr_3$, respectively, with SbF_3.

The compound $POCl_2Br$ in addition to the process of reacting $POCl_3$ with HBr in the presence of $AlCl_3$ catalyst can be prepared by the bromination of $C_2H_5POCl_2$. In this reaction ethyl bromide is the by-product. Phosphoryl chloride–dibromide, $POClBr_2$, has been reported to be prepared by the action of dry HBr on $POCl_3$ at 400–500° [171]. Kuchen and Ecke[172] isolated $POCl_2Br$ and $POClBr_2$ from a mixture resulting from heating PBr_3 and PCl_5 followed by reaction with bromine and subsequent heating with P_4O_{10}. In contrast to the mixed phosphorus trihalides, mixed phosphoryl chloride–bromide does not form by the reorganization of $POCl_3$ and $POBr_3$ at room temperature[171].

Structure and Properties

Phosphoryl halides, as shown by electron diffraction, microwave studies, and Raman spectra, have a tetrahedral structure with the phosphorus atom surrounded by four other atoms. Nagarajan and Mueller[173] showed that the chemical shift of ^{31}P NMR in the series OPF_3, OPF_2Cl, $OPFCl_2$ and $OPCl_3$; when the halogen atoms are substituted by less negative atoms, the ^{31}P resonance signal is shifted to a lower field. In the series $OPCl_3$, $OPCl_2Br$, $OPClBr_2$ and $OPBr_3$, the reverse is true. This is explained as due to the decreasing

effect of the screening of the P nucleus with increasing electronegativity of the ligand as well as the double bonding character of the P–F bond.

The mean bond dissociation energies calculated from thermochemical data for $O=PX_3$ are $D(P=O) = 129.8$ kcal/mole for POF_3, 127.5 kcal/mole for $POCl_3$, 124.9 kcal/mole for $POBr_3$, i.e., an increase in $D(P=O)$ occurs with an increase in the electronegativity of the halide[174]. Other properties of phosphoryl halides are listed in Table 8.

Reactions of Phosphoryl Chloride

Phosphoryl chloride (phosphorus oxychloride) is at present the only phosphoryl halide produced in a large volume. Its major use is as an intermediate for the synthesis of phosphate esters. Phosphorus oxychloride reacts with an excess of phenols at elevated temperature usually in the presence of catalyst such as $MgCl_2$ or $AlCl_3$ to form triaryl phosphates:

$$3ArOH + POCl_3 \longrightarrow (ArO)_3P = O + 3HCl$$

Its reaction with aliphatic alcohols to form neutral trialkyl phosphate, $(RO)_3P = O$, must be carried out under carefully controlled conditions or in the presence of an acid acceptor in order to prevent the attack of the neutral ester by HCl. Neutral chloroalkyl phosphates are formed by the reaction of $POCl_3$ with alkylene epoxides:

$$3\overset{\displaystyle O}{\overset{\displaystyle /\,\backslash}{CH_2CH_2}} + POCl_3 \xrightarrow[\text{TiCl}_4]{} (ClCH_2CH_2O)_3P = O$$

Phosphorus oxychloride forms addition compounds such as $POCl_3 \cdot BCl_3$, $POCl_3 \cdot BBr_3$, $POCl_3 \cdot AlCl_3$, $POCl_3 \cdot TiCl_4$ and $POCl_3 \cdot MoCl_5$. In addition, in complexes such as $Cl_3POSbCl_5$, X-ray analysis indicates that coordination occurs through the oxygen atom: $Cl_3PO \rightarrow SbCl_5$. This mechanism is confirmed by the lowering of the $P = O$ stretching frequency in the IR[175]. Addition compounds with $MgBr_2$, $MgBr_2 \cdot 2POCl_3$ and $MgBr_2 \cdot 3POCl_3$, are formed by the reaction of $POCl_3$ with $MgBr_2$ in a molar ratio of $\geq 2 : 1$ at room temperature. Coordination in these compounds is also through the oxygen as donor atom as evidenced by the decrease in ~ 30 cm^{-1} absorption in the P=O frequency of the adducts. The compound $PSCl_3$ without the P=O group does not react analogously with $MgBr_2$ [176]. Experimental data on other addition compounds of $POCl_3$ do not so clearly indicate whether the oxygen or chlorine atom of $POCl_3$ acts as the electron donor in the complex formation[171]. In a system such as $OPCl_3–SbCl_5$, two modes of coordination are possible:

$$OPCl_2{}^+SbCl_6{}^- \overset{(a)}{\longleftarrow} OPCl_3 + SbCl_5 \overset{(b)}{\longrightarrow} Cl_5Sb \leftarrow OPCl_3$$
As has already been shown, the coordination through the oxygen (b) has been proven to be more significant. Further evidence on this is that the formation of a coordinate bond from the oxygen to the metal weakens the back-donation of electrons from the oxygen to the phosphorus and thus reduces the $P = O$ bond order, as indicated by the strong bathochromic shift of the $P = O$ frequency[177].

Gutmann has studied the acid and base reaction in $POCl_3$ as a non-aqueous solvent.

[174] C. T. Mortimer, *Pure Appl. Chem.* **2** (1961) 71–6.
[175] D. E. C. Corbridge, *Topics in Phosphorus Chemistry*, 3 (1966) 63–363.
[176] M. Baudler, G. Fricke and H. I. Oezdemir, *Z. anorg. u. allgem. Chem.* **339**(5–6) (1965) 262–73.
[177] H. Teichmann and G. Hilgetag, *Angew. Chem., Intern. Ed.* **6**(12) (1967) 1013–23.

Experimental evidence indicates that POCl₃ may ionize as shown in the following equation:

$$POCl_3 \rightleftharpoons POCl_2^+ + Cl^-$$

or

$$2POCl_3 \rightleftharpoons POCl_2^+ + POCl_4^-$$

Thus in POCl₃ solvent, AlCl₃ would be a Lewis acid and pyridine a Lewis base[171].

$$AlCl_3 + POCl_3 \rightleftharpoons POCl_2^+ + AlCl_4^-$$

$$C_5H_5N + POCl_3 \rightleftharpoons C_5H_5N \cdot POCl_2^+ + Cl^-$$

Phosphoryl chloride addition compounds have been used for the separation of closely related metals, e.g., the 1 : 1 addition product of POCl₃ with NbCl₅ and TaCl₅ may be separated by fractional distillation to recover the Nb and Ta values[178]. The insolubility of AlCl₃.POCl₃ in organic solvents renders POCl₃ useful for the complete removal of AlCl₃ from Friedel–Crafts reaction mixtures[179].

5.2. PHOSPHORYL PSEUDOHALIDES

Phosphoryl isocyanate and phosphoryl isothiocyanate as well as the mixed halide-isocyanate and halide-isothiocyanate are known.

Phosphoryl isocyanate, OP(NCO)₃, is prepared by the action of POCl₃ on AgNCO in benzene solvent[180]. It may also be prepared by the oxidation of P(NCO)₃ with anhydrous liquid SO₃ in anhydrous liquid SO₂ solvent[181].

Phosphoryl isothiocyanate, OP(NCS)₃, can be prepared either by the reaction of POCl₃ with AgNCS, KCNS or NaCNS in benzene solvent[180, 182] or by the reaction of POCl₃ with NH₄SCN in MeCN solvent[183]. Trimethylsilanyl isothiocyanate may also be used as the source of the isothiocyanate moiety. The by-product in this case is (CH₃)₃SiCl[184]. The iso-structure of the isothiocyanate is indicated by molar refraction while the structure of the isocyanate is not so definite[180].

Both the isothiocyanate and isocyanate can be isolated as pure compounds, but they polymerize on standing or heating. The isothiocyanate reacts with 1,4-C₆H₄(NH₂)₂ and H₂N(CH₂)₆NH₂ to form phosphorus-containing polymers[182]. The isocyanate has been claimed in the patent literature[185] to impart flame-and-glow resistance to cellulosic textiles.

5.3. PHOSPHORYL HALIDE-PSEUDOHALIDES

The mixed halide–isothiocyanates such as OPF₂(NCS), OPF(NCS)₂, OPCl₂(NCS), OPCl(NCS)₂ and the mixed halide–isocyanates such as OPF₂(NCO), OPFCl(NCO), OPCl₂(NCO) have also been reported in the literature.

The compound OPF₂(NCS) is prepared by the reaction of KSCN with pyrophosphoryl

tetrafluoride at room temperature, while $OPF(NCS)_2$ is obtained through the disproportion-ation of $OPF_2(NCS)$ at around 65° [186]. For $OPF_2(NCO)$ (b.p. 69°) the method of pre-

$$\overset{O}{\underset{\|}{}}\ \overset{O}{\underset{\|}{}}$$

paration involves the action of KOCN on F_2POPF_2 [187].

The mixed chloro-isothiocyanate can be obtained by the ligand exchange between $OPCl_3$ and $OP(NCS)_3$ at 130–150°. Thus $OPCl_2(NCS)$ and $OPCl(NCS)_2$ are detected in the equilibrium mixture by means of the NMR spectra[188]. The compound $OPCl_2(NCS)$ can also be obtained by the reaction of an excess of $POCl_3$ with AgNCS in benzene solvent[180].

In the mixed phosphoryl halide–isocyanate series, $OPCl_2(NCO)$ (b.p.$_{50}$ 60 – 64°) is prepared in good yield by the reaction of PCl_5 with $H_2NCOOC_2H_5$ [189, 190]. The product is unstable and partially decomposes on storage at room temperature. Fluorination of $OPCl_2(NCO)$ with SbF_3 gives $OPF_2(NCO)$ (b.p. 68–68.5°, n_D^{25} 1.3381, d_{25} 1.5899) and $OPFCl(NCO)$ (b.p. 101 – 103°, n_D^{25} 1.4024). When $OPF_2(NCO)$ is reacted with CH_3OH in CH_2Cl_2 solvent, a high yield of $OPF_2(NHCO_2CH_3)$ is obtained. The reaction with amines gives $OPF_2(NHCONR_2)$[189]. Reaction of $OPCl_2NCO$ with the alcohols and phenols also gives the corresponding carbamates[190, 191] and $OPCl_2(NHCOOH)$ is obtained by the interaction of $OPCl_2(NCO)$ with one mole of H_2O added in the form of concentrated HCl[192].

5.4. PYROPHOSPHORYL HALIDES AND POLYPHOSPHORYL HALIDES

$$\overset{O}{\underset{\|}{}}\ \overset{O}{\underset{\|}{}}$$

Pyrophosphoryl fluoride, F_2POPF_2, is prepared by the dehydration of two moles of $HOP(O)F_2$ with P_2O_5. It has a b.p. of 71°. The symmetrical structure is consistent with NMR data[193].

The original methods for the preparation of pyrophosphoryl chloride, i.e., by the oxidation of phosphorus trichloride or by the controlled hydrolysis of phosphoryl chloride, resulted only in a 10 to 15% yield. Grunze[194] was able to isolate it in 30% yield by the fractionation of a reaction mixture of P_4O_{10} and an excess of $POCl_3$ which had been heated in a sealed tube for 48 hr at 200°. When the reaction with P_4O_{10} is carried out with PCl_5 using a $PCl_5 : P_4O_{10}$ ratio of 4 : 1, a lower temperature of 105° may be used to give a 59% yield of pyrophosphoryl chloride[195]. The yield of pyrophosphoryl chloride is increased to greater than 90% by the reaction of one mole of PCl_5 with 2 moles of $HOPO(Cl_2)$ (prepared from partial hydrolysis of $POCl_3$ or from the sealed-tube reaction of H_3PO_4 with $POCl_3$). An equimolar quantity of $POCl_3$ is formed in this reaction[196].

$$PCl_5 + 2HOP(O)Cl_2 \longrightarrow Cl_2(O)POP(O)Cl_2 + POCl_3 + 2HCl$$

[194] H. Grunze, *Z. anorg. u. allgem. Chem.* **296** (1958) 63–72.
[195] P. C. Crofts, I. M. Downie and R. B. Heslop, *J. Chem. Soc.* (1960) 3673–5.
[196] H. Grunze, *Z. Chem.* **2** (1962) 313.

Pyrophosphoryl chloride has also been obtained by the heating of $HOP(O)Cl_2$ with an excess of $POCl_3$ at 90° [197], or by the vapor phase reaction of $CH_3OP(O)Cl_2$ with an excess of $POCl_3$ at above 150° [198].

Pyrophosphoryl chloride is a fuming liquid with a b.p. $= 90°$ at 12 mm, m.p. $= -165°$, and $d_4^{25} = 1.821$ g/cm^3. It is extremely sensitive to attack by atmospheric moisture and decomposes partially at its boiling point at the range of 210–215°. The NMR chemical shift is 10 ppm from H_3PO_4.

The symmetrical pyrophosphoryl difluoride dichloride $O[P(O)ClF]_2$ has been isolated from a reaction mixture obtained by heating $POCl_2F$ with P_4O_{10} for 48 hr at 200°. It has a b.p. of 36° at 12 mm, n_D^{20} 1.3860 and d_{20}^{20} 1.7918. The symmetrical nature of the compound was confirmed by conversion to $O[P(O)(NEt_2)F]_2$ by reaction with diethyl amine and to $C_2H_5OP(O)ClF$ by reaction with ethyl alcohol [199].

Various polyphosphoryl chlorides have also been reported in the literature. Grunze[194] heated $POCl_3$ with P_4O_{10}, and after the distillation of $POCl_3$ and $P_2O_3Cl_4$ from the reaction mixture, obtained a glassy residue with a composition of (PO_2Cl) from which $(PO_2Cl)_3$ was isolated. Presumably the latter trimeric compound is a cyclic phosphoryl chloride:
A product with an empirical composition of PO_2Cl has also been obtained by the treatment of $(PNCl_2)_3$ with an excess of Cl_2O. Such a product can be heated to 300° without decomposition [200].

6. THIOPHOSPHORYL HALIDES AND THIOPHOSPHORYL PSEUDOHALIDES

6.1. THIOPHOSPHORYL HALIDES

The preparation of thiophosphoryl halides, SPX_3 (phosphorus sulfohalides), is analogous to those for the corresponding phosphoryl halides.

Thiophosphoryl Fluoride, SPF_3

This compound is prepared by the fluorination of $PSBr_3$ with antimony fluoride[201]. It can also be prepared from $PSCl_3$ by fluorination with KSO_2F[202]. Another method is

[197] M. Becke-Goehring and E. Fluck, Ger. 1,098,495, 5 June 1959, to Chemische Fabrik Joh. A. Benckiser G.m.b.H.

the fluoride–chloride exchange reaction between $PSCl_3$ and NaF in tetramethylene sulfone solvent at 170° under atmospheric pressure (53% conversion)[203].

Thiophosphoryl fluoride reacts with $(CH_3)_2NH$ to give $(CH_3)_2NP(S)F_2$ [204]. The reaction is not clear-cut since other phosphorus-containing products are also formed.

Thiophosphoryl Chloride

A convenient laboratory method for the preparation of $PSCl_3$ is by heating an intimately mixed powdered phosphorus pentachloride with powdered phosphorus pentasulfide[205]:

$$P_2S_5 + 3PCl_5 \longrightarrow 5PSCl_3$$
Commercially it is prepared by the addition of sulfur to PCl_3 in presence of a catalyst such as $AlCl_3$. In this reaction the mechanism assumes the formation of $AlCl_3 \cdot PCl_3$ complex as the intermediate[206]:

$$PCl_3 + AlCl_3 \longrightarrow AlCl_3 \cdot PCl_3$$
$$AlCl_3 \cdot PCl_3 + S \longrightarrow PSCl_3 + AlCl_3$$
Other materials such as $FeCl_3$, activated charcoal, and Na_2S_5 [207] are also active catalysts.

The heat of formation of $PSCl_{3(l)}$ at 25° is -79.2 kcal/mole. The P=S group has a dissociation energy D of 61 kcal/mole when $H_f^\circ(s) = 57$ kcal/mole or 70 kcal/mole when $H_f^\circ(s) = 66$ kcal/mole[208].

Spectral studies on $PSCl_3$ as well as other thiophosphoryl halides are in agreement with X-ray and electron diffraction studies that it has a tetrahedral structure with the phosphorus atom surrounded by three chlorine atoms and a sulfur atom[209]. The characteristic infrared adsorption frequency for the P=S group of $PSCl_3$ is 750 cm^{-1}, and is affected when the chlorine atoms are replaced by other groups[210].

Thiophosphoryl chloride is a colorless fuming liquid having two allotropic forms: the α forms which solidify at $-40.8°$, and the α form which solidifies at $-36.2°$. It is soluble in benzene, carbon tetrachloride, carbon disulfide and $CHCl_3$, and hydrolyzes slowly in water yielding orthophosphoric acid, hydrochloric acid and hydrogen sulfide[206]:

$$PSCl_3 + 4H_2O \longrightarrow H_3PO_4 + 3HCl + H_2S$$
It reacts with aqueous sodium hydroxide to give the thiophosphate Na_3PO_3S[211]. The reaction with one mole of alcohol gives $ROPSCl_2$ but its reaction with a second mole of

$$\overset{\text{S}}{\underset{\|}{}}$$

alcohol for the formation of $(RO)_2PCl$ is very poor and not clear cut. It does react with

alcoholates or an excess of the alcohols in the presence of a base to form the neutral ester $(RO)_3P\text{=}S$.

The complex $SPCl_3.AlCl_3$ according to ^{31}P–NMR and conductivity measurements appears to exist in CH_2Cl_2 solution as the chloro complex $SPCl_2^+$ $AlCl_4^-$ [212]. Speculation is that some neutral complexes with other thiophosphoryl compounds are coordinated through the sulfur atom of the P=S group, as indicated by an appreciable bathochromic shift of the P=S frequency due to the sulfur–metal coordination. Teichmann and Hilgetag[213] advanced the theory that the thiophosphoryl sulfur is a typical "soft base" and reacts preferentially with soft acid, i.e., the sub-group B-metals, halogens and sp^3 hybridized carbon and that it is largely inert to "hard acids" such as protons, $\diagdown C\text{=}O$, and tetrahedral phosphorus.

Thiophosphoryl Bromide

This compound is prepared by adding P_2S_5 to freshly prepared PBr_5 (from red phosphorus and liquid bromine) and the mixture heated in the water bath for 2 hr[201] or by the heating of PBr_3 with S under nitrogen at 130° [214]. The product is a yellow solid soluble in such organic solvents as carbon disulfide, chloroform and ether. It is attacked only slowly by cold water.

Thiophosphoryl Iodide

Baudler et al.[215] reported the preparation of PSI_3 by the reaction of PI_3 with sulfur in CS_2 solvent for 3 to 4 days at 10–15° in the absence of light. It is obtained as brick-red to brown-red leaves from CS_2 and can be kept at $-20°$, but decomposes at room temperature in the presence of light or when it is heated to its m.p. of 48°. Raman and infrared measurements show the characteristic frequencies of 309, 321, and 673 cm^{-1}.

Thiophosphoryl Mixed Halides

Thiophosphoryl fluoride–chloride and fluoride–bromide can be prepared by the fluorination of $PSCl_3$ or $PSBr_3$ with SbF_3. An interesting method is by the decomposition of N,N-diethyl amide of difluorophosphoric acid, $(C_2H_5)_2NP(S)F_2$, with HCl to give $P(S)ClF_2$ (80% yield) and with HBr to give $P(S)BrF_2$ (33% yield)[216].

Thiophosphoryl chloride–bromide can be obtained by the fractionation of a reaction mixture resulting from the heating of PBr_3 with PCl_5 followed by addition of red phosphorus and then heated with sulfur[214]. The compound $P(S)Cl_2Br$ has a b.p. of $42-44°$ at 13 mm, and the $P(S)ClBr_2$ has a b.p. of 67° at 13–14 mm.

6.2. THIOPHOSPHORYL PSEUDOHALIDES AND THIOPHOSPHORYL HALIDE-PSEUDOHALIDES

Thiophosphoryl isocyanate, $PS(NCO)_3$, and isothiocyanate, $PS(NCS)_3$, as well as the mixed halide–isocyanate and mixed halide–isothiocyanate are also known. The compound

$PS(NCO)_3$ is obtained by the addition of sulfur to $P(NCO)_3$ at 140° [217]. It is stable when formed but polymerizes to a solid on heating. The compound $PS(NCS)_3$ is prepared by the reaction of $PSCl_3$ with NH_4SCN in SO_2 solvent at $-30°$ [218],

$$SPCl_3 + 3NH_4SCN \xrightarrow[-30°]{SO_2} SP(NCS)_3 + 3NH_4Cl$$
or in CH_3CN as solvent at room temperature[219].

The thiophosphoryl fluoride diisothiocyanate, $SPF(NCS)_2$, is obtained by the reaction of $Cl_2P(S)F$ with KSCN (b.p. 46–47° at 1 mm, d_4^{20} 1.4827, n_D^{20} 1.6390). It is a colorless liquid with a sharp odor and powerful lachrymatory properties. It decomposes gradually on storage and hydrolyzes slowly in water[220]. The compounds $SPF(NCS)_2$ and $SPF_2(NCS)$ are prepared by the fluorination of $SP(NCS)_3$ with SbF_3 under reduced pressure[221].

Liquid exchange reactions between $SPBr_3$ and $SP(NCS)_3$ result in the formation of $SPBr_2(NCS)$ and $SPBr(NCS)_2$ as indicated by the new lines in the NMR spectra[218]. The equilibrium state for this ligand exchange reaction is reached after heating at 150° for 156 hr.

Compositions with various ratios of phosphorus–sulfur–halogen, other than those described, have also been reported in the literature. Many of these compounds are as yet not well characterized.

The properties of some thiophosphoryl halides and thiophosphoryl pseudohalides are listed in Table 9.

7. PHOSPHORUS OXIDES

The oxidation of white phosphorus takes place by a chain reaction between a lower and upper limit of oxygen pressures. At the lower limit, the oxygen chain carriers are destroyed by impact with the walls and at the upper limit triple collision occurs and O_3 is formed[222]. The net result is the formation of many intermediate oxidation products as represented by the many oxides reported in the literature. Of the oxides, phosphorus pentoxide only is commercially important. Phosphorus trioxide has been the subject of many recent investigations. Much less is known, however, on phosphorus tetroxide and other oxides such as P_4O_7, P_4O_8, and P_4O_9.

7.1. PHOSPHORUS MONOXIDE

Phosphorus forms a diatomic molecule, PO, with oxygen. It is unstable under ordinary conditions and is detected in the vapor state only in spectral bands. Cordes and Warkehr[223] showed that the systems correspond to $^2\Sigma \rightarrow X^2\pi$ and $^2\pi \rightarrow X^2\pi$ transitions. They reported the dissociation energy of PO as 5.30 eV. Other workers calculated the PO

dissociation energy as 6.2 eV[224] and 6.8 eV[225]. The P–O distance is 1.447 Å and the excitation energy for the molecule is 143 kcal/mole. The dissociation is to oxygen and an excited phosphorus atom[226].

A polymeric $(PO)_n$ has also been reported. It is formed by the electrolysis of $POCl_3$ in $(C_2H_5)_3N.HCl$ at 0° or by the reaction of $POBr_3$ with magnesium in C_2H_5OH solution. The product is a brownish amorphous–crystalline substance insoluble and stable in water but decomposes in an aqueous alkali solution with liberation of PH_3. It oxidizes to P_2O_5 in an oxygen atmosphere at 300° [227].

7.2. PHOSPHORUS TRIOXIDE

Phosphorus trioxide, P_2O_3 or P_4O_6, is prepared by the controlled oxidation of phosphorus at a pressure of 90 mm with air enriched to contain 75% of total oxygen[226]. A more recent method is by the oxidation of phosphorus with N_2O at 550–600° under 70 torr. A yield of 50% of P_4O_6 is obtained[228]. The usual contamination of 1 to 2% of dissolved white phosphorus is removed by conversion to the less soluble and less volatile red phosphorus by u.v. radiation followed by distillation *in vacuo*.

Phosphorus trioxide has a tetrahedral symmetry of the point group T_d. This is confirmed by two strong absorption bands at 639 and 911 cm^{-1} together with seven Raman frequencies[229]. The phosphorus atoms are located at the corners of a regular tetrahedron and each of the six oxygens located between two phosphorus atoms in the plane of symmetry passing through the trigonal axes[230]:
The P–P distance is 2.95 ± 0.03 Å.

Phosphorus trioxide is a colorless liquid at ordinary temperature and has a m.p. of 23.9° and b.p. of 175.4°. The standard enthalpy of formation ΔH_f° of P_4O_6 (crystal) is calculated to be -392 kcal/mole [taking ΔH_f° P_4O_{10} (crystal) as -713 kcal/mole]. The heat of sublimation is 16 kcal/mole and the entropy of vaporization = P_4O_6 (liq.) $\rightarrow P_4O_6$ (gas): $\Delta S_{448.56} = 21.0$ cal mole/deg[231]. The bond energy = (P–O) is calculated to be 86 kcal/mole[232]. The dielectric constant is 3.2 at 22° and the surface tension is 36.6 dynes/cm at 34.3°.

The compound hydrolyzes in an excess of water forming H_3PO_3. Upon heating to

above 210°, it disproportionates to red phosphorus and a phosphorus oxide of the approximate composition of P_nO_{2n}[231]. It displaces CO from $Ni(CO)_4$ forming successively coordinates containing one to four $Ni(CO)_3$ groups. The compound P_4O_6 $[Ni(CO)_3]_4$ is crystalline. Reaction of P_4O_6 with B_2H_6 results in the symmetrical cleavage of B_2H_6 with the formation of $H_3BP_4O_6BH_3$ [233-5].

7.3. PHOSPHORUS PENTOXIDE

Preparation, Structure and Properties

When phosphorus burns in the presence of an excess of oxygen in air, the product formed is P_4O_{10}, commonly called phosphorus pentoxide. One commercial process for collecting the fine white smoke is by condensing it continuously on a fluidized bed of granular P_4O_{10} at 129° into free flowing dustless small beads[236]. The P_4O_{10} thus obtained is the hexagonal or "H" form, the product of commerce.

The free energy of formation of P_4O_{10} is -644.8 kcal/mole and the standard entropy at 298.15°K is 54.66 ± 0.1 cal/mole/deg. The heat capacity at 298.15°K $C_p = 50.60$ cal/deg. Other molar thermodynamic properties at 298.15°K are $(H-H_0^\circ) = 8117$ cal, $(H-H_0^\circ)/T = 27.22$ cal/deg and $-(G-H_0^\circ)/T = 27.47$ cal/deg[237]. The value of enthalpy of formation of hexagonal P_4O_{10} at 25° has also been reported as -713.2 kcal/mole[238]. The mean bond energy $E(P-O)$ and dissociation energy $\bar{D}(P-O)$ were calculated as 86 and 138 kcal/mole respectively[232].

The P_4O_{10} molecule in the vapor state with a T_d symmetry has the arrangement of atoms as shown in the following diagram[230]. It has been estimated that there is essentially
no π bonding between the phosphorus and the shared oxygen and about 1.5–2.0 π-bond between the phosphorus and the unshared oxygen in addition to the δ-bond[226]. The crystals are uniaxial positive with the indexes of refraction in sodium light: $n_w = 1.469$ and $n_\varepsilon = 1.471$, both values ±0.002[231]. It has a density of 2.30.

There are two other crystalline modifications of phosphorus oxide: the O-form and a stable orthorhombic form designated as the O'-form.

The O-form is prepared by heating the H-form in a closed system for 2 hr at 400°. It is built of rings of ten PO_4 tetrahedra linking together to form a continuous three-

238 W. S. Holmes, *Trans. Faraday Soc.* **58** (1962) 1916–25.

dimensional structure[230]. The unit cell is orthorhombic with $a = 16.3$ Å, $b = 8.12$ Å, and $c = 5.25$ Å. The indexes of refraction in sodium light are $n_a = 1.545$, $n_\beta = 1.578$, $n_y = 1.589$, all values ± 0.002. The density is 2.72[231].

The O'-form which is also orthorhombic is prepared by heating the H-form in a closed system for 24 hr at 450°. The product consists of horny aggregates of relatively large orthorhombic crystals with a structure composed of infinite corrugated sheets parallel to [100] plane. The indices of refraction in sodium light are $n_w = 1.599$ and $n_\varepsilon = 1.624$, both values ± 0.002. The density calculated from the indices of refraction is 2.89. It melts slowly at $580° \pm 5°$ to give a very viscous liquid with a vapor pressure of 720 mm at 600° [231].

The conversion of H-form to the O- or O'-form is facilitated by condensing the H-form vapor on a seed bed of either the O- or O'-form, in the presence or absence of 0.2 to 0.3% moisture[239, 240].

The H-form absorbs moisture at a fast rate and dissolves in water with a hissing sound. The O'-form reacts less rapidly with water but more rapidly than the O-form. The final product in the presence of excess water in all cases is orthophosphoric acid. Under controlled conditions, the H-form hydrolyzes to form principally tetrametaphosphoric acid[241]. The reaction of P_4O_{10} with 100% H_2O_2 gives peroxomonophosphoric acid and lower polyphosphoric acids but no tetrametaphosphoric acid since cyclic phosphates are rapidly decomposed by water in the presence of much H_2O_2 [242].

Applications

The largest use for phosphoric pentoxide is the direct hydration into phosphoric acid. A very important use is as the intermediate for the preparation of triethyl phosphate. This is accomplished via the very elegant reaction of P_4O_{10} with ethyl ether to form ethyl polyphosphates which, on subsequent pyrolysis and distillation, disproportionate into triethyl phosphate.[243]. Phosphorus pentoxide is used also for the synthesis of the mixed mono- and dialkyl-phosphoric acids by direct reaction with alcohol. This reaction involves the cleavage of the POP bonds with ROH:

$$P_4O_{10} + 6ROH \longrightarrow 2ROP(OH)_2 + 2(RO)_2POH$$
$$\qquad\qquad\qquad\quad \overset{O}{\underset{\|}{}} \qquad\qquad \overset{O}{\underset{\|}{}}$$
For this reaction, the generation of P_4O_{10} *in situ* by blowing air through a solution of white phosphorus in the alcohol at 150°F has been claimed in the patent literature[244]. Phosphorus pentoxide is also used as a desiccant[245] and as a dehydrating agent in organic reactions. For the latter purpose, phosphorus pentoxide was, until recently, employed extensively in the synthesis of methyl methacrylate.

Phosphorus pentoxide reacts with ammonia to give a white powdery solid of unknown structure containing both P–N–P as well as $PONH_4$ nitrogen. This product has been employed in flameproofing compositions. Phosphorus pentoxide is used as catalyst in

the air blowing of asphalt [246] and when supported on kieselguhr acts as catalyst for the polymerization of isobutylenes[247].

7.4. PHOSPHORUS TETROXIDE AND OTHER OXIDES

Phosphorus tetroxide $(PO_2)_n$ with a molecular weight ranging from 293 to 721 is best prepared by the heating of P_4O_6 in an evacuated tube at 200–250° for several days. It is separated from the by-product, red phosphorus, by fractional sublimation. The product is a lustrous transparent crystal with a density of 2.54 at 23°. It is deliquescent in air and very soluble in water[226].

Thilo, Heinz, and Jost[248] in their study of the thermal decomposition of P_4O_6 obtained two phosphorus (III/V) oxides, rhombohedral mixed crystals of P_4O_9 and P_4O_8 (α-form) and monoclinic mixed crystals of P_4O_8 and P_4O_7 molecules (β-form). The P_4O_9, P_4O_8, and P_4O_7 molecules are structurally similar to P_4O_{10} but lack respectively one, two or three of the terminal oxygens. These mixed oxides can also be obtained by reaction between P_4O_{10} and elemental phosphorus in an inert gas atmosphere. The relationship of the structure of these oxides with that of P_4O_{10} and P_4O_6 is shown below[249]:
TABLE 10. PHYSICAL PROPERTIES OF PHOSPHORUS OXIDES

Schenk and Vietzke[250, 251] obtained a mixture of two peroxides by exposing a mixture of P_4O_{10} and oxygen to a corona discharge. One product is violet in color and radical-like. It is stable at room temperature; on heating it is converted to the colorless P_4O_{11} which is stable up to 130° and hydrolyzes according to:

$$P_4O_{11}+4H_2O \longrightarrow H_4P_2O_8+H_4P_2O_7$$
8. PHOSPHORUS SULFIDES, OXYSULFIDES AND RELATED COMPOUNDS

Phosphorus forms with sulfur four well-characterized crystalline compounds, P_4S_{10}, P_4S_7, P_4S_5 and P_4S_3. Of these, P_4S_{10} and P_4S_3 are produced commercially. The melting point diagram for the sulfur–phosphorus system is shown in Fig. 7[252].
FIG. 7. Phosphorus–sulfur system.[252] (Reprinted by permission of John Wiley & Sons Inc.)

The structures of these sulfides may be treated as insertion and addition of the correct amount of sulfur to the phosphorus tetrahedral. They are shown[253] in Fig. 8.

8.1. PHOSPHORUS SESQUISULFIDE, P₄S₃

Phosphorus sesquisulfide is prepared by heating a stoichiometric mixture of white phosphorus and sulfur at above 180° under an inert atmosphere. It is purified by distillation at 420° under ordinary pressure or by recrystallization from toluene. In an industrial scale, to moderate the highly exothermic reaction, phosphorus is added continuously to sulfur. The final purified product is a yellow rhombic crystal which dissolves 31.2 g at 17° and 15.4 g at 111° in 100 g of toluene. The structure of phosphorus sesquisulfide

is shown in Fig. 8. The entropy at 298.15°K for P_4S_3 is 48.60 cal/deg[254]. The melted P_4S_3 has a specific gravity of 1.7953 g/cm³ and a surface tension of 22.86 ergs/cm², both
FIG. 8. Structures of phosphorus sulfides.[253] (Reprinted by permission of John Wiley & Sons Inc.)

measured at 172.2°. The parachor was calculated as 329.8[255]. Other physical properties are listed in Table 11.

Under ordinary conditions phosphorus sesquisulfide is stable and unaffected by exposure to the atmosphere or water at room temperature. It decomposes gradually in boiling water but is unaffected by cold hydrochloric or sulfuric acid. It reacts rapidly with an alkaline solution to form sulfide ions, PH_3, H_2, hypophosphite, and a phosphite[256]. From

attached to the pyramidal P atoms via the lone pair. It can be converted back to P_4S_3 to the extent of 60% when heated to 150–180°. By alternate treatment with NH_3 and heating finally to 275° it gives $P_4(NH)_3$.

Phosphorus sesquisulfide reacts with sulfur in CS_2 solution to give P_4S_5. The reaction with I_2 in CS_2 is more complex, yielding $P_4S_3I_8$, $P_4S_3I_2$ as well as PI_3 and P_4S_7[252].

Phosphorus sesquisulfide ignites in air at above 100°, and glows with luminescence when oxidized in air at 40–50°, having a higher and lower limit of oxygen pressure for the appearance of the glow[252].

One major use for phosphorus sesquisulfide is in combination with potassium chlorate, sulfur and lead dioxide for match tips. Zinc oxide is usually added as a stabilizer and kieselguhr and powdered glass added to moderate the combustion reaction. The whole composition is held together by glue and resin[258].

8.2. TETRAPHOSPHORUS PENTASULFIDE, P₄S₅

This compound is formed by the action of diffuse light on a CS_2 solution of sulfur and P_4S_3 in the presence of iodine catalyst[256]. It recrystallizes as bright yellow crystals from carbon disulfide. The structure is shown in Fig. 8. At above 170° it decomposes

257 J. D. Murray, G. Nickless and F. H. Pollard, *J. Chem. Soc.* A(1967) 1726–30.

258 J. C. Morales, Span. 281,960, 24 Jan. 1963.

(reversibly) to P_4S_3 and P_4S_7, and for this reason it does not appear in the phase diagram. The crystallographic data for P_4S_5 are as follows: space group $= P2$; $a = 6.412\pm0.003$ Å; $b = 10.903\pm0.005$ Å; $c = 6.694\pm0.003$ Å; and $\beta = 111.66\pm0.1°$ [259].

8.3. TETRAPHOSPHORUS HEPTASULFIDE, P_4S_7

Several methods have been reported for the preparation of P_4S_7. The most direct methods are by heating $2P+3S$ in a glass tube or by heating $4P+7S+5\%P_4S_3$. The P_4S_3 and P_4S_{10} formed as impurities are removed by extraction with carbon disulfide. Carbon disulfide is also a good solvent for recrystallization of P_4S_7 [256]. Crystals of P_4S_7 are also obtained by reacting white phosphorus and sulfur in CS_2 in the presence of iodine catalyst and the mixture allowed to stand a few days in daylight. Mixture of P_2I_4 and sulfur in CS_2 solvent kept for five days in diffused daylight at room temperature also gives large crystals of P_4S_7[260].

The monoclinic unit cell of α-P_4S_7 contains molecules having the structure shown in Fig. 8. It has the following crystallographic data: space group $= P2_1/n$; $a = 8.895\pm0.004$Å; $b = 17.44\pm0.015$ Å; $c = 6.779\pm0.004$ Å; and $\beta = 92.73\pm0.1°$ [259].

A new phosphorus sulfide obtained from a melt of the composition P_4S_5–$P_4S_{6.9}$ with an approximate composition of $P_4S_{6.5}$ was shown by X-ray analysis to be mainly the β-P_4S_7 with structure shown also in Fig. 8. The deficiency in the sulfur analysis is due to a small fraction of the product which contains one less terminal sulfur atom[253].

Of all the crystalline phosphorus sulfides, tetraphosphorus heptasulfide reacts the most rapidly with moisture, giving off hydrogen sulfide. Hydrolysis either in alkaline or acidic solution gives mostly phosphoric and phosphorous acid along with a little phosphine. Reaction of P_4S_7 with ethanol in CS_2 gives mostly $(C_2H_5O)_2P(S)SH$ and $(C_2H_5O)_2PP(OC_2H_5)SH$. The latter decomposes further to $(C_2H_5O)_2P(S)SC_2H_5$ and $(C_2H_5O)_2P(S)H$[261].

The reaction of P_4S_7 with liquid ammonia at $-33°$ gives $(NH_4)_3PS_3$, $(NH_4)_2PS_3NH_2$, $(NH_4)_3P_3S_3(NH)_3$, and NH_4P_2SN in $1:2:1:1$ ratio[262].

8.4. PHOSPHORUS PENTASULFIDE, P_4S_{10}

This is the most well known of all phosphorus sulfides and commercially the most important. It is manufactured by the addition of phosphorus and sulfur continuously under an inert atmosphere to a reactor containing molten P_4S_{10}. The temperature is maintained at greater than 300° and the last addition of phosphorus is made after all the sulfur is added. The ratio of the reactants is maintained at close to the theoretical 4P to 10S[263, 264]. The product is purified by distillation under atmospheric pressure.

Phosphorus pentasulfide exhibits a triclinic crystal structure with two P_4S_{10} per unit cell. The structure as shown in Fig. 8 has essentially the same tetrahedral Td ($\bar{4}3m$) symmetry

[259] A. Vos, R. Olthof, F. van Bolhuis and R. Botterweg, *Acta Cryst.* 19(5) (1965) 864–7.

[263] J. Cremer, *Chem. Inqr. Tech.* 37(7) (1965) 705–9.

[264] H. Niermann, H. Harnisch and J. Cremer, Ger. 1,195,282, 24 June 1965, to Knapsack-Griesheim A.G.

as the H–form of P_4O_{10} [253]. It has the following crystallographic data: space group $= P1$; $a = 9.072$; $b = 9.199$; and $c = 9.236$, all ± 0.003 Å; $\alpha = 92.58 \pm 0.07°$; $\beta = 100.90 \pm 0.1°$; and $\gamma = 110.18 \pm 0.07°$ [259].

The reactivity of P_4S_{10} with alcohols depends on the rate of cooling of the P_4S_{10} through the phase transition range of $280-60°$. The more rapid the rate of cooling the higher is the rate of reactivity[265].

The initial decomposition temperature of P_4S_{10} is quite close to the b.p. of $513-515°$. Extensive decomposition occurs even at $600°$, as measured by the molecular weights at that temperature. The initial decomposition is believed to follow the equilibrium below:

$$P_4S_{10} \rightleftharpoons P_4S_7 + 3S$$
Upon condensation of the vapor, the equilibrium shifts back to the left[260]. Very rapid condensation of the vapor on an extremely cold surface results in a green solid which turns yellow when the temperature is allowed to go above $-100°$. It is speculated that this color may be due to the freezing of some free radicals[252].

The vapor pressure of P_4S_{10} is given according to the following equation:

$$\log p_{mm} = -4940/T + 9.17$$

On hydrolysis, phosphorus pentasulfide gives mostly hydrogen sulfide and phosphoric acid:

$$P_4S_{10} + 16H_2O \longrightarrow 4H_3PO_4 + 10H_2S$$
Presumably intermediates of thiophosphoric acids are first formed. At $100°$, P_4S_{10} on hydrolysis in 1.0 M hydrochloric acid goes rapidly to the monophosphate. When the hydrolysis is carried out in a 1 M NaOH solution at $100°$, after 1 hr, almost 75% of the phosphorus is present as the mono- and dithiophosphates[267].

The most important reaction of phosphorus pentasulfide is that with alcohols or phenols for the formation of dialkyl or diaryl phosphorodithioic acids:

$$8ROH + P_4S_{10} \longrightarrow 4(RO)_2P(S)SH + 2H_2S$$
Zinc and barium salts of these acids are used extensively as additives to lubricating oil for improving the extreme pressure properties. They also act as antioxidants, detergents and

parathion
[265] S. Robota, U.S. 3,023,086, 27 February 1962, to Hooker Chemical Corp.
[266] G. Perot, *Chimie et Industrie*, **87** (1962) 78–86.

corrosion inhibitors. Some short chain alkyl or cresylic phosphorodithioic acids and their sodium or ammonium salts are used as flotation collectors to separate such minerals as lead and zinc sulfide from the contaminating gangue.

A very important application for dimethyl and diethyl phosphorodithioic acid is as intermediate for the organic phosphorus insecticides. It may be used directly or it may be first converted to the acid chloride for subsequent reactions as shown above.

Phosphorus pentasulfide reacts with priminary amines to give $(RNH)_2P(S)SH$ or $(RNH)_3PS$ depending on the reactant ratios and the temperature[268].

Phosphorus pentasulfide is toxic and the maximum allowable concentration is 1 mg per cubic meter of air. Since it hydrolyzes to H_2S and H_3PO_4, methods for its determination are based on the analysis of the two products of decomposition[269].

8.5. MISCELLANEOUS PHOSPHORUS SULFIDES

The compound P_2S_3 has been reported in the literature. Pitochelli and Audrieth obtained a product with such empirical composition by the action of PCl_3 on H_2S. Extraction and crystallization from CS_2 showed that the product is a mixture of P_4S_3 and P_4S_7. So if P_2S_3 were formed initially, it was unstable at room temperature and underwent disproportionation in CS_2[270]. Foerthmann and Schneider[271] reported a new sulfide, P_4S_2, with a m.p. of 46° in their studies of the S–P phase diagram. They obtained it as crystalline needles by crystallizing from a mixture of P_4S_2 and white phosphorus at room temperature.

Phosphorus and sulfur also form a solid solution at below 100°. A partially crystalline polymeric phosphorus monosulfide $(PS)_x$ is prepared by the reaction of $PSBr_3$ with magnesium. The formation of $(PS_x)_n$ is by the action of SCl_2 or S_2Cl_2 on H_3PS_4[268].

8.6. PHOSPHORUS OXYSULFIDES

Phosphorus oxysulfides of the following empirical formula have been reported: $P_2O_3S_2$, $P_2O_2S_3$, $P_4O_4S_3$ and $P_6O_{10}S_5$[252]. The best known member of this series, $P_2O_3S_2$, can be obtained by heating P_4O_6 and sulfur in a sealed tube at 160° or by heating a mixture of three moles of P_2O_5 with two moles of P_2S_5. It may be purified by distillation under vacuum to give colorless hygroscopic crystals[272] that melt at about 102° and boil at 295°. However, on each redistillation only about 50–60% of the compound is recovered in the distillate. The rest is removed as polymeric residue.

Electron diffraction studies and Raman data show that the vapor of $P_4O_6S_4$ has a structure similar to that of P_4O_{10} or P_4S_{10}, i.e., it may be regarded as derived from the P_4O_{10} structure with the four terminal oxygens replaced by four sulfur atoms. The crystalline solid, however, belongs to the tetragonal system[253].

Tetraphosphorus tetrathiohexaoxide, $P_4O_6S_4$, reacts with liquid ammonia in a sealed tube at room temperature to yield $(NH_4)_2(PO_2SNH_2)$ and $PS(NH_2)_3$[273].

[273] H. Behrens and L. Huber, *Chem. Ber.* **93** (1960) 1137–43.

Hydrolysis of $P_4O_6S_4$ at 100° in 1.0 M hydrochloric acid gives after 1 hour only the monophosphate. When the hydrolysis is carried out with 1 M NaOH solution at 100°, less than 10% of the total phosphorus is the monophosphate, the main products being the monothiophosphate and two anions tentatively identified as

$$

& O & & O &
\end{bmatrix}^{-4}
$$ [267]
8.7. PHOSPHORUS SELENIDES AND TELLURIDES

The best characterized phosphorus selenide is P_2Se_5, prepared by heating a stoichiometric mixture of the elements for 12 hr at 450°. It is a black-purple amorphous solid. An attempt to recrystallize it from CCl_4 was not successful[274]. On heating it decomposes to phosphorus and selenium.

Phosphorus pentaselenide reacts with liquid ammonia. Depending on the temperature used, products such as $(NH_4)_2[PSe_3NH_2]$, $[NH_4]_3[PSe_4]$ and $[NH_4]_2$ $[PSe_2(NH_2)NH]$ are obtained. The latter compound at higher temperature deammoniates to other phosphorus–selenium–nitrogen compounds[275].

In its reaction with alkyl amines, P_2Se_5 forms compounds such as $(RNH)_3 P = Se$ and $(RNH)_2P(Se)Se^- RNH_3^+$ [276]. When P_2Se_5 reacts with alcohols, the expected $(RO)_2P(Se)SeH$ which forms is unstable and can be isolated only as its potassium salt $(RO)_2P(Se)SeK$ or its chromium(III) complexes $Cr[Se_2P(OR)_2]_3$ [274].

Tetraphosphorus triselenide, P_4Se_3, is prepared in 55–60% yield by refluxing a mixture of white phosphorus with selenium in heptane in the presence of charcoal. It has a m.p. of 245–246° [277]. When it reacts with liquid ammonia, it gives a dark red compound $[NH_4]_2[P_4Se_3(NH_2)_2]$ that when heated to 20° loses NH_3 to yield $[NH_4]_2[P_4Se_3NH]$. Continued heating to 90° yields $[NH_4][P_4Se_3NH_2]$ and finally at 200° it goes back to P_4Se_3 [275].

Phosphorus tritelluride, P_2Se_3, is prepared by the heating of tellurium with white phosphorus at 320° in a sealed tube. It is a black solid which decomposes slowly in moist air to give phosphine[252].

9. PHOSPHORUS–NITROGEN COMPOUNDS

Phosphorus forms many compounds with nitrogen. They may be regarded as nitrogen derivatives of the oxyacids of phosphorus. By such classification, the fundamental chemical relationships which characterize many of these compounds become more apparent[278, 279].

The organic N-substituted derivatives of phosphorus–nitrogen compounds prepared from amines are in general more stable and easier to prepare than the corresponding ammono

derivatives prepared from ammonia. Some of the compounds listed on chart 1 are, at present, unknown. With minor exceptions, the organic derivatives will not be included in this chapter. A review on phosphorus–nitrogen compounds by E. Fluck[280] is recommended as reference for the subject.

9.1. NITROGEN DERIVATIVES OF PHOSPHOROUS ACID

The reaction of phosphorus trichloride with a saturated solution of ammonia in chloroform at $-78°$ forms as product a mixture of phosphorous triamide and ammonium chloride. Phosphorous triamide is unstable at room temperature and attempts at isolation from ammonium chloride have not been successful. It is obtained, however, as an adduct with boron hydride, $(NH_2)_3PBH_3$, by the ammoniation of $F_3P{\cdot}BH_3$ [280].

The polymeric phosphorimidous amide, $(HN{=}P{-}NH_2)_n$, is prepared by the addition of phosphorus trichloride to ammonia in ethereal solution at $-20°$. By-product ammonium chloride is removed by washing with liquid ammonia in which the desired product is only difficultly soluble. Phosphorimidous amide is unstable at room temperature, decomposing into a brick-red solid of indefinite composition.

Phosphorous nitride, PN, is formed when an excess of PCl_3 is added to liquid ammonia. The NH_4Cl by-product may be removed by washing with liquid ammonia or by heating with diethylamine in chloroform. In the latter process, ammonium chloride is converted to chloroform soluble diethylamine hydrochloride and volatile ammonia. Phosphorous nitride is isolated as a yellow amorphous powder which is insoluble in chloroform or liquid ammonia[280].

From the reaction of PCl_3 with CH_3NH_2, Holmes et al. isolated an interesting crystalline compound of the composition $P_2N_3(CH_3)_3$ (m.p. 122.0–122.8°, b.p. 303–304°/739 mm). Molecular weight measurements and NMR data indicated that the compound has a tetrahedral structure analogous to that of phosphorous oxide, P_4O_6.
It undergoes many reactions via the phosphorus atoms such as with O_2 or S analogous to those reactions of phosphorous oxide.

[280] E. Fluck, *Topics in Phosphorus Chemistry*, **4** (1967) 293–466.

9.2. NITROGEN DERIVATIVES OF PHOSPHORIC ACID

The sodium salts of both phosphoramidic acid, $H_2NP(OH)_2$ [281], and phosphorodiamidic

acid, $(H_2N)_2POH$, were first prepared by Stokes by the saponification of the corresponding

phenyl esters with strong caustic[282]. The phenyl esters, $(C_6H_5O)_2PNH_2$ and $C_6H_5OP(NH_2)_2$, were in turn prepared by the ammoniation of the pure $C_6H_5OPOCl_2$ or $(C_6H_5O)_2POCl$. An alternative procedure for the phenyl esters is the ammoniation of the reaction mixture $C_6H_5OH-POCl_3-C_5H_5N$ prepared using the optimum ratio selected for the desired amide. The pure amides are then separated by crystallization from selective solvents[283].

The free phosphoramidic acid, $H_2NP(OH)_2$, is obtained from the sodium salt by first converting to the lead salt followed by treatment with H_2S. It has also been obtained directly from the phenyl ester by catalytic hydrogenation[280]. The compound is a white solid soluble in water with the dissociation constants of $K_1 = 1.2 \times 10^{-3}$ and $K_2 = 2.1 \times 10^{-8}$ or $pK_1 = 4.6$ and $pK_2 = 7.7$. At room temperature it decomposes slowly (more rapidly at $100°$) into ammonium polyphosphates having the same analytical composition as that of the parent compound.

The sodium salt of phosphoramidic acid is stable and resists hydrolysis in an aqueous solution at a pH above 7. It undergoes thermal condensation when heated under vacuum at $210°$ into the sodium salt of diphosphorimidic acid, $Na_4P_2O_6(NH)$, with the evolution of one mole of ammonia. Under more drastic conditions ($450°$ for seven days), three moles of sodium phosphoramidate condense with the evolution of two moles of ammonia to form sodium nitridotriphosphate[280].

$$3(NaO)_2\overset{O}{\overset{\|}{P}}NH_2 \longrightarrow 2NH_3 + N\left[\overset{O}{\overset{\|}{P}}(ONa)_2\right]_3$$
Phosphorodiamidic acid, $(H_2N)_2POH$, is obtained in high purity by the treatment of the

silver salt, $AgOP(NH_2)_2$, with HBr. The silver salt in turn is derived from the sodium salt prepared either by the saponification of the phenyl ester or by the hydrolysis of phosphoric triamide, $OP(NH_2)_3$, in aqueous sodium hydroxide.

The dissociation constant for phosphorodiamidic acid is $K = 1.2 \times 10^{-5}$. The compound

[281] R. Klement, *Inorganic Synthesis*, Vol. XI, pp. 100–101, Ed. E. G. Rochow, McGraw-Hill Book Co., New York (1960).

reacts with atmospheric moisture to form ammonium hydrogen phosphoramidate,

$$\begin{array}{c} O \\ \| \end{array}$$

$NH_4OP(OH)NH_2$. In an aqueous solution it is converted eventually to diammonium phosphate, $OP(OH)(ONH_4)_2$.

$$\begin{array}{c} O \\ \| \end{array}$$

Anhydrous sodium phosphorodiamidate, $NaOP(NH_2)_2$, undergoes thermal condensation at above 155–163° with evolution of ammonia into a polymeric compound containing the

$$\begin{array}{ccc} O & H & O \\ \| & | & \| \end{array}$$

phosphorus imide, –P–N–P–, linkages; the degree of condensation increases with the temperature and time of the reaction[280].

Several silver salts of phosphorodiamidic acid have been described by Stokes[282]. The

$$\begin{array}{cc} O & \qquad\qquad O \\ \| & \qquad\qquad \| \end{array}$$

mono-silver salt, $AgOP(NH_2)_2$, when treated with KOH forms $KOP(NHAg)_2$ which on heating in hot water disproportionates into a brown salt having a proposed structure of $AgOP(O)(NAg_2)_2$. This last compound detonates readily.

Over the years it has been assumed that the reaction product of $POCl_3$ with ammonia contains as the desired product, phosphoric triamide:

$$OPCl_3 + 6NH_3 \longrightarrow OP(NH_2)_3 + 3NH_4Cl$$
The isolation of the triamide in the pure form, however, was not achieved until the development of the elegant method of Klement and Koch[284, 285] which by treatment of the reaction mixture with diethyl amine in $CHCl_3$ solution converts the NH_4Cl to the chloroform soluble diethylammonium chloride and volatile ammonia. The chloroform insoluble $OP(NH_2)_3$ is then isolated by filtration.

Phosphoric triamide crystallizes as colorless needles from methanol. It dissolves in water with only slight dissociation. In dilute caustic, it gives the sodium salt of phosphorodiamidic acid described above. On prolonged contact with atmospheric moisture it hydrolyzes to ammonium hydrogen phosphoramidate, $OP(OH)(ONH_4)NH_2$.

When phosphoric tetramide is heated, progressive condensation occurs with the elimination of ammonia. Imidodiphosphoric tetramide, $(NH_2)_2P(O)NHP(O)(NH_2)_2$, is first formed, then diimidotriphosphoric tetramide, $(NH_2)_2P(O)NHP(O)NHP(O)(NH_2)_2$. Finally, at 450–500°, the highly polymeric phosphoryl nitride, $(OPN)_n$, is formed. The compound $(OPN)_n$ loses 50% of its weight when heated for 4 hr at 600° and 84% when heated for 3 hr at 800°[286]. The polymeric residue left after heating at 800° has a spatial structure in which one nitrogen atom is bonded to three phosphorus atoms[287].

The compound phospham, NPNH, an insoluble and amorphous polymeric product, has been known since 1811. It was originally prepared by heating the reaction product of PCl_5

and NH_3. Subsequently it has been prepared by the thermal decomposition of the trimeric or tetrameric phosphorus nitrile amide:

$$[NP(NH_2)_2]_{3-4} \xrightarrow{\Delta} [(NPNH)_{3-4}]_n + 3\text{--}4\ NH_3$$

The phosphorus atoms in these products are believed to be joined by nitrogen and imido bridges[280]. Thermal decomposition of phospham leads to triphosphorus pentanitride (P_3N_5) and phosphorus mononitride (PN).

Becke-Goehring and Scharf[288] obtained from the reaction of PCl_5 and an excess of liquid ammonia under anhydrous conditions a compound of the structure:

$$\left[\begin{array}{cc} NH_2 & NH_2 \\ | & | \\ H_2N\text{-}P\text{---}N = P\text{---}NH_2 \\ | & | \\ NH_2 & NH_2 \end{array} \right] Cl$$

The NH_4Cl by-product formed in this reaction was removed by the method of diethylamine in chloroform solution.

9.3. NITROGEN DERIVATIVES OF POLYPHOSPHORIC ACIDS

Tetramide of pyrophosphoric acid, $(NH_2)_2P(O)\text{-}O\text{-}P(O)(NH_2)_2$, is obtained by the reaction of pyrophosphoryl chloride with ammonia:

$$Cl_2P(O)\text{-}O\text{-}P(O)Cl_2 + 8NH_3 \longrightarrow (NH_2)_2P(O)\text{-}O\text{-}P(O)\ (NH_2)_2 + 4NH_4Cl$$

Ammonium chloride by-product is removed by extraction with liquid ammonia[289].

Amido derivatives of polyphosphates are obtained by the ammonolysis of the poly-phosphate P-O-P bonds. For example, amidotriphosphate is formed by the action of aqueous ammonia on ammonium trimetaphosphate:

This reaction is reversible. Acidification regenerates the trimetaphosphate ion[290].

A water-insoluble polyphosphoric amide prepared by the thermal condensation of the reaction product of $POCl_3$ and ammonia at 150–200° (NH_4Cl removed by washing with water) has been found to be a good flame retardant for polyurethane foam[291].

9.4. METAPHOSPHIMIC ACIDS

Both tri- and tetrametaphosphimic acids and their salts were first prepared by Stokes[292] by the hydrolysis of the trimeric and tetrameric phosphonitrile chlorides:

[292] H. N. Stokes, *Am. Chem. J.* **17** (1895) 275.

Subsequent modification on the preparation of trisodium trimetaphosphimate 1-hydrate involves the hydrolysis of trimeric phosphonitrile chloride in a dioxane solution with an aqueous solution of sodium acetate at 45–55° . The tripotassium trimetaphosphimate is similarly prepared by the use of an aqueous solution of potassium acetate[293]. Trimetaphosphimic acid is then obtained by the acidification of the potassium salt with perchloric acid and the insoluble potassium perchlorate removed by filtration. Upon concentration of the filtrate, the trimetaphosphimic acid is isolated as the dihydrate $H_3(PO_2NH)_3 \cdot 2H_2O$, which transforms to the anhydrous form at 33°. It is a strong acid with three replaceable hydrogens giving a single deflection in electrometric titration curves. The mono-, di- or tri-sodium salts may be prepared by progressive neutralization[294].

The potassium, rubidium, cesium and ammonium salts of tetrametaphosphimic acid have also been prepared and characterized in the various hydrated and anhydrous forms. The geometric isomerism of tetrametaphosphimate ion allows the existence of two species of the hydrated potassium salts and two modifications of the anhydrous compound[295].

Wanek and Thilo studied the hydrolysis of sodium trimetaphosphimate under a stream of moist air at 135° and found that the ring opens to form amidodiimidotriphosphate, which under these conditions is very unstable and hydrolyzes quickly to form Na_2HPO_4 [296].

Under a severe condition of alkaline hydrolysis, Stokes obtained from $(PNCl_2)_3$ also the sodium amidodiimidotriphosphate
Acid hydrolysis of sodium trimetaphosphimate was found by Quimby et al.[298] to

proceed largely through intermediate ring compounds with one, two and three oxygen atoms replacing successively the imide linkages of the ring:
In this acid hydrolysis, chain imidophosphates were never found in large amount. The P–O–P linkages in the ring are formed by the elimination of NH_3 between P–OH and P–NH_2 groups. The ring compounds containing both the imide, P–N–P and P–O–P bridges are converted to the linear imidophosphate by treatment with 30% NaOH. Cleavage occurs at the P–O–P linkage while the P–N–P bridge appears to be inert at the pH above 11[299]. Thus:

diimidotrimetaphosphate   diimidotriphosphate
9.5. NITROGEN DERIVATIVES OF THIOPHOSPHORIC ACID

Sodium salt of phosphoramidothioc acid, $Na_2PO_2S(NH_2)$, is obtained by the saponification of the diphenyl ester, $(C_6H_5O)_2PNH_2$. Sodium phosphorodiamidothioate, $NaPOS(NH_2)_2$, is obtained by hydrolysis of phosphorothioic triamide $SP(NH_2)_3$ in dilute NaOH.

A mixture of diammonium phosphoramidothioate, $(NH_4)_2PO_2S(NH_2)$, and ammonium phosphorodiamidothioate, $NH_4POS(NH_2)_2$, is obtained by the reaction of $PSCl_3$ with aqueous solution of ammonia. In this reaction the yield of the diamido compound is favored by the use of a higher concentration of ammonia. The free acids of both of the mono and diamido compounds have not been isolated[280].

Phosphorothioic triamide, $SP(NH_2)_3$, is obtained along with ammonium chloride when $PSCl_3$ is treated with an excess of ammonia. The same procedure as used in the isolation of phosphoric triamide which involves diethylamine in chloroform is employed for the separation of the desired product from ammonium chloride[300].

Phosphorothioic triamide, a colorless crystalline rhombohedric solid, is unstable in moist air, decomposing to the diammonium salt of phosphorothioic acid, $(NH_4)_2HPO_3S$.

[300] R. Klement, *Inorganic Synthesis*, Vol. VI, pp. 111–12, Ed. E. G. Rochow, McGraw-Hill Book Co., New York (1960)

When heated it loses ammonia, and at 800° the final product is triphosphorus pentanitride, P_3N_5[280], instead of the anticipated phosphorothioic nitride, SPN, the thio-analog of OPN from the corresponding thermal decomposition of $OP(NH_2)_3$. The polymeric phosphorothioic nitride, $(SPN)_n$, is however obtained via an entirely different route, that of the ammonolysis of P_4S_{10} [280]:

$$P_4S_{10} + 4NH_4Cl \longrightarrow 4(SPN)_n + 6H_2S + 4HCl$$
10. PHOSPHONITRILIC HALIDES (HALOPHOSPHAZENES)

10.1. PHOSPHONITRILIC CHLORIDES

Phosphonitrilic chlorides with a general formula of $(PNCl_2)_n$ were first discovered in 1834 by J. von Liebig[301] in very low yield from the reaction of ammonia with PCl_5. Later Stokes[302] in the reaction of NH_4Cl with PCl_5 (heated in a sealed tube at 150–200°) produced and isolated various phosphonitrilic chlorides ranging from the trimer to the hexamer and an impure heptamer in addition to a polymeric residue. Stokes also found that the trimer when heated in a sealed tube at 250° polymerized to a rubbery polymer, the first inorganic rubber.

During the last few decades, the search for a new inorganic type of polymer provided a strong impetus for research on phosphonitrilic chemistry. The first review on the subject appeared in 1943[303]. More recent surveys are by Allcock[304, 305], Fluck[306], Paddock[307], Shaw[308], and Yvernault and Casteignau[309].

Mono- and Dimeric Adducts

Phosphonitrilic chloride does not exist in the monomeric form, except possibly as an adduct. The tertiary amine adduct has been reported in the literature[303] as $PNCl_2 \cdot 2NR_3$. The monomeric formula is assumed because the adducts, whether obtained from the trimeric or tetrameric phosphonitrilic chlorides, have the same melting point.

Adducts such as $POCl_3 \cdot PNCl_2$ and $PNCl_2 \cdot 2PCl_5$ have also been reported. The compound $POCl_3 \cdot PNCl_2$ has probably the structure of $\overset{\overset{\text{O}}{\|}}{Cl_2P}-N = PCl_3$. One method for its preparation[310] is by the reaction of PCl_3 and PCl_5 with hydroxylammonium chloride:

$$2PCl_3 + PCl_5 + 2[H_3NOH]Cl \longrightarrow Cl_3P = N - \overset{\overset{\text{O}}{\|}}{P}Cl_2 + 4HCl + NH_4Cl + POCl_3$$
It is a colorless crystal, m.p. 35.7°, b.p. 102°/1 mm. A super-cooled melt has a refractive

index n_D^{25} = 1.5313. This compound is sensitive to moisture and soluble in benzene, nitrobenzene and sym-tetrachloroethane.

The $PNCl_2.2PCl_5$ adduct has actually the structure of $[Cl_3P\!=\!N\!-\!PCl_3]$ $[PCl_6]$. It may be prepared by the reaction of PCl_5 with NH_4Cl in the presence of $POCl_3$ as solvent in which case $PNCl_2.POCl_3$ is obtained as a by-product[311]. A more straightforward method of synthesis is that of Becke-Goehring and Fluck[312]:

$$3PCl_5 + NH_4Cl \longrightarrow [Cl_3P = N\!-\!PCl_3]\ [PCl_6] + 4HCl$$

This procedure involves the heating of the reactants in sym-tetrachloroethane solvent under vacuum at 80° until most of the PCl_5 is consumed. The product is isolated as needle-like pale greenish-yellow crystals, m.p. 310-315°. Reaction of $[Cl_3P\!=\!N\!-\!PCl_3]$ $[PCl_6]$ with more NH_4Cl[306] results in the formation of $[Cl_3P\!=\!N\!-\!PCl_2\!=\!N\!-\!P\!-\!Cl_3]$ $[PCl_6]$. This compound has the composition equivalent to the adduct of the dimeric phosphonitrilic chloride with 2 moles of phosphorus pentachloride:

$$(PNCl_2)_2.2PCl_5$$
Cyclic Polymers

Preparation. The preparation of cyclic and polymeric phosphonitrilic chlorides today is based essentially on the original reaction described by Stokes. One basic modification is that of Schenck and Römer[313] who found that the use of a solvent to carry out the reaction at around 140-150° improves the yield of the distillable cyclic polymers. Sym-tetrachloroethane with a b.p. of 146.3° has been the solvent of choice. However, chlorobenzene and chlorotoluene are also effective solvents.

The general procedure[314] for the preparation of the trimeric and tetrameric phosphonitrilic chloride is based on the following equations:

$$3\ PCl_5 + 3NH_4Cl \longrightarrow (PNCl_2)_3 + 12HCl$$
$$4\ PCl_5 + 4NH_4Cl \longrightarrow (PNCl_2)_4 + 16HCl$$
A slurry of ammonium chloride (about 40 to 50% excess) is heated with PCl_5 in sym-tetrachloroethane under reflux until the evolution of HCl ceases. The excess ammonium chloride is removed by filtration and the filtrate then concentrated by distilling off the solvent under reduced pressure. The buttery residue left is distilled quickly under reduced pressure to obtain a mixture of the trimer, tetramer and a little higher cyclic polymers in the distillate. The trimer and tetramer may then be separated by fraction distillation and recrystallization. The heat of formation of $(PNCl_2)$ is -178.1 ± 3 kcal/mole[315].

One modification of the above procedure is by the preparation of NH_4Cl *in situ* in chlorobenzene solvent by the reaction of gaseous HCl and NH_3. Ammonium chloride of the particle size of 5μ is thus obtained. Such fine NH_4Cl increases the yield of the cyclic polymers[316].

Another modification is by the addition of PCl_5 to a refluxing suspension of NH_4Cl in sym-tetrachloroethane during a 7-8 hr period. The yield of the trimer is thus increased

at the expense of higher linear polymer, $(PNCl_2)_n . PCl_5$. From the petroleum solvent soluble fraction of this reaction mixture, Paddock[317] and his co-workers, using a combination of fractional extraction, fractional distillation *in vacuo*, and fractional crystallization, have been able to obtain individual cyclic polymers from the trimer to the octamer.

The mechanism of formation of $[NPCl_2]_n$ is believed to proceed through the intermediate cations of the type $[Cl_3P = NPCl_3]^+$ and $[Cl_3P = N(PCl_2 = N)_n PCl_3]^+$ [318, 319], as evidenced by the fact that trimeric, tetrameric and higher cyclic polymers of phosphonitrilic chlorides have been obtained directly from compounds containing these cations by further reaction with NH_4Cl.

The intermediate products from the reaction of PCl_5 and NH_4Cl preceding the actual formation of the cyclic phosphonitrilic chlorides have been summarized by Fluck as shown in Chart 2[306]. Some reactions of these intermediates as well as the alternative routes to their synthesis are included in this chart.

CHART 2 [306]
Structure. The structure of trimeric[320] phosphonitrilic chloride (Fig. 9) as determined by X-ray diffraction studies is a six-membered ring of alternating phosphorus and nitrogen atoms in a plane with two chlorine atoms attached to each phosphorus atom. The structure of the tetramer is similar except that the ring is puckered[321]. The ten-membered ring structure of the pentamer has again a planar configuration[322].

In the skeletal structure of the phosphonitrilic system, phosphorus is tetracoordinated and nitrogen is divalent. Four of the five outer-shell electrons of phosphorus are used to form sigma bonds with the nitrogen and chlorine atoms. Two of the five L-shell electrons of nitrogen are used for the sigma bonds to the phosphorus atoms while two lone-pair
Fig. 9. The $(PNCl_2)_3$ molecule. The atoms P_1, Cl_1, Cl_2, and N_1 lie on a mirror plane,[320] (Reprinted by permission of the Chemical Society).

electrons are probably retained in the third sp^2 hybrid lobe. The remaining one electron each for phosphorus and nitrogen probably interact to form $d\pi-p\pi$ bonds by overlap of phosphorus $3d$ orbitals with nitrogen $2p$ or $2sp^3$ orbitals[304].

After a study of the theoretical and experimental evidence on the structure of the
Fig. 10. Phosphorus atoms interrupt the discrete "islands" of pi character[304]. (Reprinted by permission of the American Chemical Society.)

phosphonitrilic ring system, Allcock[304] has concluded that the rings are not truly "pseudo-aromatic", except when very negative substituents are present. For most other substituents an "island-type" pi structure is favored. That is, the rings are stabilized by skeletal pi-bonding, and the pi bonds are interrupted at each phosphorus atom (see Fig. 10).

The $\gamma_{P:N}$ of $N = P-N$ in cyclic compounds is assigned to the region of

1170–1438 cm^{-1} [323]. The trimer has a strong band at 1220 cm^{-1} and the tetramer has a strong band at 1315 cm^{-1} [324]. The phosphorus–nitrogen bond energy, $E(P = N-P)$ for $(PNCl_2)_3$ is 153 kcal/mole[315]. The NMR chemical shift relative to 85% H_3PO_4 is -20 ppm for the trimer and $+7$ ppm for the tetramer[317].

Polymerization. Cyclic phosphonitrilic chlorides polymerize to a colorless rubbery polymer when heated at 250°. The reaction is exothermic with $-\Delta H_{(polym)}$ decreasing with increasing ring size from 1.39 kcal/mole for the trimer to 0 kcal for the heptamer. The polymer is linear with a degree of polymerization of at least 15,000. It is soluble in such solvents as benzene or tetrahydrofuran. At down to $-63°$, it is still an elastomer and does not melt below 300° [304].

The polymerization reaction is reversible; depolymerization back to the cyclic oligomers occurs at above 350° and to the extent of 76–82% at 600° [325]. The phosphorus–chlorine bonds in the polymer are hydrolytically unstable. This causes the polymer to degrade slowly when exposed to atmospheric moisture.

The mechanism of the polymerization process is not entirely clear. The facts that peroxides do not seem to have an effect on the rate of polymerization and that no free radicals were detected by electron spin resonance techniques during polymerization seem to rule out the free radical mechanism. Allcock[304] favors the ionic mechanism. Compounds such as metals and carboxylic acids which facilitate the removal of the chloride ions from phosphorus are polymerization catalysts. Also conductance and capacitance measurements on equilibrating systems demonstrate the presence of ionic and polarizable species in the mixture[326]. The initiation step, therefore, probably involves the ionization of chloride ion from the phosphorus.

Derivatives. Phosphonitrilic chlorides undergo nucleophilic and electrophilic substitution reactions as well as salt and complex formation. Halogen replacements in the trimer and tetramers by hydroxide ions result in the formation of metaphosphimic acids:

$$[NPCl_2]_{3-4} + 6H_2O \longrightarrow [NP(OH)_2]_{3-4}$$
In the reaction with other nucleophilic reagents such as alkoxides, phenoxides, primary or secondary amines, and organic metallic reagents, it is possible to obtain the fully or partially substituted appropriate derivatives. For the partially substituted derivatives, halogen replacement can take place geminally or nongeminally and *cis* or *trans*. Amines such as methylamine, dimethylamine or piperidine which are strongly basic, substitute nongeminally. Ammonia and tertbutylamine substitute geminally. Phenoxide ion substitutions are predominantly non-geminal. Electron supply from the amino group, steric factor, and structure of the transition states all probably play a part in the mechanism of these substitutions[304].

Of the cyclic phosphonitrilic halides, the tetramer reacts with n-propylamine faster than the trimer. High polymers of phosphonitrilic chlorides are also highly reactive. It is suggested that this reactivity is due to the fact that the more reactive species have greater flexibility in the approach to the transition state.

Of other substitution reactions, Friedel–Crafts arylation reactions with benzene in the presence of aluminum chloride are geminal while those with organometallic reagents are completely random[304].

The alkoxy derivatives undergo a thermal rearrangement to the N-alkyl derivative:
and the bishydroxy derivative rearranges to metaphosphimic acid:

Applications. Because of their tendency to lose chlorine atoms upon exposure to atmospheric moisture, polymeric phosphonitrilic chlorides have not found practical applications. The cyclic phosphonitrilic compounds, in which all of the chlorine atoms are replaced by organic groups, e.g., $[NP(C_6H_5)_2]_4$, do not polymerize to a high molecular weight polymer.

Allcock has been successful in replacing all of the chlorine atoms in a noncross-linked high polymer $(PNCl_2)_n$ ($n \approx 15,000$) from the polymerization of pure $(PNCl_2)_3$ or $(PNCl_2)_4$. The trifluoroethoxy and phenoxy derivatives which he prepared are unaffected after immersion for several months in concentrated aqueous sodium hydroxide solution. These polymers are transparent, flexible and may be converted into films. One major drawback to them is their tendency to depolymerize to low-molecular weight cyclic homologs when heated near 200°.

The hydroquinone derivatives of the mixed trimeric and tetrameric phosphonitrilic chlorides may be cross-linked into flame-retardant polymers. The polymer of the hydroquinone derivative, in combination with the synthetic rubber Hycar, has been reported to be an excellent adhesive[327]. The hexabis (ethyleneimino) derivative
has been found to be useful as a chemosterilant for houseflies and other insects[304]. The propyl ester is employed industrially as an additive type of flame retardant for viscose rayon. It is incorporated inside the fiber by addition to the viscose rayon dope prior to the extrusion process[328].

10.2. OTHER PHOSPHONITRILIC HALIDES

Phosphonitrilic Bromides

These compounds can be prepared by the action of NH_4Br on PBr_5 in a reaction analogous to that for phosphonitrilic chlorides. John and Moeller[329] found that a comparable reaction involving PBr_3, Br_2 and NH_4Br in sym-tetrachloroethane gives a somewhat better yield of the trimer and tetramer:

$$nPBr_3 + nBr_2 + nNH_4Br \longrightarrow (PNBr_2)_n + 4nHBr \qquad (n = 3 \text{ or } 4)$$
This reaction takes about ten days for completion. After the removal of excess NH_4Br by filtration and the solvent by evaporation under reduced pressure, the residue obtained is extracted with benzene. From the benzene extracts, after evaporation of benzene, a dark semi-crystalline mass is obtained. Upon sublimation, the white crystalline product obtained contains about 92% trimer and 8% tetramer. The trimer is separated from the tetramer by fractional crystallization from anhydrous heptane.

Coxon and Sowerby[330] in their study of the reaction between PBr_5 and NH_4Br in sym-tetrachloroethane found besides the lower homologs also a small quantity of the hexameric compounds in the form of white needle crystals with a m.p. of 153–154°. Mass-spectroscopic studies indicated that the cyclic polymers were contaminated with mixed chloride-bromides due to halogen exchange reactions with the solvent sym-tetrachloroethane. This difficulty was eliminated when 1,2-dibromoethane was used as the solvent.

The solubilities in anhydrous n-heptane and petroleum ether (b.p. 90° to 110°) at 25° are for the trimer, 1.45 g and 2.30 g; for tetramer, 0.15 and 0.27 g per each 100 g of solvent respectively.

The P–N stretching frequencies are 1175 cm^{-1} for the trimer and 1272 cm^{-1} for the tetramer.

Trimeric and tetrameric phosphonitrilic bromides polymerize at near 250° in a manner similar to the chloride analogs[305]. Herring[331] also obtained the $(NPBr_2)_n$ polymer by the reaction of NaN_3 with PBr_3 at 165–167°:

$$PBr_3 + NaN_3 \longrightarrow (NPBr_2)_n + NaBr + N_2$$
Phosphonitrilic Fluorides

Both trimeric and tetrameric phosphonitrilic fluorides are prepared by the fluorination of the corresponding chlorides with NaF in acetonitrile or nitrobenzene as solvents[332, 333]. Alternative fluorinating agents such as KSO_2F [334] or a mixture of KF and SO_2 [335, 336] have also been used. By the latter procedure, the cyclic polymers from the trimer to the undecamer were prepared and characterized. Another method of preparation for the

mixture of the trimer and tetramer involves the fluorination of P_3N_5 with CF_3SF_5 or NF_3 at 700° [337].

Trimeric phosphonitrilic fluoride is a colorless liquid with a heat of vaporization $\Delta H_{vap} = 7600$ cal/mole, $\Delta S_{vap} = 23.6$ e.u. The P–N stretching frequency is 1297 cm^{-1} [336]. Tetrameric phosphonitrilic fluoride is also a colorless liquid having a heat of vaporization $\Delta H_{vap} = 8.9$ kcal/mole, $\Delta S_{vap} = 26.4$ e.u. The P–N stretching frequency is 1419 cm^{-1} [336]. Unlike the corresponding chloride, the P–N ring $(PNF_2)_4$ is planar.

The trimer is less reactive than the tetramer. It may be washed with water. The trimer undergoes thermal polymerization in a sealed tube at 350° to a rubbery material. This polymer, however, hydrolyzes readily and depolymerizes partially when heated under vacuum[332].

Phosphonitrilic Mixed Halides

Trimeric phosphonitrilic mixed chloride–bromides are also known[338]. Thus $P_3N_3Cl_5Br$ (m.p. 122.5–123.5°), a white crystalline solid, is prepared by the reaction of PCl_5, NH_4Br and Br_2. When 3 moles of PBr_3 and 2 moles of PCl_5 are reacted with an excess of NH_4Cl, $P_3N_3Cl_4Br_2$ is obtained (m.p. 132.5–135.0). Reaction of one mole of PCl_3 and 1 mole of Br_2 with excess NH_4Br yields $P_3N_3Cl_2Br_4$ (m.p. 167.5–169°).

An interesting compound is $P_4N_4Cl_2F_6$, a derivative of the tetrameric $(PNCl_2)_4$ and yet it is obtained by the heating of a mixture of PbF_2 with the trimeric $(PNCl_2)_3$ [339]. It has a m.p. of $-12.1°$, b.p. 105.8° and a heat of vaporization of 8750 cal/mole.

The physical properties of various phosphonitrilic halides are summarized in Chart 3.

11. LOWER OXYACIDS OF PHOSPHORUS

Various oxyacids of phosphorus and their structural relationship to each other are listed on the following page.

In addition, there are the lower oxyacids of phosphorus in which each molecule contains two or more phosphorus atoms in the same or different oxidation states.

11.1. HYPOPHOSPHOROUS ACID AND HYPOPHOSPHITES

Preparation. Salts of hypophosphorous acid are prepared by heating white phosphorus in an aqueous solution of an alkali or alkaline earth hydroxide. The reaction is fairly complicated and by-products such as hydrogen, phosphite and phosphine are obtained. The main reactions appear to be:

$$P_4 + 4OH^- + 4H_2O \longrightarrow 4H_2PO_2^- + 2H_2$$
$$P_4 + 4OH^- + 2H_2O \longrightarrow 2HPO_3^{2-} + 2PH_3$$
The calcium salt of hypophosphite is water soluble and serves as an easy means of separating the hypophosphite from the insoluble calcium phosphite. A typical preparation

[337] T. J. Mao, R. D. Dresdner and J. A. Young, *J. Am. Chem. Soc.* **81** (1959) 1020.
[338] R. B. Rice, L. W. Daasch, J. R. Holden and E. J. Kohn, *J. Inorg. and Nuclear Chem.* **5** (1958) 190–200.
[339] D. M. Yost and H. Russell, Jr., *Systematic Inorganic Chemistry of the Fifth- and Sixth-Group Non-metallic Elements*, pp. 108–112, Prentice-Hall Inc., New York (1944).

involves the heating of white phosphorus at 80–90° in the presence of an aqueous solution of a mixture of NaOH–Ca(OH)$_2$. The yield of NaH$_2$PO$_2$ is in the order of 55–9%[340]. Improvement in the yield (73% based on the phosphorus consumed) is claimed by the use of a 5% excess of finely divided phosphorus and the reaction carried out at 35–40° [341].
hypophosphorous acid
phosphorous acid
pyrophosphorous acid
hypophosphoric acid
orthophosphoric acid

pyrophosphoric acid

polyphosphoric acid

(HPO$_3$)$_n$
metaphosphoric acid

A similar modification carried out at 45–50° uses an emulsion of phosphorus to increase the reactive surface and amyl alcohol as catalyst to shorten the reaction time. The use of lower temperature for the reaction is claimed to have the effect of suppressing the formation of phosphine and phosphite with a resulting increase in the yield of hypophosphite[342].

Free hypophosphorous acid is generally prepared from its calcium salt by treatment

[340] E. M. Morgunova and T. D. Averbukh, *Zh. Prikl. Khim.* **40**(2) (1967) 174–84.
[341] H. Harnisch and F. Rodis, Ger. 1,112,054, 3 Aug. 1961, to Knapsack-Griesheim A.G.
[342] R. R. Pahud, Swiss 322,980, 30 Aug. 1957, to La Fonte electrique, S.A.

with an equivalent amount of sulfuric acid or oxalic acid[343]. It is not obtained by evaporation of an aqueous solution, since it would undergo oxidation to phosphorous and phosphoric acids as well as disproportionation to phosphine and phosphorous acid. Hypophosphorous acid is slightly soluble in ethyl ether and it has been found practical to extract it from an aqueous solution with ethyl ether in a continuous liquid–liquid extraction apparatus. The acid thus obtained is a colorless liquid which crystallized in cooling[344].

Hypophosphorous acid is formed also by the oxidation of PH_3 with iodine in water. This reaction has to be carried out under controlled conditions and in a weak acid medium. In the presence of excess iodine and strong acid medium, the oxidation reaction continues to the formation of phosphorous acid[345].

Hypophosphite is also formed by the oxidation of PH_3 in an aqueous solution of NaClO in accordance with the following proposed reaction scheme[346]:

$$OCl^- + H_3O^+ \rightleftharpoons HOCl + H_2O \text{ (fast)}$$

$$PH_3 + HOCl \rightarrow [PH_3O] + H^+ + Cl^- \text{ (rate detg).}$$

$$[PH_4O] + OCl^- \rightarrow H_3PO_2 + Cl^- \text{ (very fast)}$$
Structure. The hypophosphite anion of ammonium hypophosphite[347] has been shown to be a distorted tetrahedron with the phosphorus atom in the center, two oxygen atoms in two corners and two hydrogen atoms in the other two corners. The bond distances are P–O = 1.51 Å, P–H about 1.5 Å, and the bond angles: H–P–H = 92°, O–P–O = 120°. The O–P–O bond angle of the anion of the magnesium salt is quite smaller, being 109°. Infrared studies show that the hypophosphite anion of the potassium, sodium and ammonium salts exhibit C_{2v} symmetry while that of the calcium salt indicates a C_1 symmetry[348].

Properties. Pure hypophosphorous acid[347] is a white crystalline solid that melts at 26.5° and easily supercools to a viscous liquid. It is a monobasic acid with a dissociation constant of 8.0×10^{-2}, and $pk_1 = 1.1$ at 20–25°, n_D^{20} 1.4601, d_4^{20} 1.479. A water solution of hypophosphorous acid is not oxidized by atmospheric oxygen but will decompose when heated to above 140° to give phosphine, phosphoric acid and hydrogen. To avoid decomposition, the crystalline acid should not be heated to above 50°. In alkaline solution, the decomposition follows the equation:

$$H_2PO_2^- + OH^- \xrightarrow{\hspace{1.5cm}} HPO_3^= + H_2$$
and the rate of decomposition increases with the OH^- concentration[349].

The alkali and alkaline earth salts, as are also most of the heavier metal salts of hypophosphite, are quite soluble in water. The hypophosphite ion is a reducing agent and its characteristic reduction reactions are those with silver nitrate to give black, metallic silver, cupric salts to give cuprous salts and metallic copper[349], the dichromate to Cr^{+++}[350]. The oxidation potential for the half cell reaction:

[350] K. Pang and S. H. Lin, *J. Chinese Chem. Soc.* (*Taiwan*) **7** (1960) 75–80.

$$H_3PO_2 + H_2O \longrightarrow H_3PO_3 + 2H^+ + 2e^-$$
is estimated to be 0.59 V[349].

Besides salt formation through the acidic hydrogen, hypophosphorous acid also reacts with aldehydes through the P–H bonds[351]:
$$H_3PO_2 + CCl_3CHO \xrightarrow{36°} Cl_3CCH{-}P{-}OH$$

$$\xrightarrow{80-100°} (Cl_3CCH{-})_2POH$$

Analogous compounds H$_2$C—P—OH and (H$_2$C—)$_2$POH are obtained in reactions with formaldehyde[352].

For analytical purposes, hypophosphite separates cleanly from phosphites, phosphates, hypophosphates and diphosphites, etc., by gradient elution and anion exchange chromatographic technique at a pH of 6.8 (NH$_4$OAc–KCl buffer system)[353, 354], using Dowex 1–X8 resin or by the use of a cellulose powder packed column and eluting with an aqueous ammoniacal iso-propyl and tert-butyl alcohol solution[355].

Applications. The hypophosphite of the greatest industrial importance is the sodium salt (NaH$_2$PO$_2$.H$_2$O). Its main application is as reducing agent for the electroless plating of a nickel coating on metallic parts such as steel or aluminum. One proposal[356] for the mechanism of this plating reaction is as follows:

$$H_2PO_2^- + H_2O \longrightarrow HPO_3^{--} + 2H^+ + H^-$$
$$Ni^{++} + 2H^- \longrightarrow Ni° + H_2$$
$$H^+ + H^- \longrightarrow H_2$$
This plating process has been commercialized by the General American Transportation Corporation under the trademark of "Kanigen." It has been used as a relatively inexpensive and convenient method for plating of the inside of mild steel tank cars and containers used for holding corrosive materials. It is also used for the nickel plating of intricately shaped objects such as valves and pump parts and chemical processing equipments needing corrosion resistant surfaces. The nickel coating is amorphous and contains 6–15% of P depending on the concentration of the hypophosphite solution used. The hardness of the coating is increased by heating (1 hr at 400° increases the hardness from 49 Rockwell C to 70 Rockwell C), which results in the precipitation of Ni$_3$P in the nickel–phosphorus lattice[357].

The plating solution contains as chief ingredients sodium hypophosphite and nickel

sulfate. In addition, it also contains auxiliary reagents such as complexing agent (e.g., lactates) to prevent the precipitation of nickel phosphite, accelerators (e.g., malates and succinates) to speed up the rate of nickel deposition, and stabilizers (e.g., lead salts) to prevent the random decomposition of the bath[358].

Hypophosphite electroless nickel plating is also applicable to certain plastic parts. In this case a palladium pre-coating on the plastic surface is needed to initiate the plating of nickel which then becomes autocatalytic. The electroless nickel coating thus obtained serves then as the electroconducting surface for the eventual chrome-plating of the plastic piece.

In addition to Ni–P coatings, hypophosphite plating process is also useful for the application of Co–P[359], and tin[360] coatings.

A very old use for hypophosphite is as an ingredient for tonic compositions. For this purpose sodium, manganese[361], calcium[362], and methionine[363] salts are claimed in the patent literature.

Because of its reducing properties, hypophosphorous acid and its salts are claimed as anti-oxidant for the prevention of discoloration during the cooking of modified alkyd resins from polyols and monobasic carboxylic acids[364]. They are also used as a light and heat stabilizer for polyamides[365]; as light stabilizer for polyvinyl chlorides[366]; and as stabilizer to prevent the decomposition of polyurethane foam during its preparation[367].

11.2. PHOSPHOROUS ACID AND PHOSPHITES

Preparation. Phosphorous acid is usually prepared by the hydrolysis of PCl_3:

$$PCl_3 + 3H_2O \longrightarrow H_3PO_3 + 3HCl$$
One industrial method involves the spraying of PCl_3 under nitrogen into a reactor containing an excess of water in the form of steam at 185–190°. The product is then sparged of residual H_2O and HCl at 166° with the aid of nitrogen. Crystalline H_3PO_3 obtained by this method contains $< 0.05\%$ Cl^-, $< 1.4\%$ PO_4^{3-} and $< 1.5\%$ H_2O. Small-scale laboratory[369] preparation is carried out by adding water to an ice bath cooled solution of PCl_3 in CCl_4. The aqueous layer separated is removed of excess water and HCl by heating under vacuum at 60°. The purity of the crystalline acid obtained is 99.5%. Phosphorous acid can also be prepared by the direct hydration of P_4O_6 obtained from the controlled oxidation of phosphorus[370].

[370] Proctor and Gamble Co., Belg. 701,548, 19 July 1967.

Structure. X-ray diffraction studies on the magnesium salt, $MgHPO_3.6H_2O$, show he phosphorous atom to be surrounded tetrahedrally by one hydrogen atom and three oxygen atoms.

In an aqueous solution, the ionic radius of $HPO_3^=$ of NaH_2PO_3 and K_2HPO_3 in the concentration range of 1 g-equivalent per 10–100 moles of water at 25° is 1.33–1.52 Å. The radius decreases with increase in dilution, possibly due to the compression of H_2O molecules in the vicinity of $HPO_3^=$ [371].

NMR spectra of both hydrogen and phosphorus of a phosphite salt solution exhibit 1–1 spin–spin splitting, thus indicating that the hydrogen atom is attached directly to the phosphorus atom[372].

Properties. Since phosphorous acid has a structure of $HP(O)(OH)_2$ rather than $P(OH)_3$, it is a dibasic acid. At 18°, the first ionization constant is 5.1×10^{-2}, the second ionization constant is 1.8×10^{-7}. The heat of fusion of the crystalline acid is 3.07 kcal/mole, and the heat of solution in an excess of water is -0.13 kcal/mole[347].

Phosphorous acid is an extremely hygroscopic white crystalline solid, m.p. 73–74°. The specific gravity of the liquid is D_4^{76} 1.597 [369].

The potential constants for $PO_3^=$ calculated on the basis of the Urey–Bradley type potential field showed a stretching force constant of 4.808, bending force constant of 0.095 and repulsion force constant of 1.193 (all $\times 10^5$ dynes/cm)[373].

Thermal decomposition of phosphorous acid is fairly complex, but basically it involves self-oxidation-reduction reactions which result in the formation of phosphoric acid, phosphine, hydrogen and some red phosphorus. This decomposition reaction is quite rapid at 250–275° [347].

Atmospheric oxygen does not oxidize phosphorous acid except in the presence of I_2 and light. Phosphorous acid, as a reducing agent, reduces Ag^+ to metallic silver, reacts with hot concentrated H_2SO_4 to give H_3PO_4 and SO_2. It is also oxidized in aqueous solution to the phosphates by halogens, mercuric chloride and other oxidizing agents. The oxidation potential of the couple, H_3PO_3, H_3PO_4, in acid solution is estimated to be 0.28 V and in alkaline solution the potential $HPO_3^=$, $PO_4^=$ is 1.12 V[347].

Derivatives. Because of its dibasic nature, phosphorous acid forms two series of salts, the normal and the acid phosphites. Compounds such as $(NH_4O)HP(O)(OH)$, $(NH_4O)_2P(O)H.H_2O$, $LiOP(O)H(OH)$, $(LiO)_2P(O)H$ are known. The sodium and potassium salts in addition to the normal and acid salts: $Na_2PHO_3.5H_2O$, $NaH_2PO_3.2.5H_2O$, K_2HPO_3 and KH_2PO_3 also form adducts such as $Na_2HPO_3.2H_3PO_3.0.5H_2O$, $K_2HPO_3.2H_3PO_3$ [347], $2KH_2PO_3.H_3PO_3$ and $KH_2PO_3.H_3PO_3$ [374]. By specific electric conductivity measurements at various concentrations, it was found that the adducts of the potassium salts exist in aqueous solution just the same as in the solid phase. Their formation increases with increase in the concentration with negligible temperature effect at the range of 25–45° [375].

The monobasic salts, such as $Mg(H_2PO_3)_2$, $Ca(H_2PO_3)_2$ and $Sr(H_2PO_3)_2$, are prepared in greater than 99% purity by the addition of the respective carbonate or hydroxide to an excess of molten H_3PO_3 at 80°. The excess H_3PO_3 is then removed by washing with ethyl

alcohol or acetone[376]. For the preparation of such compounds as $NH_4H_2PO_3$ and $(NH_4)_2HPO_3 \cdot H_2O$, the neutralization is carried out in methyl or ethyl alcohol or in acetone as solvent[377].

Esters of phosphorous acid, both the tri $[P(OR)_3]$ and dialkyl esters, $[(RO)_2P(O)H]$, are usually produced from the reaction of PCl_3 with the corresponding alcohols under proper conditions, e.g.:

$$PCl_3 + 3ROH \longrightarrow (RO)_2\overset{\displaystyle O}{\overset{\displaystyle \|}{P}}H + RCl + 2HCl$$

$$PCl_3 + 3ROH + 3R_3N \longrightarrow (RO)_3P + 3R_3N \cdot HCl$$
Triaryl phosphites are prepared by the direct action of PCl_3 with phenols while the diaryl esters, $(ArO)_2\overset{\displaystyle O}{\overset{\displaystyle \|}{P}}H$, are best prepared by the rearrangement reaction of phosphorous acid with triaryl phosphites at 100–160° [378]:

$$3ArOH + PCl_3 \longrightarrow (ArO)_3P + 3HCl$$

$$2(ArO)_3P + H_3PO_3 \longrightarrow 3(ArO)_2\overset{\displaystyle O}{\overset{\displaystyle \|}{P}}H$$
Long chain dialkyl esters have also been prepared by direct esterification of phosphorous acid[379]:

$$H_3PO_3 + 2ROH \longrightarrow (RO)_2\overset{\displaystyle O}{\overset{\displaystyle \|}{P}}H + 2H_2O$$
An interesting reaction of phosphorous acid is that with NH_4Cl and aqueous formaldehyde to form the sequestrant, nitrilotrimethylenephosphonic acid :[380]:

$$NH_4Cl + 3H_2CO + 3H_3PO_3 \longrightarrow N[CH_2\overset{\displaystyle O}{\overset{\displaystyle \|}{P}}(OH)_2]_3 + 3H_2O + HCl$$
The trialkyl phosphites, especially the long chain ones, are readily prepared by the ester exchange reaction between the alcohol and triphenyl phosphite[381]:

$$(C_6H_5O)_3P + 3ROH \longrightarrow (RO)_3P + 3C_6H_5OH$$

For quantitative determination of lower trialkyl and dialkyl esters in the presence of each other, advantage is taken of the fact that trialkyl phosphite hydrolyzes only slowly in an alkaline alcohol solution but rapidly in an acidic alcohol solution to the dialkyl phosphonate, and that dialkyl phosphonate hydrolyzes immediately in an alkaline alcohol solution. In a mixture of trialkyl phosphite and dialkyl phosphonate, the latter can thus be titrated in an alkaline alcohol solution before the trialkyl phosphite begins to hydrolyze[382].

Applications. The important applications of phosphorous acid are based on its salts and esters. Most of the applications depend on the reducing property of the trivalent

[382] D. N. Bernhart and K. H. Rattenbury, *Anal. Chem.* 28 (1956) 1765–6.

phosphorus atom in these compounds. One use is as stabilizers for polyvinyl chloride and other polymers. When used with other stabilizing ingredients, they prevent the discoloration of the polymers by heat or u.v. light. Some of the more widely used phosphites for this purpose are triphenyl phosphite, trinonylphenyl phosphite and tri-iso-octyl phosphite. The organic groups attached to the phosphorus atom, depending on their nature, improve the compatibility of the stabilizer to the polymer system. Specific organic groups also have special synergistic action for certain systems. For example, triphenyl phosphite is most widely used for polyvinyl chloride, while trinonylphenyl phosphite is an excellent stabilizer for the GR–S polymer.

11.3. PYROPHOSPHOROUS ACID AND POLYPHOSPHOROUS ACID

In contrast to pyrophosphoric and polyphosphoric acids, all of which may be obtained by the thermal condensation of orthophosphoric acid, it is not possible to prepare pyrophosphorous or polyphosphorous acid by the analogous thermal condensation of phosphorous acid. Thermal dehydration of phosphorous acid at $80°$ and 10^{-3} mm does not yield pyrophosphorous acid after 8 hr. Pyrophosphorous acid has to be prepared by other than the thermal condensation route. One such route is the reaction PCl_3 with H_3PO_3 [383]:

$$5H_3PO_3 + PCl_3 \rightleftharpoons 3H_4P_2O_5 + 3HCl$$
This reaction is reversible and it necessitates the complete removal of HCl.

Attempts at analogous reaction to produce polyphosphorous acid had not been successful. Apparently, if polyphosphorous acid were formed, it was too unstable and underwent disproportionation reactions since only phosphoric acid and products of lower degree of oxidation were obtained [384].

Disodium pyrophosphite may be prepared by the dehydration of monosodium phosphite, $NaH_2PO_3 \cdot 2.5H_2O$, under vacuum at $150°$. Similarly, the diammonium, dipotassium, calcium, strontium, barium and lead pyrophosphites are prepared from the respective acid orthophosphites [347]. When the dehydration of NaH_2PO_3 is carried out at 300–$400°$, the reaction leads to complex oxidation and rearrangement products [385]. It is not possible to form polyphosphites by the dehydration of the acid phosphite [386].

Pyrophosphite hydrolyzes slowly to the orthophosphite in neutral solution and more rapidly in either strong acid or strong base solution. The approximate half-lives at $30°$ are pH 5–7, 1000 hr; pH 4, 60 hr; pH 3, 8 hr; pH 1.5, 5 min [347].

$$\begin{array}{ccc} H & & H \\ | & & | \\ O = P\!-\!O\!-\!P & = & O \\ | & & | \\ O{-} & & O{-} \end{array}$$
11.4. HYPOPHOSPHORIC ACID AND HYPOPHOSPHATES

Preparation. The common method for the preparation of hypophosphate is by controlled oxidation of elemental phosphorus. A procedure proposed by Genge, Nevett and Salmon [387]

[383] J. P. Ebel and F. Hossenlopp, *Bull. Soc. Chim. France*, **8** (1965) 2219-2; *ibid.* 2221-8.
[384] Ref. 383, pp. 2229–33.
[385] B. Krukowska-Fulde, *Roczniki Chem.* **35** (1961) 1203–10.
[386] D. Grant, D. S. Payne and S. Skledar, *J. Inorg. Nucl. Chem.* **26**(12) (1964) 2103–11.
[387] J. A. R. Genge, B. A. Nevett and J. E. Salmon, *Chem. and Ind.*, (*London*) (1960) 1081–2.

produces the disodium salt $Na_2H_2P_2O_6.6H_2O$ in greater than 99.5% purity. This procedure involves the use of a 35×3.5 cm column cooled internally using a 1.5 cm diameter tube, and externally using a 6.0 cm diameter tube, and packed with alternate layers of glass beads (0.3 to 0.4 cm diameter) and 35 g of red phosphorus supported on porcelain chips and glass wool. The red phosphorus is first cleaned by digesting with 10% HCl, followed by washing. A solution of 135 g of sodium chlorite in 750 cc of water is passed through the column at a rate of about 150 cc/hr, keeping the effluent temperature at 15–18°. The effluent is then adjusted to a pH of 5.2 with NaOH. Upon cooling to 0°, $Na_2H_2P_2O_6.6H_2O$ crystallizes out. If the pH were adjusted to 10, $Na_4P_2O_6.10H_2O$ would crystallize out. After two recrystallizations from water, 45 g of disodium salt of high purity is obtained. A similar procedure described in *Inorganic Synthesis*[388] reported a yield of approximately 30% of $Na_2H_2P_2O_6.6H_2O$ based on the weight of sodium chlorite consumed.

The disodium salt is also obtained by the oxidation of red phosphorus with a cold solution of calcium hypochlorite. In this procedure, the $Ca_2P_2O_6.2H_2O$ formed is acidified with H_2SO_4 to precipitate $CaSO_4.2H_2O$. The filtrate obtained upon treatment with sodium acetate forms crystals of $Na_2H_2P_2O_6.6H_2O$[389, 390]. Oxidation of red phosphorus with H_2O_2, followed by adjusting the pH of the solution to 5.2 with NaOH, also produces $Na_2H_2P_2O_6.6H_2O$[391]. Other oxidants such as $KMnO_4$, NaClO, NaBrO, or acid solutions of $K_2S_2O_8$, $NaBrO_3$ have also been used. By-products from these oxidation reactions are phosphite, orthophosphate, pyrophosphate and polyphosphate[392]. Since phosphorus sulfides such as P_4S_3, P_4S_5 and P_4S_7 and P_2I_4 also contain P–P bonds, they too produce hypophosphates as part of the product-mix on oxidative hydrolysis[393, 394].

Hypophosphoric acid, $H_2P_2O_6 \cdot 2H_2O$, is obtained by passing a solution of $Na_2H_2P_2O_6 \cdot 6H_2O$ through a column of cation exchange resin[387]. The anhydrous acid is obtained by the dehydration of the dihydrate *in vacuo* over P_2O_5 for a period of two months.

The ester of hypophosphate is prepared by the reaction of sodium dialkyl phosphite with SO_2Cl_2[395]:

$$2 \underset{\underset{\displaystyle \parallel}{\displaystyle O}}{RO)_2PNa} + SO_2Cl_2 \longrightarrow \underset{\underset{\displaystyle \parallel \ \parallel}{\displaystyle O \ \ O}}{RO)_2P-P(OR)_2} + SO_2 + 2NaCl$$

Structure. The tetrasodium salt, $Na_4P_2O_6 \cdot 10H_2O$, is monoclinic, space group $C2/c$, with 4 mols per unit cell. The cell dimensions are $a = 16.97$, $b = 6.97$, $c = 14.50$ Å, $\beta = 116°$. The disodium salt $Na_2H_2P_2O_6 \cdot 6H_2O$, has also 4 mols per unit cell, space group $C2/c$ with unit cell dimensions of $a = 14.12$, $b = 7.00$, $c = 12.71$ Å, $\beta = 115.4°$. The trisodium salt, $Na_3HP_2O_6 \cdot 9H_2O$, belongs to space group Pn with 4 mols per monoclinic unit cell. The cell dimensions are $a = 26.96$, $b = 6.00$, $c = 9.26$ Å and $\beta = 110°$ [396].

X-ray diffraction pattern, NMR studies, infrared and Raman spectra, all support the anion structure of

[388] E. Leininger and T. Chulski, *Inorganic Synthesis*, Vol. 4, pp. 68–71, Ed. J. C. Bailar, Jr., McGraw-Hill Book Co., New York (1953).

[395] J. Michalski and T. Modro, *Roczniki Chem.* **36** (1962) 483–8.

[396] D. E. C. Corbridge, *Acta Cryst.* **10** (1957) 85.

$$\begin{array}{c} \text{O O} \\ \| \ \| \\ \text{-O-P-P-O-} \\ |\ \ | \\ \text{-O O-} \end{array}$$
Properties. In the absence of moisture both $H_4P_2O_6$ and $H_4P_2O_6.2H_2O$ are stable at 0–5°. The anhydrous acid begins to melt at 73° without a sharp m.p.[397] It undergoes rearrangement and self-oxidation-reduction at room temperature into $H(HO)(O)POP(O)(OH)_2$, $H_4P_2O_7$, and $[(HO)_2P]_2O$[398]. The dissociation constants for hypophosphoric acid are $K_1 =$ about 6×10^{-3}, $K_2 =$ about 1.5×10^{-3}, $K_3 = 5.4 \times 10^{-8}$ and $K_4 = 0.93 \times 10^{-10}$ at 25° [372].

The hypophosphate anion is very stable to alkali hydroxide and does not decompose even when heated at 200° with 80–90% NaOH. It hydrolyzes slowly (half-life in 1 N acid at 25° = 180 days), however, in an acid solution:

$$\begin{array}{c} \text{O O} \\ \| \ \| \\ \text{HOP-POH} + H_2O \\ |\ \ | \\ \text{HO OH} \end{array} \xrightarrow{H^+} \begin{array}{c} \text{O} \\ \| \\ \text{HO-P-H} \\ | \\ \text{HO} \end{array} + \begin{array}{c} \text{O} \\ \| \\ \text{HOP-OH} \\ | \\ \text{OH} \end{array}$$
The rate of hydrolysis is quite rapid in 4 N HCl (1 hr completely changed).

11.5. MISCELLANEOUS LOWER OXYACIDS OF PHOSPHORUS

A series of lower oxyacids of phosphorus containing two or more phosphorus atoms of the same or different oxidation state in each molecule were reported by Blaser and Worms. The chemistry of these compounds has recently been reviewed by Ohashi[372]. These compounds are of such structures that they are difficult to name by present rules for nomenclature of phosphorus compounds. The structural formula and the abbreviated notations originally proposed by Blaser and Worms[399] will be used in this section. These notations use the phosphorus and oxygen linkage which comprised the skeleton of the compound. The oxidation state of the phosphorus atom is indicated by the corresponding number.

$$\begin{array}{c} \text{H H} \\ \text{O O} \\ |\ \ | \\ \text{2 2} \qquad \text{P-P acid, H-P-P-H} \\ \| \ \| \\ \text{O O} \end{array}$$
This acid is prepared by the hydrolysis of a carbon disulfide solution of P_2I_4 at 0°. The barium salt, $BaH_2P_2O_4$, is precipitated from the aqueous solution. The acid undergoes disproportionation reaction to form phosphine and phosphorus or phosphoric acids. However, it is stable in an aqueous solution at pH 7. It oxidizes by oxygen readily in an aqueous solution to P-P and P-P acids. The structure of the P-P acid is assumed from the method of preparation and chemical properties.

[397] H. Remy and H. Falius, *Naturwissenschaften*, **43** (1956) 177.
[398] H. Remy and H. Falius, *Chem. Ber.* **92** (1959) 2199–2205.
[399] B. Blaser and K. H. Worms, *Z. anorg. u. allgem. Chem.* **300** (1959) 225–8.

\| \ \| \\
\text{O O}
\end{array}
\end{array}
$$
Hydrolysis of PBr_3 or PI_3 in a water suspension of sodium hydrogen carbonate at 0–5°
produces the sodium salt of P–P$\overset{2\ 4}{}$ acid along with some sodium hypophosphate. By
recrystallization from water, $Na_3P_2HO_5.12H_2O$ is obtained. The P–P$\overset{2\ 4}{}$ anion is stable in
alkaline solution but when heated with 80% NaOH, it converts to the P–P$\overset{4\ 4}{}$ anion with
liberation of hydrogen. In an acid solution it hydrolyzes readily at 25° into 2 moles of
phosphorous acid[372]:

$$
\begin{array}{ccc}
\begin{array}{c}
\text{H H} \\
\text{O O} \\
| \ | \\
\text{H–P–P–OH} \\
\| \ \| \\

\text{H–P–OH} \\
\| \\
\text{O}
\end{array}
\end{array}
$$
The P–P$\overset{2\ 4}{}$ anion undergoes oxidation with bromine to the hypophosphate in an acid
solution but to the pyrophosphate in a $NaHCO_3$ solution.

$$
\overset{3}{\text{(P)}_6 \text{ ring acid,}}
$$
When red phosphorus is oxidized in a solution of potassium hypochlorite and potassium
hydroxide, a very small yield of (P)$\overset{3}{_6}$ ring acid is obtained as the crystalline potassium-
sodium salt (80–85% K and 16–18% Na).

It hydrolyzes in acidic solution to the phosphite and a minor amount of hypophosphite
and phosphate. Hydrolysis in alkaline solution produces the phosphite and some P–P$\overset{2\ 4}{}$
anion[400]. The cyclic puckered six-membered ring structure was determined by the X-ray
diffraction study of the cesium salt. Other supporting evidences for the structure are (1)
infrared spectra which show no P–H bonds and (2) pH titration curve which shows only one
inflection point[372].

$$

\end{array}
$$
As expected from the structure, it hydrolyzes readily in 0.5 N NaOH solution to the phosphite and hypophosphate[372].

4 3 4
P–P–P acid, $\text{HO}-\overset{\overset{\text{H}}{\overset{\text{O}}{|}}}{\underset{\underset{\text{O}}{\parallel}}{\text{P}}}-\overset{\overset{\text{H}}{\overset{\text{O}}{|}}}{\underset{\underset{\text{O}}{\parallel}}{\text{P}}}-\overset{\overset{\text{H}}{\overset{\text{O}}{|}}}{\underset{\underset{\text{O}}{\parallel}}{\text{P}}}-\text{OH}$
The pentasodium salt of this acid, $Na_5P_3O_8.14H_2O$, is obtained in low yield by the oxidation of P_6 ring anion in a solution of $KHCO_3$ with iodine. It is also one of the very minor products of oxidation of red phosphorus with an aqueous solution of sodium hypochlorite[372].

3 5
P–O–P acid, $\text{H}-\overset{\overset{\text{H}}{\overset{\text{O}}{|}}}{\underset{\underset{\text{O}}{\parallel}}{\text{P}}}-\text{O}-\overset{\overset{\text{H}}{\overset{\text{O}}{|}}}{\underset{\underset{\text{O}}{\parallel}}{\text{P}}}-\text{OH}$
This acid, being the anhydride of phosphorous and phosphoric acid may be prepared by several methods, e.g.:

$$
\text{H}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-\text{O}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-\text{H} + {}^-\text{O}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-\text{O}^- \longrightarrow \text{HP}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{}}}-\text{O}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-\text{O}^- + \text{H}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-\text{O}^-
$$

$$
POCl_3 + \text{HP}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{}}}-O^- + 2H_2O \longrightarrow \text{H}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-O-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-O^- + 3HCl + H^+
$$

$$
PCl_3 + {}^-\text{O}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-O^- + 2H_2O \longrightarrow \text{H}-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-O-\overset{O}{\overset{\parallel}{\underset{\underset{O^-}{|}}{P}}}-O^- + 3HCl + H^+
$$
It is also a product of the spontaneous rearrangement of anhydrous hypophosphoric acid[398].

The structure of the compound is indicated by the methods of preparation and the reactions with oxidizing agents. Two trisodium salts, the tetrahydrate and octahydrate, are known. These salts are stable in the solid state and in neutral solution, but hydrolyze in acid and alkaline solutions to the phosphite and phosphate[372].

4 4
(–P–P–O–)₂ ring acid,

$$
\begin{array}{c}
\text{OH} \quad \text{HO} \\
\text{O}\underset{\diagdown}{\overset{\diagup}{P}}\text{---}\overset{\diagup}{P}\text{O} \\
\text{O} \qquad \qquad \text{O} \\
\overset{\diagup}{P}\text{---}\overset{\diagdown}{P} \\
\text{HO} \quad \text{O O} \quad \text{OH}
\end{array}
$$
This acid is formed by the dehydration of 2 moles of tetrapotassium hypophosphate with acetic anhydride. Attempted preparation by thermal dehydration of the sodium or potassium acid hypophosphate was not successful. The crystalline tetraguanidium salt is obtained by
4 4
treating an aqueous solution containing the P–P–O₂ ring anion at 0° with guanidium chloride. The ring anion is hydrolyzed quantitatively at 150° with 60% KOH to the hypophosphate anions. Under milder conditions of hydrolysis, the pyrohypophosphate anion,
4 4   4 4
P–P–O–P–P is formed.

4 4   4 4
P–P–O–P–P acid,
$$
\text{HO}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-O-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\text{OH}
$$
The hexasodium salt of this acid is obtained in very high yield by the hydrolysis of the
4 4
tetrasodium salt of the ring acid P–P–O₂ in a 1.5 N NaOH solution at 25°. The anion
4 4   4 4
P–P–O–P–P is quite stable in alkaline solution but does hydrolyze quantitatively to the hypophosphate anion when heated at 150° with 60% NaOH. Hydrolysis in a hot acid solution results in the degradation to phosphorous acid and phosphoric acid with hypophosphoric acid as the intermediate[372].

5   4 4
P–O–P–P acid,
$$
\text{HO}\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-O-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\text{OH}
$$
Since this acid is the anhydride of phosphoric and hypophosphoric acid, it can be prepared by the reaction of POCl₃ with hypophosphoric acid:

$$
\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{\overset{\overset{\displaystyle Cl}{\overset{\displaystyle |}{}}}{Cl P Cl}} + \text{HO}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\text{OH} + 2\text{H}_2\text{O} \longrightarrow \text{HO}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-O-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\overset{\overset{\displaystyle H}{\overset{\displaystyle |}{\overset{\displaystyle O}{}}}}{\underset{\underset{\displaystyle O}{\underset{\displaystyle \|}{}}}{P}}-\text{OH} + 3\text{HCl}
$$
4 3 4
It is also prepared in good yield by the oxidation of P–P–P acid with bromine in a solution of KHCO₃. The anion hydrolyzes to the phosphate and hypophosphate anions when

heated with 60% KOH. Similar results are obtained when the hydrolysis is carried out in dilute mineral acid.

The lower oxyacids of phosphorus are of interest only from the academic standpoint. No practical applications have been developed for them.

12. PHOSPHORIC ACIDS

12.1. ORTHOPHOSPHORIC ACID

Preparation. Orthophosphoric acid is one of the most important of phosphorus compounds. It was prepared originally by the "wet process" which involved the treatment of calcined bones with sulfuric acid. A large quantity of it is still prepared by this process except that now the more abundant phosphate rock has replaced bone as the phosphatic raw material. The major reactions of calcium phosphate and the combined calcium fluoride (as occur in fluorapatite) with sulfuric acid are shown in the following formalized equations:

$$Ca_3(PO_4)_2 + 3H_2SO_4 + 6H_2O \longrightarrow 3CaSO_4.2H_2O + 2H_3PO_4$$
$$CaF_2 + H_2SO_4 + H_2O \longrightarrow CaSO_4.2H_2O + 2HF$$
The relatively insoluble $CaSO_4.2H_2O$ is filtered off and the dilute phosphoric acid, containing 30–32% P_2O_5, is then concentrated by evaporation. The acid obtained in this manner is quite impure but of sufficient quality for most fertilizer preparations. Further purification by removal of residual F^- (as the insoluble Na_2SiF_6), iron, aluminum, and other metallic impurities present originally in the phosphate ore results in an acid of adequate purity suitable for sodium phosphates used in detergent applications. Engineering modifications and process changes in the wet process have made possible the preparation of phosphoric acid of 50 to 54% P_2O_5 content prior to concentrating by evaporation.

One interesting new development in the wet process involves the acidulation of phosphate rock with hydrochloric acid. The phosphoric acid thus generated is first extracted from the water solution away from the soluble calcium chloride by-product and other impurities by means of organic solvents such as butyl or amyl alcohols. It is then recovered from the organic solvent by extraction with water[401]. If sufficient numbers of extraction stages are used in this process, phosphoric acid of high purity is obtained. Recent reviews of the wet process phosphoric acid technology have been compiled by Slack[402].

Commercially, all pure phosphoric acid suitable for application in food products is manufactured by the hydration of phosphoric anhydride obtained by the oxidation of elemental phosphorus:

$$P_4 + 5O_2 \longrightarrow P_4O_{10}$$
$$P_4O_{10} + 6H_2O \longrightarrow 4H_3PO_4$$
In this process, the phosphoric anhydride formed is hydrated immediately in the reactor systems where phosphorus is burned. The acid obtained, known as "thermal acid", is then treated with hydrogen sulfide to remove arsenic impurity as the insoluble arsenic sulfide. After filtration, the acid is diluted to 75, 80 or 85% H_3PO_4 for commercial applications.

[402] A. V. Slack, *Phosphoric Acid*, Vol. I, Part I and Part II, Marcel Dekker, Inc., New York (1968).

Properties. Solid crystalline orthophosphoric acid can be obtained on a laboratory scale by removal of free water from commercial 85% H_3PO_4 and the anhydrous liquid acid allowed to crystallize[403]. It has a m.p. of 42.35° and forms a hemihydrate with a m.p. of 29.32°. Pure phosphoric acid crystallizes only slowly and is quite easy to supercool into a glass. The glassy transition point is −121°. The heat of formation of crystalline
FIG. 11. H_3PO_4–H_2O system[405]. (Reprinted by permission of John Wiley & Sons Inc.)

H_3PO_4 is $\Delta H_f^\circ = -306.2$ kcal/mole. For the pure liquid H_3PO_4: $\Delta H_f^\circ = -303.57$ kcal/mole, $\Delta F_f^\circ = -268.73$ kcal/mole, $S^\circ = 38.3$ e.u.[404]. The liquid-solid phase diagram for the phosphoric acid–H_2O system from 0 to 11% equivalent H_3PO_4 is shown in Fig. 11[405].

The equation for the vapor pressure of an aqueous solution of phosphoric acid is:

$$\log P_{mm} = -A/T - 4.9373 \log T + 1.639 \times 10^{-5}T + 4.874 \times 10^{-8}T^{-2} + B$$

The vapor pressure equation constants, vapor pressure, heat of vaporization for selected concentrations of H_3PO_4 are summarized in Table 12[404].

The density, boiling point, specific heat, electric conductivity and approximate viscosity of phosphoric acid at selected concentration and temperature are shown in Table 13[404, 406].

TABLE 12

Weight % H_3PO_4	Vapor pressure constants		Vapor pressure mm Hg at		Heat of vaporization cal/mol H_2O vaporized	
	A	B	25°	100°	$\Delta H_{298.16}$	$\Delta H_{373.16}$
29.80	2943.8	23.4092	21.19	684	10,560	9840
50.20	2981.4	23.4275	16.61	565	10,730	10,010
70.90	3066.2	23.3837	7.80	303	11,120	10,400
80.14	3145.0	23.3422	3.86	170	11,480	10,760

Phosphoric acid is tribasic. The dissociation constants at 25° are:

$$K_1 = 0.7107 \times 10^{-2}, K_2 = 7.99 \times 10^{-8}, \text{ and } K_3 = 4.8 \times 10^{-13}$$

The heats and free energies of ionization for the three dissociations are:

	$\Delta H_{25}°$	$\Delta F_{25}°$
1st	−1.88 kcal	+2.90 kcal
2nd	+0.99 kcal	+9.82 kcal
3rd	+3.5 kcal	+16.0 kcal

At elevated temperature, phosphoric acid is quite reactive toward most metals and reactive oxides. For concentrating strong phosphoric acid at high temperature, carbon equipment is recommended. Reduction of phosphoric acid with reducing agents such as carbon or hydrogen occurs only at above 350–400°.

Raman pattern for 100% H_3PO_4 showed four lines (cm^{-1}):

$$W_1 = 910, W_2 = 359, W_3 = 1079, \text{ and } W_4 = 496[404].$$

Structure. The crystalline acid and its crystalline hydrates consist of tetrahedral PO_4 connected by hydrogen bonds. These hydrogen bonds are retained in concentrated solutions and are responsible for their viscous nature. In more dilute solution (54% H_3PO_4), the phosphate ions are hydrogen bonded to the liquid water rather than other PO_4 ions. The structure of anhydrous phosphoric acid is shown below[406, 407]:
As indicated above, three oxygen atoms of the PO_4 group are bonded covalently to hydrogen atoms which in turn are hydrogen-bonded to oxygen atoms of the neighboring PO_4 group. The fourth oxygen, even though it is hydrogen bonded, is shorter in P–O distance than that of P–OH. When a phosphoryl oxygen atom is involved in intermolecular

H-bonding, it usually shows a lowering of the phosphoryl stretching frequency together with an increase in absorption intensity[407].

Applications. Most phosphoric acids produced commercially are converted into various salts. They will be discussed in their respective sections. The free acid itself, however, has many industrial applications. One important use is for metal treatment such as in phosphatizing, in which steel or iron surface is protected by a rust-resistant coating of tertiary zinc or manganese phosphates and secondary ferrous phosphate. This treatment is carried out by applying to the metal surface a solution of phosphoric acid containing zinc or manganese ions[408]. Zinc phosphatizing gives a light gray, smooth, slate-like textured surface which is about 0.000025 in. thick. Such surface serves as an excellent corrosion-resistant undercoating for paint or enamel. Manganese phosphatizing results in a relatively coarse black absorbent surface about 0.0002 in. thick. It is applied on bolts, nuts, screws and machine parts to protect them against corrosion.

Phosphoric acid solution containing nitric acid (about 95 parts of 85% H_3PO_4 and 4–5 parts of 68% HNO_3 and additives) is very effective for the chemical polishing of aluminum articles to give them mirror-like finishes[409]. One theory for this action is that the nitric acid oxidizes the rough aluminum surface to a porous aluminum oxide film which is then removed by dissolution in phosphoric acid as aluminum phosphates. The diffusion of aluminum phosphate is faster from the microscopic mountains than the valleys on the rough aluminum surface. This results in the selective removal of the mountains, thus leaving a smooth surface. This process is known commercially as the "bright dip process."

A solution of 75% phosphoric acid, alone or with added sulfuric acid and other additives, is used as a bath for the electropolishing of stainless steel articles of regular or irregular shapes such as forks, knives, spoons and surgical instruments to give them bright finishes[410]. Inhibited phosphoric acid in 5% concentration is very effective for removal of mill scales and rust in new power generating boilers and water-formed insoluble deposits in old boilers[411].

For food applications, phosphoric acid imparts the sour and tart taste to cola drinks (0.057 to 0.084% of 75% H_3PO_4) and root beer drinks (0.013% of 75% H_3PO_4). As animal feed supplement, phosphoric acid is added to molasses. This addition, besides supplying extra phosphorus, has the added advantage of reducing the viscosity and stickiness of the molasses and thus permits easier handling. As fertilizer, phosphoric acid has been used directly by addition to irrigation water.

12.2. PYROPHOSPHORIC, POLYPHOSPHORIC AND METAPHOSPHORIC ACIDS

When orthophosphoric acid is condensed by elimination of water between two or more molecules, polyphosphoric acid is formed as a complex mixture of linear molecules of various chain length. These chains consist of PO_4 tetrahedrons joined by a shared oxygen atom at the corner of the tetrahedra.:

$n = 1$ for tripolyphosphoric acid

$n = 2$ for tetrapolyphosphoric acid

At equilibrium, the exact constituent composition of a condensed liquid phosphoric acid depends on its P_2O_5 content. Thus, acid mixtures of the same P_2O_5 content have identical compositions whether obtained by removal of water from orthophosphoric acid or by the solution of P_2O_5 in it. Compositions of strong condensed phosphoric acids with a P_2O_5 concentration up to 89.4% have been determined for their constituent polyphosphoric acids. The method for this analysis employs ion exchange chromatography using a gradient-elution technique supplemented by ascending one- and two-dimensional paper chromatography. The resin recommended is of the strongly basic quaternary ammonium type. A sample of the polyphosphoric acid is first neutralized at $-5°$ with 0.5 N NaOH and then passed through the ion exchange column at 15°. By such a technique, in addition to orthophosphoric acid, polyphosphoric acids of 2 to 14 phosphorus atoms have been separated. These data are shown in Table 14. The high poly portion indicated on the table is the polymeric material retained in the ion exchange column. It may be hydrolyzed to lower phosphoric acids by 6 N HCl[412].

The theoretical P_2O_5 value for H_3PO_4 is 72.4%. As can be seen from Table 14, at this range of P_2O_5 concentration liquid phosphoric acid is no longer pure H_3PO_4. Pure H_3PO_4, not contaminated with other phosphoric acids, is found only at between 0 and about 67.4% P_2O_5 concentration. The composition corresponding to 72.4% P_2O_5 contains 12.7% pyrophosphoric acid. This means that the liquid phosphoric acid of 72.4% P_2O_5 concentration contains some free water to counterbalance the presence of pyrophosphoric acid[413]. Upon crystallization, however, the equilibrium of the 72.4% P_2O_5 acid shifts to the formation of pure crystalline orthophosphoric acid.

12.3. SUPERPHOSPHORIC ACID

As shown in Fig. 11, the melting point of the eutectic equivalent to 105–106% H_3PO_4 is 16°. A phosphoric acid of this approximate composition (75–77% P_2O_5) is of industrial importance. Known as "superphosphoric acid", it permits the easy handling and shipping of a concentrated phosphoric acid in the liquid form[414]. "Superphosphoric acid", prepared from wet process phosphoric acid, has a P_2O_5 content of 69.5 to 70.6%. This change in the composition is due to the presence of metallic impurities present in wet process phosphoric acid.

12.4. PYROPHOSPHORIC ACID

Pyrophosphoric acid is the only member of the linear polyphosphoric acid series which is readily obtained in a crystalline form. It has a theoretical P_2O_5 content of 79.8%.

[412] R. F. Jameson, J. Chem. Soc. (1959) 752–9.

[413] Ref. 406, p. 749.

[414] T. A. Blue, Chemical Economics Handbook (1966) 761.5075B-761.5075E.

However, syrupy liquid phosphoric acid of this concentration has only 42.5% $H_4P_2O_7$, the remainder being orthophosphoric acid (17.2%), tripolyphosphoric acid (25%), tetra-polyphosphoric acid (10.5%) and higher chain polyphosphoric acids[415].

When liquid acid of 79.8% P_2O_5 content is allowed to crystallize, a white solid pyro-phosphoric acid (Form I), the common form, is obtained (m.p. $= 54.3°$). When crystalline Form I is heated in a sealed tube for several hours at about 50°, it is converted to Form II with a m.p. of 71.5°. Form II is the stable form at room temperature[416]. The ionization constants of $H_4P_2O_7$ at 18° are $K_1 = 1.4 \times 10^{-1}$, $K_2 = 1.1 \times 10^{-2}$, $K_3 = 2.1 \times 10^{-7}$, $K_4 = 4.1 \times 10^{-10}$. At 25°, the values for K_3 and K_4 are 2.7×10^{-7} and 2.4×10^{-10} respectively[404]. The heat of formation of crystalline pyrophosphoric acid is -538.0 kcal/mole and of the liquid -545.9 kcal/mole. The heat of fusion at 61° is 2.20 kcal/mole and the entropy of fusion is 6.587 cal/mole/deg[404].

The rate of hydrolysis of 0.100 molal $H_4P_2O_7$ prepared by dissolution of the crystalline acid has been determined at 30.0° and 60.0°. The half-life for the first order conversion of pyrophosphoric acid to orthophosphoric acid is given in Table 15[417].

TABLE 15. HYDROLYSIS OF PYROPHOSPHORIC ACID

% strength $\dfrac{g\ H_4P_2O_7}{g\ H_2O + g\ H_4P_2O_7} \times 100$	Molality	Temp. °C	$t_{\frac{1}{2}}$ (hr)
1.75	0.100	30.0	183
1.75	0.100	60.0	7.7
8.25	0.505	30.0	39.0
26.5	2.02	30.0	9.8
49.9	5.58	30.0	142 min

12.5. METAPHOSPHORIC ACIDS

Polymetaphosphoric Acids

Strong phosphoric acid forms an azeotrope containing 92% P_2O_5 and has a boiling point of 864° at 760 mm Hg pressure[418]. When glacial phosphoric is heated for a short time at 300°, a water-soluble acid which hydrolyzes to the pyrophosphoric acid at room temperature is obtained. This is called meta-acid-I and is generally considered a dimer $(HPO_3)_2$. Heating of glacial H_3PO_4 or meta-acid-I at 320° for 1 hr or 218° for 20 hr has been reported to give a water-insoluble crystalline meta-acid-II[404]. When meta-acid-I is heated to above 400°, a transparent water-soluble modification called meta-acid-III is formed. Heating of meta-acid-III for several hours at red heat produces a meta-acid-IV which disintegrates in water with a crackling sound. Since meta-acid-IV is difficultly soluble in water, a turbid dispersion of fragments in water is obtained. The polymeric metaphosphoric acids described above hydrolyze very slowly to orthophosphoric acid. The hydration proceeds in two steps, one of depolymerization and one of hydration.

[417] A. K. Nelson, Unpublished results, Stauffer Chemical Company.
[418] Ref. 406, p. 773.

Cyclic Metaphosphoric Acids

In addition to the poly-metaphosphoric acid described above, there are also trimeta- and tetrametaphosphoric acids both having a cyclic ring structure. In the elution of strong phosphoric acid through an ion exchange column (Table 14), small quantities of both trimeta- and tetrametaphosphoric acid are detected. It is believed that they are products of hydrolysis of the more complicated ring and branched chain polymers present in the strong phosphoric acid[412].

The best way to prepare trimetaphosphoric acid is by removal of the sodium ions from sodium trimetaphosphate (to be discussed under metaphosphates) by the use of a cation exchange resin. Tetrametaphosphoric acid can be made by adding slowly the hexagonal crystalline form of P_4O_{10} to ice water. To avoid further hydrolysis, the product is neutralized to a pH of 7 shortly after it is prepared. A 75% yield of the tetrametaphosphate (based on the P_4O_{10} used) is obtained[419]. The formation of tetrametaphosphoric acid from P_4O_{10} requires the scission of two P–O–P linkages in the P_4O_{10} tetrahedron:

$$P_4O_{10} \qquad\qquad\qquad H_4P_4O_{12}$$
Applications

For industrial applications, only superphosphoric acid and polyphosphoric acid of 82–84% P_2O_5 concentration are important. Superphosphoric acid's effectiveness depends on its high acid concentration, its easy-to-handle characteristics and its pyrophosphoric acid content. It is used in large scale for the preparation of high-strength phosphatic fertilizers. The pyrophosphoric acid content is especially beneficial in superphosphoric acid produced from wet process acids which is contaminated with metallic ions such as iron, aluminum, and magnesium. These metallic ions usually cause sludge formation when phosphoric acid is ammoniated for use as fertilizer. The pyrophosphate effectively complexes the metallic ions and holds them in solution.

Polyphosphoric acids of 82–84% P_2O_5 concentration find application as catalyst in the petroleum industry for alkylation, dehydrogenation, polymerization and isomerization reactions. They are particularly effective when supported in solid kieselguhr or diatomaceous earth. The catalytic activity of the acids depends largely on their hydrogen ions. One advantage of polyphosphoric acids is that they retain their acid characteristics at a much higher temperature than most other acids. Many of the reactions using polyphosphoric acids as catalyst are carried out at around 200°. To suppress the dehydration (and lowering of activity) of the polyphosphoric acid under reaction conditions, wherever conditions permit, 2–10% of water is introduced with the reactants[420].

13. ALKALI METAL ORTHOPHOSPHATES

All of the hydrogens in orthophosphoric acid are replaceable with metal ions. The general method for the preparation of alkali metal phosphates is to react orthophosphoric acid with an amount of alkali metal hydroxide necessary to give a concentrated solution of the desired compositions. With few exceptions, the desired compound precipitates as crystals on cooling. Formation of specific hydrates of any compound from a solution depends on the temperature range at which the crystals are precipitated. Mono-, di-, and trialkali metal phosphates and their various hydrates as well as some double salts can thus be prepared.

Preparative methods for alkali metal phosphates with the limiting compositions of their saturated solutions at a specific temperature have been reviewed recently by Shen and Callis[421]. The phase-equilibria of alkali metal orthophosphates in water have been summarized in recent surveys[422, 423] and the chemistry of sodium phosphates has been reviewed by Quimby[424].

13.1. LITHIUM ORTHOPHOSPHATES

Lithium phosphates represent the unusual compounds in the alkali metal orthophosphate series. In contrast to other alkali metal orthophosphates which are all quite water soluble, $Li_3PO_4.12H_2O$ is insoluble, and Li_3PO_4 is only soluble to the extent of 0.03 g per 100 g of solution at 25°. Dilithium phosphate does not appear in the phase diagram; and monolithium phosphate is known, but it does not form any hydrate.

The crystal structure of $Li_3PO_4.12H_2O$ is trigonal with a crystal density of 1.645. The crystal structure of Li_3PO_4 is orthorhombic and the crystal density is 2.537[425]. In Li_3PO_4, the PO_4 tetrahedra is regular with a P–O bond length of 1.55 ± 0.02 Å and the O–P–O angle of $109.7\pm2°$. The Li ions coordinate tetrahedrally to the oxygen at an average distance of Li–O $= 1.96\pm0.03$ Å[426].

13.2. SODIUM ORTHOPHOSPHATES

Crystalline sodium phosphates which are stable at between 25° to 100° are[422, 426]:

NaH_2PO_4	Na_2HPO_4	Na_3PO_4
$NaH_2PO_4.H_2O$	$Na_2HPO_4.2H_2O$	$Na_3PO_4.1/2H_2O$
$NaH_2PO_4.2H_2O$	$Na_2HPO_4.7H_2O$	$Na_3PO_4.6H_2O$
$2NaH_2PO_4.Na_2HPO_4.2H_2O$	$Na_2HPO_4.8H_2O$	$Na_3PO_4.8H_2O$
$NaH_2PO_4.Na_2HPO_4$	$Na_2HPO_4.12H_2O$	$Na_3PO_4.ca12H_2O$
$NaH_2PO_4.H_3PO_4$		

Preparation. The hemisodium salt, $NaH_2PO_4.H_3PO_4$, is prepared by mixing aqueous solutions of H_3PO_4 and NaH_2PO_4. Upon concentration under vacuum, the crystals

separated are ground fine and washed with Et_2O at 20° to remove any excess H_3PO_4. The compound is stable in humid weather to its fusion point. In a dry atmosphere, it dehydrates at 105° to condensed phosphates[427].

Both mono- and disodium phosphates are generally prepared on an industrial scale in the United States by the use of sodium carbonate as source of sodium. For the preparation of trisodium phosphate by crystallization from a solution, most of the third sodium atom has to come from the more expensive sodium hydroxide. The CO_2 from sodium carbonate cannot be removed from solution at above a pH of 8.

In the preparation of disodium phosphate, both the concentration of reactants and the temperature of reaction have to be carefully controlled. Too high a concentration or temperature results in the formation of tetrasodium pyrophosphate as a co-product. As will be shown later, the latter's presence in disodium phosphate, even in the order of 1–2%, is detrimental for its use as a cheese emulsifier. Anhydrous Na_3PO_4 can be prepared by calcining a solution containing $3Na_2O$ and $1P_2O_5$ at a temperature above 400° [421].

The most complex system of the sodium salts is the trisodium phosphate. Commercial crystalline trisodium phosphate dodecahydrate contains an excess of sodium hydroxide and is believed to consist of two isomorphous alkaline mixed salts having the formula $Na_3PO_4.1/4NaOH.12H_2O$ and $Na_3PO_4.1/7NaOH.12H_2O$[425]. Trisodium phosphate dodecahydrates having a phosphate to NaOH ratio different than those shown above have also been reported in the literature.

Sodium compounds, other than sodium hydroxides, also enter into complex formation with trisodium phosphate hydrates. Examples of such compounds are:[428]

$$4(Na_3PO_4.11H_2O)NaNO_2$$
$$7(Na_3PO_4.11H_2O)NaNO_2$$
$$5(Na_3PO_4.11H_2O)NaMnO_4$$
$$7(Na_3PO_4.11H_2O)NaMnO_4$$
$$4(Na_3PO_4.11H_2O)NaOCl$$
$$5(Na_3PO_4.11H_2O)NaCl$$
$$4(Na_3PO_4.11H_2O)NaNO_3$$
$$Na_3PO_4.NaBO_2.18H_2O$$

These compounds may be prepared by crystallizing from a liquor having the proper Na_2O-P_2O_5 ratio containing an excess of the added salt. In the presence of more than one added salt, the order of preference for complex formation is as follows:

Complex-forming salt	m.p. °C
NaOH	74
NaMnO_4	d70
NaOCl	62
NaCl	61
NaNO_3	60

If sufficient quantity of one salt is present to form the complex, any salt of lower order in the series is found to be uncombined in the product.

Structure. IR spectra of the sodium phosphate solids and Raman spectra of their solutions showed the PO_4 group to have an approximate tetrahedral configuration[426].

[427] A. Norbert, *Rev. Chim. Minerale*, 3(1) (1966) 1–59.
[428] R. N. Bell, *Ind. Eng. Chem.* 41 (1949) 2901–5.

Properties. The solubility of the mono-, di-, and trisodium orthophosphates and their hydrates is shown in Fig. 12[423]. Hemisodium orthophosphate and trisodium phosphate (both the hemihydrate and the anhydrous form) dissolve incongruently in water. A water solution of these compounds upon evaporation yields crystals of another species.

Measurements by adiabatic colorimetry yielded heat capacity values at 298.15°K
Fig. 12. Solubility of some sodium phosphates[423]. (Reprinted by permission of John Wiley & Sons Inc.)

(cal/deg) for $NaH_2PO_4 = 27.93$, $Na_2HPO_4 = 32.34$, and $Na_3PO_4 = 36.68$. The entropies (cal/deg) calculated for these compounds are $S_{298.15} = 30.47, 35.97$, and 41.54 respectively[429].

Applications. Industrial applications for the sodium phosphates depend on the chemical properties of these compounds. For example, monosodium phosphate is a water-soluble solid acid and many applications for it depend on this property. In water solution it is a mild phosphatizing agent on steel surfaces and provides an undercoating for paints such as in painted metal furniture where high quality protective coating from phosphoric acid–zinc salt phosphatizing is not necessary. The acidic property of monosodium phosphate is also effectively utilized in effervescent laxative tablets and in boiler water treatments for pH adjustments.

One large application for disodium phosphate is as a buffering agent. At 25°, pH buffers containing equimolar concentration of Na_2HPO_4 and KH_2PO_4, at a concentration ranging from 0.01 to 0.2 molar, are represented by the equation:

$$pH = 7.169 + 4.78c - 3.287(c)^{1/2}$$

where c is the total molar concentration of KH_2PO_4 plus Na_2HPO_4 [423].

[429] R. J. L. Andon, J. F. Counsell, J. F. Martin and C. J. Mash, *J. Appl. Chem.* **17** (1967) 65–70.

Another important use for disodium phosphate is as an emulsifier for the manufacture of pasteurized American processed cheese from aged cheddar cheese. The mechanism of this emulsifying action is not completely understood, but addition of about 1.8 to 2.0% by weight of disodium phosphate during processing prevents the separation of fat globules in processed cheese even when the latter is heated to a melt. Disodium phosphate used for this purpose must not contain any pyrophosphate. Presence of pyrophosphate impurity even at less than 1% level results in processed cheese which hardens upon ageing and which also won't melt when heated.

Disodium phosphate has many other applications in food products. It is added at about 0.1% to evaporated milk to maintain the correct calcium to phosphate balance. This prevents gelation of the milk during processing and subsequent storage. It is added at about 5% level to the sodium chloride brine solution used in the pickling of ham. The added phosphate reduces the exudation of juices during cooking which results in a more tender and juicy ham. Starch is chemically modified by heating with disodium phosphate. Such starch even though containing only very little phosphate has the desirable property of forming very stable cold water gel. Addition of 0.75 to 1.10% by weight of disodium phosphate to farinaceous products raises the pH to slightly on the alkaline side of neutrality. This treatment provides "quick-cooking" breakfast cereals.

Trisodium phosphate is highly alkaline in an aqueous solution as the result of the hydrolysis:

$$PO_4^{-3}+H_2O \rightleftharpoons HPO_4^{-2}+OH^-$$
Many of its applications depend on this property. Industrial hard surface (e.g., painted surfaces) cleaners and scouring powders are formulated with trisodium phosphate. The high alkalinity saponifies the oxidized oil on the painted surface or the grease in the kitchen sink to render them easy for removal.

The sodium hypochloride complex of trisodium phosphate is also strongly alkaline (pH of 1% solution = 11.8), and it has the added property of releasing active chlorine when wetted. In its use in scouring powder and automatic dishwashing formulations the high alkalinity provides cleansing action and the released chlorine gives bleaching action for stain removal as well as bactericidal action for sanitizing[430].

13.3. POTASSIUM ORTHOPHOSPHATES

The well-characterized potassium orthophosphates obtained by crystallization from saturated solutions include[421].:

$KH_5(PO_4)_2$	K_2HPO_4	$K_3PO_4.3H_2O$
KH_2PO_4	$K_2HPO_4.3H_2O$	$K_3PO_4.7H_2O$
$KH_2PO_4.2K_2HPO_4.H_2O$	$K_2HPO_4.6H_2O$	$K_3PO_4.9H_2O$[423]
$KH_2PO_4.3K_2HPO_4.2H_2O$		

Preparation. Hemi-potassium phosphate, $KH_5(PO_4)_2$, similar to the sodium analog, is prepared by mixing aqueous solutions of KH_2PO_4 and H_3PO_4 together and then concentrating under vacuum to obtain the crystalline compound. Any residual H_3PO_4 is removed by washing with diethyl ether at 20°. The $KH_5(PO_4)_2$ is not hygroscopic and may also be prepared by the reaction of H_3PO_4 with KCl at 20° in an open container[427].

[430] Product Report IPR-4, Stauffer Chemical Company.

Mono-, di-, and tripotassium phosphates can be prepared by neutralizing phosphoric acid with calculated quantity of potassium hydroxide to give a solution of the desired composition. Concentration of the solution followed by cooling results in the crystallization of the desired salt. Monopotassium phosphate, which has a solubility of 20 g per 100 g of the solution at 20°, is thus obtained.

Alternative procedures have also been reported for the preparation of monopotassium phosphate. Most of these methods proposed the use of the cheaper KCl as the source of potassium:

$$H_3PO_4 + KCl \longrightarrow HCl + KH_2PO_4$$
The HCl formed may be removed by anion exchange resins[431], long chain organic tertiary amines[432], or by distillation using octane as carrier[433]. Product obtained via these routes contains minor amount of KCl.

The compound $K_2HPO_4.3H_2O$ is prepared by the neutralization of 1 mole of H_3PO_4 with 2 moles of KOH. Since it has a solubility of over 60 g (based on the anhydrous salt) per 100 g of solution at 20°, it is necessary to concentrate the solution to a high degree before crystallization occurs on cooling. Water removal from this solution is usually carried out under reduced pressure at not higher than 50–60° to avoid possible pyrophosphate formation.

Tripotassium phosphate of commerce is the anhydrous form. It is prepared by calcining at 300–400° the reaction mixture from 3 moles of potassium hydroxide and 1 mole of phosphoric acid.

Structure. The structure of monopotassium phosphate has been investigated quite extensively. Raman data on a 35% aqueous solution show the following frequency values (cm^{-1}): $w_1 = 883$, $w_2 = 402$, $w_3 = 1069$, and $w_4 = 513$[434]. At room temperature crystalline monopotassium phosphate has a tetragonal form with each PO_4 tetrahedron linked to four others through hydrogen bonding at each of its corners. The lattice parameters as determined by X-ray diffraction are $a = 7.4528 \pm 0.0004$, and $c = 6.9683 \pm 0.0004$ Å.

Properties. The principal coefficients of thermal expansion for the range 25–150° for monopotassium phosphate follow the equations:

$$\alpha_a = 10.10 \times 10^{-6} + 21.68 \times 10^{-8} t - 2.62 \times 10^{-10} t^2$$
$$\alpha_c = 28.73 \times 10^{-6} + 17.65 \times 10^{-8} t + 1.83 \times 10^{-10} t \, ^{(435)}$$

At a low temperature just above the Curie point of $-151°$, the tetragonal cell contracts and the hydrogen bonds are shorter than at normal temperature. However, the tetrahedral symmetry about the phosphorus atom is retained. At a temperature below the Curie end point the crystal structure is changed to that of orthorhombic and this change is associated with an ordering of the H atoms and the distortion of the PO_4 group. Monopotassium phosphate has piezoelectric and ferroelectric properties and the loss of ferroelectric properties (and an increase in the dielectric constant as well as the heat capacity) at the Curie point is associated with the above reversible tetragonal to orthorhombic transition at lower temperatures[426].

[435] D. B. Sirdeshmukh and V. T. Deshpande, *Acta Crystallogr.* 22(3) (1967) 438–9.

The electric conductivity of a single crystal of KH_2PO_4 has been measured at 50–180°. The conductivity along the two axes perpendicular to the c axis is approximately 1.5 times the value of the conductivity in the c direction at < 110° and approximately the same above this temperature[436].
Applications. Monopotassium phosphate crystals can be grown to several inches long and because of its piezoelectric effect, which at room temperature is straightforward (the e.m.f. is proportional to the distortion force with essentially no hysteresis), it has been used in submarine sonar systems and other applications based on piezoelectricity[423].

The main application of dipotassium phosphate is as a buffering agent to maintain the pH of around 9 (pH of 1% solution $=$ 8.9) such as in the car radiator coolants to prevent corrosion[437]. It is also used in special fertilizers and fermentation nutrients.

Tripotassium phosphate is an ingredient in some recipes for the polymerization of styrene-butadiene rubber where it acts as an electrolyte to regulate the rate of polymerization and also to control the stability of synthetic latex formed. Another application of tripotassium phosphate depends on its alkalinity (pH of 1% solution $=$ 11.8). A water solution of it absorbs H_2S from gas streams. Such a solution may be regenerated by heating to drive off the absorbed H_2S[438].

13.4. AMMONIUM ORTHOPHOSPHATES

The following ammonium phosphates are present in the solid phases in the system $(NH_4)_2O.P_2O_5.H_2O$ from 0 to 75° [422]:

$NH_4H_5(PO_4)_2.H_2O$	$(NH_4)_2HPO_4$	$(NH_4)_3PO_4.3H_2O$
$NH_4H_5(PO_4)_2$	$2(NH_4)_2HPO_4.(NH_4)_3PO_4$	
$NH_4H_2PO_4$		

The industrially important ammonium phosphates are $NH_4H_2PO_4$ and $(NH_4)_2HPO_4$.

Preparation. Monoammonium phosphate is prepared by passing ammonia gas into an 80% solution of phosphoric acid. The composition of the product is controlled by maintaining a pH range of 3.8–4.5. Crystals of monoammonium phosphate separate out on cooling.

Diammonium phosphate is prepared by the addition of two moles of ammonia to one mole of 80% phosphoric acid solution. The correct NH_3 to H_3PO_4 ratio may also be controlled by maintaining the reaction mixture of pH 8. To prevent dissociation, the addition of the final quantity of ammonia is carried out at less than 50°. Drying of the crystals is similarly carried out at the low temperature range.

Structure. The crystal system of $NH_4H_2PO_4$ is body-centered tetragonal with 4 molecules per unit cell and lattice dimensions of $a =$ 7.48 Å, $c =$ 7.56 Å[434]. Crystals of $NH_4H_2PO_4$ exhibit piezoelectric properties. While not ferroelectric, it resembles KH_2PO_4 in that it also undergoes a transition from tetragonal to orthorhombic symmetry at low temperature ($-$125°)[426].

Properties. Of the ammonium phosphates, both $(NH_4)_3PO_4$ and the double salt $(NH_4)_3PO_4.2(NH_4)_2HPO_4$ are unstable at room temperature. They lose ammonia to

form diammonium phosphate. However, in the high ammonia region of the $(NH_4)_2O \cdot P_2O_5 \cdot H_2O$ system, triammonium phosphate occurs at up to 60° and $(NH_4)_3PO_42(NH_4)_2HPO_4$ double salt is stable at an even higher temperature. The thermal decomposition of mono-, di-, and triammonium phosphates has been studied by thermo-gravimetric and differential thermal analyses. In this test the minimum temperatures for the onset of decomposition are 30°, 140° and 170° for the tri-, di- and monoammonium phosphates respectively[439].

The vapor pressure of a saturated solution of $NH_4H_2PO_4$ is expressed by the equation

$$\log p_{mm} = -2240/T + 8.862$$

where T is 292° to 363°K.

The specific equation is: $p = 0.2773 + 7.30 \times 10^{-4}t$ cal/g $NH_4H_2PO_4$/degC at the temperature range of -25 to 100°. The pH of a 1% solution is 4.5. The heat of formation for $NH_4H_2PO_{4(c)}$, $\Delta H^\circ_{f(298 \cdot 16)}$, is -346.75 kcal/mole; free energy of formation $\Delta F^\circ_{f(298 \cdot 16)}$ is -290.46 kcal/mole and the entropy, $S^\circ_{297 \cdot 1}$, is 36.32 ± 0.1 cal/mole $NH_4H_2PO_4$/deg. The heat of neutralization of liquid H_3PO_4 with gaseous NH_3 to form $NH_4H_2PO_4$ is $\Delta H = -32.19$ kcal. Some other properties of $NH_4H_2PO_4$ are listed in Table 16[434].

The dissociation pressure of $(NH_4)_2HPO_4$ is represented by the equation, $\log p_{mm} = -4211/T + 12.040$, where T is 353° to 398°K; the vapor pressure equation of a saturated solution is $\log p_{mm} = -2240/T + 8.807$, where T is 292° to 328°K. The partial pressure of NH_3 over a saturated solution is $p_{mm} = 1$ at 25°, 9 at 50°, and 19 at 60°. The pH of 1% solution is 8.0. The heat of formation of $(NH_4)_2HPO_{4(c)}$ is $\Delta H^\circ_{f(298 \cdot 16)} = -376.12$ kcal/mole. The heat of neutralization of liquid H_3PO_4 with gaseous NH_3 to form $(NH_4)_2HPO_4$ is $\Delta H = -51.45$ kcal. The thermodynamics of the dissociation: $(NH_4)_2HPO_4 \rightarrow NH_4H_2PO_{4(c)} + NH_{3(g)}$ are $\Delta C_p = -0.81$ cal (at 49.8°), $\Delta H = 19.26$ kcal. Other properties of $(NH_4)_2HPO_4$ are listed in Table 16[434].

Applications. Mono- and diammonium phosphate are used interchangeably for many applications. They are both used as fertilizers and nutrients in fermentation broths to supply phosphorus and nitrogen. For fertilizer application, phosphorus promotes development of plant roots. It is also essential for flower development and fruit production. Nitrogen is essential for the growth of the vegetative organs. It also greatly increases the utilization of fertilizer phosphate by the plant, especially during the early growth period[439].

One very important application for ammonium phosphates is as a flame retardant agent for cellulosic materials. This action depends on the property of ammonium phosphates to dissociate to NH_3 and H_3PO_4 when heated. The phosphoric acid generated catalyzes the decomposition of cellulose to char (carbon) which is slow burning and also smothers the flame. Without the acid catalyst, cellulose decomposes on heating first to liquid fragments which on further heating convert to flammable volatiles[441].

A dilute solution of diammonium phosphate with an initial pH of 7.85, upon boiling, evolves NH_3 and in about 2.5 hr the pH drops to about 5.78. This property is used for the precipitation of colloidal wool dyes on wool fabrics. Wool dyes remain dispersed

under alkaline conditions, but precipitate rapidly and unevenly on the fabric under acidic conditions. The gradual change of the pH in the dye bath, as controlled by the decomposition of $(NH_4)_2HPO_4$, permits the gradual deposition of the dye. This makes for level dyeing of the cloth with good penetration[442].

14. ALKALINE EARTH PHOSPHATES

14.1. GENERAL PREPARATIVE METHODS

Alkaline earth phosphates in general are prepared by the reaction of alkaline earth hydroxides or oxides with phosphoric acid. Monoalkaline earth phosphates are crystallized from a solution containing an excess of phosphoric acid. Dialkaline earth phosphates are obtained as crystalline precipitates by the addition of two equivalents of the oxide, hydroxide or carbonate[443, 444] to slightly more than 1 mole of phosphoric acid. Trialkaline earth phosphates are prepared by the reverse addition of phosphoric acid to a slurry of alkaline earth hydroxides.

Another general method for the preparation of these compounds is by precipitation from the metathetical reaction between $(NH_4)_2HPO_4$ or other water-soluble dialkali-metal orthophosphates and the respective water-soluble alkaline earth salts. The tempera-

Of the alkaline earth phosphates, the calcium salts are the most important and have received the most study[446, 448, 449].

14.2. MONO- AND DICALCIUM PHOSPHATES

One important property of the mono- and dicalcium phosphates (and the analogous magnesium phosphates) is that they have incongruent water solubility, i.e., in water the solid phase is in equilibrium with a solution more acidic than the solid phase composition.

Monocalcium Phosphate

As shown in the CaO–H_2O–P_2O_5 phase diagram (Fig. 13) monocalcium phosphate decomposes in the presence of water partially to the more basic dicalcium phosphate and phosphoric acid. The extent of this reaction increases with the amount of water and temperature. Since commercial monocalcium phosphate monohydrate is prepared either by total evaporation of the aqueous reaction mixture of hydrated lime and phosphoric acid or by crystallization from the aqueous system, it is thus always contaminated with various amounts of dicalcium phosphate. A typical product from the crystallization process contains 5.8% dicalcium phosphate while those from the total evaporation process contain up to 8–9% of dicalcium phosphate.

In the commercial production of monocalcium phosphate, extreme care is needed to

[448] T. D. Farr, *Phosphorus, Properties of the Element and Some of Its Compounds*, Chemical Engineering Report No. 8, pp. 52–60, T.V.A., Wilson Dam, Alabama (1950).

[449] J. R. van Wazer, *Phosphorus and Its Compounds*, Vol. I, pp. 510–40, Interscience Publishers, New York (1958).

avoid presence of residual phosphoric acid. Free phosphoric acid renders the material hygroscopic and the absorbed water along with the acid catalyze the decomposition to more free phosphoric acid and dicalcium phosphate. Monocalcium phosphate contaminated with free phosphoric acid is thus an unstable product. In fact, a portion of the
FIG. 13. CaO–H2O–P2O5 phase diagram.[449] (Reprinted by permission of John Wiley & Sons Inc.)

dicalcium phosphate impurity present in industrial monocalcium phosphate is the result of intentional addition of an excess of lime for the removal of residual free phosphoric acid.

Dicalcium Phosphate

In an aqueous system, it decomposes to the more basic calcium hydroxyl apatite and free phosphoric acid. This decomposition is also favored by an excess of water and high temperature. It goes through an intermediate stage, that of the formation of octacalcium phosphate [$Ca_8H_2(PO_4)_6 \cdot 5H_2O$] and free phosphoric acid[450]. The decomposition of $CaHPO_4 \cdot 2H_2O$ in an aqueous solution is also accelerated by the presence of fluoride ions. The final product in this case always contains fluoroapatite, $Ca_5(PO_4)_3F$[451].

[450] W. E. Brown, J. P. Smith, J. R. Lehr and A. W. Frazier, Nature, 196, No. 4859 (1962) 1048–55.
[451] D. H. Booth and R. V. Coates, J. Chem. Soc. (1961) 4914–21.

Thermogravimetric, IR and NMR studies indicated that the water of hydration in $CaHPO_4.2H_2O$ is in two states, one loosely bound and the other tightly bound, with some mobility of water molecules between these two states[452]. Crystalline $CaHPO_4.2H_2O$ loses both of its water of hydration at a moderately elevated temperature and/or on storage. Dehydration is accelerated by the presence of moisture, as for example, when it is formulated as the polishing agent in a toothpaste. The dehydration and subsequent growth of the anhydrous dicalcium phosphate crystals result in the solidification of the paste to a hard rock-like mass.

There has been speculation that the dehydration of $CaHPO_4.2H_2O$ to $CaHPO_4$ in the presence of a little moisture is related to the decomposition of $CaHPO_4.2H_2O$ in a water slurry to hydroxyl apatite and free phosphoric acid. The formation of $CaHPO_4$ is postulated to be from the reaction of free phosphoric acid and hydroxyl apatite resulting from the decomposition of $CaHPO_4.2H_2O$. It is known that the reaction between phosphoric acid and finely divided hydroxyl apatite is reasonably rapid at room temperature[449].

Recent kinetic studies, however, show that the dehydration of $CaHPO_4.2H_2O$ in a water vapor atmosphere takes place in a single step. After an induction period, which could be long if the water vapor is low, the reaction rate increases and then reaches a maximum[453].

The instability of $CaHPO_4.2H_2O$ as prepared by the neutralization of H_3PO_4 with a slurry of lime at 38–40° is an important industrial problem. Two methods of stabilization have been developed and are in actual use. The first method involves the addition of a small quantity of pyrophosphate ion to the compound. This is carried out by adding a few per cent of tetrasodium pyrophosphate to the slurry of dicalcium phosphate during the manufacturing process[454]. The second method is for stabilizing $CaHPO_4.2H_2O$ from dehydrating in a moist toothpaste formulation and it is carried out by adding 2–3% of trimagnesium phosphate to the $CaHPO_4.2H_2O$ as a dry mix[455]. The mechanism of stabilization by both the pyrophosphate ion and trimagnesium phosphate is not well understood. However, in the hydrolysis of $CaHPO_4.2H_2O$ through the sequence to octacalcium phosphate to hydroxyl apatite and free phosphoric acid stages, it has been found that as little as 0.001 N of magnesium ion inhibits the further hydrolysis of octacalcium phosphate[450]. If the speculation that the dehydration of $CaHPO_4.2H_2O$ is through the mechanism of hydrolysis first to octacalcium phosphate then to hydroxyl apatite and phosphoric acid and subsequent reaction of hydroxyl apatite with phosphoric acid to form anhydrous $CaPHO_4$ were true, then the inhibition of hydrolysis of octacalcium phosphate by Mg^{++} would interrupt the above reaction sequence and thus account for the inhibition of dehydration of moist $CaHPO_4.2H_2O$ by $Mg_3(PO_4)_2$.

The decomposition of $Ca(H_2PO_4)_2.H_2O$ and $CaHPO_4.2H_2O$ is also important in the manufacture of fertilizers. Superphosphate is ammoniated to convert the water-soluble $Ca(H_2PO_4)_2.H_2O$ into citrate-soluble dicalcium phosphate and water-soluble mono- or diammonium phosphate, e.g.:

$$Ca(H_2PO_4)_2.H_2O + 2NH_3 \longrightarrow CaHPO_4 + (NH_4)_2HPO_4 + H_2O$$
If the temperature of this reaction is allowed to go above 40°, the $CaHPO_4$ formed is

decomposed further to the insoluble hydroxyl apatite, an undesirable product for fertilizer applications[456].

Other properties of mono- and dicalcium phosphates are summarized in Table 19[448]. The solubility product data listed are calculated thermodynamically.

TABLE 19. PROPERTIES OF MONO- AND DICALCIUM PHOSPHATES[448, 449]

$CaHPO_4$	Triclinic pinacoidal	2.892 g/cm³ at 16°	$n_\alpha = 1.587$ $n_\beta = 1.615$ $n_\gamma = 1.640$	2.18×10^{-7}. Solubility in acid solution decreases with rising temperature

14.3. OCTACALCIUM PHOSPHATE AND TRICALCIUM PHOSPHATE

Octacalcium phosphate, $Ca_8H_2(PO_4)_6 5H_2O$, and hydroxyl apatite, $Ca_5(PO_4)_3OH$, mentioned above have received extensive studies. The reason for this is that hydroxyl apatite is now recognized as the most important of the inorganic compounds in the structure of bone[457] and teeth and that octacalcium phosphate may be a precursor to it.

Octacalcium Phosphate

As shown in Table 18, pure octacalcium phosphate is prepared by the controlled hydrolysis of $CaHPO_4.2H_2O$ in a sodium acetate buffer at 40° [458]. Its structure is related to hydroxyl apatite but the two compounds are not isostructural. Octacalcium phosphate has the following unit cell dimensions: $a = 19.87$ Å, $b = 9.63$ Å, $c = 6.87$ Å, $\alpha = 89°17'$, $\beta = 92°13'$, $\gamma = 108°57'$[450]. It has a pK_{sp} of 46.9 at 25°. Infrared spectra show a broad band near 3500 cm⁻¹ and strong bands at 1000 and 1100 cm⁻¹. Octacalcium phosphate has also two characteristic bands (865 and 910 cm⁻¹) which are useful in identifying it in the presence of hydroxyl apatite. Two other major bands for the compound occur at 599 and 559 cm⁻¹ [459]. Boiling of octacalcium phosphate in water results in gradual hydrolysis to hydroxyl apatite[450].

Tricalcium Phosphate

Commercial tricalcium phosphate, as prepared by the addition of phosphoric acid to a slurry of hydrated lime, consists mostly of the amorphous form of hydroxyl apatite $Ca_5(PO_4)_3OH$. There is, however, a true tricalcium phosphate $Ca_3(PO_4)_2$. The β-form occurs in nature as the mineral whitlockite and contains 6.8 at.% magnesium. Synthetically, as shown in Table 17, it may be prepared by the reaction of a water solution of $Ca(NO_3)_2$ with that of Na_2HPO_4 in the presence of Mg^{++} or Mn^{++} as stabilizer. The β-$Ca_3(PO_4)_2$, when heated, undergoes the following progression:

$$\beta\text{-}Ca_3(PO_4)_2 \xrightarrow{1180°} \alpha\text{-}Ca_3(PO_4)_2 \xrightarrow{1430°} \alpha'\text{-}Ca_3(PO_4)_2$$
The refractive indices of β-$Ca_3(PO_4)_2$ are $n_\alpha = 1.620$ and $n_\gamma = 1.622$, while those of α-$Ca_3(PO_4)_2$ are (biaxial positive): $n_\alpha = 1.588$ and $n_\gamma = 1.591$. The solubility in citrate solution for β-$Ca_3(PO_4)_2$ is 20 to 50%, while that of α-$Ca_3(PO_4)_2$ is 85 to 98%. Infrared spectra of β-$Ca_3(PO_4)_2$ have been studied by Mooney et al.[460]

Hydroxyl apatite is generally represented by the formula $Ca_5(PO_4)_3OH$. However, by variations in the methods of synthesis, compounds having Ca/P mole ratio of from 1.41 to 1.75 as shown on Table 20[447] are obtained and which all have nearly the same X-ray patterns.

TABLE 20. CALCIUM HYDROXYL APATITE[447]

Mole ratio Ca/P	Method of preparation
1.41	Dilute $CaCl_2$ plus excess of dilute Na_2HPO_4 at 25°
1.50	$Ca(OH)_2$ added to H_3PO_4 to phenolthalein end point or by slow hydrolysis of $CaHPO_4.2H_2O$ (gets good crystals)
1.61	$Ca(OH)_2$ added to dilute H_3PO_4 to phenolthalein end point and then bo led
1.67	$Ca(OH)_2$ added to dilute H_3PO_4 then neutralized at boiling
1.75	Freshly precipitated "tricalcium phosphate" plus lime

The method described in *Inorganic Synthesis* for the preparation of $Ca_5(PO_4)_3OH$ involves the use of an aqueous NH_4OH solution to maintain a sufficiently high pH (pH = 12). Under high pH conditions, the PO_4^{3-} concentration is not exceeded by that of HPO_4^{2-} and thus avoids the formation of $Ca_8H_2(PO_4)_6.5H_2O$[461]. The reaction is shown in the following equation:

$$5Ca(NO_3)_2 + 3(NH_4)_3PO_4 + NH_4OH \longrightarrow Ca_5(OH)(PO_4)_3 + 10NH_4NO_3$$
The precipitate obtained is heated to 800°. It shows a structure corresponding to hexagonal prisms which terminate in pyramids. The $Ca_5(PO_4)_3OH$ crystal is uniaxial negative with index of refraction- $n_\epsilon = 1.644$ and $n_\omega = 1.651$ and lattice dimensions of $a = 9.422$ Å, $c = 6.883$ Å. Infra studies on hydroxyl apatite show strong bands at 1000-1100 cm^{-1} and medium intensity bands at 631, 601 and 501 cm^{-1} [458]. Hydroxyl apatite has a specific gravity of 3.21 and decomposes at 1400°. The solubility product constant is $K_{sp} = 1.53 \times 10^{-112}$ at 25° [448, 462].

Hydroxyl apatite may be regarded as the parent member of a whole series of calcium

[460] R. W. Mooney, S. Z. Tuma and R. L. Goldsmith, *J. Inorg. and Nuclear Chem.* **30** (1968) 1669–75

[461] E. Hayek and H. Newesley, *Inorganic Synthesis*, Vol. VII, pp. 63–5, Ed. J. Kleinberg, McGraw-Hil Book Co. (1963).

[462] R. A. Young and J. C. Elliott, *Arch. Oral. Biol.* **11**(7) (1966) 699–707.

phosphates with related structures. This series includes fluorapatite, $Ca_5(PO_4)_3F$, chlorapatite, $Ca_5(PO_4)Cl$, and bromapatite, $Ca_5(PO_4)_3Br$. All these apatites have the same hexagonal structure with the halogens[463] replacing the hydroxyl groups in the crystal lattice. By a diffusion process at 1200°, a 0.4 mm diameter single crystal of synthetic chlorapatite was changed into hydroxyl apatite while maintaining the single crystal form. The lattice parameters for fluorapatite are $a = 9.364$ Å, $b = 6.879$ Å, unit cell volume $= 521.3$ Å^3, and for chlorapatite $a = 9.634$ Å, $c = 6.783$ Å, and unit cell volume $= 545.2$ Å^3 [462].

Applications

Calcium phosphates are the only alkaline earth phosphates with important industrial applications. Very crude monocalcium phosphate $Ca(H_2PO_4)_2.H_2O$ as prepared by the reaction of phosphate mineral with sulfuric acid is known as superphosphate:

$$2Ca_5(PO_4)_3F + 7H_2SO_4 + H_2O \longrightarrow 7CaSO_4 + 3Ca(H_2PO_4)_2.H_2O + 2HF$$
In admixture with the $CaSO_4$ by-product it is used as fertilizer. A purer grade of monocalcium phosphate fertilizer is the "triple superphosphate" prepared by the reaction of calcium phosphate mineral with H_3PO_4:

$$Ca_5(PO_4)_3F + 7H_3PO_4 + 5H_2O \longrightarrow 5Ca(H_2PO_4)_2.H_2O + HF$$
As mineral supplement for animal feed, "stock food" grade of crude dicalcium phosphate is prepared by reacting pasty hydrated lime with 75–80% H_3PO_4. Such product contains anhydrous dicalcium phosphate as the main component along with monocalcium phosphate, tricalcium phosphate and unreacted lime.

Defluorinated phosphate rock is also used for animal feed purposes. It is prepared by heating phosphate mineral, $Ca_5(PO_4)_3F$, to 1200–1400° in the presence of water vapor and added H_3PO_4, Na_2SO_4 and SiO_2. The finished product is essentially α-$Ca_3(PO_4)_2$ and in order to meet prescribed specification it must not have more than 100 ppm F for each per cent of phosphorus[464, 465].

Calcium phosphates for human consumption or "food grade" are prepared from high quality phosphoric acid and lime. In the 1850s, monocalcium phosphate monohydrate $Ca(H_2PO_4).H_2O$ was introduced as the solid acid to react with $NaHCO_3$ to generate CO_2 for leavening in baking. Since then, its applications have greatly broadened. It is used also as the acid in effervescent tablets, as additive in phosphated flour, and as bread improver to stimulate the growth of yeast in yeast leavened products.

Anhydrous monocalcium phosphate is hygroscopic and was regarded for many years as unsuitable for use as a leavening acid. It was found, however, that when $Ca(H_2PO_4)_2$ is crystallized from a mother liquor containing added minor quantity of K^+, Na^+, and Al^{3+}, upon filtration, the minute crystals are wetted with the mother liquor containing the acid phosphates of these metals. When these crystals are dried and heat treated at 210–220°, the process resulted in the covering of each $Ca(H_2PO_4)_2$ crystal with a contiguous glassy coating of the added metal polyphosphates[466]. Such product then becomes an extremely useful baking acid in that it has a delayed reaction with $NaHCO_3$. Less CO_2 is lost in the dough mixing stage and thus allows more leavening action to occur during the baking process. The

coated $Ca(H_2PO_4)_2$ also permits the formulation of more storage stable self-rising flours and prepared baking mixes in which the leavening ingredients are premixed with the flour.

For $CaHPO_4.2H_2O$, the major application is as polishing agent in toothpaste formulations. It cleans teeth to provide a glossy surface on the tooth enamel without being too abrasive. Anhydrous dicalcium phosphate, on the other hand, is quite abrasive. It is used only in combination with the less abrasive $CaHPO_4.2H_2O$ or tricalcium phosphate for specialty toothpaste formulations in which extra abrasiveness is required as in the case of "smoker's toothpaste" for stain removal. Dicalcium phosphates are also used in pharmaceutical tablets as supplement for calcium and phosphorus.

Commercial tricalcium phosphate has particle size of the order of few microns in diameter. It is added at 1 to 2% level to coat hygroscopic salt or sugar particles so that they remain free flowing even in humid weather. It has also been claimed as a component along with organic bromides and zinc chloride in flame retardant formulations for polyacrylonitrile[467].

15. OTHER INORGANIC ORTHOPHOSPHATES

Metal ions other than alkali metal and alkaline earth metals also form orthophosphate salts. Mixed metal orthophosphates are also known. The three general methods for their preparation are: (1) high temperature solid state reaction: (2) precipitation of the less soluble phosphate from solution; and (3) crystallization from an equilibrium solution.

The procedure of choice depends on the nature of the compound. High temperature reactions are limited to the anhydrous tertiary phosphates and are carried out below the fusion point of the compound. The precipitation method is widely used because the majority of the orthophosphates are of limited solubility in an aqueous medium. For this method, phosphoric acid or water-soluble alkali phosphates are reacted with a water-soluble metal salt bearing the cation. However, in order to obtain duplicable products, exact conditions of reaction must be followed. There are a multiplicity of cases of polymorphism in many compounds and different crystalline varieties of the same compound are obtained under very nearly the same conditions[468].

The crystallization process gives definite compounds in accordance with the phase diagram[469]. In order to grow large crystals of a specific composition and crystal structure, sometimes it is necessary to heat the aqueous system under high temperature and pressure, that is by the hydrothermal process.

15.1. TRIPLY CHARGED METAL ION ORTHOPHOSPHATES

The best known of metal orthophosphates, other than the alkali-metal and alkaline earth phosphates, are the tertiary boron, aluminum and iron phosphates.

Boron Phosphate

This compound is prepared by heating stoichiometric quantity of the reaction product of

[467] F. J. Lowes, Jr., U.S. 3,271,343, 6 Sept. 1966, to Dow Chemical Co.
[468] F. d'Yvoire, *Bull. Soc. Chim. France* (1962) 1243–6.
[469] C. Y. Shen and C. F. Callis, *Preparative Inorganic Reactions*, Vol. II, pp. 153–64, Ed. W. L. Jolly, Interscience Publishers, New York (1965).

B_2O_3 and H_3PO_4 to 400–500°. It may also be obtained by adding H_3BO_3 to H_3PO_4 at 25° and then crystallized from a solution containing more than 48% P_2O_5[469].

The crystal structure of BPO_4 is similar to that of SiO_2. Each phosphorus atom is surrounded by a tetrahedron of oxygen atoms, and the boron atom is also tetrahedrally coordinated by oxygens. The crystals of BPO_4, therefore, consist of alternate tetrahedra linked together to form a continuous three-dimensional structure. Since each bond is formed by the sharing of an oxygen atom between a phosphorus and a boron atom, the compound may be thought of as a mixed anhydride of P_2O_5 and B_2O_3[470].

Boron phosphate is thermally stable, showing no appreciable vapor pressure until above 1000°. Some studies have been made to use it as catalyst supports. It is used also in ceramics.

Aluminum Phosphates

In the aluminum phosphate system, the following compounds are known:

$$AlH_3(PO_4)_2 . 3H_2O$$
$$AlH_3(PO_4)_2 . H_2O$$
$$Al(H_2PO_4)_3 . 1.5H_2O$$
$$Al(H_2PO_4)_3$$
$$Al_2(HPO_4)_3 . 3H_2O$$
$$AlH(HPO_4)_2 . 3H_2O$$
$$AlPO_4 . 3.5H_2O$$
$$AlPO_4 . 2H_2O$$
$$AlPO_4$$
All of these compounds may be crystallized from solution under equilibrium conditions.

The acidic aluminum phosphate, $AlH_3(PO_4)_2.H_2O$, is isolated as crystals by evaporating at about 100° a solution of alumina in phosphoric acid having a $P_2O_5:Al_2O_3$ ratio of about 3.5[471]. The crystals appear as rectangular platelets or as hexagonal lamallae. The trihydrate, $AlH_3(PO_4)_2.3H_2O$, is obtained by allowing a concentrated solution of P_2O_5 and Al_2O_3 (ratio between 6 and 2.6) to evaporate in air at ambient temperature. The crystals formed belong to the rhombohedral system and appear as platelets in the form of equilateral triangles or triangular pyramids with a density of 2.192[471].

Monoaluminum phosphate, $Al(H_2PO_4)_3$, is reported to exist in at least three forms. The classical variety referred to by d'Yvoire[472] as type C is obtained by evaporating in air at 95° a solution of alumina in phosphoric acid having a $P_2O_5:Al_2O_3$ ratio of ≥ 6 (long needle crystals) or under vacuum at room temperature (hexagonal prisms). These crystals have a rhombohedral lattice. Two other varieties of $Al(H_2PO_4)_3$ referred to by d'Yvoire as A and B are identified (not isolated) as components in the thermal decomposition product of acid aluminum phosphates, $AlH_3(PO_4)_2 \cdot 3H_2O$ and $AlH_3(PO_4)_2.H_2O$. The particular variety obtained depended on the nature and physical state of the starting compound and dehydrating conditions[472].

[470] J. R. van Wazer, *Phosphorus and Its Compounds*, Vol. I, pp. 550–9, Interscience Publishers Inc., New York (1958).

[471] F. d'Yvoire, *Bull. Soc. Chim. France* (1961) 2283–90.

[472] F. d'Yvoire, *Bull. Soc. Chim. France* (1961) 2277–82.

Upon heating, $Al(H_2PO_4)_3$ loses water, forming at between 290–490° the acid triphosphate $H_2(AlP_3O_{10})$ which on further heating to 900° yields the crystalline cyclic tetrametaphosphate and a long chain polyphosphate.

Not too much is known on the compound $Al_2(HPO_4)_3$. It is obtained as an amorphous precipitate containing various water of hydration when an acidic solution of aluminum sulfate and ammonium phosphate is boiled. It precipitates from solution only over a narrow range of acid concentration[471].

The dihydrate, $AlPO_4 \cdot 2H_2O$, occurs naturally in two forms: as the orthorhombic variscite and as the monoclinic metavariscite. Both forms can be prepared synthetically by boiling a solution of alumina in phosphoric acid with a $P_2O_5:Al_2O_3$ ratio of 2.7. Variscite is formed from dilute solutions, metavariscite from concentrated solutions, and a mixture of the two varieties from solutions of medium concentration.

In the preparation of other hydrates of $AlPO_4$, it is quite easy to obtain different results from apparently identical conditions. This is due to the readiness of the $Al_2O_3–P_2O_5–H_2O$ system to form metastable solutions which are probably colloidal in nature. Such systems can undergo changes with time and/or with minor changes in the preparative methods[473].

Anhydrous $AlPO_4$ can be obtained by the thermal dehydration of the hydrates or by crystallization from solution at above about 130°. Large crystals may be grown by heating in an autoclave a saturated solution of $NaAlO_2$ in H_3PO_4 very slowly from 132 to 315°[474].

Tertiary aluminum phosphate, like boron phosphate, is isostructural with SiO_2. The phosphorus atom is surrounded tetrahedrally by four oxygen atoms. It has been found to exist in at least six different crystalline modifications that are structurally parallel to some of the known forms of silica[475–7].

$$SiO_2 \begin{cases} \text{Quartz} \underset{867°}{\rightleftharpoons} \text{Tridymite} \underset{1470°}{\rightleftharpoons} \text{Cristobalite} \underset{1713°}{\rightleftharpoons} \text{melt} \\[2mm] \beta \underset{573°}{\rightleftharpoons} \alpha\,\beta \underset{117°}{\rightleftharpoons} \alpha \underset{163°}{\rightleftharpoons} \alpha_2\,\beta \underset{220°}{\rightleftharpoons} \alpha \end{cases}$$

$$AlPO_4 \begin{cases} \text{Berlinite} \underset{705°}{\rightleftharpoons} \begin{array}{c}\text{Tridymite}\\ \text{analog}\end{array} \underset{1025°}{\rightleftharpoons} \begin{array}{c}\text{Cristobalite}\\ \text{analog}\end{array} \underset{>1600°}{\rightleftharpoons} \text{melt} \\[2mm] \beta \underset{586°}{\rightleftharpoons} \alpha\,\beta \underset{93°}{\rightleftharpoons} \alpha_1 \underset{130°}{\rightleftharpoons} \alpha_2\,\beta \underset{210°}{\rightleftharpoons} \alpha \end{cases}$$
Despite the similarity between SiO_2 and $AlPO_4$, the attempts to obtain solid solutions by heating the cristobalite forms of the two compounds together have not been successful[473].

Aluminum phosphates as impurities in the wet process phosphoric acid are highly objectionable in that when wet process acid is ammoniated the insoluble aluminum phosformed tie up the phosphate value and reduce its availability to the plants as fertilizers. These precipitates also clog up fertilizer equipment. Pure aluminum phosphates are, however, quite useful. Monoaluminum phosphate in phosphoric acid solution is applied to steel plates used in electrical transformer construction. Upon heat treatment, it forms a surface coating which minimizes the occurrence of eddy currents in the transformer during its

operation. Aluminum acid phosphates, due to the formation of thermally stable aluminum phosphates, and crystalline $AlPO_4$ upon heating to a high temperature, are used also as binder in refractories[478-9].

Iron Phosphates

These compounds are quite similar to the aluminum phosphates. There are two varieties of $Fe(H_2PO_4)_3$ (A and B) which are isomorphous with the A and B forms of $Al(H_2PO_4)_3$. Formation of $Fe(H_2PO_4)_3$ is through the evaporation at 95° of a concentrated solution of $FeCl_3$ in H_3PO_4 in which the $P_2O_5:Fe_2O_3$ ratio is between 4 and 7. Variety A, in the shape of rhombohedra, is favored when crystals are allowed to form without agitation. Variety B, in the shape of leaves, is obtained when the solution is kept at 95° and subjected to successive crystallization and redissolution with frequent agitation[472].

Both varieties of $Fe(H_2PO_4)_3$ are very hygroscopic. They absorb water and undergo hydrolysis to give $FeH_3(PO_4)_2 \cdot 2.5H_2O$ and a very acidic solution[472].

Upon heating to above about 480° $Fe(H_2PO_4)_3$ undergoes decomposition similar to $Al(H_2PO_4)_3$ with the formation of a mixture of crystalline cyclic tetrametaphosphate and a long chain polyphosphate[472]. The similarity between $Fe(H_2PO_4)_3$ and $Al(H_2PO_4)_3$ is also shown by the formation of a solid solution when Al_2O_3 and Fe_2O_3 are dissolved in H_3PO_4. The substitution of Fe in the C variety of $Al(H_2PO_4)_3$ has been observed for ratio $Fe/(Fe+Al)$ less than about 0.5[472].

The industrial applications of iron phosphates are fairly limited. $FePO_4 \cdot 2.5H_2O$ formed by precipitation from the reaction of ferric chloride with an alkali metal orthophosphate in an aqueous solution is used as mineral supplement to supply iron.

15.2. MIXED ALKALI METAL—OTHER METAL ORTHOPHOSPHATES

Many crystalline orthophosphates containing two or more cations have been prepared. The best known of these is $NH_4MgPO_4 \cdot 6H_2O$ which is insoluble in an ammoniacal solution and has been used for the quantitative gravimetric determination of phosphate.

Two compounds of recent commercial importance are $NaAl_3H_{14}(PO_4)_8 \cdot 4H_2O$[480] and $Na_3Al_2H_{15}(PO_4)_8$. These compounds can be precipitated as crystals from cooling of a hot concentrated phosphoric acid solution containing the proper $Na_2O:Al_2O_3$ ratio. Their crystal structures have not been determined, but both are manufactured industrially on a large scale. The compound $NaAl_3H_{14}(PO_4)_8 \cdot 4H_2O$ was the first and the more important of the two to be commercialized. Its main use is as a leavening acid for baking. Commercially, it is used in combination with the heated treated or "coated" anhydrous monocalcium phosphate. The main advantage of such a combination is that in the dough system it has the proper rate of reaction with $NaHCO_3$ to release CO_2 gas in a proper sequence suitable for the chemical and physical changes during the baking process to yield superior baked goods. Also, its lack of reactivity with $NaHCO_3$ at room temperature when mixed with flour permits its use in self-rising flours and prepared cake mixes in which the baking powder ingredients are premixed with other baking ingredients before packaging. Such packages are quite

[480] G. A. MacDonald, U.S. 2,550,490, 24 April 1951, to Victor Chemical Co.

stable even when stored under adverse conditions of high temperature, high humidity and over-long storage.

It may be of interest to note here that the pure compound, $NaAl_3H_{14}(PO_4)_8.4H_2O$, is quite hygroscopic and difficult to handle in commercial equipment. The solution to this problem is by the exchange of some of the H^+ on the surface of the crystals with K^+, thus rendering the product non-hygroscopic without affecting its chemical properties for baking purposes[481-2].

16. PYROPHOSPHATES

16.1. GENERAL METHODS OF PREPARATION

The common method for the preparation of metal pyrophosphates is by thermal condensation of the acid orthophosphates:

$$2MH_2PO_4 \longrightarrow M_2H_2P_2O_7 + H_2O$$
$$2M_2HPO_4 \longrightarrow M_4P_2O_7 + H_2O$$
For thermally unstable pyrophosphates, e.g., $(NH_4)_4P_2O_7$[483], the preferred method is the direct neutralization of a solution of pure $H_4P_2O_7$ at low temperature with the hydroxide of the desired cation. For multiple charged metal pyrophosphates that are extremely insoluble in water, many are prepared as precipitates by the reaction of a soluble salt of the respective cation with $Na_4P_2O_7$ in an aqueous solution.

Various inorganic pyrophosphates and their methods of preparation are summarized in a recent review by Shen and Dyroff[484].

16.2. GENERAL STRUCTURE AND PROPERTIES

The structure of the pyrophosphate anion as determined by X-ray studies consists of two PO_4 tetrahedra bridged by a mutual oxygen atom.
The size of the central P–O–P angle varies with different metal pyrophosphates. Most of the crystalline salts have a bent nonlinear configuration.

Pyrophosphates have a great tendency to occur in polymorphic phases and this polymorphism may be due to three kinds of structure arrangements: (a) linear ions with P–O–P angle = 180°, (b) non-linear ions with P–O–P angle < 180°, or (c) statistically linear ions derived from suitable arrangement of nonlinear ions. Thus the P–O–P for α-$Mg_2P_2O_7$ = 144°, and for β-$Mg_2P_2O_7$ = 180°[485].

The compound $Zr_2P_2O_7$, which received detailed X-ray studies, has a P–O–P angle of

[481] J. E. Blanch and F. McCullough, Jr., U.S. 3,205,073, 7 Sept. 1965, to Stauffer Chemical Co.

[482] L. B. Post and J. E. Blanch, U.S. 3,411,872, 19 Nov. 1968, to Stauffer Chemical Co.

[483] C. Swanson and F. McCollough, *Inorganic Synthesis*, Vol. VII, pp. 65–67, Ed. J. Kleinberg, McGraw-Hill Book Co., New York (1963).

[484] C. Y. Shen and D. R. Dyroff, *Preparative Inorganic Reactions*, Vol. V, pp. 157–89, Ed. W. L. Jolly, Interscience Publishers (1968).

[485] D. E. C. Corbridge, *Topics in Phosphorus Chemistry*, 3 (1966) 232–47.

180°, and the cations coordinated sixfold by oxygen. The crystals are cubic with four molecules per unit cell. Isomorphous with $Zr_2P_2O_7$ in the cubic series is SiP_2O_7 where the silicon atom is also surrounded by six oxygen atoms. The latter is a rare example of an oxygen-containing compound of silicon having an oxidation number of $+4$ where the silicon is sixfold coordinated by oxygen.

Neutral anhydrous pyrophosphates are, in general, thermally quite stable. When heated, however, many do undergo polymorphic phase changes until melted. One of the exceptions is $Al_4(P_2O_7)_3$ which is formed by the heating of $Al_2(HPO_4)_3$ at 400°. When heated to 1000°, $Al_4(P_2O_7)_3$ decomposes to the phosphocristobalite $AlPO_4$ and P_2O_5 and at 1300–1800° $AlPO_4$ decomposes into Al_2O_3 and P_2O_5, plus a residue with an Al_2O_3/P_2O_5 ratio of 1/2.3[486].

16.3. AMMONIUM PYROPHOSPHATES

Following are the known ammonium pyrophosphates:[487]

$(NH_4)_4P_2O_7$

$(NH_4)_4P_2O_7 \cdot H_2O$

$(NH_4)_3HP_2O_7$

$(NH_4)_3HP_2O_7 \cdot H_2O$

$(NH_4)_2H_2P_2O_7$
The morphological and optical properties of these compounds are listed in Table 21.

One general method for the preparation of these compounds is by the ammoniation of an aqueous solution of pure $H_4P_2O_7$. Calculated quantity of NH_3 is added at below 10° followed by evaporation under vacuum or precipitation by addition of ethanol to obtain crystalline products.

Tetraammonium pyrophosphate monohydrate, $(NH_4)_4P_2O_7 \cdot H_2O$, is obtained as a precipitate by the addition of ethanol to a concentrated aqueous solution, pH 6.5 at 0°. Anhydrous $(NH_4)_4P_2O_7$ is obtained by precipitation with ethanol at above 25°. The monohydrate dehydrates readily upon exposure to the atmosphere. The anhydrous form loses NH_3 slowly in the open, even at room temperature, and this loss is accelerated at above 50% relative humidity.

The compound $(NH_4)_3HP_2O_7 \cdot H_2O$ is precipitated from its aqueous solution, pH 6, with alcohol at below 55°. It is non-hygroscopic and stable at room temperature at relative humidity above 45%. The anhydrous form may be obtained by dehydration of $(NH_4)_3HP_2O_7 \cdot H_2O$ at above 55° or by crystallization from an aqueous solution at above 55°.

Diammonium pyrophosphate $(NH_4)_2H_2P_2O_7$ forms dimorphs. The monoclinic form is stable at room temperature or below and may be crystallized from an aqueous solution, pH 3.4, at below room temperature by the addition of ethanol. The orthorhombic form is obtained by the same method except at a higher temperature. At room temperature, the orthorhombic form changes rapidly to the monoclinic form which is stable and non-hygroscopic.

16.4. SODIUM PYROPHOSPHATES

The following sodium pyrophosphates are known[488]:

$Na_4P_2O_7 \cdot 10H_2O$	$Na_3HP_2O_7$
$Na_4P_2O_7$	$Na_2H_2P_2O_7 \cdot 6H_2O$
$Na_3HP_2O_7 \cdot 9H_2O$	$Na_2H_2P_2O_7$
$Na_3HP_2O_7 \cdot H_2O$	$NaH_3P_2O_7$
Preparation and Properties. Anhydrous tetrasodium pyrophosphate is prepared by dehydration of Na_2HPO_4 at 500° for 5 hr[489]. Thermal-gravimetric studies showed that actual condensation occurred at 330° to 340° [488]:

$$2Na_2HPO_4 \longrightarrow Na_4P_2O_7 + H_2O$$
It can be easily recrystallized from water. The hydrate, $Na_4P_2O_7 \cdot 10H_2O$, is obtained at between −0.4° and 79° while the anhydrous form $Na_4P_2O_7$ is obtained at above 79°. Anhydrous $Na_4P_2O_7$ is reported as having five crystalline modifications with one form only stable at room temperature[490]:

$$Na_4P_2O_7 \text{ V} \underset{}{\overset{400°}{\rightleftharpoons}} \text{IV} \underset{}{\overset{510°}{\rightleftharpoons}} \text{III} \underset{}{\overset{520°}{\rightleftharpoons}} \text{II} \underset{}{\overset{545°}{\rightleftharpoons}} \text{I} \underset{}{\overset{985°}{\rightleftharpoons}} \text{melt.}$$
Crystallographic data are summarized in Table 21.

The solubility of $Na_4P_2O_7 \cdot 10H_2O$ in water is equivalent to approximately 9 g of the anhydrous salt per 100 g of solution at 25°. A 1% solution has a pH of 10.2 and the compound is stable to hydrolysis with no noticeable hydrolysis after 60 hr at 70°. The hydrate has a m.p. 79.5° and the crystals are biaxial positive with $\alpha = 1.450$, $\beta = 1.453$ and $\gamma = 1.460$ (± 0.002).

The anhydrous crystal is also biaxial positive with $\alpha = 1.475$, $\beta = 1.477$ and $\gamma = 1.496$ (± 0.002)[489] and a heat capacity $C_{p298.15°K} = 47.36$ cal/deg and entropy $S_{298.15K} = 52.63$ cal/deg[491].

Trisodium pyrophosphate is prepared by acidification of an aqueous solution of $Na_4P_2O_7$ with HCl at $\leq 35°$ followed by crystallization of the resulting $Na_3HP_2O_7 \cdot 9H_2O$ and its separation from NaCl[492]. The monohydrate is formed in solution at about 30°. Heating of $Na_3HP_2O_7 \cdot H_2O$ for several days at 150° results in the formation of the anhydrous form.

Disodium dihydrogen pyrophosphate is formed when NaH_2PO_4 is heated to 210° for 12 hr[489]:

$$2NaH_2PO_4 \longrightarrow Na_2H_2P_2O_7 + H_2O$$
In the commercial process, the conversion is carried out in a rotary-type continuous converter at 225–250° under a controlled atmosphere of water vapor to prevent metaphosphate formation. The hexahydrate, $Na_2H_2P_2O_7 \cdot 6H_2O$, exists in the solution up to about 27° where it is converted to the anhydrous form.

Monosodium pyrophosphate is also known. It is prepared by mixing equimolar proportions of $Na_2H_2P_2O_7$ and $H_4P_2O_7$ in an aqueous solution at 0°. Upon evaporation of the solution under vacuum, the crystalline $NaH_3P_2O_7$ separated has a m.p. of 185° [493]. It is very soluble in water. Addition of alcohol or acetone to a concentrated aqueous solution causes decomposition which results in the precipitation of $Na_2H_2P_2O_7$.

Applications. Tetrasodium pyrophosphate was introduced in the 1930's as a builder for soap. It is a good disperser for lime soap which formed in hard water. Since the advent of sodium tripolyphosphate and synthetic detergents, the use of $Na_4P_2O_7$ as a soap builder has greatly decreased. However, it is still used as a builder in some cleaning formulations[494].

Pyrophosphate ions form a gel when reacted with a soluble calcium salt in water solution. This property makes $Na_4P_2O_7$ useful as an ingredient for starch type instant pudding which requires no cooking[495]. Tetrasodium pyrophosphate is also used as a stabilizer for hydrogen peroxide employed in textile bleaching. This application depends on the ability of $Na_4P_2O_7$ to sequester heavy metal cations which normally catalyze the decomposition of peroxides. Other applications for $Na_4P_2O_7$ are for water treatment and as disperser for clays.

The main application for $Na_2H_2P_2O_7$ is as a leavening acid in baking. Its major advantage is that in a dough or batter system it has relatively little action with $NaHCO_3$ until heat is applied. This property permits commercial bakeries to prepare a large quantity of dough or batter at one time. Such mixtures are stable until heated in the oven during the baking to the finished products.

Most of the commercially produced $Na_2H_2P_2O_7$ contains added minor amounts of K^+, Ca^{++} and Al^{+++}. These additives permit the controlled retardation of the rate of reaction of $Na_2H_2P_2O_7$ with $NaHCO_3$ in the baking system. The reason for the slow rate of reaction of even the pure $Na_2H_2P_2O_7$ with $NaHCO_3$ at room temperature in the bake-mix is not well understood since their reaction in an aqueous solution is quite rapid. One theory proposed is that the retardation is due to the formation of a thin coating of $Ca_2P_2O_7$ on the surface of the $Na_2H_2P_2O_7$ particles from the reaction of the latter with Ca^{++} in the bake-mix. To support this theory, it has been found that the slow reaction of $Na_2H_2P_2O_7$ with $NaHCO_2$ in a bake-mix is even slower (1) in the presence of added soluble calcium salt and (2) when $Na_2H_2P_2O_7$ used is milled finer. In actual baking applications, $Na_2H_2P_2O_7$ is used largely as the leavening acid for cake doughnuts, cakes and refrigerated biscuits. One major disadvantage of $Na_2H_2P_2O_7$ as a baking acid is that it imparts an astringent aftertaste to the baked goods.

16.5. POTASSIUM PYROPHOSPHATES

The best known of potassium pyrophosphates is $K_4P_2O_7$ which is formed by the dehydration of K_2HPO_4 at 350–400°. It is very soluble in water (187 g per 100 g H_2O at 25°). In a saturated solution, the solid in equilibrium with the solution is $K_4P_2O_7 \cdot 3H_2O$. The monohydrate $K_4P_2O_7 \cdot H_2O$ is also known. Both $K_4P_2O_7$ and $K_4P_2O_7 \cdot H_2O$ are hygroscopic while $K_4P_2O_7 \cdot 3H_2O$ is hygroscopic at above a relative humidity of 45%[496].

$K_2H_2P_2O_7$ is difficult to prepare by thermal dehydration of KH_2PO_4 since the rate

[493] A. Norbert and C. Dautel, *Compt. Rend.*, Ser. C, 262(21) (1966) 1534–6.
[494] *Oil, Paint and Drug Reporter*, 28 Aug. 1967, p. 7.
[495] M. H. Kennedy and M. P. Castagna, U.S. 2,607,692, 19 Aug. 1952, to Standard Brands, Inc.

for dehydration to form $(KPO_3)_n$ is about as rapid unless the reaction is carried out under a humid atmosphere. The preferred preparative method for $K_2H_2P_2O_7$ is by the acidification of a $K_4P_2O_7$ solution with HCl to a pH of 4.5 and then alcohol added to precipitate the product.

Only $K_4P_2O_7$ is of commercial importance. It was introduced in the middle 1950's as a builder for light duty liquid detergents. It is used at about 25% by weight of the total formulation which contains approximately 50% water. The effectiveness of $K_4P_2O_7$ as a builder depends on the pyrophosphate ion. Even though it is not as effective a builder as tripolyphosphate or long chain polyphosphate ions, it has the advantage of having a high degree of hydrolytic stability (half-life of several years at 50°). Tetrapotassium pyrophosphate is more expensive than $Na_4P_2O_7$ but it is still widely used since its high water solubility permits easy formulation in liquid detergents[494].

16.6. CALCIUM PYROPHOSPHATE

When $CaHPO_4.2H_2O$ is dehydrated thermally, DTA and TGA studies show the formation of amorphous $Ca_2P_2O_7$ at 360–450°. Continuation of heating results in an exotherm at 530° due to the conversion of the amorphous $Ca_2P_2O_7$ to the crystalline γ-$Ca_2P_2O_7$[497]. Further heating converts the γ-form to the β-form at 750°[490] and to the α-form at 1171–1179°[7 498]. The α-$Ca_2P_2O_7$ melts at 1352°.

Steger and Kassner[499] have recently measured the IR spectra of α-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$ and γ-$Ca_2P_2O_7$ along with those of other pyrophosphates The indices of refraction of α-calcium pyrophosphate are $n_\alpha = 1\ 584$, $n_\beta = 1\ 599$, and $n_\gamma = 1.605$[490]. The crystals of β-$Ca_2P_2O_7$ are uniaxial and positive, with $n_\omega = 1\ 630$ and $n_\varepsilon = 1\ 639$.

Calcium pyrophosphate, because of its low water solubility and chemical inertness, is used as an abrasive for a Sn^{++} and F^- containing toothpaste For this purpose a mixture of γ·$Ca_2P_2O_7$ and β-$Ca_2P_2O_7$ forms has been found to have the desired abrasiveness and yet is still sufficiently compatible with the added fluoride and stannous ions in the formulation. To improve the compatibility of $Ca_2P_2O_7$ to Sn^{++} and F^- in toothpaste formulations even upon prolonged storage, various modifications have been introduced during the conversion of $CaHPO_4.2H_2O$. Examples of such modifications are by the addition of 750–4000 ppm of soluble alkali metal ions to the $CaHPO_4.2H_2O$ before dehydration[500] or by the dehydration in presence of added steam[501].

17. TRIPOLYPHOSPHATES

17.1. SODIUM TRIPOLYPHOSPHATE

Preparation The common commercial method for the preparation of sodium tripolyphosphate (pentasodium tripolyphosphate, $Na_5P_3O_{10}$) is by heating at a controlled

temperature range an intimate mixture of powdered $2Na_2HPO_4$ and NaH_2PO_4:

$$2Na_2HPO_4 + NaH_2PO_4 \longrightarrow Na_5P_3O_{10} + 2H_2O$$
Anhydrous sodium tripolyphosphate occurs in two crystalline forms. Form II, the low temperature variety, is obtained at about 400°. It is usually converted to Form I, the thermodynamically stable phase and the high temperature variety, by heating at 500–550°. The phase transition temperature of Form II to Form I is 417°.

Reverse transition of Form I to Form II is difficult. It can be done by heating a sample for about a month in a sealed tube in the presence of 0.1% $Na_5P_3O_{10} \cdot 6H_2O$ at 409° to 320° [502].

Laboratory preparation of $Na_5P_3O_{10}$ can be carried out by heating any mixture of sodium phosphate salts with a $Na_2O:P_2O_5$ ratio of 5 : 3 to a clear melt (850–900°) and the melt cooled quickly to a glass. Subsequently, tempering of this glass at above 470° results in the formation of crystalline Form I[503]. Form II is formed from annealing the glass for at least 2 hr at 550°, and then cooling rapidly in air. The solid undergoes a crystalline phase transition at 150–100° and disintegrates into a powder of Form II[504].

The hydrate of sodium tripolyphosphate, $Na_5P_3O_{10} \cdot 6H_2O$, is formed by the addition of either Form I or II to water. Both anhydrous forms are metastable in water and cannot be recrystallized from water. The hexahydrate can also be obtained by the hydrolysis of $(NaPO_3)_3$ in a strong alkaline solution[505]:

$$(NaPO_3)_3 + 2NaOH + 5H_2O \longrightarrow Na_5P_3O_{10} \cdot 6H_2O$$
Structure. Sodium tripolyphosphate anion consists of triply condensed PO_4 tetrahedra (Fig. 14)[506]. Titration studies show that the acid has one weak hydrogen ion in each
Fig. 14. Dimensions of the triphosphate ion in (a) $Na_5P_3O_{10}$–I; (b) $Na_5P_3O_{10}$–II[506].

end group and one strong hydrogen ion in each of all three phosphorus atoms. The dimensions of the tripolyphosphate ion are shown in Fig. 14[506].

The major difference between the structures of Form I and Form II is in the ionic

[506] D. E. C. Corbridge, *Topics in Phosphorus Chemistry*, **3** (1966) 232–66.

coordination of the sodium ions. In Form II, all sodium ions are coordinated octahedrally by oxygen while in Form I some sodium ions are surrounded by only four oxygen atoms[506].

Properties. Anhydrous $Na_5P_3O_{10}$ melts incongruently at 662° into a liquid plus crystalline $Na_4P_2O_7$. Further heating to 865° results in a complete melt which when chilled quickly forms a glass. As mentioned earlier, tempering of this glass, depending on the temperature conditions, converts it back to either Form I or Form II.

The heat capacity and entropy of sodium tripolyphosphates at 298.15°K are for Form I: $C_p = 78.16$ cal/deg, $S = 91.25$ cal/deg; Form II: $C_p = 77.2$ cal/deg, $S = 87.37$ cal/deg;
FIG. 15. Half-life of the tripolyphosphate ion as a function of pH and temperature. (Data refer to tetramethylammonium tripolyphosphate dissolved in 0.65 N tetramethylammonium bromide.)[508] (Reprinted by permission of John Wiley & Sons Inc.)

and $Na_5P_3O_{10}\cdot6H_2O$: $C_p = 137.1$ cal/deg, $S = 146.1$ cal/deg[507]. The density of sodium tripolyphosphate in Form I = 2.62 g/cm³; Form II = 2.57 g/cm³.

The solubility of $Na_5P_3O_{10}$ in water is a function of temperature. At room temperature, $Na_5P_3O_{10}\cdot6H_2O$ dissolves to an equivalent of about 13 g $Na_5P_3O_{10}/100$ g of solution. Both anhydrous Forms I and II are more soluble than $Na_5P_3O_{10}\cdot6H_2O$. However, in the temperature range of 0 to 100°, the saturating crystal phase is the hexahydrate. Because Form I forms the hexahydrate crystals very rapidly, its high initial solubility in water

[507] R. J. L. Andon, J. F. Counsell, J. F. Martin and C. J. Mash, *J. Appl. Chem.* (1967) (17) 65–70.

drops almost immediately to that of the hexahydrate. Form II, on the other hand, forms the hexahydrate at a much slower rate, so it has an immediate water solubility of about 32 g per 100 g of solution. This solubility decreases slowly with the formation of $Na_5P_3O_{10}.6H_2O$, and after 15–20 min it drops to that of the equilibrium solubility of hexahydrate. The greater ease of hydration of Form I is attributed to the presence of the four-coordinated sodium ions in the structure. Such a feature in other related compounds is known to be associated with a strong affinity for water.

The solubility characteristics of $Na_5P_3O_{10}$ described above applies only to fairly pure $Na_3P_5O_{10}$. The rate of $Na_5P_3O_{10}.6H_2O$ formation is greatly retarded by impurities such as other phosphates normally present in commercial $Na_5P_3O_{10}$. For example, in the presence of small amount of glassy metaphosphates, the amount of dissolved $Na_5P_3O_{10}$ does not decrease to that of the equilibrium solubility of $Na_5P_3O_{10}.6H_2O$ even after many hours.

The rapid conversion of Form I into $Na_5P_3O_{10}.6H_2O$ crystals is a serious problem in detergent manufacturing where sodium tripolyphosphate is used as a builder. Under certain conditions these hexahydrates could cement together and plug the detergent manufacturing equipment. As a consequence, additives and/or the correct ratio of Form I and Form II in the anhydrous material must be carefully controlled.

A 1% solution of $Na_5P_3O_{10}$ has a pH of 9.7. The rate of hydrolysis of the tripolyphosphate depends on the temperature and the pH of the solution. The products of hydrolysis are a mole each of pyrophosphate and orthophosphate. At its natural pH of 9.7, approximately 50% is hydrolyzed in 6 hr at 100° and 15% in 60 hr at 70° [504]. The nomograph showing the half-life of the tripolyphosphate anion as a function of temperature and pH is shown in Fig. 15[508]. The rate of hydrolysis in alkaline solution is accelerated by the presence of sodium ions or other cations which form stronger complexes than do sodium ions with the tripolyphosphate anion. However, these accelerating effects are minor compared to that of the effect of temperature and pH.

Crystalline $Na_5P_3O_{10}.6H_2O$, upon storage in a sealed system at room temperature, undergoes self-hydrolysis mainly as follows:

$$2Na_5P_3O_{10}.6H_2O \longrightarrow Na_4P_2O_7 + 2Na_3HP_2O_7 + 11H_2O$$

At 100°, hydrolysis is principally:

$$Na_5P_3O_{10}.6H_2O \longrightarrow Na_3HP_2O_7 + Na_2HPO_4 + 5H_2O$$
At above 140°, the products of hydrolysis recondense to $Na_5P_3O_{10}$ Form II and water[506].

Applications. Crystalline sodium tripolyphosphate was first described in 1895 by Schwartz[508]. It was not until the 1940s that it was introduced commercially as a builder for sodium alkylbenzenesulfonate containing synthetic detergents. The total production in 1967 in the United States alone exceeds 2.2 billion pounds.

For detergent application, the commercial product is usually a mixture of Form I and Form II in a ratio determined by the needs of the specific detergent manufacturer. In addition, commercial products also contain a few per cent of $Na_4P_2O_7$. The latter is the result of using a slight excess of Na_2O over the theoretical Na_2O/P_2O_5 ratio of 5 : 3 during the manufacturing process for the purpose of avoiding the formation of any insoluble sodium metaphosphate. Presence of even a minor amount of insoluble metaphosphate

[508] J. R. van Wazer, *Phosphorus and Its Compounds*, Vol. I, pp. 638–659, Interscience Publishers Inc., New York (1958).

in the product would cause turbidity in a water solution—highly undesirable for detergent applications.

The two anhydrous forms of $Na_5P_3O_{10}$ can be differentiated by their X-ray diffraction pattern or IR spectra so that their ratio in a commercial mixture can thus be determined. For industrial purposes, however, a simpler and more rapid, though not quite as accurate, method of determination is desired. The accepted procedure is a thermal test developed at Proctor and Gamble and is known as Temperature Rise Test. This procedure is based on the fact that in a water–glycerine mixture, Form I hydrates more rapidly than Form II. The test, when carried out under the directions given, percentage of Form I can be calculated by the following equation[509]:

$$\% \text{ Form I } = 4[(\text{temp. rise in } °C) - 6]$$

Data from this test have been calibrated against X-ray diffraction data. The quantity of $Na_4P_2O_7$ normally present in the commercial mixture does not interfere with this test. Heats of solution for Form I and Form II are -16.1 and -14.0 kcal/mole respectively.

Sodium tripolyphosphate, when used as a builder for synthetic detergents, constitutes approximately 45% by weight of each formulation. Through hydration in the synthetic detergent manufacturing process, except for a few per cent of degradation products, all of the original $Na_5P_3O_{10}$ is converted to $Na_5P_3O_{10} \cdot 6H_2O$.

The major function of $Na_5P_3O_{10}$ as a builder depends on its water-softening action through complexing or sequestering of Ca^{++} and Mg^{++} in hard water. At 0 ionic strength, the formation constants for some tripolyphosphate complexes are as follows[503]:

$$
\begin{array}{ll}
NaP_3O_{10}^{4-} & pK = 2.8 \\
CaP_3O_{10}^{3-} & pK = 8.1 \\
MgP_3O_{10}^{3-} & pK = 8.6
\end{array}
$$

The stability of these complexes is greater than the corresponding complexes of the pyrophosphates:

$$
\begin{array}{ll}
NaP_2O_7^{3-} & pK = 2.3 \\
CaP_2O_7^{2-} & pK = 6.8 \\
MgP_2O_7^{2-} & pK = 7.2
\end{array}
$$

Another important function of sodium tripolyphosphate in detergent is the property to suspend and peptize dirt particles. The tripolyphosphate anion is also important for its ability to lower the critical micelle concentration of the detergent.

Compared to its use as builder for detergents, other uses of $Na_5P_3O_{10}$ become minor. However, large tonnages are consumed annually as deflocculent for solid slurries to reduce the amount of water needed as in the cases of cement manufacturing[510], oil well drilling mud formulations, and kaolin clay mining.

17.2. OTHER TRIPOLYPHOSPHATES

Potassium tripolyphosphate, $K_5P_3O_{10}$, may be prepared by a method analogous to that used for the sodium compound:

$$2K_2HPO_4 + KH_2PO_4 \longrightarrow K_5P_3O_{10} + 2H_2O$$
[509] J. D. McGilvery, *ASTM Bull.* No. 191 (1933) 45–48.
[510] W. B. Chess, D. N. Bernhart and R. Gates, *Rock Products*, **10** (1961) 121–2.

Quantitative differential thermal analysis shows that this condensation reaction occurs at 200–300° with $H = 32.4$ kcal/mole[511]. However, in the actual manufacturing process, the temperature range employed is 325–400°.

Potassium tripolyphosphate melts incongruently at 614.5° with the formation of crystalline $K_4P_2O_7$ and a melt. Total liquefaction occurs at about 940° [503].

Crystalline $K_5P_3O_{10}$ is hygroscopic and extremely soluble in water. When exposed to atmospheric moisture, it absorbs 2 moles of water to form the α-form of the dihydrate. Another dihydrate, the β-form, is obtained by precipitation from an aqueous solution with methanol[503].

Tripolyphosphate salts of multiple charged cations are also known. These are made by precipitation from a solution of sodium tripolyphosphate with the respective polyvalent cations. Many crystalline salts thus obtained contain also the sodium ions. They are of the types $Na_3M^{++}P_3O_{10}$, $NaM_2^{++}P_3O_{10} \cdot aq$. These salts are slightly soluble in water but in most cases dissolve in excess of tripolyphosphate. The low solubility of $NaZn_2P_3O_{10} \cdot 9H_2O$ is used for the rapid identification of tripolyphosphate[503].

18. POLYPHOSPHATES, CYCLIC METAPHOSPHATES AND ULTRAPHOSPHATES

The polyphosphate anion may be represented by the general formula:
When $n = 0$, the compound is pyrophosphate; $n = 1$, tripolyphosphate. When n is very large, the sodium salts are represented by three high molecular weight crystalline compounds known as $NaPO_3$–II (Maddrell's salt), $NaPO_3$–III (low temperature variety of Maddrell's salt), and $NaPO_3$–IV (Kurrol's salt). The potassium salt is represented by the high molecular weight crystalline potassium polyphosphate known as potassium-Kurrol's salt, or potassium metaphosphate. In addition, there are also the sodium polyphosphate glasses, or Graham's salts, which are not pure compounds but mixtures of polyphosphates having a wide distribution of molecular weights.

The high molecular weight compounds described above, though commonly called metaphosphates, belong actually to the polyphosphate system since each molecule contains the two end groups. However, as n approaches infinity, the total composition of the compound is close to that of $(NaPO_3)_n$ or the metaphosphate.

True metaphosphates have the exact formula of $(NaPO_3)_n$ or the middle groups only in the polyphosphate anion formula. These are cyclic compounds and the first well-characterized member in the series is the sodium trimetaphosphate, $(NaPO_3)_3$, known as $NaPO_3$–I, or Knorre's salt.

Another class of condensed phosphate is the ultraphosphate. These are polymeric phosphates containing branched chains, e.g.:

[511] E. Calvert, M. Gambino and M. L. Michel, *Bull. Soc. Chim. France* (1965)(6) 1719–21.

```
      O        O        O        O
      |        |        |        |
  —O—P—O—P—O—P—O—P—O—
      |        |        |        |
      O        O        O        O
      |        |        |        |

      |        |        |        |
      O        O        O        O
```
Linear sodium polyphosphates have a ratio $Na_2O/P_2O_5 = >1$ and ≤ 2; cyclic sodium metaphosphates $Na_2O/P_2O_5 = 1$, and the ultraphosphates $Na_2O/P_2O_5 = >1$.

18.1. TETRAPOLYPHOSPHATES

The next member in the linear chain polyphosphate series from tripolyphosphate is tetrapolyphosphate. It is much more difficult to obtain by thermal condensation method than tripolyphosphate. Heating to over 550° the Pb or Ba monophosphates with metal-to-phosphorus ratio calculated for tetrapolyphosphate has been reported to yield the pure tetrapolyphosphates.

Sodium tetrapolyphosphate cannot be prepared in a pure form by thermal methods. It is prepared by opening the ring of sodium tetrametaphosphate with aqueous NaOH at temperatures up to 40°:

$$(NaPO_3)_4 + 2NaOH \longrightarrow Na_6(P_4O_{13}) + H_2O$$
This ring cleavage reaction takes advantage of the fact that hydrolysis of cyclic meta-phosphate is strongly catalyzed by OH^- (and H^+) and that the chain phosphates are sufficiently stable in an alkali solution to permit isolation. The product obtained is amorphous but can be converted to the crystalline tetrapolyphosphate salt of other cations, e.g., hexaguanidinium[512] tetrapolyphosphate and ammonium tetrapolyphosphate, $(NH_4)_6P_4O_{13} \cdot 6H_2O$.

The linear nature of the tetrapolyphosphate anion has been demonstrated by NMR studies on a solution of crystalline ammonium tetrapolyphosphate. The acid of tetra-polyphosphate has four strongly and two weakly dissociated hydrogen ions.

Tetrapolyphosphate anion is quite stable in neutral or alkaline solution but not as stable as tripolyphosphate anion over the whole pH range. Its maximum stability at 65.5° is at pH 10, and this stability decreases with decreasing pH. The hydrolytic cleavage starts at the end of the chain forming first the mono- and tripolyphosphate[513]. At pH $\leq$ 3, cyclic trimetaphosphate is additionally formed. There are no evidences for symmetric splitting into two moles of pyrophosphates[514].

The alkaline earth tetrapolyphosphates are considerably more soluble than the corresponding pyro- and tripolyphosphates. The stability of the tetrapolyphosphate complexes of these metal ions is also greater than those of pyro- and tripolyphosphate. This is as one might expect from the increasing number of tetrahedra available in the tetrapoly-phosphate for complex bonding[515].

[515] J. I. Watters and R. Machen, *J. Inorg. and Nucl. Chem.* **30** (1968) 2163–6.

18.2. HIGHER POLYPHOSPHATES

Longer linear polyphosphates above tetrapolyphosphates are more difficult to obtain in a pure form. The mineral Troemelite which occurs as crystalline plates or fibers formed by tempering a melt of the correct CaO : P_2O_5 ratio at between 920–990° has been shown to be calcium hexapolyphosphate[513, 516].

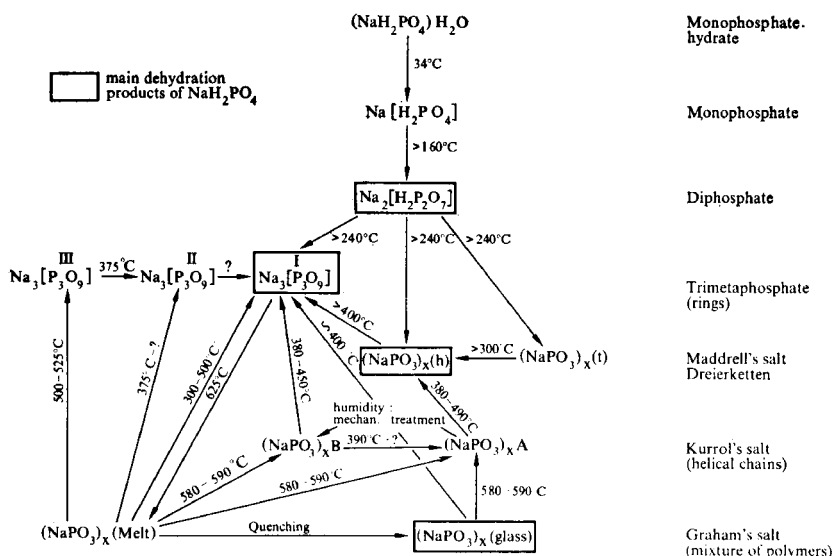
Long chain polyphosphates normally occur as mixtures of molecules of various chain length. As the linear chains become very long, the composition of each chain approaches that of $(NaPO_3)_n$ and their properties become so similar that for practical purposes the mixture behaves as a pure compound. Also in these long chains, the substitution of one for another during crystal growth is not difficult since one chain goes through several


Fig. 16. Interrelationship of metaphosphates[518]. (Reprinted by permission of Verlag Chemie, GmbH.)

unit cells of the crystal and the exact chain length has little effect on the lattice parameter of the crystals. For these reasons several high molecular weight polyphosphates are obtained as crystalline substances.

Since each long chain molecule contains a large number of metaphosphate $(NaPO_3)$ middle groups, with only two end groups, the overall composition is very near that of the metaphosphate. They are, therefore, usually referred to as metaphosphates.

Both cyclic and long chain sodium metaphosphates can be made by thermal dehydration of monosodium phosphate. They can also be made by tempering of the polyphosphate glass of $Na_2O : P_2O_5$ ratio of 1. The specific compound to be formed depends on the temperature of heating or tempering. The interrelationship of these compounds and conditions for their preparation have been summarized by Thilo[517, 518] as shown in Fig. 16.

18.3. GLASSY SODIUM METAPHOSPHATE (GRAHAM'S SALT)

Preparation. This glassy polyphosphate was first described by Thomas Graham in 1833. It is now manufactured industrially by heating NaH_2PO_4 at above 620° to a melt and then cooling rapidly[519]. Another industrial process involves the direct reaction of a spray of aqueous sodium hydroxide with the vapor from the burning of elemental phosphorus, the resultant sodium polyphosphate melt is withdrawn from the reaction zone and cooled rapidly over a cooled metal surface[520]. The product solidifies into a glass with about 90% of its content in the form of a mixture of high molecular weight polyphosphates, the remaining 10% being various cyclic metaphosphates[518]. Other glassy metaphosphates with a somewhat higher $Na_2O : P_2O_5$ ratio than Graham's salt are also known as "hexametaphosphate." This term (which is now proven incorrect) was given by Fleitman[521], who in 1849 assigned to the glassy sodium metaphosphate $(NaPO_3)_x$ which he studied a degree of polymerization of six.

The best known of commercial glassy metaphosphates goes by the registered trademark of "Calgon" (from calcium gone). It contains approximately 67.8% P_2O_5 or a $Na_2O : P_2O_5$ ratio of slightly over 1.1 : 1. Its molecular weight is in the range of 1500 to 2000 or a degree of polymerization of 15 to 20[522].

Properties. Graham's salt, as shown in Fig. 16, when annealed, depending on conditions, converts to sodium Kurrol's salt, Maddrell's salt, or cyclic trimetaphosphate. They are all crystalline compounds. In this transition, the PO_3^- units are cleaved and rearranged into new chains or cyclic rings. The cations have some influence on the crystalline arrangement of the final product. For example, annealing of metaphosphate glasses of bivalent cations such as Cu, Mg, Ni, Co, Fe and Mn convert them ultimately to the cyclic tetrametaphosphates[518].

In an aqueous solution, the maximum degree of dissociation of the polyphosphate, like that of polyphosphoric acid, is in the order of 30%. When a solution of a salt of a cation is added to a solution of an acid, corresponding to Graham's salt, the pH of the solution decreases due to the exchange of the previously undissociated hydrogen ions by the cations. It has been found that bivalent metal ions form stronger bonds with the polyphosphate anion than do the monovalent cations. Suggestions have been made that one of the reasons for the tendency of polyphosphate to ion-exchange is caused by the ability of the PO_4 tetrahedra in the chain to rotate freely about the P–O–P bonds. This mobility permits the cations to be linked to more than one PO_3^- in the form of relatively stable chelates. A support for this hypothesis is the observation that a phosphate chain the length of several phosphorus atoms is needed for firm combination with Ca ions[518].

Sodium polyphosphate is quite stable at room temperature at neutral pH. It hydrolyzes more rapidly in acid solution and at high temperatures. The hydrolysis is through the removal of the monophosphate from the ends of the chains. Degradation of the polyphosphate chain is also catalyzed by presence of cations. This action is due to the chelation of the cation on the PO_4 tetrahedra which causes the latter to become positive and thus become more susceptible to combination with OH^- ions or with water molecules[518].

[522] *Calgon In Industry*, Hagan Chemical and Controls Inc., Pittsburg, Penn. (1959).
Applications. A large use for sodium metaphosphate glass, as represented by Calgon®, is for water treatment. This application depends largely on the ability of the polyphosphate anion to sequester the many cations such as Ca^{++}, Mg^{++} and Fe^{++} present in hard water and convert them into stable soluble complexes. Cations thus complexed are unavailable for the precipitation of soap in hard water.

Minute quantities (1 to 2 ppm) of glassy sodium metaphosphate in water also inhibit the crystal growth of calcium carbonate. This is known as the "threshold treatment" and prevents the deposition of scales in boilers. One theory for this inhibitory effect is that the growing faces of the calcium carbonate crystal are covered by the adsorbed polyphosphate molecule ions and this slows down the crystal growth. Upon long standing, large crystals of calcium carbonate do form, but they are grossly distorted due to the adsorbed polyphosphate ions[523]. Presence of dissolved glassy sodium metaphosphate (40–60 ppm) also inhibits the corrosion of cleaned iron surfaces in boilers and iron pipes by the formation of a protective film.

The polyvalent anion of glassy sodium metaphosphate has also dispersive action on finely divided solids. This property is used for reducing the viscosity of clay, oil well drilling mud, and various types of pigments, e.g., titanium dioxide in paper coating.

18.4. SODIUM POLYPHOSPHATES (MADDRELL'S SALT AND SODIUM KURROL'S SALT)

As shown in Fig. 16, there are two forms of Maddrell's salt obtained by the thermal condensation of NaH_2PO_4. The molecular weight of Maddrell's salt increases when the condensation is carried out under increasing water vapor pressure and dehydration time[524].

Each form of Maddrell's salt has its own X-ray pattern but their physical and chemical properties are very similar. They are referred to in the literature as Form II (high temperature Maddrell) and Form III (low temperature Maddrell). Both forms are practically insoluble in water. The structure of Form II is shown in Fig. 17.

Commercial insoluble sodium metaphosphate (IMP) consists of a mixture of these two forms and about 2–3% of $Na_2H_2P_2O_7$. Because of its low water solubility, the mixture is used as a polishing agent in dentifrice which contains soluble fluorides as tooth decay preventative. Insoluble sodium metaphosphate can solubilize a limited amount of calcium, as for example from the tooth enamel. Dentifrice formulations using IMP therefore generally contain small amounts of calcium phosphate such as the γ-form of calcium pyrophosphate as the calcium sacrificing agent.

Sodium Kurrol's salt is prepared by tempering $(NaPO_3)_x$ glass at 580–590°. It is a fibrous crystalline material referred to in the literature also as $NaPO_3$-IV or Form IV sodium metaphosphate. When added to water it swells into a gum. Upon standing

or boiling in water, it eventually dissolves into a viscous solution. As shown in Fig. 17, the anion of the sodium Kurrol's salt consisted of a spiral chain.

18.5. POTASSIUM POLYPHOSPHATE (POTASSIUM KURROL'S SALT)

Potassium dihydrogen phosphate dehydrates rapidly into potassium Kurrol's salt at 205–230°. Because of the high cost of K^+ from KOH, many proposals have been made for the preparation of potassium metaphosphate by the direct action of KCl on phosphoric acid[525, 526]:

$$KCl + 2H_3PO_4 \rightleftharpoons KH_5(PO_4)_2 + HCl$$
$$KH_5(PO_4)_2 \rightleftharpoons KH_2PO_4 + H_3PO_4$$
$$KH_2PO_4 \rightleftharpoons (KPO_3)_n + H_2O$$
Via the above route, a product with 0–0.5 Cl content has been reported[527].

The degree of polymerization of potassium metaphosphate increases with the temperature and length of time of heating. Heating at 260° for 215–280 hr the degree of polymerization is 2300; at 445° for 115–240 hr, the degree of polymerization is 11,700. The common product has a molecular weight range of 250,000 to several million[528].

Potassium polymetaphosphate is practically insoluble in water. However, it goes into a viscous solution in the presence of other alkali metal cations such as Na^+. This phenomenon is attributed to the exchange of the Na^+ for the K^+ and thus disturbs the compact structure of the crystal to permit dissolution by water. An interesting example of this dissolution through ion exchange is found in the case of a mixture of potassium

[528] J. R. van Wazer, Phosphorus and Its Compounds, Vol. I, pp. 601–800, Interscience Publishers Inc., New York (1958).

metaphosphate and sodium metaphosphate. Even though both salts individually are practically insoluble in distilled water, the mixture in water dissolves each other through the mutual exchange of the cations[528].

The long chain molecules of potassium metaphosphate can also be cross-linked into a rubbery mass by kneading in a solution of $CaCl_2$ and NaCl.

Industrial application of potassium metaphosphate is still fairly limited. One use is in combination with $Na_4P_2O_7$ for sausages to improve the texture and homogeneity of ground meat [529]. It also reduces separation of fat and loss of meat juices during cooking and thus reduces shrinkage. The use of potassium metaphosphate in food products while prevalent in Germany has not been approved by the Food and Drug Administration in the United States.

18.6. AMMONIUM POLYPHOSPHATE

A finely divided crystalline ammonium polyphosphate precipitates when the product of ammoniation of polyphosphoric acid containing 83–84% P_2O_5 is added to water. The precipitate contains 35–40% of the original phosphorus in the polyphosphoric acid. It consists of long linear chains of the general formula $(NH_4)_{n+2}P_nO_{3n+1}$ in which n is 50 or higher[530].

Dried crystalline product prepared in this manner appears as stubby rods ($n_\alpha = 1.485$, $n_\gamma = 1.500$) and is stable at room temperature. It maintains the same crystal structure even after heating for 48 hr at 105°. It melts at 355°. Its solubility in water is in the order of 0.1 g per 100 cc after 24 hr at 25°[530].

Ammonium polyphosphate cannot be prepared by the direct thermal dehydration of $NH_4H_2PO_4$ since such reaction is accompanied by the loss of NH_3. Shen, Stahlheber and Dyroff[531] have recently described a successful thermal condensation process which involves the use of urea as the source of ammonia and dehydrating agent:

$$\underset{\substack{|| \\ }}{\overset{O}{\underset{}{}}}$$
$$H_2NCNH_2 + H_3PO_4 \longrightarrow (1/x)(NH_4PO_3)_x + CO_2 + NH_3$$
The product (Form I) obtained by heating an equal molar mixture of $NH_4H_2PO_4$ and urea under an NH_3 atmosphere at 280° for 16 hr is the same as the product obtained by the ammoniation of polyphosphoric acid described earlier. Four other crystalline modifications of ammonium polyphosphate (Forms II, III, IV and V) have been obtained by the treatment of Form I under various temperature conditions. Form IV, obtained in a mixture with glassy impurities by cooling rapidly a melt from heating Form I to 450–470°, has an X-ray diffraction pattern similar to that of potassium Kurrol's salt.

The solubility of ammonium polyphosphate, though slight in water, is also increased by ion exchange with alkali metal ions as described for Maddrell's salt and potassium Kurrol's salt.

The original development of ammonium polyphosphate by the Tennessee Valley Authority was as a superconcentrated fertilizer. It releases slowly the nitrogen and phosphorus values in the soil. It is now also used in formulations for flame retardants.

18.7. CYCLIC METAPHOSPHATES

Cyclic metaphosphates from trimeta to octameta have been observed from chromatographic study of a solution of Graham's salt after the linear polyphosphates have been removed by precipitation. With the exception of heptameta, all members from trimeta to octameta have been either isolated in minor quantities from Graham's salt or prepared by specific methods.

Trimetaphosphates

Sodium trimetaphosphate exists in three polymorphic forms (Forms I, I', I'').[517] The common and stable form is $(NaPO_3)_3$-I or Form I and is known also as Knorre's salt. All three forms may be made by tempering the sodium polyphosphate melt under specific temperature conditions[518, 519] (see Fig. 16). Form I is obtained in high purity by the use of a tempering temperature range of 300–500°[532]. It can also be made by the direct condensation of NaH_2PO_4. Thermal gravimetric studies showed this reaction to occur at the temperature range of 320–380° [533]. A high quality product, not contaminated with Maddrell's salt, is also obtained by the condensation of NaH_2PO_4 in the presence of a small percentage of ammonium nitrate[534].

Trimetaphosphate anion has been shown by X-ray structural analysis to contain a six-membered ring of alternating phosphorus and oxygen atoms. In the acid form, all hydrogen atoms are equivalent and strongly acidic. NMR studies on the solution show only one peak corresponding to the middle groups in the chain polyphosphate. Raman spectra indicate the ion in solution to be a flat ring. In crystalline $LiK_2P_3O_9 \cdot H_2O$, however, the ring is a puckered chair shape[517].

At 299.15°K, $Na_3P_3O_9$ has $C_p = 62.00$ cal/deg and $S = 68.47$ cal/deg[535].

Sodium trimetaphosphate is water-soluble, but has no calcium sequestering power. It converts rapidly to sodium tripolyphosphate $(Na_5P_3O_{10} \cdot 6H_2O)$ when heated at 100° in the presence of an excess of sodium hydroxide.

Crystals of the 6-hydrate, $Na_3P_3O_9 \cdot 6H_2O$, are triclinic rhombohedra, biaxial negative with $\alpha = 1.433$, $\beta = 1.442$, and $\gamma = 1.446$ ($\pm.002$). This hydrate effloresces at room temperature and loses water rapidly at 50°[519].

Other salts of trimetaphosphate, such as La, Ce, Pr, are prepared by the addition of a solution of the respective metal chlorides to an aqueous solution of $Na_3P_3O_9 \cdot 6H_2O$[536]. The salt $Ca_3(P_3O_9)_2 \cdot 10H_2O$ is also prepared from $Na_3P_3O_9$ by the addition of Ca^{++}. It is very soluble in water and reacts with NH_4^+ to form a compound of the approximate composition $NH_4CaP_3O_9$ [537].

Sodium trimetaphosphate reacts with methyl and ethyl alcohols in a water alkali solution at room temperature to form methyl and ethyl tripolyphosphate. It reacts with ethylene glycol to produce the 2-hydroxyethyl monophosphate[538]. One industrial application related to these reactions is the phosphorylation of starch with sodium trimeta-

phosphate. Such modified starch though containing very little phosphate, has the property of forming stable cold water gels[539]. The property of $Na_3P_3O_9$ to cleave readily into $Na_5P_3O_{10}.6H_2O$ in the presence of aqueous NaOH has been used for the *in situ* generation of $Na_5P_3O_{10}.6H_2O$ in detergents[540].

Tetrametaphosphates

Pure tetrametaphosphates are formed when dihydrogen phosphates of Al, Cu^{++}, Mg, Ni^{++}, Co^{++}, Mn^{++}, Fe^{++}, Zn and Cd are dehydrated at 400–500°. Alternatively, they are also formed when glasses resulting from cooling of the melts of the above condensation products are tempered at 400–500°.

Sodium tetrametaphosphate can be prepared by the reaction of Cu or Zn tetrametaphosphate with Na_2S in an aqueous solution[518]. A more convenient method is the selective splitting of the P_4O_{10} tetrahedra by the controlled hydrolysis of the hexagonal form of P_4O_{10} at 15°. The solution obtained is neutralized to pH 7.0 with 30% NaOH, and NaCl then added. Upon standing overnight at below 25°, $(NaPO_3)_4.10H_2O$ crystallizes out.

Sodium tetrametaphosphate also forms a tetrahydrate which has two polymorphic forms. The low temperature form is stable at below approximately 54° and the high temperature modification which forms above 54° does not revert to the low temperature form on cooling. At 100°, the hydrates lose all water to give the anhydrous compound[541].

Tetrametaphosphate ion has an eight-membered cyclic ring structure. It has been suggested that the observed existence of two crystalline varieties of the same salts is due to the two different configurations of the tetrametaphosphate rings (e.g., boat and chair)[517].

Thermally, $(NaPO_3)_4$ is less stable than $(NaPO_3)_3$. Heating at 400–500° converts it to the smaller ring compound.

In 1% NaOH and at 100°, $(NaPO_3)_4$ hydrolyzes completely in about 4 hr. The products of hydrolysis are tripolyphosphates and orthophosphate via the intermediate linear tetrapolyphosphate. Linear tetrapolyphosphate can be obtained by the controlled hydrolysis of $(NaPO_3)_4$ at below 40° with aqueous NaOH. Precipitation with ethanol gives a syrupy sodium tetrapolyphosphate layer which is converted to the crystalline hexaguanidinium 1-hydrate salt upon addition of guanidinium chloride in water[512].

The rate of cleavage of P–O–P bond in tetrapolyphosphate increases about threefold for every 10° rise in temperature. As a consequence the reactions on the degradation of tetrapolyphosphate and the opening of the tetrametaphosphate ring are competitive[512].

Higher Membered Ring Metaphosphates

Pentametaphosphate and hexametaphosphate of Na, Ag, and Ba, containing water of crystallization, have been obtained in gram quantities from fractionation of the cyclic-metaphosphate fraction of Graham's salt prepared with a Na : P ratio of $\leq$ 1.25 : 1[542].

Lithium hexametaphosphate is prepared by heating a mixture of Li_2O/P_2O_5 in a ratio near 7:5 to a temperature of 275°. The product contains only hexametaphosphate with some pyrophosphate. A water solution of it upon passing through a strong acid ion exchange resin and neutralized with Na_2CO_3 to pH 5 to 6 gives a precipitate of sodium hexametaphosphate.$6H_2O$ when CH_3OH is added.

[541] R. N. Bell, L. F. Audrieth and O. F. Hill, *Ind. Eng. Chem.* 44 (1952) 568–72.
[542] E. Thilo and U. Schuelke, *Z. anorg. u. allgem. Chem.* 341 (5–6) (1965) 293–307.

The compound $Na_6P_6O_{18} \cdot 6H_2O$ appears as monoclinic needles and becomes anhydrous when heated to above 120° without breaking the ring[543]. The anion ring has been shown to consist of six PO_4 tetrahedra connected at the corners[544].

In the cyclic metaphosphate system, the stability of the ring to cleavage by NaOH increases rapidly as the size of the ring increases. Thus, pentametaphosphate and hexametaphosphate rings are much more stable than the tri- and tetrametaphosphate rings, e.g., half-life on cleavage with 0.1 NaOH (hours): ring size (P atoms) 3 = 4.5, 4 = 150, 5 = 200 and 6 = 1000[518].

Lead octametaphosphate is formed by heating $Pb_2(P_4O_{12}) \cdot 4H_2O$ to 300–350°. The reaction product is contaminated with about 30% of high molecular weight lead polyphosphate. The sodium salt, $Na_8(P_8O_{24}) \cdot 6H_2O$, is obtained from lead salt by treatment with $Na_2S \cdot 9H_2O$ in water. It precipitates from an aqueous solution as needles upon addition of ethanol.

Sodium and potassium octametaphosphates are stable in aqueous solution for many weeks at neutral pH. They hydrolyze in 0.4N NaOH at 40°. The primary product of hydrolysis is octapolyphosphate of which a great portion hydrolyzes further to the lower polyphosphates before the rest of the octametaphosphate is cleaved[545].

18.8. ULTRAPHOSPHATES

This class of compound is condensed polymeric phosphates having a cation to phosphorus ratio of less than one. Each molecule contains varying numbers of PO_4 tetrahedra some of which are linked to the other PO_4 tetrahedra through three oxygen atoms, i.e., a branched chain structure. In contrast to linear polyphosphates in which the PO_4 tetrahedra are connected through two oxygen atoms and the bonds are resonance stabilized, the branched chain ultraphosphates are not resonance stabilized[518]:

$$
\begin{array}{ccc}
 & O & (-) \\
 & \parallel & O \\
 & & \mid \\
-O-P-O- & \rightleftarrows & -O-P-O- \\
 \mid & & \parallel \\
 O & & O \\
 (-) &
\end{array}
$$

Resonance stabilization

$$

545 U. Schuelke, *Z. anorg. u. allgem. Chem.* 360 (1968) 231–46.

attack by OH^-. The net result is that the triply linked PO_4 tetrahedra of ultraphosphate is much more easily hydrolyzed than the linear polyphosphates.

The structures of ultraphosphates are endless depending on the cation to P ratio. An example of ultraphosphate in the acid form is "azeotropic phosphoric acid" which boils at 864° at 760 mm Hg pressure. It has a P_2O_5 content of 92.4%[528].

19. CONDENSED PHOSPHATES WITH OXY ANIONS OF OTHER ELEMENTS

Orthophosphates, in addition to the ability to form homopolymers through sharing of oxygen atoms between the PO_4 tetrahedra, form copolymers also with oxy anions of other elements. There are two general types of such copolymers. One consists of PO_4 tetrahedra joined with other oxy anion tetrahedra, XO_4, in a random fashion through P–O–X linkages. Such copolymers are represented by phosphate-silicates, phosphate-sulfates, phosphate-vanadates and phosphate-arsenates. The other consists of definite compounds having specific ratios of phosphate anion to the other oxy anions. The acid forms of such compounds are called heteropoly acids. When the other oxy anion is molybdate, compounds with P:Mo ratios of 1:12, 1:11, 1:10, 2:18 and 2:17 have been reported[546].

The best known of the heteropoly acids is that with a phosphate:oxy anion ratio of 1:12 and is known as 12-heteropoly acid. They are represented by compounds such as 12-molybdophosphoric acid, 12-tungstophosphoric acid and their salts. There are also compounds containing mixed oxy anions such as 12-molybdovanadophosphoric acids and their salts.

19.1. HETEROPOLYMERS OF PHOSPHATE-SILICATE, PHOSPHATE-SULFATE, PHOSPHATE-VANADATE, AND PHOSPHATE-ARSENATE

These copolymers have been reviewed recently by Ohashi[547]. They are prepared by melting together the acids, salts or acid anhydrides of the oxy acids. The oxy acids which form copolymers with phosphates can by themselves form copolymers. Their tetrahedral anions are shown below:

Silicate   Sulfate   Vanadate   Arsenate
Copolymers of the above oxy acid anions with phosphates are usually glasses containing P–O–X linkages. When they are dissolved in water, in all cases cleavage occurs first at the P–O–X bond.

Phosphate-Silicate

In the phosphate-silicate copolymer system, the calcium salt is prepared by fusing together calcium metaphosphate [prepared by fusing of $Ca(H_2PO_4)_2$] with the desired amount of

[546] F. A. Cotton and G. Wilkinson, *Advanced Inorganic Chemistry*, 2nd ed., pp. 941–6, Interscience Publishers (1966).

[547] S. Ohashi, *Topics in Phosphorus Chemistry*, 1 (1964) 189–239.

silica gel at 980–1000°. Glassy copolymers with a SiO_2 content of 12.5% or below are clear and completely, though slowly, soluble in water. Products with a SiO_2 content of more than 12.5% are turbid in appearance and not all of the SiO_2 content is soluble in water. Dissolution of calcium phosphate silicate glass in water is more rapid in the presence of cation exchange resin (Dowex 50, H form). The solution becomes saturated when the P:Si ratio reaches about 4 and from this data it has been postulated that a compound having a P:Si ratio $=4$, e.g., $Ca_2SiP_4O_{14}$, may be present in the glass along with calcium polyphosphates of various degrees of polymerization[547].

In the sodium phosphate silicate system, when a mixture of sodium metaphosphate and sodium metasilicate is melted together in a 1:1 molar ratio, no copolymer forms. The reaction proceeds with the formation of trisodium phosphate and α-cristobalite:

$$NaPO_3 + Na_2SiO_3 \longrightarrow Na_3PO_4 + SiO_2$$

Also, no copolymers containing P–O–Si linkages are present in the $NaPO_3$–SiO_2 system with a P:Si ratio of 0.5 to 4. In this system, the phosphates are present mostly as trimetaphosphate along with pyro and tripolyphosphate and very little orthophosphate. The SiO_2 content is present mostly as α-cristobalite and little α-tridymite.

The presence of P–O–Si linkages in sodium phosphate silicate glasses is assumed from indirect evidence. When glasses with P:Si ratios greater than 6 (both in the $NaPO_3$–Na_2SiO_3 and $NaPO_3$–SiO_2 systems) are dissolved in water, polyphosphates of wide molecular weight distribution are obtained. The average chain length of the polyphosphates increases with the increase in the P:Si ratio. It is assumed then that the formation of these polyphosphates is the result of cleavage of the P–O–Si linkages present in the phosphate-silicate glasses. Such linkages are known to hydrolyze easily in water[547].

Phosphate-Sulfate

Copolymers of sodium phosphate-sulfate, containing P–O–S bonds, can be prepared only in melts in which the molar ratio $(P_2O_5 + SO_3) > Na_2O$. The nature of the starting material is unimportant[548]. Such copolymers may be prepared by the absorption of SO_3 on pyro-, tri-, or polyphosphates in the temperature range of 400–450°. The resultant melt is then chilled rapidly into a glass. Alternatively, P_4O_{10} and varying amounts of sodium pyro- or tripolyphosphate may react with sodium sulfate at about 400° to form a melt which is then cooled to a glass[547].

Thilo and Blumenthal prepared sodium phosphate-sulfate glasses by adding various quantities of either sodium trimetaphosphate or Graham's salt to molten $Na_2S_2O_7$ at about 400°. Sulfur trioxide is evolved only when the heating is prolonged or when a large excess of $Na_2S_2O_7$ is used[548].

No P–O–S linkages are formed in melts of high Na_2O content. For example, when an equimolar mixture of $NaHSO_4$ and Na_2HPO_4 are heated together, Na_2SO_4 and polyphosphates with an average chain length corresponding to the residual sodium content are obtained. Sulphur trioxide is evolved at $\geq 550°$.

Phosphate-sulfate copolymers can be isolated in solution from contaminating ionic sulfates and polyphosphate by means of anion exchange resin (the chloride form). The ionic sulfate is eluted alone and quantitatively by 0.2 N KCl. The phosphate-sulfate is eluted with 3 N HCl while the polyphosphate is eluted only by concentrated acid[548].

[548] E. Thilo and G. Blumenthal, *Z. anorg. u. allgem. Chem.* **348** (1966) 77–88.

The copolymers formed by the reaction of sodium polyphosphate and $Na_2S_2O_7$ with a molar ratio of $Na_2O/(P_2O_5+SO_3) = <1$, when dissolved in water, have been assigned the following structure:

$$\left[\begin{matrix} & O\ O & & O\ O & \\ -OSOPO & ----- & POSO- \\ & O\ O & & O\ O & \end{matrix}\right]^{n-} Na_n^+$$
This assignment is based on results of hydrolysis studies of the phosphate-sulfate fraction eluted from the anion exchange resin column. Terminal $NaSO_3$ group in the phosphate-sulfate copolymer hydrolyzes at $60°$ with a half-life of 7.5 hr at $pH = 4.5$ and 11.7 hr at $pH = 13$. One equivalent of a strongly acidic HSO_4^- ion and one weakly acidic POH end group are formed for each mole of sulfate hydrolyzed off. In contrast, the P–O–P bond in the polyphosphates portion hydrolyzes at $60°$ with a half-life of 4.4 days at a pH of 5, and 18.5 days at a pH of 8, while the S–O–S bond in the disulfate hydrolyzes with a half-life of 0.12 min in the pH range of 3–14[548].

Phosphate-Vanadate

Copolymers of phosphate-vanadate containing P–O–V linkages are presumed to form when glassy sodium polyphosphate with Na/P ratio of 1 is heated to a melt with various amounts of V_2O_5 and Na_2CO_3 at $900°$. Rapid cooling of the melt results in glasses having colors which vary from dark brown to yellow as the P/V ratio is increased. At a P/V ratio of 3, about 19% of the total vanadium is reduced to V^{IV}. At a P/V ratio above 50, the total percentage of vanadium reduced to V^{IV} is 37–38%.

Assuming that P–O–V bonds hydrolyze immediately upon dissolving in water, glasses with P/V ratio of 1 have probably essentially an alternate phosphate-vanadate structure. This is shown by the fact that the phosphate moieties in the hydrolysate contain 89% ortho-, only 11% pyro- and no higher polyphosphates. As expected, glasses of higher P/V ratio have increasingly more longer chain polyphosphates in the hydrolysate.

Phosphate-Arsenate

Glassy copolymers of phosphate-arsenate are obtained by melting a mixture of NaH_2PO_4 and NaH_2AsO_4 at $68°$ and the melt then cooled rapidly. The distribution of the arsenic atoms in the chain of the copolymer is approximately at random with a slight preference for As–O–P bonds. Since the P–O–As and As–O–As bonds are easily hydrolyzed, the copolymers are converted in a water solution to monoarsenic and ortho- or polyphosphate mixtures.

In the case of the crystalline phosphate-arsenate copolymer, obtained by annealing of the glass at $470°$ for 24 hr, Thilo[549] has shown that it crystallizes with the structure of Maddrell's salt. The arsenic atom is preferentially located in the XO_4 tetrahedra forming the "noses" of the "Dreierketten" (Fig. 17). Since these crystalline copolymers resemble in structure crystalline Maddrell's salts, they are only very slowly soluble in water. Also similar to Maddrell's salt, they dissolve in a solution of alkali metal salts other than sodium. This is due to the ion-exchange phenomenon which disturbs the close pack structure of the crystal.

Potassium phosphate-arsenate forms crystalline compounds having six membered rings

[549] E. Thilo, *Angew. Chem. Intern. Ed.* **4** (1965) 1061–71.

analogous to potassium trimetaphosphate. These trimeric rings contain one or two arsenate anions:
Obtained only as mixtures, their presence is deduced from the fact that P–O–As or As–O–As bonds are easily hydrolyzed while the P–O–P bond is rather stable to hydrolysis. Paper chromatographic analysis of the hydrolysate of potassium metaphosphate-arsenate shows that as the arsenic content is increased, the percentage of orthophosphate increases and the pyro- and trimetaphosphate decreases. This is in line with the proposed structures for the cyclic phosphate-arsenate.

19.2. 12-HETEROPOLY ACIDS AND THEIR SALTS

The term heteropoly acids has been designated for definite compounds of specific structures. Compounds containing anions of oxy acids such as phosphoric, arsenic, boric, or silicic acids and anions of other oxy acids such as molybdic and tungstic acids are examples of heteropoly acids. This section concerns itself only with examples of the phosphorus-containing 12-heteropoly acids.

When phosphoric acid is reacted with ammonium molybdate in a nitric acid solution, a yellow precipitate of ammonium 12-molybdophosphate forms. It is a complex compound having a phosphorus nucleus with a formula of $(NH_4)_3H_4[P(Mo_2O_7)_6].H_2O$. Since it is only soluble to the extent of 0.03 g/100 g H_2O at 15°, and no corresponding precipitates form with pyro- or metaphosphate ions, it is used for the qualitative determination of soluble orthophosphate. The free acid of the compound, 12-molybdophosphoric acid, $H_7[P(Mo_2O_7)_6].10H_2O$, is soluble in water and many of its normal salts such as silver, mercury and guanidinium salts are known[550].

Heteropoly acid of phosphorus with tungsten is also prepared by the direct combination of the components followed by crystallization. For example, the 12-tungstophosphoric acid, $H_7[P(W_2O_7)_6]$ xH_2O is prepared by dissolving sodium tungstate $(Na_2WO_4.2H_2O)$ and disodium phosphate in boiling water and the solution acidified with concentrated hydrochloric acid:

$$12Na_2WO_4 + Na_2HPO_4 + 26HCl + H_2O \rightarrow$$
$$H_7[P(W_2O_7)_6] \cdot xH_2O + 26NaCl$$
The precipitated acid is purified by the addition of ether. The water-insoluble heteropoly acid-ether complex being insoluble in both ether or water is washed free of impurities with dust-free air through the solution. The free acid which is extremely soluble in water is obtained as very heavy white octahedral crystals. It is easily reduced by organic reducing

550 D. M. Yost and H. Russell, Jr., *Systemic Inorganic Chemistry of the Fifth- and Sixth-Group Non-metallic Elements*, pp. 232–3, Prentice-Hall Inc., N.Y. (1944).

vapors or light to a blue color. Reoxidation is easily accomplished by heating with water.

The sodium salt is soluble in water while the potassium and ammonium salts are comparatively insoluble. 12-tungstophosphoric acid finds use as precipitant for proteins, alkaloids and certain amino acids[551].

Mixed molybdovanadophosphoric acids and their salts are also known. Three of these heteropoly acids have the following formula:

$$H_4[PMo_{11}VO_{40}]\cdot34H_2O, \quad H_5[PMo_{10}V_2O_{40}]\cdot32H_2O, \quad \text{and} \quad H_6[PMo_9V_3O_{40}]\cdot34H_2O.$$
11-molybdo-1-vanadophosphoric acid, $H_4[PMo_{11}VO_{40}]\cdot34H_2O$, is prepared using Na_2HPO_4, $NaVO_3$ and $Na_2MoO_4.2H_2O$ in the molar ratio of 1:1:11. The water solution of disodium phosphate and sodium metavanadate is acidified to a red color with concentrated H_2SO_4. A water solution of $Na_2MoO_4.2H_2O$ is added, and then the whole reaction mixture is acidified with concentrated H_2SO_4. Upon cooling the heteropoly acid is extracted
FIG. 18. Arrangement of (a) one group and (b) two groups of three WO_6 octahedra relative to the central PO_4 tetrahedron, and (c) the complete anion $PW_{12}O_{40}^{3-}$.[555]

with ethyl ether. The heteropoly acid etherate is freed of ether by sparging with air. The orange solid residue obtained is recrystallized from water. The crystalline acid effloresces slowly at room temperature which accounts for the slight variations in the amount of water of crystallization from sample to sample.

The 10-molybdo-2-vanadophosphoric acid, $H_5[PMo_{10}V_2O_{40}].32H_2O$, is similarly prepared using $Na_2HPO_4:NaVO_3:Na_2MoO_4.2H_2O$ in the molar ratio of 1 : 4 : 10. The solid obtained from the etherate upon crystallization from water yields large red crystals. It dissolves in ether to form an oil which is ether insoluble. It is soluble and forms a single phase, however, in alcohols, ethyl acetate, dimethyl sulfoxide and tetrahydrofuran.

The preparation of 9-molybdo-3-vanadophosphoric acid $H_6[PMo_9V_3O_{40}].34H_2O$, is carried out in a same manner, using a $Na_2HPO_4:NaVO_3:Na_2MoO_4.2H_2O$ in the ratio of 1 : 6 : 4.5.

[551] J. C. Bailar, Jr , *Inorganic Synthesis*, Vol. I, pp. 132–3, Ed. H. S. Booth, McGraw-Hill Book Co. 939).

Triammonium 11-molybdo-1-vanadophosphate, $(NH_4)_3H[PMo_{11}VO_{40}].3.5H_2O$, and triammonium 10-molybdo-2-vanadophosphate, $(NH_4)_3H_2[PMo_{10}V_2O_{40}].7.5H_2O$, are insoluble in water. They are prepared as precipitates by the addition of a NH_4Cl solution to a solution of the corresponding free acid. The sodium 11-molybdo-1-vanadophosphate, $Na_4[PMo_{11}VO_{40}]\cdot8H_2O$, however, is very soluble in water. It can be prepared by passing a solution of the acid through the sodium form of Dowex 50–X8 ion exchange resin and the effluent evaporated to dryness[552].

The structure of crystalline 12-tungstophosphoric acid, $H_3[PW_{12}O_{40}]5H_2O$, was studied by Keggin by X-ray technique[553]. It was found that in the anion, a PO_4 tetrahedron is located at the center of a structure surrounded by twelve WO_6 octahedra. These octahedra have shared corners and shared edges but no shared faces. It may be considered as four groups of three WO_6 octahedra. In each group there is one oxygen atom shared by all three octahedra. The orientation of the four groups is such that the four triply shared oxygen atoms are located at the corners of the central tetrahedron—that of the PO_4 anion[554, 555]. In such an arrangement, there are large spaces between the atoms which accounts for the existence of hydrates containing large numbers of water molecules, e.g., $H_3[PW_{12}O_{40}]\cdot29H_2O$. Such hydrates can be dehydrated without causing any important structural changes.

Tsigdinos and Hallada have proposed that the molybdovanadophosphoric acids they prepared have anions also of the structure analogous to that proposed by Keggin for 12-tungstophosphoric acid[552].

20. HALOACIDS OF PHOSPHORUS AND THEIR SALTS

This class of compounds may be regarded as derived from substituting the OH groups in orthophosphoric acid with halogens. The best known and well-characterized compounds in this series are the fluoro derivatives.

20.1. FLUOROPHOSPHORIC ACIDS AND FLUOROPHOSPHATES

Monofluorophosphoric Acids and Monofluorophosphates

Fluorophosphoric acids interconvert with relative ease. Their relationship to each other and to orthophosphoric acid is shown below:

$$
\underset{\substack{|\\O\\H}}{\overset{\overset{O}{\|}}{HOPOH}} \;\underset{H_2O}{\overset{HF}{\rightleftarrows}}\; \underset{\substack{|\\F}}{\overset{\overset{O}{\|}}{HOPOH}} \;\rightleftarrows\; \underset{\substack{|\\F}}{\overset{\overset{O}{\|}}{HOPF}} \;\underset{2H_2O}{\overset{4HF}{\rightleftarrows}}\; HPF_6
$$
Based on the above equilibrium, monofluorophosphoric acid is formed to a considerable amount when HF is reacted with concentrated orthophosphoric acid[556]. It can also be

[556] W. Lange, *Inorganic Synthesis*, Vol. II, pp. 155–6, Ed. C. W. Fernelius, McGraw-Hill Book Co., New York (1946).

prepared by the hydrogenation of $(C_6H_5O)_2P(O)F$ in tetrahydrofuran solvent for 10 hr at room temperature in the presence of $PtO_2.2H_2O$ catalyst[557]. The preferred preparative method is the conversion of Na_2PO_3F by the acid form of a cation exchange resin[558]. Commercial monofluorophosphoric acid is prepared by the reaction of 69% aqueous HF and phosphoric anhydride:

$$P_2O_5 + 2HF + H_2O \longrightarrow 2H_2PO_3F$$
It contains usually 15–20% each of H_3PO_4 and HPO_2F_2[559].

Monofluorophosphoric acid is a colorless viscous oily liquid, strongly resembles H_2SO_4 and is completely soluble in water. Potentiometric titration shows it to be a dibasic acid and the ionization constants have been estimated to be $K_1 = 0.28$ and $K_2 = 1.58 \times 10^{-5}$ [560]. The neutralization points for a 0.05 N solution are pH 3.5 and pH 8.5[559]. Due to intramolecular hydrogen bonding, F---H–O, it acts as a monobasic acid in aqueous solution by conductivity measurements[558]. The density of the 100% acid is $D_4^{25} = 1.818$[560]. Little decomposition occurs even when heated to 185° under reduced pressure. However, it is not distillable. It does not attack glass in the absence of water. At 30° it solidifies and at $-70°$ it becomes a rigid glass.

Sodium monofluorophosphate is prepared by heating anhydrous sodium trimetaphosphate with anhydrous sodium fluoride in a platinum dish at 800° until complete fusion of the mixture. The product obtained contains about 90% Na_2PO_3F. It is purified by dissolving in water and removing the sodium pyrophosphate contaminant as the insoluble silver pyrophosphate by the addition of Ag_2PO_3F. (Silver monofluorophosphate is prepared from Na_2PO_3F by reaction with $AgNO_3$.) Sodium monofluorophosphate is then obtained as crystals upon concentration of the aqueous solution. It melts at about 625°. It is very soluble in water and hydrolyzes to the orthophosphate and fluoride slowly in neutral solution and more rapidly in acid solution[561]. The pH of 2% solution is about 7.2[559].

The major application of sodium monofluorophosphate is as an additive in dentifrice formulation for caries inhibition[562]. Tests have also shown that when Na_2PO_3F is added at a level of 40 ppm F equivalent to the drinking water of Syrian hamsters, a reduction of dental caries in these animals is observed. Since the PO_3F^- ion apparently is not hydrolyzed appreciably in the animal body, the fluorine therefore does not have to be in the free ionic form to be active as dental caries inhibitor. The results on dental caries inhibition by Na_2PO_3F are comparable to those obtained by NaF at the same F level. Calculated on the basis of F content, the toxicity of Na_2PO_3F is only about 2/5 to 1/3 that of NaF to rats[563].

Diammonium fluorophosphate is formed in equal amount with monoammonium difluorophosphate when NH_4F is heated with P_4O_{10} at about 135°. It is obtained as an insoluble residue when the reaction product is extracted with absolute alcohol to remove ammonium difluorophosphate. Upon recrystallization from water, the monohydrate, $(NH_4)_2PO_3F.H_2O$, occurs as rectangular prisms which effloresces in air at room temperature

and becomes anhydrous at 105° [557]. On heating to 220°, $(NH_4O)_2POF$ loses NH_3 accompanied by condensation and reorganization reactions to difluoro- and monofluoropolyphosphates and polyphosphates[558].

Alkali acid monofluorophosphates such as $NaHPO_3F$, $KHPO_3F$ and NH_4HPO_3F are obtained by dissolving the corresponding dialkali metal monofluorophosphate and H_2PO_3F in water[558].

Mixed alkali metal monofluorophosphates are obtained by evaporation of a solution of the two dialkali monofluorophosphates. In this manner $NaKPO_3F$, $NaNH_4PO_3F.H_2O$ and KNH_4PO_3F are isolated[558]. Many metal monofluorophosphates are prepared by metathesis reaction from Ag_2PO_3F and the metal chlorides. Examples of compounds prepared in this manner are $CdPO_3F.8H_2O$, $MnPO_3F.3H_2O$, $NiPO_3F.7H_2O$, $Cr_2(OP_3F)_3.18H_2O$ and $Fe_2(PO_3F)_3.12H_2O$[568].

Difluorophosphoric Acid and Difluorophosphates

Commercial difluorophosphoric acid, HPO_2F_2, is prepared by the treatment of phosphoric anhydride with HF according to the following equation:

$$P_4O_{10} + 6HF \longrightarrow 2HPO_2F_2 + 2H_2PO_3F$$
It is separated from monofluorophosphoric acid by distillation under reduced pressure: b.p.$= 116°$ at 760 mm or 51° at 100 mm. The vapor pressure at between 22–108° follows the equation:

$$\log p = -421.195/T - 0.478214 \log T + 0.0137121 T$$

At between 51.6–93°,

$$\log p = 7.333 - 1732\ T.^{[559,\ 565]}$$

It has a m.p. of $-96.5 \pm 1°$ and density of d_4^{25} 1.583. The heat of vaporization is 7925 cal/g mole. When dissolved in water it behaves as a monobasic acid with a neutralization end point at pH 7.3. A neutralized solution, however, slowly turns acidic due to hydrolysis to monofluorophosphoric acid and hydrofluoric acid[559].

Many industrial applications have been suggested for difluorophosphoric acid in the patent literature. These include its use as catalysts for isomerization and polymerization of hydrocarbons. At the present its actual industrial applications are limited.

Salts of difluorophosphoric acid are well known and the most widely studied ones are those of the alkali metals. As indicated earlier, ammonium difluoride phosphate is prepared as a co-product with ammonium monofluorophosphate when a mixture of P_4O_{10} and NH_4F is heated to 135°. It is isolated by extraction with boiling absolute alcohol and recrystallized quickly from water[556].

Sodium difluorophosphate may be prepared by heating $NaHF_2$ with P_4O_{10} through several temperature stages until 300–320° when all of the $NaHF_2$ is decomposed[566]. Another procedure is by the melting of $NaPF_6$ and $(NaPO_3)_n$:

$$NaPF_6 + 2/n(NaPO_3)_n \longrightarrow 3NaPO_2F_2$$
Quite pure $NaPO_2F_2$ is thus obtained[567].

[567] H. Jonas, Ger. 813,848, 17 Sept. 1951, to Farbenfabriken Bayer.

Potassium difluorophosphate is prepared analogously by heating KPF_6 with $(KPO_3)_n$ to $400°$:

$$KPF_6 + 2/n(KPO_3)_n \longrightarrow 3KPO_2F_2$$
The melt obtained upon cooling contains 97.5% KPO_2F_2 which may be further purified by recrystallization from $1:1$ mixture of isopropanol–water at between $65°$ and $-5°$. It has a m.p of $255° \pm 2°$ and a density of 2.442 g/ml[568].

The crystals of potassium difluorophosphate have an orthorhombic structure $(a = 8.03_9,\ b = 6.20_5,\ c = 7.63_5)$. The difluorophosphate anion has the dimensions of $P–O = 1.470 \pm 0.005 Å$, $P–F = 1.575 \pm 0.005 Å$, $\angle FPF = 97.1° \pm 0.4°$, $\angle OPO = 122.4° \pm 0.4°$ [569].

Hexafluorophosphoric Acid and Hexafluorophosphates

Commercial concentrated hexafluorophosphoric acid is prepared by reacting P_2O_5 with anhydrous HF in the ratio of 1 to 12:

$$P_2O_5 + 12HF \longrightarrow 2HPF_6 + 5H_2O$$

The product contains besides HPF_6 also an equilibrium amount of the products of hydrolysis of HPF_6 which includes mono- and difluorophosphoric acids and HF.

When the solution is cooled, the hexahydrate, $HPF_6 \cdot 6H_2O$, crystallizes out, having a m.p. $31.5°$ [560]. The anhydrous acid may be prepared by the reaction of PF_5 with HF in low boiling inorganic liquids such as SO_2[559]. On standing at room temperature, it decomposes back to HF and PF_5.

Ammonium and alkali metal hexafluorophosphate can be prepared directly from the reaction of the chloride salt of the cation and PCl_5 in an excess of liquid HF in a silver or aluminum reactor:

$$NaCl + PCl_5 + 6HF \longrightarrow NaPF_6 + 6HCl$$
The hexafluorophosphate formed precipitates readily from the anhydrous HF solution[560]. Patent literature has also claimed the preparation of hexafluorophosphate by heating a mixture of alkali metal fluoride, elemental phosphorus and anhydrous HF at $180–220°$ under autogenous pressure[570]. Dry alkali metal hexafluorophosphates are also formed by heating metal fluorides with PF_5 in a closed system. This is due to the high electronegativity of fluorine which permits PF_5 to combine easily with a fluoride ion to form PF_6^-.

The solubility characteristics of hexafluorophosphates resemble those of the perchlorates. Potassium and tetramethylammonium hexafluorophosphate are only moderately soluble in water ($KPF_6 = 3.56$ g/100 solution at $0°$ and 38.3 g/100 g solution at $100°$)[559]. The sodium, ammonium and alkaline earth salts, however, are very soluble. These salts undergo hydrolysis even at ice temperature when the concentration approaches saturation[560]. They are, however, stable to dilute alkali. When heated, they dissociate with the liberation of PF_5 and this reaction serves as a convenient method for the laboratory preparation of PF_5.

It is of interest to note that KPF_6 is rated as practically non-toxic; the minimal lethal dose to female albino rats by intraperitoneal injection is 1120 mg/kg[559]. The density of KPF_6 is 2.55 g/ml and the m.p. is $575°$ (with decomposition).

[568] V. B. Tul'chinskii, I. G. Ryss and V. I. Zubov, *Zh. Neorg. Khim.* 11(12) (1966) 2694–6.
[569] R. W. Harrison, R. C. Thompson and J. Trotter, *J. Chem. Soc.* A(1966) (12) 1775–80.
[570] A. W. Jache and S. Kongpricha, U.S. 3.380,803, 30 April 1968, to Olin Mathieson Chemical Corp.

The PF_6^- anion has the phosphorus atom present as an sp^3d^2 hybrid. The salts MPF_6 where M is K, Cs, or NH_4, crystallize with a NaCl type packing of M^+ and octahedral PF_6^-.

In the crystal structure of $NaPF_6 \cdot H_2O$, the PF_6^- octahedral is distorted. The four equatorial fluorine atoms with sodium ions as nearest neighbors have a P–F distance of 1.58 Å. The apical fluorine atoms with water molecules as nearest neighbor have the P–F distance 1.73 Å[571].

20.2. CHLOROPHOSPHORIC ACID AND CHLOROPHOSPHATES

Dichlorophosphoric Acid and Dichlorophosphates

Chlorophosphoric acids are much more difficult to prepare and isolate than the fluorophosphoric acids. Of the possible chlorophosphoric acids only dichlorophosphoric acid has been prepared. One method of preparation involves the hydrolysis of $Cl_2\overset{\text{O}}{\overset{\|}{P}}O\overset{\text{O}}{\overset{\|}{P}}Cl_2$ with one mole of water at $-60°$ to $-70°$ [572]:

$$Cl_2\overset{O}{\overset{\|}{P}}O\overset{O}{\overset{\|}{P}}Cl_2 + H_2O \longrightarrow 2HO\overset{O}{\overset{\|}{P}}Cl_2$$
Dichlorophosphoric acid is also formed by the controlled hydrolysis of $POCl_3$. Product thus obtained is usually contaminated with unreacted $POCl_3$ and polyphosphoryl chlorides[573]. Heating of a mixture of $POCl_3$ and H_3PO_4 in a 2 : 1 ratio at 80–150° gave a 60% yield of $HOPOCl_2$ along with condensation products[574].

Dichlorophosphoric acid crystallizes as needles with a m.p. of $-18°$ and $d_4^{25} = 1.686$ g/ml. At room temperature it is a clear mobile liquid stable in the absence of air and soluble in organic solvents. When distilled under reduced pressure, the distillate contains pyrophosphoryl chloride and a little $POCl_3$. Distillation under normal pressures resulted in the loss of HCl and the formation of $POCl_3$ and polymeric condensed chlorophosphoric acids[575].

Further hydrolysis of HPO_2Cl_2 with a little H_2O does not result in the formation of monochlorophoric acid, only H_3PO_4 and $POCl_3$ [576].

Dichlorophosphoric acid precipitates as the nitron and brucine salt at $-15°$ [576]. Metal salts such as the dichlorophosphates of Be, Al, Ga and In, and Fe^{+++} are formed as precipitates when the anhydrous chlorides of the metals are dissolved in an excess of $POCl_3$ and a stream of Cl_2O diluted with inert gas is introduced into the solution. In this reaction, to avoid gel formation, the temperature is allowed to go to about 80°. Infrared spectra indicated $Be(PO_2Cl_2)_2$ to consist of Be^{+2} and $PO_2Cl_2^-$ while the other compounds are of polymeric structure with O bridges[577].

Manganous dichlorophosphate forms a stable adduct with ethyl acetate, $Mn(PO_2Cl_2)_2(CH_3COOC_2H_5)_2$. Its crystal structure indicates that the Mn octahedrally

coordinated to four O atoms of $PO_2Cl_2^-$ ions and two carbonyl oxygens of the $CH_3COOC_2H_5$ [578].

Miscellaneous Halophosphates

Dibromophosphoric acid cannot be prepared by reactions analogous to those for the preparation of difluorophosphoric acid and dichlorophosphoric acid. It can be isolated as a sparingly soluble nitron salt, $C_{20}H_{16}N.HOPOBr_2$ in 85% yield when a nitron–acetic acid–water solution is added to $POBr_3$ dissolved in acetone[579]. The ethyl acetate adducts of the calcium and magnesium salts, $Ca(PO_2Br_2)_2.2CH_3COOC_2H_5$ and $Mg(PO_2Br_2)_2.2CH_3COOC_2H_5$, are formed as monoclinic needles when the metal oxides are added to a solution of $POBr_3$ in $CH_3COOC_2H_5$ [580].

Dichlorophosphorothioic acid is also isolated as the difficultly soluble nitron complex, $C_{20}H_{16}N_4.HOPSCl_2$, which has a m.p. of 182°. The hydrolysis of $PSCl_3$ to $HOPSCl_2$ is carried out in an acetone solution. In this reaction the PCl bond is split while the PS bond remains intact[581].

21. PEROXYPHOSPHATES AND PHOSPHATE PEROXYHYDRATES

21.1. PEROXYPHOSPHATES

Orthophosphates form permonophosphates and perdiphosphates analogous to the better known persulfates:
$$
\begin{array}{cc}
\begin{array}{c}
O \\
\| \\
^-O-P-O-O^- \\

| \qquad\quad | \\
O \qquad\ O^-
\end{array}
\\
\text{Peroxymonophosphate anion} & \text{Peroxydiphosphate anion}
\end{array}
$$
Perdiphosphates

Potassium perdiphosphate is prepared by the anodic oxidation of potassium orthophosphate in the presence of KF and K_2CrO_4. A typical solution for oxidation contains 302.2 g KH_2PO_4, 198 g KOH (equivalent to a molar composition of $2K_2HPO_4$ plus $3K_3PO_4$), 120 g of KF and 0.355 K_2CrO_4. The solution is electrolyzed at about 14° with platinum electrodes at a current density of less than 0.15 A/cm² at the anode. By-product permonophosphate decomposes when the electrolyzed solution is allowed to stand overnight. The yield of crystalline $K_4P_2O_8$ is in the order of 80%[582].

Other metal salts of perdiphosphoric acid such as the sparingly soluble $Ba_2P_2O_8$, $Zn_2P_2O_8$, $Pb_2P_2O_8$ are prepared from an aqueous solution by the metathesis of $K_4P_2O_8$ with $BaCl_2$, $ZnSO_4$ or $Pb(NO_3)_2$ respectively[582].

Lithium perdiphosphate is obtained from the potassium salt as the tetrahydrate, $Li_4P_2O_8.4H_2O$. It is converted to the tetramethylammonium salt by the use of a column

[582] F. Fichter and E. Gutzwiller, *Helv. Chim. Acta* **11** (1928) 323–37.

containing a tenfold excess of the ion exchange resin Dowex 50–X4 charged with tetramethyl-ammonium chloride.

Free perdiphosphoric acid, $H_4P_2O_8$, has not been isolated and characterized. Its third and fourth dissociation constant, however, has been measured at 25° by pH titration of the tetramethylammonium salt with HCl. The values obtained upon extrapolation to infinite dilution are $K_3 = 6.6 \pm 0.3 \times 10^{-6}$, $K_4 = 2.1 \pm 1 \times 10^{-8}$. The first and second dissociation constant could not be measured by this method, but were estimated to be $K_1 = \simeq 2$ and $K_2 \simeq 3 \times 10^{-1}$ [583].

At room temperature, the perdiphosphate anion, $P_2O_8^{4-}$, is quite stable in neutral or basic solutions. In acidic solution, it undergoes rapid hydrolysis to permonophosphoric acid and the rate of hydrolysis increases with increase in hydrogen ion concentration:

$$H_4P_2O_8 + H_2O \longrightarrow H_3PO_5 + H_3PO_4$$
Perdiphosphate anion forms complexes with alkali metal cations as does the pyrophosphate anion. However, with alkaline earth cations such as Mg^{++}, its complex is much weaker than the corresponding pyrophosphate anion complex.

Permonophosphate

Permonophosphoric acid, as indicated above, can be prepared by the hydrolysis of perdiphosphoric acid. It is also produced by the anodic oxidation of the orthophosphate, a procedure in which a larger yield is obtained in an acidic solution. For the manufacture of a crude product containing permonophosphoric acid, patent literature has described alternative procedures which involved the reaction of P_2O_5 with aqueous solution of H_2O_2 [584] or by the heating of 85% H_3PO_4 and P_2O_5 with 95.3% H_2O_2 [585].

The acid ionization constants of permonophosphoric acid have been determined by spectrophotometric technique (UV absorption) and found to be $K_1 = 8 \times 10^{-2}$, $K_2 = 3 \times 10^{-6}$ and $K_3 \simeq 2 \times 10^{-13}$ at 25° or $pK_1 = 1.1$, $pK_2 = 5.5$ and $pK_3 = 12.8$ (the peroxide proton) as compared to H_3PO_4, $pK_1 = 2.1$, $pK_2 = 7.1$ and $pK_3 = 12.3$ [586].

Permonophosphoric acid hydrolyzes in a water solution in the presence of perchloric acid to hydrogen peroxide and phosphoric acid. The hydrolysis is first order in per-acid and the rate increases with added $HClO_4$. At all $HClO_4$ concentration and temperature studied, the hydrolysis follows the rate law:

$$\frac{-d[H_3PO_5]}{dt} = k_1[H_3PO_5]$$

where k_1 is pseudo-first order rate constant dependent on both the temperature and acidity of the solution [586].

Permonophosphoric acid is a strong oxidizing agent and liberates iodine at once from acidified KI solution. Under the same conditions, perdiphosphoric liberates iodine much more slowly and can be kept in such a dilute solution for a relatively long period of time.

Both perdiphosphate and permonophosphate can be determined polarographically with an error of $\leqq 2\%$ in a supporting electrolyte of 0.1M H_3PO_4 or H_2SO_4. Permono-phosphate yields two reduction waves. It can be determined in an alkaline solution from

[586] C. J. Battaglia and J. V. Edwards, *Inorg. Chem.* **4** (1965) 552–8.

the first reduction wave (about -0.2 V) even in the presence of $P_2O_8^{4-}$ since the latter is not reduced in an alkaline solution. In 0.1 or N KOH, the first reduction wave of $PO_5^{\equiv}$ (0.07–0.8 millimole/l) will tolerate a tenfold amount of $P_2O_8^{4-}$ [587].

One suggested use for perphosphoric acid is for the detoxification of hydrogenation catalysts which have been poisoned by small concentration of CS_2 or other sulfides[588].

21.2. PEROXYHYDRATES OF ORTHO-, PYRO-, TRIPOLY AND TRIMETAPHOSPHATES

Hydrogen peroxide forms a number of peroxyhydrates with alkaline or neutral ortho-, pyro-, tripoly or trimetaphosphates. These compounds are analogous to the hydrates with H_2O_2 replacing all or part of the H_2O in the hydrates. The general method of synthesis involves the solution of the anhydrous salt in an aqueous solution of selected concentration of H_2O_2.

Peroxyhydrates of Orthophosphates

In the Na_3PO_4–H_2O_2–H_2O system at $0°$, solution concentrations of 5.4% H_2O_2 and 4.9% Na_3PO_4 are in equilibrium with two solid phases: $Na_3PO_4 \cdot 12H_2O$ and $Na_3PO_4 \cdot H_2O_2$. At solution concentration of 26.7–28.0% H_2O_2 and 15.4–16.7% Na_3PO_4, the two solid phases are $Na_3PO_4 \cdot H_2O_2$ and $Na_3PO_4 \cdot 4.5H_2O_2$. When the concentration of H_2O_2 is $\geq 45.2\%$, decomposition occurs. At $-20°$, the system in the range of concentrations studied above, only $Na_3PO_4 \cdot 5H_2O_2$ is found in the solid phase. Decomposition occurs when the concentration of H_2O_2 is $\geq 56.9\%$[589].

The monoperoxyhydrate, $Na_3PO_4 \cdot H_2O_2$, has a decomposition temperature of $70°$, while $Na_3PO_4 \cdot 4.5H_2O_2$ has a m.p. of $65°$ and a decomposition temperature of about $120°$[589].

Mixed peroxyhydrate–hydrates of Na_3PO_4 are formed when solutions of the proper $H_2O_2 : H_2O$ ratio are allowed to react with anhydrous Na_3PO_4 suspended in an organic solvent such as $CHCl_3$ at 15–$20°$. Compounds such as $Na_3PO_4 \cdot 8H_2O \cdot 2H_2O_2$ and $Na_3PO_4 \cdot 4H_2O_2 \cdot 2H_2O$ are thus prepared[590]. The standard heat of formation of $Na_3PO_4 \cdot 4H_2O_2 \cdot 2H_2O(s)$ is -815.08 ± 0.52 kcal/mole[591].

For the system Na_2HPO_4–H_2O_2–H_2O at $0°$, solution concentrations of 27.0% H_2O_2 and 42.2% Na_2HPO_4 are in equilibrium with the two solid phases, $Na_2HPO_4 \cdot 12H_2O$ and $Na_2HPO_4 \cdot 1.5H_2O_2$. When the H_2O_2 concentration is $\geq 53.6\%$, the solid peroxyhydrate obtained is $Na_2HPO_4 \cdot 2.5H_2O_2$[589]. The decomposition temperature of $Na_2HPO_4 \cdot 1.5H_2O_2$ is $110°$.

Peroxyhydrate of Pyrophosphates

Pyrophosphates also form peroxyhydrates. Compounds such as $Na_4P_2O_7 \cdot 3H_2O_2$, $K_4P_2O_7 \cdot 3H_2O_2$, and $(NH_4)_2H_2P_2O_7 \cdot H_2O_2 \cdot 2H_2O$ are obtained as crystalline products. In the system $Na_4P_2O_7$–H_2O_2–H_2O at $0°$, the phase boundary $Na_4P_2O_7 \cdot 10H_2O$–$Na_4P_2O_7 \cdot 6H_2O_2$ occurs at about the liquid phase concentration region of 32.7–52.1% H_2O_2 and 37.0–33.3%

$Na_4P_2O_7$. The compound $Na_4P_2O_7.6H_2O_2$ obtained melts at 59° and decomposes at 75° [589].

The peroxyhydrates of $Na_4P_2O_7$, containing 1 to 3 H_2O_2, have been promoted as bleaching agents. They can be prepared by mixing the anhydrous powdered $Na_4P_2O_7$ with the proper amount of 45–75% H_2O_2 at below 60° and the paste obtained dried at 100° to a solid which is then crushed to a fine powder[592–94]. The standard heat of formation of $Na_4P_2O_7.3H_2O_2(s) = -913.93 \pm 0.08$ kcal/mole[591].

Peroxyhydrates of Tripolyphosphates and Trimetaphosphate

When sodium tripolyphosphate reacts with H_2O_2 and water in the mole ratio of 1 : 1 : 5 at < 40° in an inert organic suspending agent such as benzene, crystalline $Na_5P_3O_{10}.H_2O_2.5H_2O$ is formed. This compound has been suggested as an additive to bleaches to be used with detergents[595].

The peroxyhydrate of sodium trimetaphosphate is $Na_3P_3O_9.H_2O_2$. Magnesium silicate or the sodium salt of ethylenediamine tetraacetic acid have been recommended as stabilizers for peroxyhydrates[596].

General Properties of Peroxyhydrates. All peroxyhydrates liberate H_2O_2 when dissolved in water. The difference between the peroxyhydrate salt and the corresponding nonperoxy salts can be shown by EPR spectra. When these compounds are irradiated with UV light at −196°, the peroxyhydrate gives a signal of the radical HO_2. Owing to the stabilizing effect of the lattice, the HO_2 radicals are more stable in these compounds than in H_2O_2. They have a life of about 30 min at −80° but decompose quickly at 20°.

22. THIOPHOSPHATES (PHOSPHOROTHIOATES)

The oxygen atoms in oxyphosphorus compounds may be replaced from one to all by sulfur atoms. However, the methods of synthesis for the thiophosphorus compounds do not depend on this direct replacement reaction. An exception is that of the replacement of the oxygen in $P = O$ with sulfur from $P = S$ in the preparation of organophosphonothionic chlorides, as for example[597]:

$$
5ClCH_2 \overset{\overset{\displaystyle O}{\|}}{P}Cl_2 + P_2S_5 \longrightarrow 5ClCH_2 \overset{\overset{\displaystyle S}{\|}}{P}Cl_2 + P_2O_5
$$

$$
ClCH_2 \overset{\overset{\displaystyle O}{\|}}{P}Cl_2 + PSCl_2 \longrightarrow ClCH_2 \overset{\overset{\displaystyle S}{\|}}{P}Cl_2 + POCl_3
$$
Inorganic thiophosphates are in general prepared from sulfur-containing phosphorus compounds. They are relatively unstable in water, hydrolyzing to the corresponding oxy-compound with liberation of hydrogen sulfide. Hydrolysis is more rapid in an acid solution, especially with compounds having several sulfur atoms attached to the same phosphorus atom.

Tetrathiophosphates

Thio(ortho)phosphates, M_3PS_4, can be prepared by heating the metal, phosphorus and sulfur together in a sealed tube. Alternatively, they can be formed by the reaction of the metal phosphide with sulfur. Thus PBS_4 is obtained by heating a stoichiometric mixture of boron, phosphorus and sulfur or by heating a mixture of 1 mole of boron phosphide and 4 moles of sulfur in the absence of water vapor and oxygen.

An orthorhombic modification of BPS_4 is formed at 450–500°. It consists of one-dimensional infinite chain molecules with lattice dimensions $a = 5.60 \pm 0.06$, $b = 5.25 \pm 0.06$ and $c = 9.04 \pm 0.06$ Å and interatomic distances B–S 1.89 Å, P–S 2.16 Å and B–P 2.63 Å. It is a hygroscopic, colorless, crystalline substance which decomposes in air with evolution of H_2S. Another modification is the monoclinic form which is produced at 650–700°. It crystallizes in brownish plates which are fairly stable in air. It has unit cell dimensions of $a = 10.38$, $b = 6.05$, $c = 6.69$ Å, and $\beta = 75°$. The orthorhombic form can be converted to the monoclinic form by annealing at 650° [598].

Another example of MPS_4 is $AlPS_4$, prepared by heating AlP in a sulfur atmosphere at 650°. It is a hygroscopic solid, decomposing in air with evolution of H_2S. Its structure consists of Al and P atoms surrounded by sulfur atoms [599]:
Another example, the sodium salt of tetrathiophosphoric acid, $Na_3PS_4 \cdot 8H_2O$, is formed by the addition of P_4S_{10} to a saturated solution of Na_2S.

The free acid, tetrathiophosphoric acid, H_3PS_4, is unstable even at below room temperature. Schmidt and Wieber[600] claimed to have prepared it in an aqueous solution by the reaction of Na_3PS_4 with HCl and the compound stabilized by sudden chilling in acetone cooled to $-78°$. At 0°, H_3PS_4 decomposes with evolution of H_2S into H_3PO_3S[601].

Trithiophosphates

The action of P_2S_5 on a solution of NaOH saturated with H_2S at 20° produces a mixture of sodium thiophosphates. Sodium trithiophosphate, $Na_3PS_3O \cdot 11H_2O$, is obtained by dissolving the above reaction mixture in a 10% Na_2S solution and fractionally crystallized at 4° [601, 602]. The crystalline product obtained has an orthorhombic lattice with 4 mols per unit cell and lattice parameters of 12.40, 14.0 and 9.02 Å. Measurements by infrared indicate that the P → O fundamentals occur at ~ 1000 cm⁻¹ and the P → S probably at ~ 550 cm⁻¹ [603].

The barium salts of trithiophosphoric acid, $Ba(POS_3)_2 \cdot 6H_2O$, and other insoluble trithiophosphates such as the lead or silver salts are obtained by the reaction of the sodium salts with the corresponding metal cations[601].

Dithiophosphates

Trisodium dithiophosphate, $Na_3PS_2O_2.11H_2O$, is prepared by the partial hydrolysis of the mixed tri- and dithiophosphates obtained by the reaction of P_2S_5 in aqueous NaOH solution. This hydrolysis is carried out at $36°$ for 1 hr. The dodecahydrate salt melts at $48°$ in its water of crystallization. It is converted to the decahydrate $Na_3PS_2O_2.10H_2O$ at $58°$ and to the anhydrous form by drying *in vacuo* at $150°$ in a nitrogen atmosphere[602].

Disodium dithiophosphate, $Na_2HPS_2O_2.H_2O$, is obtained by the acidification of $Na_3PS_2O_2.11H_2O$ followed by drying *in vacuo* at $2-3°$. Tribodet claimed that when this compound is heated at $72-137°$, it converts to the tetrasodium trithiopyrophosphate, $Na_4P_2S_3O_4.2H_2O$, with evolution of H_2S. Further heating to $200-260°$ results in the formation of $Na_4P_2SO_6$ [602]

The two sulfur atoms in dithiophosphate are shown by iodine oxidation in an alkaline solution to be bonded differently to the phosphorus atom. One of the bonds is semi-polar. This suggests that the structure for $Na_2HPS_2O_2$ is $(NaO)_2(HS)P \rightarrow S$[603].

Monothiophosphates

The monothiophosphate is the most stable of the thiophosphates to hydrolysis. Trisodium monothiophosphate is obtained by the hydrolysis of $PSCl_3$, in a sodium hydroxide solution at $103-109°$:

$$PSCl_3 + 6NaOH \longrightarrow Na_3PO_3S + 3NaCl + 3H_2O$$
It is separated from by-product NaCl as $Na_3PO_3S.12H_2O$ by fractional precipitation from an aqueous solution with anhydrous methanol. The anhydrous salt obtained by stirring the hydrate in anhydrous methanol is a white crystalline solid[604].

An alternative procedure for the preparation of anhydrous sodium monothiophosphate is by the reaction of Na_2CS_3 with $(NaPO_3)_3$. The product forms rapidly in a yield of 84–90% when the reaction is carried out at $550°$ under nitrogen atmosphere or *in vacuo*. Thermo-gravimetric studies indicated that the actual reaction is between $(NaPO_3)_3$ and Na_2S resulting from the thermal decomposition of Na_2CS_3 [605].

Anhydrous Na_3PO_3S is very stable at room temperature and not affected by moisture up to a relative humidity of 31%. It is quite soluble in water, dissolving 79.2 g per liter of saturated solution at $18°$. The 12-hydrate liberates H_2S slowly at room temperature and decomposes rapidly at $60°$.

Aqueous solution of the sodium salt decomposes only very slowly when stabilized with added sodium carbonate. It has been reported, however, that the rate of hydrolysis in strongly alkaline solution is increased from 2.5×10^{-4} to 2.3×10^{-3} min^{-1} upon addition of 30 mg silicone grease per 100 ml of the solution [606]. In strongly acidic solution, titration with iodine leads to the formation of the disulfide $HO_3PSSPO_3H^=$[604]. Infrared studies of the $PO_3S^≡$ ion from several salts give a frequency of 438 cm^{-1} for γ_{P-S}. The force constant for the P–S bond is 2.68 millidynes/A. It is reported that the resonance effects in $PO_3S^≡$ involves largely the P–O bonds[607].

The disodium monothiophosphate, $Na_2HPO_3S·6.5H_2O$, is prepared by acidifying

[604] S. K. Yasuda and J. Lambert, *Inorganic Synthesis*, Vol. V, pp. 102–4, Ed. T. Moeller, McGraw-Hill Book Co., New York (1957).
[605] A. Lamotte, M. Porthault and J. C. Merlin, *Bull. Soc. Chim. France* (1965) (4) 915–19.
[606] S. Akerfeldt, *Nature*, **200**(4909) (1963) 881–2.
[607] E. Steger and K. Martin, *Z. anorg. u. allgem. Chem.* **308** (1961) 330–6.

an aqueous solution of $Na_3PO_3S.12H_2O$ with one mole of conc. HCl at $< 10°$. The product is precipitated in the cold by the addition of ethanol. It decomposes with evolution of H_2S upon standing in air or when heated to $40°$ [608].

Potassium monothiophosphate is prepared by passing a solution of $Na_3PO_3S.12H_2O$ through the H^+ form of an ion exchange resin and the eluate adjusted immediately to pH 4.5 with 2N KOH. All of the operations are carried out under ice cooling. After dilution with CH_3OH and H_2O and allowing to stand at $-10°$, KH_2PO_3S precipitates [609]. Other salts, M_2HPO_3S, are similarly prepared.

Monothiophosphoric acid (phosphorothioic acid), H_3PO_3S, is the sole product left when $Ba_3(PS_4)_2$ is acidified with H_2SO_4, the $BaSO_4$ precipitate formed removed by filtration and the filtrate allowed to stand at $0°$. Under these conditions, all higher thio acids which formed also in the original reaction decomposed with the evolution of H_2S. Monothiophosphoric acid decomposes only to an extent of 10% to H_3PO_4 and H_2S when it is allowed to stand at $-2°$ for a period of 18 weeks [601]. In a more precise study, Dittmer and Ramsay [610] showed that the hydrolysis of H_3PO_3S in an aqueous solution at constant ionic strength has a maximum rate at pH ~ 3.0 and pH ~ 8.0. The minimum rate is at pH ~ 7.0 and pH ~ 0.30.

As indicated earlier, titration of strongly acidified Na_3PO_3S with iodine resulted in the formation of $HO_3PSSPO_3H^=$. Similarly H_3PO_3S is oxidized to $HO_3PSSPO_3H^=$ by ferricyanide in a mole to mole ratio. The kinetics of the reduction of ferricyanide ion by phosphorothioate are found to be 2nd order with respect to the reactants in the pH range of 5.8 to 7.8 at the temperature range of $15°$ to $40°$ and the ionic strength $\mu = 0.035$ to 0.06. The 2nd order rate constant for the reduction of ferricyanide ion by P-S- shows a maximum at pH 6.2 at $26°$ and ionic strength $\mu = 0.06$. [611]

The industrial application of phosphorothioates are limited. A solution of a mixture of sodium thiophosphates along with sodium sulfide is used as a depressant in mining operations for the separation of molybdenite from copper sulfide ores by flotation. Such a product is prepared by the reaction of P_2S_5 with an aqueous solution of sodium hydroxide. It is known as Nokes reagent, after one of the inventors [612].

21. ARSENIC, ANTIMONY AND BISMUTH

J. D. SMITH

University of Sussex

The elements of Group V are sometimes known as pnictides. The chemistry of nitrogen and phosphorus has been worked out in great detail: the remaining elements—arsenic, antimony and bismuth—have been less thoroughly studied. As they form a closely related group, they are considered together. Interest centres on the trend from non-metallic to metallic properties with increasing atomic weight. Thus there are many parallels between phosphorus and arsenic, but considerably fewer between phosphorus and bismuth, which is a typical B metal like tin or lead. Arsenic and antimony are important largely because of their intermediate or metalloid character.

In the following sections the Group V element is given the symbol E. Halogen atoms are denoted by X and other electro-negative atoms or groups by Y or Z. Electro-positive (metallic) atoms are denoted by the symbol M.

1. THE ELEMENTS

1.1. ARSENIC

The yellow pigment orpiment (As_2S_3) and red realgar (As_4S_4) were known to Greek alchemists, who probably also succeeded in isolating the metal. The German Dominican scholar Albertus Magnus (1193–1280) described the preparation of arsenic by heating orpiment with soap, but the alchemists probably thought of the metal as a kind of mercury. The relation between As^{III} oxide and metallic arsenic, and the similarity between arsenic and tin, were established in the early eighteenth century. Arsenic compounds were also known in early Chinese civilizations both as pigments and poisons, and were used to kill mice and insects. The chief uses have remained as insecticides and weed-killers and in alloys with lead and copper. More recently, arsenic compounds have found important applications in semiconductor devices.

Arsenic minerals are widely distributed in many countries of the world: a few examples follow. The commonest minerals are those, e.g. mispickel, in which arsenic is combined both with iron or nickel and with sulphur.

Sulphides: realgar (As_4S_4); orpiment (As_2S_3)
Oxides: claudetite or arsenolite (As_2O_3)
Arsenides: mispickel (FeAsS); nickel glance (NiAsS); chloanthite ($NiAs_2$); löllingite ($FeAs_2$); niccolite (NiAs)
Arsenates: pharmacolite ($CaHAsO_4,2H_2O$); erythrite ($Co_3(AsO_4)_2,8H_2O$)

Small amounts of native arsenic are found. Traces occur widely in soil, mineral water and in the human body.

Extraction

Ores such as mispickel may be heated in the absence of air, when arsenic sublimes:

$$FeAsS \rightarrow FeS + As$$
Arsenic trapped in the residue may be released by roasting in air, when arsenic trioxide (As_2O_3) volatilizes and condenses in the flue system. It may be purified by further sublimation. The oxide may be obtained directly from arsenic-containing ores by roasting them in air, and also as a by-product in the smelting of copper or lead. It may be converted to a wide range of arsenic compounds (section 6.2), or heated with coke, when it is reduced to the metal.

Arsenic, obtained by one of the processes described above, is contaminated by oxide and, perhaps, by sulphide. Further purification can be effected by resubliming from more charcoal, and, finally, by subliming in hydrogen. The most difficult impurities to remove are antimony and Group VI elements such as sulphur. Since ultra-pure arsenic (impurities less than 1 in 10^6) is an important commercial material in the semiconductor industry, considerable effort has been put into its purification[1]. Some of the more successful methods appear to be (a) by sublimation from solutions in lead (much of the sulphur remains as lead sulphide), (b) by crystallization from molten arsenic at high pressures, and (c) by conversion to arsine, which can be scrubbed by alkali and dried and then pyrolysed at about 600°C to the elements.

Allotropes and Structures

Relationships between the various modifications of arsenic are shown in Scheme 1. The stable form at 25°C is grey or metallic arsenic, which has a rhombohedral structure (*Strukturbericht* symbol A7)[3]. Atoms are linked into sheets which are fitted together so

that each atom has six neighbours (Fig. 1). Three on one side are at a distance r_1, and three on the other side are slightly further away at a distance r_2. Similar structures are adopted by antimony and bismuth: as the atomic weight increases, the ratio r_2/r_1 becomes more

nearly unity (Table 1), showing the tendency towards higher co-ordination numbers in the more metallic elements. Arsenic vapour at 1 atm consists mainly of tetramers As_4 at 800°C, and dimers As_2 at 1750°C. The As_4 molecules comprise tetrahedra of atoms (cf. P_4) and the As–As distance is 243.5±0.4 pm [4].
FIG. 1. Plan of a sheet of atoms in rhombohedral arsenic. Atoms in the adjacent sheet (dotted) are placed over holes in the sheet beneath. Each atom has six neighbours, three at a distance r_1 and three at r_2.

Yellow arsenic, obtained by sudden cooling of arsenic vapour, is assumed to consist of As_4 molecules. It can be recrystallized from carbon disulphide (solubility: 11 g in 100 ml at 46°C; 4 g at 0°C; 0.8 g at −80°C) but is rapidly converted to grey arsenic in light, and very easily oxidized[5]. Above 300°C, arsenic vapour condenses as grey arsenic, but, at 100–200°C, glassy modifications result. These presumably consist of disordered cross-linked chains formed at temperatures low enough to prevent ready reorganization to the sheets of the crystalline grey form. The amorphous arsenic has a lower density (4730–5180 kg m^{-3}) and higher diamagnetic magnetic susceptibility (-2.89×10^{-10} m^3 mol^{-1}) than the rhombohedral form (see Table 5). The shortest As–As distance is 249 pm.

[5] G. Brauer, *Handbook of Preparative Inorganic Chemistry*, Academic Press (1963).

A third crystalline modification, made from the vapour in the presence of mercury, is orthorhombic and analogous to black phosphorus, with which it forms mixed crystals. Orthorhombic arsenic consists of chains of atoms linked into double layers: each atom has two nearest neighbours and one slightly further away. The bonds between layers are weaker than in grey arsenic.

TABLE 2. ISOTOPES OF ARSENIC $(Z = 33)$

^{81}As	33 s	β^-		^{82}Se(n, pn); ^{82}Se(γ, p)

[a] β^+, positron emission; β^- electron emission; EC, electron capture.

[b] Only those with intensities greater than 20% of initial disintegrations are given. All β^+ emitters give 0.511 MeV γ-radiation. For complete list, including radiations from shorter lived isotopes, see ref. 6.

[c] Other nuclear properties are as follows:

	^{75}As	^{76}As
Spin	3/2	2
Magnetic dipole moment (nuclear magnetons)	1.435	−0.903
Electric quadrupole moment × 10^{28} (m^2)	0.27	
N.m.r. frequency for 1 T field (MHz)	7.292	

Isotopes

Isotopes of arsenic[6] are described in Table 2. Only one isotope, ^{75}As, is stable. This has a spin of 3/2, which means that useful information can be obtained from n.m.r. The sensitivity, compared with the proton at the same field, is 0.025,[7] so successful ^{75}As spectra can be

[6] C. M. Lederer, J. M. Hollander and I. Perlman, *Table of Isotopes*, 6th edn., Wiley (1957); B. J. Wilson (ed.), *Radiochemical Manual*, Radiochemical Centre, Amersham (1966).

[7] Data of Varian Associates given by J. W. Emsley, J. Feeney and L. H. Sutcliffe, *High Resolution NMR Spectroscopy*, Pergamon (1966).

obtained only from concentrated solutions. Coupling constants involving [75]As can sometimes be derived from measurements on resonances of other magnetic nuclei. Best spectra are given by symmetrical species, e.g. AsF_6^-, since in these quadrupole relaxation effects are minimal. The quadrupole moment of [75]As is utilized in nuclear quadrupole spectroscopy. (Resonances are in the range 60–120 MHz.) [72]As and [74]As are useful positron sources, and [76]As and [77]As are β-emitters suitable for tracer experiments and activation analysis (as little as 10^{-10} g can be detected). The high energy β-particles from [76]As can readily be distinguished from other radiations.

1.2. ANTIMONY

The sulphide stibnite, Sb_2S_3, was mentioned in a papyrus from the sixteenth century BC; it was a constituent of the eye-paint used by oriental women. The Greeks and Chaldeans knew that "lead"—presumably antimony—could be obtained from stibnite, and in a vase dated 3000 BC and now in the Louvre there is antimony which is almost pure. The alchemists made extensive studies of antimony compounds, but they, too, did not distinguish between antimony and lead. Antimony was later used in gold refining, as it combines with base metals to form dross, and alloys with tin were used for type-metal. This use continues today. Antimony compounds as medicants were described in a *Treatise on Antimony* published by Nicholas Lémery in 1707.

Occurrence and Extraction

Stibnite is the most important ore. It occurs in large quantities in China and in parts of South America and Europe. It appears to be a hydrothermal deposit and often is found in veins of granite. Other sulphide ores are ullmannite $NiSbS$, livingstonite ($HgSb_4S_8$), tetrahedrite (Cu_3SbS_3), wolfsbergite ($CuSbS_2$) and jamesonite ($FePb_4Sb_6S_{14}$). Very small amounts of antimony are found native and small amounts occur as the oxides valentinite and senarmontite (Sb_4O_6), cervantite (Sb_2O_4) and stibiconite (Sb_2O_4,H_2O).

Rich stibnite ores are heated, when the sulphide melts and separates from other rock. The metal is obtained by heating the sulphide with iron:

$$Sb_2S_3 + 3Fe \rightarrow 2Sb + 3FeS$$
Poorer ores are roasted in air, when the oxide Sb_4O_6 sublimes. It may be collected and reduced to the metal by heating with charcoal or anthracite, using an alkali metal salt, e.g. carbonate or sulphate, as a flux. Antimony obtained by these methods is up to 99% pure.

Metal of 99.999% purity is available commercially[1]. Antimony from a smelting process is converted to a crystallizable derivative, e.g. $2HSbCl_6,9H_2O$. After purification, this may be hydrolysed to the oxide, and the metal made by reduction in a stream of pure hydrogen. Further purification is achieved by zone melting, which removes nickel, lead, silver and copper, or by vacuum distillation. The most difficult impurities to remove are those which form azeotropes or solid solutions with antimony, e.g. arsenic, tin and bismuth. Arsenic may be removed by zone refining in the presence of small quantities (*ca.* 0.1%) of aluminium. The ternary Al–As–Sb eutectic is lower melting than antimony, and so arsenic may be moved in the liquid zone to one end of an ingot.

Allotropy[8]

The stable form of antimony at 25°C has the same rhombohedral structure as arsenic and bismuth (see Fig. 1, p. 549). The lattice parameters and interatomic distances have been determined with great accuracy (see Table 1). At high pressure (5×10^9 N m^{-2}), rhombohedral antimony transforms to a primitive cubic lattice in which each atom is surrounded by six others at a distance of 296 pm. At still higher pressures, the metal becomes hexagonal-close-packed with an interatomic distance of 328 pm. These changes represent the transition from a metalloid structure, with co-ordination number of 3 ($+3$), to a fully metallic structure with a co-ordination number of 12. Attempts to prepare modifications corresponding to yellow or orthorhombic arsenic do not seem to have been successful, but several amorphous forms of antimony have been made. "Yellow" and "black" antimony, from liquid stibine and oxygen at low temperatures, appear to contain some hydrogen, and "explosive antimony", made by the electrolysis of antimony trichloride in hydrochloric acid, always contains residual chlorine. Both these forms are more reactive chemically than rhombohedral antimony and are rapidly and exothermically transformed into the stable form, often as a result of slight heating or mechanical stress.

Isotopes

About thirty isotopes are known[6], and the most important are described in Table 3. Two, ^{121}Sb and ^{123}Sb, occur naturally, and both n.m.r. and n.q.r. measurements are

TABLE 3. ISOTOPES OF ANTIMONY ($Z = 51$)

possible. These nuclei provide probes for the obtaining of structural information in favourable circumstances, but spectra are often complicated and difficult to interpret. Nuclear quadrupole resonances are in the range 30–120 MHz. ^{121}Sb has an excited state at 37.2 keV which can be used in Mössbauer spectroscopy. Isomer shifts for ^{121}Sb in antimony compounds parallel those for ^{119}Sn in tin compounds, ranging from about -6 mm s^{-1} in SbF_3 in which the Sb^{III} has a lone pair, to $+12$ mm s^{-1} in KSb^VF_6 in which the lone-pair electron density has been largely removed. (The isomer shift in InSb is taken as zero[9].) ^{124}Sb and ^{122}Sb are useful tracers. Both are obtained by n, γ reactions on the naturally occurring isotopes, and quantities as small as 10^{-9} g of ^{122}Sb may be detected in neutron activation analysis. A mixture containing radioactive ^{124}Sb and beryllium is a neutron source giving 1.6×10^6 neutrons per second per curie with energy 24.8 keV.

1.3. BISMUTH

The earliest references to bismuth suggest that, by the end of the fifteenth century in Germany, it was extracted from its ores by heating them with charcoal, and was used as a base for lacquer or gold on decorative articles such as caskets or chests. Demand for bismuth increased with the development of printing, and it became a usual constituent of alloys for type-metal. Some writers as early as the sixteenth century distinguished bismuth from lead, antimony and tin, but others confused these elements for a further 200 years.

Small amounts of the metal occur native with lead, silver or cobalt ores. Other minerals are the oxide Bi_2O_3, the sulphide Bi_2S_3 and the basic carbonate $(BiO)_2CO_3$. Extraction of the metal is based on standard reactions. Thus sulphide ores are roasted to oxides, which are reduced by iron or carbon.

Bismuth can also be obtained as a byproduct in the extraction of other metals. It collects either in flue dust from smelting processes (since the oxide Bi_2O_3 is slightly volatile) or, with lead, in anode slimes from copper refining. In the extraction of lead[10], bismuth appears in the smelted metal. It must be removed, as it weakens the resistance of the lead to corrosion. It also makes the lead difficult to roll and unsuitable for the manufacture of tetraethyl-lead. Bismuth may be separated from large amounts of lead either electrolytically or by the addition of calcium– or magnesium–lead alloys. The base metals, the bismuth,

Major radiations (MeV) from bismuth isotopes as follows. 210Bi: α, 5.06 (10⁻⁴%); β, 1.17. 211Bi: α, 6.273(17%), 6.617 (83%), γ, 0.35 (13%). 212Bi: α, 6.04 (25%), 6.08 (10%); β⁻, 1.52 (5%), 2.25 (54%), and several γ. 213Bi: α, 5.87; β⁻, several to 1.39. 214Bi: α, 5.51; β⁻, 1.0 (23%), 1.51 (40%) and several others to 3.26 (19%); several γ to 2.43.

and some lead give a high melting alloy, which can be separated from the molten lead. Subsequently, the bismuth can be recovered by chlorination, when volatile bismuth trichloride sublimes. The metal can then be obtained electrolytically.

Commercial bismuth has a purity of about 99%. It is used as a constituent of a wide range of alloys (see Table 15A). Much purer bismuth, up to 99.9999%, is also available and is used mainly in the semiconductor industry. This very pure bismuth may be obtained by reduction of the oxide made by heating recrystallized bismuth nitrate. The metal is distilled in high vacuum and zone refined.

Isotopes

Some of the more important isotopes are shown in Table 4. The longest lived isotope, ^{209}Bi, is, for all practical purposes, the final product of the $4n+1$ radioactive decay series, and bismuth isotopes occur in the three other decay series. A number of ^{209}Bi nuclear

quadrupole resonances in various compounds have been reported in the range 20–55 MHz. Bismuth has found applications in the atomic energy industry since the metal is low melting and [209]Bi is a strong neutron absorber.

1.4. PHYSICAL PROPERTIES

Some properties of the rhombohedral forms of arsenic, antimony and bismuth are shown in Table 5 and thermodynamic data are given in Table 6.

By comparison with the transition metals, arsenic, antimony and bismuth are volatile and low melting; antimony and bismuth have high entropies of fusion. The melting points decrease with increasing atomic weight, but antimony and bismuth have much higher

boiling points than arsenic. Hence arsenic has no liquid range at normal pressure but antimony and bismuth have long liquid ranges. This may be related to the generalization already noted that, whereas in the various forms of arsenic each atom interacts strongly with three neighbours, in antimony and bismuth interactions are spread more evenly over a larger number of neighbours. (Compare the interatomic distances in the rhombohedral forms given in Table 1 and the greater diversity of structures shown by arsenic in comparison with antimony and bismuth.) Thus, although more energy is needed to atomize arsenic than bismuth, less is needed to form As$_4$ molecules (in which each arsenic atom keeps three neighbours) than to form Bi$_4$ molecules. At the normal boiling point, E$_4$

molecules dominate in arsenic vapour, whereas they are largely dissociated in the vapours of antimony and bismuth. The formation of E_4 molecules by phosphorus, arsenic, antimony, and bismuth is not easy to explain in terms of valence theory. Delocalized bonds within the tetrahedra must be considered; a system of six localized two-centre bonds is not adequate. Many of the possible mixed molecules, e.g. $E_n^1 E_{4-n}^1$ or $E^1 E^2$, have been characterized by spectroscopic or molecular beam techniques. It is possible that all possible combinations are stable species in the gas phase. Those that have been identified show systematic trends in atomization energies, as the following data[13] indicate.

Sb$_2$, 289; BiSb, 249; Bi$_2$, 195.
Sb$_4$, 844; BiSb$_3$, 797; Bi$_2$Sb$_2$, 726; Bi$_3$Sb, 657; Bi$_4$, 587 (kJ mol^{-1}).

The Raman spectrum of arsenic at 900°C is very similar to that of phosphorus at 500°C and assignments have been made as follows[14]:

421 vw (cm^{-1})	As$_2$	250 m	As$_4$ (v_2)
400 vvw	As$_4$ ($2v_3$)	200 w	As$_4$ (v_3)
340 s	As$_4$ (v_1)	~40 vvw	As$_4$ ($v_2 - v_3$)

The values of thermal and electrical properties in Table 6 are for polycrystalline materials. They vary slightly according to the method of sample preparation. Properties of single crystals of the rhombohedral forms are, of course, strongly anisotropic, since atomic interactions are much weaker perpendicular to the sheets of atoms (along the c-axis) than parallel to them. The anisotropy is greatest for arsenic (Table 7) where interactions between sheets are weakest, but is still important for antimony and bismuth. Thus the coefficient of expansion of arsenic is much greater along c than along a; though c expands rapidly on heating, a is unchanged between 20° and 400°C. The explanation seems to be that, at room temperature, the valence angles are forced out by the packing of the sheets, beyond the angles in many molecules. As the temperature is raised and the distance between the layers increases, the valence angles contract. The effect is to compensate for the increased As–As distance so that the cell parameter a, parallel to the sheets, is almost unchanged. Similar features are revealed by measurements of the thermal expansion parallel to, and perpendicular to, the zigzag chains in selenium and tellurium[15].

As is also shown in Table 6, bismuth contracts on melting, a fact which leads to important uses in alloys. At the same time, the electrical conductivity increases (in contrast, the conductivity of metals usually decreases on melting). These changes are associated with

TABLE 7. ANISOTROPY OF ARSENIC

	Along c	Along a
Coefficient of expansion (20–400°C) (K^{-1})	47.2×10^{-6}	0
Resistivity at 295 K ($\mu\Omega$ m) $\times 10^6$	0.356	0.255
Temperature coefficient resistivity (K^{-1}) $\times 10^3$	4.5	4
Magnetic susceptibility (m^3 mol^{-1}) $\times 10^{10}$	5.58	−2.69

an increased co-ordination number in molten, compared with solid, bismuth. In other words, molten bismuth is more metallic than the solid. Arsenic expands on melting and its conductivity falls. Antimony is intermediate between arsenic and bismuth: its conductivity rises, showing that the melt is more metallic than the solid, but the effect on the interatomic distance is sufficient only partly to cancel the normal expansion on melting. Further non-metallic features of solid bismuth and antimony are their low thermal and electrical conductivities compared with other metals, and their high diamagnetism. This falls rapidly near the melting point. The high negative thermoelectric e.m.f. of bismuth relative to platinum is also unusual. The magnetic properties of single crystals of arsenic (Table 7) are strikingly anisotropic; paramagnetism along c practically cancels diamagnetism along a in polycrystalline samples.

1.5. CHEMICAL PROPERTIES

The elements do not react with water or oxygen at 20°C and so are stable in air. At higher temperatures, however, they react with most metals (see section 2), and many non-metals (not, however, with hydrogen since the hydrides are endothermic). Tervalent derivatives (Scheme 2) are usually produced, except for antimony, when some oxidation to Sb^V is common. Since elements are, in general, easier to purify than compounds, many

SCHEME 2. Reactions of the elements.
compounds of arsenic, antimony and bismuth required in high purity are made from stoichiometric quantities of ultra-pure elements, usually by reactions at elevated temperatures in quartz apparatus. The elements are not affected by dilute acids, but they all dissolve in concentrated sulphuric acid to form complex sulphates. Aqua regia oxidizes antimony to hexachloroantimonate(V) ($SbCl_6^-$). Arsenic dissolves in fused alkali, but antimony and bismuth are not much affected.

2. ALLOYS AND INTERMETALLIC COMPOUNDS

Pure arsenic, antimony and bismuth have few uses, but alloys with other metals have been made and exploited since the earliest times. The use of the Group V elements, e.g. in hardening lead to make it suitable for shot, or in increasing the resistance of copper to corrosion, has been largely empirical, but more recent research on intermetallic systems, stimulated by applications in the electronics industry, has revealed much of interest concerning chemical bonding. Structural data on intermetallic compounds is given in Table 8. A number of more comprehensive critical compilations, including detailed phase diagrams

and crystallographic data, are available[3, 16]. Thermodynamic data on intermetallic compounds is not very plentiful. For example, heats of formation have been measured by various techniques, but it has not always been possible to be sure that equilibrium has been reached. Values of -150 to -300 kJ per g atom of element E have been obtained for alkali metal compounds and rather more negative values for compounds with the alkaline earth metals. Compounds between Group V elements and transition metals have less negative heats of formation (0 to -60 kJ per g atom of E)[12].

2.1. INTERMETALLIC COMPOUNDS WITH PRE-TRANSITION ELEMENTS

The electro-negativity differences between the alkali or alkaline earth metals and the Group V elements are such that intermetallic compounds may be expected to show "salt-like" characteristics described by structures such as $Na_3^+Sb^-$. Though ionic formulations are useful in the interpretation of the chemical reactions of the intermetallic compounds, they are not entirely adequate for the solid phases themselves. These are characterized by high co-ordination numbers and interatomic distances between like atoms comparable with those in metals. However, strong interactions between unlike atoms are indicated by the high melting points of some intermetallic compounds. For example, Na_3Bi melts at 840°, sodium at 98° and bismuth at 271°C.

Intermetallic compounds with formulae M_3E (where $M = Li$, Na, K, Rb, Cs and $E = As$, Sb, Bi) are formed for all combinations of alkali and heavier Group V elements (Table 8). Sodium arsenide has the anti-tysonite (LaF_3) structure. Equal numbers of arsenic and sodium atoms (Fig. 2) make hexagonal nets as in boron nitride. The remaining sodium atoms are arranged in layers on either side of these nets. Each arsenic has five neighbours at the corners of a trigonal bipyramid (three at 294 and two at 299 pm) and six

[a] Structures are denoted by a common representative. The nomenclature of the Strukturbericht, widely used in this field, is also given.

[b] Several modifications are known. See refs. 3 and 16.

[c] These compounds are deduced from phase diagrams.

[d] M = Sc, Y, lanthanide or actinide element. Rare earth diantimonides are synthesized at 7×10^9 N m^{-2} (N. L. Eatough and H. T. Hall, Inorg. Chem. 8 (1969) 1439.

[e] There appear to be two closely related forms of Ti$_3$Sb: one cubic and one tetragonal. The tetragonal form may be stabilized by impurities; the cubic form is superconducting below 5.8 K. Several less well-characterized titanium compounds have been reported.

[f] Relations between TiP, NbAs, MnP and NiAs structures are discussed by H. Boller and E. Parthé, Acta Cryst. 16 (1963) 1095.

[g] Several other compounds of V, Cr, Mo, Co, Pd and several mixed Fe–Co–Ni compounds have been described.

[h] The marcasite structure of FeS$_2$ is denoted by C18 and the pyrites structure by C2.

[i] Many of these compounds are polymorphic and show both NiAs and MnP structures. Considerable deviations from stoichiometry are common. See text.

[j] Several other Cu–As and Cu–Sb compounds are described. Some of these are superstructures related to hexagonal close packing. The Ag–Sb system is similar. Bismuth and copper form a system with a simple eutectic and no intermediate phases.

[k] AgAs is stable only at high temperatures.

[l] These compounds are polymorphic; a second form is described as the Zn$_3$As$_2$ structure.

[m] The zincblende structure is denoted by B3. These compounds change to metallic (white tin or NaCl) structures at high pressures. The high pressure form of InSb is a superconductor; T_c, 1.6 . . . 2.1 K. S. Minomura and H. G. Drickamer, J. Phys. Chem. Solids 23 (1962) 451.

other sodium atoms (at 330 pm) form a trigonal prism. There are two sorts of sodium. One sort, a, in the AsNa net, has three arsenic neighbours at 294 pm and six sodium neighbours at 330 pm. The other sort of sodium, b, has four arsenic neighbours at the
FIG. 2. The hexagonal structure of Na_3As. (Distances in pm.)

corners of a distorted tetrahedron (one at 299 and three at 330 pm) and six sodium neighbours, three at 328 and three at 330 pm. All these Na–Na distances are less than that in sodium metal (371.6 pm). Thus the structure shows high co-ordination numbers characteristic of metals. Similar conclusions can be drawn from the cubic structure of lithium bismuthide (Li_3Bi) (Fig. 3), which is more compact than sodium arsenide. Each bismuth atom has eight lithium neighbours, a or b, at the corners of a cube and six, c, at the corners of an octahedron. There are two sorts of lithium. One sort, a or b, has six lithium neighbours at 335, four lithium neighbours at 291 and four bismuth neighbours at 291 pm. The other sort, c, has eight lithium neighbours at 291 and six bismuth neighbours at 335 pm. Again, the co-ordination numbers are high and the interatomic distances are comparable with those in the metals (e.g. Li–Li 304 pm in metallic lithium). In the compounds of the heavier alkali metals, e.g. Cs_3Bi, there is some interchange of alkali and Group V metal
FIG. 3. The structure of Li_3Bi. (Distances in pm.)

atoms. Thus in Fig. 3 the positions b and c are occupied by caesium atoms and the positions a and d by randomly distributed caesium and bismuth atoms[17]. Several ternary antimonides, e.g. K_2CsSb (see Table 12), have related structures.

Some of the alkali and Group V metal systems give compounds ME (Table 9). The arsenic and antimony compounds have parallel infinite spirals of arsenic or antimony atoms linked by bonds to the alkali metals. If the structures are represented by the formula $M_n^+(E_n)^{n-}$, the spirals $(E_n)^{n-}$ are isoelectronic with those of elemental selenium or tellurium. The bismuth compounds LiBi and NaBi have typical alloy structures, and are superconductors at low temperatures (LiBi below 2.47, NaBi below 2.22 K)[18].

TABLE 9. INTERATOMIC DISTANCES IN COMPOUNDS ME AND ME_2
(Shortest distances in metals in parentheses)

Compound	E–E (pm)	M–E (pm)	M–M(pm)	Ref.
LiAs	245, 247 (250)	278	300–378 (304)	a
NaSb	286, 284.5 (291)	331	344–445 (372)	a

[c] Ref. 3.

Potassium, rubidium and caesium also form well-defined compounds ME_2, which have the $MgCu_2$ structure. These also show high co-ordination numbers (16 for M and 12 for E). The E–E bond lengths are greater than those in the metals (a reflection of the higher co-ordination number in the alloy), but the M–M bond lengths are strikingly shorter than those in the alkali metals.

The compound Na_3Bi shows metallic conduction, but the antimony compounds are semiconductors with energy gaps as follows[19]:

n-type: Na_3Sb, 1.1; K_3Sb, 1.1; $(Na,K)_3Sb$, 1.0 eV

p-type: Rb_3Sb, 1.0; Cs_3Sb, 1.6 eV

Caesium antimonide is one of the most efficient photoemitters known. At 450 nm, the quantum efficiency is 20–30%, i.e., one electron is emitted for every 3–5 photons. The compounds MBi_2 become superconducting below the temperatures T_c: KBi_2, 3.58; $RbBi_2$, 4.25; $CsBi_2$, 4.75 K. These compounds are unusual in having much higher atomic volumes than most other superconductors with the $MgCu_2$ structure.

The intermetallic compounds M_3E are partly soluble in molten salts, e.g. LiCl–LiF or NaCl–NaI, and cryoscopic measurements suggest that there is some ionization, e.g. to Na^+, Bi^{3-} in dilute solution. The compounds ME are less soluble. Sodium antimonide

[17] J. P. Suchet, *Acta Cryst.* **14** (1961) 651.
[18] B. T. Matthias and J. K. Hulm, *Phys. Rev.* **87** (1952) 799.
[19] W. E. Spicer, *Phys. Rev.* **112** (1958) 114; K. H. Jack and M. M. Wachtel, *Proc. Roy. Soc. (London)* A, **239** (1957) 46.

(NaSb) appears to give the species Sb_2^{3-} besides Sb^{3-}; the Sb–Sb chains are thus partly preserved in solution[20]. The alkali metal compounds are readily oxidized and are hydrolysed by water or acid. The arsenic and antimony compounds yield hydrides (section 4); in this they are "salt-like", with the Group V element formally in oxidation state -3.

The best characterized compounds with the alkaline earth elements have the formula M_3E_2. Those for which the structures have been found have either the $Mn_2O_3(C\text{-}M_2O_3)$ or $La_2O_3(A\text{-}M_2O_3)$ structures. Several are dimorphic, and each of these structures is stable over a particular temperature range. The heats of formation[12] and melting points are high. Chemically, these compounds behave like the alkali metal compounds and give good yields of hydrides on hydrolysis. Some cubic phases ME_3 have also been characterized, though the complete phase diagrams of a number of systems with alkaline earth metals do not appear to be well established. The compounds $BaBi_3$ (T_c, 5.69 K), $SrBi_3$ (T_c, 5.62 K) and $CaBi_3$ (T_c, 1.7 K) are superconductors.

The compounds of scandium, lanthanides and actinides are of three main types. Those with composition ME have the sodium chloride structure, and those with composition M_4E_3 the body-centred thorium phosphide ($D7_3$) structure, in which each M atom is surrounded by eight E atoms. In thorium arsenide ($ThAs_2$), each thorium atom has nine arsenic neighbours.

Thorium arsenides or antimonides have low thermal conductivities and high electrical conductivities and may have possibilities as thermoelectric materials for use at high temperatures, provided that sufficient control over impurities can be exercised (Table 10). Material with composition $Th_3(As_{0.9}Sb_{0.1})_4$ has a figure of merit Z of about 0.5×10^{-3} K^{-1} at 800°C. See section 7.3 for definition of Z and a fuller discussion of thermoelectric properties.

TABLE 10. PROPERTIES OF THORIUM ARSENIDES AND ANTIMONIDES

2.2. COMPOUNDS WITH TRANSITION METALS

Arsenic, antimony and bismuth often give complex phase diagrams with transition elements, and many intermediate phases have been characterized. Table 8 shows that transition metals with similar electronic structures usually give intermetallic compounds of similar stoichiometries. Large groups of compounds have similar structures, and some of these are described below.

Most compounds ME have either the hexagonal nickel arsenide structure (Fig. 4) or the closely related orthorhombic manganese phosphide structure. Transitions between

[20] M. S. Foster, C. E. Crouthamel, D. M. Gruen and R. L. McBeth, *J. Phys. Chem.* **68** (1964) 980; M. Okada, R. A. Guidotte and J. D. Corbett, *Inorg. Chem.* **7** (1968) 2118.

these structures are common. In nickel arsenide, each nickel atom has six arsenic neighbours at the corners of an octahedron, and each arsenic atom has six nickel neighbours at the corners of a trigonal prism. The Ni–As distance is 243 pm. There are
FIG. 4. The hexagonal nickel arsenide structure. The arsenic atoms shown by broken lines are in adjacent unit cells.

two further important features. First, the structure may be described as a hexagonal-close-packed array of arsenic atoms with nickel atoms in octahedral holes. If some of these holes are unfilled, or if other than octahedral holes are occupied, the stoichiometry can deviate widely from ME. For example, vacancies in layers marked q in Fig. 4 are evident in $Ni_{0.95}As$; in the extreme, if all atoms in layer q are absent, the structure becomes that of cadmium iodide. Extra M atoms at points s in Fig. 4, each surrounded by five E atoms at the corners of a trigonal bipyramid, give stoichiometries such as $Co_{1.3}Sb$ to $Co_{1.03}Sb$ or Pd_5Sb_3. In the extreme, if all the sites s are occupied, as in In_2Bi, the structure becomes that of Ni_2In. The nickel arsenide structure is thus a very flexible one, accommodating considerable deviations from the ME stoichiometry. Secondly, the distance between nickel atoms in adjacent layers in nickel arsenide is 252 pm, comparable with that in nickel metal (249 pm). There is thus some indication of Ni–Ni bonding, confirmed by the observation that the coefficient of expansion perpendicular to the principal axis is eight times that along it. Metal–metal bonding is also shown by the axial ratios ($c:a$) found for compounds ME with the nickel arsenide structure. Low axial ratios indicate M–M bonding. In general, axial ratios of arsenides are greater than those of antimonides and bismuthides.

Many transition metal atoms have unpaired electrons and are therefore magnetic centres. The short M–M distances in nickel arsenide structures facilitate interactions between metal atoms, and so magnetic behaviour may be complicated. Some compounds are antiferromagnetic (Table 11). For example, neutron diffraction studies show that in CrAs or CrSb the magnetic moments are aligned, as shown on the right of Fig. 4, with those in layers p and q opposed. Other compounds are ferromagnetic, e.g. MnAs below 400 K or MnSb below 587 K. Susceptibilities of single crystals are anisotropic, and the anisotropy is strongly temperature-dependent. Thus the easy direction of magnetization in MnSb is below 520 K in the basal plane and above 520 K along the principal axis. The compound

MnBi passes over to a defect Ni_2In structure above 630 K. Below this temperature it is ferromagnetic with a strong coercive force; it thus has possibilities as a material for permanent magnets[23].

Compounds with stoichiometry ME_2 usually crystallize with the pyrites or marcasite structures, or with the distorted marcasite structure shown by $CoSb_2$. The pyrites structure is derived from the NaCl structure by retaining the cations and replacing the anions by E_2 groups disposed along threefold axes. Marcasite is orthorhombic. In both structures, M atoms are octahedrally co-ordinated by six E atoms and E_2 groups have six octahedrally disposed M neighbours. As_2 or Sb_2 groups may be replaced by combinations E^1E^2, e.g. AsSb or AsS, and a large number of ternary compounds are thus possible. Some of these are shown in Table 12 [3,21]. If the metalloid atoms are randomly distributed over possible sites, the symmetrical pyrites or marcasite structures may be retained. In other cases, where E^1E^2 groups are ordered, less symmetrical structures, e.g. those of NiSbS or FeAsS, result. Since the E^1E^2 group (E^1 = As, Sb, Bi; E^2 = S, Se, Te) has one more electron then E_2^1, arsenoselenides, for example, of a given group of elements have structural and electrical properties like those of the diarsenides of elements one place to the right in the Periodic Table. Thus the co-ordination round M is tetragonally distorted in löllingites, compounds

ME_2 of the iron group (M = Fe, Ru, Os) with eighteen valence electrons. The compounds ME_2 of the cobalt group (M = Co, Rh, Ir) and the compounds ME^1E^2 of the iron group, all with nineteen valence electrons, have monoclinic structures in which M atoms are grouped in pairs with especially short M–M distances. The compounds ME_2 of the nickel group (M = Ni, Pd, Pt) and ME^1E^2 of the cobalt group (with twenty valence electrons) have the much more symmetrical pyrites or ullmanite structures. These generalizations are related to the occupancy of the d_{xy}, d_{xz}, d_{yz} orbitals of the metal. Table 12 shows that symmetrical structures are favoured when E^1 and E^2 are similar in size.

[a] The marcasite, $CoSb_2$ and FeAsS structures are closely related. Compounds in this section have the FeAsS or $CoSb_2$ structures except for RuAsP, RuAsSb and OsAsP (FeS_2).

[b] Number of valence electrons.

[c] Compounds with the NiSbS structure (a less symmetrical form of pyrites) are shown by an asterisk.

[d] Compounds with the antifluorite structure are marked by an asterisk. The MgAgAs structure is an antifluorite superstructure.

[e] A superstructure of body-centred cubic packing, closely related to the antifluorite or Li_3Bi structures (see Fig. 3).

[f] The $CuFeS_2$ structure is the same as that of zincblende (B3) with zinc atoms replaced alternately by copper and iron. $ZnSnAs_2$ has the ZnS (B3) structure, i.e. zinc and tin atoms are disordered. It forms mixed crystals with InAs. Other related ternary sulphides, e.g. Cu_3ES_3, are known; some are described in section 7.6.

The compounds ME_2 may show either metallic conductivity or, if the number of valence electrons is twenty or less, semiconductivity (see Table 11). In general, the energy gap between valence and conduction bands increases (a) with increasing atomic weight of the element M, and (b) with decreasing atomic weight of the element E. Substitution of a Group VI for a Group V element also increases the energy gap. All these trends correspond

to gradation from metallic to covalent–ionic chemical bonding. It is interesting to note that the elements of the platinum and gold groups form particularly strong complexes with heavier metal donors: they are "class (b)" acceptors[24]. Their arsenides, antimonides and bismuthides are thus compact, and the distances between heavy metal atoms are brought within the range for which superconductivity is possible (see Table 11).

Phases of composition M_2E are also widely distributed. The compound Au_2Bi is anti-isomorphous with the alkali metal compounds already discussed. More commonly, the compounds M_2E crystallize with the tetragonal Cu_2Sb structure in which layers of M atoms

● Cu   ○ Sb
Fig. 5. The structure of Cu_2Sb.

alternate with (slightly puckered) layers of both M and E atoms (Fig. 5). Each E atom has nine neighbours (six of the nine bound to atom A are shown in Fig. 5: the other three are in adjacent unit cells). The M atoms in layers (m) have nine neighbours (five E and four M) distributed like the neighbours of atom A. The M atoms in layers (l) have twelve neighbours (eight M and four E) making a dodecahedron. Co-ordination numbers are high and bonding between like atoms is apparent. Phases with this structure show interesting and often complicated magnetic properties. For example, in Mn_2Sb at room temperature, there is long range coupling of spins in two interpenetrating lattices (Fig. 5 (a)). Since the manganese atoms in layers (l) and (m) are not equivalent, there is only partial cancellation of spins, and the lattice is ferrimagnetic. The closely related alloys Cr_2As, Mn_2As,

24 S. Ahrland, J. Chatt and N. R. Davies, *Quart. Revs. London* 12 (1958) 265.

Cu_2Sb, $Mn_{2-x}A_xSb$ (A = V, Co, Cu), $Mn_2Sb_{1-x}Z_x$ (Z = Ge, As) are antiferromagnetic with spins oriented over two unit cells as indicated in Fig. 5 (b). The alloy $Mn_{2-x}Cr_xSb$ ($x \leqslant 0.003$) may be obtained in a state intermediate between the cases (a) and (b) with a spiral orientation of magnetic moments.

The compounds ME_3, formed by the elements cobalt, rhodium and iridium, crystallize with the cubic (skutterudite) $CoAs_3$ structure, in which groups of four E atoms are arranged in squares. Each M has six E neighbours at the corners of an octahedron and each E has four neighbours (two E and two M) at the corners of a distorted tetrahedron.

2.3. COMPOUNDS WITH POST-TRANSITION ELEMENTS

Arsenic, antimony and bismuth interact with the post-transition metals to form substances ranging from intermetallic phases with properties like those of the elements, to well-defined groups of compounds when the electro-negativities of the constituent elements differ considerably. Several such groups of compounds are discussed in later sections.

Compounds with Zinc and Cadmium

Arsenides of composition M_3As_2, MAs_2 are formed by zinc and cadmium (Table 13). The compounds M_3As_2 are dimorphic, with one form like the arsenides of the calcium group. They have been investigated as semiconductors: the cadmium compound has an

TABLE 13. PROPERTIES OF ZINC AND CADMIUM DERIVATIVES

exceptionally high electron mobility and has possibilities as an Ettingshausen cooler (see p. 576). The orthorhombic compounds ZnSb and CdSb, also semiconductors, have distorted diamond-type lattices, with each atom surrounded by four others (three the same and one different) at the corners of a tetrahedron. The shortest interatomic distances are like those in the metals[25],

e.g. in CdSb: Cd–Cd, 299; Cd–Sb, 280–291; Sb–Sb, 281 pm
    in ZnSb: Zn–Zn, 258; Zn–Sb, 266–274; Sb–Sb, 281 pm
Cf. Cd–Cd in metal 298, Zn–Zn in metal 266 pm (sixfold co-ordination)

[25] K. E. Almin, *Acta chem. scand.* **2** (1948) 400.

Bismuth and mercury are miscible, but there is no evidence for compound formation; solid bismuth and cadmium are largely insoluble in each other, and bismuth and zinc form a simple eutectic.

III–V Compounds

Arsenic, antimony and bismuth give compounds ME with the elements of the aluminium group. The cubic zincblende structure predominates at normal pressures (see Table 8). The only exceptions are thallium compounds, TlSb and TlBi, which have the caesium chloride structure, and indium bismuthide InBi, which has the structure shown in Fig. 6. Each indium atom has four bismuth neighbours at the corners of a tetrahedron, and

● In   ○ Bi
FIG. 6. The tetragonal structure of indium bismuthide (W. P. Binnie, *Acta Cryst.* 9 (1956) 686).
(Distances in pm.)

each bismuth has four indium neighbours in a square to one side. Because of their very extensive applications in the electronics industry, the compounds between arsenic or antimony and aluminium, gallium or indium, often called III–V compounds, are some of the most widely studied of all substances. Very full accounts of their preparation[1] and properties[26-28] have been published.

The principal method for making III–V compounds is by the interaction of stoichiometric quantities of the elements in sealed tubes at elevated temperatures. Most applications demand extremely stringent control of impurities. These are inevitably introduced during preparation, and the procedure adopted for one application may be quite unsuitable for another. Some of the problems are indicated here in a general way; full experimental details may be found in specialized works:

(a) There may be impurities in starting materials. These are minimal in modern commercially available metals.

[26] R. K. Willardson and A. C. Beer, *Semiconductors and Semimetals*, Academic Press. Several volumes in this series are devoted to III–V compounds.

[28] *Gallium Arsenide*, Institute of Physics and Physical Society (1967); O. Madelung, *Physics of III–V Compounds*, Wiley (1964).

(b) Several of the compounds have appreciable dissociation pressures at their melting points (Table 14). These must be taken into account in controlling stoichiometry. For example, gallium arsenide is made in a sealed quartz ampoule containing gallium at one

[e] Boron arsenide (BAs) is similar to the other III–V compounds. It has the zincblende structure with a = 477.7 pm. Above ~1000°C it loses arsenic with formation of an orthorhombic lower arsenide B$_{5-7}$As. Boron arsenides are very inert chemically but dissolve in molten sodium hydroxide. (J. A. Perri, S. LaPlaca and B. Post, *Acta Cryst.* **11** (1958) 310; F. V. Williams and R. A. Ruehrwein, *J. Am. Chem. Soc.* **82** (1960) 1330.)

end and arsenic at the other. The gallium is slowly heated to the melting point of gallium arsenide and the arsenic to 605°C so that the arsenic pressure is maintained at 0.9 atm (Table 14). The ingot of gallium arsenide is allowed to solidify from one end, so that impurities are somewhat segregated. Indium arsenide may be made similarly. The antimonides of gallium and indium have low dissociation pressures and may be made in ampoules without differential heating.

(c) Impurities may be incorporated from the boat or other container. Quartz, aluminium oxide or graphite are commonly used for containers, but none is wholly free from disadvantages. For example, silicon may be incorporated from quartz into molten gallium arsenide:

$$2Ga_{(GaAs)} + SiO_2 \rightarrow 2GaO + Si_{(GaAs)}; \qquad 3GaO \rightarrow Ga_2O_3 + Ga$$

This reaction is minimized by working at temperatures as low as possible and by careful control of temperature gradients to prevent transport of the oxide GaO to cooler regions where it can disproportionate[29].

[29] J. E. Wardill and D. J. Dowling, *Chem. Brit.* **5** (1969) 226.

(d) Oxygen and water must be rigorously excluded, as oxygen is difficult to remove from the product. Hydrogen, helium or argon may be used as inert atmospheres.

(e) The III–V compounds expand on freezing (e.g. volume changes: GaSb, 7%; InSb, 12%), and allowance must be made for this so that the container does not break.

Some of the difficulties associated with preparations at high temperatures and pressures are avoided if the III–V compounds can be made at lower temperatures, e.g. by elimination of methane from adducts such as Me_3In,SbH_3 or Me_3Ga,AsH_3, or by passing hydrogen and arsenic trichloride vapour over heated gallium. The latter is converted to the monochloride GaCl which reacts with arsenic vapour formed by reduction of the trichloride:

$$6GaCl + As_4 \rightarrow 4GaAs + 2GaCl_3$$
Large crystals are difficult to prepare by this process.

Purification of III–V compounds may be effected by zone melting, but for arsenides, the pressure of arsenic must be controlled to maintain the stoichiometry. The purity may be assessed[1] by emission or mass spectroscopy, colorimetry, radioactivation analysis or by examination of electrical properties (see below).

Properties of III–V Compounds

The lattice constants and bond lengths are known with very great accuracy, and accurate electron density maps have been constructed. In contrast to the other intermetallic compounds discussed in the previous sections, co-ordination numbers in the III–V compounds are low (four), and the M–M and E–E distances are much larger than in the elements. Thus the bonding is between unlike atoms. The zincblende structures lack centres of symmetry, so the [111] and [$\bar{1}\bar{1}\bar{1}$] directions are inequivalent (Fig. 7). Careful examination of X-ray intensities suggests that at (111) faces, M atoms are bound to three E atoms
FIG. 7. Projection of the zincblende structure.

within the crystal, and at ($\bar{1}\bar{1}\bar{1}$) faces, E atoms are bound to three M atoms within the crystal. The inequivalence of the [111] and [$\bar{1}\bar{1}\bar{1}$] directions shows in the rates of chemical reactions. Thus etching agents such as $HF–HNO_3$ attack (111) faster than ($\bar{1}\bar{1}\bar{1}$) faces. Crystals of indium antimonide grow more rapidly along [$\bar{1}\bar{1}\bar{1}$], where lone pairs of E

atoms are exposed, than along [111]. The polarity of the [111] directions gives piezoelectric effects which have been observed in InSb at low temperatures[27]

The low co-ordination numbers and open structures account for the expansion on freezing and the consequent fall in the melting point as the pressure increases. Dissociation pressures are not certainly known at present. The heats of formation have been obtained, e.g. by molten tin solution calorimetry; arsenides are 20–40 kJ mol^{-1} more exothermic than antimonides. Since there is a difference of about 40 kJ mol^{-1} in the heats of atomization of arsenic and antimony, the heats of atomization of the arsenides, which may be taken as a measure of the strength of the bonding, are 60–80 kJ mol^{-1} more than the heats of atomization of the antimonides. The stronger bonding in arsenides results in part from smaller M–As compared with M–Sb distances. Variations in properties which depend on the tightness of the bonding, such as hardness, melting point and the energy gap E_g between valence and conduction bands (Table 14) are thus readily understood.

The importance of the III–IV compounds arises mainly from their electrical properties. These depend on the number of carriers capable of transferring charge, and the characteristics of the lattice, which determine the energy gap and the mobilities. For a given compound, the number of carriers can in principle be controlled, e.g. by variation from exact stoichiometry or by addition of impurities. Many of the measured electrical properties depend on the net effects of negative carriers (electrons) and positive carriers (holes). If the effects of positive carriers dominate, the substance shows a positive Hall effect coefficient and the semiconductor is p-type; if the effects of negative carriers dominate, the Hall effect coefficient is negative and the substance is an n-type semiconductor. By careful addition of impurities it is possible to make III–V compounds either p- or n-type, and many devices depend on this possibility. The most commonly added impurities are the acceptors—zinc, cadmium or magnesium—which give p-type semiconductors, or the donors—sulphur, selenium or tellurium—which give n-type semiconductors. Transition metal atoms or elements of Group IV, e.g. Ge, Sn, Pb, may be either donors or acceptors. Impurities are sometimes distributed evenly by zone levelling, in which a narrow molten zone is passed along a cylindrical crystal or ingot successively in opposite directions. The main difficulties in the development of the III–V compounds arise from unwanted impurities from starting materials or contamination during preparation, and the full potential of these compounds is far from realized. It is, of course, much easier to prepare an element, e.g. germanium, with an impurity content of less than 1 ppm than to prepare a compound with a similar impurity level.

In spite of these difficulties, research on III–V compounds has been pursued because applications of semiconductors are limited by lattice properties as well as by impurities. The wide variations in energy gap and mobilities afforded by the III–V compounds increases their potential compared with silicon and germanium, provided difficulties in preparation can be overcome. Some possibilities are indicated very briefly. Above a certain temperature which depends on E_g, the majority of carriers are derived from electrons excited from the valence to the conduction band. It is then impossible to make devices which depend on n–p junctions. The maximum operating temperature for a silicon junction is 250°C (E_g 1.09 eV) and for germanium is 100°C (E_g 0.66 eV). Table 14 shows that gallium arsenide should be effective at higher temperatures (up to 450°C) and aluminium antimonide should be usable to 500°C; the indium compounds InAs, InSb are suited for junctions operating at low temperatures. In certain cases, gallium arsenide, with its high mobility and low dielectric constant, may be preferable to germanium, e.g. for variable capacity

diodes. Gallium arsenide may also be used for microwave rectifiers, switching diodes (these have high on–off speeds), and tunnel diodes. The Hall effect can be exploited in a range of devices to measure magnetic fields, or in multipliers. The Hall effect coefficient R_H is given by $R_H = \mu/\sigma$, where μ is the carrier mobility and σ the electrical conductivity. The power transferred from an input circuit to a load connected to the Hall electrodes is proportional to the square of the mobility. Indium antimonide is thus 400 times as efficient as germanium ($\mu_n = 0.4$ m^2 V^{-1} s^{-1}). The III–V compounds have suitable energy gaps and high carrier mobilities and so show important photoelectric and electroluminescent effects. For gallium arsenide, the band structure is such that, above a certain current, the electroluminescent radiation becomes coherent, and a laser, with electrical rather than optical pumping, can be made. This is not as good as other solid-state lasers, but improvement and development may be possible. Another application is in solar batteries. It is calculated that in outer space, where the ultraviolet radiation of the sunlight is not absorbed, the optimum energy gap for a battery material is about 1.6 eV. Clearly, GaAs and AlSb are superior to silicon, which is commonly used.

Most of the applications so far have been made with gallium arsenide and indium arsenide and antimonide. The aluminium compounds could be useful for some applications, but these are limited by (a) their hydrolysis in moist air, and (b) the fact that, at their high melting points, containers are readily attacked, and so impurity contents are difficult to regulate.

Alloys with Germanium, Tin and Lead

The germanium arsenides are GeAs, m.p. 737°C, and GeAs$_2$, m.p. 732°C. The diarsenide has a layer structure which, from a chemical point of view, is intermediate between those of the two elements[30]. Thus each germanium atom has four arsenic neighbours and each arsenic atom makes three short bonds and three longer, as in arsenic metal. The shortest As–As distances are 250 and 315 pm (cf. p. 549). Tin gives two compounds with arsenic. The compound SnAs has the NaCl structure and may be represented as $Sn^{2+}Sn^{4+}As_2^{3-}$; the compound Sn$_4$As$_3$ is similar. The tin arsenides are superconductors at low temperatures[31] (T_c: SnAs, 3.41 . . . 3.65 K; Sn$_4$As$_3$, 1.16 . . . 1.19 K). The cubic SnSb is a component of some bearing alloys (Table 15A). These require a hard constituent in a softer matrix. In the tin-based alloys the hard compounds SnSb and Cu$_6$Sn$_5$ are dispersed in a tin–copper–antimony matrix, and in the lead-based alloys SnSb is in a Pb–SnSb eutectic.

Lead and antimony form a system with a simple eutectic, without intermediate phases, and the only intermediate phase in the lead–bismuth system is unstable at its melting point. The lead–bismuth eutectic is an important superconducting alloy (critical temp., 7.3 . . . 8.8 K; critical magnetic field at 4.2 K, 1.5 T; critical current density, 10^6 A m^{-2}). The ternary eutectic Sb–Sn–Bi and the quaternary eutectic Sb–Sn–Bi–Cd are important commercially because of their low melting points. They form the basis of the "fusible alloys", used for safety plugs in boilers and fire sprinklers, low-temperature solders, numerous applications in the plastics industry, and for cores in electroforming or in tubes which are to be bent. The fusible metal cores are readily removed by melting. Antimony and bismuth alloys are also used in printing. Alloys with more than 47% Bi or more than 75% Sb expand on freezing: those with less antimony or bismuth, and more tin or lead, contract.

With suitable constituents there is little volume change on freezing, and so very sharp images can be taken by solid casts. Tin-based alloys with antimony can also take sharp images because of the formation of rigid shells of the compound SnSb. Table 15A shows only a very small selection of commercially available alloys. Materials with a wide range of melting points and other physical properties have been made.

Antimony–Arsenic and Antimony–Bismuth Alloys

Antimony and bismuth are completely miscible in both solid and liquid, and the solid alloys have the same rhombohedral structure as the elements. In bismuth the valence and conduction bands overlap by 0.0184V, so the element is a metallic conductor; but addition of a few per cent of antimony separates the bands so that the alloy becomes semiconducting. The energy separation rises to a maximum at about 12 atomic % Sb and then falls. Alloys with more than 40 atomic % Sb are metallic. The changes in band structure are revealed by measurements of resistivities and Hall coefficients, which show anomalies for materials with an energy gap near to the maximum. Similar electrical properties are found for arsenic–antimony alloys: those with 9–40 atomic % As are semiconducting between 240 and 310 K[32].

Alloys of bismuth with a few per cent of antimony show large galvanothermomagnetic effects, and attempts have been made to utilize these in solid-state cooling devices[33]. When a current I_y, perpendicular to a field H_z, is passed along a conductor (Fig. 8), the
FIG. 8. The Ettingshausen effect.

electrons, which constitute the current, are deflected by the magnetic field. This results in (a) an opposing electric field along x perpendicular to both current and magnetic field (Hall effect), and (b) a thermal gradient along x (Ettingshausen effect). For most conductors, the Ettingshausen effect is small. However, when the current is carried by approximately equal numbers of electrons and holes, both positive and negative carriers are deflected in the same direction by the magnetic field. The net Hall effect is small, and the effect of the magnetic field is to produce a large thermal gradient. In any device to utilize this effect, the current must be carried through electrodes which are themselves good electrical and thermal conductors, and which therefore tend to diminish the thermal gradient. However, if the material used has a low thermal conductivity and if the conductor is long and thin, as shown in the figure, a large thermal gradient may be maintained at the centre (shaded). Equal numbers of holes and electrons are most easily obtained in semiconductors with small energy gaps or in metals where overlap of valence and conduction bands is small. Lattice thermal conductivity is smallest in structures with heavy atoms, and can be further reduced by limited isomorphous replacements with lighter atoms. Bismuth–antimony alloys seem on these criteria to be suitable materials, and those with about 3 % Sb are best. The cooling may be enhanced by shaping the block of thermomagnetic material or by using single crystals, e.g. for Bi–Sb the optimum directions are with the current along the threefold axis, the heat flow along the twofold axis and the field perpendicular to both these directions. The effect is temperature dependent and bismuth–antimony Ettingshausen coolers are most efficient in the range from 77 to 200 K. At 77 K fields provided by a small permanent magnet are suitable. Further improvement may be possible by doping to control numbers and mobilities of carriers, and by alloying to cut down thermal conductivity.

3. GENERAL ASPECTS OF THE CHEMISTRY OF ARSENIC, ANTIMONY AND BISMUTH

3.1. ATOMIC PROPERTIES

Ionization Potentials

Values of ionization potentials from atomic spectra are given in Table 15B. The first

[33] T. C. Harman and J. M. Honig, *Semiconductor Products* (July 1963), p. 19; S. R. Hawkins, C. F. Kooi, K. F. Cuff, J. L. Weaver, R. B. Horst and G. M. Enslow, *Adv. Cryogenic Engineering* **9** (1964) 367.

ionization potentials, corresponding to the removal of electrons from the outer p orbitals, decrease with increasing atomic number, as in most groups of the Periodic Table. However, the second, third and fourth ionization potentials of bismuth are slightly greater than those of antimony.

Ionization potentials are illustrated further in Fig. 9, which shows, A, the energy required to remove the first three electrons ($s^2p^3 \rightarrow s^2$), and, B, the energy to remove the next two ($s^2 \rightarrow s^0$). The line B for removal of the fourth and fifth electrons, instead of falling smoothly

TABLE 15B. IONIZATION POTENTIALS[a]

from phosphorus to bismuth, shows a pronounced step. The $4s$ electrons in arsenic penetrate within the $3d^{10}$ shell and are thus held more firmly than expected by extrapolation from phosphorus where the $3d$ shell is empty. Similarly, the $6s$ electrons in bismuth penetrate within the $4f^{14}$ shell and so are held more firmly than expected by extrapolation from antimony where the $4f$ shell is empty. A similar "alternation" shows in line A, and in plots of some other electronic parameters, such as the $s^1 \to d^1$ promotion energies for E^{4+} shown in line C [34].

Sizes

Although the size of an atom depends on its environment, it is useful to have some radius for each element which indicates roughly its size relative to other elements. Values given for arsenic, antimony and bismuth are as follows:

	As	Sb (pm)	Bi
From metal	125	145	153
Tetrahedral	118	136	146

Radii from metals are half the shortest internuclear distances (p. 549), and refer to situations in which bonds to nearest neighbours make angles just over 90°. Tetrahedral radii are derived from compounds with the zincblende (p. 570) or pyrites structures; internuclear distances in these compounds are well reproduced by addition of appropriate tetrahedral radii [35]. The radii of arsenic, antimony and bismuth in most other compounds may be taken as within the limits shown above.

3.2. BINARY COMPOUNDS

The ionization potentials discussed in the previous section show that the first three electrons may become involved in chemical bonding much more easily than the next two. Involvement of more than five electrons in bonding requires prohibitively large amounts of energy. There are thus two well-established series of compounds, in which the elements E show oxidation states III (sections 4–10) and V (sections 11–15). In a few compounds, arsenic, antimony, and bismuth show oxidation states less than three (sections 4.3 and 5.5), and in others the Group V elements appear as both E^{III} and E^V (section 16). Compounds of As^V and Bi^V are much less well known than the corresponding compounds of Sb^V. This has been attributed [34] to the effects of electron penetration (see previous section). Analogous effects appear in the chemistry of the elements S–Po and the halogens.

There are still many gaps in the thermodynamic data on compounds of arsenic, antimony and bismuth. Some free energies of formation (per gram atom of E) of binary compounds have been plotted in Fig. 10.

[34] R. S. Nyholm, *Proc. Chem. Soc.* (1961) 276; W. E. Dasent, *Non-existent Compounds*, Edward Arnold, London (1965).
[35] L. Pauling, *The Nature of the Chemical Bond*, 3rd edn., Cornell University Press, Ithaca, NY (1960), Chs. 7 and 11.

It is clear that the elements arsenic, antimony and bismuth are very closely related with rather small variations in stability within a series of compounds with a given element. Mean bond energies $\bar{H}$ (Table 16) have been calculated where the necessary data is available,

$$-3\bar{H}(\text{As}\!\!-\!\!\text{H}) = -\Delta H_f^{\circ}\text{As(g)} - 3\Delta H_f^{\circ}\text{H(g)} + \Delta H_f^{\circ}\text{AsH}_3\text{(g)}$$

For a given element E, E–X bond energies decrease with increasing atomic weight of X.
FIG. 10. Free energies of formation per gram atom E.

For compounds with a given element X, there are quite small changes in E–X bond energies for the series arsenic, antimony and bismuth. Pauling[35] electro-negativities, derived empirically from bond energies, reflect the similarity of the three elements. Allred and Rochow[36] electro-negativities, calculated from the force on electrons at distances from the nuclei equal to the covalent radii, decrease from arsenic to bismuth:

Electro-negativities	As	Sb	Bi
Pauling	2.0	1.9	1.9
Allred and Rochow	2.20	1.82	1.67

Bond dissociation energies for diatomic molecules, derived from spectroscopy, have also been collected in Table 16. There is a general decrease in bond dissociation energy $D(\text{E–X})$ for the series (E =) arsenic, antimony and bismuth.

[36] A. L. Allred and E. G. Rochow, J. Inorg. Nucl. Chem. 5 (1958) 264.

3.3. CHEMISTRY IN AQUEOUS SOLUTION

Most binary compounds of arsenic, antimony and bismuth either react with water or are insoluble in it. The chemistry of aqueous solutions of these elements is the chemistry of oxyions, or complexes with ligands other than water: species $E(H_2O)_m^{n+}$ are probably rarely formed. For many purposes, however, the actual species in solution do not matter and equations may be written with non-committal symbols such as As^{III} aq. or Sb^V aq. The basicity of the metal increases from arsenic to bismuth. Thus there is a well-developed series of arsenites and arsenates; arsenic usually appears in anionic species. Bismuth gives a series of compounds which can formally be considered as Bi^{III} salts, but these do not give clear solutions in water except in high acid concentration, when complex species are present. On dilution, basic salts, which formally contain the bismuthyl ion BiO$^+$, precipitate. These compounds, though often with simple stoichiometry, rarely have simple structures; usually bismuth–oxygen frameworks (oxycations) have anions interposed. In alkaline solution, bismuth precipitates as bismuth hydroxide, Bi(OH)$_3$. Antimony is intermediate: it forms both stable oxyanions, in antimonates and antimonites, and oxycations, in basic salts.

Relationships between the oxidation states are shown in Fig. 11, which is like those given by Phillips and Williams[37], with data for acid solution plotted with reference to $E° = 0$
FIG. 11. Oxidation state diagram for arsenic, antimony and bismuth. Species present in solution are not necessarily those indicated. For example, AsO_2^- represents $H_2AsO_3^-$ or $As(OH)_4^-$. See sections 6.3 and 12.1–3.

for H^+ $(a = 1)/H_2$ and data for alkaline solution with reference to $E° = 0$ for $H_2O/H_2,OH^-$ $(a = 1)$. Oxidation-reduction data $[E° = 0$ for H^+ $(a = 1)/H_2]$ are also given in Table 17. The similarity between the three elements, and especially between arsenic and antimony, is apparent. The Bi^V–Bi^{III} couple is strongly oxidizing, able to oxidize water to oxygen. As^V and Sb^V are weak oxidizing agents, but stronger in acid

than in alkaline solution. Many of these E^{III}–E^V oxidation-reduction reactions proceed cleanly and quantitatively, and so form the basis of wet methods of analysis (p. 583). By comparison, the high oxidation states of nitrogen are more strongly oxidizing, and those of phosphorus less strongly oxidizing than arsenic, antimony, or bismuth (Fig. 11). The greater basicity of bismuth, compared with antimony and arsenic, is shown in Fig. 11 by the lower line for acid, compared with alkaline, solution. For arsenic, the line for alkaline solution is lower, and for antimony points for acid and alkaline conditions are close. It must, however, be remembered that the positions representing various oxidation states on such diagrams depend on the precise conditions—particularly on the presence of ligands forming complexes or precipitates. Neither of the oxidation states III or V for the elements arsenic, antimony and bismuth disproportionates in solution.

The elements themselves are noble in that they are weaker reducing agents than hydrogen. They are stable with respect to disproportionation and so differ from phosphorus (Fig. 11). There are thus no reactions for the heavier elements of Group V corresponding to the reaction of phosphorus with alkali to give phosphine and hypophosphite (Chapter 20). The Sb_2O_3–Sb couple has been used in the "antimony electrode" which is suitable for the measurement of pH in the range from 3 to 8. The electrode is simple and robust, and usually

[38] L. G. Sillén and A. E. Martell, *Stability Constants of Metal Ion Complexes*, Chem. Soc. Special Publication, 17 (1964); L. G. Sillén, A. E. Martell, E. Högfeldt and R. H. Smith, *ibid.*, 25 (1971); D. D. Perrin, *Pure Appl. Chem.* 20 (1969) 133.

there is sufficient oxide on the surface of the antimony. It cannot be used in the presence of complexing agents like tartrates, or with ions of metals more noble than antimony.

3.4. ANALYSIS[39-41]

Arsenic and antimony are readily determined volumetrically. For example, the reaction between As^{III} oxide and iodine is complete in buffers of sodium bicarbonate, borax–boric acid or Na_2HPO_4–NaH_2PO_4:

$$\tfrac{1}{2}As_2O_3 + I_2 + H_2O \rightarrow \tfrac{1}{2}As_2O_5 + 2H^+ + 2I^-$$
Other convenient oxidizing agents for As^{III} are potassium bromate, potassium iodate and potassium permanganate. Similar reactions occur with antimony compounds, but precipitation of basic salts, which may occur in all except the strongest acid, must be prevented by addition of tartrate, which forms strong complexes with Sb^{III} (section 6.4). Only the most powerful oxidizing agents will oxidize Bi^{III} to Bi^V (Fig. 11) and so volumetric methods applicable to arsenic and antimony cannot be used. Bi^{III} can, however, be titrated with ethylenediaminetetraacetic acid (H_4–EDTA). The very high formation constant for the complex $[Bi(EDTA)]^-$, 10^{28}, shows that it forms even in solutions of very low pH, where less strongly complexed cations do not interfere[40]. $[Bi(EDTA)]^-$ shows strong absorption in the ultraviolet, and so concentrations as low as 10^{-6} M can be estimated spectrophotometrically.

TABLE 18. GRAVIMETRIC METHODS

Element[a]	Precipitate	Compound weighed	Ignition temperature (°C)
As^{III}	As_2S_3 from 9 M HCl	As_2S_3	105
As^V	$MgNH_4AsO_4 \cdot 6H_2O$	$Mg_2As_2O_7$	800–900
As^V	$NH_4UO_2AsO_4 \cdot xH_2O$ from acetic acid	U_3O_8	800
Sb^{III}	Sb_2S_3 from 2.5 M HCl	Sb_2S_3	280–300 in CO_2
Sb^{III}	$Sb(C_6H_5O_3)$ [b] from tartrate soln.	$Sb(C_6H_5O_3)$	100–105
Bi^{III}	BiOI by boiling soln. containing Bi^{III} and I^-	BiOI	105–110 (BiOCl similarly but above 325)
Bi^{III}	$BiPO_4$	$BiPO_4$	380–900
Bi^{III}	Cupferron[c] complex	Bi_2O_3	960
Bi^{III}	Bi by reduction with H_2CO or by electro-deposition	Bi	105

[a] The element E must be in the appropriate oxidation state before the determination.
[b] Pyrogallol.

[41] F. D. Snell, C. T. Snell and C. A. Snell, *Colorimetric Methods of Analysis*, 3rd edn., Van Nostrand, Princeton, Vol. II (1954), Vol. IIA (1959).

Gravimetric methods for arsenic, antimony, and bismuth are listed in Table 18. The methods for antimony are not very satisfactory, and so volumetric estimations are usually preferred. Small amounts of the Group V elements may be determined colorimetrically[41]. Some examples are as follows. The wavelengths given indicate strong absorptions: the wavelength used in any particular estimation depends on the absorption from any interfering species:

As: as molybdenum blue, 840 nm; as diethylthiocarbamate, 560 nm

Sb: as Rhodamine B complex, 550 nm; as SbI_4^-, 330 nm

Bi: as BiI_4^-, 330 nm; as thiourea complex, 420 nm; as dithizonate, 500 nm; as diethylthiocarbamate, 370–400 nm; with EDTA, 265 nm. (In some of these determinations interference from antimony may be prevented by complexing with tartrate)

Arsenic can often be separated from complex mixtures containing heavy metals by distillation as chloride in HCl below 108°C. Germanium tetrachloride is the only similar compound to distil under these circumstances. Arsenic may also be separated as arsine by boiling the substance under test with zinc and acid. Some classical procedures are given in Table 19. In a more modern example, arsenic in hydrocarbons has been determined by adsorption on to silica gel and removal of organic matter by a mixture of sulphuric, nitric and perchloric acids. (This mixture is commonly used for the digestion of organo-arsenic compounds[39].) The arsenic is then reduced by zinc, and the arsine is absorbed in silver diethylthiocarbamate and determined spectrophotometrically[42]. Alternatively, the arsine may be converted to arsenate by iodine in bicarbonate buffer. Excess iodine is removed, and the arsenate treated with ammonium molybdate and reduced by hydrazine sulphate.

TABLE 19. ESTIMATION OF ARSINE AND STIBINE[a]

Marsh	AsH_3, SbH_3 decomposed by heat to metallic mirror. As, but not Sb, oxidized by NaOCl
Gutzeit	AsH_3, SbH_3 absorbed on paper impregnated with $AgNO_3$ or $HgCl_2$. Can be made quantitative by comparison with standard stains for known samples
Fleitmann	AsH_3 generated in alkaline soln (Al–NaOH); SbH_3 not formed

[a] See also W. A. Campbell, *Chem. Brit.* **1** (1965) 198.

The intensely coloured "molybdenum blue" may be determined colorimetrically. Antimony can also be separated from heavy metals as the chloride. Thus, when whitemetals (Table 15A) are treated with dry chlorine, tin and antimony are volatilized quantitatively and may be separately determined in the distillate[43]. All three metals—arsenic, antimony and bismuth—may be precipitated as sulphides using hydrogen sulphide or thioacetamide in acid solution. This forms the basis of their separation in classical analysis (section 7.4).

Traces of arsenic, antimony and bismuth may be estimated by emission spectrography or by neutron activation analysis[1].

4. HYDRIDES EH₃

Besides an earlier account[44], a critical review[45] gives the most satisfactory methods for laboratory preparations of the hydrides and lists many physical properties.

4.1. PREPARATIONS

Arsine (AsH₃), and stibine (SbH₃), have been obtained by the usual methods for the preparation of covalent hydrides. The most important of these are as Table 20 shows.

TABLE 20. PREPARATION OF HYDRIDES[45]

	Reagents	% yield	Ref.
AsH₃	NaOH–As₂O₃–KBH₄	59 [a]	b
AsD₃	AsCl₃–LiAlD₄ (−90°)	83 [c]	d
SbH₃	$C_4H_4O_7SbK \cdot \frac{1}{2}H_2O$ [e]–KBH₄	51 [a]	b
SbD₃	SbCl₃–LiAlD₄ (−90°)	82 [c]	d
BiH₃	BiCl₃–LiAlH₄ (−100°)	1 [c]	f

[a] Based on BH_4^- in equation $4E(OH)_4^- + 3BH_4^- + 7H^+ \rightarrow 4EH_3 + 3H_3BO_3 + 7H_2O$. The borohydride is the most expensive starting material.

Reductions with Lithium Aluminium Hydride or Potassium Borohydride

Lithium aluminium hydride must be used in diethyl or dibutyl ether. It is important to remove the gaseous products from the reaction mixture, usually by condensing them in liquid nitrogen, to prevent further reactions, e.g. with formation of $LiAl(AsH_2)_4$ or metallic antimony. Good yields based on arsenic or antimony trichlorides are readily obtained, but use of the hydride reducing agent is inefficient unless conditions are chosen carefully[45]. Potassium borohydride may be used in aqueous solution, with less possibility of attack on grease by solvent.

Solvolysis of Arsenides or Antimonides

Arsenic or antimony is alloyed with sodium, magnesium or zinc, usually by fusing proportions of the elements to give $M_3^I E$ or $M_3^{II}E_2$, and the arsenides or antimonides are treated, either with dilute sulphuric acid, or with ammonium bromide in liquid ammonia. The hydrides produced are contaminated with less volatile lower hydrides (section 4.3), but these are easily separated in a vacuum line.

[45] W. L. Jolly and A. D. Norman, *Preparative Inorganic Reactions* **4** (1968) 1.

Arsine and stibine are also formed by the electrolytic reduction of solutions containing As^{III} or Sb^{III} [45]. Since the hydrides are poisonous, their formation can constitute a hazard in plants using electrolytic processes on arsenic or antimony compounds, and, less obviously, where arsenic and antimony may be impurities in other metal electrodes, e.g. in lead batteries. It has been suggested that copper salts suppress the formation of hydrides.

Bismuthine is too unstable for preparations in high yield; but small amounts can be made by the methods described above. It must be stored in liquid nitrogen, and any measurements at room temperature must be completed in a few minutes.

4.2. PROPERTIES

Thermodynamic and structural properties are given in Table 21. The melting points increase, and the volatilities decrease with increasing molecular weight. There is no evidence for association in the liquid. The hydrides are endothermic compounds, i.e. their heats of formation are positive, but this is largely a reflection of large heats of atomization of the elements: the E–H bond is moderately strong. The bond energies decrease from arsine to bismuthine. The hydrides are thus kinetically stable; they will decompose to the elements provided a mechanism is available. Care must be taken, for example, to keep the gases away from flames used for sealing ampoules. At room temperature, decomposition of arsine is slow, but it proceeds at a measurable rate on an arsenic, or, better, antimony surface at 300°C. The decomposition is first order in arsine[48]. A mixture of AsH_3 and AsD_3 gives some HD, but a mixture of AsH_3 and D_2 does not; exchange must therefore occur only between hydrogens bound to arsenic. Stibine is considerably less stable. Samples to be kept more than a day or two should be stored in liquid nitrogen. The extreme instability of bismuthine has been mentioned. The quantitative decomposition of stibine, but not arsine, to the elements can be initiated in a calorimeter by a small heated filament, and this provides a convenient method for the measurement of the energy of decomposition $(-\Delta E_f^{\circ})$. Mixtures of other hydrides (including AsH_3) and stibine are also quantitatively decomposed, making possible the determination of a large number of energies of decomposition. The strongest peaks in the mass spectra of the trihydrides are from MH^+ ions[49]; there are also peaks from MH_3^+, MH_2^+ and M^+. Along the series AsH_3, SbH_3, BiH_3, the relative abundances of the parent ions decrease, corresponding with weakening M–H bonds, and the relative abundances of M^+ increase, reflecting the decreasing ionization potential of the elements. The thermal decomposition of the hydrides is of historical interest in two ways. It formed the basis of Marsh's test (Table 19), which effectively decreased the use of a popular poison. Also, the detection of bismuthine, from the reaction of acid with an alloy of magnesium and thorium-C (^{212}Bi), was one of the first applications of radioactive tracers.

The standard entropies have been derived from spectral data, and, in the case of arsine, from specific heat measurements. These reveal a transition at 35 K associated with the onset of free rotation in the solid. The gaseous molecules are pyramidal (C_{3v}) and the bond lengths and angles have been found from microwave measurements and vibrational fine structure. The bond angles are close to 90°, smaller than in the trihalides, about the same as in phosphine (93.3°) but much smaller than in ammonia. The bond angles suggest that in arsine and stibine the metals use mainly p orbitals for bonding, so the lone pairs are largely s, but the quadrupole coupling constants show appreciable s involvement in the bonds. The molecules have very small dipole moments. The four fundamental vibrational frequencies, all active in both the infrared and Raman spectra, have been assigned in hydrides, deuterides and tritides. At low resolution, the peaks associated with the two M–H stretching frequencies overlap.

[48] K. Tamaru, *J. Phys. Chem.* **59** (1955) 777.

[49] F. E. Saalfeld and H. J. Svec, *Inorg. Chem.* **2** (1963) 46, 50.

Arsine and stibine are soluble in organic solvents and slightly soluble in water. They are poor donors and very few complexes with Lewis acids are known (see section 10.1). Arsine is much more reluctant than phosphine or ammonia to accept protons to form arsonium salts. Infrared frequencies assigned to $[AsH_4]^+$ have been detected in the solid formed from equimolar mixtures of arsine and hydrogen bromide at 82 K, but they rapidly disappear on warming. No stibonium $[SbH_4]^+$ salts have been described.

The hydrides are good reducing agents (Fig. 11 and Table 17) and so are destroyed by most aqueous inorganic oxidizing agents. They are oxidized in air. The black precipitates formed with silver nitrate have been used for the detection of small quantities of the gases.

4.3. LOWER HYDRIDES

The compounds As_2H_4, As_2H_5 and Sb_2H_4 have been made only in very low yields, and so information about them is limited[50]. The catenated compounds are isolated as by-products in the preparation of the trihydrides from metal arsenides or antimonides or from borohydride reductions. They may also be made by passing the trihydrides through a silent electric discharge in an ozonizer. Attempts to make the lower hydrides by the reduction of As^{III} compounds by mild reducing agents such as stannous chloride, gave only arsenic metal. It seems that As_2H_4 and As_2H_5 form only in the presence of excess trihydride.

The lower hydrides decompose rapidly at room temperature with formation of the trihydrides and non-stoichiometric E_2H. There is very little structural data but it has been possible[49] to record the mass spectra of As_2H_4 and Sb_2H_4. The heats of formation (lower limits) of the lower hydrides, deduced from appearance potential measurements, are As_2H_4 148 and Sb_2H_4 239 kJ mol^{-1}, and the M–M bond energies (upper limits) are As–As 187 and Sb–Sb 128 kJ mol^{-1}.

From mixtures of arsenides and phosphides, or arsenides and nitrides, ternary hydrides AsH_2PH_2, AsH_2NH_2, $HAs(NH_2)_2$ and $As(NH_2)_3$ have been identified. Organometallic hydrides are described in section 9.4 and silyl and germyl derivatives in section 9.6.

5. HALIDES EX₃

The trihalides of arsenic, antimony and bismuth have been described in several reviews[51].

5.1. PREPARATION

Two main methods are available. (a) Stoichiometric quantities of the elements are heated in a sealed tube, or the halogen, diluted with nitrogen, is passed over the heated metal. Excess halogen is pumped away and the halide purified by distillation or sublimation in the absence of moisture. (b) Trioxides are heated with the hydrogen halide. For arsenic

trifluoride, which is easily hydrolysed, it is convenient to prepare hydrogen fluoride in the presence of concentrated sulphuric acid:

$$As_2O_3 + 3CaF_2 + 3H_2SO_4 \rightarrow 3AsF_3 + CaSO_4 + 3H_2O$$
For halides which are less readily hydrolysed, concentrated aqueous solutions of the hydrogen halide may be used. Trioxides may also be converted to trichlorides by a mixture of sulphur and chlorine or by sulphur monochloride; tribromides may be made similarly. Bromides EBI$_3$ and iodides EI$_3$ may be conveniently made from chlorides using boron tribromide or iodide.

The trihalides are all available commercially. References to laboratory preparations are given in Table 22, which includes physical properties and thermodynamic data.

5.2. PROPERTIES

The compounds are liquids or solids at room temperature, and, with the exception of the fluorides of antimony and bismuth, the volatility decreases with increasing molecular weight. The molecules in the gas phase are all pyramidal, with bond angles close to 100° (Table 23). Accurate X-ray measurements on single crystals have been made in some cases. The bond lengths and angles of the gaseous molecules are largely preserved in the solids, though usually individual molecules are distorted, giving two long and one short intramolecular distances (e.g. 251 and 246 pm in $SbBr_3$; intermolecular Sb–Br distance, 369 pm). The molecules form layers in which the halogens are roughly close-packed, but the arrangements differ slightly from compound to compound. According to powder photographs, bismuth iodide has a structure in which bismuth ions occupy octahedral holes in a close-packed array of iodide ions, i.e. intramolecular and intermolecular Bi–I bond lengths are equal. Alternatively, the structure may be described as largely ionic with the lone pair in Bi^{III} stereochemically inactive (see section 10.3).

It is clear from the melting points and volatility shown in Table 22 that in antimony trifluoride there are especially strong intermolecular attractions. Like a number of other trifluorides of heavy metals, bismuth trifluoride crystallizes with the YF_3 structure, in which the metal has eight nearest neighbours and a ninth only slightly further away, and in which there is no recognizable molecule. The more compact structure of bismuth trifluoride, compared with the other halides of arsenic, antimony and bismuth, is reflected in its high density, high melting point and low volatility.

The liquid trihalides of arsenic and antimony have low electrical conductivities when pure. Arsenic trichloride has been suggested as a solvent for n.m.r. spectroscopy[53]. Molten

bismuth halides have higher conductivities which reach maxima 125–250° above their melting points. Solid antimony and bismuth iodides are semiconductors.

Spectroscopic Properties

Vibrational spectra (Table 23) for gaseous and liquid halides show four fundamentals all both infrared and Raman active for molecules with C_{3v} symmetry. Similar features appear in spectra from solutions in carbon tetrachloride, carbon disulphide or molten paraffins. Spectra from solutions in donor solvents show shifts attributed to complex

formation, and E-donor and E–X vibrations may be confused. Interactions between molecules, which lower the symmetry at E from C_{3v}, must be taken into account in interpreting the spectra of solids. Assignments of spectra of arsenic compounds are reasonably well established, but it is difficult to be sure of the correct allotment of the very similar symmetric and asymmetric stretching vibrations (v_1 and v_3). The assignments given in Table 23 for some of the antimony and bismuth halides are not so well established.

Nuclear quadrupole resonances (for ^{35}Cl, ^{81}Br and ^{127}I), and the coupling constants for ^{127}I, decrease along the series of halides AsX_3, SbX_3 and BiX_3. There are usually two or three closely spaced resonances, since all the halogen atoms are not usually equivalent in the solids. Nuclear quadrupole coupling constants relating to the atoms E are given in Table 23. For arsenic trichloride, the coupling constant from nuclear quadrupole resonance measurements on the solid is similar to that from microwave spectra on the vapour. For antimony and bismuth halides, the non-zero asymmetry parameters are consistent with a molecular symmetry lower than C_{3v} in the solid.

5.3. REACTIONS

Halogenations[54]

The fluorides of arsenic and antimony are important reagents in preparative inorganic chemistry for the conversion of non-metal chlorides to fluorides[51, 55, 56]:

$$[PCl_4]^+[PCl_6]^- + AsF_3 \rightarrow [PCl_4]^+[PF_6]^- + AsCl_3$$
$$SiCl_4 + SbF_3 \rightarrow SiCl_3F, SiCl_2F_2, SiClF_3$$
$$CCl_3 \cdot CCl_3 + SbF_3 \rightarrow CCl_2F \cdot CCl_2F$$
Arsenic trifluoride is very rapidly hydrolysed and is toxic, but can be easily and safely manipulated in a vacuum line. It would be preferred for the preparation of a high boiling fluoride, since arsenic trichloride (b.p. 130°) can be distilled off. Antimony trifluoride is preferred for making low boiling fluorides, which can be removed readily from antimony trichloride (b.p. 223°). It is often advantageous to add a small amount of chlorine or antimony pentachloride[54, 55], but this is, of course, not possible when the substrate is easily oxidized.

Arsenic and antimony trifluorides, though less strongly oxidizing than fluorine, can still be reduced by strong reducing agents. Fluorophosphines are obtained from the fluorides EF_3 and chloro- or iodo- phosphines with an electro-negative group attached to phosphorus, but phosphoranes result from many other chlorophosphines and phosphorus sulphides:

$$3CF_3PCl_2 + 2SbF_3 \rightarrow 3CF_3PF_2 + 2SbCl_3$$
$$3PhPCl_2 + 4SbF_3 \rightarrow 3PhPF_4 + 2Sb + 2SbCl_3$$
$$3R_3PS + 2SbF_3 \rightarrow 3R_3PF_2 + Sb_2S_3$$
$$Me_2P(S)P(S)Me_2 + 6SbF_3 \rightarrow 6Me_2PF_3 + 2Sb + 2Sb_2S_3$$
The potentiality of a fluorinating agent EF_n with respect to a chloride $E'Cl$ depends on the difference in free energies of formation per gram atom halogen ($\Delta G'/n$) of EF_n and ECl_n. The values in Table 22 show that antimony trifluoride is thermodynamically a better

[54] E. L. Muetterties and C. W. Tullock, *Preparative Inorganic Reactions* 2 (1965) 237.

[55] R. Schmutzler, *Inorg. Synth.* 9 (1967) 63, and in V. Gutmann (ed.), *Halogen Chemistry*, Academic Press, London (1967), Vol. 2, p. 31; A. L. Henne, *Organic Reactions* 2 (1944) 49; D. R. Martin, *Inorg. Synth.* 4 (1953) 134.

[56] H. J. Eméleus, P. M. Spaziante and S. M. Williamson, *Chem. Communs.* (1969) 768.

fluorinating agent than arsenic trifluoride ($\Delta G'/n$: SbF$_3$, about $+180$; AsF$_3$, $+217$ kJ mol^{-1}. Compare CF$_4$, 203; SiF$_4$, 238; NaF, 157; AgF, 75 kJ mol^{-1}). For the conversion of arsenic or antimony chlorides to fluorides, hydrogen fluoride, ammonium fluoride, or potassium fluorosulphonate have been used. Arguments similar to that above show that arsenic tribromide has potential as a brominating agent, e.g.

$$6PbO + 4AsBr_3 \rightarrow 6PbBr_2 + As_4O_6$$
The driving force for this reaction is in the formation of the strong As–O bonds from the weaker As–Br bonds (cf. Fig. 10).

Pseudohalides may be made by reactions similar to the halogenations described above. Thus arsenic trichloride reacts with silver cyanide to give the tricyanide As(CN)$_3$ (section 9.3). The radical (CF$_3$)$_2$NO$\cdot$, which in its reactions resembles a halogen, reacts with AsBr$_3$, AsI$_3$, BiBr$_3$, BiI$_3$ and BiOI with quantitative formation of the tris(trifluoromethyl-nitroxy)-derivatives [(CF$_3$)$_2$NO]$_3$E. The bismuth compound may also be made directly from metallic bismuth and (CF$_3$)$_2$NO$\cdot$. Arsenic trichloride can be converted into [(CF$_3$)$_2$NO]$_3$As by reaction with mercury(II) bistrifluoromethylnitroxide; with (CF$_3$)$_2$NO$\cdot$ in the presence of iodine, the partially substituted compound [(CF$_3$)$_2$NO]$_2$AsCl is obtained[56].

Solvent Properties

The conductivities of the halides AsF$_3$, AsCl$_3$, AsBr$_3$, SbCl$_3$ and SbBr$_3$ are markedly increased by substances which can donate halide ions, e.g. KF, Me$_4$NCl, TlBr, or accept them, e.g. SbF$_5$, FeCl$_3$, AlBr$_3$. Further, halide ions have very high mobilities in the liquid trihalides. This has led to suggestions[57] that the solvents ionize, e.g.

$$2AsX_3 \rightleftharpoons AsX_2^+ + AsX_4^-$$

From the conductivities of the pure solvents, the ionic products [EX$_2$]$^+$[EX$_4$]$^-$ must be $< 10^{-15}$ mol^2 l^{-2}. Evidence given in support of self-ionization is as follows (cf. ref. 133).

(a) The conductivity of a solution of ferric chloride in arsenic trichloride, to which a solution of tetramethylammonium chloride is added, reaches a minimum at the end point. Such conductimetric titrations can be made with a variety of halide donors and acceptors.

(b) Potentiometric titrations using silver–silver chloride electrodes can be made on similar systems.

(c) Solid compounds with EX$_4^-$ ions, e.g. [Me$_4$N][AsCl$_4$], can be isolated (see section 10.3). It has been suggested that certain solids (e.g. AsSbCl$_8$) may contain EX$_2^+$ ions. Structural determinations on some of these would be worthwhile.

(d) Complexes such as Tl(AlBr$_4$) can be prepared by precipitation from TlBr–SbBr$_3$ and AlBr$_3$–SbBr$_3$.

Though it is clear that ionic species are formed when some substances dissolve in arsenic and antimony halides, many halide transfer reactions could proceed by molecular mechanisms without requiring self-ionization of the pure solvent. More work is needed on species in solution.

The ready exchange of halogen between halides EX$_3$ and KX* provides a convenient method for the preparation of labelled EX$_3^*$ [58].

[58] M. F. A. Dove and D. B. Sowerby, in V. Gutmann (ed.), *Halogen Chemistry*, Academic Press, London (1967).

Formation of Mixed Halides

Although a number of mixed halides of phosphorus are known, the compounds of the heavier elements are much less easily isolated. The halides AsF_3 and $AsCl_3$ are immiscible below 19°C, but the ^{19}F magnetic resonance spectrum of a mixture of arsenic trichloride and an excess of arsenic trifluoride at room temperature shows three signals[59]. The strong absorption at 40.4 ppm (from $CFCl_3$) is assigned to AsF_3, and the weaker signals at 49 and 67.4 ppm are assigned to AsF_2Cl and $AsFCl_2$. Equilibrium constants for the exchange reactions can be found from the peak areas:

$$2AsF_3 + AsCl_3 \rightleftharpoons 3AsF_2Cl; \quad K \sim 5 \times 10^{-3}$$
$$2AsCl_3 + AsF_3 \rightleftharpoons 3AsFCl_2; \quad K \sim 5 \times 10^{-3}$$

Similar values are obtained from mass spectral studies. It has also been suggested that Raman spectra of mixtures of $AsCl_3$ and $AsBr_3$ show the presence of mixed halides $AsCl_2Br$ and $AsClBr_2$. Because of the rapid establishment of equilibria such as those above, it is probable that most mixed halides cannot be isolated as pure substances, but the compound SbI_2Br (m.p. 88°) is apparently obtained by the elimination of ethyl bromide from the organo-metallic compound $EtSbI_2Br_2$ (see section 14.3).

Reactions with Alcohols and Mercaptans

The trihalides react with alcohols, often in the presence of bases, or with sodium derivatives NaOR, to give arsenite and antimonite esters $E(OR)_3$ (see Table 31, p. 610)[60, 61]:

$$AsCl_3 + 3MeOH + 3Me_2NPh \rightarrow As(OMe)_3 + 3[Me_2NPhH]Cl$$
$$SbCl_3 + 3NaOSiEt_3 \rightarrow Sb(OSiEt_3)_3 + 3NaCl$$
$$SbCl_3 + 3Bu^tOH + 3NH_3 \rightarrow Sb(OBu^t)_3 + 3NH_4Cl$$
$$AsCl_3 + 3PhOH \rightarrow As(OPh)_3 + 3HCl$$
Halide esters, AsX_2Y, AsY_2X (X = hal; Y = OR) can be made similarly, or from the esters $E(OR)_3$ and alkyl or acyl halides:

$$AsCl_3 + 2NaOEt \longrightarrow AsCl(OEt)_2 + 2NaCl$$
$$AsCl_3 + EtOH \xrightarrow{CO_2} AsCl_2OEt + HCl$$
$$Sb(OEt)_3 + MeI \longrightarrow [SbMe(OEt)_3]I \rightarrow (EtO)_2SbI + EtOMe$$
$$As(OPr)_3 + MeCOCl \longrightarrow (PrO)_2AsCl + MeCOOPr$$
The halide esters can be detected in mixtures of AsX_3 and AsY_3 (X = hal; Y = OR). Nuclear magnetic resonance measurements show that the X and Y groups exchange rapidly at room temperature, but distribution of X and Y between possible species is not random, and formation of the halide esters AsX_2Y, AsY_2X is favoured. Several of these can be isolated as pure substances by distillation of appropriate mixtures of AsX_3 and AsY_3 (compare previous section). In mixtures of arsenic and antimony compounds, transfer of alkoxide to arsenic seems to be preferred:

$$AsCl_3 + Sb(OEt)_3 \rightarrow AsCl(OEt)_2 + SbCl_2OEt$$

[61] K. Moedritzer, *Inorg. Synth.* **11** (1968) 181.

Reactions with Amines

The trihalides react with secondary amines, with alkali-metal amides, or with compounds having silicon–nitrogen or tin–nitrogen bonds to give amido derivatives[62]:

$$AsCl_3 + 6Me_2NH \rightarrow As(NMe_2)_3 + 3[Me_2NH_2]Cl$$

$$SbCl_3 + 3LiNMe_2 \rightarrow Sb(NMe_2)_3 + 3LiCl$$

$$Et_2NSiMe_3 + AsCl_3 \rightarrow Et_2NAsCl_2 + Me_3SiCl$$

$$SbF_3 + 3Me_2NSnMe_3 \rightarrow Sb(NMe_2)_3 + 3Me_3SnF$$
Derivatives of bulky amines are often conveniently made by transamination:

$$As(NMe_2)_3 + Bu_2NH \rightarrow As(NBu_2)_3 + 3NMe_2H$$
Like the alkoxyhalides, most of the amidohalides, e.g. $AsX(NR_2)_2$, AsX_2NR_2, are stable with respect to reorganization and so can be isolated as pure compounds. An exception is $AsF(NMe_2)_2$ which easily reorganizes to AsF_2NMe_2 and $As(NMe_2)_3$. Mixtures of trisamido and trisalkoxy compounds give a random distribution of OR, NR_2 groups over all possible species[63].

TABLE 24. AMIDO DERIVATIVES

Properties of some amido compounds are given in Table 24, and their chemical reactions in Scheme 3. The amido compounds closely resemble the arsenite and antimonite esters (section 6.4). Compounds such as R_2AsNR_2 are important intermediates, since the As–N bonds can easily be broken by a variety of reagents.

Scheme 3. Amido compounds.[64]

Reaction scheme for Et$_2$AsNEt$_2$:

- AsCl$_3$ ⇌ (HCl / 2Et$_2$NH) Cl$_2$AsNEt$_2$
- Cl$_2$AsNEt$_2$ ⇌ (HCl / 2Et$_2$NH) ClAs(NEt$_2$)$_2$
- ClAs(NEt$_2$)$_2$ ⇌ (HCl or AsCl$_3$ / 2Et$_2$NH) As(NEt$_2$)$_3$
- Cl$_2$AsNEt$_2$ —EtMgBr→ Et$_2$AsNEt$_2$
- Et$_2$AsNEt$_2$ —H$_2$O→ (Et$_2$As)$_2$O
- Et$_2$AsNEt$_2$ —RMgX→ Et$_2$AsR
- Et$_2$AsNEt$_2$ ⇌ (HCl / 2Et$_2$NH) Et$_2$AsCl
- Et$_2$AsNEt$_2$ —2MeI→ Et$_2$AsI + [Me$_2$NEt$_2$] I
- Et$_2$AsNEt$_2$ —LiAlH$_4$→ Et$_2$AsH

Reaction scheme for As(NMe$_2$)$_3$:

- As(NMe$_2$)$_3$ —CS$_2$→ As(SCSNMe$_2$)$_3$
- As(NMe$_2$)$_3$ —CO$_2$→ As(NMe$_2$)$_2$OCONMe$_2$
- As(NMe$_2$)$_3$ —RNCY (Y = O, S)→ As(RNCYNMe$_2$)$_3$
- As(NMe$_2$)$_3$ —(CH$_2$OH)$_2$→ CH$_2$–O / CH$_2$–O AsNMe$_2$
- As(NMe$_2$)$_3$ —BrCN→ AsBr(NMe$_2$)$_2$ + Me$_2$NCN
- As(NMe$_2$)$_3$ —Cl$_2$, SbCl$_5$→ [(Me$_2$N)$_3$AsCl] [SbCl$_6$]
- As(NMe$_2$)$_3$ —Ni(CO)$_4$→ (Me$_2$N)$_3$AsNi(CO)$_3$
- As(NMe$_2$)$_3$ + cyclohexanone → 1-(dimethylamino)cyclohexene (NMe$_2$)

Arsenic trihalides and primary amines give imido-derivatives (Table 25). Some of these may also be made by transaminations.

- AsCl$_3$ —EtNH$_2$→ Cl$_2$AsNHEt —→ (ClAsNEt)$_n$
- AsCl$_3$ —EtHNSiMe$_3$→ (ClAsNEt)$_n$
- 4AsCl$_3$ —18MeNH$_2$→ As$_4$(NMe)$_6$
- 4As(NMe$_2$)$_3$ —6BuNH$_2$→ As$_4$(NBu)$_6$
[64] (a) A. Tzschach and W. Lange, Z. anorg. allgem. Chem. 326 (1964) 280; (b) H.-J. Vetter and H. Nöth, ibid. 330 (1964) 233; (c) G. Oertel, H. Malz and H. Holtschmidt, Chem. Ber. 97 (1964) 891; R. H. Anderson and R. H. Cragg, Chem. Communs. (1970) 425; H. Weingarten and W. A. White, J. Org. Chem. 31 (1966) 4041.

The compounds $(XAsNR)_n$ are slightly volatile liquids or solids, which in benzene show molecular complexities between 2 and 4. The methyl derivative ClAsNMe is trimeric in the solid, but it is not in all cases clear whether the non-integral values obtained for n are due to decompositions or to equilibria between various species. The butyl compounds seem to show lower values for n than compounds with less bulky substituents.

<div align="center">TABLE 25. IMIDO DERIVATIVES</div>

The imido compounds As$_4$(NR)$_6$ (these formulae are shown by molecular weights in benzene) have the same structure as the oxide As$_4$O$_6$ [65] (section 6.1) or the phosphorus imide P$_4$(NMe)$_6$. The phosphorus and arsenic compounds react differently with methyl iodide. Whereas the phosphorus compound gives a simple adduct, the arsenic derivative loses one NMe group:

$$As_4(NMe)_6 + 3MeI \rightarrow As_4(NMe)_5I_2 + Me_4NI$$
The product can be further degraded with methyl iodide or arsenic triiodide. Similar progressive degradation of the As$_4$N$_6$ cage is effected by hydrogen chloride:

$$As_4(NMe)_6 \xrightarrow{3HCl} As_4(NMe)_5Cl_2 \xrightarrow{3HCl} 4/3(MeNAsCl)_3 \xrightarrow{12HCl} 4AsCl_3$$
Attempts to make the t-butyl analogue of As$_4$(NMe)$_6$ yielded instead the compound (Bu^{t}NHAsNBu^t)$_2$, m.p. 80–85°C, which is assumed to have the cyclic structure [1].
[1]

The antimony compounds Sb$_4$(NR)$_6$ (R = Ph, 4-MeC$_6$H$_4$) are obtained from alkoxy-derivatives and amines:

$$4Sb(OEt)_3 + 6RNH_2 \rightarrow Sb_4(NR)_6 + 12EtOH$$
The reaction is reversible and the equilibrium is shifted from left to right by removal of the volatile ethanol.

[65] J. Weiss and W. Eisenhuth, *Z. Naturforsch.* **22b** (1967) 454; *Z. anorg. allgem. Chem.* **350** (1967) 9.

5.4. OXIDE HALIDES

The trihalides of arsenic, antimony and bismuth are readily hydrolysed and, if they are to be kept pure, are best handled in a drybox or vacuum line. The hydrolysis is usually reversible, and the halides, e.g. arsenic triiodide or bismuth trifluoride, can often be recovered quantitatively by precipitation from concentrated aqueous solutions of hydrogen halides.

Arsenic trichloride is not miscible with water at $AsCl_3:H_2O$ mole ratios of $> 1:10$. The Raman spectra[66] of concentrated ($As:H_2O$ between 0.1 and 0.05) solutions of arsenic trichloride in water suggest the formation of the complex $H_2O,AsCl_3$, which is probably in equilibrium with ionic species:

$$H_2O,AsCl_3 + H_2O \rightarrow H_3O^+ + [HOAsCl_3]^-$$
Evidence for compounds with less than three chlorine atoms per arsenic is not very strong, but small concentrations of such compounds may be present in some solutions of arsenic trichloride. At $AsCl_3:H_2O$ ratios of about 1:20, As^{III} oxide precipitates; the species in solution at this stage is the arsenious acid $As(OH)_3$ (section 6.3).

Arsenic trioxide dissolves in arsenic trifluoride to form homogeneous solutions[67], the viscosity of which increases dramatically with increasing oxide content (e.g. from

$$Z = O, NMe$$

$$(e) \qquad (m) \qquad (b)$$
10^{-3} kg m^{-1} s^{-1} for AsF_3 to 10^4 kg m^{-1} s^{-1} for $5AsF_3.6As_2O_3$ at 20°C). The ^{19}F n.m.r. spectra of fluoride–oxide mixtures show a random mixture of polymeric species with end (e), middle (m), and branching (b) groups, as well as the free AsF_3 (n). Individual species cannot be isolated. The activation energies for fluorine exchange and for viscous flow, obtained from the temperature dependence of the ^{19}F n.m.r. spectra and the viscosity, are the same, suggesting that these processes have the same mechanism. Similar polymeric species have been postulated for $As_4(NMe)_6–AsF_3$ mixtures. In this case, distribution of polymeric species is not random. Proportions of end and middle groups are more than expected, showing that chains predominate. Equilibrium constants (27°C) are as follows:

Z	$K_1 = nm/e^2$	$K_2 = eb/m^2$	K for random distribution 0.33
O	0.33	0.31	
NMe	0.1	0.05	

Polymeric species are also shown by cryoscopic, ebullioscopic, and magnetic resonance measurements on $As_2O_3–AsCl_3$, $As_2O_3–AsBr_3$, $As_2O_3–As(OMe)_3$ or $As_2O_3–As(NMe_2)_3$ mixtures[68]. Arsenic oxide fluoride AsOF has been reported as a product from the reaction

[66] T. M. Loehr and R. A. Plane, *Inorg. Chem.* **8** (1969) 73.

of arsenic trioxide and trifluoride in a sealed tube at 320° but has not been fully characterized[69].

Water is a non-electrolyte in antimony trichloride.[70] With excess water, however, antimony halides give oxide halides. The compounds SbOX have structures with sheets, $[Sb_6O_6Cl_4]^{2+}$, of antimony atoms linked by oxygen and halogen bridges, interleaved with layers of halide ions. Bismuth oxide halides (Table 26) similarly have layer structures[71].

Within a layer, each bismuth has four oxygen and four chlorine neighbours, but in the chloride and bromide, the bonds to halogens in adjacent layers are little longer than those to halogens within the layers. The low solubility of the oxide halides means that they are precipitated when solutions of the trihalides EX_3 in concentrated acids HX are diluted. A series of complex oxide halides of bismuth can be made by fusing the compounds BiOX with halides of Groups I and II. These have tetragonal structures in which metal–oxide layers (MO_2M) are interleaved with halide layers (X). Several repeating sequences parallel to the *c*-axis have been found, and some examples are as follows. More complicated sequences are also known[71].

$$\ldots \{(MO_2M)X\}(MO_2M)X \ldots \qquad LiBi_3O_4Cl_2,\ Cd_2Bi_2O_4Br_2$$
$$\ldots \{(MO_2M)XX\}(MO_2M)XX \ldots \qquad BiOX$$
$$\ldots \{(MO_2M)X(MO_2M)XX\} \ldots \qquad SrBi_3O_4Cl_3$$
$$\ldots \{(MO_2M)X(MX)X\}(MO_2M)X \ldots Ca_{1.25}Bi_{1.5}O_2Cl_3$$
5.5. LOWER HALIDES

All the elements, arsenic, antimony and bismuth, form compounds in which the formal oxidation state of the Group V element is less than three. Arsenic forms an iodide, As_2I_4,

[69] H. J. Eméleus and M. J. Dunn, *J. Inorg. Nucl. Chem.* **27** (1965) 269.
[70] J. R. Atkinson, E. C. Baughan and B. Dacre, *J. Chem. Soc.* A (1970) 1377.
[71] M. Edstrand, *Acta chem. scand.* **1** (1947) 178. Most of the structural work on oxide halides has been by L. G. Sillén. It is summarized in *Naturwissenschaften* **28** (1940) 396; **30** (1942) 318, and by A. F. Wells in *Structural Inorganic Chemistry*, 3rd edn., Oxford (1962), pp. 390, 673.

like the corresponding phosphorus compound, but it disproportionates rather easily. The antimony compound Sb_2I_4 is even more unstable. Bismuth, in common with other heavy metals, forms metal clusters, several of which have been characterized by spectroscopic and crystallographic studies.

The Compounds E_2I_4

When arsenic and iodine are heated in a sealed tube at 260°C in octahydrophenanthrene, red crystals of the iodide, As_2I_4 (m.p. 137°C), separate. These can be recrystallized from carbon disulphide at -20°C, and are stable up to 150°C in an inert atmosphere. As_2I_4 is readily oxidized. It disproportionates easily, e.g. in warm carbon disulphide and on hydrolysis. Disproportionation is quantitative at 400°C:

$$3As_2I_4 \rightarrow 4AsI_3 + 2As$$
At lower temperatures, and in carbon disulphide at 20°C, there is evidence for formation of solids with approximate composition As_4I [72].

The unstable iodide Sb_2I_4 can be detected by e.m.f. or vapour pressure measurements on solutions of antimony in molten antimony triiodide at 230°C, but only antimony and antimony triiodide are obtained when the solutions are cooled.

The Compounds BiX

Early work suggesting formation of compounds BiX_2 has been discounted[73]. Formation of the species BiX can be shown in the vapour in equilibrium with Bi–BiX_3 mixtures and consistent thermodynamic data has been obtained.

TABLE 27. THERMODYNAMIC DATA FOR HALIDES BiX [a]

	ΔH_{298} for reaction $Bi(s) + \frac{1}{3}BiX_3(g) = BiX(g)$ (kJ mol^{-1})	$H^\circ_{298} - H^\circ_0$ (kJ mol^{-1})	S° (J mol^{-1})	Consolute temperature[b] (K)
BiCl	117	9.8	263 (298 K)	1053
BiBr	102.5	10.0	301 (935 K)	811
BiI	101.7	10.5	307 (913 K)	731

The phase diagrams of Bi–BiX_3 systems show in each case a region where two liquids are in equilibrium over a large range of temperature and composition. These liquids become miscible only at a high temperature (Table 27). For Bi–$BiCl_3$ (Fig. 12) the two liquids are in equilibrium with a solid phase of composition approximately BiCl at about 320°C, but

[72] M. Baudler and H.-J. Stassen, *Z. anorg. allgem. Chem.* **343** (1966) 244; **345** (1966) 182.
[73] J. D. Corbett, *J. Am. Chem. Soc.* **80** (1958) 4757.

equilibrium is reached only very slowly. The solid phase has been isolated[74] as orthorhombic crystals, by heating bismuth–bismuth trichloride mixtures to 325°C and cooling them during several weeks to 270°C, and removing excess bismuth trichloride by sublimation, or
FIG. 12. Phase diagram for Bi–BiCl$_3$ from *J. Phys. Chem.* **63** (1959) 230.

extraction with benzene. The diamagnetic "bismuth monochloride" which remains has a structure with bismuth clusters (Fig. 13) and two different complex anions. It is thus $(Bi_9^{5+})_2$ $[BiCl_5]_4^{2-}[Bi_2Cl_8]^{2-}$ or $BiCl_{1.167}$. It is stable in vacuum up to 200°C, but disproportionates
FIG. 13. Idealized (D_{3h}) structure for the Bi_9^{5+}, a trigonal prism with further bismuth atoms above each face. In solid $BiCl_{1.167}$ the cluster is considerably distorted by the unsymmetrical environment of the anions. (Average distances in pm.)

[74] A. Hershaft and J. D. Corbett, *Inorg. Chem.* **2** (1963) 979; R. M. Friedman and J. D. Corbett, *Chem. Communs.* (1971) 422.

at higher temperatures. It is readily hydrolysed to the oxide chloride, and it disproportionates in the presence of ligands which complex strongly with bismuth trichloride.

There are apparently related bismuth clusters in the compounds Bi$_5$[AlCl$_4$]$_3$ and Bi$_8$[AlCl$_4$]$_2$, which are obtained by reduction of a mixture of bismuth and aluminium trichlorides with bismuth in sodium tetrachloraluminate as solvent. Electronic spectra show that the same bismuth clusters Bi$_5^{3+}$ and Bi$_8^{2+}$ are present in other solvents of low pCl, e.g. 3NaCl/AlCl$_3$ (eutectic) or KCl/2ZnCl$_2$; in very dilute solutions of bismuth in bismuth trichloride, which have a higher pCl, Bi$^+$ (presumably solvated) and Bi$_3^+$ predominate. Species with bismuth in low oxidation states are listed in Table 28, together with details of their characteristic spectra. Spectra of Bi$^+$ show a similar pattern of absorptions in various (molten salt) solvents. They have been interpreted in terms of p–p transitions between various states of the p^2 configuration, modified by the crystal field of the anions,

TABLE 28. BISMUTH CLUSTERS IN HALIDE MELTS

[b] N. J. Bjerrum, C. R. Boston and G. P. Smith, *Inorg. Chem.* **6** (1967) 1162, 1172.
[c] J. D. Corbett, *Inorg. Chem.* **7** (1968) 198.
[d] N. J. Bjerrum and G. P. Smith, *Inorg. Chem.* **6** (1967) 1968.

e.g. [AlCl$_4$]$^-$ or [ZnCl$_4$],$^{2-}$ by arguments similar to those used for the interpretation of d–d transitions. Stable clusters seem to be those with a maximum number of nearest neighbours. The distribution of species can be rationalized by considering the effects of counter-ions. Thus Bi$_8^{2+}$ is found with the compact ions [AlCl$_4$]$^-$ or [Al$_2$Cl$_7$]$^-$ but Bi$_5^{3+}$, with a higher charge density, requires larger, more polarizable anions, e.g. BiCl$_5^{2-}$ or Bi$_2$Cl$_8^{2-}$. If the s electrons are assumed not to take part in the bonding (see p. 577), the clusters are electron-deficient, and molecular orbital schemes like those for boron hydrides or carboranes give satisfactory accounts of the observed electronic spectra[75a].

Coloured solutions obtained by oxidizing antimony with peroxodisulphate in fluorosulphonic acid, or with arsenic pentafluoride in liquid sulphur dioxide, may contain antimony clusters[75b].

6. OXIDES E$_2$O$_3$

Extraction processes for arsenic, antimony and bismuth, using oxidizing conditions, yield the oxides E$_2$O$_3$, which sublime away from involatile ash. They can be purified by

[75] (a) J. D. Corbett and R. E. Rundle, *Inorg. Chem.* **3** (1964) 1408; (b) R. C. Paul, K. K. Paul and K. C. Malhotra, *Chem. Communs.* (1970) 453; (c) P. A. W. Dean and R. J. Gillespie, *ibid.*, p. 853.

further sublimations, by recrystallization from hydrochloric acid, or by conversion to the anhydrous chlorides which can be distilled before hydrolysis back to the oxides.

6.1. PROPERTIES AND STRUCTURES

There is little recent structural work on these compounds, but it is clear that all three oxides E_2O_3 exist in several modifications (Scheme 4).

The molecules As_4O_6, with a structure [2] like that of P_4O_6, are found in the cubic form of the solid (arsenolite), in nitrobenzene solution and in the vapour below 800°C. At 1800° the vapour consists of molecules As_2O_3. Bond lengths and angles in As_4O_6 are given in Table 29.

[k] Ref. 52.

There are apparently[76] two monoclinic forms of arsenious oxide (claudetite I and II), in which alternate arsenic and oxygen atoms are linked into sheets making open macromolecular structures (cf. orpiment, p. 613). The glassy form of arsenious oxide is similar, but the macromolecular structure is irregular. In all the structures, pyramidal AsO_3 groups

[76] K. A. Becker, K. Plieth and I. N. Stranski, *Progr. Inorg. Chem.* **4** (1962) 1.

share oxygen atoms, but the linking of the pyramids is different in the various modifications. The cubic and monoclinic forms have very similar stabilities with respect to the elements. Thus formation of cubic arsenolite by crystallization from aqueous solutions appears to be dominated by kinetic factors, since claudetite is the thermodynamically stable form. Interconversion of various forms of As^{III} oxide is slow, since rearrangements with breaking of many As–O bonds are involved. Changes are catalysed by water; presumably As–O bonds are protonated and the AsOH units can reform into a new pattern more easily than the original AsOAs units[76].

The molecules Sb_4O_6 are found in the cubic senarmontite and in the vapour below 1000°C. In the orthorhombic valentinite, alternate antimony and oxygen atoms are linked into bands (cf. sheets in claudetite), making a macromolecular structure. The cubic form appears to be the more stable below 570°C, but orthorhombic valentinite is metastable for long periods[77]. As with As^{III} oxide, the macromolecular structure has the higher density. The powder obtained by precipitation from a neutral aqueous solution is valentinite; that from aqueous sodium carbonate is mainly valentinite, with a small amount of senarmontite. Again, kinetic factors seem to be important in determining which modification is formed. The slow interconversions between the forms are consistent with transformations between molecular and macromolecular structures.

FIG. 14. (a) The co-ordination polyhedra in α-Bi_2O_3. (b) The fluorite structure of δ-Bi_2O_3 (one-quarter of the oxygen atoms are missing).

Bi^{III} oxide is polymorphic[78]. The most stable modification at 20°C (α-Bi_2O_3) has a complex monoclinic structure with layers of bismuth atoms and oxygen atoms parallel to y and z. There are two sorts of bismuth (Fig. 14). One (Bi_I) has five oxygen neighbours at the

[78] G. Gattow and H. Schröder, *Z. anorg. allgem. Chem.* **318** (1962) 176; G. Gattow and D. Schütze, *Ibid.* **328** (1964) 44.

corners of a distorted octahedron with the bismuth lone pair occupying the sixth corner [3]. Two more oxygen atoms are weakly bound. The other sort of bismuth (Bi_{II}) has six oxygen neighbours at the corners of an octahedron, distorted to suggest that here also the lone-pair affects the stereochemistry. The co-ordination polyhedra are linked to give tunnels parallel to z into which the Bi^{III} lone pairs project.

The cubic δ-form of Bi_2O_3, stable above $717°C$, has a fluorite defect structure in which oxygen vacancies are randomly distributed; each bismuth atom has eight neighbours. The relation between the macromolecular structure of δ-Bi_2O_3 and the molecular structures of As^{III} and Sb^{III} oxides is shown in Fig. 14b. If the oxygen at the centre of the cube is missing and the surrounding atoms are drawn in regularly, discrete E_4O_6 molecules result.

The β-modification and several oxygen-rich forms (Scheme 4) are related to the high temperature δ-form. Some of the oxygen-rich forms are stabilized by small amounts of elements such as B, Al, Tl, Si, Ge, P, As, V, Mn, Fe, Co, and so may be double oxides pMO_n, qBi_2O_3. For example, the bismuth germanium oxide $Bi_{12}GeO_{20}$ has a body-centred structure (space group $I23$)[79]. Germanium atoms make four bonds to oxygen at the corners of a tetrahedron and bismuth atoms are like the Bi_I atoms of α-Bi_2O_3. Five oxygen atoms form an incomplete octahedron [3] (Bi–O, 207–264 pm) and two further oxygen atoms are more weakly bound (Bi–O, 308, 317 pm). The oxide is strongly optically active and piezoelectric along the threefold axes. Double oxides may be made by fusing Bi^{III} oxide and oxides of Ca, Sr, Ba, Cd or Pb. These have $(BiO)_n$ layers, as in the oxide halides (p. 600), interleaved with M^{II} ions. Other double oxides have formulae $M^1M_4^2Bi_6O_{18}$, where M^1 = Na, K, Ca, Sr, Ba, Pb, and M^2 = Ti, Nb, Ta.

6.2. REACTIONS

The oxides are starting materials for the preparation of many other compounds of arsenic, antimony and bismuth. Reactions of As^{III} oxide are shown in Scheme 5; Sb^{III}

SCHEME 5. Reactions of As^{III} oxide.
oxide is similar. Bi^{III} oxide is more basic. It is insoluble in alkali but dissolves in acid to give bismuth salts (section 8). As^{III} and Sb^{III} oxides are used in analytical chemistry as mild

[79] S. C. Abrahams, P. B. Jamieson and J. L. Bernstein, *J. Chem. Phys.* **47** (1967) 4034.

reducing agents, and in preparative chemistry for the conversion of transition metal halides to oxyhalides[80]:

$$3MX_n + E_2O_3 \rightarrow 3MX_{n-2}O + 2EX_3$$
The volatile halide EX_3 is readily removed. In this reaction, Sb^{III} oxide has been most frequently used: the reaction is of wide application. Thiohalides may be made, using Sb^{III} sulphide.

As^{III} oxide has been used as a "fining agent" in glass manufacture. Small quantities may be incorporated into the Si–O frameworks, and redox reactions between As^{III} and As^V assist in the control of small bubbles of oxygen in the molten glass. Under certain conditions, As^{III} oxide may be a useful decolorizer by assisting in redox reactions involving transition metal (e.g. iron) oxide impurities[81].

6.3. AQUEOUS CHEMISTRY: ARSENITES AND ANTIMONITES

As^{III} oxide is not very soluble in water (0.104 mol As_2O_3 per kg water at 25°C). The solubility decreases with increasing HCl concentration, becoming a minimum (0.075 mol per kg water) at about 3 M HCl and then increasing[82]. Presumably at high HCl concentrations species with As–Cl bonds are formed (section 10.3). In neutral or acid solution, the predominant species is probably $As(OH)_3$. On crystallization, the oxide As_2O_3 is obtained.

TABLE 30. RAMAN SPECTRA OF SOLUTIONS OF ARSENIOUS ACID (cm^{-1})[a]

$As(OH)_3$	C_{3v}	ν_1, 710(a_1); ν_3, 655(e)

AsO_3^{3-}	C_{3v}	ν_1, 752(a_1); ν_3, 680(e); $\nu_{2,4}$ 340

[a] T. M. Loehr and R. A. Plane, *Inorg. Chem.* 7 (1968) 1708.

Samples of As_2O_3, which have been precipitated from HCl and sublimed, are suitable for use as a primary standard in quantitative analysis. As^{III} oxide is much more soluble in basic solutions, probably giving species $[AsO(OH)_2]^-$, $[AsO_2(OH)]^{2-}$ and AsO_3^{3-}, but not AsO_2^- (Table 30). There seems to be no evidence for formation of polymerized species, e.g. $As_2O_5^{4-}$, $As_3O_6^{3-}$, in basic solutions for As^{III} concentrations of 0.6–5 M. As–O stretching absorptions appear at 750–790 cm^{-1} and As–OH absorptions vary from 710 cm^{-1} in $As(OH)_3$ to 570 cm^{-1} in $[AsO(OH)_2]^-$. The Raman spectra show that arsenious acid does not have a structure like phosphorous acid $HPO(OH)_2$ with an As–H bond. The difference between phosphorus and arsenic is consistent with the reluctance of arsenic to reach oxidation state V and with the weaker As–H, compared with P–H, bonds. Proton n.m.r. spectra of $As(OH)_3$ show only one peak, indicating that all the protons are equivalent on the time scale of the experiment. Arsenious acid is weak (pK 9.2)[38], in accord with Pauling's rules for the structure $As(OH)_3$.

[82] A. B. Garrett, O. Holmes and A. Laube, *J. Am. Chem. Soc.* 62 (1940) 2024; K. H. Gayer and A. B. Garrett, *ibid.* 74 (1952) 2353.

When alkaline solutions of As^{III} oxide are evaporated, salts known as arsenites are obtained. These are not very well characterized, but structures appear to consist of metal ions and pyramidal AsO_3 groups linked into sheets or chains like those of the macromolecular forms of As^{III} oxide[83]. Yellow silver arsenite (contrast the arsenate which is brown) and copper arsenite (Scheele's green) may be precipitated from neutral solutions. Sodium arsenite has been used as an insecticide in cattle and sheep dips, as a long-lasting herbicide, and as a fungicide[81].

Sb^{III} oxide is very slightly soluble in water and dilute acid (3×10^{-5} mol Sb_2O_3 per kg water at 25°C) and rather more soluble in alkali (5×10^{-4} mol Sb_2O_3 per kg 0.1 M NaOH)[82]. The species in solution are not well established, but the following data have been given[38] from solubility measurements:

	$\log K$
$\frac{1}{2}Sb_2O_3 + \frac{3}{2}H_2O \rightarrow Sb(OH)_3$	~ -4
$\frac{1}{2}Sb_2O_3 + OH^- + \frac{3}{2}H_2O \rightarrow [Sb(OH)_4]^-$	-2.06
$\frac{1}{2}Sb_2O_3 + H^+ \rightarrow SbO^+ + \frac{1}{2}H_2O$	-3.11

Antimonites are not well characterized. The compounds MSb_2O_4 (M = Mg, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}) and $NiAs_2O_4$ are isostructural with the lead oxide Pb_3O_4.

6.4. ARSENITE AND ANTIMONITE ESTERS

The preparation of these compounds has been described in section 5.3. Other routes to them include the following.

(a) Transesterification:

$$As(OEt)_3 + ROH \rightarrow As(OR)_3 + 3EtOH$$
(b) From oxides and alcohols. The water is removed by a drying agent such as calcium oxide or as an azeotrope. The method is not suitable for the more volatile esters because the water cannot be satisfactorily removed by distillation:

$$As_2O_3 + 6ROH \rightarrow 2As(OR)_3 + 3H_2O \qquad (R \text{ alkyl, aryl})$$
(c) By isomerization of alkylarsonates (section 14.4). This reaction is the reverse of the Arbuzov reaction, and the contrast between arsenites and phosphites is striking:

$$MeAsO(OMe)_2 \rightarrow As(OMe)_3 \quad (52\%)$$
Mixed esters $E(OR^1)_n(OR^2)_{3-n}$ may be made by transesterification or from halide esters $E(OR^1)_nCl_{3-n}$ and alkoxides $NaOR^2$. The mixed esters tend to reorganise at high temperatures:

$$3Sb(OBu)(OEt)_2 \xrightarrow{150\ °C} Sb(OBu)_3 + 2Sb(OEt)_3$$
The arsenite and antimonite esters are colourless volatile materials (Table 31), soluble in organic solvents and very readily hydrolysed by water to alcohols and oxides E_2O_3.

[83] J. W. Menary, *Acta Cryst.* **11** (1958) 742.

They are assumed to have the C_{3v} configuration. At 220°C, tricyclohexyl antimonite decomposes giving $C_6H_{11}^{\cdot}$ and $C_6H_{11}O^{\cdot}$ radicals[84].

Thioesters $E(SR)_3$ and halide thioesters $EX(SR)_2$, $EX_2(SR)$ may be made from mercaptans by methods like those used for analogous oxygen compounds[60]. As^{III} *NN*-diethyl-dithiocarbamate $As(S_2CNEt_2)_3$, from arsenic trichloride and sodium diethyl dithiocarbamate, has a structure in which each arsenic atom makes three bonds (As–S, 235 pm) at 90°, and three longer bonds (As–S, 280–290 pm), so that the configuration round arsenic is that of a distorted antiprism[85].

The antimony compounds react with alkoxides NaOR to give the derivatives $Na^+[Sb(OR)_4]^-$. With Grignard reagents, the organometallic compounds R_3E are obtained. Arsenite and antimonite esters may be oxidized by bromine (section 12.4).

The stereochemical consequences of the lone pair are of interest in the compounds $M^+[E(OR)_4]^-$, which may be compared with the halide complexes described in section 10.3.

Potassium tartratoantimonite(III) (tartar emetic) is one of the commonest and most useful compounds of antimony and often the best source of Sb^{III} ions in solution. The older name for this compound, potassium antimonyl tartrate, is misleading because it implies SbO^+ ions, for which there is no evidence. In the d- and racemic tartrates (Table 32), both hydroxyl and carboxyl groups of the tartrate are bound to the antimony to make dimeric anions (structure [6]): hydrogen-bonded water molecules and cations fill the remaining space. An acid solution is obtained when potassium tartratoantimonite is dissolved in water. The Hg^{II} salt is precipitated from aqueous solutions: in alkali it disproportionates to Hg^0 and antimonate(V) [87].

6.5. BISMUTH–OXYGEN SPECIES IN SOLUTION

Bismuth hydroxide dissolves in acid, giving solutions which contain Bi^{III} ions. Such solutions remain clear only at high acid concentrations. As the hydrogen ion concentration is reduced, oxy-salts are precipitated. Before precipitation occurs, a series of polymeric cations can be detected in solution. The best characterized ion is $[Bi_6(OH)_{12}]^{6+}$, which has a structure (Fig. 15) like $Ta_6Cl_{12}^{2+}$ with a Bi_6 octahedron joined by oxygen bridges. The Bi–Bi distance is 370 pm (cf. 307, 353 in the metal) and the shortest Bi–O distance is 233 pm. The totally symmetric band in the Raman spectrum at 177 cm^{-1} is more intense than that at 450 cm^{-1}. It has been argued that, if the intensity of the Raman bands must be

[86] A. C. Skapski, *Chem. Communs.* (1966) 10; I. Hansson, *Acta chem. scand.* 22 (1968) 509.

[87] E. Chinoporos and N. Papathanasopoulos, *J. Phys. Chem.* 65 (1961) 1643.

attributed only to Bi–O bonds, the mode involving mainly stretching (that with higher energy) should be more intense than the mode involving mainly bending, and that the intensity of the low energy absorption must thus be attributed to Bi–Bi interactions.
FIG. 15. The ion $[Bi_6(OH)_{12}]^{6+}$.

7. SULPHIDES, SELENIDES AND TELLURIDES

Sulphides of arsenic and antimony were used as pigments for centuries. With the development of organic dyes, their importance decreased, but recently interest in the compounds of antimony and bismuth with the Group VI elements has revived. The structures of the sulphides, selenides and tellurides show an interesting gradation from the small molecules of the arsenic sulphides to the chain-like molecules of the antimony compound Sb_2S_3 and the sheet-like molecules of bismuth selenide and telluride.

7.1. PREPARATION

The compounds may be made fusing together stoichiometric quantities of the elements in sealed quartz tubes at 500–900°C. Selenides and tellurides are almost always made in this way, and very pure elements are available. Crystals usually form as the tubes are cooled. Sometimes, for example, with As_2Se_3, the product is amorphous; in this case crystals may be obtained by slow sublimation at 330°C. Realgar, As_4S_4, may be recrystallized from carbon disulphide or benzene.

The compounds E_2X_3 (X = S, Se, Te) may also be obtained by heating the oxide with the element X:

$$2As_2O_3 + 9S \rightarrow 2As_2S_3 + 3SO_2$$
The amorphous sulphides may be made by precipitation from acidified solutions of E^{III} with hydrogen sulphide. This precipitation is quantitative at pH 1–2.

7.2. STRUCTURES

Realgar, As_4S_4, is molecular in both the solid and the vapour: the dimensions of the molecule [7] are given in Table 33. Above 550°C some dissociation to As_2S_2 is observed. α-Dimorphite, As_4S_3, has a structure [8] like the phosphorous compounds P_4S_3, P_4Se_3. Orpiment vapour consists of molecules As_4S_6, with the same structure [2] as As_4O_6. In

[e] S_I within spirals, S_{II} between spirals.

the monoclinic solid, alternate arsenic and sulphur atoms, instead of forming oligomers as in realgar, form spirals (parallel to c) linked into sheets (parallel to 010) similar to, but not identical with, those in claudetite. Each arsenic is bound to three sulphur neighbours, making an AsS_3 pyramid with bond angles at As considerably less than in the vapour. Each sulphur makes two bonds to arsenic: the sulphur atoms within (S_I) and between (S_{II}) the spirals are inequivalent. Arsenic selenide is similar, but in arsenic telluride[89], though there are again chains linked into sheets, half the arsenic atoms are octahedrally co-ordinated by tellurium {Te–As (3 co-ordinate) 274; Te–As (6 co-ordinate) 286 pm}.

[7]   [8]
The stibnite structure, adopted by Sb_2S_3, Sb_2Se_3 and Bi_2S_3 (and Bi_2Se_3 at high pressure) consists of a complex network (Fig. 16). The units (i) are linked into infinite bands, as in (ii), and the bands are linked as in (iii) and (iv). Internuclear distances are given in Table 34. All five atoms in unit (i) are inequivalent. It is interesting that one type of antimony atom (see arrows) has a square pyramidal environment, with the antimony slightly below the base of the square. Compare structure [3]. This is the configuration predicted by assuming sp^3d^2 hybridization of orbitals on antimony, with a lone pair occupying one co-ordination position. Antimony has this stereochemistry in several ternary sulphide minerals and in pentaphenylantimony (section 14.1). The bond angles at antimony are very close to 90° as in other compounds with non-metals.

Fig. 17. The structure of bismuth telluride.

In bismuth telluride the molecules are infinite sheets. Atoms are in layers, in an extremely elongated rhombohedral arrangement shown in plan and elevation in Fig. 17. The molecules are perpendicular to the principal axis and weak forces hold them together (compare the bond lengths in Table 35). Bismuth selenide and antimony telluride have similar structures.

7.3. PROPERTIES

The sulphides, selenides and tellurides are highly coloured solids. Some of their physical properties are given in Table 36.

As^{III} sulphide and selenide, like As^{III} oxide, readily form glasses if samples of the liquids are quenched, and some of these glasses are important commercially. The compounds of antimony and bismuth form glasses less readily[90]. Extensively glassy regions are also observed in the systems Si(or Ge)–As–Te and Ge–Sb–Se: the glassy regions are more extensive in the silicon than in the germanium system. The glasses, which have high softening points (up to 500°C), are of some importance, since some are transparent over a large part of the infrared spectrum. The molecular species in these glasses are not very well established[90].

The solids E_2X_3 are semiconductors with energy gaps which decrease in the series; for a given X, arsenic > antimony > bismuth compound; for a given E, sulphide > selenide > telluride. Either n- or p-type properties may be obtained by controlled deviations from exact stoichiometry. For bismuth telluride an excess of bismuth gives p-type properties, perhaps because some bismuth atoms occupy tellurium sites, and an excess of tellurium gives n-type properties. Lead, as impurity, gives p-type, and copper, silver and bromine

[90] H. Krebs, *Angew. Chem. Int. Edn. Engl.* 5 (1966) 544.

n-type, semiconductivity. As first obtained from the melt, bismuth telluride is slightly non-stoichiometric with an excess of bismuth. Replacement of tellurium by sulphur or selenium gives substances of composition $Bi_2Te_{3-x}X_x$ (X = S, Se). As x increases from 0 to 1, the X atoms first occupy Te_{II} sites (note the decrease in $Bi-X_{II}$ distance in Table 35), leading to a tightening of the structure, an increase in the bond angles (e.g. $\angle BiSBi$ 90° in Bi_2Te_2S), and an increase in the energy gap. As x increases further, Te_I atoms are replaced and the energy gap decreases. Bismuth atoms cannot now occupy the (smaller) anion sites, and so the substance changes to an n-type semiconductor. Replacement of bismuth by antimony is also possible, and solid solutions are stable over considerable composition ranges. Up to 45% of the antimony atoms in Sb_2Te_3, and up to 25% of the bismuth atoms in Bi_2Te_3, can be replaced by indium. The antimony compounds remain p-type, but the Bi_2Te_3 compounds become n-type semiconductors[91].

Systems involving In, Tl, Sb, Bi, Se and Te have been widely studied, particularly because of their thermoelectric properties, used in solid-state refrigerators. If, in the arrangement of Fig. 18, the junction J_1 is at temperature T_1 and junctions J_2, J_3 at temperature T_2, the emf developed is given by $E_{AB} = (S_A - S_B)(T_1 - T_2)$. The Seebeck
FIG. 18. The thermoelectric effect.

coefficients S may be positive (p-type) or negative (n-type). The materials A and B may be chosen so that they have similar electrical conductivities κ and thermal conductivities λ but Seebeck coefficients which are of opposite sign. To use the arrangement as a refrigerator, a current is passed from the battery, so that heat is absorbed at junction J_1, and released at J_2 and J_3. The thermoelectric heat flow is in addition to the heat flow associated with thermal conductivity and to the resistive heating due to the passage of current. The heat balance shows that the transfer of heat from the junction at temperature T_1 to those at T_2 is most efficient when the "figure of merit", Z, given by $Z = S^2\kappa/\lambda$, is maximum. A good material for use in a thermoelectric refrigerator thus has a low thermal conductivity λ, a high electrical conductivity κ and a high Seebeck coefficient S. Metals have high thermal conductivities and so are unsuitable. For semiconductors, the quantities κ and S vary in opposite senses with the carrier concentration, and it can be shown that $S^2\kappa/\lambda$ is maximum when the carrier concentration is $\sim 10^{25}$ m^{-3}. Thermal conductivity, which involves transmission of lattice vibrations, is curtailed in complex or disordered structures, in structures with heavy atoms, and in structures with highly anharmonic vibrations, i.e. with atoms of unequal masses. The selenides and tellurides of bismuth may thus have particularly large thermoelectric figures of merit. Moreover, the optimum carrier concentration can be achieved by deviations from exact stoichiometry or by doping. Some data for the Bi–Te–Se system is shown in Table 35. The maximum figure of merit for bismuth telluride alloys ($ca.$ 3×10^{-3} K^{-1}) is achieved in $(Bi,Sb)_2Te_3$. The figure of merit is strongly temperature dependent: for bismuth telluride alloys the maximum is at about room temperature, and so they are particularly suitable for refrigerators. They have been used in situations where elaborate pumps are undesirable.

7.4. REACTIONS

Sulphides, selenides and tellurides are stable in air at room temperature, but realgar is easily oxidized in light. All compounds are oxidized on heating in air, and by halogens, giving the chalcogenohalides (section 7.5).

The sulphides are only slightly soluble in water: solubility products have been given[38] as 10^{-93} for Sb_2S_3, and 10^{-96} $mol^5 l^{-5}$ for Bi_2S_3. The sulphides are precipitated in the copper group of classical analysis. Arsenic and antimony sulphides dissolve in 0.5 M alkali with formation of oxy- and thio-anions, e.g. SbS_3^-. Bismuth sulphide is insoluble in alkali, but, unlike mercuric sulphide, it dissolves in nitric acid, probably with formation of nitrate complexes. Bismuth is not precipitated as sulphate, unlike lead, but, with ammonia, forms white gelatinous bismuth hydroxide (unlike copper and cadmium which form ammonia complexes). The hydroxide is readily reduced to bismuth metal. Arsenic sulphide is oxidized, by nitric acid or by hydrogen peroxide, to arsenate, but it is much less soluble in hydrochloric acid than antimony sulphide; this is exploited for separation of arsenic and antimony.

7.5. SULPHIDE, SELENIDE AND TELLURIDE HALIDES

By fusing mixtures of the compounds $E_2X_3^1$ (X^1 = S, Se, Te; E = Sb, Bi) and the halides EX_3^2 (X^2 = Cl, Br, I), ternary compounds EX^1X^2, analogous to the oxide halides (section 5) are obtained. They are stable in air and do not react with dilute acids. The
FIG. 19. The band structure of Sb^{III} sulphide bromide.

sulphide and selenide halides have structures with parallel pleated bands $(EX^1)_n^{n+}$ (Fig. 19) interspersed by halide ions. In SbSBr each antimony atom has three sulphur neighbours (one at 249 and two at 267 pm) and two bromine neighbours at 294 pm in a square pyramidal configuration. (Compare Sb_2S_3, Fig. 16 and structure [3] (p. 606).) The telluride halides BiTeBr and BiTeI have layer structures related to Bi_2Te_3 [92].

There are large regions of glass formation in the ternary system As–S–Br, and glasses with widely differing softening points may be obtained. Thus, a glass with composition $AsS_{1.8}Br_{2.5}$ has a softening point of $-60°C$. As the bromine content decreases, the

[92] E. Dönges, Z. anorg. allgem. Chem. 263 (1950) 112, 280; 265 (1951) 56; G. D. Christofferson and J. D. McCullough, Acta Cryst. 12 (1959) 14.

softening point rises (e.g. to 90° for $AsS_{2.7}Br_{0.6}$ and 200° for AsS_2), as the divalent sulphur atoms are able to link together structures of high molecular weight[90].

7.6. TERNARY SULPHIDES, SELENIDES AND TELLURIDES

Many ternary sulphides are known as minerals. Others, with melting points between 400° and 600°C, can be made by fusing appropriate quantities of the binary sulphides. Compounds with the marcasite, arsenopyrite, pyrites and ulmanite structures have been given in Table 12 (p. 567). Further ternary compounds are described in Table 37, which is not comprehensive.

The alkali metal and silver compounds, with the sodium chloride structure, are probably best described as double sulphides $M^IE^{III}S_2$, but, in some of the other compounds, anions based on ES_3 pyramids may be distinguished. These anions may be discrete as in Ag_3AsS_3, joined into chains, as in $TlAsS_2$, or small rings, as in $FePb_4S_6S_{14}$. In a number of ternary

sulphides, e.g. in $FeSb_2S_4$, $PbAs_2S_4$, and $HgSb_4S_8$, the element E has the square pyramidal environment derived from an octahedron in which a lone pair occupies one co-ordination site (compare Sb_2S_3, section 7.2, and the complex halides, section 10.3).

Several of the ternary sulphides have been investigated as semiconductors, and energy gaps of 0.2–1 eV have been reported. In the silver compounds $AgAsSe_2$, $AgAsTe_2$, $AgSbSe_2$ and $AgSbTe_2$, the normal p-type properties are enhanced by excess silver and changed to n-type by addition of zinc, cadmium or manganese. All four compounds have the same sodium chloride structure and mixtures of compounds yield a complete series of solid solutions. The thermoelectric powers of about 200 μV K^{-1} are comparable with those of systems based on bismuth telluride (Table 35).

8. SALTS OF ANTIMONY AND BISMUTH

Antimony and bismuth are sufficiently basic to form compounds which can formally be considered as salts. Halides (section 5) and sulphides (section 7) have already been discussed. Salts of oxyacids are considered in this section. There is, in general, little structural work or quantitative information. Antimony and bismuth salts are usually hygroscopic and react with water to give rather insoluble basic compounds, unless ligands are present which form strong complexes (section 10). Only basic salts of weak acids can be obtained.

8.1. PERCHLORATES

Bismuth perchlorate, $Bi(ClO_4)_3,5H_2O$, is well established. It dissolves in water to give a clear solution containing bismuth oxocations (section 6.5). The basic salts are not readily precipitated.

8.2. NITRATES

Bismuth nitrate pentahydrate may be crystallized from a solution of Bi^{III} oxide or carbonate in concentrated nitric acid. In the solid, each bismuth is co-ordinated by three unsymmetrical bidentate nitrate groups as well as three molecules of water. The metal thus has the high co-ordination number often found in hydrated salts of the heavier elements. Raman spectra of aqueous solutions containing various ratios of nitrate to bismuth and also of $Bi(NO_3)_3,5H_2O–KNO_3$ melts have been interpreted as showing that both the bidentate nitrate groups and also co-ordinated water persist in solution in a series of complexes with one to four nitrates per bismuth[93]. A basic salt $BiONO_3$ precipitates when solutions of the pentahydrate are diluted. The composition of the solid varies with the reaction conditions[94]. Basic salts, obtained by heating the pentahydrate, have been formulated with oxocations:

$$Bi(NO_3)_3,5H_2O \xrightarrow{50–60°C} [Bi_6O_6]_2(NO_3)_{11}(OH),6H_2O \xrightarrow{77–130°C} [Bi_6O_6](NO_3)_6,3H_2O \xrightarrow{400–450°C} \alpha\text{-}Bi_2O_3$$
93 R. P. Oertel and R. A. Plane, *Inorg. Chem.* 7 (1968) 1192.

In the hemihydrate $BiONO_3,\frac{1}{2}H_2O$, the bismuth atoms are arranged in the centrosymmetric cluster [9] with Bi–Bi distances 318–342 pm [94] (compare 307, 353 pm in the metal).

[9]
It does not appear to be possible to make the anhydrous nitrate from the pentahydrate, either by dehydration over sulphuric acid or by treatment with nitrogen dioxide, which often removes lattice water. With nitrogen dioxide, an adduct, probably $Bi(NO_3)_3,N_2O_4$, is formed. This decomposes to oxide nitrates:

$$Bi(NO_3)_3,N_2O_4 \xrightarrow{200^\circ C} Bi_2O(NO_3)_4 \xrightarrow{415^\circ C} Bi_4O_5(NO_3)_2$$
Infrared spectra suggest that the nitrate groups are bidentate and covalent in $Bi_2O(NO_3)_4$, but probably ionic in $Bi_4O_5(NO_3)_2$, which may thus have a structure like the oxide halides (section 5.4). Treatment of the pentahydrate $Bi(NO_3)_3,5H_2O$ with nitrogen pentoxide yields an adduct which has been formulated as $[NO_2]^+[Bi(NO_3)_4]^-$ [95]. Complex nitrate ions are found also in the compounds $M_3Bi_2(NO_3)_{12},24H_2O$ (M = Mg, Zn, Co, Ni). These are isomorphous with the cerium compound $[Mg(H_2O)_6]_3[Ce(NO_3)_6]_26H_2O$ in which each cerium is co-ordinated by six bidentate nitrate groups so that the oxygen atoms make an irregular icosahedron[96].

Antimony reacts with nitrogen dioxide in dimethylsulphoxide to give the basic salt $SbO(NO_3),(CH_3)_2SO$. Under the same conditions bismuth gives $Bi(NO_3)_3,3(CH_3)_2SO$, and arsenic does not react.

8.3. SULPHATES

The compounds $Bi_2(SO_4)_3,nH_2O$, $KBi(SO_4)_2$ and $Sb_2(SO_4)_3$ have been described. They are easily hydrolysed to basic salts.

Cryoscopic and electrical conductivity measurements[97] on dilute solutions of As^{III} oxide in 100% sulphuric acid have been interpreted as showing the formation of species such as $As(OH)(HSO_4)_2$ and $[As(OH)(SO_4H)]^+$. At higher concentrations, polymeric species are probably formed and $(AsO)_2SO_4$ precipitates. In oleum, the species $As(HSO_4)_3$, $[(HSO_4)_2As]_2O$ and $[(HSO_4)_2As]_2SO_4$ with $\cdots AsOSO \cdots$ frameworks seem probable.

8.4. PHOSPHATES

Antimony phosphate, $SbPO_4$, may be obtained from Sb^{III} oxide and phosphoric acid. It has a layer structure in which antimony atoms are linked by PO_4 tetrahedra. The co-ordination round antimony is one-sided [5] with the lone pairs on the outside of the layers. Sb–O distances are 198–219 pm [98].

Bismuth phosphate is of some importance as a carrier for the separation of plutonium in the atomic energy industry. Since it is insoluble in moderately strong nitric and sulphuric acids (solubility product $[Bi^{3+}][PO_4^{3-}] = 10^{-23}$ mol^2 l^{-2} in HNO_3)[38], it may be precipitated under conditions where uranium is strongly complexed with nitrate. The bismuth phosphate dissolves in concentrated nitric acid and so may be readily recycled.

8.5. BISMUTH FORMATE AND ACETATE

In bismuth formate[99a], HCOO groups link bismuth atoms into sheets, so that each bismuth has three oxygen neighbours at 238, three at 252 and three at 277 pm. If the six shortest Bi–O distances are considered, the co-ordination polyhedron round bismuth
FIG. 20. The distorted octahedron round bismuth in Bi(O·CO·H)₃. Three more oxygen atoms above those arrowed, together with the six shown, make a face-centred trigonal prism.

(Fig. 20) is a distorted octahedron with one face larger than the one opposite (compare α-Bi_2O_3, p. 606). If three more Bi–O distances are considered also, the atoms round bismuth form a trigonal prism with extra atoms over the rectangular faces. A similar environment is found in bismuth fluoride (section 5.2).

Bismuth oxide acetate CH_3CO_2OBi is said to have a structure like the oxide chloride (section 5.4)[99b].

9. ORGANOMETALLIC COMPOUNDS

As long ago as 1760, Cadet heated As^{III} oxide with potassium acetate and obtained a spontaneously inflammable liquid which was a mixture of cacodyl, $Me_2AsAsMe_2$, and

[98] B. Kinberger, *Acta chem. scand.* **24** (1970) 320.
[99(a)] C.-I. Stålhandske, *Acta chem. scand.* **23** (1969) 1525; [(b)]B. Aurivillius, *ibid.* **9** (1955) 1213.

cacodyl oxide, $Me_2AsOAsMe_2$. Since then, many thousands of organometallic derivatives of arsenic, antimony and bismuth have been made. The arsenic compounds are known best: their chemistry is similar to that of the analogous compounds of phosphorus. Antimony and bismuth compounds are less thoroughly studied. The field is well documented[101]. Good recent reviews have covered arsenic[100a] and antimony and bismuth[100b] derivatives. Work before 1937 is described by Krause and von Grosse, and there is a comprehensive non-critical summary of the literature from 1937 to 1964 which gives very full details[102].

9.1. TERTIARY ARSINES, STIBINES, AND BISMUTHINES, R₃E

Preparation

Although C–As, C–Sb and C–Bi bonds can be made by a variety of methods, the most important for the preparation of the symmetrical compounds R_3E is the replacement of all three groups X in the compounds EX_3 (X = halogen, OR, NR_2) by organic groups. The most widely used reagents for this purpose are Grignard and organolithium reagents, organoaluminium compounds and sodium–alkyl halides (Wurtz reaction):

$$AsCl_3 + MeMgI \xrightarrow{Bu_2O} Me_3As$$

$$As(OEt)_3 + PhMgBr \xrightarrow{Et_2O} Ph_3As$$

$$MeCH:CHLi + SbCl_3 \xrightarrow{Et_2O} (MeCH:CH)_3Sb$$

$$BiCl_3 + Et_6Al_2 \xrightarrow{Et_2O} Et_3Bi$$

$$AsCl_3 + PhCl + Na \xrightarrow{C_6H_6} Ph_3As$$
Alkyl, aryl, vinyl, allyl, ethynyl, perfluorophenyl and carborane (e.g. $PhC_2B_{10}H_{10}$—) derivatives can be made by these reactions. Unsymmetrical compounds $R^1R^2_2E$, $R^1R^2R^3E$, can be obtained from intermediates R^2_2EX (X = halogen or NR_2) and R^2R^3EX.

Oxides E_2O_3 can also be used as starting materials. The compounds R_3E are obtained with an excess of trialkylaluminium in hexane:

$$Et_6Al_2 + Sb_2O_3 \rightarrow 2Et_3Sb$$
Yields fall in the series Sb > As > Bi, and with increasing size of alkyl group. If zinc or mercury alkyls are available, they may be used to convert the halides EX_3, or the metals, into trialkyl derivatives. Pure alkyls can also be made by reduction of the halides R_3ECl_2 (section 14.3).

Properties and Structural Data

Methyl and phenyl compounds are described in Table 38; more extensive data is available in other compilations[102]. The arsines, stibines and bismuthines are colourless,

volatile liquids or solids, with latent heats and Trouton constants much as for organic compounds. In general, volatilities decrease with increasing size of R and with increasing atomic weight of E. Except for the methyl and trifluoromethyl derivatives, however, the effect on the volatility of the element E is small (compare $(CH_2:CH)_3As$, b.p. 146°C; $(CH_2:CH)_3Sb$, 160°C; $(CH_2:CH)_3Bi$, 179°C). Thermodynamic properties are not known with very great accuracy for two reasons. First, the organometallic compounds burn in oxygen to complex products, such as various oxides, metal and soot, as well as carbon dioxide and water, and this entails rather uncertain corrections to heats of combustion. Secondly, the heats of formation of the products are themselves not known very well. Nevertheless, it seems that the compounds become more endothermic in the series from arsenic to bismuth, and the mean bond energy decreases with increasing atomic weight of E. Thus the compounds R_3Bi may decompose photolytically or when heated, and, like the lead and mercury compounds, R_4Pb and R_2Hg, may be used as sources of radicals $R^·$ (e.g. $Ph^·$). Bond dissociation energies, determined kinetically, for removal of a single methyl are greater than the mean bond energy, especially for the bismuth compounds. Trends in bond energies are shown in mass spectra. Thus the most abundant peaks in the 70 eV mass spectra of the arsenic and antimony compounds are Me_2As^+, Me_2Sb^+, $PhAs^+$ and $PhSb^+$, but the ion Bi^+ predominates in the spectrum of both Me_3Bi and Ph_3Bi. By contrast, the strongest peaks in the mass spectra of tertiary amines and phosphines, R_3N and R_3P, are often those of the parent ions R_3E^+ [103]. Mass spectra of trifluoromethyl compounds CF_3EX_2 show important peaks attributed to the transfer of fluorine from carbon to the element E.

The molecules R_3E are pyramidal in both vapour and solid, but reliable structural data is very incomplete. As–C bond lengths in tertiary arsines seem to be in the range 196–199 pm, but wider variations (191–206 pm) are found in compounds where the arsenic is part of a five- or six-membered ring. Very few Sb–C or Bi–C bond lengths have been measured in compounds R_3E. The CEC angles seem to be significantly smaller in triphenylbismuth than in triarylarsines, probably indicating less involvement of the lone pair of bismuth in the E–C bonds. The angle in Me_3As has been assumed to be 96° (cf. 99.1° in Me_3P). In the crystalline derivatives of triphenyl-arsenic, -antimony and -bismuth, the rings are twisted by angles ϕ from the planes bisecting the angles between the E–C bonds. In solution (probably), and in $(4\text{-}MeC_6H_4)_3As$ or $(2,5\text{-}Me_2C_6H_3)_3As$, the angles ϕ for each aryl group are the same so the symmetry is C_3 (propeller), but, more usually, the three aryl groups are twisted by different angles, and there is no molecular symmetry in the crystal.

Molecules $R^1R^2R^3E$, with a pyramidal configuration at E, lack symmetry even in solution, and so can be resolved into optically active isomers, provided that there is a sufficiently high energy barrier between the enantiomers. For tertiary amines, the barrier to inversion is too small for resolution, but optically stable phosphines, arsines and stibines may be isolated, e.g. by stereospecific reactions of optically active onium salts or by resolution of distereoisomeric transition metal complexes [104]. Several compounds $HO_2C·C_6H_4·ER^1R^2$ have also been resolved. Barriers to inversion of about 200 kJ mol^{-1}

have been measured in arsines. Optically active arsines may be converted to optically active sulphides and may be racemized by mineral acids. The rate depends on the concentration of anions as well as on the pH, and the reaction may involve five- or six-co-ordinate intermediates: either would lead to loss of activity[105].

$$R_3As \underset{-HX}{\overset{HX}{\rightleftharpoons}} R_3HAsX \underset{-X^-}{\overset{X^-}{\rightleftharpoons}} [R_3AsX_2H]^-$$
Diarsines (section 9.2) are less stable optically and the racemization of PhMeAsAsMePh has been studied by temperature-dependent n.m.r. [106].

Organometallic compounds R_3E (R alkyl) are readily oxidized by air and must be manipulated in a nitrogen atmosphere, but phenyl derivatives are more easily handled. Controlled reactions with oxidizing agents and with alkyl halides are described in sections 14.1 and 14.3. Tertiary alkyl and aryl compounds are not hydrolysed by water or acid, but electronegative organic groups (e.g. CF_3—, C_6F_5—) are quantitatively cleaved by concentrated aqueous alkali. The formation of CF_3H provides a useful method for the estimation and analysis of trifluoromethyl derivatives[107].

A very large number of complexes of tertiary arsines and stibines with transition metal compounds have been isolated[108]: no attempt is made to describe them here. In addition, many derivatives of polydentate arsines (e.g. [10], [11], [12]) and related compounds (e.g. [13]) have been characterized:
The bond systems of the arsines are usually preserved in transition metal complexes, but sometimes unexpected rearrangements accompany complex formation[109]:

Arsenic and antimony may be incorporated in organic heterocyclic compounds[110]: for arsenic, systems with four- to ten-membered rings are known, and for antimony, five-, six- and seven-membered rings. Some of the known basic ring systems are shown. Corresponding antimony compounds can be named by substituting "stib" for "ars" and, for the six-membered rings, "antimon" for "arsen".

arsolan(e)   arsole   arsan(e)   arsenin   arsepan(e)

diarsocan(e)   arsonan(e)   arsecan(e)
The commonest method for preparation of the ring systems is by reaction between a dihalide RAsCl₂ and a dilithio- or di-Grignard reagent. The molecular structures of

$$2\ PhC{:}CH \xrightarrow{Li} Li.PhC{:}CPh.CPh{:}CPh.Li \xrightarrow[E=As,\ Sb]{PhECl_2}$$

$$Z = Ph;\ Y^1 = Y^2 = H$$

[14]   Z
9-phenyl-9-arsafluorene ([14] Z = Ph; Y' = Y² = H)[111] and 10-chloro-5,10-dihydrophenarsazine [15] have been found. In the former, the bonds to arsenic have a pyramidal configuration, with CAsC angles of 88° and 98° and As–C bond lengths 198 and 202 pm. The arsafluorene ring is flat, so only unsymmetrically substituted compounds (Y¹ ≠ Y²)

[110] F. G. Mann, *The Heterocyclic Derivatives of Phosphorus, Arsenic, Antimony and Bismuth*, 2nd edn., Wiley-Interscience (1970).
[111] D. Sartain and M. R. Truter, *J. Chem. Soc.* (1963) 4414.

can be resolved into optically active isomers. In the phenarsazine [15] the As–C bonds are slightly shorter than expected by comparison with other compounds (see Table 41, p. 633); this has been taken to imply some interaction between the lone pairs of arsenic and nitrogen with the π-electrons of the aromatic rings.

9.2. COMPOUNDS WITH E–E BONDS

Cacodyl had already been mentioned. The compounds R_2AsAsR_2 may be made as shown in Scheme 6. Though it seems that reactions (ii) and (iv) could be used to prepare

SCHEME 6. The chemistry of diarsines.
unsymmetrical diarsines, e.g. $R^1R^2AsAsR^3R^4$, mixtures of $(R^1R^2As)_2$ and $(R^3R^4As)_2$ are usually obtained instead. A number of antimony compounds made by similar reactions have been described, but their chemistry is less well explored than that of the arsenic compounds. Very little is known about dibismuthines.

The diarsines and distibines are easily oxidized; the more volatile compounds are spontaneously inflammable in air. The products depend on the reaction conditions, and in the presence of water various arsinic and arsonic acids may be isolated. Other reactions of the diarsines are shown in Scheme 6.

Some physical properties are as follows[102] (structural information is sparse):

$(CF_3)_2AsAs(CF_3)_2$: b.p. 106°C $(CF_3)_2SbSb(CF_3)_2$: b.p. 34°C/14mm
$Me_2AsAsMe_2$: m.p. -1°C; b.p. 78°C $Me_2SbSbMe_2$: m.p. 17°C; b.p. 76°C/6 mm
$Ph_2AsAsPh_2$: m.p. 127°C $Ph_2SbSbPh_2$: m.p. 125°C

The compounds $(RAs)_n$, which can be made from organoarsenic dihalides or from arsonic acids (Scheme 7), are often polymeric, with both crystalline and amorphous

SCHEME 7. The chemistry of polyarsines $(RAs)_n$.
forms. In some of the crystalline forms there are oligomers, with molecular complexities which depend on the group R. Thus arsenomethane, $(MeAs)_n$, crystallizes in yellow and red forms, with the red form more stable at room temperature. The yellow form consists of pentamer molecules with a puckered As_5 ring. In the crystalline form of arsenobenzene, $(PhAs)_6$, the arsenic atoms form a six-membered puckered ring (chair form). Other oligomers which have been detected are $(CF_3As)_4$ (in the vapour), $(CF_3As)_5$ and $(C_6F_5As)_4$ (in solution and vapour)[112]. The average bond distances in the solid arsines conceal considerable variations which are outside the limits of experimental error (Table 39). The low symmetry of the oligomers results from puckering of the rings so that the carbon and arsenic atoms

TABLE 39. STRUCTURAL DATA FOR THE COMPOUNDS $(RAs)_n$

	As–As (pm)	∠ CAsAs (°)	As–C (pm)	∠ AsAsAs (°)	Ref.
$(MeAs)_5$	242.8	96.9	195	101.8	a
$(PhAs)_6$	245.6	100.1	196.6	91	b

a J. H. Burns and J. Waser, *J. Am. Chem. Soc.* **79** (1957) 859.
b K. Hedberg, E. W. Hughes, and J. Waser, *Acta Cryst.* **14** (1961) 369.

adjacent to a particular As–As bond are in a staggered configuration. The 60 MHz n.m.r. spectra[113] of $(MeAs)_5$ and $(CF_3As)_5$ in solution above $-130°C$ show three resonances with relative intensities 2:2:1, suggesting that a rapid motion gives the rings time-averaged planes of symmetry. Small amounts of a variety of linear and cyclic methylpolyarsines are apparent in mixtures of $(MeAs)_5$ and $Me_2AsAsMe_2$, and three- and four-membered cyclic polyarsines, as well as pentamers, can be detected in the gas phase. Interconversions and equilibria between various polyarsines are complicated[114]. Several structurally similar cyclic phosphines have been characterized, e.g. $(MeP)_5$, $(CF_3P)_4$, $(CF_3P)_5$, $(PhP)_5$ and $(PhP)_6$, but there is no convincing explanation for the molecular complexities found for these cyclic compounds of phosphorus and arsenic.

The cyclic polyarsines are less readily oxidized than the diarsines R_2AsAsR_2. They form coloured derivatives with sodium, which are useful intermediates in further syntheses (Scheme 7). Red or black amorphous compounds $(RSb)_x$ have been described.

A wide variety of substituted arsenobenzenes have been made for chemotherapeutic use, though interest in this field has abated with the discovery of antibiotics. The effectiveness of $(AsPh)_5$ is limited by its low solubility in water, so attention has been directed to more soluble derivatives, especially those with substituents OH, NR_2 and SO_3H in the benzene rings. The most common method for preparation is by the reduction of the corresponding arsonic acid by hypophosphorous acid or sodium dithionite. Unsymmetrical

113 E. J. Wells, R. C. Ferguson, J. G. Hallett and L. K. Peterson, *Can. J. Chem.* **46** (1968) 2733; C. L. Watkins, L. K. Krannich and H. H. Sisler, *Inorg. Chem.* **8** (1969) 385. P. S. Elmes, S. Middleton and B. O. West, *Austr. J. Chem.* **23** (1970) 1559.
114 F. Knoll, H. C. Marsmann and J. R. van Wazer, *J. Am. Chem. Soc.* **92** (1969) 4986.

compounds, i.e. those with several differently-substituted rings, can be made from appropriate mixtures of arsonic acids. Many of these substances are described as highly coloured powders. Some are crystalline, with sharp melting points. The properties of others, e.g. Salvarsan, 3-amino-4-hydroxyarsenobenzene, structure [16], vary with the method of preparation, suggesting that they are polymeric, with molecules of various complexities. There seems to be little recent structural work[102].

Arsenomethane (MeAs)$_5$ reacts with metal carbonyls in several ways[115]: the cyclic molecule may function as a ligand which is tridentate, as in [17], or monodentate, as in [18].

[16]

$(MeAs)_5 \xrightarrow{M(CO)_6}$ [17] M = Cr,Mo,W

$\xrightarrow{M(CO)_5 \ EtOH}$ $[M(CO)_5]_2 (AsMe)_5$ [18] M = Cr,Mo,W

$\xrightarrow{Fe(CO)_5}$ [19]
In the complex [19] the As$_5$ ring is not preserved (As–As: 245.3 pm (a, c); 239.1 (b); 288.8 (d))[116]. Among the products of the reaction between arsenomethane and cobalt carbonyl is the complex As$_3$Co(CO)$_3$ [20], in which one of the arsenic atoms of an As$_4$ tetrahedron has been replaced by the Co(CO)$_3$ group. A related compound, As$_2$[Co(CO)$_3$]$_2$,

[20]
115 P. S. Elmes and B. O. West, *Coord. Chem. Rev.* **3** (1968) 279.
116 B. M. Gatehouse, *Chem. Communs.* (1969) 948; P. S. Elmes, P. Leverett and B. O. West, *ibid.* (1971) 747.

can be isolated as a red liquid from cobalt carbonyl and arsenic trichloride in tetrahydrofuran. Replacement of arsenic atoms in As_4 by $Co(CO)_3$ results in a shortening of As–As bonds compared with As_4 (As–As, 243.5 pm).

$$As_3Co(CO)_3: \text{As–As, } 237.2 \pm 0.5 \text{ pm}$$
$$As_2[Co(CO)_3][Co(CO)_2PPh_3]: \text{As–As, } 227.3 \pm 0.3 \text{ pm}[117]$$
9.3. THE COMPOUNDS R₂EX, REX₂ (X = HALOGEN)

Alkyl and some aryl halides react with metallic arsenic, particularly in the presence of copper, to give complex mixtures which contain the compounds R_2AsX and $RAsX_2$ and often R_3As, AsX_3 and As_2X_4 as well. The proportions of the various compounds obtained depend on the exact experimental conditions, but, provided that the products can be separated, e.g. by distillation, the reaction is useful preparatively:

$$\text{MeBr, As, Cu} \xrightarrow{350\text{-}370°C} \text{Me}_2\text{AsBr (34\%)} + \text{MeAsBr}_2 \text{ (62\%)} \quad [\text{Ref. 118}]$$
$$\text{b.p. 51°C/42 mm} \quad \text{b.p. 89°C/41 mm}$$

$$\text{MeCl, As, Cu} \xrightarrow{350\text{-}370°C} \text{Me}_2\text{AsCl (20\%)} + \text{MeAsCl}_2 \text{ (80\%)} \quad [\text{Ref. 118}]$$

$$\text{CF}_3\text{I, As, I}_2 \xrightarrow{220°C} \text{(CF}_3)_3\text{As (78\%), (CF}_3)_2\text{AsI (13\%), CF}_3\text{AsI}_2 \text{ (4\%)} \quad [\text{Ref. 107}]$$
Antimony reacts similarly, but yields of the organometallic compounds are lower; perhaps because they are thermally unstable at the temperatures required for formation. Only very low yields of bismuth compounds can be made this way[118]. These reactions are examples of the "direct synthesis" of organometallic compounds.

The halides can also be made by reduction of arsonic acids by sulphur dioxide in the presence of the hydrogen halide[119], by reorganization reactions, or by loss of alkylhalide from the compounds R_3EX_2 (section 14.3).

$$\text{Na}_3\text{AsO}_3 \xrightarrow{\text{MeI}} \text{Na}_2\text{MeAsO}_3 \xrightarrow{\text{HCl/NaI/SO}_2} \text{MeAsI}_2$$

$$\downarrow \text{NaOH/MeI}$$

$$\text{NaMe}_2\text{AsO}_2 \xrightarrow{\text{HCl/NaI/SO}_2} \text{Me}_2\text{AsI}$$

$$(\text{CH}_2\text{:CH})_3\text{As} + \text{AsBr}_3 \longrightarrow (\text{CH}_2\text{:CH})_2\text{AsBr} + \text{CH}_2\text{:CHAsBr}_2$$

$$\text{Me}_3\text{SbCl}_2 \longrightarrow \text{Me}_2\text{SbCl} + \text{MeCl}$$
In the preparation from R_3EX_2, alkyl iodides are eliminated most readily and fluorides often with difficulty. In many cases, the five-co-ordinate bromides and iodides cannot be made.

The addition of arsenic trichloride to acetylene in the presence of aluminium trichloride yields a mixture known as lewisite, developed, but not used, as a war gas in 1918. The main

product is *trans*-2-chlorovinyldichloroarsine HCCl:CH·AsCl₂, but other compounds such as (HCCl:CH)₂AsCl and (HCCl:CH)₃As are also produced. The reorganization reactions are probably catalysed by the aluminium chloride.

The halogen derivatives R_2EX, REX_2 are volatile liquids or solids (Table 40) with properties similar to those of the compounds R_3E and the trihalides EX_3. Volatilities decrease from fluorides to iodides and with increasing size of R; trifluoromethyl compounds

[d] Ref. 119.

[e] W. R. Cullen and J. Trotter, *Can. J. Chem.* 39 (1961) 2602.

[f] There have been unsuccessful attempts to make PhBiH₂, Ph₂BiH (E. Wiberg and K. Mödritzer, *Z. Naturforsch.* 12b (1957) 132) but the methyl compounds MeBiH₂ (b.p. (extrap.) 72°C) and Me₂BiH (b.p. (extrap.) 103°C) have been described (E. Amberger, *Chem. Ber.* 94 (1961) 1447).

are more volatile than the methyl analogues. Pure compounds can be isolated from mixtures only if boiling points are sufficiently different: thus the iodides (CF₃)₂AsI, CF₃AsI₂ are easily separated, but the corresponding fluorides are not. Fluorides and chlorides are usually colourless: bromides and iodides are usually yellow or brown.

The molecules of the mono- and di-halides, like those of the compounds R_3E and EX_3, are pyramidal. Several have been investigated (Table 41) by X-ray methods or electron diffraction, and have As–C and As–X bond lengths similar to those in the tertiary arsines and trihalides. The CAsC bond angles in the phenyl derivatives are about 105°, but a smaller value was assumed in early electron diffraction work on the methyl compounds. There is considerable variation in XAsC angles. The microwave spectrum of the difluoride MeAsF₂ yields values of the quadrupole coupling constant ($e^2Qq_{cc} = -220+4$ MHz) and asymmetry parameter ($\eta = (q_{bb}-q_{aa})/q_{cc} = -1.2\pm0.05$) which are consistent with greater *s*-character in the As–F bond than the As–C bonds, as expected from electronegativities. In the solid cyanides Me₂AsCN (m.p. 30°C) and MeAs(CN)₂ (m.p. 127°C), as in As(CN)₃, there is evidence for interaction between a nitrogen atom in each molecule and

an arsenic atom in a neighbouring molecule. This interaction probably accounts for the high melting points of the cyanides compared with the chlorides Me_2AsCl and $MeAsCl_2$, which are liquid at room temperature.

The halogen compounds are the starting materials for a wide variety of compounds in which the R₂As and RAs groups are preserved. Some reactions of the arsenic compounds are illustrated in Schemes 3 and 6–10. The antimony and bismuth compounds are like those of arsenic, but there is much less information about structures and physical properties.

9.4. HYDRIDES R₂EH, REH₂

The chemistry of the hydrides R₂AsH and RAsH₂ is summarized in Scheme 9. The arsenic compounds (Table 40) are reasonably well characterized, and many of them may be made without difficulty, provided that oxygen is rigorously excluded from reaction mixtures. The antimony compounds are much less well known and readily decompose, with formation of hydrogen and ill-defined solids. Alkylarsines may be made from NaAsH₂ and alkyl halides, or by reduction of the halides RAsCl₂ with lithium aluminium hydride. Low yields by this last route have been attributed to formation of stable Al–As bonds: borohydrides or related reducing agents may be more efficient. Phenylarsines are made by

SCHEME 8. Reactions of halides R_2AsX and $RAsX_2$ (X = Cl, Br, I).

$$R_2AsX \xrightarrow{\text{AgF}} R_2AsF$$
$$\xrightarrow{\text{AgCN}} R_2AsCN$$
$$\xrightarrow{\text{R'MgX etc.}} R'R_2As$$
$$\xrightarrow{\text{NaOSiMe}_3} R_2AsOSiMe_3$$
$$\xrightarrow{\text{(EtS)}_2Pb} R_2AsSEt$$
$$\xrightarrow{\text{NaOPh}} R_2AsOPh$$
$$\xrightarrow{\text{NaMn(CO)}_5} [R_2AsMn(CO)_4]_2$$

$$RAsX_2 \xrightarrow{\text{NH}_4F} RAsF_2$$
$$\xrightarrow{\text{AgSCN}} RAs(SCN)_2$$
$$\xrightarrow{\text{R'MgX}} R'RAsX$$
$$\xrightarrow{\text{R'OH/Et}_3N} RAs(OR')_2$$
$$\xrightarrow{\text{H}_2S} RAsS$$
$$\xrightarrow[\text{CuCl}_2]{\text{R'N}_2HSO_4} R'RAsO_2H$$
SCHEME 9. Reactions of hydrides.

$$Y:Z = CH_2:CHCN, OC:CH_2 \text{ etc.} \qquad (M = Li, Na, K, Mg)$$
reduction of the corresponding arsonic or arsinic acids, and perfluoroalkylarsines are best made from the iodides or the diarsines by reduction with hydrogen iodide and mercury[120].

$$CF_3AsI_2 \text{ or } (CF_3As)_n \xrightarrow{\text{HI/Hg}} CF_3AsH_2$$

$$(CF_3)_2AsI \text{ or } [(CF_3)_2As]_2 \xrightarrow{\text{HI/Hg}} (CF_3)_2AsH$$
The arsines and stibines do not react with water. They are readily oxidized, e.g. by air or by halogens. In this last reaction, intermediates RAsHX have been detected[121], but these readily give hydrogen halides and polyarsines.

$$MeAsH_2 \xrightarrow{I_2} MeAsHI \rightarrow (MeAs)_5 + HI$$

The hydrogen atoms in REH_2, R_2EH can be replaced by alkali or alkaline earth metals by treatment with organometallic reagents, and the resulting metal derivatives, e.g. $Mg(AsPh_2)_2$, $LiAsBu_2^t$ may be used in further syntheses. The insertion reaction with species with double bonds, Y:Z (Scheme 9) is also of wide application. The compounds $(Ph_2AsMMe_2; M = Al, Ga, In)$ have been made.

9.5. OXYGEN DERIVATIVES

Oxygen derivatives of As^{III} are as follows:

R_2AsOH, R^1R^2AsOH	$(R_2As)_2O$	$RAs(OH)_2$	$RAsO$
arsinous acids hydroxyarsines	oxybis(secondary arsines)	arsonous acids	oxoarsines

A number of arylarsinous acids have been made by reduction of the corresponding arsinic acids (section 14.4) or by alkaline hydrolysis of oxybis(secondary arsines). The free acids are not well characterized.

$$R_2AsOOH \xrightarrow{SO_2/I^-} R_2AsOH \xleftarrow{OH^-} (R_2As)_2O$$

Many arsinous acids are known as esters $R^1_2AsOR^2$, $R^1R^2AsOR^3$, which are readily obtained as volatile liquids and solids from halides R_2AsCl and sodium alkoxides (Scheme 8), or by heating oxides $(R_2As)_2O$ with alcohols in the presence of copper sulphate:

$$(R^1_2As)_2O + R^2OH \rightarrow R^1_2AsOR^2$$

The properties of the arsinite esters are intermediate between those of the arsines (section 9.1) and arsenites (section 6.4). They show no tendency to rearrange by Arbuzov-type reactions. A number of antimony compounds have been described.

The oxides $(R_2E)_2O$ (E = As, Sb) are liquids or crystalline solids, and appear to be momomeric in solution. The alkyl compounds are made by hydrolysis of the halides R_2EX; aryl compounds may also be prepared from halides and diazonium compounds (Scheme 10). The molecule of oxybis(diphenylarsine) has bond lengths As–C, 190; As–O, 167 pm. The AsOAs bond angle is 137°, and the bond angles at arsenic are close to 100° [123].

Oxygen derivatives with one organic group attached to arsenic are similar to those with two. Thus arylarsonous acids are made by reduction of the arsonic acids (section 14.4) or by hydrolysis of halides. Alkylarsonous acids are not well characterized.

$$RAsO(OH)_2 \xrightarrow{SO_2/HX} RAsX_2 \xrightarrow{OH^-} RAs(OH)_2$$

Many hydrated arsonous acids and oxoarsines have been isolated by careful control of reaction conditions [102]. Some of these derivatives are crystalline, but others are insoluble in organic solvents and amorphous. They may contain oligomeric [63] or polymeric frameworks of As–O bonds, but there is little precise structural work. The compound $\{MeCH(AsO)_2\}_2$ may have a realgar-like structure [7]. Oxostibines are also known (Scheme 10) and may be useful intermediates in syntheses.

Arsonous esters $RAs(OR)_2$ are readily made by treatment of the halides $RAsX_2$ with alkoxides, or with alcohols and tertiary amines, or by heating the oxoarsines with alcohols (sometimes with copper sulphate). As with the arsenites (section 6.4) and the arsinites, derivatives with involatile alcohols can be made by transesterification. The arsonites are volatile with pesticidal properties.

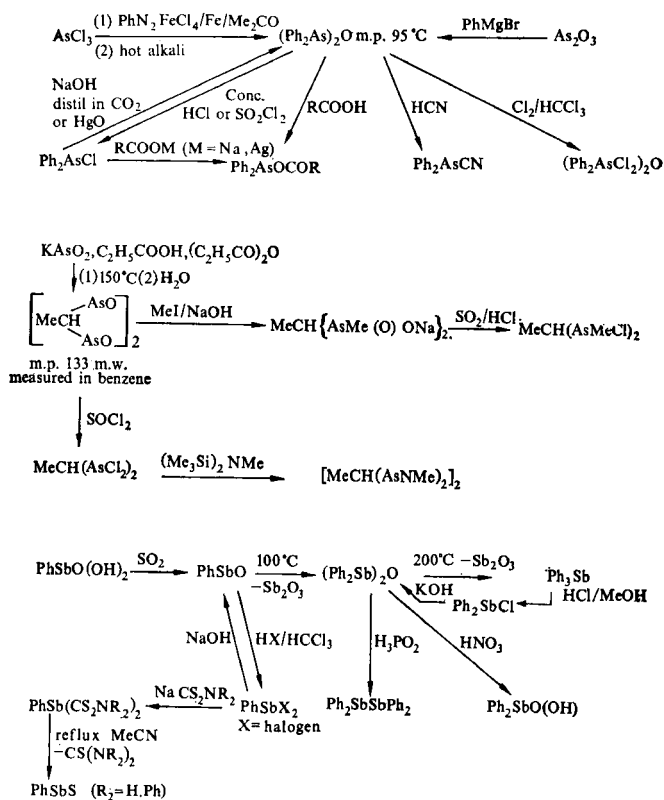
[123] W. R. Cullen and J. Trotter, *Can. J. Chem.* **41** (1963) 2983.

SCHEME 10. Reactions of oxygen compounds[101, 102, 122]


Amido groups may sometimes be cleaved from arsenic by alcohols or phenols, or by aqueous alkali.

$$MeAs(NMe_2)_2 + PhOH \rightarrow MeAs(OPh)_2$$
$$R_2AsNR_2 + OH^- \rightarrow (R_2As)_2O$$

However, the oxide $(Me_2As)_2O$ and the ester Me_2AsOPh react with sodamide to form the unstable amide Me_2AsNH_2, which decomposes to the compound $(Me_2As)_3N$. The corresponding antimony compound may also be made[124].

Sulphur compounds $R_2^1AsSR^2$, $(R_2^1As)_2S$, $R^1As(SR^2)_2$, RAsS can be prepared by routes similar to those for oxygen analogues. Fungicidal properties of many esters $R^1As(SR^2)_2$ have been investigated[102]. The substance made from methylarsine and sulphur, or from

[21]
[124] O. J. Scherer, J. F. Schmidt and M. Schmidt, Z. Naturforsch. 19b (1964) 447.

dimethylarsonic acid (section 14.4) and hydrogen sulphide, is dimethylarsino-dimethyldithioarsinate [21]. The bond lengths are As^1S^1, 207.5; As^1S^2, 221.4; As^2S^2, 227.9 $\pm$ 0.7 pm. The bond angles at As^1 are between 101 and 116° and at As^2 between 96 and 99° [125].

9.6. DERIVATIVES OF SILICON, GERMANIUM, TIN AND LEAD[126, 127]

The compounds $(R_3E^1)_nER^1_{3-n}$, $R_mE^1(ER^1_2)_{4-m}$ {R, R^1 = H, alkyl, aryl; E^1 = Si, Ge, Sn; E = As, Sb, Bi} have been compared with the organometallic compounds described in sections 9.1 and 9.4 in attempts to assess the rôle of d orbitals in EE^1 bonds. The organo-silicon, -germanium and -tin compounds are also useful synthetic intermediates.

The most important preparative routes are as follows.

(a) Halides R_3E^1X react with alkali derivatives of arsenic, antimony and bismuth in liquid ammonia, or organic solvents such as hexane or ether.

$$Me_3SiCl + Li_3Sb \rightarrow (Me_3Si)_3Sb$$

Alkali metal derivatives of Group IV elements, e.g. triphenylstannyllithium, react with organo-arsenic and -antimony halides, but these reactions are often complicated by halogen–metal exchange, so that low yields of the desired compounds with EE^1 bonds are obtained.

(b) Halides R_3E^1X react with organo-arsenic and -antimony hydrides in the presence of tertiary amines:

$$Ph_3SnCl + Ph_2AsH \xrightarrow{Et_3N} Ph_3SnAsPh_2$$
(c) Stibines and bismuthines $(R_3E^1)_3E$ (E = Sb: E^1 = Si, Ge, Sn; E = Bi: E^1 = Sn) can be made from triethyl-stibine or -bismuthine and the hydrides R_3E^1H:

$$3Ph_3SnH + BiEt_3 \rightarrow (Ph_3Sn)_3Bi + 3EtH$$
(d) E^1–N bonds may be cleaved by hydrides:

$$Me_3SnNMe_2 + Ph_2AsH \rightarrow Me_3SnAsPh_2 + NMe_2H$$
(e) The unstable germyl compounds $(H_3Ge)_3E$ (E = As, Sb) may be made from germyl bromide and the silyl compounds $(H_3Si)_3E$.

Ternary hydrides $(H_3E^1)_mEH_{3-m}$ have been made by the above reactions, or from the hydrides E^1H_4 and EH_3 in electric discharges, and have been characterized by spectroscopic methods[127]. N.m.r. spectra show resonances at τ 6 to 6.5 due to E^1H protons and at about τ 9 due to EH protons.

The molecules of trisilyl-phosphine, -arsine and -stibine are pyramidal (contrast planar trisilylamine), and infrared spectra of other compounds $(R_3E^1)_3E$ have been assigned by assuming C_{3v} symmetry (Table 42). The participation of d orbitals has been invoked to account for chemical properties but physical evidence for π-bonding is slight.

The stability of compounds with E–E^1 bonds—both thermal and towards chemical attack—seems to be greatest when E and E^1 are about the same size. The ternary hydrides,

like the hydrides E^1H_4 and EH_3, are very readily oxidized by air, and are rapidly decomposed by halogens and compounds HX (X = halogen, OH, SH).

$$GeH_3I + AsH_3 \xleftarrow{HI} (GeH_3)_3As \xrightarrow{H_2O} (GeH_3)_2O + AsH_3$$
Alkyl- and aryl-substituted derivatives are also oxidized by air.

$$Ph_3GeAsPh_2 \xrightarrow{O_2} Ph_3GeOAs(O)Ph_2 \xleftarrow{Et_3N} Ph_3GeCl + Ph_2AsO \cdot OH$$

Reactions of dimethyl(trimethylsilyl)arsine (Scheme 11) may involve cleavage of the Si–As bond or addition to unsaturated systems[128]. The products reflect the polarity Si^+–As^-. The trimethylstannyl compound $Me_3SnAsMe_2$ is similar, but less reactive: for example, there is no reaction with water or alcohols. The secondary arsine $Me_3SiAsHMe$ readily loses methylarsine[129]: the diarsine $Me_2Si(AsHMe)_2$ gives a cyclic oligomer $(Me_2SiAsMe)_4$.

$$Me_3Si(AsHMe) \rightarrow (Me_3Si)_2AsMe + MeAsH_2$$
$$Me_2Si(AsHMe)_2 \rightarrow \tfrac{1}{4}(Me_2SiAsMe)_4 + MeAsH_2$$

The organosilicon and organotin di- and tri-arsines $R_mE^1(ER_2^1)_{4-m}$ give complexes with transition metal derivatives[130].

10. COMPLEXES OF TERVALENT ARSENIC, ANTIMONY, AND BISMUTH

The compounds EX₃ (X = hal., R, H, etc.) can form several series of complexes. Electrons from the lone pair on E^{III} may be donated to suitable acceptor molecules, or the element E may expand its co-ordination number by accepting electrons from donor molecules.

10.1. THE MOLECULES EX₃ AS DONORS

Complexes with main group acceptors are usually weak and are formed most readily when X = R, H. Donor strength decreases in the series PX₃ > AsX₃ > SbX₃ > BiX₃. Stronger complexes are formed with late transition metal atoms (Class (b) acceptors)[24, 108, 130]. Even antimony trichloride reacts with iron and nickel carbonyls to give the compounds Fe(CO)₃(SbCl₃)₂ and Ni(CO)₃SbCl₃ [131].

    Me_3As,BH_3 (2) NH_4PF_6

$[(Me_3As)_2BH_2]^+[B_{12}H_{11}AsMe_3]^-$ $[(Me_3As)_2BH_2][PF_6]$

    H_2O, Me_4NOH

$[Me_4N][B_{12}H_{11}AsMe_3]$
Reactions of the adduct Me_3As,BH_3 (Table 43) are shown in Scheme 12. The sparingly soluble salts of $[(Me_3As)_2BH_2]^+$ can be rapidly recrystallized from warm water. The adducts R_2AsH,BH_3 (R = Me, CF_3) readily lose hydrogen to give a series of stable compounds $(R_2AsBH_2)_n$ (n = 3, 4). The methyl compounds are unchanged at 200°C, but they are less stable thermally and more reactive than the phosphorus analogues. The monomeric Me_2SbBH_2, from Me_4Sb_2 and B_2H_6 at 100°C, is also unchanged at 200°C: the difference in molecular complexity between the corresponding arsenic and antimony compounds is strange.

Several other adducts are described in Table 43.

10.2. THE MOLECULES EX₃ AS ACCEPTORS

When X is electronegative (e.g. hal), the molecules EX_3 are good acceptors (Table 44), and a wide range of complexes EX_3L, EX_3L_2 (where L is a monodentate ligand) have been isolated. Little detailed thermodynamic data relating to complex formation is available, but it seems clear that, to oxygen donors, antimony trichloride is a weaker acceptor than antimony pentachloride (section 15.3)[132]. More antimony trihalide complexes are known than arsenic or bismuth trihalide complexes, but a quantitative comparison of complex formation is not at present possible.

Structurally, the halide complexes are of interest because of the part played by the lone pair in determining the stereochemistry. In the 1:1 complexes, the lone pair occupies an equatorial position in a trigonal bipyramidal configuration (compare [5], p. 610, or [25], p. 643) with the donor L in an axial position. In the 1:2 complexes, the lone pair occupies a octahedral position, so that a distorted square pyramidal environment for the antimony results (compare [3], p. 606, or [27], p. 643). In each case Sb–X bonds *trans* to the donor L are longer than those *cis* (Table 44). In the weak complex $SbI_3,3S_8$, bonding between the sulphur and antimony triiodide molecules seems to involve mainly S–I interactions. The antimony iodide molecules are linked by weak bonds (Sb–I 385 pm) as in antimony triiodide itself.

Trialkyl- or triaryl-arsines or -stibines do not appear to form complexes with electron donors. The effect of the electro-negative trifluoromethyl groups shows in the formation of the weak complex between the stibine $(CF_3)_3Sb$ and pyridine.

Complexes of antimony trichloride with aromatic hydrocarbons are of two types. In the first, e.g. the naphthalene adduct in Table 44, the hydrocarbon behaves as an olefin, donating π-electron density to one co-ordination position at the antimony. There is considerable distortion of the naphthalene skeleton, with a shortening of the complexed C⠴C bond. In the second type, e.g. in the complexes with perylene [22] or phenanthrene, in the halide as solvent, the hydrocarbon appears to complex the $[SbCl_2]^+$ ion. Polycyclic hydrocarbons thus behave as weak electrolytes in antimony trichloride[133]. The cations may be readily protonated or be oxidized to radical ions by oxygen (compare section 15.3).

[22]

$$RH\ [22] + 2\,SbCl_3 \longrightarrow \left[RH, SbCl_2\right]^+ \quad + \quad \left[SbCl_4\right]^-$$

with O_2 and HCl branches:

$$\left[RH^{\cdot}\right]^+ + \tfrac{1}{2}SbCl_3 + \tfrac{1}{2}SbOCl$$

$$\left[RH_2\right]^+ + SbCl_3$$
A compound, formulated $[(C_6H_6)BiCl_2]^+[AlCl_4]^-$, has also been described[134].

10.3. COMPLEX HALIDES

The compounds EX₃ are strong acceptors towards halide ions (section 5.3). This section deals mainly with structural aspects of the resulting complex ions.

Complex Fluorides

Arsenic trifluoride reacts with alkali metal fluorides, except those of sodium and lithium, to form complexes MEF_4 [135]. The stability, with respect to decomposition to fluorides MF and arsenic trifluoride, increases with increasing atomic weight of M, as expected from lattice energy considerations. Dissociation pressures at 100°C are: $KAsF_4$, 0.18, $CsAsF_4$, 0.07 atm. The solids may contain AsF_4^- ions, isostructural with SeF_4, or more complicated anions. They dissolve in arsenic trifluoride, but AsF_4^- ions cannot be detected with certainty. Fluorarsenites are very hygroscopic and are rapidly hydrolysed by water.

A series of complex fluorides of antimony (Table 45) can be isolated from solutions of alkali metal carbonates and the appropriate amounts of antimony trioxide in hydrofluoric acid. Species in solution are not well established, but a series of complex ions is
found in the solids. The nature of these ions depends on the counterions. Thus [SbF₄]⁻ groups are said to be arranged in pairs in NaSbF₄ (distorted [23]), and in groups of four in KSbF₄ [24]. In NaSbF₄ and in CsSb₂F₇ each antimony atom forms four bonds to fluorine shorter than 230 pm, but in KSbF₄ and in K₂SbF₅ each antimony atom forms five such bonds. In the salts MSb₄F₁₃ (M = K, Rb, Cs, NH₄, Tl) apparently only three bonds to each antimony atom are shorter than 230 pm. In all cases, the co-ordination round antimony is one-sided, showing that the lone pair is stereochemically active, but the precise distribution of valencies depends on how fluorine atoms are shared. In general, bonds to bridging (shared) fluorine atoms are longer than those to non-bridging fluorine atoms. The possibilities for fluorine bridging between antimony atoms are complicated, and further work both on solids and solutions is needed completely to rationalize the bonding in complex fluorides. The problem may be complicated by incorporation of Sb–O bonds in solids isolated from aqueous solution.

Bismuth trifluoride is rather insoluble in water, and complex fluorides of bismuth are not well known. In the complex NH_4BiF_4 each bismuth atom has nine fluorine neighbours (as in BiF_3); nets of BiF_4 co-ordination polyhedra are linked to nitrogen atoms by hydrogen bonds.

Complex Chlorides

Arsenic trichloride and dry hydrogen chloride apparently do not interact, but Raman spectra of arsenic trichloride in aqueous hydrochloric acid indicate the presence of species other than $AsCl_3$. These may be extracted into ether, but not benzene, and seem to be $AsCl_4^-$ ions, presumably combined with solvated protons. Vibrational spectra are given in Table 46. Assignments have been made on the basis of the following symmetries: C_{2v} for

TABLE 46. VIBRATIONAL SPECTRA OF HALIDE COMPLEXES

ECl_4^- [25] (compare $SeCl_4$), C_{4v} for ECl_5^{2-} [27] and O_h for ECl_6^{3-}, but it is difficult to be sure of assignments based on solids, or on solutions in which the ions may be strongly solvated. In solid $C_5H_5NHSbCl_4$, the anions have infinite chains of antimony atoms linked by double chlorine bridges [26]. The bond distances show that the chains may be considered as made of $SbCl_4^-$ ions linked by weaker (Sb–Cl$_c$) bonds (Table 45). It is likely that these are broken in solvating media. The $SbCl_5^{2-}$ ions has also been isolated in crystalline derivatives. It has a distorted octahedral structure [27] in which the shortest bond is opposite the lone pair. Alternatively, the configuration of the ion may be described as square pyramidal with the antimony atom slightly below the base of the pyramid (compare with the sulphides, sections 7.2 and 7.5). The vibrational spectra have been assigned assuming C_{4v} symmetry. The $SbCl_6^{3-}$ ion, like the isoelectronic $TeCl_6^{2-}$, is symmetrical; the lone pair does not occupy a co-ordination position.

Chloride complexes of bismuth have been extensively studied in aqueous solution, and information about individual species has been obtained from ultraviolet and Raman spectroscopy (Table 47). The structures of these ions are assumed to be those of the antimony analogues, with lone pairs stereochemically active in the four- and five-co-ordinate species, but not in $BiCl_6^{3-}$. Stability constants have been determined under a

variety of conditions[38]. For comparison, values obtained for halide complexes of bismuth are given in Table 48. The stability of a given complex BiX_n increases as X changes from chloride to iodide: bismuth may thus be said to show class (b) [24] acceptor properties. The ions $BiCl_5^{2-}$ and $Bi_2Cl_8^{2-}$ have been found in $BiCl_{1.167}$ (section 5.5). Many crystalline chloride complexes have been isolated[135]; in particular, large tervalent cations, e.g. $Co(NH_3)_6^{3+}$, form insoluble compounds with ions ECl_6^{3-} [136a]. The $BiCl_5^{2-}$ ion has structure [27] and $Bi_2Cl_8^{2-}$ [23] is rather similar to $Sb_2F_8^{2-}$, except that the bridge bonds are symmetrical. In both $BiCl_5^{2-}$ and $Bi_2Cl_8^{2-}$, lone pairs occupy co-ordination positions. The absorption of solutions of halide complexes is used in the spectrophotometric estimation of bismuth (section 3.4).

Organometallic complex ions $[Ph_nBiX_{4-n}]^-$ have been described[136b].

Bromide Complexes

Bromide complexes of As^{III} have not been extensively studied. Many bromide complexes of Sb^{III} and Bi^{III} have been isolated, particularly as salts of organic bases[136a, 137]. Though the stoichiometry has been established by analysis, structural work has been begun only recently (Table 45). The reaction between pyridine and antimony tribromide, in hydrogen bromide, yielded a crystalline compound with bromide ions and complex ions $Sb_2Br_9^{3-}$ in which two $SbBr_6$ octahedra share a common face [29]. The lone pair of the Sb^{III} does not occupy a co-ordination position. The same is true in the ions $Sb^{III}Br_6^{3-}$ and $Bi^{III}Br_6^{3-}$, which deviate only slightly from O_h symmetry. In $(C_6H_8N)BiBr_4$, and the corresponding iodide, the ions are linked as in [26], with a distorted octahedral co-ordination round bismuth and the longest bonds opposite the shortest, and in $(C_5H_{12}N)_2BiBr_5$, the distorted octahedra round bismuth are linked by single bromide bridges [28]. Again, the Bi^{III} lone pairs are largely stereochemically inactive in the solid. The interactions linking $[EBr_n]^{(n-3)-}$ units may be broken in solution.

Formation constants have been given in Table 48.

Iodide Complexes

The most studied complexes are those of bismuth. Individual species have been identified[137] and formation constants given. Many crystalline antimony and bismuth iodides have been obtained, but there has been little structural work. In $Cs_3Bi_2I_9$, the $Bi_2I_9^{3-}$ ion consists of two distorted octahedra which share a common face [29].

Complex halide ions may be present in the many ternary halides of the Group V elements with zinc, cadmium and mercury[138a].

10.4. COMPLEXES WITH ORGANIC LIGANDS

Many complexes of arsenic, antimony and bismuth with organic ligands are known; no doubt many more may be made. Some of the most important are with hydroxy-acids or with polyols. For example, As^{III}, like boron, forms a series of complexes with glycols and sugars, and tartrate is a good complexing ion for Sb^{III} (section 6.4). A few stability constants have been measured [38]. In the complex oxalate $K_3Sb(C_2O_4)_3, 4H_2O$, all six oxygen atoms bound to any one antimony lie on the same side; this provides a dramatic example of a stereochemically active Sb^{III} lone pair [138b].

11. HALIDES EX_5

Pentafluorides of all three elements are known; the only other well-documented penta-halide is antimony pentachloride, but a number of compounds with more than one halogen have been isolated[51, 54]. Why arsenic fails to form a pentachloride is not clear. Thermo-dynamic quantities relevant to the formation of pentahalides from trihalides are shown in Scheme 13 and values for a number of systems are presented in Table 49. The mean bond energies in the pentahalides (h_7) are smaller than in the corresponding trihalides (h_6). Since ΔS for the reaction $AsCl_3 + Cl_2 \rightarrow AsCl_5$ is almost certainly negative, the enthalpy

change, h_3, must outweigh $T\Delta S$ for the reaction to be feasible. For reaction between antimony trichloride and chlorine, $T\Delta S$ at 298 K is -32.2 kJ mol⁻¹. If $T\Delta S$ for the AsCl₃–Cl₂ reaction is similar and if the heat of sublimation of AsCl₅ is 50 kJ mol⁻¹, formation of AsCl₅ is possible if h_2 is more negative than -338 kJ mol⁻¹, i.e. if the As^V–Cl bond energy is at least 242 kJ mol⁻¹. Such a value is not unreasonable compared with other halides (Table 49). Many attempts to make arsenic pentachloride, however, have failed. The freezing points of mixtures of AsCl₃–Cl₂, AsBr₃–Br₂, SbBr₃–Br₂ show simple eutectics, and vapour pressure measurements likewise give no evidence for formation of compounds[139]. The exchange of radiochlorine between chlorine and arsenic trichloride is much slower than the reaction between chlorine and phosphorus trichloride, and appears to involve a complex mechanism without even transient formation of AsCl₅ [140]. Phosphorus pentachloride gives the ions [PCl₄]⁺,[PCl₆]⁻ in acetonitrile. The arsenic analogues of both are known, but conductivity and Raman measurements on AsCl₃–Cl₂–MeCN mixtures show no evidence for ions[141].

Bi^V is probably too strongly oxidizing to form stable compounds with halide ions, other than fluoride.

11.1. PREPARATION AND PROPERTIES

The pentafluorides are made by the reaction between fluorine and the elements or the oxides. Bismuth pentafluoride requires a high temperature (*ca.* 600°C), but antimony and arsenic pentafluorides are made more easily. Antimony pentafluoride may be made from antimony pentachloride and anhydrous hydrogen fluoride, but replacement of the final chlorine is slow[142].

The greater volatility of the pentahalides compared with the trihalides (Table 50) is associated with the zero dipole moments of the pentahalide molecules. Arsenic pentafluoride, like sulphur hexafluoride, is very volatile, a reflection of a low heat, rather than a low entropy, of evaporation. In antimony pentafluoride, however, association between molecules is clearly shown (a) by the high viscosity (0.46 N s m^{-2} at 20°C, about that of glycerol. Compare AsF$_3$, 1.17×10^{-3} N s m^{-2} at 8.3°C), (b) by molecular weight measurements on the vapour {(SbF$_5$)$_3$ at 152°C and (SbF$_5$)$_2$ at 252°C}, (c) by the high Trouton constant, (d) by the mass spectrum and (e) by vibrational and n.m.r. spectra (see below). Bismuth pentafluoride also has a high Trouton constant—probably indicating association. The solid appears to have the uranium pentafluoride structure, with infinite chains of trans-bridged BiF$_6$ octahedra, but more detailed crystal data would be interesting. Sb^V chloride is molecular both in the liquid and in the solid down to -63°C. The n.q.r. spectrum suggests that all the antimony atoms are equivalent. Below -63°C, however, the n.q.r. and Raman spectra become more complicated, and several different environments for antimony and chlorine can be detected. A halogen-bridged structure, like that in antimony pentafluoride, is possible for the low-temperature form. There is no evidence for formation of ionic species in either antimony pentafluoride or pentachloride (cf. PCl$_5$): the pentafluoride has a low electrical conductivity (1.2×10^{-6} Ω^{-1} m^{-1} at 298 K).

Vibrational spectra of arsenic pentafluoride and antimony pentachloride have been interpreted in terms of D_{3h} symmetry (Table 51), but the fact that the [19]F n.m.r. spectrum of AsF$_5$ shows only one line, even at the lowest temperature observable, suggests that the barrier to pseudorotation—which interchanges axial and equatorial halogens—is small. Attempts have been made to calculate energy barriers, but several puzzling features of these

systems remain[143]. For antimony and bismuth pentafluorides, interpretation of vibrational spectra is less simple, since the site symmetry at the heavy atom in the liquid or solid is less than that in the isolated molecule. The ^{19}F n.m.r. spectra of a supercooled sample of antimony pentafluoride, or a solution in perfluorocyclobutane, suggested that the molecules were associated by *cis*-Sb–F–Sb bridges [30][144]. There are thus three types of fluorine: bridging (a), *trans* to bridging (b), and *cis* to bridging (c). The vibrational spectra are

[30]
consistent with this interpretation, since three high frequencies associated with the SbF$_4$ residue suggest that this has C_{2v} symmetry (*cis*-bridging) rather than D_{4h} (*trans*-bridging). Association persists up to 125°C, but at this temperature the fluorine atoms interchange sufficiently quickly for the n.m.r. spectrum at 40 MHz to show only one peak. For bismuth pentafluoride, the Raman data confirm that the bridges linking octahedrally co-ordinated bismuth atoms are *trans*.

11.2. REACTIONS

The chemistry of the pentahalides is dominated by their tendency to form complexes (section 15). Other aspects of their chemistry have been neglected, but the halides EX_5 may be used as oxidizing agents (Scheme 14). Like other non-metal halides, they react with water to give oxides or oxide halides, and with alkoxides and related metal derivatives[60].

$$SbCl_5 \xrightarrow{\text{NaOR}} Sb(OR)_5 \xrightarrow{\text{NaX}} [Na][Sb(OR)_5X] \qquad (X = Cl, OR)$$
Antimony pentachloride, like phosphorus pentachloride, dissociates in the vapour (above 200°C) to the trichloride and chlorine. The same reaction is partly responsible for the exchange of antimony between Sb^{III} chloride and Sb^V chloride in carbon tetrachloride at 50–80°C. A second mechanism, perhaps involving a chlorine bridged intermediate Sb_3Cl_{13}, is probably also involved[148].

11.3. MIXED HALIDES

Many derivatives with more than one halogen are conceivable, but few have been fully characterized (Table 52). It has been suggested[51c] that the mixed halides may, like PCl_5, exist in ionic and molecular forms (i.e. $[EX_4]^+[EX_6^!]^-$ and $EX_2X_3^!$), but more structural work is needed.

The addition of small amounts of antimony pentachloride to the pentafluoride gives a dramatic decrease in viscosity and increase in electrical conductivity. These changes have

TABLE 52. MIXED PENTAHALIDES

been attributed to the breaking of fluorine bridges between pentafluoride molecules, and the formation of ionic species such as $[Sb_nF_{5n+1}]^-$. As more pentachloride is added, the conductivity decreases and the viscosity rises again, as the ionic species are converted to the tetrameric $SbCl_4F$, which, like antimony pentafluoride, has *cis*-fluorine bridges between antimony atoms. The addition of still more pentachloride results in a fall in viscosity, as the polymeric species in solution are diluted with monomeric $SbCl_5$ molecules. It is probable that a variety of ionic and polymeric species are present in SbF_5–$SbCl_5$ mixtures: some of these may have been isolated in a series of adducts made many years ago by Ruff[149].

The viscosity and n.m.r. spectrum of material of composition SbF_3Cl_2 suggest that this may have a fluorine-bridged structure, like that of antimony pentafluoride[150]. The mixed halide (Swartz reagent) is often a more effective fluorinating agent than antimony trifluoride (cf. section 5.3), provided that yields are not lowered by oxidations[54].

$$SOCl_2 \xrightarrow{SbF_3Cl_2} SOF_2$$
$$POCl_3 \xrightarrow{SbF_3Cl_2} POFCl_2$$
$$CCl_2{:}CCl{\cdot}CCl{:}CCl_2 \xrightarrow{SbF_3Cl_2} CF_3CCl{:}CClCF_3 \xrightarrow{KMnO_4/KOH} 2CF_3COOH \quad [Ref. 151]$$
11.4. OXIDE HALIDES

Reports on oxide halides are confusing[152].

Thus fluorine was said to react with a mixture of As^{III} chloride and As^{III} oxide to give a compound $AsOF_3$, b.p. $-25.6°C$. In later work, however, the oxide fluorides $AsOF_3$, $SbOF_3$ and SbO_2F were obtained as hygroscopic, amorphous, non-volatile solids, insoluble in organic solvents.

$$[AsCl_4]^+[AsF_6]^- \xrightarrow{ClONO_2} [As(ONO_2)_4]^+[AsF_6]^- \xrightarrow{160-170} AsOF_3$$
Oxide halides molecules are said to be associated by AsO $\cdots$ As interactions.

12. OXIDES E₂O₅ AND RELATED OXYACIDS

The oxides E_2O_5 are much less well-characterized than the oxides E_2O_3, and there is little information about structures and physical properties. Ternary compounds, which may be described as double oxides, or as arsenates, antimonates and bismuthates, are better known.

12.1. ARSENIC(V) OXIDE AND ARSENATES

The reaction between As^{III} oxide and concentrated nitric acid yields a solution from which either of two solids may be recrystallized, depending on the temperature.

$$2H_3AsO_4, H_2O \text{ (recryst. } <30°C)$$
$$As_2O_3 + HNO_3 \rightarrow \qquad\qquad\qquad or \qquad \xrightarrow{>170°C} As_2O_5$$
$$As_2O_5, 5/3H_2O \text{ (recryst. } >100°C)$$

[152] J. Weidlein and K. Dehnicke, *Chem. Ber.* **98** (1965) 3053; *Z. anorg. allgem. Chem.* **342** (1966) 225; G. Mitra, *J. Am. Chem. Soc.* **80** (1958) 5639.

The hydrate $2H_3AsO_4,H_2O$ has a structure in which double sheets of AsO_4^{3-} tetrahedra and water molecules are linked by hydrogen bonds. It is similar to the hydrate $2H_3PO_4,H_2O$, with which it forms mixed crystals. It loses water at 100°C and is changed to the solid $As_2O_5,5/3H_2O$. This has a structure in which infinite band-like molecules $(H_5As_3O_{10})x$ are joined by short hydrogen bonds (O $\cdots$ O 240–245 pm) (Fig. 21). Two of the arsenic atoms in the repeating unit have the usual tetrahedral co-ordination
FIG. 21. The linked AsO_4 tetrahedra and AsO_6 octahedra in As_2O_5, $5/3H_2O$.

(As–O, 169.3 pm): the other atom, however, is six-co-ordinate (As–O, 182 pm). Both solids yield analytically pure As_2O_5 (ΔH_f°, -924.9; ΔG_f°, -782.4 kJ mol^{-1}; S^0, 105.5; C_p, 116.5 J mol^{-1} K^{-1}), when heated to constant weight at 350°C. This forms mixed crystals $(As,P)_2O_5$ which may contain up to 50 mol % P_2O_5, and it has been suggested that the structure may contain two different kinds of arsenic—only one of which may be replaced by phosphorus[153].

Arsenic acid is tribasic (at 298 K: pK_1, 2.2; pK_2, 6.9; pK_3, 11.5[38]) with similar dissociation constants to phosphoric acid. Alkali metals give two series of acid salts; like the acid phosphates, these lose water on heating.

$$NaH_2AsO_4 \rightarrow NaAsO_3 + H_2O$$

Salts of bi- and ter-valent ions are insoluble in water (Table 53). Solutions which lead to the formation of copper or chromium arsenates inside wood fibres have been used as preservatives. The insoluble arsenates are not easily leached, and so their effect is long-lasting[81].

153 A. Winkler and E. Thilo, Z. anorg. allgem. Chem. 339 (1965) 71; 337 (1965) 149; 346 (1966) 92.

The structures of many naturally occurring and synthetic arsenates have been determined (Table 54). One group has isolated AsO_4^{3-} tetrahedra linked by cations or by systems of hydrogen bonds. The tetrahedra are often distorted, with As–O distances from 165 to 175 pm. The shorter bonds probably have order greater than one; the longer bonds are associated with hydrogen atoms (As–OH). The distortion of the AsO_4 tetrahedra has been studied by [75]As n.q.r. [154]. Movement within the hydrogen bond system of the dihydrogen arsenates MH_2AsO_4 (M = K, Rb3, Cs, NH_4) provides a mechanism for ferroelectric properties.

In other arsenates, the AsO_4^{3-} tetrahedra are joined by the sharing of corners. Cyclic $As_3O_9^{3-}$ ions have been claimed in the potassium salt β-$K_3As_3O_9$. Chains (Fig. 22), with a repeating trimeric unit, are found in sodium meta-arsenate, and diopside-like chains, with a repeating dimeric unit, appear in lithium arsenate. Both these substances show fibre-like properties.

(a)

(b)
FIG. 22. (a) The repeating trimeric units of $NaAsO_3$. (b) The repeating dimeric units of $LiAsO_3$.

Synthetic arsenates and antimonates have been suggested as ion-exchange materials [154].

In a general way, the structural chemistry of the arsenates resembles that of phosphates and silicates. Some isomorphous replacement of arsenic by phosphorus is possible, but not all arsenates have the same structures as the corresponding phosphates. Condensed As–O frameworks are much less common than phosphate and silicate frameworks, and As–O–As bonds are apparently broken in aqueous solution[153]. Vibration frequencies assigned[156] to tetrahedral ions are as follows:

	ν_1	ν_2	ν_3	ν_4
AsO_4^{3-}	813	342	813	402
AsS_4^{3-}	386	171	419	216
SbS_4^{3-}	366	156	380	178

12.2. ANTIMONY(V) OXIDE AND ANTIMONATES

Sb^V oxide is obtained as a pale yellow powder by hydrolysis of antimony pentachloride with dilute ammonia, followed by dehydration at $275°C^5$. Care must be taken to avoid loss of oxygen, with reduction of some of the antimony to Sb^{III} (see section 16.1). Although Sb^V oxide is not very well characterized, thermodynamic data have been given (ΔH_f°, -974; ΔG_f°, -830 kJ mol^{-1}; S°, 125 J mol^{-1} K^{-1}). Several hydrates have been described, but it would be interesting to have comparative structural information on arsenic and antimony compounds.

Antimony is more often co-ordinated to six oxygen atoms than to four, and early X-ray work established the similarity between the sodium salts $NaSbF_6$ and $NaSb(OH)_6$. "Antimonic acid", obtained by passing the sparingly soluble alkali salts $MSb(OH)_6$ through an ion-exchange column in the acid form, gives a titration curve characteristic of a strong acid[157]. The pK_a is given[38] as 2.5. The solution probably contains $Sb(OH)_6^-$ ions, but there is evidence for condensed species in concentrated solutions at low pH [158].

[a] $M^{n+} = [Ni(H_2O)_6]^{2+}$, $[Mg(H_2O)_6]^{2+}$, $[Cu(H_2O)_3(NH_3)_3]^{2+}$, Na$^+$, Ag$^+$.

[b] A rutile superstructure in which the repeating unit corresponds to three unit cells of rutile. The columbite structure is related.

Solid antimonates have structures based on SbO_6 octahedra, with Sb–O distances 197–206 pm. These structures (Table 55) are commonly shown by ternary oxides, and so there is no reason why the antimony compounds should not be similarly described. In the rutile structure of $M^{III}SbO_4$ and in the spinel $Zn_7Sb_2O_{12}$, Sb^V and other metal ions are statistically distributed over octahedral holes in the lattice of oxide ions. In other structures, e.g. the ilmenite structure of $NaSbO_3$ or the trirutile structure of $FeSb_2O_6$, the antimony atoms are ordered in SbO_6 octahedra which may share corners or edges. In the compounds $LiSbO_3$ and $MnSb_2O_6$, there are strings of octahedra with shared edges (Fig. 23).

Oxidations involving antimonates in aqueous solution are discussed in section 16.3.

FIG. 23. SbO$_6$ octahedra with shared edges in LiSbO$_3$.

12.3. BISMUTH(V) OXIDE AND BISMUTHATES

Oxidizing agents such as chlorine or peroxydisulphide give brown or black precipitates with alkaline solutions of Bi^{III} oxide. These precipitates are taken to be ill-defined higher oxides. More definite brown compounds have been obtained by heating mixtures of alkali or alkaline earth, oxides with Bi^{III} oxide in oxygen, but structural work is still very sparse [159]. It has been claimed that sodium bismuthate has the same ilmenite structure as sodium antimonate NaSbO$_3$. Bismuthates are useful, strong, oxidizing agents, particularly in acid solution[160]; in phosphoric acid, insoluble and readily removed bismuth phosphate is formed. Glycols may be converted to compounds with carbonyl functions, and manganese (e.g. in the analysis of steel) may be quantitatively oxidized to permanganate.

12.4. ALKOXIDES

As^V alkoxides or arsenate esters have formulae (RO)$_3$AsO and (RO)$_5$As. Sb^V alkoxides are of the second type, (RO)$_5$Sb, in keeping with the greater tendency of antimony to expand its co-ordination beyond four. The alkoxides may be made by methods similar to those used to obtain E^{III} alkoxides (antimonite esters, section 6.4), e.g. from halides and alkali alkoxides, by oxidation of compounds (RO)$_3$E, or by transesterification in a solvent such as benzene which forms azeotropes with low-boiling alcohols[60, 161].

$$SbCl_5 + NaOMe \rightarrow Sb(OMe)_5 \text{ (subl. 180°C/0.01 mm)}$$

$$2(MeO)_3As + Cl_2 \rightarrow (MeO)_3AsO \text{ (b.p. 70–75°C/3–5 mm), MeOAsCl}_2, MeCl$$

$$(EtO)_3Sb + Br_2 \rightarrow (EtO)_3SbBr_2 \xrightarrow{\text{NaOEt}} (EtO)_5Sb \text{ (b.p. 134°C/0.01 mm)}$$

$$(EtO)_5Sb + PhOH \rightarrow (PhO)_5Sb \text{ (m.p. 45°C)} + EtOH$$

$$2(MeO)_3AsO + NaOMe \rightarrow Na[O_2As(OMe)_2] + As(OMe)_5 \text{ (b.p. 70°C/11 mm)}$$

$$AgAsO_4 + Me_3SiCl \rightarrow (Me_3SiO)_3AsO \text{ (b.p. 76–77°C/1.2 mm)}$$
The alkoxides are moisture-sensitive, volatile substances. Because of their thermal instability they are most readily purified by crystallization, but methyl and ethyl derivatives may be distilled at reduced pressure.

There is evidence from cryoscopic measurements that the lower Sb^V alkoxides are associated in solution[161]. The low volatility of Sb(OMe)$_5$ may also indicate association in the solid. The compound SbCl$_4$OEt is dimeric in the solid [31], with Sb–Cl 234 and

[159] R. Scholder, K-W. Ganter, H. Gläser and G. Merz, Z. anorg. allgem. Chem. **319** (1963) 375; B. Aurivillius, Acta chem. scand. **9** (1955) 1219.

Sb–O 209, 216 pm [162]. Reactions of As^V and Sb^V alkoxides have been extensively studied, especially by Kolditz and by Hass: much of this work is summarized in ref. 51c. In particular, reactions with fluorides yield derivatives

$$EF_n(OR)_m(OH)_l \ (l+m+n = 5) \quad \text{and} \quad M[EF_n(OR)_m(OH)_l] \ (l+m+n = 6),$$
and reactions with amines yield compounds with As–N frameworks. With phenyl magnesium bromide, the arsenic compound $(MeO)_3AsO$ yields tetraphenylarsonium bromide.

[31]
13. SULPHIDES E_2S_5

As^V sulphide As_2S_5 is not well characterized. It may be obtained[5] by passing hydrogen sulphide into an ice-cold solution of arsenate in concentrated hydrochloric acid and carefully dried. It easily decomposes, e.g. in hot water, to As^{III} sulphide and sulphur. Sb^V sulphide is said to be made similarly from more dilute hydrochloric acid: its solubility in the concentrated acid is attributed to the ready formation of $Sb^VCl_6^-$ ions (section 15.1).

Both sulphides exchange sulphur rapidly with hydrogen sulphide in the presence of base by formation of anionic species[163]. These may be obtained in crystalline compounds by dissolving the pentasulphides in ammonium or alkali sulphides and cooling the resulting solutions. Depending on the precise reaction conditions, a variety of compounds with

tetrahedral ions $[ES_nO_{4-n}]^{3-}$ may be isolated. Some of these are described in Table 56. Thioarsenates may also be formed by oxidation of arsenites with species containing S–S bonds. They are converted by oxidizing agents to arsenates and sulphates[164].

$$AsO_3^{3-} \xrightarrow{S_2O_3^{2-} \text{ or } S_xO_6^{2-}} AsO_3S^{3-} + SO_3^{2-}$$

$$AsO_3^{3-} \xrightarrow{S_2^{2-}} AsO_3S^{3-} + S^{2-}$$

$$AsO_3S^{3-} + 4I_2 + 10OH^- \longrightarrow AsO_4^{3-} + SO_4^{2-} + 8I^- + 5H_2O$$
The existence of Sb^V sulphide has been doubted[9b].

14. ORGANOMETALLIC COMPOUNDS

Attempts to make hydrides EH_5 of arsenic, antimony and bismuth have been unsuccessful, probably because the E–H bonds are insufficiently strong to compensate for the promotion of the Group V element to the E^V valence state (cf. Table 49). Organic derivatives ER_5 and halides $ER_{5-n}X_n$ are known[101,102]. These and related compounds in which the Group V element is formally in oxidation state V are described in this section.

14.1. PENTA-ALKYLS AND -ARYLS R₅E

Pentaphenylantimony (m.p. 169°C) can be made from the reaction of phenyl-lithium with the chlorides Ph_3SbCl_2 or Ph_4SbCl, or, in lower yield, directly from phenyl-lithium and antimony pentachloride in ether. The arsenic and bismuth analogues Ph_5As and Ph_5Bi are obtained from the chlorides Ph_3ECl_2 and phenyl-lithium at $-70°C$. The ease of preparation and the thermal stabilities of the penta-alkyls and -aryls reflect the reluctance of arsenic and bismuth to reach oxidation state V. Thus penta-alkyl derivatives of arsenic and bismuth have not been described, but methyl-, ethyl-, vinyl- and propenyl-antimony compounds are known. Penta-aryls are also accessible from tosylimines, made from triaryl compounds and chloramine-T in dry alcohol or methyl cyanide.

$$Ph_3As \xrightarrow{MeC_6H_4SO_2NClNa} Ph_3As{:}N{\cdot}SO_2C_6H_4Me \xrightarrow{2PhLi} Ph_5As$$

The alkyl and aryl compounds of antimony and arsenic are usually colourless liquids or solids, and pentamethylantimony is appreciably volatile. Pentavinylantimony is described as a green oil. The molecules ER_5 are of interest as species involving five-co-ordination. Thus pentamethylantimony (Table 57) appears from its vibrational spectrum to be a well-behaved trigonal bipyramidal species: the correct selection rules for D_{3h} are observed. Crystalline pentaphenylarsenic is isomorphous with pentaphenylphosphorus, in which the molecules have a trigonal pyramidal configuration round phosphorus. In crystalline pentaphenylantimony[165], however, the molecules are best described in terms of a square pyramid. One bond (211.5+0.5 pm) is appreciably shorter than the other four (average 221.6±0.7 pm), but quite small distortions of the CSbC angles (96–106°) would make a description in terms of a distorted trigonal bipyramid more appropriate. Square pyramidal and trigonal bipyramidal configurations have very similar energies, and may interconvert

[164] M. Schmidt and R. R. Wägerle, *Chem. Ber.* **96** (1963) 3293; *Z. anorg. allgem. Chem.* **330** (1964) 48.

as a result of small changes in intermolecular forces; the precise shape of the molecules in the crystal is not necessarily maintained in solution. The fluxional characteristics of the molecules R_5E, allowing easy exchange of axial and apical groups (cf. AsF_5), are shown in the 60 MHz n.m.r. spectra of Me_5Sb and $(4\text{-}MeC_6H_4)_5E$ (E = As, Sb), which show only one line at $-60°$ [150,169]. It is not clear how the dipole moments of Ph_5As (1.32 D) and Ph_5Sb (1.59 D) in benzene are to be interpreted.

[b] Absorptions attributed to Sb–C skeleton; symmetry species in D_{3h}.

Reactions of pentaphenylantimony are shown in Scheme 15. The thermal decomposition to triphenylantimony and biphenyl appears to be an intramolecular process, but the photolysis in benzene gives complicated products from radical intermediates[166]. The formation of tetraphenylstibonium salts is common when large anions are available: contrast the behaviour of chlorine and iodine. Bromine at $-70°C$ gives the stibonium salt $[Ph_4Sb][Br_3]$, which decomposes at 20°C to Ph_3SbBr_2 and PhBr. The phenyl groups of ^3H-substituted phenyl-lithium exchange only slowly with those of pentaphenylarsenic[167], but the salts $LiEPh_6$ (E = Sb, Bi) are easily formed. Similar compounds may account for the easy intermolecular exchange of alkyl groups between R_5Sb molecules[168]. The penta-alkyl- but not the penta-aryl-antimony compounds are hydrolysed by water. Biphenyl derivatives have been studied in some detail[169,170]; some reactions of the arsenic compounds are given in Scheme 15. The ions $As(bb')_2^+$ and $As(bb')_3^-$, with unsymmetrical biphenylyl groups (bb' = 4-methyl-2,2'-biphenylyl), have been resolved into optically active isomers, but not the unsymmetrical penta-aryl [32] with R = Ph, Y = Me, Z = H). An interesting feature of mass spectra of the binuclear compound [33] is the particularly intense peak due to the doubly charged positive ion; this probably rearranges to the structure [34] which has only paired electrons and favourable charge separation.

14.2. YLIDES[171]

The reactions between phenyl-lithium and arsonium salts $[R_3AsCHR_2]^+Br^-$ give a series of ylides comparable with the phosphorus analogues, and represented by the resonance structures

$$R_3^1As{=}CR_2^2 \leftrightarrow R_3^1\overset{+}{As}{-}\overset{-}{C}R_2^2 \tag{35}$$

Many are coloured. In some cases, sodium in liquid ammonia, or aqueous alkali, may be used in place of phenyl-lithium.

$$[Ph_3AsMe]Br \xrightarrow{PhLi} Ph_3\overset{+}{As}{-}\overset{-}{C}H_2$$

$$[Ph_3AsCH_2COPh]Br \xrightarrow{Na/liq.\ NH_3} Ph_3\overset{+}{As}{-}\overset{-}{C}H{\cdot}COPh$$
Other routes to ylides are as follows[171,172].

$$Ph_3AsCl_2 + H_2CR_2^2 \rightarrow Ph_3\overset{+}{As}-\overset{-}{C}R_2^2$$

[36]   [37]
Trimethylmethylenearsorane $Me_3\overset{+}{As}-\overset{-}{C}H_2$ (colourless, m.p. 33–35°C) is made indirectly from the trimethylsilyl compound[173].

$$Me_3As \xrightarrow{Me_3SiCH_2Cl} [Me_3AsCH_2SiMe_3]Cl \xrightarrow{BuLi} Me_3\overset{+}{As}-\overset{-}{C}HSiMe_3 \xrightarrow{Me_3SiOH} Me_3\overset{+}{As}-\overset{-}{C}H_2$$
The thermal and chemical stability of the ylides depends on the ability of the groups R^1 and R^2 to accommodate the charges in the polar structure [35]. Thus in most crystalline ylides R^2 is unsaturated, e.g. CN, SO_2Ph, CO_2Me. The ylide [36] is unchanged at its m.p. (188–190°C) and heating under reflux with alcoholic alkali is required for its hydrolysis. Trimethylmethylenearsorane is decomposed above 60°C. Its n.m.r. spectrum at 60 MHz shows two types of protons (signals at τ 10.19 {CH_2} and τ 9.19 {CH_3}), which exchange rapidly at room temperature in methanol.

$$Me_3\overset{+}{As}-\overset{-}{C}H_2 \underset{-H^+}{\overset{H^+}{\rightleftharpoons}} [Me_3AsCH_3]^+$$
Reactions of the arsenic ylides are very similar to the phosphorus analogues; the arsenic compounds are the more basic.
Arsenic ylides react with carbonyl compounds to give (a) normal Wittig products, or (b) arsines and products from rearrangement of oxirans.

(a) $R_3^1AsO + R_2^2C:CR_2^3$

(b) $R_3^1As + R_2^2C-CR_2^3$ → etc.
            O

172 D. Lloyd and M. I. C. Singer, *Chem. and Ind. (London)* (1967) 510, 787; *Chem. Communs.* (1967) 1042.

173 N. E. Miller, *Inorg. Chem.* **4** (1965) 1458; H. Schmidbaur and W. Tronich, *ibid.* **7** (1968) 168.

The relative importance of these two reactions depends on the groups R^1 and R^2. For example, ethylidenefluorene can be obtained in 91 % yield from the ylide [36] and acetaldehyde.

Little is known about antimony and bismuth ylides. Several have been postulated as intermediates, and the compounds [37] E = Sb, Bi have been isolated. The blue bismuth compound is more like the unstable pyridinium tetraphenylcyclopentadienylide than like the colourless or yellow cyclopentadienylides of phosphorus, arsenic and antimony.

Imines[174]

The compounds $R_3^+E-NR^2$, isoelectronic with ylides, have been postulated as intermediates in the catalytic conversion of isocyanates to carbodiimides by triphenylarsine oxide. Several arsenic compounds have been isolated; their reactions parallel those of ylides, but they are less stable than phosphinimines.

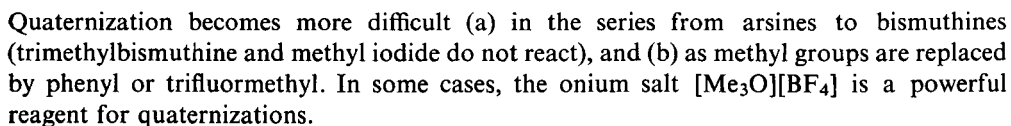
14.3. HALIDES

The Compounds R₄EX

These may be made by two methods.
(1) The quaternization reaction between the compounds R_3E and alkyl halides may be rapid and quantitative even at low temperatures.

$$Me_3As + MeI \rightarrow [Me_4As]I$$

Quaternization becomes more difficult (a) in the series from arsines to bismuthines (trimethylbismuthine and methyl iodide do not react), and (b) as methyl groups are replaced by phenyl or trifluormethyl. In some cases, the onium salt $[Me_3O][BF_4]$ is a powerful reagent for quaternizations.

$$Ph_3Sb \xrightarrow{[Me_3O][BF_4]/liq.\ SO_2} [Ph_3SbMe][BF_4] \xrightarrow{NaI} [Ph_3SbMe]I$$


174 O. J. Scherer and W. Janssen, *J. Organomet. Chem.* 16 (1969) P69; P. Frøyen, *Acta chem. scand.* 23 (1969) 2935.

(2) Grignard reagents react with compounds R_3EO or R_3ECl_2. Tetra-arylonium compounds can be made by this means.

$$Ph_3AsO + PhMgBr \rightarrow Ph_4AsOMgBr \xrightarrow{HCl} [Ph_4As][HCl_2]$$

$$Ph_3SbCl_2 + PhMgBr \rightarrow [Ph_4Sb]Br$$
Bromides and iodides are formulated as arsonium or stibonium salts. The halide ions may be replaced by a variety of anions, and some of the resulting onium compounds are soluble in water. The least soluble compounds are usually those with large anions (cf. the separation of $[Ph_4As][HCl_2]$ rather than $[Ph_4As]Cl$ above). Tetraphenylarsonium or tetraphenylstibonium derivatives are used for the isolation of complex anions, e.g. in analysis or for crystallographic studies. The As–C distances in Ph_4As^+ and Me_4As^+ have been given in the range 185–195 pm. In both cases, the carbon atoms are disposed very nearly at the corners of a tetrahedron, but the tetraphenylarsonium ion sometimes has no overall symmetry in solids because of twisting of the phenyl groups about As–C bonds. Arsonium and stibonium salts [abcdE]X contain asymmetric centres[104,105]. Optically active isomers of several halides such as benzylmethylphenylpropylarsonium bromide have been isolated, but they racemize easily, especially in non-polar solvents. Sulphates and perchlorates are more stable optically, and it may be that the ready racemization of the halides proceeds via fluxional five- co-ordinate or ionic species.
Solvents such as alcohols, water and acids stabilize the arsonium halides and slow down racemization. Resolution of stibonium salts may also be prevented by fast racemization reactions; asymmetric tetrahedral tin compounds are likewise exceedingly difficult to resolve.

Tetraphenylstibonium fluoride is more soluble in carbon tetrachloride than in water, and can be quantitatively extracted from aqueous media. The compounds Me_4SbF, Me_4SbOH and Ph_4SbOH (see Table 61) have molecular structures [175].

The Compounds R_3EX_2

Of the remaining organometallic halides, the most easily obtained have formulae R_3EX_2. Tertiary arsines or stibines are oxidized by halogens or by sulphuryl chloride.

$$(CF_3)_3As + Cl_2 \longrightarrow (CF_3)_3AsCl_2$$

$$Ph_3E + SO_2Cl_2 \xrightarrow[\text{toluene}]{0°C} Ph_3ECl_2 \quad (E = As, Sb)$$
Fluorides are usually made from chlorides.

$$(C_6H_5CH_2)_3ECl_2 + AgF \longrightarrow (C_6H_5CH_2)_3EF_2 \quad (E = As, Sb)$$

---
[175] K. D. Moffett, J. R. Simmler and H. A. Potratz, *Anal. Chem.* **28** (1956) 1356; H. E. Affsprung and H. E. May, *ibid.* **32** (1960) 1164; H. Schmidbaur, J. Weidleim and K.-H. Mitsche, *Chem. Ber.* **102** (1969) 4136.

The most easily prepared compounds are those with the lighter Group V elements, which least readily lose alkyl halides.

$$Me_3SbBr_2 \xrightarrow{180°\,C} MeBr + Me_2SbBr$$

$$Ph_3Bi + I_2 \xrightarrow[MeCN]{-35°C} Ph_3BiI_2 \xrightarrow{20°C} PhI + Ph_2BiI$$

$$(CF_3)_3SbBr_2 \xrightarrow{20°C} CF_3Br + (CF_3)_2SbBr$$
In crystals, the dihalides show a trigonal bipyramidal configuration at the Group V elements (Table 58) and, as usual in five-co-ordinate species[150], the most electro-negative groups, here the halogens, occupy apical positions. In organic solvents, the compounds

[e] R. S. McEwen and G. A. Sim, unpublished results (see ref. 177).

are monomeric. Mixtures of dihalides Me₃EX₂, Me₃EY₂ in benzene show only peak in one, the n.m.r. spectrum at room temperature, implying that the Me₃E moieties and halogens are exchanging rapidly. At lower temperatures, exchange is slowed and separate signals due to Me₃EX₂, Me₃EY₂ and Me₃EXY are detected[176]. The mixed halides cannot, however, be isolated by distillation.

The compounds Ph₃BiX₂ and Ph₃SbX₂ are not dissociated in methyl cyanide, but Ph₃AsCl₂ and Ph₃AsBr₂ are weak electrolytes, giving ions at low dilutions. The addition of halogens to the dihalides has been studied in detail: the large increase in conductivity after the addition of one equivalent has been attributed to the formation of polyhalides, e.g. [Ph₃SbBr]I₃. Some of these have been isolated[177].

The dihalides R₃EX₂ can often be recrystallized from concentrated aqueous solutions containing X⁻ ions, but they are hydrolysed in dilute solution. For example, when trimethylantimony dichloride is passed through an ion-exchange column, the hydroxide Me₃Sb(OH)₂ may be recovered from the extract and recrystallized from acetone. The

[176] G. C. Long, C. G. Moreland, G. O. Doak and M. Miller, Inorg. Chem. 5 (1966) 1358; C. G. Moreland, M. H. O'Brien, C. E. Douthit and G. C. Long, ibid. 7 (1968) 834.
[177] A. D. Beveridge and G. S. Harris, J. Chem. Soc. (1964) 6076; A. D. Beverage, G. S. Harris and F. Inglis, J. Chem. Soc. A (1966) 520.

halogens X may be replaced by a variety of other groups by reactions such as the following:

$$Me_3SbBr_2 + AgY \rightarrow Me_3SbY_2 \quad (Y = F, NO_3, \tfrac{1}{2}CO_3, \tfrac{1}{2}SO_4, \tfrac{1}{2}CrO_4, \tfrac{1}{2}C_2O_4)$$

$$Ph_3SbO + YH \rightarrow Ph_3SbY_2 \quad (Y = MeCO_2, HCO_2, NO_3)$$
Infrared spectra suggest that the anhydrous compounds Me_3SbY_2 are five-co-ordinate species. The species formed in aqueous solution have not been completely identified, but there is some evidence that a planar Me_3Sb skeleton is preserved, perhaps in ions such as $Me_3Sb(OH_2)_2^{2+}$ or $Me_3Sb(OH)(OH_2)^+$ with anions Y^-. Reactions of trimethylantimony dichloride are shown in Scheme 16. Tristrifluoromethylantimony dichloride $(CF_3)_2SbCl_2$ reacts with water to give mono- and di-hydrates (e.g. [38]), which may be formulated as

SCHEME 16. Reactions of trimethylantimony dichloride[178, 179].
species with six-co-ordinate antimony. Derivatives of tristrifluoromethylantimonic acid (e.g. [39]) may be isolated as pyridinium salts. The contrast between the weakly acidic methyl and strongly acidic trifluoromethyl compounds is notable.

$$(CF_3)_3SbCl_2 \xrightarrow{2H_2O} [H_3O][(CF_3)_3SbCl_2(OH)] \xrightarrow[C_5H_5N]{excess\ H_2O}$$

[38]

$$[C_5H_5NH][(CF_3)_3Sb(OH)_3] \xrightarrow{HX} [C_5H_5NH][(CF_3)_3SbX_3] \quad (X = Cl, Br)$$

[39]
The Compounds R₂EX₃ and REX₄

The alkyl derivatives R_2EX_3 and REX_4 are much less stable than the dihalides described in the previous section. They are made by the reaction of halogens with the tervalent mono- or di-halides, but easily lose alkylhalides, often below room temperature.

$$Me_2SbCl + Cl_2 \rightarrow Me_2SbCl_3 \rightarrow MeSbCl_2 + MeCl$$

$$MeSbCl_2 + Cl_2 \rightarrow MeSbCl_4 \rightarrow SbCl_3 + MeCl$$
Aryl derivatives, e.g. Ph_2SbCl_3 and $PhSbCl_4$ (m.p. 60–65°C), are much more stable thermally. They may be made from the stibinic or stibonic acids and aqueous hydrochloric acid.

$$Ph_2SbO(OH) \xrightarrow{HCl} Ph_2SbCl_3$$

$$PhSbO(OH)_2 \xrightarrow{HCl} PhSbCl_4$$
[178] M. Shindo and R. Okawara, *J. Organomet. Chem.* 5 (1966) 537.
[179] R. L. McKenney and H. H. Sisler, *Inorg. Chem.* 6 (1967) 1178.

The trichloride isolated (m.p. 176°C) is, however, a hydrate, with the molecular structure [40] and dimensions as follows[180]: $Sb-Cl_a$, 233.5±0.6; $Sb-Cl_b$, 248.1±0.6; Sb–C, 215.8±2; Sb–O, 220.5±2 pm; $\angle OSbCl_b$, 85±0.6°; $\angle OSbC$, 81±2°. The environment of

[40]   [41]
the antimony is very like that in the $SbCl_5$-adducts (section 15.3). The arsenic fluoride Me_2AsF_3 (m.p. 85°C) is associated, perhaps by fluorine bridges, and the phenyl derivative [41] is sufficiently stable dynamically to give two signals in the ^{19}F n.m.r. spectrum, a doublet from atoms F_a and a triplet from atoms F_b [150].

14.4. OXYGEN, SULPHUR, AND SELENIUM DERIVATIVES

The main groups of compounds are as follows:

R_3EY	$R_2E(Y)YH$	$RE(Y)(YH)_2$	$R_{5-n}E(YH)_n$
e.g. Me_3AsO, tri- methylarsine oxide	e.g. $Me_2As(O)OH$, dimethylarsinic acid	e.g. $MeAsO(OH)_2$, methylarsonic acid	e.g. Ph_4SbOH, hydroxytetra- phenylantimony(V)

(E = As, Sb, Bi; Y = O, S, Se)

In general, the oxygen compounds are the best known, though many sulphur and selenium derivatives have been made. The arsenic compounds are like the phosphorus analogues. The antimony compounds are formally similar, but, because of the tendency of antimony to form five or six bonds, the species in aqueous solutions of similar arsenic and antimony compounds may be quite different. Little is known about bismuth compounds.

Arsine and Stibine Oxides

The oxides are most commonly made by hydrolysis of the dihalides R_3EX_2, or by oxidation of the organometallic derivatives R_3E. Reaction with air is not usually easily controlled, and better oxidizing agents are mercuric oxide in alcohol, for the more easily oxidized compounds, or hydrogen peroxide—the most versatile reagent of all.

$$Me_3Sb + HgO \rightarrow Me_3SbO + Hg$$
$$Ph_3As + H_2O_2 \rightarrow Ph_3AsO + H_2O$$
Trialkyl sulphides and selenides can easily be made by refluxing arsines or stibines with sulphur or selenium.

$$Et_3As + S \rightarrow Et_3AsS$$
[180] T. N. Polynova and M. A. Porai-Koshits, *J. Struct. Chem.* **8** (1967) 92.

Sulphides have also been made from oxides or dibromides.

$$Ph_3AsO \xrightarrow{CS_2} Ph_3AsS \xleftarrow{MeOH/NH_3/H_2S} Ph_3AsBr_2$$
The negative charge localized on the oxygen results in an interesting series of hydrogen-bonded compounds, as well as many complexes with Lewis acids (section 10.2) and transition metal compounds. Trialkyl-arsine and -stibine oxides are hygroscopic, and care is needed in the isolation of anhydrous compounds. Triphenylarsine oxide crystallizes as a monohydrate. The water, which is lost at about 70°C, is held by hydrogen bonds making centrosymmetric dimers [42]. As in the derivatives R_3E, the phenyl groups are twisted so that the arsine oxide has no symmetry in the crystal. "Short" hydrogen bonds have been found in triphenylarsine oxide–hydrogen chloride [43], in which there is no direct bond
between chlorine and arsenic. The n.m.r. absorption of the phenyl protons is at τ 2.14 in $CDCl_3$ (compare Ph_3AsO, τ 2.40), and the infrared spectrum shows strong absorption at 2750–2000 cm^{-1} but not at 888 cm^{-1} (v As=O in Ph_3AsO, Table 59). The dipole moment is high (9.2 D). The ion $[Ph_3AsOH]^+$, which absorbs at 2800–3000 cm^{-1}, can be isolated in trihalides, which are strong electrolytes in methyl cyanide, but, from the reaction between triphenylarsine oxide, hydrogen bromide and mercuric bromide, the salt

$$[Ph_3AsOHOAsPh_3]_2[Hg_2Br_6]$$

is obtained. This also has a short hydrogen bond in the cation. Hydrogen bonds have been suggested in the adducts of triphenylarsine oxide with hydrogen peroxide, and nitric

acid, and in the spirocyclic adduct $C(CH_2 \cdot Ph_2As:O)_4 \cdot 2H_2O_2$ [44]. The structural data (Table 60) shows that the As–C distances are like those in phenylarsonium salts and that longer As–O distances are associated with shorter hydrogen bonds.

Hydrates of trialkyl- or triaryl-antimony oxides are less well characterized. The compound $Me_3Sb(OH)_2$ (p. 671) is a non-electrolyte, but it is not known whether the crystals contain five co-ordinate species or hydrogen-bonded complexes.

The Acids $RE(O)(OH)_2$ and $R_2E(O)OH$

Arsonic and stibonic acids may be made by several methods.

(a) Primary alkyl halides may react with sodium arsenite[182].

$$EtBr + AsO_3^{3-} \rightarrow EtAsO_3^{2-} + Br^-$$
(b) Arylarsonic acids are best made from diazonium compounds[183]. There are several variations in procedure which are sometimes known by the following names:

Bart reaction $PhN_2^+Cl^- + As(ONa)_3 \rightarrow PhAsO_3Na_2 + NaCl + N_2$
Béchamp $HOPh + H_3AsO_4 \rightarrow 4\text{-}HOC_6H_4AsO_3H_2 + H_2O$
Rosenmund

Scheller $PhN_2^+HSO_4^- + AsCl_3 \xrightarrow[\text{(2) } H_2O]{\text{(1) ROH/trace CuCl}} PhAsO_3H_2 + N_2$

¹⁸³ G. O. Doak and H. G. Steinman, *J. Am. Chem. Soc.* 68 (1946) 1987, 1989, 1991; C. S. Hamilton and J. F. Morgan, *Org. Reactions*, 2 (1944) 415.

Hundreds of arylarsonic acids have been made[101,102]. Stibonic acids made by the last reaction may be freed from inorganic antimony compounds by converting them to the pyridinium salts $[C_5H_5NH][RSbCl_5]$ which can be recrystallized from HCl/alcohol.

(c) Dihalides may be hydrolysed and oxidized with hydrogen peroxide.

$$CF_3AsI_2 \xrightarrow{H_2O_2} CF_3AsO(OH)_2$$
Arsinic acids and stibinic acids are made by analogous reactions.

$$R^1N_2Cl + R^2AsCl_2 \longrightarrow R^1R^2AsOOH$$

$$Me_2SbCl \xrightarrow{H_2O_2} Me_2SbOOH$$
Arsonic and arsinic acids are usually colourless crystalline solids, only slightly soluble in ether and non-polar solvents, but more soluble in alcohol and water. Like the alkyl carboxylic acids, the dialkylarsinic acids crystallize as centrosymmetric hydrogen-bonded dimers (Table 60). The acids are rather weak (e.g. $MeAsO(OH)_2$: pK_1, 3.61; pK_2, 8.25; $PhAsO(OH)_2$: pK_1, 3.47; pK_2, 8.48), and cacodylic acid $Me_2AsO(OH)$ is amphoteric (pK_a, 6.27; pK_b, 12.4 at 25°C)[38]. The trifluoromethyl compounds $CF_3AsO(OH)_2$ and $(CF_3)_2AsO(OH)$ are completely ionized in aqueous solution and are probably intermediate in strength between hydrochloric and nitric acids. They are thus similar to the trifluoromethyl derivatives of phosphorus and sulphur.

Arylstibonic acids are rather insoluble in both polar and non-polar solvents and molecular weight measurements show the presence of associated species. The nature of the polymerization is not known. It is probable that in alkaline solution the ions $[RSb(OH)_5]^-$ are formed.

Arsonic and stibonic acids are starting materials for the preparations of many organometallic compounds. Conversions to hydrides and halides have been mentioned. The As–C or Sb–C bonds are very stable. For example, it is possible to effect nitrations, diazotizations, Sandmeyer reactions and oxidations of methyl substituents in the aromatic rings of arylarsonic acids without removing the arsonic acid function. Cacodylic acid is unaffected by strong oxidizing agents, e.g. nitric acid or permanganate. Bistrifluoromethylarsinic acid, however, liberates trifluoromethane with strong alkali.

Methylarsonic acid and its ammonium, alkali, alkaline earth and titanium salts are used as herbicides. The chromium, iron and mercuric salts and other ammonium ferric alkylarsonates are used in horticultural and agricultural fungicides and bactericides[81]. Arylarsonic acids, especially derivatives of arsanilic acid $4\text{-}NH_2C_6H_4AsO_3H_2$, were important historically as early examples of compounds developed by planned research as chemotherapeutic agents. They were used in the treatment of syphilis and sleeping sickness. Cacodylic acid, which is more stable, less easily assimilated and less poisonous, was used in treatment of malaria. The acid $2,4\text{-}Cl_2C_6H_3AsO_3H_2$ is used as a wood preservative.

A number of azo-arsonic acids, e.g. arsenazo(III) [45], may be used for the preparation of transition metal complexes for spectrophotometric estimations. The Zr^{IV}, Th^{IV},
[45]

UO_2^{II}, Sn^{IV} and Bi^{III} salts of methylarsonic acid are precipitated at pH 1. As the acidity is decreased, metal ions are precipitated in the following order[184]: Ti^{IV}, Sn^{II}, Hg^{I}; In^{III}, Al^{III}, Y^{III}; Ce^{III}, Cu^{II}, Hg^{II}; La^{III}, Mn^{II}, Fe^{II}, Co^{II}, Ag^{I}, Cd^{II}, Pb^{II}; Be^{II}, Zn^{II}, Ni^{II}; Fe^{III}; Mg^{II}. Dibutylarsinic acid has been suggested as a complexing agent for solvent extraction of metal ions.

Hydroxy and Alkoxy Derivatives of Antimony(V)

Tetraphenylstibonium bromide may be hydrolysed, first with acid and then with ammonia, to yield the hydroxy compound Ph_4SbOH, which can be recrystallized from aqueous methanol. This has a molecular structure in the solid, with the hydroxy group occupying an axial position in the trigonal bipyramid round each antimony (Table 61) (cf. ref. 150).

TABLE 61. HYDROXY- AND ALKOXY-DERIVATIVES OF ANTIMONY(V)

	M.p. (°C)	Sb–O	Sb–C	SbC	Ref.
Ph_4SbOH		204.8	221.8	213.1	a

$Ph_3Sb(OMe)_2$	101	203 ± 0.8		212.0 ± 1	b

a A. L. Beauchamp, M. J. Bennett and F. A. Cotton, *J. Am. Chem. Soc.* **91** (1969) 297.
b K. W. Shen, W. E. McEwen, S. J. La Placa, W. C. Hamilton and A. P. Wolf, *J. Am. Chem. Soc.* **90** (1968) 1718.

The hygroscopic alkoxide Ph_4SbOMe, made from sodium methoxide and the bromide Ph_4SbBr, has a similar structure in the solid. In solution, however, axial and equatorial phenyl groups probably exchange rapidly, since the 60 MHz n.m.r. spectrum of the *p*-tolyl compound $(4-MeC_6H_4)_4SbOMe$ at $-60°$ in $CDCl_3-CCl_4$ shows only one 4-Me peak.

The slow methanolysis of methoxytetraphenylantimony occurs by an ionic mechanism.

$$Ph_4SbOMe + OMe^- \rightarrow [Ph_4Sb(OMe)_2]^- \xrightarrow{slow} Ph_3Sb(OMe)_2 + Ph^-$$

This reaction contrasts with methanolyses of tetra-arylphosphonium salts, which yield ethers and triarylphosphine oxides, and shows the greater tendency of antimony to maintain co-ordination numbers greater than four[185]. The alkoxides $R_3Sb(OR)_2$ are easily obtained from the halides R_3SbX_2 and the alkoxides RONa. With chelating alkoxides, the organoantimony(V) halides yield compounds $R_nSbCl_{4-n}(YY)$ (YY = oxinate, acac). Most of these are monomeric in benzene, and probably contain six-co-ordinate antimony[186].

15. COMPLEXES OF ARSENIC(V), ANTIMONY(V) AND BISMUTH(V)

Hundreds of complexes of the pentahalides EX_5 have been described and much structural information is available. The complexes have important applications in preparative chemistry.

15.1. HEXAFLUORO-ARSENATES(V), -ANTIMONATES(V) AND -BISMUTHATES(V)

A full range of salts $M^{n+}[EF_6]_n$ can be made, either by heating together the fluorides MF_n and EF_5, or by treating a mixture of oxides with a powerful fluorinating agent, such as bromine trifluoride.

$$AgO + As_2O_3 + BrF_3 \longrightarrow AgAsF_6$$

$$BiF_3 \xrightarrow{\ BrF_3/F_2\ } BrF_2BiF_6 \xrightarrow{\ AgBrF_4\ } AgBiF_6$$
Hexafluorobismuthates(V) are less well known than the analogous arsenic and antimony compounds.

TABLE 62. STRUCTURAL CHEMISTRY OF HEXAFLUORO-ARSENATES(V) AND -ANTIMONATES(V), MEF_6

M	Li	Na	Ag	K	Tl	Rb	Cs
$MAsF_6$	R_1	R_1	C_2	R_2	R_2	R_2	R_2
$MSbF_6$	R_1	C_1	T	T	R_2	R_2	R_2

R_1, rhombohedral $LiSbF_6$ structure. C_1, face-centred-cubic $NaSbF_6$ structure. C_2, cubic $CsPF_6$ structure. R_2, rhombohedral $KOsF_6$ structure. T, tetragonal $KNbF_6$.

The crystal structures (Table 62) show almost symmetrical octahedral anions. With small cations, e.g. Li^+, Na^+, the structures are related to that of sodium chloride, with discrete EF_6^- octahedra in anion positions, so that each cation has six fluorine neighbours. With larger cations, e.g. Rb^+, Cs^+, the structures resemble that of caesium chloride, and each cation has twelve fluorine neighbours[187].

The ions EF_6^- have been characterized by infrared and, where suitable solvents are available, by n.m.r. spectroscopy, and the absorptions (Table 63) remain roughly consistent from compound to compound. In many solids, however, the site symmetries at the heavy atoms are less than O_h and this leads to a splitting of modes degenerate in O_h and to transitions forbidden in O_h. The ^{19}F n.m.r. spectra of solutions containing AsF_6^- often show four broad lines from coupling between the ^{75}As nucleus ($I = 3/2$, Table 2, p. 550) and fluorine. At low temperatures, the spectra may collapse to a single line because of increased ^{75}As quadrupolar relaxation[188].

Ions [E$_n$F$_{5n+1}$]$^-$ may be formed in the presence of excess halide EF$_5$. The ion [As$_2$F$_{11}$]$^-$ [46] is characterized as its tetrabutylammonium salt in SO$_2$ClF solvent; Sb$_2$F$_{11}^-$ is known as

the caesium salt, and in several solvents such as liquid sulphur dioxide. This is a good solvent for reactions of antimony pentafluoride, with which it forms a 1:1 complex (see Table 64).

[46]
The $Sb_3F_{16}^-$ ion has been identified in the complex $[Br_2][Sb_3F_{16}]$: the Sb–F bond lengths are 183 (terminal) and 203 (bridge) pm, and the SbFSb angle 147°. The bridging fluorines are *trans* in the solid, but *cis* in solution.

Reactions of antimony pentafluoride in protonated solvents, and substituted hexa-fluoro-arsenates(V) and -antimonates(V) are referred to in section 15.5.

The reaction between Sb^V fluoride and sodium chloride yields compounds, e.g. $Na[cis-SbF_2Cl_4]$, with both chlorine and fluorine in the anion. Similar anions

$$[(CF_3)_3AsF_3]^-, \quad [(CF_3)_2AsF_4]^-$$

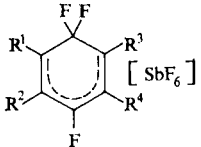
can be isolated as caesium salts from the reaction between trifluoromethylarsenic(V) fluorides and caesium fluoride[189].

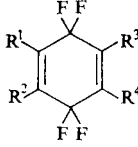
15.2. ADDUCTS OF ARSENIC AND ANTIMONY PENTAFLUORIDES

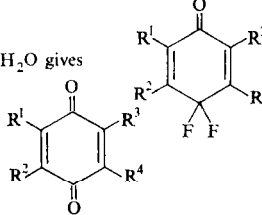
The fluorides EF_5 form many adducts of low volatility with non-metal fluorides (A–F)[190] (Table 64). These usually involve transfer of fluoride, giving in the extreme, ionic structures.

$$A\text{–}F \xrightarrow{EF_5} [A]^+[EF_6]^- \xrightarrow{EF_5} [A]^+[Sb_nF_{5n+1}]^-$$
Evidence for ions has been taken from i.r. and n.m.r. spectra (Table 63). Full structure determinations, by X-ray crystallography, of solid adducts show that ionic formulations are nearly, but not completely, adequate. Some of the compounds examined show shorter A–F(Sb) and longer (A)F–Sb distances than would be expected for $[A][EF_6]$, and so a complete description of the solid must include a small component $A\text{–}F\text{–}EF_5$ (Fig. 24).

BrF₃, SbF₅ or [BrF₂][SbF₆]   SbF$_a$, 184 (av.); SbF$_b$, 191 pm
                                            BrF$_b$, 229   BrF$_c$, 169

XeF₂, 2SbF₅ or [XeF][Sb₂F₁₁]   SbF$_a$, 183 (av.); SbF$_b$, 193; SbF$_{b'}$, 198, 205
                                             XeF$_b$, 235   XeF$_c$, 184






The solids probably ionize in suitable solvents.

Fluoride abstraction from non-metal fluorides is a very general method for the preparation of new cations, particularly where isoelectronic analogues of the cations are known. Examples in Table 64 are NF_4^+, RCO^+, Bu^{t+}, O_2^+, FCl_2^+, ClF_2^+, IF_6^+. Many of the adducts react with potassium fluoride.

$$SF_4, SbF_5 + KF \rightarrow KSbF_6 + SF_4$$
Such displacements do not necessarily imply ionic structures for the adducts. The volatility of the displaced ligand is an important factor in shifting the equilibrium to the right. Many similar reactions are known; some of these involve oxidation-reduction.

$$SF_4AsF_5 + SbF_5 \rightarrow SF_4, SbF_5 + AsF_5$$
$$2(C_5H_5)_2Fe + N_2F_4, 2SbF_5 \rightarrow 2[(C_2H_5)_2Fe][SbF_6] + N_2F_2$$
The arsenic and antimony pentafluoride adducts may be used in place of the non-metal fluorides in chemical reactions: e.g. the antimony pentafluoride adduct of bromine trifluoride is said to be a better fluorinating agent, as well as more easily handled, than the

very corrosive bromine trifluoride. Thus even refractory oxides, e.g. ThO_2, Al_2O_3, CaO, are converted to fluorides. Oxygen is liberated quantitatively from organic compounds.

(a)

(b)
Fig. 24. The structures of (a) [BrF₂], [SbF₆], and (b) [XeF], [Sb₂F₁₁].

15.3. ADDUCTS OF ANTIMONY PENTACHLORIDE

The number of complexes between antimony pentachloride and electron donors is very large indeed[190]. The list in Table 65 is far from comprehensive, and concentrates on those adducts for which structural and thermodynamic information has been obtained. Many involve halogen transfer, and others, for which the structures are not known, may do so. Often the main interest is in the cations: e.g. the adduct written as [Ph₂CN:CPh₂]⁺[SbCl₆]⁻ has a cation isoelectronic with tetraphenylallene. As with fluorine analogues (section 15.2) simple valence structures are not always adequate. Thus the structure of the compound ICl₃,SbCl₅ is intermediate between the ionic [ICl₂][SbCl₆] and the chlorine bridged ··· Cl–ICl₂–Cl–SbCl₄ ···. Many adducts, however, have molecular structures: e.g. in POCl₃,SbCl₅, the donor atom is oxygen, and a slightly distorted octahedral OSbCl₅ arrangement results. Careful structural work, mainly by Lindqvist (Table 66), shows that, as the Sb–O bond length increases, the octahedron becomes more distorted as the chlorine atoms move towards the oxygen[132]. The Sb–Cl bond lengths (233–236 pm) are almost the same as in antimony pentachloride. A similar slightly distorted octahedral array is found in adducts with nitrogen donors. The sulphur–nitrogen ring is considerably flattened in the S₄N₄ adduct, compared with the free donor, but S₂N₂ is little distorted on co-ordination.

[b] D. Neubauer and J. Weiss, *Z. anorg. allgem. Chem.* **303** (1960) 28.
[c] H. Binas, *Z. anorg. allgem. Chem.* **352** (1967) 271.
[d] R. L. Patton and K. N. Raymond, *Inorg. Chem.* **8** (1969) 2426.

Besides crystallographic evidence on the relative strengths of antimony pentachloride complexes, there is information from calorimetry and measurements of equilibrium constants. In 1,2-dichloroethane, the complexes DSbCl₅ become more dissociated, i.e. weaker, in the series:

(D =) HCONMe₂ > Me₂SO > Et₂POCl > Et₂O > H₂O > PhPOCl₂ > PhPOF₂ > MeCN
POCl₃ > SOCl₂ > PhCOCl > MeCOCl
The heats of dissociation decrease in the series:

$(D =) C_5H_5N > Me_2SO > HCONMe_2 > (MeO)_3PO > Ph_2POCl > Et_2O > Me_2CO > MeCN$
$SeOCl_2 > POCl_3 > SOCl_2 > SO_2Cl_2$
$(D =) Ph_2SeO > Ph_3AsO > Me_3PO > Me_2SO > Et_2S > Me_2CO > MeCOOEt > Et_2CO$
$Et_2O > Me_2SO_2 > Ph_2SO_2 > POCl_3 > SeOCl_2 > SOCl_2$
It seems that, towards pyridine, antimony pentachloride is about as good an acceptor as boron trichloride. The formation of complexes may be accompanied by oxidation-reduction. For example, thianthrene [47], some aromatic amines, or hydrocarbons such as perylene [22], react with antimony pentachloride in carbon tetrachloride to give coloured substances, which contain radical cations: little has been done to characterize the corresponding antimony-containing species[191] (cf. section 10.2).

 [47]
Many adducts between antimony pentachloride and alcohols, ethers, ketones, mercaptans and thioethers, have been made. These react with hydrogen chloride to give compounds formulated as onium salts. At higher temperatures the compounds $ROSbCl_4$ may be obtained from alcohol adducts.

$$R_2O, SbCl_5 \xrightarrow[-HCl]{HCl} [R_2OH][SbCl_6] \xrightarrow{CH_2N_2} [R_2OMe][SbCl_6]$$

$$[ROH_2][SbCl_6] \xrightarrow[HCl]{-HCl} ROH, SbCl_5 \xrightarrow[HCl]{-HCl} ROSbCl_4$$
Azide and cyanide adducts of antimony pentachloride, and adducts of the compounds R_3ECl_2 (E = P, As, Sb), show similar reactions.

$$MeN_3, SbCl_5 \xrightarrow[-N_2]{HCl} [H_2C:NH_2][SbCl_6]$$

$$HCN, SbCl_5 \xrightarrow{2HCl} [HClC:NH_2][SbCl_6] \xrightarrow{EtOH} [H(EtO)C:NH_2][SbCl_6]$$

$$Me_3PCl, SbCl_6 \xrightarrow{H_2O} Me_3PO \cdot SbCl_5 \xrightarrow[-40°C]{HCl} [Me_3POH][SbCl_6]$$

$$\xrightarrow{MeOH} [Me_3POMe][SbCl_6]$$

$$\xrightarrow{NaN_3} [Me_3PN_3][SbCl_6] \xrightarrow{NaN_3} [Me_3PN_3][SbCl_5N_3]$$
It has been suggested that antimony pentachloride may form complexes by chloride donation, forming $SbCl_4^+$, but at present the evidence is not very clear. Presumably such complexes would require powerful chloride acceptors.

15.4. COMPLEXES OF ARSENIC PENTACHLORIDE

Although arsenic pentachloride has not yet been made, a number of its complexes have been isolated by the following reactions[192]:

$$AsCl_3 + Cl_2 + M'Cl_n \rightarrow [AsCl_4][M'Cl_{n+1}], \text{ e.g. } M' = Al, Ga, Sb$$
$$AsCl_3 + Cl_2 + Q^+Cl^- \rightarrow Q^+AsCl_6^-, \text{ e.g. } Q^+ = Et_4N^+$$
$$AsCl_3, xD + Cl_2 \rightarrow AsCl_5, yD + [x-y]D, \text{ e.g. } D = R_3PO$$
The $AsCl_5$ can thus act as a donor, giving $AsCl_4^+$, or as an acceptor, giving $AsCl_6^-$. The $AsCl_4^+$ ion, which is isoelectronic with $GeCl_4$ or $GaCl_4^-$, is found in the mixed halide $AsCl_2F_3$ (section 11.3), or in adducts with strong halide acceptors, e.g. $AlCl_3$, $GaCl_3$, $SbCl_5$. It is presumed to be tetrahedral and some of its properties are given in Table 63. The $AsCl_6^-$ ion (Table 63) is formed in the presence of strong chloride donors. There is some evidence that the complex $AsCl_5PCl_5$, which is difficult to obtain pure, is $[PCl_4][AsCl_6]$. The structure reflects the weaker chloride acceptor properties of phosphorus compared with antimony pentachloride.

15.5. HALIDE COMPLEXES IN WATER AND OTHER PROTIC SOLVENTS

Hexafluoroarsenate(V) ions are hydrolysed only with difficulty in water. They may thus be quantitatively precipitated from aqueous solutions by nitron or tetraphenylarsonium cations. Colourless crystals of $HAsF_6 \cdot 6H_2O$ may be obtained by the evaporation of a solution made by passing hexafluoroarsenates down a cation-exchange column in the acid form. Hexa-fluoroantimonate(V) and -bismuthate(V)[193] ions are hydrolysed more readily.

The hydrates $HSbCl_6$, nH_2O ($n = 4\frac{1}{2}$, 2, 1) have been described, but $SbCl_6^-$ ions can be preserved only in solutions with high concentrations of HCl. At lower HCl concentrations, partially hydrolysed species $[Sb(OH)_nCl_{6-n}]^-$ predominate.

M (HCl)	12	8	6	5
n for main species	0	1	2	3

The hydrolysis of $SbCl_6^-$ in the pH range 2–12 is complicated. A base- and buffer-catalysed reaction probably involves S_N2 displacements in six-co-ordinate Sb^V species, and a pH independent reaction may be unimolecular[194].

A good deal of effort has been devoted to the characterization of species in anhydrous hydrogen fluoride and fluorosulphuric acid: $HF–SbF_5$ or $FSO_3H–SbF_5$ have been called "magic acids" or "superacids".

Hydrogen fluoride and antimony pentafluoride are miscible in all proportions. The electrical conductivity rises to a maximum at 3.5 mol % of SbF_5 and falls rapidly at higher SbF_5 concentrations. This behaviour and the details of the ^1H and ^{19}F n.m.r. spectra can be understood in terms of the reactions:

$$2HF + SbF_5 \rightleftharpoons H_2F^+ + SbF_6^-; \qquad SbF_6^- + nSbF_5 \rightleftharpoons [Sb_{n+1}F_{5n+6}]^-$$

Like other ions formed from solvent by proton transfer, the H_2F^+ and SbF_6^- ions have exceptionally high mobilities (H_2F^+ 0.035, and SbF_6^- 0.02 Ω^{-1} m^2 mol^{-1} at 0°)[195]. Sulphur trioxide and antimony pentafluoride react to give viscous adduct, formulated as polymeric SbF_4SO_3F. This is a strong acid in fluorosulphuric acid.

$$SbF_4SO_3F + 2HSO_3F \rightarrow H_2SO_3F^+ + [SbF_4(SO_3F)_2]^-$$
Various other species $\{SbF_n(SO_3F)_{5-n}\}$, which in fluorosulphuric acid give ions $[SbF_n(SO_3F)_{6-n}]$, have been characterized: their acidity increases as n increases from 1 to 3 [196].

The acid solvents EF$_5$–HF and EF$_5$–HSO$_3$F dissolve metals with the liberation of hydrogen[197]. They have also been used for the protonation of weak organic bases such as nitriles, ketones and hydrocarbons[198] and for the preparation of radical ions for e.s.r. studies. An inorganic example is the paramagnetic Cl$_2^+$ made from chlorine fluoride. There has been some important work on the reactions of carbonium ions.

16. MIXED VALENCY COMPOUNDS AND MECHANISMS OF REDOX REACTIONS

Antimony sometimes appears as Sb^{III} and Sb^V in the same compound[199].

16.1. ANTIMONY TETROXIDE Sb$_2$O$_4$ AND RELATED COMPOUNDS

When antimony trioxide is heated in air at 700–1000°C, a compound, Sb$_2$O$_4$, is formed. This can crystallize in two forms (α and β); in each there are two quite distinct environments for antimony. Sb^V atoms have six oxygen neighbours at the corners of a slightly distorted octahedron and Sb^{III} atoms have the usual one-sided environment [48] (cf. structure [5], p. 610). The α and β modifications differ only in the packing of the Sb^{V}O$_6$ and Sb^{III}O$_4$ polyhedra. Antimony tetroxide is more compact and has a greater density than the trioxide (Table 67). It is also very stable and is unchanged in air at 900°C. The impure solid obtained by roasting stibnite in air has been used for colouring glass yellow.

TABLE 67. PROPERTIES OF ANTIMONY TETROXIDE Sb$_2$O$_4$

Thermodynamic properties[a]	ΔH_f°, −907; ΔG_f°, −795.8 kJ mol^{-1}; S°, 127; C_p°, 114 J K^{-1} mol^{-1}

(β-form)[b] (see [48])	O$_a$–Sb–O$_a$, 87.9°; O$_b$–Sb–O$_b$, 148° (± 0.4); Sb^V–O, mean 196.8$\pm$0.9 pm

[a] Ref. 11.
[b] D. Rogers and A. C. Skapski, *Proc. Chem. Soc.* (1964) 400; *Chem. Communs.* (1965) 611.

The oxides Sb^{III}Nb^{V}O$_4$, Sb^{III}Ta^{V}O$_4$, Bi^{III}Nb^{V}O$_4$, Bi^{III}Ta^{V}O$_4$ are isostructural with the α-form which also occurs as the mineral cervantite. The oxide Bi^{III}Sb^{V}O$_4$ is isostructural with β-Sb$_2$O$_4$. A compound Sb^{III}Sb$_2^V$O$_6$OH, and not very well-defined colourless oxides and sulphides of As^{III} and As^V, have also been described.

16.2. COMPLEX HALIDES

Intensely coloured complex halides of empirical formulae M_2SbX_6 (e.g. M = Rb, Cs, R_4N) crystallize from solutions with appropriate amounts of Sb^{III}, Sb^V and MX in the 12 M acid HX. These compounds form mixed crystals with the corresponding tin compounds M_2SnX_6, and have only slightly distorted K_2PtCl_6 (antifluorite) structures in which M and EX_6^{n-} ions can be distinguished. Although the E^{III} and E^V atoms are in rather similar environments, they remain distinct in the ground state for the following reasons[199]:

(a) The compound are diamagnetic. Sb^{IV} (s^1) would be paramagnetic.

(b) Samples from radioactive $^{125}Sb^{III}$ do not yield equal amounts of $^{125}Sb^{III}$ and $^{125}Sb^V$ on dissolution as would be the case if all the antimony atoms were equivalent.

(c) The Sb^{III} atoms in M_2SbCl_6 may be replaced by Bi^{III}, In^{III} or Tl^{III} with very little change in structure.

(d) In the crystal of $(NH_4)_2SbBr_6$ there are two environments for antimony.

$$Sb^{III}Br_6^{3-}(O_h): Sb^{III}-Br, 279.5 \pm 0.6 \text{ pm}$$
$$Sb^VBr_6^-(D_{2d}): Sb^V-Br, 256.4 \pm 0.6 \text{ pm}$$

The environment of the Sb^V atoms is only slightly distorted from octahedral. Thus in structure [49] $\angle Br_aSbBr_b = 93.7$; $\angle Br_aSbBr_c = 90.2°$.

(e) Infrared and Raman spectra of Cs_2SbCl_6, $Cs_2(Sb,Bi)Cl_6$ show bands attributed to both $E^{III}Cl_6^{3-}$ (Table 46) and $E^VCl_6^-$ (Table 63).

(f) For compounds $M_2Sb_xSn_{1-x}Cl_6$ (M = NH_4, Cs), $Cs_2In_{\frac{1}{2}-y}^{III}Sb_y^{III}Sb_{\frac{1}{2}}^VCl_6$, the intensity of the absorption in the visible spectrum is proportional to the concentration of $Sb^{III}Sb^V$ pairs, and a quantitative account of this intensity is given if it is assumed that delocalization of the $5s$ electrons of Sb^{III} to Sb^V is less than 1% in the ground state. The absorption is thus due to charge transfer.

$$Sb^{III}(5s^2) + Sb^V(5s^0) \xrightarrow{h\nu} Sb^{IV}(5s^1) + Sb^{IV}(5s^1)$$
The width of the absorption is accounted for by the changes in dimensions on excitation[200].

The mixed valency salts are semiconductors. The electronic properties of materials with more than 10% antimony, i.e. enough to form a continuous path through the lattice, are consistent with a mechanism in which $Sb^{IV}Cl_6^{2-}$ formation from $Sb^{III}-Sb^V$ pairs is followed by migration of holes (migration of $Sb^{IV}Cl_6^{2-}$ through the $Sb^{III}Cl_6^{3-}$ ions).

16.3. MECHANISMS OF REDOX REACTIONS

There have been several kinetic studies of oxidations of solutions of E^{III} by various reagents (Table 68). Rate equations are sometimes rather complicated and, even for the same substrates, may differ for analogous arsenic, antimony and bismuth compounds. There may be several species of both E^{III} and oxidant in solution, and the concentrations of these may be pH dependent.

Oxidations by E^V have not been well studied. In the oxidation of iodide by Sb^V, two iodide ions are involved in the activated complex to give (by elimination of I_2) the change of 2 in oxidation state. A number of oxidations by Bi^V are, however, zero order in

[200] L. Atkinson and P. Day, J. Chem. Soc. A (1969) 2423, 2432.

reductant: the rate-determining step seems to involve oxidation of water by Bi^V possibly to give a chelated peroxide intermediate[202].

$$Bi^V\!\!\begin{array}{c}-OH\\-OH\end{array} \xrightarrow{-2H^+} Bi^{III}\!\!\begin{array}{c}-O\\|\\O\end{array} \xrightarrow{2X^-} Bi^{III}\!\!\begin{array}{c}-OH\\-OH\end{array} + X_2$$

Sb^{III}, Sb^V in HCl		
Sb^{III}, Sb^V in CCl_4	See p. 651	148

The exchange between Sb^{III} and Sb^V, i.e. oxidation of Sb^{III} by Sb^V, has been studied by spectrophotometry and radioactive tracers[58], in both water and carbon tetrachloride. In aqueous solution, the exchange is slow in alkali, or in acid solution containing anions (e.g. SO_4^{2-}) which are poor ligands for antimony, but faster in the presence of chloride. The kinetics are complicated by reactions involving several partially hydrolysed species of Sb^V, e.g. $[Sb(OH)_nCl_{6-n}]^-$. Activated complexes with two bridging chlorine atoms have been postulated to give the required two-electron change.

1. OXYGEN

1.1. DISCOVERY OF OXYGEN[1]

By the middle of the seventeenth century it was appreciated that air contained a component associated with breathing and burning. In the first theory of burning to become widely accepted, this component was called phlogiston. When something burned, it was believed to release phlogiston to the air around it. If the burning took place in a sealed system, it stopped after a time because the air in the system became saturated with phlogiston. There were serious difficulties about this interpretation. For instance, metals such as tin gain in weight when they burn. However, the theory was widely accepted until the end of the eighteenth century.

Both the experimentalists generally credited with the discovery of oxygen, Joseph Priestly and Carl Wilhelm Scheele, were believers in the phlogiston theory. Indeed, Scheele called his experiments "... proofs that Heat or Warmth consists of Phlogiston and Fire Air". Scheele obtained oxygen, which he called fire air, by heating nitrates, mercuric oxide, or manganese dioxide in retorts to the ends of which bladders had been fixed; Priestly heated mercuric oxide with a magnifying glass and collected the gas over water. Both found that the gas they had obtained would support combustion better than does common air; and after some experiments with mice Priestly ventured to breath some of it himself, with very pleasant results. Priestly isolated what he called "dephlogisticated air" on 1 August 1774; after further experiments he wrote about his results to Sir John Pringle, the President of the Royal Society, in March 1775, and his letter was read before the Society on 23 March, while a detailed account of his experiments was published in the same year in the second volume of his book *Experiments and Observations on Different Kinds of Air*. Scheele worked at about the same time, but he had difficulties with his publishers (as others have

[1] M. E. Weeks, *The Discovery of the Elements*, 6th edn., published by the *Journal of Chemical Education*, New York (1956); D. McKie, *Antoine Lavoisier*, Gollancz, London (1935); J. G. Gillam, *The Crucible*, Robert Hale, London (1954); *The Collected Papers of C. W. Scheele* (translated by L. Dobbin), Bell, Edinburgh (1931).

had since then), and his book, *Chemische Abhandlung von der Luft und dem Feuer*, did not appear until 1777.

Neither Priestly nor Scheele, however, seems fully to have understood the significance of their discoveries. When Priestly was in Paris in October 1774, he mentioned some of his results to the distinguished French Academician, Antoine Lavoisier, who was interested in combustion. Lavoisier was also in touch with Scheele. He repeated and extended Priestly's experiments, and began to consider his results in the light of the deficiencies of the phlogiston theory. He burned tin in a sealed vessel, and showed that after combustion the weight of the vessel was effectively unchanged as long as the seal was not broken; thus the increase in weight of the tin on combustion could not be derived from outside the vessel. If the tin had lost phlogiston, then the phlogiston must have negative mass. From these and other experiments he concluded that when the metal burned what really happened was that it combined with something in the air; that "something" was the gas discovered by Priestly and Scheele, which Lavoisier called "principe oxygine". His view was not absolutely correct. He thought he was talking of a principle of acidity, for "oxygine" comes from the Greek word *oxus*, meaning sharp, and hence acid. But it was Lavoisier's penetration of mind, coupled with the experiments of himself, of Priestly, and of Scheele, that led to the collapse of the phlogiston theory and to the development of modern chemistry.

1.2. GENERAL

Oxygen is the eighth element in the Periodic Table. The electronic structure can be represented in terms of one-electron wave functions as $1s^2 2s^2 2p^4$; the ground state and some of the lower excited state terms are given in Table 1, with their energies above the ground state, and some other important properties of oxygen are given in Table 2. Detailed calculations of the wave function for the oxygen atom have been made using SCF and other methods[2].

Oxygen forms compounds with all the elements of the Periodic Table except for the lightest rare gases. These compounds could in principle be formed if oxygen were to lose electrons (forming cations), to gain electrons (forming anions) or to share electrons (forming bonds). The first four ionization potentials and the first two electron affinities are given in Table 2. These values show that the loss of electrons from oxygen is a process requiring much energy. Compounds are known in which oxygen is formally cationic, such as $O_2^+ PtF_6^-$, but in all known cases the cations are polyatomic, and in general the chemistry of oxygen is not cationic. The doubly charged anion O^{-2} is a common species, even though its formation from the gaseous atom involves substantial absorption of energy; in ionic oxides the lattice energies are very high and more than compensate for the energy of formation of O^{-2}. This must also explain why the singly charged O^- is only known as an unstable species in irradiated solids and in the gas phase; in oxides it is unstable with respect to disproportionation to O_2 and O^{-2}. The coordination numbers of O^{-2} ions in oxides are set out in Table 2, and are considered in more detail in section 3.3.

Oxygen can form two additional bonds either by forming two σ-bonds with other atoms or groups, as in $(CH_3)_2O$, or by forming a σ-bond and a π-bond with the same other atom

or group, as in $\rangle C{=}O$. Species in which oxygen forms just one σ-bond with another group (e.g. OH) have been detected spectroscopically, but they are free radicals and are not normally stable under chemical conditions. For once, all scales of electronegativity agree that oxygen is a very electronegative element. The electronegativity depends on the orbitals and the electron configuration; calculations have been made of the parameters associated with the valence state of oxygen, based on spectroscopic measurements[3]. As expected, the double bonds are shorter than the single bonds, and they have higher energies and stretching frequencies. Bonds of intermediate order are found in many compounds, including oxyanions such as RCO_2^-, CO_3^{-2}, NO_3^-, or SO_4^{-2}; relationships between bond length, bond order and stretching force constants have been described for BO [4], CO [5], NO [6], SiO [7], PO [7], SO [8] and ClO [7] bonds. Like fluorine, oxygen is a ligand which tends to promote oxidation of other elements to which it is bound (cf. $Os^{VIII}O_4$).

Bonds from 2-coordinated oxygen are usually considered as formed from (roughly) sp^3 hybrid orbitals, leading to bond angles at oxygen near the tetrahedral value. This leaves two lone pairs, which are also regarded as being in roughly sp^3-orbitals. Thus in each of the compounds H_2O, Me_2O and F_2O, the angles are near 109° (Table 3). However, oxygen can also use its lone pairs to form either intermolecular σ-bonds or intramolecular π-bonds additional to the normal σ-bonds.

Additional σ-bonds. Despite its high electronegativity, oxygen is a lone pair donor. Compounds like Me_2O form complexes with acceptors such as BF_3, and values for the energies of some donor–acceptor bonds involving oxygen are given in Table 4, with some values for other elements for comparison. Water is a well-known donor ligand in transition metal chemistry; oxygen is also a hydrogen bond acceptor, as in carboxylic acid dimers and in ice. All these interactions involve the lone pairs. In ice and in basic beryllium acetate, the angles at the 4-coordinated oxygen atoms are roughly tetrahedral, which also implies that the lone pairs are in approximately sp^3-orbitals; similarly, in H_3O^+, which is isoelectronic with NH_3, the angle is near 109°. In compounds, where it forms two σ-bonds (e.g. Me_2O), oxygen is a hard (class A) base, though in compounds like $Me_2C{=}O$ it has some "soft" character. Water comes near the "small Δ" end of the spectrochemical series; water and OH^- have small *trans*-effects, and in the nephelauxitic series water and OH^- come close to F^- as ligands with the smallest effect.

Internal π-bonding. If an attached atom or group Q has empty orbitals of π-symmetry relative to the Q–O σ-bond, these will overlap the lone pair orbitals at oxygen, and the overlap may lead to the formation of a donor π-bond. Thus in carbon monoxide the CO bond is of higher order than 2, and the strength of the bond can be attributed at least partly to an interaction of the form $(O^+{\equiv}C^-)$. In compounds in which oxygen is forming two or more σ-bonds, donor π-bonding like this will affect bond angles at oxygen. The donor π-overlap will be greatest when the lone pairs are in pure p-orbitals. If one lone pair is in a pure p-orbital, the two σ-bonds and the other lone pair must be built from one s- and two p-orbitals. This would lead (if all three σ-orbitals are equivalent) to an angle of 120°. If both lone pairs are in pure p-orbitals, the σ-bonds must be built from sp-orbitals,

and the angle at oxygen will be 180°. These possibilities, which are represented below in valence-bond terms, are extremes: intermediate angles might be expected, deriving from a balance between π-bonding (widening the angle, and removing electrons from oxygen) and charge distribution (which will tend to keep electrons on the oxygen atom):

Internal π-bonding will lead to shorter and stronger bonds, and should weaken the donor properties of the oxygen atom; the shortness and strength of bonds between oxygen and boron[9], silicon[10] or transition elements[11] have been accounted for in terms of this type of interaction. Several compounds are known in which oxygen is bound to one or two π-acceptors and in which the angle at oxygen is unusually wide (see Table 3). A similar argument could be used to explain why angles in Q_3O^+ might be nearer 120° than 109°; π-interactions between silicon and Q would be greatest if the lone pair at Q were in a pure p-orbital. However, this argument should be used with some caution; the angle at oxygen in RbOH is 180°, yet there is unlikely to be significant π-bonding between rubidium and oxygen.

Oxygen is known in a variety of formal oxidation states, from $+2$ to -2. Of these, the positive states are (by definition) only found when oxygen is bound to a more electronegative element—which must be fluorine—or forms part of a cation such as O_2^+. In other oxidation states greater than -2 the oxygen atom concerned must either be bound to at least one other oxygen atom or form part of a cation or free radical. A potential diagram for the redox chemistry of oxygen in aqueous solution is given in Table 5.

1.3. ISOTOPES OF OXYGEN

Unstable Isotopes

The known radioactive isotopes of oxygen are all artificial; they are listed in Table 6 with representative nuclear reactions by which they have been made. The half-lives are all so short that the isotopes are unsatisfactory for tracer work, though some tracer studies[12] have been made with O^{15}.

TABLE 6. RADIOACTIVE ISOTOPES OF OXYGEN

Isotope	Formation	$t_{\frac{1}{2}}$, sec	Decay	Reference
O^{13}	$O^{16}(He^3, He^6)O^{13}$			a
O^{14}	$C^{12}(He^3, n)O^{14}$	73	β^+	b
O^{15}	$O^{16}(He^3, \alpha)O^{15}$	122	β^+	b
O^{19}	$O^{18}(n, \gamma)O^{19}$	29.4	β^-	b
O^{20}	$O^{18}(t, p)O^{20}$	14	β^-	b

Stable Isotopes

By far the most abundant isotope of oxygen is O^{16}, but natural oxygen (both element and compounds) contains small amounts of O^{17} and O^{18} (Table 7). The proportions of

[12] C. T. Dollery and J. B. West, *Nature* **187** (1960) 1121.

these isotopes depend to a significant extent upon the source of oxygen. Natural processes such as the evaporation of water lead to some fractionation because of the influence of molecular weight upon physical properties; there are small differences in the proportion of O^{18} in water from different natural sources, and indeed the proportion of O^{18} in ocean water varies with the depth[13]. There is also some isotopic fractionation in chemical cycles in nature that involve oxygen. The variations in apparent atomic weight of natural oxygen may be as great[14] as ± 0.0003.

TABLE 7. STABLE ISOTOPES OF OXYGEN

Isotope	Mass [a]	Natural abundance [a]
O^{16}	($C^{12} = 12.000\,000\,0$) 15.994 915	99.7587
O^{17b}	16.999 134	0.0374
O^{18}	17.999 160	0.2039

[a] W. H. Johnson and A. O. Nier, *Handbook of Physics*, McGraw-Hill, 2nd edn., 1967, pp. 9-63.
[b] Nuclear spin = 5/2; nuclear magnetic moment = 1.8930 nuclear magnetons; nuclear quadrupole moment = $-4e \times 10^{-27}$ cm². (From J. A. Pople, W. G. Schneider and H. J. Bernstein, *Nuclear Magnetic Resonance*, McGraw-Hill, 1959.)

Many different processes have been described for producing molecular oxygen or oxygen compounds enriched in O^{17} or O^{18}; some make use of the slightly different equilibrium constants for compounds of O^{16} and O^{17} or O^{18}, but most depend on some physical property of O_2 or oxygen compounds such as H_2O or N_2O. In practice the most important processes are the fractional distillation of water and (for high enrichments) the thermal diffusion of oxygen gas; the gas fed into the column for separation by thermal diffusion may be obtained by the electrolysis of water that has already been enriched in O^{18} by fractional distillation. Heavy water of enrichment up to 98 atom-% O^{18} and 20 atom-% O^{17} is commercially available, as is oxygen gas 99% in O^{18} or 90-95% in O^{17}. These are the most commonly used starting materials; of course it is possible to produce enriched O_2 by the electrolysis of enriched water. Samples of oxygen and its compounds are usually analysed for isotopic composition by mass spectrometry; if compounds are involatile, their oxygen must be converted into some volatile species first.

O^{18}. Oxygen-18 has been extensively used to study mechanisms of reactions, and in particular of hydrolysis. The exchange rates of many common oxyacids and oxyanions have been studied quantitatively or semi-quantitatively[15]; the structures of simple molecules containing oxygen have been determined by microwave spectroscopy[16] with the help of samples enriched in O^{18}, and vibrations involving the movement of oxygen atoms have been identified by the extent to which they shift in samples enriched in O^{18}. In the infrared

spectra of adducts of molecular oxygen with compounds of transition metals, there is a band near 800–900 cm^{-1} that is assigned to the (O–O) stretching mode. In (tbuNC)$_2$Ni(O$_2$) and (tbuNC)$_2$Pd(O$_2$) this band splits into three when the complex is prepared from O$_2$ containing 25 atom-$\%$ O^{18}: the three components are due to stretching modes in L$_2$M(O$_2^{16}$), L$_2$M(O^{16}O^{18}) and L$_2$M(O$_2^{18}$); the relative intensities and the differences in frequency between the bands confirm this assignment[17]. A similar approach has led to the identification in matrices at low temperatures of active species containing more than one oxygen atom.

The preparation of O^{18} in naturally occurring systems has been much studied in connection with climatology and palaeoclimatology. The variation in O^{18} content of arctic snow over the year helps to establish the origin of the water from which the snow was formed[18]. In palaeoclimatology it is the oxygen isotopic composition of carbonate in fossils that is measured[19, 20]. The variation with temperature of the equilibrium constant for the reaction

$$H_2O^{18} + 1/3(CO_3^{16})^{-2} \rightleftharpoons H_2O^{16} + 1/3(CO_3^{18})^{-2}$$
has been determined accurately. Certain fossil shell-fish contain carbonate rock. The temperature at which this carbonate was precipitated can be determined from the isotopic distribution of the carbonate in the shell, using the equation

$$t = 16.5 - 4.3\delta + 0.14\delta^2$$

where t is the temperature in °C and δ is a measure of the difference between the O^{18} content of the sample and of the standard working gas. This use of the O^{18} content of carbonate is sometimes referred to as the carbonate thermometer.

In practice, matters are not so simple[19]. For the information obtained to have any meaning, certain conditions must be fulfilled. The carbonate must have been precipitated in isotopic equilibrium with the surrounding water; the isotopic composition of that water must be known; and there must have been no subsequent exchange. Though some shell-fish (e.g. coral) precipitate carbonate that is not in equilibrium with the surrounding water, in molluscs the equilibrium is maintained. For shells from open oceans it is usually assumed that the O^{18} content of the surrounding water was not very different from that of ocean water nowadays; for isolated oceans this may well not be so because of such things as evaporation, and allowance must be made for this (perhaps by using the O^{18} content of the phosphate of the shell). But it is with the third condition that the most serious difficulties arise. It is hard enough to make sure that the oxygen from the carbonate in the shell is extracted and analysed without exchange; it is even harder to make sure that nothing untoward has happened to the sample between fossilization and analysis. Fortunately there are some internal tests that can be applied. For example, in most, but not all, fossil shells studied the ratio of (O^{18}:O^{16}) to Sr^{+2} is the same as it is in oceans at present; therefore shells in which this ratio is very different may be supposed to have undergone "diagenetic" changes (in other words they are useless for isotopic analysis). However, there is always the nagging possibility that a particular sample may be atypical—some molluscs, for instance, do not deposit carbonate uniformly throughout the year—and it is rare that

[20] R. Bowen, *Palaeotemperature Analysis*, Elsevier, Amsterdam (1966).

enough good samples from a particular area are available for a proper statistical analysis. Some claims about palaeotemperature may have been based on very slender evidence derived from the carbonate thermometer; but when all is said and done the remarkable thing is that such an extrapolation to the temperatures of past ages is even possible.

O^{17}. The isotope O^{17} is important despite its small natural abundance because it is the only stable isotope of oxygen with nuclear spin, and so is the only one that can be used to study oxygen n.m.r. or oxygen hyperfine interactions in electron resonance spectroscopy[21]. Unfortunately, however, the spin of 5/2 is associated with a large quadrupole moment, leading to broad n.m.r. lines because of the relatively rapid relaxation of the oxygen nuclei. Chemical shifts are difficult to determine, and coupling is often not observed at all. However, broadening due to quadrupolar relaxation has itself been used to give information about the field gradient at the oxygen nucleus; lines are sharper when oxygen is bound to an electropositive element, even in a high oxidation state, because then the oxygen atom approximates to the ion O^{-2} in which the field gradient at the nucleus is zero.

Some values for O^{17} chemical shifts are given in Table 8; they were measured relative to H_2O^{17} (usually as external standard), and some of the uncertainties are substantial. It is clear from these and other values that oxygen forming two σ-bonds gives resonance in the range -250 to 0 ppm from H_2O^{17} ($+$ve to high field), but that oxygen forming a double bond gives resonance in the range -1400 to -250 ppm. The dichromate ion[22], for instance, gives two resonances, the one (stronger and sharper) at -1129 ppm due to the terminal, and the other (weaker and broader) at -345 ppm due to the bridging oxygen atoms. Similarly[23], aqueous acetone gives a single O^{17} resonance in the $>C=O$ region, at -523 ppm, indicating that the molecule dissolves unchanged; formaldehyde gives a resonance at -51 ppm, in the "single-bond" region, so it is concluded that the species present is the hydrated form $H_2C(OH)_2$. Acetaldehyde gives two peaks, the one at -550 ppm associated with the unchanged molecule CH_3CHO, and the other at -67 ppm associated with the hydrated form $CH_3CH(OH)_2$. Exchange between these two species and the solvent is slow on the n.m.r. timescale.

For doubly-bound oxygen there is a correlation between the chemical shift and the frequency of the first ultraviolet/visible absorption band[24]. Furthermore, a correlation has been reported between bond length, bond order and O^{17} chemical shifts in some Cr(VI)–O species[25]. The full range of validity of the latter correlation has still to be established.

Ion hydration has been extensively studied by O^{17} n.m.r. spectroscopy. For certain paramagnetic ions there are "contact shifts" which with Co^{+2} and Ni^{+2} lead to the observation of separate resonances due to water in the hydration shell of the cation and to the solvent itself. For certain diamagnetic ions which exchange their hydration water slowly with the solvent, separate O^{17} resonances for solvent and for solvating water have been observed (Table 9). There are other cases where exchange on other grounds is known to be slow, but where, none the less, the only O^{17} resonance observed is that due to the solvent. The addition of Co^{+2} or Dy^{+3} ions to the solution causes the solvent resonance to shift to low field through the "contact shift" mechanism, and so can expose the resonance due to the hydrated diamagnetic cation; this device has also been used to separate the

resonances of water and of phosphoric acid[26]. The hydration of ions or complexes of Be^{+2}, Al^{+3}, Ga^{+3}, VO^{+2}, Tl^{+3}, Co^{+2}, Ni^{+2} and Cu^{+2} has been studied using these and similar techniques. Finally, O^{17} n.m.r. affords information about H bonding and the structure of aqueous solutions; O^{17} resonances, like proton resonances, are shifted to low field by hydrogen bonding[27].

The e.s.r. spectra of organic compounds containing O^{17} have been important in relation to calculations of the electronic structures of these compounds, and particularly of heterocyclic compounds. The hyperfine interaction constants in O^{17}-labelled $Mn(acac)_3$ has been used[28] as the basis for an estimate of the covalent character of the metal–oxygen bonds. The e.s.r. spectrum of a sample of CF_3OOCF_3 that had been photolysed in the

presence of small amounts of O_2 enriched ($\sim 30\%$) in O^{17} showed that a free radical had been formed with three different sets of O^{17} hyperfine splitting constants, and it was concluded[29] that the radical was the trioxide species CF_3COOO. Hyperfine structure in the e.s.r. spectrum of $[(H_3N)_5Co(O_2)Co(NH_3)_5]^{+5}$ due to O^{17} in the peroxy-bridge provided the first direct evidence that the unpaired electron is associated with the bridge as well as with the cobalt nuclei[30].

1.4. OCCURRENCE AND EXTRACTION

Oxygen is the most abundant element[31]. In combined form it makes up 46.60% by weight of the rocks of the earth's crust, and (as the element) $20.946 \pm 0.002\%$ by volume of

dry air at sea level. Nowadays the atmosphere is the primary source of oxygen for large-scale commercial production of the gas or liquid, but chemical processes have been devised and extensively used in the past. Most are based on substances which combine with oxygen at one temperature and release it on heating. The old Brin process made use of the reaction between barium oxide and oxygen at 600°:

$$BaO + 0.5O_2 \underset{\text{low pressure}}{\overset{\text{high pressure}}{\rightleftharpoons}} BaO_2$$
The barium oxide is heated with air that has been freed of CO_2, water vapour, organic matter and dust; the pressure is lowered, and pure oxygen is evolved. A modification of the process has recently been devised[32] in which use is made of the fact that the melting point of BaO_2 (450°) is much lower than that of BaO (1923°). Several similar processes have been proposed for making pure oxygen, which has also been made electrolytically, but almost all oxygen is now produced by the liquefaction and fractional distillation of air. Methods for doing this differ in detail. The Linde double column consists of one fractionating column operating at about atmospheric pressure, and another operating at 5–6 atm. At the higher pressure nitrogen boils at −170°, and so may be condensed using liquid oxygen from the column at lower pressure as refrigerant. After initial compression and cooling by water, the air is further cooled by heat exchange with gases leaving the columns; the cooling by expansion that follows may take place under Joule–Thompson conditions, by doing external work, or by a combination of the two. In the production of oxygen gas, the use of heat exchangers called regenerators is of considerable importance[33].

Alternative sources of oxygen for enclosed systems have become of increasing importance in the past few years with the development of space craft and nuclear submarines. Schemes have been devised for producing oxygen from CO_2 by means of algae, or by catalytic hydrogenation followed by electrolysis of the water formed[34]. Oxygen "candles" have been proposed for carrying oxygen; these consist of salts of oxy-anions which are both thermally unstable and rich in oxygen, such as $LiClO_4$, $NaClO_3$ or KO_2. A lithium perchlorate candle has been described consisting of 84.82% by weight of $LiClO_4$, 10.94% Mn and 4.24% of Li_2O_2; the solid is compressed to a density of 2.32 g/cc, and the oxygen available on heating is equivalent, volume for volume, to that from liquid oxygen[35].

In the laboratory[36], oxygen may be made by heating potassium permanganate or other salts thermally unstable and rich in oxygen, but commercial oxygen can be purified by successive treatment with $KMnO_4$, with KOH, and with concentrated H_2SO_4. The best method of making pure oxygen in the laboratory is to catalyse the decomposition of 30% H_2O_2 with thin nickel sheet suspended by a platinum wire; electrolysis may also be used.

1.5. STRUCTURAL PROPERTIES

Electronic Structure

The electronic structure of the oxygen molecule can be represented very simply as O=O. This representation indicates that the O–O bond should be short and strong (as it is—see Table 10) but offers no explanation for the paramagnetism of the molecule. To account for this property in terms of simple valence-bond theory, it is necessary to invoke

three-electron bonds[37] or to use the "double quartet" approach[38]. In simple molecular orbital terms, the paramagnetism is explained by the two unpaired electrons in the anti-bonding π_g-orbital[39]. The configuration is

$$(\sigma_g 1s)^2(\sigma_u 1s)^2(\sigma_g 2s)^2(\sigma_u 2s)^2(\sigma_g 2p)^2(\pi_u 2p)^4(\pi_g 2p)^2.$$

Although in B_2, C_2 and N_2 the $(\sigma_g 2p)$ level is above the $(\pi_u 2p)$ level because of interaction with $(\sigma_g 2s)$, in O_2 the order is as shown. More detailed calculations using the LCAO SCF method with configurational interaction[40] gives good agreement with the observed value for the total energy, but the agreement between the observed and the calculated values for the dissociation energy is less satisfactory.

The photo-electron spectrum of molecular oxygen excited using HeI radiation (21.23 eV) gives at least four and possibly five bands, all with vibrational progressions. The adiabatic ionization potentials and observed vibration frequencies are given in Table 11A.

The band at lowest I.P. corresponds to removal of an anti-bonding π_g electron producing O_2^+ in its electronic ground-state $^2\Pi_g$; as would have been expected, the vibration frequency is greater than in O_2. The next band, with a long vibrational progression, corresponds to removal of a π-bonding electron giving $O_2^+(^4\Pi_u)$; peaks associated with the production of $O_2^+(^2\Pi_u)$ may also occur in this region. The next band corresponds to removal of a σ-bonding electron giving $O_2^+(^4\Sigma_g)$, and the fifth band may correspond to the formation of O_2^+ $(^4\Sigma_u)$ or $O_2^+(^2\Sigma_g^-)$. In each case the electron removed is bonding, as shown by the drop in vibration frequency on ionization[40a].

Molecular and Crystal Structure

The O–O distance in gaseous O_2 has been determined very accurately by analysis of the Schumann–Runge bands in the u.v. and also by microwave spectroscopy (see Table 10). The O–O distances in liquid and solid oxygen have not been accurately determined, but the diffraction measurements for the three solid forms are consistent with (O–O) bonded distances close to those for free O_2, as is the small change in (O–O) stretching frequency with change in phase.

The structure of crystalline γ-oxygen (the highest temperature form)[41] is very like that of α-F$_2$. There are eight molecules in the unit cell: two are roughly spherically disordered, on $m3(T_h)$ sites, and six are cylindrically disordered on $\overline{4}2m(D_{2d})$ sites, with the $\overline{4}$ (S_4) axis perpendicular to the molecular axis. This phase is soft and transparent, and less dense than the others; its structure is regarded as more like that of liquid oxygen than like that of the
FIG. 1. The structure of α-oxygen; monoclinic $C2/m$. Atom centres and intermolecular distances are indicated; molecules are centred at 000 and $\frac{1}{2}\frac{1}{2}0$, with O-O bonds approximately normal to the (O-O) plane. (Reproduced with permission from C. S. Barrett, L. Meyer and J. Wasserman, *J. Chem. Phys.* **47** (1967) 592.)

β-form. This is consistent with the relatively small heat and volume changes on melting (smaller than the corresponding changes associated with the transition of β to α—see Table 15c)[42, 43], and with the closely similar vibrational spectra of γ-O_2 and liquid O_2. The β-form is rhombohedral[42, 43] and the α-form is monoclinic (Table 11B). The structure of the α-form is given in Fig. 1; the O_2 molecules lie parallel to one another, and with their molecular axes perpendicular to the O–O planes[43].
FIG. 3. Potential energy as a function of internuclear distance for states of the O_2 molecule. The dotted lines show results of different calculations for the $^3\pi_u$ state. (Reproduced with permission from D. H. Volman, *Advances in Photochemistry* 1 (1963) 46.)

1.6. SPECTROSCOPIC PROPERTIES

Electronic Spectra

The spectrum of isolated O_2. The ground state[44] of O_2 is $^3\Sigma_g^-$. The states $^1\Delta_g$ and $^1\Sigma_g^+$ are derived from the same electron configuration; transitions to each of these states from the ground state are formally forbidden, but are observed as very weak bands in the absorption of O_2 at ~ 8000 cm^{-1} ($^1\Delta_g \leftarrow {}^3\Sigma_g^-$) and $\sim 13,200$ cm^{-1} ($^1\Sigma_g^+ \leftarrow {}^3\Sigma_g^-$). Transitions to the next states involve excitation of a π_u-electron to a π_g-orbital. Fragments of a very weak band series due to the transition $^3\Delta_u \leftarrow {}^3\Sigma_g^-$ were detected by Herzberg[45] close to the weak band series for the transition $^3\Sigma_u^+ \leftarrow {}^3\Sigma_u^-$ near 36,000 cm^{-1} (the Herzberg bands) and the even weaker series[46] associated with the transition $^1\Sigma_u^- \leftarrow {}^3\Sigma_g^-$ near 37,000 cm^{-1}. All three of these transitions are forbidden. The strong Schumann–Runge bands near 50,000 cm^{-1} are

r_e = equilibrium internuclear distance; T_e = electronic energy above the ground state; ω_e = harmonic fundamental vibrational frequency; $\omega_e x_e$ = vibrational constant for second-order anharmonic term; $\omega_e y_e$ = vibrational constant for third-order anharmonic term.

[a] G. Herzberg, *The Spectra of Diatomic Molecules* 2nd edn., van Nostrand, New York (1950).
[b] P. Brix and G. Herzberg, *Canad. J. Phys.* **32** (1954) 110.
[c] G. Herzberg, *Canad. J. Phys.* **31** (1953) 657.

derived from the allowed transition $^3\Sigma_u^- \leftarrow {}^3\Sigma_g^-$; they converge to a limit at 57,128 cm^{-1} and a continuum to about 70,000 cm^{-1}. At higher energies the spectrum becomes complex, and fragments of several Rydberg series have been detected[47] (Fig. 2).

Band systems associated with all these transitions except $^3\Delta_u \leftarrow {}^3\Sigma_g^-$ have been analysed, and the derived molecular constants are given in Table 12; promotion of an electron from π_u to π_g leads to a lengthening of the O–O bond and a decrease in the vibration frequency, as simple theory predicts. On the other hand, ionization strengthens the bond by removing an antibonding electron. In the spectrum of solid α-oxygen at 4°K, the structure of the bands indicate that the molecular constants for the gas and for α-O$_2$ are very similar but not exactly the same[48]. In γ-O$_2$ and β-O$_2$ the bands are broader than in the liquid or in α-O$_2$ [49]. There are further splittings of the vibrational bands in the spectrum of the crystal[48, 49].

Potential energy curves have been calculated for all the bound states, and for some of the repulsive ones (Fig. 3).

The lower states dissociate to two ^3P oxygen atoms, but the $^3\Sigma_u^-$ state gives one ^3P and one ^1D atom. There is clear evidence for predissociation in the Schumann–Runge system[50]; the relevant repulsive states seems to be $^3\Pi_g$, but the details of the process are not clear.

Bands involving intermolecular interactions. In the spectra of condensed or compressed oxygen there are bands that are not due to transitions of isolated O$_2$ molecules[51]; some of these features lie under the banded spectra of the O$_2$ transitions[52]. They are attributed to transitions in molecular complexes (perhaps short-lived collision complexes), but there must be more than one type of intermolecular process involved, for in compressed oxygen the intensities of different bands vary in different ways as the pressure is changed or as foreign gases are added. The band near 15,800 cm^{-1} is attributed to the (0–0) transition associated with simultaneous excitation of two $^3\Sigma_g^-$ oxygen molecules to the $^1\Delta_g$ state[53]. Systems of $^1\Delta_g$ molecules show emission at this wavelength due to "energy pooling" of two molecules[54]:

$$2O_2(^1\Delta_g) \rightarrow 2O_2(^3\Sigma_g^-) + h\nu(15,800 \text{ cm}^{-1})$$
Similar simultaneous excitation of two molecules gives bands near 21,000 cm^{-1} [(0–0) transition of $^1\Delta_g + {}^1\Sigma_g^+ \leftarrow 2\,^3\Sigma_g^-$] and 26,500 cm^{-1} [(0–0) transition of $2\,^1\Sigma_g^+ \leftarrow 2\,^3\Sigma_g^-$]. In O$_2$ gas, the band at 7890 cm^{-1} is induced by the presence of a foreign gas, such as CO$_2$; the band at 9370 cm^{-1}, however, is only induced by increasing the pressure of O$_2$, and so is assigned to a transition in a collision complex of O$_2$ molecules[52].

The strong bands largely responsible for the blue colour of liquid oxygen are due to (0–0), (0–1) and (0–2) transitions from the $2\,^1\Delta_g \leftarrow 2\,^3\Sigma_g^-$ and the $^1\Delta_g + {}^1\Sigma_g^+ \leftarrow 2\,^3\Sigma_g^-$ bands mentioned above[53].

Vibrational Spectra

The fundamental of O$_2$ is forbidden in the infrared, though it has been detected in the infrared spectra of oxygen gas at high pressures, of liquid oxygen, and of all three forms

of solid oxygen; the vibration is Raman active, and has been observed in the Raman spectra of all five phases of elementary O_2 (Table 13). The infrared spectra of the different phases of solid oxygen also show broad bands or shoulders to high frequencies of the fundamental band. In α-O_2, the fundamental is very sharp, and there is a broad band centred at 1605 cm^{-1}; the sharp peak is assigned to vibrations of molecules near a lattice imperfection, and the broad band to a combination of v with lattice modes[55]. Vibrational

lattice modes were observed[56] in the Raman spectra of solid α-O_2 (at 44 cm^{-1} and 78 cm^{-1}) and β-O_2 (46 cm^{-1}). The strong winging on the Rayleigh line in the Raman spectra of solid γ-O_2 and liquid O_2 is associated with external motion; the torsional motion is highly hindered in each phase, and the r.m.s. torsional amplitude increases[56] from 9° for α-O_2 to 18° for liquid O_2.

Microwave and e.s.r. Spectra of O_2 $^3\Sigma_g^-$

The O_2 molecule has no permanent dipole moment, but its magnetic moment, associated with electron spin, is coupled to the total rotational angular momentum. This leads to a splitting of the K-levels into three non-degenerate rotational states:

$$J = K+1, J = K \text{ and } J = K-1.$$

Transitions between levels where $\Delta J = \pm 1$ are allowed and give rise to weak absorption

[55] B. R. Cairns and G. C. Pimentel, J. Chem. Phys. **43** (1965) 3432.

in the microwave region of the spectrum[57]. At atmospheric pressure the lines are broad, but fine structure has been studied at low pressures[58, 59].

The e.s.r. spectrum is very complicated. It arises because of the interaction of the molecular magnetic moment with the magnetic field; the spectrum is influenced by second-order coupling with the orbital motion of the electron and by a rotation-induced magnetic

TABLE 14. MAGNETIC AND RELATED PROPERTIES

Magnetic susceptibility
Gas [a]
$\chi_g T = 3115 \pm 7 \times 10^{-5}$ c.g.s. units at 293°K
Liquid [b]
$\chi_g(T-\theta') = C'$, where $\theta' = -71°$; $C' = 38,600 \times 10^{-6}$
Solid[c-e]
γ roughly as for liquid ($\theta' \sim -60$)
$\beta \quad \chi = 160 \times 10^{-6}$ c.g.s. units at 43°K
$= 127 \times 10^{-6}$ c.g.s. units at 24°K
$\alpha \quad 14 < T < 20°K, \chi = 49.3[1 + 0.00276 + (T - 14.50)^2] \times 10^{-6}$
$1.5 < T < 4.2°K, \chi = 50.7[1 - 0.01719 + (T - 2.906)] \times 10^{-6}$

Verdet constants
O_2 gas (0°, 1 atm; 5460 Å) 5.986×10^{-6} min oe^{-1} cm^{-1} [f]
O_2 liquid (5461 Å) 0.776×10^{-2} min oe^{-1} cm^{-1} at 90.1° [g]
   0.945×10^{-2} min oe^{-1} cm^{-1} at 63.4°

Kerr constants
O_2 gas (0°, 1 atm; $\lambda = 6500$ Å) $B = 6.94 \times 10^{-12}$ c.g.s. units [h]
O_2 liquid (5461 Å) $B = 22.38 \times 10^{-9}$ c.g.s. units [i]

moment[60]. Analysis of the spectrum gives values for the internuclear distance and the spin–orbit coupling constant. There has been disagreement about some features of the spectrum and their interpretation[61].

1.7. MAGNETIC PROPERTIES

Elementary oxygen is paramagnetic in all phases. The susceptibility of the gas at 1 atm and 20°C corresponds closely with that calculated from the "spin-only" formula[62]; at
